This review outlines a decade of research that employs quantitative kinetic methods of autooxidation to phospholipids aggregated into membranes. The classical rate law for autoxidation:

$$-\frac{d[O_2]}{dt} = \frac{k_p}{(2k_t)^{1/2}}[R{-}H]R_i^{1/2}$$

was found to apply to heterogeneous systems of bilayers and micelles, where k_p and $2k_t$ are the rate constants for chain propagation and termination, respectively, and R_i, the rate of chain initiation, is controlled by thermal initiators. The *oxidizability* of a typical lipid chain, linoleate 18:2, at 30°C was similar (0.02–0.04 $M^{-1/2}$ $s^{-1/2}$) in different media (solution, micelles, bilayers) and for different procedures using water-soluble or lipid-soluble initiators and inhibitors. A reduction in the absolute rate constant for termination, $2k_t$, by a hundredfold in bilayers of dilinoleoylphosphatidyl choline (DLPC) compared to that in *tert*-butyl alcohol solution, and a drop in the k_p by a factor of five are interpreted in terms of diffusion of polarized peroxyl radicals from the hydrophobic bilayer phase to the aqueous surface, where peroxyls are strongly solvated by water. Such phenomena may also account for significant changes as observed by ^{31}P NMR spectra in bilayer lamellar structure accompanying extensive peroxidation. Analysis of the hydroperoxides formed by peroxidation of mixed bilayers of DLPC + DPPC (16:0) initiated by a water-soluble initiator, azobis(2-amidinopropane·HCl) (ABAP), showed a linear trend between the ratio of *cis,trans* to *trans,trans* geometrical isomeric hydroperoxides and [DPLC] consistent with a peroxidation mechanism proposed in homogeneous solution.

The antioxidant activities, k_{inh}, of three classes of antioxidants: (*a*) polyalkyl-6-hydroxychromans (e.g., vitamin E), (*b*) polyalkyl-4-methoxyphenols, and (*c*) trialkylphenols, were measured in DLPC membranes. The results show an overall leveling and depression of k_{inh} values in DLPC membranes in the series (*a*) (by several orders of magnitude), (*b*), and (*c*) compared to known values in solution in chlorobenzene. In aqueous bilayers it is proposed that k_{inh} values are attenuated by hydrogen bonding by water at both the *para* ether oxygen and phenolic groups. Restricted diffusion (e.g., of α-tocopherol) may also reduce antioxidant activities in membranes. A synergistic effect between ascorbic acid and α-tocopherol was discovered under conditions of inhibited peroxidation of linoleate in SDS micelles. The natural peptide glutathione, GSH, however, acts as a *co-antioxidant* with vitamin E by trapping peroxyls in the aqueous phase.

Solid cholesterol was found to partition directly into PC lipsomes by shaking, above or below the phase transition temperature, and membrane-bound cholesterol, unlike the solid, undergoes facile peroxidation. A water-soluble form of α-tocopherol complexed with bovine serum albumin (α-toc:BSA) is an effective antioxidant for autoxidations of linoleate in SDS micelles. In contrast, α-toc:BSA required a long equilibration time (e.g., 12 h) with liposomes (DLPC) before the α-tocopherol was transferred to the liposomes to provide effective antioxidant action.

Carbon radicals from thermolysis under nitrogen of the lipidic azo initiator, 6,6′-azobis(6-cyanododecanoic acid), 6,6′, in unilamellar liposomes were spin-trapped by phenyl *tert*-butyl nitrone (PBN) to give membrane-bound trapped radicals as observed by broad anisotropic ESR spectra. However, under oxygen, 6,6′ in liposomes formed derived peroxyl radicals, which were trapped in the aqueous phase by water-soluble 4-trimethylammonium-PBN.

The Total (peroxyl) Radical Trapping Antioxidant Parameter (TRAP) of a biological fluid, the number of peroxyl radicals trapped per volume of fluid under "oxidative stress" under known conditions of chain initiation (R_i), was determined for blood plasmas of humans. A control group (n = 6) gave an average TRAP of 775 μM peroxyls trapped compared to athletes (n = 5) where the average TRAP of 1226 μM was 45% higher. Vigorous exercise was found to increase the uric acid contribution to TRAP.

Dans cette revue, on décrit une décade de recherches faisant appel à des méthodes quantitatives d'auto-oxydation appliquées aux phospholipides agrégés dans des membranes. On a trouvé que la loi de vitesse classique des auto-oxydations :

$$-\frac{d[O_2]}{dt} = \frac{k_p}{(2k_t)}[R{-}H]R_i^{1/2}$$

s'applique aux systèmes hétérogènes des bicouches et des micelles, alors que k_p et $2k_t$ sont respectivement les constantes de vitesse de la propagation et de la terminaison de la chaîne et que R_i, la constante de vitesse de l'initiation de la chaîne, est contrôlée par les initiateurs thermiques. L'*oxydabilité* d'une chaîne lipidique typique, le linoléate 18 : 2, à 30°C, est assez constante (0,02–0,04 $M^{-1/2}$ $s^{-1/2}$) dans divers milieux (solution, micelles et bicouches) et diverses

[1]This Syntex Award Lecture was delivered by Dr. Barclay at the Annual Conference of the Canadian Society for Chemistry, Edmonton, Alberta, June 4, 1992.

procédures utilisant des initiateurs et des inhibiteurs solubles dans l'eau ou liposolubles. On attribue une réduction de la constante absolue de la vitesse de terminaison, $2k_t$, qui est plus de cent fois plus lente dans des bicouches de dilinoléylphosphatidyl choline (DLPC) par comparaison avec la même réaction dans une solution d'alcool *tert*-butylique, et une réduction par un facteur de cinq de la valeur de k_p à une diffusion des radicaux peroxyles polarisés de la bicouche hydrophobe vers la surface aqueuse où les radicaux hydroxyles sont fortement solvatés par l'eau. Un tel phénomène peut aussi expliquer les changements significatifs qui accompagnent une peroxydation extensive. L'analyse des hydroperoxydes qui se forment lors de la peroxydation de bicouches mixtes de LDPC + DPPC (16 : 0) initiées par un initiateur hydrosoluble, l'azobis(2-amidinopropane)·HCl) (ABAP), présente une tendance linéaire entre le rapport des isomères géométriques *cis,trans/trans,trans* des hydroperoxydes et [DLPC]; cette observation est en accord avec un mécanisme de peroxydation proposé pour les réactions en milieu homogène.

On a mesuré les activités antioxydantes, k_{inh}, de trois classes d'antioxydantes : (*a*) les polyalkyl-6-hydroxychromanes (comme la vitamine E); (*b*) les polyalkyl-4-méthoxyphénols et (*c*) les trialkylphénols dans des membranes de DLPC. Les résultats présentent un effet global limitant et, par comparaison avec les valeurs connues en solution dans le chlorobenzène, une diminution des valeurs de k_{inh} dans les membranes DLPC des séries (*a*) (plusieurs puissance de 10), (*b*) et (*c*). Dans les bicouches aqueuses, on suggère que les valeurs de k_{inh} sont atténuées par une liaison hydrogène entre l'eau et les oxygènes en *para* ainsi que les groupes phénoliques. Une diffusion restreinte (comme avec l'α-tocophérol) peut aussi réduire les activités anti-oxydantes dans les membranes. Dans des conditions de peroxydation inhibée du linoléate dans des micelles de SDC, on a découvert un effet synergique entre l'acide ascorbique et l'α-tocophérol. Toutefois, le peptide naturel glutathion, GSH, agit comme *co-antioxydant* avec la vitamine E en piégeant les peroxyles dans la phase aqueuse.

On a trouvé que, en l'agitant au-dessus at au-dessous de la température de transition de phase, le cholestérol solide se partitionne directement dans les liposomes PC et que, comparativement au produit solide, le cholestérol lié à la membrane subit une peroxydation facile. Une forme d'α-tocophérol complexée avec de l'albumine de sérum bovin et soluble dans l'eau (α-toc : BSA) est un antioxydant efficace pour les auto-oxydations du linoléate dans le SDS. Par ailleurs, le complexe α-toc : BSA nécessite une longue période d'équilibre (environ 12 h) avec les liposomes (DLPC) avant que l'α-tocophérol soit transféré aux liposomes pour fournir une action antioxydante efficace.

Utilisant de la phényl *tert*-butyl nitrone (PBN), on a piégé les radicaux carbonés provenant de la thermolyse, sous atmosphère d'azote, de l'initiateur azo lipidique, 6,6′-azobis(acide-6-cyanododécanoïque), 6,6′, dans des liposomes unilamellaires; on a ainsi obtenu des radicaux piégés, liés à une membrane, que l'on a observé par leurs spectres RPE anisotropiques. Toutefois, en présence d'oxygène, le 6,6′ dans les liposomes conduit à des radicaux peroxyles dérivés que l'on a piégé en phase aqueuse par le 4-triméthylammonium-PBN soluble dans l'eau.

Le Paramètre de Piégeage Total de Radicaux (peroxyles) d'un Antioxydant d'un fluide biologique est le nombre total de radicaux peroxyles piégés par unité de volume de fluide sous «stress oxydant», dans ces conditions connues d'initiation (R_i) de chaîne; on a déterminé ce paramètre pour des plasmas sanguins humains. Un groupe de contrôle (n 6) conduit à une valeur de ce paramètre qui est égale 775 μm de peroxydes piégés; par comparaison, ce paramètre est égal à 1226 μm (45% plus élevé) pour des plasmas de sang d'athlètes. On a trouvé que l'exercice vigoreux augmente la contribution de l'acide urique à ce paramètre.

[Traduit par la rédaction]

1. Introduction

Free radical peroxidation of unsaturated chains in biomembrane lipids disrupts the important structural and protective function of membranes and is associated with a variety of significant pathological events. Various environmental factors, operating *externally*, that affect us adversely include ultraviolet radiation, pollutants (e.g., smog), and tobacco smoke. Such factors can promote cancer and cataract. Other events that may be promoted *internally* by oxygen-centred radicals include atherosclerosis, inflammation, damage to neuronal tissue leading to stroke, and damage to sensitive tissue during reperfusion. Several *medical* aspects of "oxidative stress" have been included in various books (1–3) and conference proceedings (4–9).

The biomedical aspects of cellular oxidative damage have catalyzed interest in this field of membrane research and resulted in a remarkable increase in activity and publications related to the biological phenomena of membrane damage. On the other hand, *quantitative kinetic* studies at the molecular–chemical level have lagged behind. Over a decade ago the author visited Keith Ingold's laboratory at the National Research Council, Ottawa, where we initiated a study that led to applications of quantitative kinetic methods of autoxidation and inhibition to membranes. This research was continued at Mount Allison University and this paper describes some of the progress made over the last decade. Our research benefitted greatly from the continued encouragement of Keith Ingold and the participation of other collaborators.

Our research has certain basic objectives, which are formulated in terms of fundamental questions:

1. Can free radical reactions propagated by peroxyls, ROO·, be initiated *under controlled conditions* of the rate of chain initiation, R_i, and quantitative measurements be made in membranes?

2. Is the classical rate law for autoxidation applicable to model membrane systems?

3. What is the effect of such microenvironments as bilayers and micelles on the *oxidizability* and *products* from the polyunsaturated fatty acid (PUFA) chain of lipid membranes?

4. What is the activity of phenolic antioxidants in membranes compared to that in homogeneous solution, and do cooperative interactions occur between lipid-soluble antioxidants (vitamin E) and water-soluble ones (vitamin C, Trolox, and thiols)?

5. What role does diffusion or partitioning play in distributing substances such as vitamin E, cholesterol, and PUFA-derived peroxyl radicals in membranes?

This research employed phosphatidylcholine (PC) bilayers, since these mimic the behaviour of natural phospholipid membranes in many respects (10), as multilamellar vesicles (MLV) or unilamellar vesicles (ULV) prepared by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

known methods (11) of extrusion, dialysis, or sonication. The lamellar structures, MLV or ULV, of these vesicles were studied by electron microscopy (e.g., ref. 12) or ^{31}P NMR in our research. Some experiments were also done in sodium dodecylsulfate (SDS) as a model biphasic system of hydrophobic and hydrophilic phases.

2. Kinetics and mechanism: peroxidation and inhibition

Various chemical and physical methods used to measure the extent of lipid peroxidation have been reviewed (13–15) and the GC/MS method improved (16). The well-known thiobarbituric acid (TBA) test, based on a colour reaction of TBA with malondialdehyde formed during peroxidation of certain PUFA, has some disadvantages (17). Our approach for quantitative studies used direct oxygen uptake studies and, where desirable, product analyses.

2.1. The kinetic approach to peroxidation, and the oxidizability of linoleate in different media: solution, micelles, membranes

Quantitative kinetic methods of autoxidation are superior in the study of peroxidation of lipids. These methods are well known for reactions in homogeneous solution (18–20) and were first applied to model membrane systems in Ingold's laboratory in 1981 (21). In this method, the rate of free radical chain initiation, R_i, is controlled by using a thermal azo initiator with a known constant, k_i, and the R_i is measured with an efficient antioxidant. Oxygen uptake is measured with a sensitive pressure transducer system custom-made in our laboratory for reactions in aqueous dispersions (22). When combined with HPLC product analysis for specific oxidation products (23, 24), these procedures provide the best approach for quantitative studies of phospholipid peroxidation.

The known mechanism for free radical chain autoxidation is outlined in eqs. [1]–[4].

[1] Initiation: $\mathrm{R{-}N{=}N{-}R} \xrightarrow{2k_i} 2\mathrm{R}\cdot + \mathrm{N_2}$

Propagations:

[2] $\mathrm{R}\cdot + \mathrm{O_2} \xrightarrow{\text{fast}} \mathrm{R{-}O{-}O}\cdot$ (peroxyl)

[3] $\mathrm{R{-}O{-}O}\cdot + \mathrm{R{-}H(substrate)} \xrightarrow{k_p} \mathrm{ROOH} + \mathrm{R}\cdot$

[4] Termination: $2\mathrm{R{-}O{-}O}\cdot \xrightarrow{2k_t}$ nonradical products + $\mathrm{O_2}$

A simple steady state expression is used for the kinetic equations for oxygen uptake,

$$[5] \quad -\frac{d\mathrm{O_2}}{dt} = k_p[\mathrm{RO_2}\cdot][\mathrm{R{-}H}]$$

At steady state, the rate of initiation = the rate of termination as shown in eq. [6], where e = initiator efficiency. This correction, e, is needed since only those radicals which "escape" the solvent cage in which they are formed can react with oxygen and initiate reaction.

$$[6] \quad 2k_i \times e[\mathrm{RN_2R}] = 2k_t[\mathrm{RO_2}\cdot]^2$$

Substituting for $[RO_2\cdot]$ in eq. [5]:

$$[7] \quad -\frac{d\mathrm{O_2}}{dt} = \frac{k_p}{2k_t^{1/2}}[2k_i \times e(\mathrm{RN_2R})]^{1/2} \times [\mathrm{R{-}H}] = \frac{k_p}{2k_t^{1/2}} \times [\mathrm{R{-}H}] \times R_i^{1/2}$$

The susceptability of a substrate to undergo autoxidation, known as its oxidizability, is given by eq. [8]:

$$[8] \quad \text{Oxidizability} = \frac{k_p}{2k_t^{1/2}} = \frac{-d\mathrm{O_2}/dt}{[\mathrm{R{-}H}] \times R_i^{1/2}}$$

For quantitative determinations the R_i must be measured and this is usually done by adding a phenolic inhibitor, known to trap two peroxyls, and by measuring the induction period during which oxidation is suppressed when eq. [9] applies.

$$[9] \quad R_i = 2 \times [\mathrm{ArOH}]/\tau$$

where τ = inhibition period. The absolute rate constants for chain propagation, k_p, eq. [3], and termination, $2k_t$, eq. [4], were determined by the modified rotating sector method (25).

These quantitative kinetic studies showed that the classical rate law for autoxidation, eq. [7], operates in SDS micelles for the oxidation of linoleic acid photoinitiated by benzophenone (26). Oxygen uptake was shown to be first order in linoleate concentration and half order in light intensity (or R_i). Such excellent quantitative studies in micelles are relatively straightforward. Micelles are optically clear and "solutions" are prepared almost as easily as homogeneous solutions in organic solvents. Micelles are used as models for membranes since they are said to be "a halfway house" between homogeneous solutions and bilayers (27); however, they are *not* really very similar to biomembranes. Micelles are a very *dynamic* species with short half-lives between monomers and aggregates whereas membranes are composed of static aggregates of dual chain phospholipids. If lipids are suddenly removed from the protective bilayer the latter is said to become "*leaky*", with catastrophic results!

Classical quantitative kinetic studies are much more difficult to carry out in membranes than in homogeneous solution or micelles, for several reasons. Thermal azo initiators have a very low initiator efficiency ($e \simeq 9\%$) when solubilized in the bilayer phase because of high cage recombination in this region of high microviscosity (21) and it is not desirable to insert large amounts of initiator into the bilayer. Secondly, *the concentration of oxidizable lipid in a pure PC is a fixed value, independent of the amount used.* Therefore, special procedures are required to check the rate law for autoxidation. A couple of key "breakthroughs" enabled us to solve these kinetic problems:

1. Collaborative research with Keith Ingold and Graham Burton of the National Research Council showed that quantitative kinetic studies of autoxidation in membranes could be carried out by inserting thermal azo initiators into the aqueous phase and measuring the R_i with a water-soluble antioxidant, Trolox (28).

2. We discovered that the kinetic order in membrane oxidizable substrate [RH] can be determined by using a mixed bilayer system containing variable amounts of an unsaturated substrate, dilinoleoylphosphatidylcholine (DLPC), mixed with saturated PC's such as dimyristoylphosphatidylcholine (DMPC) or dipalmitoylphosphatidylcholine (DPPC) (29, 30).

These developments permitted us to measure the kinetic orders in oxidizable substrate and in the R_i as illustrated in Figs. 1 and 2 (29). It was now possible to determine the oxidizability of a typical lipid chain, e.g., linoleate, in solution and in micellar and bilayer phases. More importantly, the absolute rate constants for propagation, k_p, and termi-

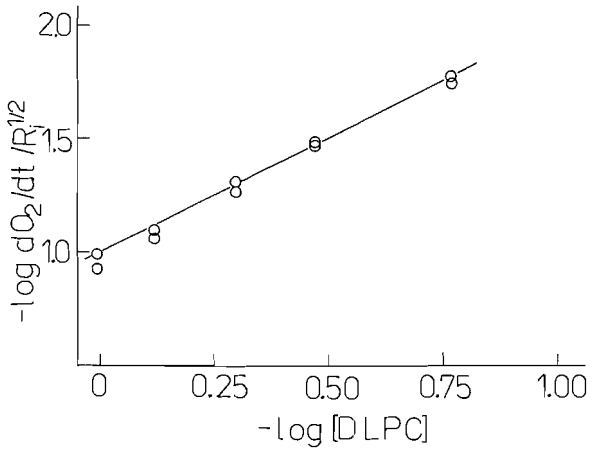

FIG. 1. Kinetic order plot for the autoxidation of mixed bilayers of DLPC + DMPC, initiated by lipid-soluble ADVN.

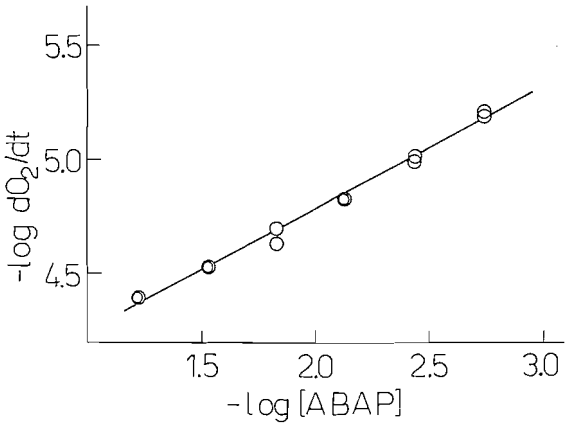

FIG. 2. Kinetic order plot of oxygen consumption with concentration of the water-soluble initiator, ABAP, for autoxidation of mixed bilayers of DLPC + DPPC.

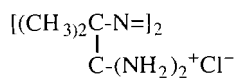
nation $2k_t$, were determined in these different media. Some of the these results are collected in Table 1. The oxidizability of the linoleate lipid chain, a general property of its overall susceptibility to free radical autoxidation, varies within a limited range of 0.02–0.04 $M^{-1/2}$ $s^{-1/2}$ even under a wide variety of conditions and in different media, which were varied from homogeneous solution, SDS micelles, linoleate monomers in saturated DMPC, and finally DLPC bilayers. Also various combinations of lipid-soluble and water-soluble initiators and inhibitors were used in these studies, showing that oxidizability, as expected, is independent of the method of initiation and inhibition. It is of particular significance to find that aggregation of lipid chains into bilayers does not change their oxidizability. We find it remarkable that the charged water- soluble initiator, ABAP, appears to have access to the various layers of the MLV systems and especially that water-soluble Trolox can trap peroxyl radicals in membranes apparently as effectively as lipid-soluble vitamin E! These phenomena will be discussed in more detail (*vide infra*).



2.2. *Absolute rate constants,* k_p *and* $2k_t$*, in bilayers and the "Floating Peroxyl Radical Hypothesis"*

Absolute rate constants provide important insights into the behaviour of peroxyl radicals in membranes. We discovered a remarkable *decrease* in the termination rate constant, $2k_t$, for autoxidation of the DLPC bilayer compared to that in homogeneous solution, say in *tert*-butyl alcohol (see Table 1). The decrease amounted to as much as a hundredfold. Peroxyl radicals are known to be strongly polarized; the dipole moment of benzylperoxyl was determined to be 2.45 D (31). A collaborative study with Susan Boyd, Mount St. Vincent University, and Russell Boyd, Dalhousie University, showed that various saturated and unsaturated peroxyl radicals have large dipole moments in the 2.3–2.6 D range (32). We speculate that such polar peroxyl radicals would diffuse rapidly away from the nonpolar bilayer phase where they are formed initially towards the more polar aqueous surface. This so-called "Floating Peroxyl Radical Hypothesis" is illustrated schematically in Fig. 3. The consequence of this postulate is that polar peroxyl radicals would

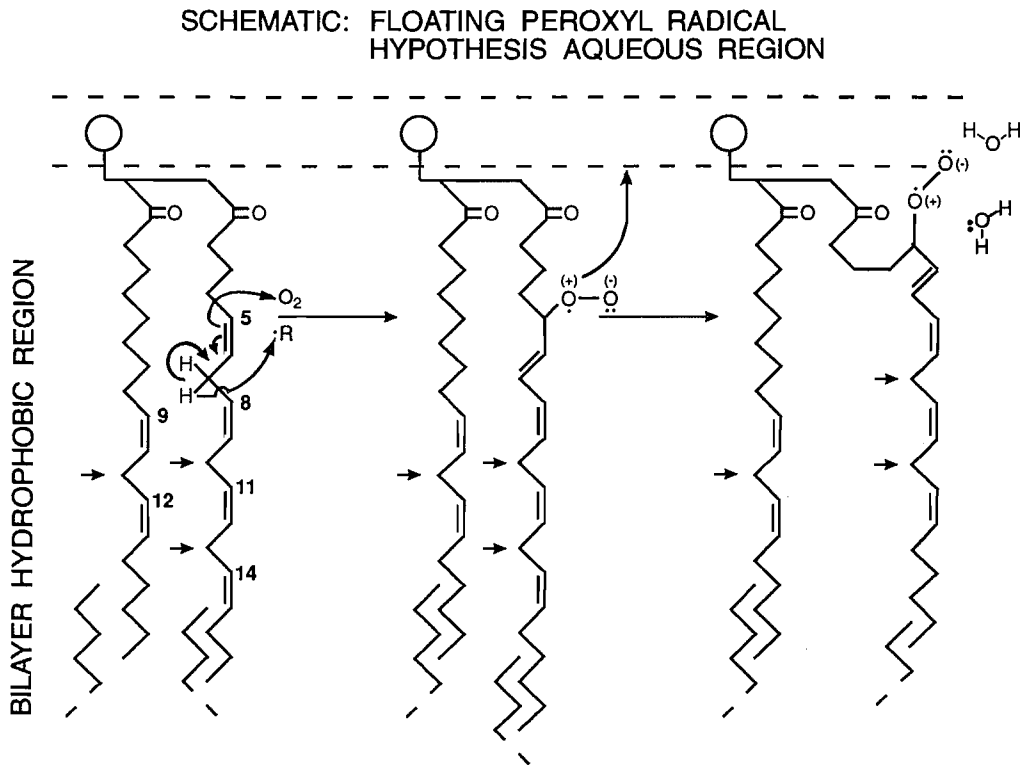


FIG. 3. Schematic for diffusion of polar lipid peroxyl radicals from a hydrophobic region to a polar interface during peroxidation.

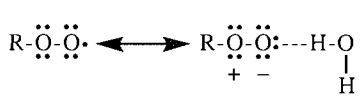
terminate in the aqueous-lipid interface. The reduction in $2k_t$ would be due to stabilization of the polar peroxyl radicals by hydrogen bonding with water: The reduction in k_p



found in bilayers follows because the solvated peroxyls would not readily abstract the labile CH_2 groups that are deeper in the bilayer.[2]

Such diffusion of peroxyls would have very important consequences for bilayer structure and integrity. Some ^{31}P NMR studies give indications of the effect on lamellar structure. Factors affecting the ^{31}P NMR line shapes of membranes include particle tumbling and lateral diffusion of the chains within the particles (33), the former being restricted in larger liposomes and the latter depending on the microviscosity inside the bilayer. These factors are shown in some typical ^{31}P NMR spectra in Fig. 4. Multilamellar liposomes and large unilamellar ones show the effect of restricted tumbling motion whereby the ^{31}P NMR lines are very broad with a chemical shift anisotropy $\Delta\sigma \simeq -40$ ppm (Fig.4*a*). On the other hand, smaller unilamellar liposomes give a single isotropic line shape (Fig.4*c*). Very significant changes occur in the lamellar structure of liposomes during the course of extensive peroxidation as illustrated in Fig. 4 for controlled peroxidation of egg lecithin liposomes (Fig.4*d*). We started with unilamellar vesicles showing a single symmetrical line shape. There was no observable change in ^{31}P spectra up to 10% overall oxidation based on oxygen uptake studies. However, by 30% oxidation the unsymmetrical anisotropic spectrum appeared and it predominated on further oxidation. Such results indicate that the vesicles must fuse together and form larger ones or larger ones may even fracture and encapsulate smaller ones and become multilamellar. Such gross changes in lamellar structure could have been initiated by diffusion of peroxyl radicals during oxidation. The consequences of such structural damage on the protective properties required of biomembranes could be quite catastrophic!

2.3. Products of peroxidation and mechanism

The products of free radical autoxidation of linoleate are known to be the 9- and 13-hydroperoxy-substituted 9-*cis*,11-*trans*; 10-*trans*,12-*cis*; 9-*trans*,11-*trans*; and 10-*trans*,12-*trans* octadecadienoates, which are analyzed by reduction and conversion to the corresponding hydroxymethyl esters (structures are shown in Fig. 5). Outstanding research by Porter and co-workers (summarized in ref. 23) showed that the product ratios of kinetic products to thermodynamic products, the *cis*,*trans* to *trans*,*trans* ratios, are directly related to the hydrogen atom donating ability of the medium; for example, to the linoleate concentration. The Porter mechanism for lipid peroxidation is summarized schematically in Fig. 5. A student and I enjoyed the hospitality of Porter's laboratory at Duke University on several occasions and the technology for HPLC analyses of these oxidation products was transferred to our laboratory. These product analyses were very important to our studies in biphasic systems. The same linear trend of *cis*,*trans* to *trans*,*trans* (*c*,*t*/*t*,*t*) product ratios was observed for peroxidation of lino-

[2]However, recent spectral data for *tert*-butylperoxyl radicals show that, while k_p is much lower in water than in nonpolar solutions, the overall termination is similar in polar and nonpolar solvents (ref. 75).

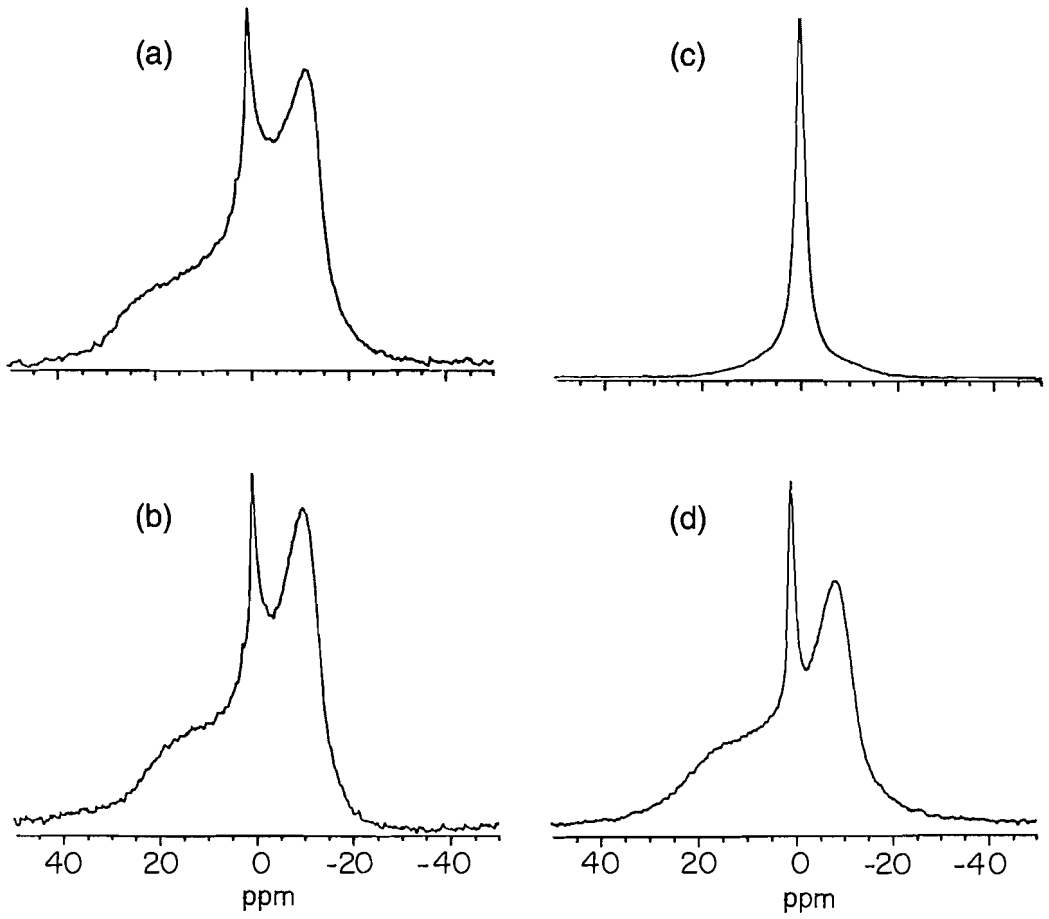

FIG. 4. ^{31}P nmr spectra of phosphatidylcholine liposomes (0.1 mmol) in 2.0 mL of THAM buffer (pH 7.0) at 40°C; (*a*) multilamellar DPLC, purified by HPLC; (*b*) oxidized DLPC, 60% conversion of active methylene groups; (*c*) unilamellar egg lecithin; (*d*) egg lecithin from (*c*) after >30% oxidation.

leate in SDS micelles when the reaction was initiated by lipid-soluble or water-soluble azo initiators and by lipid-soluble or water-soluble photo initiators, implying that the autoxidation mechanism is the same (e.g., Porter) under these different conditions (26).

It was especially important to determine the trend in product analysis with substrate concentration during initiation with a *water-soluble* initiator in membrane autoxidation. The results from such experiments using the initiator ABAP and varying linoleate concentration with mixed bilayers of DLPC + DPPC are illustrated in Fig. 6. The linear trend in *c,t/t,t* ratio with [DLPC] indicates (1) that the general mechanism of Porter applies to mixed bilayer systems and (2) that the water-soluble initiator, ABAP (or ABAP-peroxyls), has access to the hydrophobic region of bilayers to provide effective H-atom abstraction from reactive methylene groups at position 12. Such results complement our kinetic results obtained with water-soluble initiators (28), and they facilitate further quantitative kinetic studies. It is no longer necessary to incorporate the initiator into the bilayer phase during membrane preparation to control the rate of free radical chain initiation.

2.4. *Kinetics of inhibition and antioxidant activities in membranes*

The mechanism of action and activity of protective free radical chain-breaking antioxidants is the major interest of our research. Several recent reviews reflect a continuing outstanding interest and activity in this field (7, 34–37). The mechanism and kinetics of a typical phenolic antioxidant (e.g., vitamin E) are outlined in eqs. [10]–[14] below:

$$[10]\quad \mathrm{ROO\cdot} + \mathrm{ArOH} \xrightarrow{k_{\text{inhibitor}}} \mathrm{ROOH} + \mathrm{ArO\cdot}$$

$$[11]\quad \mathrm{ROO\cdot} + \mathrm{ArO\cdot} \xrightarrow{\text{fast}} \mathrm{ROOArO}$$

During inhibition, the rate of peroxyls formed (initiation) equals the rate of peroxyls trapped, therefore

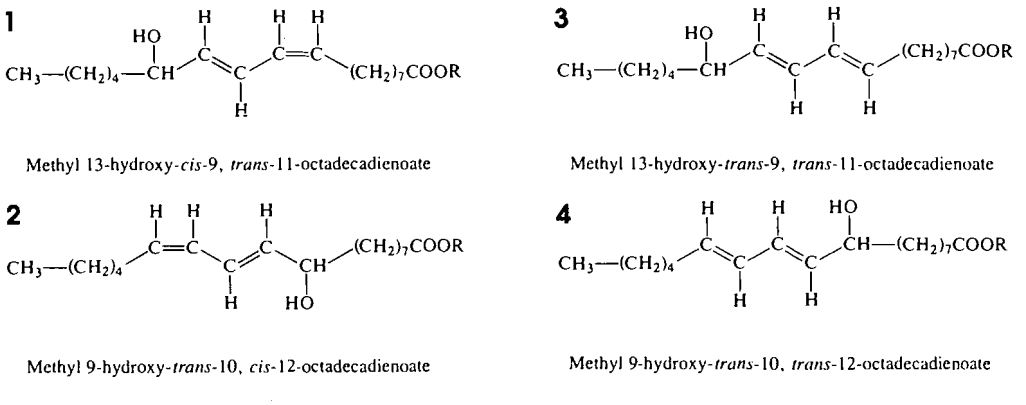
$$[12]\quad R_i = 2k_i e[\text{Initiator}] = k_{inh} \times 2[\mathrm{ArOH}] \times [\mathrm{ROO\cdot}]$$

$$[13]\quad [\mathrm{ROO\cdot}] = R_i/k_{inh} \times 2[\mathrm{ArOH}]$$

and substituting for [ROO·] into eq. [5] gives the suppressed O_2 uptake during inhibition:

$$[14]\quad \frac{dO_2}{dt} = \frac{k_p}{k_{inh}} \times \frac{[\mathrm{R{-}H}] \times R_i}{2[\mathrm{ArOH}]}$$

To be efficient antioxidants phenols should possess certain general structural features. (1) They should give stabilized phenoxyl radicals in order to promote the rate-limiting hydrogen atom transfer, eq. [10]. (2) The resulting k_{inh} must be several orders of magnitude greater than the rate constant for propagation of the substrate; e.g., the ratio of k_p/k_{inh} needs



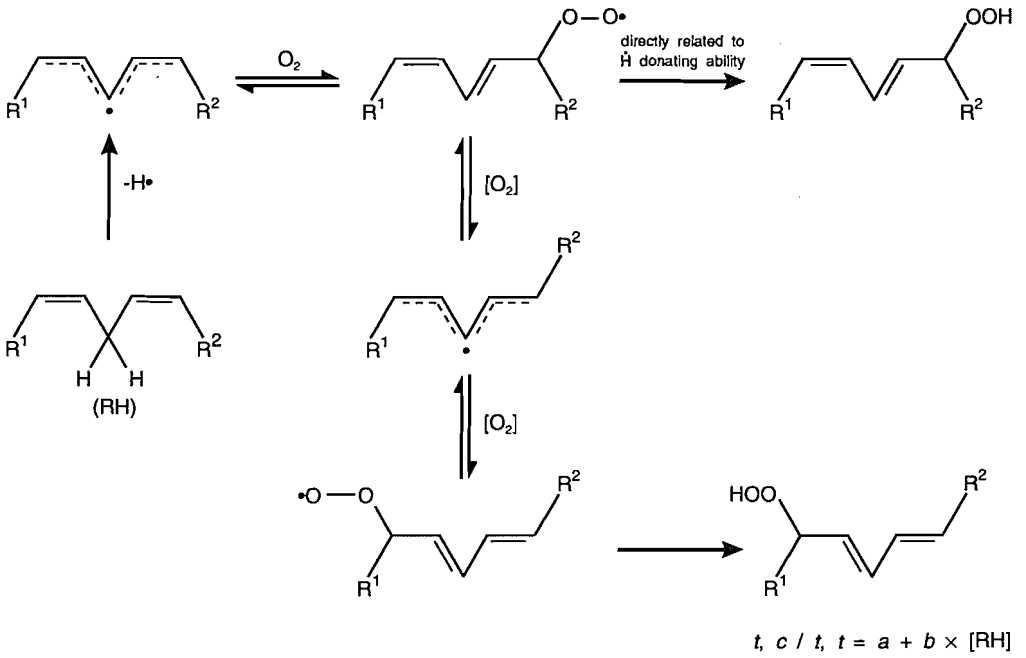


FIG. 5. Mechanistic scheme for peroxidation of unsaturated lipids, and hydroxy esters **1**–**4** prepared from peroxidized membranes for analysis (see Fig. 6).

to be small. (3) The phenoxyl radical ArO· must *not* itself initiate new radical chains by hydrogen abstraction. Hindered phenols, such as the vitamin E class, are known to meet these requirements (35).

The discovery by Ingold's group of the remarkable antioxidant activity of vitamin E (35) and their finding that it is the major lipid-soluble chain-breaking antioxidant in human blood (38) has led to the search for new synthetic models that might be more active than vitamin E itself (39, 40). Such studies were usually carried out in homogeneous solution, the main exceptions being some studies in micelles by our laboratory (26) and by others (41, 42). *The determination of antioxidant activities in* membrane systems *is a more significant but a much more difficult experiment.* Nevertheless, we were able to conduct such measurements in DLPC liposomes for which the required propagation rate constant, $k_p = 36\ M^{-1}\ s^{-1}$, was also determined (43). Melinda Vinqvist of our laboratory conducted very careful oxygen uptake studies during antioxidant–inhibition periods (eq. [14]) on an ultra-sensitive pressure transducer system. The values for k_{inh} were measured by using the integrated expression for the kinetics during inhibition, eq. [15].

$$[15] \quad \Delta[O_2]_t = -k_p/k_{inh} \times [R\text{—}H]\ln(1 - t/\tau)$$

where τ is the inhibition period, and the oxygen uptake, $[O_2]_t$, is measured at various times, t, during this period. The k_{inh}'s are then obtained from the linear plots of $\Delta[O_2]$ versus $\ln(1 - t/\tau)$ and the known k_p for this system ($36\ M^{-1}\ s^{-1}$).

The antioxidant activities of three important classes of phenols were determined during suppressed, thermally initiated, autoxidation of DLPC in MLV liposomes. The three classes of structures shown in Fig. 7 include (*a*) the hydroxychromans of the vitamin E class, (*b*) the polyalkyl 4-methoxyphenols, and (*c*) polyalkylphenols. The actual experimental traces of oxygen uptake under known and controlled rate of free radical chain initiation, R_i, are indicative of the antioxidant efficiencies of these three classes. Quantitative data, the absolute rate constants for inhibition,

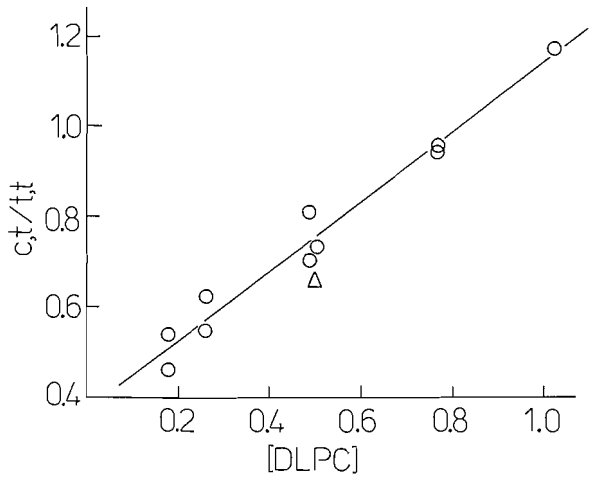

FIG. 6. Concentration dependence of the product ratios (*cis,trans/trans,trans*) of hydroxy linoleate esters derived from the autoxidation of mixtures of DLPC + DPPC. [DLPC] is the substrate concentration in the total (reaction) volume of DLPC + DPPC. The result from palmitoyl linoleoyl PC is shown as Δ.

k_{inh}'s, obtained from the corresponding linear plots of oxygen uptake versus $-\ln(1 - t/\tau)$, are also shown here. Values of k_{inh} in membranes and some results in homogeneous solution are given in Table 2. Very striking differences found for activities of these phenolic antioxidants in membranes compared to homogeneous solution are summarized below.

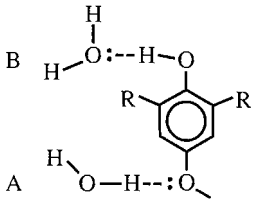
1. The activities of all three classes a, b, *and* c *are dramatically reduced in bilayers compared to solution.* For example, α-tocopherol (vitamin E) is more than 500 times *less* reactive in membranes than in chlorobenzene. A similar, though less dramatic, trend was discovered for the other antioxidants.

2. The activities of all three classes of inhibitors are quite similar in bilayers; e.g. there appears to be a levelling effect operating. This is in marked contrast to differences observed by Ingold's group for measurements in solution where some hydroxy anisoles (DBHA) and phenols (BHT, our "breakfast cereal antioxidant") showed k_{inh}'s orders of magnitude *less* than those of the vitamin E class, *a*. We now find that "BHT" has close to the same activity as vitamin E in membranes.

These major changes in protective activity of phenols in membranes compared to solution were at first very surprising and certainly disturbing! In homogeneous solution of *non-protic* solvents like chlorobenzene, the main factors controlling antioxidant activities are electronic and steric effects. Thus the different antioxidant activities of phenols such as polyalkylhydroxychromans of the vitamin E class and hydroxy anisoles were explained by Ingold and co-workers in terms of carefully considered electronic and steric effects (39). They concluded that the stabilization of the aryloxyl radical formed in the rate-determining inhibition step, eq. [10] above, depends mainly on the extent of orbital overlap between the 2*p* lone pairs on the *para* ether oxygen and the aromatic π system. The lone pairs in the heterocyclic chroman ring are constrained to be nearly perpendicular to the aromatic ring so there is stabilization of the α-tocopheroxyl radical by a type of through resonance referred to as "stereoelectronic effects" (39). We conclude that the remarkable lowering and levelling of activities in biphasic membrane systems must be due to environmental effects, namely, differential solvation effects and diffusion control in viscous bilayers. These two phenomena are evaluated as follows:

1. *The main environmental factor controlling phenolic antioxidant activities in membranes is the solvation effect of water*

We assume that the hydroxychromans reside near the polar head group of membranes as demonstrated for vitamin E (44) and that the trapping of polar peroxyl radicals occurs in this region. In these circumstances, the activity of these compounds is reduced by hydrogen bonding with water at both the ether oxygen at site A and the phenolic group, site B, as illustrated: The combined effects of solvent inter-



action at A and B level the antioxidant activity of the hydroxychromans toward that of BHT, whereas vitamin E is more than 200 times *more* reactive in chlorobenzene. The *higher* reactivity of **4***b* (DBHA) in bilayers is interesting in view of its diminished reactivity in solution, attributed to steric effects provided by *two* ortho tert-*butyl groups* to the approach of peroxyl radicals (39). In aqueous membranes there is a balance between steric inhibition of hydrogen transfer to peroxyl and steric hindrance to solvation of the phenolic OH by *ortho-tert*-butyl groups, so that the main effect operating to give DBHA higher "residual" activity is steric hindrance to hydrogen bonding at the phenolic hydroxyl. For the same reason the antioxidant activity of the polyalkyl phenols **7***c* and **8***c* switches on changing from chlorobenzene to membranes, so that **8***c* now is much less reactive because *ortho* methyl groups are not so effective at blocking solvation at the phenolic hydroxyl.

Through the generosity of samples provided by Professor K. Mukai of Ehime University, Japan, we were able to determine the antioxidant activities of two new synthetic polyalkyl hydroxy chromans, one bearing two isopropyl groups *ortho* to the hydroxyl (**4***a*) and the other *ortho-tert*-butyl and methyl (**4***b*). The results of this study, shown in Table 3, are very interesting indeed. The activities of **4***a* and **5***b* *in solution* are similar to that of 5,7-dimethyltocol, **6***a* (39), indicating that the reduction in activity here compared to PMHC is due to the absence of the stabilizing electron-donating methyl group at position 8 on the aryloxyl radical; steric hindrance to attack by peroxyl is not significant. *In DLPC membranes* these synthetic model compounds are *significantly more active as antioxidants* than any other compounds of the vitamin E class, being more active by one order of magnitude than α-tocopherol itself and three to four times more active than PMHC. These results demonstrate the importance of hydrogen bonding at the phenolic hydroxyl in controlling antioxidant activity. Steric hindrance to such effects provided by two *ortho*-isopropyl groups in **4***a* and an *ortho-tert*-butyl in **5***a* "free" the phenolic hydroxyl for more facile hydrogen atom transfer in the rate-controlling inhibition step, eq. [10].

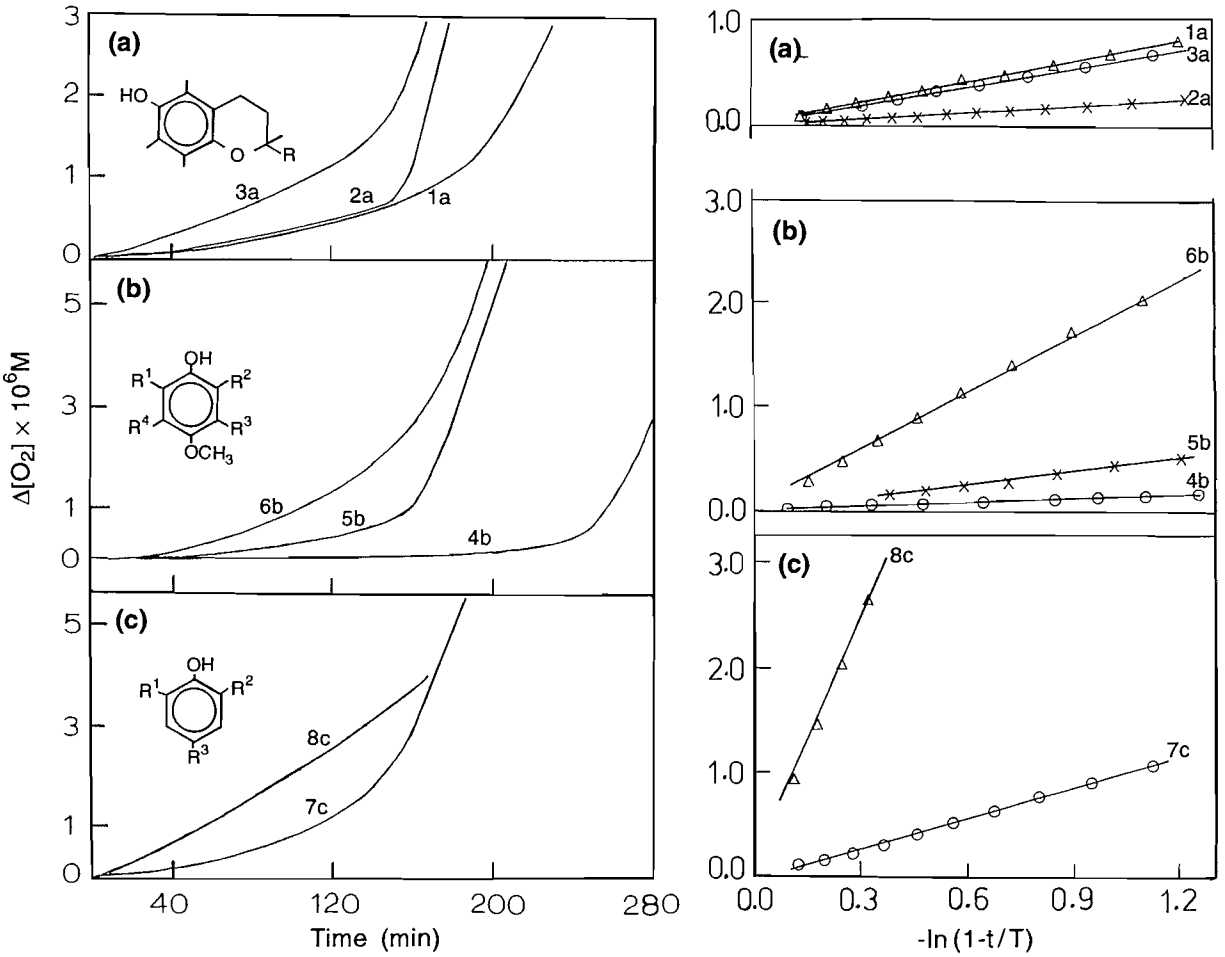

FIG. 7. Effects of antioxidants on peroxidation of DLPC liposomes thermally initiated by azobis-2,4-dimethylvaleronitrile (ADVN) at 37°C, and plots of oxygen uptake during inhibition periods versus $-\ln(1 - t/\tau)$ during peroxidation. **1***a*, α-tocopherol; **2***a*, R = CH_3; **3***a*, R = COOH; **4***b*, $R_1 = R_2 = C(CH_3)_2$, $R_3 = R_4 = H$; **5***b*, $R_1 = R_2 = R_3 = CH_3$, $R_4 = H$; **6***b*, $R_1 - R_4 = CH_3$; **7***c*, $R_1 = R_2 = C(CH_3)$, $R_3 = CH_3$; **8***c*, $R_1 - R_3 = CH_3$ (for amounts used, see ref. 43).

Our results demonstrate clearly the need to measure antioxidant activities of compounds in model membrane systems (as well as in solution) in order to judge their potential protective capacity against peroxyl radical attack in natural biological systems. The results may also be useful in designing new antioxidants that could be more reactive against peroxyl radicals *in membranes*.

2. *Diffusion limiting effects of bilayers on phenolic antioxidants*.

The long phytyl hydrocarbon chain of α-tocopherol may restrict the freedom of motion of this antioxidant in the viscous bilayer region and cause some diffusion control of interaction with peroxyl radicals. As a result, molecules without this chain but possessing the hydroxychroman system (**2***a*,**4***a*,**5***a*) are more active antioxidants than α-tocopherol, and this may in part be due to their greater freedom of motion. Diffusion control between micelles is cited to cause reduced antioxidant activity of lipopholic phenols such as α-tocopherol (41). Also, it is interesting to note that PMHC, **2***a*, is able to transfer between liposomal membranes whereas diffusion of α-tocopherol between membranes is suppressed (45).

A recent proposal of a two-step mechanism of phenolic antioxidant action, electron transfer followed by proton transfer (46), does not change these conclusions on the effects of aqueous membranes on antioxidant activities.

2.5. Cooperative interaction of antioxidants: synergism

Biological systems contain a variety of substances that act as free radical chain breaking antioxidants and these can be classified into a *lipid-soluble group*, which includes tocopherols, β-carotene, ubiquinones, vitamin(s) K, and estrogens, and a *water-soluble group*, which includes ascorbate, uric acid, and thiols such as glutathione. Biomembranes are protected against attack by oxygen-centred radicals through combinations of antioxidants and there is probably a "cascade" of free radical trapping and repair mechanisms involved where some antioxidants may be regenerated at the expense of others. Such an interaction between vitamin E and vitamin C was first suggested many years ago by Golumbic (47). Steven Locke, in our laboratory, was the first to demonstrate the synergistic effect of ascorbic acid and α-tocopherol *under controlled conditions of peroxidation*, using a model system consisting of linoleate in SDS micelles (48). This was followed by independent findings that ascorbate in the aqueous phase of liposomes can interact with vitamin E in the lipid phase to prolong the antioxidant capacity of vi-

tamin E; e.g., synergistic interactions occurred between them in the different phases (49, 50). For ascorbic acid (A—H) to regenerate α-tocopherol from the α-tocopheroloxyl radical, the reaction [16]

[16] $A—H + \dot{E} \rightarrow E + \dot{A}$

must compete with the "fast" addition reaction of peroxyl radicals with Ė (e.g., eq. [11]) and the latter has been estimated to be at least two orders of magnitude faster than reaction [16] (48). However, concentration factors, especially a relatively high concentration of ascorbate and favourable site-specific interactions, may favour reaction [16].

The tripeptide glutathione, GSH, which occurs intracellularly in relatively high concentrations (e.g., millimolar), is known to have antioxidant properties in biological systems (ref. 51, and references therein) and these properties appear to be "vitamin E dependent." The role of GSH and other thiols is not well understood and remains a matter of continuing interest (6). Model experiments in our laboratory using liposomes showed that GSH does *not* regenerate α-tocopherol from the radical but it does act as a *co-antioxidant* to extend the inhibition of oxidation when reaction is initiated in the aqueous phase (51). It is suggested that GSH may function mainly by trapping radicals in the aqueous phase of membranes. We found very recently that thiols such as GSH and homocysteine are able to prevent the oxidative decay of aqueous solutions of ascorbate and even to regenerate ascorbate from its primary oxidation product, dehydroascorbate. The implication for biological fluids is particularly significant. Sulfhydryl groups (e.g., GSH and plasma proteins) present in relatively high concentrations function to protect or "repair" ascorbate while the latter is able to act synergistically with vitamin E to maintain its concentration in the lipid phase. There is evidence for such combined interactions of antioxidants in human blood plasma (52). Evidence has been given to indicate that ascorbate is the "outstanding antioxidant" in human blood plasma at the expense of the thiol plasma proteins, with the implication that the recommended daily allowance (RDA) of vitamin C should be doubled (53).

2.6. *Free radical peroxidation and neuronal tissue damage. Is there a relationship between antioxidant action and protection against central nervous system damage?*

Lipid peroxidation is implicated in the loss of neuronal tissue following brain or spinal cord injury, stroke, and

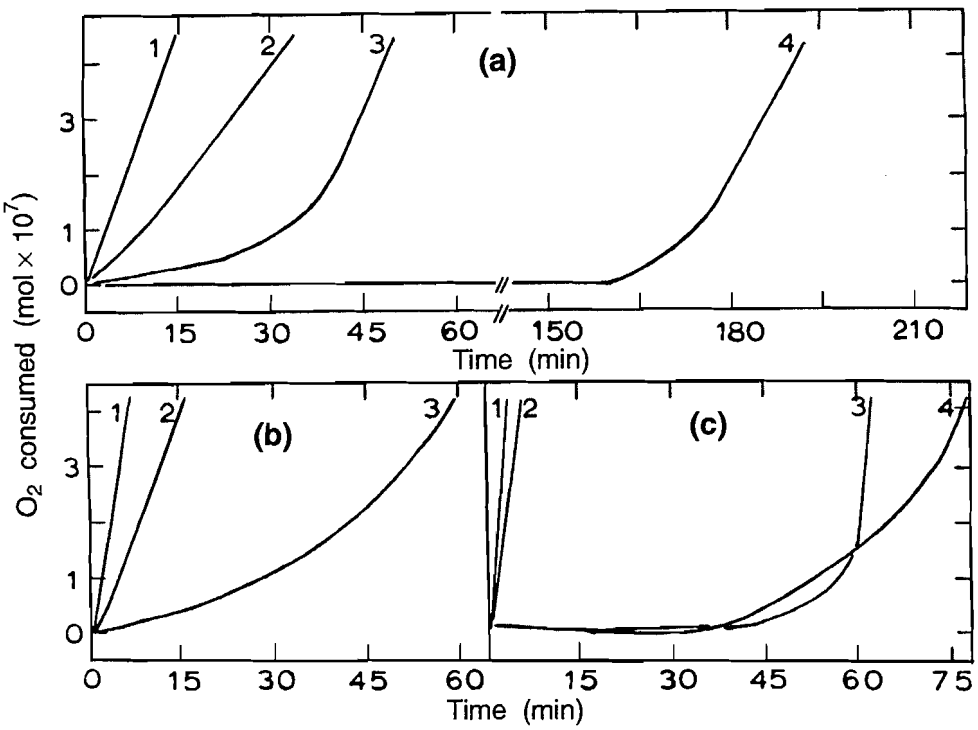

FIG. 8. Autoxidation of DLPC (2.50×10^{-5} mol) in phosphate buffer, pH 7.0. (*a*) Multilamellar DLPC liposomes. Initiated with DBHN (1.23×10^{-5} mol) at 30°C: 1, uninhibited reaction; 2, effect of α-T·BSA (1.76×10^{-8} mol); 3, inhibited by Trolox (0.431×10^{-8} mol); 4, inhibted by α-tocopherol (bilayer, 6.43×10^{-8} mol). (*b*) Large unilamellar DLPC liposomes. Initiated with ABAP (3.66×10^{-5} mol) at 30°C: 1, uninhibited reaction; 2, effect of α-T·BSA (1.24×10^{-8} mol) and immediate initiation with ABAP; 3, effect of α-T·BSA (1.24×10^{-8} mol) with shaking (4 h) *before* initiation with ABAP. (*c*) Small unilamellar DLPC liposomes. Initiated with ABAP (3.66×10^{-5} mol); 1, uninhibited reaction; 2, effect of α-T·BSA (1.24×10^{-8} mol) and immediate initiation with ABAP; 3, inhibited by Trolox (2.49×10^{-8} mol); 4, effect of α-T·BSA (1.24×10^{-8} mol) with shaking (12 h) *before* initiation with ABAP.

neurological disorders (e.g., Parkinson's disease) (54). The Upjohn Company has developed a number of novel "21-aminosteroids" that show promise in the treatment of head and spinal cord injuries (54). The question arises as to the antioxidant activity of such compounds, especially under our conditions of controlled rate of free radical chain initiation. Exploratory results in our laboratory using one such compound (U74500A, ref. 54), incorporated into DLPC liposomes or added in methanol solution, shows that it does act as an effective antioxidant when reaction is initiated either in the aqueous phase with ABAP or in the lipid phase with azobis-2,4-dimethylvaleronitrile (DMVN). In that latter case, the antioxidant activity of the amino steroid ($k_{inh} = 0.60 \times 10^3$ M^{-1} s^{-1}) was somewhat less than that of water-soluble Trolox ($k_{inh} = 1.64 \times 10^3$ M^{-1} s^{-1}) but the former gave a higher stoichiometric factor, $n = 3$ compared to $n = 2$ for Trolox. The mechanism of antioxidant action of these amino steroids is unknown. It may involve electron transfer from tertiary amino groups to peroxyl radicals, followed by hydrogen transfer.

3. Partitioning and diffusion in membranes

3.1. Cholesterol

Cholesterol is a very important constituent of biomembranes. Half of all deaths in the U.S. are attributed to atherosclerosis due to deposits of cholesterol plaque derived from low-density lipoproteins (LDL) that circulate in the blood. The public's attention to "cholesterol levels" became widespread after the 1973 discovery by Brown and Goldstein at the University of Texas of LDL-specific receptors on biomembranes that function to remove cholesterol from LDL and sequester it into the membrane phase, thereby preventing arterial blockage (55). Our recent research on cholesterol led to two very significant results!

1. *We found that solid cholesterol can partition directly from its solid state into phosphatidylcholine bilayers* by shaking the two together at 37°C (56). Both spectroscopic (^{31}P NMR of the membranes and ^2H quadrupole NMR of labelled cholesterol) and analytical data showed that the solid cholesterol partitions up to 21 mol% into the membrane phase. The implication is that cholesterol atherosclerotic plaque may be cleared by transfer to phospholipids directly.

2. *Cholesterol, when transferred into saturated liposomes (DMPC or DPPC), undergoes free radical peroxidation when initiated by either a water-soluble initiator, ABAP, or in the membrane phase with DMVN. The oxidation is inhibited more efficiently by the water-soluble antioxidant, Trolox, than by lipid-soluble α-tocopherol (56).* This latter unexpected result is attributed to diffusion control, in the bilayer region of high microviscosity, of the large molecules, α-tocopherol and cholesterol peroxyl radical, which must meet in the rate-controlling inhibition reaction. In contrast to its susceptibility to peroxidation in bilayers, solid cholesterol does *not* undergo peroxidation under conditions of controlled initiation with a water-soluble or a lipid-soluble initiator.

These fundamental studies on cholesterol partitioning and peroxidation in model membranes have additional biomed-

ical implications as a result of research of independent groups in Canada at the University of Manitoba (57) and in Russia (58). Both groups conclude that oxidation of cholesterol in LDL may play an important role in the development of atherosclerosis. Further research in this aspect of LDL will be of considerable interest.

3.2. α-Tocopherol (vitamin E)

The insolubility of α-tocopherol in water prevents its direct transport through an aqueous phase into preformed phospholipid bilayers. Therefore, it is introduced by co-evaporation with the phospholipid from an organic solvent. This limited the application of this otherwise excellent antioxidant to studies on reconstituted membranes. α-Tocopherol is transported in blood within plasma lipoproteins (e.g., LDL and HDL) (7). In experiments designed to mimic the natural transfer of α-tocopherol into membranes, we prepared a *water soluble* form of α-tocopherol (8×10^{-4} M) by complexing it with a readily available protein, bovine serum albumin (BSA). This α-T.BSA proved to be an excellent antioxidant for free radical autoxidations initiated *in SDS micelles* for reactions initiated by either a lipid-soluble initiator (DMVN) or a water-soluble one (ABAP). The α-T.BSA gave well-defined induction periods immediately upon injection into a reaction and the suppression of oxygen uptake was comparable to that provided by Trolox or α-T.SDS.

Remarkably different results were discovered when α-T.BSA was added to autoxidations initiated *in DLPC membranes*. Some typical oxygen uptake traces are shown in Fig. 8. In reactions initiated by di-*tert*-butylhyponitrite (DBHN) in the lipid phase, α-T.BSA did not give any definite induction period, but only a reduction of the rate (Fig. 8*a*, Nos. 1 and 2) whereas both Trolox and membrane-bound α-tocopherol were efficient inhibitors (Nos. 3 and 4). These results demonstrate again the different behaviour of micellar and bilayer systems.

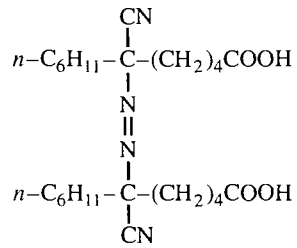
When samples of α-T.BSA were equilibrated under nitrogen with DLPC bilayers for up to 12 h *before initiation* of autoxidation, effective inhibition was observed as shown in Fig. 8*c*, No. 4. Such results indicate rather slow transfer of α-tocopherol from the protein to the bilayer, and only when it is released from the protein does it act as an effective antioxidant.

3.3. Diffusion and spin-trapping of radicals

Spin trapping of carbon- and oxygen-centred radicals in biomembranes and model systems is expected to provide important information on the dynamics of radicals in membranes. Radicals trapped in the lipid phase of micelles (59) or membranes (60) show anisotropic line shapes due to restriction of motion whereas those located in the bulk phase should exhibit isotropic or near-isotropic behaviour. Such behaviour should allow for determination of the position and possibly the site of action of radicals in membranes.

In a test of this idea, Steven Locke from our group and Peter Krygsman in Ed Janzen's laboratory carried out spin-trapping experiments using the water-soluble initiation, ABAP, in membranes. In this study, ABAP was encapsulated in the *inner aqueous core* of unilamellar, saturated PC membranes (DMPC) and a water-soluble spin trap, 4-carboxyphenyl-*tert*-butylnitrone (PBN), was added to the outer bulk phase. After irradiation (1 min, 75 W), isotropic radical signals, assigned to carbon radicals derived from ABAP, appeared; a_N = 15.4 G, a_H^β = 3.84 G. We conclude that charged ABAP or derived radical is able to penetrate the bilayer structure of membranes. This accounts at least in part for the useful properties of this azo initiator in quantitative kinetic and product studies from membrane peroxidation.

Spin-trapping results provide some support for the hypothesis that polar lipid peroxyl radicals diffuse to the aqueous phase. For this research we were able to employ the interesting lipidic azo initiator (6,6′) provided by Ned Porter



(61). Thermolysis under nitrogen of this 6,6′ diazene in unilamellar vesicles of DMPC containing the spin trap, PBN, gave an ESR spectrum, Fig. 9*a*, with a broadened high absorption typical of radicals with restricted motion in bilayers and to which we assign the structure 6-cyanododecanoic acid (CDDA) spin adduct; a_N = 15.8 G, a_H^β = 3.55 G, τ_c = 1.2 x 10^{-10} s. When this experiment was carried out using multilamellar vesicles (MLV) of DMPC, 6,6′, and PBN the ESR spectrum was completely anisotropic (Fig. 9*b*), an indication of an immobilized spin adduct in the larger, more complex bilayer system. Figure 9*c* shows the effect of oxygenation of the MLV system on the site of spin trapping of radicals derived from the 6,6′ diazene. In this experiment, a water-soluble spin trap 4-trimethylammonium-PBN was used. The isotropic spectrum now observed indicates that radicals are trapped in the bulk, aqueous phase. The structure assigned in this case is a trapped oxygen-centred radical, the CDDA-O-O· peroxyl, a_N = 15.8 G, a_H^β = 3.05 G, g = 2.0056. This kind of experiment supports the hypothesis that polar lipid peroxyl radicals will diffuse out of a bilayer towards the aqueous phase.

4. Exercise and "oxidative stress"

4.1. What is meant by "oxidative stress"?

Oxidative stress has been defined in the biological–biomedical field as "a disturbance in the prooxidant-antioxidant balance in favour of the former" (3). Recent workshops on oxidative stress held in Canada (62) and the United States (63) indicate the increased attention given to this

concept as applied to human biological systems. A review (64) in the latter (63) indicates the wide variety of analytical and spectroscopic methods used to measure "Oxidative Stress Status" (OSS) in humans. Oxidative stress in a biological system implies that some oxygen-related damage by reactive oxygen species, such as free radicals, and its effects are implicated in the pathology of several diseases and aging (1–9). As emphasized before (64), it is desirable to establish a routine and reliable method to determine the OSS in humans. As outlined below, we have used a general *kinetic approach* to measure the antioxidant capacity of human blood plasma and now report on a pilot study to determine the effect of physical exercise on OSS.

4.2. The protective antioxidant capacity of human blood plasma (TRAP)

Human blood plasma is a readily available biological fluid that has been used recently as a model for determination of protective antioxidant capacity in humans (52, 53). The principles involved in the kinetics of autoxidation and the antioxidant action of efficient phenolic antioxidants are used to measure the antioxidant capacity of blood plasma and other fluids. For this measurement, we generate peroxyl radicals in the fluid at a constant (and measured) rate and measure the time (τ) during which natural antioxidants in the fluid "trap" peroxyl radicals and thereby suppress oxygen uptake by oxygen-sensitive compounds in plasma, such as lipids and proteins. The rate at which peroxyls are generated is then measured by adding the water-soluble antioxidant, Trolox, known to trap two peroxyl radicals for each molecule of Trolox. The "Total Radical-trapping Antioxidant Parameter" (TRAP), the number of peroxyl radicals trapped per volume of plasma, is defined by eq. [17] (52)

$$[17] \quad \text{TRAP} = R_i \text{ (rate of ROO}\cdot \text{ formation)} \times \tau$$

$$[18] \quad R_i \text{ (measured)} = 2 \times [\text{Trolox}]/\tau_{\text{Trolox}}$$

This method to measure TRAP, developed with Ingold's group (52), involves only two relatively simple measurements: the time a known volume of plasma inhibits peroxidation, and then a measurement of the rate, R_i, at which peroxyls are generated. The procedure is illustrated schematically in Fig. 10.

4.3. "Trap" of bio-fluids and effect of exercise

Lipid peroxidation in humans is enhanced during intense physical exercise (65). Methods used to determine the possible effect of exercise on OSS in humans include the measurement of vitamin E levels (66–68), plasma levels of malondialdehyde (69), and effects on enzyme levels (68, 70–72).

It was anticipated that the kinetic TRAP procedure would be a sensitive and reliable method to determine the OSS in humans and could also be used to determine the effect of exercise on OSS.

Some TRAP values of blood plasma from various sources and of amniotic fluids are given in Table 4. A group of six students, non-smokers and non-drinkers, on a known diet were studied as a "control" group. Their average TRAP values, 775 μM peroxyls trapped, varied only 10–15% over a 4 month period. The higher TRAP values of athletes, and of amniotic fluids, are related to increased levels of uric acid, a known antioxidant. Lower levels of urate in animals, such as rats, and consequently lower TRAP, may be related to evolutionary trends and life span (73).

We carried out a pilot study of the effect of strenuous exercise on athletes with interesting results as shown in Table 5. Before a 1.5 h varsity soccer practice, the athletes had a high TRAP, 1126 μM, or 45% higher than a selected student sample of non-athletes. Immediately after their 1.5 h practice, the athletes experienced a slight decrease of 13% in their TRAP values, but the average TRAP remained high. The urate contribution to their TRAP actually increased by 11%. Thus the urate's share of TRAP actually increased as a result of exercise. This is probably at the expense of vitamin C (which was not monitored), since the amounts of other natural antioxidants did not change significantly: vitamin E from 12.5 to 12.5 μM and thiols from 460 to 464 μM.

These studies used rather selected groups and the conclusions may not apply to any individual. For example, one of our co-workers performed aerobics "to exhaustion" as compared to her instructor with the results shown in Table 6. In

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

this case the individual ("researcher") experienced a 25% increase in TRAP during aerobics and her urate increased an amazing 100%! The instructor with already a typical average TRAP experienced very little increase although the urate increased by 35%.

These TRAP measurements on human plasma, although only exploratory in nature, do indicate that they are indicative of physical conditioning and exercise. Blood is *the* common fluid taken for various types of clinical testing. It is postulated that clinical testing for antioxidant capacity of the plasma would be useful, especially for humans exposed chronically to toxic substances such as cigarette smoke.

5. Future directions

1. The mechanisms of action and activity of antioxidants are now well established in homogeneous solution; however, our studies indicate that very significant differences occur in model membranes where future testing should be done. In addition, the interaction between antioxidants in vivo needs to be better understood because important differences may emerge when compared to model systems (74).

2. The biomedical aspects of oxygen-centred radicals continue to be of intense interest and lipid peroxidation is implicated in various degenerative diseases. Nevertheless, direct evidence of the role of peroxidation in real biomembranes (e.g., intact cells) is not yet extensive. NMR imaging of tissue slices or whole vital organs subjected to oxidative stress is expected to provide such evidence.

3. A variety of drugs are "traditionally" prescribed to treat inflammatory diseases such as arthritis and neuronal damage. Drugs with antioxidant properties are potentially useful as anti-inflammatory agents. It is desirable to direct efforts towards scientific drug design in this field and antioxidants should play a role in this research.

Acknowledgements

I am grateful to Keith Ingold of the National Research Council (NRC) for his scientific leadership and enthusiasm which initiated this research. Graham Burton of the NRC provided practical help especially during the early phases. Professor Ned Porter of Duke University provided the technology for product studies, and Bruce Forrest assisted with NMR studies at the Atlantic Regional Magnetic Resonance Centre. Interest in peroxyl radicals is continuing through collaborative theoretical studies by Russell Boyd and Susan Boyd at Dalhousie University.

This research would not have been completed without the enthusiastic participation of students and other co-workers at Mount Allison University. In addition, Roger Smith and Allister MacDonald provided valuable technical help. Financial support provided by the Natural Sciences and Engineering Research Council of Canada, the Terry Fox Fund for Cancer Research (New Brunswick), and a NATO Grant for International Collaborative Research is gratefully acknowledged.

An ion-exchange/atomic absorption method for the measurement of ionized calcium and magnesium at micromolar concentrations

AMITHA K. HEWAVITHARANA AND BYRON KRATOCHVIL[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 28, 1992[2]

AMITHA K. HEWAVITHARANA and BYRON KRATOCHVIL. Can. J. Chem. **71**, 17 (1993).

A quantitative ion-exchange/atomic absorption method is described for measuring the concentration of free (hydrated) calcium and magnesium in solution at micromolar levels. Sample solutions are pumped through a micro-column of strong acid-type cation-exchange resin until equilibrium has been achieved between resin and solution. After removal of interstitial solution by first air, then water, the sorbed metal ion is eluted from the resin with nitric acid directly into an atomic absorption spectrophotometer. In a 0.1 M 1:1 electrolyte, here KNO_3, the amount of metal ion sorbed on the resin is directly proportional to the free metal ion concentration in solution over a concentration range of 1.25 to 5×10^{-5} mol/L (12–50 μmol/L). Selectivities for free calcium and magnesium in the presence of complexing ligands such as citrate and phosphate compare well with calculated values.

AMITHA K. HEWAVITHARANA et BYRON KRATOCHVIL. Can. J. Chem. **71**, 17 (1993).

On décrit une méthode quantitative d'échange d'ions/absorption atomique qui permet de mesurer la concentration du calcium et du magnésium libre (hydraté) en solution, à des niveaux micromoléculaires. On pompe des solutions d'échantillons dans une microcolonne d'une résine échangeuse de cations d'un type fortement acide jusqu 'à l'obtention d'un équilibre entre la résine et la solution. Après avoir enlevé la solution interstitielle à l'aide d'air, puis d'eau, on élue l'ion métallique de la résine à l'aide d'acide nitrique directement dans un spectrophotomètre d'absorption atomique. Dans un électrolyte 1 : 1 à 0, 1 M, dans ce cas du KNO_3, la quantité d'ion métallique adsorbée sur la résine est directement proportionnelle à la concentration d'ion métallique en solution, à des concentrations allant de 1,25 à 5×10^{-5} mol/L (12–50 μmol/L). On a comparé les sélectivités pour le calcium et le magnésium libre en présence de ligands complexants comme le citrate et le phosphate avec les valeurs calculées.

[Traduit par la rédaction]

Knowledge of the concentrations of ionic (free, hydrated) calcium and magnesium in the presence of complexed or bound metal ion in solution is frequently of interest because the free form is often the most biologically or environmentally active form. Several methods have been proposed for measuring pCa. These include ion selective electrode potentiometry and spectrophotometry using calcium indicators. Each method has significant drawbacks, however, such as interferences from other metals, pH sensitivity, and inconvenience. For magnesium the problem is even greater, for there are no satisfactory magnesium ion-selective electrodes or spectrophotometric reagents. Therefore a method for measuring pMg could be quite useful.

A recently developed approach to metal ion speciation involves pumping the sample solution through an ion-exchange column until the column has reached equilibration. The technique has been employed to determine free copper ion concentrations in natural waters (1), free nickel in sewage (2), and free calcium at millimolar levels in solutions containing a range of ligands (3). In this paper the technique is shown to give linear calibration curves for free magnesium and calcium ion concentrations at micromolar levels in solutions containing ligands such as citrate or phosphate. The theory behind the method has been outlined in previous studies of nickel (2) and copper (3) systems. The same principles described for these ions apply to both calcium and magnesium.

An ideal system for measuring pM, where M is any metal, introduces little or no perturbation of the system. The column equilibration technique meets this criterion by pumping fresh sample solution past the ion-exchange resin until the resin has come to equilibrium with the solution. In this way the uptake of ions by the resin has not changed the composition of the sample solution with which it is in equilibrium. A necessary requirement of the method is that the sample solution contain sufficient univalent electrolyte, usually a sodium or potassium salt, to allow no more than a percent or so of the total exchange capacity of the resin to be taken up by the metal ion being measured. This level must be matched in the calibration solutions. For some matrices, such as sea water, serum, or blood plasma, the concentration of sodium and potassium may already be at a level sufficient to provide the swamping conditions necessary for many divalent ions.

Experimental

Apparatus

The major components of the instrument consist of a Minipuls model 2 peristaltic multichannel pump and a Perkin Elmer model 4000 atomic absorption spectrophotometer. The flow system is shown in Fig. 1. Construction of the micro-column, which for this study contained about 0.7 mg of 100–200 mesh Dowex 50 strongly acidic cation-exchange resin, is described elsewhere (4). Depending on the position of the 6-port rotary valve (A in Fig. 1), solution, air, or water may be pumped through the column; valve C allows a choice of either water or eluent. By means of valve B the flow from either valve A or C can be directed through the column while the other is diverted to waste.

The calcium ion selective electrode used in this study was based on the neutral carrier ETH 1001 designed by the research group of W. Simon (ETH, Zurich), and was provided by the research group of Dr. D. J. Harrison of this department; it was used with a standard calomel electrode as reference. pH measurements were made with a Fisher glass–calomel electrode pair calibrated with Fisher standard buffers at pH 4 and 7. All pH and voltage readings were made with a Fisher model 520 digital pH/ion meter.

Reagents

All chemicals used were reagent grade or better. Stock solutions of $Ca(NO_3)_2$ and $Mg(NO_3)_2$ were prepared by dissolving $CaCO_3$ and metallic Mg in HNO_3. Potassium nitrate was used to maintain the desired ionic strength, with the potassium ion concentration held at a level sufficient to ensure the resin exchange sites were primarily in the K^+ form. Analytical grade 100–200 mesh Dowex 50W X8 strong acid-type cation exchanger (J. T. Baker Chemical Co.) was pretreated as described in the literature (5). The ion-exchange capacity of this resin is reported as 5.1 mequiv./g on a dry basis.

Procedure

The flow rate through the column was maintained at 5 mL/min with the peristaltic pump. The flow system and procedure were based on that described in previous work (1–3), with one modification. In the previous system the ion-exchange equilibrium established during the load cycle was found to be perturbed by the wash cycle that immediately followed. Dilution of the sample solution by the initial front of the wash water lowered the swamping electrolyte concentration, resulting in an increase in uptake by the resin of the divalent ion under study. Therefore in this work an air-purge cycle was introduced between the loading and wash cycles to reduce this perturbation. The valve system shown in Fig. 1 was used to perform the following sequence of operations.

The column was first washed by pumping water through it for 1 min. Next the solution of interest was loaded by passing it through the column to waste until complete breakthrough was achieved (upper diagram in Fig. 1). At this stage the composition of the column influent and effluent are the same and the resin is in equilibrium with the test solution. After the loading cycle, air was passed through the column for 1 min to remove interstitial sample, followed by backwash water through valves C and B for 1 min (lower diagram in Fig. 1). This wash cycle was followed by a 30-s elution of the sorbed ions with 2 mol/L HNO_3 directly into the atomic absorption spectrophotometer (AAS). During elution the AAS was set to integrate the peak area. After elution the column was washed with water before introduction of the next test solution.

Results and discussion

Time of equilibration and calibration curves

The time required to achieve complete equilibration of the resin with a sample solution was examined using 2.5×10^{-5} mol/L Ca^{2+} or Mg^{2+} in 0.1 mol/L KNO_3. The column was equilibrated for varying lengths of time, the sorbed calcium or magnesium eluted, and the peak area measured as described earlier. The results show that the time required to achieve complete equilibration was less than 3 min for both metals at this concentration. Therefore, equilibration times of 3 min were used for all Ca^{2+} and Mg^{2+} standards prepared with the same electrolyte concentration.

Calibration plots were linear for concentrations of Ca^{2+} or Mg^{2+} over the range of 1.25 to 5×10^{-5} mol/L, in 0.1 mol/L KNO_3. All solutions were adjusted to pH 5.2 ± 1 using small amounts of KOH or HNO_3 as needed. Calibration plots were linear over this range for both elements.

Selectivity of the method for free over bound calcium and magnesium

The presence of complexing ligands results in the binding of metal ions and thereby lowers free metal ion concentrations in solution. Depending on ligand charge, the metal ligand complexes may be cationic, anionic, or neutral. In the ion-exchange column-equilibration method employed here, it is assumed that only free, hydrated metal ions are sorbed onto the resin. However, sorption of cationic or neutral

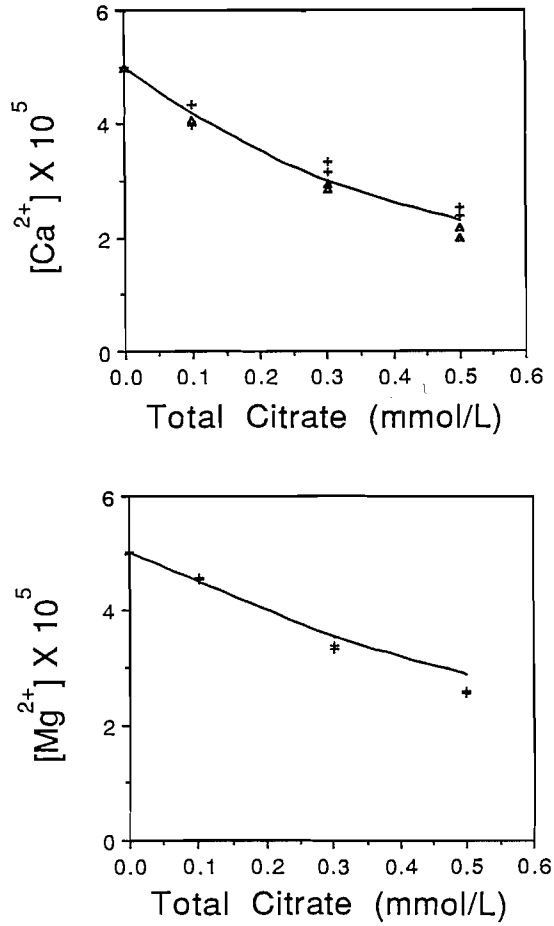

FIG. 2. Variation of free Ca^{2+} (top) and free Mg^{2+} (bottom) concentrations with total citrate, at pH range 6–7, as measured by: +, ion exchange and Δ, ISE potentiometry. Solid lines show the calculated values. Total Ca^{2+} and Mg^{2+} is 5×10^{-5} mol/L throughout.

