Table 4 shows the limiting equivalent conductivities (Λ_0) obtained by the Fuoss–Hsia equation applied to these solute–solvent systems. These values, too, being strictly related to the solute dissociation constant, are strongly dependent on temperature variation and on thermomechanical properties of the solvent.

The Λ_0 values vs. temperature were fitted by a polynomial equation of the type (12)

$$[5] \qquad \Lambda_0 = \sum_{i=0}^{3} b_i T^i \qquad T/\mathrm{K}$$

which reproduces the experimental data within an average uncertainty $\overline{\Delta\Lambda_0}$, evaluated as follows:

$$[6] \qquad \overline{\Delta\Lambda_0} = \frac{1}{N}\sum_{N} |\Lambda_0^{\mathrm{calcd}} - \Lambda_0^{\mathrm{exptl}}|$$

where N is the number of experimental points, equal to $\pm$ 0.13 cm^2 S mol^{-1}.

Table 5 summarizes the b_i (i = 0, 1, 2, 3) coefficients of eq. [5] along with the standard deviations $\sigma(\Lambda_0)$ for each electrolyte. The trend Λ_0 vs. t/°C for these species is char-

acterized by a continuous and regular increase with temperature for all the selected electrolytes.

The single-ion conductivities were evaluated by splitting the limiting equivalent conductivities (Λ_0) into ionic contributions on the basis of the fundamental assumption of a reference electrolyte (Ph_4PBPh_4 in this case), using the following relationships (13):

$$[7] \quad \lambda_0^+(Ph_4P^+) \equiv \lambda_0^-(BPh_4^-) \equiv \frac{1}{2}\Lambda_0(Ph_4PBPh_4)$$

In practice, one assumes that the two voluminous tetraphenyl derivative ions (opposite charge but similar structure) can be characterized by the same thermodynamic behaviour, and therefore by the same ionic activity coefficients and the same ionic mobility when dissolved in any solvent and at any temperature.

The limiting ionic conductivities ($\lambda_0^{\pm}$) for all the species investigated in this work were obtained by applying the relations:

$$[8] \quad \Lambda_0(Ph_4PBPh_4) = \Lambda_0(Ph_4PBr) + \Lambda_0(NaBPh_4) - \Lambda_0(NaBr)$$

$$[9] \quad \lambda_0^+(Na^+) = \Lambda_0(NaBPh_4) - \lambda_0^-(BPh_4^-)$$

$$[10] \quad \lambda_0^-(Br^-) = \Lambda_0(Ph_4PBr) - \lambda_0^+(Ph_4P^+)$$

$$[11] \quad \lambda_0^-(Pi^-) = \Lambda_0(NaPi) - \lambda_0^+(Na^+)$$

$$[12] \quad \lambda_0^+(H^+) = \Lambda_0(HPi) - \lambda_0^-(Pi^-)$$

starting from the smoothed Λ_0 values fitted by eq. [5]. The results of this analysis are reported in Table 6 and displayed, in a graphic form, in Fig. 3.

For comparison purposes, Table 7 shows the limiting ionic conductivities in some different solvents. As is particularly evident, the hydrogen ion appears to be the species with the highest mobility in all the cases collected in Table 7. For the Na^+ ion, for example, the limiting conductivity values seem to be comparable with those obtained in HMPT solutions, even if generally lower than the values obser solvents characterized by solvent properties suc ascribable to ED, but where the thermokinetic r effects are not equal to those provided in this solv one may observe that the mobility values of tetraphe picrate ions in ED are the lowest of those ions lis Table 7.

The Walden products, $\lambda_0^{\pm}\eta_0$, of the selected ions ar ported in Table 8. As one can see, the rule appears to substantially obeyed over this wide temperature range fro the large tetraphenyl derivatives to the picrate anion, in cluding the relatively small Na^+ ion, which is probably strongly solvated. The greatest exception to this rule, limited because its empirical nature is nowadays largely utilized to assess the values of ionic mobilities under different experimental conditions, is represented by the hydrogen ion.

The imperfectly defined chemical nature of this species in nonaqueous solvents, in conjunction with the observed high values of ionic mobility in almost all the alcoholic solvents, suggests a hypothetical mechanism for electrical conductivity in these media similar to the well-known mechanism proposed for water solutions. In this mechanism the hydrogen ion could act alternatively as structure maker and structure breaker in the network bonding between neighbouring solvent molecules, in order to explain the transport phenomenon described above.

The interionic distance parameter

Table 9 summarizes the ion-size fitting parameter $\mathring{a}$ provided by the Fuoss–Hsia equation for analysis of the experimental conductivity data for the selected electrolytes in this nonaqueous solvent (ED). As one can see from Fig. 4, the trend of $\mathring{a}$ vs. t/°C seems perfectly delineated with respect to the temperature variable, and it follows those trends described above for $K = K(T)$.

However, a careful examination of the ion-size fitting parameter $\mathring{a}$ and the K values of Table 1 suggests a prudent evaluation of the former quantity. In fact, Skinner and Fuoss (14) studied the conductometric behaviour of $NaBPh_4$ in water, and these authors found $\mathring{a} = 6.64 \pm 0.06$ Å for $K_A = 0$. Later, Covington and Tait (15) reexamined the same problem, and provided the value $\mathring{a} = 9.9 \pm 0.9$ Å for $K_A = 0$. These authors also showed that the calculated ion size $\mathring{a} = 6.64$ Å as determined by Skinner and Fuoss for $K_A = 0$ can be increased to $\mathring{a} = 10$ Å, using the experimental data of Skinner and Fuoss if a small association constant is imposed. From these considerations, it is clear that the ion-size parameter $\mathring{a}$ is not completely independent of the association constant in solution, because an identical set of conductivity data can be fitted with a smaller $\mathring{a}$ if it is assumed that any association phenomenon takes place in solution, and vice versa.

Moreover, for those electrolytic solutions with a consistent association investigated here, determination of the $\mathring{a}$ parameter and K values should be less ambiguous. For the $NaBPh_4$ electrolyte in ED solutions, our $\mathring{a}$ values seem to agree with those reported by other authors working in DMSO (16), which is an aprotic but almost isodielectric solvent if compared with ED.

Conclusions

Some closing notes can now be written about our electroanalytical studies in ethane-1,2-diol.

At first, we found that all the salts studied are moderately dissociated in this solvent medium, this fact being expected because of the medium dielectric constant of the solvent at all the temperatures investigated. The most outstanding feature of the dissociation constants reported in this work is that the salts containing larger ions show a progressive amount of association. However, excluding the ionogen solute HPi, the dissociation constant seems to decrease with increasing size of the anion, and the decrease is also observed in the case of the largest cation if compared to that of the smaller cation. These observations can be accounted for by assuming that the stabilization of the anions in ED solution increases in the order $BPh_4^- < Pi^- < Br^-$, and the stabilization of the cations is in the order $Ph_4P^+ < Na^+$. Thus, the behaviour in ED of the selected sodium salts appears perfectly consistent with measurements in other simple alcohols (17) where K decreases with the increasing anion size.

Concerning the single-ion conductivity, it should be noted that the mobility of the small Na^+ cation is less than that of the Br^- anion. This fact suggests that the Na^+ ion could be more strongly solvated by ED molecules than the Br^- species. Furthermore, the transport behaviour of Pi^- and $PH_4P^+ \equiv BPh_4^-$ ions appears small and slightly different in this solvent. A reliable explanation for this can probably be found in the low-density surface charge, masked by an extensive delocalization, and from the high viscosity of the medium, which makes difficult any ionic migration in solution.

Acknowledgments

It is a pleasure to thank Prof. C. Preti for his continuous encouragement to carry out this work and for constructive suggestions concerning this paper. L.M. wishes to thank the Hospal-Dasco s.p.a. (Modena, Italy) for the award of a research fellowship. We also gratefully acknowledge the financial support of The Consiglio Nazionale della Ricerche (C.N.R.) of Italy.

1992 Alfred Bader Award Lecture
Probing the specificity of synthetically useful enzymes[1]

J. BRYAN JONES
Department of Chemistry, University of Toronto, Toronto, ON M5S 1A1, Canada

Received April 13, 1993

J. BRYAN JONES. Can. J. Chem. **71**, 1273 (1993).

Factors involved in controlling and predicting the structural specificity and stereospecificity of synthetically useful enzymes, including pig liver esterase, subtilisin BPN' and Carlsberg, α-chymotrypsin, and an L-lactate dehydrogenase, are discussed.

J. BRYAN JONES. Can. J. Chem. **71**, 1273 (1993).

On discute des divers facteurs impliqués dans le contrôle et dans la prédiction de la spécificité structurale et de la stéréospécificité d'enzymes synthétiques utiles, y compris l'estérase du foie de cochon, la subtilisine BPN' et Carlsberg, l'α-chymotrypsine et une déshydrogénase de la L-lactate.

Enzymes are now broadly accepted as useful catalysts for a broad range of organic synthesis, with their capacities for inducing asymmetric transformations being the most exploited (1). However, despite the widespread uses of both enzymes and microorganisms in asymmetric synthesis, relatively little is known of the factors that determine the structural specificity and stereospecificity of enzymes. In view of the increasingly broad spectrum of new and unnatural substrate structures that synthetically useful enzymes are being called on to accommodate, it is becoming more and more essential to delineate the enzyme–substrate interactions that regulate and control enzyme specificity. This will then permit the selection of the enzymes that are best suited for any given chiral synthon preparation, and will facilitate the development of active-site models capable of accurately forecasting whether an enzyme will accept a new structure as a substrate, and of reliably predicting what the stereochemical outcome of the reaction will be. Knowledge of the factors determining specificity will also facilitate the rational tailoring of enzyme specificity by the site-directed mutagenesis techniques of protein engineering.

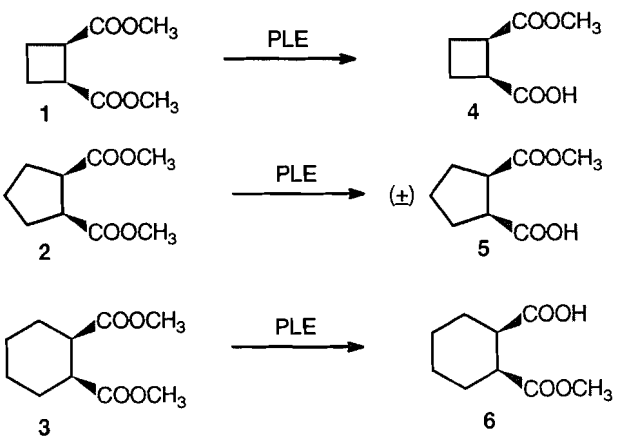
The classes of enzymes most widely applied are the hydrolases and the oxidoreductases and this lecture will focus on probing the specificity of representative, synthetically useful, members of both of these groups.

Hydrolases

An active site model for pig liver esterase

Hydrolases are currently the enzyme group receiving the most attention. Within this group, the esterase that has seen the most extensive utilization is pig liver esterase (PLE, EC 3.1.1.1)) (2). PLE is a serine protease that catalyzes the hydrolysis of a broad range of carboxylic acid esters. It is capable of enantiomeric and enantiotopic group specificity and has been widely employed for resolving racemic esters and for producing chiral acid-ester synthons from prochiral diester substrates. Despite its proven value in asymmetric synthesis, organic chemists became somewhat uneasy in their continued use of PLE because of some uncertainty about the fidelity of its stereospecificity.

For an enzyme to receive universal approval as a routine catalyst for synthetic applications, it is important that its stereospecificity be seen to be unwavering in its absolute configuration preferences from one substrate to another. In this regard, PLE posed a dilemma in that its stereochemistry appeared to be somewhat fickle towards certain substrate groups. For example, within the homologous series of monocyclic meso diesters **1**–**3**, the stereoselectivity of PLE hydrolysis reverses itself. For the cyclobutane diester **1**, the *S*-ester is hydrolyzed to give **4**, while for the cyclohexane substrate **3**, the acid-ester **5** from *R*-ester cleavage is formed. Both **4** and **5** are enantiomerically pure. The cyclopentane substrate **2** represents the changeover point, with the acid-ester **5** being virtually racemic (3*a*). This behaviour turned out to be general, with similar stereospecificity reversals being observed in other substrate series also (3*b*).



Initially we felt that the apparent variability of PLE's stereospecificity was due to the fact that the commercially available material was a melange of similar proteins, with some having *R*, and others *S*, stereospecificity preferences and that separating the mixture into its components would provide us with enzymes of both *R* and *S* types. Separation of PLE into its components by isoelectric focussing gave six distinct fractions of different isoelectric points. However, when each of these fractions was employed to hydrolyze diesters such as **1**–**3**, the stereospecificity results were un-

[1]This is an invited personal review article based on the Alfred Bader Award Lecture presented by Professor Jones at the Annual Conference of the Canadian Society for Chemistry, Edmonton, Alberta, 3 June 1992.

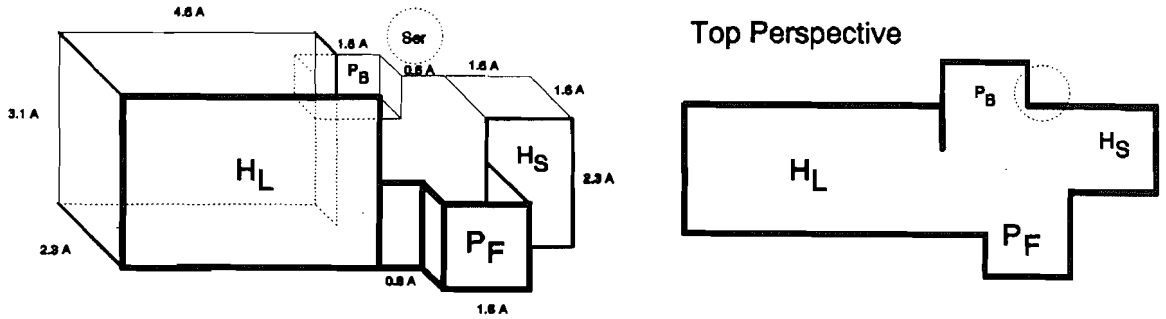


FIG. 1. Active-site model for PLE.

changed (4), thereby demonstrating that, although commercial PLE is a mixture, it behaves as if it is a single species. Thus the stereospecificity reversal patterns observed are a fundamental attribute of PLE's active site. This stimulated us to create an active-site model that would permit all PLE's specificity characteristics to be interpreted.

As with other active-site model proposals (5), the lack of an X-ray structure dictated an empirical approach. We surveyed all the known literature substrates and, using computer graphics, overlaid them to determine the active site volumes and orientations that permitted each substrate to be accommodated satisfactorily in steric terms, and in accord with the experimentally observed stereospecificities. The picture that emerged was surprisingly simple (6), and is depicted in Fig. 1.

The model comprises five binding loci. The boundaries of the binding pockets represent the physical restrictions that amino acids of the enzyme place on substrates binding in the active site and, with the exceptions noted below, substrates may not penetrate them. The catalytically essential region is that of the serine residue that initiates hydrolysis by its attack of the carbonyl group of the susceptible ester function. The binding regions controlling specificity are composed of four pockets, of which two are hydrophobic. Two others are more polar in character. The two hydrophobic zones, which interact with the aliphatic or aromatic hydrocarbon portions of a substrate, are designated $H_{L(arge)}$ and $H_{S(mall)}$. The larger of the two, H_L, has a volume of approximately 33 Å^3, while the smaller H_S pocket has a volume of roughly 5.5 Å^3. Polar groups such as hydroxyl, amino, carbonyl, nitro, etc. are excluded from these areas. However, the hydrophobic pockets can accommodate less polar heteroatom functions such as halogen, and ether or ketal oxygen atoms, if necessary. The remaining two sectors accept groups that are more polar (P) or hydrophilic. They are located at the front (P_F) and back (P_B) of the active site, respectively. Unlike the other binding regions, the rear boundary of the P_B pocket is open, and hydrogen-bonding or similar groups may extend out beyond the back of this region. The area above the model is also open, and is completely accessible to any substrate moiety that needs to locate there. Such groups may extend in this direction without restriction.

This model reveals the structural basis for the stereospecificity reversals in that, for homologous series of substrates such as **1–3**, small hydrophobic groups bind in H_S until they become too large to do so, at which point the substrate orientation must be turned around to place the larger hydrophobic group in the H_L pocket, where there is room to accommodate it. It is this "turning over" requirement that is responsible for the *S*-to-*R* (and vice versa) switches observed experimentally. The situation is exemplified in Fig. 2 for the **1–3** substrate series (6).

The pocket sizes created in the initial Fig. 1 model represented the minimum volumes. Their actual sizes have subsequently been systematically probed with substrates of varying steric requirements (7). The dimensions of H_S, P_B, and P_F have been confirmed as originally identified, but H_L's capacity for large groups turned out to be greater than first specified. Its maximum dimensions have now been established[2] as 6.1Å × 4.6Å × 3.1Å. To the best of our knowledge, when applied correctly (6), this final model now permits all known PLE specificity to be satisfactorily interpreted, and also enables the stereospecificity of PLE-catalyzed hydrolysis to be correctly forecast for new substrate structures.

Probing enzyme specificity

Because of their simplicity, active-site specifications of the Fig. 1 type are presently the models of choice of organic chemists using enzymes synthetically, even when X-ray structures are available. However, they do not provide the understanding of enzyme specificity that in the long term is essential for identifying the range of substrate structures any synthetically useful enzyme can accept, and for selecting the most appropriate enzyme for transforming a given substrate structure into a desired synthon. Accordingly, in order to gain insights into the factors that control and determine enzyme specificity, we have begun to probe the nature of enzyme–substrate interactions in a systematic manner. This involves studying only synthetically useful enzymes for which good X-ray structures are available, using graphics analyses to select substrate or inhibitor structures that address a particular specificity question most appropriately, and, after kinetic studies on the selected structures, analyzing the experimental data with the aid of graphics and molecular modelling methods. The eventual goal of this approach is to maximize the synthetic potential of each enzyme. However, no natural enzyme can be expected to handle the ever-increasing range of substrate structures imposed by the chiral synthon demands of asymmetric synthesis. An important corollary of this strategy is thus its potential for identifying unfavourable amino acid residues at an active site that preclude conversion of a synthetically desirable substrate structure. This opens up the possibility of using the site-directed mutagenesis techniques of protein engineering to correct unsuitable amino acid positions, and eventually to

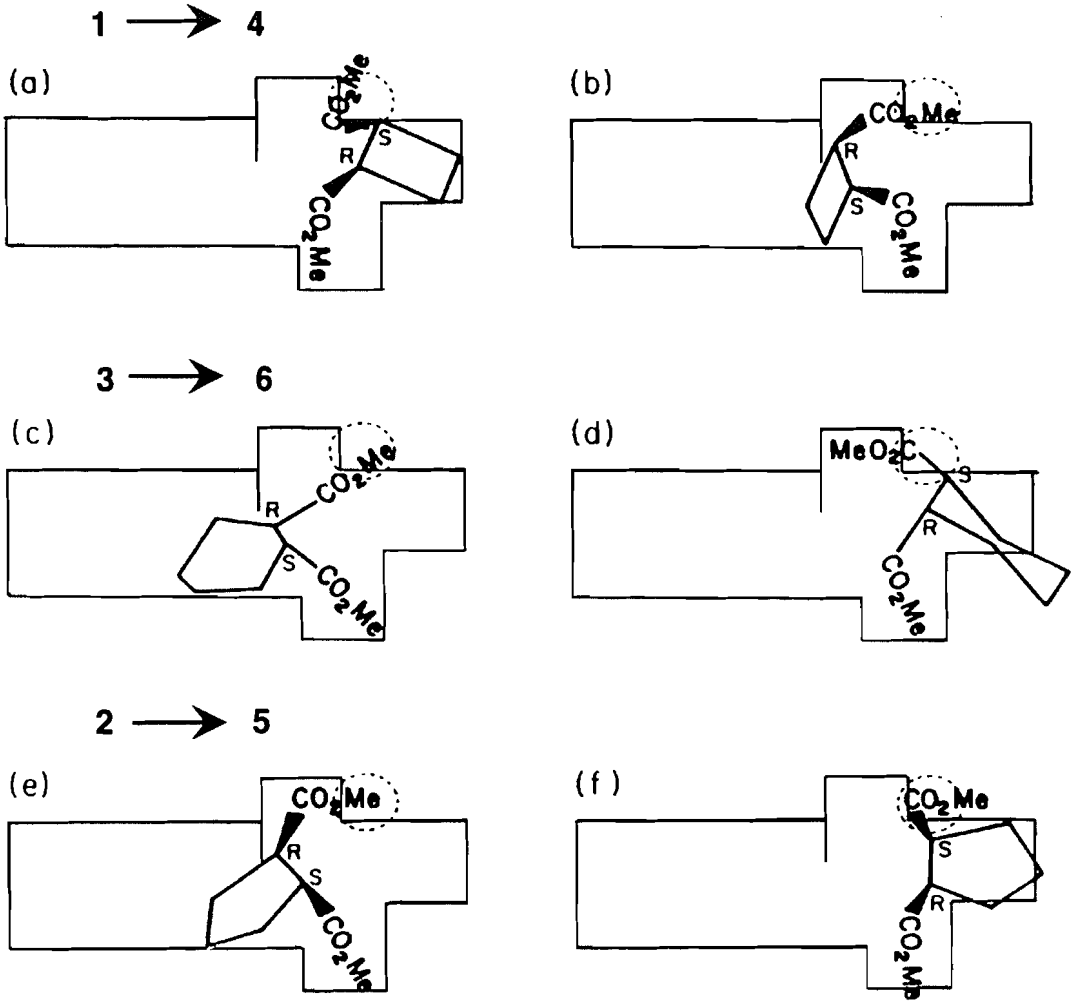

FIG. 2. The top-perspective view of the active-site model is used to illustrate the binding-mode selections for diesters **1**–**3**. Hydrolysis of an ester group can only occur when it locates within the spherical locus of the catalytically active serine function. **Dimethyl cyclobutane-1,2-dicarboxylate (1).** The *S*-centre ester hydrolysis orientation shown in (*a*) permits all substrate groups to be accommodated in the active site binding pockets, with the cyclobutane ring fitting cleanly into, and filling, the H_S pocket. The alternative binding mode required for hydrolysis of the *R*-centre ester would place a portion of the cyclobutane ring in the H_L pocket (*b*). Since binding of hydrophobic groups must occur in the H_S rather than the H_L site if sterically possible, substrate binding as in (*a*) is preferred, in accord with the observed formation of the 2*S*-acid product **4**. **Dimethyl cyclohexane-1,2-dicarboxylate (3).** The binding depicted in (*c*) shows the preferred ES-complex for hydrolysis of the *R*-center ester to the 2*R*-acid **6**, with the cyclohexane ring bound in the large hydrophobic pocket. Hydrolysis of the *S*-ester would require the orientation shown in (*d*). This is precluded since the H_S pocket is clearly too small to accept the six-membered ring. **Dimethyl cyclopentane-1,2-dicarboxylate (2).** In this instance, both *R*- and *S*-centre ester functions can be acceptably located in the serine sphere, as shown in (*e*) and (*f*), respectively. The cyclopentane group is marginally too large for optimum fit into H_S, resulting in a slight preference for hydrolysis via (*e*) that translates into a 17%ee of the corresponding 2*R*-acid **5**.

tailor an enzyme's specificity so that any given structural requirement will be accommodated.

Probing the structural specificity of hydrolases

The target enzymes selected as being representative of synthetically useful hydrolases were subtilisin BPN′ (SBPN, EC 3.4.21.14), subtilisin Carlsberg (SC, EC 3.4.21.14), and α-chymotrypsin (CT, EC 3.4.21.1). These serine proteases favour ester substrates possessing hydrophobic groups that bind well into the S_1 active site pocket, as represented schematically in Fig. 3(*a*) for the ES-complex formed by SBPN and its excellent substrate *N*-acetyl-L-phenylalanine methyl ester (NAPME). In this ES-complex, the hydrophobic benzyl group of NAPME fits nicely into the S_1 pocket, which in this case provides an appropriate environment as a result of the hydrophobic amino acid residues that form it. However, the unnatural substrates that SBPN may in the future be called on to hydrolyze could well include polar residues, towards which the natural S_1 environment would be hostile. We therefore decided to see if the S_1 pocket of the wild-type (WT) enzyme could be protein-engineered to be more accommodating of polar groups.

N-Tosyl-L-argininine methyl ester (TAME) was selected as a substrate structure whose positively charged side chain was much more polar than that of NAPME, and for which a poor interaction was anticipated between its guanidinium group and the hydrophobic S_1 environment of WT-SBPN if binding in the Fig. 3(*b*) manner took place. We therefore explored the prospect of making the S_1 trough more receptive to TAME-like side chains by changing the Gly166 residue at the bottom of S_1 to amino acids such as Asn or Ser

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

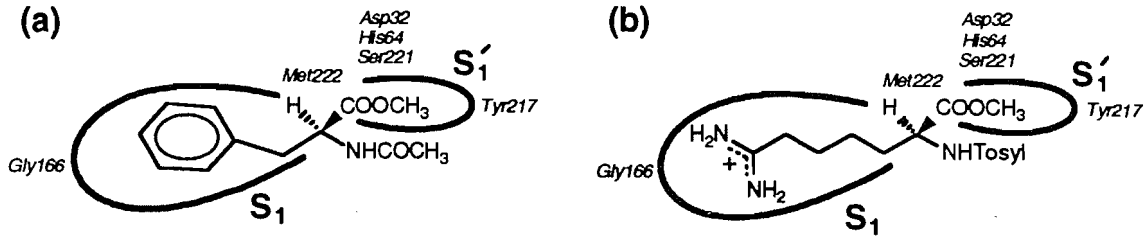

FIG. 3. Schematic representation of the active site of subtilisin BPN'. In (*a*) the nonpolar benzyl group of NAPME binds well in the hydrophobic S_1 pocket, which has a Gly166 located at its end. The S'_1 region that accommodates the leaving group is not very large, being blocked off at the end by Tyr217. S'_1 also contains the serine residue of the catalytically vital Ser221-His64-Asp32 serine protease triad. In (*b*) TAME is depicted in an orientation that site-directed mutagenesis of Gly166 to Asn or Ser should promote by creating a favourable hydrogen-bonding environment for the guanidinium function, thereby ameliorating the inhospitality of the hydrophobic milieu of S_1 towards polar groups.

whose side chains are capable of hydrogen bonding to polar groups such as guanidinium. The results obtained supported the validity of this strategy, with the effectiveness of TAME binding being increased by up to 2.4-fold, as reflected by the improvement in K_m from 34 mM for WT-SBPN to 21 and 14 mM for the Gly166Asn and Gly166Ser mutants, respectively. The G166S enzyme was the most effective catalyst of this series for TAME hydrolysis, and graphics analysis indicated it to be the optimum 166 mutant for this substrate (8).

The S'_1 site is also an important region in terms of specificity control. It is the zone in which the leaving groups of amide and ester substrates locate prior to, and during, the acylation step. In SBPN, the S'_1 site is not very large, having at its end a bulky hydroxybenzyl side chain of Tyr217 (Fig. 3) with the potential to restrict its ability to accept large leaving groups. In such situations, replacement of the relatively large Tyr217 at the end of the S'_1 region of SBPN by the smaller Leu residue (as present in subtilisin Carlsberg) should increase the space available for accommodating leaving groups. This was confirmed for the Tyr217Leu mutant, prepared by the Genencor International group (9), using the tetrapeptide substrates **7***a*,*b*. For **7***a*, its *p*-nitroanilide leaving group is still present in the rate-determining acylation step, and the catalytic constant k_{cat} is increased by a factor of 5.6 when the volume of S'_1 is increased by substituting the smaller Leu side chain for that of Tyr217 of the WT-SBPN. In contrast, for the ester substrates such as TAME or **7***b*, for which leaving groups have already departed prior to the deacylation rate-determining step, the k_{cat} values for the Tyr217Leu and WT enzymes are virtually identicial, as expected, with the differences in size between the thiobenzyl and methoxy functions being without effect on the catalytic constant (8).

Succinyl-L-Ala-L-Ala-L-Pro-L-Phe-X

7*a*, X = *p*-nitroanilide; **7***b*, X = thiobenzyl

Mutation of Met222 to Phe represents the converse situation in that the volume of S'_1 is markedly reduced by the substitution of the benzyl side chain for that of methionine. The rate of hydrolysis of the amide substrate **7***a*, with its medium-sized leaving moiety, is now reduced by this mutation, with the k_{cat} value observed for hydrolysis of **7***a* with the Met222Phe being 14-fold lower than for the WT enzyme. Once again, as expected because deacylation is rate determining for esters, the k_{cat}'s for WT and Met222Phe-catalyzed hydrolyses of TAME and **7***b* are unaffected. While reducing catalytic effectiveness is seldom a worthwhile goal, in this case the combination of the sharply reduced amide hydrolysis efficiency and unchanged esterase activity of SBPN Met222Phe is of particular synthetic interest. This mutant should be an excellent catalyst for the preparation of peptides by coupling of amino acid ester components in that the ester-to-acyl enzyme steps will proceed normally, but little subsequent hydrolysis of the newly formed peptide bond can occur. The potential thus exists for practical peptide synthesis in aqueous solution.

Probing hydrolase stereospecificity

So far, the use of enzymes in asymmetric synthesis has often been confined to the creation of chiral synthons with only one stereocentre. However, in principle, the large chiral environments provided by enzymes have the capacity to discriminate and control many stereocentres concurrently, potentially providing access to any multiple-stereocentre combination desired in syntheses of chiral targets. We have begun to explore this with the two-stereocentre substrates **9** and **10**, in which the natural L (*S*) configuration preferred by esterases is maintained at the α-amino position, but with either an *S*(**9**) or *R*(**10**) configuration at C-3. These *p*-nitro compounds were selected because of their synthetic potential as chloramphenicol precursors (10). The question was: will serine proteases such as subtilisin Carlsberg (SC) or α-chymotrypsin (CT) discriminate the second, C-3, centre?

The kinetic results, together with those on the *p*-nitrophenylalanyl parent **8** of **9** and **10**, showed that the replacement of either the *pro-R* or *pro-S* C-3-H by an OH group caused a $>10^4$-fold reduction in the hydrolysis rates, as reflected by the specificity constants, k_{cat}/K_M, for both SC- and CT-catalyzed reactions. While the rates of SC and CT hydrolyses of **9** and **10** were low, they remained preparatively viable. However, the SC, the hydrolysis rates of **9** and **10** were about the same, being 126 and 360 M^{-1} s^{-1}, respectively, showing that the enzyme did not distinguish significantly between a C-3 *S* or *R* centre and that separation of a diastereomeric mixture of **9** and **10** could not be achieved using SC hydrolysis. On the other hand, while the rate of CT hydrolysis of **9** was also low (k_{cat}/K_M 70 M^{-1} s^{-1}), **10** was not a substrate at all so that CT could very effectively be applied to separate the individual diastereomers from a mixture of **9** and **10**.

The reasons for the dramatic rate reductions for both SC

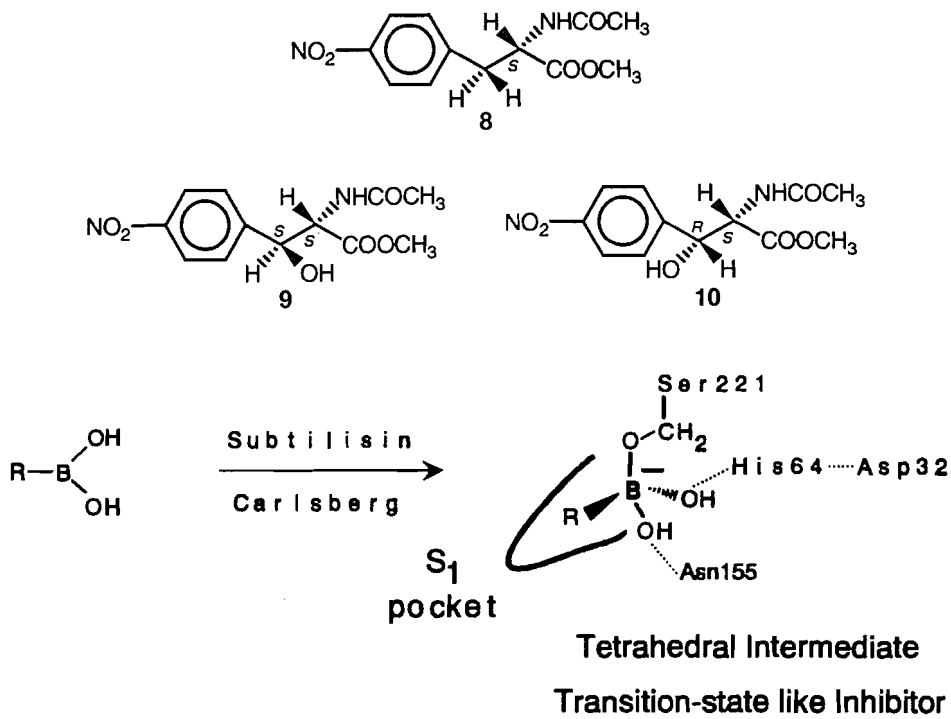

FIG. 4. Schematic representation of boronic acid inhibitor binding to subtilisin Carlsberg.

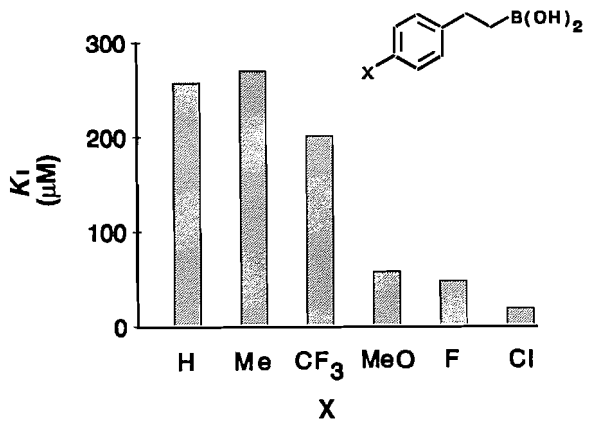

FIG. 5. *para*-Substituent effects on phenylboronic acid inhibitors of subtilisin Carlsberg.

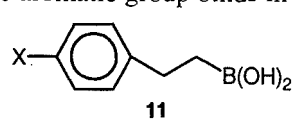
and CT on introducing a C-3 OH substituent of either configuration, and for the differences in the abilities of the two enzymes to distinguish between the two C-3 configurations, were revealed by molecular modelling. The acyl enzyme intermediates derived from the *p*-nitrophenylalanyl parent compound **8** for each of SC and CT were minimized by molecular mechanics and molecular dynamics using the BioSym DISCOVER program. For the SC-complex, the C-3 hydrogens of **8** were located in the bottom of the S_1 pocket in environments of about equal steric constraints that are large enough to accept either an *S*- or *R*-centre hydroxyl group, but not without engendering some unfavourable steric interactions, specifically with Ala152 and Asn155 for an *S* OH and with Ser 125 for an *R* OH. Thus the consequences of replacing either the C3 *pro-S* or *pro-R* hydrogens by hydroxyl, as in **9** or **10**, respectively, both result in reduced hydrolysis rates, and to approximately the same degree. On the other hand, while the situation for the *pro-S* C-3 H of **9** in the CT-complex parallels closely that of the SC situation, the *pro-R* C-3 H of **10** is already in van der Waals contact with Cys191, Met192, Gly193, and Asp194 and this site cannot accommodate anything larger than hydrogen. Thus when the *pro-R* C-3 H is replaced by OH, as in **10**, formation of an acyl enzyme is precluded and the *S*, *R* diastereomer **10** is a non-substrate. In fact, **10** does not bind at all to CT, as demonstrated by its ineffectiveness ($K_I > 150$ mM) as a competitive inhibitor.

Exploiting electrostatic contributions to binding

When the electrostatic potential surfaces of SC and CT are calculated using the BioSym DELPHI programme, the patterns for the two enzymes are very different. We wondered if such electrostatic differences could be exploited to improve the strength or selectivity of binding to enzymes for appropriately designed substrates or inhibitors. For example, the calculations showed that, at the bottom of the S_1 pocket of SC, there was a region of positive potential that could contribute to increased binding strength of a substrate or inhibitor possessing a group of negative potential capable of interacting with this positive enzyme locus. The initial evaluations of this concept were carried out with the boronic acid inhibitors **11**. When bound to serine proteases, boronic acids of this type are transition state inhibitors that form EI-complexes of the type represented in Fig. 4, in which the aromatic group binds in S_1.



11

a, X = H *d*, X = OCH_3
b, X = CH_3 *e*, X = F
c, X = CF_3 *f*, X = Cl

In such orientations, the *para* substituents should then project into the positive region at the base of S_1. The results observed with the series of inhibitors **11***a–f* support this concept, as shown in Fig. 5, with the strength of binding increasing, as reflected by the decreasing K_I values, as the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

negative potential character of the *para* substituent increases (11). For the *p*-chloro inhibitor **11***f*, with the most negative *para* group and thus the greatest electrostatic attraction with the base of S_1, binding is 13.5-fold stronger than for the parent compound **11***a*. The possibility that the observed trends simply reflected desolvation energy differences between the inhibitors on forming the respective EI-complexes was excluded by calculations and from literature tabulations of experimental solvation data.

Oxidoreductases

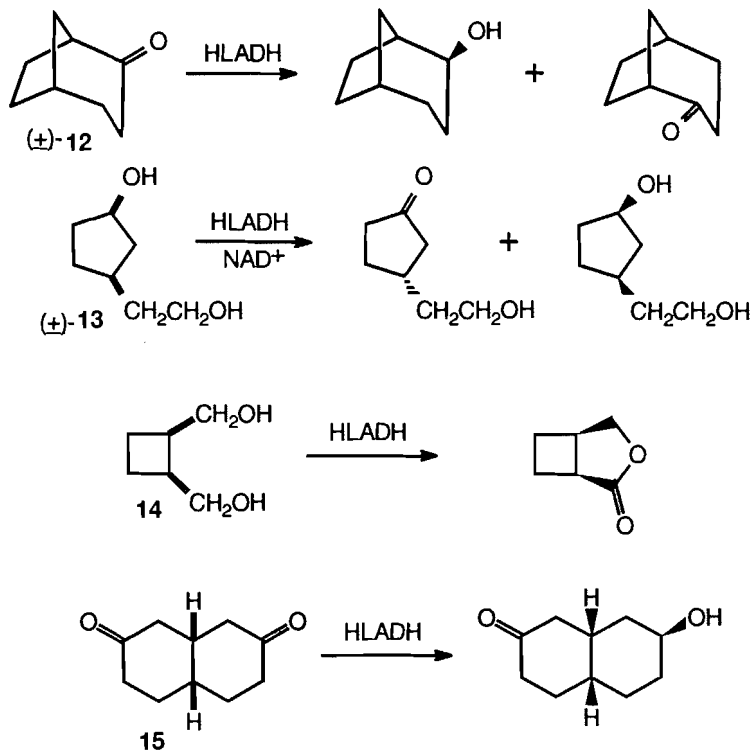
Oxidoreductases, such as horse liver alcohol dehydrogenase (HLADH) have proven of considerable interest in asymmetric synthesis. Illustrative examples of HLADH use include resolution, combined with diastereotopic face selectivity, of racemic ketones such as **12**, and additionally of regioselectivity, as in the oxidation of **13**, and of the enantiotopic group and face distinctions involved in the conversions of **14** and **15** (1*c*).

With the potential of a broad specificity oxidoreductase like HLADH well documented, we decided to examine an enzyme of this group with narrower specificity, with the intent of probing the factors determining structural and stereospecificity. The oxidoreductase selected was the L-lactate dehydrogenase of *Bacillus stearothermophilus* (BSLDH). BSLDH is an excellent candidate for such exploratory studies since it is a very stable, thermophilic, enzyme of known protein sequence and its properties have already been the subject of several studies (12). Also, its gene has been cloned and the protein very efficiently overexpressed, thereby enabling large quantities of BSLDH to be produced inexpensively from small fermentation volumes (13). Furthermore, the feasibility of altering the specificity of the native enzyme by site-directed mutagenesis of key active-site amino acid residues has been established (12).

On the structural specificity of BSLDH

BSLDH is an NAD/H coenzyme-dependent, fructose-1,6-diphosphate (FDP) activated, enzyme whose in vivo function is to catalyze pyruvate $\rightleftharpoons$ L-lactate oxidoreductions of the type

$$\underset{\mathbf{16}}{\text{RCOCOOH}} + \text{NADH} + \text{H}^+ \rightleftharpoons \underset{\mathbf{17}}{\text{RCH(OH)COOH}} + \text{NAD}^+$$



While its strongly preferred substrate is pyruvate (**16**, R = Me) with its small R group, BSLDH will accept as substrates a broad range of α-ketoacids, albeit with substantial rate penalties for large or branched R groups. Nevertheless, preparative-scale reactions to produce a range of enantiomerically pure L-α-hydroxyacids **17** are feasible, as illustrated in Fig. 6 (12).

Much is known about the structure of the active site of BSLDH (14). The key features are represented in Fig. 7. The narrow substrate specificity is due, at least in part, to the fact that the 98–110 and 235–248 loops close over the ketoacid substrate during the formation of the active ES-complex, thereby leaving only a restricted volume for the R side chains. Graphics analyses revealed that, in the productive ES-complex, large R groups would engender a bad steric interaction with the loop residue Gln102 and indicated that these adverse interactions with bulky, especially branched-chain, substrates could be diminished by reducing the size of the 102-position amino acid side chain. The validity of this analysis was tested by using site-directed mutagenesis to replace Gln102 by Asn, an amino acid of similar hydrophobicity but having one fewer CH_2 group in its side chain and thus providing more room for bigger side chains. The results obtained supported the application of such protein en-

gineering approaches to expand the structural specificity of enzymes, with the Gln102Asn mutant now being a better enzyme than WT-BSLDH for substrates such as **16**, R = $CH_3(CH_2)_{2-5}$, $(CH_3)_2CH$, $(CH_3)_2CHCH_2$, $CH_3CH_2CH(CH_3)$, and C_6H_5 (15).

Probing BSLDH stereospecificity

The stereospecificity of enzymes is their most important property for asymmetric synthetic applications. However, as noted already, little is known about the factors that determine and control enzyme stereospecificity. With L-LDH's being so committed to *Re*-face carbonyl attack to give (*S*)-α-hydroxyacids, BSLDH provides an excellent instrument for beginning to identify and understand important stereospecificity determinants, initially of oxidoreductases, but eventually of all enzymes. Among the methods of probing the factors controlling enzyme stereospecificity, evaluating how effectively an enzyme resists attempts to change this capability is potentially one of the most powerful. The natural L stereospecificity of BSLDH is determined by the orientation of 2-ketoacids, such as pyruvate (**16**, R = CH_3), in the ES-complex such that the hydride equivalent from NADH is delivered to the *Re* face of the carbonyl group. This is depicted schematically in Fig. 8(*a*). An important interaction helping to maintain this pyruvate orientation is that between the substate's COO^- and Arg171. As one measure of BSLDH's commitment to the L pathway, we elected to evaluate its resistance to being induced to catalyze D-lactate formation. Reduction of pyruvate to D-lactate requires delivery of the NADH-"hydride" to the *Si* face of pyruvate. One of the ways that can be envisaged of inducing this *Si*-face attack would be via an ES-complex in which the orientation of pyruvate was reversed, as illustrated in Fig. 8(*b*).

Towards this goal, Arg171 was replaced by Tyr and Trp. Despite the elimination of the key Arg171-COO^- binding

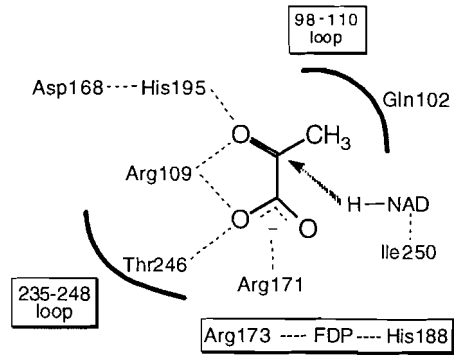

FIG. 7. Important active-site amino acid residues of BSLDH.

orientation, the Arg171Trp/Tyr mutants were still completely L-stereospecific (16). In a subsequent study, the WT-Arg171 was retained but a second COO^--binding Arg residue was introduced in place of Gln102, thereby providing a competitive possibility between the Fig. 8(*a*) and 8(*b*) pyruvate orientations and the prospect of formation of racemic products. As expected (17), the best substrates for this mutant were dicarboxylic α-ketoacids that concurrently exploit both the Arg171 and 102Arg binding sites. However, once again, this Gln102Arg mutation did not disturb the L proclivity of BSLDH in any preparatively significant way, with only L-α-hydroxyacids being produced in preparative-scale reeactions. Nevertheless, this mutant provided the first indication that it was possible to disturb the natural L-stereospecificity of BSLDH in that, in contrast to the WT situation for which oxidation of L-malate was much faster than for the D enantiomer, the rates of oxidation of L- and D-malate for the Gln102Arg mutant had become approximately equal (12). In the latest experiments, the 171 Trp/Tyr and 102Arg mutations were combined in order to eliminate any prospect of the natural Arg171-COO^- interaction and at the same time to provide the opportunity for a reversal of pyruvate orientation via 102Arg-COO^- binding. Furthermore, the formation of the natural, Arg171-directed, Fig. 8(*a*) type complex is clearly impossible for the Arg171Trp/Tyr;Gln102Arg double mutants. Despite the binding constraints designed into these double mutants, their fidelity with respect to L-stereospecificity remained dominant, with preparative-scale reductions of α-ketoacids affording only the L-hydroxyacids.

The question of how the above BSLDH mutants maintain their control of L-stereospecificity is thus an intriguing one. The X-ray structure of the 171Trp/102Arg/97Gly triple mutant that is now being refined should provide new insights into these questions. Already it is clear that Arg171Trp replacement is not wholly benign, and that the 171Trp side chain shifts out of the active site (18). Because none of the 171 or 102 mutations disturbs the natural stereospecificity of BSLDH, it is evident that there must be fail-safe, L-directing, interactions that take over when Arg 171 is not present. One such fail-safe candidate is Thr246. Other X-ray data (14) indicate that the Thr246 side chain is close enough to the substrate carboxylate function for effective hydrogen bonding (Fig. 7), although explaining how such a secondary, hydrogen-bonding, interaction could override carboxylate binding to 102Arg-containing mutants in the productive ES-complexes remains a quandary. This is particularly true for small substrates such as pyruvate for which, other than

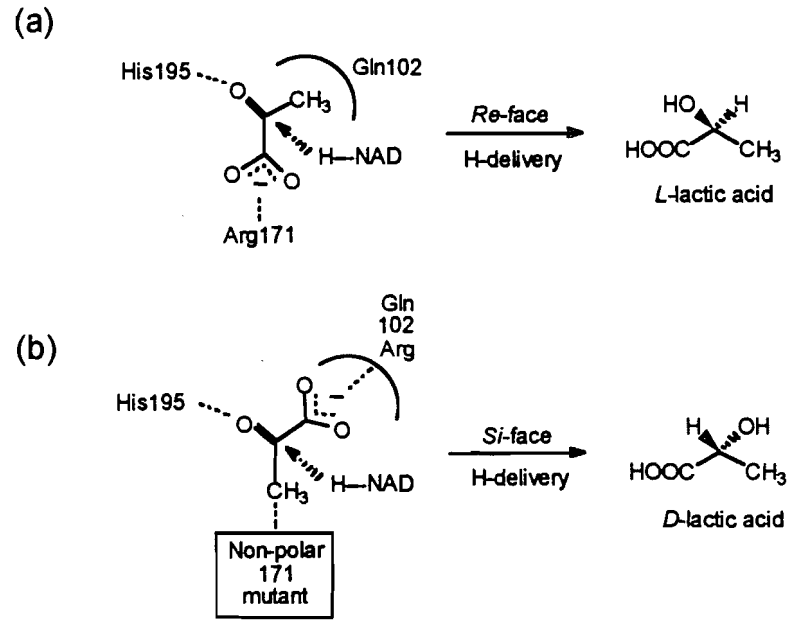

FIG. 8. Schematic representation of pyruvate bound at the active site of BSLDH in orientations leading to L- or D-lactic acid formation. Part (*a*) represents the natural binding mode that results in L-lactate formation. Part (*b*) illustrates a reversal of the natural binding orientation of pyruvate that might be induced by mutations such as Arg171Trp/Tyr, Gln102Arg, and combinations thereof, that would lead to D-lactate as the product.

the carbonyl group being reduced, the carboxylate group is the only function capable of binding strongly to the enzyme.

We have started to investigate the role of Thr246 by studying the catalytic properties of several 246 mutants, including Thr246Ala/Val/Leu/Ser. Although none of the mutants was as effective an oxidoreductase as WT-BSLDH, they did exhibit some interesting catalytic properties with respect to substrate inhibition. Substrate inhibition is a common phenomenon in enzyme-catalyzed reactions and can be a major problem in preparative-scale applications because of the very high substrate concentrations that are employed in large-scale transformations. In fact, substate inhibition can be very serious for BSLDH, particularly with pyruvate as substrate, and can result in reductions being brought to a virtual standstill. However, when no hydroxyl group is present in the 246 side chain, as for Thr246Val/Ala, substrate inhibition is virtually eliminated, as shown by the constant V_{max} values at high [S] for these two mutants (Fig. 9). Substrate inhibition of BSLDH arises from the strong complexation of pyruvate with the E.NAD$^+$ complex in the catalytic cycle. This does not occur with Thr246Val/Ala because pyruvate no longer binds effectively to E.NAD$^+$, as reflected by the dramatic increases in apparent K_I for pyruvate for this step for these two mutants (Fig. 10) (19). The effect is especially evident for the smaller 246Ala side chain where, with a K_I(app) of almost 800 mM, pyruvate is clearly not binding at all to E.NAD$^+$. Also, for WT-BSLDH, the rate-determining step (k 250 s^{-1} (13)) for pyruvate reduction is closure of the 98–110 loop. Mutation of Thr246 to Ala slows the loop closure rate such that the hydride transfer process becomes at least partially rate limiting, as refleted by the k_H/k_D kinetic isotope effect of 2.4.

Although the Arg171 and Gln102 mutations did not disturb the stereospecificity of the enzyme, there were serendipitous benefits to these changes in that thermal stability of BSLDH was further increased, dramatically so for the Arg171Tyr enzyme, for which the T_m(app) was increased by 9.4°C over that of WT-BSLDH. The greatest increase in T_m(app) was 10.7°C for Arg171Tyr, Gln102Arg. At high ionic strength, even higher thermal stabilization was manifest. Notably, in the presence of 100 mM K_2SO_4, the Arg171Tyr, Gln102Arg mutant retains 30% activity even after heating for 30 min at 100°C, conditions under which the already moderately thermostable WT-enzyme is completely inactivated in less than 2 min (18). This has considerable potential synthetic benefits since preparative-scale BSLDH-catalyzed reactions at temperatures of up to 100°C can now be contemplated, subject to NAD-coenzyme survival for sufficient time. The reason for the increased thermal stabilizations on replacing the Arg171 by hydrophobic residues such as Trp seems due to more favourable hydrophobic subunit contacts. This view is supported by preliminary X-ray structural evidence for a mutant BSLDH containing tryptophan in the 171 position. In this structure, the 171W side chain is rotated around the C_a—C_b bond, relative to the wild-type arginine side chain. The mutant indolyl group is thus located completely outside of the active site, and it projects into the space occupied by the other subunit in the BSLDH dimer in a manner that increases the hydrophobic subunit interface area (ref. 20 and footnote 3).

While the data presented in this lecture represent a beginning towards identifying the factors that determine enzyme specificity, it is evident that much needs to be done before enzymes and substrates can be tailored with confidence to permit optimum results in all asymmetric synthetic applications, and to maximize their performance and stability as catalysts. However, in view of the tremendous progress now being made in protein research, many exciting new insights

into enzyme catalysis and specificity can be anticipated in the next few years.

Acknowledgments

I am grateful to have this opportunity to acknowledge the many excellent students and postdoctoral fellows who have contributed, either directly or indirectly, to the body of knowledge of which the work described was built, and with whom it has been such a privilege to work. Most of the results presented were obtained by Pierre Bonneau, Jim Hogan, Helmut Kallwass, Tom Keller, Valeri Martichonok, Wendy Parris, Louis Provencher, Roman Sakowicz, Peter Seufer-Wasserthal, and Eric Toone. The subtilisin–mutants work was done in collaboration with Dave Estell and Tom Graycar of Genencor International and the BSLDH mutant X-ray structures by Michael James and R. Kodandapani at the University of Alberta. I am particularly indebted to my colleague and long-term collaborator, Marv Gold, without whose protein and molecular biology insights and expertise the BSLDH work would not have been possible. I also thank the Natural Sciences and Engineering Research Council of Canada and the Protein Engineering Network of the Canadian Centres of Excellence for generous financial support. Finally, I express my appreciation to Dr. Alfred Bader for setting up the Bader Award of the Canadian Society for Chemistry, for which I feel very privileged and honoured to have been selected. This is also an appropriate occasion to recognize the long-standing commitment and support by Dr. Bader of Canadian, and world, chemistry in other areas, not the least of which is the huge range of routine and state-of-the-art research chemicals that the company that he founded, Aldrich, has made available over the years and without which our research could never have been done.

University of Toronto, Department of Metallurgy and Materials Science, Toronto, ON M5S 1A4, Canada

Received October 1, 1992[2]

G.J. KIPOUROS and S.N. FLENGAS. Can. J. Chem. **71**, 1283 (1993).

The standard electrode potentials for the formation of the pure solid and molten compounds Li_2ZrCl_6, Li_2HfCl_6, Na_2ZrCl_6, Na_2HfCl_6, K_2ZrCl_6, K_2HfCl_6, Cs_2ZrCl_6, and Cs_2HfCl_6 have been calculated from measured vapour pressures corresponding to their thermal decomposition at equilibrium and from available thermochemical data. Reversible potentials for the formation of Na_2ZrCl_6 and of K_2ZrCl_6 in solution according to the reaction

$$Zr(s) + 2ACl\ (\text{in } ACl\text{–}A_2MCl_6) + 2Cl_2(g,\ 1\ atm) = A_2MCl_6\ (\text{in } ACl\text{–}A_2MCl_6)$$

where A is Na or K, have been calculated from available equilibrium vapour pressures as functions of the mole fractions of the alkali hexachlorocompounds. Standard potentials for the above reaction and "formal" potentials are also given. The latter are useful in predicting the electrochemical behaviour of dilute solutions of the hexachlorozirconates in alkali metal chlorides.

G.J. KIPOUROS et S.N. FLENGAS. Can. J. Chem. **71**, 1283 (1993).

Utilisant les pressions de vapeur correspondantes à leur décomposition thermique à l'équilibre ainsi que des données thermochimiques disponibles, on a calculé les potentiels standard d'électrode pour la formation des composés purs solide ainsi que fondu suivants : Li_2ZrCl_6, Li_2HfCl_6, Na_2ZrCl_6, Na_2HfCl_6, K_2ZrCl_6, K_2HfCl_6, Cs_2ZrCl_6 et Cs_2HfCl_6. On a calculé les potentiels réversibles pour la formation du Na_2ZrCl_6 et du K_2ZrCl_6 en solution, selon la réaction :

$$Zr(s) + 2ACl\ (\text{dans } ACl\text{–}A_2MCl_6) + 2Cl_2(g,\ 1\ atm) \rightleftarrows A_2MCl_6\ (\text{dans } ACl\text{–}A_2MCl_6)$$

dans laquelle A représente Na ou K; pour ce faire, on a utilisé les équilibres disponibles de tension de vapeur en fonction des fractions molaires des composés hexachloroalcalins. On rapporte aussi les potentiels standard et «formels» des réactions mentionnées ci-dessus. Les derniers sont utiles pour prédire le comportement électrochimique de solutions diluées d'hexachlorozirconates dans des chlorures de métaux alcalins.

[Traduit par la rédaction]

Introduction

The knowledge of the thermodynamic and electrochemical properties of $ZrCl_4$ and of $HfCl_4$ and of their solutions of alkali chloride melts is important for the development of new processes for the recovery of the corresponding refractory metals by high-temperature fused-salt electrolysis. Pure $ZrCl_4$ and $HfCl_4$ are non-ionic, covalently bonded compounds that do not conduct electricity and are very volatile. However, $ZrCl_4$ and $HfCl_4$ vapours at specific partial pressures and temperatures react with alkali chlorides and form stable stoichiometric complex compounds of the general formula A_2MCl_6, where A represents an alkali metal like Li, Na, K, or Cs and M is a refractory metal such as Hf or Zr. The compounds have been investigated extensively in this laboratory and equilibrium vapour pressures representing the reactions

$$[1] \quad A_2MCl_6(s, l, \text{solution}) = 2ACl(s, l, \text{solution}) + MCl_4(v)$$

have been measured (1–5). Some phase relationships in the binary mixtures ACl–A_2MCl_6 have also been determined.

The use of such solutions in the electrolytic cells for the recovery of Hf or Zr by fused-salt electrolysis has been considered (6–11). However, the corresponding reversible electrode potentials for the formation of the complex compounds from the elements have not been measured. Direct emf measurements would require the construction of an electrochemical cell consisting of a metal M indicator electrode and of a chlorine electrode, where both are immersed in a melt consisting of pure A_2MCl_6 or a solution of A_2MCl_6 in ACl. These measurements, however, are impossible experimentally, as previous work in this laboratory has shown (12, 13) that the tetravalent specie M^{4+} is reduced by the metal M to lower valence specie, according to chemical reactions like

$$[2] \quad \left(\frac{4}{n} - 1\right) M(s) + MCl_4(\text{solution}) = \frac{4}{n} MCl_n(\text{solution})$$

where n could have values like 1, 2, or 3.

Even under very careful experimental conditions the measured emf's are time dependent and should only be described as "mixed potentials" (14). In a high-temperature electrolytic cell the anodic and the cathodic overvoltages are expected to have low values. Therefore, in addition to the internal voltage drop due to the resistance of the electrolyte (IR drop), most of an applied potential should be used for the reversible decomposition of the complex chlorocompounds. This potential is the reverse of the reversible emf for the formation of the complexes.

In the present investigation a method is presented for calculating standard cell potentials from thermodynamic data from the equilibrium vapour pressures measured in this lab-

oratory (1–5). From this information reversible decomposition potentials for the recovery of Zr metal from solutions of A_2ZrCl_6 in alkali chlorides at various compositions were also calculated from available activity data (15).

Procedure

The formation of the pure A_2MCl_6 solid compounds (1–5), at temperatures below the eutectic temperature of the corresponding A_2MCl_6–ACl binary mixtures, proceeds according to the reaction

[3] $2ACl(s) + M(s) + 2Cl_2(g, 1\ atm) = A_2MCl_6(s)$

where A_2MCl_6, ACl, and M are, respectively, pure solids. Similarly, the formation of pure molten A_2MCl_6 compounds occurs only at temperatures higher than their melting temperatures according to the reaction

[4] $2ACl(l) + M(s) + 2Cl_2(g, 1\ atm) = A_2MCl_6(l)$

where A_2MCl_6 and ACl are, respectively, pure liquids.

For the formation of A_2MCl_6 as a solute in a solution containing n_1 moles of A_2MCl_6 and n_2 moles of ACl, the corresponding reaction may be written as

[5] $M(s) + 2Cl_2(g, 1\ atm) + [(A_2MCl_6)_{n_1} \cdot (ACl)_{n_2}] = [(A_2MCl_6)_{n_1+1} \cdot (ACl)_{n_2-2}]$

where the quantities in brackets indicate solutions and n_1, n_2 are, respectively, infinitely large mole numbers. Through this requirement, solutions to the left or to the right of the equal sign represent solute species having partial molar Gibbs free energies defined by a constant mole fraction, $x_1 = n_1/(n_1 + n_2)$.

Information on the formation potentials in reactions [3], [4], and [5] may be obtained by thermodynamic cycles using available Gibbs free energies for the reactions given below as

[6] $2ACl(s) + MCl_4(v, 1\ atm) = A_2MCl_6(s)$ $\quad \Delta G_6^0$

[7] $M(s) + 2Cl_2(g, 1\ atm) = MCl_4(v, 1\ atm)$ $\quad \Delta G_7^0$

[8] $A_2MCl_6(s) = A_2MCl_6(l)$ $\quad \Delta G_8^0$

[9] $2ACl(l) = 2ACl(s)$ $\quad -2\Delta G_9^0$

From reactions [6] and [7], by addition, reaction [3] is readily obtained, for which

[10] $\Delta G_3^0 = \Delta G_6^0 + \Delta G_7^0$

where ΔG^0_3 is the Gibbs free energy of formation of pure solid A_2MCl_6, as in reaction [3].

From reactions [6], [7], [8], and [9], reaction [4] is readily derived for which

[11] $\Delta G_4^0 = \Delta G_6^0 + \Delta G_7^0 + \Delta G_8^0 - 2\Delta G_9^0$

where ΔG_4^0 is the Gibbs free energy of formation of pure molten A_2MCl_6, as in reaction [4].

For the formation of A_2MCl_6 in solution, as in reaction [5],

[12] $\Delta G_5 = \overline{G}_{A_2MCl_6} - 2\overline{G}_{ACl} - G_M^0 - G_{Cl_2}^0$

where $\overline{G}_{A_2MCl_6}$, $\overline{G}_{ACl}$ and, respectively, the partial molar Gibbs free energy contents of A_2MCl_6 and ACl in a solution having a mole fraction of x_1.

From the Gibbs free energies for reactions [5] and [4], by subtraction,

[13] $\Delta G_5 - \Delta G_4^0 = \overline{\Delta G}_{A_2MCl_6} - 2\,\overline{\Delta G}_{ACl}$

where $\overline{\Delta G}_{A_2MCl_6}$ and $\overline{\Delta G}_{ACl}$ are, respectively, the Gibbs partial molar free energies of mixing for A_2MCl_6 and ACl with respect to the standard states of the pure molten salts at the same temperatures. The latter are related to the activities by the relationships

[14] $\overline{\Delta G}_{A_2MCl_6} = RT \ln a_{A_2MCl_6}$

and

[15] $\overline{\Delta G}_{ACl} = RT \ln a_{ACl}$

From the well-known relationship between the Gibbs free energy for a chemical reaction, ΔG_R, and the corresponding electrode potential

[16] $\Delta G_R = -zFE$

the standard potentials for reactions [3] and [4] are calculated as

[17] $\Delta G_3^0 = -4FE_3^0$

[18] $\Delta G_4^0 = -4FE_4^0$

for which E_3^0 and E_4^0 are, respectively, the standard formation potentials for A_2MCl_6 with respect to the solid and the molten pure salt states as standard. F is the Faraday constant given as 23 060 cal mol^{-1} V^{-1}.

From eqs. [13], [14], [15], and [18], the expression for the formation Nernst potential of A_2MCl_6, representing eq. [5], is given as

[19] $$E_5 = E_4^0 - \frac{RT}{4F} \ln \frac{a_{A_2MCl_6}}{a_{ACl}^2}$$

where E_4^0 is defined by eq. [18] and E_5 is the emf of an electrochemical cell containing metal M and gaseous chlorine electrodes at standard chlorine pressure, when both are immersed in a molten salt solution containing A_2MCl_6 and ACl at mole fractions x_1 and $1 - x_1$, respectively. This potential is also the potential at which the metal M will first appear at the cathode during molten salt electrolysis, assuming reversible behaviour.

Results and discussion

Calculations of standard electrode potentials

Equilibrium vapour pressures representing reaction [6] were measured in this laboratory for the pure solid stoichiometric compounds Li_2ZrCl_6, Li_2HfCl_6 (2); K_2ZrCl_6, K_2HfCl_6 (3); Na_2ZrCl_6, Na_2HfCl_6 (4); and Cs_2ZrCl_6, Cs_2HfCl_6 (5). Based on the reported data the standard Gibbs free energies of formation of the pure solid chlorozirconate and chlorohafnate compounds were calculated as functions of temperature of the form

[20] $\Delta G_6^0 = A + BT$

The results are given in Table 1 where A and B are constants and T is in degrees K.

The standard Gibbs free energy of formation of the pure zirconium or hafnium tetrachloride vapours, representing reaction [7], were calculated as functions of temperature from

TABLE 1. Standard free energies of formation of the pure solid chlorohafnate and chlorozirconate compounds according to reaction [6], given as functions of temperature

CsCl	−2 471	85.708	−13.055	6.66	918

available data (16). The data were expressed by equations of the general form

[21] $$\Delta G_7^0 = a_1 + a_2T + a_3T \ln T + a_4T^2 + a_5T^{-1}$$

and the values for the coefficients are given in Table 2. T is in degrees K.

The standard Gibbs free energies of fusion for the alkali chlorozirconate and the alkali chlorohafnate compounds were calculated as functions of temperature from heat capacities measured in this laboratory (16–18) and the data for ΔG_8^0 were expressed as functions of temperature in eq. [22].

[22] $$\Delta G_8^0 = b_1 + b_2T + b_3T \ln T + b_4T^2$$

The coefficients for these equations are given in Table 3. Also, the standard free energies of fusion for the alkali chlorides, ΔG_9^0, were obtained from available thermochemical data (19) and their temperature dependence expressed by eq. [23].

[23] $$\Delta G_9^0 = c_1 + c_2T + c_3T \ln T + c_4T^2 + c_5T^{-1}$$

The coefficients for these equations are given in Table 4 and T is in degrees K.

From the data in Tables 1 and 2, the standard formation electrode potentials for the alkali chlorozirconate and chlorohafnate compounds representing reaction [3] were calculated using eqs. [10] and [16], with respect to pure solids as

[a]Only two coefficients needed for each chloro compound.

the standard states of reference. These potentials are tabulated in Table 5 as functions of temperature of the general form

$$[24] \quad E_3^0 = d_1 + d_2T + 2.17 \times 10^{-5}\,T \ln T - 5.96 \times 10^{-9}\,T^2$$

where the constants d_1 and d_2 are given for each compound and T is in degrees K.

The standard formation potentials at 923 K are plotted as a function of the radius of the alkali metal cation in Fig. 1. It is readily seen that the hafnium compounds are more stable than the corresponding zirconium compounds. The relationship is nearly linear, as observed for the thermal decomposition temperatures of the pure solid compounds (1, 2).

A similar procedure was followed for the calculation of the standard formation potentials of the alkali chlorozirconate and alkali chlorohafnate compounds with respect to pure liquids as the standard states for A_2MCl_6 and ACl, as per reaction [4]. All data needed for this calculation may be found in Tables 1–4, and were used in connection with eq. [11]. These calculations were performed only for the compounds for which the necessary data were available.

The temperature dependence for the electrode potentials for each of these compounds is given in Table 6 in the form of the general equation

$$[25] \quad E_4^0 = e_1 + e_2T + e_3T \ln T - e_4T^2 \qquad (T \text{ in K})$$

Standard potentials with respect to the liquid state of reference were calculated at the melting temperature of the pure complex compounds.

The standard free energies in Tables 1–4 are given in cal mol^{-1}. These may be converted to the SI units of joule mol^{-1} by multiplication by 4.184.

Calculation of the reversible decomposition potentials of solutions containing alkali chlorozirconate and chlorohafnate compounds

In a real high-temperature electrolytic cell for the recovery of zirconium or hafnium metals by fused-salt electrolysis, the electrolyte could be chosen to be a solution of the alkali chlorozirconate or chlorohafnate compounds in a molten bath of alkali chlorides. Metal recovery during electrolysis should proceed by the reverse of reaction [5]. The corresponding reversible decomposition potentials may be calculated from eq. [19], in which the standard formation potentials for the pure molten alkali chlorozirconate or chlorohafnate compounds are given in Table 6. The necessary values for the activities of the alkali chlorides in the binary systems NaCl-Na_2ZrCl_6 and KCl-K_2ZrCl_6 were reported previously (15, 20). The calculations were based on a modified form of the Gibbs-Duhem equation in which the unit activity states for the complex compounds are the pure molten stoichiometric compounds A_2ZrCl_6, where A is an alkali metal cation. Complex stoichiometry occurs in a solution containing 66.7 mol% alkali chloride within the overall primary system ACl-$ZrCl_4$. However, at this composition, the activities of ACl are not zero but have finite values representing the activities of ACl within a complex A_2ZrCl_6, which is also a congruently melting compound. Activities for both the ACl and A_2ZrCl_6 compounds at the corresponding melting temperatures are given in Table 7. The plot of the calculated potentials from eq. [19] is given as Fig. 2. The "true" standard electrode potential representing reaction [5] is obtained from eq. [19], in which A_2ZrCl_6 activities are set to unity and the activities of ACl have the corresponding limiting values of the activities of the alkali chlorides within each compound. These are 0.28 for NaCl in the Na_2ZrCl_6 and 0.24 for KCl in K_2ZrCl_6. The corresponding "true" standard potentials are 1.959 V for Na_2ZrCl_6 and 1.890 V for K_2ZrCl_6.

Formal potentials may also be calculated from the limiting values for the activity coefficients for the complex compounds A_2MCl_6 at $x_{A_2MCl_6} = 0$. Formal potentials define the infinitely dilute solution standard state at unit mole fraction of A_2MCl_6. The overall concentration dependence of the activity coefficients within the pseudobinary systems ACl–A_2MCl_6 has been given (15, 20) by the equation

$$[26] \quad \log_{10} \gamma_{A_2MCl_6} = \frac{0.06}{2.3RT} + \frac{x_{ACl}^2 b}{2.3RT}$$

where b are constants specific to Na_2ZrCl_6 and K_2ZrCl_6 and are given in Table 7. At $x_{ACl} = 1$, $x_{A_2MCl_6} = 0$ and the corresponding Henrian activity coefficients are readily calculated from eq. [26] as

$$\gamma'_{Na_2ZrCl_6} = 2.913$$

and

$$\gamma'_{K_2ZrCl_6} = 1.995$$

Formal potentials are obtained from the expression,

$$[27] \quad E_{5(\text{formal})} = E_4^0 - \frac{RT}{4F} \ln \gamma'_{A_2ZrCl_6}$$

For Na_2ZrCl_6 at its melting temperature of 919 K and for K_2ZrCl_6 at its melting temperature of 1072 K, the corresponding formal potentials are 1.988 and 1.940 V. The limiting potentials for unity and zero mole fractions of the alkali chlorozirconates, respectively, are also shown in Fig. 2.

For Cs_2ZrCl_6, vapour pressure data within the CsCl-Cs_2ZrCl_6 pseudobinary were available only over a limited composition range and calculations of its activities were only approximate. Accordingly, plots of E_5 versus $\log_{10} x_{Cs_2ZrCl_6}$ were not constructed. However, its formal potential at its melting temperature of 1090 K could be calculated from eqs.

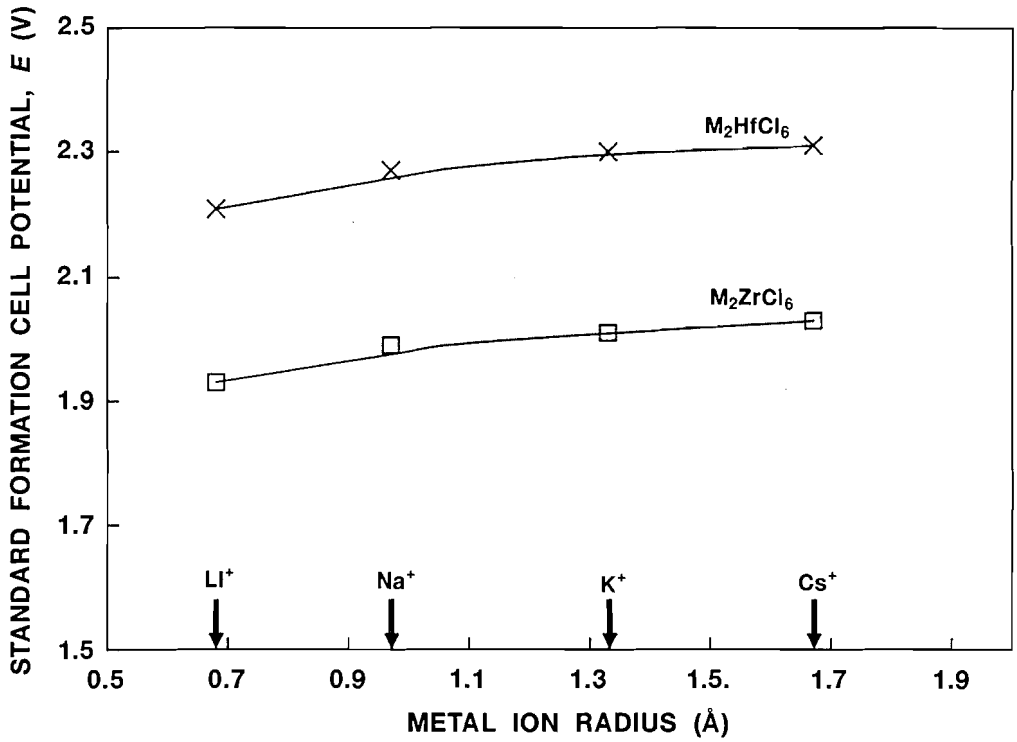

FIG. 1. Standard formation cell potentials of the solid alkali chlorozirconate and chlorohafnate compounds plotted as functions of the radii of the alkali metal cations.

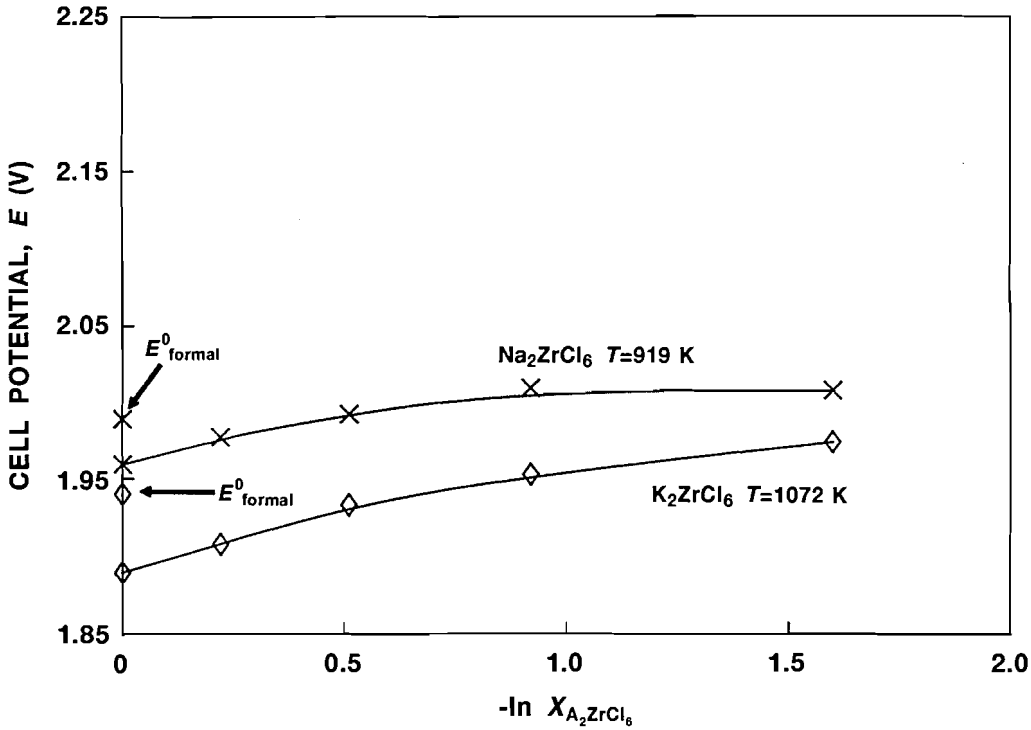

FIG. 2. Cell potentials in the solutions of Na_2ZrCl_6 in NaCl and K_2ZrCl_6 in KCl, as functions of the mole fractions of the complex compounds. Cell potentials represent the reactions for the formation of the complexes from the elements, according to eq. [5]. The "true" standard potentials with respect to the liquid standard states are shown at the extrapolation of these curves to unit mole fractions. Also, "formal" potentials are given as 1.989 V for Na_2ZrCl_6 and 1.940 V for K_2ZrCl_6.

[26] and [27], using the approximate value (15, 20) for b of 930 cal/mol. For $x_{Cs_2ZrCl_6} = 0$, the Henrian activity coefficient is 1.534. The approximate formal potential at 1090 K was calculated from the standard formation potential in Table 6, using eq. [27], as 2.167 V. Current-voltage curves obtained during the electrowinning of Zr metal by fused-salt electrolysis from solutions of Cs_2ZrCl_6 in CsCl containing about 5 mol% Cs_2ZrCl_6, at 950 K, indicated a decomposition voltage of 2.1 V. Instantaneous emf measurements obtained in a previous investigation (14) at 973 K indicated a formal potential having the value of 2.218 V. This value could be significantly different from the true equilibrium value because of the changes in the initial composition of the solution due to the metal solubility reactions mentioned earlier. Nevertheless, the calculated formal potential of 2.167 V appears to be a reasonable value that is compatible with experimental evidence. Comparable calculations for melts containing $HfCl_4$ could not be made because the required vapour pressure data on the A_2HfCl_6-ACl pseudobinary systems are not available.

Conclusions

The standard formation cell potentials for Li_2ZrCl_6, Li_2HfCl_6, Na_2ZrCl_6, Na_2HfCl_6, K_2ZrCl_6, K_2HfCl_6, Cs_2ZrCl_6, and Cs_2HfCl_6 have been calculated, with respect to solid and liquid standard states, from available thermochemical data and experimentally measured vapour pressures. Cell potentials for the ACl–A_2ZrCl_6 melts at various compositions were also calculated from the standard formation cell potentials and existing activity data.

It is shown that the correct form of the Nernst equation for a cell representing the formation of a complex compound according to reaction [5] is eq. [19]:

$$E_5 = E_4^0 - \frac{RT}{4F} \ln \frac{a_{A_2MCl_6}}{a_{ACl}^2}$$

From the limiting condition that the solutions of A_2MCl_6 in ACl are expected to obey Henry's law when $x_{A_2MCl_6} = 0$, formal potentials for Na_2ZrCl_6, K_2ZrCl_6, and Cs_2ZrCl_6, respectively, have been calculated. These potentials are useful in that they predict the decomposition potentials of dilute solutions as

$$[28] \quad E_{(decomposition)} = E_{5(formal)} - \frac{RT}{4F} \ln x_{A_2MCl_6}$$

The calculated standard formation potentials from eq. [19] indicate that thermodynamically the Na_2ZrCl_6 complex compound is slightly more stable than K_2ZrCl_6 and that solid Cs_2ZrCl_6 appears to be the most stable of these compounds. This also explains why the CsCl–Cs_2ZrCl_6 melts have shown the least ability to react with Zr metal, as compared with melts containing NaCl and KCl (12, 13).

An examination of β-enolization in benzobicyclo[2.2.2], [3.2.1], and [3.2.2] ketones[1]

DAVID J. MUIR AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, ON N6A 5B7 Canada

Received March 11, 1993

DAVID J. MUIR and J. B. STOTHERS. Can. J. Chem. **71**, 1290 (1993).

Under homoenolization conditions (*t*-BuO$^-$/*t*-BuOH/185°C), the 3,3-dimethylbenzobicyclo[2.2.2]- and [3.2.1]octen-2-ones (**7**, **8**) and their [3.2.2] homolog (**9**) each undergo β-enolate rearrangement to a single ketone. These rearrangement processes, however, are in competition with Haller–Bauer cleavage, in contrast to the behavior of bicyclo-[2.2.2]octenone, which is not cleaved under these reaction conditions, although Haller–Bauer cleavage was found as a minor process for the [3.2.1] and [3.2.2] analogs. The structures of all products were determined primarily from their ^{1}H and ^{13}C magnetic resonance spectra.

DAVID J. MUIR et J.B. STOTHERS. Can. J. Chem. **71**, 1290 (1993).

Dans des conditions d'homoénolisation (*t*-BuO$^-$/*t*-BuOH/185°C), les 3,3-diméthylbenzobicyclo[2.2.2]- et [3,2,1]oct-2-énones (**7** et **8**) et leur homologue [3.2.2] (**9**) subissent toutes une transposition β-énolique conduisant à une seule cétone. Ces réactions de réarrangements sont toutefois en compétition avec le clivage de Haller–Bauer; ce comportement est en opposition à ce qui est observé avec la bicyclo[2.2.2]octénone qui n'est pas clivée dans ces conditions, même si le clivage de Haller–Bauer est un processus mineur avec ses analogues [3.2.1] et [3.2.2]. La détermination de la structure des produits a été réalisée principalement par résonance magnétique nucléaire du ^{1}H et du ^{13}C.

Introduction

Since the discovery of the homoenolization process whereby proton abstraction occurs from a carbon remote from the carbonyl group under strongly basic conditions (1), many examples have been reported for polycyclic ketones (2), as well as for some acyclic systems (3), and a few monocyclic cases (4). In the majority of these examples, the process involves abstraction from β-carbons to form β-enolate intermediates, although there are a few examples involving γ-enolate formation (5).

Several years ago, we investigated β-enolate rearrangements of bicyclo[2.2.2]- and [3.2.1]octanones **1** and **2** under homoenolization conditions (*t*-BuO$^-$/*t*-BuOH/185°C) and, recently, the behavior of the [3.2.2] homolog **3** was examined. While **1** is slowly equilibrated with **4** (6), both **2** and **3** are irreversibly transformed slowly to **5** (7) and **6** (8), respectively. In another study, we found that the reactivity of **1** contrasts sharply with that of bicyclooctenone Δ^5-**1**, which is rapidly equilibrated with a mixture of Δ^2- and Δ^3-**4** under the same conditions (9). Ketone Δ^5-**1** had a half-life of ca. 8 h, rearranging >100 times faster than **1**, with the equilibrium more strongly biased toward the [3.2.1] skeleton and with no evidence of any other product. This activating effect of the double bond in the [2.2.2] system gave rise to the notion that introduction of a double bond in the [3.2.1] and [3.2.2] systems could enhance their rates of rearrangement and thereby provide viable synthetic routes to other carbon skeletons. For example, the isomerization of Δ^6-**2** could offer a route to substituted 3,3-dimethylbicyclo[3.3.0] octane derivatives, a number of which have been employed in the syntheses of various natural products (10). Upon examination, however, it was found that Δ^6-**2** (11) and Δ^6-**3** (8) are each converted to six products, in distinct contrast to the simple rearrangements observed for **1**, Δ^5-**1**, **2**, and **3**.

From these results, it was clear that the olefinic bond enhanced β-enolate formation over that exhibited by the saturated counterparts **1**, **2**, **3**, and **6**, but subsequent migration of the double bond in the [3.3.0] and [4.3.0] skeletons led to reduction of these α,β-unsaturated ketones. Therefore, it seemed reasonable that an investigation of the behavior of the benzo analogs **7**–**9** under typical homoenolization conditions would be interesting since migration of the double bond cannot occur, but the activating effect of a π-system is retained. In this paper, we present the results of these experiments.

Results and discussion

Ketone **7** was prepared as outlined in Scheme 1. As reported previously (12), the reaction of benzyne with 1,3-cyclohexadiene gave a mixture of four addition products in which the major Diels–Alder component **10** was accompanied by two minor components arising from ene addition and one from [2+2] addition. Since these were not easily separated, the total product was hydroborated and then oxidized with alkaline H_2O_2. Upon oxidation by Swern's method (13), this material gave a product containing >85% **11**. Methylation with MeI/$NaNH_2$/Et_2O afforded **7**, which was readily purified by column chromatography.

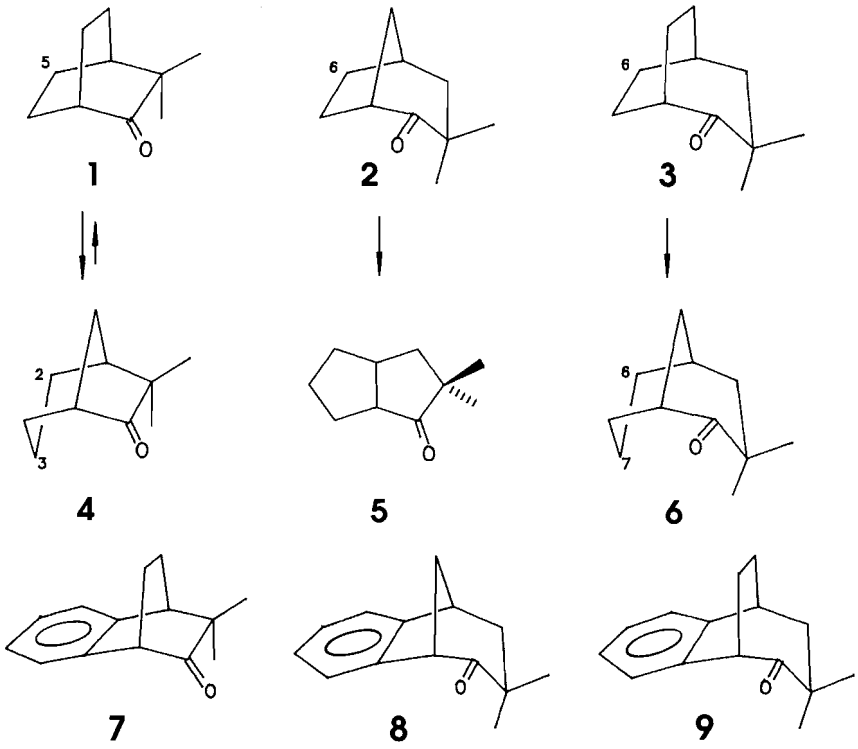
The preparation of **8** is outlined in Scheme 2. Treatment of benzonorbornadiene, generated from benzyne and cyclopentadiene (12, 14), with borane – methyl sulfide complex followed by reaction with alkaline H_2O_2 gave benzonorbornenol, which was oxidized by Swern's method (13) to benzonorbornenone (**12**). Ring expansion of **12** was accomplished by cyclopropanation of its silyl enol ether **13** to **14**, homoketonization of which gave **15**, a sequence we have found to be effective for many related bicyclic ketones (15). Methylation with MeI/$NaNH_2$/Et_2O furnished **8**.

Ring expansion of **11** following the sequence analogous to that employed for **12** → **15** gave 6,7-benzobicyclo-[3.2.2]nonen-2-one, which was dimethylated to furnish **9**.

Following our usual procedures (16), ketone **7** was dissolved in anhydrous *t*-BuO$^-$/*t*-BuOH (1.0 M) to furnish a solution 0.25 M in **7**. Aliquots of this solution were quickly transferred to glass tubes under nitrogen, sealed under vacuum, and heated to 185°C for varying periods of time (3, 6, 9, 12, 24, 48 h). Neutral material from each tube was iso-

[1]Part 145 in the series ^{13}Cmr studies; for Part 144 see ref. 8.

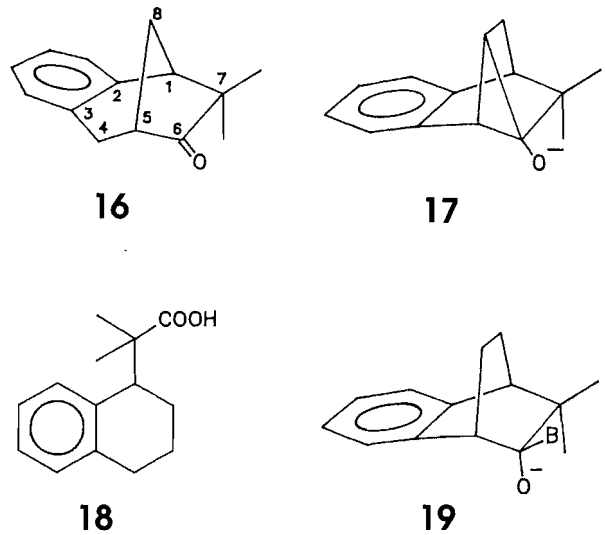
lated by pentane extraction. The aqueous washings were acidified before extraction with ether to isolate the acidic material. Upon analysis by glc and ^{13}Cmr, each neutral fraction was found to contain **7** and one new ketone. Within 6 h, their relative proportions became constant (47:53), with the new compound in small excess, but the yield of the neutral fraction dropped as that of the acidic fraction slowly increased with time to constitute 43% of the total product after 48 h.



The new ketone, easily isolated from **7** by chromatography on silica, contained a cyclopentanone ring, to judge from its carbonyl absorption (δ_C 225.6, 1742 cm^{-1}), and could be assigned structure **16** by analogy with the rearrangement of **1**. Generation of β-enolate **17** by proton abstraction from C-7 in **7**, with subsequent cleavage of the original C-1,C-2 bond, gives **16** directly. The ^{1}Hmr spectrum fully supported this assignment containing two methyl singlets, two methylene groups absorbing as AB portions of larger spin systems, and two bridgehead methine absorptions as well as the aryl pattern of the benzo substituent.

Each of the acidic fractions contained one acid, which was assigned structure **18** on the basis of the observed spectral data. Haller–Bauer cleavage of **19**, formed by attack of the base at the carbonyl carbon in **7**, can lead to the formation of a benzylic anion and would readily account for the generation of **18**. While the *tert*-butyl ester of **18** must be the initial product, it has been found that these esters do not survive the reaction conditions and are isolated as the corresponding carboxylic acids (17). One can conclude that benzylic stabilization of the intermediate anion from cleavage of **19** renders this process strongly competitive with the β-enolate rearrangement of **7**.

As anticipated, the same ratio of **7** and **16** was found from experiments with **16** as the initial ketone. Their equilibration within 6 h is distinctly faster than that found earlier for their olefinic counterparts, since equilibration of Δ^5-**1** requires ca. 20 h. The [3.2.1] skeleton, however, is favored by a factor of >10 in the olefinic system (9). Another difference is the fact that Haller–Bauer cleavage is a major mode of reaction for **7** but is not observed for Δ^5-**1**.



A series of runs with **8** in *t*-BuO$^-$/*t*-BuOH at 185°C was carried out as described for **7**. The yields of neutral products steadily decreased with time and each fraction contained **8** and an isomer, the proportion of which increased with time. The acidic fraction contained a single component constituting nearly half of the total product after 96 h.

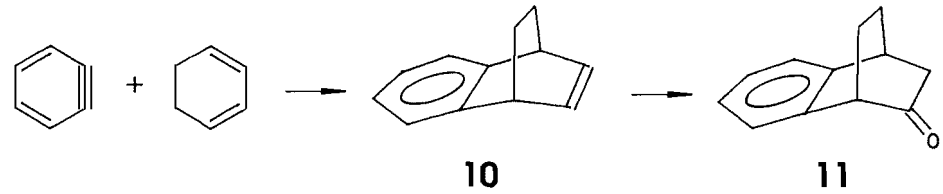
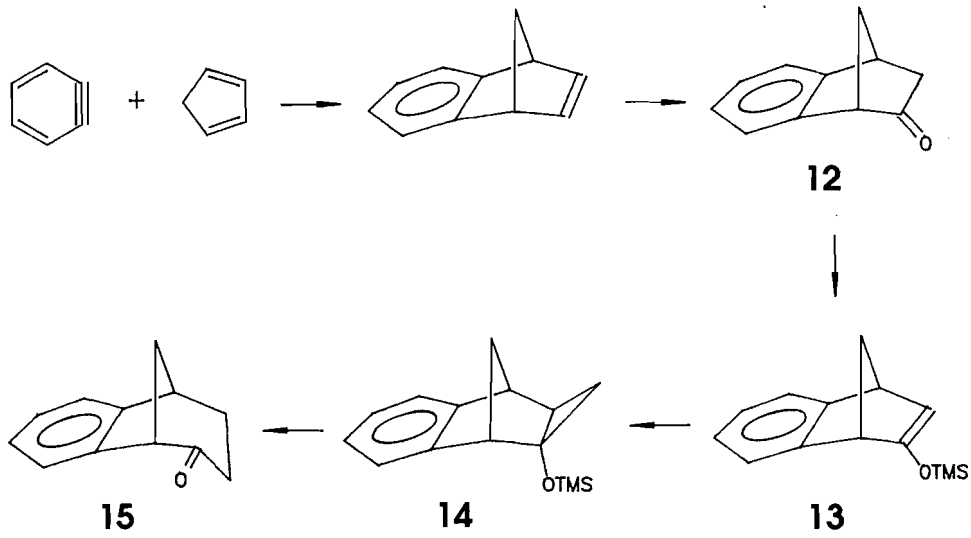
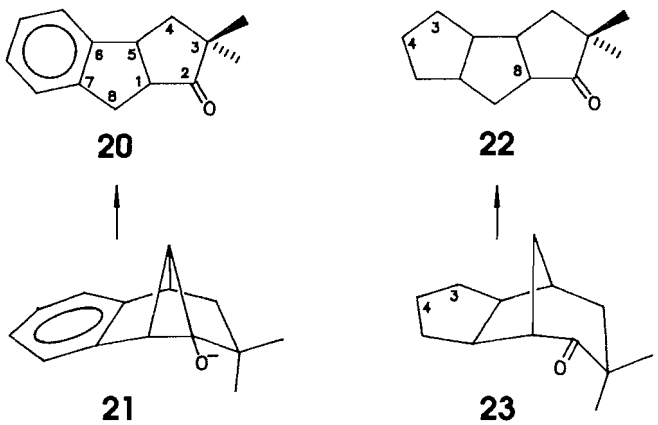


SCHEME 1

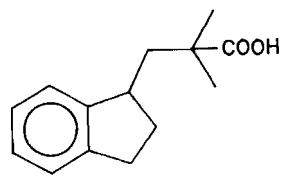


SCHEME 2

The new ketone was readily separated by preparative thin-layer chromatography and shown to be isomeric with **8** by precise mass measurement. Its carbonyl absorption (δ_C 226.0, 1738 cm^{-1}) was distinctly different from that of **8** (δ_C 214.3, 1705 cm^{-1}) and indicated the presence of a cyclopentanone ring. Thus, the ketone was assigned structure **20**, arising by rearrangement after proton abstraction from C-8 in **8** to form **21**, or an equivalent β-enolate. This assignment was confirmed by the nmr results.



Ketone **22** is formed by β-enolate rearrangement of **23** under strongly basic conditions; Δ^3- and Δ^4-**23** also undergo this process (20). With **8**, however, a substantial acidic fraction was obtained in contrast to the findings for **23** and its unsaturated derivatives from which no acidic products were formed. A single component was present in each of the acidic fractions from **8**, according to the ^{13}Cmr spectra, and was found to be **24**. The generation of **24** must be similar to that of **18**, with Haller–Bauer cleavage enhanced by benzylic stabilization of the intermediate anion formed upon opening of the [3.2.1] species corresponding to **19**. These processes may be compared to that for Δ^6-**2** for which this cleavage is presumably facilitated by allylic stabilization of the resulting anion. The lower yields of acids from Δ^6-**2** (20% after 96 h) indicate that the allylic species is less stabilized than the benzylic intermediate generated through cleavage of **8**.



The distribution of the components in the products from the runs with **8** as a function of time is listed in Table 1. From these data, **8** exhibited a half-life of ~16 h, which may be compared with the value of ~40 h found for its olefinic analog Δ^6-**2** under the same conditions (11).

In a third series of experiments, the behavior of **9** upon treatment with *t*-BuO^-/*t*-BuOH at 185°C was found to be analogous to that of **8**. The yields of the neutral fractions decreased with time and each contained a new ketone, the proportion of which increased with time. The acidic fractions contained one component that made up ca. 45% of the product after 48 h.

Preparative tlc of the neutral fractions provided samples

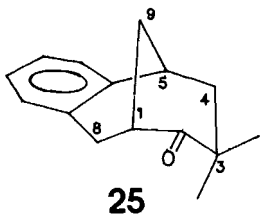
TABLE 2. Composition[a] of the products from homoenolization of **9** (t-BuO$^-$/t-BuOH/185°C)

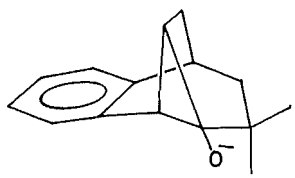
Time (h)	**9**	**25**	**27**
3	63	8	14
6	53	17	22
12	41	25	25
24	22	43	22
48	6	44	36
96	<2	49	38

[a]Listed as percentage of the isolated material; the relative amounts of **9** and **25** were determined by glc and ^{13}Cmr.

of the new ketone, which was found to be isomeric with **9** by precise mass measurement. Its carbonyl absorption (δ_C 220.5, 1698 cm^{-1}) is very similar to that for 3,3-dimethylbicyclo[3.3.1]non-6-en-2-one (δ_C 221.3, 1700 cm^{-1}) (8). The ^{1}H, ^{13}C, ^{1}H{^{1}H}, and ^{13}C{^{1}H} COSY nmr data led to the assignment of structure **25**, readily envisaged to arise from **9** by proton abstraction at C-8 to form β-enolate **26**, or an equivalent species, with subsequent cleavage of the original C-1,C-2 bond.

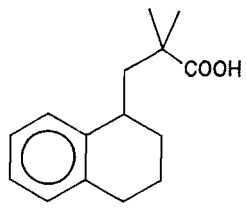


25



26

As found for **7** and **8**, ^{13}Cmr spectra showed that the acidic fractions from **9** contained a single component. This carboxylic acid, $C_{15}H_{20}O_2$ by precise mass measurement, exhibited signals for eight sp^3 carbons from two methyl, four methylene, one methine, and a quaternary site, together with those for the benzo group and the carboxyl carbon. This acid, assigned structure **27**, presumably arises from Haller–Bauer cleavage of the species analogous to **19**. The composition of the product isolated in these experiments with **9** is listed in Table 2. These data permit comparison of the half-life of **9** with that of its olefinic counterpart Δ^6-**3** under the same conditions, namely, ~8 vs. ~24 h, respectively.



27

Both **3** and **9** undergo rearrangement to stable isomeric ketones **6** and **25**, respectively, whereas their olefinic analog Δ^6-**3** is isomerized to Δ^6-**6**, which, in turn, rapidly equilibrates with Δ^7-**6**, which undergoes a second β-enolate rearrangement. In **25**, the double bond is "locked" in position and cannot activate a suitable proton abstraction for a second β-enolate rearrangement. In both Δ^6-**3** and **9**, the π-system renders each susceptible to Haller–Bauer cleavage, a process that is not observed for **3**.

In summary, we have found that the benzo grouping increases the rate of disappearance of **7**, **8**, and **9** relative to that of Δ^5-**1**, Δ^6-**2**, and -**3**, respectively. Although this appears to supprt our notion that benzylic stabilization of the intermediate carbanions arising through putative β-enolates **17**, **21**, and **26** could accelerate rearrangement, the benzo group renders **7**–**9** susceptible to Haller–Bauer cleavage and precludes synthetic applications of β-enolate rearrangement in these systems, at least with t-BuO$^-$/t-BuOH as base.

Experimental

Boiling points and melting points are uncorrected. Gas–liquid chromatography was carried out on Varian 3300 and 3700 instruments using columns of 5% OV-101 on Chromosorb G and 5% SE-30 on Chromosorb W, respectrively. Tetrahydrofuran (THF) and ether were dried over sodium/benzophenone and freshly distilled before use.

Infrared spectra were recorded using a Bruker/IBM FTIR spectrometer. Mass spectral data were obtained with a Finigan MAT 8230 instrument at 70 eV for routine spectra and at 20 eV for exact mass measurements. Proton and carbon nmr spectra were recorded with Varian Gemini-200, XL-200, or XL-300 spectrometers. The protonation level for each carbon was found by recording the APT or DEPT spectra. Specific assignments for the sp^3 carbon signals of the ketones employed for the homoenolization experiments and their isomeric products were obtained by heteronuclear correlation with the ^{1}H signals. The HETCOR sequence of the Varian software with a 2048 × 512 data point matrix was used to reveal the one-bond interactions and the FLOCK (18) sequence served to identify the two- and three-bond interactions. The HOMCOR sequence of the Varian software was employed for ^{1}H{^{1}H} COSY-45 spectra with a 1024 × 1024 data matrix.

3,3-Dimethyl-5,6-benzobicyclo[2.2.2]octen-2-one (7)

Benzenediazonium-2-carboxylate was prepared according to Logullo, Seitz, and Friedman (14) from anthranilic acid (33.2 g), isoamyl nitrite (53.4 mL), and trifluoroacetic acid (0.2 mL) in tetrahydrofuran (150 mL) in the glassware described by Crews and Beard (12). After draining the solvent and washing with THF, the solvent was replaced with CH_2Cl_2 (150 mL). Then, freshly prepared cyclohexadiene (33 mL) was added rapidly and the reaction mixture was refluxed for 4 h. After the solvent was removed, the black oil was taken up in pentane and the solids removed by filtration and washed thoroughly with pentane. After removal of the solvent, the product was distilled to furnish a mixture of four olefins (27.3 g, 72% yield), bp 102–106°C/15 Torr (1 Torr = 133.3 Pa). The major component was benzobicyclo[2.2.2]octadiene (**10**), constituting ca. 50% of the product, together with two products from ene addition (each ca. 20%) and one from [2+2] addition (ca. 10%) (12). With two additional runs, 87.5 g of the mixture of olefins was obtained. Since these products were not

easily separated by chromatography, the mixture was used in the following step.

This mixture of olefins (87.5 g, 560 mmol) was dissolved in hexane (250 mL) and the solution cooled to 0°C before 10 M $BH_3 \cdot Me_2S$ (45 mL) was added dropwise. This reaction mixture was stirred for 3 h at room temperature and then refluxed for another hour. The solution was cooled to 0°C before the sequential, dropwise addition of ethanol (150 mL), 3 M NaOH (100 mL), and 30% H_2O_2 (100 mL). This mixture was refluxed for 1.5 h, and then cooled before its addition to brine (100 mL). The layers were separated and the aqueous phase extracted with hexane (5 × 200 mL). The combined extracts were washed with brine (150 mL) before drying over anhydrous $MgSO_4$. The solvent was removed to afford 67.8 g of waxy product consisting of a 4:2:1 mixture of three alcohols according to its ^{13}Cmr spectrum.

Dimethyl sulfoxide (0.9 mL, 12.6 mmol) and CH_2Cl_2 (10 mL) were combined and cooled to −78°C under nitrogen before oxalyl chloride (2.0 M in CH_2Cl_2, 3.2 mL) was added dropwise. The solution was stirred for 15 min and then a portion of the product from the preceding step (1.0 g, 5.75 mmol) in CH_2Cl_2 (5 mL) containing DMSO (1 mL) was added dropwise. After rapid addition of Et_3N (4 mL), the solution was allowed to warm to room temperature before it was poured into water (50 mL). The layers were separated and the aqueous phase was extracted with CH_2Cl_2 (50 mL). The combined extracts were washed with HCl (50 mL, 1 M) and brine (50 mL) before drying over anhydrous $MgSO_4$. Removal of the solvent gave a yellow oil (0.9 g) containing ca. 80% of benzobicyclo[2.2.2]octenone (**11**), judging from its ^{13}Cmr spectrum, which represented a 50% yield from the mixture of olefins; ^{13}Cmr ($CDCl_3$) δ_C: CH_2, 23.4, 24.9, 36.3; CH, 41.8, 52.4; aryl CH, 123.7, 125.4, 126.8, 127.2; aryl C, 136.4, 142.8; C=O, 211.7.

To a stirred suspension of freshly powdered $NaNH_2$ (2.87 g, 73.5 mmol) in dry ether (10 mL) was added a solution of impure **11** (2.0 g, 11.6 mmol) in dry ether (10 mL) and this mixture heated under reflux for 2 h with vigorous stirring. The mixture was then cooled and methyl iodide (4.4 mL) was added slowly before refluxing the mixture for 16 h after which time a second addition of methyl iodide (1.4 mL) in dry ether (5 mL) was made. After refluxing for 3 h, the mixture was cooled to 0°C and the excess $NaNH_2$ destroyed by the addition of cold water (50 mL). The ether layer was separated and the aqueous phase extracted with ether (2 × 75 mL). The combined extracts were washed with brine before drying over anhydrous $MgSO_4$. Removal of the solvent gave ketone **7** (2.13 g, 92% yield) as a yellow oil that glc analysis indicated to be >90% pure. Chromatography on silica furnished suitable samples for the homenolization experiments. An analytical sample was obtained by sublimation at 100°C/1 Torr; mp 37.0–37.5°C; ir ($CHCl_3$): 1725 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.73 (s, 3H, *endo*-3-Me), 1.23 (s, 3H, *exo*-3-Me), 1.47 (dddd, 1H, J = 12.6, 11.8, 5.2, 2.6 Hz, *syn*-H-8), 1.71 (ddt, 1H, J = 12.8, 11.8, 3.2 Hz, *syn*-H-7), 1.99 (dddd, 1H, J = 12.8, 10.2, 5.2, 2.0 Hz, *anti*-H-7), 2.20 (dddd, 1H, J = 12.6, 10.2, 3.2, 3.0 Hz, *anti*-H-8), 2.93 (dd, 1H, J = 2.6, 3.0 Hz, H-4), 3.55 (dd, 1H, J = 2.0, 3.2 Hz, H-1), 7.13–7.24 (m, 4H, aryl H); ^{13}Cmr ($CDCl_3$) δ_C: 23.8 (*exo*-3-Me), 26.0 (*endo*-3-Me), 21.4 (C-8), 23.1 (C-7), 44.3 (C-3), 48.1 (C-4), 52.6 (C-1), 124.8, 125.3, 126.8, 127.1 (aryl CH), 135.2, 143.6 (aryl C), 216.7 (C=O). Exact Mass calcd. for $C_{14}H_{16}O$: 200.1202; found: 200.1201.

*Benzonorbornenone (**12**)*

Benzenediazonium-2-carboxylate was prepared from anthranilic acid (34.5 g), isoamyl nitrite (54 mL), and trichloroacetic acid (250 mg) in THF (200 mL) following the procedure of Logullo, Seitz, and Friedman (14) using the glassware described by Crews and Beard (12). The solvent was replaced with CH_2Cl_2 (150 mL) and freshly distilled cyclopentadiene (50 mL) was added before the mixture was heated under reflux for 5 h. After removal of the solvent, the residue was taken up in pentane and the insoluble material removed by filtration through Celite. After the pentane was removed, the residue was distilled to furnish benzonorbornadiene (22.0 g, 65% yield), bp 84–86°C/12 Torr (lit. (21) bp 82.5–83.0°/12 Torr).

This product was dissolved in dry hexane (75 mL) in a flame-dried flask under dry nitrogen and cooled to 0°C before dropwise addition of 10 M $BH_3 \cdot Me_2S$ (9.5 mL) with stirring. The ice-bath was removed and stirring was continued for 3 h before cooling again to 0°C. The temperature was maintained at <40°C during the sequential dropwise addition of absolute ethanol (100 mL), 30 M NaOH (40 mL), and 30% H_2O_2 (40 mL). This reaction mixture was refluxed for 1 h and, after cooling to room temperature, the product was recovered by pentane extraction (4 × 100 mL). These extracts were washed with water (50 mL) and brine (50 mL); these washings were back-extracted with pentane (25 mL). The combined extracts were dried over anhydrous $MgSO_4$ before the solvent was removed to furnish white, crystalline benzonorbornenol (22.3 g, 90% yield), mp 67–70°C (lit. (22) mp 74.1–75.4°C), which was used without further purification.

A solution of anhydrous dimethyl sulfoxide (0.7 mL) in dry CH_2Cl_2 (5 mL) was cooled to −78°C, under nitrogen. This solution was rapidly stirred during the dropwise addition of a solution of trifluoroacetic anhydride (1.0 mL) in CH_2Cl_2 (3 mL) and stirring was continued for 10 min. Then a solution of benzonorbornenol (800 mg) in CH_2Cl_2 (5 mL) was slowly added and the solution stirred for 10 min before the cold bath was removed. After this mixture had warmed to room temperature, triethylamine (2 mL) was added and stirring was continued for 45 min before the addition of brine (10 mL). The organic layer was separated and the aqueous layer extracted with CH_2Cl_2 (10 mL). The combined organic extracts were dried over anhydrous magnesium sulfate before removal of the solvent. Distillation of the residue through a short-path column gave **12** (760 mg, 95% yield) bp 98–102°C/2 Torr (lit. (23) bp 65–75°C/0.02 Torr).

*6,7-Benzobicyclo[3.2.1]octen-2-one (**15**)*

A solution of lithium diisopropylamide (LDA) was prepared in a flame-dried flask under nitrogen at −78°C by dropwise addition of diisopropylamine (5.8 mL, 41.5 mmol) to *n*-butyllithium (14.5 mL, 2.5 M in hexane, 36.3 mmol) in dry THF (25 mL). After stirring for 15 min, a solution of **12** (4.1 g, 25.9 mmol) in THF (5 mL) was added and stirring continued for 1 h at −78°C. A quenching solution of trimethylsilyl chloride (6.6 mL) and triethylamine (2 mL) in dry THF (5 mL) was prepared in a flamed, nitrogen-purged centrifuge tube. The precipitate was removed by centrifugation and the clear solution rapidly added at −78°C to the reaction mixture, which was then allowed to warm to room temperature before the addition of cold, saturated aqueous Na_2CO_3 solution (100 mL). The product was extracted with pentane (3 × 100 mL) and the extracts washed with brine (50 mL) before drying over anhydrous $MgSO_4$. After removal of the solvent, Kugelrohr distillation afforded **13** (5.6 g, 94% yield), bp 115°C/2 Torr; ^{1}Hmr ($CDCl_3$) δ: 0.17 (s, 9H, $SiMe_3$), 2.30 (ddt, 1H, J = 6.9, 0.5, 1.7 Hz, *anti*-H-7), 2.51 (dt, 1H, J = 6.9, 1.6 Hz, *syn*-H-7), 3.47 (m, 1H, H-1), 3.75 (dt, 1H, J = 3.3, 1.7 Hz, H-4), 5.35 (bd, 1H, J = 3.3 Hz, H-3), 6.9–7.3 (m, 4H, aryl H); ^{13}Cmr ($CDCl_3$) δ_C: $SiMe_3$, −0.1; CH_2, 67.4; CH, 48.3, 53.8, 110.5; aryl CH, 120.4, 121.6, 123.8, 124.5; C, 150.5, 153.3, 171.0. Exact Mass calcd. for $C_{14}H_{18}OSi$: 230.1127; found: 230.1133.

To a flask fitted with a reflux condenser, nitrogen purge, and magnetic stirrer was added zinc–silver couple (3.82 g, 58.4 mmol). The apparatus was flame-dried and then cooled to room temperature before the addition of CH_2I_2 (2.6 mL, 32.9 mmol) in dry ether (10 mL). The mixture was warmed with stirring until refluxing occurred without external heating. Upon cessation of reflux, a solution of **13** (4.5 g, 19.6 mmol) in ether (30 mL) was added and the mixture refluxed for 17 h before cooling to room temperature. While the mixture was stirred, pyridine–ether (1:1, 14 mL) was added slowly until precipitation ceased. Then the precipitate was removed by filtration and thoroughly washed with ether. After evaporation of the ether, the residue was taken up in pentane and

For personal use only.

passed through Celite to remove the last traces of precipitate before drying over anhydrous $MgSO_4$. Kugelrohr distillation of the material remaining after the removal of the solvent gave the cyclopropanated ether **14** (2.9 g, 61% yield), bp 125–128°C/2 Torr; ^{13}Cmr ($CDCl_3$) δ_C: $SiMe_3$, 0.8; CH_2, 21.2, 42.0; CH, 26.1, 43.0, 49.2; quat C, 67.5; aryl CH, 120.8, 122.9, 124.7, 125.1; aryl C, 149.0, 150.6. Exact Mass calcd. for $C_{15}H_{20}OSi$: 244.1284; found: 244.1283.

To a methanolic NaOH solution (3 M, 20 mL) was added ether **14** (2.84 g). The reaction mixture was stirred at room temperature for 24 h before the addition of brine (50 mL) and extraction with pentane (3 × 50 mL). The combined extracts were washed with brine (50 mL) before drying over anhydrous $MgSO_4$. The solvent was removed to furnish ketone **15** (1.98 g, 98% yield; ir (liq. film): 1719 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: CH_2, 29.4, 34.3, 43.2; CH, 40.1, 57.3; aryl CH, 123.1_6, 123.2_2, 126.8, 127.9; aryl C, 142.2, 146.0; C=O, 209.4. Exact Mass calcd. for $C_{12}H_{12}O$: 172.0889; found: 172.0885.

3,3-Dimethyl-6,7-benzobicyclo[3.2.1]octen-2-one (8)

To a stirred suspension of freshly powdered $NaNH_2$ (1.14 g, 29.2 mmol) in dry ether (5 mL) was added a solution of **15** (837 mg, 4.87 mmol) in dry ether (5 mL) and the mixture heated under reflux for 2 h with vigorous stirring. The mixture was cooled and methyl iodide (1.8 mL, 29 mmol) was added slowly before the mixture was refluxed for 16 h after which time a second addition of methyl iodide (0.6 mL, 9.8 mmol) in dry ether (5 mL) was made. After refluxing for 3 h, the mixture was cooled to 0°C and the excess $NaNH_2$ destroyed by the addition of cold water (25 mL). The ether layer was separated and the aqueous phase extracted with ether (2 × 25 mL). The combined ether extracts were washed with brine before drying over anhydrous $MgSO_4$. Removal of the solvent gave essentially pure **8** (912 mg, 93% yield) from which trace impurities were readily removed by chromatography on neutral alumina; ir (liq. film): 1705 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.38 (s, 3H, *endo*-3-Me), 1.14 (s, 3H, *exo*-3-Me), 1.85 (dt, 1H, J = 13.5, 2.8 hz, *endo*-H-4), 2.04 (dd, 1H, J = 13.5, 3.9 Hz, *exo*-H-4), 2.21 (d, 1H, J = 11.4 Hz, *syn*-H-8), 2.71 (ddt, 1H, J = 11.4, 2.8, 4.8 Hz, *anti*-H-8), 3.41 (m, 1H, H-5), 3.69 (d, 1H, J = 4.8 Hz, H-1), 7.1–7.4 (m, 4H, aryl H); ^{13}Cmr ($CDCL_3$) δ_C: 29.8 (*exo*-3-Me), 32.0 (*endo*-3-Me), 41.0 (C-5), 42.0 (C-8), 43.6 (C-3), 44.3 (C-4), 57.2 (C-1), 123.2, 123.5, 126.9, 127.9, (aryl CH), 142.0, 147.0 (aryl C), 214.3 (C=O). Exact Mass calcd. for $C_{14}H_{16}O$: 200.1202; found: 200.1206.

3,3-Dimethyl-6,7-benzobicyclo[3.2.2]nonen-2-one (9)

To a solution of LDA prepared at −78°C from diisopropylamine (4.0 mL) and *n*-butyllithium (10 mL, 2.5 M in hexane) in THF (10 mL) was added **11** (3.1 g) in THF (5 mL) and this mixture was stirred at −78°C for 45 min. During this time, a flame-dried, nitrogen-purged centrifuge tube was charged with trimethylsilyl chloride (4.5 mL), triethylamine (1.5 mL), and THF (2 mL). The precipitate was removed by centrifugation and the clear supernatant liquid was injected rapidly into the reaction mixture. The solution was allowed to warm to 0°C and then was poured into a saturated aqueous solution of Na_2CO_3 (100 mL) in a separatory funnel. The layers were separated and the aqueous layer extracted with ether (3 × 75 mL). The combined extracts were washed with brine before drying over $MgSO_4$. After removal of the solvent, the residual yellow oil (5.2 g) was purified by Kugelrohr distillation at 120°C/1.5 Torr to furnish the trimethylsilyl enol ether of **11** (3.6 g, 81% yield).

Following the preparative procedure described above for **14**, a solution of methylene iodide (2.0 mL) in ether (5 mL) was added to Zn–Ag couple (2.5 g) and the mixture heated until reflux proceeded without external heating. When reflux ceased, the grey solution was sonicated for 15 min before the silyl enol ether of **11** (3.0 g) was added. The reaction mixture was refluxed for 40 h and then cooled to 0°C before a 1:1 pyridine–ether solution was added until no more white precipitate formed (5 mL). The precipitate was removed by filtration and the solid was washed with ether (3 × 30 mL). After the ether washings were dried over $MgSO_4$, removal of the solvent gave a yellow oil (2.9 g). Kugelrohr distillation gave the desired cyclopropanated ether (2.4 g, 71% yield); bp 120°C/1.5 Torr; ^{13}Cmr ($CDCl_3$) δ_C: $SiMe_3$, 1.1; CH_2, 11.1, 21.7, 25.4; CH, 19.1, 35.5, 42.6; quat C, 57.7; aryl CH, 123.8, 124.0, 125.8, 126.3; aryl C, 139.7, 141.4. Exact Mass calcd. for $C_{16}H_{22}OSi$: 218.1441; found: 218.1443.

The cyclopropyl ether (2.4 g) was dissolved in 3 M methanolic NaOH solution (25 mL) and stirred for 18 h. The solution was then poured into 100 mL of 10% aqueous NaCl solution and the product extracted with pentane (3 × 75 mL). After washing with brine, the extracts were dried over $MgSO_4$. The solvent was removed to furnish 6,7-benzobicyclo[3.2.2]nonen-2-one (1.7 g, 98% yield); ir (liquid film): 1705 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.84–2.05 (m, 5H), 2.10–2.27 (m, 2H), 2.44 (m, 1H), 3.29 (m, 1H, H-5), 3.61 (m, 1H, H-1), 7.13–7.29 (m, 4H); ^{13}Cmr ($CDCl_3$) δ_C: CH_2, 24.5, 26.3, 31.1, 38.3; CH, 37.1, 55.0; aryl CH, 126.7, 127.0, 127.2, 127.7; aryl C, 136.9, 141.9; C=O, 211.6. Exact Mass calcd. for $C_{13}H_{14}O$: 186.1045; found: 186.1046.

This ketone (1.7 g) was methylated as described above for **7** and **8** using $NaNH_2$ (2.15 g) and methyl iodide (3.4 mL, 1.7 mL). The usual work-up gave **9** as an oily liquid (1.7 g, 89% yield). This product was chromatographed through silica with hexane – ethyl acetate as eluent and this material sublimed at 100°C/1 Torr to yield **9** as long, white needlelike crystals: mp 97.5–98.5°C; ir ($CHCl_3$): 1692 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.42 (s, 3H, *endo*-3-Me), 1.07 (s, 3H, *exo*-3-Me), 1.7–2.1 (m, 6H), 3.26 (m, 1H, H-5), 3.76 (m, 1H, H-1), 7.0–7.3 (m, 4H, aryl H); ^{13}Cmr ($CDCl_3$) δ_C: CH_3, 29.4, 30.1; CH_2, 24.3, 28.1, 45.9; CH, 37.9, 55.2; quat C, 45.3; aryl CH, 126.4, 126.8, 127.1, 127.6; aryl C, 137.0, 141.9; C=O, 211.7. Exact Mass calcd. for $C_{15}H_{18}O$: 214.1358; found: 214.1362.

Homoenolization experiments

Following the general procedure described previously (16), solutions of **7**, **8**, and **16** in *t*-BuO^-/*t*-BuOH, prepared from potassium metal and *t*-BuOH (H_2O content <50 μg/mL), were made up under N_2 in a mole ratio: ketone/*t*-BuO^-/*t*-BuOH, 1:4:40. Aliquots were then quickly transferred to predried, thick-walled glass tubes and the solutions degassed before sealing under vacuum. In the case of **9**, samples of the solid ketone (27 mg) were weighed directly in the reaction tubes and aliquots of the base solution (0.5 mL) added to each under nitrogen. These tubes were degassed and sealed under vacuum. The tubes were heated in an oil bath at 185°C for varying periods of time. After cooling, the reaction mixture was washed from the tube with brine and the product was extracted with pentane. The combined extracts were washed with 3 M NaOH solution (10 mL) and brine before drying over anhydrous $MgSO_4$. Evaporation of the solvent gave the neutral fraction, which was initially examined by glc and identified by ^{13}Cmr spectra. The aqueous alkaline washings were acidified with 6 M HCl solution to pH 1 and then extracted with ether. After drying, the solvent was removed to furnish an acidic product that was identified by ^{13}Cmr.

7,7-Dimethyl-2,3-benzobicyclo[3.2.1]octen-6-one (16)

The new ketone was separated from **7** by column chromatography on silica and was assigned structure **16** from the following data: ir (liq. film): 1742 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.72 (s, 3H, *endo*-7-Me), 1.25 (s, 3H, *exo*-7-Me), 2.06 (dd, 1H, J = 1.0, 11.9 Hz, *anti*-H-8), 2.56 (dddd, 1H, J = 1.3, 4.1, 5.5, 11.9 Hz, *syn*-H-8), 2.85 (dddd, 1H, J = 2.0, 2.1, 5.5, 5.9 Hz, H-5), 2.94 (bd, 1H, J = 17.2 Hz, *endo*-H-4), 2.95 (bd, 1H, J = 4.1 Hz, H-1), 3.16 (dd, 1H, J = 5.9, 17.2 Hz, *exo*-H-4), 7.0–7.25 (m, 4H, aryl H); ^{13}Cmr ($CDCl_3$) δ_C: 21.7 (*endo*-7-Me), 24.7 (*exo*-7-Me), 30.3 (C-8), 34.6 (C-4), 45.4 (C-1), 49.6 (C-5), 52.9 (C-7), 125.7, 126.9, 128.8, 129.2 (aryl CH), 132.5, 141.5 (aryl C), 225.6 (C-6). The assignments were completed with the aid of a ^{13}C{^{1}H}COSY spectrum obtained using the HETCOR sequence of the Varian software. Exact Mass calcd. for $C_{14}H_{16}O$: 200.1202; found: 200.1197.

*2-Methyl-2-(1',2',3',4'-tetrahydro-1'-naphthyl)-propionic acid (**18**)*

The acid obtained from **7** was purified by sublimation at 120°C/1 Torr, mp 99–101°C, and identified as **18** from the following data: ir (KBr disc): 2400–3400, 1709 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.11 (s, 3H, Me), 1.13 (s, 3H, Me), 1.5–1.7 (m, 2H, H-3'), 1.9–2.2 (m, 2H, H-2'), 2.67 (m, 2H, H-4'), 3.46 (m, 1H, H-1'), 7.05–7.20 (m, 4H, aryl H); ^{13}Cmr ($CDCl_3$) δ_C: CH_3, 22.6, 22.7; CH_2, 22.7, 25.5, 30.4; CH, 43.6; quat C, 47.6; aryl CH, 125.4, 125.9, 128.9, 129.4; aryl C, 136.8, 140.2; COOH, 185.3. Exact Mass calcd. for: $C_{14}H_{18}O_2$: 218.1307; found: 218.1305.

*3,3-Dimethyl-6,7-benzobicyclo[3.3.0]octen-2-one (**20**)*

The new ketone was separated from **8** by preparative tlc on Silica Gel 60 F-254 plates (0.5 mm) with petroleum ether – ether (90:10) as eluent and was assigned structure **20** from the following data: ir (liq film): 1738 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.68 (s, 3H, 3-Me), 1.14 (s, 3H, 3-Me), 2.06 (dd, 1H, J = 13.4, 4.0 Hz, *endo*-H-4), 2.34 (dd, 1H, J = 8.3, 13.4 Hz, *exo*-H-4), 3.1–3.3 (m, 2H, H-8), 3.20 (m, 1H, H-1), 3.90 (ddd, 1H, J = 4.0, 8.0, 8.3 Hz, H-5), 7.14–7.30 (m, 4H, aryl H); ^{13}Cmr ($CDCl_3$) δ_C: 25.2, 25.9 (3-Me's), 35.4 (C-8), 43.4 (C-4), 43.8 (C-5), 46.3 (C-3), 50.6 (C-1), 124.0, 124.9, 127.0(2) (aryl CH), 142.1, 146.2 (aryl C), 226.0 (C=O). These assignments were confirmed from the results of ^{1}H{^{1}H}COSY-45 and one-bond ^{13}C{^{1}H}COSY spectra, using the HOMCOR and HETCOR sequences of the Varian software at 200 and 300 MHz, respectively, and a long-range ^{13}C{^{1}H}COSY spectrum, using the FLOCK sequence (18) at 300 MHz (2048 × 128 matrix, 2.2 kHz (^{13}C), 1.2 kHz (^{1}H) spectral widths, 1.0 s relaxation delay, Δ_1 = 0.09 s and Δ_2 = 0.024 s). Exact Mass calcd. for $C_{14}H_{16}O$: 200.1202; found: 200.1196.

*3-(1'-Indanyl)-2,2-dimethylpropionic acid (**24**)*

The acidic product isolated from **8** was recrystallized from aqueous EtOH to give beige, powdery crystals, mp 105–107°C, and identified as **24** on the basis of these data: ir (KBr disc): 2400–3400, 1696 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.39 (s, 6H, $(Me)_2$), 1.65–1.90 (m, 2H, H-2'), 2.25–2.50 (m, 2H, H-3'), 2.75–3.05 (m, 2H, H-3), 3.18 (m, 1H, H-1'), 7.18–7.32 (m, 4H, aryl H); ^{13}Cmr ($CDCl_3$) δ_C: 26.2, 25.4 (2-Me's), 31.8 (C-2'), 34.0 (C-3), 41.9 (C-1'), 42.4 (C-2), 46.4 (C-3'), 123.4, 124.3, 126.2, 126.4 (aryl CH), 143.6, 147.5 (aryl C), 184.9 (COOH). Exact Mass calcd. for $C_{14}H_{18}O_2$: 218.1307; found: 218.1305.

*3,3-Dimethyl-6,7-benzobicyclo[3.3.1]nonen-2-one (**25**)*

The ketone obtained from **9** was purified by tlc, as described above for **20**, and recrystallized from aqueous EtOH, mp 112–115°C. It was assigned structure **25** on the basis of the following data: ir ($CHCl_3$): 1698 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.49 (s, 3H, *endo*-3-Me), 1.09 (s, 3H, *exo*-3-Me), 1.95 (dt, 1H, J = 13.6, 2.7 Hz, *endo*-H-4), 2.05 (dd, 1H, J = 13.6, 4.7 Hz, *exo*-H-4), 2.07–2.25 (m, 2H, H-9), 2.85 (bd, 1H, J = 17.1 Hz, *endo*-H-8), 2.92 (m, 1H, H-1), 3.15 (m, 1H, H-5), 3.16 (dd, 1H, J = 17.1, 7.0 Hz, *exo*-H-8), 7.01 (d, 1H, $J \sim 3$ Hz), 7.12–7.17 (m, 3H); ^{13}Cmr ($CDCl_3$) δ_C: 28.9 (*exo*-3-Me), 29.7 (*endo*-3-Me), 30.2 (C-9), 33.7 (C-5), 34.6 (C-8), 43.0 (C-3), 43.6 (C-1), 48.0 (C-4), 126.4, 126.6, 128.6, 128.8 (aryl CH), 134.8, 140.7 (aryl C), 220.5 (C=O). Exact Mass calcd. for $C_{15}H_{18}O$: 214.1358; found: 214.1352.

*2,2-Dimethyl-3-(1',2',3',4'-tetrahydro-1'-naphthyl)-propionic acid (**72**)*

The single acid isolated from the runs with **9** was purified by recrystallization from EtOH to yield white needles, mp 87–88°C, and identified as **27** on the basis of the following data: ir ($CHCl_3$): 2400–3400, 1698 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.33 (s, 3H, 2-Me), 1.34 (s, 3H, 2-Me), 1.70 (m, 2H, H-3'), 1.84 (m, 2H, H-2'), 1.87 (dd, 1H, J = 14.5, 2.9 Hz, H-3), 2.09 (dd, 1H, J = 14.5, 10.0, H-3), 2.73 (m, 2H, H-4'), 2.94 (m, 1H, H-1'), 7.03–7.18 (m, 4H, aryl H); ^{13}Cmr ($CDCl_3$) δ_C: CH_3, 24.6, 27.2; CH_2, 19.3, 28.1, 29.5, 47.2; CH, 34.7; quat C, 42.1; aryl CH, 125.6, 125.7, 128.9, 129.1; aryl C, 140.2, 141.7; COOH, 184.8. Exact Mass calcd. for $C_{15}H_{20}O_2$: 232.1464; found: 232.1462.

Acknowledgments

We are grateful for the continued financial support of the Natural Sciences and Engineering Research Council of Canada and we thank Professor W. F. Reynolds for kindly providing the FLOCK pulse sequence and for his helpful comments on the selection of appropriate operating parameters.

Switchover of reactions of solvated electrons with nitrate ions and ammonium ions in propanol–water solvents

TAE BUM KANG[1] AND GORDON R. FREEMAN[2]
Chemistry Department, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received December 8, 1992

TAE BUM KANG and GORDON R. FREEMAN. Can. J. Chem. **71**, 1297 (1993).

The reaction rate constants of e_s^- with ammonium nitrate (~0.1 mol m^{-3}) in 1-propanol–water and 2-propanol–water binary solvents correspond to $[e_s^- + (NO_3^-)_s]$ reaction in the water-rich solvents, and to $[e_s^- + (NH_4^+)_s]$ reaction in alcohol-rich solvents. The overall rate constant is smaller in solvents with 40–99 mol% water, with a minimum at 70 mol% water. The Arrhenius temperature coefficient is 26 kJ mol^{-1} in each pure propanol solvent, increases to 29 kJ mol^{-1} at 40 mol% water, then decreases to 17 kJ mol^{-1} in pure water solvent. The high reaction rates in the single component solvents, alcohol or water, are limited mainly by solvent processes related to shear viscosity (diffusion) and dielectric relaxation (dipole reorientation). Rate constants reported for concentrated solutions (50–1000 mol m^{-3}) of ammonium and nitrate salts in methanol (Duplâtre and Jonah. J. Phys. Chem. **95**, 897 (1991)) have been quantitatively reinterpreted in terms of the ion atmosphere model.

TAE BUM KANG et GORDON R. FREEMAN. Can. J. Chem. **71**, 1297 (1993).

Les constantes de vitesse de la réaction des e_s^- avec le nitrate d'ammonium (environ 0,1 mol m^{-3}) dans les solvants binaires 1-propanol–eau et 2-propanol–eau ressemblent à celles de la réaction des $[e_s^- + (NH_4^+)_s]$ dans des solvants riches en alcool. La constante globale de vitesse est plus faible dans les solvants ayant de 40 à 99 mol% d'eau; on observe un minimum à 70 mol% d'eau. Le coefficient de température d'Arrhénius, qui est de 26 kJ mol^{-1} dans chacun des deux propanols, augmente à 29 kJ mol^{-1} à 40 mol% d'eau avant de diminuer jusqu'à 17 kJ mol^{-1} dans l'eau pure. Les vitesses de réaction élevées observées dans les solvants purs, alcool ou eau, sont principalement limitées par des processus de solvant reliés à la viscosité de cisaillement (diffusion) et à la relaxation diélectrique (réorientation dipolaire). On a fait appel au modèle ionique atmosphérique pour réinterpréter les constantes de vitesse rapportées antérieurement (Duplâtre et Jonah. J. Phys. Chem. **95**, 897 (1991)) pour des solutions concentrées de sels d'ammonium et de nitrate dans le méthanol.

Introduction

The reaction of e_s^- with $(NO_3^-)_s$ in alcohol solvents is complex (1–5). An intermediate product apparently undergoes a relatively irreversible further reaction with a solvent molecule to complete the capture of the electron by the nitrate (4). Addition of Ca^{2+} or Mg^{2+} in an equimolar amount to lithium nitrate solutions in ethanol, increases the rate of electron reaction with nitrate by a factor of 30 (1). The catalytic effect is due to ion pairing, which reverses the Coulumbic interaction from the repulsion between e_s^- and $(NO_3^-)_s$ to attraction between e_s^- and $(M^{2+}NO_3^-)_s$ (1), and possibly also offers an easier irreversible step to form $M\langle^{OH}_{ONO}$ rather than the $(NO_2^- + OH^-)_s$ that might form in the absence of the M^{2+} (3, 4).

The initial, transient product of the $e_s^- + (NO_3^-)_s$ reaction is presumably $(NO_3^{2-})_s$. In alkaline water solvent at pH = 9.5 a broad optical absorbance band with a maximum at 250 nm has been attributed to it (6). This absorbance, measured at 290 nm, is formed during the 1-μs radiolysis pulse and decays with a half-life of 12.5 μs at room temperature (~295 K?). In neutral or acidic water (pH ≤ 7.0) the absorbance is weaker and the half-life is only 3 μs. The suggested reactions were (6)

[1] $NO_3^{2-} + H_2O \rightarrow NO_2 + 2OH^-$ pH = 9.0 – 9.5, $t_{1/2}$ = 12.5 μs

[2] $HNO_3^- \rightarrow NO_2 + OH^-$ pH = 4.5 – 7.0, $t_{1/2}$ = 3 μs

An optical absorption at 400 nm was attributed to NO_2. However, at pH = 9.5 and with 0.1 M *tert*-butanol to scavenge OH radicals, there was an absorbance at 400 nm immediately after the 1-μs radiolysis pulse and it increased by only 30% when the NO_3^{2-} decomposed over a 30-μs period (6). At 100 μs after the pulse the absorbance at 400 nm had returned to the end-of-pulse value, after which it decayed on a much longer timescale. The reactions

[3] $2NO_2 \rightarrow N_2O_4$

[4] $N_2O_4 + 2OH^- \rightarrow NO_2^- + NO_3^- + H_2O$

were suggested to occur on a millisecond timescale (6). The end-of-pulse absorbance at 400 nm has not been explained, nor its relatively small increase when the NO_3^{2-} decayed, nor the decay back to the end-of-pulse value at 100 μs. Thus the reaction mechanism in water is not completely known.

Electrons in a higher energy state, before the water has relaxed around them to form the solvated state, have much higher apparent rate constants with concentrated solutions (10^2–10^3 mol m^{-3}) of sodium nitrate than do solvated electrons with dilute solutions (~0.1 mol m^{-3}) of the salt (7). Electrons prior to solvation, e_{ps}^-, might react directly with $(NO_3^-)_s$ to form $(NO_3^{2-})_s$, or with ion pairs to form $(NaNO_3^-)_s$. The reverse of the reaction between the solvated species, $e_s^- + (NO_3^-)_s \rightleftharpoons (NO_3^{2-})_s$, is perhaps not observed after capture of e_{ps}^- because the local solvent structure in that case does not contain an adequate site for e_s^-.

In pure alcohol solvents the overall rate constant for $e_s^- + (NO_3^-)_s$ at 298 K is much smaller than that in pure water (Table 1). This would be consistent with a more rapid protolysis of NO_3^{2-} by water, followed by reaction [2], be-

cause the ionic dissociation of water, and hence the concentration of H_s^+ in water, is greater than that of alcohols (the negative exponents pK_s of the autoprotolysis constants (8) are listed in Table 1). However, the rate constants for $e_s^- + (NO_3^-)_s$ in pure alcohol solvents vary inversely with the autoprotolysis constants (vary directly with the negative exponents of the constants, Table 1). This suggests that, while protolysis of NO_3^{2-} is important in water, a different reaction, such as H-atom abstraction, probably occurs in alcohols. The dissociation energies of the $R_2C(OH)$—H bonds (9) decrease in the appropriate order to correlate with the increasing reactivity of the solvent (Table 1). The reaction might be

[5] $(NO_3^{2-})_s + R_2CHOH \rightarrow (NO_2^-)_s + OH_s^- + R_2\dot{C}OH$

Hydrogen atom transfer is sometimes associated with electron transfer reactions, as in the $[(H_2O)_5FeOH]^{2+} + [(H_2O)_6Fe]^{2+}$ exchange (10, 11), and might involve correlated electron and proton transfers.

It is certain that in pure alcohol solvents the solvent participates chemically in the overall $e_s^- (NO_3^-)_s$ reaction.

The recent suggestion (5) that NH_4^+ catalyses e_s^- capture by NO_3^- in methanol through ion pairing is not valid, because pairing of NH_4^+ and NO_3^- in methanol is negligible (12). We have investigated the high reactivity by measuring reaction rate constants and activation energies for (e_s^- + ammonium nitrate) in 1-propanol–water and 2-propanol–water solvents. The rate constant for lithium nitrate is much smaller in 1-propanol than in 2-propanol, and this is a clue to the reaction mechanism (4). Solvated electron reactivity in methanol (3) is similar to that in 1-propanol (4), because solvation properties are similar in different primary alcohols. The measured behavior in 1-propanol can therefore be extrapolated to that in methanol.

Experimental

Materials

The solvents were purified as described earlier (4). Ammonium nitrate (Aldrich, 99.999%), after opening the bottle, was stored in a vacuum desiccator that contained P_2O_5.

Samples were prepared as described in ref. 13.

Methods of temperature control, irradiation, optical measurement, and determination of reaction rate constants were similar to those in refs. 14 and 15. The 100-ns pulses of 336 fJ (2.10 MeV) electrons delivered doses of ~4 J kg^{-1}. The temperature was controlled to ±0.1 K.

Briefly, a 10^{-3} mol m^{-3} solution of solvated electrons was generated by ionizing ~10^{-7} of the solvent molecules with a 100-ns pulse of high-energy electrons. The decay of the solvated electrons was followed by kinetic absorption spectroscopy. The rate of decay was continually processed by computer and the value of the decay half-life was plotted as a function of time on the oscilloscope along with the optical absorbance trace. The decay half-life was independent of time for the reactant solutions, where the concentration of, say, ammonium nitrate was at least an order of magnitude greater than that of e_s^-. This meant that the decay of e_s^- was first order. In pure solvent, where ~10^{-3} mol m^{-3} of H_s^+ and free radicals were produced along with the e_s^- by the radiation, the decay half-life increased with time, and the order was between one and two.

Results and discussion

Second-order rate constants k_2 were determined from the slopes of plots of the measured first-order decay rates of e_{solv}^- in ammonium nitrate solutions over a 5- to 10-fold concentration range within the overall range 0.02–0.6 mol m^{-3}. The solvent composition was varied from pure 1-propanol or 2-propanol to pure water. The temperatures were within the overall range 208–364 K.

Arrhenius plots of k_2 were linear for solvent compositions ≤50 mol% water, and were curved for ≥70 mol% water (Figs. 1 and 2). The change in linearity and in the average slope of the Arrhenius plots of k_2 on going from alcohol-rich to water-rich solvents reflects behavior of Arrhenius plots of shear viscosity (16, 17) and dielectric relaxation time (18–20) in pure 1- or 2-propanol and pure water. Thus the rates of the reactions seem limited mainly by solvent processes, such as the solvent rearrangement involved in solvation and desolvation of reactants and products, or the reaction of solvent with NO_3^{2-}.

The values of k_2 for ammonium nitrate were similar in the two isomeric propanols, contrary to the behavior of lithium nitrate (Fig. 3). The rate constant for ammonium nitrate was about 100 times greater than that for lithium nitrate in 1-propanol, and 10 times greater in 2-propanol (Table 2). The large rate constants for ammonium nitrate in the alcohol-rich solvents are attributed to the reaction of e_s^- with $(NH_4^+)_s$. By contrast, the rate constant for $e_s^- + (NH_4^+)_s$ in water at room temperature has been reported to be very small, (2 or 1.3) × 10^3 m^3 mol^{-1} s^{-1} (21). A recent value of k_2 for e_s^- reaction with ammonium perchlorate in pure water solvent at 298 K is 1.5 × 10^3 m^3 mol^{-1} s^{-1} (22). However, in the primary alcohol 1-butanol containing 20 mol% water, the value of k_2 for ammonium perchlorate at 298 K is 1.2 × 10^7 m^3 mol^{-1} s^{-1} (22). The rate constant for lithium perchlorate is <10^2 m^3 mol^{-1} s^{-1}, so the high rate constant is due to $(NH_4^+)_s$ (22). The rate constant for $(NH_4^+)_s$ in pure 1-propanol sol-

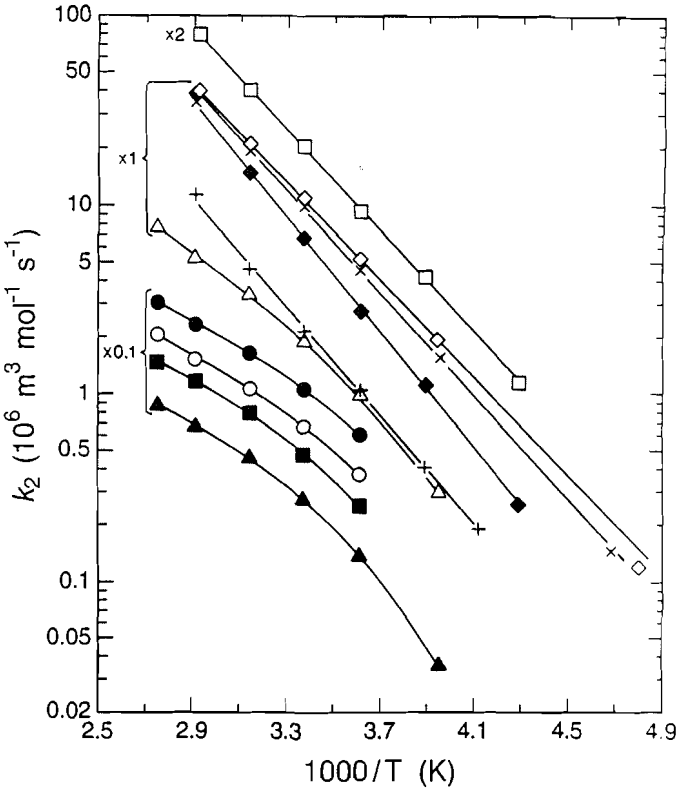

FIG. 1. Arrhenius plots of k_2 of e_s^- reaction with ammonium nitrate in 1-propanol–water solvents. Mol% water: X, 0; ◇, 10; □, 20; ◆, 35; +, 50; △, 70; ▲, 80; ■, 93; ○, 97; ●, 100. To separate the lines the values of k_2 have been multiplied by the factors indicated.

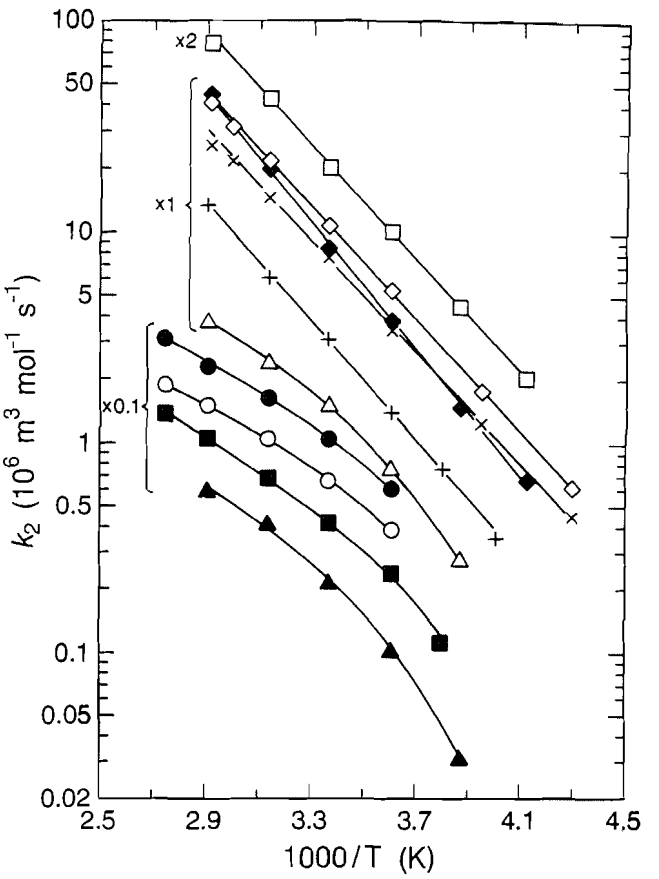

FIG. 2. As Fig. 1, but in 2-propanol–water.

vent, which is also a primary alcohol, would be about 1×10^7 m^3 mol^{-1} s^{-1}; the 20 mol% water has relatively little effect on the $(NH_4^+)_s$ reaction (Fig. 3).

In the secondary alcohol 2-propanol, k_2 for ammonium nitrate is tenfold larger than that for lithium nitrate (Table 2); the large value is attributed to reaction of $(NH_4^+)_s$. Thus the reactivity of e_s^- with $(NH_4^+)_s$ in both primary and secondary alcohols is $\sim 10^4$ times larger than in water (Table 2 and ref. 22). This great difference cannot be attributed to the different electron trap depths, because the optical absorption energy of e_s^- in water is smaller than that in primary alcohols, but larger than that in secondary alcohols (23). We attribute the difference of reactivity of e_s^- with $(NH_4^+)_s$ in water and alcohols to different solvation structures of the NH_4^+. We suggest that NH_4^+ is symmetrically solvated in water and has little tendency to accept an electron. For example, the hydrogen-bonded NH_4^+ fits easily into the liquid water structure. We suggest that NH_4^+ is unsymmetrically solvated in an alcohol. A tetrahedrally hydrogen-bonded NH_4^+ would not fit into the liquid alcohol structure. This asymmetric structure evidently facilitates electron attachment and the subsequent decomposition of $NH_4 \rightarrow H + NH_3$. A similar, but much smaller, effect occurs for the reaction ($e_s^- + H_s^+$) on going from water to an alcohol (24).

The S-curve for $k_2(e_s^-$ + ammonium nitrate) in Fig. 3 represents reaction of e_s^- with $(NO_3^-)_s$ in the water-rich solvents, and with $(NH_4^+)_s$ in the alcohol-rich solvents. The Arrhenius temperature coefficient E_2 of the overall reaction has a small maximum in the transition region (Fig. 3). By contrast, the values of E_2 for the lithium nitrate reactions reach a high maximum in the pure alcohols: 46 kJ mol^{-1} in 1-propanol, and 42 kJ mol^{-1} in 2-propanol (Table 2). These high activation energies are attributed to reaction of e_s^- with $(NO_3^-)_s$, involving an alcohol molecule.

The high values of k_2 and E_2 for ammonium nitrate in the propanols containing 35 mol% water (Fig. 3) correspond to an Arrhenius pre-exponential factor of $A_2 = 1.1 \times 10^{12}$ m^3 mol^{-1} s^{-1}. This large value must contain an entropy factor for solvent rearrangement around the transition state.

Reinterpretation of Duplâtre and Jonah data (5)

Solvated electron reaction rate constants in methanol containing various combinations of the ions NH_4^+, ClO_4^-, Li^+, and NO_3^- at high concentrations, 50–1000 mol m^{-3}, were measured with 25-ps pulses of electrons (5). The temperature was ~296 K.[3] Their interpretation of the data included the assumption that the association constant of ammonium and nitrate ions in methanol,

$$[6] \quad (NH_4^+)_s + (NO_3^-)_s \rightleftharpoons (NH_4NO_3)_s$$

was $K_6 >> 10^4$ M^{-1} (10 m^3 mol^{-1}). However, electrical conductance measurements of ammonium nitrate solutions in methanol, at concentrations from 1 to 995 mol m^{-3} and temperatures from 283 to 328 K, have shown that ion pairing is negligible (12), so reaction [6] can be neglected. The rate constant data in ref. 5 therefore require reinterpretation.

At ion concentrations between 100 and 1000 mol m^{-3} (0.1

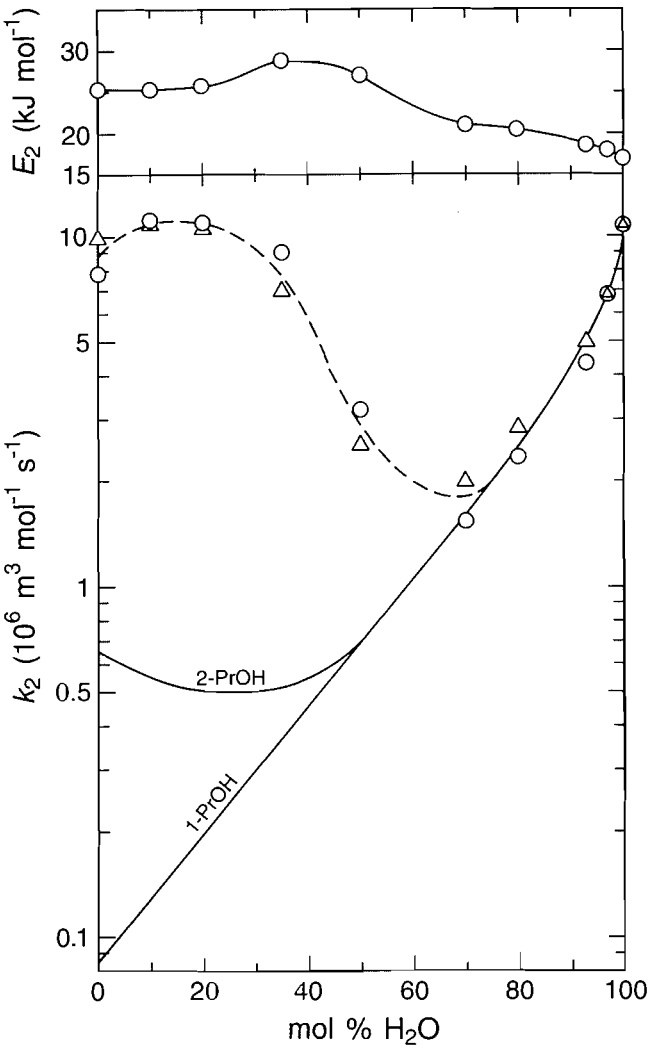

FIG. 3. Arrhenius temperature coefficients E_2 at temperatures near 298 K in both propanols, and values of k_2 (e_s^- + ammonium nitrate) at 298 K in 1-propanol–water (△) and 2-propanol–water (○). The k_2 full lines represent the e_s^- + lithium nitrate reaction (ref. 4). The values of E_2 for the ammonium nitrate reactions in the 1-propanol and 2-propanol systems at a given water content were the same within 1 kJ mol^{-1}.

and 1.0 M) the Debye–Hückel-type eq. [1] of ref. 5 becomes progressively less applicable. (The authors neglected the solvent density, so the ionic strength I in their eqs. [1] and [2] was actually the molar concentration C. This error did not affect the curve-fitting procedure.) At such high concentrations it is preferable to add another term in the manner of the Debye–Hückel–Onsager equation for conductivity (25*a*). We thereby obtain

$$[7] \quad \ln k_2(e_s^- + S) = \ln k_2^0(e_s^- + S) - \frac{aZ_S C^{1/2}}{1 + bC^{1/2}} - dZ_S C$$

where $k_2^0(e_s^- + S)$ is the rate constant at very low ion concentrations, Z_S is the number of protonic charges on the reactant S, b and d are empirical constants that are fitted to the data (25*b*), and (25*c*, *d*)

$$[8] \quad a = \frac{eF^2}{\pi}\left(\frac{1}{2\varepsilon RT}\right)^{3/2}$$

where e = protonic charge, F = Faraday, $\varepsilon = \varepsilon_0\varepsilon_r$ = electric permittivity of the solvent, R = gas constant, and all units are SI. The value of a is related to that of B in the Debye–Hückel–Onsager equation for molar conductivity, which is (12)

$$[9] \quad B = \frac{0.586eF^2}{6\pi}\left(\frac{1}{2\varepsilon RT}\right)^{3/2}$$

In the simpler form of eq. [7] with $d = 0$, the parameter b used to be thought of as a measure of the closest approach of the ions in relatively dilute solutions. However, b is best regarded as an adjustable parameter even for dilute solutions (25*b*). For the concentrated solutions considered here, the model is inadequate to give detailed interpretation to either b or d. This remains a challenge for theorists.

For reaction of e_s^- with $(NH_4^+)_s$ in methanolic ammonium perchlorate at 296 K, $\varepsilon_r = 33.0$ and $a = 0.275$ (m^3 mol^{-1})$^{1/2}$, which gives the full curve in Fig. 4 with $k_2^0 = 1.9 \times 10^6$ m^3 mol^{-1} s^{-1}, $b = 0.466$ (m^3 mol^{-1})$^{1/2}$, and $d = 1.06 \times 10^{-3}$ m^3 mol^{-1}. The value of k_2^0 was taken from the plateau value in Fig. 3 of ref. 5, rather than using k_2^0 as an adjustable parameter. The curve calculated from eq. [7] fits the data at least as well as did the curve of Duplâtre and Jonah (Fig. 4).

For reaction of e_s^- with $(NO_3^-)_s$ in methanolic solutions of lithium nitrate, some of which contained additional lithium perchlorate, the curves calculated from eq. [7] fit the experimental data better than the qualitative curves drawn in Fig. 2 of ref. 5 (see present Fig. 5). Duplâtre and Jonah had neglected the value of $k_2^0 = 2.6 \times 10^4$ m^3 mol^{-1} s^{-1}, obtained at lithium nitrate concentrations 0.02–1.4 mol m^{-3} (3). The value of a is 0.275 (m^3 mol^{-1})$^{1/2}$ as in Fig. 4, but $b = 0.182$ (m^3 mol^{-1})$^{1/2}$ and $d = 1.38 \times 10^{-4}$ m^3 mol^{-1}. The concentration C used in eq. [7] is the total salt concentration, and all of the experimental data in Fig. 5 are fitted by the same equation.

The values of b and d for the methanolic ammonium perchlorate solutions are larger than those for the lithium nitrate/perchlorate solutions. This is probably related to the fact that dissolution of lithium nitrate in methanol at 298 K is 19 kJ mol^{-1} exothermic, while for ammonium nitrate it is 11 kJ mol^{-1} endothermic (26). The ammonium nitrate solutions are therefore "less ideal" electrolytes than are the lithium nitrate solutions, which is indicated by the larger values of b and d for the former.

The value $k_2 = 1.9 \times 10^6$ m^3 mol^{-1} s^{-1} for ammonium nitrate in methanol did not vary with ionic strength (Fig. 3 of ref. 5). The overall reaction of e_s^- with $(NO_3^-)_s$ is multistep, electron capture by $(NO_3^-)_s$ being followed by reaction [5], for example. We suggest that $(NH_4^+)_s$ reacts rapidly with $(NO_3^{2-})_s$:

$$[10] \quad (NO_3^{2-})_s + (NH_4^+)_s \rightarrow NO_2 + OH_s^- + NH_3$$

Thus the net reaction is rapid whether e_s^- first encounters an $(NH_4^+)_s$ or a $(NO_3^-)_s$. Since the $(NH_4^+)_s$ and $(NO_3^-)_s$ ions "screen" each other in ammonium nitrate solutions, and the two ions have opposite ionic strength effects for the reactions with e_s^-, there is no net effect of ionic strength.

There is some uncertainty about the location of the charge in the products of reaction [10], and possibly of reactions [1], [2], and [5]. In the gas phase, the electron affinity (27) of

For ○, the C axis represents the concentration of lithium perchlorate added to 0.5 M lithium nitrate. ——, eq. [7] with parameter values given in the text; . . ., qualitative curves from ref. 5.

NO_2 (220 kJ/mol) is ≥42 kJ mol^{-1} greater than that of OH (117 kJ mol^{-1}) or $(CH_3)_2CHO$ (178 kJ/mol), and probably of $(CH_3)_2COH$. This would tend to favor initial formation of NO_2^- rather than OH^- or $(CH_3)_2\bar{C}OH$. However, the free energy of solvation of the smaller OH^- in water is 100 kJ mol^{-1} greater than that of the larger NO_2^- (28), which favors the ultimate formation of NO_2 + OH_s^- in reactions [1] and [2]. The free energy of solvation of OH^- in alcohols is probably also greater than that of NO_2^-, which would favor formation of OH_s^- in reaction [10]. Relative solvation energies might favor formation of $(NO_2^-)_s$ rather than $(R_2\bar{C}OH)_s$ in reaction [5].

The approximately linear increase of the *apparent* $k_2[e_s^- + (NO_3^-)_s]$ with addition of ammonium perchlorate to 0.5 M lithium nitrate solutions (Fig. 3 of ref. 5) is attributed to reaction [10] and to the direct reaction of $(NH_4^+)_s$ with e_s^-. Thus ammonium ions dominate the reaction rate in alcohols.

Solvent effects on the reactivity of solvated electrons with ammonium and nitrate ions in 1-butanol–water solvents

RUZHONG CHEN AND GORDON R. FREEMAN[1]

Chemistry Department, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received December 8, 1992

RUZHONG CHEN and GORDON R. FREEMAN. Can. J. Chem. **71**, 1303 (1993).

Values of the rate constants, k_2 (10^6 m^3 mol^{-1} s^{-1}), of solvated electrons, e_s^-, with several related salts, in pure water and pure 1-butanol solvents at 298 K are, respectively, as follows: $LiNO_3$, 9.2, 0.19; NH_4NO_3, 10, 8.3; NH_4ClO_4, 1.5×10^{-3}, 12 in 20 mol% water; $LiClO_4$, 1.0×10^{-4}, $<1.0 \times 10^{-4}$. The value of $k_2(e_s^- + NO_{3,s}^-)$ in water solvent is 48 times larger than that in 1-butanol solvent, whereas $k_2(e_s^- + NH_{4,s}^+)$ in water is 10^{-4} times smaller than the value in 1-butanol. This enormous reversal of solvent effects on e_s^- reaction rates is the first observed for ionic reactants. The solvent participates chemically in the $(e_s^- + NO_{3,s}^-)$ reaction, and the overall rate constant *increases* with *increasing* viscosity and dielectric relaxation time. This unusual behavior is attributed to a greatly increased probability of reaction of an encounter pair with increasing duration of the encounter. Effective reaction radii κR_r for $(e_s^- + NO_{3,s}^-)$ and $(e_s^- + NH_{4,s}^+)$ were estimated with the aid of measured electrical conductances of the salt solutions in all the solvents. Values of κR_r are $(2–7) \times 10^{-10}$ m, except for $NH_{4,s}^+$ in 100 and 99 mol% water, which are 2.6 and 2.7×10^{-14} m, respectively. The effective radii of the ions for mutual diffusion increase with increasing butanol content of the solvent, from ~50 pm in water to ~150 pm in 1-butanol, due to the increasing average size of the molecules that solvate the ions.

RUZHONG CHEN et GORDON R. FREEMAN. Can. J. Chem. **71**, 1303 (1993).

Les valeurs des constantes de vitesse, k_2 (10^6 m^3 mol^{-1} s^{-1}), des électrons solvatés, e_s^-, avec plusieurs sels apparentés, dans l'eau pure et dans le 1-butanol, à 298 K, sont les suivantes : $LiNO_3$, 9,2, 0,19; NH_4NO_3, 10, 8,3; NH_4ClO_4, $1,5 \times 10^{-3}$, 12 (avec 20% d'eau); $LiClO_4$, $1,0 \times 10^{-4}$, $<1,0 \times 10^{-4}$. La valeur de $k_2(e_s^- + NO_{3,s}^-)$ dans l'eau est 48 fois plus forte que dans le 1-butanol comme solvant; par ailleurs, la valeur de $k_2(e_s^- + NH_{4,s}^+)$ dans l'eau est 10^{-4} fois plus faible que dans le 1-butanol comme solvant. Cet énorme différence des effets de solvant sur les vitesses de réaction des e_s^- est la première à être observée avec des réactifs ioniques. Le solvant participe chimiquement dans la réaction de $(e_s^- + NO_{3,s}^-)$ et la constante globale de vitesse augmente avec une augmentation de la viscosité et du temps de relaxation diélectrique. On attribue ce comportement inhabituel à une grande augmentation de la probabilité de réaction d'une paire de rencontre avec une augmentation de la durée de la rencontre. Faisant appel à des mesures de conductances électriques des solutions de sels dans tous les solvants, on a évalué les rayons efficaces de réaction, κR_r, des réactions $(e_s^- + NO_{3,s}^-)$ et $(e_s^- + NH_{4,s}^+)$. Les valeurs de κR_r s'étalent de 2 à 7×10^{-10} m, excepté pour le $NH_{4,s}^+$ dans les solutions contenant 99 ou 100 mol% d'eau alors que les valeurs sont respectivement de 2,7 et $2,6 \times 10^{-14}$ m. De ~50 pm en eau à ~150 pm en 1-butanol, les rayons efficaces des ions pour la diffusion mutuelle augmentent avec une augmentation de la concentration de butanol dans le solvant; ce résultat est causé par une augmentation de la grosseur moyenne des molécules qui solvatent les ions.

[Traduit par la rédaction]

Introduction

In the present work we report solvent effects on the rate of reaction of solvated electrons with solvated ions, and on the transport (conductance) of ions in solution. Rates of reaction between two species depend on the coming together (transport) of the species, and on the probability that they react when they encounter each other. Division of the reaction rate constant by the ionic conductance in the same solvent partially separates the solvent effect on transport from that on the probability of reaction of the encounter pair. We used 1-butanol–water binary solvents over the entire range of miscibility (1), and the newly discovered "switchover" reactant, ammonium nitrate (2).

Alcohols (3) and alcohol binary solvents (4, 5) have a wide range of physical and solvation properties (6, 7), so they are excellent media in which to study solvent effects on reaction kinetics.

Experimental

All chemicals and 1-butanol were from Aldrich Chemical Co. Lithium nitrate (99.999%), ammonium nitrate (99.999%), lithium perchlorate (reagent grade), and ammonium perchlorate (99.8%) were used as received; after opening a bottle, it was stored in a vacuum desiccator that contained P_2O_5. 1-Butanol (spectrometric grade, 99.5%, gold label) was dried for 1 week on Davison molecular sieves (3 Å), then treated for 1 day under UHP argon (99.999%, Liquid Carbonic Canada Ltd.) with sodium borohydride (2 g L^{-1}) at 330 K. The alcohol was then fractionally distilled under argon, through an 80 × 2.3 cm column packed with glass helices, discarding the first 20% and last 40%. The middle 40% portion was collected and stored in a flask under argon. The water content, measured by Karl–Fisher titration, was 0.05 mol%. The solvated electron half-life after a 100-ns pulse of 2.1 MeV electrons (4 J kg^{-1}) at 298 K was about 10 μs.

Water was purified in a Barnstead Nanopure II ion exchange system. The solvated electron half-life after a 100-ns pulse of 2.1 MeV electrons was about 12 μs.

Techniques

The methods of sample preparation and kinetic optical absorption spectroscopy were the same as those in the preceding work (2).

Electrical conductivity measurements were done with an impedance bridge (model 1608-A, General Radio Co.) at 1 kHz. Most of the time the conductance mode (Gp) was used. For conductances <0.6 μS, the bridge was set to one of the capacitance modes (Cp) and the conductance was calculated from the capacitance data. The conductance cells were obtained from Yellow Springs Instruments (model YSI-3403), and calibrated at 298.15 K using the secondary standard solution YSI-1361. Temperature was controlled to within ±0.01 K at 273 K, and to ±0.02 K at 344 K. Conductances were measured when the specified temperature had

been constant for 30 min. The molar conductance (Λ) was obtained from the plot of specific conductance against solute concentration.

Results and discussion

Physical properties

1-Butanol is not completely miscible with water (8). The rate constants were measured over the miscible range. The following mol% water were used: 0, 10.0, 20.0, 35.0, 45.0, 99.0, and 100.0. The values of viscosities for the mixed solvents were obtained from ref. 1. The values of relative permittivities for the mixed solvents were obtained from ref. 9. However, only data in the range of 0–23 mol% water were available, so we use those for isobutanol–water mixed solvents (10) as an approximation for other compositions.

Rate constants

Arrhenius plots of k_2 for $LiNO_3$, NH_4NO_3, and NH_4ClO_4 in mixed solvents are given in Figs. 1–3. The mol% of water represented by the symbols in these figures are shown in Table 1. Due to the low solubility of NH_4ClO_4 in solvents of 0 and 10 mol% water, its k_2 was not measured at these compositions.

For the reaction of e_s^- with $NH_{4,s}^+$ in NH_4ClO_4 solutions at 100 and 99 mol% water, the equilibrium $NH_{4,s}^+ \rightleftharpoons NH_3 + H_s^+$ affects the measured rate constants. The value of k_2 for $NH_{4,s}^+$ in water is $\sim 10^{-4}$ times smaller than that for H_s^+, so a small amount of dissociation of NH_4^+ causes a significant increase in the observed rate of reaction of e_s^-. The concentration of H_s^+ when $[NH_{4,s}^+] = 1$–140 mol m^{-3} is $[H_s^+] \approx \sqrt{K_a[NH_{4,s}^+]}$, where K_a is the dissociation constant. Values of K_a in water at different temperatures (11) are listed in Table 2. Values of K_a in the 99 mol% H_2O mixed solvent

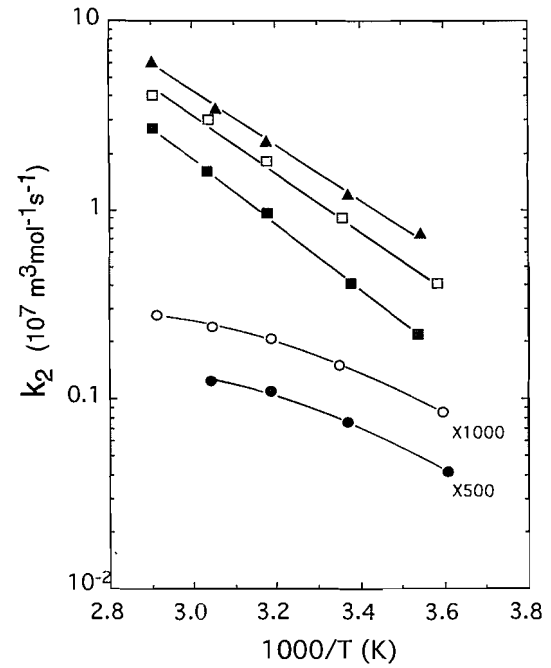

FIG. 3. Arrhenius plots of k_2 of e_s^- reaction with NH_4ClO_4 in 1-butanol–water mixed solvents. Symbols representing mol% water are given in Table 1. To separate the lines, some values of k_2 have been multipled by the factors indicated.

are not available, so we used those for water as an approximation. The values of k_2 ($e_s^- + NH_{4,s}^+$) were calculated from the slopes of plots of ($k_{obs} - k_2'[H_s^+]$) against $[NH_{4,s}^+]$, where k_2' is the rate constant for the reaction of e_s^- with H_s^+ in water (5).

In alcohol solvent we have the following equilibrium:

[a]From ref. 32, p. 2241.

$NH_{4,s}^+ + BuOH \rightleftharpoons NH_3 + BuOH_{2,s}^+$. Values of K_a for 1-BuOH–H_2O are not available, but those for methanol–water and ethanol–water have been reported (12*a*); K_a in pure ethanol is about 6 times larger than that in pure water (12*b*). In the alcohol-rich region k_{obs} is $>1 \times 10^5$ s^{-1} at 298 K for the concentration range of $[NH_{4,s}^+] = 0.02$–0.2 mol m^{-3}. Based on K_a in ethanol, the estimated $k_2'[H_s^+]$ is $<10^4$ s^{-1} for the range of $[NH_{4,s}^+]$ we used. Therefore, the influence of $[H_s^+]$ on k_{obs} is negligible and the values of $k_2(e_s^- + NH_{4,s}^+)$ were directly calculated from the slopes of plots of k_{obs} against $[NH_{4,s}^+]$.

The solvent composition dependences of k_2 at 298 K are shown in Fig. 4. In the water-rich region the reaction of e_s^- with $NH_{4,s}^+$ is very slow ($k_2 = 1.5 \times 10^3$ m^3 mol^{-1} s^{-1} in water, which agrees with a recently reported value (13)). However, in the alcohol-rich region, the reaction is fast ($k_2 \approx 10^7$ m^3 mol^{-1} s^{-1}). Therefore, the observed rate constants with NH_4NO_3 are mainly due to $NO_{3,s}^-$ in the water-rich region and mainly due to $NH_{4,s}^+$ in the alcohol-rich region.

The rate constants at 297 K for the reaction of e_s^- with the lithium perchlorate are 1.0×10^2 m^3 mol^{-1} s^{-1} in water, and $<1.0 \times 10^2$ m^3 mol^{-1} s^{-1} in 1-butanol (Table 3), so these ions did not contribute appreciably to the measured e_s^- reaction rates in the other solutions.

In models of the kinetics of chemical reactions in solution, the solvent is generally assumed to be a uniform continuum, and two effects determine how fast the reaction will be (14). Foremost is the intrinsic rate at which the reaction occurs, which is a molecular-level quantity that requires a quantum or semiclassical theory for its evaluation. The other effect for biomolecular reaction rates is statistical and accounts for the probability of existence of adjacent reactive entities in solution. The Smoluchowski–Debye–Stokes–Einstein model is such an example (15–18). We here use it to examine the reactions of solvated electrons with ionic solutes. Once the effects of the bulk fluid are accounted for, the unexplained features are attributed to effects of the nonhomogeneous structure of the solvent.

For a diffusion-controlled reaction between species i and j (18):

$$[1] \quad k_2 = 4\pi N_A(D_i + D_j)\kappa R_r f$$

where 4π steradians indicates that all directions of approach of i and j lead to reaction, N_A is Avogadro's constant, D_i, and D_j (m^2 s^{-1}) are the diffusion coefficients of i and j, R_r is the reaction radius of the reacting pair, and κ is the probability of reaction during one encounter. The factor f reflects the effect of Coulombic interaction between the reactants on their probability of obtaining the closeness of approach at which reaction occurs (17),

$$[2] \quad f = \frac{U(R_r)}{k_B T}\left[\exp\left(\frac{U(R_r)}{k_B T}\right) - 1\right]^{-1}$$

where, $U(R_r)$ is the potential energy of interaction between the reactants at distance R_r, k_B is Boltzmann's constant, and T is the temperature.

The potential energy when S is an ion of charge $z\xi$ is given by:

$$[3] \quad U(R_r) = -\frac{z\xi^2}{4\pi\varepsilon_0\varepsilon R_r}$$

where $-\xi$ is the charge on the electron, ε_0 is the permittivity of vacuum, and ε is the relative permittivity of the solvent between the electron and the ion.

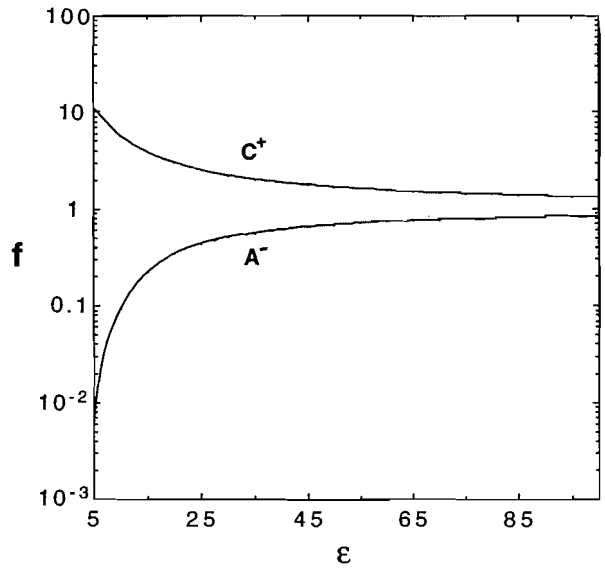

FIG. 5. Dielectric permittivity dependence of the Debye factor f at 298 K. C^+, $NH_{4,s}{}^+$, using R_r = 1.0 nm; A^-, $NO_{3,s}{}^-$, using R_r = 1.5 nm.

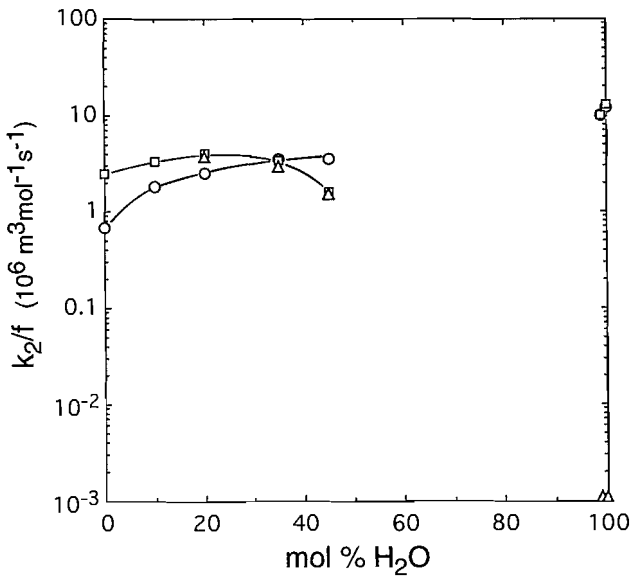

FIG. 6. Solvent composition dependence of k_2/f at 298 K in 1-butanol–water mixed solvents. Symbols are as in Fig. 4.

Values of f were calculated for a range of ε, using a value of R_r appropriate to each solute. The results for 298 K are shown in Fig. 5. When the reactants attract each other (z = +1), the value of f is >1; for repulsion (z = −1), f is <1. The solvent composition dependences of k_2/f at 298 K are shown in Fig. 6. For the reaction of (e_s^- + $NO_{3,s}{}^-$) the observed values of k_2 decrease monotonically with increasing alcohol content of the solvent (Fig. 4). Removal of the Coulombic interaction (k_2/f) reduces the apparent difference between the water-rich and alcohol-rich regions.

Values of f at other temperatures were not calculated, because values of ε are not available.

The Coulombic interaction does not explain the shape of the curve of $k_2(e_s^-$ + $NH_{4,s}{}^+)$ against solvent composition (Fig. 6). The diffusion coefficients and effective reaction radii (κR_r) also influence the reaction rates.

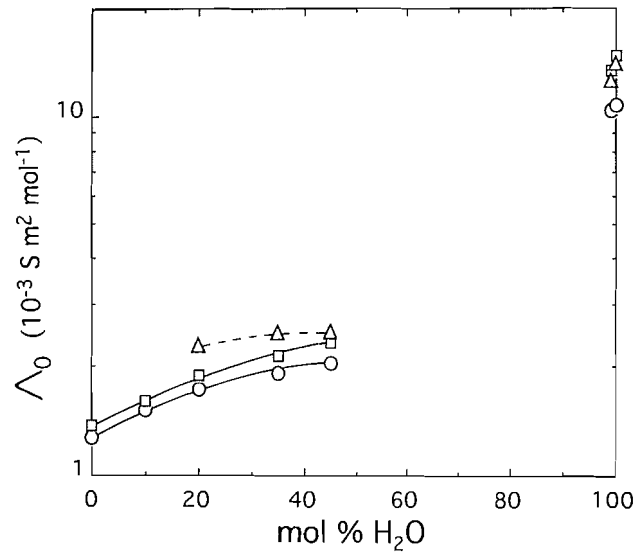

FIG. 7. Solvent composition dependence of the molar conductivities Λ_0 of salts at 298 K in 1-butanol–water mixed solvents. Symbols as in Fig. 4.

Electrical conductivities

The diffusion coefficients in eq. [1] are related to the molar electrical conductivities λ (S m^2 mol^{-1}) of the respective ions (19):

$$[4] \quad D = \lambda k_B T / z_i^2 \xi^2 N_A$$

Combining eq. [1] with eq. [4] we get:

$$[5] \quad \kappa R_r = \frac{\xi^2}{4\pi k_B} \times \frac{k_2}{fT\left[\frac{\lambda_i}{z_i^2} + \lambda_e\right]}$$

$$= 1.48 \times 10^{-16} k_2/fT\,[(\lambda_i/z_i^2) + \lambda_e]$$

where λ_i and λ_e are the molar conductivities of the reactant ion and e_s^-, respectively.

The values of the individual ionic conductivities in the mixed solvents are not known, so we have used approximations based on measured salt conductances. In pure water at 298 K the ratios of the λ's of e_s^- (20):$NH_{4,s}{}^+$ (21):$NO_{3,s}{}^-$ (21) are 2.59:1.04:1.00. The diffusion coefficients ($\propto\lambda_i/z_i^2$) are in the same ratios. Thus, diffusion of e_s^- dominates the relative motion of each reactant pair.

In water we have the following ratios: $[\lambda(e_s^-) + \lambda(NO_{3,s}{}^-)]/\Lambda_0$ (Li_s^+ + $NO_{3,s}{}^-$) = 2.3; $[\lambda(e_s^-) + \lambda(NH_{4,s}{}^+)]/\Lambda_0(NH_{4,s}{}^+$ + $ClO_{4,s}{}^-$) = 1.8; $[\lambda(e_s^-) + \lambda(NH_{4,s}{}^+)]/\Lambda_0$ ($NH_{4,s}{}^+$ + $NO_{3,s}{}^-$) = 1.7; and $[\lambda(e_s^-) + \lambda(NO_{3,s}{}^-)]/\Lambda_0$ ($NH_{4,s}{}^+$ + $NO_{3,s}{}^-$) = 1.7. Thus, eq. [5] can be approximated as

$$[6] \quad \kappa R_r \approx 1 \times 10^{-16} k_2/fT\,\Lambda_0$$

where Λ_0 is the molar conductance in the dilute solutions.

The solvent composition dependence of the molar conductivities Λ_0 of the salts at 298 K, and the approximate values of κR_r at 298 K, are shown in Figs. 7 and 8, respectively. The most interesting observation is that κR_r for the reaction (e_s^- + $NH_{4,s}{}^+$) increases by a factor of more than 10^3 when the mixed solvent changes from the water-rich region to the alcohol-rich region. The activation energy of the reactions, E_2, and the activation energy of the conductance, E_Λ, of the salts are plotted against solvent composition in Figs.

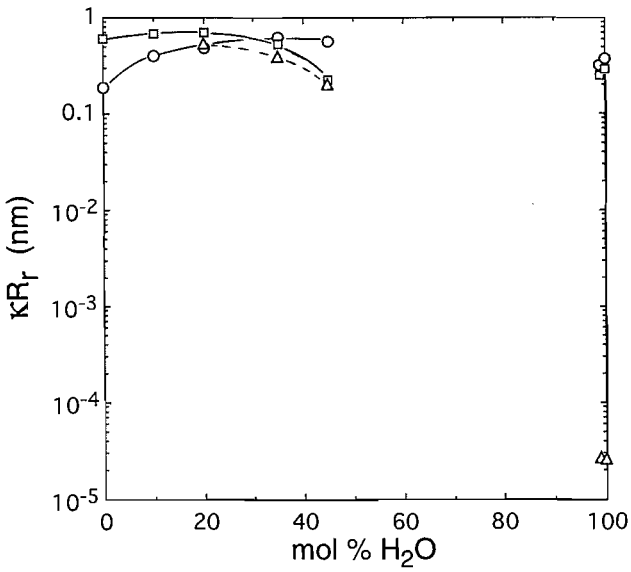

FIG. 8. Solvent composition dependence of κR_r, eq. [6], at 298 K in 1-butanol–water mixed solvents. Symbols as in Fig. 4.

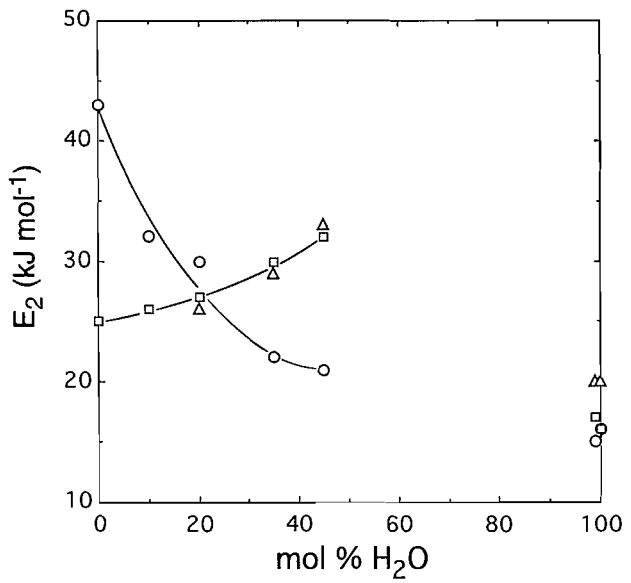

FIG. 9. Solvent composition dependence of the activation energies E_2 near 298 K in 1-butanol–water mixed solvents. Symbols as in Fig. 4.

9, and 10, respectively. For a diffusion-controlled reaction, E_2 is essentially that for the mutual diffusion of e_s^- and S, which encounter each other at random,

[7] $e_s^- + S \rightarrow (e_s^-, S)$

and react,

[8] $(e_s^-, S) \rightarrow$ product

In slow reactions most encounter pairs diffuse apart again,

[9] $(e_s^-, S) \rightarrow e_s^- + S$

in which case the measured E_2 is mainly due to the activation energy of reaction [8].

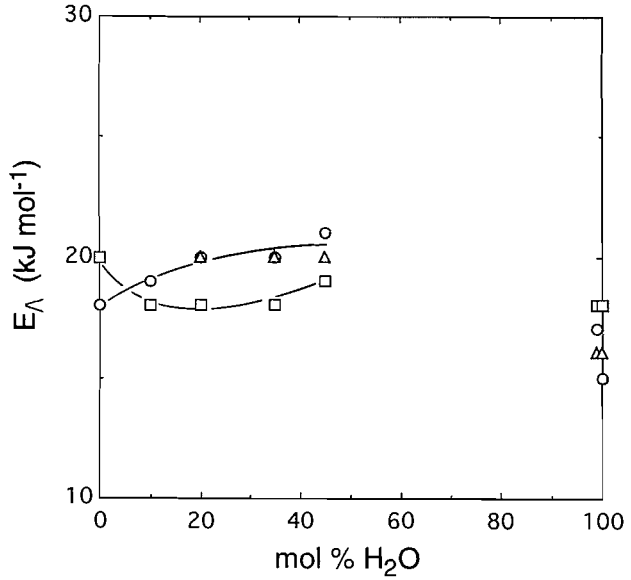

FIG. 10. Solvent composition dependence of the activation energies E_Λ of conductance near 298 K in 1-butanol–water mixed solvents. Symbols as in Fig. 4.

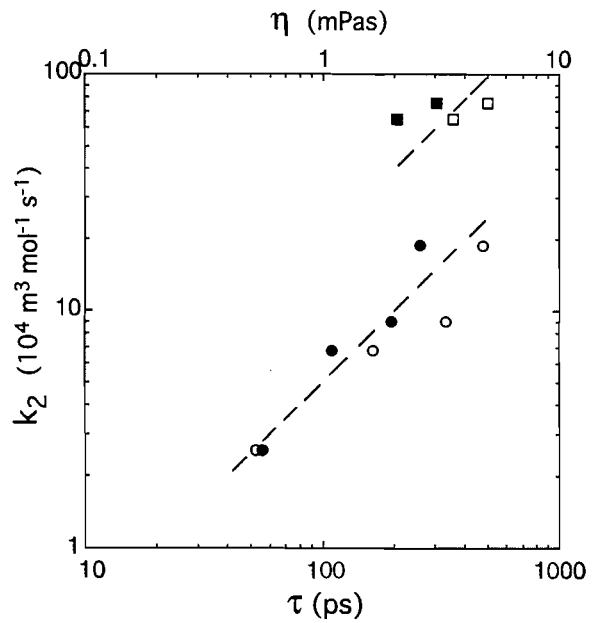

FIG. 11. k_2 (e_s^- + $NO_{3,s}^-$) in pure C_1–C_4 alcohol solvents at 298 K, as functions of viscosity η (●, ■) and dielectric relaxation time τ (○, □). ○, ● primary alcohols; ■, □ secondary alcohols. References for k_2: C_1 and C_2 (22); C_3 (18); 1–C_4 (present work); 2–C_4 (5). Solvent properties: η (23); τ (24, 25). The dashed lines have slopes = 1.0.

$e_s^- + NO_{3,s}^-$

E_Λ of the reactant salts is similar to the E_2 that might be expected for a diffusion-controlled reaction. The values of E_2 for the reaction (e_s^- + $NO_{3,s}^-$) increase with increasing alcohol content, reaching a maximum in pure 1-butanol that is about 3 times larger than that in pure water (Fig. 9). The values of E_Λ decrease with increasing alcohol content in the alcohol-rich region, and the magnitude of change is much smaller than that of E_2. This agrees with the observation that

[k]$LiClO_4$ concentrations 60–600 mol m^{-3} in water, and 90–440 mol m^{-3} in 1-butanol.

the reaction (e_s^- + $NO_{3,s}{}^-$) is a nearly diffusion-controlled reaction in water and gradually deviates from it as the alcohol content is increased.

The reaction (e_s^- + $NO_{3,s}{}^-$) in alcohol solvents is complex. The proposed reaction sequence is (2, 5, 18, 22):

$$[10] \quad e_s^- + NO_{3,s}{}^- \rightleftharpoons (e_s^-, NO_{3,s}{}^-)$$

$$[11] \quad (e_s^-, NO_{3,s}{}^-) + ROH \rightarrow NO_{2,s}{}^- + OH_s^- + \dot{R}OH$$

Alcohol molecules apparently participate chemically in the reaction. The changes in k_2 for the reaction (e_s^- + $NO_{3,s}{}^-$) in different pure alcohol solvents are shown in Fig. 11 as functions of solvent viscosity (23) and dielectric relaxation time (24, 25). As the length of the alkyl group in the primary alcohols is increased, the solvent fluidity *decreases* and k_2 *increases*. This inverse relationship between k_2 and solvent fluidity is attributed to the increasing duration of reactant encounter pairs as solvent fluidity decreases, and a greatly enhanced probability of reaction [11] with increasing encounter duration.

For secondary alcohol solvents, k_2 is 4–7 times larger than in their primary alcohol counterparts. This is attributed to the relatively reactive α-C—H group on the secondary alcohol.

e_s^- + $NH_{4,s}{}^+$

The reaction (e_s^- + $NH_{4,s}{}^+$) is nearly diffusion controlled in the alcohol-rich region and much slower in the water-rich region. The value of κR_r in pure 1-butanol is 10^3 times larger than that in pure water at 298 K (Fig. 8). In ammonium nitrate solution, E_2 represents the reaction (e_s^- + $NH_{4,s}{}^+$) in the alcohol-rich region and (e_s^- + $NO_{3,s}{}^-$) in the water-rich region. The value of E_2 for the reaction (e_s^- + $NH_{4,s}{}^+$) is larger in pure 1-butanol than in pure water (Fig. 9).

The rate constants in water for several other cations, Ag_s^+ (4*c*), H_s^+, Tl_s^+, Cu_s^{2+} (5), are all (2.5–4.2) × 10^7 m^3 mol^{-1} s^{-1}, so the respective values of κR_r are much larger than that for $NH_{4,s}{}^+$ in water.

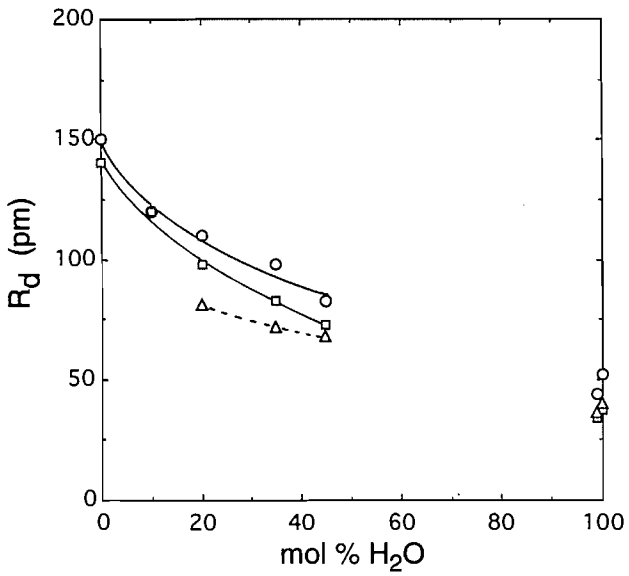

FIG. 12. Solvent composition dependence of R_d at 298 K in 1-butanol–water mixed solvents. Symbols as in Fig. 4.

The solvation of ammonium ions in aqueous solution has been extensively studied by the method of apparent volume of individual ions (26); of entropies of dilution (27); of viscosities (28); of water activity (29); of NMR (30); and of IR and Raman spectra (31, 32). All these studies show that the ammonium ion in aqueous solution has properties similar in many respects to those of a water molecule (structure, volume, molecular weight, charge distribution; see Table 3). Its influence on water properties is usually negligible compared with the change caused by the other cations.

In a study of entropies of solution, Frank and Robinson stated that (27) ". . . the difference [between NaCl and NH_4Cl] is in the direction to be expected if the NH_4^+ exerts an additional stabilizing influence on the water structure by virtue of its tetrahedral shape and its ability to form hydrogen bonds." In a study of Raman spectra of aqueous electrolyte solutions, Vollmar wrote (32) ". . . the electrostatic forces exerted on their nearest neighbors by H_2O and by NH_4^+ are probably very similar. In particular both H_2O and NH_4^+ form hydrogen bonds of about the same strength." As this unique property of solvated ammonium ions in water is responsible for many thermodynamic and spectroscopic properties of the aqueous solutions of ammonium salts, we believe that it is also responsible for the kinetic behavior of solvated ammonium ion reaction in water. Since $NH_{4,s}^+$ is symmetrically solvated in water, it has little tendency to accept an electron.

Relatively little is known about behavior of electrolyte solutions in alcohols. Each alcohol molecule contains one -OH group that can bond with others to form a chain or ring structure in the liquid, but not a three-dimensional structure like that of water. This would greatly influence the solvation structure of an ammonium ion in it. It is, therefore, reasonable to suggest that $NH_{4,s}^+$ is unsymmetrically solvated in an alcohol, and that this greatly facilitates electron attachment and subsequent decomposition, $NH_4 \rightarrow H + NH_3$. More thermodynamic and spectroscopic studies of electrolyte solutions in alcohols would be of great help for our embryonic understanding of solvation effects in different solvents.

The rate parameters for the reactions in 1-butanol–water mixed solvents are summarized in Table 4.

Effective radii for mutual diffusion

The Stokes radius, R_d, for mutual diffusion of ions in an electrolyte solution is given by (19)

$$[12] \quad R_d = \left(\frac{1}{R_{d_i}} + \frac{1}{R_{d_j}}\right)^{-1} = 8.2 \times 10^{-16} \Big/ \eta\left(\frac{\lambda_i}{z_i^2} + \frac{\lambda_j}{z_j^2}\right)$$

In our case, $i = e_s^-$, $j = NH_{4,s}^+$ or $NO_{3,s}^-$, so $|z_i| = |z_j| = 1$. As discussed before for κR_r, we use the approximation $(\lambda_{e_s^-} + \lambda_j) = 1.8\ \Lambda_0$, so

$$[13] \quad R_d \approx 5 \times 10^{-16}/\eta\Lambda_0$$

The solvent composition dependences of R_d are shown in Fig. 12. Equation [12] shows that R_d emphasizes the more mobile ion. In the alcohol-rich region, R_d increases as the alcohol content increases. This is attributed to the larger size of the molecules that solvate the ions. The decrease of R_d as a small amount of alcohol is added to water indicates that the microscopic viscosity of the liquid in the vicinity of the ions is lower than the shear viscosity of the bulk liquid; the ions remain in the disordered water.

This paper is dedicated to Professor Robert H. Burnell on the occasion of his 65th birthday

YONG-JIN WU, DEAN W. STRICKLAND, TRACY J. JENKINS, PEI-YING LIU, and D. JEAN BURNELL. Can. J. Chem. **71**, 1311 (1993).

The direct formation of 2,2-disubstituted 1,3-cyclopentanedione compounds by a Lewis acid catalysed reaction with 1,2-bis(trimethylsilyloxy)cyclobutene proceeds in good to excellent yields with unhindered ketals, but steric hindrance reduces the yields considerably. A carbonyl group α or β to the ketal, or a carbon–carbon double bond α to the ketal, stops the reaction completely. Orthoesters do not give geminally acylated products in synthetically useful yields.

YONG-JIN WU, DEAN W. STRICKLAND, TRACY J. JENKINS, PEI-YING LIU et D. JEAN BURNELL. Can. J. Chem. **71**, 1311 (1993).

La formation directe des cyclopentane-1,3-diones 2,2-disubstituées par la réaction catalysée par les acides de Lewis du 1,2-bis(triméthylsilyoxy)cyclobutène se produit avec des rendements allant de bon à excellent avec les acétals non empêchés; toutefois, l'empêchement stérique réduit considérablement les rendements. Un groupement carbonyle en α ou en β de l'acétal ou une double liaison carbone–carbone en α de l'acétal inhibe complètement la réaction. Les orthoesters ne conduisent pas à des rendements utiles de produits acylés d'une façon géminée.

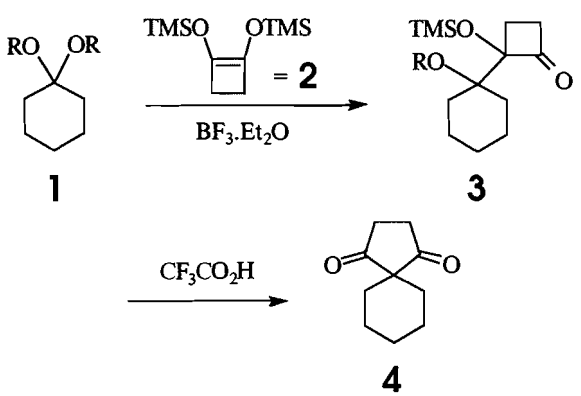
Introduction

Kuwajima and coworkers (1, 2) reported that methyl, ethyl, and benzyl ketals, for example, the cyclohexanone ketal **1** in Scheme 1, in the presence of boron trifluoride etherate react with 1,2-bis(trimethylsilyloxy)cyclobutene (**2**) (3) to give a cyclobutanone derivative **3**. Treatment of that intermediate with trifluoroacetic acid results in rearrangement to a geminally acylated product, such as **4**. This two-step process for the construction of 2,2-disubstituted 1,3-cyclopentanediones has been used in a number of syntheses (2, 4, 5). However, in conjunction with our synthetic approaches to sesquiterpenes with the tricyclo[6.2.1.0^{1,5}]-undecane ring system (6), to triquinane sesquiterpenes (7), and to A-ring aromatic steroids (8) we showed that the aldol step and the subsequent rearrangement can be executed in a single synthetic operation when one employs a large excess of the Lewis acid. Furthermore, the yields of the 1,3-cyclopentanediones obtained in this way are superior to the yields by the two-step method. The reaction with 1,2-bis(trimethylsilyloxy)cyclopentene proceeds in an analogous fashion (9). Results similar to ours with **2** were reported by Ayyangar's group (10), and our procedure found application in a method of direct conversion of alkynyl ketals to polycyclic ketones (11). This method of geminal acylation has been examined with a variety of simple substrates in order to ascertain its applicability to the synthesis of more complex natural products. The results are presented here.



SCHEME 1

Results and discussion

By and large, reactions followed the procedure, which is herein referred to as the "standard conditions," that was developed for the synthesis of isokhusimone (6*b*). This can be summarized as addition over 5–10 min of a dichloromethane solution of 2–3 equivalents of **2** to a dichloromethane solution of the ketal and 10–15 equivalents of freshly distilled boron trifluoride etherate at −78°C.[2] The reaction mixture was stirred for approximately 12 h during which time it was allowed to attain room temperature. An aqueous reaction work-up was followed by purification by flash column chromatography.

Use of different ketals

Whereas Kuwajima and co-workers (1, 2) used mainly methyl and ethyl ketals, we successfully employed ketals derived from 1,2-ethanediol and 2,2-dimethyl-1,3-propanediol in syntheses (6–8). Under the standard conditions we obtained a 68% yield of 2,2-dimethyl-1,3-cyclopentanedione (cf. 40% from 2,2-dimethoxypropane in ref. 5) from 2,2,5,5-tetramethyl-1,3-dioxane, and from 2-ethyl-2-methyl-1,3-dioxolane we obtained a 91.5% yield of 2-ethyl-2-methyl-1,3-cyclopentanedione (6*b*). The cyclopentanone-derived

[1]Author to whom correspondence may be addressed.

[2]The concentrations of the reactants were not critical, but it was important that **2** be pure. Therefore, redistillation of **2** under vacuum (3) is recommended strongly if impurities are evident in its ^{1}H nmr spectrum. The procedure described in ref. 6*b* may be carried out entirely at room temperature, but the isolated yields tend to be a little lower.

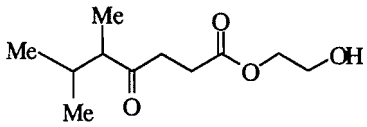
For personal use only.

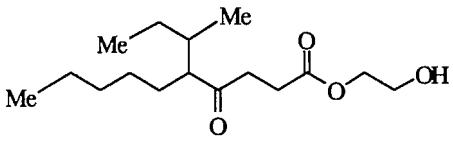
ketal **5** gave a lower yield than the cyclohexanone counterpart **6**. The ketal derived from (±)-2,3-butanediol **7** gave a much poorer yield of **4**, and ketal **8** derived from (±)-1,2-diphenyl-1,2-ethanediol completely resisted the conditions, so that such a ketal may be considered as a protecting group during a geminal acylation under standard conditions (Table 1).

Alkyl groups in the α position

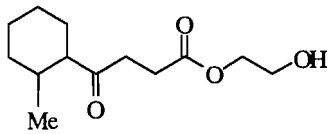
The reaction proved to be very sensitive to congestion about the ketal carbon. A series of ketals derived from ketones with α-methyl groups and 1,2-ethanediol were examined. The yields of their bisacylation products ranged from modest to nonexistent (Table 2). One reason for poor yields was a tendency for the 1,2-ethanediol generated during the reaction to participate in an acid-catalysed ring opening of the double acylation product to lead ultimately to a ketoester. Indeed, with the ketal **9*a*** derived from 3-methylbutanone only a very small amount of the desired cyclopentanedione was detected in the ^{1}H nmr spectrum of the crude product, and the keto-ester **18** was the only product that was isolated by chromatography, albeit in low yield. Evidence for a similar ring-opening process was apparent in the ^{1}H nmr



18



19



20

spectrum of the crude product of **12**, and the reactions of **11** and **13** gave significant amounts of ring-opened products **19** and **20**, respectively, as a 1:1 mixture of diastereomers. There is some precedence for ring-opening in work by Kuwajima (2, 12) in which $SnCl_4$ was the Lewis acid catalyst. This could be overcome to a degree by the use of a ketal derived from a more hindered diol, e.g., **9*b***. A ketal derived from a more hindered ketone, i.e., **10**, proved unreactive, and it was recovered unchanged after being subjected to the standard conditions. Ketals **12**, **13**, and **14** derived from cyclic α-methyl ketones fared better, but the yields were still poor compared to **5** and **6**. This sensitivity to substitution places a serious limit on the utility of the geminal acylation process, but sometimes a lack of reactivity can be used to advantage. Thus, in the synthesis of isokhusimone (Scheme 2) the doubly ketalized substrate **21** was treated with excess **2** and $BF_3 \cdot Et_2O$. The less hindered ketal underwent geminal acylation efficiently while the more hindered side-chain ketal was merely hydrolysed during work-up to give **22** in

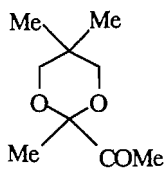
very good yield (6*b*). The bicyclic systems in ketals **15**, **16**, and **17** can be considered as α-substituted, but these were more reactive than the α-methyl cases. Ketal **15** appeared by gc–ms to react efficiently under standard conditions, but chromatography led to considerable destruction of the product. Ketals **16** and **17** gave good yields of the expected geminal acylation products.

Oxygen functions near the ketal

Kuwajima claimed that ketones do not react with **2** in the presence of $BF_3 \cdot Et_2O$ (2). In fact, ketones can give good yields of geminal acylation products.[3] Nevertheless, a ketone next to the target ketal will completely stop the reaction of both the ketal and the ketone. No geminal acylation product was observed when the 2,3-butanedione monoketal **23** was treated with **2** under the standard conditions. Also,



23

in no case could we obtain a geminal acylation product with any ketal bearing an ester or lactone carbonyl in its β-position (i.e., **24**, **25**, **28**, **29**, or **30** in Table 3). An ester group

[3]Details of our work with ketones will be described elsewhere.

at a γ-position, as in **26**, or further away, as in **27** (*6b*), was not deleterious. However, under standard conditions neither the diacetate **31** nor, not surprisingly, its corresponding diol **32** gave any diketone product, but the reaction was compatible with dimethyl (**33**) and dibenzyl (**34**) ethers.

Unsaturation near the ketal

Geminal acylation failed with conjugated cyclic enones when the unsaturation remained in its original position during ketalization, such as with **35**, **36**, and **37** (Table 4). Attempts at reactions with such substrates led invariably to recovery of the enone itself, which must have resulted largely by hydrolysis during the aqueous work-up. A ketal **38** derived from butenone gave a complex mixture with much of the product in a polymeric form. However, ketal **39**, derived from acetophenone, underwent geminal acylation smoothly, and substrates in which the double bond had migrated to the β,γ-position during acid-catalysed ketalization, i.e., **40** and **41**, also underwent the desired reaction with very good yields. A 72% yield was realized for the geminal acylation of ketal **42**, which also had a distant ester function. In this instance there was a small amount of double bond isomerization.[4]

[4]Prolonged exposure to the acidic reaction medium led to some isomerization of the double bond in the products of **40** and **41**, also.

54 15%

SCHEME 4

Some unsaturated bicyclic ketones gave only products that must have been derived by initial geminal acylation followed by rupture of the bicyclic framework (Scheme 3). Ketal **43** gave a 12% yield of **45**, the consequence of closure of an intermediate allylic cation (**44**) on to an enol oxygen. The major product (42%) was **46**, which was, considering our efforts to exclude moisture from the reaction medium, likely the result of hydrolysis of **45** during work-up rather than of capture of adventitious water by **44**. On the other hand the similar ketal **47** gave **48** in 56% yield as the only isolated product.

Reactions of orthoesters

The reaction of orthoesters with **2** seemed like an interesting entry to 1,3-cyclopentanediones with an oxygen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

function at C-2. However, with the simple examples **49** and **50**, hydrolysis to the corresponding ester, presumably during work-up, was the predominant result. A small amount of geminal acylation did lead to the cyclopentanedione **51** from **49** (Scheme 4), but it was unstable under the reaction conditions, and concomitant acid-catalysed opening of the cyclopentanedione ring yielded some keto-ester **53**. In the case of **50** the intermediate **52** was not detected, and the only recognizable product was the keto-ester **54**. The appalling yields of both types of geminally acylated product preclude any synthetic application of this reaction with orthoesters.

Experimental

General

For details of the instruments, the format of the spectral data, and the abbreviations see ref. 13. All nmr spectra were recorded in $CDCl_3$ unless otherwise noted.[5] Ketalizations were by the acid-catalysed action (*p*-toluenesulfonic acid or Amberlyst-15) of a large excess of 1,2-ethanediol in benzene with azeotropic removal of water. In more sluggish cases and with some enones a method involving 1,2-bis(trimethylsilyloxy)ethane and trimethylsilyl trifluoromethanesulfonate (TMSOTf) was employed (14). Monoketal **23** was prepared by the method of Levine and Mauney (15). Ketals were purified by distillation or column chromatography. The reactions were run under an atmosphere of dry N_2 following the procedure described in ref. 6*b*, as outlined in the above section. Aqueous "work-up" followed one of these procedures: (*i*) the reaction mixture was poured into ice-cold saturated $NaHCO_3$ solution, the organic layer was washed again with saturated $NaHCO_3$ solution, then washed with saturated NaCl solution (×2), dried over anhydrous $MgSO_4$, and concentrated in vacuo; (*ii*) the reaction mixture was poured into ice-water, the organic layer was washed again with water (×2), then washed with saturated $NaHCO_3$ solution and saturated NaCl solution, dried over anhydrous $MgSO_4$, and concentrated in vacuo; (*iii*) the reaction mixture was poured into water at room temperature, the organic layer was washed again with water (×2) then saturated NaCl solution, dried over anhydrous $MgSO_4$, and concentrated in vacuo. (In some instances *i* gave emulsions in the initial $NaHCO_3$ wash.) Flash column chromatography ("chromatography") used 230–400 mesh silica gel, and elution was normally with hexane containing an increasing proportion of ethyl acetate, the approximate proportion of ethyl acetate at the initial point of elution being noted below as a percentage. Care was required in determining which chromatographic fractions contained the desired diketone products because these compounds generally are very poorly detected using standard tlc visualization methods, e.g., uv light, I_2, and acid-based sprays (ceric ammonium nitrate – H_2SO_4, phosphomolybdic acid, and anisaldehyde–H_2SO_4). In some instances we used gc–ms to identify the correct fractions.

Reaction of 5

Addition of **2** (1.1 mL, 4.1 mmol) in CH_2Cl_2 (6.0 mL) to a solution of ketal **5** (208 mg, 1.63 mmol) and $BF_3 \cdot Et_2O$ (3.0 mL, 24 mmol) in CH_2Cl_2 (60 mL), then work-up *i*, led, after chromatography (5%), to *spiro[4.4]nonane-1,4-dione* (168 mg, 68%) as colorless crystals: mp 58–59.5°C; ir ν_{max}: 1720 cm^{-1}; ^1H nmr δ: 2.48 (4H, br s), 1.61 (8H, br s); ^{13}C nmr δ: 215.8 (2C, 0), 63.0 (0), 34.7 (2C, 2), 34.6 (2C, 2), 26.6 (2C, 2); ms: 152 (100, M^+), 124 (35), 111 (48), 97 (52), 96 (44), 95 (33), 69 (28), 68 (52), 67 (61), 56 (61), 41 (37). Exact Mass calcd. for $C_9H_{12}O_2$: 152.0837; found: 152.0831.

Reaction of 7

Addition of **2** (2.0 mL, 7.5 mmol) in CH_2Cl_2 (8.0 mL) to a solution of ketal **7** (425 mg, 2.29 mmol) and $BF_3 \cdot Et_2O$ (4.6 mL, 37 mmol) in CH_2Cl_2 (20 mL), then work-up *ii*, led, after chromatography (10%), to 183 mg (48%) of *spiro[4.5]decane-1,4-dione* (**4**), which was identical with a sample previously prepared in this laboratory (6*b*).

*Reaction of 9*a

Addition of **2** (1.6 mL, 6.0 mmol) in CH_2Cl_2 (8.0 mL) to a solution of ketal **9***a* (0.26 g, 2.0 mmol) and $BF_3 \cdot Et_2O$ (3.7 mL, 30 mmol) in CH_2Cl_2 (20 mL), then work-up *ii*, led, after chromatography (5%), to *2-hydroxyethyl 5,6-dimethyl-4-oxoheptanoate* (**18**) (59 mg, 19%) as a pale yellow liquid; ir ν_{max}: 3459 (br), 1737, 1711 cm^{-1}; ^1H nmr δ: 4.23 (2H, nar m), 3.82 (2H, nar m), 2.81 (1H, very br), 2.80 (2H, br t, J = 6.7 Hz), 2.60 (2H, br t, J = 6.7 Hz), 2.36 (1H, quintet, $J \approx$ 7.0 Hz), 1.97 (1H, octet, $J \approx$ 6.8 Hz), 1.04 (3H, d, J = 7.0 Hz), 0.91 (3H, d, J = 6.7 Hz), 0.87 (3H, d, J = 6.8 Hz); ^{13}C nmr δ: 213.3, 173.1, 66.1, 60.9, 52.7, 36.4, 30.2, 27.8, 21.2, 18.7, 12.8; ms: no M^+, 199 (2), 186 (2), 174 (7), 155 (22), 145 (24), 112 (21), 101 (100), 85 (24), 71 (73), 45 (29), 43 (70). Exact Mass calcd. for $C_8H_{14}O_4$ ($M^+ - C_3H_6$ via McLafferty): 174.0892; found: 174.0890.

*Reaction of 9*b

Compound **2** (2.0 mL, 7.4 mmol) in CH_2Cl_2 (8.0 mL) was added over 1 h to a solution of ketal **9***b* (390 mg, 7.46 mmol) and $BF_3 \cdot Et_2O$ (4.5 mL, 37 mmol) in CH_2Cl_2 (20 mL) at −78°C, then the mixture was stirred for 27 h during which time it attained room temperature. Work-up *ii* gave material that was a mixture of the spirodiketone and unreacted **9***b*, so $BF_3 \cdot Et_2O$ (4.5 mL, 37 mmol) and **2** (2.0 mL, 7.4 mmol) were added again to a CH_2Cl_2 solution of the product mixture. After stirring for 19 h, work-up *ii* yielded 213 mg (56%) of product that ^1H nmr revealed was very largely *2-methyl-2-methylethyl-1,3-cyclopentanedione*. Attempts to purify this product by chromatography led largely to its destruction, but a small amount (50 mg) of homogeneous material was recovered: ir ν_{max}: 1759 (m), 1721 (s) cm^{-1}; ^1H nmr δ: 2.74 (4H, symmetrical m), 2.01 (1H, septet, J = 6.9 Hz), 1.06 (3H, s), 0.93 (6H, d, J = 6.9 Hz); ^{13}C nmr δ: 216.8 (2C), 59.5, 35.6 (2C), 33.8, 17.3 (2C), 15.3; ms: 154 (28, M^+), 139 (100), 112 (24), 111 (32), 83 (25), 56 (18), 55 (27), 43 (12), 41 (20). Exact Mass calcd. for $C_9H_{14}O_2$: 154.0993; found: 154.0989.

Reaction of 11

Addition of **2** (0.88 mL, 3.3 mmol) in CH_2Cl_2 (8.0 mL) to a solution of ketal **11** (0.22 g, 1.1 mmol) and $BF_3 \cdot Et_2O$ (2.0 mL, 16 mmol) in CH_2Cl_2 (20 mL), then work-up *ii*, led, after chromatography (15%), to *2-(1-methylpropyl)-2-pentyl-1,3-cyclopentanedione* (0.68 g, 28%) as a very pale yellow liquid: ir ν_{max}: 1719 cm^{-1}; ^1H nmr δ: 2.66 (4H, nar m), 1.80–1.61 (3H, m), 1.45 (1H, m), 1.31–0.95 (7H, m), 0.92 (3H, d, J = 6.9 Hz), 0.85 (3H, t, J = 7.2 Hz), 0.83 (3H, t, J = 7.0 Hz); ^{13}C nmr δ: 218.5, 218.1, 64.1, 41.0, 36.9, 36.8, 32.9, 32.2, 24.4 (2C), 22.2, 13.9, 13.2, 12.3; ms: no M^+, 195 (34), 169 (53), 168 (25), 154 (33), 139 (54), 126 (28), 125 (56), 112 (100), 69 (27), 55 (65), 41 (80). Exact Mass calcd. for $C_{12}H_{19}O_2$ ($M^+ - C_2H_5$): 195.1384; found: 195.1380. A later chromatographic fraction contained a mixture of the diastereomers of *2-hydroxyethyl 6-methyl-4-oxo-5-pentyloctanoate* (**19**) (46 mg, 15%) as an oil: ir ν_{max}: 3457 (br), 1736, 1709 cm^{-1}; ^1H nmr δ: 4.26 (2H, m), 3.85 (2H, m), 2.96–2.38 (6H, m), 1.76–1.05 (11H, m), 0.96–0.84 (9H, nar m).

Reaction of 12

Addition of **2** (2.0 mL, 7.4 mmol) in CH_2Cl_2 (8.0 mL) to a solution of ketal **12** (0.35 g, 2.5 mmol) and $BF_3 \cdot Et_2O$ (4.5 mL, 37 mmol) in CH_2Cl_2 (20 mL), then work-up *ii*, led, after chromatography (15%), to *6-methylspiro[4.4]nonane-1,4-dione* (146 mg, 36%) as a colorless liquid: ir ν_{max}: 1718 cm^{-1}; ^1H nmr δ: 2.81–2.57 (4H, br m), 2.25 (1H, br m), 1.85 (5H, br m), 1.54 (1H, br m),

[5]The complete set of ^1H and ^{13}C nmr spectra of the products of the reactions of ketals **5**, **7**, **9***a*, **9***b*, **11**–**15**, **17**, **26**, **33**, **34**, **39**–**43**, **47**, and of the orthoesters **49** and **50** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Reaction of ***15***[6]

Addition of **2** (0.92 mL, 3.4 mmol) in CH_2Cl_2 (7.0 mL) to a solution of ketal **15** (209 mg, 1.37 mmol) and $BF_3 \cdot Et_2O$ (2.6 mL, 25 mmol) in CH_2Cl_2 (16 mL), then work-up *iii*, gave 254 mg of a crude product, of which 81% (by gc–ms) was the geminally acylated product. Serious losses were incurred during chromatography (5%), which nevertheless provided some homogeneous *spiro(bicyclo[4.1.0]heptane-2,2'-cyclopentane-1,3-dione)* as a low-melting solid (64 mg, 30%): mp 38–41°C; ir ν_{max}: 1759 (m), 1720 (s) cm^{-1}; ^{1}H nmr (CD_2Cl_2) δ: 2.88 (2H, m), 2.64 (2H, m), 1.80 (1H, m), 1.66 (1H, m), 1.25–1.52 (4H, m), 1.10 (1H, m), 0.78 (1H, m), 0.52 (2H, m); ^{13}C nmr (CD_2Cl_2) δ: 215.1 (0), 214.8 (0), 53.7 (0), 34.7 (2), 34.5 (2), 24.7 (2), 22.3 (2), 15.7 (2), 14.7 (1), 10.6 (1), 6.4 (2); ms: 178 (73, M^+), 163 (18), 150 (18), 136 (15), 135 (17), 123 (15), 122 (37), 121 (18), 111 (32), 94 (26), 93 (31), 91 (21), 79 (100), 77 (29), 55 (34). Exact Mass calcd. for $C_{11}H_{14}O_2$: 178.0993; found: 178.1003.

Reaction of ***17***

Addition of **2** (2.0 mL, 7.6 mmol) in CH_2Cl_2 (5.0 mL) to a solution of ketal **17** (428 mg, 2.54 mmol) and $BF_3 \cdot Et_2O$ (4.8 mL, 38 mmol) in CH_2Cl_2 (50 mL), then work-up *i*, gave, after chromatography (4%), the hydrolysis product *bicyclo[2.2.2]octan-2-one* (72 mg, 17%) and *spiro(bicyclo[2.2.2]octane-2,2'-cyclopentane-1,3-dione)* as colorless crystals (362 mg, 74%): mp 99–100°C; ir ν_{max}: 1738 (sh), 1718 cm^{-1}; ^{1}H nmr δ: 3.00 (2H, m), 2.56 (2H, m), 1.83 (1H, br s), 1.76 (1H, br s), 1.61–1.68 (6H, m), 1.35–1.49 (4H, m); ^{13}C nmr δ: 213.1 (2C, 0), 62.4 (0), 34.0 (2C, 2), 32.1 (1), 26.5 (2), 24.1 (2C, 2), 23.0 (1), 21.2 (2C, 2); ms (from gc–ms): 192 (25, M^+), 112 (100), 81 (23), 80 (15), 79 (40), 77 (21), 55 (20), 53 (20), 41 (27). Exact Mass calcd. for $C_{12}H_{16}O_2$: 192.1150; found: 192.1141.

Reaction of ***26***

Addition of **2** (1.0 mL, 3.8 mmol) in CH_2Cl_2 (6.0 mL) to a solution of ketal **26** (290 mg, 1.54 mmol) and $BF_3 \cdot Et_2O$ (2.8 mL, 23 mmol) in CH_2Cl_2 (40 mL), then work-up *i*, gave, after chromatography (10% acetone in petroleum ether), *2-((2-carbethoxy)ethyl)-2-methyl-1,3-cyclopentanedione* (298 mg, 91%) as a colorless oil: ir ν_{max}: 1724 cm^{-1}; ^{1}H nmr δ: 4.06 (2H, q, J = 7.1 Hz), 2.82 (4H, s), 2.26 (2H, t, J = 7.5 Hz), 1.96 (2H, t, J = 7.5 Hz), 1.23 (3H, t, J = 7.1 Hz), 1.13 (3H, s); ^{13}C nmr δ: 215.5 (2C, 0), 172.6 (0), 60.4 (2), 55.1 (0), 34.6 (2C, 2), 28.6 (2C, 2), 19.7 (3), 13.9 (3); ms: 212 (11, M^+), 184 (9), 167 (15, $M^+ - CH_3CH_2O$), 166 (17), 138 (36), 125 (100), 110 (20), 97 (24), 69 (22), 55 (36), 43 (20), 41 (34). Exact Mass calcd. for $C_{11}H_{16}O_4$: 212.1048; found: 212.1046.

Reaction of ***33***

Addition of **2** (1.26 mL, 4.74 mmol) in CH_2Cl_2 (6.0 mL) to a solution of ketal **33** (301 mg, 1.58 mmol) and $BF_3 \cdot Et_2O$ (1.94 mL, 15.8 mmol) in CH_2Cl_2 (50 mL), then work-up *i*, gave, after chromatography (5% acetone in petroleum ether), *2,2-bis(2-methoxyethyl)-1,3-cyclopentanedione* (251 mg, 74%) as a colorless oil: ir ν_{max}: 1760, 1720 cm^{-1}; ^{1}H nmr δ: 3.12 (4H, t, J = 6.0 Hz), 3.04 (6H, s), 2.54 (4H, s), 1.85 (4H, t, J = 6.0 Hz); ^{13}C nmr δ: 217.9 (2C, 2), 68.4 (2C, 2), 58.5 (2C, 3), 55.5 (0), 37.8 (2C, 2), 36.2 (2C, 2); ms: no M^+, 156 (14, $M^+ - CH_2{=}CH\text{-}OMe$ by McLafferty), 141 (42), 125 (7), 112 (8), 109 (23), 81 (10), 55 (12), 53 (10), 45 (100), 41 (12). Exact Mass calcd. for $C_8H_{12}O_3$ ($M^+ - CH_2{=}CH\text{-}OMe$): 156.0786; found 156.0783. Another small chromatographic fraction was tentatively identified as *2-methoxyethyl-2-methyl-1,3-cyclopentanedione*, a colorless oil (17 mg): ir ν_{max}: 1759 (shoulder), 1715 cm^{-1}; ^{1}H nmr δ: 3.20 (2H, t, J = 7.2 Hz), 3.08 (3H, s), 2.67 (4H, s), 2.00 (2H, t, J = 7.2 Hz), 1.03 (3H, s); ^{13}C nmr δ: 217.2 (2C, 0), 68.3 (2), 58.7 (3), 53.6 (0), 35.8 (2), 35.0 (2C, 2), 21.6 (3); ms: 170 (1, M^+), 156 (5), 140 (14), 125 (42), 109 (11), 69 (53), 59 (30), 55 (28), 45 (100), 43 (16), 41 (61).

Reaction of ***34***

Addition of **2** (0.33 mL, 1.2 mmol) in CH_2Cl_2 (5.0 mL) to a solution of ketal **34** (211 mg, 0.62 mmol) and $BF_3 \cdot Et_2O$ (1.1 mL, 9.3 mmol) in CH_2Cl_2 (30 mL), then work-up *i*, gave, after chromatography (5% acetone in petroleum ether), *2,2-bis(2-benzyloxyethyl)-1,3-cyclopentanedione* (194 mg, 86%) as an oil: ir ν_{max}: 1757, 1710 cm^{-1}; ^{1}H nmr δ: 7.39 (10H, m), 4.43 (4H, s), 3.48 (4H, t, J = 7.0 Hz), 2.50 (4H, s), 2.15 (4H, t, J = 7.0 Hz); ^{13}C nmr δ: 217.6 (2C, 0), 137.2 (2C, 0), 128.2 (4C, 1), 127.6 (2C, 1), 127.5 (4C, 1), 72.8 (2C, 2), 65.8 (2C, 2), 55.5 (0), 37.3 (2C, 2), 35.8 (2C, 2); ms: 366 (2, M^+), 169 (18), 141 (14), 126 (8), 125 (4), 108 (3), 107 (3), 91 (100), 78 (3), 77 (4), 65 (10).

Reaction of ***39***

Addition of **2** (1.1 mL, 4.3 mmol) in CH_2Cl_2 (6.0 mL) to a solution of ketal **39** (232 mg, 1.43 mmol) and $BF_3 \cdot Et_2O$ (2.6 mL, 21 mmol) in CH_2Cl_2 (30 mL), then work-up *iii*, led, after chromatography (15%), to *2-methyl-2-phenyl-1,3-cyclopentanedione* as a yellow oil (206 mg, 77%): ir ν_{max}: 1765 (m), 1724 cm^{-1}; ^{1}H nmr δ: 7.38–7.19 (5H, m), 2.82 (4H, wide symmetrical m), 1.43 (3H, s); ^{13}C nmr δ: 213.0 (0), 136.8 (0), 129.3 (1), 127.9 (1), 126.3 (1), 61.9 (0), 35.2 (2), 19.7 (3); ms: 188 (100, M^+), 145 (36), 132 (32), 105 (26), 104 (74), 103 (30), 78 (24), 77 (26), 51 (21). Exact Mass calcd. for $C_{12}H_{12}O_2$: 188.0837; found: 188.0835.

Reaction of ***40***

Addition of **2** (0.57 mL, 2.1 mmol) in CH_2Cl_2 (5.0 mL) to a solution of ketal **40** (119 mg, 0.85 mmol) and $BF_3 \cdot Et_2O$ (1.57 mL,

[6]We thank Mr. Sheldon Crane for performing this reaction.

For personal use only.

12.8 mmol) in CH_2Cl_2 (50 mL), then work-up *i*, led, after chromatography (3% acetone in petroleum ether), to *spiro[4.5]dec-7-ene-1,4-dione* (91 mg, 75%) as colorless crystals: mp 53–54°C; ir ν_{max}: 1749, 1716, 1438 cm^{-1}; ^1H nmr δ: 5.76 (2H, m), 2.82 (4H, symmetrical m), 2.13 (4H, m), 1.73 (2H, t, J = 6.1 Hz); ^{13}C nmr δ: 214.4 (2C, 0), 125.1 (1), 122.9 (1), 55.3 (0), 34.1 (2C, 2), 27.0 (2), 25.8 (2), 20.8 (2); ms: 164 (100, M^+), 149 (11), 136 (44), 135 (36), 122 (28), 121 (24), 108 (22), 107 (43), 80 (53), 79 (93), 77 (37), 55 (25). Exact Mass calcd. for $C_{10}H_{12}O_2$: 164.0837; found: 164.0843.

Reaction of ***41***

Addition of **2** (3.0 mL, 11 mmol) in CH_2Cl_2 (10 mL) to a solution of ketal **41** (722 mg, 3.42 mmol) and $BF_3 \cdot Et_2O$ (7.0 mL, 57 mmol) in CH_2Cl_2 (60 mL), then work-up *i*, led, after chromatography (10–16% EtOAc in hexane), to 37 mg (16%) of recovered isophorone and *7,9,9-trimethylspiro[4.5]dec-7-ene-1,4-dione* (601 mg, 85%) as colorless crystals: mp 85–86°C; ir ν_{max}: 1721 cm^{-1}; ^1H nmr δ: 5.20 (1H, br s, irradiation of this signal resulted in a 1% nOe for δ 1.76 and a 1.5% nOe at δ 0.94), 3.05 (2H, m), 2.63 (2H, m), 2.03 (2H, br s), 1.76 (3H, s), 1.65 (2H, s), 0.94 (6H, s, irradiation of this signal resulted in a 17% nOe for δ 5.20 and a 7% nOe for δ 1.65); ^{13}C nmr δ: 214.2 (2C, 0), 129.6 (1), 128.6 (0), 59.0 (0), 43.3 (2), 34.7 (2C, 2), 32.8 (0), 30.1 (2C, 3), 29.1 (2), 23.6 (3); ms: 206 (100, M^+), 191 (22), 178 (11), 163 (31), 145 (28), 131 (31), 107 (21), 91 (21). Exact Mass calcd. for $C_{13}H_{18}O_2$: 206.1306; found: 206.1306.

Reaction of ***42***

Addition of **2** (0.70 mL, 2.5 mmol) in CH_2Cl_2 (5.0 mL) to a solution of ketal **42** (225 mg, 1.24 mmol) and $BF_3 \cdot Et_2O$ (2.3 mL, 18 mmol) in CH_2Cl_2 (40 mL), then work-up *i*, gave a mixture of double bond isomers in a ratio of 11:1. The major product, *8-carbethoxy-7-methylspiro[4.5]dec-7-ene-1,4-dione*, was isolated by chromatography (7%) as a colorless oil (223 mg, 72%): ir ν_{max}: 1721 (s), 1645 (m) cm^{-1}; ^1H nmr δ: 4.18 (2H, q, J = 6.9 Hz), 3.03–2.64 (4H, m), 2.38 (2H, br s), 2.24 (2H, s), 2.11 (3H, s), 1.74 (2H, t, J = 6.3 Hz), 1.29 (3H, t, J = 7.2 Hz); ^{13}C nmr δ; 213.8 (2C, 0), 167.5 (0), 143.4 (0), 122.7 (0), 59.8 (2), 56.4 (0), 34.2 (2C, 2), 33.6 (2), 28.2 (2), 22.2 (2), 21.5 (3), 14.2 (3); ms (from gc-ms): 250 (6, M^+), 205 (26), 204 (100), 177 (26), 176 (75), 175 (24), 91 (45), 77 (32), 55 (27). Exact Mass calcd. for $C_{14}H_{18}O_4$: 250.1204; found: 250.1206. The minor isomer was not obtained homogeneously, but from a fraction containing the major isomer the following data suggested its structure to be *8-carbethoxy-9-methylspiro[4.5]dec-7-ene-1,4-dione*: ^1H nmr δ: 5.11 (s) with the remaining signals masked by those of the major isomer; ^{13}C nmr δ: 213.2 (2C, 0), 172.9 (0), 137.5 (0), 117.5 (1), 60.8 (2), 56.4 (0), 44.4 (1), 34.7 (2C, 2), 25.0 (2), 22.9 (3), 14.1 (3) with one methylene signal hidden; ms (from gc–ms): 250 (25, M^+), 177 (100), 131 (41), 121 (41), 93 (28), 91 (59), 77 (53), 55 (27).