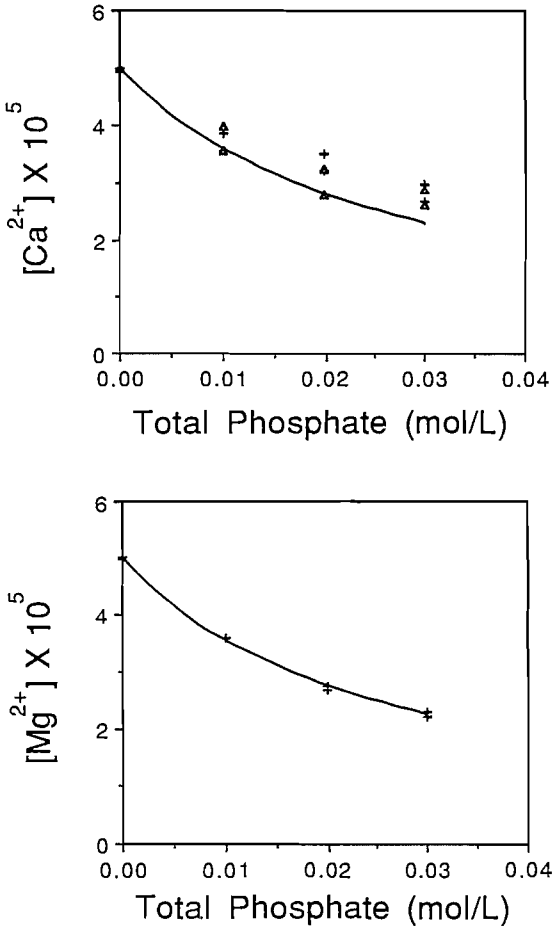

FIG. 3. Variation of free Ca^{2+} (top) and free Mg^{2+} (bottom) concentrations with total phosphate, at pH 7, as measured by: +, ion exchange and Δ, ISE potentiometry. Solid lines show the calculated values. Total Ca^{2+} and Mg^{2+} is 5×10^{-5} mol/L throughout.

complexes would give rise to falsely high free metal values (1). To assess the extent to which this process might occur, the free metal in solutions containing 5×10^{-5} mol/L total calcium or total magnesium and variable concentrations of citrate and phosphate was measured by the ion-exchange method as described above and, for calcium, also by potentionmetry using a calcium ion selective electrode. The pH values of the solutions were adjusted to fall in the range of 6–6.9. The fraction of free metal ion in each solution was also calculated from equilibrium-constant data by computer using the program COMICS (6).

Results obtained for the fraction of free calcium and free magnesium in the presence of varying amounts of total citrate are shown in Fig. 2. Calculated values, shown as solid lines in the figures, are based on complexes of the type $MCit^-$, MHCit, MH_2Cit^+, $KCit^{2-}$ (7), and $KHCit^-$ (8). Here M denotes either Ca^{2+} or Mg^{2+} and Cit denotes the triply charged citrate anion Cit^{3-}. Where values were not available for 0.1 ionic strength (7), they were recalculated from other ionic strengths using the Davies equation. The agreement among calculated and free calcium concentrations measured by ion exchange and potentiometry can be considered satisfactory, especially in light of the low levels and the uncertainities in reported equilibrium constant values. The results indicate that the column selectively sorbs free calcium in the presence of calcium–citrate species. Similar agreement is obtained for magnesium, indicating high selectivity by the method for free magnesium in the presence of citrate.

The variation of free metal fractions in the presence of varying amounts of total phosphate at pH 7 was studied in a similar manner; results are shown in Fig. 3. Calculated values are based on formation of the complexes MPO_4^-, $MHPO_4$, $MH_2PO_4^+$ (9), KPO_4^{2-}, $KHPO_4^-$, and KH_2PO_4 (10). Ionic strength corrections were carried out as for the citrate system. Here, too, agreement between the calculated and measured values was satisfactory for both metal ions. The differences in agreement between calculated and measured values are likely due to a combination of factors, including uncertainties in measured pH and metal ion concentrations, uncertainties in reported stability constants, and ionic strength corrections using the Davies equation. The agreement between calculated and measured values for free magnesium with both citrate and phosphate is especially good. Thus, even though the resin might be expected to sorb cationic or neutral calcium or magnesium–ligand complexes, under the conditions used such sorption processes appear to be negligible. Since there is no reliable ion selective electrode

available for magnesium, a comparison with other than calculated values was not possible.

The advantages of this ion-exchange method over ion selective potentiometry are twofold. One is that the resin is not affected by the presence of small amounts of nonionic solutes in the sample solution except insofar as they alter ionic activities through bulk solvent effects. Another is that use of atomic absorption spectroscopy provides both high sensitivity and selectivity. The major disadvantage is that sample solutions must contain sufficient swamping electrolyte possessing a univalent cation so that at equilibrium the column has fewer than 1% of its exchange sites occupied by calcium or magnesium ions. A concentration of about 0.1 mol/L is ample for this purpose when the concentrations of ions under study are of the order of 10^{-5} mol/L or less.

In summary, this work describes a procedure for the estimation of free calcium and free magnesium at micromolar levels in the presence of ligands such as citrate and phosphate. The method should be applicable over a wide pH range and can be made even more sensitive by increasing the amount of resin in the column. Small resin quantities have the advantage of more rapid equilibration and smaller sample volume requirements, but since preparation of the column is relatively simple, a variety of columns containing differing resin quantities can be prepared beforehand, and interchanged as required to match sample solution properties or available volumes.

Received January 15, 1992

S. J. CATHUM. Can. J. Chem. **71**, 21 (1993).

A method has been developed to determine the enthalpy of atom formation in a graphite furnace without invoking the order of reaction. The method is based on the equation $\ln (AT) = -\Delta H^0/RT + C$, where A is the peak-height absorbance, T is the absolute temperature, ΔH^0 is the enthalpy of atom formation which, for highly endothermic reactions, is considered to be equal to the activation energy, R and C are the universal gas constant and the constant of integration, respectively. The plot of $\ln (AT)$ vs. $1/T$ is similar to an Arrhenius-type plot and should yield the activation energy. Atomization mechanisms for eight elements, Cu, Co, Ga, Au, Ni, Fe, Ag, and Al, are proposed by correlating the experimental enthalpy with a very limited set of possible primary reactions. One significant result of this work is that the experimentally observed enthalpy of reaction correlates well with the activation energy, this means no excess energy other than the enthalpy of atomization is involved in the reaction.

S. J. CATHUM. Can. J. Chem. **71**, 21 (1993).

On a développé une méthode permettant de déterminer l'enthalpie de formation atomique dans un four graphite, sans impliquer l'ordre de la réaction. La méthode repose sur l'équation $\ln (AT) = -\Delta^0/RT + C$, dans laquelle A est l'absorbance à la hauteur maximale du pic, T est la température absolue et ΔH^0 est l'enthalpie de formation atomique que l'on considère, pour des réactions fortement endothermiques, comme étant égale à l'énergie d'activation alors que R et C sont respectivement la constante universelle des gaz et la constante d'intégration. La courbe de $\ln (AT)$ vs. $1/T$ est semblable à une courbe de type Arrhenius et elle devrait fournir l'énergie d'activation. Utilisant une corrélation de l'enthalpie expérimentale avec un ensemble limité de réactions primaires possibles, on propose des mécanismes d'atomisation pour huit éléments, Cu, Co, Ga, Au, Ni, Fe, Ag et Al. Un résultat important de ce travail établit qu'il existe une bonne corrélation entre l'enthalpie de réaction observée expérimentalement et l'énergie d'activation; ce résultat signifie qu'il n'y a pas d'énergie en excès, à l'exception de l'enthalpie d'atomisation, d'impliquer dans la réaction.

[Traduit par la rédaction]

Introduction

In graphite furnace atomic absorption spectrometry, GF-AAS, researchers are concerned with the laws of analyte reactions during atomization. These laws are mainly divided into two types: thermodynamic and kinetic. In thermodynamics, conclusions are reached on the basis of changes in the Gibb's free energy of the system. From the value of Gibb's free energy it is possible to predict the direction in which a chemical reaction will take place. Thermodynamics cannot, however, give information on the rate of atom formation by which the analyte is converted into atoms. In many situations studied so far, much information can be obtained from both thermodynamic and kinetic measurements. A complete picture of atom formation and loss is incomplete unless both two approaches are considered. Hence, to postulate a mechanism of atom formation it would be helpful to consider all thermodynamic and kinetic data that are available.

To illustrate the relationship between the above two approaches one can assume copper oxide (CuO) is the precursor for gaseous copper atoms. When atomization occurs two steps need to be considered, one step is the reduction of CuO by graphite,

$$CuO_{(s)} + C_{(s)} \rightarrow Cu_{(s)} + CO_{(g)} \quad \text{(reduction)}$$

and the other is the sublimation of the reduced metal,

$$Cu_{(s)} \rightarrow Cu_{(g)} \quad \text{(sublimation)}$$

For the reduction of $CuO_{(s)}$ by $C_{(s)}$ to take place, about 19.2 kJ mol^{-1} of energy must be acquired by collisions between copper oxide and carbon, whereas sublimation of copper requires 337.6 kJ mol^{-1} of energy. The latter is, therefore, likely to be slow compared to the former, and hence is the rate-determining step.

The thermodynamic approach (1–3) has been used in studying the mechanism of atomization in GF-AAS. Campbell and Ottaway (1) concluded from their study of 27 elements that the reduction of the metal oxide by carbon was thermodynamically feasible. Sturgeon *et al.* (4, 5) used a combined thermodynamic and kinetic approach to obtain the activation energy of atom release from the onset of a plot of natural logarithm of the absorbance vs. the reciprocal of the absolute temperature. Frech *et al.* (2) developed a thermodynamic model to study the distribution of solid, liquid, and gaseous analyte species in the graphite furnace as a function of temperature for 16 elements. Chakrabarti *et al.* (3) reported the importance of carbon in determining the partial pressure of CO as well as other gaseous species, such as O and O_2, in a graphite furnace. Fuller used a kinetic approach (6), developed under isothermal conditions, to study the mechanism of atom formation emphasizing the need for considering thermochemical properties of the element and its chemical compounds that may form during atomization.

By applying thermodynamics and assuming that the change in the analyte vapour pressure varies directly as the rate of atom release (7), one can formulate an Arrhenius-type plot to determine the heat of atomization. The necessary assumptions are the ideal gas behaviour of the analyte atomic vapour and equality of the activation energy with the en-

thalpy of the reaction. The latter seems to be not unreasonable and has sufficient support from various authors (4, 5, 8, 9). The experimental activation energy, or the enthalpy of atomization, is defined here as the energy required to produce gaseous atoms (4, 10). Several factors play an important role in determining the observed value of the enthalpy of atomization. Among these factors is the energy required, in the rate-determining step, to break existing bonds to release the free atoms. In the category of breaking bonds, one may include desorption and re-deposition of gaseous analyte atoms on the graphite surface.

This work is an attempt to determine the enthalpy of atomization by a method derived from basic principles of thermodynamics. A comparison between the method and those reported in the literature (4, 11) will be made. The mechanisms of atomization of Cu, Co, Ga, Au, Ni, Fe, Ag, and Al will be proposed.

Theory

This method assumes that the release of atoms from the graphite surface is a desorption process (4, 12–14). Once a desorption process is assumed for a system, thermodynamic relationships can be applied to experimental data to yield the heat of desorption (15). A number of authors (16–18) have also reported that thermodynamic equilibrium is established at each stage of atom formation between the solid phase and the gaseous analyte atoms as follows:

$$[1] \quad M_w \leftrightharpoons M_g$$

where M_w is the number of analyte atoms left unatomized on the graphite surface and M_g is the number of atoms in the gas phase. The expression for the equilibrium constant K_p for the above reaction is given by

$$[2] \quad K_p = P = \exp(-\Delta G^0/RT)$$

where P is the atomic vapour pressure of the element in the atomizer at time t, R and T are the gas constant and the absolute temperature, respectively, and ΔG^0 is the standard Gibb's free energy change which is defined by the following general equation:

$$[3] \quad \Delta G^0 = \Delta H^0 - T\Delta S^0$$

where ΔH^0 is the standard enthalpy and ΔS^0 is the standard entropy change. According to eq. [2], K_p, and hence P, increases with temperature. Thus, M_g will also increase as the temperature increases. On substituting eq. [3] into eq. [2] and taking natural logarithm of both sides of the resulting equation, one gets

$$[4] \quad \ln P = -\Delta H^0/RT + C'$$

where C' is a constant and ΔH^0 is the molar enthalpy of vaporization, sublimation, or desorption. From eq. [4], a plot of ln P vs. $1/T$ should be linear with slope $= -\Delta H^0/R$ and intercept $= C'$. The value of P, however, is difficult to measure in the graphite furnace as a function of time during atomization because of the extremely small value of this vapour pressure. For this reason it would be better to relate P to the absorbance, A, i.e. $A = f(P)$. Thus, for ideal gas behaviour one gets

$$PV = nRT$$

where V is the graphite furnace volume approximately equal to the analysis volume and n is the number of moles of absorbing atoms that have gone to the gas phase, $n = M_g/L$, where L is Avogadro's number. In this case, eq. [4] can be rewritten as follows:

$$\ln(M_g RT/LV) = -\Delta H^0/RT + C'$$

The measured absorbance is related to the number of analyte atoms through the general equation, $A = QM_g$, where Q is a constant containing all the necessary physical and geometrical constants. Therefore, the above equation may be expressed as follows:

$$\ln(ART/QLV) = -\Delta H^0/RT + C'$$

which is slightly modified to

$$[5] \quad \ln(AT) = -\Delta H^0/RT + C$$

where

$$C = C' + \ln(QLV/R)$$

The plot of ln (AT) vs. $1/T$ is similar to the Arrhenius plot and can be used to obtain ΔH^0 from the slope. Agreement between their experimentally determined activation, E_a, energy and the enthalpy of sublimation for several elements Sturgeon *et al.* (4, 5, 12) have reported that E_a may be equated to ΔH^0. The Arrhenius plot then becomes in effect a van't Hoff plot (19) and one can conclude that the atomization of the analyte element at the appearance temperature is thermodynamically favourable.

The following energy terms play an important role in proposing a mechanism of atomization (6): The enthalpy of vaporization, ΔH^0(M), of the element (sublimation if there is no liquid phase); the enthalpy of vaporization (or sublimation) of the metal oxide, ΔH^0(MO); the dissociation energy of the metal oxide, D_0(M—O); and the dissociation energy of the metal carbide, D_0(M—C). These energy terms are summarized in Table 1. The release of analyte atoms into the gas phase is determined to a large extent by these terms as well as some other kinetic factors. To evaluate the reduction of $MO_{(s)}$ by $C_{(s)}$ these terms should be considered. Generally, production of gaseous analyte atoms $M_{(g)}$ is given by the following equations:

$$[6] \quad MO_{(s)} + C_{(s)} \rightarrow M_{(s)} + CO_{(g)}$$

$$[7] \quad MO_{(s)} + CO_{(g)} \rightarrow M_{(s)} + CO_{2(g)}$$

$$[8] \quad MO_{(s)} \rightarrow MO_{(g)}$$

$$[9] \quad MO_{(g)} \rightarrow M_{(g)} + (1/2)O_{2(g)}$$

$$[10] \quad M_{(s)} \rightarrow M_{(g)}$$

The reduction of metal oxide by carbon, eq. [6], becomes favourable as the temperature increases. As mentioned above the extent of the reaction in each of the above chemical equations depends on many factors. Of prime importance are the change in the Gibb's free energy and the absolute temperature which have a tremendous effect on the relative magnitude of the equilibrium constant involved in the reaction. The latter helps in predicting which reaction is thermodynamically more favourable at a given temperature. The following three reactions determine the thermo-

dynamic competitiveness of carbon and carbon monoxide as reducing agents in the graphite furnace:

[11] $C_{(s)} + O_{2(g)} \rightarrow 2CO_{(g)}$

[12] $C_{(s)} + O_{2(g)} \rightarrow CO_{2(g)}$

[13] $2CO_{(g)} + O_{2(g)} \rightarrow 2CO_{2(g)}$

Assuming unit activities for all of the above species a quantitative comparison of relative affinities of carbon or carbon monoxide for oxygen may be made as follows: the particular advantage of carbon as a reducing agent over the other two reactions can be understood by reference to the change in the Gibb's free energy, ΔG^0. As T increases ΔG^0 becomes more negative for reaction [11], remains almost the same for reaction [12], and becomes more positive for reaction [13]. Because the change in the entropy, ΔS^0, for reaction [11] is positive, the greater the temperature, the more negative ΔG^0 will be and hence the greater will be the thermodynamic advantage of reaction [11] over reactions [12] and [13]. With the unit activity assumption for all of the species reaction [13] is more effective (as a reducing agent) than reactions [11] and [12] only at temperatures below 973 K. However, the change in the Gibb's free energy is the measure of the actual drive of the reaction towards equilibrium. In the graphite furnace, the activity of carbon is one and the fugacity of carbon monoxide is much less than one (20, 21). The partial pressure of CO in the graphite furnace at a heating rate of 1500 K/s is about 0.001 atm (21). At equilibrium, the decrease in ΔG^0 as the temperature increases means K_p will increase and therefore products will be favoured over reactants to a greater extent. The reduction of the metal oxide by carbon is well documented in the literature (1, 4, 5, 19, 22, 23). And even if the reduction of the metal oxide is not thermodynamically favourable at the appearance temperature formation of free metal atoms may be attributed to the thermal dissociation of the metal oxide (4). Another important factor that has a profound effect on the reduction of the metal oxide is the kinetics of the reaction. The rate of formation of the free metal from the oxide depends on the energy barrier to be surmounted, amounts of species that appear in the rate law of the chemical reaction and the pre-exponential factor of the Arrhenius law. If the reduction of the metal oxide by carbon in eq. [6] is kinetically controlled the rate of disappearance of the metal oxide from the surface may be expressed by a pseudo first-order reaction. This is possible since carbon is present in a large amount which is considered constant, whereas the rate of reduction of the metal oxide by carbon monoxide is expressed by second-order kinetics. In order for the carbon monoxide to reduce the metal oxide the carbon monoxide molecule must become adsorbed onto the condensed phase of the metal oxide. At a low surface coverage of carbon monoxide (where the partial pressure of CO is very low) the reduction of the metal oxide occurs at a lower rate than the reduction by carbon. Moreover, the metal oxide is in intimate contact with the graphite surface during atomization which should kinetically favour reduction by carbon over that by CO. It is therefore reasonable to conclude that reduction by carbon is the most predominant pathway for generating free analyte atoms.

Experimental

Apparatus

Absorbance measurements were made with a Perkin-Elmer atomic absorption spectrophotometer, model 503, equipped with a Deuterium Arc Background Corrector and a Heated Graphite Atomizer (HGA) model 400, operated in the gas-stop mode. Argon gas of purity 99.997% and pyrolytically coated electrographite tubes (The Perkin-Elmer Corporation, part No. B009-1504) were used. Hollow cathode lamps of Al, Ga, Au, Ni, Ag, and Fe (Westinghouse), Co (Varian Techtron), and Cu (Cathodeon) were used.

Standards and reagents

Standards were prepared by using chemicals or elements of the highest purity commercially available. Stock solutions of cobalt, iron, nickel, and gallium were prepared separately by dissolving the appropriate mass of pure metal in nitric acid (ULTREX, Baker Chemical Co.) and making up the solution to 1000 μg mL^{-1} in 1% (v/v) nitric acid. The stock solution of silver was prepared by dissolving an appropriate mass of silver nitrate in ultrapure water and diluting the solution to 1000 μg mL^{-1} with ultrapure water. The stock solution of copper was prepared by dissolving copper metal in 50% (v/v) nitric acid (ULTREX) with heating; the final solution was made to 1000 μg mL^{-1} in 1% (v/v) nitric acid by diluting with ultrapure water. The stock solution of aluminum was

prepared by dissolving pure aluminum in 20% (v/v) nitric acid with heating and diluting the solution to 1000 μg mL^{-1} with ultrapure water. The stock solution of gold was prepared by dissolving the appropriate mass of the gold metal in aqua regia and diluting the solution with ultrapure water to 1000 μg mL^{-1}. All test solutions were prepared daily by serial dilution of the stock solutions with ultrapure water to contain 1% (v/v) nitric acid. Ultrapure water of resistivity of 18.3 megohm-cm was obtained directly from a milli-Q2 water purification system (Millipore Corporation).

Procedure

The experimental and instrumental conditions used are listed in Table 2. The tube wall temperature was measured by automatic pyrometers series 1100 and 300 (Ircon Inc., Skokie, Ill.) — the former for high temperatures and the latter for low temperatures. The pyrometer was focused through the injection hole on the inner surface of the graphite tube and the temperature of the sample area (a few mm^2) was monitored. It seems most appropriate to use the tube wall temperature as, in fact, if the atomization is determined by solid phase dissociation, the tube wall temperature is in any case the most relevant one. If the atomization is governed by gas phase dissociation this process will be predominant in the hottest zone, the zone at the middle part of the tube where the sample is deposited. Because of the large activation energies to be expected for the dissociation reaction, the number of atoms generated at the cold extreme ends of the graphite tube will be small.

In all cases 10 μL aliquots were deposited manually in the graphite furnace with an Eppendorf micropipet fitted with disposable plastic tips. The signals were stored on floppy discs using a digital oscilloscope, model 4094 (Nicolet Corporation), and recalled later for evaluation.

Results and discussion

Plots of ln (AT) vs. $1/T$ for the eight elements are shown in Fig. 1. Enthalpies of atomization have been calculated from the slopes of the linear segments using data points at the beginning of the absorbance, i.e., immediately after the appearance temperature. The latter is defined as the temperature at which the absorbance is 0.0044 A.U. Table 3 shows the enthalpy of atomization, ΔH^0, measured by this method. Also, shown in this table is a comparison with the activation energy, E_a, measured for this work by the method of Sturgeon *et al.* (4) and the Smets' method (11). Figure 2 shows a typical plot for copper compared with those of Sturgeon *et al.* (4) and Smets (11). To make the comparison possible all of the data points of the three methods are normalized.

The results shown in Fig. 2 and those presented in Table 3 indicate that there is no significant difference among the three methods. This means that, for the elements under investigation, the ΔH^0 and E_a values are about the same. Over the initial part of the leading edge of the absorbance, a

[a]Graphite furnace was operated in the gas-flow mode.

thermodynamic equilibrium may be established in a thin boundary or diffusion layer above the solid phase wherein multiple release-adsorption processes occur resulting in equilibrium prior to diffusion of the atomic vapour into the analysis volume. In such circumstances equilibrium exists and the Arrhenius plot yields the enthalpy for the overall reaction of atomization (12). Hence, one may conclude that at the very beginning of the absorbance, atom formation can be modelled by either kinetics or thermodynamics (24).

All of the plots of ln (AT) vs. $1/T$ of the elements under investigation show bending towards the abscissa as they approach the absorbance maximum. This bending was also reported by Sturgeon *et al.* (4, 5) and Smets (11). There are several explanations for this curvature (7, 12, 24–27). The explanation put forward by this work is the temperture dependence of the activation energy and the pre-exponential factor in the Arrhenius law which cause this deviation. In derivation of those plots it has been assumed that the pre-exponential factor and the activation energy do not vary with temperature. This assumption is not necessarily true. Ac-

cording to the Arrhenius plot, when the pre-exponential factor is temperature dependent, the activation energy is also temperature dependent (26). One may also state that the order of reaction (7) and the non-homogeneity of the atomic vapour inside the graphite furnace (28) may be another cause for this nonlinearity.

The experimental enthalpy of atomization, which is mainly related to breaking bonds in molecular species, can be correlated with the energy associated with the rate-determining step. With the determination of this term it is possible to propose a mechanism for atom formation. One should also consider the heat of formation of the metal carbides and the metal oxides since these are the most likely two chemical compounds that may form during atomization. The heat of formation is useful in explaining the thermal stability of the chemical compound at a given temperature. For example, a chemical compound with a high negative heat of formation is thermally more stable than that having a less negative heat of formation. Table 4 presents the heat of formation of metal oxides and metal carbides of the elements under investigation. The heat of formation in Table 4 equals the heat of atomization, as reported by L'vov (29). It can be seen from these data that all metal oxides are thermally more stable than the carbides. Some of the metal oxides and carbides, such as those of Au and Ag, are unstable at high temperatures. Thus, one may conclude that the oxides are likely to be the precursors to atom formation for this group of metals (taken as nitrates). The main contribution of this work is that the results presented have been obtained by using an equation derived from the basic principles of thermodynamics without invoking the order of the reaction. This is especially useful for atomization reactions that do not proceed by first-order kinetics. The experimentally observed enthalpies are in agreement with those obtained by applying the method of Sturgeon *et al.* (4) and Smets (11). Our results confirm the experimental observation by Sturgeon *et al.* (4) that atom formation involves no energy barrier other than the enthalpy of atomization, and the experimentally measured activation energy is equal to the enthalpy of atomization.

[a]Data were collected from refs. 39 and 42.

The purpose of studying the atomization mechanism is to understand the sequence of atomization reactions. Before postulating a mechanism of atomization one has to consider thermodynamic feasibilities of the proposed elementary reactions and their relative rates. In this context, the enthalpy of reaction is a useful concept and can be used to probe the reaction mechanism (31). An elementary reaction that requires higher energy (expressed as the enthalpy of the reaction) relative to other steps is likely to be slow and hence can be considered the rate-determining step. This approach is useful to generate data for studying the mechanism of atomization and has been reported in the literature (4, 31).

Proposed mechanism of atomization

Aluminum

Upon heating, the aqueous solution of aluminum nitrate is converted into Al_2O_3 (5, 30) before the graphite furnace attains the appearance temperature of 2070 K. The high heat of formation of Al_2O_3 compared to that of the simple carbide Al_4C_3 (Table 5) rules out the formation of any significant amount of the carbide.

The overall reaction for producing free aluminum from Al_2O_3 is

[14] $Al_2O_{3(s)} + 3C_{(s)} \rightarrow 2Al_{(s)} + 3CO_{(g)}$

The Gibb's free energy change for the above reaction (cal-

For personal use only.

culated at the appearance temperature, 2070 K) is −129 kJ mol^{-1} which indicates that the reaction is thermodynamically favourable. In the calculation it has been assumed that the partial pressure of the carbon monoxide equals 0.001 atm (21) and that ΔH^0 and ΔS^0 do not change appreciably with temperature. This is a reasonable assumption. The following atomization mechanism is proposed:

[15] $Al_2O_{3(s)} + C_{(s)} \rightarrow Al_2O_{2(g)} + CO_{(g)}$

[16] $Al_2O_{2(g)} \rightarrow 2Al_{(g)} + O_{2(g)}$

[17] $O_{2(g)} + 2C_{(s)} \rightarrow 2CO_{(g)}$

For reaction [15] to proceed only 38.0 kJ mol^{-1} of energy is required, whereas reaction [16] must acquire 1527.1 kJ mol^{-1}. The latter is likely to be slow and hence is considered the rate-determining step. Comparison of the experimentally determined enthalpy of atomization, 1390 ± 50 kJ mol^{-1}, with the heat of atomization of Al_2O_2, 1527 kJ mol^{-1} (32), suggests that gaseous aluminum atoms mainly come from the dissociation of Al_2O_2. The latter has been observed mass-spectrometrically in the graphite furnace by Styris.[2] Another possible mechanism for the formation of gaseous aluminum atoms is by autocatalytic reduction of aluminum oxide by gaseous carbides, such as Al_4C_3 that may form during atomization (33–37).

[18] $4Al_{(g)} + 3C_{(s)} \rightarrow Al_4C_{3(s)}$

[19] $2Al_4C_{3(s)} \rightarrow 3Al_2C_{2(g)} + 2Al_{(g)}$

[20] $2Al_2O_{3(s)} + 3Al_2C_{2(g)} \rightarrow 10Al_{(g)} + 6CO_{(g)}$

Gallium

Below the appearance temperature of gallium, 1500 K, Ga(III) nitrate or hydroxide in aqueous solutions are converted into Ga_2O_3 (ref. 32, p. 1093). The latter is reduced to metal by carbon at 1500 K. There are no carbides of gallium that are stable at room temperature (32), but formation of volatile carbides at low temperature is possible. The calculated ΔG_{1500} value, −260.2 kJ mol^{-1} (Table 5), suggests that the reduction of Ga_2O_3 by carbon at the appearance temperature is thermodynamically favourable. The overall reduction-reaction is therefore

[21] $Ga_2O_{3(s)} + 3C_{(s)} \rightarrow 2Ga_{(s)} + 3CO_{(g)}$

which, like the aluminum reaction, indicates that it is not an elementary reaction as such a reaction would require the collision of four molecules, the probability of which is very small. The following mechanism is, therefore, proposed:

[22] $Ga_2O_{3(s)} + C_{(s)} \rightarrow 2GaO_{(g)} + CO_{(g)}$

[23] $GaO_{(g)} + C_{(s)} \rightarrow 2Ga_2O_{(s)} + CO_{(g)}$

[24] $Ga_2O_{(s)} + C_{(s)} \rightarrow 2Ga_{(s)} + CO_{(g)}$

[25] $Ga_{(s)} \rightarrow Ga_{(g)}$

The observed value of the enthalpy of atomization, 261 ± 10 kJ mol^{-1}, correlates with the heat of vaporization of gallium, 277.0 kJ mol^{-1}, rather than with the enthalpy of reaction [22], 245.1 kJ mol^{-1}. The formation of the gaseous oxide (GaO) may explain the relatively low atomization efficiency of gallium (38).

TABLE 6. Some properties of the elements

Element	Appearance temperature, K	Melting point, K	Phase at appearance temperature
Al	2070	934	Liquid
Cu	1450	1357	Liquid
Co	1480	1768	Solid
Ga	1500	303	Liquid
Au	1450	1358	Liquid
Ni	1960	1728	Liquid
Fe	1500	1808	Solid
Ag	960	1235	Solid

Copper

Upon heating, an aqueous solution of copper nitrate is converted into copper oxide (CuO) before the furnace attains the appearance temperature of 1450 K (4, 5, 39). Upon further heating, copper oxide is reduced by carbon to free copper, which then sublimes to gaseous atoms. The calculated ΔG_{1450} value is −288.7 kJ mol^{-1} (Table 5). The experimental enthalpy of atomization (337 ± 10 kJ mol^{-1}) correlates with the heat of sublimation of copper (337.6 kJ mol^{-1}). Because the heat of desorption of copper from the graphite surface is approximately equal to the heat of sublimation of copper (24), the correlation between the experimentally observed enthalpy and the heat of sublimation is reasonable. The following atomization mechanism is therefore proposed:

[27] $CuO_{(s)} + C_{(s)} \rightarrow Cu_{(s)} + CO_{(g)}$

[28] $Cu_{(s)} \rightarrow Cu_{(g)}$

Reaction [27] requires only 46.8 kJ mol^{-1} of energy, whereas reaction [28] requires 337.6 kJ mol^{-1} of energy, the latter therefore is the rate-determining step. The fair agreement between the heat of sublimation of copper and the experimentally determined enthalpy of atomization support the above mechanism. Although Cu is in liquid form at the appearance temperature (Table 6), it seems that the atomization of Cu occurs by sublimation. This is explained by thermodynamic calculations. According to these calculations the small amount of copper may vaporize totally at a temperature below the melting point of copper without passing through the liquid phase.

Recently, Wang *et al.* (40) determined an activation energy of 130 ± 8 kJ mol^{-1} for copper under vacuum conditions using the higher temperature region of the Arrhenius plot and reported that the initial part of such a plot is unusable for studying the atomization mechanism. Their mechanism for copper atom formation is $Cu(NO_3)_2 \rightarrow CuO_{(ads)} \rightarrow Cu_{(ads)} \rightarrow Cu_{(g)}$, in which the desorption of copper atoms from the graphite surface at individual active site is the rate-determining step.

Cobalt

Upon heating, an aqueous solution of cobalt (as nitrate or chloride) is converted into CoO below the appearance temperature (4, 30). At higher temperature CoO is reduced by carbon to Co as follows:

$$CoO_{(s)} + C_{(s)} \rightarrow Co_{(s)} + CO_{(g)}$$

The above reaction is thermodynamically favourable with $\Delta G_{1480} = -172.0$ kJ mol^{-1}. The observed enthalpy of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

atomization (395 ± 17 kJ mol^{-1}) correlates with the heat of sublimation of the pure metal (428.4 kJ mol^{-1}). The formation of gaseous cobalt atoms is believed to be as follows:

[29] $CoO_{(s)} + C_{(s)} \rightarrow Co_{(s)} + CO_{(g)}$

[30] $Co_{(s)} \rightarrow Co_{(g)}$

The reduction of CoO by carbon requires 127.4 kJ mol^{-1} of energy, whereas the sublimation of cobalt requires 428.4 kJ mol^{-1}; hence, the latter is considered the rate-determining step. The fair agreement between the experimental enthalpy of atomization and the heat of sublimation of cobalt supports the above atomization mechanism. Based on thermochemical calculations, Ham and McAllister (19) have also reported similar atomization mechanism for Co. They used, for their calculations, small amounts of Co (as nitrate or chloride) normally taken for determination by the graphite furnace.

Nickel

Upon heating, an aqueous solution of nickel nitrate or chloride is thermally decomposed into NiO (4, 5) below the appearance temperature, 1960 K. On further heating, NiO is reduced by carbon to Ni, which then sublimes. The overall reduction-reaction is

$$NiO_{(s)} + C_{(s)} \rightarrow Ni_{(s)} + CO_{(g)}$$

The calculated ΔG_{1960} at the appearance temperature of nickel (1960 K) is −295.8 kJ mol^{-1}. The observed enthalpy of atomization (428 ± 15 kJ mol^{-1}) correlates with the heat of sublimation of Ni (428.4 kJ mol^{-1}). The following atomization mechanism is proposed:

[31] $NiO_{(s)} + C_{(s)} \rightarrow Ni_{(s)} + CO_{(g)}$

[32] $Ni_{(s)} \rightarrow Ni_{(g)}$

For reaction [31] to proceed 129.2 kJ mol^{-1} of energy is required, whereas sublimation of Ni requires 430.1 kJ mol^{-1}. The latter, therefore, is the rate-determining step. The good agreement between the experimentally determined enthalpy of atomization and the enthalpy of sublimation of pure nickel suggests that nickel atoms is formed by sublimation of the reduced metal. Although nickel is liquid at the appearance temperature (Table 6), the observed enthalpy of atomization correlates with the heat of sublimation and not with the heat of vaporization of the pure metal which is 375 kJ mol^{-1}. Probably, the reason for this is similar to that mentioned above for copper.

Iron

Upon heating an aqueous solution of ferric or ferrous nitrate to a temperature higher than 848 K at low oxygen partial pressure (ref. 32, vol. 3, p. 1008) it is converted into FeO, which is reduced by carbon to Fe at the appearance temperature of 1500 K as follows:

$$FeO_{(s)} + C_{(s)} \rightarrow Fe_{(s)} + CO_{(g)}$$

The calculated ΔG_{1500} for the above reaction is −130.1 kJ mol^{-1}. At 1500 K Fe sublimes. The observed enthalpy of atomization (409 ± 18 kJ mol^{-1}) correlates with the heat of sublimation of Fe (415.3 kJ mol^{-1}). The following atomization mechanism is therefore proposed:

[33] $FeO_{(s)} + C_{(s)} \rightarrow Fe_{(s)} + CO_{(g)}$

[34] $Fe_{(s)} \rightarrow Fe_{(g)}$

The enthalpies of reactions [33] and [34] are 161.4 and 415.5 kJ mol^{-1}, respectively. Because of the high energy required reaction [34] is likely to be slow and hence is the rate-determining step. The correlation of the measured enthalpy of atomization with the enthalpy of sublimation of Fe gives support for the above mechanism.

Silver

When an aqueous solution of a soluble Ag salt is heated, Ag_2O is formed at a temperature below 523 K. When the concentration of the oxygen is extremely small (as is the case in a graphite furnace), the Ellingham diagram (41) predicts that, even in the absence of carbon, Ag_2O decomposes into 2 Ag and (1/2) O_2 when heated above 473 K. At the appearance temperature of silver, 960 K, the absorbance is attributed to the sublimation of Ag. The observed enthalpy of atomization (260 ± 8 kJ mol^{-1}) correlates with the heat of sublimation of silver, 283.0 kJ mol^{-1} (39, 42).

Gold

Aqueous solutions of gold chloride, upon heating, produce Au_2O_3 well below 1450 K (the appearance temperature). Upon further heating, Au_2O_3 decomposes to 2Au and (3/2) O_2. Since Au is in liquid state (Table 6) at the appearance temperature, the correlation of the heat of formation with the heat of vaporization of Au is possible. The observed enthalpy of atomization (371 ± 17 kJ mol^{-1}), however, correlates well with the heat of sublimation (368.2 kJ mol^{-1}) and not with the heat of vaporization (343 kJ mol^{-1}), probably for reasons similar to those mentioned above for nickel and copper.

M. Angustias Romero, M. Purificación Sánchez, Miguel Quirós, Francisco Sánchez, Juan Manuel Salas, Miguel N. Moreno, and René Faure. Can. J. Chem. **71**, 29 (1993).

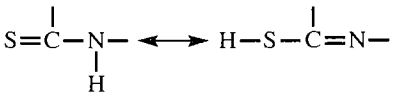
Complexes of 6-amino-2-thiouracil (H_2ATU) with the metal ions Ni(II), Co(II), Zn(II), Cd(II), Cu(I), Ag(I), and Hg(II) have been isolated and characterized by means of elemental analysis, infrared, NMR, and visible spectroscopies, and magnetic measurements. The crystal structure of $[Zn(HATU)_2(H_2O)] \cdot 2H_2O$ has been solved by X-ray diffraction showing that the metal atom is five-coordinated by a water molecule and two ligands that bind through the sulphur and N1 atoms, closing a four-member chelate ring. Diffuse reflectance spectra and magnetic measurements suggest that $[Co(HATU)_2(H_2O)] \cdot 2H_2O$ has a similar structure to that of the zinc complex, and that the nickel complexes $[Ni(HATU)_2]$ and $[Ni(HATU)_2(H_2O)_2]$ have, respectively, a tetrahedral and a D_{4h}-distorted octahedral environment.

M. Angustias Romero, M. Purificación Sánchez, Miguel Quirós, Francisco Sánchez, Juan Manuel Salas, Miguel N. Moreno et René Faure. Can. J. Chem. **71**, 29 (1993).

Les complexes de 6-amino-2-thiouracil (H_2ATU) avec les ions métalliques Ni(II), Co(II), Zn(II), Cd(II), Cu(I), Ag(I) et Hg(II) ont été isolés et caractérisés par analyse élémentaire, spectroscopies infrarouge, RMN et visible et par mesures magnétiques. La structure cristalline de $[Zn(HATU)_2(H_2O)] \cdot 2H_2O$ a été résolue par diffraction des rayons X. Le métal Zn est pentacoordinné par une molécule d'eau et deux ligands dont la liaison de chacun se fait à travers l'atome du soufre et N1, formant ainsi un chelate de quatre membres. Le spectre de réflectance diffuse et les mesures magnétiques montrent que $[Co(HATU)_2(H_2O)] \cdot 2H_2O$ a une structure similaire à celle du complexe de zinc; les deux complexes $[Ni(HATU)_2]$ et $[Ni(HATU)_2(H_2O)_2]$ ont, respectivement, un environnement tétraédrique et octaédrique distordu D_{4h}.

Introduction

This article continues our work on the interaction of metal ions with thiopyrimidine derivatives containing the NH—C=S group, and which display the tautomerism:



6-Amino-2-thiouracil (H_2ATU) exhibits antiviral and chemotherapeutic activity (1). The X-ray study of this compound showed that the thione form is the one present in solid state (2).

We previously reported the synthesis and characterization of several complexes of 4,6-diamino-2-thiopyrimidine (3), 4-amino-5-nitroso-6-oxo-2-thiopyrimidine (4), and 2-thioisoorotic acid (5) and, following this line, we describe in this paper the synthesis and characterization of eight new compounds formed by the interaction of H_2ATU with Co(II), Ni(II), Zn(II), Cd(II), Hg(II), Cu(I), and Ag(I). The crystal structure of $[Zn(HATU)_2(H_2O)] \cdot 2H_2O$ has been solved by single crystal X-ray diffraction.

Experimental

Preparations

6-Amino-2-thiouracil (H_2ATU) and 6-amino-2-methylthiouracil (HMATU) were prepared using previously described methods (6). The metal complexes $[Ni(HATU)_2]$ (**1**), $[Co(HATU)_2(H_2O)] \cdot 2H_2O$ (**2**), $[Zn(HATU)_2(H_2O)] \cdot 2H_2O$ (**3**), $[Cd(HATU)_2(H_2O)] \cdot H_2O$ (**4**), $Cu(HATU) \cdot H_2O$ (**5**), $Ag(HATU) \cdot 1/2H_2O$ (**6**), and $Hg(HATU)_2$ (**7**) were synthesized by adding 2 mmol of the metal salt (nickel, cobalt, zinc, and cadmium acetate, silver nitrate, copper perchlorate, and mercury chloride) dissolved in the minimum amount of water to an aqueous solution (50 mL) of 2 mmol of H_2ATU (4 mmol for the copper compound since part of the ligand is used in reducing the Cu(II) to Cu(I)). The mixtures were heated at 70–80°C for 1 h with continuous stirring and then allowed to cool to room temperature until the solid compounds appeared, when they were filtered off, washed with water and ethanol, and dried with diethyl ether. A second nickel complex, $[Ni(HATU)_2(H_2O)_2]$ (**8**), was obtained by evaporation of the filtrate of **1**. Elemental analyses of the isolated complexes are shown in Table 1.

Methods

Infrared spectra were recorded as KBr pellets in a Perkin–Elmer 983-G spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker AM300 300 MHz spectrometer, using DMSO-d_6 as solvent and TMS as internal standard. Magnetic susceptibilities were measured at room temperature using a Faraday Bruker Magnet B-E15 electrobalance with $HgCo(NCS)_4$ as standard. Diffuse reflectance spectra were recorded in a Schimadzu MPC-3100 spectrophotometer.

X-ray work

A prismatic crystal of **3** was mounted at room temperature on a Nonius CAD-4 diffractometer with graphite-monochromatized MoKα radiation (λ = 0.71069 Å). Twenty-five randomly oriented reflections were used to obtain the lattice parameters and the orientation matrix. The observed extinctions were consistent with the space groups $C2/c$ and Cc, the structure satisfactorily solved in the former. Data were measured in the 2–70° 2θ range with a $\omega:\theta/3$ scan and corrected for Lorentz and polarization factors but not for absorption.

[a]Calculated values are in parentheses.

The metal atom was located from a Patterson synthesis and the remaining non-hydrogen atoms from subsequent Fourier syntheses. The structure was refined by full-matrix least squares. The non-coordinated water molecule (O2W) appears in the ΔF map as a very broad peak, indicating intense thermal motion, and it could only be refined isotropically, attempts for disordering it into two positions not yielding satisfactory results. The possibility of a wrong assignment for N6 and O4 due to the pseudo symmetry plane that the ligand has through S, C2, and C5 is clearly ruled out by the location of the amino hydrogens as well as by the values of the C6—N6 and C4—O4 distances. All hydrogen atoms of the organic ligand were located in ΔF maps and refined with fixed B (4.0 Å^2) and no geometric constraints.

Final residues are indicated in Table 2, together with other crystal data. Non-hydrogen coordinates are listed in Table 3. Hydrogen coordinates, thermal parameters, and structure factor tables are included in the supplementary material.[3] Calculations were made by means of the Enraf–Nonius SDP System.

Results and discussion

Spectroscopic studies

H_2ATU is in the thione form in the solid state (2) and, accordingly, its spectrum displays the characteristic thioamide bands (7) at 1546 (thioamide **1**) and 1185 cm^{-1} (thioamide **3**). In the complexes with the ligand in monoanionic form (**1**–**8**), the latter is not observed, and appearing in its place are two intense new bands at 1245 ± 10 and 995 ± 10 cm^{-1}. These spectra exhibit a remarkable similarity to that of 6-amino-2-methylthiouracil (HAMTU) over the whole region below 1500 cm^{-1}. Similar features have been observed in the spectra of complexes of 4,6-diamino-2-thiopyrimidine (3*a*), where the ligand is S,N bidentately coordinated.

Several vibration modes, including mainly ν(C=O), δ(NH_2), and δ(H_2O), converge in a single broad peak with several shoulders centred at 1625 cm^{-1} in the spectra of **2**–**6** and **8**, while two separate peaks at 1605 and 1645 cm^{-1} are visible for **1** and **7**. All spectra exhibit only minor changes

Table S-1 has also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 IEZ, U.K.

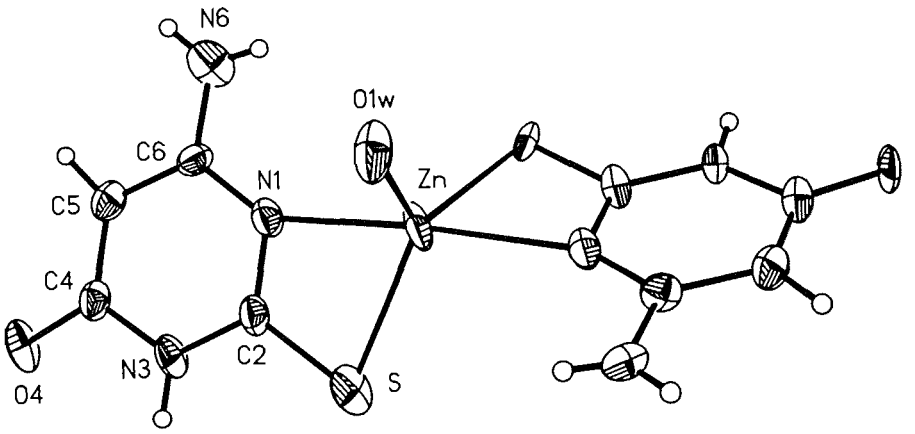

FIG. 1. View of the molecule of $[Zn(HATU)_2(H_2O)]$. 50% probability thermal ellipsoids are shown.

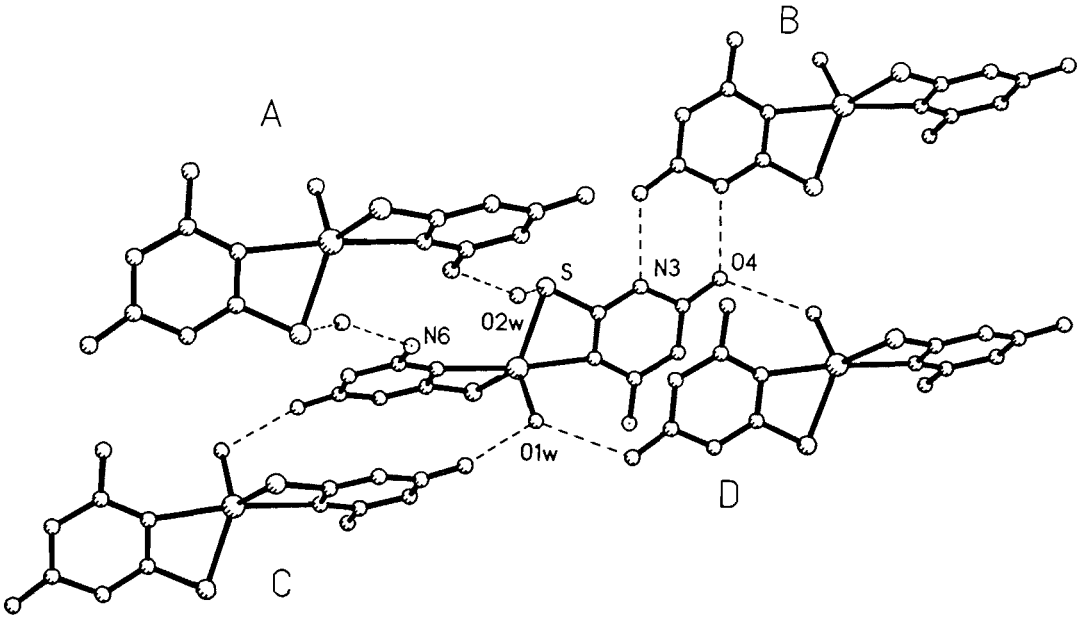

FIG. 2. Hydrogen bonds formed between a molecule of $[Zn(HATU)_2(H_2O)]$ and some of its neighbours. Considering the central molecule as placed at x, y, z, the symmetry codes for the rest are as follows: Molecule A: $1/2 - x, 1/2 - y, -z$. Molecule B: $1 - x, -y, 1 - z$. Molecule C: $-1/2 - x, 1/2 - y, -z$. Molecule D: $1/2 - x, 1/2 - y, 1 - z$.

when the samples are heated at 250°C (anhydrous complexes); the compound **8**, in particular, when heated at this temperature, displays a spectrum appreciably different from that of compound **1**.

The signals of the ^1H and ^{13}C spectra of H_2ATU and its zinc, cadmium, and mercury complexes are listed in Table 4. The spectrum of 6-amino-2-methylthiouracil (HAMTU) has also been included for comparison. Assignments were made comparing the spectra with those of 6-methyl-2-thiouracil (8), 4,6-diamino-2-thiopyrimidine (3*b*), 2-thiouracil (9), and pyrimidine-2-thione (10).

The spectra of zinc and cadmium complexes are virtually identical, the only significant difference with respect to the free ligand being the downfield shift by more than 6 ppm of the C6 resonance. This may be due to N1 deprotonation and coordination, the binding through the amino group being ruled out by the unchanged NH_2 signal in the proton spectra; the sulphur atom seems not to bind in solution as deduced from the unchanged C2 resonance.

Contrarily, the ^{13}C spectrum of the mercury complex exhibits an upfield shift of C2 by more than 10 ppm and a downfield shift of C6 by 8 ppm, this spectrum being almost identical to that of HAMTU. We can explain this fact by supposing that a strong binding of the mercury to the sulphur atom takes place in solution, generating an electronic distribution similar to that of the methyl derivative, with the mercury playing a role similar to that of the methyl group.

The solid state diffuse reflectance spectrum of 8 is typical for Ni(II) in a tetragonally distorted octahedral environment (D_{4h} symmetry) (11), with bands at 7860, 9760, 12 440, 14 700, and 25 150 cm^{-1}, assignable to the transitions from the ground state $^3B_{1g}$ to, respectively, ^3E_g (T_2), $^3B_{2g}$, $^3A_{2g}$, ^3E_g (T_1), $^3A_{2g}$, and ^3E_g (P) (the two latter are overlapped), the transitions to the ^3E_g levels being more intense, as expected.

The other nickel(II) complex (**1**) displays a spectrum assignable to a tetrahedral environment, with bands at 15 850 ($^3T_1 \rightarrow {}^3T_1$ (P), band with a shoulder) and 7600 cm^{-1} ($^3T_1 \rightarrow$

$^3A_2$), the transition $^3T_1 \rightarrow {}^3T_2$ not being observed. The forbidden transitions to levels ^1D are observable as weak bands at 10 150 and 10 810 cm^{-1}. The room temperature magnetic moments of the two nickel complexes are 3.20 and 3.44 Bohr magneton (B.M.) respectively, with a higher orbital contribution for the tetrahedral geometry.

On the other hand, the diffuse reflectance spectra of the cobalt complex (**2**, room temperature magnetic moment 4.42 B.M.), with bands at 22 200 (shoulder), 17 750, 12 800, and 5400 cm^{-1}, does not fit for either an octahedral or for a tetrahedral environment (11), but is very similar to the spectrum of $[CoL_2Br]Br$ (L = acetone-4-phenylthiosemicarbazone) (12), in which the geometry around the metal ion is a distorted trigonal bipyramid. The presence of relatively intense bands between 11 500 and 13 000 cm^{-1} is usually taken as diagnostic for five-coordinated Co(II) (13), although it is not easy to distinguish between the trigonal bipyramidal and the square pyramidal environments.

Description of the crystal structure of
$[Zn(HATU)_2(H_2O)] \cdot 2H_2O$

The X-ray diffraction study of **3** shows that the metal atom is placed in a crystallographic twofold axis that relates two 2-thiopyrimidinato ligands that bind the zinc atom through their sulphur and nitrogen-1 atoms. The twofold axis also passes through a coordinated water molecule, which completes a coordination number of five for this complex (Fig. 1).

The geometry is somewhat irregular, but may be described as a trigonal bipyramid in which the N1 atoms of the two ligands occupy the axial apices with the sulphur atoms deviating 0.76 Å from the equatorial plane due to the formation of the four-member chelate ring (the "equatorial plane" is defined as the mediatrix plane of the N1–N1 segment). This also distorts the bond angles around the metal atom.

The distance Zn—O1W (Table 5) is similar to those in other compounds with water (14) coordinated to Zn, whereas the distances Zn—S and Zn—N1 are comparable to those in compounds with five-membered S,N coordinated chelate rings around zinc (15); we have not found any bibliographic reference including a Zn—N—C—S four-member chelate. The chelate ring deviates appreciably from planarity, with C2 placed 0.08 Å out of the plane defined by Zn, S, and N1.

The distances C2—S and C2—N1 are, respectively, significantly longer and shorter than those in the free ligand (*2b*), as could be expected for the deprotonation of N1. Changes in the angles around C2 and N1 (−4.7° for S—C2—N1, +6.5° for N3—C2—N1, −5.3° for C2—N1—C6) are due to the same reason plus the chelation effect. The changes in the remaining distances are below 3σ whereas the changes in the remaining angles are below 2.5°. The pyrimidine moiety is virtually planar with endocyclic atoms deviating less than 0.01 Å from the average plane, with only O4 placed 0.04 Å out of it. The dihedral angle between this plane and the one defined by Zn, S, and N1 is 5.4° and the dihedral angle between the two pyrimidine planes coordinated to the metal atom is 50.5°.

The hydrogen bonding network is represented in Fig. 2, the corresponding distances appearing in Table 5. The O2W · · · S contact has been considered as a weak hydrogen bond because the distance involved is just below the sum of

the van der Waals radii (16). The loose attachment of O2W to the structure may explain the high thermal motion of this atom.

Reçu le 19 juin 1992

CLAUDINE BLANDY, JEAN-LOUIS PELLEGATTA, ROBERT CHOUKROUN, BERNARD GILOT et ROLAND GUIRAUD. Can. J. Chem. **71**, 34 (1993).

L'estérification de l'acide stéarique a été étudiée en utilisant comme catalyseurs des titanates greffés sur alumine ou silice. La réaction de greffage, obtenue par action de $CH_3Ti(OR)_3$ sur les sites acides du support, a été étudiée avec différents temps de contact et différentes concentrations. L'utilisation du titanate supporté conduit à une efficacité plus grande que celle du titanate employé en milieu homogène. L'activité du catalyseur est fortement augmentée en présence d'un solide broyé. Le catalyseur a pu être réutilisé plusieurs fois. La stabilité de la liaison (M)–$Ti(OR)_3$ (avec M = Al_2O_3 ou SiO_2) a été mise en évidence par des mesures cinétiques et par des réactions d'échanges des groupements alkoxy fixés sur le titane avec un alcool lourd.

CLAUDINE BLANDY, JEAN-LOUIS PELLEGATTA, ROBERT CHOUKROUN, BERNARD GILOT, and ROLAND GUIRAUD. Can. J. Chem. **71**, 34 (1993).

The esterification of stearic acid using titanates fixed on alumina or silica as catalysts has been studied. The anchoring of titanium, obtained by action of $CH_3Ti(OR)_3$ with the acid sites of the support, has been studied using different contact times and different concentrations. The heterogeneized catalyst leads to a better efficacity than the homogeneous system. The activity of the catalyst is strongly increased by using crushed solid instead of balls. The catalyst has been recovered and recycled. The stability of the (M)–$Ti(OR)_3$ bond (with M = Al_2O_3 or SiO_2) has been shown by kinetic measures and exchange reactions of the alcoxy groups fixed on titanium with heavy alcohol.

Introduction

Nous avons étudié l'estérification de l'acide stéarique par l'isopropanol pour laquelle l'utilisation de catalyseurs acides n'est pas assez sélective car elle conduit à haute température à la deshydratation de l'isopropanol et à un ralentissement de la réaction dû à la présence d'eau (1).

L'utilisation des titanates en milieu homogène, largement développée en estérification et transestérification (2), permet, tout en diminuant le temps de réaction, d'obtenir des esters de masse molaire élevée et d'indice d'acide faible. Mais il faut, pour obtenir l'ester pur, les éliminer en fin de réaction par une hydrolyse à la vapeur d'eau suivie d'une filtration.

Nous avons donc cherché à greffer le catalyseur sur un support solide pour éviter ces opérations de finition et permettre une production continue par passage sur le solide catalytique. Les essais préliminaires ont montré que les performances du système homogène étaient maintenues en hétérogène (3). Nous avons donc étudié les conditions d'obtention, la récupération et la réutilisation du titanate greffé.

Resultats et discussion

Greffage sur un solide

La fixation d'un composé du titane sur un support peut se réaliser en faisant réagir une liaison Ti—Cl avec des groupements hydroxyle de la surface du solide (4). Nous avons préféré utiliser la réaction de $CH_3Ti(Oi\text{-}Pr)_3$ avec les sites de Brönsted, même très faibles, d'une alumine ou d'une silice. On peut écrire la réaction de greffage :

$$[1] \quad CH_3Ti(Oi\text{-}Pr)_3 + HO\text{-}[M] \rightarrow CH_4 + [M]OTi(Oi\text{-}Pr)_3$$

avec M = Al, Si.

On peut suivre facilement la réaction [1] par mesure du volume de méthane dégagé et par dosage du titane dans le solide. Les quantités fixées sont fonction de l'état du solide, de la durée du contact et de la concentration de la solution de $CH_3Ti(Oi\text{-}Pr)_3$.

Comme on pouvait s'y attendre, la réaction de fixation est beaucoup plus rapide sur des solides en poudre qu'avec les billes poreuses. Nous avons testé l'influence du temps de contact du titanate avec le support : pour une concentration de 0,07 M de $CH_3Ti(Oi\text{-}Pr)_3$, on obtient 8,6 et 10,1 mg/g de titane fixé sur le support pour des temps respectifs de 12 et 72 h. Pour un temps de contact donné, la quantité de titane greffé augmente avec la concentration de la solution de $CH_3Ti(Oi\text{-}Pr)_3$. La figure 1 montre l'influence de la concentration pour un temps de contact de 12 h. On constate donc que, si les billes sont plus faciles à manipuler, leur greffage est limité par diffusion du réactif à l'intérieur des pores, phénomène déja observé lors de la fixation de $TiCl_4$ sur de la silice (4). Nous verrons que les mêmes limitations vis à vis de la réaction d'estérification diminueront l'activité apparente du catalyseur.

Le spectre d'émission des rayons X (RX) montre une répartition homogène des atomes de titane dans le solide (1,1 atome de titane/nm^2).

Nous avons également cherché à réaliser un greffage de $(N_3)_2Ti(Oi\text{-}Pr)_2$ sur de la silice pour essayer de fixer le ti-

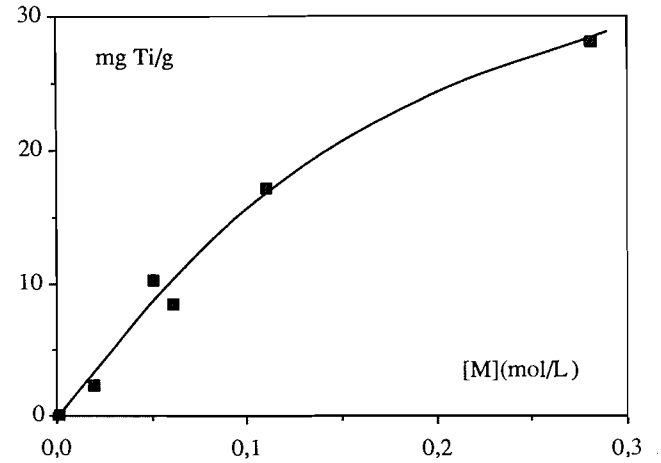

FIG. 1. Greffage sur le support : influence de la concentration en $CH_3Ti(Oi\text{-}Pr)_3$, temps de contact : 12 h, température : 25°C.

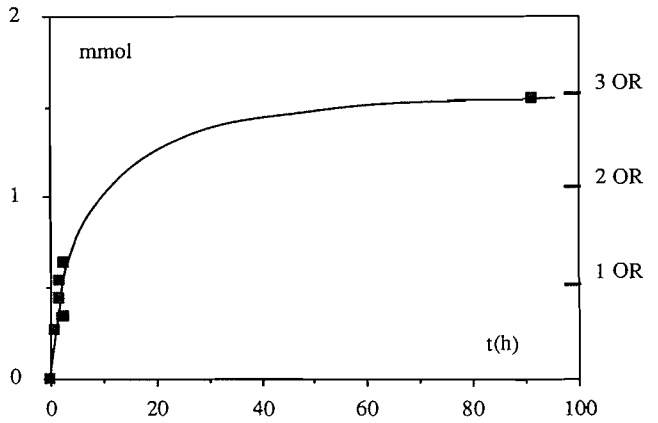

FIG. 2. Réaction du support greffé avec le 1-dodécanol à 50°C : production du 2-propanol (mmol) en fonction du temps (h) (à droite sont indiqués les nombres de groupements alcoxy échangés).

tane sur deux sites acides voisins avec libération de N_3H comme cela a déjà été observé en phase homogène en présence d'alcools (5). Nous avons obtenu la formation d'une seule liaison Si—O—Ti par titane, comme cela a déja été décrit lors du greffage sur silice de Cp_2TiCl_2 et $TiCl_4$ (6).

Caractérisation et irréversibilité du greffage

Pour faire le bilan de la réaction de greffage et vérifier la stabilité des liaisons Si—O—Ti, nous utilisons l'échange des groupements alkoxy par réaction du composé greffé avec un alcool lourd selon la réaction :

$$[Si]\ OTi(Oi\text{-}Pr)_3 + 3C_{12}H_{25}OH \rightarrow 3i\text{-}PrOH + [Si]\ OTi(OC_{12}H_{25})_3$$

La libération de l'isopropanol attendue a été suivie au cours du temps par chromatographie en phase gazeuse. La figure 2 montre que l'échange est relativement lent à 50°C et correspond à la stoechiométrie attendue. Le titane reste donc bien fixé sur le support, les liaisons Si—O—Ti n'étant pas rompues.

Une opération analogue avec le solide greffé par $(N_3)_2Ti(Oi\text{-}Pr)_2$ nous a montré l'existence d'une seule liaison support–titane et donc l'intérêt de cette méthode d'échange pour connaître la nature des solides mis en jeu.

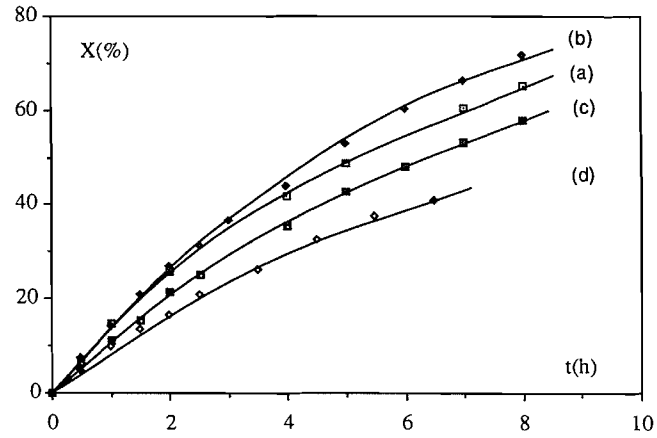

FIG. 3. Catalyse par le titanate greffé : avancement de l'estérification à 180°C en fonction du temps (h) pour (*a*) Al_2O_3, (*b*) Al_2O_3 greffée, (*c*) Al_2O_3 greffée partiellement hydrolysée, (*d*) réaction non catalysée. Indice d'acide de départ $n = 200$.

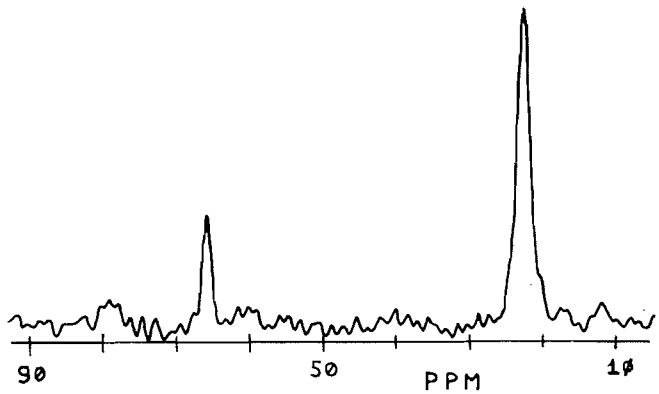
Le catalyseur hétérogène a également été caractérisé par son spectre de RMN du ^{13}C à l'état solide (voir spectre 1) qui se présente sous la forme de deux singulets (δ = 65,8 et



22,3 ppm) attribuables respectivement aux C_α (méthine) et C_β du groupe isopropyle par comparaison avec les déplacements obtenus pour $CH_3Ti(Oi\text{-}Pr)_3$ à l'état pur (δ = 76,3 (C_α) et 25,1 ppm (C_β)) (7).

Utilisation du solide greffé

Comme pour les estérifications de l'acide stéarique en milieu homogène, nous avons utilisé un réacteur semi-continu (8). La réaction étudiée :

$$CH_3(CH_2)_{16}COOH + C_3H_7OH \rightarrow CH_3(CH_2)_{16}COOC_3H_7 + H_2O$$

se produit lentement en absence de catalyseur mais elle est aussi très légèrement accélérée par le support seul qui présente des sites acides.

La figure 3 compare des courbes donnant les taux de conversion en fonction du temps pour différentes conditions de réaction : avec l'alumine greffée la vitesse de réaction est augmentée (courbe (*b*)), les courbes (*a*) et (*d*) correspondent à l'alumine seule et à la réaction non catalysée; on peut paraître surpris de ne pas voir un grand écart entre les courbes (*a*) et (*b*) mais il faut rappeler qu'en début de réaction, lorsque la concentration en acide est grande, la contribution de la réaction non catalysée est importante (3) et masque l'effet du titane. On verra plus loin (figure 7) que ce n'est plus

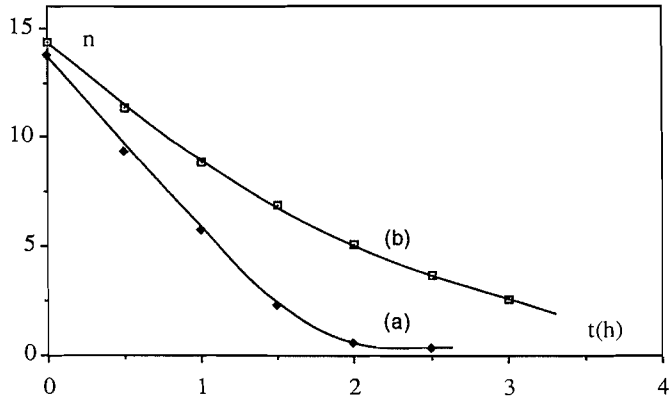

FIG. 4. Comparaison de la catalyse homogène et hétérogène : tracé de l'indice d'acide (n) en fonction du temps (h) à 180°C; (a) catalyseur hétérogène contenant 11 mg Ti/g; (b) catalyseur homogène, soit 8 mmol L^{-1} de Ti(O*i*-Pr)$_4$.

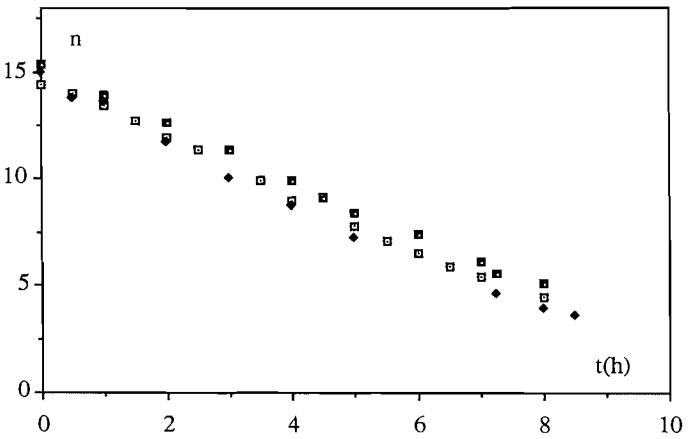

FIG. 5. Réutilisation du titanate supporté : tracé de l'indice d'acide (n) en fonction du temps (h) à 180°C pour 34 g L^{-1} de silice contenant 2,4 mg Ti/g.

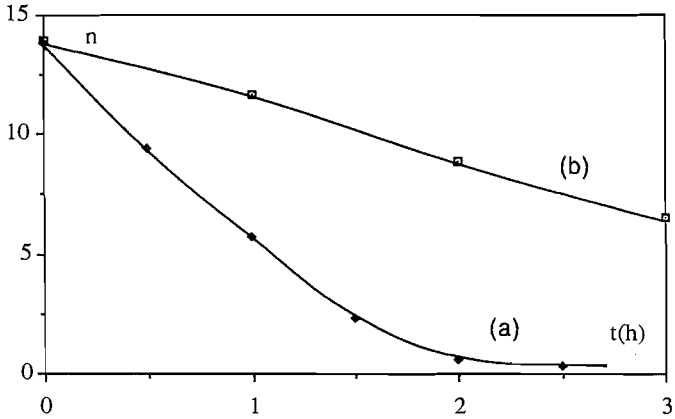

FIG. 6. Limitation diffusionnelle : tracé de l'indice d'acide (n) en fonction du temps (h) à 180°C pour 44 g L^{-1} de catalyseur hétérogène contenant 17 mg Ti/g (a) en poudre, (b) en billes.

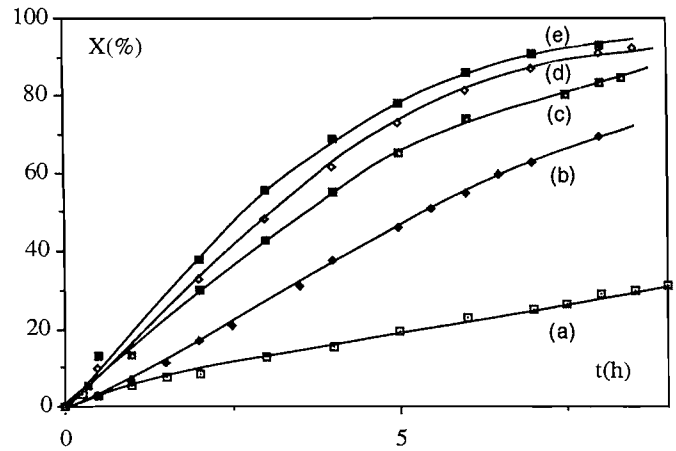

FIG. 7. Influence de la teneur en titane du solide : avancement relatif de la réaction (%) en fonction du temps (h) à 180°C pour 34 g L^{-1} de silice contenant (a) 0, (b) 2,4, (c) 7,6, (d) 17,1 et (e) 28,1 mg Ti/g. Indice d'acide de départ n = 15.

le cas lorsque l'indice d'acide est beaucoup plus faible. La courbe (c) correspond à l'utilisation d'un catalyseur greffé partiellement hydrolysé (réemployé sans précaution). On voit que cette hydrolyse n'a pas libéré les sites acides du support : la liaison Ti—O*i*—Pr semble donc plus sensible à l'hydrolyse que les liaisons Al—O—Ti.

Nous avons ensuite pour une même concentration apparente en titane comparé l'activité du catalyseur hétérogène avec celle de Ti(O*i*-Pr)$_4$ utilisé en milieu homogène. La figure 4 montre que, dans ces conditions (à 180°C), le titane greffé est plus efficace que le titane employé en milieu homogène. Les constantes de vitesse apparentes sont assez différentes : $1,7 \times 10^{-4}$ s^{-1} pour le milieu homogène, $5,2 \times 10^{-4}$ s^{-1} pour l'hétérogène. Ce résultat est facile à interpréter si on considère qu'un composé dimère ne peut se former à la surface du solide et donc que tout le titane fixé est actif.

Stabilité et réutilisation du catalyseur supporté

L'activité catalytique se maintient au cours de la réaction puisque le même modèle cinétique peut représenter l'ensemble des points expérimentaux relatifs à une expérience. On peut, moyennant quelques précautions en fin de réaction (élimination de l'alcool sous vide), réutiliser efficacement le catalyseur. La figure 5 montre trois cycles de réutilisation successifs de 10 h. Les dosages de titane permettent d'affirmer que celui-ci reste solidement accroché au support : on en retrouve 97% après 8 h d'utilisation continue et 90% après les trois cycles, soit après 30 h d'utilisation.

Si le catalyseur ne se transforme pas au cours de la réaction, il est par contre très probable qu'à 180°C les groupements alkoxy fixés sur le titane s'échangent dès le début de la réaction avec un ou plusieurs groupements acyle. Les échanges entre acide stéarique et titanate sont déja connus en milieu homogène (9).

Nous développons une étude analogue par action de divers acides sur le catalyseur supporté.

Limitations diffusionnelles

Nous avons ensuite comparé les activités des billes et d'une poudre obtenue à partir des billes broyées. La figure 6 montre que le broyage cause une très grande augmentation d'activité : pour obtenir 50% d'avancement, il faut 3 h avec les billes et seulement 50 min pour la même quantité de catalyseur broyé. De même, si on greffe sur des billes des teneurs en titane croissantes (concentration en $CH_3Ti(O$*i*$-Pr)_3$ plus importante) on n'obtient pas un accroissement correspondant d'activité (figure 7). En effet, en présence d'une

Silice	$Na_2O < 3000$ pm	277 $m^2 g^{-1}$	
Rhône-Poulenc	$CaO < 1500$ ppm	Billes 5–6 mm	$3,3 < H_0 < 4,8$
SPH 540	$SO_4^- < 400$ ppm	Poudre 90% < 200 μm	

[a] H_0 = fonction d'acidité de Hammet (10).

faible quantité de titane, les sites les plus accessibles sont greffés les premiers et, en augmentant la quantité de titane, on greffe les sites moins accessibles peu utiles à la catalyse.

Conclusion

Le greffage du titane sur un support solide semble une solution intéressante pour la catalyse. Il est préférable d'utiliser un solide en poudre (même grossière). L'absence probable de dimère conduit à-des activités importantes à basse température. Le solide greffé est très stable : on peut envisager des applications pour l'obtention d'esters ou de polyesters exempts de titane sans opération de finissage compliquée.

Nous pensons étudier maintenant l'emploi de ces solides pour des réactions de transestérification à basse température.

Partie expérimentale

Techniques analytiques

Les acidités des supports ont été estimées par la méthode de titrage par une amine en présence de rouge neutre et de *p*-dimethylaminoazobenzène comme indicateurs (10). Les supports sont chauffés sous vide à 160°C pendant 24 h avant utilisation; leurs caractéristiques sont données dans le tableau 1. Les catalyseurs supportés sont obtenus sous atmosphère inerte en utilisant comme solvant du toluène distillé sur sodium et dégazé avant usage. Les composés $CH_3Ti(Oi\text{-}Pr)_3$ et $(N_3)_2Ti(Oi\text{-}Pr)_2$ ont été synthétisés en utilisant les méthodes décrites respectivement selon les références 11 et 5.

Les avancements de réaction sont déterminés par le suivi de l'indice d'acide (*n*) du mélange réactionnel selon la norme AFNOR, T 60-112, 1959. Les dosages de titane ont été déterminés par colorimétrie à 410 nm sur des complexes dans des solutions sulfuriques d'eau oxygénée obtenus par un traitement à reflux de 12 h dans l'acide. Les chromatographies en phase gazeuse ont été effectuées sur Intersmat IGC 121ML équipé d'une colonne de 2 m remplie de 10% Carbowax 20 M sur support Chromosorb PAW 80/100. Les spectres d'émission de RX ont été enregistrés sur Camebax SX50. Le spectre RMN du ^{13}C a été enregistré sur Bruker MSL 300 à 75,47 MHz équipé d'une tête de mesure de type «double bearing», en polarisation croisée (temps de contact 5 ms) et en utilisant le TMS comme référence externe.

Préparation du catalyseur greffé

On ajoute à température ambiante une solution de $CH_3Ti(Oi\text{-}Pr)_3$ (0,11 g; 0,87 mmol) dans le toluène (15 mL) sur une suspension de Al_2O_3 (2 g) dans le toluène (10 mL). On mesure le volume de méthane dégagé à l'aide d'une «Topler pump» (0,9 CH_4/Ti). Le solide est ensuite lavé à l'isopropanol et séché sous vide à 160°C pendant 24 h. La valeur obtenue pour le dosage de titane (13 mg Ti/g) correspond au nombre de sites acides atteints lors du greffage.

Réaction d'estérification

Elle est effectuée dans un réacteur semi-continu sous pression atmosphérique avec une alimentation automatique d'alcool de façon à maintenir sa concentration constante dans le milieu réactionnel (débit de l'ordre de 100 mL/h). L'acide stéarique (200 g; 0,7 mol) est chauffé à 180°C dans le réacteur en présence du catalyseur avec un rapport molaire [catalyseur]/[acide] variant de 0,07 à 0,7%. La distillation en continu de l'isopropanol permet d'éliminer l'eau formée et conduit à une estérification totale.

Réutilisation du catalyseur

Il est nécessaire d'éliminer complètement l'alcool du réacteur par barbotage de gaz inerte avant de séparer le solide catalytique de l'ester car il faut empêcher toute libération d'eau avant séparation.

Remerciements

Nous remercions Mr Autefage (INSA, Toulouse, France) pour les enregistrements d'émission de RX et M. Lefebvre (IRC, Villeurbanne, France) pour la RMN du ^{13}C. La société Rhône-Poulenc nous a fourni la silice. Ce travail a été soutenu financièrement par la région Midi Pyrénées (France).

Vinyl ether hydrolysis XXVIII. The mechanism of reaction of methyl α-(2,6-dimethoxyphenyl)vinyl ether[1]

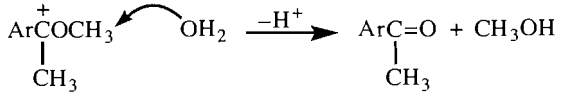
J. JONES[2] AND A. J. KRESGE[3]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 8, 1992

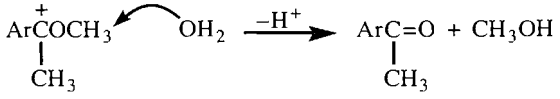
J. JONES and A. J. KRESGE. Can. J. Chem. **71**, 38 (1993).

The acid-catalyzed hydrolysis of methyl α-(2,6-dimethoxyphenyl)vinyl ether in aqueous solution at 25°C occurs with the hydronium ion catalytic coefficient $k_{H^+} = 2.86\ M^{-1}\ s^{-1}$ and gives the solvent isotope effect $k_{H^+}/k_{D^+} = 3.68$; this indicates that reaction occurs by rate-determining proton transfer from the catalyst to the substrate to generate an alkoxycarbocation intermediate. An oxygen-18 tracer study shows further that, despite the steric hindrance provided by its two *ortho* substituents, this cation then reacts by addition of water to the cationic carbon atom to generate a hemiacetal, and not by nucleophilic attack of water on the methyl group remote from the carbocationic center:



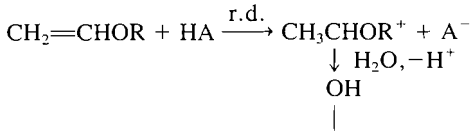
J. JONES et A. J. KRESGE. Can. J. Chem. **71**, 38 (1993).

L'hydrolyse acidocatalysée de l'oxyde de méthyle et de l'α-(2,6-diméthoxyphényl)vinyle, en solution aqueuse, à 25°C, se produit avec un coefficient catalytique de l'ion hydronium, $k_{H^+} = 2{,}86\ M^{-1}\ s^{-1}$, et un effet isotopique du solvant $k_{H^+}/k_{D^+} = 3{,}68$; ces résultats indiquent que l'étape déterminante de la réaction implique un transfert de proton du catalyseur vers le substrat avec la formation d'un intermédiaire alkoxycarbocation. Une étude à l'aide d'un marqueur contenant de l'oxygène-18 montre de plus que ce cation réagit alors par addition d'eau sur l'atome de carbone cationique pour générer un hémiacétal et, non pas, par une attaque nucléophile de l'eau sur le groupe méthyle qui se trouve loin du centre carbocationique :



[Traduit par la rédaction]

The generally accepted reaction mechanism for acid-catalyzed hydrolysis of vinyl ethers consists of rate-determining protonation of the vinyl group on the β-carbon, followed by rapid hydration of the alkoxycarbocation thus formed and fast decomposition of the ensuing hemiacetal intermediate, eq. [1].[4] An alternative scheme involving nucleo-



[1]

philic attack of water on the alkyl group of the cation, eq. [2], has been ruled out by an early study using oxygen-18

[2]

enriched water as the solvent, which showed that the oxygen atom of the alcohol product was not enriched in the oxygen tracer (2). This alternative mechanism is also inconsistent with the fact that ethyl vinyl ethers are more reactive than methyl vinyl ethers (3), inasmuch as nucleophilic attack on an alkyl group such as that shown in eq. [2] would occur more rapidly on methyl than on ethyl.

It is possible, however, that this alternative mechanism might operate in the hydrolysis of vinyl ethers with substituents that shield the α-carbon atom of its vinyl group, for then addition of water to the carbocationic center needed to form the hemiacetal intermediate in the conventional mechanism of eq. [1] would be impeded. This idea is supported by the fact that 2,4,6-trimethoxyacetophenone could not be converted into its dimethyl ketal by acid-catalyzed addition of methanol,[5] despite the ease with which this reaction can be used to prepare ketals of acetophenones without two *ortho* substituents (4). The synthesis of ketals by this route is similar to the hydrolysis of vinyl ethers by the conventional mechanism in that it requires addition of an oxygen nucleophile to an alkoxy carbocation, and its failure in the case of 2,4,6-trimethoxyacetophenone presumably occurs because approach to the carbocationic center is hindered by the *ortho* methoxyl groups, eq. [3].

We have undertaken to determine whether this structural feature can produce a mechanistic change in vinyl ether hydrolysis. Since only the *ortho* substituents are needed to produce this effect, we have chosen to perform our study with methyl α-(2,6-dimethoxyphenyl)-vinyl ether, **1**.

1

Experimental

Materials

Methyl α-(2,6-dimethoxyphenyl)vinyl ether was prepared by *O*-methylation of 2,6-dimethoxyacetophenone. A solution of 2.0 g 2,6-dimethoxyacetophenone (Aldrich), 2.5 g methyl *p*-toluenesulfonate, 1.5 g potassium *tert*-butoxide, and 3,5 g 18-crown-6-ether in 75 mL dimethylformamide was stirred at 100°C for 15 days. The reaction mixture was then cooled to room temperature, 150 mL of water was added, and the resulting solution was extracted with three 100-mL portions of diethyl ether. The combined ether extracts were dried with $MgSO_4$, the ether was removed by evaporation, and the residue was subjected to flash chromatography using 90:10 hexane: ethyl acetate as the eluant. This produced 2.2 g of a colorless solid: mp 48–50°C; ^{1}H NMR ($CDCl_3$), δ: 3.86 (s, 3H), 3.96 (s, 6H), 4.31 (*d*, *J* = 2.1 Hz, 1H), 4.65 (*d*, *J* = 2.1 Hz, 1H), 6.68–6.74 (m, 2H), 7.35–7.44 (m, 1H); MS, *m/e*: 194 (49%), 179 (42%), 163 (100%), 151 (20%), 135 (50%), 105 (28%), 91 (40%); HRMS, *m/e*, calcd.: 194.0943; found: 194.0931.

All other materials were best available commercial grades.

Kinetics

Rates of hydrolysis of methyl α-(2,6-dimethoxyphenyl)vinyl ether were determined by monitoring the increase in absorbance of the 2,6-dimethoxyacetophenone reaction product at λ = 270 nm. Measurements were made with a Cary 2200 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.05°C. Reactions were performed by first allowing 3.0-mL portions of aqueous acids contained in quartz cuvettes to come to temperature equilibrium with the spectrometer cell compartment: 5.0-μL portions of acetonitrile stock solutions of substrate (ca. 10^{-2} M) were then added to the cuvettes, the cuvettes were shaken to effect mixing, and absorption measurements were begun. The data so obtained conformed well to the first-order rate law, and observed first-order rate constants were evaluated by least-squares fitting to an exponential function.

Product analysis

The origin of the carbonyl oxygen atom in the 2,6-dimethoxyacetophenone product of hydrolysis of methyl α-(2,6-dimethoxyphenyl)vinyl ether was determined by conducting the reaction in oxygen-18 enriched water. A solution containing 0.01 M $HClO_4$ was prepared by mixing one part of 1.0 M acid with 10 parts of enriched water (Aldrich, 20 at.% oxygen-18), and 10 μL of an acetonitrile stock solution of vinyl ether substrate (10^{-2} M) was added to 0.50 mL of this acid solution; this mixture was shaken to effect mixing and was then allowed to stand at room temperature. After 15 min (the hydrolysis half-time under these conditions is 20 s), the reaction mixture was extracted with two 0.5-mL portions of diethyl ether, the combined extracts were dried with $MgSO_4$, and the dried solution was subjected to analysis by gas chromatography (HP 5890) – mass spectroscopy (VG 70-250S), using electron impact ionization with an electron energy of 70 eV.

k_{H^+}/k_{D^+} = 3.68 ± 0.07	

[a]Ionic strength = 0.10 M ($NaClO_4$).

A control experiment was also performed in which an authentic sample of 2,6-dimethoxyacetophenone was used in place of methyl α-(2,6-dimethoxyphenyl)vinyl ether; the ketone was treated in exactly the same way for the same period of time as the vinyl ether.

Results

Rates of hydrolysis of methyl α-(2,6-dimethoxyphenyl)-vinyl ether were determined in dilute perchloric acid solutions of H_2O and D_2O. The data are summarized in Table 1 and are displayed in Fig. 1. It may be seen that observed first-order rate constants obtained in both solvents are accurately proportional to acid concentration; least-squares analysis gave the catalytic coefficients k_{H^+} = 2.86 M^{-1} s^{-1} and k_{D^+} = 0.778 M^{-1} s^{-1}, which provide the solvent isotope effect k_{H^+}/k_{D^+} = 3.68.

Mass spectral analysis of the product remaining in a spent hydrolysis reaction mixture showed a pattern identical to that obtained from an authentic sample of 2,6-dimethoxyacetophenone, with a parent peak at *m/e* 180, a more-abundant peak corresponding to loss of a methyl group at *m/e* 165, and additional less-abundant peaks produced by further loss of methyls at *m/e* 150 and 135. Each of these peaks was accompanied by weaker signals one mass unit higher, whose intensities were consistent with expectation for ions containing carbon-13 at its natural abundance.

Mass spectral analysis of the product obtained from a hydrolysis reaction conducted in oxygen-18 enriched water gave a pattern with the same features plus additional peaks two

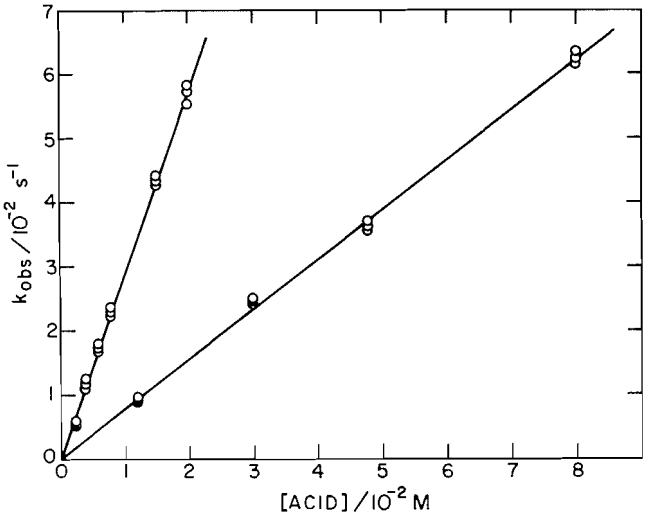

FIG. 1. Relationship between acid concentration and observed first-order rate constants for the hydrolysis of methyl α-(2,6-dimethoxyphenyl)vinyl ether in aqueous solution at 25°C; upper line: H_2O, lower line: D_2O.

mass units higher, i.e., at *m/e* 182, 167, 152, and 137, with carbon-13 satellites one mass unit above each of these. This shows that the 2,6-dimethoxyacetophenone hydrolysis product had become enriched in oxygen-18. The extent of this enrichment could be estimated by comparing the intensities of the signals of the ions in each of the groups at *m/e* 180–183, 165–168, and 159–153 (the signals at *m/e* 137 and 138 were too weak to be useful); the average of these three independent determinations, 22.6 ± 2.4%, agrees with the enrichment of the water used as the solvent, 19.8%.

A control experiment showed that 2,6-dimethoxyacetophenone does not undergo oxygen exchange with solvent water under the conditions of the vinyl ether hydrolysis reaction. This ketone was dissolved in oxygen-18 enriched water (19.8% enrichment) containing 0.01 M $HClO_4$, and, after a period of time corresponding to 40 hydrolysis half-times, was extracted from this solvent and subjected to mass spectral analysis. The spectrum obtained was identical with that given by a sample of 2,6-dimethoxyacetophenone that had not been exposed to enriched water.

Discussion

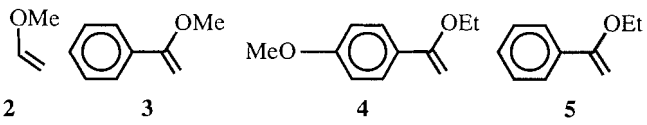
The solvent isotope effect on hydron transfer from the hydronium ion is generally smaller than that on hydron transfer from other oxygen acids because it contains an inverse ($k_H/k_D < 1$) secondary component in addition to a primary effect in the normal ($k_H/k_D > 1$) direction (5), and the isotope effect observed here for the hydrolysis of methyl α-(2,6-dimethoxyphenyl)vinyl ether, $k_{H^+}/k_{D^+} = 3.7$, is in fact a near-maximum value for this kind of effect (6). This isotope effect thus has an appreciable primary component, and it consequently provides clear indication that the present reaction occurs by rate-determining hydron transfer from the hydronium ion.

This conclusion is consistent with either the conventional reaction mechanism of eq. [1] or the alternative route of eq. [2], and it is therefore not diagnostic. The result of the oxygen-18 tracer experiment performed here, however, is diagnostic. In the conventional mechanism, addition of water to the carbocationic center of the alkoxycarbocation intermediate produces a hemiacetal whose hydroxyl group has the same isotopic composition as the solvent water. Decomposition of the hemiacetal then gives a carbonyl compound whose carbonyl oxygen atom is derived from the hemiacetal hydroxyl group and must therefore also have the same isotopic composition as the solvent water.[6] The hydrolysis of methyl α-(2,6-dimethoxyphenyl)vinyl ether by the conventional mechanism in oxygen-18 enriched water will thus produce 2,6-dimethoxyacetophenone with the same isotopic composition as the solvent, as observed.

In the alternative mechanism, on the other hand, nucleophilic attack on the alkyl group remote from the cationic center displaces a carbonyl compound whose carbonyl oxygen atom is derived from the original vinyl ether. Hydrolysis by this mechanism in oxygen-18 enriched water will therefore not produce an oxygen-18 enriched product, contrary to the present observation.

An oxygen-18 enriched product could also have been formed in the present case if 2,6-dimethoxyacetophenone underwent hydration–dehydration under the conditions of the hydrolysis reaction. The control experiment designed to detect this, however, showed that this did not happen. It is safe to conclude, therefore, that the vinyl ether hydrolysis reaction investigated here occurs by the conventional mechanism.

It is interesting that hydrolysis of the present substrate occurs only 3.8 times more rapidly than that of the parent substance with no α-substituent, methyl vinyl ether, **2**, for which $k_{H^+} = 0.76\ M^{-1}\ s^{-1}$ (6). The present substrate is also



2 **3** **4** **5**

19 times less reactive than methyl α-phenylvinyl ether, **3**, for which $k_{H^+} = 53\ M^{-1}\ s^{-1}$ (6), despite the fact that the addition of methoxy groups to the aromatic ring might have been expected to make the present substrate more reactive: ethyl α-(4-methoxyphenyl)vinyl ether, **4**, for example, undergoes hydrolysis 5.5 times more rapidly than its unsubstituted analog, ethyl α-phenylvinyl ether, **5** (4*b*, 6). These unusual substituent effects imply that the aromatic ring of methyl α-(2,6-dimethoxyphenyl)vinyl ether is not very effective at stabilizing the positive charge of the carbocationic intermediate formed in its hydrolysis reaction, presumably because steric interactions between the cationic side chain and its *ortho* methoxy groups have forced the aromatic ring to rotate out of coplanarity with the cation's σ-bonded framework. This puts the methoxyl groups of the aromatic ring into positions where they can impede approach of a nucleophile to the cationic carbon atom, but apparently that impediment is not sufficient to exclude reaction by this route if the nucleophile is as small as a water molecule.

[6]This argument ignores oxygen kinetic isotope effects, but these will be small (see ref. 7) and can be neglected.

Synthesis and characterization of dimethyl- and dimethoxyphenylbis(*N*,*N*-dialkyldithiocarbamato)tellurium(IV) and chlorodimethyl- and chlorodimethoxyphenyl-(*N*,*N*-dialkyldithiocarbamato)tellurium(IV). Crystal structures of $Me_2Te[S_2CNMe_2]_2$ and $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe_2]_2$

JANE H. E. BAILEY[1] AND JOHN E. DRAKE

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 1, 1992

JANE H. E. BAILEY and JOHN E. DRAKE. Can. J. Chem. **71**, 42 (1993).

The compounds $Me_2Te[S_2CNR_2]_2$, $Me_2TeCl[S_2CNR_2]$, $(p\text{-}MeOC_6H_4)_2Te[S_2CNR_2]_2$, and $(p\text{-}MeOC_6H_4)_2TeCl[S_2CNR_2]$, where R = Me, Et, have been prepared and characterised primarily by vibrational and NMR spectroscopy. Variable temperature NMR spectroscopy and qualitative time studies indicate that in solution the dimethoxyphenyltellurium derivatives undergo the reductive-elimination noted for analogous phenyl derivatives but the reductive-elimination does not occur with the dimethyl tellurium derivatives. The crystal structures of $Me_2Te[S_2CNMe_2]_2$, **1**, and $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe_2]_2$, **5**, were completed. The cell parameters for **1**, which crystallizes as monoclinic in space group $P2_1/n$, are a = 13.550(2), b = 13.034(2), c = 17.854(2) Å, β = 106.61(1)°, V = 3021.6(7) Å^3, Z = 8, R = 0.0368, and R_w = 0.0402 and for **5**, which crystallizes as monoclinic in space group $C2/c$, are a = 35.36(1), b = 11.063(3), c = 12.778(3) Å, β = 96.16(3)°, V = 4963(3) Å^3, Z = 8, R = 0.0627, and R_w = 0.0646.

JANE H. E. BAILEY et JOHN E. DRAKE. Can. J. Chem. **71**, 42 (1993).

On a préparé les composés $Me_2Te[S_2CNR_2]_2$, $Me_2TeCl[S_2CNR_2]$, $(p\text{-}MeOC_6H_4)_2TeCl[S_2CNR_2]_2$ dans lesquels R = Me et Et et on les a caractérisés principalement par spectroscopies vibrationnelle et RMN. La spectroscopie RMN à température variable et des études qualitatives en fonction du temps indiquent que, en solution, les dérivés diméthoxyphényltellure subissent l'élimination réductrice notée avec les dérivés phénylés analogues; toutefois, l'élimination réductrice ne se produit pas avec les dérivés diméthyl tellure. On a déterminé les structures cristallines du $Me_2Te[S_2CNMe_2]_2$, **1**, et du $(p\text{-}MeOC_6H_4)Te[S_2CNMe_2]_2$, **5**. Le composé **1** cristallise dans le groupe d'espace $P2_1/n$ avec a = 13,550(2), b = 13,034(2) et c = 17,854(2) Å, β = 106,61(1)°, V = 3021,6(7) Å^3, Z = 8, R = 0,0368 et R_w = 0,0402 alors que le composé **5** cristallise dans le groupe d'espace $C2/c$ avec a = 35,36(1), b = 11,063(3) et c = 12,778(3) Å, β = 96,16(3)°, V = 4963(3) Å^3, Z = 8, R = 0,0627 et R_w = 0,0646.

[Traduit par la rédaction]

Introduction

In the majority of the extensive studies carried out on dithiocarbamate complexes (1–7), the dithiocarbamate group is observed to act in a bidentate fashion (3–7). This appears to be particularly true for transition metal compounds (8, 9) and the relatively few examples of monodentate ligands appear to occur with mixed ligands as is the case for $Pt[S_2CN(i\text{-}Bu)_2]_2[PMe_2Ph]_2$ (10). Within main group elements, bidentate ligands are still common as with $BuSn[S_2CNEt_2]$ (11) and $Zn[S_2CNR_2]_2$ species (12, 13) but we found only anisobidentate linkages with germanium compounds (14–17). This was also the case in previous reports of diphenyl(*N*,*N*-dialkyldithiocarbamato)tellurium(IV) compounds (18, 19). These compounds underwent extensive reductive-elimination in solution regardless of the nature of the dithiocarbamate ligand. In this study we report on changes that are observed when the phenyl groups are substituted by methyl and paramethoxyphenyl groups.

Experimental

Materials

$TeCl_4$, $(p\text{-}MeOC_6H_4)_4Sn$, Me_3SnH, anisole, toluene, *n*-hexane, diethyl ether, petroleum ether, carbon tetrachloride, and chloroform were obtained from Aldrich. With the exception of chloroform and toluene, which were distilled, all others were used as received. Carbon disulfide, obtained from BDH Chemical, was distilled from P_4O_{10} prior to use. Both NaS_2CNMe_2 and NaS_2CNEt_2, purchased from Aldrich as hydrated salts, were dried in vacuum for 4–5 days prior to use. All deuterated solvents were obtained from Aldrich.

Me_2TeCl_2 and $(p\text{-}MeOC_6H_4)_2TeCl_2$ were prepared by a previously described method (20) by reaction of $TeCl_4$ with Me_3SnH and $(p\text{-}MeOC_6H_4)_4Sn$, respectively.

*Synthesis of dimethylbis(*N,N*-dimethyldithiocarbamato)-tellurium(IV), $Me_2Te[S_2CNMe_2]_2$, **1**, and dimethylbis(*N,N*-diethyldithiocarbamato)tellurium(IV), $Me_2Te[S_2CNEt_2]_2$, **2***

Typically, sodium *N*,*N*-dimethyldithiocarbamate (2 mmol, 0.29 g), which had been previously dried *in vacuo* for 4–5 days, was introduced from a finger tube attached to the side of a flask, into a solution of dimethyltellurium dichloride (1 mmol, 0.23 g) in dried carbon disulfide (15 mL). The contents were refluxed at 45°C for 3 h while nitrogen gas was bubbled through. The solution was filtered to remove sodium chloride and any unreacted materials. A few drops of petroleum ether were added to the solution before it was left in the refrigerator at −6°C. Typically crystals formed after approximately three days. The product $Me_2Te[S_2CNMe_2]_2$ was filtered, washed with *n*-hexane, and dried in vacuum; 0.31 g; 77% yield; yellow crystals; mp 120–122°C. Similarly $Me_2Te[S_2CNEt_2]_2$ was formed; 72% yield; yellow crystals; mp 107–109°C. Anal. calcd. for $C_{12}H_{26}N_2S_4Te$: C 31.73, H 5.77, N 6.17; found: C 29.93, H 6.03, N 6.41.

*Synthesis of chlorodimethyl(*N,N*-dimethyldithiocarbamato)-tellurium(IV), $Me_2TeCl[S_2CNMe_2]$, **3**, and chlorodimethyl-(*N,N*-diethyldithiocarbamato)tellurium(IV), $Me_2TeCl[S_2CNEt_2]$, **4***

Typically, sodium *N*,*N*-dimethyldithiocarbamate (1 mmol, 0.14 g) was slowly added, as described above, to a solution containing an equimolar amount of dimethyltellurium dichloride (1 mmol, 0.23 g) in carbon disulphide (15 mL). A continuous stream of nitrogen gas was maintained throughout the experiment. The mixture was stirred in an ice bath for 15 min before the solution was

allowed to warm to ambient and then refluxed for 3.5 h. Sodium chloride and any unreacted material were filtered off and the remaining solution left in the refrigerator to crystallize. The product $Me_2TeCl[S_2CNMe_2]$ was washed with *n*-hexane and recrystallized from chloroform; 0.21 g; 67% yield; yellow crystals; mp 100–102°C. Anal. calcd. for $C_5H_{12}NS_2ClTe$: C 19.17, H 3.86, N 4.47; found C 19.24, H 3.98, N 4.53%. Similarly $Me_2TeCl[S_2CNEt_2]$ was formed; 63% yield; yellow crystals; mp 101–103°C. Anal. calcd. for $C_7H_{16}NS_2ClTe$: C 24.63, H 4.72, N 4.10; found: C 24.71, H 4.83, N 4.28.

*Synthesis of dimethoxyphenylbis(*N,N*-dimethyldithiocarbamato)-tellurium(IV), (*p*-$MeOC_6H_4)_2Te[S_2CNMe_2]_2$, **5**, and dimethoxyphenylbis(*N,N*-diethyldithiocarbamato)-tellurium(IV), (*p*-$MeOC_6H_4)_2Te[S_2CNEt_2]_2$, **6***

Typically, dimethoxyphenyltellurium dichloride (1 mmol, 0.41 g) was dissolved in CS_2 (8 mL) in an ice bath. The salt, NaS_2CNMe_2 (2 mmol, 0.29 g) previously dried *in vacuo* for 3–4 days, was slowly introduced from a side arm. The mixture was stirred for 20 min while a continuous stream of nitrogen gas was maintained. The ice bath was then removed and the solution was refluxed for 3.5 h. The product mixture was then filtered and placed in a refrigerator at −6°C to evaporate the solvent. The resulting solid was washed with *n*-hexane and recrystallized from chloroform; 0.37 g; 63% yield; yellow crystals, mp 112–114°C. Similarly (p-$MeOC_6H_4)_2Te[S_2CNEt_2]_2$ was formed; 70% yield; yellow crystals; mp 68–70°C. Anal. calcd. for $C_{24}H_{34}N_2O_2S_4Te$: C 45.16, H 5.37, N 4.39; found: C 45.59, H 5.57, N 4.28.

*Synthesis of chlorodimethoxyphenyl(*N,N*-dimethyldithiocarbamato)tellurium(IV), (*p*-$MeOC_6H_4)_2TeCl[S_2CNMe_2]$, **7**, and chlorodimethoxyphenyl(*N,N*-diethyldithiocarbamato)-tellurium(IV). (*p*-$MeOC_6H_4)_2TeCl[S_2CNEt_2]$, **8***

Sodium *N,N*-dimethyldithiocarbamate (1 mmol, 0.14 g) was gradually introduced to a solution containing dimethoxyphenyltellurium dichloride (1 mmol, 0.41 g) in CS_2 (10 mL). The solution was kept under a nitrogen gas atmosphere throughout the procedure. After the solution was stirred in an ice bath for 30 min it was allowed to reach ambient temperature. The mixture was then refluxed for 4 h at 45°C. Sodium chloride and any unreacted materials were removed by filtration. After several days of refrigeration the product (p-$MeOC_6H_4)_2TeCl[S_2CNMe_2]$ was formed, washed with *n*-hexane, and recrystallized from chloroform; 0.34 g; 68% yield; mp 91–93°C. Similarly (p-$MeOC_6H_4)_2TeCl[S_2CNEt_2]$ was formed; 61% yield, yellow crystals; mp 81–83°C. Anal. calcd. for $C_{19}H_{23}NO_2S_2ClTe$: C 43.42, H 4.60, N 2.67; found: C 43.94, H 4.69, N 2.85.

Physical measurements

All solvents were dried and distilled prior to use. Elemental analyses were performed by Guelph Laboratories. Density measurements were obtained using the flotation method in carbon tetrachloride and benzene. The infrared spectra were recorded on a Bohmem infrared spectrometer as KBr pellets for the middle range and between polyethylene films for the far infrared spectra. Samples for Raman spectroscopy were sealed in capillary tubes and the spectra recorded on a Ramanor U-1000 spectrometer using the 4880 Å excitation line of an argon ion laser. ^1H and $^{13}C\{H\}$ NMR spectra were recorded on a Bruker AC 300 spectrometer in either CS_2 or $CDCl_3$ using tetramethylsilane as the internal standard for CS_2 solutions. ^{125}Te NMR spectra were recorded on a Bruker AC 200 and referenced to dimethyltellurium. All melting points were determined on a Fisher-Johns apparatus.

X-Ray crystallographic analysis

A crystal of $Me_2Te[S_2CNMe_2]_2$, **1**, was sealed in a thin-walled glass capillary and mounted on a Rigaku four-circle AFC6S diffractometer, with graphite monochromated Mo Kα radiation. The orientation matrix for data collection was refined using 25 high-angle reflections ($34° < 2\theta < 39°$). On the basis of the systematic absences *h*0*l*: $h + l \neq 2n$, 0*k*0: $k \neq 2n$, and the successful solution and refinement of the structure, the space group was determined to be $P2_1/n$ (No. 14).

The data were collected by the ω–2θ scan technique to a maximum 2θ value of 50.0° and at a maximum scan rate of 32.0 deg min^{-1}. The intensities of three representative reflections which were measured after every 150 reflections remained constant throughout data collection indicating crystal and electronic stability (no decay correction was applied). An empirical absorption correction, based on azimuthal scans of several reflections, was applied which resulted in transmission factors ranging from 0.87 to 1.00. The data were corrected for Lorentz and polarization effects. All data processing was performed on a VAX workstation 3520 using the TEXSAN crystallographic package (Version 5.0 obtained from Molecular Structure Corp., The Woodlands, TX) (21).

A crystal of (p-$MeOC_6H_4)_2Te[S_2CNMe_2]_2$, **5**, was sealed in a capillary and mounted along the largest dimension on a Syntex P_21 diffractometer. The X-ray diffraction data were collected by the procedures described in detail elsewhere (15) by the coupled θ(crystal)/2θ(counter) method to a maximum 2θ value of 40° at a variable scan speed of 2.02–4.88 deg min^{-1}. On the basis of the systematic absences *hkl*: $h + k \neq 2n$; *h*0*l*: h, $l \neq 2n$, and the successful solution and refinement of the structure, the space group was determined to be $C2/c$ (No. 15). The least-squares refinement of the setting angles of 15 reflections in the range $15° < 2\theta < 30°$ led to the cell dimensions given in Table 1. During data collection, the intensities of three monitor reflections measured every 100 reflections remained constant and so no decay correction was applied. The data were corrected for Lorentz and polarization effects. Sources of scattering factors and computer programs used have been given elsewhere (15).

The final atomic coordinates and isotropic thermal parameters (Tables 2 and 3) are given respectively for **1** and **5** for the non-hydrogen atoms and important distances and bond angles in Tables 4 and 5. The molecular structures of both compounds are displayed in Figs. 1 and 2. Tables of final thermal parameters of non-hydrogen atoms, final fractional coordinates, and thermal parameters of hydrogen atoms as well as tables of observed and calculated structure factors have been deposited.[2]

Results and discussion

The dimethyltellurium(IV) and dimethoxyphenyltellurium(IV) derivatives were made by the reaction of the appropriate diorganotellurium dichloride with the sodium salts of *N,N*-dimethyl- and *N,N*-diethyldithiocarbamic acids in two-fold excess or equimolar amounts.

$$R_2TeCl_2 + 2NaS_2CNR'_2 \rightarrow R_2Te[S_2CNR'_2]_2 + 2NaCl$$

$$R_2TeCl_2 + NaS_2CNR'_2 \rightarrow R_2TeCl[S_2CNR'_2] + NaCl$$

(R = Me or *p*-$MeOC_6H_4$; R′ = Me or Et)

In earlier papers (18, 19) we noted the difficulty of relying on solution-phase spectra for characterization. Thus every effort was made to prepare X-ray quality crystals but, unfortunately, this was only achieved for two of the products.

*The crystal structures of $Me_2Te[S_2CNMe_2]_2$, **1**, and (p-$MeOC_6H_4)_2Te[S_2CNMe_2]_2$, **5***

In both cases the geometry around tellurium is best described as the saw-horse structure typical of tellurium(IV) compounds in which the lone-pair is apparently stereochemically active and occupying an equatorial position in a distorted trigonal bipyramid. The two organic groups occupy the other two equatorial positions with the axial posi-

tions being occupied by a sulfur atom from each of the dithiocarbamate groups (Figs. 1 and 2). The average Te—C bond length in $Me_2Te[S_2CNMe_2]_2$, **1** is 2.13(1) Å, not significantly shorter than the average distance of 2.145(15) Å for $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe_2]_2$, **5**. The Te—C bond length for the analogous phenyl derivative, $Ph_2Te[S_2CNMe_2]_2$, is also essentially the same at 2.140(5) Å (18). However, the fact that all are so similar may well be significant because, in general, a shorter Te—C bond is expected for bonds involving aromatic as opposed to alkyl linkages to tellurium. Thus in a collation of reported bond lengths involving organic derivatives (22), the mean Te—C(aromatic) bond length is 2.116 Å compared with a value of 2.158 Å for the Te—C(alkyl) bond. On this basis, the Te—C bonds in $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe_2]_2$, $Ph_2Te[S_2CNMe_2]_2$, and other analogous species such as $Ph_2Te[S_2CNEt_2]_2$ (23) and $Ph_2Te[S_2CNBu_2]_2$ (19) are relatively long and the bond in $Me_2Te[S_2CNMe_2]_2$ is relatively short.

In $Me_2Te[S_2CNMe_2]_2$ the Te—S bond distances cover the range 2.605(2) to 2.654(1) Å at an average of 2.63(1) Å, comparable to the average distance in $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe_2]_2$ of 2.62(1) Å. These values are also essentially the same as the value of 2.621(1) Å reported for $Ph_2Te[S_2CNMe_2]_2$ (18) and the related compounds $Ph_2Te[S_2CNEt_2]_2$ (23) and $Ph_2Te[S_2CNBu_2]_2$ (19), where the Te—S bonds range from 2.6179(4) to 2.6303(9) Å for the two forms

[a]The esd's on mean values have been calculated with the use of the scatter formula $\sigma = [\Sigma(d_i - d)^2/N]^{1/2}/(N-1)^{1/2}$, where d_i is the ith and d is the mean of N measurements.

of the ethyl derivative and 2.622(2) Å for the butyl derivative.

The deviation of the S—Te—S angles from 180° increases along the series (p-MeOC$_6$H$_4$)$_2$Te[S$_2$CNMe$_2$]$_2$, 177.8(1)°, Ph$_2$Te[S$_2$CNMe$_2$]$_2$, 172.0(1)°, and Me$_2$Te[S$_2$CNMe$_2$]$_2$, 167.58(7) and 165.39(7)°, which is suggestive of a trend based on the nature of the organo group attached to tellurium. However, more data on alkyl tellurium R$_2$Te[dtc]$_2$ species are needed to ensure that the distortion is indeed larger for such groups. For the C—Te—C bond angles, the values are smallest for (p-MeOC$_6$H$_4$)$_2$Te[S$_2$CNMe$_2$]$_2$ at 92.6(4)° compared to 99.4(1)° for Ph$_2$Te[S$_2$CNMe$_2$]$_2$. The values of 93.9(2)° and 95.5(3)° for Me$_2$Te[S$_2$CNMe$_2$]$_2$ are not only closer to those of the methoxyphenyl derivatives but also to the two forms of Ph$_2$Te[S$_2$CNEt$_2$]$_2$, 94.2(1)° and 94.077(1)° (23) and Ph$_2$Te[S$_2$CNBu$_2$]$_2$, 95.3(2)° (19), so no obvious trend exists. In all three dimethyldithiocarbamate derivatives, the aniso-bonded sulfur atoms are at a similar distance from tellurium ranging from 3.167(2) to 3.244(2) Å in Me$_2$Te[S$_2$CNMe$_2$]$_2$, 3.183(3) to 3.258(3) Å in (p-MeOC$_6$H$_4$)$_2$Te[S$_2$-

[a]The esd's on mean values have been calculated with the use of the scatter formula $\sigma = [\Sigma(d_i - d)^2/N]^{1/2}/(N - 1)^{1/2}$, where d_i is the ith and d is the mean of N measurements.

$CNMe_2]_2$, and 3.186(2) Å in $Ph_2Te[S_2CNMe_2]_2$ (18), and subtend similar bite angles which average to 60.8(3)° in $Me_2Te[S_2CNMe_2]_2$ and to 60.8(7)° in $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe_2]_2$, comparable to 61.0(1)° in $Ph_2Te[S_2CNMe_2]_2$ (18). Distances close to 3.2 Å and bite-angles close to 61° appear to be characteristic of all dithiocarbamates aniso-bonded to tellurium (18, 19, 23). The sum of the van der Waals radii of tellurium and sulfur is considerably longer at 4.0 Å (24), while the bite-angle in a fully bidentate ligand is over 64° (25). There was no sign of any bridging by the dithiocarbamate group as has been reported for $Ph_3Te[S_2CN(i\text{-}Pr)_2]$ (26); there being no Te---S intermolecular distances below 4.0 Å involving the aniso-sulfur atom and the tellurium atom of an adjacent molecule in either **1** or **5**.

The similarities in the characteristics associated with the Te—S bonding extend to the bonds in the ligands themselves. In both $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe_2]_2$, **5**, and $Me_2Te[S_2CNMe]_2$, **1**, the C—S terminal bond, 1.66(1) and 1.69(1) Å in **5** and ranging from 1.674(8) to 1.689(7) Å in **1**, is considerably shorter than the C—S(Te) bond which is 1.78(1) Å in **5** and ranges from 1.738(8) to 1.771(8) Å in **1**. The C—S bond length in CS_3^{2-} is reported to be 1.71 Å (27), emphasizing that the partial π-bond delocalization clearly extends to the S_2C—N bond which is considerably shorter, 1.32(1) and 1.35(1) Å in **5** and 1.330(9) to 1.355(9) Å in **1**, than the N—CH_3 bonds which range from 1.44(1) to 1.50(1) Å in **5** and 1.43(1) to 1.47(1) Å in **1**.

Infrared and Raman spectra

The assignments of selected features in the infrared and Raman spectra of compounds **1** to **8** are given in Table 6. The assignments are made in conjunction with those made earlier on a variety of analogous diphenyltellurium derivatives (18, 19). The characteristic ν(C—NR_2) stretch, which is observed readily in all eight compounds, ranges from 1480–1508 cm^{-1}, well within and near the mean of the generally accepted range of 1450–1550 cm^{-1}. The average C—NR_2 bond lengths in $Me_2Te[S_2CNMe_2]_2$, **1**, and $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe]_2$, **5**, and the mean of the ν(C—NR_2) vibrational frequencies in the two compounds are much closer to those expected for a C=N double bond (approximately 1.27 Å and 1600 cm^{-1}) than for a C—N single bond (approximately 1.46 Å and 1000 cm^{-1}), reflecting the significant π-character in the bond.

The conventional assignment of the C—S vibration in dithiocarbamates in the 980 cm^{-1} region places it well above the weighted averaged of ν(C—S) in the CS_3^{2-} ion which is closer to 800 cm^{-1} (28). This is consistent with the average C—S bond length of the terminal or aniso-bonded sulfur atom, being 1.681(8) and 1.68(2) Å, respectively, for $Me_2Te[S_2CNMe_2]_2$, **1**, and $(p\text{-}MeOC_6H_4)_2Te[S_2CNMe_2]_2$, **5**, compared with the C—S bond length of 1.71 Å in the CS_3^{2-} ion

(27). The symmetrical Te—S stretching vibration shows up clearly in the Raman spectra of all four *bis* species in the range 362–372 cm^{-1} which is 9–15 cm^{-1} to higher wavenumber than the corresponding asymmetric Te—S stretch. A similar phenomenon was noted for the Te—Cl stretches in Me_2TeCl_2 (29). The value of ν(Te—S) is generally higher for the $Me_2TeCl[S_2CNR_2]$ and $(p\text{-}MeOC_6H_4)_2TeCl[S_2CNR_2]$ species which is presumably indicative of a shorter Te—S bond in the halo-derivatives, as was found for $Ph_2TeCl[S_2CNEt_2]$, $Ph_2TeCl[S_2CN(i\text{-}Pr)_2]$ (18), and $Ph_2TeBr[S_2CNEt_2]$ (19). Moreover, as was the case for the $Ph_2TeCl[S_2CNR_2]$ species (18), the characteristic Te—Cl stretching vibration is in the 180–209 cm^{-1} range for **3**, **4**, **7**, and **8**, presumably reflecting a longer Te—Cl bond than that in Me_2TeCl_2 where the Te—Cl vibrations are in the range 241–276 cm^{-1} (29). In Me_2TeCl_2, where the Te—C bond length is 2.09 Å (30) the Te—C stretches were both assigned at 544 cm^{-1} (29). Two distinct peaks are seen in this region for compounds **1** to **4**, particular in the Raman effect, which are assigned to the symmetric and asymmetric Te—C stretching vibrations, respectively. The slightly lower frequencies in the dithiocarbamates are consistent with the Te—C bond length in $Me_2Te[S_2CNMe_2]_2$ being longer than in Me_2TeCl_2, and presumably therefore in the other species **2**, **3** and **4**.

NMR spectroscopy

Previously reported studies (18, 19) on the diphenyltellurium analogues, $Ph_2Te[S_2CNR_2]_2$, indicated that in solution such species undergo rapid exchange, rearrangement, and reductive-elimination regardless of the nature of the alkyl group in the dialkyldithiocarbamate ligand. It was of interest to note if this would also be the case for these dimethyl- and dimethoxyphenyl-tellurium derivatives. The ^1H and ^{13}C NMR spectra reported in Table 7 were recorded immediately after dissolution in $CDCl_3$ solution. In all cases only one set of peaks is observed for the NR_2 groups, as was the case for the diphenyltellurium compounds (18, 19). Studies on related compounds have lead to the conclusion that the exchanges indicated by this equivalence are predominantly metal-centred rearrangements (31, 32).

For all of the dimethyltellurium dithiocarbamate species, **1** to **4**, the peaks remain unchanged even after several days in solution. In the ^1H NMR spectra, the first-order triplet-quartet pattern associated with the $N(CH_2CH_3)_2$ group in **2** and **4** remains sharp over time and with temperature change so that the exchange bringing about equivalence must be fast on the NMR time scale. The chemical shifts of the $N(CH_3)_2$ groups in **1** and **3** and of $N(CH_2CH_3)_2$ groups in **2** and **4** are essentially the same for the *bis* and *mono*-substituted species, as was found for the corresponding diphenyl derivatives (18). The chemical shift of the CH_3-group attached to tellurium is the same for **1** and **2** and also identical for **3** and **4**, so these shifts are apparently dependent on the number of dithiocarbamate groups attached to tellurium. Thus there is an upfield shift of 0.38 ppm on substituting one chlorine atom in Me_2TeCl_2 by a dithiocarbamate group and a shift of a further 0.29 ppm when the second chlorine is replaced. Similar comments are applicable to the changes in the chemical shifts in the ^{13}C NMR spectra as can readily be seen in Table 7.

In contrast to the dimethyltellurium series, the ^1H and ^{13}C NMR spectra of the dimethoxyphenyltellurium species, **5**–**8**, change rapidly with time. Nevertheless, the chemical shifts of the spectra recorded immediately after the solutions were formed show the same sorts of trends for the methyl and ethyl groups in the dithiocarbamate entities as just described for compounds **1**–**4**. The methyl protons in the methoxyphenyl groups appear in the ^1H NMR spectra as sharp singlets at close to 3.8 ppm in all four species and also essentially in the

[a]^{13}C-NMR chemical shifts given in [ ]; s = singlet, d = doublet, t = triplet, q = quartet.

same position, 55.3 ± 1 ppm, in the ^{13}C NMR spectra. The ^1H NMR chemical shifts of the phenyl rings are also similar regardless of the nature of the attached dithiocarbamate group or whether it is a *bis*- or *mono*-substituted derivative. In all cases the two sets of peaks are seen as expected for the *meta* and *ortho* protons. In the ^{13}C NMR spectrum of $(p\text{-}MeOC_6H_4)_2TeCl_2$, two peaks are predominant in the phenyl region at 115.7 and 135.5 ppm which are attributable to C(3,5) and C(2,6) respectively, where C(1) is the carbon atom attached to tellurium (33). The corresponding peaks in $(p\text{-}MeOC_6H_4)_2Te$ occur at 115.3 and 139.7 ppm. The peak attributable to C(1) is reported at 162.4 and 159.6 ppm, respectively, for $(p\text{-}MeOC_6H_4)_2TeCl_2$ and $(p\text{-}MeOC_6H_4)_2Te$ and that attributable to C(6) at 125.4 and 104.4 ppm (33). In all of the compounds, **5** to **8**, the ^{13}C NMR chemical shifts of the ring carbon atoms bear a much closer resemblance to those of $(p\text{-}MeOC_6H_4)_2TeCl_2$ than $(p\text{-}MeOC_6H_4)_2Te$. This is consistent with electronegativity effects associated with the dithiocarbamate group being fairly similar to a chlorine atom and the environment around tellurium in the solid state being mantained in solution when the compounds are initially dissolved.

The ^1H and ^{13}C NMR spectra recorded one week after compounds **5** and **6** are dissolved in $CDCl_3$ no longer appear as just described but in fact are dominated by peaks attributable to $(p\text{-}MeOC_6H_4)_2Te$ and the diligands, in accord with the reductive-elimination:

$$(p\text{-}MeOC_6H_4)_2Te[S_2CNR_2]_2 \rightarrow (p\text{-}MeOC_6H_4)_2Te + R_2NCS_2S_2CNR_2$$

When spectra were recorded after a few hours, the intensity of peaks associated with $(p\text{-}MeOC_6H_4)_2Te[S_2CNR_2]_2$ had diminished considerably, as much as 90% in 48 h, and those associated with $(p\text{-}MeOC_6H_4)_2Te$ and $R_2NCS_2S_2CNR_2$ had correspondingly increased. The collection time involved in obtaining ^{125}Te NMR spectra (Table 8) was sufficiently long

$(p\text{-}MeOC_6H_4)_2Te$				671

[a]L = dithiocarbamate, R = Me, p-$MeOC_6H_4$.

that even the initial spectra often showed evidence of $(p\text{-}MeOC_6H_4)_2Te$ and after a week there was no evidence of any *bis* species still being present.

For the $(p\text{-}MeOC_6H_4)_2TeCl[S_2CNR_2]$ species, **7** and **8**, within a week the ^{1}H, ^{13}C, and ^{125}Te NMR spectra all showed the presence of $(p\text{-}MeOC_6H_4)_2TeCl_2$, $(p\text{-}MeOC_6H_4)_2Te$, and diligand although peaks attributable to the original molecules **7** and **8** were still of equivalent importance. This is consistent with the following mode of decomposition:

$$2(p\text{-}MeOC_6H_4)_2TeCl[S_2CNR_2]$$
$$\rightarrow (p\text{-}MeOC_6H_4)_2Te[S_2CNR_2]_2 + (p\text{-}MeOC_6H_4)_2TeCl_2$$
$$\downarrow$$
$$(p\text{-}MeOC_6H_4)_2Te + R_2CNS_2S_2CNR_2$$

The relative rates of each step are presumably such that the concentration of *bis* species is never high enough to be detected.

The contrast between the ease of reductive-elimination of $(p\text{-}MeOC_6H_4)_2Te[S_2CNR_2]_2$ to give $(p\text{-}MeOC_6H_4)_2Te + [S_2CNR_2]_2$ and the stability of the $Me_2Te[S_2CNR_2]_2$ species is surprising in view of the fact that in both cases the overall reaction involves the breaking of two apparently identical Te—S bonds and the making of one S—S bond. In view of the similarity in the structures of **1** and **5** it is difficult to argue that the difference results from the non-availability of a kinetic pathway in the case of the dimethyl derivative. However, if it is assumed that the reactions are close to being thermally neutral, then the reductive-elimination could be unfavourable if the Te—C bonds in $Me_2Te[S_2CNR_2]_2$ are stronger relative to those in Me_2Te, while the reductive-elimination could become favourable in the case of the dimethoxyphenyl species if the Te—C bonds in $(p\text{-}MeOC_6H_4)_2Te[S_2CNR_2]_2$ are now weaker relative to those in $(p\text{-}MeOC_6H_4)_2Te$. In this regard we return to a point made during the discussions of the structures that suggested that the Te—C bonds in $Me_2Te[S_2CNR_2]_2$ are relatively shorter than is normal for Te—C(alkyl) bonds while the Te—C bonds in $(p\text{-}MeOC_6H_4)_2Te[S_2CNR_2]_2$ and $Ph_2Te[S_2CNR_2]_2$ species are relatively longer than is normal for T—C(aryl) bonds.

The boron trifluoride – base system: application of the coordination model of reaction mechanisms[1]

XIAOBO OU, ROBERT WALLACE, AND ALEXANDER F. JANZEN[2]
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 1, 1992

XIAOBO OU, ROBERT WALLACE, and ALEXANDER F. JANZEN. Can. J. Chem. **71**, 51 (1993).

The mechanism of reaction of boron trifluoride with amines, dialkyl ethers, and pyridine has been analyzed on the basis of the coordination model of reaction mechanisms. This model is tested mathematically by carrying out kinetic simulations of pathways P(*X*,*C*), accompanied by the calculation of structures of postulated intermediates by GAUSSIAN86 methods. Analyses of reaction mechanisms, including calculation of concentration vs. time curves, are reported for the following systems: NH_3–BF_3, $MeNH_2$–BF_3, Me_2O–Et_2O–BF_3, Me_2O–Et_2O:BF_3, pyridine–BF_3, pyridine–Me_3N–BF_3, F_3B:N–N:BF_3, and (N–N)BF_2^+.

XIAOBO OU, ROBERT WALLACE et ALEXANDER F. JANZEN. Can. J. Chem. **71**, 51 (1993).

Faisant appel au modèle de coordination des mécanismes réactionnels, on a analysé le mécanisme réactionnel du trifluorure de bore avec les amines, les éthers dialkylès et la pyridine. On a évalué le modèle d'une façon mathématique en effectuant des simulations cinétiques des diverses voies réactionnelles P(*X*,*C*), tout en calculant les structures des intermédiaires présumés par des méthodes gaussiennes-86. On rapporte des analyses des mécanismes réactionnels, y compris des calculs de concentration vs. temps, pour les systèmes suivants : NH_3–BF_3, $MeNH_2$–BF_3, Me_2O–Et_2O–BF_3, Me_2O–Et_2O:BF_3, pyridine–BF_3, pyridine–Me_3N–BF_3, F_3B:N–N:BF_3 et (N–N)BF_2^+.

[Traduit par la rédaction]

The coordination model of reaction mechanisms (1–3) describes in a formal way the discrete changes in coordination number and electron count of individual atoms and represents the connectivity of atoms in multistep pathways in graphical form as pathway P(*X*,*C*).[3] In this paper we wish to describe a mathematical test of the coordination model by comparing calculated results with extensive experimental data that are available for the reactions of boron trifluoride with Lewis bases (4–6). The model assumes that intermolecular steps, +C, are limited by the rate of diffusion and that steps which decrease the coordination number, −C and $-C^c$, are slower and depend on the strength of the bond that is cleaved, but cyclic intramolecular *n*-center steps, $+C^c$, are statistically favoured, particularly in the case of 3-, 4-, 5-, and 6-center steps. Kinetic simulation of pathways P(*X*,*C*) is carried out by associating elementary rate constants with the four coordination number operators +C, −C, $+C^c$, and $-C^c$, while molecular orbital calculations are helpful in estimating relative rate constants for intermediates where experimental data are not available.

Any mechanistic description of the BF_3–base system must accommodate the following experimental facts: (*a*) the formation of base:BF_3 is a bimolecular process with rate constants in the range 10^8–10^{10} M^{-1} s^{-1} (7); (*b*) rates of reaction of base:BF_3 are inversely proportional to the gas phase enthalpies of dissociation (5); (*c*) equilibrium data for BF_3–base systems (8); (*d*) two modes of exchange in BX_3–base systems involving both halogen and base exchange (5, 9); (*e*) excess BF_3 accelerates the rate of fluorine exchange in base:BF_3 (5); (*f*) the boron cation (amine)$_2BF_2^+$ is an elusive species although, once formed, it is stable even in water (4); (*g*) some adducts such as HMPA:BF_3 and tetramethylurea:BF_3 are in equilibrium with the ionic species (base)$_2$-$BF_2^+BF_4^-$ (10); (*h*) the formation of mixed base adducts such as $(Me_3N)(pyridine)BF_2^+$ depends on the order of addition of base (4); and (*i*) formation of chelated boron cations with bidentate ligands (N–N)BF_2^+ occurs in some cases (11), but not in others (12).

Results and discussion

The NH_3–BF_3 and $MeNH_2$–BF_3 systems

The analysis of the NH_3–BF_3 system by the coordination model begins by considering all possible interactions between the atoms of ammonia and boron trifluoride, of which the strongest will most likely involve B—N, H--N, and H--F bonds. The model is tolerant of higher coordination numbers as these reflect interactions between reactants and intermediates, but weakly bound intermediates will decompose rapidly and consequently their effect can be neglected, unless they are a prerequisite for further reaction along a multistep pathway. Pathways P(*X*,*C*) are constructed after choosing a minimum set of coordination numbers for the NH_3–BF_3 system, i.e., B(3) B(4) N(3) N(4) F(1) F(2) H(1) H(2), and this minimum set of coordination numbers is used for all base–BF_3 systems, with the exception of pyridine, where N(2) N(3) is more appropriate, and dialkyl ether, where O(2) O(3) is used. The formation of B—N, H--N, and H--F bonds in the NH_3–BF_3 system is an example of pathway P(3,1), as illustrated in eqs. [1]–[3].

For the testing of the coordination model, each +C and −C must be associated with elementary rate constants and these are selected as follows: intermolecular steps, +C, are

[1]Presented at the 203rd ACS National Meeting, San Francisco, April 5–10, 1992.

[2]Author to whom correspondence may be addressed.

[3]Notation: A graph P(*X*,*C*) consists of a vertex set *X* of reactants, intermediates, and products, and an edge set *C* of coordination number operators +C, −C, $+C^c$, and $-C^c$, which are drawn above the edges for forward steps and below for reverse steps; dashed lines refer to intermolecular steps, +C or −C, and solid lines to cyclic intramolecular steps, $+C^c$ or $-C^c$; $+C_{M(m)N(n)}$ increases the coordination number of elements M and N by 1, from *m* to *m* + 1 and *n* to *n* + 1, and $-C_{M(m)N(n)}$ decreases the coordination numbers by 1 from *m* + 1 to *m* and *n* + 1 to *n*; $+C^{n\text{-center}}_{M(m)N(n)}$ and $-C^{n\text{-center}}_{M(m)N(n)}$ define coordination changes that occur via cyclic *n*-center steps; and pathway P(5,2) contains 5 vertices and 2 edges, as described previously (1).

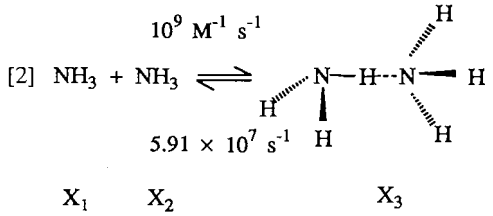
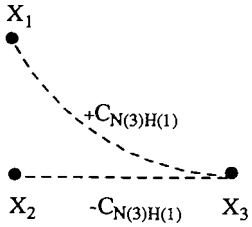
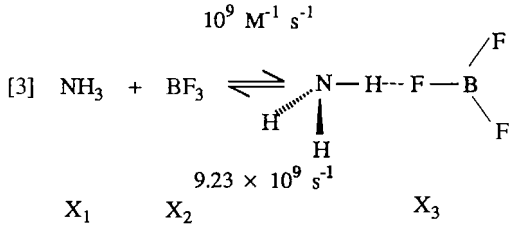
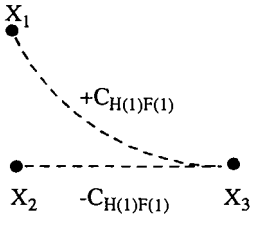
P(3,1)









assigned rate constants equal to the diffusion-controlled value of about 10^9 M^{-1} s^{-1}, while rate constants associated with bond cleavage, −C, are calculated with the aid of equation $k = Ae^{-\Delta H/RT}$, where $A = 10^{11}$, $T = 298$ K, and ΔH is the bond enthalpy associated with a specific −C, as listed in Table 1. The rate constants are shown in eqs. [1]–[3], and by selecting rate constants in this way, without any further modification, ΔH becomes the only adjustable parameter of our mechanistic analysis, and a semiquantitative but stringent test of the coordination model is now possible, even for multistep processes.

Kinetic simulations were carried out by means of the Runge–Kutta algorithm (13) on a 386PC using the MathCad 3.1 program (14), and the calculated concentration vs. time curves for the reaction of NH_3 and BF_3 in a 1:1 molar ratio using the rate constants of eqs. [1]–[3] are shown in Fig. 1. Identical pathways P(3,1) are assumed for the reaction of BF_3 with $MeNH_2$ and the kinetic simulation of a 1:1 reaction using the bond enthalpies of Table 1 and the rate constants of eqs. [4]–[6] are displayed in Fig. 2.

$$[4]\quad MeNH_2 + BF_3 \underset{8.36 \times 10^{-9}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} MeNH_2{:}BF_3$$

$$[5]\quad MeNH_2 + MeNH_2 \underset{3.20 \times 10^{8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} MeHN\text{-}H\text{--}NH_2Me$$

$$[6]\quad MeNH_2 + BF_3 \underset{9.23 \times 10^{9}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} MeHN\text{-}H\text{--}F\text{-}BF_2$$

The experimental rate constants for reaction of boron trifluoride with ammonia and methylamine were determined by Kistiakowsky and Williams (7), $k(NH_3) = 2.7 \times 10^8$ and $k(MeNH_2) = 6.7 \times 10^8$ M^{-1} s^{-1} at 25°C, and the slower reaction with ammonia was attributed to an activation energy ranging from 8 kJ for ammonia to near zero for heavier amines; however, the activation energies could not be confirmed experimentally. The coordination model does not assume an activation energy for +C, and a theoretical CNDO study has concluded that no activation energy is necessary for the formation of $H_3N{:}BF_3$ (15), but the slower reaction of ammonia as compared to methylamine, which is displayed in Fig. 1 as a lower yield of $H_3N{:}BF_3$ (0.72 M) as compared to $MeNH_2$ (0.84 M) after 10^{-8} s, must arise from a weaker B—N and a stronger N--H bond for the ammonia reaction because the rate constants, +C, are fixed at 10^9 M^{-1} s^{-1} and N--F bond enthalpies were estimated to be equal (Table 1). The weaker B—N bond of $H_3N{:}BF_3$ results in a slightly greater dissociation of the ammonia adduct, eq. [1], while greater hydrogen bonding between ammonia molecules increases the concentration of the hydrogen-bonded intermediate, eq. [2], and thereby reduces slightly the overall rate of formation of $H_3N{:}BF_3$, as compared to $MeNH_2{:}BF_3$. Statistical factors (16) related to the number of equivalent pathways by which H--N or H--F bonds can be formed were not included in our calculation, but they would also favour the ammonia intermediates and further reduce the overall rate of formation of the ammonia adduct, as compared to the methylamine adduct, in agreement with experiment.

The Me_2O–Et_2O–BF_3 system

This system was studied by Rutenberg, Palko, and Drury (8), by means of ^{19}F NMR and their reported equilibrium composition of three mixtures of Et_2O, Me_2O, and BF_3 is shown in Table 2. We calculated concentration vs. time curves for the same mixtures using the bond enthalpies of Table 1 and rate constants of eqs. [7] and [8], and Fig. 3 shows the results for an initial mixture of $Et_2O{:}Me_2O{:}BF_3$ = 7.51:2.27:3.06. As seen in Fig. 3, equilibrium is reached rapidly, within about 10^{-9} s, and a comparison of calcu-

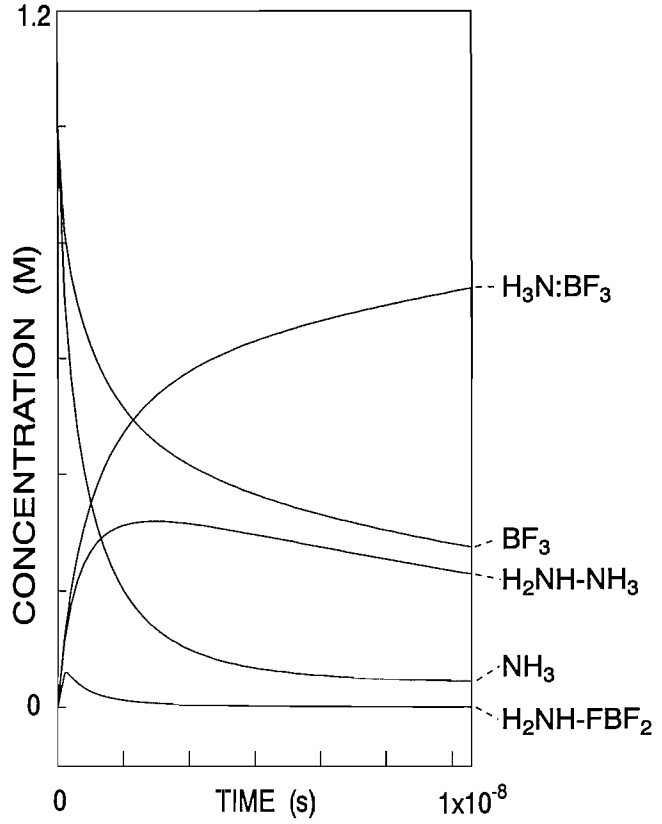

FIG. 1. Calculated concentration vs. time curves for the 1:1 reaction of BF_3 with NH_3. Input rate constants are given in eqs. [1]–[3]. The concentration of $H_3N:BF_3$ after 1×10^{-8} s is 0.72 M.

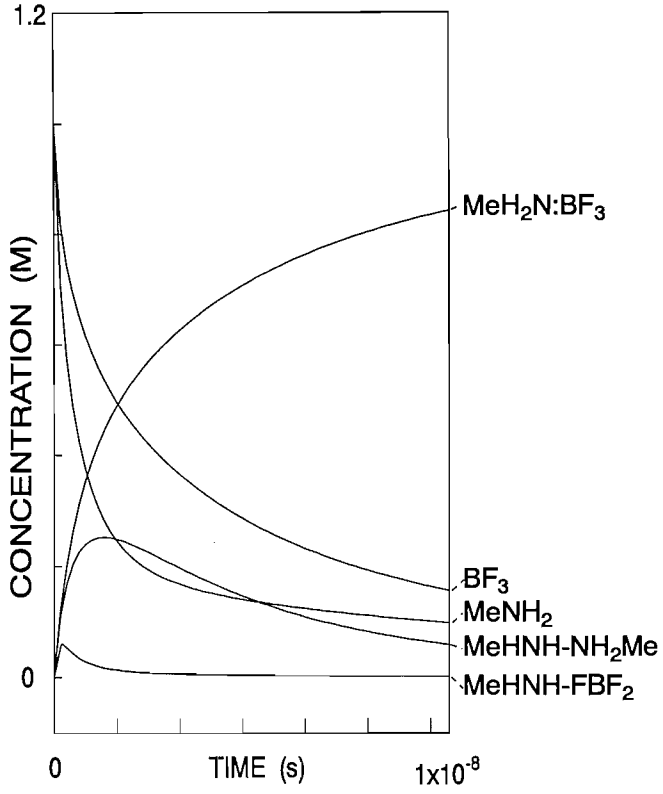

FIG. 2. Calculated concentration vs. time curves for the 1:1 reaction of BF_3 with $MeNH_2$. Input rate constants are given in eqs. [4]–[6]. The concentration of $MeNH_2:BF_3$ after 1×10^{-8} s is 0.84 M.

lated and experimental equilibrium concentrations for all three sets of initial conditions, Table 2, shows moderately good agreement. An exact agreement is not expected because all

$$[7] \quad Me_2O + BF_3 \underset{26.3\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} Me_2O:BF_3$$

$$[8] \quad Et_2O + BF_3 \underset{1.77 \times 10^3\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} Et_2O:BF_3$$

the data of Table 2 are based on simplifications: the ^{19}F NMR results of Rutenberg *et al.* neglect the effect of ionic species such as base:BF_2^+ and (base)$_2BF_2^+$ on the chemical shift and linewidth, while our calculations neglect entropy effects and assume a uniform rate constant for the formation, +C, of base:BF_3 adducts.

The Me_2O and $Et_2O:BF_3$ system

If rapid diffusion-controlled steps, +C, have rate constants of about 10^9 M^{-1} s^{-1}, then slow reactions must depend on −C, or on ratios of C's, and the concentration of reactive intermediates in slow reactions must be exceedingly low. A slow reaction may be analyzed by calculating

the outcome of a reaction of Et_2O:BF_3 with Me_2O, in a 4.00:2.76 ratio, using identical rate constants, eqs. [9] and [10], as for the previous Me_2O–Et_2O–BF_3 system which reached equilibrium within about 10^{-9} s. The calculations show that after 6×10^{-6} s the concentration of Et_2O:BF_3

$$[9] \quad Et_2O{:}BF_3 \underset{10^9\ M^{-1}\ s^{-1}}{\overset{1.77 \times 10^3\ s^{-1}}{\rightleftharpoons}} Et_2O + BF_3$$

$$[10] \quad Me_2O + BF_3 \underset{26.3\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} Me_2O{:}BF_3$$

(3.96 M) and Me_2O (2.72 M) decreased slightly while Me_2O:BF_3 (0.041 M) slowly increased, but the concentration of the reactive intermediate BF_3 was maintained at a low concentration of about 10^{-6} M. Synthetic reactions utilizing R_2O:BF_3 are often carried out in the presence of excess dialkyl ether, and this calculation illustrates a common role of solvent as stabilizer and dispenser of reactive intermediates.

The pyridine–BF_3 system

The behaviour of the base–BF_3 systems discussed above is largely determined by the cleavage of B—N and B—O bonds and all calculations point to a small or negligible concentration of uncomplexed BF_3. However, the existence of two modes of exchange in these systems has been known for a long time and exchange is particularly influenced by an excess of BF_3. The most likely role of excess BF_3 is to form fluorine-bridged intermediates, and we therefore associate the two modes of exchange with the cleavage, −C, of two types of bonds, namely, bridging B--F--B bonds, as well as B—N or B—O bonds, and our proposed mechanism of reaction of pyridine with boron trifluoride is summarized as pathway P(9,4).

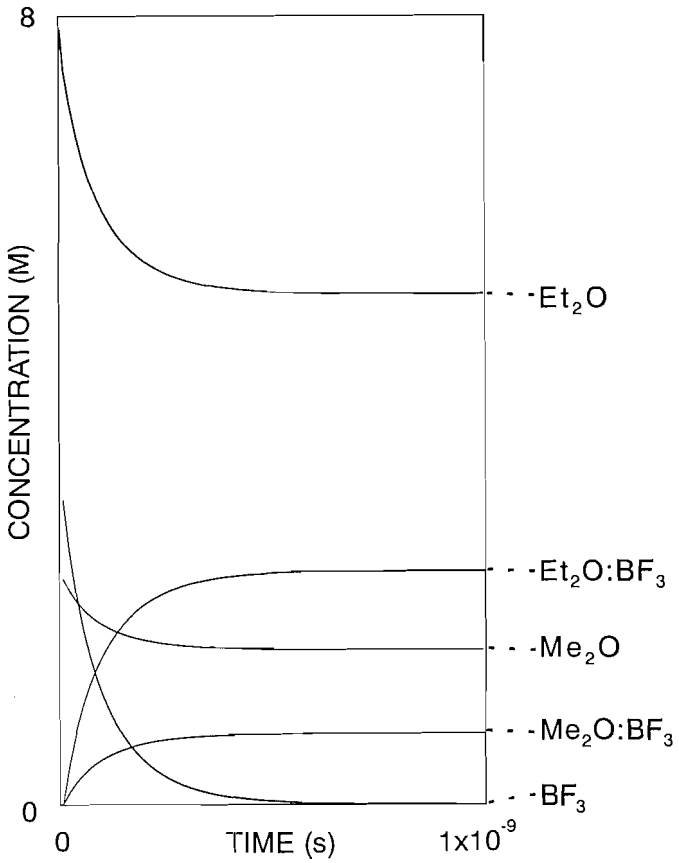

FIG. 3. Calculated concentration vs. time curves for the reaction of BF_3 with Me_2O and Et_2O. Input rate constants are given in eqs. [7] and [8].

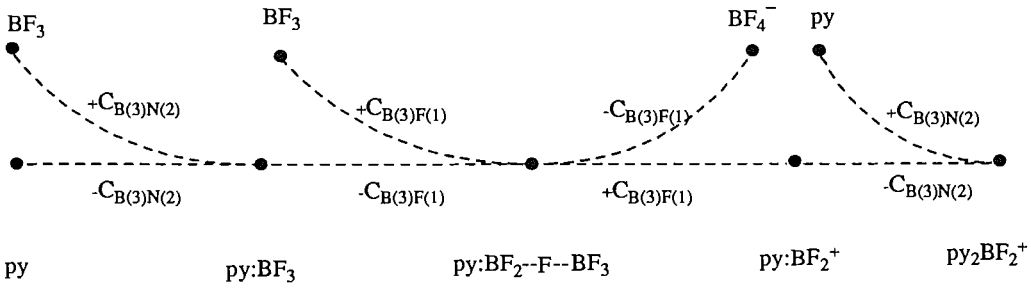

A systematic study of $(base)_2BF_2^+$ cations has been reported recently by Farquharson and Hartman (4) and fluorine-bridged adducts such as $base:BF_2\text{--}F\text{--}BF_3$ have been postulated before (17); furthermore, $F_3B\text{--}F\text{--}BF_3^-$ is stable at low temperature but undergoes rapid bond cleavage at ambient temperature (18). To simplify the analysis of the pyridine–BF_3 system, we considered only one fluorine-bridged intermediate in pathway P(9,4) although it is implicitly assumed that BF_3 can interact with all fluorine-containing species to generate other intermediates such as $py_2BF\text{--}F\text{--}BF_3^+$. Inclusion of the latter cation in a larger pathway would be a straightforward task and would be necessary if the analysis were extended to species such as py_2BF^{2+} or py_3BF^{2+}.

Our calculations require an estimate of the strength of these bridging B--F--B bonds for which experimental data are not available but, since NMR studies of fluorine exchange show "activation energies" in the range of about 15–25 kJ for boron fluorides (19), we assume that bond enthalpies are of about this magnitude. We carried out GAUSSIAN86 calculations of two possible fluorine-bridged intermediates and, as seen in Fig. 4, these show significant differences in relative bond lengths. We therefore assign, somewhat crudely, a bond strength of 25 kJ for the shorter bridging bond and 15 kJ for the longer bridging bond. An experimental B—N bond energy is not available for $py_2BF_2^+$; thus we assume the same value as for $py:BF_3$, and with these approximations it is possible to assign the rate constants of eqs. [11]–[14] and calculate a concentration vs. time curve for a 1 : 1.5 reaction of pyridine and BF_3, as shown in Fig. 5.

$$[11]\quad py + BF_3 \underset{4.53 \times 10^{-8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} py:BF_3$$

$$[12]\quad py:BF_3 + BF_3 \underset{2.34 \times 10^{8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} py:BF_2\text{--}F\text{--}BF_3$$

$$[13]\quad py:BF_2\text{--}F\text{--}BF_3 \underset{10^9\ M^{-1}\ s^{-1}}{\overset{4.13 \times 10^{6}\ s^{-1}}{\rightleftharpoons}} py:BF_2^+ + BF_4^-$$

$$[14]\quad py + py:BF_2^+ \underset{4.53 \times 10^{-8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} py_2BF_2^+$$

Figure 5 reveals that species $py:BF_2\text{--}F\text{--}BF_3$, $py:BF_2^+$, and $py_2BF_2^+$ are present in relatively modest concentration and since the rate constants for cleavage of B--F--B bonds are large it is not surprising that previous attempts to identify individual species in solution by NMR have been met with difficulty. The acceleration of fluorine exchange by excess BF_3 is readily explained by eqs. [12] and [13], and the stability of $(base)_2BF_2^+$, once isolated (4), is consistent with the estimated rate constants of eq. [14], which predict a large and favourable equilibrium constant.

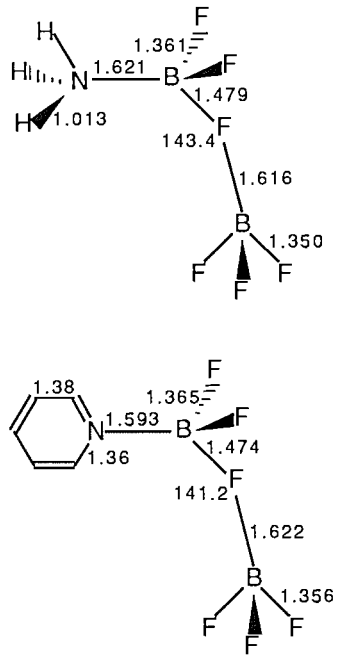

FIG. 4. GAUSSIAN86 calculations of $H_3N:BF_2\text{--}F\text{--}BF_3$ and $py:BF_2\text{--}F\text{--}BF_3$ at the 3-21G* level with full optimization, except for fixed geometry of pyridine.

Pathway P(9,4) is in agreement with previous mechanisms that require dissociation of boron-base bonds or halogen-bridge bonds, but it differs significantly in its suggestion that base exchange occurs via intermediates $(base)_2BF_2^+$ or $(base)(base')BF_2^+$ rather than exchange by collision or S_N2 processes. The latter mechanisms, if correct, would require a change in the minimum set of coordination numbers to include either B(5) or N(5), but pathway P(9,4) makes such proposals unnecessary.

$(R_3N)(py)BF_2^+$ and order of addition of base

Farquharson and Hartman found that $(R_3N)(py)BF_2^+$ is formed more rapidly when R_3N is added to $py:BF_2Br$ than when pyridine is added to $R_3N:BF_2Br$ (4). We considered the order of addition of base by analyzing the addition of trimethylamine to $py:BF_3$, eqs. [15]–[19], as compared to adding pyridine to $Me_3N:BF_3$, eqs. [20]–[24], using the bond enthalpies of Table 1 and the assumption that B—N bond

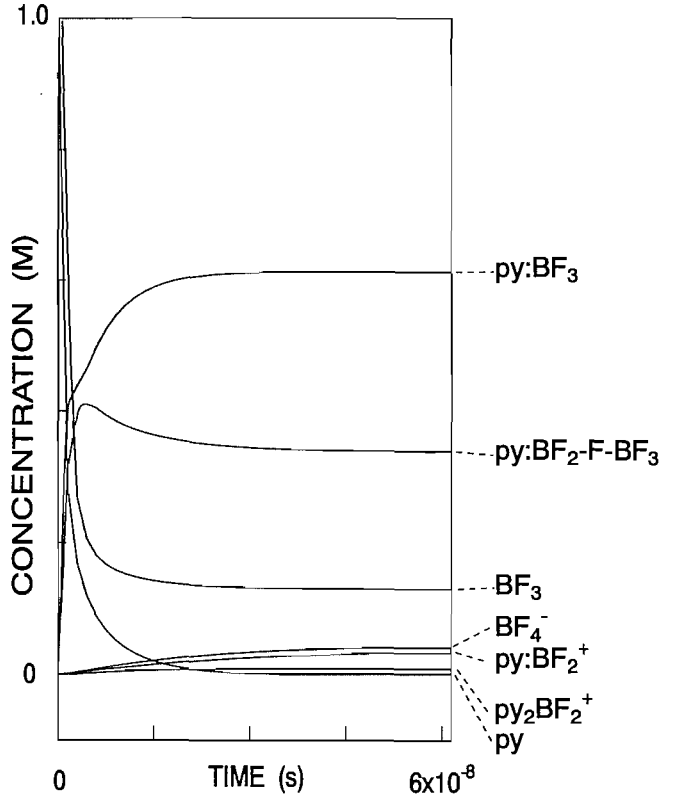

FIG. 5. Calculated concentration vs. time curves for the 1:1.5 reaction of pyridine with BF_3. Input rate constants are given in eqs. [11]–[14]. Concentration of $py_2BF_2^+$ after 6×10^{-8} s is 0.0085 M.

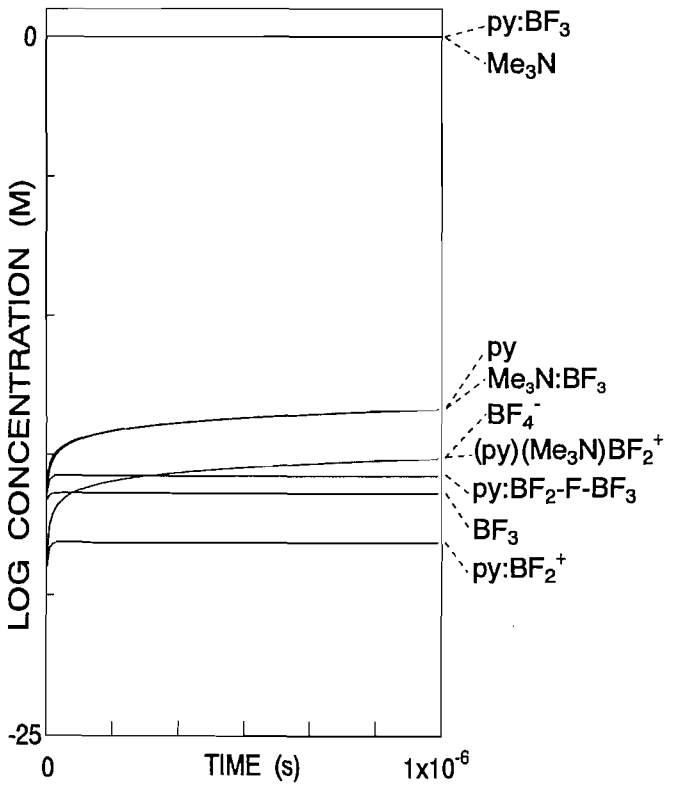

FIG. 6. Calculated log. concentration vs. time curves for the 1:1 reaction of Me_3N with $py:BF_3$. Input rate constants are given in eqs. [15]–[19]. Concentration of $(py)(Me_3N)BF_2^+$ after 1×10^{-6} s is 2.7×10^{-16} M.

strengths in $(Me_3N)_2BF_2^+$, $(Me_3N)(py)BF_2^+$, and $py_2BF_2^+$ are the same as in $Me_3N:BF_3$ and $py:BF_3$.

An abbreviated mechanism for the 1:1 reaction of Me_3N with $py:BF_3$, which includes the essential features of cleavage of B—N and B--F--B bonds, but omits other possible fluorine-bridged intermediates such as $Me_3N:BF_2$--F--BF_3, is shown in eqs. [15]–[19], and the calculated log(conc) vs. time curve is shown in Fig. 6.

$$[15]\quad py:BF_3 \underset{10^9\ M^{-1}\ s^{-1}}{\overset{4.53 \times 10^{-8}\ s^{-1}}{\rightleftharpoons}} py + BF_3$$

$$[16]\quad Me_3N + BF_3 \underset{2.12 \times 10^{-12}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} Me_3N:BF_3$$

$$[17]\quad py:BF_3 + BF_3 \underset{2.34 \times 10^{8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} py:BF_2\text{--}F\text{--}BF_3$$

$$[18]\quad py:BF_2\text{--}F\text{--}BF_3 \underset{10^9\ M^{-1}\ s^{-1}}{\overset{4.13 \times 10^{6}\ s^{-1}}{\rightleftharpoons}} py:BF_2^+ + BF_4^-$$

$$[19]\quad py:BF_2^+ + Me_3N \underset{2.12 \times 10^{-12}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} (Me_3N)(py)BF_2$$

The reverse reaction of pyridine with $Me_3N:BF_3$ is summarized in eqs. [20]–[24] and the log(conc) vs. time curve is shown in Fig. 7.

$$[20]\quad Me_3N:BF_3 \underset{10^9\ M^{-1}\ s^{-1}}{\overset{2.12 \times 10^{-12}\ s^{-1}}{\rightleftharpoons}} Me_3N + BF_3$$

$$[21]\quad py + BF_3 \underset{4.53 \times 10^{-8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} py:BF_3$$

$$[22]\quad Me_3N:BF_3 + BF_3 \underset{2.34 \times 10^{-8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} Me_3N:BF_2\text{--}F\text{--}BF_3$$

$$[23]\quad Me_3N:BF_2\text{--}F\text{--}BF_3 \underset{10^9\ M^{-1}\ s^{-1}}{\overset{4.13 \times 10^{6}\ s^{-1}}{\rightleftharpoons}} Me_3N:BF_2^+ + BF_4^-$$

$$[24]\quad Me_3N:BF_2^+ + py \underset{4.53 \times 10^{-8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} (Me_3N)(py)BF_2^+$$

Figures 6 and 7 show the concentrations after 1×10^{-6} s. Although equilibrium is far from established, the results do show that the initial concentration of $(py)(Me_3N)BF_2^+$ depends markedly on the order of addition of base, being 2.7×10^{-16} M for addition of Me_3N versus 1.7×10^{-20} M for addition of pyridine, and this increases to 5.6×10^{-14} M and 2.6×10^{-18} M, respectively, after 7.2×10^{-5} s, but longer times were impractical because of the limitation of our kinetic simulation program. An inspection of the rate constants of eqs. [15]–[24] shows clearly that the effect can be attributed mainly to the smaller N—B bond strength of the $py:BF_3$ adduct, which favours dissociation and eventual production of $py:BF_2^+$ and $(Me_3N)(py)BF_2^+$. This dissociation of base:BF_3 to produce free BF_3 is required in eqs. [17] and [22] for the cleavage of boron–fluorine bonds. Another effect may also be important, namely, the relative strength of bridging bonds B--F--B, but the lack of experi-

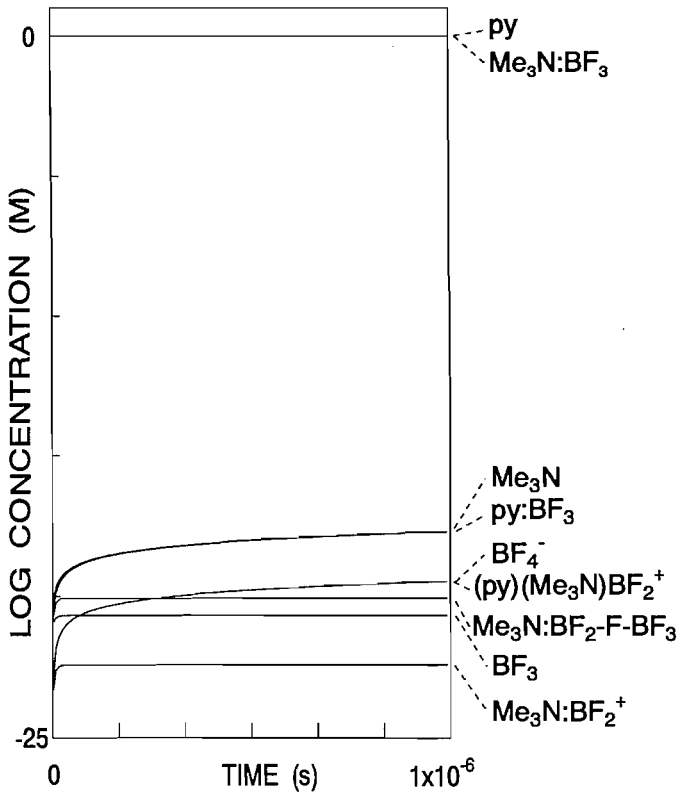

FIG. 7. Calculated log. concentration vs. time curves for the 1:1 reaction of pyridine with $Me_3N:BF_3$. Input rate constants are given in eqs. [20]–[24]. Concentration of $(py)(Me_3N)BF_2^+$ after 1×10^{-6} s is 1.7×10^{-20} M.

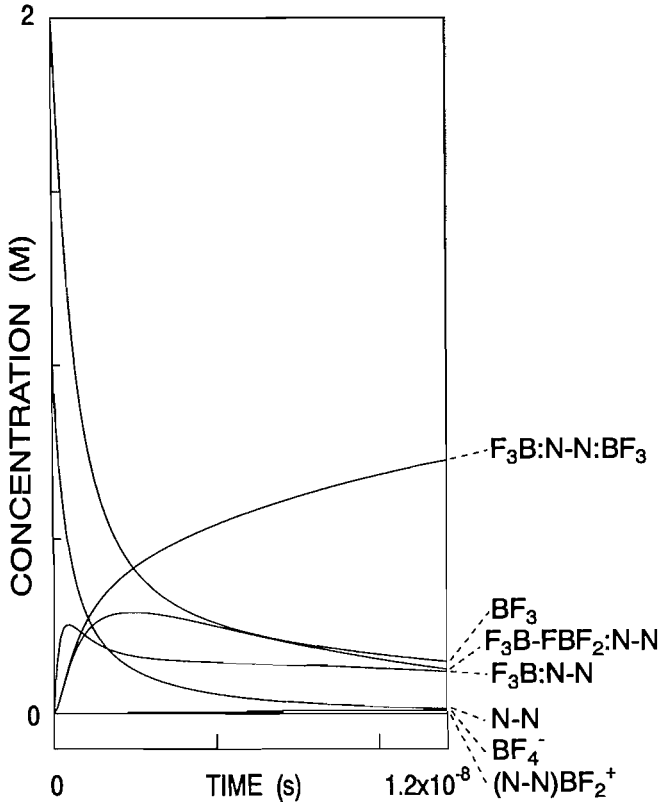

FIG. 8. Calculated concentration vs. time curves for the 2:1 reaction of BF_3 with bidentate ligand, N—N. Input rate constants are given in eqs. [25]–[29]. Concentration of $F_3B:N–N:BF_3$ and $(N–N)BF_2^+$ after 1.2×10^{-8} s is 0.73 M and 0.01 M, respectively.

mental bond strength data prevents a realistic test of this suggestion, although selective cleavage of fluorine-bridging bonds has been described for related systems (1, 2, 20).

$(N–N)BF_2^+$ and n*-center steps*

Entropy effects have been neglected in the analysis of the base–BF_3 systems discussed above, but cyclic *n*-center steps, $+C^{n\text{-center}}$, are strongly favoured by entropy, particularly 3- to 6-center steps where interacting atoms are in close proximity (1), and this introduces the possibility that changes in the ratio of $+C^{n\text{-center}}/+C$ may affect the outcome of a chemical reaction. To estimate a rate constant for ring closure, it may be noted that entropies of gas-phase reactions of BF_3 with acyclic amines are generally negative with $\Delta S = -202 \pm 8$ J mol^{-1} deg^{-1} at 0°C (21). It is also known that formation of a five-membered ring (chelate effect) in a multistep reaction of, say, $Cd^{2+}(aq)$ with ethylenediamine rather than with acyclic $MeNH_2$ leads to enhanced stability because of changes in ΔS from -67.3 to $+14.1$ J mol^{-1} deg^{-1} (22); moreover, the five-membered ring in phosphate esters also accelerates the rate of hydrolysis by factors of 10^6 to 10^8 (23). It is therefore reasonable to assume that ring closure, $+C^{5\text{-center}}$, involves a more positive entropy change than reaction with acyclic bases, +C, and we crudely estimate that entropy changes lead to an increase in the ratio $+C^{5\text{-center}}/+C$ of about 100, thus $k = 10^{11}$ s^{-1} for the ring-closure step of eq. [29].

Pathway P(10,5) and eqs. [25]–[29] may be suggested as a mechanism for reaction of BF_3 with a bidentate ligand N–N, and the question of interest is the relative yield of

$$[25]\quad N–N + BF_3 \underset{8.36 \times 10^{-9}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} N–N:BF_3$$

$$[26]\quad F_3B:N–N + BF_3 \underset{8.36 \times 10^{-9}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} F_3B:N–N:BF_3$$

$$[27]\quad N–N:BF_3 + BF_3 \underset{2.34 \times 10^{8}\ s^{-1}}{\overset{10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} N–N:BF_2\text{--}F\text{--}BF_3$$

$$[28]\quad N–N:BF_2\text{--}F\text{--}BF_3 \underset{10^9\ M^{-1}\ s^{-1}}{\overset{4.16 \times 10^{6}\ s^{-1}}{\rightleftharpoons}} N–N:BF_2^+ + BF_4^-$$

$$[29]\quad N–N:BF_2^+ \underset{8.36 \times 10^{-9}\ s^{-1}}{\overset{10^{11}\ s^{-1}}{\rightleftharpoons}} (N–N)BF_2^+$$

acyclic $F_3B:N–N:BF_3$ versus cyclic $(N–N)BF_2^+$ because the experimental evidence is not clear on this point; some authors have found only acyclic product (12), while others found cyclic cations in high yield (11). If we assume that typical B—N and B--F--B bond strengths of Table 1 apply to this system, with the B—N bond strength equal to that of $Me_3N:BF_3$, then the rate constants of eqs. [25]–[29] can be used to calculate the conc. vs. time curve shown in Fig. 8 for a 2:1 reaction of BF_3 and N–N. The results of Fig. 8 show clearly that $F_3B:N–N:BF_3$ (0.73 M) is favoured over $(N–N)BF_2^+$ (0.01 M) after 1.2×10^{-8} s. These initial concentrations are in agreement with the results of Brown and

Singaram (12) who found only $F_3B{:}NH_2CH_2CH_2NH_2{:}BF_3$ in their 2:1 reaction of BF_3 with ethylenediamine. An inspection of the rate constants of eq. [26] confirms that $F_3B{:}N{-}N{:}BF_3$ will always be favoured over any competitive reaction with BF_3. Contrary to these calculations, however, are the observations of Wiberg and Buchler (11) who reported high yields (66%) of $(N{-}N)BF_2^+BF_4^-$ in their reaction of BF_3 with the bidentate ligands tetrakis(dimethylamino)ethene and *o*-bis(dimethylamino)benzene. These authors also reported an appreciable amount (13–26%) of $^+HN{-}NH^+2BF_4^-$ among the reaction products, and the latter result leads us to suggest that an additional mechanistic feature may be responsible for the formation of cyclic products, namely, a protected species $F_3B{:}N{-}N{-}H^+$ that prevents the bidentate ligand from further reaction with BF_3, as in eq. [26]; subsequent deprotonation then favours cyclic $(N{-}N)BF_2^+$, as in eq. [29]. The synthesis of a related cyclic cation $(N{-}N)PF_4^+$ is also accompanied by the formation of $N{-}NH^+PF_6^-$, where N–N is bipyridine, 4-fluorobipyridine, and phenanthroline (2), but the simulation of a more complex pathway that includes protonation and deprotonation steps is beyond the capacity of our kinetic program, although analogous systems have been studied by NMR in which protonation–deprotonation is coupled to a rapid 5-center step, e.g., the base–$R_2P(O)OC(CF_3)_2C(CF_3)_2OH$ system (24).