Reaction of ***43***

Addition of **2** (0.89 mL, 3.3 mmol) in CH_2Cl_2 (6.0 mL) to a solution of ketal **43** (202 mg, 1.33 mmol) and $BF_3 \cdot Et_2O$ (2.5 mL, 20 mmol) in CH_2Cl_2 (40 mL), then work-up *i*, led, after chromatography (5%), to *8-oxatricyclo[7.2.1.0^{3,7}]dodeca-3(7),10-dien-4-one* (**45**) (29 mg, 12%) as a colorless oil: ir ν_{max}: 1690 (m), 1611, 1386 cm^{-1}; ^1H nmr δ: 6.29 (1H, dd, J = 2.7, 5.5 Hz), 5.81 (1H, dd, J = 2.6, 5.5 Hz), 5.33 (1H, dd, J = 2.6, 6.1 Hz), 3.06 (1H, m), 2.60–2.21 (7H, m), 1.93 (1H, d, J = 14.0 Hz); ^{13}C nmr δ: 207.7 (0), 179.6 (0), 144.4 (1), 126.8 (1), 115.4 (0), 85.2 (1), 40.1 (2), 38.1 (1), 33.4 (2), 32.2 (2), 28.0 (2); ms (from gc–ms): 194 (14, M^+), 91 (36), 89 (12), 66 (100), 65 (27). A more polar chromatographic fraction was composed of *2-((3-hydroxycyclopent-4-enyl)methyl)cyclopentane-1,3-dione* (**46**, mainly in its enol form) as a colorless oil (108 mg, 42%): ir ν_{max}: 3404 (br), 1683 (m), 1621, 1411 cm^{-1}; ^1H nmr δ: 6.14 (1H, m), 6.00 (1H, m), 5.10 (1H, d, J = 5.5 Hz), 2.67–2.18 (9H, m); ^{13}C nmr δ: 203.6 (0), 184.5 (0), 137.4 (1), 134.8 (1), 110.0 (0), 84.2 (1), 36.9 (2), 34.2 (1), 32.6 (2), 26.5 (2), 17.5 (2); ms: no M^+, 176 (6, $M^+ - H_2O$), 66 (100), 65 (20), 55 (17), 54 (24). Exact Mass calcd. for $C_{11}H_{12}O_2$ ($M^+ - H_2O$): 176.0851; found: 176.0841.

Reaction of ***47***

Addition of **2** (0.73 mL, 2.8 mmol) in CH_2Cl_2 (6.0 mL) to a solution of ketal **47** (182 mg, 1.10 mmol) and $BF_3 \cdot Et_2O$ (2.0 mL, 16 mmol) in CH_2Cl_2 (40 mL), then work-up *i*, gave, after chromatography (6%), *8-oxatricyclo[7.2.2.0^{3,7}]triscadeca-3(7),10-dien-4-one* (**48**) (117 mg, 56%) as a colorless solid: mp 72–74°C; ir ν_{max}: 1682 (m), 1619, 1415 (m) cm^{-1}; ^1H nmr δ: 6.10 (1H, m), 5.90 (1H, m), 4.65 (1H, br s), 2.77–2.08 (9H, m), 1.62–1.55 (2H, m); ^{13}C nmr δ: 204.1 (0), 182.4 (0), 133.4 (1), 124.5 (1), 112.7 (0), 74.6 (1), 33.1 (2), 29.2 (1), 26.3 (2), 24.7 (2), 22.9 (2), 21.0 (2); ms: 190 (6, M^+), 112 (52), 111 (24), 80 (100), 79 (72), 76 (31), 55 (20), 53 (18), 51 (20). Exact Mass calcd. for $C_{12}H_{14}O_2$: 190.0993; found: 190.0988.

*Reaction of trimethyl orthovalerate (****49****)*

A solution of **2** (1.2 mL, 4.1 mmol) in CH_2Cl_2 (6.0 mL) was added over 20 min to a solution of trimethyl orthovalerate (**49**) (275 mg, 1.70 mmol) and $BF_3 \cdot Et_2O$ (3.1 mL, 25 mmol) in CH_2Cl_2 (30 mL) at room temperature. The reaction was stirred for 90 h. Work-up *iii* gave 260 mg of a volatile brown oil for which gc–ms analysis indicated that the major product was *methyl valerate*. Chromatography (10%) provided only 52 mg (16%) of *2-butyl-2-methoxy-1,3-cyclopentanedione* (**51**) as a yellow oil: ir ν_{max}: 1775 (m), 1731 cm^{-1}; ^1H nmr δ: 3.26 (3H, s), 2.93 and 2.68 (2H each, coupled multiplets), 1.74 (2H, m), 1.30 (4H, br m), 0.88 (3H, t, J = 7.0 Hz); ^{13}C nmr δ: 210.9 (2C, 0), 87.5 (0), 54.5 (3), 34.9 (2), 34.0 (2C, 2), 24.3 (2), 22.6 (2), 13.7 (3); ms (from gc–ms): 184 (38, M^+), 169 (0.2), 141 (55), 113 (10), 100 (14), 85 (54), 71 (86), 57 (100), 55 (35), 41 (65). Exact Mass calcd. for $C_{10}H_{16}O_3$: 184.1099; found: 184.1104. A less polar chromatographic fraction (5%) yielded *methyl 5-methoxy-4-oxononanoate* (**53**) (16 mg, 4%) as a yellow oil (contaminated with a little methyl valerate): ir ν_{max}: 1742, 1719 cm^{-1}; ^1H nmr δ: 3.68 (3H, s), 3.62 (1H, apparent t, J = 6.3 Hz), 3.38 (3H, s), 2.84 (2H, complex m), 2.61 (2H, apparent t, J = 6.5 Hz), 1.65 (2H, m), 1.34 (4H, br m), 0.90 (3H, distorted t, $J \approx$ 6.7 Hz); ^{13}C nmr δ: 211.5 (0), 173.2 (0), 87.1 (1), 58.2 (3), 51.8 (3), 32.3 (2), 31.8 (2), 27.2 (2C, 2), 22.5 (2), 13.9 (3); ms (from gc–ms): no M^+, 185 (4), 153 (1), 131 (15), 115 (9), 101 (70), 71 (30), 69 (83), 59 (17), 55 (24), 45 (100). Exact Mass calcd. for $C_{10}H_{17}O_4$ ($M^+ - CH_3$): 185.1177; found: 185.1168.

*Reaction of trimethyl orthobenzoate (****50****)*

A solution of **2** (1.1 mL, 3.9 mmol) in CH_2Cl_2 (6.0 mL) was added over 30 min to a solution of trimethyl orthobenzoate (**50**) (240 mg, 1.32 mmol) and $BF_3 \cdot Et_2O$ (2.4 mL, 19 mmol) in CH_2Cl_2 (30 mL) at −78°C. The reaction was stirred for 26.5 h during which time the reaction was allowed to attain room temperature. Work-up *iii* provided a brown oil (331 mg), but chromatography (5%) yielded only 47 mg (15%) of *methyl 5-methoxy-4-oxo-5-phenylpentanoate* (**54**) as a yellow oil: ir ν_{max}: 1729 cm^{-1}; ^1H nmr δ: 7.42–7.35 (5H, m), 4.72 (1H, s), 3.61 (3H, s), 3.40 (3H, s), 2.81 (2H, complex m), 2.52 (2H, m); ^{13}C nmr δ: 206.9, 173.0, 135.8, 128.7 (2C), 128.6, 126.9 (2C), 88.9, 57.3, 51.7, 32.3, 27.4; ms: 236 (0.6, M^+), 205 (1), 204 (2), 131 (14), 121 (100), 115 (15), 105 (16), 91 (18), 77 (41), 55 (12). Exact Mass calcd. for $C_{13}H_{16}O_4$: 236.1048; found: 236.1057.

Phthalocyanine-modified silica gels and their application in the purification of unsymmetrical phthalocyanines

CLIFFORD C. LEZNOFF,[1] COLIN R. MCARTHUR, AND YONGNIAN QIN
Department of Chemistry, York University, North York (Toronto), ON M3J 1P3, Canada

Received February 8, 1993

CLIFFORD C. LEZNOFF, COLIN R. MCARTHUR, and YONGNIAN QIN. Can. J. Chem. **71**, 1319 (1993).

Five species of phthalocyanine-modified silica gels were prepared. The loadings of phthalocyanine on these silica gels were determined by acidic hydrolysis. The concept of using the aggregation phenomenon to advantage to aid chromatographic separation of unsymmetrical phthalocyanines was investigated by employing these modified silica gels as chromatographic media to purify unsymmetrical phthalocyanines. Four groups of phthalocyanine mixtures were prepared by mixed condensation. One of the desired unsymmetrical phthalocyanines was successfully purified by conventional column chromatography while others were separated by the new method described herein.

CLIFFORD C. LEZNOFF, COLIN R. MCARTHUR et YONGNIAN QIN. Can. J. Chem. **71**, 1319 (1993).

On a préparé cinq espèces de gels de silice modifiés par des phtalocyanines. On a déterminé la quantité de phtalocyanine présente sur ces gels de silice en faisant appel à une hydrolyse acide. On a étudié le concept de l'utilisation du phénomène d'agrégation pour faciliter la séparation chromatographique de phtalocyanines non symétriques en utilisant ces gels de silice modifiés comme milieux chromatographiques pour la purification de phtalocyanines non symétriques. On a préparé quatre groupes de mélanges de phtalocyanines par condensations mixtes. On a réussi à purifier une des phtalocyanines non symétriques désirées par chromatographie conventionnelle sur colonne alors que les autres ont été séparées par la méthode décrite ici.

[Traduit par la rédaction]

Unsymmetrical phthalocyanines present challenges in the development of new methods of synthesis and separation. The potential use of phthalocyanines for photodynamic therapy (PDT) of cancer has sparked considerable interest in the photobiology of these compounds (1–9). To find a suitable phthalocyanine as photosensitizer, it is necessary to tune the position of its absorption band. Such fine tuning can be achieved by the stepwise introduction of peripheral substituent groups or by the stepwise adjustment of the size of the π-conjugated macrocyclic systems (10–13). Thus, unsymmetrical phthalocyanines are important goals in synthesis. Although symmetrical tetra- and octasubstituted phthalocyanines are well known, the synthesis of simple mono- and disubstituted and other unsymmetrical phthalocyanines remains a difficult problem (10–21). For instance, all tetrasubstituted phthalocyanines so far synthesized contain one substituent in each of the benzene rings, and no phthalocyanines such as 1,2,3,4- or 1,2,3,8-tetrasubstituted phthalocyanines have been reported.

Successful methods for the synthesis of unsymmetrical phthalocyanines can be divided into three groups according to strategy: (1) the polymer support route (14, 16, 19, 20); (2) the homogeneous mixed condensation route (12–14, 21); and (3) the subphthalocyanine route (11). There are difficulties with all three routes for large-scale preparation of unsymmetrical alkoxy-substituted phthalocyanines.

Route 1 is not suitable for large-scale preparation of unsymmetrical phthalocyanines. Route 3 is not suitable for the preparation of alkoxy-substituted phthalocyanines, as this method uses BBr_3, an ether-cleaving reagent. Route 2, the ordinary method of forming unsymmetrical phthalocyanines by mixed condensation of different phthalonitriles, most often gives statistical mixtures of phthalocyanines, which are very difficult to separate by common chromatographic methods. Although purifications of desired unsymmetrical phthalocyanines from mixed condensations by common chromatographic methods have been reported, success has been achieved only with those phthalocyanines having greatly differing polarities and after numerous repetitions of chromatographic separations. There appear to be two reasons for such difficulties. First, a number of very similar phthalocyanine species exist in the mixture. With site-isomers considered, a mixture from a mixed condensation conceivably can contain more than 20 species of similar phthalocyanines! Second, strong aggregation (22–24) exists among the different phthalocyanine species. Generally speaking, one of the basic premises and presumptions of chromatography is that each gradient to be separated should behave independently without interfering with another. The premise is not valid if aggregation occurs. Thus, a well-defined band on column chromatography or a single spot on thin-layer chromatography (TLC) is by itself insufficient evidence of purity and should be accompanied by mass spectral and other spectroscopic data (15).

In this investigation, the homogeneous mixed condensation route was used, together with work aimed at developing a more powerful method of separation. For the latter, we envisioned and investigated a new strategy which *takes advantage of the aggregation* that would be expected to occur between immobilized phthalocyanines and those in the synthetic mixture.

Five species of phthalocyanine-modified silica gels (Pc-Si-Gels) were prepared. These Pc-Si-Gels can be divided into three groups. In the first group, flash grade silica gel (**1**), preactivated with concentrated hydrochloric acid (25), reacted with thionyl chloride to give chlorinated silica gel (**2**). A reaction between **2** and 2,9,16,23-tetrakis(2-hydroxymethyl-2-methylbutoxy)phthalocyanine (**3**) (14) gave a modified silica gel (**4**), which contained phthalocyanine entities bonded to silica through Si—O—C linkages (Scheme 1). It should be noted that the phthalocyanine entities could be bonded to silica through more than one Si—O—C linkage (26), so its structure shown in Scheme 1 represents a simplified model.

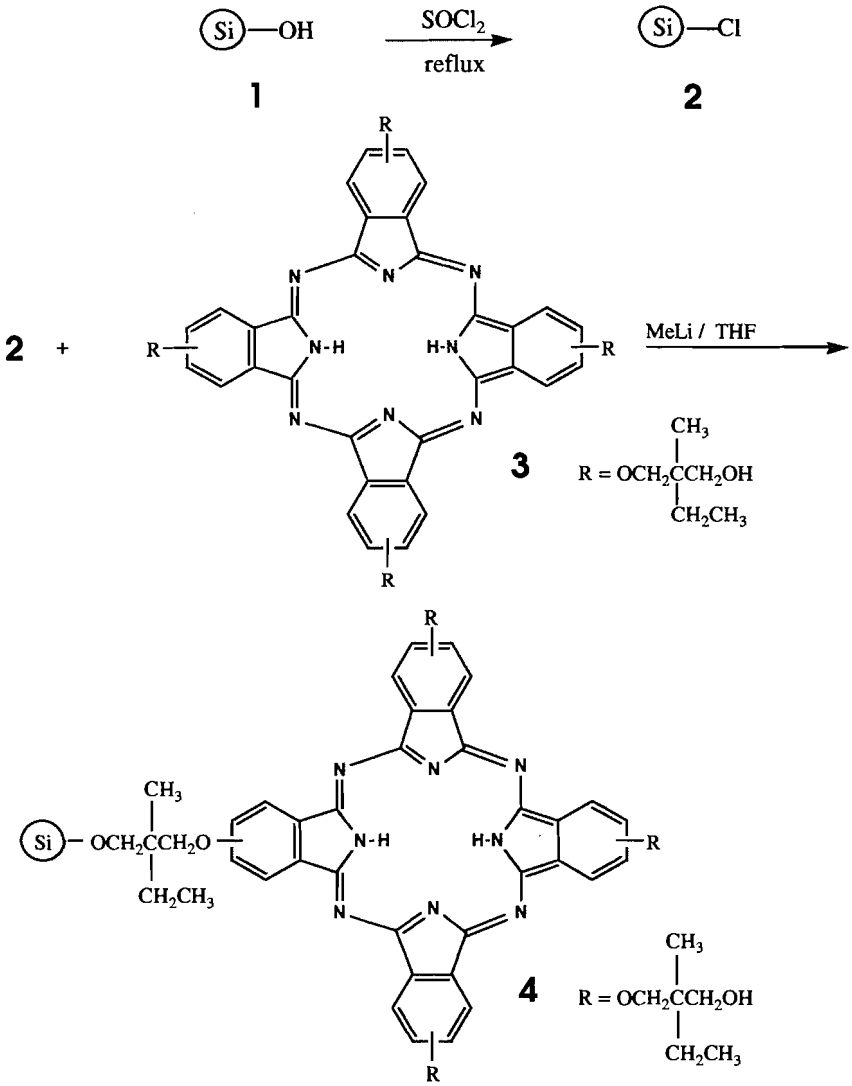

SCHEME 1

In the second group of Pc-Si-Gels, the metal atoms of metallophthalocyanines are bonded with the oxygen atoms of silica gels (Scheme 2). Thus, reactions of 2,9,16,23-tetra-*tert*-butylphthalocyanine (**5**) (27), 2,9,16,23-tetraneopentoxyphthalocyanine (**6**) (28), or unsubstituted phthalocyanine (**7**) with trimethyl aluminum and **1** gave 2,9,16,23-tetra-*tert*-butylphthalocyaninato aluminum(III) silica (**8**), 2,9,16,23-tetraneopentoxyphthalocyaninato aluminum(III) silica (**9**), or phthalocyaninato aluminum(III) silica (**10**), respectively.

In the third group, the metal atom of the phthalocyanine is bonded to the nitrogen atom of an aminopropyl derivative of silica (29) (Scheme 3). During the process of preparation, **1** reacted with (3-aminopropyl)trimethoxysilane (**11**) to give 3-aminopropylsilyl silica (**12**), which then reacted with methylaluminum(III) phthalocyanine (**13**) and gave phthalocyaninato aluminum(III) aminopropylsilyl silica (**14**).

To determine the loadings of immobilized Pc in the Pc-Si-Gels, three accurately weighed samples of each of the Pc-Si-Gels were hydrolysed with hydrochloric acid. Comparison of the UV spectra of the filtrates with reference solutions, also under acidic conditions, gave the values of the loadings, which are summarized in Table 1. In all examples the silica gels recovered from acidic hydrolyses were colourless and indeed hydrolyses were continued until the silica gels were colourless. Three species of the Pc-Si-Gels, namely **4**, **9**, and **14**, were chosen to pack columns. One of the Pc-Si-Gels, **4**, was abandoned as it was found to be unstable in the alcoholic solvent (2-methoxyethanol:toluene = 4:6) used in the column-cleaning process. Among the Pc-Si-Gels **8–10**, compound **8** was formed in lower yield while **10** was abandoned in favour of **14**, a chain-extended analog of **10**, and hence **8** and **10** were not examined further.

Four homogeneous mixed condensations were used to prepare mixtures of unsymmetrical phthalocyanines. The mixed condensation of 2,3-dihydro-1,3-diimino-1*H*-benz[*f*]isoindole (**15**) with 5-neopentoxy-1,3-diiminoisoindoline (**16**) or 5-*tert*-butyl-1,3-diiminoisoindoline (**17**) gave mixtures containing 2,9,16-trineopentoxy-31*H*,33*H*-tribenzo[*b*,*g*,*l*]-naptho[2,3-*q*]porphyrazine (**18**) or 2,9,16-tri-*tert*-butyl-31*H*,33*H*-tribenzo[*b*,*g*,*l*]naphtho[2,3-*q*]porphyrazine (**19**) (Scheme 4). The mixed condensation of **16** and **17** gave a mixture containing 2-*tert*-butyl-9,16,23-trineopentoxyphthalocyanine (**20**) (Scheme 5). The mixed condensation of 4,5-di-(1-octyn-1-yl)phthalonitrile (**21**)[2] and 4-methoxy-

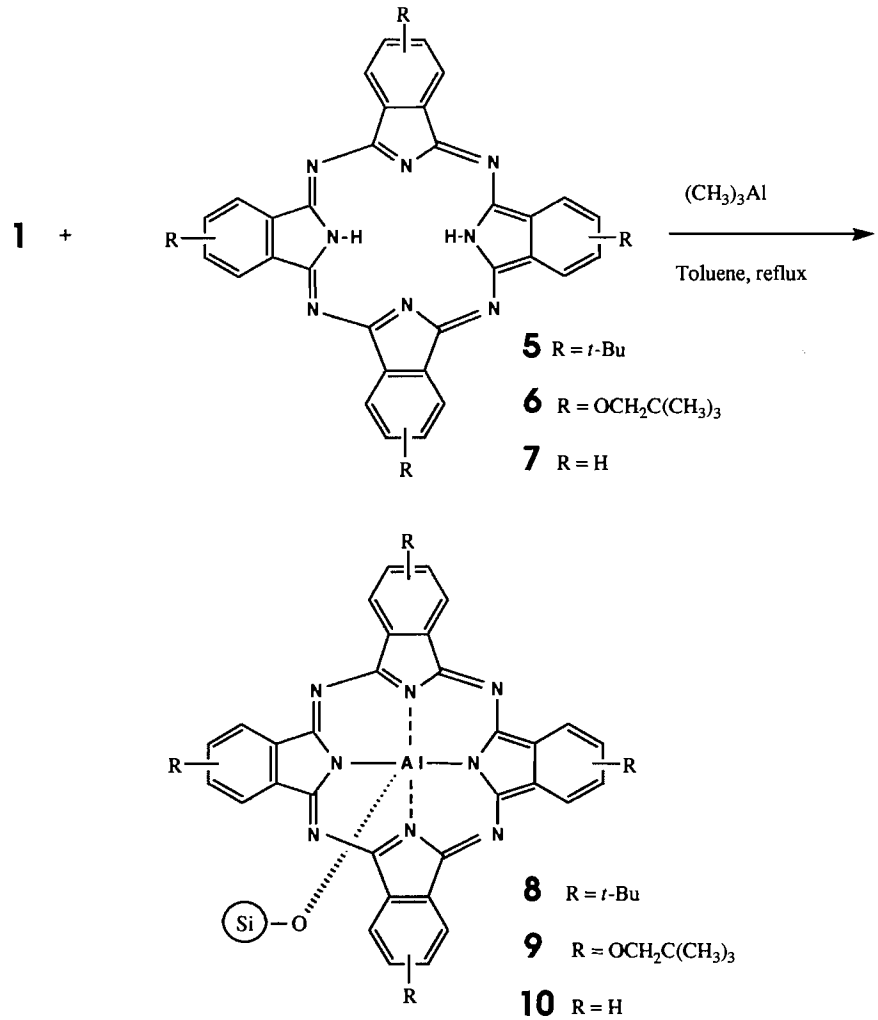

SCHEME 2

methyloxyphthalonitrile (**22**) (30) with DBU and zinc acetate gave a mixture containing 2,3-di-(1-octyn-1-yl)-9,16,26-tri-(methoxymethyloxy)phthalocyanine zinc(II) (**23**) (Scheme 6).

Among those desired phthalocyanines, **23** was successfully purified by ordinary column chromatography with the help of reverse phase HPLC as a monitor. The other three species, **18**, **19**, and **20**, could not be completely purified by ordinary column chromatography, but were successfully purified by Pc-Si-Gel column chromatography with the help of reverse phase HPLC or UV as a monitor.

The mass spectra and other data showed that complete separations were achieved. For instance, the mass spectrum of **18** showed that none of the phthalocyanines (porphyrazines) containing di-, tri-, or tetrabenzo groups or tetraneopentoxyphthalocyanines contaminated the desired unsymmetrical phthalocyanine. As a comparison, the same crude products were subjected to ordinary flash chromatography for as many as four repetitive columns. Even so, the mass spectra of the purest fractions showed that substantial contamination by undesired phthalocyanines still occurred (e.g., *m/z* 858, tetraneopentoxyphthalocyanine; 786, dibenzodineopentoxyphthalocyanine (dibenzodinaphthoporphyrazines)).

It should be noted that each of the unsymmetrical phthalocyanines (**18**–**20**, **23**) are likely a mixture of several closely related site-isomers. So far, we have not seen any successful example of the separation of such phthalocyanine isomers by chromatographic methods. This method does not readily separate similar isomers such as 2,9,16,23-, 2,10,16,24-, 2,9,17,24-, and 2,9,16,24-tetraneopentoxyphthalocyanine (**6**) and this mixture has normally been represented as the 2,9,16,23 isomer.

The experiments showed that the Pc-Si-Gels have some enhanced ability relative to standard silica gel for the purification of phthalocyanines. The separation ability of Pc-Si-Gels may depend on a number of complicated factors: amongst others, the nature of the phthalocyanines to be separated, the solvent system employed, and the chemical nature and physical condition of the phthalocyanines bonded to the polymer. Further studies of this new strategy are required before a general statement in this regard can be made. As well, additional work will be aimed at further enhancement of the capabilities of Pc-Si-Gels in practical applications.

Experimental

High-purity argon was used to maintain inert atmosphere conditions. Infrared (IR) spectra were recorded on a Pye Unicam SP-3200 infrared spectrophotometer using KBr discs for solids or

TABLE 1. Some properties of Pc-Si-Gels

Pc-Si-Gels	Pc loading (mg/g) (mmol/g)	Yield[a] (%)	Colour
4	18.7 (0.020)	66.5	Dark green
8	14.4 (0.019)	47.0	Dark blue
9	28.7 (0.033)	~100	Dark green
10	22.3 (0.044)	55.6	Dark blue
14	29.9 (0.056)	~100	Dark blue-grey

[a]Usually, the functional groups on silica gel are used as the limiting reagents, but in these cases, since the functional groups on silica gel were in excess, the yields were calculated using the phthalocyanines as the limiting reagents.

as neat films between NaCl discs for liquids. Nuclear magnetic resonance (NMR) spectra for carbons and protons were recorded on a Bruker AM300 NMR spectrometer using tetramethylsilane as the internal standard. The positions of the signals are reported in δ units. The splittings of the signals are described as singlets (s), doublets (d), triplets (t), quartets (q), or multiplets (m). The ^1H NMR spectra of 10^{-4} M solutions of the phthalocyanines were obtained by averaging 500–3000 scans over the absorption range. The ^{13}C NMR spectra of 5×10^{-4} M solutions of the phthalocyanines were obtained by averaging 7000–15 000 scans. The ultraviolet–visible spectra (UV–VIS) were recorded on a Hewlett Packard HP8451A diode array spectrophotometer. Mass spectra (MS) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the El mode for relatively small molecules (generally less than 800 amu). The Fast Atom Bombardment mode (FAB) spectra were obtained with a Kratos Profile or Kratos MS-50 analyzer mass spectrometer equipped with a FAB ion source of standard Kratos design and Ion Tech atom gun for relatively large molecules (generally greater than 800 amu).

Melting points (mp) were determined using a Kofler hot stage

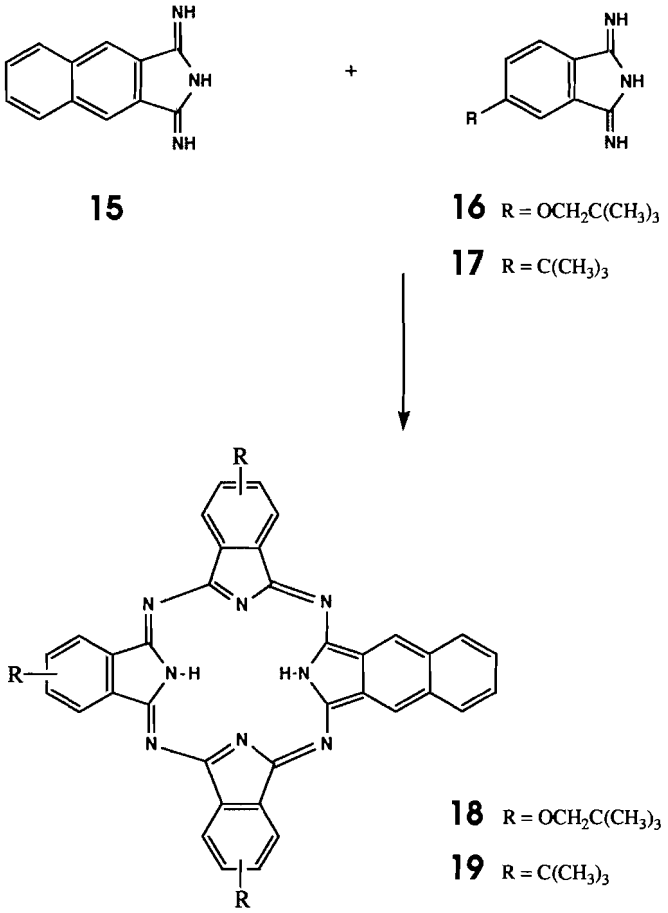
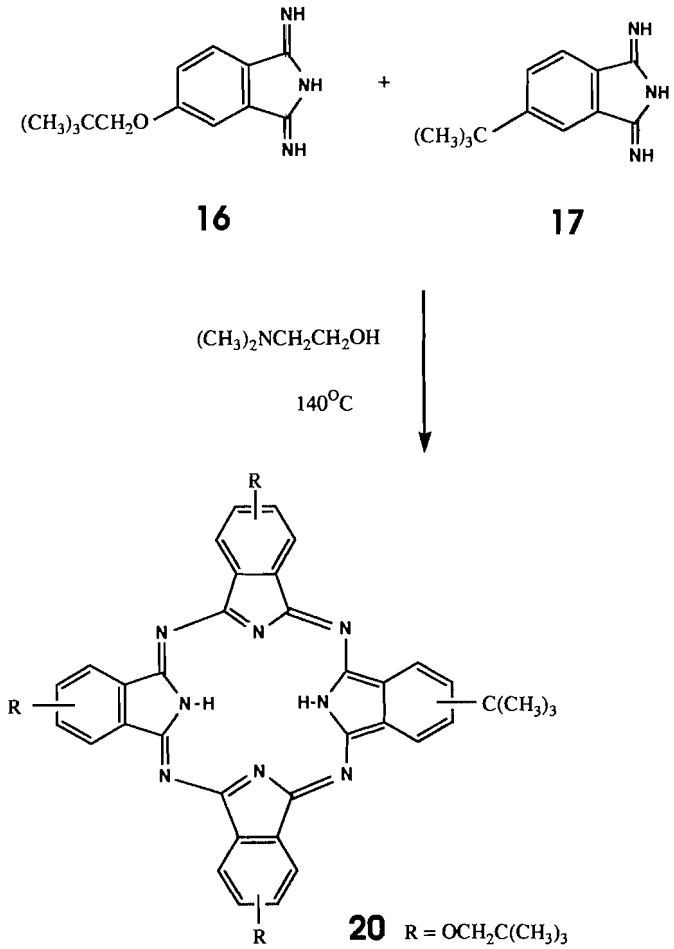


SCHEME 4



SCHEME 5

melting point apparatus and are uncorrected. Thin-layer chromatography (TLC) was performed using Kodak 13181 silica gel TLC sheets unless otherwise stated. Flash chromatography was performed using silica gel of particle size 20–45 μm (purchased from Terochem Laboratories Ltd., equivalent to Merck 9385). Neutral alumina column chromatography was performed using Brockmann I standard grade (150 mesh, 155 m^2/g). Reaction mixtures were stirred with a magnetic stirrer, except those that required sonication. Ultrasound treatment was carried out using a Branson 1200 sonicator. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ont. All diiminoisoindolines were used directly without purification, after evaporation of the solvent in condensation experiments. All yields were not optimized by detailed investigation of the effects of temperature, reaction time, and other conditions.

Activated flash silica gel (1)

Flash grade silica gel (20–45 μm, purchased from Terochem Laboratories Ltd.) was heated under reflux with concentrated hydrochloric acid for 4 h. The ratio of concentrated hydrochloric acid to **1** was 4–5 mL/g. After cooling to room temperature, **1** was filtered, washed with distilled water until the filtrate was neutral, preliminarily dried in an oven, and thoroughly dried under vacuum (140°C, 0.05 Torr (1 Torr = 133.3 Pa), 3 h).

Chlorinated silica gel (2)

Freshly distilled thionyl chloride (30 mL) was injected into a round-bottom flask that contained 5.7 g of **1** under argon. After heating under reflux with stirring for 24 h, the mixture was filtered under argon in a Schlenk tube. After washing with dry dichloromethane (20 mL, three times) by injection, the chlorinated silica gel was obtained as a white powder.

To determine the chlorine loading, three accurately weighed samples of **2** (about 50 mg each) were taken out and immediately treated with 10 mL of distilled water with stirring. After 10 min, the suspensions were titrated with a 0.1 M aqueous solution of potassium hydroxide and compared with a blank assay. The chlorine loadings were determined to be ~1.0 ± 0.1 mmol per gram of silica gel. Different batches of silica gel yielded chlorine loadings of 0.8–1.8 mmol/g.

2,9,16,23-Tetrakis(2-hydroxymethyl-2-methylbutoxy)phthalocyanine (3) modified silica gel (4)

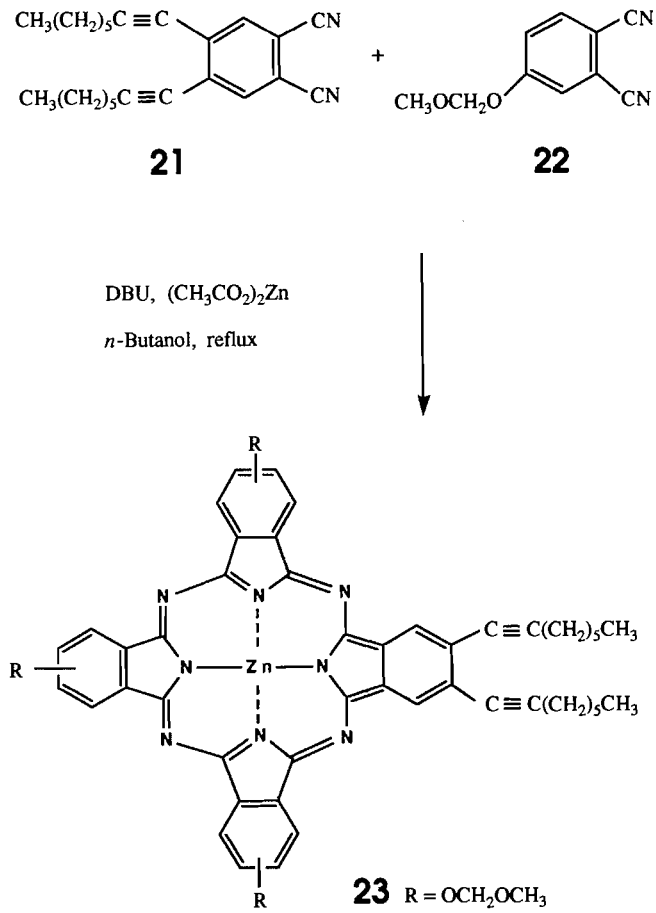
A solution of **3** (162 mg, 0.17 mmol) (14) in 30 mL of dry tetrahydrofuran (THF) and 0.5 mL of 1.4 M methyllithium solution in toluene was injected into a round-bottom flask that contained 5.7 g of **2**. The mixture was stirred at room temperature for 24 h. After filtering and washing with dry toluene and dry THF (three times each), a dark green powder of Pc-Si-Gel **4** was obtained.

To determine the loading of phthalocyanine on silica gel, three accurately weighed samples of **4** (about 50 mg each) were hydrolysed in 10 mL of hydrochloric acid solution (HCl:THF:H_2O = 1:8:1) by heating under reflux for 1 h, and then were filtered. Comparison of the UV–VIS spectra of the filtrate with a solution of **3** as a reference showed that the loading of phthalocyanine on **4** was 18.7 mg per gram of silica gel (0.020 mmol/g). The yield was 66% with **3** as the limiting reactant.

2,9,16,23-Tetra-tert-butylphthalocyaninatoaluminum(III) silica (8)

Trimethylaluminum (8.5 mL of 2 M solution in toluene) was injected into a round-bottom flask that contained 8.5 g of **1** and 30 mL of dry toluene under argon. The suspension was stirred at room temperature overnight, then filtered and washed once with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.



SCHEME 6

dry toluene. A solution of 2,9,16,23-tetra-*tert*-butylphthalocyanine (**5**) (27) (260 mg, 0.35 mmol) in 40 mL of dry toluene was then injected. The reaction was monitored by removal of an aliquot and examination by UV–VIS spectroscopy to ensure that all of **8** was consumed. The suspension was stirred under reflux for 48 h, at which time the reaction was complete, and then was filtered. The dark blue powder was first washed with dry toluene until the solvent was almost colourless, then washed with dry THF three times, with dry dichloromethane three times, and dried in the air.

Three accurately weighed samples (about 50 mg each) were hydrolysed by heating under reflux for 2 h with 10 mL of hydrochloric acid solution (HCl:THF:H_2O = 1:8:1). After filtration, the comparison of the UV–VIS spectrum of the filtrate with that of a similar acidic reference solution of the starting material **5** showed that the loading of **5** on **8** was 14.4 mg per gram of silica gel (0.019 mmol/g). The yield was 47% with **5** as the limiting reactant.

2,9,16,23-Tetraneopentoxyphthalocyaninatoaluminum(III) silica (9)

Trimethylaluminum (6.0 mL of 2 M solution in toluene) was injected under argon into a round-bottom flask that contained 6.0 g of **1** and 25 mL of dry toluene. The suspension was stirred at room temperature overnight, then filtered and washed once with dry toluene. A solution of 2,9,16,23-tetraneopentoxyphthalocyanine (**6**) (28) (168 mg, 0.20 mmol) in 30 mL of dry toluene was then injected. The suspension was stirred under reflux for 48 h until the reaction was complete (as monitored for **8** above) and then was filtered. The filtrate was almost colourless. The dark green powder was then washed with dry toluene three times, with dry THF three times, with dry dichloromethane three times, and dried in the air. Three accurately weighed samples (about 50 mg each) were taken and hydrolysed by heating under reflux for 2 h with 10 mL of hydrochloric acid solution (HCl:THF:H_2O = 1:8:1). After filtration, comparison of the UV–VIS spectrum of the filtrate with that of a reference solution of the starting material **6** showed that the loading of **6** on **9** was 28.7 mg per gram of silica gel (0.033 mmol/g). The yield was 100% with **6** as the limiting reactant.

Phthalocyaninatoaluminum(III) silica (10)

Unsubstituted phthalocyanine **7** (1.28 g, 2 mmol) was mixed with 50 mL of a 1.9 M solution of trimethylaluminum in toluene under argon. This mixture was treated with ultrasound for 24 h to improve solubility and then filtered through a Schlenk tube into a flask containing 24 g of **1**. After heating under reflux for 48 h under argon, the mixture was filtered in the Schlenk tube and washed with dry toluene and dry dioxane. The dark blue modified silica gel was then treated with dry dioxane, which allowed the unbound unsubstituted phthalocyanine to be removed by floatation. After the floatation procedure was repeated a few times, no visible unbound phthalocyanine remained and the Pc-Si-Gel **10** was obtained as a dark blue powder.

To determine the loading of **7** on **10**, three accurately weighed samples of **10** (about 50 mg each) were taken and hydrolysed by heating for 2 h under reflux with 10 mL of hydrochloric acid solution (HCl:THF:H_2O = 1:8:1). After filtration, comparison of the UV–VIS spectrum of the filtrate with that of an acidic reference sample, which was prepared by hydrolysis of **13** and diluted to a suitable concentration for the UV–VIS spectrum, showed that the loading of **7** on **10** was 22.3 mg per gram of silica gel (0.044 mmol/g). The yield was 55.6%, with **7** as the limiting reactant.

3-Aminopropylsilyl silica (12)

Activated dry silica gel (**1**, 55 g) was mixed with 30 mL (160 mmol) of (3-aminopropyl)trimethoxysilane (**11**) and 250 mL of dry toluene. The suspension was stirred under reflux overnight, and then filtered. The solids were washed with dry toluene and anhydrous ether to give **12**.

To determine the amino group loading, three accurately weighed samples (about 50 mg each) were treated with 5 mL of 0.05 M aqueous solution of sulphuric acid for 10 min, then filtered and titrated with a 0.1 M aqueous solution of potassium hydroxide. Comparison with a blank assay showed that the amino loading on **12** was 0.8–1.3 mmol per gram of silica gel.

Phthalocyaninato methylaluminum(III) (13)

A mixture of 1.6 g (3.1 mmol) of metal-free unsubstituted phthalocyanine **7**, 10 mL of a 1.9 M solution of trimethylaluminum (19 mmol) in toluene, and 100 mL of dry toluene was treated with ultrasound for 24 h to give a solution of phthalocyaninato methylaluminum(III) **13**. Without purification and characterization, **13** was used to prepare **14** immediately.

Phthalocyaninatoaluminum(III) aminopropylsilyl silica (14)

The newly prepared **12** (55 g) and 100 mL of dry toluene were poured with vigorous stirring into a round-bottom flask containing 110 mL of a hot solution of **13** under argon. After heating under reflux for 1 h, at which time reaction was complete (as monitored for **8** above), the suspension was filtered to give a dark blue-grey powder and an almost colourless filtrate. The powder was then washed with dry toluene three times, followed by dry dioxane three times, to give **14**.

To determine the phthalocyanine loading on **14**, three accurately weighed samples of **14** (about 50 mg each) were taken and hydrolysed by heating for 1 h under reflux with 10 mL of hydrochloric acid solution (HCl:THF:H_2O = 1:8:1). After filtration, comparison of the UV–VIS spectrum of the filtrate with that of an acidic reference sample, prepared by hydrolysis of **13** and diluted to a suitable concentration for the UV–VIS spectrum, showed that the loading of **7** was 29.0 mg per gram of **14** (0.056 mmol/g). The yield was ~100% with **7** as the limiting reactant.

*2,9,16-Trineopentoxy-31*H,*33*H-*tribenzo*[b,g,l]*naphtho-[2,3,*-q]*porphyrazine (18)*

A solution of **15** derived from 178 mg (1 mmol) of 2,3-dicyanonaphthalene (**12**) (Tokyo Kasei) and **16** derived from 642 mg (3 mmol) of 4-neopentoxyphthalonitrile (**15**) (28) in 4 mL of 2-*N*,*N*-dimethylaminoethanol was heated under reflux for 48 h. The dark green mixture was then poured into 100 mL of water, and the precipitate was filtered and washed with methanol a few times until the filtrate was colourless. After flash chromatography with toluene as solvent, 356 mg of a phthalocyanine mixture was obtained in about 43.5% yield. The phthalocyanine mixture was then subjected to common flash silica gel chromatography using carbon tetrachloride/toluene (30/0–70/100) as the eluting solvent, while monitoring with UV–VIS spectroscopy, to afford crude **18**. Further purification was effected by column chromatography with **14** or **9** as the static phase. After evaporation of the solvent and precipitation from methanol, the desired 2,9,16-trineopentoxy-31*H*,33*H*-tribenzo[*b*,*g*,*l*]naphtho[2,3-*q*]porphyrazine (**18**, 104.5 mg) was obtained, in 12.7% yield, as a purple solid; IR (KBr, cm^{-1}): 3300 (w, NH), 1620 (vs, C=C), 1240 (s, COC), 1100 (s, COC), 1020 (vs, NH), 750 (s, CH_{arom}); UV–VIS (1,2-dichlorobenzene, nm) (log ϵ): 734 (5.00), 690 (4.94), 670 (4.70), 622 (4.22), 400 (4.49), 344 (4.72), 300 (4.51); ^{1}H NMR ($CDCl_3$) δ: 7.0–9.1 (vbr, aromatic), 4.0–4.2 (m, -O*CH*$_2$C-, 6H), 1.1–1.6 (m, -*CH*$_3$, 27H), −3.6 (br N-*H*); ^{13}C NMR (toluene-d_8) δ: 116–162 (C_{arom}), 78 (*C*H$_2$-O), 27.2(*C*-CH$_3$), 19.7–21.2 (C-*C*H$_3$); MS (FAB) *m/z*: 823 (M^+ + 1 100%), 752 (19%), 681 (9%). Anal. calcd. for $C_{51}H_{50}N_8O_3$: C 74.42, H 6.12, N 13.61; found: C 73.84, H 6.32, N 13.26.

The mass spectrum of **18** showed no contamination by undesired phthalocyanines. As a comparison, the same crude product was subjected four times to ordinary flash silica gel chromatography. The mass spectrum of its purest components indicated that it still contained some 2,9,16,23-tetraneopentoxyphthalocyanine.

*2,9,16-Tri-*tert*-butyl-31*H,*33*H-*tribenzo*[b,g,l]*naphtho-[2,3-*q]*porphyazine (19)*

A solution of **15** derived from 178 mg (1 mmol) of 2,3-dicyanonaphthalene (Tokyo Kasei) and **17** derived from 552 mg (3 mmol) of 4-*tert*-butylphthalonitrile (27) (Toyko Kasei) in 4 mL of 2-*N*,*N*-dimethylaminoethanol was heated under reflux for 48 h. The dark blue mixture was then poured into 100 mL of water to form a precipitate. The precipitate was filtered and washed with methanol a few times until the filtrate was colourless. After column chromatography with ordinary flash silica gel as the static phase and toluene as the eluting solvent, 198 mg of a phthalocyanine mixture was obtained in about 27% yield. The phthalocyanine mixture was then separated again by flash silica gel chromatography to get the crude **19**. Further purification was effected by column chromatography with Pc-Si-Gel **14** or **9** as the static phase, with carbon tetrachloride/toluene (70/30–0/100) as the eluting solvent and using UV–VIS spectroscopy as a monitor. After evaporation of the solvent and precipitation from methanol, 52.8 mg of pure 2,9,16-tri-*tert*-butyl-31*H*,33*H*-tribenzo-[*b*,*g*,*l*]naphtho[2,3-*q*]porphyazine (**19**) was obtained, in 7.2% yield, as a purple solid, IR (KBr, cm^{-1}): 3300 (w, NH), 1620 (vs, C=C), 1010 (vs, NH), 750 (s, CH_{arom}); UV–VIS (1,2-dichlorobenzene, nm) (log ϵ): 730 (5.10), 686 (5.09), 666 (4.82), 618 (4.47), 346 (4.85), 302 (4.52); ^{1}H nmr (toluene-d_8) δ: 6.9–8.1, 8.6–9.5 (vbr, aromatic), 1.7–1.8 (m, -*CH*$_3$, 27 H), −2.3 (br N-*H*); ^{13}C nmr (toluene-d_8) δ: 122.5–152.8 (C_{arom}), 35.8–36.0 (*C*-CH$_3$), 32.1–32.3 (C-*C*H$_3$); MS *m/z*: 733 (M^+ +1, 100%), 718 (22%), 703 (9%), 676 (17%). Anal. calcd. for $C_{48}H_{44}N_8$: C 78.66, H 6.05, N 15.29; found: C 78.19, H 6.25, N 15.14.

The mass spectrum of **19** showed no contamination by undesired phthalocyanines. As a comparison, an attempt was made to purify the same crude **19** by a series of four ordinary flash chromatographic operations. The mass spectrum of its purest part showed that it still contained some 2,9,16,23-tetra-*tert*-butylphthalocyanine.

*2-*tert*-Butyl-9,16,23-trineopentoxyphthalocyanine (20)*

A solution of **16** derived from 107 mg (0.5 mmol) of 4-neopentoxyphthalonitrile (28) and **17** derived from 276 mg (1.5 mmol) of 4-*tert*-butylphthalonitrile (27) in 2 mL of 2-*N*,*N*-dimethylaminoethanol was heated under reflux for 48 h. The dark blue mixture was then poured into 50 mL of distilled water to form a precipitate. The precipitate was filtered and washed with methanol for a few times until the filtrate was colourless. After column chromatography with flash silica gel as the static phase and toluene as the eluting solvent, 115 mg of a phthalocyanine mixture was obtained, in about 28% yield, as a purple solid. The phthalocyanine mixture was then subjected to both ordinary flash chromatography and chromatography using Pc-Si-Gels **9** or **14** with carbon tetrachloride/toluene (70/30–0/100) as the eluting solvent. Reverse phase HPLC was used as the monitor to check the purity of the eluted fractions. After six repetitive chromatographic separations and precipitation from methanol, 10.5 mg of the desired 2-*tert*-butyl-9,16,23-trineopentoxyphthalocyanine (**20**) was obtained, in 2.5% yield, as a purple solid; IR (KBr, cm^{-1}): 3300 (w, NH), 1620 (vs, C=C), 1240 (s, COC), 1100 (s, COC), 1020 (vs, NH); 750 (s, CH_{arom}); UV–VIS (1,2-dichlorobenzene, nm) (log ϵ): 708 (5.20), 674 (5.11), 640 (4.66), 607 (4.47), 348 (4.85); ^{1}H nmr ($CDCl_3$) δ: 7.3–9.7 (vbr, aromatic), 4.1–4.6 (m, -O*CH*$_2$C-, 6H), 1.1–1.6 (m, -*CH*$_3$, 36H), −3.5 (br N-*H*); ^{13}C nmr (toluene-d_8) δ: 118–160 (C_{arom}), 78 (*C*H$_2$-O), 27.2 (*C*-CH$_3$), 19.7–21.2 (C-*C*H$_3$); MS (FAB) *m/z*: 829 (M^+ + 1, 100%), 759 (20%). Anal. calcd. for $C_{51}H_{56}N_6O_3$: C 73.89, H 6.81, N 13.52; found: C 73.98, H 6.84, N 13.12.

2,3-Di-(1-Octyn-1-yl)-9,16,23-trimethoxymethyloxyphthalocyaninato zinc(II) (23)

A mixture of **21** (425 mg, 1.24 mmol) (19), **22** (467 mg, 2.48 mmol) (19), DBU (2 mL), and 1-butanol (4 mL) was heated under reflux with stirring in an argon atmosphere. After 5–10 min, 184 mg (1.0 mmol) of dry zinc acetate was added. After heating for 4–5 h, the dark green-blue mixture was poured into 400 mL of water, and then extracted three times with toluene. The organic phase was washed with water until it was neutral, then dried with magnesium sulphate. After filtration and evaporation, the crude product underwent a preliminary silica flash column chromatography with toluene/ethyl acetate (50/50–0/100) as the eluting solvent. A mixture of phthalocyanines (320 mg) was obtained in about 40% yield, and reverse phase HPLC showed it contained about 40% of the desired phthalocyanine **23**. After three more separations by flash column chromatography with toluene/ethyl acetate (92/8–86/14) as the eluting solvent, 100 mg of the desired 2,3-dioctynyl-9,16,23-trimethoxymethyloxyphthalocyaninato zinc(II) (**23**) was obtained, as a purple solid, in 12.4% yield with **22** as the limiting reactant; IR (KBr, cm^{-1}): 1620 (vs, C=C), 1240 (s, COC), 1100 (s, COC), 750 (s, CH_{arom}); UV–VIS (1,2-dichlorobenzene, nm) (log ϵ): 698 (5.12), 682 (5.02), 624 (4.39), 357 (4.80); ^{1}H nmr (Benzene-d_6) δ: 6.94–8.81 (vbr, aromatic, 11H), 4.73–5.02 (m, -O-C*H*$_2$-O, 6H), 2.97–3.16 (m, C*H*$_3$-O, 9H), 2.57–2.70 (m, C≡C-C*H*$_2$-, 4H), 1.07–1.87 (m, -C-C*H*$_2$-C-, 16 H), 0.54–0.64 (tri, CH$_2$-C*H*$_3$, 6H); MS (FAB) *m/z*: 972 (M^+, 100%), 928 (85%), 888 (50%). Anal. calcd. for $C_{54}H_{52}N_8O_8Zn$: C 66.56, H 5.38, N 11.50, Zn 6.71; found: C 65.81, H 5.14, N 11.12, Zn 6.64.

The development of resistance to endocrine therapy as well as chemotherapy is presently a major problem in the treatment of breast cancer. To minimize this obstacle, new, more selective and potent, chemotherapeutic agents should be designed. One way to improve selectivity is to link a cytotoxic moiety to a molecule possessing an affinity to the estrogen receptor (ER). The latter would be used to direct the cytotoxic portion of the molecule towards the target cells. Our initial approach led us to the synthesis of new triphenylethylene–platinum(II) complexes **1***a–c*. The commercially available desoxyanisoin (**10**) was efficiently transformed in seven steps into the platinum(II) complexes **1***a–c* with an overall yield exceeding 30%. The biological activity of compounds **1***a–c* was evaluated in vitro on ER+ and ER− human breast tumor cell lines: MCF-7 and MDA-MD-231.

G. BÉRUBÉ, P. WHEELER, C.H.J. FORD, M. GALLANT et Z. TSALTAS. Can. J. Chem. **71**, 1327 (1993).

Le dévelopement de la résistance aux thérapies hormonales aussi bien qu'à la chimiothérapie est présentement un problème majeur dans le traitement du cancer du sein. De manière à minimiser cet obstacle, de nouveaux agents chemothérapeutiques plus selectifs et puissants devraient être conçus. Afin d'améliorer la sélectivité, il est possible de lier une portion cytotoxique à une molécule possédant une affinité pour le récepteur de l'estrogène (ER). Cette dernière serait utilisée pour diriger la portion cytotoxique de la molécule aux cellules cibles. Notre approche initiale nous a mené à la synthèse de complexes de triphényléthylène–platine(II) **1***a–c*. La désoxyanisoïne (**10**) commerciale fut transformée, en sept étapes, en complexes de platine(II) **1***a–c* avec un rendement global excédent 30%. L'activité biologique des composés **1***a–c* fut évaluée in vitro sur des cellules cancéreuses du sein : ER+ (MCF-7) et ER− (MDA-MD-231).

Introduction

Breast cancer is the most common form of cancer among women in North America. In 1993, it is estimated that more than 5000 women will die of this disease in Canada. Much progress has been accomplished for the treatment and the detection of this malady. Unfortunately, resistance to endocrine therapy as well as cytotoxic chemotherapy is still considered one of the major obstacles to successful treatment of breast cancer (1). Thus, many researchers are developing new drugs that are designed to overcome the problem of drug resistance. An attractive solution to this impediment is drug targeting. As we know, the aim of drug targeting is to deliver drugs only to those sites needing treatment; when this objective is met, not only the efficacy of the treatment will be improved, but toxic side effects will also be minimized (2). Therefore, we believe that new, more selective and potent, chemotherapeutic agents should be designed to rapidly eradicate the disease, preferably before any sign of resistance occurs.

The concept of linking an anti-cancer agent to a ligand with affinity for a tumor cell has some encouraging experimental precedent. As early as the 1960s, researchers investigated the possibility of linking nitrogen mustard groups to the steroidal skeleton in order to induce cytotoxic effects on hormone-dependent tumor cells (3). Since that time, several compounds (steroids and others) have been linked to various alkylating agents, including nitrogen mustards (4), nitrosoureas (5), and platinum complexes (6). However, in the early attempts, the cytotoxic moiety was often inappropriately linked to the estrogenic portion at the binding sites of the molecules, i.e., carbon 3 or 17 (steroid numbering, **3**, Scheme 1). This resulted in an inefficient interaction with the ER, and consequently a low biological activity. More recently, compounds **5** and **6**, synthesized in Germany (7, 8), showed very promising biological activities. The platinum complex **5** was found to be more potent than the parent drug cisplatin (**2**) and was selective on hormone-dependent breast cancer in vivo (in vitro, no selectivity was shown (7)). On the other hand, compound **6** showed selectivity on hormone-dependent breast cancer in both situations, i.e., in vitro and in vivo (8). In both cases, the exact mechanism(s) of action remains to be elucidated.

The new derivatives **1***a–c* were synthesized on the structural basis of the steroidal antiestrogens ICI 164 384 (**3**) and ICI 182 780 (**4**) recently described in the literature (9). Cytotoxic triphenylethylene with a long alkyl chain in the middle part of the molecule will, therefore, mimic the pure antiestrogens ICI 164 384 and ICI 182 780 bearing a 7-α side chain (see Scheme 1). This structural analogy should confer upon the new platinum(II) complexes both antiestrogenic and cytotoxic activity. We wish to report the details of our initial effort towards the synthesis of such derivatives (10) as well as their in vitro biological activity on MCF-7 (ER+) and MDA-MD-231 (ER−) human breast cancer cell lines.

Results and discussion

Synthesis of platinum(II) complexes

As shown in Scheme 3, three new (1,2-diaminoethane)

dichloroplatinum(II) complexes **1***a–c* were synthesized from commercially available desoxyanisoin (**10**). Initially the appropriate iodotetrahydropyranyl ethers were prepared. The choice of the length of the starting bromoalcohol **7** with 6, 8, and 10 carbon atoms is important since it has been observed that at least 6 carbon atoms are needed to give platinum derivatives such as compound **6** good estrogen receptor binding activity (11). The high affinity of compound **6** was possibly due to the interaction with an additional binding site removed from the receptor (11). As illustrated in Scheme 2, the alcohols **7***a–c* were protected as a tetrahydropyranyl ether (12) to give compounds **8***a–c*, which, upon treatment with sodium iodide in dry acetone, gave the iodotetrahydropyranyl ethers **9***a–c* (95% average yield for the two steps).

Alkylation of desoxyanisoin (**10**) with the iodotetrahydropyranyl ethers **9***a–c* was achieved using sodium hydride in tetrahydrofuran to give compounds **11***a–c* with an average yield of 65% (98% taking in consideration the alkyl iodide recovered, Scheme 3). Addition of an excess of *p*-methoxyphenylmagnesium bromide to ketones **11***a–c* and subsequent treatment of the crude tertiary alcohols with pyridinium-*p*-toluenesulfonate in ethanol at reflux afforded directly the triphenylethylene alcohols **12***a–c* with an average yield of 90% as the result of dehydration of the tertiary alcohol intermediates and simultaneous deprotection of the tetrahydropyranyl ethers (12). With the desired triphenylethylenes in hand the following sequence of reactions are simple functional group transformations. Initially, alcohols **12***a–c* were transformed to the bromides **13***a–c* (85% average yield) with carbon tetrabromide and triphenylphos-

Reagents: (a) NaH, I-$(CH_2)_n$-OTHP, THF, 25°C, 17 h, 65% (98%); (b) $MeOC_6H_4MgBr$, ether, 25°C, 17 h; (c) crude tertiary alochol, ethanol, PPTS, reflux, 5 h, 90% from **11**; (d) CBr_4, Ph_3P, ether, 25°C, 24 h, 85%; (e) $H_2NCH_2CH_2NH_2$, methanol, reflux, 24 h, 95% crude; (f) BBr_3, CH_2Cl_2, -60°C to 25°C (15 h) to reflux (2 h); (g) K_2PtCl_4, DMF: H_2O, 2 days, 60% from **14**

SCHEME 3

phine in dry ether (13). The amines **14***a–c* were obtained with an average yield of 95% by refluxing bromides **13***a–c* in the presence of an excess of ethylenediamine in dry methanol (11). Finally, demethylation with boron tribromide gave the intermediate tris-phenols **15***a–c*, which, upon treatment with potassium tetrachloroplatinate(II) in a mixture of dimethylformamide and water, led to the desired platinum(II) complexes **1***a–c* (60% average yield for the two steps (11, 14, 15)).

In vitro antitumor activity

Two human breast tumor cell lines were chosen, based on their estrogen receptor content, to evaluate the antitumor activity of our new platinum(II) complexes (16). The "cytotoxic antiestrogens" (**1***a* = Pt-6, **1***b* = Pt-8, **1***c* = Pt-10) were tested along with controls (vehicle, cisplatin = Cis-Pt, tamoxifen = TAM) on both ER+, i.e., MCF-7, and ER−, i.e., MDA-MD-231, human mammary carcinomas in order to assess the potential selective anti-neoplastic effect on hormone-dependent breast cancer. The antitumor activity was evaluated with a colorimetric assay that uses the ability of viable cells to reduce a soluble tetrazolium salt, 3(4,5-dimethylthiazol)-2,5-diphenyltetrazolium bromide (MTT), into an insoluble formazan precipitate (17). A recent report (18) indicates that the MTT assay can be used to replace the [^{3}H]-uridine assay for chemosensitivity screening. The colorimetric assay has the advantages of being safer, less costly, and simpler than the radiometric assay.

As shown by the MTT assays on human breast cancer cell lines, the new compounds demonstrated similar activity on either MCF-7 (ER+) or MDA-MD-231 (ER−) cells (see Table 1). Interestingly, the longer the side chain, the better the activity. This could be explained in the following fashion: a more lipophilic compound (Pt-10) could theoretically penetrate more easily the lipophilic cell membranes, therefore killing the cells more readily and (or), assuming an identical rate of infiltration in the cells, a compound with a longer chain could possibly alkylate DNA more efficiently due to fewer steric interactions between the triphenylethylene moiety and DNA. These interesting biological results also indicate that our new products are not selective to-

wards ER+ human breast cancer cells. It is important to indicate that the desired selectivity might be expressed more clearly (and possibly only) in vivo as was demonstrated previously for compound **5**. The fact that these compounds exhibit activity against both ER+ and ER− tumor cells may have advantages in that selective accumulation in the ER+ tumor could quench any ER− tumor cells that are known to spring up from the initial ER+ cells or destroy any ER− cells already present in the original, and predominantly ER+, tumor. This hypothesis will be further evaluated both in vitro and in vivo in the future.

Three new platinum(II) complexes have been synthesized and tested for biological activity. The synthesis of this type of compound is straightforward and efficient. The strategy described could be used to synthesize other types of DNA alkylating agents such as nitrogen mustards and nitrosoureas. Work is in progress in our laboratory to synthesize similar derivatives with improved biological activity.

Experimental

Synthesis of Pt(II) complexes

General procedures

Anhydrous reactions were performed under an inert atmosphere, the setup assembled and cooled under dry nitrogen. Unless otherwise noted, starting material, reactant, and solvents were obtained commercially and were used as such or purified and (or) dried by standard means (19). Organic solutions were dried over magnesium sulphate ($MgSO_4$), and evaporated on a rotatory evaporator and under reduced pressure. All reactions were monitored by thin-layer chromatography (TLC). The plates were visualized by UV fluorescence, or by staining with iodine or spraying with an aqueous solution of phosphomolybdic acid followed by heating the plate at ~135°C. Commercial TLC plates were Sigma T 6145 (polyester silica gel 60 Å (0.25 mm)). Preparative TLC was performed on 1 mm silica gel 60 Å, 20 × 20 plates (Whatman, 4861 840). Flash chromatography was performed according to the method of Still et al. (20) on Merck grade 60 silica gel, 230–400 mesh. All solvents used in chromatography had been distilled. Melting points (mp) were recorded on an Electrothermal 9100 apparatus and are uncorrected. The infrared spectra (IR) were taken on a Nicolet model 205 FT-IR spectrophotometer. Mass spectral assays (MS, *m/e*) were obtained using a VG Micromass 7070 HS instrument using an ionization energy of 70 eV. Elemental analyses were conducted by Microanalysis Laboratories Limited, Markham, Ontario. Nuclear magnetic resonance (NMR) spectra were obtained in $CDCl_3$ solution, unless otherwise noted, on a General Electric GE 300-NB (300 MHz) instrument: chemical shifts were measured relative to internal standards: tetramethylsilane (TMS, δ 0.0 ppm) for ^1H and $CDCl_3$ (δ 77.0 ppm) for ^{13}C NMR. Multiplicities are described by the following abbreviations: s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), dd (double doublet), tq (triple quartet), mm (multiple multiplets), and so on. The NMR assignments were assisted by ^{13}C–^1H correlation (HETCORR) 2-D spectra.

General procedure for conversion of bromoalcohols to iodotetrahydropyranyl ethers

*1-Tetrahydropyranyloxy-6-bromohexane (**8**a).* A solution of 6-bromo-1-hexanol **7***a* (5.0 g, 27.6 mmol), dihydropyran (2.58 g (2.8 mL), 30.6 mmol), and pyridinium *p*-toluenesulfonate (PPTS, 10 mg, 3.97×10^{-5} mol) in dichloromethane (CH_2Cl_2, 50 mL) was stirred for 5 h under nitrogen. Afterwards, sodium bicarbonate ($NaHCO_3$, 500 mg) and $MgSO_4$ (5.0 g) were added to the reaction mixture and stirred 15 min before being filtered on a short pad of Celite/silica gel (1 cm/4 cm) using CH_2Cl_2 as eluent. The filtrate was evaporated to a viscous oil **8***a* (7.16 g, 98%), which was used without further purification in the next step. IR (neat): 1170–1000 (C—O), cm^{-1}. ^1H NMR (δ ppm): 4.57 (1H, t apparent, J = 3.2 Hz, -OCHO-), 3.87, 3.74, 3.50, and 3.38 (4H, 4 × m, -CH_2OCHOCH_2-), 3.41 (2H, t, J = 6.7 Hz, -CH_2Br), 1.3–2.0 (14H, m, BrCH$_2$-(CH_2)$_4$-CH$_2$O-THP). MS (*m/e*): 265 (M^+ +1), 163 (M^+ −OTHP).

*1-Tetrahydropyranyloxy-6-iodohexane (**9**a).* To a solution of crude bromide **8***a* (7.16 g, 27 mmol) in dry acetone was added sodium iodide (6.07 g, 40.5 mmol). The reaction mixture was stirred at 25°C for 5 h. Then, most of the solvent was evaporated and the residue was transferred to an extraction flask with ether (100 mL) and water (100 mL). The organic phase was washed with water (6 × 50 mL), dried, filtered, and concentrated to a viscous liquid. The crude iodide **9***a* (8.26 g, 98%) was used as such at the alkylation step. IR (neat): 1170–1000 (C—O) cm^{-1}. ^1H NMR (δ ppm): 4.57 (1H, t apparent, J = 3.2 Hz, -OCHO-), 3.87, 3.74, 3.50, and 3.38 (4H, 4 × m, -CH_2OCHOCH_2-), 3.19 (2H, t, J = 7.0 Hz, -CH_2I), 1.3–2.0 (14H, m, ICH$_2$-(CH_2)$_4$-CH$_2$O-THP). MS (*m/e*): 311 (M^+ −H), 211 (M^+ −OTHP).

*1-Tetrahydropyranyloxy-8-bromooctane (**8**b):* 98% yield. IR (neat): 1170–1000 (C—O) cm^{-1}. ^1H NMR (δ ppm): 4.58 (1H, t apparent, J = 3.5 Hz, -OCHO-), 3.87, 3.73, 3.50, and 3.38 (4H, 4 × m, -CH_2OCHOCH_2-), 3.41 (2H, t, J = 6.8 Hz, -CH_2Br), 1.2–2.0 (18H, m, BrCH$_2$-(CH_2)$_6$-CH$_2$O-THP). MS (*m/e*): 293 (M^+ +1).

*1-Tetrahydropyranyloxy-8-iodooctane (**9**b):* 98% yield. IR (neat): 1170–1000 (C—O) cm^{-1}. ^1H NMR (δ ppm): 4.58 (1H, t apparent, J = 3.5 Hz,-OCHO-), 3.87, 3.73, 3.50, and 3.38 (4H, 4 × m, -CH_2OCHOCH_2-), 3.19 (2H, t, J = 7.0 Hz, -CH_2I), 1.2–2.0 (18H, m, ICH$_2$-(CH_2)$_6$-CH$_2$O-THP). MS (*m/e*): 339 (M^+ −H), 239 (M^+ −OTHP).

*1-Tetrahydropyranyloxy-10-bromodecane (**8**c):* 99% yield. IR (neat): 1170–1000 (C—O) cm^{-1}. ^1H NMR (δ ppm): 4.58 (1H, t apparent, J = 3.5 Hz, -OCHO-), 3.87, 3.73, 3.50, and 3.38 (4H, 4 × m, -CH_2OCHOCH_2-), 3.41 (2H, t, J = 6.8 Hz, -CH_2Br), 1.2–2.0 (22H, m, BrCH$_2$-(CH_2)$_8$-CH$_2$O-THP). MS (*m/e*): 321 (M^+ +1).

*1-Tetrahydropyranyloxy-10-iododecane (**9**c):* 98% yield. IR (neat): 1170–1000 (C—O) cm^{-1}. ^1H NMR (δ ppm): 4.58 (1H, t apparent, J = 3.5 Hz, -OCHO-), 3.87, 3.73, 3.50, and 3.38 (4H, 4 × m, -CH_2OCHOCH_2-), 3.19 (2H, t, J = 7.0 Hz, -CH_2I), 1.2–2.0 (22H, m, ICH$_2$-(CH_2)$_8$-CH$_2$O-THP). MS (*m/e*): 367 (M^+ −H).

General procedure for conversion of desoxyanisoin to triphenylethylene platinum(II) complexes

*A. Synthesis of 1,2-bis(4-methoxyphenyl)-X-tetrahydropyranyloxy-alkylones **11**a–c.* To a stirred suspension of sodium hydride (732 mg, 18.3 mmol, 60% dispersion in mineral oil) in dry tetrahydrofuran (THF, 150 mL) was added rapidly desoxyanisoin (**10**) (4.47 g, 17.4 mmol). The reaction mixture was heated (50°C) with a water bath for 1 h under a nitrogen atmosphere. After cooling, the iodotetrahydropyranyl ether (18.3 mmol) was added dropwise and the resulting mixture stirred overnight (17 h). Most of the solvent was then evaporated and the residue was diluted with ether (200 mL) and treated with water (50 mL). The ethereal phase was washed thoroughly with water (6 × 50 mL), dried, and evaporated to give an oil that was purified by flash chromatography (hexane:acetone, 85:15). A viscous oil was obtained. The aver-

age yield was 65% (98% taking into account the alkyl iodide recovered).

*1,2-Bis(4-methoxyphenyl)-8-tetrahydropyranyloxy-octanone (**11**a):* IR (neat): 1674 (C=O), 1599 (C=C), 1254 (C=O) cm^{-1}. ^1H NMR (δ ppm): 7.95, 6.84 and 7.21, 6.80 (8H, 2 × two d, J = 8.88 and 8.66 Hz, 2 × *para*-substituted anisyl group), 4.55 (1H, t, J = 3.45 Hz, -OCHO-), 4.44 (1H, t, J = 7.23 Hz, -CH-), 3.82 and 3.47 (2H, two m, -CH_2OTHP), 3.70 and 3.34 (2H, two m, -CHOCH_2-), 3.77 and 3.71 (6H, two s, 2 × -OCH_3), 2.20–1.10 (16H, br singlets, 8 × -CH_2-). ^{13}C NMR (δ ppm): 198.57, 162.97, 158.23, 132.03, 130.69(2), 129.69, 128.91(2), 113.98(2), 113.44(2), 98.62, 67.37, 62.13, 55.17, 54.93, 52.08, 33.83, 30.60, 29.50, 29.30, 27.47, 25.92, 25.32, 19.53. MS (*m/e*): 440 (M^+), 356 (M^+ −DHP).

*1,2-Bis(4-methoxyphenyl)-10-tetrahydropyranyloxy-decanone (**11**b):* IR (neat): 1674 (C=O), 1599 (C=C), 1255 (C—O) cm^{-1}. ^1H NMR (δ ppm): 7.95, 6.86 and 7.21, 6.81 (8H, 2 × two d, J = 8.87 and 8.62 Hz, 2 × *para*-substituted anisyl group), 4.56 (1H, t, J = 3.45 Hz, -OCHO-), 4.44 (1H, t, J = 7.23 Hz, -CH-), 3.82 and 3.47 (2H, two m, -CH_2OTHP), 3.70 and 3.35 (2H, two m, -CHOCH_2-), 3.81 and 3.74 (6H, two s, 2 × -OCH_3), 2.20–1.10 (20H, br singlets, 10 × -CH_2-). ^{13}C NMR (δ ppm): 198.77, 163.07, 158.32, 132.20, 130.82(2), 129.84, 129.03(2), 114.09(2), 113.55(2), 98.75, 67.58, 62.26, 55.32, 55.10, 52.24, 33.98, 30.72, 29.65, 29.53, 29.33(2), 27.64, 26.14, 25.44, 19.64. MS (*m/e*): no molecular ion, 384 (M^+ −DHP).

*1,2-Bis(4-methoxyphenyl)-12-tetrahydropyranyloxy-dodecanone (**11**c):* IR (neat): 1674 (C=O), 1599 (C=C), 1254 (C—O) cm^{-1}. ^1H NMR (δ ppm): 7.95, 6.87 and 7.21, 6.81 (8H, 2 × two d, J = 8.88 and 8.67 Hz, 2 × *para*-substituted anisyl group), 4.57 (1H, t, J = 3.45 Hz, -OCHO-), 4.40 (1H, t, J = 7.23 Hz, -CH-), 3.82 and 3.47 (2H, two m, -CH_2OTHP), 3.70 and 3.34 (2H, two m, -CHOCH_2-), 3.80 and 3.73 (6H, two s, 2 × -OCH_3), 2.20–1.10 (24H, br singlets, 12 × -CH_2-). ^{13}C NMR (δ ppm): 198.74, 163.04, 158.31, 132.18, 130.78(2), 129.82, 129.00(2), 114.05(2), 113.52(2), 98.73, 67.58, 62.24, 55.28, 55.04, 52.20, 33.97, 30.69, 29.65, 29.55, 29.44(2), 29.39(2), 27.61, 26.14, 25.42, 19.63. MS (*m/e*): no molecular ion, 412 (M^+ −DHP).

*B. Synthesis of X,Y,Y-tris(4-methoxyphenyl)-X-alken-1-ols **12**a–c.* A Grignard reagent was prepared from 460 mg (18.9 mmol) of magnesium and 2.98 g (2 mL, 15.9 mmol) of 4-bromoanisole in the presence of a crystal of iodine in 100 mL of dry ether. The Grignard reagent was usually ready after stirring at room temperature overnight (17 h), but sometimes required heating at reflux to initiate the reaction. A solution of ketone **11** (3.0 mmol) in dry ether was treated with the excess of Grignard reagent for 3 h under nitrogen at 25°C and was then hydrolysed with 50 mL of 10% aqueous ammonium chloride. The ethereal phase was washed with water (5 × 50 mL), dried, and evaporated to give the crude tertiary alcohol intermediate. The oily residue was dehydrated and deprotected in 100 mL of 95% ethanol in the presence of PPTS (100 mg, 0.34 mmol) at reflux for 2.5 h. After evaporation of the solvent, the residue was taken with ether and extracted with water (5 × 50 mL), dried, and evaporated to an oil. Flash chromatography (hexanes:acetone, 85:15) gave **12** in 90% average yield as a viscous oil.

*7,8,8-Tris(4-methoxyphenyl)-7-octen-1-ol (**12**a):* IR (neat): 3640–3150 (OH), 1605 (C=C), 1242 (C—O), cm^{-1}. ^1H NMR (δ ppm): 7.13, 6.85 and 7.01, 6.69 and 6.78, 6.54 (12H, 3 × two d, J = 8.70, 8.70, and 8.78 Hz, 3 × *para*-substituted anisyl group), 3.78, 3.71, and 3.64 (9H, 3 × s, 3 × -OCH_3), 3.51 (2H, t, J = 6.65 Hz, -CH_2OH), 2.40 (2H, m, -C=CCH_2-), 1.90 (1H, br s, -OH), 1.50–1.10 (8H, m, -CH_2-(CH_2)$_4$-CH_2-). ^{13}C NMR (δ ppm): 157.93, 157.48, 157.09, 139.06, 137.40, 136.34, 135.88, 134.88, 131.76(2), 130.46(4), 113.25(2), 113.11(2), 112.58(2), 62.61, 55.02, 54.88, 54.82, 35.69, 32.43, 29.35, 28.81, 25.25. MS (*m/e*): 446 (M^+), 359 (M^+ −$C_5H_{10}OH$).

*9,10,10-Tris(4-methoxyphenyl)-9-decen-1-ol (**12**b):* IR (neat): 3690–3150 (OH), 1605 (C=C), 1242 (C—O) cm^{-1}. ^1H NMR (δ ppm): 7.13, 6.87 and 7.02, 6.72 and 6.78, 6.55 (12H, 3 × two d, J = 8.70, 8.73, and 8.81 Hz, 3 × *para*-substituted anisyl group), 3.81, 3.75, and 3.68 (9H, 3 × s, 3 × -OCH_3), 3.59 (2H, t, J = 6.65 Hz, -CH_2OH), 2.40 (2H, m, -C=CCH_2-), 1.90 (1H, br s, -OH), 1.60–1.10 (12H, m, -CH_2-(CH_2)$_6$-CH_2-). ^{13}C NMR (δ ppm): 158.02, 157.55, 157.22, 139.29, 137.42, 136.50, 136.03, 135.04, 131.87(2), 130.56(4), 113.34(2), 113.19(2), 112.67(2), 62.99, 55.16, 54.99(2), 35.82, 32.71, 29.59(2), 29.19, 28.91, 25.62. MS (*m/e*): 474 (M^+), 359 (M^+ −$C_7H_{14}OH$).

*11,12,12-Tris(4-methoxyphenyl)-11-dodecen-1-ol (**12**c):* IR (neat): 3640–3150 (OH), 1605 (C=C), 1242 (C—O), cm^{-1}. ^1H NMR (δ ppm): 7.13, 6.87 and 7.02, 6.70 and 6.78, 6.55 (12H, 3 × two d, J = 8.70, 8.73, and 8.80 Hz, 3 × *para*-substituted anisyl group), 3.81, 3.74, and 3.67 (9H, 3 × s, 3 × -OCH_3), 3.62 (2H, t, J = 6.65 Hz, -CH_2OH), 2.40 (2H, m, -C=CCH_2-), 1.80 (1H, br s, -OH), 1.60–1.10 (16H, m, -CH_2-(CH_2)$_8$-CH_2-). ^{13}C NMR (δ ppm): 157.92, 157.47, 157.12, 139.29, 137.32, 136.46, 136.02, 135.02, 131.84(2), 130.54(4), 113.28(2), 113.14(2), 112.63(2), 62.92, 55.10, 54.98, 54.92, 35.80, 32.62, 29.62, 29.45, 29.32(2), 29.19, 28.90, 25.63. MS (*m/e*): 502 (M^+), 359 (M^+ −$C_9H_{18}OH$).

*C. Synthesis of 1-bromo-X,Y,Y-tris(4-methoxyphenyl)-X-alkenes **13**a–c.* A solution of alcohol **12** (5.83 mmol), carbon tetrabromide (7.73 g, 23.3 mmol), and triphenylphosphine (6.11 g, 23.3 mmol) in dry ether (250 mL) was stirred at room temperature (25°C) for 20 h under a nitrogen atmosphere. The triphenylphosphine oxide precipitate was filtered and the resulting solution was washed thoroughly with water (5 × 50 mL), dried, and evaporated to an oil. The crude material was purified by flash chromatography (hexanes:acetone, 95:5) to give the bromide **13** in 85% average yield as a viscous oil.

*1-Bromo-7,8,8-tris(4-methoxyphenyl)-7-octene (**13**a):* IR (neat): 1605 (C=C), 1242 (C—O), cm^{-1}. ^1H NMR (δ ppm): 7.13, 6.86 and 7.02, 6.69 and 6.78, 6.54 (12H, 3 × two d, J = 8.67, 8.69, and 8.74 Hz, 3 × *para*-substituted anisyl group), 3.79, 3.72, and 3.64 (9H, 3 × s, 3 × -OCH_3), 3.30 (2H, t, J = 6.84 Hz, -CH_2Br), 2.41 (2H, m, -C=CCH_2-), 1.73 (2H, p, J = 7.20 Hz, -CH_2CH_2Br), 1.26 (6H, m, -CH_2-(CH_2)$_3$-CH_2CH_2Br). ^{13}C NMR (δ ppm): 158.02, 157.55, 157.19, 138.91, 137.55, 136.31, 135.83, 134.80, 131.77(2), 130.46(4), 113.29(2), 113.17(2), 112.61(2), 55.06, 54.91, 54.84, 35.62, 33.87, 32.53, 28.66(2), 27.72. MS (*m/e*): 508 (M^+), 510 (M^+ +2), 359 (M^+ −C_5H_{10}Br).

*1-Bromo-9,10,10-tris(4-methoxyphenyl)-9-decene (**13**b):* IR (neat): 1605 (C=C), 1242 (C—O), cm^{-1}. ^1H NMR (δ ppm): 7.13, 6.87 and 7.02, 6.71 and 6.77, 6.55 (12H, 3 × two d, J = 8.73, 8.79, and 8.79 Hz, 3 × *para*-substituted anisyl group), 3.82, 3.76, and 3.69 (9H, 3 × s, 3 × -OCH_3), 3.37 (2H, t, J = 6.87 Hz, -CH_2Br), 2.42 (2H, m, -C=CCH_2-), 1.80 (2H, p, J = 7.35 Hz, -CH_2CH_2Br), 1.40–1.10 (10H, m, -CH_2-(CH_2)$_5$-CH_2CH_2Br). ^{13}C NMR (δ ppm): 158.05, 157.57, 157.21, 139.22, 137.46, 136.46, 136.01, 134.00, 131.87(2), 130.57(4), 113.33(2), 113.19(2), 112.67(2), 55.18, 55.04, 54.98, 35.80, 34.08, 32.74, 29.53, 29.02, 28.87, 28.56, 28.05. *E. Synthesis of 1-[(2-aminoethyl)amino]-X,Y,Y-tris(4-hydroxyphenyl)-X-alkenes **15**a–c.* A solution of trimethyl ether **14** (0.665 mmol) in dry CH_2Cl_2 (30 mL) was treated with a solution of boron tribromide (2.33 mL (1 M), 2.33 mmol) at −60°C, under a nitrogen atmosphere. After the addition, the reaction mixture was allowed to warm to room temperature (25°C) and was stirred for 17 h. The mixture was refluxed during 2 h. The reaction was cooled with an ice bath before adding 15 mL of methanol. The resulting solution was concentrated to 2–3 mL, treated with saturated $NaHCO_3$ solution (30 mL), and extracted with ethyl acetate (5 × 30 mL). The crude yields range from 50 to 85%. Compounds **15***a–c* were used without further purification in the next step.

*F. Synthesis of 1-[*cis*-[(2-aminoethyl)amino]dichloroplatinum-(II)]-X,Y,Y-tris(4-hydroxyphenyl)-X-alkenes **1**a–c.* A solution of potassium tetrachloroplatinate(II) (219 mg, 0.527 mmol) in 7.5 mL of a mixture of dimethylformamide (DMF) and water (2:1) was added to a warm (35°C) solution of diamine **15** (0.527 mmol) in 5 mL of DMF. The resulting mixture (pH 9–10) was stirred in the dark for 2–3 days until the pH value reached 4–5. Then, 1 drop of dimethyl sulfoxide was added and the stirring was continued for 2 h. The solvent was evaporated and the residue was suspended in saturated potassium chloride solution (30 mL; **note**: a vigorous stirring was essential to pulverized the lumps of platinum(II) complex). The resulting suspension was filtered, washed with water (100–250 mL), and dried in a desiccator. The product can be further purified either by flash chromatography or by preparative TLC (CH_2Cl_2:methanol, 9:1). The crude yields range from 70 to 95%.

*1-[*cis*-[(2-Aminoethyl)amino]dichloroplatinum(II)]-7,8,8-tris(4-hydroxyphenyl)-7-octene (**1**a):* mp >148°C (dec.). IR (KBr): 3640–3050 (N—H, O—H), 1605 (C=C), 1223 (C—O) cm^{-1}. ^1H NMR (acetone-d_6, δ ppm): 8.6–8.2 (3H, br s, 3 × -OH), 7.02, 6.83 and 6.94, 6.64 and 6.69, 6.48 (12H, 3 × two d, J = 8.57, 8.59, and 8.59 Hz, 3 × *para*-substituted phenol), 5.64, 5.08, and 4.97 (3H, 3 × br s, $-NHCH_2CH_2NH_2$), 3.15 (6H, br s, $-CH_2NHCH_2CH_2NH_2$), 3.03 (2H, br s, $-CH_2CH_2NH$-), 2.80–2.55 (2H, br s, $CH_2CH_2-CH_2NH$-), 2.39 (2H, m, $-C{=}CCH_2$-), 1.80–1.10 (4H, m, $-C{=}CCH_2-(CH_2)_2$-). ^{13}C NMR (acetone-d_6, δ ppm): 156.70, 156.20, 155.88, 139.39, 138.78, 136.16, 135.93, 134.64, 132.55(2), 131.43(2), 131.26(2), 115.61(2), 115.44(2), 114.84(2), 56.11, 53.43, 47.67, 36.21, 27.58, 26.81. In vitro antitumor activity

Microcytostasis assay

MTT was dissolved in phosphate-buffered saline (PBS) at a concentration of 5 mg/mL and stored in a dark environment at 4°C for a maximum of 3 weeks. Cell lines were grown until they were subconfluent, then trypsinized, washed in PBS, and resuspended in fresh media. A total of 100 μL medium containing 10^4 viable cells was plated per well into 96-well microtitre plates. Cells were allowed to attach to the plates for 24 h at 37°C in a 5% CO_2 atmosphere. The new drugs were dissolved in 0.25 mL of 95% ethanol and 4.75 mL of fresh media to a concentration of 1000 μ*m*. Drug dilutions were prepared in culture medium (range 1–1000 μ*m*). Medium was removed from the cells and test dilutions were added in 100 μ*m* fresh medium. Tests were carried out with 10 control wells (cells, no drug treatment) and 3 wells for each test dilution. Cells were exposed to the drug for 24 h at 37°C in 5% CO_2. Medium was removed and the cells were washed three times with sterile PBS. Next, 100 μL fresh medium was added to each well, followed by a 24 h recovery period. Subsequently, the medium was aspirated from each well and 100 μL 1:10 dilution of

MTT stock (5 mg/mL) was added to each well, followed by a 4 h incubation period at 37°C. MTT/medium blank controls with no cells also received 100 μM MTT/well. After incubation, medium was aspirated from each well, 100 μL DMSO was added per well, and the plates were agitated on a plate shaker for 20 min at room temperature (RT). The plates were read spectrophotometrically using a dual wavelength filter (570 and 630 nm) with a BIO-Tek EL310 E1A reader interfaced with a Samsung Deskmaster 386 microcomputer. Absorbance at 630 nm was used as the reference wavelength for detecting artefacts in the plastic plates and was subtracted from the 570 nm values. Wells with medium only (no cells) were processed in exactly the same manner as the rest of the plate, and the mean absorbance for these wells was subtracted from the absorbance values in the other wells.

Acknowledgments

We are grateful to the School of Pharmacy, Memorial University of Newfoundland, and to The Newfoundland Cancer Foundation for financial support of this work. We wish to thank members of the Chemistry Department (MUN): Dr. C. R. Jablonski, Ms. N. Brunet for NMR spectra, and Dr. B. Gregory and Miss M. Baggs for MS spectra.

Received May 21, 1993

R.A. SHAW, H.H. MANTSCH, and B.Z. CHOWDHRY. Can. J. Chem. **71**, 1334 (1993).

Infrared spectra of the cyclic peptide cyclosporin A and three analogues have been measured in a number of organic solvents (CCl_4, $CDCl_3$, acetonitrile, DMSO, and 50:50 acetonitrile:D_2O). Seven of the eleven amide groups of cyclosporin A are methylated, the remaining four N-H protons forming strong intramolecular hydrogen bonds in the crystal and in $CDCl_3$ solution. These hydrogen bonds give rise to amide I (C=O stretching) bands at positions characteristic of β-turns, γ-turns, and β-sheet domains in proteins and model polypeptides. Increasing the polarity of the solvent eliminates some of these features; however, the spectra in DMSO and acetonitrile–D_2O retain strong amide I absorptions characteristic of hydrogen-bonded carbonyl groups. The conformation of cyclosporin A in water cannot be observed directly due to low solubility; these findings suggest that the structure likely retains strong intramolecular hydrogen bonding. Spectra of the three analogues are consistent with this interpretation. Implications respecting the mechanism of pharmacological action of cyclosporin A are discussed.

R.A. SHAW, H.H. MANTSCH et B.Z. CHOWDHRY. Can. J. Chem. **71**, 1334 (1993).

On a mesuré les spectres infrarouges du peptide cyclique, cyclosporine A, et de trois de ses analogues dans divers solvants organiques (CCl_4, $CDCl_3$, acétonitrile, DMSO et mélange 50 : 50 d'acétonitrile : D_2O). Sept des onze groupes amides de la cyclosporine sont méthylés et les quatre autres groupes N-H forment de fortes liaisons hydrogènes dans le cristal et en solution dans le $CDCl_3$. Ces liaisons hydrogènes donnent lieu à des bandes amides I (élongation C=O) à des positions caractéristiques des domaines des tours β et γ et des feuillets β des protéines et des polypeptides modèles. Une augmentation de la polarité du solvant élimine une partie de ces caractéristiques; toutefois, les spectres dans le DMSO et dans le mélange acétonitrile–eau retiennent les fortes absorptions caractéristiques des groupes carbonyles fortement impliqués dans des liaisons hydrogènes. On ne peut pas observer directement la conformation de la cyclosporine A dans l'eau à cause de sa faible solubilité; ces observations suggèrent que la structure la plus probable conserve une forte liaison hydrogène intramoléculaire. Les spectres des trois analogues sont en accord avec cette interprétation. On discute des implications de ces résultats sur le mécanisme d'action pharmacologique de la cyclosporine A.

[Traduit par la rédaction]

Introduction

Cyclosporin A (CsA, see Scheme 1) is a cyclic undecapeptide that serves as an immunosuppressive agent, inhibiting the rejection of transplanted organs. The mechanism underlying this effect is not understood, but one of the first steps is believed to involve binding to the protein cyclophilin, a *cis–trans* isomerase whose activity in vitro is inhibited by complexation with CsA (1).

Cyclosporin A contains only hydrophobic amino acids, seven of which are N-methylated. The crystal (2, 3) and solution (chloroform) (2, 4) structures of cyclosporin A are virtually identical to one another. Structural features include the following:

(*i*) Three H-bonds forming a twisted β-sheet involving residues 11 through 1 to 7 (11-1-7), with (*a*) a type II′ β-turn (10-membered ring) formed by hydrogen bonding between the C=O of Abu-2[3] and the N-H of Val-5; (*b*) the adjacent H-bond connecting the N-H of Abu-2 to the C=O of Val-5; (*c*) a third H-bond connecting the C=O of MeVal-11 to the N-H of Ala-7.

(*ii*) A γ-turn (7-membered ring) formed by hydrogen bonding between the N-H of D-Ala-8 and the C=O of MeLeu-6 (C_6=O ← H-N_8).

(*iii*) An open loop structure for residues 7 through 8 to 11 (7-8-11).

Cyclosporin has 11 amide carbonyl groups, but only four amide protons, all of which form intramolecular H-bonds. This conformer of CsA is also stabilized by the N-CH_3 group of MeVal-11, which extends into the centre of the open loop to form close van der Waals contacts with several of the backbone atoms. No experimental structures are available for the analogues CsC, CsD, or CsH.

The similarity between the crystal and NMR structures of cyclosporin A might reasonably be taken to suggest that the active conformation is very similar. It turns out that this is not the case: the structure of CsA bound to cyclophilin has been measured using both NMR and X-ray crystallography, and has been shown to differ substantially from any known structure of the free molecule (5–11). This finding has spurred renewed interest in the solvent dependency of the conformation. The conformation in aqueous solution is of particular interest, as this structure may more closely resemble that of the molecule bound to cyclophilin.

The very low solubility of cyclosporin precludes direct studies of the conformation in water. Molecular dynamics calculations suggest that the backbone conformation is largely

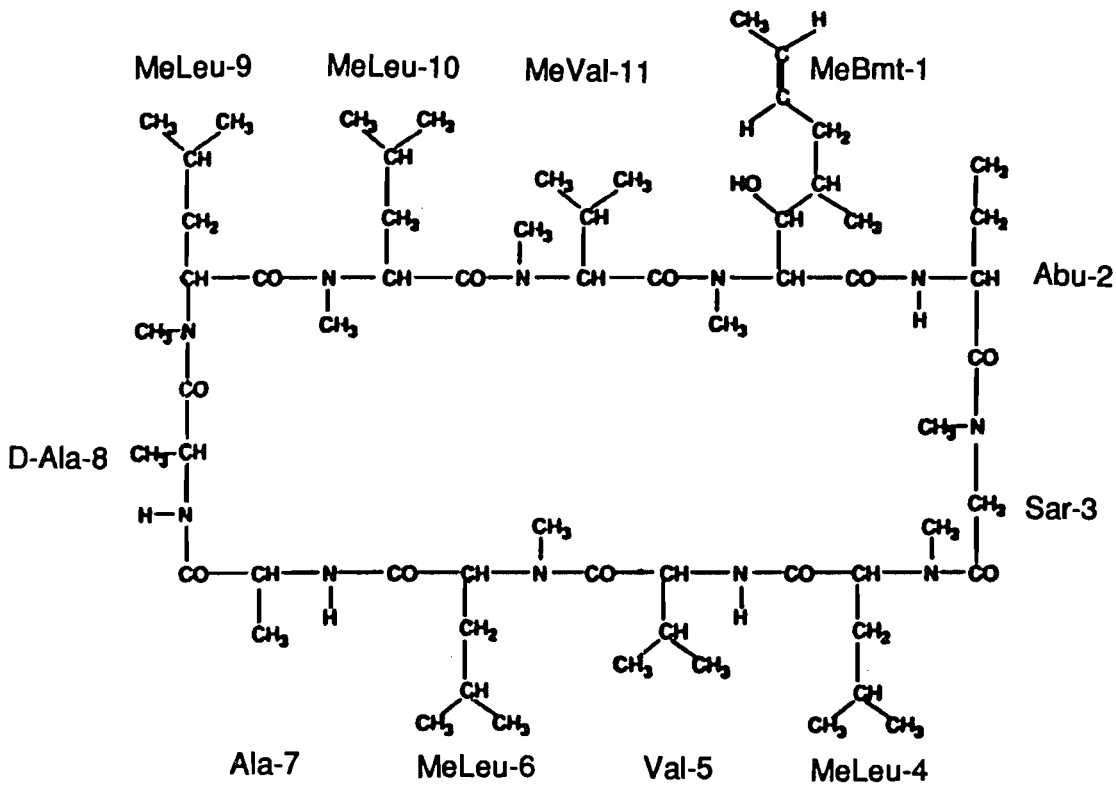

SCHEME 1. Cyclosporin A. The other cyclosporins differ from CsA in the following; cyclosporin C (CsC) has Abu-2 replaced by Thr-2, cyclosporin D (CsD) has Abu-2 replaced by Val-2, and cyclosporin H (CsH) has L-MeVal-11 replaced by D-MeVal-11.

independent of the solvent polarity (12). NMR spectra in DMSO suggest the presence of a variety of geometries, apparently showing conformational differences in the backbone as well as in the side chains (2, 13). NMR studies of CsA in various mixtures of $CDCl_3$ and CD_3OD suggest that the $CDCl_3$ conformer is also the dominant one in CD_3OD, although the relative abundance is reduced to ~30% (14). Recent CD studies of CsA, CsC, CsD, and CsH (see Scheme 1) indicate that the dominant conformational features are similar for CsA, CsC, and CsD, but significantly altered for CsH (15).

Infrared spectra are easily measured in a variety of solvents including CCl_4, $CDCl_3$, and DMSO, which are unsuitable for CD work due to spectral cutoff in the 185–260 nm region. Hydrogen bonding and distortion (rehybridization) of the amide linkages give rise to a range of amide I (C=O stretching) bands between 1600 and 1700 cm^{-1}. Analysis of this spectral region has become a powerful technique for determining the secondary structure of proteins and polypeptides, the absorption pattern for these amide I modes providing a signature that can be interpreted to reveal the relative importance of characteristic structures such as α-helix, β-sheet, and turns (for a recent review, see ref. 16).

To examine the influence of the nature of the solvent on the conformation of cyclosporin, we have measured the FT-IR spectra of cyclosporin A and three analogues (CsC, CsD, CsH) in CCl_4, $CDCl_3$, acetonitrile, DMSO, and 50:50 acetonitrile:D_2O.

Experimental

Cyclosporins A, C, D, and H were kindly supplied by Dr. T.G. Payne (Sandoz Ltd., Basel, Switzerland). Infrared spectra were obtained using 20 mg/mL cyclosporin (~17 mM) at pathlengths of 10 μm. Spectra were run in acetonitrile, DMSO, carbon tetrachloride, deuterochloroform, and 50:50 acetonitrile:D_2O using a Digilab FTS-60 spectrometer and MCT detector; 256 scans were typically coadded at a resolution of 2 cm^{-1}, and Fourier self-deconvolution was performed using software developed in our laboratory. All figures display spectra that have been deconvolved, using bandwidths of 11 cm^{-1} (CCl_4), 13 cm^{-1} ($CDCl_3$), 14 cm^{-1} (CH_3CN), 14 cm^{-1} (DMSO), and 20 cm^{-1} (CH_3CN–D_2O), and K values of 1.3 (CH_3CN–D_2O) and 1.8 (all others).

Results

Figure 1 shows the spectra of CsA in five different solvents, plotted together for comparison. Figures 2–5 show the spectra of the various cyclosporins measured in carbon tetrachloride, chloroform-d_1, acetonitrile, and acetonitrile–D_2O, respectively. Under all conditions the spectrum of CsD is virtually identical to that of CsA, as demonstrated by the spectra measured in CCl_4 (see Fig. 2). Therefore, the spectra of CsD are not plotted in the other figures.

The interpretation of the cyclosporin spectra is based on general rules derived from infrared studies of proteins and model peptides. The success of infrared spectroscopy in probing these structures is largely founded upon the fact that the amide I (C=O stretch) frequency is sensitive to hydrogen bonding. These modes generally appear between 1610 and 1690 cm^{-1}; a band at 1610 cm^{-1} denotes a very strongly H-bonded C=O group, while an absorption at 1690 cm^{-1} indicates the complete absence of H-bonding and possibly a deviation from coplanarity of the amide group. Between these extremes lies a gradient of H-bonding strengths, strongest at lowest frequencies and absent at the highest. Generally, bands above 1660 cm^{-1} arise from non-H bonded structures while

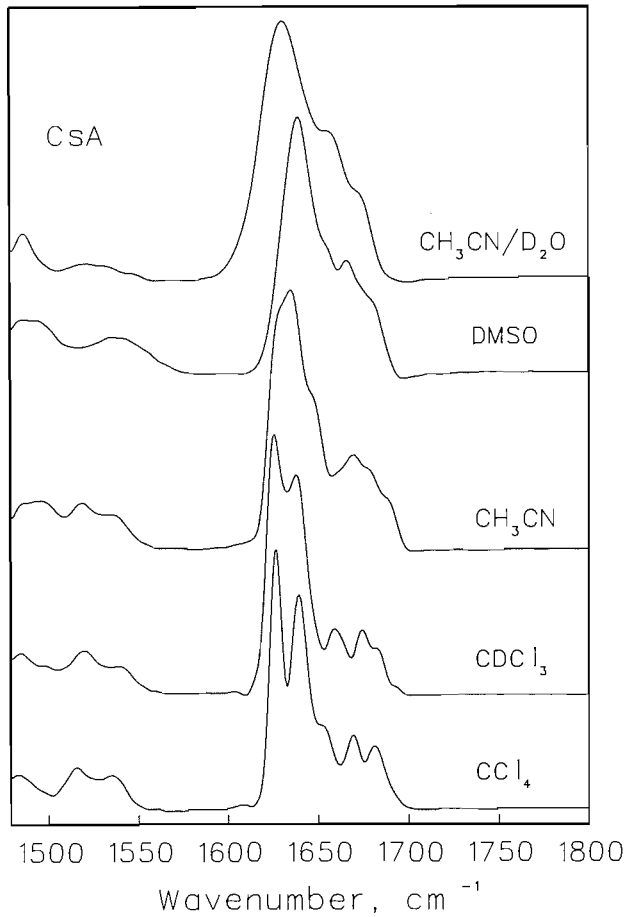

FIG. 1. FT-IR spectra of cyclosporin A in various solvents.

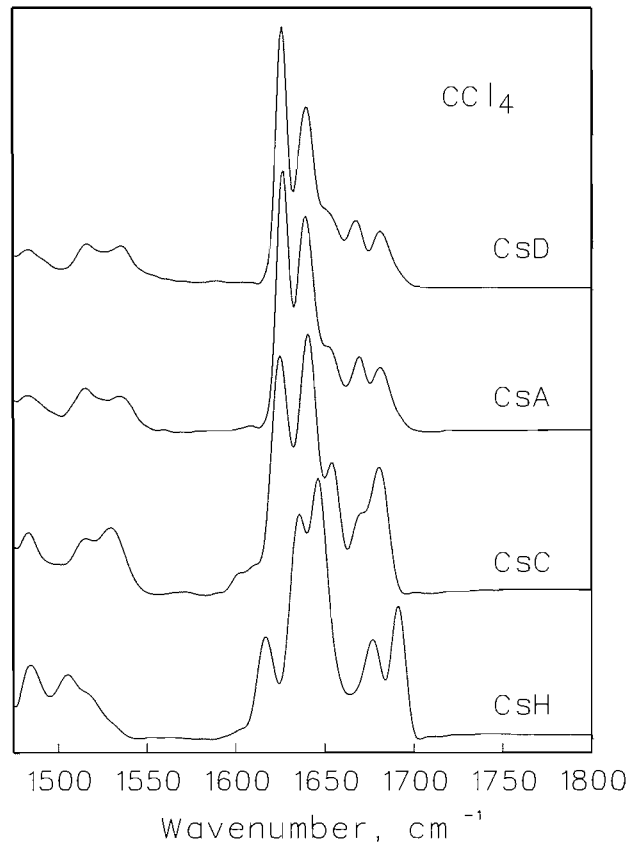

FIG. 2. FT-IR spectra of cyclosporins in CCl_4.

bands below 1645 cm^{-1} correspond to strong H-bonds such as those found in β-type structures (17). Features in the 1645–1660 cm^{-1} range may arise from weaker H-bonds, e.g., α-helices, or unordered structures. A recent study of model cyclic peptides (18) has shown that the two C=O groups defining a β-turn and adjacent H-bond give rise to infrared absorptions that cannot be resolved one from another, appearing at 1645 cm^{-1} in acetonitrile, 1642 cm^{-1} in chloroform, 1642 cm^{-1} in DMSO, and 1644 (1640) cm^{-1} in H_2O (D_2O).

The NMR structure of CsA in $CDCl_3$ includes a β-sheet domain, with one H-bond defining the type II′ β-turn (C_2=O ← H-N_5) and two other H-bonds extending the β-sheet (C_5=O ← H-N_2 and C_{11}=O ← H-N_7), as well as a γ-turn centered around Ala-7 (C_6=O ← H-N_8). These features, which define the backbone structure, should give rise to characteristic signatures below 1645 cm^{-1} in the infrared spectra.

The CsA spectrum in $CDCl_3$ shows two strong features in the 1620–1645 cm^{-1} range typical of strongly H-bonded C=O groups. By analogy with the model peptide study, we assign the band at 1638 cm^{-1} as a superposition of two amide I bands corresponding to the first two carbonyl groups (C_2=O ← H-N_5 and C_5=O ← H-N_2) involved in the β-sheet structure. The amide I band observed at 1625 cm^{-1} for CsA, CsC, and CsD also denotes even more strongly H-bonded C=O groups. We assign this band as a superposition of the absorptions arising from the third H-bond of the β-structure (C_{11}=O ← H-N_7) and the H-bond forming the γ-turn (C_6=O ← H-N_8).

With seven of the 11 amide protons replaced by methyl groups, these four intramolecular H-bonds play a major role in stabilizing the backbone structure of CsA in $CDCl_3$. The stability of this conformer in other solvents may be assessed by monitoring changes in those amide I bands that most clearly reflect the H-bonding in $CDCl_3$ solution, i.e., the bands at 1625 and 1638 cm^{-1}. Therefore the remainder of our interpretation focuses largely upon these bands.

The CsH spectrum is unique in that there is no band at 1625 cm^{-1}, this feature being replaced by a new absorption at 1616 cm^{-1}. This position indicates a very strongly H-bonded C=O, likely due to strengthening of the γ-turn or the C_{11}=O ← H-N_7 H-bond relative to the analogous bond in CsA. For CsH inversion of the MeVal-11 chiral center, compared to CsA, disrupts van der Waals interactions of the N-CH_3 group that stabilize the conformation of CsA and presumably also CsC and CsD (2). This effect is likely to lead to a weakening of the C_{11}=O ← H-N_7 H-bond, leaving the γ-turn as the more plausible source of the band at 1616 cm^{-1}. The feature at 1693 cm^{-1} may then be assigned as the C_7=O enclosed by the γ-turn, with the high frequency induced by strain (non-coplanarity) associated with formation of the 7-membered ring. The weakened C_{11}=O ← H-N_7 bond may give rise to the band at ~1649 cm^{-1} in the spectrum of CsH.

Surprisingly, the spectra measured in CCl_4 differ substantially from counterparts measured in $CDCl_3$ solution, particularly above 1650 cm^{-1}. The spectra of CsH are particularly informative, as the feature at 1616 cm^{-1} is notice-

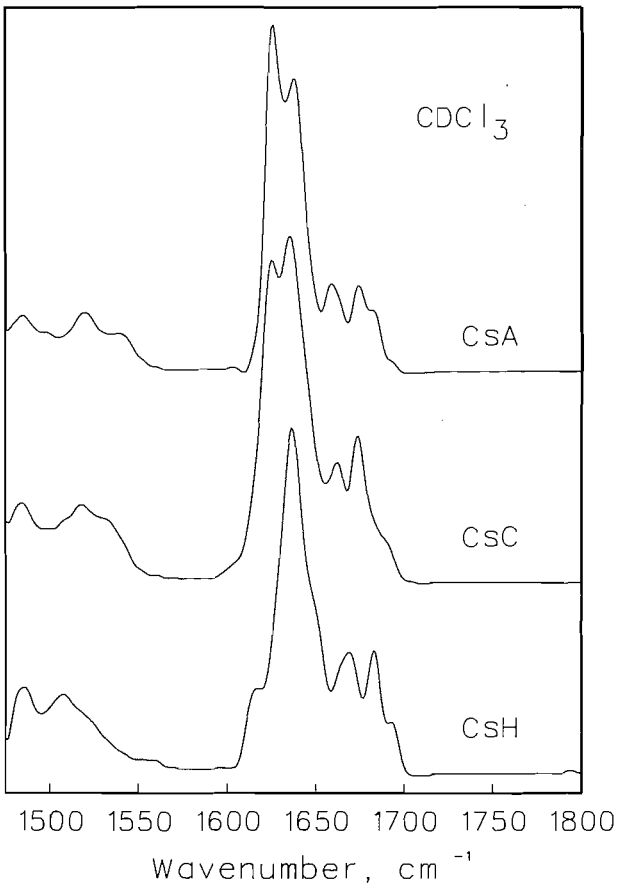

FIG. 3. FT-IR spectra of cyclosporins in $CDCl_3$.

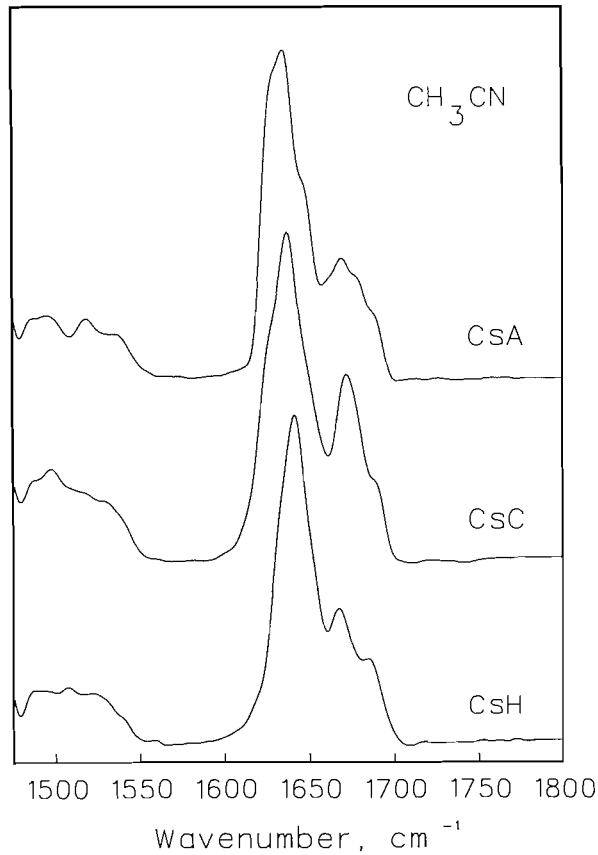

FIG. 4. FT-IR spectra of cyclosporins in acetonitrile.

ably less intense in $CDCl_3$ than in CCl_4. This suggests that in $CDCl_3$ the H-bond responsible for the 1616 cm^{-1} band is disrupted by the solvent, likely through formation of weak C=O ← D-C type hydrogen bonds with the solvent deuterium.

The same phenomenon seems likely as the cause of analogous changes in the spectra of CsA and CsC. For each molecule the structure in which all N-H's form intramolecular H-bonds, i.e., the dominant structure found in $CDCl_3$ solution, is most highly populated in the completely apolar solvent CCl_4. Figure 1 shows a gradual loss of the lowest frequency amide I band and broadening of the remaining features with increasing solvent polarity. Against this background, differences between the spectra in CCl_4 and $CDCl_3$ solutions may be ascribed to $CDCl_3$ competing with N-H in the C_{11}=O ← H-N_7 and (or) C_6=O ← H-N_8 H-bonds. This effect would account for the minor (6%) conformer inferred from the NMR spectra in $CDCl_3$ (2).

For CsA in acetonitrile, the 1635 cm^{-1} band remains as an indicator that the first two H-bonds of the β-structure (10- and 14-membered rings) remain intact. The lower frequency amide I band at ~1625 cm^{-1} is weakened relative to the analogous absorptions in CCl_4 and $CDCl_3$. This suggests a relatively low, yet still significant, population of the intramolecular H-bonds responsible for this absorption. In contrast, the CsH spectrum loses all features below 1642 cm^{-1} in the spectra of more polar solvents (see bottom trace, Figs. 2–5). Hydrogen bonds giving rise to peaks at 1616 and ~1638 cm^{-1} in CCl_4 are broken, indicating that these bonds in CsH are more exposed to the solvent than are the analogous H-bonds in CsA.

The amide II features between 1500 and 1550 cm^{-1} are distinct and well resolved for all spectra measured in CCl_4. In acetonitrile, bands in this spectral region become particularly broad and overlapped for CsC and CsH. This reflects two related influences: hydrogen bonding of the amide hydrogens to the solvent, and the presence of a distribution of structures as opposed to the single rigid conformer in CCl_4. For CsA the relatively clean amide II features confirm that although there is some solvent perturbation of the intramolecular H-bonds, this effect is much less pronounced than is the case for CsC and CsH.

DMSO has been shown to disrupt protein secondary structures through strong H-bonding to the amide N-H protons (19). Typically, the result is that the amide I region is dominated by a strong band in the 1660–1670 cm^{-1} range that is characteristic of "free" C=O oscillators. All cyclosporin spectra in DMSO solution show a moderately strong feature in this region; however, the dominant feature in each case is a band at 1639 cm^{-1} (Fig. 6). This indicates that the β-sheet structure is retained in DMSO, as previously found for model hexapeptides (18). The elimination of the lower frequency bands observed in the CCl_4 solution spectra at 1627 (CsA), 1624 (CsC), and 1616 cm^{-1} (CsH) implies compete disruption of the C_{11}=O ← H-N_7 and C_6=O ← H-N_8 hydrogen bonds in DMSO. For CsH there is no counterpart to the band observed at 1691 cm^{-1} in CCl_4 and ascribed to the C_7=O enclosed by the γ-turn in that solvent; this provides further evidence supporting both the original assignment and

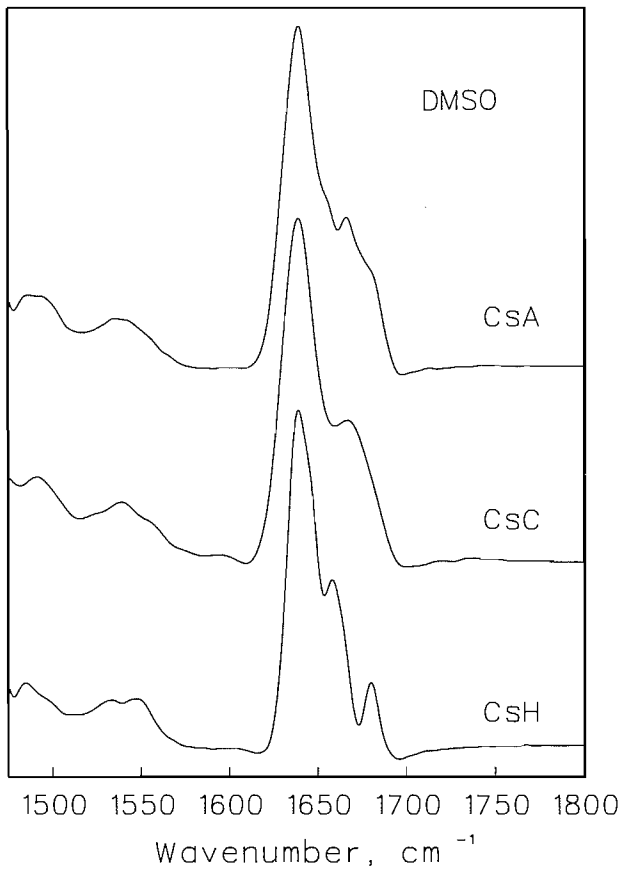

FIG. 5. FT-IR spectra of cyclosporins in DMSO.

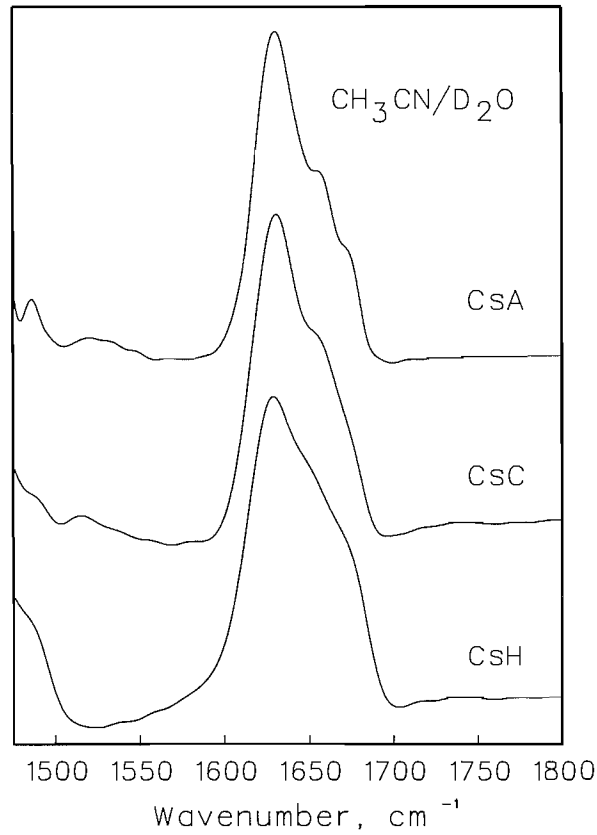

FIG. 6. FT-IR spectra of cyclosporins in 50:50 acetonitrile:D_2O.

the suggestion that DMSO disrupts the γ-turn of all three cyclosporins.

The three spectra in acetonitrile–D_2O show very similar profiles to one another, dominated by the lowest frequency amide I band at 1630 (CsA), 1631 (CsC) and 1628 cm^{-1} (CsH). These bands demonstrate that the β-sheet structure is retained, the relatively low frequencies arising from H/D exchange of the amide NH groups. The broad, featureless bands suggest a situation analogous to that for DMSO; retention of the β-sheet structure, with the remaining loop free to adopt a variety of conformations. Weak residual features in the region of the amide II bands also indicate incomplete H/D exchange.

Discussion

The above analysis gauges solvent effects in terms of conformational *changes* relative to the CsA structure in $CDCl_3$ established independently by NMR spectroscopy. This is the kind of application for which infrared spectroscopy is ideally suited, and we are confident that the major conclusions drawn from this study are soundly based.

The more subtle features of the NMR structure are also consistent with the infrared spectra. It is unreasonable to postulate that only four C=O absorptions contribute to the pair of bands at lowest frequency in the CCl_4 and $CDCl_3$ solution spectra. While we are confident that these bands are associated *predominantly* with the specific H-bonds discussed above, it should be recognized that other H-bonds are present and will contribute intensity in the 1620–1645 cm^{-1} region. For example the OH of MeBmt forms a hydrogen bond to the C=O of the same residue, likely contributing intensity to the band at ca. 1640 cm^{-1} in most of the spectra. A variety of γ-turn type interactions are also populated, e.g., C_5=O ← H-7_7, C_{11}=O ← H-N_2, and C_3= O ← H-N_5, and the relative populations of these are undoubtedly influenced by changing the solvent.

It should be noted that this study serves as a useful calibration for further infrared studies of cyclic polypeptides. Each of the two common types of turn are represented in the structure of cyclosporin: the assignments of the γ-turn at ~1625 cm^{-1} and the β-turn at ~1640 cm^{-1} serve as benchmarks for subsequent studies, as does the assignment of the 1693 cm^{-1} band to the C=O bond enclosed by the strong γ-turn in CsH. General trends observed here can also be useful as a guide in *selecting* appropriate solvents for related studies. The infrared spectral differences introduced by varying the solvent clearly correspond to structural changes induced by different solvents. The trends observed here confirm that solvation in CCl_4 maximizes intramolecular H-bonding. Particularly for cyclic polypeptides, it should prove useful to approach spectral interpretation by comparing to the "simplified" spectrum measured in CCl_4. The inherently narrow bands and the appearance of the spectrum in comparison to those measured in $CDCl_3$ and acetonitrile strongly suggest that a single conformer predominates in CCl_4 solution.

The structure of cyclophilin-bound CsA contains no intramolecular H-bonds (5–7), leaving the question of whether aqueous solvation might induce a conformer similar to the bound structure. Spectra measured in acetonitrile–D_2O all show bands characteristic of strong intramolecular D-bonds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

It thus seems unlikely that any dominant conformer in this solvent resembles the bound structure, and in turn we conclude that it appears that aqueous solvation does not disrupt intramolecular H-bonds to the extent required to produce a structure resembling that of bound cyclophilin.

Concluding remarks

Infrared spectra of CsA measured in $CDCl_3$ are in complete accord with the NMR structure of CsA determined in the same solvent. The spectral changes observed in other solvents suggest that increasing the solvent polarity does not disrupt the β-turn or the adjacent H-bond. The infrared spectra also indicate that CsA, CsC, and CsD adopt very similar backbone conformations.

As indicated previously by CD measurements (15), the conformation of CsH is markedly different from that of CsA, CsC, and CsD, both in structure and in the susceptibility to solvent disruption. Strong H-bonds that are evident in apolar solvents are broken in acetonitrile, whereas the analogous bonds in the other cyclosporins remain relatively strong.

Solvation in DMSO or acetonitrile–D_2O clearly leaves strong intramolecular H-bonds intact in all the cyclosporins studied. This finding indicates that interactions with physiological solvents alone (e.g., H_2O) are unlikely to produce cyclosporin conformers that mimic the conformation of the cyclophilin-bound molecule.

Photochemistry of lignin model compounds on solid supports[1]

L. HURRELL, L.J. JOHNSTON,[2] N. MATHIVANAN, and D. VONG
Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, ON K1A 0R6, Canada

Received April 15, 1993

L. HURRELL, L.J. JOHNSTON, N. MATHIVANAN, and D. VONG. Can. J. Chem. **71**, 1340 (1993).

The photochemistry of several substituted α-(aryloxy)acetoveratrones that are models for chromophores in lignin has been studied using a combination of laser flash photolysis and product studies in solution and on silica, Na-X zeolite, and cellulose. The lifetimes of the triplet ketones vary substantially with the electron-donating ability of the substituents in the α-aryloxy ring, with values ranging from 30 ns for the 4-methoxy derivative to 5.5 μs for the 4-cyano ketone in acetonitrile. The triplet ketones are considerably longer lived on a silica surface than in solution and do not decay with first-order kinetics; however, they are all shorter lived than triplet acetoveratrone under the same conditions, indicating that β-phenyl quenching and (or) β-cleavage dominate their decay. The same triplets show quite different kinetic behavior in Na-X or cellulose and there is no indication in these systems for the importance of either β-phenyl quenching or β-cleavage in determining the rates of triplet decay. Product studies for α-guaiacoxyacetoveratrone indicate that β-cleavage from the singlet excited state is responsible for product formation; in contrast to solution results, the phenacyl–phenoxyl radical pairs react exclusively by geminate recombination to give rearranged ketones resulting from *ortho* and *para* ring coupling of the two radicals. Product formation is very inefficient for this ketone in cellulose, indicating either a low singlet reactivity or efficient geminate recombination of the initial radical pair to regenerate starting material.

L. HURRELL, L.J. JOHNSTON, N. MATHIVANAN et D. VONG. Can. J. Chem. **71**, 1340 (1993).

Utilisant une combinaison de photolyse éclair au laser et une étude des produits en solution, sur de la silice, sur une zéolite Na-X et sur de la cellulose, on a étudié la photochimie de plusieurs α-(aryloxy)acétovératrones qui sont des modèles pour les chromophores de la lignine. Les temps de vie des cétones triplet varient beaucoup avec les capacités des substituants du cycle aryloxy à donner des électrons; les valeurs varient de 30 ns pour le dérivé 4-méthoxy à 5,5 μs pour la 4-cyanocétone dans l'acétonitrile. Les cétones triplet ont des temps de vie beaucoup plus élevés sur une surface de silice qu'en solution et leur dégénérescence n'est pas du premier ordre; toutefois, leurs temps de vie sont tous plus courts que celui du triplet de l'acétovératrone dans les mêmes conditions et ces résultats indiquent que la relaxation β-phényle et (ou) un clivage β dominent leur dégénérescence. Les mêmes triplets présentent un comportement cinétique très différent avec Na-X ou la cellulose et il ne semble pas que, dans ces systèmes, la relaxation β-phényle ou un clivage β joue un rôle important dans la détermination de la vitesse de dégénérescence de l'état triplet. Des études de produit pour l'α-guaïacoxyacétovératrone indiquent que le clivage β à partir de l'état singulet excité est responsable pour la formation des produits; par opposition aux résultats obtenus en solution, les paires de radicaux phénacyle–phénoxyle réagissent exclusivement par recombinaison géminée conduisant à des cétones transposées résultant de couplages en *ortho* et en *para* des deux radicaux. Pour cette cétone dans la cellulose, la formation de produits est très inefficace; ce résultat suggère que la réactivité du singulet est faible ou que la recombinaison géminée de la paire initiale de radicaux pour régénérer le produit de départ est efficace.

[Traduit par la rédaction]

Introduction

There is currently a large amount of interest in studying the basic reaction mechanisms that are responsible for the light-induced yellowing of low-grade paper products made from high-yield mechanical pulps. It has been established that the rapid photoreversion results from photooxidation of lignin in the wood pulp and it is believed that reactions of phenoxyl radicals, probably to give quinones, are key steps in the process (1–3). One of the major routes for the formation of phenoxyl radicals is hydrogen abstraction by excited ketone chromophores from phenolic groups within the lignin framework. However, it is known that pulps with fully alkylated phenol groups still undergo some photoyellowing, indicating that other reactions are also important (4). One of these is β-cleavage of α-aryloxyacetophenone ketone units to yield phenoxyl and phenacyl radicals. Cleavage reactions of ketyl radicals produced by hydrogen abstraction reactions of triplet ketones provide a second potential source of phenoxyl radicals (5, 6). Recently, the photochemistry of α-guaiacoxyacetoveratrone (**1**) and related compounds in solution and in heterogeneous environments has been studied as a model for the β-cleavage processes in lignin (7–12).

7

The photochemistry of a variety of substituted α-aryloxyacetophenones has been studied in solution. The earlier work suggested that the triplet excited ketone decayed by a competition between β-phenyl quenching and β-cleavage (13, 14). In simple aryloxyacetophenones the triplet lifetimes were short (<1 ns) and the products resulted from (*a*) scavenging of the phenacyl and phenoxyl radicals by hydrogen donors, (*b*) *ortho* and *para* coupling of the phenacyl and phenoxyl

radicals to give α-arylacetophenones isomeric with starting materials, and (*c*) dimerization of phenacyl radicals (14). Similar chemistry has been observed for the lignin model ketone **1**, except that in this case substantial amounts of oligomeric materials were formed (reaction [1]) (7). Recently, detailed CIDNP studies have demonstrated that a variety of phenacyl- and aryloxy-substituted α-phenoxyacetophenones undergo β-cleavage primarily from the excited singlet state, in contrast to the usual triplet reactivity of most aromatic ketones (15, 16). Irradiation of ketone **1** in solution in the presence of triplet quenchers has also provided evidence that β-cleavage occurs predominantly, if not exclusively, from the singlet ketone in aprotic solvents; in alcohols both singlet and triplet reactions lead to products (11). The solvent effects on both the triplet lifetime and quantum yield for disappearance of starting ketone have been rationalized on the basis of a slower rate of β-phenyl quenching for the triplet in hydrogen-bonding solvents, thus allowing β-cleavage to compete as a triplet deactivation mechanism.

Despite the many studies of model compounds in solution, there have been relatively few detailed examinations of product studies or time-resolved experiments for these materials in heterogeneous environments that mimic the behavior of pulp itself. A recent diffuse reflectance laser flash photolysis study of bleached thermomechanical pulp samples has detected a long-lived transient assigned to an aryl ketone triplet distributed over a variety of sites in the lignin macromolecule (17). It is obvious that a detailed understanding of the effects of an organized environment on the behavior of both the excited states and the radicals generated from them is essential for understanding the chemistry involved in the photoreversion process. Accordingly, we have examined the behavior of several model ketones (**1**–**7**) on three solid supports (silica gel, Na-X zeolite, and cellulose) using a combination of diffuse reflectance laser flash photolysis and product studies. The diffuse reflectance flash photolysis techniques developed by Wilkinson and coworkers over the last decade have considerable potential for studying transients such as triplets, radicals, and radical ions in opaque solids (18–26). The present studies provide insight into the manner in which the initial photochemistry and the behavior of photogenerated radical pairs are modified for lignin model ketones in a constrained environment. They also provide useful background information to aid in the interpretation of transient results on lignin and pulp samples.

Results

Laser flash photolysis in solution

For comparison with the diffuse reflectance work, absorption spectra and lifetimes for triplets **1**–**6** were also measured in acetonitrile and ethanol, using either 266 or 308 nm excitation. The low ketone concentrations (~5 × 10^{-5} M) used in these experiments necessitated the use of flow samples in order to replenish the solution for every laser shot and prevent the rapid buildup of products that generated longer lived transients. The triplet lifetime for **1** was approximately 250 ns in acetonitrile, which is comparable to the previously reported value of 230 ns in that solvent (11). The triplet lifetime was substantially longer in ethanol (~1 μs), again in agreement with the literature results (11).

Either 308 or 266 nm excitation of ketones **2**–**6** in acetonitrile generated triplet–triplet absorptions with λ_{max} at 390–400 nm, as shown for **5** in Fig. 1. The measured triplet lifetimes in acetonitrile and ethanol are listed in Table 1. The 3-methoxy derivative (**3**) has a substantially longer lifetime in acetonitrile (0.75 μs) than does triplet **1**. The unsubstituted and 4-cyano ketones (**2**, **6**) have even longer lifetimes of 1.8 and 5.5 μs, respectively; in the latter case traces of residual oxygen that are difficult to remove from flow samples may account for the observed decay kinetics. In contrast, both the 4-methoxy and 2,6-dimethoxy derivatives (**4**, **5**) have quite short triplet lifetimes: 30 and 16 ns, respectively. The decay of triplet **5** is shown as an insert in Fig. 1. The triplet lifetimes for **1**, **2**, and **3** are all significantly longer in ethanol than in acetonitrile; in contrast, the short-lived triplets (**4** and **5**), as well as the long-lived 4-cyano derivative, show much less effect of changing to a hydrogen-bonding solvent.

Diffuse reflectance laser flash photolysis

Laser excitation of ketone **1** on either silica or Na-X zeolite (2% by weight, ~6 × 10^{-5} mol g^{-1} loading) gave a strongly absorbing transient with λ_{max} at 390 nm. Similar results were observed upon excitation of **1** on microcrystalline cellulose, although in this case the observed transient was broader and the signals were weaker. In each case the ob-

served transient can be assigned to the triplet–triplet absorption spectrum of the ketone, based on the known solution spectrum for this species (11) and on the observed quenching by triplet quenchers such as oxygen and dienes on silica. Representative spectra for each support are shown in Fig. 2. The broadness of the spectrum on cellulose may be related to aggregation effects, as observed previously for methoxyacetophenones in various heterogeneous environments (19, 27). Transient absorption spectra for acetoveratrone (**7**) on the three solid supports were also recorded and showed virtually identical results to those for ketone **1**.

The decay kinetics for ketones **1** and **7** were examined under matched conditions for each of the supports. The triplet decay for a deaerated sample of **1** on silica is shown in Fig. 3. The decay cannot be fitted with single exponential kinetics; however, a half-life of 6 μs (Table 1) can be estimated from the data. In contrast to these results, triplet acetoveratrone on silica was much longer lived (Fig. 3), with ~80% of the initial signal remaining 100 μs after laser excitation and with a half-life in excess of 400 μs. The marked difference in decay kinetics for triplets **1** and **7** suggests that an additional decay pathway (either β-cleavage or β-phenyl quenching) contributes to the decay of triplet **1** on silica.

As noted above, triplet **1** on silica was efficiently quenched by oxygen and dienes (e.g., 2,4-hexadiene or *trans,trans*-2,4-hexadienol). In the presence of relatively minor amounts of either oxygen or diene the kinetics for decay of triplet **1** gave reasonably good fits to a single exponential. For example, a sample of **1** plus 6×10^{-5} mol g^{-1} hexadienol decayed with a rate constant of 2.8×10^6 s^{-1}. Addition of higher concentrations of dienol further shortened the triplet lifetime, although luminescence problems made it difficult to obtain reliable rate constants under these conditions. The more rapid triplet decay in the presence of dienol indicates a dynamic quenching mechanism, involving some mobility of either the triplet ketone or dienol. A rough estimate based on a single dienol concentration gives a value of $\sim 2 \times 10^{15}$ dm^2 mol^{-1} s^{-1} for the rate constant for diene quenching. This value has been obtained by using a surface area of 480 m^2 g^{-1} for the silica and assuming a flat two-dimensional surface. The estimated rate constant is in reasonable agreement with measured numbers for energy transfer quenching of triplet benzophenone on silica (25). The initial signal intensity was also decreased in the presence of higher concentrations of dienol, consistent with a component due to a static quenching mechanism under these conditions.

The triplet decay kinetics for **1** and **7** in Na-X were also nonexponential and occurred over a wide range of timescales. Individual decay traces for each ketone on two different timescales that differ by a factor of 10 are shown in Fig. 4. These do not give adequate fits to either second-order kinetics or to a combination of two monoexponential decays, and probably reflect a distribution of decay kinetics arising from multiple sites. Comparison of the data in Fig. 4 for the two ketones shows that triplet **1** decays more rapidly than triplet **7** in the zeolite cavity. However, it is also obvious that triplet **1** is very substantially longer lived in the zeolite than in either solution or on a silica surface. Again

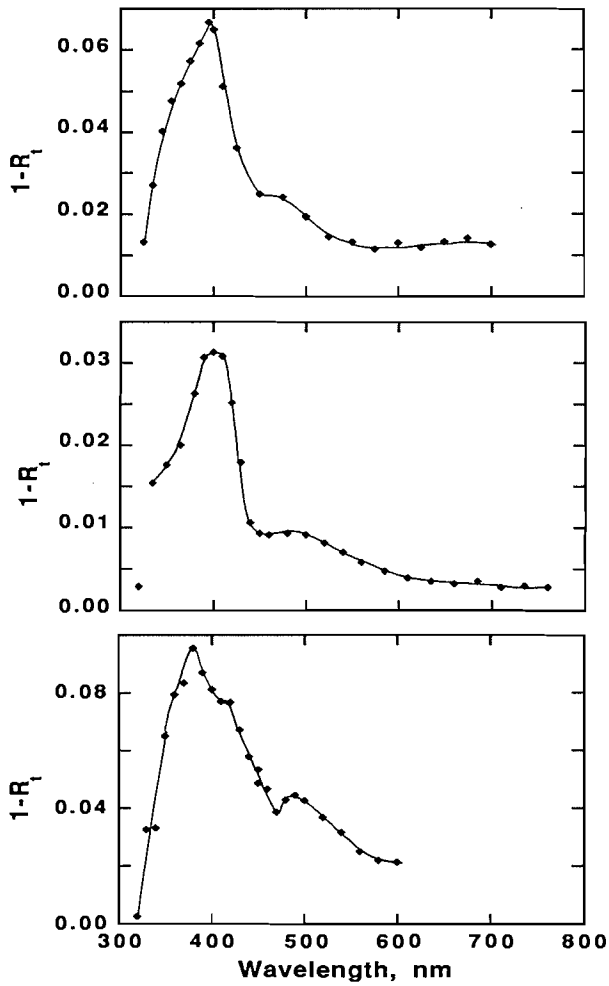

FIG. 2. Triplet diffuse reflectance spectra measured after 308 nm laser excitation of ketone **1** on silica (top), Na-X zeolite (middle), and cellulose (bottom).

this behavior is typical of that observed for other triplets in zeolites (19, 23, 25).

The decay kinetics for triplets **1** and **7** in cellulose are also complex. However, in this case there is some evidence for two distinct types of kinetics. For example, there is a component (~30–50% of initial signal) that decays within 1–2 μs, while most of the residual long-lived signal remains after 100 μs (Fig. 5). Spectra recorded at different time delays after laser excitation are very similar, indicating that the fast and slow components are both due to triplets. There is little difference between the results for **1** and **7**, except for the observation of a slightly larger amount of the fast component for the latter. The similar decay kinetics for both **1** and **7** may indicate similar decay processes for both. It is also noteworthy that the signal intensities for cellulose samples are weaker than for either silica or zeolite even after correction for differences in the amount of light absorbed. This may be the result of a fraction of rapidly decaying triplets that are not observable on our shortest timescale for the cellulose samples.

Neither the intensity of the triplet-triplet absorption nor the decay kinetics for triplet **1** on cellulose was affected by the presence of oxygen. These results are in good agreement with earlier studies for triplet benzophenone on cellulose (28, 29)

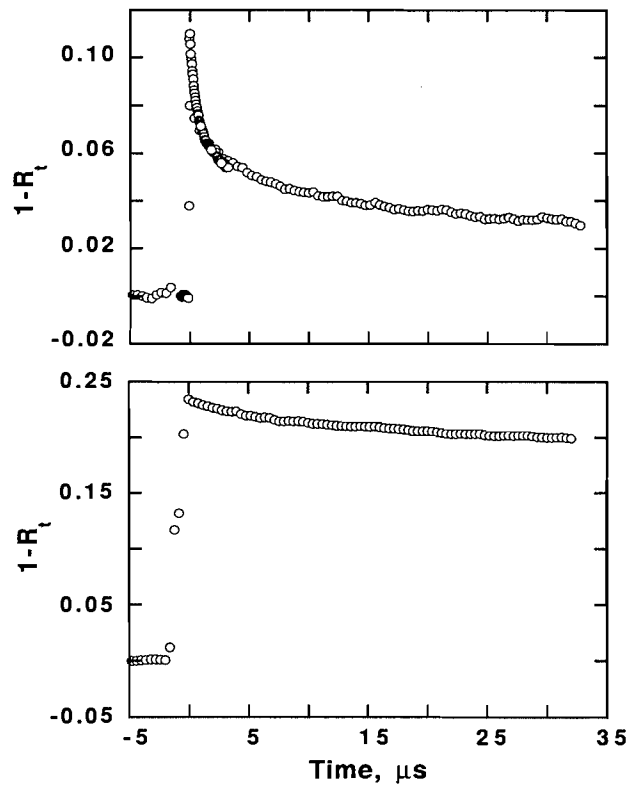

FIG. 3. Decay of triplets **1** (top) and **7** (bottom) at 400 nm on silica. The decay trace for **1** is a combination of two kinetic traces recorded on two different timescales, in order to better capture the early part of the decay.

and indicate that oxygen penetration throughout the cellulose framework is very slow.

There is no evidence in any of our results for ketone **1** on solids for the intermediacy of the phenoxyl radicals that are known to be formed by β-cleavage. Since these species have relatively low extinction coefficients (30) and are only formed with moderate quantum yields (7, 11), this is perhaps not too surprising. However, we had hoped that radicals would be more readily detectable for some of the other ketones (e.g., **3** and **4**) since these would generate phenoxyl radicals with higher extinction coefficients. For example, the relative extinction coefficients for the 2-methoxy, 3-methoxy, unsubstituted, and 4-methoxyphenoxyl radicals of 0.25, 0.8, 1.0, and 2.3 indicate that compound **1** would give the weakest phenoxyl signals, assuming equal quantum yields for radical formation (30). Accordingly, we investigated ketones **2**–**6** on both silica and cellulose.

The transient absorption spectra for ketones **2**–**6** at 2% loading on silica all have λ_{max} at 390–400 nm in good agreement with the results for **1** and **7**. None of these ketones gave decays that could be fitted with single exponential kinetics. However, the half-lives given in Table 1 indicate that changes in substitution do result in substantial differences in the rates of triplet decay. Furthermore, the overall trends on silica are qualitatively similar to those observed in acetonitrile solution. Thus, the 4-methoxy and 2,6-dimethoxy ketones decay the most rapidly both in solution and on silica, while the 4-cyano ketone is the longest lived. On cellulose each of these ketones gives results that are similar to those obtained for **1** and **7** on this support, both in terms of spectrum and decay kinetics. However, we were unable to provide any definitive spectroscopic evidence for phenoxyl radical formation following excitation of any of these ketones on solid supports. Representative spectra for **3** on silica and cellulose are shown in Fig. 6.

Product studies

Irradiation of **1** on silica for short periods of time followed by extraction of the sample as outlined in the experimental section gives a mixture of two products that are isomeric with starting material, based on GC-MS analysis. The relative amounts of the two compounds vary considerably from one sample to the next, although there is usually twice as much of the longer retention time material. The mass balance is typically ≥85% at low conversions (≤20%) but prolonged irradiation leads to the formation of a variety of additional products that appear to result from further photochemistry of the two primary products. The mass balance also decreases for longer irradiation times, probably as a result of oligomerization reactions. The two primary photoproducts are assigned to the α-arylacetoveratrones (**8***a*,*b*) formed as a result of *ortho* and *para* coupling of the phenacyl and phenoxyl radicals. These two products have been reported previously following irradiation of **1** in solution. The two isomers were identified on the basis of comparison of retention times and spectroscopic data with those of an authentic sample and with literature data, as outlined in the experimental section. The silica irradiations always led to a larger amount of the *ortho* isomer, although the relative yields varied from one sample to the next. Minor amounts (5–10%) of the hydrogen abstraction products (acetoveratrone and guaiacol) were recovered in some early experiments in which the solvent was not rigorously removed by vacuum drying before irradiation. These are assumed to arise from residual solvent rather than by hydrogen abstraction from the parent ketone, since they disappeared for well-dried samples.

There was no evidence for the production of the phenacyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

radical dimer, suggesting that **8** is formed via in-cage radical coupling. Such a reaction could in principle occur from either the singlet or triplet state of the ketone since the slow mobility of the radicals on the surface would allow intersystem crossing for a triplet radical pair to compete with diffusional cage escape of the radicals. To examine whether triple **1** was involved in product formation on silica, the photochemistry of **1** on silica was examined in the presence of 2×10^{-4} mol g^{-1} *trans,trans*-2,4-hexadienol; this concentration of dienol is sufficient to react with >90% of the triplet ketones. Two samples of **1** (6.6×10^{-5} mol g^{-1}) on silica that were identical except for the presence of dienol were irradiated using 350 nm Rayonet lamps to eliminate absorption of incident light by the dienol. Product extraction and analysis indicated that the yields of **8** and of recovered **1** were identical within experimental error for the samples with and without dienol. Further, no additional products were observed in the diene sample and the amount of recovered ketone was the same for the two samples. It should be pointed out that complications due to trapping of phenoxyl or phenacyl radicals by diene should lead to increased yields of either hydrogen abstraction or diene addition products and these were not detected; further, a lower mass balance would have been expected in the diene experiment if increased yields of nonextractable materials were formed.

Irradiation of **1** in either Na-X or cellulose for prolonged periods of time resulted in pronounced yellowing of the samples. However, extraction of the samples showed only recovered starting material (80–90% recovery) with undetectable amounts of the usual solution products. The loss of starting material is presumably due to the formation of oligomeric products. Inspection of ground state UV spectra for the samples before and after irradiation indicated that the low product yields were *not* primarily due to screening of the light by photoproducts. These results are in agreement with previous experiments in which inefficient product formation (relative to solution) was observed when **1** was irradiated on lignin-free paper fibers (7).

Discussion

The combination of product studies and triplet lifetimes for ketone **1** in solution indicates that the triplet decay is dominated by β-phenyl quenching in aprotic solvents such as acetonitrile and by a combination of β-phenyl quenching and β-cleavage in protic solvents such as alcohols (11). The slower triplet decays in ethanol have been rationalized on the basis of a slower rate of β-phenyl quenching due to hydrogen bonding. Our solution results for the substituted ketones indicate that there are substantial substituent effects on the triplet lifetimes for ketones **1–6** in acetonitrile. Both *meta* and *para* methoxy substituents decrease the triplet lifetime relative to the parent (**2**) while a 4-cyano substituent lengthens it. The β-phenyl quenching mechanism in β-arylpropiophenones and α-phenoxyacetophenones is well established to occur via charge transfer quenching involving the carbonyl n,π^* state for ketones with either n,π^* or π,π^* lowest excited triplet states (13, 31–34). Thus, our results are consistent with a faster rate of β-phenyl quenching for those ketones containing β-aryl groups with stronger electron-donating properties (i.e, methoxy). Such effects have been observed previously upon comparison of triplet lifetimes for 4-methoxy-β-phenylpropiophenones with and without methyl substituents in the β-aryl ring (34).

The substituent effects on the solution lifetimes for ketones **1–6** are consistent with β-phenyl quenching as the controlling factor, particularly as this has been demonstrated to be the case for **1**. The fact that the triplet lifetimes for most of the ketones are substantially longer in ethanol than in acetonitrile also points towards similar mechanisms for triplet decay in each case. However, it is also possible that the substituents are altering the rate of β-cleavage. Of particular interest in this regard is recent work in which the rate constants for β-cleavage for α-(aryloxy)acetophenones were shown to be substantially higher when the α-aryloxy ring was substituted with electron-releasing groups such as 4-methoxy (14). These results suggest that electron-donating substituents may be expected to increase the rates for both β-cleavage and β-phenyl quenching. However, given the recent conclusions regarding the importance of singlet processes for these ketones (15, 16), detailed product studies with and without triplet quenchers and under conditions where all radicals are scavenged would be required to determine whether or not β-cleavage is a significant triplet decay pathway in any particular case. Despite this, the long lifetime for the 4-cyano ketone (**6**) suggests that both of the possible deactivation pathways are slow for electron-withdrawing substituents.

Product studies indicate that the chemistry of **1** on silica occurs via β-cleavage, as in solution. In the absence of hydrogen donors, the radical pairs recombine to give the rearranged ketone (**8**) and presumably also to regenerate starting material. The absence of the phenacyl radical dimer that is formed in solution indicates that geminate recombination dominates and suggests that singlet chemistry may be largely responsible for product formation. This hypothesis is confirmed by product studies in the presence of triplet quenchers, in which no change in the relative product yields was observed in the presence of sufficient diene to completely quench all triplet excited states. The high cage effect for recombination of phenacyl-phenoxyl radicals demonstrates that these radicals are not very mobile on the silica surface. These results are in contrast to those obtained for other radical pairs on silica surfaces. For example, on silica, benzyl radicals generated from a triplet precursor recombine with product ratios that are very close to the statistical ratio obtained in solution, leading to cage effects of ~0 (35). Similar radicals generated as a singlet pair show a cage effect of 40% (36). The predominance of ketone **8***a*, which corresponds to *ortho* coupling of the two radicals, is also indicative of restricted mobility of the radicals. For example, ring coupling of phenylacetyl–benzyl radical pairs has been shown to yield both *ortho* and *para* products with the *ortho* isomer being favored when the mobility of the radical pairs is more severely restricted (37).

The triplet states of ketones **1–6** are all substantially longer lived on a silica surface than in solution. The nonexponential nature of the decay kinetics suggests that there may be a distribution of triplet decays on the surface. It is also of interest to note that triplets **1–6** all decay more rapidly than triplet acetoveratrone. This sugests that additional decay pathways, presumably β-phenyl quenching and (or) β-cleavage, are responsible for the enhanced triplet decay. The results for **1** in the presence of diene quencher indicate that product formation on silica arises primarily, if not ex-

For personal use only.

clusively, from singlet excited state chemistry, demonstrating that, at least for this ketone, β-phenyl quenching is the dominant triplet decay pathway. It is also interesting to note that the relative decay rates for the series of ketones that we have examined show exactly the same trends on silica as in solution. Although surface adsorption obviously imposes substantial restrictions to the mobility of the triplet ketone and leads to pronounced decreases in the kinetics for triplet decay, the triplet lifetimes still reflect the substituent effects that are observed in solution. Similar results have been observed previously for triplet valerophenone and butyrophenone as compared to acetophenone included in Silicalite (19).

The results for ketone **1** included in Na-X are markedly different from those in solution or on a silica surface. Firstly, product formation is very inefficient in this case and only starting material is isolated even after lengthy irradiations. Secondly, the triplet ketone decays much more slowly than on the silica surface. Interestingly, there is still some difference between the decay kinetics for acetoveratrone and **1**, although it is certainly less pronounced than on the silica surface. This could be taken as evidence that either β-phenyl quenching or β-cleavage contributes to the triplet decay for **1**. However, it is likely that complexation with cations (i.e., Na^+) present in the zeolite cavities is responsible for the long and nonexponential triplet decays for both ketones in Na-X (38). Thus, the different sizes and polarities of **1** and **7** may also lead to substantial differences in either the strength of interaction between the ketone and the Na cations or in the type and (or) number of accessible complexation sites; such effects will certainly contribute to the observed differences in the triplet decays of **1** and **7**.

Product studies for ketone **1** in cellulose are similar to those in Na-X, in that product formation is a relatively inefficient process. In terms of the behavior of the triplet ketones on this support, the results are intermediate between those of silica and Na-X. The triplet decays show both a fast and a slow component and the results for acetoveratrone are similar to those for **1** and the other α-(aryloxy)acetoveratrones. Therefore, there is no reason to postulate that the fast component in the decay of triplet **1** results from ketones for which either β-phenyl quenching or β-cleavage is an important decay pathway. One possible explanation for the two different types of kinetics is that some ketones are close together and decay by self-quenching, which is known to be an efficient triplet deactivation mechanism in solution and on silica (25). The lower signal intensities for cellulose compared to those for either silica or Na-X zeolite, even after accounting for differences in absorption at the excitation laser wavelength, may indicate that a fraction of the triplets generated on this support decay on a timescale that is too short for our detection window. The 1–2 μs component that is observed may represent triplets that undergo self-quenching in the time window that we can monitor, while the longer lived fraction is due to isolated ketones, probably in a distribution of different sites. An alternate explanation is that the ketones responsible for the fast component are in an environment where they can decay by interaction with the cellulose framework; one possibility could be hydrogen abstraction from the cellulose to generate a ketyl radical, although such processes are usually less efficient for π,π^* ketones. In this regard it should be noted that similar ketyl radicals have recently been shown to have lifetimes shorter than 0.5 μs in solution and, thus, would not be easily observable in our experiments (6). This explanation seems less likely, given that we have been unable to extract any of the expected products of ketyl radical fragmentation from irradiated samples on cellulose.

It is clear that product formation from ketone **1** on cellulose is an inefficient process. Further, there is no evidence that β-cleavage of the triplet occurs to a significant extent. It is likely that some singlet β-cleavage still occurs since this has been demonstrated to be an important pathway in solution (11, 15, 16) and on a silica surface. However, the low product yields suggest either that this is a minor process or that geminate recombination of the initial radical pair to regenerate starting material predominates over *ortho* or *para* ring addition to give rearranged ketones **8**. If the latter is true, it indicates that the cellulose framework imposes very substantial restrictions on both the translational and rotational mobility of the phenacyl–phenoxyl radical pairs.

The present results demonstrate that the behavior of the excited states of α-(aryloxy)acetoveratrones and of the radical pairs generated from them is quite sensitive to environmental factors. It is clear that one cannot simply extrapolate directly from solution results in order to understand the behavior in any particular heterogeneous system. However, studies of model compounds in structured environments such as cellulose that mimic many of the features of wood pulps can provide valuable insight into the primary steps involved in the photoreversion of lignin-rich paper products.

Experimental

Instrumentation

Melting points were measured on a Mel-Temp II melting point apparatus and are uncorrected. ^1H and ^{13}C NMR spectra were recorded on a Bruker AM400 spectrometer with deuterochloroform as solvent and residual chloroform (7.24 ppm) as the reference. Gas chromatograph – mass spectra (GC/MS) were recorded on a Hewlett-Packard model 5790A instrument equipped with a 12 m × 0.2 mm cross-linked methyl silicone (HP-1) column. Gas chromatographs were obtained with a Hewlett-Packard 5890 system equipped with the same column. UV-visible spectra were recorded on a Varian Cary 3 spectrometer equipped with a diffuse reflectance accessory for measuring solid samples.

Materials

Davisil 634 silica gel (480 $m^2\ g^{-1}$, 60 Å pore diameter, 100–200 mesh), acetoveratrone, phenols, and *trans,trans*-hexa-2,4-dienol were obtained from Aldrich. Microcrystalline cellulose DS-0 and 13X zeolite (NaX) were obtained from Fluka and BDH, respectively. Ketones **1–6** were synthesized by reaction of α-bromoacetoveratrone with the corresponding phenol in acetone in the presence of potassium carbonate according to the literature procedure reported for α-guaiacoxyacetoveratrone (39). The ketones were recrystallized from ethanol before use. The physical and spectroscopic data for ketone **1** are in agreement with the reported values in the literature (39). Melting points and spectral data for ketones **2–6** are given below.

α-(Phenoxy)acetoveratrone (2): mp 95–96°C; ^1H NMR: 3.90 (s, 6H, 3- and 4-OCH_3), 5.18 (s, 2H,CH_2), 6.86 (d, J = 8.4 Hz, 1H, 5-H), 6.89–6.95 (m, 3H, 2′-, 4′-, and 6′-H), 7.21–7.27 (m, 2H, 3′- and 5′-H), 7.52 (d, J = 2 Hz, 1H, 2-H), 7.79 (dd, J = 8.4 and 2 Hz, 1H, 6-H); ^{13}C NMR: 55.87, 55.97, 70.5, 110.0, 110.2, 114.7, 121.4, 122.7, 127.6, 129.4, 149.1, 153.8, 157.9, 193.0; MS, *m/e*: 272 (M^+), 165 (M^+ − 107). Anal. calcd. for $C_{17}H_{15}NO_4$: C 68.69%, H 5.05%, N 4.71%; found: C 68.26%, H 5.06%, N 4.86%.

Sample preparation

Silica and zeolite were activated by heating at 100°C and 200°C, respectively, for about 12 h and the activated solids were stored in a desiccator before use. Cellulose was used as received. The solid support and known amounts of the ketone (plus coadsorbate, if required) were stirred in 1:3 dichloromethane–hexane (3 mL g^{-1}) for 3 h. The solvent was then removed on a vacuum pump and the sample was dried at 60°C under vacuum for 2 h.

Laser flash photolysis

The experimental setup for diffuse reflectance and transmission laser flash photolysis has been described elsewehere (25). Either a Lumonics HY-750 Nd:YAG laser (fourth harmonic; 266 nm; 10-ns pulses; <30 mJ/pulse) or a Lumonics EX-530 excimer laser (XeCl gas mixture; 308 nm; 8-ns pulses; <45 mJ/pulse) was used for sample excitation. Solutions of ketones ($\sim 6 \times 10^{-5}$ M) in acetonitrile were deaerated by purging with nitrogen. All the solution experiments were done using a 7 mm × 7 mm quartz flow cell attached to a sample reservoir to minimize problems related to sample depletion and buildup of products. For the diffuse reflectance experiments, the solid samples were contained in 3 mm × 7 mm quartz cells and were purged with nitrogen for 30 min. The solid sample was either moved or shaken during the experiments to provide a fresh sample surface for each laser shot. The diffuse reflectance data are reported as $1 - R_t$, where $R_t = J_t/J_0$; J_t is the reflected light from the sample at time t after laser excitation and J_0 is the initial reflected light from the sample.

Product studies

A sample containing ketone **1** on silica (5% loading by weight) was prepared as described earlier. The sample was placed in a Pyrex tube, degassed by purging with nitrogen, and irradiated with 300 nm lamps in a Rayonet reactor. The irradiation cells were mounted on a vertically rotating bar in order to provide uniform exposure of the sample. After 16 h photolysis, the products were extracted by continuous extraction of the sample with 1:2 chloroform-methanol at 60°C. GC and GC–MS analysis of the extract revealed the presence of two materials that were isomeric with the starting ketone. The retention time and mass spectrum for the minor component of the mixture are in agreement with those for an authentic sample of α-(4-hydroxy-3-methoxyphenoxy)acetoveratrone. Additional evidence for this assignment is provided by conversion of the free phenolic groups in the product mixture to their silicon-protected analogs by treatment with *tert*-butyldimethylchlorosilane and pyridine in dichloromethane. This led to the disappearance of the two primary products and the appearance of two new silicon-protected isomers. These were isolated as a mixture by column chromatography on silica gel using 5% ethyl acetate – dichloromethane as the eluent. The ^{1}H NMR, GC, and GC–MS data for one component corresponded to the data for an authentic sample of α-[(4-*tert*-butyldimethylsilylhydroxy)-3-methoxyphenoxy]acetoveratrone. The ^{1}H NMR and GC–MS data for the second component are consistent with the silicon-protected form of α-(2-hydroxy-3-methoxyphenoxy)acetoveratrone.

For product studies in the presence of the triplet quencher, silica samples containing 2% each of α-guaiacoxyacetoveratrone and *trans,trans*-hexa-2,4-dienol were prepared. The samples with and without dienol were irradiated with 350 nm Rayonet lamps and extracted as outlined above. Product yields were determined by GC using hexadecane as an internal standard. No significant difference in either the amount of recovered ketone or the product yields were observed for the samples containing diene as compared to those with ketone alone.

Acknowledgments

This work was supported by a National Centres of Excellence grant to the Mechanical and Chemimechanical Wood Pulps Network. We thank Dr. Ross Barclay and Dr. James Hilborn (Mount Allison University) for their generous gift of α-(4-hydroxy-3-methoxyphenoxy)acetoveratrone and its *tert*-butyldimethylsilyl derivative.

MICHEL GIRARD, FRANÇOIS CLAIRMONT, ASPI MANECKJEE, NICOLE MOUSSEAU, BRIAN A. DAWSON, and LARRY W. WHITEHOUSE. Can. J. Chem. **71**, 1349 (1993).

Ronidazole and dimetridazole, two important veterinary drugs, were found to react readily in the presence of cysteine, under neutral aqueous conditions, leading to the formation of 5-*S*-cysteinyl-1-methylimidazole-2-methanol carbamate and 5-*S*-cysteinyl-1,2-dimethylimidazole respectively through nitro displacement. The reaction products were identified by spectroscopic techniques. The rate of reaction was accelerated by increasing the pH of the medium and was accompanied by a slight change in the product distribution. The reaction was also observed, albeit at a slower rate than that of cysteine, with glutathione, another ubiquitous thiol substrate found in biological systems. While this type of nucleophilic reaction has previously been observed for suitably substituted nitrobenzene derivatives, to the best of our knowledge its occurrence with nitro-heteroaromatics has never been reported. The ready reaction of the parent nitro drugs under such mild aqueous conditions suggests that this may be an alternative path for the formation of nonextractable bound residues in tissues.

MICHEL GIRARD, FRANÇOIS CLAIRMONT, ASPI MANECKJEE, NICOLE MOUSSEAU, BRIAN A. DAWSON et LARRY W. WHITEHOUSE. Can. J. Chem. **71**, 1349 (1993).

On démontre que le ronidazole et le dimétridazole, deux médicaments vétérinaires importants, réagissent facilement avec la cystéine, dans des conditions aqueuses neutres, pour former le carbamate du 5-*S*-cystéinyl-1-méthylimidazole-2-méthanol et le 5-*S*-cystéinyl-1,2-diméthylimidazole respectivement par déplacement du groupe nitro. Les produits de la réaction ont été identifiés à l'aide de techniques spectroscopiques. L'augmentation du pH du milieu réactionnel a eu pour effet d'accélérer la réaction ce qui, par ailleurs, conduit à une légère modification de la distribution des produits. La même type de réaction a été observé avec le glutathion, un autre thiol retrouvé fréquemment dans les systèmes biologiques. Cette réaction de substitution nucléophilique avait déjà été rapportée pour certains nitrobenzènes convenablement substitués, mais n'avait jamais encore été décrite avec les nitro-hétéroaromatiques. En considérant la facilité avec laquelle cette réaction s'effectue à partir des 5-nitroimidazoles, il apparait plausible de considérer ce processus comme voie alternative pour la formation de résidus entre ces médicaments et les macromolécules tissulaires.

Introduction

Ronidazole (RNZ, 1-methyl-5-nitroimidazole-2-methanol carbamate) (**1**) and dimetridazole (DMZ, 1,2-dimethyl-5-nitroimidazole) (**2**) are veterinary drugs widely used for the treatment of microbial infections in food-producing animals. Metabolism studies (1, 2) have shown that small amounts of these drugs are retained in tissues as nonextractable protein-bound adducts of unknown toxicity. While the nature of these adducts remains unknown, a general structure has been proposed, based on the widely accepted mechanism of activation for these nitroimidazoles (2) involving formation of reduced 4-thiosubstituted imidazoles. To gain further insight into the structure of these biomolecular adducts, the reactivity of ronidazole and dimetridazole towards thiol-containing substrates has been studied. Thus, the preparation of 5-amino derivatives of DMZ and RNZ, bearing thio substituents at C-4 of the imidazole ring, and obtained through Michael type nucleophilic reactions performed under strongly reducing conditions, was reported (3). In the present study, the reactivity of DMZ and RNZ towards thiol substrates under neutral and basic aqueous conditions was examined and it was found that both compounds react readily with loss of the characteristic strong UV maximum associated with the conjugated nitro group. Herein, the structural identification of the reaction products, parameters of the reaction, and the possible metabolic relevance of these findings are reported.

Experimental

Instrumentation

HPLC experiments were performed using a Waters 600E multisolvent delivery system, a Waters 990+ photodiode array detector, and a Waters 700 satellite WISP autosampler. Proton and carbon-13 NMR spectra were recorded at 300 K on a Bruker AM400 spectrometer equipped with an Aspect 3000 computer and process controller, using DISNMR version 891101.0. Standard microprograms from the Bruker Software Library were employed. $^{1}H-^{13}C$ direct and long range correlation spectra were obtained in inverse detection mode. The nOe difference experiments were carried out using a 2.0 s delay after irradiation for 2.0 s. After subtraction of the off-resonance control free-induction-decay (FID) from those acquired for each decoupling frequency, the resulting FID was processed with a line-broadening of 2.0 Hz. FAB mass spectra were obtained on a VG ZAB 2F at a resolution of 2000, a mass range of 100–950 in 5 s, an accelerating votage of 7000 V, an M-Scan FAB source, and using Xe at 10 kV. "Magic bullet," thioglycerol, and glycerol were used as matrices.

Materials and methods

Dimetridazole, cysteine, and glutathione were purchased from Sigma Co. (St. Louis, Mo.). Ronidazole was obtained from MSD-AGVET (Merck Frosst, Kirkland, Qué.). Chemicals used were analytical reagent grade or better; solvents were HPLC grade. HPLC separations were on Brownlee Spheri-5 phenyl columns (250 × 4.6 mm i.d., 5 μm for analytical, and 250 × 7.5 mm i.d. for semi-preparative; Brownlee Laboratories, Santa Clara, Calif.) with a mobile phase consisting of pH 3.6 (adjusted with acetic acid)

0.05 M ammonium acetate:acetonitrile (95:5) at a flow rate of 1 mL/min. For preparative experiments, fractions containing the desired product were pooled and freeze-dried.

*Preparation of 5-thiosubstituted imidazoles **3**, **4**, **5**, and **6***

The 5-thiosubstituted imidazoles were obtained from the appropriate combination of starting imidazole and thiol substrate as reported in Table 1. The reaction proceeded at the indicated pH and with the same substrate-to-thiol molar ratio (1:3) as in the following example.

The following procedure was used in a typical experiment: dimetridazole (71 mg, 0.5 mmol) was added to a 0.01 M NaH_2PO_4 buffer solution (5 mL) containing cysteine (187 mg, 1.5 mmol) under inert atmosphere, and the pH adjusted to 9 with 1 M NaOH. The mixture was placed in a water-bath incubator/shaker at 37°C and the progress of the reaction was monitored by HPLC. At completion, the reaction mixture was neutralized with phosphoric acid. The majority of the buffer salts and unreacted starting material were removed by a pre-purification step on a short C-18 or phenyl-bonded silica column (Sep-Pak or Bond-Elut). Typically, an aliquot (1 mL) was adsorbed on a 3 mL column and the eluate was discarded. Aqueous washings (3 × 1 mL) were combined, concentrated under reduced pressure, and the resulting solution purified by semi-preparative HPLC using the conditions described in the previous section. The fractions containing the desired product were pooled and the solvent was removed by lyophilization. The purified product was identified as 5-*S*-cysteinyl-1,2-dimethylimidazole (**4**) by spectroscopic methods. Structural data for the imidazoles **3**–**6** were as follows:

*5-S-Cysteinyl-1-methylimidazole-2-methanol carbamate **3**:* C-13 and proton NMR chemical shifts, see Table 2; UV λ_{max} (from HPLC): 229 nm; FAB-MS: *m/z* 275 [M^++1]; high-resolution FAB-MS: *m/z* 275.0863 for $C_9H_{15}N_4O_4S$ (M+H), calcd. 275.0814.

*5-S-Cysteinyl-1,2-dimethylimidazolec **4**:* C-13 and proton NMR chemical shifts, see Table 2; UV λ_{max} (from HPLC): 231 nm; FAB-MS: *m/z* 216 [M^++1].

*5-S-Glutathionyl-1,2-dimethylimidazole **5**:* C-13 and proton NMR chemical shifts, see Table 2; UV λ_{max} (from HPLC): 241 nm; FAB-MS: 402 [M^++1].

*5-S-Cysteinylglycinyl-1,2-dimethylimidazole **6**:* C-13 and proton NMR chemical shifts, see Table 2; UV λ_{max} (from HPLC): 225 nm; FAB-MS: 273 [M^++1].

Results

Reactivity towards cysteine

Reverse-phase HPLC (RP-HPLC) monitoring of the reaction between ronidazole and excess cysteine, incubated under neutral aqueous conditions, showed the formation of an unknown product, reaching 25% of the integrated area after 93 h of incubation (Table 1, entry 1). Due to the poor solubility of RNZ in neutral aqueous media a large amount of unreacted RNZ (67%) was detected. Using photodiode array detection it was possible to examine the UV spectrum of the unknown. The 310 nm maximum characteristic of 5-nitroimidazoles was not observed, a finding not unlike that observed under strong reducing reaction conditions (3), and suggesting the loss of the nitro group. The UV spectrum featured a single maximum at 229 nm, again consistent with the absence of the conjugated nitro group. Upon isolation, the unknown was identified using standard spectroscopic techniques. The proton and carbon-13 NMR spectra displayed signals (Table 2) indicating the presence of one unit of cysteine and one unit of the imidazole ring moiety. The proton chemical shift assignments were straightforward and unambiguous. The carbon-13 chemical shifts were assigned using carbon–proton correlation experiments with inverse detection. Standard experiments were used to obtain both direct and multiple-bond correlation. Results were consistent with the presence of a sulfur substituent at C-5 of the imidazole ring and chemical shifts correlated well with values calculated from additivity rules. Further evidence for the position of the cysteine substituent was obtained from nOe experiments which showed enhancements for the olefinic resonance upon irradiation of the cysteine resonances. The high-resolution FAB mass spectrum showed a fragment at *m/z* 275.0863, corresponding to molecular formula

$C_9H_{15}N_4O_4S$ (calcd. 275.0814) for $[M^+ + 1]$, consistent with the proposed structure. Thus, on the basis of the previous considerations, the structure of the unknown was assigned as 5-*S*-cysteinyl-1-methylimidazole-2-methanol carbamate (**3**). Unlike that observed under strong reducing conditions (3), the carbamate group remained unsubstituted under these conditions. The reaction was conducted under inert atmosphere or in the presence of air without any apparent change in product distribution.

The reactivity of dimetridazole (DMZ) towards cysteine was examined under similar reaction conditions, readily leading to the formation of 5-*S*-cysteinyl-1,2-dimethylimidazole (**4**) as the major reaction product (Table 1, entry 3). The structural identification was based mainly on the similarity of the chemical shifts and coupling pattern observed in the proton and carbon-13 NMR spectra (Table 2) with those of **3**. The rate of reaction, monitored by following the disappearance of dimetridazole by HPLC, appeared faster than that of RNZ, with only 8% of the original imidazole detectable after 42 h.

Both RNZ and DMZ showed increased reactivity when the reactions were conducted at pH 9. Only 12% of the initial RNZ remained unreacted after 120 h of incubation while no DMZ was detectable after 18 h (Table 1, entries 2 and 4, respectively). However, this increased reaction rate at higher pH did not translate into comparable increases in the amounts of 5-thiosubstituted imidazoles formed. The yield of RNZ-derived imidazole **3** was only marginaly higher, while the relative amount of the DMZ-related compound **4** appeared slightly lower. In both cases the use of basic reaction conditions may have facilitated the formation of side reaction products, often observable as early eluting peaks in the HPLC traces. Probable side reactions would include carbamate hydrolysis, imidazole ring opening, and nitro reduction products.

Reactivity towards glutathione

Ronidazole and excess glutathione (GSH) reacted at pH 9 (Table 1, entry 5) and led to the formation of a complex mixture of unidentified compounds, likely products of carbamate and partial glutathione hydrolysis, ronidazole ring opening, and possibly nitro group reduction. Reaction under neutral conditions resulted in almost complete recovery of starting RNZ. On the other hand, when dimetridazole was reacted with excess GSH at pH 9 (Table 1, entry 6), the expected imidazole **5** was formed as the major reaction product (35%) along with a minor constituent (17%), easily separated by HPLC, which was identified as the 5-thiosubstituted imidazole dipeptide **6**. Structures were deduced mainly from carbon-13 and proton NMR data presented in Table 2. The latter compound lacked the glutamine residue present in glutathione. The reaction monitored by HPLC proceeded at a slower rate than that observed with cysteine, a likely consequence of the steric hindrance due to the larger glutathione molecule.

Indirect evidence that the reaction proceeded through attack by the thiol group was obtained when methionine, a

natural amino acid bearing a methyl substituted thiol group, failed to react with dimetridazole (Table 1, entry 7).

Discussion

The reactivity of the two nitroimidazoles examined in this study involved substitution of the nitro group by thiol-containing compounds in fair to good yield. The rate enhancement observed by raising the pH of the reaction is consistent with the nucleophilic reaction proceeding through the thiolate ion. Such thiol-mediated nitro group displacements have been shown to occur readily in appropriately substituted aromatic compounds, and were the subject of a review (4). The classical addition/elimination mechanism has usually been suggested to account for the formation of most products (5). The ease with which the reaction proceeded was explained in terms of the polarizability of the thiolate ion, which would minimize repulsion in the transition state. Reaction conditions generally reported for the preparation of these aromatic thioethers usually involve in situ generation of the thiol anion in polar aprotic solvent. However, to the best of our knowledge, the reaction observed in this study is the first example of this type of reaction occurring with nitro-substituted heteroaromatic compounds and proceeding under aqueous (protic) conditions.

The formation of appreciable amounts of cystine (dicysteine) in the RNZ and DMZ reactions conducted under inert atmosphere suggests that the reaction more likely proceeds via a radical anion mechanism, involving the formation of the nitro anion radical intermediate **8**. In such a case, cystine would be formed upon dimerization of the thiyl radical generated upon one-electron reduction of the thiolate to form the radical anion **8** (eq. [1]). In a recently published article (6), the RNZ-derived nitro radical anion **8** (R = $OCONH_2$) was detected in intact rat hepatocytes, lending support to its intermediacy in the biological activation mechanism of 5-nitroimidazole drugs.

Consideration of the ease with which 5-thiosubstituted imidazoles are formed from their parent nitro compounds, notably under such mild aqueous conditions, leads us to hypothesize that this process may have some biological significance. Until now the only mechanism to account for the formation of thiosubstituted imidazole adducts was one involving a reductive process that was shown to occur in mammalian cells under very specific conditions (1, 2), the end product being 4-thiosubstituted imidazoles. The results presented in this study describe an alternative chemical mechanism for the substitution of 5-nitroimidazoles. This mechanism was demonstrated to lead to the formation of 5-thiosubstituted imidazoles and offers an alternative pathway by which drug-bound residues are formed with tissue macromolecules.

Fourier transform infrared spectroscopy studies of cyanide ion solutions of dimethylformamide and aqueous dimethylformamide

DAVID J. JOBE[1] AND KENNETH CHARLES WESTAWAY[2]

Department of Chemistry and Biochemistry, Laurentian University, Sudbury, ON P3E 2C6, Canada

Received February 25, 1993

DAVID J. JOBE and KENNETH CHARLES WESTAWAY. Can. J. Chem. **71**, 1353 (1993).

Fourier transform infrared spectroscopy has been used to investigate the behaviour of HCN and alkali metal and tetraethylammonium cyanides in DMF and aqueous DMF. The cyanide ion exists as free ions and ion pairs in pure DMF but as water-solvated and DMF-solvated ions in aqueous DMF. The aqueous DMF solutions can be treated as a pseudo two-phase system with a distribution coefficient of 0.018 between the aqueous and DMF-rich pseudo phases. A kinetic analysis of the cyanide ion – benzyl chloride reaction in DMF and aqueous DMF has shown that the rate constant for the S_N2 reaction is markedly decreased with the addition of as little as 2.5% water. This decrease is primarily due to changes in transition state solvation. The S_N2 reactions between cyanide ion and benzylmethyl-4-substituted phenylsulphonium perchlorates in 20% aqueous DMF have also been investigated.

DAVID J. JOBE et KENNETH CHARLES WESTAWAY. Can. J. Chem. **71**, 1353 (1993).

On a utilisé la spectroscopie infrarouge par transformation de Fourier pour étudier le comportement du HCN et des cyanures de tétraéthylammonium et des métaux alcalins dans le DMF et le DMF aqueux. Dans le DMF pur, les ions cyanures existent sous la forme d'ions libres et de paires d'ions alors que, dans le DMF aqueux, ils existent sous la forme d'ions solvatés par l'eau ou par le DMF. On peut traiter les solutions aqueuses de DMF comme un système à pseudo deux phases avec un coefficient de partage de 0,018 entre les phases pseudo aqueuses et pseudo DMF. Une analyse cinétique de la réaction de l'ion cyanure avec le chlorure de benzyle dans le DMF et dans le DMF aqueux démontre que la constante de vitesse de la réaction S_N2 est de beaucoup diminuée par l'addition d'aussi peu que 2,5% d'eau. Cette diminution est principalement due à des changements dans la solvatation de l'état de transition. On a aussi étudié les réactions S_N2 de l'ion cyanure avec les perchlorates de benzylméthyl(substitués en position 4)phénylsulfonium dans de DMF contenant 20% d'eau.

[Traduit par la rédaction]

Introduction

Loupy and Seyden-Penne investigated the effect of counterion association on the nucleophilicity of the cyanide ion in dipolar aprotic solvents (1–3). Their studies demonstrated that the rates of substitution and elimination reactions are dependent on both the cation of the cyanide salt (MCN) and the solvent. To assist in their interpretation of the kinetic results, solutions of cyanide salts were characterized in dipolar aprotic solvents using infrared (IR) spectroscopy (4, 5). This work showed that the cyanide ion IR absorptions are strongly dependent on the cation but show only a slight dependence on the solvent. From these studies, Loupy et al. concluded that the alkali and alkaline earth metal cyanide salts exist as ion pairs having stoichiometries of $M^+/solvent/CN^-$, M^+/CN^-, and $M^+/CN^-/M^+$ in dimethylformamide (DMF) and dimethyl sulphoxide (DMSO). The "free" or non-complexed cyanide anion was observed only when the cation was the larger tetraphenylarsonium ion. The effect of mixed solvents on the form and nucleophilicity of the cyanide ion has not been studied.

In this study, DMF and aqueous DMF solutions containing either potassium cyanide, sodium cyanide, tetraethylammonium cyanide (Et_4NCN), or hydrogen cyanide were characterized using Fourier Transform Infrared Spectroscopy (FT-IR). Then, FT-IR spectroscopy was used to determine the rate constants for the S_N2 displacement reactions between cyanide ion and several substrates in these solvents. This study was undertaken to determine if the addition of water decreased ion pairing and hence removed the dependence of the reaction rate on the cation.

Experimental

Reagents

The alkali metal salts, potassium cyanide and sodium cyanide (Fisher, analytical grade), and tetraethylammonium cyanide (Sigma, 94%) were used as purchased. All the cyanide solutions were prepared on a percent volume (v/v) basis with spectroscopic grade DMF (Caledon) and deionized, double-distilled water. The benzyl chloride (Aldrich >99%) was washed with an aqueous sodium bisulfite solution (6), dried over $CaCl_2$, and purified by distillation, bp 126°C at 26 Torr (1 Torr = 133.3 Pa).

The salts, benzylmethyl-4-chlorophenylsulphonium perchlorate (CS) and benzylmethyl-4-methoxyphenylsulphonium perchlorate (MeOS), were synthesized by passing an aqueous solution of the tosylate salt through an Amberlite IRA-400, 60–100 mesh anion (Cl^-) exchange column that had been converted to the ClO_4^- form. After the solvent had been removed on a rotary evaporator, the resulting salt was recrystallized from ethanol. The tosylate salts were synthesized according to the procedure described by Schowen (7).

HCN was synthesized by adding a 50% H_2SO_4–water mixture to a three-necked flask containing 5 g of potassium cyanide (8). The resulting $HCN_{(g)}$ was passed through a $CaCl_2$ drying tube and collected in a 50-mL round-bottomed flask cooled in an ice bath. The HCN was stored as a solution in dry DMF to keep it from evaporating.

FT-IR spectra

All spectra were recorded at room temperature (ca. 23°C) on a Bomem Michelson 100 FT-IR spectrometer using a CaF_2 solution cell. The path length for the cell was determined by a diffraction method to be 0.0104 cm. Due to the low IR absorption for DMF in the 2000–2300 cm^{-1} region, only 25–40 scans were required to obtain good quality spectra. However, between 100 and 500 scans

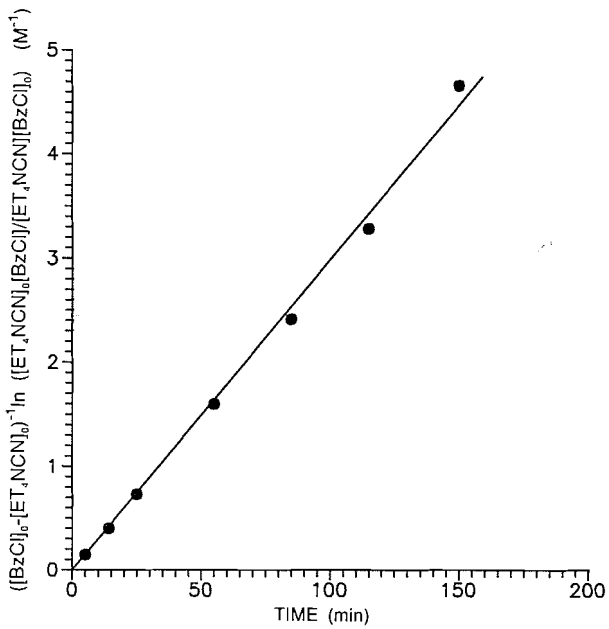

FIG. 1. A typical rate plot of $([BzCl]_0 - [Et_4NCN]_0)\ln([Et_4NCN][BzCl]_0/[Et_4NCN]_0[BzCl])$ versus time for the reaction of benzyl chloride with tetraethylammonium cyanide in 15% aqueous DMF at 30.00°C.

were needed to obtain acceptable spectra for samples containing more than 20% water. In some cases, these spectra had to be background corrected due to slight differences in the solvent composition between the reference and sample solutions.

Kinetic studies

The rate constants for the S_N2 reactions between benzyl chloride (BzC) and cyanide ion were determined at 30.00 ± 0.01°C, Table 1. One-millilitre aliquots were removed from the thermostated solution and the FT-IR spectra were taken using an average of 25 scans. Since the samples could not be quenched before analysis, the average time between the removal of the sample and the termination of the acquisition was used to calculate the rate constant. This period was typically 2 min. Using the average time rather than the time the aliquot was removed does not alter the slope (rate constant) of the second-order plot.

For those kinetic studies where a sulphonium salt was the substrate, a 5.0-mL sample containing tetraethylammonium cyanide and the appropriate sulphonium salt was prepared, Table 1. A portion of this solution was transferred to the CaF_2 cell and the rate constant was measured at 23.0 ± 0.5°C. For the benzylmethyl-4-chlorophenylsulphonium perchlorate reaction with cyanide ion, only 10 scans were used to obtain a spectrum so more data points could be collected for this fast reaction.

The percent reaction was calculated from the decrease in the water-solvated cyanide ion peak in the FT-IR spectrum. Then, the rate constants (k_2), Table 1, were determined from the slopes of the least-squares fit of the second-order plots (9). A typical rate plot for the reaction of benzyl chloride with cyanide ion in aqueous DMF is shown in Fig. 1. The plots had correlation coefficients between 0.992 and 0.997. All reactions were followed to 80% of completion, except for the reaction in 20% aqueous DMF, which was monitored to 54% of completion. The rate constants obtained by this method are precise to within ±5%.

Results and discussion

FT-IR characterization

FT-IR spectra for MCN in DMF

Figure 2 shows the FT-IR spectra obtained for various concentrations of tetraethylammonium cyanide in both dry and aqueous DMF. The spectra of tetraethylammonium cyanide in dry DMF, Fig. 2(*a*), have two concentration-dependent absorptions, at 2054 and 2062 cm^{-1}. The FT-IR spectrum for this salt has identical maxima and similar intensity ratios to the spectrum obtained by Loupy and Corset for tetraphenylarsonium cyanide (4, 5). The similarity is not unexpected given that the tetraethylammonium cation is also large and would be expected to promote the formation of the "free" cyanide ion. The FT-IR absorption for the "free" cyanide ion has been assigned to the peak at 2054 cm^{-1} while the peak at 2062 cm^{-1} has been assigned to either a M^+/CN^- or a $M^+/DMF/CN^-$ ion pair. The assignment of the cation-associated form to the absorption at 2062 cm^{-1} was confirmed by adding tetraethylammonium chloride to a DMF solution containing tetraethylammonium cyanide. The increase in the absorption at 2062 cm^{-1} and the slight decrease in the absorption at 2054 cm^{-1} indicates that more of the cyanide ion pair is formed in the presence of the excess tetraethylammonium ion.

The assignment of the FT-IR absorption peak at 2054 cm^{-1} to the "free" cyanide ion is supported by the change in the sodium cyanide spectrum when the macrocyclic crown ether, 15-crown-5 ether, is added. The FT-IR spectrum for sodium cyanide in DMF in the absence of 15-crown-5 ether has strong FT-IR absorption maxima at 2062 and 2080 cm^{-1}. The addition of 15-crown-5, which is known to complex sodium ions (10), results in a decrease in the absorption at both 2062 and 2080 cm^{-1} and an increase in the absorption at 2054 cm^{-1}. Presumably the decrease in the absorptions at 2062 and 2080 cm^{-1} occurs because the Na^+/CN^- and $Na^+/DMF/CN^-$ ion pairs are converted into the "free" cyanide ion.

Due to the low solubility, obtaining an FT-IR absorption

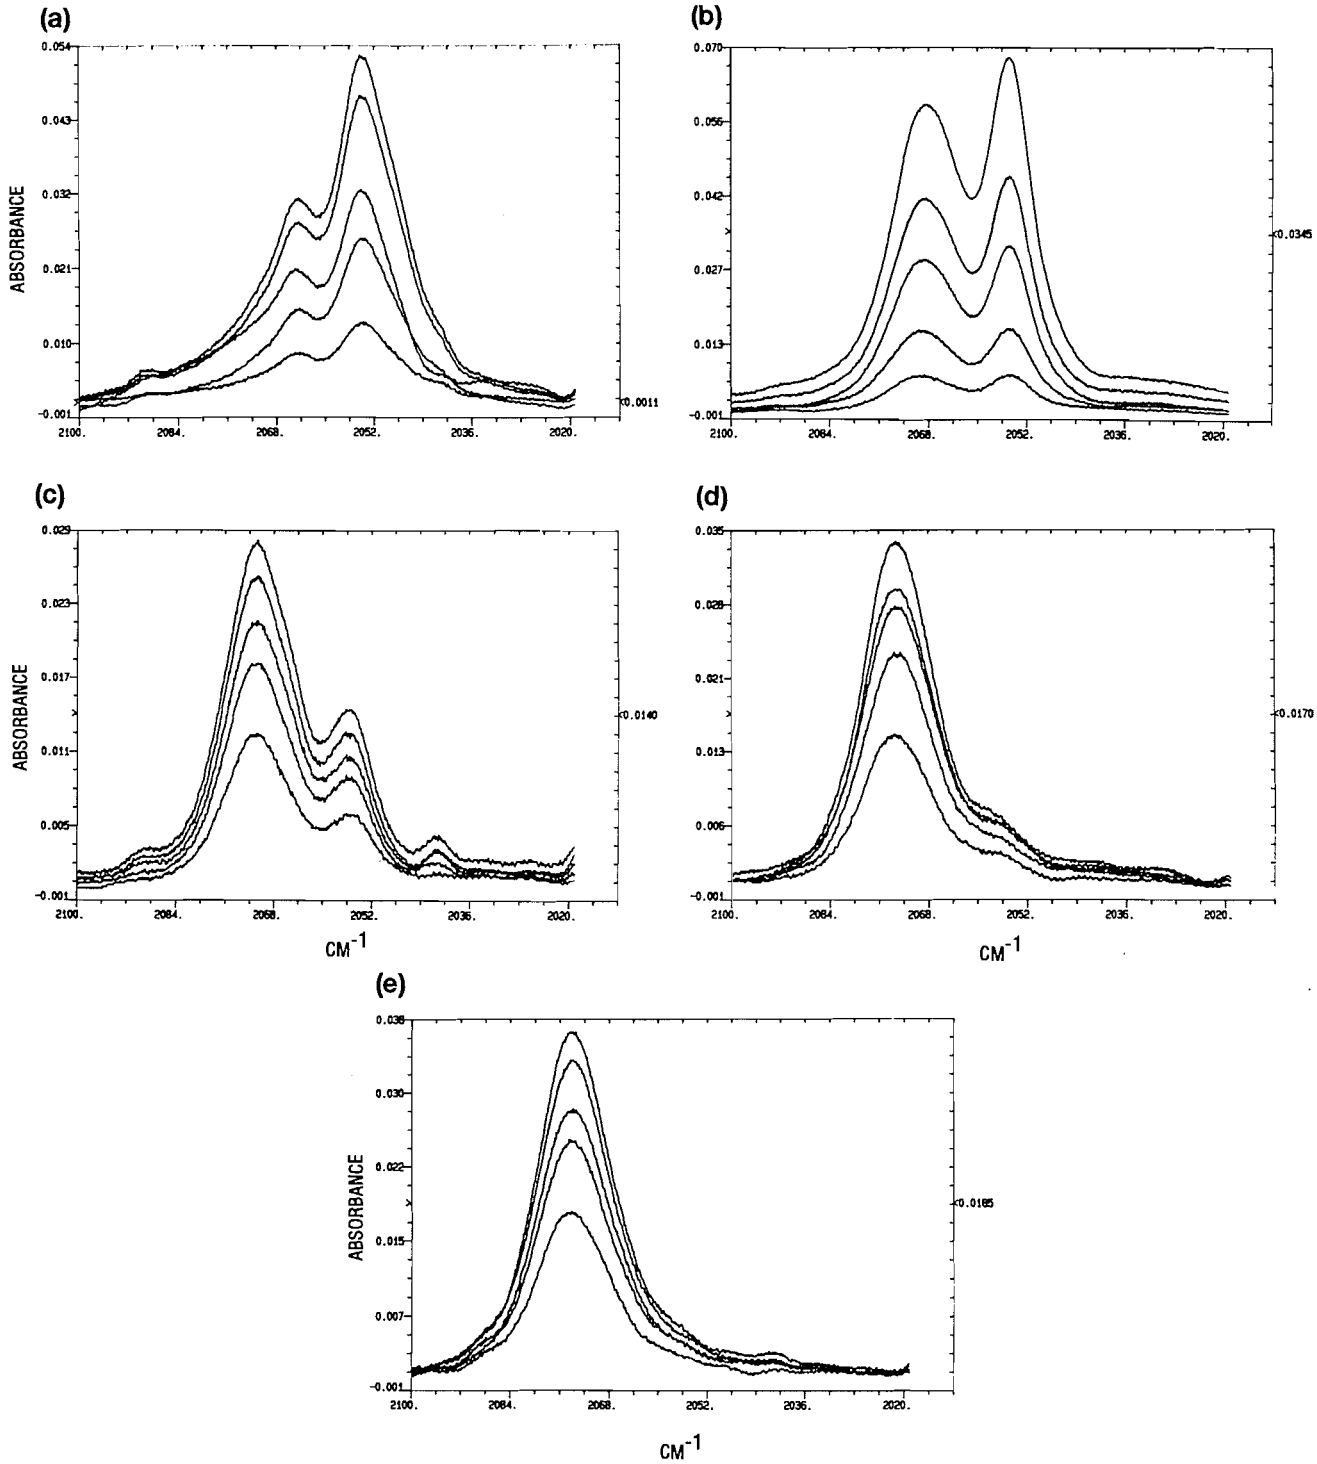

FIG. 2. Spectra obtained for tetraethylammonium cyanide in (*a*) dry DMF and (*b*) 2%, (*c*) 5%, (*d*) 15%, and (*e*) 20% aqueous DMF.

spectrum of potassium cyanide in DMF was difficult. The spectrum obtained for a saturated potassium cyanide – DMF solution after 500 scans has FT-IR absorption maxima at 2054 and 2070 cm^{-1}. The same absorption maxima were observed by Loupy and Corset for potassium cyanide in DMSO (4). The absorption at 2054 cm^{-1} would indicate that potassium cyanide is either strongly dissociated in DMF or, as Loupy and Corset reported for potassium cyanide in DMSO, the potassium cyanide ion pair absorbs at a lower wave number than the sodium cyanide ion pair. If Loupy and Corset are correct, the wave number for the K^+/CN^- ion pair just happens to coincide with the wave number for the absorption of the "free" anion.

In contrast to the spectra obtained for tetraethylammonium cyanide, potassium cyanide, and sodium cyanide, the spectrum of HCN in dry DMF is much simpler. The FT-IR absorption spectrum for a 0.16 M HCN solution in DMF has a single absorption with a maximum at 2079 cm^{-1} and $\epsilon_{2079} = 160$. Thus, the only cyanide species in dry DMF is the unionized HCN.

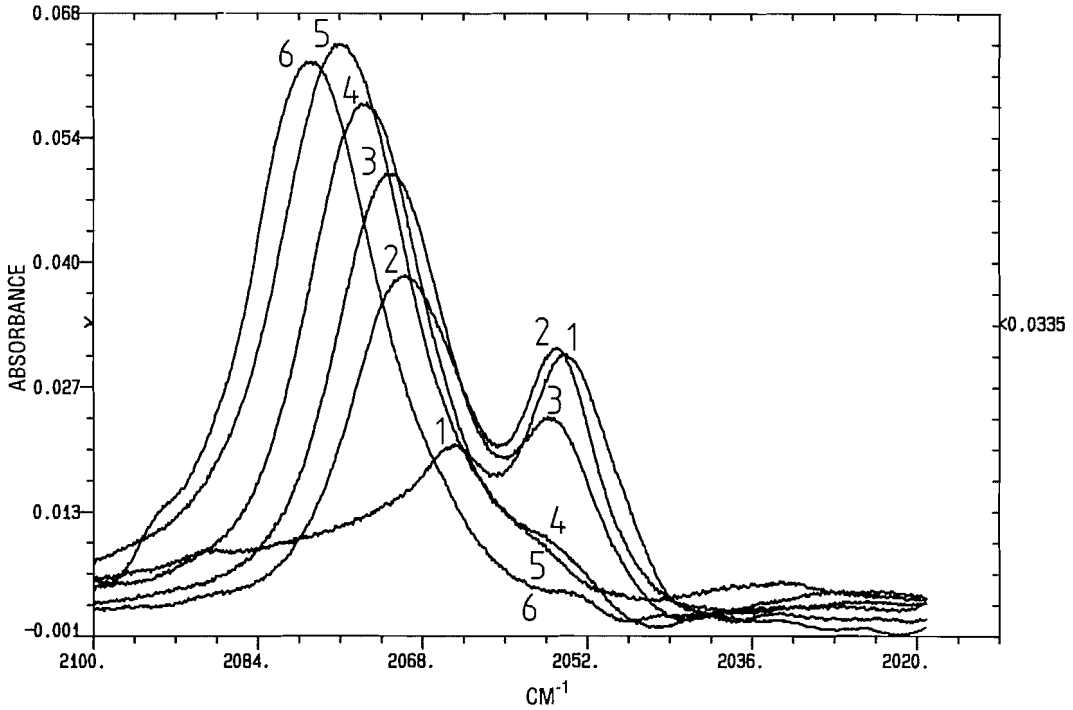

FIG. 3. Spectra obtained for a 0.20 M tetraethylammonium cyanide solution in (1) 0%, (2) 2.5%, (3) 5.0%, (4) 15%, (5) 38%, and (6) 80% aqueous DMF.

Addition of water to MCN–DMF solutions

Adding water to a solution containing 0.20 M tetraethylammonium cyanide in DMF alters the cyanide ion absorptions significantly, Fig. 3. The addition of 2.5% water results in a very small increase in the 2054 cm^{-1} peak, the apparent disappearance of the absorption at 2062 cm^{-1}, and a new absorption at approximately 2071 cm^{-1}. This new absorption at 2071 cm^{-1} could be due to either a shift in the wave number for the ion pair or to the formation of a new species. It is important to note that this new absorption has a much greater intensity than the absorption at 2062 cm^{-1} in dry DMF. Thus, if this absorption were due to a shift in the wave number of the ion pair, the increase in the intensity of the peak at 2071 cm^{-1} would have to be accompanied by a decrease in the absorption at 2054 cm^{-1}. However, the absorption at 2054 cm^{-1} has increased slightly and it is reasonable to assume that the new absorption is due to the formation of a new species, either a water-solvated cyanide ion or a DMF solvent-separated ion pair. Since the DMF solvent-separated ion pair would be expected to absorb at a wave number between the tight ion pair (2062 cm^{-1}) and the "free" cyanide ion (2054 cm^{-1}), one must conclude that the absorption at 2071 cm^{-1} is due to a water-solvated cyanide ion.

The presence of the water-solvated cyanide ion, $(CN^-)_W$, means an equilibrium exists between it and the "free" or DMF solvated cyanide ion, $(CN^-)_{DMF}$.

[1] $$(CN^-)_W \rightleftarrows (CN^-)_{DMF}$$

Given that cyanide ion in pure water absorbs at 2079 cm^{-1} (11), the solvation shell around the water-solvated cyanide ion in the 2.5% solution must contain some DMF because the wave number for this species is between the wave numbers for the cyanide ion in pure water and pure DMF.

The addition of more water to form a 5% solution results in a marked decrease in the absorption at 2054 cm^{-1} and an increase in both the intensity and wave number of the water-solvated cyanide ion. This trend continues up to 38% water. Presumably, increasing the water content converts more of the DMF-solvated cyanide ion into the water-solvated form. In fact, at $\geq$20% water, the absorbance due to the DMF-solvated cyanide ion is very small (negligible) with respect to the total cyanide ion absorbance. In 80% water, the wave number of the water-solvated species is 2079 cm^{-1} and the intensity of the absorption is identical to that obtained for a solution containing the same concentration of tetraethylammonium cyanide in pure water.

The spectra obtained for potassium cyanide in 5%, 15%, and 20% aqueous DMF were identical to those obtained using the same concentrations of tetraethylammonium cyanide (cf. Fig. 2). Since the spectra for the two salts are identical even though the cation is different, one must conclude that the absorption at the higher wave number is due to a water-solvated ion and not an ion pair. This supports the existence of the equilibrium between the DMF- and water-solvated cyanide ions.

The intensities of the peaks for tetraethylammonium cyanide in aqueous DMF are also concentration dependent. Due to the strong overlap of the two cyanide ion absorptions in these spectra, a computer program was developed to resolve the spectra into multiple Gaussian peaks (12, 13). The resulting absorptions and their wave number maxima are given in Table 2. The constant ratio of the 2054 to 2072 cm^{-1} intensities in 5% aqueous DMF with increasing salt concentration indicates that the distribution of the DMF- and water-solvated cyanide ions is independent of the $[Et_4NCN]/[H_2O]$ ratio. This is also observed in the 15% and 20% aqueous DMF solutions. This behaviour would be expected only if

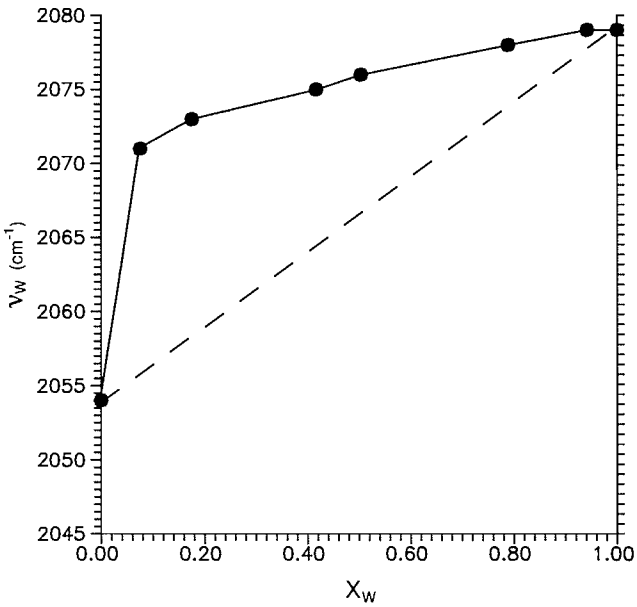

FIG. 4. The absorption wave number for the water solvated cyanide ion (ν_W) versus the mole fraction of water (x_W) in aqueous DMF solutions.

more water than the amount necessary to solvate the ions were present. Assuming this to be the case, the mixed solvent system can be treated as a pseudo two-phase system with the cyanide ion distributed between a water- and a DMF-rich phase.

The ratio of the absorbances at 2054 to those at 2069 cm^{-1} for the 2% aqueous DMF solutions, on the other hand, decreases slightly in a regular fashion from 1.08 to 0.95 as the concentration decreases from 0.34 M to 0.071 M, Table 2. When the [Et_4NCN]/[H_2O] ratio is large, the distribution of the cyanide ions between the two pseudo phases is shifted in favour of the DMF-rich phase because the solvent shell around the water-solvated cyanide ion contains fewer water molecules. As the [Et_4NCN]/[H_2O] ratio decreases, there are more water molecules available to solvate the cyanide ions and the equilibrium shifts towards the water-solvated ion.

For the 20% aqueous DMF solutions, the absorption due to the DMF-solvated cyanide ion accounts for 7% of the total absorbance, Table 2. If one assumes the concentration of this species is negligible, a Beer's Law plot of the absorption at 2074 cm^{-1} versus [Et_4NCN] yields $\epsilon_{2074} = 31 \pm 1$ M^{-1} cm^{-1} for the water-solvated cyanide ion. To compare this value to the molar extinction coefficient for cyanide ion in water, FT-IR spectra were obtained for 0.065–0.31 M aqueous solutions of both potassium cyanide and tetraethylammonium cyanide. A single absorption at 2079 cm^{-1} was observed for all these solutions, indicating that only water-solvated cyanide ions exist in water. A plot of the absorption at 2079 cm^{-1} versus [CN^-] yielded $\epsilon_{2079} = 31 \pm 1$ M^{-1} cm^{-1}, comparable to the value 29 M^{-1} cm^{-1} reported by Jones and Penneman (11) for a 10 M aqueous potassium cyanide solution. It is worth noting that the molar extinction coefficients for cyanide ion in water and in 20% aqueous DMF are identical.

Although the molar extinction coefficients of the cyanide ion in water and in 20% aqueous DMF are identical, the wave numbers for their maxima are different. The lower wave number in the 20% aqueous DMF indicates that the environment around the water-solvated cyanide ion is different than that in pure water. This suggests that the solvent shell around the cyanide ion in mixed solvents contains some DMF. The wave number for the water-solvated cyanide ion absorption (ν_W) increases with the mole fraction of water in the mixed solvent, Fig. 4. At 80% water, the wave number for this absorption is, within experimental error, equal to that for cyanide ion in water and has shifted 10 cm^{-1} relative to that for the cyanide ion in 2% aqueous DMF. This shift of ν_W to higher wave numbers as the mole fraction of water increases is expected because the solvation shell of the water-solvated cyanide ion becomes less like DMF (ν = 2054 cm^{-1}) and more like water (ν = 2079 cm^{-1}). The nonlinear change in ν_W with increasing mole fraction of water in the mixed

For personal use only.

solvent also supports the solvent sorting (two-phase) model. If DMF and water formed an ideal single phase, the variation in ν_W for the water-solvated cyanide ion should follow the dashed line in Fig. 4.

The absorption maximum for the DMF-solvated cyanide ion, Table 2, also increases as the water content increases. As with the water-solvated cyanide ion, this wave number shift indicates that the solvation shell for the DMF-solvated cyanide ion changes slightly with water content. Given the direction of the wave number shift, there is likely more water in the DMF solvent shell as the water content increases.

The treatment of the 2% and 5% aqueous DMF solutions is more difficult because they contain significant amounts of the water-solvated and DMF-solvated ions. The molar extinction coefficient for the water-solvated cyanide ion is the same in water and in 20% aqueous DMF ($\epsilon = 31\ M^{-1}\ cm^{-1}$) even though ν_W differs by 5 cm^{-1}. Since the molar extinction coefficient for the water-solvated cyanide ion is not sensitive to significant changes in the composition of the solvent, one can assume that the molar extinction coefficient for the water-solvated form is 31 $M^{-1}\ cm^{-1}$ in all the aqueous DMF solutions. Using this value, the concentration of cyanide ion in the aqueous phase can be calculated and, by subtraction, the concentration of cyanide ion in the DMF phase can be obtained. The resulting concentrations from the 2% and 5% aqueous DMF solutions give $\epsilon = 37 \pm 7\ M^{-1}\ cm^{-1}$ for the DMF-solvated cyanide ion in aqueous DMF, Table 2. This is 3 times larger than the apparent extinction coefficient reported by Loupy and Corset (4). However, these authors were unable to determine the concentrations of the contributing species.

If one assumes the pseudo two-phase model, a distribution coefficient for the cyanide ion between the two pseudo phases, K_D, is given by:

$$[2] \quad K_D = c_{DMF}/c_W$$

where c_{DMF} and c_W are the cyanide ion concentrations in the DMF and water pseudo phases, respectively. These concentrations are:

$$[3] \quad c_i = n_i/V_i$$

where n_i and V_i are the number of moles of cyanide ion and the volume, respectively, of pseudo phase i. Assuming the volume of the pseudo phase i is equal to the volume of solvent i used to prepare the solution, the volume fraction of pseudo phase i, ϕ_i, is given by:

$$[4] \quad \phi_i = V_i/V_T$$

where V_T is the total volume of the solution.

The ratio of the number of moles of cyanide ion in the DMF phase to the water phase (n_{DMF}/n_W) is given by:

$$[5] \quad n_{DMF}/n_W = A_{2054}\epsilon_{2074}/A_{2074}\epsilon_{2054} = [CN^-]_{DMF}/[CN]_W$$

where $[CN^-]_{DMF}$ and $[CN^-]_W$ are the bulk concentrations of the DMF- and water-solvated cyanide ion, respectively.

Since $\phi_W + \phi_{DMF} = 1$, substituting eqs. [3]–[5] into eq. [2] yields:

$$[6] \quad K_D = \{\phi_W/(1 - \phi_W)\}\, A_{2054}\epsilon_{2074}/A_{2074}\epsilon_{2054}$$
$$= \{\phi_W/(1 - \phi_W)\}[CN^-]_{DMF}/[CN^-]_W$$

The values of K_D calculated using this model are given in Table 2. An examination of the K_D values shows that it is constant within experimental error at $0.018_2 \pm 0.004$. Given that the K_D value does not change significantly over a wide range of solvent composition, the assumption of a pseudo two-phase model is valid.

It is also worth noting that the values for K_D in the 2% aqueous DMF increase slightly as the ratio of salt to water increases. This trend, which is within the error associated with K_D, probably reflects the fact that the solvation shell around both the cyanide ion species varies with water content. However, this does not affect the validity of the pseudo two-phase model.

It is worth noting that the cyanide ion in water and HCN in DMF both have a single absorption at 2079 cm^{-1}. However, the molar extinction coefficient for HCN is 160, or 5 times that for the cyanide ion in water. Also, adding water to dry DMF solutions containing HCN does not alter the wave number of the C≡N bond absorption although there is a slight (<10%) reduction in the intensity of the peak when the water content is increased to 20%. When enough KOH is present to neutralize the HCN in the 20% aqueous DMF solution, the intensity of the peak decreases fivefold to the absorption expected for a potassium cyanide solution of the same concentration. These results indicate that even in a 20% aqueous DMF solution all, or virtually all, of the HCN stays in the molecular form.

Kinetic studies

Reaction of benzyl chloride with tetraethylammonium cyanide

Figure 5 shows the time-dependent FT-IR spectra obtained for the S_N2 reaction between benzyl chloride and tetraethylammonium cyanide in 2.5%, 5%, 15%, and 20% aqueous DMF. In these spectra, the decrease in the intensity of the cyanide ion absorptions (2054–2074 cm^{-1}) is accompanied by an increase in the intensity of a peak at 2250 cm^{-1}, where the product, benzyl nitrile, absorbs. An interesting feature of the spectra for the reaction in 2.5% and 5% aqueous DMF is that the peak ratio for the two solvated cyanide ions (2054–2074 cm^{-1}) does not change throughout the reaction. This indicates that the interconversion between the two forms of the cyanide ion is much faster than the reaction between cyanide ion and benzyl chloride. Therefore, the rate-determining step in the mechanism is the S_N2 reaction between cyanide ion and benzyl chloride.

This reaction in dry DMF was too fast to measure. Even at 0°C, the reaction was at least 95% complete in 4 min. White and Baizer (14) also found that the reaction between tetraalkylammonium cyanides and alkyl halides in dry DMF was extremely fast. Presumably this is because there is a high concentration of the DMF-solvated cyanide ion in the reaction mixture. White and Baizer also found that the reaction was considerably slower when sodium cyanide rather than tetraalkylammonium cyanide was used. This probably occurs because the cyanide ion exists as the less reactive ion pair when sodium cyanide is the nucleophile.

Adding water to the solvent decreases the rate constant (k_2) markedly, Table 1. Even in 2.5% aqueous DMF, the reaction is slow; it is only 91% complete after 1.5 h at 30.00°C. The rate continues to decrease as the amount of water in the solvent increases. Haberfield et al. (15, 16) showed that changing a dipolar aprotic to a protic solvent reduces the free energy of the reactants only slightly but markedly increases

For personal use only.

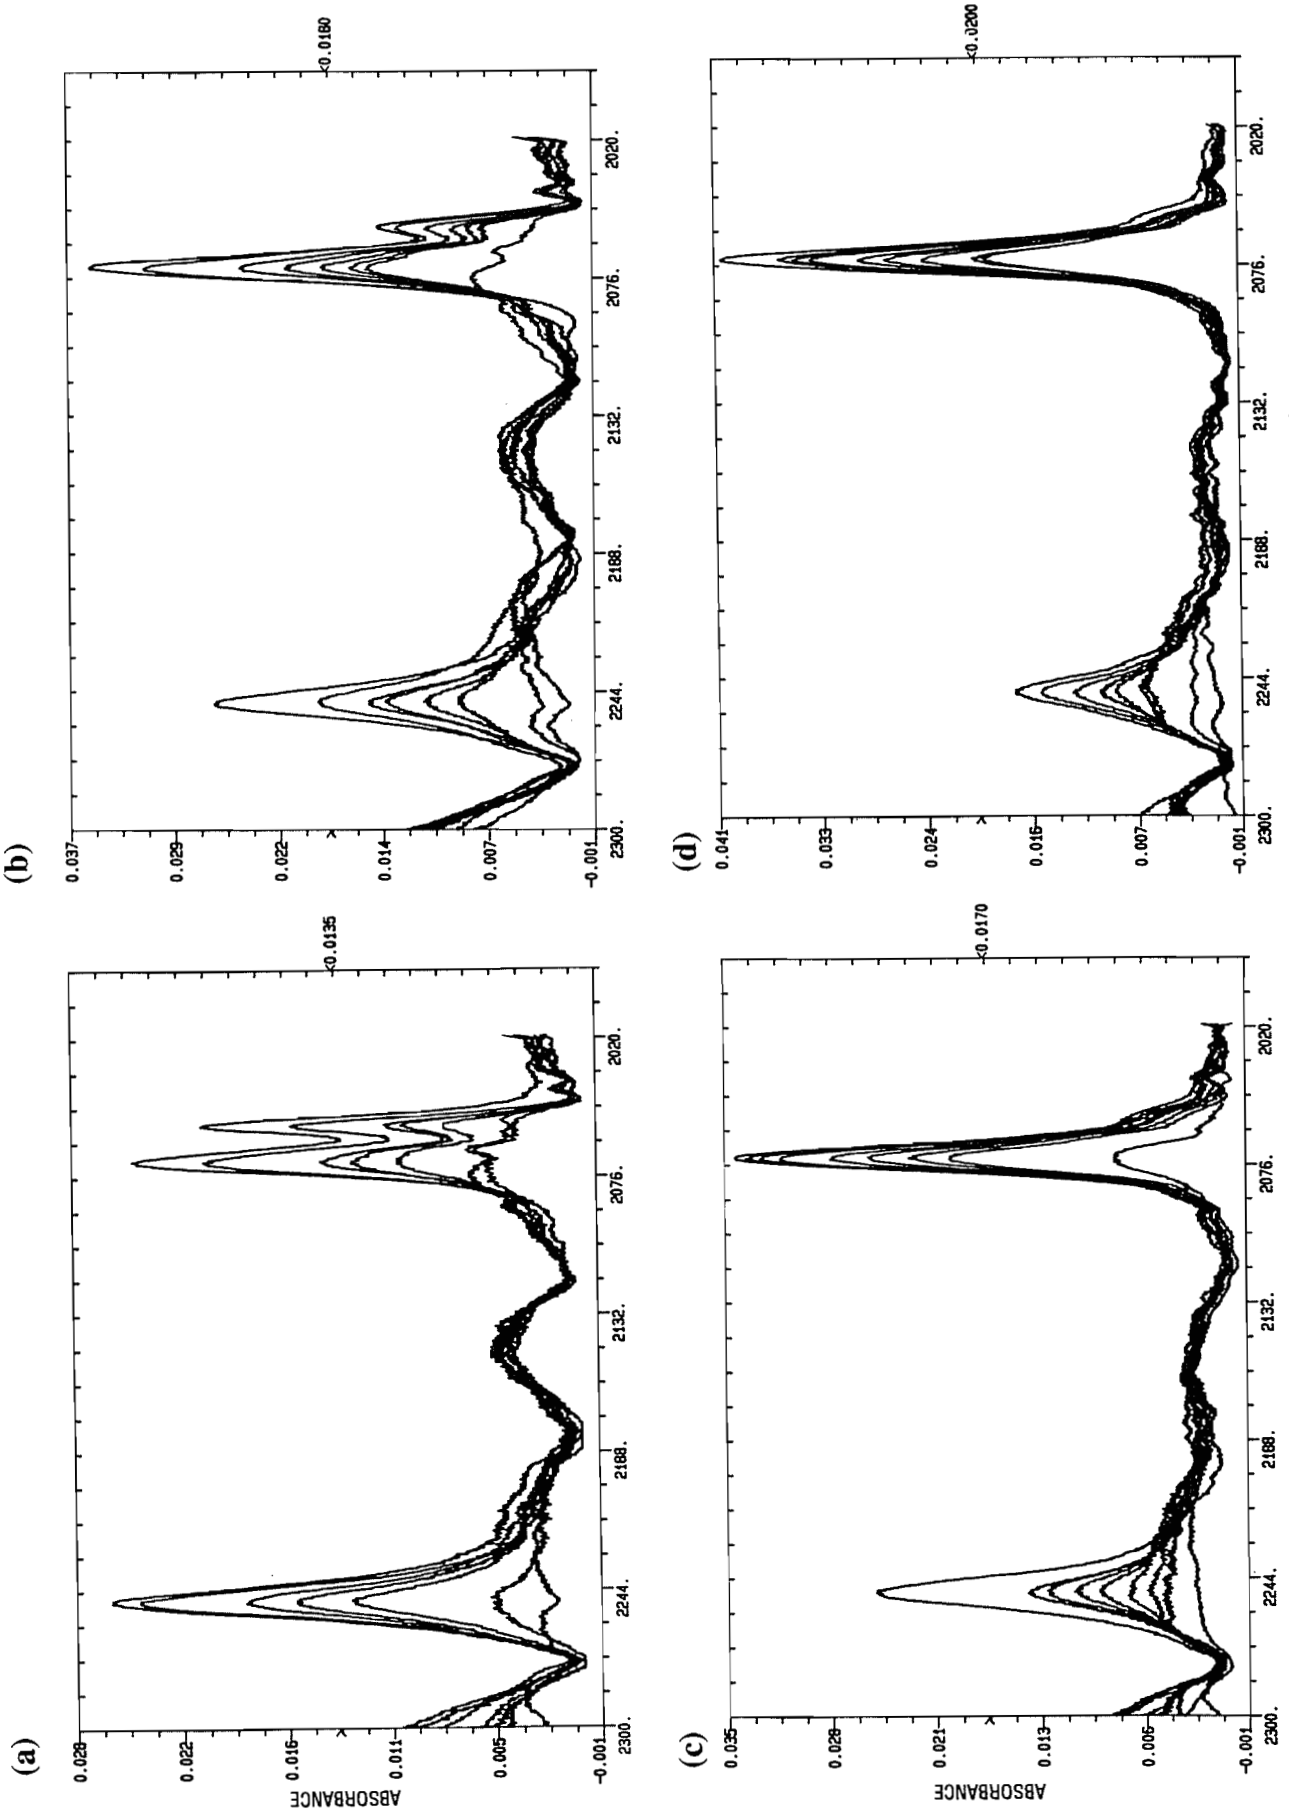

FIG. 5. Time-resolved spectra for the S_N2 reaction of benzyl chloride with tetraethylammonium cyanide in (*a*) 2.5%, (*b*) 5%, (*c*) 15%, and (*d*) 20% aqueous DMF at 30.00°C.

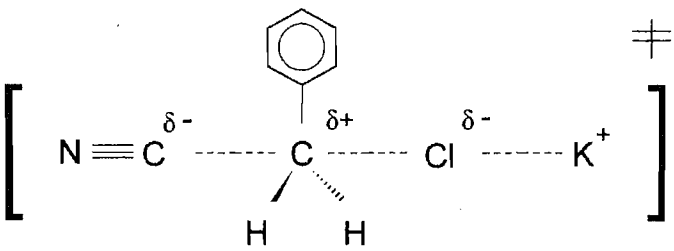

FIG. 6. Electrophilic catalysis in the removal of the leaving group by potassium ion in the S_N2 reaction between cyanide ion and benzyl chloride.

the free energy of the ionic S_N2 transition state. Since both of these effects increase the free energy of activation, the rate of reaction decreases as the percent water increases. Adding water also reduces the rate by shifting the equilibrium between the DMF- and water-solvated cyanide ions towards the less reactive water-solvated cyanide ion.

Another noteworthy observation is the 20% increase in k_2 when the cyanide salt is changed from tetraethylammonium cyanide to potassium cyanide in 5% aqueous DMF, Table 1. A possible explanation for this is that the potassium ion provides electrophilic catalysis in the removal of the leaving group, Fig. 6. Electrophilic catalysis has been proposed for elimination reactions in organic solvents (17, 18).

Finally, when HCN and benzyl chloride were added to dry DMF or 20% aqueous DMF at 30.00°C, the HCN absorption did not decrease and there was no evidence of any product absorption at 2250 cm^{-1} even after 48 h. Thus, no reaction occurs in either DMF or 20% aqueous DMF when the cyanide ion is added as HCN. Therefore, HCN does not ionize and react with benzyl chloride in either solvent.

Reaction of benzylmethyl-4-substituted phenylsulphonium salts with tetraethylammonium cyanide in 20% aqueous DMF

The S_N2 reactions of cyanide ion with benzylmethyl-4-chlorophenylsulphonium perchlorate and benzylmethyl-4-methoxyphenylsulphonium perchlorate in 20% aqueous DMF yielded spectra similar to those obtained when benzyl chloride was the substrate. The absorption at 2074 cm^{-1} for the water-solvated cyanide ion decreased and the benzyl cyanide absorption at 2250 cm^{-1} increased. The least-squares fits of the second-order plots for these reactions had correlation coefficients of 0.996 and 0.992 for the benzylmethyl-4-chlorophenylsulphonium perchlorate and benzylmethyl-4-methoxyphenylsulphonium perchlorate, respectively. The rate constants for these reactions are also given in Table 1. The ratio of the rate constants for the two substrates (k_{Cl}/k_{MeO}) is ca. 11. A similar ratio was obtained when these two substituents were present in the leaving group in the S_N2 reactions between benzyldimethyl-4-substituted phenylammonium ions with thiophenoxide ion in DMF (19). The large k_{Cl}/k_{MeO} value shows that these reactions are very susceptible to changes in the leaving group and will be useful for elucidating how substituents alter the structure of the S_N2 transition state.

Kinetic analysis of the benzyl chloride – cyanide ion reactions

The FT-IR spectra clearly demonstrate that there are two forms of cyanide ion in these systems, a DMF- and a water-solvated species. Given that (*i*) the rate constant was too large to measure in dry DMF and (*ii*) the rate decreases as the water content in the solvent increases, the DMF-solvated ion must be the more reactive species. This conclusion is supported by the work of Parker (20), who demonstrated that anions are much less strongly solvated and, therefore, are much more reactive in dipolar aprotic solvents than in protic solvents.

TABLE 3. Rate constants, k_2', for the reaction of the DMF-solvated cyanide ion with benzyl chloride in various aqueous DMF solutions at 30.00°C

% H_2O	$k_2'/10^{-3}$ (L mol^{-1} s^{-1})
2.5	10.6
5.0	12.5
15	5.5_6
20	8.4_0

The ratio of the absorptions, and hence the ratio of the concentrations of the two cyanide ion species, remains constant throughout the reaction. This means there is a rapid pre-equilibrium between the two forms of the cyanide ion followed by a rate-determining reaction between the DMF-solvated cyanide ion and benzyl chloride, eq. [7]:

$$[7] \quad (CN^-)_W \overset{K_D}{\rightleftharpoons} (CN^-)_{DMF} + BzCl \xrightarrow{k_2'} BzCN + Cl^-$$

where the subscripts W and DMF refer to the water and DMF pseudo phases, respectively, k_2' is the second-order rate constant for the reaction between the DMF-solvated cyanide ion and benzyl chloride, and K_D is the distribution coefficient for the cyanide ion between the two pseudo phases, eq. [6].

The kinetic expression for the rate-determining step is

$$[8] \quad \text{rate} = k_2' [CN^-]_{DMF}[BzCl]$$

Since $[CN^-] = [CN^-]_{DMF} + [CN^-]_W$, eq. [6] can be rearranged to give:

$$[9] \quad [CN^-]_{DMF} = K_D/\{\phi_W/(1 - \phi_W) + K_D\} \cdot [CN^-]$$

Substituting eq. [9] into eq. [8] yields:

$$[10] \quad \text{rate} = k_2 [CN^-][BzCl]$$

where the experimentally determined rate constant, k_2, is

$$[11] \quad k_2 = k_2' K_D/\{\phi_W/(1 - \phi_W) + K_D\}$$

The k_2' values were determined in the various aqueous DMF solvents using the average K_D, and the second-order rate constants, k_2, Table 1. These k_2' values, along with the percent water in the mixed solvent, are given in Table 3.

Given the error in K_D (22%) and k_2 (5%), the error in the k_2' values is in the order of 30%. Although the k_2' values could be the same in all the aqueous DMF solutions (the average is 9.3 ± 3.0), it seems more likely that they decrease slightly as the water content in the mixed solvent increases. This is more likely because k_2' in 15% aqueous DMF is lower than k_2' in 5% aqueous DMF, even when the sizable error in k_2' is considered.

Using the above model, the k_2' values should be independent of solvent composition and equal to the rate constant for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

the reaction in dry DMF. However, these rate constants are at least two orders of magnitude lower than the rate constant for this reaction in dry DMF. Since K_D accounts for the shift in the equilibrium between the DMF- and the water-solvated cyanide ion, the much smaller values for k_2' in aqueous DMF must be due to changes in the solvation of the reactants and (or) the transition state.

As noted above, the absorption wave number for the DMF-solvated cyanide ion, and hence the number of water molecules in the solvation shell, increases with increasing water content. The increased number of water molecules will lower the free energy of the cyanide ion, increase the activation energy, and decrease k_2'. However, it is unlikely that this effect is large because the shift in the wave number for the peak is small and Haberfield et al. (15, 16) showed that the free energy of the transition state is much more sensitive to changes in solvent than the free energy of the reactants. Therefore, it must be concluded that the decrease in k_2' is primarily due to an increase in the free energy of the transition state. It is important to note that this conclusion would be reached even if the reaction were assumed to occur in a single homogeneous phase.

Finally, it is interesting to note that k_2' decreases markedly when the solvent is changed from dry DMF to 2.5% aqueous DMF and decreases only slightly as the water content is increased further to 20%. This means that the change that occurs in transition state solvation when a protic solvent is added to a dipolar aprotic solvent is virtually complete when as little as 2.5% water is present.

Conclusion

This FT-IR study has shown that cyanide salts exist as both water-solvated and DMF-solvated ions, and not as ion pairs, in aqueous DMF solutions. The concentrations of these two species are dependent upon the composition of the solvent, and the equilibrium between the two forms of the cyanide ion can be described using a pseudo two-phase model.

The rate constants for the S_N2 reaction between tetraethylammonium cyanide and benzyl chloride have been analyzed using the pseudo two-phase model. The reaction proceeds in two steps: a fast pre-equilibrium between the two forms of the cyanide ion followed by a rate-determining reaction between the DMF-solvated cyanide ion and benzyl chloride. The rate constant for the rate-determining step decreases markedly with as little as 2.5% water and then only slightly as the water content is further increased to 20%. These changes are primarily due to solvation effects in the transition state.

Changing the cyanide salt to KCN from tetraethylammonium cyanide increased the rate of reaction slightly. This may be due to electrophilic catalysis in the removal of the leaving group. Both spectroscopic and kinetic studies have shown that HCN does not ionize in DMF or aqueous DMF solutions and no reaction was found even in 20% aqueous DMF. This clearly demonstrates that cyanide ion is the reactive species in the S_N2 reaction with benzyl chloride.

Finally, the cyanide ion displacement reaction of sulphonium salts with different leaving groups is sensitive to changes in the substituent on the leaving group. Thus, these reactions make a good system for studying substituent effects on the structure of the S_N2 transition state.

YOULA S. TSANTRIZOS, XIAO-JIN XU, FRANÇOISE SAURIOL, and ROSEMARY C. HYNES. Can. J. Chem. **71**, 1362 (1993).

Fusarium lateritium Nees is a natural antagonist of the plant pathogen *Eutypa armeniacae*. In an effort to show that this biological phenomenon is chemically mediated, the bioactive metabolites of *F. lateritium* were investigated. The cytotoxic alkaloids 2-(1-hydroxyethyl)-4(3*H*)quinazolinone (**1**) and 2-acetyl-4(3*H*)quinazolinone (**2**), and the three cyclohexadepsipeptides, enniatins B (**3**), B_1 (**4**), and A_1 (**5**), were isolated and characterized. Metabolites **3**, **4**, and **5** were found to exhibit strong antifungal activity against *E. armeniacae*. The structures of the novel metabolites **1** and **2** were elucidated by spectroscopic analysis and that of **2** was confirmed by X-ray crystallography. The absolute stereochemistry of **1** was investigated by ^1H and ^{19}F NMR analysis of its Mosher ester derivative.

YOULA S. TSANTRIZOS, XIAO-JIN XU, FRANÇOISE SAURIOL et ROSEMARY C. HYNES. Can. J. Chem. **71**, 1362 (1993).

Le *Fusarium lateritium* Nees est un antagoniste naturel de la plante pathogène *Eutypa armeniaceae*. Dans le but de démontrer que ce phénomène biologique est d'origine chimique, on a étudié les métabolites bioactifs du *F. lateritium*. On a isolé et caractérisé les alcaloïdes cytotoxiques 2-(1-hydroxyéthyl)-(3*H*)quinazolin-4-one (**1**) et 2-acétyl-(3*H*)quinazolin-4-one (**2**) ainsi que les trois cyclohexadepsipeptides enniatines B (**3**), B_1 (**4**) et A_1 (**5**). On a trouvé que les métabolites **3**, **4** et **5** montrent une forte activité antifongique envers la *E. armenacieae*. On a élucidé les structures de ces nouveaux métabolites **1** et **2** par analyse spectroscopique et on a confirmé celle du composé **2** par cristallographie de rayons X. On a étudié la stéréochimie absolue du composé **1** par analyse RMN du ^1H et du ^{19}F de son dérivé ester de Mosher.

[Traduit par la rédaction]

Introduction

In 1983, Carter (1*a*) described the use of *Fusarium lateritium* Nees macroconidia as a biofungicide for the protection of commercial apricot orchards from *Eutypa armeniacae* infections (1). *Eutypa armeniacae* is an aggressive plant pathogen associated with sapwood necrosis (commonly known as "dieback disease") in fruit trees, grapevines, and ornamental plants around the world (2). Thus, an investigation into the metabolites of *F. lateritium* that exhibit antifungal activity against *E. armeniacae* was undertaken.

A biologically active mixture of metabolites was obtained from *F. lateritium* cultures grown on solid Czapex-Dox plus yeast medium. The subsequent bioassay-guided separation of the active components led to the isolation of the novel alkaloids 2-(1-hydroxyethyl)-4(3*H*)quinazolinone (**1**) and 2-acetyl-4(3*H*)-quinazolinone (**2**), and the three enniatins B (**3**), B_1 (**4**), and A_1 (**5**). The structural identity of these compounds was explored extensively by 2D-NMR studies using COSY, HMQC, and HMBC experiments. It is noteworthy that the general structure of the enniatin cyclodepsipeptides has been known since the late 1940s (3). However, the complete NMR data, for all nine of the known enniatins (Fig. 1), were reported only very recently; during preparation of this manuscript, the ^1H and ^{13}C NMR of enniatins A_1 and B_1 were reported by Blackwell, Miller and co-workers for the first time (4).

Results and discussion

The agricultural importance of *F. lateritium* as both a biofungicide (2, 5) and a bioherbicide (6) has been known for some time, although investigations into the metabolites of this organism have been limited to the isolation of the antibiotic lateropyrone (7), the mycotoxin diacetoxyscirpenol (8), and the insecticidal cyclodepsipeptide beauvericin (5, 9). The production of enniatins from *F. lateritium* has also been described; however, they were isolated as a mixture and only partly identified (5, 9).

In this work, a bioassay-guided purification scheme was developed for the isolation of *F. lateritium* metabolites exhibiting antifungal activity against the plant pathogen *E. armeniacae*. A crude metabolite mixture of *F. lateritium* was extracted from infected solid Czapex-Dox medium with CH_2Cl_2 and partitioned by reversed phase flash column chromatography (10). Metabolite **1** eluted from the column in 45–55% aqueous MeOH and it was isolated as an amorphous white solid after further purification by normal phase flash column chromatography.

The ^1H NMR of **1** (Table 1) revealed the presence of a methyl group at δ 1.53 (d, 3H), coupled to an adjacent -CH-O- moiety at δ 4.73 (q, 1H). The remaining signals were assigned to four neighboring aromatic protons (δ 7.49, 7.66, 7.79, and 8.18) whose relative positions were determined by selective decoupling experiments. The ^{13}C NMR indicated the presence of 10 nonequivalent carbon atoms, a methyl at δ 22.4, a -CH-O- at δ 68.6, three quaternary olefinic carbons at δ 122.2, 149.6, and 161.6 (two of which had to be attached to a heteroatom), four protonated olefinic carbons at δ 127.2, 127.5, 127.8, and 135.9, and an amide carbonyl at δ 164.3. Although the signal at δ 127.5 was unusually broad and of very low intensity for a protonated carbon, HMQC NMR clearly showed its ^1J coupling to the proton at δ 7.66. This effect may be due to further long-range coupling with ^{15}N.

High-resolution CI-MS of **1** gave a molecular ion at 191.08201 for the ($M^+ + 1$) ion (calculated: 191.08205), indicating an elemental composition of $C_{10}H_{10}N_2O_2$. Its IR

[c]Overlapping signals in the ^1H NMR (δ 7.78–7.88).

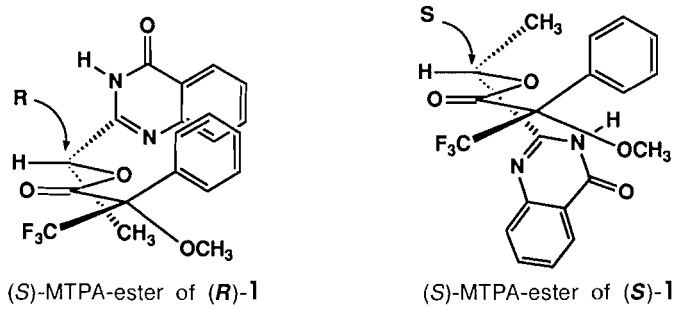

FIG. 2. Absolute stereochemistry of metabolite (**1**).

spectrum supported the existence of N—H, O—H, C=N, and amide C=O bonds. Based on this data, as well as the long-range H–C connectivity suggested by the HMBC NMR, the structure of 2-(1-hydroxyethyl)-4(3*H*)quinazolinone was assigned to metabolite **1**.

The absolute stereochemistry of **1** was investigated using Mosher's method (11). In this technique, the absolute stereochemistry of a carbinol center is based on the assumption that the most stable conformation of its Mosher's ester (MTPA-esters) is that which places the carbonyl proton, the ester carbonyl, and the trifluoromethyl group of the MTPA moiety on the same plane (12). Consequently, in the case of the MTPA-esters of **1** (Fig. 2), the methyl substituent of the **S** enantiomer will be located under the shielding effects of the phenyl group and appear upfield from the equivalent signal in the **R** enantiomer. Using the same argument, the methoxy substituent of the MTPA moiety will be exposed to the shielding effects of the quinazolinone ring system and it should be shifted upfield in the (*S*)-MTPA-ester of the **S** enantiomer but not in that of the **R**.

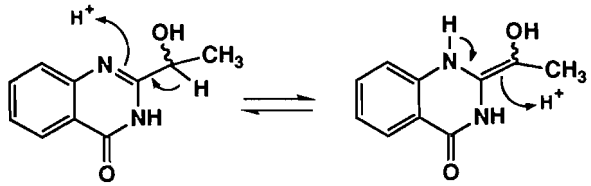
TABLE 2. ^1H and ^{19}F NMR data of the (*S*)-MTPA-esters **1**[a] (270 MHz, $CDCl_3$)

	(*S*)-MTPA-ester (**R**)-**1**		(*S*)-MTPA-ester (**S**)-**1**	
	^1H (δ)	^{19}F (δ)	^1H (δ)	^{19}F (δ)
$-CH_3$	1.71 (d, J = 6.6 Hz)		1.63 (d, J = 6.6 Hz)	
$-OCH_3$	3.55		3.49	
-CON*H*-	8.9		9.2	
$-CF_3$		−71.7		−71.4

[a]Only the signals shown above were unambiguously assigned (due to multiple overlapping, the remaining signals in the ^1H NMR spectrum of the MTPA-esters of **1** were not assigned).

Fluorine NMR analysis has also been used for making stereochemical assignments of MTPA-esters. The fundamental argument is again based on the preferred coplanar conformation of the trifluoromethyl group and the ester carbonyl. However, the relative extent of this preference has been shown to depend on the magnitude of steric interactions between the phenyl group of the MTPA moiety and the adjacent carbinol substituent (13). Therefore, it is expected that the destabilizing quinazolinone–phenyl interactions in the (*S*)-MTPA-ester (**R**)-**1** will force the trifluoromethyl group away from the carbonyl deshielding plane and result in an upfield shift of the $-CF_3$ signal (relative to that of the (*S*)-MTPA-ester (**S**)-**1**) in the ^{19}F NMR.

The (*S*)-MTPA-ester of metabolite **1** was prepared from the (*R*)-MTPA chloride following standard literature procedures (12). Both the ^1H and ^{19}F NMR spectra were consistent with the presence of a diastereomeric mixture, composed of the (*S*)-MTPA-ester (**R**)-**1** and the (*S*)-MTPA-ester (**S**)-**1** in a ratio of ~1.5:1 (Table 2). Thus, the small, negative optical rotation observed for metabolite **1** was attributed to the major **R** enantiomer. It has been speculated that the loss of optical purity is perhaps due to an equilibrium between compound **1** and its **1′** tautomer.



1 **1′**

The closely related metabolite **2** was eluted from the reversed phase column in 60–70% aqueous MeOH and it was further purified by crystallization from CH_2Cl_2. Unlike the enniatin metabolites (**3**, **4**, and **5**), metabolites **1** and **2** were not produced in liquid cultures of *F. lateritium* in any appreciable amounts (liquid Czapex-Dox plus 5% yeast and malt extract were tried). The ^1H NMR of **2** (Table 1) revealed the presence of an acetyl methyl at δ 2.75, four aromatic protons (δ 7.6–8.3), and a very broad signal at δ ~9.9 (1H). The ^{13}C NMR was consistent with the presence of an acetate unit (C=O, δ 194.1; Me, 24.5) and an amide (δ 160.5), in addition to seven other aromatic or olefinic carbons: four protonated and three quaternary, of which two had chemical shifts consistent with the presence of =C-N moieties (δ 147.7 and 145.3). The CI-MS data of metabolite **2** gave a molecular ion at 189 (M^+ + 1) suggesting an elemental composition of $C_{10}H_8N_2O_2$, and its IR data supported the existence of N—H, N=C, and C=O bonds (a strong, very broad carbonyl absorption at 1692 cm^{-1} was observed which was attributed to both an amide and a conjugated ketone). Based on this data, the structure of 2-acetyl-4(3*H*)quinazolinone was assigned to **2**, which was later confirmed by X-ray crystallography (ORTEP diagram shown in Fig. 3).[2]

Metabolites **1** and **2** are new members of the quinazoline family of natural products (Fig. 4). Such compounds exhibit a variety of biological properties and have been isolated from both plant and microbial sources. Among the best known examples are the plant metabolites rutaecarpine (**6**, hypertensive agent (14)), arborine (**7**, antipyretic and anthelmintic agent (15)), febrifugine **8** and isofebrifugine **9** (antimalarial (16)), and the microbial metabolites tryptanthrin (**10**, antibiotic (17)), fumiquinazolines A (**11**), B (**12**), and C (**13**) (cytotoxic agents (18)).

The enniatin metabolites **3**, **4**, and **5** were first eluted from the reversed phase flash column as a mixture (with 80–100% aqueous MeOH) and subsequently purified by semipreparative HPLC. FAB MS showed the characteristic molecular ions of enniatins B (**3**), B_1 (**4**), and A_1 (**5**), along with several metal complex ions (Na^+, K^+, and Cs^+) indicative of the ionophoric properties of these compounds (19). All of the IR and NMR data of metabolites **3**, **4**, and **5** were consistent with their identification as the enniatins B (20), B_1 and A_1 (5), respectively.

The enniatin metabolites are known to exhibit insecticidal (21, 22), antibiotic (23), and phytotoxic activities (24), and to also inhibit cholesterol biosynthesis (25). In this work, the antagonistic effect of *F. lateritium* against the important plant pathogen *E. armeniacae* was investigated. Potent antifungal activity against *E. armeniacae* was observed with metabolites **3**, **4**, and **5**. Therefore, it appears that the production of enniatins B (**3**), B_1 (**4**), and A_1 (**5**) by *F. lateritium* may play a key role in the biological effects of this organism as a biofungicide (1).

As part of a broader biological screening work of microbial metabolites, some of the compounds presented in this paper were evaluated for their ability to inhibit HIV replication in C8166 cells (as evidenced by a reduction of HIV-

[2]X-ray data for metabolite **2** (16 pages) have been deposited as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of atomic parameters and of bond lengths and angles (5 pages) have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

induced cytopathogenic effects (26)). Metabolite **2** was found to cause 23% inhibition of syncytia formation at concentrations of 3 μg/mL. Higher concentrations were not tested since it was found to be cytotoxic to the host cells at concentrations >6 μg/mL. Strong cytotoxicity at concentrations >0.8 μg/mL was also observed with enniatin B_1 (**4**), which was found to cause a 41% inhibition of the HIV protease enzyme at concentrations of 100 μg/mL. (Details on the biological properties of all five metabolites will be published elsewhere.)

Experimental

General

Nuclear magnetic resonance spectra were obtained at 20–22°C using Jeol 270 MHz-CPF, Varian XL-200 MHz, Varian Gemini 200, and Varian Unity 500 MHz instruments. ^1H and ^{13}C NMR chemical shifts are quoted in ppm and are referenced to the internal deuterated solvent downfield from tetramethylsilane (TMS). ^{19}F NMR was recorded in $CDCl_3$; $CFCl_3$ was used as an external reference.

Mass spectra were performed at the Biomedical Mass Spectrometry Unit, McGill University, and the Mass Spectrometry Centre, Department of Chemistry, University of Ottawa. FAB mass (Cs^+ particles, diethanolamine matrix) spectra were obtained using a Concept 2H Kratos instrument, EI mass spectra were obtained using a VG 7070 instrument, and high-resolution $(NH_3)Cl$ mass spectra were obtained using a ZAB 2F HS instrument (resolution: 10^4).

Melting points were measured using a Gallenkamp capillary apparatus and they are uncorrected. Ultraviolet spectra were recorded on a Hewlett Packard 8452A diode array spectrophotometer. Infrared spectra were recorded on a Bomem Michelson 102 FTIR spectrophotometer calibrated to the 1602 cm^{-1} line of polystyrene.

Chromatography

Reversed phase flash column chromatography was carried out on silica gel (Merck Kieselgel 60, 230–400 mesh, no. 9385) reacted with *n*-octadecyltrichlorosilane. C18 reversed phase silica gel was prepared following previously reported procedures (10*a*).

HPLC

Doubly distilled H_2O and HPLC grade MeOH and MeCN were filtered through a 0.45 μm filter membrane (Millipore Corp., Bedford, Mass.) before they were used in HPLC. Analysis and purification were carried out on a semipreparative, reversed phase, C18 column; Waters Nova-Pak (25 mm × 100 mm, 6 μm, 60A) using a Waters instrument (pump model W600EP, UV/VIS detector model M486P, Rheodyne injector). All retention times were automatically recorded from the time of injection.

General extraction of active metabolites from F. lateritium

Stock cultures of *F. lateritium* were maintained on Czapex-Dox (Difco) plus 5% yeast agar in slant tubes at 4°C. A small amount of mycelium was used to inoculate 40 Czapex-Dox plus 5% yeast agar plates, which were then incubated in the dark, at room temperature, for a period of 5 weeks. A crude metabolite mixture was isolated from the infected agar plates by soaking the agar in CH_2Cl_2 (2 × 500 mL) over a period of 24 h. Evaporation of the CH_2Cl_2 led to the isolation of a metabolite mixture (~240 mg) exhibiting strong antifungal activity against *E. armeniacae*.

The crude metabolite mixture was first purified by flash column chromatography on a C18 reversed phase column (20 mm × 20 cm) (11*a*), using a linear solvent gradient from 0.1% aqueous AcOH to 100% MeOH, at a flow rate of ~4 cm/min. Metabolites **1** and **2** eluted from the column in 45–55% and 60–70% aqueous MeOH, respectively, while metabolites **3**, **4**, and **5** eluted in 80–100% aqueous MeOH. Metabolite **1** was further purified by normal phase flash column chromatography using EtOAc, whereas metabolite **2** was purified by crystallization from CH_2Cl_2. Approximately 5–8 mg of each metabolite **1** and **2** were isolated. Pure metabolites **3**, **4**, and **5** were isolated after semipreparative HPLC on a C18 reversed phase column, eluted with 55% MeOH, 15% H_2O, and 30% MeCN. At a flow rate of 5 mL/min, the retention times for metabolites **3**, **4**, and **5** were 22–23, 26–27, and 33–34 min, respectively. The yields of pure enniatins isolated from 40 infected plates were approximately 12 mg of B (**3**), 15 mg of B_1 (**4**), and 3 mg of A_1 (**5**).

2-(1-Hydroxyethyl)-4(3H)quinazolinone (1): TLC: EtOAc, R_f = 0.34; mp 155–156°C, $[\alpha]_D$ −26.6 (the calculated $[\alpha]_D$ for the *R* enantiomer was based on ~20% ee of *R* in the sample of metabolite **1** isolated, *c* 0.258, MeOH, 20°C). UV (MeOH, nm): max 226, min 264, 304: IR (MeCN): 3550, 3542 (NH, OH), 1690 (-CO-NH-), and 1605 (C=N) cm^{-1}. ^1H NMR (500 MHz, CD_3OD) δ: 1.53 (d, J = 6.6 Hz, 3H, -C*H*$_3$), 4.73 (q, J = 6.6 Hz, 1H, C*H*-OH), 7.49 (ddd, J_{9-10} = 8.1 Hz, J_{8-9} = 7.8 Hz, J_{7-9} = 2.4 Hz, 1H, H9), 7.66 (d, J_{7-8} = 8.1 Hz , 1H, H7), 7.79 (ddd, J_{7-8} = 8.1 Hz, J_{8-9} = 7.8, J_{8-10} = 2.3 Hz, 1H, H8), and 8.18 (dd, J_{9-10} = 8.1 Hz, J_{8-10} = 2.3 Hz, 1H, H10) ppm. ^{13}C NMR: Table 1. MS (HR, $(NH_3)Cl$): *m/z* calcd. for (M^+ + 1) ion: 191.08205; found: 191.08201.

Preparation of the (S)-MTPA-ester 1

(*R*)-MTPA chloride (10 μL, 52 μmol) was added to a solution of **1** (3.3 mg, 17.4 μmol) in pyridine (~100 μL). After the reaction mixture was allowed to stir at room temperature for 15 h, it was diluted with 10 mL CH_2Cl_2 and the pyridine was removed by extraction with 5% aqueous $CuSO_4$ solution (3 × 10 mL). The residue obtained from the CH_2Cl_2 layer after evaporation was purified by preparative TLC (CH_2Cl_2–EtOAc (1:1), R_f = 0.75). ^1H NMR (270 MHz, $CDCl_3$) δ: 1.63 and 1.71 (d, J = 6.6 Hz, ratio ~1:1.5, Me), 3.49 and 3.55 (s, ratio ~1:1.5, -OMe), 5.9 (m, carbinol C*H*), 7.3–8.2 (overlapping aromatic signals), 8.9 and 9.2 (s, ratio ~1.5:1, -CON*H*-) ppm. ^{19}F NMR (270 MHz, $CDCl_3$) δ: −71.7 and −71.4 (ratio 1.5:1) ppm.

2-Acetyl-4(3H)quinazolinone (2): TLC: CH_2Cl_2/EtOAc (3:1), R_f = 0.59; mp 188.0–188.5°C. UV (H_2O, nm): max 232, min 302. IR ($CDCl_3$): 3351 (NH), 1692 (-CO-NH- and -CO-Me), and 1606 (C=N) cm^{-1}. ^1H NMR (270 MHz, $CDCl_3$) δ: 2.75 (s, 3H, -CO-C*H*$_3$), 7.60 (ddd, J_{9-10} = 8.0 Hz, J_{8-9} = 6.1 Hz, J_{7-9} = 2.3 Hz, 1H, H9), 7.78–7.88 (m, 2H, H7 and H8), 8.33 (dd, J_{9-10} = 8.0 Hz, J_{8-9} = 2.3 Hz, 1H, H10), and ~9.9 (bs, 1H, CO-N*H*) ppm. ^{13}C NMR: Table 1. MS (EI, VG 7070E mass spectrometer), *m/z* (% relative intensity, assignment): 189 (100, M^+ + 1), 175 [25, (M^+ + 1) − CH_2], 133 [20, (M^+ + 1) − (CH-CO-CH_3)].

Enniatin B (3): TLC: CH_2Cl_2/EtOAc (1:3), R_f = ~0.73, mp 167–169°C. $[\alpha]_D$ −114.6 (*c* 0.32, $CHCl_3$, 20°C). IR ($CHCl_3$): 1664 (C=O, amide) and 1732 (C=O, ester) cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$): N-Me-Val δ: 0.88 (d, $J_{\beta-\gamma}$ = 6.8 Hz, 3H, γ-Me), 1.05 (d, $J_{\beta-\gamma}$ = 6.3 Hz, 3H, γ-Me), 2.30 (m, 1H,*[3] H_β), 3.12 (s, 3H, N-Me), 4.51 (d, $J_{\alpha-\beta}$ = 9.3 Hz, 1H, H_α) ppm. Hiv δ: 0.95 (d, $J_{\beta-\gamma}$ = 6.8 Hz, 3H, γ-Me), 0.97 (d, $J_{\beta-\gamma}$ = 5.9 Hz, 3H, γ-Me), 2.27 (m, 1H,* H_β), 5.13 (d, $J_{\alpha-\beta}$ = 8.8 Hz, 1H, H_α) ppm. ^{13}C NMR[4] (500 MHz, $CDCl_3$): N-Me-Val δ: 19.1 and 20.2 (2 γ-Me), 27.7 (C_β), 33.06 (N-Me), 63.0 (C_α), and 169.1 (C=O, amide) ppm. Hiv δ: 18.3 and 18.5 (2 γ-Me), 29.7 (C_β), 75.5 (C_α), and 170.1 (C=O, ester) ppm. FAB MS (Cs^+ particles, diethanolamine matrix), *m/z* (assignment): 640 (M + H)$^+$, 662 (M + Na)$^+$, 678 (M + K)$^+$, 745 (M + DEA + H)$^+$, 772 (M + Cs)$^+$.

Enniatin B_1 (4): TLC: CH_2Cl_2/EtOAc (1:3), R_f ~0.73, mp 122–123°C; $[\alpha]_D$ −106.7 (*c* 0.34, $CHCl_3$, 20°C).[5] IR ($CHCl_3$): 1664

[3]An asterisk (*) indicates overlapping signals; integration and (or) *J* values not clear.

[4]Assignments based on the HMQC and HMBC NMR data.

[5]Enniatin B_1 was isolated by Blackwell, Miller and co-workers (4) as a pale yellow oil having $[\alpha]_D$ +173.8; however, the sign of the optical rotation is a typographical error (private communication).

FAB MS (Cs^+ particles, diethanolamine matrix), *m/z* (assignment): 668 $(M + H)^+$, 690 $(M + Na)^+$, 706 $(M + K)^+$, 773 $(M + DEA + H)^+$, 800 $(M + Cs)^+$; (Cs^+ particles, glycerol matrix), *m/z* (assignment); 668 $(M + H)^+$.

Bioassays against E. armeniacae

Biological testing of enniatins B (**3**), B_1 (**4**), and A_1 (**5**) for their ability to inhibit the grown of *E. armeniacae* were carried out on Czapex-Dox plus 5% yeast agar plates. Samples of each compound ranging in amounts from 8 to 170 μg were absorbed onto sterile paper disks and each was placed at the edge of a sterile plate. The plates were inoculated at the center with a constant size plug of *E. armeniacae* mycelium, cut from the edge of an actively grown colony of this fungus. The inhibition zone from the center of the paper disk to the edge of the *E. armeniacae* growth was measured from 1 to 3 days after the growth on the control plates had reached its maximum (i.e., plates were completely covered with mycelium).

Initially, all samples showed an inhibition zone of 8–14 mm, however, after an incubation period of ~15 days there was little or no inhibition observed with enniatins B and B_1, whereas the plates tested with enniatin A_1 showed a consistent and persisting inhibition zone of 5–10 mm. The difference observed between the 8 μg and the 170 μg samples was very small, most likely due to the poor solubility and absorption of the compounds into the agar medium; thus a dose versus inhibition response could not be evaluated.

Acknowledgements

The authors are indebted to Drs. M. V. Carter (Hawthorndene, South Australia) and D. Ramsdell (Department of Botany and Plant Pathology, Michigan State University) for providing us with the isolate of *F. lateritium* used in this work. We are also indebted to Bio-Méga Inc. for carrying out all of the antiviral and cytotoxicity bioassays. We are most grateful to the Natural Sciences and Engineering Research Council (NSERC) of Canada and to Concordia University for financial support.

Structures, binding energies, and thermodynamic functions of NH_4^+, $NH_3^{\cdot+}$, and their H_2O complexes

DAVID A. ARMSTRONG, ARVI RAUK,[1] AND DAKE YU
Department of Chemistry, The University of Calgary, Calgary, AB T2N 1N4, Canada

Received March 30, 1993

DAVID A. ARMSTRONG, ARVI RAUK, and DAKE YU. Can. J. Chem. **71**, 1368 (1993).

Ab initio calculations are performed for $(H_2O)_n \cdots H_4N^+$ and $(H_2O)_n \cdots H_3N^{\cdot+}$ complexes for $n = 0$–5. For $n = 0$ and 1, the geometries of the complexes are optimized at the HF/6-31+G* and MP2/6-31+G* levels, and the energies are evaluated at the G2 level. For $n = 2$–5, the geometry optimizations and frequency calculations are carried out at the HF/6-31+G* level, and the MP2/6-31+G* energies are calculated at the HF optimized geometries. Basis set superposition errors are corrected by the Boys–Bernardi scheme at the HF/6-31+G* level. The gas phase thermodynamic properties C_P^0, S^0, and $H^0 - H_0^0$, are evaluated as functions of temperature using standard statistical methods. Based on the calculated binding energies and the thermodynamic functions, the incremental changes in enthalpies and free energies, ΔH_n and ΔG_n, for the gas phase equilibria $(H_2O)_{n-1}M^+ + H_2O \rightarrow (H_2O)_nM^+$ for $M^+ = NH_4^+$ and $NH_3^{\cdot+}$, are evaluated in comparison with the experimental data for $(H_2O)_n \cdots H_4N^+$, the present results suggest conformations for the hydrated complexes observed in the experiments. The total free energy change for filling the first hydration shell is significantly more negative for $NH_3^{\cdot+}$ than for NH_4^+.

DAVID A. ARMSTRONG, ARVI RAUK et DAKE YU. Can. J. Chem. **71**, 1368 (1993).

On a effectué des calculs *ab initio* sur les complexes $(H_2O)_n \cdots H_4N^+$ et $(H_2O)_n \cdots H_3N^{\cdot+}$ dans lesquels $n = 0$–5. Pour $n = 0$ et 1, on a optimisé les géométries aux niveaux HF/6-31+G* et MP2/6-31+G* et les énergies au niveau G2. Pour $n = 2$–5, on a effectué les calculs des optimisations de géométrie et de fréquence au niveau HF/6-31+G* et on a calculé les énergies au niveau MP2/6-31+G* sur des géométries optimisées au niveau HF. On a corrigé les erreurs dues aux superpositions d'ensembles en faisant appel à la méthode de Boys–Bernardi au niveau HF/6-31+G*. Faisant appel à des méthodes statistiques standard, on a évalué les propriétés thermodynamiques C_P^0, S^0 et $H^0 - H_0^0$ en phase gazeuse en fonction de la température. En se basant sur les énergies de liaison calculées et sur les fonctions thermodynamiques, on a évalué les augmentations incrémentielles des enthalpies et des entropies libres, ΔH_n et ΔG_n, pour les équilibres gazeux $(H_2O)_{n-1}M^+ + H_2O \rightarrow (H_2O)_nM^+$ dans lesquels $M^+ = NH_4^+$ et $NH_3^{\cdot+}$. Par comparaison avec les résultats expérimentaux pour $(H_2O)_n \cdots H_4N^+$, ces calculs suggèrent les conformations des complexes hydratés observées dans les expériences. Le changement total d'énergie libre pour remplir la première couche d'hydration est beaucoup plus négative pour le $NH_3^{\cdot+}$ que pour le NH_4^+.

[Traduit par la rédaction]

1. Introduction

Experimental and theoretical investigations of gas phase ion–solvent clusters for solvents such as water have been of interest for many years (1–6). Mass spectrometric investigations provide accurate thermodynamic data on the binding of solvent molecules, but do not as a rule lead to explicit structural information (1, 2). Vibrational data on aquo ion complexes is also rare (7). *Ab initio* calculations, which yield structures and vibrational frequencies as well as binding energies that can be correlated with those obtained experimentally, therefore play an important complementary role (3). In particular, they make comparisons of the relative stabilities of different structures possible (3, 4). They can also be carried out on systems where experiment is technically difficult.

This publication describes a study of the gas phase aquo complexes of the ammonium and amminium ions, NH_4^+ and $NH_3^{\cdot+}$. The specific interest in amminium ions arises from a prior (8) interpretation of experimental data that showed that the solution free energy of the trialkyl amminium system, $(CH_3)_3N^{\cdot+}$, is probably some 30 kJ mol^{-1} larger in magnitude than that of the corresponding ammonium species, $(CH_3)_3NH^+$. For these larger species high-level *ab initio* calculations of "solvation" are of course not practical. The $NH_3^{\cdot+}$ species was chosen so that the effect of the difference in forming aquo complexes between it and ammonium could be examined by *ab initio* methods at reasonably high levels. The NH_4^+ ion serves as a standard since the free energies for $(H_2O)_{n-1}H_4N^+ + H_2O \rightarrow (H_2O)_nH_4N^+$ have been studied experimentally in the gas phase by a number of research groups (9, 10). Therefore there are accurate experimental results with which comparisons of the theoretical predictions can be made.

The binding energies and structures for the complexes formed by successive addition of water molecules to ammonium and amminium ions in reaction [1]

[1] $(H_2O)_{n-1}M^+ + H_2O \rightarrow (H_2O)_nM^+$

were determined by carrying out *ab initio* calculations at the HF and MP2 levels with 6-31+G* basis sets on all complexes with n up to 5. The complexes $H_2O \cdots HNH_3^+$ and $H_2O \cdots HNH_2^{\cdot+}$ were also studied at the G2 level (11) to provide an indication of the level of accuracy to be expected from the HF and MP2 calculations.

Computational details are provided in Sect. 2, and the results are reported in Sect. 3. In Sect. 4, the results are discussed in comparison with the experimental and theoretical studies in the literature. Conclusions have been summarized in Sect. 5.

2. Computational details

Ab initio *calculations*

All *ab initio* calculations presented here were performed with the Gaussian 90 molecular orbital packages (12). In the

cases of calculations on the free radical species, $\langle S^2 \rangle$ was invariably close to 0.76, indicating negligible spin contamination of the UHF wave function. For $(H_2O)_n \cdots H_4N^+$ and $(H_2O)_n \cdots H_3N^{\cdot+}$, with $n = 0$ and 1, it is possible to evaluate their energies at the G2 level (11) of theory. The G2 procedure includes the following: a geometry optimization with the standard Hartree–Fock (HF) method and the 6-31G* split-valence basis set; a vibrational frequency calculation at the HF optimized geometry; the second-order Moller–Plesset (MP2) geometry optimization with 6-31G* basis set; and a series of single-point post-HF calculations carried out on the MP2 optimized geometry, to obtain an accurate evaluation of the correlation energies. The geometries of these complexes are also optimized at the HF and MP2 levels with the 6-31+G* basis set, to include diffuse functions that are important in studying hydrogen-bonding systems. The procedure proposed by Boys and Bernardi (13) was used to estimate and correct for the basis set superposition error (BSSE) at the HF/6-31+G* level on the HF/6-31+G* optimized geometries. It should be noted that the Boys–Bernardi scheme represents an overestimate of the BSSE (14).

For the complexes associated with more than one water molecule, the geometry optimizations were performed at the HF/6-31+G* level. The H-bonded complexes are characterized by very flat potential energy surfaces. Convergence of the geometries was to the limit imposed internally in Gaussian 90 without symmetry constraints.[2] All structures are energetically close to minima, as confirmed by frequency calculations that yield all real frequencies. All the vibrational frequencies calculated at the HF/6-31G* and HF/6-31+G* levels were scaled by a factor of 0.89 (15) in considering the zero-point energy (ZPE) and in the calculations of thermodynamic properties. Correlation corrections to the total energies were estimated by single-point calculations with the same basis set at the level of MP2 theory.

Thermodynamic functions

Ideal gas thermodynamic functions C_P^0, S^0, and $H^0 - H_0^0$ in the temperature range 100–298.15 K and 1 bar (1 bar = 100 kPa) pressure were calculated by standard statistical thermodynamic methods based on the rigid rotor – harmonic oscillator model. The lowest vibrational modes, which correspond to torsional motions of bound H_2O molecules, were treated as internal rotations. As the barriers for the internal rotations around the hydrogen bonds are very small, the calculations were carried out using the free rotor model. Without symmetry constraints, the geometry optimization usually resulted in low (or no) symmetry structures. For the hydrogen-bonded systems, more than one conformer is often accessible without significant change in the total energy. Therefore, in calculating the entropies of the complexes, the symmetry numbers used were taken as the number of rotation operations in the molecular point group of the highest possible symmetry of the complex.[2] Calculations of accurate $\Delta_f H^0$ and $\Delta_f G^0$ values for NH_4^+, $NH_3^{\cdot+}$, and $H_2O \cdots HNH_2^{\cdot+}$ have been presented in ref. 16.

[2]Optimizations without symmetry constraints invariably yield C_1 symmetry structures. Many of the structures converged to geometries with apparently higher symmetry. The actual presence of higher symmetry has no energetic consequences and was not pursued. For the purpose of evaluation of the rotational partition functions, however, structures of the highest symmetry close to the converged geometries were assumed.

The binding energies of the complexes at 0 K are defined as E(complex) $- \Sigma E$(fragment), where E is the *ab initio* total energy (including the ZPE contribution). The *incremental* energy changes, ΔE_n, for reaction [1] at 0 K, were also calculated from the E values with $n = 1$–5. Based on that information and the calculated thermodynamic functions for the fragments and complexes, the corresponding incremental changes in enthalpy (ΔH_n), entropy (ΔS_n), and free energy (ΔG_n) for reaction [1] at 298 K were then found.

3. Results

The HF/6-31+G* optimized structures of the isolated NH_4^+ and $NH_3^{\cdot+}$, and some of their water complexes, are plotted in Figs. 1 and 2, respectively. The main geometric features of the complexes can be determined by the listed characteristic parameters and the symmetry types. The energies evaluated at different levels are reported in Table 1, and the incremental binding energies, $\Delta E_n (= E[(H_2O)_n M^+] - E[(H_2O)_{n-1} M^+] - E(H_2O))$, with and without BSSE correction, are listed in Table 2. For the purpose of BSSE correction, $E[(H_2O)_{n-1}M^+]$ was evaluated in the presence of the basis functions of the nth H_2O, and similarly, the energy of the nth H_2O, $E(H_2O)$, was calculated in the presence of the basis functions of $(H_2O)_{n-1}M^+$ (13).

For clarity, we introduce a condensed notation (i,j,k) to denote the number and distribution of bound H_2O molecules on M^+, where i, j, and k stand for the number of H_2O bonded to H atoms of M^+, to H atoms of H_2O, and to the N atom of M^+, respectively. The total number of H_2O molecules bonded to M^+ is $n = i + j + k$.

Throughout the paper, three dots (···) have been used to separate complexed partners and proximity denotes the nature of the interaction. Thus $(H_2O)_2 \cdots H_2NH_2^+$ denotes a complex formed by bonding two water molecules on the H atoms of NH_4^+. The "isomeric" complex with the second water bonded to the first one would be denoted as $H_2O \cdots H_2O \cdots HNH_3^+$. Subsequently complexes of these two kinds are identified as (2,0,0) and (1,1,0) in our condensed notation. Similar notations are used for $M^+ = NH_3^{\cdot+}$ species.

The thermodynamic functions for H_2O, $(H_2O)_n \cdots H_4N^+$, and $(H_2O)_n \cdots H_3N^{\cdot+}$ are reported in Table 3. The enthalpy and free energy changes for reaction [1] calculated from the S^0 and $H^0 - H_0^0$ values, and the BSSE corrected ΔE_n of Table 2, are given in Table 4. The ΔH_n vs. the number of bonded H_2O molecules are also plotted in Fig. 3, compared with the available experimental data.

4. Discussion

Equilibrium structures and energetic considerations

The structures of the isolated H_2O, NH_4^+, and $NH_3^{\cdot+}$ have been discussed elsewhere (16) and it may be noted here that the optimized geometries at the HF/6-31+G* level are in reasonable agreement with experimental geometries.

Basis set superposition errors were expected to be small for the hydrogen-bonded species because of the large separations involved. Comparison of columns I and I_{BSSE} in Table 2 reveals that the magnitude of BSSE falls in the range of 3.1–3.8 kJ mol^{-1} except in the cases of (3,0,1) and (3,0,2) of $H_3N^{\cdot+}$ complexes, where the correction for the axially coordinated H_2O is less than 1 kJ mol^{-1}.

$(H_2O)_n \cdots H_4N^+$ complexes.

Pullman et al. (4) investigated three possible configurations of the complex formed with one H_2O and NH_4^+, namely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12

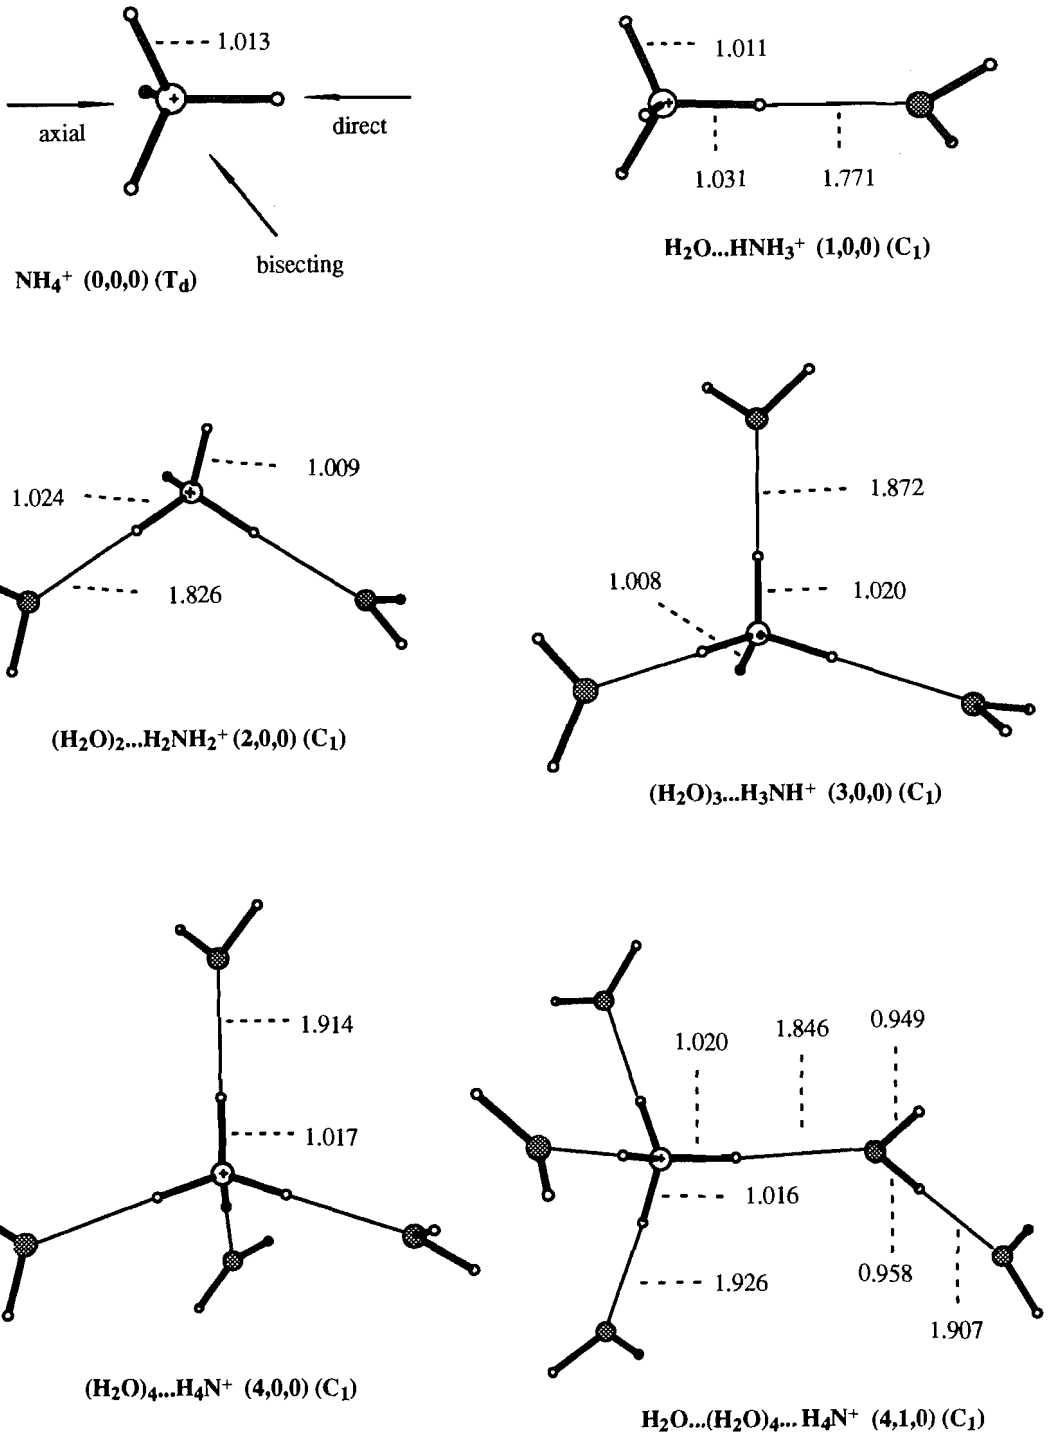

FIG. 1. HF/6-31+G* optimized structures for NH_4^+ and its water complexes. Filled circles represent oxygen atoms, large open circles are nitrogen, and small open circles are hydrogen. Bond lengths in Å, angles in degrees.

the direct (1,0,0), and bisecting and axial approaches of H_2O to NH_4^+ (see Fig. 1 for the definitions). The last two would both be denoted as (0,0,1) in our condensed notation. The direct approach was found to form the most stable complex at the HF level with an extended polarized basis set, and the bisecting and axial species were found to be 13 and 17 kJ mol^{-1} higher in energy, respectively. In the present study, only one stable complex was found, i.e., the (1,0,0) structure formed from direct approach. With C_s and C_2 symmetry constraints on the bisecting and axial complexes, respectively, the estimated relative stabilities (referring to the (1,0,0) structure) are 12 and 15 kJ mol^{-1} from the HF/6-31+G* energies evaluated at the HF/6-31+G* optimized geometries (HF/6-31+G*//HF/6-31+G*), which are similar to those found by Pullman et al. (4). However, frequency calculations suggest these complexes are not stable. In the present publication, we will only discuss the NH_4^+ complexes that arise from direct approaches.

The first H_2O molecule forms a linear complex (1,0,0) with the H atom of NH_4^+. The O ··· H distance is 1.77 Å, well

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12

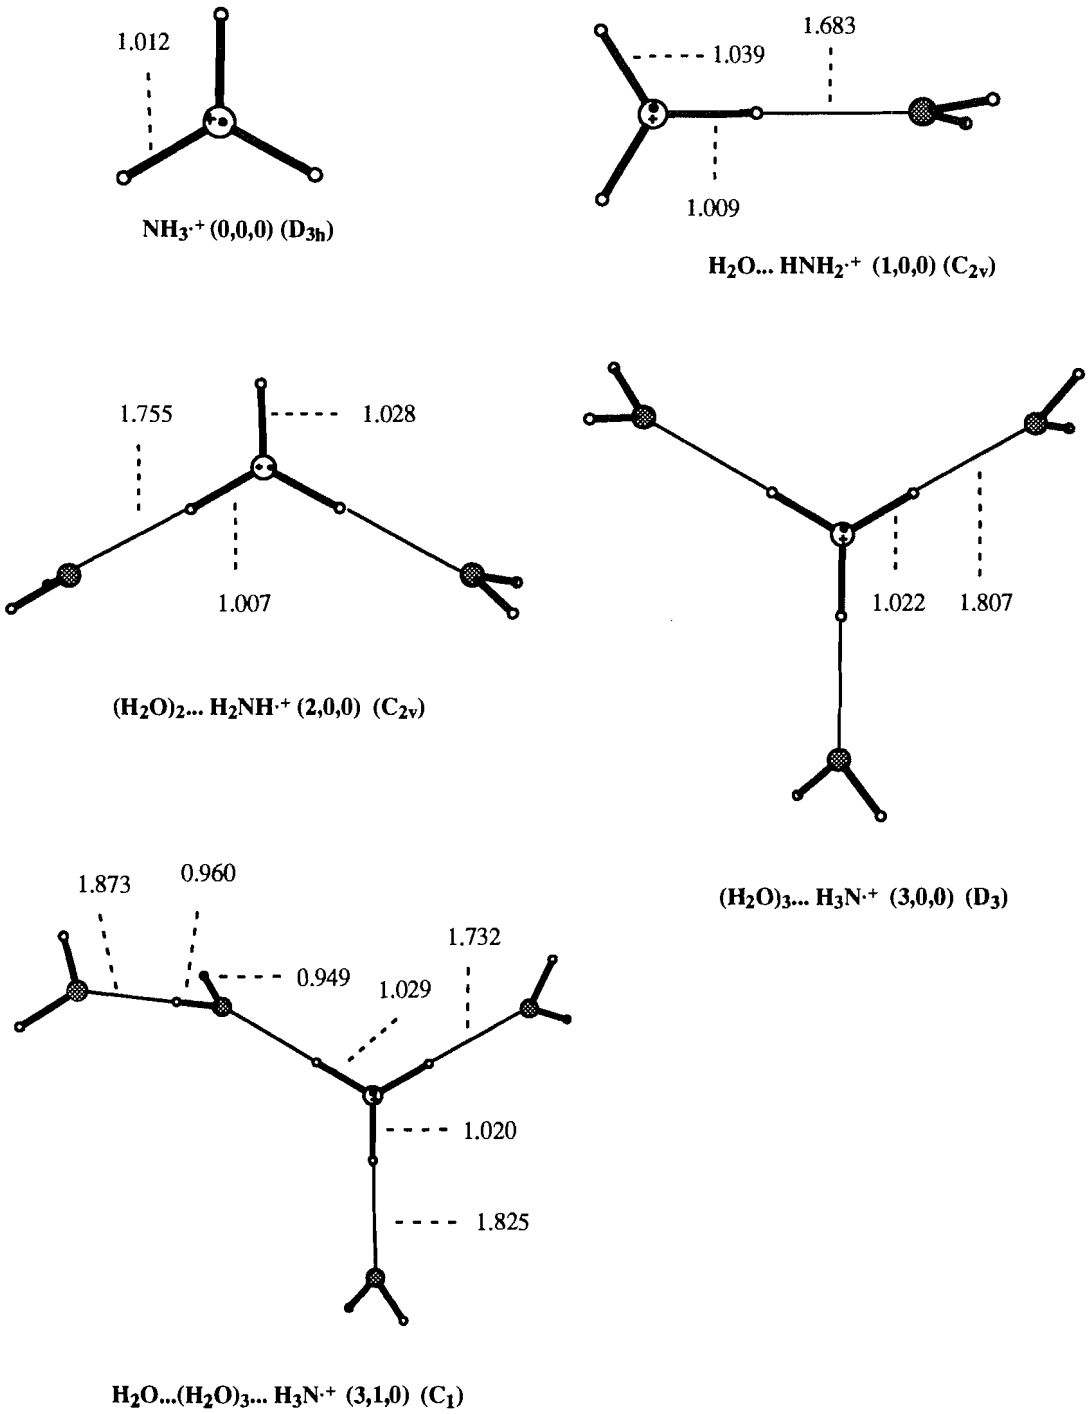

FIG. 2. HF/6-31+G* optimized structures for $NH_3^{\cdot+}$ and its water complexes. Filled circles represent oxygen atoms, large open circles are nitrogen, and small open circles are hydrogen. Bond lengths in Å, angles in degrees.

within the van der Waals separation 2.6 Å. The hydrogen-bonded N—H distance is 0.018 Å longer than that of isolated NH_4^+, while the other N—H bonds are almost identical to those of isolated NH_4^+. The changes in H_2O bond structure are minor. The orientation of the H_2O is not tipped as it is for the donor H_2O of the water dimer (16), indicating that the structure is dominated by charge–dipole interaction. For this species, the structure was also optimized at the MP2/6-31+G* level. The general features of the MP2/6-31+G* geometry are very similar to those of HF/6-31+G*, but the H bond is stronger; and the O—H distance is 1.713 Å, 0.058 Å shorter than that predicted at the HF level.

The binding energy of $H_2O \cdots HNH_3^+$ was evaluated at several levels of theory up to G2. The G2 level binding energy is -77.2 kJ/mol^{-1}, and served as reference for the performance of lower levels of theory, which must be employed for the larger species. The BSSE uncorrected HF/6-31+G*/HF/6-31+G* energies including the ZPE corrections give a value within 1 kJ/mol^{-1} of the G2 value, being -76.4 kJ mol^{-1}. The MP2/6-31+G*//HF/6-31+G*

[a] i, j, and k are the number of H_2O molecules bonded to H atoms of M^+, to H atoms of H_2O, and to the N atom of M^+, respectively.
[b] Symmetry number used in calculating S^0.

found a binding energy of 77 kJ mol^{-1} at the HF level with extended polarized basis set. The values reported by Welti et al. (5) including configuration interaction are −84.7 and −83.1 kJ mol^{-1} at the CISD and CISDQ levels, respectively. The BSSE at HF/6-31+G* for this interaction energy was found to be 3.8 kK mol^{-1}, yielding an value of interaction energy −72.6 kJ mol^{-1}.

The results for this complex suggest that the true binding energies may lie in between those evaluated at HF/6-31+G*//HF/6-31+G* + ZPE and MP2/6-31+G*//HF/6-31+G* + ZPE levels. If the G2 values for $H_2O \cdots HNH_3^+$ (and $H_2O \cdots HNH_2^{\cdot+}$) are used as references, the results listed in Table 2 also indicate that for the HF/6-31+G*//HF/6-31+G* + ZPE binding energies there is a fortuitous cancellation of correlation errors. Therefore, we will discuss the bond strength based on the values obtained at this level from now on.

In $(H_2O)_2 \cdots H_2NH_2^+$, (2,0,0) structure, the two water molecules form almost symmetric hydrogen bonds with the H atoms of NH_4^+; both are within 2° from linear. The O ··· H separations are both 1.826 Å, increased by 0.055 Å from that of $H_2O \cdots HNH_3^+$. The local structures of NH_4^+ and H_2O are altered little. The binding energy of the second H_2O molecule is calculated to be 61.7 kJ mol^{-1}. Thus the incremental binding energy of the second water is reduced by 10.9 kJ mol^{-1} from that of the first.

An exhaustive search of all possible local minima of the $(H_2O)_2 \cdots H_2NH_2^+$ potential surface was not conducted. However, a second configuration was examined, in which the second water molecule is H bonded to the first one, i.e., a (1,1,0) structure, $H_2O \cdots H_2O \cdots HNH_3^+$. This complex was found to be 16.9 kJ mol^{-1} less stable than the (2,0,0) isomer, $(H_2O)_2 \cdots H_2NH_2^+$. The hydrogen bond length of O ··· HN is reduced by 0.178 Å, compared with that of $H_2O \cdots HNH_3^+$. The O ··· HO hydrogen bond length is 1.821 Å and 3° from linear. It is of interest to note that this hydrogen bond length is 0.193 Å shorter than the corresponding one in water dimer $H_2O \cdots HOH$ (16), and the binding energy ($E(1,1,0) - E(1,0,0) - E(H_2O)$) of 44.8 kJ mol^{-1} is substantially larger than that of $H_2O \cdots HOH$, 10.0 kJ mol^{-1} at the same level. This indicates a strong "secondary" effect of the central charge of NH_4^+.

The additions of the third H_2O molecule to NH_4^+ were also

[e] Reference 10.

investigated for two configurations, namely, $(H_2O)_3 \cdots H_3NH^+$ and $H_2O \cdots (H_2O)_2 \cdots H_2NH_2^+$, structures (3,0,0) and (2,1,0) of Fig. 1. The three nearly equivalent O ··· H hydrogen bond lengths are 1.872 Å in $(H_2O)_3 \cdots H_3NH^+$, and the hydrogen bonds are within 2° deviation from linear. The incremental binding energy of the third H_2O is found to be 53.0 kJ mol^{-1}, 8.7 kJ mol^{-1} less than the second. $H_2O \cdots (H_2O)_2 \cdots H_2NH_2^+$ is 11.9 kJ mol^{-1} higher in energy than $(H_2O)_3 \cdots H_3NH^+$. The water dimer bonded O ··· HN bond length is shorter by 0.1 Å than water monomer O ··· HN, reflecting the effect of the "secondary" water molecule. The O ··· HO hydrogen bond of structure (2,1,0) is longer by 0.048 Å than that in $H_2O \cdots H_2O \cdots HNH_3^+$ (1,1,0) but still substantially shorter than that of $H_2O \cdots HOH$. The corresponding binding energy, 40.5 kJ mol^{-1}, reduced by 4.3 kJ mol^{-1} from that of (1,1,0) is 4 times that of $H_2O \cdots HOH$.

The binding of a fourth H_2O to the remaining H atom of NH_4^+ forms $(H_2O)_4 \cdots H_4N^+$, (4,0,0), and fills the first hydration shell of NH_4^+. The four O ··· H hydrogen bond lengths are 1.914 Å, and the bonds are within 2° of being linear. The incremental binding energy of the last water in the first hydration shell is 45.8 kJ mol^{-1}, about 63% that of the first one. The average binding energy for the first shell H_2O molecules is 53.8 kJ mol^{-1}. A complex $H_2O \cdots (H_2O)_3 \cdots H_3NH^+$ (3,1,0) is also found to be a local minimum but less preferred by 9.0 kJ mol^{-1} than $(H_2O)_4 \cdots H_4N^+$. The O ··· HO distance is 1.891 Å and the angle is only 1° from linear. The length of the O ··· HN from the "water dimer" is also found to be about 0.1 Å shorter than the two O ··· HN bonds from water monomers. Again, the binding energy for the "water dimer" in (3,1,0) was found to be reduced by 3.7 kJ mol^{-1} from that of the (2,1,0) structure. It is clear from the above investigation that, given a choice, attachment of water to H—N^+ is preferred to attachment to H—O.

Three possibilities of adding a fifth water molecule to the (4,0,0) structure $(H_2O)_4 \cdots H_4N^+$ have been examined: binding to N in an axial or bisected fashion (Fig. 1) or attachment to one of the H atoms of one of the hydrogen-bonded water molecules. The geometry optimizations indicated that the preferred binding sites of the fifth H_2O are the H atoms of the water molecules, to form complex (4,1,0), $H_2O \cdots (H_2O)_4 \cdots NH_4^+$. No stable axial or bisected structures, which would be denoted as (4,0,1), were found. Attempts at optimization of a (4,0,1) structure from reasonable starting points yield a (4,1,0) structure. Similar to $(n - 1,1,0)$ structures, $H_2O \cdots (H_2O)_n \cdots H_nNH_{4-n}^+$, the O ··· HN bond with the second water attached is reduced by about 0.1 Å, compared with the other three O ··· HN distances. The O ··· HO forms a fairly strong hydrogen bond, with an O ··· H distance 0.7 Å shorter than the corresponding van der Waals separation and only 1° deviation from linear. The incremental binding energy ΔE_5 is 33.4 kJ mol^{-1} at the HF level.

$(H_2O)_n \cdots H_3N^{\bullet+}$ complexes.

The optimized $H_2O \cdots HNH_2^{\bullet+}$ structure, (1,0,0) in our condensed notation, has C_{2v} symmetry, the radical center $N^{\bullet+}$ being planar and the OH_2 molecule lying in a plane perpendicular to it (Fig. 2). The hydrogen bond is stronger by 11.9 kJ mol^{-1} than that in $H_2O \cdots HNH_3^+$, as reflected by the O ··· H separation, which is 0.088 Å shorter (1.683 vs. 1.771 Å). The hydrogen-bonded N—H bond is lengthened by 0.027 Å but there are no significant changes in local H_2O structure from the isolated one. The binding energy was found to be 87.9 kJ mol^{-1} at the HF level, and 91.2 kJ mol^{-1} at the G2 level. The BSSE corrected value is 84.5 kJ mol^{-1}. Again,

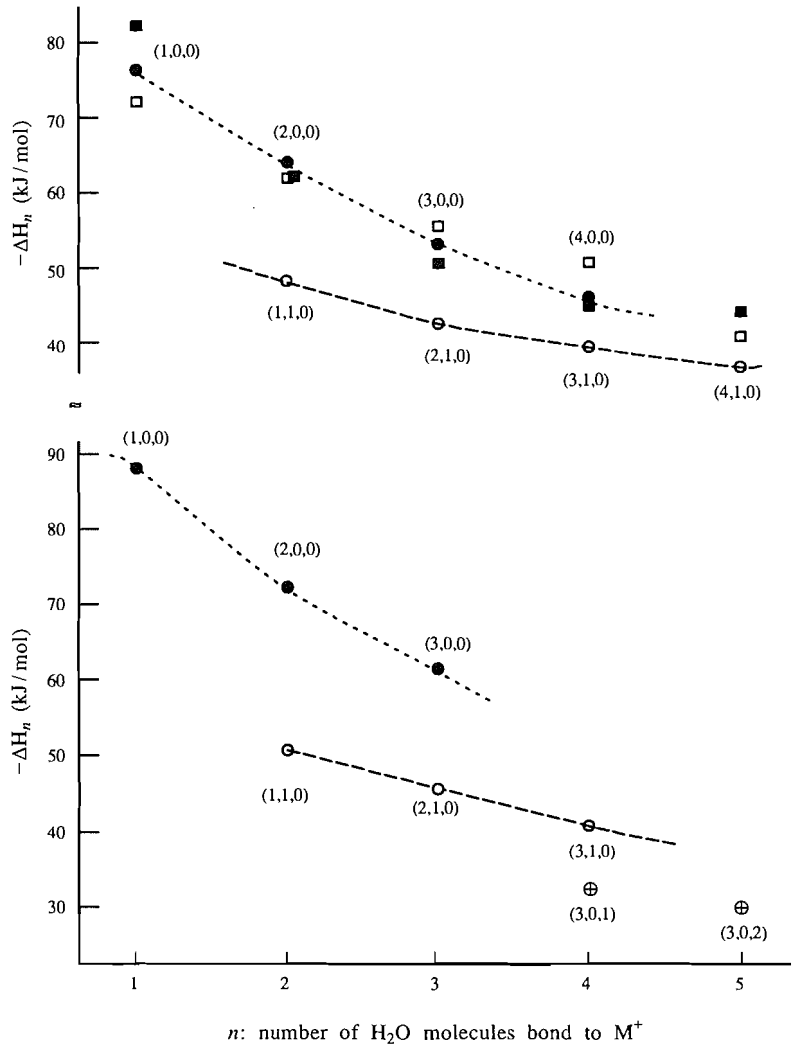

FIG. 3. Experimental and calculated $\Delta_r H_{n-1}$ for NH_4^+ and $NH_3^{\bullet+}$. Experimental values for NH_4^+ are taken from refs. 9 (□) and 10 (■). Circles display calculated data: ● indicates n H_2O molecules bonded to H atoms of NH_4^+ or $NH_3^{\bullet+}$; ○ indicates $n-1$ H_2O molecules bonded to NH_4^+ or $NH_3^{\bullet+}$, and one H_2O bonded to an H atom of H_2O; ⊕ indicates one or two H_2O bonded to the N atom while the rest are bonded to H atoms of $NH_3^{\bullet+}$.

the G2 value is between the HF and MP2 (97.7 kJ mol^{-1}) binding energies, and HF is slightly closer to the G2 value.

The possibility of forming a $H_2O \cdots NH_3^+$ complex through three-electron or one-electron bonding involving the singly occupied molecular orbital of N, i.e., a (0,0,1) complex, was examined previously (16). It was found that $H_2O \cdots NH_3^{\bullet+}$ (0,0,1) does not correspond to a stationary point on the potential energy surface, in the gas phase.

The preferred addition sites for the second and third H_2O molecules to $NH_3^{\bullet+}$ are also the H atoms of $NH_3^{\bullet+}$. The optimized $(H_2O)_2 \cdots H_2NH^{\bullet+}$ has C_{2v} symmetry, with the water H atoms perpendicular to the radical plane. The two symmetric hydrogen bond lengths equal 1.752 Å, longer by 0.069 Å than that in $H_2O \cdots HNH_2^{\bullet+}$. The incremental binding energy, ΔE_2, of the second water molecule is 70.5 kJ mol^{-1}, smaller by 14.0 kJ mol^{-1} than ΔE_1. For NH_4^+, the difference between ΔE_1 and ΔE_2 is smaller, being 10.9 kJ mol^{-1}, suggesting the incremental binding energy decreases faster for $NH_3^{\bullet+}$ complexes.

On binding the second water molecule to the H atom of H_2O, a slightly less stable isomer of $H_2O \cdots H_2O \cdots HNH_2^{\bullet+}$ (1,1,0), which is 21.8 kJ mol^{-1} higher in energy than $(H_2O)_2 \cdots H_2NH^{\bullet+}$, is obtained. The hydrogen bond lengths of O ··· HO are 1.821 Å with corresponding binding energy of 48.7 kJ mol^{-1}. The O ··· HN distance is reduced by 0.09 Å from that of the complex with single water, $H_2O \cdots HNH_2^{\bullet+}$. The "secondary" effect of the central charge is even stronger than the cases for NH_4^+ complexes, reflected by the binding energy for the $H_2O \cdots HOH$ in their (1,1,0) structures (48.7 vs. 44.8 kJ mol^{-1}). Note that these binding energies are much larger than that for the water dimer, 10.0 kJ mol^{-1} at the same level of theory.

In the (3,0,0) structure, $(H_2O)_3 \cdots H_3N^{\bullet+}$, the planes defined by the water molecules form angles of 67.3° with the $NH_3^{\bullet+}$ plane and give this complex D_3 symmetry. The D_{3h} structure has an almost identical total energy but with a small imaginary frequency (58i cm^{-1}). In fact, the internal rotations in the hydrogen-bonded complexes are essentially unhindered, more than one rotational conformer being accessible without a significant change in total energy (16). The hydrogen bond lengths in $(H_2O)_3 \cdots H_3N^{\bullet+}$ are 1.807 Å, 0.124 Å longer than that of $H_2O \cdots HNH_2^{\bullet+}$. The incremen-

For personal use only.

tal binding energy of the third H_2O is 60.0 kJ mol^{-1}. The (2,1,0) isomer, $H_2O \cdots (H_2O)_2 \cdots H_2NH^{\cdot+}$, is found to be less stable by 17.9 kJ mol^{-1} at the HF level, 3.9 kJ mol^{-1} less than the difference between the (2,0,0) and (1,0,0) structures.

For the addition of the fourth water molecule to the (3,0,0) structure, two possible sites need to be considered, binding to one of the H atoms of the first-shell water molecules, to form a (3,1,0) structure $H_2O \cdots (H_2O)_3 \cdots H_3N^{\cdot+}$ and an axial binding to form (3,0,1) structure $(H_2O)_3 \cdots H_3N^{\cdot+} \cdots OH_2$. Both structures are found. The more stable (3,1,0) complex has a linear O ··· HO hydrogen bond with a bond length 1.873 Å. The corresponding O ··· HN distance is shorter by 0.075 Å and the other two O ··· HN separations are lengthened by 0.018 Å from those in $(H_2O)_3 \cdots H_3N^{\cdot+}$. The binding energy is found to be 38.3 kJ mol^{-1} at the HF level, only half of that for the first H_2O bonded on the first hydration shell. The secondary interaction can be seen clearly by comparing the successive reductions in binding energies. Thus $\Delta E_1 - \Delta E_2 = 14.0$ and $\Delta E_2 - \Delta E_3 = 10.5$, while $\Delta E_3 - \Delta E_4 = 21.7$ kJ mol^{-1}.

The (3,0,1) complex $(H_2O)_3 \cdots H_3N^{\cdot+} \cdots OH_2$ is also predicted to be stable, though in a very shallow potential well. The binding energies were found to be 33.5 kJ mol^{-1} at the HF level. Compared with the (3,1,0) complex, $H_2O \cdots (H_2O)_3 \cdots H_3N^{\cdot+}$, the binding energy is 4.8 kJ mol^{-1} less, indicating that the H atoms of the H_2O molecules are still the preferred positions of attachment.

In $(H_2O)_3 \cdots H_3N^{\cdot+} \cdots OH_2$, (3,0,1), the radical center is little altered from planarity. This leads us to explore the possibility of adding another water molecule to the N atom of (3,0,1) structure. A structure $(H_2O)_3 \cdots H_3N^{\cdot+} \cdots (OH_2)_2$, i.e., (3,0,2), optimized with constraints has an imaginary frequency of 37i cm^{-1}, indicating the tendency of the fifth H_2O to transfer to a H atom of another H_2O, possibly to form a (3,1,1) structure. The estimated binding energies, with the (3,0,2) structure that undoubtedly would be present in solution, are 28.7 at HF levels. We did not pursue structures of the (3,1,1) type further.

Vibrational frequencies and zero-point energy (ZPE)

The calculated vibrational frequencies indicate that the complexes correspond to minima in the potential energy surfaces, with the exception of $(H_2O)_3 \cdots H_3N^{\cdot+} \cdots (OH_2)_2$. For many of the complexes, the first few vibrational frequencies are very small, confirming that the corresponding potential wells are very flat, permitting different conformers to be reached without significantly increasing the total energies of the complexes.

For a complex with n hydrogen bonds, there are $6 \times n$ vibrational modes more than the sum of those in the fragments. Even if the torsional modes are treated as free internal rotations, the remaining $5 \times n$ modes may contribute to the ZPE change in a significant way. It is found that even for weakly interacted systems, the ZPE correction to the binding energy ranges from 4 to 10 kJ mol^{-1} per hydrogen bond, and thus plays an important role in evaluating accurately the binding energies.

Gas phase thermodynamic functions

In the case of NH_4^+, values of ΔH_n, ΔS_n, and ΔG_n for reaction [1] have been measured for $n = 1$–5 in the gas phase (9, 10). These are compared with the present calculated values in Table 4 and the ΔH_n values are also plotted as a function of n in Fig. 3. The plots of Fig. 3 and the data for the $(n,0,0)$ and $(n-1,1,0)$ clusters listed in Table 4 suggest that the experimentally measured incremental free energy values are for structures of the $(n,0,0)$ type for $n \leq 4$. The level of agreement between the calculated and experimental data is excellent. Indeed it is a clear confirmation that the species studied experimentally are all of the $(n,0,0)$ type.

From Fig. 3 it is evident that the curves for $(n,0,0)$ and $(n-1,1,0)$ complexes will merge at approximately $n = 5$. The present data, which are still in reasonable agreement with experiment at that point, showed that the structure with the fifth water bonded to it is a structure of (4,1,0) type.

A search of the literature on ion clusters did not reveal any studies of $NH_3^{\cdot+}$ complexes with water. However, from Table 4 and Fig. 3 one can see that the trends for the $(n,0,0)$ and $(n-1,1,0)$ complexes with increasing n resemble those for NH_4^+ in that $(n-1,1,0)$ species are bound less strongly. There are, however, three points of particular interest. First, the binding of the initial three waters in $NH_3^{\cdot+}$ is much stronger than in the case of the first four waters bound to NH_4^+. This is such that $\Delta_r G_g(3) = \Sigma_{n=1}^{3} \Delta G_n$ for this species is slightly more negative than $\Delta_r G_g(4) = \Sigma_{n=1}^{4} \Delta G_n$ for NH_4^+ (−128.7 vs. −119.4 kJ mol^{-1}). Secondly, for $(n-1,1,0)$ type complexes, the ΔG_n are also more negative for $NH_3^{\cdot+}$ species than for NH_4^+. For $n = 2$–4, the differences in free energy change between $NH_3^{\cdot+}$ and NH_4^+ species are 6.8, 2.0, and 3.5 kJ mol^{-1}, respectively. Third, at least one, and possibly two H_2O molecules can occupy sites axial to the N^+ center of $NH_3^{\cdot+}$ (above and below the plane of the H atoms) with a further stabilization. As indicated in Table 4, the addition of the fourth water molecule (from (3,0,0) structure to (3,0,1) structure) gives a free energy change of −7.1 kJ mol^{-1}. In the gas phase the structure (3,0,2) is unstable and corresponds to a similar amount of destabilization. However, in liquid water both sites will undoubtedly be occupied. These considerations imply that the solution free energy of $NH_3^{\cdot+}$ could be more negative than that of NH_4^+.

5. Conclusions

The present study confirmed that the experimentally observed incremental changes in free energies for $(H_2O)_n \cdots H_4N^+$ $(n \leq 4)$ are due to the formation of $(n,0,0)$-type complexes, i.e., water molecules binding to the H atoms of H_4N^+. The calculated incremental changes for enthalpy and free energy are in good agreement with the experimental data. The results for $NH_3^{\cdot+}$ aquo complexes provide new information on the hydration of $NH_3^{\cdot+}$. The change in free energies also suggests that water molecules form stronger aquo complexes with $NH_3^{\cdot+}$ than they do with NH_4^+.

Étude thermodynamique des trois isomères de l'acide hydroxybenzoïque

RAPHAËL SABBAH[1] ET THI HUY DUC LE

Centre de thermodynamique et de microcalorimétrie du Centre national de la recherche scientifique, 26, rue du 141e R.I.A., 13003 Marseille, France

Reçu le 21 avril 1993

RAPHAËL SABBAH et THI HUY DUC LE. Can. J. Chem. **71**, 1378 (1993).

L'étude thermodynamique des trois isomères de l'acide hydroxybenzoïque a été réalisée par calorimétrie de combustion, de sublimation, par mesures de capacités calorifiques par la méthode de chute et par analyse thermique différentielle. Elle nous a permis de déterminer les fonctions thermodynamiques suivantes (exprimées en kJ mol^{-1}) :

	ortho	*méta*	*para*
$-\Delta_c H^0_m$(s, 298,15 K)	3020,0 ± 1,3	3017,9 ± 1,1	3005,4 ± 2,1
$-\Delta_f H^0_m$(s, 298,15 K)	592,1 ± 1,3	594,1 ± 1,1	606,6 ± 2,1
$\Delta_{sub} H^0_m$(298,15 K)	96,27 ± 0,49	124,99 ± 0,74	114,05 ± 0,69
$-\Delta_f H^0_m$(g, 298,15 K)	495,8 ± 1,4	469,1 ± 1,3	492,6 ± 2,2
$\Delta_{fus} H_m(T_{fus}$ K)	18,2	26,2	
T_{pt}/K	433	475	

À partir de ces résultats expérimentaux, il nous a été possible de déterminer l'énergie de conjugaison des trois isomères, de constater que l'isomère *ortho* serait le plus stable et d'en discuter la raison. Par ailleurs, les valeurs de l'enthalpie d'atomisation expérimentale sont compatibles avec celle que nous avons calculée par voie incrémentale.

RAPHAËL SABBAH and THI HUY DUC LE. Can. J. Chem. **71**, 1378 (1993).

A thermodynamic study of the three hydroxybenzoic acids was carried out by combustion and sublimation calorimetry, heat capacity measurements, and differential thermal analysis. The experimental results (in kJ mol^{-1}) are summarized as :

	ortho	*meta*	*para*
$-\Delta_c H^0_m$(s, 298,15 K)	3020.0 ± 1.3	3017.9 ± 1.1	3005.4 ± 2.1
$-\Delta_f H^0_m$(s, 298,15 K)	592.1 ± 1.3	594.1 ± 1.1	606.6 ± 2.1
$\Delta_{sub} H^0_m$(298,15 K)	96.27 ± 0.49	124.99 ± 0.74	114.05 ± 0.69
$-\Delta_f H^0_m$(g, 298,15 K)	495.8 ± 1.4	469.1 ± 1.3	492.6 ± 2.2
$\Delta_{fus} H_m(T_{fus}$ K)	18.2	26.2	
T_{tp}/K	433	475	

From these experimental results, it was possible to determine for the three isomers (*i*) the resonance energies. From their comparison, the *ortho* isomer seems to be the most stable. This result is discussed using a structural consideration; (*ii*) the enthalpies of atomization. These values are in good agreement with that calculated using a contribution method.

I. Introduction

Dans le cadre de nos études sur l'énergétique des liaisons intra- et intermoléculaires dans les substances organiques, nous avons décidé de nous intéresser à l'étude des trois isomères de l'acide hydroxybenzoïque. C'est une suite logique aux travaux précédemment réalisés au laboratoire sur les acides aminés (1) si l'on souhaite mettre en évidence et comprendre l'effet des substituants sur les propriétés des molécules étudiées.

Si l'on consulte les travaux thermodynamiques consignés dans la littérature au sujet des trois acides traités dans ce mémoire, on se rend compte qu'il sont peu nombreux (cf. III.3. Résultats).

Compte tenu de leurs propriétés et de leurs applications directes et indirectes dans différents secteurs économiques (2), nous avons entrepris leur étude par nos moyens expérimentaux d'investigation (cf. II.2. Appareillage, techniques et mode opératoire) afin d'élucider certaines questions liées à leur structure et à leur utilisation courante.

II. Partie expérimentale

II.1. Produits

L'acide hydroxy-2 benzoïque (communément appelé acide salicylique) est un produit Baker, pureté initiale 99,6%. Il a été repurifié par sublimation sous une pression résiduelle de 10^{-2} Torr (1 Torr = 133,322 Pa) à 150°C. L'acide hydroxy-3 benzoïque est un produit Aldrich, pureté initiale 98%. Il a été recristallisé dans le méthanol absolu puis sublimé sous une pression résiduelle de 10^{-2} Torr à 200°C. L'acide hydroxy-4 benzoïque est un produit Aldrich, pureté initiale 99%. Il a été recristallisé dans l'éthanol absolu puis sublimé sous une pression résiduelle de 10^{-2} Torr à 200°C.

Il ne nous a pas été possible de déterminer par ATD le degré de pureté de l'acide hydroxy-4 benzoïque car cette substance se décompose à la fusion. Par contre, dans les deux autres cas, nos expériences d'ATD nous ont permis de déterminer le degré de pureté des échantillons repurifiés (tableau 1).

II.2. Appareillage, techniques et mode opératoire

Pour mener à bien cette étude, nous avons utilisé la calorimétrie de combustion de faibles quantités de substance, la calorimétrie de sublimation, l'analyse thermique différentielle et la mesure des capacités calorifiques.

II.2.1. Calorimétrie de combustion

Pour réaliser les expériences par calorimétrie de combustion, nous avons utilisé l'appareillage décrit dans la référence 3. La micro-

[b]1 atm = 101,325 kPa.
Les valeurs placées entre parenthèses ont été estimées.

bombe qui lui est associée a été décrite dans un précédent mémoire (4). La sensibilité de la pile du calorimètre CRMT est de 62,4 μV mW^{-1} à 298,15 K; celle de l'amplificateur est de 30 mV. L'oxygène N45, utilisé dans nos expériences, provient de l'Air Liquide; son degré de pureté est égal à 99,995%.

II.2.2. Calorimétrie de sublimation

Pour mesurer directement la quantité de chaleur mise en jeu par la sublimation des substances étudiées, nous avons utilisé un calorimètre Tian–Calvet, dont la sensibilité de la pile est de 64,3 μV mW^{-1} entre 333 et 363 K, associé à une cellule d'effusion de Knudsen. L'appareillage et le mode opératoire ont été décrits dans la référence 5. Seule a été ajoutée par la suite la robotisation de l'ouverture et de la fermeture des cellules d'effusion. Le signal issu du calorimètre est amplifié par un nanovoltmètre Keithley modèle 147 (sensibilité utilisée 100 μV) puis digitalisé à l'aide d'un voltmètre numérique Keithley modèle 175. L'acquisition et le traitement des données ont été réalisés à l'aide d'un programme écrit par nos soins et traité par un ordinateur Zénith modèle 158.

La très faible pression de vapeur saturante des substances étudiées ne nous a pas permis de les sublimer à 298,15 K. En conséquence, l'isomère *ortho* a été étudiée à 333 K et les deux autres isomères à 368 K avec un trou d'effusion de 0,5 mm (*ortho*), 1 mm (*méta*) et 2 mm (*para*).

II.2.3. Analyse thermique différentielle

En utilisant l'appareillage et le mode opératoire décrits dans la référence 6, cette technique nous a permis de suivre le comportement thermique des trois acides hydroxybenzoïques et de mesurer la température du point triple ainsi que l'enthalpie de fusion des isomères *ortho* et *méta* (tableau 1).

III. Résultats

Nous avons consigné dans le tableau 2 les grandeurs physiques à 298,15 K des substances étudiées intervenant dans les calculs menant aux résultats expérimentaux.

III.1. Calorimétrie de combustion

L'èquivalent énergétique du calorimètre (U_{calor}) a été obtenu à partir d'une série de 10 combustions d'acide benzoïque, échantillon 39i du NBS, pour lequel $\Delta_c u^0$(s, 298,15 K) = −(26 414 ± 3) J g^{-1}. Dans ces expériences, nous avons utilisé environ 5 mg d'acide et 0,2 mg de coton (dont l'énergie de combustion, préalablement déterminée au laboratoire, a pour valeur $\Delta_c u^0$(s, 298,15 K) = −(16 399 ± 23) J g^{-1} (7)). Nous trouvons pour U_{calor}(298,15 K) la valeur (16,05 ± 0,01) J V^{-1} s^{-1}.

Les résultats expérimentaux obtenus par calorimétrie de combustion sont consignés dans les tableaux 3, 4 et 5. Ces résultats correspondent à la réaction :

$$C_7H_6O_3\ (s) + 7\ O_2\ (g) \rightarrow 7\ CO_2\ (g) + 3\ H_2O\ (l)$$

En ce qui concerne l'acide hydroxy-2 benzoïque, notre valeur de l'enthalpie de combustion, $\Delta_c H^0$(s, 298,15 K) = −(3020,0 ± 1,3) kJ mol^{-1}, est compatible avec celles de la littérature comprises entre −3017,5 et −3026,1 kJ mol^{-1} (7, 8). Quant aux deux autres isomères, nous trouvons dans la littérature, pour cette grandeur thermodynamique, les valeurs de Colomina et al. (9) : −(3021,6 ± 0,4) kJ mol^{-1} pour l'acide hydroxy-3 benzoïque et −(3017,6 ± 0,5) kJ mol^{-1} pour l'acide hydroxy-4 benzoïque. Comme on peut le constater, ces valeurs diffèrent légèrement des nôtres.

III.2. Calorimétrie de sublimation

L'étalonnage de notre système calorimétrique a été réalisé par effet Joule avant et après les expériences.

À cause de la très faible pression de vapeur saturante des substances étudiées, nous avons admis l'identité $\Delta_{sub}H_m(T) \equiv \Delta_{sub}H^0_m(T)$. Par ailleurs, pour calculer $\Delta_{sub}H^0_m$(298,15 K) à partir de $\Delta_{sub}H^0_m(T)$, nous avons utilisé la relation suivante :

$$\Delta_{sub}H^0_m(298{,}15\ \text{K}) = \Delta_{sub}H^0_m(T) + \int_T^{298{,}15\ \text{K}} [C^0_{p,m}(g) - C^0_{p,m}(s)]dT$$

après nous être assurés par ATD que la substance ne présente aucun changement de phase entre 298,15 K et T. En ce qui concerne l'intègrale

$$\int_T^{298{,}15\ \text{K}} C^0_{p,m}(s)dT$$

elle a été obtenue par la méthode de chute en utilisant un

calorimètre Tian–Calvet et un four maintenus respectivement à 298,15 K et T. Quant à l'intégrale

$$\int_T^{298,15\ K} C^0_{p,m}(g)dT$$

elle a été déterminée à l'aide d'une méthode incrémentale utilisant les données des capacités calorifiques à l'état gazeux de la littérature pour les molécules de benzène, de phénol et d'acide benzoïque (10).

Nous avons consigné dans le tableau 6 les différents résultats expérimentaux obtenus.

Quant aux valeurs de la littérature, celles-ci sont peu nombreuses. En effet, seuls les acides hydroxy-2 et hydroxy-4 benzoïques ont fait l'objet de mesures indirectes. Pour l'acide hydroxy-2 benzoïque, nous avons trouvé trois valeurs de l'enthalpie de sublimation qui sont cohérentes avec la nôtre :

Colomina et al. (9) : $\Delta_{sub}H_m(315,4\ K) = (95,7 \pm 0,1)$ kJ mol^{-1}

Davies et Jones (11) : $\Delta_{sub}H_m(368 < T/K < 408) = (94,8 \pm 0,4)$ kJ mol^{-1}

de Kruif et Van Ginkel (12) : $\Delta_{sub}H_m(312 < T/K < 332) = (94,9 \pm 0,4)$ kJ mol^{-1}

Pour l'acide hydroxy-4 benzoïque, il existe une seule valeur : 116,1 kJ mol^{-1}, obtenue par Davies et Jones (11) dans l'intervalle $398 < T/K < 432$.

III.3. Enthalpie de formation des trois acides hydroxybenzoïques à l'état gazeux

Il est possible, à partir des résultats consignés dans les tableaux 3–6 de déterminer l'enthalpie de formation des substances étudiées à l'état gazeux et à 298,15 K. Celle-ci est respectivement égale à $(-495,8 \pm 1,4)$, $(-469,1 \pm 1,3)$ et $(-492,6 \pm 2,2)$ kJ mol^{-1} dans le cas des isomères *ortho*, *méta* et *para*.

III.4. Pression de vapeur saturante des trois acides hydroxybenzoïques

Comme indiqué dans la référence 13, il nous est possible, à partir de nos essais, d'évaluer la pression de vapeur saturante des substances étudiées (tableau 6) en utilisant la relation suivante :

$$P(T) \approx \Delta P(T) = dm/dt(2\pi RT/M)^{1/2}1/aF$$

dans laquelle $\Delta P(T)$ est la pression de part et d'autre du trou d'effusion; $P(T)$, la pression mesurée par effusion à la température T; dm/dt, la masse effusée par unité de temps; R, la constante des gaz parfaits; M, la masse molaire de la substance; F, le facteur de Clausing (14) et a, l'aire de l'orifice d'effusion.

III.5. Analyse thermique différentielle

Les résultats expérimentaux obtenus sont rassemblés dans le tableau 1. Le manque de valeurs thermodynamiques consignées dans la littérature pour les deux isomères *ortho* et *para* ne nous a pas permis de les comparer à nos résultats expérimentaux.

L'analyse thermique différentielle des trois isomères de l'acide hydroxybenzoïque nous a posé quelques problèmes. En effet, l'acide hydroxy-4 benzoïque se décompose à la fusion avec bris d'ampoule, dû vraisemblablement à un dégagement gazeux d'anhydride carbonique (décarboxylation) qui augmente la pression à l'intérieur de l'ampoule de verre mince (2). Quant aux deux autres isomères, en fin d'expérience, nous avons constaté un changement de coloration laissant supposer une décomposition de ces substances à la fusion. Ce changement de coloration est léger dans le cas de l'isomère *ortho*, beaucoup plus prononcé dans celui de l'isomère *méta*. Ne possédant pas les moyens expérimentaux permettant l'analyse en fonction du temps des produits soumis au traitement thermique et compte tenu du manque de travaux consignés dans la littérature à ce sujet, il ne nous a pas été possible de tirer des conclusions plus concrètes sur le comportement thermique de ces substances.

Enfin précisons que l'incertitude qui accompagne les résultats expérimentaux représente l'écart moyen, σ_m, et tient compte des erreurs sur les termes et facteurs de l'expression utilisée pour calculer ces résultats.

IV. Discussion

IV.1. Existence d'une liaison hydrogène intramoléculaire dans l'isomère ortho

L'enthalpie de sublimation d'une substance organique est liée aux interactions intermoléculaires qui comprennent les énergies relatives aux forces de van der Waals et, le cas échéant, aux liaisons hydrogène.

Dans ce travail, l'acide hydroxy-2 benzoïque a une enthalpie de sublimation inférieure de 17,78 kJ mol^{-1} à celle de l'acide hydroxy-4 benzoïque. Cette différence doit être attribuée au fait que la molécule d'acide hydroxy-2 benzoïque présente moins de liaisons hydrogène intermoléculaires que les deux autres isomères. En effet, cet acide est le seul à pouvoir former une liaison hydrogène intramoléculaire entre l'atome d'oxygène du groupement carboxyle et celui d'hydrogène de la fonction hydroxyle (15). Dans un précédent travail (1) l'un de nous (R.S) a mis en évidence, à partir d'une étude sur les acides aminobenzoïques, que l'enthalpie de sublimation de l'isomère *ortho* était inférieure de 11,2 kJ mol^{-1} à celle de l'isomère *para*. En conséquence, la chélation s'affaiblit en passant des acides hydroxybenzoïques aux aminobenzoïques. Une confirmation à cette constatation peut être trouvée dans l'ouvrage de Julg (16) à propos de l'énergie mise en jeu par les liaisons hydrogène dans les deux cas précédents : O—H···O (25 kJ mol^{-1}), N—H···O (11 kJ mol^{-1}).

D'autres observations faites sur les propriétés physicochimiques des acides hydroxybenzoïques tendent à prouver l'existence de cette liaison intramoléculaire dans le cas de l'acide hydroxy-2 benzoïque.

1. À partir de nos expériences de sublimation, il s'avère que la pression de vapeur saturante de l'acide hydroxy-2 benzoïque est, quelle que soit la température, toujours plus forte que celle de l'acide hydroxy-4 benzoïque.

2. L'acide hydroxy-4 benzoïque présente, à l'état liquide, des associations intermoléculaires, par liaisons hydrogène, plus nombreuses que l'acide hydroxy-2 benzoïque. En conséquence, il est moins soluble que l'isomère *ortho* dans un liquide non associé comme le benzène.

3. La température du point triple (ou de fusion), qui renseigne sur la force des liaisons intermoléculaires, est plus élevée dans le cas de l'acide hydroxy-4 benzoïque. Il en est de même pour l'enthalpie de fusion (tableau 1).

4. La constante d'acidité de l'acide hydroxy-2 benzoïque est plus de 10 fois plus forte que celle de l'isomère *méta* et près de 40 fois plus forte que celle de l'isomère *para* (2). On ne peut expliquer cette différence qu'en admettant la présence d'une chélation dans l'isomère *ortho* donnant ainsi à l'oxygène du groupement carboxyle la possibilité de drainer vers lui les électrons de façon à favoriser, d'une part, la formation d'une liaison hydrogène intramoléculaire avec l'hydrogène du groupement hydroxyle et, d'autre part, la dissociation de la fonction carboxylique.

IV.2. Calcul de l'enthalpie de sublimation de l'acide hydroxy-4 benzoïque par voie incrémentale

Comme nous l'avons déjà fait, nous avons essayé de retrouver par le calcul, à partir des contributions énergétiques apporteés par le noyau benzénique et les deux fonctions acide et hydroxyle, l'enthalpie de sublimation de l'acide hydroxy-4 benzoïque. Dans le réseau cristallin, celui-ci se trouve à l'état moléculaire et ne présente pas de liaison hydrogène intramoléculaire. Afin de tenir compte des interactions que peuvent avoir le noyau benzénique et les fonctions acide et hydroxyle au sein du cristal d'acide hydroxy-4 benzoïque, nous avons cherché à calculer ces contributions à partir des grandeurs énergétiques de molécules ayant une nature chimique voisine de celle qui nous intéresse. Dans le cas présent, le problème se simplifie du fait que nous possédons l'enthalpie de sublimation de l'acide benzoïque à 298,15 K; celle-ci est égale à 89,74 kJ mol^{-1} (17). Il suffit donc d'ajouter à cette valeur la contribution du chaînon OH. Nous avons déterminé la contribution de ce chaînon à partir des deux composés : benzène et phénol, en cherchant dans la littérature les principales données qui nous permettaient d'obtenir leur enthalpie de sublimation à 298,15 K. Pour le benzène, il nous a fallu calculer cette grandeur à partir de $\Delta_{vap}H^0_m$(298,15 K) et $\Delta_{fus}H_m$(298,15 K). La première de ces deux grandeurs est empruntée à la littérature (18). Quant à la seconde, nous l'avons calculée à partir de $\Delta_{fus}H_m$(278,68 K) = 9,84 kJ mol^{-1} (10) et en utilisant la règle de Sidgwick (19) :

$$\Delta_{fus}H_m(T) = \Delta_{fus}H_m(298{,}15\ \text{K}) + k(T - 298{,}15)$$

avec k = 0,055 kJ mol^{-1} K^{-1}. Nous trouvons : $\Delta_{sub}H^0_m$(298,15 K) = 44,83 kJ mol^{-1}. En ce qui concerne le phénol, son enthalpie de sublimation à 298,15 K est égale à 68,7 kJ mol^{-1} (8). En conséquence, la part du chaînon OH est égale à ± 23,87 kJ mol^{-1}. Il s'ensuit que l'enthalpie de sublimation de l'acide hydroxy-4 benzoïque, calculée à partir des différentes contributions, égale à 113,61 kJ mol^{-1}, est en parfait accord avec la valeur expérimentale.

IV.3. Energie de conjugaison

L'énergie de conjugaison est, par définition, égale à la différence entre l'énergie de la molécule réelle conjuguée et celle qu'elle aurait si les systèmes insaturés qu'elle comporte étaient indépendants. Nous l'avons déterminée en utilisant les enthalpies de combustion à l'état gazeux de la molécule dans ses états réel et fictif. La première de ces grandeurs est déterminée expérimentalement tandis que la seconde nécessite le recours aux systématiques. Pour notre part, nous avons utilisé celle de Klages consignée dans la référence 20. Les résultats obtenus sont pour l'*ortho* : E_{conj} = 268 kJ mol^{-1}, pour le *méta* : E_{conj} = 238 kJ mol^{-1} et pour le *para* : E_{conj} = 262 kJ mol^{-1}.

Comme nous pouvons le constater, l'isomère *ortho* possède l'énergie de conjugaison la plus élevée. Ceci est vraisemblablement dû à la présence dans la molécule de cet isomère d'une liaison hydrogène intramoléculaire entre l'oxygène du groupement carboxyle et l'hydrogène de la fonction hydroxyle formant ainsi un second cycle. Signalons que le même classement et la même observation ont été faits lors de l'étude des acides aminobenzoïques (1).

IV.4. Enthalpie d'atomisation

L'enthalpie d'atomisation est liée à la transformation suivante : molécule (considérée comme gaz idéal, état fondamental, T) → atomes (chacun d'eux considéré comme gaz idéal, état fondamental, T).

À partir de l'enthalpie de formation d'une molécule à l'état gazeux et de celle des différents constituants C, H, O, que l'on emprunte aux tables (21) et dont les valeurs sont respectivement égales à (716,67 ± 0,44), (217,997 ± 0,006) et (249,17 ± 0,10) kJ mol^{-1}, il est possible de calculer son enthalpie d'atomisation expérimentale. Nous trouvons pour nos trois isomères les valeurs suivantes : *ortho* : $\Delta_{a,exp}H^0_m$(298,15 K) = (7568 ± 2) kJ mol^{-1}; *méta* :

$\Delta_{a,exp}H^0_m(298,15\ K) = (7541 \pm 2\ kJ)\ mol^{-1}$ et *para* : $\Delta_{a,exp}H^0_m(298,15\ K) = (7565 \pm 3)\ kJ\ mol^{-1}$. Ces résultats sont cohérents si on les compare à la valeur de l'enthalpie d'atomisation calculée ($\Delta_{a,calc}H^0_m(298,15\ K) = 7542\ kJ\ mol^{-1}$) à partir de celle de l'acide benzoïque (7117 kJ mol^{-1})(8, 21) en remplaçant la contribution enthalpique de la liaison C_b—H = 415,88 kJ mol^{-1} (22) par celle de la liaison C_b—OH = 841 kJ mol^{-1} (23).

The analyses of the ^{1}H nuclear magnetic resonance spectra of 2-(diphenylphosphino)benzaldehyde in CS_2/C_6D_{12} and acetone-d_6 solutions yield stereospecific coupling constants from which the populations of the O-*cis* and O-*trans* conformers are derived. The free energy differences favouring the O-*trans* conformer at 300 K are 2.7 and 0.9 kJ/mol, in the polar and nonpolar solutions, respectively; in the crystal only the O-*cis* conformer exists. The coupling constant, $^{4}J(CHO, P)$, is estimated as $-7.1(2)$ Hz in the O-*trans* confomer and $^{3}J(CHO, P)$ as $+29.4(1.3)$ Hz. Their magnitudes depend on the proximity of the C—H bond to the lone pair on phosphorus. $^{n}J(C, P)$ are reported for triphenylphosphine and for the benzaldehyde derivative as dilute solutions in the two solvents, demonstrating a significant solvent dependence for some of these coupling constants. Some simple relationships are proposed between $^{n}J(C, P)$ and the torsion angle about the C—P bond, estimates of the latter coming from AM1 and STO 3G MO computations. $^{n}J(C, P)$ are also sensitive to intrinsic ring substituent perturbations, as are the $^{n}J(H, P)$; for example, $^{5}J(H, P)$ is negative in the disubstituted ring of 2-(diphenylphosphino)benzaldehyde but positive in the phenyl groups. The $^{n}J(H, P)$ are also discussed with respect to their dependence on the torsion angles about the C—P bonds. It appears that the conformational properties of the aromatic rings in triphenylphosphine and its formyl derivative are very similar. Further, the phosphorus atom is polarized such that the carbonyl bond is attracted towards the positive region near phosphorus, and the C—H bond of the formyl group more towards the lone-pair region; the actual torsion angles represent a compromise between these attractive forces and the repulsive forces between bonds on neighbouring aromatic moieties. CNDO/2 MO and INDO MO FPT computations of $^{n}J(C, P)$ and $^{n}J(H, P)$ are of mixed utility, although the former bear out the idea that the proximate O=C—H···lone-pair interaction dominates $^{3}J(CHO,P)$ and $^{4}J(CHO,P)$.

TED SCHAEFER, RUDY SEBASTIAN, ROBERT W. SCHURKO et FRANK E. HRUSKA. Can. J. Chem. **71**, 1384 (1993).

L'analyse des spectres de résonance magnétique nucléaire du ^{1}H du 2-(diphénylphosphino)benzaldéhyde en solution soit dans le CS_2/C_6D_{12} ou dans l'acétone-d_6 permet d'obtenir les constantes de couplage stéréospécifiques à partir desquelles on peut déterminer les populations des conformères O-*cis* et O-*trans*. Les différences d'énergie libre favorisant le conformère O-*trans*, à 300 K, sont de 2,7 et 0,9 kJ/mol respectivement pour les solutions polaires et non polaires; dans la forme cristalline, seul le conformère O-*cis* existe. On a évalué que la constante de couplage $^{4}J(CHO, P)$ est de $-7,1(2)$ Hz dans le conformère O-*trans* alors que la constante $^{3}J(CHO, P)$ est de $+29,4(1,3)$ Hz. Leurs amplitudes varient avec la distance entre la liaison C—H et la paire libre du phosphore. On rapporte les constantes $^{n}J(C, P)$ pour la triphénylphosphine et pour le dérivé benzaldéhyde en solutions diluées dans les deux solvants et on démontre ainsi une forte dépendence sur le solvant pour quelques-unes de ces constantes. On propose quelques relations simples entre des $^{n}J(C, P)$ et l'angle de torsion autour de la liaison C—P évalué par des calculs OM AM1 et STO 3G. Comme c'est le cas pour les constantes $^{n}J(H, P)$, les constantes $^{n}J(C, P)$ sont aussi sensibles aux perturbations intrinsèques causées par les substituants du cycle; par exemple, la constante $^{5}J(H, P)$ est négative dans le cycle disubstitué 2-diphénylphosphino)-benzaldéhyde, mais elle est positive dans les groupes phényles. On discute aussi des constantes $^{n}J(H, P)$ en fonction de leur dépendance sur les angles de torsion autour des liaisons C—P. Il semble que les propriétés conformationnelles des cycles aromatiques de la triphénylphosphine et de son dérivé formylé soient très semblables. De plus, l'atome de phosphore est polarisé d'une telle manière que la liaison carbonyle est attirée vers la région positive près du phosphore alors que la liaison C—H du groupe formyle s'approche de la région de la paire libre; les angles de torsion réels représentent un compromis entre les forces d'attraction et de répulsion entre les liaisons des portions aromatiques voisines. Les calculs d'OM CNDO/2 et INDO FPT des constantes $^{n}J(C, P)$ et $^{n}J(H, P)$ ne sont pas toujours utiles même si les premiers relient correctement le fait que la proximité de l'interaction O=C—H···paire libre domine les constantes $^{3}J(CHO, P)$ et $^{4}J(CHO, P)$.

[Traduit par la rédaction]

Introduction

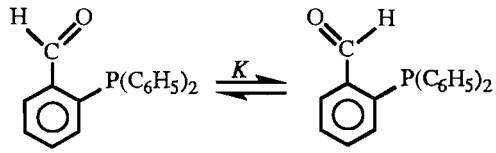
In the crystal, 2-(diphenylphosphino)benzaldehyde (DPPB) exists as the O-*cis* conformer (1). The P···O distance, 2.83 Å, is considered (1) as too long for a strong interaction. Of course, the direction of the lone pair of electrons on phosphorus need not lie in the plane of the formyl group, nor does it. As expected on steric grounds, however, the formyl group is in the *exo* position, that is, it lies above the plane containing the three ipso carbon atoms of the aromatic rings. This arrangement is conveniently described with reference to **1**. In the absence of the formyl group,**1** would represent one of the two C_{3v} conformers of triphenylphosphine. The other conformer of C_{3v} symmetry, defined by vanishing torsion angles, θ, would be that in which the C_3 axis lies in the planes of the phenyl groups. The C_3 axis in triphenylphosphine forms a normal to the plane containing the three ipso carbon atoms and also lies along the direction of the lone pair. Both of the C_{3v} conformers of triphenylphosphine are unstable because of close approaches of the *ortho* C—H bonds in neighbouring phenyl groups. On average, the stable conformer will have C_3 symmetry (2) with $0 < \theta < 90°$, although at a given instant none of the three torsional angles need be equal.

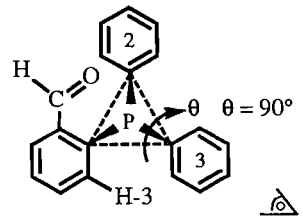
[1]Author to whom correspondence may be addressed.

In DPPB, however, none of the torsion angles will be equal on average. For steric reasons the formyl group mainly occupies a region near the lone-pair but the direction of the lone-pair does not lie in the plane of the formyl group; such an arrangement implies lone-pair, lone-pair repulsions (O-*cis* conformer). To a first approximation, the formyl group lies in the plane of its benzene ring because the barrier to internal rotation in benzaldehyde is much larger than thermal energies available at ambient temperatures (3). Consequently, the disubstituted ring twists about the P—C bond so as to relieve the lone-pair repulsion. The two phenyl groups also twist about their P—C bonds to relieve *ortho* C—H interactions; the twist direction has the same sense for all the aromatic moieties, clockwise, say, as viewed along the vectors from each *para* carbon atom to the phosphorus atom (see **1**). As θ increases from zero for the disubstituted ring the P···O distance in the O-*cis* conformer remains constant, apart from small changes caused by slight alterations in bond lengths and angles. At some value of θ, less than 90°, it is then surmised that a compromise is reached between lone-pair, lone-pair repulsions and those between the C=O bond and the π cloud of the nearest phenyl group.

In the light of this discussion, it is perhaps unexpected that DPPB exists as the O-*cis* conformer in the solid. Because the carbonyl group is highly polar (4), the carbon and hydrogen atoms are both positively charged (most of the positive charge resides at carbon, however). Intuition therefore suggests the O-*trans* as more stable than the O-*cis* conformer of DPPB; the formyl group lies in the region of the lone pair on phosphorus. Such intuition is supported by the conformational properties of some 2-(alkylthio)benzaldehydes in solution (5), in which the orientation of the 3*p* lone pair on sulfur controls the orientation of the formyl substituent, repelling the C=O bond.

Alternatively, it might be argued that the net charge on phosphorus is positive and, while the lone-pair region is one of negative charge,[2] the twist of the disubstituted benzene ring about the P—C bond is such that, perhaps together with some extra polarization of the phosphorus atom caused by the C=O bond dipole, a net small stabilization of the O-*cis* conformer occurs. It is also possible, however, that packing forces in the crystal determine the observed conformation.





1

Accordingly, the first aim of this work is to establish the conformational behaviour of the formyl group of DPPB in a nonpolar as well as in a polar solution. The long-range spin–spin coupling constant over five formal bonds, ^5J(H, CHO), between the formyl and ring protons, is a sensitive indicator (10, 11) of the equilibrium constant, *K*. The values of *K* can then be compared with some semiempirical, AM1, and ab initio, STO-3G, molecular orbital calculations of the stabilities of the free O-*cis* and O-*trans* conformers.

If, as it does, *K* turns out to be of order unity in solution and dependent on the solvent, then the possibility exists that the through-space, or, better, proximate, coupling constants, $^4J(CHO, P)$ and $^3J(CHO, P)$, can be characterized as to sign and magnitude in the two conformers. A recent discussion (12) of proximate $^{5,6}J$(H, F) and $^{4,5}J$(C, F), for which the ^{13}C nuclei and protons exist in the same C—H bond, points out the importance of sign determinations and also that, while the theoretical treatments are promising, they do not agree very well with experiment. Nevertheless, it is clear (12) that the orientation of the C—H bond with respect to the in-plane lone-pair on fluorine, the one in the plane defined by coplanar C—F and C—H vectors, will likely determine the sign of $^{5,6}J$(H, F). In DPPB, the lone-pair sits on phosphorus and, in the O-*trans* conformer, a proximate coupling pathway can be represented by P···H—C=O. It is unlikely that the lone-pair direction and the formyl group are coplanar, so that, by analogy to ^nJ(H,F) and ^{n-1}J(C, F), either sign of $^4J(CHO, P)$ is a possibility. Furthermore, the proximate contribution to $^3J(CHO, P)$ is of interest.

Therefore, the second aim of the present work is the measurement of the signs and magnitude of $^4J(CHO, P)$ and of $^3J(CHO, P)$. Their values are then extrapolated to those appropriate to the individual conformers; the results are of interest in theoretical approaches to coupling mechanisms and in conformational analysis.

From the experiments of Jakobsen and co-workers (13, 14), the signs of ^nJ(C, P), n = 1–3, in triphenylphosphine are known. Their studies of tri(*o*-tolyl)phosphine indicate (14) a remarkable stereospecificity of ^2J(C, P) in that the coupling constant is +26.44(3) Hz when the aromatic C—C bond in question is oriented towards the region of the lone pair on phosphorus[3] and is less than 1 Hz in magnitude for

[2]The lone-pair on phosphorus in DPPB is not a pure lone-pair like, for example, the oxygen $p\pi$ orbital in water, but a quasi lone-pair in the sense that it is a molecular orbital consisting perhaps predominantly of orbitals located on phosphorus (6–9). The available STO-3G* molecular orbital computations on triphenylphosphine (9) imply that the lone-pair is an sp^2 hybrid in the sense that in the HOMO the ratio of the sum of the squares of the coefficients of the *s* orbitals on phosphorus to that of the *p* orbitals is 1 to 2. Our own STO-3G computations on DPPB imply that, of the phosphorus orbitals, it is predominantly the 3*s* and $3p_z$ orbitals that contribute to the HOMO and that the lone-pair on phosphorus can be thought of as an $sp^{1.9}$ hybrid in the O-*cis* conformer and $sp^{1.8}$ in the O-*trans*. The degree of localization of the HOMO at phosphorus, however, defined as the sum of the squares of the coefficients of the phosphorus orbitals divided by the sum of the squares of the coefficients of *all* contributing orbitals, is only 45% for the O-*cis* conformer of DPPB (compare 47% for triphenylphosphine (9) using the STO 3G* basis). The lone-pair on phosphorus is thus a quasi lone-pair. A naive approach, in which the bond angles at phosphorus are used to define hybridization states, would yield the lone-pair hybrid in triphenylphosphine as $sp^{1.2}$.

[3]For a recent review on the qualitative influence of electron lone pairs on spin–spin coupling constants, see ref. 15. If the lone-pair were completely localized it would have minimal influence on the conformational dependence of ^nJ(X, P); see also footnote 2.

the opposite orientation (below the plane of the ipso carbon atoms; see **1**). ^3J(C, P) displays a somewhat less remarkable but similar dependence on the orientation of the lone-pair direction. It is of interest whether ^nJ(H, P) in triphenylphosphine and its derivatives behave like the corresponding ^{n-1}J(C, P). The analysis of the somewhat complex ^{1}H nmr spectra of 2-substituted triphenylphosphines has not been reported.

The third aim of the present work is thus the extraction of ^nJ(H, P) for DPPB and their comparison with ^{n-1}J(C, P), not only in the same molecule but also with ^{n-1}J(C, P) for triphenylphosphine (TPP) in a similar state. Hence dilute solutions of DPPB and of TPP in CS_2/C_6D_{12}/TMS and acetone-d_6/TMS solvent mixtures are here the subject of nmr investigations.

Experimental

Saturated solutions, less than 3 mol% in 2-(diphenylphosphino)-benzaldehyde (Aldrich), were prepared in CS_2/C_6D_{12}/TMS and acetone-d_6/TMS solvent mixtures, the comparisons of which are given in Table 1. Similar data are given for triphenylphosphine solutions in Table 4. These solutions were filtered into 5-mm o.d. nmr sample tubes. The tubes were degassed by five cycles of the freeze–pump–thaw procedure and were then flame-sealed to yield fairly symmetrical tops (smooth spinning).

The ^{1}H nmr spectra were obtained by our standard techniques (16, 17) on a Bruker AM300 spectrometer, taking care to shim finally on the free induction decay arising from internal tetramethylsilane. Acquisition times were 51.2 s in ordinary accumulations of free induction decays and were 47.0 s during the double resonance experiments. Spectral windows were sufficiently small to ensure digital resolutions as high as 0.01 Hz/real point; digitization was further improved by zero-filling to four or six times the original number of data points.

Because $|^4J(CHO, P)| > 5$ Hz, relative sign determinations were most easily performed by partial decoupling procedures (18), ^{1}H{*CH*O}, in which transitions of the formyl proton corresponding to different spin states of ^{31}P were irradiated in separate experiments. A similar set of experiments, in which proton transitions of the ^{13}CHO group corresponding to distinct ^{31}P spin states were irradiated while recording the coupled ^{13}C nmr spectrum of this group, gave the relative signs of $^4J(CHO, P)$ and $^3J(CHO, P)$.

The proton-decoupled ^{13}C nmr spectra of the four samples of TPP and DPPB were acquired in a manner designed to define small ^nJ(C, P) values with a precision of at least 0.02 Hz. One coupling constant, ^3J(C-3, P) in the disubstituted ring of DPPB in acetone-d_6 solution, was not very cleanly resolved and may be 0.03 Hz larger in magnitude than that reported in Table 4.

Molecular orbital computations on various conformations of DPPB utilized the program GAUSSIAN 86 (19) and employed the AM1 (20) and STO-3G (21) parameterizations.

Results and discussion

Spectral analyses

The ^{1}H nmr spectra of DPPB were analyzed as due to two separate 6-spin systems, one for the C_5H_4(CHO)P fragment and the other for the two equivalent C_6H_5P fragments. The formyl proton does not couple with the protons in the two phenyl groups, to within experimental error. H-3 in the C_6H_4(CHO)P moiety displays a through-space coupling interaction of ±0.05 ± 0.02 Hz with the *ortho* protons of the two phenyl groups, added as a simulation during the formal analysis with the program NUMARIT (22), completely reworked by R. Sebastian. The ensuing spectral parameters are presented in Tables 1 and 2.

The ^{1}H{C^1*HO*} partial decoupling experiments give $^4J(CHO, P)/^4J(H\text{-}6, P) < 0$, $^4J(CHO), P)/^5J(H\text{-}5, P) > 0$, $^4J(CHO, P)/^4J(H\text{-}4, P) < 0$, and $^4J(CHO, P)/^3J(H\text{-}3, P) < 0$. The ^{13}CHO{*CH*O} experiments showed that $^4J(CHO, P)/^3J(CHO, P) < 0$. Because all ^nJ(H, P) in triphenylphosphine are positive (23–25), it appears that $^4J(CHO, P)$ is negative and $^3J(CHO, P)$ positive. Then ^5J(H, P) in the disubstituted aromatic ring is negative.

Tables 3 and 4 contain the ^{13}C nmr chemical shifts and values of ^nJ(C, P) for DPPB and TPP in the polar and nonpolar solutions.

a reliable measure of the equilibrium between the O-*trans* and O-*cis* conformers. This statement implies that ^5J essentially vanishes for an antizigzag arrangement of the intervening bonds and that the intrinsic substituent perturbation of ^5J is small. These assumptions have been examined in detail, particularly for relatively electronegative substituents such as fluorine (10) and chlorine (11). It is noted here that the electronegativities of phosphorus and hydrogen are very similar. Application of the ratio to DPPB yields $K = P_t/P_c = {}^5J$(H-5, CHO)/^5J(H-3, CHO) = 0.631(2)/0.219(2) = 2.9 for the CS_2/C_6D_{12} solution and, similarly, $K = 1.4$ for the acetone-d_6 solution, at 300 K. Hence the free energy differences favoring the O-*trans* conformer are 2.7 and 0.9 kJ/mol; the latter value pertains to the polar solution.

The predominance of the O-*trans* conformer in both solutions contrasts sharply with its absence in the crystal. Furthermore, both AM1 and STO-3G MO computations, to be described below, predict a dipole moment lower by 0.3 D for the O-*cis* than for the O-*trans* conformer. Therefore, to first order in reaction field theory (26) the O-*trans* conformer should become more stable in the more polar solvent, contrary to our results.

The proximate coupling constants, ^{4}J(CHO, P) and ^{3}J(CHO, P)

^4J(C*H*O, P) is −5.853(3) Hz in the CS_2/C_6D_{12} solution and is −5.136(4) Hz in the acetone-d_6 solution. A two-site analysis, using these numbers and the values of ^5J(H, CHO) as indicators of the O-*cis*/O-*trans* equilibrium constants, yields ^4J(O=C—H···P) as −7.1(2) Hz and ^4J(H—C=O···P) as −2.3(3) Hz. ^4J(O=C—H···P), the coupling constant in the O-*trans* conformer, is the proximate coupling constant mediated by the lone-pair on phosphorus. However, ^4J(H—C=O···P) is not zero in the O-*cis* conformer, although the C—H bond of the formyl group points away from the lone-pair. These matters are discussed further below.

^3J(C*H*O, P) is 21.80(2) Hz in CS_2/C_6D_{12} and 17.34(2) Hz in acetone-d_6. A two-site equilibrium entails ^3J(O=C—H···P) as 29.4 ∓ 1.3 Hz and ^3J(H—C=O···P) as 0.0 ± 3.2 Hz. If $^3J \geq 0$, then the maximum value of ^3J(O=C—H···P) is 29.4 Hz. In any event, ^3J(C*H*O, P) has a large component transmitted via a proximate C—H···lone-pair interaction. Some information about the P—C torsion angles is now sought from AM1 and STO-3G MO computations.

C_3 ring[b,c]	29.8	42.5	46.1	38.4
CHO group[d]	0.0	5.7	0.0	8.2
Relative energy (kJ/mol)[e]	0.00	0.47	22.9	0.00[f]

[a]See structures **1–3** in the text.
[b]The torsion angle is the angle by which the plane of the phenyl group deviates from the normal (lone-pair direction) to the pyramid base defined by the three carbon atoms bonded to phosphorus. The sense of twist is such that, were these angles equal and the formyl group absent, the molecule would have C_3 symmetry (propeller).
[c]For triphenylphosphine, these torsion angles are equal to 29.2° and 43.2°, respectively, as given by the AM1 and STO-3G MO optimizations; a vanishing torsion angle implies C_{3v} symmetry.
[d]The angle by which the formyl group twists out of the plane of its phenyl group; see structures **2** and **3**.
[e]The text described the geometry-optimization procedures.
[f]The total energy is −1130.130 066 au.

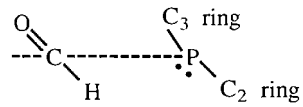
Torsion angles from AM1 and STO-3G MO calculations

During the computations of the torsion angles about the three P—C bonds in the O-*cis* and O-*trans* conformers of DPPB, the only constraint on the geometries was that the nuclei of each benzene ring remain in their plane; otherwise all bond angles and bond lengths were allowed to vary during the optimization procedures, including the angle by which the formyl group turned out of the plane of its bonded benzene ring. Table 5 contains the computed torsion angles and the relative energies of the conformers. The torsion angle is the angle by which the plane of the aromatic group (see **1**) deviates from the normal (lone-pair direction) to the pyramid base defined by the three carbon atoms bonded to phosphorus. The sense of twist about the P—C bond is the same for the three planes; if the formyl group were absent and all torsion angles the same, then the molecule would have C_3 symmetry (propeller).

The torsion angles differ considerably for the AM1 and STO-3G MO minimizations. Comparison of the computed bond lengths and angles with those for the crystal (1) shows reasonable agreement for the minimal basis set and some marked disagreements for the semiempirical parameterization. For example, for the O-*cis* conformer the experimental P—C lengths are 1.839, 1.833, and 1.838 Å; the corresponding STO-3G (AM1) values are 1.845(1.765), 1.838(1.751), and 1.842(1.753) Å. Again, the P···O distance in the crystal is 2.83 Å whereas it is computed as 2.83 Å with the STO-3G basis set and as 2.89 Å by AM1 (O-*cis* conformer). Another comparison involves the C—C—C bond angles at the ipso positions: they are 117.4°, 118.2°, and 118.8° in the crystal, range from 117.1° to 117.9° for the STO-3G structure, but from 119.4° to 119.9° for that from AM1. Furthermore, AM1 has the O-*cis* conformer as 22.9 kJ/mol less stable than the O-*trans* conformer, a result somewhat unlikely in view of its sole presence in the crystal and its similar stability to that of the O-*trans* conformer in solution; the O-*cis* is computed as 0.47 kJ/mol less energetic than the O-*trans* conformer with the minimal basis set, a more likely estimate (albeit at absolute zero). Accordingly, the STO-3G results are taken as more reliable for DPPB and the corresponding torsion angles are used in the discussion below. Their magnitudes (Table 5) for the O-*trans* conformer are also rather similar to the mean torsion angle of 43.7° found in the crystal for tri(*o*-tolyl)phosphine (27); it should be noted, however, that neither this compound nor triphenylphosphine (28) has C_3 symmetry in the crystal, very likely due to packing constraints.

The torsion angles presumably represent an energetic compromise among intramolecular repulsions between *ortho* C—H bonds and (or) the formyl substituent on neighbouring aromatic groups, having maxima either at 0° or 90°. Conjugative interactions of the lone-pair on phosphorus with the aromatic π system, favoring torsion angles of 90°, are probably small, as for triphenylphosphine (29). Consequently, the conjugative contribution to the intrinsic barrier to rotation about the P—C bonds is very likely small. Hence it is also likely that the minima in the internal potential surface, represented by the structures in Table 5, are fairly shallow over a significant range near the torsion angles given in Table 5; the repulsive parts of the potential are probably steeply dependent on the distances between atoms on neighbouring rings. Although our computing resources did not allow an extensive exploration of this problem for such a large molecule, one AM1 procedure, with geometry optimization and allowance for relaxation of the other two torsion angles, predicted that the molecular energy did not change by more than 1.5 kJ/mol as the disubstituted ring was rotated by ±15° from its optimum value of 31° in the O-*trans* conformer. This result implies substantial excursion of the torsion angles in Table 5, at least at ambient temperatures (floppy molecule). With these qualifications in mind, the following remarks about the O-*cis* and O-*trans* conformers are of interest.

The torsion angles for the O-*trans* conformer, 42.3°–44.8°, suggest that the formyl group can be accommodated easily in the *exo* conformation, as does our STO-3G optimization for triphenylphosphine for which the three torsion angles are calculated as 42.5°. Alternatively, the *ortho* C—H repulsions determine the torsion angles, and the small twist of 5.7° of the formyl group out of its aromatic plane, as in **2**, is caused by repulsion from the neighboring phenyl group or attraction towards the lone-pair direction.



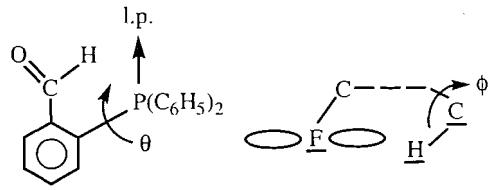
2 **3**

In the O-*cis* conformer, the largest change in the torsional angles is that for the ring carrying the formyl group, which increases by 8° from its value in the O-*trans* conformer, while the aldehydic function twists out of its aromatic plane by 8°, as in **3**, that is, away from the lone-pair region on phosphorus.

Structural implications for ^4J(CHO, P) and ^3J(CHO, P)

The values of ^4J(C*H*O), P) deduced above for the O-*cis* and O-*trans* conformers refer to structures in which the for-

myl group and the lone-pair vector are not coplanar. An INDO MO FPT (30) computation of $^4J(CHO, P)$, perturbing the 1*s* orbital at the formyl proton site, was done for AM1 optimized geometries, those in which rotation occurred about the C-2, P bond (see **4**). Between $\theta = 0$, lone-pair in the formyl plane, and $\theta = 68°$, the computed $^4J(CHO, P)$ closely



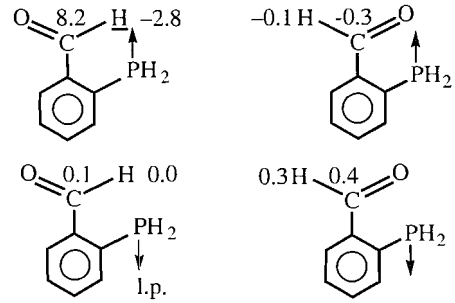
4 **5**

follows $-13.8 \cos^2 \theta$ in units of Hz. For a θ of 42.3° (Table 5), $^4J(CHO, P)$ is then −7.5 Hz, not far from the −7.1 Hz deduced from experiment for the O-*trans* conformer. Of course, the agreement is somewhat accidental, in that the computed value depends on the parameterization of the calculational scheme, as well as on the computed bond lengths and angles for a given θ, which will also oscillate about the equilibrium value. The computation does emphasize the importance of the proximity of the C—H bond of the formyl group and the lone-pair direction.

The computed $^4J(CHO, P)$ becomes positive at a θ of 75° in **4**. This result is reminiscent of a recent set of relative sign determinations (12), from which it appears that the negative proximate $J(H, F)$, for $\phi = 0$, can become positive for sufficiently large ϕ values (see **5**). An assessment of the critical ϕ awaits improvements in the theory of coupling constants and (or) reliable computations or measurements of ϕ for the molecules in question.

The estimate of −7.1 Hz for $^4J(CHO, P)$ in the O-*trans* conformer of DPPB can be compared with the −7.9 Hz obtained for $^4J(CH(CH_3)_2, P)$ in 2-isopropylphenyl diphenylphosphine (31); the sign is deduced from the measurement of $^4J(CH(CH_3)_2, P)/^3J(CH(CH_3)_2, P)$ as negative, it being likely that ^3J is positive. The torsion angle for the isopropylphenyl moiety is not known, nor is the conformational distribution of the isopropyl group. From models, the predominance of the arrangement $(CH_3)_2C$—H···P appears probable. By how much the C—H bond of the isopropyl group twists out of the plane of its bonded aromatic ring is also not known. The barrier to rotation about the Csp^2—Csp^3 bond in isopropylbenzene is much smaller than the internal rotational barrier in benzaldehyde (32). For the O-*cis* conformer of DPPB, $^4J(CHO, P)$, at −2.3(3) Hz, corresponds to a *cis–trans* arrangement of the intervening bonds, consistent with a σ electron coupling mechanism. The analogous situation for $^4J(CHO, F)$ in 2-fluorobenzaldehyde has been reviewed (33).

The large value of 29.4 ± 1.3 Hz for $^3J(O{=}C{-}H{\cdots}P)$, as compared to 0.0 ± 3.2 Hz for $^3J(H{-}C{=}O{\cdots}P)$, implicates the C—H lone-pair interaction in the coupling mechanism for the former coupling constant. A model CNDO MO FPT calculation was done for four conformations of 2-formylphenylphosphine, whose geometries had been optimized by STO 3G MO computations. The lone-pair direction on phosphorus lies in the aromatic plane. The computed coupling constants are displayed in the diagrams. Qualitatively, these numbers, in sign and relative magnitude, bear out the importance of the C—H lone-pair proximity for the coupling mechanism. $^3J(CHO, P)$ and $^4J(CHO, P)$ are indeed small in magnitude unless the C—H bond lies near the lone pair.



$^nJ(C, P)$ in DPPB and TPP

In Table 4 it is demonstrated that $^nJ(C, P)$ in TPP are solvent dependent, particularly $^1J(C, P)$, which changes from −12.92(2) Hz in CS_2/C_6D_{12} to −11.73(2) Hz in acetone-d_6 solution. In a 36% w/w solution of TPP in CS_2/acetone-d_6 (52:12 w/w), $^1J(C, P)$ is −12.51(3) Hz (14), consistent with such a result. $^2J(C, P)$ and $^3J(C, P)$ are less sensitive to solvent, the former increasing by only 0.05(4) Hz in the polar solvent. $^2J(C, P)$ is very sensitive to orientation of the lone pair on phosphorus with respect to the aromatic plane (14, 34), so that the solvent effect on $^1J(C, P)$ must be intrinsic, that is, the two solvents perturb the internal rotational potential in TPP in a similar manner.

$^1J(C, P)$ in the phenyl rings of DPPB is smaller in magnitude than in TPP, but (Table 3) the solvent perturbations of $^1J(C, P)$ are roughly the same in size as those caused by the presence of the formyl substituent on the neighbouring aromatic group. $^1J(C, P)$ in the disubstituted ring (Table 4) is less susceptible to solvent effects and is −14.93(2) Hz in the nonpolar solvent, as compared to −12.92(2) Hz in TPP. The sum of the three $^1J(C, P)$ values for DPPB is close to that in TPP. For example, in acetone-d_6 solution the two sums differ by 0.5 ± 0.1 Hz, so that, while the individual values of $^1J(C, P)$ differ by as much as 4.2 Hz, the perturbation by the formyl substituent is distributed in a compensatory manner among the three P—C bonds. There is no simple relationship (13) between $^1J(C, P)$ and the *s*/*p* ratio of the bonding orbitals employed by phosphorus. A proper theory of $^1J(C, P)$, not yet available, will also need to account for its solvent susceptibility.[4]

Again, for the two phenyl rings in DPPB, the solvent perturbations of $^{2,3,4}J(C, P)$ are not in general negligible compared to those caused by the formyl substituent on the neighbouring benzene moiety (Table 3). In a given solvent, $\Sigma^nJ(C, P)$ is the same for the two phenyl groups of DPPB and TPP, to within 0.1–0.2 Hz in about 40 Hz. This result may be indicative of a substituent perturbation of $^nJ(C, P)$ as distinct from a change in the average torsion angle for the two

[4]The dipole moment of TPP is dominated by the lone-pair contribution (44), meaning that the orbital is an *s*/*p* hybrid. If the more polar solvent increases the lone-pair "polarity," thereby increasing its *p* character, then the orbitals used to bond to carbon will have reduced *p* character. Via an exchange interaction (spin polarization) this *p* character makes a negative contribution (45) to $^1J(C,P)$. Therefore $^1J(C,P)$ should increase algebraically in acetone, as confirmed in Table 4.

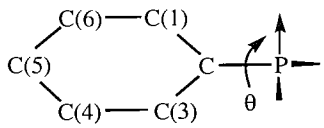
phenyl groups of DPPB; the MO computations described above suggest as much.

That, however, ^2J(C, P) is very sensitive to torsion about the P—C bond (15, 35) is confirmed by the data in Table 4 for the disubstituted ring in DPPB (see also **1** for the numbering of the ring positions and **6** for an extreme torsion angle, $\theta = 0$). ^2J(C-1, P) is 27.4 Hz while ^2J(C-3, P) is



6 $\theta = 0$

± 0.2 Hz.[5] A negative sign for this small coupling constant is suggested by the -3.9 ± 2.0 Hz measured for the analogous coupling constant in 1,6-diphosphatriptycene (34), in which the lone pair on phosphorus is situated in the aromatic plane. The ^2J(C, P) in the triptycene derivative, corresponding to ^2J(C-1, P), is 44.4 ± 0.15 Hz. If this number is taken as defined by a torsion angle, θ, of 0° then the value of $-3.9 + 2.0$ Hz corresponds to a θ of 180°. Hence, write $^2J(C, P) = A + B\cos^2(\theta/2)$. Then, A is $-3.9 + 2.0$ Hz and B is 48.3 ± 1.8 Hz. Our STO-3G computations on the internal barrier to rotation in TPP yield a potential given by the sum of evenfold terms in θ. For such a potential the expectation value of $\cos^2(\theta/2)$ must be 0.5. Hence ^2J(C, P) in TPP is predicted to be 20.3 ± 3.0 Hz; it is measured as 19.7 Hz (Table 4). As to ^2J(C-1, P) in DPPB, the STO-3G MO value for θ is 42.3°, which, if the molecule were rigid, would entail a predicted value of 38.1 ± 3.6 Hz. For ^2J(C-3, P), the θ would be 137.7°, so that its value would follow as 2.4 ± 2.2 Hz, compatible with its measurement. Of course, the molecule is not rigid and the disubstituted ring will oscillate by an unknown value about the optimum θ. Nevertheless, it is clear that ^2J(C-1, P) is reduced substantially in magnitude by the formyl substituent.

An analogy has previously been drawn between ^3J(H, P) in TPP and ^3J(H, F) in fluorobenzene (35). If such an analogy holds for ^2J(C, P) and ^2J(C, F), it may be noted that ^2J(C, F) in fluorobenzene is +21.0 Hz (35), whereas ^2J(C-1, F) and ^2J(C-3, F) in 2-fluorobenzaldehyde are 8.2 and 20.5 Hz, respectively (36). The sharp reduction in ^2J(C-1, F) is analogous to that suggested above for ^2J(C-1, P) in DPPB. Of course, in DPPB the conformational behaviour is more complex than in a fluorobenzene derivative; it may well be that the substituent perturbation of ^2J(C-1, P) is θ dependent. Its dependence on the O-*cis*–O-*trans* equilibrium appears small, ^2J(C-1, P) being invariant to solvent (Table 3). Our computations of ^2J(C, P) by the INDO MO FPT technique were not very useful[6] in assessing the θ and substituent dependencies of ^nJ(C, P) or ^nJ(H, P).

Turning to ^3J(C, P), the coupling corresponding to $\theta = 0°$ (see **6**) is $+13.8 \pm 0.5$ Hz in the diphosphatriptycene and is $+1.4 \mp 0.15$ Hz for $\theta = 180°$ (35). An equation for ^3J(C, P) similar in form to that postulated for ^2J(C, P) above, together with the arguments presented there, implies ^3J(C, P) as $(1.4 \mp 0.15) + (13.8 \pm 0.5)0.5$ or $+ 8.3 \pm 0.4$ Hz; its actual value is +6.8 Hz (Table 4), a number more compatible with a ^3J(C, P) vanishing at $\theta = 180°$. Be that as it may, the ^3J(C-6, P) of 3.9 Hz in DPPB once more implies a substantial reduction due to the formyl substituent at C-1. The analogy with ^3J(C, F) in fluorobenzene is again appropriate in that ^3J(C, F) changes from +7.8 Hz in fluorobenzene (36) to 1.9 Hz for ^3J(C-6, F) and to 9.1 Hz for ^3J(C-4, F) in 2-fluorobenzaldehyde (36). Hence, although ^3J(C, P) is stereospecific, it also seems very sensitive to substituent perturbations.

Finally, ^4J(C, P) is -1.4 ± 0.5 Hz in the triptycene derivative, so that its small magnitudes in TPP and DPPB, ≤ 0.5 Hz, may correspond to negative values or, perhaps, to either sign among these magnitudes. Certainly, ^5J(H, P) in DPPB is also small and varies in sign for DPBP, as discussed below.

$^nJ(H, P)$ in TPP and DPPB

For TPP, in benzene solution two analyses of the ^{1}H nmr spectra yield ^3J(H, P) as 7.58(3) and 7.52(1) Hz (24, 25). As mentioned above, the barrier to internal rotation about the P—C bonds is calculated to be evenfold. If it is assumed that ^3J(H, P) follows a relationship $A + B\cos^2(\theta/2)$, one has $7.56(4)\text{ Hz} = A + 0.5B$. For the disubstituted ring of DPPB, ^3J(H-3, P) is 4.46 Hz in CS_2/C_6D_{12} solution and 4.50 Hz in acetone-d_6 (Table 1). According to the STO-3G MO computations in Table 5, θ is 42.3° for the O-*trans* and 50.4° for the O-*cis* conformer. Were these expectation values and not simply minima, a weighting of these angles according to the values of K deduced in a previous section would be appropriate. As it is, an approximation to ^3J(H-3, P) is given by $A + B(1 - \cos^2(\theta/2))$ with θ as 46°, so that $4.48 = A + B(0.15)$. The two relationships yield A as 3.2(3) and B as 8.8(3) Hz; the quoted errors are meant to indicate the concomitant ambiguities that may well include intrinsic solvent effects on ^3J(H, P), see Table 2, as well as intrinsic substituent perturbations. That the latter are not very large, or at least roughly equal for CH_3 and CHO groups, is indicated by a recent report of ^3J(H-3, P) as 4.4 Hz in tri(*o*-tolyl)phosphine in solution (37). In the crystal, θ values for this compound are close to those given for DPPB in Table 5.

Turning to ^4J(H, P), its θ dependence is relatively strong. Thus, ^4J(H, P) is 1.49(3) or 1.43(1) Hz for TPP (25, 26), similar to the 1.51 Hz for the phenyl groups in DPPB. The disubstituted ring of the latter, however, has ^4J(H-4, P) as 0.447(3) and 0.480(3) Hz in the polar and nonpolar solutions, respectively, as contrasted to 3.777(3) and 3.713(3) Hz for ^4J(H-6, P). Now, for ^4J(H-6, P) the formyl substituent is at-

[5]The assignment of C-3 is based on that in tri(*o*-tolyl)phosphine (14) in which ^2J(C-3, P) is smaller in magnitude than ^3J(C-4, P) in the present notation. The torsion angles for this molecule have an average value of 43.7° in the crystal (27), very similar to those calculated for DPPB (Table 5). Furthermore, the ^2J(C, P) values are 26.4 and 0.4 Hz, implying only small or similar perturbations by the methyl and formyl substituents. The available evidence indicates the existence only of the *exo* conformer of tri(*o*-tolyl)phosphine in solution (2, 37), that in which the three methyl groups lie near the lone pair on phosphorus, that is, above the plane defined by the three carbon atoms bonded to phosphorus (see **1**).

[6]For example, for model calculations on geometry-optimized STO 3G MO structures of phenylphosphine, the INDO MO FPT values of ^3J(C, P) and ^3J(H, P) are negative for all likely torsion angles (lone-pair directions with respect to the aromatic plane), although for ^2J(C, P) the numbers are qualitatively compatible with the θ dependence used here.

tached to the coupling fragment and, by analogy to ^3J(C-6, P), a substantial substituent perturbation, either an increase or decrease, of ^4J(H-6, P) may be anticipated. Hence, the use of ^4J(H, P) in TPP and ^4J(H-4, P) in DPPB in a treatment analogous to that of ^3J(H, P) yields ^4J(H, P) = 0.0(2) + 2.9(2) $\cos^2(\theta/2)$, where, of course, the θ applicable to ^4J(H-4, P) is (180 − 46). The error indications are meant to allow for thermal averaging of θ in DPPB. Application of this relationship to ^4J(H-6, P) yields 2.5(4) Hz compared to the measured value of 3.7 Hz. If the latter had been used in the treatment above, instead of ^4J(H-4, P) one would have had $^4J = -1.8 + 6.5 \cos^2(\theta/2)$ and ^4J(H-4, P) would be calculated as −0.8 Hz. However, ^4J(H-4, P) is positive, ^4J(H-4, P)/^4J(C*H*O, P) being determined as negative in the double resonance experiments. Consequently, within the assumptions concerning the θ dependence, it follows that a substantial intrinsic substituent dependence exists for ^4J(H-6, P). As far as the analogy with J(H, F) holds, ^4J(H, F) being 5.8 Hz in fluorobenzene (39) and ^4J(H-6, F) being 7.0 Hz in 2-fluorobenzaldehyde (10), the conclusion above appears valid.

^5J(H, P) is positive in TPP (25), as it is for the phenyl groups in DPPB, 0.7–0.8 Hz. By way of contrast, ^5J(H, P) in the disubstituted ring is −0.4 Hz. Because of the similar θ values for the two kinds of rings in DPPB (Table 5), the negative sign is likely a consequence of a perturbation from the formyl substituent. Again, ^5J(H, F) is 0.3 Hz in fluorobenzene (38), but −0.2 Hz in 2-fluorobenzaldehyde (10). ^5J(H, F) has almost equal contributions from σ and π electron mechanisms, which, however, differ in sign; the σ electron mechanism is thought to be the most sensitive to ring substitution (39). A determination of ^6J(P, CH_3) in tri(*p*-tolyl)phosphine is in order because its magnitude will give the π electron contribution to ^5J(H, P) (39); ^6J(P, CH_3) is anticipated as negative in sign.

The present discussion shows that a reliable theoretical treatment of ^nJ(C, P) and ^nJ(H, P) would enhance the utility of these coupling constants in conformational analysis. In particular, their intrinsic perturbations by ring substituents, which themselves may be dependent on θ, that is, on the lone-pair orientation, need a theoretical elucidation.

*Coupling between H-3 and H-*ortho *of the phenyl groups*

The coupling constant, ^6J(H-3, H-*ortho*), formally one over six bonds and of magnitude 0.05 ± 0.02 Hz, is attributable to the proximity of the C—H-3 bond of the disubstituted aromatic ring and the *ortho* C—H bonds of the two phenyl groups. A similar coupling interaction occurs in a derivative of 2,2′-dihydroxybenzophenone, in which two intramolecular C=O···HO hydrogen bonds constrain the phenyl groups to a conformation leading to close contacts of the hydrogen atoms of two C—H bonds on neighbouring aromatic rings (40). Models of DPPB imply that the conformation, in which the lone-pair lies near the plane of the disubstituted benzene and is oriented towards the formyl group, could have minimum distances as small as 1.3 Å between the protons in the relevant C—H bonds. Such a distance would no doubt lead to a large through-space coupling constant. Of course, the coupling constant must be averaged over all excursions of the phenyl groups about the C—P bonds and the closest contact distance would no doubt occur only in a conformation of high relative energy. Nevertheless, the existence of this ^6J is consistent with the predominance of the lone-pair orientation under discussion.

The chemical shift of H-3

In CS_2 solution, $\delta(C_6H_6)$ is 7.218 (16). Using the chemical shifts of the phenyl protons in DPPB and in benzaldehyde (4.0 mol% in the same solvent mixture (41)) as reference points, H-3 is more screened by 0.5 ppm than expected on the basis of additivity. Qualitatively, this is a consequence of its proximity to the phenyl groups, H-3 being, on average, in the screening volume of these diamagnetically anisotropic rings for the conformation in which the lone pair points towards the formyl group. H-4 and H-5, being more distant from the phenyl groups, experience excess shieldings of only 0.22 and 0.10 ppm, respectively.

Other spectral parameters

The solvent perturbation of the coupling constants within the phenyl groups (Table 2) displays the pattern common to a variety of C_6H_5X molecules, for instance, for X = CHO, C≡CH, C≡N, C≡C, CHO, as measured in this laboratory. The pattern displays increases in ^3J, $^4J_{oo}$, and ^5J in the more polar solvent and a decrease in $^4J_{op}$; $^4J_{mm}$ is insensitive to solvent. It is most unlikely that this pattern is an artefact of the analyses. Hence the solvent dependence of ^nJ(H, P) for the phenyl groups is interesting in that ^4J(H, P) also decreases in the more polar solvent. However, the generally larger solvent dependence of ^nJ(H, P) may also indicate slightly different excursional motion about the two C—P bonds in the two solvents.

^nJ(H, H) for ring protons in the disubstituted ring are also solvent dependent. Here an added complication comes from the different proportions of O-*cis* and O-*trans* conformers in the two solvents because the unsymmetric formyl substituent may, after all, perturb a given J in a manner dependent on its orientation with respect to the bonds in question. That the solvent does not strongly perturb the long-range coupling constants of the formyl proton is suggested by the 0.430(1) and 0.432(2) Hz found for ^5J(H, CHO) in benzaldehyde in the two solvents (41). In 2-chlorobenzaldehyde, it appears that a small solvent dependence of ^5J(H, CHO) exists, but that the *cis* and *trans* values are affected in a compensatory manner (11). In other words, the ratio of ^5J(H-3, CHO) to ^5J(H-5, CHO) is still a good measure of the equilibrium constant.

The C—H···P and C=O···P interactions

The small free energy differences between the O-*cis* and O-*trans* conformers in the two solutions prompt the following remarks. It is accepted (29, 42) that conjugation between the π orbitals of the phenyl group and the lone pair on phosphorus is very weak in phenylphosphines. The conjugational barrier to torsion about the P—C bonds is therefore small. Hence the average conformation of triphenylphosphine is a consequence mainly of the minimization of the repulsions between *ortho* C—H bonds of different phenyl groups, these having maxima at $\theta = 0°$ and $\theta = 90°$ (see **1**). The average torsion angles at equilibrium, substantial excursions of which will occur at ambient temperatures, appear to be about 40 ± 5°. Addition of one *ortho* substituent to each phenyl group, as in tri(*o*-tolyl)phosphine, does not alter the torsion angles dramatically because these substituents can lie near the lone pair, therby avoiding repulsions from the neighbouring moieties.

In DPPB in solution the nmr parameters and the STO-3G MO computations are consistent only with a proximity of the lone pair to the formyl substituent. However, the molecular orbital computations imply that the lone-pair electrons on phosphorus and oxygen are not directly opposed to each other in the O-*cis* conformer (see **3**). Furthermore, the Mulliken population analysis has the charge on phosphorus as +0.52 (electron units) while that on oxygen is −0.21. For a torsion angle of 50° (Table 5) the oxygen atom may well avoid the electron density due to the lone pair and experience a net attraction to the phosphorus region. In contrast, the charge on hydrogen in the formyl group is +0.05, so that in the O-*trans* conformer a smaller torsion angle is anticipated, calculated as 42°, because of a net attractive interaction with the lone-pair region on phosphorus (see **2**).

This rationalization is consistent with the computed out-of-plane torsions of the formyl group — 8° in the O-*cis* and 5° in O-*trans* conformer — in the sense pictured in **2** and **3**. In the O-*trans* conformer both the C—H bond of the formyl group and the lone-pair vector lie above the aromatic plane carrying the formyl group. However, in the O-*cis* conformer the C═O and the lone-pair lie on opposite sides of this plane. Parenthetically, the negative values of ^6J(H, CHO) are consistent with an average out-of-plane conformation of the formyl group in DPPB. ^6J(H, CHO) should be negative for significant values of the out-of-plane angles (43) and is possibly largest in the acetone-d_6 solution. Furthermore, the larger reaction field in the polar solvent, acetone-d_6, can increase the magnitude of the local C═O dipole relative to its value in the CS_2/C_6D_{12} solution, thereby stabilizing the O-*cis* conformer, as measured. What the reaction field is in the crystal in which only the O-*cis* conformer appears is a moot point.

A comparison of the conformational behaviour of the formyl groups in DPPB and 2-(alkylthio)benzaldehydes is instructive. In 2-methylthiobenzaldehyde the thiomethyl group is situated in the benzene plane and the directional, mainly 3*p*, lone-pair on sulfur lies perpendicular to that plane (5); the O-*cis* and O-*trans* conformers have very similar stability. As the size of the alkyl group increases, the population of the O-*cis* conformer decreases until, for a *tert*-butyl group on sulfur, only the O-*trans* conformer is detected (5). In 2-(*tert*-butylthio)benzaldehyde, the *tert*-butyl moiety lies in a plane roughly perpendicular to the benzene plane. In consequence, the directional lone-pair on sulfur is twisted into the benzene plan and repels the C═O bond. By analogy, if the torsion angle of the disubstituted aromatic ring in DPPB were zero, then only the O-*trans* conformer would be detected. An equivalent statement would be that, for trivalent phosphorus, there are regions that attract electrophilic groups and others that attract nucleophilic substituents. One may therefore infer that the lone-pair on phosphorus has considerable *p* character, as deduced from the molecular orbital calculations described at the outset.

Kinetics and mechanism of the oxidation of alcohols by ferrate ion

DONALD G. LEE[1] AND HUIFA GAI
Department of Chemistry, University of Regina, Regina, SK S4S 0A2, Canada

Received February 24, 1993

DONALD G. LEE and HUIFA GAI. Can. J. Chem. **71**, 1394 (1993).

A kinetic study of the reduction of ferrate ion under basic conditions has been completed. The observation that a typical aliphatic ether, tetrahydrofuran, is oxidized at a rate comparable to that of aliphatic alcohols, such as cyclopentanol, indicates that the reaction between ferrate and alcohols is likely initiated by attack of the oxidant at an α-C—H bond, a conclusion that is consistent with the occurrence of primary deuterium kinetic isotope effects (2.8–4.3 at 25°C) when α-hydrogens are replaced by deuterium. Because only acyclic products are obtained from the oxidation of cyclobutanol by ferrate, it may be concluded that free radical intermediates are involved in the reaction. The insensitivity of the reaction rates to substituent effects during the oxidation of substituted mandelic acids indicates that substantial charges are not built up in the transition state. All of these observations are most readily accommodated by a mechanism in which the reaction is initiated by a 2+2 addition of an Fe=O bond to the α-C—H of an alcohol to give an organometallic intermediate that subsequently decomposes by homolytic cleavage of the resulting C—Fe bond. Comparisons are made with the reactions between alcohols and other high-valent transition metal oxides.

DONALD G. LEE et HUIFA GAI. Can. J. Chem. **71**, 1394 (1993).

On a réalisé une étude cinétique de la réduction de l'ion ferrate dans des conditions basiques. Le fait qu'un éther typique, le tétrahydrofurane, est oxydé à une vitesse comparable à celle des alcools, comme le cyclopentanol, indique que la réaction entre le ferrate et les alcools est probablement initiée par une attaque de l'oxydant sur la liaison α-C—H; cette hypothèse est en accord avec le fait que l'on observe un effet isotopique primaire du deutérium (2,8–4,3, à 25°C) lorsqu'on remplace les hydrogènes-α par du deutérium. En se basant sur le fait que l'on n'obtient que des produits aliphatiques lors de l'oxydation du cyclobutanol par le ferrate suggère que des intermédiaires radicalaires sont impliqués dans la réaction. Le fait que les vitesses de réaction d'oxydation d'acides mandéliques substitués ne soient pas sensibles à la nature des substituants indique qu'il n'y aurait pas d'accumulation de charge dans l'état de transition. Le meilleur mécanisme permettant d'expliquer tous ces résultats implique une réaction initiée par une addition 2+2 d'une liaison Fe=O sur la liaison α-C—H d'un alcool qui conduit à un intermédiaire organométallique que se décompose par la suite par un clivage homolytique de la liaison C—Fe qui en résulte. On a fait des comparaisons avec les réactions des alcools avec d'autres oxydes de métaux de transition de valence élevée.

[Traduit par la rédaction]

Introduction

The use of iron-based oxidants is attractive from an environmental standpoint because iron, unlike many other transition metals, is considered to be nontoxic. Therefore, despite its current rather high cost, it is possible that ferrate (FeO_4^{2-}) may become preferable to other common oxidants such as chromate, permanganate, or ruthenate, which contain toxic heavy metals. It is known, for example, that ferrate can be used to oxidize alcohols to the corresponding carbonyl compounds in yields comparable to those obtained with other oxidants (1), that it is particularly useful for the conversion of primary alcohols into aldehydes (2–4), and that it reacts selectively with the primary hydroxyls of carbohydrates (5). Sodium ferrate, dissolved in nonpolar solvents with the assistance of phase transfer agents (6), may also be used for the oxidation of alcohols that have limited solubility in aqueous solutions.[2]

In many ways ferrate's properties resemble those of manganate (MnO_4^{2-}) (7) and ruthenate (RuO_4^{2-}) (8, 9). In common with those reagents, ferrate is known to have only limited stability in aqueous solutions, especially below pH 7 (10).

Several possible mechanisms, including electron transfer (4), hydrogen atom transfer (11), hydride ion transfer (1), and the formation of intermediate ferrate esters (12) have been suggested for the oxidation of alcohols by ferrate. However, molecular orbital calculations indicate that other high-valent transition metal oxides react with alkanes and alcohols by 2+2 additions between a metal–oxo double bond and a carbon–hydrogen or an oxygen—hydrogen bond as illustrated in eqs. [1] and [2] (13). Addition to an O—H bond results in the formation of an ester while C—H addition yields an organometallic intermediate, which may subsequently undergo a rearrangement as in eq. [3] or cleavage of the M—C bond to produce either free radicals or carbocations as in eq. [4] (14).

Although this general mechanism readily accommodates all known experimental observations, including those for Gif and related reactions (15), and for oxidations by high-valent iron complexes (16), there is not unanimous agreement concerning some of the details. For example, it has been suggested that the reaction of other high-valent transition metal oxides with alkanes is initiated by a 2+2 reaction in which carbon becomes attached to oxygen with concomitant formation of a metal hydride as in eq. [5] (17). However, since the hydrogen of the metal hydride would likely migrate to oxygen (as depicted in eq. [6]) it is impossible to decide between a sequence involving reaction [2] followed by reaction [3] or one in which reaction [6] follows reaction [5], because they both lead to the same product.

In this paper we wish to describe the kinetics and mechanism of the reaction between alcohols and ferrate ion in alkaline solutions and to make comparisons with the mechanisms for the oxidation of alcohols by other high-valent transition metal oxidants. Because ferrate stability is of crucial importance, we began with a reinvestigation of its stability in aqueous base and then proceeded with a kinetic

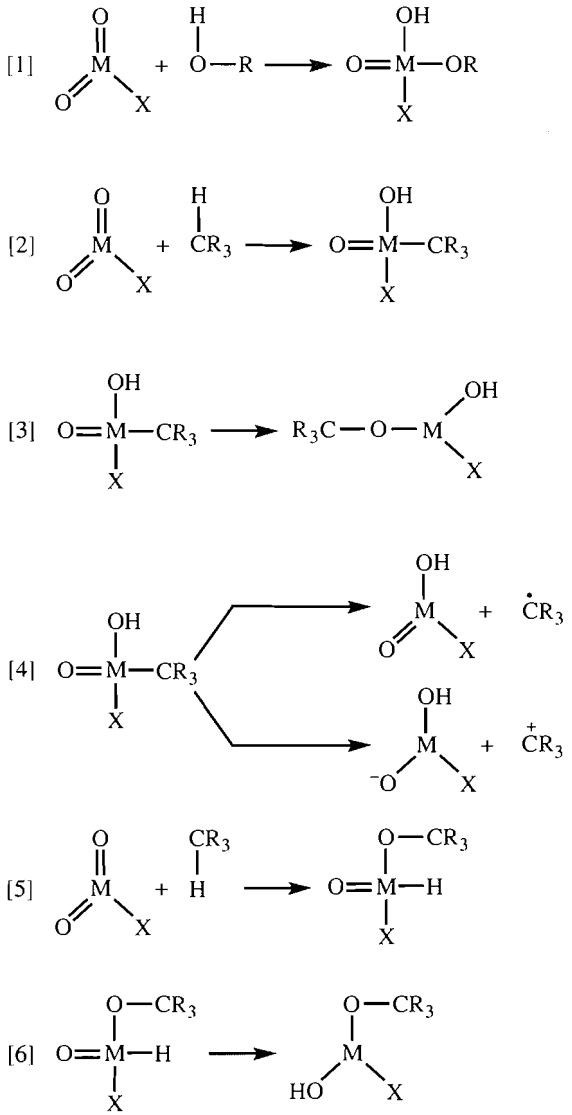
study of its reactions with alcohols under conditions where it is most stable.



Experimental

Preparation and purity of potassium ferrate

Potassium ferrate was prepared by oxidation of ferric nitrate nonahydrate by hypochlorite using the procedure reported by Bartzatt (18). The purity of the product, determined by titration with ferrous chloride using sodium diphenylamine as an indicator (19), was 98.6 ± 0.5%.

Reduction of ferrate by water

The rates of reduction of ferrate by water were determined by monitoring the decrease in absorbance at 508 nm. For each experiment a small portion of solid potassium ferrate was added to an aqueous solution buffered at a particular pH, the volume was adjusted to give an absorbance of 0.3–0.8, and 2.0 mL were transferred to a 10-mm quartz cell in the thermostated cell compartment of an 8450A Hewlett-Packard spectrophotometer. Absorbances were then plotted against time and the initial rates $(-dA/dt)$ obtained from the slope of a tangent to the resulting curve at time zero.

Oxidation of alcohols

Oxidation rates were determined by transferring a specific amount of an alcohol (using a microlitre syringe for liquid compounds) to 2.0 mL of a freshly prepared ferrate solution and monitoring the absorbance at 508 nm. The observed rate of oxidation was then corrected (if necessary) for the rate of reduction of ferrate by water under identical conditions. (These corrections usually reduced the observed rates by 10% or less.)

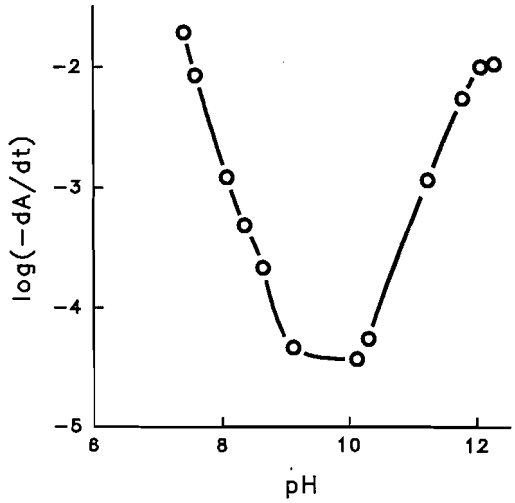


FIG. 1. The effect of pH changes on the initial rate of reduction of ferrate ion by water. Temperature = 25.0 ± 0.1°C.

Product analysis

The only product obtained from the oxidation of 2-propanol was acetone. When 2-propanol (3.9 g, 65 mmol) was reacted with potassium ferrate (10.8 g, 54.5 mmol) in 70 mL of buffered solution at pH = 9.0–9.6 and the product extracted into methylene chloride (3 × 50 mL), dried, and distilled, only acetone (2.2 g, 38 mmol, 58%) and unreacted 2-propanol (1.25 g, 21 mmol) were isolated.

The products obtained from the oxidation of mandelate ion were benzaldehyde and benzoate ion. Addition of potassium ferrate (1.5 g, 7.6 mmol) to a solution of mandelic acid (1.0 g, 6.6 mmol) in 100 mL of aqueous buffer (pH = 9.0–9.6) over a period of 1 h with good stirring followed by extraction (3 × 50 mL CH_2Cl_2), drying, and flash evaporation yielded a liquid product that exhibited an infrared spectrum identical to that of benzaldehyde. The yield was 0.23 g (2.2 mmol, 33%). When the pH of the buffered solution was reduced to 1.5 by addition of concentrated HCl and again extracted with methylene chloride, dried, and flash evaporated, a solid product (0.42 g) was obtained. ^1H NMR analysis of this product was consistent with it being a 7:3 mixture of benzoic acid and unreacted mandelic acid. The yield of benzoic acid was therefore approximately 0.29 g (2.4 mmol, 36%).

Only acyclic products and a trace of cyclobutanone were obtained when cyclobutanol was oxidized. Potassium ferrate (1.5 g, 7.6 mmol) was added slowly (over about 1 h) to cyclobutanol (0.50 g, 6.9 mmol) in 100 mL of buffered solution (pH = 9.0–9.6) with stirring. On completion of the reaction, concentrated HCl was added to reduce the pH to 1.5 and the solution was extracted with methylene chloride (3 × 100 mL). Careful distillation of the solvent gave a liquid residue that was found to contain only acyclic products and a trace of cyclobutanone (<1%).

Results

Rates of reduction of ferrate by water

A plot of initial reaction rates $(-dA/dt)_0$ against pH indicated that the lowest rate of reduction of ferrate by water occurs at pH = 9.4–9.7 (Fig. 1). From plots of log $(-dA/dt)_0$ vs. log $(A - A_f)$ it was found that the rate with respect to ferrate is second order below pH 9 (Fig. 2) and first order above pH 10 (Fig. 3). The reaction can therefore be exper-

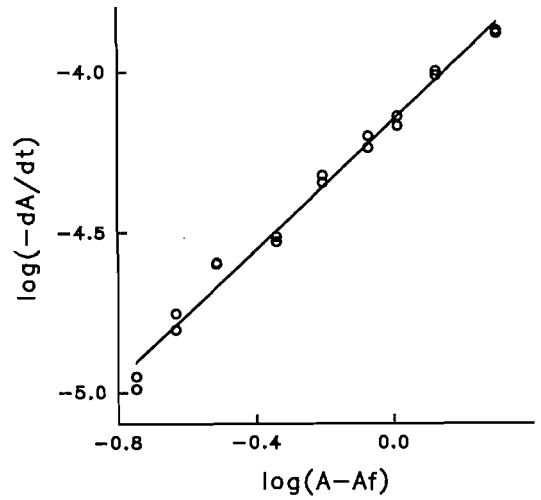

FIG. 3. The relationship between the initial rate of reduction and concentration of ferrate (as determined by the absorbance at 508 nm). pH = 10.3. Slope = 1.05 ± 0.06. r = 0.994.

essed as in eq. [7], a result that is in agreement with previously reported observations (20).

[7] $$\text{Rate} = k_1 [FeO_4^{2-}] [OH^-] + k_2 [FeO_4^{2-}]^2/[OH^-]^{1.6}$$

When the rates of reduction were studied as a function of temperature, plots of $\ln(k/T)$ vs. $1/T$ were linear for both k_1 and k_2 (Figs. 4 and 5). The activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, for these reactions were then calculated from the slopes and intercepts, respectively. The results are summarized in Table 1.

Oxidation rates

Most oxidation rates were measured at pH 9–10 where the rate of reduction of ferrate by water is minimal. Under these conditions, plots of $(A - A_f)$ vs. time are linear (Fig. 6), indicating that the reaction is first order in ferrate. Plots of log k vs. log[alcohol]$_0$ are linear with unit slope (Fig. 7), indicating that the rate of the reaction is also first order with respect to alcohol. Therefore, the total rate law for the reduction of ferrate at a particular pH (eq. [8]) has been verified.

Kinetic isotope effects

Substitution of deuterium for the α-hydrogen in both 2-propanol and mandelic acid caused a decrease in the rate of reaction as indicated by the data in Table 2. The magnitude of the decrease is indicative of a primary isotope effect.

Effect of substituents

The rate of oxidation of mandelic acid was not sensitive to the introduction of substituents into the ring as indicated by the data in Table 3. A Hammett plot for these data has a slope of zero with only a small amount of random scatter.

Variations in the structure of aliphatic alcohols caused greater effects on the rate of reaction, with alcohols containing electron-withdrawing groups exhibiting rates that are larger, in general, than for 2-propanol or alcohols bearing electron-donating substituents (Table 4).

[a]Temperature = 25.0 ± 0.1°C.

Activation parameters

Activation parameters for the oxidation of 2-propanol and mandelic acid were determined from measurement of the respective rate constants at different temperatures. Because pH is also temperature dependent it was necessary to correct the observed rate constants (k_{obs}) at a particular temperature for pH changes. Although plots of ln k_{cor}/T vs. $1/T$ are linear with high correlation coefficients (Figs. 8 and 9), the uncertainties in the calculated values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are consequently somewhat larger than suggested from a consideration of plot statistics. This added uncertainty is reflected in the values for the activation parameters reported in Table 5.

Oxidation of tetrahydrofuran

Previous results from several laboratories have shown that it is possible to distinguish between reactions that are initiated by O—H addition and those that are initiated by addition to the α-C—H bond from a comparison between the rates of oxidation of alcohols and ethers of similar structure (14). The rates of oxidation of several aliphatic alcohols and tetrahydrofuran were consequently compared. The results are presented in Table 4.

Discussion

Reduction of ferrate by water

The data summarized in Fig. 1 indicate that ferrate exhibits its greatest stability at pH 9–10, below which decomposition occurs by a reaction that is second order with respect to ferrate ion concentration and approximately first order in hydronium ion concentration. These kinetics suggest a reaction scheme in which hydrogen ferrate ion reacts with another ferrate ion to give a dimer that undergoes reduction by loss of dioxygen as summarized in eqs. [9]–[11]. The enhanced reactivity of $HFeO_4^-$ as compared to FeO_4^{2-} is consistent with the known chemistry of chromate (CrO_4^{2-}) and manganate (MnO_4^{2-}) ions (20, 21).

[9] $FeO_4^{2-} + H_2O \rightleftharpoons HFeO_4^- + OH^-$

[10] $HFeO_4^- + FeO_4^{2-} \rightleftharpoons Fe_2O_7^{2-} + OH^-$

[11] $Fe_2O_7^{2-} + 2H_2O \longrightarrow O_2 + H_2FeO_4^- + H_2FeO_3^-$

The increased reactivity of ferrate in solutions with pH above 10 is unusual when compared to the established chemistry of CrO_4^{2-}, RuO_4^{2-}, and MnO_4^{2-}. It is more reminiscent of permanganate, which undergoes reduction to manganate in sodium hydroxide solutions with concentrations of 1 M or greater (7). Although it is not possible on the basis of these kinetic data to define with confidence a reaction mechanism, a possible sequence of reactions that is consistent with the observed kinetics and results in the reduction of ferrate ion has been summarized in Scheme 1.

The observation (Table 1) that the entropy of activation is much less favorable for the reaction below pH 10 is consistent with the suggestion that a dimer is involved.

The oxidation of aliphatic alcohols

As previously discussed, alcohols can react with high-valent transition metal oxides such as ferrate by a 2+2 addition of a carbon–hydrogen bond to a metal–oxo double bond (eq. [2]) or by a 2+2 addition of the oxygen–hydrogen bond to a metal–oxo bond (eq. [1]). Distinction between these two possibilities can usually be made by comparing the rates of oxidation of aliphatic alcohols and ethers. Oxidants that react preferentially with O—H bonds will exhibit higher rates of reaction with alcohols than with ethers (which lack O—H bonds). For example, Westheimer and co-workers (22), noting that chromic acid reacts approximately 1500 times faster with isopropyl alcohol than diisopropyl ether, concluded that the initial reaction between chromic acid and alcohols involved ester formation (as in eq. [1]). Conversely, oxidants that react by way of 2+2 additions to α-C—H bonds oxidize alcohols and ethers with approximately equal ease. For example, it has been observed that ruthenium tetroxide reacts with 2-propanol and tetrahydrofuran at comparable rates (at 25°C, $k_{2\text{-propanol}} = 1.58 \times 10^{-2}\ M^{-1}\ s^{-1}$ while $k_{THF} = 5.38 \times 10^{-2}\ M^{-1}\ s^{-1}$ in 0.9 M $HClO_4$) (23).

From the data in Table 4, it is apparent that ferrate also reacts with aliphatic alcohols and THF at similar rates and, consequently, suggests that the mechanism involves an initial 2+2 addition between an α-C—H bond and a Fe=O double bond to give an organometallic intermediate, **1**, as in eq. [12]. A primary kinetic isotope effect for the oxidation of 2-propanol-2-*d* (Table 2) is also consistent with this conclusion.

[12] 
1

The observation that the unusually large rate constant observed for the oxidation of 1,1,1,3,3,3-hexafluoro-2-propanol (Table 4) is due almost entirely to a more favorable entropy of activation (Table 5) suggests that it is not unreasonable to propose a tightly structured intermediate for these reactions.

Decomposition of **1** could occur by either homolysis or heterolysis of the C—Fe bond (14). Heterolysis would yield an α-hydroxy carbocation while homolysis would give an α-hydroxy free radical. Distinction between these two possibilities can be made by observing the products obtained from the oxidation of cyclobutanol because it has been shown by Rocek and co-workers (24) that the α-hydroxycyclobutyl free radicals undergo a very rapid ring-opening reaction with consequent formation of acyclic products. When free radicals are not involved, the only product obtained is cyclobutanone (25).

Since the oxidation of cyclobutanol by ferrate resulted in the formation of only acyclic products, it seems likely that cleavage of the C—Fe bond occurs homolytically as in eq. [13].

For alcohols not containing a strained ring, homolytic cleavage of the C—Fe bond of the intermediate (**1**) would

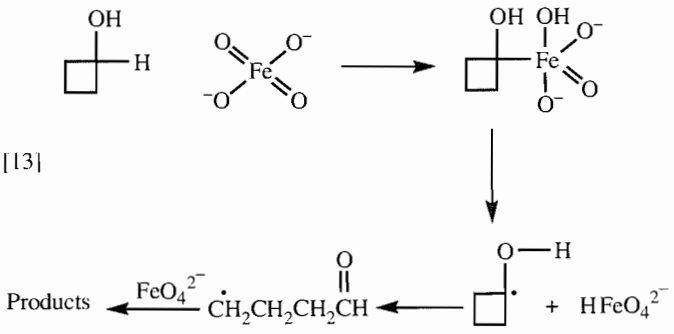
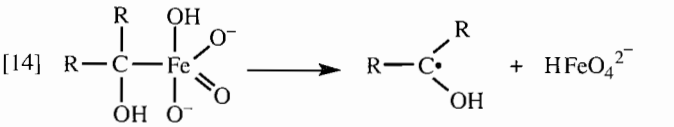
likely be followed by hydrogen transfer to yield a ketone as in eqs. [14] and [15].



[13]



[14]

[15]

The oxidation of mandelic acid

A primary deuterium kinetic isotope effect is also observed for the oxidation of mandelic acid (Table 2), suggesting that the reaction mechanism may be similar to that proposed for 2-propanol. The enthalpy of activation (Table 5), much less than for 2-propanol, reflects a decrease in the strength of C—H bonds adjacent to an aromatic ring. The less favorable entropy of activation for mandelic acid as compared to 2-propanol is likely associated with additional solvation that would be required for a transition state bearing three (rather than two as in the case of 2-propanol) negative charges.

The insensitivity of the rate of reaction to substituents on the ring (Table 3) is also consistent with a 2+2 rate-limiting step in which additional charge is not built up adjacent to the ring in the transition state.

Conclusion

The results obtained from a kinetic study of the oxidation of 2-propanol and mandelic acid by ferrate ion at pH 9–10 are readily accounted for by assuming that the reaction is initiated by a 2+2 addition of the α-C—H bond to an iron–oxo double bond, followed by subsequent homolytic cleavage of the resulting carbon—iron bond.

Novel access to (3*R*)- and (3*S*)-3-hydroxy-L-aspartic acids, (4*S*)-4-hydroxy-L-glutamic acid, and related amino acids

STEPHEN HANESSIAN[1] AND BENOIT VANASSE
Department of Chemistry, Université de Montréal, Montréal, QC H3C 3J7, Canada

Received April 12, 1993

STEPHEN HANESSIAN and BENOIT VANASSE. Can. J. Chem. **71**, 1401 (1993).

Derivatives of L-aspartic and L-glutamic acids can be converted into α-hydroxy acids via oxygenation of the corresponding enolates.

STEPHEN HANESSIAN et BENOIT VANASSE. Can. J. Chem. **71**, 1401 (1993).

Des dérivés de l'acide L-aspartique et L-glutamique sont convertis en α-hydroxy acides via des réactions d'oxygénation des énolates correspondants.

There is at present much interest in the asymmetric synthesis of non-proteinogenic as well as unusual amino acids of natural occurrence (for recent excellent monographs, see ref. 1; for selected recent reviews, see ref. 2). In this regard, the β- and γ-hydroxy α-amino acid motif, which can be found in a number of natural products (e.g., cyclosporin (3*a*) and lysobactin (3*b*); see also ref. 4), presents a challenging area for studies in stereocontrolled synthesis. Most of the synthetic routes to β- and γ-hydroxy α-amino acids and their derivatives have been developed only recently and they rely basically on chemical (1, 2), or enzymatic methods (4, 5). In connection with other ongoing projects in our laboratory, we became interested in the synthesis of (3*R*)- and (3*S*)-3-hydroxy-L-aspartic acids. Although the four optical isomers have been obtained by resolution (6) and by individual synthesis (7), recent reports have described alternative methods relying on asymmetric processes using amino acids (8, 9), on utilizing (*R*, *R*)-(+)-tartaric acid as a chiral template (10–16), and on other methodology.

We wish to disclose a novel access to (3*R*)- and (3*S*)-3-hydroxy-L-aspartic acids and (4*S*)-4-hydroxy-L-glutamic acid, as well as to α,γ-dihydroxy amino acids (17), by the stereocontrolled hydroxylation of the dianions derived from appropriate amino acids or their functional equivalents. Although there are ample precedents for the hydroxylation of ester (18),[2] lactone (19), and lactam (20) enolates, there are few practical examples in the amino acid series (21), one, to the best of our knowledge, in the case of acidic amino acids (22), and none with amino lactones. Our choice of L-aspartic and L-glutamic acids as substrates was instigated by the fact that the corresponding β- and γ-hydroxy acids, respectively, are found in nature. In planning our strategy for the stereocontrolled hydroxylation of dianions we wished to control the process by capitalizing on internal asymmetric induction resulting from the inherent chirality and functional disposition of a resident *N*-substituted amino group. We reasoned that by the judicious choice of oxidation reagent, we could alter the stereochemical course of the hydroxylation by taking advantage of the steric bulk in the substrate on the one hand, and chelation of proximal *N*-substituted groups on the other, as illustrated by paths A and B for the enolate resulting from L-aspartic acid in Scheme 1.

To test our plan, we chose the readily available (23) lactone **1** as a model in which the geometry of the dianion is fixed. Thus, lactone **1** was treated with a variety of bases, and the resulting enolate was treated with the Davis oxaziridine reagent (24) on the one hand, and the Mimoun-Vedejs, oxodiperoxymolybdenum pyridine hexamethylphosphoric triamide (MoOPH) reagent (25) on the other (Scheme 2).

As can be appreciated from the results in Table 1, regardless of the nature of the base, hydroxylation with MoOPH led to the preponderance of the *syn* product, albeit in modest yields. The isomeric lactones **2** and **3** were easily separated by chromatography, and variable quantities (up to 20%) of unreacted starting materials were recovered, which is not uncommon with dianions of this type (26). We rationalize the preponderance of this *syn* product by an initial coordination with the carbamate anion (N or O) followed by intramolecular delivery of oxygen as shown in Fig. 1. In view of the initial coordination with MoOPH, the nature of the cation seems to play little or no role in the selectivity.

With the oxaziridine, however, the major product is the *anti* isomer **2**, which most likely results from an approach of the oxidant from a position opposite to the bulky NHCbz group. Moreover, there appears to be an important difference in the ratio of the product **2** and **3**, particularly in the presence of NaHMDS, which gives the highest proportion of the *anti* isomer **2**. The origin of this dependence of selectivity on the nature of the cation is not clear, but could, in part, be due to the states of aggregation of mono and dianions as well as to the reactivity of the intermediate hemiaminal-type species formed with the reagent (18*b*).

Having confirmed the validity of the plan for a reagent and resident functional group-based strategy of hydroxylation with the cyclic model, we investigated the same reactions with *N*-benzyloxycarbonyl-L-asparate **4**. Table 2 summarizes the results in this series, where once again, the combination of the oxaziridine reagent with NaHMDS was found to give the highest selectivity (7:1) in favor of the *erythro* (2*S*,3*R*) isomer **6**.

Acid hydrolysis of **5** and **6**, respectively, gave (3*S*)-3-hydroxy-L-aspartic acid (14) and (3*R*)-4-hydroxy-L-aspartic acid (7), respectively.

With MoOPh, the *threo* isomer (*syn* attack) was favored (Table 2, entries 5–7), but the effect was much less pronounced than in the cyclic model. It is possible that chelation is also taking place in this series although, contrary to the lactone case (Table 1), there seems to be a dependence

on the nature of the cation. In an effort to clarify the nature of the dianionic species and the influence of the ester group on the selectivity of hydroxylation, we investigated the *N*-tosyl series with different combinations of methyl and *tert*-butyl ester groups (Scheme 4, Table 3).

Thus, localizing the charge on nitrogen (*N*-Ts series) (Scheme 1, R^2 = Ts), in combination with the presence of the bulky α-ester groups, clearly favors the formation of the *erythro* isomer, where a ratio of 45:1 can be obtained (Table 3, entry 5). Interestingly, the bulk of the ester group also has

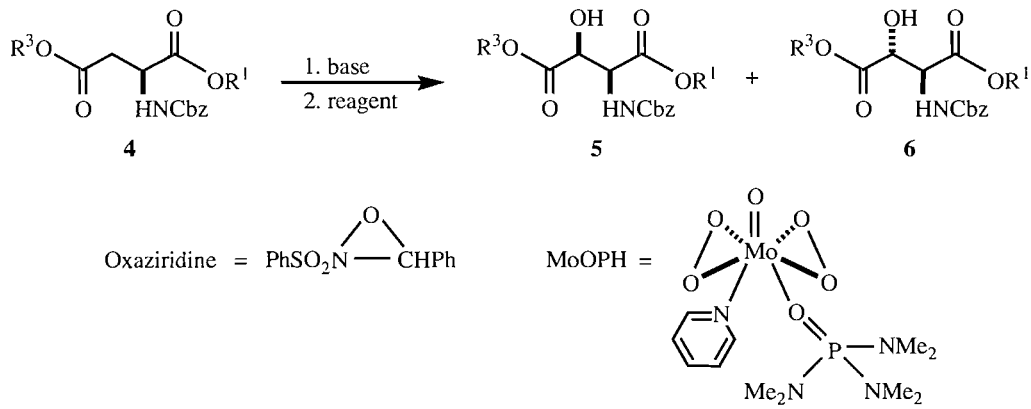

SCHEME 3

a synergistic effect in the case of MoOPH, where the selectivity can be increased to 1:4 in favor of the *threo* isomer (Table 3, entry 6), compared to the dimethyl ester series. Evidently in the *N*-Cbz series, selectivity is decreased, possibly due to the larger size of the chelated dianionic species, or due to its different state of aggregation. It should be pointed out that Tamm and co-workers (27) also postulated internal chelation in the hydroxylations with MoOPH.

In view of the limited number of methods for the preparation of enantiomerically pure γ-hydroxy-L-glutamic acid (4, 28–30), it was of interest to extend the hydroxylation reaction to *N*-benzyloxycarbonyl dimethyl L-glutamate **7** (Scheme 5, Table 4). Treatment of the dianion of **7** with MoOPH under a variety of conditions resulted in complete recovery of unchanged starting material, as was recently observed in a related case (21). However, when the oxaziridine was used as oxidant, hydroxylation took place to give the (4*S*)-hydroxy analog as the major (9:1) isomer, when LiHMDS was used as the base. In this series, KHMDS and NaHMDS proved to be much less selective than with **4**. Acid hydrolysis gave (4*S*)-4-hydroxy-L-glutamic acid (28).

The selectivity in this case is intriguing in view of the relative nonproximity of the carbamate to the enolate function. It is possible that the lithium enolate in this case is more conducive to the formation of a π-complex (31) with the aromatic ring of the carbamate, thus imposing an element of conformational constraint, and favoring an approach of the electrophilic reagent that leads to the observed product.

The methodology developed in this work provides an expeditious access to optically pure β- and γ-hydroxylated amino acids in the aspartic and glutamic acid series, respectively. The ability to control the stereochemistry of hydroxylation of dianions of the type reported here, based on the nature of the reagent used, and on the choice of functional group present, should stimulate further development in asymmetric synthesis[3] of related amino acids.

Experimental section

General data

Tetrahydrofuran was distilled over benzophenone and sodium prior to use. Analytical thin-layer chromatography (TLC) was carried out on Merck Kieselgel silica gel 60 F_{254} glass plates. Flash chromatography was performed according to the procedure of Still et al. (33) with Merck silica gel, 230–400 mesh. Infrared (IR) spectra were recorded in chloroform on a Perkin–Elmer 781 spectrometer. The wavenumbers reported are referenced to the polystyrene 1601 cm^{-1} absorption. Nuclear magnetic resonance spectra were obtained on a Bruker WH-400 (^1H 400 MHz) spectrometer with chloroform-*d* as solvent and tetramethylsilane as an internal standard, unless otherwise indicated. ^1H NMR multiplicities are recorded by use of the following abbreviations: s, singlet; d, doublet; dd, double doublet; t, triplet; q, quartet; m, multiplet; b, broad; *J*, coupling constant (hertz). High-resolution FAB mass spectra were obtained by means of Kratos MS5OTCTA and AEI-MS 902 spectrometers at the Université de Montréal. Melting points were mea-

[3]The reactivity of dianions resulting from various N-substituted dialkyl aspartates and glutamates depends on the nature of the electrophile, see for example, ref. 32.

Hydroxylation of ***1*** *with 3-phenyl-*N*-phenylsulfonyloxaziridine*

To a solution of lactone **1** (235 mg, 1 mmol) and 3-phenyl-*N*-phenylsulfonyloxaziridine (392 mg, 1.5 mmol) in THF (5 mL) was added a solution of sodium bis(trimethylsilyl)amide (1 M, 2 mL, 2 mmol) in THF (4 mL) at −78°C. After 15 min, the solution was quenched by addition of camphorsulfonic acid (1.0 g, 4 mmol) in THF (1.0 M), diluted with ethyl acetate, then washed with aqueous solutons of 10% HCl, 5% sodium bicarbonate, and brine. The organic layers were combined, dried ($MgSO_4$), and evaporated to dryness. The crude products were then purified by flash chromatography (ethyl acetate – hexanes, 4:6) to give (2*S*,3*S*)-3-benzyloxycarbonylamino-2-hydroxy-γ-butyrolactone, **2** (140 mg, 56%), and (2*R*,3*S*)-3-benzyloxycarbonylamino-2-hydroxy-γ-butyrolactone, **3** (10 mg, 4%).

For **2**: mp 105–106°C; $[\alpha]_D$ −30 (*c* 1, $CHCl_3$); IR ν_{max} (film): 3600–3200 (OH + NHCbz), 1785 (γ-lactone), 1720–1690 (carbamate) cm^{-1}; ^1H NMR (400 MHz, *O*-acetyl derivative) δ: 2.21 (3H, s, OAc), 3.9 (1H, dd, $J_{4,3}$ = 8.8 Hz, and J_{gem} = 8.8 Hz, H-4a), 4.2–4.16 (1H, m, H-3), 4.34 (1H, d, $J_{2,3}$ = 9.3 Hz, H-2), 4.39 (1H, dd, $J_{4,3}$ = 8.2 Hz, and J_{gem} = 8.8 Hz, H-4b), 5.0 (2H, s, CH_2Ph), 5.5–5.7 (1H, s, *NH*), 7.3–7.40 (5H, s, Ph); MO (O-Acetyl-derivative), *m/z*: 274 (MH^+); $C_{14}H_{15}NO_6$ (273.279).

For **3**: $[\alpha]_D$ +10.75 (*c* 1, $CHCl_3$); IR ν_{max} (film): 3600–3200 (OH + NHCbz), 1785 (γ-lactone), 1740 (ester and carbamate) cm^{-1}; ^1H NMR (400 MHz, O-acetyl derivative) δ: 2.21 (3H, s, OAc), 3.9 (1H, dd, $J_{4,3}$ = 8.8 Hz, and J_{gem} = 8.8 Hz, H-4a), 4.2–

4.16 (1H, m, H-3), 4.34 (1H, d, $J_{2,3}$ = 6.8 Hz, H-2), 4.39 (1H, dd, $J_{4,3}$ = 8.2 Hz, and J_{gem} = 8.8 Hz, H-4b), 5.0 (2H, s, CH_2Ph), 5.5–5.7 (1H, s, *NH*), 7.3–7.40 (5H, s, Ph); MO (O-acetyl derivative), *m/z*: 294 (MH^+); $C_{14}H_{15}NO_6$ (293.279).

Hydroxylation of ***1*** *with MoOPH*

To a solution of lactone **1** (117 mg, 0.5 mmol) in THF at −78°C was added a solution of potassium bis(trimethylsily)amide (0.5 M, 4 mL, 2 mmol) in THF (4 mL) followed by MoOPH (434 mg, 1 mmol). After 15 min, the reaction mixture was quenched by addition of aqueous 10% HCl. The solution was diluted with ethyl acetate, then washed with successively aqueous solutions of 10% HCl, 5% sodium bicarbonate, and brine. The organic layers were combined, dried ($MgSO_4$), and evaporated to dryness. The crude products were then purified by flash chromatography (ethyl acetate – hexanes 4:6) to give **2** (5 mg, 4%) and **3** (45 mg, 65%).

Hydroxylation of ***4*** *with 3-phenyl-*N*-phenylsulfonyloxaziridine*

To a solution of dimethyl *N*-benzyloxycarbonyl-L-asparate **4** (295 mg, 1 mmol) and 3-phenyl-*N*-phenylsulfonyloxaziridine (392 mg, 1.5 mmol) in THF (5 mL) at −78°C was added, dropwise, a solution of sodium bis(trimethylsilyl)amide (1 M, 2.0 mL, 2 mmol) in THF (5 mL). After 15 min, the reaction mixture was quenched by addition of camphorsulfonic acid and processed as described for the synthesis of **2**. The products were then purified by flash chromatography (ethyl acetate – hexanes 4:6) to give (2*S*,3*R*)-dimethyl 3-hydroxy-*N*-benzyloxycarbonyl-L-aspartate **6**, isolated as an oil (190 mg, 61%) and (2*S*,3*S*)-dimethyl 3-hydroxy-*N*-benzyloxycarbonyl-L-aspartate **5**, isolated as an oil (27 mg, 9%).

For **6**: $[\alpha]_D$ +14.58 (*c* 1, $CHCl_3$); IR ν_{max} (film): 3400–3300 (NHCbz), 1750–1730 (esters and carbamate) cm^{-1}; ^1H NMR (300 MHz) δ: 3.34 (1H, d, *J* = 5.3 Hz, OH), 3.78 (3H, s, C(4)OOMe), 3.80 (3H, s, C(1)OOMe), 4.72 (1H, d, $J_{2,3}$ = 3.9 Hz, H-2), 4.75 (1H, d, $J_{3,NH}$ = 9.3 Hz, H-3), 5.10 (2H, s, CH_2Ph), 5.61 (1H, d, $J_{NH,2}$ = 9.3 Hz, NH), 7.34 (5H, s, Ph); MS, *m/z*: 312 (MH^+, 100%); $C_{14}H_{17}NO_7$ (311.294).

For **5**: $[\alpha]_D$ +24.2 (*c* 1, $CHCl_3$); IR ν_{max} (film): 3400–3300 (NHCbz), 1750–1730 (esters and carbamate) cm^{-1}; ^1H NMR (300 MHz) δ: 3.46 (1H, d, *J* = 5.0 Hz, OH), 3.73 (3H, s, C(4)OOMe), 3.83 (3H, s, C(1)OOMe), 4.53 (1H, d, $J_{2,3}$ = 2.0 Hz, H-2), 4.64 (1H , dd, $J_{3,2}$ = 2.2 Hz and $J_{3,NH}$ = 8.4 Hz, H-3), 5.14 (2H, s, CH_2Ph), 5.79 (1H, d, $J_{NH,2}$ = 8.4 Hz, NH), 7.34 (5H, s, Ph); MS, *m/z*: 312 (MH^+, 100%); $C_{14}H_{17}NO_7$ (311.294).

Hydroxylation of ***4*** *with MoOPH*

To a solution of dimethyl *N*-benzyloxycarbonyl-L-aspartate **4** (158 mg, 0.53 mmol) in THF at −78°C was added a solution of potassium bis(trimethylsilyl)amide (0.5 M, 4 mL, 2 mmol) in THF (4 mL) followed by addition of MoOPH (434 mg, 1 mmol). After 15 min, the reaction mixture was quenched by addition of an aqueous solution of 1 N HCl and processed as described above. The crude products were then purified by flash chromatography (ethyl acetate – hexanes 4:6) to give **6** (27 mg, 16%) and **5** (55 mg, 34%), isolated as oils.

*Hydroxylation of di-*tert*-butyl-*N*-p-tolylsulfonyl-*L*-aspartate with 3-phenyl-*N*-phenylsulfonyl oxaziridine*

To a solution of di-*tert*-butyl-*N*-*p*-tolylsulfonyl-L-aspartate (104 mg, 0.27 mmol) at −78°C was added, dropwise, a solution of lithium hexamethyldisilazane (0.78 mmol) in THF (5 mL). After 2 h, 3-phenyl-*N*-phenylsulfonyl oxaziridine (102 mg, 0.39 mmol) in THF (2 mL) was added. The reaction was quenched, after 15 min, by addition of camphorsulfonic acid (0.26 g, 1.1 mmol) in THF (1.0 M). The solution was diluted with ethyl acetate and processed as described above. The crude products were purified by flash chromatography (ethyl acetate – hexanes 1:1) to give (2*S*-3*R*)-di-*tert*-butyl-3-hydroxy-*N*-tosyl-L-aspartate and (2*S*,3*S*)-di-*tert*-butyl-3-hydroxy-*N*-tosyl-L-aspartate as a 45:1 (*anti*:*syn*) mixture of diastereomers (62 mg, 57%); IR ν_{max} (film): 3400–2900 (OH + NHCbz), 1750–1730 (esters) cm^{-1}; ^1H NMR (300 MHz) δ: 1.23 (9H, s, *tert*-butyl), 1.57 (9H, s, *tert*-butyl), 2.40 (3H, s, CH_3), 3.02 (1H, m, OH-3), 4.275 (1H, dd, $J_{2,OH}$ = 10.8 Hz and $J_{2,3}$ = 2.26 Hz, H-2), 4.39–4.42 (1H, M, H-3), 5.3 (1H, d, $J_{NH,2}$ = 10.8 Hz, NH), 7.29 (2H, d, *J* = 8 Hz, Ph), 7.75 (2H, d, *J* = 6.5 Hz, Ph).

*Hydroxylation of di-*tert*-butyl-*N*-benzyloxycarbonyl-*L*-aspartate with MoOPH*

To a solution of di-*tert*-butyl-*N*-benzyloxycarbonyl-L-aspartate (100 mg, 0.264 mmol) in THF (10 mL) at −78°C was added a solution of lithium bis(trimethylsilyl)amide (2.1 mmol) in THF (4 mL). After 2 h, MoOPH (229 mg, 0.527 mmol) was added as a solid in one portion at −78°C. After 4 h, the solution was quenched by addition of an aqueous solution of 1 N HCl, then processed as described above. The crude products were purified by flash chromatography (ethyl acetate – hexanes 2:8) to give 42 mg, 40%) of (2*S*,3*R*)-di-*tert*-butyl-3-hydroxy-*N*-benzyloxycarbonyl-L-aspartate and (2*S*,3*S*)-di-*tert*-butyl-3-hydroxy-*N*-benzyloxycarbonyl-L-aspartate isolated as a 1:4 (*anti*:*syn*) mixture of diastereomers; IR ν_{max} (film): 3600–3300 (OH + NHCbz), 1730 (esters) cm^{-1}; ^1H NMR (300 MHz, for the OAc derivative) δ: 1.469 (9H, s, *tert*-butyl), 1.496 (9H, s, *tert*-butyl), 2.109 (3H, s, OAc), 4.852 (1H, dd, $J_{2,NH}$ = 8,1 Hz and $J_{2,3}$ = 3.2 Hz, H-2), 5.125 (2H, s, CH_2Ph), 5.355 (1H, d, $J_{2,3}$ = 3.2 Hz, H-3), 5.585 (1H, d, $J_{NH,2}$ = 8.1 Hz, NH), 7.36 (5H, s, Ph); MS, *m/z*: 278 (50%) 222 (55%), 89 (95%); HRMS, calcd. for $C_{20}H_{29}NO_7$: 395.1944; found: 395.4520.

Hydroxylation of dimethyl N*-benzyloxycarbonyl-*L*-glutamate (7) with 3-phenyl-*N*-phenylsulfonyl oxaziridine*

To a solution of dimethyl *N*-benzyloxycarbonyl-L-glutamate (120 mg, 0.408 mmol) and 3-phenyl-*N*-phenylsulfonyl oxaziridine (160 mg, 0.612 mmol) in THF (5 mL) at −78°C (acetone – Dry Ice) was added, dropwise, a solution of lithium bis(trimethylsilyl)amide (1 M, 1.22 mL, 1.22 mmol) in THF (5 mL). After 15 min, the solution was quenched by addition of camphorsulfonic acid (0.408 g, 1.8 mmol) in THF (1.0 M). The solution was diluted with ethyl acetate, washed with an aqueous solution of 10% HCl, then processed as described above. The crude products were purified by flash chromatography (ethyl acetate – hexanes 1:1) to give (92 mg, 70%) of (2*S*,4*S*)-dimethyl 4-hydroxy-*N*-benzyloxycarbonyl-L-glutamate as a 9:1 mixture of inseparable diastereomers; $[\alpha]_D$ +9.0 (*c* 1, $CHCl_3$); IR ν_{max} (film): 3600–3200 (NHCbz + OH), 1760–1690 (esters and carbamate) cm^{-1}; ^1H NMR (300 MHz) δ: 2.2 (2H, m, H-3a and H-3b), 3.5 (1H, d, *J* = 4.4 Hz, OH), 3.73 (3H, s, COOMe), 3.75 (3H, s, COOMe), 4.25 (1H, m, H-2), 4.64 (1H, m, H-4), 5.11 (2H, s, CH_2Ph), 5.8 (1H, d, $J_{NH,4}$ = 7.8 Hz, NH), 7.34 (5H, s, Ph); MS, *m/z*: 326 (30%, MH^+), 282 (100%, $-CO_2$); HRMS, calcd. for $C_{15}H_{19}NO_7$: 325.1161; found: 325.1120.

*(3*R*)-3-Hydroxy-*L*-aspartic acid*

A solution of **6** (100 mg, 0.321 mmol), in 6 N HCl, was heated at reflux for 1.5 h. The solution was cooled, diluted with EtOAc, processed in the usual way, and the aqueous layer was evaporated to a volume of 2 mL. Acetone was then added and the resulting crystals were isolated by filtration to give the title compound as a white crystalline solid (33 mg, 69%); mp >200°C, $[\alpha]_D$ +45.6 (*c* 0.5, HCl 1 N) (lit. (16) mp >220°C, $[\alpha]_D$ +49 (*c* 2.85, HCl 1 N)).

*(3*S*)-3-Hydroxy-*L*-aspartic acid*

A solution of **5** (100 mg, 0.321 mmol), in 6 N HCl, was heated at reflux for 1.5 h. The solution was processed as described above to give the title compound as a white crystalline solid (33 mg, 69%); mp >200°C, $[\alpha]_D$ +1 (*c* 2, HCl 1 N) (lit. (7) mp >200°C, $[\alpha]_D$ +1.3 (*c* 2, HCl 1 N)).

*(4*S*)-4-Hydroxy-*L*-glutamic acid*

A solution of **8** (100 mg, 0.308 mmol), in 6 N HCl, was heated at reflux for 1.5 h. The solution was cooled, then processed as described above to give the title compound as a white crystalline solid (35 mg, 69%); mp >200°C, $[\alpha]_D$ +55 (*c* 1, HCl 5 N) (lit. (28) mp >200°C, $[\alpha]_D$ +61 (*c* 1, HCl 5 N)).

Highly stereocontrolled syntheses of 2,3-disubstituted 1,4-butyrolactones using ionic and free radical reactions

STEPHEN HANESSIAN,[1] BENOIT VANASSE, HUA YANG, AND MARCO ALPEGIANI
Department of Chemistry, Université de Montréal, Montréal, QC H3C 3J7, Canada

Received April 12, 1993

STEPHEN HANESSIAN, BENOIT VANASSE, HUA YANG, and MARCO ALPEGIANI. Can. J. Chem. **71**, 1407 (1993).

N-Substituted 3-amino-1,4-butyrolactones undergo highly stereocontrolled substitution reactions via anionic and free radical processes.

STEPHEN HANESSIAN, BENOIT VANASSE, HUA YANG et MARCO ALPEGIANI. Can. J. Chem. **71**, 1407 (1993).

Les dérivés des 3-amino-1,4-butyrolactones *N*-substitués réagissent de façon hautement stéréocontrollée dans de réactions de type anioniques et radicalaires.

The past decade has seen a resurgence in asymmetric processes in virtually all facets of preparative organic chemistry where chirality is an issue (1). Efforts in the area of amino acid chemistry (2) have focused on the synthesis of natural and unnatural analogs in connection with natural product synthesis (for some recent examples, see ref. 3), and a continuing interest in the design of enzyme inhibitors and peptidomimetics (ref. 4 for recent reviews). Thus, the search for enantiomerically pure "small" molecules as mimics and surrogates of proteinogenic amino acids has become an important area of research activity.

In the preceding paper (5), we described methods for the stereocontrolled hydroxylation of enolates derived from *N*-substituted dialkyl aspartates and glutamates, as well as from 3-*N*-substituted butyrolactones. It was shown that by utilizing steric control, influenced by resident functionality, hydroxylation of enolates took place from a side opposite to a bulky substituent. On the other hand, using a reagent capable of coordinating with the *N*-substituent, hydroxylation could be directed to produce significant amounts of the other diastereomer.

We now report on the utilization of (*S*)-3-benzyloxycarbonylamino butyrolactones, **1** and **2**, readily available from *L*-aspartic acid (6), as chiral templates for site-selective and stereocontrolled functionalizations at C-2 via the corresponding enolates and radicals. In this context, the 2-azido and 2-bromo products would constitute versatile 4-carbon chirons with preparatively useful applications (see, for example, ref. 7), as shown in Scheme 1.

Previous studies (6) with the same lactone showed that treatment of the dianion with methyl iodide led to the expected *anti* product (X = Me) as the preponderant isomer (88:12 *anti*:*syn*). More recently, this work was extended by Ohno and co-workers (8) to the corresponding ethyl (55%) and 2-propyl (15%) products, with high selectivity. Such 2-alkyl butyrolactones were subsequently transformed into monocyclic β-lactams (9).

We first addressed the problem of electrophilic bromination of the dianion **3** generated in the presence of LiHMDS. Using *N*-bromosuccinimide and bromine as the brominating reagents produced a single crystalline product **4**, in yields of 45% and 51%, respectively, with recovery of starting material. The stereochemical outcome of the reaction was proved by detailed NMR studies. Changing the base to LDA or KHMDS, among others, did not affect the reaction or the stereochemistry. Surprisingly, when bromodimethylsulfonium bromide (10) was used as the brominating reagent, a crystalline 2,2-dibromo lactone **5** was formed in 55% yield. Once again, starting material could be recovered from the reaction mixture.

Attempts to displace the bromine atom in **4** with azide ion, under different conditions (solvent, temperature), led to decomposition, presumably due to participation of the *N*-benzyloxycarbonyl group followed by subsequent reactions of the resulting 2-benzyloxy-1,3-oxazolinium ion.

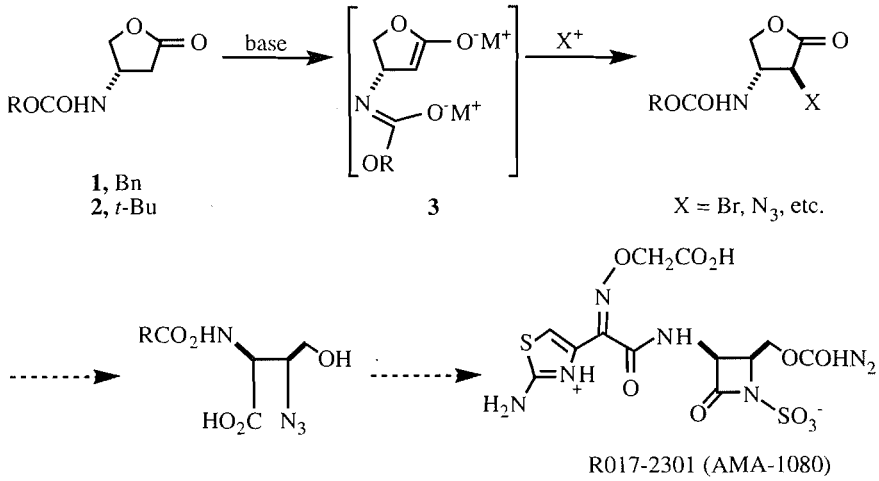
We next investigated electrophilic amination of the dianion of **1**, as well as of the corresponding *N*-*tert*-butoxycarbonyl analog **2**. Since we sought to have two functional groups that could be chemically manipulated independently of one another, we looked into the prospects of electrophilic azidation reactions. Enolate anions of simple 2-azetidinones have been transformed into the 3-azido derivatives by treatment with arylsulfonyl azides in 30–76% yield (11). Evans and Britton (12) showed that treatment of the potassium enolate of anions bearing a chiral oxazolidone auxiliary with triisopropylbenzenesulfonyl azide produces the corresponding 2-azido derivatives in good yields and high selectivity. While our work was in progress, Nitta et al. (9) reported the azidation of the dianion **3** (R = *t*-Bu) with tosyl azide in the presence of trimethylsilyl chloride, to give the corresponding azido derivative **7** in 58% yield (Scheme 2).

Treatment of the dilithium dianion of **1** with tosyl azide produced a single crystalline azido derivative **6** in 55% yield with recovery of starting material. The same reaction with the *N*-Boc derivative also produced the expected 2-azido derivative **7** in agreement with the published results (9). Several attempts to improve the yield, including changes in the nature of the base (e.g., KHMDS) and the use of tripsyl azide, were not successful. The lower reactivity of such dianions toward weak electrophiles is not uncommon (9, 11).

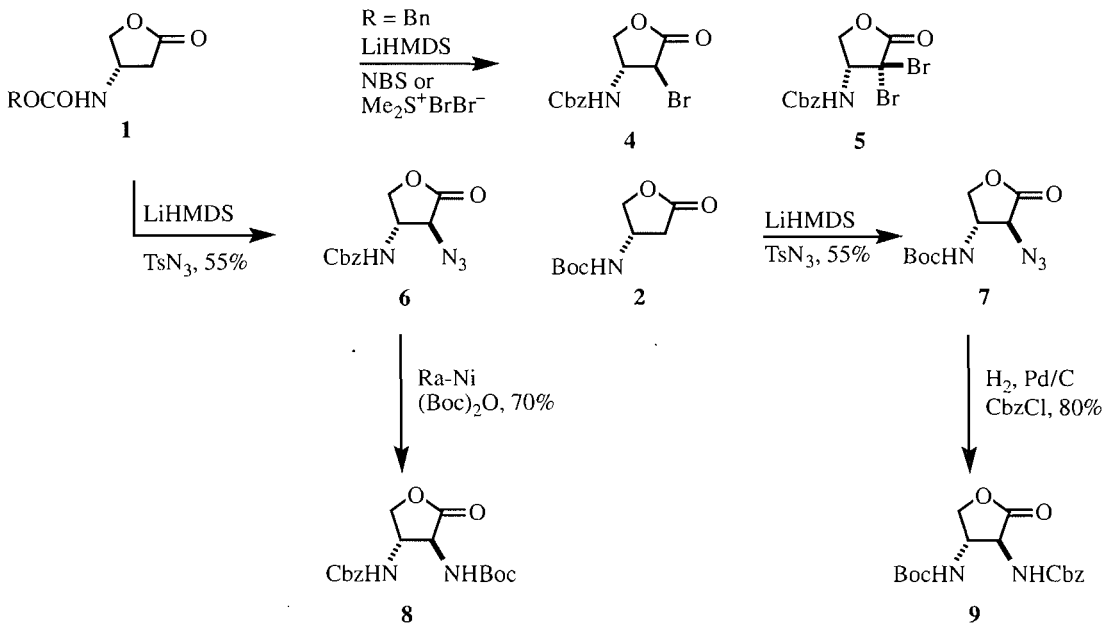
The lactones **6** and **7** offer the flexibility of differentiating the two vicinal amino groups with different protective groups. Thus, the azido group can be transformed to *N*-Cbz or *N*-Boc groups simply by reduction in the presence of the appropriate carbamoylating agent, as shown in Scheme 2.

With the availability of the 2-bromo derivative **4**, we became interested in their utilization in a free-radical *C*-allylation reaction (ref. 13, and, for a recent application to carbohydrate lactones, ref. 14), with a particular emphasis on the stereochemical outcome as compared to the analogous anionic reaction (6, 7). As a parallel study, we also

[1]Author to whom correspondence may be addressed.



SCHEME 1



SCHEME 2

prepared the 2-phenylseleno lactone **10** for a series of reactions shown in Scheme 3.

Thus, treatment of either the 2-bromo or the 2-phenylseleno lactones **4** or **10** with allyltributylstannane, in refluxing benzene and in the presence of a radical initiator, led to the formation of the *C*-allyl derivative **11** in yields of 82% and 55%, respectively. It is of interest that the allylation of the dianion of **1** gave an 88:12 (*anti*:*syn*) mixture of *C*-allyl derivatives (6, 8). In spite of the more modest yield obtained with the phenylseleno derivative, the method is more practical since the bromination is sometimes accompanied by the dibromo compound **5**. When subjected to the same radical-induced *C*-allylation, **5** afforded the *gem* di-*C*-allyl product **13** accompanied by the monoallyl derivative. The two-step sequence proceeding through the phenylseleno derivative **12** gave an excellent and reproducible yield of **13**. Thus the lactone motifs **1** and **2** can be readily functionalized with a high degree of stereocontrol to provide chirons useful in a number of synthetic endeavors related to natural and unatural products.

Experimental

General data

Tetrahydrofuran was distilled over benzophenone and sodium prior to use. Analytical thin-layer chromatography (TLC) was carried out on Merck Kieselgel silica gel 60 F_{254} glass plates. Flash chromatography was performed according to the procedure of Still et al. (15) with Merck silica gel, 230–400 mesh. Infrared (IR) spectra were recorded in chloroform on a Perkin–Elmer 781 spectrometer. The wavenumbers reported are referenced to the polystyrene 1601 cm^{-1} absorption. Nuclear magnetic resonance spectra were obtained on a Bruker WH-400 (^1H 400 MHz) spectrometer with chloroform-*d* as solvent and tetramethylsilane as an internal standard, unless otherwise indicated. ^1H NMR multiplicities are recorded by use of the following abbreviations: s, singlet; d, doublet; dd, doublet doublet; t, triplet; q, quartet; m, multiplet; b, broad; *J*, coupling constant (hertz). High-resolution FAB mass spectra were

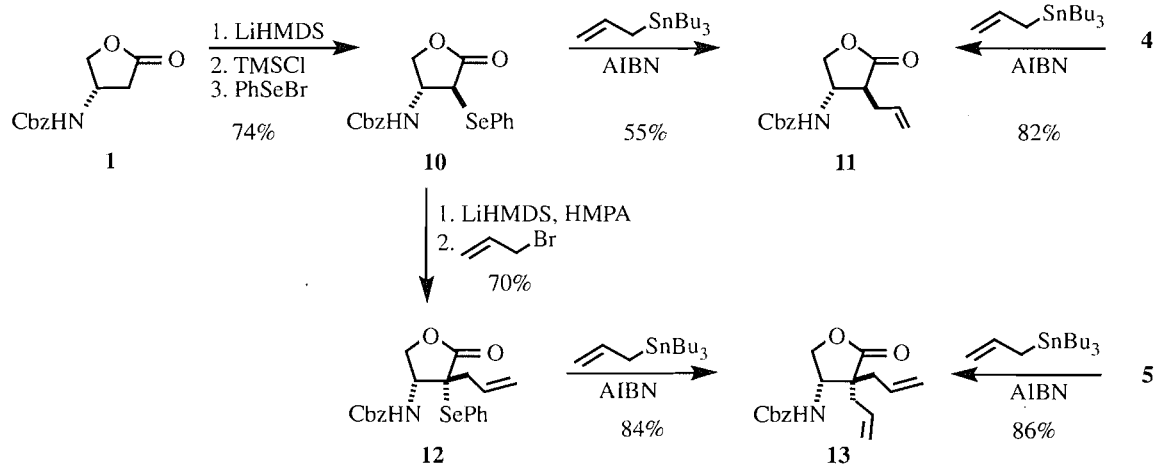

SCHEME 3

obtained by means of Kratos MS5OTCTA and AEI-MS 902 spectrometers at the Université de Montréal. Melting points were measured on a Büchi apparatus and are uncorrected. Optical rotations were measured on a Perkin–Elmer 241 polarimeter at 25°C.

(2S,3S)-3-Benzyloxycarbonylamino-2-bromo-1,4-butyrolactone (4)

Method A

A solution of butyllithium in hexanes (1.52 M, 1.3 mL, 2 mmol) was added dropwise to a solution of hexamethyldisilazane (0.422 mL, 2 mmol) in THF (4 mL) at 0°C. After 15 min, the solution was cooled down to −78°C, a solution of the lactone **1** (235 mg, 1 mmol) in THF (5 mL) was added, and the mixture was stirred at that temperature for 30 min. The reaction flask was covered with aluminum foil and a solution of *N*-bromosuccinimide (267 mg, 1.5 mmol), in THF (3 mL) was then added to the resulting dianion mixture at −78°C. After 3 min, trimethylsilyl chloride (0.33 mL, 2.6 mmol) was added to quench the reaction. The mixture was diluted with ether and washed successively with 10% aqueous HCl, 5% aqueous $NaHCO_3$, and brine and dried over $MgSO_4$. Concentration and flash column chromatography (EtOAc–hexanes 3:7) furnished the title compound **4** (160 mg, 51%) as a white solid, and the starting material (35 mg, 15%). Recrystallization from a mixture of ethyl acetate and hexanes gave colorless crystals, mp 97–99°C; $[\alpha]_D$ −32 (*c* 1, THF); IR ν_{max} (film): 3400 (NHCbz), 1800 (γ-lactone), 1740 (carbamate) cm^{-1}; ^1H NMR (400 MHz) δ: 4.28–4.31 (1H, d, $J_{2,3}$ = 9 Hz, H-2), 4.42–4.48 (2H, m, H-3 and H-4a), 4.70–4.74 (1H, m, H-4b), 5.13 (2H, CH_2Ph), 5.28 (1H, NH), 7.3–7.45 (5H, Ph); MS, *m/z*: 315 (MH^+). Anal. calcd. for $C_{12}H_{12}NO_4Br$: C 45.87, H 3.82, N 4.46; found: C 45,81, H 3.79, N 4.42.

Method B

The dianion was generated as described in Method A. Then a solution of bromine (0.077 mL, 1.5 mmol) in THF (3 mL) was added dropwise, in the dark at −78°C. After 3 min, the reaction was quenched with trimethylsilyl chloride (0.33 mL, 2.6 mmol) and worked up as described above to afford the title compound **4** (141 mg, 45%), as a white solid, and the starting material (35 mg, 15%).

(3S)-3-Benzyloxycarbonylamino-2,2-dibromo-1,4-butyrolactone (5)

A solution of the lactone **1** (235 mg, 1 mmol) in THF (5 mL) was added dropwise to a solution of lithium hexamethyldisilazide (2 mmol) in THF (4 mL) at −78°C. The mixture was stirred at −78°C for 30 min, then the flask was covered with aluminum foil, and a solution of bromodimethylsulfonium bromide (333 mg, 1.5 mmol) in THF (3 mL) was added dropwise. After stirring for 15 min at −78°C, the reaction was quenched with trimethylsilyl chloride (0.33 mL, 2.6 mmol). After allowing to warm up to room temperature, the resulting mixture was diluted with ether and washed successively with 10% aqueous HCl, 5% aqueous $NaHCO_3$, and brine and dried over $MgSO_4$. Evaporation of the solvent and flash column chromatography (ethyl acetate – hexanes 3:7) yielded starting material (35 mg, 15%), and the title compound **5** (200 mg, 51%) as a white solid. Recrystallization from a mixture of ethyl acetate and hexanes gave colorless crystals, mp 87–88°C; $[\alpha]_D$ +18.0° (*c* 1, THF); IR ν_{max} (film): 3400–3100 (NHCbz), 1800 (γ-lactone), 1740 (carbamate) cm^{-1}; ^1H NMR (400 MHz) δ: 4.42–4.48 (2H, m, H-3 and H-4a), 4.70–4.74 (1H, m, H-4b), 5.13 (2H, s, CH_2Ph), 5.28 (2H, NH), 7.3–7.45 (5H, Ph); MS, *m/z*: 394 (MH^+). Anal. calcd. for $C_{12}H_{11}NO_4Br_2$: C 36.66, H 2.80, N 3.56; found: C 36.34, H 2.76, N 3.49.

(2S,3S)-2-Azido-3-benzyloxycarbonylamino-1,4-butyrolactone (6)

A solution of the lactone **1** (1.0 g, 4.25 mmol) in THF (20 mL) was added dropwise to a solution of lithium hexamethyldisilazide (9.5 mmol) in THF (20 mL) at −78°C. The mixture was stirred at −78°C for 30 min, and a solution of *p*-toluenesulfonyl azide (1.0 g, 5.08 mmol) in THF (10 mL) was added rapidly, at −78°C. After stirring for 5 min, the reaction was quenched with trimethylsilyl chloride (1.6 mL, 12.75 mmol). The resulting mixture was diluted with ether and washed successively with 10% aqueous HCl, 5% aqueous $NaHCO_3$, and brine and dried over $MgSO_4$. Concentration and flash column chromatography (ethyl acetate – hexanes 3:7) gave the title compound **6** (0.65 g, 55%) as an oil that solidified upon standing. A small quantity of starting material (0.1 g, 10%) was also isolated. The product was recrystallized from a solvent mixture of ethyl acetate – hexanes, mp 86–87°C; $[\alpha]_D$ −99 (*c* 1, THF); IR ν_{max} (film): 2130 (azide), 1785 (γ-lactone), 1700 (carbamate) cm^{-1}; ^1H NMR (400 MHz) δ: 4.1–4.2 (1H, d, $J_{2,3}$ = 8 Hz), 4.42–4.48 (2H, m, H-3 and H-4a), 4.70–4.74 (1H, m, H-4b), 5.13 (2H, s, CH_2Ph), 5.28 (1H, NH), 7.3–7.45 (5H, Ph); MS, *m/z*: 277 (MH^+), 91 (100%, C_7H_7). Anal. calcd. for $C_{12}H_{12}N_4O_4$: C 52.17, H 4.35, N 20.29; found: C 51.92, H 4.31, N 20.04.

*(2S,3S)-3-Benzyloxycarbonylamino-2-*tert*-butoxycarbonylamino-1,4-butyrolactone (8)*

Raney nickel (0.5 g) and di-*tert*-butyl dicarbonate (1.09 g, 5.0 mmol) were added successively to a solution of the lactone **6** (1.03 g, 3.73 mmol) in THF (20 mL). Filtration of the suspension through Celite and concentration of the filtrate furnished a crude sample, which was purified through flash column chromatography (ethyl acetate – hexanes 45%) to give the title compound **8** (0.887 g, 70%) as a white solid, mp 150–152°C; $[\alpha]_D$ +25.3

(*c* 1, $CHCl_3$); IR ν_{max} (film): 3300 (NHBoc, NHCbz), 1780 (γ-lactone), 1720 (carbamate) cm^{-1}; ^1H NMR (60 MHz) δ: 1.47 (9H, s, *tert*-butoxy), 3.8–4.35 (3H, m, H-2, H-3, and H-4a), 4.70–4.74 (1H, m, 4-Hb), 5.03 (2H, s, CH_2Ph), 5.28 (1H, m, NH), 6.3 (1H, m, NH), 7.3–7.45 (5H, Ph); MS, *m/z*: 351 (80%, MH^+).

*(3S)-3-*tert*-Butoxycarbonylamino-1,4-butyrolactone (2)*

10% Palladium-on-charcoal (0.4 g) and di-*tert*-butyl dicarbonate (4.09 g, 18.7 mmol) were added successively to a solution of the lactone **1** (4.0 g, 17.0 mmol) in THF (10 mL). The resulting mixture was vigorously stirred overnight under an atmosphere of hydrogen. Filtration of the suspension through Celite and concentration of the filtrate yielded a crude sample, which was purified through flash column chromatography (ether) to give the title compound **2** (3.2 g, 85%) as a white solid, mp 113–114°C; $[\alpha]_D$ −54.3 (*c* 1.15, $CHCl_3$) (lit. (8) mp 106–108°C; $[\alpha]_D^{25}$ −61 (*c* 1.0, EtOH); IR ν_{max} (film): 1780 (γ-lactone), 1700 (carbamate) cm^{-1}; ^1H NMR (400 MHz) δ: 1.45 (9H, s, *tert*-butyl), 2.45 (1H, dd, $J_{2,3}$ = 3.9 Hz and J_{gem} = 17.9 Hz, H-2a), 2.85 (1H, dd, $J_{2,3}$ = 7.7 Hz and J_{gem} = 17.9 Hz, H-2b), 4.2 (1H, m, H-4b), 4.5–4.8 (2H, m, H-3 and H-4a), 5.09 (2H, s, CH_2Ph), 5.5 (1H, NH), 7.3–7.40 (5H, Ph); MS, *m/z*: 202 (MH^+), 146 (*tert*-butyl).

*(2S,3S)-2-Azido-3-*tert*-butoxycarbonylamino-1,4-butyrolactone (7)*

A solution of the lactone **2** (0.854 g, 4.25 mmol) in THF (20 mL) was added dropwise to a solution of lithium hexamethyldisilazide (9.5 mmol) in THF (20 mL) at −78°C. The mixture was stirred at −78°C for 30 min. A solution of *p*-toluenesulfonyl azide (1.0 g, 5.08 mmol) in THF (10 mL) was then added rapidly to the resulting dianion suspension at −78°C. After stirring for 5 min, the reaction was quenched with trimethylsilyl chloride (1.6 mL, 12.75 mmol). After warming up to room temperature, the resulting mixture was diluted with ether and washed successively with 10% aqueous HCl, 5% aqueous $NaHCO_3$, and brine and dried over $MgSO_4$. Concentration and flash column chromatography (ethyl acetate – hexanes 3:7) furnished the title compound **7** (0.57 g, 55%) as an oil that solidified upon standing. Starting material (0.1 g, 11.7%) was also recovered. Compound **7** was recrystallized from a mixture of ethyl acetate and hexanes, mp 107–109°C; $[\alpha]_D$ −70 (*c* 1.0, EtOH) (lit. (9) mp 110–111°C; $[\alpha]_D$ −69 (*c* 1.0, EtOH)); IR ν_{max} (film): 2130 (azido), 1800 (γ-lactone), 1735 (carbamate) cm^{-1}; ^1H NMR (400 MHz) δ: 1.45 (9H, s, *tert*-butyl), 4.1–4.2 (1H, d, $J_{2,3}$ = 8 Hz, H-2), 4.42–4.48 (2H, m, H-3 and H-4a), 4.70–4.74 (1H, m, H-4b), 5.28 (1H, m, NH). Anal. calcd. for $C_9H_{14}N_4O_4$: C 44.63, H 5.79, N 23.14; found: C 44.59, H 5.71, N 23.11.

*(2S,3S)-2-Benzyloxycarbonylamino-3-*tert*-butoxycarbonylamino-1,4-butyrolactone (9)*

10% Palladium-on-charcoal (50 mg) was added to a solution of the lactone **7** (0.25 g, 1.03 mmol) in THF (5 mL). The resulting mixture was stirred under an atmosphere of hydrogen for 40 min, and the suspension was filtrated through Celite. Triethylamine (0.153 mL, 1.1 mmol) and benzyl chloroformate (0.142 mL, 1 mmol) were then added successively to the filtrate, which was precooled down to 0°C. After allowing the mixture to stir overnight, water was added, and the solution extracted several times with ether. The combined organic phases were dried ($MgSO_4$) and concentrated to give a crude sample as an oil, which was purified through flash column chromatography (ethyl acetate – hexanes, 1:1) to give the title compound **9** (0.28 g, 80%) as a white crystalline solid, mp 118–120°C; $[\alpha]_D$ −33.2 (*c* 1, $CHCl_3$); IR ν_{max} (film): 3300 (NHBoc + NHCbz), 1780 (γ-lactone), 1720 (carbamate) cm^{-1}; ^1H NMR (60 MHz); δ: 1.47 (9H, s, *tert*-butoxy), 3.8–4.35 (3H, m, H-2, H-3 and H-4a), 4.70–4.74 (1H, m, H-4b), 5.03 (2H, s, CH_2Ph), 5.28 (1H, m, NH), 6.3 (1H, m, NH), 7.3–7.45 (5H, Ph); MS, *m/z*: 351 (10%, MH^+).

(2S,3S)-3-Benzyloxycarbonylamino-2-phenylselenyl-1,4-butyrolactone (10)

A solution of the lactone **1** (1.0 g, 4.25 mmol) in 10 mL THF was added dropwise to a solution of LiHMDS (9.00 mmol) in 25 mL THF at −78°C under an argon atmosphere with stirring. After 1 h at that temperature, trimethylsilyl chloride (1.8 mL, 14.18 mmol) was added, and the resulting mixture was stirred at 0°C for 2 h. It was then recooled down to −78°C, followed by addition of *N*-(phenylseleno)phthalimide (1.28 g, 4.24 mmol) in THF (15 mL) at −78°C through a canal. After 30 min stirring at −78°C, the mixture was poured into a mixed solution of 200 mL 5% aqueous HCl, 100 mL ether, and 100 mL pentane. The organic phase was separated and washed successively with water, 10% aqueous $NaHCO_3$, and brine and dried over sodium sulfate. Concentration and flash column chromatography (ethyl acetate – hexanes 3:7) afforded the title compound as an off-white solid (1.22 g, 74%). IR ν_{max} (film): 1780 (lactone), 1710 (carbamate) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 3.83 (1H, d, *J* = 4 Hz, H-2), 4.10 (1H, dd, J_{gem} = 10 Hz and $J_{4,3}$ = 3 Hz, H-4), 4.25 (1H, dd, J_{gem} = 10 Hz and $J_{4,3}$ = 4 Hz, H-4), 4.35 (1H, m, H-3), 5.10 (2H, s, CH_2Ph), 5.60 (1H, bd, NH), 7.50–7.25 (8H, m, Ph and SePh), 7.70 (2H, m, SePh); MS (EI), *m/z*: 391 (M), 300 (M − Bn), 284 (M − BnO); HRMS calcd. for $C_{18}H_{17}NO_4Se$: 391.0322; found: 391.0348.

(2S,3S)-2-C-Allyl-3-benzyloxycarbonylamino-1,4-butyrolactone (11)

A solution of **10** (320 mg, 0.82 mmol), allyl tributyltin (0.31 mL, 0.99 mmol), and AIBN (15 mg, 0.0914 mmol) in benzene (3.7 mL) was degassed and brought to reflux under an argon atmosphere for 16 h. The volume of the mixture was reduced and the residue was purified through flash column chromatography (ethyl acetate – hexanes 0:1–3:7) to yield the title compound as a colorless thick oil (125 mg, 55%); $[\alpha]_D$ −34 (*c* 1.0, $CHCl_3$); IR ν_{max} (film): 1780 (lactone), 1720 (carbamate) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 2.70–2.35 (3H, m, H-2, CH_2 CH=CH_2), 4.01 (1H, dd, J_{gem} = 8 Hz and $J_{4,3}$ = 7 Hz, H-4), 4.28 (1H, m, H-3), 4.52 (1 H, dd, J_{gem} = 8 Hz and $J_{4,3}$ = 7 Hz, H-4), 4.98 (1H, bs, NH), 5.11 (2H, s, CH_2Ph), 5.15 (1H, bd, *J* = 11.5 Hz, CH=CH_2-*cis*), 5.20 (1H, bd, *J* = 18 Hz, CH=CH_2-*anti*), 5.90–5.70 (1H, m, *CH*=CH_2), 7.43–7.31 (5H, m, Ph); MS (EI), *m/z*: 275 (M), 184 (M − Bn), 167 (M − HOBn), 140 (M − O=C − OBn); HRMS calcd. for $C_{15}H_{17}NO_4$: 275.1157; found: 275.1174.

(3S)-2-C-Allyl-3-benzyloxycarbonylamino-2-phenylselenyl-1,4-butyrolactone (12)

A solution of compound **10** (208 mg, 0.53 mmol) in 3 mL THF was added dropwise to a solution of LiHMDS (1.20 mmol) in 3 mL THF at −78°C under an argon atmosphere. After being stirred at −78°C for 30 min, HMPA (2 mL) was then added, followed by addition of allyl bromide (0.23 mL, 2.66 mmol). The resulting mixture was allowed to stir at −78°C for 2 h, and then treated with 10% aqueous HCl. The mixture was extracted with ether several times and the combined organic phases were washed successively with water, $NaHCO_3$, and brine and dried over $MgSO_4$. The solvent was removed to give a crude sample, which was purified by flash column chromatography (ethyl acetate – hexanes 3:7) to furnish the title compound as a colorless viscous oil (160 mg, 70%). IR ν_{max} (film): 1770 (lactone), 1725 (carbamate) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 2.70–2.50 (2H, m, CH_2CH=CH_2), 4.15–4.05 (1H, m, H-4), 4.70–4.50 (2H, m, H-3, H-4), 5.11 (2H, s, CH_2Ph), 5.23–5.15 (2H, m, CH=CH_2), 5.28 (1H, b, NH), 6.00–5.85 (1H, m, *CH*=CH_2), 7.50–7.30 (8H, m, Ph and SePh), 7.65 (2H, m, SePh); MS, *m/z*: 431 (M); HRMS, calcd. for $C_{21}H_{21}NO_4Se$: 431.0635; found: 431.0700.

(3S)-2,2-Di-C-Allyl-3-benzyloxycarbonylamino-1,4-butyrolactone (13)

A solution of **12** (0.35) g, 0.814 mmol), allyl tributyltin (0.38 mL, 1.226 mmol), and a catalytic amount of AIBN in 3 mL benzene was degassed and brought to reflux under an atmosphere of argon for 1.45 h. The solvent was removed and the residue was subjected to flash column chromatography (ethyl acetate – hexanes 0:1–3:7) to give the title compound as a colorless thick oil (0.217 g, 84%); $[\alpha]_D$ +23 (*c* 2.1, $CHCl_3$). IR ν_{max} (film): 1770 (lactone), 1720 (carbamate) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ:

2.55–2.27 (4H, m, $CH_2CH{=}CH_2$), 3.80 (1H, t, J = 9 Hz, H-4), 4.47 (1H, t, J = 9 Hz, H-4), 4.71 (1H, q, J = 9 Hz, H-3), 5.03 (1H, bd, J = 9 Hz, NH), 5.11 (1H, d, J_{gem} = 12 Hz, *CH*Ph), 5.17 (1H, d, J_{gem} = 12 Hz, *CH*Ph), 5.35–5.18 (4H, m, $CH{=}CH_2$), 5.90–5.70 (2H, m, $CH{=}CH_2$), 7.38 (5H, m, Ph); MS (EI), m/z: 315 (M), 224 (M − Bn); HRMS, calcd. for $C_{18}H_{21}NO_4$: 315.1471; found: 315.1475.

Metal pyrazolate polymers. Part 4. Synthesis, characterization, and magnetic properties of $[Co(pz^*)_2]_x$ complexes (where pz* = pyrazolate, 3-methylpyrazolate, and 4-substituted 3,5-dimethylpyrazolate)

MARTIN K. EHLERT, ALAN STORR,[1] AND ROBERT C. THOMPSON[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC V6T 1Z1, Canada

Received February 8, 1993

MARTIN K. EHLERT, ALAN STORR, and ROBERT C. THOMPSON. Can. J. Chem. **71**, 1412 (1993).

The title compounds were prepared and characterized by X-ray powder diffraction, scanning electron microscopy, vibrational and electronic spectroscopy, and magnetic susceptibility measurements. Indirect evidence supports polymeric one-dimensional chain structures involving double pyrazolate bridges linking pseudo-tetrahedrally coordinated metal centres in all six compounds. The spectroscopic studies indicate a greater degree of distortion of the CoN_4 chromophore from regular stereochemistry in the 4-substituted 3,5-dimethylpyrazolate complexes. The magnetic studies reveal anisotropy in the susceptibilities and the presence of significant antiferromagnetic exchange. Magnetic modelling employing both Ising and Heisenberg models suggests the exchange behaviour is probably of the Heisenberg type with zero-field splitting effects producing Ising-like exchange at low temperatures. The derived J values (~ -2 to -6 cm^{-1}) have been used to qualitatively rank the magnitude of exchange as follows: 4-Hpz ≈ 3-Mepz ≫ 4-Medmpz ≈ 4-Cldmpz ≈ 4-Brdmpz ≈ 4-Hdmpz.

MARTIN K. EHLERT, ALAN STORR et ROBERT C. THOMPSON. Can. J. Chem. **71**, 1412 (1993).

On a préparé les composés mentionnés dans le titre et on les a caractérisé par diffraction des rayons X par des poudres, microscopie électronique à balayage, spectroscopies vibrationnelle et électronique et par mesures de susceptibilité magnétique. Des données indirectes sont en accord avec des structures de chaines polymériques unidimensionnelles impliquant dans les six composés des ponts pyrazolates doubles reliant des centres métalliques à coordination pseudo-tétraédrique. Les études spectroscopiques indiquent que, par rapport à sa stéréochimie habituelle dans les complexes de 3,5-diméthylpyrazolates substitués, le chromophore CoN_4 est plus déformé. Les études magnétiques révèlent l'existence d'une anisotropie dans les susceptibilités et la présence d'échanges antiferromagnétiques importants. Le modelage magnétique réalisé à l'aide de modèles de Ising et de Heisenberg suggère que le comportement d'échange est probablement du type Heisenberg avec des effets de couplage de champ zéro produisant un échange de type Ising à basses températures. On a utilisé les valeurs de J (de ~ -2 à -6 cm^{-1}) qui en découlent pour établir que l'amplitude de l'échange diminue dans l'ordre suivant : 4-Hpz ≈ 3Mepz ≫ 4-Medmpz ≈ 4-Cldmpz ≈ 4-Brdmpz ≈ 4-Hdmpz.

[Traduit par la rédaction]

Introduction

Previous papers in this series described the results of investigations of copper(II)-based pyrazolate polymers, compounds in which the metal ions are linked by double pyrazolate bridges to form extended chain structures (1–3). These materials exhibit intrachain antiferromagnetic coupling between the d^9 metal centres, the magnitude of which has been discussed in terms of differences in structural detail between different compounds. Further information about the structures adopted by binary metal pyrazolates and, in particular, about the nature of pyrazolate ligand-mediated magnetic exchange requires the study of systems with other d-electron configurations. In this paper we report on the synthesis, characterization, and magnetic properties of a series of Co(II) complexes incorporating the pyrazolate anion and several of its C-substituted derivatives. These compounds possess the general formula $[Co(pz^*)_2]_x$ (where pz* = pyrazolate (4-Hpz), 3-methylpyrazolate (3-Mepz), 3,5-dimethylpyrazolate (4-Hdmpz), 3,4,5-trimethylpyrazolate (4-Medmpz), 4-chloro-3,5-dimethylpyrazolate (4-Cldmpz), and 4-bromo-3,5-dimethylpyrazolate (4-Brdmpz)).

Cobalt pyrazolates have formed the basis of a few studies in the past. In the early part of this century, Fischer (4) and Heim (5) noted that insoluble solids could be precipitated from cobalt-containing aqueous solutions of pyrazole in the presence of base. Interest in 3,5-dimethylpyrazole as a reagent for the gravimetric determination of cobalt was more thoroughly pursued in the late 1950's by Pflaum and Dieter (6) who determined that the blue-violet precipitate formed from Co(II) salts and 3,5-dimethylpyrazole in basic aqueous solution had the formulation $[Co(4\text{-}Hdmpz)_2]_x$. In 1970, Bagley, Nicholls, and Warburton published a study of pyrazole, and of pyrazolate complexes of Co(II) (7). Pyrazole, 3-methylpyrazole, and 3,5-dimethylpyrazole were employed in the preparation of compounds. Infrared and electronic spectroscopic studies were conducted on the compounds and room temperature magnetic moments were measured from which the authors suggested that the compounds possess polymeric structures in which the (substituted)pyrazolate ions act as bridging ligands and the Co(II) ions are tetrahedrally coordinated. In 1973, Singh, Satpathy, and Sahoo reported the synthesis of $[Co(4\text{-}Hdmpz)_2]_x$ by condensation of $[Co(acac)_2]_4$ with hydrazine (8). Their characterization of the compound included the only variable temperature magnetic susceptibility measurements (90–300 K) of a cobalt pyrazolate system prior to the present study. In the late 1970's, Vos and Groeneveld prepared a number of 4-substituted pyrazolates of cobalt (9–11); however, it is not clear whether pure samples of these compounds were actually obtained in the work because analytical results deviated significantly from the expected values.

In spite of numerous attempts in the course of the present work, none of the binary cobalt(II) pyrazolates could be isolated in crystalline form suitable for single crystal X-ray diffraction studies. Hence it was necessary to employ a va-

TABLE 1. Preparation conditions and analytical results

$[Co(3\text{-}Mepz)_2]_x$:

Co powder (0.8 g, 14 mmol), 3-MepzH (6 g, 75 mmol)
100°C, 18 h
CH_2Cl_2 extraction, product yield ~3 g
Anal. calcd. for $C_8H_{10}CoN_4$: C 43.5, H 4.6, N 25.3
found: C 44.1, H 4.7, N 25.3

$[Co(4\text{-}Hdmpz)_2]_x$:

Co powder (2.32 g, 39.4 mmol), 4-HdmpzH (6.00 g, 62.4 mmol)
115°C, 6 days
THF extraction, product yield 0.851 g
Anal. calcd. for $C_{10}H_{14}CoN_4$: C 48.2, H 5.7, N 22.5
found: C 48.0, H 5.6, N 22.3

$[Co(4\text{-}Medmpz)_2]_x$:

Co powder (2.00 g, 33.9 mmol), 4-MedmpzH (5.51 g, 50.0 mmol)
128°C, 24 h
THF extraction, product yield 4.00 g
Anal. calcd. for $C_{12}H_{18}CoN_4$: C 52.0, H 6.5, N 20.2
found: C 52.2, H 6.5, N 20.4

$[Co(4\text{-}Cldmpz)_2]_x$:

Co massive (4.623 g, 78.44 mmol), 4-CldmpzH (2.7 g, 21 mmol)
130°C, 48 h
THF extraction, product yield 0.180 g (57% yield)
Anal. calcd. for $C_{10}H_{12}Cl_2CoN_4$: C 37.8, H 3.8, N 17.6
found: C 37.5, H 3.8, N 17.4

$[Co(4\text{-}Brdmpz)_2]_x$:

Co massive (4.566 g, 77.48 mmol), 4-BrdmpzH (6.79 g, 38.8 mmol)
130°C, 40 h
THF extraction, product yield 0.312 g (81% yield)
Anal. calcd. for $C_{10}H_{12}Br_2CoN_4$: C 29.5, H 3.0, N 13.8
found: C 29.8, H 3.0, N 14.0

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12

riety of indirect methods to obtain structural information on these materials.

Experimental

Syntheses

Pyrazole (4-HpzH), 3-methylpyrazole (3-MepzH), and 3,5-dimethylpyrazole (4-HdmpzH) were purchased from Aldrich and used without further purification. 4-Chloro-3,5-dimethylpyrazole (4-CldmpzH), 4-bromo-3,5-dimethylpyrazole (4-BrdmpzH), and 3,4,5-trimethylpyrazole (4-MedmpzH) were prepared as described previously (3).

$[Co(4\text{-}Hpz)_2]_x$

All solvents employed in this synthesis were degassed and all manipulations were performed under dinitrogen atmosphere. $CoCl_2 \cdot xH_2O$ (3.31 g, <14 mmol) and pyrazole (6.08 g, 89.3 mmol) were dissolved in 80 mL of water. NaOH (1.60 g, 40.0 mmol) was dissolved in 40 mL of water. The NaOH solution was added dropwise to the vigorously stirred $CoCl_2$–pyrazole solution at room temperature. The reaction mixture was suction filtered and the product was washed sequentially with water, ethanol, and, finally, petroleum ether. This afforded a purple filtercake, which was dried under vacuum for 1.5 h at room temperature. This yielded ~2 g of $[Co(4\text{-}Hpz)_2]_x$ as a fine purple powder. Anal. calcd. for $C_6H_6CoN_4$: C 37.3, H 3.1, N 29.0; found: C 37.5, H 3.2, N 29.3.

$[Co(3\text{-}Mepz)_2]_x$ and $[Co(4\text{-}Xdmpz)_2]_x$ (X = H, Me, Cl, and Br)

The remaining five binary Co(II) (substituted)pyrazolates were all synthesized in essentially the same manner. Cobalt metal (either powdered or massive) was combined with the appropriate molten substituted pyrazole and the mixture was heated with stirring in a dioxygen atmosphere. This resulted in formation of the product as a fine purple powder admixed with excess cobalt and substituted pyrazole. The pyrazole was removed by washing with polar solvent. If the excess cobalt metal was in powdered form it was removed by dredging a slurry of the reaction mixture in a solvent with a magnet until all of the cobalt metal was removed, and if the cobalt was present in massive form it was removed manually. In all cases the Co(II) pyrazolates were obtained as purple powders. Specific reaction conditions and analytical results are presented in Table 1.

Physical characterization

Infrared spectra (4000–250 cm^{-1}) were recorded using a Perkin–Elmer model 598 spectrometer and calibrated against polystyrene film. Samples were mulled in Nujol and sandwiched between KBr plates or KRS-5 plates (Harshaw Chemical Co.). Infrared frequencies have been deposited.[2] Electronic spectra (200–2500 nm) were recorded using a Cary 5 spectrometer. Samples were mulled in Nujol and sandwiched between quartz plates.