In conclusion, the coordination model of reaction mechanisms has been tested mathematically by comparing calculated with experimental results for the reactions of boron trifluoride with amines and ethers, and the model appears to account in a satisfactory manner for all experimental details, at least in a semi-quantitative manner. This model allows chemical reactions to be analyzed in three stages: firstly, construct a pathway P(*X*,*C*) which specifies the connectivity of all atoms of that pathway; secondly, apply molecular orbital calculations to the postulated intermediates to assist in the task of estimating relative bond strengths and selecting individual steps of multistep pathways; and, thirdly, carry out kinetic simulations of all possible pathways P(*X*,*C*) and obtain the conc. vs. time curves on which further analysis and prediction is based.

Methods

The kinetic simulations were carried out by means of the standard fourth-order Runge–Kutta algorithm (13) here implemented in terms of MathCad software (14). Difficulties associated with the fact that rate constants varied over a wide range, i.e., "stiffness" of the equations, were dealt with by partitioning the time interval into sections and by choosing as large a time interval within each section as was consistent with obtaining an accurate solution. All calculations were carried out on a 386PC using the MathCad 3.1 program, and a typical kinetic simulation of a four-step, nine-species system required 30 min of computational time per time interval.

Ab initio SCF geometries were calculated for $H_3N{:}BF_2{-}F{-}BF_3$ and $py{:}BF_2{-}F{-}BF_3$ using the GAUSSIAN86 program at the 3-21G* level with full optimization, except for pyridine where a fixed geometry was chosen (25).

Introduction

The Sharpless epoxidation (1) has been hailed as one of the milestones in organic chemistry. The reaction gives chiral epoxides with predictable stereochemistry and high enantiomeric purity. Since its discovery, the reaction has been used in numerous syntheses of natural products (2). The reaction has, however, one serious limitation in that it can only be applied to allylic alcohols. The hydroxy group in the allylic position plays a critical role in assembling the reactants together (3), thus accelerating the reaction as well as conferring high stereoselectivity. For simple alkenes without the pendant hydroxy group, Sharpless epoxidation is not useful. There is no ready method for preparing simple chiral epoxides with high enantioselectivity.[2] In a preliminary report, we outlined an approach to this problem (5).

We previously showed that trimethyl- or triphenyl-silyl epoxides can be protodesilylated in the presence of fluoride ion to give the corresponding epoxides with retention of stereochemistry (6). It seemed to us that alkenylsilanols, which are structurally similar to allylic alcohols, should be amenable to Sharpless epoxidation. The silyl group could then be excised by fluoride ion to give the simple epoxides. The overall transformation (Scheme 1) is then an enantioselective synthesis of simple epoxides. The success of this approach is, however, predicated on the assumption that alkenylsilanols would behave like allylic alcohols in the Sharpless epoxidation reaction, an assumption that remains to be tested.

Results

Preliminary studies

Since silanols are known to dimerize readily to the disiloxanes, we chose β-styryldiphenylsilanol (**1**) as our first example to investigate in the expectation that the more bulky phenyl groups (relative to, e. g., methyl groups) on the silicon may inhibit the dimerization sufficiently to permit the Sharpless epoxidation to take place. Compound **1** was prepared by the reaction of *trans*-β-styryllithium (**2**), generated by metal–halogen exchange of *trans*-β-bromostyrene with *tert*-butyllithium, with diphenyldichlorosilane followed by aqueous hydrolysis. The silanol **1**, obtained in 90% yield, was indeed stable and did not dimerize to disiloxane on flash chromatography. The disiloxane **3** could, however, be obtained from **1** on long standing. Epoxidation of **1** with *m*-chloroperbenzoic acid (MCPBA) gave the corresponding epoxysilanol **4** in 75% yield. Treatment of **4** with tetraethylammonium fluoride hydrate in MeCN gave styrene oxide in excellent yield (Scheme 2).

When **1** was subjected to Sharpless epoxidation conditions [$Ti(O\text{-}i\text{-}Pr)_4$/(+)-diethyl tartrate (DET)/*tert*-butyl hydroperoxide (TBHP)] in CH_2Cl_2 at −40°C, the reaction was very slow. The reaction was faster at −20°C, giving **4** in 70% yield after 48 h. The epoxide **4** was optically active ($[\alpha]_D^{22}$ −4.8 (*c* 0.25, C_6H_6)). The hydroxy group was critical in this reaction as demonstrated by the fact that the disiloxane **3**, though structurally similar to **1**, was not epoxidized under similar conditions even after a prolonged reaction time at a higher temperature. Protodesilylation of **4** by fluoride ion gave (S)-styrene oxide with 7% enantiomeric excess (ee) according to optical rotation as well as ^1H nmr using tris[3-(heptafluoropropylhydroxymethylene)-(+)-camphorato]europium(III), [(+)-Eu(hfc)$_3$]. The use of molecular sieves, as recommended by Sharpless and coworkers (7), improved slightly the rate of epoxidation and increased the ee of the styrene oxide obtained to 20%.

Notwithstanding the rather modest ee obtained in these experiments, the results were considered encouraging. The epoxidation of **1** is likely to have taken place by a mechanism, whatever it may be (8), similar to the allylic alcohol oxidation. This is supported by the fact that the silanol function was necessary for the epoxidation to take place. Furthermore, the absolute configuration of the epoxide **4** was in agreement with the stereochemical model proposed by Katsuki and Sharpless for allylic alcohols (1). We attributed the low stereoselectivity of the reaction to the steric effect of the diphenylsilyl group. While the Sharpless epoxidation has been successful with allylic primary and secondary alcohols, there is little information on the stereoselectivity for allylic tertiary alcohols. We decided to examine the correponding dimethylsilanol **6**.

*Styrene oxide via Sharpless epoxidation of β-styryldimethylsilanol (**6**)*

Compound **6** could not be prepared in good yield by the reaction of β-styryllithium (**2**) with dimethyldichlorosilane

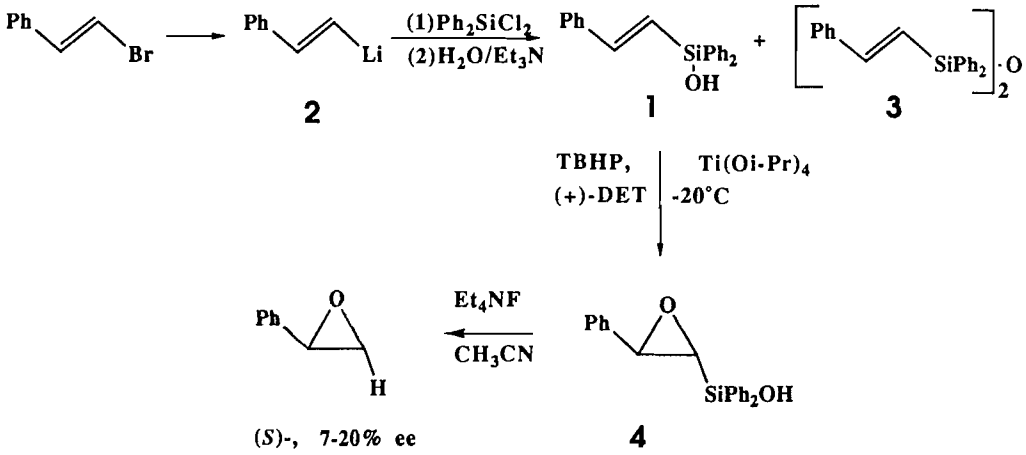

SCHEME 2

or dimethyldiethoxysilane. The difficulty was due to the relative ease of substitution leading to distyryl or disiloxane compounds. Alternative methods of preparing silanols have to be sought. In connection with other research projects in this laboratory, we observed that aminomethylsilyl compounds (9) can be converted to silanols under oxidative conditions (10). Thus, reaction of β-styryllithium with chloromethyldimethylchlorosilane (**7**) gave compound **8** in 82% yield. Heating **8** in pyrrolidine at 80°C for 20 h gave the aminosubstituted silane **9** in 73% yield (Scheme 3). Oxidation of **9** with MCPBA/$CaCO_3$ in CH_2Cl_2 or TBHP/$VO(acac)_2$ in acetone gave a mixture of the silanol **6** and the disiloxane **10** that could be separated by flash chromatography.

Compound **6** can be more conveniently synthesized by an alternative route (Scheme 4). Reaction of β-styryllithium with dimethylchlorosilane (**11**) gave the silane **12** in 92% yield. Oxidation of **12** with silver nitrate/silver oxide in tetrahydrofuran (THF) at room temperature for 9 h gave **6** in good yield (71%). The relative amount of silver nitrate to silver oxide used was critical to the success of the reaction. Too much of either component led to greater amount of the disiloxane **10**, presumably due to the catalytic effect of the acidic or basic nature of the reagents.

Epoxidation of the freshly purified **6** under Sharpless conditions with (+)-DET in CH_2Cl_2 at −20°C for 40 h gave compound **13** in 50% yield. Fluoride ion cleavage of **13** gave (*S*)-styrene oxide (90% yield) with high enantiomeric excess (85–95%, depending on different runs, according to optical rotation and ^1H nmr with (+)-$Eu(hfc)_3$).

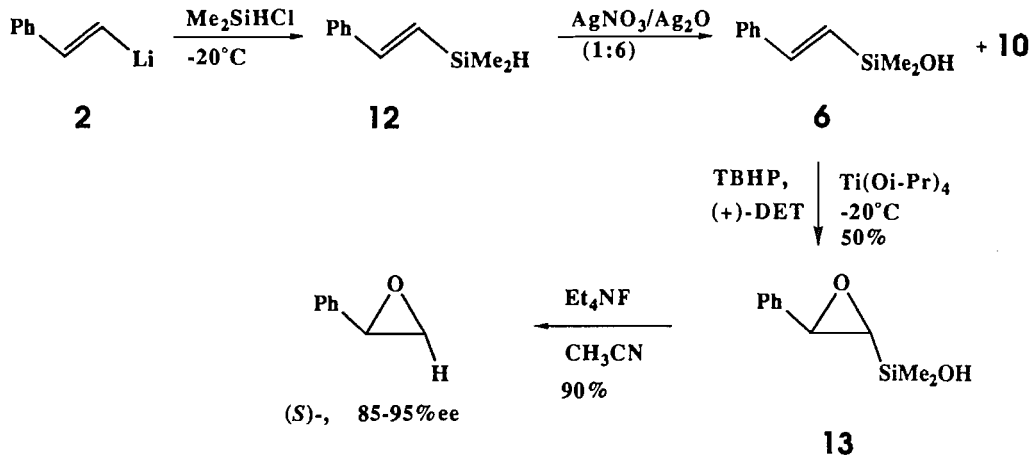

SCHEME 4

1,2-Epoxyheptane (19)

The success in preparing styrene oxide enantioselectively encouraged us to explore the Sharpless epoxidation of other alkenylsilanols. A convenient method of generating the requisite vinylmetallic reagents was by way of hydroalumination of alkynes. Thus, treatment of 1-heptyne with diisobutylaluminium hydride (DIBAL) followed by quenching the mixture with dimethylchlorosilane gave 1-heptenyldimethylsilane (**15**). Oxidation of the silane **15** with $AgNO_3$/Ag_2O gave the silanol **16** in 75% yield (Scheme 5). Epoxidation of **16** with (+)-diisopropyl tartrate (DIPT) and the usual reagents at −20°C gave the epoxysilanol **18**. Compound **18** appeared to be unstable on column chromatography, so the crude product was protodesilylated directly by tetraethylammonium fluoride hydrate in CH_3CN to give (S)-(−)-1,2-epoxyheptane, $[\alpha]_D^{18}$ −18.5 (*c* 0.25, CH_2Cl_2). The ee was determined to be 85% by ^1H nmr using (+)-Eu(hfc)$_3$].

1,2-Epoxy-2-methylundecane (26)

We are interested in extending the generality of this reaction. Compound **26** represents a simple epoxide with two alkyl substituents in one of the epoxide carbon. The precursor silanol **23** was prepared by a general route (Scheme 6) recently developed by us (11). Reaction of (2-methylallyl)-dimethyl-*N*,*N*-diisopropylaminosilane (**20**) with Schlosser's base (*n*-BuLi/*t*-BuOK) (12) generated the carbanion **21**. Quenching the carbanion **21** with *n*-octyl bromide gave a mixture of the γ- and α-alkylation products **22**γ and **22**α in a ratio of 14:1. The crude mixture was hydrolysed and purified at the same time by passing through a column of wet (10% H_2O) alumina to give the silanol **23**. Sharpless epoxidation of **23** using (+)-DET gave the disiloxane **24**, presumably via the silanol **25** first. The crude **24** was treated by fluoride ion to give (S)-(−)-**26**, $[\alpha]_D$ −12.2 (*c* 0.3, EtOH). Its ee was determined to be 90% by ^1H nmr with (+)-Eu(hfc)$_3$.

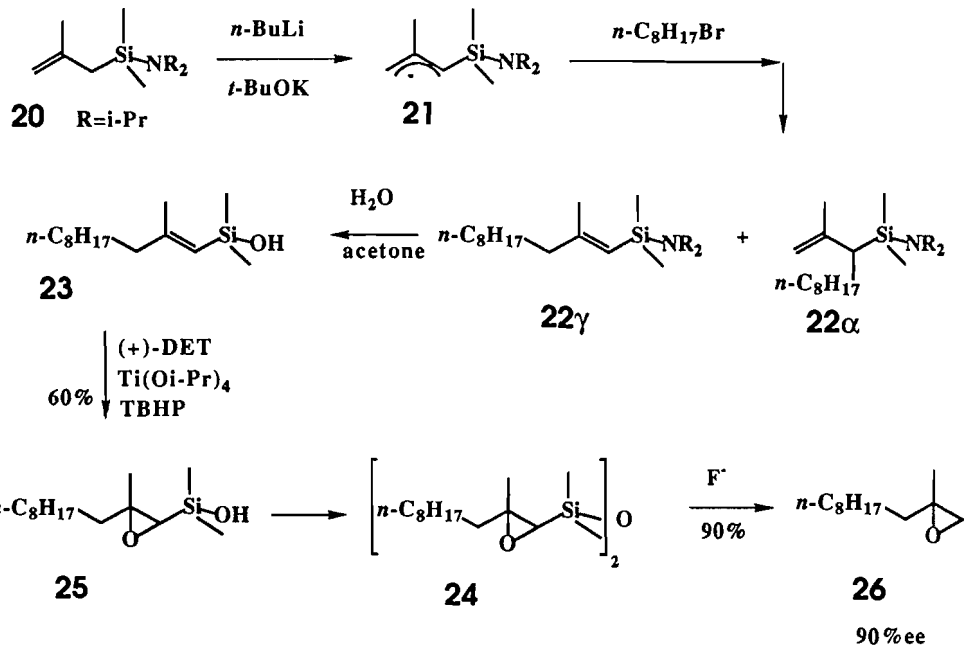

SCHEME 6

Enantioselective synthesis of (S)-(−)-frontalin (33)

We demonstrated the application of the alkenylsilanol methodology by the enantioselective synthesis of (*S*)-(−)-frontalin (**33**), an aggregation pheromone produced by the female southern pine beetle, *Dendroctonus frontalins* (13). Alkylation of the carbanion **21** with the alkyl iodide **27**, followed by mild hydrolysis, gave the silanol **29** (Scheme 7). Epoxidation of **29** under Sharpless conditions using (+)-DET gave the disiloxane **30**, presumably through the dimerization of the silanol **31**. Protodesilylation of **30** under the usual conditions gave the epoxy compound **32**, $[\alpha]_D$ +1.8 (*c* 3, EtOH). The ee of **32** was determined to be 85% using ^{1}H nmr with the Eu chiral shift reagent. Acid-catalysed deketalization of **32** following literature procedure gave (*S*)-(+)-frontalin (**33**) (18).

Discussion

The mechanism of the Sharpless epoxidation is a subject of much discussion (8). An important, and synthetically useful, feature of the asymmetric epoxidation reaction is its ability to accommodate a wide variety of allylic alcohols. The present results suggest that alkenylsilanols can be accommodated in the same manner as allylic alcohols. Presumably, the alkenylsilanol coordinates to the active Ti-tartrate

catalyst together with the alkyl peroxide. It has been argued that the high and consistent enantioselectivity in the epoxidation of allylic alcohols is due to the stereoelectronic orientation required by the olefinic moiety in attacking the coordinated peroxide along the O—O bond axis. Since the atomic radius of silicon is considerably larger than that of carbon, it seems that the stereoelectronic requirement in the epoxidation step may be sufficiently flexible to accommodate the increased bond length of Si—O and Si—C bonds in the alkenylsilanol. This is to be contrasted with the epoxidation of homoallylic alcohols where the enantioselectivity was found to be poor (19). Furthermore, the face selection in the epoxidation of homoallylic alcohol is opposite from that observed for allylic alcohols (19) and alkenylsilanols. This suggests that the facial selection is governed less by the distance between the double bond and the hydroxy group than by the relative angle of the two functionalities.

In any event, the Sharpless epoxidation of alkenylsilanols coupled with fluoride-promoted protodesilylation provides an entry to the enantioselective synthesis of simple epoxides. It remains to be seen whether the silyl moiety in the chiral epoxysilanols can be replaced by electrophiles other than proton. Should that be the case, the synthetic utility would be greatly enhanced.

Experimental[3]

*β-Styryldiphenylsilanol (**1**)*

To a solution of β-bromostyrene (16.0 g, 87.0 mmol) in ether (120 mL), a solution of *tert*-butyllithium (1.7 M in pentane, 60 mL, 92.0 mmol) was added dropwise at −78°C. After stirring for 5 h, diphenyldichlorosilane (21.2 g, 84.0 mmol) was added. The mixture was stirred at room temperature overnight, and then at reflux for 14 h. The resulting suspension was poured into a mixture of triethylamine (1.4 mL), ether (20 mL), and water (40 mL) at 0°C. The mixture was extracted with ether three times and the combined extracts were dried ($MgSO_4$) and concentrated *in vacuo*. The residue was purified by flash chromatography (hexane–$CHCl_3$, 1:3) to give a light yellow oil **1** (27.0 g, 90% yield).Compound **1** had ^{1}H nmr ($CDCl_3$): 2.62 (s, 1H, D_2O exchangeable), 6.72 and 7.20 (AB, 2H, J = 19 Hz), 7.28–7.51 (m, 5H); ms (EI): 302 (31), 224 (74), 199 (46), 180 (100). Exact Mass calcd. for $C_{20}H_{18}OSi$: 302.112; found: 302.117.

*1-(2-Phenyl-1,2-epoxyethyl)diphenylsilanol (**4**)*

A mixture of MCPBA (0.40 g, 2.3 mmol), $NaHCO_3$ (0.80 g), and compound **1** (0.64 g, 2.1 mmol) in CH_2Cl_2 (5 mL) was stirred for 24 h at room temperature. The resulting white solids were removed by filtration and the filtrate was washed with aqueous 5% Na_2SO_3 solution, then aqueous 5% Na_2CO_3 solution, then water, and dried ($MgSO_4$). The solvent was evaporated and the residue was purified by flash chromatography (hexane – ethyl acetate – $CHCl_3$, 8:1:1) to gve a pale yellow oil **4** (0.48 g, 75% yield). Compound **4** had ^{1}H nmr ($CDCl_3$): 1.62 (s, 1H), 2.79 (d, 1H), 2.90 (d, 1H), 7.30–7.8 (m, 5H); ms (CI, NH_3): 336 ($M+NH_4^+$, 17), 319 (MH^+, 48), 318 (M^+, 79), 301.

(S)-Styrene oxide via Sharpless epoxidation of 1

To a mixture of CH_2Cl_2 (30 mL) and 4A molecular sieves (2 g), titanium(IV) isopropoxide (0.50 g, 2.6 mmol) was added followed by a solution of (+)-diethyl L-tartrate (0.50 g, 3.1 mmol) in CH_2Cl_2 (5 mL) at −20°C. The mixture was stirred for 10 min. The silanol **1** (0.77 g, 2.6 mmol) in CH_2Cl_2 (8 mL) and TBHP (3 M in 2,2,4-trimethylpentane, 2.1 mL) were added. The mixture was kept at 0°C and stirred for 24 h. The mixture was filtered to remove the molecular sieves. To the filtrate, an aqueous solution of 10% tartaric acid (8 mL) was added and the mixture was stirred at 0°C for 30 min. The stirring was continued at room temperature until the aqueous layer became clear. The organic phase was then separated, washed with water, and dried ($MgSO_4$). The solvent was removed *in vacuo* and the residue was diluted with ether, followed by addition of 1 N NaOH solution at 0°C. The mixture was stirred for 1 h. The organic phase was separated, washed with brine, dried ($MgSO_4$), and evaporated. The residue was purified by flash chromatography (hexane – ethyl acetate – $CHCl_3$, 6:1:2) to give compound **4** (0.60 g, 71% yield), identical in spectroscopic data with the racemic compound prepared above. A solution of **4** (0.20 g, 0.67 mmol) thus obtained and tetraethylammonium fluoride hydrate (0.16 g, 1.0 mmol) in CH_3CN (8 mL) was stirred for 3 h at room temperature. Water was added and the mixture was extracted with ether. The combined organic phase was dried ($MgSO_4$) and evaporated. The residue was purified by flash chromatography (hexane – ethyl acetate, 100:3) to give (*S*)-styrene oxide (0.07 g, 90% yield) identical in all respects with an authentic sample. It had $[\alpha]_D^{22}$ −8.90° (*c* 0.25, benzene). When the epoxidation was carried out without the 4A molecular sieves, the styrene oxide obtained had $[\alpha]_D^{22}$ −3.70 (*c* 0.25, benzene).

*β-Styryldimethylsilane (**12**)*

To a solution of β-bromostyrene (9.9 g, 50 mmol) in ether (75 mL) was added dropwise a solution of *tert*-butyllithium (1.57 M in pentane, 70 mL) at −20°C. The mixture was stirred for 2 h. Dimethylchlorosilane (5.6 mL) was added slowly at −20°C and the mixture was stirred overnight at room temperature. The mixture was filtered to remove the solids, and water was added to the filtrate. The organic phase was washed with water, dried ($MgSO_4$), and evaporated. The residue was purified by flash chromatography (hexane) to give **12** as a colourless liquid (6.1 g, 92% yield); ^{1}H nmr ($CDCl_3$): 0.22 (d, 6H, J = 3 Hz), 4.20 (m, 1H), 6.45 (A of AB, dd, 1H, J = 19, 3 Hz), 7.01 (B of AB, 1H, J = 19 Hz), 7.28–7.5 (m, 5H); ms (EI): 162 (44), 147 (100). Exact Mass calcd. for $C_{10}H_{14}Si$: 162.087; found: 162.086.

*β-Styryldimethylsilanol (**6**)*

A mixture of 4A molecular sieves (1.0 g), silver nitrate (0.14 g, 0.82 mmol), silver oxide (0.88 g, 3.8 mmol), and **12** (0.60 g, 3.7 mmol) in THF (90 mL) was stirred for 9 h at room temperature. The mixture was filtered through a layer of silica gel and the filtrate evaporated. The residue was purified by flash chromatography (hexane – ethyl acetate, 9:1) to give **6** as a light yellow liquid (0.46 g, 71% yield); ir (film): 3287 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.30 (s, 6H), 1.66 (s, 1H, D_2O exchangeable), 6.49 and 7.01 (AB, 2H, J = 19 Hz), 7.25–7.35 (m, 5H); ms (EI): 178 (45), 160 (100), 145 (83). Exact Mass calcd. for $C_{10}H_{14}OSi$: 178.081; found: 178.081.

*β-Styrylchloromethyldimethylsilane (**8**)*

To a solution of β-bromostyrene (7.0 mL, 50 mmol) in ether (75 mL) was added dropwise a solution of *tert*-butyllithium in pentane (1.57 M, 70 mL) at −25°C. The mixture was stirred at −25°C for 2 h. Chloromethyldimethylchlorosilane (7.6 g, 50 mmol) was added dropwise to the dark red solution. After the addition was completed, the reaction mixture was allowed to warm to room temperature and stirred overnight. The mixture was filtered and the filtrate was washed with water and dried ($MgSO_4$). Distillation of the solution gave 9.0 g (82% yield) of a colourless liquid **8**, bp 77–80°C/0.08 Torr (1 Torr = 133.3 Pa); ^{1}H nmr ($CDCl_3$): 0.31 (s, 6H), 2.89 (s, 2H), 6.45 and 6.99 (AB, 2H, J = 20 Hz), 7.26–7.52 (m, 5H); ms (EI): 212 (4), 210 (19), 161 (100). Exact Mass calcd. for $C_{11}H_{15}SiCl$: 210.063; found: 210.067.

*β-Styryl-N-pyrrolidinylmethyldimethylsilane (**9**).*

A mixture of **8** (4.9 g, 23 mmol) and pyrrolidine (8 mL) was heated at 80°C in a bomb for 20 h. The reaction mixture was cooled, added to water, and extracted with ether. The ether phase was dried

[3]For experimental details, see refs. 9*a* and 14. The homogeneity of new compounds after flash chromatography was verified by thin-layer chromatography.

For personal use only.

($MgSO_4$) and distilled to give 3.9 g of colourless liquid **9**, bp 96–98°C/0.1 Torr; ^{1}H nmr ($CDCl_3$): 0.24 (s, 6H), 1.76 (m, 4H), 2.16 (s, 2H), 2.49 (m, 4H), 6.51 and 6.94 (AB, 2H, J = 19 Hz), 7.26–7.52 (m, 5H); ms (EI): 245 (11), 230 (3), 145 (14), 84 (100). Exact Mass calcd. for $C_{15}H_{23}NSi$: 245.160; found: 245.162.

*β-Styryldimethylsilanol (**6**) from oxidation of **9***

To a suspension of MCPBA (2.3 g, 13 mmol) and $CaCO_3$ (2.0 g, 20 mmol) in CH_2Cl_2 (40 mL), a solution of **9** (2.7g, 11 mmol) in CH_2Cl_2 (8 mL) was added at −30°C. The reaction mixture was stirred at −30°C and the progress of the reaction was followed by gas chromatography. Upon complete disappearance of the starting material **9**, the mixture was quenched with 5% aqueous Na_2SO_4. The organic phase was washed with water, dried ($MgSO_4$), and evaporated. The residue was purified by flash chromatography (hexane – ethyl acetate, 5:1) to give compound **6** (0.25 g, 13% yield) and the disiloxane **10** (1.4 g, 78% yield). Compound **10** showed no OH absorption in the ir. It had ^{1}H nmr ($CDCl_3$): 0.31 (s, 6H), 6.50 and 7.01 (AB, 2H, J = 19 Hz), 7.28–7.54 (m, 5H); ms (EI): 338 (3), 254 (75), 219 (44), 161 (37), 145 (52), 127 (100). Alternatively, oxidation of **9** could be accomplished by heating **9** (1.9 g, 7.8 mmol), $VO(acac)_2$ (0.03 g), and TBHP (3 M in 2,2,4-trimethylpentane, 6 mL) in acetone (5 mL) at 70°C overnight. Work-up as above gave **6** (0.3 g, 16%) and **10** (0.6 g. 46%).

*1-(2-Phenyl-1,2-epoxyethyl)dimethylsilanol (**13**)*

To a solution of $Ti(O\text{-}i\text{-}Pr)_4$ (0.68 g, 2.4 mmol) in CH_2Cl_2 (20 mL) at −20°C was added a solution of ethyl L-tartrate (0.58 g, 2.9 mmol) in CH_2Cl_2 (10 mL). The mixture was stirred for 10 min. A solution of **6** (0.46 g, 1.8 mmol) in CH_2Cl_2 (10 mL) was added, followed by a solution of TBHP (3 M in 2,2,4-trimethylpentane, 1.6 mL). The mixture was stirred at −20°C for 40 h. To the reaction mixture, saturated Na_2SO_4 solution (5 mL) and ether (150 mL) were added and stirred at room temperature for 4 h. The mixture was filtered through a layer of silica gel (1 cm) and washed thoroughly with ether. To the combined filtrate was added 10% NaOH solution (10 mL) and the mixture was stirred for 15 min at 0°C. The organic phase was washed with brine, dried ($MgSO_4$), and evaporated. The residue was purified by flash chromatography (hexane – ethyl acetate, 8:1) to give the silanol **13** (0.23 g, 50% yield); ir (film): 3390 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.30 (s, 3H), 0.32 (s, 3H), 1.87 (s, 1H), 2.35 (d, 1H, J =3 Hz), 3.81 (d, 1H, J =3 Hz), 7.25–7.35 (m, 5H); ms (EI): 194 (33), 161 (31), 120 (25), 91 (45), 75 (100). Exact Mass calcd. for $C_{10}H_{14}O_2Si$: 194.076; found: 194.078.

*(S)-(−)-Styrene oxide via **13***

A solution of **13** (0.20 g, 0.67 mmol) and tetraethylammonium fluoride hydrate (0.16 g, 1.0 mmol) in acetonitrile (8 mL) was stirred for 3 h at room temperature. The mixture was partitioned between water and ether. The ether phase was dried ($MgSO_4$) and evaporated. The residue was purified by flash chromatography (hexane–ether, 25:1) to give (*S*)-(−)-styrene oxide (0.11 g, 90% yield), $[\alpha]_D^{18}$ −15.0°C (*c* 0.25, ether).

*1-Heptenyldimethylsilane (**15**)*

To a solution of 1-heptyne (0.9 6g, 10 mmol) in *n*-hexane (4 mL), a solution of DIBAL in toluene (1.5 M, 6.7 mL, 10 mmol) was added dropwise at room temperature over 30 min under an argon atomsphere. The mixture was warmed to 50°C and stirred for 4 h. The mixture was cooled to 0°C and a solution of dimethylchlorosilane (1.1 mL, 10 mmol) in THF (8 mL) was added. The resultant mixture was stirred overnight at room temperature. The mixture was transferred to a solution of 5% sulfuric acid (10 mL) and *n*-hexane (10 mL) cooled with an ice bath. The aqueous phase was washed with ether. The combined organic phase was washed with 10% aqueous sodium bicarbonate solution, dried ($MgSO_4$), and evaporated. The residue was purified by flash chromatography (hexane) to give **15** (1.21 g, 77%) as a colorless liquid; ^{1}H nmr ($CDCl_3$): 0.12 (d, 6H, J = 3 Hz), 0.89 (t, 3H, J = 7 Hz), 1.29 (m, 6H), 4.03 (m, 1H), 5.60 (bd, 1H, J = 19 Hz), 6.17 (dt, 1H, J = 19, 6 Hz); ms(EI): 156 (0.8), 141 (18), 127 (30), 97 (26), 85 (50), 71 (38), 59 (100). Exact Mass calcd. for $C_9H_{20}Si$: 156.133; found: 156.137.

*1-Heptenyldimethylsilanol (**16**)*

A mixture of molecular sieves 4A (1.0 g), silver nitrate (0.10 g, 0.6 mmol), silver oxide (0.60 g, 2.6 mmol), and 1-heptenyldimethylsilane (**15**, 0.40 g, 2.6 mmol) in THF (70 mL) was stirred at 30°C for 9 h. The mixture was filtered through a layer of silica gel. The filtrate was evaporated and the residue was purified by flash chromatography (hexane – ethyl acetate, 9:1) to give **16** as a pale yellow liquid (0.30 g). The disiloxane **17** was also isolated from the column as a pale yellow oil (0.04 g). Compound **16** had ir (film): 3286 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.98 (s, 6H), 0.88 (t, 3H, J = 7 Hz), 1.29 (m, 6H), 1.54 (s, 1H, D_2O exchangeable), 2.10 (m, 2H), 5.64 (bd, J = 19 Hz, 1H), 6.19 (dt, J = 19, 7 Hz, 1H); ms (EI): 172 (1.0), 157 (100), 101 (28), 97 (21). Exact Mass calcd. for $C_8H_{17}OSi$ $(M-15)^+$: 157.105; found:157.103.

Compound **17**: ir (film), no absorption at 3286 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.98 (s, 12H), 0.88 (t, 6H, J = 7 Hz), 1.29 (m, 12H), 2.10 (m, 4H), 5.57 (bd, 2H, J = 19 Hz), 6.09 (dt, 2H, J = 19, 7 Hz).

*1-(1,2-Epoxyheptanyl)dimethylsilanol (**18**)*

Diisopropyl L-tartrate (1.1 mL, 5.2 mmol) and 4A molecular sieves (0.5 g) were added sequentially at −20°C to a solution of dichloromethane (8 mL) and titanium isopropoxide (1.3 mL, 4 mmol). The mixture was stirred for 0.5 h. A solution of **16** (0.35 g, 2 mmol) in dichloromethane (4 mL) and a solution of TBHP (3 M, 4 mL) in 2,2,4-trimethylpentane were added sequentially via syringe at −20°C. The mixture was stirred for 44 h at −20°C. A mixture of saturated Na_2SO_4 solution (4 mL) and ether (150 mL) was added and stirred for 4 h. The white solid formed was filtered through a layer of Celite (1 cm) and silica gel (1 cm) and washed thoroughly with ether. To the filtrate was added a solution of 10% sodium hydroxide (15 mL) and the mixture was stirred for 2 h at 0°C. The organic layer was washed with brine and dried over $MgSO_4$. The organic solvent was removed *in vacuo* to give compound **18** (0.30 g, 70%) as a residual oil. Compound **18** appeared to be unstable on column chromatography. The crude product was therefore used directly for the following step without purification. Compound **18** had ir (film): 3390 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.19 (s, 3H), 0.21 (s, 3H), 0.89 (t, 3H, J = 7 Hz), 1.30 (m, 8H), 1.99 (d, 1H, J = 2 Hz), 2.88 (m, 1H); ms (EI): 188 (1), 158 (25), 131 (55), 116 (49), 75 (100). Exact Mass calcd. for $C_9H_{20}O_2Si$: 188.123; found: 188.123.

*(−)-1,2-Epoxyheptane (**19**)*

A solution of compound **18** (0.10 g, 0.52 mmol) and tetraethylammonium fluoride hydrate (1.2 g, 3.5 mmol) in acetonitrile (2 mL) was stirred at 60°C for 6 h. The mixture was partitioned between water and pentane–ether (20:1) solutions. The organic phase was dried ($MgSO_4$) and the solvent removed by careful distillation. The residue was purified by flash chromatography (pentane–ether, 25:1) to give 1,2-epoxyheptane (0.045 g). It had $[\alpha]_D^{18}$ −18.5 (*c* 0.25, CH_2Cl_2). Its ^{1}H nmr spectrum ($CDCl_3$): 0.89 (t, 3H), 1.30 (m, 4H), 1.49 (m, 2H), 2.45 (dd, 1H, J = 5, 3 Hz), 2.74 (dd, 1H, J = 5, 4 Hz), 2.90 (m 1H) was identical to that of an authentic racemic sample prepared by epoxidation of 1-heptene. The enantiomeric excess (ee) was determined to be 85% by ^{1}H nmr using tris-3-(heptafluoropropylhydroxymethylene)-(−)-camphorato europium(III) as chemical shift reagent (CSR). The proton at 2.74 ppm was split by the chiral CSR (1.5 equiv.) into two peaks and integration of the two peaks in the racemic versus the optically active compounds gave the ee.

*3-(2-Methylpropenyl)-N,N-diisopropylaminodimethylsilane (**20**)*

A solution of freshly prepared 2-methylpropenylmagnesium chloride in THF (1 M, 150 mL) was added to a solution of *N,N*-diisopropylaminodimethylchlorosilane (19.4 g, 0.1 mol) (15) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

THF (50 mL). The mixture was refluxed overnight. Much of the THF was removed by distillation. The residue was extracted thoroughly with petroleum ether. The combined extracts were distilled under reduced pressure to give 20.1 g (96% yield) of compound **20** as a colourless liquid, bp 118–119°C/45 Torr; ^{1}H nmr (CCl_4): 0.15 (s, 6H), 1.20 (d, 12H, J = 7 Hz), 1.60 (s, 2H), 1.80 (s, 3H), 3.30 (m, 2H), 4.53 (b, 2H); ms (EI): 213 (6), 198 (18), 158 (100). Exact Mass calcd. for $C_{12}H_{27}NSi$: 213.438; found: 213.438.

(E)-1-(2-Methylundec-1-enyl)dimethylsilanol (23)

To a stirred mixture of potassium *tert*-butoxide (2.46 g, 22 mmol) in *n*-hexane (15 mL) at 0°C, was added a solution of *n*-butyllithium in hexane (*c* 1.6 M, 13.6 mL). The mixture was warmed to room temperature and stirred for 30 min. The mixture was then cooled to −78°C. To the cooled mixture was added 10 mL of ether, followed by a solution of **20** (4.26 g, 20 mmol) in ether (10 mL). After addition, the mixture was stirred at room temperature for 4 h. The mixture was again cooled to −-78°C. A solution of octyl bromide (3.86 g, 20 mmol) in ether (10 mL) was added, and the mixture was stirred for 6 h at −78°C and for 12 hr at room temperature. The reaction mixture was quenched with saturated NH_4Cl solution (50 mL). The organic phase was dried ($MgSO_4$), and evaporated to dryness. The crude residue was passed through a column of wet (10% water) alumina, eluting progressively with pet. ether and pet. ether – ether (10:1) to give compound **23** (2.94 g, 61% yield). ^{1}H nmr (CCl_4): 0.16 (s, 6H), 0.9 (t, 3H), 1.3 (m, 14H), 1.83 (s, 3H), 2.10 (t, 2H), 5.10 (s, 1H); ms (EI): 242 (4), 227 (14), 75 (100). Exact Mass calcd. for $C_{14}H_{30}OSi$: 242.207; found: 242.206.

1,1'-Bis[(1S, 2S)-1,2-epoxyundecyl]-1,1,1',1'-tetramethyldisiloxane (24)

To a mixture of 4A molecular sieves (1.0 g), and Ti(O-i-Pr)$_4$ (1.5 g, 5.3 mmol) in CH_2Cl_2 (10 mL) at −20°C was added a solution of diethyl L-tartrate (1.1 g, 5.3 mmol) in CH_2Cl_2 (10 mL). The mixture was stirred for 15 min, and then added to a solution of TBHP in toluene (3.3 M, 4 mL, 13.2 mmol), and stirred for 30 min. A solution of **23** (0.75 g, 3.1 mmol) in CH_2Cl_2 (10 mL) was added and the mixture was stirred for 16 h at −20°C. The mixture was warmed to 0°C. Water (20 mL) was added and stirred for 15 min. A solution of 30% NaOH (6 mL) saturated with NaCl was added and stirred for 1 h. The mixture was warmed to room temperature and partitioned between the aqueous phase and the organic phase. The aqueous phase was extracted three times with CH_2Cl_2 (30 mL). The combined organic phase was dried ($MgSO_4$) and concentrated. The residue was purified by flash chromatography (pet. ether – ether 20:1) to give **24** (0.44 g, 50% yield) as a viscous oil; ^{1}H nmr ($CDCl_3$): 0.20 (s, 12H), 0.85 (t, 6H), 1.24 (m, 32 H), 1.97 (s, 2H); ms (EI): 498 (8), 315 (30), 149 (100).

(S)-1,2-Epoxy-2-methylundecane (26)

A mixture of compound **24** (0.44 g, 0.9 mmol) and tetraethylammonium fluoride hydrate (0.65 g, 2.1 mmol) in acetonitrile (10 mL) was refluxed for 4 h. The mixture was diluted with water (20 mL) and extracted with ether (3 × 15 mL). The combined ether extracts were dried ($MgSO_4$) and evaporated. The residue was purified with flash chromatography (pet. ether – ethyl acetate, 20:1) to give **26** (0.28 g, 91% yield) as a colourless liquid. It had $[\alpha]_D$ −12.2 (*c* 0.3, EtOH); ^{1}H nmr ($CDCl_3$): 0.89 (t, 3H), 1.27 (m, 23H), 2.55 (s, 2H); ms (EI): 184 (5), 169 (37), 85 (6), 70 (100). Exact Mass calcd. for $C_{12}H_{24}O$: 184.183; found: 184.183. Its ee was determined by ^{1}H nmr with (+)-Eu(hfc)$_3$ (1.0 equiv.) to be 90%. In this case, the shift in the 2.55 ppm peak was used.

2-Methyl-(2-iodoethyl)-1,3-dioxolane (27)

The compound was prepared according to literature procedure (16).

(E)-2-Methyl-(6,6-ethylenedioxy-hept-2-enyl)-dimethylsilanol (29).

Compound **29** was prepared according to the same procedure as described for the preparation of **23** using **27** as the alkyl halide. The yield of **29** was 59%. It had ^{1}H nmr (CCl_4): 0.21 (s, 6H), 1.28 (s, 3H), 1.4–1.7 (m, 4H), 1.85 (s, 3H), 2.08 (bt, 2H), 2.23 (s, 1H), 3.85 (m, 4H), 5.15 (s, 1H); ms (EI): 244 (4), 170 (2), 87 (100). Exact Mass calcd. for $C_{12}H_{24}SiO_3$: 244.149; found: 244.148.

(S)-1,2-Epoxy-6,6-ethylenedioxy-2-methylheptane (32)

Compound **29** was epoxidized under Sharpless conditions as described for **24**. Compound **30** was obtained in 63% yield and was subjected to protodesilyation as described above to give **32** in 92% yield. Compound **32** had $[\alpha]_D$ +1.8 (*c* 3, EtOH); ^{1}H nmr (CCl_4): 1.25 (2s, 6H), 1.50 (m, 6H), 2.40 (s, 2H), 3.81 (s, 4H); ms (EI): 171 (M−15, 9), 87 (100). Exact Mass calcd. for $C_9H_{15}O_3$ (M−15): 171.102; found: 171.102. Its ee was determined by ^{1}H nmr with (+)-Eu(hfc)$_3$ (1.5 equiv.) to be 85% by using the shifts of the 2.40 ppm peak.

(S)-(−)-Frontalin (33)

Hydrolysis of **32** (0.20 g) with 2 M H_2SO_4 (2 mL) in THF (4 mL) according to literature (17) procedure gave **33** (0.11 g), identical in spectroscopic data with literature values (18). Alternatively, the hydrolysis could be carried out by mixing **32** (0.20 g) with 2 M H_2SO_4 (0.25 mL), and silica gel (0.5 g) in ether (10 mL) at room temperature and stirring for 4 h. After removal of the solid by filtration, the filtrate was washed with K_2CO_3 solution, dried, and evaporated. The residue was purified by flash chromatography (pet. ether – ether, 20:1) to give **33** (0.14 æ, 91% yield). It had $[\alpha]_D$ −32.6 (*c* 0.15, $CHCl_3$) (lit. (18) $[\alpha]_D$ −50.7 (*c* 1.0, $CHCl_3$). The ee was determined by ^{1}H nmr with (+)-Eu(hfc)$_3$ (2 equiv.) to be 85%. The peak at 3.46 ppm (or 3.92 ppm) was used.

Structural and computational studies of ligands for the glycine binding site on the excitatory amino acid receptor complex: 1. 6,7-Dimethyl and 6,7-dimethoxy 2,3-quinoxalinedione

MACIEJ KUBICKI[1] AND PENELOPE W. CODDING[2]

Departments of Chemistry and of Pharmacology and Therapeutics, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received May 11, 1992

MACIEJ KUBICKI and PENELOPE W. CODDING. Can. J. Chem. **71**, 68 (1993).

The crystal structures of two quinoxalinedione derivatives, 6,7-dimethyl-1,4-dihydro-2,3-quinoxalinedione dihydrate (**1**) and 6,7-dimethoxy-1,4-dihydro-2,3-quinoxalinedione hydrate (**2**), and AM1 molecular orbital computational investigations of electronic properties and hydrogen bond strengths are reported. The space group for **1** is $P\bar{1}$ with a = 7.0109(1) Å, b = 8.5901(3) Å, c = 10.7890(5) Å, α = 112.704(3)°, β = 96.053(3)°, and γ = 107.589(2)°. For **2**, the space group is *Pbca* with a = 12.2769(6) Å, b = 6.9291(3) Å, and c = 25.8644(7) Å. The geometries of these two compounds are similar; small differences are mostly due to the different electronic characters of the substituents and to intermolecular interactions in the crystals. There are two main factors determining the packing schemes of these compounds, π-stacking between neighboring molecules and hydrogen bonds, including bonds with the water molecules of crystallization. The AM1 semi-empirical calculations show differences between net atomic charges and dipole moments. For both structures, calculations confirm the asymmetry of hydrogen bonds that is observed in the crystal structures.

MACIEJ KUBICKI et PENELOPE W. CODDING. Can J. Chem. **71**, 68 (1993).

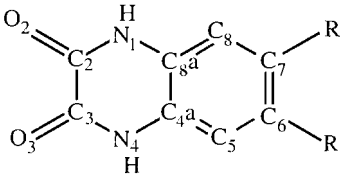
On a déterminé les structures cristallines de deux dérivés de la quinoxalinedione, le dihydrate de la 6,7-diméthyl-1,4-dihydroquinoxaline-2,3-dione (**1**) et l'hydrate de la 6,7-diméthoxy-1,4-dihydroquinoxaline-2,3-dione (**2**) et on a effectué des calculs moléculaires AM1 de leurs propriétés électroniques et de la force de leurs ponts hydrogènes. Le composé **1** cristallise dans le groupe d'espace $P\bar{1}$, avec a = 7,0109(1), b = 8,5901(3) et c = 10,7890(5) Å, α = 112,704(3)°, β = 96,053(3)° et γ = 107,589(2)° alors que le composé **2** cristallise dans le groupe d'espace *Pbca*, avec a = 12,2769(6), b = 6,929(3) et c = 25,8644(7) Å. Les géométries de ces deux composés sont semblables; les petites différences sont principalement dues aux caractères électroniques différents des substituants et à des interactions intermoléculaires dans les cristaux. Deux facteurs principaux déterminent les schémas d'empilement de ces composés, un empilement π entre des molécules voisines et des liaisons hydrogènes, comprenant des liaisons avec des molécules d'eau de cristallisation. Les calculs semi-empiriques AM1 montrent qu'il existe des différences entres les charges atomiques nettes et les moments dipolaires. Pour les deux structures, les calculs confirment l'asymétrie des liaisons hydrogènes qui est observée dans les structures cristallines.

[Traduit par la rédaction]

Introduction

Excitatory amino acid (EAA) receptors are commonly regarded as the main neutrotransmitter receptors mediating synaptic excitation in the mammalian central nervous system, CNS (1). Because they are involved in many physiological phenomena and their dysfunction leads to neurological disorders, including epilepsy (2) and hypoglycemia (3), their agonists and antagonists are of growing interest as potential therapies for CNS disorders.

The EAA receptors are divided into three subtypes, based on selective agonists for each subtype: *N*-methyl-D-aspartate (NMDA), kainate, and quisqualate (ref. 4, and references therein). A structural analogue of this latter compound, α-amino-3-hydroxy-5-methyl-4-isoxazelopropionic acid (AMPA), was found to be more specific in binding studies, thereby allowing subdivision of the type of quisqualate receptor, Q/AMPA, that is present in mammalian CNS. The number of known NMDA receptor antagonists is extensive (for review, see ref. 5) and it has been shown that glycine is involved in the activation of this receptor and that a strychnine-insensitive glycine binding site is associated with the receptor complex. Quinoxalinedione derivatives were found to be ligands for the glycine site and to be highly potent kainate and AMPA receptor antagonists (6), causing growing interest in this group of compounds. Small structural changes, e.g., changing the position of a nitro group from 6,7-dinitro- to 5,7-dinitro- in the 1,4-dihydro-2,3-quinoxalinediones, can cause large changes in the affinities for the non-NMDA receptors (4). Thus, an extensive study of the structures and intermolecular interactions found in quinoxalinediones was undertaken to account for their activity profiles. Here, we present the results of the X-ray crystallographic studies and semi-empirical molecular orbital calculations on two quinoxalinedione derivatives, 6,7-dimethyl-1,4-dihydro-2,3-quinoxalinedione dihydrate (**1**) and 6,7-dimethoxy-1,4-dihydro-2,3-quinoxalinedione hydrate (**2**), which differ in their ability to inhibit glycine binding.



R = Me for **1**, OMe for **2**

Compound **1** has high affinity for the glycine binding site and an IC_{50} value of ca. 7.1 μM while **2** has lower affinity

for the binding site and an IC_{50} value of 113 μM.[3] The focus for this study is the determination of packing modes that may establish the relative importance of different types of potential intermolecular forces: hydrogen bonds, π-stacking, and van der Waals interactions.

Experimental

The samples were provided by ICI Americas Inc., Wilmington, Del. Colorless crystals of both samples were obtained by recrystallization from DMF (**1**) and pyridine (**2**) by a slow evaporation. X-ray intensity data were collected at room temperature on an Enraf–Nonius CAD-4F automated diffractometer with Ni-filtered CuK_α radiation, $\lambda(CuK_\alpha)$ = 1.54178 Å, using an $\omega/2\theta$ scan mode. Accurate unit-cell parameters were obtained by least-squares treatment of the setting angles of 25 reflections (28.68° ≤ θ ≤ 49.35° for **1**, 26.41° ≤ θ ≤ 49.11° for **2**). Three standard reflections, 1,5,−3; 3,4,6; and 3,−1,0 for **1**, and −6,0,0; −5,1,5; and −1,1,1 for **2**, were measured after every 2000 s; they showed no significant changes in their intensities (<1.5% for both compounds) or in their profile shapes. The crystal data not in the abstract are listed in Table 1. Lorentz and polarization corrections were applied.

Both structures were solved by direct methods using SHELXS86 (7). In **1**, the correct solution was obtained in space group $P1$, with two molecules in the asymmetric unit. As they were clearly related by a center of symmetry, the molecular coordinates were then transformed into $P\bar{1}$ and further refinement was performed in this space group. The refinements were done by the full-matrix least-squares method with SHELX-76 (8); in each case, the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized. The non-hydrogen atoms were refined with anisotropic thermal parameters, all hydrogen atoms were found in the subsequent ΔF maps, and both their positional and isotropic thermal parameters were also refined. In each structure, an isotropic extinction correction was made at the final stages of refinement. The empirical extinction parameter x was used to correct F_c according to the formula $F_c' = F_c(1 - xF_c^2/\sin\theta)$; x converged at 5.7(3) × 10^{-7} for **1** and at 4.1(5) × 10^{-7} for **2**. The atomic scattering factors for non-hydrogen atoms were taken from Cromer and Mann (9) and for hydrogen atoms from Stewart *et al.* (10). Other computer programs used were ORTEP (11), PLUTO (12), and CSU88 (13). The final atomic coordinates[4] for both structures are given in Table 2 with the atom labeling as noted on the chemical diagram. The bond distances and angles are listed in Table 3.

Calculation methodology

To obtain further insight into the geometrical differences between those compounds and into the stability of potential intermolecular binding modes, we performed semi-empirical calculations using the AM1 Hamiltonian included in the MOPAC 6.0 program (23, 24). Three calculations were done for each compound; the structures for each calculation were the following: *A*, the isolated molecule; *B*, the quinoxalinedione molecule separated by 6.0 Å from each of four water molecules (which could serve as hydrogen bonding partners); and *C*, the quinoxalinedione molecule hydrogen bonded to each water molecule through a single interaction as shown in Fig. 1*a* for compound **1**. In each calculation, the geometry was optimized; the final hydrogen bonding geometry for *C* is shown in Fig. 1*b* for compound **1**. To evaluate atomic charges, dipole moments, and overlap populations, a stationary point, *ab initio* calculation was done using the GAUSSIAN 90 program (25), the STO-3G basis set, and the optimized AM1 geometry.

Results

In both crystals, hydrogen bonding connects the molecules into three-dimensional structures that have an asymmetrical distribution of bonds around the quinoxalinedione molecules, although each individual quinoxalinedione is

symmetric about a plane perpendicular to the molecular plane. The geometry of these hydrogen bonds is tabulated in Table 4. Thermal-ellipsoid representations of the molecules, together with the hydrogen bonding networks, are presented in Figs. 2 and 3 for **1** and **2**, respectively. In **1**, the molecules are linked to one another directly through a hydrogen bond from N1—H1 to the carbonyl oxygen atom, O2, and indirectly by a hydrogen bonding bridge formed by one of the water molecules of crystallization. This water molecule links the same carbonyl oxygen atom (O2) to the other carbonyl oxygen atom (O3) in a neighboring molecule at $-x$, $-y$, $1-z$. The other amine group (N4—H4) is hydrogen bonded to the other water molecule. The crystallographic center of symmetry generates a cluster of four water molecules, which are interconnected by hydrogen bonds.

In compound **2**, the molecules are again linked directly to one another by a hydrogen bond from an amino group (N1—H1) to a carbonyl oxygen atom and indirectly by a water molecule, providing a hydrogen bonding bridge that is, however, between an amino group and a carbonyl oxygen atom rather than between two carbonyl oxygen atoms as in **1**. The water molecule of crystallization in **2** also bridges one carbonyl oxygen atom to itself to form an infinite chain along the *b* axis.

Overall, in both of these structures the two N—H groups and one of the two carbonyl oxygen atoms are involved in a single hydrogen bond while the other carbonyl oxygen atom is involved in two hydrogen bonds. The singly hydrogen-

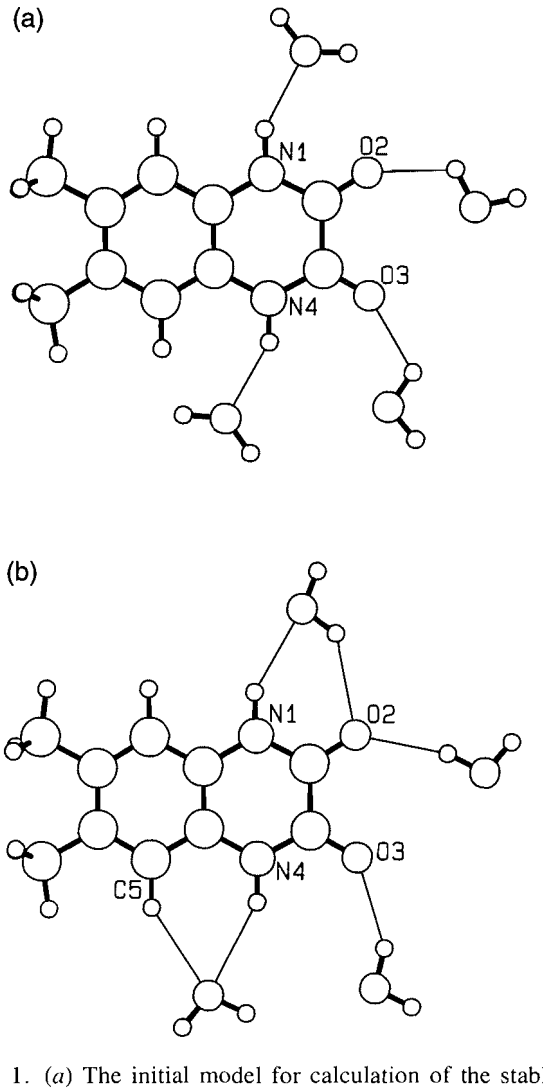

FIG. 1. (*a*) The initial model for calculation of the stable hydrogen bonding pattern for compound **1**, which places one hydrogen bonding partner in contact with each N-H or C=O group in the quinoxalinedione. (*b*) The AM1 optimized hydrogen bonding pattern, which has an unsymmetrical arrangement of hydrogen bonds even though the molecule possesses molecular symmetry.

bonded carbonyl oxygen atom (O3) is also involved in a number of weak, quasi-hydrogen bond interactions, tabulated in Table 4.

The difference in the hydrogen bonding patterns for the two carbonyl oxygen atoms is also reflected in the C=O distances: the greater the involvement in hydrogen bonds, the longer the observed C=O distances. The distance C3—O3 in **1** is 5σ shorter than the other C=O distances. This atom, O3 in **1**, is involved in one hydrogen bond of moderate length (O3···O is 2.828(1) Å). The other singly hydrogen-bonded oxygen atom, O3 in **2**, is involved in a significantly shorter and thus stronger hydrogen bond (O3···H—N4 is 2.805(2) Å). The other two carbonyl oxygen atoms are each involved in two hydrogen bonds.

Another packing interaction important in both structures is π-stacking between neighboring molecules. In **1**, the distances between the plane of the (x,y,z) molecule and the planes of the neighboring molecules $(-x,-y,2-z)$ and $(1-x,-y,2-z)$ are 3.353(2) Å and 3.506(2) Å, respectively. In **2**, the distances between the (x,y,z) molecule and the planes of the neighboring molecules at $(1/2-x,-1/2+y,z)$ and $(1/2-x,1/2+y,z)$ are 3.303(2) Å and 3.330(2) Å, respectively. However, the stacking modes are different in the two structures. In **1**, there is head-to-tail stacking between the molecules connected by the center of symmetry, while in **2** there is head-to-head stacking between the molecules connected by the *b* glide plane, which is stabilized by hydrogen bonds with the water molecule. The molecular packing arrangements for **1** and **2** are presented in Figs. 4 and 5, respectively.

In each compound the quinoxaline is planar, but the deviations from the least-squares plane are greater in **2**. Calculations of the least-squares planes of the constituent rings of the quinoxaline support this difference in planarity; the angle between planes of the 6-carbon atom ring and the 6-membered heterocyclic ring is 1.01(2)° for **1**, and is 2.89(4)° for **2**. The deviations of the carbonyl oxygen atoms, O2 and O3, from the plane of the quinoxaline moiety are also greater for **2**; the values are 0.091(1) Å and 0.104(1) Å for O2 and O3, respectively, while these values are **1** are 0.042(1) Å and −0.010(1) Å. In **2**, the methoxy group at C7 is almost coplanar with the ring system (the dihedral angle C8—C7—O7—C71 is 1.1(2)°); the other methoxy group is slightly tilted out of the plane (the angle C5—C6—O6—C61 is −6.2(2)°) but this tilt still allows significant overlap between the oxygen atom lone pairs and the aromatic system, as shown by the similarity in the C7—O7 and C6—O6 bond distances.

The differences in bond lengths and bond angles between the two structures are mostly due to differences in the substituents. The change of substituents at positions 6 and 7 causes the distances C5—C6 and C7—C8 to differ, between the two structures, by more than $3\sigma_+$ (where σ_+ is defined as $(\sigma_1^2 + \sigma_2^2)^{1/2}$) and the bond angles are different in the substituent region. These differences in bond angles within the carbon rings are similar to those described by Domenicano and Murray-Rust (14) in their studies on the influence of the substituents on the geometry of the benzene ring. These differences include the sharpening of the C5—C6—C7 and C6—C7—C8 angles and widening of the C4a—C5—C6 and C7—C8—C8a angles with the change from a methyl to a methoxy substituent. The greater asymmetry of the exocyclic bond angles around C6 and C7 in **2** is due to the steric effect of the methoxy substituent.

Notable in the geometry of the compounds is the long C2—C3 bond, suggesting significant sigma character to this bond between two sp^2 hybridized atoms. The geometry of the N-C(=O)-C(=O)-N fragment in compounds **1** and **2** is similar to that found for other 1,4-dihydro-2,3-quinoxalinedione derivatives and for the oxamide molecule (18); in these structures the central C—C bond lengths vary from 1.506(6) to 1.522(2) Å, (15–17). However, the longer central C—C bond pattern is not found in quinoxalines lacking the 1,4-dihydro-2,3 dione pattern (19–22). This difference suggests the predominant bonding in this ring is delocalization over the individual amide groups and weak overlap between the groups.

The *ab initio* STO-3G stationary point calculations show that the most significant effect of the change in substituents between **1** and **2** is in the dipole moment, which is 4.431 debye for the methyl compound and 3.315 debye for the methoxy compound. Also, the overlap between C5 and C6

is diminished in the methoxy compound from an overlap population of 0.500 for **1** to 0.475 for **2**.

The optimized AM1 hydrogen-bonded structures reproduce the asymmetrical motif found in the crystal. Differences between the AM1 heats of formation for the nonbonded collection of molecules in *B* and the hydrogen bonding pattern in *C* show that the inactive compound, **2**, forms a slightly more stable hydrogen-bonded network, with a stabilization (difference between structures *B* and *C*) of 14.30 kcal whereas the methyl derivative is stabilized by 13.23 kcal. Although the hydrogen bond energies estimated by AM1 calculations do not compare well with experimental data (26), the relative ordering found for these two very similar systems should be correct.

Mulliken population analysis for the stationary point calculation on *C* (see Fig. 1*b*) shows the induced asymmetry arising from the hydrogen bonding pattern. As shown in Table 5, hydrogen bond formation has the effect of slightly

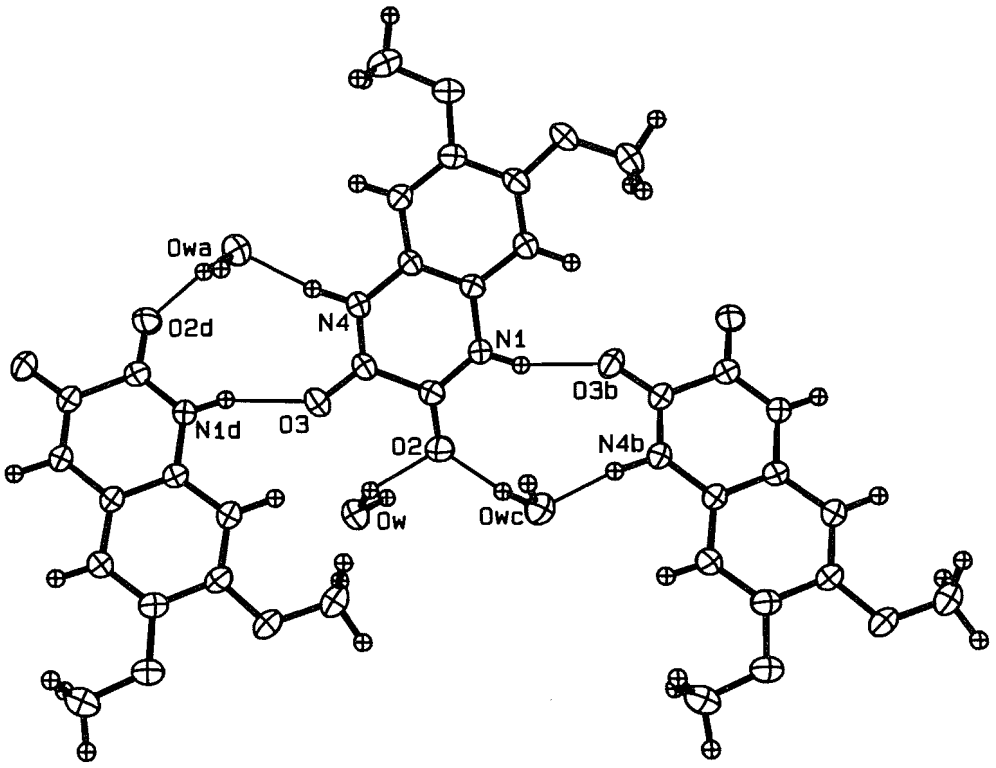

FIG. 3. The hydrogen bonding scheme for **2**. The symmetry codes are (*a*) $-x$, $1/2+y$, $1/2-z$; (*b*) $1/2+x$, y, $1/2-z$; (*c*) $1/2-x$, $1/2+y$, z; (*d*) $-1/2+x$, y, $1/2-z$.

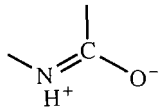
reducing the overlap in the carbonyl bond and the N—H bond and increasing the overlap in the N—C bond of the amide fragment. Thus, the intermolecular interactions favor this resonance form for the amide group:



Of the two amides in the heterocyclic ring, the asymmetrical hydrogen bonding pattern induces a greater change in the amide fragment with two hydrogen bonds to the carbonyl oxygen atom. The change in overlap population for this C=O is decreased by three to four times the change in the singly H-bonded carbonyl and the decreases in the N—C and N—H bond overlaps are twice the change for the other amide group. In the hydrogen-bonded structure, in contrast to the isolated molecule, which is symmetrical, the carbonyl oxygen atoms differ in charge by 0.03, with the doubly hydrogen-bonded oxygen atom (O3) more negative.

Discussion

The unsymmetrical distribution of hydrogen bonds found in each crystal, with the carbonyl oxygen atom involded in one hydrogen bond while the other is involved in two hydrogen bonds, was reproduced by the geometric optimization using the AM1 Hamiltonian of the hydrogen-bonded structure in Fig. 1*a* to give the structure in Fig. 1*b*. This pattern appears to be an important interaction motif for these molecules and may model recognition interactions at the EAA receptor. Hydrogen bonding induces asymmetry in the molecule that is evident in the C=O bond lengths and the overlap populations. The two compounds differ slightly in the stabilization gained by the formation of this hydrogen bonding motif; interestingly, the less active compound forms the more stable motif.

The bond distances observed in the crystal structures indicate that the quinoxalinedione comprises two relatively isolated amide groups. This is supported by the Mulliken overlap populations, which show low overlap for the C2—C3 bond (0.353) that is unchanged upon formation of hydrogen bonds so that the amide groups respond separately and differently to the asymmetrical intermolecular environment. The amide involved in two hydrogen bonds to the oxygen atom and one to the N-H group shows the stronger preference for the ionic resonance form.

The geometry and intermolecular interactions found in the two crystal structures and the two sets of calculations are similar and provide little new information regarding the basis for the difference in activity of compounds **1** and **2**. The most important difference between the two compounds is connected to the different substituents on the side of the molecule opposite to the hydrogen bonding region. Structure–activity data (see footnote 3) on this series of compounds indicate that electronegative substituents (in the 5, 6, 7, or 8 positions) — halogen atoms or nitro groups — greatly enhance the activity of the quinoxalinediones; correspondingly, the electron pairs on the ether oxygen of the methoxy groups should cause compound **2** to be more active than the methyl compound. However, the orientation of the methoxy groups, which is somewhat determined by π overlap between the lone pair electrons on the oxygen atom and the aromatic rings, places the bulky methyl groups toward the sides (the 5 and 8 positions) of the quinoxalinedione moiety

(see Fig. 3), possibly obstructing access to the N-H groups or interfering with a recognition point on the binding site. Structure–activity data show that a 5,7-dinitro derivative has the highest activity in this series; thus, the binding site may recognize electronegative groups rather than the methyl portion of the 6,7-dimethoxy substituent in the regions of the 5 and 8 positions.

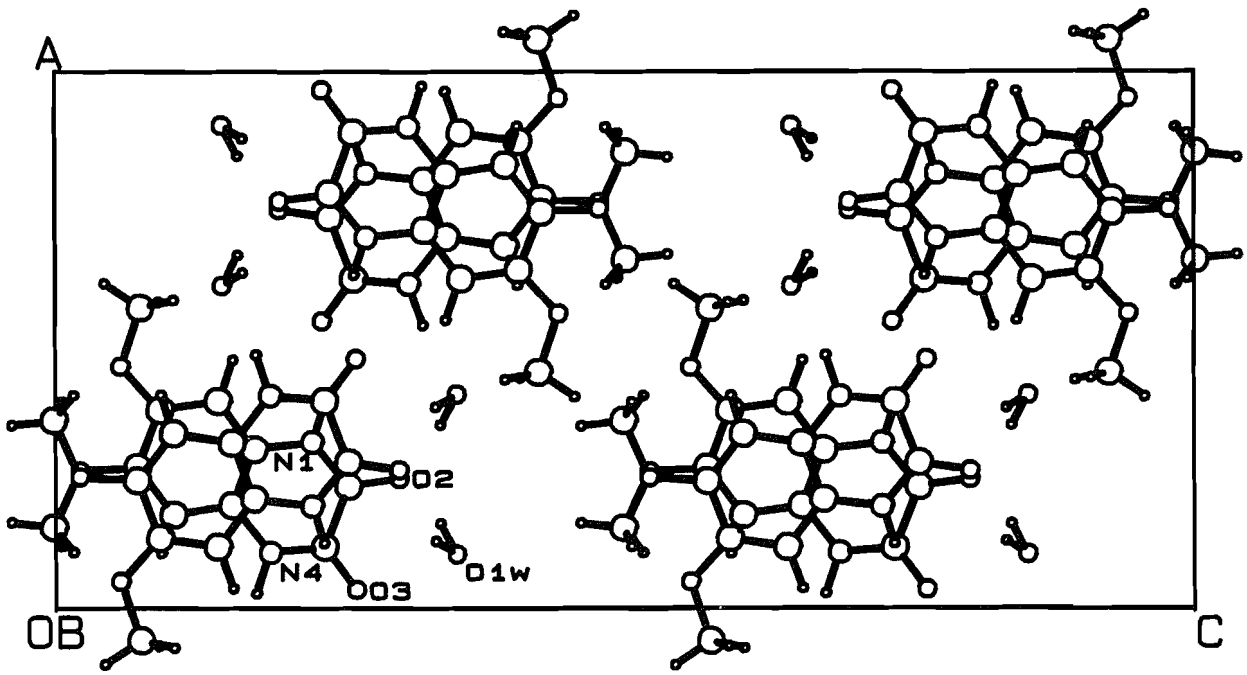

FIG. 5. The molecular packing in the unit cell for **2** as seen along the [010] direction. In contrast to compound **1**, the molecules stack head-to-head.

The charge distributions in the phenyl ring fragments are different in the two compounds; the overall dipole moment is larger by 1 debye for the methyl compound. In the methoxy compound, **2**, the negative charge of the carbonyl oxygen atoms is partially balanced by the charge of the methoxy oxygen and carbon atoms; this could explain the difference in the stacking modes of these compounds as the charge distribution in **2** does not particularly favor head-to-tail stacking.

In conclusion, there are at least two important features present in the crystal structures and the calculated MO structures that provide models for biological recognition. These are the asymmetrical hydrogen bonding pattern displayed by the two amide groups, which could mimic the peptide linkages in glycine and endogenous neurotransmitters, and the distribution of the charge throughout the molecule that determines crystal packing and could determine ligand orientation in the binding site.

KENNETH CURRY, HUGH MCLENNAN, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **71**, 76 (1993).

The geometric isomers of 1-amino-1,2-cyclopentanedicarboxylic acid were isolated as the hydrolysis products of 2-cyclopentanecarboxylic acid-5,5′-hydantoin. The hydantoin ester was formed from ethyl -2-oxocyclopentanecarboxylate via a Bucherer–Bergs reaction. Hydrolysis of the hydantoin at elevated temperatures gave a mixture of *trans*- and *cis*-1-amino-1,2-cyclopentanedicarboxylic acids indicating epimerization during hydrolysis. The *trans* product has not been described previously and the *cis* not extensively characterized. X-ray crystallography reveals that both isomers are zwitterionic in the solid state and the *cis* isomer molecules are linked by unusually strong hydrogen bonding. Structures were confirmed by ^{13}C NMR, X-ray crystallography, and elemental analysis. Physical data are also presented.

KENNETH CURRY, HUGH MCLENNAN, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **71**, 76 (1993).

Les isomères géométriques de l'acide 1-amino-cyclopentane-1,2-dicarboxylique ont été isolés comme produits d'hydrolyse de la 5,5′-hydantoïne de l'acide cyclopentane-2-carboxylique. On a obtenu l'ester hydantoïne par une réaction de Bucherer–Bergs sur le 2-oxocyclopentanecarboxylate d'éthyle. L'hydrolyse de l'hydantoïne à température élevée conduit à un mélange des acides 1-amino-cyclopentane-1,2-dicarboxyliques *trans* et *cis* indiquant qu'une épimérisation se produit au cours de l'hydrolyse. Le produit *trans* n'avait pas été décrit antérieurement alors que le composé *cis* n'avait pas été très bien caractérisé. La cristallographie des rayons X révèle que, dans la phase solide, les deux isomères sont zwitterioniques et que les molécules de l'isomère *cis* sont reliées par des liaisons hydrogènes inhabituellement fortes. On a confirmé les structures par RMN du ^{13}C, par diffraction des rayons X et par analyse élémentaire. On rapporte aussi les données physiques.

[Traduit par la rédaction]

Introduction

Considerable recent interest has been generated in the pharmacology of acidic amino acids related to glutamic and aspartic acids because of the perceived role of these compounds as synaptic transmitters in the mammalian central nervous system. One method of analyzing the receptors that mediate these neuronal events is to produce rigid analogs of glutamic and aspartic acids (1–3). The synthesis of the glutamic acid analogs, *trans*- and *cis*-1-amino-1,3-cyclopentanedicarboxylic acids, has already been described (4) and we report here on the synthesis of the corresponding aspartic acid analogs, *cis*-**4** and *trans*-**5** 1-amino-1,2-cyclopentanedicarboxylic acids (Fig. 1).[3]

Experimental

Melting points were determined on a Fisher–Johns apparatus; UV λ_{max} was determined on an L.K.B. Ultrospec II or a Pye–Unicam SP-8-100 dual beam spectrophotometer.

Ethyl 2-cyclopentanecarboxylate-1-spiro-5-hydantoin, 2

Compound **2** was prepared by a modification of the method of Connors and Ross (5), resulting in two products that were separated by fractional crystallization from chloroform and methanol. After cooling, **2** was isolated as a white solid, 51 g (56%), mp 141°C (lit. (5) mp 145°C), and confirmed by ^{13}C NMR. The second product was determined by ^{13}C NMR to be 2-cyclopentanecarboxylic acid-1-spiro-5-hydantoin **3**. Yield 10.4%. NMR data are presented in Table 1.

2-Cyclopentanecarboxylic acid-1-spiro-5-hydantoin, 3

Hydrolysis of **2** in 4 M hydrochloric acid (HCl) gave 43.5 g of a colorless crystalline material, mp 220°C (lit. (5) mp 225–226°C); UV λ_{max} 307 nm. ^{13}C NMR (Table 1) revealed this to be a single product consistent with the predicted structure of **3**. Anal. calcd. for $C_8H_{10}N_2O_4$: C 48.48, H 5.09, N 14.14; found: C 48.60, H 5.14, N 14.22.

cis- *and* trans-*1-Amino-1,2-cyclopentanedicarboxylic acids, 4 and 5*

Compound **3** (14.0 mmol, 2.8 g) was suspended in 100 mL of 6 M HCl and placed in a pressure reaction vessel. The vessel was sealed and maintained at 155–160°C for 6 h. The vessel was allowed to cool to room temperature and the resulting solution evaporated to dryness *in vacuo* at 60°C to leave a yellow solid. The solid was dissolved in isopropyl alcohol and treated with propylene oxide to remove residual hydrogen chloride. A white solid precipitated on standing and revealed two ninhydrin staining spots running on silica gel 60 TLC and eluting with 90:10 methanol–water, R_f 0.22 (*trans*), 0.48 (*cis*). The two amino acids were separated by fractional crystallization from water and methanol or by column chromatography on silica gel 60 with a gradient of 50:50 to 100:0, methanol–chloroform. In the case of fractional crystallization the first isomer to precipitate was *trans*, mp 220°C, UV λ_{max} 185.4 nm, structure confirmed by ^{13}C NMR and X-ray crystallography (Table 1 and Figs. 2 and 3). The amino acids were prepared for elemental analysis by precipitation from isopropyl alcohol with addition of propylene oxide to solutions of the chloride salts. The powders were then dried *in vacuo* at 70°C for 24 h. Anal. calcd. for $C_7H_{11}NO_4$: C 48.55, H 6.40, N 8.09; found (anhydrous mate-

*X-ray crystallographic analyses of compounds **4** and **5***

Crystallographic data for *cis*-**4** and *trans*-**5** (both compounds crystallize as monohydrates) are presented in Table 2. Unit-cell parameters were determined by least-squares refinement on diffractometer setting angles for 25 reflections (θ = 42–58° and 28–49° for the *cis* and *trans* isomers, respectively). The data were processed[4] and corrected for Lp and absorption (empirical, azimuthal scans for four reflections).

[a]The atoms O(5–8), N(2), and C(8–14) constituting this molecule correspond, respectively, to atoms O(1–4), N(1), and C(1–7) of molecule A.

Both structures were solved by direct methods. The non-hydrogen atoms of both compounds were refined with anisotropic thermal parameters. For the *cis* isomer the two hydrogen atoms associated with the carboxylic acid moieties (H(7) and H(8)) were refined with isotropic thermal parameters and the remaining hydrogen atoms were fixed in idealized positions (the orientations of the $-NH_3^+$ groups based on observed difference map peaks, O/N/C-H = 0.98 Å, $B_H = 1.2\ B_{bonded\ atom}$). Conformational disorder in the five-membered ring of the *trans* isomer was indicated by anomalous thermal parameters for the atom C(4). A split-atom model for C(4) was refined, the occupancy factors (0.6/0.4) being determined by refinement with fixed isotropic thermal parameters. In the final stages of refinement the occupancy factors were kept fixed and anisotropic thermal parameters were employed for C(4) and C(4A). All ordered hydrogen atoms in the *trans* isomer were refined with isotropic thermal parameters and the disordered hydrogen atom positions were calculated as described above for the *cis* isomer.

The solution of the structure of the *cis* isomer was initiated in the noncentrosymmetric (but racemic) space group $Pca2_1$ on the basis of the *E*-statistics. The two molecules in the asymmetric unit are

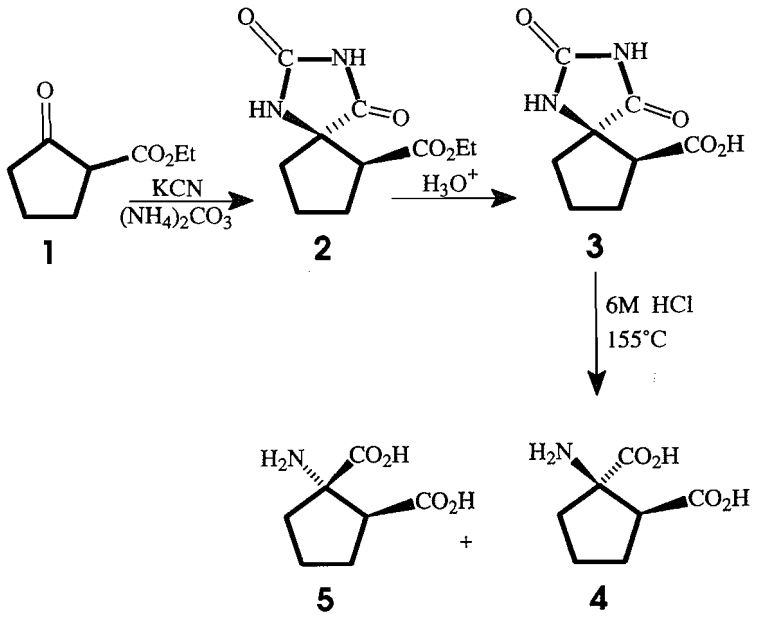

FIG. 1. Schematic for the synthesis of *cis* and *trans*-1-amino-1,2-cyclopentanedicarboxylic acids.

related to one another by a pseudo-inversion centre at approximately (1/8, 1/4, 0.34) (see Table 3). Attempts to refine the structure in the centrosymmetric space group *Pcam* (after appropriate coordinate translations) were unsuccessful. Parallel refinement of the opposite polarity (anomalous dispersion corrections for C, N, O) resulted in marginally higher residuals, the R and R_w ratios being 0.0402/0.0401 = 1.003 and 0.0524/0.0522 = 1.004, respectively. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (9).

Final atomic coordinates and equivalent isotropic thermal parameters for the non-hydrogen atoms are given in Table 3. Bond lengths and angles, selected torsion angles, and details of the hydrogen bonding are presented in Tables 4–6. Hydrogen coordinates, anisotropic thermal parameters, torsion angles, least-squares planes, intermolecular distances, and structure factors are included as supplementary material.[5]

Results and discussion

Since previous studies had indicated that Bucherer–Bergs hydantoin formation gave one geometric isomer exclusively (5) it was expected that the final product would consist of the *cis* amino acid only. Figure 1 shows the synthetic route and indicates that the most efficient method of hydrolysis with hydrochloric acid leads to epimerization of the final product into *trans* and *cis* amino acids. The *trans* isomer has not been described previously and is of particular interest because the rigidity of the ring and close proximity of the carboxyl groups result in a compound that resembles a folded conformation of glutamic and aspartic acids.

Using a version of the Simplex method (6), the optimum reaction conditions were determined and gave a total yield of approximately 65% for the formation of hydantoin **3** and its ester **2**. The yield of hydantoin was found to be dependent on time, temperature, and concentration of reactants. In particular, the presence of cyanide seemed to suppress the reaction, thus its concentration was kept low by gradual addition over a 24 h period. For unhindered systems, hydantoin formation takes place in 4–6 h; in the present study it was necessary to increase this period to 48 h. As the reaction proceeds, ethyl 2-cyclopentanecarboxylate-1-spiro-5-hydantoin **2** was formed and hydrolyzed *in situ* to give increasing amounts of **3**. The stereospecificity of the Bucherer–Bergs reaction has been discussed in detail with reference to restricted ring systems (7, 8) and, in the present synthesis, conditions are further restrained by the presence of an ester group at C(2) of the cyclic ketone **1**. Alkaline hydrolysis of **3** gave yields that were very low. Refluxing for 48 h in 2 M barium hydroxide gave no product at all while hydrolysis with 2 M sodium hydroxide at 140°C gave only very low yields of the *cis* amino acid (<5%). The best results were obtained with acid hydrolysis using 6 M HCl at 155°C for 6 h. The reaction mixture was found to contain both *cis*-**4** and *trans*-**5** amino acids with a total yield of 46%.