Powder X-ray diffractograms were recorded using either an automated Rigaku Rotaflex RU-200BH rotating anode powder X-ray diffractometer (Ni filtered or graphite monochromated, Cu $K\alpha$ radiation) or a Philips powder X-ray diffractometer equipped with a

Philips PW 1830 generator (Mn filtered, Fe $K\alpha$ radiation). Samples were prepared by applying a thin film of compound slurried in octane to a glass slide and allowing the slurry to dry. In such cases the sample packing force is perpendicular to the glass sample support (cf. Results and discussion). For a preferred orientation study conducted on $[Co(4\text{-}Medmpz)_2]_x$, a sample packed with the force directed parallel to the sample support was prepared using a glass slide with a U-shaped brass ridge glued to the surface. A second glass plate was held firmly on top of this ridge, creating a thin cavity running parallel to the glass support surface. This cavity was then filled with sample powder by packing from the open end. The top plate was then removed to reveal the suitably prepared sample.

Differential scanning calorimetry (DSC) measurements were obtained with a Mettler DSC 20 standard cell and TC10 TA processor.

Scanning electron micrographs (SEM) of samples were recorded with a Hitachi S-570 scanning electron microscope. Samples were prepared by applying a thin suspension of a given compound in petroleum ether to an aluminum stub, allowing the suspension to dry, and then sputter-coating the stub and sample with a thin layer of a gold–palladium alloy.

Magnetic measurements were performed using either a Princeton Applied Research vibrating sample magnetometer (VSM) described previously (12), or a Quantum Design MPMS SQUID magnetometer. Studies conducted with the SQUID magnetometer employed pressed pellet samples held inside a gelatin capsule suspended in a quartz tube. Variable temperature magnetic susceptibility data using this instrument were recorded in the temperature range 2–300 K in an applied field of 10 kOe. Magnetic data for the compounds were corrected for the diamagnetism of the sample and the sample holder. The following corrections were applied (all values $\times 10^{-6}$ cm^3 mol^{-1}): Co(II), −12; 4-Hpz, −38; 3-Mepz, −50; 4-Hdmpz, −62; 4-Medmpz, −74; 4-Cldmpz, −79; and 4-Brdmpz, −90. Corrections for the temperature-independent paramagnetism of the Co(II) ion were also applied using the formula, $\chi_{TIP} = 8N\mu_B{}^2/10Dq$, with the Dq (ligand field parameter) values (see below) estimated from the electronic spectra of the complexes. Field dependence studies were performed with the same instrument in the field range 0–55 kOe.

Elemental analyses were performed by Mr. P. Borda of this department.

Results and discussion

Synthesis and thermal properties

Reaction of cobalt metal with molten C-substituted pyrazoles in the presence of dioxygen has permitted the synthesis of five Co(II) substituted pyrazolates. Because $[Co(4\text{-}Hpz)_2]_x$ slowly oxidizes in air when exposed to moisture, the molten ligand precursor – metal reaction described above could not be used to synthesize this compound. Instead, a metathetical reaction employing $CoCl_2$, 4-HpzH, and NaOH under anaerobic conditions was used (9). The Co(II) (substituted)pyrazolates are insoluble, infusible, involatile solids; all six compounds considered here were obtained as fine purple powders and, with the exception of $[Co(4\text{-}Hpz)_2]_x$, they are air-stable. The Co(II) (substituted)pyrazolates are thermally robust. In the case of $[Co(3\text{-}Mepz)_2]_x$, DSC studies demonstrated that the complex undergoes an endothermic event at 405°C with concomitant decomposition. Qualitative observation of the other Co(II) compounds using a melting point apparatus revealed that the compounds can be heated to temperatures >360°C without decomposing.

Scanning electron microscopy and X-ray powder diffraction

The particle morphologies of these compounds were examined by SEM, and images of the $[Co(4\text{-}Hpz)_2]_x$, $[Co(3\text{-}Mepz)_2]_x$, $[Co(4\text{-}Hdmpz)_2]_x$, and $[Co(4\text{-}Medmpz)_2]_x$ complexes are presented in Figs. 1(*a*)–(*d*). The 4-Hpz, 4-Hdmpz, and 4-Medmpz derivatives possess elongated, crystallite morphologies, whereas the 3-Mepz derivative consists of particles that are quasi-spherical agglomerations of microcrystallites. In the case of $[Co(4\text{-}Hdmpz)_2]_x$ the particles are extremely small, with dimensions in the submicron regime. These morphologies become important in the discussion of the magnetic properties of these complexes.

Although attempts were made, no X-ray diffraction quality single crystals of the cobalt(II) pyrazolates were prepared; however, some powder diffraction studies were undertaken. Initial studies were made using a diffractometer equipped with a copper anode in the X-ray generator. The X-ray absorption edge of cobalt is coincident with the Cu $K\alpha$ X-radiation generated by the instrument and, because of this, the cobalt in these compounds undergoes X-ray fluorescence (13) and high-intensity, noisy backgrounds result in the recorded diffractograms. Because of the poor quality of the diffractograms and the possibility that the high background contribution might be masking an amorphous component of the materials, diffractograms were also recorded using an apparatus equipped with an iron anode X-ray generator. Diffractograms for the alkylated Co(II) pyrazolates were recorded using this instrument (there were insufficient amounts of the halogenated Co(II) pyrazolates to conduct such studies) and showed these materials to be highly crystalline. The *d*-spacings and relative intensities of the diffraction lines for these compounds have been deposited.[2] Furthermore, comparison of the diffractogram of $[Co(4\text{-}Hdmpz)_2]_x$ with that of $[Zn(4\text{-}Hdmpz)_2]_x$ (14) reveals the two complexes to be isomorphous.

Compounds with elongated crystallite morphologies (as seen in the SEM images described above) tend to have their crystallites oriented such that the longitudinal axes of the particles are arrayed perpendicular to the direction of the original packing force (in this case, gravity). Advantage was taken of the geometry of the iron anode X-ray diffractometer to see if this preferred orientation of microcrystallites occurs in the bulk compounds. Two samples of $[Co(4\text{-}Medmpz)_2]_x$ were prepared such that the packing force used in preparation was in one case perpendicular to the sample support (a glass slide) and in the other case parallel to the support. The first indication of preferred orientation comes from the relative intensity of the most intense line at the *d*-spacing 9.982 Å. In the perpendicular packed sample the most intense line is relatively more intense compared to the lesser lines than it is in the parallel packed sample. There are other observations that further demonstrate the presence of preferred orientation in this material. Comparison between the two diffractograms of the pairs of diffraction lines at *d*-spacings 7.451 and 7.061 Å, 4.610 and 4.460 Å, and 3.378 and 3.338 Å shows that their relative intensities are reversed, hence preferred orientation of the crystallites is present in this compound. Studies of magnetic properties conducted on the Co(II) (substituted)pyrazolates, which are discussed below, revealed orientation effects. The results of these X-ray diffraction experiments are important because, at least in the case of $[Co(4\text{-}Medmpz)_2]_x$, they provide independent experimental verification of the presence of preferred particle orientation.

Electronic spectra

The electronic spectra of the cobalt(II) (substituted)-pyrazolates are shown in Figs. 2(*a*) and (*b*). It is apparent

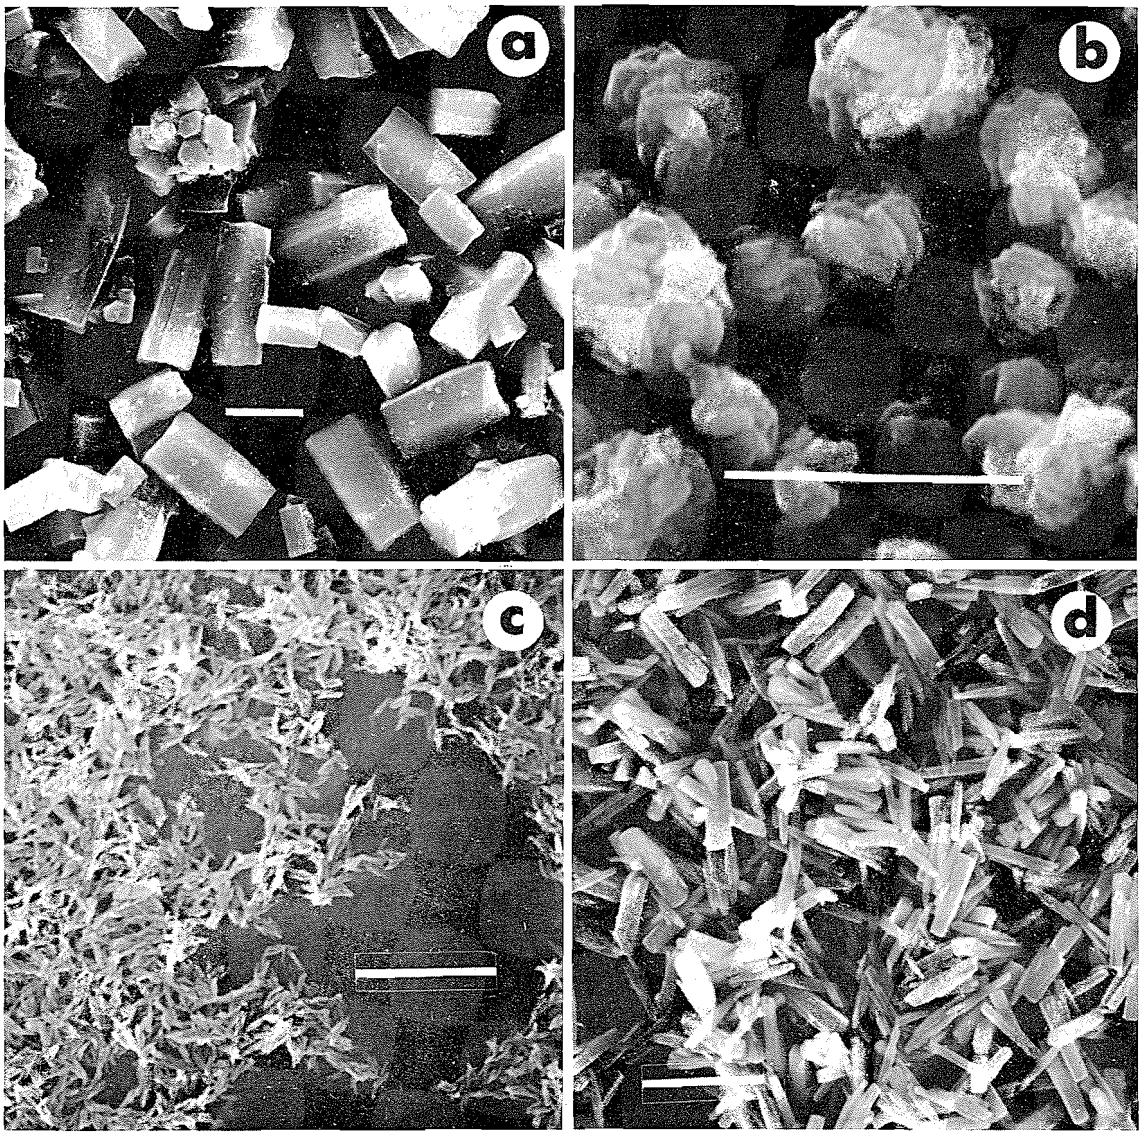

FIG. 1. SEM images of (*a*) $[Co(4\text{-}Hpz)_2]_x$, (*b*) $[Co(3\text{-}Mepz)_2]_x$, (*c*) $[Co(4\text{-}Hdmpz)_2]_x$, and (*d*) $[Co(4\text{-}Medmpz)_2]_x$. The white bar in each image represents a length of 5 μm.

from these figures that the compounds can be divided into two groups, the 3,5-dimethyl derivatives forming one group, and $[Co(4\text{-}Hpz)_2]_x$ and $[Co(3\text{-}Mepz)_2]_x$ forming the other group. With regard to possible chromophore geometries, the structured band at ~550 nm (ν_3) in these compounds is too low in energy for an octahedral complex with aromatic, nitrogen donor ligands (15); the complexes are more likely to possess four-coordinate Co(II) ions. The spectra do not have the general appearance of the spectra of square-planar Co(II) species (16) and the intense colour of the cobalt(II) (substituted)pyrazolates suggests a non-centrosymmetric chromophore. In addition, the spectra for both groups are similar in general appearance to the spectra of some oligometallic Co(II) 3,5-dimethylpyrazolate complexes, which have been shown by single crystal X-ray diffraction to contain pseudo-tetrahedral cobalt centres (17). Therefore, it is concluded that the $[Co(pz^*)_2]_x$ complexes studied here possess (pseudo-)tetrahedral CoN_4 chromophores. Band positions and relative intensities for the compounds have been tabulated in Table 2.

Using visually estimated band centres for ν_2 and ν_3 and the tetrahedral formalism, Dq and B values were estimated (18) to be 485 ± 20 and 770 ± 40 cm^{-1}, respectively, for the 3,5-dimethyl derivatives and 545 ± 20 and 690 ± 40 cm^{-1}, respectively, for the other two complexes. These Dq and B values are similar to those found for a number of $[Co(py^*)_4]^{2+}$ cations (py* = pyridine, 4-methylpyridine, and 3-methylpyridine) (19–21). The smaller values of Dq and larger values of B observed for the 3,5-dimethyl derivatives are consistent with weaker metal–ligand interactions in this group of compounds. Based on absorption band widths and fine-structure resolution, we propose that the 3,5-dimethyl derivatives possess CoN_4 chromophores that are more distorted from regular tetrahedral geometry than are the CoN_4 chromophores of $[Co(4\text{-}Hpz)_2]_x$ and $[Co(3\text{-}Mepz)_2]_x$. It is this basic difference in chromophore geometry which likely contributes most to the differences in the electronic spectra (and hence calculated "tetrahedral" ligand field parameters) between these two groups of compounds.

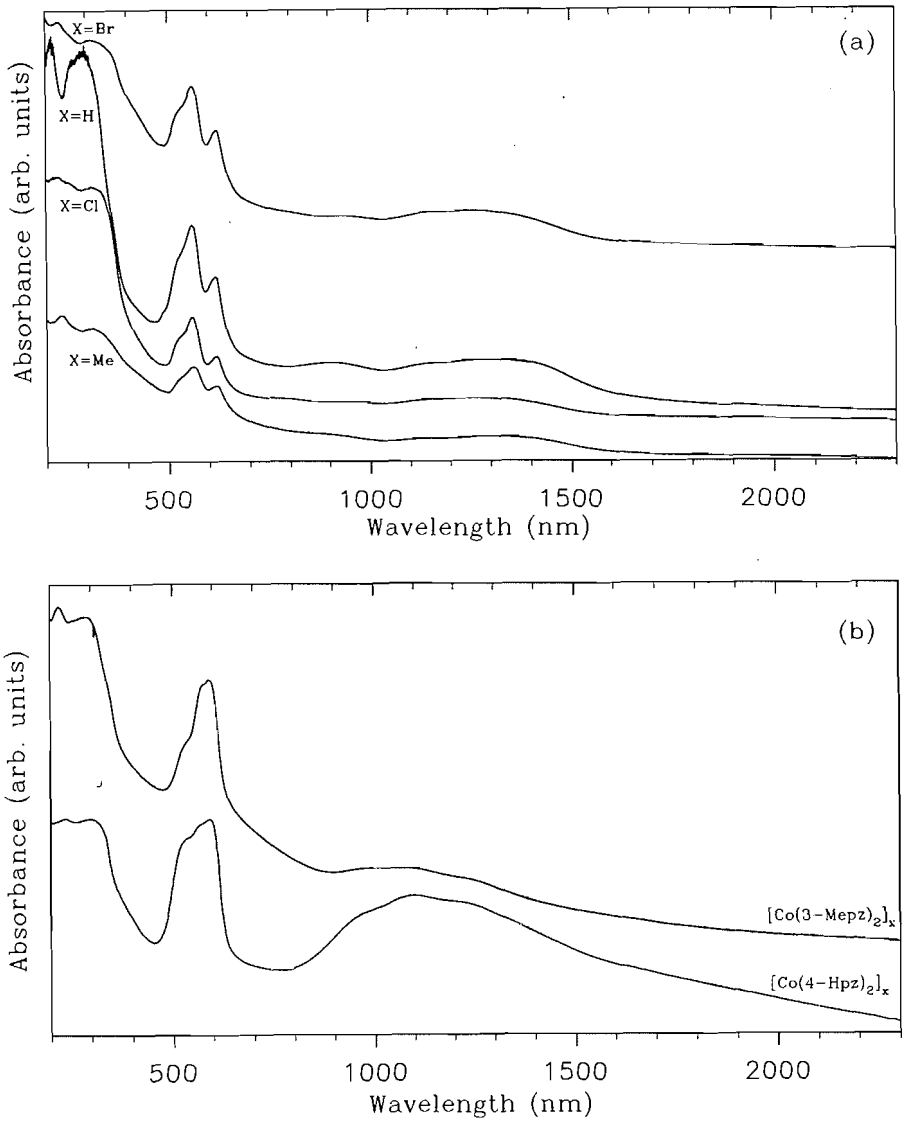

FIG. 2. Electronic spectra of the Co(II) (substituted)pyrazolates: (*a*) the 4-Xdmpz derivatives and (*b*) $[Co(4\text{-}Hpz)_2]_x$ and $[Co(3\text{-}Mepz)_2]_x$.

Infrared spectra

Infrared spectra for the compounds considered here were recorded mainly as "fingerprints" and as preliminary checks of product purity. In the case of $[Co(4\text{-}Hpz)_2]_x$, comparison of its infrared spectrum with those of $[Cu(4\text{-}Hpz)_2]_x$ (1), $[Ni(4\text{-}Hpz)_2]_x$ (22), and Na[4-Hpz] (22) provides some additional support for the proposed stereochemistry of the CoN_4 chromophore. The $[M(4\text{-}Hpz)_2]_x$ (M = Co, Ni, Cu) complexes each show two strong bands in the 250–600 cm^{-1} region. It is suggested that the bands observed for the $[M(4\text{-}Hpz)_2]_x$ compounds in this region are due principally to M–N vibrations since Na[4-Hpz] shows no absorptions in this region. For $[Co(4\text{-}Hpz)_2]_x$ and $[Cu(4\text{-}Hpz)_2]_x$, these bands occur at similar positions (334 and 322 cm^{-1} in the Co(II) species and 362 and 342 cm^{-1} in the Cu(II) species) with the same relative intensities (the higher energy band in each pair being of lower intensity). On the other hand, the M–N bands in $[Ni(4\text{-}Hpz)_2]_x$ occur at substantially higher energies (459 and 414 cm^{-1}) and their relative intensities are reversed compared to the above. This difference suggests that the coordination environment in the nickel complex is quite different from the environments of the other two. The electronic spectrum and magnetic properties of the nickel(II) complex are consistent with a square-planar coordination geometry (22), this suggesting that $[Co(4\text{-}Hpz)_2]_x$ possesses a chromophore similar to that of $[Cu(4\text{-}Hpz)_2]_x$ (1): a pseudo- or more regular tetrahedral stereochemistry (supported also by the electronic spectrum as described above).

Structural considerations

Since diffraction-quality single crystals of the Co(II) (substituted)pyrazolates could not be prepared, a discussion of their magnetic properties is preceded by a consideration of their probable structures. Their thermal and solubility properties are consistent with polymeric structures. The empirical formulae of the compounds could be satisfied if their structures consisted of chains of Co(II) ions doubly bridged by (substituted)pyrazolate ligands as confirmed in the $[Cu(4\text{-}Xpz)_2]_x$ compounds (1, 2) and proposed for the $[Cu(4\text{-}Xdmpz)_2]_x$ species (3). The electronic spectra of the Co(II) complexes indicate that they possess (pseudo-)tetrahedral CoN_4 chromophores and, furthermore, that the 4-X-3,5-dimethylpyrazolate compounds have geometries quite

distorted from the ideal tetrahedral stereochemistry. Such chromophores preclude the formation of oligometallic species analogous to the one proposed by Blake et al. for Ni(II) pyrazolates (23). There are other indirect pieces of evidence that suggest that the Co(II) compounds considered here consist of chains of (pseudo-)tetrahedrally coordinated metal ions. The structures of the dimetallic and trimetallic Co(II) 3,5-dimethylpyrazolates (described above), which contain pseudo-tetrahedrally coordinated cobalt ions, may easily be envisaged as being small segments of an extended linear chain (17). Finally, $[Zn(4\text{-}Hdmpz)_2]_x$ most certainly consists of chains of tetrahedrally coordinated Zn(II) ions as this ion contains a spherically symmetric, filled, 3*d* electronic shell and the polymer is derived from the dimeric species in which the Zn(II) ions are tetrahedrally coordinated (13). The cobalt analogues of these zinc compounds are isomorphous with the latter (14, 17) and this lends further credence to the proposed structures for the binary cobalt pyrazolates. Thus, a picture emerges of the general structure of these compounds and it is illustrated in Fig. 3.

Earlier it was noted that the electronic spectra indicate the 4-X-3,5-dimethylpyrazolates of cobalt(II) possess more distorted tetrahedral geometries than $[Co(4\text{-}Hpz)_2]_x$ or $[Co(3\text{-}Mepz)_2]_x$. The structure proposed in Fig. 3 may account for this experimental observation. When the R groups on each pyrazolate ring in the figure are both hydrogen atoms ($4\text{-}Hpz^-$) or if only one R group per ring is a methyl group ($3\text{-}Mepz^-$), molecular models indicate that there is negligible steric interaction between one pyrazolate ring and its adjacent, translational, equivalent. In these two cases there is no obvious intra-chain, inter-ligand effect to cause distortion of the chromophores away from the ideal T_d symmetry in which the angle, α (Fig. 3), would be 109.47° and the dihedral angle between fused $Co(N—N)_2Co$ rings would be 90°. However, if the CoN_4 chromophores are strictly tetrahedral and both R groups on each pyrazolate ring are methyl substituents, then there would be a substantial repulsive steric interaction between adjacent, translationally equivalent, pyrazolate ligands. The structure could minimize this repulsion by lengthening the Co—N bonds and (or) undergoing an S_4 elongation of the chromophore along the chain axis. The latter process would entail a compression of α to a value less than the tetrahedral angle and, as bond angle deformations are generally lower energy processes than bond length changes, the α-angle compression is likely to account for most of the deformation described above. The proposed large chromophore distortion in the 4-X-3,5-dimethylpyrazolates relative to the pyrazolate and 3-methylpyrazolate species is also supported by the magnetic properties of these compounds, which are considered below.

Magnetic properties

Magnetic susceptibility studies on random oriented powders (see below) show $[Co(4\text{-}Hpz)_2]_x$, $[Co(3\text{-}Mepz)_2]_x$, $[Co(4\text{-}Hdmpz)_2]_x$, and $[Co(4\text{-}Medmpz)_2]_x$ to exhibit susceptibility maxima at 38, 25, 11, 15 K, respectively. The halogenated dimethyl cobalt(II) derivatives show incipient maxima at ~10 K. These findings indicate the presence of antiferromagnetic coupling in all of the compounds. The susceptibility data for $[Co(4\text{-}Hdmpz)_2]_x$ are in excellent agreement with those reported by Singh et al. (8). At the lowest temperatures studied, the magnetic susceptibilities of all six compounds rise with decreasing temperature. This phenomenon is commonly observed in antiferromagnetically coupled systems and has been ascribed to small amounts of structural paramagnetic impurity (3). In addition, magnetization studies over a range of fields (0–55 kOe) revealed that two of the compounds, $[Co(3\text{-}Mepz)_2]_x$ and $[Co(4\text{-}Medmpz)_2]_x$, contained traces of ferromagnetic impurity (estimated <0.1% metallic cobalt). As the susceptibility measurements were made in an applied field above the saturation field for metallic cobalt, the presence of this impurity made a temperature-independent contribution to the susceptibility data for these compounds and the data have been corrected for this (22).

During initial magnetic studies of these compounds, discrepancies were observed between the data collected using the VSM and SQUID magnetometers. Both instruments subject the samples to homogeneous applied fields, but the orientations of the fields with respect to the way in which the samples are packed into their holders are orthogonal; in the VSM instrument the applied field is perpendicular to the sample packing force direction and in the SQUID magnetometer the field is parallel to that direction. Co(II) complexes often exhibit considerably anisotropic magnetic properties. The elongated crystallite morphologies observed in the SEM images of $[Co(4\text{-}Hpz)_2]_x$, $[Co(4\text{-}Hdmpz)_2]_x$, and $[Co(4\text{-}Medmpz)_2]_x$ and the preferred orientation observed in the powder X-ray diffraction study of $[Co(4\text{-}Medmpz)_2]_x$ led to the hypothesis that the crystallites in the samples used for magnetic studies were subject to a certain degree of preferred orientation that was partially resolving the anisotropic magnetic properties of these complexes. To test this hypothesis, pellets of the samples were pressed under high pressure in the hope that this would maximize the preferred orientation of the sample particles. Based on the morphologies of the crystallites, the model depicted in Fig. 4 is proposed for the preferred orientation exhibited by these compounds. If one assumes that the polymer chain axes of these complexes run parallel to the long axes of the crystallites, one then recognizes that application of an external field normal to the pellet face depicted in Fig. 4 (referred to as the perpendicular direction) will permit an enhanced sampling of the magnetic properties of these compounds in the plane normal to the chain axis. Application of the external field in the direction parallel to the pellet face (referred to as the random orientation) should actually result in random sampling of crystallite orientations because there is little difference in the crystallite edge lengths perpendicular to the long axis and, of course, there is a random distribution of long-axis orientations within the plane perpendicular to the packing-force direction.

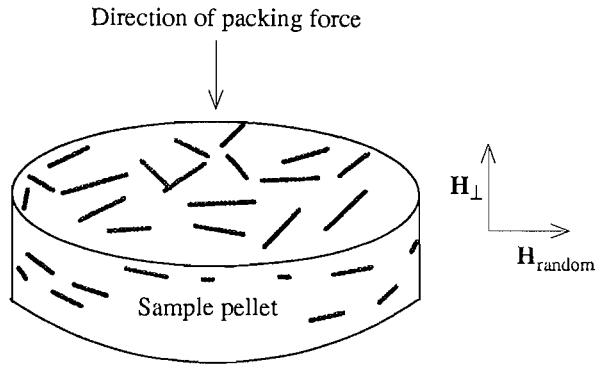

FIG. 4. Diagram showing the preferred orientation of crystallites in samples used for magnetic studies of the Co(II) (substituted)pyrazolates.

Susceptibility versus temperature studies were conducted on all of the compounds in the two orientations depicted in Fig. 4 and the results are shown in Fig. 5. The SQUID magnetometer was used for both orientations for five of the compounds; in the case of $[Co(4\text{-}Hpz)_2]_x$, the random orientation values were obtained from the VSM instrument and the perpendicular orientation values were obtained with the SQUID instrument. Magnetic susceptibility and effective magnetic moment versus temperature data for the compounds are tabulated and have been deposited.[2] The 4-X-3,5-dimethylpyrazolates show essentially no difference between the random and perpendicular orientation susceptibilities from room temperature down to approximately 30 K; however, below this temperature the susceptibilities of the two orientations begin to diverge, with the perpendicular orientation values larger than the random orientation values in all four cases. In the case of $[Co(3\text{-}Mepz)_2]_x$ (Fig.

For personal use only.

5(*f*)), there is little difference between the measured susceptibilities in the two orientations at the lower temperatures, and the divergence that is observed is the opposite of what was observed in Figs. 5(*a*) through (*d*). The poorer resolution of susceptibilities in the two orientations with this complex may be due either to a smaller anisotropy in its magnetic properties and (or) to the fact that the particles of this material appear to be roughly spherical aggregates of smaller microcrystallites (see Fig. 1(*b*)). As a result, they are not likely to exhibit much preferred orientation. These oriented pellet studies have clearly demonstrated anisotropy in the magnetic properties of four of the cobalt(II) (substituted)pyrazolates considered in this section; however, the studies do not yield quantitative information about the magnitudes of anisotropies.

Finally, we note that the procedures employed in the orientation studies utilizing the SQUID magnetometer required exposing the samples to the atmosphere for up to 1 h. This generally presented no problems since all of the compounds are air-stable except one. $[Co(4\text{-}Hpz)_2]_x$ undergoes slow oxidation in moist air and for this reason we used the VSM instrument for the random orientation study of this sample (Fig. 5(*e*)). The perpendicular orientation study, however, required the use of the SQUID instrument and, while there was no visible evidence of sample decomposition, some partial oxidation to diamagnetic cobalt(III) may have occurred. Having stated this, it is very unlikely that the apparent anisotropy exhibited by this compound is totally due to decomposition because such a degree of decomposition would be visually detected.

Magnetic modelling

Attempts to model the random-orientation susceptibility data for all of the complexes were made using published models that employ the Hamiltonian:

$$[1] \quad \hat{H}_{spin} = -2J \sum_{i \neq j}^{n} (S_i^z S_j^z) + \alpha(S_i^x S_j^x + S_i^y S_j^y)$$

where, when $\alpha = 1$ the Heisenberg model is obtained and when $\alpha = 0$ the Ising model results. The Heisenberg model for antiferromagnetically coupled linear chains of $S = 3/2$ metal centres developed by Hiller et al. (24) based on the numerical calculations of Weng (25) is

$$[2] \quad \chi_{chain} = \frac{Ng^2\mu_B{}^2}{kT}\left[\frac{1.2500 + 17.041x^2}{1 + 6.7360x + 238.47x^3}\right]$$

where $x = |J|/kT$. In our work the Weng equation was combined with a Curie law term,

$$[3] \quad \chi_{para} = \frac{Ng^2\mu_B{}^2 S(S+1)}{3kT}$$

in the following way;

$$[4] \quad \chi_M = [1 - P]\chi_{chain} + P\chi_{para}$$

to account for the presence of paramagnetic impurities in the compounds. Fits to the susceptibility data were achieved using a nonlinear least-squares procedure with the following as the function minimized:

$$[5] \quad F = \left[\frac{1}{n}\sum_{i=1}^{n}\frac{(\chi_i^{obs} - \chi_i^{calc})^2}{(\chi_i^{obs})^2}\right]^{1/2}$$

The F value provides a measure of the goodness of fit between theory and experiment.

The derived best-fit parameters over various temperature ranges are listed in Table 3 and the curves calculated from these fits are shown in Figs. 6(*a*) through (*f*). For $[Co(4\text{-}Hpz)_2]_x$ and $[Co(3\text{-}Mepz)_2]_x$, fits to the data over the full temperature ranges studied reproduce reasonably well the temperatures at which the maxima in the susceptibilities are observed; however, the fits do not adequately model the sharpness of the maxima. For the $[Co(4\text{-}Xdmpz)_2]_x$ complexes, the low-temperature data are modelled poorly as the temperatures at which the calculated susceptibility maxima appear are too high. Modelling of the high-temperature data yields very good fits for all six compounds with only two parameters, J and g, but extrapolation of these fits to low temperatures, as shown in the figures, reveals shortcomings. Modelling of the low-temperature data only reveals that the quality of the fits to the data for $[Co(4\text{-}Hpz)_2]_x$ and $[Co(3\text{-}Mepz)_2]_x$ is poor and, while the fits for the $[Co(4\text{-}Xdmpz)_2]_x$ compounds are excellent, the calculated g values are unrealistically low, suggesting the fits are probably fortuitous. The $S = 3/2$, Heisenberg model accounts for the magnetic behaviour over limited temperature ranges (particularly at higher temperatures), but it does not describe the behaviour of the complexes over the full temperature ranges examined.

Generally, for antiferromagnetic systems, stronger exchange should lead to maxima at higher temperatures and to lower overall susceptibilities. In spite of the fact that the compounds in the present group exhibit susceptibilities of similar overall magnitude, the dimethyl derivatives show maxima at significantly lower temperatures than $[Co(4\text{-}Hpz)_2]_x$ or $[Co(3\text{-}Mepz)_2]_x$. This inconsistency may be due to zero-field splitting (ZFS), which manifests itself in powder susceptibility measurements as a reduction of the observed susceptibility (particularly at lower temperatures). Referring to the proposed structure of the compounds under consideration (Fig. 3), if compression of the α angle is the only significant distortion in these complexes, then an axially symmetric CoN_4 chromophore results and single-ion susceptibilities are influenced by the ZFS parameter, D. A priori, it is difficult to predict the sign of D, but angular overlap model calculations performed on idealized Co(II) chromophores (15) predict that for values of α lower then the tetrahedral angle, D should be negative, in which case $m_s = \pm 3/2$ would be the ground state. Such a ZFS effect would have important consequences for exchange coupling in these systems because at temperatures where $kT < 2D$ the $m_s = \pm 1/2$ state becomes depopulated and the spin vector is essentially restricted to alignment along the principal axis of the CoN_4 chromophore (it is proposed, but not required, that the principal chromophore axis is parallel to the polymer chain axis). In this case, the coupling can occur only through that single component of the spin vector and the single-ion anisotropy will have caused the coupling to appear Ising-like. Conversely, if D is positive, then the $m_s = \pm 1/2$ state becomes the ground state and in an exchange-coupled system, the coupling will appear to be XY-like at temperatures where $kT < 2D$. Thus, attempts to quantify exchange interactions were made employing available anisotropic models.

Smith and Friedberg (26) have developed expressions for modelling susceptibility data that account for axial ZFS and Heisenberg exchange coupling simultaneously provided

[a]Fixed at zero.

$|J| >> |D|$. It is possible to estimate whether this condition is met in the present compounds by considering the modelling results and the oriented pellet studies together. The Heisenberg modelling studies suggest that the $|J|$ values for the complexes lie in the range ~2–6 cm^{-1}. Assuming that the anisotropy exhibited in the oriented pellet studies is due to ZFS effects, a crude estimate of its magnitude may be made. The temperatures at which the susceptibilities of the two orientations begin to diverge (which is a lower limit to the magnitude of the anisotropy) indicate that $|D|$ is of the order of 10 cm^{-1}. Clearly, the condition required to apply the expressions of Smith and Friedberg (26) is not met in these compounds. If $|D|$ is much greater than the lower limit suggested by the oriented pellet studies, then at low temperatures only the lowest Kramers' doublet of the electronic states manifold is populated and the Co(II) ions will behave as $S' = 1/2$ ions. Anisotropically coupled, $S = 1/2$, linear chain models have been studied theoretically. Closed-form expressions have been derived for the magnetic susceptibility (27, 28) and they are presented below:

$$[6a] \quad \chi_{\parallel} = \frac{Ng_{\parallel}^2\mu_B^2}{4kT}\exp(-|J|/kT)$$

$$[6b] \quad \chi_{\perp} = \frac{Ng_{\perp}^2\mu_B^2}{4|J|}\left[\tanh\left(\frac{J}{2kT}\right) + \left(\frac{J}{2kT}\right)\mathrm{sech}^2\left(\frac{J}{2kT}\right)\right]$$

$$[6c] \quad \chi_p = \tfrac{1}{3}\chi_{\parallel} + \tfrac{2}{3}\chi_{\perp}$$

Implicit in the assumption that $S' = 1/2$ models apply to the behaviour of these compounds is the condition that $g_{\parallel}$ and $g_{\perp}$ are anisotropic *effective* components of the true g-tensor for the $S = 3/2$ Co(II) ion. In an axially distorted system, the relationships between the effective, g', components and the true g values are as follows (15): $g'_{\parallel} = 3g_{\parallel}$ and $g'_{\perp} = 0$. Thus, if Ising-like exchange is present in these compounds, use of eq. [6*a*] alone in eq. [6*c*] should provide an adequate fit to the observed data. It is important to note that, according to the model, $\chi_{\parallel} \rightarrow 0$ as $T \rightarrow 0$, while the measured susceptibilities show an increase in magnitude as $T \rightarrow 0$, behaviour ascribed to the presence of paramagnetic impurity. Because of the anisotropy in these compounds, inclusion of a Curie law term may be inadequate to account for the lowest temperature susceptibility data. Consequently, the low-temperature data were fit using eq. [6*c*] with $\chi_{\perp}$ fixed at zero and this was combined with a Curie–Weiss law paramagnetic impurity term,

$$[7] \quad \chi_{para} = \frac{Ng^2\mu_B^2S(S+1)}{3k(T-\Theta)}$$

where $g = \frac{1}{3}g'$. The best-fit results are presented in Table 4 where the F values show this model to provide excellent fits to the low-temperature data, better, in fact, than does the Heisenberg model with a Curie law paramagnetic impurity term. Of course, the former is a four-parameter model while the latter is only a three-parameter model. Fits to the low-temperature data using the Heisenberg model coupled with the Curie–Weiss paramagnetic impurity term only yield marginal decreases in the F values at the expense of indeterminate $\%P$. It should be noted that the $\%P$ values and Weiss constants obtained with the Ising parallel susceptibility model are rather large in magnitude.

A major problem in analyzing the magnetic data arises from the presence of paramagnetic impurities and the fact that their contributions to the overall susceptibilities are maximized in the low-temperature region. Accordingly, an attempt was made to fit the data in the region of susceptibility maxima without correcting for paramagnetic impurities, using both the Ising and Heisenberg models. The halogenated derivatives do not exhibit discrete susceptibility maxima and

TABLE 5. Derived magnetic parameters fits of the $S = 1/2$, Ising $\chi_\parallel$ and $S = 3/2$, Heisenberg models to data in the region of the susceptibility maxima (estimated standard deviation in last digit in parentheses)

Compound	Temperature range (K)	Model	$-J$ (cm^{-1})	g or $g'_\parallel$	F
$[Co(4\text{-}Hpz)_2]_x$	19–54	Ising	24.0(2)	8.86(5)	0.0097
		Heisenberg	5.9(5)	2.5(1)	0.033
$[Co(3\text{-}Mepz)_2]_x$	20–45	Ising	19.8(1)	8.74(3)	0.0033
		Heisenberg	4.3(1)	2.36(3)	0.0097
$[Co(4\text{-}Hdmpz)_2]_x$	10–20	Ising	8.6(2)	6.09(6)	0.011
		Heisenberg	1.81(3)	1.62(1)	0.0068
$[Co(4\text{-}Medmpz)_2]_x$	12–20	Ising	10.4(3)	6.12(9)	0.0089
		Heisenberg	2.15(4)	1.62(2)	0.0072

were not included in this analysis. The results are presented in Table 5 and the calculated curves corresponding to the best-fit parameters are shown in Figs. 6(*a*) through (*f*) (these curves span only the susceptibility maxima and the Ising curves are seen as distinct from the Heisenberg ones only for 6(*e*) and (*f*)). Only in the case of $[Co(4\text{-}Hpz)_2]_x$ does the Ising model provide a substantially better fit than the Heisenberg model. In fact, the Heisenberg model provides a marginally better fit to the data for the 4-Hdmpz and 4-Medmpz derivatives; however, the resulting g values are unrealistically low.

EPR studies on monometallic analogues provide some support for application of the Ising susceptibility model to these compounds. Compounds with the general formula $Co[R_2B(pz^*)]_2$ (R = H or phenyl and pz* = 4-Hpz, 4-Hdmpz, or 4-Medmpz) were found to exhibit $g_\parallel >> g_\perp$ (29), which is the condition required for application of the Ising exchange model. In light of this, we attempted to fit the data for $[Co(4\text{-}Hpz)_2]_x$ and $[Co(3\text{-}Mepz)_2]_x$ over wide temperature ranges employing the Ising model, but allowing a contribution due to $\chi_\perp$. In the case of $[Co(4\text{-}Hpz)_2]_x$, the full random-orientation powder susceptibility data set was modelled allowing J, $g'_\parallel$, and $g'_\perp$ to vary with the resulting best-fit values of $-39.5(2)$ cm^{-1}, 7.56(2), and 3.59(1), respectively ($F = 0.0080$). With $[Co(3\text{-}Mepz)_2]_x$, data over the range 2–300 K were modelled in a similar fashion. The derived values of J, $g'_\parallel$, $g'_\perp$, and %P were $-38.3(5)$ cm^{-1}, 6.19(7), 4.24(5), and 0.82(3)%, respectively ($F = 0.010$). When such modelling efforts were made with the data for the $[Co(4\text{-}Xdmpz)_2]_x$ species, $g_\parallel$ invariably tended to zero and for the halogenated species, J became indeterminate.

In the Hamiltonian, eq. [1], if the z-component is set at zero and $\alpha = 1$, then another important form of anisotropic exchange coupling, X–Y exchange, is obtained. Katsura (30) derived an open-form expression for $\chi_\perp$ in X–Y coupled $S = 1/2$ linear chains and Duxbury et al. (31) developed numerical approximations to Katsura's expression; however, they did not provide explicit expressions for those approximations. Another important shortcoming in the application of the X–Y model here is that no expression for $\chi_\parallel$ in linear chain systems is available and, within the framework of an axially distorted, $S = 3/2$ chromophore, $g'_\parallel = g$ and $g'_\perp = 2g$ (15). Thus, neglect of $\chi_\parallel$ would incur considerable error in the fitting procedure.

Summary and conclusions

Synthetic routes to six binary pyrazolate and substituted pyrazolate complexes of Co(II) are described. The materials are microcrystalline and, although none could be obtained in a form suitable for single crystal X-ray diffraction studies, indirect evidence supports polymeric doubly pyrazolate-bridged chain structures with pseudo-tetrahedral cobalt centres. Magnetic susceptibility studies reveal anisotropy in the susceptibilities and the presence of significant antiferromagnetic exchange. No single model currently available for quantification of exchange interactions adequately describes the observed magnetic properties over wide temperature ranges. In spite of this difficulty, the modelling exercises facilitate the qualitative interpretation of the magnetic properties. The high-temperature susceptibility data for all of the compounds can be adequately fit with the antiferromagnetically coupled $S = 3/2$ linear chain model. This procedure yields true g values in the range expected for (pseudo)tetrahedrally coordinated Co(II) ions. At temperatures below those of the susceptibility maxima, the ob-

For personal use only.

served susceptibilities decrease more rapidly than can be accounted for by the Heisenberg model. This fact, along with the results of the oriented pellet studies, reveals the presence of anisotropy effects. Application of the $S' = 1/2$, Ising parallel susceptibility model to the low-temperature data yields excellent fits and reasonable $g_{\parallel}'$ values. The derived J values from the Ising and Heisenberg models can be used to qualitatively rank the magnitude of exchange coupling in these complexes as follows:

$$\text{4-Hpz} \approx \text{3-Mepz} >> \text{4-Medmpz} \approx \text{4-Cldmpz} \approx \text{4-Brdmpz} \approx \text{4-Hdmpz}$$

This division of the compounds into two exchange strength groups also correlates with their ligand field properties and proposed chromophore distortions. A weaker ligand field is consistent with the type of distortion proposed in the dimethyl species relative to the other two complexes. The pyrazolate ligands are most certainly the medium of magnetic exchange in these complexes and one might reasonably expect that a weaker interaction between the ligands and Co(II) centres would manifest itself in smaller magnitudes of exchange. As a final comment on the nature of the exchange interaction, the true exchange behaviour is probably of the Heisenberg type and, although the modelling results indicate that low-temperature, 1-D, Ising-like exchange may be manifest in these compounds, the anomalously sharp susceptibility maxima most likely result from single-ion ZFS effects. Further interpretation of the order of the magnitudes of exchange coupling or of its nature is not warranted without detailed knowledge of the structures of these compounds.

Oligometallic cobalt 3,5-dimethylpyrazolate complexes: synthesis, structural and magnetic studies

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR,[1] ROBERT C. THOMPSON,[1] AND JAMES TROTTER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC V6T 1Z1, Canada

Received February 12, 1993

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **71**, 1425 (1993).

Three oligometallic 3,5-dimethylpyrazolate (dmpz) bridged Co(II) compounds have been synthesized and characterized spectroscopically: dimeric $[Co(dmpz)_2(Hdmpz)]_2$, the related oligometallic compound, $Co(dmpz)_2 \cdot 0.344(Hdmpz)$, and the trimetallic $[Co(dmpz)_2Cl(Hdmpz)]_2Co$. The first and last of these compounds have been studied magnetically and by single crystal X-ray diffraction. Crystals of $[Co(dmpz)_2(Hdmpz)]_2$ are orthorhombic, $a = 17.022(1)$, $b = 29.224(2)$, $c = 13.576(3)$ Å, $Z = 8$, space group *Fddd*; and those of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ are triclinic, $a = 11.742(3)$, $b = 18.604(4)$, $c = 8.950(2)$ Å, $\alpha = 99.76(2)°$, $\beta = 102.32(2)°$, $\gamma = 93.36(2)°$, $Z = 2$, space group $P\bar{1}$. The structures were solved by the Patterson method and were refined by full-matrix least-squares procedures to $R = 0.035$ and 0.042 ($R_w = 0.034$, 0.047) for 938 and 3853 reflections with $I \geq 3\sigma(F^2)$, respectively. Magnetic susceptibility studies on the dimeric and trimetallic complex show them to exhibit antiferromagnetic behaviour. Analysis of the magnetic data (2–300 K) for the trimetallic complexes reveals antiferromagnetic coupling between the terminal and central Co(II) ions with J (Heisenberg) ≈ -3 cm^{-1}. Either intramolecular next-nearest neighbour or intermolecular antiferromagnetic exchange is also present in this compound. The dimeric complex shows significant antiferromagnetic exchange between cobalt centres. Susceptibility data over the range 12–300 K are adequately modelled with the Ising $S = 1/2$ dimer model ($J \approx -23$ cm^{-1}).

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON, et JAMES TROTTER. Can. J. Chem. **71**, 1425 (1993).

On a synthétisé trois composés oligométalliques du Co(II) portant du 3,5-diméthylpyrazolate (dmpz) ponté et on les a caractérisés par des méthodes spectroscopiques : le $[Co(dmpz)_2(Hdmpz)]_2$, le composé oligométallique apparenté, $Co(dmpz)_2 \cdot 0{,}344(Hdmpz)$, et le composé trimétallique, $[Co(dmpz)_2Cl(Hdmpz)]_2Co$. On a étudié les premier et dernier composés magnétiquement et par diffraction des rayons X par des cristaux uniques. Les cristaux du $[Co(dmpz)_2(Hdmpz)]_2$ sont orthorhombiques, groupe d'espace *Fddd*, avec $a = 17{,}022(1)$, $b = 29{,}224(2)$ et $c = 13{,}576(3)$ Å, $Z = 8$ alors que ceux du $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 11{,}742(3)$, $b = 18{,}604(4)$ et $c = 8{,}950(2)$ Å, $\alpha = 99{,}76(2)°$, $\beta = 102{,}32(2)°$ et $\gamma = 93{,}36(2)°$ et $Z = 2$. On a résolu les structures par la méthode de Patterson et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}035$ et 0,042 ($R_w = 0{,}034$ et 0,047) pour respectivement 938 et 3853 réflexions avec $I \geq 3\sigma(F^2)$. Les études de susceptibilité magnétique sur le complexe dimère et trimétallique montrent qu'ils présentent un comportement antiferromagnétique. Une analyse des données magnétiques (2–300 K) du complexe trimétallique révèle l'existence d'un couplage antiferromagnétique entre les ions Co(II) terminal et central, avec J (Heisenberg) ≈ -3 cm^{-1}. Dans ce composé, il existe aussi un échange antiferromagnétique intramoléculaire ou intermoléculaire avec le deuxième voisin. Le complexe dimère présente un échange antiferromagnétique important entre les centres de cobalt. Le modèle dimère de Ising, $S = 1/2$ ($J = -23$ cm^{-1}), permet d'expliquer adéquatement les données de susceptibilité entre 12 et 300 K.

Introduction

We recently reported on a number of metal pyrazolate complexes containing copper or zinc (1–6). Particular emphasis was placed on studies of the magnetic properties of copper(II) oligometallic and polymeric systems (1, 4–6), studies in which it was demonstrated that pyrazolate and substituted pyrazolate ligands are efficient mediators of antiferromagnetic exchange between copper centres.

As part of our investigations of binary metal pyrazolates, generally, we have synthesized a number of polymeric cobalt(II) pyrazolates (7). In the course of this work, two 3,5-dimethylpyrazolate-bridged complexes, the dimeric $[Co(dmpz)_2(Hdmpz)]_2$ and the trimetallic $[Co(dmpz)_2Cl(Hdmpz)]_2Co$, were isolated in crystalline form suitable for single crystal X-ray diffraction studies. The structures and magnetic properties of these complexes, together with some studies on a dimeric–oligometallic material with the empirical formula $Co(dmpz)_2 \cdot 0.344(Hdmpz)$, form the basis of this communication. These materials provide important insights into the structure – magnetic property relationships in pyrazolate-bridged cobalt(II) systems. In addition, they provide structural models for interpreting systems such as the polymeric cobalt(II) pyrazolates where, due to the microcrystalline nature of the samples, no single crystal X-ray data are available (7).

Experimental

Syntheses

3,5-Dimethylpyrazole (Hdmpz) was purchased from Aldrich and used without further purification.

$[Co(dmpz)_2(Hdmpz)]_2$

A mixture of $CoCO_3 \cdot xH_2O$ (0.465 g) and 3,5-dimethylpyrazole (2.88 g), in sufficient acetone to dissolve the 3,5-dimethylpyrazole (~1–2 mL), was reacted, with stirring, at 75°C for 24 h. The solid mixture obtained on cooling was extracted with acetone to yield an insoluble dark purple powder and a solution of 3,5-dimethylpyrazole. Collection of the purple powder yielded 1.22 g $[Co(dmpz)_2(Hdmpz)]_2$. Anal. calcd. for $C_{30}H_{44}Co_2N_{12}$: C 52.2, H 6.4, N 24.3; found: C 51.8, H 6.5, N 24.6.

The sample of this material on which the single crystal X-ray diffraction studies were performed formed one half of a larger,

elongated octahedral crystal from the sample of $Co(dmpz)_2 \cdot 0.344(Hdmpz)$. An X-ray powder diffraction study on the bulk sample confirmed it to be the same as the single crystal sample.

$Co(dmpz)_2 \cdot 0.344(Hdmpz)$

This material was produced in a manner similar to that of $[Co(dmpz)_2(Hdmpz)]_2$ with the following differences. Approximately 0.1 g of $CoCO_3 \cdot xH_2O$ and 4 g of 3,5-dimethylpyrazole were used. The reaction mixture was heated at 100°C for 40 h, without stirring. This yielded 0.18 g of large purple crystals with the nominal formulation $Co(dmpz)_2 \cdot 0.344(Hdmpz)$. Anal. calcd. for $C_{11.7}H_{16.8}CoN_{4.7}$: C 49.9, H 6.0, N 23.3; found: C 49.9, H 6.2, N 23.2.

$[Co(dmpz)_2Cl(Hdmpz)]_2Co$

$[Co(acac)_2]_4$ (0.551 g, 2.14 mmol) and excess 3,5-dimethylpyrazole (mp = 108–110°C) were combined and heated, with stirring, at 160°C for 2 h under a dinitrogen atmosphere. The mixture was then cooled to room temperature and the resultant solid extracted with 40 mL of CH_2Cl_2. Filtration, followed by removal of solvent from the filtrate, yielded a pink solid. The pink solid was heated at 130°C (above the mixture melting point), without stirring, for 18 h. During this heating period the reaction mixture was exposed to a slow flow of dinitrogen gas carrying CH_2Cl_2 vapour (Cl source). After this time, a dark purple solid remained at the bottom of the reaction vessel and excess 3,5-dimethylpyrazole and acetylacetone had collected on cooler parts of the apparatus. The purple solid was washed with 80 mL of acetone in small portions to leave the product as insoluble, well-formed purple crystals together with a small amount of light blue material. The latter was removed by washing with methanol and the remaining product was then dried in air yielding 0.142 g (23%) of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ as dark purple crystals. Anal. calcd. for $C_{30}H_{44}Cl_2Co_3N_{12}$: C 43.9, H 5.4, N 20.5; found: C 44.2, H 5.5, N 20.3

Physical characterization

Infrared spectra (4000–400 cm^{-1}) were recorded as Nujol mulls between KBr plates using a Perkin–Elmer model 598 spectrometer and were calibrated against polystyrene film. Electronic spectra (200–2500 nm) were recorded using a Cary 5 spectrometer on Nujol mull samples between quartz plates. Electronic band positions and assignments are listed in Table 1.

Differential scanning calorimetry measurements were obtained with a Mettler DSC 20 standard cell and TC10 TA processor.

Magnetic measurements were performed using a Quantum Design MPMS SQUID magnetometer. Powdered samples (approximately 30 mg) were packed into a PVC sample holder specially designed to possess a constant cross-sectional area. Magnetic susceptibility data were recorded in the temperature range 2–300 K in an applied field of 10 kOe. Susceptibility data were corrected for diamagnetism: Co, −12; Cl, −26; dmpz(H), −62 (all values × 10^{-6} cm^3 mol^{-1}). A correction of 4.0×10^{-4} cm^3 mol^{-1}, derived from ligand field *D*q values, was also applied for the temperature-independent paramagnetism of the Co(II) ion. The estimated uncertainty in the susceptibility data is ±1%.

Elemental analyses were performed by Mr. P. Borda of this department.

X-ray crystallographic analyses of $[Co(dmpz)_2(Hdmpz)]_2$ and $[Co(dmpz)_2Cl(Hdmpz)]_2Co$

Crystallographic data for both complexes appear in Table 2. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 55.6–92.0° for $[Co(dmpz)_2(Hdmpz)]_2$, and 11.6–34.7° for $[Co(dmpz)_2Cl(Hdmpz)]_2Co$. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random variations. The data were processed,[2] corrected for Lorentz and polarization effects, and for absorption (empirical, based on azimuthal scans for three reflections).

[b]kK = 10^3 cm^{-1}. Abbreviations: w, weak; m, medium; s, strong; vs, very strong; sh, shoulder.

[c]Assignments are based on the tetrahedral formalism. Abbreviations: SF, spin-forbidden; IL/CT, internal ligand or charge transfer.

$[Co(dmpz)_2(Hdmpz)]_2$ is isomorphous and isostructural with the corresponding zinc complex (3), the structure analysis being initiated with the coordinates of the non-hydrogen atoms of the zinc analog. The $[Co(dmpz)_2(Hdmpz)]_2$ molecule lies on a crystallographic twofold axis. The analysis of the structure of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the Patterson functions, this choice being confirmed by the subsequent successful solution and refinement of the structure. The structure of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ was solved by conventional heavy atom methods, the coordinates of the metal atoms being determined from the Patterson function and those of the remaining non-hydrogen atoms from subsequent difference Fourier syntheses. The non-hydrogen atoms were fixed in idealized positions (methyl group orientations based on observed difference map positions, C—H = 0.98 Å, $B_H = 1.2\ B_{\text{bonded atom}}$). Corrections for secondary extinction were applied for [Co-

Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(F^2)$.

$(dmpz)_2(Hdmpz)]_2$, the final value of the extinction coefficient being 4.72×10^{-7}. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (8).

Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles appear in Tables 3–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes for the two structures are included as supplementary material.[3]

[3]Supplementary material mentioned in the text may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6.

Tables of hydrogen atom coordinates and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

Results and discussion

Synthesis and structural studies

During attempts to prepare X-ray diffraction quality single crystals of poly(cobalt(II) 3,5-dimethylpyrazolate), three oligometallic Co(II) species were obtained in macroscopic crystalline form: a dimeric complex with the formula, $[Co(dmpz)_2(Hdmpz)]_2$, a dimeric–oligometallic material with the empirical formula, $Co(dmpz)_2 \cdot 0.344(Hdmpz)$, and a trimetallic complex with the formula $[Co(dmpz)_2Cl(Hdmpz)]_2Co$. The dimeric and dimeric–oligometallic Co(II) compounds were prepared by heating $CoCO_3 \cdot xH_2O$ in very concentrated acetone solutions of 3,5-dimethylpyrazole. More specifically, the pure dimer was prepared by heating a stirred reaction mixture at 75°C and the dimeric–oligometallic mixture was prepared by heating a quiescent reaction mixture at 100°C. The behaviours of these compounds closely parallel those of the analogous Zn(II) compounds, $[Zn(dmpz)_2(Hdmpz)]_2$ and $Zn(dmpz)_2 \cdot 0.323(Hdmpz)$ (3). For example, at lower reaction temperatures (≤90°C), samples

of pure $[M(dmpz)_2(Hdmpz)]_2$ (M = Co, Zn) may be prepared, but at higher temperatures (≥100°C), materials with the empirical formula $M(dmpz)_2 \cdot x(Hdmpz)$ (M = Co, Zn; $x < 1$) are formed instead. It was previously suggested in the case of $Zn(dmpz)_2 \cdot 0.323(Hdmpz)$ that the material consists of a mixture of dimeric and longer chain oligometallic species (3). We propose that $Co(dmpz)_2 \cdot 0.344(Hdmpz)$ possesses an analogous composition, and evidence in support of this will be presented after discussion of the structure of $[Co(dmpz)_2(Hdmpz)]_2$.

$[Co(dmpz)_2(Hdmpz)]_2$ is isomorphous and isostructural with $[Zn(dmpz)_2(Hdmpz)]_2$ (3). The molecular structure (Fig. 1) consists of two cobalt ions bridged by two dmpz anions with each cobalt being end-capped by a pyrazolate ion and a neutral Hdmpz molecule. The coordination geometry about the cobalt centres is pseudo-tetrahedral (crystallographic D_2 point symmetry) with Co—N bond lengths between the bridging and terminal dmpz moieties of 1.998(2) and 2.010(3) Å, respectively. N—Co—N bond angles range from 99.2(1)° to 114.4(2)° (average = 107.8°) and the dihedral angle between the normals of the central $Co(N–N)_2Co$ and terminal $Co(N–N)_2H$ planes is 87.8°. The cobalt centres in the molecule are separated by a nonbonding distance of 3.777 Å. Figure 2 depicts the unit cell packing of $[Co(dmpz)_2(Hdmpz)]_2$. The figure shows how individual molecules lie in sheets parallel to the *ab*-plane of the crystal lattice such that all of their terminal ligands are coplanar. Within each sheet, Co–Co vectors of individual molecules align in a coparallel manner and, moreover, chains of Co–Co vectors running along the *a*-axis are not only coparallel, but collinear. Adjacent sheets are oriented such that the dimer molecules in the neighbouring sheets are staggered by translation of one dimer length along the *a*-axis. This structural arrangement has important consequences for the formation of $Co(dmpz)_2 \cdot 0.344(Hdmpz)$, as will be discussed below.

The infrared data for $[Co(dmpz)_2(Hdmpz)]_2$ reflect the presence of strong hydrogen bonding in the molecule with the appearance of two broad ν_{NH} bands at ~2380 and ~1870 cm^{-1} and a γ_{NH} band appearing at 865 cm^{-1} (cf. $[Zn(dmpz)_2(Hdmpz)]_2$ (3)).

Returning to discussion of the structural composition of

[a]Primed and double-primed atoms have coordinates related to those in Table 3 by the symmetry operations: 5/4-x, 1/4-y, z; and x, 1/4-y, 1/4-z, respectively.

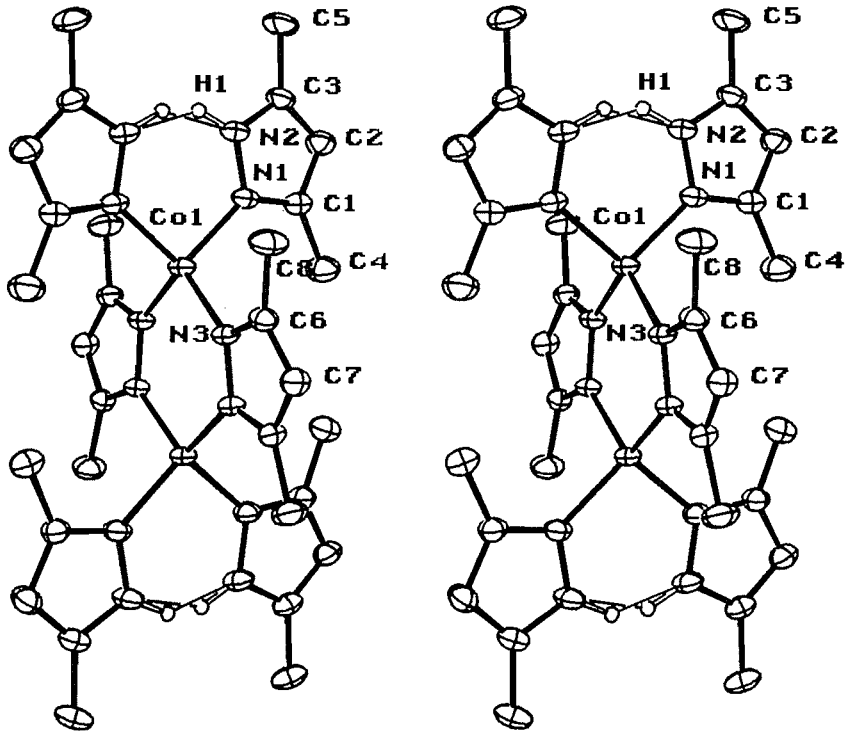

FIG. 1. Stereoscopic view of the $[Co(dmpz)_2(Hdmpz)]_2$ molecule; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

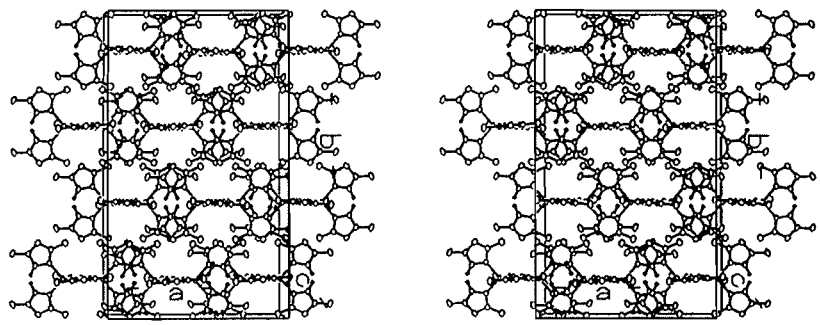

FIG. 2. Stereoscopic view of the unit cell packing in the crystal structure of $[Co(dmpz)_2(Hdmpz)]_2$.

$Co(dmpz)_2 \cdot 0.344(Hdmpz)$, if a structure consisting of a doubly pyrazolate-bridged chain of Co(II) ions with end-capping neutral ligands is assumed for this compound, then the nominal formulation corresponds to a mean chain length of 5.8 Co(II) ions. One possible composition is a biphasic distribution; the bulk compound consists of a mixture of the dimeric phase and the infinite polymer phase such that their ratio yields the observed empirical formula. Electronic spectroscopy indicates that such a dispersion is very unlikely. The electronic spectra of $Co(dmpz)_2 \cdot 0.344(Hdmpz)$ and $[Co(dmpz)_2(Hdmpz)]_2$ (Table 1) are very similar and are consistent with that of a fairly regular tetrahedral CoN_4 chromophore (9) like the type structurally characterized in the dimer. Pure polymeric $[Co(dmpz)_2]_x$ exhibits a distinctly different electronic spectrum (7), one consistent with a more distorted tetrahedral geometry about cobalt (9). There is no evidence of this polymer in the spectrum of $Co(dmpz)_2 \cdot 0.344(Hdmpz)$, thus disproving the biphasic distribution model, which requires the sample to be ~66% (by mole Co(II) ions) polymer phase. Moreover, microscopic examination of the sample revealed it to consist entirely of macroscopic crystals, all of the same colour and morphology. Most of the crystals were opaque, but a few of the smaller crystals were quite transparent. One might expect the presence of two crystal morphologies in a biphasic distribution.

Observation of a small sample of crystals of $Co(dmpz)_2 \cdot 0.344(Hdmpz)$ heated in a melting point apparatus indicated that, between 180 and 200°C, colourless crystals of Hdmpz sublimed from the sample. There appeared to be no physical deterioration of the sample crystals at that point. Heating of the sample to the apparatus limit of 360°C revealed no further change. Microscopic examination of the sample before the heating process revealed it to consist of large, almost opaque, dark purple crystals whose morphology is best described as elongated octahedral. The crystal facets were shiny and the crystal edges sharp. After heating, microscopic examination showed that the crystal facets had now become dull and chalky; however, the crystal edges were still sharp and the crystals had maintained their me-

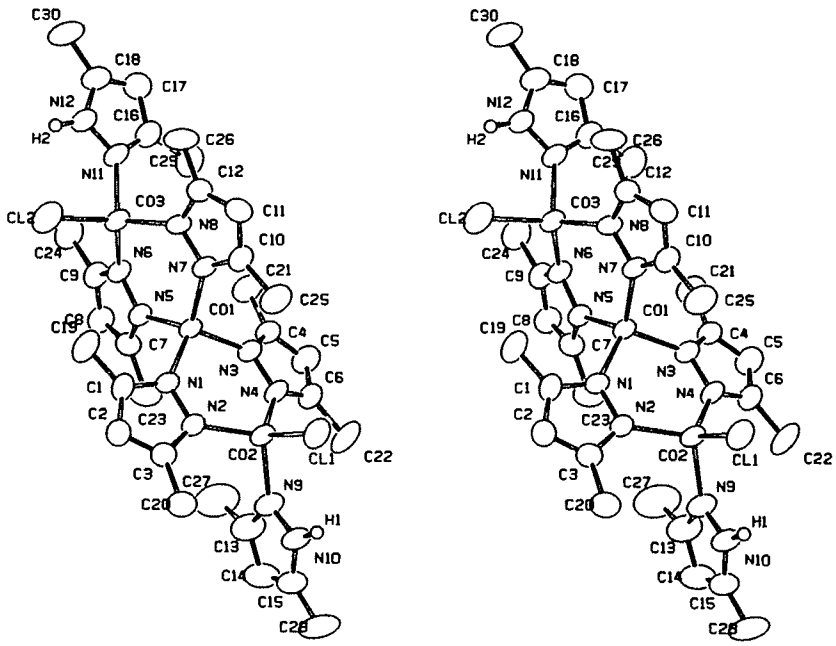

FIG. 3. Stereoscopic ORTEP diagram of the $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ molecule; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

chanical integrity. Evidently the thermolysis of this material, resulting in volatilization of Hdmpz consistent with polymerization, left the original crystals largely intact. This suggests that either the crystal lattice of this material can tolerate considerable molecular reorganization, or that relatively little reorganization occurs during volatilization of Hdmpz.

The results of the single crystal diffraction study of $[Co(dmpz)_2(Hdmpz)]_2$ are important in this discussion because the crystal selected for X-ray study formed one half of a larger, elongated octahedral crystal from the sample of $Co(dmpz)_2 \cdot 0.344(Hdmpz)$! This particular half crystal was chosen because it was much more transparent than the remainder of the whole crystal or the other crystals in the sample. A well-formed, but opaque, crystal that had been selected previously for study was found to diffract X-rays too poorly to be useful. In other words, the crystal structure of the dimeric species appears to be compatible with the bulk sample of $Co(dmpz)_2 \cdot 0.344(Hdmpz)$, but not necessarily representative of the molecular contents of most of the crystals in the bulk sample.

The information presented about $Co(dmpz)_2 \cdot 0.344(Hdmpz)$ above suggests that most of the sample consists of oligometallic species with the general formula, $[Co(dmpz)_2]_n(Hdmpz)_2$. Figure 2 illustrates that the crystal lattice of $[Co(dmpz)_2(Hdmpz)]_2$ contains columns, parallel to the *c*-axis, of overlapped terminal pyrazolyl rings with the ring planes normal to the *c*-axis. Thus, the structure of the dimeric phase appears particularly amenable to polymerization of the dimer molecules. This may occur through a process of molecular dislocation in which a dimer molecule from one *ab*-sheet in the lattice moves into the gap between dimer molecules in an adjacent sheet (Fig. 2) with the concomitant release of four molecules of Hdmpz. If such a process occurs in this material, then one might expect chain lengths to increase by steps of four. In other words, oligometallic chains would be present in the bulk material containing 2, 6, 10, etc. metal ions. That both the zinc (3) and cobalt oligometallic species possess mean chain lengths close to six (6.2 and 5.8, respectively) is consistent with (but by no means proof for) such a process.

As mentioned above, the trimetallic complex $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ was prepared during attempts to grow diffraction-quality single crystals of $[Co(dmpz)_2]_x$. Once it was recognized that the trimetallic complex could be prepared, the reaction conditions were modified to intentionally prepare this compound in bulk quantities. This is described in the experimental section. The compound is air-insensitive and sparingly soluble in CH_2Cl_2 and acetone. The DSC thermogram of the complex shows an endothermic event at 293°C (probably melting) followed immediately by exothermic decomposition.

$[Co(dmpz)_2Cl(Hdmpz)]_2Co$ crystallizes in the space group $P\bar{1}$ as a trimetallic molecule with the Co(II) ions in an approximately linear arrangement (Fig. 3). The terminal Co(II) ions are linked to the central cobalt by double 3,5-dimethylpyrazolate bridges. The central cobalt is coordinated by four pyrazolate nitrogen atoms in a pseudo-tetrahedral fashion with Co—N bond lengths ranging from 1.988(4) to 2.001(4) Å (average = 1.993 Å), N—Co—N bond angles ranging from 107.1(2)° to 113.9(2)°, and a dihedral angle between the fused N—Co—N planes running along the approximate molecular Co–Co–Co axis of 90.2° (the angle formed by these three cobalt centres is 169.2°). The terminal Co(II) ions are each coordinated by two bridging pyrazolate nitrogen atoms, one terminal 3,5-dimethylpyrazole nitrogen atom, and one terminal chloride ion in a distorted tetrahedral manner. The average terminal Co—N bond length is somewhat longer than the average bridging Co—N bond length (2.030(5) versus 1.981(5) Å, respectively) and the average Co—Cl bond length is 2.25(1) Å. Both $Co(N–N)_2Co$ rings in the complex exhibit a half-boat conformation in which the terminal cobalt is displaced from the mean plane defined by the central cobalt and the four nitrogen atoms. The average dis-

tance between cobalt centres within the $Co(N–N)_2Co$ rings is nonbonding at 3.627 Å. There are two molecules per unit cell related by an inversion centre. The "pyrrolic" hydrogen atom of the terminal Hdmpz ligand is hydrogen bonded to the chloride ligand of an adjacent molecule and vice versa (average N...Cl = 3.376 Å), creating chains of the trimetallic complex running along the *a*-direction of the crystal lattice. The infrared spectrum of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ exhibits a strong, relatively sharp, ν_{NH} band at 3265 cm^{-1}, consistent with the hydrogen bonding, which is significantly weaker than that in the dimeric compound, as indicated in its crystal structure.

The electronic spectrum of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ (Table 1) reveals considerable structure in the formally ν_2 and ν_3 transitions with bandwidths of the order of 6000 and 2500 cm^{-1} in the former and latter transitions, respectively. The large bandwidths and band structure are principally due to the presence of two different chromophores revealed by the X-ray diffraction study on the complex. The compound possesses a central CoN_4 chromophore of close to regular tetrahedral symmetry and two terminal CoN_3Cl chromophores of lower symmetry; the crystallographic symmetry of the CoN_3Cl chromophores is C_1 and they have very approximate C_{3v} point symmetry (see Fig. 3).

Magnetic properties

Magnetic susceptibility measurements (2–300 K) were made on powdered samples of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ and $[Co(dmpz)_2(Hdmpz)]_2$. Susceptibility and effective magnetic moment data have been deposited.[3] Data for $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ are presented as a magnetic moment versus temperature plot in Fig. 4. The magnetic moment of the compound decreases from a value of 7.44 μ_B at 300 K to 2.96 μ_B at 2 K. This decrease in moment as the sample is cooled may reflect one or both of zero-field splitting (ZFS) and antiferromagnetic exchange effects. A plot of χ_M versus temperature for $[Co(dmpz)_2(Hdmpz)]_2$ is given in Fig. 5. The presence of a maximum in χ_M at ~27 K indicates antiferromagnetic coupling between the Co(II) centres. At the lowest temperatures studied the magnetic susceptibility begins to increase again and this is most likely due to the presence of structural paramagnetic impurity in the sample. In an effort to quantify the magnitudes of the exchange interaction in these complexes, we have attempted to fit their magnetic data to two types of theoretical exchange models: isotropic Heisenberg models and anisotropic Ising models. The specific models employed for the dimeric and trimetallic complexes are discussed separately below.

In the case of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$, a spin vector coupling scheme first proposed by Kambe for trimetallic systems (10), and later generalized by Sinn (11), was used to derive an expression for the magnetic susceptibility of a Heisenberg, exchange-coupled, $S = 3/2$ linear trimetallic system. The expression is rather long and has been deposited.[3] The equation assumes no difference between central and terminal Co(II) *g* values and allows one to vary the exchange coupling constants, J (nearest neighbour) and J_{13} (next-nearest neighbour), independently. In addition to applying this equation, fits to various temperature ranges of data were made using a trimetallic $S' = 1/2$ Ising model (12), an $S' = 1/2$ Heisenberg model (13), and the trimetallic Heisenberg $S = 3/2$ equation combined with the molecular field equation (14):

$$\chi'_{calc} = \frac{\chi_{calc}}{1 - (2zJ'/Ng^2\mu_B{}^2)\chi_{calc}}$$

where z is the number of interacting neighbouring molecules and J' is the magnitude of exchange coupling with those molecules. The equation above compensates for secondary intermolecular interactions. Fits of the experimental data to the models were achieved using a nonlinear least-squares procedure with the following as the function minimized:

$$F = \left[\frac{1}{n}\sum_{i=1}^{n}\frac{(\chi_i^{obs} - \chi_i^{calc})^2}{(\chi_i^{obs})^2}\right]^{1/2}$$

The F value provides a measure of the goodness of fit between theory and experiment. Experimental susceptibility versus temperature data are compared with theory in Fig. 4 and values of the exchange coupling constant, J, the other fitting parameters, and the fitting function, F, for various fits are listed in Table 6.

Table 6 shows clearly that the models based on the $S' = 1/2$ formalism yield very poor fits, even over a narrow temperature range. Though not shown here, allowing J_{13} to vary in these models causes only a marginal improvement in the quality of the fits, but at the expense of an indeterminate J_{13}. It is only the $S = 3/2$ based models that have yielded good fits to the susceptibility data. A good quality fit was achieved for the data from 12–300 K by neglecting J_{13} (Fig. 4). At the lowest temperatures, however, the observed magnetic moment can be seen (Fig. 4) to drop well below the moment predicted by the model. Recalling that the molecular structure demonstrates considerable distortion of the terminal Co(II) ions away from ideal tetrahedral symmetry and that the electronic spectrum for the complex supports this observation, it is possible that the low observed magnetic moments at low temperatures are due to zero-field splitting effects. Attempts to model the lower temperature data (<10 K) with the ZFS expression for $S = 3/2$ ions (14), however, yielded a poor fit ($F = 0.10$) and an indeterminate D.

The best fit over the full data range was achieved by allowing both J and J_{13} to vary (Fig. 4). If the best fit results are to be believed, then $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ exhibits a next-nearest neighbour exchange interaction that is ~60% of the nearest neighbour interaction. Some precedence for this is found in the work of Mackey and Martin on the magnetic properties of the linear trimetallic nickel(II) complex, $[(Ni(1,2,4\text{-triazole})_3,(OH_2)_3)_2Ni][NO_3]_6 \cdot 2H_2O$ (15). It was concluded in this work that the complex experiences a next-nearest neighbour exchange coupling of a magnitude ~50% of that of the nearest neighbour exchange. Reedijk and co-workers reported studies of trimetallic and bimetallic, first row transition metal complexes in which the bridging ligands were alkylated 1,2,4-triazolyl moieties (12, 16–22) and several of these reports describe work performed on Co(II) species. In their analyses of the magnetic properties of these compounds, however, J_{13} was assumed to be zero and they cited several experimental findings to justify neglect of J_{13} in their modelling procedures (12, 17, 19, 21). Moreover, in a recent communication, Antolini et al. described the structural and magnetic characterization of a mixed valence Co(II)–Co(III) complex in which a central Co(III) ion is connected to two terminal Co(II) ions by tri-

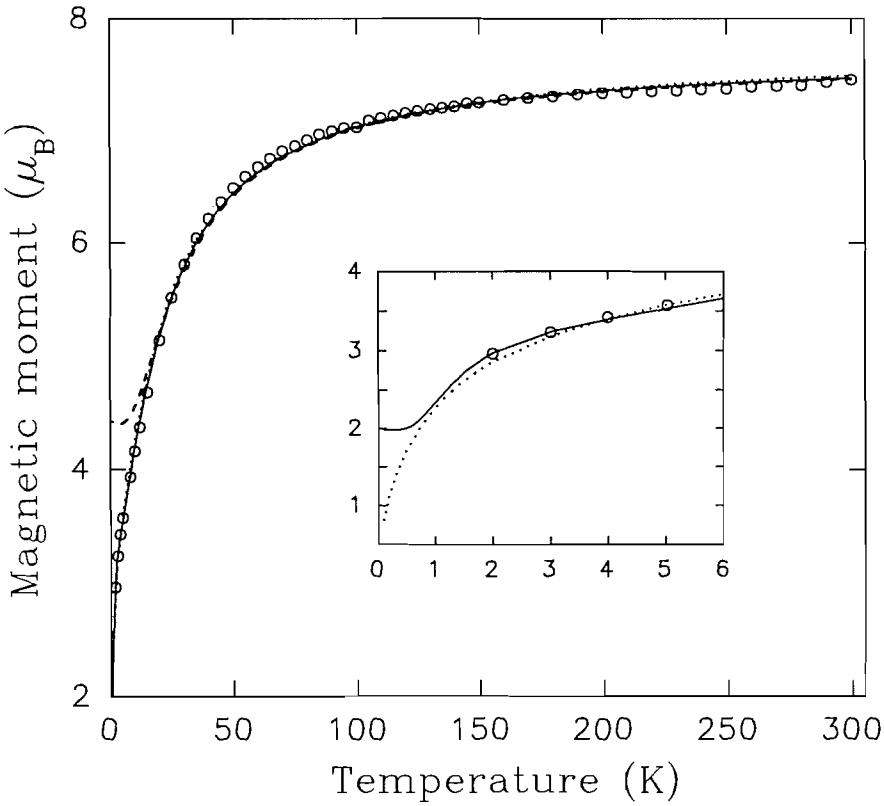

FIG. 4. Plot of effective magnetic moment versus temperature for $[Co(dmpz)_2Cl(Hdmpz)]_2Co$. The solid line represents the best fit of the trimetallic Heisenberg model with J and J_{13} variable. The dashed line represents the same model with J_{13} fixed at zero. The dotted line represents the preceding model coupled with a molecular field term.

ple triazolyl bridges (23). The terminal Co(II) ions of the mixed valence complex were found to be magnetically uncoupled.

Consideration of the crystal structure of $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ suggests an alternative interpretation of the exchange interactions in the complex. In the crystal lattice each $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ molecule is linked to two adjacent neighbours through hydrogen bonds. There is considerable precedence for the mediation of magnetic exchange via hydrogen-bonded bridges (24), and, to explore this possibility, the magnetic susceptibility of the complex was modelled using the trimetallic Heisenberg $S = 3/2$ equation with J_{13} fixed at zero and coupled with the molecular field expression to account for intermolecular interaction. This model yields a good fit to the data over the whole temperature range and an even better fit if only the data above 12 K are considered (dotted curve Fig. 4). However, application of the molecular field correction is justifiable only if $J/zJ' > 5$–10 (14) and the results in Table 6 correspond to smaller ratios. Further experimentation might provide additional insight regarding the low-temperature properties of this trimetallic compound. The inset of Fig. 4 shows μ_{eff} predicted by the two models extrapolated to very low temperature. If susceptibility measurements could be made to these low temperatures, then the two modes of coupling could possibly be distinguished. Furthermore, magnetization studies could also shed light on the problem. A caveat here, though, is that if paramagnetic impurity is present in the sample it may be masking the true low-temperature behaviour of the complex as paramagnetic impurity contributions to the magnetic properties of antiferromagnetically coupled systems are greatest at the lowest temperatures.

We turn now to a discussion of the magnetic properties of the dimeric molecule, $[Co(dmpz)_2(Hdmpz)]_2$. The dimeric Heisenberg model for $S = 3/2$ gives

$$\chi_{dimer} = \frac{Ng^2\mu_B{}^2}{kT} \cdot \frac{e^{2x} + 5e^{6x} + 14e^{12x}}{1 + 3e^{2x} + 5e^{6x} + 7e^{12x}}$$

where $x = J/kT$ (14). The dimeric Ising model for $S = 1/2$ gives

$$\chi_{dimer} = \frac{1}{3}\left[\frac{Ng^2\mu_B{}^2}{2kT} \cdot \frac{e^x}{1 + e^x}\right]$$

where $x = J/kT$ (25). Attempts were made to fit the data over various temperature ranges and when the lowest temperature data were included in fits, the expressions shown above were combined with the Curie law term,

$$\chi_{para} = \frac{Ng^2\mu_B{}^2S(S + 1)}{3kT}$$

or the Curie–Weiss law term.

$$\chi_{para} = \frac{Ng^2\mu_B{}^2S(S + 1)}{3k(T - \theta)}$$

in the following way;

$$\chi_M = [1 - P]\chi_{dimer} + P\chi_{para}$$

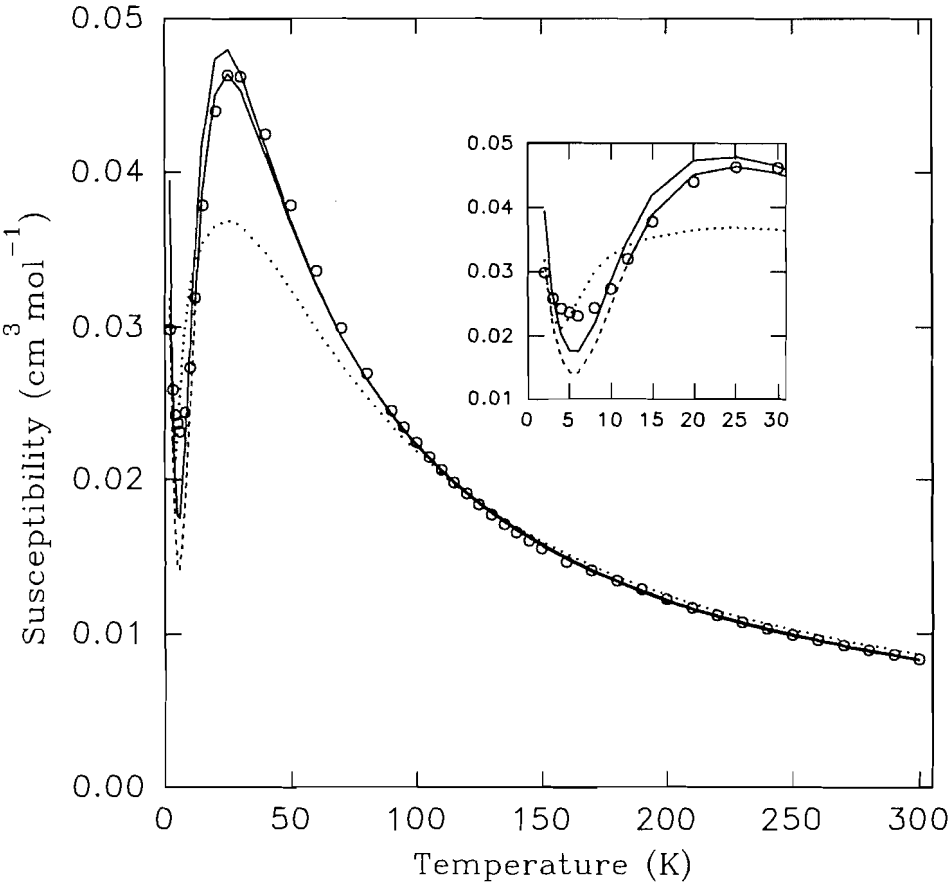

FIG. 5. Plot of magnetic susceptibility versus temperature for $[Co(dmpz)_2(Hdmpz)]_2$. The solid lines represent the best fits of the dimeric Ising model (with a Curie–Weiss law term) from 2–300 K (upper line) and 12–300 K (lower line, the dashed line is an extrapolation of the fit). The dotted line represents the best fit of the Heisenberg model (with a Curie–Weiss law term).

TABLE 6. Derived magnetic parameters for $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ with uncertainties in the last digit in parentheses

Model[a]	Temperature range (K)	$-J$ (cm^{-1})	$-J_{13}$ (cm^{-1})	$-zJ'$ (cm^{-1})	g	F
HT1/2	2–300	9(1)	0[b]	—	4.63(8)	0.19
	2–40	4.9(9)	0[b]	—	3.9(1)	0.14
IT1/2	2–50	7(2)	—	—	11.9(5)	0.17
HT3/2	2–40	1.2(4)	0[b]	—	1.72(8)	0.15
	2–300	2.3(4)	0[b]	—	2.08(4)	0.20
	12–300	3.6(1)	0[b]	—	2.287(9)	0.027
	2–300	2.84(3)	1.76((2)	—	2.292(3)	0.011
HT3/2MF	2–300	2.48(5)	0[b]	0.75(1)	2.304(5)	0.015
	12–300	2.3(3)	0[b]	0.8(2)	2.305(5)	0.013

[a]Abbreviations: HT1/2, Heisenberg trimetallic $S' = 1/2$; IT1/2, Ising trimetallic $S' = 1/2$; HT3/2, Heisenberg trimetallic $S = 3/2$; HT3/2MF, Heisenberg trimetallic $S = 3/2$ plus molecular field exchange.
[b]Fixed at zero.

where $100P$ represents the percent paramagnetic impurity ($\%P$). In addition, fits were made combining the Heisenberg and Ising equations listed above with the molecular field equation. The data were fit in the same manner for the dimer as described for $[Co(dmpz)_2Cl(Hdmpz)]_2Co$ and the results of these modelling efforts are listed in Table 7 and depicted in Fig. 5.

It is clear that the data in the 12–300 K region can be reasonably well fit with either the Heisenberg $S = 3/2$ or Ising $S' = 1/2$ models, with a generally better fit employing the Ising model. Fits employing the full data set (2–300 K) are significantly poorer for both models. Modifications to each model involving the inclusion of a molecular field term or a Curie–Weiss law paramagnetic impurity term gave a significant improvement to the fit in only one case. The fit involving the Ising model and a Curie–Weiss term is excellent

[b]When allowed to vary, $\%P$ took on a physically unrealistic negative value. Consequently, $\%P$ was fixed at zero.

over the whole temperature range (Table 7); however, this fit comes at the expense of a significantly larger paramagnetic impurity content.

Our inability to satisfactorily fit the data below 12 K may rise from our inability to explicitly model ZFS effects or the paramagnetic impurity (the effect of which is greatest at low temperatures). It should be noted that the dimer possesses a $S = 0$ magnetic ground state, which precludes one from treating ZFS effects and exchange separately in different temperature regimes.

In summary, our studies on the trimetallic complex $[Co(dmpz)_2Cl(dmpzH)]_2Co$ have revealed the presence of antiferromagnetic exchange coupling between the terminal and central Co(II) ions with J(Heisenberg) ≈ -3 cm^{-1} and, furthermore, that this exchange coupling alone is insufficient to account for the magnetic behaviour at low temperatures. Either intramolecular next-nearest neighbour or intermolecular antiferromagnetic exchange may also be present. The magnetic properties of the dimeric molecule, $[Co(dmpz)_2(Hdmpz)]_2$, reveal significant antiferromagnetic exchange between the metal centres. Magnetic susceptibility data over the temperature range 12–300 K are adequately modelled with either the Heisenberg $S = 3/2$ ($J \approx -5$ cm^{-1}) or the Ising $S' = 1/2$ ($J \approx -23$ cm^{-1}) dimer model, with a better fit obtained using the Ising model.

Received April 15, 1993

HEINZ-BERNHARD KRAATZ, P. MICHAEL BOORMAN, and MASOOD PARVEZ. Can. J. Chem. **71**, 1437 (1993).

The reaction of NaSeMes (Mes = mesityl, 2,4,6-$(CH_3)_3C_6H_2$) with $WCl_4(PPh_2Me)_2$ in THF leads to the formation of $W(SeMes)_4 \cdot THF$ (**1**), a possible mononuclear tetrakis(selenolato) complex of tungsten. The identity of the red crystalline material has been confirmed by elemental analysis and NMR spectroscopic methods (^1H, ^{13}C, and ^{77}Se NMR). The reaction of $W(SeMes)_4 \cdot THF$ with *tert*-butyl isocyanide results in the formation of $(^tBuNC)(MesSe)_2W(\mu\text{-}Se)_2W(SeMes)_2(CN^tBu)$ (**2**). Compound **2** crystallized in the monoclinic space group $C2/c$ (no. 15) with a = 23.933(2) Å, b = 16.776(2) Å, c = 15.595(2) Å, β = 122.98(2)°, and four formula units per unit cell. Refinement by full-matrix least squares gave final residuals of R = 0.038 and R_w = 0.028. The two metal centres in **2** are in a trigonal bipyramidal (tbp) coordination environment. The two tbps are connected via a common edge (axial–equatorial). The W—W bond length of 2.732(1) Å and the diamagnetism of **2** indicate the presence of a metal–metal bonding interaction.

HEINZ-BERNHARD KRAATZ, P. MICHAEL BOORMAN et MASOOD PARVEZ. Can. J. Chem. **71**, 1437 (1993).

La réaction du NaSeMes (Mes = mésityle, 2,4,6-$(CH_3)_3C_6H_2$) avec le $WCl_4(PPh_2Me)_2$ dans le THF conduit à la formation de $W(SeMes)_4 \cdot THF$ (**1**), un complexe tétrakis(sélénolato) mononucléaire du tungstène. On a confirmé l'identité du produit cristallin rouge par analyse élémentaire et par RMN du ^1H, du ^{13}C et du ^{77}Se. La réaction du $W(SeMes)_4 \cdot THF$ avec l'isocyanure de *tert*-butyle conduit à la formation du $(t BuNC)(MesSe)_2W(\mu\text{-}Se)_2W(SeMes)_2(CNtBu)$ (**2**). Le composé **2** cristallise dans le groupe d'espace $C2/c$ (n° 15) avec a = 23,933(2), b = 16,776(2) et c = 15,595(2) Å, β = 122,98(2)° et quatre unités de formule par unité élémentaire. L'affinement de la structure par la méthode des moindres carrés (matrice complète) conduit à des valeurs finales de R = 0,038 et R_w = 0,028. Deux des centres métalliques du composé **2** se trouvent dans un environnement de coordination trigonale bipyramidale (tbp). Les deux centres tbp sont reliés par une arête commune (axiale-équatoriale). La longueur de la liaison W—W (2,732(1) Å) et le diamagnétisme du composé **2** indiquent la présence d'une interaction liante métal–métal.

[Traduit par la rédaction]

Introduction

The coordination chemistry of the selenolato ligand (RSe^-, R = alkyl or aryl) is still an underdeveloped field (1). Over recent years, fueled partly by the quest for precursors for new materials possessing useful properties, efforts have been concentrated on selenolato complexes of group 12 metals (2). The use of bulky aryl substituents has proven extremely helpful in obtaining characterizable complexes with sometimes unexpected structural features. Although numerous examples of mononuclear and multinuclear thiolato complexes of early transition metals are known (3, 4), selenolato complexes of early transition metals are very rare (1). Despite an earlier report by Andrä about the synthesis of homoleptic group 5 and 6 metal selenolates from $Al(SeR)_3$ (R = phenyl and naphthyl) and metal halides, the true nature of these complexes has not been established (5). A review of the recent literature shows that structural data for complexes possessing terminal selenolates in particular are rare and to the best of our knowledge there are no mononuclear homoleptic selenolato complexes of any early transition metal known.[4] In fact, $CpCr(CO)_3(SePh)$ (7), $(OC)_4Cr(CNEt)(SePh)$ (8), and $(\eta^7\text{-}C_7H_7)W(CO)_2(SePh)$ (9) are the only structurally characterized mononuclear selenolato complexes of any early transition metal. Very recently, Chisholm and co-workers reported the first two examples of homoleptic binuclear selenolato complexes of molybdenum and tungsten (10) of the type $M_2(SeMes)_6$ (Mes = 2,4,6-trimethylphenyl).[5] Mononuclear tetrakis(thiolato) complexes of molybdenum (11, 12) and tungsten (13), and more recently hexakis(thiolato) complexes of niobium and tantalum (14), are easily accessible. They can be valuable starting materials for the preparation of larger clusters and have been used in HDS modelling reactions (15). Analogous selenolato complexes are of interest in their own right, but also in terms of their reactivity as compared to that of thiolato complexes. ^{77}Se NMR spectroscopy may be an additional probe for the characterization of the complexes in solution.

As part of our ongoing investigation of the reactivity of aryl selenolates with group 6 metal centres, we now report the synthesis of $W(SeMes)_4 \cdot THF$ (**1**) and provide evidence for its identity. Additional evidence stems from its reactivity towards *tert*-butyl isocyanide and the formation of the centrosymmetric binuclear complex $(^tBuNC)(MesSe)_2W(\mu\text{-}Se)_2W(SeMes)_2(CN^tBu)$ (**2**) of which the crystal structure is reported.

Experimental section

All operations were carried out under an argon atmosphere, using standard double manifold techniques. Analytical grade THF was dried with sodium and distilled from Na/benzophenone. NaSeMes (16) and $WCl_4(PPh_2Me)_2$ (17) were prepared according to litera-

ture procedures. 2,4,6-$(CH_3)_3C_6H_2SeH$ was prepared in 52% yield by a modified version of the literature procedure (18). ^1H NMR (δ in ppm; $CDCl_3$): 6.98 (s, 2H $HSeC_6H_2(CH_3)_3$, 2.44 (s, 6H, 2,6-Me), 2.34 (s, 3H, 4-Me), 1.31 (s, 1H, *H*SeMes, J_{HSe} = 54 Hz). ^{13}C NMR (δ in ppm, $CDCl_3$): 138.2 (*p*-C), 135.47 (*o*-C), 128.58 (*m*-C), 124.67 (i-C), 24.24 (*o*-CH_3), 20.62 (*p*-CH_3). ^{77}Se NMR (δ in ppm; $CDCl_3$): 14.1 (d, J_{HSe} = 54 Hz). Elemental analyses (C,H N) were performed by the University of Calgary, Department of Chemistry, Analytical Service Laboratory. IR spectra (2000–200 cm^{-1}) were recorded as Nujol mulls between CsI plates using a Mattson 4030 Galaxy Series FT-IR spectrometer. Routine ^1H NMR spectra were recorded on a Bruker ACE-200 spectrometer (referenced to external $SiMe_4$). ^{31}P NMR spectra were recorded on a Varian XL-200 spectrometer (referenced to external H_3PO_4). ^{77}Se NMR spectra were recorded on a Bruker AM-400 spectrometer (referenced to external PhSeSePh, δ = 460 ppm). The pulse width was 9 μs (40°) with an acquisition time of 0.082 s and a dead time of 1–2 s.

Synthesis of W(SeMes)$_4$·THF (1)

A 100 mL round-bottom flask with sidearm was charged with $WCl_4(PPh_2Me)_2$ (0.42 g; 0.58 mmol), NaSeMes (0.50 g; 2.31 mmol), and a stirring bar. The vessel was cooled to −196°C and degassed THF (20 mL) was added to the cold reactants. The mixture was degassed three times using freeze–thaw cycles and then allowed to warm up to room temperature. The solution was stirred for 3 h. The deep red solution was then filtered through a pad (1 cm) of Celite 545. The volume of the solution was reduced to 10 mL. After addition of *n*-hexane (5 mL) and storage of the solution at −20°C overnight, 0.35 g of red crystals were deposited (58% based on $WCl_4(PPh_2Me)_2$). ^1H NMR (δ in ppm, CD_3CN): 7.11 (s, 2H, Se-2,4,6-$(CH_3)_3C_6H_2$), 3.65 (m, 2,5-H of THF), 2.18 (s, 6H, *o*-CH_3 of Se-2,4,6-$(CH_3)_3C_6H_2$), 2.17 (s, 3H, *p*-CH_3 of Se-2,4,6-$(CH_3)_3C_6H_2$), 1.81 (m, 3,4-H of THF). $^{13}C\{^1H\}$ NMR (δ in ppm, CD_3CN): 143.4 (i-C of SeMes), 135.0 (*m*-C of SeMes), 132.1 (*o*-C of SeMes), 129.3 (*p*-C of SeMes), 68.3 (2,5-C of THF), 26.3 (3,4-C of THF), 25.7 (2,6-CH_3 of SeMes), 24.6 (4-CH_3 of SeMes). $^{77}Se\{^1H\}$ NMR (δ in ppm relative to Me_2Se; THF, D_2O insert): 1128 ($\nu_{1/2}$ = 116 Hz). Anal. calcd. for $C_{40}H_{52}OSe_4W$ (MW = 1048.55): C 45.82, H 5.00; found: C 46.0, H 5.1.

Preparation of (^{t}BuNC)(MesSe)$_2$W(μ-Se)$_2$W(μ-SeMes)$_2$(CN^{t}Bu) (2)

MesSeH (0.54 g, 2.75 mmol) was dissolved in degassed DME (15 mL) and the solution was cooled to −78°C. A solution of *n*-butyllithium in *n*-hexane (1.25 mL of a 2.5 M solution) was added slowly to the selenol, giving a colourless solution of LiSeMes. This solution was added to a stirring slurry of $WCl_4(PPh_2Me)_2$ (0.5 g, 0.69 mmol) in DME (15 mL) via a canula. The reaction mixture was allowed to warm up to room temperature. Over a period of 3 h, the reaction solution turned deep red. *tert*-Butyl isocyanide (0.31 mL, 2.75 mmol) was added via a syringe upon which the solution turned green immediately. After stirring for an additional hour, the solvent was removed in vacuo and the remaining residue was extracted with *n*-hexane (2 × 25 mL). The green *n*-hexane extracts were collected, reduced in volume to 15 mL, and stored at −20°C overnight. After this time, orange X-ray quality crystals deposited on the bottom of the flask. Yield: 0.28 g = 55% (based on $WCl_4(PPh_2Me)_2$. IR (Nujol mull): 2041 vs (ν(NC)), 1312s, 1206s, 968m, 947w, 873w, 843w, 507s, 486s, 426s. ^1H NMR (δ in ppm; $CDCl_3$): 6.83 (s, 4H, Se-2,4,6-$(CH_3)_3C_6H_2$), 2.35 (s, 12H, *o*-CH_3 of Se-2,4,6-$(CH_3)_3C_6H_2$), 2.27 (s, 6H, *p*-CH_3 of Se-2,4,6-$(CH_3)_3C_6H_2$), 1.45 (s, 9H, $(CH_3)_3CNC$). $^{13}C\{^1H\}$ NMR (δ in ppm; $CDCl_3$): 141.1 (Me_3CNC), 133.9 (i-C of SeMes), 131.9 (*m*-C of SeMes), 128.4 (*o*-C of SeMes), 127.4 (*p*-C of SeMes), 31.5 Me_3CNC), 24.8 (2,6-CH_3 of SeMes), 20.6 (4-CH_3 of SeMes). ^{77}Se NMR (δ in ppm; $CDCl_3$): 508 ($\nu_{1/2}$ = 10 Hz), 369 ($\nu_{1/2}$ = 15 Hz). ^{14}N NMR (δ in ppm; $CDCl_3$): −170 ($\nu_{1/2}$ = 162 Hz). Data collection and refinement

A dark red triangular crystal of **2** of dimensions 0.13 × 0.30 × 0.28 mm was mounted onto a glass fiber and coated with epoxy resin. Accurate cell dimensions and the crystal orientation matrices were determined on a Rigaku AFC6S diffractometer by a least-squares refinement of 25 reflections ($20.0 < \theta < 36.3°$); 2346 reflections with $I > 3\sigma(I)$ were observed. The intensity data were collected at a temperature of −103°C ± 1°C, using the ω–2θ scan method and monochromatized MoK_α radiation (λ = 0.71069 Å) in the range $2° < \theta < 25°$. To monitor crystal decay, the intensities of three standard reflections were measured after every 200 reflections. An empirical absorption correction was applied (transmission factor: 0.4230–0.9987). The data were corrected for Lorentz and polarization effects and absorption ($\mu(MoK_\alpha)$ = 85.71 cm^{-1}). The structure was solved by direct methods using the TeXsan program package (19). The refinement was by full-matrix least-squares calculations, initially with isotropic and finally with anisotropic temperature factors for the non-hydrogen atoms. H-atoms were included in the model at geometrically idealized positions (C—H 0.95 Å) with a fixed common isotropic temperature factor. The refinement converged with R = 0.038 and R_w = 0.028. Scattering factors were those of Cromer and Mann (20) and Stewart et al. (21). Allowance was made for anomalous dispersion (22). A difference map at the end of the refinement showed no chemically significant features (Δρ of −1.82–1.73 e Å^{-3}, which were close to the W and Se atoms). All crystallographic plots were obtained using ORTEP II (23).

A summary of crystal data is given in Table 1 and atomic positional parameters are given in Table 2. Anisotropic thermal parameters (Table S1), hydrogen positional parameters (Table S2), a full listing of bond distances and bond angles (Table S3), and a listing of calculated and observed structure factors (Table S4) have been deposited as supplementary material.[6]

[6]Supplementary material mentioned in the text can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

Tables of hydrogen positional parameters and of bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Results

*Reaction of WCl$_4$(PPh$_2$Me)$_2$ with MesSe$^-$: preparation of W(SeMes)$_4$·THF (**1**)*

The reaction between WCl$_4$(PPh$_2$Me)$_2$ and sodium mesityl selenolate in THF or DME results in the formation of a deep red solution. Lithium mesityl selenolate, prepared in situ by the addition of butyllithium to a cooled solution of mesityl selenol in THF or DME, gives the same red solution. From this solution, dark red crystals can be obtained by adding an approximately equal amount of *n*-hexane and storing overnight at −20°C. These crystals are very soluble in organic solvents, such as methylene chloride, acetone, or acetonitrile. ^{1}H and ^{13}C NMR spectroscopy confirms the presence of only one selenolate environment. The integration of the THF and aromatic selenolate resonances gives a ratio of four selenolates per molecule of THF. The ^{13}C–{^{1}H} NMR spectrum of the crystals in CD$_3$CN confirms the presence of only one selenolate environment. The ^{77}Se–{^{1}H} NMR spectrum of the red crystals in THF shows a single broad resonance at 1128 ppm (Me$_2$Se = 0 ppm). No coupling between the ^{77}Se nuclei and the ^{183}W nucleus (I = 1/2; 14.4% abundance) is observed. In view of the broadness of the signal this is not too surprising, since the gyromagnetic ratio of tungsten is small (1.1131×10^7 rad T^{-1} s^{-1}); the W–Se coupling constants are generally small since coupling constants are directly proportional to γ for both coupling nuclei (24). Ibers and co-workers reported $^1J_{W-Se}$ between 34 Hz for the diselenene complex [W(Se$_2$C$_2$(COOCH$_3$)$_2$)$_3$]$^{2-}$ (25) and 113 Hz for the coupling of the bridging selenides to one of the tungsten centers in (Ph$_4$P)$_2$[W$_3$Se$_8$O] (26). This shift is much more deshielded than that of d^{10} metal systems of group 12 elements (27, 28). However, similar shifts have been observed for other tungsten(IV) systems, such as for the confacial bioctahedral complex [Cl$_3$W(μ-Se)(μ-SePh)$_2$WCl$_3$]$^{2-}$ (923 ppm) (29), for the mononuclear tungsten-diselenene complex [W(Se$_2$C$_2$(COOCH$_3$)$_2$)$_3$]$^{2-}$ (839 ppm), and for [W$_2$Se$_2$(Se$_2$C$_2$(COOCH$_3$)$_2$)$_4$]$^{2-}$ (1360 ppm) (26). The fact that W(SeMes)$_4$·THF is diamagnetic (based on the observation of sharp and unshifted resonances in the ^{1}H and ^{13}C spectra), is not unexpected. [W(O-2,6-(CH(CH$_3$)$_2$)$_2$C$_6$H$_3$)$_4$] and [W(S-C(CH$_3$)$_3$)$_4$], the only known examples of WX$_4$-type complexes, where X is an anionic ligand, are diamagnetic d^2 species (13). Similarly, the Mo(IV) complexes [Mo(S-C(CH$_3$)$_3$)$_4$)] (11) and [Mo(S-2,4,6-(CH(CH$_3$)$_2$)$_3$C$_6$H$_2$)$_4$] (12) are diamagnetic. It is possible to consider that all four complexes are being derived from a tetrahedron. Distortion from an ideal tetrahedral environment leads to the pairing of the electrons, which renders the complexes diamagnetic. The distortion from ideal T_d symmetry is the largest for [W(O-2,6-(CH(CH$_3$)$_2$C$_6$H$_3$)$_4$], which has the metal center in a nearly square-planar coordination environment.

The spectroscopic evidence and the elemental analysis are compatible with the formulation of the red diamagnetic crystalline material as W(SeMes)$_4$·THF (**1**). **1** crystallizes from solution as very thin plates and all attempts to grow crystals suitable for a single-crystal X-ray diffraction study have failed.

To confirm that **1** is present in the initial reaction solution and to get more information about the formation of **1**, we monitored the reaction between WCl$_4$(PPh$_2$Me)$_2$ and LiSeMes in DME by ^{31}P and ^{77}Se NMR spectroscopy. The ^{31}P NMR spectrum of the reaction solution shows that in the course of the reaction PPh$_2$Me is liberated as expected (^{31}P–{^{1}H} δ of PPh$_2$Me −25.9 ppm). The ^{77}Se NMR spectrum of the reaction solution shows that the resonance due to free mesityl selenolate is absent (^{77}Se{^{1}H} δ of LiSeMes in THF 721 ppm), indicating the consumption of all free selenolate. The red reaction solution contains essentially only one selenium-containing species, which gives rise to a signal in the ^{77}Se NMR spectrum at 1128 ppm; this is identical to the chemical shift of **1**.

*Reaction of W(SeMes)$_4$ with CN^{t}Bu: synthesis of the complex (^{t}BuNC)(MesSe)$_2$W(μ-Se)$_2$W(μ-SeMes)$_2$(CN^{t}Bu) (**2**)*

Since it was not possible to obtain suitable crystals of **1**, we thought that the characterization of a predictable reaction product might provide further evidence for the identity of **1** as the tungsten tetrakis(selenolate).

The two known M(SR)$_4$ systems (Mo(S^{t}Bu)$_4$ and Mo(TIPT)$_4$) react with simple ligands. For example *tert*-butyl isocyanide reduces Mo(S^{t}Bu)$_4$ to give the Mo(II) complex Mo(S^{t}Bu)$_2$(CN^{t}Bu)$_4$ (30). ^{t}BuSS^{t}Bu is a by-product of this reaction. In contrast to that, the aromatic tetrathiolato complex, Mo(TIPT)$_4$ (TIPT = 2,4,6-triisopropylphenylthiolate), resists reduction in the presence of ^{t}BuNC and forms the simple adduct, Mo(TIPT)$_4$(CN^{t}Bu) (12). It was anticipated that the reactivity of **1** would be similar to that of Mo(TIPT)$_4$, leading to a related product.

Addition of LiSeMes to a stirring slurry of WCl$_4$(PPh$_2$Me)$_2$ in DME produced a deep red reaction solution. This solution shows a single resonance in the ^{77}Se {^{1}H} NMR spec-

trum at 1128 ppm, indicating the presence of **1**. Upon the addition of *tert*-butyl isocyanide to the stirring solution, it immediately changed colour from dark red to green. Extraction with *n*-hexane yielded a green solution, which deposited large orange crystals upon cooling to −20°C. These crystals have been identified as (^{t}BuNC)(MesSe)$_2$W(μ-Se)$_2$W(μ-SeMes)$_2$(CN^{t}Bu) (**2**) by X-ray crystallography. **2** crystallizes without any solvent of crystallization in the lattice. The complex is moderately air stable. An ORTEP representation of **2** is shown in Fig. 1. Bond distances and angles are listed in Table 3. **2** is isostructural with (MePh$_2$P)(PhSe)$_2$W(μ-Se)$_2$W(SePh)$_2$(PPh$_2$Me), which has been obtained from the reaction of WCl$_2$(PPh$_2$Me)$_4$ with Me$_3$SiSePh in THF (31) (vide infra). **2** can be described as

For personal use only.

a centrosymmetric dimer with distorted trigonal bipyramidal geometry around each tungsten center, and an overall structure of an edgesharing bitrigonal bipyramid. The two trigonal bipyramids are connected via a common axial edge and not via an equatorial edge. At this point it should be mentioned that the reaction of Otsuka's $Mo(S^tBu)_4$ with PPh_2Me was shown to lead to the formation of (Me_2PhP)-$(^tBuS)_2Mo(\mu\text{-}S)_2Mo(S^tBu)_2(PPhMe_2)$ (30).

Each tungsten center in **2**, formally W(IV), is bonded to two equatorial mesityl selenolates, an axial isocyanide, and two Se atoms that bridge the two W atoms. Both mesityl substituents of the selenolates are pointing up towards the axial isocyanide. This geometry maximizes the π-type interaction between the lone pair on the selenolates with the empty $d_{x^2-y^2}$ orbital of the metal center. However, this geometry causes steric congestion and is probably the cause for the ^{t}Bu group of the isocyanide ligand bending away from the mesityl rings (C(1)—N(1)—C2) = 168(1)°). The W(1)—C(1)(isocyanide) distance (2.11(1) Å) is similar to those reported for the seven coordinated W(II) isocyanide complexes, $[W(CN^tBu)_7]^{2+}$ (range 2.069(6)–2.142(8) Å; mean 2.108 Å) (32) and $[(^tBuNC)_3W(CO)_2I_2]$ (2.092(13), 2.145(13), 2.099(13) Å) (33). The W—Se (selenolate) and Se—C distances are comparable to those observed for $W_2(SeMes)_6$, $W_2(O^iPr)_2(SeMes)_4$ (10), and η^7-$C_7H_7W(CO)_2$-SePh (9). The W—Se—C angles are significantly larger than those observed for the aforementioned tungsten–selenolate complexes.

The selenide bridge is asymmetric, with the W(1)—Se(1) and W(1)—Se(1*) distances differing in length by 0.123 Å. The W_2Se_2 cores of the polyselenide complexes $W_2Se_9^{2-}$ and $W_2Se_{10}^{2-}$ show a similar distortion of the bridging region (26). The W(1)—W(1*) separation of 2.732(1) Å and the diamagnetism of the complex indicate the presence of an attractive metal–metal interaction. However, the W(IV)—W(IV) separation is longer than expected for a formal W=W double bond (34).

For spectroscopic purposes, the crystals were dissolved in $CDCl_3$ to give a green solution. The ^{1}H NMR spectrum shows a single sharp resonance for the aromatic protons of the mesityl selenolate with a chemical shift of 6.83 pm and two signals for the methyl substituents at 2.35 and 2.27 ppm. In addition, there is a singlet for the isocyanide ^{t}Bu group at 1.45 ppm. The methyl protons of the ^{t}Bu groups are somewhat more shielded than in the thiolato complex $Mo(S^tBu)_2(CN^tBu)_4$ (δ 1.98) (30).

The ^{13}C–$\{^1H\}$ NMR signal for the ^{t}Bu group appears at 31.5 ppm, which is deshielded compared to free ^{t}BuNC. However, this is comparable to values obtained for $Mo(S^tBu)_2(CN^tBu)_4$ (δ 31.4, 30.8) and the related acetylene complexes $Mo(S^tBu)_2(CN^tBu)_2(HCCH)$ (δ 30.3), $Mo(S^tBu)_2(CN^tBu)_2(HCCPh)$ (δ 29.7, 30.3), and $Mo(S^tBu)_2(CN^tBu)_2(PhCCPh)$ (δ 29.8) (35, 36). The ^{14}N NMR spectrum of **2** reveals a broad resonance at −170 ppm ($\nu_{1/2}$ = 162 Hz), deshielded compared to free ^{t}BuNC (−185 ppm). The IR spectrum of **2** shows a strong ν(NC) band at 2141 cm^{-1}. The ^{77}Se NMR spectrum shows two resonances, but the position of the signals is surprising compared to that of known tungsten–selenide–selenolate species (25, 26, 29). A very sharp resonance appears at 508 pm ($\nu_{1/2}$ = 10 Hz); a second resonance appears at 369 ppm ($\nu_{1/2}$ = 15 Hz). The ratio of the two signals is approximately 1:2, so that we tentatively assign the resonance at 508 ppm to μ-Se and the resonance at 369 ppm to -SeMes. Unfortunately, the quality of the spectrum does not permit a definite assignment of coupling constants ($J_{^{183}W-^{77}Se}$).

The formation of **2** might be rationalized by assuming that $W(SeMes)_4$ will react similarly to $Mo(TIPT)_4$ with CN^tBu. A plausible first step may involve adduct formation to give the five-coordinate 12-electron species $W(SeMes)_4(CN^tBu)$. The documented lability of the Se—C bond, even for Se—C(aryl) bonds, (29, 31, 37) can then lead to Se—C bond cleavage and formation of a selenido species, which can dimerize to give **2**. Since only a handful of homoleptic thiolato complexes of group 6 metals are known, direct quantitative comparisons between M—S—C and analogous M—Se—C are not yet possible. However, based on results by Schrock and co-workers (12, 13) and Otsuka and co-workers (30) and our own studies, we come to the conclusion that in terms of the tendency towards chalcogen–carbon bond cleavage the Se–aryl bond closely resembles the S–alkyl bond. A more detailed theoretical comparative analysis will be necessary to evaluate this problem in more detail. We will continue our efforts in the search for homoleptic selenolato complexes of the early transition metals.

MONIQUE PERRIN, ALAIN THOZET, PILAR CABILDO, ROSA MA CLARAMUNT, EDUARD VALENTI, and JOSÉ ELGUERO. Can. J. Chem. **71**, 1443 (1993).

The title compound $C_{12}N_6H_{14}$, **1**, crystallizes in the space group $P2_1/n$ (a = 8.222(2) Å, b = 27.336(8) Å, c = 5.574(2) Å, α = 90.00°, β = 100.97(4)°, γ = 90.00°), Z = 4, d = 1.308 g cm^{-3}. The conformation about the N—C bonds linking the pyrazole rings can be defined as *EZ*, with "pyridine-like" nitrogen atoms in an *anti* disposition (ϕ_1 = −155.3(3)°) and "pyridine-like" and "pyrrole-like" nitrogen atoms in a *syn* disposition (ϕ_2 = −6.2(5)°), with regard to the central pyrazole. Intermolecular hydrogen bonds between the central and the terminal pyrazole ring of configuration *Z* form centrosymmetric dimers. They pack in sheets nearly parallel to the (−2 3 1) plane. Its tautomerization barrier has been determined in methanol-d_4; the value, 11.9 kcal mol^{-1}, is similar to those of 3,5-dimethyl-4-chloropyrazole (12.8 kcal mol^{-1}) and 3,5-dimethyl-4-nitropyrazole (12.1 kcal mol^{-1}). These values together with the shape of the conformational potential surface (calculated using the AM1 Hamiltonian) suggest that, in compound **1**, prototropy and rotation about the N—C bonds linking the three pyrazole rings take place simultaneously.

MONIQUE PERRIN, ALAIN THOZET, PILAR CABILDO, ROSA MA CLARAMUNT, EDUARD VALENTI et JOSE ELGUERO. Can. J. Chem. **71**, 1443 (1993).

3,5-Bis(4-methylpyrazol-1-yl)-4-methylpyrazole **1**, $C_{12}N_6H_{14}$, cristallise dans le groupe spatial $P2_1/n$ (a = 8.222(2) Å, b = 27.336(8) Å, c = 5.574(2) Å, α = 90.00°, β = 100.97(4)°, γ = 90.00°), Z = 4, d = 1.309 g cm^{-3}. La conformation autour des deux liaisons N—C qu'unissent les trois noyaux de pyrazole peut être définie comme *EZ*, avec les atomes d'azote du type pyridinique dans une disposition *anti* (ϕ_1 = −155.3(3)°) et les atomes d'azote pyridinique et pyrrolique dans une disposition *syn* (ϕ_2 = −6.2(5)°) par rapport au pyrazole central. Des liaisons hydrogène intermoléculaires entre un pyrazole central et un pyrazole lateral de configuration *Z* forment des dimères centrosymétriques. L'enchaînement intermoléculaire donne lieu à des feuilles presque parallèles au plan (−2 3 1). La barrière à la tautomérie a été mesurée dans méthanol-d_4; la valeur obtenue, 11.9 kcal mol^{-1} est analogue à celles du 3,5-diméthyl-4-chloropyrazole (12.8 kcal mol^{-1}) et du 3,5-diméthyl-4-nitropyrazole (12.1 kcal mol^{-1}). Ces valeurs ainsi que la forme de la surface de potential (calculée avec la méthode AM1) suggèrent que dans le composé **1**, prototropie et rotation autour des laisons N—C unissant les trois noyaux de pyrazole, ont lieu simultanement.

Our interest in polydentate ligands led us to prepare and study the rhodium(I) complexes of 3,5-bis(4-methylpyrazol-1-yl)-4-methylpyrazole **1** (1), but the structure of the ligand itself was not determined. We describe here its molecular structure and a detailed NMR and semi-empirical study of the annular tautomerism involving the nitrogen atoms of the central ring. This molecule presents an interesting case in which tautomerism of the central ring is linked to conformational isomerism of the lateral pyrazoles.

Chemistry

3,5-Bis(4-methylpyrazol-1-yl)-4-methylpyrazole **1** was first prepared by bromination of 4-methylpyrazole (2) although its correct structure was established afterwards (3). Compound **1**, together with 3,5-bis(4-chloropyrazol-1-yl)-4-chloropyrazole (obtained by chlorination of pyrazole) (4), are the only representatives of this class of polydentate ligands. In fact, halogenation of pyrazoles unsubstituted on the nitrogen is a rather complex reaction (5–7). If position 4 of an *N*H-pyrazole is unsubstituted, then the reaction proceeds normally and the 4-bromo derivative is obtained. When position 4 is substituted, then an *N*-bromopyrazole is formed. These last compounds have been isolated in some cases but, normally, they rearrange to 5-bromopyrazoles, either by an intramolecular shift or, more probably, by an intermolecular mechanism (4). *N*-Bromopyrazoles are generally considered brominating agents (pz^- Br^+) but, owing to the pseudohalogen character of the pyrazol-1-yl substituent, they can react as "pyrazolating" agents (pz^+ Br^-). This explains the formation of *N*–*C* dimers (2, 4). If R = H, they can be further "pyrazolated" and trimers **1** result (2–4). If $R \neq$ H, *N*-bromination leads to a cyclic trimer (2, 8, 9). Finally, if

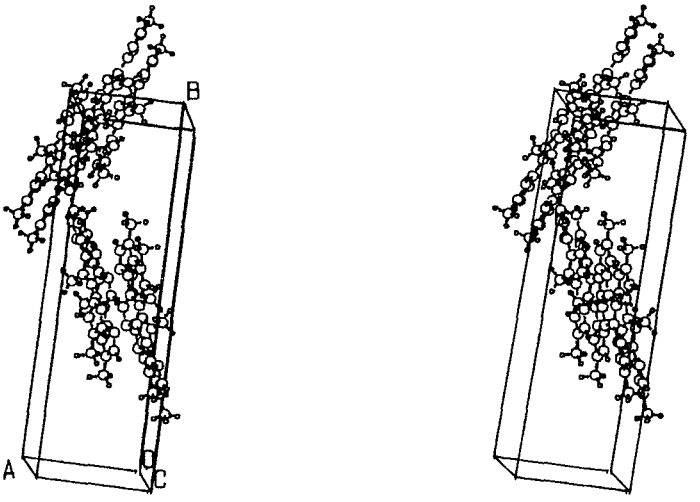

FIG. 2. Stereodrawing of the two dimers.

the substituents *R* and *R'* are too bulky, such as in campho[*c*]pyrazole, then, instead of trimers, only a *C*-brominated pyrazole is obtained.[2]

Stepwise preparation of *N–C* dimers (useful building blocks for supramolecular structures) is conveniently carried out using 3(5)-hydrazinopyrazoles (10). Although possible in principle, the stepwise preparation of trimers **1** is not known and some preliminary attempts indicated that it would involve some difficulties. Thus, we have optimized Hüttel's synthesis (2) (see experimental part) to improve the yield of compound **1** (R = CH_3).

Crystal and molecular structure of compound 1

Figure 1 shows the numbering scheme for compound **1** and Fig. 2 is a stereoview of the two dimers. Bond lengths and angles are listed in Tables 1 and 2. The three pyrazole rings can be considered as planar (to within ±0.01 Å). The angle between rings 1 and 2 is 23.6(1)° and that between rings 2 and 3 is 6.3(1)°. The related torsional angles are N6—N1—C6—N2 = −155.3(3)° and N4—C1—N3—N5 = −6.2(5)°. The three pyrazole rings deviate from C_{2v} symmetry (11), their geometry being quite similar to that of other pyrazoles (12).

The five most characteristic hydrogen bond interactions are summarized in Table 3 and the hydrogen bond network

is represented in Fig. 3. Two strong intermolecular N—H···N interactions hold together the two molecules of the dimer. The two C—H···N intermolecular bonds, although weaker, also contribute to the stabilization of the dimer. In pyrazoles formed by only one ring, cyclic dimers, trimers, and tetramers are formed by N—H···N hydrogen bonds of the same pyrazole (13). In the case of compound **1**, this situation would correspond to intermolecular N4—H2···N5 hydrogen bonds. The reason this "standard" situation is not followed in compound **1** may be related to the possibility of an extra stabilization due to C5—H5···N2 hydrogen bonds. From the intramolecular hydrogen bonds, the one between the methyl group and the adjacent nitrogen atom belongs to the class of weak C—H···N interactions that are related to the stabilization of one of the conformations of the methyl groups (14). The N4—H2···N5 is weaker than the intramolecular hydrogen bond of the same proton; in particular, the angle is not very favorable for the interaction (15). The situation corresponds to a 3-centered hydrogen bond (a theoretical study of water

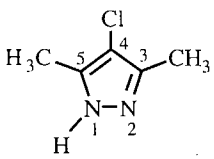
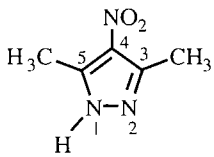
[b]Me4 = C11, Me4′ = C7, Me4″ = C12.

^{1}H NMR study of the prototropy of compound 1 and related pyrazoles

Very few activation energies for pyrazole tautomerism have been reported. Grant and co-workers (17) determined the values for pyrazole itself and for 3,5-dimethylpyrazole in hexamethylphosphorotriamide (HMPA): 14 and 15 kcal mol^{-1}, respectively. We report in Table 4 the results obtained in the case of compound **1** and for 3,5-dimethyl-4-chloropyrazole **2** and 3,5-dimethyl-4-nitropyrazole **3**. The preparation of compounds **2** and **3** is described in the literature (5).



2



3

In methanol-d_4, the three barriers are similar and a little lower than in HMPA, which is normal taking into account the strong solvating properties of the latter. The results of Table 4 correspond to N-D pyrazoles and a small primary isotope effect is included in the value of $\Delta G^{\neq}$ (the values reported by Nesmeyanov *et al.* (18) for isotope effects on the tautomerism of pyrazoles are probably much exaggerated).[3]

Semiempirical calculations of the potential surface of compound 1

Tautomerism between the *a* and *b* forms of compound **1** involves the rotation of the two pyrazole rings about the C3(5)—N bonds. To explore if this rotation is simultaneous or consecutive to the prototropy, we decided to analyze the complete potential conformational hypersurface. The semiempirical SCF-MO AM1 method (19*a–c*) was selected because of its ability to reproduce the experimental strength of hydrogen bonds (19*b*). The surface was explored by rotating ϕ_1 and ϕ_2 every 30° (Fig. 4), while forcing the planarity of each pyrazole ring. The absolute minimum lies at ϕ_1 = 162.85° and ϕ_2 = 32.92° near the molecular structure found in the crystal (ϕ_1 = −155.3(3)°, ϕ_2 = −6.2(5)°). Both correspond to a conformation that can be denoted *EZ*, with "pyridine-like" nitrogen atoms in the *anti* disposition and "pyridine-like" and "pyrrole-like" nitrogen atoms of the central pyrazole in a *syn* disposition.

This molecule can adopt four planar conformations (Scheme 1), which are useful for the following discussion. $\delta\Delta H_f$ is the difference, in kcal mol^{-1}, of the heats of formation of the absolute minimum (ΔH_f = 209.474 kcal mol^{-1}) and each one of the four conformations. Those four planar conformations are not local minima of the AM1 hypersurface as the structures are not fully minimized. It should be noted that planarity has been forced within the five atoms of each pyrazole ring, and thus the differences in energy with the absolute minimum would not only be due to changes in ϕ_1 and ϕ_2 but to the inability of the pyrazole rings to distort as well. However, this contribution is negligible except for ϕ_1 = ϕ_2 = 0°, a conformation for which the contribution can be evaluated as 1.70 kcal mol^{-1}. In this case, distortion relieves steric hindrance between the methyl group of the central pyrazole ring and the adjacent 5′ hydrogens.

The tautomerization/isomerization process (from ϕ_1 = 162.85 and ϕ_2 = 32.92° to ϕ_1 = 197.18 and ϕ_2 = 327.08°) through the transition state *ZE* requires an activation energy of 2.14 kcal mol^{-1}. (This value corresponds to a full optimisation of the absolute minimum and the transition state.) The different values of $\delta\Delta H_f$ of Scheme 1 roughly represent two kinds of repulsive interactions: N lone pair/N lone pair (ϕ_1 = 0°) and N—H/C—H (ϕ_2 = 180°). These interactions amount to 3.0 and 2.1 kcal mol^{-1}, respectively, values that must be considered at the uppermost limit due to the lack of complete optimization. In rhodium(I) dinuclear complexes (1), the N lone pair/N lone pair interaction becomes attractive and the structure of the pyrazolate ligands corresponds to the *ZZ* conformation.

Tautomerization without rotation of the lateral pyrazole rings leads to a conformation ϕ_1 = 32.92, ϕ_2 = 162.85°. To this *ZE*-like structure corresponds an $\delta\Delta H_f$ of 4.9 kcal mol^{-1}. Since the activation energy (see NMR discussion) is similar to those of other pyrazoles where there is no need to account for rotational isomerism, the conclusion is that in compound **1** the rotation of the lateral pyrazole rings should

be synchronous with prototropy. Although the energy required to rotate the 3- and 5-pyrazolyl substituents and the conformations of minimum energy are not known for the transition state of the prototropy (where there is no longer an NH and an N atom with a lone pair (20)), the conclusion of synchronicity is probably true.

Experimental section

Preparation of 3,5-bis(4-methylpyrazol-1-yl)-4-methylpyrazole (1)

4-Methylpyrazole was prepared in 70% yield from hydrazine and methylmalonaldehyde tetraethylacetal (21; see ref. 5, p. 407). Following Hüttel's procedure (2) but with a 4-methylpyrazole (2.46 g)/bromine (1.6 g) 3:2 stoichiometry and 3 h reflux, 1.16 g of compound **1** was obtained, yield 48% (Lit. (2) yield 24%); mp 165–166°C (lit. (2) mp 167–168°C). Anal. calcd for $C_{12}N_6H_{14}$: C 59.48, H 5.82, N 34.69; found: C 59.27, H 5.93, N 34.73.

X-ray crystallography

Table 5 shows the crystal analysis parameters. Crystals were obtained by slow evaporation of a dichloromethane–hexane solution. The intensities collected on the diffractometer were corrected for Lorentz and polarisation factors. An empirical absorption correction was applied using the measurement of Ψ scans. The SDP (22) system was used for initial computation. The crystalline structure was solved by direct methods using MULTAN (23) and SHELX-76 (24). The nonhydrogen atoms were refined, allowing for isotropic and then anisotropic vibrations. The hydrogens of the methyl groups were included at calculated positions and were refined first as a rigid group, then freely. The other hydrogens were found on a difference map. In each case, isotropic thermal parameters were kept fixed. Geometrical computations were done with PARST (25), and plots were made with PLUTO (27).[4]

NMR measurements

The variable temperature proton NMR spectra were recorded on a Bruker AC 200 spectrometer operating at 200.13 MHz in a 5-mm dual probe with CD_3OD as solvent. The temperature of the probe was calibrated by the methanol standard method and there was a delay of 15 min before registering the NMR spectra at each temperature. The rotational barriers were measured by line shape analysis of the signals of protons H3 and H5 in the case of compound **1** and Me3 and Me5 signals in the case of compounds **2** and **3** (27). The middles of the signals of compound **1** at low temperature (H3′ and H3″, 7.885 ppm; H5′ and H5″, 8.12 ppm) are slightly different from the averaged values at room temperature (7.77 and 8.01 ppm).

Computational details

Calculations were performed on a VAX-8350 belonging to "Laboratorios Dr. Esteve", with the standard version of AM1 (19*a*), as implemented in the MOPAC package of programs (19*c*). The RHF method was used throughout. The geometries of the conformational hypersurface points were determined by minimizing the energy with respect to all geometrical variables except for the three that define ϕ_1 and ϕ_2, and for those that maintain the planarity of the pyrazole rings (10 extra dihedral angles were set to 0° or 180°), using the BFGS algorithm until the gradient norm of the energy was less than 1.0. The absolute minimum was determined by minimizing the energy with regard to all geometrical variables from the lower energy points in the conformational hypersurface.

Acknowledgment

MARK L.J. REIMER, JOHN B. WESTMORE, and MANORANJAN DAS. Can. J. Chem. **71**, 1450 (1993).

Electron ionization positive-ion mass spectra are reported for 18 substituted nickel(II) β-diketonates and monothio-β-diketonates, $Ni^{II}(RCXCHCOR')_2$, where X = O or S; R = phenyl, 2-thienyl, 5-methyl-2-thienyl, or 2-naphthyl; and R′ = difluoromethyl, trifluoromethyl, pentafluoroethyl, or *n*-heptafluoropropyl. Each mass spectrum contains a prominent molecular ion, $[NiL_2]^+$, which, for β-diketonates, fragments mainly by elimination of the odd-electron R″˙ species; the resulting ion decomposes by losses of one or more even-electron neutral species to yield ions containing nickel(II). In contrast, the major fragmentation of the molecular ion of monothio-β-diketonates is loss of $Ni^{I}L$ to yield an abundant L^+ ion. Furthermore, while most ions contain nickel(II), some prominent ions contain nickel(I); among these are $[Ni^{I}SC(R)=CH]^+$ and $[Ni^{I}(HCCR)]^+$. Interesting ions are formed by hydrogen transfer processes. The $[NiHL]^+$ ion is favored in the spectra of β-diketonates having a phenyl substituent, consistent with hydrogen transfer to the metal from the aryl group. On the other hand, the $[Ni(L-H)]^+$ ion, favored for the monothio-β-diketonates, could be formed by hydrogen transfer from the central position of the chelate ring or from an aryl substituent. Alternative mechanisms of formation are discussed. Some minor ions are formed by fluorine transfer to nickel. The trends in their abundances are influenced by the hardness of nickel as an acid in its different oxidation states, under the influence of the ligand donor atoms, and by the hardness of the carbon atoms of the perfluoroalkyl substituents.

MARK L.J. REIMER, JOHN B. WESTMORE et MANORANJAN DAS. Can. J. Chem. **71**, 1450 (1993).

On a déterminé les spectres de masse des ions positifs par ionisation électronique de 18 β-dicétonates et monothio-β-dicétonates de nickel(II), $Ni^{II}(RCXCHCOR')_2$, dans lesquels X = O ou S; R = phényle, 2-thiényle, 5-méthyl-2-thiényle ou 2-naphtyle; et R′ = difluorométhyle, trifluorométhyle, pentafluoroéthyle ou *n*-heptafluoropropyle. Chaque spectre de masse comporte un ion moléculaire important, $[NiL_2]^+$, qui, pour les β-dicétonates, se fragmente principalement par élimination de l'espèce R″˙ à électron célibataire; l'ion qui en résulte se décompose par perte d'une ou de plusieurs espèces neutres comportant un nombre pair d'électrons, pour fournir des ions contenant du nickel(II). Par opposition, la fragmentation principale de l'ion moléculaire des monothio-β-dicétonates comporte une perte de $Ni^{I}L$ qui conduit à un ion L^+ abondant. De plus, alors que la plupart des ions contiennent du nickel(II), quelques ions importants contiennent du nickel(I); parmi ceux-ci, on remarque le $[Ni^{I}SC(R)=CH]^+$ et le $[Ni^{I}(HCCR)]^+$. Il se forme des ions intéressants par des processus de transfert d'hydrogène. L'ion $[NiHL]^+$ est favorisé dans les spectres des β-dicétonates possédant un substituant phényle; ce résultat est en accord avec un transfert d'hydrogène du groupe aryle vers le métal. D'autre part, l'ion $[Ni(L-H)]^+$, favorisé pour les monothio-β-dicétonates, pourrait se former par un transfert d'hydrogène de la position centrale du cycle chélate ou d'un substituant aryle. On discute des mécanismes alternatifs à ces formations. Il se forme des ions mineurs par transfert de fluor vers le nickel. Les tendances dans les abondances sont influencées par la dureté du nickel, agissant comme acide dans ses différents états d'oxydation, sous l'influence d'atomes ligands donneurs et par la dureté des atomes de carbone des substituants perfluoroalkyles.

[Traduit par la rédaction]

Introduction

We pointed out in the previous publication (1) that many metal β-diketonates are thermally stable and have sufficient volatility for study by gas chromatography (2). Because of these properties, they have recently been used as precursors for chemical vapor deposition (3–5), a promising technique for the preparation of thin films of high T_c superconducting oxides (6). The alkaline earth complexes used for this purpose have been characterized by mass spectrometry (7). Analytical methods can also be devised for metals by combining mass spectrometry with gas chromatography.

The mass spectra of these complexes are of interest in their own right because the wide variety of compounds available permits assessment of the influence exerted by bonding and structure factors, i.e., (*i*) the central metal atom, (*ii*) the ligand donor atoms, and (*iii*) different organic substituents attached to the ligand. Conversely, because of this, the mass spectra can often be used to draw conclusions about the condensed phase chemistry of the metals. Much of the early mass spectral work, starting from the first extended study (8), has been reviewed (9–12).

The electron ionization (EI) positive-ion mass spectra of organic compounds often show an abundant molecular ion ($M^{+\cdot}$), which initially eliminates an odd-electron ($OE^{\cdot}$) neutral species; generally, the resulting ion then loses one or more even-electron (EE^0) neutral species. In the case of transition metal compounds the odd- ($OE^{+\cdot}$) or even-electron (EE^+) character of the metal-containing ions can be altered by a formal change of the oxidation state of the metal (8, 13, 14). For example, we may depict the molecular ion, $[NiL_2]^+$, of a nickel complex either as $[Ni^{II}L_2]^{+\cdot}$ or as

$[Ni^{III}L_2]^+$ by formal movement of an electron between nickel and ligand (L).

While the major features of the mass spectra of complexes of many metals conform to a number of broad generalizations including, for example, the relative stabilities of metal oxidation states, there are often more subtle features associated with a particular metal or ligand. These features include the formation of new bonds between the metal and an atom, or substituent, originally part of the ligand. Thus, formation of metal–hydrogen, metal–halogen, or metal–carbon bonds has been noted in the reviews cited above. In the case of nickel, there is a marked tendency for formation of nickel–hydrogen bonds. In this paper we present the EI mass spectra of a series of fluorinated β-diketonate complexes of nickel(II), having the general form $Ni^{II}(RCXCHCOR')_2$, as listed in Table 1. Particularly noteworthy in these spectra are the $[NiHL]^+$ and $[Ni(L-H)]^+$ ions, which result by hydrogen transfer either from the aryl substituent or from the central position of the chelate ring; for these ions mechanisms of formation are suggested. In contrast, ions arising by fluorine transfer to nickel are of limited number and of low abundance. While the prominent ions in the spectra can be assigned structures containing Ni(II), there are also ions for which the less favored, but well-known, Ni(III) or Ni(I) states seem more reasonable. Trends in observed ion abundances are interpreted in light of the ability of nickel to undergo a change in valency, the principle of Hard and Soft Acids and Bases (HSAB), and the inductive effects of the ligand donor atoms and of the R and R′ groups. We have discussed these concepts previously (1). For two compounds ion decomposition pathways were supported by linked electric–magnetic field scans. The work described here is a continuation of our survey of transition metal β-diketonate and monothio-β-diketonate complexes.

Experimental

Mass spectrometry

For these studies a VG 7070E-HF double-focusing (EB geometry) mass spectrometer (VG Analytical Ltd., Manchester, England) equipped with a data system based on a DEC PDP-11/73 microcomputer (Digital Equipment Corp., Maynard, Mass.) was used. Samples were admitted to the ion source on a direct insertion probe. In many cases ambient heating from the ion source was sufficient to obtain steady evaporation and reproducible mass spectra; in other cases the probe temperature was raised but it never exceeded 100°C. Low-resolution EI mass spectra were recorded under the following conditions: ion accelerating voltage, 6 kV; ionizing energy, 70 eV; trap current, 200 μA; source temperature, 200°C, scan rate, 1.0 s/decade; resolution, 1400 (10% valley definition). Ion decomposition mass spectra of selected ions in the spectra of **2***a*, **3***a*, and **3***b* were recorded by linked scanning, at a scan rate of 5.0 s/decade, as follows: (*a*) product ion scans at a constant magnetic field/electric field ratio (i.e., B/E constant with accelerating voltage (V) fixed), and (*b*) constant neutral loss scans such that $B[1-(E/E_0)]^{1/2}/E$ was constant, with V fixed. Precursor ions were collisionally activated in the first field-free region of the instrument by adjusting the helium pressure in the collision cell to achieve approximately 50% attenuation of the parent ion signal.

Ligand synthesis

The fluorinated β-diketones used in the syntheses of complexes **3***a* and **4***a* were purchased from Aldrich Chemical Co. (Milwaukee, Wis.). The remaining β-diketones were synthesized by a Claisen condensation of the appropriate methyl ketone ($RCOCH_3$) with the fluorinated ethyl ester ($R'COOC_2H_5$), as previously described (15, 16). The fluorinated monothio-β-diketones were synthesized from their corresponding β-diketones (16–20).

Synthesis of nickel chelates

(a) β-Diketonates

Upon addition of nickel(II) acetate tetrahydrate (0.22 mmol) in water (5 mL) to a solution of the ligand (0.44 mmol) in absolute ethanol (3 mL) a cloudy, pale green suspension formed. The suspension was heated on a steam bath for 15 min and then cooled in an ice bath for 1 h. The precipitate was filtered off under mild suction, washed with cold water, and dried in an oven (100°C) for 3 h to give the desired product (15, 21).

(b) Monothio-β-diketonates

Nickel(II) acetate tetrahydrate (0.5 mmol) in hot ethanol (10 mL) was added to a solution of the ligand (1.0 mmol) in ethanol (5 mL). The resulting brown precipitate was filtered off and recrystallized from a 1:1 acetone/light petroleum (bp 40–60°C) solution. The products were dark brown solids (20, 22–24).

Results and discussion

Although these complexes may exist as polymeric species in the solid state, the mass spectra indicate that they vaporize as monomers; thus, no trace of polymeric ions could be detected in the mass spectra of **2***a* and **3***a* when scanning to an upper mass limit greater than twice the molecular mass. Neither was $[NiL_2H]^+$ observed. Thus, there is no evidence for species that could have been formed by ionization of polymeric neutrals, or by ion-neutral reactions.

Nickel(II) β-diketonates

Table 2 lists assignments and relative abundances for significant ions in the mass spectra of the nine Ni(II) β-diketonates; representative mass spectra are shown in Fig. 1. The mass spectrum of **4***a* agrees well with one reported previously (25). Also obtained for **2***a* (but not shown) were product ion mass spectra of collisionally activated $[NiL_2]^+$, $[Ni^{II}L(L-R')]^+$, and $[Ni^{II}L]^+$ ions.

[a]Relative abundances are calculated for the m/z values cited, which are the biggest signals for the group of peaks corresponding to the listed ion type. Thus, a correction factor should be applied to calculate the true relative abundance ratios among nickel-containing and nickel-free ions.

[b]Since these abundances are calculated as indicated in footnote [a] their values will be lower when a contribution from isotopes of an ion type of lower mass are significant. For $[HL]^+$ the correction is negligible.

[c]Probably CF_3^+, except for **1***a* and **2***a*, for which the assignment can be $C_3HO_2^+$.

1*a* and **2***a* (R′ = CHF_2; Fig. 1(*a*) shows the mass spectrum of **2***a*). The two most abundant nickel-containing ions are $[NiL_2]^+$ and $[Ni^{II}L(L-R')]^+$, the latter formed from $[Ni^{II}L_2]^{+\bullet}$ by elimination of the OE$^\bullet$ radical $CHF_2^\bullet$ (R″) (confirmed for **2***a* by the product ion spectrum of $[NiL_2]^+$). A product ion scan also confirmed subsequent consecutive EE^0 neutral losses of (L−R′) and (L−R) from $[Ni^{II}L(L-R')]^+$ to give $[Ni^{II}L]^+$ and $[Ni^{II}R]^+$, respectively. We can also propose a parallel pathway of EE^0 eliminations of (L−F), HF, and C_3O_2 to give $[Ni^{II}F(L-R')]^+$, $[Ni^{II}(L-CHF-HF)]^+$, and $[Ni^{II}R]^+$, respectively. The $[Ni^{II}L]^+$ ion, which is probably also directly formed from $[Ni^{II}L_2]^{+\bullet}$ by loss of L$^\bullet$, decomposes by loss of CO, to give $[Ni^{II}(L-CO)]^+$ (confirmed for **2***a* by the product ion scan) or by loss of :CHF, to give $[Ni^{II}F(L-R')]^+$. Although not supported here, the latter decomposition has been confirmed for an analogous cobalt complex by a product ion scan (1). The formation of the bare Ni^+ ion, which has also been reported in the mass spectrum of nickel(II) acetylacetonate (26, 27), confirms that reduction of nickel(II) has occurred. A probable formation route is by loss of (L−R′) and F$^\bullet$ from $[Ni^{II}F(L-R')]^+$, since we have confirmed the analogous decomposition for a similar cobalt complex (1). We infer that the nickel-free $[L-2F]^+$ and $[L-CO-2F]^+$ ions are formed by losses of the neutral species $Ni^{II}F_2$ from the $[Ni^{II}L]^+$ and $[Ni^{II}(L-CO)]^+$ ions, respectively. Precedents for such reactions are known (28) but our attempts to confirm these decompositions by product ion scanning were unsuccessful.

We note, for later discussion, the presence of $[NiHL]^+$ and $[Ni(L-H)]^+$ ions, formed from $[NiL_2]^+$ by hydrogen transfer reactions.

Scheme 2 shows fragmentation pathways proposed for **3***a*, **4***a*, and **5***a* (R′ = CF_3; Fig. 1(*b*) shows the mass spectrum of **4***a*). Once again, the major nickel-containing ions are $[NiL_2]^+$ and $[Ni^{II}L(L-R')]^+$. Many of the mechanisms discussed for Scheme 1 in the preceding paragraph still apply. A new decomposition pathway involves sequential elimination of the EE^0 neutrals CO_2, HCCR, and :CF_2 from $[Ni^{II}L(L-R')]^+$ to give $[Ni^{II}L(HCCR)]^+$, $[Ni^{II}L]^+$, and $[Ni^{II}F(L-R')]^+$, respectively (although elimination of :CF_2

*decomposition confirmed for **2***a* by product ion scan
⇒ step involving metal valence change

SCHEME 1. Fragmentation pathways proposed for compounds **1***a* and **2***a* (R′ = CHF_2).

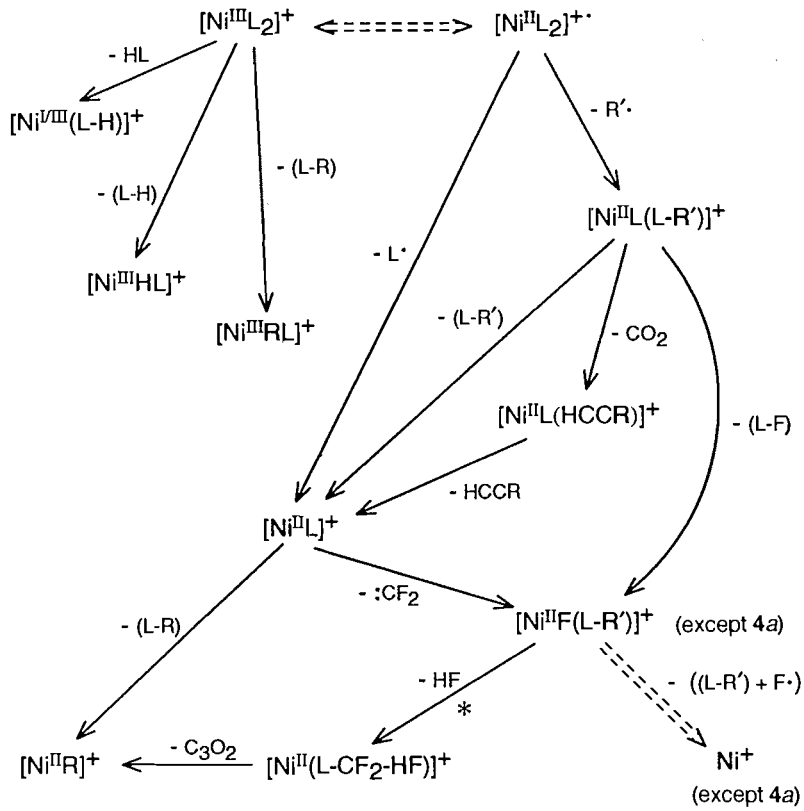
mimics loss of :CHF, noted above). For **3***a*, elimination of HF from $[Ni^{II}F(L-R')]^+$ has been confirmed by a product ion scan. It is interesting that the proposed, partially supported, stepwise eliminations of $:CF_2$ and HF from $[Ni^{II}L]^+$ have been confirmed from the analogous $[Co^{II}L]^+$ ion, even though elimination of CHF_3 is more favorable energetically. The formation of $[Ni^{III}RL]^+$ from $[NiL_2]^+$ by the loss of (L−R) implies formation of a nickel–carbon bond, and has a parallel in the mass spectrum of a similar cobalt complex (R = C_4H_3S, R′ = CF_3) (1). In contrast to **1***a* and **2***a*, the presence of $[Ni^{II}F(L-R')]^+$ is the only evidence supporting transfer of fluorine to nickel; nickel-free ions formed by elimination of NiF_2 are not observed.

Scheme 3 shows fragmentation routes suggested for **6***a*, **7***a* (R′ = C_2F_5), **9***a*, and **10***a* (R′ = *n*-C_3F_7). (The mass spectra of **7***a* and **10***a* are shown in Figs. 1(*c*) and 1(*d*).) As before, the major nickel-containing ions are $[NiL_2]^+$ and $[Ni^{II}L(L-R')]^+$. A new feature is the loss of the OE· neutral F· from $[NiL_2]^+$ to yield the low-abundance $[Ni^{II}L(L-F)]^+$ ion that, in turn, can lose the EE^0 neutral CO to give $[Ni^{II}L(L-COF)]^+$. For **6***a* and **7***a*, a minor ion formed by elimination of $:CF_2$ from $[NiL_2]^+$ indicates fluorine-to-nickel transfer.

Ni(II) Monothio-β-diketonates

Table 3 lists ion assignments and relative abundances for significant ions in the mass spectra of the nine Ni(II) monothio-β-diketonates; as examples of representative mass spectra those of **4***b*, **7***b*, and **10***b* are shown in Fig. 2. The mass spectra of **3***b* and **4***b* agree well with those previously reported (24). Also obtained for **3***b* (but not shown), and used in the elucidation of fragmentation pathways, were product ion mass spectra of collisionally activated $[NiL_2]^+$, $[Ni^{II}L(L-R'CO)]^+$, $[Ni^{II}L]^+$, and $[Ni^{I}SC(R)=CH]^+$ ions.

Scheme 4 shows decomposition pathways proposed for **3***b*, **4***b*, and **5***b* (R′ = CF_3; Fig. 2(*a*) shows the mass spectrum of **4***b*). In each spectrum, $[NiL_2]^+$ is the most abundant nickel-containing ion, but L^+ gives rise to the base peak for **3***b* and **4***b*; in the case of **3***b* the product ion mass spectrum indicates that L^+ is formed from $[NiL_2]^+$ by elimination of $Ni^{I}L$. We have proposed (1) that L^+ adopts a cyclic structure that is highly stabilized by the presence of sulfur. From $[NiL_2]^+$, losses of the OE· neutrals F·, R″·, and L· yield the $[Ni^{II}L(L-F)]^+$, $[Ni^{II}L(L-R')]^+$, and $[Ni^{II}L]^+$ ions, respectively. The pathway $[Ni^{II}L(L-R')]^+ \rightarrow [Ni^{II}L(L-R'CO)]^+ \rightarrow [Ni^{II}L]^+$ involves stepwise elimination of the EE^0 neutrals CO and $R(C_2S)H$. An alternative route to $[Ni^{II}L]^+$ involves elimination of COS from $[Ni^{II}L(L-R')]^+$ to give $[Ni^{II}L(HCCR)]^+$, which then loses HCCR. Loss of the OE· species R′C·(=O) from $[Ni^{II}L]^+$ through reduction of nickel produces the $[EE]^+$ ion $[Ni^{I}SC(R)=CH]^+$. The subsequent loss of $R(C_2S)H$ should be the preferred pathway to Ni^+. Elimination of atomic sulfur is inferred in formation of



*decomposition confirmed for **3***a* by product ion scan
⇒ step involving metal valence change

SCHEME 2. Fragmentation pathways proposed for compounds **3***a*, **4***a*, and **5***a* (R′ = CF_3). Pathways are common to all complexes, except where noted.

$[Ni^{II}(L-S)]^+$ from $[Ni^{II}L]^+$ and of $[Ni^{I}(HCCR)]^+$ from $[Ni^{I}SC(R)=CH]^+$; this inference is supported by the formation of $[Ni^{III}L(L-S)]^+$ from $[Ni^{III}L_2]^+$ in the mass spectrum of **11***b*, where no alternative fragmentation is possible. Elimination of neutral $Ni^{II}S$ from $[Ni^{II}L(L-R'CO)]^+$ gives the metal-free ion $[2L-2S-R'CO]^+$, a documented reaction for Co(III) monothio-β-diketonates (1). A small peak at *m/z* 321 in the mass spectrum of **3***b* is assigned as $[NiSL]^+$; its formation by retention of a sulfur atom and elimination of the OE· neutral RC·(=CHC(=O)R′) from $[NiL_2]^+$ is supported by a product ion scan.

Scheme 5 shows decomposition pathways suggested for complexes substituted with pentafluoroethyl (**6***b*, **7***b*, and **8***b*) and *n*-heptafluoropropyl (**9***b*, **10***b*, and **11***b*) groups. (Mass spectra of **7***b* and **10***b* are shown in Figs. 2(*b*) and 2(*c*).) In all spectra, L^+ gives rise to the base peak and $[NiL_2]^+$ is, once again, the most abundant nickel-containing ion. Many of the fragmentation pathways parallel those observed for the trifluoromethyl derivatives, as discussed above. A new feature of these spectra is the increased abundance of ions formed by fluorine transfer to nickel. Thus, the analogues of the $[Ni^{III}FL(L-CF_3)]^+$ and $[Ni^{III}FL(L-C_2F_5)]^+$ ions observed here are not detected for complexes **3***b*, **4***b*, and **5***b*. The inferred elimination of $Ni^{II}F_2$ from $[Ni^{II}L]^+$ to give $[L-2F]^+$ also provides support for fluorine-to-metal transfer.

The $[Ni^{II}L(L-F-HF)]^+$ ion, observed only in the mass spectra of **9***b* and **10***b*, could arise by loss of HF from $[Ni^{II}L(L-F)]^+$, with formation of a five-membered ring and stabilization of the positive charge by sulfur, as shown in mechanism A. The difficulty of forming strained four- and three-membered rings, respectively, may explain the ab-

sence of analogous ions from the mass spectra of the perfluoroethyl and perfluoromethyl substituted complexes. The absence of the corresponding ion from the mass spectra of the corresponding β-diketonates may be attributed to less effective stabilization of the positive charge by oxygen.

Ions formed by hydrogen transfer

An interesting feature of the mass spectra of many metal-containing compounds is the presence of ions formed by reactions involving hydrogen transfer, for which reactions the mechanistic and electronic requirements are not well

[c]The isotopic contributions of L^+ to the observed peak height (first number shown in the parentheses) is the second number shown in the parentheses.

understood. The availability of both phenyl- and thienyl-substituted complexes in the present study permits further investigation of these mechanisms. As noted earlier, the mass spectra exhibit the ions $[NiHL]^+$ and $[Ni(L-H)]^+$, which the product ion mass spectra of **2***a* and **3***b* indicate are formed from $[NiL_2]^+$ by losses of the EE^0 neutrals (L−H) and LH, respectively. Table 4 shows relative ion currents, %TIC(Ni), carried by these ions. (In a given mass spectrum we have computed the %TIC(Ni) value as the current carried by an ion expressed as a percentage of the total ion current (TIC) carried by all nickel-containing ions.)

The %TIC(Ni) values of these ions formed by hydrogen transfer are sensitive to the nature of the chelate ring donor atoms and also to the substituents on the ring. Thus, for phenyl-substituted β-diketonate complexes with corresponding perfluoroalkyl substituents, formation of $[NiHL]^+$ is strongly favored over formation of $[Ni(L-H)]^+$. For 2-thienyl and 5-methyl-2-thienyl substituents the prominences of the $[NiHL]^+$ ions relative to the $[Ni(L-H)]^+$ ions are less marked. For corresponding monothio-β-diketonate complexes, formation of $[NiHL]^+$ is less likely than formation of $[Ni(L-H)]^+$, even for the phenyl-substituted complexes.

The formation of these ions can be discussed in terms of the origins of the transferred hydrogens. While these origins have not been determined here, the mass spectra of related complexes, and their deuterium-labelled analogues, have been studied. Thus, in the mass spectrum of bis(1,3-diphenyl-1,3-propanedionato-2-*d*)nickel(II) (R = R′ = phenyl), the $[NiHL]^+$ ion is more abundant than $[Ni(L-H)]^+$, while $[Ni^{II}L]^+$ is even less significant (29). In the formation of $[NiHL]^+$, hydrogen rearrangement from the *ortho* position of a phenyl ring is the major process (~76%) (30); this was rationalized (29) by mechanism B (X = O). A minor process involves a contribution by hydrogen transfer from the central position of the chelate ring, for which we propose

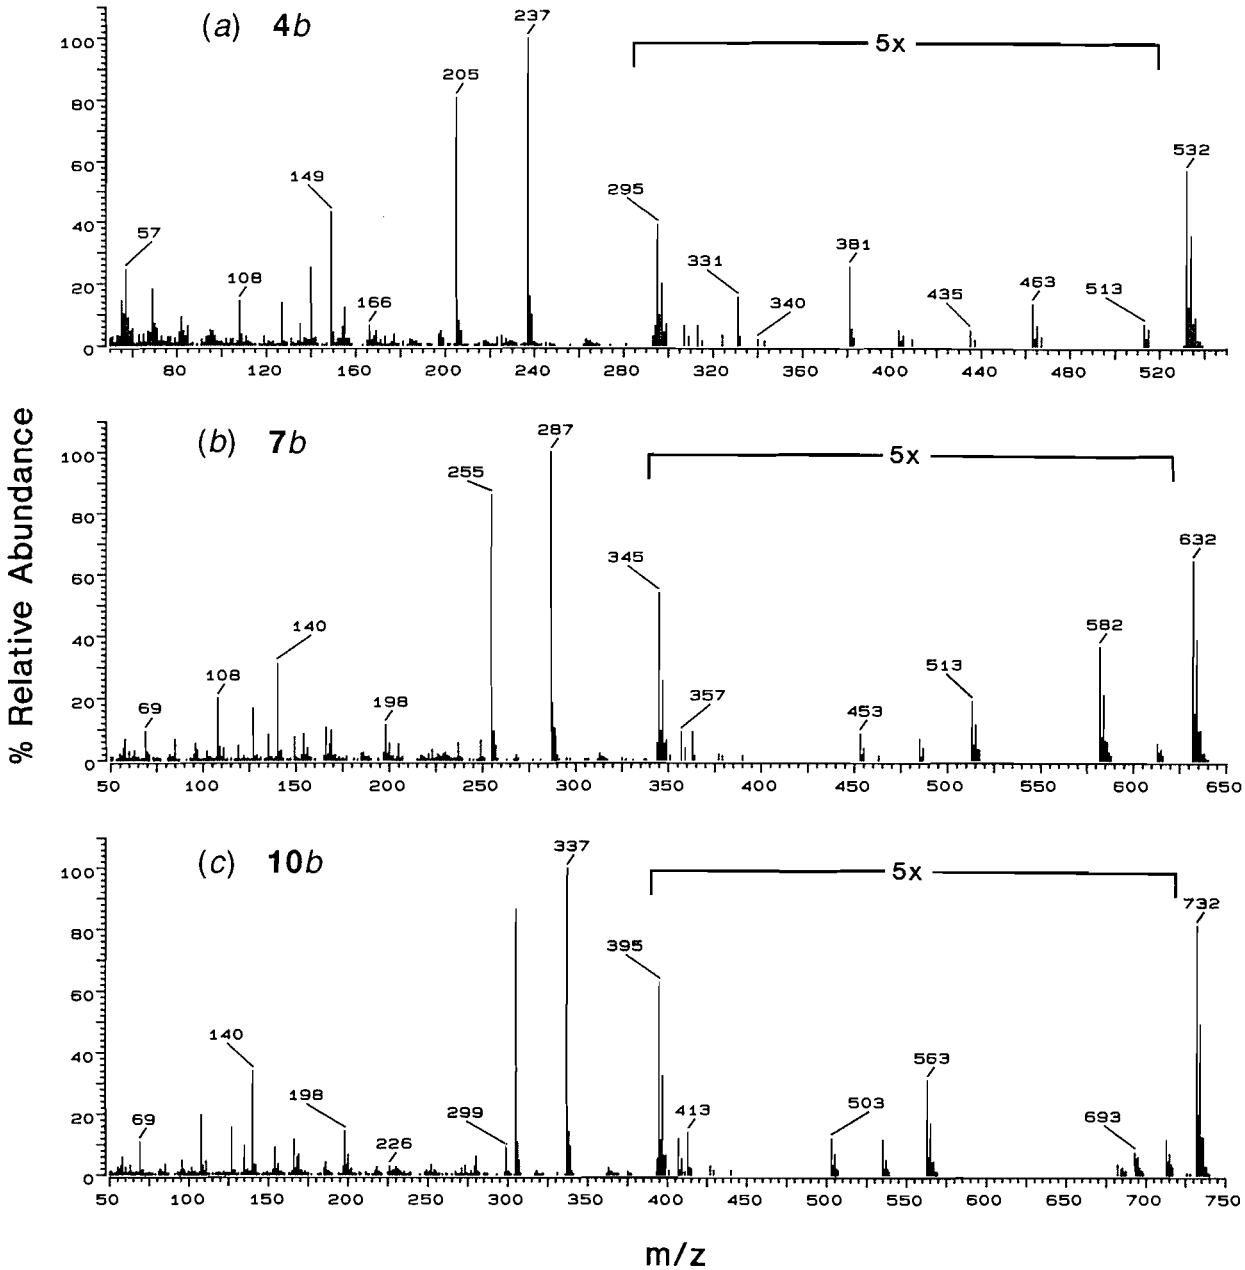

FIG. 2. EI mass spectra of (*a*) bis-[1,1,1-trifluoro-4-mercapto-4-(2-thienyl)-but-3-en-2-onato]-nickel(II), **4***b*; (*b*) bis-[1,1,1,2,2-pentafluoro-5-mercapto-5-(2-thienyl)-pent-4-en-3-onato]nickel(II), **7***b*; (*c*) bis-[1,1,1,2,2,3,3-heptafluoro-6-mercapto-6-(2-thienyl)-hex-5-en-4-onato]nickel(II), **10***b*.

mechanism C, although it was suggested (30) that the results are also consistent with extensive scrambling of the *o*-phenyl and chelate ring hydrogens prior to fragmentation. Similar results were reported for formation of $[CoHL]^+$ from cobalt(II) (29) and of $[RhHL]^+$ from rhodium(III) analogues (31). For either mechanism the structure of the $[NiHL]^+$ ion formed is the same, with nickel in the +3 oxidation state if we regard the hydrogen ligand as the two-electron donor hydride ion.

If, as is probable, hydrogen migration from the phenyl group to nickel is also the more important process for the current complexes then the favored formation of $[Ni^{III}HL]^+$ can be rationalized because mechanism B is not applicable to thienyl-substituted complexes (i.e., the thienyl group lacks a second "*ortho*" hydrogen). It is conceivable that, instead of the concerted mechanism shown, a two-step process operates, i.e., after hydrogen transfer to nickel, rotation about the phenyl–carbon bond permits oxygen to bind to the aryl carbon vacated by the transferred hydrogen. In principle, this mechanism is available to thienyl-substituted complexes. The low abundance of the product ion in this case may mean that this mechanism is not important, or that differing electronic effects may play a role.

The origin of the transferred hydrogen in the formation of $[Ni(L-H)]^+$ is less well known. For a number of copper(II) complexes the hydrogen transferred to the neutral species originates from the central position of the chelate ring (29, 30, 32); these results are consistent with mechanism D

(Met = Cu, X = O), proposed earlier (29). Unfortunately, the data in Table 4 do not reveal any clear trend to support or oppose this mechanism for nickel.

For monothio-β-diketonate complexes the formation of $[Ni^{III}HL]^+$ is suppressed relative to the β-diketonates. We may speculate that the charge site in mechanism B is less well developed when X is the less electronegative S atom. On the other hand, formation of $[Ni(L-H)]^+$ seems to be enhanced for monothio-β-diketonates. This enhancement is even more striking in the formation of $[Rh(L-H)]^+$ from a rhodium(III) analogue, for which we have observed that ~93% of the hydrogen transferred to the neutral fragment originates from

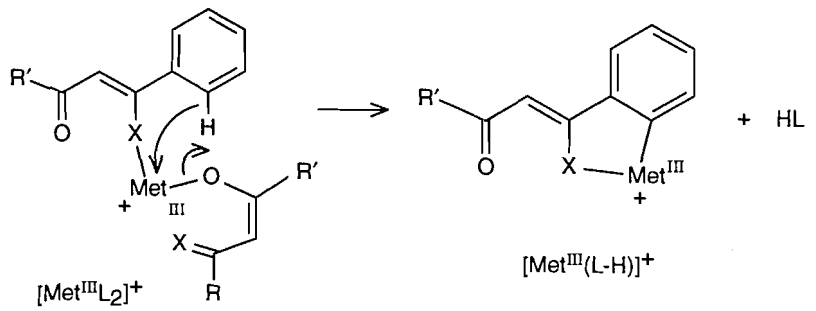
the phenyl group (31). Thus, in this case, mechanism E (Met = Rh, X = S) may be preferable.

The structures of the $[Met(L-H)]^+$ ion, the electronic environment of the metal, and its formal oxidation state, differ for mechanisms D and E. The preference of copper complexes for mechanism D may be related to the ease of formation of the copper(I) oxidation state, whereas the preference of the rhodium complexes for mechanism E may be influenced by the reluctance of rhodium(III) to be reduced to lower oxidation states. In the case of nickel, both nickel(I) and nickel(III) states can be formed with relatively little difficulty so that both mechanisms D and E are feasible. Thus, nickel chelates appear to be particularly suitable for further studies of the role of the metal, ligand donor atoms, and substituents on hydrogen transfer reactions.

E



Fluorine transfer reactions

The mass spectra of the β-diketonates show evidence, albeit minor, of fluorine transfer to nickel. Thus, compounds **1***a* and **2***a* show the $[Ni^{III}F(L-R')]^+$ ion (R′ = CHF_2), a probable decomposition product ($[Ni(L-CHF-HF)]^+$), and the $[L-F]^+$, $[L-2F]^+$, and $[L-CO-2F]^+$ ions formed by the inferred elimination of NiF_2. Compared to **1***a* and **2***a*, compounds **3***a* and **5***a* show comparable abundances of $[NiF(L-R')]^+$ (R′ = CF_3), somewhat lower abundances of the analogous daughters $[Ni(L-CF_2-HF)]^+$, and no evidence for elimination of NiF_2. Compounds **6***a*, **7***a*, **9***a*, and **10***a* show none of these species but **6***a* and **7***a* show low-abundance $[NiFL(L-CF_3)]^+$ ions, discussed below, formed by a different reaction. These observations can be rationalized by the hard acid–soft base (HSAB) concept, in terms of which Ni^{II} has borderline hard acid properties. We see that fluorine migrations to nickel decrease in both number and significance with increasing fluorine content of R′. Thus, nickel(II) is able to abstract a hard fluorine atom from the carbon of a CHF_2 substituent but is less effective at abstracting fluorine from the harder carbons of CF_3, C_2F_5, or n-C_3F_7 groups. We have discussed the relative hardnesses of the carbon atoms in the perfluoroalkyl substituents in more detail in the previous publication (1).

For compounds **6***a* and **7***a* the fluorine transfer ion, noted above, can be formulated as $[Ni^{III}FL(L-CF_3)]^+$ (Scheme 5). Noting that an increase of valence hardens a metal, nickel(III) is evidently hard enough to abstract a fluorine atom from the perfluoroethyl group. We have argued previously that fluorine should be abstracted more readily from an α-carbon (1).

The mass spectra of the monothio-β-diketonates having CF_3 substituents show no evidence of ions formed by fluorine transfer to nickel; this is consistent with the softening of nickel by sulfur. The observation of $[Ni^{III}FL(L-CF_3)]^+$ for compounds **6***b*, **7***b*, and **8***b*, which have C_2F_5 substituents, and of $[Ni^{III}FL(L-C_2F_5)]^+$ for **11***b*, which has the n-C_3F_7 substituent, and of $[L-F]^+$ and $[L-2F]^+$ indicate that nickel(III) is still hard enough to abstract fluorine from these substituents, presumably from their α-carbons.

Conclusions

A prominent molecular ion in each mass spectrum reflects the capacity of the ligand to accommodate the positive charge and (or) the ability of nickel(II) to undergo oxidation to nickel(III). Subsequent fragmentation of the β-diketonates proceeds mainly by elimination of the $OE^{\bullet}$ radical $R''^{\bullet}$ followed by one or more EE^0 neutral losses. Conversely, the major fragmentation of the $M^{+\bullet}$ ion of the monothio-β-diketonates is loss of $Ni^{I}L$ to yield an abundant L^+ ion. While the major ions of both series of complexes contain nickel(II), the monothio-β-diketonates show a greater tendency to form some important nickel(I)-containing ions (e.g., $[Ni^{I}SC(R)=CH]^+$ and $[Ni^{I}(HCCR)]^+$). This is consistent with the HSAB concept; nickel(I) is a soft acid and the ligands are soft bases.

The formation of the $[Ni^{III}HL]^+$ ion by hydrogen transfer to nickel agrees with mechanism B. On the other hand, formation of the $[Ni^{I/III}(L-H)]^+$ ion may occur by transfer of hydrogen from the central position of the chelate ring (mechanism D) or from an aryl group (mechanism E). Such reactions are sensitive to the nature of the metal, and to donor atoms and substituents of the ligand. Nickel chelates appear to be particularly suitable for further studies of these effects.

Received April 2, 1993

EDWARD PIERS, RICHARD W. FRIESEN, PAUL KAO, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **71**, 1463 (1993).

The results of a study of Diels–Alder reactions of the bicyclic dienes **6**–**8** with a variety of dienophiles are reported. Although **6** and **7** undergo cycloaddition reactions smoothly and efficiently, thermal Diels–Alder reactions of **8** are generally sluggish or, under the conditions investigated, do not proceed at all. Additions of tetracyanoethylene (TCNE) to **6**–**8** are highly face-selective, with preferential attack of the dienophile on the side of the dienes opposite to the angular methoxycarbonyl group. Reaction of **7** with maleic anhydride (MAN) is completely face-selective and proceeds preferentially via an *endo* transition state. Diels–Alder reactions of **6** and **7** with methyl acrylate (MAC) and nitroethylene (NE) are entirely regioselective, but the face-selectivities, which vary from ~2:1 to ~3:1, are rather low. The use of this chemistry as a method for the synthesis of functionalized, stereochemically defined, perhydro-1*H*-phenalenes is demonstrated.

EDWARD PIERS, RICHARD W. FRIESEN, PAUL KAO, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **71**, 1463 (1993).

On rapporte les résultats d'une étude sur des réactions de Diels–Alder des dienes bicycliques **6**–**8** avec divers diénophiles. Même si les composés **6** et **7** subissent des réactions de cycloadditions faciles et efficaces, les réactions de Diels–Alder thermiques du composé **8** sont généralement difficiles ou, dans les conditions utilisées, elles ne se produisent pas du tout. Les additions du tétracyanoéthylène (TCNE) sur les composés **6**–**8** se font d'une façon très face-sélectives avec une attaque préférentielle du diénophile sur le côté du diène qui est opposé au groupe méthoxycarbonyle angulaire. La réaction du composé **7** avec l'anhydride malélique (ANM) est complètement face-sélective et se produit préférentiellement par le biais d'un état de transition *endo*. Les réactions de Diels–Alder des composés **6** et **7** avec l'acrylate de méthyle (ACM) et le nitroéthylène (NE) sont complètement régiosélectives, mais les sélectivités relatives à la face, qui varient d'environ 2 : 1 à environ 3 : 1, sont relativement basses. On démontre l'utilité de cette chimie comme méthode de synthèse de perhydro-1*H*-phénalènes fonctionnalisés de stéréochimie définie.

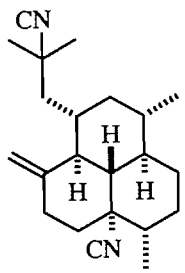
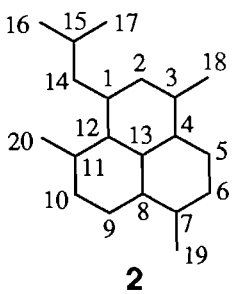
Introduction

The structurally novel marine natural product (−)-8,15-diisocyano-11(20)-amphilectene, obtained from the sponge *Hymeniacidon amphilecta*, has been shown by X-ray diffraction analysis to possess the constitution and relative stereochemistry depicted in structural formula **1** (1). This substance is a member of the small family of biologically active amphilectane-type diterpenoids that share the carbon skeleton **2** (1–3).



1



2

Recently, we described, inter alia, the synthesis of the structurally unique dienes **6**–**8** via effective routes that employed, as the key steps, the palladium(0)-catalyzed ring closure of the enol triflate-vinylstannanes **3**–**5**, respectively (4, 5) (eq. [1]). One of the reasons for developing the methods that led to the preparation of **6**–**8** and related dienes (4, 5) was related to the possibility of using these substances as substrates for Diels–Alder reactions. It was hoped that an investigation into the Diels–Alder chemistry of **6**–**8** would set the stage for subsequent use of similar methodology for effecting the total synthesis of 8,15-diisocyano-11(20)-amphilectene (**1**) and related amphilectane diterpenoids. We report herein the details of a study (6) of the reaction of the dienes **6**–**8** with symmetrically and unsymmetrically substituted dienophiles.

Results and discussion

General considerations

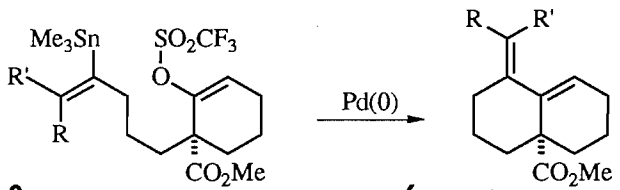
Prior to a description of the work carried out during the course of this study, it may be helpful to point out that four questions were to be addressed during the exploration of Diels–Alder reactions of the dienes **6**–**8**. These may be formulated as follows. (*a*) What is the face-selectivity of dienophile addition to the diene system present in **6**–**8**? A preference for attack on the β face[2] of the dienes would be expected, but the extent of this preference could, of course, vary with the structure of the dienophile. (*b*) For each of those dienophiles in which there is the potential for *endo*- or *exo*-selectivity in the cycloaddition transition states, which mode of attack is favored upon addition of the dienophile to each

[1]Author to whom correspondence may be addressed.

[2]Throughout this discussion, the α face of the diene refers to the side of the molecule on which the methoxycarbonyl group is situated, while the β face refers to the side of the diene opposite to the CO_2Me moiety.

of the α and β faces of the dienes? (*c*) In the case of unsymmetrically substituted dienophiles, what will be the preferred regiochemistry of addition of these reagents to the dienes? (*d*) Of the geometrically isomeric dienes **7** and **8**, one would expect the *cisoid-trans* diene **7** to undergo Diels–Alder reactions at rates much faster than those associated with the *cisoid-cis* diene **8**. Will the latter substance undergo cycloaddition reactions with dienophiles, particularly with those that are rather unreactive? The investigations outlined below provide useful information about each of these points.

[1]



3 R = R' = H
4 R = $CH_2OSi(t\text{-}Bu)Me_2$, R' = H
5 R = H, R' = $CH_2OSi(t\text{-}Bu)Me_2$

6 R = R' = H

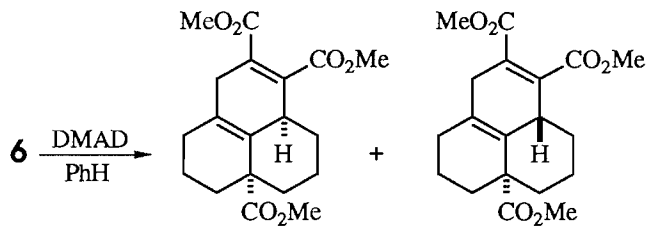
8 R = H, R' = $CH_2OSi(t\text{-}Bu)Me_2$

Diels–Alder reactions of the dienes ***6–8*** *with symmetrical dienophiles*

Reaction of the "parent" diene **6** with two equivalents of dimethyl acetylenedicarboxylate (DMAD) in benzene (reflux, 6 h) (eq. [2]) gave, in 78% yield, a crystalline material that exhibited mp 136–137°C. Analyses (gas–liquid chromatography (glc) – low-resolution mass spectrometry (lrms) and ^1H nmr spectroscopy) of this material showed that it consisted of a mixture of isomers of molecular mass 348, in a ratio of approximately 3:1. These two substances were inseparable by flash chromatography on silica gel (7). Recrystallization of the mixture from Et_2O–$CHCl_3$ produced colorless cubic crystals with mp 137.5–138.5°C. The ^1H nmr analysis of this material showed that the ratio of isomers was substantially unchanged. X-ray crystallographic analysis of the mixture (vide infra) revealed that the major isomer was the triester **9** and, consequently, the minor Diels–Alder product was assigned structure **10**. Thus, the face-selectivity of the reaction of **6** with the linear, sterically undemanding dienophile DMAD is modest. Nevertheless, there is a small preference for attack of DMAD on the β face of **6**.

[2]



9 **10**

The issue of face-selectivity in the Diels–Alder reactions of the dienes **6–8** was investigated further by use of the symmetrical dienophiles tetracyanoethylene (TCNE) and maleic anhydride (MAN). In terms of its ability to approach the diene systems present in **6–8**, TCNE would be expected to be sterically more demanding than the (linear) dienophile DMAD. On the other hand, use of MAN would provide information not only about face-selectivity, but would also shed light on the issue of *endo*- versus *exo*-selectivity in the cycloaddition reactions. The structural formulas of the products formed from the reactions involved are shown in Chart 1 and the results derived from this part of the study are summarized in Table 1.

Treatment of the diene **6** with TCNE (Table 1, entry 1) provided a white solid that consisted of two products in a ratio of 96:4 (glc analysis). Fractional crystallization of this material gave a pure sample of the major isomer as colorless cubic crystals that exhibited mp 146–147°C. This substance was expected to be the tricyclic ester **11**, resulting from preferential attack of the dienophile on the β face of the diene **6**. In the ^1H nmr spectrum of this material, the tertiary allylic proton H_A gives rise to a broad doublet (J = 12.5 Hz) at δ 3.31. Although the size of the observed coupling constant is consistent with a *trans* diaxial coupling between H_A and H_B in **11**, molecular models indicate that a similar strong coupling between H_A and H_B in **12** would be expected. Thus, ^1H nmr spectroscopy did not easily lead to an ambiguous structural assignment. Therefore, a single crystal X-ray analysis of the major isomer was undertaken (vide infra). This exercise confirmed that the major Diels–Alder adduct has the constitution and relative stereochemistry depicted in **11**. The minor product, although not isolated, was shown by glc–lrms to be isomeric with **11** and, therefore, was assumed to be **12**.

Reaction of the *cisoid-trans* diene **7** with TCNE at room temperature (Table 1, entry 2) afforded a mixture of two products in a combined yield of 74%. Integration of the signals due to the *t*-Bu groups in the ^1H nmr spectrum of this material indicated that the two substances were present in a ratio of approximately 7:1. The fact that the two compounds could not be separated by chromatography on silica gel precluded the acquisition of a pure sample of the minor product. However, based on the previous results derived from

[g]Ratio determined by analysis of the crude product mixture by ^1H nmr spectroscopy.

the reaction of TCNE with the diene **6**, it is reasonable to conclude that the major and minor products possess structures **13** and **14**, respectively.

When the reaction of diene **7** with TCNE was carried out at −78°C (Table 1, entry 3), a single isomer **13** was produced in 84% yield. This substance (mp 119–120°C) was shown to be identical with the major product of the room temperature Diels–Alder reaction. In the ^1H nmr spectrum of **13**, H_A gives rise to a broad doublet (J = 12.5 Hz) at δ 3.10.

The cycloaddition reaction between the *cisoid-cis* diene **8** and TCNE proved to be very slow at or below ambient temperatures. However, when a solution of the two reactants in diethyl ether was refluxed for 15 h, a single crystalline product was obtained in 72% yield (Table 1, entry 4). In the ^1H nmr spectrum of this substance, the two tertiary allylic protons give rise to an unresolved multiplet centered at δ 3.26, while the CH_2O protons produce well-separated signals at δ 3.93 (doublet of doublets, J = 7.5, 10.5 Hz) and 4.25 (doublet of doublets, J = 4.0, 10.5 Hz). The expectation that the product was the result of face-selective attack of TCNE on the β face of the diene **8** was confirmed by a single crystal X-ray analysis (vide infra), which showed conclusively that the cycloadduct has the constitution and relative stereochemistry shown in **15**.

A single Diels–Alder adduct was obtained from the reaction of the *cisoid-trans* diene **7** with MAN (Table 1, entry 5). It is known (8) that MAN has a strong predilection for an *endo* transition state. For example, the reaction of cyclopentadiene with MAN provides the *endo* adduct with a stereoselectivity of greater than 98%. Thus, it appears very likely that the reaction of MAN with **7** would proceed via an

endo transition state. In this event, approach of MAN to the α face of the diene would be precluded, since, in this arrangement, there would be a strong steric interaction between the angular CO_2Me function of **7** and the anhydride portion of the dienophile. On the basis of these predictions and the results of the TCNE experiments (Table 1, entries 1–4), it was concluded that the sole product of the reaction of the diene **7** with MAN possesses the structure shown in **16**.

The reaction of MAN with the *cisoid-cis* diene **8** was very sluggish. The starting material **8** was completely consumed only after a solution of the two reactants in benzene had been refluxed for approximately 3 days. A single Diels–Alder product was isolated in low yield (18%) (Table 1, entry 6). On the basis of the arguments presented above (reaction of MAN with **7**) and taking into account the result of the reaction of diene **8** with TCNE (Table 1, entry 4), it was concluded that this adduct possesses structure **17**.

The major material obtained from this reaction was an amorphous white solid that precipitated from the reaction mixture. This substance was found to be quite insoluble in common solvents (chloroform, acetone, methanol, benzene) and resisted crystallization. The ir spectrum included absorptions due to anhydride and ester functions and the ^1H nmr spectrum (CD_3SOCD_3) did not contain signals for the $OSi(t\text{-}Bu)Me_2$ moiety. The peak of highest mass in the mass spectrum of this material corresponds to a molecular formula of $C_{22}H_{22}O_8$. Although this substance was not investigated further, it is clear that it is not a simple, primary, Diels–Alder adduct.

Diels–Alder reactions of the dienes **6–8** *with unsymmetrical dienophiles*

Theoretically, it is possible that each of the Diels–Alder reactions of the dienes **6–8** with an unsymmetrical dienophile could produce eight isomeric products. Fortunately, in practice, this worst case scenario was not realized. In fact, each of the cycloaddition reactions studied produced, at most, three products. Even so, conclusive determination of the structures of the products obtained was not straightforward. In particular, ^1H nmr spectroscopy did not lead to unambiguous conclusions regarding the constitution and relative stereochemistry of the cycloadducts. Consequently, the structures of four products were determined directly or indirectly by X-ray crystallographic analyses. Once these structures were secured, ^1H nmr spectroscopy was of considerable use in assigning structures to related substances.

The reactions of each of the dienes **6–8** with the unsymmetrical dienophiles methyl acrylate (MAC) and nitroethylene (NE) (9) were investigated. The results obtained are summarized in Table 2 and the structural formulas of the various products produced are shown in Chart 2.

Reaction of the diene **6** with MAC gave an excellent yield of a colorless oil that, on the basis of analyses by glc and ^1H nmr spectroscopy, consisted of a mixture of three Diels–Alder adducts in a ratio of about 2.7:1:1.7. These substances were shown, as outlined below, to be compounds **18**, **19**, and **20**, respectively.

The three products were difficult to separate by chromatography. However, subjection of the mixture to drip column chromatography on silica gel gave pure samples of **18** and **20**, as well as fractions that contained only mixtures of compounds **18** and **19**.

The first product to be eluted was **20**, a colorless oil. In the ^1H nmr spectrum of this material the two CO_2Me functions produced singlets at δ 3.67 and 3.68, while H_A appeared as a doublet of triplets (J = 3, 12 Hz) at δ 2.31. Reduction of **20** with lithium aluminum hydride in refluxing diethyl ether provided the diol **30** in 83% yield (eq. [3]). A single crystal X-ray crystallographic analysis (vide infra) on the latter substance (mp 162.5–164°C) confirmed its structure and, thereby, the structure of the diester **20**.

[3] 
20 **30**

[4] 
18 **31**

The second component to be eluted was the major Diels–Alder product **18**. Although the ^1H nmr spectrum of **18** did not provide conclusive evidence for the structure of this cycloadduct, two signals (δ 2.35, broad doublet, J = 13 Hz; 2.73, doublet of doublet of doublets, J = 2.8, 6, 13 Hz) were distinctive. These one-proton resonances can be assigned with confidence to protons H_A and H_B, respectively, in structural formula **18**. Reduction ($LiAlH_4$, THF) of **18** gave the corresponding diol in 97% yield (eq. [4]). An X-ray crystallographic analysis (vide infra) showed that the latter substance (mp 182.5–184°C) possesses structure **31**. Consequently, the major Diels–Alder product derived from reaction of the diene **6** with MAC is **18**.

The product **18** arises from attack of MAC on the β face of the diene **6** via an *endo* transition state, while **20** is produced via a pathway involving α-face attack and an *exo* transition state. It seemed reasonable to assume that the minor Diels–Alder adduct should be that arising from an approach of MAC to the β face of **6** and an *exo* transition state and should, therefore, possess structure **19**. That this conclusion was correct was shown as follows. A solution of a mixture of **18** and **19** (ratio 3:1, respectively) in methanol containing sodium methoxide was refluxed for 2 weeks. The isolated material (86% yield) consisted of a mixture of **18** and **19** in a ratio of 1:6, respectively. Thus, these two substances are epimeric at the stereogenic center associated with the secondary CO_2Me function.

Reaction of the *cisoid-trans* diene **7** with MAC (Table 2, entry 2) produced a crude product that, on the basis of its ^1H nmr spectrum, consisted of at least three components. Unfortunately, extensive overlap of the potentially diagnostic resonances precluded a determination of the product ratios. Medium-pressure column chromatography of the product mixture on silica gel gave, in order of elution, pure adduct **23** (31%), a trace of an unidentified diester, and a 3:1 mixture of the major and minor products **21** and **22** (56%). The

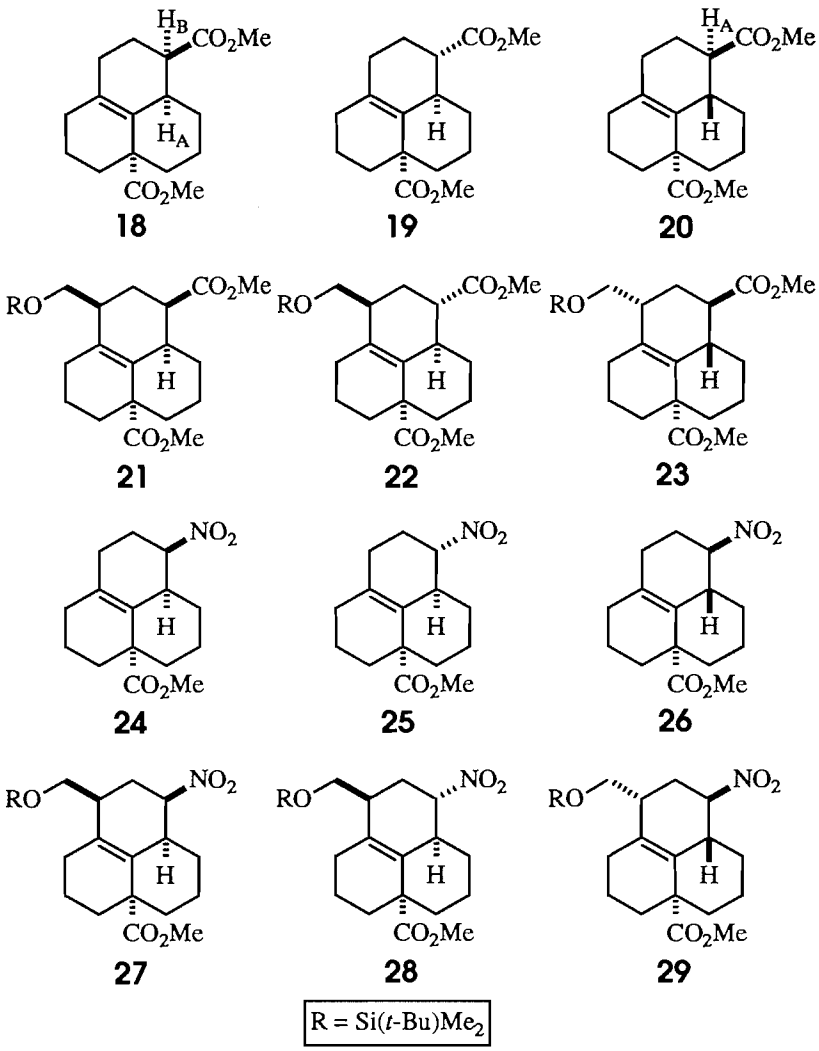

CHART 2

ratio of the latter substances was determined by ^{1}H nmr spectroscopy (integration of the *t*-Bu groups).

A pure sample of the major product **21** was obtained by subjecting the 3:1 mixture of **21** and **22** to drip column chromatography on silica gel. Treatment of pure **21** with sodium methoxide in refluxing methanol produced a 1:9 mixture of **21** and **22** and, thus, as expected, the major and minor Diels–Alder adducts were found to be epimeric at the chiral center bearing the secondary CO_2Me function. A pure sample of **22** was procured by chromatography of the 1:9 mixture of **21** and **22**.

At this stage, by analogy with the results obtained from the reaction of the diene **6** with MAC (Table 2, entry 1), it seemed reasonable to conclude that the three products (48:16:36) derived from reaction of **7** with MAC possess structures **21**, **22**, and **23**, respectively. Comparison of certain signals in the ^{1}H nmr spectra of these substances with the corresponding resonances in the spectra of the products derived from reaction of **7** with nitroethylene provided strong evidence for this conclusion (vide infra).

A successful Diels–Alder reaction between MAC and the *cisoid-cis* diene **8** was not achieved (Table 2, entry 3). After a benzene solution of **8** and MAC was refluxed for 4 days, 92% of the diene was recovered. Heating of a benzene solution of the two substances at 180°C (sealed tube) for 42 h led only to decomposition of the diene. Interestingly, treatment of **8** with DMAD under a variety of conditions did not produce any Diels–Alder adducts either.

It appears that, in the case of substrate **8**, successful thermal Diels–Alder reactions with relatively unreactive dienophiles such as MAC and DMAD are precluded. In fact, the Diels–Alder adducts produced by the reactions of **8** with the more reactive dienophiles TCNE and MAN (Table 1, entries 4 and 6) may well have been formed via a two-step mechanism (10), as illustrated in eq. [5] for the TCNE reaction. In this case, since the reaction is stereospecific (compare entries 3 and 4, Table 1), ring closure would have to be faster than rotation about the (formal) single bond between carbons **a** and **b** in the intermediate **32**.

Treatment of the parent diene **6** with nitroethylene (NE) in diethyl ether (Table 2, entry 4) gave, in 83% yield, a mixture of the cycloaddition adducts **24**, **25**, and **26** (~3:1:2, respectively, by glc analysis). The *CH*NO_2 proton signals in the ^{1}H nmr spectrum of this mixture were observed at δ 4.44 (compound **26**), ~4.71 (m, compound **25**), and ~4.74 (m, compound **24**). The relative intensity of the signals at δ 4.44 and 4.70–4.76 was found to be about 1:2, respectively. Subjection of the mixture to column chromatography on sil-

ica gel provided a pure sample of product **26**, the first substance to be eluted. Although the adducts **24** and **25** were not obtained in pure form, these substances were found to be epimeric at the stereogenic center containing the nitro function. Thus, treatment of a small sample of a mixture of **24**, **25**, and **26** (3:1:2) with potassium *tert*-butoxide in *tert*-butyl alcohol provided a mixture of the same three substances (composition 0.7:3.1:2, respectively, by glc analysis) in 87% yield.

On the basis of these results, along with those obtained from the reaction of **6** with MAC (vide supra), the three products (~3:1:2) derived from the cycloaddition of **6** with NE were assigned structures **24**, **25**, and **26**, respectively. Further evidence for these assignments was obtained by ^1H nmr spectra comparisons. Specifically, the chemical shift and coupling constants associated with the C*H*NO_2 protons in each of the substances **24–26** are similar to those of the structurally analogous nitro esters **27–29**, respectively. The structures of the latter trio of compounds have been assigned unambiguously (vide infra). The C*H*NO_2 protons in **24** and **27** give rise to multiplets at δ 4.74 and 4.75 while, in **25** and **28**, the corresponding signals appear at 4.71 (multiplet) and 4.68 (doublet of doublet of doublets, J = 4, 9, 12 Hz). In compounds **26** and **29**, the resonances for the C*H*NO_2 protons are found at δ 4.44 (doublet of triplets, J = 3.8, 10.5 Hz) and 4.58 (doublet of doublet of doublets, J = 3, 10.5, 12 Hz).

Further evidence for the completely regioselective nature of the Diels–Alder reaction of **6** with NE was obtained as follows. Treatment of a 3:1:2 mixture of **24–26** with sodium methoxide in methanol, followed by addition of an aqueous solution of titanium trichloride and ammonium acetate (11), provided a single ketone in 90% yield (eq. [6]). Apparently, under the reaction conditions, the primary product **34** derived from the nitro ester **26** epimerizes to the more stable diastereomer **33**.[3] The carbonyl group of **33** produces an absorption at 1710 cm^{-1} in the infrared spectrum. The relative stereochemistry of this substance was confirmed by a ^1H nmr nuclear Overhauser enhancement (nOe) difference experiment, in which irradiation at δ 3.69 (CO_2Me) increased the intensity of the resonance (2.82, br d, J = 13 Hz) due to the angular allylic proton.

Treatment of **33** with potassium *tert*-butoxide in THF caused isomerization of the substrate into the more stable α,β-unsaturated ketone **35** (eq. [7]). The infrared (1668 cm^{-1}) and ^{13}C nmr (δ 133.8, 155.3, 199.6) spectra of the latter substance confirmed the presence of the enone moiety.

[3]Molecular models indicate that, in compound **34**, the six-membered ring B must adopt a twist-boat conformation. On the other hand, in substance **33**, the three rings can comfortably adopt half-chair (A, C) or chair (B) conformations. Molecular mechanics calculations predict that **33** should be approximately 2.6 kcal/mol more stable than **34**. We are grateful to Professor L. Weiler for carrying out these calculations.

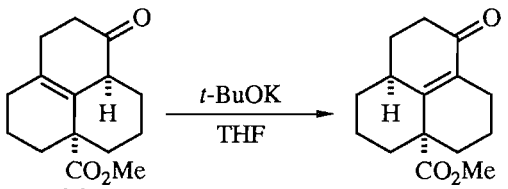
[7]



33 35

Reaction of the *cisoid-trans* diene **7** with NE was carried out in diethyl ether at room temperature (Table 2, entry 5). Analysis of the crude product by ^{1}H nmr spectroscopy showed the presence of essentially two products **27** and **29**, ratio ~3:1), along with a trace of a third substance (**28**). Column chromatography of the mixture gave compounds **29** (the first substance to be eluted) and **27** in isolated yields of 24 and 57%, respectively. Recrystallization of **27** from chloroform produced crystals (mp 89–90°C) suitable for X-ray crystallographic analysis (vide infra), which showed conclusively that **27** correctly represents the structure of the major Diels–Alder adduct.

The adduct that was produced in trace amounts was shown to possess the structure **28**. Thus, treatment of **27** with potassium *tert*-butyl alcohol at 100°C caused epimerization at the stereogenic center associated with the nitro function and produced, in 92% yield, compound **28** (eq. [8]). Diagnostic signals in the ^{1}H nmr spectrum of **28** were found to be identical (chemical shift, multiplicity) with the corresponding resonances of the trace component present in the crude Diels–Alder product mixture.

	3.75	dd (4, 10)

[a]The signals for both protons are partially hidden under the CO_2Me resonances.
[b]This signal is partially hidden under the CO_2Me resonances.

Treatment of the Diels–Alder adduct **29** (an oil) with tetra-*n*-butylammonium fluoride in THF, followed by reaction of the resultant alcohol **36** with *p*-nitrobenzoyl chloride in the presence of 4-(*N*,*N*-dimethylamino)pyridine (DMAP), gave the crystalline *p*-nitrobenzoate **37** (eq. [9]). An X-ray crystallographic analysis (vide infra) of this substance confirmed its structure and, thereby, the structure of the Diels–Alder adduct **29**.

In the ^{1}H nmr spectra of the series of compounds **21–23** and **27–29**, the signals due to the $CH_2OSi(t\text{-Bu})Me_2$ protons were particularly diagnostic and were helpful in making structural assignments. In each case, these two protons are magnetically nonequivalent and, thus, typically give rise to a pair of doublets, with the geminal coupling constant being 10 Hz. The appropriate data is summarized in Table 3. As can be seen from this data, each pair of structurally related compounds (**21**, **27**; **22**, **28**; **23**, **29**) exhibit signals for the $CH_2OSi(t\text{-Bu})Me_2$ protons that, in terms of chemical shifts and, where determinable, coupling constants, are similar. Since the structures of **27–29** are firmly established (vide supra) these data provide additional evidence for the structural assignments with respect to compounds **21–23**.

Reaction of the *cisoid-cis* diene **8** with NE did not proceed at room temperature. However, when a solution of the reactants in diethyl ether was refluxed for 7 h (Table 2, entry 6) no diene remained. Analysis of the crude product by ^{1}H nmr spectroscopy indicated the presence of three components (~2.5: trace:1). These substances, which could be separated by column chromatography and were obtained in isolated yields of 54%, 3%, and 21%, were shown to possess ^{1}H nmr spectra identical with those of the nitro esters (**27**, **28**, **29**, respectively) obtained from the Diels–Alder reaction of NE with the *cisoid-trans* diene **7**.

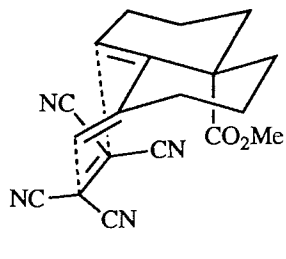
Since the composition of the product mixture derived from **8** and NE is essentially identical with that obtained from **7** and NE, it appears that, under the conditions of the former reaction, the *cisoid-cis* diene **8** isomerizes to the geometric isomer **7** prior to the Diels–Alder reaction. When solutions of **8** in diethyl ether or THF were refluxed in the absence of NE, the diene could be recovered unchanged in high yields, even after extended reflux times. Thus, it appears that the isomerization of **8** into **7** is promoted by NE itself (electron-transfer mechanism?) or by traces of impurity arising from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

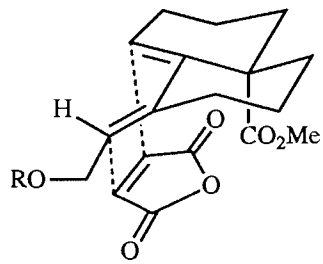
the preparation of NE. In any case, it was clear that the Diels–Alder reaction of **8** itself with NE is, not unexpectedly, sluggish.

Discussion of results from Diels–Alder studies

With respect to face-selectivity, the Diels–Alder reactions that were investigated varied considerably. The reactions of the dienes **6–8** with the dienophiles TCNE and MAN (Table 1) are highly face-selective and produce predominantly or exclusively the products resulting from attack of the reagents on the β face of the substrates. These results can be rationalized on the basis of steric effects. Thus, the transition states derived from α-face attack of TCNE would be destabilized by severe steric repulsion between the angular CO_2Me function and one of the cyano groups (see **38**). Similarly, attack of MAN on the α faces of **7** and **8** via *endo* transition states (MAN has a strong preference for *endo* orientations) would lead to a substantial steric repulsion (see **39**). Clearly, transition states derived from β-face attack of TCNE or MAN (*endo* orientation) would be expected to be considerably more stable than those (e.g., **38**, **39**) involving α-face attack.



38 (**6** + TCNE)



39 (**7** + MAN)

On the other hand, face-selectivities associated with the linear dienophile DMAD and the unsymmetrical dienophiles MAC and NE are quite low. Thus, reaction of **6** with DMAD proceeds via β- and α-face attack in a ratio of about 3:1, respectively (eq. [2]), while, in the reactions of **6** and **7** with MAC and NE, the ratios of β- to α-face attack vary from about 1.8:1 to 3:1 (Table 2). Not surprisingly, the products of α-face attack of MAC and NE on the dienes **6** and **7** are formed only via *exo* transition states. On the other hand, β-face attacks proceed predominantly via *endo* transition states (Table 2, entries 1, 2, 4, 5).

The Diels–Alder reactions of the dienes **6** and **7** with the unsymmetrical dienophiles MAC and NE are highly regioselective (Table 2). The regioselective nature of the reactions involving the diene **7** are particularly interesting. Although different models may be used to rationalize these observations, the biradical arguments developed by Dewar et al. (12) will be employed here.[4]

On the reasonable assumption that the presence of the angular CO_2Me function has little or no effect on the regiochemistry of the cycloaddition reactions, the dienes **6** and **7** may be represented in general terms by **41** and **42**, respectively (Scheme 1). Reaction of **41** with MAC or NE can, theoretically, provide two intermediate biradicals, **44** and **47**. Consideration of the relative stability of these two species allows one to predict which regioisomer should predominate in the product mixture (12). The allyl radical is stabilized by more alkyl substituents in **44** than in **47** and, therefore, the latter species should be less stable than the former. Hence, the regioisomers predicted to be preferred from the reactions of **41** (equivalent to **6**) with MAC and NE are those with general structure **50**. In fact, these are the only regioisomers formed (Table 2, entries 1 and 4). None of the regioisomeric substances (general structure **53**) were produced.

The interaction of **42** with MAC and NE can, theoretically, lead to the intermediate biradicals **45** and **48**. In **45**, the allyl radical is stabilized by three alkyl substituents. On other hand, the allyl radical system in **48** is also trisubstituted. However, although the alkyl-type substituents would be expected to have a stabilizing effect on this radical, it may be proposed that the inductively electron-withdrawing CH_2OR' function destabilizes the species. On this basis, one would predict that **45** is more stable than **48** and that, therefore, the preferred Diels–Alder products from the reaction of **42** (equivalent to **7**) with MAC and NE should possess the general structure **51**. In practice, the cycloadditions produced only **51** and none of the isomeric substances of general structure **54** could be observed in the crude product mixtures.

To demonstrate further that the $CH_2OSi(t\text{-}Bu)Me_2$ function does play an important role in directing the regiochemistry of the cycloaddition reactions of the diene **7**, the Diels–Alder reaction of the diene **40** (5) with the unsymmetrical dienophile MAC was investigated. The two biradicals **46** and **49** that could be (theoretically) formed from the diene system of general structure **43** (equivalent to **40**, see Scheme 1) would possess very similar substitution patterns and, consequently, would be expected to be of similar stability. In turn, one would expect the formation of mixtures of **52** and **55** in ratios approaching 1:1.

In the event (see Scheme 2), treatment of the diene **40** (5) with MAC in refluxing benzene provided (84%) an oil that, on the basis of analysis by glc–lrms, was shown to be a mixture of at least five isomeric diesters **56**. Reaction of this mixture with an excess of lithium diisopropylamide in THF, followed by treatment of the resultant mixture of enolate anions with benzeneselenenyl chloride, gave a mixture of selenides. This mixture was treated immediately with aqueous hydrogen peroxide and acetic acid in THF and the resultant mixture of dienes was allowed to react with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in benzene. Chromatography of the crude product gave, in 82% yield from **56**, a mixture of the isomeric diesters **57** and **58** in a ratio of about 1.4:1, respectively (analysis by ^1H nmr spectroscopy). The structural assignments were made on the basis of the relative chemical shifts of the signals due to the CH_2CH_3 protons in the ^1H nmr spectra of **57** and **58**. In **57**, this resonance (quartet, J = 7.5 Hz) appears at δ 2.60. The corresponding signal (quartet, J = 7.5 Hz) in **58**, which would be expected to be at lower field due to the proximity of the ethyl and methoxycarbonyl groups, appears at δ 2.86.

The results summarized above show that the regioselectivity of the Diels–Alder reaction of the diene **40** with MAC is, not unexpectedly, low. In contrast, the cycloadditions of the diene **7** with unsymmetrical dienophiles (MAC, NE) are

[4]The following discussion is not meant to imply a two-step mechanism for the cycloaddition reactions. These processes, in terms of the proposals of Dewar et al. (12), are considered to occur via *concerted, non-synchronous* pathways in which the transition state energies differ little from those of the corresponding biradicals.

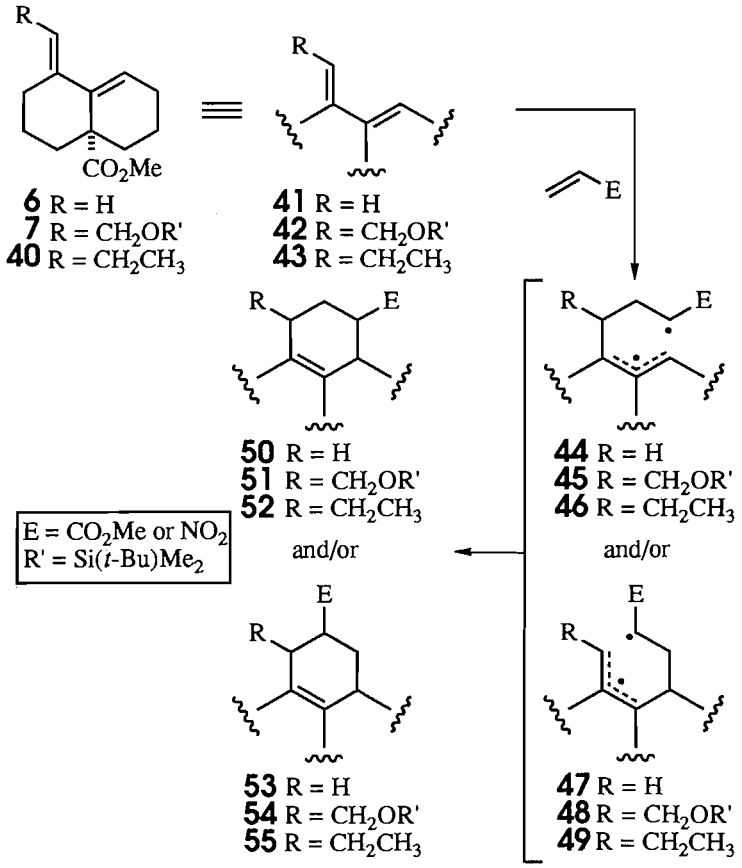
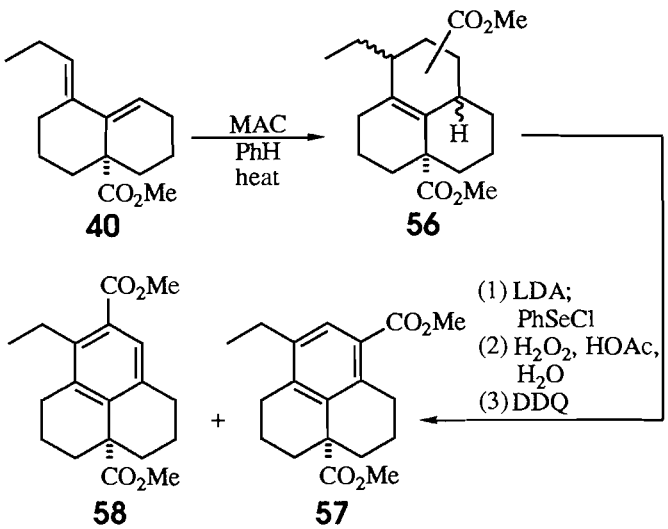


SCHEME 1

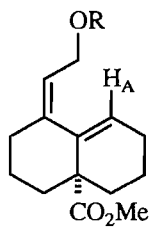


SCHEME 2

highly regioselective. Thus, the $CH_2OSi(t\text{-Bu})Me_2$ group in **7** has a notable directing effect on the regiochemistry of the cycloaddition reactions.

The "parent" diene **6**, as well as the *cisoid-trans* dienes **7** and **40**, are reasonably reactive substrates for Diels–Alder cycloadditions. In contrast, the *cisoid-cis* diene **8** is very reluctant to undergo Diels–Alder reactions. Indeed, only the reactions of **8** with very reactive dienophiles (TCNE, MAN) gave "normal" Diels–Alder adducts (Table 1, entries 4, 6) and, even then, the yield in one case (entry 6) was very low.

As mentioned previously, it is likely that these products are formed via a two-step process rather than a concerted cycloaddition pathway. With less reactive dienophiles, either no cycloaddition was observed (Table 2, entry 3; dimethyl acetylenedicarboxylate) or alternative processes took place (Table 2, entry 6).

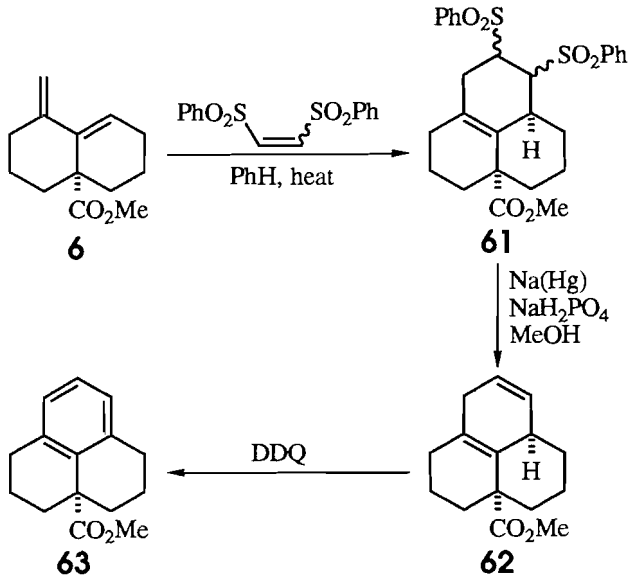


8 R = $Si(t\text{-Bu})Me_2$
59 R = $p\text{-}O_2NC_6H_4CO$

An X-ray crystallographic study (5) has shown that in the *p*-nitrobenzoate **59** (derived from the diene **8**), the diene system is twisted away from planarity to the extent of about 54°. If the crystal structure data accurately reflect the ground state conformation of substance **59** (and, thereby, of **8**) in solution, the sluggish nature of the Diels–Alder reactions of **8** would not be unexpected. Probably more important, however, is the fact that, if the diene unit in **8** is to attain planarity, a strong steric interaction between the CH_2OR group and H_A (see **8**, **59**) would be introduced. Clearly, this repulsion would destabilize cycloaddition transition states.

Additional synthetic applications

The studies summarized above show that Diels–Alder cycloadditions involving dienes **6** and **7** constitute an effec-

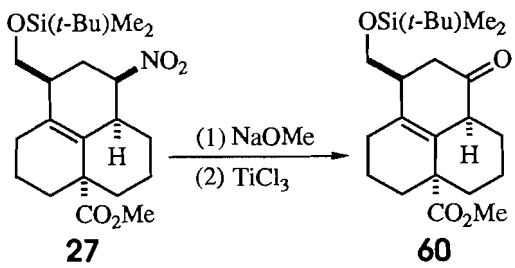


SCHEME 3

tive method for the preparation of functionalized perhydrophenalenes. With respect to a possible synthetic approach to amplilectane-type diterpenoids such as the natural product **1**, the fact that **21**, the major cycloaddition product from **7** and MAC, can be equilibrated to give primarily **22** is particularly noteworthy. Furthermore, the conversion of a mixture of cycloadducts (**24–26**, derived from **6** and NE, Table 2, entry 4) into the stereochemically homogeneous keto esters **33** and **35** illustrates the synthetic utility of the developed chemistry. We record here two additional examples that demonstrate the preparative value of Diels–Alder adducts derived from the dienes **7** and **6**.

The nitro ester **27**, the major product obtained from **7** and NE (Table 2, entry 5), upon sequential treatment with sodium methoxide and titanium trichloride under conditions identical with those employed earlier (conversion of **24–26** into **33**) provided, in excellent yield, the β,γ-unsaturated ketone **60** (eq. [10]). The ir spectrum of this stereochemically homogeneous substance exhibited carbonyl absorptions at 1740 and 1729 cm^{-1}.

[10]



Reaction of the diene **6** with 1,2-bis(phenylsulfonyl)-ethylene in refluxing benzene gave the Diels–Alder adduct **61** (see Scheme 3). Although the latter material appeared to be a single isomer, its relative stereochemistry was not determined. Nevertheless, on the basis of previous results, it seems highly likely that the cycloaddition had proceeded via attack of the dienophile on the β face of **6** and that, therefore, the angular allylic proton and the CO_2Me function are in a *syn* relationship, as shown in **61**.

Treatment of **61** with sodium amalgam in methanol in the presence of sodium dihydrogen phosphate gave the diene ester **62** (mp 51–52°C) in 85% yield. Dehydrogenation of the latter material with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in benzene produced (87%) the tricyclic aromatic ester **63**. The symmetrical nature of the structure of the latter substance was clearly shown by the ^1H and ^{13}C nmr spectra.

*X-ray crystal structures of compounds **9**, **11**, **15**, **30**, **31**, **27**, and **37***

The main purpose of the structure analyses was to establish the relative stereochemistries at the chiral centres of the compounds studied. All seven of these compounds crystallize in centrosymmetric space groups, therefore each crystal is racemic and is composed of equal numbers of the stereoisomers shown in Figs. 1–3 and their mirror images. The absolute configurations for the chiral centres of the molecules depicted in Figs. 1–3 are given in Table 4. It should be noted that the crystallographic numbering scheme employed for **9** (**10**) differs from that employed for the remaining six structures. The conformations of the individual six-membered rings constituting the central ring systems are summarized in Table 5.

The crystal structures of **30** and **31** are dominated by hydrogen bonding. In **30** each disordered OH group is hydrogen bonded either to the same group on another molecule related by a centre of symmetry or to the other OH group on a molecule related by a translation along the *ab* diagonal (O(1)—H(O1a)···O(1)(2 − *x*, 2 − *y*, 1 − *z*), O(1)—H(O1b)···O(2)(1 + *x*, 1 + *y*, *z*), O(2)—H(O2a)···O(2)(−*x*, 1 − *y*, 1 − *z*), and O(2)—H(O2b)···O(1)(*x* − 1, *y* − 1, *z*); H···O = 1.95(5), 1.95(6), 2.02(4), 2.00(7) Å; O···O = 2.814(3), 2.754(2), 2.792(3), 2.754(2) Å, O—H···O = 170(6), 165(5), 170(5), 178(6)°; respectively). The equivalence of the two possible O—H···O hydrogen bonds that can be formed for each OH group is the reason for the statistical disordering of the OH protons in **30**. Molecules of **31** are each linked to four others by O—H···O hydrogen bonding (O(1)—H(O1)···O(2)(*x* − 1, *y*, *z* − 1) and O(2)—H(O2)···O(1)(1 + *x*, 1/2 − *y*, 1/2 + *z*), H···O = 2.04(8) and 1.82(5) Å, O···O = 2.690(5) and 2.695(6) Å, O—H···O = 165(11) and 168(5)°, respectively). Normal van der Waals interactions dominate the crystal structures of the five remaining compounds.

Experimental

General information

Distillation temperatures, which refer to short-path (Kugelrohr) distillations, and melting points are uncorrected. Proton (^1H) and carbon (^{13}C) nuclear magnetic resonance spectra were recorded on $CDCl_3$ solutions. For the ^{13}C nmr data, signals with negative intensities in attached proton test (APT) experiments are designated as −ve following the chemical shift value. Conventional column chromatography and flash chromatography (7) were carried out with 230–400 mesh silica gel (E. Merck). Gas–liquid chromatography (glc) was carried out on instruments equipped with 25 m × 0.21 mm fused silica columns coated with cross-linked SE-54. Thin-layer chromatography (tlc) was performed with commercial, aluminum-backed silica gel plates. Reagents and solvents were purified and dried using standard methods.

Note. Unless otherwise noted, all reactions were carried out under an atmosphere of argon in flame or oven-dried glassware.

*Reaction of the diene **6** with dimethyl acetylenedicarboxylate (DMAD)*

A stirred solution of the diene **6** (50 mg, 0.24 mmol) and DMAD (70 mg, 0.49 mmol) in dry benzene (10 mL) was refluxed and the

disappearance of the diene was monitored by glc. After 6 h, the solvent was removed under reduced pressure. Flash chromatography (15 g silica gel, 3:1 petroleum ether – Et_2O) of the residual material provided 66 mg (78%) of a slightly off-white solid (mp 136–137°C). Analysis (glc–lrms) of this material showed that it consisted of a mixture of two isomers with molecular mass of 348, while the ^1H nmr spectrum revealed that the two substances were present in a ratio of 3:1. Recrystallization (Et_2O–$CHCl_3$) of the solid

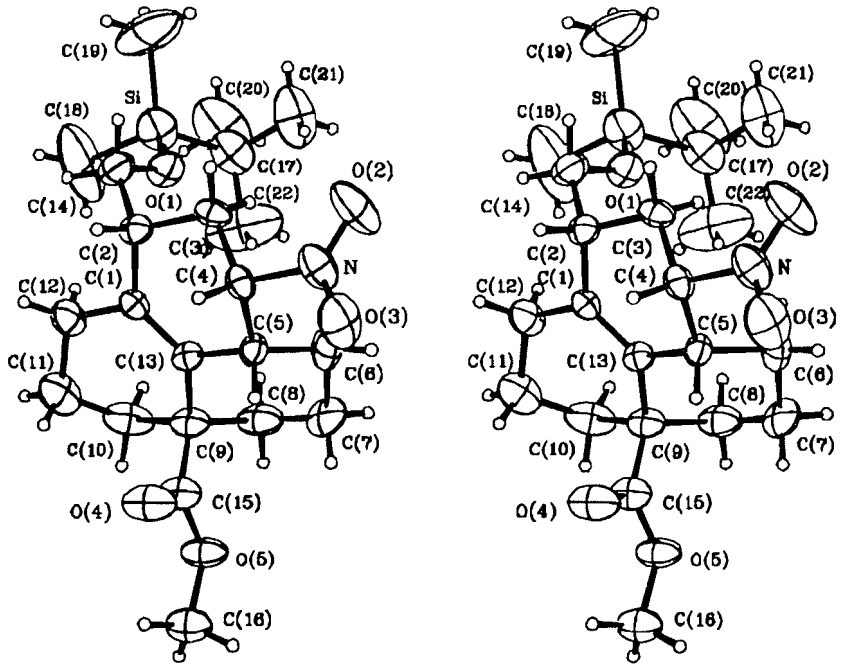

FIG. 2. Stereoview of **27** showing the crystallographic atom numbering scheme; 25% probability thermal ellipsoids are shown for the non-hydrogen atoms.

For personal use only.

provided colorless, cubic crystals (mp 137.5–138.5°C), the ^{1}H nmr spectrum of which showed that the two isomers were still present in a ratio of 3:1. X-ray crystallographic analysis of this crystalline mixture disclosed that the major isomer was the triester **9**. The minor component of the mixture was assigned structure **10**. The mixture exhibited ir ($CHCl_3$): 1719, 1199 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.12–2.34 (m, 12H), 2.67–2.90 (m, 1H), 2.98–3.15 (m, 2H), 3.67, 3.70 (s, s, 3H, ratio 1:3), 3.75, 3.76 (s, s, 3H, ratio 1:3), 3.78, 3.80 (s, s, 3H, ratio 3:1). Exact Mass calcd. for $C_{19}H_{24}O_6$: 348.1573; found: 348.1580.

*Reaction of the diene **6** with TCNE (Table 1, entry 1)*

To a cold (0°C), stirred solution of the diene **6** (225 mg, 1.09 mmol) in dry THF (10 mL) was added, dropwise, a solution of TCNE (147 mg, 1.15 mmol) in dry THF (10 mL). The mixture was warmed to room temperature and stirred for 30 min. Removal of the solvent, followed by flash chromatography (35 g silica gel, 5:1 petroleum ether – ethyl acetate) of the residual material gave 302 mg (83%) of a white solid. Analysis of this material by glc and by glc–lrms showed that it consisted of a mixture of two isomers (**11** and, presumably, **12**) in a ratio of 96:4. Recrystallization of the mixture from diethyl ether – chloroform provided the pure, major isomer **11** as colorless, cubic crystals that exhibited mp 146–147°C. An X-ray crystallographic study on this material confirmed the structural assignment. Compound **11** exhibited ir ($CHCl_3$): 2255, 1728, 1603 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.33 (dt, 1H, J = 3, 13 Hz), 1.38–1.75 (m, 5H), 1.90 (m, 1H), 2.00 (br d, 1H, J = 18 Hz), 2.14–2.38 (m, 4H), 2.89 (d, 1H, J = 18 Hz), 3.19 (br d, 1H, J = 18 Hz), 3.31 (br d, 1H, J = 12.5 Hz), 3.73 (s, 3H). In decoupling experiments, irradiation at δ 2.89 simplified the m at 2.14–2.38, changed the br d at 3.19 to a br s, and sharpened the br d at 3.31; irradiation at δ 3.19 simplified the multiplets at 1.38–1.75 and 2.14–2.38 and converted the resonance at 2.89 to a br s; ^{13}C nmr (75.3 MHz) δ: 18.4, 21.2, 29.7, 30.7, 35.5, 36.4, 36.6, 37.5, 41.3 (−ve), 45.3, 48.1, 52.4 (−ve), 109.4, 110.1, 111.1, 111.2, 126.0, 127.7, 174.7. Anal. calcd. for $C_{19}H_{18}O_2N_4$: C 68.25, H 5.43, N 16.76; found: C 68.29, H 5.44, N 16.78. Exact Mass calcd.: 334.1431; found: 334.1435.

*Reaction of the diene **7** with TCNE (Table 1, entries 2 and 3)*

To a stirred solution of the diene **7** (50 mg, 0.143 mmol) in dry THF (10 mL) at room temperature was added solid TCNE (21.5 mg, 0.168 mmol). The yellow solution was stirred for 1 h. Concentration of the reaction mixture, followed by flash chromatography of the residual oil on silica gel (18 g, 4:1 petroleum ether – diethyl ether) gave 50.5 mg (74%) of a 7:1 mixture of the esters **13** and **14**, respectively, as a colorless foam. These isomers were found to be inseparable by chromatography on silica gel. The mixture exhibited ^{1}H nmr (400 MHz) δ: 0.15, 0.16, 0.17, 0.18 (all s, 6H, ratio ~1:1:7:7), 0.94, 0.97 (s, s, 9H, ratio ~1:7), 1.20–2.33 (series of m), 2.44 (br d, major isomer), 2.91 (br s, minor isomer), 3.10 (br d, major isomer), 3.25 (m, major isomer), 3.74, 3.75 (s, s, 3H, ratio ~1:7), 3.98 (br t, major isomer), 4.23 (dd, major isomer), 4.34 (dd, minor isomer).

To a cold (−78°C), stirred solution of the diene **7** (100 mg, 0.285 mmol) in dry THF (4 mL) was added, dropwise, a solution of TCNE (73 mg, 0.57 mmol) in dry THF (5 mL). After the solution had been stirred for 2 h at −78°C, it was concentrated and the residual material was subjected to flash chromatography (27 g silica gel, 4:1 petroleum ether – diethyl ether). A single isomer **13** (114 mg, 84%) was obtained as a colorless foam. Crystallization of this material from hexane–acetone gave colorless, needle-like crystals of **13**. This substance exhibited ir (KBr): 2253, 1729, 840, 782 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.17, 0.18 (s, s, 3H each), 0.97 (s, 9H), 1.27 (dt, 1H, J = 3.5, 13.5 Hz), 1.37–1.50 (m, 3H), 1.72 (m, 1H), 1.87–2.32 (series of m, 6H), 2.44 (br d, 1H, J = 13 Hz), 3.10 (br d, 1H, J = 12.5 Hz), 3.25 (m, 1H), 3.75 (s, 3H), 3.98 (m, 1H), 4.23 (dd, 1H, J = 4.5, 10.5 Hz). In decoupling experiments, irradiation at δ 3.25 simplified the signals at 3.98 and 4.23 to a br d (J = 10.5 Hz) and a d (J = 10.5 Hz), respectively, while irradiation at δ 4.23 changed the resonances at 3.25 and 3.98 to broad doublets (J = 4.5 Hz and 7.0 Hz, respectively); ^{13}C nmr (75.3 MHz) δ: 18.4, 18.5, 23.6, 25.8 (−ve), 28.7, 30.5, 35.7, 38.0, 39.8 (−ve), 43.0, 43.8, 47.6 (−ve), 50.0, 52.7 (−ve), 62.1, 110.3, 110.5, 114.4, 112.3, 126.3, 129.6, 174.9. Exact Mass calcd. for $C_{25}H_{31}O_3N_4Si$ (M^+ − Me): 463.2166; found: 463.2168.

*Reaction of the diene **8** with TCNE (Table 1, entry 4)*

A stirred solution of the diene **8** (60 mg, 0.171 mmol) and TCNE (180 mg, 1.41 mmol) in diethyl ether (10 mL) was refluxed gently for 15 h. Concentration of the mixture, followed by flash chromatography of the residual material on silica gel (18 g, 4:1 petroleum ether – diethyl ether), afforded 59.1 mg (72%) of the tricyclic

ester **15** as a colorless glass. Analysis of this material by ^{1}H nmr spectroscopy showed the presence of only one isomer. Crystallization from hexane–acetonitrile gave compound **15** as colorless, needle-like crystals that exhibited mp 127–128°C. An X-ray crystallographic analysis of this substance confirmed the structural assignment. Compound **15** displayed ir ($CHCl_3$): 2254, 1718 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.17, 0.18 (s, s, 3H each), 0.96 (s, 9H), 1.41–1.77 (m, 6H), 1.82–1.94 (m, 2H), 1.98–2.17 (m, 2H), 2.21–2.36 (m, 2H), 3.26 (m, 2H), 3.70 (s, 3H), 3.93 (dd, 1H, J = 7.5, 10.5 Hz), 4.25 (dd, 1H, J = 4.0, 10.5 Hz). Decoupling experiment: irradiation at δ 4.24 sharpened the m at 3.26 and changed the dd at 3.93 into a d (J = 7.5 Hz); ^{13}C nmr (75.3 MHz) δ: 18.4, 19.3, 21.7, 25.8 (−ve), 28.0, 30.5, 35.3, 36.0, 41.7 (−ve) 42.0, 46.6, 46.9 (−ve), 48.7, 52.6 (−ve), 61.9, 109.4, 110.1, 111.5, 112.1, 129.1, 129.6, 175.1. Anal. calcd. for $C_{26}H_{34}O_3N_4Si$: C 65.24, H 7.16; found: C 65.40, H, 7.12. Exact Mass calcd.: 478.2400; found: 478.2406.

Reaction of the diene 7 with MAN (Table 1, entry 5)

A stirred solution of the diene **7** (100 mg, 0.285 mmol) and MAN (56 mg, 0.57 mmol) in dry benzene (20 mL) was refluxed gently for 18 h. The solvent was removed under reduced pressure. Flash chromatography (27 g silica gel, 3:2 petroleum ether – diethyl ether) of the residual solid gave 80 mg (63%) of the anhydride **16** as a white solid. Recrystallization from hexane afforded colorless, cubic crystals that exhibited mp 103.5–105°C; ir (KBr): 1860, 1781, 1730, 838 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.04, 0.07 (s, s, 3H each), 0.89 (s, 9H), 1.21 (dt, 1H, J = 4, 13 Hz), 1.29–1.68 (m, 5H), 1.74 (m, 1H), 1.92–2.02 (m, 2H), 2.11 (m, 1H), 2.26 (br d, 1H, J = 12.5 Hz), 2.40 (m, 1H), 2.51–2.64 (m, 2H), 3.35 (m, 2H), 3.65 (dd, J = 5.5, 10.5 Hz), 3.66 (s, 3H), 3.74 (dd, 1H, J = 4, 10.5 Hz). In decoupling experiments irradiation at δ 3.35 simplified the m at 2.51–2.64 to two signals, a br d at 2.59 (J = 12 Hz) and a dd at 2.53 (J = 4, 5.5 Hz), while irradiation at δ 3.74 changed the resonance at 2.53 to a br t (J = 5.5 Hz) and simplified the dd at 3.65 to a d (J = 5.5 Hz). Exact Mass calcd. for $C_{24}H_{36}O_6Si$: 448.2281; found: 448.2276.

Reaction of the diene 8 with MAN (Table 1, entry 6)

A stirred solution of the diene **8** (100 mg, 0.285 mmol) and MAN (56 mg, 0.57 mmol) in dry benzene (5 mL) was refluxed gently for 3 days. During this time, a white solid precipitated from the colorless solution. The cooled mixture was filtered and the filtrate was concentrated. Flash chromatography of the residual oil on silica gel (15 g, 5:1 petroleum ether – diethyl ether) produced 22.4 mg (18%) of the anhydride **17** as a colorless oil. This material exhibited ir (neat): 1864, 1784, 1729, 837, 779 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.06, 0.07 (s, s, 3H each), 0.89 (s, 9H), 1.15 (m, 1H), 1.35–2.20 (series of m, 11H), 2.56 (m, 1H), 2.68 (m, 1H), 3.43 (t, 1H, J = 9 Hz), 3.50 (dd, 1H, J = 1, 9 Hz), 3.51 (dd, 1H, J = 7, 10 Hz), 3.67 (s, 3H), 3.72 (dd, 1H, J = 4, 10 Hz). Decoupling experiments: irradiation at δ 2.56 simplified the t at 3.43 to a d (J = 9 Hz); irradiation at δ 2.68 changed the signals at 3.50, 3.51, and 3.72 to doublets (J = 9, 10, 10 Hz, respectively); irradiation at δ 3.43 changed the resonance at 2.56 to a br d (J = 12 Hz); irradiation at δ 3.72 sharpened the signals at 2.68 and 3.51 to a br d (J = 7 Hz) and a d (J = 7 Hz), respectively. Exact Mass calcd. for $C_{24}H_{36}O_6Si$: 448.2281; found: 448.2276.

The white solid (75 mg) that had precipitated during the course of the reaction was washed with diethyl ether and dried. This material exhibited ir (KBr): 1849, 1779, 1718 cm^{-1}; ^{1}H nmr (400 MHz, CD_3SOCD_3): no signals due to the OSi(*t*-Bu)Me_2 group. Exact Mass calcd. for $C_{22}H_{22}O_8$: 414.1315; found: 414.1315.

Reaction of the diene 6 with MAC (Table 2, entry 1)

A stirred solution of the diene **6** (500 mg, 2.43 mmol) and MAC (0.44 mL, 4.8 mmol) in dry benzene (50 mL) was refluxed gently and the disappearance of the diene was monitored by glc. Additional amounts of MAC were added after reaction times of 22 and 46 h (4.8 and 2.4 mmol, respectively). After a total reaction time of 72 h, the reaction mixture was concentrated. Flash chromatography (70 g silica gel, 10:1 petroleum ether – diethyl ether) of the residual oil afforded 603 mg (85%) of a colorless oil. Analysis of this material by ^{1}H nmr spectroscopy and glc–lrms showed that it consisted of a mixture of three isomers (each of molecular mass 292) in a ratio of about 2.7:1:1.7. These substances were eventually identified as compounds **18**, **19**, and **20**, respectively.

Subjection of the mixture to drip column chromatography on silica gel (80 g, 15:1 petroleum ether – diethyl ether) provided pure samples of the major product **18** (the second component to be eluted) and of substance **20** (the first compound to be eluted). Although a pure sample of the minor, most polar, product was not obtained, this substance was subsequently identified as the diester **19**.

The major Diels–Alder adduct **18** (distillation temperature 195–200°C/0.5 Torr (1 Torr = 133.3 Pa)) exhibited ir (neat): 1732 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.15 (dt, 1H, J = 4, 8 Hz), 1.24 (dt, 1H, J = 4, 12.5 Hz), 1.28–1.73, 1.77–2.12 (series of m, 13H), 2.35 (br d, 1H, J = 13 Hz), 2.73 (ddd, 1H, J = 2.8, 6, 13 Hz), 3.67, 3.71 (s, s, 3H each). Exact Mass calcd. for $C_{17}H_{24}O_4$: 292.1674; found: 292.1674.

The diester **20** (distillation temperature 160–162°C/0.5 Torr) displayed ir (neat): 1720 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.21 (m, 1H), 1.33–1.70, 1.75–2.05 (series of m, 14H), 2.17 (m, 1H), 2.31 (dt, 1H, J = 3, 12 Hz), 2.38 (m, 1H), 3.67, 3.68 (s, s, 3H each). Exact Mass calcd. for $C_{17}H_{24}O_4$: 292.1674; found: 292.1676.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

To a stirred solution of a mixture of the diesters **18** and **19** (ratio 3:1, respectively, obtained from fractions of the column chromatography described above, 24.9 mg) in dry methanol (20 mL) was added sodium methoxide (10 mg) and the resulting solution was refluxed gently for 2 weeks. The mixture was concentrated and diethyl ether (25 mL) was added to the residual slurry. The mixture was filtered and the filtrate was dried ($MgSO_4$) and concentrated. Distillation (160–170°C/0.6 Torr) of the residual oil provided 22 mg (88%) of a colorless oil that consisted of a mixture of **18** and **19** in a ratio of 1:6 (glc analysis). The ^{1}H nmr spectrum (400 MHz) of the material exhibited the following unique signals for compound **19**: δ 0.99 (dq, 1H, J = 4, 12 Hz), 2.19–2.27 (m, 2H), 2.49 (br t, 1H, J = 11 Hz), 3.69 (s, 6H).

*Reduction of the diester **18**. Preparation of the diol **31***

Solid $LiAlH_4$ (17 mg, 0.45 mmol) was added to a stirred solution of the diester **18** (85 mg, 0.29 mmol) in dry THF (10 mL) and the resulting slurry was refluxed for 1 h and then was cooled to room temperature. Hydrochloric acid (1 M, 5 drops) was added cautiously and then the mixture was treated with cold water (5 mL). The phases were separated and the aqueous phase was extracted with diethyl ether (3 × 25 mL). The combined extracts were dried ($MgSO_4$) and concentrated to provide 66.8 mg (97%) of the diol **31** as a white solid. Recrystallization from ethanol–hexane gave colorless cubes that exhibited mp 182.5–184.5°C. The structure of **31** was confirmed by an X-ray crystallographic analysis. This material displayed ir (Nujol): 3271, 3189 cm^{-1}. It was not sufficiently soluble in common deuterated solvents ($CDCl_3$, CD_3SOCD_3, C_6D_6, CD_3COCD_3) to allow for acquisition of a satisfactory ^{1}H nmr spectrum. Anal. calcd. for $C_{15}H_{24}O_2$: C 76.23, H 10.24; found: C 76.17, H 10.24. Exact Mass calcd.: 236.1777; found: 236.1777.

*Reduction of the diester **20**. Preparation of the diol **30***

To a stirred suspension of $LiAlH_4$ (43 mg, 1.13 mmol) in dry diethyl ether (20 mL) at 0°C was added, dropwise, a solution of the diester **20** (218 mg, 0.747 mmol) in dry diethyl ether (10 mL). After the mixture had been stirred at 0°C for 30 min, it was refluxed for 6.5 h. Hydrochloric acid (1 M, 5 mL) and water (10 mL) were added cautiously. The organic phase was separated and the aqueous phase was extracted with diethyl ether (3 × 10 mL). The combined organic extracts were dried ($MgSO_4$) and concentrated to give 146 mg (83%) of the diol **30** as a crystalline solid. Recrystallization from methanol produced colorless cubic crystals that displayed mp 162.5–164°C. An X-ray crystallographic analysis confirmed that this substance possessed structure **30**. This material showed ir (Nujol): 3310, 3195 cm^{-1}. It was sparingly soluble in common deuterated solvents and its ^{1}H nmr spectrum in CD_3OD was uninformative. Anal. calcd. for $C_{15}H_{24}O_2$: C 73.23, H 10.24; found: C 73.17, H 10.21. Exact Mass calcd.: 236.1777; found: 236.1776.

*Reaction of the diene **7** with MAC (Table 2, entry 2)*

A stirred solution of the diene **7** (170 mg, 0.485 mmol) and MAC (0.18 mL, 1.95 mmol) in dry benzene (10 mL) was refluxed gently. Additional amounts (1 mmol) of MAC were added to the reaction mixture after reaction times of 24, 48, and 56 h. After a total reaction time of 72 h, the solution was concentrated. Analysis (^{1}H nmr spectroscopy) of the crude product indicated the presence of at least three components. Medium-pressure column chromatography of the crude oil on silica gel (40 g, 8:1 petroleum ether – diethyl ether) provided, in addition to a trace amount of an unidentified compound, two major fractions. The first material to be eluted (65.7 mg, 31%) was a single compound that was identified as the Diels–Alder adduct **23**, while the second fraction (118.3 mg, 56%) was shown by ^{1}H nmr spectroscopy to consist of a 3:1 mixture of the diesters **21** and **22**. Thus, the cycloaddition reaction involving the diene **7** and MAC gave, in 87% yield, a mixture of **21**, **22**, and **23** (48:16:36, respectively).

Subjection of the 3:1 mixture of **21** and **22** to drip column chromatography (27 g silica gel, 8:1 petroleum ether – diethyl ether) provided a pure sample of the major adduct **21**.

A pure sample of the minor isomer **22** was obtained as follows. A stirred solution of the diester **21** (20 mg) and sodium methoxide (~2 mg) in dry methanol (5 mL) was refluxed gently for 6 days and then was concentrated. Analysis of the crude material by ^{1}H nmr spectroscopy indicated the presence of **21** and **22** in a ratio of ~1:9, respectively. Drip column chromatography of this material on silica gel (10 g, 5:1 petroleum ether – diethyl ether) gave a pure sample of **22**.

The major adduct **21**, a colorless oil, displayed ir (neat): 1733, 837, 776 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.04, 0.05 (s, s, 3H each), 0.89 (s, 9H), 1.09 (dt, 1H, J = 4, 13 Hz), 1.20–2.08 (series of m, 12H), 2.20 (m, 1H), 2.30 (m, 1H), 2.39 (br d, 1H, J = 13.5 Hz), 2.76 (ddd, 1H, J = 2.7, 6, 13.5 Hz), 3.63–3.70 (m, 2H), 3.67, 3.71 (s, s, 3H each). Exact Mass calcd. for $C_{24}H_{40}O_5Si$: 436.2645; found: 436.2643.

The minor product **22**, a colorless oil, exhibited ir (neat): 1735, 837, 777 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.06 (s, 6H), 0.91 (s, 9H), 1.16 (dt, 1H, J = 3.5, 13.5 Hz), 1.30 (m, 1H), 1.39–1.64, 1.70–2.06, 2.16–2.32, 2.36–2.48 (series of m, 5H, 5H, 3H, 2H), 3.47 (dd, 1H, J = 8.5, 10 Hz), 3.66–3.72 (m, 1H, buried under OMe signals), 3.68, 3.69 (s, s, 3H each). Exact Mass calcd. for $C_{24}H_{40}O_5Si$: 436.2645; found: 436.2645.

Compound **23**, a colorless oil, showed ir (neat): 1733, 838, 777 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.06, 0.07 (s, s, 3H each), 0.91 (s, 9H), 1.15–1.72 (series of m, 8H), 1.78 (dt, 1H, J = 6, 12.5 Hz), 1.87–2.02, 2.06–2.27, 2.34–2.46 (series of m, 3H, 3H, 2H), 3.44 (t, 1H, J = 10 Hz), 3.65, 3.67 (s, s, 3H each), 3.74 (dd, 1H, J = 3.8, 10 Hz). Exact Mass calcd. for $C_{24}H_{40}O_5Si$: 436.2644; found: 436.2645.

*Reaction of the diene **6** with NE (Table 2, entry 4)*

To a solution of the diene **6** (150 mg, 0.728 mmol) in dry diethyl ether (7 mL) was added neat NE (9) (0.5 mL) and the resultant mixture was stirred at room temperature for 3 h. Concentration of the mixture, followed by flash chromatography (27 g silica gel, 15:1 petroleum ether – ethyl acetate) of the residual oil afforded 168 mg (83%) of a very pale-green solid. Analysis of this material by glc and by glc–lrms indicated that it consisted of a mixture of three isomers (3:1:2), each with molecular mass 279. These substances were assigned structures **24**, **25** and **26**, respectively. The ^{1}H nmr spectrum (400 MHz) of this mixture exhibited δ: 1.14–2.43 (series of m, 16H), 2.75 (m, 1H, angular allylic protons of all three isomers), 3.69, 3.72 (s, s, 3H, ratio 1:2), 4.44 (dt, ~0.33 H, J = 3.8, 10.5 Hz, CHNO$_2$ of **26**), ~4.71, 4.74 (overlapping multiplets, minor and major, respectively, ~0.67 H total, CHNO$_2$ of **25** and **24**, respectively).

A 30 mg sample of this mixture was added to dry *tert*-butyl alcohol (4 mL) containing 4 mg of potassium *tert*-butoxide and the resultant stirred mixture was heated at 80°C for 16 h. Dilute (1%) aqueous acetic acid (5 mL) and water (5 mL) were added sequentially to the cooled reaction mixture. The phases were separated and the aqueous phase was extracted with diethyl ether (2 × 10 mL). The combined organic extracts were washed with saturated aqueous sodium bicarbonate (2 × 10 mL), dried ($MgSO_4$), and concentrated. Flash chromatography of the residual oil on silica gel (10 g, 10:1 petroleum ether – ethyl acetate) gave 26 mg (87%) of a mixture of the nitro esters **24**, **25**, and **26** (0.7:3.1:2, respectively, by glc analysis).

Drip column chromatography of the 3:1:2 mixture of **24**, **25**, and **26** (135 mg) on silica gel (18 g, 20:1 petroleum ether – diethyl ether) gave a pure sample of **26**, the first component to be eluted. This material exhibited ir ($CHCl_3$): 1718 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.20–1.75, 1.90–2.35 (series of m, 8H, 8H), 2.75 (m, 1H), 3.69 (s, 3H), 4.44 (dt, 1H, J = 3.8, 10.5 Hz). In a decoupling experiment, irradiation at δ 4.44 simplified the m at 2.75 to a br d (J = 13 Hz).

*Preparation of the keto ester **33***

To a stirred solution of the mixture of the nitro esters **24**, **25**, and **26** (3:1:2, 162 mg, 0.581 mmol) in spectral grade methanol (8 mL)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

at room temperature was added solid sodium methoxide (31 mg, 0.57 mmol) and the resultant yellow solution was stirred for 20 min. A freshly prepared solution of titanium trichloride (358 mg, 2.32 mmol) and ammonium acetate (1.12 g, 14.5 mmol) in water (8 mL) was added. The mixture immediately turned green in color and, as the reaction progressed, became blue and finally yellow. A finely divided solid precipitated. The mixture was stirred for 3 h and then was filtered. The collected solid was washed with diethyl ether (50 mL). The phases of the combined filtrate were separated and the aqueous phase was washed with diethyl ether (3 × 25 mL). The combined organic extracts were washed with saturated aqueous sodium bicarbonate (20 mL), dried ($MgSO_4$), and concentrated. Distillation (132–133°C/0.1 Torr) of the residual oil provided 129 mg (90%) of the ketone **33**, a colorless oil that displayed ir (neat): 1710, 1450, 1226, 1160 cm^{-1}; ^1H nmr (400 MHz) δ: 1.15–130 (m, 2H), 1.36 (tt, 1H, J = 3.2, 13 Hz), 1.45–1.69 (m, 4H), 1.74 (d of quintets, 1H, J = 13, 3.4 Hz), 2.00–2.10 (m, 3H), 2.27–2.57 (m, 5H), 2.82 (br d, 1H, J = 13 Hz), 3.69 (s, 3H). In a nuclear Overhauser enhancement (nOe) difference experiment, irradiation at δ 3.69 (CO_2Me) caused enhancement of the broad d at 2.82 (angular allylic proton); ^{13}C nmr (75.3 MHz) δ: 19.3, 23.0, 30.6, 30.7, 31.0, 36.0, 37.4, 37.9, 48.4, 48.5, 52.1, 130.1, 130.6, 176.6, 213.0. Exact Mass calcd. for $C_{15}H_{20}O_3$: 248.1413; found: 248.1410.

Preparation of the enone ester ***35***

To a stirred solution of the ketone **33** (10 mg) in dry THF (5 mL) at room temperature was added approximately 1–2 mg of potassium *tert*-butoxide and the resulting mixture was stirred for 24 h. Water (5 mL) was added, the phases were separated, and the aqueous layer was extracted with diethyl ether (3 × 20 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Drip column chromatography of the residual oil on silica gel (10 g, 1:5 petroleum ether – diethyl ether) produced 5.5 mg (55%) of the enone **35** as a white solid. Recrystallization from diethyl ether provided material that displayed mp 159–160°C; ir ($CHCl_3$): 1723, 1668, 1603 cm^{-1}; ^1H nmr (400 MHz) δ: 1.35–2.42 (series of m, 15H), 2.50 (ddd, 1H, J = 1.8, 5.5, 18.2 Hz), 2.89 (ddd, 1H, J = 6, 13, 18.2 Hz), 3.72 (s, 3H). In a decoupling experiment, irradiation at δ 2.89 simplified the signal at 2.50 to a dd (J = 1.8, 5.5 Hz); ^{13}C nmr (75.3 MHz) δ: 15.3, 18.3, 22.7, 29.0, 31.0, 33.0, 34.8, 36.4, 47.5, 52.4, 68.3, 133.8, 155.3, 175.8, 199.6. Exact Mass calcd. for $C_{15}H_{20}O_3$: 248.1413; found: 248.1356.

Reaction of the diene ***7*** *with NE (Table 2, entry 5)*

To a stirred solution of the diene **7** (190 mg, 0.542 mmol) in dry diethyl ether (5 mL) was added neat NE (9) (0.6 mL). After the mixture had been stirred at room temperature for 3 h, the solvent was removed under reduced pressure. The residual oil was passed through a plug of silica gel (elution with diethyl ether). Concentration of the eluate provided an oil that consisted of a mixture of three nitro esters **27**, **28**, and **29** (~3:trace:1 by ^1H nmr spectroscopy). Medium-pressure column chromatography (40 g silica gel, 10:1 petroleum ether–diethyl ether) afforded 56 mg (24%) of **29** (the first compound to be eluted, distillation temperature 180–195°C/0.03 Torr) as a colorless oil and 130.4 mg (57%) of **27** (the second product to be eluted, mp 89–90°C (from chloroform)) as a colorless crystalline material. An X-ray crystallographic analysis confirmed the structure of the latter substance.

Product **27** displayed ir ($CHCl_3$): 1728, 1547, 1384, 838, 777 cm^{-1}; ^1H nmr (400 MHz) δ: 0.06, 0.07 (s, s, 3H each), 0.90 (s, 9H), 1.11 (dt, 1H, J = 3.9, 13 Hz), 1.23–1.66 (m, 6H), 1.73 (m, 1H), 1.91–2.08 (m, 3H), 2.09–2.17 (m, 2H), 2.33 (m, 1H), 2.44 (br d, 1H, J = 13.4 Hz), 2.69 (m, 1H), 3.66 (dd, 1H, J = 3, 10 Hz), 3.72 (s, 3H), 3.73 (dd, 1H, J = 5, 10 Hz), 4.75 (m, 1H). In decoupling experiments irradiation at δ 2.69 simplified the multiplets at 1.23–1.66 and 4.75; irradiation at 3.66 sharpened the m at 2.33 to a br t; irradiation at 4.75 sharpened the m at 2.09–2.17 and changed the m at 2.69 to a br d (J = 11 Hz). Anal. calcd. for $C_{22}H_{37}O_5NSi$: C 62.38, H 8.80; found: C 62.49, H 8.92. Exact Mass calcd. for $C_{21}H_{34}O_5NSi$ (M^+ − Me): 408.2207; found: 408.2212.

Compound **29** exhibited ir (neat): 1729, 1549, 1378, 838, 778 cm^{-1}; ^1H nmr (400 MHz) δ: 0.07, 0.08 (s, s, 3H each), 0.91 (s, 9H), 1.25–1.75, 1.88–2.08, 2.16–2.33 (series of m, 8H, 3H, 3H), 2.46 (ddd, 1H, J = 0.9, 3, 12 Hz), 2.78 (br t, 1H, J = 12 Hz), 3.50 (dd, 1H, J = 8, 10 Hz), 3.67 (s, 3H), 3.75 (dd, 1H, J = 4, 10 Hz), 4.58 (ddd, 1H, J = 3, 10.5, 12 Hz). Decoupling experiments: irradiation at δ 2.46 sharpened the m at 2.16–2.33 and changed the m at 4.58 to a dd (J = 10.5, 12 Hz); irradiation at δ 2.78 simplified the multiplets at 1.25–1.75 and 1.88–2.08 and sharpened the ddd at 4.58 to a br d (J = 10.5 Hz); irradiation at δ 3.50 sharpened the m at 2.16–2.33 and changed the dd at 3.75 to a d (J = 4 Hz); irradiation at δ 4.58 sharpened the m at 2.16–2.33, simplified the signal at 2.46 to a dd (J = 0.9, 12 Hz), and changed the br t at 2.78 to a br d (J = 12 Hz). Exact Mass calcd. for $C_{21}H_{34}O_5NSi$ (M^+ − Me): 408.2207; found: 408.2203.

To a stirred solution of the nitro ester **27** (38 mg, 0.09 mmol) in dry *tert*-butyl alcohol (4 mL) was added potassium *tert*-butoxide (~1.5 mg) and the resultant solution was heated at ~100°C for 18 h. The mixture was cooled and then was treated with 5 mL of dilute aqueous acetic acid, 5 mL of diethyl ether, and 5 mL of water. The organic phase was separated and the aqueous layer was washed with diethyl ether (3 × 10 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (10 g silica gel, 10:1 petroleum ether–diethyl ether) of the residual oil provided 35 mg (92%) of the nitro ester **28** as a colorless crystalline solid that displayed mp 62–63°C. This substance, which showed diagnostic ^1H nmr signals with chemical shifts identical with those of the Diels–Alder adduct formed in trace amounts, exhibited ir ($CHCl_3$): 1721, 1548, 1379, 839 cm^{-1}; ^1H nmr (400 MHz) δ: 0.07, 0.08 (s, s, 3H each), 0.91 (s, 9H), 1.07 (dq, 1H, J = 3.5, 12.5 Hz), 1.17 (dt, 1H, J = 3.2, 13.1 Hz), 1.23–1.35 (m, 1H), 1.39–1.70 (m, 4H), 1.83–1.94 (m, 2H), 2.09 (m, 1H), 2.14–2.35 (m, 4H), 2.84 (m, 1H), 3.59 (dd, 1H, J = 6.3, 10 Hz), 3.68 (dd, 1H, J = 3.4, 10 Hz), 3.71 (s, 3H), 4.68 (ddd, 1H, J = 4, 9, 12 Hz). In decoupling experiments, irradiation at δ 2.84 sharpened the m at 2.14–2.35 and simplified the signals at 1.07 and 4.68 to a dt (J = 3.5, 12.5 Hz) and a dd (J = 4, 12 Hz), respectively; irradiation at δ 3.59 sharpened the m at 2.14–2.35; irradiation at δ 4.68 simplified the m at 2.14–2.35 and changed the m at 2.84 to a br d (J = 12 Hz). Exact Mass calcd. for $C_{21}H_{34}O_5NSi$ (M^+ − Me): 408.2206; found: 408.2204.

Preparation of the p*-nitrobenzoate* ***37***

To a stirred solution of the silyl ether **29** (106 mg, 0.251 mmol) in dry THF (10 mL) at room temperature was added, dropwise, a solution of tetra-*n*-butylammonium fluoride (0.5 mL, 1 M, THF). The solution was stirred for 16 h and then was concentrated. Flash chromatography of the residual oil on silica gel (27 g, 2:1 petroleum ether–diethyl ether) provided 55.6 mg (72%) of the alcohol **36** as a colorless oil. This material displayed ir (neat): 3478, 1713, 1546, 1379 cm^{-1}; ^1H nmr (400 MHz) δ: 1.19–1.79, 1.92–2.35 (series of m, 7H, 7H), 2.40 (ddt, 1H, J = 1, 6.5, 12.5 Hz), 2.80 (m, 1H), 3.60 (dd, 1H, J = 1.5, 11 Hz), 3.72 (s, 3H), 3.90 (ddd, 1H, J = 4, 10, 12.5 Hz).

To a stirred solution of the alcohol **36** (46.9 mg, 0.152 mmol) in dry THF (10 mL) at room temperature was added 4-(*N*,*N*-dimethylamino)pyridine (22.3 mg) and *p*-nitrobenzoyl chloride (42.4 mg, 0.228 mmol). The mixture was refluxed for 1 h and then was concentrated. Flash chromatography (18 g silica gel, 1:1 petroleum ether–diethyl ether) of the residual material provided 63 mg (91%) of the *p*-nitrobenzoate **37** as a white solid. Recrystallization of this material from benzene gave colorless crystals, mp 142.5–143.5°C. An X-ray crystallographic study showed that this substance possesses the constitution and relative stereochemistry shown in **37**. Compound **37** exhibited ir ($CHCl_3$): 1724, 1550, 1530, 1350 cm^{-1}; ^1H nmr (400 MHz) δ: 1.23–1.82, 1.96–2.10, 2.30–2.49 (series of m, 8H, 3H, 3H), 2.65 (m, 1H), 2.82 (br t, 1H,

For personal use only.

J = 10 Hz), 3.65 (s, 3H), 4.40 (dd, 1H, J = 7.3, 11.2 Hz), 4.53 (dd, 1H, J = 3, 11.2 Hz), 4.63 (dt, 1H, J = 4, 11 Hz), 8.25–8.35 (m, 4H). Anal. calcd. for $C_{23}H_{26}N_2O_8$: C 60.26, H 5.72, N 6.11; found: C 60.05, H 5.70, N 6.00. Exact Mass calcd.: 458.1689; found: 458.1684.

*Reaction of the diene **8** with NE (Table 2, entry 6)*

A stirred solution of the diene **8** (500 mg, 1.426 mmol) and NE (9) (~1 mL) in dry diethyl ether (20 mL) was refluxed for 7 h and then was concentrated. The residual oil was passed through a plug of silica gel (elution with diethyl ether). Removal of the solvent from the eluant produced a mixture of three nitro esters (**27**, **28**, **29**; ~2.5:trace:1, by ^{1}H nmr spectroscopy). Medium-pressure column chromatography of this material on silica gel (90 g, 10:1 petroleum ether – diethyl ether) provided, in order of elution, 127 mg (21%) of **29**, 19 mg (3%) of **28**, and 328 mg (54%) of **27**. These materials exhibited ir and ^{1}H nmr spectra identical with those of the same substances obtained previously (vide supra).

*Reaction of the diene **40** with MAC*

A stirred solution of the diene **40** (760 mg, 3.24 mmol) and MAC (2.9 mL) in dry benzene (60 mL) was refluxed for 3 days and then was concentrated. Flash chromatography (100 g silica gel, 10:1 petroleum ether – diethyl ether) without any attempt to separate isomers provided 873 mg (84%) of a mixture of diesters **56** as a colorless oil. Analysis of this material by glc–lrms indicated the presence of at least five isomers, each with molecular mass 320.

To a cold (0°C) stirred solution of lithium diisopropylamide (2.5 equiv.) in dry THF (6 mL) was added, dropwise, a solution of the mixture of diesters **56** (50 mg, 0.156 mmol) in dry THF (2 mL). The solution was stirred at 0°C for 30 min and at room temperature for 30 min. Solid benzeneselenenyl chloride (75 mg, 2.5 equiv.) was added and the solution was stirred for 30 min. Water (1 mL), acetic acid (0.04 mL, 4 equiv.), and hydrogen peroxide (0.18 mL, 10 equiv.) were added sequentially and the mixture was stirred for 1 h. Saturated aqueous sodium bicarbonate (10 mL) was added and the organic phase separated. The aqueous phase was extracted with diethyl ether. The combined organic solutions were washed with brine, dried ($MgSO_4$), and concentrated. The residual oil was dissolved in dry benzene (10 mL) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (40 mg) was added to the solution. The stirred mixture was refluxed for 4 h and then was concentrated. Drip column chromatography (18 g silica gel, 7:1 petroleum ether – diethyl ether) of the remaining material and distillation (130–140°C/0.1 Torr) of the oil thus obtained provided 40.3 mg (82%) of a mixture of the diesters **57** and **58** (ratio 1.4:1), a colorless oil that displayed ir (neat): 1724, 1598, 1565 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.18, 1.22 (t, t, 3H, ratio 1:1.4, J = 7.5 Hz), 1.43–1.90, 2.30–2.40 (series of m, 6H, 2H), 2.60, 2.86 (q, q, 2H, ratio 1.4:1, J = 7.5 Hz), 2.69–2.82 (m), 3.00 (ddd, J = 18, 7, 4 Hz), 3.20 (dt, J = 18, 9 Hz), 3.63, 3.86, 3.87 (s, s, s, 2.4:1.4:1), 7.38, 7.59 (s, s, 1H, ratio 1:1.4). Exact Mass calcd. for $C_{19}H_{24}O_4$: 316.1674; found: 316.1683.

*Preparation of the keto ester **60***

Using a procedure identical with that used for the preparation of the keto ester **33**, the nitro ester **27** (81 mg, 0.191 mmol) was converted into the keto ester **60**. Flash chromatography (27 g silica gel, 3:1 petroleum ether – diethyl ether) of the crude product, followed by distillation (205–215°C/0.05 Torr) of the acquired liquid, provided 62 mg (83%) of the keto ester **60**, a colorless oil that displayed ir (neat): 1740, 1729, 838, 779 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.02, 0.04 (s, s, 3H), 0.89 (s, 9H), 1.10 (dq, 1H, J = 3.8, 12.5 Hz), 1.23 (dq, 1H, J = 3, 12.8 Hz), 1.33 (tq, 1H, J = 3.5, 13.5 Hz), 1.42–1.77 (m, 4H), 1.99–2.08 (m, 2H), 2.19–2.31 (m, 3H), 2.50–2.67 (m, 3H), 2.77 (br d, 1H, J = 12 Hz), 3.44 (dd, 1H, J = 6, 10 Hz), 3.53 (dd, 1H, J = 3.4, 10 Hz), 3.70 (s, 3H). Exact Mass calcd. for $C_{22}H_{36}O_4Si$: 392.2384; found: 392.2378.

*Preparation of the tricyclic esters **62** and **63***

A stirred solution of the diene **6** (50 mg, 0.243 mmol) and 1,2-bis(phenylsulfonyl)ethylene (90 mg, 0.292 mmol) in dry benzene (10 mL) was refluxed for 24 h and then was concentrated. Flash chromatography (18 g silica gel, 7:2:5 dichloromethane – diethyl ether – petroleum ether) of the residual oil provided 102 mg (82%) of the ester **61** as a white amorphous solid. This material (Exact Mass calcd. for $C_{27}H_{30}O_6S_2$: 514.1485; found: 514.1485), which appeared to be a single isomer, was not characterized further.

A mixture of the ester **61** (179 mg, 0.348 mmol), 2% sodium amalgam (2.7 g, 6.8 equiv. of sodium), and sodium dihydrogen phosphate monohydrate (615 mg) in dry methanol (5 mL) was stirred at room temperature for 24 h. The mixture was poured into water (10 mL) and the mixture was extracted with diethyl ether (3 × 10 mL). The combined extracts were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (30 g silica gel, 2:1 petroleum ether – diethyl ether) of the remaining oil, followed by distillation (120–124°C/0.6 Torr) of the acquired oil, yielded 69 mg (85%) of the diene ester **62**, a white waxy solid (mp 51–52°C) that displayed ir ($CHCl_3$): 1715 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.35–1.80, 1.95–2.14 (series of m, 8H, 4H), 2.52–2.63 (m, 2H), 2.70 (m, 1H), 3.67 (s, 3H), 5.60 (br d, 1H, J = 9 Hz), 5.76 (m, 1H). Exact Mass calcd. for $C_{15}H_{20}O_2$: 232.1463; found: 232.1463.

To a stirred solution of the diene **62** (20 mg, 0.086 mmol) in dry benzene was added 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (20 mg, 1.02 equiv.). The mixture was refluxed for 30 min, was cooled to room temperature, and was filtered. Concentration of the filtrate and flash chromatography (10 g silica gel, 100:1 diethyl ether – petroleum ether) of the crude solid gave 17 mg (87%) of the ester **63** as an off-white solid. Recrystallization (petroleum ether) provided a white solid (mp 60–61°C) that exhibited ir ($CHCl_3$): 3009, 1719 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.55 (dt, 2H, J = 5, 13 Hz), 1.68–1.90 (m, 4H), 2.35 (dt, 2H, J = 13, 4 Hz), 2.78–2.85 (m, 4H), 3.65 (s, 3H), 6.95 (br d, 2H, J = 7.5 Hz), 7.11 (t, 1H, J = 7.5 Hz); ^{13}C nmr (75.3 MHz) δ: 19.5, 28.5, 34.7, 47.5, 52.1, 126.1, 126.5, 135.5, 136.5, 177.2. Exact Mass calcd. for $C_{15}H_{18}O_2$: 230.1307; found: 230.1311.

*X-ray crystallographic analyses of **9**, **11**, **15**, **27**, **30**, **31**, and **37***

Crystallographic data for the seven compounds analyzed appear in Table 6. The final unit-cell parameters were obtained by least squares on sin θ/λ values for 25 reflections with 2θ = 93.0–98.7, 60.8–84.6, 59.6–83.6, 50.4–79.2, 71.8–88.0, 40.8–81.3, and 70.0–87.8° for **9**, **11**, **15**, **27**, **30**, **31**, and **37**, respectively. The intensities of three standard reflections, measured every hour of X-ray exposure time throughout the data collections, showed only small random fluctuations in each case except for compound **27**, which exhibited a linear decay of 2.7%. The data were processed[5] and corrected for Lorentz and polarization effects, linear decay for **27**, and absorption for **11**, **15**, and **30** (numerical integration, based on 104–126 sampling points).

The structure analyses of **9**, **30**, and **37** were initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics, these choices being verified by the successful completion of the structure analyses. The structures were all solved by direct methods, the coordinates of the non-hydrogen atoms being determined from E-maps and subsequent difference Fourier syntheses. The asymmetric unit of **15** contains two crystallographically independent molecules.

The structures of **9**, **15**, and **30** were found to be disordered. In **9** there are two disordered regions: a 1:1 conformational disorder of the C(8–13) ring (modeled by a split atom refinement of C(9) and C(10)) and a disordering of C(5) that results in a configurational inversion at the asymmetric carbon atom C(4) (modeled by

[5]Computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN80, multisolution program by P. Main, S.J. Fiske, S.E. Hull, L. Lessinger, G. Germain, J.P. Declercq, and M.M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W.R. Busing, K.O. Martin, and H.A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C.K. Johnson.

[a] U_{eq} = 1/3 trace diagonalized *U*.

a split atom refinement of C(5)). As a result of the latter disordering, the crystals actually contain both of the diastereomers **9** and **10** in a ratio of 84:16. In each of the two independent molecules of **15**, conformational disordering of one of the cyclohexene rings was modeled by split atom refinement of C(11). In **30** the hydrogen atoms of both of the hydroxyl groups were 1:1 disordered and were modeled by split-atom refinement. Site occupancy factors for the disordered structures were initially estimated from relative Fourier map peak heights and were subsequently adjusted[6] to result in approximately equal equivalent isotropic thermal parameters for the two component atoms at each disordered site. The disordering in both **9** and **15** probably extends beyond the mod-

[6] Attempts to refine even some of the population parameters led to nearly singular matrices due to high correlations with the thermal parameters.

eled regions, but attempts at more sophisticated and extensive treatment of the disorder were not attempted. As a result, some of the geometrical parameters involving the disordered regions show significant deviations from expected values, in particular when the minor components are involved. Compound **27** displays substantial thermal motion at room temperature, particularly for the peripheral substituents, and may be disordered. The poor quality of the data for **27** precludes any attempts at refining a disordered model.

The low-occupancy disordered carbon atoms C(5′) in **9**, C(11*) and C(11″) in **15** were refined with isotropic thermal parameters. All other non-hydrogen atoms were refined with anisotropic thermal parameters. The ordered hydrogen atoms for **9**, all hydrogen atoms for **11** and **30**, and the O-H hydrogen atoms for **31** were refined with isotropic thermal parameters. The remaining hydrogen atoms were fixed in idealized positions ($C(sp^2)$—H = 0.97, $C(sp^3)$—H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$) with the exception of the 16% occupancy disordered component of **9**.

Isotropic Type I extinction corrections were applied for **11**, **15**, **27**, **30**, **31**, and **37**, the final values of the extinction parameter g being $3.0(5) \times 10^4$, $3.9(2) \times 10^4$, $0.72(5) \times 10^4$, $0.25(3) \times 10^4$, $0.57(9) \times 10^4$, and $0.28(4) \times 10^4$, respectively. Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (13). Final atomic coordinates and equivalent isotropic thermal parameters are given in Table 7. Bond lengths, bond angles, general and intra-annular torsion angles, hydrogen atom parameters, anisotropic thermal parameters, and measured and calculated structure factor amplitudes for the seven structures are provided as supplementary material.[7]

Total synthesis of amphilectane-type diterpenoids: (±)-8,15-diisocyano-11(20)-amphilectene

EDWARD PIERS,[1] MONTSE LLINAS-BRUNET, AND RENATA M. OBALLA
Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, BC V6T 1Z1, Canada

Received April 6, 1993

EDWARD PIERS, MONTSE LLINAS-BRUNET, and RENATA M. OBALLA. Can. J. Chem. **71**, 1484 (1993).

A total synthesis of the structurally novel, antimicrobial diterpenoid (±)-8,15-diisocyano-11(20)-amphilectene (**2**) is described. Alkylation of 2-methoxycarbonyl-3-methylcyclohexanone (**13**) with (*E*)-1-(*tert*-butyldimethylsiloxy)-6-iodo-3-(trimethylstannyl)-2-hexene (**14**) provided, stereoselectively, the functionalized keto ester **15**, which was converted efficiently into the diene **17**. Diels–Alder reaction of **17** with acrolein, followed by base-catalyzed equilibration of the resultant product mixture, gave the aldehydes **19** (58%) and **20** (29%). Allylic oxidation of the alkene **24** (derived from **19**) afforded the enone **25**. Reduction (Na, NH_3, *t*-BuOH) of **25** gave **28**, which was converted, via a sequence of eight synthetic steps, into the diacid **45**. Efficient transformation of the carboxyl functions of **45** into isonitrile groups completed the synthesis of (±)-**2**.

EDWARD PIERS, MONTSE LLINAS-BRUNET et RENATA M. OBALLA. Can. J. Chem. **71**, 1484 (1993).

On décrit une synthèse totale du diterpéne antimicrobien, (±)-8,15-diisocyanoamphilect-11(20)-ène (**2**) qui est structuralement nouveau. L'alkylation de la 2-méthoxycarbonyl-3-méthylcyclohexanone (**13**) avec le (*E*)-1-(*tert*-butyldiméthylsiloxy)-6-iodo-3-(triméthylstannyl)hex-2-ène (**14**) permet d'accéder stéréosélectivement au cétoester fonctionnalisé **15**, que l'on transforme efficacement en un diène **17**. La réaction de Diels–Alder du composé **17** avec l'acroléine, suivie de l'équilibration catalysée par une base du mélange de produits résultant, donne les aldéhydes **19** (58%) et **20** (29%). L'oxydation allylique de l'alcène **24** (dérivé du composé **19**) fournit l'énone **25**. La réduction (par Na, NH_3, *t*-BuOH) du composé **25** conduit au composé **28** qui, par une synthèse à huit étapes, donne le diacide **45**. La transformation efficace des fonctions carboxyles du composé **45** en groupes isonitriles complète la synthèse du composé (±)-**2**.

Introduction

The small family of amphilectane-type diterpenoids share the structurally interesting tricyclic carbon skeleton **1** (1–3). One member of this group of marine natural products, (−)-8,15-diisocyano-11(20)-amphilectene, was isolated from *Hymeniacidon amphilecta*, a sponge of the Order Halichondrida collected at Glover Reef, Belize (1). This substance, which was shown by X-ray diffraction analysis to possess the constitution and relative configuration shown in formula **2** (1), exhibits antibiotic activity against *Staphyloccocus aureus, Bacillus subtilis*, and *Candida albicans*.

Recently, we have reported, inter alia, the efficient preparation of the dienes **3**–**5** (4, 5) and have studied in some detail the Diels–Alder reactions of these substrates with a variety of dienophiles (6). For the present work, the cycloaddition reaction of the diene **4** with methyl acrylate (eq. [1]) is particularly pertinent. This process produced, in high yield (87%), a mixture of products **6**, **7**, and **10** (~3:1:2, respectively). With regards to the possibility of using this chemistry to effect a total synthesis of **2**, the completely regioselective nature of the transformation was gratifying. Thus, substances structurally related to **6** and **7** (e.g., **8** and **9**) should serve as suitable intermediates for the synthesis of **2**. In this regard, it has been shown (6) that, upon treatment with sodium methoxide in methanol, compound **6** epimerizes to give primarily the "desired" isomer **7**. By analogy, equilibration of **8** and **9** should produce predominately **9**. Similarly, although the relative configuration at C* in **9** is "incorrect" for the synthesis of **2**, it should be possible to make the necessary stereochemical adjustment at some (later) stage of the synthesis.

Unfortunately, the face-selectivity of the Diels–Alder reaction of **4** with methyl acrylate is mediocre (**6** + **7**:**10** ≈ 2:1). Furthermore, it would appear to be rather difficult to make efficient use of an intermediate structurally related to **10** (e.g., **11**) for the synthesis of **2**. Nevertheless, the overall efficiency of the reactions involved (synthesis of dienes such as **4** (5), Diels–Alder reactions of **4** (6)) encouraged us to attempt a total synthesis of (±)-**2** via a route that makes use of this chemistry. We report herein the details of this study (7).

Results and discussion

(a) Preparation of the tricyclic enone 25 (Scheme 1)

The synthesis of (±)-**2** began with methyl 2-methyl-6-oxocyclohexanecarboxylate (**13**) (see Scheme 1). This substance had been prepared previously in our laboratory (8) by reaction of methyl 6-oxo-1-cyclohexenecarboxylate (**12**) (9) with lithium methyl(phenylthio)cuprate (10). However, we found subsequently that this conversion is generally more efficient and less capricious if lithium methyl(cyano)cuprate (11) is used in place of the (phenylthio)cuprate. Thus, treatment of **12** with Me(CN)CuLi in tetrahydrofuran (THF)–Et_2O at −78°C gave **13** in 86% yield.

Alkylation of **13** with (*E*)-1-(*tert*-butyldimethylsiloxy)-6-iodo-3-(trimethylstannyl)-2-hexene (**14**) (5) was attempted under a variety of conditions. Use of potassium or sodium hydride as base and THF or 1,2-dimethoxyethane as solvent produced good yields (70–75%) of alkylated material. However, the product invariably consisted of a mixture of the desired C-alkylation product **15** and the corresponding O-alkylation substance (~3–4:1, respectively). Eventually, it was found that alkylation of the potassium enolate of **13** with **14** in refluxing toluene gave the required keto ester **15**, accompanied by only traces of the O-alkylation product. The isolated yield of **15** was 66% (~70% based on recovered **14**).

For steric reasons, alkylation at C-1 of the enolate anion of **13** would be expected to occur from the face of the enolate opposite to the adjacent secondary methyl group. Thus, the relative configuration of the alkylation product **15** could be assigned with confidence.

Sequential treatment of the intermediate **15** with lithium diisopropylamide (LDA) and *N*-phenyltrifluoromethanesulfonimide (12) in THF gave a solution of the enol trifluoromethanesulfonate (triflate) **16**. Although the latter substance could be isolated and subsequently cyclized in a separate step, the overall conversion of **15** into the required diene **17** could be achieved more conveniently and more efficiently by use of a one-pot protocol (5). Thus, direct treatment of the reaction mixture containing **16** with ~0.06–0.07 equivalents of tetrakis(triphenylphosphine)palladium(0), followed by a period of reflux and an appropriate work-up procedure, provided the diene **17** in 86% overall yield from **15**.

The tricyclic carbon skeleton necessary for the synthesis of the amphilectene **2** was to be derived from the diene **17** via a Diels–Alder reaction. In this connection, the earlier work (6) on the cycloaddition reaction of the diene **4** with methyl acrylate served as an informative prelude to the present study. However, since the reaction of **4** with methyl acrylate is quite sluggish (6), we chose, in the current work, to use the more reactive dienophile acrolein.

Treatment of the diene **17** with an excess of acrolein in refluxing benzene gave a high yield of four Diels–Alder adducts. The composition (~62:8:28:2) of this mixture was determined by ^1H nmr spectroscopy, involving integration of the aldehydic proton signals at δ 9.79, 9.62, 9.65, and 9.87, respectively. On the basis of the earlier work (6) (vide supra), the four cycloaddition products were assigned structures **18–21**, respectively. Compounds **18** and **19** are the result of attack of the dienophile on the face of the diene opposite to the angular CO_2Me function (*endo* and *exo* transition states, respectively), while substances **20** and **21** are derived from approach of acrolein to the bottom face of **17** (*syn* to the CO_2Me group) via *exo* and *endo* transition states, respectively. Thus, as expected (6), the face-selectivity (~7:3 in favor of top-side attack of the dienophile) of the cycloaddition reaction is modest and, although an *endo* transition state is favored in the approach of acrolein to the top face of **17**, bottom-side attack takes place predominately via an *exo* orientation of the dienophile.

Flash chromatography of the mixture on silica gel (13) gave a mixture of **19–21** (~4:14:1) (33%) and pure **18** (53%). In compound **18**, the CHO group has a pseudoaxial orientation on the cyclohexene ring and is in a 1,3-diaxial-type relationship with the $CH_2OSi(t\text{-}Bu)Me_2$ function. Consequently, one would expect that equilibration of **18** and **19** would favor the latter epimer. Indeed, treatment of **18** with sodium methoxide in methanol produced **19** in 92% yield. In the ^1H nmr spectrum of **19**, the coupling constants associated with the proton α to the CHO function show clearly that this hydrogen is pseudoaxially oriented (see experimental).

Molecular models indicate that equilibration of the epimers **20** (pseudoequatorial CHO) and **21** (pseudoaxial CHO) should favor the former isomer. Evidence for this expectation was acquired from the observation that treatment of a mixture of **19–21** (4:14:1, see above) with sodium methoxide in methanol provided cleanly an oil that consisted only of substances **19** and **20**.

Of the four aldehydes **18–21**, intermediate **19** was required for the synthesis of (±)-**2**. To optimize the acquisition of **19** from the diene **17**, the crude product derived from the reaction of **17** with acrolein was immediately subjected to equilibration with sodium methoxide in methanol. As expected (vide supra), this protocol produced cleanly and efficiently a mixture that consisted only of the aldehydes **19** and **20**. Fortunately, separation of these substances by flash chromatography (13) was readily accomplished and, by this means, **19** and **20** were obtained in isolated yields of 58 and 29%, respectively.

Reductive conversion of the formyl function in **19** into a methyl group was accomplished efficiently by known meth-

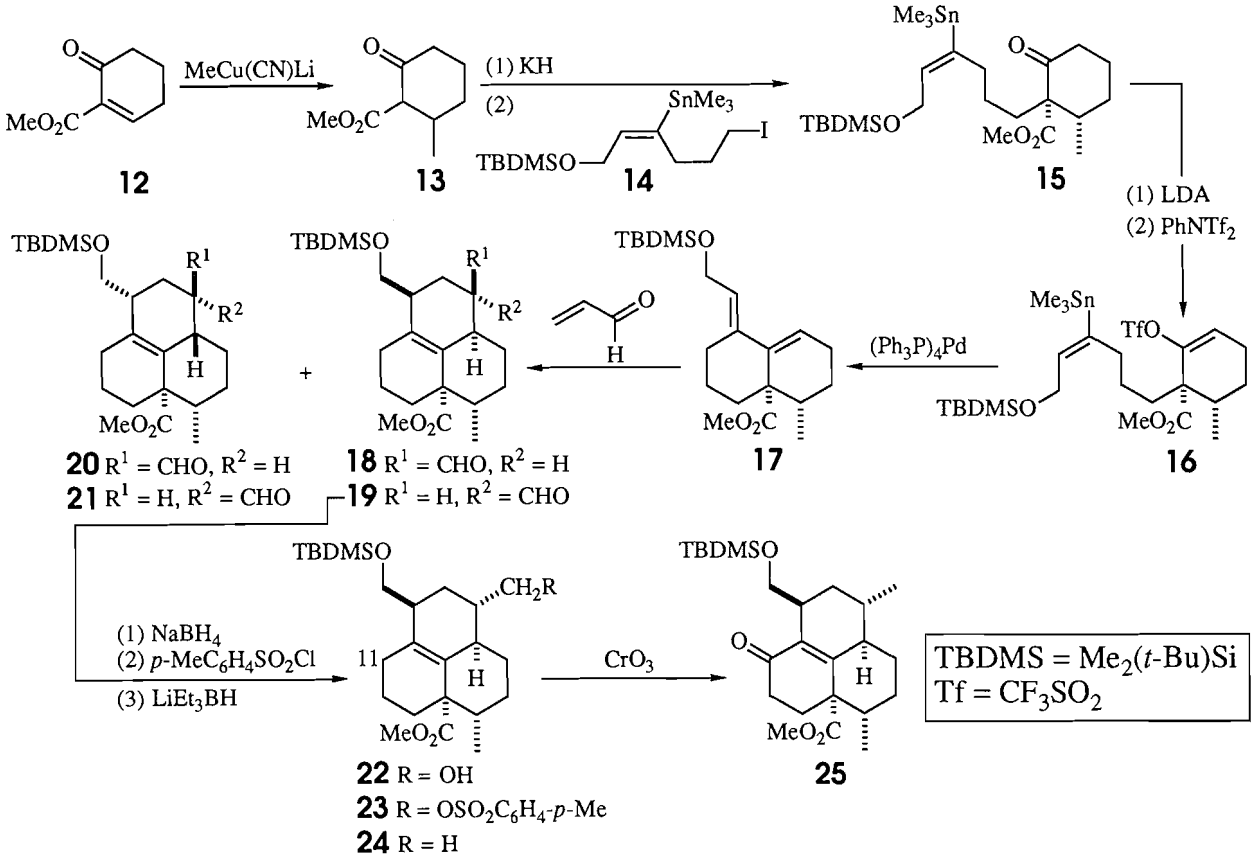

SCHEME 1

ods. Reduction of **19** with sodium borohydride in methanol, followed by treatment of the resultant alcohol **22** with *p*-toluenesulfonyl chloride in dichloromethane containing 4-*N*,*N*-dimethylaminopyridine (DMAP), provided the *p*-toluenesulfonate **23** (87% from **19**). Reaction of **23** with lithium triethylborohydride in THF (14) afforded the tricyclic olefinic ester **24** (90%).

At this stage of our envisaged synthesis of (±)-**2**, a carbonyl function had to be introduced at C-11 (amphilectane numbering) of the intermediate **24**. Not only would this function subsequently serve as a precursor for the required exocyclic methylene group, but, in theory, it would also provide a "handle" for effecting the necessary, stereochemically controlled, reduction of the olefinic double bond in **24**. In the event, treatment of **24** with chromium trioxide-3,5-dimethylpryazole complex (15) in dichloromethane afforded the α,β-unsaturated ketone **25** in 77% yield.

(b) Conversion of the enone 25 into the ketone 28

A successful, chemoselective reduction of the enone **25** with an alkali metal in ammonia (16) could, in theory, produce either or both of the intermediate enolate anions **27** and **29** (see Scheme 2). Protonation of these species during work-up would give the ketones **28** (the desired product) and (or) **30**, respectively. The question as to which pathway should be preferred may be addressed on the basis of proposals originally set forth by Robinson (17) (see also ref. 18).

Transfer of the two electrons to the enone system of **25** would afford (16) an anionic intermediate that can adopt two "reasonable" conformations, **26***a* and **26***b*. It has been proposed (17) that the allylic anion portion of intermediates such as these should be planar. Furthermore, protonation of **26***a* would be expected (17) to take place face-selectively to provide, via transition state **A**, the enolate **27**, in which the three rings are produced directly in chair (or half-chair) conformations. Similarly, selective protonation (17) of the allylic anion of **26***b* from the bottom face of the molecule would give **29**, which, again, has the three six-membered rings in stable conformations.

It has been convincingly argued (17) that the transition states for protonation of intermediates such as **26** have, in terms of molecular shape, a significant amount of reactant-like character. Consequently, the relative stability of the transition states **A** and **B** should be related to the relative stability of **26***a* and **26***b*. Of the latter two conformers, it appears that **26***b* is, due to the presence of more angle and torsional strain and, perhaps more importantly, due to a notable steric repulsion between the $ROCH_2$ and MO moieties, considerably less stable than **26***a*. On this basis, one would predict that transition state **A** would be preferred to transition state **B** and that, therefore, the predominant product derived from dissolving metal reduction of **25** should be substance **28**.

Top-face protonation of **26***a* via **A** is sterically hindered by the pseudoaxial CH_2OR function. However, protonation of **26***b*, via **B**, is impeded by the pseudoaxial methyl group and by the fact that the proton must be delivered in an orientation *gauche* to the angular CO_2Me group. Thus, in terms of ease of approach of a proton source, transition state **A** is, again, preferred.

In practice, finding a suitable procedure for successful alkali metal – ammonia reduction of **25** was not straightforward. Treatment of **25** with an excess (~15 equiv.) of lith-

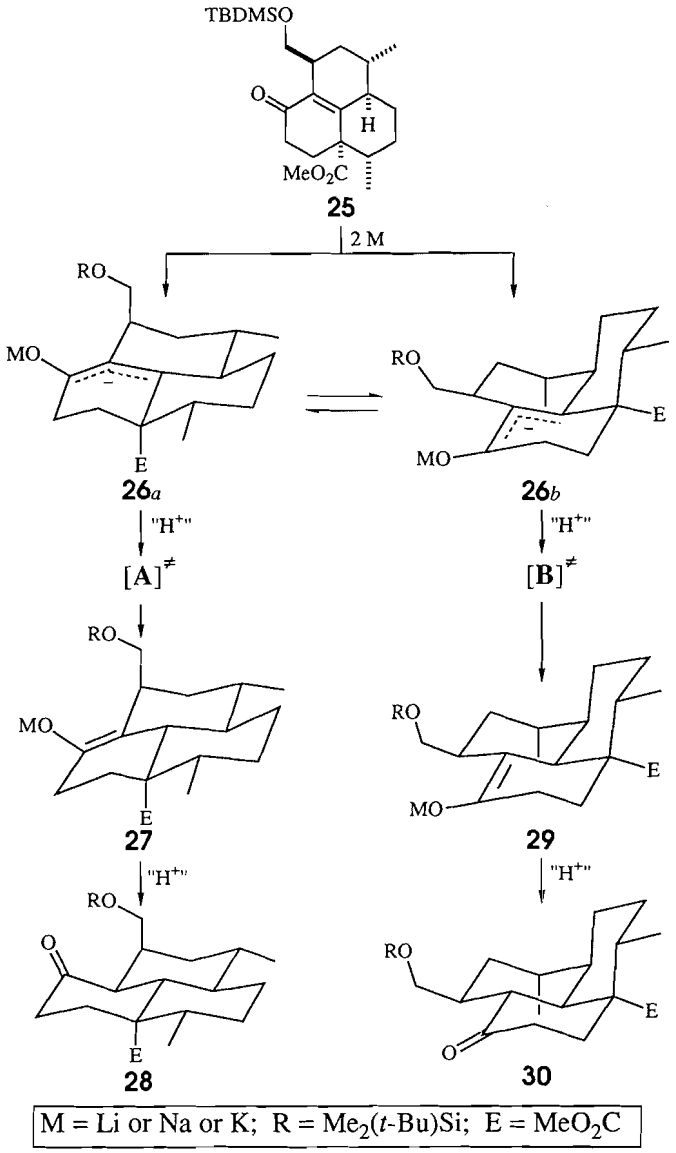
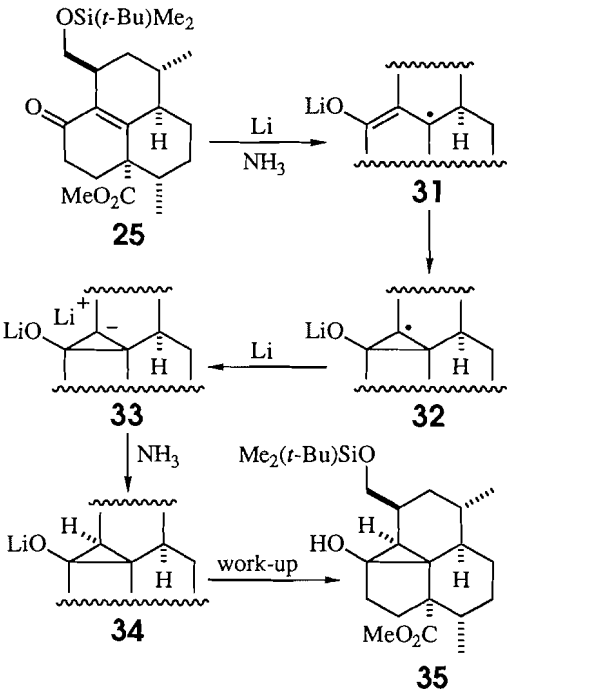
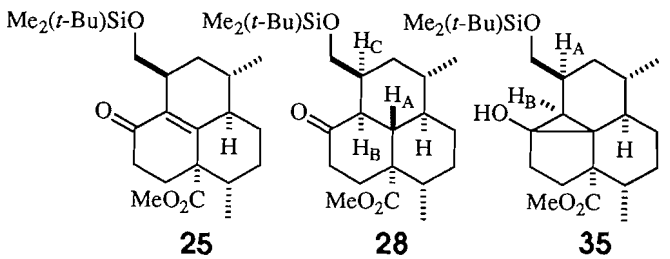


SCHEME 2



SCHEME 3

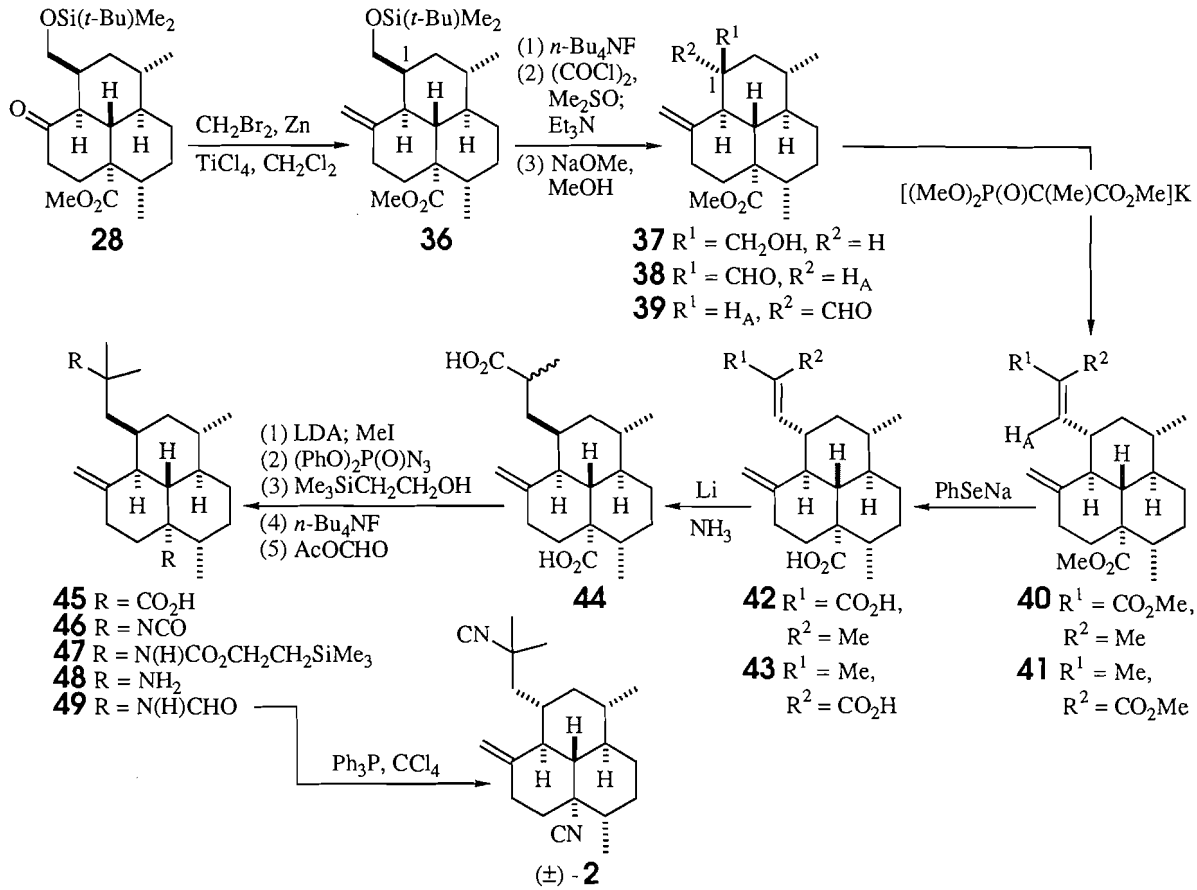


ium in ammonia – diethyl ether gave cleanly one product. The ir spectrum of this (quite unstable) material showed absorptions due to ester (1719 cm^{-1}) and hydroxyl (3240 cm^{-1}) groups. In the ^1H nmr spectrum, a singlet due to the OH function (D_2O exchange) appeared at δ 5.01. Although signals due to the $CH_2OSi(t\text{-Bu})Me_2$ protons were present, no resonance for a CHOH hydrogen was observed. On the other hand, a high-field one-proton signal (δ 1.02, d, J = 8 Hz) was present and, on this basis, it was tentatively concluded that the product possesses the cyclopropanol structure shown in **35**. Further evidence for this conclusion was derived from a ^1H nmr decoupling experiment. Thus, irradiation at δ 2.44 (m, unequivocally assigned to proton H_A in **35**) caused the doublet at δ 1.02 (H_B) to collapse to a singlet. The configuration of the stereogenic center bearing H_B is (provisionally) assigned on the basis of the size of J_{AB} (8 Hz). Molecular models indicate that a *trans* relationship between H_A and H_B would have resulted in a much weaker coupling between these hydrogens.

Mechanistically, it may be proposed that conversion of the enone **25** into **35** proceeds via a pathway summarized in Scheme 3. Transfer of an electron to **25** would produce the radical anion **31**. Cyclization of **31** to give the isomeric radical anion **32**, followed by a second electron transfer, would provide the anionic intermediate **33**. Protonation of **33** with ammonia to give the alkoxide **34** and a subsequent work-up would afford the tetracyclic product **35**.

Reaction of the enone with excess lithium in NH_3–Et_2O in the presence of *tert*-butyl alcohol (2 equiv.) gave better results. However, the desired product **28** was accompanied by varying amounts of the cyclopropanol **35** and, at times, by the starting material **25**. The capricious nature of this reaction was discouraging. On the other hand, when **25** was treated with excess lithium in the presence of *t*-BuOH and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA), the starting material was consumed and the cyclopropanol **35** was not produced. However, the desired ketone **28** was accompanied by products resulting from reduction of the ester function.

Replacement of lithium with other alkali metals was investigated. The results obtained from reaction (NH_3, Et_2O, 2 equiv. of *t*-BuOH) of **25** with 10–15 equivalents of potassium metal also proved to be variable. Gratifyingly, these conditions did not produce any of the cyclopropanol **35**. However, although some experiments gave good yields of **28**, others produced mixtures of the desired product and the



SCHEME 4

starting material **25**. Since the latter substances are inseparable by chromatography on silica gel, this method for effecting an efficient conversion of **25** into **28** also proved to be unsatisfactory.

The best, most consistent results were obtained from use of sodium metal. Treatment of **25** with sodium (15 equiv.) and *t*-BuOH (2 equiv.) in NH_3–Et_2O consistently gave excellent yields of the required tricyclic ketone **28**.

The ^1H nmr spectrum of the reduction product provided strong evidence for the conclusion that this substance possesses the (expected) relative configuration shown in **28**. Explicitly, the signal due to the proton H_A (δ 1.56) is a doublet of doublets (J = 13, 11 Hz), while the hydrogen H_B gives rise to a dd (J = 13, 4 Hz) at δ 2.32. The observed coupling constants (J_{AB} = 13 Hz, J_{BC} = 4 Hz) are consistent with the stereostructure **28**, but are incompatible with the alternative possibility **30** (see Scheme 2 for conformational representations).

(c) Conversion of the ketone 28 into the (±)-8,15-diisocyano-11(20)-amphilectene (2) (Scheme 4)

Attempted conversion of the carbonyl group of **28** into an exocyclic methylene group by treatment of this material with methylenetriphenylphosphorane under a variety of conditions gave back only starting material. Presumably, competition between the reagent acting as a base (enolate anion formation) and a nucleophile favors the former process. Similarly, starting material was obtained from treatment of **28** with $Ph_3P{=}CHLi$ (19). On the other hand, reaction of **28** with a reagent derived from dibromomethane, zinc dust, and titanium tetrachloride (20) afforded the required alkene **36** in very good yield (Scheme 4).

For a successful synthesis of (±)-**2** from **36**, the configuration at C-1 (amphilectane numbering) of the latter substance had to be inverted. Since the $CH_2OSi(t\text{-}Bu)Me_2$ group on this stereogenic center is axially oriented, the required epimerization was envisaged to be effected via an appropriate, thermodynamically driven, equilibration process. In the event, cleavage of the silyl ether function of **36** with tetra-*n*-butylammonium fluoride in THF, followed by oxidation (21) of the resultant alcohol **37**, provided the aldehyde **38** (83% from **36**). As expected, treatment of **38** with sodium methoxide in MeOH provided cleanly and efficiently (95%) the epimeric substance **39**.

Decoupling experiments in ^1H nmr spectroscopy verified that the formyl groups in compounds **38** and **39** are axially and equatorially oriented, respectively. In the spectrum of **38**, irradiation at δ 9.92 (CHO signal) changed the resonance (multiplet, δ 2.88) due to H_A (see Scheme 4) to a quartet (overlapped ddd), with a coupling constant of 3 Hz. On the other hand, irradiation at δ 9.45 in the spectrum of **39** modified the signal (δ 2.50) due to H_A to a ddd (J = 10, 10, 4 Hz). Thus, it is evident that the H_A protons in **38** and **39** are equatorial and axial, respectively.

Reaction of the aldehyde **39** with the potassium salt of trimethyl 2-phosphonopropionate in the presence of 18-crown-6 (22) provided, in excellent yield, a mixture of the geometrically isomeric α,β-unsaturated esters **40** and **41** in a ratio of ~4:1, respectively. The configurations of the en-

For personal use only.

oate double bonds in these substances, which were readily separated by flash chromatography (13) on silica gel, were determined by ^{1}H nmr spectroscopy. The olefinic enoate proton H_A in **40**, being *cis* to the CO_2Me function, should resonate at lower field than the corresponding hydrogen in **41** (H_A *trans* to the CO_2Me group). In the ^{1}H nmr spectra of the minor and major products, H_A gives rise to signals at δ 5.73 (broad doublet, J = 10 Hz) and 6.56 (broad doublet, J = 9 Hz), respectively. Thus, it was clear that the major enoate product possesses the *E* configuration.

Attempts to effect efficient, chemoselective reduction of the enoate carbon–carbon double bond of **40** proved to be fruitless. Consequently, the required reduction was carried out on the corresponding diacid **42**. Treatment of **40** with PhSeNa in refluxing THF–hexamethylphosphoramide (HMPA) (23) for 78 h[2] gave **42** in 88% yield. Reaction of the latter substance with lithium in ammonia–THF (24) gave, in excellent yield, the diacid **44**, which consisted of a mixture of epimers in a ratio of approximately 4:1. The major isomer could be obtained in pure form by flash chromatography (13) of the mixture on silica gel.[3]

An alkylation reaction was employed to introduce the last carbon atom necessary to complete the synthesis. Treatment of **44** (mixture of epimers) with an excess of LDA in THF, followed by reaction of the resultant trianion with methyl iodide, gave the required diacid **45**.

Completion of the total synthesis of (±)-**2** required the degradation of the carboxyl groups of **45** to isonitrile functions. These synthetic operations were carried out conveniently and efficiently as follows.

Treatment of **45** with diphenyl phosphorazidate and triethylamine (25) in toluene at 80°C, followed by reaction of the resultant diisocyanate **46** (ir: 2170 cm^{-1}) with 2-(trimethylsilyl)ethanol (26) in the presence of triethylamine in the same solvent (100°C), produced the dicarbamate **47** (colorless oil, ir: 1731 cm^{-1}). Acquisition of the diamine **48** was accomplished by reaction of **47** with tetra-*n*-butylammonium fluoride in warm THF (26). Treatment of **48** with acetic formic anhydride in diethyl ether (27) gave the diformamide **49**, which, as expected, consisted of a mixture of rotamers associated with the amide functions.

The final step for the synthesis of the amphilectene **2** required the overall dehydration of the two formamide functions present in **49**. Although a number of methods for the transformation of formamides into isonitriles are known, we found that the protocol developed by Appel et al. (28) is, at least in the present case, particularly effective. Thus, treatment of **49** with triphenylphosphine – carbon tetrachloride in the presence of triethylamine (28) afforded crystalline (±)-8,15-diisocyano-11(20)-amphilectene (**2**) (41% from the diacid **45**). Racemic **2** (mp 84–86°C) exhibited ^{1}H and ^{13}C nmr spectra identical with those derived from natural (−)-**2**.[4]

[2]With shorter reaction times, it is possible to effect the chemoselective cleavage of the α,β-unsaturated ester function.

[3]Treatment of the α,β-unsaturated ester **41** with PhSeNa in refluxing THF–HMPA (23) provided the diacid **43**, which, like **42**, could be cleanly reduced (Li, NH_3–THF (24)) to **44**. Alternatively, a mixture of **40** and **41** could be converted efficiently, via the corresponding mixture of diacids **42** and **43**, into the diacid **44**.

[4]We are very grateful to Dr. D.J. Faulkner for a sample of natural (−)-**2**.

Conclusion

The structure of the antimicrobial diterpenoid (−)-8,15-diisocyano-11(20)-amphilectene (**2**) contains seven contiguous stereogenic centers. In the work reported above, which culminated in the first recorded total synthesis of (±)-**2**, the relative configurations at carbons 4, 7, 8, 12, and 13 (amphilectane numbering) were established under conditions of kinetic control. The reactions involved consisted of an alkylation of the keto ester **13** with the iodide **14** (centers 7 and 8), a key Diels–Alder reaction of the diene **17** with acrolein (center 4), and a reduction (Na, NH_3, *t*-BuOH) of the enone **25** (centers 12 and 13). On the other hand, the correct relative stereochemical orientations at carbons 3 and 1, the two remaining stereogenic centers, were secured by thermodynamically controlled epimerizations of the aldehydes **18** and **38**, respectively. Starting from the keto ester **13**, the synthesis of (±)-**2** involved approximately 20 synthetic operations and was accomplished in an overall yield of about 1.5%.

Experimental

General information

Distillation temperatures, which refer to short-path (Kugelrohr) distillations, and melting points are uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on $CDCl_3$ solutions, unless otherwise noted. Signal positions (δ values) were measured relative to the resonances of Me_4Si (internal standard) or $CHCl_3$ (δ 7.25). Carbon nuclear magnetic resonance (^{13}C nmr) spectra were taken on $CDCl_3$ solutions (unless otherwise noted) and signal positions are given relative to the signal for $CDCl_3$ (δ 77.0). Flash chromatography (13) was carried out with 230–400 mesh silica gel (E. Merck). Thin-layer chromatography (tlc) was carried out with commercial aluminum-backed silica gel plates. Gas–liquid chromatography (glc) was performed on instruments equipped with 25 m × 0.21 mm fused silica columns coated with cross-linked SE-54. Reagents and solvents were purified and dried using standard methods. Aqueous NH_4Cl–NH_4OH (pH 8) refers to a solution prepared by addition of ~50 mL of aqueous NH_4OH (30%) to ~950 mL of saturated aqueous NH_4Cl.

Note: Unless otherwise noted, all reactions were carried out under an atmosphere of dry argon in flame- or oven-dried glassware.

Note: All compounds for which high-resolution mass measurements are given exhibited one spot on tlc analyses and produced clean ^{1}H nmr spectra.

Methyl 2-methyl-6-oxocyclohexanecarboxylate (13)

To a cold (−78°C) stirred solution of lithium methyl(cyano)cuprate (11) (28.3 mmol) in dry THF–Et_2O (10:1, 220 mL) was added a solution of methyl 6-oxo-1-cyclohexenecarboxylate (**12**) (9) (3.36 g, 21.8 mmol) in 10 mL of dry THF. The clear yellow solution was stirred at −78°C for 2 h. Aqueous NH_4Cl–NH_4OH (pH 8) (250 mL) and Et_2O (125 mL) were added and the mixture was allowed to warm to room temperature. The mixture was opened to the atmosphere and was stirred vigorously until the aqueous layer was deep blue. The phases were separated and the aqueous layer was extracted three times with Et_2O. The combined organic extracts were washed sequentially with saturated aqueous NH_4Cl and

For personal use only.

brine, dried ($MgSO_4$), and concentrated. Distillation (80–90°C/0.1 Torr (1 Torr = 133.3 Pa)) of the residual oil gave 3.19 g (86%) of compound **13**, the spectral data of which agreed with those obtained previously (8).

*Methyl (±)-[1α, 1(*E*), 2α]-1[6-[[(1,1-dimethylethyl)-dimethylsilyl]oxy]-4-(trimethylstannyl)-4-hexenyl]-2-methyl-6-oxocyclohexanecarboxylate (**15**)*

To a stirred suspension of KH (9.8 mmol) in dry toluene (80 mL) at room temperature was added, dropwise, a solution of the keto ester **13** (1.66 g, 9.8 mmol) in dry toluene (10 mL). After the mixture had been stirred for 30 min, a solution of (*E*)-1-(*tert*-butyldimethylsiloxy)-6-iodo-3-(trimethylstannyl)-2-hexene (**14**) (5) (4.44 g, 8.8 mmol) in dry toluene (10 mL) was added and the reaction mixture was refluxed for 48 h. The mixture was cooled to 0°C and aqueous NH_4Cl–NH_4OH (pH 8) (~50 mL) was added. The phases were separated and the aqueous phase was washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography of the residual material on silica gel (600 g, 98:2 and 94:6 petroleum ether – Et_2O) gave 250 mg of the iodide **14** and 3.18 g (66%; 70% based on recovered **14**) of the keto ester **15**. The latter material, a colorless oil, exhibited ir (neat): 1743, 1715, 1088, 836 cm^{-1}; ^1H nmr (400 MHz) δ: 0.06 (s, 6H), 0.11 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.90 (s, 9H), 1.11 (d, 3H, J = 7 Hz), 1.11–1.20 (m, 2H), 1.22–1.32 (m, 1H), 1.57–1.87 (m, 4H), 1.90–2.02 (m, 2H), 2.24 (m, 2H), 2.39 (br d, 1H, J = 15 Hz), 2.63 (ddd, 1H, J = 15, 13.5, 6.5 Hz), 3.65 (s, 3H), 4.27 (d, 2H, J = 5.5 Hz, $^4J_{Sn-H}$ = 17 Hz), 5.65 (t, 1H, J = 5.5 Hz, $^3J_{Sn-H}$ = 79 Hz). Exact Mass calcd. for $C_{23}H_{43}O_4{}^{120}Sn$ (M^+ − Me): 531.1952; found: 531.1957.

*Methyl (±)-1(1*E*, 4aα, 5α)-1-[2-[[(1,1-dimethylethyl)-dimethylsilyl]oxy]ethylidene]-1,3,4,5,6,7-hexahydro-5-methyl-4a(2*H*)-naphthalenecarboxylate (**17**)*

To a cold (−48°C), stirred solution of LDA (5.14 mmol) in dry THF (50 mL) was added a solution of the keto ester **15** (2.55 g, 4.67 mmol) in dry THF (10 mL). After the solution had been stirred at −48°C for 1 h, *N*-phenyltrifluoromethanesulfonimide (2.84 g, 7.93 mmol) was added as a solid. The yellow solution was warmed to room temperature and was stirred at this temperature for 30 min. Analysis of the reaction mixture by tlc showed that all of the starting material **15** had been converted into the enol trifluoromethanesulfonate **16**. Solid $(Ph_3P)_4Pd$ (0.37 g, 0.32 mmol) was added and the resulting solution was refluxed overnight. The solution was cooled to room temperature and the solvent was removed under reduced pressure. The remaining crude material was filtered through a short column of silica gel (100 g, elution with 1:1 petroleum ether – Et_2O). Concentration of the eluate gave a yellowish oil, which was subjected to flash chromatography (500 g silica gel, 96:4 petroleum ether – Et_2O). Concentration of the appropriate fractions, followed by removal of last traces of solvent (vacuum pump), gave 1.46 g (86%) of the diene **17**, a colorless oil that displayed ir (neat): 1728, 1655, 837, 776 cm^{-1}; ^1H nmr (400 MHz) δ: 0.02 (s, 6H), 0.87 (s, 9H), 1.13 (ddd, 1H, J = 13, 13, 4 Hz), 1.42–1.63 (m, 4H), 1.71–1.82 (m, 2H), 2.15 (m, 2H), 2.52 (br d, 1H, J = 15 Hz), 2.64 (br d, 1H, J = 13 Hz), 3.64 (s, 3H), 4.18, 4.22 (ddd, ddd, 1H, 1H, J = 13, 7, 1 Hz in each case), 5.42 (ddd, 1H, J = 7, 1.5, 1.5 Hz), 5.73 (br t, 1H, J = 7 Hz). In decoupling experiments, irradiation at δ 1.13 caused collapse of the signal at 2.64 to a br s, while irradiation at δ 2.64 converted the signal at 1.13 into a dd (J = 13, 4 Hz). Exact Mass calcd. for $C_{21}H_{36}O_3Si$: 364.2434; found: 364.2428.

*Diels–Alder reaction of the diene **17** with acrolein. Isolation of methyl (±)-(3α, 3aα, 7β, 9β, 9aα)-7-[[[(1,1-dimethylethyl)dimethylsilyl]oxy]methyl]-9-formyl-2,3,5,6,7,8,9,9a-octahydro-3-methyl-1*H*-phenalene-3a(4*H*)-carboxylate (**18**)*

A stirred solution of the diene **17** (73 mg, 0.20 mmol) and acrolein (0.5 mL, 7.48 mmol) in dry benzene was refluxed for 20 h. After the mixture had been cooled to room temperature, the volatile material was removed under reduced pressure and the crude residual oil was subjected to flash chromatography (50 g silica gel, 9:1 petroleum ether – Et_2O). The initial fractions produced 28 mg (33%) of a mixture of three aldehydes. Analysis of this mixture by ^1H nmr spectroscopy (integration of the *CH*O signals, δ 9.62, 9.65, 9.87) showed that the three substances were present in a ratio of ~4:14:1. These Diels–Alder adducts were assigned structures **19**, **20**, and **21**, respectively. The later fractions from the flash chromatography provided 45 mg (53%) of the aldehyde **18**, a colorless oil that showed ir (neat): 2852, 1724, 837, 775 cm^{-1}; ^1H nmr (400 MHz) δ: 0.05 (s, 6H), 0.89 (s, 9H), 1.09 (d, 3H, J = 7 Hz), 1.19 (ddd, 1H, J = 13, 13, 3 Hz), 1.25–1.40 (m, 2H), 1.49–1.71 (m, 6H), 1.86–2.07 (m, 3H), 2.2 (m, 1H), 2.33 (br d, 1H, J = 13 Hz), 2.60 (ddd, 1H, J = 13, 5, 2 Hz), 2.82 (br d, 1H, J = 13 Hz), 3.67 (s, 3H), 3.66 (m, 2H), 9.79 (s, 1H). Exact Mass calcd. for $C_{24}H_{40}O_4Si$: 420.2695; found: 420.2695.

*Epimerization of the aldehyde **18**. Preparation of methyl (±)-(3α, 3aα, 7β, 9α, 9aα)-7-[[[(1,1-dimethylethyl)-dimethylsilyl]oxy]-methyl]-9-formyl-2,3,5,6,7,8,9,9a-octahydro-3-methyl-1*H*-phenalene-3a(4*H*)-carboxylate (**19**)*

A solution of the aldehyde **18** (42 mg, 0.115 mmol) in 3 mL of 0.1 M sodium methoxide in dry methanol was stirred at room temperature for 1 h. Water (10 mL) was added and the mixture was extracted with pentane. The combined extracts were washed with water, dried ($MgSO_4$), and concentrated. Flash chromatography (15 g silica gel, 9:1 petroleum ether – Et_2O) of the residual material gave 40 mg (92%) of the aldehyde **19**, a colorless oil that displayed ir (neat): 2858, 1724, 838, 776 cm^{-1}; ^1H nmr (400 MHz) δ: 0.06 (s, 6H), 0.90 (s, 9H), 1.02 (d, 3H, J = 7 Hz), 1.09 (m, 1H), 1.23 (ddd, 1H, J = 13, 13, 3 Hz), 1.34–1.37 (m, 6H), 1.80–1.90 (m, 2H), 1.98 (ddd, 1H, J = 13, 4, 4 Hz), 2.19 (m, 2H), 2.27 (dddd, 1H, J = 11, 8, 3.5, 2.5 Hz), 2.46 (br d, 1H, J = 13 Hz), 2.83 (br s, 1H), 3.50 (dd, 1H, J = 10, 8 Hz), 3.67 (s, 3H), 3.68 (dd, 1H, J = 10, 4 Hz), 9.62 (d, 1H, J = 2.5 Hz). In a decoupling experiment, irradiation at δ 9.62 changed the signal at 2.27 to a ddd (J = 11, 8, 3.5 Hz). Anal. calcd. for $C_{24}H_{40}O_4Si$: C 68.53, H 9.58; found: C 68.78, H 9.59. Exact Mass calcd.: 420.2695; found: 420.2693.

*Diels–Alder reaction of the diene **17** with acrolein. Equilibration of the crude product mixture. Isolation of the aldehydes **19** and methyl (±)-(3α, 3aα, 7α, 9β, 9aβ)-7-[[[(1,1-dimethylethyl)dimethylsilyl]oxy]methyl]-9-formyl-2,3,5,6,7,8,9,9a-octahydro-3-methyl-1*H*-phenalene-3a(4*H*)-carboxylate (**20**)*

A stirred solution of the diene **17** (233 mg, 0.64 mmol) and acrolein (1.2 mL, 18 mmol) in dry benzene (20 mL) was refluxed for 20 h. The mixture was cooled and concentrated under reduced pressure. The crude material was passed through a small column of silica gel (10 g, 1:1 petroleum ether – Et_2O). Concentration of the eluate gave a mixture of aldehydes. This material was dissolved in a 0.1 M solution of sodium methoxide in dry methanol (10 mL) and the solution was stirred at room temperature for 1 h. Water (20 mL) was added and the mixture was extracted three times with pentane. The combined organic extracts were washed with water, dried ($MgSO_4$), and concentrated. Flash chromatography (90 g silica gel, 9:1 petroleum ether – Et_2O) of the residual material gave 158 mg (58%) of the aldehyde **19** (spectra identical with those obtained previously, vide supra) and 77 mg (29%) of the aldehyde **20**. The latter substance, a colorless oil, displayed ir (neat): 2707, 1724 (br), 838, 777 cm^{-1}; ^1H nmr (400 MHz) δ: 0.06 (s, 6H), 0.91 (s, 9H), 1.03 (d, 3H, J = 7 Hz), 1.15–1.25 (m, 2H), 1.36–1.97 (m, 8H), 2.08–2.22 (m, 3H), 2.31–2.36 (m, 2H), 2.55 (m, 1H), 3.43 (dd, 1H, J = 10, 10 Hz), 3.64 (s, 3H), 3.72 (dd, 1H, J = 10, 4 Hz), 9.65 (d, 1H, J = 3.5 Hz). Exact Mass calcd. for $C_{24}H_{40}O_4Si$: 420.2695; found: 420.2700.

*Methyl (±)-(3α, 3aα, 7β, 9α, 9aα)-7-[[[(1,1-dimethylethyl)-dimethylsilyl]oxy]methyl]-2,3,5,6,7,8,9,9a-octahydro-9-(hydroxymethyl)-3-methyl-1*H*-phenalene-3a(4*H*)-carboxylate (**22**)*

To a cold (0°C), stirred solution of the aldehyde **19** (722 mg, 1.72 mmol) in methanol (60 mL) was added solid sodium boro-

For personal use only.

hydride (79 mg, 2.08 mmol) and the mixture was stirred for 1 h. Saturated aqueous NH_4Cl (40 mL) was added and the mixture was extracted with dichloromethane. The combined extracts were washed with brine, dried ($MgSO_4$), and concentrated to give 687 mg (95%) of the alcohol **22**, a colorless oil that showed ir (neat): 3406 (br), 1723, 837, 776 cm^{-1}; ^1H nmr (400 MHz) δ: 0.04 (s, 6H), 0.90 (s, 9H), 1.04 (d, 3H, J = 7 Hz), 1.27 (m, 2H), 1.34–1.67 (m, 10H), 1.90 (m, 2H), 2.15 (m, 2H), 2.36 (br d, 1H, J = 13 Hz), 3.50 (dd, 1H, J = 10, 7 Hz), 3.55 (dd, 1H, J = 10, 7 Hz), 3.64 (s, 3H), 3.65 (m, 2H). Anal. calcd. for $C_{24}H_{42}O_4Si$: C 68.20, H 10.01; found: C 68.13, H 10.10. Exact Mass calcd.: 422.2852; found: 422.2846.

*Methyl (±)-(3α, 3aα, 7β, 9α, 9aα)-7-[[[(1,1-dimethylethyl)-dimethylsilyl]oxy]methyl]-2,3,5,6,7,8,9,9a-octahydro-3-methyl-9-[[[(4-methylphenyl)sulfonyl]oxy]methyl]-1H-phenalene-3a(4H)-carboxylate (**23**)*

A solution of the alcohol **22** (678 mg, 1.61 mmol), *p*-toluenesulfonyl chloride (614 mg, 3.22 mmol), and 4-*N*,*N*-dimethylaminopyridine (492 mg, 4.03 mmol) in dry dichloromethane (20 mL) was stirred at room temperature overnight. Water (30 mL) and diethyl ether (40 mL) were added and the phases were separated. The aqueous layer was washed with diethyl ether. The combined organic phases were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (80 g silica gel, 4:1 petroleum ether – Et_2O) of the crude material gave 851 mg (92%) of the *p*-toluenesulfonate **23**, a colorless oil that displayed ir (neat): 1723, 1178, 837, 776 cm^{-1}; ^1H nmr (400 MHz) δ: 0.02 (s, 6H), 0.87 (s, 9H), 1.01 (d, 3H, J = 6 Hz), 1.09–1.50 (m, 5H), 1.60 (m, 2H), 1.68–1.85 (m, 4H), 2.00–2.15 (m, 4H), 2.35 (br d, 1H, J = 12 Hz), 2.44 (s, 3H), 3.43 (dd, 1H, J = 10, 7.5 Hz), 3.58 (dd, 1H, J = 10, 4 Hz), 3.62 (s, 3H), 3.91 (dd, 1H, J = 9.5, 7.5 Hz), 4.03 (dd, 1H, J = 9.5, 5 Hz), 7.34, 7.78 (d, d, 2H each, J = 8 Hz in each case). Exact Mass calcd. for $C_{24}H_{40}O_3Si$ (M^+ – $MeC_6H_4SO_3H$): 404.2747; found: 404.2757.

*Methyl (±)-(3α, 3aα, 7β, 9α, 9aα)-7-[[[(1,1-dimethylethyl)-dimethylsilyl]oxy]methyl]-3,9-dimethyl-1H-phenalene-3a(4H)-carboxylate (**24**)*

To a cold (0°C) solution of the *p*-toluenesulfonate **23** (1.242 g, 2.16 mmol) in dry THF (25 mL) was added a solution of lithium triethylborohydride in THF (5.4 mmol). The solution was warmed to room temperature, was stirred for 3 h, and was recooled to 0°C. Aqueous sodium hydroxide (3 N, 8 mL) and aqueous hydrogen peroxide (30%, 8 mL) were added slowly and the mixture was stirred at 0°C for 40 min. Water (25 mL) was added and the mixture was extracted thoroughly with pentane. The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (500 g silica gel, 95:5 petroleum ether – Et_2O) of the residual material gave 785 mg (90%) of the ester **24**, a colorless oil that showed ir (neat): 1725, 837, 775 cm^{-1}; ^1H nmr (400 MHz) δ: 0.06 (s, 6H), 0.91 (s, 9H), 0.93 (d, 3H, J = 6 Hz), 1.01 (d, 3H, J = 6 Hz), 1.25 (m, 2H), 1.26–1.70 (m, 7H), 1.76 (ddd, 1H, J = 13, 4, 4 Hz), 1.85 (br d, 1H, J = 16 Hz), 1.95 (m, 2H), 2.05 (m, 1H), 2.19 (m, 1H), 2.41 (br d, 1H, J = 13 Hz), 3.45 (dd, 1H, J = 10, 9.5 Hz), 3.64 (s, 3H), 3.66 (dd, 1H, J = 10, 5 Hz). Anal. calcd. for $C_{24}H_{42}O_3Si$: C 70.88, H 10.41; found: C 71.00, H 10.50. Exact Mass calcd.: 406.2903; found: 406.2895.

*Methyl (±)-(3aα, 4α, 6aα, 7α, 9β)-9-[[[(1,1-dimethylethyl)-dimethylsilyl]oxy]methyl]-2,3,5,6,6a,7,8,9-octahydro-4,7-dimethyl-1-oxo-1H-phenalene-3a(4H)-carboxylate (**25**)*

To a cold (−20°C), stirred suspension of chromium trioxide (2.25 g, 22.5 mmol) in dry dichloromethane (25 mL) was added, in one portion, 3,5-dimethylpyrazole (2.18 g, 22.5 mmol). The mixture was stirred at −20°C for approximately 30 min. A solution of the alkene **24** (365 mg, 0.899 mmol) in dry dichloromethane (10 mL) was added; the mixture was warmed to 0°C and then was stirred for 1.5 h. Dry diethyl ether (30 mL) was added and the mixture was filtered through a column of Florisil (elution with dry diethyl ether). The eluate was concentrated and the residual material was subjected to flash chromatography (80 g silica gel, 9:1 petroleum ether – Et_2O). Concentration of the appropriate fractions gave 291 mg (77%) of the enone **25**, a crystalline solid, mp 53–54°C, that exhibited ir (KBr): 1725, 1672, 1596, 836, 776 cm^{-1}; ^1H nmr (400 MHz) δ: 0.03 (s, 3H), 0.06 (s, 3H), 0.89 (s, 9H), 1.02 (d, 3H, J = 6 Hz), 1.04 (d, 3H, J = 6 Hz), 1.08 (m, 1H), 1.14 (ddd, 1H, J = 13, 13, 5 Hz), 1.58 (m, 4H), 1.68 (ddd, 1H, J = 14, 14, 5 Hz), 1.97 (ddd, 1H, J = 13, 4, 2 Hz), 2.24 (m, 2H), 2.44 (ddd, 1H, J = 18, 5, 3 Hz), 2.50 (ddd, 1H, J = 18, 14, 5 Hz), 2.69 (ddd, 1H, J = 13, 5, 3 Hz), 2.98 (m, 1H), 3.32 (dd, 1H, J = 9.5, 9.5 Hz), 3.62 (dd, 1H, J = 9.5, 4 Hz), 3.70 (s, 3H). Anal. calcd. for $C_{24}H_{40}O_4Si$: C 68.53, H 9.58; found: C 68.66, H 9.69. Exact Mass calcd.: 420.2696; found: 420.2702.

*Methyl (±)-(3aα, 4α, 6aα, 7α, 9α, 9aα, 9bβ)-9-[[[(1,1-dimethylethyl)dimethylsilyl]oxy]-methyl]decahydro-4,7-dimethyl-1-oxo-1H-phenalene-3a(4H)-carboxylate (**28**)*

A solution of the enone **25** (35 mg, 0.083 mmol) and *tert*-butyl alcohol (17 μL, 0.18 mmol) in dry diethyl ether (0.8 mL) was added via cannulation to a stirred solution of sodium (29 mg, 1.26 mmol) in ammonia (3 mL, freshly distilled from sodium). The mixture was refluxed for 40 min. Isoprene was added dropwise until the blue color of the solution disappeared. Saturated aqueous NH_4Cl (10 mL) and diethyl ether (5 mL) were added. While the mixture was stirred for 4 h, it was warmed occasionally with a water bath (~40–45°C) until the ammonia was distilled. During this time, diethyl ether was added occasionally to the mixture. The phases were separated and the aqueous phase was extracted with diethyl ether (2 × 10 mL). The combined organic extracts were washed with water, dried ($MgSO_4$), and concentrated. Flash chromatography of the crude material on silica gel (20 g, 9:1 petroleum ether – Et_2O) afforded 30 mg (86%) of the ketone **26**, a white solid (mp 79–81°C, from pentane) that exhibited ir (KBr): 1724, 1707, 836, 776 cm^{-1}; ^1H nmr (400 MHz) δ: 0.03 (s, 3H), 0.05 (s, 3H), 0.89 (s, 9H), 0.90 (d, 3H, J = 6 Hz), 0.95 (d, 3H, J = 6 Hz), 0.79–1.00 (m, 1H), 1.12 (ddd, 1H, J = 13.5, 13.5, 3.5 Hz), 1.28 (m, 1H), 1.32–1.47 (m, 3H), 1.52 (m, 1H), 1.56 (dd, 1H, J = 13, 11 Hz), 1.74 (dddd, 1H, J = 11, 11, 11, 3 Hz), 1.88 (ddd, 1H, J = 13.5, 3, 3 Hz), 2.08 (dddd, 1H, J = 13, 3, 3, 3 Hz), 2.32 (dd, 1H, J = 13, 4 Hz), 2.35–2.50 (m, 2H), 2.53 (m, 1H), 2.62 (ddd, 1H, J = 13.5, 8, 3.5 Hz), 3.60 (dd, 1H, J = 10, 10 Hz), 3.65 (dd, 1H, J = 10, 5.5 Hz), 3.68 (s, 3H). In decoupling experiments, irradiation at δ 1.12 simplified the m at 2.53 and collapsed the signal at 1.88 to a br s; irradiation at δ 1.88 sharpened the m at 2.53 and changed the resonance at 1.12 to a dd (J = 13.5, 3.5 Hz); irradiation at δ 2.32 simplified the m at 2.53 and changed the dd at 1.56 to a d (J = 11 Hz). Exact Mass calcd. for $C_{23}H_{39}O_4Si$ (M^+ – Me): 407.2618; found: 407.2610.

*Methyl (±)-(3aα, 4α, 6aα, 7α, 9β, 9aα, 9bβ)-9-[[[(1,1-dimethylethyl)dimethylsilyl]oxy]-methyl]decahydro-4,7-dimethyl-1-methylene-1H-phenalene-3a(4H)-carboxylate (**36**)*

To a stirred solution of the ketone **28** (51 mg, 0.05 mmol) in dry dichloromethane (3 mL) was added, in small portions over a period of about 30 min, a THF slurry of a reagent prepared from CH_2Br_2, Zn dust, and $TiCl_4$ as described by Lombardo (20). After about 1 mL of the reagent solution had been added, analysis of an aliquot of the reaction mixture by glc showed that the reaction was complete. The mixture was diluted with Et_2O (15 mL) and saturated aqueous sodium bicarbonate (10 mL) was added. The mixture was stirred vigorously until a clear organic phase was obtained. The phases were separated and the aqueous layer was washed with Et_2O. The combined organic solutions were washed (brine), dried ($MgSO_4$), and concentrated. Flash chromatography (10 g silica gel, 95:5 petroleum ether – Et_2O) of the residue gave 40 mg (79%) of the alkene **36**, a white solid (mp 46–48°C) that displayed ir (KBr): 1726, 1636, 1095, 840, 788 cm^{-1}; ^1H nmr (400 MHz) δ: 0.02 (s, 6H), 0.88 (d, 3H, J = 6 Hz), 0.89 (s, 9H), 0.90 (d, 3H, J = 6 Hz),

*Methyl (±)-(3aα, 4α, 6aα, 7α, 9β, 9aα, 9bβ)-9-formyldecahydro-4,7-dimethyl-1-methylene-1*H*-phenalene-3a(4*H*)-carboxylate (**38**)*

To a cold (−78°C), stirred solution of dimethyl sulfoxide (9.3 μL, 0.131 mmol) in dry CH_2Cl_2 (2 mL) was added oxalyl chloride (10 μL, 0.117 mmol) and the solution was stirred at −78°C for 15 min. A solution of alcohol **37** (20 mg, 0.065 mmol) in dry CH_2Cl_2 (0.8 mL) was added, stirring was continued for 20 min, Et_3N (45 μL, 0.325 mmol) was added, stirring was continued (−78°C) for 5 min, and then the mixture was allowed to warm to room temperature. Water (5 mL) and Et_2O (10 mL) were added, the phases were separated, and the aqueous layer was washed with Et_2O. The combined organic extracts were washed (brine), dried ($MgSO_4$), and concentrated. Flash chromatography (6 g silica gel, 94:6 petroleum ether – Et_2O) of the remaining material gave 17.3 mg (87%) of the aldehyde **38**, a white solid (mp 68–70°C) that exhibited ir (KBr): 2857, 1720, 1638 cm^{-1}; ^1H nmr (400 MHz), δ: 0.89 (d, 3H, J = 6 Hz), 0.91 (m, 1H), 0.96 (d, 3H, J = 6 Hz), 1.03 (m, 1H), 1.15 (ddd, 1H, J = 13, 13, 4 Hz), 1.18–1.32 (m, 2H), 1.38–1.58 (m, 4H), 2.03 (m, 3H), 2.15 (br dd, 1H, J = 15, 13 Hz), 2.38 (ddd, 1H, J = 15, 4, 4 Hz), 2.53 (ddd, 1H, J = 13, 4, 4 Hz), 2.60 (dd, 1H, J = 12, 3 Hz), 2.88 (m, 1H), 3.69 (s, 3H), 4.42, 4.85 (br s, br s, 1H each), 9.92 (d, 1H, J = 2 Hz). In decoupling experiments, irradiation at δ 2.15 changed the ddd at 1.15 to a dd (J = 13, 4 Hz), sharpened the ddd at 2.38 to a broad, unresolved signal, altered the ddd at 2.53 to a dd (J = 13, 4 Hz), and changed the broad singlets at 4.42 and 4.85 to sharp doublets (J = 2 Hz in each case); irradiation at δ 2.38 changed the signals at 1.15, 2.15, and 2.53 to a dd (J = 13, 13 Hz), a broad d (J = 13 Hz), and a dd (J = 13, 4 Hz), respectively; irradiation at δ 2.88 simplified the multiplets at 1.38–1.58 and 2.03, sharpened the dd at 2.60 to a d (J = 12 Hz), and converted the d at 9.92 to a s; irradiation at δ 9.92 caused the m at 2.88 to collapse to a ddd (J = 3, 3, 3 Hz). Exact Mass calcd. for $C_{19}H_{28}O_3$: 304.2038; found: 304.2035.

*Methyl (±)-(3aα, 4α, 6aα, 7α, 9α, 9aα, 9bβ)-9-formyldecahydro-4,7-dimethyl-1-methylene-1*H*-phenalene-3a(4*H*)-carboxylate (**39**)*

A solution of the aldehyde **38** (17 mg, 0.056 mmol) in 1.5 mL of dry 0.1 M sodium methoxide in methanol was stirred at room temperature for 1 h. Water (5 mL) was added and the mixture was extracted thoroughly with pentane. The combined organic extracts were washed (brine), dried ($MgSO_4$) and concentrated. Flash chromatography (5 g silica gel, 93:7 petroleum ether – Et_2O) of the residual material gave 16 mg (95%) of the aldehyde **39**, a white solid (mp 65–67°C) that showed ir (KBr): 2853, 1723, 1645 cm^{-1}; ^1H nmr (400 MHz) δ: 0.85 (dddd, 1H, J = 13, 13, 13, 4 Hz), 0.94 (d, 3H, J = 6 Hz), 0.95 (m, 1H), 0.96 (d, 3H, J = 6 Hz), 1.05 (m, 1H), 1.09 (ddd, 1H, J = 13, 13, 4 Hz), 1.14 (ddd, 1H, J = 12, 12, 12 Hz), 1.26 (ddd, 1H, J = 13, 13, 4 Hz), 1.37 (m, 1H), 1.52 (dddd, 1H, J = 13, 4, 4, 4 Hz), 1.67 (ddd, 1H, J = 13, 4, 4 Hz), 2.04 (m, 2H), 2.12 (ddd, 1H, J = 14, 14, 3.5 Hz), 2.29 (ddd, 1H, J = 14, 3.5, 3.5 Hz), 2.45 (dd, 1H, J = 10, 10 Hz), 2.50 (dddd, 1H, J = 10, 10, 4, 4 Hz), 2.64 (ddd, 1H, J = 13, 3.5, 3.5 Hz), 3.73 (s, 3H), 4.45, 4.75 (s, s, 1H each), 9.45 (d, 1H, J = 4 Hz). In a decoupling experiment, irradiation at δ 9.45 changed the dddd at 2.50 to a ddd (J = 10, 10, 4 Hz). Exact Mass calcd. for $C_{19}H_{28}O_3$: 304.2038; found: 304.2035.

*Methyl (±)-(3aα, 4α, 6aα, 7α, 9α(*E*), 9aα, 9bβ)-decahydro-9-(3-methoxy-2-methyl-3-oxo-1-propenyl)-4,7-dimethyl-1-methylene-1*H*-phenalene-3a(4*H*)-carboxylate (**40**) and the geometric isomer **41***

A 35% dispersion of KH in mineral oil (~23 mg) was washed three times with dry THF (3 mL) and the remaining KH (~8 mg, 0.2 mmol) was covered with 4 mL of dry THF. To this stirred suspension (0°C) was added trimethyl 2-phosphonopropionate (35 μL, 0.2 mmol) and 18-crown-6 (~1 mmol, recrystallized from MeCN) and the mixture was stirred at room temperature for 20 min. A solution of the aldehyde **39** (40 mg, 0.132 mmol) in dry THF (1.5 mL) was added and the mixture was stirred at room temperature for 3.5 h. Water (10 mL) and Et_2O (15 mL) were added and the phases were separated. The aqueous layer was extracted twice with Et_2O. The combined extracts were washed (brine), dried ($MgSO_4$), and concentrated. Flash chromatography (15 g silica gel, 94:6 pentane–Et_2O) of the residual material gave 9.5 mg (19%) of the Z ester **41** (the first product to be eluted) and 38 mg (77%) of the E ester **40**.

The ester **41**, a white solid with mp 100–103°C, exhibited ir (KBr): 1718, 1648, 1212, 1151, 1110 cm^{-1}; ^1H nmr (400 MHz) δ: 0.83 (dddd, 1H, J = 13, 13, 13, 4 Hz), 0.89 (d, 3H, J = 6 Hz), 0.90 (d, 3H, J = 6 Hz), 0.93 (dd, 1H, J = 11, 11 Hz), 1.03 (m, 2H), 1.23 (dddd, 1H, J = 13, 13, 13, 4 Hz), 1.35 (m, 1H), 1.48 (dddd, 1H, J = 14, 14, 14, 4 Hz), 1.59 (m, 2H), 1.85 (d, 3H, J = 1 Hz), 1.90–2.10 (m, 4H), 2.23 (ddd, 1H, J = 14, 3.5, 3.5 Hz), 2.62 (ddd, 1H, J = 13, 3.5, 3.5 Hz), 3.32 (dddd, 1H, J = 10, 10, 10, 4 Hz), 3.70 (s, 3H), 3.75 (s, 3H), 4.56 (s, 1H), 4.68 (d, 1H, J = 1 Hz), 5.73 (br d, 1H, J = 10 Hz). Exact Mass calcd. for $C_{23}H_{34}O_4$: 374.2456; found: 374.2454.

The ester **40**, a white solid with mp 106–108°C, displayed ir (KBr): 1718, 1642, 1277, 1224, 1157 cm^{-1}; ^1H nmr (400 MHz) δ: 0.85 (dddd, 1H, J = 13, 13, 13, 4 Hz), 0.91 (d, 6H, J = 6 Hz), 0.95 (dd, 1H, J = 11, 11 Hz), 1.06 (m, 3H), 1.26 (ddd, 1H, J = 13, 13, 3 Hz), 1.36 (m, 1H), 1.48 (m, 2H), 1.89 (s, 3H), 2.06 (m, 4H), 2.23 (ddd, 1H, J = 14, 4, 4 Hz), 2.53 (dddd, 1H, J = 11, 11, 9, 4 Hz), 2.63 (ddd, 1H, J = 13, 3.5, 3.5 Hz), 3.70 (s, 3H), 3.71 (s, 3H), 4.35 (s, 1H), 4.67 (s, 1H), 6.56 (d, 1H, J = 9 Hz). Exact Mass calcd. for $C_{23}H_{34}O_4$: 374.2456; found: 374.2462.

*(±)-[(3aα, 4α, 6aα, 7α, 9α(*E*), 9aα, 9bβ]-9-(2-Carboxy-1-propenyl)-decahydro-4,7-dimethyl-1-methylene-1*H*-phenalene-3a(4*H*)-carboxylic acid (**42**)*

To a stirred suspension of oil-free NaH (75 mg, 3.1 mmol) in dry THF (1 mL) were added benzeneselenol (0.33 mL, 3.1 mmol) and dry HMPA (1.11 mL, 6.4 mmol). The deep red solution was treated with a solution of the diester **40** (48 mg, 0.128 mmol) in dry THF (1 mL) and the mixture was refluxed for 78 h. The solution was allowed to cool to room temperature and was concentrated under reduced pressure. The residual material was treated with water (4 mL), and the basic mixture was washed with pentane

For personal use only.

(5 mL). The aqueous phase was acidified with 10% hydrochloric acid and the mixture was extracted with Et_2O (3 × 5 mL). The combined extracts were washed (brine), dried ($MgSO_4$), and concentrated. Flash chromatography of the residue (15 g silica gel, Et_2O) produced 39 mg (88%) of the diacid **42**, a white solid (mp 273–275°C) that exhibited ir (KBr): 1687, 1665, 1648 cm^{-1}; ^1H nmr (400 MHz) δ: 0.90 (m, 1H), 0.91 (d, 3H, J = 6 Hz), 0.99 (d, 3H, J = 6 Hz), 1.00–1.15 (m, 3H), 1.32 (m, 1H), 1.39 (m, 2H), 1.52 (m, 2H), 1.87 (s, 3H), 2.05 (m, 3H), 2.22 (m, 2H), 2.60 (m, 2H), 4.40 (s, 1H), 4.68 (s, 1H), 6.54 (br d, 1H, J = 9 Hz). Exact Mass calcd. for $C_{21}H_{30}O_4$: 346.2144; found: 346.2152.

*Preparation of the dicarboxylic acid **44***

To a stirred solution of lithium metal (4.5 mg) in dry ammonia (3 mL, freshly distilled from sodium metal) was added, via cannulation, a solution of the diacid **42** (20 mg, 0.058 mmol) in dry THF (1 mL) and the mixture was refluxed for 30 min. Solid ammonium chloride was added in small portions until the blue color was discharged. Diethyl ethyl (4 mL) was added, the mixture was warmed gently to distill the ammonia, and the residual mixture was acidified with 6 N hydrochloric acid. The mixture was extracted with Et_2O (3 × 5 mL). The combined extracts were washed (brine), dried ($MgSO_4$), and concentrated. Flash chromatography (10 g silica gel, 55:45 pentane–Et_2O) gave 10 mg (50%) of **44** as a single isomer (white solid, mp 248–250°C) and 8 mg (40%) of **44** as a mixture of two epimers (ratio ~1.5:1, by ^1H nmr spectroscopy). The single isomer exhibited ir (KBr): 1702, 1644 cm^{-1}; ^1H nmr (400 MHz, acetone-d_6) δ: 0.75 (m, 1H), 0.80–0.92 (m, 5H), 0.94 (d, 3H, J = 6 Hz), 1.04 (ddd, 1H, J = 13, 13, 5 Hz), 1.10 (d, 3H, J = 6 Hz), 1.30–1.40 (m, 2H), 1.46 (m, 1H), 1.59 (m, 1H), 1.71 (m, 1H), 1.77 (m, 1H), 1.97 (m, 3H), 2.12–2.30 (m, 4H), 2.64 (m, 2H), 4.74 (s, 1H), 4.79 (s, 1H). Exact Mass calcd. for $C_{21}H_{32}O_4$: 348.2295; found: 348.2300.

*(±)-(1α, 3α, 3aα, 6α, 6aα, 9aα, 9bβ)-6a-Carboxydecahydro-α,α,3,6-tetramethyl-9-methylene-1H-phenalene-1-propanoic acid (**45**)*

To a cold (0°C), stirred solution of LDA (1.0 mmol) in dry THF (1.5 mL) was added a solution of the diacid **44** (35 mg, 0.1 mmol, mixture of epimers) in dry THF (2 mL). The mixture was allowed to warm to room temperature and was stirred for 2.5 h. Methyl iodide (~0.5 mL, passed through a small, dry basic alumina column) was added and the mixture was stirred at room temperature for 1 h. The solution was acidified with 10% hydrochloric acid and the mixture was extracted with Et_2O (3 × 5 mL). The combined extracts were washed (brine), dried ($MgSO_4$), and concentrated. Flash chromatography (5 g silica gel, 1:1 pentane–Et_2O) gave 20 mg (55%) of the diacid **45**, a white solid (mp 245–247°C) that showed ir (KBr): 1705 cm^{-1}; ^1H nmr (400 MHz, acetone-d_6) δ: 0.79–0.92 (m, 5H), 0.93 (d, 3H, J = 6 Hz), 1.01–1.12 (m, 2H), 1.15 (s, 3H), 1.18 (s, 3H), 1.30–1.50 (m, 5H), 1.60 (m, 1H), 1.78–2.00 (m, 5H), 2.12–2.32 (m, 2H), 2.65 (ddd, 1H, J = 12, 4, 4, 4 Hz), 4.69 (s, 1H), 4.79 (s, 1H). Exact Mass calcd. for $C_{22}H_{34}O_4$: 362.2457; found: 362.2463.

*(±)-(1α, 3α, 3aα, 6α, 6aα, 9aα, 9bβ)-Dodecahydro-6a-isocyano-1-(2-isocyano-2-methylpropyl)-3,6-dimethyl-9-methylene-1H-phenalene [(±)-8,15-diisocyano-11(20)-amphilectene (**2**)]*

To a stirred solution of the diacid **45** (19 mg, 0.052 mmol) in dry toluene (0.4 mL) were added dry Et_3N (38 μL, 0.273 mmol) and diphenyl phosphorazidate (38 μL, 0.186 mmol) and the mixture was heated to 80°C. Evolution of nitrogen began immediately. After a period of 2 h, the ir spectrum of the material obtained from a small sample of the mixture showed an absorption at 2170 cm^{-1} (-N=C=O, compound **46**). No carbonyl absorption was present. Dry 2-(trimethylsilyl)ethanol (0.15 mL, 1.06 mmol) and dry Et_3N (76 μL, 0.546 mmol) were added and the mixture was heated at 100°C for 60 h. During this time, after periods of 20 h and 40 h, additional amounts of $Me_3SiCH_2CH_2OH$ (0.15 mL) and Et_3N (76 μL) were added. The reaction mixture was cooled, diluted with Et_2O, and passed through a small column of silica gel (2 g, elution with Et_2O). The eluate was concentrated and the residue was subjected to flash chromatography (15 g silica gel, 9:1 pentane–Et_2O) to provide 16 mg (52%) of the dicarbamate **47**, a colorless oil that exhibited ir (neat): 3448, 3371, 1731, 1645, 1505 cm^{-1}; ^1H nmr (400 MHz) δ: 0.04 (s, 9H), 0.06 (s, 6H), 0.64–0.86 (m, 3H), 0.87 (d, 3H, J = 6 Hz), 0.93 (d, 3H, J = 6 Hz), 0.90–1.10 (m, 7H), 1.22–1.32 (m, 2H), 1.31 (s, 3H), 1.34 (s, 3H), 1.42 (m, 1H), 1.68–2.10 (m, 7H), 2.21 (br ddd, 1H, J = 13, 3.5, 3.5 Hz), 3.52 (br d, 1H, J = 13 Hz), 4.10 (m, 4H), 4.43 (s, 1H), 4.50 (s, 1H), 4.55 (s, 1H), 4.80 (s, 1H).

To a stirred solution of the dicarbamate (16 mg, 0.027 mmol) in dry THF (0.6 mL) was added a solution of tetra-*n*-butylammonium fluoride in THF (0.21 mL) and the mixture was heated at 50°C for 2 h. The mixture was cooled and concentrated. The residue was treated with pentane (3 mL) and aqueous NH_4Cl–NH_4OH (2 mL, 1.6 mL of saturated aqueous NH_4Cl diluted with 0.4 mL of concentrated aqueous NH_4OH) and the mixture was stirred rapidly for 15 min. The phases were separated and the aqueous layer was washed with pentane (2 × 2 mL). The combined organic extracts were concentrated to provide the crude diamine **48** (~9 mg) as a pale yellow oil. This material was dissolved in dry Et_2O (0.5 mL) containing 30 μL (0.23 mmol) of acetic formic anhydride and the solution was stirred at room temperature for 2 h. Water (2 mL) and Et_2O (3 mL) were added and the phases were separated. The aqueous layer was extracted with Et_2O (2 × 2 mL) and the combined extracts were washed (brine), dried ($MgSO_4$), and concentrated to give the diformamide **49** (~10 mg) as a white solid. The ^1H nmr spectrum of this material showed that it was a mixture of *cis* and *trans* isomers with respect to the formamide functions. A solution of this material in dry CH_2Cl_2 (0.5 mL) was treated with Ph_3P (22.5 mg, 0.086 mmol), dry CCl_4 (8 μL, 0.08 mmol) and dry Et_3N (30 μL, 0.18 mmol) and the mixture was heated at 55°C for 6.5 h. The mixture was concentrated and the solid residue was extracted (triturated) with 1:1 pentane–Et_2O. The combined organic extracts were concentrated and the residue was subjected to flash chromatography (2 g silica gel, 93:7 pentane–Et_2O) to afford 7 mg (41% from the diacid **45**) of (±)-8,15-diisocyano-11(20)-amphilectene (**2**), a crystalline solid (mp 84–86°C) that displayed ir (KBr): 2127, 1647 cm^{-1}; ^1H nmr (400 MHz) δ: 0.78–0.94 (m, 2H), 0.92 (d, 3H, J = 6 Hz), 1.00 (d, 3H, J = 6 Hz), 1.02–1.15 (m, 2H), 1.20–1.50 (m, 4H), 1.45 (t, 3H, J = 2 Hz), 1.47 (t, 3H, J = 2 Hz), 1.54 (m, 2H), 1.85 (dd, 1H, J = 11, 11 Hz), 1.93–2.04 (m, 2H), 2.09 (dd, 1H, J = 15, 2 Hz), 2.23–2.36 (m, 4H), 4.68 (s, 1H), 4.87 (s, 1H); ^{13}C nmr (75.3 MHz, C_6D_6) δ: 15.9, 19.9, 30.0, 30.2, 30.5, 31.5, 33.5, 33.9, 35.6, 39.7, 40.9, 41.2, 42.9, 45.7, 46.3, 55.5, 56.5 (t, J = 4 Hz), 66.9 (t, J = 4 Hz), 106.6, 150.0, 158.1 (t, J = 4 Hz), 159.9 (t, J = 4 Hz). Exact Mass calcd. for $C_{22}H_{32}N_2$: 324.2565; found: 324.2556.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada for financial support and for an Undergraduate Student Research Award (to R.M.O.). We are grateful to Dr. Miguel Romero for carrying out model studies related to the conversion of the diacid **45** into (±)-**2**.

OSVALD KNOP, T. STANLEY CAMERON, PRADIP K. BAKSHI, WITOLD KWIATKOWSKI, S.C. CHOI, and D. ADHIKESAVALU. Can. J. Chem. **71**, 1495 (1993).

Recrystallization of a primary or secondary alkylammonium tetraphenylborate (TB) from approximately 1:1 mixtures of Me_2CO (or MeEtCO) and water yields, against expectation, the TB of the corresponding iminium cation and thus provides an easy route to a variety of aliphatic Schiff bases. The crystal structures of five such salts have been determined: **A**, $[Me_2C{=}NHMe]BPh_4$ (*Cmcm*, a = 10.747(2) Å, b = 15.641(4) Å, c = 13.453(4) Å, Z = 4); **B**, $[Me_2C{=}NMe_2]BPh_4$ (*Cmca*, a = 13.196(4) Å, b = 14.469(3) Å, c = 25.122(4) Å. Z = 8); **C**, $[Me_2C{=}NHEt]BPh_4$ ($P2_1/n$, a = 12.146(3) Å, b = 14.099(2) Å, c = 14.177(3) Å, β = 96.23(2)°, Z = 4); **D**, $[MeEtC{=}NHMe]BPh_4$ ($Cmc2_1$, a = 10.967(5) Å, b = 15.642(5) Å, c = 13.430(4) Å, Z = 4); **E**, $[Me_2C{=}NH(\beta\text{-}CH_2CH_2Ph)]BPh_4 \cdot H_2O$ ($C2/c$, a = 30.747 Å, b = 9.845(4) Å, c = 19.741(5) Å, β = 97.12(2)°, Z = 8). The building principles of these and related TBs are discussed in detail, as also is the tendency of the small iminium ions to orientational disorder. The range of the C=N bond length in these and other iminium salts is quite narrow, with 1.283(12) Å as the mean (uncorrected) value. Where a hydrogen atom(s) is attached to the iminium nitrogen, it will form a hydrogen bond (simple or bifurcated) with the aromatic π system of the nearest phenyl ring(s). The narrowness of the C=N bond-length range with respect to substitution on the cation has prompted a detailed 6-31G* *ab initio* study of the effect, on the geometry of the $[H_2C{=}NH_2]^+$ ion, of a partial or complete replacement of the H atoms by one of the following substituents: F, Cl, CN, Li, and Na. The 46 structures optimized in planar geometry were supplemented by a number of optimizations of similarly substituted ethylenes as well as by a few optimizations in perpendicular geometry. Analysis of the numerical results involves the bond lengths and angles, Mulliken ε_M and (in part) Löwdin ε_L net charges on the atoms, and electron densities $\rho_c = \rho(r_c)$ at the bond critical points. Only a limited use has been made of comparisons involving the total electronic energies E (substitutional isomerism). Since the above substituents span the entire electronegativity scale, and CN provides for the possibility of conjugation, the effects they produce are expected to bracket the effects that would be produced by any other substituents. The calculations confirm the essential narrowness of the C=N bond-length range in iminium ions. They also show that, at least in the 6-31G* scheme, the nitrogen in $[H_2C{=}NH_2]^+$ carries a significant *negative* net charge (both in terms of ε_M and ε_L), which is contrary to the conventional representation of the ion as $H_2C{=}N^+H_2$. The *trends* observed in the parameters are smooth and highly self-consistent except for the tri- and tetrasubstituted ions containing Li or Na, where interligand repulsions may invalidate the assumption of planarity. Many of the parameters can be represented to a high degree of correlation as linear functions $\alpha_0 + \alpha_C n_C(X) + \alpha_N n_N(X)$ of the numbers n of substituent atoms X on the C and N atoms. This representation makes it possible to estimate the contribution to the parameter value from the substitution at the distant atom of the C=N bond, i.e., the extent of localization of the effect produced by the substituent. The success of the linearization of the parameter variation raises the important question of whether the apparent additivity is genuine and intrinsic or merely a property of the 6-31G* optimization scheme. In other words, will additivity be retained, functionally, for sets of parameters obtained from higher level *ab initio* calculations, and will it be eventually verified by experiment?

OSVALD KNOP, T. STANLEY CAMERON, PRADIP K. BAKSHI, WITOLD KWIATKOWSKI, S.C. CHOI et D. ADHIKESAVALU. Can. J. Chem. **71**, 1495 (1993).

La recristallisation d'un tétraphénylborate d'alkylammonium primaire ou secondaire (TB) dans des mélanges approximativement 1 : 1 d'acétone (ou de butanone) et d'eau conduit, contre toute attente, au TB du cation iminium correspondant; ceci fournit une voie de synthèse facile pour une variété de bases de Schiff aliphatiques. On a déterminé les structures cristallines de cinq de ces sels : **A**, $[Me_2C{=}NHMe]BPh_4$ (*Cmcm*, a = 10,747(2), b = 15,641(4) et c = 13,453(4) Å, Z = 4); **B**, $[Me_2C{=}NMe_2]BPh_4$ (*Cmca*, a = 13,196(4), b = 14,469(3) et c = 25,122(4) Å, Z = 8); **C**, $[Me_2C{=}NHEt]BPh_4$ ($P2_1/n$, a = 12,146(3), b = 14,099(2) et c = 14,177(3) Å, β = 96,23(2)°, Z = 4); **D**, $[MeEtC{=}NHMe]BPh_4$ ($Cmc2_1$, a = 10,967(5), b = 15,642(4) et c = 13,430(4) Å, Z = 4); **E**, $[(Me_2C{=}NH(\beta\text{-}CH_2CH_2Ph)BPh_4 \cdot H_2O$ ($C2/c$, a = 30,747, b = 9,845(4) et c = 19,741(5) Å, β = 97,12(2)° et Z = 8). On discute en détail des principes d'empilement de ces TB et de leurs composés apparentés ainsi que de la tendance des petits ions iminium à se trouver dans un désordre orientationnel. La plage des longueurs des liaisons C=N de ces sels d'iminium et d'autres composés apparentés est très mince, avec une valeur moyenne (non corrigée) de 1,283(12) Å. Lorsqu'un (ou des) hydrogène(s) est (ou sont) attaché(s) à l'azote de l'iminium, il(s) forme(nt) une liaison hydrogène simple (ou bifurquée) avec le système π aromatique du (ou des) noyau(x) phényle(s) le(s) plus proche(s). L'étroitesse de la plage des longueurs des liaisons C=N en fonction de la substitution sur le cation nous conduit à réalisé une étude détaillée *ab in-*

itio 6-31G* complète de l'effet, sur la géométrie de l'ion $[H_2C{=}NH_2]^+$, du remplacement complet ou partiel des atomes de H par un des groupes suivants : F, Cl, CN, Li et Na. On a optimisé 46 structures en géométrie planaire ainsi qu'un certain nombre d'éthylènes substitués de la même manière en plus de quelques optimisations dans la géométrie perpendiculaire. L'analyse des résultats numériques implique les longueurs de liaison et les angles, les charges nettes de Mulliken, ϵ_M, et (en partie) de Löwdin, ϵ_L, sur les atomes et les densités électroniques, $\rho_c = \rho(r_c)$, aux points critiques de la liaison. On n'a fait qu'une utilisation restreinte de comparaisons impliquant les énergies électroniques totales, *E* (isomérie de substitution). Puisque les substituants utilisés couvrent l'ensemble de l'échelle de l'électronégativité et que le CN offre la possibilité de conjugaison, on s'attend à ce que les effets produits recouvrent l'ensemble des effets qui pourraient être provoqués par d'autres substituants. Pour l'essentiel, les calculs confirment que la plage des longueurs des liaisons C=N est étroite dans les ions iminium. Ils montrent aussi, au moins au niveau 6-31G*, que l'azote du $[H_2C{=}NH_2]^+$ porte une charge nette *négative* importante (tant en termes de ϵ_M que de ϵ_L), ce qui est contraire à la représentation conventionnelle de l'ion, $H_2C{=}N^+H_2$. Les *tendances* observées dans les paramètres sont graduelles et très autocohérentes, excepté pour les ions tri- et tétracoordinés contenant du Li ou du Na; dans ces cas, les répulsions intercoordinats peuvent invalider l'hypothèse de planéité. On peut obtenir une bonne corrélation de plusieurs paramètres par les fonctions linéaires $\alpha_0 + \alpha_C n_C(X) + \alpha_N n_N(X)$ des nombres *n* de substituants X sur les atomes C et N. Grâce à cette corrélation, on peut évaluer la contribution à la valeur du paramètre à partir de la substitution sur l'atome éloigné de la liaison C=N, c'est-à-dire l'étendue de la localisation de l'effet produit par le substituant. Le succès de la linéarisation de la variation du paramètre soulève une question importante : est-ce que l'additivité apparente est réelle et intrinsèque ou s'agit-il simplement d'une propriété du schéme d'optimisation 6-31G*? En d'autres termes, est-ce que l'additivité sera fonctionnellement maintenue pour des ensembles de paramètres obtenus par des calculs *ab initio* à des niveaux plus élevés et permettra-t-elle éventuellement de vérifier des expériences?

[Traduit par la rédaction]

Aliphatic $[RR'C{=}NR''R''']^+$ Schiff cations are notorious for the ease with which they hydrolyze to the corresponding aldehyde or ketone and the alkylammonium cation (2). Because of this their synthesis and use require rigorously anhydrous conditions (for example, refs. 2–11). It came therefore as a surprise to find that solutions of $MeNH_3^+$ and $Me_2NH_2^+$ tetraphenylborates in mixtures of acetone and water, when concentrated by evaporation at room temperature, yield crystals of the $Me_2C{=}NHMe^+$ and $Me_2C{=}NMe_2^+$ iminium tetraphenylborates, and that these crystals can be handled without special precautions in atmospheric air. The simple expedient of recrystallization from an acetone–water solution thus provides an easy synthetic route to the two iminium salts.

Encouraged by this discovery, we have successfully used this method to prepare several other tetraphenylborates of this type and determined the crystal structures of $[Me_2C{=}NHMe]BPh_4$ (**A**), $[Me_2C{=}NMe_2]BPh_4$ (**B**), $[Me_2C{=}NHEt]BPh_4$ (**C**), $[MeEtC{=}NHMe]BPh_4$ (**D**), and $[Me_2C{=}NH(\beta\text{-phenethyl})]BPh_4 \cdot H_2O$ (**E**). (Table 1). Formation of the iminium cation was ascertained by the appearance of the diagnostic ν(C=N) ir absorption band at ca. 1680 cm^{-1} (Table 2).[4] From the crystal structures of **A**–**E** and those of other tetraphenylborates (15–22) we have been able to elucidate some of the principles of ion packing in tetraphenylborates of small cations, and also to provide evidence for the existence of hydrogen bonding between cation or H_2O hydrogens and the aromatic π system of the phenyl ring(s). In addition, *ab initio* (6-31G*) calculations on a variety of substituted $[LL'C{=}NL''L''']^+$ cations have made it possible to examine the effects of substitution on the geometry and the net charges in such cations, as well as the existence of a correlation between the C=N bond length and the electron density $\rho(r_c)$ at the bond critical point (cf. ref. 23).

Crystal structures

The positional parameters of non-hydrogen atoms in **A**–**E** are listed in Table 3 and the bond lengths and angles in the cations of **A**–**E** in Table 4. Tables of other parameters and derived quantities have been deposited.[5] The contents of the deposited tables are as follows:

A. Positional parameters and isotropic temperature factors of hydrogen atoms.

B. Anisotropic thermal parameters of non-hydrogen atoms.

C. Bond lengths and bond angles in the anions of **A**–**E**.

D. CBC valence angles α and α' in **A**–**E**.

E. Deviations from best planes through phenyl rings and through cations in **A**–**E**.

F. Dihedral angles between best planes through the phenyl rings.

G. Molecular parameters for the CN groups of the cyano-substituted iminium ions of Tables 7 and 8.

H. Power regressions $\rho_c = sd^{-v}$ of the electron density at the bond critical point on the corresponding bond lengths in iminium ions.

J–N. Observed and calculated structure factors for **A**–**E**.

P. Coefficients of the linear regressions $d = a_0 + a_C n_C + a_N n_N$ for the bond lengths and interligand distances (Å) in X-substituted planar iminium ions.

Q. Coefficients of the linear regressions $\epsilon = b_0 + b_C n_C + b_N n_N$ for the Mulliken ϵ_M and Löwdin ϵ_L net charges in X-substituted planar iminium ions.

R. Coefficients of the linear regressions $\rho_c = c_0 + c_C n_C + c_N n_N$ for the electron densities at the bond critical points in X-substituted planar iminium ions.

S. Comparison of Mulliken ϵ_M and Löwdin ϵ_L net charges (e) in planar F and CN substituted iminium ions.

T. Coefficients of the exponential regressions $\epsilon_M(X) = p + q \exp[-s\epsilon_M(C \text{ or } N)]$ for the mono- and disubstituted iminium ions and ethylenes.

[4]Only values directly relevant to **A**–**E** are listed. For a comprehensive list of ν(C=N) frequencies in other iminium salts see Table I of ref. 14.

Preliminary observations

Because of its bulk the tetraphenylborate (TB) ion is often used as a counter-anion of convenience when it is desired to prepare well-crystallized salts of large composite cations or simply to stabilize such cations. This is reflected in the generous number of crystal structure determinations of tetraphenylborates in the literature. By the same token, however, in the majority of these structures the large cation, often of awkward shape, dominates the packing geometry and this tends to obscure, in all but a small number of the known

structures, the basic principles that govern the ion packing and the conformational behaviour of the anion in TB structures with small or medium-size cations.[6]

To understand the crystal chemistry of the title compounds it is instructive to compare the alkali TBs, as exemplified by the K^+ (16) and NH_4^+ (18) salts, with the tetramethylammonium salt Me_4NBPh_4 = 4MTB (16). The tetragonal (*I*4*m*, *Z* = 2) TBs form an isostructural series (25), in which the cation size ranges from Na to Cs; 4MTB is orthorhombic (*Cmcm*, *Z* = 4). In both cases the structure consists of columns in which cations alternate with anions. In the alkali salts the axes of these columns coincide with the 4 axes, in 4MTB they are parallel to the *b* axis. In the former, the quasi-spherical cation is inside a "tetrahedral" cavity formed by two pairs of phenyl rings, one pair from the anion above and the other from the anion below the cation, all three ions in the same column (Fig. 1*a*). In 4MTB, however, the cation is too large for this type of packing to remain favourable: the phenyl-ring coordination of the cation is still "tetrahedral," but now only one pair of rings comes from an anion neighbour in the same column, the other two rings come one each from anions in neighbouring columns (Fig. 1*b*). To achieve such partial hetero-column coordination the vertical positions of the N and B atoms in neighbouring columns must be adjusted, which results in a lowering of the space-group symmetry.

In $KBPh_4$ the ions are arranged in a tetragonally distorted NaCl-type packing, with the N and B atoms on tetragonal Bravais *I* sublattices (Fig. 2*a*)[7] In 4MTB the orthorhombic distortion of the N and B sublattices is appreciable but the NaCl-type packing is still recognizable (Fig. 2*b*). Moderate increase in the effective cation size may thus be expected to bring about a change in the space-group symmetry consistent with the transition from homo-column to partial hetero-column cation coordination, i.e., from *I*42*m* to *Cmcm* or subgroup as a likely candidate.

*Compounds **A**, **B**, and **D***

Projections on (100) of these three structures and of 4MTB are shown in Fig. 3. **A** and **D** have unit cells of roughly similar shapes, while that of **B** is doubled along *c*. The space-group relations of these orthorhombic structures can be represented as $Cmc2_1$ (**D**) ⊂ [*Cmcm* (**A**), *Cmca* (**B**)] ⊂ *Fmmm* ⊂ *Fm*3*m*. The ion packing in all three is of the same type as in 4MTB (*Cmcm*). The structure of the latter is closely similar to both **A** and **D**: columns of alternating ions are parallel to *b*. The structure of **B** consists of $a \times b \times (c/2)$ segments, each of almost *Cmcm* symmetry, translated along *c* and related by the *a* translations of *Cmca* in the $z = \pm\frac{1}{4}$ planes. As in 4MTB, **A**, and **D**, the cation in **B** is coordinated by four phenyl rings, one pair from an anion in the same column and the other two, one each, from neighbouring columns. However, because of the presence of the *a* glide mirrors the "tetrahedral" coordination cage is not completely enclosed but open on one side (Fig. 1c).

The structures of **A**, **D**, and 4MTB may be regarded as distorted NaCl-type packings based on dichromatic C_A Bravais lattices; the chromatic reversal changes the orientation of the anion.

Insertion of the carbon atom into the $Me_2NMe_2^+$ cation in 4MTB to form $[Me_2C{=}NMe_2]^+$ in **B** expands the volume per formula unit by approximately 18 Å^3; the tabulated increment for the insertion of an ethylenic carbon, $CH_2 \rightarrow C{=}CH_2$, is 13.1 Å^3 (26).

*Compound **C***

The ion packing in **C** may be regarded as of a very distorted zincblende type. The cations form an approximate fc arrangement; the anions are arranged in columns of quasi-2_1 symmetry parallel to *c* (Fig. 4). The $[Me_2C{=}NHEt]^+$ cation, in a general position and with a skeleton not far from planar (Table E), is enclosed by rings 1 and 4 from one and rings 2 and 3 from another anion neighbour (Fig. 5). The cavity formed by the four rings is less symmetric than in 4MTB, **A**, **D**, or **B** (cf. Figs. 1 and 8). The N—H vector is directed at ring 1 (see below and Fig. 9). Since **C** and **B** have the same molecular weight, their volumes per formula unit would be expected to be closely similar: indeed, V_1(**C**) = 603(1) Å^3, V_1(**B**) = 600(1) Å^3.

*Compound **E***

The anions, the cations, and the water molecules in this structure are arranged in layers ∥(100), each layer containing all three component species (Fig. 6). Within a layer the anions form columns generated by the *c* glide reflection. The phenyl rings are segregated in double layers ∥(100) at $z = 0, \frac{1}{2}$; the water molecules are dispersed between the anion columns. The N—H group of the cation is hydrogen-bonded to the water molecule, which in turn forms hydrogen bonds to an anion (see below and Fig. 9). The hydrogen-bonding system is thus of the same type as that found in $(n\text{-}Bu_3NH)BPh_4 \cdot H_2O$ and presumably also in $(n\text{-}Pr_3NH)BPh_4 \cdot H_2O$ (17), whereas in the anhydrous Me_3NH^+ and Et_3NH^+ TBs the N—H group interacts directly with a phenyl ring (19, 21; Knop et al., to be published).

Cation disorder

As shown above, the packing in the structures of 4MTB, **A**, **B**, and **D** is dominated by the anion geometry. The volume of the "tetrahedral" inter-anion space that is available to the cation within the anion–cation columns is regulated by the B...B distances, which in turn depend on the shape and dimensions of the cation. In 4MTB the regular shape of the tetrahedral cation permits the cation to wedge itself between the nearest pair of phenyl rings, in a symmetric orientation and with little freedom of movement inside the phenyl-ring coordination cage (Fig. 2*b*). As a result the structure is completely ordered. In **B**, however, the cation is rectangular, and the cation shapes in **A** and **D** are even less

[6]Crystal structures of the corresponding "*anti*" compounds $[Ph_4X]^+[an]^-$ and of $[Ph_4Y]^0$ (X from Group V, Y from Group IV) have been classified by Müller (24).

[7]For the present purpose the tetragonal *I* lattice (*Z* = 2) may be represented as a tetragonal *F* lattice (*Z* = 4). In Fig. 2*a* the tetragonal bc cell has been transformed into the corresponding fc cell, the correct space-group designation now being *F*4*m*2.

[a]Bond lengths and angles are not corrected for thermal motion.

regular. Introduction of a cation less "tetrahedral" than Me_4N^+ into the symmetric wedge-shaped space inside the pair of phenyl rings results in orientational disorder. The existence of the disorder complicated the structure determinations of **A**, **B**, and **D**, especially as initially it was not realized that recrystallization of $MeNH_3BPh_4$ and $Me_2NH_2BPh_4$ from aqueous acetone would yield the iminium TBs **A** and **B** instead of the expected original compounds.

The electron-density map in the cation plane of **A** (*m* in (100), Fig. 7*a*) shows clearly the twofold positional disorder across $m \| (001)$ at $z = \pm\frac{1}{4}$ (cf. Fig. 3), which interchanges z and $z' = \frac{1}{2} - z$. The almost exact coincidence of C(N) and C(C2)′, and of C(C1) and C(C1)′, precludes resolution of the corresponding composite peaks. The presence of disorder is also manifested in some of the U_{ii} values, notably in the U_{11} of C(C1) and C(N),

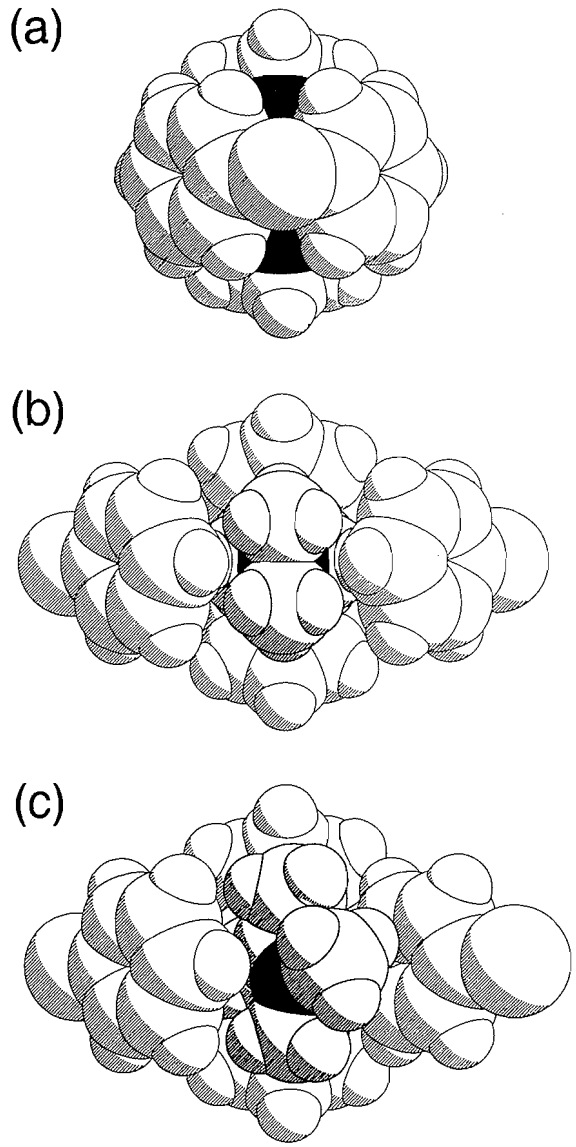

FIG 1. The quasi-tetrahedral enclosure of the cation by (*a*) two pairs of phenyl rings belonging to neighbouring anions in the same vertical cation–anion column (in $KBPh_4$); (*b*) a pair of phenyl rings of an anion neighbour in the cation–anion column and two phenyl rings each belonging to an anion in different neighbouring columns (in 4MTB); and (*c*) ditto in **B** (see text). The cation is inside the heavy outline, with the K and N atoms shown in black. Since the effective coordination number of the K^+ ion is ill-defined, the choice of $r(K^+)$ is arbitrary; however, the exact choice of the ionic radius matters little, as the cation coordination is the same in all the alkali TBs, from Na to Cs.

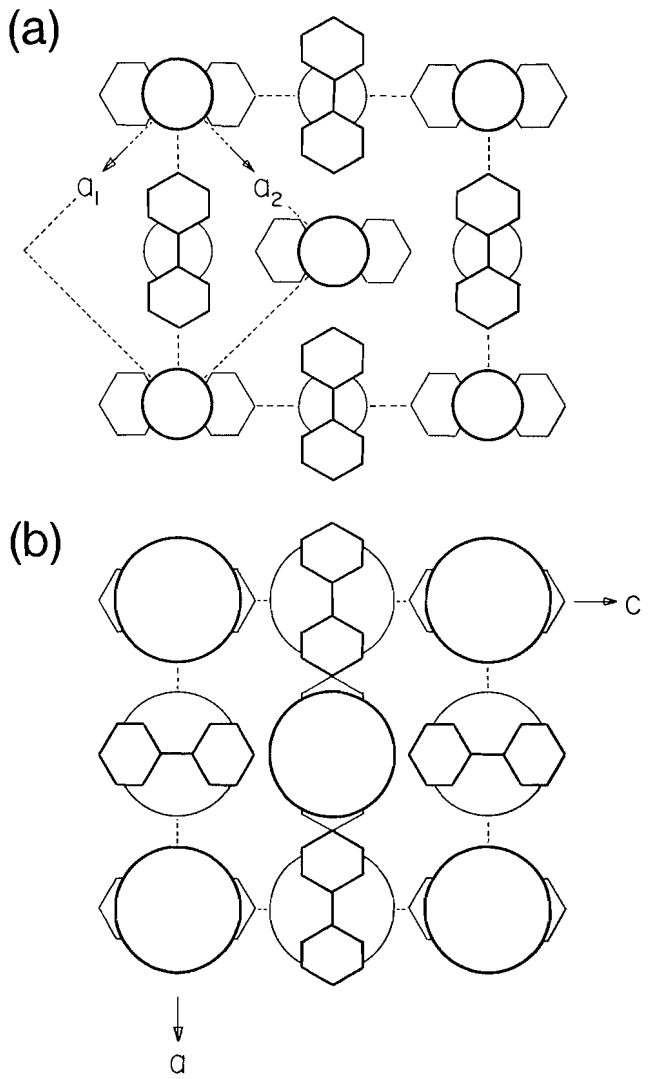

FIG. 2. Schematic representation of the ion packing and anion orientation is (*a*) $KBPh_4$ and (*b*) Me_4NBPh_4 (see text). All the phenyl rings shown are tilted upward from the page.

and to a smaller extent in the U_{11}(N) and U_{22}[C(N)] (Fig. 7*a*).

In **B** the plane of the cation is perpendicular to (100); the disorder is across a mirror plane ∥(100) (Figs. 7*b* and 8*e*). Here again the very close coincidence of the C(N1) and C(C2)′, C(C1) and C(C1)′, and C(N2) and C(N2)′ peaks renders resolution impossible.

The cation disorder that is present in **D** is of a simpler kind. The cation, in a general position, is disordered across *m*(100), i.e., $x' = -x$ (Figs. 3 and 8*b*).

While the peak heights in the electron-density maps through the cations are not a reliable guide to distinguishing between the C and N atoms in the C=N bond, in **A** the absence of a methyl carbon on the nitrogen permits unique identification. In **B**, refinement with the C and N positions of Table 3 reversed produced peak contours of unsatisfactory shapes and thus confirmed the present assignment.

Attempts to refine the three structures as fully ordered in subgroups of lower symmetry produced less satisfactory results (see Experimental).

It is interesting to note that an orientational disorder even greater than in **B** has been reported for the cation in the tetragonal (*I*4/*mmm*, $Z = 2$) $[Me_2C{=}NMe_2]ClO_4$ (27), in which crystal the ion packing is of the NaCl-type. In this even less constraining environment of nearest ClO_4^- neighbours in twofold disorder the cations are situated in mirror planes ∥(001), and their orientations are distributed over four symmetry-equivalent C—N directions. Not surprisingly, therefore, the "C=N" bond length resulting from the structure determination of the perchlorate, 1.30(4) Å, approximates the mean of the azo N=N and ethylenic C=C bond lengths.

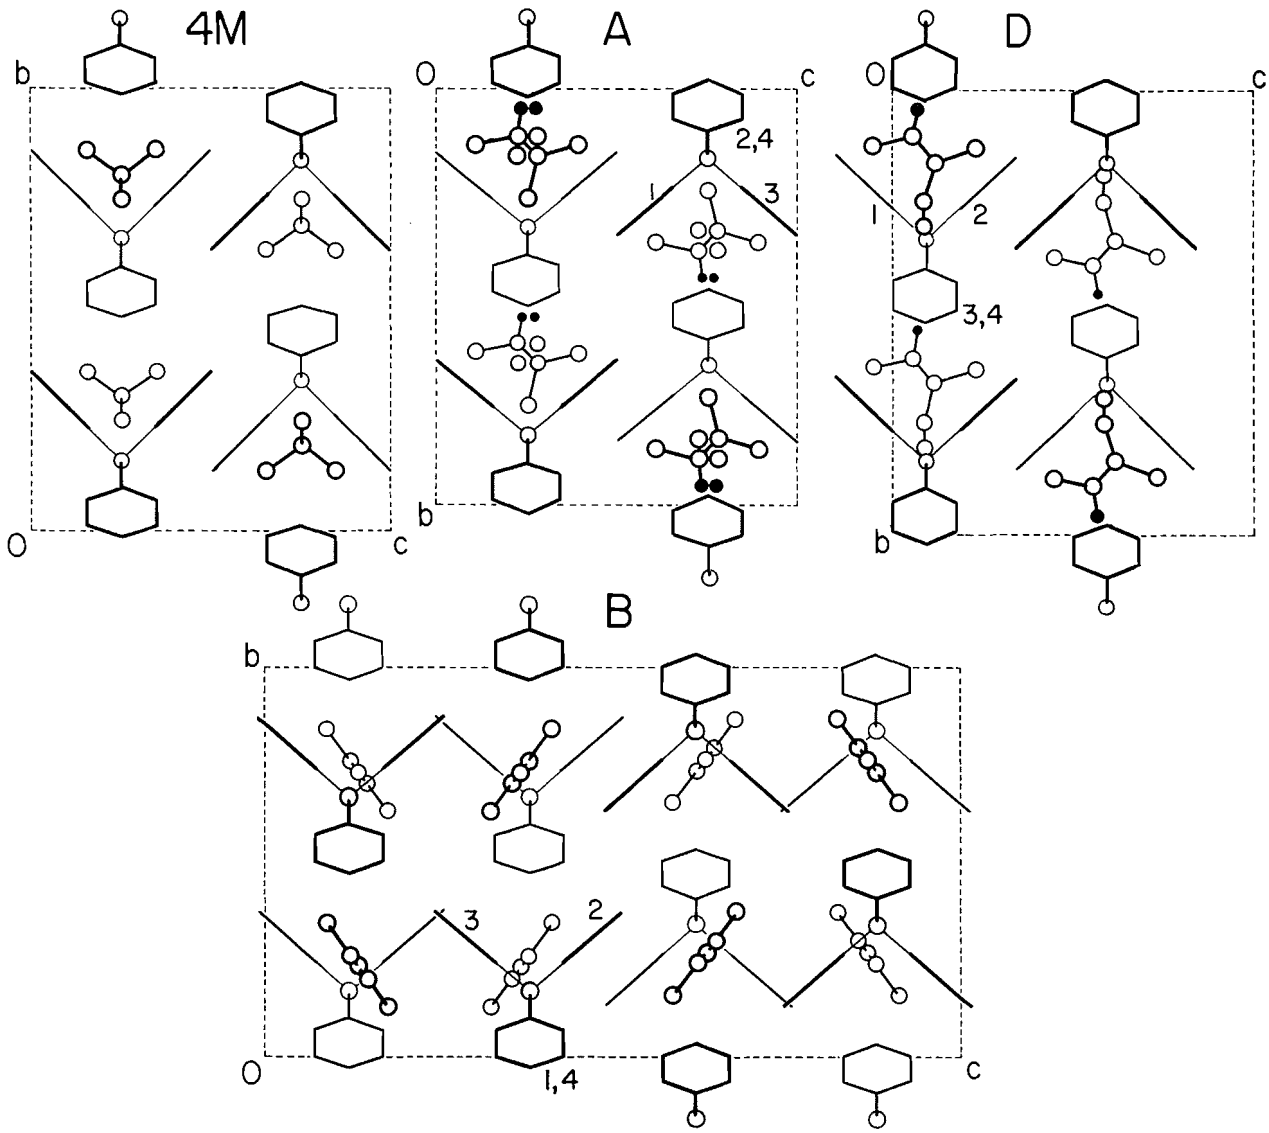

FIG. 3. Projection on (100) of the unit-cell contents of 4MTB (16), **A**, **B**, and **C**. The packing in the segment of **B** between $z = 1/4$ and $z = 3/4$ corresponds to that in the unit cells in the upper row.

Tetraphenylborate anion

The maximum possible symmetry of the anion, D_{2d}, is realized only in its unsolvated alkali and ammonium salts (16, 18, 25). Of the five proper subgroups of D_{2d}, C_{2v} is observed as the anion symmetry in **A** and 4MTB, while the crystallographic anion symmetry in **B** and **D** is C_s; the skeletal symmetry of the anion is very close to D_{2d}. The anion is asymmetric in **C** and **E**, but even in the latter its conformation is not far from D_{2d}.

The overall mean of the CBC valence angles α in **A**–**E** and 4MTB (Table D) is 104.0(10)° and that of α', 112.8(13)°. Here α represents the angle that in the D_{2d} conformation of the anion would be bisected by the S_4 axis; for conformations of subgroup symmetries other than S_4 there are two such angles, α_1 and α_2 (Tables D and 5). The valence angle α appears to be influenced by the size, shape, and position of the cation that it encloses and possibly also by hydrogen bonding betweeen the cation and the rings (Table 5 and next section).

The phenyl rings in all five structures exhibit satisfactory planarity (Table E), the mean deviation of the C atoms from the respective best planes through the 20 rings being 0.006 Å. The boron atoms are not coplanar with their phenyl rings: the mean deviation for the 20 rings is 0.12(4) Å. The non-coplanarity is seen particularly clearly in the anions of **A**, **B**, **D**, and 4MTB, in which the B atom is situated in a mirror (or pseudo mirror) plane bisecting the valence angle α. Comparison of the dihedral angle ϕ between the two rings that define α (i.e., the angle between the best planes through these rings) with the corresponding α (Tables 5, D, and F) shows that $\phi < \alpha$ instead of $\phi = \alpha$, which would be the case if the B atom were coplanar with each ring plane. The angle $\delta = \frac{1}{2}(\alpha - \phi)$ between the B–C vector and a ring plane can be appreciable (cf. Table 5); the tilt, with respect to the B–C vector, of the ring planes is toward the bisector of the CBC angle α.

The mean endocyclic CCC angles in the phenyl rings of **A**–**E** and 4MTB (Tables 4 and C) are 114.7(6)° at the C(α) carbon, 122.9(10)° at C(β), 120.4(9)° at C(γ), and 118.8(8)° at C(δ), showing clearly the effect of the bonding to the B

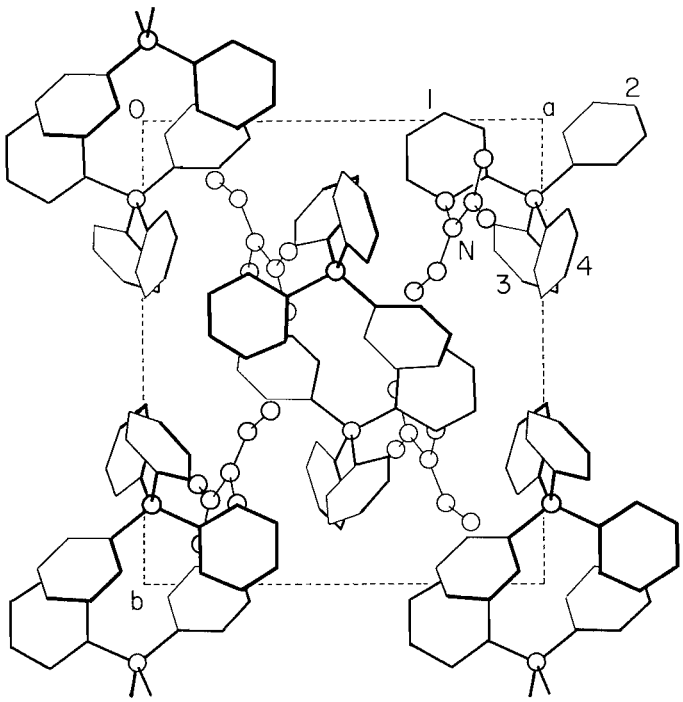

FIG. 4. Projection of the unit-cell contents of **C** on (001).

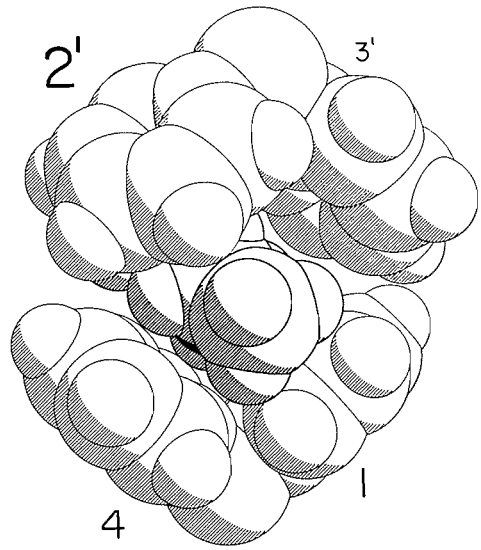

FIG. 5. The asymmetric enclosure of the cation in **C** by two pairs of phenyl rings, each pair from a different anion. Compare with Figs. 1 and 4.

atom at C(α) and the attendant compensation at the other carbon atoms.

Hydrogen bonding

The N–H vectors in **A**, **C**, and **D**, and the O–H vectors in **E**, are seen to point into a phenyl ring (**C**, **E**) or between a pair of phenyl rings enclosing the cation (**A**, **D**) (Figs. 8 and 9). These geometries suggest the formation of N^+—H...π^- and N^+—H...O—H...π^- bonds between the cation or the water molecule and the aromatic π system. More specifically, a single N–H vector points into a ring (**C**) or forms a bifurcated hydrogen bond (**A**, **D**). The two O–H vectors of the water molecule in **E** form a hydrogen bond each, analogous to the situation involving the two N–H vectors in the azoniacycloheptane TB, $[(CH_2)_6NH_2]BPh_4$, of ref. 20 (Fig. 8*c*). The geometric relation between the H-bonded cation and the phenyl ring is not affected by the presence of orientational disorder of the cation in **A** and **D**, since the alternative cation orientations are symmetric with respect to the H-bonding geometry. In **E** the situation is more complicated in that the N^+–H vector forms a hydrogen bond to the ring via the intermediary of the H_2O molecule. This type of situation has previously (17) been found in $(n\text{-}Bu_3NH)BPh_4 \cdot H_2O$, in which structure the local geometry is essentially the same as in **E** (Fig. 3 of ref. 17).

The distance of the N or O atom from the centre c_π of the associated phenyl ring varies from approximately 3.1 to approximately 3.8 Å. In **C**, N...c_π is 3.76 Å, whereas in $[(CH_2)_6NH_2]BPh_4$ (20) the corresponding two distances are much shorter, 3.08 and 3.10 Å. In **A**, N...c_π is 3.32 Å, and in **D** at low temperature the corresponding two distances are 3.10 and 3.55 Å, respectively (the N atom is in an asymmetrically bifurcated position). In the hydrated species, the two O_w...c_π distances are, respectively, 3.26 and 3.44 Å in **E**, and 3.12 and 3.19 Å in the n-Bu_3NH salt (17). These observed O_w...c_π values are in the same range as the estimates obtained from *ab initio* or other calculations (28–30) for the C_6H_6...H_2O complex, 3.1–3.4 Å. The N or O atom in general is not exactly above the centre of the associated phenyl ring, nor does the N–H or O–H vector point to the centre of the ring. Rather it appears to be directed at some point in the π-electron density region above the ring.

In contrast, in 4MTB and **B**, where no H(N) are available, the cation is farther away from its coordinating rings (in 4MTB, N...c_π = 4.40 Å, C(Me)...c_π = 3.93 Å; Fig. 8*d*) and the H(C) vectors tend to avoid the rings. The tendency of an H(N)-containing cation to orient itself preferentially to form a N^+—H...π^- grouping is shown even more clearly in anhydrous R_3NH TBs, especially when these are compared with $R_3S^+BPh_4^-$ (19, 21).[8] In **B**, in the absence of hydrogen bonding, the NMe_2 end of the cation is turned away from the nearest ring pair (Fig. 8*e*).

Although the formation of a N^+—H...π^- bond would be expected to reduce the valence angle α or the angle φ between the planes of the phenyl rings involved or both, the available data (Table 5) do not provide clear-cut evidence of such a reduction. In $KBPh_4$ and NH_4 BPh_4 the simplicity and small size of the cation result in a high-symmetry packing in which the inter-ion distances and angles are too equalized for these structures to be used as reference. However, the dihedral angle ϕ_1 in pairs of rings enclosing the cation in **A**, **D**, and **C** (possibly also in $[(CH_2)_6NH_2]BPh_4$) are consistently smaller than in 4MTB and **B**, where there is no hydrogen bonding; a similar claim could be made for the valence angle α_1 (Table 5). Details of additional TB structures containing the anion in situations of suitable symmetry are desirable before more definite conclusions can be drawn.

While structurally documented only here and there, formation of a hydrogen bond to an aromatic π system is not a novelty and may in fact be more common than the available

[8]A detailed discussion of these matters, with additional new crystal-structure determinations of TBs, is in preparation and is planned to appear as a sequel in this series.

documentation[9] might suggest. The view that X—H...π and X^+—H...π^- (X = N, O) groupings indeed constitute H-bonded systems receives support from the observed lowering of the ν(XH) ir stretching frequencies relative to a non-H-bonded reference frequency (17, 18). However, caution is indicated when invoking spectroscopic evidence: the ir spectrum *and* the crystal structure must be available, and the reference frequency must be judiciously chosen and clearly and unambiguously defined. When X—H...π involves a water molecule, i.e., X = O_w, the ultimate reference frequency is that in water vapour. The two absorption bands in the spectrum of $(n\text{-}Bu_3NH)BPh_4 \cdot H_2O$, observed at 3564 and 3508 cm^{-1} and interpreted as ν_w(OH) (Fig. 5 of ref. 17), would thus suggest significant O_w—H...π interaction. However, in ammonium and alkylammonium TBs, the problem of how to establish a reference frequency that would serve for detecting frequency lowering induced by the formation of N^+—H...π^- bonds is much more difficult. Here frequency comparisons intended to demonstrate the presence of hydrogen bonding must be interpreted with great caution.[10] In the particular case of NH_4BPh_4 the conclusion from a detailed X-ray and ir study (18) is that a ν(NH) frequency lowering indeed exists and is attributable to a weak N^+—H...π^- interaction. By implication, it is reasonable to assume that a similar interaction exists also in the structures discussed in this paper.

Iminium ions: *ab initio* study

The experimental geometry of the unsubstituted $[H_2C{=}NH_2]^+$ ion and thus the C—N distance do not appear to be known. However, the mean of the limited number of the available C—N distances in substituted iminium ions (uncorrected for thermal motion; Table 6) is 1.283(12) Å, i.e., corresponding to a double bond. This value may thus be accepted, provisionally, as a representative (uncorrected) length of the polar C=N bond in iminium ions.

The range of *d*(C=N) in Table 6 is quite narrow. Although a number of C=N bonds with lengths between 1.30 and 1.38 Å are listed in Table XX of ref. 14, these bonds are untypical in that they appear to be subject to steric or electronic interactions that would be absent is simple $[RR'C{=}NR''R''']^+$ ions with H, alkyl, or halogen assubstituents. To substantiate or otherwise the narrowness of the *d*(C=N) range as well as to obtain a clearer idea of the effect of substitution, we undertook 6-31G* optimization of the equilibrium geometries of substituted iminium ions (Tables 7, 8, and G). Aiming at maximum economy of the computational effort we chose F and Cl as the monatomic substituents with the most substantial electron-withdrawing powers, and Li and Na as substituents acting in the opposite direction, in the expectation that the changes induced by these substitutions would bracket the *d*(C=N) variation. Substitution by cyano groups was included to probe the effect of

[9] N^+—H...π^- (15, 18–21); N^+—H...O_w—H...π^- (17); O—H...π (22, 31, 32). See also Addendum.

[10] For a full discussion see refs. 18 and 33 and subsequent papers on the subject in this journal by Knop et al.

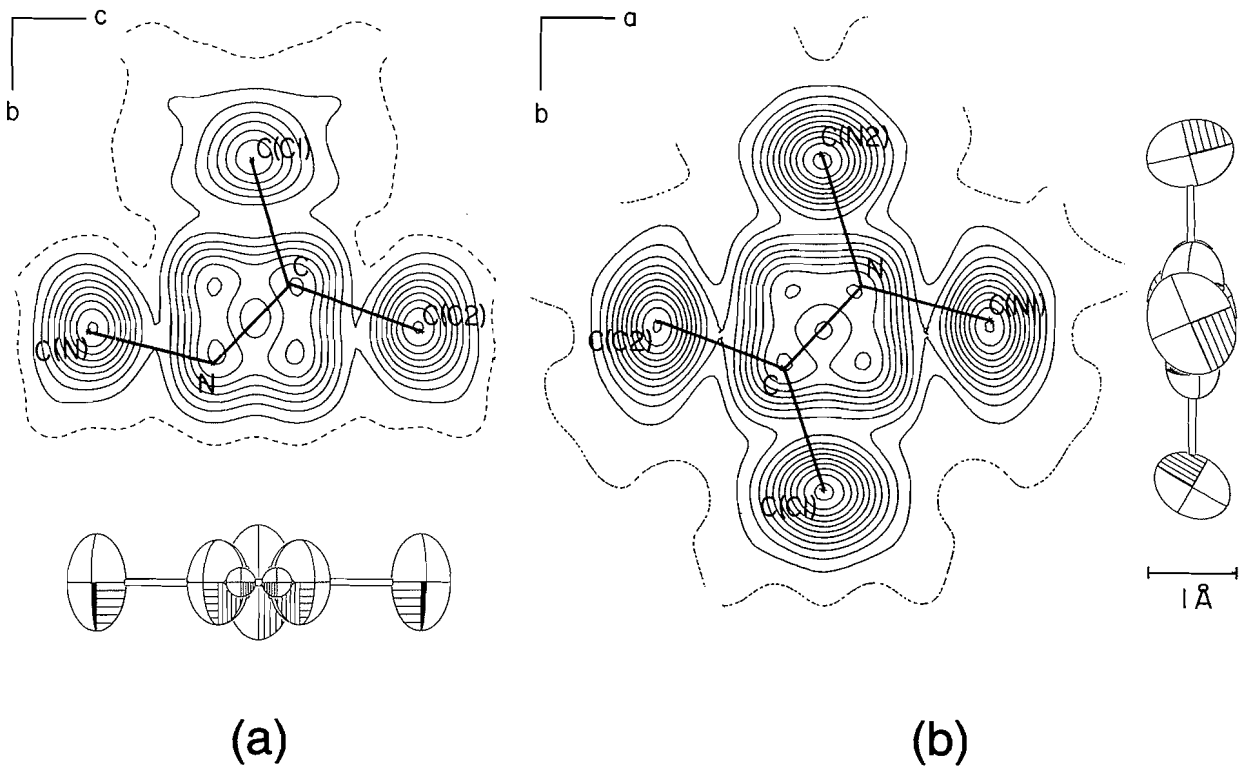

FIG. 7. Electron-density maps in the plane of the cation. Contour intervals, 0.4 e/Å^3. (*a*) $Me_2C{=}NHMe^+$ in **A**. Cation plane is $m\|(100)$, cation disorder is across the vertical $m\|(001)$. A projection of the cation on the (010) plane (perpendicular to the page) is also shown. (*b*) $Me_2C{=}NMe_2^+$ in **B**; the cation plane is about 45° inclined to (001). The cation disorder is across the vertical $m\|(100)$. A projection of the cation on the (100) plane (perpendicular to the page) is also shown.

[a]Angles in deg. Subscript 1 refers to the rings involved in the hydrogen bonding or closest to the cation. The (B—C)/ring plane angles $\delta_1 = (\alpha_1 - \phi_1)/2$ and $\delta_2 = (\alpha_2 - \phi_2)/2$ measure the tendency of the two rings to close up on the bisector of α (see text).

[b]Water molecule bonded to phenyl rings (Figs. 6 and 9).

π conjugation. This choice of substituents was furthermore intended to make unnecessary an investigation of the effect of individual composite substituents (e.g., CH_3, NH_2), which would have added significantly to the already extensive projected computer requirements.[11] The optimizations were carried out in planar geometry, C_{2v} or C_s (but see below).

The choice of the 6-31G* basis set (see Experimental) represents a compromise between wishing to obtain reasonably realistic molecular geometry and keeping the computational effort within practical bounds. While we are well aware of the limitations imposed by this choice as concerns the values of the individual optimized parameters, we would expect that the *trends* that may emerge will constitute a sufficiently valid and realistic approximation to the actual, as yet unknown trends.

We have also included in the optimizations a limited number of similarly substituted ethylene derivatives as well as $[H_2C{=}BH_2]^-$ (Table 9). Comparison of the experimental with the optimized geometry of ethylene itself shows that the C—C and C—H distances are underestimated by 0.022 and 0.009 Å, respectively, and the HCH angle by 1.4° (Table 9). These are not serious discrepancies; one would expect the calculated distances and angles in the optimized iminium geometries to be consistently underestimated by similar amounts.

The optimized molecular parameters can, in general, be

[11]In particular, the above choice was hoped to encompass the effects of substitution in species such as $[Me_2C{=}NMe_2]^+$, for which Kollman (34) suggested that the C—N distance might be expected to be larger than in $[H_2C{=}NH_2]^+$ because of Me hyperconjugation with the carbonium ion centre and C...C repulsions.

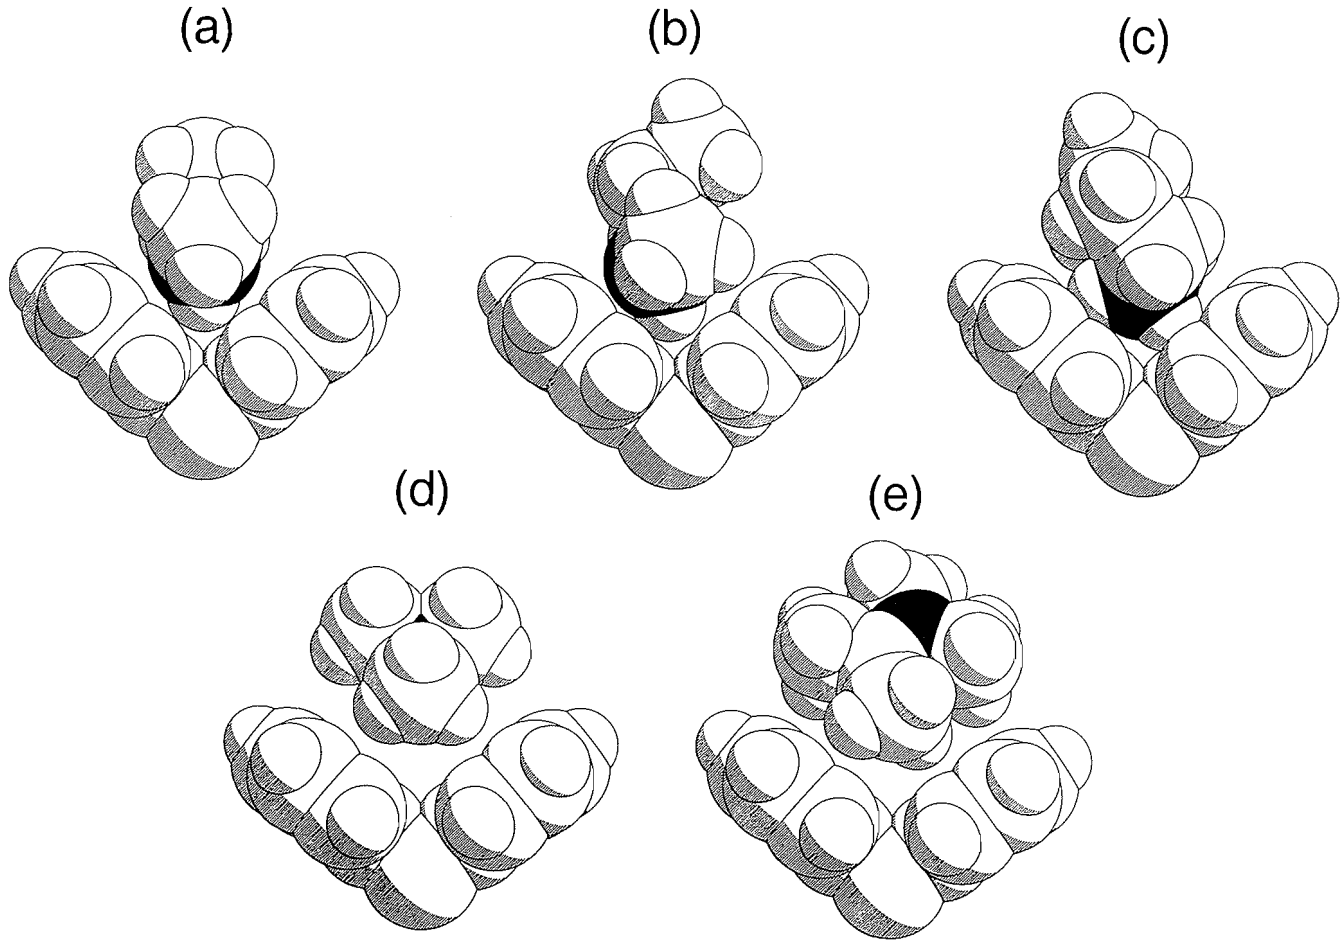

FIG. 8. Coordination of the cation in **A** (*a*), **D** (*b*), $[(CH_2)_6NH_2]BPh_4$ (20) (*c*), 4MTB (16) (*d*), and **B** (*e*), by the nearest pair of phenyl rings of the anion. The N atoms are shown in black. For the disordered cations in *a*, *b*, and *c* only one orientation is shown. The N atom is *a*–*c* is H-bonded to the ring(s), by bifurcated bonds in *a* and *b*, and by normal bonds in *c*. The cation is either symmetric with respect to (*a*, *d*), or disordered across (*b*, *e*), a vertical plane bisecting the boron atom; in *a*, *c*, and *d* the plane of the paper is parallel to a crystallographic mirror plane.

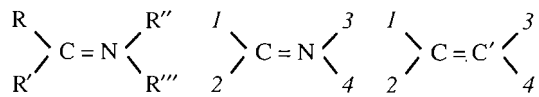
represented as linear functions $\alpha_0 + \alpha_C n_C + \alpha_N n_N$ of n_C and n_N, the numbers of substituents on the C and N atoms, respectively (Tables P–R). These approximations are on the whole remarkably successful, giving r^2 mostly well over 0.9 and not often below this value. They show that the changes resulting from the substitution are essentially additive, and their uniform functional form makes it possible to separate the contributions from the C and N atoms to the changes in the optimized parameters and thus to assess the relative importance of these contributions. The linear parametric representation in n_C and n_N also permits looking for possible relationships between the coefficients of the regressions.

The validity of the observations and conclusions that follow is of course contingent on the presumed self-consistency of the 6-31G* scheme for elements of the first and second rows of the periodic system, as well as on the assumption that each of the optimized geometries corresponds to the *global* E(6-31G*) minimum for that ion or molecule in the prescribed symmetry. Attention will be drawn to situations where there are reasons for thinking that these assumptions may not hold.

No effort was made to analyze the results for orbital populations and similar features. This and further calculations will have to await another occasion.

Notation

The optimized parameters discussed below are the bond lengths and interligand distances d, the bond angles, the Mulliken ε_M and Löwdin ε_L net charges on the atoms, the electron densities $\rho_c = \rho(\boldsymbol{r}_c)$ at the bond critical points, and the dipole moments μ. The following numbering scheme has been adopted to specify the substitutions:



Thus FHFH and *13* in the fluoro iminium set both designate $[F^1H^2C{=}NF^3H^4]^+$, and HCyCyH and *23* both stand for $[H^1(NC)^2C{=}N(CN)^3H^4]^+$ in the cyano set; and similarly for the ethylene derivatives. Where confusion might arise, the iminium and the ethylene derivatives are distinguished as, for example, $LiHHH^+$ and LiHHH.

For reasons that will be apparent later it will be convenient to refer to X = H, F, Cl, and CN as group **A** and to X = Li and Na as group **B** substituents.

Relative stability of substitution isomers

Substitution in $HHHH^+$ yields two types of planar isomers, the *cis/trans* $XHXH^+/XHHX^+$ (*13*/*14*), and the pairs

that arise from substitution either on the C or on the N atom, viz. $XXHH^+/HHXX^+$ (*12/34*) and the complementary pairs $XHHH^+/HHXH^+$ (*1/3*) and $XXXH^+/XHXX^+$ (*123/134*). For the **B**-substituted *cis/trans* pairs the difference $\Delta E = E(13) - E(14)$ is of the order of 5 kcal/mol, favouring the *trans* form. For X = **A** the $|\Delta E| < 0.5$ kcal/mol (−0.03 kcal/mol for X = Cl) are too small to claim, even in terms of the 6-31G* scheme, the existence of a trend. However, X = H requires $\Delta E = 0$ by definition, and if the ΔE values are regressed parabolically on $\chi(X)$, $\chi(\Delta E = 0)$ would fall at 3.3 (Fig. 10). The error estimate derived from 1σ of the regression is $|0.7|$, so that the existence of a trend favouring the *trans* form over the entire $\chi(X)$ range cannot be ruled out, given the flatness of the regression line in the vicinity of $\Delta E = 0$.

For the *C*- and the *N*-substituted isomers the respective ΔE differences show strong and clear trends (Fig. 10). The ΔE in each of the three series can be regressed linearly on $\chi(X)$, resulting in $r^2 > 0.99$. With the effective $\chi(CN)$ taken as 2.43, $\sigma(12/34) = 0.00543$ au ~ 2% of range, $\sigma(1/3) = 0.00156$ au ~ 1% of range. For *123/134* the ΔE values for **B** fall slightly below the straight line through the points for

[a]For ligand numbering see text. Parameters for the cyano groups Cy are listed in Table G (see footnote 5).

X = **A**. This is probably a consequence of nonplanarity (see below). If these two points are disregarded the lines for the *1/3* and *123/134* pairs practically coincide.

The sign of ΔE for the *1/3*, *12/34*, and *123/134* sets reverses between X = CN and X = Li, i.e., the *C*-substituted isomers are more stable than the corresponding *N*-substituted isomers when X = **A** but less stable when X = **B**. This appears to relate to the electronegativity difference $\chi(X) - \chi(H)$, which changes sign between X = Cl (and CN) and X = Li. The effect of the *gem* substitution on the relative stability appears to be additive: $a_1(12/34) = 2a_1(1/3)$, where a_1 is the slope of the ΔE regression.

The regression lines for *1/3* and *12/34* (and *123/134* ?) intersect at $\Delta E = 0$, $\chi = 1.8$. This point would be expected to correspond to $HHHH^+$, i.e., to X = H and $\chi(\Delta E = 0) = \chi(H) \sim 2.2$. The observed $\chi(\Delta E = 0)$ is thus 0.4 lower than $\chi(H)$. This difference seems to arise from the symmetry of the substitution in the pairs with respect to the C=N bond:

[a]For ligand numbering see text. Parametrs for the cyano groups Cy are listed in Table G (see footnote 5).

in reality, $\chi(\Delta E = 0) \sim 1.8$ corresponds not to the tabulated χ(H) but to the difference $[\chi(N) - \chi(H)] - [\chi(C) - \chi(H)] = \chi(N) - \chi(C) \sim 0.5$.

Bond lengths

In answer to the question that had prompted this investigation, viz. what is the total variability of d(C=N) in iminium ions, the d(C=N) values of Table 7 range from 1.249 to 1.311 Å if the values for LiLiLiLi$^+$ and NaNaNaNa$^+$ are disregarded (see below). The total range is thus only 0.06 Å, i.e., smaller than the 6-31G* estimate for the similarly substituted ethylenes, 0.09 Å (Table 9), and this in spite of the fact that the χ(X) of the substituents span practically the entire electronegativity scale and that the C≡N bond of the cyano group provides for the possibility of π conjugation. In view of this it is reasonable to believe that the d(C=N) for substituents such as CH_3, NH_2, or OH,[11] when similarly optimized, would be amply accommodated within the 0.06 Å range. The experimental d(C=N) values of Table 6 fall easily within the calculated limits. Allowing for the underestimation of bond lengths in the 6-31G* optimizations, it would seem that explanations for uncorrected experimental d(C=N) values larger than, say, 1.33 Å should

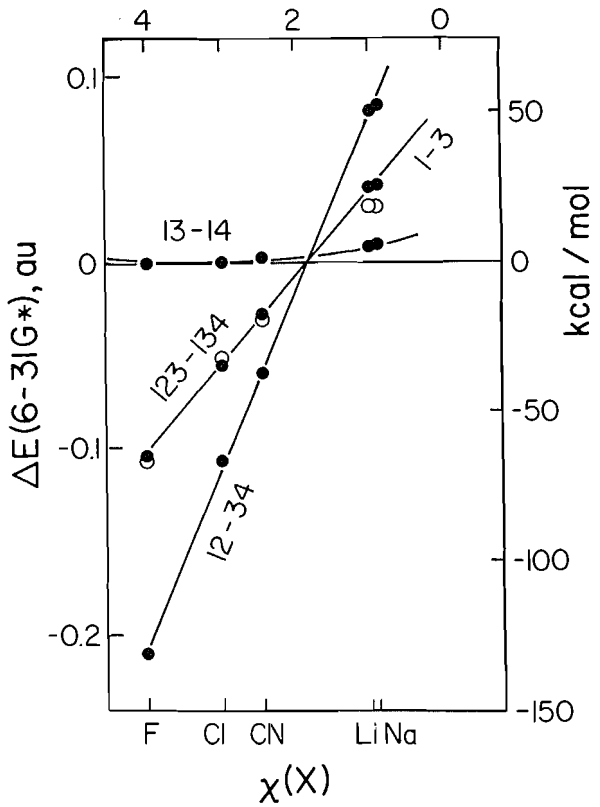

FIG. 10. Variation of the difference in the 6-31G* total electronic energy of substitutional iminium isomers $\Delta E = E(12) - E(34) = E(XXHH^+) - E(HHXX^+)$, etc. with Pauling's electronegativity $\chi(X)$.

be looked for elsewhere than in substitution on C or N per se.[12]

Although the vagaries of the 6-31G* treatment might be expected, given the narrowness of the d(C=N) range, to perturb the trend in d(C=N), the $d(C{=}N)_X$ for a particular X can be represented as a function of n_C and n_N in a reasonably clear-cut manner (Table P). The effect of the substitution at C is dominant in the lengthening (relative to $HHHH^+$) of C=N when X = **B**; that of the substitution at N is dominant in the lengthening of C=N when X = CN; and for F and Cl the substitution at C lengthens C=N modestly, although for X = F this change is opposed by the contribution from N. The mean a_0 from the regressions, $\bar{a}_0$ = 1.262(3) Å, is indistinguishable from d(C=N) = 1.263 Å in the unsubstituted ion.

The change in d(C=N) on substitution is displayed even more dramatically when $\Delta d(C{=}N) = d(C{=}N)_X - d(C{=}N)_H$ is examined in conjunction with $\Delta\rho_c(C{=}N) = \rho_c(C{=}N)_X - \rho_c(C{=}N)_H$ (Fig. 11); ρ_c may be regarded as an estimator of bond covalency (23). As the plot shows, Δd(C=N) and $\Delta\rho_c$(C=N) do not necessarily go hand in hand: a C=N bond lengthening on substitution may correspond to an increase *or* a decrease in the C=N covalency, and similarly for bond contraction. Thus the C=N bond lengthens on *any* substitution by Cl or CN, but $\Delta\rho_c$(C=N) is positive for substitution at C and negative for substitution at N. F-substitution produces a C=N expansion and an increase in ρ_c(C=N) in $FHHH^+$ and $FFHH^+$, but it has the opposite effect in $HHFH^+$ and $HHFF^+$. The reverse is observed for Li and Na, for which the magnitude of the change is appreciable.

Interestingly, the effect of the corresponding substitutions in ethylene is not always in the same direction as that in $HHHH^+$. Substitution by F and Cl results in a C=N bond expansion in $XHHH^+$ and $XXHH^+$ but in a C=C *contraction* of comparable magnitude in XHHH and XXHH (Fig. 11). The lowering of ρ_c(C=C) in FFHH on introduction of the second fluorine atom is striking.

The variation of the X—C and X—N bond lengths with X and with the degree of substitution is successfully represented by the regressions in Table P, more closely so for d(X—N) than for d(X—C). The exception is X = Cl, for which the fit is not as close as for the other X. The **B**—C and **B**—N bonds contract with increasing substitution, as do the F—C (and F—N) bonds, though to a lesser extent. For Cl and CN the dominant a term (a_C for X—C and a_N for X—N) is positive.

The a_0 values in Table may be regarded as the "limiting" d(X—C) and d(X—N), i.e., the bond lengths resulting from extrapolation to zero substitution. These limiting bond lengths are found to correlate to a high degree ($r^2 = 0.985$; $a_0^N - a_0^C = 0.084 - 0.077a_0^C$, σ = 0.07 Å ~ 5% of range; Fig. 12*a*).

The C—C_{CN} and N—C_{CN} bonds are contracted owing to the proximity of the C=N and C≡N bonds: d(C—C_{CN}) = 1.425(6) Å, d(N—C_{CN}) = 1.373(5) Å. Their lengths show a weak dependence on the variation in the associated d(C=N) and d(C≡N):

$$d(C{-}C_{CN}) = 8.337 + 0.022d(C{=}N) - 6.111d(C{\equiv}N),$$
$$r^2 = 0.89,\ \sigma = 0.003\ \text{Å} \sim 13\%\ \text{of range}$$

$$d(N{-}C_{CN}) = 8.949 + 0.264d(C{=}N) - 7.000d(C{\equiv}N),$$
$$r^2 = 0.84,\ \sigma = 0.003\ \text{Å} \sim 20\%\ \text{of range.}$$

The total variation in d(C=N) and d(C≡N) in the iminium ions is 0.044 and 0.003 Å, respectively, for the substitution at C, and 0.035 and 0.002 Å, respectively, for the substitution at N; the corresponding ranges for d(C—C_{CN}) and d(N—C_{CN}) are 0.020 and 0.014 Å, respectively. The length of the N—C_{CN} bond is more than 10 times as sensitive to changes in d(C=N) as that of the C—C_{CN} bond.

The H—C and H—N bond lengths do not vary substantially with X, even though they tend to increase slightly, for a given X, with the degree of substitution. That mean d(H—C) tends to increase with the decreasing χ(X):

X =	F	Cl	CN	Li	Na
$\bar{d}$(H—C) =	1.075(1)	1.075(1)	1.075(1)	1.088(9)	1.091(10) Å
$\bar{d}$(H—N) =	1.007(1)	1.007(1)	1.010(2)	1.004(3)	1.005(3) Å

The overall means for the C—F, N—F, C—Cl, and N—Cl bonds in Table 7 are 1.249(7), 1.302(12), 1.666(7), and 1.691(6) Å, respectively.

Bond angles

The variation in the bond angles is less regular than in the bond lengths and the trends are on the whole qualitative rather than quantitative. In the $XHHH^+$ and $HHXH^+$ sets, for ex-

[12]This would not apply to extreme cases of substitution, such as that with mixed X = F, Li ligands (see below), unlikely to be encountered in practical circumstances.

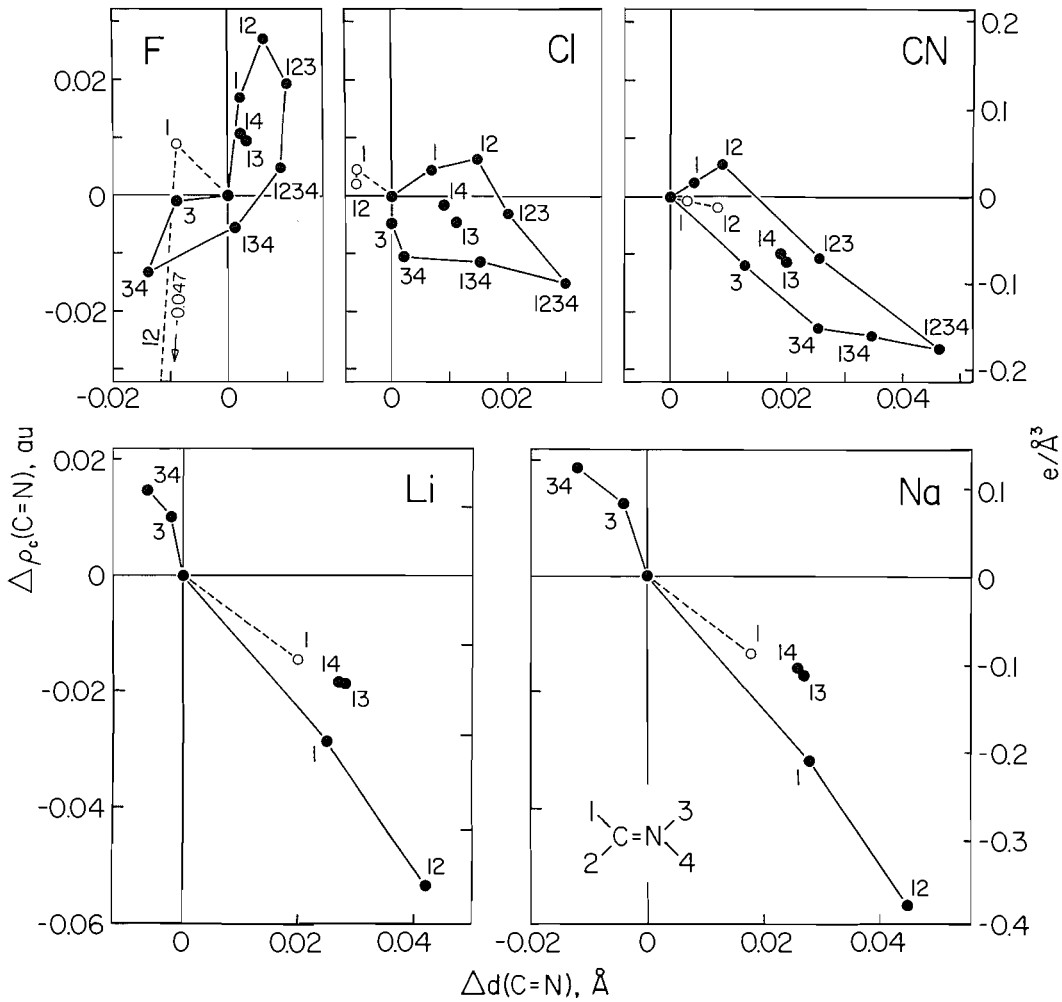

FIG. 11. Variation of the change $\Delta\rho_c$(C=N) in the electron density at the critical point in the C=N bond with the change Δd(C=N) in the C=N bond length in substituted iminium ions, both changes with respect to $[H_2C{=}NH_2]^+ = HHHH^+$. The corresponding changes in $XHC{=}C'H_2$ and $X_2C{=}C'H_2$ relative to $H_2C{=}CH_2$ are shown by the open circles (for these, read C=C′ instead of C=N).

ample, the *1*CN and CN*3* angles increase with $d(1\text{–C})$ and $d(\text{N–}3)$, respectively. For the F-substituted series these expressions have been obtained for the *gem* angles:

$$(1C2)_F = 120.20 - 2.35n_C + 1.90n_N,$$
$$r^2 = 0.95, \sigma = 0.7^\circ \sim 8\% \text{ of range}$$

$$(3N4)_F = 115.36 + 1.67n_C - 2.30n_N,$$
$$r^2 = 0.89, \sigma = 0.9^\circ \sim 12\% \text{ of range}$$

$$(3N4)_F = 1383.9 - 20.237(1C2)_F + 0.080347[(1C2)_F]^2,$$
$$r^2 = 0.97, \sigma = 0.5^\circ \sim 6\% \text{ of range}$$

For the other X, the variations are more erratic. Nevertheless, even partial regressions may be informative in that they indicate the relative importance and sign of the individual contributions to the angle variation with the degree of substitution. Thus including only the *1*, *3*, *12*, and *34* species one finds

$$(1C2)_{Cl} = 118.5 + 0.10n_C + 1.80n_N,$$
$$r^2 = 0.77, \sigma = 1.5^\circ \sim 30\% \text{ of range}$$

$$(3N4)_{Cl} = 114.3 + 1.86n_C + 0.74n_N,$$
$$r^2 = 0.73, \sigma = 1.3^\circ \sim 38\% \text{ of range}$$

$$(1C2)_{Li} = 118.8 + 1.81n_C - 3.11n_N,$$
$$r^2 = 0.92, \sigma = 2.3^\circ \sim 20\% \text{ of range}$$

$$(3N4)_{Li} = 110.0 + 1.52n_C + 10.88\, n_N,$$
$$r^2 = 0.92, \sigma = 4.9^\circ \sim 23\% \text{ of range}$$

$$(1C2)_{Na} = 117.1 + 3.48n_C - 2.68n_N,$$
$$r^2 = 0.88, \sigma = 3.6^\circ \sim 25\% \text{ of range}$$

$$(3N4)_{Na} = 105.9 + 3.84n_C + 16.36n_N,$$
$$r^2 = 0.90, \sigma = 7.6^\circ \sim 26\% \text{ of range}$$

$$(3N4)_{Li} = -12.58 + 2.4849(1C2)_{Li} - 0.011891[(1C2)_{Li}]^2,$$
$$r^2 = 0.97, \sigma = 2.1^\circ \sim 10\% \text{ of range}$$

While *statistically* these regressions may be found wanting, the coefficients of n_C and n_N show that the *gem* angle at C is substantially influenced by the substitution at N and vice versa. They also show that the contraction of the $(1C2)_X$ angle arises (with the exception of X = F) from the substitution at N, whereas (again excepting F) the $(3N4)_X$ angle increases with *any* substitution at N *and* C. Furthermore, the sum

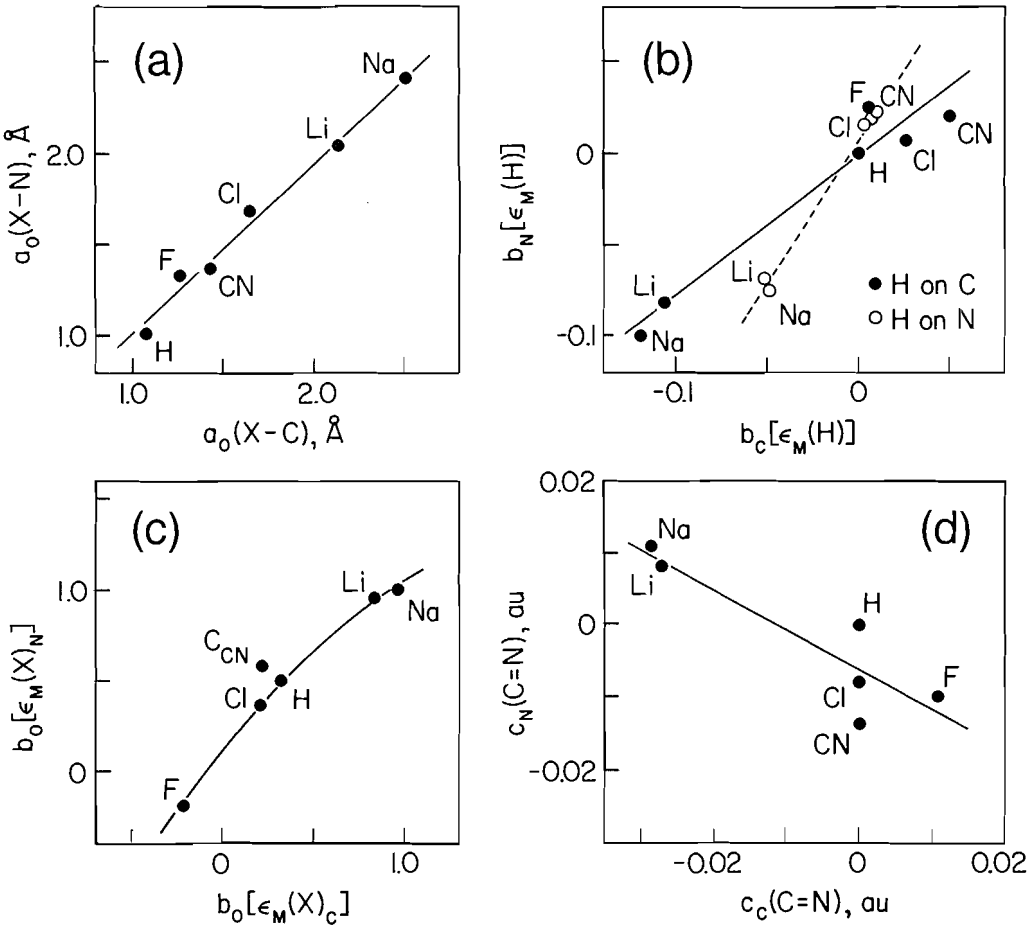

FIG. 12. Relations between regression coefficients of Tables P–R. (*a*) $a_0[d(X—N)]$ vs. $a_0[d(X—C)]$. (*b*) Full circles, $b_N[\varepsilon_M(H)_C]$ vs. $b_C[\varepsilon_M(H)_C]$; open circles, $b_N[\varepsilon_M(H)_N]$ vs. $b_C[\varepsilon_M(H)_N]$. On substitution, $\varepsilon_M(H)$ on the remaining H atoms increases with the degree of substitution when X = **A** but decreases when X = **B**, regardless of whether the H atoms are on C or on N. (*c*) Dependence of $\varepsilon_M(X)$ on the substitution site when $\varepsilon_M(X)$ is extrapolated to zero substitution, i.e., $n_C = n_N = 0$, $\varepsilon_M(X)_0 = b_0[\varepsilon_M(X)]$. (*d*) c_N vs. c_C for $\rho_c(C{=}N)_X$.

$(1C2)_X + (3N4)_X$ (X ≠ F) of the *gem* angles also increases with *any* substitution. This means that the substituents other than F reduce, at least in the mono- and *gem*-disubstituted species, the sum of the non-*gem* angles $720° - (1C2)_X - (3N4)_X$, with consequences for interligand repulsion.

The very large bond angles obtained for the highly **B**-substituted species may be open to question, as they possibly arise from the planarity constraint (see below).

Net charges

Both Mulliken ε_M and Löwdin ε_L net charges are discussed in the following, but only the former constitute a comprehensive set.[13] As we are about to demonstrate, the ε_L charges (Table S) differ considerably from the corresponding ε_M (subject of course to $\Sigma\varepsilon_M = \Sigma\varepsilon_L = +1$ or 0), but the trends they exhibit are much the same, at least to the extent we have investigated. Our detailed analysis is therefore confined to ε_M.

Linear regressions of ε_M and ε_L on n_C and n_N yield, with only a few exceptions, high correlations. Of the 50 such regressions in Table Q only seven have r^2 between 0.78 and 0.9; of the remaining 43, 38 have $r^2 > 0.95$. The ε_M set for the substituted iminium ions is thus not only highly self-consistent but also additive with respect to the degree of substitution. The condition (not used in the independent individual regressions) $b_0[\varepsilon_M(C)]_X + b_0[\varepsilon_M(N)]_X + 2b_0[\varepsilon_M(H)_C]_X + 2b_0[\varepsilon_M(H)_N]_X = 1$ is satisfied to ~0.7% for X = F on to ~3.3% for X = Na.

Of the individual results, that of fundamental interest concerns the unsubstituted ion and the conventional way of representing the charge on it, viz. $H_2C{=}N^+H_2$. If this formula implies that the N atom carries a positive net charge, then on the present evidence this representation is incorrect. Neither $\varepsilon_M(N) = -0.657$ nor $\varepsilon_L = -0.250$ is positive; in fact, both are strongly negative. When these charges on N are contrasted with those on C, $\varepsilon_M(C) = 0.038$ and $\varepsilon_L(C) = 0.042$, the difference is seen to be substantial. The sum $\varepsilon_M(C) + 2\varepsilon_M(H)_C = 0.684$ and $\varepsilon_M(N) + 2\varepsilon_M(H)_N = 0.315$ (0.526 and 0.473, respectively, for ε_L) indicate that the

[13]The reason for the incomplete coverage of ε_L is historico-practical: in the final stages of this investigation GAUSSIAN 86, which was used throughout and which calculates ε_M but not ε_L, was supplemented by GAMESS, which calculates both ε_M and ε_L (see Experimental). The last-named program was used in a limited way for special purposes other than obtaining ε_L, but as the desirability to compare ε_M and ε_L became apparent, some of the optimizations were repeated using GAMESS solely to generate ε_L.

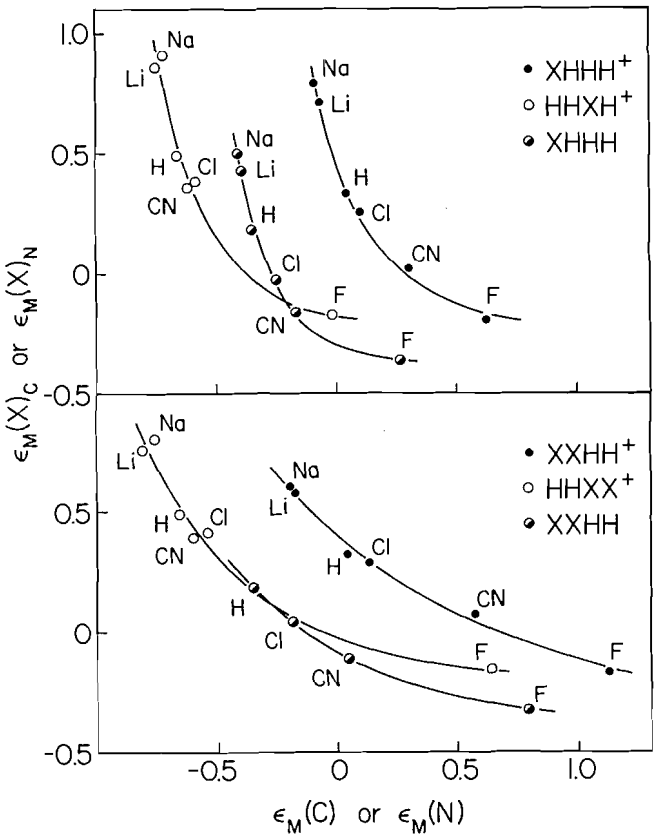

FIG. 13. Variation of the Mulliken net charges ε_M on X with $\varepsilon_M(C)$ and $\varepsilon_M(N)$ in X-monosubstituted iminium ions and ethylenes. For X = CN, $\varepsilon_M(X) = \varepsilon_M(CN) = \varepsilon_M(C) + \varepsilon_M(N)$. The fitted curves represent exponential regressions of $\varepsilon_M(X)$ on $\varepsilon_M(C)$ and $\varepsilon_M(N)$, respectively (see text and Table T).

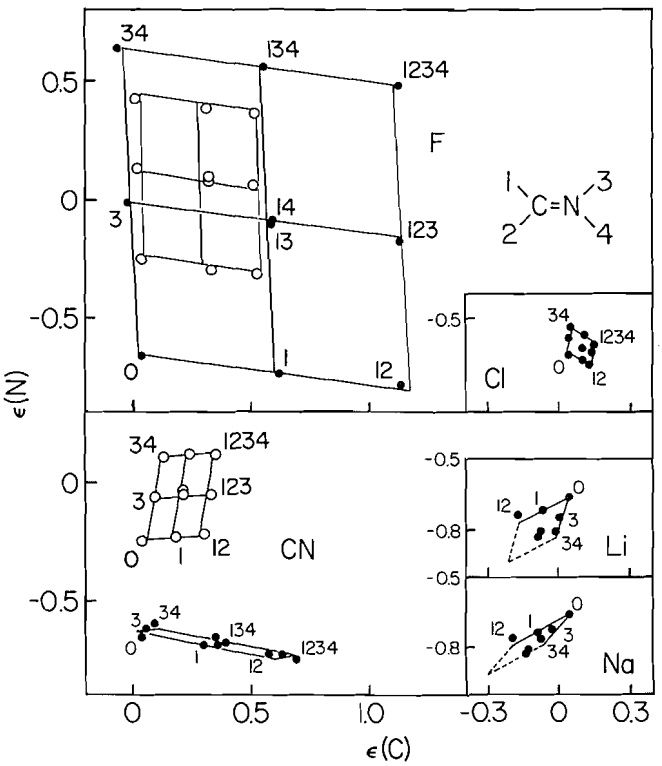

FIG. 14. Correlation of the Mulliken net charges $\varepsilon_M(C)$ and $\varepsilon_M(N)$ (and the Löwdin net charges $\varepsilon_L(C)$ and $\varepsilon_L(N)$ for X = F and CN) in X-substituted iminium ions. For notation see text. Full circles, ε_M; open circles, ε_L.

charge on the nitrogen half of the ion remains less positive even on inclusion of the charges on the H atoms.

As is evident from Table Q, $\varepsilon_M(N)$ will become positive only on *N*-substitution by F, whereas $\varepsilon_M(C)$ can become negative for X = F and Li, and *will* be negative when X = Na.

As for the net charges on the H atoms, $\varepsilon_M(H)$ is always positive for X = **A**, but $\varepsilon_M(H)_C$ is negative in $NaNaNaH^+$ and almost zero in $NaHNaNa^+$. The $\varepsilon_L(H)$ are available only for X = F and CN; they are positive for both ligands. The sensitivity of $\varepsilon_M(H)$ to substitution is displayed in a plot of the coefficients of the regressions of $\varepsilon_M(H)_C$ and $\varepsilon_M(H)_N$ on n_C and n_N (Fig. 12*b*). The two fits ($\varepsilon_M(H)_C$, $r^2 = 0.944$; $\varepsilon_M(H)_N$, $r^2 = 0.990$) show a neat separation between X = **A** and X = **B** (**B** being the electron-donating substituents).

The relationship between $\varepsilon_M(X)$ and $\varepsilon_M(C)$ or $\varepsilon_M(N)$ in the mono- and the *gem*-disubstituted ions is shown in Fig. 13.[14] There is a clear division between the *C*- and the *N*-substituted ions, the curve for the XHHH ethylenes occupying a more or less intermediate position. The position of the curve for XXHH is less well defined. Remarkably, the $\varepsilon_M(X)$ vs. $\varepsilon_M(C)$ or $\varepsilon_M(N)$ curves can be fitted to exponential expressions $\varepsilon_M(X) = p + q \exp[-s\varepsilon_M(C \text{ or } N)]$ to $r^2 > 0.96$, as can the curves for the ethylenes (Table T).

The $XHXH^+$, $XHHX^+$, and the tri- and tetrasubstituted sets yield similar functional dependence, as far as it is possible to determine from the somewhat uncertain ε_M values for the higher-substituted iminium ions and ethylenes (see later). In fact, the curves corresponding to $\varepsilon_M(C)$ and $\varepsilon_M(X)_C$ in $XHXH^+$ and $XHHX^+$, and those corresponding to $\varepsilon_M(N)$ and $\varepsilon_M(X)_N$, differ very little from the curves for $XHHH^+$ and $HHXH^+$, respectively, thus pointing to the largely localized character of the $\varepsilon_M(C)$ vs. $\varepsilon_M(X)_C$ and $\varepsilon_M(N)$ vs. $\varepsilon_M(X)_N$ relationship.

A synoptic impression of the ε(N) vs. ε(C) relationship is obtained from Fig. 14. The expected difference in the electron-transfer properties of the **A** and **B** substituents is immediately apparent. The plot for X = F conveys at a glance the essentially additive nature of the relationship and of the difference between the effect of substitution at C and that at N. Comparison of this plot with the plot for Cl shows that the range of ε_M for X = Cl is about six times smaller than that for F. This, in a somewhat different way, is also true of the effects produced by CN substitution.

For X = **B** approximate additivity obtains only for the mono- and disubstituted ions. When the ε values from the optimizations for the higher-substituted ions are entered in Fig. 14, the parallellogram geometry disappears and the points, especially those for $XXXX^+$, fall in unexpected places. Since the expectation stems from a preconceived notion that assumes persistence of the additivity and is thus a self-fulfilling prophecy, one cannot exclude the possibility that the answers provided by the calculation *are* correct and that the additivity breaks down. It is more likely, however, that either the optimizations of Tables 7–9 for the tri- and tetrasubstituted Li and Na species do not correspond to

[14]For X = CN, $\varepsilon(CN) = \varepsilon(C_{CN}) + \varepsilon(N_{CN})$.

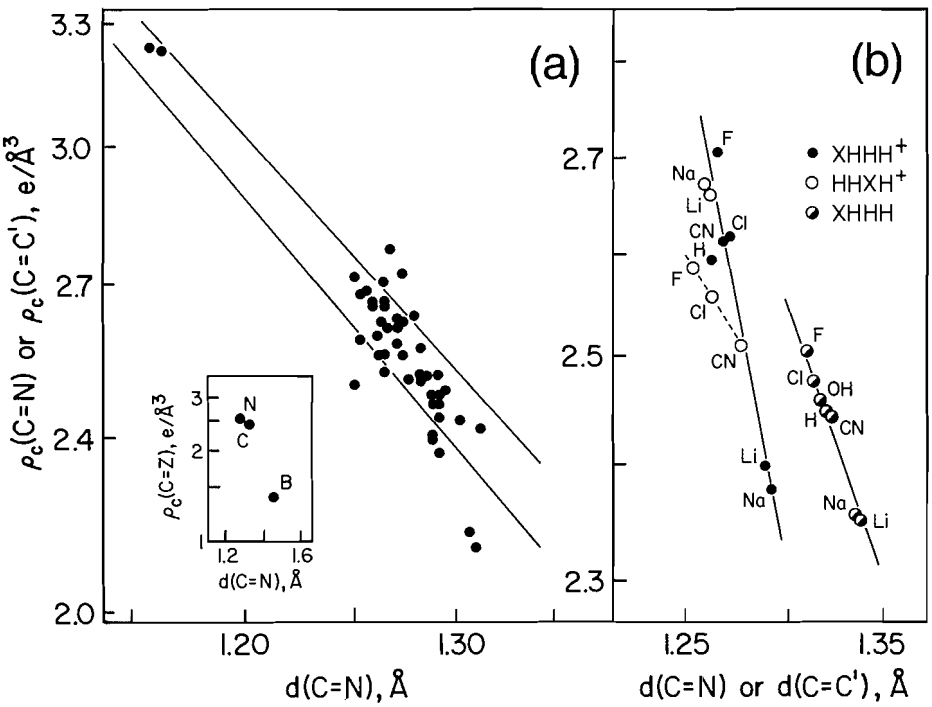

FIG. 15. (*a*) Logarithmic plot of ρ_c(C=N) vs. d(C=N) for the iminium ions of Table 7. The band corresponds to the $\pm 1\sigma$ limits of a section of the $\rho_c = sd^{-v}$ correlation for C—N bonds of all orders (cf. text and ref. 23). (*b*) Logarithmic plot of ρ_c(C=N) vs. d(C=N) for monosubstituted iminium ions, and of ρ_c(C=C) vs. d(C=C) for monosubstituted ethylenes. Inset: plot of log ρ_c(C=Z) vs. log d(C=Z) for $[H_2C{=}NH_2]^+$, $H_2C{=}CH_2$, and $[H_2C{=}BH_2]^-$.

the *global* E(6-31G*) minima for planar geometry, or that interligand repulsions in these species begin to interfere with the planarity, in which case optimization in nonplanar geometries is indicated. This matter is discussed in more detail below.

Figure 14 also displays the differences that arise when ε_L rather than ε_M values are used in the analaysis of trends in the net charges. Numerically, the ε_L values generally are smaller than the corresponding ε_M. In the X = F set it makes little difference to the trends whether ε_M or ε_L are employed. In the CN set, however, the range of the ε_M(N) values is markedly compressed, whereas the ε_L values generate a parallellogram of the expected shape.

The coefficients b_0 of the regressions of ε_M(X) on n_C and n_N (Table Q) represent the net charges on X extrapolated to zero substitution, i.e., $n_C = n_N = 0$. The $\varepsilon_M(X)_0 = b_0[\varepsilon_M(X)]$ for substitution at N correlate smoothly with those for substitution at C (Fig. 12*c*), with the exception of X = CN. A parabolic fit yields $b_0[\varepsilon_M(X)_N] = -0.153 + 1.394b_0[\varepsilon_M(X)_C] - 0.534\{b_0[\varepsilon_M(X)_C]\}^2$, $r^2 = 0.97$, $\sigma = 0.10 \sim 8\%$ of range. The anomaly for X = CN is not unexpected, given the composite nature of the ligand and the presence of the C≡N bond.

Electron density at the bond critical point

Results of the regressions of ρ_c on n_C and n_N are presented in Table R. The coefficients for $\rho_c(C{=}N)_C$ show modest degree ($r^2 = 0.80$) of correlation (Fig. 12*d*).

The ρ_c(C—X) and ρ_c(N—X) would be expected to be approximated by simple power functions of the corresponding d(C—X) and d(N—X) bond lengths, $\rho_c = sd^{-v}$ (cf. ref. 23). With the exceptions of ρ_c(N—Cl), which correlates poorly with d(N—Cl), this is indeed the case (Table H). For X = F this relationship is satisfied to $r^2 > 0.98$. For the other bonds the regressions are not quite as good but still satisfactory. It must be remembered, however, that the ranges of these ρ_c,d are narrow and the results of the regressions may therefore be somewhat misleading. A proper test of conformity to the power dependence would be the success of immersion of these pairs in the global 6-31G* ρ_c(C—X) vs. d(C—X) and ρ_c(N—X) vs. d(N—X) regressions, which span the entire range of bond orders. Such a test will have to await the completion of our comprehensive investigation of the global regressions now in progress.[15]

These remarks apply equally or even more to the relationship between ρ_c(C=N) and d(C=N). In the rectified plot of Fig. 15*a* the distribution of the ρ_c,d points for the iminium ions of Table 7 would largely lack orientation were it not for the two points for LiLiLiLi$^+$ and NaNaNaNa$^+$, about which there may be certain reservation (see below). However, when these and all the other points are mapped on the previously established[15] 6-31G* $\rho_c = sd^{-v}$ power regression comprising C—N bonds of *all* orders, the majority of the points by far fall inside the $\pm 1\sigma$ limits of this overall regression. There is thus no doubt that the points for the iminium ions conform, within reasonable statistics, to the ρ_c,d behaviour established for C—N bonds in general.[16]

The gross features of the overall ρ_c,d regressions for C—N bonds may, however, tend to obscure the behaviour of the ρ_c,d pairs *in the small*. In Fig. 15*b* the ρ_c(C=N),d(C=N)

[15]O. Knop, S.C. Choi, and R.J. Boyd, to be published. See also ref. 23.

[16]When the ρ_c,d values for the C≡N and those for the C—C_{CN} bonds of the cyano-substituted ions (Tables 7,8, and G) are entered in Fig. 15*a*, the points fall within the $\pm 1\sigma$ band. The positions of the ρ_c,d points for C=N in LiLiLiLi$^+$ and NaNaNaNa$^+$ are then seen to be very close to the C≡N group of points.

values for the monosubstituted $XHHH^+$ and $HHXH^+$, as well as the $\rho_c(C{=}C'),d(C{=}C')$ values for XHHH, not only satisfy separate linear regressions to high r^2, but they even mimic the break between X = **A** and X = **B** for $HHXH^+$ (see below). The linearity of the rectified plot for XHHH is particularly impressive.

The inset of Fig. 15*a* gives an idea of the variation of $\rho_c(C{=}Z)$ with $d(C{-}Z)$ in the unsubstituted species, viz. in $[H_2C{=}NH_2]^+$, $H_2C{=}CH_2$, and $[H_2C{=}BH_2]^-$ (cf. Table 9).

The cyano group as ligand

The parameters of the CN groups in Tables 7, 8, and G vary only slightly with substitution: $d(C{\equiv}N)_C$ of CN on the C atom, 1.136(2) Å; $d(C{\equiv}N)_N$, 1.131(1) Å; $\langle CC{\equiv}N\rangle$, 179.0(8)°; $\langle NC{\equiv}N\rangle$, 179.6(2)°; $\bar{\varepsilon}_M(C_{CN})_C$, 0.309(28); $\bar{\varepsilon}_M(N_{CN})_C$, −0.244(11); $\bar{\varepsilon}_M(C_{CN})_N$, 0.626(17); $\bar{\varepsilon}_M(N_{CN})_N$, −0.230(9); $\bar{\rho}_c(C{\equiv}N)_C$, 0.4864(8) au; $\bar{\rho}_c(C{\equiv}N)_N$, 0.4823(5) au. Nevertheless, the ε_M and ε_L show a weak dependence on n_C and n_N, both for C_{CN} and N_{CN} individually and for the CN group as a unit, $\varepsilon(CN) = \varepsilon(C_{CN}) + \varepsilon(N_{CN})$ (Table Q). Perhaps not surprisingly, the $\varepsilon_M(N_{CN})_C$ and $\varepsilon_M(N_{CN})_N$ values are about the same, while the $\varepsilon_M(C_{CN})_N$ value is on the average about twice that for $\varepsilon_M(C_{CN})_C$.

The individual contributions to the joint effect, which conjugation with the C≡N bond and the net charge on the distant atom of the C=N bond have on the cyano-substituted atom of the C=N bond, are detailed as follows:

$$\varepsilon_M(C)_{CN} = -0.502 - 0.386\varepsilon_M(N) + 4.493\varepsilon_M(C_{CN}) + 2.637\varepsilon_M(N_{CN}),$$
$$r^2 = 0.986,\ \sigma = 0.024 - 6\%\ \text{of range}$$

$$\varepsilon_M(N)_{CN} = -0.122 - 0.246\varepsilon_M(C) - 0.235\varepsilon_M(C_{CN}) + 1.378\varepsilon_M(N_{CN}),$$
$$r^2 = 0.984,\ \sigma = 0.009 \sim 6\%\ \text{of range}$$

$$\varepsilon_L(C)_{CN} = 0.773 + 0.190\varepsilon_L(N) + 11.05\varepsilon_L(C_{CN}) - 0.949\varepsilon_L(N_{CN}),$$
$$r^2 = 0.942,\ \sigma = 0.021 \sim 12\%\ \text{of range}$$

$$\varepsilon_L(N)_{CN} = -0.553 - 0.171\varepsilon_L(C) + 12.82\varepsilon_L(C_{CN}) + 2.204\varepsilon_L(N_{CN}),$$
$$r^2 = 0.984,\ \sigma = 0.015 \sim 8\%\ \text{of range}$$

The difference in sign and magnitude of the individual ε_M and ε_L components of these expressions for ε(C) and ε(N) elucidates the difference in the appearance of the two ε(N) vs. ε(C) plots in Fig. 14, in particular the compression of the $\varepsilon_M(N)$ range compared to the $\varepsilon_L(N)$ range.

The electron density at the critical point of the C≡N bond decreases with the increasing number of CN groups in the ion (Table R). Here, too, the parameter is more sensitive to the substitution on the N atom of C=N: $(c_N/c_C)_C = 1.6$, $(c_N/c_C)_N = 4.5$.

The effect of the adjacent C=N and C≡N bonds on ρ_c in the $C{-}C_{CN}$ and $N{-}C_{CN}$ bonds can be expressed as

$$\rho_c(C{-}C_{CN}) = -0.5459 - 0.397\rho_c(C{=}N) + 2.056\rho_c(C{\equiv}N),$$
$$r^2 = 0.907,\ \sigma = 0.0011\ \text{au} \sim 12\%$$

$$\rho_c(N{-}C_{CN}) = -1.9021 + 0.259\rho_c(C{=}N) + 4.383\rho_c(C{\equiv}N),$$
$$r^2 = 0.992,\ \sigma = 0.0005\ \text{au} \sim 5\%$$

On the one hand, these ρ_c values are much more sensitive to changes in $\rho_c(C{\equiv}N)$; on the other hand, the latter changes are much smaller than the changes in $\rho_c(C{=}N)$ on substitution.

Mixed F,Li ligands

The effect of substitution can be maximized by replacing all four H atoms in $HHHH^+$ by a combination of ligands from the opposite ends of the electronegativity scale, viz. F and Li. The three substitutions in Table 10, $LiLiFF^+$, $FFLiLi^+$, and $LiFFLi^+$, were chosen to accentuate the effect. Indeed, the effect on $d(C{=}N)$ and $\rho_c(C{=}N)$ is seen to be dramatic (Fig. 16). In both *gem* isomers the C=N bond contracts by about 0.05 Å with respect to $d(C{=}N)$ in $FFFF^+$, 1.272 Å, i.e., over three times the maximum contraction observed on pure F substitution in $HHHH^+$. However, $\rho_c(C{=}N)$ in $LiLiFF^+$ has decreased by about 0.03 au ~ 0.2 e/Å^3 and that of $FFLiLi^+$ has *increased* by about 0.06 au ~ 0.4 e/Å^3 with respect to the $FFFF^+$ reference. Thus while the $d(C{=}N)$ contraction is about the same, the substitution with Li at C in $FFFF^+$ decreases, and that at N increases, the covalent character of the C=N bond. As indicated in Fig. 16, the transfer of electronic charge (in terms of ε_M) on Li substitution is almost entirely between Li and C in $LiLiFF^+$, and almost entirely between Li and N in $FFLiLi^+$, whereas on H substitution in $FFFF^+$ the situation for $FFHH^+$ is similar to $FFLiLi^+$ but in $HHFF^+$ a non-negligible electronic charge is transferred also to the N atoms.[17]

The electronic charges transferred to the C and N atoms, respectively, when $FFFF^+ \rightarrow LiFFLi^+$ and $FFFF^+ \rightarrow HFFH^+$ are almost equal and, in these two *trans* substitutions, of comparable magnitude. Yet the changes in the C=N bond length are in the opposite directions, even though numerically they are quite similar. This seems to indicate that in $LiFFLi^+$ the interligand repulsion dominates the electronic effects and results in a net expansion of the C=N bond.

Interligand separations

When the $X^1{-}H^3$ separation in $XHHH^+$ is regressed linearly on the $X^1{-}H^2$ separation, a very good correlation results ($n = 6$, $r^2 = 0.997$, $\sigma = 0.033$ Å ~ 3% of range), and similarly for $d(X^3{-}H^1)$ in $HHXH^+$ regressed on $d(X^3{-}H^4)$ ($n = 6$, $r^2 = 0.994$, $\sigma = 0.036$ Å ~ 3% of range) (Fig. 17). The $X^1{-}H^3$ and $X^3{-}H^1$ distances are about 0.2 Å or less smaller than the sums of the corresponding van der Waals radii for H, F, and Cl (Pauling's values).

However, a plot of $d(X^1{-}H^3)$ against $d(X^1{-}H^2)$ for $XHC{=}C'H_2$ (Fig. 17) shows a break in the correlation line between X = Cl and X = Li, while the portion for X = **A** correlated to $r^2 = 0.993$, $\sigma = 0.019$ Å ~ 4% of range. The existence of this feature in the ethylene series calls for a closer examination of the $d(X^1{-}H^3)$ against the *gem*-d(H–H) plots for the monosubstituted iminium ions. Indeed, fitting only the **A** points for $XHHH^+$ to $d(X^1{-}H^2)$ yields $r^2 = 0.9982$, $\sigma = 0.010$ Å ~ 2.3% of range compared to the above $r^2 = 0.9968$, $\sigma = 0.033$ Å ~ 3% range for **A** + **B**. While by itself this difference does not constitute compelling evidence

[17]Interpretation of H–F calculations involving adjacent Li atoms is not without problems (cf. ref. 35) and caution is indicated.

[a]First line, ε_M; second line, ε_L.

for segregation of the points into **A** and **B**, the $HHXH^+$ set behaves in a similar way, and plots of the *gem*-(H—H) and H^1–H^3 distances against *gem*-*d*(X—H) consistently show discontinuities that correspond to the gaps in the X^1–H^3 and X^3–H^1 plots. The H—H separations in **A** and in **B**, especially the *gem* ones, remain essentially constant on substitution.

Similar discontinuities are observed in the disubstituted $XHXH^+$ and $XHHX^+$ iminium ions (Fig. 18). In the *trans* isomer the gap between **A** and **B** is clearly visible in the $d(X^4$–$H^2)$ and $d(X^4$–$H^3)$ vs. $d(X^1$–$H^2)$ plots but not in the $d(X^1$–$H^3)$ vs. $d(X^1$–$H^2)$ plot, which indicates that the substitution at N affects the geometry in a significantly different way than the substitution at C. Nonetheless, all four X–H separations in XHHX increase from X = H to X = Na.

In the *cis* isomer there are discontinuities between X = Cl and X = Li for all three separations, X^1–X^3, X^2–H^4, and H^2–H^4, when these are plotted against X^1–H^2. While the gap for the *gem*-(X—H) distances is small, those for $d(X^1$–$X^3)$ and $d(H^2$–$H^4)$ are unmistakable: the increasing X^1–H^3 repulsion can no longer be easily compensated for and necessitates a gradual decrease in the H^2–H^4 distance. This is clearly reflected in the bond angles (Table 7).

In the *gem*-disubstituted isomers (Fig. 19) the discontinuity in $d(X^1$–$H^3)$ is insignificant in the plot against $d(X^1$–$X^2)$ of $XXHH^+$ but dramatic in the plot against $d(X^3$–$X^4)$ of $HHXX^+$, and readily visible in the plots for *gem*-(H–H). This again indicates that in the *C*-substituted isomers the effect of substitution at C is continuous for **A** + **B**, while the *N*-substitution differentiates between **A** on the one hand and **B** on the other.

The effect of tri- and tetrasubstitution on the interligand separations is more difficult to assess. The **A** derivatives give clear trends, but some of the interligand separations for **B** behave in an unexpected, seemingly erratic, manner (see above for ε). For $XXXH^+$ of **A**, the X^1–X^2, X^2–H^4, and X^3–H^4 distances all increase with $d(X^1$–$X^2)$, and the same is true of the X^1–X^3, X^4–X^2, and X^1–H^2 distances in $XHXX^+$ of **A** with respect to $d(X^3$–$X^4)$ (Fig. 19). However, the positions of the X = Li points for both $XXXH^+$ and $XHXX^+$ seem to be anomalous. In particular, the X^2–H^4 and X^4–H^2 distances are extremely short, the latter especially so.

The $d(X^1$–$X^3)$ vs. $d(X^1$–$X^2)$ and $d(X^3$–$X^4)$ correlation lines in the fully substituted $XXXX^+$ (Fig. 19) are well defined and practically coincident. The X^1–X^3 vs. X^3–X^4 line accommodates the point for X = Li, but the X^1–X^3 vs. X^1–X^2 line contains only the **A** points. The point of intersection of the joint correlation line with the 45° line corresponds to the crossover of the *gem*-(X–X) and the X^1–X^3 distances; it appears to separate the "conforming" from the "nonconforming" points.

When the size and number of the X atoms in the substituted iminium ions increase, the bond lengths and angles will adjust quasi-homometrically to minimize interligand repulsions. However, *d*(C=N) can only vary within the range *d*(C—N)–*d*(C≡N) ~ 0.35 Å. This bond length is thus a limiting factor in the adjustment. Since in the optimization the ion geometry has been constrained to planar, eventually

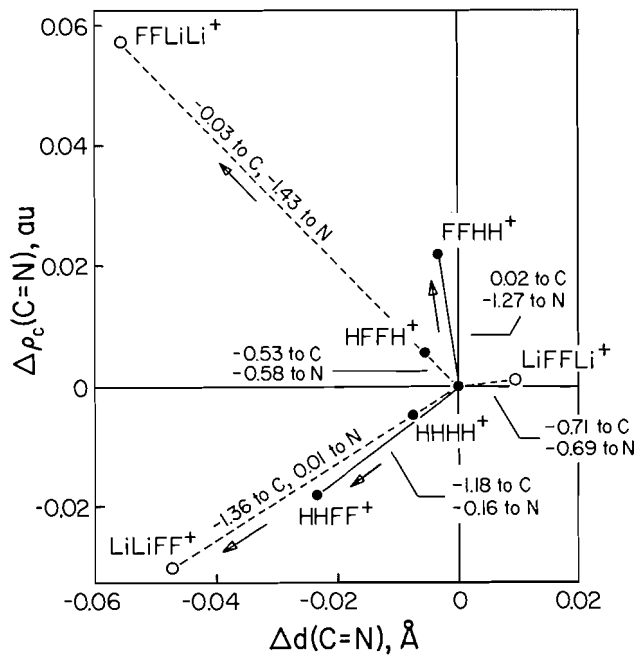

FIG. 16. Variation of the change $\Delta\rho_c$(C=N) in the electron density at the critical point in the C=N bond with the change Δd(C=N) in the C=N bond length in F- and Li,F-substituted iminium ions, both changes relative to $FFFF^+$. The amounts of ε_M charge transferred to the C and N atoms on replacing F in $FFFF^+$ by Li or H, respectively, are shown. This plot can be compared with that of Fig. 11.

the adjustment in d(C=N) will no longer be able to compensate for the increased L^1–L^3 and L^2–L^4 interactions, which compete with the *gem*-(L–L) interactions. Deviations from planarity may then be expected, reducing the C_{2v} symmetry of $XXHH^+$, $HHXX^+$ and $XXXX^+$ to C_2 (with the dihedral angles XCX/HNH, HCH/XNX, and XCX/XNX equal to 90° for the limiting, perpendicular geometry) and the C_s symmetry elsewhere to C_1.