X-ray crystal structure of cis-**4** *and* trans-**5** *1-amino-1,2-cyclopentanedicarboxylic acid monohydrates*

Stereoviews of the asymmetric units (showing atom labeling schemes) of *cis*-**4** and *trans*-**5** (monohydrates) are shown in Fig. 2. The *cis* and *trans* isomers have (1*SR*,2*RS*) and (1*SR*,2*SR*) relative stereochemistries, respectively. Bond lengths and angles in the two isomers (Table 4) are generally as expected. The major structural differences between the two isomers, on the molecular level, can be seen by a comparison of the torsion angles in Table 5. The five-membered rings in both of the crystallographically independent

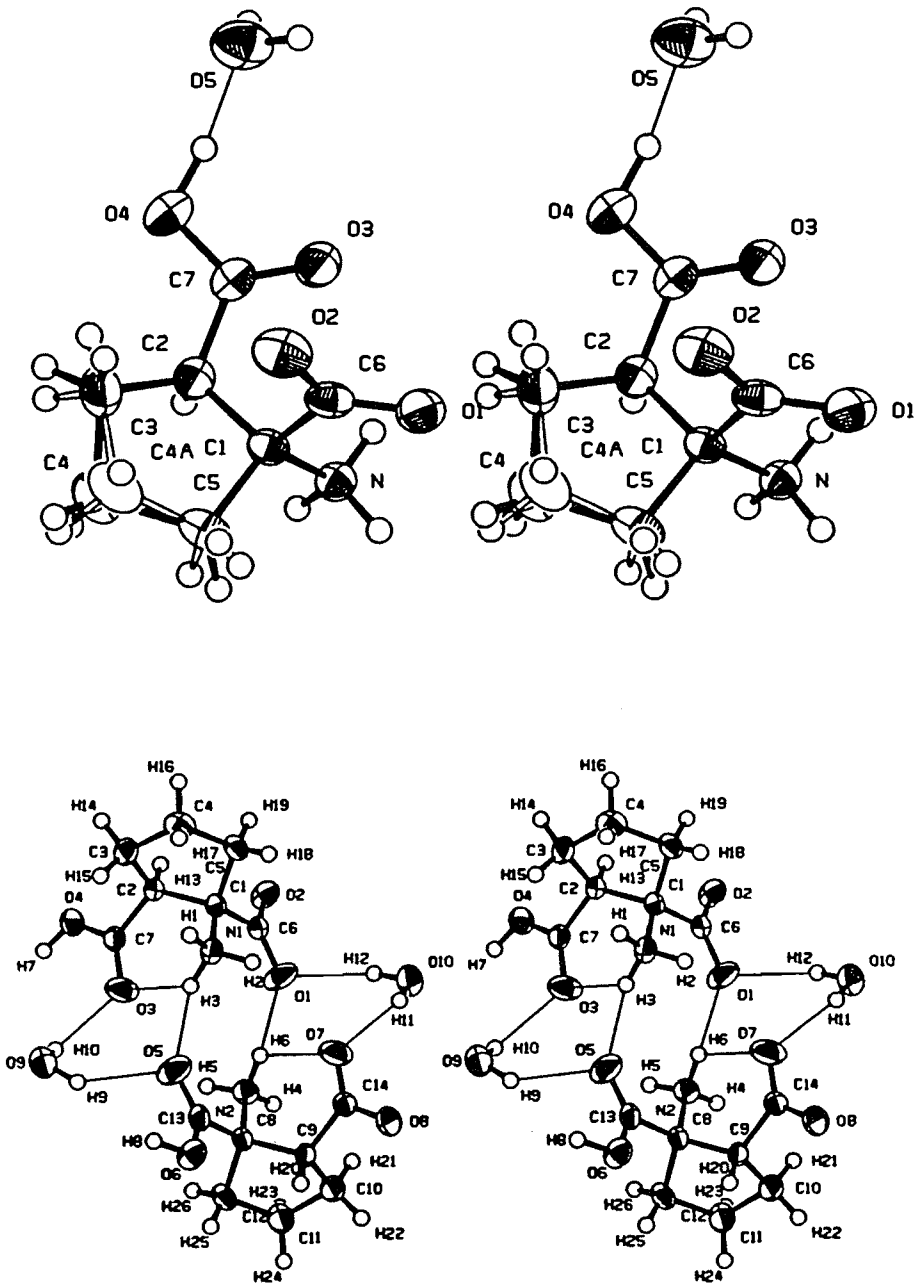

FIG. 2. Stereoviews of *trans*- and *cis*-1-amino-1,2-cyclopentanedicarboxylic acids.

molecules of the *cis* isomer and the minor component of the disordered cyclopentane ring in the *trans* isomer (that containing C(4A)) may be classified as C1-envelopes with varying degrees of irregularity. The conformation of the five-membered ring in the major component of the *trans* isomer is that of a C3-envelope.

Both molecules exist as zwitterions in the solid state. The deprotonated carboxylate group is that bonded to C1 in the *trans* isomer, while for the *cis* isomer the C1-carboxylate group is deprotonated in molecule A (containing N1) and the C1 and C2-carboxylate groups are nearly equivalent and share what is most likely a symmetrically O···H···O hydrogen-bonded proton in molecule B (containing N2) (see below).

Extensive hydrogen bonding dominates the packing arrangements in both crystal structures (see Table 6 and Fig. 3). Both crystal structures contain dimeric units with the individual molecules linked by N—H···O hydrogen bonds about crystallographic (*trans* isomer) or approximate (*cis* isomer) inversion centres. In the *trans* isomer these dimeric units are linked to one another along both the *b* and *c* axes by pairs of N—H···O hydrogen bonds and bridging OH···(H)O—H···O hydrogen-bonded water molecules, forming infinite sheets. In the *trans* isomer the protonated carboxylic acid group is strongly hydrogen-bonded to the water molecule (H···O = 1.57(3), O···O = 2.586(2) Å). The dimeric units in the *cis* isomer are also cross-linked by hydrogen bonds to form infinite sheets parallel to the *ab* plane, but the hydrogen bonding between dimers is different from that

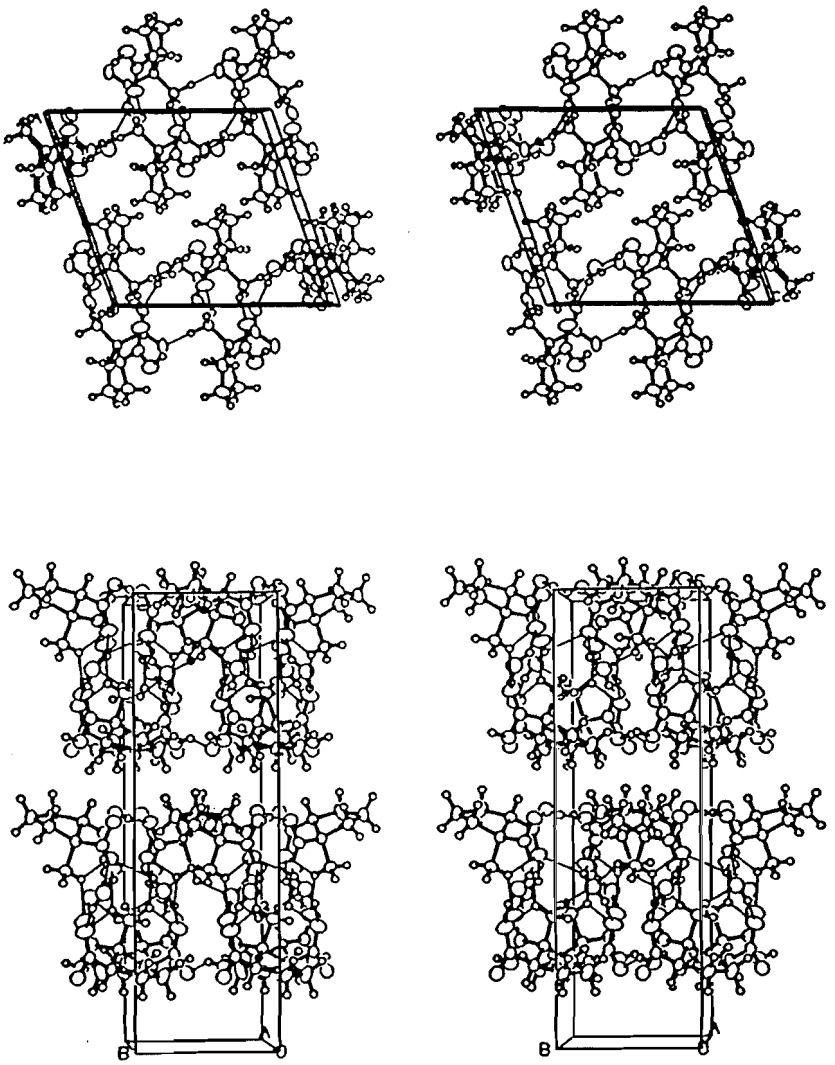

FIG. 3. Packing arrangements for *trans*- and *cis*-1-amino-1,2-cyclopentanedicarboxylic acids.

observed in the structure of the *trans* isomer. Molecules A are linked head-to-tail along *a* by very strong (O···H = 1.51(5), O···O = 2.478(3) Å) hydrogen bonds between protonated and deprotonated carboxylate groups. Molecules B are also linked to one another by the same type of hydrogen bond (O···H = 1.47(8), O···O = 2.455(3) Å), but to dimers translated along the *b* axis with respect to those linked through molecules A. In addition, the dimers in the *cis* isomer are bridged along both *a* and *b* by pairs of bridging $(O\cdots H_2O\cdots HN)_2$ hydrogen-bonded water molecules (O···N = 2.837(5)–2.973(5), O···O = 2.890(4)–3.031(5) Å). The existence of extra bifurcated hydrogen-bonding interactions (1.5 per molecule) in the structure of the *cis* isomer, along with other packing considerations (especially the orientation of the cyclopentane rings with respect to the hydrophobic channels between the hydrogen-bonded layers), is probably responsible for the higher density of the *cis* isomer in the solid state.

As a result of the very strong (O)CO···H···OC(O) hydrogen bonding in the *cis* isomer (see Table 6) the distinction between the COO^- and COOH groups becomes somewhat ambiguous. In molecule A, with the longer O···O distance, the C—O bond lengths (C(7)—O(4) = 1.289(4) and C(6)—O(2) = 1.248(5) Å) and the location of the refined hydrogen atom H(7) (bonded to O(4)) are consistent with protonation of the C(7) carboxylate group. In molecule B, the O···O distance in the strong hydrogen bond is 0.023(5) Å shorter than in molecule A and the two C—O distances involved are not significantly different (C(13)—O(6) = 1.266(5) and C(14)—O(8) = 1.273(4) Å). However, the hydrogen atom H(8) involved in this interaction refined to a position nearer to O(6), the oxygen atom having the shorter C—O bond. In view of the relatively large thermal parameter for H(8) and the near equivalence of the dimensions of the C(13) and C(14) carboxylate moieties, it is likely that the O(6)···H(8)···O(8) interaction is symmetric. The COO^- and COOH functions are clearly distinguished in the *trans* isomer with C—O bond lengths of 1.247(2) and 1.252(2) Å in the former and C—O(H) and C=O distances of 1.301(2) and 1.212(2) Å in the latter.

Cobalt(II) catalyzed oxidation of 2-substituted 1,3-dioxolanes with molecular oxygen[1]

PEI LI AND HOWARD ALPER[2]

Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

PEI LI and HOWARD ALPER. Can. J. Chem. **71**, 84 (1993).

Cobalt(II) chloride catalyzed oxidation of 2-substituted 1,3-dioxolanes in 1,2-dimethoxyethane afforded formate esters and acids in high yields. It was found that the presence of catalytic amounts of $ZnCl_2$ increased the rate of oxidation. A free-radical mechanism is proposed, involving participation of superoxocobalt, and the esterification of the alcohol and acid.

PEI LI et HOWARD ALPER. Can. J. Chem. **71**, 84 (1993).

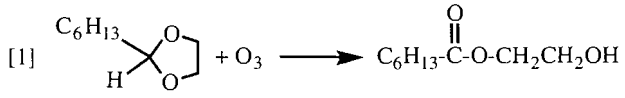
L'oxydation des 1,3-dioxolanes substitués en position-2, effectuée dans le 1,2-diméthoxyéthane et catalysée par le chlorure de cobalt(II), fournit des esters formiques et des acides avec des rendements élevés. On a trouvé que la présence de quantités catalytiques de $ZnCl_2$ augmente la vitesse d'oxydation. On propose un mécanisme radicalaire impliquant le superoxocobalt et l'estérification de l'alcool et de l'acide.

[Traduit par la rédaction]

Introduction

An impressive part of the chemistry of carbohydrates has dealt with acetals, and especially cyclic acetals. Many studies have focussed on the synthesis of cyclic acetals as temporary protecting groups for aldehydes and ketones. However, during the past few years, the role of acetals has been changing. The cleavage of cyclic acetals to afford synthetically useful derivatives has been investigated in some depth, and some of the routes have already proven to be major tools for structural modifications (1). Therefore, cyclic acetals may now be considered not only as classical protecting groups, but also as reactive functional groups (1, 2).

In 1971, Deslongchamps and Moreau (3) first discovered that ozone reacts readily with acetals to give the corresponding esters in high yield. For example, acetal **1** in dichloromethane or ethyl acetate reacts quantitatively with ozone, in 10 min at −78°C, to give the β-hydroxy ester **2** (eq. [1]).

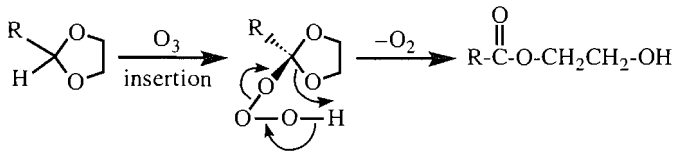


[1] C_6H_{13}-(dioxolane-H)-O + O_3 ⟶ C_6H_{13}-C(=O)-O-CH_2CH_2OH

1 **2** (98%)

The mechanism of the oxidation of acetals by ozone has been extensively studied (4–7), and it has been proposed that ozone inserts into the C—H bond of the acetal to give a hydrotrioxide intermediate, which in turn affords the corresponding hydroxy ester (Scheme 1). More recently, the oxidation of dioxolanes by nitrogen tetroxide (N_2O_4) was reported to give glycol esters in 85–92% yield (8). The reactions are believed to proceed via a free-radical chain mechanism.

There is very little information in the literature about the metal-catalyzed oxidation of acetals. Only one paper by Kuramshin *et al.* (9) reported that homogeneous cobalt catalyzed oxidation of 1,3-dioxacyclanes in the presence of



SCHEME 1

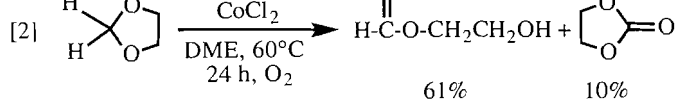
acetic acid and chlorobenzene under an oxygen atmosphere resulted in the formation of β-hydroxy esters. Although the oxidation of acetals by ozone or other oxidants has been well established and used in organic syntheses, these methods suffer from one serious drawback, lack of selectivity. For example, if acetal derivatives contain other oxidizable groups, the reactions with ozone usually result in a mixture of products. Furthermore, the noted catalytic oxidation of acetals by cobalt was carried out in an acidic medium. This limits its application to those acetals which are sensitive to the pH of the solution.

The goal of the present research was to develop a catalytic process to selectively oxidize cyclic acetals to the corresponding ester derivatives in a neutral medium under oxygen. The scope and limitation of this new reaction was investigated using a variety of 1,3-dioxolanes.

Results and discussion

Treatment of 1,3-dioxolane with atmospheric oxygen in 1,2-dimethoxyethane (DME) containing a catalytic amount of anhydrous cobalt(II) chloride (substrate:Co^{2+} = 200:1) for 24 h at 60°C gave ethylene glycol monoformate in 61% yield along with 10% ethylene carbonate (eq. [2]).

However, when the oxidation of phenylacetaldehyde ethylene acetal was performed under similar reaction condi-



[2] (dioxolane-H)-O $\xrightarrow[\text{DME, 60°C}]{\text{CoCl}_2}$ H-C(=O)-O-CH_2CH_2OH + (dioxolanone)=O

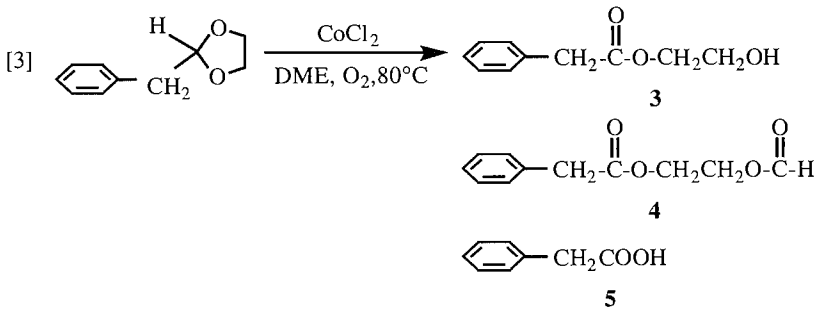
24 h, O_2 61% 10%

tions, but using a 100:1 ratio of substrate:$CoCl_2$, the expected product, ethylene glycol benzoate (**3**), was not the major product. Instead, two new compounds were observed (**4** and **5**).

[1]Dedicated to the memory of Professor Jean-Louis Roustan; an outstanding educator, a sensitive, caring undergraduate-student advisor, and a wonderful colleague.

[2]Author to whom correspondence may be addressed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.



The formation of products **4** and **5** was unexpected, especially **4**, which contains an additional carbon atom. There are two possibilities; either **3** has reacted with solvent (DME) or with itself. As a check, the oxidation of phenylacetaldehyde ethylene acetal was carried out in the presence of 1,4-dioxane instead of DME. It was found that **4** and **5** were still the major products after reaction for 42 h at 85–90°C. This result clearly indicates that the extra carbon of compound **4** was not from DME.

During the reaction, **3** was observed to be the major product formed within 20 h. It slowly disappeared with increasing reaction time and, after 56 h, only **4** and **5** were present. This result indicates that phenylacetaldehyde ethylene acetal can be oxidized to compounds **4** and **5** in a one-step reaction. Such oxidation is very useful because (1) it results in homologation, and (2) two functional groups are introduced simultaneously, one of which is the formate ester. Therefore, research was focussed on determining the optimum reaction conditions to achieve a high yield of **4** and **5**, and the use of such conditions to oxidize a variety of 2-substituted 1,3-dioxolanes to the corresponding formate esters and acids.

Effect of catalyst

A series of metal catalysts were investigated for the oxidation of phenylacetaldehyde ethylene acetal to compounds **4** and **5**. The first group of metal catalysts examined was $FeCl_3$, $CrCl_3$, and $CoCl_2$. It was found that the catalytic effect of these metal complexes increases in the order $FeCl_3 < CrCl_3 < CoCl_2$. In other words, cobalt chloride has reached the highest reactivity towards oxidation. The second group of metal catalysts examined were cobalt complexes containing a variety of ligands including $Co(OAc)_2$, $Co(OCOPh)_2$, $CoCl_2(PPh_3)_2$, $CoBr_2$, $Co(NO_3)_2{\cdot}4H_2O$, and $CoSO_4{\cdot}7H_2O$. Anhydrous $CoCl_2$ was again found to be the most effective catalyst, with $CoSO_4{\cdot}7H_2O$ being inactive. It is noteworthy that $CoBr_2$ results initially at a higher rate than anhydrous $CoCl_2$. For example, after 2 h, reaction in the presence of $CoBr_2$ reached 56% conversion, whereas the use of anhydrous $CoCl_2$ resulted in 45% conversion. However, the catalytic efficiency of $CoBr_2$ as the catalyst apparently decreased after 4 h. As a result, considering the completion of the reaction, $CoCl_2$ is a better catalyst than $CoBr_2$.

Effect of reaction temperature

Increasing the reaction temperature results in a substantial increase in reaction rate (see Table 1). Since the boiling point of DME is 85°C, the oil bath temperature should not exceed 90°C. Otherwise, solvent loss may occur under a flow of oxygen.

TABLE 1. Effect of reaction temperature[a]

T (°C) (oil bath)	Time (h)	Conversion (%)
45–50	28	42
60–65	28	68
85–90	23	100

[a]Reaction conditions: phenylacetaldehyde ethylene acetal (2.5 mmol), anhydrous $CoCl_2$ (0.1 mmol), DME (15 mL).

TABLE 2. Effect of concentration of $CoCl_2$ on the oxidation of phenylacetaldehyde ethylene acetal[a]

Substrate:$CoCl_2$ (mmol)	Time (h)	Conversion (%)	Product ratio[b] (**3**/**4**)
50:1	42	100	1:5
25:1	41	100	1:6
10:1	41	100	1:5.3

[a]Reaction conditions: acetal (5 mmol), DME (15 mL), 85–90°C.
[b]Determined by gas chromatography.

Effect of concentration of anhydrous cobalt chloride

During the oxidation reactions, it was found that the starting material was completely converted after approximately 1 day at 85–90°C. However, the rate of disappearance of glycol ester **3** was quite slow, with 56 h needed to achieve completion of the reaction. Thus it was of interest to determine whether the concentration of $CoCl_2$ influences the rate of disappearance of glycol ester **3**. The results (Table 2) demonstrate that the concentration of cobalt chloride has no significant effect on the rate of further oxidation of glycol ester **3**. Among these experiments, the use of a 25:1 ratio of substrate to $CoCl_2$ seemed to give the best ratio between **3** and **4**.

Effect of additives

Attempts were made to enhance the rate of oxidation of **3** to **4** by the addition of a Lewis acid ($ZnCl_2$), Lewis base (pyridine), or a dehydration agent (4A molecular sieves). The results are presented in Table 3.

It was observed that the addition of a catalytic amount of $ZnCl_2$ dramatically enhanced the rate of oxidation of glycol ester. However, the addition of pyridine and molecular sieves either had no effect or led to negative results. At this point,

[a]Ratio of substrate:$CoCl_2$:$ZnCl_2$ was 25:1:2.5.
[b]Isolated yield.
[c]The yield of acetic acid was not determined.

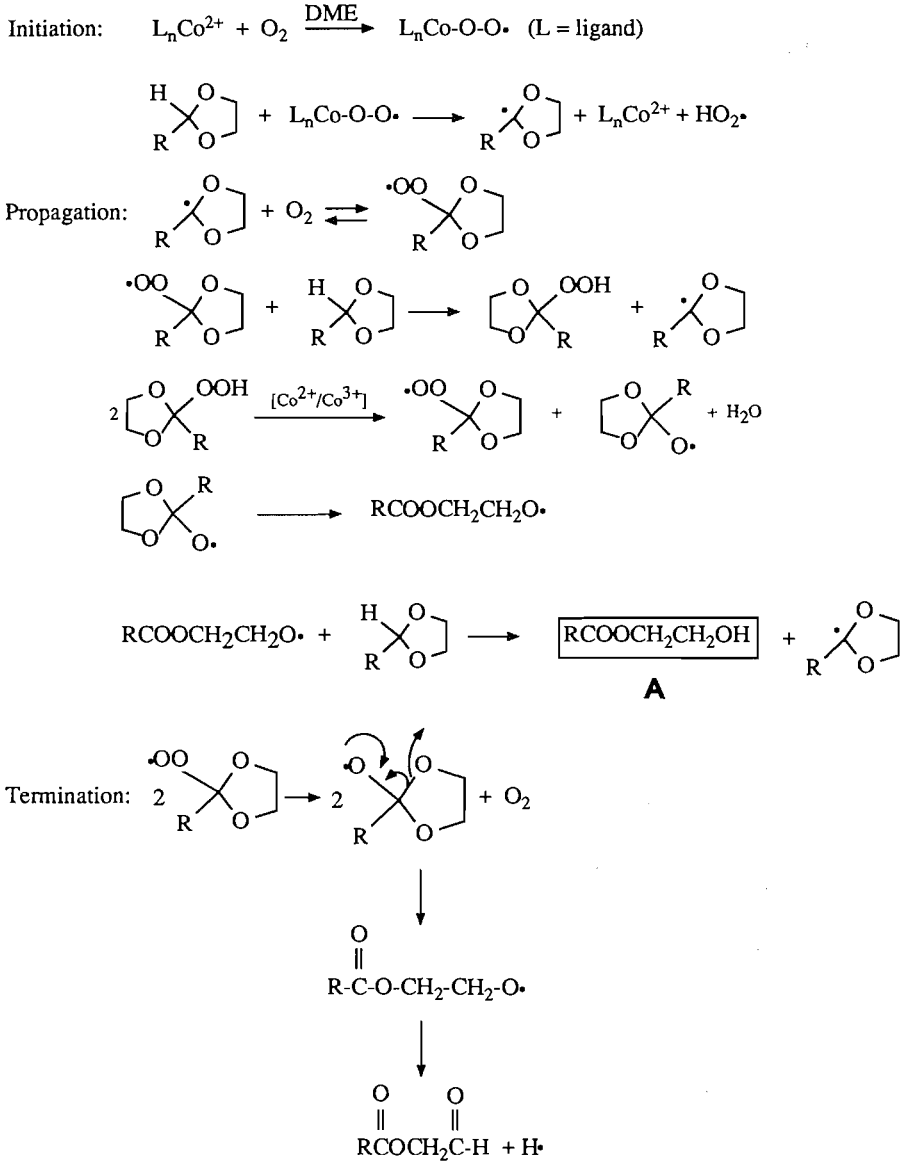
it was necessary to determine whether $CoCl_2$ or $ZnCl_2$ played an essential role in this oxidation. When the oxidation of phenylacetaldehyde ethylene acetal was catalyzed by $ZnCl_2$ (substrate:$ZnCl_2$ = 10:1) in the presence of DME, the rate of oxidation was much slower than that of the reaction catalyzed by $CoCl_2$. Only 21% conversion was obtained after 30 h at 80–90°C. This result indicated that $CoCl_2$ was the key catalyst. The presence of $ZnCl_2$ promoted the rate of further oxidation of the glycol ester.

Results for the conversion of a variety of 2-substituted 1,3-dioxolanes to the corresponding formate esters and acids using a mixed catalyst (substrate:$CoCl_2$:$ZnCl_2$ = 25:1:2.5) system are illustrated in Table 4. Some of the substrates were prepared according to the reaction shown in eq. [4].

The oxidation of 2-phenyl, benzyl, *n*-heptyl, as well as methyl-substituted 1,3-dioxolanes afforded formate esters and acids in high yields. Those 1,3-dioxolanes containing alkyl substituents such as R′ = CH_3 underwent oxidation at a

[4] 
lower rate, and no reaction was observed when electron-withdrawing groups were present. Moreover, when the oxidation of *trans*-cinnamaldehyde ethylene acetal (R = C_6H_5CH=Ch-) was attempted, none of the desired products were observed. Instead, benzoic acid was obtained in 92% yield after 24 h at 90°C. When this reaction was stopped after 4 h, benzaldehyde was produced in 64% yield. Hence, benzoic acid was formed as a result of further oxidation of benzaldehyde. Finally, oxidation of 3,4-(methylenedioxy) toluene did not occur due to the deactivation by the aromatic ring. A possible mechanism for the reaction of 1,3-dioxolanes is outlined in Schemes 2–4. Key to the conversion of the 1,3-dioxolane to the hydroxyester **A** (Scheme 2) is the intermediacy of the 1,3-dioxolanyl radical. The aldehydic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.



SCHEME 2

ester related to **A**, formed in the termination process, may then be oxidized to **B**. Reaction of the latter with **A** would afford **C** (Scheme 3). Finally the cobalt-induced generation of the radical from **C** followed by fragmentation would form the formate ester and acid (Scheme 4).

A study of the course of these reactions was performed with phenylacetaldehyde ethylene acetal (R = $C_6H_5CH_2$) as substrate. The proposed mechanism receives support from the following evidence:

1. Glycol ester $C_6H_5CH_2COOCH_2CH_2OH$ (**A**, R = Ph-

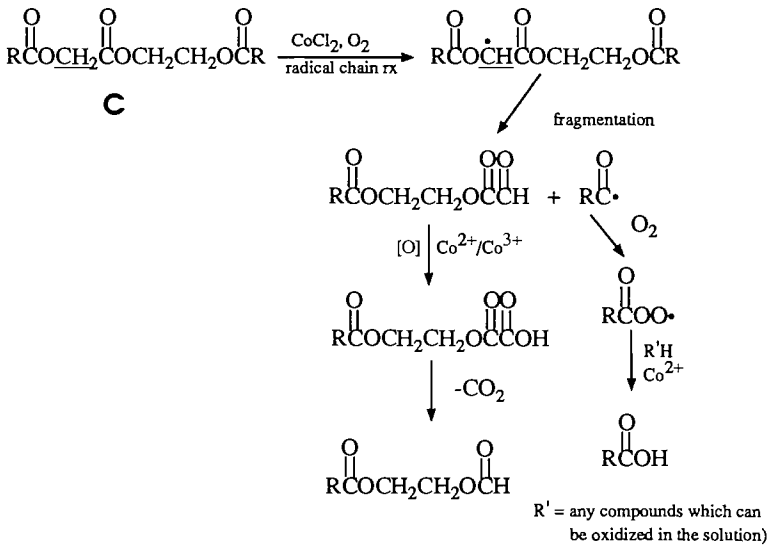
For personal use only.



SCHEME 4

CH_2) was isolated as a primary product. When the reaction was carefully followed by GC, it was observed that the peak corresponding to the glycol ester decreased slowly, while those due to the formate ester and acid increased. That is, the glycol ester must be an intermediate and undergo further reaction, affording the formate ester acid.

2. Compound **B** was detected by GC/mass spectrometry: *m/e* 194$[M]^+$; 119$[C_6H_5CH_2CO]^+$; 91$[C_6H_5CH_2]^+$; 59$[CH_2COOH]^+$; 45$[COOH]^+$.

3. Compound **C** was isolated and identified by IR, ^1H NMR, and MS, as well as by elemental analysis. IR($CDCl_3$): $\nu_{C=O}$ 1738, 1730 cm^{-1}; ^1H NMR($CDCl_3$): δ 3.63 (s, 4H, $2C_6H_5\underline{CH_2}$), 4.23 (m, 4H, -$COOCH_2CH_2OCO$-), 4.58 (s, 2H, $PhCH_2\underline{COOCH_2}CO$-), 7.25 (m, 10H, 2Ph). MS: *m/e* 194$[PhCH_2\underline{COO}CH_2COO]^+$, 164$[PhCH_2COOCH_2CH_2]^+$, 118$[C_6H_5CHCO]^+$, 91$[C_6H_5CH_2]^+$.

4. Compounds **B** and **C** disappeared at the end of the reaction.

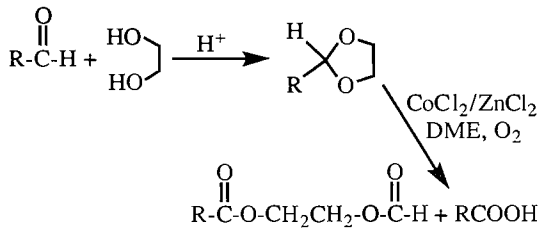
5. The presence of $ZnCl_2$ greatly enhanced the rate of disappearance of the glycol ester **A**. This result indicated that the glycol ester might react via an esterification process since $SnCl_2$ is known to be an excellent promoter for the esterification step (10).

6. The underlined methylene group in compound **C** could be oxidized by this system. This was tested by the oxidation of a similar type of substrate (ethyl acetoxy acetate). During the oxidation, the decomposition of this compound to smaller molecules was observed with an alcohol intermediate analyzed by GC/MS (*m/e* 89$[CH_3COOCHOH]^+$, 59$[CH_3COO]^+$). The reaction mixture was acidic and CO_2 evolution was determined.

7. Carbon dioxide evolution was determined by bubbling the evolved gases through a solution and a white precipitate of $BaCO_3$ was formed.

In conclusion, 2-substituted 1,3-dioxolanes can be oxidized to the corresponding formate esters and acids in high yields. This process is effectively catalyzed by anhydrous $CoCl_2$ and $ZnCl_2$ (substrate:$COCl_2$:$ZnCl_2$ = 25.1:1:2.5) in the presence of DME, and has the following advantages:

1. Aldehydes can be converted to formate esters and acids via a two-step reaction: (*a*) the preparation of acetal from the aldehyde, and (*b*) the oxidation of the acetal.



2. The oxidation of acetals is a novel method for preparing synthetically useful products.

Experimental section

Infrared spectra were recorded using a Perkin–Elmer 783 spectrometer. Proton magnetic resonance spectra were obtained with a Varian T60, EM360A, GEMINI 200, or XL300 spectrometer, whereas carbon magnetic resonance spectra were recorded on a Varian XL-300 or GEMINI 200 spectrometer. Mass spectral and gas chromatographic – mass spectrometric determinations were made with a VG-7070E spectrometer and a Varian 3300 chromatograph, fitted with a Megabore DB5 capillary column in tandem with the VG-7070E spectrometer, respectively. Analyses by gas chromatography were carried out with programmable Varian Vista 6000 or 3400 gas chromatographs equipped with flame ionization detectors and a Varian 4270 integrator. Glass columns (3 cm) packed with 3% OV101 or 3% OV-17 on Chromosorb W 80–100 mesh were utilized for gas chromatographic determinations.

The organometallic complexes and most organic chemicals were purchased from Fisher Scientific Company, Alfa Products Company, and Aldrich Chemical Company. They were used as received in almost all cases. Oxygen was obtained from Air Products Company. Solvents employed for extraction were distilled following standard procedures.

General procedure for the oxidation of 2-substituted 1,3-dioxolanes

A mixture of anhydrous $CoCl_2$ (0.027 g, 0.2 mmol) and $ZnCl_2$ (0.068 g, 0.5 mmol) in DME (15 mL) was stirred under oxygen atmosphere at 85–90°C for several minutes. The 2-substituted 1,3-dioxolane (5 mmol) was then added, and stirring was continued until conversion of the substrate was almost complete (GC determina-

tion). The following work-up was used in all cases: the reaction mixture was cooled to room temperature, filtered through a small silica column to remove the pink precipitate, and the filtrate was concentrated by rotary evaporation. To the residue was added 20 mL distilled water, and the solution was basified with 5 N NaOH. This solution was then extracted with ether (3 × 20 mL). The organic phase was washed with distilled water (50 mL), and dried ($MgSO_4$). The dried organic phase was concentrated and afforded an oily crude product, which was purified by thin-layer chromatography. The aqueous phase was acidified with dilute hydrochloric acid and extracted with ether (3 × 20 mL). Drying and concentration of this ethereal extract yielded a white solid, which was purified by recrystallization. Pure products were characterized by IR, ^1H and ^{13}C NMR, as well as by mass spectrometry. The results are listed in Table 4.

Several of the products are known materials. Their structures were identified by comparing the spectral data with that for authentic materials. The following data were obtained for the other products.

I, *R* = C_6H_5, *R'* = *H*

*$C_6H_5COOCH_2CH_2OCHO$ (**II**):* IR: $\nu_{C=O}$ 1735, 1720 cm^{-1}, ν_{C-O} 1282, 1170 cm^{-1}; ^1H NMR($CDCl_3$) δ: 3.95 (t, 2H, -CH_2CH_2O-CHO), 4.45 (t, 2H, PhCOOCH_2CH_2-), 7.48 (m, 3H, *meta* and *para* protons), 8.04 (m, 2H, *ortho* protons), 8.10 (s, 1H, -OCHO); MS: *m/e* 194[M]$^+$, 105[C_6H_5CO]$^+$, 77[C_6H_5].

Two other by-products were also isolated. They were identified as follows:

$C_6H_5COOCH_2CH_2OH$ (1% yield): IR($CDCl_3$): ν_{OH} 3440 cm^{-1}, $\nu_{C=O}$ 1720 cm^{-1}, ν_{C-O} 1280, 1122 cm^{-1}; ^1H NMR($CDCl_3$) δ: 2.40 (2, 1H, OH), 3.92 (t, 2H, CH_2OH), 4.43 (t, 2H, $COOCH_2$), 7.43 (m, 2H, *meta* protons), 7.52 (m, 1H, *para* proton), 8.03 (m, 2H, *ortho* protons); ^{13}C NMR($CDCl_3$) δ: 61.19 (-CH_2OH), 66.53 ($COOCH_2$-), 128.43, 129.70, 129.84, 133.22, (aromatic carbons), 167.09 (-COO-); MS *m/e* 148[M − H_2O]$^+$, 105[C_6H_5CO]$^+$, 77[C_6H_5]$^+$.

Practical and simple techniques are described for using nonmodified domestic microwave ovens as safe and convenient laboratory devices to obtain numerous esters. High pressures are avoided by conducting reactions with reactants impregnated on solid mineral supports in "dry media" or by phase transfer catalysis (PTC) in the absence of organic solvents. Two kinds of microwave effects are involved: (1) displacement of the equilibrium by evaporation of volatile polar molecules (water or alcohols) in esterifications and transesterifications; (2) acceleration of ionic reactions in carboxylate alkylations. As solvents are avoided, there is no need for sealed vessels and water separators.

ANDRÉ LOUPY, ALAIN PETIT, MOHAMED RAMDANI, CELINE YVANAEFF, MUSTAPHA MAJDOUB, BOUCHTA LABIAD et DIDIER VILLEMIN. Can. J. Chem. **71**, 90 (1993).

Nous décrivons ici des techniques simples et pratiques d'utilisation des fours microondes domestiques non modifiés comme procédés sûrs et commodes pour obtenir de nombreux esters. Les hautes pressions sont évitées en effectuant les réactions avec des réactifs imprégnés sur supports minéraux en «milieu sec» ou par catalyse par transfert de phase (CTP) en absence de solvant. Deux types d'effets des microondes sont mis en jeu: (1) déplacement d'équilibre par évaporation de molécules polaires volatiles (eau ou alcools) lors d'estérifications et de transestérifications; (2) accélération des réactions anioniques dans le cas des alkylations de carboxylates. Dans la mesure où les solvants sont évités, il n'est pas nécessaire d'utiliser de la vaisselle scellée et des appareils pour séparer l'eau.

Esters are among the most important industrial products (1). They are usually synthesized by one of three main methods (2): (*i*) esterification of carboxylic acids, (*ii*) transesterification of methyl or ethyl esters, and (*iii*) alkylation of carboxylate anions. These reactions have been studied widely, but a great need still exists for versatile and simple processes whereby esters may be formed under very mild conditions (3). This is especially so for the two first methods where equilibria are involved.

We have been concerned with microwave activation in "dry media" (4–6) and its application for synthetic and simplificative purposes to the preparation of esters, taking advantage of two possible specific effects: rate enhancements, essentially due to thermal effects (7–9, 39) and displacements of equilibria by removal of volatile polar molecules (water or light alcohols).

Results

Esterification of carboxylic acids

$$RCOOH + R'OH \overset{\text{Acid}}{\rightleftharpoons} RCOOR' + H_2O$$

This type of reaction is generally catalyzed by acids, the equilibrium being shifted to the right by azeotropic removal of water using Dean–Stark apparatus. Acids such as Nafion-H (10, 11), silica–alumina (12), zeolites (13–15), zirconium oxide (16, 17), heteropoly-acids (18), or supported acids on polymers (19) have been used as catalysts.

The influence of microwaves on the rate of esterification in the presence of solvents has been studied (7–9). A large acceleration of the reaction was observed in sealed Teflon vessels due to thermal and pressure effects. However, yields were limited to around 70%. We thought that this limitation with rather heavy alcohols could be removed simply by operating in the absence of any solvent, and consequently by the possibility of evaporation of water due to microwave absorption.

We therefore studied the behaviour of a variety of acids and alcohols, including hindered and long-chain acids with heavy alcohols, which are generally difficult cases. Different acids, including KSF montmorillonite, 13X zeolite (20, 21), and neat *p*-toluenesulfonic acid (PTSA), were tested. In the first case, the effect of isopropenyl acetate as a water scavenger was studied. The results are given in Table 1.

The most favourable reaction conditions involved the use of neat PTSA, which led to good yields under exceptionally mild conditions (3–10 min), in a nonmodified domestic microwave oven. KSF montmorillonite and 13X zeolite were found to be less efficient.

Transesterification of methyl esters

$$RCOOCH_3 + R'OH \overset{\text{Acid or base}}{\rightleftharpoons} RCOOR' + CH_3OH$$

[e]PTSA = 0.8 mM, no reaction; PTSA = 4 mM, yield = 45%.

In this case, the reaction can be catalyzed by either acid or base (22). The equilibrium can classically be shifted to the right by azeotropic distillation (23), addition of molecular sieves (24), or by carrying out the reaction under partial vacuum in the absence of organic solvent (25). Under microwave irradiation without solvent, the most volatile component, CH_3OH, could be easily removed by evaporation.

We have studied the acid-catalyzed transesterification of methyl benzoate to octyl benzoate by solid acids, including K10 montmorillonite, Spherosil-S (26), Amberlyst-15 (recommended in this type of reaction) (27, 28), and PTSA, neat or impregnated on alumina or silica gel (29–31) (Table 2).

We also studied base-catalyzed transesterification of methyl to octyl benzoate, testing different bases impregnated on alumina, or in the presence of Aliquat 336 as a phase transfer catalyst (Table 3).

Finally, the most significant results were extrapolated for the most difficult case of methyl mesitoic ester. These results are indicated in Table 4.

From these tables, one can conclude that the best conditions are as follows:

Under acidic catalysis, *neat PTSA* leads to almost quantitative transesterifications, both with benzoic and mesitoic esters; yields obtained from Amberylst-15 (polysulfonic acid ion exchange resin) and Spherosil-S (grafted sulfonic acid on silica) are much lower. PTSA, when impregnated on a solid support, was less efficient and gave a lower yield (Table 2) than did neat PTSA. This fact is significant for silica gel (from 97 to 61%), and dramatic for alumina (<1%) where nonreactive species are generated, and is in disagreement with results of previous studies that claim absorbed PTSA to be an efficient dehydrating agent of alcohols (29–31). In all cases studied, the presence of a support had a negative effect.

Basic catalysis *under solid–liquid phase transfer catalysis (PTC) conditions* is generally more efficient than under conditions using supported bases: K_2CO_3 + Aliquat gives 90% yield, against only 72% for KOH/alumina in the case of methyl benzoate; $KOCH_3$, even in the absence of phase transfer agent, is the most efficient base in promoting mesitoate transesterification.

Carboxylate alkylations

In preliminary work dealing with potassium acetate, we pointed out the possibility of alkylation by microwave irradiation, either in solid–liquid PTC conditions without solvent (32), or by carrying out reactions on solid mineral supports in dry media (5, 33). Extension of this work to the more difficult cases is considered here. Table 5 indicates the results, involving the same esters as above to allow comparison.

It is clear that *PTC conditions are noticeably more efficient than reactions performed on alumina,* as was also apparent in acetate alkylation by classical heating (34). Quantitative yields of esters are always observed using PTC conditions, except in the case of cyclohexylester, where the main pathway is β-elimination.

Discussion

Using microwave irradiation in a domestic oven, in the absence of solvent and under atmospheric pressure, we have demonstrated three efficient and easy-to-perform methods to obtain esters. All of them have operative times of 10 min or less. The synthetic interest is obvious, because it is possible to obtain esters in almost quantitative yields under very mild

[b]Aliquat 336 = 1.5 mM.

conditions with a standard, nonmodified, microwave oven. This is also the case when they are poorly accessible (e.g., double long-chain esters).

Esterification and transesterification

Under microwave irradiation these methods are very efficient; they avoid pervaporation using a water-permeable polyetherimide membrane (35). The effect of microwave irradiation is twofold: (*i*) enhancement of reaction by a thermal effect, and (*ii*) evaporation of water or methanol due to the strong microwave interaction of these materials (cf. final temperatures ≥ 150°C in tables).

Acidic catalysis

Neat PTSA is by far the best agent to promote equilibrium shifting. The maximum yield is obtained when 0.5 mol. equiv. PTSA is used both in esterification and transesterification. Smaller or greater amounts of PTSA lead in both cases to significant reduction in yields.

When impregnated on silica gel, and more so when on alumina, PTSA loses its efficacy. Furthermore, other kinds of supported sulfonic acids, Spherosil-S (grafted on silica) or Amberlyst-15 (exchange resin), also lead to limited yields. The conclusion may be that *when they act as supports the solid acids lose their efficacy*. Certain of them have large specific areas (e.g., K10 = 220–270 m^2/g) or lamellar structures with consequent interfoliar spaces (e.g., montmorillonites). They consequently are able to absorb, either by physisorption or chemisorption, molecules of H_2O or CH_3OH. This absorption can limit evaporation of these molecules. Furthermore, under the microwave effect, the reverse reaction can be promoted.

Another hypothesis is the possibility of ester hydrolysis

by intralamellar water molecules present inside montmorillonites (K10 or KSF). To check these possibilities, further work is in progress.

We have to emphasize here the decisive role of microwaves in acidic transesterification, as no reaction can be observed under dynamic or static vacuum in classical conditions (25).

Basic catalysis

The most efficient "dry" systems are those involving PTC conditions rather than supported reagents on mineral supports. This conclusion was drawn for esterifications under traditional heating (34). We verified it here for transesterification with K_2CO_3 either in presence of Aliquat (yield = 88% within 2 h at 55°C) or impregnated on alumina (yield = 50% under the same conditions). One can propose two interpretations for these observations: (*i*) a dilution effect in the support, leading to a loss in reactivity; (*ii*) the PTC system absorbs microwaves more strongly than the alumina. This last assumption is verified in Table 3, as final temperatures due to irradiation are 140–165°C for bases/alumina and 180–190°C for bases + Aliquat.

These results represent a large improvement over experimental conditions that need either partial vacuum (25) or gas–liquid PTC conditions (36), i.e., high temperatures under pressure, to go to completion.

Anionic alkylation

This is the most efficient and simple method where primary alcohols (even very heavy ones) are concerned. Yields are quantitative within 2 min or less of microwave irradiation. The results we obtained represent large improvements when compared to those obtained under traditional heating: for instance, the preparation of octadecyl mesitoate classically needs 8 h at 85°C (37) while comparable yields are obtained in 45 s under microwave irradiation.

Another interesting point is the non-necessity of preforming the anionic species $RCOO^-K^+$ to perform the reaction. One can prepare it *in situ*, as for example in the reaction

$$PhCOOH + K_2CO_3 + n\text{OctBr} \rightarrow PhCOO_n\text{Oct}$$

which gave a 99% yield within 5 min under microwave compared with only 50% after 20 h at 85°C (38). Here, the effect of microwave irradiation is twofold: (*i*) a shifting to the right of the previous acid–base equilibrium by evaporation of H_2O:

$$2\ PhCOOH + K_2CO_3 \rightleftarrows 2\ PhCOO^-K^+ + H_2O + CO_2$$

and (*ii*) an acceleration of benzoate alkylation.

A further advantage lies in the considerable superiority of PTC conditions when compared to supported reactions, except for the alkylation of $CH_3CO_2^-K^+$ where the two methods are equally operative. As before, two assumptions can be made: (*i*) a dilution effect on the support, resulting in reduced reactivity; (*ii*) a diminution in the strength of microwave–material interaction when species are more hindered and heavier (long-chain acids or halides).

Conclusion

We propose here three microwave methods for ester synthesis in dry media. Two of them (esterification and transesterification) need equilibrium shifting of volatile polar molecules (water or methanol), which is here very efficiently and simply conducted *in the absence of solvent and of mineral supports*. Neat *p*-toluenesulfonic acid is used for acid-catalyzed esterification and transesterification, and K_2CO_3 in the presence of a transfer agent (Aliquat 336) is used for base-catalyzed transesterifications. Finally, in the most efficient procedure, alkylations of carboxylic anions are performed quantitatively (≥ 97%) in 1–2 min by simply mixing the potassium salt of the organic acid (possibly generated *in situ*), the alkylating agent (1 mol. equiv.), and a catalytic amount of transfer agent. All three methods are easily used and can be selected, if necessary, according to substituents.

The results described herein, i.e., almost quantitative yields in a few minutes, are characterized by very simple work-up and can be conducted very efficiently at ambient pressure using nonmodified microwave ovens as safe and convenient laboratory devices. These procedures undeniably possess considerable advantages over classical thermal conditions as reaction times are significantly reduced and yields widely enhanced, with apparatus simplified and reduced in cost.

One of the chief limitations of the microwave method is, in general, the difficulty in carrying out reactions safely if larger quantities of products are required. It seems that the dry-media method could achieve this (33, 40). Thus, for reactions on a larger scale (up to 0.5 mol), yields are always excellent (96.5%) for acetate alkylation by *n*-octyl bromide under PTC conditions without solvent; they remain always very acceptable (around 80%) for acid- and base-catalyzed transesterifications and esterifications. Although the reaction rates can be reduced when the reactions are scaled up, large rate enhancements are still observed.

Experimental section

Reaction mixtures (acids or methyl esters + alcohols in presence of catalyst; see below) were introduced in open Erlenmeyer flasks or beakers. They were irradiated (power and reaction times are indicated in the tables) with a Philips Whirlpool 5964 commercial domestic microwave oven operating at 2450 MHz. An approximate temperature measurement was performed by introducing a digital thermometer to the sample at the end of each irradiation. In these temperature evaluations, variations between several readings were less than 5°C. The reaction mixtures were extracted with organic solvent (methanol, diethyl ether or dichloromethane) and filtered. Organic esters were analyzed by gas chromatography and ^1H NMR and comparison made with authentic samples. Yields were evaluated by GC using an internal standard or by NMR. Gas chromatographic analyses were performed on a Carlo Erba Vega 6000 apparatus fitted with a capillary OV1 column (10 or 25 m) under a pressure of 0.4 bar (1 bar = 100 kPa) using helium as carrier gas.

The procedure described below involved from 5 to 20 mmol of standing materials (see tables).

Acid-catalyzed esterifications and transesterifications (Tables 1, 2, and 4)

Reactions with pure PTSA

Carboxylic acid or methyl ester, alcohol, and PTSA were mixed and shaken together in the proportions indicated in the tables and consequently treated as described above.

Reactions on acidic solid supports (montmorillonites, zeolite 13X, Spherosil-S, Amberlyst-15)

Carboxylic acids or methyl esters were impregnated on the support (via solutions in EtOH or CCl_4 in the case of acids and evaporation of solvent under reduced pressure). Alcohols were then added in the amounts indicated in the tables. After mechanical shaking for 1 min, the mixtures were microwaved and treated as previously described.

Impregnated PTSA on alumina or silicagel

PTSA (5 g) was adsorbed on the support (20 g) via a solution in 50 cm^3 EtOH. Solvent was removed by evaporation under reduced pressure. This impregnated PTSA was then used as the acidic solid support as described above.

Base-catalyzed transesterifications (Tables 3 and 4)

Impregnated bases on alumina

The different bases (K_2CO_3, KOH, KF, $KOCH_3$, or KO*t*Bu) were impregnated on basic alumina (alumina 90 type I, 70–230 mesh, Merck) via aqueous or alcoholic solutions (base:alumina = 1:4 w/w) and dried under reduced pressure (1 Torr; 1 Torr = 133.3 Pa) for 2 h at 140°C. Alcohols and esters were then added according to the amounts indicated in the tables. Reactions were carried out as described above.

PTC without solvent

Methyl ester (10 mmol), alcohol (10 or 20 mmol), neat base (5 mmol), and Aliquat 336 (0.5–1.5 mmol) were introduced into a flask and shaken vigorously before irradiation. Treatment remains as previously described..

Carboxylate alkylations (Table 5)

Impregnated salts on alumina

The potassium salts of carboxylic acids were prepared from the acid and a stoichiometric amount of KOH in EtOH and subsequent evaporation of solvent. The salts were impregnated on alumina (1:4 w/w) from ethanolic solutions and dried under reduced pressure (1 Torr). Reactions were then performed by mixing 10 mmol of supported potassium salt and 10 mmol of alkylating agent. After irradiation, treatment and analysis were carried out as described above.

PTC without solvent

The potassium salt (10 mmol), the alkylating agent (10 mmol), and Aliquat 336 (5 mmol) were mixed together and then irradiated. In some cases (cf. Table 5), reactions were performed by generation of the potassium salt *in situ* by reacting the carboxylic acid in the presence of base.

Synthesis, NMR spectroscopy, and crystal structure of [9](*N*6,9)-6-aminopurinophane

ALFREDO CAPRETTA, HOWARD N. HUNTER, CHRISTOPHER S. FRAMPTON,[1] AND RUSSELL A. BELL[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 21, 1992[3]

ALFREDO CAPRETTA, HOWARD N. HUNTER, CHRISTOPHER S. FRAMPTON, and RUSSELL A. BELL. Can J. Chem. **71**, 96 (1993).

[9](*N*6,9)-6-Aminopurinophane, **9**, was synthesized by Mitsunobu coupling of 9-azidononanol, **5**, and **6**-chloropurine, **6**. Reduction of the azide allowed for intramolecular nucleophilic displacement of chloride by the resultant amine and cyclization to the cyclophane. Variable temperature proton NMR showed the presence of two conformers below −25°C separated by an activation barrier having a $\Delta G_c^{\neq}$ = 50.2 ± 2.5 kJ mol^{-1}. The conformers arose from partial rotation about the C6—N6 bond, with the *anti* conformation assigned to the major isomer, **9***a*, and the *syn* conformation to the minor, **9***b*. The crystal structure of the [9](*N*6,9)-6-aminopurinophane, $C_{14}H_{21}N_5$, was determined at 173 K. The crystals are monoclinic, of space group $P2_1/n$, with a = 16.941(3) Å, b = 8.512(2) Å, c = 19.300(2) Å, β = 95.90(1)°, V = 2769(1) Å^3, D_c = 1.24 g cm^{-3}, D_m = 1.27 g cm^{-3}, for Z = 8, λ(CuKα) = 1.540598 Å. R_1 = 0.0364, R_2 = 0.0395 for 2846 reflections, ((R_1) = 0.0319, R_2 = 0.0365 for 2556 reflections with $I > 2.5\sigma(I)$). The purine ring shows small but significant distortions from planarity. The N(1)—C(6)—N(6)—C(1′) fragment adopts an *anti* conformation, which is twisted by approximately 35° from the plane of the purine ring, and the exocyclic 6-nitrogen is partially pyramidalized. Such pyramidalization is consistent with the Bader–Wiberg theory of barriers to rotation about bonds.

ALFREDO CAPRETTA, HOWARD N. HUNTER, CHRISTOPHER S. FRAMPTON et RUSSELL A. BELL. Can. J. Chem. **71**, 96 (1993).

On a synthétisé le [9](*N*6,9)-6-aminopurinophane, **9**, par un couplage selon Mitsunobu du 9-azidononanol, **5**, avec la 6-chloropurine, **6**. La réduction de l'azoture permet ensuite un déplacement nucléophile intramoléculaire du chlorure par l'amine qui se forme et conduit à une cyclisation fournissant le cyclophane. La RMN du proton à température variable a mis en évidence, à −25°C, la présence de deux conformères séparés par une barrière d'activation dont le $\Delta G_c^{\neq}$ = 50,2 ± 2,5 kJ mol^{-1}. Les conformères proviennent d'une rotation partielle autour de la liaison C6—N6; on a attribué la conformation *anti* à l'isomère prépondérant, **9***a*, et la conformation *syn* au produit mineur, **9***b*. On a déterminé la structure cristalline du [9](*N*6,9)-6-aminopurinophane, $C_{14}H_{21}N_5$. Les cristaux sont monocliniques, groupe d'espace $P2_1/n$, avec a = 16,941(3), b = 8,512(2) et c = 19,300(2) Å, β = 95,90(1)°, V = 2769(1) Å^3, D_c = 1,24 g cm^{-3}, D_m = 1,27 g cm^{-3}, Z = 8, λ(CuK$_\alpha$) = 1,540598 Å, R_1 = 0,0364 et R_2 = 0,0395 pour 2846 réflexions ((R_1) = 0,0319, R_2 = 0,0365 pour 2556 réflexions avec $I > 2{,}5\sigma(I)$). Le cycle de la purine présente une légère, mais définitive, distorsion par rapport à la planéité. Le fragment N(1)—C(6)—N(6)—C(1′) adopte une conformation *anti* qui dévie par environ 35° par rapport au plan du noyau de purine et l'azote exocyclique en position 6 est partiellement pyramidalysé. Une telle pyramidalisation est en accord avec la théorie de Bader–Wiberg relative aux barrières à la rotation autour des liaisons.

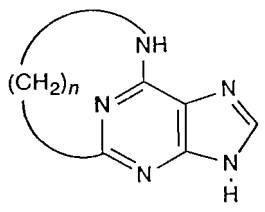
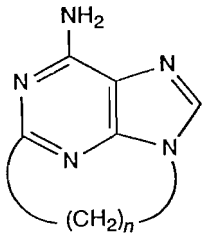
Introduction

Simple [*n*]-heterocyclophanes have been of continuing interest to oganic chemists because of their structural and spectroscopic properties (1). Emphasis has been placed on the synthesis of cyclophanes with relatively short methylene bridges but, even with the steric and ring strains so introduced, it is remarkable how the chains retain sufficient flexibility to exist in more than one conformation, as, for example, in [8](3,6)-pyridazinophane (2). Our interest has been in utilizing the methylene protons in an [*n*]-cyclophane chain as reporter atoms of the magnetic anisotropy associated with the purine and pyrimidine bases found in ribo- and deoxyribonucleic acids in a manner similar to that employed by Agarwal *et al.* in their study of benzene anisotropy (3). In consequence, the synthetic objectives are molecules that have a methylene chain sufficiently taut to bridge the heteroaromatic ring without introducing severe bending strains into the ring or the chain.

Syntheses of very few [*n*]-cyclophanes of the heteroaromatic purine ring system have been described, although a number of [*m*,*n*]-purinophanes have been prepared (4). Ienaga *et al.* (5) have reported the use of the Dimroth rearrangement to synthesize [*n*](2,6)-6-aminopurinophanes, **1** (*n* = 7,9), and [*n*](2,9)-6-aminopurinophane derivatives, **2**



1 *n* = 7, 9, 11



2 *n* = 9, 11

[3]Revision received August 25, 1992.

(n = 9,11). Ienaga and Pfleiderer (6) have recounted the preparation of the corresponding [n](2,*N*6)-adenosine derivatives (n = 7,9,11). A series of heteroatom derivatives, [n](6,9)-6-thiapurinophanes (n = 9,10,11) has been produced by Higuchi *et al.* (7) and an [8](*N*6,9)-6-aminopurinophane, **3**, has been reported by Bell and Hunter (8). Only these latter compounds have their methylene chain constrained to lie directly over the purine ring and, as a consequence, their ^{1}H NMR spectra show a number of highly shielded proton signals.

The crystal structure of [8](*N*6,9)-6-aminopurinophane (9) shows there are appreciable strains present in the molecule, with the N6 and C8′ atoms being moved out of the heteroaromatic plane by 0.314 Å and 0.459 Å, respectively, towards the methylene chain, and the five- and six-membered rings twisted with respect to each other by 5.45°. In view of these distortions we have undertaken the synthesis of [9](*N*6,9)-6-aminopurinophane and report herein its synthesis, NMR spectroscopy, and X-ray crystal structure.

Results and discussion

Synthesis

The strategy for the synthesis of [9](*N*6,9)-6-aminopurinophane, **9**, is outlined in Scheme 1 and, while it follows the methodology developed for the construction of [8](*N*6,9)-6-aminopurinophane (8), a more direct approach has been devised. 1,9-Nonanediol, **4**, and 6-chloropurine, **6**, were the two starting fragments. By use of the elegant procedure of Castro and co-workers (10),[4] 1,9-nonanediol could be routinely converted into 9-azidononanol, **5**, in 85–90% yields. Once reduced, the azido group (effectively a protected amine) provides the nitrogen atom at the 6 position of the cyclophane.

The Mitsunobu reaction (11),[5] which has proved useful in providing good yields of *N*9-alkylated purines, was planned as the procedure for coupling 9-azidononanol to 6-chloropurine. However, the reaction was approached with some caution as one of the reagents, triphenylphosphine, is known to be an efficient reductant of azides (the "other" Staudinger reaction) (12).[6] By carrying out the reaction with prior mixing of the triphenylphosphine, diethylazodicarboxylate (DEAD), and 6-chloropurine, and then addition of 9-azidononanol, a modest yield of 23% of purified 6-chloro-9-(1-azidononyl)purine, **7**, could be obtained. Clearly the lower than normal yield (normal range 65–80%) (11) was a result of unwanted triphenylphosphine reductive processes. No attempt was made to isolate these additional products. Reduction of the azido group to the amine **8** was then readily accomplished with a further 1 mole-equivalent of triphenylphosphine and 1.5 equivalents of water in tetrahydrofuran (THF). Curiously, this reduction proceeded in high yields only if the concentration of **7** was of the order of one molar or greater. The reasons for this behaviour are not entirely clear, but reactions conducted at concentrations of 10–100 mmolar afforded distinctly poorer yields of amine product.

The final, and crucial, cyclization step in the synthesis was an intramolecular nucleophilic aromatic substitution process depicted in the step **8** to **9** in the scheme. While the nonamethylene chain permitted ready access of the amine nitrogen to carbon-6 of the 6-chloropurine, it was anticipated that the reaction rate would be slower than that recorded for the octamethylene chain because of the additional degrees of freedom present with the extra methylene group (13). After refluxing for 48 h in acetonitrile all of the chloro-amine **8** had reacted, as judged by thin-layer chromatography (TLC), but chromatographic purification of the products yielded only 26% of the desired cyclophane. Much of the starting **8** appeared to have degraded, presumably by the presence over the long time period of adventitious water and (or) oxygen.

High-resolution mass spectroscopy (HRMS) together with proton and carbon-13 NMR spectroscopy further confirmed the homogeneity of the [9](*N*6,9)-6-aminopurinophane. Crystallization of a sample of **9** from chloroform–toluene (1:3) yielded large acicular crystals that were found to be suitable for X-ray crystallographic analysis.

NMR spectroscopy

The ^{1}H NMR spectrum of the cyclophane **9** recorded in $CDCl_3$ at 25°C illustrated the pronounced effect the magnetic anisotropy of the purine system had on the bridge protons (see Fig. 1, spectrum (*b*)). With chemical shifts ranging from δ 4.53 to −0.01, many of the nine diastereotopic bridge proton pairs appeared as well-resolved multiplets while others were broadened to various degrees. Such behaviour is characteristic of an exchange process operating in an intermediate rate region and indicated that the methylene chain was undergoing interconversion between two or more conformers. When **9** was heated to 75°C and its spectrum recorded ($CDCl_3$, sealed tube; see Fig. 1, spectrum (*a*)), the majority of the signals became sharp, demonstrating that the fast-exchange limit had been reached. Assignments were made based on 2D-COSY and 2D ^{13}C–^{1}H heteronuclear shift-correlated spectra at the elevated temperature (see Table 1).

The low-temperature ^{1}H NMR spectrum of **9** (CD_2Cl_2:$CFCl_3$ solvent) was especially informative and showed the presence of two "frozen" conformers (see Fig. 1, spectrum (**c**)). At −59.5°C, two species, unequal in population, were clearly evident. Most pronounced were the two sharp singlets between δ 7.7 and 8.4, a set for each conformation, corresponding to H2 and H8 on the purine ring. Signals from the aliphatic chain, at this temperature, ranged from δ 4.84 to −1.30. While the methylene hydrogens of C1′ and C9′ for each conformer were reasonably well resolved, the significant broadening seen in the high-field resonances is likely a result of residual exchange of protons in very different chemical shift environments. The chemical shift dependence of the N6H resonance on temperature was strong, moving from δ ca. 8.0 at −59.9°C to 5.2 at 75°C. Likewise the high-field signal at δ −1.30 moved to ca. δ 0.2 as the temperature was increased.

Assignments for the two conformers observed in the low-temperature spectrum of **9** were made by the analysis of the 2D COSY and the 2D ^{13}C–^{1}H heteronuclear shift-correlated spectra recorded at −59.5°C (see Table 1). Because the two conformers were of unequal population, approximately 75% of the *anti* form **9***a* and 25% of the *syn* form **9***b* as subsequently assigned (see Fig. 2), it was possible to use the 2D ^{13}C–^{1}H experiment to correlate each carbon in the two conformers with its attached geminal pair of diastereotopic hy-

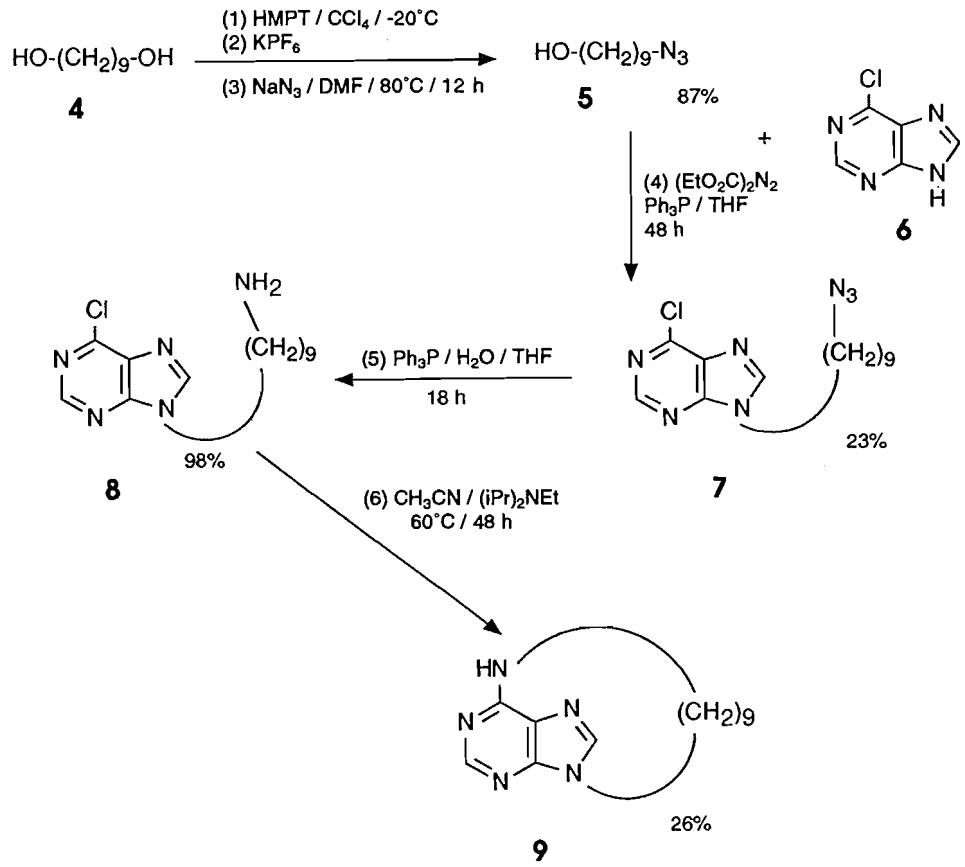

SCHEME 1

drogens; the sole exception was C3′ where the correlation was too weak to be reliably distinguished from noise. The chemical shifts of C1′ and C9′ were defined by comparison with [8](*N*6,9)-6-aminopurinophane, **3**, (C1′ δ 43.03, C8′ δ 45.03), 6-octylaminopurine (C1′ δ 40.72), and 6-chloro-*N*9-octylpurine (N-C1′ δ 44.48) (9), and thence their attached pairs of protons defined. Use was then made of the 2D COSY experiment where each proton could be linked with its neighbours along the chain and allowed each carbon to be assigned. Again the lack of a ^{13}C–^{1}H correlation for C3′ stopped the linking from the C1′ end of the minor conformer but it was possible to proceed uniquely from C9′ to C4′. It should be pointed out that the 2D experiments do not permit the assignment of the *pro-R* and *pro-S* hydrogens in each diastereotopic pair; additional data are required for this, for example the magnitude of the spin–spin coupling constants of a given proton to all of its neighbours and then application of the Karplus equation. Unfortunately, the severe overlaps together with the line broadening of our spectra at −59.5°C did not allow for the derivation of coupling constants of adequate accuracy for unambiguous assignments of *pro-R* and *pro-S* hydrogens. Alternative approaches to this problem are presently being undertaken.

To obtain the activation barrier for interconversion between the two observed conformers, variable temperature NMR experiments were carried out over the range −98.9°C to +30°C. The H2 and H8 protons on the purine ring were the most clearly defined, well-separated, singlets in the spectrum and were used for a line shape analysis (14). A linear chemical shift versus temperature change was noted for both H2 and H8 in proceeding from −98.9°C towards the coalescence temperature of these protons and this change was taken into account in calculating the activation barrier. Coalescence of the signals occurred at −25°C and the Gibbs' energy of activation, $\Delta G_c^{\neq}$, at this temperature was determined to be 50.2 ± 2.5 kJ mol^{-1}. Reitz *et al.* (15) have reported the barrier for rotation about the C6—N6 bond in both 9-benzyl-6-(isopropylamino)purine and 9-benzyl-6-(methylamino)purine to be 54.0 kJ mol^{-1} and the similarity in magnitude to that obtained for **9** strongly suggested that the two observed conformers were the result of partial rotation about the C6—N6 bond where the C1′ carbon may be *anti* (adjacent to N7) or *syn* (adjacent to N1), **9***a* and **9***b* respectively (see Fig. 2). To further confirm this postulate, molecular mechanics calculations (16) were performed on the two proposed conformers and the *anti* conformer was found to be 4–6 kJ mol^{-1} more stable than the *syn* conformer. This relationship was consistent with that observed experimentally if the major conformer was assigned structure **9***a* and the minor conformer structure **9***b*. Final and convincing evidence for these assignments was obtained from the X-ray crystal structure of **9** (see below) where it adopted the lower energy *anti* conformation. Moreover, this structure (see Figs. 3 and 4) and the molecular mechanics model **9***a* were found to be virtually identical, lending strong credence to the conviction that the other observed conformer should be assigned *syn* structure **9***b*.

It is intriguing to note that the previously reported [8]-purinophane, **3**, showed only one conformation to be present in solution (the *anti* form) over a wide temperature range. The addition of one methylene unit has been sufficient to give

the aliphatic bridge of the [9]-purinophane enough flexibility to permit rotation about the C6—N6 bond to take place.

Diffraction studies and conformational analysis

The two symmetry-independent molecules of [9](*N*6,9)-6-aminopurinophane (hereafter referred to as molecules A and B),[7] are shown in Figs. 3 and 4 with the atom labelling scheme. Crystal data and other information related to data collection are given in Table 2 while bond lengths and bond angles are shown in Table 3, and dihedral and torsional angles may be found in Table 4. As may be deduced from the latter tables, both molecules A and B are conformationally similar and have essentially the same geometry. It is pertinent to compare the structural results presented in this paper with those obtained (9) for [8](*N*6,9)-6-aminopurinophane, **3**. With the addition of an extra methylene group in the aliphatic chain one would expect the strain energy that was shown to be present in **3** would be slightly less. However, for both molecules A and B there are still a significant number of intramolecular nonbonding contacts less than the accepted van der Waals distances of 3.30 Å, C···C; 3.20–3.25 Å, C···N; 2.90–3.10 Å, C···H; 2.75–3.00 Å, N···H (18). Particularly close approaches by atoms in molecule A are shown by: C(1′)···C(5), 3.02; C(7′)···N(9), 3.00; H(11)···C(6), 2.57; H(72)···C(8), 2.50; H(11)···N(7), 2.38; H(72)···N(9), 2.55 (all in Å); with close approaches between similar atoms in molecule B.

The bond lengths of the adenine moiety are in good agreement with **3** and also agree well with previously pub-

[7]Both the CREDUC and MISSYM outputs from the NRCVAX crystallographic packages (17) failed to detect any additional symmetry.

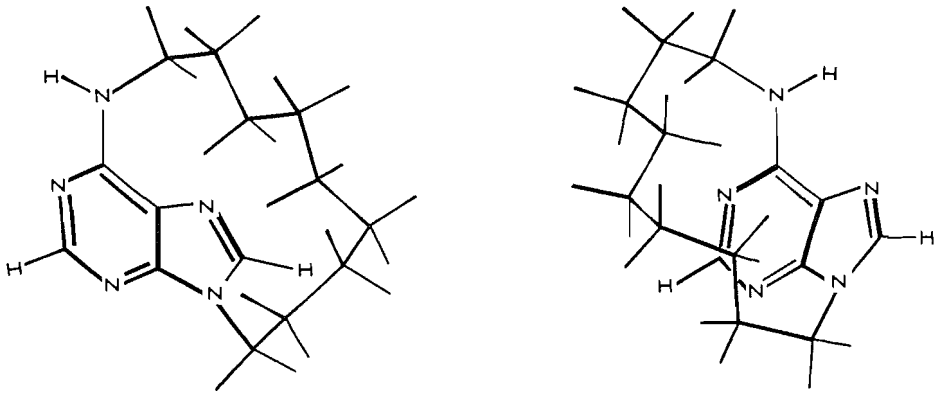

FIG. 2. Molecular mechanics models of *anti*-[9](*N*6,9)-6-aminopurinophane, **9***a*, and *syn*-[9](*N*6,9)-6-aminopurinophane, **9***b*. Bridge methylene protons have been omitted for clarity.

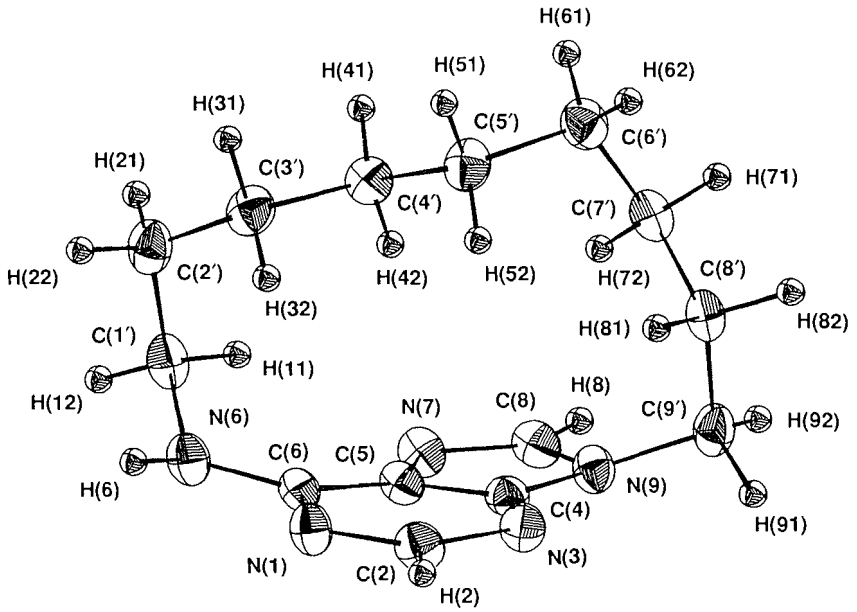

FIG. 3. Molecule A. (*pR*)-[9](*N*6,9)-6-Aminopurinophane showing the complete atom numbering.

lished average values (19) (to within 2.1σ; $\sigma = (\sigma_1^2 + \sigma_2^2)^{1/2}$). Interestingly, the largest deviation found is for C(2)—N(3), 2.1σ (A) and 1.6σ (B), which is consistent with that found for **3**. Similarly, the bond angles are in agreement with previous adenine structures, lying within 2.9σ of the average reported values.

The adenine moiety shows the same pattern of small deviations from planarity as observed in **3**. The dihedral angle between the mean planes through the pyrimidine and imidazole rings is 3.85(6)° (A) and 4.47(6)° (B) (cf. 5.45(9)° for **3**); this reduction in magnitude of the dihedral angle gives the impression that the twisting motion of the adenine group has been somewhat relaxed, leading to a reduction in strain energy in the adenine ring system. In contrast, however, both N(6), N(6B) and C(9′), C(9′B) are displaced out of the plane of the rings to which they are attached (in the direction of the aliphatic chain) to a greater extent than in **3**; (N(6), 0.325(2); N(6B), 0.362(2); C(9′), 0.577(3); C(9′B), 0.624(3); Å). If one examines the N—C—C—C and C—C—C—C torsional angles, deviations from the idealized values of 60, 120, and 180° rarely exceed 10° (average, 9.9° (A) and 11.0° (B)), with the exception, however, of one angle in particular, C(9′)—C(8′)—C(7′)—C(6′), (29.9° (A) and 28.1° (B)). It is at this position that the conformation of the aliphatic chain begins to differ from **3** and is being forced away from the adenine ring system; this, in turn appears to pull C(9′) further out of the mean plane. The N(1)—C(6)—N(6)—C(1′) fragment adopts an *anti* conformation (as does **3**), which is twisted about the N(6)—C(6) bond by approximately 35° from the plane of the purine ring. This twisting motion reduces the overlap of the nitrogen lone pair with the purine π-system. Bond lengths and angles in the aliphatic chain (average values 1.524 Å and 114.9°, respectively, for both A and B) are in very good agreement with average values reported previously (20, 21). A stereoview of the crystal packing is shown in Fig. 5. The view is down *b*. The molecules pack in layers parallel to (−1 0 1). There are no unusual intermolecular contacts and the crystal packing appears to be dominated by van der Waals forces only.

The slightly lower barrier to rotation about C6—N6 in **9**

when compared to the noncyclic examples reported by Reitz *et al.* (15) warrants further scrutiny. Inspection of Dreiding models suggested the strain of the cyclophane system should increase the barrier to rotation rather than decrease it. As noted above, however, the H6—N6—C1′ fragment in **9** is twisted about the C6—N6 bond by approximately 35°, whereas in the aliphatic examples studied by Reitz *et al.* (15) the ground state has this fragment essentially planar. Thus, in the [9]-purinophane, the ground state energy of the system has been raised and less energy should be required to achieve rotation about the C6—N6 bond. The magnitude of the decrease is smaller (ca. 4 kJ mol^{-1}) than might be anticipated considering the twist is already 35° and the highest point of the barrier is presumably with a twist of 90°. However, the entire methylene chain must reorganize itself in proceeding from the *anti* to the *syn* conformation and there will be torsional energies associated with this that contribute to the activation barrier and partially offset the increased ground state energy.

The *origin* of the barrier to rotation about the C6—N6 bond of **9** and other *N*6-alkyl substituted purines has been of particular concern to chemists, and the data from the crystallographic structure of **9** offer some insight into this. The barrier is generally considered to arise from destruction of the overlap of the nitrogen atom's lone pair of electrons with the electron-deficient heteroaromatic ring (15, 22). Recently, theoretical studies by Bader *et al.* (23) and Wiberg and Laidig (24) and experimental work by Brown and coworkers (25) on substituted amides suggest that it is the movement apart of the two atoms about which rotation is taking place and the consequent changes in the electron–nucleus attractions and electron–electron repulsions that are the principal contributors to the activation barrier. For a planar amide, rotation about the C—N bond results in lengthening of this bond and pyramidalization of the N atom as the energy maximum is reached. 6-Aminopurines contain an amidine system (N1—C6—N6) and are entirely analogous to an amide. Thus, X-ray crystallographic studies of a number of *N*9-substituted 6-aminopurines show the average length of the C6—N6 bond to be 1.337 Å (26*a*) and show the N and H atoms of the -NH_2 group to be basically coplanar with the heteroaromatic ring, the N atom being only 0.01–0.09 Å out of the C6—H61—H62 plane (26*b–f*). The N6 atom may be regarded as essentially sp^2 hybridized, as its chemical properties testify. Note that a fully pyrimidalized (or sp^3 hybridized) N, as in dimethylamine, places the N atom 0.41 Å out of the basal C—C—H plane. Monosubstitution of N6 with carbon groups causes small changes to this basic geometry (27). The C6—N6—$C_{subst.}$ angle increases slightly to 121–123° while the average C6—N6 bond length becomes 1.341 Å. However, there is no change in the

slight pyramidalization of the N atom as it ranges from 0.00 Å (27*b*) to 0.05 Å (27*a*) out of the plane defined by C6—H6—$C_{subst.}$. Our purinophane **9** is unique in having a 35° rotational twist enforced upon the C6—N6 bond and, as such, it represents a test of the Bader–Wiberg theory for this class of compounds. From Table 3, the average C6—N6 bond length for molecules A and B of **9** is 1.347 Å, a value at the upper end of the accepted average magnitude for this bond, and scarcely convincing evidence for the theory. However, against this must be set the distinct pyramidalization of N6, which is 0.25 Å out of the C6—H6—C1′ plane in molecule A and 0.22 Å from the corresponding plane in molecule B. That is, N6 is over 50% pyrimidalized, a situation fully consistent with the Bader–Wiberg proposals.

The crystallographic data for [8]-purinophane **3** (9) are also pertinent here because the H6—N6—C1′ fragment of **3** was twisted with respect to the purine ring by 30°. Inspection of the data shows the N6 atom again is pyrimidalized appreciably, being 0.23 Å out of the C6—H6—C1′ plane but, as in the [9]-purinophane, the C6—N6 bond length of 1.349 Å is only marginally longer than the average. Evidently, for this class of compounds rotation about the exocyclic C6—N6 bond is accompanied by strong pyramidalization but the extent of bond lengthening is much less distinctive than is observed for the amide cases (25).

Experimental methods

Melting points were recorded on a Gallenkamp capillary tube melting point apparatus and are uncorrected. Proton magnetic resonance (^{1}H NMR) spectra were recorded on a Varian EM-390, a Bruker AC-200, or a Bruker AM-500 spectrometer with chloroform-*d* as the solvent unless otherwise noted. Unless specified, the usual internal references were tetramethylsilane (TMS) or chloroform. The abbreviations (s) = singlet, (d) = doublet, (t) = triplet, (q) = quartet, (m) = multiplet, and (br) = broad are used in the description of the spin–spin splitting pattern present in the spectra. The natural abundance carbon-13 magnetic resonances (^{13}C NMR) were recorded on an AM-500 (at 125.776 MHz) or AC-200 (at 50.324 MHz) instrument using chloroform-*d* as the solvent and internal reference unless otherwise noted. All ^{13}C spectra were broad band decoupled. Low-resolution mass spectra (MS) and high-resolution mass spectra (HRMS) were obtained on either a VG Micromass 7070F or a VG ZAB-E mass spectrometer with samples being introduced through a direct inlet system. Ions were generated using electron impact (EI) or through chemical ionization (CI) with NH_3 as the reactant gas. Infrared spectra (IR) were recorded on a Perkin–Elmer 283 spectrometer. IR samples were run as neat liquids using NaCl windows. The symbols (s) = strong and (br) = broad were used in the recording of the IR data to indicate the intensity of the recorded bands. Ultraviolet (UV) spectra were recorded on a Perkin–Elmer Lambda 9 UV/VIS/NIR spectrophotometer.

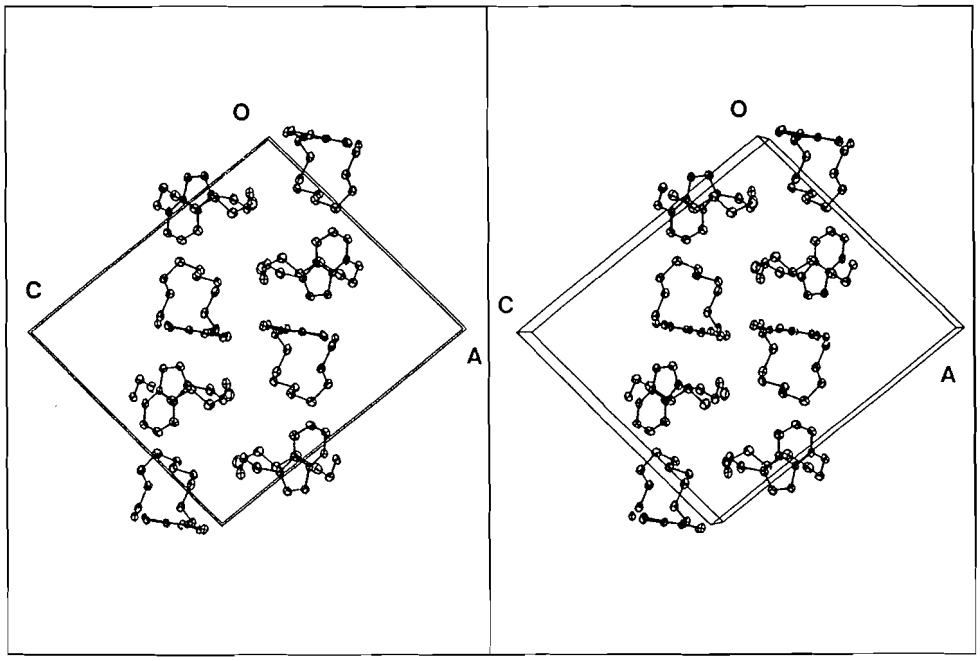

FIG. 5. Stereoview of the crystal packing of [9](*N*6,9)-6-aminopurinophane. The view is down the *b* axis.