To assess the effect of the interligand repulsions on interligand distances we have plotted the *gem* separations $d(L^3$–$L^4)$ against $d(L^1$–$L^2)$ (Fig. 20) and the non-*gem* separations $d(L^2$–$L^4)$ against $d(L^1$–$L^3)$ (Fig. 21). From Fig. 20 it is clear that, for X = **A**, $d(L^1$–$L^2)$ and $d(L^3$–$L^4)$ correlate and that the variation is in the first approximation additive, analogous to the net charges (Table P).

For **B** the additivity also holds but only up to disubstitution, and the linear combinations represent $d(L^1$–$L^2)$ and $d(L^3$–$L^4)$ less well than for **A**. Nonetheless, these representations are adequate to display the smallness of the effect that the substitution at the distant atom of the C–N bond has on the *gem*-(L–L) distances: the a_N/a_C and a_C/a_N ratios are well within ±0.1 (Fig. 20, inset). The substitution at the distant atom may have a lengthening (for X = F) or a contracting (for X = **B**) effect; for X = Cl and even more for X = CN this effect is negligible.

The points for the tri- and tetrasubstituted ions of the **B** group deviate considerably from the positions expected from additivity. This is consistent with the behaviour of these ions in Figs. 17–19.

An analogous behaviour is evident in Fig. 21. For X = CN and Cl (less so for X = F) the points for *1* and *3*; for *12*, *34*, and *14*; and for *123* and *134* bunch closely together. This indicates that in these cases it matters little to the non-*gem* interligand distances whether the substitution is at C or at N or both. For Li and Na, however, the *1* and *3*, and the *12*, *34*, and *14*, points are widely separated, as are also the *123* and *134* points for Na. The latter two points for Li fall in an unexpected region, casting suspicion on the optimization results or on the additivity hypothesis or both.

For **A** the regularity of the trends for any substitution indicates that here quasi-homometric adjustment is at work: the L^1–L^3 and L^2–L^4 repulsions are "non-crowding." For **B**, the discrepancies observed for *123* and *134* indicate significant incipient L^1–L^3 and L^2–L^4 repulsions, which tend to squeeze together the *gem* ligands and greatly distort the bond angles. The effects of these repulsions are amplified even more in the fully substituted *1234* ions.

Optimization in nonplanar geometry

The irregularities and anomalies in the parameter trends for **B** convinced us of the desirability of abandoning the planarity constraint, at least for the higher-substituted ions. Exploratory 6-31G* calculations for $XXXX^+$ in C_2 symmetry presented difficulties and led to the conclusion that the energy variation near the minimum is very flat, and that in any event it would take an inordinately large amount of computer time and effort if justice were to be done to the nonplanarity problem, important and interesting as it may be. Facing up to the practicalities of the situation, we decided not to proceed with an expansion of the present project. Nevertheless, we have attempted optimization for three ions in "perpendicular" C_{2v} geometry, i.e., with the dihedral angles LCL/L′NL′ equal to 90°. The results are compared in Table 10 with the results for the corresponding planar geometries.

In all three cases, viz. $NaNaHH^+$, $LiLiLiLi^+$, and $NaNaNaNa^+$, the energy of the planar form is lower than that of the perpendicular form, by 19.85, 19.89, and 12.42 kcal/mol, respectively, and the same is true of $Na_2C{=}CNa_2$, where the difference is 6.7 kcal/mol (Table 9). However, for $Li_2C{=}CLi_2$ the perpendicular form appears to be more stable, albeit by a relatively small amount, 4.4 kcal/mol. These results would seem to indicate that the lowest-energy conformation is the C_2-distorted planar conformation (D_2 for the two ethylenes).

There is some evidence that the conformational problem for the higher-**B**-substituted iminium ions and ethylenes may be further complicated by uncertainties involving globality of the optimizations. This would suggest even more strongly that its resolution is less straightforward and may require considerably more computational effort than originally envisaged.

Summary and conclusions

From chemistry

Recrystallization of a primary or secondary alkylammonium tetraphenylborate from approximately 1:1 mixtures of acetone (or another ketone) and water produces, against expectation, the corresponding iminium tetraphenylborate. Thus $MeNH_3BPh_4$ recrystallized from acetone and water will yield $Me_2C{=}NHMe^+BP_4^-$. Since aliphatic iminium cations generally are quite unstable in the presence of water and require anhydrous conditions for their synthesis and handling, this simple method permits the preparation, as tetraphenylborates, of a variety of iminium ions without special pre-

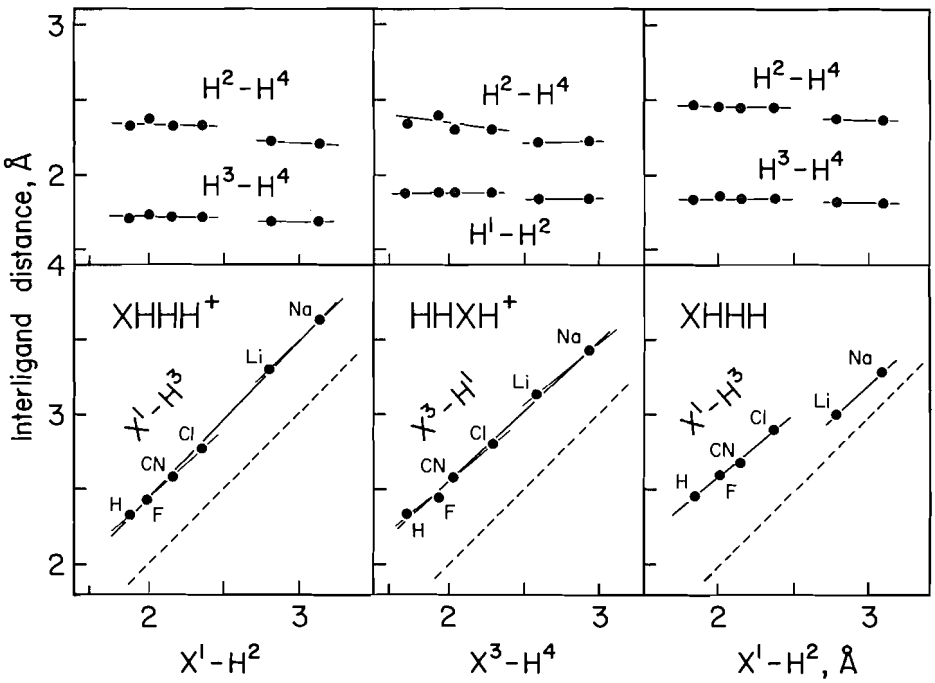

FIG. 17. Variation of the X–H and H–H interligand distances d with the *gem*-d(X—H) distances in X-monosubstituted iminium ions and ethylenes. Broken lines, d = *gem*-d(X—H).

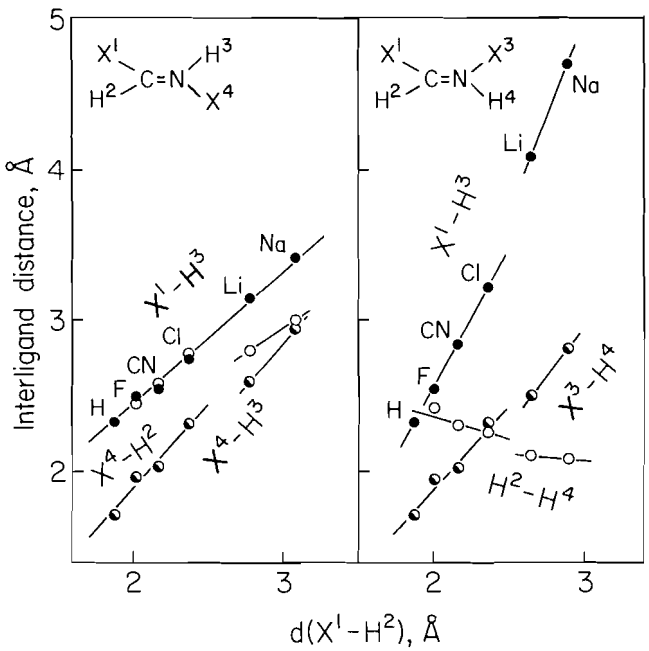

FIG. 18. Variation of the interligand distances d(X–H) with $d(X^1-H^2)$ in the *cis*/*trans* X-disubstituted iminium ions $XHXH^+$ and $XHHX^+$. Broken line, d(X–H) = $d(X^1-H^2)$.

cautions. Five such iminium tetraphenylborates, **A**–**E** (Table 1), have been prepared and their crystal structures determined.

From crystallography

The ion packing in the structures of the anhydrous **A**, **B**, **D**, and $Me_4N^+BPh_4^-$ is dominated by columns of the anions. The cations are accommodated in spaces generated by the phenyl rings of neighbouring anions. Depending on the size and shape of the cation, these phenyl rings may come from anion neighbours in the same column, or a pair of rings may come from one column and the other two rings form anions in neighbouring columns (Figs. 1–3). The structure of **C** is somewhat more complicated, with the cation less tightly enclosed between two pairs of rings, one pair each from two adjacent cations (Figs. 4 and 5). A different type of columnar arrangement of the anions is found in the hydrated **E** (Fig. 6). The small cations are prone to orientational disorder inside their cavities, which complicates determination of the true length of the C=N bond in the iminium cation.

A hydrogen atom(s) attached to the cation nitrogen will enter into a N^+—H...π^- hydrogen bond to the nearest phenyl ring(s); depending on the circumstances, this bond may be simple or bifurcated. In the hydrated **E** salt the hydrogen bonding between the cation and an anion is through the intermediary of the water molecule, N^+—H...O_w—H...π^- (Fig. 9). In these and similar iminium tetraphenylborates a hydrogen bond to the aromatic π system will form whenever the opportunity arises. This tendency will be documented more fully in a later paper.

From ab initio *studies*

6-31G* Optimization involving elements of the first and second rows of the periodic system are known to yield equilibrium molecular geometries that generally agree reasonably well with experiment. The corresponding total electronic energies can be considerably lowered by higher-level treatment, but this is of relatively little consequence for this study, since minimal use is made of energy comparisons, and then only in closely similar chemical situations (simple substitutional isomerism). We are therefore confident that the *trends* observed in the calculated parameters are substantially valid, especially as the considerable body of numerical results we have assembled shows a large measure of self-consistency

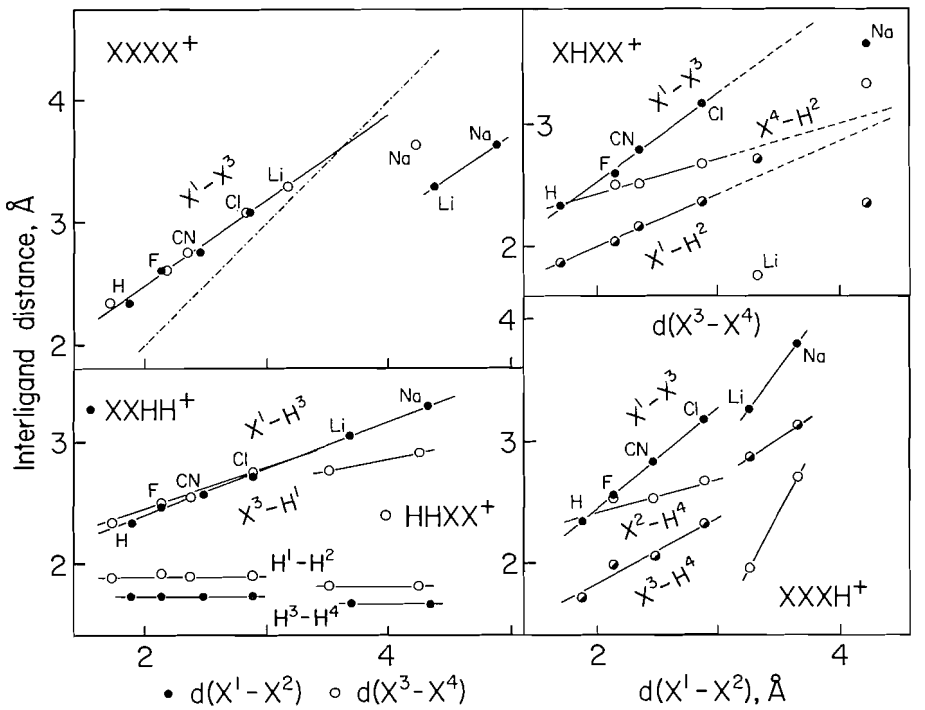

FIG. 19. Variation of the interligand distances in X-substituted iminium ions with $d(X^1–X^2)$ or $d(X^3–X^4)$. Dot-dash line, $d(X^1–X^3) = d(X^1–X^2)$, $d(X^1–X^3) = d(X^3–X^4)$.

and does not militate against standard chemical ideas. While, in the absence of an exhaustive investigation of the appropriate energy surface, questions may be raised about the *globality* of an individual, isolated, energy minimization, the present optimization of matching *series* of substituted iminium ions permits detection of anomalies and remedial action in suspect cases. The parameter variation in most of the (valence-isoelectronic) substitution series is smooth, thus lending credence to internal consistency if not necessarily to absolute validity.

The main findings can be summarized as follows:

1. The range of the C=N bond length in the substituted iminium ions is quite narrow (ca. 0.06 Å if the fully Li- and Na-substituted ions are excluded; Table 7) and in agreement with the range available from experiment (uncorrected mean, 1.283(12) Å; Table 6).

2. As would be expected, the effect of substitution on the molecular parameters of $[H_2C{=}NH_2]^+$ depends on the substitution site (C or N), the number of H atoms replaced, and on the type of substituent (**A** = H, F, Cl, CN; **B** = Li, Na). The differences are reflected clearly in the relative stabilities of the substitution isomers (Fig. 10).

3. Substitution by Cl or CN lengthens the C=N bond; that by F lengthens it except in $[H_2C{=}NHF]^+$ and $[H_2C{=}NF_2]^+$, where there is a contraction (Fig. 11). Li and Na as substituents expand the C=N bond when the substitution is at C but contract it when the substitution is at N (mono- and *gem*-disubstitution; Fig. 11). In the two cases of extreme substitution, $[Li_2C{=}NF_2]^+$ and $[F_2C{=}NLi_2]^+$, the C=N bond is shortened by over 0.04 Å relative to $[H_2C{=}NH_2]^+$ (Fig. 16).

4. The variation of several of the parameters with X substitution can be represented, to a good approximation and to a high degree of correlation, by linear functions $\alpha_0(X) + \alpha_C n_C(X) + \alpha_N n_N(X)$ of the number of X atoms on the C (n_C) and the N (n_N) atoms (Tables 10–12, Figs. 14 and 20). This mode of representation is important and informative, in that it makes it possible to estimate the contribution to the parameter values from the substitution at the distant atom of the C=N bond, i.e., the range and sign of action of that substituent. This approximate additivity is satisfied by X = **A** for any degree of substitution and by X = **B** up to and including disubstitution.

5. Both the Mulliken ε_M and the Löwdin ε_L net charges on the N atom of $[H_2C{=}NH_2]^+$ are strongly negative. This is contrary to the conventional formulation of the ion as $H_2C{=}N^+H_2$. Moreover, $[\varepsilon(C) + 2\varepsilon(H)_C] > [\varepsilon(N) + 2\varepsilon(H)_N]$, i.e., the NH_2 half of the ion also is less positively charged than the CH_2 half, both in terms of ε_M and ε_L. With the exception of $[Na_2C{=}NHNa]^+$ and $[NaHC{=}NNa_2]^+$, the net charge $\varepsilon_M(H)$ on the H atom is always positive regardless of the degree and type of substitution.

6. Complete sets of the Löwdin ε_L charges have been obtained only for X = F and CN. They are compared with the corresponding Mulliken ε_M net charges in Table S.

7. The variation of the net charge $\varepsilon_M(X)$ on the substituent atom with the net charge $\varepsilon_M(C)$ or $\varepsilon_M(N)$ on the parent atom can be approximated to $r^2 > 0.96$ by exponential functions $\varepsilon_M(X) = p + q \exp[-s\varepsilon_M(C \text{ or } N)]$ (mono- and *gem*-disubstituted ions; also the ethylene analogs; Table T, Fig. 13).

8. The correlation of the electron density $\rho_c(C{=}N)$ at the critical point in the C=N bond with the $d(C{=}N)$ bond length can be satisfactorily immersed in the "universal" $\rho_c(C{—}N) = k[d(C{—}N)]^{-v}$ correlation (Fig. 15; cf. ref. 23).

9. Detailed examination of the interligand distances (Figs. 17–21) suggests that planarity is maintained in all the iminium ions of Table 7 except for the tri- and tetrasubstituted ions with X = Li or Na as substituents. It seems likely that interligand repulsions force the latter to adopt nonplanar conformations with torsion angles LCL/LNL < 90°, of C_1

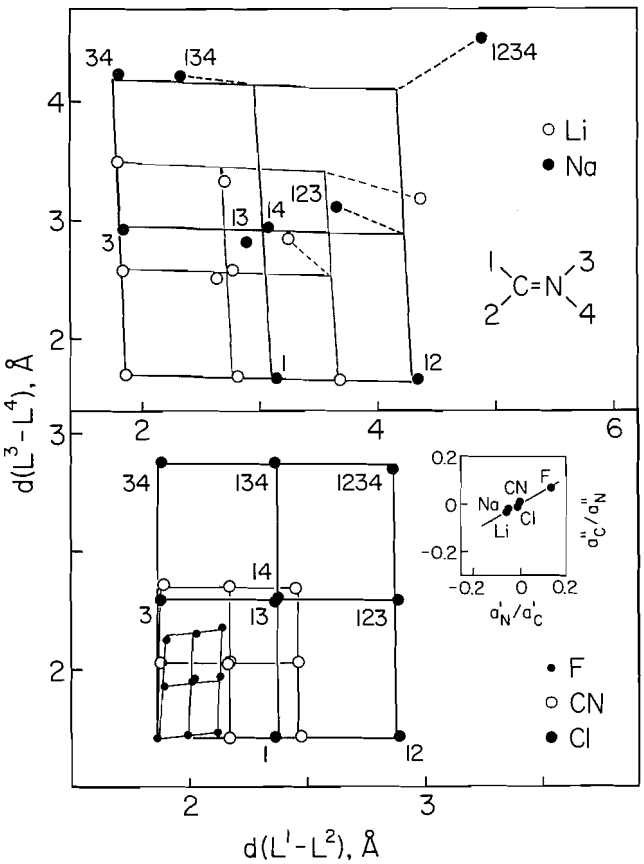

FIG. 20. Variation of the interligand distance $d(L^3–L^4)$ in substituted iminium ions with $d(L^1–L^2)$. The straight lines represent the regressions $d(L^3–L^4) = a''_0 + a''_C n_C + a''_N n_N$ and $d(L^1–L^2) = a'_0 + a'_C n_C + a'_N n_N$ of Table P. For X = Li and Na the values for *123*, *134*, and *1234* are not included in the regressions. The broken lines join the expected (from additivity) and the actual positions of the points. Note the different $d(L^3–L^4)$ scales. Inset: response of the *gem*-(L–L) distances to substitution as measured by coefficients of the regressions.

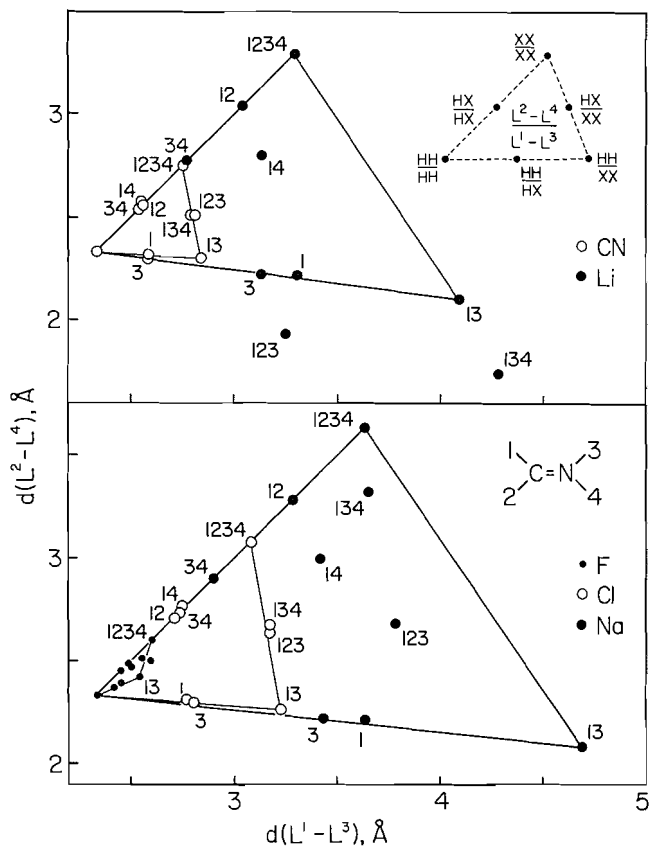

FIG. 21. Variation of the interligand distances $d(L^2–L^4)$ in X-substituted iminium ions with $d(L^1–L^3)$. HH/HX, etc. in the inset indicate the type of interligand separation: $d(H^2–H^4)$ vs. $d(H^2–X^3)$, etc.

symmetry for the tri- and of C_2 symmetry for the tetrasubstituted ions. This matter remains to be investigated.

Experimental

Preparation

An aqueous solution of $NaBPh_4$ was combined with an aqueous or ethanolic solution of an alkylammonium halide in stoichiometric amounts. The resulting precipitate of the alkylammonium tetraphenylborate was washed several times with water by decantation and then redissolved in acetone. Water was added dropwise until precipitation began to occur, upon which acetone was added only just to redissolve the solid formed. Typically, this occurred to an acetone–water volume ratio of approximately 1:1 (for compound **B** the measured ratio was 55:45 by volume), i.e., in a strongly aqueous medium. The resulting solution was allowed to recrystallize by slow evaporation at room temperature, yielding the appropriate iminium tetraphenylborate.

Structure determination

An ENRAF–Nonius CAD-4 four-circle diffractometer (**A**, **D**) and a Rigaku AFC5R diffractometer (**B**, **C**, **E**) were used in the data acquisition (cf. Table 1). The intensities ($\omega/2\theta$ scans) were reduced and corrected for Lorentz and polarization effects by routine procedures (36); empirical absorption corrections ($\mu_{Mo} \sim 0.6$ cm^{-1}) were applied (12). Scattering factors for neutral atoms and anomalous dispersion corrections were taken from ref. 37. Positions of the nonhydrogen atoms were found from an *E*-map and the remaining nonhydrogen atoms were located from successive Fourier syntheses. The H(C) atoms were placed geometrically (C—H, 1.08 Å) and refined isotropically or not refined (U_{iso}(H) = $1.2B_{eq}$(C) of the attached C atom). The function minimized by full-matrix least aquares was $\Sigma w(\Delta|F|)^2$. The anisotropic temperature factor is defined as $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. Weighting schemes and other particulars of refinement are quoted below. Tables J–N of the structure factors for **A**–**E** have been deposited.[5]

It should be pointed out that, in general, alkylammonium tetraphenylborate crystals are weak scatterers. Significant reflections were seldom observed above a $(\sin\theta)/\lambda$ limit of 0.48 Å^{-1} ($\theta = 20°$ for Mo radiation). Since in this laboratory X-ray data collection routinely extends to a limit of 0.55 Å^{-1} ($\theta = 23°$), the ratios of observed reflections to total measured unique reflections never exceeded 50%. Attempts to collect the data at lower temperatures produced little if any improvement in these ratios (see, for example, **D**).

The computer preograms of refs. 36 and 38–43 were used in the crystallographic investigation.

Compound A

The systematic absences (*hkl*, $h + k$ odd; 0*kl*, *k* odd; *h*0*l*, *h*,*l* odd; *hk*0, $h + k$ odd; *h*00, *h* odd; 0*k*0, *k* odd; 00*l*, *l* odd) pointed to *Cmcm* or $Cmc2_1$ as possible space groups. The structure was successfully refined in the former, with the cations in twofold orientational disorder. The H(N) atom was located from a difference map and the N–H distance was fixed in the refinement to 1.02 Å. Weighting scheme, $w = 1.595/[\sigma^2(F) + 0.00072F^2]$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

Because of the cation disorder in *Cmcm* the structure was also refined in $Cmc2_1$, with the cations ordered. In this refinement there were many serious correlations between the atomic parameters. Refinement with constrained interatomic distances and with a large number (1000) added to each element of the leading diagonal finally converged at $R = 0.079$, with unreasonable temperature factors on the N atom. The correlations were so serious that all attempts to lower R further failed. Because of the cation disorder in *Cmcm* the space gorup *Cmca* was also considered but rejected, since its adoption would have required many reflections with large measured intensities to be absent.

Compound B

Systematic absences: hkl, $h + k$ odd; $0kl$, k odd, $h0l$, h,l odd; $hk0$, h,k odd; $h00$, h odd; $0k0$, k odd; $00l$, l odd. These and the E-statistic pointed to *Cmca* as the maximum space group. Refinement in this group was successfully carried out, with the cations in twofold positional disorder. Weighting scheme, $w = 1.000/[\sigma^2(F) + 0.000221F^2]$. The alternative refinement, in *Cc2b*, with the cations ordered, was more successful than was the alternative refinement of **A** in $Cmc2_1$. In this instance, the final converged R was 0.044, compared with 0.048 for *Cmca*. However, a Hamilton test showed that this reduction in R was not significant even at the 10% level.

Compound C

The systematic absences ($h0l$, $h + l$ odd; $h00$, h odd; $0k0$, k odd; $00l$, l odd) led to $P2_1/n$ as the correct space group. Weighting scheme, $w = 4F_o^2/\sigma^2(F_o^2)$, $\sigma^2(F_o^2) = [S^2(C + R^2B) + (pF_o^2)^2]/(\mathrm{LP})^2$ (S = scan rate, C = total integrated peak count, R = scan time to background counting time ratio, B = total background count, LP = Lorentz-polarizaiton factor, p = reduction factor).

Compound D

Intensities were collected at room temperature and later recollected at −70°C. The refinement results reported here are for the low-temperature collection. The systematic absences were the same as for **A**, i.e., pointing to *Cmcm* or $Cmc2_1$ as possible space groups. However, in *Cmcm*, neither direct methods nor difference maps revealed the positions of *all* the nonhydrogen atoms in the cation, and the noncentrosymmetric group was therefore adopted. Weighting scheme, $w = 1.388/[\sigma^2(F) + 0.00197F^2]$.

Compound E

Systematic absences: hkl, $h + k$ odd; $h0l$, h,l odd; $0kl$, k odd; $hk0$, $h + k$ odd; $h00$, h odd; $0k0$, k odd; $00l$, l odd. Space group, $C2/c$. The H(N) and H(O) hydrogens were located from a difference map; the N—H and O—H distances and the HOH angle were constrained in the refinements to 1.02 Å, 1.00 Å, and 105°, respectively. Unit weights were used in the refinement.

Ab initio *calculations*

The programs used in this part of the investigation were GAUSSIAN 86 (44), AIMPAC (45) and, in the later stages, GAMESS (46).

Acknowledgments

We thank Miss K.N. Robertson and Dr. S.P. Roe for assistance with some of the early experimental work, Dr. M. Falk for obtaining the FT-ir spectra, and Professor R.J. Boyd for occasional advice on *ab initio* calculations. This investigation was supported by grants from the Natural Sciences and Engineering Research Council of Canada to the two first-named authors.

ADDENDUM: We thank one of the reviewers for drawing our attention to references 47–53. While the results reported there refer mostly to X—H...π interactions with X other than N, they do strengthen the case for the existence of hydrogen bonding to aromatic π systems as a positive rather than passive type of bonding interaction. A recent search of the Cambridge Structural Database using a novel search procedure (54) has uncovered further examples of N—H...π bonds, often unnoticed by the original authors. In Part 4 of this series (see footnote 8) we shall report on numerous additional examples of N—H...π bonding in tetraphenylborate structures and provide a detailed discussion of the geometric scope of such bonding.

Oxidation of H_2S to S by air with Fe(III)–NTA as a catalyst: catalyst degradation

DIAN CHEN, RAMUNAS J. MOTEKAITIS, AND ARTHUR E. MARTELL[1]
Department of Chemistry, Texas A&M University, TX 77843-3255, U.S.A.

AND

DEREK MCMANUS
ARI Technologies, Geneva, IL 60134, U.S.A.

Received January 15, 1993

DIAN CHEN, RAMUNAS J. MOTEKAITIS, ARTHUR E. MARTELL, and DEREK MCMANUS. Can. J. Chem. **71**, 1524 (1993).

The oxidation of H_2S to S by air is represented by the overall reaction:

$$2H_2S + O_2 \rightarrow 1/4S_8 + 2H_2O$$

The process is used with a catalyst for the removal of H_2S from natural gas. A typical catalyst would be an iron(III) chelate system such as iron(III)–nitrilotriacetate (NTA is a tribasic acid, H_3L, and NTA^{3-} represents the trinegative anion). The catalyst reactions are

$$2FeNTA + H_2S \rightarrow 2FeNTA^- + 1/8S_8 + 2H^+$$

$$2FeNTA^- + 1/2O_2 + H_2O \rightarrow 2FeNTA + 2OH^-$$

The main difficulty with the process is the degradation of the metal chelate catalyst. Thus the Fe(II,III)–NTA system degrades through the formation of a number of weaker chelating agents and eventually to carbon dioxide, water, and ammonia. The degradation products identified are iminodiacetic acid (IDA), glycine, and oxalate. All of these degradation products were measured quantitatively by HPLC, and a degradation scheme is presented for the catalytic process. The fact that thiosulfate greatly decreases the degradation rate, and the fact that the degradation products were observed only in the stoichiometric reactions in which the ferrous NTA was oxidized by air, led to the interpretation that the hydroxyl radical or the superoxide radical ion is the reactive species that attacks the NTA and the intermediate degradation products and is responsible for the degradation of the organic ligands present.

DIAN CHEN, RAMUNAS J. MOTEKAITIS, ARTHUR E. MARTELL et DEREK MCMANUS. Can. J. Chem. **71**, 1524 (1993).

On peut représenter l'oxydation du H_2S en S sous l'influence de l'air par la réaction globale suivante :

$$2H_2S + O_2 \rightarrow 1/4S_8 + 2H_2O$$

On utilise cette réaction catalysée pour enlever du H_2S du gaz naturel. Un catalyseur typique est un système de chélate du fer(II), comme le fer(II)–nitrilotriacétate (NTA est un acide tribasique, H_3L et NTA^{3-} représentent l'anion trinégatif). Les réactions du catalyseur sont

$$2FeNTA + H_2S \rightarrow 2FeNTA^- + 1/8S_8 + 2H^+$$

$$2FeNTA^- + 1/2O_2 + H_2O \rightarrow 2FeNTA + 2OH^-$$

La principale difficulté associée à ce processus est la dégradation du chélate métallique agissant comme catalyseur. Ainsi, le système Fe(II,III)–NTA se dégrade par formation d'un certain nombre d'agents chélatants plus faibles et éventuellement en bioxyde de carbone, en eau et en ammoniac. Les produits de dégradation qui ont pu être identifiés sont l'acide iminodiacétique (AID), la glycine et l'oxalate. Faisant appel à la CLHP, on a mesuré quantitativement tous ces produits de dégradation et on présente un schéma de dégradation pour le processus catalytique. Le fait que le thiosulfate diminue beaucoup la vitesse de dégradation et que l'on a observé les produits de dégradation uniquement lorsqu'on a effectué des réactions stoechiométriques dans lesquelles de NTA aqueux était oxydé par l'air conduit à suggérer que le radical hydroxyle (ou l'ion radicalaire superoxyde) est l'espèce réactive qui attaque le NTA et les produits intermédiaires de dégradation et qu'il est responsable de la dégradation des ligands organiques présents.

[Traduit par la rédaction]

Introduction

In 1960 a patent issued to Hartley et al. (1) reported that the Fe(III)–chelate rapidly oxidizes H_2S to sulfur and this reaction is used to remove H_2S from natural gas. The main factor that prevented industrial application was the magnitude of ligand loss. Since then, considerable work (2–5) has been done to solve this difficulty. McManus (2) described a liquid chromatographic technique that enabled quantitative measurement of aminopolycarboxylate ligands and their degradation products. Haruta and Soeta (4) described the conversion of H_2S to $Na_2S_2O_3$ with the addition of tartrate for increasing the $Na_2S_2O_3$ recovery. The use of iron(III) aminopolycarboxylates for the oxidation of H_2S was described by Diaz (6, 7) and by McManus and Kin (8). Other effective polyvalent metal chelate catalysts were identified by Bedell (9). The catalysts employed were stabilized by a number of additives, such as sulfhydryl compounds used by Diaz (6, 7) and a larger number of inorganic and organic compounds used by Bedell (9). The use of thiosulfate by McManus and Kin (8) was found to greatly lengthen the lifetime of the polyvalent metal aminopolycarboxylate catalysts, and they also described the addition of sorbitol and other polyhydroxy organic compounds to be beneficial because of their ability to form soluble complexes of iron(III) at high pH.

Although the previous work examined the chemistry of catalysts and identified major degradation products, a plausible mechanism of degradation was not established. The metal complexes of the ligands that have been identified as catalysts, and their degradation products, are stable organic

compounds that would not ordinarily be expected to undergo degradation under the conditions that prevail in the process. Further information is therefore needed to explain why degradation occurs, to describe the reactions in detail, and to point the way to further improvements in the process.

This paper reports kinetic studies of the degradation of the Fe(II,III)–NTA (nitrilotriacetate) redox system under operating conditions whereby H_2S is continuously oxidized by air, as well as stoichiometric degradation reactions of the Fe(II,III)–NTA complexes with one of the reacting species (O_2, H_2S) missing. The rate of degradation of NTA and of two other ligands that act as redox catalysts for the oxidation of H_2S, EDTA (ethylenediaminetetraacetic acid) and HEDTA (hydroxyethylethylenediaminetriacetic acid), are also compared. This information, plus the fact that lowering pH increases the rates of degradation of NTA and of intermediate degradation products and that thiosulfate greatly decreases the rates of degradation, led to the conclusion that a free radical reaction is responsible for the degradation reactions. Two possible candidates, the superoxide radical ion $^{\bullet}O_2^-$, and hydroxyl radical HO$^{\bullet}$, are suggested as possible initiators of the free radical reactions. The evidence pointing to one or the other of these intermediates is discussed.

Experimental

Materials

The following materials were ordered in the highest purity available and were used without further purification: nitrilotriacetic acid trisodium salt (99+% Aldrich); $Fe(NO)_3 \cdot 9H_2O$ (Certified A.C.S.) and $Na_2S_2O_3 \cdot 5H_2O$ (Reagent A.C.S., Fisher Scientific Company); $FeCl_2 \cdot 4H_2O$ and $Ni(NO_3)_2 \cdot 6H_2O$ (Baker Analyzed Reagents); $CuCl_2 \cdot 2H_2O$ (Baker Analyzed Reagent); MeOH (Mallinckrodt Chrom AR HPLC); hexadecyltrimethyl ammonium bromide (99%, Sigma); H_2O double distilled water; H_2S (99.5%, Gas Analytical Service). Catalase (Biomedicals, Inc., Ex: Bovine liver, E.C.1.11.1.6; sterile aqueous solution; activity, 40 000 units per milligram solid; unit definition, one unit decomposes one micromole of H_2O_2 per minute; 25.0°C; pH 7.0; approx. 30 000 units per millilitre).

HPLC equipment

An IBM L. C. pump No. 771008 equipped with a chromatography accessory, UV–visible spectro monitor 3100 (LDC Analytical), and a chart recorder 6885 (Kipp and Zone) were used.

Redox reaction conditions

Iron–NTA solution: One litre of solution contained 7.24 g of $Fe(NO)_3 \cdot 9H_2O$ and 9.96 g of $N(CH_2COONa)_3 \cdot H_2O$. The redox reaction was carried out in a glass apparatus, Fig. 1, and the pH and redox potential in both the absorber and oxidizer were monitored. The H_2S flow rate was 2.0 mL min^{-1} and the air flow rate was 1.0 L min^{-1}. The temperature was maintained at 25 ± 1°C throughout.

NMR spectra

The proton NMR spectra were recorded with a Varian XL-200 NMR spectrometer, and chemical shifts are reported in ppm.

Degradation of Fe(III)–NTA with uncontrolled pH

One litre of the NTA solution described above was placed in the oxidizer compartment (Fig. 1). The pump was then started and some of the solution was pumped into the absorber compartment, with a flow rate of 100 mL min^{-1}. The pH and redox meters were then turned on. At this stage the air pump was turned on and the air flow was adjusted to 1.0 L min^{-1}. The valve of the H_2S cylinder was turned on and the H_2S flow was adjusted to 2.0 mL min^{-1}. The time of the start of the reaction was recorded, and the pH and redox meter readings were recorded from time to time. Every half hour the flow rates of H_2S and air were checked and adjusted if necessary. Any FeS and S that deposited in the tubing was cleaned out occasionally.

The operation of the other experiments were carried out in the same manner except that the sulfur was filtered off every 7 or 8 h and the pH was continuously adjusted to 8.5 by the addition of NaOH solution.

HPLC analysis procedure

The analyses of NTA, IDA, and oxalate were measured by following the method of McManus (2).

Preparation of iron-free samples

To 12.0 mL of solution taken from the continuous reactor, 140 mg of NaOH in 5 mL water was added dropwise with stirring. The stirring was continued for 10 min and the reaction mixture was allowed to stand at room temperature for 20 min. The $Fe(OH)_3$ that precipitated was filtered off carefully and was washed several times with water. The filtrate combined with the washings was transferred to a 50-mL volumetric flask. The solution was adjusted with acid to pH 4.2 and then diluted with water to 50 mL.

Analysis of NTA, IDA, and oxalate as their copper(II) complexes

A 7-mL sample of solution was taken from the volumetric flask and placed in a 10-mL volumetric flask. To this was added 2.5 mL of 0.050 M $CuCl_2$ solution and the mixture was diluted to 10 mL with water. The mobile phase contained: 0.0010 M Cu(II), 60:40 H_2O:MeOH, 2% CH_3COOH, 0.2% $CH_3(CH_2)_{15}(CH_3)_3NBr$, adjusted to pH 4.2 with NaOH solution. This phase is presumed to contain the alkyl ammonium salts of the negative copper complexes of NTA, IDA, and oxalate.

Operating conditions

Analytical column: IB-SIL 5 C8, reverse phase, 4.5 × 150 mm; column temperature: ambient; flow rate, 1.5 cm^3 min^{-1}; detection, UV absorption at 280 nm; sample, 20 μL; recorder 10 mV full scale; chart speed, 0.5 cm min^{-1}.

Analysis of glycine and glyoxylate as their Ni(II) complexes

For the analysis of glycine and glyoxylate as the complexes formed with Ni(II), the procedure is identical to that described above for the copper complexes of NTA, IDA, and oxalate, the only difference being the use of 2.5 mL of 0.050 M $Ni(NO_3)_2$ solution instead of $CuCl_2$ solution, and the mobile phase contained 0.0010 M Ni(II) rather than Cu(II) and was presumed to contain the alkylammonium salts of the negative nickel complexes of glycine and glyoxylate. For the measurement of glycine, the UV absorption was measured at 270 nm; for glyoxylate, the UV absorption was measured at 250 nm. The other operating conditions were the same as above. The retention time for IDA is about 3.0 min, 7.0 min for the oxalate, and 21 min for the NTA. The separations of these quantitative calibrations for the HPLC analysis of NTA, IDA, and oxalate and for glycine and glyoxylate were obtained from varying amounts of known samples of these compounds, and the peak heights at the indicated amplification settings vs. concentration of the species were plotted. The linear nature of these plots indicated accurate HPLC determinations of these molecular species over a considerable range of concentration.

Identification of the hydroxylation products by paper chromatography

The paper chromatographic measurements of the hydroxylation products of benzoic acid were made by the procedure of Grinstead (10). Benzoic acid and its hydroxylation products were separated from the Fe(III), the remaining NTA, and its degradation products by acidification of the reaction mixture and extracting five times with ether. The extracts were combined and reduced to a small volume by evaporation of the solvent. The ether residue was chromatographed on Whatman No. 1 filter paper, with 4:1 (by volume) isopropyl alcohol, 7 M NH_4OH as the eluant. Under ultraviolet light six spots appeared on the paper. The R_f value and the color of the spots were compared with those of standard compounds, and the six spots were assigned as follows:

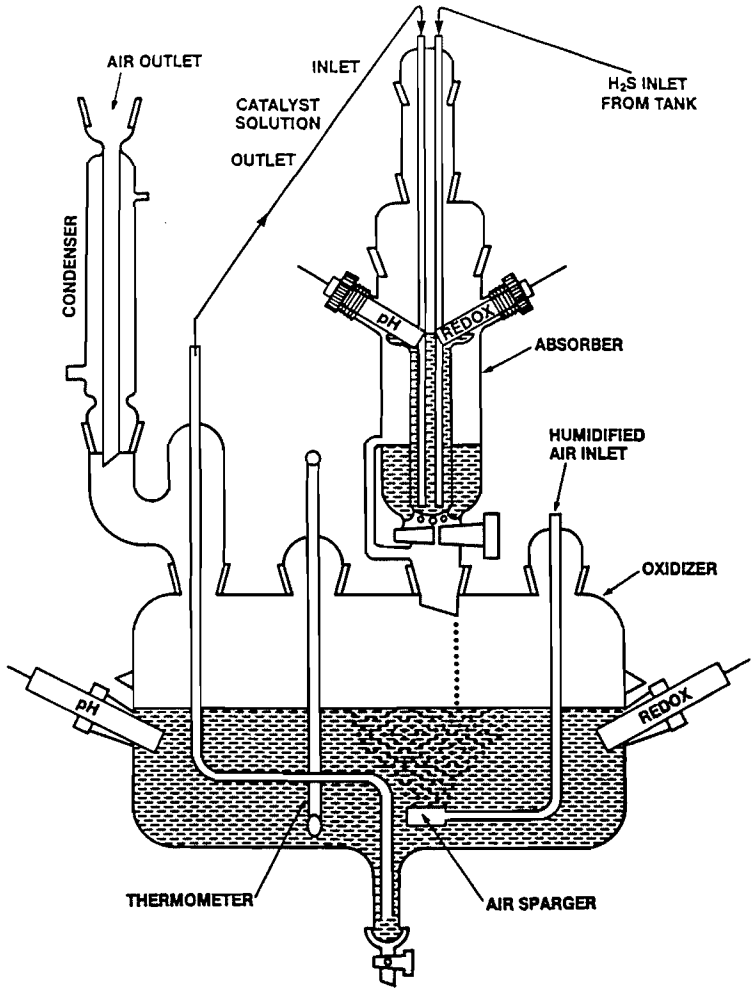

FIG. 1. Continuous apparatus.

Compound	R_f value
1. *o*-Hydroxybenzoic acid	0.78
2. Benzoic acid	0.64
3. 2,5-Dihydroxybenzoic acid	0.54
4. 2,3-Dihydroxybenzoic acid	0.41
5. *m*-Hydroxybenzoic acid	0.25
6. *p*-Hydroxybenzoic acid	0.090

Identification of the hydroxylation products by NMR

The ether residue obtained as described above was loaded on a silica gel (60 Å) column and eluted first with benzene and then with a benzene and ether mixed solvent beginning with 1% ether, which was slowly increased to 20%. At the end MeOH was used as the eluant. Each 30 mL of eluate was collected; after the solvent was removed its NMR spectrum was determined. The benzoic acid was eluted first. The second eluate was salicylic acid, which was then followed by *m*-hydroxybenzoic acid and *p*-hydroxybenzoic acid.

The NMR measurements of the silica gel separation products confirm the formation of salicylic acid, *m*-hydroxybenzoic acid, and *p*-hydroxybenzoic acid: salicylic acid: ^{1}H NMR (D_2O):6.51 (t, 1H, phenyl), 6.56 (d, 1H, phenyl), 7.00 (t, 1H, phenyl), 7.16 (d, 1H, phenyl); *m*-hydroxybenzoic acid: ^{1}H NMR (D_2O): 6.56 (d, 1H, phenyl), 6.86 (m, 2H, phenyl), 6.96 (t, 1H, phenyl); *p*-hydroxybenzoic acid: ^{1}H NMR (D_2O): 6.39 (d, 2H, phenyl), 7.45 (d, 2H, phenyl).

The dihydroxybenzoic acids were not found in the NMR measurements, and the yield of each was concluded to be less than 5%, which is the limit of sensitivity of the NMR technique.

Identification of the hydroxylation products by mass spectral measurements

The mass spectra were obtained with a VG analytical 70S high-resolution double-focusing mass spectrometer with an attached VG analytical 11/250J data system. The operator was Dr. David Jacobs of the Departmental Research Services Facility. Mass spectral data of the hydroxylation products gave the molecular weight 138 for the three monohydroxybenzoic acids, which had been partially separated on a silica gel column.

Results

The degradation of the Fe(III)–NTA catalyst in a continuous reaction system with no control of pH is shown in Table 1 and illustrated in Fig. 2. The NTA decreases rapidly with time, and over 95% of it is lost in 100 h. During this time the pH, which starts at 8.6, drifts gradually downward, reaching 3.6 at the end of the run. IDA was the first and main reaction product (Fig. 2). Its concentration increased steadily throughout the run, although its rate of formation seemed to decrease slightly toward the end. The second and subsequent degradation product containing nitrogen was glycine, as indicated in Fig. 2. The amount of glycine produced was considerably less than IDA, showing that the rate of degradation of the latter is slower than that of NTA. The sum of the concentrations of NTA, IDA, and glycine in Fig. 2 shows

52.0	1.17×10^{-2}	1.69×10^{-2}	1.95×10^{-2}	5.7×10^{-3}
69.0	4.1×10^{-3}	2.22×10^{-2}	2.46×10^{-2}	5.9×10^{-3}
93.0	2.10×10^{-3}	2.80×10^{-2}	2.58×10^{-2}	6.0×10^{-3}

a material balance of about 100%, indicating that very little of the ligand degraded all the way to ammonia, even after 100 h. The formation of oxalate, presumably from the acetate side chains of NTA, IDA, and glycine, starts off more slowly than expected at first, but rises above the rate of IDA formation. This behavior is not considered unusual since oxalate is expected to form both in the formation and degradation of IDA. It shows a somewhat slower rate of formation near the end of the run and it is suggested that this may be due to the further oxidation of oxalate to carbon dioxide (13). It is noteworthy that no glyoxylate was found among the degradation products.

The degradation of the Fe(II,III)–NTA chelate in an experiment in which the pH was kept constant at 8.5 and in which the sulfur was removed by filtration every 6–7 h (Table 2 and Fig. 3) gave a lower rate of degradation of NTA. In fact glycine, which was produced in a small amount at pH 7, was not formed at pH 8.5. Thus, it appears degradation is promoted under acidic conditions.

To further determine the effect of pH, the redox reactions were run at pH 7.0 and 5.5. The pH was regulated by the addition of NaOH solution initially and at short time intervals (every 30 min or less). The NTA degradation at these pH values is compared in Fig. 4 with the degradation observed at pH 8.5 (also shown in Fig. 3). The results confirm that the rate of degradation of NTA increases as the pH is decreased.

Kinetic analysis of the degradation of NTA at 25.0°C at pH 8.5, 7.0, and 5.5 (Fig. 4) suggests that the degradation of NTA is a first-order reaction. The observed degradation rate constants of NTA obtained from the data in Fig. 4 are

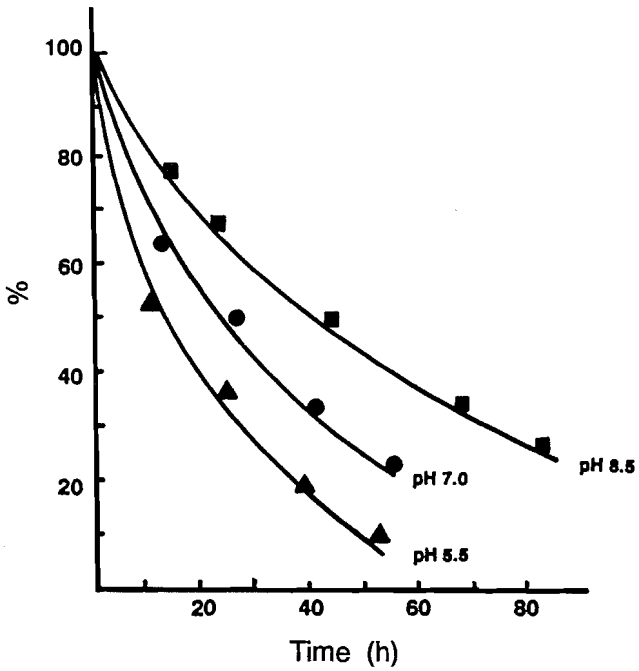

FIG. 4. Degradation of Fe(III)–NTA at pH 8.5, 7.0, and 5.5; 25.0°C; H_2S flow rate (2.0 mL/min); % is mole per cent of species based on initial concentration of NTA, 0.036 M = 100%.

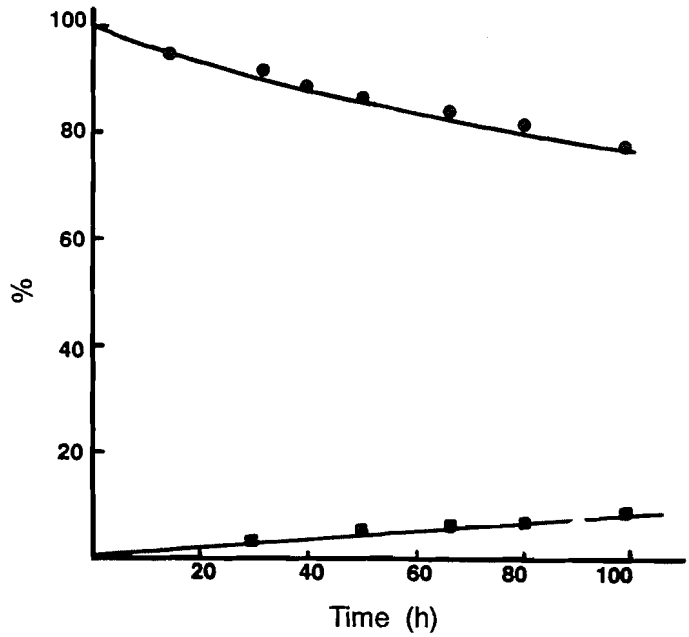

FIG. 5. Degradation of Fe(III)–NTA at pH 8.5 with 5% $Na_2S_2O_3 \cdot 5H_2O$: ●, NTA; ■, IDA; % is mole per cent of species based on initial concentration of NTA, 0.036 M = 100%.

pH 8.5, 4.4×10^{-6} s^{-1}; pH 7.0, 7.0×10^{-6} s^{-1}; pH 5.5, 1.1×10^{-5} s^{-1}. This increase in rate constant with a decrease in pH agrees with the qualitative observation, stated above, that degradation is more rapid at low pH.

A similar run at pH 8.5 with 32 g of $Na_2S_2O_3$ in the solution as a stabilizer is shown in Table 3 and illustrated in Fig. 5. It is seen that the sodium thiosulfate greatly reduces the rate of degradation of the NTA. A small amount of IDA was found as the only degradation product in concentrations large enough to measure.

To determine which part of the process involved degradation of NTA, a number of stoichiometric reactions were carried out. A ferric–NTA solution of the same concentration as used in the redox runs at pH 8.5 was treated with air for 2 days. HPLC analysis carried out as described above indicated the presence of only NTA after 1 and 2 days, and that no degradation reaction had occurred. Also, a ferric–NTA solution was treated with H_2S at the same rate as the experimental redox runs for 2 days, and analysis of the reaction products in the same manner showed the absence of degradation products. However, when a similar ferrous–NTA solution was treated with air for 2 days and the results were subjected to HPLC analysis, the results showed evidence of degradation with the formation of 1.7% of IDA and slightly less than 1.0% of oxalate. These experiments indicate that the degradation of NTA is a side reaction that occurs during the oxidation by air of the ferrous–NTA to the ferric–NTA chelate system.

39.0	3.20×10^{-2}	1.17×10^{-3}
50.0	3.17×10^{-2}	1.69×10^{-3}
66.0	3.06×10^{-2}	2.12×10^{-3}
80.0	2.97×10^{-2}	2.32×10^{-3}
99.0	2.93×10^{-2}	2.80×10^{-3}

To obtain information on the question of whether H_2O_2 is an intermediate in the reaction, the Fe(III)–NTA solution was mixed with catalase (catalase solution added to a dilution of 1:100) and the redox reaction was carried out at pH 7.0 for 50 h. The results show that the NTA degradation slowed down on the addition of catalase. This result confirms the formation of H_2O_2 as an intermediate product, because the enzyme rapidly catalyzes the decomposition of H_2O_2 and should slow down reactions requiring H_2O_2 as an intermediate.

To investigate the possible formation of the hydroxyl radical, an equimolar amount (0.0362 M) of benzoic acid was mixed with Fe(III)–NTA, and the redox reaction was carried out at pH 8.5 for 100 h, as described above. The results indicate that the benzoic acid was hydroxylated to a mixture of *o*-, *m*-, and *p*-hydroxybenzoic acid. The products were characterized by NMR, paper chromatography, and mass spectra. This is strong evidence for the formation of the hydroxyl radical, because the benzene ring is not hydroxylated by molecular oxygen. There still remains the possibility that the less reactive $\cdot O_2^-$ radical is involved. This question is addressed below.

These results are similar to those obtained by Grinstead (10). He reported that when a solution of Fe(III)–NTA is mixed with ascorbic acid and benzoic acid under oxygen, the latter is hydroxylated to a mixture of *o*-, *m*-, and *p*-hydroxybenzoic acid. He also confirmed the formation of H_2O_2 as an intermediate by the use of catalase.

Because the iron chelates of EDTA and of HEDTA have been used as redox catalysts for the oxidation of H_2S to S_8

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

by air, it was considered of interest to compare the rates of degradation of the iron chelates of these ligands with that described above for NTA. Figure 6 shows the measured rates of degradation of all three iron chelate systems starting with the same concentration of Fe(III) in each case, with the molar ratio of ligand to metal being 2:1 for NTA, EDTA, and HEDTA. No stabilizer or additional ligand was added. It is obvious from Fig. 6 that NTA degrades more slowly than do the other two ligands and the most rapid rate of degradation was observed in the case of HEDTA. The superiority of NTA over the other ligands with respect to degradation was first pointed out by McManus and Kin (8).

Discussion

Graphic formulas indicating the reaction of H_2S with the catalyst, the Fe(III)–NTA chelate, to produce sulfur and the Fe(II)–NTA chelate, and regeneration of the ferric–NTA catalyst by oxidation with air, are illustrated in Scheme 1. The iron(III)–NTA system is shown to consist of two complexes in equilibrium, a 1:1 monohydroxo iron – NTA complex and a 1:2 iron(III)–NTA complex, in accordance with the description given by Motekaitis and Martell.[2] The six-coordinate representation of the 1:2 complex represents one of the possibilities for this complex. It may very well be seven-coordinate, in view of the seven-coordinate crystal structure of the 1:2 complex described by Clegg et al. (11). However, it is possible that the structures and coordinate bonding of the Fe(III)–NTA complexes in the solid state and in solution may be different.

The degradation reactions illustrated by Figs. 2, 3, and 5 show that IDA is the first compound produced, and that it is followed by the formation of glycine. The oxalate that is formed apparently comes from the side chains (acetate groups) that are cleaved from the NTA, IDA, and glycine. On the basis of the evidence now available, the following degradation scheme is tentatively suggested. Because the ligands undergoing degradation are usually very stable, and the degradation occurs during the re-oxidation of the ferrous–NTA system with air (molecular oxygen), it is suggested that only free radicals have enough energy to degrade these chelating ligands. The review by Walling (12) (see also the paper by McManus (2)) indicates that the hydroxyl radical may be formed under the reaction conditions that prevail, leading to the following sequence of reactions.

[1] $2FeNTA^- + O_2 + 2H_2O \rightarrow 2FeNTA + H_2O_2 + 2HO^-$

[2] $FeNTA^- + H_2O_2 \rightarrow FeNTA + OH^- + HO^{\cdot}$

[3] $R^1R^2NCH_2COO^- \xrightarrow{{}^{\cdot}OH} R^1R^2NH + {}^-OOC{-}COO^- + 2H_2O + H^+$

$R^1\,R^2 = CH_2COO^-$ NTA

$R^1 = H;\ R^2 = CH_2COO^-$ IDA

$R^1 = R^2 = H$ Glycine

[4] $^-OOC{-}COO^- + 2HO^{\cdot} \rightarrow 2CO_2 + 2OH^-$

Equations [1] and [2] are in accord with the fact that low pH increases the rate of degradation, in that low pH favors the formation of the free radical. The formation of carbon dioxide from oxalate has been described (13).

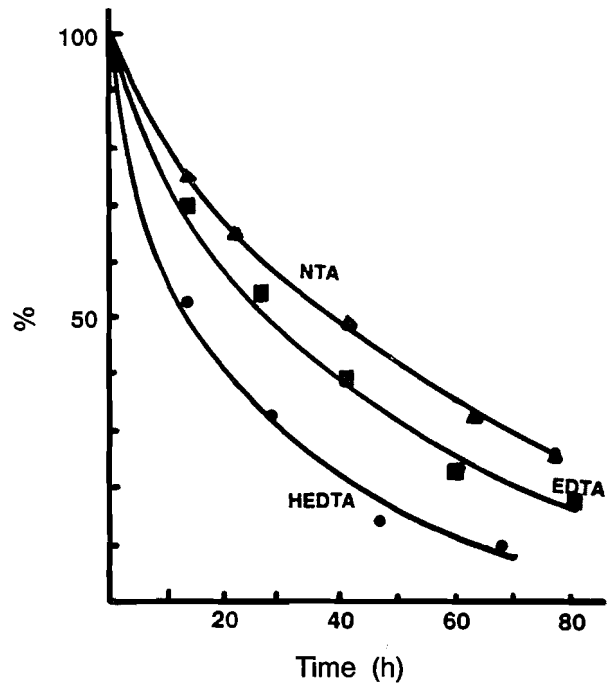

FIG. 6. Degradation of Fe(III)–NTA, Fe(III)–EDTA, and Fe(III)–HEDTA at p[H] 8.5 and 25.0°C; H_2S flow rate = 2.0 mL/min. % is mole per cent of species based on initial concentration of NTA, EDTA, and HEDTA, 0.036 M = 100%.

The stabilizing effect of thiosulfate (Fig. 4), reported previously by McManus and Kin (8), as well as other stabilizers described by Diaz (6, 7) and Bedell (9), can be understood since they have one property in common. They are all free radical scavengers, and decrease the degradation represented by eqs. [1]–[4] by decreasing the concentration of free radical in the reaction mixture.

While the above reaction sequence describes the degradation of the NTA on the basis of the intermediates actually detected in the reaction mixture, it does not give a rationale for the initial attack on the NTA, and the degradation products, iminodiacetic acid and glycine. The following reactions involve species and intermediates that have been inferred but not demonstrated to be present.

[5] $R^1R^2NCH_2COO^- + HO^{\cdot} \rightarrow R^1R^2N\dot{C}HCOO^- + H_2O$

[6] $R^1R^2N\dot{C}HCOO^- + FeNTA \rightarrow R^1R^2\overset{+}{N}CHCOO^- + FeNTA^-$

[7] $R^1R^2\overset{+}{N}CHCOO^- + H_2O \rightarrow R^1R^2\underset{|}{\overset{OH}{N}}CHCOO^- + H^+$

[8] $R^1R^2\underset{|}{\overset{OH}{N}}CHCOO^- \rightarrow R^1R^2NH + OHCCOO^-$

Reaction [5] is inferred by the presumed presence of ·OH generated by the Fenton reaction (Fe(II) + H_2O_2), and the facile hydroxylation of benzoic acid in the reaction mixture. Reactions [6] and [7], favored by the considerable concentration of Fe(III) chelate in the reaction mixture, may

[2]To be published.

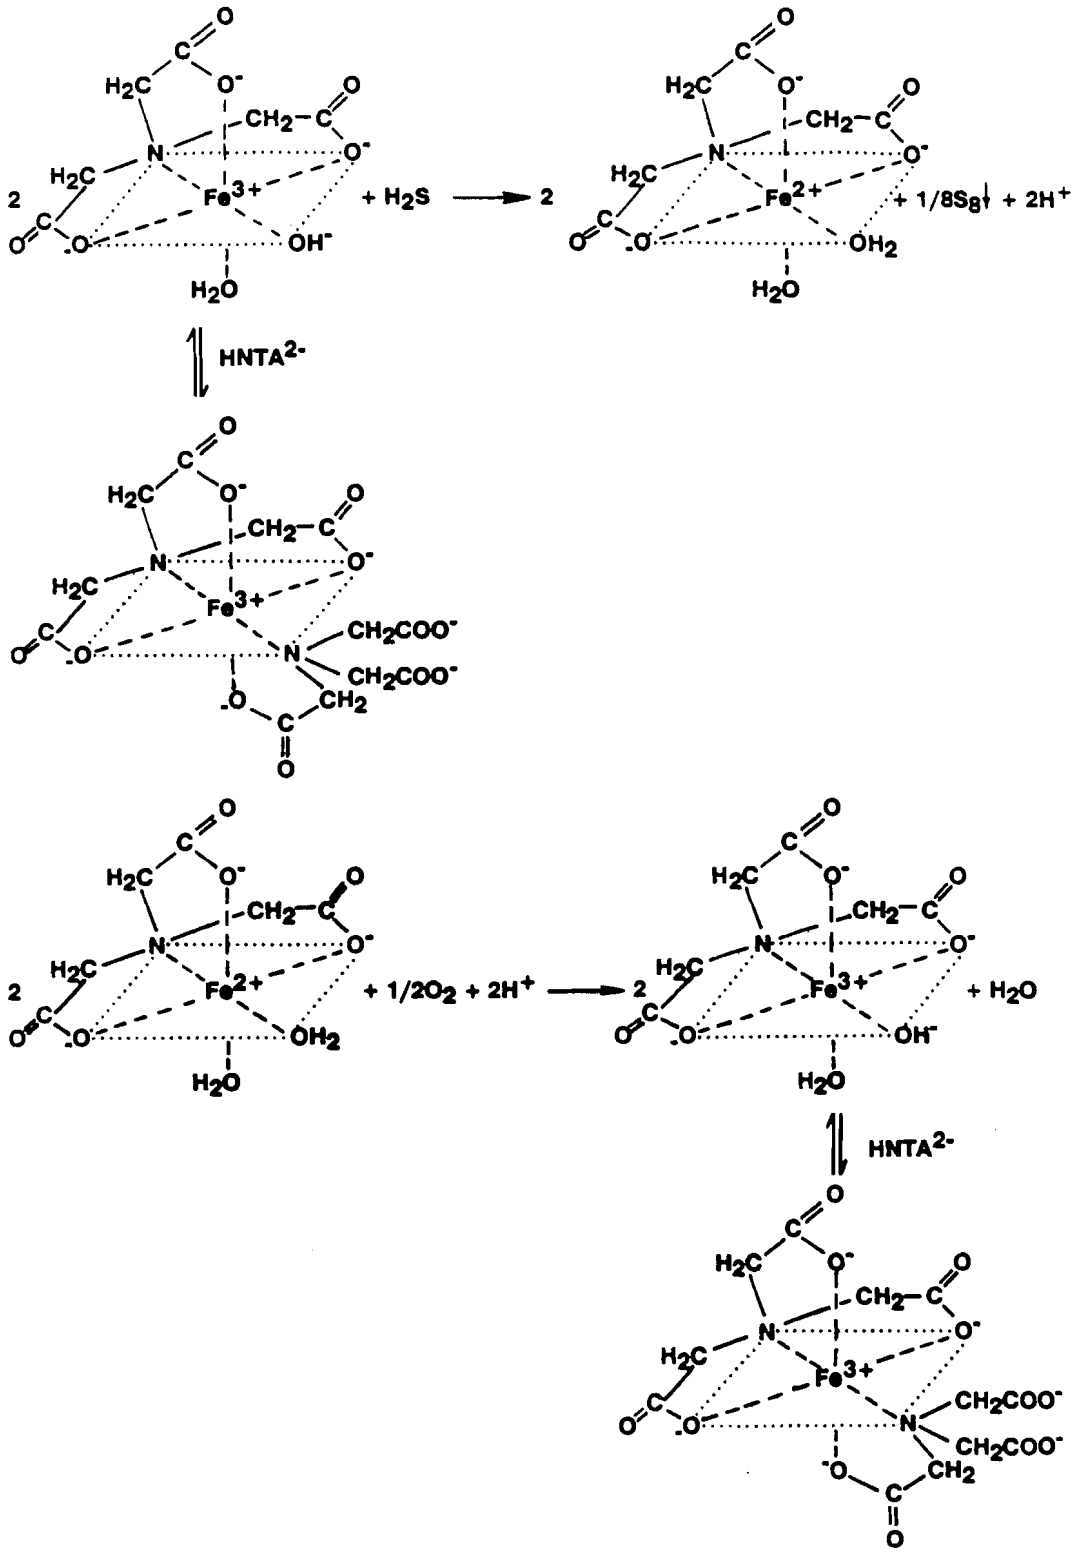


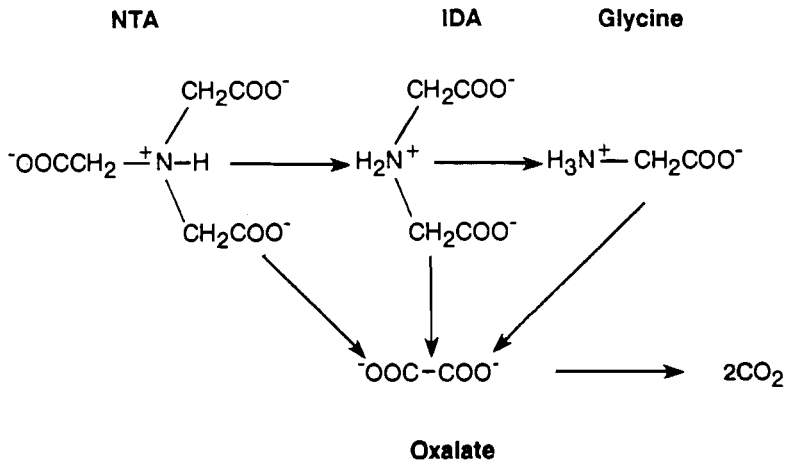
SCHEME 1. Reactions for the oxidation of H_2S to S with the Fe(II,III)–NTA system as catalyst.

be considered as occurring in sequence or as concerted. The failure to detect glyoxylate in the reaction mixture may be due simply to its rapid oxidation to oxalate. Alternatively, its absence may be due to the superoxide radical as the oxidizing agent, rather than the hydroxyl radical, leading to the following sequence of reactions:

[9] $H_2O_2 + HO^{\bullet} \rightarrow O_2^{\bullet-} + H_2O + H^+$

[10] $R^1R^2NCH_2COO^- + O_2^{\bullet-} + H^+$

$\rightarrow R^1R^2N\dot{C}HCOO^- + H_2O_2$



SCHEME 2. Proposed degradation scheme for NTA.

$$[11]\quad R^1R^2N\dot{C}HCOO^- + {}^{\bullet}O_2 \rightarrow R^1R^2NCHCOO^-$$
($^{\bullet}O_2$ attached to N)

$$[12]\quad R^1R^2NCHCOO^- + FeNTA^- \rightarrow R^1R^2NH + {}^-OOC{-}COO^- + FeNTA$$
($^{\bullet}O_2$ attached to C)

While the above reactions are somewhat speculative, all the reactants are present, and both $^{\bullet}OH$ and $O_2^{\bullet-}$ have been inferred as possible intermediates. The oxidation of the aminopolycarboxylate ligands is considered a free radical reaction because the ligands are not oxidized by oxygen, even in the presence of Fe(III), under the reaction conditions employed.

The reductive carbonylation of either platinum(IV) fluorosulfate, $Pt(SO_3F)_4$, or palladium(III) fluorosulfate, $Pd(SO_3F)_3$, either in solution of fluorosulfuric acid, HSO_3F, or in the solid state with CO at pressures of 0.5 to 2 atmospheres and at 25°C, affords in high yield complexes of the type $M(CO)_2(SO_3F)_2$, M = Pd or Pt. The square-planar complexes are readily converted by solvolysis in liquid antimony(V) fluoride in the presence of CO at a pressure of about 1 atmosphere to white, thermally stable, salts of the composition $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, which contain the novel, square-planar cations $[Pd(CO)_4]^{2+}$ and $[Pt(CO)_4]^{2+}$. The two cations exhibit the highest CO stretching frequencies reported so far, about 120 cm^{-1} higher than in free CO, which suggests the absence or near absence of π-back donation for the M—CO bond.

G. HWANG, C. WANG, F. AUBKE, H. WILLNER et M. BODENBINDER. Can. J. Chem. **71**, 1532 (1993).

La carbonylation réductrice des fluorosulfates de platine(IV), $Pt(SO_3F)_4$, ou de palladium(III), $Pd(SO_3F)_3$, soit en solution dans l'acide fluorosulfurique, HSO_3F, ou à l'état solide avec du CO à des pressions allant de 0,5 à 2 atmosphères et à 25°C fournissent, avec des rendements élevés, des complexes du type $M(CO)_2(SO_3F)_2$ dans lesquels M = Pd ou Pt. Par hydrolyse dans le fluorure d'antimoine liquide en présence de CO à une pression d'environ 1 atmosphère, on peut facilement transformer les complexes plans carrés en des sels blancs, thermiquement stables, de composition $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd ou Pt, qui contiennent les nouveaux cations plans carrés $[Pd(CO)_4]^{2+}$ et $[Pt(CO)_4]^{2+}$. Les fréquences de vibration d'élongation du CO de ces deux cations sont les plus élevées à avoir été rapportées jusqu'à maintenant, soit environ 120 cm^{-1} plus haut que le CO libre; ce résultat suggère l'absence complète ou pratiquement complète de rétrodonation π pour la liaison M—CO.

[Traduit par la rédaction]

This communication describes the syntheses and vibrational spectra of two thermally stable compounds with the square-planar cations $[Pt(CO)_4]^{2+}$ and $[Pd(CO)_4]^{2+}$, stabilized in each case by $[Sb_2F_{11}]^-$. Neither cation has been reported previously. They display the highest CO stretching frequencies ($\nu_{av.} \sim 2260$ cm^{-1}) and stretching force constants ($f_r \times 10^2 \sim 20.6$ N m^{-1}) for metal CO derivatives, which suggests little or no π-backdonation for the M—CO bonds in the two cations.

Carbon monoxide, CO, is viewed as the prototype of a π-acceptor ligand (1), and synergic bonding, that is, σ-donation from the filled 5σ-molecular orbital of CO to a suitable, empty metal orbital of σ symmetry and π-backdonation from a filled metal *d*-orbital to the π_g MO's of CO, is an essential feature of transition metal carbonyl chemistry (1). Vibrational spectroscopy (2, 3), where νCO in metal carbonyls is lowered well below the value of gaseous CO at 2143 cm^{-1} (4), ^{13}C NMR (5), X-PES (6), and numerous molecular structure determinations have provided support for this bonding concept.

There are, among the longest known metal carbonyl derivatives, some examples where νCO is observed at slightly higher wavenumbers than for CO itself (7, 8). These include three platinum(II) carbonyl chlorides, first reported by Schützenberger in 1870 (9), and gold(I) carbonyl chloride, Au(CO)Cl (10), known since 1925. In spite of these early beginnings, the number of noble metal carbonyl derivatives has remained limited (11, 12) until very recently, and only two reports of carbonyl cations, $[Cu(CO)][CO_2CF_3]$ (13*a*) and $[Cu(CO)][AsF_6]$ (13*b*), involving coinage metal derivatives have appeared.

Two recent developments have suggested promising new synthetic pathways to these unusual compounds. The use of very weakly coordinating anions like $B(OTeF_5)_4^-$ has allowed the synthesis first of $Ag(CO)B(OTeF_5)_4$ (14) and later of $Ag(CO)_2B(OTeF_5)_4$ (15) and their characterization by low temperature X-ray crystallography. The latter contains a weakly coordinated, nearly linear $[Ag(CO)_2]^+$ group.

The far more thermally stable linear $[Au(CO)_2]^+$ cation has been obtained by reductive carbonylation of gold tris-(fluorosulfate), $[Au(SO_3F)_3]_2$ (16), initially in solution of fluorosulfuric acid as a solvated cation (17) and subsequently in a solid salt of the formula $[Au(CO)_2][Sb_2F_{11}]$ (18). This material is synthesized from $Au(CO)SO_3F$ (17) and liquid SbF_5 by solvolysis in a CO atmosphere. The linear cation $[Au(CO)_2]^+$ is fully characterized by ^{13}C NMR and vibrational spectroscopy including a normal coordinate analysis, valence force field calculations (18), and a spectral comparison to the isoelectronic species $[Au(CN)_2]^-$ and $Hg(CN)_2$. The average CO stretching frequency is found at

2235.5 cm^{-1}, the highest reported at the time of publication (18).

We have now applied this synthetic strategy to the syntheses of $[Pt(CO)_4][Sb_2F_{11}]_2$ and $[Pd(CO)_4][Sb_2F_{11}]_2$. Reductive carbonylation of $Pt(SO_3F)_4$ in HSO_3F (19) proceeds at 25°C to yield a diamagnetic yellow solid of the composition $Pt(CO)_2(SO_3F)_3$, which is identified by ^{13}C and ^{19}F NMR and by vibrational spectra as $[Pt(CO)_4][Pt(SO_3F)_6]$ (20). The cation $[Pt(CO)_4]^{2+}$ appears to be, just like the isoelectronic anion $[Pt(CN)_4]^{2-}$ (21), square planar. The weighted average value of νCO is unprecedentedly high (2251 cm^{-1}). Band overlap with bands due to the anion $[Pt(SO_3F)_6]^{2-}$ (19) makes a complete vibrational assignment very difficult, and all attempts to obtain single crystals from HSO_3F solution have so far failed.

Under more stringent conditions (80°C and ~0.6 atm pressure of CO; 1 atm = 101.3 kPa) more extensive reduction of $Pt(SO_3F)_4$ is observed:

$$[1]\quad Pt(SO_3F)_4 + 3CO \xrightarrow[80°C]{HSO_3F} Pt(CO)_2(SO_3F)_2 + CO_2 + S_2O_5F_2$$

The reaction allows isolation of *cis*-$Pt(CO)_2(SO_3F)_2$ (22) and its characterization ($\nu CO_{avg.}$ = 2202 cm^{-1} (IR) and 2198.5 cm^{-1} (Raman)). The fluorosulfate groups appear to be coordinated to Pt in a monodentate fashion, as is the case for $Au(CO)SO_3F$ (17, 22).

The synthesis of the corresponding palladium(II) compound, $Pd(CO)_2(SO_3F)_2$, from Pd(II)Pd(IV)$(SO_3F)_6$ (23), may be performed either in a solid – gas phase reaction according to:

$$[2]\quad Pd(II)Pd(IV)(SO_3F)_{6(s)} + 5CO_{(g)} \xrightarrow[\approx 0.5\ atm\ CO]{25°C} 2Pd(CO)_2(SO_3F)_{2(s)} + S_2O_5F_{2(g)} + CO_2$$

or in HSO_3F as solvent. In both instances a yellow solid of the composition $Pd(CO)_2(SO_3F)_2$ forms. According to the vibrational spectra, the solid – gas phase reaction leads almost exclusively to the *cis* isomer while in HSO_3F an isomeric mixture forms (22). This mixture, or pure *cis*-$Pd(CO)_2(SO_3F)_2$, are both suitable for the subsequent solvolysis in liquid antimony(V) fluoride according to:

$$[3]\quad Pd(CO)_2(SO_3F)_2 + 8SbF_5 + 2CO \xrightarrow[\approx 0.5\ atm\ CO]{60–80°C} [Pd(CO)_4][Sb_2F_{11}]_2 + 2Sb_2F_9SO_3F$$

As noted previously (18), the reaction mixture is initially very viscous and gentle heating to 60–80°C is suggested, to allow magnetic stirring. The yellow colour of the starting material fades to colourless, but solid material suspended in liquid SbF_5 persists throughout the reaction. Removal of all volatiles in vacuo leaves a white, hygroscopic powder of the composition $[Pd(CO)_4][Sb_2F_{11}]_2$. Careful trap-to-trap distillation of the volatile materials from the solvolysis in the presence of CO provides no evidence for either CO_2 or $S_2O_5F_2$, which rules out any reduction to Pd(I). Since a number of palladium(I) carbonyl derivatives are known (12), further reduction is a distinct possibility. The reaction product $Sb_2F_9SO_3F$ is identified by its vibrational spectrum (24).

Formation of $[Pt(CO)_4][Sb_2F_{11}]_2$ proceeds in a very similar manner. Solid *cis*-$Pt(CO)_2(SO_3F)_2$ dissolves in liquid SbF_5 at room temperature to a clear colourless liquid. When ~0.6 atm of gaseous CO is admitted to the reactor a white solid starts forming on the surface of the solution. Since there is no colour change, the progress of the solvolysis is conveniently monitored by the uptake of CO from the gas phase, which together with the weight balance of the reaction allows an insight into the composition of the product. This is important here because, as in case of $[Au(CO)_2][Sb_2F_{11}]$ (18), no reliable metal analysis has been obtained due to interference between antimony and the noble metals. Tetrakis(carbonyl) platinum(II) undecafluorodiantimonate(V), $[Pt(CO)_4][Sb_2F_{11}]_2$, is a white, moisture-sensitive solid.

Appearance and the vibrational spectra are extremely similar for both salts, in particular in the range below 800 cm^{-1}. The slightly lower thermal stability of $[Pd(CO)_4][Sb_2F_{11}]_2$ is expected from previously reported CO derivatives of Pt(II) and Pd(II) (12, 25). Unlike $[Au(CO)_2][Sb_2F_{11}]$ (18), both $[M(CO)_4][Sb_2F_{11}]_2$ (M = Pd or Pt) are nearly insoluble in liquid SO_2 and attempts to obtain single crystals have failed for lack of an appropriate solvent. As the facile displacement of CO during the conversion of $[Au(CO)_2][Sb_2F_{11}]$ to $[Au(NCCH_3)_2][SbF_6]$ indicates (18), donor solvents may be unsuitable in recrystallization attempts. Our efforts are therefore currently directed at a complete vibrational analysis of both $[M(CO)_4]^{2+}$ cations (M = Pd or Pt), a normal coordinate analysis, and valence force field calculations, in order to allow a comparison with the corresponding data for the isoelectronic anions $[Pd(CN)_4]^{2-}$ and $[Pt(CN)_4]^{2-}$ (21).

A number of aspects discussed so far, and the molecular geometries of the cations, are very unusual in transition metal carbonyl chemistry (1). Some remote precedents will be briefly summarized.

The use of a strong protonic acid in the attempted syntheses of noble metal carbonyls is reported by Manchot et al. (26) in an attempt to obtain a silver(I) carbonyl species in a solution of concentrated H_2SO_4. Subsequently the generation of Cu(I) and Ag(I) carbonyl cations in various strong protonic acids (27, 28) and the use of these solutions as carbonylation catalysts (29–31) are reported.

The conversion of fluorosulfate into fluoroantimonate(V) derivatives has been reported previously by us, and a number of unusual and highly electrophilic cations like I_2^+ or Br_2^+ (32), $(CH_3)_2Sn^{2+}$ (33), and, most recently, $[Au(CO)_2]^+$ (18) have been stabilized by SbF_6^-, $Sb_2F_{11}^-$, or $Sb_3F_{16}^-$.

An intriguing difference from transition metal carbonyls (1) is the relative ease of formation. Reaction temperatures are usually between 25 and 80°C and CO uptake from the gas phase by solutions or suspensions is accomplished with pressures of ~0.5 atm.

The unusual nature of the compounds discussed here extends to the starting material *cis*-$Pd(CO)_2(SO_3F)_2$. There are only two precedents of the type *cis*-$Pd(CO)_2R_2$ (R = C_6F_5 or C_6Cl_5) (34). Both are only moderately stable at −30°C in a CO atmosphere, while *cis*-$Pd(CO)_2(SO_3F)_2$ is thermally stable up to 117°C (22). Previously known binary metal carbonyl cations are octahedral and are of the $[M(CO)_6]^+$ type (M = Mn, Tc, or Re) (35) with a +1 complex charge. There do not appear to be any square-planar binary carbonyl species reported (1). Carbonyls of Pd and Pt of the type $M(CO)_n$ (n = 1–4) are obtainable by matrix isolation (36, 37) only.

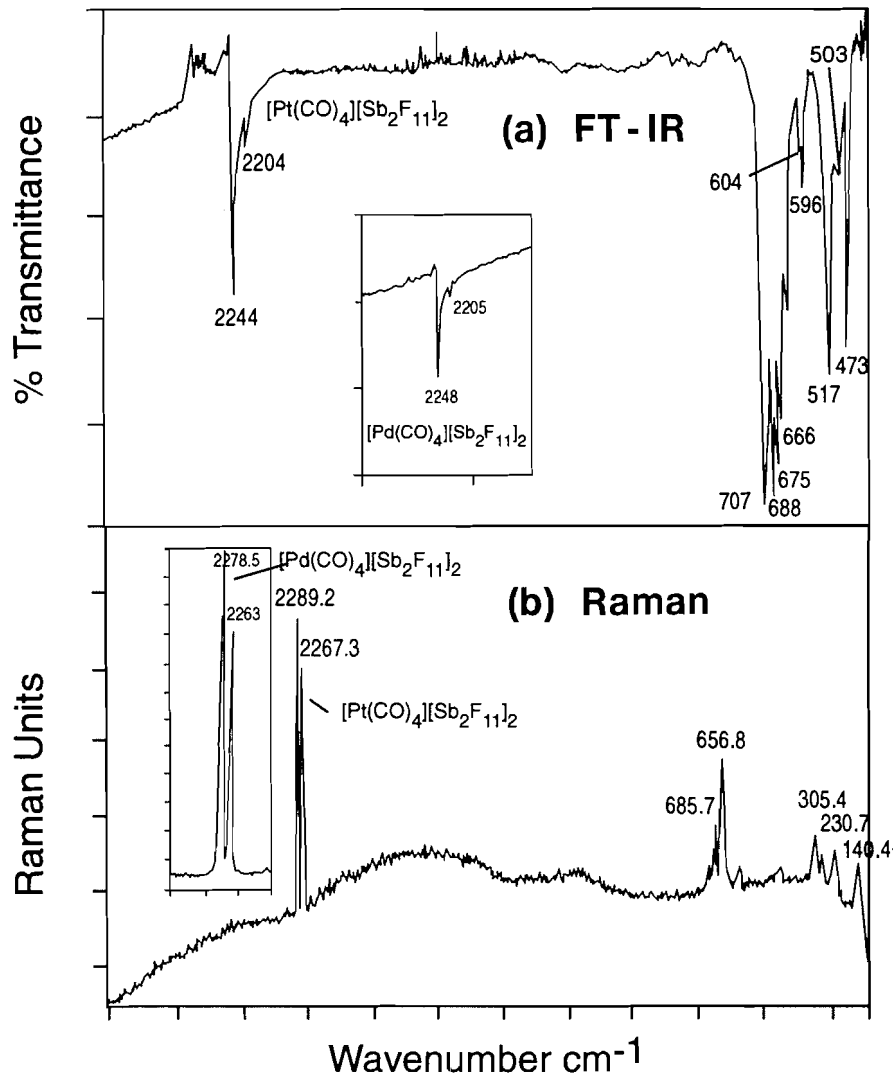

FIG. 1. Vibrational spectra of $[Pt(CO)_4][Sb_2F_{11}]_2$ and $[Pd(CO)_4][Sb_2F_{11}]_2$ (partial).

According to their vibrational spectra, the $M(CO)_4$ species appear to be tetrahedral (36, 37).

The relatively high thermal stability of $[Pd(CO)_4][Sb_2F_{11}]_2$ (to ~155°C), $[Pt(CO)_4][Sb_2F_{11}]_2$ (to ~200°C), and also of $[Au(CO)_2][Sb_2F_{11}]$ (to ~156°C) (18) is remarkable for another reason. Both $Ag(CO)B(OTeF_5)_4$ (14) and $Ag(CO)_2B(OTeF_5)_4$ (15) decompose with CO release below 25°C with formation of $AgB(OTeF_5)_4$ (14) and $AgB(OTeF_5)_4$. All three noble metal carbonyl fluoroantimonates undergo a more complex decomposition, which leads eventually to the formation of the corresponding metals rather than to a clean cleavage of CO.

It is not surprising that only $[Sb_2F_{11}]^-$ and, in the case of $[Pt(CO)_4]^{2+}$, the $[Pt(SO_3F)_6]^{2-}$ ion are capable of stabilizing the three binary carbonyl cations of the noble metals. Both anions rank, according to a scale based on ^{119}Sn Mössbauer spectroscopy (38), as the weakest nucleophiles. It is also not surprising that *cis*-$M(CO)_2(SO_3F)_2$ (M = Pd or Pt) are isolated from HSO_3F (22), even though the $[M(CO)_4]^{2+}_{(solv.)}$ cations are initially formed as indicated by the ^{13}C NMR spectra, in analogy to the $[Au(CO)_2]^+$–$Au(CO)SO_3F$ system (17, 18).

By far the most unusual aspect of the binary carbonyl cations of Pt(II) and Pd(II) are their vibrational spectra. The FT-IR and Raman spectra of $[Pt(CO)_4][Sb_2F_{11}]_2$ and the CO stretching range of $[Pd(CO)_4][Sb_2F_{11}]_2$ are shown in Fig. 1. Both compounds give identical vibrational spectra except for some small shifts in the CO stretching region and below 400 cm^{-1}. The band spacings make it obvious that the unusually high CO stretching modes cannot be the result of vibrational coupling as, for example, in BH_3CO (39).

The case for square-planar geometries for both cations rests on four observations: (*i*) the compounds are diamagnetic; (*ii*) the mutual exclusion rule is observed in the νCO range; (*iii*) vibrations due to $Sb_2F_{11}^-$ suggest the absence of significant covalent anion–cation interaction, and (*iv*) the bands in the CO stretching range display similar band positions and intensity patterns to those observed for CN vibrations of the isoelectronic anions $[Pd(CN)_4]^{2-}$ and $[Pt(CN)_4]^{2-}$ (21).

The CO stretching frequencies for $[Pd(CO)_4]^{2+}$ ($\nu_{avg.}$ = 2259 cm^{-1}) and $[Pt(CO)_4]^{2+}$ ($\nu_{avg.}$ = 2261 cm^{-1}) are unprecedentedly high, even when compared to those of $[Au(CO)_2]^+$ ($\nu_{avg.}$ = 2235.5 cm^{-1}) (18). The individual band positions are listed in Table 1 and are compared to those of related species. Also listed are stretching force constants obtained according to Jones (40), where vibrational spectra of the isotopomers are available (18, 21), or according to

[g] This work.

Cotton and Kraihanzel (41, 42), where this is not yet the case. There is generally a very good correspondence between both sets of force constants as small differences in stretching frequencies and stretching force constants found for $[Pt(CO)_4][Sb_2F_{11}]_2$ and $[Pt(CO)_4][Pt(SO_3F)_6]$ (20) are seemingly due to differences in anion basicity (38).

It appears from the data for the noble metal carbonyl derivatives collected in Table 1 that the synergic bonding model (1) cannot be invoked. CO stretching frequencies, which for terminally bonded carbonyl groups usually absorb between 2125 and 1850 cm^{-1}, below the value of 2143 cm^{-1} for CO (4), are now generally observed between 2200 and 2290 cm^{-1}. CO stretching force constants usually between 15 and 18×10^2 N m^{-1} are now in excess of 20 in the case of the binary carbonyl cations.

Judging by the force constant $f_r = 21.3 \times 10^2$ N m^{-1} calculated for HCO^+ (18), where π-backdonation is impossible, this process can only make an insignificant contribution to the bonding in noble metal carbonyl cations. As discussed for $[Au(CO)_2]^+$ (18), the ability of gold, platinum, and apparently also palladium to form strong covalent bonds to non-metals, possibly aided by relativistic effects (43) and polar contributions, is seen as an important factor in describing the bonding in this small but interesting group of cationic coordination complexes of CO with the noble metals.

Appendix

Experimental

The sources of the chemicals used in this study (22), the preparation and (or) purification of $S_2O_6F_2$, HSO_3F, and SbF_5 (18), the equipment used for reductive carbonylation reactions in HSO_3F (17, 22) or in a solid state – gas reaction (22), and our instrumentation to obtain vibrational spectra (18, 22) have all been reported and described very recently. The synthesis of the starting material *cis*-$Pt(CO)_2(SO_3F)_2$ from $Pt(SO_3F)_4$ (19) and of *cis*-$Pd(CO)_2(SO_3F)_2$ from $Pd(SO_3F)_3$ (23), is described elsewhere as well (22). The published synthesis of $[Au(CO)_2][Sb_2F_{11}]$ by solvolysis of $Au(CO)SO_3F$ in liquid SbF_5 (18) was adopted for the syntheses of $[Pd(CO)_4][Sb_2F_{11}]_2$ and $[Pt(CO)_4][Sb_2F_{11}]_2$.

Synthetic reactions

(a) $[Pd(CO_4)][Sb_2F_{11}]_2$

A sample of 184 mg (0.511 mmol) of $Pd(CO)_2(SO_3F)_2$, obtained by reductive carbonylation of $Pd(SO_3F)_3$ in HSO_3F and analyzed (calcd:C 6.66, S 17.78; found: C 6.67, S 17.97), was placed in a round-bottom flask and an excess of SbF_5 was added by distillation. After warming to room temperature, gaseous CO was admitted to the reactor and the pressure was adjusted to 0.6 atm of CO. The reactor was sealed off. The mixture was stirred and heated for 48 h at 60°C. In this time the colour of the mixture had changed from yellow to white. After removal of all volatiles, with the reactor first at 25 and later at 60°C, 581 mg (0.517 mmol) of a white solid was obtained. The weight and microanalysis confirmed the composition as $[Pd(CO)_4][Sb_2F_{11}]_2$ (Anal. calcd.: C 4.27; found: 4.41). The extremely hygroscopic solid is thermally stable to 140°C and melts on further heating at 155°C.

(b) $[Pt(CO)_4][Sb_2F_{11}]_2$

A sample of freshly prepared $Pt(CO)_2(SO_3F)_2$ (472 mg, 1.051 mmol) (Anal. calcd.: C 5.34, S 14.27; found: C 5.41, S 14.17) was placed in a round-bottom flask. After addition of an excess of SbF_5 (~10–15 g) by distillation, a clear viscous liquid formed. Previously dried CO was admitted to the reactor and a white solid film was seen forming on the surface of the liquid phase. The CO pressure was adjusted to 0.6 atm, and the stirred mixture was kept overnight at 80°C. During this time a white solid had formed. The total CO uptake determined by measuring the pressure in a vacuum line of known volume was 2.25 mmol. Removal of all volatiles yielded 1.296 g (1.069 mmol) of a hygroscopic white solid of the composition $[Pt(CO)_4][Sb_2F_{11}]_2$ (Anal. calcd.: C 3.96, F 34.48; found: C 4.05; 3.72; F 35.6). The solid was stable in a sealed capillary to about 200°C.

An analysis of vibronic coupling in the triplet absorption spectrum of pyrazine

GAD FISCHER

Department of Chemistry, The Faculties, Australian National University, Canberra 2601, Australia

Received January 18, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

GAD FISCHER. Can. J. Chem. **71**, 1537 (1993).

New measurements of the singlet–triplet ($\tilde{a}^3B_{3u} \leftarrow \tilde{X}^1A_g$) absorption spectra of pyrazine and pyrazine-d_4 at longer pathlengths and higher vapour pressures have been recorded. Particular attention was paid to the hot band region to the red of the electronic origin. The activities of the out-of-plane vibrations, ν_4 and ν_{10a}, were identified in sequence bands, and their triplet state vibrational frequencies were determined, 295 (276, -d_4) and 254 (194, -d_4) cm^{-1}, respectively. Model calculations were undertaken to match the observed singlet and triplet absorption and emission spectra for vibronic coupling induced by (*i*) $\nu_{10a}(b_{1g})$, and (*ii*) ν_4 and $\nu_5(b_{2g})$. The calculations allowed the ordering and the relative energies of the higher lying triplet states to be determined. The $^3B_{2u}$ and $^3B_{1u}$ electronic states are above the ground electronic state by about 3.9 and 4.4 eV, respectively. The ordering is in analogy with the corresponding singlet states but opposite to that predicted by most theoretical calculations.

GAD FISCHER. Can. J. Chem. **71**, 1537 (1993).

On a mesuré les spectres d'absorption singulet–triplet ($\tilde{a}^3B_{3u} \leftarrow \tilde{X}^1A_g$) de la pyrazine et de la pyrazine-d_4 à des longueurs d'onde plus grandes et à des tensions de vapeur plus élevées que celles utilisées jusqu'à maintenant. On a particulièrement fait attention à la région des bandes chaudes situées vers le rouge par rapport à l'origine électronique. On a identifié les activités des vibrations en dehors du plan, ν_4 et ν_{10a}, dans la séquence des bandes et on a déterminé les fréquences de leurs états vibrationnels triplets, respectivement 295 (276 pour le -d_4) et 254 (194 pour le -d_4). On a réalisé des calculs modèles pour comparer aux spectres d'absorption et d'émission triplet et singulet du couplage vibronique induit par (*i*) ν_{10a} (b_{1g}) et (*ii*) ν_4 et ν_5 (b_{2g}). Les calculs ont permis d'ordonner et de déterminer les énergies relatives des états triplets se trouvant à des niveaux élevés. Les niveaux des états électroniques $^3B_{2u}$ et $^3B_{1u}$ sont respectivement 3,9 et 4,4 eV au-dessus de l'état électronique fondamental. L'ordre est semblable à celui observé avec les états singulets correspondants; il est toutefois l'inverse de celui prédit par la plupart des calculs théoriques.

1. Introduction

For a number of molecules, the increase in our knowledge of their electronic states and vibrational frequencies makes it now possible to undertake more general modelling of their electronic spectra, and to achieve a better understanding of their intramolecular dynamics. Benzene and some of the azabenzenes fall in this category. The model calculations can be based on the vibronic and spin-orbit interactions involving the relevant singlet and triplet states. The ensuing theoretical results allow for a greater understanding of the sources of transition intensity, better identification of those vibrations vibronically active — even if they are not effective in inducing intensity, more secure assignments of vibrational frequencies, and more satisfactory descriptions of the radiationless decay paths.

Pyrazine, 1,4-diazabenzene, has been the subject of very considerable investigation. The lowest singlet system of pyrazine, $\tilde{A}\ ^1B_{3u} \leftrightarrow \tilde{X}\ ^1A_g$, has been very extensively studied, experimentally in absorption and emission, and also theoretically (1–17). It has served as a prototype for modelling vibronic coupling, and has been used as a test case illustrating the nature of the vibronic interactions (15, 16). In the theory of radiationless transitions pyrazine has served as the best known and most studied example of intermediate level structure (18–23). At energies corresponding to the low-lying vibrational levels of the first excited singlet state the triplet vibrational manifold is believed to be sparse. The singlet–triplet interactions are said to be in the strong coupling regime and are responsible for the non-exponential fluorescence decay.

Much less attention has been paid to the lowest triplet system (7, 8, 24–31). This is in part due to the greater experimental difficulties encountered in measuring the singlet–triplet absorption spectrum. However, this factor does not lessen the importance of gaining a full characterization of the lowest triplet state, since in addition to obtaining a more complete picture of pyrazine electronic spectroscopy, the triplet state is believed to play a key role in the scheme of radiationless transitions involving the first excited singlet state (18, 19). The singlet–triplet spectrum also allows for testing the applicability of the models of vibronic coupling developed for the singlet state. This is of particular relevance for pyrazine since the triplet has the same electron configuration as the lowest excited singlet state. Both are $n\pi^*$-type states of B_{3u} orbital symmetry. Because intensity must be induced by spin-orbit interaction, the vibronic coupling as a mechanism-inducing intensity in the singlet–triplet spectrum of pyrazine is not as explicit as it is for the singlet state transitions. Nevertheless, this must not be viewed as an argument against the occurrence of vibronic coupling. Indeed, theoretical calculations of the triplet state energies can be interpreted to indicate heightened vibronic coupling activity involving the b_{2g} modes because of a greatly decreased electronic state energy gap. Experimental evidence to this effect is obtained indirectly from phosphorescence spectra of pyrazine in mixed crystals at low temperatures (7, 8, 29). Progressions in the $b_{2g}(\nu_4)$ and $b_{1g}(\nu_{10a})$ modes are observed, an indication of vibronic activity and of large vibrational frequency changes. Furthermore, it should be noted that some experimental results, as for example those involving microwave-induced delayed phosphorescence, have been interpreted in terms of a triplet state distorted by pseudo Jahn–Teller vibronic coupling involving the lower frequency b_{2g} vibrational mode (25, 27).

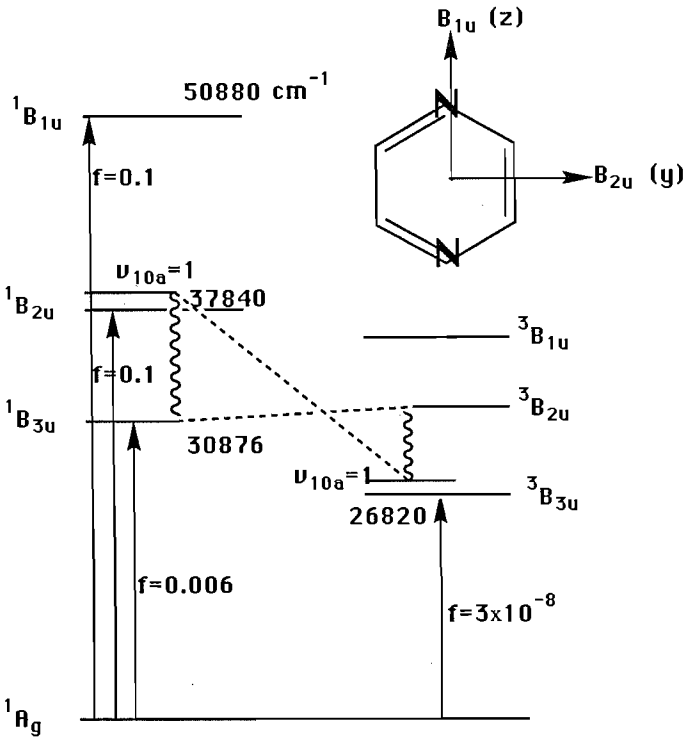

FIG. 1. Schematic representation of some of the low-lying pyrazine electronic states and delineation of the four-state model involving vibronic couplings via mode 10a, and spin-orbit interactions. The energies of the three singlet and the lowest triplet states were spectroscopically determined. The two higher triplet states are assigned according to this work. Oscillator strengths and state energies are taken from ref. 1.

In the singlet absorption spectrum, intensity is vibronically induced by both b_{1g} and b_{2g} vibrations. This is evident through the appearance in the vapour spectra of all three types of rotational contours (1). Most prominent are the allowed bands, which are type C (out-of-plane polarized), and type B (in-plane polarized).[1] The latter originate from Herzberg–Teller vibronic coupling involving the b_{1g} mode ν_{10a} with the $^1B_{2u}(\pi\pi^*)$ state some 7000 cm^{-1} to higher energy, see Fig. 1. The vibrational frequency is very considerably reduced in the excited state. It is one of the features that has focussed interest on the spectroscopy of pyrazine and that has stimulated much of the work on vibronic coupling models. Most of the frequency decrease of this vibration is attributed to vibronic coupling. Being the sole vibration of its symmetry type, no Duschinsky effect is induced by the coupling (32, 33). Vibronically induced bands, through coupling via b_{2g} modes with the $^1B_{1u}$ state removed some 20 000 cm^{-1}, are also weakly evident and are responsible for the type A rotational contours.

In modelling the vibronic coupling through the b_{1g} mode, ν_{10a}, for pyrazine and pyrazine-d_4 in the vapour and in a number of different host crystals, Chappell and Ross (14) obtained good agreement with experiment by making appropriate adjustment of the electronic energy intervals. In contrast, the other parameters in the vibronic coupling calculations, namely, the vibrational frequencies and the magnitudes of the vibronic coupling, were held constant throughout. Because of the close similarity of the lowest excited singlet and triplet states, the triplet state may be expected to provide a further testing ground for models of vibronic coupling developed for the singlet state. In particular, by employing the same input data as used in the singlet state calculations, consisting of the vibrational frequencies and coupling strengths, the triplet electronic states energy gap may be determined and compared to theoretical prediction.

The vibronically active modes are either not seen or are only weakly evident in the triplet spectra (24–31). However, information on the vibronic coupling can be obtained indirectly. One source is the vibrational frequency changes associated with the electronic excitation. Even in the absence of vibronically induced transition intensity, triplet state vibrational frequencies of vibronically active modes may be determined from sequence structure (hot bands) observed in the singlet–triplet absorption spectrum of the vapour, and from the identification of overtones.

Qualitatively, the singlet and triplet absorption spectra have much in common. The totally symmetric vibrations appear with similar relative intensities. The sequence bands deriving from the low-frequency out-of-plane vibrations also appear with similar intensities and frequencies. The isotope effect is the same, about 154 cm^{-1}. Only with respect to the appearance of the vibronically active modes are there any distinguishing features.

In this paper we report on new measurements of the absorption spectra. Particular emphasis has been placed on the hot band structure to the red of the electronic origins. It is there that sequence bands associated with vibronically active modes can be expected, and may be most readily identified. They are not subject to overlap by the more intense cold bands. It is the low-frequency out-of-plane modes that are expected to be the most vibronically active in the lowest excited singlet and triplet states (1). Their Boltzmann factors will not be too small, relative to the cold bands, to preclude observation.

In conjunction with the new experimental work a number of vibronic coupling calculations involving the lowest excited triplet state have been undertaken. The calculations include the following: (*a*) Extension of the model previously employed for the b_{1g} singlet state coupling (16) to a four-state problem involving the lowest singlet and triplet B_{3u} and B_{2u} states, where states of the same spin multiplicity are vibronically coupled by the sole b_{1g} mode, and states of different spin multiplicity are spin-orbit coupled. A four-state model was earlier proposed to explain the intensity distributions in progressions of the b_{1g} mode observed in phosphorescence and phosphorescence-excitation spectra (12). However, for the sole b_{1g} mode no consideration needed to be given to normal coordination rotation (the Duschinsky effect), and perturbation theory was satisfactorily used to account for the spin-orbit interaction. (*b*) Application and extension of the model to the four-state problem involving the $^3B_{3u}$, $^3B_{1u}$, $^1B_{3u}$, and $^1B_{1u}$ states through coupling by the two b_{2g} modes ν_4 and ν_5.

The new experimental results together with the vibronic coupling calculations undertaken have allowed a revision to be made of the vibrational frequencies in the singlet and triplet states, have suggested which modes are vibronically active in the triplet state, and have provided estimates of the locations of some of the higher lying triplet electronic states.

[1]Pyrazine is assumed a planar molecule belonging to the D_{2h} symmetry point group. The axis convention is depicted in Fig. 1.

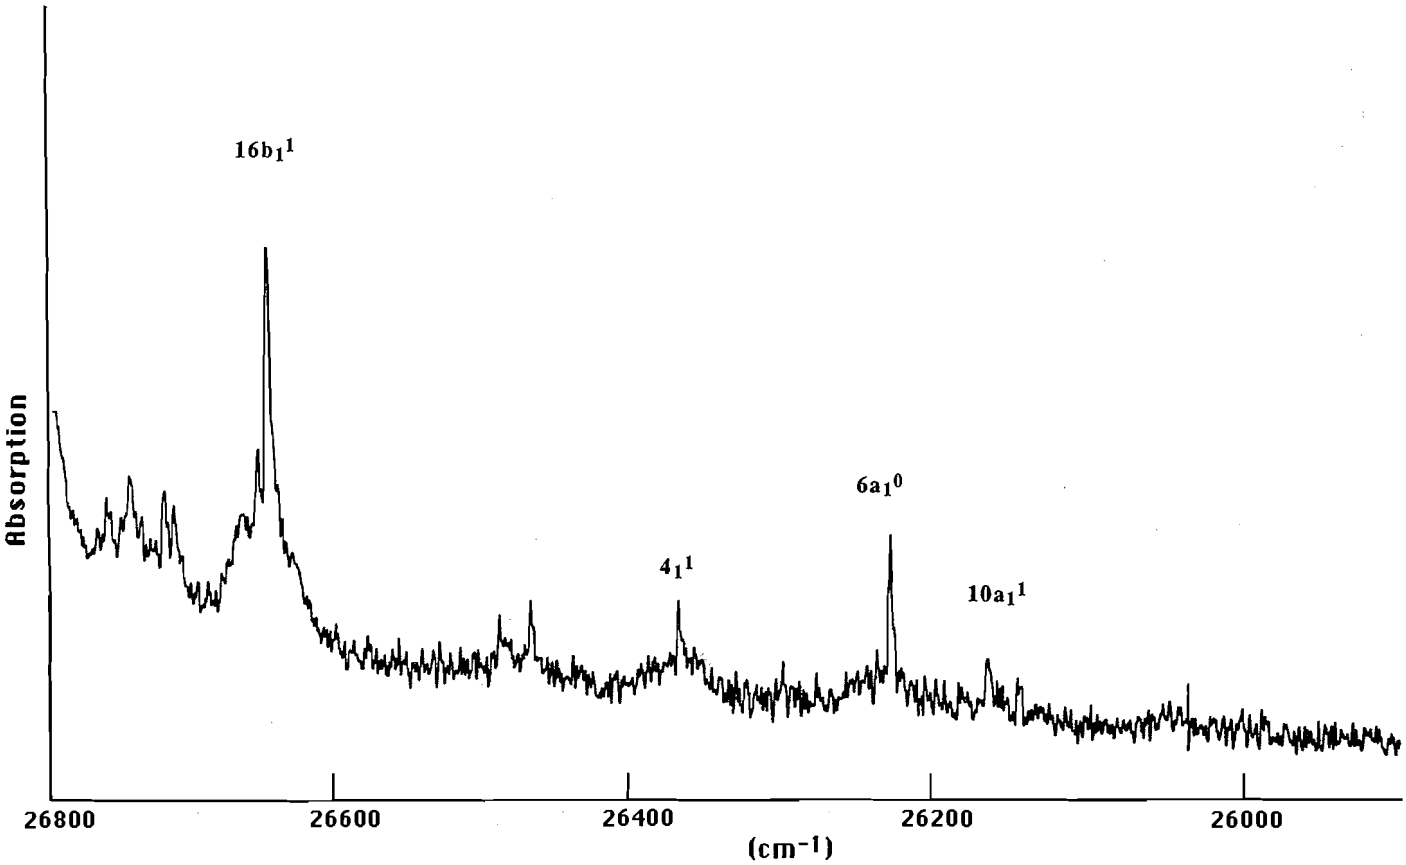

FIG. 2. Microdensitometer tracing of the singlet–triplet absorption spectrum of pyrazine vapour in the hot band region.

2. Experimental

A new series of singlet–triplet absorption spectra were recorded on a 3.4-m spectrograph, at higher vapour pressures and longer pathlengths, 264 m. A 6-m multiple-traversal cell with facilities for heating was used. Calibration was by the iron lines of an iron hollow-cathode lamp. Vapour pressures of about 7 Torr (1 Torr = 133.3 Pa) were used in all room-temperature measurements, and for the 40°C runs ambient pyrazine vapour pressures were used. The pyrazine and pyrazine-d_4 were commercially available (Aldrich) and were vacuum distilled prior to use. A mass spectrum of the deuterated sample showed the following: 93.7% -d_4, 5.5% -d_3, and 0.8% -d_2. Only one spurious band, namely the origin for pyrazine-hd_3, was identified in the pyrazine-d_4 spectra.

3. Results

The absorption spectra to the red of the electronic origins for pyrazine and pyrazine-d_4 are presented in Figs. 2 and 3, respectively, and lists of the bands and their proposed assignments are given in Table 1. Included in the table are the observed relative intensities taken from microdensitometer tracings of the photographically recorded spectra. They are compared with the relative spectral intensities calculated for the proposed assignments from approximate Franck–Condon factors[2] and from Boltzmann factors. It is seen that good agreement is achieved between the two in support of the proposed assignments. Further support for the assignments is obtained from the vibronic coupling calculations described in Sect. 5. The spectra are almost identical to the singlet absorption spectra in the same region, apart from the bands assigned 4_1^1 and $10a_1^1$.

4. Vibrational frequencies

For electronic transitions of the type encountered for the low-lying electronic states of the azines, that is, those involving the promotion of an electron from a nonbonding (n), or bonding (π) orbital to an antibonding orbital (π^*), most vibrational frequencies are reduced, although many only marginally. In addition, Herzberg–Teller vibronic coupling can induce substantial changes in the frequencies of the vibronically active modes. This is clearly the case for the b_{1g} mode ν_{10a} identified in the singlet absorption and fluorescence spectra. Much of the frequency decrease from 919 to 383 cm^{-1} can be attributed to vibronic coupling. In terms of a simple model of zero-order states chosen to correspond to the states hypothetically obtained in the absence of the vibronic interaction, an estimate of the reduction in vibrational frequency, δ, can be obtained from perturbation theory,

$$[1] \quad \delta = 2V^2/\Delta E$$

where V is the vibronic coupling matrix element and ΔE is the energy separation of the zero-order, non-interacting states. This result applies for the vibration ν_{10a} because it is the only vibration of symmetry b_{1g} and hence no Duschinsky rotation need be taken into consideration. Equation [1] gives the dependence of the vibrational frequency shift on the energy separation of the vibronically coupled states.

There are six other out-of-plane vibrations, two of each symmetry type, b_{2g}, b_{3u}, and a_u. Also for these it is possible

[2]The appropriate Franck–Condon factors have been taken from unpublished tables (J. Christie).

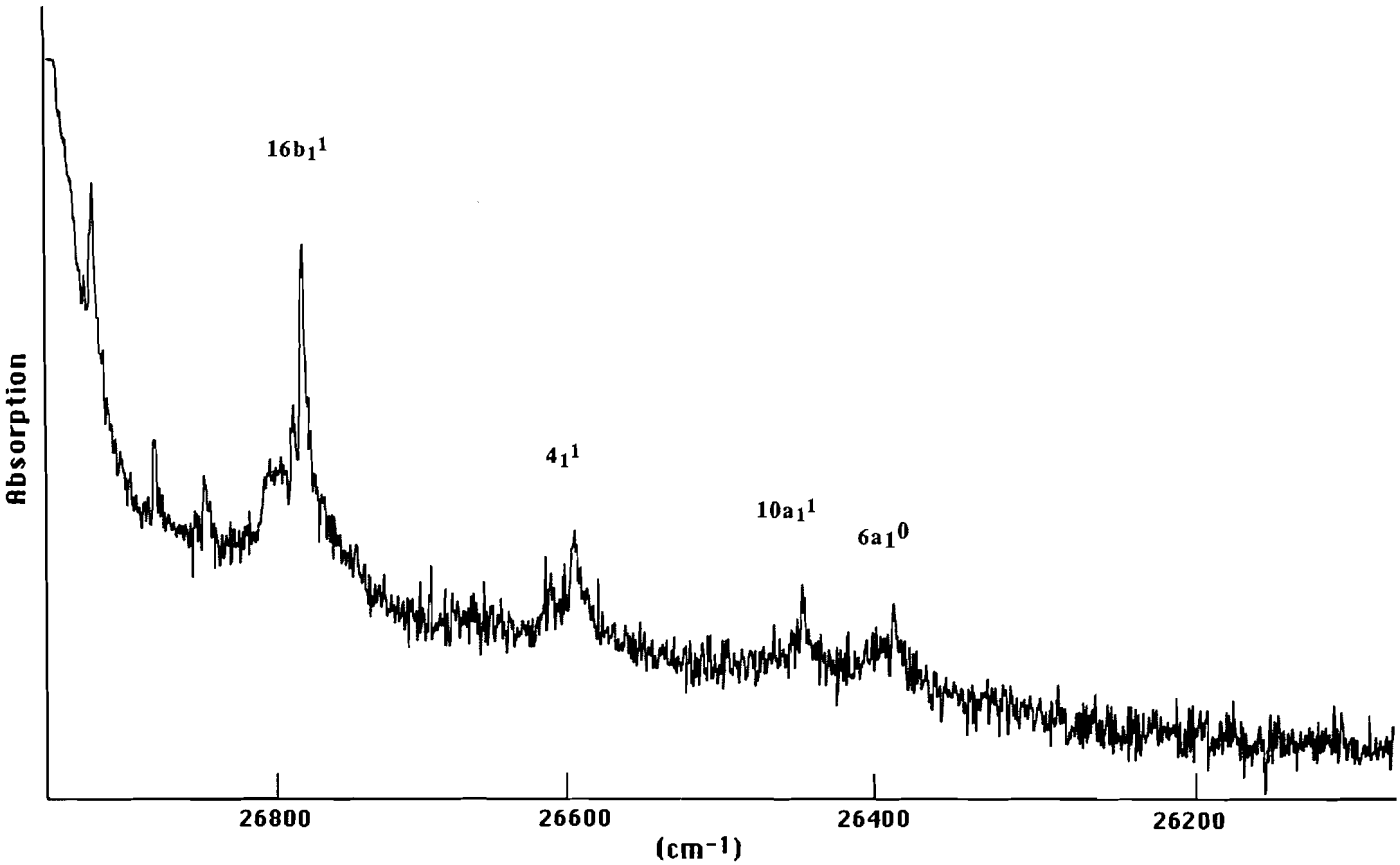

FIG. 3. Microdensitometer tracing of the singlet–triplet absorption spectrum of pyrazine-d_4 vapour in the hot band region.

to provide approximate estimates of the changes in vibrational frequencies in terms of the vibronic coupling. Because of the occurrence of a vibronically induced Duschinsky rotation, eq. [1] does not apply here. However, using a simple two-state model it can be shown (33) that for the case of two vibronically active modes of the same symmetry, the excited state frequencies relative to the ground state frequencies are approximately given by

$$[2] \quad \nu_a' = \nu_a'' - 2V_a^2/\Delta E + 4V_a^2V_b^2/\Delta E^2\Delta E_{ab}$$
$$\nu_b' = \nu_b'' - 2V_b^2/\Delta E - 4V_a^2V_b^2/\Delta E^2\Delta E_{ab}$$

where ν_a' is the larger of ν_a' and ν_b', and $\Delta E_{ab} = (\nu_a'' - \nu_b'')$.

It is clear from eqs. [1] and [2] that the frequency changes of all those vibrations vibronically active, but not necessarily inducing transition intensity, depend on the separations of the coupled states. Even under the assumption that the vibronic coupling strengths are the same for the lowest excited singlet and triplet states of pyrazine — it should be recalled that both are of the same electron configuration — the vibrational frequencies of the vibronically active modes may nevertheless differ because of differing electronic state energy gaps.

A number of calculations of the electronic state energies of pyrazine have been reported. Among the most recent are the electronic state locations as computed by Walker and Palmer (34) and listed in Table 2. It can be seen that for the relatively low-lying electronic states of pyrazine, the singlet–triplet splittings for states of the same electron configurations are small, less than 1 eV, and for many only ~0.1 eV. The $^{1,3}B_{1u}$ splitting is an exception. Thus, for example, the lowest excited singlet and triplet states, $^{1,3}B_{3u}(n\pi^*)$, are calculated to be separated by ~0.6 eV. The experimentally observed value is ~0.5 eV. However, for the $^{1,3}B_{1u}(\pi\pi^*)$ states this splitting is very much larger, estimated to be in the range 3–4 eV, although our vibronic coupling calculations show it to be much less.

It follows that a consideration of the electronic state energy gaps can provide information on the singlet and triplet state vibrational frequencies relative to the ground electronic state. Or the converse, a consideration of the vibrational frequencies in the excited states can provide estimates of the relative singlet and triplet state separations. Thus, for example, a cursory inspection of Table 2 reveals that for the case that the two b_{3u} modes are effective in coupling the $B_{3u}(n\pi^*)$ and $A_g(\pi\pi^*)$ states, the vibrations may be expected to have similar frequency reductions in both the excited singlet and triplet states. The calculated separations of the singlet states and of the triplet states are approximately the same. The frequencies of ν_{16b} in the excited states are in complete accord with this conclusion, Table 3. They are approximately the same in singlet and triplet excited states. Furthermore, because the frequencies are the same, it is possible to conclude that significant vibronic coupling of the $^1B_{3u}$ with the ground electronic state can be excluded. The excited state frequencies of ν_{11}, the other b_{3u} mode, have not been sufficiently well assigned to permit comment.

The opposite conclusions are reached for the two b_{2g} modes. They vibronically couple the lowest excited $B_{3u}(n\pi^*)$ states with the higher lying $B_{1u}(\pi\pi^*)$ states, Fig. 1. How-

ever, the measured energy separation between the two singlet states (2.5 eV) is much larger than the calculated energy separation between the two triplet states (0.7 eV). Hence, in accordance with eq. [2], the vibrational frequencies for the b_{2g} modes can be expected to be substantially different in the singlet and triplet states. A similar situation applies for the b_{1g} mode, ν_{10a}. It is the vibration effective in coupling the $B_{3u}(n\pi^*)$ and $B_{2u}(\pi\pi^*)$ states. The state separations, according to the computed values of Walker and Palmer listed in Table 2, vary significantly between the singlet (0.9 eV) and triplet manifolds (1.4 eV).

It will be seen in the following section that the locations of the B_{2u} and B_{1u} triplet states obtained in this work differ markedly from the calculated positions of Table 2. In fact, our vibronic coupling calculations give good agreement if the $^3B_{1u}$ and $^3B_{2u}$ assignments in the electron energy-loss spectra of Walker and Palmer are reversed. Nevertheless, even with the revised assignments, the relevant singlet and triplet state separations still differ, supporting the observation of different vibrational frequencies for modes 4, 5, and 10a in the singlet and triplet excited states.

The vibrational frequencies for the totally symmetric and the out-of-plane modes, for the ground and first excited singlet and triplet states, are listed in Table 3. These particular symmetry representations have been included because they contain the majority of the vibrations active in the spectra, and accordingly are the ones that have experienced frequency changes and possibly normal coordinate displacements in the case of the a_g modes. The 12 non-totally symmetric, in-plane modes have been omitted from the table. They were not identified in the absorption and emission spectra, although one, mode 6b, was tentatively identified as a sequence band.

For the a_g modes the ratio of frequencies for the two isotopes $(\nu_i)_h/(\nu_i)_d$, measured (1.98) and calculated from the product rule (2.0), are in excellent agreement for the ground electronic state. For the singlet and triplet excited states, it was assumed that the frequencies of the C—H (C—D) stretching mode have not changed significantly from their ground state values. This assumption is in accord with the very localized nature of these vibrations, and has subsequently allowed the product rule to be employed for the de-

termination of the frequency of ν_{8a} for pyrazine-d_4 in the first excited singlet state. Bands at 1234 and 1265 cm^{-1} have been assigned to the vibration 8a in the triplet state spectra of pyrazine-h_4 and -d_4, respectively, although a possible Fermi resonance between 8a (1234 cm^{-1}) and $6a^2$(1221 cm^{-1}) may have perturbed the former. No band in the singlet absorption spectrum of pyrazine-d_4 has been assigned to ν_{8a}.

Formally, the b_{1g} and b_{2g} out-of-plane modes can vibronically couple the $B_{3u}(n\pi^*)$ state with the $B_{2u}(\pi\pi^*)$ and $B_{1u}(\pi\pi^*)$ states, respectively. Transitions to these $\pi\pi^*$ states in the singlet manifold are electric-dipole allowed from the ground state. Intensity is induced by this means and several of the out-of-plane vibrations were identified in the singlet absorption and fluorescence spectra. Although vibronic coupling undoubtedly occurs in the triplet manifold, it is the spin-orbit coupling mechanism that induces intensity in the singlet–triplet absorption and emission spectra. Consequently, it is not surprising that no positive identification of single quanta of these out-of-plane modes was made in the singlet–triplet absorption spectra (24, 26). Highly tentative assignments have been made in the singlet–triplet excitation spectra of pyrazine in mixed crystals at low temperatures (29). The frequencies of the vibrations 16a and 16b are based on the observed sequence and overtone bands. In the table the frequencies entered for the b_{1g} and b_{2g} modes in the triplet state were determined solely from the sequence bands.

The major revision from earlier assignments concerns the b_{2g} modes 4 and 5. A detailed four-state vibronic coupling calculation involving these modes is described later. Suffice it here to point out a general observation. If two modes of the same symmetry are active in vibronic coupling, then, because of the induced Duschinsky rotation, there is a tendency for the vibration of lower frequency to induce greater intensity in the excited state relative to its activity in the ground state. This is a consequence of the generally greater energy separation for ground state coupling than for excited state coupling. Spectra depicting this have been recorded for a number of molecules (36). Hence it follows that the frequency of 517 cm^{-1} (-d_4, 463) observed in the absorption spectrum, $^1B_{3u} \leftarrow {}^1A_g$, must be assigned to $\nu_{4'}$ and not $\nu_{5'}$ as was previously done. In the ground state the corresponding frequency is 756 cm^{-1} (-d_4, 651), and $\nu_{5''}$ is 983 cm^{-1} (-d_4, 860), in accordance with the assignments proposed by Innes, Ross, and Moomaw (1).

A similar "Duschinsky type" argument, invoking eqs. [2], is proposed to suggest that the frequency of ν_{17a} in the singlet state cannot have decreased substantially from its ground state value. For the two a_u modes, 16a and 17a, the opposite situation applies. Ground state coupling is more significant than excited state coupling. It is one of the exceptional cases where the roles of the two radiatively coupled states are reversed, leading to greater excited state than ground state frequencies for 16a and possibly also 17a.

5. Vibronic coupling calculations

In a comparison of the singlet–singlet and singlet–triplet spectra, and in the context of vibronic coupling, it is the vibrations of b_{1g} and b_{2g} symmetries that are of most interest. Progressions of these vibrations are evident in the absorption and emission spectra. Numerous models have been proposed to represent the coupling induced by the single b_{1g} mode. Some have included totally symmetric vibrations to act as tuning modes. No such, or similar, calculations have been carried out for the b_{2g} modes, although their activity has been unambiguously noted in the fluorescence and phosphorescence spectra. In the singlet–triplet absorption and emission spectra the two b_{2g} vibrations, where identified, appear with little relative intensity. But theoretically, because of the much smaller electronic energy separation in the triplet manifold, the two vibrations are expected to be involved in very significant vibronic coupling, despite the fact that they fail to induce measurable amounts of intensity in the singlet–triplet spectra. In the following a detailed description is given of the vibronic coupling calculations undertaken for (*a*) the b_{1g} mode (10a), and (*b*) the b_{2g} modes (4 and 5).

(a) b_{1g} *Mode*

Very considerable effort has been devoted to the modelling of the activity of the b_{1g} mode, 10a, in the singlet absorption and emission spectra. In this work, the model is extended to a four-level system of singlet and triplet B_{3u}, and singlet and triplet B_{2u} states coupled by vibronic and spin-orbit interactions. The vibronic interactions are restricted to linear terms ($\Delta v = \pm 1$), and only spin-orbit interactions between $n\pi^*$ and $\pi\pi^*$ states are included. Spin-orbit interactions between like states are excluded on symmetry grounds. A schematic representation of the interacting states is depicted in Fig. 1. The two interaction pathways involve comparable matrix elements and energy denominators and thus may be expected to be of the same overall magnitude. Hence, interference between the two intensity-inducing pathways can be expected to occur. Just as in the calculations of Siebrand and Zgierski (12) for the b_{1g} mode, so here the interference may be expected to cause different intensity patterns in the vibrational progressions of the vibronically active modes in the singlet–triplet absorption and emission spectra. However, this point was not investigated in the current work.

In this study the zero-order description is to be interpreted as corresponding to the energies and wavefunctions of the vibronic levels in the absence of the vibronic and spin-orbit interactions. The calculations are undertaken for both pyrazine-d_0 and -d_4. The input parameters listed in Table 4 are for each isotope, respectively: the vibrational frequency of ν_{10a}, the vibronic coupling strength, the spin-orbit interactions, and the electronic state energy separations. The different spin sublevels are assumed to be orthogonal. In the calculations one set of input parameters was used for each isotopic species. In particular, this meant that the same zero-order vibrational frequency and vibronic coupling strength were used for both the singlet and triplet states. Furthermore, the vibrational frequencies and coupling strengths for the two isotopic species have been constrained to conform with the Teller–Redlich product rule (37) and with Herzberg-Teller theory (36). Of the electronic state separations only one, namely $E_{t't}$ (where s',t' and s,t refer to the upper and lower singlet and triplet states, respectively, here $^{1,3}B_{2u}$ and $^{1,3}B_{3u}$), was not previously directly, experimentally determined. It is used as a parameter to achieve agreement with the observed singlet–triplet absorption spectra. Apart from the spin-orbit coupling strength and the separation of the triplet states, the input parameters were taken almost without change from previous calculations of Chappell and Ross (14) carried out for the singlet state vibronic coupling.

The calculated results are presented in Table 5. The observed frequencies of ν_{10a} in the triplet state listed in the table were determined from the assigned sequence bands in the absorption spectra. In view of the fact that for each isotope agreement is sought between the calculated results, which depend essentially on five input parameters, and the observed results, consisting of the energies of the first three vibrational quanta in the excited singlet state, one or more vibrational quanta in the triplet state, and two state energy separations (ΔE_{st} and $\Delta E_{s't}$), the calculations may be seen as unique. Furthermore, whereas two different sets of observed results are included for the two isotopes, the input parameters for the two isotopes are not independent. The vibrational frequencies are related by the product rule

$$\frac{\nu_{10a}(d)}{\nu_{10a}(h)} = \sqrt{\left(\frac{m_h I_z(d)}{m_d I_z(h)}\right)}$$

where the I_z are the moments of inertia about the z axis, and the m the masses of the isotopic molecules; and the vibronic coupling strengths are related by Herzberg–Teller theory (36)

$$\frac{V_h}{V_d} = \sqrt{\left(\frac{\nu_{10a}(h)}{\nu_{10a}(d)}\right)}$$

Very good overall agreement is achieved for both isotopes when the $^3B_{2u}$ states are located some 4600 cm^{-1} above the lowest triplet states. This is considerably less than the 10 000 cm^{-1} or more obtained in the majority of theoretical determinations of the electronic state energies, but it does agree with the location of a triplet state seen in the electron energy-loss spectrum (34).

The magnitude of the spin-orbit interaction was chosen by comparison of the calculated emission intensity of the transition in which one quantum of ν_{10a} is excited in the ground state with the observed intensity of this transition in the phosphorescence in mixed crystals of pyrazine in benzene (8). The experimentally measured oscillator strengths (1) for the various singlet–singlet and singlet–triplet absorptions are marked in Fig. 1. From the observed band heights in the phosphorescence spectrum (8) the oscillator strength for the transition $10a_1^0$ was estimated to be about 5×10^{-10}. The oscillator strength of the origin band in absorption has been measured to be 1.4×10^{-8} (26). For a spin-orbit coupling strength of 4 cm^{-1} a calculated oscillator strength equiva-

lent to that observed is obtained. Because of the relatively large errors associated with the estimates of the oscillator strengths, no allowance was made for the fact that the observed results referred to both vapour and mixed crystal. Furthermore, the comparison drawn between the calculated and observed results is deemed valid since it was shown through dynamic studies of microwave-induced delayed phosphorescence that the phosphorescence is very largely polarized $B_{1u}(z)$ (Fig. 1), and that the radiative rate is very much larger than the radiationless rate (30). It was also shown that the radiative rates for phosphorescence polarized along the other two axes are some one to two orders of magnitude smaller, but nevertheless much larger than the radiationless rates. Hence in the comparison with the phosphorescence, the radiationless transitions may be ignored in the model calculations. As a general point, it should be added that the calculated energies of the vibrational levels are not very sensitive to the magnitude of the spin-orbit interaction for values in the range of 4 cm^{-1}, and hence the magnitude of the spin-orbit interaction is not a critical factor insofar as the assignment of ν_{10a} and the location of the higher triplet state are concerned.

In vibronic coupling calculations of this type convergence of results with the number of zero-order states included in the calculation is always a problem. Here, the seriousness of the problem was checked by comparing the results of calculations for the cases where the maximum number of quanta was limited to 30 and 40. For the levels of concern to this study, and these include the low-lying vibrational levels of all four electronic states, convergence in energies was to better than 0.1 cm^{-1}.

(b) b_{2g} *Modes*

The activity of b_{2g} modes in the phosphorescence spectra has been experimentally observed. In the low-temperature phosphorescence spectra of pyrazine (and pyrazine-d_4) in the various hosts benzene, *p*-dioxane, and pyrazine (pyrazine-d_4), progressions in a ground state vibration with frequency of about 756 cm^{-1} (-d_4, 651) were noted (8, 29). According to the recent review of azine spectroscopy (1) the correct assignment is to the lower of the two frequencies of the b_{2g} modes, that is ν_4''. A relatively weaker band, particularly noticeable in the spectrum of pyrazine-d_4 in dioxane at 1.3 K, was assigned to ν_5''. Its frequency is 839 cm^{-1} (-h_4, 980). In the singlet–triplet absorption and phosphorescence-excitation spectra, no similar progressions involving ν_4' or ν_5' have been identified.

In the singlet absorption spectrum of pyrazine vapour, $^1B_{3u} \leftarrow {}^1A_g$, a progression in a 517 cm^{-1} frequency is evident. It is assigned as ν_4'. Analysis of the fluorescence obtained following SVL (single vibronic level) excitation of the bands at $0^0 + 517$ and at $0^0 + (2 \times 517)$ cm^{-1} indicate that in the ground state ν_4'' is 756 cm^{-1} (3). Of particular interest is the appearance of a band at $0_0 + 972$ cm^{-1} in the fluorescence following excitation of the former band. It is in approximate agreement with the ground state vibrational frequency of ν_5'', and suggests that, in accordance with theory, there is a rotation of the normal coordinate space of the b_{2g} modes upon electronic excitation. That is

$$[3] \quad Q_4' = cQ_4'' + dQ_5''$$

where the Q' and Q'' are the normal coordinates in the excited and ground states, respectively, and c and d are constants, such that $c^2 + d^2 = 1$.

The occurrence of odd members in the vibrational progressions of the b_{2g} modes in the phosphorescence spectra requires vibronic as well as spin-orbit coupling. In parallel with the model previously proposed for the b_{1g}-induced vibronic coupling, two equivalent routes are available: vibronic coupling between the two triplet states, $T_1(B_{3u})$ and $T_3(B_{1u})$, and with spin-orbit coupling between T_3 and $S_1(B_{3u})$; or spin-orbit coupling between T_1 and $S_3(B_{1u})$ and with vibronic coupling between the singlet states S_3 and S_1. A four-level model that incorporates these states and interactions is set up, but now includes two vibrational modes and not one as in the previous b_{1g} case. The vibronic coupling is induced by the two b_{2g} modes ν_4 and ν_5. A further important difference from the previous calculations concerns the very much larger energy separation of the two singlet states. It is about 20 000 cm^{-1} as compared to 7000 cm^{-1}. Finally, it should be noted that in distinction to the b_{1g} mode activity where normal coordinate rotation is absent since there is only one vibration of that symmetry representation, the normal coordinate rotation is of consequence for the b_{2g} modes. The Duschinsky effect contributes to asymmetry in the absorption and emission spectra, see above eq. [3], and must be included in the calculations. In our four-state and two-vibrational-mode model, it is automatically included.

The input parameters for the calculations are listed in Table 6, and the calculated and experimentally measured frequencies are presented in Table 7. In parallel with the approach used for the b_{1g} calculations, the same set of vibrational frequencies and coupling strengths was used for both singlet and triplet states. The requirements of conformity with the product rule and with Herzberg–Teller theory have imposed further restrictions on the choice of parameters for the two isotopes. Essentially, only five of the input parameters were allowed to be varied. They comprised the two vibrational frequencies, the two vibronic coupling strengths, and the triplet states (T_3–T_1) energy gap.

The magnitude of the spin-orbit interaction governs the intensities of the origin and the totally symmetric vibrational bands in the triplet absorption spectra, since it has been shown that these bands acquired their intensity by direct spin-orbit coupling with singlet state(s) of B_{1u} symmetry (30). It is assumed in these calculations that only S_3 is involved, solely on the basis that other B_{1u} states are energetically further removed. In consequence, very narrow limits can be

placed on the range of values for V_{so}. It was found that V_{so} must lie in the range 5–15 cm^{-1} and, in analogy with the previous set of calculations carried out for ν_{10a}, that the calculated vibrational frequencies are insensitive to variations of V_{so} in this range. The best agreement with the measured intensity of the singlet–triplet absorption spectrum was obtained for a spin-orbit coupling of about 10 cm^{-1}.

The two energy gaps E_{st} (S_1–T_1) and $E_{s't}$ (S_3–T_1) are also known. The locations of the triplet and the two singlet states have been experimentally measured. The final choice of input parameters, Table 6, was obtained through comparison of the calculated and observed spectra. In particular, good agreement was sought with the frequencies of ν_4 in the singlet and triplet absorption spectra. Also, qualitative agreement was required with the relative intensities induced by the two b_{2g} modes, Table 8. The calculations show that in absorption the intensity ratios $I(4_0^1)/I(5_0^1)$ are so large that the bands 5_0^1 are accordingly weak and are not expected to be readily seen. On the other hand, in emission the ratios are much smaller. Some weak bands do appear in fluorescence (3) at frequencies corresponding to ν_5''. Their intensities relative to 4_1^0 are in agreement with the calculated ratios. The calculated results of Table 8 clearly illustrate the lack of mirror symmetry between the absorption and emission spectra.

In the calculation the maximum number of combined quanta for the two vibrations in each of the four electronic states was limited to 16. This resulted in two matrices of size 272 × 272. This ensured that for the low-lying vibrational states in each of the electronic states, convergence in their energies to better than 0.1 cm^{-1} was achieved.

In recent model calculations on the vibronic activity of the b_{1g} mode, some of the totally symmetric vibrations were included. Through this approach it was possible to reproduce some of the anomalies in the frequencies and intensities of those transitions involving the totally symmetric vibrations. Totally symmetric modes were not included in the calculation here. As the model already contains a large number of parameters it was argued that no justification existed to introduce further parameters by the inclusion of some of the totally symmetric modes, particularly since the number of relevant experimental observations is so limited.

Other alternative assignments of the hot bands, Fig. 2, were considered. In one, the case where the assignments of the $b_{1g}(\nu_{10a})$ and $b_{2g}(\nu_4)$ modes are interchanged was considered. To satisfy this alternative, the measured triplet state frequencies of ν_4 are required to be 91 and 120 cm^{-1} for pyrazine-h_4 and -d_4, respectively. As a general rule the vibrational frequency of the protonated species is expected to be larger than that of the deuterated species, suggesting that this alternative assignment for ν_4 cannot be correct. To check this conclusion further, calculations were undertaken in an attempt to match the totality of these triplet and the excited singlet state frequencies. No calculations were able to give

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

complete agreement, thus excluding this alternative assignment for the b_{1g} and b_{2g} modes in the triplet state.

6. Densities of states

The high-resolution studies on the $^1B_{3u}$–^1A_g fluorescence excitation spectrum of pyrazine allowed an estimate to be made of the density of triplet states in the region of the origin band (18). The estimate was considerably higher than the density of states calculated on the basis of the vibrational frequencies. However, because ground state frequencies were used for those vibrations whose excited state frequencies were unknown, it was argued that the calculated value must be viewed as an underestimate since, in general, excited state frequencies are less than their ground state counterparts. The assignments in this work of ν_4 and ν_{10a} in the triplet state to vibrations with very reduced frequencies relative to both the ground and excited singlet states has posed the question whether the incorporation of these frequencies in the calculation of the densities of states may lead to much better agreement with the density of states estimated from the counting of lines in the high-resolution spectra.

Using the Haarhoff approach (38), it was found that whereas the density of states at an excess energy above the triplet state of 4056 cm^{-1} is 26 cm using the ground state vibrational frequencies, it is almost an order of magnitude larger, 193 cm, when those of the triplet state frequencies that have been determined, and are listed in Table 3, are used to replace the corresponding ground state frequencies. In particular, this bears on ν_4 and ν_{10a}. The density of states value is larger than that determined in previous calculations and may go part of the way to providing an explanation for the discrepancy between the two different approaches to the estimation of the density of states. Furthermore, it should be noted that no allowance was made for anharmonicity in arriving at these estimates, that the anharmonicity may be very significant for the low-frequency vibrations, and that therefore the calculated density of states should be even larger. For the low-frequency vibrations large numbers of quanta may be involved. Thus, for example, for the vibrations ν_{10a} and ν_4 some 16 and 14 harmonic quanta, respectively, are required to match the triplet–singlet energy gap.

7. Isotope effect

It is of some interest to examine the individual contributions that the vibrations make to the overall measured isotope effect of about 154 cm^{-1} in both the singlet and triplet absorption spectra.

The isotope effect, Δ, is defined as the difference in transition frequencies for transitions between the vibrationless levels of the same two electronic states for two isotopic species,

$$[4] \quad \Delta = [\nu_0 + \tfrac{1}{2}\Sigma(\nu'_d - \nu''_d)] - [\nu_0 + \tfrac{1}{2}\Sigma(\nu'_h - \nu''_h)]$$

where the summations are over all the vibrations (ν' upper state and ν'' lower state), the subscripts h and d refer respectively to pyrazine-h_4 and -d_4, and ν_0 is the frequency separation between the minima of the two potential surfaces.

For the case of the one b_{1g} mode, one obtains by substitution

$$[5] \quad \Delta(b_{1g}) = \tfrac{1}{2}[\nu''_h(1 - R'') - \nu'_h(1 - R')]$$

where R' and R'' are the ratios of the vibrational frequencies, ν_d/ν_h, in the excited and ground states respectively. Now for the b_{1g} mode, the calculated values R' (0.7812) and R'' (0.7610) are almost the same. Assuming that they are the same and equal to R, the isotope effect is then given by

$$[6] \quad \Delta(b_{1g}) = \frac{\delta(h)}{2}(1 - R)$$

where $\delta(h)$ is defined as the decrease in frequency of the -h_4 isotope, $\delta(h) = \nu''_h - \nu'_h$. Substituting eq. [1] for the frequency decrease determined by perturbation theory, one obtains a relation between the isotope effect and the vibronic coupling strength,

$$[7] \quad \Delta(b_{1g}) = \frac{V^2}{\Delta E}(1 - R)$$

This shows that, provided the major part of the vibrational frequency reduction derives from vibronic coupling, eq. [7] holds and the isotope effect is inversely proportional to the energy separation of the coupled electronic states. For mode 10a this is the case. The isotope effect increases from 54 cm^{-1} for the singlet state absorption to 69 cm^{-1} for the triplet state absorption. There is a similar increase for mode 4 (26 to 43 cm^{-1}), although because there are two b_{2g} modes, eq. [7] does not apply for it.

It should be noted that modes 4 and 10a contribute 112 cm^{-1} to the isotope effect in triplet state absorption as compared to 80 cm^{-1} for singlet state absorption, out of a total isotope effect of about 154 cm^{-1}. This difference of 32 cm^{-1} must be accounted for by other vibrations. In this respect at least, the lowest excited singlet and triplet states do differ. However, since only a few of the triplet state vibrational frequencies are known, it is not possible at this time to identify the vibrations, nor is it possible to use the isotope effects to determine other instances of large vibronically induced frequency reductions. One vibration that may possibly qualify in this context is ν_{6b}.

8. Conclusions

The majority of theoretical calculations carried out over the past decade or two on electronic state energies of the singlet and triplet states of pyrazine have indicated significant variations in the energy separations of some singlet and triplet states of the same electronic configurations. Insofar as the relative vibronic coupling activity in the singlet and triplet electronic state manifolds is concerned, this is predicted to have some important ramifications. In particular, the b_{2g} modes are expected to be more vibronically active in the triplet ($^3B_{3u}$–^1A_g) than singlet ($^1B_{3u}$–^1A_g) state transitions because of reduced electronic state energy gaps. Analyses of the triplet absorption spectra in the hot band regions to the red of the electronic origins, for pyrazine and pyrazine-d_4 vapour, combined with vibronic coupling calculations support the prediction. The vibrational frequencies of ν_4 for pyrazine-h_4 and -d_4 in the triplet state have been determined, as well as the approximate location of the $^3B_{1u}$ state. The frequencies are less than in the excited singlet state, an indication of increased vibronic coupling resulting from the smaller energy gap.

On the other hand, the location of the $^3B_{2u}$ state following from the assignment of ν_{10a} in the triplet absorption spectra and from vibronic coupling calculations, is not in agreement with the theoretical calculations. The state lies below the $^3B_{1u}$ state, in complete analogy with the singlet state or-

For personal use only.

dering. Furthermore, the triplet state energy gap ($^3B_{2u}$–$^3B_{3u}$), is smaller than the corresponding singlet state gap, a fact that is also in contradiction to the theoretical calculations. Of the three triplet states under discussion in this work only the $^3B_{3u}$ state lies below the $^1B_{3u}$ state in pyrazine vapour; both the $^3B_{2u}$ and $^3B_{1u}$ states are at higher energies.

Insofar as the calculated density of states at an energy corresponding to the vibrationless level of the $^1B_{3u}$ is concerned, the discrepancy with the observed value remains, but it is reduced because of the significantly smaller frequencies for ν_4 and ν_{10a}. Contributions from another triplet state to the vibrational density of states are excluded, at least insofar as the $^3B_{2u}$ and $^3B_{1u}$ states are concerned.

The S_2–S_0 absorption, emission, and emission excitation spectra of thiophosgene in a perfluoroalkane solvent have been measured as a function of the analytical concentration, C, of the solute. Strong evidence of the formation of van der Waals dimers at 10^{-4} M $< C < 10^{-1}$ M and of higher oligomers at $C > 10^{-1}$ M has been found. Variations in the absorption spectra at $C < 10^{-1}$ M have been analyzed successfully in terms of a single $2Cl_2CS \rightleftarrows (Cl_2CS)_2$ equilibrium, for which the value of K is $(5.0 \pm 0.4) \times 10^2$ M^{-1} at 295 K. The mole fractions of monomer and dimer have been calculated at each C, and have been used to construct the absorption spectrum of the dimer. Both the monomer and dimer have similar $S_0 \rightarrow S_1$ and $S_0 \rightarrow S_2$ absorption spectra, but the dimer has an oscillator strength that is about twice that of the monomer. The effects of self-aggregation on the S_2–S_0 emission and excitation spectra have been analyzed. Absorption by the dimer in the ultraviolet also leads to emission, but with a different quantum efficency compared with direct excitation of the monomer. The implications of these observations on the interpretation of the spectroscopy, photophysics, and photochemistry of thiophosgene in solution are assessed.

ANDRZEJ MACIEJEWSKI, MARIAN SZYMANSKI et RONALD P. STEER. Can. J. Chem. **71**, 1548 (1993).

On a mesuré les spectres d'absorption, les spectres d'émission et les spectres d'émission d'excitation S_2–S_0 du thiophosgène dans un solvant de type perfluoroalcane en fonction de la concentration analytique, C, du soluté. On démontre la formation des dimères de van der Waals à 10^{-4} M $< C < 10^{-1}$ M et la formation d'oligomères supérieurs à $C < 10^{-1}$ M. On a analysé, avec succès, les variations des spectres d'absorption à $C < 10^{-1}$ M en fonction d'un équilibre simple $2Cl_2CS \rightleftarrows (Cl_2CS)_2$, dont la valeur de K est de $(5{,}0 \pm 0{,}4) \times 10^2$ M^{-1} à 295 K. Pour chacune des concentrations, C, on a calculé les fractions molaires du monomère et du dimère et on les a utilisées pour établir le spectre d'absorption du dimère. Le monomère et le dimère ont les mêmes spectres d'absorption $S_0 \rightarrow S_1$ et $S_0 \rightarrow S_2$, mais l'amplitude d'oscillation du dimère est environ le double de celle du monomère. On a analysé l'influence de l'auto-agrégation sur les spectres d'émission et d'excitation S_2–S_0. L'absorption du dimère dans l'UV donne également un spectre d'émission mais avec un quantum d'efficacité différent si on le compare avec l'excitation directe du monomère. On a déterminé l'influence de ces observations sur l'interprétation de la spectroscopie, de la photophysique et de la photochimie du thiophosgène en solution.

[Traduit par la rédaction]

Introduction

The formation of dimers, trimers, and oligomers in solutions containing solutes that exhibit relatively strong specific interactions, such as hydrogen bonding or charge transfer, is well documented (1–8). van der Waals dimers and larger clusters of more weakly bound molecules can also be formed and can easily be isolated and studied in cold, supersonic expansions (9–13). Many such homomolecular (A_x) and heteromolecular (A_yB_z) systems have now been examined using both traditional and jet methods (1–17).

Despite the widespread occurrence of self-association, its influence on the photochemistry and photophysics of weakly interacting solutes in solution has been clearly delineated in a surprisingly small number of systems (3–7, 18–21). For example, the interpretation of the effects of self-association on the photochemistry and photophysics of hydrogen-bonding solutes is greatly complicated by the existence of multiple equilibria in which a rather large number of *n*-mers can participate (1, 3–6).

We have been studying the spectroscopy, photophysics, and photochemistry of compounds containing the thiocarbonyl (C=S) group for almost 20 years (22–25). Although mindful of the need to search for the effects of self-association, we have to date found no evidence of it in these systems. Recently we began to study the details of the photophysics of thiophosgene, Cl_2CS, in perfluoroalkane solvents. Unlike the thiocarbonyl-containing molecules we examined previously, we have found clear evidence for the existence of a monomer–dimer equilibrium in solutions of thiophosgene in perfluoroalkane solvents (26, 27).

Thiophosgene is an excellent potential model compound for multi-state photochemical and photophysical studies because it emits from all of its S_2 ($^1(\pi,\pi^*)$), S_1 ($^1(n,\pi^*)$), and T_1 ($^3(n,\pi^*)$) states and because it undergoes photodissociation from both S_1 and S_2 (22, 25, 26, 28–36). On the other hand, its spectroscopy and photophysics have been difficult to interpret because of the unexpected complexity of its S_2–S_0 spectra (33–36), the existence of a dark, weakly absorbing, excited state in the near uv (27), the low quantum yields of emission from S_1 and T_1 in solution (26), and the effects of self-association (26). Many of these problems have now been identified and solved. Moreover, we recently came to realize that the existence of ground state van der Waals dimers of Cl_2CS in solution might provide an avenue for examining the photophysics of a highly electronically excited, but weakly bound, simple dimeric system. We have been interested in exploring the photophysics of the excited electronic states of the Cl_2CS van der Waals dimer since our discovery of $2S_1 \rightarrow S_2 + S_0$ electronic energy pooling following pulsed

visible laser excitation of the vapor (37, 38). The mechanism of this process is essencially unexplored, but it must proceed via an electronically excited encounter complex. Thus the ability to from a $(Cl_2CS)_2$ van der Waals dimer in solution and excite it in a strong uv absorption band appears to be one potential means of obtaining further information about the partitioning of electronic energy among the monomeric dissociation products of the excited dimer. Our original intent was to try to accomplish this by synthesizing $(Cl_2CS)_2$ in a supersonic expansion. However, our failure to find bands associated with van der Waals dimer in the $S_2 - S_0$ fluorescence excitation spectrum of supersonically expanded thiophosgene forced us to abandon this experiment temporarily. Our recent observation of ground state dimer in perfluoroalkane soutions of Cl_2CS has now rekindled this interest.

To this end we have now characterized the monomer–dimer equilibrium of Cl_2CS in solution and have assessed its importance in interpreting the uv–visible spectra, photophysics, and photochemistry of this model compound. The general chemistry of this equilibrium is reported here, and forms the basis for the assessment of the effects of self-association on the photochemistry and photophysics of Cl_2CS and a future report of the photophysics of the S_2 dimer.

Experimental

The methods of purification of the thiophosgene solute and perfluoro-1,3-dimethylcyclohexane solvent and of preparation and degassing of the solutions have been previously described (26, 27). Solute concentrations were determined by two methods for calibration purposes. (*i*) A known pressure of pure Cl_2CS vapor ($P >$ 10 Torr (1 Torr = 133.3 Pa), measured with a Baratron pressure transducer) from a precalibrated volume was transferred quantitatively under vacuum into an accurately measured volume of solvent, thoroughly mixed and degassed. (*ii*) Weights of, first, the empty cell, then, in sequence, the cell containing pure degassed solvent and added solute, were measured accurately and the concentration calculated using the density of the pure solvent. The two methods agreed to within ±7%. Standard samples prepared in this way were used to construct calibration curves of absorbance vs. molar concentration for several wavelengths of interest. Initial concentrations of Cl_2CS in the perfluoroalkane solvent were then obtained routinely by measuring the absence of a freshly prepared degassed sample at a selected wavelength using pure solvent as a reference. A number of cells of various path lengths (10.0–0.0045 cm) connected to a common manifold enabled the same sample to be measured at various absorbances.

The equipment and the methods used to measure the absorption, emission, and emission excitation spectra have also been described in detail previously (26, 27, 36). Briefly, emission and excitation spectra were measured with a Spex Fluorolog 222 instrument using either the standard 450-W high-pressure Xe arc source or the expanded beam from a tunable dye laser. Both emission and excitation spectra were corrected for the spectral characteristics of the measuring system. The spectral correction curve for the former was extended to 900 nm using an Optronics Laboratories HTS-110 high-intensity standard of spectral irradiance. Excitation spectral corrections were accomplished by measuring the relative intensity of the source as a function of wavelength using a Rhodamine B quantum counter operating in its linear response range. The corner geometry method was used to avoid artefacts in the emission and excitation spectra due to high absorbances of the solutions (39). (Solutions whose absorbances in a 1-cm cell were as high as 10 could be examined without significant error.)

Photochemical decomposition products are formed in relatively large yield at excitation wavelengths < 280 nm in this system and were observed to absorb in a range that was coincident with the long-wavelength tail of the S_2–S_0 and the dark excited state absorptions. For this reason measurements of Cl_2CS concentration and molar extinction coefficient were always taken on freshly prepared samples. Thereafter absorption measurements at λ near λ_{max} were used only to monitor the extent of Cl_2CS photodecomposition during or after prolonged exposure to exciting light in the emission measurements.

Results and discussion

The electronic absorption spectrum of thiophosgene consists of two weak, broadly overlapping, transitions in the visible, assigned to singlet and triplet $n \rightarrow \pi^*$ promotions (26, 40), a strong, broad transition to a $^1(\pi,\pi^*)$ state in the near uv (34, 36, 41), a weak absorption that overlaps the long-wavelength tail of the $\pi \rightarrow \pi^*$ system tentatively assigned to a transition to a dark, doubly excited, $^1(n^0,\pi^{*2})$ state (27), and at least two additional unassigned strong features further to the blue in the quartz ultraviolet (41, 42). We have shown previously that excitation of Cl_2CS solutions in the visible produces weak red – near infrared emission from both the S_1 $^1(n,\pi^*)$ and T_1 $^3(n,\pi^*)$ states (26) and that excitation in the strong uv absorption band at $\lambda < 300$ nm results in the production of strong S_2 $^1(\pi,\pi^*) \rightarrow S_0$ fluorescence in the near uv – blue (35, 36). Analysis of the low-energy emission is complicated by the fact that the fluorescence and phosphorescence overlap strongly and are very weak, whereas analysis of the photophyics of the fluorescent $^1(\pi,\pi^*)$ state is complicated by the presence of a non-emissive state of only slightly lower energy (27) and the fact that its main nonradiative decay process in perfluoroalkane solution involves efficient crossing of a low (ca. 1450 cm^{-1}) barrier (36, 43).

Analysis of the spectroscopy, photochemistry, and photophysics of the entire system is further complicated by the self-association of the solute in solution (1–7, 17–21). Self-association can be detected in the absorption spectra only by a careful examination of changes in the apparent molar extinction coefficients, ε, as a function of wavelength over a wide range of concentrations.

We previously noted (26), qualitatively, that the shape of the visible absorption band only changes noticeably on its long-wavelength side on increasing the thiophosgene concentrations from ca. 10^{-4} M to ca. 1 M, that λ_{max} remains almost invariant, but that $\varepsilon(\lambda_{max})$ increases significantly at higher concentrations and, particularly, in the pure liquid compared with more dilute solutions. Changes in the uv absorption spectra with changing concentration are more dramatic, as shown in Fig. 1 where ε is plotted vs. log C for several different wavelengths. We define the "as measured" values of $\varepsilon = A/(Cl)$ in terms of the measured absorbance A, in a cell of length l, of a solution in which the analytical molar concentration of thiophosgene solute is C. Note that ε decreases with increasing C in the region of the dark excited state (DES) near 300 nm, increases with increasing C further to the blue near the maximum of the $\pi \rightarrow \pi^*$ transition (ca. 255 nm), but is relatively constant at 467 nm (λ_{max} of $S_1 \leftarrow S_0$) over the whole range of concentration up to ca. 0.1 M. No further changes in ε can be detected at $C \leq 5 \times 10^{-5}$ M, but very large differences may be noted between solutions of ca. 0.1 M concentration and the pure solute. Modest changes in the S_2–S_0 emission and emission excitation spectra are also observed when C varies from low ($<10^{-4}$ M) to high ($\sim 10^{-1}$ M) concentration (vide infra).

We attribute these observations to self-association of the thiophosgene solute in the perfluoroalkane solutions;

$$[1] \quad 2M \rightleftarrows D$$

$$[2] \quad D + M \rightleftarrows T \overset{M}{\rightleftarrows} Ol_1 \overset{M}{\rightleftarrows} Ol_2 \text{ etc.}$$

where M, D, T, and Ol represent monomer, dimer, trimer, and oligomer, respectively. We interpret the fact that the spectral and photophysical properties of the thiophosgene solutions are invariant with C at $C \lesssim 5 \times 10^{-5}$ M as indicating that the solute exists exclusively in monomeric form at these low concentrations. The large changes (not shown in Fig. 1) at $C > 10^{-1}$ M are attributed to the formation of trimers and higher oligomers. The fact that the spectroscopic and photophysical properties of the solutions of concentration 5×10^{-1} M $< C < 10^{-1}$ M can be analyzed in terms of a model that involves only two solute species, monomer and dimer (vide infra), is strong evidence that only one self-association equilibrium, eq. [1], is important in this intermediate concentration range.

If monomer–dimer equilibrium is the only important self-association process in solution and if both M and D absorb at the same wavelengths, then Dearden (44) and Ito (45) have shown that the mole fractions of monomer, α, can be found by measuring ε at various C using

$$[3] \quad \alpha_1 = \frac{(1 - Q)}{1 - (QC_1/C_2)^{1/2}}$$

$$[4] \quad Q = \frac{\varepsilon_1 - \varepsilon_M}{\varepsilon_2 - \varepsilon_M}$$

where the subscripts 1 and 2 indicate two different concentrations. Here ε_M is the molar extinction coefficient of the monomer alone, a quantity which must be determined independently. Values of ε_M can readily be found in our case by taking the limiting values of ε at low C. The equilibrium constant for the monomer–dimer equilibrium (eq. [1]) in dilute ideal solutions is given by

$$[5] \quad K = \frac{1 - \alpha}{2\alpha^2 C}$$

whereas the measured ε is related to ε_M and ε_D (the molar extinction coefficient of the dimer) by

$$[6] \quad \varepsilon = \varepsilon_M\alpha + \frac{1}{2}\varepsilon_D(1 - \alpha)$$

The most accurate values of α and K will be obtained at those wavelengths where the differences between ε_M and ε_D are greatest. For Cl_2CS in perfluoroalkane solvents this occurs in the 300–340 nm region where the DES absorption occurs most strongly, as shown in Fig. 2 and 3. Analysis of ε vs. λ data in the $330 \geq \lambda \geq 300$ nm region, for 11 concentrations of Cl_2CS such as those shown in Fig. 2, according to the above method yields the results for α and K as a function of C shown in Table 1. Note that α is independent of λ within experimental error and varies smoothly from 1.00 at $C \leq 3 \times 10^{-5}$ M to 0.085 at $C = 1.09 \times 10^{-1}$ M. The value of K is independent of C, with the possible exception of a slight apparent increase at concentrations greater than ca. 0.1 M. The average value of K at $C \leq 0.1$ M and a temperature of 295 ± 1 K is $(5.0 \pm 0.4) \times 10^2$ in units of M^{-1}. Similar though less precise results are obtained by using the ε vs. C data in other wavelength regions. The fact that α varies smoothly with changing C but that the value of K is independent of C indicates that the single monomer–dimer equilibrium, ideal solution, model adopted adequately describes the system, at least at $C \leq 0.1$ M.

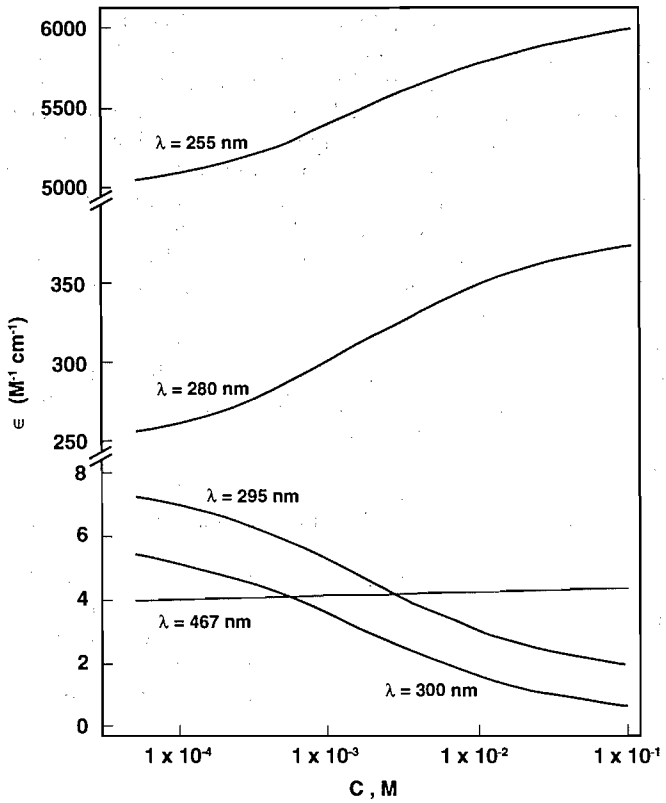

FIG. 1. Apparent values of the molar extinction coefficient for selected wavelengths within the $S_2 \leftarrow S_0$, DES $\leftarrow S_0$, and $S_1 \leftarrow S_0$ absorption bands as a function of the analytical concentrations of Cl_2CS in PF-1,3-DMCH.

With values of K and α as a function of C in hand, it is then possible to calculate the values of ε_D as a function of λ, using eq. [6], and to construct an absorption spectrum of the dimer. A representative set of data showing the consistency of the values of ε_D at a given λ over a wide range of C and α is given in Table 2. A complete set of values of ε_M and ε_D at 5- or 10-nm intervals over the range $350 \geq \lambda \geq 200$ nm is given in Table 3. For completeness, the values of $\varepsilon(\lambda)$ for the monomer have been further deconvolved into values of ε for the DES and the $^1(\pi,\pi^*)$ states using the method described in ref. 27. The results are displayed graphically in Fig. 3. Table 4 presents a representative set of $\varepsilon(\lambda)$ data obtained in the visible for various C, together with the results of a similar calculation of $\varepsilon_M(\lambda)$ and $\varepsilon_D(\lambda)$ using the accurate values of α obtained in the uv. Note from Tables 3 and 4 and Fig. 3 that the shapes of the monomer and dimer spectra are very similar, and that at all wavelengths, except those on the red wings of an absorption, the ratio $\varepsilon_D/\varepsilon_M$ is slightly greater than 2. Such a value of this ratio is consistent with the notion that the van der Waals dimer consists of two nearly independently acting chromophores each of which contributes about equally to the oscillator strength of the dimeric species. This observation is consistent with those obtained

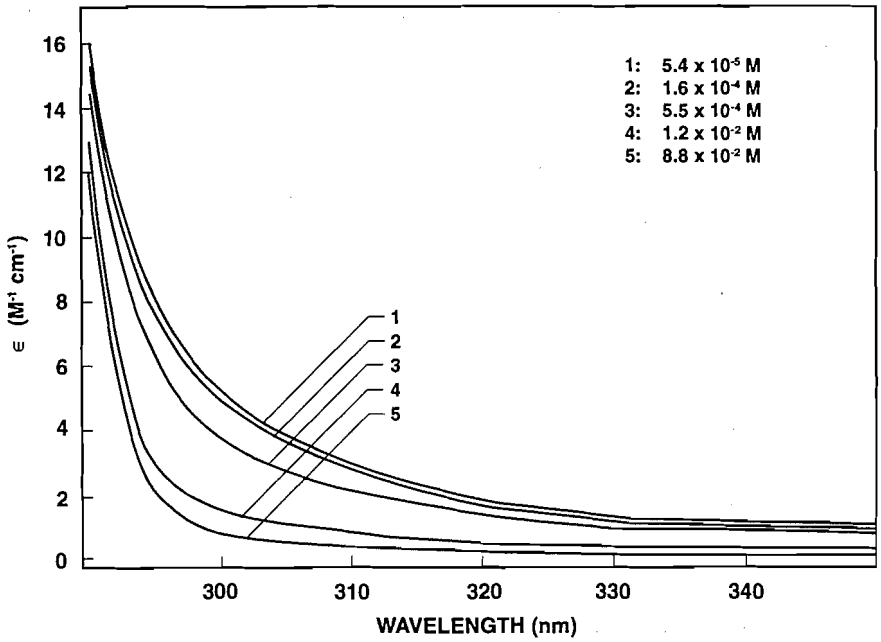

FIG. 2. Concentration effects in the long-wavelength tail of the uv absorption spectrum of Cl_2CS in PF-1,3-DMCH.

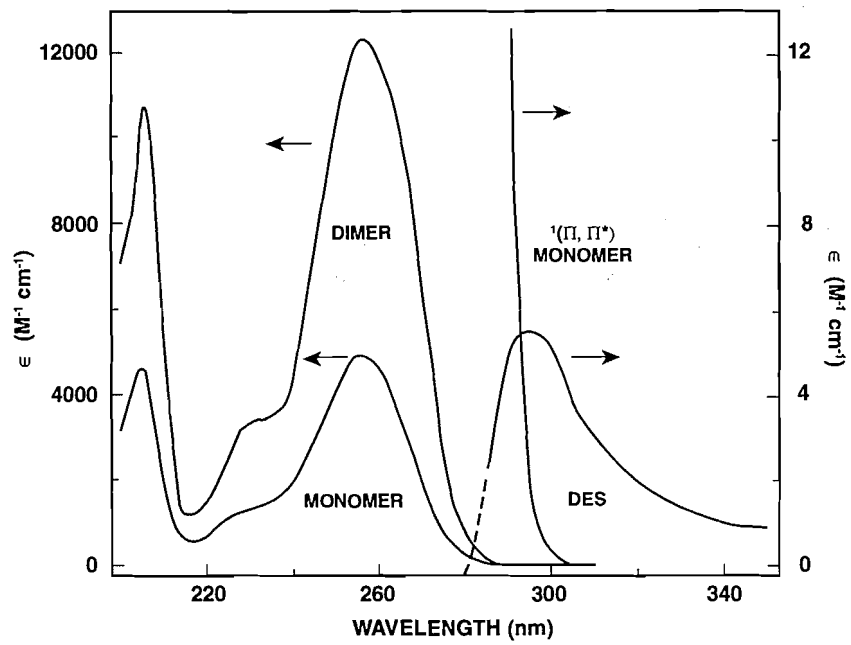

FIG. 3. Quantitative absorption spectra of Cl_2CS monomer and dimer in PF-1,3-DMCH.

in analogous systems in which a single weakly bound complex is formed from two identical monomeric molecules (1, 4–6, 14, 15, 46, 47).

With quantitative data available for the composition of the solutions as a function of C and for ε_M, ε_D, and ε_{DES} as a function of λ, it is then possible to more fully interpret the emission and emission excitation spectra of Cl_2CS in perfluoroalkane solutions in the $250 < \lambda < 500$ nm region. The DES of the monomer is dark ($\phi_f < 10^{-8}$) and contributes nothing to the emission although it absorbs weakly in the $290 < \lambda < 340$ nm range (27). No evidence of a comparable DES is found in the dimer. Changes in the uv–blue emission (Fig. 4) and near-uv emission excitation (Fig. 5) spectra with changing C can thus be attributed to changes both in the composition of the solution in the ground state and in the nature and fluorescence yields of the emitting species.

Note that the emission spectra (normalized in Fig. 4) remain almost invariant in the range $C < 0.1$ M, i.e., for solutions in which the solute composition changes from nearly pure monomer to largely dimer. We take this as evidence that either (*i*) the monomer and dimer have similar emission spectra, or (*ii*) the excited dimer dissociates to excited monomer, which is then the dominant fluorescent species over the entire $C < 0.1$ M concentration range. At $C \gtrsim 0.1$ M, a marked shift in the emission spectrum to shorter

wavelengths is taken as convincing evidence that the main emitting species at these higher concentrations are different from those at $C < 0.1$ M. Excited trimers and higher oligomers are again implicated. A complete analysis of the intensity and wavelength dependence of the emission on concentration is complicated by the need to account not only for the changing composition of the solution and the nature of the emitting species, but also for the different rates of self-quenching of the emitters. Such an analysis will be presented in a subsequent paper (48).

We have previously shown (35, 36) that the S_2–S_0 excitation spectrum of the monomer in perfluoroalkane solu-

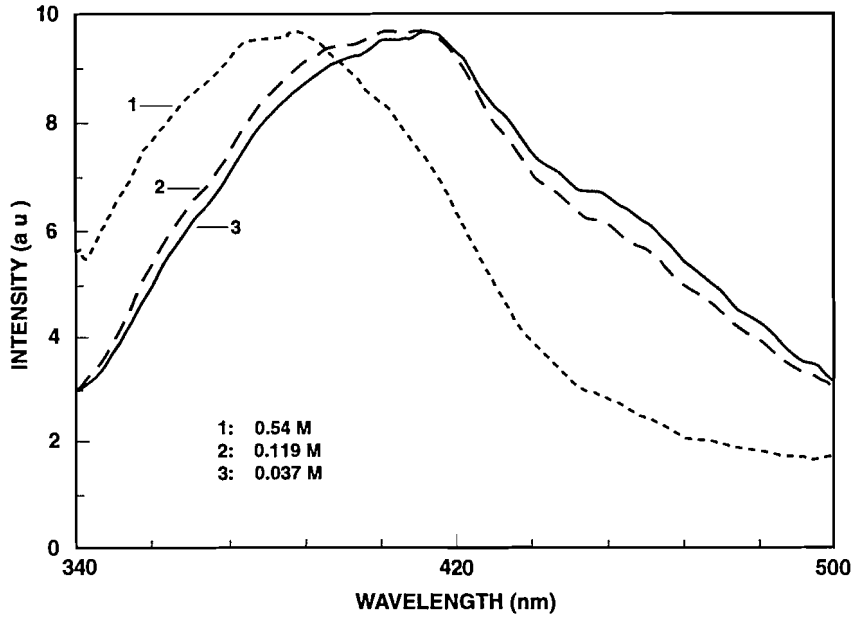

FIG. 4. Emission spectra of Cl_2CS in PF-1,3-DMCH for three samples of different analytical concentration normalized to the same peak emission intensity; $\lambda_{ex} = 295$ nm.

tion differs from the corresponding absorption spectrum because of the onset of a fast radiationless relaxation process (likely photodissociation) at modest E_{vib} in S_2 that causes abrupt fluorescence weakening at excitation wavelengths < 272 nm. Differences in the excited state behavior of the monomer and dimer must therefore be deduced by comparing the absorption and excitation spectra at each C in the 10^{-4}–10^{-1} M concentration range. In the present work, it is important to note that artefacts associated with the excitation of solutions of large absorbance are not responsible for the observed changes in the excitation spectra with changing thiophosgene concentration. Such artefacts have been avoided through the use of the corner geometry technique (vida supra). Thus the excitation spectra (normalized in Fig. 5) offer additional strong evidence not only that two (or more) different species are absorbing at thiophosgene concentrations in the $3 \times 10^{-4}\ M < C < 9 \times 10^{-2}\ M$ range, but also that the two absorbing species produce uv–visible fluorescence with different quantum efficiencies at different excitation wavelengths. We interpret the fact that the excitation spectrum retains a similar shape but shifts to slightly longer wavelengths at higher C as showing that the dimer is weakly bound, and that, like the monomer, excitation of the dimer in the red edge of its uv absorption band produces a higher quantum yield of emission than does excitation further to the blue. This interpretation is consistent with the notion that the dimer relaxes nonradiatively at higher excitation energies, but that the onset of this relaxation process occurs at a lower energy than that of the monomer. The nonradiative relaxation process in the excited dimer could involve dissociation of the dimer to two intact monomers, at least one of which is electronically excited. The spectra are also consistent with the requirement that the origin of the dimer S_2–S_0 absorption system should be located at a lower energy than that of the monomer. The dimer must be stabilized by at least a few kilojoules per mole, and the magnitude of the wavelength shift on the red edge of the excitation spectrum appears to be consistent with this stabilization requirement.

The dimer could in fact be stabilized by a number of weak

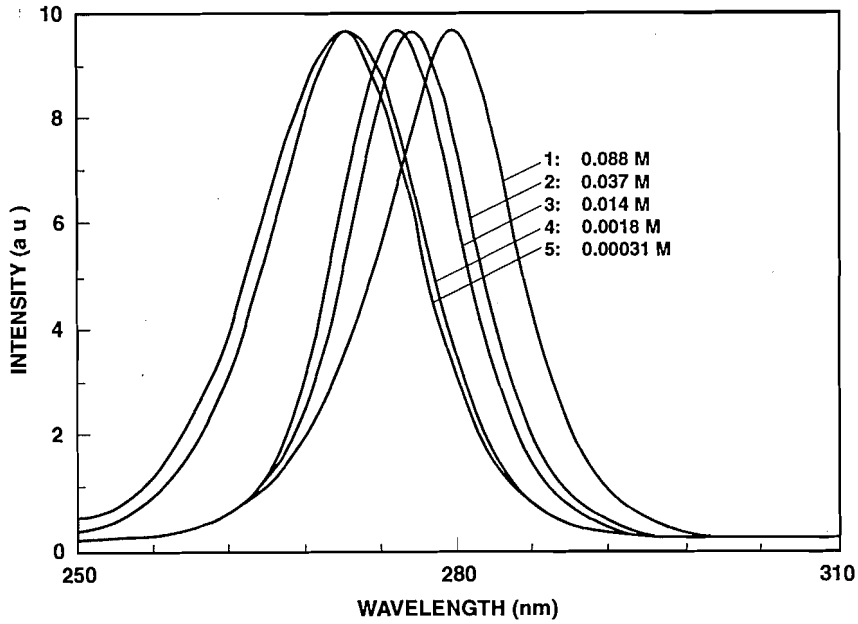

FIG. 5. Excitation spectra of Cl_2CS in PF-1,3-DMCH measured at λ_{em} = 410 nm for five samples of different analytical concentration (normalized to the same peak intensity).

electrostatic interactions. The small ground state electric dipole moment of Cl_2CS (μ = 0.28 D) (25) suggests that dipole-dipole interactions may only contribute in a minor way to the stabilization energy, and in this system stronger charge transfer and hydrogen-bonding interactions are not possible. Thus dispersive interactions are likely to provide the most important contributions to the binding energy in this species. The large polarizability of ground state Cl_2CS (10.2 $Å^3$) (25) is consistent with this view. A similar conclusion was reached recently in the case of van der Waals complexes of aromatic thiones with rare gas atoms (49), and supports in a general way the approach that Morokuma (5, 50) has taken in analyzing and describing intermolecular interactions. Theoretical calculations of the energies of van der Waals dimers of various possible geometries would be most useful for interpreting these experimental data.

Conclusions

Self-aggregation of the solute is an important phenomenon in perfluoroalkane solutions of thiophosgene at room temperature and must be accounted for in analyzing and interpreting the spectroscopy, photophysics, and photochemistry of this model system. At concentrations below ca. 5×10^{-5} M the solute is for practical purposes all in monomeric form, and at higher concentrations up to ca. 0.1 M only one self-aggregation process, formation of van der Waals dimer, need be considered. At still higher concentrations evidence of further self-aggregation can be found in both the absorption and uv–blue emission spectra.

Using a method developed by Ito (45) and by Dearden (44), the mole fractions of monomer at various concentrations have been determined and have been used to calculate the value of the equilibrium constant, $K = (5.0 \pm 0.4) \times 10^2\ M^{-1}$, for the monomer–dimer equilibrium at room temperature. Using these data the molar extinction coefficients of the dimer can be calculated as a function of wavelength and the absorption spectrum of the dimer constructed. Both monomer and dimer have similar spectra, but the dimer exhibits an oscillator strength which is ca. twice that of the monomer, a fact consistent with the notion that it contains two, almost independent, weakly interacting monomeric chromophores.

The effects of self-aggregation are also reflected in the emission and emission excitation spectra, which, among other things, show that absorption by dimer in the uv also leads to emission. Thus thiophosgene in perfluoroalkane solution presents an important opportunity to study the partitioning of electronic energy among several possible products following uv excitation of a weakly bound van der Waals dimer.

Finally we note that thiophosgene in perfluoroalkane solution appears to be a relatively uncomplicated system with respect to its self-aggregation in the ground state. The monomer can be studied in the absence of higher *n*-mers at low concentration, and relatively "clean" mixtures of monomer plus dimer are formed over a wide span of concentrations in the intermediate concentration ranges. Thus the thiophosgene system appears to be a simpler system to study than most hydrogen-bonding solutes, which generally self-aggregate in a more complex fashion.

The a'' vibrations of singlet propynal[1]

J.K.G. WATSON
Herzberg Institute of Astrophysics, National Research Council of Canada, Ottawa, ON K1A 0R6, Canada

Received March 10, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

J.K.G. WATSON. Can. J. Chem. **71**, 1556 (1993).

The a'' vibrational frequencies of all possible H and D isotopomers of propynal (HCCCHO) are shown to allow two solutions for the a'' harmonic potential constants. Equations relating the solutions are given. In the $\tilde{X}^1A'$ ground electronic state one solution can be rejected as chemically unrealistic, but in the $\tilde{A}^1A''$ excited electronic state the choice is more difficult. It is shown that a choice can be made on the basis of the observed cross-sequence intensities in the $\tilde{A}$–$\tilde{X}$ band system.

J.K.G. WATSON. Can. J. Chem. **71**, 1556 (1993).

On démontre que les fréquences de vibration a'' de tous les isotopomères H et D possibles du propynal (HCCCHO) permettent deux solutions pour les constantes du potentiel harmonique a''. On donne les équations donnant une corrélation des solutions. Dans l'état électronique fondamental $\tilde{X}^1A'$, on peut rejeter une solution sur la base qu'elle est chimiquement irréaliste, toutefois, dans l'état électronique excité $\tilde{A}^1A''$, le choix est plus difficile. On démontre qu'un choix peut quand méme être fait en se basant sur les intensités des séquences croisées du systèma de bandes $\tilde{A}$–$\tilde{X}$.

[Traduit par la rédaction]

1. Introduction

The $\tilde{A}^1A''$–$\tilde{X}^1A'$ electronic transition of propynal (1–5, footnote 2) is relatively weak, and therefore the vibronically-induced 1–0 and 0–1 bands in the out-of-plane a'' vibrations can be readily observed as in-plane-polarized type *ab* bands among the main type *c* bands of the system (3, 4, footnote 2). These observations, together with the vibrational spectrum (6, 7), make it possible to get a complete set of a'' fundamentals for both the $\tilde{X}$ and the $\tilde{A}$ electronic states of the four possible H and D isotopomers. Similar data are available for the $\tilde{a}^3A''$ electronic state (8, 9). Using these data, the harmonic potentials for the $\tilde{X}$, $\tilde{a}$, and $\tilde{A}$ states have been discussed by Lin and Moule (10) and by Williams (11). Neither of these papers mention the fact that there are two rather similar solutions for the out-of-plane harmonic potentials of the upper states that give identical calculated values for the a'' vibrational frequencies of all the H and D isotopomers. Thus other data are required to resolve this ambiguity, and the present paper is devoted to a discussion of this problem for the singlet state. There is a similar ambiguity for the ground state, but in that case the alternative solution can be ruled out as being chemically unreasonable.

The 1–1 sequence bands in the a'' modes are observed in the spectrum and, because of the change in a'' potential between the two states, cross-sequence bands of the type ν_k'–ν_l'' are also observed, where ν_k' and ν_l'' are different a'' modes in the $\tilde{A}$ and $\tilde{X}$ states. The intensities of these sequences and cross-sequences are determined by simple Condon vibrational overlap considerations, and it is shown here that the cross-sequence intensities in particular can be used to distinguish between the two possible a'' potentials for the $\tilde{A}$ state after the alternative solution for the $\tilde{X}$ state has been eliminated.

2. Theory of double solutions for potential constants

Least-squares fits of the out-of-plane vibrational frequencies of each electronic state were found to converge to one or other of two different solutions for the potential constants, depending upon the choice of the initial estimates. The two solutions yield identical values for the calculated frequencies of the various isotopomers. Such ambiguities result from multiple solutions of the algebraic relationships between the potential constants and the data, as discussed previously for XY_3 molecules (12). In general, such an ambiguity can only be resolved if it can be shown that these relations can be manipulated to give a sufficient set of equations that are **linear** in the potential constants. Such algebraic relations are useful for demonstrating the existence or otherwise of ambiguities, although they do not provide values of the potential constants that are optimised in a least-squares sense. The algebraic approach is best regarded as a way of understanding the results of a least-squares fit.

In the present case, the problem is to determine the 6 out-of-plane potential constants from a total of 12 frequencies, ν_{10}, ν_{11}, and ν_{12} of 4 isotopomers. The frequency data for one isotopomer gives us three relationships between the six potential constants F_{ij}, $i \le j$:

$$[1] \quad S_1 \equiv \lambda_{10} + \lambda_{11} + \lambda_{12} = \text{tr } \mathbf{FG}$$

$$[2] \quad S_2 \equiv \lambda_{11}\lambda_{12} + \lambda_{12}\lambda_{10} + \lambda_{10}\lambda_{11} = \frac{1}{2}\{(\text{tr } \mathbf{FG})^2 - \text{tr } (\mathbf{FGFG})\}$$

$$[3] \quad S_3 \equiv \lambda_{10}\lambda_{11}\lambda_{12} = (\det \mathbf{F})(\det \mathbf{G})$$

where $\lambda_k = (2\pi\nu_k)^2 = (2\pi c\omega_k)^2$ are the usual frequency parameters and $\mathbf{F}$ and $\mathbf{G}$ are the Wilson potential and kinetic matrices (13). Obviously, these three equations leave the six potential constants indeterminate. A second isotopomer gives a further three relationships with different $\boldsymbol{\lambda}$ and $\mathbf{G}$ matrices. However, the product [3] gives no new information, only a test of consistency. Thus the $\mathbf{F}$ matrix is still indeterminate. A third isotopomer will probably provide sufficient information to remove the indeterminacy, but there will probably still be ambiguities because there are multiple so-

[a]The atom numbering convention is shown in Fig. 1, and the coordinates are defined in the text before eq. [4].
[b]$\rho_{ij} = 1/r_{ij}$, $\sigma = 1/\sin\theta_{345}$.
[c]The chain 123 is assumed to be linear.
[d]The sign of $(\theta_{234}-\pi)$ is defined as positive for the chain 321 bending towards atom 5.

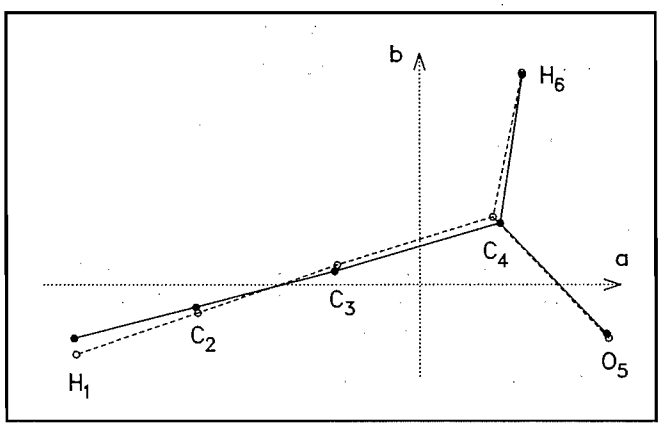

FIG. 1. Numbering convention for atoms of propynal. The structures of the $\tilde{X}$ state (full lines) and the $\tilde{A}$ state (broken lines) are each shown relative to their own principal axes of inertia.

lutions of the algebraic equations for **F**. These multiple solutions give identical frequencies for the various isotopomers, but the forms of the normal coordinates are different and so the solutions can distinguished by using data, such as vibration–rotation interaction parameters, that are sensitive to these forms.

The question of whether a unique solution can be obtained from frequency data reduces to the question of whether the equations [1]–[3], together with the corresponding equations for the other isotopomers, can be reduced to a set of independent linear equations equal to or greater in number than the number of potential constants. Such a set of linear equations has a unique solution.

In the present case, let us label the four isotopomers HCCCHO, DCCCHO, HCCCDO, and DCCCDO as HH, DH, HD, and DD, respectively. The atom numbering convention is shown in Fig. 1. The out-of-plane coordinates are taken as S_{10}, the angle of the C_4H_6 bond relative to the $C_3C_4O_5$ plane, S_{11}, the angle of the C_2H_1 bond relative to the $C_2C_3C_4$ plane, and S_{12}, the angle of the C_3C_2 bond relative to the $C_3C_4O_5$ plane. The corresponding **B** matrix elements are given in Table 1. From these, the **G** matrix elements are calculated according to

$$[4] \qquad G_{rs} = \sum_i m_i^{-1} B_{r,ic} B_{s,ic}$$

The hydrogen isotope changes in the **G** matrix are quite simple:

$$G_{rs}^{HD} = G_{rs}^{HH} + \delta_{r,10}\delta_{s,10}\Delta G_{10,10}$$

$$[5] \qquad G_{rs}^{DH} = G_{rs}^{HH} + \delta_{r,11}\delta_{s,11}\Delta G_{11,11}$$

$$G_{rs}^{DD} = G_{rs}^{HH} + \delta_{r,10}\delta_{s,10}\Delta G_{10,10} + \delta_{r,11}\delta_{s,11}\Delta G_{11,11}$$

where

$$[6] \qquad \Delta G_{10,10} = (m_D^{-1} - m_H^{-1})\rho_{46}^2$$
$$\Delta G_{11,11} = (m_D^{-1} - m_H^{-1})\rho_{12}^2$$

We now use these expressions in eqs. [1]–[3] for the four isotopomers. The linear sums [1] give one redundancy relation

$$[7] \qquad S_1^{DD} = S_1^{HD} + S_1^{DH} - S_1^{HH}$$

which is the linear sum rule (13), two unambiguous potential constants

$$[8] \qquad F_{10,10} = (S_1^{HD} - S_1^{HH})/\Delta G_{10,10}$$
$$F_{11,11} = (S_1^{DH} - S_1^{HH})/\Delta G_{11,11}$$

and the linear combination of **F** matrix elements tr (**FG**). Similarly, the quadratic sums give tr (**FGFG**), $(FGF)_{10,10}$ from the HD–HH difference, $(FGF)_{11,11}$ from the DH–HH difference, and then F_{12}^2 from the double D substitution. Finally, the products give one piece of information, det **F**. These eight data are to be solved for the **F** matrix. Extensive algebra shows that there is a fourth independent linear relation from which $F_{10,11}$ is determined unambiguously in terms of the original data by

$$[9] \qquad F_{10,11} = (G_{10,11}G_{12,12} - G_{10,12}G_{11,12}) \times \frac{[S_2^{HD}S_1^{DH} + S_2^{DH}S_1^{HD} - S_2^{HH}S_1^{DD} - S_2^{DD}S_1^{HH} - S_3^{HH} + S_3^{HD} + S_3^{DH} - S_3^{DD}]}{[S_2^{HH}(\det \mathbf{G}^{DD}) - S_2^{HD}(\det \mathbf{G}^{DH}) - S_2^{DH}(\det \mathbf{G}^{HD}) + S_2^{DD}(\det \mathbf{G}^{HH})]}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

With this information the remaining equations can be manipulated to show that $(FG)^2_{10,12}$, $(FG)_{10,12}(FG)_{11,12}$, and $(FG)^2_{11,12}$ are determined unambiguously, where

$$[10]\quad \begin{aligned}(FG)_{10,12} &= F_{10,10}G_{10,12} + F_{10,11}G_{11,12} + F_{10,12}G_{12,12}\\ (FG)_{11,12} &= F_{11,10}G_{10,12} + F_{11,11}G_{11,12} + F_{11,12}G_{12,12}\end{aligned}$$

These together provide two possible solutions for $(FG)_{10,12}$ and $(FG)_{11,12}$. For either solution, we can combine together six linear equations to determine the six elements of **F** unambiguously. Thus there are at most two possible solutions $\mathbf{F}^{(1)}$ and $\mathbf{F}^{(2)}$, related to each other by the linear equations

$$[11]\quad \begin{aligned}F^{(2)}_{10,10} &= F^{(1)}_{10,10}\\ F^{(2)}_{11,11} &= F^{(1)}_{11,11}\\ F^{(2)}_{10,11} &= F^{(1)}_{10,11}\\ \text{tr}\,(\mathbf{F}^{(2)}\mathbf{G}) &= \text{tr}\,(\mathbf{F}^{(1)}\mathbf{G})\\ (F^{(2)}G)_{10,12} &= -(F^{(1)}G)_{10,12}\\ (F^{(2)}G)_{11,12} &= -(F^{(1)}G)_{11,12}\end{aligned}$$

If one solution **F** has been obtained by fitting the data, it is easy to obtain the other by solution of these equations, which are equivalent to

$$[12]\quad \mathbf{F}^{(2)} = \mathbf{Y}^{\mathrm{T}}\mathbf{F}^{(1)}\mathbf{Y}$$

where

$$[13]\quad \mathbf{Y} = \begin{bmatrix}1 & 0 & -2G_{10,12}/G_{12,12}\\ 0 & 1 & -2G_{11,12}/G_{12,12}\\ 0 & 0 & -1\end{bmatrix},\quad \mathbf{Y}^2 = \mathbf{E}$$

or

$$[14]\quad Y_{rs} = \delta_{rs} - 2(G_{r12}/G_{1212})\delta_{12s}$$

Substitution of these two **F** matrices into eqs. [1]–[3] for the four isotopomers shows that if one satisfies all these equations then so does the other. The basic reason for this is that

$$[15]\quad \mathbf{YGY}^{\mathrm{T}} = \mathbf{G}$$

for all four isotopomers. Thus it is not possible to distinguish these solutions on the basis of this isotopomeric frequency data. However, they may be distinguishable on the basis of data that depends on the form of the normal coordinates, and this is where the intensities of the sequence and cross-sequence bands are useful. The relationship between the two possible **L** matrices in the transformation $\mathbf{S} = \mathbf{LQ}$ is

$$[16]\quad \mathbf{L}^{(2)} = \mathbf{YL}^{(1)}$$

3. Sequence intensities

The vibration–rotation coordinate transformation between different electronic states is rather complicated because of the necessity of using different rotational Eckart conditions appropriate to the different geometries of the two states (14, 15). Using the lower-state coordinates as independent variables, we find that the upper-state normal coordinates Q'_k are given in terms of the lower-state normal coordinates Q''_l by

$$[17]\quad Q'_k = \sum_{i\alpha} m_i^{1/2} l'_{i\alpha k}\left[\sum_{\beta}\Lambda_{\alpha\beta}(r^e_{i\beta})'' - (r^e_{i\alpha})'\right] + \sum_{i\alpha\beta l} l'_{i\alpha k}\Lambda_{\alpha\beta}l''_{i\beta l}Q''_l$$

where the **l** matrices for the upper and lower states are the transformation matrices from mass-weighted Cartesian displacements to normal coordinates, given in terms of standard matrices (13) by

$$[18]\quad \mathbf{l} = \mathbf{m}^{-1/2}\mathbf{B}^{\mathrm{T}}(\mathbf{L}^{-1})^{\mathrm{T}}$$

and the matrix $\mathbf{\Lambda}$ is the Eckart rotation matrix (also called the "axis-switching matrix" (14) because it corresponds to a sudden switch from one Eckart system to the other) such that

$$[19]\quad [(\mathbf{r}^e)']^{\mathrm{T}}\,[\mathbf{m}(\mathbf{r}^e)'' + \mathbf{m}^{1/2}\mathbf{l}''\mathbf{Q}'']\Lambda^{\mathrm{T}}$$

is a symmetric matrix. $\mathbf{\Lambda}$ is a function of $\mathbf{Q}''$, and expanding it to first-degree terms we have the zero-order Eckart rotation matrix $\mathbf{\Lambda}^e$ such that

$$[20]\quad \mathbf{P} = [(\mathbf{r}^e)']^{\mathrm{T}}\,\mathbf{m}(\mathbf{r}^e)''(\mathbf{\Lambda}^e)^{\mathrm{T}}$$

is a symmetric matrix, and, from eq. [17], the expression for the dimensionless excited state normal coordinate $q'_k = (\gamma'_k)^{1/2}Q'_k$, where $\gamma_k = hcw_k/\hbar^2$, is

$$[21]\quad q'_k = (\gamma'_k)^{1/2}\sum_{i\alpha} m_i^{1/2}l'_{i\alpha k}\cdot\left[\sum_{\beta}\Lambda^e_{\alpha\beta}\,(r^e_{i\beta})'' - (r^e_{i\alpha})'\right] + \sum_l D_{kl}q''_l + O(q''^2)$$

where

$$[22]\quad \mathbf{D} = (\gamma')^{1/2}\{(\mathbf{l}')^{\mathrm{T}}\mathbf{\Lambda}^e\mathbf{l}'' + [(\mathbf{l}')^{\mathrm{T}} \times \mathbf{\Lambda}^e\mathbf{m}^{1/2}(\mathbf{r}^e)'']\,\mathbf{J}^{-1}\,[\mathbf{m}^{1/2}[(\mathbf{r}^e)']^{\mathrm{T}} \times \mathbf{\Lambda}^e\mathbf{l}'']\}\,(\gamma'')^{-1/2}$$

Here **J** is the matrix

$$[23]\quad \mathbf{J} = \mathbf{E}\,(\text{tr}\,\mathbf{P}) - \mathbf{P}$$

E being the unit matrix. The first term in eq. [21] represents the Franck–Condon shift of origin, and the second term is the Duschinsky rotation and rescaling of the normal coordinates. The main effect of $\mathbf{\Lambda}^e$ is to redistribute the intensity of the rotational lines within the bands (14), rather than on the total intensities of the bands. When the Eckart rotation is small, $\mathbf{\Lambda}^e$ can be replaced by the unit matrix and the second term in eq. [22] can be ignored.

In the harmonic approximation, the vibrational wavefunctions for the zero-point level and for the ν_k fundamental levels are

$$[24]\quad \begin{aligned}\psi(0) &= \pi^{-N/4}\exp\left(-\frac{1}{2}\sum_m q_m^2\right)\\ \psi(\nu_k) &= 2^{1/2}\pi^{-N/4}\,q_k\exp\left(-\frac{1}{2}\sum_m q_m^2\right)\end{aligned}$$

where N is the number of vibrational degrees of freedom. These functions are normalised in **q**-space. For non-totally-

[a]The two solutions for the potential in each state give identical calculated wavenumbers.

symmetric vibrations such as the out-of-plane modes there is no Franck–Condon change of origin. Thus the Condon overlap integrals for the 0–0 band and the ν'_k–ν''_l sequence are obtained in the form

$$C(0\text{–}0) = \pi^{-N/2} \int (\det \mathbf{D})^{1/2} \cdot \exp\left\{-\frac{1}{2}(\mathbf{q}'')^{\mathrm{T}}(\mathbf{E} + \mathbf{D}^{\mathrm{T}}\mathbf{D})\mathbf{q}''\right\} \mathrm{d}^N q''$$

$$[25] \quad C(\nu'_k\text{–}\nu''_l) = 2\pi^{-N/2} \int (\det \mathbf{D})^{1/2} \sum_m D_{km} q''_m q''_l \cdot \exp\left\{-\frac{1}{2}(\mathbf{q}'')^{\mathrm{T}}(\mathbf{E} + \mathbf{D}^{\mathrm{T}}\mathbf{D})\mathbf{q}''\right\} \mathrm{d}^N q''$$

The factors $(\det \mathbf{D})^{1/2}$ are due to renormalisation of ψ' to $\mathbf{q}''$ space. The integrals can be evaluated (16) by transforming the exponent to a sum of squares and reducing the integral to a product of N standard one-dimensional integrals. Here we are interested in the ratio of the two integrals in eq. [25], which is found to be

$$[26] \quad \frac{C(\nu'_k\text{–}\nu''_l)}{C(0\text{–}0)} = \sum_m D_{km}(A^{-1})_{ml} = (X^{-1})_{kl}$$

Here $\mathbf{A}$ and $\mathbf{X}$ are the matrices

$$[27] \quad \mathbf{A} = \frac{1}{2}(\mathbf{E} + \mathbf{D}^{\mathrm{T}}\mathbf{D}) \qquad \mathbf{X} = \frac{1}{2}(\mathbf{D}^{\mathrm{T}} + \mathbf{D}^{-1})$$

The first form of eq. [26] involving the symmetric matrix $\mathbf{A}$ is more convenient for numerical calculations, whereas the second form involving the non-symmetric matrix $\mathbf{X}$ shows better the symmetry between the electronic states.

4. Results

The observed a'' fundamental frequencies of the four H and D isotopes of propynal in the $\tilde{X}$ and $\tilde{A}$ electronic states are given in Table 2. These are uncorrected for anharmonicity. In the calculations of the harmonic potential the $\tilde{X}$- and $\tilde{A}$-state structures shown in Fig. 1 were employed. The $\tilde{X}$-state structure is (17)

$$H_1C_2 = 1.055,\ C_2C_3 = 1.209,\ C_3C_4 = 1.445,$$
$$C_4O_5 = 1.215,\ C_4H_6 = 1.106\ \text{Å}$$
$$\angle H_1C_2C_3 = 180°,\ \angle C_2C_3C_4 = 178.4°,$$
$$\angle C_3C_4O_5 = 123.8°,\ \angle C_3C_4H_6 = 113.9°$$

where the $C_3C_2H_1$ chain is bent away from the O atom. The $\tilde{A}$-state structure is only approximate, based on the rotational constants and Franck–Condon considerations (3, 4):

$$H_1C_2 = 1.073,\ C_2C_3 = 1.238,\ C_3C_4 = 1.363,$$
$$C_4O_5 = 1.325,\ C_4H_6 = 1.091\ \text{Å}$$
$$\angle H_1C_2C_3 = 180°,\ \angle C_2C_3C_4 = 181.6°,$$
$$\angle C_3C_4O_5 = 122.8°,\ \angle C_3C_4H_6 = 118.1°$$

In this structure the $C_3C_2H_1$ chain is bent towards the O atom.

Least-squares fits of the potential constants to the frequencies in Table 2 converged fairly rapidly, and gave two well-defined solutions for each electronic state, depending on the choice of initial potential constants in the refinement. These solutions are related according to eq. [12], and give identical calculated frequencies, given in Table 2. The standard deviations are 0.6 cm^{-1} for the $\tilde{X}$ state and 1.7 cm^{-1} for the $\tilde{A}$ state. The sets of potential constants are given in Table 3.

For each electronic state, one solution is presumably the "correct" solution, and the other has no physical reality: it is merely an artefact of the shortage of information. Thus the alternative solutions in these kinds of situations are often physically or chemically ridiculous. That seems to be the case for solution 2 in the $\tilde{X}$ state, where the large value of $F_{12,12}$ and the large interaction constants $F_{10,12}$ and $F_{11,12}$ do not agree with "intuition" (i.e. experience with similar molecules). The excited state is rather different. In the first place, the solutions are much more similar to each other; and, in the second place, experience with stable ground-state molecules is a less reliable guide. Thus it is desirable to use additional data to choose between the two $\tilde{A}$-state solutions. The difference between the $\tilde{X}$ and $\tilde{A}$ states with respect to this ambiguity may be related to the different distributions of

frequencies in the two cases. The $\tilde{X}$ state has a wide spread (721 cm^{-1}) between the highest and lowest a'' frequency, and as a result the spurious solution can be quite different from the correct solution. On the other hand, the $\tilde{A}$ state has an unusually narrow spread (116 cm^{-1}) of frequencies, and the spurious solution has to be fairly close to the correct solution.

Table 4 contains the calculated sequence intensities of the HCCCHO isotopomer for the four possible pairs of solutions. The Eckart rotation about the c axis was found to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

very small (0.47°), and essentially the same results were obtained by ignoring it. It is seen from Table 4 that the intensities come in pairs that are essentially indistinguishable experimentally. This follows from the facts that the Eckart rotation is small and that the matrix **Y** in eq. [16] is essentially the same in both electronic states. Thus if both upper- and lower-state solutions are changed to their alternatives, the **Y** matrices largely cancel out and the intensities are practically unchanged. However, the two pairs are quite different. One pair (1–1 and 2–2) gives strong ν'_{11}–ν''_{12} and ν'_{12}–ν''_{11} cross sequences, while the other pair (2–1 and 1–2) gives strong ν'_{10}–ν''_{12} and ν'_{12}–ν''_{10} cross sequences, together with a rather weak ν'_{10}–ν''_{10} sequence. The observed intensities clearly support the former.

Thus the cross-sequence intensities, in conjunction with the "intuitive" choice for the ground state, give 1–1 as the correct solutions for the $\tilde{X}$ and $\tilde{A}$ states. Calculated sequence and cross-sequence intensities for the D isotopes with these solutions are presented in Table 5. The agreement with observation is satisfactory for DCCCHO, but somewhat less good for HCCCDO. The latter isotopomer has an unusually small spread of frequencies (90 cm^{-1}), and the forms of its normal coordinates are particularly sensitive to the values of the potential constants. Thus accurate sequence and cross-sequence intensities of this isotope might be useful data for refining the potential constants.

5. Discussion

This work has shown that the ambiguity in the a'' harmonic potentials of the $\tilde{X}$ and $\tilde{A}$ states of propynal can be resolved by using the cross-sequence intensities together with the fact that one of the solutions for the ground state seems chemically unreasonable. The preferred solutions here are similar to those obtained by Williams (11), although he makes no reference to the alternative solutions. However, there seems to be some error in the results presented by Williams. For example, the calculated cross-sequence intensities in his Table IV are much weaker than those observed and calculated here. His intensities are correctly calculated from the $\mathbf{L}^{-1}$ matrices in his Table III. However, the latter do not seem correct, at least for the $\tilde{X}$ state. For example, the value of $F_{10,11}$ (his numbering) for the $\tilde{X}$ state calculated from

$$[28] \quad \mathbf{F} = (\mathbf{L}^{-1})^{\mathrm{T}} \boldsymbol{\lambda} \mathbf{L}^{-1}$$

does not agree with the value in his Table I, while $(G^{-1})_{10,11}$ (his numbering) calculated from

$$[29] \quad \mathbf{G}^{-1} = (\mathbf{L}^{-1})^{\mathrm{T}} \mathbf{L}^{-1}$$

seems to be about 10% too large.

In principle, the observed inertial defect Δ_0 of the $\tilde{A}$ state (5) might allow a distinction between the two possible harmonic potentials. The inertial defect depends on the out-of-plane potential through Coriolis coupling with in-plane vibrations (19–21). Thus a harmonic potential for the in-plane vibrations is required. To study this possibility, Δ_0 was calculated with both a'' harmonic potentials in conjunction with the a' potential of Williams (11). It was found that both gave Δ_0(calcd) = 0.20 $Å^2$ for HCCCHO, in quite good agreement with Δ_0(obsd) = 0.175 $Å^2$. Thus this test does not discriminate between the two solutions.

In formaldehyde it is well known (18) that the first excited singlet state is non-planar. The large drop in the $F_{10,10}$ potential constant in propynal to 25% of its ground-state value is a reflection of the same tendency. However, as a result of the conjugation in propynal the effect is delocalised into the ethynyl group, and $F_{11,11}$ drops to 36% of its ground-state value. The net result is that propynal in its $\tilde{A}$ state seems to be essentially planar, although possibly with a rather flat-bottomed out-of-plane potential. Evidence for the latter comes from the anharmonicity of the out-of-plane vibrations (3, 4), and also from the intensity of the relatively strong sequence band ν'_{10}–ν''_{10}.

Predicting thermodynamic stability of diatomic dications: a case study of BeF^{2+}

MARCIN KOLBUSZEWSKI AND JAMES S. WRIGHT[1]

Ottawa–Carleton Chemistry Institute, Department of Chemistry, Carleton University, 1125 Colonel By Drive, Ottawa, ON K1S 5B6, Canada

Received February 10, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

MARCIN KOLBUSZEWSKI and JAMES S. WRIGHT. Can. J. Chem. **71**, 1562 (1993).

General criteria are discussed for the prediction of thermodynamically stable diatomic dications (i.e., cations of +2 charge). For a diatomic AB^{2+}, the most useful quantity for this purpose is Δ, the difference in energy between the attractive channel with asymptote $A + B^{2+}$ and the repulsive channel with asymptote A^+ and B^+. Excluding noble gas compounds and using this measure, diatomic dications that may be thermodynamically stable include BeF^{2+}, MgO^{2+}, MgF^{2+}, $MgCl^{2+}$, and SiF^{2+}, as well as several other less likely combinations. The dication BeF^{2+} was selected for further analysis. *Ab initio* calculations show that the $X^2\Pi$ state of this ion is thermodynamically stable by 1.08 eV and undergoes an avoided crossing that causes the effective dissociation energy to be 2.07 eV. The excited state $A^2\Sigma^+$ is also very low-lying and predicted to be long-lived. The $X^2\Pi$–$A^2\Sigma^+$ band system is electric dipole allowed but very weak in intensity. Possible mechanisms of formation of BeF^{2+} are discussed.

MARCIN KOLBUSZEWSKI et JAMES S. WRIGHT. Can. J. Chem. **71**, 1562 (1993).

On discute de critères généraux permettant de prédire la stabilité thermodynamique de dications diatomiques (comme les cations de charge +2). Pour une entité diatomique AB^{2+}, la quantité la plus utile est le Δ, la différence d'énergie entre la canal attractif avec asymptote $A + B^{2+}$ et le canal répulsif avec asymptote $A^+ + B^+$. Excluant les composés des gaz rares et utilisant cette mesure, les dications diatomiques qui peuvent être thermodynamiquement stables incluent le BeF^{2+}, le MgO^{2+}, le MgF^{2+}, le $MgCl^{2+}$ et le SiF^{2+} ainsi que plusieurs autres combinaisons moins probables. On a choisi le dication BeF^{2+} pour d'autres études. Des calculs *ab initio* montrent que l'état $X^2\Pi$ de cet ion est thermodynamiquement stable par 1,08 eV avec une énergie de dissociation effective de 2,07 eV. L'état excité $A^2\Sigma^+$ est aussi très bas et sa vie devrait être longue. Le système de bande $X^2\Pi$–$A^2\Sigma^+$ est un dipôle électrique permis d'intensité très faible. On discute des mécanismes de formation possibles du BeF^{2+}.

[Traduit par la rédaction]

Introduction

The gas-phase study of molecular +2 ions (dications) is progressing rapidly, thanks to advances in charge-stripping mass spectrometry, electron impact spectroscopy, and double charge-transfer spectroscopy. Reviews of these techniques and the results obtained using them are given in refs. 1 and 2. A growing number of theoretical studies have also added to the understanding of potential curves and chemical bonding in dications. In homonuclear diatomics of the second period, so far only C_2^{2+} (3), N_2^{2+} (4), and O_2^{2+} (5) have been observed experimentally, but potential curves for ground and excited states are available for Be_2^{2+} (6), B_2^{2+} (7), and F_2^{2+} (8) from theoretical calculations. A variety of heteronuclear diatomics have also been studied. For example, NO^{2+} has been well characterized experimentally (9) and CNe^{2+} has been predicted theoretically to have a metastable ground state that could be observable (10).

To the best of our knowledge, however, no diatomic dication has yet been experimentally observed which is *thermodynamically stable,* where the minimum in the potential curve lies below the lowest dissociation products. At first sight this is not surprising in view of the strong repulsion between the monocations A^+ and B^+ in the diatomic AB^{2+}. However, in an important paper Frenking et al. (11) showed that the helium compounds $HeBe^{2+}$, HeB^{2+}, and HeC^{2+} are all thermodynamically stable by 20.1, 16.6, and 17.7 kcal/mol, respectively. The dications $NeBe^{2+}$ and $ArBe^{2+}$ were predicted to be even more stable (12), and the authors have suggested that these noble gas compounds could be observed experimentally. The bonding interaction was shown to be primarily electrostatic, arising from the polarization of the noble gas by the Be^{2+} ion.

In this paper we discuss the criteria for stability given by various authors, and consider whether diatomic dications that do not contain noble gases could also be thermodynamically stable. If such compounds do exist, they could be easier to synthesize than the noble gas compounds. Promising candidates for stability include BeF^{2+}, MgO^{2+}, MgF^{2+}, $MgCl^{2+}$, and SiF^{2+}. For the most part these dications have not been examined previously. From among these we have selected BeF^{2+} for a more thorough investigation. We use extensive *ab initio* calculations to analyze the potential curves of this molecular ion, and discuss its stability in ground and electronic excited states.

Thermodynamic stability of dications

The principles underlying the formation of diatomic dications are by now rather well understood. In a paper in 1955 that was remarkable for its foresight, Bates and Carson (13) showed that the dominant interactions in the dication of type AB^{2+} can be analyzed in terms of a repulsive channel **R** leading to A^+ and B^+, and an attractive channel **A** leading to $A + B^{2+}$. This pioneering work laid the foundation for many of the developments to follow.

For example, in a series of papers Radom and Gill and coworkers (14, 15) analyzed the dissociation of the dication AB^{2+} in terms of an avoided crossing (AC) model, where an interaction occurs between an attractive channel that correlates to $A + B^{2+}$, and a repulsive channel that correlates to $A^+ + B^+$. The location of the crossing between diabatic potential curves allows prediction of the location of the maximum in the metastable lower state. The extension of the

model (15) includes diabatic interactions and polarization (ACDCP model). This model neglects the chemical bonding along the potential curves, which may be particularly important for the A^+–B^+ interaction. The virtue of these models is that they require only the ionization potentials of the atoms and the polarizability of the atom A to make useful predictions about potential curves.

Further development along these lines by Bruna and Wright (7) extended these ideas to include higher lying electronic states with different dissociation limits, and a molecular orbital treatment of the bonding interactions. A related approach was used by Frenking et al. (11), who used an MO approach to discuss the chemical bonding in dications in terms of donor–acceptor interactions.

An alternative model, introduced by Hurley and Maslen (16), considers that the important interaction in AB^{2+} can be estimated by considering the potential curve of the isoelectronic neutral molecule, superimposed on the Coulomb repulsion potential of the monocations A^+ and B^+. This idea was also proposed in the original work of Bates and Carson (13). The model was successfully applied to O_2^{2+} and N_2^{2+} and properties were predicted for several other molecules, including F_2^{2+}. Recently an *ab initio* study of F_2^{2+} in the ground state confirmed the usefulness of this model (8). Although it would be expected to be most useful for homonuclear diatomics, it was also shown to give good predictions of potential curves in the case of CO^{2+} (17).

Because the second ionization potential of any atom is always significantly greater than the first, the dissociation channel for the homonuclear dication A_2^{2+} correlating with the monocations $A^+ + A^+$ must always lie below the asymmetric channel $A^{2+} + A$. Since the difference is in general much too large to be compensated for by any bonding interactions among the species, the consequence is that homonuclear dications will not be thermodynamically stable but can at best be metastable. We can therefore begin any search for absolute stability of diatomic dications by eliminating the homonuclear case. By extension of this argument, the heteronuclear case where the atoms lie close together in ionization potential is also unlikely to be thermodynamically stable.

Since we wish to predict stability for the case of the heteronuclear dication AB^{2+}, the single most useful criterion is Δ, the difference in energy between attractive and repulsive channels (13–15). This quantity, which is currently defined as Δ = $IP_2(B) - IP_1(A)$, was introduced by Bates and Carson (13) except with opposite sign. When Δ is positive but small, say less than 5 eV, then the combination of bonding interactions in the repulsive channel and charge-induced polarization in the attractive channel may be sufficient to cause the ground-state potential curve to lie below the lowest dissociation limit. When Δ is negative, implying that dissociation to monocations lies above the asymmetric dissociation to $A + B^{2+}$, then a thermodynamically stable ground state is essentially guaranteed. These two cases correspond to Figs. 5*b* and 5*a* in the discussion given by Frenking et al. (11). Since the calculation of Δ depends only on atomic IP data, we can tabulate values for all possible combinations of interest, in particular those that contain atoms from the second and third periods. In fact, these atomic data were also available to Bates and Carson, who therefore in 1955 could have given the same predictions that we present in this paper. What could not be done at that time, however, was to give an accurate molecular calculation that can verify the prediction for diatomics composed of atoms from the second or third periods.

Tables 1–3 show the value of Δ for combinations of atoms from the second period exclusively (Table 1), from the third period exclusively (Table 2), or mixed diatomics containing one atom from each period (Table 3). All IP data were taken from the compilation by Moore (18). For the second period, Table 1 shows that there is a generally decreasing trend in Δ, as expected, as the compound becomes more ionic. The homonuclear case has a minimum value of Δ = 8.9 eV for the Be_2^{2+} molecule, which is known to be metastable in its ground electronic state (6). Ionic compounds of Be are particularly interesting. Thus only $BeNe^{2+}$ has a negative Δ, consistent with the results of Frenking et al. that $BeHe^{2+}$ and $BeNe^{2+}$ are thermodynamically stable (11, 12). The next most likely possibility is BeF^{2+} with Δ = +0.8 eV. The dication CNe^{2+}, with Δ = +2.8 eV, is also a possibility. However, accurate calculations reported by Koch and Frenking (10) showed that CNe^{2+} lies above its lowest dissociation limit by 1.94 eV. All other possible combinations from Table 1 have Δ greater than 3 eV, and it is unlikely that any of them

have sufficient bonding interactions to be thermodynamically stable.

Third-period dications (Table 2) show the expected stability of compounds of Ar, which were reported by Frenking et al. (12). Thus $MgAr^{2+}$ has the only negative entry for Δ, but $SiAr^{2+}$ is also very low-lying at 0.6 eV. For non-noble gas compounds, the most promising combination is $MgCl^{2+}$, at only 2.1 eV. Other combinations would appear to lie too high to be serious possibilities.

Table 3, which contains the mixed dications, shows a considerable number of negative entries. Four compounds of type XNe^{2+} have negative entries, where X = Mg, Al, Si, and P, and two others (S and Cl) have values near 2 eV. Among the non-noble gas compounds, MgF^{2+} and SiF^{2+} are both negative and thus predicted to be stable. The magnesium dications MgN^{2+} and MgO^{2+} are very low-lying at 0.5 and 1.4 eV, respectively, and may be stable. Other systems lying below 2 eV include AlF^{2+} and SiN^{2+}.

There are distinct advantages when trying to detect a dication to start from a stable neutral precursor, and an outstanding candidate from Table 1 is BeF^{2+}, which has the low Δ value of 0.8 eV. In addition, high-accuracy calculations can be performed for all diatomics composed of second-period atoms. We now focus on the electronic states of this particular dication.

Method of calculation

We used a flexible 6*s*4*p*2*d*1*f* basis set on Be and 6*s*5*p*2*d*1*f* on F, derived from the 10*s*6*p* primitive set of Gaussian-type orbitals given by Huzinaga (19). A 10*s*/5*s* contraction (20) and 5*p*/3*p* (21) contraction on Be was used to obtain a valence triple-zeta basis. In addition, the beryllium basis set was augmented with 2*d*1*f* polarization functions (α_d = 0.3, 0.05; α_f = 0.26) (22) and semidiffuse *sp* ($\alpha_{s,p}$ = 0.025) functions. On fluorine we used the 10*s*6*p*/5*s*4*p* valence triple-zeta basis of Dunning (20), with the addition of semidiffuse *s*,*p* functions ($\alpha_{s,p}$ = 0.074) (21) and 2*d*1*f* polarization functions (α_d = 3.107, 0.855, α_f = 1.917) (23).

The multireference single- and double-excitation (MRD-CI) method of Buenker and co-workers (24) was used to obtain total energies. The molecular orbitals of the ground state $X^2\Pi$ were used for the CI expansion. At the CI step, excitations from the two lowest σ MO's were excluded and the high-lying counterpart MO's were discarded, leaving 7 electrons to populate 79 MO's.

Thirty-six reference configurations were used for the two lowest $^2\Pi$ states and 24 reference configurations for the $^2\Sigma^+$ states. A configuration selection threshold of 5.0 microhartree (μE_h) led to CI spaces on the order of 10 000, selected from the generated space of 867 123 ($^2\Pi$) and 610 113 ($^2\Sigma^+$). Energies arising from the matrix diagonalization were extrapolated to zero selection threshold and subsequently corrected using the generalized Davidson (25) correction for higher-order excitations. These energies, denoted MRCI(+Q), were used to obtain potential curves and spectroscopic constants.

Calculations were carried out at 40 internuclear geometries spanning the range from 2.0 to 50.0 bohr. Additional calculations were carried out at 1000.0 bohr to establish the dissociation limits for the channels of interest. The calculated energy corresponding to the repulsive channels was lowered by 0.001 E_h, in order to account for the Coulomb repulsion still present at 1000 bohr.

Calculated MRCI(+Q) energy values were fitted to a polynomial function over the range R = 2.5–5.0 bohr with an rms deviation smaller than 0.1 millihartree. Vibrotational levels were calculated using the Numerov–Cooley method. The resulting $E_{v,J}$ levels were fitted to a standard spectroscopic expansion in the constants ω_e, $\omega_e x_e$, B_e, and α_e.

Radiative properties were calculated following the procedure described in ref. 26. All calculations were carried out in the subgroup C_{2v}. Transition moments were calculated using the length form of the dipole moment operator. The total transition moment squared $\Sigma R^2_{e'e''}$ is equivalent to $KR^2_{e'e''}$, where K takes into account all possible space and spin components of both states (for the $A^2\Sigma^+$–$X^2\Pi$ system, K = 4). The band strength is defined as

$$S_{v'v''} = K|\int \phi_{v'}(R)R_{e'e''}(R)\phi_{v''}(R)\mathrm{d}R|^2$$

where φ is the vibrational wavefunction and $R_{e'e''}$ is a polynomial fit to the calculated $R_{e'e''}$ values. The absorption oscillator strength is defined as

$$f_{v'v''} = \frac{2}{3}K'\Delta E_{v'v''}S_{v'v''}$$

where in this case $K' = \frac{1}{4}$ (i.e., for absorption from $X^2\Pi$), and $\Delta E_{v'v''}$ is in atomic units. For emission from the upper state $A^2\Sigma^+$, the Einstein coefficients (in s^{-1}) are given by

$$A_{v'v''} = 2.1419 \times 10^{10}K''\Delta E^3_{v'v''}S_{v'v''}$$

where $K'' = \frac{1}{2}$. Total fluorescence lifetimes involve the summation of $A_{v'v''}$ values over all v'', so that $\tau^{-1}_{v'} = \Sigma_{v''}A_{v'v''}$.

Results and discussion

Dissociation channels and electronic states

Information about the lowest dissociation channels of BeF^{2+} is summarized in Table 4. As discussed earlier, the

$2^2\Sigma^+$	$\sigma^2\sigma^0\sigma\pi^4$	**II**	14.67

[a]Vertical excitation energy from the minimum of $X^2\Pi$ at 3.09 bohr.

lowest channel corresponds to the repulsive channel **I** correlating with Be^+ and F^+ in their ground states. The next channel **a** is the attractive channel at +0.79 eV, correlating with Be^{2+} + F in their ground states. The higher channels **II**, **III**, and **IV** correspond to $Be^+ + F^+$ in excited states. For this table the CI energy was calculated separately for the ions of Be and F. Therefore the energy of Be^+ and Be^{2+} is just the SCF energy, in the frozen core approximation. The energy of the first attractive channel **a** is overestimated at the MRCI(+Q) level by 0.15 eV, but the remaining channels agree with the experimental values to within 0.03 eV.

As shown in Table 4, channel **I** correlates with four states and channel **a** with two. The only common state for these two channels is $^2\Pi$, and it is the mixing between $^2\Pi$ states that is of greatest interest. The state $A^2\Sigma^+$ correlates with channel **a**, and therefore will be expected to be at least metastable.

The dominant configuration of the 10 lowest lying states is shown in Table 5. In this notation core orbitals (1σ and 2σ) are omitted, and the molecular orbitals 3σ,4σ,5σ and 1π,2π are designated $\sigma\sigma\sigma$ and $\pi\pi^*$, respectively. Thus the state $3^2\Pi$, which has configuration $3\sigma^24\sigma^21\pi^22\pi$, is designated $\sigma^2\sigma^2\pi^2\pi^*$, etc.

The electronic configurations of most interest are $\sigma^2\sigma^2\pi^3$, $\sigma^2\sigma\sigma\pi^3$ and $\sigma^2\sigma\pi^4$. The two former configurations belong to symmetry $^2\Pi$, whereas the latter is $^2\Sigma^+$. In $\sigma^2\sigma^2\pi^3$ the occupancy corresponds to filled $2s$,$2p_\sigma$ orbitals on F ($2p_\sigma$ lies on the bond axis), with three electrons in the $2p_\pi$ orbitals on F (perpendicular to the bond axis). This configuration is therefore ionic, and corresponds to Be^{2+} + F. The $\sigma^2\sigma\sigma\pi^3$ configuration has one σ-electron in $2p_\sigma$ on F and the other in $2s$ on Be; this configuration therefore has the covalent form $Be^+ + F^+$. For the configuration $\sigma^2\sigma\pi^4$, the second σ-MO corresponds essentially to $2p$ on F, so the best representation for this configuration is also the ionic form Be^{2+} + F. We will refer to these ionic and covalent configurations frequently in the discussion which follows.

Table 5 also shows the vertical excitation energies T_v, measured from the potential minimum in the ground electronic state. Only the state $A^2\Sigma^+$ is low-lying, with all other states lying higher than 10 eV above the ground state. This makes the discussion of the low-lying states very straightforward.

Potential energy curves

Potential energy curves for the various electronic states are shown in Fig. 1. Most of the potential curves are repulsive,

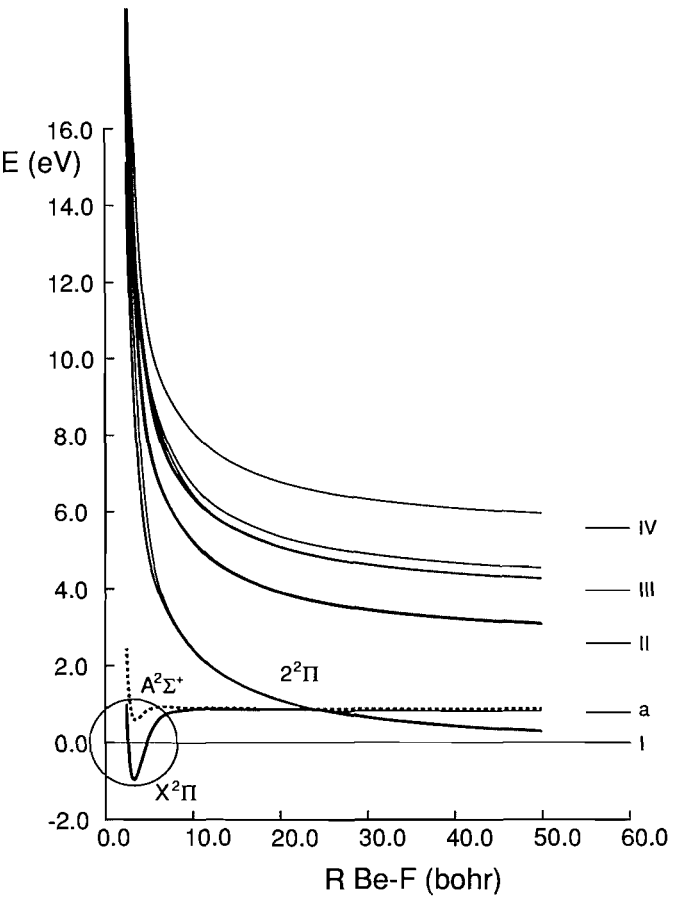

FIG. 1. Potential curves for the low-lying electronic states of BeF^{2+}. The dissociation energy of the five lowest channels is shown at the right.

including all those correlating with channels **II**, **III**, and **IV** (14 states, see Table 4). This is to be expected, since these states correlate with $Be^+ + F^+$. The repulsive states are dense and close-lying and cannot be clearly distinguished in the figure.

The ground state is $X^2\Pi$. This state shows an avoided crossing at long range with the excited state $2^2\Pi$. Most significant is the fact that the well depth in this state is such that the potential minimum, which occurs at R_e = 3.09 bohr, lies 1.08 eV below the lowest asymptote **I**. The BeF^{2+} dication is therefore thermodynamically stable. The avoided crossing, which occurs near R = 24 bohr, lies 0.99 eV above the lowest limit. The effective dissociation energy D_{eff} is 2.07 eV, measured from the potential minimum. The very broad shape of this dissociation barrier indicates that, except for vibrational levels near the very top of the barrier, the tunneling lifetime of the molecule in the ground electronic state is essentially infinite.

The $A^2\Sigma^+$ state is also bound relative to its own dissociation limit, which is channel **a**. This state is bound by 0.45 eV, and has its minimum at R_e = 3.23 bohr. Although this state is not formally thermodynamically stable, because of the presence of a lower lying dissociation limit, the coupling interaction between $A^2\Sigma^+$ and $X^2\Pi$ is probably weak except at large R. This means that lower vibrational levels in the excited state $A^2\Sigma^+$ could well be long-lived, so that spectral transitions between these two states could be observable.

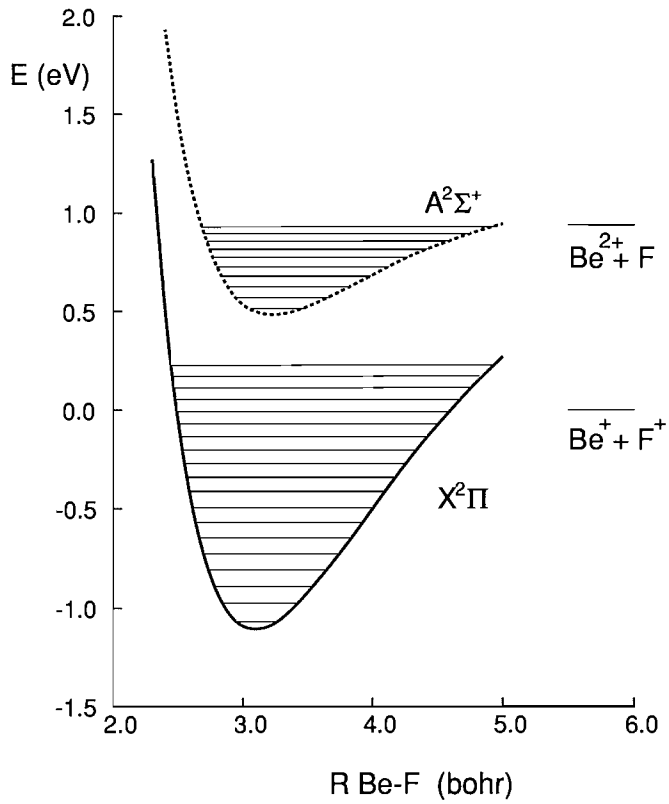

FIG. 2. Expanded view of the potential curves for the ground state $X^2\Pi$ and the lowest excited state $A^2\Sigma^+$, showing some of the bound vibrational levels for each state. The lowest dissociation limit is channel **I** and the next lowest is channel **a** (see Fig. 1).

The shapes of the two potential curves can be understood in terms of the dominant configurations in each region. Considering $^2\Pi$ states first, the attractive channel has the ionic configuration $\sigma^2\sigma^2\pi^3$ near the asymptotic limit. This configuration remains the dominant configuration in the region of the potential minimum for $X^2\Pi$. The solid curve that approaches channel **I** has the covalent configuration $\sigma^2\sigma\sigma\pi^3$. This configuration also describes the excited state $2^2\Pi$ at short R. Thus we have two diabatic potentials, one of which is attractive (ionic) and one of which is repulsive (covalent). These states interact weakly near 24 bohr so that an avoided crossing results, with the resulting potential minimum and effective barrier in the adiabatic potential curve for the ground state $X^2\Pi$. The excited state $A^2\Sigma^+$, with ionic configuration $\sigma^2\sigma\pi^4$, correlates directly to attractive channel **a** and thus has the simple Morse-like form, with a shallow potential minimum.