Tetrahydrofuran (THF) was dried by refluxing and distilling from sodium and benzophenone under dry nitrogen. THF was collected from the distillation apparatus as required. *N*,*N*-Dimethylformamide (DMF) was refluxed and subsequently distilled from BaO. Acetonitrile was distilled from P_2O_5 followed by distillation from CaH_2, discarding the first 5% and the last 10%. The NMR solvent chloroform-*d* was stored over molecular sieves (4Å) prior to use.

Unless specified, column chromatography was performed by the "flash" method of Still, Kahn, and Mitra (28). The silica gel used for column chromatography (5.0% of 100 mesh up; 47.6% of 100–200 mesh and 47.4% of 200 mesh down) was purchased from Terochem. Silica gel 60 F_{254} (E. Merck Co.) plates of 0.2 mm thickness were used for analytical thin-layer chromatography (TLC). Visualization was achieved using a UV lamp at 254 nm or via treatment of the TLC with either a molybdic acid spray (20 g of molybdic acid and 15 g of ceric sulphate dissolved in 1 L of 10% sulphuric acid) or a ninhydrin spray (0.2% ninhydrin in ethanol) followed by heating.

Synthesis of 9-azidononanol, 5

The procedure followed is similar to that described by Castro (10*b*) or Boigegrain *et al.* (10*a*). 1,9 Nonanediol (2.5 g, 15.6 mmol)

[a] $U_{eq} = {}^1/_3(U_{11} + U_{22} + U_{33} + 2\cos\beta U_{13})$.

was dissolved in 15 mL of dry THF under a nitrogen atmosphere and cooled to −20°C. Carbon tetrachloride (6.0 mL, 9.6 g, 62.2 mmol) was added followed by slow dropwise addition of hexamethylphosphorus triamide (HMPT) (3.1 mL, 2.8 g, 17.1 mmol) via a syringe. The reaction mixture was then added to 100 mL of H_2O and washed with 100 mL of diethyl ether. Potassium hexafluorophosphate (5.5 g, 30 mmol) was added to the aqueous solution, which was then extracted with three 100-mL portions of $CHCl_3$. The combined organic extracts were dried over anhydrous Na_2SO_4 and evaporated under reduced pressure. The oily residue was dissolved in 50 mL of DMF and stirred for 12 h in the presence of NaN_3 (5 g, 77 mmol) at 80°C. The solvent was subsequently evaporated under reduced pressure and the residue taken up into 100 mL of H_2O followed by extraction with four 100-mL portions of ether. The ether extracts were dried over Na_2SO_4 and the solvent evaporated under a reduced pressure. The crude product was purified by vacuum distillation. TLC with 5% methanol in $CHCl_3$ using the molybdic acid spray for visualization showed the desired product having an $R_f = 0.54$. The yield was 87% (2.51 g, 13.6 mmol). The compound showed: bp 89°C at 0.01 Torr (1 Torr = 133.3 Pa). IR: 3360 cm^{-1} (br, OH), 2095 cm^{-1} (s, N_3). ^{1}H NMR (200 MHz), δ: 1.22 (m,, 10H, $(CH_2)_5$), 1.49 (m, 4H, CH_2-CH_2-OH and CH_2-CH_2-N_3), 3.16 (t, 2H, J = 6.8 Hz, CH_2-N_3) and 3.51 (t, 2H, J = 6.6 Hz, CH_2-OH). ^{13}C NMR (200 MHz), δ: 25.57 (C3), 26.54 (C5), 28.66 (C6), 28.93 (C7), 29.17 (C4), 29.28 (C8), 32.56 (C2), 51.30 (C9), 62.64 (C1). MS [EI], *m/z* (RI%): 203 $[M + 18]^+$ (17), 186 $[M + 1]^+$ (7), 178 (40), 158 $[M + 1 - N_2]^+$ (65), 70 (60), 56 (40), and 44 (100).

Synthesis of 6-chloro-9-(1-azidononyl)purine, 7

The procedure used was similar to that of Iwakawa *et al.* (11*b*). To a mixture of 6-chloropurine (1.59 g, 10.28 mmol), triphenylphosphine (2.7 g, 10.28 mmol), and diethyl azidocarboxylate (2.20 g, 2 mL, 12.60 mmol) in 40 mL of dry THF was added a solution of 9-azidononanol (2.00 g, 10.80 mmol) in 40 mL of THF. The solution was allowed to stir at room temperature for 48 h, at which time the reaction mixture was concentrated under reduced pressure. The residue was chromatographed on silica gel using 1% methanol in $CHCl_3$, yielding a viscous yellow oil. TLC of the product with 5% methanol in $CHCl_3$ gave an $R_f = 0.52$. The yield was 23% (759 mg, 2.36 mmol). The compound showed: ^{1}H NMR (200 MHz), δ: 1.22 (m, 10H, $(CH_2)_5$), 1.56 (m, 2H, CH_2-CH_2-N_3), 1.92 (m, 2H, CH_2-CH_2-N9), 3.20 (t, 2H, J = 6.5 Hz, CH_2-N_3), 4.27 (t, 2H, J = 7.5 Hz, CH_2-N9), 8.10 (s, 1H, C8H), 8.73 (s, 1H, C2H). ^{13}C NMR (200 MHz), δ: 26.16 (C8′ or C5′), 26.19 (C5′ or C8′), 28.37 (C6′ or C7′), 28.45 (C7′ or C6′), 28.55 (C4′ or C3′), 28.79 (C3′ or C4′), 29.43 (C2′), 44.15 (C9′), 51.00 (C1′), 131.15 (C5), 145.06 (C8), 150.37 (4), 151.39 (C2), 151.52 (C6). HRMS: Exact Mass calcd. for $C_{14}H_{20}N_7Cl$: 321.1468; found: 321.1470. MS [EI], *m/z* (RI%): 321 $[M]^+$ (3), 265 $[M - CH_2N_3]^+$ (41), 209 $[M - (CH_2)_5N_3]^+$ (56), 155 (100).

Synthesis of 6-chloro-9-(1-aminononyl)purine, 8

The procedure used was similar to that of Vaultier *et al.* (12). To 6-chloro-9-(1-azidononyl)purine (500 mg, 1.56 mmol) in 1.6 mL of THF was added triphenylphosphine (410 mg, 1.56 mmol), H_2O (45 μL, 2.34 mmol), and a boiling chip. The evolution of N_2 began immediately. The mixture was left standing at room temperature for 18 h. TLC of the reaction mixture showed the complete disappearance of the azide starting material and the appearance of a ninhydrin positive spot on the baseline. The solution was then concentrated, redissolved in 50 mL of $CHCl_3$, and extracted with three 20-mL portions of 0.01 M HCl. The combined aqueous solutions were adjusted to pH 8 with 1 M NaOH and extracted with three 30-mL portions of $CHCl_3$. These combined organic solutions were dried over anhydrous Na_2SO_4 and evaporated under reduced pressure. The product normally was subjected immediately to cyclization conditions. TLC with 10% methanol in $CHCl_3$ using ninhydrin spray for visualization showed the desired product with an $R_f = 0.05$. The yield of **8** was 98% (451 mg, 1.53 mmol) via NMR. The compound showed: ^{1}H NMR (90 MHz) (hydrochloride salt in D_2O; internal reference: 3-(trimethylsilyl)propionic acid sodium salt), δ: 1.30 (m, 14H, $(CH_2)_7$), 3.00 (t, 2H, CH_2-NH_3^+), 4.38 (t, 2H, CH_2-N9), 7.70 (s, 1H, C2H), and 8.37 (s, 1H, C8H).

Synthesis of [9](N6,9)-6-aminopurinophane, 9

6-Chloro-9-(1-aminononyl)purine (100 mg, 0.338 mmol) was dissolved in 5 mL acetonitrile. Diisopropylethylamine (1 mL, 5.74 mmol) was added and the solution diluted with an additional 45 mL of acetonitrile to give a 6.8 mM solution of **8**. The reaction was left stirring at 60°C for 48 h at which time the solution was evaporated and the resultant residue was chromatographed on silica gel using 5% methanol in $CHCl_3$. Recrystallization from toluene gave analytically pure crystals of the cyclophane. TLC of the product in 10% methanol in $CHCl_3$ gave an $R_f = 0.46$. The yield of **9** was 26% (23 mg, 0.088 mmol). The compound showed: mp 121–123°C. UV: λ_{max} 276.4 (ε = 13 478, methanol). ^{1}H NMR (500 MHz at 75°C; sealed tube with $CDCl_3$), δ: 0.11

X-ray crystallography

Crystals of [9](*N*6,9)-6-aminopurinophane were grown from chloroform–toluene (1:3) solution. The density was determined by suspension in an aqueous solution of $ZnCl_2$. Large transparent acicular crystals were examined under a polarizing microscope for homogeneity. A small irregular crystal, 0.10 × 0.20 × 0.40 mm, was cut from a larger crystal and mounted on the tip of a glass fibre with epoxy cement. The crystal was cooled by liquid nitrogen using a device supplied by Molecular Structure Corporation, Texas, and the unit cell parameters were determined at 173 K from a least-squares refinement of the angular positions of 25 reflections with θ in the range $39.7 \leq \theta \leq 40.0°$ recorded on a Rigaku AFC6R diffractometer with use of graphite monochromated CuKα radiation (λ = 1.540 598 Å at 298 K). Intensity data were also recorded on a Rigaku AFC6R diffractometer at 173 K by use of ω–2θ scan for 3232 reflections (*h*,*k*, ± *l*), with $\theta \leq 50.0°$. Three standard reflections were monitored every 150 reflections and showed no sign of instrument instability or crystal decay. Corrections were made for Lorentz-polarization effects but not for absorption. Reflections with $3\sigma_I \geq (I) \geq -3\sigma_I$ were treated by the method of French and Wilson (29). Systematically absent data (264 reflections) were removed and symmetry-equivalent data were averaged to give 2846 independent reflections, $R_{int} = 0.0249$, of which 2556 were within $I \geq 2.5\sigma(I)$. Atomic positional parameters and U_{eq} for non-hydrogen atoms are given in Table 5.[8]

Structure solution

The structure was solved by direct methods based on 494 reflections with $|E| > 1.2$ and 30 sets of starting phases with use of the program SHELXS-86 (30). Full-matrix least-squares refinement of the coordinates of the non-hydrogen atoms followed by a three-dimensional difference electron density synthesis revealed the positional parameters of all the hydrogen atoms. The temperature factors of all of the non-hydrogen atoms were made anisotropic and the hydrogen atoms were assigned a common overall isotropic temperature factor and included in refinement. Further cycles using block-matrix least squares, minimizing $\Sigma\omega(|F_o| - |F_c|)^2$, were terminated when the maximum shift/error reached 0.004. A correction for secondary extinction was made by the method in SHELX-76 (31). Final $R_1 = 0.0364$ and $R_2 = 0.0395$, $S = 1.3618$. Scattering factors were taken from ref. 32. Calculations employed XTAL (33), data reduction and mean planes; SHELX-76 (31), structure refinement; MOLGEOM (34) and CHEM-X (35), molecular geometry; and SNOOPI (36), diagrams running on a VAX 8650 computer.

[8]Tables of anisotropic temperature factors, hydrogen positional parameters, bond lengths and angles involving hydrogen atoms, best planes, and the moduli of F_o and F_c have been deposited. Complete sets of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of crystal data, hydrogen positional parameters, and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Reaction de méthanation du gaz de synthèse : Influence de la température de calcination des catalyseurs à base de nickel

M. GHAZI[1] ET J. BARRAULT

Laboratoire de catalyse en chimie organique, Université de Poitiers, Unité de recherche associée 350, Centre national de la recherche scientifique, 40, avenue du Recteur Pineau, 86022 Poitiers CEDEX, France

Reçu le 6 mars 1992

M. GHAZI et J. BARRAULT. Can. J. Chem. **71**, 107 (1993).

En raison de leur activité et sélectivité importantes, les catalyseurs au nickel sont souvent utilisés pour réaliser la réaction de méthanation du gaz de synthèse; cependant le procédé conventionnel basé sur ces solides ne répond plus aux exigences économiques actuelles. Afin d'augmenter leur stabilité, trois catalyseurs à teneur en nickel comparable, ont été étudiés en réaction de méthanation après avoir subi des calcinations à différentes températures. Les résultats obtenus montrent que le solide calciné à haute température (973 K) est le plus prometteur puisqu'il garde une activité appréciable et surtout une stabilité importante même dans des conditions de réactions très sévères (température = 773 K).

M. GHAZI and J. BARRAULT. Can. J. Chem. **71**, 107 (1993).

Due to their important activity and selectivity, nickel catalysts are often used to realize the methanation reaction; however, the usual process based on these catalysts is not fitted for the present economic situation. To raise their stability, three catalysts with similar nickel content but calcinated at different temperatures have been studied for the reaction of methanation. The results obtained show that the catalyst calcinated at the highest temperature (973 K) shows the greatest promise because a great part of its activity and of its stability is preserved even when the reaction conditions are extreme (temperature of 773 K).

Introduction

Les catalyseurs au nickel trouvent des applications industrielles très vastes comme dans l'hydrogénation des composés organiques insaturés, le vaporéformage ou la méthanation du gaz de synthèse. Ils présentent un double intérêt : du point de vue fondamental, le nickel semble mieux se prêter aux études de mécanismes réactionnels, les phases adsorbées sont plus simples à étudier et il y a moins de produits formés. Du point de vue économique, il est possible d'orienter sélectivement la réaction.

Le choix du nickel dans la réaction de méthanation est également justifié par les résultats de Vannice (1) et ceux de notre laboratoire (2, 3) qui montrent que ce métal est l'un des plus actifs après le ruthénium et le fer. Ces derniers ont été écartés, l'un en raison de son prix et l'autre en raison de la facilité de la réaction de dismutation à son contact, réaction qui conduit à un dépôt de carbone et une désactivation plus rapide.

Les catalyseurs au nickel ont cependant une faible résistance aux impuretés contenues dans les charges, en particulier les composés soufrés et azotés. Ces molécules peuvent créer des liaisons de chimisorption suffisamment fortes par l'intermédiaire des doublets libres de l'atome de soufre ou d'azote avec le métal pour avoir un effet toxique très marqué. Généralement, une teneur de 5 ppm en soufre conduit à la désactivation totale du catalyseur.

Le procédé conventionnel de méthanation basé sur l'utilisation de ces catalyseurs ne répond plus aux exigences économiques de la mise en oeuvre de la réaction puisque les catalyseurs au nickel, peu thiorésistants, doivent fonctionner à la température la plus basse possible avec un gaz pur, désulfuré (coûteux) et de composition ajustée. Les progrès dans la réaction de méthanation sur catalyseurs au nickel auront donc deux exigences : (*i*) recherches de catalyseurs stables thermiquement conduisant à une amélioration des rendements énergétiques, et (*ii*) augmentation de la thiorésistance de ces catalyseurs.

Diverses propositions ont été faites dans ce sens pour améliorer la stabilité des catalyseurs au nickel : la modification du nickel par addition de divers promoteurs (3–7); la formation d'alliages entre le nickel et d'autres métaux de type : molybdène, tungstène, iridium (8–11).

Mais c'est la conception du catalyseur et sa préparation qui ont été fondamentalement modifiées à l'exemple des travaux de Kruissink *et al.* (12) ou de Bartholomew *et al.* (13) où les systèmes catalytiques étudiés sont alors des systèmes spinellisés ($NiAl_xO_y$) dont la nature et l'arrangement exact dépendent des processus d'activation.

Dans le but d'améliorer la stabilité thermique des catalyseurs nous avons étudié l'influence de la température de calcination des catalyseurs à teneur en nickel comparable sur leur activité et sélectivité dans la réaction de méthanation du gaz de synthèse.

Partie expérimentale

Appareillage

La réaction d'hydrogénation du monoxyde de carbone est réalisée sous pression ($P < 10$ MPa) à l'aide d'un montage décrit dans des publications antérieures. Les réactifs et produits sont analysés à pression atmosphérique à l'aide d'un chromatographe en phase gazeuse (3, 14).

Préparation des catalyseurs

Une série de catalyseurs au nickel supportés par l'alumine Rhône-Poulenc GFS 400 (extrudés de 1,2 à 2 mm, surface BET = 230 m^2/g) a été étudiée. Ces solides ont été préparés par la technique classique d'imprégnation lente à 353 K de solutions aqueuses du sel correspondant (nitrate de nickel) sur l'alumine. Les poudres obtenues sont ensuite séchées à l'étuve à 393 K puis calcinées sous air à 673 K ou 973 K.

Dans le tableau 1, nous avons résumé les propriétés des catalyseurs étudiés dans la réaction de méthanation du gaz de synthèse. La composition métallique des catalyseurs est donnée en % poids.

Avant la réaction, les catalyseurs sont réduits par l'hydrogène

TABLEAU 1. Les propriétés principales (température de calcination, % de carbone déposé, dispersion, teneur du nickel en % poids . . .) des catalyseurs étudiés

Catalyseurs	Température de prétraitement (K)	Surface BET (m^2/g)	Carbone (%)	Quantité adsorbée H_2 ($\mu mol/g \cdot cat$)	Quantité adsorbée CO ($\mu mol/g \cdot cat$)	Dispersion (CO/Ni)
$Ni(7,9)/Al_2O_3$ GFS 400	393 (séché)	140	2,38	60	140	0,104
$Ni(8,5)/Al_2O_3$ GFS 400	673	140	2,42	50	125	0,086
$Ni(8,6)/Al_2O_3$ GFS 400	973	70	0,56	0	15	0,010

(débit = 10 L/h) à 773 K pendant 10 h après montée linéaire de la température (4°C/min).

Caractérisation des catalyseurs

Les catalyseurs ont été caractérisés par des méthodes simples : l'adsorption de monoxyde de carbone et d'hydrogène et l'analyse des dépôts carbonés par oxydation en température programmée.

Chimisorption du monoxyde de carbone

La technique utilisée est une méthode chromatographique déjà décrite (15) et mise en oeuvre de la façon suivante : un échantillon de catalyseur de masse déterminée est dégazé sous courant d'hélium, puis réduit par l'hydrogène à la température désirée. La réduction est suivie d'un dégazage en présence d'hélium à une température égale à celle de réduction, puis l'échantillon est refroidi à température ambiante. On introduit alors des quantités connues (pulses) de CO ou d'H_2 et on détermine les quantités chimisorbées par le catalyseur à l'aide d'un détecteur à conductivité thermique.

Analyse des dépôts carbonés

La quantité d'espèces carbonées déposées sur le catalyseur au cours de la réaction CO + H_2 est déterminée par oxydation en température programmée. Le gaz carbonique formé est analysé également avec une cellule à conductivité thermique (16).

Conditions de mise en oeuvre de la réaction CO + H_2

La réaction d'hydrogénation du monoxyde de carbone étant fortement exothermique, les grains de catalyseurs sont dilués dans du carbure de silicium (inerte vis-à-vis de la réaction). Les conditions de réaction sont les suivantes : la pression totale = 3 MPa; le rapport molaire H_2/CO = 3; la masse du catalyseur = 5 g; le débit total des réactifs = 30 L/h; la température de réaction est comprise entre 423 K et 773 K de façon à apprécier la stabilité des catalyseurs à haute température.

Resultats et discussion

Influence du prétraitement sur les catalyseurs au nickel

Trois catalyseurs à teneur en nickel comparable et prétraités à différentes températures de calcination (tableau 1) ont été étudiés dans la réaction de méthanation de CO + H_2.

L'évolution de l'activité des catalyseurs au nickel exprimée en taux de transformation global de CO (TTG_{CO} (%)) en fonction du temps de travail (h) est présentée sur la figure 1. Les catalyseurs calcinés à basse température (393 et 673 K) sont actifs initialement mais se désactivent après quelques heures de fonctionnement illustrant ainsi le comportement général des catalyseurs au nickel. Le solide calciné à haute température (973 K) semble au contraire répondre à l'objectif recherché. En effet, jusqu'à une température de réaction de l'ordre de 673 K le catalyseur n'a aucune activité catalytique. Au-delà, l'activité du catalyseur croit rapidement avec la température et le phénomène de vieillissement n'est plus observé et ce, même dans des conditions de réaction très sévères (773 K).

Influence du soufre sur les catalyseurs au nickel

En raison de la désactivation très rapide des catalyseurs au nickel calcinés à basse température au contact du gaz de synthèse, nous n'avons pas pu déterminer sans ambiguïté l'effet du soufre sur l'activité de ces catalyseurs. Il semble toutefois que l'action d'une faible teneur de soufre dans la charge (5 ppm) désactive complètement ces catalyseurs.

Cependant, le comportement du solide calciné à 973 K est très intéressant, puisqu'en plus de sa stabilité à haute température, on constate que sa désactivation en présence de soufre est réversible comme le montre la figure 2. Au cours de cette manipulation, la réaction est d'abord étudiée en l'absence d'H_2S, puis l'impureté soufrée de concentration connue est additionnée aux réactifs (après avoir obtenu une certaine stabilisation de l'activité du catalyseur), enfin l'impureté est supprimée de façon à apprécier la réversibilité de l'empoisonnement. Dans cette première étape nous avons volontairement limité la concentration en H_2S à une valeur inférieure à 50 ppm.

On observe après addition de 10 ou 20 ppm d'H_2S à la charge, une diminution très importante (×6) de l'activité du catalyseur. Lorsqu'on supprime l'H_2S, le catalyseur semble retrouver ses propriétés initiales.

Par rapport au comportement des catalyseurs calcinés à basse température, on met donc en évidence ici deux propriétés particulièrement intéressantes du catalyseur calciné à haute température : (*i*) un effet d'empoisonnement réversible de l'H_2S peu fréquement signalé dans la bibliographie; (*ii*) une stabilité accrue dans des conditions de réactions très sévères (température de réaction = 773 K).

Ces résultats exploratoires de la réaction de méthanation du gaz de synthèse sur un catalyseur conventionnel : nickel/alumine, nous conduisent aux remarques suivantes :

(*a*) Le catalyseur au nickel est actif dans la réaction de méthanation du gaz de synthèse, cependant sa stabilité est très faible. Cette désactivation est souvent attribuée à la formation du carbonyle de nickel $Ni(CO)_4$ (17). Certains auteurs pensent même que l'activité de ces catalyseurs est fonction de la taille des cristallites, à l'exemple de Van Meerten et coll. (18) qui ont montré que la formation (même faible) du carbonyle de nickel durant la réaction accroît la taille des particules entrainant ainsi un changement perpétuel de la surface du nickel.

Une étude très intéressante de Richardson *et al.* (19) sur l'influence de la taille des cristallites montre qu'au cours de la réaction, la distribution des cristallites s'élargit et on voit apparaître différentes tailles de particules variant jusqu'à un facteur 3 en volume. D'après ces mêmes auteurs, lorsque la taille des particules augmente, le degré d'accessibilité des

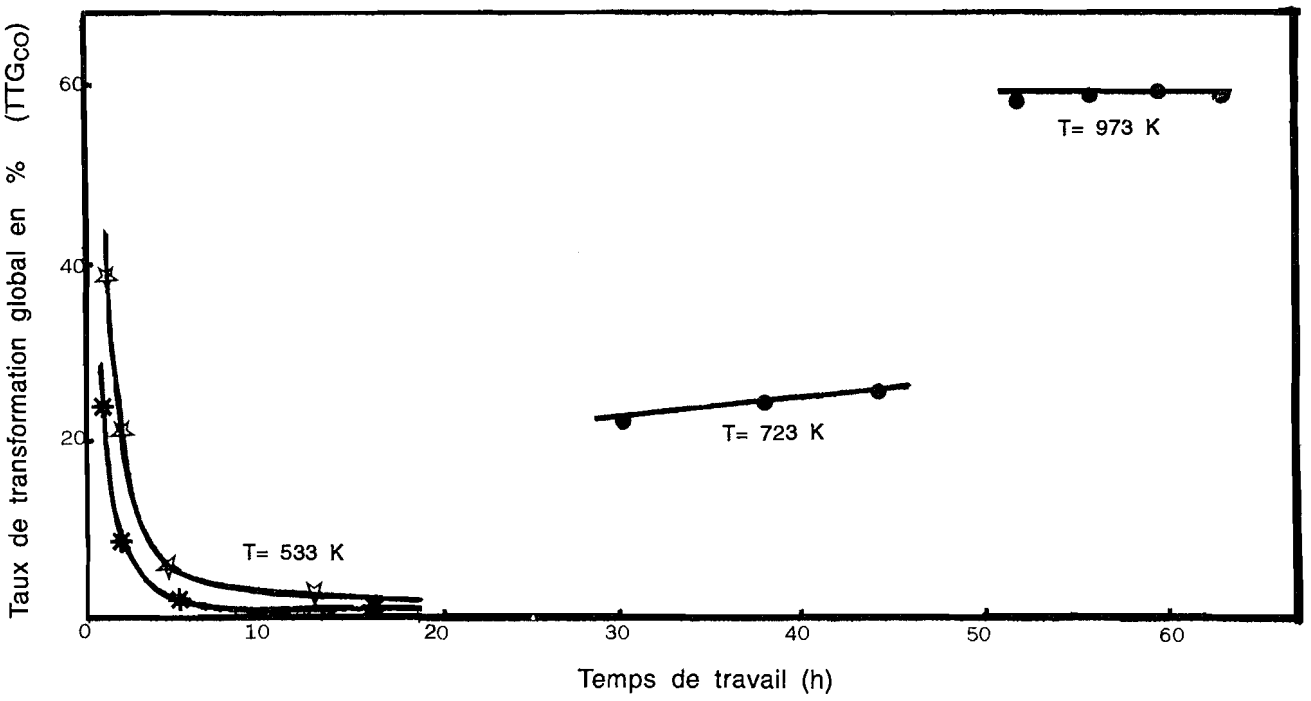

FIG. 1. Evolution de l'activité des catalyseurs au nickel au cours du temps dans la réaction de méthanation de CO + H_2. P = 3 MPa, H_2/CO = 3. Débit total = 30 L/h. (✱) séché à 393 K; (☆) calciné à 673 K; (●) calciné à 973 K.

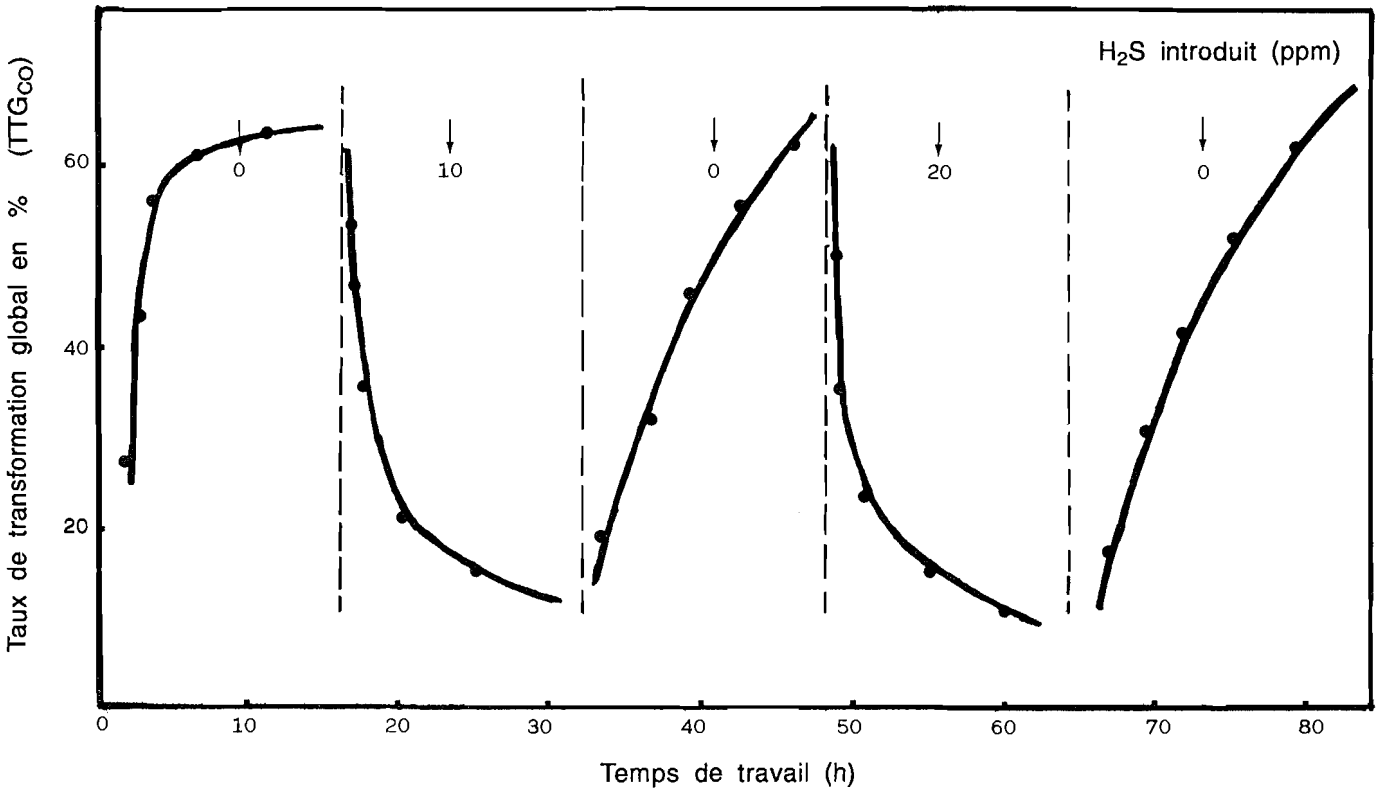

FIG. 2. Influence du soufre sur l'évolution de l'activité du catalyseur Ni(8,6)/Al_2O_3 GFS 400 calciné sous air à 973 K au cours du temps dans la réaction de méthanation de CO + H_2. P = 3 MPa. H_2/CO = 3. Débit total = 30 L/h. Température de réaction = 773 K.

réactifs diminue du même facteur. Les résultats présentés sur la figure 3 semblent aller dans le sens de ces observations. On constate en effet que lorsque la température de calcination passe de 673 à 973 K, la distribution des diamètres moyens des pores s'élargit variant jusqu'à un facteur 2 en volume.

D'autres auteurs (20–23) montrent que sur les catalyseurs au nickel, deux facteurs de désactivation intervien-

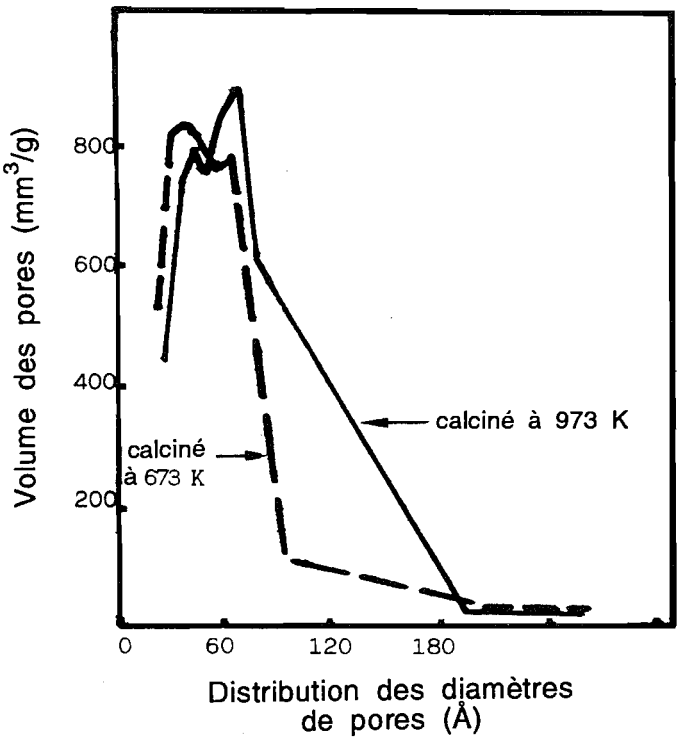

FIG. 3. Influence de la température de prétraitement sur la distribution des diamètres moyens des pores des catalyseurs nickel/alumine.

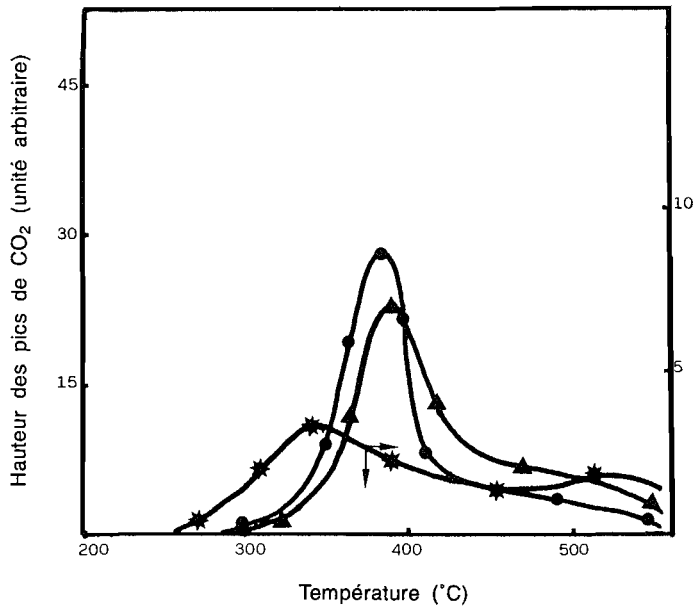

FIG. 4. Comparaison des dépôts carbonés par oxydation en température programmée des catalyseurs nickel/alumine. (●) séché à 393 K; (▲) calciné à 673 K; (✱) calciné à 973 K.

nent simultanément : le frittage de la phase métallique et un dépôt d'espèces carbonées. En fait, le frittage métallique qui explique pour l'essentiel la perte d'activité initiale du catalyseur se stabilise au bout d'un certain temps de réaction et la désactivation ultérieure résulte de l'empoisonnement par le carbone.

L'examen des résultats des analyses de carbone effectuées sur les catalyseurs au nickel présentés dans le tableau 1, montre que la quantité de carbone déposée sur le catalyseur calciné à haute température est diminuée d'un facteur 4. Cette faible valeur est en accord avec l'importante sélectivité en CO_2 observée pour ce catalyseur dans la réaction $CO + H_2$.

D'après les travaux cités précédemment (20, aussi communication orale), la présence du CO_2 dans le mélange réactionnel limite la désactivation en déplaçant l'équilibre de la réaction de dismutation du CO vers la gauche, défavorisant ainsi la formation de carbure ou d'espèces carbonées stables comme le montrent les résultats présentés sur la figure 4. La désactivation des catalyseurs métalliques par le «carbone» est un problème souvent rencontré et de grande importance pour la régénération des catalyseurs. L'analyse globale des dépôts carbonés par oxydation en température programmée (OTP) présentée sur la figure 4 montre que les dépôts carbonés les plus stables se forment au contact des catalyseurs calcinés à basse température (393 et 673 K). Lorsque le solide est calciné à la température de 973 K, on observe une diminution sensible (×4) de la quantité de carbone avec un déplacement du pic principal vers la gauche indiquant une oxydabilité plus facile des espèces carbonées formées. Il est difficile à partir de ces résultats d'établir une relation entre la stabilité des catalyseurs et la teneur ou la nature des dépôts carbonés. Généralement la formation des dépôts carbonés stables correspond à une désactivation plus rapide du catalyseur (24).

(*b*) On note encore une fois, l'extrême sensibilité du nickel à la présence d'impuretés soufrées. Cette propriété est très commentée dans la bibliographie. D'après les travaux de Fitzharris *et al.* (23), il semble que la désactivation rapide d'un catalyseur en présence de soufre est due non pas à un mécanisme «électronique» mais seulement à un blocage «géométrique» des sites actifs du nickel. En effet, ces auteurs en mesurant des énergies d'activation identiques, avec et sans soufre, ont conclu que les atomes de soufre adsorbés paraissent bloquer les sites actifs du nickel à la surface sans affecter les énergies des sites de nickel voisins. Un fait similaire a déjà été observé lors de l'étude de cette réaction sur un nickel déposé sur un film de cuivre (25, 26).

(*c*) Le phénomène évoqué ci-dessus ne semble pas se produire pour le catalyseur au nickel calciné à haute température (973 K), puisque ce dernier est assez actif à haute température et que la désactivation en présence de soufre est réversible. D'après Bartholomew *et al.* (13) ceci pourrait résulter de modifications électroniques ou de la formation de composés mixtes tel un aluminate de nickel ($NiAl_2O_4$) dans lequel les ions Ni^{2+} seraient difficiles à réduire. Le catalyseur résultant serait donc moins sensible aux poisons soufrés et les sites réactionnels ne seraient pas bloqués irréversiblement.

On peut remarquer que les capacités d'adsorption de l'hydrogène et du monoxyde de carbone, présentées dans le tableau 1, sont considérablement diminuées après la calcination à haute température traduisant la formation d'une phase spinelle d'oxydes mixtes de type «aluminate» : $NiAl_xO_y$ signalée précédemment.

Des modifications plus importantes (réduction du support, migration d'espèces partiellement réduites, . . .) pourraient être envisagées puisqu'une différence de comportement importante est mise en évidence par les expériences d'adsorption d'hydrogène et de monoxyde de carbone. Un

tel comportement est à l'origine de la notion de forte intéraction entre métal et support (FIMS) proposé par Tauster *et al.* (27). Il en résulterait la formation de nouveaux centres réactionnels qui favoriseraient l'adsorption dissociative du monoxyde de carbone (28, 29).

Conclusion

La résolution des problèmes de l'activité, la stabilité thermique et la thiorésistance des catalyseurs au nickel reste difficile à réaliser.

Les résultats obtenus montrent cependant que le protocole d'activation à haute température (973 K) où il semble établi que le nickel se trouve impliqué dans une structure spinelle, permet d'obtenir des catalyseurs bien plus stables même à température de réaction élevée ce qui peut présenter un intérêt pour l'objectif recherché dans cette étude et une voie prometteuse qui est en cours d'exploitation.

M. HACHEY, F. GREIN, and R. P. STEER. Can. J. Chem. **71**, 112 (1993).

Ab initio CI studies have been performed to determine the geometry of the ground and first electronically excited states of the chlorothioformyl radical, ClCS, and the vertical excitation energies of its ten lowest doublet states and two lowest quartet states. The results are used to construct a more complete energy level correlation diagram for the photofragmentation of Cl_2CS. The lowest excited electronic state of ClCS lies only 0.79 eV (adiabatic) above the ground state. Its discovery indicates that the results of previous photofragmentation experiments may need to be reinterpreted.

M. HACHEY, F. GREIN et R. P. STEER. Can. J. Chem. **71**, 112 (1993).

On a effectué des calculs *ab initio* pour déterminer la géométrie de l'état fondamental et des premiers états électroniquement excités du radical chlorothioformyle, ClCS. On a aussí déterminé les énergies d'excitations verticales des dix états doublets et des deux états quadruplets les plus bas. On a utilisé les résultats pour construire un diagramme de corrélation plus complet des niveaux d'énergie de la photofragmentation du Cl_2CS. L'état électronique excité le plus bas du ClCS ne se trouve qu'à 0,79 eV (adiabatique) au-dessus de l'état fondamental. Cette découverte indique qu'il sera peut-être nécessaire de réinterpréter les résultats antérieurs des expériences de photofragmentation.

Introduction

Thiophosgene, Cl_2CS, is one of a small number of interesting tetraatomic molecules known to undergo photodissociation via two parallel channels; a molecular process giving, in this case, Cl_2 + CS ($\tilde{X}^1\Sigma^+$), and a free radical fragmentation yielding Cl + ClCS (1, 2). The free radical process was first described by Okabe (3) who calculated quantum yields of Cl atom production of 0.38, 0.90, and 1.00 in the limit $P = 0$ at λ_{ex} = 435.8, 366.0, and 253.7 nm respectively, on the basis of the yields of HCl obtained from the photolysis of Cl_2CS–heptane mixtures. Okabe also derived a number of thermodynamic quantities relating to the photofragmentation of Cl_2CS, including an estimate of the C—Cl bond dissociation energy in the ground state (D_0^0 = 2.75 ± 0.02 eV; 63.4 ± 0.5 kJ mol^{-1}). This estimate was based on the assumption that the abrupt break-off of $\tilde{A} \rightarrow \tilde{X}$ fluorescence in Cl_2CS (4) observed between λ_{ex} = 455.0 and 447.2 nm is due to predissociation of the $\tilde{A}$ state by an unbound state that yields cold, ground state Cl and ClCS fragments. However, the molecular and free radical dissociation channels in Cl_2CS are almost equi-endothermic (2). Given this, the fact that ϕ_{Cl} is apparently much less than 1 for excitation energies higher than the predissociation limit in the $\tilde{A}$ state, and the knowledge that Okabe would have had great difficulty in detecting a Cl_2 product using his photochemical methods, it appears that there is reason to be cautious in assigning the fluorescence-weakening process in the $\tilde{A}$ state to predissociation through the free radical dissociative channel.

Ondrey and Bersohn (1) investigated the photoframentation of Cl_2CS by exciting at 248 nm in its strong $\tilde{B} \leftarrow \tilde{X}$ absorption system under collision-free conditions in an effusive molecular beam. Free radical dissociation was also found to be the major channel at this wavelength (estimated ϕ = 0.8 ± 0.1), but parallel molecular fragmentation was clearly identified on the basis of the prompt appearance of CS^+ in the time-of-flight ion spectrum. Ondrey and Bersohn interpreted the free radical photofragmentation dynamics by using Okabe's data (3) and assuming that the ClCS fragment was produced in its electronic ground state. They then used a simple impulsive spectator model (5) to predict that about 60% of the available "excess" energy would be released as vibrational excitation of ClCS and about 37% would appear in the translational degrees of freedom of the separating fragments. The latter was, however, only in modest agreement with the experimental result of 29 ± 1%, and led us to question, in particular, the assumption that ClCS was produced in its electronic ground state.

The interpretation of the photofragmentation dynamics of Cl_2CS in its $\tilde{B}$ state is made particularly difficult by the complexity of its $\tilde{B} \leftarrow \tilde{X}$ (uv) spectrum, aspects of which are still not understood (6–8). Although there is agreement that the $^1(\pi,\pi^*)$ excited state of $^1A_1$ symmetry is responsible for the major part of the oscillator strength of the uv absorption, there appear to be several weakly absorbing states at these energies, including one of $n^0\pi^{*2}$ configuration (9, 10). The onset of a $\tilde{B} \rightarrow \tilde{X}$ fluorescence-weakening process (predissociation) is clearly observed at $E_{vib} \sim 1450 \pm 50$ cm^{-1} in the laser-induced fluorescence excitation spectrum of supersonically expanded Cl_2CS, but the nature of the state responsible is essentially unknown.

These features of the spectroscopy and photofragmentation dynamics/energetics of Cl_2CS have led us to reexamine this molecule both theoretically and experimentally. In preparation for further studies of the photofragmentation, we have therefore calculated the structures and electronic ener-

gies of the chlorothioformyl radical. Our intent is to determine (*i*) if laser-induced fluorescence spectroscopy might be used as a diagnostic tool for this species, and (*ii*) if the electronically excited states of ClCS need to be considered in interpreting the photofragmentation processes.

Theoretical methods

The geometry of the $\tilde{X}^2A'$ ground state of ClCS, with electron configuration $(1\text{–}15a')^2(1\text{–}4a'')^2 16a'$, was optimized by ROHF, UHF, and UMP2 methods, at various levels of basis sets, using the GAUSSIAN 90 computer programs (11). Later on, a MRD-CI geometry optimization was also performed.

The vertical excitation energies of ClCS were obtained by multireference configuration–interaction calculations, using the MRD-CI programming package of Buenker, Peyerimhoff, and co-workers (12–15). For carbon, the 10*s*6*p* basis set of Huzinaga (16), in the Dunning 5*s*4*p* contraction (17), was augmented by *s* and *p* Rydberg orbitals with α_s = 0.023 and α_p = 0.021, and by a *d*-polarization function with α_d = 0.75 (18). For S and Cl, the (12*s*9*p*/6*s*4*p*) basis sets (19, 20) were augmented by polarization *d*-functions with α = 0.54 for S, and 0.68 for Cl (21). The CI wavefunction was constructed from $\tilde{X}^2A'$ and $1^2A''$ MO's.

Extensive testing showed that $1^2A''$ MO's gave a better description of the ground state and of π^* excited states, due to the occupation of the π^* orbital in $1^2A''$. Only results obtained with $1^2A''$ MO's will be given.

Five roots of both the $^2A'$ and $^2A''$ symmetry species were calculated. Using about 25–50 reference configurations, 5–10 million configurations were generated, of which 22 000–36 000 were selected when using a selection threshold of 10 μh. "Estimated full-CI energies" (a more appropriate term would be quadruples-corrected MRD-CI energies) obtained by the Davidson formula (22) will be given. The molecule is located in the *x*-*y* plane.

Results and discussion

Geometry optimization of ground state $\tilde{X}^2A'$ *and lowest excited state* $1^2A''$

Optimized geometries for the $\tilde{X}^2A'$ state of ClCS, obtained by ROHF, UHF, and UMP2 methods using the 6-31G and 6-31G* basis sets, are given in Table 1. For the latter basis set, UCISD and RCISD results, obtained by Chan and Goddard (23), are also given. It is seen that the 6-31G results differ significantly from the 6-31G* results. With the addition of polarization functions, both R_{CS} and R_{CCl} shorten by 0.04–0.07 Å. Such observations are in line with numerous discussions in the literature on the effect of polarization functions on bond distances (see, for example, refs. 24 and 25). The ClCS bond angle is hardly affected by this change of basis set. Results obtained with 6-31+G* are virtually identical with the 6-31G* results listed in Table 1. There are no experimental geometry parameters for ClCS.

For comparison, the optimized geometry of Cl_2CS, obtained from 6-31G (this work)/6-31G* (ref. 23), is R_{CS} = 1.624/1.591 (1.602) Å, R_{CCl} = 1.781/1.722 (1.728) Å, and α(ClCS) = 124.2/124.0°(124.4), with experimental values (26) in parentheses. Contractions of the CS and CCl bonds similar to those observed for ClCS under the effect of polarization functions are noted.

For ClCS, CISD results using the 6-31G* basis set (from ref. 23, also given in Table 1) lead to R_{CS} = 1.55–1.56 Å, and R_{CCl} = 1.69 Å.

TABLE 1. Optimized geometries for $^2A'$ ground state of ClCS

Method and basis set	R_{CS} (Å)	R_{CCl} (Å)	α(ClCS) (°)
ROHF			
6-31G	1.605	1.754	136.3
6-31G*[a]	1.561	1.685	136.3
UHF			
6-31G	1.658	1.767	133.6
6-316*[a]	1.585	1.691	135.3
UMP2			
6-31G	1.569	1.820	136.9
6-31G*[a]	1.522	1.680	138.0
RCISD			
6-31G*[a]	1.565	1.689	135.8
UCISD			
6-31G*[a]	1.546	1.687	136.9
MRD-CI[b]	1.580	1.688	134.1

[a]Reference 23.
[b]See text for details.

MRD-CI optimizations on the $\tilde{X}^2A'$ state were performed by optimizing the CS and CCl distances and ClCS angle in turn, while keeping the other two parameters fixed at the best previous value. Two full cycles led to R_{CS} = 1.580 Å, R_{CCl} = 1.688 Å, and α(ClCS) = 134.1°. The only significant change relative to the best previous geometry parameters is found for the CS distance, which increases by about 0.02 Å.

MRD-CI geometry optimizations were also performed on the lowest $^2A''$ state of ClCS. CISD/6-31G* optimizations on this state, performed previously by Chan and Goddard (23), gave R_{CS} = 1.553 Å, R_{CCl} = 1.628 Å, and α = 180°. The present MRD-CI optimization resulted in R_{CS} = 1.588 Å, R_{CCl} 1.651 and α = 180°.

According to Walsh's rules (27), the lowest excited state, $1^2A''$, of HCO, HCS, and corresponding halogen compounds is expected to be linear. This is due to the promotion of an electron from n_C, which prefers a bent molecule, to π^*, which is shape-neutral, such that the preference of lower-lying MO's for a linear structure becomes critical. Linearity of the $1^2A''$ state has been confirmed for HCO (28) and HCS (29).

Molecular orbital characteristics

To describe the excited states by their leading configuration, the characteristics of ClCS molecular orbitals will briefly be discussed. Using the valence bond structure Cl—Ċ=S as guideline, one expects a minimal basis set to give one σ(C—Cl) MO, one σ(C—S) and one π(C—S) MO, and the corresponding antibonding orbitals. All σ MO's belong to the *a'*, all π MO's to the *a''* species. The lone pairs on Cl will give two *a'* and one *a''*, whereas the lone pairs on S give two *a'* MO's. The singly occupied orbital is of *a'* type, and is expected to be localized on C. It will be denoted as n_C.

The ordering and principal composition of valence MO's is shown in Table 2. All MO's have some mixing from other AO's not included in this notation.

TABLE 2. Molecular orbitals of ClCS

MO	Main character
$10a'$	σ(C—Cl)
$11a'$	σ(C—S)
$12a'$	n_{Cl}
$13a'$	n_S
$14a'$	n_{Cl}
$15a'$	n_S
$16a'$	n_C[a]
$17a'$	σ*(C—Cl)
$21a'$	σ*(C—S)[b]
$3a''$	n_{Cl}
$4a''$	π(C—S)
$5a''$	π*(C—S)[c]

[a]Single occupied in ground state.
[b]$18a'$ to $20a'$ are s, p_x, and p_y Rydberg orbitals, respectively.
[c]All higher a'' MO's are of Rydberg type.

TABLE 3. Vertical excitation energies ΔE of ClCS

State	ΔE(eV)	Configuration	
$1^2A'$ $\tilde{X}$	0.00	G.S.[a]	G.S.
$1^2A''$ $\tilde{A}$	1.58[b]	$16a'\rightarrow5a''$	(n_C,π^*)
$2^2A'$ $\tilde{B}$	3.14	$15a'\rightarrow16a'$	(n_S,n_C)
$1^4A''$	3.40	$15a'\rightarrow5a''$	(n_S,π^*)
$1^4A'$	3.55	$4a''\rightarrow5a''$	(π,π^*)
$2^2A''$	3.67	$4a''\rightarrow16a'$	(π,n_C)
$3^2A''$	4.57	$15a'\rightarrow5a''$	(n_S,π^*)
$3^2A'$	4.71	$4a''\rightarrow5a''$	(π,π^*)
$4^2A'$	4.99	$16a'\rightarrow17a'$	$(n_C,\sigma^*(C—Cl))$
$5^2A'$	5.20	$16a'\rightarrow18a'$	(n_C,R_{4s})
$4^2A''$	5.69	$16a'\rightarrow16a''$	(n_C,R_{4p})
$5^2A''$	6.23	$3a''\rightarrow16a'$	(n_{Cl},n_C)

[a]The ground state (G.S.) configuration is $(1\text{–}15a')^2(1\text{–}4a'')^2 16a'$. Excited state configurations are given relative to the G.S.
[b]The calculated adiabatic excitation energy is 0.79 eV. See text for details.

Two Rydberg orbitals appear in the excited state configurations. They are $18a'$, which is R(4s), and $6a''$, which is R(4p_z).

Excitation energies

Vertical excitation energies, calculated at the ground state geometry with R_{CS} = 1.59 Å, R_{CCl} = 1.69 Å, and α(Cl-CS) = 134.1° are given in Table 3. The lowest five $^2A'$ and $^2A''$ states, and the two lowest quartet states $1^4A'$ and $1^4A''$, cover an energy range up to about 6 eV.

Also given are the leading configurations of each state, using the orbital designation of Table 2.

The adiabatic excitation energy, T_e, for the $\tilde{A} \leftarrow \tilde{X}$ transition, is found to be 0.79 eV, which places the lowest electronic transition in the infrared.

For any carbonyl or thiocarbonyl system one expects low-lying excited states of (n,π^*) and (π,π^*) configuration, occurring as singlet and triplet for closed-shell systems, and as doublet and quartet for open-shell systems. For ClCS, these excited states are $3^2A''$ and $1^4A''$, resulting from (n_S,π^*), and $3^2A'$ and $1^4A'$, resulting from (π,π^*). As expected, the quartet states are at lower energy than the corresponding doublet states. All other excited states involve the singly occupied orbital n_C. By removing an electron from n_C, one finds excitations to π^* ($1^2A''$), the lowest excited state, to σ*(C—Cl)($4^2A'$), and to two Rydberg states ($5^2A'$ and $4^2A''$). Furthermore, excitations into n_C occur, originating from n_S ($2^2A'$), π ($2^2A''$), and n_{Cl} ($5^2A''$). Obviously, single excitations out of or into n_C cannot give rise to quartet states, since n_C is either empty or doubly occupied. Therefore, no other quartet states, besides the two calculated ones, are expected at low energies.

Note that excitations into σ*(C—S) occur only at higher energy, since three Rydberg orbitals lie below this orbital ($21a'$).

TABLE 4. Oscillator strengths for transitions from $\tilde{X}^2A'$ state of ClCS, and comparison with literature values for HCO

		ClCS	HCO[a]
$1^2A''$	(n_C,π^*)	0.0003	0.003
$2^2A'$	(n_S,n_C)	0.0183	0.029
$2^2A''$	(π,n_C)	0.0012	0.012
$3^2A''$	(n_S,π^*)	0.0006	0.006
$3^2A'$	(π,π^*)	0.0100	0.041
$4^2A'$	$(n_C,\sigma^*(C—Cl))$	0.0047	
$5^2A'$	(n_C,R_{4s})	0.0362	0.020
$4^2A''$	(n_C,R_{4p})	0.0032	
$5^2A''$	(n_{Cl},n_C)	0.0040	

[a]Reference 30.

Oscillator strengths

Oscillator strengths were calculated (by the dipole length method) for vertical transitions from the ground state to the excited doublet states. They are given in Table 4, and are compared with oscillator strengths calculated for the corresponding transitions in HCO (30).

The transition to (π,π^*) is expected to have the largest f-value, but it is exceeded here by $2^2A' \leftarrow X$ (n_S,n_C) and by one of the Rydberg transitions involving the (n_C,R_{4s}) state. Oscillator strengths for corresponding HCO transitions are always higher.

For H_2CO and H_2CS, the (n,π^*) oscillator strengths are very small, whereas the (π,π^*) oscillator strengths are 0.256 for H_2CO (31) and 0.38 for H_2CS (32). Transitions to Rydberg states have f-values of about 0.04 for s (33) and 0.02–0.04 for p (32).

Discussion

The electronic energies of ClCS (Table 3) now permit us to construct much more complete energy level and photofragmentation correlation diagrams for Cl_2CS. The available data are summarized in Fig. 1, together with correlations for two of the possible photodissociation channels. The electronic energies of Cl_2CS are the electronic origins of the $\tilde{a} \leftarrow \tilde{X}$ (34), $\tilde{A} \leftarrow \tilde{X}$ (35), and $\tilde{B} \leftarrow \tilde{X}$ (6–8) transitions, an estimate of the energy of the origin of the $\tilde{b} \leftarrow \tilde{X}$ transition based upon the electron-impact energy loss spectrum (36), and the origin of a weak transition to a "dark" state near

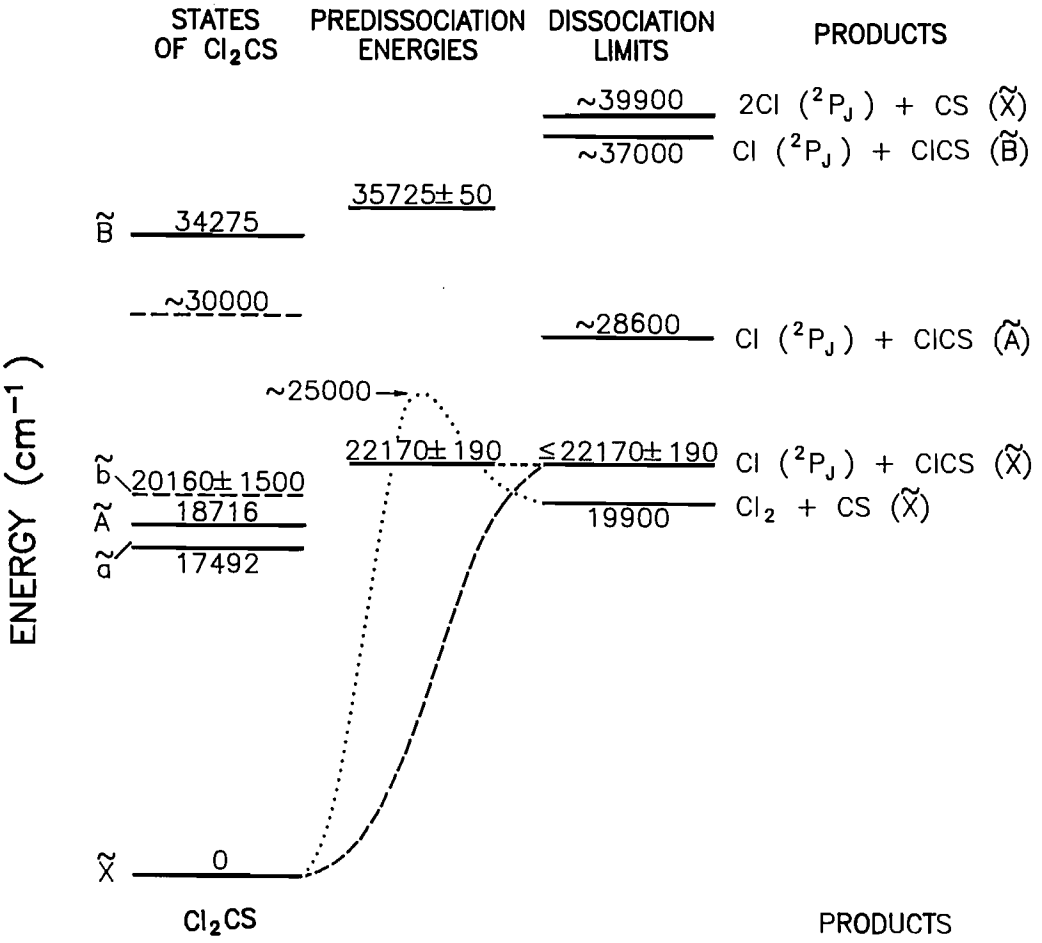

FIG. 1. Energy level and partial state correlation diagram for Cl_2CS and its UV–visible dissociation products. The energies of the electronic states of Cl_2CS are from the origins of the optical absorption spectra. The electronic energy of the $\tilde{b}$ state is estimated from the onset of absorption in the electron energy-loss spectrum (ref. 36). The predissociation energies are from the onsets of fluorescence weakening in the fluorescence excitation spectra. The barrier height on the ground state molecular dissociation path is calculated (ref. 2). The energies of the free radical dissociation products are from the present work. Dissociation limits leading to $Cl_2(^3\Pi)$ have been omitted for clarity.

30 000 cm^{-1} (10). The predissociation energies are those obtained from the onsets of fluorescence-weakening processes in the $\tilde{A}$–$\tilde{X}$ and $\tilde{B}$–$\tilde{X}$ excitation spectra (4, 6).

On the product side, the value of T_e for the adiabatic $\tilde{A}$–$\tilde{X}$ transition in ClCS (0.79 eV, 6400 cm^{-1}) has been used directly. Chan and Goddard's value of 5800 cm^{-1} is slightly lower (23). The lowest possible energy for the $\tilde{B}$ state of ClCS was obtained by optimizing the geometry of the $2^2A'(\tilde{B})$ state using the CIS method and D95 basis set available in the Gaussian 90 package (11). A single-point calculation at this geometry (R_{CS} = 1.976 Å, R_{CCl} = 1.693 Å, α = 139.5°), using MRD-CI, gave an adiabatic transition energy of 1.89 eV (15 200 cm^{-1}) for the $\tilde{B}$ state. The endothermicity of the molecular fragmentation to Cl_2 + CS($\tilde{X}$) is based on good thermodynamic data (2, 3). The energy required for the fragmentation to 2Cl + CS($\tilde{X}$) is obtained by adding to this the ground state dissociation energy of Cl_2 (2.475 eV) (37). Chlorine atoms may be produced in either of two spin-orbit states ($^2P_{3/2}$, $^2P_{1/2}$) separated by 881 cm^{-1} (38). Only the lower of these ($^2P_{3/2}$) is shown in Fig. 1 for clarity. Molecular dissociation channels leading to $Cl_2(^3\Pi)$ have also been omitted.

The $\tilde{X}$ state of Cl_2CS correlates smoothly with the $\tilde{X}$ state of ClCS plus a ground state chlorine atom in the free radical dissociation channels. Ground state Cl + ClCS will also correlate with a repulsive singlet state, which is likely not to be readily observable in the absorption spectrum of the parent molecule (39). Either such a repulsive state or the unbound portion of the ground state surface could be responsible for the observed predissociation of the $\tilde{A}$ state of Cl_2CS some 3400 cm^{-1} above its zero point. Thus, Okabe's suggestion (3) that the fluorescence-weakening process in the $\tilde{A}$ state of Cl_2CS yields ground state Cl and ClCS is probably correct. However, the details of the curve crossing that leads to this fluorescence weakening are unknown. Therefore the predissociation energy in the $\tilde{A}$ state of Cl_2CS only provides an upper limit for the dissociation energy of the ground state, i.e., $D_0 \leq 2.75 \pm 0.02$ eV (22 170 ± 190 cm^{-1}). An *ab initio* calculation places D_0 slightly lower at 2.47 eV (19 940 cm^{-1}) (2). In Fig. 1 the stack of electronic energies of ClCS is placed in relation to the observed electronic energies of Cl_2CS by adding the calculated (or estimated) adiabatic transition energies in ClCS to the upper limit of the ground state Cl-CSCl dissociation energy. If D_0 is actually less than 22 170 cm^{-1}, the whole set of ClCS states should be lowered by the same increment.

The ground state reaction of Cl_2 plus CS to form Cl_2CS is Woodward–Hoffman forbidden. Therefore a barrier exists

in the molecular dissociation channel on the ground state surface. H_2CO is similar (40). The height of this barrier for dissociation along a path in which the transition state has C_s symmetry has been calculated by *ab initio* methods (4-31G basis) to be about 25 000 cm^{-1} (2). Although the latter calculation is likely to give only a very crude estimate of the barrier height, the fact that no molecular dissociation products appear on photolysis in the visible (3) suggests that the barrier greatly exceeds the endothermicity of 19 900 cm^{-1}.

Figure 1 reveals that a number of photofragmentation channels are energetically accessible following excitation of Cl_2CS at 248 nm (40 323 cm^{-1}), the wavelength employed by Ondrey and Bersohn (1). Three of these are free radical channels in which the products are Cl atoms plus ClCS in its lowest three electronic states. The Cl + ClCS($2^2A'$) channel is slightly exothermic and would leave only 39 kJ mol^{-1} for the translational, rotational, and vibrational motion of the dissociated fragments. Therefore, this channel can be ruled out on the basis of Ondrey and Bersohn's experiment, where the translational energy alone accounts for 67 kJ mol^{-1}. However, the remaining two free radical channels require careful examination.

For photodissociations involving simple bond scission, the internal energy of the excited molecule minus the bond dissociation energy, D_0, gives E_{avail}, the energy that is available to be partitioned among the translational, rotational, vibrational, and electronic degrees of freedom of the fragments. In Cl_2CS excited at 248 nm, E_{avail} = 233 kJ mol^{-1} if D_0 is taken to be *equal* to 265 kJ mol^{-1} (22 170 cm^{-1}). The average translational energy of ClCS was measured by Ondrey and Bersohn (1) to be 67 kJ mol^{-1}. Thus, if ClCS is produced in its electronic ground state, the fraction of E_{avail} that is partitioned into the translational degrees of freedom of ClCS is f_T = 0.288. On the other hand if ClCS is produced in its $\tilde{A}$ state, 80 kJ mol^{-1} above $\tilde{X}$, then only 154 kJ mol^{-1} is available to be partitioned into the vibrational, rotational, and translational degrees of freedom of the fragments and f_T = 0.438. However, if D_0 is in fact <265 kJ mol^{-1} (as discussed above), then f_T will be <0.438.

We recently calculated the free radical dissociation energy on the ground state surface of Cl_2CS by *ab initio* methods using a 4-31G** basis set and obtained D_0 = 239 kJ mol^{-1} (2). If this value rather than D_0 = 265 kJ mol^{-1} is employed in the calculation of E_{avail}, one obtains f_T = 0.26 if the ClCS radical is assumed to be in its ground state and f_T = 0.37 if ClCS is in its $\tilde{A}$ state. Only f_T = 0.37 is in agreement with the prediction of the impulsive spectator model (1, 5), which gives $(f_T)_{sp}$ = 0.369.

Conclusion

The excellent agreement between $(f_T)_{sp}$ and f_T calculated for D_0 = 239 kJ mol^{-1} and a ClCS ($\tilde{A}$) product may be fortuitous. Nevertheless, the result is sufficiently interesting to encourage us to reinvestigate the photofragmentation dynamics of Cl_2CS experimentally. Although it would be difficult to detect $\tilde{A} \rightarrow \tilde{X}$ emisson from ClCS in the near infrared ($\lambda_{em} \geq 1.49$ μm), laser-induced fluorescence methods might well be used as a diagnostic tool for this species. The strong $\tilde{B}$–$\tilde{X}$ transition in the chlorothioformyl radical, which we predict should be observed in the visible (origin near 575 nm), would appear to be particularly useful in this respect provided the $\tilde{B}$ state is bound.

HIROTO TACHIKAWA, ANDERS LUND, and MASAAKI OGASAWARA. Can. J. Chem. **71**, 118 (1993).

Model calculations were made on the hydrated electron by using the *ab initio* MO method combined with the MR-SD-CI method and the coupled cluster theory. The models used in the calculations were water clusters denoted by $[e^-(H_2O)_n(H_2O)_m]$, where n = 2,3,4, and 6 for the first solvation shell and m = 0–28 for the second and third solvation shells. In these model calculations, the interactions between the excess electron and the water molecules in the first solvation shell are explicitly calculated by *ab initio* MO methods and the water molecules in the second and third solvation shells were represented by the fractional charges obtained at the MP2/D95V** level. The stabilization energies and the solvation radius $r(e^-–O)$, in terms of the distance between the center of the cavity and an oxygen atom of the surrounding water molecules, increased monotonically with the number of water molecules in the first solvation shell. On the other hand, the first excitation energy was not dependent on the number of water molecules in solvation shells, but constant, with the value of ca. 2.0 eV. On the basis of the present calculations, we suggest that (1) the energetic stability of excess electrons depends on both short-range interaction and long-range interaction, (2) the first excitation energy is critically affected by only the short-range interactions, and the excitation is theoretically attributed to the $1s \rightarrow 2p$ transition of the excess electron.

HIROTO TACHIKAWA, ANDERS LUND et MASAAKI OGASAWARA. Can. J. Chem. **71**, 118 (1993).

Des modélisations ont été faites sur l'électron hydraté en utilisant la méthode d'OM *ab initio* en parallèle avec la méthode MR-SD-Cl et la théorie de l'agrégat couplé. Les modèles utilisés dans les calculs sont des agrégats d'eau dénotés $[e^-(H_2O)_n(H_2O)_m]$ où n = 2,3,4 pour la première couche de solvatation et m = 0–28 pour les deuxième et troisième couches. Dans ces calculs, les interactions entre les électrons d'excès et les molécules d'eau dans la première couche de solvatation sont calculées explicitement par des méthodes d'OM *ab initio*; les molécules d'eau dans la deuxième et la troisième couches de solvatation ont été représentées par les charges fractionelles obtenues au niveau MP2/D95V**. Les énergies de stabilisation et le rayon de solvatation $r(e^-–O)$, fonctions de la distance entre le centre de la cavité et un atome d'oxygène des molécules d'eau environnantes, augmentent de façon monotone avec le nombre de molécules dans la première couche de solvatation. D'autre part, la première énergie d'excitation ne s'est pas avérée dépendante du nombre de molécules d'eau dans les couches de solvatation, mais plutôt constante d'une valeur d'environ 2.0 eV. À partir des calculs développés, nous suggérons (1) que la stabilité énergique des électrons d'excès est dépendante des interactions à courte et longue distances et (2) que la première énergie d'excitation n'est affectée que par les interactions à courte portée et que cette excitation est attribuée théoriquement à la transition $1s \rightarrow 2p$ de l'électron d'excès.

Introduction

Significant progress has recently been made in the theoretical treatment of the hydrated electron (1). Information about the solvation structure, electronic properties, and statistical fluctuation of the hydrated electron has been obtained by various kinds of computer experiment. In particular, quantum molecular dynamics (MD) simulation was successful in unraveling the equilibrium and dynamical electronic structure of water cluster anions (1*m*). When the size of cluster $(H_2O)_n$ is small ($8 \leq n \leq 32$), the negative charge is pushed out to the surface of the cluster anion (surface state). The charge is included within the cluster (interior state) when the size is large ($n \leq 32$) (1*e*). Cluster anions with the interior state may be considered models of the hydrated electron. The electron in these clusters is characterized by a localized, roughly spherical, density fluctuation in the ground state, which is very much like a hydrogenic 1*s* state. The average radius for a system comprising 500 water molecules and one electron was found to be 2.05 Å. The existence of three *p*-like states above the ground state was also confirmed. The wave functions corresponding to these states are localized with approximately mutually perpendicular orientation. The most probable energy splitting between the lowest and highest eigenvalue is about 0.8 eV. Above the *p*-like states lies a band of unbound delocalized states of indefinite symmetry.

The present study is aimed at comparing the above picture of the hydyrated electron to that obtained by molecular orbital calculations. The molecular orbital method was first applied to the hydrated electron by Natori and Watanabe (2). Following this pioneering work, *ab initio* MO calculations were made by Newton (3) on the excess electron in a water cluster surrounded by a continuum medium. The results suggested more than four water molecules for capturing an electron effectively. Noell and Morokuma applied their fractional charge MO method to the hydrated systems (4). The system they calculated was composed of an excess electron, the first solvation molecules explicitly considered by molecular orbitals, and surrounding solvent molecules represented by fractional charges. The results favored a six coordination model, rather than a four coordination model, for the first solvation shell around the electron. In 1988, Clark and Illing (5) proposed theoretical models on the basis of *ab initio* HF calculations. They added in their calculations a 31G basis set (hydrogen-atom type) for representing an excess

electron in the center. The solvation energies calculated for several solvents showed a moderate correlation with the observed maximum wavelength of the absorption spectra.

In the previous study we made *ab initio* calculations on water dimer anions (6); a multi-reference single and double excitation (MR-SD) CI calculation was applied to the excess electron in two water molecules with a surface orbital to represent the surface state *in vacuo*. The results suggested that the first and second electronic excitations were bound–bound and bound–free excitations, respectively (6). In the present study we dealt with models composed of the first solvation shell and surrounding molecules. The calculations were made with special reference to the electronic states in the ground and low-lying excited states. This is the first attempt to study the excited state of hydrated electrons by *ab initio* calculations including electron correlation by the MR-SD-CI and coupled cluster methods. It should be emphasized, however, that this type of calculation has an intrinsic limitation in comparison with the statistical mechanics method. The calculation was made with fixed geometrical nuclear structure of the water structure. Hence, the concept of the first solvation shell and outer solvation shells is only valid in a static condition such as frozen glasses (7).

Method

Models

The solvation shells composed of three layers of water molecules denoted by $[e^-(H_2O)_n(H_2O)_m]$ (n = 2,3,4, and 6, m = 0–28) were considered as model systems for the hydrated electron. Here n is the number of water molecules in the first solvation shell and m is the number in the second and the third solvation shells. The solvent molecules in the first solvation shell denoted by n were explicitly accounted for with molecular orbitals and the geometry of each cluster anion was fully optimized. The second and the third solvation shells composed of m solvent molecules were represented by the fractional charges (q_O = −0.66 and q_H = +0.33 for r(O—H) = 0.962 Å and the H—O—H angle = 104.41°) obtained at the MP2/D95V** level (8). The outer shell molecules were added to the optimized small cluster anions to which each of the molecules is connected by hydrogen bonding (8). We assumed that the hydrogen bonding structure of the water dimer is linear. The distance of the hydrogen bond r(O···HO) and bending angle were 1.867 Å and 21.3°, respectively (6).

MO calculation

In the previous paper, we determined the structure and the electronic states of the water dimer anion by means of *ab initio* Hartree–Fock and MR-SD-CI calculations (6). We applied the same procedure to the present model calculation. Geometry optimizations of equilibrium points were performed by using the energy gradient method based on the Hartree–Fock theory with a 6-31+G basis set (10–12). Energies on the equilibrium points were further refined by Møller–Plesset second-order perturbation theory (13). In the

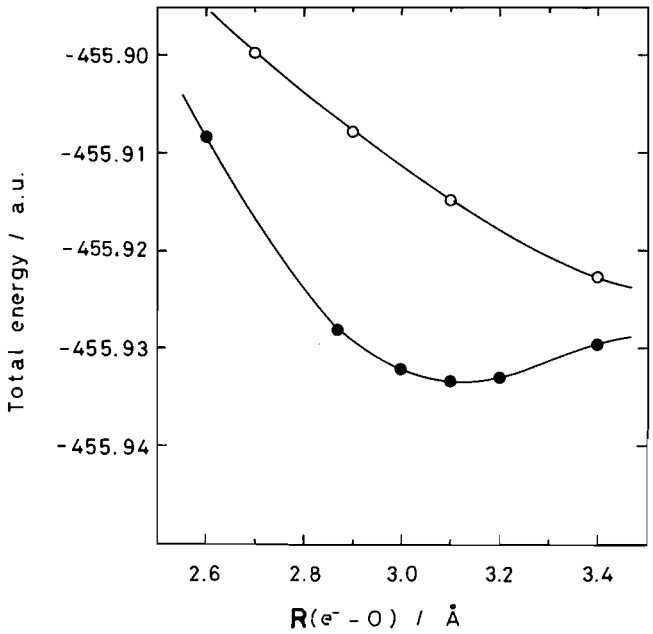

FIG. 2. Potential energy curves for the excess electron system $[e^-(H_2O)_6]$ (—●—) and for the neutral system $[(H_2O)_6]$ (—○—) calculated as a function of $r(e^-–O)$ and the distance between the cavity center and the oxygen atom, respectively. The calculations were performed at the HF/6-31+G level.

calculations of the excitation energies, the coupled cluster method with a 6-31+G basis set and the MR-SD-CI method with Huzinaga's (621/51) basis set were carried out in order to obtain the electron correlations (14–16). We added an *sp*-type diffuse orbital (exponent = 0.0845) to Huzinaga's basis set in this calculation. In the MR-SD-CI calculations, we chose two groups for the active space, as listed in Table 1.

Results and discussion

Structural models

Figure 1 shows the structural models with different coordination numbers (n = 2,3,4, and 6). The structures were fully optimized by means of *ab initio* HF/6-31+G calculations. Table 2 summarizes the corresponding parameters for n = 2, 3, and 4. Three types of geometrical structure, an OH orientation form, a dipole orientation from, and the intermediate form proposed previously by us, were considered as possible orientational forms for the water molecules in the

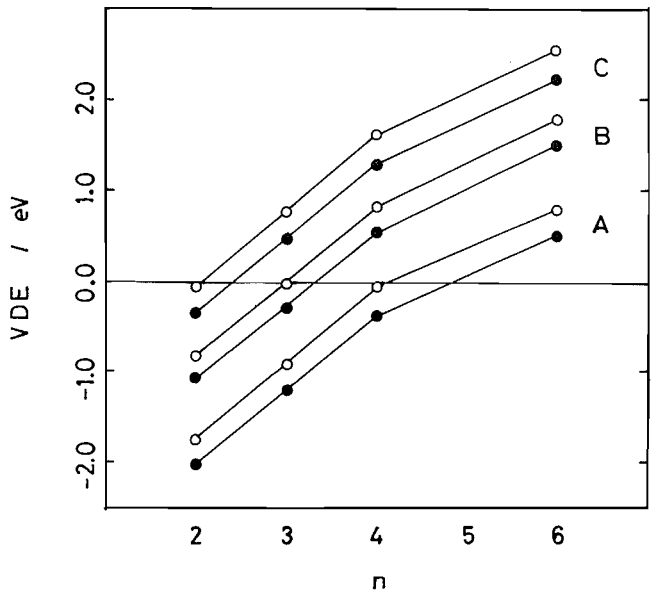

FIG. 3. Vertical detachment energies (VDE's) as a function of the number of coordinating water molecules in the first solvation shell. (*A*) Without the second and third shells. (*B*) Including six water molecules in the second solvation shell. (*C*) Including 28 water molecules in the second and third solvation shells. Open and solid circles denote the HF/6-31+G values and MP2/6-31+G values, respectively.

first solvation shell (6, 7, 17). The dipole orientation form was energetically favored for n = 3 and 4, and the intermediate form was favored for n = 2 within the approximation. The electron–oxygen distance, $r(e^-–O)$, in terms of the distance between the center of the cavity and the nucleus of an oxygen of the first solvation shell molecules, increases monotonically with increasing coordination number n.

For n = 6, we assumed an intermediate form by analogy with the cluster anion with n = 2 and optimized the geometrical structure for $r(e^-–O)$. Figure 2 shows the potential energy curves for the negatively charged system $[e^-(H_2O)_6]$ and the neutral system $[(H_2O)_6]$ calculated as a function of $r(e^-–O)$. The negatively charged system shows a bound state with a potential minimum. To evaluate the vertical electron detachment energy (VDE) of the cluster anion, we calculated the potential energy curve of the neutral system (Fig. 2). In the neutral system, all water molecules are affected by the repulsive interactions due to the hydrogen–hydrogen repulsion force. It means that an excess electron injected into the water cluster composed of six water molecules with the intermediate form plays a role of binding water molecules together. The VDE at the minimum point shows a positive value. The cluster is thus able to capture an electron at the center of the cluster.

Effect of n *and* m *on the VDE*

Figure 3 shows the VDE of the water cluster anions, $[e^-(H_2O)_n(H_2O)_m]$, for m = 0, 6, and 28. The VDE was calculated as a function of the number n of water molecules in the first solvation shell at the HF/6-31+G and MP2/6-31+G levels. The lines *A*, *B*, and *C* correspond to the systems having zero, six, and 28 water molecules in the second and the third solvation shells, respectively. As the differences in

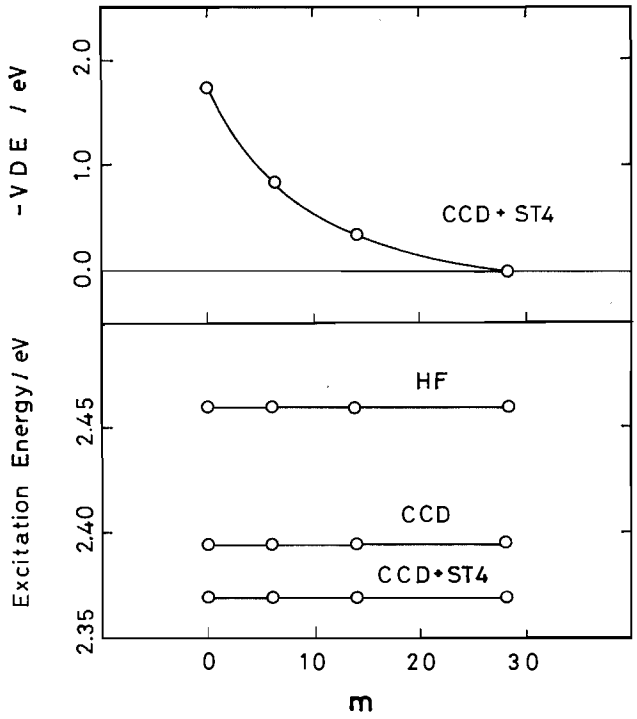

FIG. 4. Excitation energies and the vertical detachment energies (VDE's) of the $[e^-(H_2O)_2(H_2O)_m]$ system calculated as a function of m. The values are obtained by the Hartree–Fock method (HF), Møller–Plesset's perturbation theory (MP2, MP3, and MP4DQ), and the coupled cluster theory (CCD and CCD+ST4) with a 6-31+G basis set.

VDE due to the electron correlation were all found to be 0.28 eV for n = 1–4, the MP2 value for n = 6 was extrapolated from the HF results for the sake of reducing the consumption of CPU time.

Figure 3 shows that the stability of the models depends not only on the number of water molecules in the first solvation shell but on the one in the outer solvation shells as well. It is also suggested that the first solvation shells composed of small numbers of water molecules, two or three molecules for example, may stably trap an excess electron provided that the first solvation shell is surrounded by sufficient numbers of water molecules. However, the stabilization energies for n = 2 and 3 are much smaller than the energy for n = 6. The VDE of the system with the combination of n = 6 and m = 28 is 2.51 eV. This is in good agreement with the calculated value in the framework of the continuum model (3). The model shells composed of the fractional charges of 28 water molecules seem to be energetically equivalent to the continuum model (3). In Kevan's model for trapped electrons, six water molecules surround an excess electron with OH dipole pointing to the cavity center. This model was deduced from the analysis of the two-pulse electron-spin-echo modulation patterns obtained in irradiated 10 M NaOH aqueous glasses at 77 K. The energetics in the present study support Kevan's model, although the molecular dipole properties are slightly merged into the OH form. However, this does not exclude the possibility that the electrons are localized in sites composed of only a few water molecules in frozen matrices; if a potential around the electron is effectively formed, the excess electron could be captured by two or three water molecules, for example, giving rise to the characteristic absorption with its maximum at ca. 700 nm. This possibility is suggested by the result that the electron affinities of the n = 2–3 systems can be positive when sufficient numbers of water molecules exist around the first solvation shell.

According to the results of MD calculations, the first solvation shell of the excess electron in a water cluster is composed of six water molecules with the OH orientation form. It was also suggested that the electron–hydrogen distance $r(e^-–H)$ was 2.05 Å (1m). The distance 2.264 Å (n = 6) obtained in the present study is in reasonable agreement with that value.

Electronic excitation

The excitation energies for the n = 2 systems, $[e^-(H_2O)_2(H_2O)_m]$, were calculated as a function of m. This system was

n	G-I	G-II
2	2.02	1.97
3	2.02	2.04
4	1.86	1.88
6	1.99	1.98

[a]Values are in eV.