This interpretation of the charge distribution in each state was obtained by analysis of the configurations contributing to the CI wave function. The interpretation was checked by performing a Mulliken population analysis. At the potential minimum of the ground state, we obtained partial charges of +1.75 on Be and +0.25 on F, confirming that the interaction is essentially ionic, of the form Be^{2+} + F.

The shapes of the two lowest states are shown over a smaller range in Fig. 2. Here it can be seen that $X^2\Pi$ has 15 vibrational levels that lie below the asymptotic limit (channel **I**). The potential well in the excited state $A^2\Sigma^+$ also supports about 10 bound vibrational levels.

TABLE 6. Spectroscopic constants of bound states of BeF^{2+} and LiO

Species	BeF^{2+}		LiO[a]	
parameter	$X^2\Pi$	$A^2\Sigma^+$	$X^2\Pi$	$A^2\Sigma^+$
T_e (eV)	0.00	1.59	0.00	0.29

α (cm^{-1})	0.019	0.029	0.015	0.020

[a]Values taken from Huber and Herzberg (27).

Spectroscopic constants for the two-lying states are shown in Table 6, along with the constants for the isoelectronic neutral molecule LiO (27). Since the LiO molecule is polarized in the form Li^+O^-, the electron configurations are analogous to those in BeF^{2+} and the ground state is $^2\Pi$ in each case. According to Partridge et al. (28), the reason that $^2\Pi$ lies lower in LiO and BeO^+ is that the electrons along the σ (bond axis) direction on O are closer to the cation and thus experience a greater attractive force. In the case of BeF^{2+}, a similar argument could be used to account for the greater stability of the state ($^2\Pi$), with two $2p_\sigma$ electrons on the bond axis, rather than the state ($^2\Sigma^+$) with only one such electron. However, the splitting between the $^2\Pi$ and $^2\Sigma^+$ states in the series of alkali oxides LiO, NaO, KO,..., which change order from a $^2\Pi$ ground state (LiO, NaO, KO) to $^2\Sigma^+$ in the higher oxides, has been analyzed in more detail by Goddard and coworkers (29). They show that the ordering of the states is actually the result of a balance between Pauli repulsion forces (favoring $^2\Sigma^+$) and quadrupole interactions (favoring $^2\Pi$). By analogy, the series of dications BeF^{2+}, MgF^{2+}, ... may also show an inversion in the order of $^2\Pi$ and $^2\Sigma^+$ states as the atomic number of the cation increases.

The bond distance in the ground state of BeF^{2+} is even shorter than in LiO (3.09 vs. 3.20 bohr). This is another indication that the BeF^{2+} dication has the strongly attractive ionic configuration (near its minimum) and is not mixed with the covalent repulsive configuration. The dissociation energy is much less than in LiO, however, partly due to the avoided crossing described earlier.

The strength of the bond in BeF^{2+} is comparable with other molecules in which charge-induced polarization is responsible for the bonding. For example, for $BeHe^{2+}$, D_e = 0.87 eV (11) and for $BeNe^{2+}$, D_e = 1.25 eV (12). In both noble gas compounds the minima correspond to a Be^{2+} + X structure, with little or no covalent bonding.

The $X^2\Pi$–$A^2\Sigma^+$ band system

The $X^2\Pi$–$A^2\Sigma^+$ band system has an electric-dipole-allowed transition near 1.6 eV, so transition between these states will occur in the near IR and could be of help in identifying the BeF^{2+} ion. Since the minima occur at 3.09 and 3.29 bohr for the X and A states, respectively, the relatively small shift of 0.14 bohr suggests that Franck–Condon factors (FCF's) should be favorable and that transitions between vibrational levels in upper and lower states should be nearly diagonal. However, as shown in Fig. 2, the levels are

[c]Einstein coefficients (s^{-1}).
[d]Oscillator strength.
[e]Fluorescence lifetime of v' level (ms). The series of Einstein coefficients was summed over 20 v'' levels and is converged.

closely spaced, with harmonic frequencies in lower and upper states of only 717 and 497 cm^{-1}, respectively. Thus we can anticipate that intensity of absorption from each lower vibrational level may be spread over several upper levels, and vice versa.

Table 7 shows some radiative data for emission from a given upper level v' to the lower levels $v'' = 0$–5. The table is arranged so that the top line in each block of v'' levels gives the transition energies, the next line gives the FCF's, the third line gives the Einstein coefficients, and the fourth line gives the oscillator strengths. The fluorescence lifetime of each v' level is given at the bottom of the table.

The FCF's are indeed nearly diagonal, and in fact the largest FCF (= 0.706) occurs for the 0–0 transition. Transitions from levels $v' = 1,2$ occur with $\Delta v = \pm 1$ and the range increases for higher levels. The Einstein coefficients and oscillator strengths are all very low, so that lifetimes for the v' levels are of the order of 10 ms ($v' = 0$) or 1 ms (the other v' levels). This will cause low intensity and make the A–X emission band very difficult to observe.

A very similar situation holds for the isoelectronic LiO molecule, data for which are given in Table 6. In this case the upper state $A^2\Sigma^+$ has the shorter bond length, but the shift between the minima is similar at 0.18 bohr. Detailed radiative data for the A–X band were given by Yoshimine et al. (30). FCF's are very similar to those of BeF^{2+}, e.g., their largest reported value of 0.577 also occurred for the 0–0 transition. Oscillator strengths for transitions from $X^2\Pi$ in LiO are about a factor of four higher than in BeF^{2+}, and this band system has not yet been experimentally observed in LiO (27). Thus, although the transition is electric dipole allowed in each case, the intensity is so low as to make experimental observation very difficult.

Since the polarization in each system corresponds to $Be^{2+}F$ and Li^+O^-, the reason for the low intensity is the same. In each case the (absorption) transition occurs in the perturbed $2p^5$ manifold on F or O^-, i.e., from $2p_\sigma$ to $2p_\pi$. Since this corresponds to a type of p–p transition, it is forbidden in the isolated atom. Polarization of the atom by the cation breaks the symmetry, making it partially allowed but still weak. Unfortunately, therefore, this band system will probably be of no help in identifying the BeF^{2+} dication, and we now consider its simple formation and detection in a mass spectrometer.

Formation of the ion

There are several possible ways to generate diatomic dications. It was proposed by Bates and Carson (13) that noble gas compounds of type $NeMg^{2+}$ should be formed readily in three-body collisions of Mg^{2+} + 2Ne. To the best of our

knowledge, however, this mechanism has never led to observation of any noble gas dications.

In the case of BeF^{2+}, the precursor BeF was prepared by Hildenbrand and Murad (31) by effusing vapors of Be(s) and CaF_2(s). The species BeF^+ was detected in a mass spectrometer. They also observed formation of BeF^+ above 15 eV from the reaction

$$BeF_2 + e^- \rightarrow BeF^+ + F + 2e^-.$$

Once the BeF^+ ion has been generated it has the high D_e of 6.25 eV (28). The ion is thus quite stable and could be further ionized to the dication according to $BeF^+ \rightarrow BeF^{2+} + e^-$. We estimate the IP for this reaction to be 21.4 eV.

Another mass-spectrometric experiment, described by Galindo-Uribarri et al. (32), generates XY^- ions by sputtering from solids X and Y, followed by collision with argon gas at MeV energies (accelerator mass spectroscopy) to produce XY^{2+} ions. This approach led to detection of many ions in the mass range 20–26, due to a window in this range free of interference from atomic ions with these masses. Unfortunately BeF^{2+} has mass 27 and may therefore suffer from interference with Al ions.

A more promising route to products is to generate an excited beam of Be^{2+} ions and react these with the stable reagent, gaseous F_2. The abstraction reaction is then

$$Be^{2+} + F_2 \rightarrow BeF^{2+} + F$$

For formation of BeF^{2+} ($X^2\Pi$), we estimate this reaction to be exothermic by 0.47 eV. Beams of doubly charged Be ions have been prepared in two-laser produced plasmas (33), so the experiment should be feasible. The more exothermic products $BeF^+ + F^+$ would also be formed in the same reaction, so the product ratio for formation of both channels would depend on the detailed dynamics of the reaction and on whether the products are formed under collision-free conditions. The same reaction is endothermic to produce $A^2\Sigma^+$, but since the ion beam can easily be created with energies of several electronvolts and the A-state is expected to be long-lived, mass-spectrometric detection would probably see both $X^2\Pi$ and $A^2\Sigma^+$ states on a millisecond time scale.

Conclusions

By considering energy differences for dissocation of a dication AB^{2+} into the repulsive channel $A^+ + B^+$ and the attractive channel $A + B^{2+}$, we predict that several diatomics not including noble gases may be thermodynamically stable, including BeF^{2+}, MgN^{2+}, MgO^{2+}, MgF^{2+}, $MgCl^{2+}$, SiN^{2+}, SiO^{2+}, and SiF^{2+}. *Ab initio* calculations prove that this is the case for the ground state $X^2\Pi$ of BeF^{2+}, which has the positive value of $\Delta = 0.79$ eV. The ground state is indeed thermodynamically stable and has a dissociation energy of 1.08 eV (uncorrected for zero-point energy) relative to the lowest dissociation limit $Be^+ + F^+$. Due to an avoided crossing with the upper state $2^2\Pi$, a barrier is created so that the effective dissociation energy from $X^2\Pi$ is 2.07 eV. The low-lying excited state $A^2\Sigma^+$ is metastable relative to the lowest possible dissociation limits, but is probably very long-lived since it dissociates uphill to an attractive channel and is only weakly connected by radiative transitions to the ground state. The A–X band has been shown to be of low intensity even though it is electric dipole allowed. Several mechanisms are proposed to form the dication BeF^{2+}. The most promising of these would be the exothermic ion–molecule reaction of Be^{2+} and gaseous diatomic fluorine.

Proton transfer equilibrium reactions in some substituted 3*H*-indole probe molecules: role played by the TICT state

RANJIT S. SARPAL, MICHEL BELLETÊTE, and GILLES DUROCHER[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal, QC H3C 3J7, Canada

Received April 23, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

RANJIT S. SARPAL, MICHEL BELLETÊTE, and GILLES DUROCHER. Can. J. Chem. **71**, 1570 (1993).

Five substituted derivatives of the main chromophore, 2-phenyl-3,3-dimethyl-3*H*-indole (**1**), have been studied over a wide range of acidity by UV absorption and steady state fluorescence spectroscopy. These are as follows: 2-[(*p*-amino)phenyl]-3,3-dimethyl-3*H*-indole (**2**), 2-[(*p*-dimethylamino)phenyl]-3,3-dimethyl-3*H*-indole (**3**), 2-[(*p*-amino)-phenyl]-3,3-dimethyl-5-carboethoxy-3*H*-indole (**4**), 2-[(*p*-methylamino)phenyl]-3,3-dimethyl-5-carboethoxy-3*H*-indole (**5**), and 2-[(*p*-dimethylamino)phenyl]-3,3-dimethyl-5-carboethoxy-3*H*-indole (**6**). The dependence of absorption and fluorescence spectral characteristics upon acidity has allowed us to characterize four species, namely, the anion (A), the neutral molecule (N), the cation (C), and the dication (DC), for molecules **2** and **3**. Molecules **4**, **5**, and **6** give rise to an additional anion due to the hydrolysis of the ester group. The relative order of protonations to available sites is discussed. The ring-protonated species have shown the Ph_c and indole rings to be coplanar in both the ground and first excited singlet states. A low-energy non-emissive twisted intramolecular charge transfer (TICT) state taking its origin in the dimethylamino moiety is suggested from INDO-S calculations to explain the strong fluorescence quenching of these ring-protonated species. Acidity constants for the various prototropic equilibria have been determined experimentally both in the ground and in the excited singlet states. Förster cycle calculations have been used to supplement the various equilibrium constants. Possible applications in organized assemblies are discussed.

RANJIT S. SARPAL, MICHEL BELLETÊTE et GILLES DUROCHER. Can. J. Chem. **71**, 1570 (1993).

Faisant appel à l'absorption UV et à la spectroscopie de fluorescence en état stationnaire, on a étudié cinq produits de substitution du 2-phényl-3,3-diméthyl-3*H*-indole (**1**) à diverses acidités. Il s'agit des 2-[(*p*-amino)phényl]-3,3-diméthyl-3*H*-indole (**2**), 2-[(*p*-diméthylamino)phényl]-3,3-diméthyl-3*H*-indole (**3**), 2-[(*p*-amino)phényl]-3,3-diméthyl5-carboéthoxy3*H*-indole (**4**), 2-[(*p*-méthylamino)phényl]-3,3-diméthyl-5-carboéthoxy-3*H*-indole (**5**) et 2-[(*p*-diméthylamino)-phényl]-3,3-diméthyl-5-carboéthoxy-3*H*-indole (**6**). La relation entre les caractéristiques spectrales d'absorption et de fluorescence et l'acidité nous ont permis de caractériser quatre espèces, soit l'anion (A), la molécule neutre (N), le cation (C) et le dication (DC) des molécules **2** et **3**. Les molécules **4**, **5** et **6** donnent aussi lieu à la formation d'un anion additionnel qui provient d'une hydrolyse de l'ester. On discute de l'ordre relatif des protonations des divers sites. On a démontré que les espèces protonées des cycles benzénique et indolique sont coplanaires tant dans l'état fondamental que dans le premier état excité. Sur la base de calculs INDO-S, on suggère qu'un état de transfert de charge intramoléculaire déformé, de basse énergie, non radiatif et dont l'origine se trouverait dans la portion diméthylamino peut expliquer la forte désactivation de fluorescence de ces espèces protonées sur le cycle. On a déterminé expérimentalement les constantes d'acidité des divers équilibres prototropiques tant dans l'état fondamental que dans les états excités. On a utilisé des calculs de cycles de Förster comme suppléments aux diverses constantes d'équilibre. On discute de diverses applications possibles pour des systèmes organisés.

[Traduit par la rédaction]

Introduction

Proton and electron transfer reactions are among the most elementary processes in chemistry and biochemistry (1). Since the original work of Förster (2) and Weller (3) on 1-naphthylamine-4-sulfonate, considerable research work on proton transfer has been done over the years (4–15). Due to these efforts, the acid-base behavior of various substituent groups attached to aromatic moieties in both the S_0 and S_1 electronic states is now well understood. If $\pi \rightarrow \pi^*$ is the lowest energy transition, amino and hydroxy substituents become stronger acids in the S_1 state, which shifts band wavenumber maxima to higher and lower values upon protonation and deprotonation, respectively. To the contrary, esters and tertiary ring nitrogen atoms become strongly basic in the S_1 state, which shifts wavenumber maxima to lower values upon protonation. Thus, the acid-base chemistry becomes a direct function of the electronic structures of aromatic compounds in ground as well as in excited states. Various combinations of these substituent groups with homo- and heterocyclic chromophores have been reported in the literature (16–31). Results show that for the same set of basic centers, the preferential attack of protons has varied from molecule to molecule. To name a few: in amino-substituted quinolines, acridine, and benzimidazole the first preferred protonaton site is the tertiary ring nitrogen (16–20), whereas in oxazoles and thiazoles the preferential proton attack occurs on the terminal amino group (21, 22). Also, ground state protonaton sites are reported to be different from excited state sites for the same molecule, which is attributed to the change in acidity and basicity of the reaction centers (23, 24). All these observations cast serious doubt on the reliable prediction of any kind of equilibrium reactions, and lend strong support to the benefits of their experimental determination.

Important applications, such as use of proton transfer equilibrium in sensing interfacial proton concentration of microheterogeneous media (32–34) and use of phototautomers as effective light protectors and materials in continuous lasers, have surfaced (35–37). Another aspect of acidity and basicity dependence that becomes especially important is evident when absorption and fluorescence probing of organized assemblies is done by external/internal probes that

have one (or more than one) basic center(s). The nature of the species used in probing environments must be defined a priori; otherwise, observations can be misleading. The various species generated as a function of pH should then be used to make estimates about the nature of the environment in organized assemblies.

In the past few years, our laboratory has been particularly interested in examining 3*H*-indole derivatives in various environments (38–41). INDO-S, AMPAC, and X-ray crystallography have been successfully used to quantify various spectroscopic and structural parameters. Because of their spectral dependence on different environments, their fluorescence probing properties in microheterogeneous media have recently been identified (42, 43). As a further extension of these studies, we want to report in this paper the acidity dependence of the following molecules in water.

	A	B	C	D
1	H	-	-	H
2	N	H	H	H
3	N	CH_3	CH_3	H
4	N	H	H	CO_2Et
5	N	H	CH_3	CO_2Et
6	N	CH_3	CH_3	CO_2Et

Molecule **1** has already been studied in our recent communications (41, 43, 44), and is included here for comparison purposes only. The aim of this paper is manifold. We first want to investigate the order of the various protonating sites and to identify the different prototropic species. We also want to follow the order of basicity of the substituent groups in the S_0 and S_1 states and to see whether there is any kind of tautomerism. The proton-induced fluorescence quenching phenomenon will also be looked at to obtain the acidity constants of the various equilibria studied in both S_0 and S_1 states. Possible application to organized assemblies will also be discussed briefly.

2. Experimental section

Synthesis and purification of molecule **3** was done according to the method of Skrabal et al. (45), whereas the other molecules were synthesized by a modified method of Skrabal et al. (46) and will be published elsewhere.[2] Analytical grade reagents sodium hydroxide, sulfuric acid, and phosphoric acid were used as received. Deionized triply distilled water was used in all studies.

The absorption spectra were recorded on a Philips PU-8800 UV-VIS spectrophotometer. Corrected fluorescence spectra were measured on a Spex Fluorolog-2 spectrofluorimeter with a F2T11 special configuration. Fluorescence quantum yields of all the mentioned species were measured using molecule **3** in ethanol (Φ_F = 0.33) (39) as a fluorescence standard. Fluorescence lifetimes were obtained from a multiplexed time-correlated single-photon counting fluorimeter (Edinburgh Instruments, model 299T) (40). A modified Hammett's acidity scale (47) for H_2SO_4-H_2O mixtures and Yagil's basicity scale (48) for NaOH-H_2O mixtures were used below pH 1 and above pH 13, respectively. Solutions in the pH range 3–11 were prepared by adding appropriate amount of NaOH and H_3PO_4. Stock solutions of all the compounds were prepared in methanol and 0.1 mL of this was added to 10 mL of all the aqueous solutions. The concentration of the compounds used was never more than 1×10^{-5} M. Isosbestic wavelengths were used for excitation in all the acid-base equilibria. The method of Ireland and Wyatt (9) was used in the determination of the ground and excited state pK_a values.

3. Results and discussion

3.1. Acid-base concentration behavior of molecules 2 and 3

The effects of acid-base concentration on the ground and excited state spectral characteristics of molecules **2** and **3** were studied in the H_-/pH/H_0 range of 16 to −9 and are described in this section. Four major species, namely, the monoanion (A), the neutral species (N), the monocation (C), and the dication (DC), were observed. Relevant absorption and fluorescence spectral data are listed in Table 1, which also includes results on molecule **1**. Table 2 features all the proton transfer equilibrium constants determined experimentally. Figure 1 displays absorption and corrected fluorescence spectra of the various prototropic species detected over the wide range of acidity used. Scheme 1 reproduces the various prototropic reactions in equilibrium for molecule **2**.

3.1.1. Neutral-monoanion acid-base equilibrium

The absorption maximum of molecule **2** centered at $\bar{\upsilon}_A$ = 29 600 cm^{-1} remained the same from pH 7.5 to H_- = 14. With a further increase of the base concentration, this band started shifting to lower energy and the formation of the new species was incomplete even at H_- = 16, the highest base concentration used in this study. The fluorescence band maximum at $\bar{\upsilon}_F$ = 22 300 cm^{-1} did not change from pH 7.5 to H_- = 13, but the fluorescence was quenched with a further increase of the base concentration to H_- = 16. At H_- = 16, the spectrum showed a new fluorescence band peaking at lower frequency.

Based on the solvatochromic shifts observed in various nonpolar, polar, and polar protic solvents (footnote 2, (*b*)) and from the behavior of molecule **1** in different protic media (43), the absorption and fluorescence maxima at pH 7.5 should be assigned to the neutral species of molecule **2** and the low-energy absorption maximum at high base concentration should be ascribed to a monoanion formed by N-H deprotonation. Such deprotonations were also reported earlier (17, 20–22). Deprotonation of a ring carbon atom in this basicity range ($14 < H_- < 16$) is ruled out on the basis that it usually occurs at much higher base concentrations and the resulting anions are usually fluorescent with low quantum yields (49, 50). The new low-energy band at H_- = 16 might be assigned to the dianion formed by deprotonation of the amino group and one of the carbon atoms. The ground state pK_a value for the amino group deprotonation equilibrium could not be calculated due to the incompleteness of the reaction but should be higher than 16. The excited state pK_a value (pK_a^*) was found by monitoring the decay of fluorescence intensity of the neutral species. The fluorimetric titration gives a pK_a^* value of 13.9 that is close to some reported literature values for amine deprotonation (14, 20–22, 49, 50).

[a]Too much overlap between the fluorescence profiles of the conjugate acid–base species.
[b]Ring protonation.
[c]Ring deprotonation.

The fact that $pK_a^* < pK_a$ means that the amino group becomes a stronger acid in the excited state.

For molecule **3**, on increasing the base concentration, the intensity of the absorption band of the neutral species remained invariant until H_- = 15 but was slightly red-shifted at H_- = 16. On the other hand, the fluorescence band of this species started decreasing in intensity only at H_- = 13.5 without the appearance of any other new band. It was noticed that the bandwidth at H_- = 16 is much larger than that observed for the neutral species at pH 7.5. These spectral changes can be attributed to the deprotonation of one ring carbon atom as there is no other available proton on nitrogen in this molecule, and also because the pK_a^* for methyl group deprotonation is higher than that for ring carbon deprotonation (49). The broadening of the band at H_- = 16 might be due to a mixing of the monoanion formed by deprotonation of the carbon atom with the neutral species. The ground state pK_a could not be calculated due to the incompleteness of the reaction. The excited state pK_a was calculated by using the fluorimetric titration curve of the neutral band (see Table 2).

3.1.2. Monocation – neutral species acid–base equilibrium

The absorption bands of the neutral species of molecules **2** and **3** were altered drastically by lowering the pH. The gradual appearance of a largely red-shifted, structured, highly intense band was observed at the expense of the neutral band by lowering the pH and the whole reaction was completed at pH 2.5. A clear-cut isosbestic point was observed, as exemplified in Fig. 2 for molecule **2** undergoing this equilibrium. Similarly, under these pH conditions the fluorescence intensity of the neutral species was significantly reduced, transforming into well-defined structured bands without much change in their positions, contrary to the observations made in the absorption spectra (see Fig. 1).

Because these molecules have two basic centers, the monocation can be generated by protonating either of the available sites. In these molecules, the first preferred pro-

tonation site should be the tertiary indole ring nitrogen atoms, based on the following arguments:

1. Had the protonation occurred at the terminal amino-nitrogen, the spectral characteristics of this species would have resembled those of the neutral species of molecule **1** because, once the lone pair on the amino group is coordinated by a proton, it no longer affects the total energy of the system (8, 9, 14, 21, 22).

2. Protonation of tertiary ring nitrogens leads to lowering the S_0–S_1 energy gap of the system when the lowest energy transition is $\pi\pi^*$ in character (8, 9, 16–22, 39).

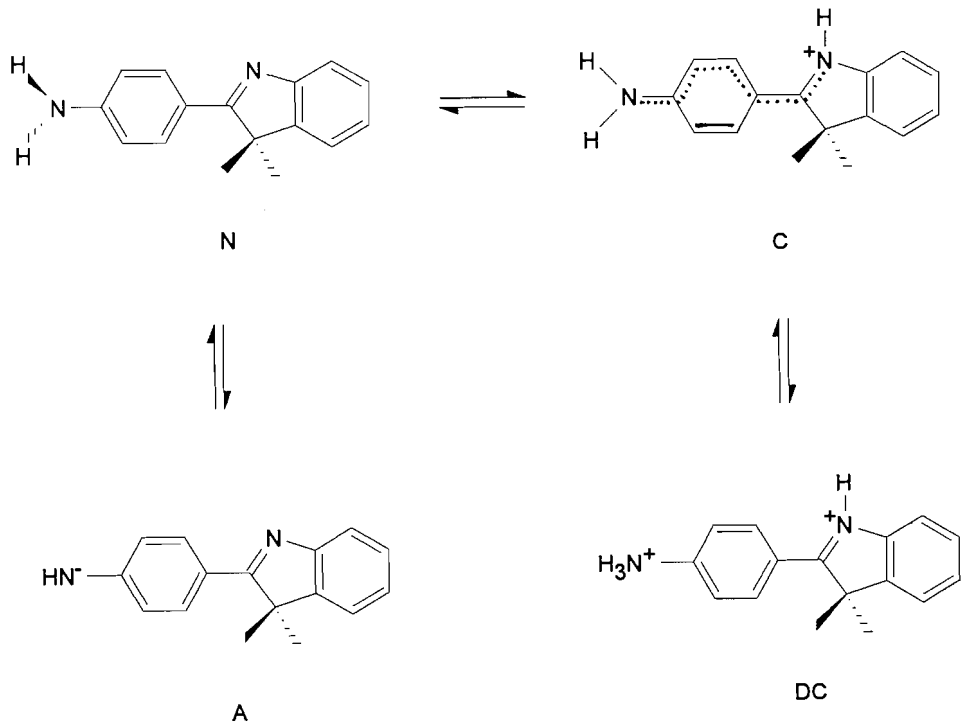
3. The pK_a value of ring nitrogens is usually higher (~5) than that for terminal nitrogens (~4) (9).

3.1.2.1. Absorption spectra. Because of the large red shift (~5000 and ~4600 cm^{-1} for molecules **2** and **3**, respectively) observed in the absorption spectrum when going from the neutral to the cation species and also because of the calculated differences in the ground state structures, discussed below, the nearly planar structure C is suggested as the ground state monocation species (see Scheme 1).

As far as the absorption red shift is concerned, INDO-S calculations on molecule **3** have already shown that protonation of the ring nitrogen center increases the conjugation throughout the molecular frame in the ground electronic state, giving rise to a much more hindered phenyl ring torsional movement (higher potential barrier for rotation) (39). These calculations predicted a first singlet-singlet energy transition for the monocation at 24 770 cm^{-1} compared to 31 270 cm^{-1} for the neutral species, accounting for a red shift of approximately 6500 cm^{-1} in the gas phase. This shift is expected to be reduced in water as the neutral species is stabilized by hydrogen bonding and the monocation, since it is already protonated, is not. Table 1 shows that the first electronic absorption band for molecule **3** in water is red-shifted by 4600 cm^{-1} when protonation occurs, which seems reasonable enough when compared to theoretical calculations.

To study the effect of protonation of the ring nitrogen atom on the geometry of the molecule, the structural properties of these molecules in their neutral and cationic forms were obtained by the AMPAC molecular orbital package (Table 3). It was clearly established earlier (39) that both crystallographic measurements and AM1 geometry optimization agree very well, so that the AMPAC method has proven a valuable tool in the prediction of the ground state structures and energies for this class of molecules. The nine atoms constituting the 3*H*-indole moiety are coplanar and so is the phenyl group of atoms. It is shown in Table 3 that the two atomic planes of molecules **2** and **3** are tilted in the neutral form whereas this torsional angle is much reduced in the monocation. Accordingly, one should expect the bonds C(8)—C(2) and C(2)—N(1) to be affected by this structural change. Indeed, Table 3 shows that the length of the C(8)—C(2) bond decreases whereas the C(2)—N(1) bond length increases upon protonation. However, the C(8)—C(2) bond length is still higher than the C—C distance (1.379 Å) in a phenyl ring (51). By comparison, in molecule 3 the C(8)—C(9) and C(9)—C(10) bond distances in the Ph_c ring of the cation are 1.413 and 1.385 Å, respectively. Other parts of the molecule are practically not affected by the protonation, except for the donor group environment where the bond length N(16)—C(11) decreases in the cation. AMPAC also shows that the dimethylamino group of molecule **3** is pyramidal in the neutral form whereas this donor group is nearly coplanar with the Ph_c ring in the monocationic form (Table 3, angles θ_1 and θ_2). All these calculations strongly suggest that these molecules become more planar in their monocationic form and consequently the conjugation over the whole molecule should increase upon protonation.

3.1.2.2. Fluorescence spectra. When comparing the fluorescence of the neutral species and the monocation at room temperature in water, small red shifts of 500 and 900 cm^{-1} were observed for molecules **2** and **3**, respectively, while



SCHEME 1

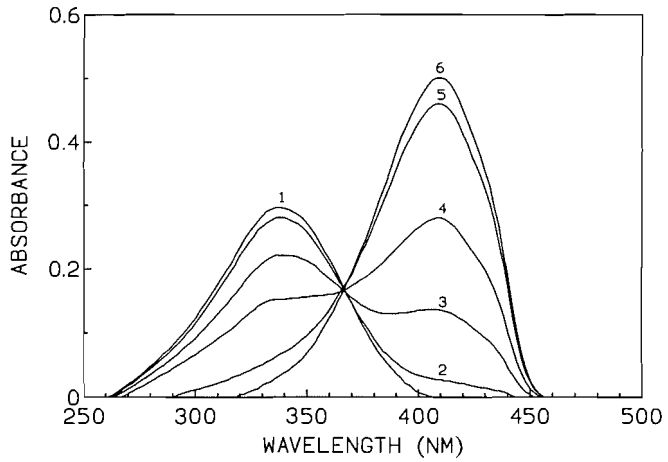


FIG. 2. Absorption spectra of molecule **2** at various pH (1 = 8.5, 2 = 6.4, 3 = 5.9, 4 = 5.7, 5 = 5.4, and 6 = 2.1).

large bathochromic shifts were observed in the absorption spectra (5000 and 4600 cm^{-1} for **2** and **3**, respectively). This might be due to (1) changes in protonation sites via photoautomerism in the excited state or (2), since it has been shown above that the ground state of the cation is much more planar than that of the neutral species, the small red shifts in the fluorescence spectra of the cations might be due to the smaller relaxation of their excited Franck–Condon (FC) states. This is equivalent to saying that the ground state cationic species give rise to fewer conformers than the neutral species. We then examined the excitation and fluorescence spectra of both species for molecule **2** in ice at 77 K, where the ground state nuclear configurations of the solutes are trapped even in the singlet excited states since the FC excited state relaxation is avoided. The fluorescence spectra of the cationic species at pH 2 at room temperature and at 77 K for molecule **2** are shown in Fig. 3. The near-equivalence of both spectra confirms that the protonation sites are similar in both the ground and excited singlet states, thus contraindicating any phototautomerism.

The vibrational structure is well resolved at 77 K. The absorption band of the neutral species (center of mass) is red-shifted by 1500 cm^{-1} at 77 K whereas the center of mass of the fluorescence band is practically not affected, causing a reduced Stokes shift that is entirely attributed to the stabilization of the ground state neutral species. This confirms quite well what is already known about molecule **3**, that no important modification of the nuclear configuration occurs during the relaxation of the Franck–Condon excited singlet state in fluid solutions (38, 39). The same pattern is observed for the cation species, where its absorption band is red-shifted by 510 cm^{-1} at 77 K and its fluorescence band is at nearly the same position. This shows that even for this species, practically no relaxation of the FC state occurs before emission takes place, even at room temperature. We then conclude that the ground state dynamics between the various possible conformers in the neutral species is responsible for the large Stokes shifts observed between the absorption and fluorescence spectra compared to those observed in the monocationic species.

On the other hand, based on what has been said above, one should expect the more planar cation (structure C) to be much more fluorescent in water than its neutral counterpart. To the contrary, Table 1 shows a completely different behavior for molecules **2** and **3** and for all the esters listed in Table 4. The quantum yield of the neutral species is reduced by nearly two orders of magnitude in the monocation. A high fluorescence quantum yield in these neutral molecules has always been interpreted as being correlated with a lack of rotational

freedom in the dimethylanilino ring. This rotational freedom can be hindered by increasing the viscosity of the media (41) or by hydrogen bonding and (or) polarity effects (38–40, 43). Since the fluorescence lifetimes and fluorescence quantum yields (2.6 ns and 0.5, respectively) of the neutral and monocation species of **2** are the same and very high in ice at 77 K when rotation is hindered, it shows that the quenching in water is of dynamic nature and that the excited FC state of the various monocations in water studied in this paper relaxes to a geometry in which some part of the dimethylanilino moiety is twisted from its planar ground state geometry. Because the fluorescence quantum yield of molecule **1** is not at all effected by protonation (see Table 1) compared to the other *para*-substituted derivatives (in the benezene ring), we tentatively assign the fluorescence quenching of the neutral species by protonation to the formation of a non-emissive twisted intramolecular charge transfer state (TICT) originating in the dimethylamino group (52*a–d*).

We have recently undertaken detailed semiempirical INDO-S molecular orbital calculations on the effect of rotating both the dimethylamino and the dimethylanilino groups in the neutral and monocation species. Preliminary results on molecule **3** and its monocation are now available. As far as molecule **3** is concerned, rotation of the $(CH_3)_2$ N- group by 90° does not give rise to any TICT state, but rotation of the dimethylanilino moiety by 90° stabilizes a highly polar TICT state. Though electron transfer to this state seems energetically allowed in all polar solvents, no decrease of the fluorescence quantum yield (Φ_F) of the emissive locally excited state in these media is observed at room temperature (40). This shows that the barrier to TICT state formation is probably too high for relaxation from the excited Franck–Condon state to occur.

The picture is totally different for the monocation of molecule **3**. Rotation of both the $(CH_3)_2$ N- and the dimethylanilino groups by 90° stabilizes the TICT state by about the same amount of energy, which is higher by 30% than that

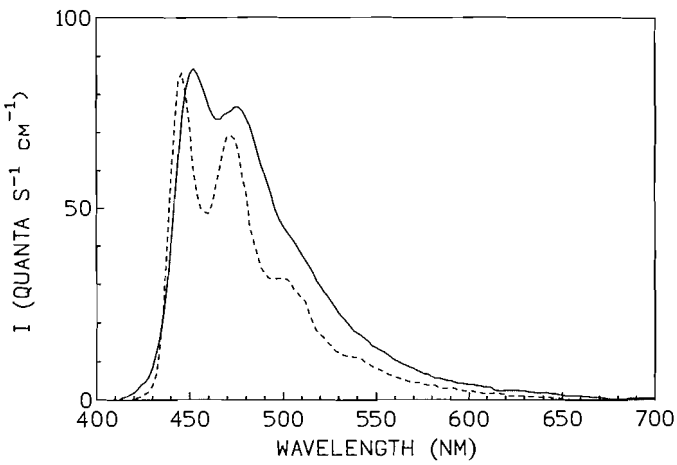

FIG. 3. Room temperature (—) and low temperature (77 K) (---) fluorescence spectra of the monocation of molecule **2**.

obtained for the case of the neutral molecule. But since the locally excited state is much less destabilized following dimethylamino torsion than for dimethylanilino twisting, a very weak rotational energy barrier of about 100 cm^{-1} is obtained for the dimethylamino torsion compared to about 1300 cm^{-1} for the dimethylanilino group. These energy barriers were obtained from the excited states correlation diagram (INDO-S) for planar and twisted forms. The stabilization energies, taking into consideration the solute-solvent interactions, have also been accounted for (52*e*). Hence, dimethylamino twisting in the monocations studied here is most likely responsible for the important fluorescence quenching of these species in water. The details of these calculations will be given in a subsequent paper where the photophysics will be emphasized.[3] These energetic and ki-

netic factors were also used recently to explain the probability of TICT formation in dimethyl-, methyl-, and aminobenzonitrile compounds (52*f*).

If the conclusion above is valid one would expect that, since the ionization potential is higher for an NH_2 group than for $NHCH_3$ or $N(CH_3)_2$ groups, the Φ_F value would be higher for **2** than for **3**, and also for **4**, **5**, and **6** in this decreasing order, for the monocation species in water. This is exactly what Tables 1 and 4 show. It was also shown recently that the 4-(*N*,*N*-dialkylamino)pyrimidines (4-DAAP), which give the usual *b** and *a** (TICT) fluorescences in polar aprotic solvents, show strong fluorescence quenching in protic solvents and no fluorescence at all for their cations (53).

The ground state pK_a value determined for the neutral species – monocation equilibrium is 5.4 for molecule **2**, higher than that for its unsubstituted derivatives reported earlier (3.25) (43). This means that the amino substituent pushes the electron density toward the ring nitrogen atom, making it more basic. The ground state pK_a value of molecule **3** for the same equilibrium is slightly higher than that of molecule **2** because the dimethylamino group is a better donor. Thus, the relative order of increasing basicity for this equilibrium is **3** > **2** > **1**. The very large overlap between the respective profiles of the neutral and monocation species in the fluorescence spectra precludes the calculation of the excited state pK_a values for this equilibrium. Since both the absorption and fluorescence intensity changes remain constant at pH ≃ 2.5 for the monocation, it can be safely concluded that both absorption and fluorescence data would yield similar pK_a values. This is probably because the rate constants for interconversion between the neutral and monocation species are low compared to the observed lifetimes of both species. Therefore, the prototropic equilibrium is not established in the excited state, so that the fluorescence intensities measured at this pH reflect the relative ground state concentration of the neutral and monocation species. Similar behavior was observed for molecule **1** (43) and has also been reported by others (19, 20).

3.1.3. Dication–monocation acid–base equilibrium. With further lowering of the pH, the intense structured absorption band of the monocation decreased in intensity for both molecules, concurrent with the appearance of a high-energy, lower intensity broad band at $\bar{\upsilon}_A$ = 29 600 cm^{-1} and $\bar{\upsilon}_A$ = 29 400 cm^{-1} for **2** and **3**, respectively. A sharp isosbestic point was also observed for this equilibrium, making chemistry simple in the sense that only two prototropic species are involved in the equilibrium reaction. It was completed at H_0 = −2 and the band remained unaffected both in position and intensity until H_0 = −9, the highest acid strength used. In a similar acidity range, the fluorescence

spectral characteristics behaved differently. The structured weak fluorescence band of the monocation was slowly transformed into a broad, highly intense, low-energy band. The reaction was completed only at $H_0 = -8$, contrary to what happens in the ground state where the reaction was completed at lower acidity.

This new high-energy absorption band can be assigned to the dication formed by protonation of both the basic centers, without involving ring carbon atom protonation. It has already been shown that molecule **1** undergoes ring protonation under these acidity conditions (43). The above assignment is based on the following:

1. The spectral characteristics of the dication are similar to those of the molecule **1** monocation (Table 1), in terms of both position and intensity. This is because, once the amino group is protonated, its effect on the spectroscopic properties of the basic chromophore is made negligible. Also, if the second protonation had occurred on the ring carbon atom, it would have caused further lowering of the energy of the system as had already been observed in molecule **1** (43).

2. The ground state pK_a value of the ring protonation is too low (−3.4), as noticed in molecule **1**, compared to what is observed for this equilibrium (see below).

It is generally observed that the fluorescence intensity of neutral aromatic amines is quenched before the formation of the monocation (20, 24) by amino group protonation. Shizuka and Tsutumi (54, 55) showed that this is due to the protonation of one of the aromatic sites if the charge transfer state is the lowest excited state. This phenomenon has been termed proton-induced fluorescence quenching, which competes with the proton transfer equilibrium. Though all the factors for molecules **2** and **3** favor this process, excessive overlap between the spectra of the respective monocation and dication species and the low quantum yield of the monocation did not allow us to draw definite conclusions regarding this aspect of our study.

The ground state pK_a value found for this equilibrium is lowered to 0.05 and −0.20 for **2** and **3**, respectively (Table 2), compared to pK_a values of around 4 normally observed for aromatic amine equilibria (9). This is ascribed to the positive charge already on the ring nitrogen, which makes the terminal nitrogen electron deficient by delocalizing the electron density toward the aromatic ring. The decrease in fluorescence intensity of the monocation with change in acidity could not be monitored due to the reasons already mentioned above. Therefore, the fluorimetric titration curve was constructed from the increase in fluorescence intensity of the dication at a wavelength where overlapping of the two species is negligible. Values of −4.0 and −4.30 were obtained for the pK_a^* of **2** and **3**, respectively. A decrease in pK_a^* compared to the pK_a value is good evidence that the lone pair of the terminal nitrogen atom is involved in conjugation with the rest of the molecule more effectively in the excited state. Due to the more efficient charge migration to the nitrogen ring for molecule **3**, the pK_a and pK_a^* values for the terminal atom protonation are lowered compared to those of molecule **2**. A difference in the ground and excited state equilibrium constants means that the rate constants for the interconversion between the two species are higher in the excited state compared to the fluorescence decay rate of both the species. This allows complete equilibrium to be established (7, 8).

*3.2. Acid-base concentration behavior of molecules **4–6***

Molecules **4**, **5**, and **6** in an acidity range similar to that mentioned in Sec. 3.1 will be described in this section. Five main prototropic species, namely, the dianion (DA), monoanion (MA), neutral species (N), monocation (C), and dication (DC), were identified in the acidity range used. The various spectroscopic quantities measured are reproduced in Table 4 and the acidity constants for all the prototropic equilibria found experimentally are listed in Table 2. Figure 4 displays the absorption and fluorescence spectra of the various prototropic species. Scheme 2 represents the various prototropic species in equilibrium.

*3.2.1. Molecule **4***

This molecule exists in the neutral form from pH 7 to 9. This assignment is based on the similarity of the spectral characteristics when compared with those in different solvents (40). When the pH was increased from 9, another absorption band, shifted to higher energy and almost as intense as that of the neutral molecule, started to appear, at the expense of the neutral band, with a clear isosbestic point. Its formation was complete at pH ≈ 12. Similar effects were observed in the fluorescence spectra except that the fluorescence intensity of this species at pH 12 was significantly higher. The new species formed at pH 12 is assigned to formation of the monoanion (MA) caused by hydrolysis of the ester group, based on the following arguments:

1. When the same pH titration was reversed by decreasing the pH from 12 to 9, the reaction was irreversible. The absorption and fluorescence spectra are not modified, either in position or intensity, between pH 9 and 12.

2. The fluorescence quantum yield of the monoanion is higher than that of the neutral species. A low fluorescence quantum yield for the neutral species in these molecules in protic-polar solvents is assumed to be linked with the formation of nonfluorescent TICT states (52 and footnote 3). It is well known that TICT state formation is highly dependent upon the strength of the donor and acceptor moieties (52). Following the hydrolysis, the acceptor property of the ester is significantly reduced due to the delocalization of the negative charge on both oxygen atoms (Scheme 2). This is also evident in the blue shifts observed in the absorption and fluorescence spectra compared with those of the neutral species.

3. This interpretation is further supported by the near similarity in fluorescence quantum yields of the monoanions of **4**, **5**, and **6** to those of the neutral molecules **2** and **3** that do not contain any ester group.

A similar kind of hydrolysis was reported earlier, though at a higher basicity (56). This can be linked with the electron-withdrawing nature of the ring nitrogen coupled with the carbonyl oxygen. Further increase in base concentration to $H_- = 16$ yielded the dianion (DA), due to amino group deprotonation as discussed for molecule **2**.

When the pH was lowered from 7, the same order of protonations as obtained for molecules **2** and **3** was observed. Similar spectral shifts (see Table 4) were obtained on increasing the acidity and therefore the same interpretation of the results follows naturally. The effect of the electron-withdrawing nature of the ester group can be seen in the pK_a values of the ring nitrogen and terminal amino group protonation equilibria (Table 2). The pK_a and pK_a^* values are lower than those of molecule **2**. We did not observe any

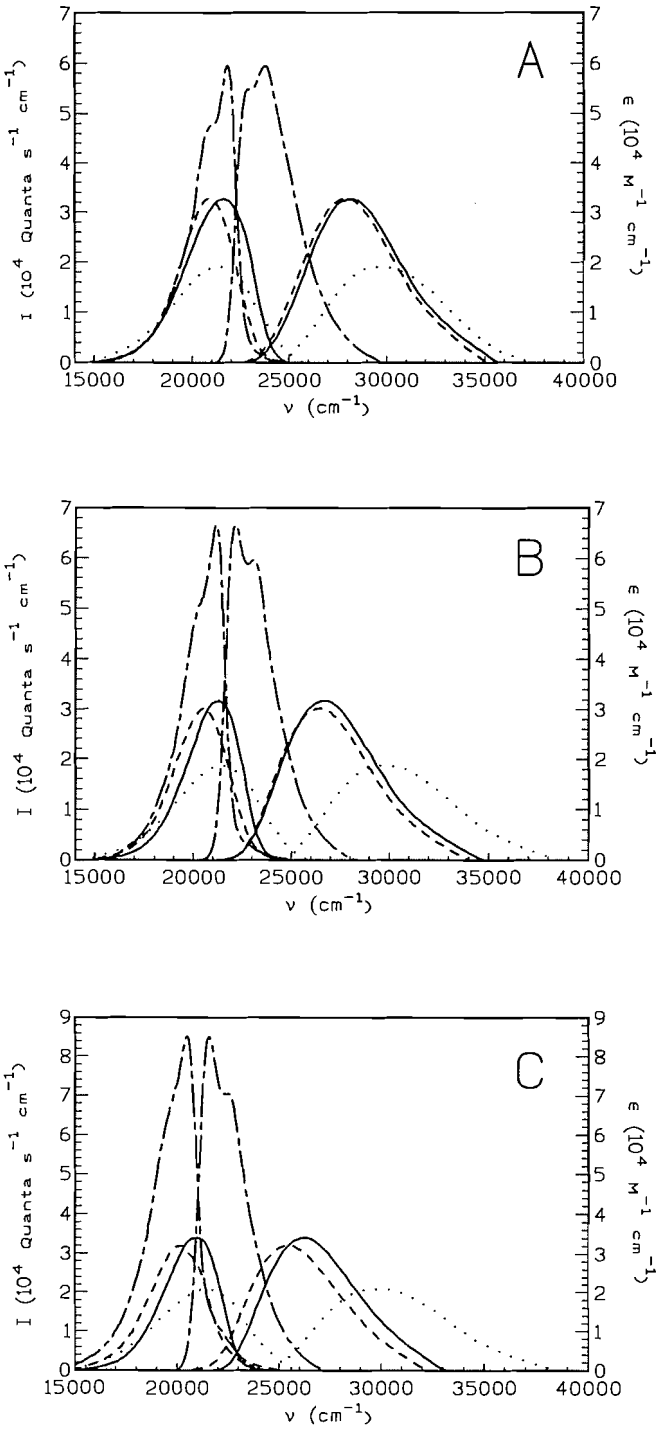

FIG. 4. Absorption and corrected fluorescence spectra of the various prototropic species of molecules **4** (A), **5** (B), and **6** (C); (——) monoanion, (- - - - -) neutral, (—·—·—) monocation, (·····) dication.

carbonyl group protonation in the acidity range studied, probably due to the presence of two positive charges already present on the molecule. Carbonyl group protonations around $H_0 \approx -6$ were reported earlier (28).

3.2.2. Molecule 5

This molecule behaves similarly to molecule **4** as far as the order of protonations and shifts in spectroscopic parameters are concerned. The magnitude of the various parameters mentioned in Tables 2 and 4 has shown the direct dependence on the donor capability of the methyl-substituted amino group.

3.2.3. Molecule 6

This molecule is a homolog of molecule **3** but with an additional ester group. As expected, it showed acidity dependence similar to that of molecules **4** and **5** from $H_- = 13$ to $H_0 = -9$. Further addition of base decreased the fluorescence intensity of the monoanion band, leading to the formation of dianion by the ring deprotonation. At $H_- = 16$, no additional broadening or appearance of any new fluorescent band was noticed, as for the other molecules. The pK_a^* value for the ring deprotonation equilibrium was found by plotting the decrease in the fluorescence intensity of the neutral species in the fluorimetric titration curve.

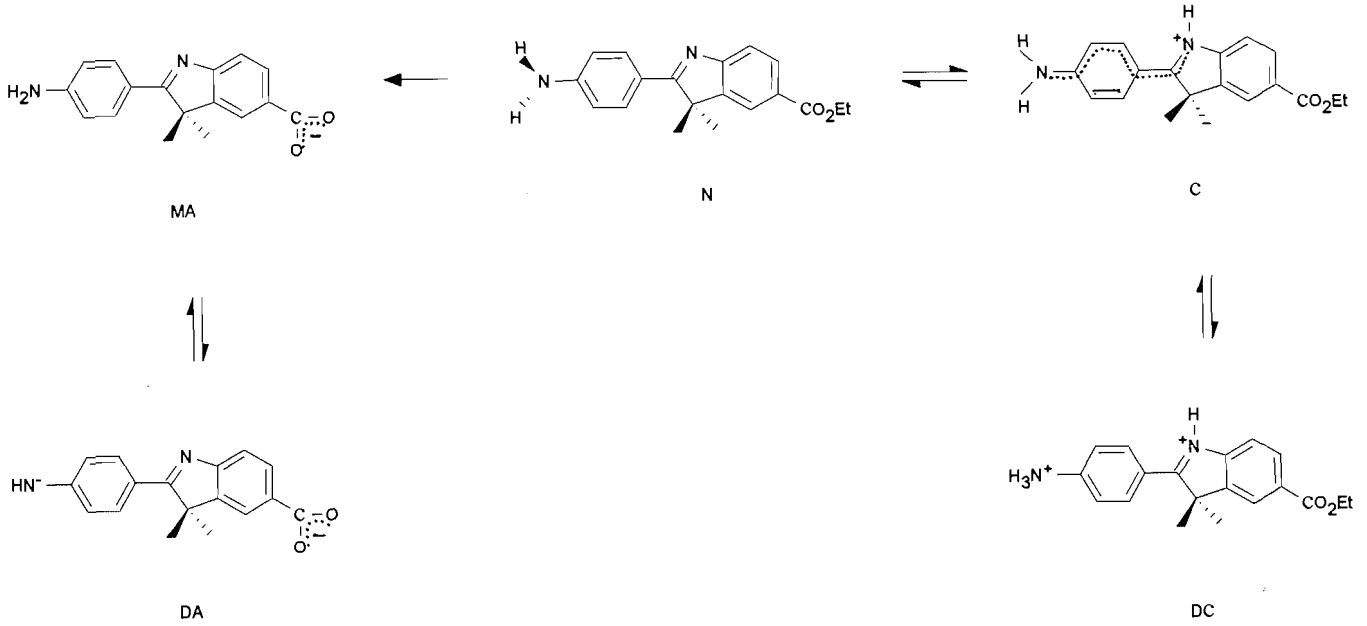
3.3. Förster cycle calculations

It was observed that the prototropic equilibrium is not established in the excited state when the ring nitrogen is involved in the protonation equilibrium. Thus, the Förster cycle calculation (2) can be a good means of estimating the values of pK_a^*. Also, since for the amino group protonation a complete equilibrium in the S_1 state is established, the validity of the Förster cycle calculations can be tested on these systems. Förster cycle calculations were done, using absorption (pK_a^* (Abs)) and fluorescence (pK_a^* (Flu)) center-of-mass wavelengths. All the calculated constants are listed in Table 5. This method could not be used for the neutral species – anion equilibrium due to incompleteness in the reaction.

For both the above-mentioned equilibria, the agreement between the pK_a^*(Abs) and pK_a^*(Flu) is very bad for all the molecules except molecule **1**, although the protonating sites are considered the same in the S_0 and S_1 states. From Table 5, a reduced basicity is shown by the fluorescence data compared to the absorption data. This observation is in contrast to the general behavior of the amino group (9, 16–22). One has to remember, however, that the Förster cycle strictly applies only when equal solvent relaxations exist in the ground and excited states of the species participating in the equilibrium (2). The results discussed above and the photophysical results to be published later (footnote 3) emphasize the fact that solvent relaxations differ for the species in equilibria in their ground and excited electronic states. If one had to choose between the two pK_a^* values calculated from the Förster cycle, obviously the pK_a^*(Abs) values better correlate with what is known from the literature about these basic centers. For amino group protonation the pK_a^*(Abs) emphasizes the trend in acidity observed in the pK_a (Table 2) with the donor–acceptor properties of the substituents. The pK_a^*(Abs) values shown in Table 5 are lower than the experimentally determined ones in Table 2. Such low values were also reported earlier (16).

Concluding remarks

Analysis of the absorption and fluorescence spectra of the various prototropic species of these *para*-substituted 3*H*-indole molecules, coupled with the study of the fluorescence emission and fluorescence excitation spectra of the ring protonated species at 77 K and the semiempirical AMPAC molecular orbital calculations, has shown that in these ring protonated species, the Ph_c and the indole rings are coplanar in the ground and first electronic singlet excited states



SCHEME 2

	Equilibrium			
	Ring nitrogen protonation		Amino group protonation	
Molecule	pK_a^*(Abs)	pK_a^*(Flu)	pK_a^*(Abs)	pK_a^*(Flu)
1	9.55	9.13	—	—
2	15.9	6.45	−10.45	1.73
3	15.36	7.59	−13.85	−0.41
4	11.97	3.36	−12.89	0.13
5	12.57	4.38	−15.91	−1.63
6	12.04	4.9	−17.17	−2.89

in rigid as well as in fluid solutions. In the neutral species, the dimethylamino groups are rather pyramidal in the ground state, taking part in hydrogen bonding interactions with water. This effect would explain the slight fluorescence quenching of the neutral species. On the other hand, INDO-S semiempirical calculations have shown that a non-emissive low-energy TICT state might be responsible for the drastic fluorescence quenching of the monocation species.

Acid–base chemistry studies have resulted in the determination of four prototropic species in molecules **2** and **3**, whereas the ester-substituted **4**, **5**, and **6** molecules have given rise to an additional anion due to hydrolysis of the ester group. In all these molecules the first protonation site is the ring nitrogen in preference to the terminal nitrogen. Although the ring nitrogen becomes more basic upon excitation, the proton transfer equilibrium is not established in the excited state. On the other hand, the terminal amino group undergoes a complete proton transfer equilibrium in the S_1 state. The various proton transfer equilibria have shown a direct dependence upon the donor and acceptor properties of the substituent groups. Förster cycle calculations support the nature of the various substituent groups, i.e., the amino group acquires more acidity in the excited state while the ring nitrogen becomes more basic.

Because these molecules show strong dependence on pH and in turn generate charged species of various types, these species could yield good information about the nature of charged membranes (positively or negatively charged), especially, since the spectra of the charged species are well separated from the neutral entity in these molecules. The ring nitrogen prototropic equilibrium could be put to profit to sense interfacial proton concentration at anionic surfaces.

The negative ion BN^- and its role in determining the ground state of BN via photodetachment. An MRDCI *ab initio* study

ROBERT C. MAWHINNEY, PABLO J. BRUNA, AND FRIEDRICH GREIN[1]

Department of Chemistry, University of New Brunswick, Fredericton, NB E3B 6E2, Canada

Received March 15, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

ROBERT C. MAWHINNEY, PABLO J. BRUNA, and FRIEDRICH GREIN. Can. J. Chem. **71**, 1581 (1993).

Extensive multireference CI calculations using a contracted 6*s*5*p*3*d*1*f* Gaussian basis set on the B and N atoms indicate that the $X^2\Sigma^+$, $A^2\Pi$, and $B^2\Sigma^+$ states of BN^- are bound with respect to the electron attachment BN + e^-. The $1^4\Sigma^+$, $1^4\Delta$, $1^4\Sigma^-$, and $1^4\Pi$ states of BN^- are resonant states, all autodetaching into neutral BN. The electron affinity $X^3\Pi \rightarrow X^2\Sigma^+$ is predicted to be 2.84 eV (with a best estimate of 3.10 eV). Other features studied for BN^- include the infrared spectrum of the $X^2\Sigma^+$ ground state as well as the electronic radiative properties involving the excited states $A^2\Pi$ and $B^2\Sigma^+$. The present study supports a $X^3\Pi$ ground state for BN, with $a^1\Sigma^+$ lying about 0.03 eV higher. As an alternative to optical spectroscopy on BN, experimental studies of the photodetachment spectrum of BN^- are proposed in order to find the ordering and energetic separation of the lowest $^3\Pi$ and $^1\Sigma^+$ states of BN.

ROBERT C. MAWHINNEY, PABLO J. BRUNA et FRIEDRICH GREIN. Can. J. Chem. **71**, 1581 (1993).

Des calculs extensifs d'IC à références multiples réalisés à l'aide d'un ensemble de base gaussien 6*s*5*p*3*d*1*f* sur les atomes de B et de N indiquent que les états $X^2\Sigma^+$, $A^2\Pi$ et $B^2\Sigma^+$ du BN^- sont liés lors de la fixation d'électron BN + e^-. Les états $1^4\Sigma^+$, $1^4\Delta$, $1^4\Sigma^-$ et $1^4\Pi$ du BN^- sont des états de résonance qui s'autodétachent tous pour donner du BN neutre. On fait la prédiction que l'affinité électronique de $X^3\Pi \rightarrow X^2\Sigma^+$ est de 2,84 eV (la meilleure évaluation est de 3,10 eV). Les autres caractéristiques du BN^- étudiées comprennent le spectre infrarouge de l'état fondamental $X^2\Sigma^+$ ainsi que les propriétés électroniques radiatives impliquant les états excités $A^2\Pi$ et $B^2\Sigma^+$. Les résultats de notre étude sont en accord avec un état fondamental $X^3\Pi$ pour le BN ayant un état $a^1\Sigma^+$ à environ, 0,03 eV plus haut. Comme alternative à la spectroscopie optique du BN, on propose des études expérimentales du spectre de photoablation du BN^- qui devraient permettre de déterminer l'ordre et la séparation énergétique des états $^3\Pi$ et $^1\Sigma^+$ du BN.

[Traduit par la rédaction]

1. Introduction

The characterization of the ground state of the first-row isoelectronic diatomics C_2, BN, and CN^+ represents a challenging task for experimental as well as theoretical spectroscopists. The main reason for this difficulty lies in two electronic states, $^1\Sigma_{(g)}^+$ and $^3\Pi_{(u)}$, being separated energetically by less than 0.1 eV (1, 2). Despite the fact that electronic transitions into these lowest triplet and singlet states have been recorded in some instances, a *direct* spectroscopic determination of the $^3\Pi_{(u)}$–$^1\Sigma_{(g)}^+$ separation is prevented by the multiplicity selection rules. The spectroscopist is thus compelled to look at small vibrational or rotational perturbations in the available spectra (3).

The C_2 molecule, which has been studied experimentally more extensively than BN or CN^+ (1), represents a good example. For simplicity, the C_2 states are labelled according to the revised, final assignment given by Ballik and Ramsay (4). Until around 1960 the C_2 ground state was thought to be $^3\Pi_u(3\sigma_g 1\pi_u^3)$ since the intense $^3\Pi_g$–$^3\Pi_u$ (Swan) band system was observed in the laboratory as well as in spectra from outer space (4, 5). However, a seminal study by Ballik and Ramsay (4) on the band system $b^3\Sigma_g^-$–$a^3\Pi_u$ detected perturbations in the upper state caused by the lowest lying $^1\Sigma_g^+$ state. Additional analysis of the Phillips band system $A^1\Pi_u$–$X^1\Sigma_g^+$ confirmed that C_2 has a $X^1\Sigma_g^+(1\pi_u^4)$ ground state, with $a^3\Pi_u$ lying at a T_e of about 0.09 eV (6).

Unfortunately, for neither BN nor CN^+ has the question about the nature of the ground state been settled experimentally. The main reason is the lack of experimental studies on band systems equivalent to those of C_2. For instance, according to the 1977 compilation by Huber and Herzberg (1), the only experimental data available for CN^+ are restricted to the singlet manifold. On the other hand, for BN, information exists on two triplet transitions, namely $2^3\Pi$–$1^3\Pi$ (7, 8) and $n^3\Sigma^-$–$1^3\Sigma^-$ (9) as well as two singlet band systems $c^1\Sigma^+$–$a^1\Sigma^+$ and $c^1\Sigma^+$–$b^1\Pi$ (10). Since the transitions $1^3\Sigma^-$–$1^3\Pi$ and $1^1\Pi$–$1^1\Sigma^+$ of BN (corresponding to the Ballik-Ramsay and Phillips bands in C_2) have not been studied experimentally, nothing can currently be said about the existence of perturbations similar to those in the C_2 molecule.

It is well established that *ab initio* methods may provide reliable data to complement experimental results (2, 11). In principle, modern theoretical computational techniques are able to describe electronic states of different multiplicity or character (bound or unbound, valence or Rydberg, etc.) with a fairly uniform degree of accuracy. However, to achieve an accuracy of better than 0.1 eV (about 2 kcal mol^{-1} or 800 cm^{-1}) requires the use of rather large AO basis sets and extensive multireference wave functions (12).

All *ab initio* studies on BN published to date favor $X^3\Pi(5\sigma 1\pi^3)$ to be the ground state, with $a^1\Sigma^+(1\pi^4)$ lying up to 0.1 eV higher. In a prior investigation from this laboratory by Karna and Grein (ref. 13, hereafter KG1), many excited states were studied by carrying out MRD-CI calculations using an AO basis set of triple-zeta plus polarization quality. KG1 reported $T_e(a^1\Sigma^+)$ to be 0.10 eV. Later, Martin et al. (14) performed quadratic CI (QCISD(T)) calculations especially tailored to reinvestigate the $^1\Sigma^+$–$^3\Pi$ separation in BN. Unfortunately, this study was not conclusive since ΔE values ranging from −0.03 to +0.03 eV were obtained depending on the technical conditions of the calculations. They recommended a best estimate of $T_e(a^1\Sigma^+) = 0.012$ eV, with $X^3\Pi$ being the ground state.

A very detailed *ab initio* study on the same topic has recently been published (15) which uses a multireference CI treatment and a fairly extended $5s4p3d2f1g$ contracted basis set. This work came to the conclusion that $X^3\Pi$ is more stable than $a^1\Sigma^+$ by 0.047 ± 0.012 eV. Taking into account the high degree of sophistication used in these studies, one can conclude that theory (nonrelativistic model and only correlating valence electrons) strongly supports $X^3\Pi$ to be the ground state.

We decided to address the question of the $^1\Sigma^+$–$^3\Pi$ separation in BN from another point of view, aimed to assist future *experimental* determinations of that quantity. In short, we propose, as an alternative to the optical spectroscopy on BN, the study of the photoelectron detachment spectrum of BN^-. This anion has a $X^2\Sigma^+$ ($4\sigma^2 5\sigma 1\pi^4$) ground state (16) and is expected to be as stable as the experimentally observed isoelectronic C_2^- species (1). Moreover, simple arguments indicate that photodetachment from the ground state of BN^- is able to generate neutral BN either in the $^3\Pi$ ($1\pi\rightarrow\infty$) or $^1\Sigma^+(5\sigma\rightarrow\infty)$ state (17). To assist future experiments in that direction, reliable potential curves and spectroscopic data on the low-lying state of BN^- will be reported here.

2. Technical details

Each atomic orbital basis set consisted of the 49 contracted Gaussian functions, $6s5p3d1f$. The primitive set $10s6p$ from Huzinaga (18) has been contracted to $5s4p$ according to Dunning (19). Additional semidiffuse $(1s,1p)$ and polarization functions $(3d,1f)$ were added to each atom, with exponents taken from the literature (19–21). In the same order as above, the exponents of the extra functions are 0.018, 0.019, 0.822, 0.187, 0.05, and 0.5 for B and 0.045, 0.048, 1.986, 0.412, 0.07, and 1.0 for N.

The potential curves were studied for internuclear distances from 1.95 to 3.40 bohr. For BN^-, all CI calculations were carried out by using the SCF MO's obtained for the ground state $X^2\Sigma^+(4\sigma^2 5\sigma 1\pi^4)$, whereas all potential curves of BN have been studied with the SCF MO's from the $^3\Sigma^-(4\sigma^2 5\sigma^2 1\pi^2)$ state of BN.

The MRD-CI method (22) has been used. This method includes selection of configurations and extrapolation techniques. The core orbitals $1\sigma(1s_N)$ and $2\sigma(1s_B)$ are kept doubly occupied throughout (frozen core approximation), while the nine highest lying virtual orbitals have been discarded (5 in a_1, 2 each in b_1 and b_2). Thus, the active MO space consists of 87 orbitals to describe the valence correlation among eight (BN) or nine (BN^-) valence electrons (VE). Single-point calculations at the respective equilibrium geometries have been carried out by using parent natural orbitals (NO). The number of reference configurations varied from 40 to 55 depending on the states. The total CI space generated had an average dimension of 1.5×10^6, with the secular equations directly diagonalized varying from 16 000 to 25 000. Configuration thresholds of 2.5 μhartree (MO's) and 1.0 μhartree (NO's) have been used.

All total and relative energies to be reported are estimated full-CI energies. The latter are obtained by applying a generalized Langhoff–Davidson correction to the extrapolated MRD-CI energies (2, 23). As shown by Knowles et al. (24) for a series of molecular species, the estimated full-CI energies reproduce the exact full-CI energies (for a given AO basis set) within ±5 kcal mol^{-1}.

3. Atomic energies

The quality of the AO basis set has been assessed by computing several electronic states of both the neutral and negatively charged atoms. Table 1 summarizes the results.

The calculated transition energies of B and N reproduce experimental values (25) quite well, with errors of less than 0.1 eV. Thus, the transition energies of BN and BN^- should be of similar accuracy.

Electron attachment upon $B(^2P_u, s^2p)$ generates three electronic states of B^-, all arising from the global configuration s^2p^2 (26). However, only $B^-(^3P_g)$ has a positive electron affinity (EA), with a predicted value of 0.27 eV, in almost perfect agreement with the experimental value of 0.277 eV (27). The excited B^- states ^1D_g and ^1S_g are resonant states (i.e., they lie above the ground state of B), with estimated EA values of −0.23 and −0.59 eV, respectively. These results indicate that a semiempirical estimate of −1.01 eV for EA ($B,^3P_g \rightarrow B^-,^1S_g$) is about 0.40 eV too high (see footnote *e*, Table 1).

The negative ion $N^-(^3P_g,s^2p^4)$ is known to be unbound upon electron attachment on N. An experimental EA of −0.07 eV (27) has to be compared with our theoretical estimate of −0.27 eV. The predicted EA of BN might be too low by roughly 0.25 eV, similar to the error obtained for the N atom. This assumption is based on the fact that in going from BN ($X^3\Pi$,$a^1\Sigma^+$) to BN^- ($X^2\Sigma^+$), electron attachment leads to the occupation of the MO's 5σ or 1π, which are mainly localized on the N atom (see Sect. 4.1).

4. Electronic states of BN^-

A summary of several dissociation channels of BN^- and BN is given in Table 2. Spectroscopic data predicted for the low-lying doublet and quartet states of BN^- are collected in Table 3.

The second and third dissociation limits of BN^- are placed above the ground state products $B(^2P_u)$ + $N(^4S_u)$. This situation contrasts with that observed for AlP^- (17), in which the first three asymptotes lie below the ground state of Al + P. The channel $B^-(^3P_g)$ + $N(^4S_u)$ gives rise to doublet, quartet, and sextet Σ^+ and Π states of BN^-. Earlier studies on

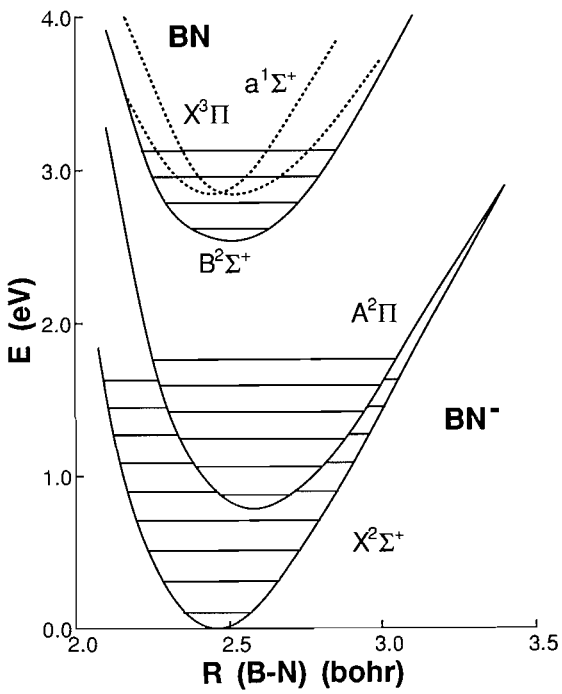

FIG. 1. Potential curves of the states $X^2\Sigma^+$, $A^2\Pi$, and $B^2\Sigma^+$ of BN^-, and $X^3\Pi$ and $a^1\Sigma^+$ of BN.

CSi^- (28) and AlP^- (17) indicated that the $^6\Sigma^+$ and $^6\Pi$ states lie well above the ground state of the neutral species. Therefore, sextet states of BN^- were not considered in this study.

4.1 Doublet states

As reported by Karna and Grein (ref. 16, hereafter KG2) the lowest doublet states of BN^- are $X^2\Sigma^+(4\sigma^2 5\sigma 1\pi^4)$, $A^2\Pi(1\pi\rightarrow 5\sigma)$, and $B^2\Sigma^+(4\sigma\rightarrow 5\sigma)$. The potential curves are shown in Fig. 1.

The transition energies of BN^- obtained in the present study are about 0.3 eV smaller than those of KG2. At the same time, we obtain an EA(BN) about 0.3 eV higher than the earlier estimates of 2.54 eV. Therefore, a relative stabilization of 0.6 eV in the excited states of $A^2\Pi$ and $B^2\Sigma^+$ of BN^- with respect to $BN(X^3\Pi)$ has a dramatic influence on the character of the $B^2\Sigma^+$ state, which is now predicted to be bound.

Our R_e values for $X^2\Sigma^+$ and $A^2\Pi$ agree within 0.02 bohr with KG2's results, but the present ω_e data are roughly 100 cm^{-1} lower. The discrepancies are somewhat larger for $B^2\Sigma^+$, namely +0.05 bohr for R_e and −470 cm^{-1} for ω_e.

The electron charge density contours as obtained from SCF calculations on the $X^2\Sigma^+$ state of BN^- (at R = 2.40 bohr) are displayed in Fig. 2. The corresponding MO's of $X^3\Pi$ (BN) look similar. Most of the valence MO's are strongly localized: 3σ is an *sp* hybrid on the B atom, whereas both 5σ and

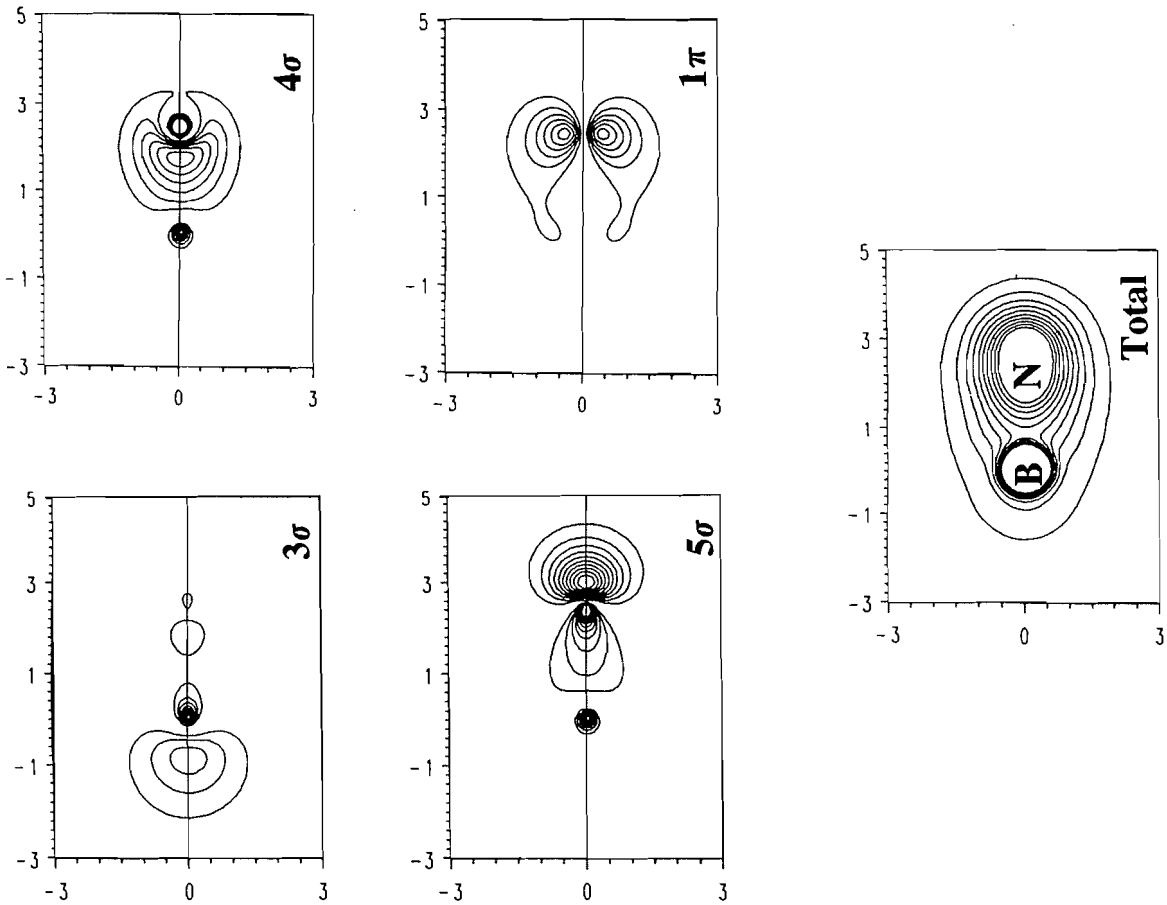

FIG. 2. Electron charge density contours for the valence MO's of ground state BN^- at R = 2.40 bohr. The contour line ranges from 0.05 (outermost) to 0.5 (innermost), in steps of 0.05.

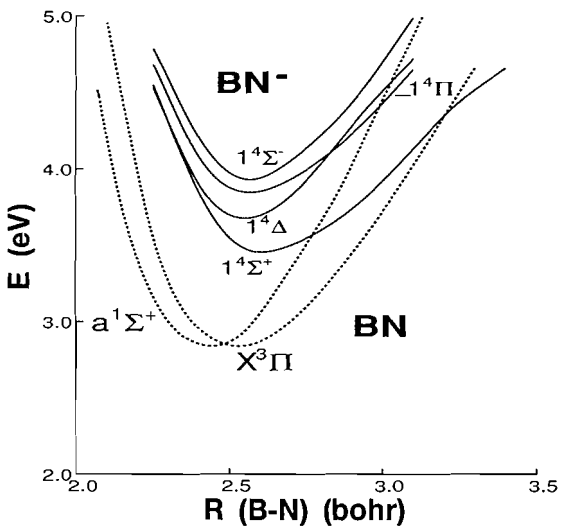

FIG. 3. Potential curves of the metastable states $1^4\Sigma^+$, $1^4\Delta$, $1^4\Pi$, and $1^4\Sigma^-$ of BN^-. Energies relative to the minimum of $X^2\Sigma^+(BN^-)$.

1π are essentially N species. Only 4σ shows some B—N bonding character.

The total density distribution reveals an excess of electronic charge around the N atom, as pointed out by contour lines that are well spread out spatially. By contrast, those around B are not only more compact but also retain a good deal of spherical symmetry (similar to a local B^+ (s^2) structure). Thus, the overall charge distribution for the ground state of BN^- corresponds to $B^{\delta+}N^{(1+\delta)-}$. Since the $X^3\Pi$ state of BN has a $B^{\delta+}N^{\delta-}$ polarity (Sect. 5), it can be concluded that in the ground state of BN^- the extra electron is attached mainly to the N center.

4.2 Quartet states

Near equilibrium, the lowest lying quartet states arise from the electronic configurations ... $5\sigma 1\pi^3 2\pi(1^4\Sigma^+ < 1^4\Delta < 1^4\Sigma^-)$ and ... $5\sigma 1\pi^3 6\sigma(1^4\Pi)$. Formally, these states can be generated by electron attachment into the 2π (π^*) or 6σ (σ^*) MO's of the $^3\Pi$(... $5\sigma 1\pi^3$) state of BN. The potential curves are displayed in Fig. 3.

These quartet states are less stable than the ground state of BN. The $1^4\Sigma^+$ and $1^4\Sigma^-$ states lie 0.56 and 1.05 eV above $X^3\Pi$, respectively; the $1^4\Pi$ state has an intermediate T_e value (Table 3). The autoionizing character of these quartets has been investigated by carrying out additional MRD-CI calculations at R = 2.55 bohr that allow the outermost s and p AO's on the B atom to become more diffuse. The original semidiffuse exponents of α_s = 0.018 and α_p = 0.02 have been reduced in two steps, each by a factor of 2. The MRD-CI results with α_s = 0.0045 and α_p = 0.005 indicate a lowering of the total energies for all four quartet states, which are finally clustered within an energy range of 0.20 eV. An additional calculation for $X^3\Pi$ of BN with this

[c]R = 2.85 bohr.
[d]R = 3.00 bohr.

modified basis set indicates that they lie only from 0.1 to 0.3 eV above $X^3\Pi$ of BN.

Earlier studies on C_2^- (29) reported a similar autoionizing character for the corresponding lowest quartet states. By contrast, a prior investigation from this laboratory on AlP^- (17) found that $1^4\Sigma^+$, $1^4\Delta$, $1^4\Sigma^-$, and $1^4\Pi$ are bound.

5. Dipole moments and infrared spectrum

The dipole moment μ has been computed for the $X^2\Sigma^+$ and $A^2\Pi$ states of BN^- and the $X^3\Pi$ and $a^1\Sigma^+$ states of BN. The variation of μ with nuclear separation R is given in Table 4 and shown graphically in Fig. 4. The data for BN^- have been obtained with the B atom placed at the origin of the coordinate system.

The $X^3\Pi$ and $a^1\Sigma^+$ states of BN are highly ionic, with dipole moments slightly below 2.0 D near equilibrium. Both states have a B^+N^- polarity, as pointed out earlier by KG1 (13). The $X^2\Sigma^+$ and $A^2\Pi$ states of BN^- exhibit a significant dependence of the dipole moment on geometry, much higher than that predicted for the ground state of BN. These features are reflected in the dipole moment derivatives $\partial\mu/\partial R$ calculated at the corresponding equilibrium distances. The computed values in D/bohr are −0.8765 for $X^2\Sigma^+$ and −2.6760 for $A^2\Pi$ of BN^-, and 0.4194 for $X^3\Pi$ and −1.3235 for $a^1\Sigma^+$ of BN.

Within the double-harmonic approximation (30, 31), the infrared intensity associated with the fundamental absorption is given by the expression:

$$I = 65.53257 \times \left|\frac{\partial\mu}{\partial R}\right|^2_{R_e}$$

with I in km/mol and $\partial\mu/\partial R$ in D/bohr. The data from above thus correspond to infrared intensities (in km/mol) of 50.3 for $X^2\Sigma^+$ and 469.3 for $A^2\Pi$ of BN^- and of 11.5 for $X^3\Pi$ and 114.8 for $a^1\Sigma^+$ of BN. This simple approximation indicates that in BN^- the infrared absorption of $A^2\Pi$ is about 10 times higher than for the ground state. As already suggested by the $\mu(R)$ data given in Fig. 4, the infrared intensities for the $^3\Pi$ and $^1\Sigma^+$ states of BN are much smaller. An earlier SCF study reported IR intensities (in km/mol) of 27 for $X^3\Pi$ and 75 for $a^1\Sigma^+$ of BN (32).

Table 5 summarizes the predicted radiative data for a few vibrational levels v' of the ground state of BN^-. The diagonal matrix elements $R_{v'v'}$ represent the expectation values of the dipole moment $\mu_{v'}$, with the B atom placed at the origin of the coordinate system. The variation of μ with geometry is independent of the system of coordinates, as is also the case for the non-diagonal matrix elements $R_{v',v'-1} = \int \psi_{v'}\mu(z)\psi_{v'-1}d\tau$. The small variation of the dipole moment with geometry is indicated by an increase in polarity of only 0.076 D when going from $v' = 0$ to $v' = 5$. The lifetimes $\tau_{v'}$ (in ms) predicted for the first three excited vibrational levels are 148 for $v' = 1$, 67 for $v' = 2$, and 43 for $v' = 3$.

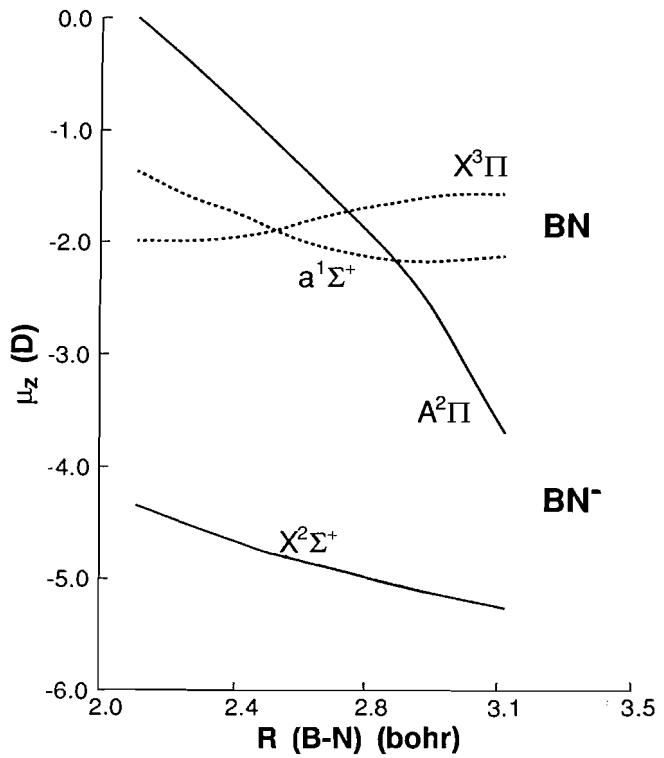

FIG. 4. Variation of the dipole moment μ with bond length R(BN) for the two lowest states of BN and BN^-.

As seen in Fig. 1, depopulation of levels with $v' \geq 4$ may occur via vibrational deexcitation within $X^2\Sigma^+$ as well as via radiative emission into the $A^2\Pi$ state (which in turn undergoes deexcitation, both vibrational and electronic). The overall rate for the cascading mechanism $X^2\Sigma^+$ ($v' \geq 4$) → $A^2\Pi(v)$ → $X^2\Sigma^+$ ($v' < 4$) is controlled by the first step since, as shown in Sect. 7, the radiative lifetime $A^2\Pi \rightarrow X^2\Sigma^+$ lies in the μs scale, and the vibrational deexcitation in $A^2\Pi$ occurs in the ms region.

Taking $v' = 8$ of $X^2\Sigma^+$ as an example, the directly calculated sum $\Sigma_f A_{if}$ of the Einstein coefficients (with $i = 8$ and $f = 0, 1, \ldots 4$) is about 2.2×10^{-2} s^{-1}. This rate constant for spontaneous emission from $v' = 8$ of $X^2\Sigma^+$ via $A^2\Pi$ intercombination corresponds to $\tau = 45$ s, much longer indeed than vibrational lifetimes of milliseconds predicted for $X^2\Sigma^+$.

A similar analysis for the $A^2\Pi$ state indicates vibrational relaxation lifetimes of about 18 ms for $v = 1$ and 9 ms for $v = 2$. This process is much longer than $\tau_0(A^2\Pi \rightarrow X^2\Sigma^+) = 14.4$ μs (Sect. 7.1), so that the vibrationally excited $A^2\Pi$ state essentially decays via emission into the electronic ground state.

6. Dissociation energies

The dissociation energy D_e for $X^2\Sigma^+$ of BN^- is found to be 6.79 eV, compared with 4.22 eV predicted for the $X^3\Pi$ state of BN. These values have been obtained by combining the total energies at equilibrium (NO results) with those of $1^6\Pi$ ($5\sigma 1\pi^2 2\pi 6\sigma$) for BN^- and $1^5\Pi(5\sigma 1\pi^2 2\pi)$ for BN at $R = 20.0$ bohr. According to a thermochemical cycle connecting ground state species, $D_e(BN^-) = D_e(BN) + [EA(BN) - EA(B)]$. An increase in the B—N bond strength of about 2.6 eV upon electron attachment implies that the EA of BN is higher than that of the B atom by the same amount.

A summary of experimentally inferred data for $D_e(BN)$ as collected by Reddy et al. (33) gives an average $D_e = 4.0 \pm 0.5$ eV for five out of nine values, with an additional estimate of about 3.36 eV, and three others from 5.4 to 6.4 eV. On the other hand, earlier *ab initio* studies reported $D_e(BN, X^3\Pi)$ values of 4.21 eV (13), 4.42 eV (32), 4.62 ± 0.1 eV (14), and 4.56 ± 0.1 eV (15). The last three results are not directly calculated D_e values but estimates obtained by adding correction terms from ±0.25 eV (15) to ±0.58 eV (32). Assuming a best estimate of 4.55 ± 0.1 eV for $D_e(X^3\Pi)$, our directly calculated value shows an error of −0.33 ± 0.1 eV. This would suggest a recommended $D_e(X^2\Sigma^+)$ of 7.12 ± 0.1 eV for BN^-.

Since the $a^1\Sigma^+$ state of BN correlates adiabatically with the second dissociation channel (Table 2), its dissociation energy should be larger by about 2.38 eV. Thus, $D_e(a^1\Sigma^+)$ is expected to lie near 6.9 eV. In refs. 14, 15, and 32, however, it has been assumed that $X^3\Pi$ and $a^1\Sigma^+$ of BN have the same dissociation products.

7. Radiative properties for electronic transitions of BN^-

Optical spectroscopy can be used to study three band systems of BN^-, namely $A^2\Pi$–$X^2\Sigma^+$, $B^2\Sigma^+$–$X^2\Sigma^+$, and $B^2\Sigma^+$–$A^2\Pi$. The purpose of this section is to discuss the radiative data associated with these bands, such as Franck–Condon factors ($q_{v'v''}$), Einstein emission coefficients ($A_{v'v''}$), oscillator strengths ($f_{v'v''}$), and radiative lifetimes ($\tau_{v'}$).

The different parameters have been calculated as outlined below. The transition moment $\bar{R}_{e'e''} = \langle\psi_{e'}{}^a/\bar{P}/\psi_{e''}{}^b\rangle$ has been calculated with $\bar{P} = e\,\bar{r}$ (length form; $\psi_{e'}{}^a$ and $\psi_{e''}{}^b$ are appropriate b_1 or b_2 (C_{2v}) components in the case of the spatially degenerate $A^2\Pi$ state. As standard notation, double and single primes label the lower and upper electronic states (same notation for the corresponding vibrational levels). The values of $R_{e'e''}$ are given in Table 6 and shown graphically in Fig. 5.

The term $\Sigma R^2_{e'e''}$ corresponds to $KR^2_{e'e''}$, with K taking into account the overall multiplicity and spatial degeneracies. In the present case, $K = 2$ for $^2\Sigma^+$–$^2\Sigma^+$ and $K = 4$ for $^2\Pi$–$^2\Sigma^+$ transitions. The band strength $S_{v'v''}$ is computed via the expression $S_{v'v''} = K|\int \phi_{v'}(R)R_{e'e''}(R)\phi_{v''}(R)dR|^2$, by using a polynomial expansion to represent the (discrete) $R_{e'e''}$ data and the appropriate vibrational wavefunctions $\phi_v(R)$ of each electronic state as weight functions (34). The absorption oscillator strength $f_{v'v''}$ is defined as $f_{v'v''} = 2/3\ K'\Delta E_{v'v''}S_{v'v''}$, with $\Delta E_{v'v''}$ in atomic units and $K' = [(2\text{-}\delta_{0\Lambda''})(2S'' + 1)]^{-1}$. Thus, $K' = {}^1/_2$ and ${}^1/_4$ for absorption from $X^2\Sigma^+$ and $A^2\Pi$, respectively.

The Einstein coefficient for spontaneous emission $A_{v'v''}$ (s^{-1}) is given by $A_{v'v''} = 2.1419 \times 10^{10}\ K''(\Delta E_{v'v''})^3 S_{v'v''}$, with $\Delta E_{v'v''}$ in atomic units and $K'' = [2\text{-}\delta_{0\Lambda'})(2S' + 1)]^{-1}$. Emission from $B^2\Sigma^+$ and $A^2\Pi$ implies $K'' = {}^1/_2$ and ${}^1/_4$, respectively. The natural fluorescence lifetime $\tau_{v'}$(s) corresponds to $\tau_{v'} = [\Sigma_{v''}A_{v'v''}]^{-1}$.

Earlier experience from the literature suggests that radiative lifetimes obtained by combining experimental $\Delta E_{v'v''}$ (when available) with theoretically derived $S_{v'v''}$ data deviate from experiments by about 10% (34, 35). Since the present estimates are based exclusively on theoretical results, the reported lifetimes might be accurate within 20%.

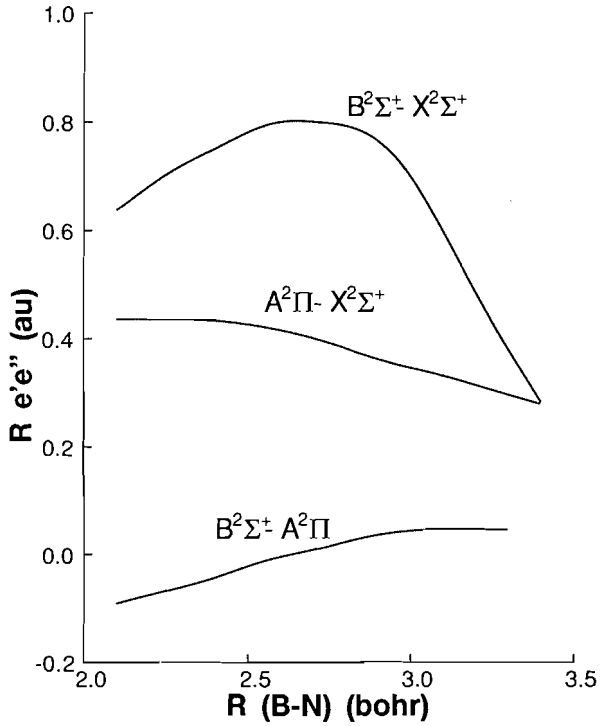

FIG. 5. Variation of the transition moment $R_{e'e''}$ (degeneracy factor K not included) with bond length R(BN) for the B–X, A–X, and B–A band systems of BN^-.

7.1 The $A^2\Pi$–$X^2\Sigma^+$ *transition*

The transition moment $R_{e'e''}$ for $A^2\Pi$–$X^2\Sigma^+$ varies smoothly with geometry (Fig. 5 and Table 6), so that changes of $\tau_{v'}(A^2\Pi)$ with v' are essentially dictated by $(\Delta E_{v'v''})^3$ and $q_{v'v''}$. Table 7 collects the corresponding radiative data.

For the upper state R_e is 0.128 bohr larger and ω_e about 210 cm^{-1} smaller than for the ground state. These changes are reflected in the existence of relatively broad Franck–Condon envelopes (see $q_{v'v''}$ data in Table 7). When compared with the equivalent $A^2\Pi_u$–$X^2\Sigma_g^+$ band of C_2^- (experimentally not yet observed), a similar Franck–Condon distribution is expected on the basis of predicted changes of $\Delta R_e = 0.12$ bohr and $\Delta\omega_e = -135$ cm^{-1} upon excitation (29, 36, 37).

The radiative lifetime $\tau_{v'}(A^2\Pi)$ decreases smoothly with vibrational excitation, namely from 14.4 μs for $v' = 0$ to 8.7 μs for $v' = 5$. Therefore, the electronic decay $A^2\Pi(v') \rightarrow X^2\Sigma^+$ is about 10^3 times faster than vibrational relaxation within the $A^2\Pi$ state (Sect. 5).

Theoretical predictions (37) on $A^2\Pi_u \rightarrow X^2\Sigma_g^+$ of C_2^- gave $\tau_{v'}$ values of 49.9 μs for $v' = 0$ and 25.0 μs for $v' = 5$, a range of lifetimes roughly 3 times longer than for BN^-. An analysis of the corresponding spectroscopic data indicates that the main difference between BN^- and C_2^- lies in the transition energy T_e of the $A^2\Pi_{(u)}$ state.

The oscillator strength $f_{v'v''}$ is estimated to be 0.40×10^{-2} for f_{00} and 0.266×10^{-2} for f_{01}. In line with the discussion above, these values are somewhat larger than those assigned to C_2^-, namely 0.34×10^{-2} and 0.129×10^{-2}, respectively (37).

7.2 The $B^2\Sigma^+$–$X^2\Sigma^+$ *transition*

The predicted radiative properties for the $B^2\Sigma^+$–$X^2\Sigma^+$ transition are summarized in Table 8. Near equilibrium this band system is associated mainly with the excitation $4\sigma \leftrightarrow 5\sigma$ (parallel band), which generally exhibits a higher intensity than that generated by the excitation $5\sigma \leftrightarrow 1\pi$ (perpendicular band). Examples have been discussed in ref. 26.

Two main factors are responsible for the higher intensity of the transition $B^2\Sigma^+$–$X^2\Sigma^+$ versus $A^2\Pi$–$X^2\Sigma^+$. First, the excitation $4\sigma \leftrightarrow 5\sigma$ is primarily of s–p type, whereas $5\sigma \leftrightarrow 1\pi$ is mainly an intrashell p–p transition. Since the former is the only one being allowed in atomic transitions, its intrinsic character is transferred to the equivalent molecular excitations. Accordingly, in terms of the $R_{e'e''}$ parameter, the values for the parallel band are higher than those of the perpendicular band. Second, the B state ($4\sigma \rightarrow 5\sigma$) lies at higher energies than the A state ($5\sigma \rightarrow 1\pi$). In summary, parallel bands are characterized by higher absorption numbers $f_{v'v''}$ (lower state) and shorter radiative lifetimes (upper state) than those of perpendicular type. The relative orders of magnitude are roughly 10 for $f_{v'v''}$ and 10^{-3} for $\tau_{v'}$.

The data shown in Tables 6–9 and in Fig. 5 confirm the expectations from above. For instance, near equilibrium the transition moment $R_{e'e''}$ ($B^2\Sigma^+$–$X^2\Sigma^+$) is roughly twice that of $R_{e'e''}$($A^2\Pi$–$X^2\Sigma^+$), whereas $T_0(B^2\Sigma^+)$ of 2.51 eV has to be compared with $T_0(A^2\Pi)$ of 0.80 eV. Moreover, the radiative lifetimes of the B and A states lie in the ns and μs time region, respectively.

As shown in Fig. 1 (MO results), the minimum of the $X^3\Pi$(BN) state lies between the v' levels 1 and 2 of $B^2\Sigma^+(BN^-)$. On the other hand, using the relative energies from the NO calculations and spectroscopic parameters from Table 3 and those discussed in Sect. 8, the zero vibrational level of $X^3\Pi$(BN) appears to lie about 0.026 eV (210 cm^{-1}) below $v' = 2$ of $B^2\Sigma^+(BN^-)$. In principle, the latter is the lowest lying vibrational level that may autodetach into $X^3\Pi + e^-$. However, since our theoretical predictions are expected to underestimate uniformly the separation BN–BN^- by not less than 0.25 eV, a more realistic picture would indicate that up to $v' = 3$ the $B^2\Sigma^+$ state is mainly depopulated via radiative emission (see below).

Since the upper and lower states of the $B^2\Sigma^+$–$X^2\Sigma^+$ band system have similar equilibrium geometries, the Franck–Condon distribution is mainly concentrated in the diagonal elements (Table 8). Accordingly, the diagonal absorption numbers $f_{v'v''}$ are about 100 times larger than the nondiagonal terms. A f_{00} ($B \leftarrow X$) value of 0.354×10^{-1} for BN^- compares with 0.436×10^{-1} reported for the equivalent transition of C_2^- (37).

7.3 The $B^2\Sigma^+$–$A^2\Pi$ *transition*

The radiative data for the $B^2\Sigma^+$–$A^2\Pi$ transition are given in Table 9. For this band system, the absolute value of the transition moment remains below 0.1 au (Fig. 5 and Table 6). However, the energy term $E_{v'v''}^3$ contributing to the Einstein coefficients is large enough to give $A_{v'v''}$ values in the order of 10^3–10^4 s^{-1}, which in turn lead to radiative lifetimes from 127 ($v' = 3$) to 175 ($v' = 0$) microseconds.

Strictly speaking, the total lifetime $\tau_{v'}$ of $B^2\Sigma^+(v')$ has to be computed via the expression $\tau_{v'} = [\Sigma_{v''}A_{v'v''}(B^2\Sigma^+(v')$–$X^2\Sigma^+(v'')) + \Sigma_{v''}A_{v'v''}(B^2\Sigma^+(v')$–$A^2\Pi(v''))]^{-1}$. Comparing the respective $A_{v'v''}$ data from Tables 8 and 9, it is seen that those for $B \rightarrow X$ emission are 10^3 times higher than those for $B \rightarrow A$ decay. Therefore, the first three or four levels of $B^2\Sigma^+$ are mainly depopulated via emission into the $X^2\Sigma^+$ ground state.

The low absorption intensity for the $B^2\Sigma^+ \leftarrow A^2\Pi$ tran-

sition is demonstrated by an f_{00} number of about 0.9×10^{-5} (Table 9). The corresponding transition $B^2\Sigma_u^+$–$A^2\Pi_u$ of C_2^- does not contribute to the spectrum since it is dipole forbidden.

8. The $X^3\Pi$, $a^1\Sigma^+$, $1^1\Pi$, and $1^3\Sigma^-$ states of BN

Table 10 collects the spectroscopic parameters of the lowest lying state of BN that can be generated by photodetachment of BN^- (Sect. 9). Earlier theoretical and experimental results are also given.

The question of the $X^3\Pi$–$a^1\Sigma^+$ separation has recently been investigated theoretically by Martin et al. (15). Their work employed state-of-the-art computational methods (multireference CI and averaged couple-pair functional, ACPF) as well as flexible AO basis sets (van Duijneveldt's 13*s*8*p* primitive set, augmented with even-tempered 6*d*4*f*2*g* polarization functions in an atomic natural orbital (ANO) contraction scheme). The most sophisticated results were obtained with a 5*s*4*p*3*d*2*f*1*g* contracted basis. In some cases, relativistic corrections were also included.

Martin et al. (15) concluded that the ground state of BN indeed corresponds to $X^3\Pi$, the $a^1\Sigma^+$ state lying 0.05 ± 0.01 eV higher. This result confirms earlier predictions by Karna and Grein (13) about the nature of the ground state of BN and the very low excitation energy of $a^1\Sigma^+$ (T_e = 0.1 eV, MRD-CI calculations with a TZP basis set). [a]With parent NO's (estimated full CI) the T_e values are: 0.01 for $a^1\Sigma^+$, 0.47 for $1^1\Pi$, and 1.18 for $1^3\Sigma^-$.

[b]Total energy (in hartree): −79.26384 (MO's) and −79.26731 (NO's).

[c]The data tabulated correspond to R_0, $\Delta G(1/2)$, and B_0.

[d]The T_e values from extrapolated MRD-CI energies (without full-CI correction) are 0.05 eV (MO's) and 0.03 eV (NO's). The best estimate of T_e ($a^1\Sigma^+$) from the results given here is 0.03 ± 0.02 eV.

present work, using a better basis set and larger CI expansion, the energetic separation between $X^3\Pi$ and $a^1\Sigma^+$ ranges from 0.05 to 0.01 eV, depending on the option used (MO vs. NO, extrapolated energy with or without correction for full CI). Therefore, our best estimate is 0.03 ± 0.02 eV, in agreement with the result by Martin et al.

The present estimates of R_e and ω_e are in fairly good agreement with those from ref. 15. For $X^3\Pi$, our values of R_e = 2.520 bohr and ω_e = 1488 cm^{-1} have to be compared with average values R_e = 2.532 ± 0.008 bohr and ω_e = 1474 ± 15 cm^{-1} derived from Table IV in ref. 15 (their best estimates given in Table 10 are slightly different). A similar analysis for $a^1\Sigma^+$ points out a comparable degree of accuracy. The present estimates R_e = 2.425 bohr and ω_e = 1660 cm^{-1} reproduce averaged data of 2.429 ± 0.002 bohr and 1679 ± 10 cm^{-1}, respectively (ACPF and MRCI results from Table III, ref. 15).

The $1^1\Pi(5\sigma 1\pi^3)$ state constitutes the second excited state

of BN, with a present estimate for T_e of 0.45 eV, close to an excitation energy of 0.50 eV reported earlier by KG1 (13). Experimentally little is known for this singlet state, which has been assumed to be the lower state in a rather weak $c^1\Sigma^+$–$b^1\Pi$ emission band (10). The transition $b^1\Pi(1^1\Pi)$–$a^1\Sigma^+$ lies in the infrared region ($T_{00} \approx 3200$ cm^{-1}).

The $1^3\Sigma^-(5\sigma^1 1\pi^2)$ state lies near $T_e = 1.10$ eV. This triplet state is connected to $a^1\Sigma^+(1\pi^4)$ by the double-excitation $1\pi^2 \rightarrow 5\sigma^2$, accompanied by a significant decrease in bond strength, as pointed out by changes in R_e of +0.373 bohr and ω_e of −570 cm^{-1}.

A $^3\Sigma^-$–$^3\Sigma^-$ transition recently detected by Verma (9) has been assumed to involve this $1^3\Sigma^-$ state of BN. An experimentally determined rotational constant $B = 1.455$ cm^{-1} corresponds to an $R_e(1^3\Sigma^-)$ of 2.59 bohr, about 0.2 bohr shorter than the theoretical estimates (Table 10). Moreover, this experimental $R_e(1^3\Sigma^-)$ is longer than that of $X^3\Pi$ by only 0.07 bohr, whereas the corresponding derease in ω_e is relatively large (~450 cm^{-1}, Table 10). On the other hand, theory supports a vibrational frequency $\omega_e(1^3\Sigma^-)$ near the experimental region (1100 vs. 1049 cm^{-1}).

Neither the $1^1\Pi$–$a^1\Sigma^+$ nor $1^3\Sigma^-$–$X^3\Pi$ band systems of BN (equivalent to the Phillips and Ballik–Ramsay bands of C_2) have been observed experimentally. However, their radiative properties have been studied theoretically (39).

9. Electron affinities and photodetachment transitions

The relative energies of selected states of BN^- and BN, together with the corresponding Franck–Condon factors for photodetachment, are summarized in Table 11.

9.1 Electron affinities

At the MRD-CI-MO level of computation, $X^2\Sigma^+(BN^-)$ lies 2.77 eV below $X^3\Pi(BN)$. The electron affinity EA($^3\Pi$) increases to 2.84 eV at the more sophisticated MRD-CI-NO level of treatment. Assuming that this study underestimates the energy separation BN^-–BN by about 0.25 eV, EA($^3\Pi$) might lie close to 3.10 eV. The latter value compares with an experimental estimate of 3.40 eV for EA(C_2) (36, 38). Indeed electron attachment stabilizes both molecules in a degree comparable to that of the strongly electronegative F and Cl atoms, with EA's near 3.5 eV (27).

On a relative scale, however, electron attachment strengthens the BN bond more than it affects that of C_2. As shown in Sect. 6, dissociation energies and electron affinities are connected by the expression $D_e(XY^-) - D_e(XY) = EA(XY) - EA(X)$. Using EA data from this work and literature values for C_2 (36, 38) and C (27), the right-hand side amounts to 2.82 eV for BN and 2.13 eV for C_2. Looking for the changes in D_e, and taking into account that $D_e(BN, X^3\Pi)$ is about 4.55 eV and $D_e(C_2, X^1\Sigma_g^+)$ about 6.30 eV (1), it is easily seen that the relative increase $\Delta D_e/D_e$ upon electron attachment is more significant for BN (62%) than for C_2 (34%).

In the process $X^3\Pi(5\sigma 1\pi^3) + e^- \rightarrow X^2\Sigma^+(5\sigma 1\pi^4)$ the attached electron occupies the 1π MO. Another concurrent attachment reaction (into 5σ) may generate BN^- in the $A^2\Pi(5\sigma^2 1\pi^3)$ excited state, with an EA of 2.03 eV. In principle, the reaction $X^3\Pi$ (BN) + $e^- \rightarrow A^2\Pi$ (BN^-) could be an experimentally accessible mechanism to generate excited BN^- and to study the emission spectrum $A^2\Pi \rightarrow X^2\Sigma^+$.

Electron attachment to the $a^1\Sigma^+(4\sigma^2 1\pi^4)$ state of BN gives rise to only one bound electronic state of BN^-, namely $X^2\Sigma^+(4\sigma^2 5\sigma 1\pi^4)$. Since near equilibrium $B^2\Sigma^+$ has the configuration $4\sigma 5\sigma^2 1\pi^4$, this state of BN^- cannot be generated from $X^3\Pi$ or $a^1\Sigma^+$ of BN via a single-electron process. Electron attachment has to be accompanied simultaneously by the excitation $4\sigma \rightarrow 5\sigma$. Since these two-electron processes occur with very low probability, their contribution to the formation of BN^- states is negligible.

9.2 Photodetachment transitions

Extraction of one electron from each of the highest lying MO's of the ground state $X^2\Sigma^+(4\sigma^2 5\sigma 1\pi^4)$ formally gives rise to the following states of BN: (*i*) $X^3\Pi$, $1^1\Pi$ $(1\pi \rightarrow \infty)$; (*ii*) $a^1\Sigma^+$ $(5\sigma \rightarrow \infty)$; and (*iii*) $1^3\Sigma^+$, $(2,3)^1\Sigma^+$ $(4\sigma \rightarrow \infty)$. Similarly, single-electron photodetachment from $A^2\Pi$

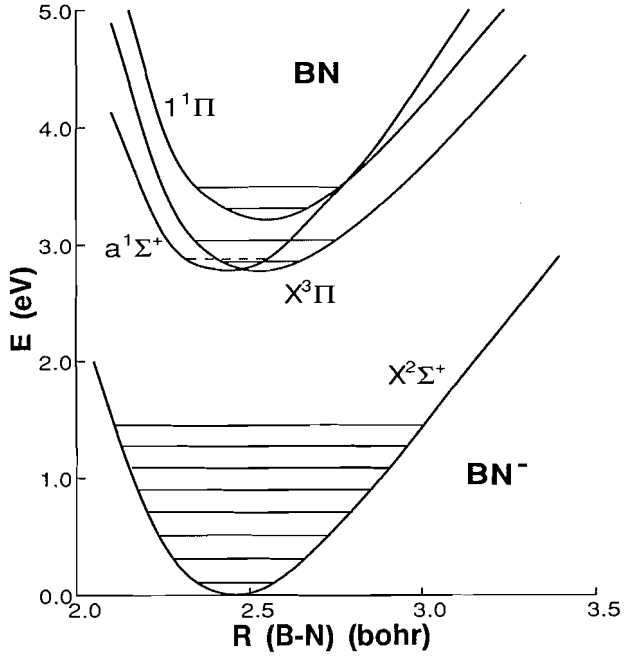

FIG. 6. Potential curves of the lowest states of BN generated via photodetachment from $X^2\Sigma^+$ of BN^-.

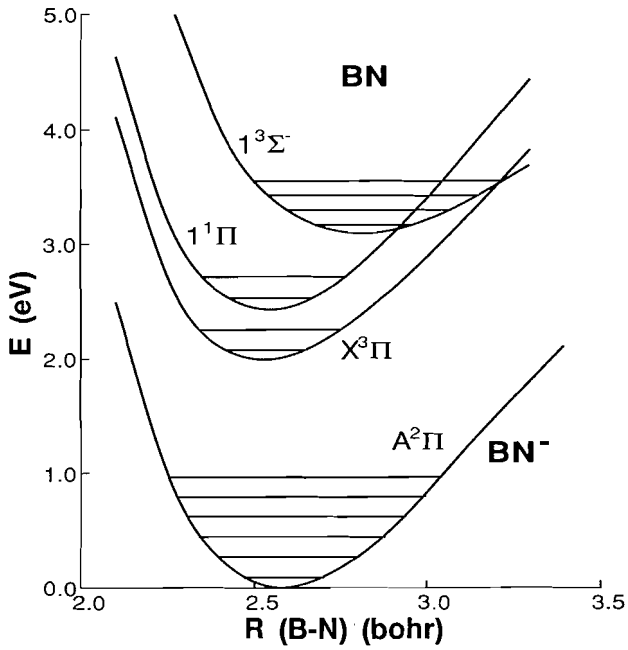

FIG. 7. Potential curves of the lowest states of BN generated via photodetachment from $A^2\Pi$ of BN^-.

$(4\sigma^2 5\sigma^2 1\pi^3)$ of BN^- leads to (*i*) $X^3\Pi$, $1^1\Pi$ $(5\sigma \rightarrow \infty)$; (*ii*) $1^3\Sigma^-$, $1^1\Delta$, $(2,3)^1\Sigma^+$ $(1\pi \rightarrow \infty)$; and (*iii*) $2^3\Pi$, $2^1\Pi$ $(4\sigma \rightarrow \infty)$.

In this paper we focus on the processes leading to the $X^3\Pi$, $1^1\Pi$, $a^1\Sigma^+$, and $1^3\Sigma^-$ states of BN. Figures 6 and 7 show the potential curves of BN and BN^- involved in the photodetachment spectrum. The corresponding relative Franck–Condon factors are given in Table 11. Other photodetachment transitions are analyzed elsewhere.[2] A diagram showing relative energies is given in Fig. 8.

[2]R.C. Mawhinney, P.J. Bruna, and F. Grein. To be published.

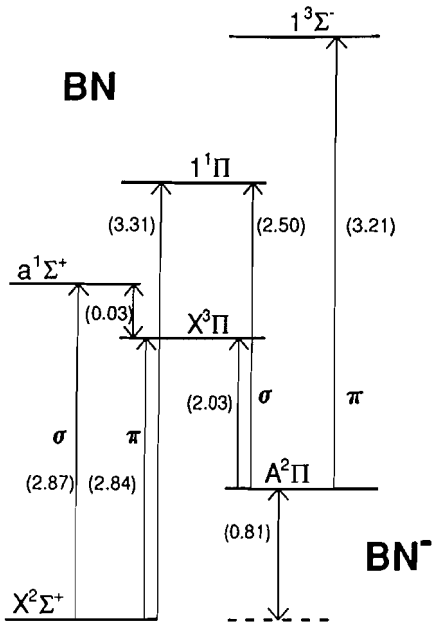

FIG. 8. Schematic diagram showing the relative energies of selected states of BN and BN^-. The labels σ and π characterize the MO's of BN^- from which photodetachment takes place.

The process $X^3\Pi(v') \leftarrow X^2\Sigma^+(v'' = 0)$ generates a short vibrational progession consisting of the strong line 0,0, and a secondary peak 1,0 with about $^1/_4$ relative intensity. Both lines are separated by $\omega_e(X^3\Pi) \simeq 1490\ cm^{-1}$ (Table 10). If hot bands from $v'' = 1$ of $X^2\Sigma^+$ contribute to the photodetachment spectrum, upper levels v' up to 3 can be populated. The corresponding transitions $1^1\Pi(v') \leftarrow X^2\Sigma^+(v'')$ are shifted to higher energies by about 0.47 eV (about 3800 cm^{-1}). As expected, the Franck–Condon distribution of this band is essentially the same as for $X^3\Pi \leftarrow X^2\Sigma^+$. The photodetachment $1^1\Sigma^+ \leftarrow X^2\Sigma^+$ $(5\sigma \rightarrow \infty)$ is accompanied by small changes in R_e and ω_e (Table 11). Therefore, the line 0,0 is the only one expected to contribute to this portion of the spectrum.

Simple rules about the relative intensities of photoelectron ionization bands discussed by Eland (40) can be applied to the equivalent photodetachment processes. One rule states that the partial cross-section for ionization (i.e., relative ionization probability) is proportional to the number of equivalent electrons available for ionization. Therefore, in the case of linear molecules, $\pi \rightarrow \infty$ bands are expected to show twice the intensity of that arising from $\sigma \rightarrow \infty$ ionization (photodetachment). A second rule states that the ionization cross section is proportional to the statistical weight of the final (ionic) state produced. For $\pi \rightarrow \infty$ detachment from $X^2\Sigma^+$ of BN^- into both $X^3\Pi$ and $1^1\Pi$ of BN, it follows that the triplet and singlet bands should appear with relative intensities in a 3:1 ratio.

Combining both rules (that is, by photodetachment $1\pi \rightarrow \infty$ as well as $5\sigma \rightarrow \infty$ from $X^2\Sigma^+$), the experimental spectrum is expected to consist of three band systems $X^3\Pi < a^1\Sigma^+ < 1^1\Pi$ with a total intensity ratio of 3:2:1. On the basis of spectroscopic information from Tables 10 and 11, these bands cover an energy region of about 5350 cm^{-1} above the transition $X^3\Pi(v' = 0) \leftarrow X^2\Sigma^+(v'' = 0)$.

To estimate the relative strength of each vibrational transition, the total band intensities have to be multiplied by the

For personal use only.

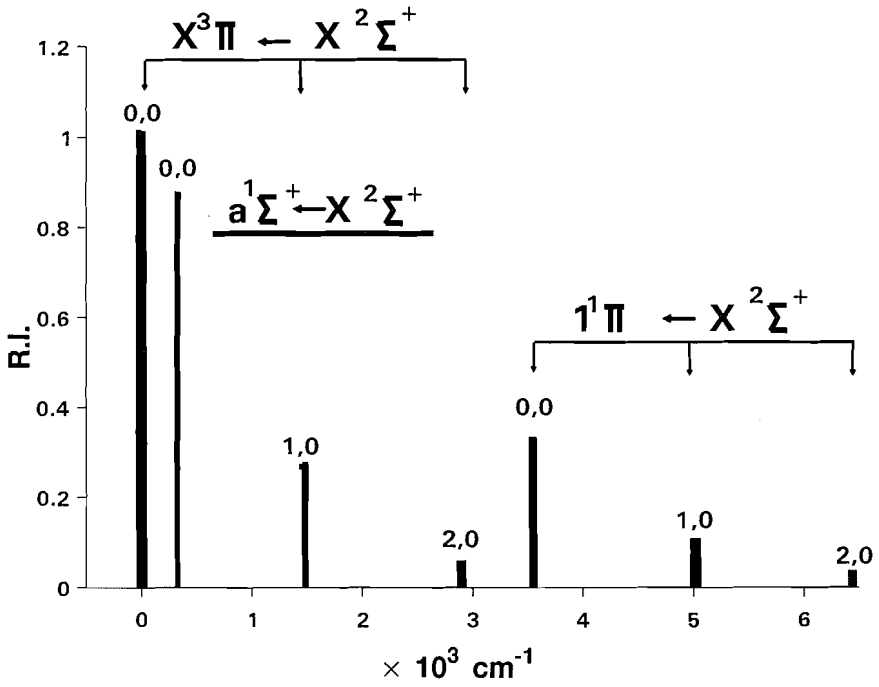

FIG. 9. Relative intensity (R.I.) and vibrational structure (v', v'') predicted for the photodetachment from $X^2\Sigma^+(v'' = 0)$ of BN^- into the $X^3\Pi$, $a^1\Sigma^+$, and $1^1\Pi$ states of BN. The $a^1\Sigma^+$ state is assumed to lie about 300 cm^{-1} above $X^3\Pi$ ($v' = 0$).

appropriate Franck–Condon factors. A total relative intensity of three for $X^3\Pi(v')$ decomposes into 2.273 for $v' = 0$, 0.605 for $v' = 1$, and 0.122 for $v' = 2$ when the vibrational structure is taken into account. Similarly, a relative intensity of one for $1^1\Pi$ decomposes into 0.729 for $v' = 0$, 0.220 for $v' = 1$, and 0.043 for $v' = 2$. The $a^1\Sigma^+$ band consists mainly of a strong $v' = 0$ peak with a relative intensity of 1.967.

For simplicity, the ratios from above are normalized with respect to the strongest line of the spectrum, namely $X^3\Pi(v' = 0)$. Figure 9 has been drawn on the basis of these intensity ratios. From this analysis the following points can be made:

1. Two close-lying peaks contribute to the maximum intensity region. The strongest line corresponds to $v' = 0$ of $X^3\Pi$ (100% relative intensity), followed by $v' = 0$ of $a^1\Sigma^+$ (~87%). According to the best theoretical estimates, both lines are separated by approximately 400 ± 100 cm^{-1}, with the strongest photodetachment peak being energetically the lowest.

2. The $v' = 1$ ($X^3\Pi$) line, shifted by about 1490 cm^{-1} relative to $v' = 0$, should appear with a 27% relative intensity. Since the energy separation between these two vibrational levels of $X^3\Pi$ is known from optical spectroscopy (1, 7, 8, 10), the location of the $v' = 1$ line in the photodetachment spectrum indirectly helps to pick up the corresponding $v' = 0$ counterpart from the low-energy region discussed above.

3. A weak line (about 5% intensity) near 2900 cm^{-1} corresponds to $v' = 2$ of $X^3\Pi$.

4. The $1^1\Pi \leftarrow X^2\Sigma^+$ band system essentially consists of the lines $v' = 0$ (32% intensity) and $v' = 1$ (about 10%), the former shifted by approximately 3800 ± 200 cm^{-1} with respect to $v' = 0$ ($X^3\Pi$). It should be pointed out that radiative emission from $1^1\Pi$ into $a^1\Sigma^+$ is dipole allowed; according to ref. 39, the radiative lifetime $\tau_{v'}(1^1\Pi)$ is 162 μs for $v' = 0$. The photodetachment process $1^1\Pi \leftarrow X^2\Sigma^+$ might constitute an appropriate experimental route to generate the $1^1\Pi$ state of BN and to study its emission spectrum.

Photodetachment from the $A^2\Pi(5\sigma^2 1\pi^3)$ state of BN^- can be recorded experimentally. A drawback to study ionization of $A^2\Pi$, however, might lie in the radiative process $A^2\Pi \rightarrow X^2\Sigma^+$ occurring in the 10-μs time scale.

As already observed for the transition $a^1\Sigma^+ \leftarrow X^2\Sigma^+$, ejection of a 5σ electron does not affect significantly the BN bonding because of the quasi-lone-pair character of the MO (Sect. 4.1 and Fig. 2). In line with this feature, no vibrational structure is expected for the bands $X^3\Pi \leftarrow A^2\Pi$ and $1^1\Pi \leftarrow A^2\Pi$ (Table 11).

Determination of the energy separation between the $v' = 0$ levels of both $X^3\Pi$ and $1^1\Pi$ via photodetachment from $A^2\Pi$ is extremely important as an independent experimental route to deconvolute the low-energy region of the composite $X^3\Pi$, $a^1\Sigma^+ \leftarrow X^2\Sigma^+$ spectrum. Moreover, the relative separation $A^2\Pi$–$X^2\Sigma^+$ of BN^- can be indirectly derived by photodetachment from $X^2\Sigma^+$ and from $A^2\Pi$ into their common $X^3\Pi$ and $1^1\Pi$ states of BN.

The transition $1^3\Sigma^- \leftarrow A^2\Pi$ ($\pi \rightarrow \infty$) is accompanied by a relatively large change in bond length and frequency (Table 11 and Fig. 7). Accordingly, the Franck–Condon envelope consists of no less than five terms separated by $\omega_e(1^3\Sigma^-) \simeq$ 1050 ± 100 cm^{-1} (Table 10). The upper state $1^3\Sigma^-$ may decay into $X^3\Pi$ via radiative emission, a process having lifetimes from 11.2 μs ($v' = 0$) to 3.9 μs ($v' = 5$) (39).

10. Summary and conclusions

The BN^- species, like isoelectronic C_2^-, has three stable electronic states, $X^2\Sigma^+(4\sigma^2 5\sigma 1\pi^4)$, $A^2\Pi$ ($1\pi \rightarrow 5\sigma$), and $B^2\Sigma^+(4\sigma \rightarrow 5\sigma)$. The low-lying states $1^4\Sigma^+$, $1^4\Delta$, $1^4\Sigma^-$, and $1^4\Pi$ autodetach into BN ($X^3\Pi$) + e^-. A detailed comparison of BN^- with C_2^-, AlP^-, $GaAs^-$, Si_2^-, and Ge_2^- is given in ref. 17. There it is shown that the heavier isoelectronic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

anions exhibit a larger number of bound states. All doublet and quartet states listed above are more stable than the respective ground state of the neutral species. Such a markedly strong difference between first- and higher row compounds is mainly governed by the stabilization of the $\pi^*(\pi_g)$ MO upon substitution (2, 17, 41, 42).

An electron affinity of 3.10 eV (best estimate) for BN compares with an experimental value of 3.40 eV for C_2 (29, 36–38). A recent *ab initio* study (43) on the process $BNB \rightarrow BNB^-$ finds EA values of about 2.96 eV (directly calculated) and 3.33 eV (best estimate), quite similar to our result for $BN \rightarrow BN^-$. On the other hand, a relatively high EA(BN) is reflected in a fairly large increase in the BN bond strength as pointed out by ground state dissociation energies of 4.55 eV for BN and of 7.12 eV for BN^- (best estimates, ±0.1 eV).

Optical spectroscopy can be used to investigate BN^- as it has been done for C_2^- (1, 5, 44). The present radiative data on BN^- should be of assistance in future experiments. In general, the electronic spectrum of BN^- shows features similar to those observed experimentally for the isoelectronic first-row diatomics C_2^-, CN, and CO^+ (1). For instance, the parallel band system $B^2\Sigma^+_{(u)}$–$X^2\Sigma^+_{(g)}$ is invariably of higher intensity than the perpendicular transition $A^2\Pi_{(u)}$–$X^2\Sigma^+_{(g)}$. In line with this difference in intensities, the radiative lifetimes of the B and A states lie in the ns and μs time scale, respectively. The emission process $B \rightarrow A$ (dipole allowed only for heteronuclear species) is of secondary importance when compared with $B \rightarrow X$ decay.

The low-energy region of the photodetachment spectrum originating from $X^2\Sigma^+$ of BN^- should be instrumental in determining experimentally the nature of the ground state of BN. According to this work and literature data (13–15), the $X^3\Pi$ state is predicted to be the ground state, with $a^1\Sigma^+$ lying about 0.03 eV higher. Unfortunately, this small energy difference is comparable to the accuracy of the *ab initio* results. Therefore, the final word on the relative positioning of $X^3\Pi$ and $a^1\Sigma^+$ will have to come from experiment or future, much improved, *ab initio* studies. Since both low-lying states of BN can be generated via ionization from $X^2\Sigma^+$ of BN^-, photodetachment spectroscopy represents an alternative technique to optical spectroscopy. On the basis of a Franck–Condon analysis and simple rules governing relative intensities in photoelectron spectrocopy, we have devised a model spectrum which should be of help to experimentalists.

Rotational analyses of bands of the $\tilde{A}^1B_1$–$\tilde{X}^1A_1$ system of *cis*-glyoxal[1]

R.Y. DONG,[2] R. NANES,[3] AND D.A. RAMSAY

Herzberg Institute of Astrophysics, National Research Council of Canada, Ottawa, ON K1A 0R6, Canada

Received March 10, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

R.Y. DONG, R. NANES, and D.A. RAMSAY. Can. J. Chem. **71**, 1595 (1993).

Rotational analyses have been carried out for the 5^1_0, 5^0_1, and 5^1_1 bands of the $\tilde{A}^1B_1$–$\tilde{X}^1A_1$ system of *cis*-glyoxal, where ν_5 is the totally symmetric C—C=O bending frequency. The vibrational frequencies $\nu_5' = 302.81$ cm^{-1} and $\nu_5'' = 284.51$ cm^{-1} are smaller than the corresponding frequencies for *trans*-glyoxal by nearly a factor of two. A vibronically induced band with a different type of rotational structure has been analysed and shown to be an *a*-type band. The coupling vibration is the out-of-plane C—H wagging vibration $\nu_6(a_2)$ and is similar in form and frequency to the vibronically active $\nu_8(b_g)$ vibration for *trans*-glyoxal.

R.Y. DONG, R. NANES et D.A. RAMSAY. Can. J. Chem. **71**, 1595 (1993).

On a effectué des analyses rotationnelles des bandes 5^1_0, 5^0_1 et 5^1_1 du système $\tilde{A}^1B_1$–$\tilde{X}^1A_1$ du *cis*-glyoxal, ou ν_5 est la fréquence de déformation totalement symétrique du C—C=O. Les fréquences de vibration $\nu_5' = 302{,}81$ cm^{-1} et $\nu_5'' = 284{,}51$ cm^{-1} sont environ deux fois plus faibles que les fréquences correspondantes du *trans*-glyoxal. On a analysé une bande induite vibroniquement avec un type différent de structure rotationnelle et on démontre qu'il s'agit d'une bande de type *a*. La vibration de couplage correspond à la vibration d'oscillation hors du plan C—H $\nu_6(a_2)$ et elle est semblable du point de vue de la forme et de la fréquence à la vibration vibroniquement active $\nu_8(b_g)$ du *trans*-glyoxal.

[Traduit par la rédaction]

Introduction

The 0–0 band of *trans*-glyoxal ($C_2H_2O_2$) at 4550 Å was first rotationally analysed by Gerald King in 1957 (1) using spectra taken on a 20-ft Ebert spectrograph (2), which he had constructed at University College, London. The analysis correctly identified the sub-bands in the symmetric top portion of the band but no attempt was made to analyse the asymmetric top structure in the central portion of the band. The latter was analysed later by Paldus and Ramsay (3). The 4550 Å band is the 0–0 band of the $\tilde{A}^1A_u$–$\tilde{X}^1A_g$ (π^*–n) system of *trans*-glyoxal. Many other bands in this system for $C_2H_2O_2$, C_2HDO_2, $C_2D_2O_2$, and $^{13}C_2H_2O_2$ have been rotationally analysed (3–6), giving accurate rotational and vibrational constants for levels in the ground and excited states and also permitting a determination of the geometric structures in both states.

In 1971, the *cis* isomer was found by Currie and Ramsay (7). A band at 4875 Å had a similar structure to the 4550 Å band except that it had about twice as many sub-bands. Rotational analysis gave constants consistent with a *cis* structure for the molecule. The 4875 Å band is assigned as the 0–0 band of the $\tilde{A}^1B_1$–$\tilde{X}^1A_1$ (π^*–n) system of *cis*-glyoxal. The band had been seen but not identified in some laser-excited fluorescence studies (8). The 4880 Å line of an argon ion laser is an excellent line for exciting *cis*-glyoxal and subsequent laser studies have yielded ground state vibrational constants for *cis*-$C_2H_2O_2$, C_2HDO_2, and $C_2D_2O_2$ (9).

cis-Glyoxal has a large dipole moment (~4.8 D) and seven lines in the microwave spectrum were observed by Durig et al. (10). Two of these were shown to be misassigned by Mamleev et al. (11) who observed many more transitions, including some from vibrationally excited levels in the ground state. The rotational constants obtained for the ground state are in good agreement with those derived from the optical spectrum.

In the present work, rotational analyses are presented for four bands in the absorption spectrum, including one vibronically induced band. Accurate molecular constants are obtained for two vibrational levels in the excited state and one in the ground state.

Experimental

Glyoxal was prepared by passing ethylene over a mixture of SeO_2 and P_2O_5 heated to 200°C.

Absorption spectra were photographed in the region 4600–5200 Å using the 12th order of a 7.3-m Ebert spectrograph with a resolving power of ~600 000 and Kodak III-O plates. The absorption cell was 2 m long and was heated to 85°C to increase the amount of the *cis* isomer. Three bands of *cis*-glyoxal were found near 4805, 4816, and 4945 Å using an absorption path length of 40 m and pressures of glyoxal ranging from 5 Torr for the first two bands to 25 Torr for the long-wavelength band (1 Torr = 133.3 Pa). Another band of *cis*-glyoxal with a different type of rotational structure was also identified near 4710 Å using the same path length and 4 Torr of glyoxal at a temperature of 181°C.

An iron hollow cathode lamp was used to provide reference spectra and the plates were measured using a comparator with a photoelectric scanning device. Standard wavelengths were taken from the tables of Crosswhite (12) and the vacuum corrections of Edlén (13) were applied. There was much overlapping of the lines in the absorption spectra but for single lines the precision of measurement is ~0.003 cm^{-1}.

Rotational analysis

(a) The 4805, 4816, and 4945 Å bands

These bands have *c*-type rotational structures similar to that of the 0^0_0 band. The 4945 Å band is relatively free from overlapping absorption and a rotational analysis was carried out in the manner described earlier (7). It was found that the upper state constants were the same as for the 0^0_0 band, hence only the lower state constants were varied in the final fit of

the band. The differences between the rotational constants in the upper and lower states are given in Table 1 together with the band origin. Altogether 952 lines were fitted with a standard deviation of 0.018 cm^{-1}. Since the band originates in a totally symmetric level of the ground state at 284.51 cm^{-1} and since the inertial defect is small (Δ = +0.036 amu Å^2), the most reasonable assignment is 5^0_1, where ν_5 is the totally symmetric CCO bending frequency. This assignment is consistent with single vibronic level fluorescence studies (14).

Rotational analysis of the 4805 Å band shows that it originates in the ground state and the rotational constants for the upper state are quite reasonable if the band is assigned as 5^1_0. The band is overlapped at the high-frequency end by the 8^0_1 band of *trans*-glyoxal and at the low-frequency end by the 4816 Å band described below. Consequently only 328 lines were assigned and the standard deviation of the fit was 0.019 cm^{-1}.

Confirmation of the assignments of the 5^1_0 and 5^0_1 bands was obtained by calculating the frequencies for the 5^1_1 band. This band lies ~18 cm^{-1} on the high-frequency side of the 0^0_0 band and is heavily overlapped by it. However, many of the unassigned lines in the original measurements of the 0^0_0 band were assigned without difficulty to the stronger lines in the calculated spectrum of the 5^1_1 band. The number of lines assigned was insufficient, however, to justify any further refinement of the molecular constants.

The 4816 Å band is also heavily overlapped and so far has

resisted attempts at rotational analysis. It appears that the band does not originate in the ground state and the most reasonable assignment is 7^1_1, where ν_7 is the torsional frequency. If this assignment is correct, then $\nu'_7 - \nu''_7$ is $\sim$256 cm^{-1} and is considerably larger than the corresponding difference for *trans*-glyoxal, viz. 106.55 cm^{-1} (4). The principal rotational constants A, B, and C for the $\nu''_7 = 1$ level are known from microwave studies (11) and, using these constants, a fit can be made to the strong 0–1 and 1–0 Q branches giving a band origin in the region of 20 763.5 cm^{-1}. However, it is likely that the values of D_K in both the lower and upper states are strongly affected by Coriolis interactions with ν_{12}, as was found for *trans*-glyoxal (4). Further progress must therefore await a more complete determination of the constants for the lower state by microwave spectroscopy.

(b) The 4711 Å band

The band near 4711 Å has a different type of rotational structure characteristic of an *a*-type transition. Indeed the band was readily analysed on the basis that it originates in the ground vibrational level of the molecule and consists of ^qR, ^qQ, and ^qP branches. Altogether 846 rotational assignments were made and were fitted by least squares with a standard deviation of 0.019 cm^{-1}. Many of the lines have multiple assignments, which limits the accuracy of the fit, but the validity of the assignments is supported by the calculation of the relative intensities as well as the frequencies of the lines. The vibrational assignment of this band is discussed below.

Discussion

The vibrational frequencies for *cis*- and *trans*-glyoxal are summarized in Table 2. The C—C=O symmetric bending frequencies ν'_5 and ν''_5 for *cis*-glyoxal are well determined in the present work and differ by nearly a factor of two from the corresponding frequencies for *trans*-glyoxal. The ν''_2 frequency for *cis*-glyoxal was determined from laser-excitation studies (8, 9) and lies close to the corresponding frequency for *trans*-glyoxal. A ν''_4 frequency has also been assigned from laser-excited fluorescence studies (14) but is considerably different from the corresponding frequency for the *trans* species. The torsional frequency in the ground state ν''_7 has been estimated from relative intensity measurements in the microwave spectrum (114 ± 8 cm^{-1} (10), 108 ± 10 cm^{-1} (11)). The frequency difference $\nu'_7 - \nu''_7 =$ 256 cm^{-1} is derived from the present work. The frequency $2\,\nu'_7 =$ 688 cm^{-1} has been obtained from laser-excitation studies (14). If the torsional frequency in the excited state is assumed to be harmonic then $\nu'_7 =$ 344 cm^{-1} and $\nu''_7 =$ 88 cm^{-1}. Clearly, further studies are desirable.

The only other frequencies that are well established for *cis*-glyoxal are those that are deduced from vibronically induced bands. The rotational analysis of the 4711 Å band above shows that it is an *a*-type band. The transition is therefore vibronically $^{cv}B_2$–$^{cv}A_1$ and since the electronic transition is B_1–A_1, the coupling vibration must have a_2 symmetry species. The coupling vibration is therefore the C—H wagging vibration $\nu_6(a_2)$ (H^+—C^-—C^+—H^-) and is similar in form to the $\nu_8(b_g)$ vibration in *trans*-glyoxal (in earlier references (8, 9) the *cis* vibration was unfortunately labelled as ν_8, see ref. 14). The frequency ν'_6 deduced from the present work and the frequency ν''_6 deduced from laser-excitation studies (9) are indeed similar to the corresponding ν_8 frequencies for *trans*-glyoxal.

The mechanism for the vibronic coupling is presumably similar for the two isomers. In *trans*-glyoxal the $\nu_8(b_g)$ vibration couples the $\tilde{A}\,^1A_u$ state to electronic states with B_u symmetry of which the closest is a state arising from a π^*–π excitation. In *cis*-glyoxal the $\nu_6(a_2)$ vibration couples the $\tilde{A}\,^1B_1$ state to electronic states with B_2 symmetry of which the closest is again expected to be a π^*–π state with the electron configuration

$$\overbrace{\ldots (b_1)^2(a_2)}^{\pi}\ \overbrace{(a_1)^2(b_2)^2}^{n}\ \overbrace{(b_1)}^{\pi^*}\quad {}^{1,3}B_2$$

An important difference between the two isomers is that whereas the vibronically induced bands for the *trans* isomer are *a*- + *b*-type hybrids, the corresponding bands for *cis*-glyoxal are pure *a*-type bands.

Electronic spectroscopy of yttrium monosulfide: molecular beam studies and density functional calculations[1]

ANDREW M. JAMES, RENÉ FOURNIER, BENOIT SIMARD, AND MARGOT D. CAMPBELL[2]

Steacie Institute for Molecular Sciences, National Research Council of Canada, 100 Sussex Drive, Ottawa, ON K1A OR6, Canada

Received April 13, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

ANDREW M. JAMES, RENÉ FOURNIER, BENOIT SIMARD, and MARGOT D. CAMPBELL. Can J. Chem. **71,** 1598 (1993)

The yttrium monosulfide molecule (YS) has been investigated using the techniques of molecular beam fluorescence spectroscopy and density functional theory. Fluorescence spectra in the region of the electronic orgin of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system (ν_{00} = 14 826.07 cm^{-1}) were recorded using a ring dye laser, the experimental resolution being 120 MHz. The $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band, and a cold band of a hitherto unreported $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ system ($\nu_{v'0}$ = 14 926.02 cm^{-1}) have been rotationally analysed. (The $\pm 1/2$ notation implies that the state has either $^4\Pi_{1/2}$ or $^4\Pi_{-1/2}$ symmetry.) Improved molecular rotational constants were obtained for the $v = 0$ levels of the $X^2\Sigma^+$ and $B^2\Sigma^+$ states (r_0(X) = 2.27191(17) Å, r_0(B) = 2.32202(19) Å, γ_0(B) = −0.15150(14) cm^{-1} (2σ error bounds)). The magnetic hyperfine and spin rotation parameters determined for the $X^2\Sigma^+$ state were found to be in good agreement with previous work. An accurate bond length has been derived for the upper vibrational level of the 14 926.0 cm^{-1} band ($r_{v'}$ = 2.49510(16) Å). The $v = 1$ level of the $B^2\Sigma^+$ state is found to be strongly perturbed by another vibrational level of the $^4\Pi_{\pm 1/2}$ state. The spin-forbidden $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ transition gains intensity via spin-orbit mixing between the $^4\Pi$ state and the $B^2\Sigma^+$ state. Radiative lifetimes of the observed bands were measured by digitizing the fluorescence decay traces obtained upon excitation with a pulsed dye laser. The results of the density functional treatment provide broad confirmation of the experimental measurements. A molecular orbital description of the bonding in the YS molecule is presented.

ANDREW M. JAMES, RENÉ FOURNIER, BENOIT SIMARD et MARGOT D. CAMPBELL. Can J. Chem. **71**, 1598 (1993).

On a étudié la molécule de monosulfure d'yttrium (YS) à l'aide de techniques de spectroscopie de fluorescence de rayons laser et par la théorie de la densité fonctionnelle. Pour enregistrer les spectres de fluorescence dans la région de l'origine électronique du système $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (ν_{00} = 14 826,07 cm^{-1}) on a utilisé un laser à colorant cyclique pour lequel la résolution expérimentale est de 120 MHz. On a analysé la rotation de la bande $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) et une bande froide d'un système $^4\Pi_{1/2} \leftarrow X^2\Sigma^+$ non rapporté jusqu'à mainenant ($\nu_{v'0}$ = 14 926,02 cm^{-1}). On a obtenu des constantes de rotation améliorées pour les niveaux $v = 0$ des états $X^2\Sigma^+$ et $B^2\Sigma^+$ (r_0(X) = 2,27191(17) Å, r_0(B) = 2,32202(19) Å et γ_0(B) = −0,15150(14) cm^{-1} (limites d'erreur de 2σ)). On a trouvé que les paramètres magnétiques hyperfins et de rotation de spin déterminés pour l'état $X^2\Sigma^+$ sont en bon accord avec ceux obtenus au cours d'un travail antérieur. On a déterminé une longueur de liaison précise pour le niveau vibrationnel supérieur de la bande à 14 926,0 cm^{-1} ($r_{v'}$ = 2,49510(16) Å). On a trouvé que le niveau $v = 1$ de l'état $B^2\Sigma^+$ est fortement perturbé par un autre niveau vibrationnel de l'état $^4\Pi_{\pm 1/2}$. La transition $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ non permise par les spin augmente d'intensité par le biais d'un mélange spin-orbite entre l'état $^4\Pi$ et l'état $B^2\Sigma^+$. On a mesuré les temps de vie de radiation des bandes observées en procédant à la digitalisation des courbes de dégénérescence de la fluorescence obtenues lors de l'excitation à l'aire d'un laser à colorant pulsé. Les résultats du traitement fonctionnel de la densité fournissent une large confirmation des mesures expérimentales. On présente une description de l'orbitale moléculaire de la liaison dans la molécule de YS.

[Traduit par la rédaction]

Introduction

Difficulties arise in the spectroscopic study of molecules containing a transition metal atom due to the high density of low-lying electronic states associated with partially occupied *d* orbitals (1, 2). In addition, the large nuclear spins of the transition elements can give rise to complex magnetic hyperfine structure patterns in the already congested spectra of these molecules. However, unravelling the spectroscopy of such systems can pay rich dividends when one considers how central to chemistry is an understanding of bonding involving transition metals. Our work focusses on the electronic spectroscopy of gas phase, transition-metal-containing diatomic molecules. Preparing the molecule of interest in a gaseous environment permits the extraction of detailed information on the properties of a single transition metal – ligand bond, free from interference by other ligands or a host matrix. The versatile technique of chemical reaction in a laser-generated plasma, coupled with supersonic expansion of the products, leads to the formation of intense, internally cold beams of refractory transition metal molecules, which may then be probed by laser spectroscopic techniques (3–6). We have used this approach to make detailed investigations of molecules containing a group three transition metal atom (Sc, Y, or La) bound to a simple ligand. The group three transition elements have the simplest open-*d* shell electronic structure [$(n - 1)d^1 ns^2$], and should therefore give rise to less daunting spectra than their counterparts towards the middle of the transition periods. Experimental determination of the spectroscopic properties of these transition metal molecules furnishes the theoretician with data to check the accuracy of high level *ab initio* calculations. Yttrium monosulfide is a particularly apt candidate in this respect, since the metal–ligand bond is expected to contain both covalent and ionic contributions to a significant extent.

The experimental database relating to the spectroscopy of yttrium monosulfide is rather limited. McIntyre et al. (7) have reported esr and infrared spectra of the YS molecule isolated in an argon marix at 4 K. Stringat, Fenot, and Féménias (8) have obtained electronic spectra of gas phase YS in the

red and near-infrared spectral regions, using a hollow cathode discharge source. Several bands belonging to the $A^2\Pi \leftarrow X^2\Sigma^+$ and $B^2\Sigma \leftarrow X^2\Sigma^+$ systems were reported, a number of them perturbed. A rotational analysis of the $B^2\Sigma \leftarrow X^2\Sigma^+$ (0,0) band was effected, despite the limited resolution and high source temperature. In 1990, Azuma and Childs (9) performed an elegant laser – radio frequency double resonance study on the ground state of YS, pumping the $B^2\Sigma \leftarrow X^2\Sigma^+$ (0,0) band. The ultra-high resolution of this technique (10–15 kHz) permitted very precise determinations of the hyperfine structure and spin-rotation constants for the $X^2\Sigma^+$ state, although no attempt was made to fit the optical frequencies in order to improve the upper state rotational constants. Recently, we employed molecular beam Stark spectroscopy to determine the permanent electric dipole moments of the $X^2\Sigma^+$ and $B^2\Sigma^+$ states of YS (6). Values of 6.098(64) D ($X^2\Sigma^+$ state, $v = 0$, 2σ error bound) and 4.572(92) D ($B^2\Sigma^+$ state, $v = 0$) were obtained. The marked reduction in the dipole moment (μ) upon $B^2\Sigma \leftarrow X^2\Sigma^+$ excitation was unexpected, and warranted further investigation. The density functional calculations reported here demonstrate that the large difference between the dipole moments of the $X^2\Sigma^+$ and $B^2\Sigma^+$ states of YS can be attributed to the differing extents of valence orbital hybridization in each state. We also present experimental and theoretical evidence for a $^4\Pi$ state in the vicinity of the $B^2\Sigma^+$ state.

Experimental

A brief outline of the experimental procedure is given, as a detailed description can be found elsewhere (10). The metal atom plasma was formed by pulsed laser vaporisation of an yttrium target rod (Goodfellows, 99.9%). An excimer laser (Lumonics model 430) operating on the 308 nm line, or a Nd:YAG laser (Lumonics HY400) generating third hamonic radiation (355 nm), were employed as vaporization sources. There were no noticeable differences in the efficiency of production of YS when 355 nm radiation was substituted for 308 nm. Vaporisation took place in a Smalley-type cluster source fixture, in the presence of a flowstream of CS_2-seeded helium gas (0.5% concentration) from a molecular beam valve (Newport BV-100). The post-reaction gas mixture, containing YS molecules, was expanded into a vacuum chamber, where laser-induced fluorescence was excited 4.3 cm downstream from the molecular beam orifice. Fluorescence was imaged through a monochromator (Spex, 0.75 m, 1200 lines/mm) on to a photomultiplier (cryo-cooled Hamamatsu R943). Low-resolution survey spectra and fluorescence decay profiles were recorded using a pulsed dye laser (Lumonics Hyperdye, 0.08 cm^{-1} linewidth), operating on the dyes Kiton Red, DCM, and LD690. The decay traces were sampled by feeding the photomultiplier signal to a digitizer (Tektronix 7912AD). The high-resolution fluorescence spectra were obtained using a cw ring dye laser (Coherent CR699-29), operating on DCM dye. The resolution of the experimental arrangement was found to be 120 MHz. The high-resolution spectra were calibrated by the wavelength meter system incoporated in the ring laser, its operation being checked by a Burleigh WA-20 wavemeter. The absolute accuracy of the ring dye laser calibration system is 200 MHz.

Density functional calculations : computational details

We performed Kohn–Sham density functional calculations on the lowest doublet and quartet states of YS, and YO for comparison, using the Linear Combination of Gaussian-Type Orbitals-Density Functional program deMon (11). We used the local exchange-correlation potential of Vosko et al. (12) throughout the self-consistent field procedure and included gradient corrections to exchange (13) and correlation (14) in the final energy evaluation. The vibrational frequencies were calculated in the harmonic approximation from energy second derivatives obtained as finite differences of analytical first derivatives. The orbital basis sets we employed have the following contraction patterns, which show the number of primitive Gaussian functions in each contracted function, first for s symmetry, second for p, and then for d : oxygen : (6311/311/1); sulfur: (73111/611/1); yttrium: (633321/532111/531). The yttrium has two diffuse p functions to give extra flexibility in describing the polarization of the $5s$ orbital. The auxiliary basis sets for fitting the charge density and exchange-correlation potential were fully uncontracted and consisted of eight s, four p, and four d functions on oxygen, nine s, four p, and four d functions on sulfur, and ten s, five p, and five d functions on yttrium.

The formalism on which our method is based holds rigorously only for the lowest states of a given symmetry and spin multiplicity. The calculated doublet–quartet energy separations have physical meaning and are truly "first principles." It should be noted that methods based on the local spin density approximation seem to underestimate the energy of high-multiplicity states relative to low-multiplicity states, but the trend is apparently not systematic (15, 16). Results for states that are not the lowest of their symmetry and spin multiplicity should be viewed with some caution. They involve additional, and poorly understood, approximations. For a discussion of exact and approximate treatment of excited states in density functional theory, the reader should consult the articles listed in ref. 17.

Description of the spectra

We completed a low-resolution survey of the YS spectrum over the region 600–800 nm, observing numerous vibronic bands of the $A^2\Pi \leftarrow X^2\Sigma^+$ and $B^2\Sigma \leftarrow X^2\Sigma^+$ transitions, as well as several new bands extraneous to these systems. In this work, we concentrate on the portion of the spectrum between 630 and 700 nm, in the vicinity of the electronic origin of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system, where two interesting new bands were discovered and investigated. Other new features and their interaction with the $A^2\Pi \leftarrow X^2\Sigma^+$ and $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ systems will be the subject of future publications.

Figure 1(a) shows a part of the low-resolution LIF spectrum in the region of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band. Approximately 100 cm^{-1} to higher energy of this band, a new and considerably less intense band was detected, with rotationless origin at 14 926.02 cm^{-1}. Dispersing the emission from this band confirmed that it originated from the $v = 0$ level in the ground state of YS. Figure 1(b) shows a portion of the pulsed dye laser LIF spectrum in the vicinity of the $B^2\Sigma \leftarrow X^2\Sigma^+$ (1,0) band. In this region, two double-headed cold bands of comparable intensity were found, located at 15 264.2 cm^{-1} and 15 300.1 cm^{-1} (approximate location of rotationless origins). At the outset, it was not clear which of these bands should be designated $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (1,0), since it appeared that the (1,0) band was being strongly perturbed by an almost degenerate band from another system. (As we demonstrate below, the upper vibrational levels of the 14 926.0 cm^{-1} and 15 300.1 cm^{-1} bands are neighbouring vibrational levels of a $^4\Pi_{\pm 1/2}$ state.) Lifetime measurements on the 15 264.2 cm^{-1} and 15 300.1 cm^{-1} bands (vide infra)

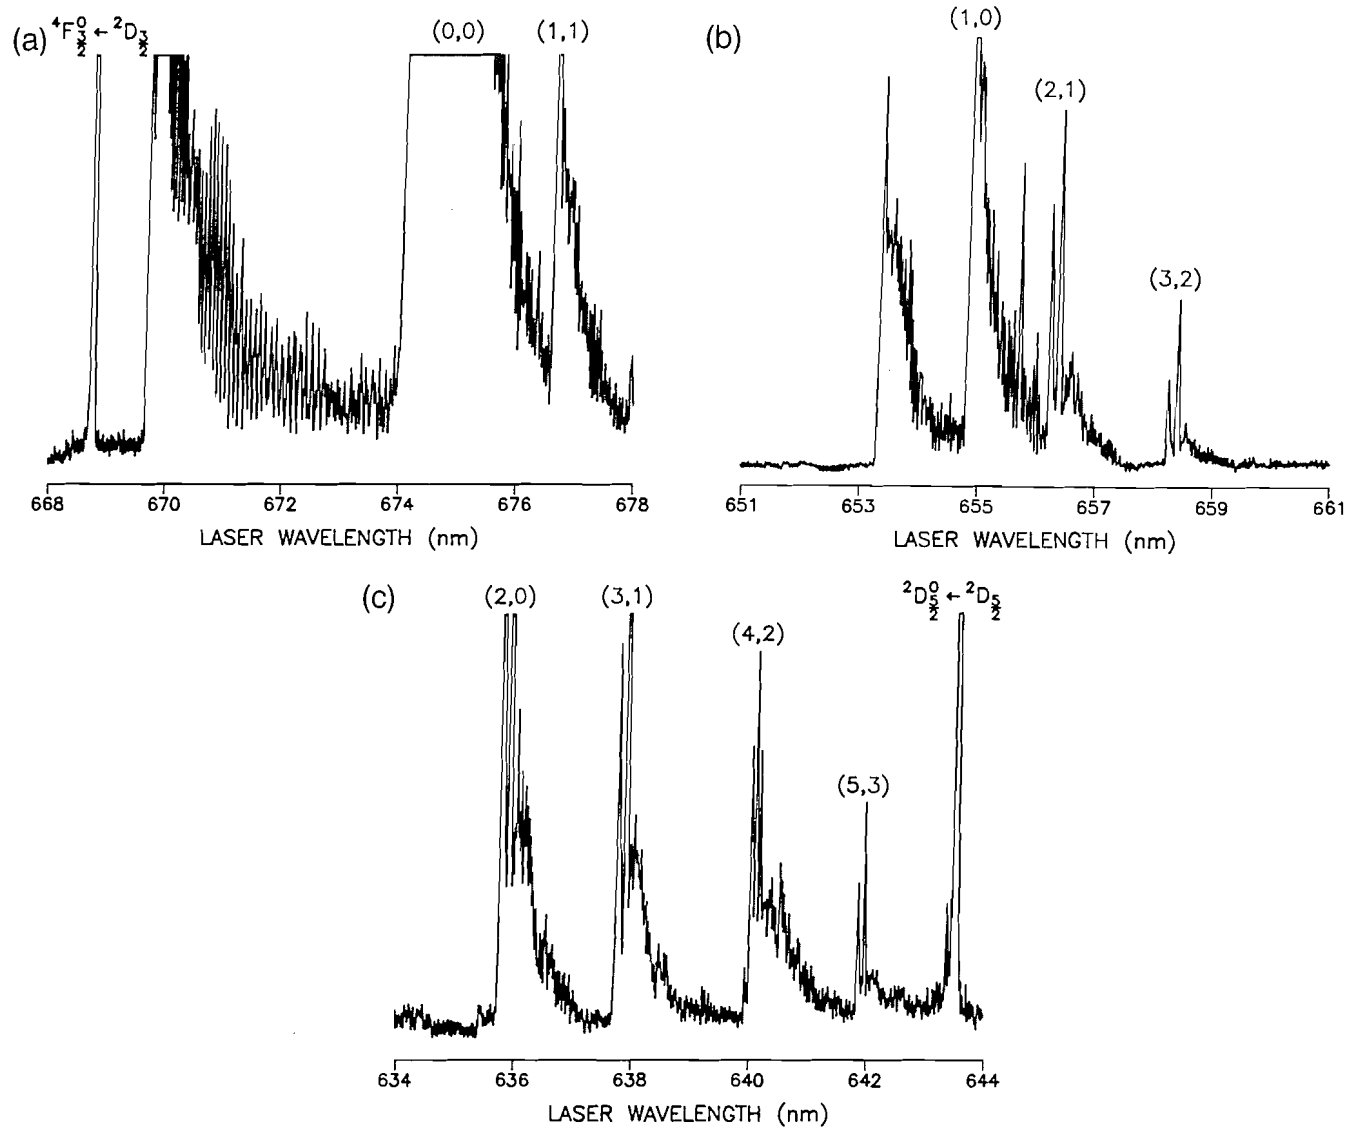

FIG. 1. Low-resolution LIF spectra recorded with the pulsed dye laser. The vertical scale is the LIF intensity. The (v', v'') labels refer to the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system. (*a*) Spectrum in the region of the electronic origin of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system. The feature at 670.0 nm is the (v',0) band of the $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ system discussed in the text. (*b*) Spectrum in the region of the (1,0) band of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system. The feature at 653.2 nm is the (v' + 1, 0) band of the $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ system. (*c*) Spectrum in the region of the (2,0) band of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system.

revealed that the 15 264.2 cm^{-1} band derived more character from the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system than did the 15 300.1 cm^{-1} band. Thus for our purposes it will henceforth be referred to as the (1,0) band, recognizing the caveat that its upper vibrational level is strongly mixed with that of the 15 300.1 cm^{-1} band. In Fig. 1(*c*), the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$(2,0) band is shown, accompanied by neighbouring sequence bands, the identity of all features having been confirmed by recording dispersed emission spectra. Unlike the (1,0) band, the (2,0) band is clearly unperturbed and resembles the (0,0) band. Figures 2(*a*) and 2(*b*) show portions of the cw – ring laser LIF spectra recorded for the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$(0,0) band and the 14 926.0 cm^{-1} band, respectively. Unequivocal line assignment in these bands was greatly facilitated by identification of the hyperfine structure patterns associated with each rovibronic line. The hyperfine structure observed in these spectra is due entirely to the $X^2\Sigma^+$ state. Our experimental resolution did not enable us to resolve the splittings due to the small Fermi contact interaction in the $B^2\Sigma^+$ state (b = −78 MHz (9)). Figure 3 shows how the hyperfine structure patterns arise in the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ transition. In the $X^2\Sigma^+$ state, at low rotational excitation, a $b_{\beta S}$ coupling scheme obtains in which the yttrium nuclear spin (^{89}Y, $\boldsymbol{I}$ = 1/2), is coupled to the spin of the unpaired electron ($\boldsymbol{S}$) to give a resultant $\boldsymbol{G}$, which takes values of 0 or 1. In this case, the three G = 1 hyperfine levels are almost degenerate, and the hyperfine structure is manifested in the spectra as a doublet with a 3:1 intensity ratio between the two components. The more intense component corresponds to transitions out of the G = 1 levels, the weaker one to transitions from the G = 0 level. The best example of $b_{\beta S}$ coupling is furnished by the line $R_1(0)$ in the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band (Fig. 2(*a*)). The splitting between the G = 0 and G = 1 components is equal to the Fermi contact interaction for the $X^2\Sigma^+$ state. With increasing rotational excitation, $b_{\beta J}$ coupling sets in, the spin-rotation interaction gradually decoupling $\boldsymbol{S}$ from $\boldsymbol{I}$, and cou-

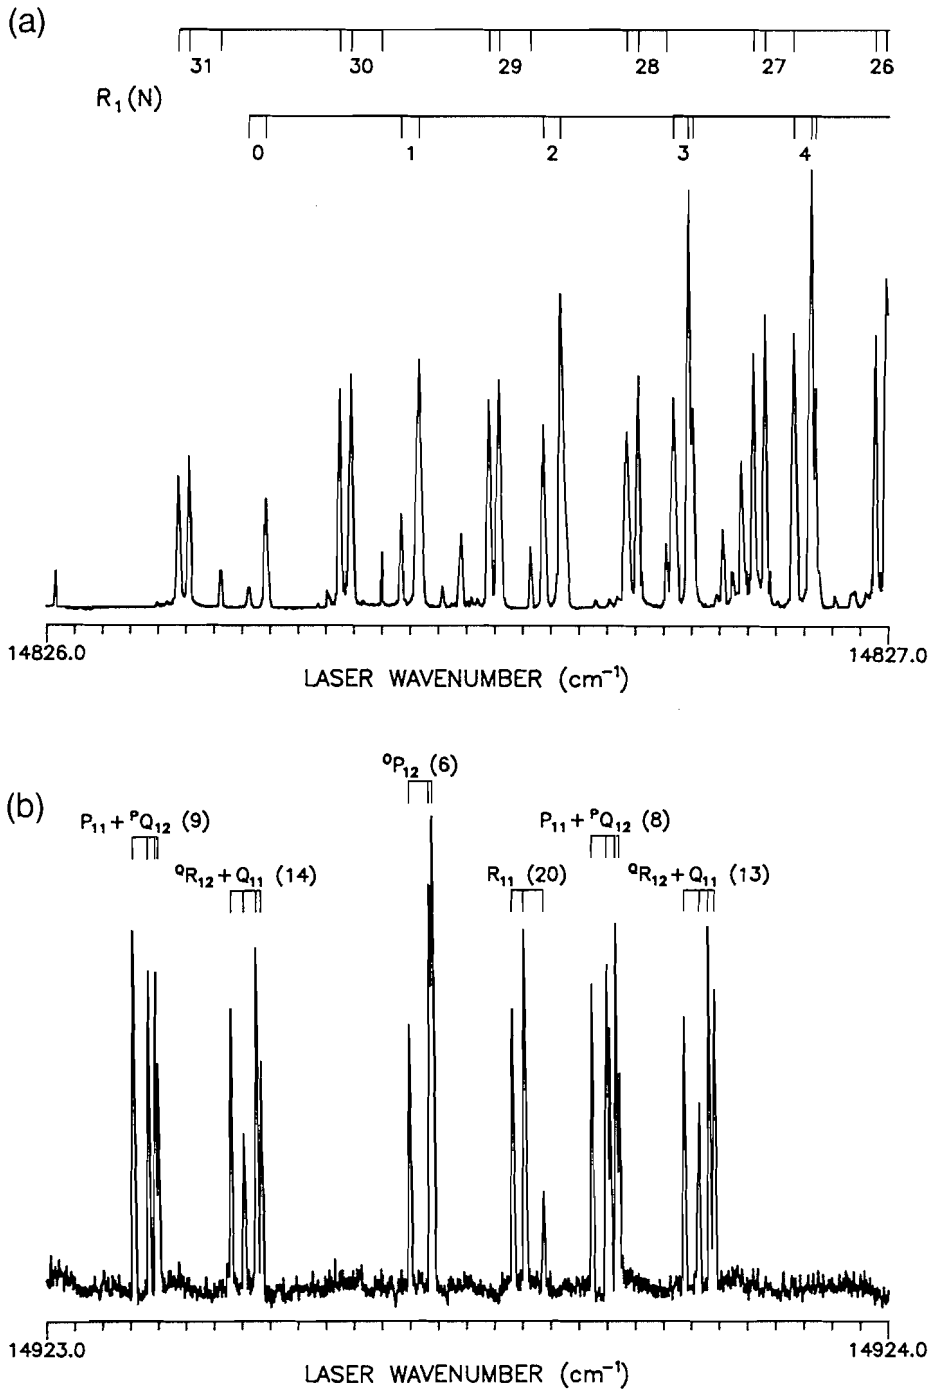

FIG. 2. Portions of the cw – ring laser LIF spectra recorded for (*a*) the (0,0) band of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system, and (*b*) the (v',0) band of the $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ system. Vertical scale is the LIF intensity.

pling it to N, the vector representing nuclear rotation. The three $G = 1$ levels split apart, giving, in the limiting case of fully developed $b_{\beta J}$ coupling, two pairs of hyperfine levels. The primary splitting between the levels is due to the spin-rotation interaction, the secondary splitting to the Fermi contact term. The $R_1(N)$ lines returning from the bandhead in the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band (Fig. 2(*a*)) provide good examples of fairly well-developed $b_{\beta J}$ coupling. Figure 3 shows the situation where the coupling is intermediate between $b_{\beta S}$ and $b_{\beta J}$ in the $X^2\Sigma^+$ state, the coupling in the $B^2\Sigma^+$ state being $b_{\beta J}$ even in the absence of rotation on account of the large spin-rotation parameter. With the selection rule $\Delta F = \pm 1$ in operation, only three hyperfine components are seen for lines of the P_2 and R_1 branches of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band, while the P_1 and R_2 branches exhibit four hyperfine components. The *e*/*f* symmetry of the upper state levels in this band could thus be established unequivocally from the number of hyperfine components associated with a line. Similar arguments may be applied to rationalize the hyperfine structure in the 14 926.0 cm^{-1} band, which we demonstrate below to be a $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ transition. Figure 4 shows a typical fluorescence decay trace obtained in

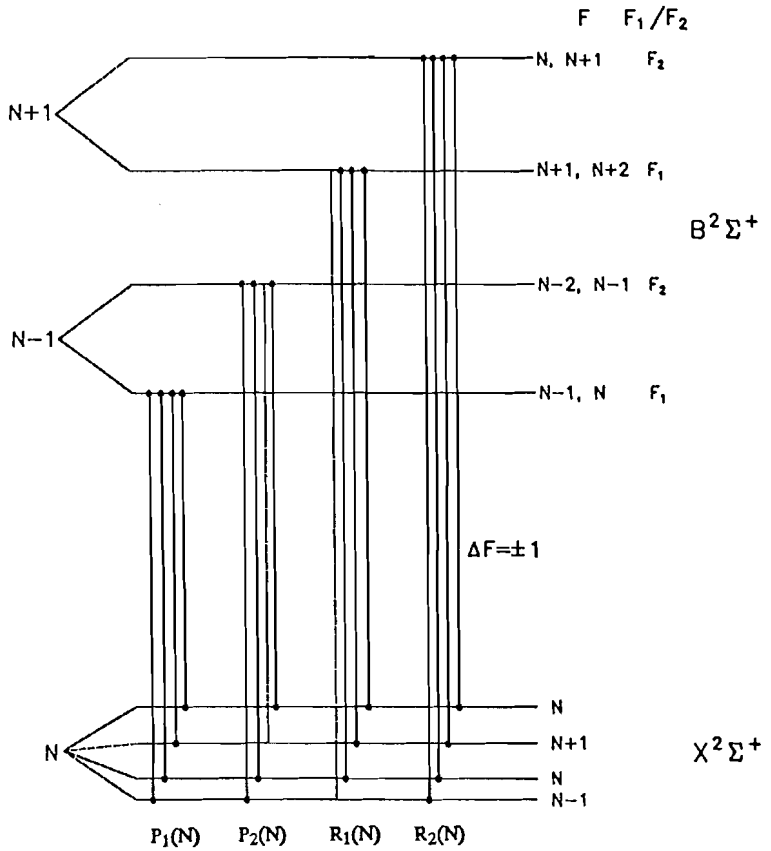

FIG. 3. Energy level diagram for the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ transition, showing allowed hyperfine transitions.

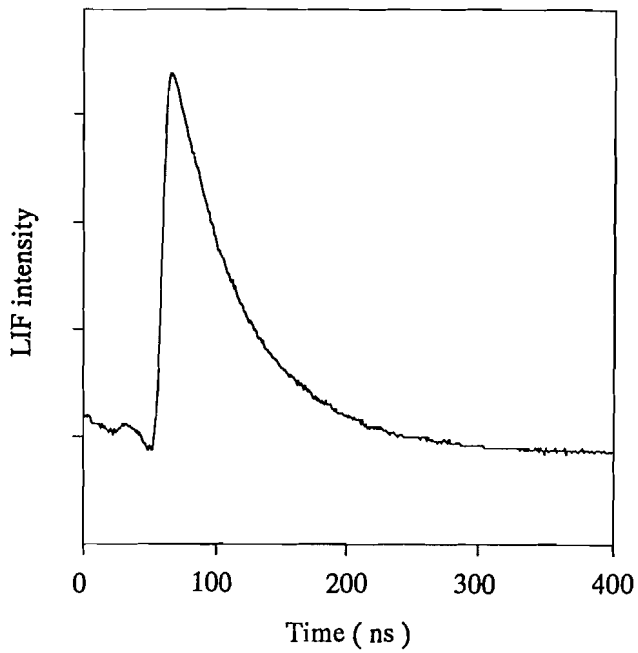

FIG. 4. Fluorescence decay trace obtained by exciting the R_1 bandhead of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band.

this case by exciting the R_1 bandhead of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (2,0) band. Decay profiles were recorded for all the bands whose LIF spectra are presented here, excepting the 14 926.0 cm^{-1} band which was found to be too weak to permit recording of an adequate trace.

TABLE 1. Fluorescence lifetimes of some vibronic levels of the $B^2\Sigma^+$ and $^4\Pi_{\pm 1/2}$ states of YS

State	v	$T_v(cm^{-1})$	τ(ns)
$B^2\Sigma^+$	0	14 826.0	125.6(113)[a]
	1	15 264.2	188.4(108)
	2	15 717.1	114.4(22)
$^4\Pi_{\pm 1/2}$	$v' + 1$	15 300.1	232.7(234)

[a]Numbers quoted in parentheses are the uncertainties (2σ) in the units of the last quoted decimal place.

Data analysis

Fluorescence decay traces

Lifetimes were extracted from raw digitized data by first performing a background subtraction and then subjecting a portion of the trace well clear of the excitation pulse to a simple linear least-squares analysis. Deconvolution of the excitation pulse was not carried out, since the observed lifetimes were substantially longer than the laser pulse duration (9 ns). All the observed decays appeared to follow a single exponential function, and were fitted as such. Results of the analysis are presented in Table 1. Measurements are unlikely to be affected by "field of view" problems, since the molecules remain within the fluorescence collection zone for about 1 μs. Each reported lifetime is the weighted average of several independent determinations. The uncertainties quoted in parentheses represent the spread in lifetimes over repeated measurements. The rather large error bounds found for some of the bands were due to electrical noise recorded

on the decay traces that affected the analysis. As measurements were made under collision-free, molecular beam conditions, and as the fluorescence quantum yield should be unity at these energies, the data in Table 1 may be regarded as intrinsic radiative lifetimes.

The relatively short lifetimes exhibited by the $v = 0$ and $v = 2$ bands of the $B^2\Sigma^+$ state are typical of a strongly allowed radiative transition. In a system where an electronically excited state decays to a single, isolated lower state, and in which the vibrational frequency of the upper state is less than that of the lower state, the radiative lifetime of the upper state should increase with increasing vibrational quantum number (18). Such behaviour is expected in YS, where $\omega_e(B^2\Sigma^+)$ (=449.7 cm^{-1}) < $\omega_e(X^2\Sigma^+)$ (= 492.7 cm^{-1}) (8). The contradictory experimental observation that the $B^2\Sigma^+$ state $v = 0$ level is longer lived than the $v = 2$ level, is an indication that one of the vibrational levels is being perturbed by another state. Unlike the (0,0) band, which lies only 100 cm^{-1} from the 14 926.0 cm^{-1} band, the (2,0) band is quite isolated from any other experimentally observed cold bands. Thus a plausible explanation for the observed trend in lifetimes is that the $v = 0$ level is mixed with the presumably long-lived upper state level of the 14 926.0 cm^{-1} band, leading to an increase in the lifetime of the $v = 0$ level relative to the $v = 2$ level. Unfortunately, since we were unable to measure the lifetime of the upper state level in the 14 926.0 cm^{-1} band, we cannot comment further on this point.

Inspection of the data in Table 1 suggests that there is a strong interaction between the upper state levels in the 15 264.2 and 15 300.1 cm^{-1} bands, leading to an increase in the lifetime of the former, and a decrease in the lifetime of the latter. We present evidence below to demonstrate that the upper vibrational level of the 15 300.1 cm^{-1} band belongs to a $^4\Pi_{\pm 1/2}$ state. Since the upper level in the 15 264.2 cm^{-1} band has the shorter lifetime, we assign it as the $B^2\Sigma^+$ $v = 1$ level, and the other level as belonging to the $^4\Pi_{\pm 1/2}$ manifold, even though the magnitudes of the lifetimes indicate that the extent of mixing is quite considerable. The interaction between the $B^2\Sigma^+$ state $v = 1$ level and the neighbouring vibrational level of the $^4\Pi_{\pm 1/2}$ state may be understood by way of a simple two-state intensity borrowing mechanism (19). In the absence of an interaction between the $B^2\Sigma^+$ state and the $^4\Pi_{\pm 1/2}$ state, the oscillator strength for the $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ transition would be zero, and only a single bnd would be observed. If the measured radiative lifetimes of the upper state levels in the 15 264.2 and 15 300.1 cm^{-1} bands are denoted by τ_- and τ_+ respectively (the − and + referring to the directions of the energy shifts experienced by the levels when the perturbation is switched on), and the lifetimes of the parent, unperturbed $B^2\Sigma^+$ and $^4\Pi_{\pm 1/2}$ state levels by τ_1 and τ_2, respectively, then by conservation of transition intensity we may write for the radiative decay of the upper state levels:

$$[1] \quad \frac{1}{\tau_-} + \frac{1}{\tau_+} = \frac{1}{\tau_1} + \frac{1}{\tau_2}$$

The radiative lifetime for the vibrational level of the $^4\Pi_{\pm 1/2}$ state in the 15 300.1 cm^{-1} band, in the absence of the perturbation ineraction (τ_2), may be calculated using the data in Table 1. The unperturbed radiative lifetime for the $B^2\Sigma^+$ state $v = 1$, τ_1, is approximated by the lifetime of the $v = 2$ level, making a small correction for the differing v^3 factors for transitions from $v = 1$ and $v = 2$ to the ground state. The lifetime of the unperturbed $B^2\Sigma^+$ $v = 1$ level is thus estimated to be 112.4(22) ns. Substituting this value and τ_- = 188(11) ns, τ_+ = 233(24) ns in eq. [1] yields $\tau_2^{-1} = (7.1 \pm 7.6) \times 10^{-4}$ ns, implying that τ_2 could lie in the range 680 ns → infinity. The relative error on the result is very large due to the ill-conditioning of eq. [1] arising from the large errors associated with the determination of τ_- and τ_+. All we can say with certainty is that the lifetime of the perturbing state is very long, and possibly infinite. This result is quite consistent with the spin-forbidden nature of the $^4\Pi_{\pm 1/2} \rightarrow X^2\Sigma^+$ transition. We can not, however, rule out the possibility that the $^4\Pi_{\pm 1/2}$ state decays slowly to a nearby quartet state.

The $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ *(0,0) band*

Line positions for the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band are reported in Table 2(*a*). Molecular constants were extracted from the rotational line data for the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band using a nonlinear least-squares procedure. There follows a description of how the pertinent eigenvalue expressions for the $B^2\Sigma^+$ and $X^2\Sigma^+$ state levels were obtained and incorporated into the fitting procedure. The effective Hamiltonian for a $^2\Sigma$ state may be written as:

$$[2] \quad H_{\text{eff}} = B\mathbf{N}^2 - D\mathbf{N}^4 + \gamma\mathbf{N}.\mathbf{S} + b_F\mathbf{I}.\mathbf{S} + [3I_zS_z - \mathbf{I}.\mathbf{S}]c/3$$

where B is the rotational constant, D the centrifugal distortion constant, γ the spin-rotation constant, b_F the Fermi contact parameter, and c the dipolar interaction parameter, the quantum numbers having their usual definition. Since with our experimental resolution there was no detectable hyperfine splitting in the $B^2\Sigma^+$ state, the last two terms in eq. [2] were dropped for the evaluation of the upper state eigenvalues. The matrix elements for the first three terms are diagonal, and give rise to the well-known pair of expressions for the energies of *e* and *f* rotational levels in a $^2\Sigma$ state (20):

$$[3] \quad F_1(N) = BN(N+1) - DN^2(N+1)^2 + \frac{1}{2}\gamma N \qquad (e \text{ levels})$$

$$[4] \quad F_2(N) = BN(N+1) - DN^2(N+1)^2 - \frac{1}{2}\gamma N(N+1) \qquad (f \text{ levels})$$

Equations [3] and [4] were used directly to represent the $B^2\Sigma^+$ state energy levels. Since the spin rotation constant in the upper state is large, it was represented by a centrifugal expansion thus:

$$[5] \quad \gamma = \gamma_0 + \gamma_1 N(N+1) + \gamma_2 N^2(N+1)^2$$

In the $X^2\Sigma^+$ state, the spin-rotation parameter is smaller than the Fermi contact term, and therefore the hyperfine energy levels were determined by diagonalization of the appropriate 4 × 4 energy matrix, which is presented in Table 3. The matrix elements are those derived by Radford using a case $b_{\beta J}$ basis set (21). Our treatment was simplified by discarding all terms involving the spin-dipolar parameter, c, as our experimental resolution did not warrant their inclusion. The observed line positions of Table 2(*a*) were fitted using a

modified Levenberg–Marquardt algorithm. The energy matrix for the ground state hyperfine levels was diagonalized and the resulting eigenvalues added to $B''N(N + 1) - D''N^2(N + 1)^2$ to generate the lower state term values. These were combined with term values calculated for the upper state using eqs. [3] and [4]. The values of the various spectroscopic parameters were varied until the best fit of calculated to experimental line positions was obtained. The results of the fitting procedure are presented in Table 4(*a*). Rotational perturbations in the upper state were found to set in beyond $N = 36$, so lines terminating on these levels were not included in the fit. The random error of measurement (109 MHz) is well below the experimental accuracy of 200 MHz. The Fermi contact and spin-rotation parameters obtained for the ground state are in good agreement with those determined by Azuma and Childs (9). The sign and magnitude of the spin-rotation constant in the $B^2\Sigma^+$ state ($\gamma_0 = -0.15150(14)$ cm^{-1}) are a manifestation of an interaction of the "unique perturber" type between this state and the $A^2\Pi$ state, where Stringat et al. (8) determined the Λ-doubling parameter p to be $+0.155$ cm^{-1}.

The 14 926.0 cm^{-1} band

The band located at 14 926.0 cm^{-1} (see Fig. 2(*b*)) qualitiatively resembles the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band, in that it is red-degraded and possesses four discernible rotational branches with the same hyperfine structure patterns as the (0,0) band. Similarly, there was no evidence for hyperfine structure in the upper state at the experimental resolution of 120 MHz. Line assignments were confirmed in two ways. Firstly, the combination differences $\Delta_2F''(J)$ were formed for the *e* and *f* manifolds. The B'' values thus determined were found to be in good agreement with the value reported in Table 4(*a*). Secondly, the hyperfine splitting patterns of the lines in the 14 926.0 cm^{-1} band were compared with those of the corresponding lines with the same N'' values in the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band. The patterns were found to match, well within the limits of experimental error, confirming the assignments of the quantum number N'' and the *e*/*f* symmetry labelling for lines of the 14 926,0 cm^{-1} band. A rotational energy level diagram for the upper state level of the 14 926.0 cm^{-1} band, shown in Fig. 5, was constructed as follows. Firstly, the rotational and hyperfine parameters determined for the $X^2\Sigma^+$ state $v = 0$ level (Table 4(*a*)) were used to calculate the term values of the rotational–hyperfine levels in the lower state. The upper state rotational term values were obtained by adding the appropriate ground state term values to the experimental line positions reported in Table 2(*b*). This procedure yielded either three of four determinations of the position of each upper state rotational level, which were found to coincide, well within the experimental uncertainty. These values were averaged and are plotted for the lowest rotational levels of the upper state in

TABLE 2(*b*). Observed line wavenumbers and residuals (obs. − calc., in parentheses) for the $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ ($v = 0$) 14 926.0 cm^{-1} band of $^{89}Y^{32}S$

Residual mean square error = 106.2 MHz.

TABLE 3. Energy matrix for the rotational, spin-rotation, and magnetic hyperfine structure parts of the Hamiltonian of a $^2\Sigma^+$ state, using case $b\beta J$ basis functions

(*e*) $J = N + 1/2$		(*f*) $J = N - 1/2$	
$F = N + 1$	$F = N$	$F = N$	$F = N - 1$
$\left[b + \frac{c}{(2N+3)}\right]\frac{A}{2(2N+1)} + \frac{\gamma N}{2} + BN(N+1)$	0	0	0
0	$\left[b + \frac{c}{(2N+3)}\right]\frac{B}{2(2N+1)} + \frac{\gamma N}{2} + BN(N+1)$	$\left[b + \frac{c}{2}\right]\frac{C}{2(2N+1)}$	$\left[b + \frac{c}{2}\right]\frac{D}{2(2N+1)}$
0	$\left[b + \frac{c}{2}\right]\frac{C}{2(2N+1)}$	$\left[-b + \frac{c}{(2N-1)}\right]\frac{E}{2(2N+1)} - \frac{\gamma(N+1)}{2} + BN(N+1)$	0
0	$\left[b + \frac{c}{2}\right]\frac{D}{2(2N+1)}$	0	$\left[-b + \frac{c}{(2N-1)}\right]\frac{F}{2(2N+1)} - \frac{\gamma(N+1)}{2} + BN(N+1)$

$A = (N + 1)(N + 2) - I(I + 1) - (N + 1/2)(N + 3/2)$
$B = N(N + 1) - I(I + 1) - (N + 1/2)(N + 3/2)$
$C = \{(2N - I + 1/2)(I + 1/2)(2N + I + 3/2)(I + 1/2)\}^{1/2}$
$D = \{(2N - I + 1/2)(I - 1/2)(2N + I + 1/2)(I + 3/2)\}^{1/2}$
$E = N(N + 1) - I(I + 1) - (N - 1/2)(N + 1/2)$
$F = N(N + 1) - I(I + 1) - (N - 1/2)(N + 1/2)$

B is the rotational constant and γ the spin-rotation constant; $b = b_F - c/3$, where b_F is the Fermi contact parameter and *c* the dipolar interaction parameter. The quantum numbers have their usual definition.

Fig. 5. The derived energy level pattern is quite characteristic of a state with non-zero orbital angular momentum in Hund's case (*a*). The splitting between *e* and *f* levels with the same *J* value, which is found to increase almost linearly with $J + 1/2$, is due to Λ-doubling. The existence of a level with $J = 1/2$ indicates that the Ω value for the state is either $+1/2$ or $-1/2$. There now arises the question of how the new $\Omega = \pm 1/2$ state should be assigned. The $A^2\Pi$ state has been

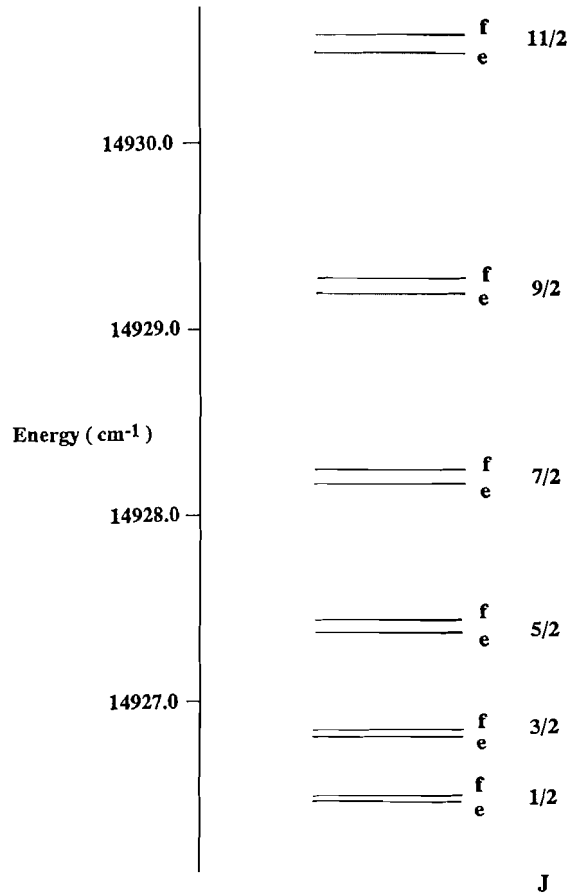

FIG. 5. Rotational energy levels in the v' level of the $^4\Pi_{\pm 1/2}$ state, derived from the experimental data reported in Table 2(*b*).

well characterized experimentally (8), so it can be ruled out immediately. Another possibility is that the new state is of doublet spin symmetry and is derived from the configuration $\sigma_2^2\pi_1^3\sigma_3^2$. (The parentage of these molecular orbitals can be found in the "Results of Calculations" section below.) Calculations on the isovalent molecule YO suggest that this "charge transfer" type state should have a bond length considerably longer than that in the ground state (22), as is found experimentally by taking combination differences for the upper state in the 14 926.0 cm^{-1} band. However, such a dramatic bond-length change upon excitation would be expected to produce an extended vibronic progression in the upper state vibrational quantum number in the allowed $^2\Pi \leftarrow X^2\Sigma^+$ transition. This expectation is at odds with the experimental observation of only one, or possibly two (including the new band at 15 300.1 cm^{-1}), bands belonging to the new system in the energy region of interest. Furthermore, transitions to both the $\Omega = 1/2$ and $\Omega = 3/2$ spin-orbit components of this doublet state would be allowed, and there is no evidence for any other bands that could be due to transitions from the ground state to the $\Omega = 3/2$ component. Similar arguments may be applied to rule out assignment to other $^2\Pi$ states based on charge transfer type excitations. There remains another possibility: that the new state belongs to the quartet spin manifold. Calculations (vide infra) place the lowest lying quartet states in approximately the same energy region as the $B^2\Sigma^+$ state. On the basis of the above arguments we assign the symmetry of the new state to be $^4\Pi_{\pm 1/2}$, arising from the configuration $\sigma_2^2\pi_1^3\sigma_3^2$. The rotational branches in the 14 926.0 cm^{-1} band are identified as $P_{11} + {}^PQ_{12}$, ${}^OP_{12}$, $Q_{11} + {}^QR_{12}$, and R_{11}. The spin-forbidden $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ transition acquires intensity through spin-orbit contamination of the $\Omega = \pm 1/2$ spin-orbit components by the $B^2\Sigma^+$ state. The other spin-orbit components of the $^4\Pi$ state, $\Omega = 3/2$ and $\Omega = 5/2$, cannot be observed in excitation from the $X^2\Sigma^+$ state on account of the strict $\Delta\Omega = 0$ selection rule for the spin-orbit operator (19), which leads to non-zero matrix elements between the $^4\Pi$ ($\Omega = \pm 1/2$) and $B^2\Sigma^+$ ($\Omega = \pm 1/2$) states only. The spin-orbit interaction mechanism explains why the 14 926.0 cm^{-1} band can be observed, despite unfavourable Franck–Condon overlap with the ground state. This point is developed further in the Discussion section.

One possible assignment for the 14 926.0 cm^{-1} band is that it arises from a $^4\Pi_{-1/2} \leftarrow X^2\Sigma^+$ excitation. In such a case, the new band at 15 300.1 cm^{-1} band could be due to the corresponding $^4\Pi_{+1/2} \leftarrow X^2\Sigma^+$ vibronic transition, implying a spin-orbit splitting in the $^4\Pi$ state of approximately +374 cm^{-1}. However, a calculation of the spin-orbit splitting for the $^4\Pi$ state using atomic spin-orbit parameters suggests that it should be of the order of +266.5 cm^{-1}, a considerable discrepancy. Furthermore, in a $^4\Pi$ state, the rotational constant for the $\Omega = 1/2$ component should be greater than that of the $\Omega = -1/2$ component. A deperturbation analysis of the 15 264.2 and 15 300.1 cm^{-1} bands is currently under way. From a preliminary centres of gravity analysis, using the data in Table 4 and the Pekeris relation to estimate the

rotational constant in the $v = 1$ level of the B state (0.13242 cm^{-1}), we calculate the rotational constant of the perturbing level to be 0.1149 cm^{-1}. This is appreciably smaller than the rotational constant determined for the upper level of the 14 926.0 cm^{-1} band, contradicting the suggested assignment. A more plausible explanation is that the upper level in the 15 300 cm^{-1} band belongs to the sam spin-orbit component of the $^4\Pi$ state as the upper level in the 14 926.0 cm^{-1} band (see Discussion).

Since we lack rotational line data on any of the other spin-orbit components of the $^4\Pi$ state, a definitive assignment of the 14 926.0 cm^{-1} band to a $^4\Pi_{+1/2} \leftarrow X^2\Sigma^+$ or $^4\Pi_{-1/2} \leftarrow X^2\Sigma^+$ transition cannot easily be made. Cheung et al. (23) have given a detailed treatment of the derivation of the matrix elements of the rotational Hamiltonian of a $^4\Pi$ state in case (*a*) coupling. In a $^4\Pi_{+1/2}$ state, the Λ doubling increases in an approximately linear fashion with $J + 1/2$ on account of the $p + 2q$ term appearing in the diagonal matrix element. However, in a $^4\Pi_{-1/2}$ state, although there is no diagonal term in $J + 1/2$ (apart from a distortion constant), the off-diagonal $o + p + q$ term connecting the $\Omega = +1/2$ and $\Omega = -1/2$ components has a similar effect upon matrix diagonalization. Thus in fitting the 14 926.0 cm^{-1} band, we decided at the outset to employ a simple expression for the rotational energies of the *e* and *f* levels of the $^4\Pi_{\pm 1/2}$ state:

$$[6] \quad E(^4\Pi_{\pm 1/2}) = T + B(z + 3) - D(z^2 + 13z + 5) \pm (J + 1/2)[a + bz]$$

where $z = (J + 1/2)^2$, the upper and lower signs referring to the *e* and *f* levels respectively. B, D, a, and b are, respectively, effective rotational, centrifugal distortion, Λ-doubling, and Λ-doubling distortion parameters. Equation [6] is simply a reduced form of the diagonal matrix elements for a $^4\Pi_{+1/2}$ state, as given by Cheung et al. The observed line positions in Table 2(*b*) were submitted to least-squares analysis in the manner described for the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) band. In the present case, the rotational and hyperfine parameters for the $X^2\Sigma^+$ state $v = 0$ level were not varied, since these were already determined with high precision in the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ (0,0) analysis. The results of fitting the $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ band (423 hyperfine lines) are presented in Table 4(*b*). Since the rotational constant is contaminated by a number of effects, we quote a 10σ error bound on the bond length, rather than the more typical 2σ error. The negative centrifugal disortion constant and the anomalously large Λ-doubling distortion terms reflect the effects of *S*-uncoupling within the $^4\Pi$ state. The RMS error (283 MHz) is somewhat higher than the experimental resolution (120 MHz), reflecting the need for data on the other spin-orbit components. Rigorous analyses involving diagonalization of the complete Hamiltonian matrix were also attempted, using an estimated value of the spin-orbit parameter of +266.5 cm^{-1}. Due to the lack of data on any other spin-orbit parameters of the $^4\Pi$ state, several of the parameters obtained from these fits were poorly determined and highly correlated. However, whether the upper state was assumed to be of $^4\Pi_{+1/2}$ or $^4\Pi_{-1/2}$ symmetry, the rotational constant was always well determined and in reasonable agreement with the value obtained from the fit using Eq. [6]. The bond length in the $^4\Pi_{\pm 1/2}$ state is some 9.8% longer than that in the $X^2\Sigma^+$ state. This is quite consistent with the results of the density functional treatment (vide infra) where the bond length in the lowest lying quartet state is calculated to be 10% longer than in the ground state (see Table 5(*a*)). The negative sign for the Λ-doubling terms linear in $J + 1/2$ indicate that the $^4\Sigma^-$ state, which is assumed to be responsible for the Λ-doubling, lies above the $^4\Pi_{\pm 1/2}$ state.

Results of calculations

The calculated spectroscopic properties of YO and YS are shown in Table 5(*a*) along with those from the theoretical study of Langhoff and Bauschlicher (22) and experimental values. Gradient corrections are known to considerably improve the accuracy of bond energies relative to purely local functionals and bring the discrepancies down to typically a few kcal/mol (24). The generally very good agreement obtained here between experiment and theory is probably somewhat fortuitous. In YO, the lowest quartet state is calculated to lie 26 166 cm^{-1} above the ground state, in excellent agreement with the value calculated by Langhoff and Bauschlicher. In YS, the lowest quartet state is calculated to be much more stable, lying only 17 439 cm^{-1} above the ground state, on account of the lower electronegativity of sulfur relative to oxygen. The other calculated properties (ω_e, μ, $d\mu/dr$) are not highly accurate, but sufficiently so to give the correct trends. Overall, the agreement of the present calculations with those of Langhoff and Bauschlicher and with experiment is quite good. It should be noted that the density functional method does not allow us to further break down the *s*, *p*, and *d* composition of a molecular orbital into constituent contributions from individual *ns*, *np*, and *nd* orbitals. Thus in the ensuing discussion, we make the assumption that one particular *ns*, *np*, or *nd* orbital dominates the *s*, *p*, or *d* contribution to a particular molecular orbital.

The bonding can be characterized from the Mulliken populations of Table 5(*b*). As expected, bonding in YO and YS is rather similar. The valence configuration can be denoted as $\sigma_1^2\sigma_2^2\pi_1^4\sigma_3^1$. for the $X^2\Sigma^+$ state and as $\sigma_1^2\sigma_2^2\pi_1^3\sigma_3^1\delta_1^1$ for the $^4\Pi$ state. The σ_1 orbital is a low-lying *s* orbital of sulfur (oxygen) with some participation from yttrium *s*, $p\sigma$, and $d\sigma$ orbitals. The π_1 and σ_2 orbitals are bonding combinations of sulfur (oxygen) valence *p* orbitals and yttrium 4*d* orbitals, with substantially heavier weight on sulfur (oxygen). The participation of the yttrium 5*s* orbital in the σ_2 molecular orbital is calculated to be less than 8% in each case (see Table 5(*b*)). In both YO and YS, the σ_3 orbital closely resembles the yttrium 5*s* orbital, with only about 5% 5*p* character. The σ_3 orbital is semi-occupied in the lowest doublet and quartet states of YS and YO, so that the states correlate to a $4d^2\,5s^1$ yttrium atom. Note, however, that the binding energies given in Table 5(*a*) are calculated relative to the calculated (and true) ground state of the yttrium atom, which has a $4d^1\,5s^2$ configuration.

In the dissociation limit of YS (YO), there are four electrons in the 3*p* shell of sulfur (oxygen) and two in the 4*d* shell of yttrium. The "ideal covalent" populations on the sulfur for the π_1 and σ_2 orbitals are therefore $4/6 = 0.67$. The actual populations in YS are larger (0.73 and 0.69), and they are larger still on oxygen in YO (0.78 and 0.79), as expected on the basis of atomic electronegativities. The bond order in the YS ground state (2.54) is quite large and the Mulliken charges (±0.20) fairly small. The bond in YS is thus largely covalent, with a small but nevertheless significant ionic contribution. As expected, the bond in YO is more ionic.

Formally, the lowest quartet state in these molecules is accessed from the ground state by "exciting" one electron from a bonding π_1 orbital, which is centred mostly on sulfur (oxygen), to a nonbonding, purely atomic, yttrium *d* orbital. The density functional calculation does not distinguish between the $^4\Phi$ and $^4\Pi$ states that are formed by promotion into the δ_1 molecular orbital. A $^4\Pi$ state could also arise by excitation from the π_1 orbital into a higher lying σ orbital, but this transition would probably lie at significantly higher energy. If a "rigid-orbital" description was strictly valid, upon excitation of the $^4\Pi$ state, the bond order would decrease by roughly 0.5, and the negative charge on the yttrium would increase by $1 - 0.25 = 0.75$. Actually, the calculated bond order decreases by 1.2 and the charge remains essentially unchanged. This is because the change in configuration is accompanied by a substantial relaxation of the orbitals: the

population on the sulfur (oxygen) atom goes from 0.73 to 0.91 (0.78 to 0.91) for the π_1 orbital and from 0.69 to 0.78 (0.79 to 0.84) for the σ_2 orbital. The tendency towards achieving approximate charge neutrality makes the π_1 and σ_2 orbitals more atomic-like and therefore weakens the bond. The reduction in bond order is manifested in the observed and calculated magnitudes of the bond length for the $^4\Pi$ state, which indicate a bond substantially weaker than in the $X^2\Sigma^+$ state (see Table 5(*a*)).

The first doublet excited state corresponds to excitation from the σ_3 orbital, which is mostly yttrium 5*s* with about 5% 5*p* character, to the σ_4 orbital. The calculated composition of the σ_4 orbital may be summarized in terms of Mulliken populations as (YS): 0.46 *pz*, 0.29 dz^2, 0.05 dx^2, 0.05 dy^2 on yttrium, 0.0 *s*, 0.13 *pz* on sulfur; (YO): 0.67 *pz*, 0.22 dz^2, 0.05 dx^2, 0.05 dy^2 on yttrium, −0.08 *s*, 0.08 *pz* on oxygen. Clearly, the σ_4 orbital is strongly hybridized and points away from the ligand. This polarization counteracts the principal component of the dipole moment. The net effect is that the dipole moments in the doublet excited states are much smaller than in the corresponding ground states, values of 3.19 D (YS) and 0.70 D (YO) being calculated. The precise values are not trustworthy, but they illustrate the general trend of excitation from the largely unhybridized σ_3 orbital to the strongly hybridized σ_4 orbital.

Discussion

The small fraction of 5*p* character (5%) calculated for the σ_3 orbital of YS is somewhat at odds with the interpretation of the hyperfine structure presented by Azuma and Childs (9). They used a simple treatment that assumed that the reduction in the Fermi contact term from the atomic value was due entirely to ligand-induced 5*s*–5*p* hybridization effects. In this way, the orbital composition of σ_3 was determined to be 53% 5*s*, 47% 5*p*. A possible explanation for the discrepancy between their analysis and our calculation is that *s* orbitals of higher principal quantum number are mixed into the σ_3 orbital by the ligand field of sulfur, reducing the electron density at the nucleus. Such a process would reduce the magnitude of the contact interaction in the molecule relative to the atom, and is known to operate in CaOH[3] and MnF (25). It is difficult to reconcile the analysis of Azuma and Childs with the experimentally observed trends in the dipole moments. Appreciable hybridization of both the σ_3 and σ_4 orbitals would not be expected to produce the experimentally observed reduction in μ upon $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ excitation.

The small dipole moment calculated for the $^4\Pi$ state can be rationalized crudely in terms of the $^4\Pi \leftarrow X^2\Sigma^+$ excitation involving the back-transfer of an electron from a sulfur- (oxygen-) centred orbital (π_1) to one localized on yttrium (δ_1). In language familiar to spectroscopists, this excitation constitutes a "charge transfer" transition. In diatomic molecules where the ionic contribution to bonding dominates the covalent contribution, the reduction in bond strength accompanying such a transition would be attributed primarily to a diminution in the electrostatic contribution to the bonding. In systems such as YS and YO, where calculation indicates that covalent bonding predominates, a molecular orbital description of the excitation is more appropriate.

It seems likely that, in common with the upper level in the 14 926.0 cm^{-1} band, the upper level in the 15 300.1 cm^{-1} band also belongs to the $^4\Pi_{\pm 1/2}$ state. Analysis of the lifetimes data supports this assertion: the very long or possibly infinite lifetime determined for the upper level of the 15 300.1 cm^{-1} band is consistent with a state that is not optically coupled to the ground state. For simplicity, we denote the upper levels of the two new bands as v' and $v' + 1$, respectively. Using the vibrational constants reported by Stringat et al. (8), the $v = 1$ level of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system is calculated to lie 15 273.0 cm^{-1} above the ground state $v = 0$ level, in the absence of perturbations. The downward shift experienced by the $B^2\Sigma^+$ $v = 1$ level is therefore 15 273.0 − 15 264.2 = 8.8 cm^{-1}. Assuming that the $v' + 1$ level is shifted up by the same amount, its unperturbed position is calculated to be 15 300.1 − 8.8 = 15 291.3 cm^{-1}. Assuming that the v' level experiences only a small shift on account of interaction with the $B^2\Sigma^+$ $v = 0$ level, the difference in energy between the unperturbed vibrational levels of the $^4\Pi_{\pm 1/2}$ state is 15 291.3 − 14 928.0 = 365.3 cm^{-1}. The ratio of this vibrational interval to the ground state vibrational frequency is 365.3/492.7 = 0.741, in reasonable agreement with the ratio $\omega_e(^4\Pi_{1/2})/\omega_e(X^2\Sigma^+) = 0.770$ computed from the density functional data in Table 5(*a*).

The foregoing discussion begs the question as to why we observe only two vibronic bands of the $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ system in the spectral region of interest. The explanation is related to the intensity distribution in the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system. There are basically two criteria to be met for a spin-forbidden $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ vibronic transition to exhibit observable intensity. Firstly, the spin-orbit matrix element coupling the relevant levels of the $^4\Pi_{\pm 1/2}$ and $B^2\Sigma^+$ states must be significantly non-zero. Secondly, the two interacting vibrational levels must lie fairly close in energy. A calculation of the Franck–Condon factors ($S^2_{v'v''}$) for the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ system reveals that they drop off rapidly with increasing v': $S^2_{00} = 0.659$; $S^2_{10} = 0.280$; $S^2_{20} = 0.054$; $S^2_{30} = 0.006$. Clearly, only the (0,0) and (1,0) bands are intense, as is borne out by experiment. Thus the only vibrational levels of the $^4\Pi_{\pm 1/2}$ state which can be observed experimentally are those that are energetically the closest to the $v = 0$ and $v = 1$ levels of the $B^2\Sigma^+$ state. Explicit calculation using Slater determinants to represent the wavefunctions of the $^4\Pi_{\pm 1/2}$ and $B^2\Sigma^+$ states reveals that, in a first-order approximation, the matrix element of the spin-orbit operator connecting these two states is zero. Clearly, a second-order mechanism must be invoked to explain the non-zero $^4\Pi \leftrightarrow B^2\Sigma^+$ interaction. Given that transitions to both the $\Omega = 1/2$ and $\Omega = -1/2$ spin-orbit components gain intensity through the spin-orbit interaction, our failure to observe transitions to the other spin-orbit component must remain an open question.

Conclusions

The yttrium monosulfide molecule has been investigated using molecular beam fluorescence spectroscopy and density functional theory. Improved molecular constants for the $v = 0$ levels of the $X^2\Sigma^+$ and $B^2\Sigma^+$ states have been obtained. Two vibrational levels of a state with $^4\Pi_{\pm 1/2}$ symmetry have been observed in excitation from the ground state, the spin-forbidden $^4\Pi_{\pm 1/2} \leftarrow X^2\Sigma^+$ transition gaining intensity through spin-orbit mixing between the $B^2\Sigma^+$ state and the $^4\Pi_{\pm 1/2}$ state. The bond length for one of these $^4\Pi_{\pm 1/2}$ vibrational levels was determined to be 2.49510(16) Å. The other $^4\Pi_{\pm 1/2}$ vibrational level is responsible for strongly

Received March 16, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

H.A. BASCAL, K.J. JORDAN, and R.H. LIPSON. Can. J. Chem. **71**, 1615 (1993).

Fluorescence excitation spectra of HgCl produced and cooled in a corona-excited supersonic jet discharge are presented. The dominant feature between ≈ 368 and 267 nm is an extensive vibrationally and isotopically resolved band system which is assigned to the $B^2\Sigma^+(v') \leftarrow X^2\Sigma^+(v'' = 0, 1,$ and 2) valence-to-ion-pair state transition of the radical. Transition wavenumbers for vibrational bands with $75 \geq v' \geq 21$ and $2 \geq v'' \geq 0$ were measured, and B-state Dunham parameters were derived which are valid between $75 \geq v' \geq 0$. The equilibrium bondlength for the B-state was determined to be 2.960(2) Å by Franck–Condon calculations. B–X Franck–Condon factors are tabulated which are expected to help in the interpretation of $HgCl_2$ photodissociation and HgCl laser spectra.

H.J. BASCAL, K.J. JORDAN et R.H. LIPSON. Can. J. Chem. **71**, 1615 (1993).

On rapporte le spectre d'excitation de fluorescence du HgCl produit et refroidi dans une décharge de jet supersonique à couronne excitée. La caractéristique dominante entre environ 368 et 267 nm est un système de bande extensif résolu tant d'un point de vue vibrationnel qu'isotopique et que l'on attribue à la transition $B^2\Sigma^+(v') \leftarrow X^2\Sigma(v'' = 0, 1$ et 2) de l'état valence à paire d'ions du radical. On a mesuré les nombres d'onde des transitions des bandes vibrationnelles avec $75 \geq v' \geq 21$ et $2 \geq v'' \geq 0$ et on a déduit des paramètres de l'état B de Dunham qui sont valides entre $75 \geq v' \geq 0$). En se basant sur des calculs de Franck–Condon, on a déterminé que la longueur à l'équilibre pour l'état B est égale à 2,960(2) Å. On présente un tableau comportant les facteurs B–X de Franck–Condon qui devraient être utiles dans l'interprétation des spectres laser du HgCl et de photodissociation du $HgCl_2$.

1. Introduction

The ion-pair states of the group IIB metal monohalide radicals have achieved prominence as the upper level for molecular electronic transition lasing on the $B^2\Sigma^+ \rightarrow X^2\Sigma^+$ transition. The mercuric monohalides, including HgCl, have received the most attention, because their coherent outputs lie in the important blue-green spectral region (1). However, despite considerable work which began with Wieland in 1929 (2–6), an understanding of their ion-pair ↔ valence state transitions remained primarily qualitative. The reasons for this are due to the unique properties of ion-pair states, compared with their valence or Rydberg counterparts.

In the case of HgCl, the excited $B^2\Sigma^+$ ion-pair state dissociates to a pair of oppositely charged ground-state ions: $Hg^+(^2S_{1/2}) + Cl^-(^1S_0)$. The binding at large internuclear separations is predominantly Coulombic, resulting in a very deep potential energy curve (≈ 39 900 cm^{-1} (6)). In contrast, $X^2\Sigma^+$ has a much smaller binding energy (≈ 8350 cm^{-1} (6)) which is due almost entirely to covalent-ionic mixing with the B-state. However, $B^2\Sigma^+$ has a longer equilibrium bond length ($r_e(B) \approx 3.02$ Å (6)) than the ground state ($r_e(X) \approx 2.42$ Å (6)) and a much smaller vibrational frequency ($\omega_e' \approx 192$ cm^{-1} versus $\omega_e'' \approx 293$ cm^{-1} (7)).

Because of these contradictory properties, transitions from low vibrational levels in $B^2\Sigma^+$ ($v' = 0$–9) probe the outer wing of the ground state potential, exciting high closely spaced vibrational levels ($v'' = 11$–31). While this Franck–Condon condition favors bound–bound HgCl electronic transition lasing, the $B \rightarrow X$ fluorescence spectrum has a near continuum appearance due to the presence of 14 naturally occurring isotopomers, and because of spectral congestion due to transitions from the many ro-vibrational levels populated in the discharges used to generate the radical from the metal dihalide precursor.

In early studies, Wieland reported B–X transitions for excited state levels as high as $v' = 68$, corresponding to a term value which is ≈ 27% of the B-state binding energy (4). He was able to determine excited state quantum numbers by measuring the vibrational isotope shifts from spectra obtained using 92% enriched $Hg^{37}Cl$, relative to a natural abundance (and therefore, predominantly $Hg^{35}Cl$) sample. However, the residuals in his analysis were typically of the order of ≈1 cm^{-1} and in some instances, as high as 8 cm^{-1}. Recently, Tellinghuisen and co-workers (6) used a similar approach to overcome many of the difficulties associated with ion-pair ↔ valence transitions. They found that exciting single isotopomer samples ($^{200}Hg^{35}Cl$ and $^{200}Hg^{37}Cl$) in a mild Tesla discharge produced relatively uncongested spectra, also amenable to analysis. In this way they could refine Wieland's work to a precision of ≈ 0.4 cm^{-1}, and were able to determine the B-state equilibrium bond length by Franck–Condon calculations to an accuracy of ±0.01 Å. The highest observed B-state vibrational level in these later studies was $v' = 25$, whose term value is only ≈ 11% of the excited state dissociation energy.

Absorption spectra for the metal monohalide radicals are scarce. There are the inherent difficulties in producing enough of the radical to detect an appreciable direct absorption. The $B \leftarrow X$ transition is particularly challenging to study for many of the same reasons outlined above for emission work. In this case, however, Franck–Condon considerations dictate that transitions from low v'' will probe the inner wing of the B-state potential energy curve, exciting high vibrational v' levels. A knowledge of the B–X absorption spectrum is useful, because as shown for HgBr (8, 9), direct optical

pumping of the radical is a viable means of producing a population inversion for lasing. Our group has demonstrated that vibrationally and isotopically resolved fluorescence excitation spectra of natural abundance samples of HgBr (10) and HgI (11) could be obtained by generating and cooling the radicals in a corona-excited supersonic jet discharge. In this work, we have applied similar methods to the study of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ transition of HgCl. Analysis of the resultant spectra has yielded precise Dunham coefficients which are valid for $0 \leq v' \leq 75$, and a subsequent Franck–Condon calculation has allowed the B-state equilibrium bond length to be refined.

2. Experimental

The experimental setup used to record fluorescence excitation spectra of jet-cooled HgCl radicals is similar to that previously reported (10, 11). Briefly, $HgCl_2$ precursor (BDH, melting point = 276°C) was placed in a heated quartz bulb nozzle (pinhole diameter ≈ 0.5 mm) mounted inside a vacuum chamber, which was evacuated to ≤ 50 mTorr by a Roots blower/mechanical pump combination (Edwards EH1200/E2M80). A stainless steel electrode was placed concentrically down the long axis of the bulb, with a piece of sealing teflon press fitted around its sharpened end at the pinhole. The other end of the electrode was attached to a solenoid valve (General Valve 9-181-901) located outside the chamber, for pulsed gas operation. Gas delivery was synchronized to the arrival of the laser pulse at a repetition rate of 10 Hz by means of a home-built sequencer.

$HgCl_2$ vapor was entrained in ≈ 2 atm of He to form a supersonic jet. HgCl radicals were generated in a corona-excited supersonic expansion, produced by applying positive dc voltage (≈ 1.9 kV/1 MΩ load resistor) to the electrode. The grounded chamber served as the cathode.

Fluorescence was excited in the jet discharge ≈ 0.5–1.0 cm below the pinhole using a Nd:YAG (Spectra Physics GCR-4) pumped-dye laser (Lumonics HD500). Ultraviolet (UV) radiation was generated by second harmonic generation in a KDP crystal housed in an autotracking assembly (Inrad AT-II). Typical UV energies were 1–3 mJ/pulse. Fluorescence excitation spectra were obtained by scanning the laser at a rate of 0.04 cm^{-1}/s, and detecting undispersed emission with a photomultiplier (Hamamatsu R372). Ultraviolet transmitting filters (Corning) were placed in front of the phototube to reject visible emission from the jet discharge. The fluorescence excitation signal was processed in a gated boxcar averager, digitized, and stored in a computer.

Frequency calibration was achieved by simultaneously exciting the optogalvanic spectrum of Ne in an Fe/Ne hollow cathode lamp with a small portion of the fundamental laser beam. These signals were processed in a separate gated boxcar averager, digitized and stored on disk. At longer wavelengths ($\lambda \geq 680$ nm), where Ne lines are sparse, portions of both the fundamental beam and the generated UV output were used simultaneously to excite the optogalvanic spectrum. Since the data was digitized the calibration procedure involved fitting the Ne line wavenumbers (in cm^{-1}) as a quadratic function of data point number. The actual data point number assigned to a given optogalvanic peak was determined by visually moving a cursor over the spectrum displayed on the computer monitor, and then selecting and storing that point on disk using software developed in the lab. The Ne wavenumber versus data point number function was then used to calculate unknown transition line wavenumbers by interpolation, using the same method of visual peak determination. The relative precision for the measurement of an unknown line was estimated to be ≈ ±0.1 cm^{-1}.

3. Observed spectra, assignments, and analysis

The relevant potential energy curves, transitions, and frequencies for HgCl are presented schematically in Fig. 1.

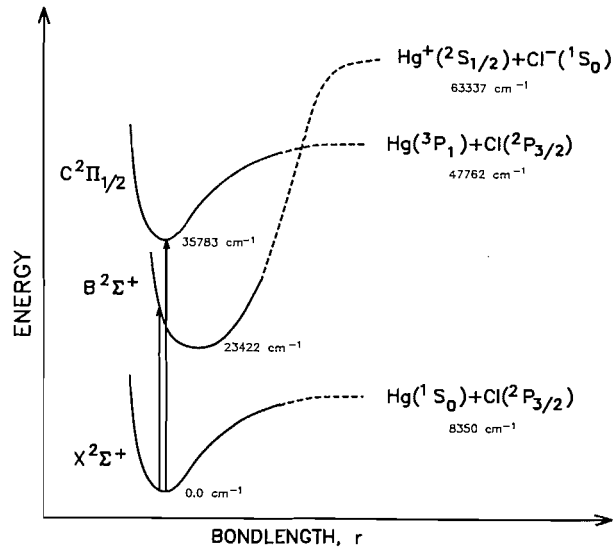

FIG. 1. A schematic of the relevant potential energy curves for HgCl showing their dissociation products. Frequencies for the potential curve minima and dissociation limits (in cm^{-1}) are referenced to the bottom of the HgCl ground state. Arrows indicate the important transitions discussed in this work.

Excitation spectra were recorded between 367 and 267 nm. The dominant features could be assigned to either members of the $B^2\Sigma^+$–$X^2\Sigma^+$ band system, or to He and Hg atomic transitions originating from metastable levels populated in the jet discharge. At the short wavelength end of the spectrum, perturbations were evident between the B-state and higher-lying Rydberg states. Consequently, the vibrational analysis described below was restricted to transitions having $\lambda > 285.5$ nm.

The presence of the atomic lines (Table 1) in the HgCl spectrum was expected, given a similar observation in our previous studies (10, 11). In this work the frequency measurements for the He lines are, for the most part, in better agreement with the literature values (12) than those for Hg, in the same frequency region. This indicates that the calibration method is sound, but that the Hg transition frequencies are more likely to shift as a result of the UV laser fluences used in this work. However, as this hypothesis was not tested experimentally the reasons for the shifts can not be stated with any certainty. Since the atomic lines provide internal calibration, the absolute accuracy for the measurement of an unknown HgCl feature is estimated to be < ±0.4 cm^{-1}.

The overall appearance of the HgCl fluorescence excitation spectrum resembles that observed for HgBr and HgI. The strongest features were readily assigned to the $B^2\Sigma^+(v') \leftarrow X^2\Sigma^+(v'' = 0)$ progression (Fig. 2*a*). Each member of the progression is a doublet composed of one strong and one weak band. The local vibrational interval which corresponds to the spacing between like components of two adjacent doublets, $(v' + 1, v'')$ and (v', v''), decreases smoothly from ≈ 169 cm^{-1} at 366 nm to ≈ 125 cm^{-1} at 285 nm. The doublet spacing for a common v' level arises from a vibrational isotope shift due to the two naturally occurring isotopes of Cl: ^{35}Cl and ^{37}Cl. That interval increases from ≈ 86 cm^{-1} near 366 nm to ≈ 217 cm^{-1} at 285 nm. The inten-

[a]Observed — literature (ref. 12) residual/cm^{-1}.

sities of the doublet components reflect the normalized natural abundance ratios of $^{35}Cl:^{37}Cl = 1:0.33$ (13).

Both doublet components have a similar, distinctive substructure of red-shaded bands (Fig. 2*b*). The pattern arises from vibrational isotope shifts due to the seven naturally occurring isotopes of atomic Hg. The intensity of each isotopomer peak within a doublet component reflects the normalized natural abundance of the particular Hg atom involved ($^{196}Hg:^{198}Hg:^{199}Hg:^{200}Hg:^{201}Hg:^{202}Hg:^{204}Hg$ = 0.005:0.336:0.565:0.776:0.444:1.00:0.230 (13)). This made individual molecular isotopomer identification straightforward. Assignments were made for 12 of the 14 possible HgCl species. The two exceptions were $^{196}Hg^xCl$, x = 35 and 37. As expected, the isotopic transition frequencies within a doublet component are ordered $\nu(^{198}Hg^xCl) > \nu(^{199}Hg^xCl) > \nu(^{200}Hg^xCl) > \nu(^{201}Hg^xCl) > \nu(^{202}Hg^xCl) > \nu(^{204}Hg^xCl)$.

Due to Franck–Condon considerations $\Delta v = v' - v''$ will be $\geqslant 0$ for $B \leftarrow X$ transitions excited in the UV. The higher frequency component of a (v',v'') doublet can therefore be assigned to the $Hg^{35}Cl$ isotopomer. However, care must be

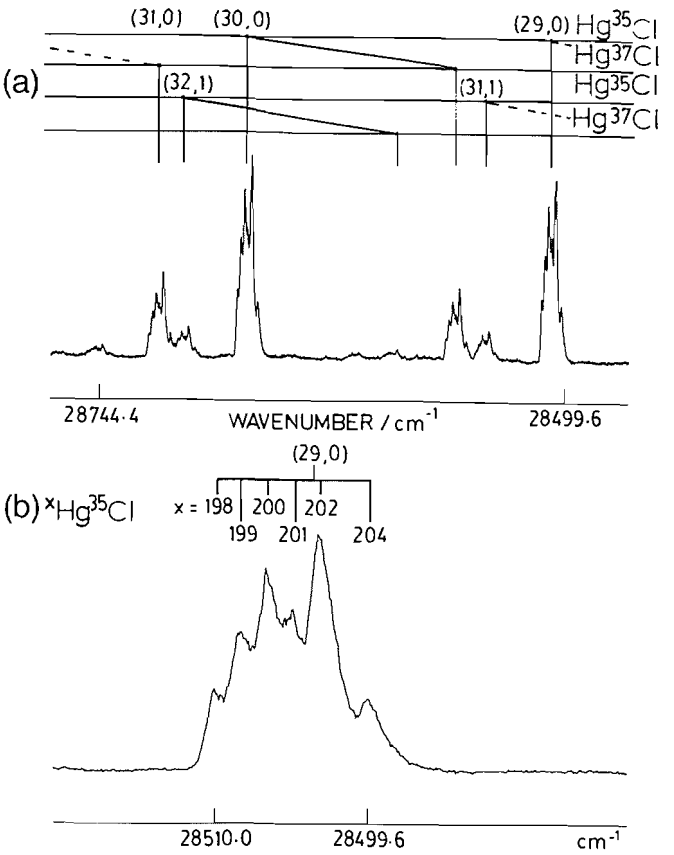

FIG. 2. (*a*) A small portion of the $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ fluorescence excitation spectrum at the long wavelength region of the spectrum near 349.4 nm, showing vibrational and Hg^xCl (x = 35, 37) isotopomer assignments. (*b*) A close-up of the (29, 0) band for the $Hg^{35}Cl$ isotopomer showing the isotopic fine structure due to the numerous isotopes of Hg.

exercised in the analysis of high vibrational levels of an ion-pair state, and with HgCl in particular. Vibrational isotope shifts can equal and exceed the local vibrational spacings. As shown in Fig. 2*a*, the $Hg^{35}Cl$–$Hg^{37}Cl$ isotope splittings are already close to the local $\Delta G'_{v'+1/2}$ at the longer excitation wavelengths used in this work. To a first approximation, the vibrational level, v^0, where the isotope shift equals the vibrational spacing can be calculated from:

$$[1] \quad v^0 = \rho_i/(1 - \rho_i)$$

where ρ_i is defined here as $\rho_i = \sqrt{\mu(^{200}Hg^{35}Cl)/\mu_i}$, and μ_i is the reduced mass of a particular HgCl isotopomer.

The crossover vibrational level for Hg^xCl is calculated from eq. [1] to be $v^0 \approx 42$. As illustrated in Fig. 3, this means that the weaker $Hg^{37}Cl$ doublet component will appear at a higher frequency than the nearest $Hg^{35}Cl$ band for $v' \leqslant 42$, and at a lower frequency for $v' \geqslant 42$. However, the vibrational quantum number of the $Hg^{37}Cl$ band is actually one higher than its $Hg^{35}Cl$ partner.

Crossovers in HgCl are also expected for integer multiples of v^0 near $v' \approx 84$, 126, 168, and so on, with an additional unit increase in the relative numbering of the Hg^xCl bands per v^0 interval. As noted for the valence-to-ion-pair state transitions of the halogens (14, 15), additional information such as the electronic origin of the excited state po-

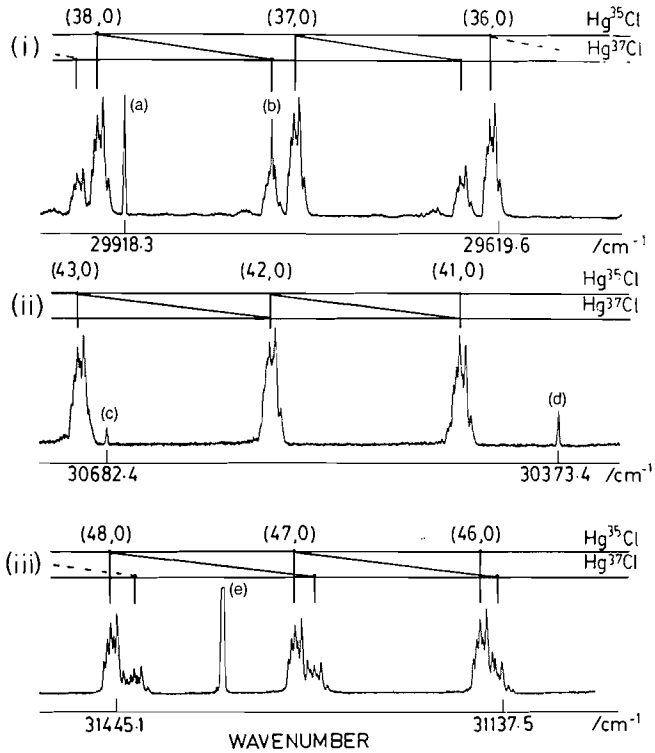

FIG. 3. An overview of the HgCl $B^2\Sigma^+ \leftarrow X^2\Sigma^+$ fluorescence excitation spectrum in the region of the first "crossover" point at (42, 0). Bands having the same vibrational assignment but belonging to a radical with a different Cl isotope are connected by a diagonal line. The features labelled (a)–(e) are atomic transition of He and Hg originating from metastable levels. Assignments and transition wavenumbers are listed in Table 1. (*i*) *B*–*X* vibrational bands just to longer wavelengths of (42, 0). In this region, the $Hg^{35}Cl$–$Hg^{37}Cl$ vibrational isotope shift is less than the local vibrational spacing. (*ii*) *B*–*X* vibrational bands near (42, 0). In this region, the $Hg^{35}Cl$–$Hg^{37}Cl$ vibrational isotope shift is approximately equal to the local vibrational spacing. (*iii*) *B*–*X* vibrational bands just to shorter wavelengths of (42, 0). In this region, the $Hg^{35}Cl$–$Hg^{37}Cl$ vibrational isotope shift is greater than the local vibrational spacing.

TABLE 2. Dunham coefficients (cm^{-1}) for the $B^2\Sigma^+$–$X^2\Sigma^+$ transition of $^{200}Hg^{35}Cl$

Dunham parameter	$B^2\Sigma^+$	$X^2\Sigma^+$
$T_e' + Y_{0,0}$	23421.8084(1218)[a]	—
$Y_{1,0}$	192.25105(1349)	293.353[b]
$Y_{2,0}$	−0.5351495(5147)	−1.7692[b]
$10^3\ Y_{3,0}$	1.011594(6686)	−0.7741[b]
$10^4\ Y_{4,0}$	—	−3.966[b]
$10^8\ Y_{5,0}$	−2.25(36)	—
r_e[c]	2.960(2)[e]	2.3948(26)[d]

[a]Quoted errors are 1σ standard errors.
[b]Constrained to values in ref. 7.
[c]Angstrom units.
[d]Value from ref. 6.
[e]Recommended value for equilibrium bondlength as discussed in text.

tential energy curve is then required to decide which crossover region is being probed because the standard deviations of "local" least squares fits for all choices of nv^0, $n = 1, 2, \ldots$, will be of similar quality. Crossovers within a doublet component for adjacent HgCl isotopomers however, are only expected to be important for $v' > 2600$.

The spectral analysis was carried out with the ground state vibrational constants constrained to the values determined by Tellinghuisen (7). The excited-state numbering was determined by fitting small portions of the spectrum to a local mass-reduced term value formula, and varying the v' numbering until the standard deviation of the fit was unambiguously minimized. When this best set of quantum numbers was used with previously published molecular vibrational constants (7), they generated transition wavenumbers which agreed with our values over a common v' range ($v' = 21$–25). For the final fit, bandhead frequencies measured at the peak of the rising edge of each rotational envelope were fitted to a mass-reduced Dunham expansion of the form (in cm^{-1}):

$$[2] \quad \nu_i = T_e' + \sum_n Y'_{n,0}[\rho_i(v' + 1/2)]^n - \sum_m Y''_{m,0}[\rho_i(v'' + 1/2)]^m$$

where T_e' is the electronic origin of the *B*-state, $Y'_{n,0}$ and $Y''_{m,0}$ are *B*-state and *X*-state Dunham parameters, respectively. No effort was made to correct the transition wavenumbers by the bandhead-to-origin shifts, which were estimated to be $< 0.16\ cm^{-1}$ from published constants (6). In this analysis $^{200}Hg^{35}Cl$ was chosen as the reference isotopomer so that the resultant excited *B*-state constants could be used with the published ground state parameters without additional scaling (7). Hotbands with $v'' = 1$, 2, and 3 were also assigned but the quality of the (v',3) bands was sufficiently poor that they were excluded from the final fit. In the end, 1026 isotopic bandhead frequencies with quantum numbers $76 \geq v' \geq 21$ and $2 \geq v'' \geq 0$ were analyzed. To establish a set of molecular constants which are also valid at the bottom of the *B*-state potential energy curve, calculated $^{200}Hg^{35}Cl$ (v',0) transition wavenumbers, $0 \leq v' \leq 21$ (7), were also included in the data set. The standard deviation of the least-squares fit was $\sigma \approx 0.26\ cm^{-1}$. Transition wavenumbers and their vibrational and isotopic assignments are provided as supplementary material.[4] The particular set of Dunham parameters chosen for data reduction, and listed in Table 2, is the ones that gave the best fit. The number of significant figures for each constant was obtained by a systematic round-off procedure (16, 17). They reproduce the calculated transition wavenumbers to better than $0.01\ cm^{-1}$.

Although the standard deviation of the fit is satisfactory, systematic trends in the observed–calculated residuals are evident. However, they fall within the $\pm 3\sigma$ error limits, and were therefore deemed acceptable. More work is necessary to determine whether these trends are due to the calibration procedure, model-dependence of the fitting function, or both.

4. The B-state potential energy curve

Since the HgCl radicals generated in the jet discharge were vibrationally warm, we were able to locate and use the

[a]FCF $< 10^{-4}$.
[b]For $J' = J'' = 0$.

Franck–Condon intensity minima in the hot-band vibrational progressions to establish the B-state equilibrium bond length. $B \leftarrow X$ transitions probe the inner turning points of the excited state potential energy curve where the high v' wave functions have their largest amplitudes. The intensity minima, therefore, reflect the nodal structure of the ground-state vibrational wave functions superimposed on the electronic transition Franck–Condon factors, FCFs.

A definite minimum in the $v'' = 2$ progression for $Hg^{35}Cl$ was found at $(v',v'') = (34,2)$. Another minimum at (43,1) for $Hg^{35}Cl$ was also picked out from the spectra. However, this latter assignment was made with less confidence because $v' = 43$ comes in the first crossover region where overlapping $Hg^{37}Cl$ bands are expected to have non-zero intensities.

The equilibrium bond length of the B-state potential was determined by the following procedure: RKR–Morse potential curves for both $X^2\Sigma^+$ and $B^2\Sigma^+$ were constructed (18).[5] Here, the vibrational constants in Table 2 were used in an RKR calculation to determine the width of the two potential energy curves as a function of v (19).[5] The inner wings of the potentials were then calculated using Morse functions which incorporated r_e values from the literature. Morse parameters were determined using the vibrational frequency and the dissociation energy for each electronic state. The outer turning points followed immediately.

Vibrational wave functions were evaluated numerically in the two potentials over the range $75 \geq v' \geq 0$ and $2 \geq v'' \geq 0$, and FCFs derived (20). Franck–Condon minima were predicted to lie near (57,1) and (46,2) using our initial choices for the equilibrium bond lengths: $r_e(X) = 2.3948(16)$ Å (ref. 21) and $r_e(B) = 3.02$ Å (ref. 6). The poor agreement between the predicted and experimentally observed locations of the minima suggested that the B-state r_e was too long, since the ground state bond length was established from rotational data. Consequently, a series of RKR–Morse/FCF calculations were carried out with $r_e(X)$ constrained to the initial value above, but $r_e(B)$ varied until the predicted intensity minima agree with the experimental observations. Each decrease in $r_e(B)$ of ≈ 0.004 Å dropped the minima by $\approx$ one quantum in v'. The locations of both intensity gaps were well reproduced with a B-state bond length of 2.960 Å. Since the calculation was sensitive to the relative positions of the two potentials, the error in the excited state bond length was estimated to be ±0.002 Å. FCFs for $30 \geq v' \geq 0$ and $31 \geq v'' \geq 0$ are listed in Table 3 while those for $75 \geq v' \geq 0$ and $2 \geq v'' \geq 0$ are presented graphically in Fig. 4.

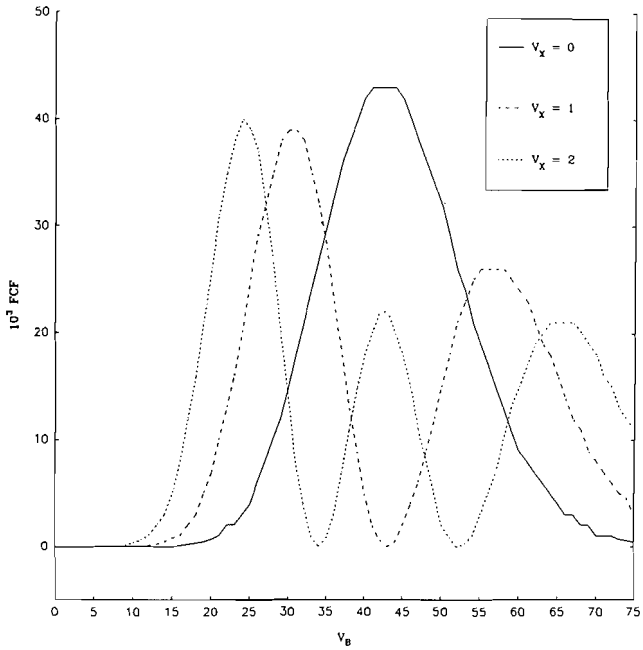

FIG. 4. B–X Franck-Condon factors, 10^3FCF, as a function of v' for the first three v'' levels in the ground state.

5. Perturbations

While the majority of the $B \leftarrow X$ bands measured in this work were accounted for, a number of strong vibrationally and isotopically resolved features at shorter wavelengths were not well reproduced by the parameters in Table 2. We assign these bands to members of the B–X band system, and attribute their poor fit to perturbations. Similar effects have been noted in our previous work on HgBr (10) and HgI (11), where $B \leftarrow X$ bands appeared to acquire strong intensity well outside the predicted Franck–Condon maximum due to excited-state interactions, possibly with the $C^2\Pi_{1/2}$ Rydberg state. However, because high order Dunham series such as those represented by the constants in Table 2 can have poor extrapolation properties (22), constants from low-order polynomial fits in $(v + 1/2)$ for HgCl bands having $75 \geq v' \geq 65$ were also used to predict (v',v'') transition frequencies beyond $v' = 75$. The shorter wavelength transitions could not be well predicted with these expressions either.

Unlike HgBr or HgI, vibrational bands of the C–X transition of HgCl are not strongly present in fluorescence excitation. Of all the mercuric halide radicals, the reported analyses for the C–X band system of HgCl are the most contradictory, although its weak intensity is well documented (3, 23–26). The latest work by Horne et al. (26) places the C–X (0,0) transition near 35 828 cm^{-1}. Indeed, although bands due to $C \leftarrow X$ are not at all obvious, some of the strongest perturbed B–X features appear in this region (Fig. 5). The B-state quantum numbers for bands predicted to lie near C–X (0,0) center around $v' \approx 84$, which corresponds to the second crossover point in the B-state potential. This numbering is corroborated spectrally by the fact that each of the irregularly spaced bands in this vicinity exhibits a more complicated isotopic substructure than expected for an isolated Hg^xCl band (x = 35 or 37), but one which is consistent with two isotopic bands, $Hg^{35}Cl$ (v',v'') and $Hg^{37}Cl$ $(v'+2,v'')$, passing through each other. A quantitative interpretation of the perturbations in HgCl will require further work.

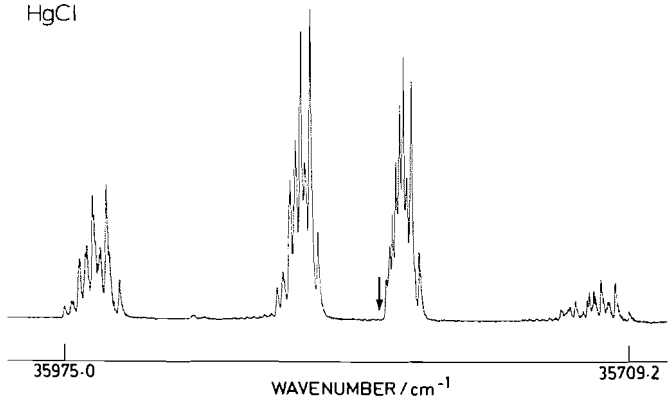

FIG. 5. Fluorescence excitation spectrum near 279.1 nm. The strongest features are assigned to perturbed members of the B–X band system which appear to derive their intensity through excited state interactions with the $C^2\Pi_{1/2}$ Rydberg state. The arrow indicates the location of the C–X (0,0) transition according to ref. 26.

6. Discussion and conclusions

The results of this work complete the $B \leftarrow X$ analyses of the HgX series (X = Cl, Br, I). Our HgCl B–X vibrational numbering and transition wavenumbers agree with Wieland's (4), but the precision of our measurements exceeds that of the older work by at least an order of magnitude. Our constants in Table 2 are also expected to be more useful since Wieland required two expressions to represent the large range of excited state vibrational levels: one for $v' \leq 30$ and the second for $v' \geq 30$. However, both our Dunham series and the older formulas will almost surely fail outside the range of fitted data, due the apparent perturbations between $B^2\Sigma^+$ and $C^2\Pi_{1/2}$ and because of the poor extrapolation properties of Dunham series in general.

The HgCl B-state bond length of $r_e(B) = 2.960(2)$ Å established in this work lies between the most recent experimental values of 3.02 Å (6) and 2.94 Å (27) (also from Franck–Condon calculations), and is larger than the theoretical estimate of 2.93 Å suggested by Wadt (28). It should be kept in mind, however, that in the absence of rotational data, Franck–Condon calculations can only give a precise value of $\Delta r_e = r_e(B) - r_e(X)$. In the older calculations the ground state equilibrium bond length was constrained to be 2.42 Å. A fairer comparison, therefore, requires an examination of Δr_e since our work used the shorter $r_e(X) = 2.3948(16)$ Å obtained from a rotational analysis of the HgCl $D^2\Pi_{3/2}$–$X^2\Sigma^+$ transition (21). Even then, our Δr_e value of $\approx$ 0.56 Å remains bracketed by that obtained by Wadt (28), and Cheung and Cool (27) ($\Delta r_e = 0.52$ Å), and Tellinghusien and co-workers (6) ($\Delta r_e = 0.60$ Å).

The behaviour of our FCFs for the $B \rightarrow X$ emission spectrum calculated using the ion-pair-state equilibrium bond length from this work agrees well with those tabulated by Cheung and Cool (27), in that both studies predict the strongest member of the $(0,v'')$ progression to be (0,17), and an intensity minimum for (1,17). However, we disagree with the detailed work of ref. 6 which places the intensity minimum at (1,19).

Since both the $(v',1)$ and $(v',2)$ intensity minima in our

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

fluorescence excitation spectrum could be reproduced simultaneously using an RKR–Morse potential for the $B^2\Sigma^+$ ion-pair state, it would appear then that a Morse function provides an adequate slope for the inner wall of the excited state potential. A similar conclusion was reached for HgI as well (11). We are currently reeaxamining our HgBr spectra for intensity minima which will also allow its B-state bond length to be refined in this way.[6] Nevertheless, until the disagreement between our predicted HgCl $(1,v'')$ intensity minimum and that from ref. 6 can be reconciled, general confidence in the RKR–Morse approximation must remain an open question.

Lasing on the HgCl $B \rightarrow X$ transition near 502 nm has been demonstrated using a variety of techniques. These include the photolytic dissociation of $HgCl_2$ with vacuum ultraviolet radiation (29), and electron beam pumping of Hg vapor/Cl_2 or CCl_4/high pressure rare gas mixtures (30–33). Direct optical pumping of the HgCl $B \leftarrow X$ transition has not been attempted although a similar approach was successful for HgBr (8, 9). The largest FCF for the HgCl $v' \leftarrow 0$ progression is for the (42,0) transition near 327 nm. However, the $B \leftarrow X$ aborption band is sufficiently broad ($\Delta\lambda >$ 80 nm) that either Nd:YAG or XeF pumping near 350 nm should provide a viable means of achieving laser action in this molecular system.

The $E^1\Sigma^+$–$X^1\Sigma^+$ system of GeS in emission

WALTER J. BALFOUR[1] AND BELVAI J. SHETTY[2]

Department of Chemistry, University of Victoria, Victoria, BC V8W 3P6, Canada

Received March 11, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

WALTER J. BALFOUR and BELVAI J. SHETTY. Can. J. Chem. **71**, 1622 (1993).

A new group of bands has been observed in emission in the 500–600 nm region under conditions that generate known systems of GeS. It has been deduced from the appearance and position of the bands, and from their intensity distribution, that these bands constitute the long-wavelength component of the $E^1\Sigma^+$–$X^1\Sigma^+$ system of GeS, which gives rise to strong absorption and emission in the ultraviolet. E–X Franck–Condon factors have been estimated.

WALTER J. BALFOUR et BELVAI J. SHETTY. Can. J. Chem. **71**, 1622 (1993).

Opérant dans des conditions qui génèrent des systèmes connus de GeS, on a observé un nouveau groupe de bandes dans la région d'émission allant de 500 à 600 nm. On déduit de la présence et de la position des bandes, ainsi que de la distribution de leur intensité, que ces bandes constituent la composante à grande longueur d'onde du système $E^1\Sigma$–$X^1\Sigma^+$ du GeS qui donne lieu à une forte absorption et émission dans l'UV. On a évalué les facteurs E–X de Franck–Condon.

Introduction

In recent years, considerable spectroscopic data have been gathered on the $E^1\Sigma^+$–$X^1\Sigma^+$ system of the isovalent diatomics SiO (1, 2), SiS (3, 4), and SiSe and SiTe (5, 6). One of the common features of these studies is the observation that bands belonging to the E–X system fall in two distinct spectral regions, one in the ultraviolet and the other in the visible. The bands in the visible region appear only in emission. These observations are a direct result of the substantial change in geometry that occurs upon excitation from the $X^1\Sigma^+$ state to the $E^1\Sigma^+$ state: the ultraviolet bands constitute one arm of the Condon parabola, the visible bands the other.

The corresponding germanium compounds can also be expected to exhibit similar spectroscopic properties. However, to date the bands belonging to the E–X system of germanium compounds have been reported only in the ultraviolet region. Of these, the GeS molecule has been the subject of interest of many researchers. Two ultraviolet band systems of GeS, $A^1\Pi$–$X^1\Sigma^+$ and $E^1\Sigma^+$–$X^1\Sigma^+$, are known and have been vibrationally analysed (7, 8). The rotational analysis of these band systems is made difficult because of the overlapping of bands due to significant natural abundances of the isotopomers $^{70}Ge^{32}S$, $^{72}Ge^{32}S$, $^{73}Ge^{32}S$, $^{74}Ge^{32}S$, and $^{76}Ge^{32}S$. More recently Magat et al. (9) have achieved the rotational analysis of a few bands belonging to the A–X system by making use of the accurate ground state rotational constants available from microwave spectral studies (10, 11).

In Drummond and Barrow's absorption study of the E–X system (8) a v'-0 progression was observed extending to $v' = 36$. However, the vibrational constants they reported were derived from a data set restricted to $v' \leq 17$. Linton (12) observed two new transitions, $b^3\Pi_1$–$X^1\Sigma^+$ (350–400 nm) and $a^3\Sigma^+$–$X^1\Sigma^+$ (420–650 nm), in experiments that were completely free from the previously known $A^1\Pi$–$X^1\Sigma^+$ and $E^1\Sigma^+$–$X^1\Sigma^+$ band systems: a chemiluminescent flame produced by the reaction of Ge with OCS.

We have examined the GeS spectrum in emission between 200 and 650 nm and, in addition to the known A–X (270–380 nm) bands, and the E–X ultraviolet bands, we have noted a new group of bands between 500 and 600 nm. Our conjecture that these new bands form the long-wavelength component of the E–X system has been confirmed by a combined vibrational analysis of the ultraviolet and visible bands and associated Franck–Condon calculations.

Experimental details

The spectrum of the germanium monosulfide molecule was excited in a microwave discharge (2450 MHz, 100 W) using a 5 cm long sealed quartz tube (10 mm diameter) containing milligram quantities of pure elemental germanium (in slight stoichiometric excess) and sulfur, along with neon gas at a pressure of 2–4 Torr (1 Torr = 133.3 Pa). To maintain a steady vapour pressure of GeS in the discharge column the sealed tube was heated with an electrical wire furnace wound around a quartz tube supporting the sealed tube. Further experimental details and advantages of the method can be found in a previous publication (5). The E–X bands of GeS in the ultraviolet (220–285 nm) region were photographed in the first order of a 3.4-m Ebert grating spectrograph with a 1180 groves mm^{-1} grating blazed at 750 nm. The bands in the visible (500–600 nm) region were photographed in the first order of a 1.5-m Baird-Atomic grating spectrograph. The band-heads were measured against the iron lines excited in a Fe–Ne hollow cathode lamp.

Results and discussion

In the present studies of GeS in emission we have observed extensive band structure throughout the visible and ultraviolet, including the $A^1\Pi$–$X^1\Sigma^+$ and $E^1\Sigma^+$–$X^1\Sigma^+$ systems, but not the bands found by Linton (12) in chemiluminescence. Our spectra, in the ultraviolet down to 220 nm, include bands reported by Drummond and Barrow (8) up to $v = 21$ of the E-state. Their observations extend somewhat further towards the convergence limit near 214 nm. Some 30 bands in the 500–600 nm region have been observed that have not previously been reported. Their occurrence together with known GeS bands, and the complete absence of any identifiable impurity spectra, suggested that the new bands also belong to GeS. They are red-degraded and have a similar appearance to the E–X bands in the ultraviolet. We have considered the probability that these new visible bands constitute part of the E–X system and find that they can indeed be integrated in a satisfactory way.

The detailed vibrational analysis of the ultraviolet and the

visible bands has revealed that while the former arise from transitional between vibrational levels $0 \leq v \leq 21$ in the $E^1\Sigma^+$ state and $0 \leq v \leq 8$ in the $X^1\Sigma^+$ state, the latter involve transitions from $33 \leq v \leq 40$ in the $E^1\Sigma^+$ state to $60 \leq v \leq 68$ in the $X^1\Sigma^+$ state of GeS. A least-squares fit, combining all of our observed band-heads in the ultraviolet and visible region, yielded the following constants: T'_e = 38 887.63(1.37), ω'_e = 308.79(19), $\omega'_e X'_e$ = 1.377(8), ω''_e = 574.51(26) and $\omega''_e X''_e$ = 1.800(4) (cm^{-1}). Values in parentheses are standard deviations. These constants from the global fit of E–X bands may be compared with those obtained from measurements of the first few vibrational intervals in the ground state from rotational analysis of A–X bands (9) and infrared emission spectra (13), where the $v = 1$ to $v = 0$ interval was found to be 571.0 cm^{-1}. The constants above give 570.9 cm^{-1}, in excellent agreement. The standard deviation of the fit (4.8 cm^{-1}) is well within the experimental uncertainties in band-head positions. Unlike the bands in the A–X system, the bands in the E–X system do not show sharp, well-defined heads. A major source of the uncertainty in the measured band-heads comes from overlapping, unresolved, isotopic structure. For the same reason no isotopic information useful to the assigning of specific vibrational quantum numbers is evident. Band-heads and their vibrational assignments are listed in Table 1.

We have used Franck–Condon calculations (14) to verify the above interpretation of the visible GeS bands. The vibrational constants necessary to compute the Rydberg–Klein–Rees (RKR) potential energy curves were taken from the present study. Equilibrium rotational data (B_e and α_e) for the ground electronic state are available from microwave studies (10, 11), but similar data for the E-state have not been measured. Initially we estimated B'_e and α'_e parameters by assuming percentage changes upon excitation to be the same for GeS as measured for the isovalent SiS (15). The estimated r'_e was 0.2356 nm. We subsequently adjusted the r'_e value to 0.22811 nm, while preserving the shape of the potential curve, to match the calculated relative intensity distribution of the v'-0 progression to experiment. The RKR curves used are given in Table 2. The Franck–Condon factors obtained from these curves are shown in Table 3. The predictions of these calculations agree well with the observations in both the ultraviolet and visible regions.

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

WALTER J. BALFOUR, SCOTT G. FOUGERE, DIETER KLAPSTEIN, and WERNER M. NAU. Can. J. Chem. **71**, 1627 (1993).

The gas phase infrared and liquid phase Raman spectra of the title compounds have been recorded and vibrational analyses performed. The spectra show evidence for the presence in both the liquid and vapour phases of two rotational isomers: *cisoid-Z* and *transoid-Z* with reference to orientation of isocyanato and methyl groups relative to the carbonyl group.

WALTER J. BALFOUR, SCOTT G. FOUGERE, DIETER KLAPSTEIN et WERNER M. NAU. Can. J. Chem. **71**, 1627 (1993).

On a enregistré le spectre Raman du composé mentionné dans le titre en phase liquide ainsi que son spectre infrarouge en phase gazeuse et on a effectué des analyses vibrationnelles. Les spectres mettent en évidence, dans la phase liquide et dans la phase gazeuse, l'existence de deux isomères rotationnels : *cisoïde-Z* et *transoïde-Z* en fonction de l'orientation des groupes isocyanato et méthyle par rapport au groupe carbonyle.

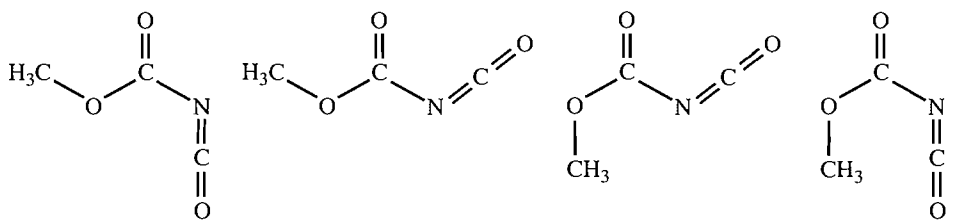
Introduction

Several papers in recent years have dealt with the infrared and Raman spectra of simple organic isocyanates (1–3). Klapstein and Nau (4) reported infrared, uv, and ^{13}C nmr data for seven carbonyl isocyanates and eight acyl isocyanates and were able to draw a number of general conclusions regarding group frequencies and conformational properties. Their results were subsequently combined with complementary Raman observations to obtain detailed vibrational analyses for acetyl and three chloroacetyl isocyanates (5). The present paper examines the vibrational spectra of the related methoxycarbonyl isocyanate (MCI) and its thio derivative (TMCI). These spectra offer clear evidence for the presence in both liquid and gas phases of more than one rotational conformer. If we neglect rotation of the methyl group and assume a planar molecular framework for the heavy atoms as resonance would favour, there are four isomeric forms to consider, with *cisoid/transoid* and *E/Z* referring to the orientations of the isocyanato and methyl groups, respectively, relative to the carbonyl group:



transoid-Z *cisoid-Z* *cisoid-E* *transoid-E*

A detailed analysis of the conformers of MCI, TMCI, and other carbonyl isocyanates has shown that the important contributing structures for MCI and TMCI at room temperature are the *cisoid-Z* and *transoid-Z* conformers (6). In this work we present analyses of the vapour infrared and liquid Raman spectra of MCI and TMCI.

Experimental procedure

Samples of MCI and TMCI were synthesized from commercially available (Aldrich, Milwaukee) chlorocarbonyl isocyanate following the general method of Hagemann (7). The chlorocarbonyl isocyanate was first distilled to remove traces of toluene, indicated to be present as an impurity by ^{13}C nmr, and then converted into the desired methoxy or thiomethoxy compound by reaction with the nucleophiles CH_3OH or CH_3SH, respectively. In the case of MCI, diethyl ether was used as solvent and the primary *N*-carbonyl-substituted carbamoyl chloride was isolated as a white crystalline solid which was then thermally decomposed with elimination of hydrogen chloride to yield product. For the thiomethoxy compound the product was obtained directly following reflux and removal of the 1,2-dichloroethane solvent by distillation. MCI and TMCI are colorless liquids with normal boiling points of 97 and 125°C, respectively.

Infrared spectra of the vapour phase were recorded on a Bruker IFS-25 Fourier transform spectrometer over the range 4000–

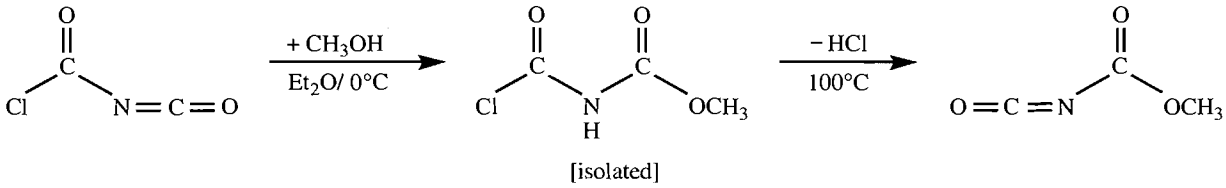
400 cm^{-1}, at a resolution of 2 cm^{-1}. The Raman spectra were measured perpendicular to the incident laser beam on a Jobin–Yvon RAMANOR HG2S monochromator. A Spectra Physics 2020 argon ion laser operating with 500 mW (focussed) power at 514.5 nm was used for excitation. The samples were liquids sealed in glass nmr tubes. Spectra were scanned between 3500 and 100 cm^{-1} and calibrated with reference to chloroform and known argon ion plasma lines. Raman displacements of sharp, unblended features are the average of three independent measurements and have an estimated uncertainty of ±3 cm^{-1}.



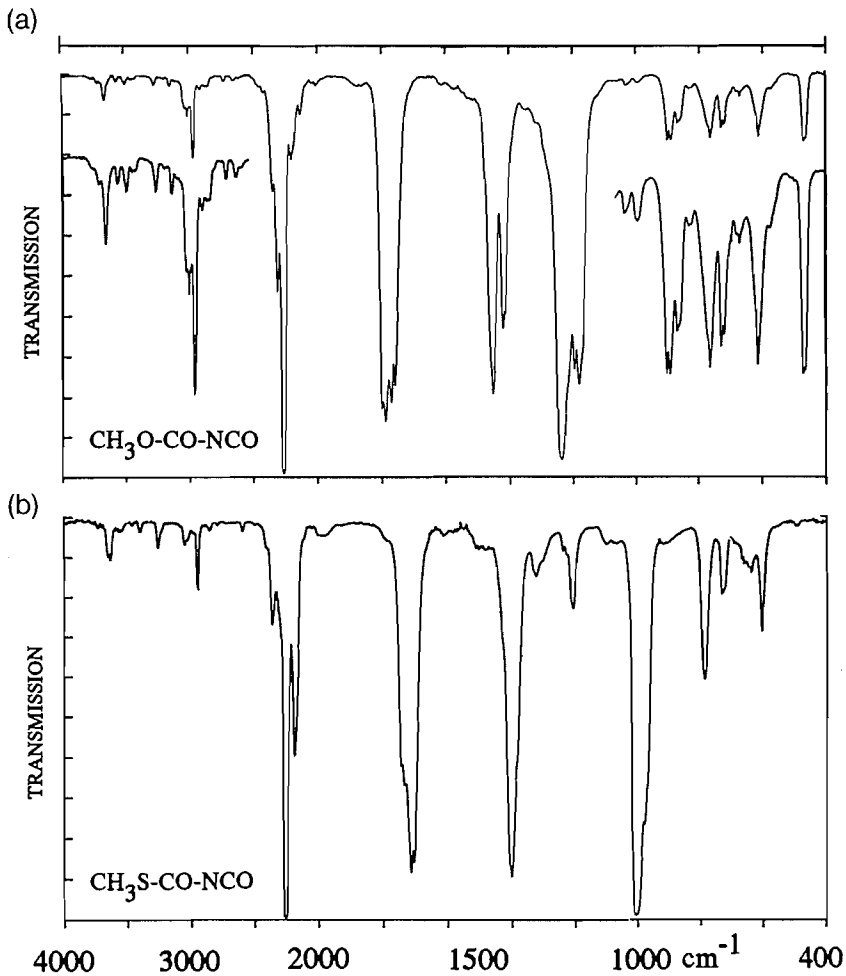


FIG. 1. The vapour phase infrared spectra of MCI and TMCI; (*a*) $CH_3OCONCO$, P = 5 Torr; insert, P = 13 Torr; (*b*) $CH_3SCONCO$, P = 7 Torr.

Results and discussion

MCI and TMCI, in any of the possible planar conformations, can be treated under C_s symmetry, the 24 normal modes spanning the irreducible representations $16a' + 8a''$. All vibrations are both infrared and Raman active. The respective spectra are presented in Figs. 1 and 2. The carbonyl stretching (infrared) region for both compounds is shown in greater detail in Fig. 3 where in each case two absorptions are evident.

A number of observations combine to favour assigning the higher frequency component to the *transoid-Z* conformer and the lower one to the *cisoid-Z* conformer (6). First, the *transoid-E* conformation is clearly improbable for steric reasons. Secondly, the higher frequency component (1795 cm^{-1}) in MCI shows an AB hybrid contour, expected only for the *transoid-Z* isomer. (The *cisoid-Z* and *cisoid-E* isomers should show B-type carbonyl stretching bands.) Thirdly, semi-empirical (AM1) calculations predict a higher frequency for the *transoid-Z* isomer. It is not possible to distinguish between the *cisoid-Z* and *cisoid-E* choices for the lower frequency component (1764 cm^{-1}) solely from observations in the car-

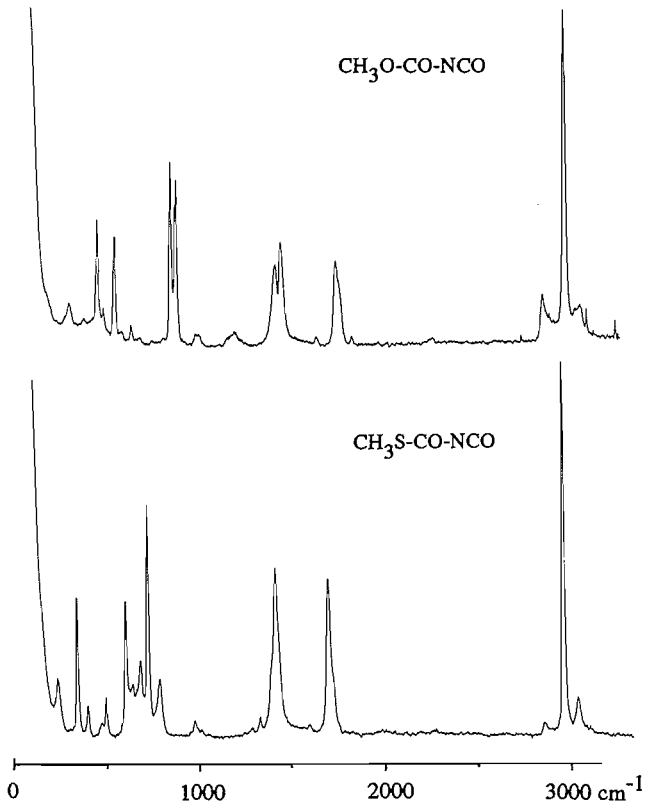

FIG. 2. Raman spectra of MCI and TMCI liquids.

bonyl stretching region. However, reference to the C—N stretching region provides a clear distinction. The C—N stretching modes for the two isomers are reasonably well resolved from each other at 892 and 862 cm^{-1} in the infrared spectrum of MCI. Experimentally the 862 cm^{-1} band gains intensity while the 892 cm^{-1} loses intensity upon heating (6). The (scaled) AM1 calculated frequencies are 888 cm^{-1} (*cisoid-Z*), 867 cm^{-1} (*transoid-Z*), and 852 cm^{-1} (*cisoid-E*). One can thus confidently assign the 862 cm^{-1} band to the *transoid-Z* isomer, with the second isomer being the *cisoid-Z* form. The temperature dependence of the 862 cm^{-1} band parallels that of the 1795 cm^{-1} carbonyl band, while the behaviour of the 892 cm^{-1} band follows that of the 1764 cm^{-1} carbonyl band. This allows unambiguous assignment of the two conformers of MCI as *transoid-Z* and *cisoid-Z*, with the latter being the more stable (6). Similar arguments hold for TMCI, allowing some conformeric vibrational assignments (see Table 2).

Vibrations of the methyl group

The stretching vibrations for a methyl group, whether attached to an oxygen atom or to a sulphur, are found in the 3050–2900 cm^{-1} region. Their assignments follow directly from the expectation that the symmetric mode will give the most intense Raman line in the region and that the frequencies of the two asymmetric counterparts will have frequencies similar to one another and lie slightly higher than the symmetric mode. The deformation modes can be assigned by comparison to methyl (8) and thiocarbamate (9) esters. The symmetric deformation lies typically near 1450 cm^{-1} for the CH_3—O group and 1320 cm^{-1} for the CH_3—S group (10). In the spectra of MCI and TMCI it is probable that the symmetric and asymmetric deformations are nearly degenerate as only one frequency attributable to CH_3 deformation can be identified. Infrared bands at 1194 and 1180 cm^{-1} have been assigned to the *a'* and *a''* CH_3—O rocking modes. The corresponding frequencies for CH_3—S, since these modes are mass-sensitive, are anticipated to be lower, e.g., 968 cm^{-1} is observed in CH_3S—CO—NH_2 (9), and a vibration with 973ir/965R cm^{-1} is assigned to the CH_3—S rocking motion.

NCO stretching vibrations

A strong infrared absorption in the 2280–2250 cm^{-1} region is characteristic of the isocyanate functional group. As with other organic isocyanates that we have studied, this asymmetric NCO stretch appears only weakly in the Raman spectra. On the other hand, the corresponding symmetric motion leads to rather weak ir absorption but intense Raman activity. These generalizations allow unambiguous assignments to be made for ν_{as} (NCO) and ν_s(NCO).

CH_3—O and CH_3—S stretching vibrations

The infrared spectrum of MCI shows nothing of great significance in the region between 1180 and 900 cm^{-1} where methoxy C—O stretching frequencies are to be expected. A weak Raman line at 1006 cm^{-1} is tentatively attributed to this mode. The corresponding C—S stretch in TMCI can be assigned with more confidence to a moderately intense Raman feature at 684 cm^{-1}. Again the corresponding infrared absorption is very weak. The mode is reported at 696 cm^{-1} in CH_3S—CO—NH_2 (9) and 692 cm^{-1} in CH_3—S—CH_3 (10). The adjacent bonds, from O or S to the carbonyl group, are somewhat stronger through resonance than are those to the methyl group, and this is reflected in somewhat higher values for the associated stretching frequencies: 1235 cm^{-1} for MCI and 727 cm^{-1} for TMCI.

Skeletal bending vibrations

The COC/CSC deformation mode lies at 321 and 240 cm^{-1} in MCI and TMCI, respectively. They represent the lowest frequency motions identified in the spectra, with the possible exception of poorly resolved shoulders on the rising Rayleigh scattered background, which may be due to the methyl torsion. The CNC bends are also expected to be low-lying but probably have frequencies below 150 cm^{-1}. The δ(COC/CSC) values may be compared with 320 and 253 cm^{-1} found for the analogous carbamates (9, 11). Bending vibrations within the C—NCO group can be assigned with reference to other organic isocyanates (6).

Observations and their assignments are listed for MCI and TMCI in Tables 1 and 2, respectively.

Acknowledgments

This research was supported through operating grants to W.J.B. and D.K. from the Natural Sciences and Engineering Research Council of Canada (NSERC). W.J.B. is also grateful to NSERC for an equipment grant to purchase the argon ion laser used in the Raman experiments while D.K. acknowledges support from the St. Francis Xavier University Council for Research. This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

A.T. WEN and A.P. HITCHCOCK. Can. J. Chem. **71**, 1632 (1993).

Oscillator strengths for C 1*s* excitation of gas phase Cp_2TiCl_2 and $CpTiCl_3$ (Cp = η^5-C_5H_5), and Cl 2*p* and Ti 2*p* excitation of gas phase Cp_2TiCl_2, $CpTiCl_3$, and $TiCl_4$ have been derived from electron energy loss spectra recorded under electric dipole scattering conditions. The C 1*s* spectra are interpreted with the aid of semiempirical extended Hückel calculations and comparisons with the C 1*s* spectra of other cyclopentadienyl complexes. The Ti 2*p* spectra are interpreted using the extended Hückel results and comparisons with atomic multiplet – crystal field calculations for Ti^{4+} taken from the literature.

A.T. WEN et A.P. HITCHCOCK. Can. J. Chem. **71**, 1632 (1993).

Utilisant les spectres relatifs à la perte d'énergie électronique enregistrés dans des conditions de diffusion des dipôles électriques, on a déterminé les forces de l'oscillateur pour l'excitation C 1*s* du Cp_2TiCl_2 et du $CpTiCl_3$ en phase gazeuse (Cp = η^5-C_5H_5) et les excitations Cl 2*p* et Ti 2*p* du Cp_2TiCl_2, du $CpTiCl_3$ et du $TiCl_4$ en phase gazeuse. On interprète les spectres C 1*s* à l'aide des calculs semi-empiriques étendus de Hückel et des comparaisons des spectres C 1*s* d'autres complexes du cyclopentadiényle. On interprète les spectres Ti 2*p* en utilisant des résultats de Hückel étendus et des comparaisons avec des calculs multiplet atomique – champ cristallin pour le Ti^{4+} tirés de la littérature.

Introduction

Organometallic compounds pose interesting challenges with regard to understanding electronic structure and bonding. In addition, they provide useful models for the interaction of organic compounds with metal surfaces. Inner shell excitation spectroscopy by photoabsorption (1) or inelastic electron scattering (2) provides a site-selective probe of molecular unoccupied electronic structure. The core excitation spectra of organometallic complexes have been used in a number of recent studies to investigate the nature of metal–ligand bonding and ligand–ligand interaction via the metal centre (3–10). In this work we compare the core excitation spectra of Cp_2TiCl_2, $CpTiCl_3$, and $TiCl_4$. Improved knowledge of the spectroscopy and electronic structure of these compounds is desirable since they are involved in stereospecific polymerization of olefins (Ziegler–Natta catalysis). In addition, Cp_2TiCl_2 is being investigated as an antitumour agent (11) and a fertilizer (12).

In an early investigation of a number of 3*d*-transition metal complexes the metal 2*p* spectra were observed to have a strong dependence on ligand type, with apparently less dependence on *d*-count or symmetry (7). This empirical observation was rationalized by attributing the lower energy features to $2p \rightarrow (3d\pi\text{–}p\pi)^*$ transitions and the higher energy structure to $2p \rightarrow (3d\sigma\text{–}p\sigma)^*$ transitions since the species with strong low-energy transitions are typically species like metallocenes, which have primarily π-bonding, while those with strong higher energy transitions are metal-carbonyl species, which have strong σ-bonding as well as a π contribution. Recently Decleva et al. carried out SCF-CI ab initio calculations to explore the environmental sensitivity of metal 2*p* spectra (13). They observed a very large and characteristic sensitivity of the 2*p* spectra to the type of ligand, which they argued supports the empirical interpretation. At the same time, ab initio atomic multiplet – crystal field calculations (14–17) have met with considerable success at explaining the high-resolution metal 2*p* spectra of the elements (18), their oxides and halides (19), as well as a number of organometallic complexes (20). The physical model of this approach is qualitatively different from the empirical "π^*/σ^*" model (7); in particular, it predicts a much stronger spectral dependence on molecular geometry and 3*d*-count and a much weaker dependence on the nature of the ligand–metal bonding, which in effect only enters the crystal field calculation through the average crystal field parameter for a metal ion in a crystal field (Δ_0 or $10Dq$ in an octahedral field). Simplistically one can contrast the physical basis of the models as covalent versus ionic.

The compounds investigated in this work ($TiCl_4$, $CpTiCl_3$, and Cp_2TiCl_2) were chosen to explore the relative applicability of these two models. The Ti—Cl bond is strongly ionic and thus one might expect the crystal field approach to be more applicable to these species than to the metallocene and carbonyl complexes that were studied previously (7). As the number of Cp ligands increases, $d\pi^*\text{–}p\pi^*$ interactions should become stronger so the "π^*/σ^*" model would predict a systematic increase in the intensity of the lowest energy transition through this series of compounds that would have maximum intensity in the Ti 2*p* spectrum of $TiCp_2Cl_2$. Our goal was to use the measured spectral shape to further distinguish between these two models and, ideally, to learn which has greater predictive power.

Experimental

The inner-shell electron energy loss spectrometer and operating techniques have been described previously (2). The spectra were obtained by inelastic electron scattering with a high-velocity incident electron beam (E_0 = 2.5 keV plus the energy loss), small scattering angle (<2°), and 0.6 eV fwhm resolution. To achieve adequate vapour pressure of these low-volatility complexes in the collision region of the spectrometer, the sample cell, inlet line, and collision chamber were heated as needed. The samples were obtained commercially (Strem Chemical Co.) and used without further purification.

TABLE 1. Molecular geometries of $TiCl_4$, $CpTiCl_3$, and Cp_2TiCl_2 used for EHMO calculations

Property	$TiCl_4$[a]	$CpTiCl_3$[b]	Cp_2TiCl_2[c]
Symmetry	T_d	C_{3v} (eff. O_h)	C_{2v}
R(Ti—Cl) (Å)[d]	2.170	2.20–2.25	2.36
R(Ti—Cp) (Å)[e]	—	2.01	2.06
R(Ti—C) (Å)	—	2.31	2.37
$\phi_{Cl-Ti-Cl}$ (°)	107.6	104.1, 102.2	94.5
$\phi_{Cl-Tp-Cp}$ (°)[e]	—	114.3, 117.2	106.4

[a]Gas phase electron diffraction (23).
[b]Solid state X-ray diffraction (24).
[c]Solid state X-ray diffraction (25).
[d]Differences of up to 0.05 Å are found between Ti—Cl bond lengths in gas phase and solid state $TiCl_4$ (23). Thus part of the increase in R(Ti—Cl) in the species containing Cp rings may be associated with extramolecular relaxation in the solid state.
[e]Distance (angle) to the centre of the Cp ring, which was taken to have a symmetric geometry with R(C—C) = 1.38 Å and R(C—H) = 1.10 Å.

The C 1*s*, Cl 2*p*, and Ti 2*p* spectra were converted to absolute oscillator strengths using a procedure described and tested previously (21). A precision of 5% is estimated from reproducibility of analyzing independent data sets, while absolute accuracy is about 20%, according to comparisons with other known optical oscillator strength data.

Extended Hückel calculations (EHMO) were carried out using standard methods. The default Hückel parameters were used, except that Cl 3*d* orbitals were included in the basis set since previously this was found to be important in obtaining correct (relative) energies for the lower energy unoccupied orbitals (22). The geometries were taken from gas phase electron diffraction or solid state X-ray diffraction data reported in the literature (23–25) and are summarized in Table 1. To facilitate interpretation of the core spectra, EHMO calculations relevant to the core excited states were carried out within the equivalent ionic core virtual orbital (EICVOM) model (26). EICVOM uses the "$Z + 1$" approximation to account for the core hole potential and includes an additional unit positive valence charge to give the correct number of valence electrons in the system and to account for relaxation of the valence electrons in the core excited states. Separate calculations were carried out with the C 1*s* core hole on each symmetry inequivalent site. The virtual orbital energies of the ground state of the cation were assumed to approximate the relative energies (term values) of core → valence excited states while the intensities of each transition were assumed to be proportional to the sum of the squares of the coefficients of electric dipole coupled atomic orbitals on the core excited atom for each virtual MO (27). As found in previous work (5–10, 22, 28, 29), EHMO with this approach reproduces the shapes of the discrete and, with lower quality, the near-continuum portions of core excitation spectra, giving confidence in using the virtual MO character as a guide to spectral assignment. Predicted spectra were generated from the calculations by summing Gaussian lines of position given by the eigenvalue, area given by Σc^2(N 2*p*) at the C 1*s* excited atom, and widths selected according to a graded scheme designed to approximate the observed increase in linewidth with increasing transition energy. In this work the predicted spectra were constructed using widths of 8 eV fwhm for orbitals of eigenvalue (ϵ) above 8 eV; 6 eV for $6 < \epsilon < 8$; 4 eV for $0 < \epsilon < 6$; 2 eV for $-4 < \epsilon < 0$; 1.2 eV for $-8.0 < \epsilon < -4.0$; and 0.7 eV for $\epsilon < -12$ eV. Based on comparisons with experiment, the value of 8 eV for the width of the highest energy transitions is probably underestimated.

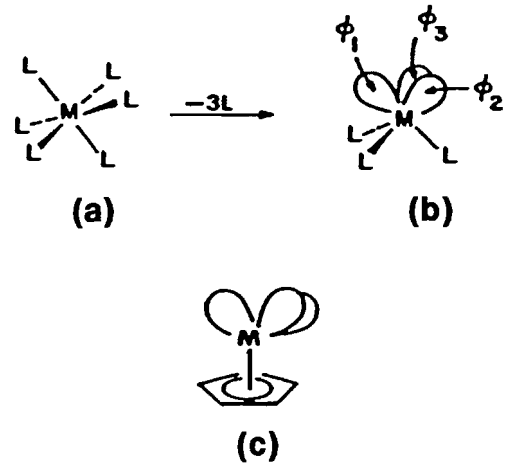
Molecular orbital descriptions of Cp_2TiCl_2, $CpTiCl_3$, and $TiCl_4$

EHMO calculations were carried out for the ground states of all three molecules, as well as Cp^-, $TiCl_3^+$, and $TiCl_2^{2+}$, in order to provide a quantitative basis for the molecular orbital interaction diagrams presented in Fig. 1. $TiCl_4$ is a tetrahedral complex that has a ground state configuration of:

$$(1a_1)^2(1t_2)^6(1e)^4(2t_2)^6(2a_1)^2(3t_2)^6(1t_1)^6\ (2e)^0(4t_2)^0 \qquad {}^1A_1$$

The lower energy 2*e* and $4t_2$ unoccupied orbitals are almost entirely composed of Ti 3*d* orbitals. According to crystal field theory the energy difference between the 2*e* and $4t_2$ orbitals is Δ_t, the crystal field splitting of the orbitals associated with a Ti^{4+} d^0 configuration in a tetrahedral field. For the ground state of $TiCl_4$ EHMO predicts that Δ_t is 0.73 eV (see Fig. 1*a*). This separation is predicted to increase to 1.02 eV in the Ti 2*p* excited state. The EHMO ground state prediction of Δ_t for $TiCl_4$ is rather smaller than the experimental value determined by UV absorption spectroscopy (~0.95 eV (30)) or that from other semiempirical calculations (~1.0 eV) (31).

The MO diagram of $CpTiCl_3$ is presented in Fig. 1*b* together with a correlation to the orbital energies of Cp^- and $TiCl_3^+$. The symmetry of this complex is only C_s. However, the pattern of the MOs suggests that the apparent symmetry is rather close to O_h. This can be rationalized readily within a fragment MO model (32). Consider a hypothetical octahedral species ML_6 (sketch **a**) where L is a simple σ donor ligand (such as Cl^-) and has one valence orbital with two electrons pointing towards the metal centre.



The σ-bonding skeleton can be constructed from six equivalent sp^3d^2 hybrid metal orbitals and the σ-ligand orbitals. The valence orbitals of a pyramidal ML_3 fragment (C_{3v}) can be obtained from an octahedron by removal of three facial L ligands, leaving three low-lying acceptor orbitals directed towards the vacated ligand sites (sketch **b**). If the original species has a $3d^0$ metal centre (e.g., Ti^{4+}), then there will be three unfilled valence orbitals that closely correlate to the t_{2g} set of the octahedron (31). On the other hand, if the three L ligands are removed from $CpML_3$ (such as $CpTiCl_3$), leading to the CpM fragment (sketch **c**), the resulting three hybrid orbitals will point towards the empty ligand sites. This is exactly the same pattern seen in the above generation of the ML_3 fragment from ML_6. In other words, the CpM group is expected to be very similar to ML_3. This means that the Cp^- ligand with six electrons is topologically equivalent to three facial ligands of the σ donor (Cl^- in our case) and thus $CpTiCl_3$ has a pseudo-octahedral symmetry.

Compared to $TiCl_4$, the $\pi(e_1'')$ HOMO's of the Cp^- ligand

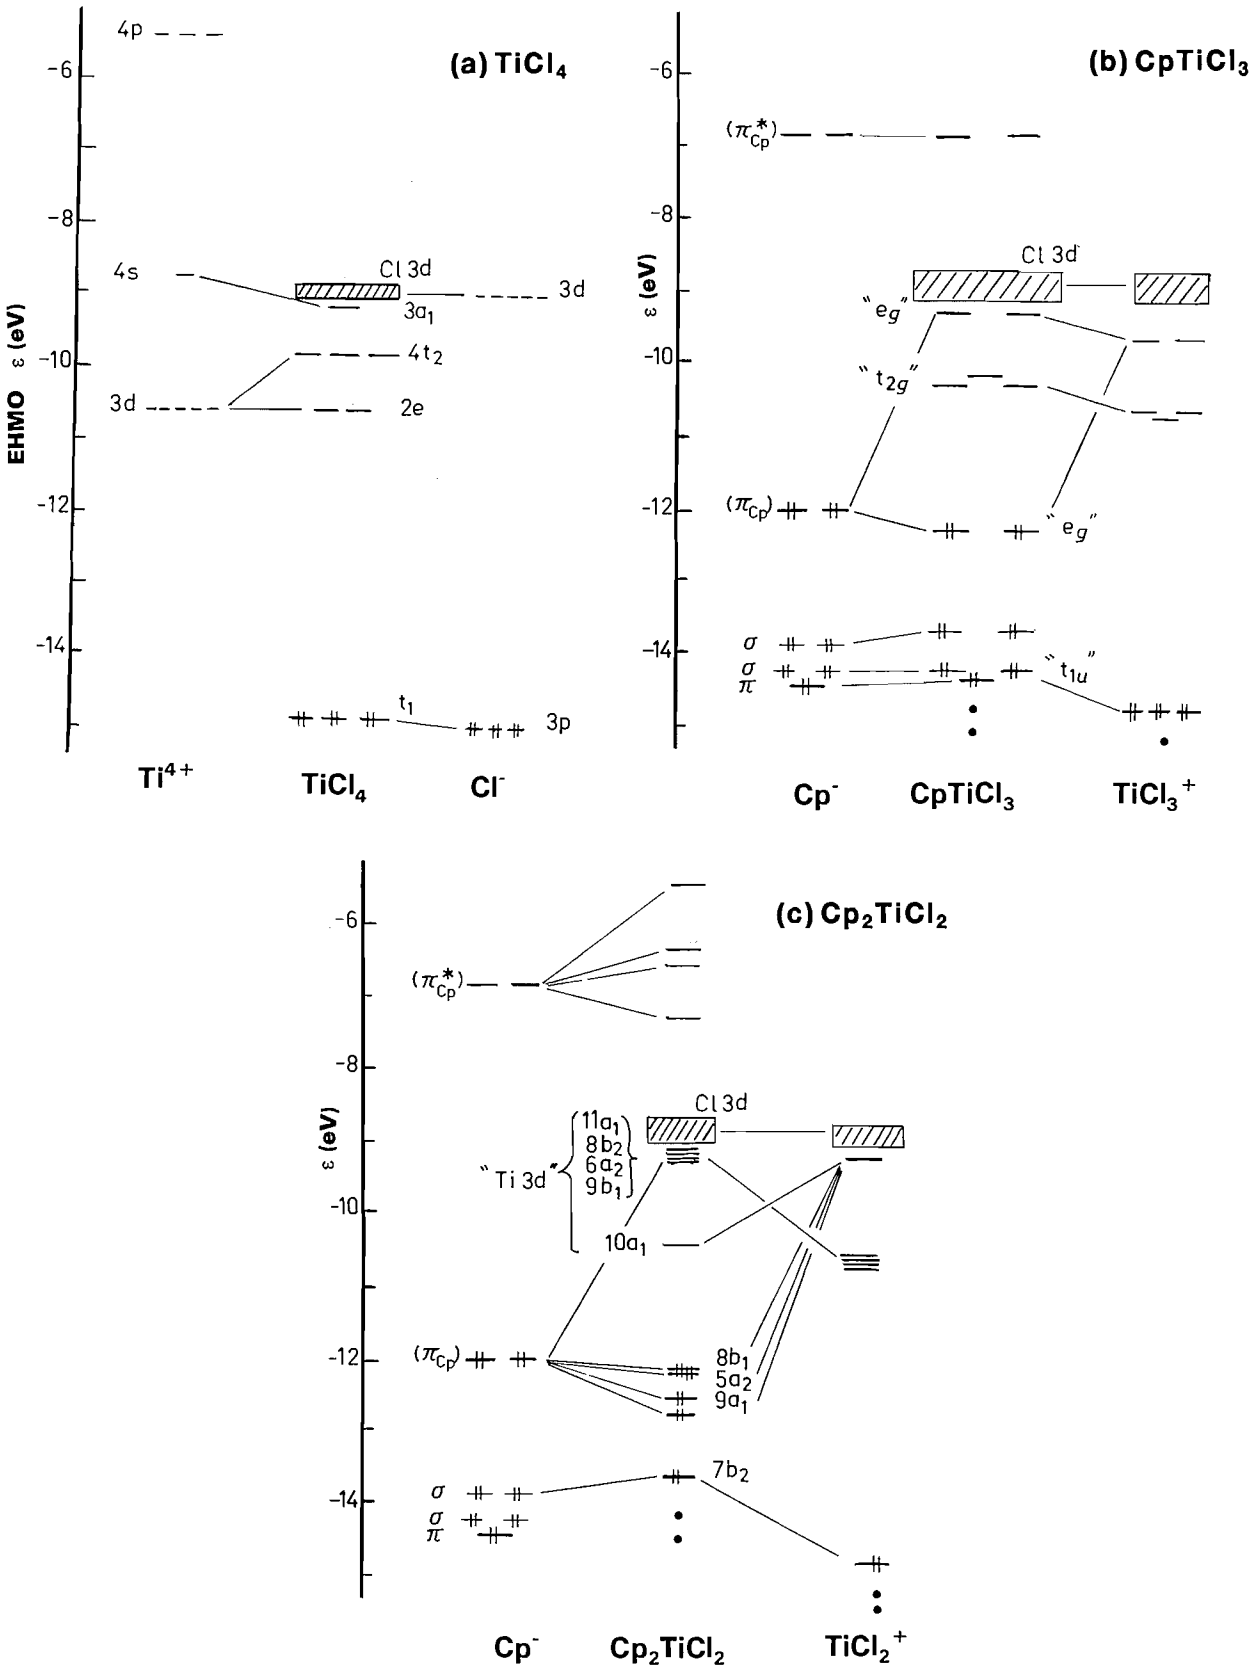

FIG. 1. Molecular orbital schemes for (*a*) $TiCl_4$, (*b*) $CpTiCl_3$, and (*c*) Cp_2TiCl_2. The orbital energies and symmetry character are based on extended Hückel calculations of the ground state. Hatched blocks represent a number of closely spaced orbitals. Only the dominant fragment origins of the MOs are shown. For $TiCl_4$ and Cp_2TiCl_2 the fragment analysis is incomplete. The "Cl_4^{4-}" (for $TiCl_4$) and Cp_2^{2-} (for Cp_2TiCl_2) units have symmetry-adapted combinations of the Cl^- and Cp^- orbitals shown, with little interaction with the Ti^{4+} AOs.

provide a better energy match with the vacant $1e$ set of $TiCl_3^+$. This can be considered to be the orbital basis for the fact that the Cp^- ligand bonds more strongly to the $TiCl_3^+$ cation than does a fourth Cl^- anion. Based on the analogy with an octahedral bonding pattern, we have labelled the three lowest energy unoccupied MOs as a "t_{2g}" MO, which, in reality, is split slightly in both the ground and excited states by about 0.15 eV. Since this splitting is much smaller than our experimental resolution we do not expect to be able to detect it. These three orbitals have primarily Ti $3d$ character (d_{z^2}, $d_{x^2-y^2}$, d_{xy}). At about 1.1 eV higher energy there are two closely spaced empty orbitals with large Ti $3d$ character, arising mainly from $TiCl_3^+$-based Ti $3d$ $1e(d_{xz}, d_{yz})$ orbitals. In accord with the octahedral analogy these two orbitals are labelled "e_g." The "e_g" orbitals also have contributions from the occupied π(Cp) e_1'' orbitals. At still higher energy one finds the π^*_{Cp} (e_2'') orbitals. Symmetry analyses of the EHMO wave functions indicates that the "e_g" MOs are of π^* character, while the "t_{2g}" are of σ^* character. For this reason, the $2e$ ("e_g") MOs of $TiCl_4$ ($CpTiCl_3$) are often referred to as $\pi^*(e$, Ti—Cl) while the t_2 ("t_{2g}") MOs are referred to as $\sigma^*(t$, Ti—Cl) (33–35). EHMO predicts that "Δ_0" for $CpTiCl_3$ is 1.10 eV in the ground state, increasing to 1.14 eV after C $1s$ excitation and to 1.28 eV after Ti $2p$ excitation. These values are significantly larger than the EHMO-predicted crystal field splitting in $TiCl_4$, consistent with the general rule that O_h are larger than T_d crystal field splittings ($\Delta_t = 5/9\ \Delta_0$ if metal–ligand bond lengths are the same). Based on applying on-site dipole selection rules to the MO scheme for $CpTiCl_3$, we expect intense peaks associated with the "t_{2g}" and "e_g" levels in the Ti $2p$ spectrum as well as strong C $1s \rightarrow \pi^*_{Cp}$ transitions and observable C $1s \rightarrow$ "$2e_g$" transitions in the C $1s$ spectrum of $CpTiCl_3$. The effect of core hole relaxation on the energy and character of the unoccupied orbitals and thus on the transition intensity should be taken into account by the EICVOM approach (10, 26). The intensities of both Ti $2p$ and C $1s$ core excitation to the "t_{2g}" and "e_g" levels should be informative with regard to Ti—Cp bonding.

The orbital scheme for Cp_2TiCl_2 is presented in Fig. $1c$. As for the other two species, the low-lying unoccupied orbitals are mainly of Ti $3d$ character. Because of the low symmetry of this complex (at best C_{2v} if the Cp rings are appropriately aligned) the five Ti $3d$ orbitals are nondegenerate and span a range of 1.38 eV in the ground state according to the EHMO results (1.38 eV with C $1s$ and 2.14 eV with Ti $2p$ excitation). The $10a_1$ LUMO has large Ti $3d_{z^2}$ and Ti $d_{x^2-y^2}$ character. The next four orbitals ($9b_1$, $6a_2$, $8b_2$ and $11a_1$) are mainly Ti $3d$ in character, but do have some admixture of Cl $3d$ and π^*_{Cp} character. The relative orbital energies and composition predicted by EHMO ground state calculations are in agreement with Fenske–Hall ($36a$) and SCF-SW-Xα ($36b$) calculations for Cp_2TiCl_2. Compared to $CpTiCl_3$, Cp_2TiCl_2 is expected to have a wider range of Ti $2p \rightarrow 3d$ transitions, with perhaps a broader and (or) structured higher energy peak, and a significant C $1s \rightarrow$ "Ti $3d$" contribution.

These considerations of the frontier orbitals of these three compounds indicate that substitution of one or two Cp^- for Cl^- ligands in $TiCl_4$ does not affect the dominant Ti $3d$ character of the low-lying unoccupied electronic structure very much, although there is a reversal of symmetry between $TiCl_4$ and $CpTiCl_3$ and a larger splitting in Cp_2TiCl_2. This suggests that all three molecules should have closely related geometries and core excitation spectra. Critical geometric parameters for all three molecules are summarized in Table 1. The Ti—Cp bond strength in $CpTiCl_3$ is 74 kcal mol^{-1} (37), similar to that of the Ti—Cl bond in $TiCl_4$. Even in Cp_2TiCl_2, where two of the Cl ligands in $TiCl_4$ have been replaced, there is relatively little change in molecular stability, although there is a significant increase in the Ti—Cl bond length.

The occupied MOs of all three molecules have been investigated by photoelectron spectroscopy (34, 38, 39). There are three major bands in the photoelectron spectrum of $CpTiCl_3$ that are associated with MOs derived largely from the Cl $3p$ orbitals but with some Ti-orbital participation. These are shifted by ~1 eV to lower energy relative to the corresponding bands of $TiCl_4$. Such a red shift has been attributed to the π-donor nature of the Cp ring pointing towards the central Ti atom, which reduces the bonding strength of the Cl lone pairs. The reduced Ti—Cl bonding is reflected in the increased Ti—Cl bond length with Cp substitution. PES has provided direct evidence that the Cp ring influences the Ti—Cl bonding through shifts in the occupied MO levels. To our knowledge, there has not been an experimental study of the *unoccupied* MOs of $CpTiCl_3$ or Cp_2TiCl_2 by electron transmission or core excitation spectroscopy.

C $1s$ spectra of $CpTiCl_3$ and Cp_2TiCl_2

The C $1s$ spectra of $CpTiCl_3$ and Cp_2TiCl_2 are presented in Fig. 2 on an oscillator-strength-per-carbon-atom intensity scale. The hatched line indicates the C $1s$ ionization potential (IP) estimated from that of $3d$ metallocenes (40). Energies, term values, and proposed assignments are summarized in Table 2.

The C $1s$ spectra are characterized by four very intense features: two sharp bands below the IP and two broader features at higher energy, above the C $1s$ IP. The first feature in the spectra of both species is attributed to C $1s$ excitations to final orbitals of mainly Ti $3d$ character, although within the EICVOM model it is the C $2p$ component of these MOs which gives rise to the transition intensity. In $CpTiCl_3$ there are two resolved components of the first band. These are attributed to the "t_{2g}" (284.4 eV) and "e_g" (285.5 eV) levels. The much higher intensity of the C $1s \rightarrow$ "e_g" transition is consistent with its larger C $2p$ admixture (see Fig. 1 and the earlier discussion of the MO structure). The "Ti $3d$" band in the C $1s$ spectrum of Cp_2TiCl_2 does not show any resolved structure although it is significantly broader than the experimental resolution and exhibits low- and high-energy shoulders on closer inspection. A Gaussian curve fit, which required three components for a satisfactory fit, was used to derive the sub-band energies reported in Table 2. The main C $1s$ spectral feature, occurring at 287.0 eV in both species, is the C $1s \rightarrow \pi^*_{Cp}$ transition. As in metallocenes (5) only a single (C $1s^{-1}$, π^*_{Cp}) feature is observed. Splittings associated with symmetry reduction or interaction of π^* orbitals on the two adjacent Cp rings in Cp_2TiCl_2 might be expected. These are either smaller than our experimental resolution or, alternatively, core hole localization distorts the electronic structure such that only the excitation to the lowest energy π^*_{Cp} orbital has appreciable intensity. The latter situation was recently determined to be operative in metal carbonyl complexes (10). The two broad bands in the C $1s$

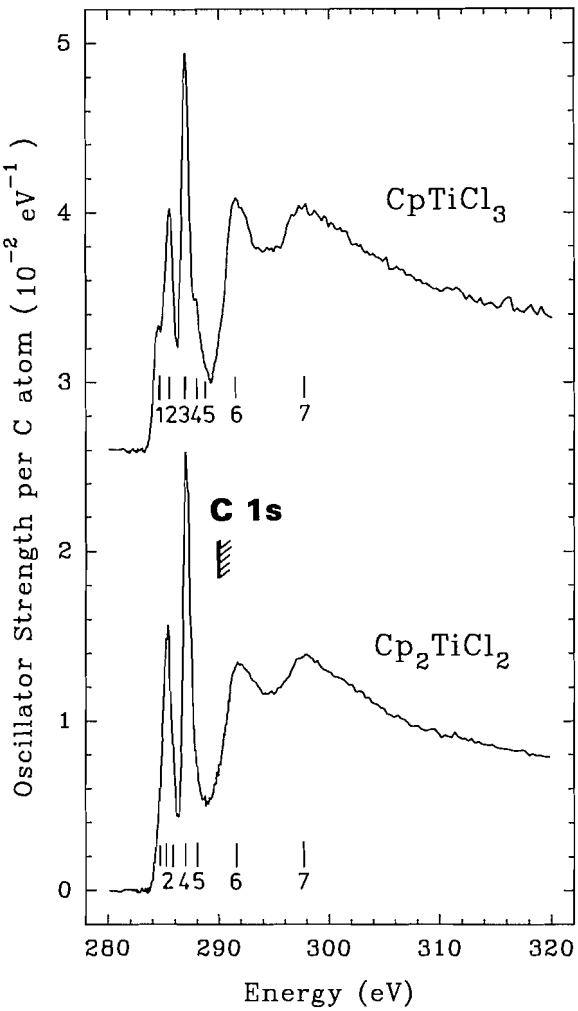

FIG. 2. Carbon 1*s* oscillator strength spectra of $CpTiCl_3$ and Cp_2TiCl_2 derived from electron energy loss spectra recorded using 2.5 keV final electron energy, 0.6 eV fwhm resolution, and 2° scattering angle. The hatched lines indicate the estimated C 1*s* IP. The spectra have been scaled on a basis of oscillator strength per carbon. The $CpTiCl_3$ spectrum has been offset vertically by 0.026 $(eV)^{-1}$ for clarity.

continuum are attributed to resonances associated with quasi-stationary states corresponding to (C $1s^{-1}$, σ^*) configurations.

The EHMO predictions of the C 1*s* spectra of $CpTiCl_3$ and Cp_2TiCl_2 are presented in Fig. 3. The EHMO spectra are plotted on the orbital energy scale. A line diagram of the spectral contributions from each of the chemically distinct carbon sites (three in $CpTiCl_3$; five in Cp_2TiCl_2) (C_s, crystal geometry (25)) is also presented. The Gaussian broadened weighted sum, scaled relative to the MO transitions in a way to approximate the experimental intensities, has been combined with the oscillator strength for ionization of atomic carbon to construct the "EHMO-predicted spectrum." The experimental C 1*s* spectrum for each species has also been plotted, with the energy scale set so as to align the sharpest feature with the maximum in the EHMO-predicted spectrum. The difference in the EHMO orbital energy scale and the experimental transition energies is 295.0 eV for $CpTiCl_3$ and 294.7 eV for Cp_2TiCl_2. Ideally the orbital energies in the EICVOM approach should be equal to the negative of the experimental term values (T = IP − E). The EHMO-EICVOM calculations for the C 1*s* spectra of these two species give orbital energies that are about 5 eV greater than the experimental term values (T = IP − E). A similar discrepancy has been found in all previous comparisons of EHMO-EICVOM predicted and experimental C 1*s* spectra (5–10, 22, 28, 29).

The splitting of the first band in the C 1*s* spectrum of $CpTiCl_3$ corresponds to the "t_{2g}"–"e_g" Δ_0 (10Dq) crystal field splitting in the quasi-octahedral field of $CpTiCl_3$. The experimental splitting (1.07 eV) is in good agreement with that predicted by EHMO (1.14 eV in the C 1*s* excited state, based on the maximum separation in the $C_{2,5}$ components). The greater intensity of the C $1s \rightarrow$ "e_g" transition (relative to the C $1s \rightarrow$ "t_{2g}" transition) is attributable to the larger C 2*p* character which arises from the interaction of $TiCl_3$ 1*e* orbitals with the Cp ring e_1'' MOs. In principle the C $1s \rightarrow$ "t_{2g}" transition should exhibit a further splitting. However, according to the EHMO results, this will be only about 0.15 eV, considerably smaller than our experimental resolution (0.6 eV).

While the C 1*s* spectrum of Cp_2TiCl_2 also contains low-lying C 1*s* excitations to MOs of large "Ti 3*d*" character, the details of the first band differ significantly from that for $CpTiCl_3$. In particular, the band is rather broad with signs of both a low-energy and a high-energy shoulder. The positions of the three features listed in Table 1 were derived from a fit of three Gaussian lines to band 1. The absence of any resolved splitting reflects the lower symmetry of this complex and thus the larger number of MOs to which the Ti 3*d* orbitals contribute. According to the EHMO calculations C 1*s* excitations to the $10a_1$ LUMO only occur from two of the five carbons of each Cp ring. Thus EHMO predicts a low-intensity first peak in the C 1*s* spectrum, which is a reasonable match, with regard to relative position and intensity, to the low-energy shoulder of the first band.

The prominent spectral feature around 287 eV in both complexes is assigned to C $1s \rightarrow \pi^*_{Cp}$ transitions. Its large oscillator strength is ascribed to the good dipole-spatial overlap between the carbon 1*s* orbital and the large C 2*p* character of the π^*_{Cp} orbitals. In the ground state of $CpTiCl_3$ the π^* e_2'' MOs are energetically well separated from other orbitals (see Fig. 1) and have little interaction with $TiCl_3$ orbitals. A dominant π^*_{Cp} character is supported by the EHMO calculation, which predicts very little variation of the transition energy for C 1*s* excitations at different sites. In Cp_2TiCl_2 the complex contains four unoccupied orbitals of mainly π^*_{Cp} character. In the ground state there is a rather large energy splitting of these orbitals (1.7 eV). If this splitting and a distributed C 2*p* character was retained in the π^*_{Cp} MOs of the C 1*s* excited states one would expect a number of resolved intense π^*_{Cp} features or at least a significant broadening of the π^*_{Cp} feature in Cp_2TiCl_2 relative to that in $CpTiCl_3$. This is not the case. The EICVOM-EHMO calculations indicate that there are a number of C $1s \rightarrow \pi^*_{Cp}$ transitions distributed over almost 3 eV. However, due to the strong polarizing effect of the core hole on the π^*_{Cp} orbitals, the only intense transition is that to the lowest energy π^*_{Cp} MO at each site (see the line diagrams in Fig. 3). Relative to $CpTiCl_3$, EHMO predicts some broadening and a higher energy shoulder for the π^*_{Cp} feature of Cp_2TiCl_2. Experimentally the π^*_{Cp} feature in Cp_2TiCl_2 is narrower than that in $CpTiCl_3$.

TABLE 2. Energies (E, eV), term values (T, eV), and proposed assignments for features in the C 1s spectra of $CpTiCl_3$ and Cp_2TiCl_2

$CpTiCl_3$			Cp_2TiCl_2			Assignment (final orbital)	
No.	E	T	No.	E	T	$CpTiCl_3$	Cp_2TiCl_2

There is a broad peak and high-energy shoulder around 288–289 eV in the C 1*s* spectrum of $CpTiCl_3$. EHMO does not predict any spectral features in this area. This is consistent with these features arising from excitations to orbitals with a large Rydberg character, such as the 3*p*/C–H states seen in the C 1*s* spectra of many hydrocarbon species around this energy (41). A corresponding signal is not observed in Cp_2TiCl_2 but the spectrum does not return to the baseline between the π^*_{Cp} feature and the continuum onset at 290 eV, indicating that there are unresolved states at these energies.

The first band in the continuum at ~291 eV is attributed to C $1s \rightarrow \sigma_1^*$ (C=C) excitation while the broader, higher energy, asymmetric band centered around 298 eV is ascribed to C $1s \rightarrow \sigma_2^*$ (C=C) excitation. The σ_1^* and σ_2^* terminology is adopted from earlier interpretations of the C 1*s* spectra of a large number of six-member aromatic species (benzene, pyridine (42), substituted benzenes (43)) as well as other organometallic compounds containing η^5-C_5H_5 ligands (5, 10), which all show a characteristic pattern of two resonances around 291 and 298 eV in the C 1*s* continuum. The σ_1^* (C=C) band in both of these Ti species is about 1 eV below its counterpart in ferrocene (5) but the σ_2^* (C=C) band occurs at the same energy. The net effect is that there is a larger energy splitting between the two σ* resonance features in $CpTiCl_3$ or Cp_2TiCl_2 than in $FeCp_2$. This indicates there is a stronger interaction between the adjacent C—C bonds of $CpTiCl_3$ relative to that in ferrocene, consistent with the results from IR studies (44). The possible cause of this might be the difference between the partially charged $Cp^{\delta-}$ ligand in the ionically bonded $CpTiCl_3$ molecule and the relatively neutral Cp ring in the more covalently bonded $Fe(Cp)_2$ complex. The extra electron (or charge) density (δ-) transferred from Ti to Cp would partially "populate" one of the e_1'' (π) bonding orbitals of Cp, which is only half filled in free Cp. This would increase the C—C bond strength and lead to a stronger C—C bond interaction. Thus the details of the C 1*s* spectra of these complexes support the view that the Ti–Cp interaction in these complexes is strongly ionic.

Overall, the C 1*s* spectra of $CpTiCl_3$ and Cp_2TiCl_2 resemble those of other metallocenes (5, 10), especially the π^*_{Cp} feature and the positions and relative intensities of the continuum features. The resemblance reflects the fact that the virtual electronic structure of all cyclopentadienyl complexes is rather similar and that the chlorine atoms have very little influence on carbon 1*s* excitation due to poor orbital overlap. However, there are systematic trends in the intensities and energies of the two major bands below the C 1*s* ionization threshold. The most notable variation of intensity is in the first band of C $1s \rightarrow$ metal 3*d* character. It has the largest oscillator strength (peak area) in the $CpTiCl_3$ and Cp_2TiCl_2 complexes and the smallest in nickelocene (5). This intensity variation is directly related to the increasing number of 3*d* electrons as the 3*d* period is traversed, which reduces the empty 3*d* character and thus the number/density of low-lying unoccupied MOs of mixed Cp – metal 3*d* character. The smaller width of the first peak in ferrocene, cobaltocene, and nickelocene (5) relative to that of $CpTiCl_3$ is attributed to the absence of C $1s \rightarrow 2t_{2g}^*$ (3*d*) transitions in the late-period metallocenes because the $2t_{2g}^*$ orbitals are filled in these species. The particularly low intensity of the first peak in the C 1*s* spectra of cobaltocene and nickelocene is ascribed to the partial occupancy of the $4e_{1g}^*$ orbital (5).

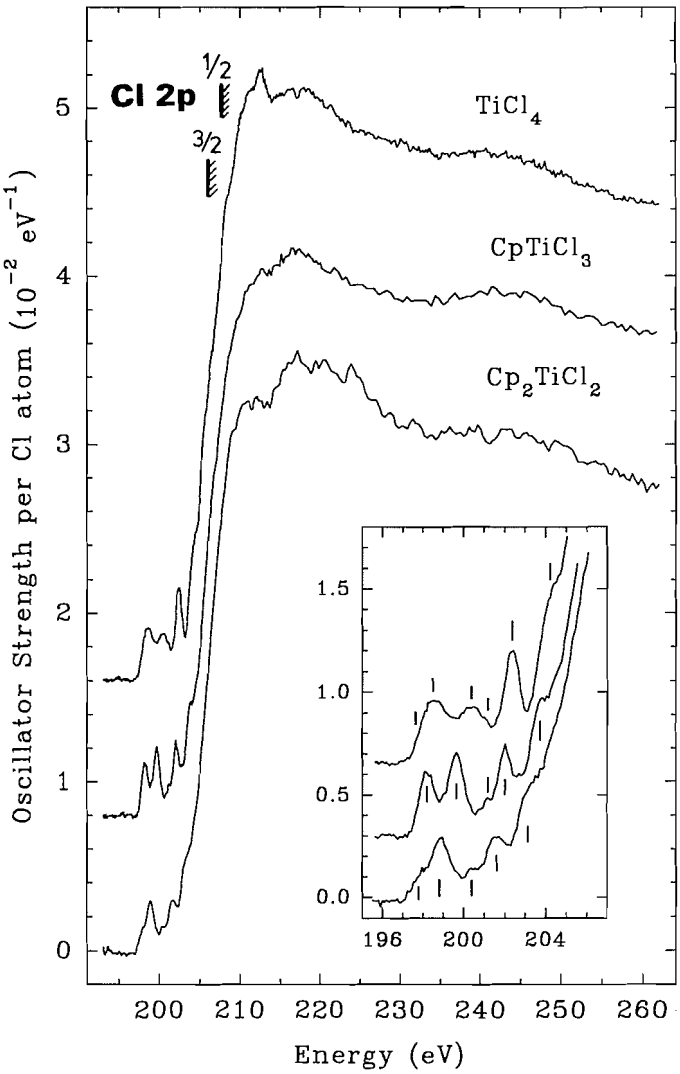

FIG. 4. Chlorine 2*p* oscillator strength spectra of $TiCl_4$, $CpTiCl_3$, and Cp_2TiCl_2 (presented on a per-Cl basis). See Fig. 2 for experimental details. The hatched lines indicate the estimated Cl 2*p* IPs. The $CpTiCl_3$ and $TiCl_4$ spectra have been offset vertically by 0.008 and 0.016 $(eV)^{-1}$ for clarity. The inset is an expansion of the pre-edge structure, plotted in the same order as the main plot.

Cl 2*p* spectra

The Cl 2*p* spectra of Cp_2TiCl_2, $CpTiCl_3$, and $TiCl_4$ are presented in Fig. 4 (on an oscillator-strength-per-Cl intensity scale), while an expansion of the weak pre-edge structure is presented as an insert. The hatched lines indicate the location of the Cl $2p_{3/2}$ and Cl $2p_{1/2}$ IPs. These have been measured for $TiCl_4$ (45) and are assumed to be the same in the other two compounds since Cl 2*p* IPs are not strong functions of the Cl environment (40). The energies, term values, and proposed assignments of the Cl 2*p* spectral features are listed in Table 3. The Cl 2*p* spectra of these three species are very similar, although there are minor variations in the pre-edge features, probably associated with the changing molecular symmetry. The similarity of these spectra is consistent with similar Ti—Cl bonding in all three compounds. Cl 3*s*/3*p* valence orbitals are completely filled in a Cl^- ligand so that core excitations to unoccupied valence

MOs are likely to be weak. Also, Cl $2p$ excitation samples the Cl $3s$ and Cl $3d$ character of the unoccupied MOs. This is likely to be small for low-lying unoccupied orbitals since the Cl $3s$ AOs contribute mostly to occupied MOs and the Cl $3d$ AOs are mostly involved in states above threshold rather than in the discrete structure. Both of these points explain the relatively weak character of the pre-edge structure in these Cl $2p$ spectra.

The first peak at 198.5 eV in $TiCl_4$ has a term value of more than 8 eV. This is a clear indication that the Cl $2p$ excited state has large valence character since the lowest energy Rydberg states have term values smaller than 6 eV. We assign this feature to Cl $2p \rightarrow (4t_2)$ transitions. Below this peak, there appears to be a weak shoulder around 197.8 eV, which is considered to be associated with Cl $2p \rightarrow 2e$ transitions. The 0.7 eV difference in energy between these two features is a measure of Δ_t for Cl $2p$-excited $TiCl_4$. This splitting is smaller than that found in the ground state (0.95 eV) (31). The lower value may be a consequence of differences in core hole relaxation in the two (Cl $2p^{-1}$, Ti $3d$) states. Based on the Cl $2p$ spin-orbit splitting in $TiCl_4$ (1.1 eV (45, 46)), the Cl $2p_{1/2} \rightarrow 4t_2/2e$(Ti $3d$) transitions are expected to occur under the high-energy side of the first band. The weak shoulder at 200.4 eV is attributed to Cl $2p_{3/2} \rightarrow 4s$ Rydberg transitions. The sharpest peak in the Cl $2p$ spectrum of $TiCl_4$ (202.4 eV) is assigned to Cl $2p_{3/2} \rightarrow 3a_1$ transitions, an MO derived mainly from Cl $3d$ orbitals. This feature also may contain contributions from Cl $2p_{1/2} \rightarrow$ Cl $4s$ transitions, the spin-orbit partner of the 200.4 eV feature. The large intensity is believed to be associated with the strong Cl $2p_{3/2} \rightarrow 3a_1$ resonance, as the $3d$ is usually much stronger than the $4s$ channel due to better spatial overlap. The corresponding Cl $2p_{1/2} \rightarrow 3a_1$ transition is likely the shoulder at 204.2 eV, which probably also contains other underlying Rydberg transitions and the leading edge of the Cl $2p$ continuum.

The pre-edge regions of the Cl $2p$ spectra of $CpTiCl_3$ and Cp_2TiCl_2 also exhibit particularly low-lying structures (those below 200 eV) that are attributed to Cl $2p$ excitations to the Cl $3d$ component of the low-lying "Ti $3d$" orbitals. The change from a well-structured doublet in $CpTiCl_3$ to a broader band in Cp_2TiCl_2 is similar to that observed for the first band in the C $1s$ spectra of these species and likely reflects the differences in molecular symmetry and thus Ti $3d$ splittings in these two compounds. The relatively sharp band around 202 eV seen in all three molecules is attributed primarily to Cl $2p \rightarrow 3d$ transitions.

Relative to $1s$ ionization, $2p$ ionization continua have a much more gentle rise at threshold. This is the result of a delayed onset for the dominant $2p \rightarrow \epsilon d$ ionization channel, which is associated with a centrifugal barrier. This atomic phenomenon is the cause of the broad maximum around 215 eV in the Cl $2p$ spectra. Weak structure superimposed on the top of this maximum may correspond to double excitations: monopole valence shell excitations that are a consequence of the large change in charge at the core excited Cl atom. The broad structure around 240 eV is attributed to an extended fine structure oscillation associated with backscattering by Cl or Ti. Similar broad features have been observed in the gas phase Cl $2p$ spectra of CH_xCl_{4-x} (x = 0–3) species, which has been analyzed as EXAFS (47).

Ti 2p spectra

The Ti $2p$ spectra of these three compounds are presented in Fig. 5. The hatched lines indicate the Ti $2p_{3/2}$ and $2p_{1/2}$ IPs. Those for $TiCl_4$ are taken from gas phase XPS (45). Those for Cp_2TiCl_2 are derived from its solid state IPs (48) by applying a correction of +7.1 eV, derived from XPS measurements of the Ti $2p$ IPs of gaseous and solid $TiCl_4$ (46). The Ti $2p$ IPs of $CpTiCl_3$ were determined by linear interpolation of the IPs of $TiCl_4$ and Cp_2TiCl_2. The energies, term values, and proposed assignments are listed in Table 4.

Each spectrum exhibits two main bands, with each band exhibiting a similar but not identical fine structure. The major splitting is associated with the Ti $2p_{3/2}$ (L_3) and $2p_{1/2}$ (L_2) spin-

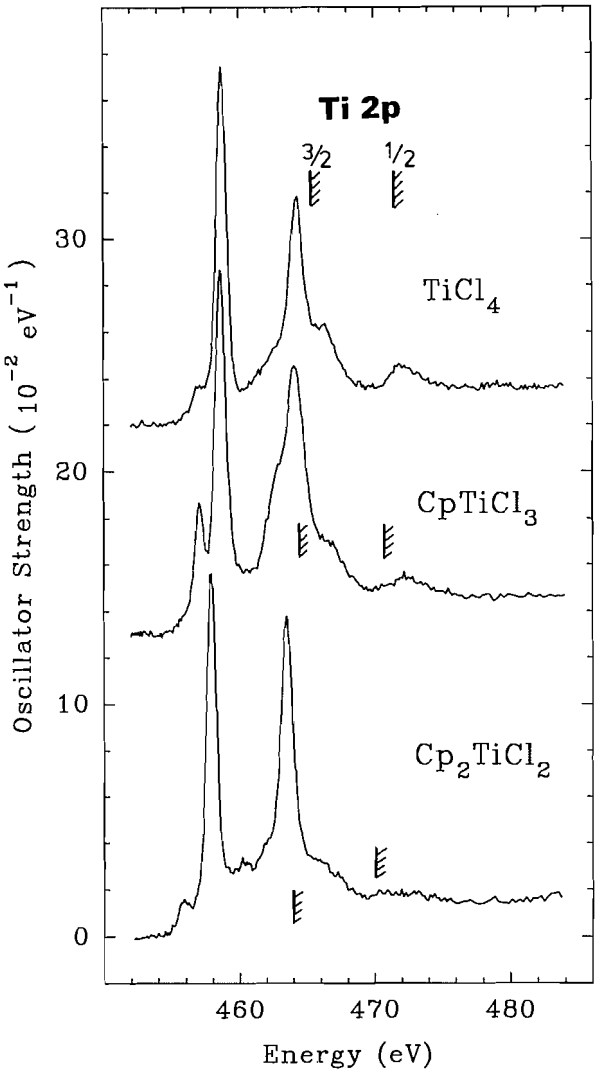

FIG. 5. Titanium 2*p* oscillator strength spectra of $TiCl_4$, $CpTiCl_3$, and Cp_2TiCl_2. The hatched lines indicated measured (45, 46, 48) or estimated Ti 2*p* IPs. See Fig. 2 for experimental details.

orbit splitting. The separation of the most intense L_3 and L_2 features is 5.6, 5.4, and 5.6 eV for $TiCl_4$, $CpTiCl_3$, and Cp_2TiCl_2, respectively. This is essentially the same L_3–L_2 splitting as observed in the Ti 2*p* X-ray absorption spectra of TiO_2 (5.5 eV (16, 49)) and $FeTiO_3$ (5.4 eV (16)). However, the excitation spin-orbit splitting is about 0.5 eV **smaller** than the spin-orbit splitting found in the XPS spectrum of $TiCl_4$ (6.1 eV (45, 46)). This difference may be associated with exchange interactions that modify the energies of the Ti 2*p* excited states (16).

Currently, there are two major theoretical models dealing with the electronic structures of transition metal complexes: the crystal field theory treating a perturbed metal atom or ion; and molecular orbital theory, which, when combined with a consideration of the crystal field splittings of the metal orbitals is denoted ligand field theory. Figure 6 presents the EHMO predictions for Ti 2*p* → 3*d* excitation in all three complexes. (Fig. 6*a*) and selected crystal field calculations for Ti^{4+} (15), in comparison with the experimental Ti 2*p* spectra. Each L_3 and L_2 band has two main components, with additional weaker structure. Within the atomic multiplet – crystal field picture (15) this splitting (e.g., that between the weak 457 eV and the much stronger 459 eV peak in $TiCl_4$) is associated with the crystal field splitting (Δ_t in $TiCl_4$) modified by a strong exchange interaction. The splittings in the Ti 2*p* experimental spectra are similar to those seen in other Ti compounds (e.g., TiO_2 (2.5 eV) (16, 49) and $FeTiO_3$ (2.2 eV) (16)) but they are larger than those found in the corresponding C 1*s* spectrum (0.8–0.9 eV) or those predicted by EHMO (0.7–1.4 eV for the ground state, and 1.0–2.1 eV for Ti 2*p* excitation). This is a clear indication of the strong coupling between crystal field and atomic multiplet (exchange) interactions in metal 2*p* excitation. Within the MO picture the separation is explained by the splitting of the "Ti 3*d*" MOs dictated by the symmetry of each compound. The splitting of the 3*d* orbitals in these three compounds is shown by the line diagrams in Fig. 6*a*, which indicate the energies and Ti 3*d* densities in the unoccupied orbitals of equivalent core species (e.g., VCl_4^+ for $TiCl_4$). The pattern in each case illustrates very clearly the preceding discussion of the lowest energy bands in the C 1*s* and Cl 2*p* spectra of these compounds: *e* lies below t_2 in $TiCl_4$; "t_{2g}" lies below "e_g" in $CpTiCl_3$ with smaller splittings of each orbital; and there are five relatively widely spaced orbitals of large 3*d* character in Cp_2TiCl_2. The assignments proposed in Table 4 are based on comparison with the EHMO calculations.

It is clear that the EHMO treatment is much less successful at describing the discrete portion of the Ti 2*p* spectra than it was at describing the C 1*s* spectra. In particular, the relative intensities of the lower and higher energy Ti 2*p* components are poorly reproduced. However, it is noteworthy that EHMO predicts that the lowest energy band of $CpTiCl_3$ should be more intense than in $TiCl_4$ or Cp_2TiCl_2. This is seen experimentally, although not to the extent that EHMO predicts. Since EHMO cannot explicitly treat the exchange interactions of atomic multiplet theory (15) it is not surprising there is only limited agreement with experiment.

One goal of investigating the core spectra of these complexes was to test the simple "π^*/σ^*" model for metal 2*p* spectra proposed earlier, based on an investigation of the metal 2*p* spectra of a series of largely covalent complexes (7). One of the predictions of that model was a continuous increase in the intensity of the lower energy "$d\pi^*$–$p\pi^*$" band relative to the higher energy "$d\sigma^*$–$p\sigma^*$" band as the number of Cp rings is increased. Clearly the experimental spectra do not show this effect. These comparisons indicate that both the simple "π^*/σ^*" model and conventional semiempirical MO treatments do not correctly account for some important interactions, such as the largely ionic ligand–metal interactions in these complexes.

Because of the dominant ionic character of these complexes the atomic multiplet – crystal field model (14–20) should be well suited to describing the Ti 2*p* spectra. If one assumes a completely ionic bonding description, their Ti 2*p* spectra should be compared to the crystal field analysis for (p^6, d^0) → (p^5, d^1) transitions in the appropriate symmetry (T_d for $TiCl_4$, O_h for $CpTiCl_3$, and C_{2v} for Cp_2TiCl_2). However, only results for cubic environments have been reported in the literature (15–17). There are significant differences between the appearance of the Ti 2*p* spectra in the two papers that report spectra for Ti^{4+} (15, 17), although similar calculational methods were used. The Ti L_2 features are much more intense than the corresponding L_3 features in the results reported by van der Laan and Kirkman

[a]Calibration: $TiCl_4$ +57.6(1) eV; $CpTiCl_3$: +57.5(1) eV; Cp_2TiCl_2: +56.8(2) relative to N $1s \rightarrow \pi^*$ in N_2 (401.1 eV).
[b]IPs from XPS (45).
[c]The Ti $2p$ IPs of Cp_2TiCl_2 were derived by adding the difference of the gas minus the solid IPs of $TiCl_4$ (7.1 eV (46)) to the IPs of solid Cp_2TiCl_2 (48). The IPs of $CpTiCl_3$ were obtained by interpolation, assuming a linear chemical shift with number of Cl atoms.

(17) compared to the results of de Groot et al. (15). The differences appear to be related to a less complete treatment of the line broadening effects in ref. 17. Since the Ti $2p$ spectra predicted for octahedral and tetrahedral fields are virtually identical for the same magnitude of crystal field parameter (17) and since the L_3:L_2 intensity ratios and relative line widths in the calculations of de Groot et al. (15) are more similar to our experimental results, we have chosen to compare our $TiCl_4$ and $CpTiCl_3$ spectra with the (Ti^{4+} in O_h) results of de Groot et al. (15). Also, since there are no results available for (Ti^{4+} in C_{2v}), we have used the (Ti^{4+} in O_h) results as a very crude first-order comparison to the Ti $2p$ spectrum of Cp_2TiCl_2.

De Groot et al. (15) report a series of spectra calculated for different crystal field strengths. We have selected the spectra that most closely match the experimental results, namely Δ_0 = 1.0, 1.2, and 1.0 eV for $TiCl_4$, $CpTiCl_3$, and Cp_2TiCl_2, respectively. These literature spectra are compared with experiment (Fig. 6*b*) after shifting the calculated energy scales by 6.5, 6.8, and 7.2 eV and scaling the intensity for best match. The chosen energy shifts are smaller but in the same sense as the Ti $2p$ chemical shifts (45, 46, 48). The decrease in the Ti $2p$ orbital energy is probably the main factor governing the shift of the main L_3 spectral feature from 456.9 eV in $TiCl_4$ down to 455.8 eV in Cp_2TiCl_2. Since IPs and excitation energies differ systematically due to differences in core hole screening, it is reasonable to postulate experimental–theory shifts in this series of compounds that differ from their Ti $2p$ chemical shifts.

As Fig. 6*b* shows, there is good agreement between the crystal field – atomic multiplet prediction and experiment for $TiCl_4$ although the intensity of the L_2 signal relative to the L_3 signal is overestimated. We note that this discrepancy would be at least a factor of two worse if we had chosen to compare with the (Ti^{4+} in T_d) results of van der Laan and Kirkman (17) even though the energy pattern is very similar. Similarly the de Groot et al. (15) prediction for the Ti $2p$ spectrum of a Ti^{4+} ion with Δ_0 = 1.2 eV is in good agreement with the Ti $2p$ spectrum of $CpTiCl_3$. In particular, increasing the crystal field parameter increases the intensity of the first band ("t_{2g}") relative to the second ("e_g"), the major change between the spectra of $TiCl_4$ and $CpTiCl_3$. The spectrum of Cp_2TiCl_2 should not be expected to be well reproduced by any of the calculations for Ti^{4+} in O_h since the symmetry of the crystal field plays a major role in determining the spectral shape. Thus it is not surprising that the best match to the O_h predictions is significantly worse for Cp_2TiCl_2 than for the other two compounds. However, we interpret the reduction in intensity of the first band relative to the second as an indication of a lower effective crystal field in Cp_2TiCl_2 than in $CpTiCl_3$, consistent with the much larger Ti—Cl bond length (Table 1). This interpretation is supported by the need to select a calculated spectrum with a lower Δ_0 value to find the best possible match to Cp_2TiCl_2.

Another possibility is that the Ti $2p$ spectra of the Cp complexes should be compared with calculations for Ti^{3+} or even Ti^{2+}, if one emphasizes a more covalent description of the Ti—Cp bond. The atomic multiplet – crystal field calculations (16, 17) indicate that a much more complex spectrum covering a wider spectral region would be expected on account of the greater number of states associated with (p^5, d^2) or (p^5, d^3) configurations than with the (p^5, d^1) configuration. Based on the relatively simple appearance of the measured spectra we do not believe a description based on Ti^{3+} or Ti^{2+} is appropriate. Thus the Ti $2p$ spectra support an ionic bonding model for all three complexes. Interestingly, based on PES and MO calculations Bruce et al. (50) have suggested that permethylation of the Cp rings in Cp_2TiCl_2 gives rise to an effective one-electron reduction. Observation of a Ti $2p$ spectrum of $Cp^*_2TiCl_2$ ($Cp^* = \eta^5$-$C^5(CH_3)_5$), which was significantly more complex than that of Cp_2TiCl_2, would be evidence in favour of this suggestion.

The relatively small difference in the crystal field values deduced from matching the experimental and calculated spectra supports the idea that Cl and Cp ligands generate a comparable ligand field. The peak separations in the experimental Ti $2p$ spectra are 1.8, 1.9, and 2.1 eV in $TiCl_4$, $CpTiCl_3$, and Cp_2TiCl_2, respectively. This is about 50% larger than the crystal field parameter estimated from the best match

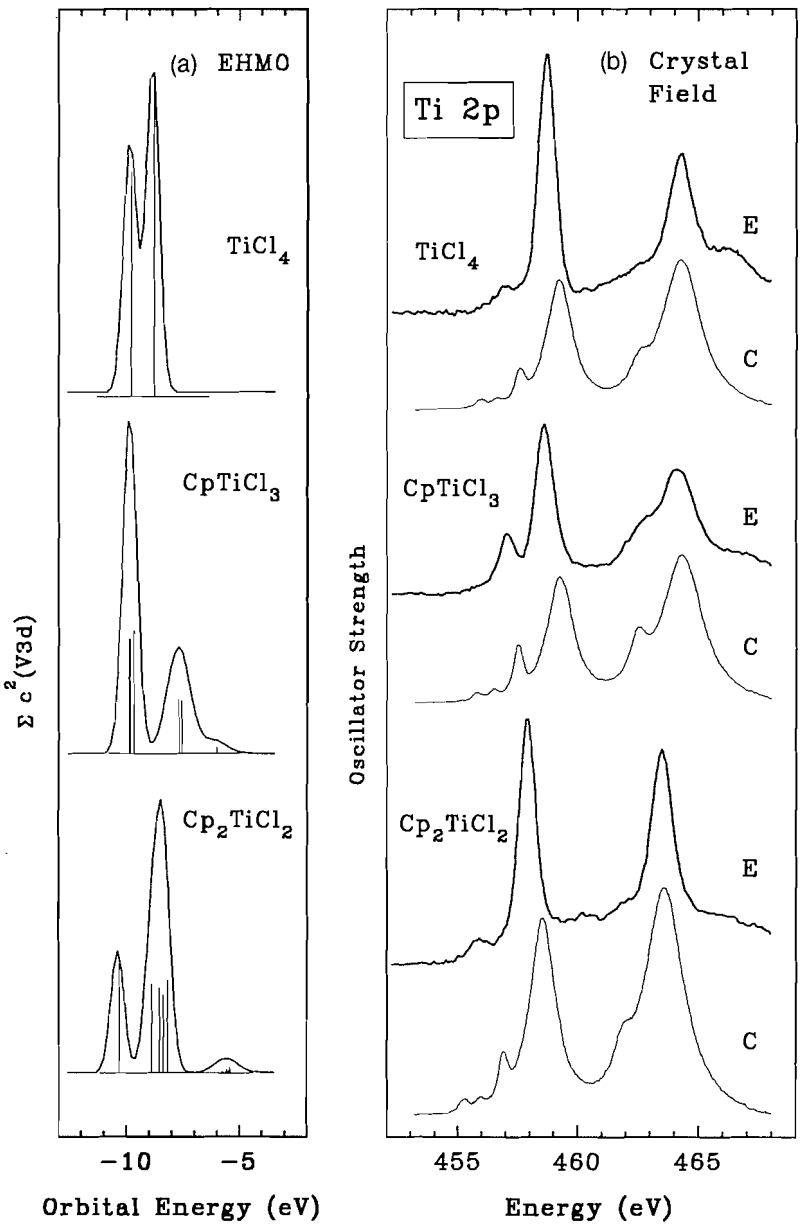

FIG. 6. (*a*) EHMO calculation of the Ti $2p \rightarrow 3d$ transitions in $TiCl_4$, $CpTiCl_3$, and Cp_2TiCl_2. (*b*) Expanded presentation of the Ti $2p$ structure compared to crystal field calculations (15) (E = experimental, C = calculated).

to the crystal field calculations. The difference arises from the complex interplay of crystal field and exchange terms (15). Due to their spatial localization, the exchange interactions are much stronger in the Ti $2p$ than the C $1s$ or Cl $2p$ states. This is consistent with the larger crystal-field-related splitting in the Ti $2p$ than in the C $1s$ or Cl $2p$ spectra. Core hole relaxation, i.e., interaction between the core hole and the valence electrons, particularly the excited electron in the upper orbital of the transition, could also have a very large effect on the Ti $2p$ spectrum since Ti $3d$ orbitals are very much localized on the Ti atom.

While the major features of the Ti $2p$ spectra are reproduced by the atomic multiplet – crystal field calculations (at least for the two cases where appropriate symmetry results are available), there are some experimental features that are not predicted, in particular, the broad maxima at 467 and 472 eV (see Fig. 5). Based on their similar appearance, these features are believed to have a common origin in all three species. They are considered to be monopole shake-up excitations in which a valence $\rightarrow$ valence transition accompanies the main $2p_{3/2} \rightarrow 3d$ and $2p_{1/2} \rightarrow 3d$ transitions. Strong shake-up satellites occur at 9.5 eV above the main line in the Ti $2p$ photoelectron spectrum of $TiCl_4$ (45, 46). In the Ti $2p$ excitation spectrum the shake-up separation ranges from 7.8 to 8.4 eV, depending on the compound (see Table 4). Ligand-to-metal charge transfer transitions, which stabilize the localized Ti core hole, have been proposed to explain the XPS shake-up satellites (45, 46, 51) and are generally considered to be an important aspect of the electronic structure of ionic $3d$ transition metal compounds (52). Ligand-to-metal charge transfers may also be involved in the double excitation features at 467 and 472 eV in these Ti $2p$ excitation spectra. However, Van de Laan (53) has studied similar structures in the Ti $2p$ X-ray absorption spectra of TiO_2 and

$SrTiO_3$ and argues that the features are better considered as polaron transitions: ligand–ligand excitations that distort the ligand charge distribution in a way that screens the core excited atom by polarization.

If one assumes that ligand–metal charge transfer is involved, $1e(Cl) \rightarrow 2e^*(Ti)$ and $3t_2(Cl) \rightarrow 4t_2^*(Ti)$ transitions are possible candidates for explaining the double excitations in $TiCl_4$. The EHMO calculation for the Ti excited state predicts that the gap between the occupied and unoccupied e MOs is ca. 4.6 eV, slightly lower than that of the two t_2 MOs (4.8 eV). Thus the 467 eV shake-up feature in $TiCl_4$, 7.8 eV above the main Ti $2p_{3/2} \rightarrow 3d$ feature, is attributed to $t_2 \rightarrow t_2^*$ transitions. A similar assignment was given by Wallbank et al. (45) for the shake-up features in the XPS spectra of $TiCl_4$. The interpretation of these bands in $CpTiCl_3$ follows similar reasoning. Two possible monopole charge transfer transitions are the "e_g" (Cl) → "e_g" (Ti 3d) and "t_{2g}" (Cl) → "t_{2g}" (Ti 3d) shake-up excitations. According to the EHMO calculation for the Ti 2p excited state, there is an occupied "e_g" MO at −15.1 eV that is constructed almost solely of Cl 3p orbitals. The separation of the occupied and unoccupied "e_g" MOs is 5.5 eV, a reasonably close match to the 7.5 eV separation between the 467 eV shake-up band and the main $2p_{3/2} \rightarrow$ Ti 3d line. The occupied "t_{2g}" MO ($\epsilon = -15.3$ eV) derives mainly from the Cl 3p orbitals but also has a sizable Ti 3d component. The energy separation of the occupied and unoccupied "t_{2g}" MOs is only 4.7 eV. Based on the better energy match, we prefer to assign the 467 eV feature to "e_g" (Cl) → "e_g" (Ti) monopole shake-up transitions accompanying the main Ti $2p_{3/2} \rightarrow 3d$ excitation. This interpretation is supported by Larsson's studies (54) on the octahedral species TiO_6^{8-} and TiF_6^{2-}. We note that the intensity of the 467 eV feature decreases systematically with the decreasing number of Cl ligands in this series of molecules. This is consistent with our assignment of this feature to a Cl → Ti charge transfer monopole excitation. However, it would also be consistent with van der Laan's polaron proposal (53) if ligand–ligand excitations at Cl are involved.

The relative intensity of corresponding L_3 ($2p_{3/2}$) and L_2 ($2p_{1/2}$) features in $CpTiCl_3$ and Cp_2TiCl_2 is about 1:1, much smaller than the 2:1 value associated with the degeneracy of $^2P_{3/2}$ and $^2P_{1/2}$ ion states. Even so, the L_3/L_2 intensity ratio in these Ti species is larger than that in Ti and TiO_2 (49). Exchange interactions and differences in core hole relaxation effects are believed to be the origin of the nonstatistical intensity ratios (18, 49). The L_2 transitions are broader than the corresponding L_3 transitions. This increased breadth reflects a shorter lifetime and increased natural linewidth, associated with additional L_2L_3M super-Coster–Kronig decay channels that are available to L_2 excited states (55). De Groot et al. (15) discussed this effect and have included it in their predictions of Ti 2p spectra in cubic environments. For L_2L_3M super-Coster–Kronig decay to occur, the difference between the $L_2(2p_{1/2})$ and L_3 ($2p_{3/2}$) core hole energy must be larger than the binding energy of the d electron (56). Thus the probability of super-Coster–Kronig decay depends on the M-shell (valence) energetics and therefore on the crystal field splitting. The increased L_2 linewidth is most evident in the Ti 2p spectrum of $CpTiCl_3$ and less so in the other two species. This observation is consistent with our interpretation that the crystal field is largest in $CpTiCl_3$.

Summary

The C 1s, Cl 2p, and Ti 2p inner shell spectra of Cp_2TiCl_2, $CpTiCl_3$, and $TiCl_4$ have been interpreted with the aid of EHMO calculations and comparison with literature atomic multiplet – crystal field calculations for $2p^63d^0 \rightarrow 2p^53d^1$ excitations in Ti^{4+}. The results support a strongly ionic character for the metal–ligand bonds in these compounds. Analysis of the Ti 2p spectra indicates that the crystal fields of $TiCl_4$ and Cp_2TiCl_2 are rather similar whereas that of $CpTiCl_3$ is larger. The spectral splittings associated with the crystal field are found to differ in the C 1s, Cl 2p, and Ti 2p spectra, because of the influence of exchange interactions and possible differences in core hole relaxation effects. The ability to detect crystal-field-related splittings in the ligand core excitation spectra has also been documented recently in a study of the N 1s spectra of TiN and N implanted into Ti (57). Relatively strong multi-electron excitations are identified in the Ti 2p spectra of all three compounds studied. The Ti 2p spectra do not support the simple "π^*/σ^*" model proposed earlier (7). Overall, the core excitation spectra of these three compounds display many similarities. This is consistent with the similar strength of the Ti—Cp and Ti—Cl bonds and the assumption commonly made in discussions of these compounds that Ti—Cp and Ti—Cl are roughly exchangeable, at least until steric hindrance becomes a factor (58).

High-resolution spectroscopy with a CCD array detector: application to the 2880 Å emission band system in I_2

JOEL TELLINGHUISEN
Department of Chemistry, Vanderbilt University, Nashville, TN 37235 U.S.A.

Received May 19, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

JOEL TELLINGHUISEN. Can. J. Chem. **71**, 1645 (1993).

The 2880 Å system in the Tesla discharge spectrum of I_2 in Ar is reexamined using a CCD array detector to record spectra for both $^{127}I_2$ and $^{129}I_2$. This charge-transfer transition terminates on a weakly bound valence state, giving a highly congested spectrum with fine violet-degraded band structure barely perceivable on a pseudocontinuous background. The superior signal-to-noise capabilities of the array detector permit a great improvement in the precision and number of measured bandheads, as compared with previous results obtained from photographically recorded spectra. The new data span a larger range of vibrational levels in the lower state and lead to a change in the previous v'' numbering by -3 units. Both states can now be located precisely on the absolute energy axis through least-squares fits in which the lower state energy is represented as a near-dissociation expansion. The primary spectroscopic constants (cm^{-1}) are $T_e' = 47\,084$, $\omega_e' = 103.93$, $\omega_e x_e' = 0.14$, $T_e'' = 12\,260$, $\omega_e'' = 18.6$, $\omega_e x_e'' = 0.21$. The lower state has a dissociation energy of 287.5 cm^{-1} and supports 35 bound levels, subject, however, to possible further revision due to a remaining uncertainty of 1 unit in the v'' numbering. The previous tentative electronic assignment of this system remains in effect: The upper state is likely the 0_g^- state that correlates with $I^-(^1S) + I^+(^3P_1)$, while the lower state is the 0_u^- component of the lowest valence $^3\Pi_u$ multiplet.

JOEL TELLINGHUISEN. Can. J. Chem. **71**, 1645 (1993).

Utilisant un détecteur CCD qui permet d'enregistrer simultanément les spectres du $^{127}I_2$ et du $^{129}I_2$, on a réexaminé le système à 2880 Å du spectre de décharge Tesla de I_2 dans l'argon. Cette transition de transfert de charge se termine sur un état de valence faiblement lié résultant en un spectre d'une grande congestion dans lequel la structure fine de la bande violet dégradé est à peine perceptible dans un bruit de fond pseudocontinu. Les capacités supérieures signal à bruit du détecteur utilisé permettent d'obtenir une grande amélioration de la précision et du nombre de bandes mesurées par rapport aux résultats obtenus antérieurement à l'aide de spectres obtenus photographiquement. Les nouvelles données recouvrent un domaine plus étendus de niveaux vibrationnels de l'état le plus bas et elles amènent un changement de -3 unités dans la numérotation antérieure de v''. Faisant appel à la méthode des moindres carrés dans laquelle l'énergie de l'état le plus bas est représenté comme une expansion près de la dissociation, on peut maintenant localiser avec précision les deux états sur l'axe d'énergie absolue. Les constantes spectroscopiques primaires (cm^{-1}) sont les suivantes : $T_e' = 47\,084$, $\omega_e' = 103{,}93$, $\omega_e x_e' = 0{,}14$, $T_e'' = 12\,260$, $\omega_e'' = 18{,}6$, $\omega_e x_e'' = 0{,}21$. L'énergie de dissociation de l'état le plus bas est égale à 287,5 cm^{-1} et elle supporte 35 niveaux de liaison; cette évaluation est toutefois sujette à des révisions ultérieures à cause d'une incertitude résiduelle d'une unité dans la numérotation de v''. Les attributions électroniques antérieures de ce système ne sont pas changées : l'état le plus élevé est vraisemblablement l'état 0_g^- qui est relié avec $I^-(^1S) + I^+(^3P_1)$ alors que l'état le plus bas est la composante 0_u^- du multiplet $^3\Pi_u$ de la valence la plus basse.

[Traduit par la rédaction]

Introduction

Prior to 1970 the spectroscopy of the diatomic halogens was remarkably sketchy. Iodine was perhaps the most studied of this group; yet by the time of Mulliken's landmark review in 1971 (1), only two electronic states of this molecule, $X^1\Sigma_g^+$ and $B\ 0_u^+(^3\Pi)$, could be claimed to have been determined definitively. Fragmentary vibrational analyses existed for several additional states observed in both absorption and emission studies. However, as later work would demonstrate, most of the band systems recorded and described by various authors during the previous half century had been incorrectly interpreted. This was particularly true of the rich UV–visible emission spectrum, for which only two electronic transitions, $F\ 0_u^+ \rightarrow X$ and $E\ 0_g^+ \rightarrow B$, had been correctly interpreted as ion-pair → valence charge-transfer systems, and those based on vibrational assignments spanning only limited regions of v in the excited states. The situation was scarcely better in any of the other homo- or heteronuclear halogens.

In the 1970s the halogens gained prominence, both as targets of new experiments made feasible by the advent of narrow-band fixed-frequency and tunable lasers, and as lasants themselves in high-pressure discharges (2, 3). Among the players in the former arena was Gerry King, who with his research colleagues published ground-breaking papers on the high-resolution multiphoton excitation of ion-pair electronic states in I_2 (4–6). About the same time I published a new interpretation of the strong emission band systems responsible for the lasing in I_2 and Br_2 (7), according to which the emission in both molecules originated from the lowest 2_g ion-pair state and terminated on the first excited valence state, 2_u ($^3\Pi$), neither of which had been identified previously for either molecule. For I_2 this interpretation placed the upper 2_g state right in the region of the five ion-pair states analyzed by King's group; yet symmetry considerations and spectroscopic constants seemed to imply that it was distinct from the King five. This was the beginning of a string of halogen spectroscopy puzzles that prompted a number of fruitful exchanges of preprints, letters, and phone conversations between Gerry King and myself.

One of the more enduring of these puzzles was the question of precisely where the various ion-pair states lay in I_2. Mulliken had shown the lowest group of six Hund's case c states beginning around 33 000 cm^{-1} above the ground state. Within four years of King's initial multiphoton study, three other groups had interpreted multiphoton ionization experi-

ments in terms of ion-pair states lying in precisely this region. Yet the properties of the high-pressure emission spectra suggested that the lasing transition, now know as $D' \rightarrow A'$, resulted from a pooling of deposited energy in the D' state, which could be most easily understood if D' were the lowest member of its cluster of states, and if this cluster were the lowest of all, correlating ionically with $I^- + I^+(^3P_2)$. My group discussed this problem in 1980 and again in 1983 (8, 9). Interestingly, the work that appears to "put the last nail in this coffin" has come again from King's lab (10): He and McLean showed recently that those studies which found states below 40 000 cm^{-1} suffered from photon miscounting, and were actually not 2-photon but 3-photon (1 + 2) excitations, $F\ 0_u^+ \leftarrow B \leftarrow X$ and $F'\ 0_u^+ \leftarrow B \leftarrow X$, to ion-pair states correlating with $I^+(^3P_0)$ and $I^+(^1D)$, respectively.

In the last 15 years the state of knowledge of halogen spectroscopy has been vastly improved, mainly through the efforts of half a dozen groups employing laser techniques resembling those utilized in King's pioneering studies (11). The obvious advantage of such techniques is the simplicity of interpreting the resulting sparse spectral patterns; by contrast the problem of spectral congestion is particularly severe for conventional emission spectra of the halogens because of their large reduced masses. Yet some of the electronic states responsible for features in the high-pressure halogen discharge spectra have remained inaccessible to such multiple laser methods, meaning emission spectroscopy is still the only game to play with them. For the most part the D'–A' systems qualify as cases in point. Another example is the narrow band system with peak intensity near 2880 Å in the Tesla discharge spectrum of I_2 in Ar, which was the main subject of the aforementioned 1983 paper from my group (9).

In fact, the 2880 Å system in I_2 is a particularly extreme example of spectral congestion. In peak emission intensity, this system is second only to the $D' \rightarrow A'$ system (8), so not surprisingly it had been reported in prior work dating back at least to 1940. Yet our 1980 study was the first to note the presence of fine violet-degraded band structure, a dead giveaway that this system involved a weakly bound lower state. To extract the bandhead measurements reported in our 1983 paper (9), we had to push the limits of photographic technology: Since the heads could not be readily perceived on an optical comparator or on densitometer traces, we resorted to high-contrast positive enlargements, which permitted better visual interpretation than was possible at the low signal-to-noise level of the one-dimensional comparator and densitometer spectra. It is largely for this reason that I have selected this case to test the capabilities of the technology that seems destined to supplant the photographic emulsion in image recording — the charge-coupled device (CCD) array detector.

Using a commercially available CCD array detector having square pixels 25 μm on a side, I have rerecorded the 2880 Å system of I_2 for both $^{127}I_2$ and $^{129}I_2$. This pixel width is more than two times greater than the best physical resolution achievable with our spectrometer using photographic recording. Still, the results of the present study are very optimistic for the future of such detectors in application to congested spectra. As compared with the photographically recorded 1983 spectra, I have doubled the number of assigned bands while halving the standard deviation in the least-squares analysis of these bands. This improvement has removed the relative numbering ambiguity that prompted us to allow for an alternative assignment in the 1983 analysis, and it has reduced the uncertainty in the absolute numbering of the lower state from four units to one. The best guess for the electronic assignment of this system remains as given in 1983: $0_g^-(^3P_1) \rightarrow 0_u^-(^3\Pi)$, where the origin belongs to the second ion-pair cluster and the terminus is a member of the lowest $^3\Pi_u$ multiplet, having molecular orbital designation 2431 (1).

Experimental

Spectra were recorded using Tesla discharge emission sources, spectroscopic equipment, and procedures like those employed in the previous study (9) with only minor modifications, except for the substitution of a CCD array detector for the photographic plates. The sources contained excess $^{127}I_2$ or $^{129}I_2$ and 200–800 Torr Ar (1 Torr = 133.3 Pa) and were operated in open air. (The Dry Ice cooling that was used to bring out some weak heads in the 1983 work was not necessary here.) Atomic calibration spectra were obtained from microwave discharge Fe/I_2 lamps; wavelengths were taken from Crosswhite (12). The spectrometer was a Jobin–Yvon HR1500 1.5-m instrument equipped with a 3600-groove/mm holographic grating (1.55 Å/mm reciprocal dispersion near 2880 Å). Exposures were typically 20 s for the Fe calibration spectra (5 μm slit width), and 50–500 s for the I_2 spectra (20–500 μm slit widths).

The detector was a Photometrics CCD9000 array having 1024 × 256 square pixels 25 μm on a side and furnished with a UV sensitizing coating that extended its useful response range down into the VUV region. This detector was interfaced to an Intel 386SX microcomputer through a Photometrics AT200 camera controller. The accompanying software permits recording in image or trace mode for each of as many as 16 defined tracks. In trace mode, various binning options are available for the pixels contributing to a given wavelength channel; in all of the present experiments, I used pixel-by-pixel digitization of all vertical elements in each channel, followed by accumulation in the computer. Most spectra were recorded in dual tracks 42 pixels high; because of the slight curvature in the spectrometer entrance slit, the vertical displacement of these two tracks yielded about one-half channel offset of one with respect to the other. Although this offset was fortuitous, it may in fact be the ideal choice for extracting maximal information from such recordings.

After correction for a DC bias the digitized signal for each pixel and for a binned row of pixels is essentially linear in the light exposure (intensity × time) over a large range of accumulated charge. Although it is usually desirable to correct for "dark current" (thermal charge accumulation), at the ~160 K operating temperature of the CCD array the dark charge was negligible in the present experiments. It is also necessary to calibrate the detector elements for variations in effective sensitivity. For example, exposures to continuous light sources in image mode revealed a number of blemishes in the defined regions for both tracks. These may have been due to dirt on the window or on the array surface, or to imperfections in the array itself. Regardless, it is easy to compensate for such effects by ratioing the unknown spectrum to a spectrum recorded using a source of continuum light in the region of interest. I chose a slightly different tack: I used the discharge source itself as the reference "continuum," by simply opening the entrance slit to a width large enough to ensure that all fine structure would be washed out. Since the spectral features of interest represent small percentage changes on the fine wavelength scale of a spectrum that shows considerable intensity variation on the coarse scale, ratioing a high-resolution spectrum to a low-resolution spectrum in this fashion effectively amplifies the fine structure while canceling the rather severe variation in overall intensity associated with the coarse structure.

As might be expected, the Tesla discharge is a fierce source of

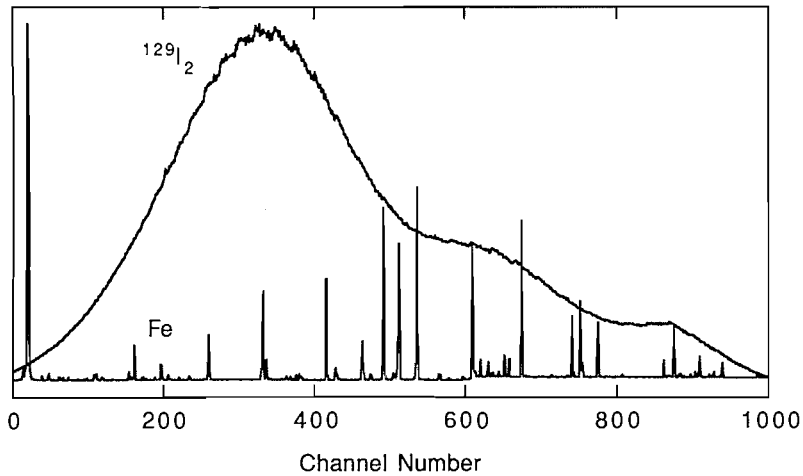

FIG. 1. Typical Tesla discharge spectrum of $^{129}I_2$ together with microwave discharge Fe calibration spectrum, recorded near 2870 Å. The intensity scales are arbitrary but relative to an approximate zero at the baseline of the Fe spectrum. Wavelength decreases with increasing channel number. Fine structure is evident in the I_2 spectrum, which was recorded using a slit width of 20 μm and an exposure of 500 s. The Fe spectrum was exposed 20 s using a 5-μm slit.

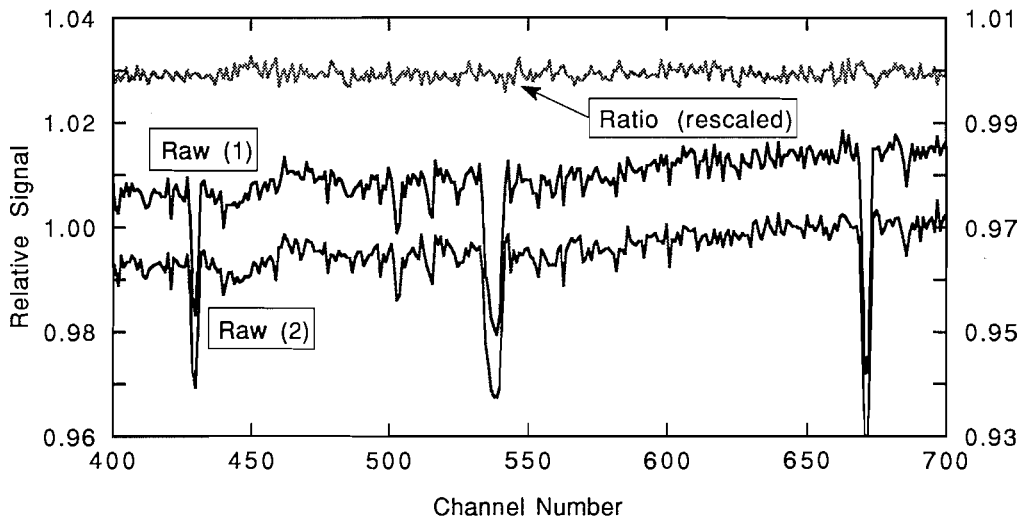

FIG. 2. Spectra recorded near 2870 Å on a single track in separate exposures of 30 and 60 s to a D_2 continuum source, using a 500 μm slit width. The raw spectra have been corrected for bias, and they and their ratio (scale to right) have been rescaled for display.

electronic noise. One might anticipate that this would play havoc with the array detector and its associated electronics. Fortunately this turns out to be only partly true: as long as the discharge was off during the readout stage (and to a much lesser extent, during array initialization), such problems were entirely negligible.

Detector performance tests

Overview

Figure 1 shows a typical I_2 discharge spectrum and its companion Fe calibration. One advantage of electronic over photographic recording is immediately evident on first use of such an array: the user can expose and reexpose in trial-and-error fashion until the result is satisfactory. By contrast, the photographic emulsion cannot be erased or examined between exposures, and so the achievement of an adequate overlay of calibration and unknown spectra necessarily entails a modicum of "flying blind," since it is crucial that the spectrometer not be perturbed in any way between these recordings. With the array detector the only interaction with the instrument is electronic (plus possibly a manual slit width adjustment) during a series of exposures. The largest drift I encountered in "before" and "after" wavelength calibration checks could be accounted for by atmospheric pressure changes over the several hours duration of that set of experiments.

Figure 2 illustrates the signal-to-noise capabilities of the array detector. The structure in the two lower "raw" spectra is mainly attributable to aberrations in the detector. However, the noise level in their ratio is less than 0.13%. Specifically, over the more extended range of channels 101–900, this ratio shows an average of 1.0000, a standard deviation of 0.00124, and maximal excursions of −0.00367 and +0.00403. Since this simple one-shot test yielded exposures below 20% of the maximum working capacity of the charge wells, it is likely that this noise figure could be significantly reduced with more effort. It is also clear that this ratioing procedure will prove essential in cases where signal-to-noise and precision are primary concerns.

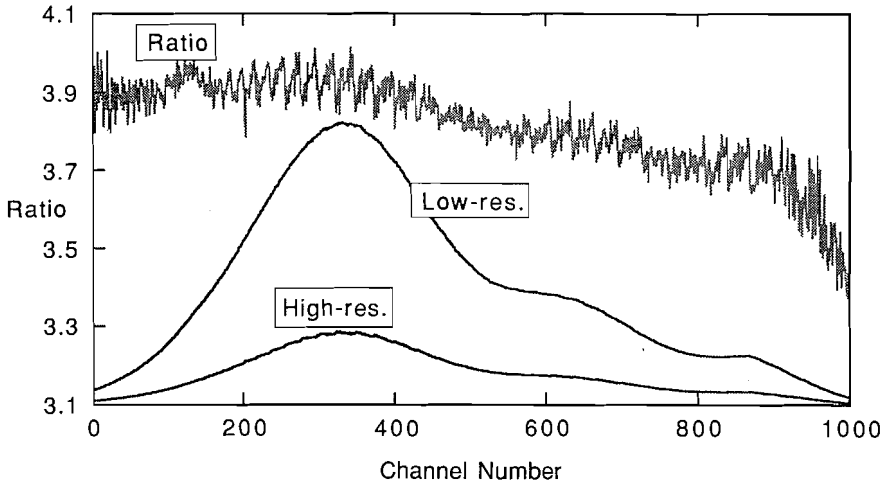

FIG. 3. Low-resolution (500 μm slit, 60 s exposure) and high-resolution (20 μm slit, 500 s exposure) spectra of $^{129}I_2$ in 2870 Å spectral region, and their ratio. (The high-resolution spectrum is the same as in Fig. 1.)

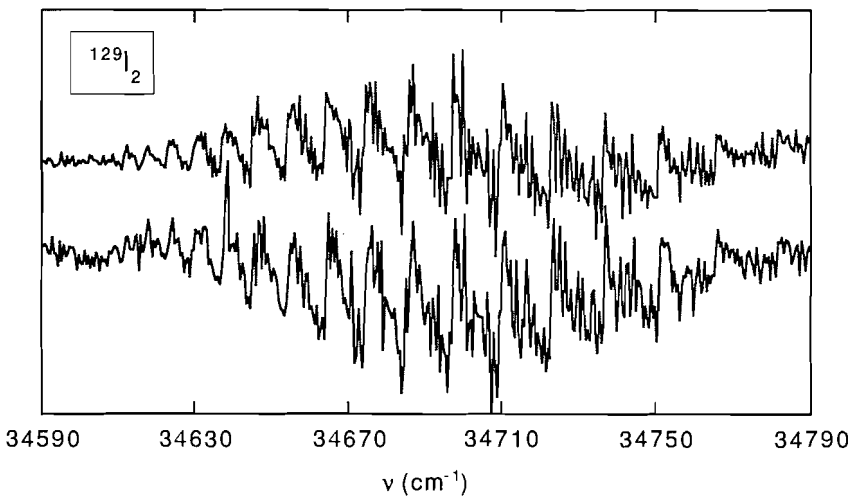

FIG. 4. Calibrated spectra for $^{129}I_2$ in the region of the 2880 Å main peak. For each of the two tracks, spectra were obtained from low- and high-resolution spectra like those in Fig. 3 by the procedure described in the text.

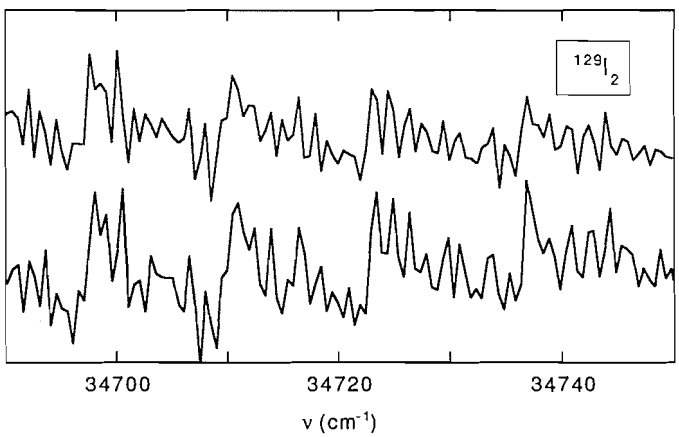

FIG. 5. A segment of Fig. 4 at expanded wavenumber scale, showing level of consistency of spectra recorded on the two tracks.

The practical significance of the S/N performance is made clearer in Fig. 3, which displays low- and high-resolution spectra of $^{129}I_2$ and their ratio. Vibrational bandhead structure is now evident across the entire spectrum, where it was barely perceptible away from the main peak in Fig. 1. In practice, working spectra were obtained by scaling the low- and high-resolution spectra to a common average intensity, then subtracting the former from the latter. Typical results of this procedure, applied to both tracks and calibrated, are displayed as a function of the wavenumber in Fig. 4. That the very fine structure is real and not artifactual is clear from the blowup in Fig. 5. The latter demonstration is made all the more compelling by the fact that the two tracks are offset by half a channel with respect to each other.

Even a cursory comparison of Fig. 4 with the photographic spectrum in Fig. 1 of ref. 9 convinces one of the impressive improvement achieved with the array detector.

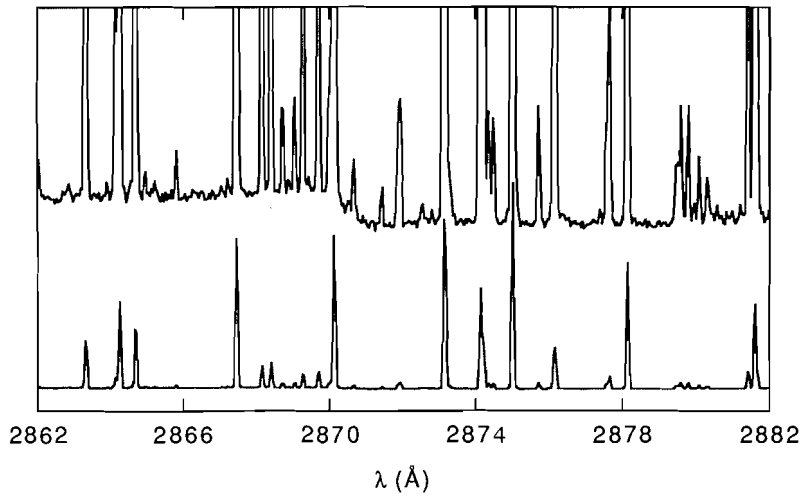

FIG. 6. A 20 Å segment of an Fe calibration spectrum recorded near 2870 Å, displayed at low and high sensitivity (× 20, upper). This region comprises ~500 array channels. The shoulder near 2870 Å in the upper trace is attributed to a light leak.

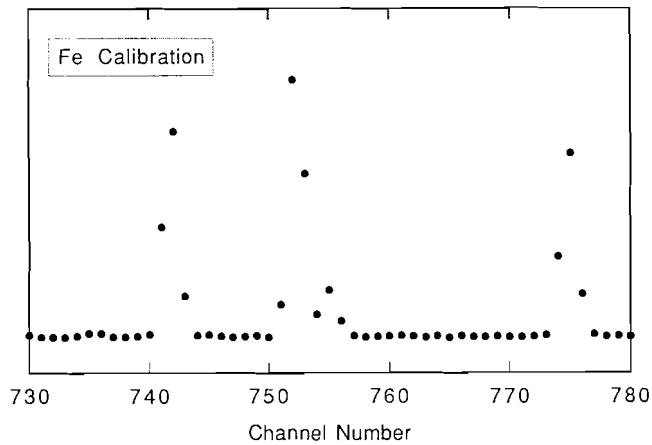

FIG. 7. A 50-channel region of a typical atomic Fe spectrum.

A less obvious advantage of spectra like those displayed in Figs. 4 and 5 is that they are free from contamination by the calibration spectra, since the two are recorded separately. In photographic mode it is necessary to measure regions of the recorded images where both calibration and unknown spectra occur together, in order to obtain a reliable plate function. Where intense atomic calibration lines occur in such spectra, they obscure the overlapping unknown features. Although it is of course possible to obtain additional densitometer records of unknowns free from this overlap, it requires extra effort and is often considered not worth the bother.

Atomic calibration spectra

The large dynamic range of the array detector is a tremendous asset when dealing with spectra that span an extreme range of intensities. Such is often the case with atomic calibration spectra, like the Fe spectrum obtained from a microwave discharge. Figure 6 shows a region of a typical Fe calibration spectrum recorded near 2870 Å, displayed at two different intensity magnifications. It is easy to locate and measure ~40 lines in this 20 Å spectrum segment. By contrast, dynamic range limitations of photographic emulsions would typically force a forfeiture of either some of the most intense lines to overexposure or some of the weakest to underexposure.

There is, however, a problem of a different sort with these array spectra. As was noted previously, the 25-μm pixel width is still large compared with the ultimate resolution achievable with photographic images. In fact it is so wide that a typical sharp atomic line recorded on the 1.5-m JY spectrometer appears in only three channels, as is shown in Fig. 7. The question arises, how best to locate the peak centers. The simplest procedure is an exact parabolic fit, and in fact this approach proved as good (in terms of the calibration fit statistics) as attempts involving more complicated procedures, like fitting Lorentzians to more than three points in the vicinity of each peak.

The statistics of a typical calibration fit are illustrated in Fig. 8. The error band on the plate function is only ~0.003 Å in width (2 σ), which is comparable to the best results achievable from photographic calibration spectra recorded on this instrument. However, this result is partly a consequence of the much larger number of Fe lines that could be measured and included in the present fits: 35–50 cf. 8–15 in a typical photographic spectrum. The estimated standard deviation in an individual measurement, typically 0.005–0.010 Å, is about a factor of two larger than achievable for spectra recorded photographically on this instrument. It is this figure that represents the limiting measurement precision for single, sharp, unknown features, and so the present array does concede a factor of two in ultimate precision to the photographic emulsion. Still, it is worth noting that this standard deviation corresponds to only ~5 μm on the image, or about one fifth of a pixel. In view of the three-point parabolic fitting procedure used to estimate peak positions, this is quite respectable.

Spectrum analysis

Data and interpretation

Calibrated spectra like those illustrated in Figs. 4 and 5 were measured directly on a Macintosh IIsi microcomputer, using the cursor tool of a graphics program (KaleidaGraph). All but one or two of the 45 bands reported in Table I of ref. 9 were also measured in the present study, most of them 6–10 times from different spectra. An additional 62

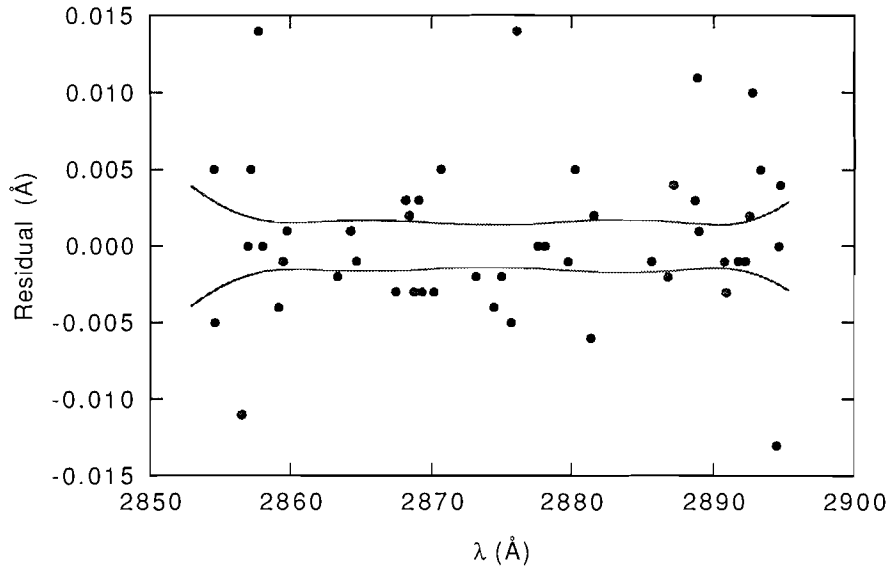

FIG. 8. Least-squares residuals from a fit of 48 Fe lines recorded near 2870 Å to a cubic polynomial (points), and 1-σ error band (curves) on the resulting fit function. The standard deviation of this fit was 0.006 Å.

bands were also assigned in the present work. Only features that appeared to be violet-degraded band edges were included in the measurements, and then only if they occurred clearly in both of the companion tracks obtained from a single exposure. The final assignment list included some weak features that were observed in only a single exposure. These were accordingly downweighted by a factor of 5 in the final fitting. This figure was crudely based on the estimated precision and number of measurements but was supported by the statistics of the fits. All (averaged) assignments for both isotopomers are presented in Table 1, together with their least-squares residuals, obtained as described below. Note that the assignment corresponds to Assignment 1 from ref. 9, which was the preferred interpretation. However the v'' numbering has been reduced by three units, for reasons discussed below.

The interpretation of this spectrum remains as given in ref. 9 and illustrated in Fig. 9. The upper state is an ion-pair state, most likely a member of the second cluster of six such states arising from $I^- + I^+(^3P_1)$ and $I^- + I^+(^3P_0)$. By analogy with the other similar ion-pair states, its internuclear distance should be about 3.6 Å. The transition terminates on the repulsive branch of a weakly bound, van der Waals type, lower state, accounting for the fine violet-degraded band structure. This state must correlated with two ground-state I atoms if the upper state belongs to the second ion-pair cluster. In the off chance that the upper state correlates with $I^- + I^+(^1D)$, the lower state would dissociate to $I(^2P_{3/2}) + I(^2P_{1/2})$. From here on, however, I will assume the lower correlation for both states.

In its intensity properties, this I_2 transition closely resembles the characteristic excimer bands observed in most of the diatomic rare-gas halide molecules and in some other rare gas van der Waals species, for example CsXe (3, 13). The piling up of intensity in the main peak at the long-wavelength end of the spectrum is attributable to nearly parallel upper and lower potentials, resulting in a nearly flat difference potential. The intensity pattern is determined almost entirely by the shapes of these potentials in the Franck–Condon region and by upper-state population distributions; it does not depend on whether the accessed region of the lower state falls below, at, or above the dissociation limit. In the present case, emission from the lowest v' levels happens to be mainly discrete, whereas, by contrast, it appears to be diffuse in most of the rare-gas halide $B \rightarrow X$ systems.

Least-squares analysis

To extract spectroscopic parameters from the assignments in Table 1, I again followed the procedures of ref. 9. Since only low v levels of the deeply bound upper state are observed, it is appropriate to represent its energy levels in terms of the usual polynomial in $(v + \frac{1}{2})$. However, the observations on the lower state extend almost to the dissociation limit, so I have examined both polynomial fits and near-dissociation expansions (NDEs) (14, 15) for it. In both cases the measured wavenumbers can be expressed as

$$[1] \quad \nu(v',v'') = \Delta T + G'_v - G''_v$$

If the polynomial representation is taken for G''_v, $\Delta T = T'_e - T''_e$. On the other hand the NDE represents the energy relative to the dissociation limit, so that its use for the lower state yields $\Delta T = T'_e - T_{\mathcal{D}}$, where $T_{\mathcal{D}}$ represents the asymptotic energy relative to the minimum of the ground-state potential. Thus the difference between these two ΔT values provides an estimate of the dissociation energy $\mathcal{D}''_e$ of the lower state.

For the NDE representation of the lower state, I have used the same form as in ref. 9,

$$[2] \quad G''_v = -X_5 (v_{\mathcal{D}} - v'')^{10/3} F(v'')$$

where $v_{\mathcal{D}}$ represents the (noninteger) vibrational quantum number at dissociation, and $F(v'')$ is an ad hoc function needed to correct for the deviation from the limiting long-range behavior. As before I have used for $F(v'')$ a simple polynomial in $z \equiv (v_{\mathcal{D}} - v'')$:

$$[3] \quad F = 1 + c_1 z + c_2 z^2 + \ldots$$

The constant X_5 is related to the limiting $-C_5/R^5$ dependence of the lower potential, assuming this state is the 0_u^-

[a]In the least-squares fits, measurements marked with an asterisk were downweighted by a factor of 5, and those in parentheses were omitted. Residuals are calculated minus observed, from polynomial/NDE fit (see text).

[b]Vibrational numbering of lower state is reduced by three units from that of Table I in ref. 9.

component of the 2431 $^3\Pi$ multiplet; I have adopted the value calculated in ref. 9 using Mulliken's (1) estimate of C_5.

In the framework of the rotating oscillator model, a single potential curve holds rigorously for all isotopic forms of a molecule in a given electronic state. In that case the vibrational energy is a unique function of the argument $\rho(v + \frac{1}{2})$, where ρ^2 is the ratio of isotopomer reduced masses. Choosing $^{127}I_2$ as the reference species makes $\rho \equiv 1.0000$ for it and 0.99221 for $^{129}I_2$. To accommodate data for multiple isotopomers in a single fit involving NDEs, one can define an effective v for all species through

$$[4] \quad \rho\left(v + \frac{1}{2}\right) = \left(v_{\text{eff}} + \frac{1}{2}\right)$$

and then use this v_{eff} in place of v where it appears in the NDE.

In the present spectra, it is not apparent that any of the observed transitions access the level $v'' = 0$ in the lower state. Thus the vibrational numbering in this state remains uncertain and can only be determined from the isotope effect. Unfortunately, weakly bound states are notoriously insensitive to isotopic substitution; thus simple calculations fail to determine this important property. Accordingly I have found it useful to incorporate an additional adjustable parameter in the fits, by defining the working v'' as $v'' + n$, where n represents a correction to the nominal v''. The latter quantity is clearly subject to an arbitrary constant shift, and the parameter n compensates for this to achieve minimum variance. Of course without data for multiple isotopomers, n is rigorously indeterminate, and the (nonlinear) fit must fail. At the outset I used the v'' numbering from ref. 9.

An additional numbering problem arose in our 1983 work. Because the anharmonicity in the lower state was small, and because the v'' progressions were short for all $v' > 0$, we were reluctant to rule out on statistical grounds an alternative *relative* numbering scheme, in which all bands for $v' = 1$ have their v'' numbers reduced by one unit, all for $v' = 2$ have theirs dropped by two, etc. The 1983 data yielded a variance 26% higher for this alternative assignment than for the preferred one, and so we presented the alternative as a possible, though unlikely, interpretation of the data. The improved quality and quantity of the present data make this alternative assignment virtually inadmissible. For example, a limited subset of 36 of the bands in Table 1 (corresponding roughly to those bands measured in 1983) gave an increase of 60% in this variance comparison. However, the full data set gave a factor of 5 increase, which suffices to eliminate this interpretation from contention.

The double polynomial and the polynomial/NDE fits both

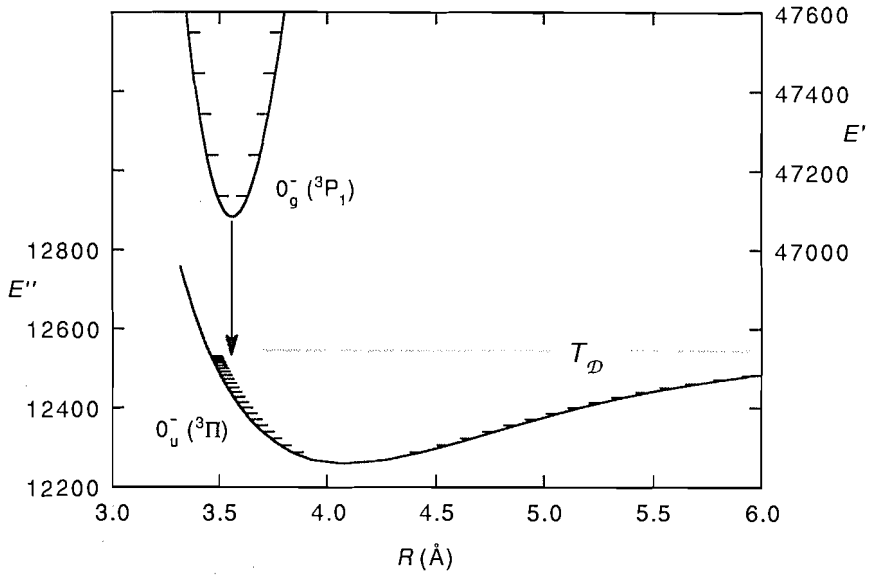

FIG. 9. Potential diagram illustrating emission process responsible for 2880 Å band system of I_2. Energies (cm^{-1}) are relative to the minimum of the ground state. (Note separate scales for lower and upper curves, to left and right, respectively.) The energy of the first dissociation limit is marked with the shaded horizontal line, and tick marks indicate observed vibrational levels.

[a]Data span $v' = 0$–6, $v'' = 1$–22. Parameter standard errors (1 σ) in parenthesis, in terms of final digits. Parameters have been rounded by a systematic procedure that preserves their accuracy (16).

[b]Polynomials in $v + \frac{1}{2}$ for both upper and lower states.

[c]Polynomial in $v + \frac{1}{2}$ for upper state, NDE for lower state.

[d]ΔT_e for polynomial fit, $\Delta T_e - \mathcal{D}_e''$ for NDE fit.

[e]Conventional vibrational parameters for lower state in polynomial column, parameters as defined in eq. [3] in NDE column. In the latter, initial fits showed c_2'' to be uncertain by more than its magnitude, so it was set to zero.

[f]Held fixed at value given in Table III of ref. 9.

[g]Standard deviation for measurements of unit weight.

[h]T_e and $\mathcal{D}_e$ values assume dissociation of lower state to two ground-state atoms (12 547.2 cm^{-1} above the X-state minimum) and dissociation of upper state to $I^-(^1S) + I^+(^3P_1)$.

clearly indicate a reduction by three units in the v'' numbering of our 1983 paper, and it is this numbering that is used in Table 1. More specifically, the double polynomial fit of these data (as numbered in Table 1) yields, for the v'' adjustment parameter, $n = 0.16 \pm 0.56$, with very similar results from the polynomial/NDE fit. Thus I consider the new numbering quite probable, but with the possiblity that it is still in error by one unit. The two fits give virtually identical results for the upper-state G_v parameters and nearly identical estimated variances, but the double polynomial fit requires one more parameter (7 vs. 6) to accomplish this. Both sets of results are summarized along with some related derived properties in Table 2.

Compared with the 1983 results, the present reanalysis has affected mainly the parameters for the lower state that are most sensitive to the renumbering, namely T_e'', $\mathcal{D}_e''$ and ω_e''. The properties of the upper state have also changed by statistically significant amounts, e.g., $\omega_e' = 103.93(7)$ cm^{-1}, cf. 105.7(4) cm^{-1} previously. A comparison of the 1983 data with their counterparts in Table 1 reveals essentially random differences. Thus the changes in the upper-state parameters probably stem from subtle sources of model error in the fitting, relating to differences in the range of v spanned in both states and the numbers of parameters used to describe the lower state. Note, however, that the estimate of T_e' does *not* depend on the numbering, since it is based on the extrapolation to dissociation in the lower state. Thus the change in ΔT in the polynomial/NDE fit, from 34 522(6) cm^{-1} in the earlier work to the present 34 536.5(4) cm^{-1}, reflects mainly the inclusion of six higher v'' levels in the present work, which brings the observations to within 18 cm^{-1} of dissociation as compared with the previous 56 cm^{-1}.

The superior extrapolating behavior of near-dissociation

expansions for levels near dissociation argues in favor of the NDE results in Table 2 over the polynomial representation for the lower state. For this reason the residuals included in Table 1 are those from the polynomial/NDE fit. The NDE parameters are also used below to calculate the lower-state Rydberg–Klein–Rees (RKR) potential, needed for Franck–Condon calculations.

Potential curves and Franck–Condon factors

Because of the manner in which the emission terminates on the repulsive branch of the weakly bound lower potential, the intensity properties of this transition can be reliably treated using a bound-free model (13). This was done in our 1983 work and its results should remain valid now, since the earlier intensity modeling calculations utilized only low-resolution spectra, in which no vibrational structure could be perceived. Thus, for the repulsive branch of the lower potential I have simply adopted those results from ref. 9 that characterize its location and slope in the Franck–Condon region, namely $U''(R_e') = T_e' - 34\ 650(20)$, and $(dU''/dR)_{R_e'} = -850(80)\ cm^{-1}/Å$.

Of course, to calculate discrete FCFs one requires full potentials for both states. For the lower state I have accomplished this using a Morse–RKR potential (17) — a Morse repulsive branch having the above-mentioned properties, with an attractive branch constructed by adding the RKR widths to this repulsive branch. The required Morse branch was obtained using the experimental $\omega_e x_e$ value in Table 2 to define the Morse β parameter, and then solving for $\mathcal{D}_e$ and $\Delta R = R_e' - R_e''$ using the information on the location and slope given just above, together with the T_e'' value given in Table 2. The resulting parameters are included in Table 3, together with other properties of the resulting full potential.

The upper potential was represented by a Rittner-type potential, using a previously devised modification to the repulsion term (18),

$$[5]\quad U' = \mathcal{D}_e' - C_1/R - C_3/R^3 - C_4/R^4 - C_6/R^6 + b\exp(-\beta R^p)$$

The constants C_1 (rigorously known), C_3, and C_4 were obtained as before (18), and C_6 and p were adjusted in trial-and-error fashion to give a potential with the correct $\mathcal{D}_e$ and ω_e, and roughly correct R_e and $\omega_e x_e$.[1] The results of this determination are given in Table 3. Note that although the upper and lower potentials are well determined with respect to each other, there is nothing in either the 1983 results or the present work to precisely locate these potentials along the R axis. The adopted value of $R_e' \approx 3.56$ Å, which serves to anchor the pair, is purely an educated guess.

Franck–Condon factors calculated using these potentials are presented in Table 4. The assignments in Table 1 generally track these FCFs fairly well; in fact the latter were used in the final stages of the analysis to aid in the assignment of the weaker bands. The reader might notice that the FCFs sum to considerably less than unity for most of the v' levels included in this table. This is because the fraction of emission that terminates in the vibrational continuum of the lower state

[1]An incorrect sign was given for C_3 in ref. 18, when a previously derived value for the D' state was inadvertently used for $D\ 0_u^-(^3P_2)$. For the $0_g^-(^3P_1)$ state, however, the ion-quadrupole interaction *is* calculated to be identical to that for D' in both sign and magnitude.

TABLE 3. Parameters (cm^{-1} and Å units) for potentials involved in 2880 Å emission system of I_2[a]

increases with increasing v', such that for v' levels much higher than those studied here, the emission is almost entirely bound-free.

Conclusion

I have reexamined the 2880 Å emission system of I_2, using sources and methods identical to those used in a similar study 10 years ago, except for the subsitution of a CCD array detector in place of the previously used photographic plates. The high S/N capabilities of this detector have permitted me to more than double the number of identifiable violet-degraded bandheads that belong to this electronic transition, with a concomitant increase in precision by a factor of two. The new data lead to a clear rejection of an alternative assignment presented in 1983 and to a reduction by three units in the numbering of the vibrational levels of the lower state. The improved and extended data have permitted a more precise characterization of both states, particularly with respect to their absolute energies, which are now grounded on a much shorter extrapolation of the lower state to its dissociation limit.

Although the S/N performance of the CCD array detector used here is clearly superior to that of the photographic technology used in the previous study, the 25-μm pixel width limits the ultimate resolution of this array to a factor of two below that of photographic methods in equivalent applications in my laboratory. However, there are CCD array detectors now available with pixel widths a factor of four smaller. Thus in spectroscopic applications, there is every reason to expect this technology to be able to match the photographic emulsion in resolving power.

The electronic assignment of the 2880 Å system remains tentative, but no new results have surfaced in the past decade to force a change from the 1983 designation, $0_g^-(^3P_1) \rightarrow 0_u^-(^3\Pi)$. In particular, the states involved in this transition have spectroscopic properties that distinguish them from other known states of I_2 (11). Considering other diatomic halogens, only recently has this transition been convincingly identified in any other case, that in Cl_2 by Ishiwata et al. (19), who have used the label B' for the lower state. Interestingly, in Cl_2 this state has properties very similar to those of the other components of the 2431 $^3\Pi_u$ multiplet. This would appear to reflect the expected stronger tendency toward Hund's case a in Cl_2 vs. case c in I_2. However, the properties of this state in these two molecules are so strikingly different as to make the intermediate case of Br_2 of great interest.

Acknowledgments

I would like to thank Marcus Mendenhall for many valuable discussions on CCD array detectors, and for running some early proof-of-principle experiments that demonstrated the feasibility of the present experiments. I also thank my wife Patricia for help calibrating the spectra. The purchase of the CCD array detector was supported in part by National Science Foundation Grant CHE-8910823.

Received April 5, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

LINDA J. JOHNSTON, N. MATHIVANAN, FABRIZIA NEGRI, WILLEM SIEBRAND, and FRANCESCO ZERBETTO. Can. J. Chem. **71**, 1655 (1993).

An experimental and theoretical study is reported of the 600 nm band system of phenoxyl and several methoxy substituted phenoxyls. These radicals, generated in freon, show a diffuse band in this region with a vibrational structure that is incompletely resolved but consistent with the 500 cm^{-1} "progression" observed earlier for phenoxyl in the vapour and in a rigid matrix. The low intensity of this band is considerably enhanced by *ortho*-methoxy substitution. To establish its assignment and analyze its structure, semi-empirical and *ab initio* quantum chemical calculations have been performed. It is found that, on the basis of the ordering of the states and the magnitude of their transition moments, all calculations favour a $\pi\pi^*$ ($^2B_2 \rightarrow {}^2A_2$) rather than the earlier proposed $n\pi^*$ assignment for this band. Of the methods used, only the (*ab initio*) CASSCF method is found to be able to simulate the observed vibrational structure adequately. This simulation is based on optimized structures and vibrational force fields calculated for the $1B_2$ and $1A_2$ states of phenoxyl. It identifies the dominant mode of about 500 cm^{-1} as ν_{6a}, the characteristic deformation mode of phenyl rings, but shows that higher members of the "progression" receive large intensity contributions from higher frequency modes. The chosen assignment and the assignments of higher-energy transitions reported in the literature are compared with those for the better known benzyl radical. It is shown that some of the phenoxyl assignments reported in the literature contain errors.

LINDA J. JOHNSTON, N. MATHIVANAN, FABRIZIA NEGRI, WILLEM SIEBRAND et FRANCESCO ZERBETTO. Can. J. Chem. **71**, 1655 (1993).

Une étude expérimentale et théorique est présentée concernant le système de bandes près de 600 nm du phénoxyle et de plusieurs phénoxyles comportant un ou deux groupes méthoxy. Ces radicaux, produit dans le fréon, montrent une bande diffuse dans cette région; la structure vibrationelle n'est pas complètement résolue mais est en accord avec la "progression" de bandes de 500 cm^{-1} observée plus tôt pour le phénoxyle dans la vapeur et dans une matrice rigide. L'intensité de cette bande faible est haussée considérablement par des substituants *ortho*-méthoxy. Pour établir l'attribution de cette bande et pour analyser sa structure, on a fait des calculs avec des méthodes de chimie quantique, non seulement semi-empirique mais aussi *ab initio*. On a trouvé que, selon l'ordre des états et la magnitude des moments de transition, tous ces calculs favorisent l'attribution de la bande à une transition $\pi\pi^*$ ($^2B_2 \rightarrow {}^2A_2$) au lieu de l'attribution $n\pi^*$ proposée précédemment. De toutes les méthodes utilisées, seule la méthode (*ab initio*) CASSCF peut simuler d'une façon acceptable la structure vibrationnelle observée. Cette simulation est basée sur les structures optimisées et les champs de force vibrationnels calculés pour les états $1B_2$ et $1A_2$ du phénoxyle. Elle mène à l'identification du mode normal de 500 cm^{-1}, qui domine le spectre, avec le mode ν_{6a}, c'est-à-dire le mode caractéristique pour la déformation des noyaux benzéniques; cependant, des modes normaux d'une fréquence plus élevée contribuent largement à l'intensité des membres de la progression sauf les plus bas. L'attribution choisie et les attributions rapportées dans la littérature des transitions plus hautes sont comparées avec celles du radical benzyle qui est mieux connu. On démontre des erreurs dans quelques unes des attributions des spectres du phénoxyle.

1. Introduction

Phenoxyl radicals are important intermediates in free radical reactions. Their observation and spectroscopic identification was first reported by Porter and co-workers (1, 2), who, however, did not discuss the assignment of the observed absorption spectra. Subsequent investigations by several groups (3–5) have led to assignments for the two moderately weak band systems observable in the near uv. In unsubstituted phenoxyl, these bands are situated near 400 and 315 nm and show vibrational structure consistent with $\pi\pi^*$ assignments for both. Less is known about an additional, very weak and diffuse band observed in the visible part of the spectrum, near 600 nm. Although very weak in phenoxyl itself, this band approaches the strength of the near-uv bands in some *ortho*-substituted derivatives (see, for example, ref. 6). In solution, its vibrational structure is poorly resolved, but in an early vapour-phase experiment, Ward (7) was able to observe four distinct maxima with spacings of about 500 cm^{-1}. The same maxima were observed subsequently by Pullin and Andrews (8) in a much noisier matrix-isolation spectrum of phenoxyl.

Ward (7) assigned his visible spectrum to an $n\pi^*$ transition, based on the argument that a corresponding band system is not observed in the benzyl radical. However, this argument is questionable since it is now known (9) that in benzyl there are two very weak transitions in the 450 nm region followed by a stronger transition near 320 nm. It is quite conceivable that the presence of an oxygen atom rearranges these bands so as to produce the pattern observed in phenoxyl. Neither Ward (7) nor Pullin and Andrews (8) at-

tempted to assign the vibrational structure; the absence of a discernable carbonyl-stretch progression would appear to argue against an $n\pi^*$ assignment.

In a more recent paper, Ebbesen and Previtali (10) have assigned what appears to be the same 600 nm band to the spectrum of a solvated electron. Their spectrum was generated by laser irradiation (266 nm) of phenol in several alcohols which resulted in the formation of a phenoxyl radical identified by its uv absorption bands. This interpretation of the visible band is based on earlier reports of solvated electrons generated by irradiation of phenolate ions and phenols in water (11–13). Although Ebbesen and Previtali (10) do not show the entire spectrum but only the absorption region from 450–750 nm, the fact that their bands show neither the solvent shifts nor the kinetics typical of solvated electrons suggests that the spectrum they observed in this region is an absorption band of phenoxyl rather than of a solvated electron.

In the present paper, we report a series of measurements and calculations aimed at securing the assignment of this band. Specifically, we measure the structure and intensity of the band for the parent radical and a number of derivatives. These measurements are compared with the results of quantum-chemical calculations. To simulate the structure of the band theoretically, we need the corresponding Franck–Condon factors. To this end we calculate the structure and the vibrational force field in the two states involved in the transition by quantum-chemical methods. For practical reasons, we use *ab initio* methods for phenoxyl itself, but semi-empirical methods for two derivatives, namely 2-methoxy- and 2,6-dimethoxyphenoxyl, both of which show much stronger absorption in the 600 nm region than the parent radical.

Although we are mostly concerned with the 600 nm band, it will prove necessary to reconsider the assignment of the higher-energy bands as well. Unfortunately, some confusion has crept into the symmetry assignments proposed in the literature. In a theoretical paper, Chang et al. (3) assumed that phenoxyl belongs to the point group C_{2v}, which seems highly probable, and assigned the ground state to the representation A_1. Tripathi and Schuler (5) followed their assignment but, assuming that the reported A_1 assignment is a misprint, reassigned the ground state to A_2. Neither assignment can be correct, however, since phenoxyl has an unpaired π-electron in an orbital that is antisymmetric with respect to the two-fold axis, so that the ground state must be either B_1 or B_2, depending on the choice of axes. Following the generally adopted notation, we choose z to be along C—O, and x to be perpendicular to the plane; with this choice, the ground state is $^2B_2$, $\pi\pi^*$ states are either $^2A_2$ or $^2B_2$ and $n\pi^*$ states are either $^2A_1$ or $^2B_1$. The assignment adopted by Tripathi and Schuler (5), following Chang et al. (3), should therefore read $^2B_2 \rightarrow {}^2B_2$ for the bands near 400 nm and $^2B_2 \rightarrow {}^2A_2$ for those near 315 nm. The observation of nontotally symmetric modes in the Raman spectrum under resonance with the 400 nm origin band (4, 5) supports the assignment of these two excited states to different symmetries, so that nontotally symmetric modes can gain Raman intensity by coupling them.

The proposed assignment implies a lowest-energy $\pi\pi^*$ state of $^2A_2$ symmetry, in agreement with the only calculation of excitation energies available to date. This calculation (3), based on the CNDO/S Hamiltonian and a model geometry, also predicts that there is a lower-energy $n\pi^*$ state of $^2B_1$ symmetry with a vanishing transition moment. There are a number of other quantum-chemical calculations on phenoxyl reported in the literature which, however, deal mostly with the ground state (14–20). They show strong disagreement with respect to the ground-state structure, in particular the CO bond length. One may therefore expect that these methods would also yield widely different values for the $^2B_2$–$^2B_1$ $n\pi^*$ transition energy. To establish the relative ordering of the lowest energy $n\pi^*$ and $\pi\pi^*$ states, it will thus be necessary to establish reliable structural parameters for the ground state. For this, we adopt a multi-configuration self-consistent-field *ab initio* method. Results for three *ab initio* methods are reported in the literature (15, 19, 20). Restricted and unrestricted Hartree–Fock (ROHF and UHF) calculations yield very different structures (19, 20). The higher level complete-active-space self-consistent-field method (CASSCF) presumably yields the most reliable structure (20). It is close to the structure obtained with the UHF approach but the latter yields a wavefunction that is unacceptable due to strong spin contamination.

In our calculations, we use the CASSCF method, after some preliminary semi-empirical calculations, to compute the structure and force field of the ground state, the ordering of the electronic states and, finally, the structure and force field of the excited state that we propose to be responsible for the 600 nm spectrum, namely the $1A_2$ $\pi\pi^*$ state.

2. Experimental

Materials

All phenols were commercially available and were purified by recrystallization or distillation. Di-*tert*-butyl peroxide was purified by passing it through an alumina column immediately before use. Solvents were spectroscopic grade and were used without further purification.

Laser flash photolysis experiments

The laser flash photolysis system has been described in detail elsewhere (21). For these experiments a Lumonics EX-530 excimer laser (Xe–Cl gas mixture; 308 nm; 8 ns pulses; ≤45 mJ/pulse) was used for sample excitation. Samples were contained in 7 × 7 mm^2 quartz flow cells connected with Teflon tubing to a flow reservoir. Flow samples were necessary to minimize problems due to product buildup. All solutions were deaerated by purging with nitrogen prior to and during the experiment. Extinction coefficients were measured using Aberchrome-540 in toluene as the actinometer (22). The yields of phenoxyl radical and the colored form of the actinometer were measured as a function of laser intensity for samples of di-*tert*-butyl peroxide plus phenol and actinometer, respectively, with matched optical densities at 308 nm. The ratio of the slopes of the two signal intensity vs. laser intensity plots was then used along with the known quantum yield and extinction coefficient for the actinometer (23) to calculate the product of the extinction coefficient times quantum yield for phenoxyl radical production. Since the experiments were carried out with sufficient phenol to ensure complete trapping of all *tert*-butoxyl radicals by phenol, the quantum yield for phenoxyl radical production can be equated to the known quantum yield for *tert*-butoxyl radical formation from di-*tert*-butyl peroxide (0.82).[2]

3. Results

Phenoxyl radicals were generated by hydrogen abstraction from the corresponding phenols by *tert*-butoxyl radi-

[1] 
have been measured and are generally in the 10^8–10^9 M^{-1} s^{-1} range (24). All our experiments were carried out with sufficient phenol (typically 0.1 M) to ensure that all of the *tert*-butoxyl radicals decayed by hydrogen abstraction in order to maximize the phenoxyl radical signal intensities. Representative spectra for phenoxyl, 2-, 3-, and 4-methoxyphenoxyl and 2,6-dimethoxyphenoxyl in Freon-113 are shown in Figs. 1 and 2. All of these show a narrow structured absorption band in the 370–410 nm region. There is an additional broader absorption at longer wavelengths (500–700 nm) for most of these radicals. The position of this band and its intensity relative to the 400 nm band vary considerably with the substitution pattern of the phenoxyl radical.

The structured near-ultraviolet bands of phenoxyl have been studied by several groups (3–5) but not much attention has been paid to the broad band. In phenoxyl itself, this band is very weak and remains essentially structureless under our experimental conditions. In the *p*-methoxy compound, it has disappeared altogether, but in the *ortho*-substituted

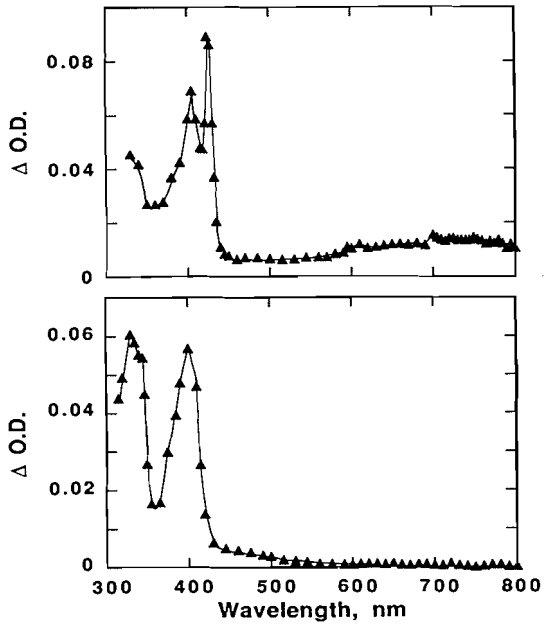

FIG. 2. Transient absorption spectra of 3-methoxyphenoxyl (top) and 4-methoxyphenoxyl (bottom) radicals generated by 308 nm laser excitation of di-*tert*-butyl peroxide plus the appropriate phenol in Freon-113.

phenoxyls, it is much stronger than in phenoxyl itself and shows some structure. It is also redshifted with maxima located near 640 nm in 2-methoxyphenoxyl and near 680 nm in 2,6-dimethoxyphenoxyl compared to the maximum near 575 nm in the parent radical. In 3-methoxyphenoxyl, the observed band is very weak but seems to be considerably broader than in the other compounds, with a maximum near 700 nm.

Among the observed broad-band spectra, that of 2-methoxyphenoxyl shows the clearest evidence of resolved vibrational structure compatible with the presence of a low-frequency progression such as that observed by Ward (7) in the vapour. However, the resolution is too poor to allow a frequency estimate.

Apart from its intrinsic interest, the visible band is valuable for monitoring phenoxyls during chemical reactions since relatively few simple organic molecules absorb in this region. Although in phenoxyl itself the band is uncomfortably weak, it appears that judiciously chosen *ortho*-substituents may render it attractive for this application.

4. Computational methods

To assign the 600 nm band, we started our analysis with a series of simple semi-empirical calculations, based on π-electron, CNDO, MNDO, and INDO Hamiltonians. Our π-electron calculations employed a modified version (25, 26) of the QCFF/PI program (27) and were based on the half-electron self-consistent-field (28) (HE-SCF) method, followed by configuration interaction (29) (CI) among all 33 determinants that are singly excited relative to the ground state configuration.

Our MNDO calculations (30) were based both on the UHF (31) and the HE-SCF + CI methods (28, 29). These methods were used to calculate the structure and force field of the ground state. At the optimized ground state structure of both QCFF/PI and MNDO-UHF, CNDO/S (32) calculations were

carried out in order to determine the energies and transitions moments of the excited states. Similar calculations were carried out with the INDO/S method (33), followed by CI based on Rumer diagrams (34), at the structure optimized by INDO/1. These MNDO-CNDO/S and INDO/1-INDO/S methods were also used to calculate the excitation energies and transition moments of a number of substituted radicals, two of which will be considered here, namely 2-methoxy- and 2,6-dimethoxyphenoxyl, both showing strongly enhanced absorption in the 600 nm region.

The calculated ground-state equilibrium structures of phenoxyl are listed in Table 1, columns 1–4; additional structural parameters, based on calculations reported in the literature, are listed in columns 5–9. Since there is strong disagreement between the calculated structures, we carried out a higher-level *ab initio* calculation, for which we chose the CASSCF method with the split valence 3-21G basis set and an active space including the seven π electrons and orbitals of phenoxyl, for a total of 784 configurations. These calculations, labelled CASSCF(7,7)/3-21G, were performed with the GAUSSIAN 92 program package (35).

Since our CASSCF results differ in some respects from earlier results (20) obtained with the same method and basis set, we briefly outline our procedure. We started our ground-state CASSCF optimization with the ROHF molecular orbitals and the structure obtained in ref. 20 with these same orbitals. For this structure we obtained an energy of −303.3380 au and a gradient significantly different from zero. The structure (shown in Table 1) and energy obtained after optimization are identical with those obtained for the lowest energy ground state structure in ref. 20. Using the same active space of seven π orbitals, we optimized the $1A_2$ state structure starting the CASSCF calculation with the optimized ground-state molecular orbitals. The resulting structure is superior to that obtained previously in that the energy is lower by about 0.89 eV, probably because in the earlier calculations (20) two of the seven π orbitals in the active space were replaced by (ineffective) σ orbitals.

Despite the lack of agreement between the calculated ground-state structures, all methods lead to the same ordering of the lower excited states and to qualitatively similar intensities for the lower transitions, as shown in Table 2. Table 3 indicates that the presence of *ortho*-methoxy groups does not change this ordering and confirms the one-to-one correspondence between the bands in phenoxyl and those in the two substituted phenoxyls.

In the following we adopt the CASSCF(7,7)/3-21G structure, not only because it is obtained by the most elaborate method used, but also because it gives the best agreement with the available experimental data. Specifically, the presence of a quinoid distortion is indicated by the fit of the INDO results to ESR data, reported in ref. 17. In Table 4 we list the calculated vibrational frequencies (scaled by 0.95) for phenoxyl-d_0, -2,4,6-d_3, and -d_5 and compare them with the few observed frequencies. For comparison we also list the "best" semi-empirical frequencies of phenoxyl-d_0, obtained by the QCFF/PI method.

The scaling factor of 0.95 is close to unity, in keeping with the observation that CASSCF frequencies tend to be less overestimated than frequencies obtained at the HF level. The same scaling factor has been found to be appropriate for the benzyl radical.[3]

On the basis of these calculations, we assign the 1505 cm^{-1} band to mode ν_{8a} instead of the CO-stretching mode, as proposed earlier (5). For the latter, we obtain a frequency of 1269 cm^{-1}, in qualitative agreement with the calculated CO bond length. Deuteration causes mixing between the CC and CO stretching modes, leading to anomalous isotope effects. Preliminary calculations of the resonance Raman spectrum support the assignment of the most prominent band to ν_{8a}. This assignment also agrees with the observed activity of ν_{8a} in the *p*-hydroxyphenoxyl radical (4). In general, the agreement between the calculated and observed frequencies of the

three isotopomers of phenoxyl is satisfactory, although the frequency of ν_{8a} is overestimated in phenoxyl-d_0 and -d_3.

In Table 5 we list the structure of the $^1A_2$ excited state of phenoxyl calculated at the CASSCF(7,7)/3-21G level. To explain the observed absorption spectra, the change in structure between the $^1B_2$ and $^1A_2$ states is the principal parameter. Since the same method is used for both states the relative rather than the absolute accuracy of these methods is crucial for our purpose. To demonstrate the proposed assignment of the 600 nm band, it will be necessary to show that the calculated displacements of the normal modes can account for the structure of this band.

5. Analysis

The ground-state structures in Table 1, obtained with the various methods used by us and by others show large divergencies. No direct experimental information is available; in the parent molecule, phenol, the benzene ring is close to a regular hexagon (36). However, the CASSCF calculations lead to a quinoid structure for phenoxyl. Support for a quinoid distortion is provided by INDO calculations of spin densities (17) which require such a structure in order to reproduce experimental results. Although the UHF/3-21G results also yield a quinoid structure (19), the resulting wavefunction is strongly spin-contaminated (S^2 is about 1.4 instead of the proper value of 0.75), so that these results are not reliable. The semi-empirical Hamiltonians tend to either overestimate or underestimate the quinoid distortion of the benzene ring, except for the QCFF/PI method which yields a structure close to that predicted by CASSCF. Table 2 shows that the order of the excited states obtained at this structure with the CNDO/S or the QCFF/PI method is the same as that obtained with an *ab initio* CI calculation at the CASSCF structure including only single excitations (37) (CIS) or even with the INDO/S method at the INDO/1 structure. The fact that all these methods yield the same ordering of the states, although the calculated energies show wide variations, indicates that this ordering is likely to be correct. It follows that the lowest excited state is an $n\pi^*$ state of B_1 symmetry, followed by a $\pi\pi^*$ state of A_2 symmetry, either of which may be responsible for the visible band.

The transition moments in Table 2 clearly favour a $\pi\pi^*$ assignment. Despite considerable scatter, they all show the pattern of a weak transition followed by two stronger tran-

sitions of comparable strength, which in turn are followed by a strong $B_2 \rightarrow B_2$ transition at shorter wavelength (38). This pattern is close to what is observed experimentally and implies that the weakest transition corresponds to $1B_2 \rightarrow 1A_2$ $\pi\pi^*$. If an $n\pi^*$ assignment were adopted, which transition is consistently predicted to have a near-zero transition moment, one would have to explain why the stronger $\pi\pi^*$ transition at higher energies is not observed, not even in substituted phenoxyls.

The $\pi\pi^*$ assignment also agrees qualitatively with the observed spectral structure which shows no evidence of the carbonyl stretching progression expected for $n\pi^*$ transitions. On the other hand, the observed spectrum is very different from that for the $\pi\pi^*$ transitions to the $2B_2$ and $2A_2$ states and hence would seem to require a detailed explanation. This we attempt to supply by simulating the absorption spectrum on the basis of the calculated changes in structure and force field between the two states. The corresponding dimensionless displacements B_i of the equilibrium positions of the normal modes between the states, as derived from the CASSCF calculations, are listed in Table 5. These displacements yield the Franck–Condon factors which govern the vibrational intensity distribution in the spectrum.

Figure 3 depicts a simulation covering the first 2000 cm^{-1} of the $1B_2 \rightarrow 1A_2$ transition for a vibronic band width of 80 cm^{-1} chosen to allow comparison with the spectrum observed by Ward (7). The two spectra show the same four prominent bands with a spacing of about 500 cm^{-1} (~550 cm^{-1} in the calculated spectrum). To facilitate assignment of these bands, we also depict a calculated line spectrum in Fig. 3. Comparison with Table 5 shows that the 500 cm^{-1} fundamental corresponds to ν_{6a} in benzene derivatives, a ring-deformation mode active in many transitions involving a quinoid structure in the lower or upper state. This

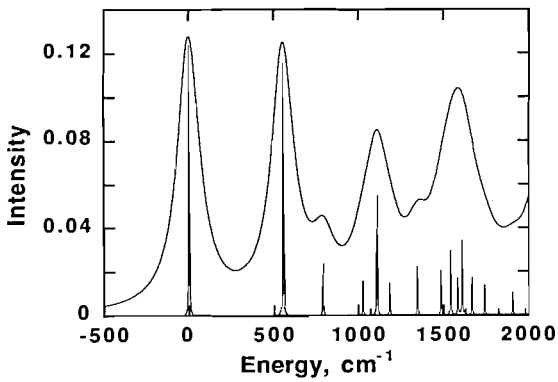

FIG. 3. Vibrational structure of the $1B_2 \rightarrow 1A_2$ absorption spectrum of the phenoxyl radical calculated for a linewidth of 80 cm^{-1}.

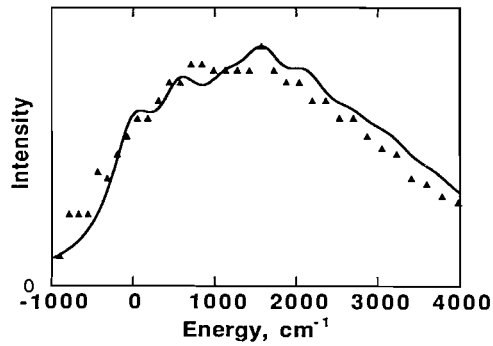

FIG. 4. Comparison of the observed (▲) and calculated spectra for the visible absorption band of the phenoxyl radical.

mode forms a prominent progression in phenoxyl, but its overtone bands also contain significant contributions of fundamentals in the ranges 1000–1200 cm^{-1} and 1500–1600 cm^{-1}, respectively. The calculated spectrum shows additional weak bands or shoulders near 800 cm^{-1} and 1300 (= 800 + 500) cm^{-1} which are not resolved in the observed spectrum (7) but whose presence is suggested by the observed intensity in these regions.

In Fig. 4 we show the entire calculated spectrum, which extends well beyond 2000 cm^{-1}, for a vibronic linewidth of 350 cm^{-1}, to allow comparison with the observed solution spectrum, measured point by point. To fit the calculated curve to the measured points, we have simply equated their two maxima. While this does not necessarily yield the best fit, it is enough to illustrate the similarity of the calculated and observed structures. The calculated spectrum does not contain hot-band contributions, which would improve the fit.

This confirms that the visible phenoxyl band can be assigned confidently to the $1B_2 \rightarrow 1A_2$ $\pi\pi^*$ transition. Theory predicts that the missing $n\pi^*$ transition is to be found at lower energies, a prediction supported by the observed diffuseness of the 600 nm band in the vapour, which suggests rapid internal conversion across a narrow energy gap. The intensity of the $n\pi^*$ transition is probably considerably smaller than that of the $1B_2 \rightarrow 1A_2$ transition, since all calculations predict a transition moment close to zero.

The calculations performed on the methoxy-substituted phenoxyls are in agreement with this conclusion within the accuracy one may expect from the two semi-empirical methods used. They both account reasonably well for the observed blue shifts upon ortho-methoxy substitution and the INDO/S method also accounts satisfactorily for the observed increase in intensity (the CNDO/S method predicts an increase only for the mono-substituted radical). These calculations refer to the lowest-energy rotamer only; the presence of other rotamers at room temperature would presumably modify these results to some extent.

6. Discussion

According to our analysis, the lowest excited state of phenoxyl is an $n\pi^*$ state which remains undetected. It is followed by the weak $1B_2 \rightarrow 1A_2$ $\pi\pi^*$ transition near 600 nm discussed in this paper, and by two medium weak $\pi\pi^*$ transitions of symmetry $1B_2 \rightarrow 2B_2$ and $1B_2 \rightarrow 2A_2$, at 400 and 315 nm, respectively. The first strong transition occurs at 230 nm (38) and is assigned to $B_2 \rightarrow B_2$. In the closely related and much studied benzyl radical (39), the lower main band structures are observed near 450, 300, and 260 nm, with an additional weak feature near 270 nm.

The quantum-chemical calculations indicate a one-to-one correspondence between the phenoxyl and benzyl transitions, with the weak 270 nm band in benzyl corresponding to a 255 nm shoulder observed in phenoxyl and assigned to $B_2 \rightarrow B_2$; the 300 and 260 nm bands in benzyl correspond to the 315 and 230 nm bands in phenoxyl and the 450 nm band in benzyl represents two nearly degenerate transitions which correspond to the 400 and 600 nm bands in phenoxyl. Thus the main difference between the two spectra is due to the large separation of the lowest two $\pi\pi^*$ transitions in phenoxyl compared to benzyl.

It is not difficult to account for this difference in terms of orbital energies. The HOMO and LUMO π orbitals are of A_2 symmetry and thus receive no contributions from the O atom or the CH_2 group. As a result, they have roughly the same energy in both radicals. The $1A_2$ state is governed, however, by contributions of the H → S and S → L configurations as shown in Table 2. While in benzyl these two configurations contribute roughly equal amounts, in phenoxyl the presence of the O atom leads to stronger contributions of the H → S component which lowers the energy of the $1A_2$ state. Similar considerations indicate that the $2B_2$ states in both radicals should have roughly the same energy, relative to the ground state, in agreement with the observed spectra. Hence comparison with benzyl lends further support to our assignment of the 600 nm transition in phenoxyl.

The larger difference in energy between the $1A_2$ and $2B_2$ states in phenoxyl relative to benzyl probably implies that vibronic coupling between these states is less important for phenoxyl than it was found to be for benzyl. In the latter radical, inclusion of this vibronic coupling was necessary in order to reproduce the observed spectrum (40). In phenoxyl, however, we obtained an adequate simulation without including vibronic coupling.

The quinoid structure calculated for the ground state of phenoxyl is similar but slightly more pronounced than that previously calculated for benzyl by the same methods, QCFF/PI (9) and CASSCF (40). The bond length changes accompanying the $1B_2 \rightarrow 1A_2$ transition are also found to be quite similar for the two radicals, but the $C_2C_1C_6$ angle undergoes a much larger change in phenoxyl (4° against 1.5° for benzyl); this implies of course that the other angles change accordingly. In particular the large change in $C_2C_1C_6$ angle

in phenoxyl is confirmed by the observed activity of ν_{6a}, which is stronger than in benzyl. Of the two radicals, phenoxyl is thus slightly less aromatic and more olefinic.

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

SHAHUL H. NILAR, AJIT J. THAKKAR, ANNE E. KONDO, and WILLIAM J. MEATH. Can. J. Chem. **71**, 1663 (1993).

The "giant dipole" molecules, $NR_1R_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$, n = 0, 1, 2, are studied theoretically for three sets of substituents: $R_1 = R_2 = H$, $R_1 = H$, $R_2 = CH_3$, and $R_1 = R_2 = CH_3$. For each of these nine molecules, the energies, and permanent and transition dipole moments for the 20 lowest electronic states are calculated using the intermediate neglect of differential overlap (INDO) approximation at the configuration interaction with single excitations (CIS) level. Static polarizabilities and hyperpolarizabilities for the ground states are reported for these "push–pull" molecules. The changes in the physical properties of interest due to increase in conjugation length and the inductive effect of substituents on the donor group attached to the rings are discussed. The energies and permanent and transition dipole moments for the ten lowest electronic states are tabulated for use in future studies of the spectral and dynamical effects of permanent dipole moments on laser-induced one- and multi-photon electronic transitions in realistic models for many-level giant dipole molecules.

SHAHUL H. NILAR, AJIT J. THAKKAR, ANNE E. KONDO et WILLIAM J. MEATH. Can. J. Chem. **71**, 1663 (1993).

On a étudié d'une façon théorique les molécules à "dipôle géant", $NR_1R_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$ dans lesquelles n = 0, 1 et 2 et portent trois ensembles de substituants, $R_1 = R_2 = H$, $R_1 = H$, $R_2 = CH_3$ et $R_1 = R_2 = CH_3$. Pour chacune de ces neuf molécules et utilisant l'approximation de négligence intermédiaire du recouvrement différentiel (INDO) de l'interaction de configuration avec des excitations simples (ICS), on a calculé les énergies et les moments dipolaires permanents et de transition des vingt états électroniques les plus bas. On rapporte aussi les polarisabilités et hyperpolarisabilités statiques des états fondamentaux de ces molécules qui "poussent et tirent". On discute des changements dans les propriétés physiques des propriétés intéressantes qui sont causés par une augmentation dans la longueur de la conjugaison et par l'effet inductif des substituants sur le groupe donneur attaché aux noyaux. On présente un tableau des énergies et des moments dipolaires permanents et de transition des dix états électroniques les plus bas qui pourront être utilisés dans des études futures des effets spectraux et dynamiques des moments dipolaires permanents sur les transitions électroniques mono-ou multi-photoniques induites au laser dans des modèles réels pour des molécules à plusieurs niveaux de dipôle géant.

[Tradiut par la rédaction]

1. Introduction

Materials that exhibit large nonlinear optical responses are required for a variety of applications in laser technology and optical processing of information (see, for example, ref. 1). Hence the design of molecules with such properties is of great current interest. Organic molecules with easily delocalized conjugated π electrons almost invariably have large dipole polarizabilities and hyperpolarizabilities (see, for example, refs. 2, 3). Electron donor and acceptor groups attached to opposite ends of the conjugated system are thought to facilitate charge transfer across the conjugated pathway and thus enhance the nonlinear response properties. Amino and nitro groups are prototypical donors and acceptors, respectively. Thus the prototype of a so-called "push–pull" molecule containing a conjugated pathway capped by donor and acceptor groups is *para*-nitroaniline, $NH_2—C_6H_4—NO_2$. Such molecules often have excited electronic states of a charge transfer character, and so there can be large differences between the dipole moments of the ground and charge transfer states. If this is the case, interesting spectral and dynamical effects are associated with laser-induced electronic transitions in these so-called "giant dipole molecules" (4–7).

The explicit spectral and dynamical effects of permanent dipole moments on continuous wave and pulsed laser-induced one- and multi-photon electronic transitions have been studied using few-level model systems (4–11). To extend such electronic studies to more realistic many-level molecular systems, we calculated the transition energies, and permanent and transition dipole moments for three series of giant dipole diphenyl molecules. Moreover, in view of their potential use as non-linear optical materials, we calculated the static polarizabilities and hyperpolarizabilities of these molecules. The first series consists of the *p*-amino-*p'*-nitrodiphenylacetylenes, $NH_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$ with n = 0, 1, 2, single crystals of which have been synthesized recently by Graham and co-workers (12). A more efficient donor group can be produced by replacing the hydrogen atoms in the amino substituent by methyl groups which have an inductive effect. Thus, we decided to study three sets of molecules $NR_1R_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$, n = 0, 1, 2. The first series has $R_1 = R_2 = H$ as in the work of Graham et al. (12), the second has $R_1 = CH_3$ and $R_2 = H$, and the third has $R_1 = R_2 = CH_3$. The charge transfer is ex-

pected to increase as one progresses from the original series to the dimethylated series.

The layout of this paper is as follows. Section 2 contains a brief description of the quantum mechanical methods we use, and section 3 deals with our calculated energies, dipole moment matrix elements, polarizabilities, and hyperpolarizabilities. Hartree atomic units are used throughout except where explicitly stated otherwise.

2. Methodology

A. Molecular geometries

The geometries for the $NH_2—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$ series of molecules were taken from the X-ray diffraction study of Graham et al. (12) with small adjustments to impose C_{2v} symmetry. These adjustments include taking the two phenyl rings to be coplanar, and averaging the two different NO bond lengths to a common value. In no case was a bond length changed by more than 0.01 A. The geometries of the other molecules $NCH_3R_2—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$, with $R_2 = H$ and $R_2 = CH_3$, were constructed as follows. All geometrical parameters in the $—N—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$ moiety and the N—H bond length were chosen to be the same as in the corresponding unmethylated molecule, and the geometry of the NCH_3 moiety was taken from X-ray structural studies of *N,N*-dimethyl aniline (13). The excited state geometries were assumed to be the same as those in the ground states, and thus all transitions are treated as vertical. Our coordinate system has its origin at the center of the bridge, the *z*-axis along the bridge axis pointing toward the nitro group, and the phenyl rings in the *xz*-plane.

B. Model Hamiltonian

The quantum mechanical calculation of transition moments and energies corresponding to a manifold of excited states requires a method that goes beyond the Hartree–Fock approximation. One suitable method is CI — configuration interaction (14, 15). However, *ab initio* CI calculations with a one-particle basis set large enough to produce useful results are not feasible for molecules as large as the ones we are considering. Therefore, we use a CI procedure based upon a semiempirical Hamiltonian in the zero differential overlap family of approximations (16, 17). The molecules considered are just small enough to allow use of an all-valence-electron scheme; higher members of these series ($n > 2$) could be studied only in a π-electron approximation with our resources.

A spectroscopically parameterized method is clearly the most suitable for our purposes. We chose INDO/S, the spectroscopic version of the intermediate neglect of differential overlap method (18), over CNDO/S, its complete neglect of differential overlap precursor (19). INDO/S retains one-centre exchange integrals that CNDO/S does not. These integrals are important for a reasonable description of singlet–triplet separations, and have a significant effect on oscillator strengths (18). The parameters in INDO/S were adjusted (18) so that the electronic spectra of benzene and the azabenzenes calculated using a single-excitation CI procedure agreed as closely as possible with experiment (18). INDO/S has been successful in predicting the frequencies and oscillator strengths of dipole-allowed transitions in conjugated systems (18, 20, 21).

A "γ-formula" for the distance dependence of the effective Coulomb repulsion between electrons located on different atoms has to be chosen. We considered three functional forms: the Mataga–Nishimoto (MN) formula (22), the Ohno–Klopman (OK) recipe (23, 24), and the Pariser–Parr (PP) approximation (25). The steepness of the variation of the repulsion with interatomic distance decreases in these formulas in the order: MN, OK, and PP. Table 1 compares ground state dipole moments for $NH_2—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$, $n = 0, 1, 2$, obtained from self-consistent-field (SCF) INDO/S calculations with these three different parameterizations. The dipole moments are large, of the order of 10 D. They increase as the number of acetylenic bonds is increased, regardless of which calculation scheme one considers. For each of the molecules, the INDO/S dipole moments increase in the order: MN, OK, and PP parameterization. For calibration purposes, we performed *ab-initio* SCF computations on these molecules with the minimal STO-3G and split-valence 3-21G basis sets (15, 26). For these molecules, the MN parameterization produces INDO/S dipole moments within 2% of the *ab initio* 3-21G values that are usually accurate to a few tenths of a Debye (3–5% in our molecules). The OK and PP parameterizations, respectively, lead to dipole moments 9–11% and 17–20% larger than the 3-21G values. On the basis of these ground state dipole moments alone, the MN scheme seems the most appropriate. However, Archibong and Thakkar (27) have found the OK parameterization leads to static polarizabilities and hyperpolarizabilities of the linear $C_{2n}H_2$ polyynes in far better agreement with accurate *ab initio* results than the MN parameterization. Since static polarizabilities and hyperpolarizabilities are among the properties of interest in this work, and since they depend on the entire spectrum of states that are also of interest in studies of laser–molecule interactions, we decided the OK formula was more appropriate for the purposes of this paper.

TABLE 1. Ground state dipole moments (in Debyes) of the "giant dipole" molecules, $NH_2—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$, $n = 0, 1, 2$[a]

	Ground state dipole moments				
n	NM	OK	PP	STO-3G	3-21G
0	8.75	9.51	10.23	6.59	8.56
1	9.10	10.00	10.73	6.94	9.14
2	9.30	10.33	11.08	7.05	9.41

[a]The table contains values obtained by the INDO/S method using the NM, OK, and PP parametrizations of the Coulomb integrals, and by *ab initio* SCF calculations using the STO-3G and 3-21G basis sets. See text for further details.

C. Selection of configurations

Since our computational resources do not permit full CI calculations to be performed on the molecules of interest, it becomes necessary to decide on the configurations to be included in the calculations. In their CNDO/S perturbation theory studies on two-photon spectroscopy, Dick and Hohlneicher (8) discussed the possibility of predicting transition energies for both dipole-allowed and dipole-forbidden transitions at a similar level of accuracy. They concluded that inclusion of double excitations in the CI procedure can be important (8, 28). Hence, we began with CI calculations including selected single and double excitations. After many

trial calculations we concluded that, given the limitations of the computer program (18) we used and our computer resources, we could not include an adequate number of double excitations to obtain results stable against small changes in the selected set of double excitations. Moreover, the INDO/S scheme was parameterized for CI calculations using single excitations only, and hence inclusion of higher excitations may require reparameterization. We then decided to restrict ourselves to single excitations only; so our calculations can be labelled INDO/S-CIS.

After numerous tests, we settled on CI calculations including all possible configurations generated by single excitations from the 20 highest occupied molecular orbitals into the 35 lowest virtual orbitals. This resulted in approximately 200 configurations for each symmetry block of the CI matrix. The transition energies, permanent dipoles and oscillator strengths obtained by this process were stable, with respect to modest changes in the number of virtual orbitals to which excitations are included, within a few hundred cm^{-1} and 1% respectively. These uncertainties are substantially smaller than the inherent errors in the INDO/S single excitation CI scheme which we estimate to be between 1000 and 3000 cm^{-1} for transition energies and 50% for permanent and transition moments. These error estimates are based on our expectation that the INDO/S CIS method is likely to do less well on systems that contain triple bonds, such as those considered in this work, than systems closer in nature to the benzenoid molecules for which it was parameterized (18).

D. Response properties

The energy E of a molecule in a weak, homogeneous, and static electric field can be expanded in a Taylor series, thus (29, 30)

$$[1]\quad E(\bar{F}) = E(\bar{O}) - \boldsymbol{\mu}_i F_i - \frac{1}{2}\boldsymbol{\alpha}_{ij}F_iF_j - \frac{1}{6}\boldsymbol{\beta}_{ijk}F_iF_jF_k - \ldots$$

in which μ_i, α_{ij}, and β_{ijk}, respectively, are components of the dipole moment vector, and the origin-independent dipole polarizability and hyperpolarizability tensors of the molecule. The subscripts denote Cartesian components (x, y, or z) and a repeated subscript implies summation over the latter. In C_{2v} molecules with the symmetry axis along the z axis, such as those with $R_1 = R_2$ in this work, the α and β tensors have three independent components each (29). In C_s molecules, such as those with R_1 different from R_2 in this work, the α and β tensors have four and six independent components, respectively. Differentiation of eq. [1] with respect to the field strength leads to an expression for the field dependent dipole moment $\bar{\boldsymbol{\mu}}(\bar{F})$:

$$[2]\quad \boldsymbol{\mu}_i(\bar{F}) = \boldsymbol{\mu}_i(\bar{O}) + \boldsymbol{\alpha}_{ij}F_j + \frac{1}{2}\boldsymbol{\beta}_{ijk}F_jF_k + \ldots$$

We used the finite perturbation method (31, 32) in which a finite field is introduced in the Hamiltonian, and the polarizabilities are obtained by numerical differentiation of the field-dependent energy or dipole moment of the molecule. We chose to differentiate the induced dipole moment following previous semiempirical work (33). The field-dependent dipole moments were computed at the INDO/S-SCF level in OK parameterization with a homogeneous field added to the Hamiltonian. The finite-field method applied at the SCF level is equivalent (34–36) to both the coupled Hartree–Fock (CHF) method and the static limit of the random phase approximation (RPA), and hence our polarizabilities are semiempirical (INDO/S) CHF polarizabilities.

TABLE 2. INDO/S (OK) ground state dipole moments (in Debyes) for three series $NR_1R_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$, n = 0, 1, 2, of "giant dipole" molecules

	Ground state dipole moments		
n	$R_1 = R_2 = H$	$R_1 = H$, $R_2 = CH_3$	$R_1 = R_2 = CH_3$
0	9.51	9.66	9.87
1	10.00	10.15	10.35
2	10.33	10.47	10.67

The finite field SCF procedure described above is theoretically more accurate than calculating polarizabilities from a sum over the INDO/S-CIS states. This is so because when only single excitations are included in a CI calculation, the sum-over-states is equivalent to the Tamm–Dancoff method (37, 38) which is an approximation to the RPA method. In quantum chemical parlance, the sum-over-CIS-states is an *un*coupled Hartree–Fock method which is an approximation to the finite-field coupled Hartree–Fock (CHF) method we use. *Ab initio* uncoupled Hartree–Fock calculations may be moderately useful for dipole polarizabilities but are completely inadequate for hyperpolarizabilities (39).

It is conceivable that these theoretical considerations fail for parametrized semiempirical methods, and that a sum over INDO/S–CIS states may produce polarizabilities closer to experiment than the INDO/S CHF method. However, we do not explore this possibility here. To resolve this issue, comparative studies are under way in our laboratory on small molecules for which both accurate *ab initio* calculations and gas-phase experiments are available.

Use of the finite-field method requires some care. Some of the precautions we took are described below. Convergence studies were carried out to verify that sufficiently small field strengths were used in the numerical differentiation to avoid contamination from even higher-order polarizabilities. Since the various components of the polarizability α and hyperpolarizability β are quite different in magnitude, different field strengths were used for different components. The stability of the finite differences was substantially improved by always using fields in pairs with the same magnitude but in opposite directions (40).

3. Results and discussion

A. Ground state dipole moments

Table 2 lists INDO/S (OK parameterization) SCF values of the ground state permanent dipole moments for each of the three series of giant dipole molecules $NR_1R_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$. Since single excitations do not mix with the ground state, the same dipole moments are predicted by the INDO/S-CIS calculation. In each series, the large dipole moments increase with the length of the conjugation path but the rate of growth seems to diminish. For a fixed number of acetylenic bonds n, the dipole moments increase as the donor amino group is increasingly methyl-

TABLE 3. Dipole moment matrix elements μ_{ij} in Debyes and transition energies ω_{ij} in cm^{-1} for the 10 lowest A_1 states of $NH_2—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$, $n = 0, 1, 2$[a]

ated. This increase can be attributed to the inductive effect of the methyl groups.

Steigman et al. (41) reported dipole moments, measured in chloroform solvent, of 14.0 and 16.0 D respectively for the $n = 1$ and $n = 2$ members of the series $NH_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$, and 15.5 D for $N(CH_3)_2—C_6H_4—(C{\equiv}C)—C_6H_4—NO_2$. These are about 50% larger than both the INDO/S values in Table 2 and the *ab initio* 3-21G values in Table 1. These large discrepancies are probably due to solvent effects since errors of the order of 5 D are highly unlikely for *ab initio* 3-21G SCF values (15). To check this possibility, we performed INDO/S (OK) self-consistent-reaction-field (SCRF) calculations for these molecules in chloroform solvent using the same Onsager radius of 6.4 Å used by Steigman et al. (41) in their data analysis. This increased our dipole moments to 12.8 and 14.6 D, respectively, for the $n = 1$ and $n = 2$ unmethylated molecules, and to 13.7 D for the $n = 1$ dimethylated molecule. The calculated solvent shifts are in the right direction but a bit too small; we think they are as good as can reasonably be expected given the uncertainty in the Onsager radius.

B. Excited state dipole moments

The permanent dipole moments μ_{ii} ($i = 1, \ldots, 10$) of the ten lowest states of A_1 symmetry are listed in Tables 3 and 4, respectively, for the $NH_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$ and $N(CH_3)_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$ series. Data for higher states and for states of A_2, B_1, and B_2 symmetry is available upon request. The dipole moments of the ten lowest states of the singly methylated series $NHCH_3—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$, $n = 0$, 1, 2, respectively are listed in Tables 5–7. All the states have large permanent dipole moments; quite a few are larger than 20 D and one is 39 D! Moreover, the dipole moment differences $\delta_{ij}\mu = \mu_{ii} - \mu_{jj}$ are often larger than 10 D; this is significant because it is $\delta_{ij}\mu$, and not the individual μ_{ij}, that is responsible for many of the interesting effects of permanent dipoles in laser–molecule interactions (5, 9). Some of the excited state dipole moments (μ_{ii}, $i > 1$) increase with the length of the conjugated pathway, some decrease, and some are nonmonotonic functions of n. Thus there is no simple dependence of the dipole moment differences $\delta_{ij}\mu$ on the length of the acetylenic bridge.

C. Transition energies and moments

Tables 3–7 also list transition energies ω_{ij} and transition moments μ_{ij} for pairs of states with $i, j \leq 10$. Data for states of other symmetry and for $i, j > 10$ are available upon request. These data have recently been used to study the effects of permanent dipole moments on the dynamics associated with the time evolution of molecular states populated by both one- and two-colour, single- and multi-photon, pump-probe laser–molecule interactions (42).

First consider the two C_{2v} series $NR_1R_2—C_6H_4—(C{\equiv}C)_n—C_6H_4—NO_2$. In each of these series, the lowest dipole-allowed-transition shows a small blue shift with the addition of the first acetylenic bond, followed by a red shift for the molecule with two triple bonds. The initial blue shift is due to the stabilization of the highest occupied molecular orbital (HOMO) by the triple bond. The subsequent red shift is due to the narrowing of the gap between the π and π^* molecular orbitals because of the increase in π conjugation.

The lowest dipole-allowed transition energy in the dimethylated series is red shifted relative to the unmethylated series because the inductive effect of the methyl groups stabilizes the HOMO. The transition moment for this lowest $\pi \rightarrow \pi^*$ transition increases in magnitude with conjugation in each series. The calculated transition energies for

the other strong dipole-allowed transitions behave in a similar manner. An unequivocal comparison of the $NHCH_3—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$ results with those for the other two series is not possible because its lower symmetry effectively reduces the number of single excitations included in the CI calculation.

Steigman et al. (41) observed, in chloroform solvent, two strong transitions at 26 400 cm^{-1} and 36 500 cm^{-1} for the

n = 1 unmethylated molecule, and at 24 000 and 34 000 cm^{-1} for the n = 1 dimethylated molecule. These could correspond to the strong 1 → 2 and 1 → 5 transitions in Tables 3 and 4. To make a meaningful comparison, we estimate solvent shifts with an expression[3] obtained by a first order perturbative treatment of the reaction field (43), together with the same Onsager radius of 6.4 Å used earlier in section 3A. In this way, we find that in chloroform solvent, the transitions in Table 3 are red shifted to ω_{12} = 29 621 cm^{-1} and ω_{15} = 41 768 cm^{-1} for the n = 1 unmethylated molecule. Similarly, the transitions in Table 4 are shifted to ω_{12} = 28 680 cm^{-1} and ω_{15} = 39 299 cm^{-1} for the n = 1 dimethylated molecule. These solvent-corrected transition frequencies are in better but not perfect agreement with the measured values (41). Much closer agreement with experiment can be obtained by using an Onsager radius of 4.685 Å, but this radius produces absurd solvent shifts for the ground state dipole moments when used in a SCRF calculation of the type discussed in section 3A.

D. Polarizabilities and hyperpolarizabilities

Tables 8 and 9 list the unique non-vanishing components of the static dipole polarizability (α) and hyperpolarizability (β) tensors for the two $N(R_1)_2—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$ series with R_1 = H and R_1 = CH_3, respectively. Tables 10 and 11 list the components of the α and β tensors, respectively, for the lower symmetry $NHCH_3—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$ series. The accuracy of the calculated components should decrease in the order $\alpha_{zz} > \alpha_{xx} > \alpha_{yy}$ and $\beta_{zzz} > \beta_{zzx} > \beta_{xxz} > \beta_{yyz}$ because the INDO/S method uses a minimal basis which can be adequate for intramolecular polarization along the chain (z axis) and, to a lesser extent, in the molecular xz plane, but is quite inadequate for the description of out-of-plane polarization (27, 31, 44). However, this is not a severe limitation since the least accurate components are also the smallest ones. The longitudinal components α_{zz}, β_{zzz} are of greatest interest. Measurements of electric field induced second harmonic generation (EFISH) lead (45, 46) to the projection of the vector invariant of β upon the ground state dipole moment: $\vec{\beta} \cdot \vec{\mu}/\mu$ in which the vector invariant $\vec{\beta}$ has components given by $\beta_i = \beta_{xxi} + \beta_{yyi} + \beta_{zzi}$ for $i = x, y, z$.

First consider the two C_{2v} series $N(R_1)_2—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$. The dipole moment is along the z axis, and hence $\vec{\beta} \cdot \vec{\mu}/\mu = \beta_z$. Moreover, β_z is dominated by β_{zzz} because the longitudinal component is so large. Both the longitudinal dipole polarizability α_{zz} and hyperpolarizability β_{zzz} increase roughly linearly with the number of acetylenic links, and are larger in the dimethylated series than in the unmethylated series. Not surprisingly, the other components do not depend appreciably on either the length of the conjugated pathway or the degree of methylation of the amino group.

Tables 10 and 11 list components of the α and β tensors, respectively, for $NHCH_3—C_6H_4—(C\equiv C)_n—C_6H_4—NO_2$, n = 0, 1, 2. Table 11 also lists β_z and $\vec{\beta} \cdot \vec{\mu}/\mu$. In this case, β_{xxz} makes a substantial contribution to β_z. Although β_x is large, $\vec{\beta} \cdot \vec{\mu}/\mu \approx \beta_z$ because the x component of the dipole moment is small. Both α_{zz} and $\vec{\beta} \cdot \vec{\mu}/\mu$ increase roughly linearly with the length of the acetylenic bridge. The longitudinal polarizability α_{zz} increases as the number of methyl groups on the amino group increase, but $\vec{\beta} \cdot \vec{\mu}/\mu$ seems to be about the same whether the amino group carries one or two methyl groups. This trend is exactly that obtained in the EFISH measurements of Stiegman *et al.* (41). The measured $\vec{\beta} \cdot \vec{\mu}/\mu$ values, after conversion from their "X convention" to our "T convention" in the nomenclature of ref. 47, are 11 100, 21 300, and 21 300 au. for the n = 1 molecules with 0, 1, and 2 methyl substituents on the amino group; these are in satisfactory agreement with our values of 7248, 9051 and 9086 au, respectively, given that our values are static gas phase ones, whereas theirs are at an optical frequency and in chloroform solvent. A discussion of solvent effects on hyperpolarizabilities may be found in ref. 48.

[3]Equation [18] in ref. 43 contains a typographical error: the first factor in the second term on the right hand side should be $-1/a^3$.

The 353 nm $^1n\pi^*$ transition of 4*H*-pyran-4-one and a deuterated derivative

ROBERT D. GORDON[1] AND WILLIAM K.C. PARK
Department of Chemistry, Queen's University, Kingston, ON K7L 3N6, Canada

Received March 12, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

ROBERT D. GORDON and WILLIAM K.C. PARK. Can. J. Chem. **71**, 1672 (1993).

The 353 nm vapour absorption of 4*H*-pyran-4-one, and its 3,5-d_2 derivative, has been measured and assigned to a forbidden, $^1A_2$ ($n\pi^*$) – $^1A_1$ electronic transition, with electronic origin near 28 360 cm^{-1}, made allowed by vibrations involving out-of-plane ring and C—H motions. Although the molecule remains planar upon excitation, other effects of conjugation on the nature of the excited state are less marked than in 2-cyclopenten-1-one.

ROBERT D. GORDON et WILLIAM K.C. PARK. Can. J. Chem. **71**, 1672 (1993).

On a mesuré l'absorption (à 353 nm) de la 4*H*-pyran-4-one et de son dérivé 3,5-d_2 et on l'a attribuée à une transition électronique non permise, $^1A_2$ ($n\pi^*$) – $^1A_1$, ayant une origine électronique près de 28 360 cm^{-1} et qui est rendue permise par des vibrations impliquant des mouvements du cycle et des C—H hors-plan. Même si la molécule demeure planaire lors de son excitation, d'autres effets de conjugaison sur la nature de l'état excité sont moins marqués que dans la cyclopent-2-èn-1-one.

Introduction

Studies of $n\pi^*$ electronic transitions in cyclic ketones, including ρ-benzoquinone (ρBQ) (1), cyclopentanone (CP) (2), cyclobutanone (CB) (3), tetramethyl-1,3-cyclobutanedione (TMCBD) (4), and 2- and 3-cyclopenten-1-one (2- and 3-CP) (5), have been a recurring theme in the work of Professor G.W. King and his former students. The present study of the 353 nm $^1n\pi^*$ absorption spectra of 4*H*-pyran-4-one (PN-h_4, Fig. 1), and its partially-deuterated derivative 3,5-d_2-4*H*-pyran-4-one (PN-d_2), continues that theme. Despite limitations imposed by the comparatively broad and diffuse nature of the observed vibronic bands, significant information has been obtained, and interesting comparisons can be made with the corresponding $^1n\pi^*$ systems in other cyclic ketones. The spectrum of PN is also of interest in the light of recent work (6) on its thione derivative.

Microwave studies (7) show that PN has a planar C_{2v} structure. Simple molecular orbital arguments predict that the lowest energy singlet electronic transition, $\tilde{A}\ ^1A_2$ ($n\pi^*$) $\leftarrow \tilde{X}\ ^1A_1$, is forbidden, and that higher energy transitions, to $^1A_1$ and $^1B_2$ $\pi\pi^*$ states, are allowed. The $^1n\pi^*$ transition is expected to gain intensity from the stronger $\pi\pi^*$ transitions by vibronic interaction involving a_2 or b_1 modes.

The near-ultraviolet absorption of PN in solution (8) is consistent with these predictions. The lowest energy absorption (λ_{max} = 300 nm, ϵ_{max} = 20 L mol^{-1} cm^{-1} in cyclohexane) is weak and shifts to higher energy in ethanol, as expected for an $n\pi^*$ transition, while the second band (λ_{max} = 240 nm, ϵ_{max} = 10^4 L mol^{-1} cm^{-1} in cyclohexane) is stronger and undergoes a small shift to lower energy in ethanol, as expected for $\pi\pi^*$ transitions.

The infrared and Raman spectra of PN have been studied (9, 10), and the assignments confirmed by *ab initio* calculations (9). Ground state fundamentals relevant to this study are listed in Table 1.

Experimental methods

PN-d_2 was prepared by refluxing PN-h_4 (Aldrich) in a DCl/D_2O solution for 28 h at 98°C. The resulting solution was neutralized with NaOD and extracted with CH_2Cl_2. The product, isolated by vacuum distillation, was shown from its NMR spectrum (11) to be the 3,5-d_2 isotopomer.

Vapour absorption spectra were photographed on a 1.5 m spectrograph, using a multiple-reflection cell with a 14 m pathlength, with PN at its saturated vapour pressure at 80–110°C.

Results

Densitometer traces of the 353 nm absorption of PN-h_4 and -d_2 are shown in Fig. 1. Observed bands and their assignments are listed in Table 2. Since the bands are broad (40–50 cm^{-1} FWHM) and featureless, their wavenumbers can be measured only to ±5 cm^{-1}, and their rotational contours cannot be used to determine their polarizations.

The strongest bands form a progression in 1240 cm^{-1}, beginning at 29 220 cm^{-1} in PN-h_4 but shifted 115 cm^{-1} to lower wavenumber in PN-d_2. We assign the 1240 cm^{-1} interval to the C=O stretching mode ν_3', significantly reduced in wavenumber from its 1702 cm^{-1} ground state value, as expected in an $n\pi^*$ transition. The 29 220 cm^{-1} band must be a vibronic origin, involving an a_2 or b_1 deuterium-sensitive mode. We assign it to the a_2 CH bending mode ν_{11}', but, as noted in Table 1, it could be of b_1 symmetry.

The isotope shift of the 11_0^1 vibronic origin suggests that the electronic origin should lie between 27 900 and 28 500 cm^{-1}, and the weak bands below 28 370 cm^{-1} seem obvious candidates for hot vibronic origins, involving one or more of the low-wavenumber out-of-plane modes ν_{18}'', ν_{17}'', or ν_{13}''. If the weak 28 210 cm^{-1} band in each isotopomer is assigned 18_1^0, the (unobserved) electronic origin would be near (28 210 + 149 ≅) 28 360 cm^{-1} in each isotopomer. This assignment is supported by the appearance of a very weak PN-h_4 band at 27 970 cm^{-1}, whose −390 cm^{-1} separation from the proposed origin corresponds to a known ground state a_2 fundamental, ν_{13}''. The stronger 28 505 and 28 780 cm^{-1} PN-h_4 bands can then be assigned as the cold vibronic origins 18_0^1 and 17_0^1, if it is assumed that ν_{18} and ν_{17} undergo small decreases in wavenumber upon excitation.

The weak 28 075 cm^{-1} PN-h_4 band, at $\Delta\tilde{\nu}$ = −285 cm^{-1}, cannot be a hot vibronic origin, since there is no 285 cm^{-1} ground state fundamental. However, if the 28 620 cm^{-1} band at $\Delta\tilde{\nu}$ = 260 cm^{-1} in each isotopic species is assigned 13_0^1,

sequence bands with an interval of (260 − 395 =) −135 cm^{-1} would be expected in ν_{13}. The 28 075 and 28 370 cm^{-1} PN-h_4 bands can then be assigned as $18_1^0 13_1^1$ and $18_0^1 13_1^1$, respectively, and their intensities, relative to their parents, are consistent with these assignments. The −135 cm^{-1} sequence interval is also attached to the strong 11_0^1 and $3_0^1 11_0^1$ parent bands.

No sequence bands are resolved in low-wavenumber modes other than ν_{13}. As shown in Table 1, ν_{17} and ν_{18} change very little upon excitation, and sequences in these modes would be very closely spaced. Unresolved sequences in these modes may be responsible, in part, for the very broad observed bands.

In addition to the strong $3_0^{\nu'} 11_0^1$ progression, a number of weaker bands can be assigned to progressions in ν_3', attached to the vibronic origins 18_1^0, 18_0^1, 13_0^1, and 17_0^1. A weaker progression with a 1400 cm^{-1} interval, attached to 11_0^1, is assigned to the C=C stretching mode ν_4'.

A very weak band was observed at 27 292 cm^{-1} which, unlike all the other PN bands, has a sharp head. At $\Delta\tilde{\nu}$ = −1068 cm^{-1}, it is too intense to be a hot X_1^0 band. Since it does not fit into the pattern established for the $^1n\pi^*$ system, we tentatively assign it as the origin of the $^3A_2$ $n\pi^*$ transition.

The absorption of thin polycrystalline films of PN, grown from the melt between fused silica discs, was measured at 77 K. Broad bands, beginning near 31 900 cm^{-1} and separated by approximately 1200 cm^{-1}, were observed. If these bands can be identified with the strong $3_0^{\nu'} 11_0^1$ progression in the vapour, the 31 900 cm^{-1} band in the crystal can be assigned 11_0^1. The stronger bands in cyclohexane solution (8) form a similar 1200 cm^{-1} progression, beginning near 31 030 cm^{-1}. If these assignments are correct, the $^1n\pi^*$ absorption of PN shifts to higher energies, relative to the gas phase, by ca. 1800 cm^{-1} in cyclohexane solution, and by ca. 2700 cm^{-1} in the crystal.

Discussion

The weak 353 nm absorption of PN vapour is consistent with its recording a forbidden $\tilde{A}\ ^1A_2$ ($n\pi^*$) ← $\tilde{X}\ ^1A_1$ electronic transition, made allowed by vibronic interaction with a_2 and b_1 modes. The unobserved electronic origin is near 28 360 cm^{-1} in both isotopic species studied. As in the forbidden $^1n\pi^*$ transitions of ρBQ, CP, and 3CP, low-wavenumber, out-of-plane ring (or C=O) bending and twisting modes are vibronically active. In PN, however, the most active vibration is the higher-wavenumber, deuterium-sensitive CH wagging mode ν_{11}. This is also the case in the structurally similar molecule ρBQ, where a CH wagging mode of a_u (a_2 in C_{2v}) symmetry is strongly active. It is by analogy to ρBQ that we have assigned the $\Delta\tilde{\nu}$ = 860 cm^{-1} vibronic origin in PN to the a_2 mode ν_{11}'. It could, however, be of b_1 symmetry.

A very weak, comparatively sharp band at 27 292 cm^{-1} may well mark the origin of the $^3A_2$ ($n\pi^*$) system. If so, the 1068 cm^{-1} S_1–T_1 splitting is rather smaller than those in ρBQ (1) (1349 cm^{-1}) and TMCBD (4) (1410 cm^{-1}).

The effects of $n\pi^*$ excitation often extend beyond the C=O chromophore, and excited-state delocalization of this sort should be enhanced in molecules with conjugated C=O bonds. To assess the extent to which the effects of excitation are delocalized in PN, its $^1n\pi^*$ excited state is compared in Table 3 to the corresponding state in several other cyclic carbonyls.

In the spectra of most unconjugated carbonyl molecules, a progression in the C=O wagging mode indicates that the carbonyl group has become pyramidal in the $n\pi^*$ excited state. When the C=O bond is conjugated, however, as in acrolein (12), ρBQ, or 2-CP, the molecule retains its planar

Cyclopentanone (CP)	2	Pyramidal	30 264	1225	Not observed

[a]Observed progression in 1068 cm^{-1} unlikely to be of pure $\nu_{C=O}$ character.

ground state geometry. PN fits into this pattern, as there is no evidence in the spectrum for a change of shape upon excitation.

Lengthening and weakening of the C=O bond upon $n\pi^*$ excitation is indicated by a progression in the C=O stretching mode, and a substantial reduction in its excited-state wavenumber, $\nu'_{C=O}$, from the ground state value of ca. 1750 cm^{-1}. The decrease in $\nu'_{C=O}$ should be less in conjugated molecules where the effects of excitation are delocalized over two or more bonds. Further evidence for this delocalization is a second progression in the stretching mode of the conjugated C=C bond. Thus, in the $^1n\pi^*$ spectra of acrolein (12) and 2CP, there are progressions of almost equal intensity in $\nu_{C=O}$ and $\nu_{C=C}$. In PN, however, the $\nu_{C=C}$ progression is much weaker than the $\nu_{C=O}$. Furthermore, as shown in Table 3, the value of $\nu'_{C=O}$ in PN is closer to that in the unconjugated molecules 3CP and CP than to that in the conjugated 2CP.

A conjugated C=O bond should also shift the $^1n\pi^*$ transition to lower energy. The PN electronic origin, though lower in energy than that of 3CP and CP, is significantly higher than that of 2CP.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

Thus, although conjugation in the excited state of PN prevents its carbonyl group from becoming pyramidal, other effects of $n\pi^*$ excitation are less affected by conjugation in PN than in 2CP.

Finally, in many cyclic carbonyls, $n\pi^*$ excitation has been found to have a large effect on the low-wavenumber, out-of-plane vibrations of the ring (5). Ring bending fundamentals in ρBQ (1) and 3CP (5) increase by more than 30%, while the ring bending mode in 2CP (5), harmonic in the ground state, becomes markedly anharmonic upon excitation. In PN, on the other hand, ring bending (ν_{17} and ν_{18}) is hardly affected by excitation, while the ring twisting fundamental, ν_{13}, decreases by 34%.

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

CAROL DALLAIRE, MICHAEL A. BROOK, ALEX D. BAIN, CHRISTOPHER S. FRAMPTON, and JAMES F. BRITTEN. Can. J. Chem. **71**, 1676 (1993).

The tetrakis(trimethylsilyl)ethynyl derivatives of Si, Ge, Sn, and Pb were prepared and examined spectroscopically. NMR and Mössbauer spectroscopy and X-ray crystal structure data clearly demonstrate an electronic interaction in the ground state between the distal $SiMe_3$ groups and the central metal atom, leading to a strong shielding of the central metal atom; the respective nmr signals of the central metal are among the most shielded examples reported for a tetrahedral Group 14 metal centre with four carbon ligands. The nature of these electronic interactions is discussed.

CAROL DALLAIRE, MICHAEL A. BROOK, ALEX D. BAIN, CHRISTOPHER S. FRAMPTON et JAMES F. BRITTEN. Can. J. Chem. **71**, 1676 (1993).

On a préparé les dérivés tétrakis(triméthylsilyl)éthynyles du Si, du Ge, du Sn et du Pb et on a examiné leurs spectres. Les spectres RMN et de Mössbauer et les données relatives aux structures cristallines démontrent clairement l'existence d'une interaction électronique dans l'état fondamental entre les groupes $SiMe_3$ distales et l'atome métallique central; ces interactions donnent lieu à un blindage important de l'atome métallique central et les signaux RMN respectifs de chaque métal central sont parmi les exemples les plus blindés rapportés pour un métal central tétraédrique du groupe 14 portant quatre coordinats carbonés. On discute de la nature de ces interactions électroniques.

Introduction

Organosilicon chemistry has found extensive application in organic synthesis. This utility results primarily from the ability of silyl groups, usually trimethylsilyl groups, to behave as "super" (1) or "bulky" (2) protons. In essence, a $SiMe_3$ group is more electropositive than a proton and is thus more susceptible to nucleophilic attack on electronic grounds, but is less susceptible to nucleophilic attack for steric reasons. Thus, under conditions with which proton transfer readily takes place, the corresponding silyl groups are stable.

In the case of trimethylsilylalkynes, the materials are higher boiling and much more stable than the corresponding hydrocarbons, particularly in the case of diynes or polyynes (3). Thus, they have been used synthetically as surrogates for acetylenes and related alkynes, notably by Vollhardt (4) (Scheme 1). Polymeric versions of these compounds have also attracted attention recently as materials of potential interest for nonlinear optical applications (5); related materials have been examined as components of membranes (6). In both cases, the properties of interest in the polymers depend upon the presence of silicon in the molecules.

Silylalkynes will, however, react selectively with strong electrophiles. Indeed, under these conditions, the silylacetylenes are more reactive than the parent hydrocarbons. For example, a variety of Lewis acid activated electrophiles add cleanly to silylalkynes, leading to regioselective C—C bond formation (Scheme 2 (7), Scheme 3 (3)).

When compared with a simple alkyne, the origins of the reactivity of a silylalkyne towards electrophiles include the inductive effects of the silyl group, thermodynamic effects (the ultimate cleavage of silicon from the molecule is generally accompanied by the formation of a strong Si—X (X—Br, Cl, F, ≈96–193 kcal/mol) or Si—O bond (≈126–192 kcal/mol) at the expense of a Si—C bond (≈76 kcal/mol) (8), and the stabilization of the intermediate β-silyl vinyl cation via the β-effect.

As part of a program to try to establish the relative importance of these effects, we have been interested in studying the different mechanisms for and extent of electronic transmission from one Group 14 metal to another along an acetylene "wire" in the ground state.

During previous studies of the vinyl β-effect (9) we prepared a series of Group 14 dimetallated alkynes **1**, **2**, **3** and **4** (Fig. 1*a*) that appeared to be potential candidates for this study. The central metal is sensitive to a variety of spectroscopic techniques and can thus reflect the degree of electronic transmission from the distal $SiMe_3$ groups; any such transmission would be amplified by the presence of four distal $SiMe_3$ groups. In this paper, we report our examination of these compounds by different spectroscopic techniques to determine the extent of interaction between the two metals. The magnitude and mechanism of electronic transmission will be discussed.

Results

Preparation of compounds 1–4

The materials for this study can be conveniently prepared starting from lithium trimethylsilylacetylide, which is formed from the reaction of *n*-BuLi with trimethylsilylacetylene. With the exception of lead, the ensuing anion can be quenched by the readily available Group 14 chloro derivatives MCl_4 in THF to give, cleanly in most cases, the corresponding tetrakis(trimethylsilylethylnyl) metals

$M(C{\equiv}CSiMe_3)_4$ (M = Si **1**, Ge **2**, Sn **3**). The lead compound **4** was prepared by quenching $Pb(OAc)_4$ with $Me_3SiC{\equiv}CMgBr$ (prepared from $Me_3SiC{\equiv}CH$ and MeMgBr).

Spectroscopic characterization

These Group 14 nuclei are susceptible to examination by several spectroscopic methods; we have focused on NMR, Mössbauer spectroscopy and X-ray crystallography.

Nuclear magnetic resonance

The central metal

The nuclear magnetic resonance spectra of ^{1}H, ^{13}C, ^{29}Si and the remaining Group 14 elements (^{73}Ge for **2**, ^{119}Sn for **3**, ^{207}Pb for **4**) were measured for compounds **1**–**4**. As the chemical shifts of many Group 14 acetylides have been determined, it is relatively straightforward to evaluate by comparison the additional effect of a second Group 14 element on the alkyne.

Tetraalkynylmetals typically have large negative upfield shifts.[3] The presence of the four distal Me_3Si groups serves to substantially increase the upfield shifts of the central atom (Table 1). The chemical shifts reported here are among the furthest upfield to be reported for tetrahedral Group 14 metals substituted with four carbon ligands.

The distal Me_3Si groups

The central metal also has an effect on the terminal $SiMe_3$ groups. The ^{29}Si NMR chemical shifts show this to be small but observable; the effect of amplification has been lost (Table 2). The differences in the chemical shift correspond to increased shielding by the central atom as Si is substituted with less electronegative and more polarizable metals. The final entry in the table shows, additionally, how the degree of shielding is moderated by the type of carbon ligand on the central metal; less electronegative alkyl sp^3 hybridized carbon ligands, rather than alkyne *sp* orbital ligands, increase the degree of electronic shielding of the distal $SiMe_3$ by the central metal.

Mössbauer for tin

An additional diagnostic tool for tin compounds is Mössbauer spectroscopy. Regrettably, there are few reported values for alkynyltin compounds. Nevertheless, some general trends may be observed. An increase of *s* electron density is manifested in increased chemical isomer shifts. As *sp* orbitals are more electronegative than sp^2 or sp^3 orbitals, a decrease in chemical isomer shift is expected as sp^3 carbon ligands are sequentially replaced with sp^2 and *sp* hybridized ligands. Similarly, when electronegative groups on the alkyne terminus are replaced by electron-donating groups, an increase in isomer shift value is expected as *s* electron density is increased. However, any π-type interactions will have the effect of shielding the *s* electrons at the tin nucleus, decreasing the observed isomer shift (12). The data shown in Table 3, particular entry 12, demonstrate the latter effect (13, 14).

X-ray

We were unable to obtain suitable crystals for X-ray crystal structure analysis of the lead compound **4**. However, single crystals of compounds **2** and **3** could be readily analyzed; a structure for **1** has previously been reported (15). An ORTEP plot of the structure of **3** is shown in Fig. 1*b*; bond lengths and angles for **2** and **3** are collected in Tables 4, 5 and Tables 6, 7, respectively. A comparison of the C≡C bond lengths, the Me—Si—Me bond angles in the $SiMe_3$ groups,

and the C≡C—**Si**—**Me** angles in the compounds we prepared and those to be found in the literature shows only small deviations. However, a comparison of R_3**M**—**C**≡C—X bond lengths is more intriguing (Table 8); clearly these bond lengths are very dependent upon the nature of the group on the other end of the acetylene wire (X) and the ligands (R) borne by the metal.

Beginning with a consideration of R_3M (R = trialkyl) compounds, a change from X = C to Si/Ge/Sn leads on average to a longer bond (1.84 Å (Table 8 entries 6 and 7) versus 1.83 Å (entries 2–4)). When that distal metal group bears electron-withdrawing ligands such as N*t*Bu or $(C{\equiv}CSiMe_3)_3$, the bond is further lengthened to 1.85 Å (entries 8–11). In contrast, if R = alkynyl, much shorter bond lengths can be seen (entry 12 versus 9–11, entry 16 versus 14 and 15).

Discussion

In all three spectroscopic techniques, we have seen evidence for electronic transmission between the two Group 14 elements linked by an acetylene. In the NMR experiments, this is manifested by significant shielding of the central metal in **1–4** by the four distal $SiMe_3$ groups and to a lesser extent of the $SiMe_3$ groups by the central metal, a significantly smaller Mössbauer isomer shift (I.S.) for the Sn derivatives when the distal $SiMe_3$ groups are present, and shorter bond lengths between the central metal and the adjacent C of the alkyne.

The electronic interaction between the two Group 14 metals could arise strictly from inductive donation through the σ-framework or from a combination of inductive effects and interactions of the π-system including resonance and π-polarization. The $SiMe_3$ group, as judged by Hammett parameters, possesses a very small capacity for σ-electronic donation (26); the parameters are −0.03 and −0.05 for σ_{meta}

and σ_{para}, respectively. Thus, the observations described above are better explained by a π-interaction that links the two Group 14 metals through the alkyne.

π-Type electronic interactions (conjugation) between Group 14 metals and adjacent C—C π-systems have previously been invoked for silicon, germanium, and tin compounds (27–30). The inclusion of a fourth atom in the conjugation, a distal Group 14 atom **M**—C≡C—Si, is a natural extension of this. The most compelling example of π-interactions between Group 14 substituted alkynes is in the UV spectra of silyl-terminated polyynes. These are considerably red shifted compared with the H or C terminated polyynes (20, 31).

π-Interactions may arise from either $(n–d)\pi$ or $(p–d)\pi$ (32) (or $(n–\sigma^*)\pi$ or $(p–\sigma^*)\pi$ interactions.[4] These would be anticipated to occur through σ*-orbitals in the case of silicon; *d* orbitals are apparently not very important in the interaction with first-row elements (32, 33). There is expected to be an increased propensity for *d* orbital involvement with the lower Group 14 elements. However, as has been noted by Dewar and co-workers (28), Whitesides et al. (29), and others, although *d* orbitals are energetically more available, they are increasingly mismatched in size with the C≡C π-system as one progresses down the periodic table, attenuating the resonance effect.

[4]See, however, counter arguments favouring the interaction of σ*-orbitals (33).

NMR

The chemical shift reflects the shielding a nucleus experiences. However, with the exception of protons, for which the correlation is reasonably straightforward, the nature of the electronic factors within the molecule that lead to an observed shift remains somewhat contentious. Nevertheless, it may be concluded that the observed magnitude of the change in chemical shift for the central metal is too large to originate, over three bonds, from σ-inductive effects alone. Chemical shifts are more dramatically affected by the presence of heteroatom lone pairs or π-systems on adjacent atoms. The large shift with four distal $SiMe_3$ groups (e.g., entries 3, 4, Table 1) reinforces the suggestion of a π-interaction between the two metals through the alkyne π-system.

Mössbauer

The Mössbauer results are also consistent with the proposed conjugation. Simple inductive effects by the distal $SiMe_3$ group would increase the *s* electron density and would be expected to lead to an *increase* in the Mössbauer I.S. in contrast to our observations. Again, this implies that electronic transmission between the Group 14 metals exists through the π-system of the alkyne.

X-ray

X-ray structures of polyynes and **1–3** show alternating single and triple bonds of essentially normal length (20) although some shortening of the single and lengthening of the triple bonds would be expected if π-conjugation was operative. The only significant shortening of single bonds arose with compounds **1–3** near the central atom. We attribute this to a π-polarization of the bond when the "spectator ligands" are *sp* ((R-*C*≡*C*)$_3$ **M**—**C**≡C-R′) rather than sp^3 hybridized ((R)$_3$ **M**—**C**≡C-R′).[5] Such an explanation cannot, however, account for the similarly short bond lengths in Me_3Si—$(C≡C)_4$-$SiMe_3$ (Table 8, entry 5) At the time, it was suggested that 1.20 Å was typical of C—Si bond lengths when the C ligand was *sp* hybridized. However, all crystal structures published since (Table 8) show significantly longer bond lengths (1.84 Å).

[5]We thank a referee for helpful suggestions in clarifying this.

Conclusion

Two Group 14 metals, connected by an acetylene wire, interact electronically through π-interactions. The effect is seen in the strong shielding of the central metal in compounds **1–4** and the low isomer shift in the Mössbauer spectrum of **3**. Any effect of π-conjugation is insufficiently strong to affect the C≡C bond length, as shown from the X-ray crystal structures of **1–3**; π-polarization is a better explanation of these results.

Experimental

Apparatus, materials, and methods

Due to the hydrolytic instability of the halogen derivatives of the Group 14 metals, all reactions were carried out in dry apparatus under a nitrogen atmosphere using septa and syringes for the transfer of reagents. Methylchlorosilanes were obtained from Dow Corning. Other silicon, germanium, tin, and lead compounds were obtained from Aldrich. All compounds were distilled prior to use. Tetrahydrofuran (THF) and diethyl ether were freshly distilled under a nitrogen atmoshere over benzophenone/potassium. Dichloromethane (CH_2Cl_2) was freshly distilled under a nitrogen atmosphere over calcium hydride (CaH_2) or phosphorus pentoxide (P_2O_5). Chloroform-*d* was obtained from Merck Sharp and Dohme Isotopes, Montreal, and used without further purification. (Trimethylsilyl)acetylene ($Me_3SiC{\equiv}CH$) was obtained from Aldrich or prepared according to ref. 34, by reaction of $LiC{\equiv}CH$ with Me_3SiCl.

The continuous wave ^1H NMR spectra were recorded on a Varian EM 390 (90 MHz) spectrometer and the Fourier spectra on a Bruker AM 500 (500 MHz) or Bruker AC 200 (200 MHz) spectrometer. ^{13}C, ^{29}Si, ^{73}Ge ^{119}Sn, and ^{207}Pb NMR measurements were performed on a Bruker WM 250 (at 250 MHz for protons). The ^{207}Pb solid state NMR spectrum was measured on a Bruker MS-100 spectrometer. Unless otherwise specified, the samples were dissolved in chloroform-*d* using tetramethylsilane (TMS) as internal standard ($SnMe_4$ for tin, $PbMe_4$ for lead, and $GeMe_4$ for germanium, respectively). Coupling constants (*J*) are recorded in hertz (Hz). The abbreviations s = singlet, d = doublet, t = triplet, dd = doublet of doublets, dt = doublet of triplets, dq = doublet of quartets, and m=multiplet are used in reporting the spectra.

EI mass spectra and chemical ionization (NH_3) mass spectra were recorded at 70 eV with a source temperature of ca. 200°C either on a VG Micromass 7070 F mass spectrometer equipped with a data system comprising a PDP 8A with VG 2000 software or a VG analytical ZAB E mass spectrometer equipped with a VG 11-250 data system. High-resolution mass spectral (HRMS) data were obtained with the VG-ZAB-E instrument by the electron impact (EI) method.

Infrared spectra were run on a Perkin–Elmer 283 spectrometer in $CHCl_3$ solution, $CHCl_3$ film, neat film, or as a KBr pellet.