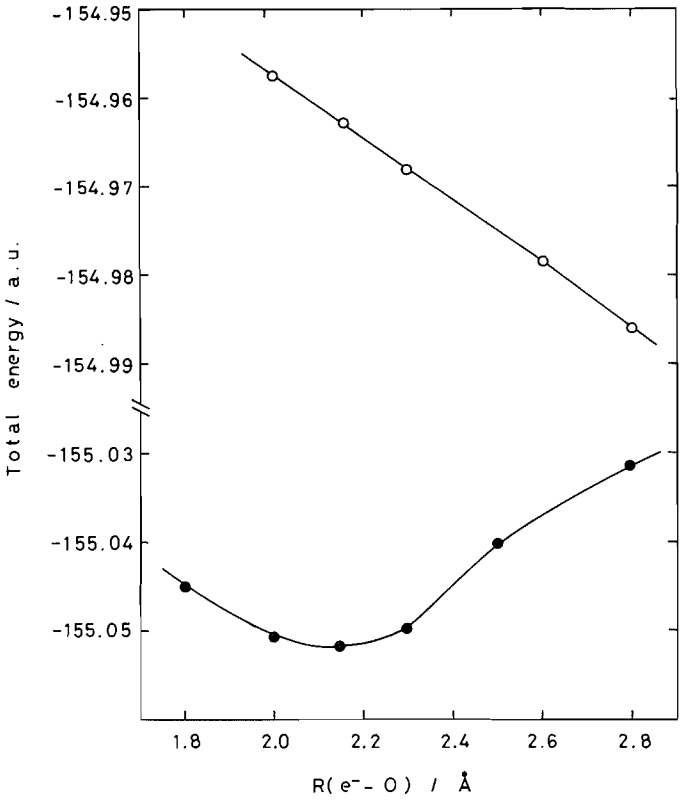

FIG. 6. Potential energy curves of $[e^-(H_2O)_2(H_2O)_{14}]$ at the ground (—●—) and first excited states (—○—) calculated with the coupled cluster theory (CCD/6-31+G) as a function of $r(e^-$–O).

chosen for the sake of simplicity, but the pertinency of the example will be identified in the following paragraph. The results are shown in Fig. 4 together with the VDE's for comparison. The VDE tends to increase with increasing m until it reaches at a constant value at $m = 28$, although the absolute values may not have much sense. In contrast, the excitation energy to the first excited state is constant regardless of the value of m. It is not affected by the number of surrounding solvent molecules in the second and third solvation shells.

Figure 5 shows the energy levels calculated at the MR-SD-CI level of low-lying doublet states for the model systems with $n = 2$, 3, 4, and 6. The first excitation energies calculated with two groups of the active space at the MR-SD-CI level are summarized in Table 3. The results of the MR-SD-CI calculations were not affected by the correction of quadruple electron excitations (MR-SD-CI+Q). The cal-

[c]H_2 is outer hydrogen atom.
[d]Experimental spin density is 0.004 (ref. 9).

culated values range around 2.0 eV for all the model systems examined.

Figure 6 shows the potential energy curves of $[e^-(H_2O)_2(H_2O)_{14}]$ at the ground and first excited states calculated by the coupled cluster theory (CCD). The potential curve of the ground state has a bound state, but the first excited state is always repulsive. Since the potential curve of the first excited state is substantially steep, the excitation energy is expected to depend sensitively on the geometry of the ground state. In actuality, however, the excitation energies are hardly affected by the number of the coordination water molecules, as shown in Fig. 5.

The effect of the water molecules in the first solvation shell on the excess electron could be regarded as short-range interaction, and that of the molecules in the outer shells as long-range interaction. The present study demonstrated that the solvation energy was, of course, affected by both the short-range interactions and the long-range interactions. On the other hand, the first excitation energy is critically determined only by the short-range interactions.

Contour maps

Figures 7 and 8 show contour maps of the singly occupied molecular orbitals at the ground state (^2A_g) and the first excited state (^2A_u), respectively. The maps were obtained for a hexacoordination form (n = 6) by MR-SD-CI calculations. In the ground state, the orbital occupied by an excess electron is composed of an *s*-like orbital, which is formed by overlapping of the diffuse orbitals of surrounding water molecules. Similar results were obtained previously for methanol cluster anions (18). The excess electron is mainly distributed over the cavity. In the first excited state (^2A_u), however, the corresponding orbital is composed of *p*-like orbitals whose nodal planes go through the cavity center; the orbital spreads over the coordinating water molecules. The first optical excitation is attributed to the transition from 1*s*- to 2*p*-like orbitals of the excess electron. The results are consistent with the picture obtained by MD calculations (1*m*).

Spin population

Table 4 summarizes the spin populations in the *s*-type orbitals of the hydrogen atoms of the model systems. The spin population was obtained from the sum of the spin populations on the *s*-type functions in the atomic basis. The procedure was the same as that employed previously by Clark and Illing (5). In the n = 4 system, the spin populations of all the hydrogen atoms are equal to each other, because the model is a dipole orientation structure with C_s symmetry. The spin populations calculated for the hexacoordination model

($n = 6$) are comparable to the experimental values obtained by Kevan (*7a*, *7b*), but those for the $n = 4$ model (ca. −0.26) are much larger. The sign of the hyperfine constant on the oxygen atoms is positive, in agreement with previous results (3–5). It seems that positive hyperfine coupling constants, which are generally observed in solvated electrons, are caused by the spin polarization mechanism as already pointed out by Clark and Illing (5).

Antibody–oligosaccharide interactions: the synthesis of 2-deoxy-α-L-rhamnose containing oligosaccharide haptens related to *Shigella flexneri* variant Y antigen[1]

H. RIZK HANNA[2] AND DAVID R. BUNDLE[3]

Institute for Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received July 6, 1992

H. RIZK HANNA and DAVID R. BUNDLE. Can. J. Chem. **71**, 125 (1993).

A series of di- and trisaccharide glycosides based on the α-L-Rha(1→3)β-D-GlcNAc and α-L-Rha(1→3)α-L-Rha(1→3)β-D-GlcNAc elements have been synthesized to locate the minimal oligosaccharide determinant of the *Shigella flexneri* O-polysaccharide, which is built from a tetrasaccharide repeating unit, [→2) α-L-Rha*p*(1→2)α-L-Rha*p*(1→3)α-L-Rha*p* (1→3)β-D-GlcNAc*p*(1-]$_n$. These compounds also serve to identify the carbohydrate surface of the *Shigella* antigen that interacts with a monoclonal antibody, currently the subject of crystallographic studies. Two strategies utilizing suitably protected glycals **1** and **19** were employed to obtain analogs bearing either terminal or glycosylated 2,6-dideoxy-α-L-*arabino*-hexopyranosyl (2-deoxy-α-L-rhamnopyranosyl) residues. *N*-Iodosuccinimide activation of the glycals in the presence of selectively protected mono- and disaccharide alcohols afforded 2-deoxy-2-iodo-α-L-rhamnopyranosides and these were ultimately reduced during deprotection stages to afford the desired functionality. Di-*O*-acetyl L-rhamnal **1** reacted with monosaccharides **2** and **7**, and with disaccharide **11**, to yield disaccharides **4** and **8**, and trisaccharide **12**, each bearing a terminal 2-deoxy-α-L-rhamnopyranosyl residue. The selectively protected 3-*O*-benzoyl-4-*O*-benzyl-L-rhamnal **19** was synthesized from L-rhamnal and used to prepared trisacceharide **22**, which contained an internal 2-deoxy-2-iodo-α-L-rhamnopyranosyl unit. Removal of protecting groups gave the oligosaccharides **6**, **10**, **14**, and **23**. Oligosaccharides that contained a 2-deoxy-α-L-rhamnopyranosyl residue showed enhanced inhibitory power: in the case of trisaccharide **23** a 1.8 kcal mol^{-1} relative increase in free energy of binding compared to a larger pentasaccharide epitope, α-L-Rha*p*(1→2)α-L-Rha*p*(1→3)α-L-Rha*p*(1→3)β-D-GlcNAc*p*(1→2)α-L-Rha*p*-1→OMe. These data suggest that the rhamnose O-2 hydroxyl of residue **C** points toward and has important interactions with binding site amino acids.

H. RIZK HANNA et DAVID R. BUNDLE. Can. J. Chem. **71**, 125 (1993).

Dans le but déterminer l'oligosaccharide déterminant minimal du O-polysaccharide *Shigella flexneri*, formé à partir du motif de tétrasaccharide [→2) α-L-Rha*p*(1→2)α-L-Rha*p*(1→3)α-L-Rha*p*(1→3)β-D-GlcNAc*p*(1-]$_n$, on a synthétisé une série de glycosides di- et trisaccharides basés sur les éléments α-L-Rha(1→3)β-D-GlcNAc et α-L-Rha(1→3)α-L-Rha(1→3)β-D-GlcNAc. On a utilisé ces composés pour identifier la surface carbohydrate de l'antigène *Shigella* qui interagit avec l'anticorps monoclonal qui fait l'objet d'études cristallographiques. On a utilisé deux stratégies, faisant chacune appel aux glycals **1** et **19** protégés d'une façon appropriés, pour obtenir des analogues des restes 2,6-didésoxy-α-L-*arabino*-hexapyranosyle (2-désoxy-α-L-rhamnopyranosyle) terminal ou glycosé. Une activation des glycals par la *N*-iodosuccinimide en présence d'alcools mono- ou disaccharidiques conduit au 2-désoxy-2-iodo-α-L-rhamnopyranosides qui sont finalement réduits durant les étapes de déprotection pour fournir les fonctionnalités désirées. Le di-*O*-acétyl L-rhamnal **1** réagit avec les monosaccharides **2** et **7** et avec le disaccharide **11** pour conduire aux disaccharides **4** et **8** et au trisaccharide **12** qui portent tous un reste 2-désoxy-α-L-rhamnopyranosyle. On a synthétisé le 3-*O*-benzoyl-4-*O*-benzyl-L-rhamnal sélectivement protégé (**19**) à partir du L-rhamnal et on l'a utilisé pour préparer le trisaccharide **22** qui contient une unité interne de 2-désoxy-2-iodo-α-L-rhamnopyranosyle. L'enlèvement des groupes protecteurs conduit aux oligosaccharides **6**, **10**, **14** et **23** qui contiennent une unité de 2-désoxy-α-L-rhamnopyranosyle et qui présentent une puissance inhibitrice élevée; dans le cas du trisaccharide **23**, on observe une augmentation de 1,8 kcal mol^{-1} de l'énergie libre de liaison par rapport à celle d'un pentasaccharide épitope beaucoup plus important, α-L-Rha*p*(1→2)α-L-Rha*p*(1→3)α-L-Rha*p*(1→3)β-D-GlcNAc*p*(1→2)α-L-Rha*p*-1→OMe. Ces données suggèrent que l'hydroxyle O-2 du rhamnose du reste **C** pointe vers, et interagit d'une façon importante avec, le site de liaison des acides aminés.

[Traduit par la rédaction]

Introduction

Monoclonal antibodies produced in response to immunization of mice with killed cells of *Shigella flexneri* variant Y bacteria exhibit a tendency to bind to structural elements of the cell surface O-antigen that span the junction of biological repeating units (1, 2). The latter structure is a tetrasaccharide, which is polymerized to provide the O-polysaccharide:

[→2)α-L-Rha*p*(1→2)α-L-Rha*p*(1→3)
Units **A** **B**

α-L-Rha*p* (1→3)β-D-GlcNAc*p*(1-]$_n$
C **D**

Mapping of the antibody binding sites that recognize this structure using linear oligosaccharides of different length has identified a residue sequence **BCDA** that frequently appears to be the optimal epitope size for binding (2). A Fab sample from an $IgG_3\kappa$ monoclonal antibody exhibiting these features is now the subject of a high-resolution crystal structure study (3). Characterization of the molecular features of the antigenic determinant that interacts with the antibody surface requires a series of oligosaccharides that have functional group modifications at single sites (4, 5). Chemical synthesis of monodeoxy analogs has been used extensively for this purpose and represents one of the most conservative changes (>CH—OH → >CH_2) that may be used to identify and quantify the incremental contributions of important polar contacts (6).

The disaccharide **CD**, α-L-Rha*p* (1→3) β-D-GlcNAc*p*-1→OMe, was selected as the structural element around which to make functional group replacements, because inhi-

bition data with the pentasaccharide **ABCDA** (7), tetrasaccharide **BCDA** (8), and trisaccharides **BCD** (9) and **CDA** suggested that the major contribution to binding occurred in the **BCD** or **CDA** fragments (2). In this study we report the synthesis and relative activities of a series of di- and trisaccharide methyl glycosides centred on this epitope and containing 2-deoxy-α-L-*arabino*-hexopyranosyl residues.

Results and discussion

Di-*O*-acetyl-L-rhamnal **1** was prepared from tri-*O*-acetyl-α-L-rhamnopyranosyl bromide by reaction with magnesium–mercury amalgam (10).[4] Reaction of glycal **1** with the selectively protected monosaccharide alcohol, methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside **2**, in the presence of *N*-iodosuccinimide (11) provided an epimeric mixture of 1,2-*trans*-2-deoxy-2-iodo glycosides **3** and **4**. Variation of solvent and reaction conditions influenced the yield and ratio of products **3** and **4** (Table 3, experimental section). Extended reaction times in dichloromethane appeared to represent optimal conditions. The major product **3** possessed the α-*manno* configuration judged from ^{1}H and ^{13}C nmr spectral evidence (H-1′ δ 5.26 ppm $^3J_{1,2} < 1$ Hz, $^3J_{2,3} \approx 5$ Hz). A heteronuclear one-bond coupling constant for the anomeric carbon atom of 173 Hz unambiguously established the anomeric configuration of the α-L-rhamnopyranosyl residue (12). Based upon similar considerations (^{1}H nmr $^3J_{1,2}$ 9.0 Hz, $^3J_{2,3}$ 9.2 Hz) the minor product **4** had the β-L-*gluco* configuration. The 2-deoxy-2-iodo-rhamnopyranoside **3** was reduced to the 2-deoxy-*arabino-hexo*-pyranoside **5** in 82% yield following reduction by tributyltin hydride. Alternatively, nickel boride (13) also converted **3** into **5** but in lower yield (68%). Hydrogenation and *trans*-esterification of **5** gave the target disacharide **6**.

In a related series of experiments methyl 3,4-di-*O*-benzyl-α-L-rhamnopyranoside **7** and disaccharide **11** (7) were reacted with di-*O*-acetyl-L-rhamnal **2**. The disaccharide **8** and

trisaccharide **12** were obtained after chromatography in yields of 56 and 80%. Although use of acetonitrile instead of dichloromethane was not generally advantageous (Table 3), here the reaction time was decreased from 12 days to 30 h and the yield rose to 72%. The corresponding β-L-gluco isomers were not isolated and if present were effectively removed by silica gel chromatography. Compounds **8** and **12** were deprotected by first reducing the 2-iodo moiety to yield compounds **9** and **13**, then the benzyl groups were removed by hydrogenolysis and, finally, acetate esters by transesterification. Trisaccharide **13** was also de-*O*-benzylated by catalytic transfer hydrogenation (14). The purity of the products was indicated by ^{1}H and ^{13}C nmr spectra and the anomeric configuration was unambiguously established by measurement of $^{1}J_{CH}$ values for the anomeric carbon atoms of the deprotected structures **10** and **14**. The native tri-

saccharide sequence **CDA** was constructed by reaction of disaccharide **11** with 2-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranosyl chloride to give the protected trisaccharide **15** and ultimately trisaccharide **16**.

To introduce an internal 2-deoxy-rhamnose residue, a selectively protected rhamnal derivative was required. L-Rhamnal **17** (15) was selectively benzoylated under controlled conditions to provide 3-*O*-benzoyl-L-rhamnal **18** in 65% yield (16). Benzylation then provided the required intermediate **19**. Methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glycopyranoside **2** was reacted with the rhamnal **19** for 10 days and, after chromatography, **20** (60%) was obtained as the only disaccharide product. Transesterification afforded the selectively protected disaccharide alcohol **21**, which was glycosylated by tri-*O*-acetyl-α-L-rhamnopyranosyl bromide in the presence of silver triflate promoter.The protected trisaccharide **22** was deblocked in three steps without characterizing the intermediate derivatives. The benzylidene group was removed and the diol was acetylated. Tributyltin hydride reduction gave a 2-deoxy-rhamnose intermediate and transesterification followed by hydrogenolysis then afforded the trisaccharide **23**.

The disaccharides **6** and **10** and the trisaccharides **14**, **16**, and **23** were evaluated as inhibitors for the binding of the *Shigella flexneri* variant Y polysaccharide antigen to monoclonal antibodies, one (GC4) an IgM (17) and the other SYA/J6, an $IgG_3\kappa$. A solid phase assay employing antibody-coated enzyme immunoassay plates and enzyme-labelled polysaccharide antigen was used to obtain association constants for each inhibitor, which permitted the relative inhibitory power to be estimated as well as relative free energies $\Delta(\Delta G)$ for compounds **6**, **10**, **14**, **16**, and **23** (18, 19). In this assay purified antibody is immobilized on the wells of microtiter plates and enzyme- or biotin-labeled an-

tigen is allowed to bind to solid phase antibody in the presence of increasing amounts of inhibitor. Under appropriate conditions it can be shown that the reciprocal antigen concentration at the 50% inhibition point corresponds to the association constant for the antibody–inhibitor pair (18, 19). Even when this does not strictly hold, the relative association constant or binding energy can be related to a reference inhibitor. For the antibody SYA/J6 these data are presented in Table 1 and are related to a native pentasaccharide structure α-L-Rha*p*(1→2)-α-L-Rha*p*(1→3)-β-D-GlcNAc*p*-(1→2)-α-L-Rha*p*-1→OMe, synthesized in other studies (7).

The pentasaccharide **ABCDA'** (7) and tetrasaccharide **BCDA** (8) have comparable activity, suggesting that the

terminal α-L-Rha residue **A** lies outside the antibody binding site. However, the 1.8 kcal mol^{-1} loss in binding energy when residue **B** is omitted indicates that this residue is a crucial part of the antigenic epitope. Since the tetrasaccharide **ABCD** shows comparable activity to the frame-shifted tetrasaccharide **BCDA′** (data not shown; see ref. 2) the trisaccharide **BCD** is concluded to be the essential recognition element of the bacterial antigen by antibody SYA/J6. Antibody GC-4 (Table 2) shows similar trends although the effective inhibitory power of disaccharide ligands suggests this binding site accommodates a smaller ligand. The relatively weaker activity of trisaccharide **CDA** compared to **BCD** suggests that the **A** residue makes unfavorable contacts with the protein.

The trisaccharides containing a 2-deoxy-rhamnose residue, **C′DA** and **BC′D**, both exhibit enhanced activity with antibodies compared to the corresponding unmodified trisaccharides, a trend that is also seen for the disaccharide analogues. The increased binding strength may be rationalized by assuming that the face of the oligosaccharide that presents the 2-OH group of rhamnose **C** points towards and interacts strongly with protein. Removal of the 2-OH group may then lead to stronger binding by extending nonpolar interactions or by relaxing the requirement of buried OH groups to be paired with an H-bond acceptor (20). The latter interpretation is consistent with more elaborate modelling studies, which are the subject of other publications.

Experimental

General procedures

Solvents were distilled before use and were dried where necessary by literature procedures (21). Reactions performed with dried solvents were conducted under dry nitrogen. Thin-layer chromatography (tlc) was performed on Silica Gel 60 F_{254} (Merck) with detection by uv light and (or) charring with sulphuric acid. Silica Gel 60 (Merck, 70–230 mesh) and redistilled solvents were used for column chromatography. Hexane refers to a mixture of hexanes supplied by Home Oil Company, Wichita, Kansas. Rexyn 101 refers to a strong cation-exchange resin (Fisher Scientific).

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer 243 spectropolarimeter.

The ^1H and ^{13}C nmr spectra were recorded with Bruker AM 200 and AM 500 spectrometers. Solutions in organic solvents were referenced to internal tetramethysilane and relative to 1.0% v/v internal acetone (δ_H 2.225 ppm) in D_2O solutions. Internal acetone (δ_C 30.50 ppm) was used as the internal ^{13}C reference for solutions in D_2O. Chemical shifts and coupling constants are first-order values and assignments are based upon homo- and heteronuclear shift correlation spectroscopy.

Enzyme immunoassays were performed according to published procedures (18, 19). *Shigella flexneri* O-polysaccharide was re-

ductively aminated and biotinylated (19). Protein A purified antibody was used to coast immunoassay microtiter plates and inhibition assays were conducted as previously described (19).

*1,5-Anhydro-3,4-di-*O*-acetyl-2,6-dideoxy-*L*-*arabino*-hex-1-enitol* ***1***

2,3,4-Tri-*O*-acetyl-α-L-rhamnopyranosyl bromide (102 g, 289 mmol) was dissolved in dry DMF (200 mL distilled over barium oxide). The mixture was cooled with an ice-water bath for 10 min and treated with small portions of magnesium amalgam (200 g) (10). The reaction flask was evacuated for 10 min and the reaction flask closed under vacuum. The ice-water bath was removed after 0.5 h and the reaction mixture stirred vigorously for 2 h. The complete consumption of the starting material, R_F 0.2, to the faster rhamnal derivative, R_F 0.3, was shown by tlc (ethyl acetate: hexanes, 1:3). The reaction mixture was filtered on a bed of Celite and the solvent was removed. The syrupy residue was dissolved in dichloromethane (300 mL) and washed with 0.1 M hydrochloric acid (50 mL), a saturated solution of sodium hydrogen carbonate (100 mL), and water (100 mL). The organic phase was dried over $MgSO_4$, filtered, evaporated, and chromatographed over silica gel, eluting first with hexanes, then ethyl acetate – hexane, 1:7 followed by 1:4. This afforded **1** as a colourless liquid, 48.2 g (78%); $[\alpha]_D$ +64.8 (*c* 1.14, chloroform); (lit. (22) $[\alpha]_D$ 68 ($CHCl_3$)); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 6.4 (dd, 1H, $J_{1,2}$ 6.1 Hz, $J_{1,3}$ 1.4 Hz, H-1), 5.3 (m, 1H, $J_{3,4}$ 6.2 Hz, H-3), 5.00 (dd, 1H, $J_{4,5}$ 8.2 Hz, $J_{3,4}$ 6.2 Hz, H-4), 4.76 (dd, 1H, $J_{2,3}$ 3 Hz, H-2), 4.06 (m, 1H, $J_{4,5}$ 8.2 Hz, H-5), 2.05 (s, 3H, Ac), 2.01 (s, 3H, Ac), 1.28 (d, 3H, $J_{5,6}$ 6.5 Hz, H-6).

*Methyl 2-acetamido-3-*O*-(3′,4′-di-*O*-acetyl-2′-deoxy-2′-iodo-α-*L*-rhamnopyranosyl)-4,6-*O*-benzylidene-2-deoxy-β-*D*-glucopyranoside* ***3*** and *methyl 2-acetamido-3-*O*-(3′,4′-di-*O*-acetyl-2′6′-dideoxy-2′-iodo-β-*L*-glucopyranosyl)-4,6-*O*-benzylidene-2-deoxy-β-*D*-glucopyranoside* ***4***

Methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside **2** (2.00 g, 6.2 mmol) and 3,4-di-*O*-acetyl-L-rhamnal **1** (2.00 g, 9.3 mmol) were added to a solution of *N*-iodosuccinimide (2.00 g, 9 mmol) in dry dichloromethane (100 mL) in a flask wrapped with aluminum foil. The closed reaction flask was stirred at room temperature for 10 days. The progress of the reaction was monitored by tlc using a solvent mixture of methanol – ethyl acetate – hexanes, 1:10:3. The reaction mixture was then diluted with dichloromethane (100 mL), washed with sodium thiosulfate solution (15%) followed by water, dried, filtered, evaporated, and chromatographed on a silica gel column (ethyl acetate – hexanes, 1:7 followed by 1:1) to give 2.65 g (64.6%) of the 2′-deoxy-2′-iodo-disaccharide **3**: $[\alpha]_D$ −67.6 (*c* 0.88, chloroform); mp 236–239°C (recryst. ethyl acetate); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 7.36 (m, 5H, aromatic), 5.85 (d, 1H, $J_{NH,2}$ 8 Hz, NH), 5.5 (s, 1H, CHPh), 5.26 (bs, 1H, H-1′), 4.96 (q, 1H, $J_{3',4'}$, 9 Hz H-4′), 4.72 (d, 1H, $J_{1,2}$ 8 Hz, H-1), 4.52 (m, 1H, $J_{2',3'}$ 5 Hz, H-2′), 4.51 (q, 1H, $J_{3'4'}$ 9 Hz, H-3′), 4.34 (q, 1H, $J_{6A,6B}$ 10.5 Hz, $J_{5,6}$ 5 Hz, H-6A), 4.25 (t, 1H, H-5), 4.11 (m, 1H, H-5′), 3.75 (t, 1H, H-4), 3.57 (t, 1H, H-3), 3.5 (m, 2H, H-2, H-6B), 2.03 (s, 3H, OAc), 2.01 (s, 3H, OAc), 1.95 (s, 3H, NHAc), 0.7 (d, 3H, $J_{5'6'}$ 6 Hz, H-6′); ^{13}C nmr (500 MHz, $CDCl_3$) δ_C: 101.9 (C-1′, $J_{C,H}$ 173 Hz), 101.8 (CHPh, $J_{C,H}$ 157 Hz), 101.3 (C-1, $J_{C,H}$ 164 Hz), 57.9 (C-2), 57.1 (OMe), 30.1 (C′-2), 23.4 (NHAc), 21.0, 20.7 (2 × OAc), 16.8 (C-6′); the rest of the spectra is in agreement with compound **3**. B: The blocked trisaccharide **13** (300 mg, 0.35 mmol) was dissolved in ethanol (99%, 10 mL) and treated with cyclohexene (5 mL) and palladium hydroxide (70 mg) (14). The mixture was refluxed for 60 h, filtered, evaporated, and chromatographed on a silica gel column using 5% methanol in ethyl acetate to give a solid (117 mg). This solid (117 mg) was treated overnight with a saturated methanolic ammonia solution, filtered, and evaporated to give 99 mg (56%) of the deprotected trisaccharide **14**.

Methyl O-*(2″-*O*-acetyl-3″,4″-di-*O*-benzyl-α-L-rhamnopyranosyl)-(1→3)-*O*-(2′-acetamido-4′,6′-O-benzylidene-2′-deoxy-β-D-glucopyranosyl)-(1→2)-3,4-di-*O*-α-L-rhamnopyranoside **15***

A mixture of methyl 2-*O*-(2′-acetamido-4,6-*O*-benzylidene-2′-deoxy - β -D-glucopyranosyl) - 3,4-di- *O*-benzyl-α-L-rhamnopyranoside **11** (0.8 g, 1.23 mmol), 2-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranosyl chloride (1.00 g, 2.47 mmol), 1,1,3,3-tetramethyl urea (0.8 mL, 6.7 mmol), and molecular sieves (4Å, 0.5 g) in anhydrous dichloromethane (45 mL) was stirred under nitrogen and cooled to −30°C. The mixture was then treated, in three portions, with silver trifluoromethane sulphonate (0.52 g, 2.00 mmol) and allowed to warm gradually, overnight, to room temperature. The solid was removed by filtration and the filtrate was washed successively with sodium bicarbonate solution and water. The organic layer was dried ($MgSO_4$), filtered, concentrated, and chromatographed on a silica gel column, using ethyl acetate – hexanes (1:1) as eluant, to give a syrup, 0.95 g (76%), of **15**: $[\alpha]_D$ −18.5 (*c* 1.16, chloroform); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 7.5–7.2 (m, 25H, aromatic), 5.63 (d, 1H, NH), 5.5 (s, 1H), 5.19 (m, 1H), 4.97–4.5 (m, 10H), 4.3 (q, 1H), 4.0–3.3 (m, 16H), 2.1 (s, 3H, OAc), 1.82 (s, 3H, NHAc), 1.35 (d, 3H, H-6), 0.85 (d, 3H, H-6″).

Methyl O-*α-L-rhamnopyranosyl-(1→3)-*O*-2-acetamido-2-deoxy-β-D-glucopyranosyl-(1→2)-α-L-rhamnopyranoside **16***

A solution of the trisaccharide **15** (0.9 g, 0.88 mmol) in 80% aqueous acetic acid (25 mL) was hydrogenolyzed, for 4 days, at 70 psi in the presence of 10% palladium on charcoal. Filtration, repeated co-evaporation with toluene, and chromatographic purification on a silica gel column using ethyl acetate – methanol (7:1) as eluant gave 389 mg of colourless solid. The solid was dissolved in methanol (20 mL) containing a catalytic amount of sodium methoxide and kept at room temperature for 12 h. The sodium ions were removed with Rexyn 101 (H^+) ion-exchange resin. Filtration, followed by evaporation of the solvent, gave 280 mg (60%) of the trisaccharide **16**, $[\alpha]_D$ −57.7 (*c* 0.69, MeOH); mp 160–163°C (recrystallized from MeOH – ethyl acetate); ^{1}H nmr (200 MHz, D_2O) δ: 4.73 (d, 1H, H-1), 4.7 (d, 1H, H-1″), 4.62 (d, 1H, H-1′), 3.9–3.12 (m, 17H), 1.93 (s, 3H, NHAc), 1.13 (d, 3H, H-6), 1.09 (d, 3H, H-6″); ^{13}C nmr (200 MHz, $CDCl_3/CD_3OD$) δ_C: 102.4 (C-1′), 101.3 (C-1″), 99.5 (C-1), 62.6 (C-3′), 79.5 (C-2), 75.7 (C-5′), 72.5 (C-4), 72.0 (C-4″), 70.7 (C-2″), 70.5 (C-3″, C-4′), 68.9 (C-5″), 68.8 (C-3), 67.9 (C-5), 61.1 (C-6′), 55.1 (C-2′), 54.3 (OMe), 22.2 (NHAc), 16.9 (C-6, C-6″). Anal. calcd. for $C_{21}H_{37}NO_{14}$: C 47.81, H 7.01, N 2.66; found: C 47.68, H 6.99, N 2.58.

*1,5-Anhydro-2,6-dideoxy-L-*arabino*-hex-1-enitol **17***

A solution of 3,4-diacetyl-L-rhamnal **1** (20.0 g, 93 mmol) in methanol (50 mL) was treated with a solution of sodium methoxide (2 mL of 0.4 M solution) for 1 h at room temperature, at which point tlc (ethyl acetate – hexanes, 1:1) of the reaction mixture indicated the consumption of all the starting material. Sodium ions were removed with Rexyn 101 (H^+) ion-exchange resin. Filtration, evaporation, and crystallization from ethyl acetate – hexanes gave 10.6 g (87.2%) of L-rhamnal **17**: $[\alpha]_D$ +25.7 (*c* 1.03, chloroform); mp 77–78°C (lit. (15) mp 70–73°C); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 6.26 (dd, 1H, $J_{1,2}$ 5.4 Hz, $J_{1,3}$ 1.4 Hz, H-1), 4.65 (dd, 1H, $J_{2,3}$ 1.4 Hz, H-2), 4.27 (bd, 1H, OH), 4.18 (m, 1H, H-3), 3.9 (bd, 1H, OH), 3.79 (m, 1H, $J_{4,5}$ 10 Hz, $J_{5,6}$ 6 Hz, H-5), 3.35 (m, 1H, $J_{3,4}$ 7.5 Hz, H-4), 1.33 (d, 3H, $J_{5,6}$ 6 Hz, H-6); ^{13}C nmr (200 MHz $CDCl_3$) δ_C: 144.8 (C-1), 102.7 (C-2), 75.2 (C-4), 74.5 (C-5), 70.3 (C-3), 17.2 (C-6). $J_{1,2}$ 8 Hz, H-1), 4.71 (dd, 1H, $J_{1',2'}$ 1.4 Hz, H-2'), 4.65 (d, 1H, CH_2Ph), 4.54 (d, 1H, CH_2Ph), 4.33 (m, 2H, H-3, H-6A), 4.21 (m, 1H, $J_{4',5'}$ 9 Hz, $J_{5',6'}$ 6 Hz, H-5'), 3.775 (t, H-4), 3.63–3.46 (m, 7H, H-2, H-5, H-6B, H-4', and OMe), 2.00 (s, 3H, Ac), 0.9 (d, 3H, H-6'); ^{13}C nmr (200 MHz, $CDCl_3$) δ_C: 102.00, 101.7, 101.1 (C-1, C-1', and CHPh), 58.07 (C-2), 57.00 (OMe), 31.64 (C-2'), 23.39 (Ac), 17.35 (C-6'). Anal. calcd. for $C_{36}H_{39}INO_{10}$: C 55.97, H 5.09, I 16.4, N 1.8; found: C 55.78, H 5.21, I 16.38, N 1.73.

Methyl 2-acetamido-3-O-(4'-O-benzyl-2'-deoxy-2'-iodo-α-L-rhamnopyranosyl)-4,6-O-benzylidene-2-deoxy-β-D-glucopyranoside ***21***

The 2-deoxy-2-iodo-disaccharide **20** (3.69 g, 5 mmol) in methanol (150 mL) and dichloromethane (10 mL) was treated with a catalytic amound of sodium methoxide. The reaction mixture was stirred at room temperature for 48 h, when tlc (ethyl acetate – hexanes, 3:1) indicated the consumption of all the starting material. The sodium ions were removed with Rexyn 101 (H^+) ion-exchange resin. Filtration, evaporation, and drying in vacuum over phosphorus pentoxide gave 2.97 g (93%) of **21**, $[\alpha]_D$ −128.7 (*c* 0.99 methanol); mp 198–199°C; ^1H nmr (500 MHz, $CDCl_3$) δ: 7.38–7.2 (m, 10H, aromatic), 6.36 (d, 1H, NH), 5.32 (s, 1H, CHPh), 5.24 (s, 1H, H-1'), 4.74 (d, 1H, H-1), 4.56 (d, 1H, CH_2Ph), 4.5 (d, 1H, CH_2Ph), 4.42 (d, 1H, H-2'), 4.28 (q, 1H, H-3'), 4.04 (m, 2H), 3.74 (m, 2H), 3.52 (m, 2H), 3.36 (s, 3H, OMe), 3.28 (m, 1H), 3.24 (t, 1H), 2.72 (d, OH), 2.08 (s, 3H, Ac), 0.9 (d, 3H, H-6'),; ^{13}C nmr (200 MHz, $CDCl_3/CD_3OD$) δ_C: 102.5, 101.9, 101.5 (C-1, C-1', CHPh), 38.3 (C-2'), 22.4 (AcNH), 17.0 (C-6'). Anal. calcd. for $C_{29}H_{36}INO_9$: C 52.02, H 5.42, N 2.09; found: C 51.90, H 5.56, N 1.98.

Methyl O-(2",3",4"-tri-O-acetyl-α-L-rhamnopyranosyl)-(1→3)-O-(4'-O-benzyl-2'-deoxy-2'-iodo-3'-O-α-L-rhamnopyranosyl)-(1→3)-2-acetamido-4,6-O-benzylidene-2-deoxy-β-D-glucopyranoside ***22***

A mixture of the disaccharide **21** (2.97, 4.44 mmol), 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl bromide (3.2 g, 9.00 mmol), 1,1,3,3-tetramethylura (2.7 mL, 22.6 mmol), and 4Å molecular sieves in anhydrous dichloromethane (200 mL) was stirred under nitrogen and cooled to −60°C. The mixture was then treated, in portions, with silver trifluoromethane sulfonate (2.2 g, 8.6 mmol) and allowed to warm gradually to room temperature. After 24 h the solids were removed by filtration and the filtrate was washed successively with sodium bicarbonate solution and water. The organic layer was dried ($MgSO_4$), filtered, evaporated, and chromatographed on a silica gel columm, using hexanes – ethyl acetate (1:4) as eluant, to give 4.00 g (96%) of **22**: $[\alpha]_D$ −62.2 (*c* 1.00, chloroform); mp 124–126°C; ^1H nmr (500 MHz, $CDCl_3$) δ: 7.46–7.24 (m, 10H, aromatic), 5.92 (d, 1H, $J_{NH,2}$ 8.5 Hz, NH), 5.50 (s, 1H, CHPh), 5.35–5.31 (m, 2H, H-2", H-3"), 5.25 (s, 1H, H-1'), 5.1 (t, 1H, $J_{4",3"} + J_{4",5"}$ = 19.5 Hz, H-4'), 5.01 (d, 1H, $J_{1",2"}$ 1.2 Hz, H-1"), 4.79 (d, 1H, CH_2Ph), 4.53 (d, 1H, CH_2Ph), 4.51 (d, 1H, $J_{1,2}$ 8.5 Hz, H-1), 4.4 (dd, 1H, $J_{1',2'}$ 1.2 Hz, $J_{2',3'}$ 4.0 Hz, H-2'), 4.34 (q, 1H, $J_{5,6A}$ 5.0 Hz, $J_{6A,6B}$ 10.5 Hz, H-6A), 4.2 (m, 1H, H-5"), 4.14–4.01 (m, 3H, H-2, H-5'), 3.75 (m, 1H, H-6B), 3.57–3.46 (m, 2H, H-4, H-5), 3.43–3.35 (m, 5H, H-3', H-4', OMe), 2.08 (s, 6H, 2 × OAc), 2.05 (s, 3H, OAc), 1.98 (s, 3H, NHAc), 1.27 (d, 3H, $J_{5',6'}$ 6.0 Hz, H-6'), 0.86 (d, 3H, $J_{5',6'}$ 6.0 Hz, H-6'); ^{13}C nmr (500 MHz, $CDCl_3$) δ_C: 102.13, 101.68, 101.51, 99.64 (C-1, C-1', C-1", CHPh), 66.16 (C-6), 57.01 (OMe), 56.61 (C-2), 34.75 (C-2'), 23.38 (AcNH), 20.67 (3 AcO), 17.38, 17.14 (C-6', C-6"). Anal. calcd. for $C_{41}H_{52}INO_{16}$: C 52.29, H 5.57, I 13.48, N 1.49; found: C 52.08, H 5.56, I 13.33, N 1.58.

Methyl O-α-L-rhamnopyranosyl-(1→3)-O-2-deoxy-L-rhamnopyranosyl-(1→3)-2-acetamido-2-deoxy-β-D-glucopyranoside ***23***

A solution of the trisaccharide **20** (813 mg, 0.86 mmol) in 80% aqueous acetic acid was heated at 80°C for 1 h. Evaporation of the solvents followed by chromatographic purification on a silica gel column using dichloromethane–methanol (20:1) as eluant gave 420 mg (57%) of a solid. Its ^1H nmr and ^{13}C nmr spectra showed the absence of the benzylidene protecting group.

This trisaccharide (420 mg, 0.492 mmol) was dissolved in pyridine (7 mL) and treated with acetic anhydride (1.00 mL, 10.5 mmol). The mixture was stirred at room temperature (18 h) and the solvents were then evaporated to a colourless syrup. The dried syrup was dissolved in toluene (20 mL) and treated under nitrogen with tributyltin hydride (0.26 mL, 0.97 mmol) and benzoyl peroxide (5 mg). The mixture was heated at 75°C for 2 h and the reaction was quenched with methanol (5 mL). Evaporation of the solvents and chromatographic purification over a silica gel column using dichloromethane–methanol (45:1) as eluant gave 359 mg (90%) of a fully protected 2'-deoxy trisaccharide, identified by its ^1H nmr and ^{13}C nmr spectra.

The trisaccharide (359 mg, 0.44 mmol) in methanol (20 mL) was treated with catalytic amount of sodium methoxide in methanol and stirred at room temperature for 18 h. The mixture was neutralized with Rexyn 101 (H^+) resin and filtered. The filtrate was concentrated to a solid (250 mg), which was dissolved in ethanol (18 mL, 99%) and water (3 mL) and hydrogenated over 10% palladium on carbon at a hydrogen pressure of 70 psi for 5 days. Filtration, evaporation, and chromatographic purification over a silica gel column using ethyl acetate – methanol (10:1) gave 200 mg (88%) of pure **23**: $[\alpha]_D$ −102.1 (*c* 0.76, methanol); mp 277–278°C; ^1H nmr (500 MHz, D_2O) δ: 5.03 (m, 1H, H-1'), 5.00 (s, 1H, H-1"), 4.48 (d, 1H, H-1), 4.04 (m, 1H, H-5'), 4.02 (m, 1H, H-2"), 3.94 (m, 1H, H-6A), 3.87–3.7 (m, 5H, H-2, H-5, H-3', H-3", H-5"), 3.55–3.4 (m, 7H, H-3, H-4, H-6B, H-4", OMe), 3.23 (t, 1H, H-4'), 2.11 (m, 1H, H-2'e), 2.03 (s, 3H, NHAc), 1.85 (m, 1H, H2'a), 1.32 (d, 3H, H-6"), 1.27 (d, 3H, H-6'); ^{13}C nmr (125 MHz, D_2O) δ_C: 102.42 (C-1"), 102.06 (C-1), 99.45 (C-1'), 82.22 (C-4), 77.11 (C-3'), 76.77 (C-4"), 76.13 (C-4'), 72.77 (C-5), 70.95 (C-5'), 70.89 (C-5"), 69.53 (C-3), 69.26 (C-3"), 69.13 (C-2"), 61.55 (C-6), 57.7 (OMe), 55.89 (C-2), 37.38 (C-2'), 22.85 (AcNH), 17.31 (C-6', C-6"). Anal. calcd. for $C_{21}H_{37}NO_{13}$: C 49.31, H 7.29, N 2.74; found: C 49.19, H 7.3, N 2.63.

A study of hydrogen abstraction reactions by halogen atoms with HFCO and HClCO: determination of transition state structures, barrier heights, and vibrational frequencies

J. S. FRANCISCO[1] AND N. MINA-CAMILDE
Department of Chemistry, Wayne State University, Detroit, MI 48202, U.S.A.

Received May 11, 1992

J. S. FRANCISCO and N. MINA-CAMILDE. Can. J. Chem. **71**, 135 (1993).

Theoretical barriers and reaction energetics were determined using *ab initio* calculations at the PMP4/6-311++G** level with UMP2/6-311G** optimized geometries for hydrogen abstraction reactions of HFCO and HClCO by fluorine and chlorine atoms. The largest barriers are predicted for fluorine and chlorine atom abstractions of hydrogen from HFCO. Fluorine and chlorine atom abstractions of hydrogen from HClCO are predicted to be barrierless. The predicted barrier for fluorine atom abstraction of hydrogen from HFCO is calculated to be 1.3 kcal mol^{-1} and is in good agreement with the experimental value of 1.8 ± 0.4 kcal mol^{-1}.

J. S. FRANCISCO et N. MINA-CAMILDE. Can. J. Chem. **71**, 135 (1993).

Utilisant des calculs *ab initio* au niveau PMP4/6-311++G** avec des géométries optimisées UMP2/6-311G**, on a déterminé les barrières théoriques et les énergies des réactions d'enlèvement d'hydrogène du HFCO et HClCO par des atomes de fluor et de chlore. Les calculs prédisent que les barrières les plus élevées sont celles de l'enlèvement d'hydrogène du HFCO par les atomes de fluor et de chlore. Les calculs prédisent qu'il n'y a pratiquement pas de barrière à l'enlèvement de l'hydrogène du HClCO par des atomes de fluor et de chlore. On a calculé que la barrière à l'enlèvement de l'hydrogène du HFCO par le fluor est de 1,3 kcal mol^{-1}, ce qui est en bon accord avec la valeur expérimentale de 1,8 ± 0,4 kcal mol^{-1}.

[Traduit par la rédaction]

Introduction

Bimolecular hydrogen exchange reactions of the type

[1] $X + HY \rightarrow HX + Y$

where X and Y are halogen atoms, have been the focus of a number of recent studies. Neumark and co-workers studied several X + HY reactions where X and Y are like and unlike halogen atoms for triatomic systems (1–4). There is also a substantial body of experimental and theoretical work in the literature (5–9) on hydrogen abstraction reactions by halogens from alkanes of the type

[2] $X + RH \rightarrow HX + R$

However, there are few experimental or theoretical investigations of hydrogen abstraction reactions due to halogens from hydrogen carbonyl halides. Such reactions have atmospheric importance since hydrogen carbonyl halides are suggested to be reservoir species resulting from the degradation of alternative halocarbon compounds (10, 11). Consequently, it is of interest to study the reaction of halogen atoms such as F and Cl with HFCO and HClCO. The reaction of Cl atoms with HFCO and HClCO removes active chlorine from ClO_x catalytic cycles that destroy ozone in the stratosphere (12). The reaction of F atoms with HFCO or HClCO also serves to remove F atoms from FO_x catalytic cycles (12). The formation of stable HF and HCl serves as a major sink for halogen atoms such as F and Cl. Unfortunately, few experimental investigations of these reactions have been carried out. Francisco and Zhao (13) made experimental measurements of the reaction rate for the reaction of F + HFCO. Wallington *et al.* (14) measured the first rate coefficient for the reaction of Cl + HFCO. Sanhueza and Heicken (15) measured the room temperature rate for the chlorine atom attack of HClCO. Niki *et al* (16), in a later study, confimed the measurements of Sanhueza and Heicken. To provide insight into the potential energy surfaces that govern the reaction dynamics, we examine the potential energy surface of the X + HYCO system, where X, Y = F, Cl, by means of *ab initio* electronic structure theory. We report the locations of saddle point geometries and vibrational frequencies and the energetics for these reactions.

Computation methodology

All calculations were performed with the GAUSSIAN 88 system of program (17). All equilibrium geometries and transition structures were fully optimized with Schlegel's analytical gradient method (18) of optimization employing unrestricted Hartree–Fock (UHF) and second-order unrestricted Møller–Plesset (UMP2) methods along with 6-31G* and 6-311G** bases (19, 20). Geometries were optimized to better than 0.001 Å for bond distances and 0.1° for bond angles. With a convergence of at least 10^{-9} on the density matrix, the rms force was less than 10^{-4} a.u. for the optimized structures. No symmetry constraints were imposed on the optimization. The fourth-order Møller–Plesset perturbation calculation for single-point energies included single, double, triple, and quadruple excitations (MP4SDTQ) using the frozen core approximation (21). Spin projected energies are denoted by the term PMP4 (22). UMP2/6-311G* calculated values of $\langle s^2 \rangle$ for FCO and ClCO and the hydrogen abstration transition states before spin projection varied from 0.75 to 0.77. Single-point energy calculations of higher order of perturbation and with larger basis set were performed using geometries optimized at the UMP2 level and spin projections were applied to annihilate the highest spin contaminant of the unrestricted wave function. Vibrational frequencies and zero-point energies were obtained at the UHF/6-31G* optimized geometries from analytical second derivatives (23).

Results and discussion

Structures and vibrational frequencies

The optimized equilibrium geometries for all reactants, products, and transition structures are listed in Tables 1 and 2.

Calculated structural features for HFCO and HClCO are compared with experimentally derived values. Significant rms (root-mean-square) errors occur at the Hartree–Fock level of theory. The rms error is 0.019 Å for bond lengths and 1.0° for bond angles. Consequently, post Hartree–Fock treatments are necessary for a good description of the bonding of the species involved in the HXCO system. In general, bond lengths and angles are improved with the inclusion of electron correlation, but results of calculations at the UMP2/6-311G** level of theory show the best agreement with the experimental geometries. The rms error calculated at the UMP2/6-311G** level of theory is 0.006 Å for bond lengths and 0.7° for bond angles.

The reaction path for the abstraction of hydrogen involves the approach of the incoming halogen atom along the CH axis of the formyl halide, as shown in Fig. 1. The three atoms involved in the bond-breaking and bond-forming process are not co-linear along the CH axis. An interesting structural feature of these transition states is that the X′HC angle widens as a result of the chlorination of the HXCO for the attack of either fluorine or chlorine atom. For F + HFCO, the FHC angle is 162.1°, while for F + HClCO, the F′HC angle is 171.4°. For the Cl + HFCO and Cl + HClCO systems, the Cl′HC angles are 174.8° and 177.8°, respectively. These results suggest that the attacking halogen experiences the largest interaction with formyl chloride. The difference in the CH bond length in the transition state for the attacking halogen is another interesting structural feature. The CH bond lengths are 1.170 and 1.156 Å for F + HFCO and F + HClCO, respectively, while for Cl + HFCO and Cl + HClCO they are 1.360 and 1.254 Å, respectively. From these results, the transition state for abstraction of hydrogen by fluorine appears to be reactant-like in character since the bond lengths are increased by, at most, only 7%. The transition state for abstraction of hydrogen by chlorine appears to be product-like. The CH bond is elongated by at most 30% of the way from the reactant value. This is in accord with the greater endothermicity of the Cl + HYCO reaction compared with that of the F + HYCO reaction.

The vibrational frequencies for the transition states discussed above, along with those for reactants and products, are collected in Table 3. Vibrational frequencies for all the transition states show one imaginary eigenvalue, which at-

tests to the fact that the transition structures are first-order saddle points.

Heats of reaction and barrier heights

Reliable heats of formation are available for most of the reactants and products involved in the X + HYCO system. The literature values are given in Table 5. The heats of reaction for pathways calculated with experimental enthalpies are used to assess the reliability of the theoretical calculations. It is interesting to note that to obtain reliable heats of reactions for reactions in the X + HYCO system, electron correlation must be included. This is evidence by the fact that the rms error for the heats of reaction is 27.7 kcal mol^{-1} at the Hartree–Fock level. However, the most significant reduction in rms errors is by the inclusion of higher-order electron correlation at the PMP4SDT level of theory and the use of a large basis set. The use of the 6-311++G** basis set as opposed to the 6-31++G** basis set reduces the heats of reaction by 6.4 kcal mol^{-1} (rms), which suggests that the use of small and medium basis sets in estimation of the energetics has significant basis set superposition errors associated with the results. Nevertheless, compared with experimental results, the rms error in the calculated heats of reaction for all reactions of the H + HYCO system is 2.2 kcal mol^{-1} at the PMP4/6-311++G**//UMP2/6-311G** + ΔZPE level of theory. The average error in calculated heats of reaction for reactions involving fluorine is no different from the errors for reactions involving chlorine. This suggests that the level of theory used is sufficient enough to estimate the energetics for fluorine and chlorine reactions in the H + HYCO system.

There are some interesting trends that emerge from these data. The heats of reaction for the hydrogen abstraction by fluorine atoms are significantly more exothermic than those due to attack by chlorine atoms. It is also noteworthy that the heats of reaction for the hydrogen abstraction processes by either fluorine or chlorine atoms are significantly influenced by chlorination of the HXCO structure. The difference in heats of reaction is ca. 11 kcal mol^{-1}. Nevertheless, on thermodynamical grounds, all the reactions for the X + HYCO system are favored since all are predicted to be exothermic. The kinetics for the X + HYCO system, however, ultimately determine the relative importance and rate ordering of the abstraction process, but this is largely governed by the activation energy. Activation energies for the X + HYCO system are given in Table 6 as determined from the total energies in Table 4.

The only experimental measurement of the activation energy for the X + HYCO system is for the F + HFCO reaction. Francisco and Zhao (13) measured an activation energy of 1.8 ± 0.4 kcal mol^{-1} for this reaction. The calculated activation energy at the PMP4/6-311++G**//UMP2/6-311G** level of theory is 1.3 kcal mol^{-1}. The present result is in better agreement with the experimental measurement than the previous calculation, which ignored the triples contribution to the MP4 energies. In general, Cl atoms are more reactive than OH radicals toward organic compounds. The activation energy (11) for OH + HFCO as calculated at the PMP4/6-311++G**//MP2/6-311G** level of theory is 6.0 kcal mol^{-1}. For chlorine attack of HFCO, the calculated activation energy at the PMP4/6-311++G**//UMP2/6-311G** level is 2.6 kcal mol^{-1}; when zero-point energy corrections are incorporated, the small barrier disappears.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

However, a comparison of the activation energies for the Cl + HFCO and OH + HFCO reactions suggests that chlorine atoms are more reactive than the OH radical because of lower activation energies. An examination of the predicted activation barriers for the F + HClCO and Cl + HClCO reactions shows that they are lower than the corresponding reactions with HFCO. At the UMP2/6-311G** level of theory, the activation energy barrier for F + HClCO is small. The highest level of calculations including spin projection, correlation, and a large basis set. i.e., the PMP4/6-311++G**//UMP2/6-311G** level of the theory, predicts a negligible barrier for the reaction. For the Cl + HClCO reaction, no activation energy barrier is predicted for the abstraction of hydrogen.

Inspection of the activation energies for the X + HYCO system reveals several features: (*i*) the activation energy is largely influenced by the substituent on the HYCO moiety. Fluorination of HYCO increases the activation energy barriers relative to the chlorinated HYCO, regardless of fluorine or chlorine attack of the hydrogen. It can be argued that the increase in the activation barrier for fluorine substitution on HYCO results from a stronger CH bond energy. An examination of the CH bond dissociated energies in HFCO and HClCO, which are 94.4 and 83.8 kcal mol^{-1} at the PMP4/6-311++G**//UMP2/6-311G** level of theory, respectively (24), shows a correlation that does emerge between the activation energies and the CH bond energies. However, a 10.6 kcal mol^{-1} difference in the CH bond dissociation energy between HFCO and HClCO does not reflect a 10 kcal mol^{-1} difference between the activation energies, which suggests that the correspondence between the activation energies and the CH bond dissociation energies is not directly correlated; (*ii*) the activation energy barriers for the attack of fluorine atoms are lower than for the attack of chlorine atoms. Regarding the second feature, this is in accord with the general observation that F atoms are more reactive than Cl atoms toward organic compounds.

Summary

The main conclusions of this work are as follows:

1. Activation energy barriers for chlorine atom abstractions of hydrogen from HFCO are higher than those for the fluorine atom. The present calculation predicts small or no activation energy barriers for the extraction of hydrogen from HClCO by either chlorine or fluorine atoms.

2. Activation energy barriers for fluorine and chlorine atom abstractions of hydrogen from HYCO are influenced by the substituent on HYCO. However, there is no apparent direct or linear correlation between the substituent and the increase in CH bond strength with the activation energy.

Ab initio SCF and Møller–Plesset studies on hexachlorides of selenium and tellurium and their dianions

MARIUSZ KLOBUKOWSKI

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 24, 1992

MARIUSZ KLOBUKOWSKI. Can. J. Chem. **71**, 141 (1993).

SCF and Møller–Plesset calculations were done for four chalcogen hexahalide systems ($SeCl_6$, $SeCl_6^{2-}$, $TeCl_6$, and $TeCl_6^{2-}$) to study their geometric structures and relative stabilities in their ground electronic states. Flexible all-electron and valence-electron polarized basis sets were used. For some of the basis sets used, the stationary points located on the SCF potential energy surface of the ions in O_h symmetry were found to possess negative eigenvalues of the Hessian matrix; the structural parameters of the corresponding stationary points in C_{3v} symmetry were determined. At the MP2 level, all ions were found to restore the octahedral symmetry.

MARIUSZ KLOBUKOWSKI. Can. J. Chem. **71**, 141 (1993).

Dans le but d'étudier leurs structures géométriques et les stabilités relatives de leurs états électroniques fondamentaux, on a effectué des calculs en champ auto-cohérent et de Møller–Plesset sur quatre hexahalogénures de chalcogène ($SeCl_6$, $SeCl_6^{2-}$, $TeCl_6$ et $TeCl_6^{2-}$). On a utilisé des ensembles de base avec tous les électrons flexibles ou avec les électrons de valence polarisés. Pour certains des ensembles de base utilisés, on a trouvé que les points stationnaires situés sur la surface d'énergie potentielle en champ auto-cohérent des ions de symétrie O_h possèdent des valeurs propres de la matrice de Hessian qui sont négatives; on a déterminé les paramètres structuraux des points stationnaires correspondants de symétrie C_{3v}. Au niveau MP2, on a trouvé que tous les ions retrouvent leur symétrie octaédrique.

[Traduit par la rédaction]

Introduction

The hexachlorotellurate(IV) and hexachloroselenate(IV) ions possess electronic and geometric structure in which the central ion is surrounded by one lone electron pair in addition to the six bonding pairs. According to the valence shell electron pair repulsion theory (VSEPR), such AB_6E systems should possess distorted, non-octahedral geometries in their ground electronic states (1). However, these hexachlorochalcogenate ions were not found to exhibit such structural deviations and appear to exist in regular octahedral geometry (2). Urch (3) attributed this regular geometry to the large size of the ligand compared with the radius of the central ion.

The stereochemically active lone electron pair in the AB_6E systems could lower the O_h symmetry to C_{3v}, C_{2v}, or C_s in its motion from one face of the octahedron to another (4). Of these lower symmetries, the potential minimum is most likely to be of C_{3v} symmetry while the remaining two would correspond to transition states (5). In our previous SCF studies on XeF_6 and isoelectronic systems (6) the stationary points in both C_{3v} and C_{2v} were found. In the concurrent study on the geometry of hexafluorochalcogenate(IV) ions,[1] we found for the TeF_6^{2-} ion that the SCF stationary point of C_{3v} symmetry represents a local minimum, while that of C_{2v} symmetry is a transition state.

In the present work, our previous studies have been extended to explore the possibility of non-octahedral structures in hexachlorochalcogenates. The computational studies involved SCF and Møller–Plesset (restricted to the second-order perturbation expansion, MP2) calculations in the assumed O_h geometry, followed by the evaluation of the Hessian at the stationary points in order to determine whether they are genuine (local) minima on the potential energy surface. In cases when the Hessian was found to possess negative eigenvalues, search for stationary points was done in the symmetry suggested by the symmetry of the harmonic vibrational mode that corresponded to the negative eigenvalue. This procedure was followed both at the SCF and MP2 level. At the MP2 level, instead of the all-electron approach, which proved prohibitively time-consuming, valence-electron calculations were done using effective core potentials; despite earlier warnings (7–9), the nodeless orbitals of the effective core potential method were shown to perform very well in computations of correlation effects (10). In addition to reducing the computation time, the effective core potentials for tellurium, derived from relativistic Hartree–Fock wavefunctions based on the Cowan–Griffin formalism (11), permitted the introduction of some relativistic effects through the use of relativistic effective potentials and corresponding basis sets (12).

All calculations were done on SUN 4/370 and IBM RS/6000 workstations using the GAMESS (13), HONDO 8.1 (14), and Gaussian 90 (15) systems of programs.

Calculations, results, and discussion

Basis sets

For tellurium, in all-electron calculations the largest basis set available in our compilation (16) was used in the double-zeta valence contraction (433321/43321/421), which can be denoted as (6*s*5*p*3*d*); this basis set was identical with the one used in our previous work (6). In the near-Hartree–Fock calculations the well-tempered basis set (23*s*19*p*13*d*) (17) was contracted to (10*s*8*p*3*d*). The valence-electron calculations were done using both the effective-core potentials of Hay and Wadt (18) with the (3*s*3*p*) basis contracted to (21/21) and the compact effective potentials of Stevens *et al.* (19) with (5*s*5*p*) basis contracted to (41/41). All the basis sets for tellurium were augmented with a diffuse *s*-type function whose exponent ($\zeta_s = 0.018$) was optimized in calculations on the ^5S state of $5s^25p^36s^1$ configuration of the atom.

In all-electron calculations, the standard (4333/433/4) basis for selenium (16) was used in contraction (5*s*4*p*2*d*); the primitive well-tempered basis (19*s*14*p*10*d*) was contracted

[b]The differences are defined as $\Delta E = E_t(AB_6^{2-},O_h) - E_t(AB_6,O_h)$.

to (9*s*7*p*2*d*). In the valence-electron approach the CEP basis (19) was used, contracted to (41/41). All selenium basis sets were augmented with diffuse *s*- and *p*-type functions (ζ_s = 0.021 and ζ_p = 0.055). The exponent of the *s*-type function was determined by energy minimization of the ^5S state of the $4s^24p^35s^1$ configuration of Se; the exponent of the *p*-type function was obtained from calculations on the ion Se^- in the ^2P state of the configuration $4s^24p^5$.

For chlorine, the all-electron calculations were done using both the more economical (5321/521) basis (16) and the more accurate well-tempered basis (17) in which the (18*s*13*p*) set was contracted to (8*s*6*p*); in the valence-electron calculations, the CEP basis (20) was contracted to (31/31). All chlorine basis sets were augmented with a diffuse *p*-type function with ζ_p = 0.049 (21).

The exponents of both one and two *d*-type polarization functions were taken from our previous work (16).

In the tables of results, the following symbols were used to identify the basis sets: CEP (abbreviated to C in figures) for compact effective potentials both on central atom and on ligands, ECP (E) for effective core potentials on central atom and compact effective potentials on ligands, AE-GB (G) for small, compact all-electron basis sets, and AE-WT (W) for large, well-tempered basis sets. Subscripts (1 or 2) were added to these abbreviations to indicate the number of polarization functions used. For $SeCl_6$ systems, the dimensions of the contracted basis sets with a single polarization function were: 126 (168), 126 (168), 171 (213), and 244 (286) for ECP, CEP, AE-GB, and AE-WT basis sets, respectively (the values in parentheses are dimensions of the basis sets with two polarization functions). For $TeCl_6$, the corresponding contracted basis sets were of dimensions: 123 (165), 123 (165), 178 (220), and 251 (no calculations were done with two polarization functions with the well-tempered basis set; the molecular basis in this case would contain 293 contracted functions).

For the AE-WT basis sets, due to their large size and long expansions of the contracted functions, no analytical gradients could be calculated; these basis sets were used only in single-point calculations in O_h symmetry.

SCF calculations

The energies and bond lengths calculated in the assumed O_h symmetry are shown in Table 1. The bond lengths show satisfactory stability with the change of basis set, especially for the $SeCl_6^q$, q = 0, −2 systems. Slightly stronger variation of bond lengths is seen for the $TeCl_6^{2-}$ ion. The calculated bond lengths are fairly close to the experimental values of 2.411 Å for $SeCl_6^{2-}$ obtained from X-ray studies by Knop *et al.* (22) and 2.54 Å for $TeCl_6^{2-}$, estimated by Gutsev and Boldyrev (23). For the neutral systems, the estimated empirical bond lengths of 2.2 Å for $SeCl_6$ and 2.3 Å for $TeCl_6$ (24) are within 0.5 Å of the present computed values. The structure of the $SeCl_6$ was also studied by Boyd and coworkers (24) who used a STO-3G* basis set and obtained a higher energy of −5101.7898 E_h and a slightly longer bond length of 2.322 Å.

The doubly charged negative ions were found to be more stable than the neutral molecules even at the SCF level, in contrast to the results obtained for hexafluorochalcogenates,[1] where the electron correlation was needed to stabilize anions. There is a significant dependence of the stability on the basis set used. The largest deviation is obtained with the CEP basis set; this effect may be attributed to the presence of more diffuse functions in that basis, which increases the relative stability of the ion. The effect of two polarization functions is very small.

The SCF vibrational frequencies are presented in Table 2: the stationary points for the anions in O_h symmetry are genuine minima except for the ECP and AE-GB basis sets for $SeCl_6^{2-}$ and the AE-GB basis for $TeCl_6^{2-}$.

The stationary points were sought in C_{3v} symmetry; the results are shown in Table 3 and the geometry is defined in Fig. 1. Both the bond lengths and bond angles show smaller deviations from the octahedral values than found previously for hexafluorides.[1] In the previous calculations on the $SeCl_6^{2-}$ ion in C_{3v} symmetry, Boyd (22) obtained the following structural parameters of the stationary point using the STO-3G* basis: $r_e(SeCl_u)$ = 2.488 Å, $r_e(SeCl_l)$ = 2.190 Å, $\angle(Cl_uSeCl_u)$ = 105.5°, and $\angle(Cl_lSeCl_l)$ = 86.2 and the corresponding total energy of −5101.7984 E_h. The differences between these values and the present results are due to the less flexible structure of the STO-3G* basis set.

Møller–Plesset calculations

In the MP2 calculations done in the valence-electron approximation, all valence electrons were correlated using full valence and virtual spaces. The equilibrium total energies and bond lengths obtained in assumed O_h symmetry are collected in Table 4 and shown in Fig. 2. The electron correlation effects increase the bond lengths of the neutral systems,

leaving them essentially unchanged in the ions. The change is practically independent of the basis set used.

The electron correlation effects increase the stability of the negative ions with respect to the neutral systems by about 1 eV for $SeCl_6^{2-}$ and 0.75 eV for $TeCl_6^{2-}$. The expanded *d*-type polarization set adds about 0.5 eV to the stability of $TeCl_6^{2-}$.

Harmonic vibrational frequencies, calculated in the MP2 approach at the corresponding stationary points using analytical gradients and numerical Hessian, are displayed in Figs. 3 and 4 together with the SCF values and compared in Table 5 with experimental frequencies (25–27). For the neutral systems (Fig. 3), correlation effects reduce the SCF values of the vibrational frequencies by 10–15% and result in an almost uniform shift of the calculated SCF spectrum.

The MP2-induced changes in the SCF vibrational frequencies of the ions are qualitatively different: all vibrations except ω_4 and ω_3, both of t_{1u} symmetry, decrease their

frequencies. The electron correlation effects *increase* frequencies of the two t_{1u} modes, with the value of the ω_4 mode increased significantly, reflecting the fact that the stationary points become minima for all basis sets investigated. It is interesting to observe (Fig. 4) that the MP2 values for the various basis sets are very closely spaced even though differences were large at the SCF level. Electron correlation brings about a better agreement with experimental values; however, the ordering of the two highest stretching vibrations differs from that proposed experimentally.

Conclusions

The results of the present calculations indicate that while at the SCF level non-octahedral structures were found for both $SeCl_6^{2-}$ and $TeCl_6^{2-}$ ions, none of these low-symmetry structures survived an improved treatment that included estimating electron correlation effects via the Møller–Plesset method. The non-octahedral geometries found in the SCF calculations are most likely due to instabilities of the Hartree–Fock solutions (28). Thus, on the level of theory used in the present work, hexachloroselenate(IV) and hexachlorotellurate(IV) ions were found to possess the symmetry of a regular octahedron in the ground electronic states. However, to gain any insight into the origin of the non-VSEPR behaviour of the anions, configuration interaction calculations would be required for a definite answer.

The conclusions about the geometry were made on the basis of calculations done in the valence-electron approximation with the outermost *d*-shell electrons treated as a part of the core. However, at least at the SCF level where the all-electron calculations were done, the possible polarization of the *d*-shell does not seem to affect qualitative aspects of this study.

The present work can be improved by: (1) explicitly including *d*-shell electrons in the valence space; (2) adding *f*-type polarization functions; (3) replacing the single-refer-

For personal use only.

ence MP2 scheme by an MC-SCF or MR-CISD approach; (4) preforming fully relativistic calculations instead of using the single-component averaged relativistic effective core potentials for the heavy atoms that were employed in the present work. All of these potential improvements are beyond our present computational possibilities.

1992 Merck–Frosst Award Lecture
Orbital symmetry and the photochemistry of cyclobutene[1]

WILLIAM J. LEIGH[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 24, 1992

WILLIAM J. LEIGH. Can. J. Chem. **71**, 147 (1993).

Direct photolysis of alkyl-substituted cyclobutene derivatives in solution with monochromatic far-UV light sources results in competing ring opening to the corresponding substituted 1,3-butadiene derivatives and fragmentation to the corresponding alkene and alkyne via formal [2+2] cycloreversion. The excited states leading to the two types of products have been identified. Cycloreversion occurs stereospecifically and arises as a result of excitation of the π,R(3*s*) Rydberg state, which is of comparable energy to the π,π^* state in alkylcyclobutenes. In spite of its stereospecificity, the reaction is nonconcerted; evidence is presented to suggest that it occurs by a mechanism involving [1,2] migration (ring contraction) to yield a cyclopropylcarbene intermediate, which then fragments to yield the alkyne and alkene. The stereochemistry at C3 and C4 in the starting cyclobutene is retained in the alkene produced in the reaction. Ring opening proceeds nonstereoselectively (from the π,π^* singlet state) in well over a dozen systems that have been investigated, and possible mechanisms to account for this are discussed. It is proposed that orbital symmetry plays a role in the reaction, but only in the early stages of ring opening. Bicyclic cyclobutene derivatives in which the cyclobutene double bond is located across the [0] bridge undergo ring opening with a high degree of disrotatory stereoselectivity. Possible reasons for this unusual behavior are discussed in light of recent *ab initio* theoretical results.

WILLIAM J. LEIGH. Can. J. Chem. **71**, 147 (1993).

La photolyse directe de dérivés du cyclobutène substitués par des groupes alkyles, réalisée en solution, à l'aide de sources de lumière UV-lointain monochromatique, conduit à une compétition entre l'ouverture de cycle conduisant aux dérivés buta-1,3-diènes substitués correspondants et une fragmentation conduisant à l'alcène et à l'alcyne correspondants par le biais d'une cycloréversion [2+2] formelle. Les états excités conduisant à ces deux types de produits ont été identifiés. La cycloréversion se produit stéréospécifiquement et elle est le résultat de l'excitation de l'état Rydberg π,R(3*s*) dont l'énergie est comparable à celle de l'état π,π^* des alkylcyclobutènes. Malgré sa stéréospécificité, la réaction n'est pas concertée; on présente des données suggérant qu'elle se produit par un mécanisme impliquant une migration [1,2] (contraction de cycle) qui conduit à un intermédiaire cyclopropène qui se fragmente ensuite pour donner l'alcène et l'alcyne. La stéréochimie en C3 et en C4 du cyclobutène de départ est conservée dans l'alcène qui se forme au cours de la réaction. L'ouverture du cycle se produit d'une façon qui n'est pas stéréospécifique (à partir d'un état singulet π,π^*) dans plus d'une douzaine de systèmes que nous avons examinés; on discute des divers mécanismes possibles pour expliquer les résultats. On propose que la symétrie des orbitales joue un rôle dans la réaction, mais seulement au début de la réaction d'ouverture de cycle. Les cyclobutènes bicycliques dans lesquels la double liaison du cyclobutène se trouve sur le pont [0] subissent la réaction d'ouverture de cycle avec un degré élevé de sélectivité disrotatoire. On discute des raisons possibles de ce comportement inhabituel à la lumière de résultats théoriques *ab initio* récents.

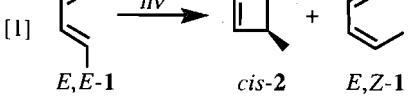
Introduction

The thermal and photochemical interconversions of cyclobutene and 1,3-butadiene play a central role in any textbook treatment of orbital symmetry selection rules and pericyclic reactions (1–3). Figure 1 illustrates the classical orbital and state correlation diagrams for the controtatory (C_2 symmetry) and disrotatory (C_s symmetry) interconversion pathways (1). The ground states of cyclobutene and 1,3-butadiene correlate in C_2 symmetry, so that conrotatory interconversion proceeds with no symmetry-imposed barrier. In C_s symmetry, on the other hand, the ground state of the diene correlates with a doubly excited state of cyclobutene (and vice versa); the result is a substantial barrier to ground state disrotatory interconversion owing to orbital symmetry considerations. The barrier results from the avoided crossing of the two surfaces in the intermediate stages of the reaction (see Fig. 1*b*). Since the lowest (π,π^*) excited singlet state of 1,3-butadiene correlates with the π,π^* singlet state of cyclobutene in C_s symmetry, the direct photochemical interconversions are predicted to proceed in disrotatory fashion.

As indicated above, the thermal interconversions are predicted by orbital symmetry to proceed in conrotatory fashion, and there are hundreds of examples in the literature that demonstrate that this is indeed the case (for reviews, see ref. 4). The degree of conrotatory stereospecificity in the thermal interconversions often exceeds 99%. Similarly, there are numerous examples that illustrate the preferred disrotatory stereochemistry of the photochemical ring closure of 1,3-butadiene derivatives to the corresponding cyclobutene (5; also ref. 3*a*, pp. 495–499, and refs. cited). For example, *E*,*E*-2,4-hexadiene (*E*,*E*-**1**) has been reported to yield *cis*-3,4-dimethylcyclobutene (*cis*-**2**) stereospecifically, albeit in low quantum yield owing to competing *cis*,*trans* isomerization, upon direct photolysis in solution (eq. [1]) (5*c*).

Van der Lugt and Oosterhoff proposed that disrotatory ring closure starts in the diene S_1 state, crosses onto the S_2



[1]This article is based on the Merck–Frosst Award Lecture delivered by Professor Leigh at the Annual Conference of the Canadian Society for Chemistry, Edmonton, Alberta, June, 1992.

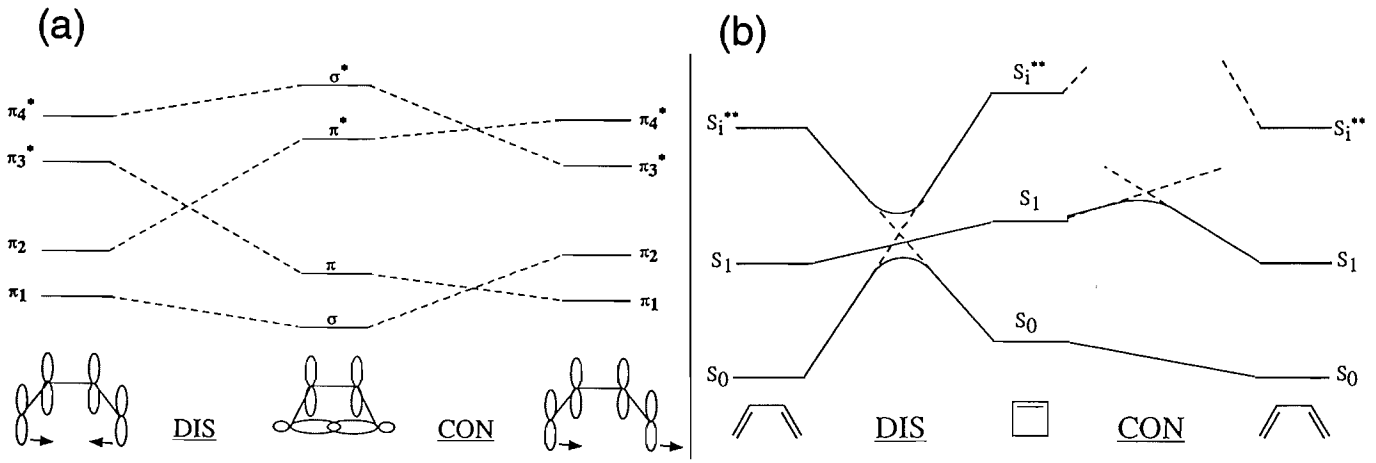

FIG. 1. Orbital (*a*) and state (*b*) correlation diagrams for the con- and disrotatory interconversions of cyclobutene and 1,3-butadiene (1).

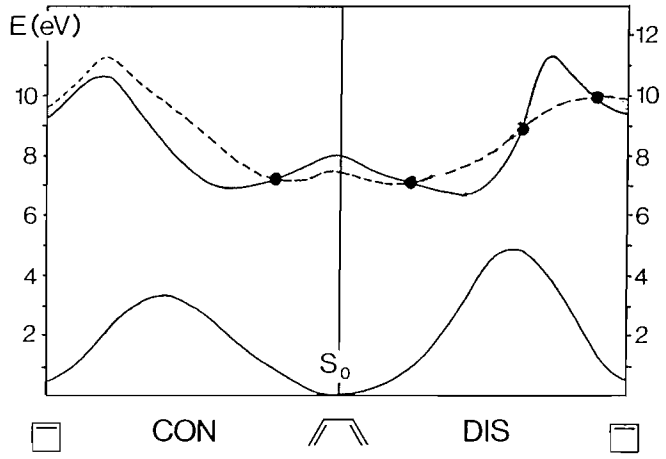

FIG. 2. Calculated (*ab initio*) state correlation diagrams for the con- and disrotatory interconversions of cyclobutene and 1,3-butadiene (9*b*).

potential energy surface and proceeds to a well (the avoided crossing) from which internal conversion to the ground state surface occurs (see Fig. 2) (6). The process cannot occur entirely on the S_1 surface (even though the S_1 state of butadiene correlates directly with the S_1 (π,π^*) state of cyclobutene in C_s symmetry) because the cyclobutene excited singlet state is at least 50 kcal/mol higher in energy than that of the diene (6, 8). The geometry of the reacting molecule at the S_2 energy minimum is similar to that at the transition state for the thermal disrotatory process, so once the excited molecule has entered the ground state surface, it can proceed to cyclobutene or revert to diene. The *ab initio* calculations of Grimbert *et al.* suggested that these general features are common to the ground and excited state energy surfaces for both the conrotatory and disrotatory ring closure reactions (7). However, in the latter case the energy gap between the S_2 and S_0 surfaces is substantially smaller so that the rate of $S_2 \rightarrow S_0$ internal conversion at the avoided crossing is greater for the disrotatory reaction pathway (7). Morihashi *et al.* showed that the probability of the $S_2 \rightarrow S_0$ transition is 10^{12} times greater for the disrotatory pathway than for the conrotatory one (9). The state correlation diagrams for the conrotatory and disrotatory interconversions of cyclobutene and 1,3-butadiene, from the *ab initio* calculations of Morihashi and Kikuchi (9*b*), are summarized in Fig. 2.

Each of the studies described above makes the classical assumption that orbital symmetry is conserved throughout the transformation; i.e., that C_s and C_2 symmetry are maintained in the disrotatory and conrotatory interconversions, respectively. More recent calculations have specified less stringent symmetry requirements for the excited state reaction and explored the possibility that it proceeds asymmetrically. On the basis of semi-empirical (MINDO/3) calculations, Pichko *et al.*, proposed that the photochemical ring closure of 1,3-butadiene occurs by disrotatory closure of the *relaxed* butadiene singlet (10). Thus, following Franck–Condon excitation, butadiene initially relaxes to the allylmethylene biradical geometry, and then undergoes disrotatory terminal-group rotation (over an activation barrier of 8.4 kJ/mol) to reach the geometry at which internal conversion to the ground state surface occurs.

Bernardi and Robb and their co-workers have reported MCSCF *ab initio* calculations (11) that suggest that internal conversion to the ground state surface during ring closure occurs via a conical intersection (12), or a point where ground and excited state surfaces are degenerate. The calculated geometry of the molecule at the conical intersection for ring closure is described as a tetraradicaloid structure in which all π-bonds in the molecule are broken. This more complex mechanism for the reaction will be discussed in more detail later in this account.

Until recently, the *only* example that demonstrates the stereochemistry of photochemical cyclobutene ring opening was that of Saltiel and Ng-Lim, who reported the results of direct photolysis of the tricyclic, isomeric cyclobutene derivatives *cis*- and *trans*-**3** (eqs. [2] and [3]) (13). Diene **4** is the product of (photochemically allowed) disrotatory ring-opening of *cis*-**3**. The apparent failure of *trans*-**3** to yield this product is an indication that ring opening does *not* proceed by the formally forbidden, conrotatory pathway; in this case, the disrotatory pathway is effectively blocked since it must yield the highly strained *cis,trans* isomer of **4**.

The apparent neglect of this prototypical excited state

pericyclic reaction by photochemists is presumably due to the fact that, in general, phenylated cyclobutenes do not

[2] 
[3] 
undergo ring opening upon photolysis in solution (14–16).[3] For example, 1,2-diphenylcyclobutene yields only the products of formal [2+2] cycloreversion upon direct photolysis in hydrocarbon solution (14, 16), undergoes solvent addition upon photolysis in methanol solution (15), and fluoresces with high efficiency (16) (see eq. [4]). Evidently,

[4] 
[5] 
tolysis (185 + 254 nm) of cyclobutene itself in pentane solution results in the formation of 1,3-butadiene, methylenecyclopropane, acetylene, and ethylene in the quantum yields shown in eq. [7] (21).

[6] 
[7] 
Our interest in this area was initiated by the report of Inoue *et al.* of the photochemistry of **7** and **10**. We originally set about to show simply that photolysis of these molecules with *monochromatic* far-UV radiation, under conditions where the primary diene products *are not* subject to secondary photolysis with the 254 nm component of the low-pressure mercury lamp, would afford results that are both internally consistent and compatible with the earlier report by Saltiel and Ng Lim on the photochemistry of *cis*- and *trans*-**3**. Indeed, photolysis of **10** in pentane with a low-pressure mercury lamp in conjunction with a γ-irradiated LiF crystal filter to remove the 254 nm component of the light source (OD^{185} ~ 0.2; OD^{254} > 5), or with an ArF excimer laser (193 nm), resulted in the formation of 1,3-cycloheptadiene (**12**) and cyclopentene (**11**) in comparable yields (eq. [8]) (22). As expected, the absence of **12** as a product of photolysis of **10** with the unfiltered light source is simply due to its substantial photolability at 254 nm; this diene undergoes photochemical ring closure to yield **10** with a quantum yield of ca. 0.35 (*5d,e*).

[3]Also, W. J. Leigh and A. Postigo, unpublished results.

conjugated cyclobutenes undergo ring opening upon photolysis only if the reaction is accompanied by the relief of ring strain, as for example with the cases of benzocyclobutenes (17) and Dewar aromatics (18). Interestingly, the former have been reported to open nonstereospecifically, while Dewar aromatics yield the corresponding fully aromatic isomer adiabatically from both the singlet and triplet excited states. With unstrained systems, photochemical ring opening evidently occurs only with cyclobutenes bearing nonconjugating substituents, necessitating the use of far-UV photochemical techniques for the study of the reaction.

The photochemistry of alkylcyclobutenes

Inoue *et al.* reported in 1983 that photolysis of bicyclo[4.2.0]oct-7-ene (**7**) in pentane solution with an unfiltered low-pressure mercury lamp (185 + 254 nm) gives rise to *cis,cis*- and *cis,trans*-1,3-cyclooctadiene (**8**), cyclohexene (**9**), and ethylene (eq. [5]) (19). The apparent nonstereospecificity of ring opening was explained by noting that **8** absorbs strongly at 254 nm (the major component of the low-pressure mercury lamp) and undergoes facile *cis,trans* photoisomerization upon photolysis at this wavelength (20). Photolysis of bicyclo[3.2.0]hept-6-ene (**10**) under similar conditions was found to afford only cyclopentene (**11**) and acetylene (eq. [6]) (19). Adam *et al.* later reported that pho-

[8] 
To our considerable surprise, however, photolysis of **7** under similar conditions gave rise to *mixtures* of *cis,cis*- and *cis,trans*-**8**, in addition to cyclohexene (**9**) and small amounts of the methylenecyclopropane derivative **13** (eq. [9]). To demonstrate that the apparent nonstereospecificity of diene formation was not due to secondary photolysis effects, **10** was photolyzed in the presence of small amounts of *c,c*-**8** under the above conditions, and the photolysate was monitored for the formation of the *cis,trans* isomer between 0.3 and 3% conversion. None could be detected within the limits of sensitivity of our analytical method, verifying that secondary diene photolysis does not contribute to the observed product distributions under conditions of monochromatic photolysis to low conversions.

Even more interesting results were obtained from monochromatic far-UV photolysis of the monocyclic derivatives *cis*- and *trans*-3,4-dimethylcyclobutene (**2**); these afforded mixtures of the three isomeric 2,4-hexadienes weighted in favour of the *formally forbidden* diene isomer(s) in each case (eq. [10]). Similar investigations of the photochemistry of a wide variety of mono-, bi-, and tricyclic alkylcyclobutene derivatives have been reported since our initial study (23–29), and indicate that the nonstereospecificity of the photochemical ring opening reaction is quite general. The results of these studies will be discussed in detail throughout this account.

Identification of the excited state(s) responsible for ring opening and cycloreversion

It has long been known that population of the triplet state of alkylcyclobutenes through triplet sensitization results in (2+2) dimerization, and does *not* lead to unimolecular isomerization or fragmentation (30; see, however, ref. 18). Thus, it is clear that both ring opening and cycloreversion arise from the excited singlet state manifold. As numerous workers have pointed out (19, 21, 22), there are two excited singlet states of similar energies in simple alkylcyclobutenes, the π,π^* (valence) state and the π,R(3*s*) (Rydberg) state (31). In principle, both could give rise to ring opening and cycloreversion products, though by very different mechanisms.

Since population of the π,R(3*s*) state in simple alkenes involves promotion of a π-electron to a spatially diffuse 3*s* orbital, the classical picture of the electronic structure of this state is that of a semi-ionized species that possesses radical cation character at the C=C bond (32). Since cyclobutene radical cations are known to undergo (thermal) ring opening in the gas phase (33) (the stereochemistry is evidently unknown), it is possible that Rydberg state involvement could account for the nonstereospecificity associated with this aspect of cyclobutene photochemistry, if Rydberg-derived ring opening occurs nonstereospecifically or in conrotatory fashion competitive with π,π^* state-derived disrotatory ring opening. The possibility that the cycloreversion process is derived from Rydberg state excitation is a more concrete one. It is well known that direct photolysis of simple alkenes in solution results in the predominant formation of products derived from carbene intermediates formed via [1,2]-hydrogen or alkyl migrations (32). In simple di-, tri-, and tetrasubstituted alkenes, the π,R(3*s*) state is lower in energy than the π,π^* state in the gas phase as well as in solution (31), and has been conclusively identified as the one responsible for the formation of these types of products (32, 34). With cycloalkenes, ring contraction is often the predominant mode of Rydberg-derived [1,2]-alkyl migration. In the case of cyclobutene, ring contraction would yield cyclopropylcarbene, which is known to fragment to acetylene and ethylene (35). In substituted systems, the alkene that is produced in this process is formed stereospecifically, with the stereochemistry defined by the substitution in the carbene (35). The possible stereospecific formation of *Z*-2-butene from photolysis of *cis*-**2** by this mechanism is illustrated in eq. [11].

[11] 
cis-**2** *Z*-**14**

To define the individual contributions of the π,π^* and π,R(3*s*) states to the formation of the various products of cyclobutene photolysis, it is necessary to systematically vary the relative energies of the two states. The obvious ways of doing this involve either preferentially lowering the energy of the π,R(3*s*) state with alkyl substituents at the C=C bond or preferentially lowering the π,π^* state with conjugating substituents at the C=C bond. The first approach was exploited in a study of the photochemistry of the series of monocyclic compounds **2**, **15**, and **16**; unfortunately, there are no regular variations in photoproduct distributions throughout the series that might allow a correlation to be made (27). Since phenylated cyclobutenes do not ring-open upon photolysis, the second approach similarly does not allow identification of the role of the Rydberg state in contributing to the ring opening reaction.

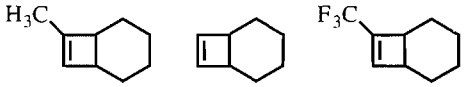
The approach we employed for the solution of this problem involved systematically *raising* the energy of the π,R(3*s*) state relative to that of the π,π^* state by trifluoromethyl substitution (28). The strong electron-withdrawing character of this substituent was expected to destabilize the radical-cation-like alkene Rydberg without substantially altering the energy of the π,π^* state (since it is nonconjugative). The gas- and solution-phase UV absorption spectra and π-ionization potentials (measured by photoelectron spectroscopy) of the series of bicyclo[4.2.0]oct-7-ene derivatives **7**, **17**, and **18** verify that trifluoromethyl substitution does indeed have the anticipated effect on the singlet excited state manifold of cyclobutene derivatives, just as it does in simple alkenes such as norbornene (34). Thus, the π,R(3*s*) state is substantially lower in energy than the π,π^* state in **17**, but higher in energy than the π,π^* state in **18** (28).



17 **7** **18**

Photolysis of the three compounds in pentane solution with 193 nm light results in competitive ring opening and cycloreversion as shown in eq. [12]. Table 1 lists the quantum yields for formation of dienes and cyclohexene from photolysis of the three compounds, the isomeric diene distributions obtained from each, and the positions of the π,R(3*s*) and π,π^* band maxima from the gas-phase UV-absorption spectra (28).

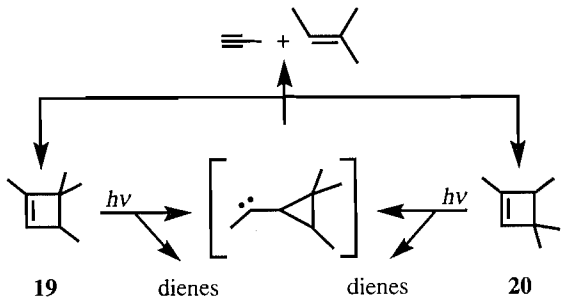
[c]Position of absorption band maximum in gas-phase UV absorption spectrum.
[d]Total quantum yield for diene formation.
[e]Ratio of yields of isomeric dienes (error is ca. 10%).

As the data in Table 1 show, the quantum yield for cycloreversion, while substantial in the cases of **7** and **17**, is very small for the trifluoromethyl-substituted compound **18**. This trend indicates that cycloreversion arises nearly exclusively from the Rydberg state. On the other hand, the quantum yields for ring opening *increase* in opposite fashion, indicating that this aspect of cyclobutene photoreactivity is due to π,π^* state excitation. The effect of varying the photolysis wavelength on the observed product distributions from the three compounds is also consistent with these conclusions. Significantly, since ring opening of all three derivatives is nonstereospecific (and yields similar distributions of isomeric dienes), the apparent violation of orbital symmetry selection rules cannot be due to the intervention of more than one singlet excited state.

Scope and mechanism of the cycloreversion reaction

The suggestion that Rydberg-derived cycloreversion proceeds by a mechanism involving initial [1,2]-alkyl migration (ring contraction) to yield a cyclopropylcarbene termediate, which then fragments to yield the corresponding alkyne and alkene (eq. [11]), has been investigated directly (24). Cyclopropylcarbenes are known to undergo *ring contraction* to yield cyclobutenes in addition to fragmenting to an alkene and acetylene. With this in mind, we studied the photochemistry of the isomeric, unsymmetrically substituted cyclobutenes **19** and **20**. The two compounds were found to interconvert in low yield upon photolysis in solution; the most reasonable mechanism for this process is via common cyclopropylcarbene intermediate(s), one of which is shown in eq. [13].

[13]



19 dienes dienes **20**

The cycloreversion reaction is suppressed when it must produce a relatively unstable alkene or alkyne product. Thus, photolysis of *cis*- and *trans*-bicyclo[5.2.0]non-8-ene (**21**) yields cycloheptene (**22**) in both cases (eq. [14]), but the quantum yield for formation of this product (185 nm) is ca. five times lower for the *trans* isomer (Φ = 0.26 from *cis*-**21** vs. Φ = 0.05 from *trans*-**21**) (25). The difference is presumably due to the fact that in the latter case, stereospecific "cycloreversion" must produce *trans*-cycloheptene. Even

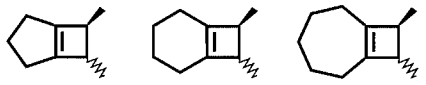
[14] 
21 22

more remarkably, the fragmentation reaction is completely suppressed in the photolyses of compounds **23**–**25** (30, 29);[4] in these cases, fragmentation would produce highly strained C5–C7 cycloalkynes.



23 24 25

Scope and mechanism of the ring opening reaction

It is clear from the various examples already discussed that, in general, the photochemical ring opening of cyclobutene does not follow orbital symmetry selection rules. Nevertheless, certain observations suggest very strongly that orbital symmetry does (or at least, *can* in certain instances) play a role in the reaction. The most compelling of these is the fact that compounds **23**–**25** consistently open with a high (though not complete) degree of disrotatory stereospecificity (eq. [15]) (ref. 29 and footnote 4). There are a number of structural features present in these compounds that set them apart from the monocyclic and other bicyclic systems that have been studied; the role that these features play in altering the general behavior of cyclobutenes with respect to ring opening will be discussed in more detail later.

[15] 
23-25 *E,E*-**26** *E,Z*-**26**

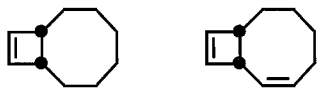
cis: ⟶	72-90%	10-28%
trans: ⟶	10-22%	90-78%

We believe that orbital symmetry *does play a role* in the photochemical ring opening of alkylcyclobutenes, but only in the initial stages of the reaction on the excited state potential energy surface. One piece of supporting evidence for this idea can be obtained from the behavior of *cis*- and *trans*-**3**, whose photochemistry was reinvestigated in light of our results for the numerous other cyclobutenes we have studied (26). It was found that, in fact, both isomers yield ring opening products upon photolysis (214 nm) in solution (eq. [16]). However, *trans*-**3** yields diene with ca. 5 times lower efficiency than does the *cis* isomer. This would be the expected result if disrotatory motions are involved in the initial stages of ring opening; such motions are impeded in *trans*-**3** because the disrotatory pathway leads to the highly strained *cis,trans* isomer of 1,1′-bicyclohexenyl (**4**). Similarly, the permethylated cyclobutene **27** undergoes ring opening with less than half the efficiency of *cis*-**15** (footnote 3); in this case, disrotatory motions are presumably impeded because of the necessity of buttressing two of the methyl groups at C3 and C4 as the rotation occurs.

[4]Also W. J. Leigh, K. Zheng, and A. Postigo, unpublished results.

[16] 
27 *cis*-15

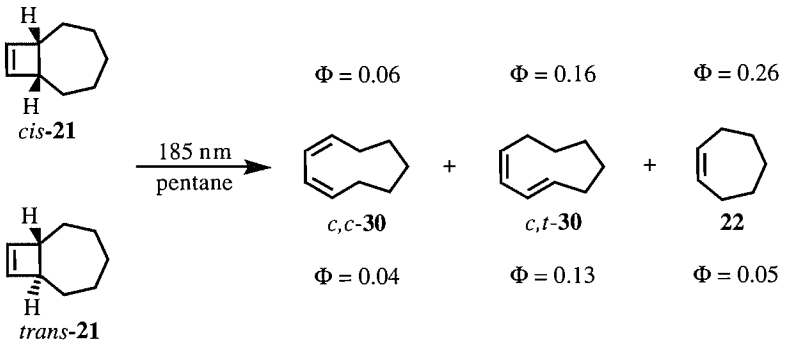
It may also be pertinent to note that the efficiency of photochemical ring opening appears to depend on the bond strength of the C3—C4 bond (25), just as is the case in ground state electrocyclic ring opening reactions (4*d*). This is demonstrated by a comparison of the diene/alkene ratios obtained from photolysis of compounds *cis*-**28** (ca. 1.0) and *cis*-**29** (3.6) (23). Molecular models show that the π-system of the cyclooctenyl C=C bond in *cis*-**29** is almost perfectly coplanar with the fragmenting cyclobutenyl C—C bond. The weakening of the latter in *cis*-**29** compared to the corresponding bond in *cis*-**28** is also manifested in the relative rates of thermal ring opening of the two compounds (23, 36).



cis-**28** *cis*-**29**

If the above assessment of the initial stages of ring opening is correct, the ultimate loss of stereochemistry must then be due to intervening processes that occur after ring opening is initiated, and which compete with the normal internal conversion processes that are thought to characterize photopericyclic reactions (i.e., internal conversion to the ground state surface at the avoided crossing (6–9)). Several possibilities have been suggested (22, 25): (*i*) internal conversion to upper vibrational levels of ground state cyclobutene, from which conrotatory ring opening occurs; (*ii*) internal conversion to ground state biradical(oid) species; and (*iii*) adiabatic, disrotatory ring opening to yield diene in the first excited singlet state, from which *cis,trans* isomerization ensues. While the first possibility has not yet been investigated experimentally, the results of photolysis of compounds **21** (25) and **29** (23) are consistent with the second, biradical mechanism for ring opening; in both cases, the *cis* and *trans* isomers yield very similar distributions of *cis,cis* and *cis,trans* dienes (eq. [17]), suggesting the involvement of a common set of intermediates, or at least that reaction of the two isomers proceeds through a common point on the excited state surface prior to product formation (25). It is interesting to note that the major diene isomer formed from photolysis of the two isomers of **21** is the less thermodynamically stable *cis,trans* isomer.

The adiabatic ring opening mechanism has been studied in greatest detail, since in this case it is a somewhat more straightforward task to design experiments with which to test



[17]

the mechanism. If ring opening occurs exclusively to yield fully open, excited dienes by the disrotatory pathway, then the observed diene distribution from cyclobutene ring opening would be expected to be dictated by the decay characteristics of the excited dienes, and thus predictable provided that the quantum yields for *cis,trans* isomerization and other photochemical processes of the dienes are known (Scheme 1) (22). While analyses of this type have been carried out for most of the cyclobutene derivatives discussed above, predicted diene distributions very rarely match those actually observed from photolysis of the cyclobutene derivative. In all of these cases, however, the stable ground state conformation of the diene is very different from the planar *s-cis* conformation in which the excited diene would be formed by disrotatory ring opening, so that independent characterization of the excited state behavior of the dienes themselves may not provide a realistic indication of their behaviour when formed by cyclobutene ring opening (22, 25) (the photochemistry of dienes is known to be conformation dependent (37)).

With this in mind, we have studied the photochemistry of the bicyclic cyclobutenes *cis*- and *trans*-**24** (29), whose isomeric dienes are constrained to be *s-cis* (AM1 calculations predict a twist angle of ca. 36° in the parent diene, 1,2-bismethylidenecyclohexane). The work has recently been extended to include the analogous bicyclo[4.2.0]hept-1^5-ene (**23**) and bicyclo[5.2.0]non-1^7-ene (**25**) systems (eq. [15]) (footnote 4). Table 2 lists the observed *EE/EZ* diene ratios from photolysis of these compounds, along with the corresponding ratios calculated from the independently determined quantum yields for *cis,trans* isomerization of the dienes according to the equation given in Scheme 1.

Several interesting trends emerge from these data. First of all, the high degree of disrotatory stereospecificity observed for the ring opening of *cis*- and *trans*-**24** is quite general within this special class of constrained systems. Secondly, these compounds undergo ring opening with considerably higher efficiency than other compounds with dialkyl substitution at the cyclobutene double bond (e.g., **15**). This can be explained conveniently enough by noting that the ancillary ring induces additional strain in the cyclobutenyl ring, as evidenced by the substantially lower activation energies for thermal ring opening of these compounds compared to those of monocyclics (38). Thirdly, the *EE/EZ* diene ratios observed in the photolyses of these compounds are reproduced by the values calculated on the basis of the adiabatic mechanism defined in Scheme 1 in only two cases (*cis*-**23** and *cis*-**24**). We conclude that the adiabatic ring opening pathway cannot account for the nonstereospecificity of the reaction.

Thus, it might be concluded that the general nonstereospecificity of the reaction is due to intervening internal conversion processes that occur before the system reaches the avoided surface crossing for disrotatory ring opening. If this is the case, then the unusually high degree of stereospecificity that is observed for **23–25** might be attributed to structurally induced suppression of these processes. Keeping in mind that the rates of internal conversion processes are affected by rovibrational factors, it is worth noting that the "alkyl substituents" on the C=C bond are more or less locked in **23–25**; furthermore, the isomeric dienes are highly constrained with respect to rotation about the central C—C bond. In principle, either or both of these factors could af-

fect the rates of internal conversion processes at partially open geometries. Because the rigidity of these compounds varies regularly throughout the series, accompanying variations in the degree of stereospecificity would be expected. However, it is difficult to understand why the variation observed within the series of *cis*-dimethyl compounds (increasing stereospecificity with increasing ancillary ring size) is *opposite* to that observed within the series of *trans*-dimethyl compounds (decreasing stereospecificity with increasing ancillary ring size).

Bernardi and Robb and their co-workers recently reported MCSCF calculations on the photochemical ring opening of 7-methylbicyclo[4.2.0]oct-7-ene (**17**) (39), experimental results for which were discussed earlier. This report follows an earlier study of the photochemical ring closure of 1,3-butadiene, in which was reported the existence of real surface crossings ("conical intersections") between the excited and ground state surfaces for disrotatory conversion of butadiene to cyclobutene (*vide supra*) (11). It was proposed that during the ring closure reaction of 1,3-butadiene, funnelling to the ground state surface occurs at the conical intersection rather than at the avoided surface crossing. The geometry of the reacting species at this stage is one in which all the π-bonds in the molecule are broken, a tetraradicaloid species with the C2—C3 bond twisted by 78°. Excited state ring opening of **17** was proposed to proceed through three such surface crossings; the three conical intersection structures have the common feature of having the (former) cyclobutene double bond twisted by an angle close to 90°. The formation of three isomeric dienes in the reaction is explained as being due to the fact that three different surface crossings exist and, at each one, the reacting species can further relax to give all three of the diene isomers after entering the ground state surface (39).

This theoretical model can adequately explain why ring opening leads to a distribution of isomeric dienes in most of the cyclobutene systems that have been studied experimentally. It might also explain why nearly common distributions of products are formed in systems such as *cis*- and *trans*-**21**, if there is a single conical intersection geometry that is accessible from both isomers of the cyclobutene. Compounds **23–25** are special in that they are prevented from achieving the 80–90° twist angle that characterizes the geometry of the system at the conical intersection. It is possible that in such cases, the system is forced to open largely via the avoided crossing, or perhaps adiabatically, or perhaps via other surface crossings[5] in a pathway that leads predominantly to the disrotatory product(s). It is clear that further study is required in order to develop a complete understanding of the remarkable complexities of this "prototypical" photoelectrocyclic reaction.

Acknowledgments

The work discussed in this account is that of four individuals of whom I am extremely proud: Brad Clark, Nien Nguyen, Zheng Kangcheng, and Al Postigo. I owe an enormous debt to them for their patience and sheer hard work, as I do to my other graduate students who have toiled in our other areas of interest — Brian Fahie, Scott Mitchell, Mark Workentin, Greg Sluggett, Jo-Ann Banisch, and Mike St. Pierre. I am also indebted to the Natural Sciences and Engineering Research Council of Canada for its very generous support of our research through operating and equipment grants, and to the Petroleum Research Fund, which supported some of our work in the cyclobutene area. Finally, I would like to thank the Canadian Society for Chemistry for honouring me with the 1992 Merck–Frosst Centre for Therapeutic Research Lecture Award.

A new synthesis of castasterone and brassinolide from stigmasterol. A concise and stereoselective elaboration of the side chain from a C-22 aldehyde

THOMAS G. BACK,[1] PETER G. BLAZECKA, AND M. VIJAYA KRISHNA[2]
Department of Chemistry, University of Calgary, Calgary, Alta., Canada, T2N 1N4

Received August 18, 1992

THOMAS G. BACK, PETER G. BLAZECKA, and M. VIJAYA KRISHNA. Can. J. Chem. **71**, 156 (1993).

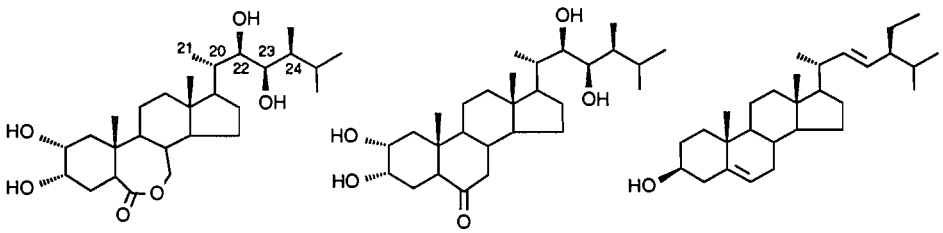
Brassinolide (**1**) and castasterone (**2**) were prepared from aldehyde **7**, in turn available from stigmasterol (**3**). The addition of (*E*)-1-propenyllithium to **7**, followed by diastereoselective Sharpless epoxidation of allylic alcohol **8** using (L)-(+)-diethyl tartrate, and regioselective epoxide-opening of (*threo*) epoxy alcohol **15** with isopropylmagnesium chloride in the presence of a catalytic amount of cuprous cyanide afforded diol **17**. The epoxidation and cuprate addition steps were investigated in greater detail with the simpler model aldehyde **4**. Hydrolysis of **17** provided **2**, which was converted preferentially into **1** or its regioisomer **22** by Baeyer–Villiger oxidation with trifluoroperoxyacetic acid or peroxyseleninic acids, respectively.

THOMAS G. BACK, PETER G. BLAZECKA et M. VIJAYA KRISHNA. Can. J. Chem. **71**, 156 (1993).

On a préparé le brassinolide (**1**) et la castastérone (**2**) à partir de l'aldéhyde **7** que l'on peut obtenir à partir du stigmastérol (**3**). L'addition du (*E*)-1-propényllithium au composé **7**, suivie par une époxydation diastéréosélective selon Sharpless de l'alcool allylique **8**, utilisant du (L)-(+)-tartrate de diéthyle, et une ouverture régiosélective de l'alcool (*thréo*)-époxydique **15**, à l'aide de chlorure de chlorure d'isopropylmagnésium en présence d'une quantité catalytique de cyanure cuivreux, conduit au diol **17**. Utilisant l'aldéhyde modèle **4**, beaucoup plus simple, on a examiné en détail les étapes d'époxydation et d'addition du cuprate. L'hydrolyse du composé **17** fournit le produit **2** que l'on a transformé d'une façon préférentielle en **1**, ou en son régioisomère **22**, grâce à une oxydation de Baeyer–Villiger avec respectivement de l'acide trifluoroperoxyacétique ou des acides peroxyséléniniques.

[Traduit par la rédaction]

In 1979, Grove, Mandava, and co-workers (1) reported the isolation and structure elucidation of brassinolide (**1**), a novel plant growth-promoter from *Brassica napus* L. pollen. The product was a highly oxygenated steroid with an unprecedented B-ring lactone that displayed activity at concentrations several orders of magnitude lower than those of other plant growth regulators (1–3). In certain plant species, noticeable growth enhancement was observed even at the nanogram level. Field trials in several countries demonstrated substantial improvements in the yields of crops such as wheat, corn, rye, potatoes, and others, when brassinolide or related brassinosteroids were applied, even at low concentrations (3*a*, 3*b*). These compounds also display antiecdysteroid activity in insects (3*c*) and improve the stress resistance of various crops to heat, cold, drought, and salinity (3*d*, 3*e*, 3*f*). The low abundance of brassinolide in natural sources, its potent biological activity, and its intriguing structure have made it and its congeners the targets of several recent syntheses (4). The brassinolide side chain, with its vicinal diol function at C-22 and C-23, and the four contiguous chiral centers at C-20, C-22, C-23, and C-24, presents a special challenge in such endeavours. We now report the preparation of brassinolide (**1**) and its 6-keto analogue, castasterone (**2**), by a simple new approach that elaborates the desired side chain in just three steps from a C-22 aldehyde precursor, which in turn is easily available from inexpensive stigmasterol (**3**).



Brassinolide (1) **Castasterone (2)** **Stigmasterol (3)**

Results and discussion

Our general approach to the brassinolide side chain is shown retrosynthetically in Scheme 1. The desired product results from the regio- and stereoselective attack of an isopropyl nucleophile at C-24 of a (*threo*)-23,24-epoxy 22-aldehyde, with inversion of configuration. The key intermediate epoxy alcohol is obtained by the stereoselective epoxidation of the corresponding allylic alcohol, which in turn represents the Cram addition product of a propenyl anion to a C-22 aldehyde.

Both the simple cyclosterol C-22 aldehyde **4** (5) and the more highly elaborated analogue **7** (4*d*, 4*e*) were prepared from stigmasterol (**3**) by literature methods. The former, more readily available aldehyde, was employed as a model sys-

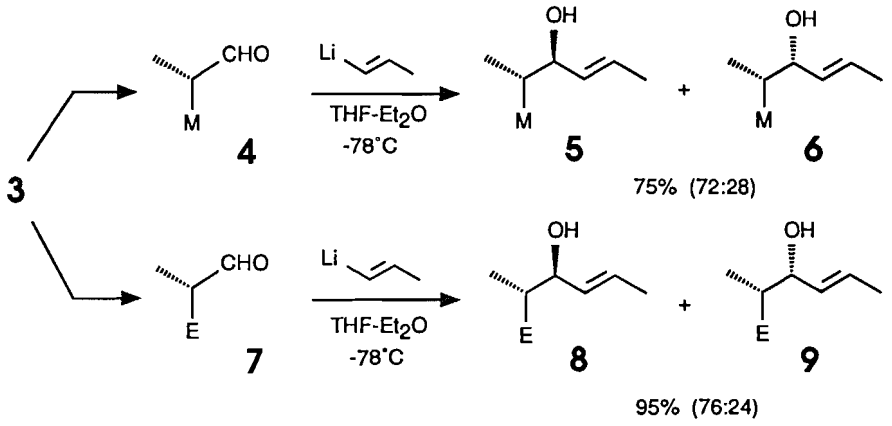

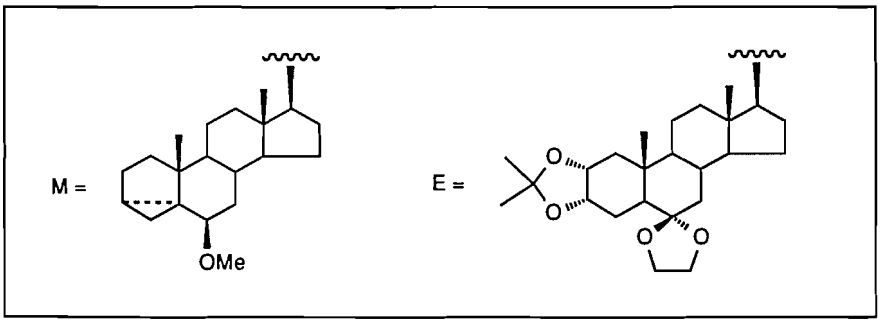

SCHEME 2

tem for the optimization of the three steps in Scheme 1 (see ref. 6 for a preliminary communication), and these were then applied to **7** for the actual preparation of the desired target compounds **1** and **2**. The propenylation of aldehydes **4** and **7** was achieved with (*E*)-1-propenyllithium at −78°C, affording mixtures of the epimeric allylic alcohols **5** and **6**, and **8** and **9**, respectively, as shown in Scheme 2 (M = model steroid nucleus; E = elaborated steroid nucleus). The propenyllithium reagent is easily obtained from (*E*)-1-chloropropene and is known to be configurationally stable (7). As expected, the additions favoured the Cram products **5** and **8** over their anti-Cram isomers **6** and **9** (8).[3] Separation of each epimeric pair was accomplished by routine chromatography. The stereochemical assignments of the known compounds **5** and **6** were previously reported (9), and those of **8** and **9** were made by comparison of their NMR spectra with those of **5** and **6**, and confirmed by the ultimate conversion of **8** into the naturally occurring products **1** and **2**.

The further transformations of allylic alcohol **5** are shown in Scheme 3. Epoxidation of **5** to the corresponding (*threo*) and (*erythro*) epoxy alcohols **10** and **11**, respectively, was investigated under a variety of conditions, summarized in Table 1. *m*-Chloroperbenzoic acid (MCPBA) is an effective epoxidizing agent (10) and, in the case of allylic alcohols, frequently reacts with high stereoselectivity due to complexation of the peracid with the hydroxyl group of the substrate (11). It has been reported that secondary (*E*)-allylic alcohols afford predominantly (*threo*) epoxy alcohols (12), which in the case of **5** would afford the desired diastereomer **10**. Moreover, MCPBA oxidations of the steroidal (*E*)-allylic alcohols **13***a* (4*a*) and **13***b* (4*f*) were reported to afford the corresponding (*threo*) epoxy alcohols **14***a* and **14***b* with excellent diastereoselectivity (eq. [1]). Although the alkene moieties of **13***a,b* are trisubstituted instead of disubstituted as in **5**, in each case the bulkier substituent (i-Pr vs. Me in **13***a,b*; Me vs. H in **5**) is oriented *trans* to C-22. We therefore reasoned that if the side-chain conformations of **13***a,b* and **5** were comparable, then similar stereochemical outcomes might be expected. However, entry 1 in Table 1 reveals that poor stereoselectivity was observed with **5**, unexpectedly favouring the unwanted (*erythro*) isomer **11**. Similarly unsatisfactory results were obtained with *o*-nitrobenzeneperoxyseleninic acid[4] (entry 2), while the urea – hydrogen peroxide complex in the presence of acetic anhy-

dride (14) slightly favoured the (*threo*) isomer **10**, but with a lower overall yield (entry 3). Epoxidations of allylic alcohol **5** with *tert*-butyl hydroperoxide in the presence of catalytic amounts of $VO(acac)_2$ or $Mo(CO)_6$ (ref. 15, for a review) were also investigated. The former catalyst is known to produce opposite stereoselectivities to those observed with either the latter catalyst, or with peracids (12). In the present case, the use of $VO(acac)_2$ afforded the (*erythro*) isomer **11** almost exclusively (entry 4), while $Mo(CO)_6$ (entry 5) gave, as expected, similar results to those observed with MCPBA. The tendency of **5** to form substantial or dominant amounts of **11** under all of the conditions in entries 1–5 of Table 1 is possibly due to a preferred side-chain conformation where the face of the C(23)—C(24) π-bond that is required for epoxidation to **10** is directed toward C(16) of the D-ring, resulting in its partial steric protection. The more highly substituted allylic alcohols **13***a* and **13***b* presumably adopt a different side-chain conformation that permits *threo*-selective epoxidation to **14***a* and **14***b*. Further evidence is required, however, for a firm conclusion concerning this point.

14*b* St= E (96%)

Finally, we turned our attention to the Sharpless asymmetric epoxidation method (16) employing $Ti(O\text{-}iPr)_4$ in the presence of (D)- or (L)-diethyl tartrate (D-DET or L-DET). While this technique is more commonly employed for the enantioselective epoxidation of prochiral allylic alcohols, we hoped that the tartrate-controlled asymmetric environment of the epoxide-forming transition state could override the propensity of **5** towards diastereoselective formation of the unwanted (*erythro*) isomer **11** with achiral oxidants. Entries 6 and 7 in Table 1 indicate that the use of D-DET affords a similar product distribution to MCPBA, whereas L-DET achieves the desired stereoselectivity favouring the (*threo*)

[e]Isolated yield.

isomer **10**. The latter is therefore the method of choice from among those studied.

Ring-opening of epoxides has been reported with both lower order (17) and higher order (18) cuprates, as well as by the Cu(I)-catalyzed reactions of organolithium and Grignard reagents (19). Higher order reagents of general structure $R_2Cu(CN)Li_2$ have been particularly recommended for this type of transformation (20). Previous studies with Me_2CuLi (11*a*, 21) and $Me_2Cu(CN)Li_2$ (22) indicated that 2,3-epoxy alcohols afford principally 1,3-diols instead of their 1,2-diol regioisomers. However, in the present case, we reasoned that the greater steric bulk of the isopropyl group relative to methyl in the cuprate reagent should favour attack at the less hindered epoxide carbon atom (C-24). Thus, preferential vicinal diol formation leading to the required **12** from **10** (Scheme 3) was anticipated. Our results, obtained with various cuprate reagents, are shown in Table 2. We observed that the (*threo*) epoxy alcohol **10** reacted considerably faster than its (*erythro*) isomer **11**, thus obviating the need for the difficult separation of the two diastereomers prior to the reaction of **10** with the cuprate. Instead, the mixture of **10** and **11** was employed directly, thus requiring only the more facile separation of the more polar diol **12** from the unreacted (*erythro*) epoxy alcohol **11**. The yields shown in Table 2 are based on the amount of the (*threo*) isomer present in the starting material. No attempts were made to isolate the corresponding 1,3-diol (i.e., the 22,24-diol using steroid numbering) regioisomer in the examples in Table 2, but there was no evidence to indicate that it was a major product. The reagents in entries 1–3 gave poor yields of **12** because they decomposed faster than they reacted with **10**, resulting in the recovery of both diastereomers **10** and **11**. The more stable 2-thienyl(cyano)-copper lithium (23) reagent in entry 4 failed to react at all. Improved results were obtained with $i\text{-}Pr_2Cu(CN)Li_2$, particularly when using ether as the solvent (entry 6), as recommended by Lipshutz *et al.* (20). Our best results, however, were realized with the CuCN-catalyzed Grignard reaction in entry 9, which cleanly afforded the desired product **12** in high yield. Diol **12** has been prepared by several previous routes (4*a*, 4*m*, 4*s*) and its identical spectral and physical characteristics to those reported in the literature confirm its stereochemistry.

The above protocol was then applied to the more highly elaborated allylic alcohol **8**, as illustrated in Scheme 4. Sharpless epoxidation with L-DET afforded a mixture of (*threo*) and (*erythro*) epoxy alcohols **15** and **16** in the ratio of 63:37, as determined by NMR integration, along with a small amount of recovered starting material. Treatment of the mixture of **15** and **16** with isopropylmagnesium chloride and a catalytic amount of CuCN resulted in the formation of the desired 22,23-diol **17** as the principal product, along with a smaller amount of the regioisomer **18**. The (*erythro*) epoxy alcohol **16** remained virtually unreacted and was recovered intact. Removal of the acetonide and ethylene ketal protecting groups from **17** under standard conditions afforded castasterone (**2**) with properties identical to those reported in the literature (4*c*, 4*f*, 4*k*, 4*q*). The conversion of **2** into brassinolide (**1**) was then completed by the known method of Baeyer–Villiger oxidation of the corresponding tetraacetate **19** with trifluoroperoxyacetic acid to afford predominantly the 7-oxa regioisomer **20**, followed by saponification of the lactone tetraacetate (4*c*). The preferential formation of the desired regioisomer **20** under these conditions is somewhat anomalous, as the migration of the more substituted carbon atom is generally observed in Baeyer–Villiger oxidations. It is interesting to note that, in contrast to the oxidation of **19** with trifluoroperoxyacetic acid, **2** reacted with benzeneperoxyseleninic acid (24) or its *o*-nitro derivative in aqueous THF to produce chiefly the 6-oxa regioisomer **22**, while the tetraacetate **19** failed to react appreciably with either peroxyseleninic acid under similar conditions. Several previous studies (25) of Baeyer–Villiger oxidations of 6-keto steroids have been reported and it was suggested that inductive effects of substituents at C-3, as well as at C-1 and C-2, influence the regiochemistry of these processes (25*a*). Our results indicate that the type of oxidant, as well as the nature of the steroid substituents, plays a key role in determining the regiochemical outcome. Further work is required for a clear understanding of the importance of conformational, steric, and electronic effects, and possibly of complexation between the substituents and the peracid moiety in the Baeyer–Villiger oxidations of 6-keto steroids.

The above approach thus provides a concise, efficient, and stereoselective synthesis of the castasterone and brassinol-

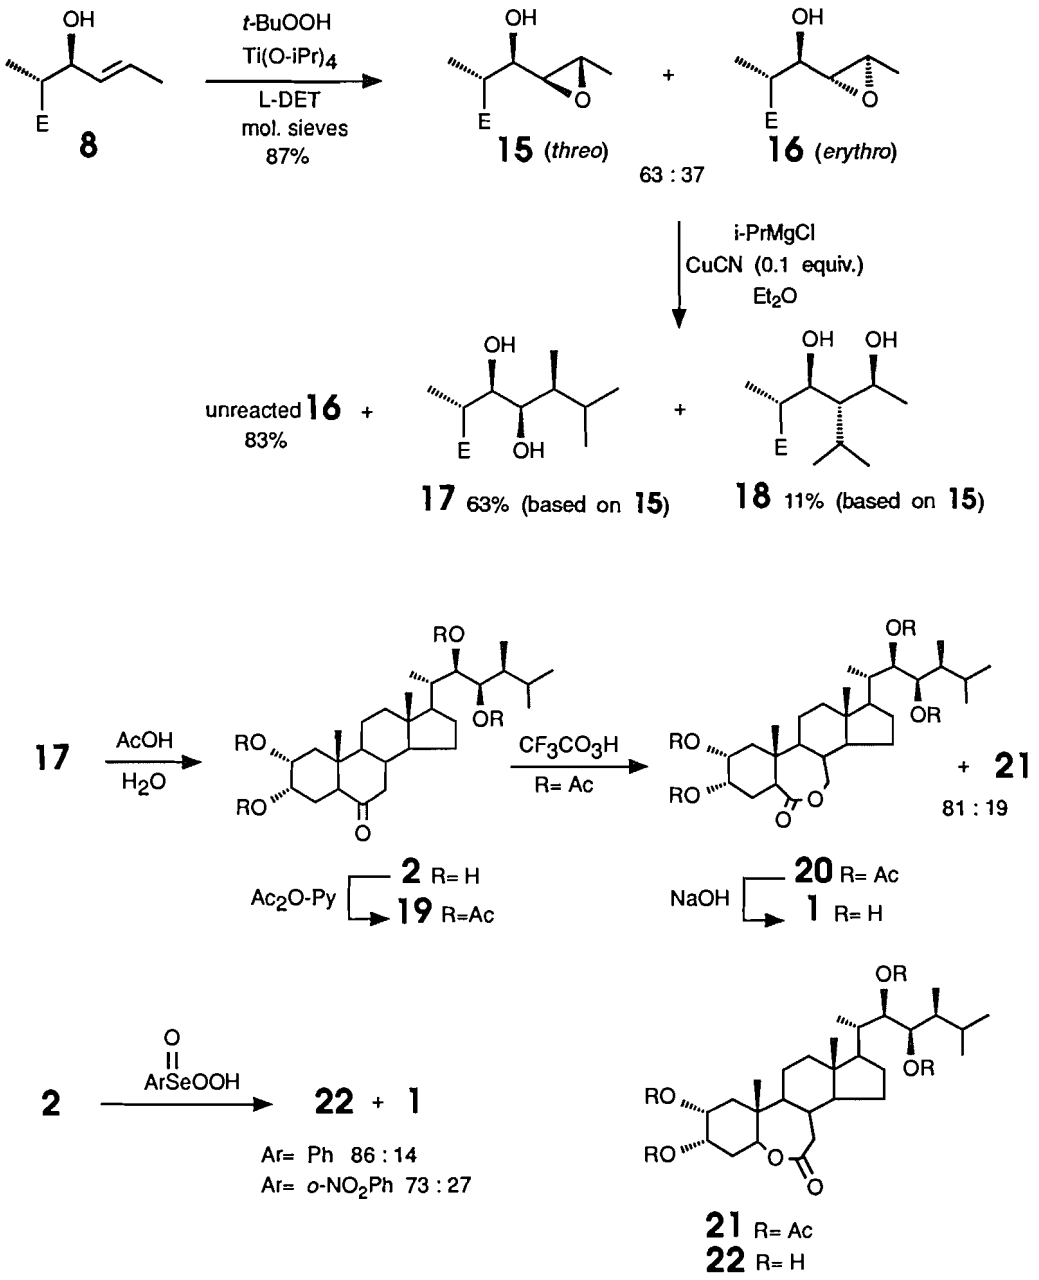

SCHEME 4

ide side chain, affording an overall yield of 22% of castasterone (**2**) from the known aldehyde **7**. Since the procedure employs readily available reagents and the required aldehyde is itself obtained from inexpensive stigmasterol (**3**), this method is one of the most practical routes to brassinosteroids **1** and **2** reported to date.

Experimental section

Melting points were obtained on an A.H. Thomas hot-stage apparatus and are uncorrected. ^1H and ^{13}C NMR spectra were acquired on a Bruker AC-E 200 or AM 400 instrument in deuteriochloroform solvent with either residual chloroform or tetramethylsilane as the internal standard, unless noted otherwise. Analytical TLC was carried out using aluminum sheets coated with 0.2 mm of silica gel and a fluorescent indicator (SG 60 F_{254}, E.M. Merck). Spots were visualized by spraying with a 2% solution of $CeSO_4$ in 12% aqueous H_2SO_4, followed by heating briefly. Flash chromatography was performed on silica gel by the method of Still *et al.* (26).

o-Nitrobenzeneseleninic acid (27), (*E*)-1-propenyllithium (7), and lithium 2-thienyl(cyano)cuprate (2-ThCu(CN)Li) (23) were prepared by literature procedures, and i-$Pr_2Cu(CN)Li_2$ was produced by the same method as employed previously for $Me_2Cu(CN)Li_2$ (20). The other cuprates in entries 1–3 in Table 2 were produced by the addition of i-PrLi (from the reaction of Li powder containing 0.5% Na with i-PrCl in petroleum ether) to CuI, CuBr·SMe_2, or CuSPh, respectively, in THF. Reagents used in the Sharpless asymmetric epoxidations were purified according to published procedures (28). Organolithium compounds were titrated with 2,5-dimethoxybenzyl alcohol (29) or diphenylacetic acid (30) as the indicator prior to use. Ether, THF, and dichloromethane were dried by distillation from CaH_2, $LiAlH_4$, and P_2O_5, respectively. All other reagents were obtained from commercial sources and purified by standard methods as required.

*(3β,5α,6β,22S,23E)-6-Methoxy-3,5-cyclo-26,27-dinorcholest-23-en-22-ol (**5**) and its (22R) isomer (**6**)*

A solution of aldehyde **4** (1.943 g, 5.639 mmol) in 12 mL of dry THF was added dropwise over 45 min to a stirred solution of (*E*)-1-propenyllithium (9.93 mL of a 0.71 M solution in ether, 7.1 mmol) at −78°C under argon and stirring was continued for an additional 4 h. The reaction was quenched at this temperature with 20% aqueous NH_4Cl solution and diluted with ether, washed with 5% aqueous $NaHCO_3$, saturated aqueous NaCl, dried ($MgSO_4$), and evaporated under vacuum. The oily residue was flash chromatographed, eluting with 10% ethyl acetate – hexanes, to afford 1.184 g (54%) of the less polar (22*S*) allylic alcohol **5** that crystallized from hexanes, mp 98–100°C (lit. (9) mp 103–104°C); R_f 0.48 (20% EtOAc–hexanes). Further elution afforded 0.464 g (21%) of the more polar (22*R*)-allylic alcohol **6** as a colourless gum; R_f 0.32 (20% EtOAc–hexanes). Both products had spectral properties in accord with those reported in the literature (9).

*(threo)-(3β,5α,6β,22R,23R,24S)-23,24-Epoxy-6-methoxy-3,5-cyclo-26,27-dinorcholestan-22-ol (**10**) and its (erythro) isomer (**11**)*

(+)-L-Diethyl tartrate (L-DET) (107 μL of a 5.00% v/v solution in CH_2Cl_2, 0.0311 mmol) was placed under an Ar atmosphere and cooled to −20°C. The following were then added in the indicated order: powdered 4 Å molecular sieves (14 mg), $Ti(OiPr)_4$ (154 μL of a 5.00% v/v solution in CH_2Cl_2, 0.0259 mmol), and *tert*-butyl hydroperoxide (61 μL of an 8.5 M solution in CH_2Cl_2, 0.52 mmol). The mixture was stirred for 1 h at −20°C, followed by the addition of a solution of the (22*S*)-allylic alcohol **5** (100.2 mg, 0.2592 mmol) in 1 mL of dry CH_2Cl_2. The reaction mixture was allowed to stand at −25°C for 6 days. Four more equivalents of *tert*-butyl hydroperoxide were added at regular intervals over the last 4 days. The reaction was quenched by the addition of 1 mL of 30% aqueous NaOH (saturated with NaCl), diluted with ether, and stirred for 10 min. Magnesium sulfate (1 g) and Celite (0.5 g) were added and the mixture was stirred for another 15 min, followed by filtration through a pad of Celite and removal of the solvent under vacuum. The residue was flash chromatographed, eluting with 30% EtOAc–hexanes, to give 99.4 mg (95%) of a mixture (single spot on TLC, 30% EtOAc–hexanes) of the epoxy alcohols **10** and **11** as a colourless gum with R_f 0.45 (30% EtOAc–hexanes) and a *threo*:*erythro* ratio of 70:30 as determined by NMR integration. The ^1H NMR signals of the (*threo*) isomer **10** in the mixture were assigned on the basis of their literature values (4*m*), while those of the (*erythro*) epoxy alcohol **11** were assigned by comparison of the spectrum of the mixture with that of a pure sample of **11** recovered from the cuprate addition reactions shown in Table 2 (*vide infra*). The *threo*:*erythro* ratio was determined by integration of the signals at δ 3.62 (m, 1 H, H-22) and δ 2.90 (dq, J = 5.2, 2.4 Hz, 1 H, H-24) from **10**, and at δ 3.87 (m, 1 H, H-22) and δ 3.13 (dq, J = 5.3, 2.2 Hz, 1 H, H-24) from **11**.

Other epoxidation methods that were studied for the conversion of **5** into **10** are summarized in Table 1.

*(3β,5α,6β,22R,23R,24S)-6-Methoxy-3,5-cycloergostane-22,23-diol (**12**)*

An ethereal solution of i-PrMgCl (0.54 mL of a 2.0 M solution, 1.1 mmol) was added to a suspension of CuCN (9.7 mg, 0.11 mmol) in 1 mL of ether at −78°C. The turbid grey mixture was stirred for 45 min at this temperature, followed by the addition of a solution of epoxy alcohols **10** and **11** (87.6 mg, 0.218 mmol; *threo*:*erythro* ratio of 52:48). The reaction mixture was stirred for 1 h at −78°C, and then at 0°C for 6 h. The reaction was quenched with 20% aqueous NH_4Cl solution, diluted with ether, the phases were separated, and the aqueous layer was extracted once with ether. The combined ether extracts were washed with 5% aqueous $NaHCO_3$, water, and aqueous NaCl, dried ($MgSO_4$), and evaporated under vacuum. The crude product was flash chromatographed, eluting with 40 → 70% ether–hexanes, to remove unreacted (*erythro*) epoxy alcohol **11** (R_f 0.70, 80% ether–hexanes), followed by 38.5 mg (76% based on the (*threo*) epoxide **10**) of the diol **12** as a colourless gum, recrystallized from chloroform–hexanes to give a white solid with mp 76–79°C (lit (4*a*) mp 70–73°C; lit. (4*s*) mp 84–90°C); R_f 0.50, (80% ether–hexanes); IR (KBr): 3545, 3462, 1246, 1067, 978, 754 cm^{-1}; ^1H and ^{13}C NMR spectra (4*m*), and low-resolution mass spectrum (4*s*) were in close agreement with those reported in the literature. Exact Mass calcd. for $C_{29}H_{50}O_3$: 446.3760; found: 446.3752.

Results with other cuprate reagents that were investigated for the conversion of **10** into **12** are summarized in Table 2.

*(2R,3S,5α,22S,23E)-6,6-Ethylenedioxy-2,3-isopropylidenedioxy-26,27-dinorcholest-23-en-22-ol (**8**) and its (22R) isomer (**9**)*

A solution of the aldehyde **7** (1.057 g, 2.367 mmol) in 15 mL of dry ether was added dropwise over 45 min to a stirred solution of (*E*)-1-propenyllithium (6.45 mL of a 0.55 M solution in ether, 3.6 mmol) at −78°C under argon, and the resulting mixture was stirred at this temperature for an additional 4 h. The reaction was quenched with 20% aqueous NH_4Cl, the phases were separated, and the aqueous layer was extracted once with ether. The combined ether extracts were washed with saturated aqueous $NaHCO_3$ and saturated aqueous NaCl, and dried ($MgSO_4$). Removal of the solvent under vacuum left a white, solid foam that was flash chromatographed, eluting with 5 → 10% acetonitrile–dichloromethane, to afford 78.4 mg (7%) of unreacted **7**, R_f 0.56 (10% acetonitrile–dichloromethane), 256.7 mg (22%) of the less polar (22*R*)-allylic alcohol **9**, R_f 0.39 (10% acetonitrile–dichloromethane), and 839.4 mg (73%) of the more polar (22*S*)-allylic alcohol **8**, R_f 0.31 (10% acetonitrile–dichloromethane).

Compound **8** was a gum with IR (film): 3482, 1669, 1217, 1057, 959, 789, 735 cm^{-1}; ^1H NMR (200 MHz) δ: 5.71–5.44 (complex m, 2 H, H-23 and H-24), 4.24 (m, 1 H), 4.16 (m, 1 H), 4.07 (m, 1 H), 3.91 (m, 3 H), 3.73 (m, 1 H), 1.71 (d, J = 5.1 Hz, 3 H, 25-Me), 1.46 (s, 3 H, acetonide), 1.31 (s, 3 H, acetonide), 0.89 (d, J = 6.0 Hz, 3 H, 21-Me), 0.82 (s, 3 H, 19-Me), 0.67 (s, 3 H, 18-Me); ^{13}C NMR (50.3 MHz) δ: 133.8 (CH), 125.2 (CH), 109.6 (C), 107.5 (C), 74.0 (CH), 72.9 (CH), 72.8 (CH), 65.4 (CH_2), 64.1 (CH_2), 55.7 (CH), 52.9 (CH), 52.4 (CH), 45.4 (CH), 42.6 (CH_2), 42.3 (C), 41.4 (CH), 40.9 (CH_2), 39.5 (CH_2), 37.9 (C), 32.9 (CH), 28.6 (CH_3), 27.6 (CH_2), 26.5 (CH_3), 24.1 (CH_2), 21.9 (CH_2), 20.7 (CH_2), 17.7 (CH_3), 13.3 (CH_3), 11.94 (CH_3), 11.85 (CH_3); mass spectrum, m/z (relative intensity): 488 (M^+, 13), 473 (34), 455 (45), 417 (35), 387 (60), 359 (45), 329 (59), 277 (58), 259 (62), 239 (57), 178 (73), 108 (87), 99 (84), 81 (100). Exact Mass calcd. for $C_{30}H_{48}O_5$: 488.3502; found: 488.3497.

Compound **9** was a gum with IR (film): 3476, 1672, 1217, 1055, 968, 787, 764, 735 cm^{-1}; ^1H NMR (200 MHz) δ: 5.67 (dq, J = 15.3, 6.2 Hz, 1 H, H-24), 5.47 (ddd, J = 15.3, 7.4, 1.2 Hz, 1 H, H-23), 4.25 (m, 1 H), 4.08 (m, 2 H), 3.91 (m, 3 H), 3.74 (m, 1 H), 1.73 (d, J = 6.3 Hz, 3 H, 25-Me), 1.46 (s, 3 H, acetonide), 1.31 (s, 3 H, acetonide), 0.94 (d, J = 6.7 Hz, 3 H, 21-Me), 0.82 (s, 3 H, 19-Me), 0.70 (s, 3 H, 18-Me); ^{13}C NMR (50.3 MHz) δ: 129.6 (CH), 128.3 (CH), 109.6 (C), 107.5 (C), 74.6 (CH), 72.9 (CH), 72.8 (CH), 65.5 (CH_2), 64.2 (CH_2), 55.4 (CH), 53.0 (CH), 52.9 (CH), 45.5 (CH), 42.7 (CH_2 + C), 41.9 (CH), 41.0 (CH_2), 39.5 (CH_2), 38.0 (C), 32.9 (CH), 28.6 (CH_3), 27.5 (CH_2), 26.5 (CH_3), 24.3 (CH_2), 21.9 (CH_2), 20.7 (CH_2), 17.9 (CH_3), 13.3 (CH_3), 12.3 (CH_3), 12.1 (CH_3); mass spectrum, m/z (relative intensity); 488 (M^+, 10), 473 (32), 455 (20), 417 (38), 387 (48), 359 (59), 329 (32), 277 (64), 259 (45), 239 (46), 178 (61), 108 (90), 99 (100), 81 (97). Exact Mass calcd. for $C_{30}H_{48}O_5$: 488.3502; found: 488.3489.

*(threo)-(2R,3S,5α,22R,23R,24S)-6,6-Ethylenedioxy-2,3-isopropylidenedioxy-23,24-epoxy-26,27-dinorcholestan-22-ol (**15**) and its (erythro) isomer (**16**)*

(+)-L-Diethyl tartrate (L-DET) (622 μL of a 5.00% v/v solution in dichloromethane, 0.182 mmol) was added to powdered 4 Å molecular sieves (200 mg) under argon at −20°C, followed by $Ti(O\text{-}iPr)_4$ (901 μL of a 5.00% v/v solution in dichloromethane, 0.151 mmol) and *tert*-butyl hydroperoxide (629 μL of a 4.81 M solution in dichloromethane, 3.03 mmol). The mixture was stirred

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

for 1 h at −20°C, after which a solution of the (22*S*)-allylic alcohol **8** (739.3 mg, 1.513 mmol) in 7 mL of dry dichloromethane was added and the reaction mixture was allowed to stand at −25°C for 6 days. An additional 2 equivalents of *tert*-butyl hydroperoxide were added over this period. The reaction was quenched by the addition of 1 mL of water and then stirred for 30 min as the reaction mixture warmed to room temperature. Aqueous NaOH (0.5 mL of a 30% solution) saturated with NaCl was then added and the mixture was stirred vigorously for 1 h. The phases were separated and the aqueous portion extracted twice with dichloromethane. The combined dichloromethane extracts were washed several times with water, once with saturated aqueous NaCl, and dried ($MgSO_4$). Removal of the solvent under vacuum left a white, solid foam, which was flash chromatographed, eluting with 10% acetonitrile–dichloromethane, to afford 30.3 mg (4%) of unreacted allylic alcohol **8**, as evidenced by TLC and ^{1}H NMR spectroscopy, and 663.7 mg (87%) of a mixture of the slightly more polar (*threo*) and less polar (*erythro*) epoxy alcohols **15** (R_f 0.43, 20% acetonitrile–dichloromethane) and **16** (R_f 0.48, 20% acetonitrile–dichloromethane), respectively, with the *threo*:*erythro* ratio of 63:37 as determined by NMR integration. Further chromatography afforded a purer (ca. 90%) sample of the (*threo*) isomer **15**, while a homogeneous sample of (*erythro*)-**16** was recovered from the reaction of the mixture of **15** and **16** with cuprate reagents (*vide infra*).

Compound **15** had ^{1}H NMR (200 MHz) δ: 4.27 (m, 1 H), 4.10 (m, 1 H), 3.92 (m, 3 H), 3.75 (m, 1 H), 3.66 (m, 1 H), 2.93 (dq, J = 5.2, 2.4 Hz, 1 H, H-24), 2.76 (m, 1 H, H-23), 1.48 (s, 3 H, acetonide), 1.33 (s, 3 H, acetonide), 1.33 (d, J = 5.1 Hz, 3 H, 25-Me), 1.02 (d, J = 6.1 Hz, 3 H, 21-Me), 0.84 (s, 3 H, 19-Me), 0.70 (s, 3 H, 18-Me). The *threo*:*erythro* ratio was determined by integration of the signals at δ 2.93 and δ 2.76 from **15**, and at δ 3.15 and δ 2.66 from **16**.

(2R,3S,5α,22R,23R,24S)-6,6-Ethylenedioxy-2,3-isopropylidenedioxyergostane-22,23-diol (17) and (2R,3S,5α,22R,23S,24S)-6,6-ethylenedioxy-2,3-isopropylidenedioxy-23-isopropyl-26,27-dinorcholestane-22,24-diol (18)

Isopropylmagnesium chloride (2.89 mL of a 2.0 M ether solution, 5.8 mmol) was added to a suspension of CuCN (51.7 mg, 0.578 mmol) in 1 mL of ether at −78°C. The mixture was stirred for 1 h at this temperature, followed by the addition of a solution of epoxy alcohols **15** and **16** (583.1 mg, 1.155 mmol; *threo*:*erythro* ratio of 63:37) in 10 mL of ether over 10 min. The reaction mixture was stirred for 2 h at −78°C, and then at 0°C for 3 h. The reaction was quenched with 20% aqueous NH_4Cl solution, the phases separated, and the aqueous layer extracted twice with ether. The combined ether extracts were washed with saturated aqueous $NaHCO_3$, water, and aqueous NaCl, dried ($MgSO_4$), and evaporated under vacuum. The crude product was flash chromatographed, eluting with 30 → 60% ether–hexanes, to afford 64.1 mg (11%) of a compound having ^{1}H and ^{13}C NMR spectra identical to those of the (22*S*)-allylic alcohol **8** (R_f 0.65, 80% ether–hexanes), followed by 179.3 mg (83% recovery) of the pure unreacted (*erythro*) epoxy alcohol **16** (R_f 0.48, 80% ether–hexanes), 44.2 mg (11% based on the (*threo*) epoxide **15**) of the 22,24-diol **18** (R_f 0.37, 80% ether–hexanes), and 252.3 mg (63% based on the (*threo*) epoxide **15**) of the desired 22,23-diol **17** (R_f 0.27, 80% ether–hexanes), identical in all respects to an authentic sample (4*q*).

Compound **16** was a gum with IR (film): 3470, 1217, 1086, 1055, 959, 918, 733 cm^{-1}; ^{1}H NMR (200 MHz) δ: 4.27 (m, 1 H), 4.10 (m, 1 H), 3.92 (m, 4 H), 3.75 (m, 1 H), 3.14 (dq, J = 5.3, 2.3 Hz, 1 H, 24-H), 2.65 (m, 1 H, 23-H), 1.48 (s, 3 H, acetonide), 1.34 (d, J = 5.3 Hz, 3 H, 25-Me), 1.33 (s, 3 H, acetonide), 0.96 (d, J = 6.3 Hz, 3 H, 21-Me), 0.84 (s, 3 H, 19-Me), 0.70 (s, 3 H, 18-Me); ^{13}C NMR (50.3 MHz) δ: 109.6 (C), 107.5 (C), 72.8 (CH), 72.7 (CH), 70.3 (CH), 65.4 (CH_2), 64.1 (CH_2), 61.6 (CH), 55.7 (CH), 52.8 (CH), 52.0 (CH), 51.8 (CH), 45.4 (CH), 42.6 (CH_2), 42.3 (C), 40.9 (CH_2), 39.5 (CH_2), 38.1 (CH), 37.9 (C), 32.9 (CH), 28.6 (CH_3), 27.5 (CH_2), 26.5 (CH_3), 24.0 (CH_2), 21.9 (CH_2), 20.7 (CH_2), 17.0 (CH_3), 13.3 (CH_3), 12.7 (CH_3), 11.8 (CH_3); mass spectrum, m/z (relative intensity); 504 (M^+, 11), 489 (44), 473 (15), 460 (12), 445 (39), 431 (52), 359 (19), 293 (69), 249 (71), 239 (44), 235 (80), 99 (89), 43 (100). Exact Mass calcd. for $C_{30}H_{48}O_6$: 504.3451; found: 504.3440.

Compound **18** was a gum with IR (film): 3461, 1217, 1086, 1055, 756, 735 cm^{-1}; ^{1}H NMR (200 MHz) δ: 4.27 (m, 1 H), 4.10 (m, 1 H), 3.94 (m, 5 H), 3.75 (m, 1 H), 1.48 (s, 3 H, acetonide), 1.33 (s, 3 H, acetonide), 1.27 (d, J = 6.8 Hz, 3 H, 25-Me), 0.95 (d, J = 6.0 Hz, 3 H, 21-Me), 0.90 (d, J = 6.9 Hz, 6 H, isopropyl CH_3 groups), 0.84 (s, 3 H, 19-Me), 0.69 (s, 3 H, 18-H); ^{13}C NMR (50.3 MHz) δ: 109.7 (C), 107.5 (C), 73.4 (CH), 72.9 (CH), 72.8 (CH), 67.4 (CH), 65.5 (CH_2), 64.1 (CH_2), 55.9 (CH), 53.0 (CH), 52.6 (CH), 51.4 (CH), 45.5 (CH), 42.7 (CH_2), 42.4 (C), 41.0 (CH_2), 39.7 (CH_2), 39.2 (CH), 38.0 (C), 33.0 (CH), 28.6 (CH_3), 27.8 (CH), 27.7 (CH_2), 26.5 (CH_3), 25.7 (CH_3), 24.1 (CH_2), 22.0 (CH_2), 20.8 (CH_2), 20.3 (CH_3), 18.1 (CH_3), 13.4 (CH_3), 11.9 (CH_3); mass spectrum, m/z (relative intensity): 548 (M^+, 5), 533 (32), 515 (5.5), 486 (6), 471 (9), 446 (19), 431 (53), 418 (43), 389 (31), 360 (100), 337 (33), 235 (85), 131 (47), 99 (84), 43 (81). Exact Mass calcd. for $C_{33}H_{56}O_6$: 548.4077; found: 548.4101.

Castasterone (2) and brassinolide (1)

The 22,23-diol **17** (201.8 mg, 0.3677 mmol) was hydrolyzed as described previously (4*q*) to afford 150.7 mg (88%) of castasterone (**2**) (R_f 0.43, 10% ethanol–chloroform), mp 248–250°C (from ethyl acetate) (lit. (4*c*) mp 250–252°C; lit (4*q*) mp 248–252°C), identical in all respects to an authentic sample (4*q*).

Acetylation of **2** to the tetraacetate **19** (98%) and oxidation with trifluoroperoxyacetic acid was effected by a literature method (4*d*) to afford an 81% yield of a mixture of 7-oxalactone **20** and 6-oxalactone **21**, obtained in the ratio of 81:19, as determined by NMR integration. Pure **20** was isolated by flash chromatography, eluting with 20 → 30% ethyl acetate – hexanes, and had properties in close agreement with the literature (4*d*). Lactone **21** contained some **20** even after chromatography, but its presence in the mixture was inferred from the ^{1}H NMR signal of its 5α-proton at δ 4.47 (dd, J = 10.9, 5.9 Hz), compared with that of **20** at δ 2.99 (dd, J = 12.3, 4.6 Hz).

Saponification of **20** was achieved with NaOH in methanol water (4*d*), to afford pure brassinolide after flash chromatography and recrystallization from methanol, mp 273–276°C (lit. (1) mp 274–275°C), with spectral properties in accordance with those reported in the literature (1, 4*a*, 4*c*, 4*d*).

Oxidation of castasterone (2) with peroxyseleninic acids

Hydrogen peroxide (37 μL of 30%, 0.36 mmol) was added to a solution of benzeneseleninic acid (4.3 mg, 23 μmol) in 1 mL of THF and 0.5 mL of water at room temperature. A solution of castasterone (**2**) (8.4 mg, 18 μmol) in 2 mL of THF and 0.5 mL of water was then added and the mixture was stirred for 48 h, followed by heating at 75°C for 18 h. An additional 20 equivalents of hydrogen peroxide were added during this time. The reaction mixture was diluted with ether, washed with saturated aqueous $NaHCO_3$, and dried ($MgSO_4$). Removal of the solvent under vacuum gave a residue containing the 7-oxa- and 6-oxalactones **1** and **22** in the ratio of 14:86, as well as some unreacted **2**. The 7-oxa:6-oxa ratio was determined by integration of the ^{1}H NMR signals due to the 5α-protons at δ 3.13 (dd, J = 12.2, 4.5 Hz) from **1**, and at δ 4.61 (dd, J = 11.1, 5.6 Hz) from **22**.

When the above reaction was repeated using *o*-nitrobenzeneseleninic acid in place of benzeneseleninic acid, the ratio of **1**:**22** was 27:73.

Synthesis and basicity of 2-*N*-quinolyl- and 2-*N*-isoquinolyl-1,1,3,3-tetramethylguanidines

NASER FOROUGHIFAR[1], KENNETH T. LEFFEK, AND YONG GU LEE[2]
Department of Chemistry, Dalhousie University, Halifax, N. S., Canada B3H 4J3

Received September 18, 1992

NASER FOROUGHIFAR, KENNETH T. LEFFEK, and YONG GU LEE. Can. J. Chem. **71**, 164 (1993).

A series of 2-*N*-quinolyl- and 2-*N*-isoquinolyl-substituted 1,1,3,3-tetramethylguanidines has been synthesized and the pK_a of each has been measured in acetonitrile and water solvents, together with the pK_a of the corresponding aminoquinoline or aminoisoquinoline. The pK_a values in acetonitrile and water fall on the same correlation line as previously determined for 2-*N*-pyridylguanidines and aminopyridines. Replacement substituent constants (σ_a) are reported for several quinolyl and isoquinolyl groups in the two solvents.

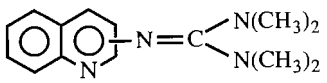
NASER FOROUGHIFAR, KENNETH T. LEFFEK et YONG GU LEE. Can. J. Chem. **71**, 164 (1993).

On a synthétisé une série de 1,1,3,3-tétraméthylguanidines substituées par des groupes 2-*N*-quinoléyle et 2-*N*-isoquinoléyle et on a déterminé le pK_a de chacun de ces produits, ainsi que ceux des aminoquinoléines et aminoisoquinoléines correspondantes, dans l'acétonitrile et dans l'eau. Les valeurs des pK_a dans l'acétonitrile et dans l'eau tombent sur la même ligne de corrélation que celle établie antérieurement pour les 2-*N*-pyridylguanidines et pour les aminopyridines. On rapporte les constantes de remplacement des substituants (σ_a) de plusieurs groupes quinoléyles et isoquinoléyles dans les deux solvants.

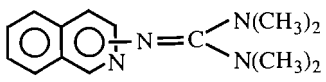
[Traduit par la rédaction]

Introduction

This work continues the study of the basicity of 2-*N*-substituted 1,1,3,3-tetramethylguanidines (TMG) in water and acetonitrile solvents (1, 2). A series of 2-*N*-quinolyl (**1**) and isoquinolyl (**2**) derivatives have been prepared from the analogous aminoquinoline compounds and their pK_a's determined, together with those of the starting materials. Some quinoline compounds with N-containing basic substituents have been found to be physiologically active as hypertensive agents (3, 4) or antimalarial drugs (5–7), and it is possible that some of the new TMG compounds may show such activity.



1



2

The pK_a's of these aminoquinolines and quinolyl TMG's allow a further refinement of the relationship between the basicity in acetonitrile and that in water. They also allow the evaluation of the replacement substituent constants for the quinolyl groups.

Results and discussion

The pK_a values of the conjugate acids of the bases in acetonitrile and water solvents are collated in Table 1. All of the bases are stronger in acetonitrile than in water, as previously observed, reflecting the weaker proton-accepting power of acetonitrile relative to water (2, 10). The solvent effect on the pK_a is consistent with that previously reported (2) and if the 13 compounds in Table 1 are combined with those measured previously, the relationship expressed by eq. [1] is obtained for a total of 51 TMG, pyridine, and quinoline bases, which has the same values for the slope and intercept as previously calculated (2) for 38 of these bases.

$$[1] \quad pK_a^{AN} = (1.11 \pm 0.02)\, pK_a^{W} + 7.0 \pm 0.2$$

This equation, which has a correlation coefficient (c.c.) of 0.986, provides a reliable means of calculating the pK_a of such bases in acetonitrile from that in water with a standard deviation of less than 0.5 pK_a units for a strong base. Within this limit, the pK_a change with solvent for these classes of base is independent of the structure of the base and depends only on the properties of the solvents.

In the series of aminoquinolines, in which the ring nitrogen atom is protonated (11), the strongest base is the 4-amino-2-methylquinoline when the amino group is *para* to the ring N atom, followed by the 1-aminoisoquinoline when the amino group is *ortho* to the ring N atom. These structures allow through-resonance in the protonated molecule between the positively charged ring nitrogen and the amino group, giving these structures an enhanced stability, i.e., increasing the base strength of the amine. Of the remaining structures, only the 5-aminoquinoline allows through-resonance but this compound shows no enhanced basicity over that of the amino group in any other position on the quinoline or isoquinoline ring. A minimum basicity occurs in the 8-aminoquinoline. In contrast to this, in the TMG series in which the 2-*N* atom of the TMG group is protonated, the 2(8′-quinolyl) TMG is the strongest base, indicating the probable involvement of both the TMG N atoms and the ring N atom in the binding of the proton. Protonated TMG bases have the positive charge considerably delocalized over all three N atoms (12) and it is probable that in the protonated 2-(8′-quinolyl) TMG the ring N atom is close enough to the proton that it too is weakly bonded to the proton. The other quinolyl TMG compounds all give approximately the same pK_a. Involvement of the ring N atom and the TMG N atoms in the proton binding may also account for the greater basicity of 2-(1′-isoquinolyl) TMG relative to that of 2-(5′-isoquinolyl) TMG.

Using the Hammett correlations previously determined (2)

TABLE 1. pK_a values for derivatives of TMG and quinoline bases in acetonitrile and water solvents

No.	Compound	pK_a^{AN}	pK_a^{W}
1.	3-Aminoquinoline	12.58 ± 0.04	4.86[a]
2.	2-methyl-4-Aminoquinoline	17.98 ± 0.11	9.78 ± 0.15
3.	5-Aminoquinoline	13.04 ± 0.03	5.46[a]
4.	6-Aminoquinoline	13.35 ± 0.14	5.63[a]
5.	8-Aminoquinoline	11.14 ± 0.01	3.99[a]
6.	1-Aminoisoquinoline	15.10 ± 0.06	7.62[a]
7.	5-Aminoisoquinoline	13.21 ± 0.04	5.59[b]
8.	2(3′-Quinolyl) TMG	18.57 ± 0.12	10.32 ± 0.06
9.	2(2′-Methyl-4′-quinolyl) TMG	18.93 ± 0.12	10.45 ± 0.22
10.	2(5′-Quinolyl) TMG	18.69 ± 0.12	10.90 ± 0.04
11.	2(6′-Quinolyl) TMG	18.68 ± 0.15	11.22 ± 0.02
12.	2(8′-Quinolyl) TMG	20.46 ± 0.15	11.74 ± 0.03
13.	2(1′-Isoquinolyl) TMG	—[c]	12.03 ± 0.04
14.	2(5′-Isoquinolyl) TMG	17.68 ± 0.19	10.83 ± 0.07

[a]From ref. 8.
[b]From ref. 9.
[c]Picrate insufficiently soluble in acetonitrile.

TABLE 2. Replacement substituent constants for quinolyl groups in water and acetonitrile solvents

Group	σ_a^{W}	σ_a^{AN}
3-Quinolyl	0.72	0.92
5-Quinolyl	0.37	0.87
6-Quinolyl	0.17	0.87
8-Quinolyl	−0.15	0.10
1-Isoquinolyl	−0.32	—
5-Isoquinolyl	0.41	1.31

for the conjugate acids of 2-*N*-substituted TMG compounds, eqs. [2] (c.c. 0.989) and [3] (c.c. 0.987), a σ_a value may be calculated, i.e., a σ value that the aryl group would show if the group replaces a phenyl group in a molecule (13),

$$[2] \quad pK_a^{AN} = -(2.31 \pm 0.14)\sigma + 20.7 \pm 0.1$$

$$[3] \quad pK_a^{W} = -(1.64 \pm 0.11)\sigma + 11.5 \pm 0.1$$

for each of the aryl groups attached to the TMG. Values of σ_a^{AN} and σ_a^{W} (relative to the phenyl group), calculated from eqs. [2] and [3] respectively, for the quinolyl and isoquinolyl groups are shown in Table 2. A value of $\sigma_a = 0.23$ has been reported (14) for the 6-quinolyl group in water, which is not significantly different from our value of 0.17, given that the standard deviations of the parameters in Table 2 are of the order of ±0.2. In water, the only groups with negative σ_a values (base strengthening) are the 8-quinolyl and 1-isoquinolyl groups where the ring N atom and the TMG N atoms may both be involved with proton binding.

There is a clear solvent effect on σ_a between water and acetonitrile, as is required by eqs. [1], [2], and [3]. Combination of these three equations leads to eq. [4]. Since pK_a^{W} is greater than 10 for all the quinolyl groups in Table 2, σ_a^{AN}

$$[4] \quad \sigma_a^{AN} = \sigma_a^{W} + 0.14\,pK_a^{W} - 1.22$$

should always be greater than σ_a^{W} by more than 0.2 units. Table 2 indicates a solvent effect on σ_a much larger than this but the standard deviation of the σ_a of about ±0.2 precludes a quantitative estimate of the solvent effect. Equation [4] provides a means to smooth the data and yields ($\sigma_a^{AN} - \sigma_a^{W}$) values of 0.2–0.4. The only other example in the literature of a solvent effect on σ_a is for the 2-pyridyl group (15), which showed a change of 0.17 between 56% acetone and 60% DMSO, while the 3-pyridyl and 4-pyridyl groups showed an insignificant change between these solvents.

Experimental

Substituted 2-quinolyl- and 2-isoquinolyl-1,1,3,3-tetramethylguanidines were synthesized using a modification of the procedure of Bredereck, as previously described (16). The aminoquinolines were commercially available (Aldrich) and were dried and purified as necessary.

The picrates of the bases were made by reaction with an equimolar amount of picric acid in 95% ethanol (1, 2), followed by recrystallization from ethanol. The melting points are uncorrected. The ^1H and ^{13}C nmr spectra were run in chloroform-*d* (except where noted) with TMS as the internal standard, using either a Bruker AC 250F or a Nicolet 360 nmr spectrometer, at the Atlantic Resonance Centre, Dalhousie University. The mass spectra were recorded on a modified Du Pont CEC model 21–104 mass spectrometer at 70 eV. The ^{13}C nmr signals are reported in the sequence shown on structures **3** and **4** for the quinoline and isoquinoline compounds, respectively, followed (in one structure) by the ring-substituted methyl group.

M. BALÓN, P. GUARDADO, C. CARMONA, J. HIDALGO, and M. A. MUÑOZ. Can. J. Chem. **71**, 167 (1993).

A kinetic study is reported on the oxidation of diphenylamine (DPA) by peroxodisulfate (PDS) anions in H_2SO_4 and buffered acetic acid – acetate 20% v/v methanol–water media. The primary detectable product of the reaction is *N*-phenyl-*p*-benzoquinoneimine (PBQ), which undergoes acid-catalyzed hydrolysis giving different decomposition products. At pH > 4 (acetic acid – acetate buffers) the hydrolytic decomposition is very slow and it does not interfere with PBQ formation, but in H_2SO_4 media of pH < 2.5, PBQ decomposes as it is formed. In these media, the reaction obeys the kinetic rate law:

$$\left[\text{rate} = \frac{a\,[\text{PDS}]\,[\text{DPA}]_T}{1 + b\,[\text{PDS}]}\right]$$

a, the kinetic parameter, being acid dependent. Neither radical promoters (Ag^+) nor radical traps (allyl alcohol) influence the reaction rate. In acetic acid – acetate buffers of pH > 4 the kinetic rate law is simple: first order in each one of the reactants, and acid independent. These results have been interpreted by assuming the formation, in a preequilibrium step, of an *N*-diphenylhydroxylamine-*O*-sulfonate intermediate, which further rearranges to yield PBQ. The rate-determining step of the reaction changes with the protonation state of the intermediate, whose protonation pK_a has been kinetically estimated as 2.4.

M. BALÓN, P. GUARDADO, C. CARMONA, J. HIDALGO et M. A. MUÑOZ. Can. J. Chem. **71**, 167 (1993).

On a réalisé une étude cinétique de l'oxydation de la diphénylamine (DPA) par les anions peroxodisulfate, dans de l'acide sulfurique et dans des solutions tamponnées acide acétique – acétate dans un mélange méthanol–eau à 20% v/v. La *N*-phényl-*p*-benzoquinoneimine (PBQ) est le produit primaire de la réaction qui subit une hydrolyse acidocatalysée conduisant à divers produits de décomposition. À un pH > 4 (tampons acide acétique – acétate), la décomposition par hydrolyse est très lente et elle n'interfère pas avec la formation de la PBQ; toutefois, dans l'acide sulfurique (pH < 2,5), la PBQ se décompose au fur et à mesure de sa formation. Dans ces milieux, la loi de vitesse cinétique de la réaction est:

$$\left[\text{vitesse} = \frac{a\,[\text{PDS}]\,[\text{DPA}]_T}{1 + b\,[\text{PDS}]}\right]$$

dans laquelle *a* est le paramètre cinétique qui dépend de l'acide. Ni les promoteurs de radicaux (Ag^+) ni les pièges à radicaux (alcool allylique) n'influencent la vitesse de réaction. Dans les tampons acide acétique – acétate de pH > 4, la loi de vitesse cinétique est simple; elle est du premier ordre dans chacun des réactifs et elle est indépendante de l'acide. On interprète ces résultats en faisant l'hypothèse qu'il y a formation, dans une étape de prééquilibre, d'un intermédiaire *O*-sulfonate de la *N*-diphénylhydroxylamine qui se transpose par la suite en PBQ. L'étape qui détermine la vitesse de la réaction change avec l'état de protonation de l'intermédiaire dont on a évalué cinétiquement le pK_a de protonation à 2,4.

[Traduit par la rédaction]

Introduction

The oxidation reactions of aromatic amines by peroxodisulfate (PDS) anions have been extensively studied (1). Depending on the experimental conditions and the nature of the amine, the reactions can afford a variety of products derived from competitive mechanisms initially involving PDS attack on the amine nitrogen atom (2). Medium acidity is one of the major factors influencing the partitioning of the products, but its influence on the competitive mechanism is not yet well understood.

In contrast to the extensive literature on these reactions in neutral and basic media, very few reports have appeared on the reactions under acidic conditions. This is because the acidity range accessible for such studies is severely limited by the pK_a's of the amines (typically around 4) (3), since in their protonated forms they do not react with PDS. Diphenylamine (DPA), whose pK_a is 0.78 (3), is therefore of particular value for the study of the influence of the acidity on the kinetics of its reaction with PDS.

The kinetics of the oxidation of DPA by PDS have previously been investigated in aqueous methanol phosphate buffers (4) and in sodium hydroxide – acetonitrile–water media (5). In both solvent systems the reactions were simple, first order in each of the reactants and pH independent, but yielding different reaction products, *ortho*-diphenylamine sulfate and *N*-phenyl-*p*-benzoquinoneimine (PBQ), respectively. In this paper we report a more extensive study of this reaction over a wider acidity range (H_0/pH 0–6).

Experimental

Materials

DPA (>99%) was supplied by Aldrich Quimica and was used as received. Stock solutions of ca. 1×10^{-3} M were prepared in methanol and further diluted in aqueous H_2SO_4 or acetic acid – acetate buffers to obtain final solutions at the desired pH's. Potassium peroxodisulfate and other chemicals were AnalaR grade (Merck) and were used without further purification.

Kinetic measurements

Kinetic measurements were performed spectrophotometrically by monitoring the absorbances of the reaction mixtures with time at the absorption maxima of DPA, 278 nm (sulfuric acid media of

[a]PDS consumed after complete PBQ formation.
[b]Calculated from A_∞ data of several randomly selected kinetic runs followed at the absorption maxima of PBQ at 446 nm (ϵ = 4266 M^{-1} cm^{-1}). Yields are referred to $[DPA]_0$ concentrations.

$H_0 < 2.5$), or at the absorption maxima of the reaction product PBQ, 446 nm (acetic acid – acetate buffers of pH > 4), with a LKB Ultrospec Plus spectrophotometer connected to a Multitech personal computer to control the spectrophotometric system, and the uptake and processing of the data. The temperature control in the cell holder of the spectrophotometer was better than ±0.1°C.

Kinetic runs were carried out under pseudo-first-order conditions in solutions containing PDS in, at least, a tenfold excess. Pseudo-first-order rate constants, k_{obs}, were obtained by a nonlinear least-squares fitting of the absorbance–time data to eq. [1] where A_0, A_∞, and k_{obs} are floating parameters.

$$[1] \quad A_t = A_\infty + (A_0 - A_\infty) \exp(-k_{obs}t)$$

Usually, an excellent agreement between experimental and calculated A_t values was obtained for several half-lives (standard deviation of fitting $< \pm 2.0 \times 10^{-6}$). Rate constants in duplicate runs were reproducible to within better than 8%. In some instances, the reactions exhibited a short induction period. However, when it was eliminated the above treatment was fully satisfactory.

Results

Product analysis

Typical reaction mixtures were monitored by UV–visible spectrophotometry at 25°C in 20% v/v methanol–water media in the H_0/pH region 0–6. At pH > 4 (acetic acid – acetate buffers) the reaction proceeds cleanly with formation of a product absorbing at 446, 285, and 264 nm. In addition, the repetitive spectra exhibit isosbestic points at 300 and 240 nm, indicating that there is no significant buildup of intermediates. This reaction product was isolated as previously described (5) and identified by UV–vis, IR, and ^{13}C NMR spectra as *N*-phenyl-*p*-benzoquinoneimine (PBQ).

PBQ yield was examined as a function of the reactant concentrations, temperature, and pH. As data in Table 1 show, neither the reactant concentrations nor the temperature nor the pH of the reaction media significantly affect the PBQ yield. Conversely, it appears to be markedly dependent on the ratio of the reactant concentrations. Thus, when the DPA:PDS ratio is greater than 10, no PBQ formation could be detected by TLC analysis (Kieselgel 60F Merck plates, 70:30 benzene – petroleum ether). In this case, the reaction follows an entirely different course; *o*- and *p*-diphenylamine sulfate being the reaction products. These typical products of the Boyland–Sims oxidations (16) could not be detected by TLC analysis of reaction mixtures containing PDS in excess over DPA.

Table 1 also presents results on the PDS consumed in the reactions. In these experiments, reaction mixtures containing a moderate excess of PDS over DPA were allowed to go to complete PBQ formation. Different ratios of PDS:DPA were taken and, after the reaction was over, the mixtures were extracted with ether (PBQ slowly reacts with PDS) and the remaining PDS in the aqueous phase was estimated by iodometry. The average number of moles of PDS consumed was 1.2 ± 0.1, based on DPA as the limiting reagent.

Below pH 4, the initial course of the reaction is similar, but PBQ slowly decomposes to a significant extent during the reaction. This reaction is acid catalyzed, so that at pH <2.5 only traces of PBQ could be detected in the spectra of the reaction mixtures. In these media, the spectra of the completed reaction mixtures were comparable with those of PBQ subjected to the same acidic conditions. Furthermore the quantitative transformation of PBQ is demonstrated by the spectra in Fig. 1. In this figure the spectral changes with time for a reaction mixture in H_2SO_4 media are compared with the spectra of a reaction mixture of the same composition at pH = 5 that was further acidified at the end of the reaction until an acid (H_2SO_4) concentration of 0.02 M was reached.

PBQ is known to hydrolyze in acid media (6), the initial products being *p*-benzoquinone and aniline, which can further condense to other polymeric products. This hydrolytic reaction is acid catalyzed with a half-life smaller than 20 s at 25°C in 0.01 M H_2SO_4 20% v/v methanol–water media.

Kinetic studies; rate laws

The kinetics of DPA oxidation by PDS were monitored by UV–visible methods at 25°C in 20% v/v methanol–water media, whose pH's were maintained in the 0–6 H_0/pH region by adding appropriate H_2SO_4 solutions (H_0 ~0–~2.5) or acetic acid – acetate buffer (pH's 4–6) solutions. Throughout these H_0/pH regions the reaction exhibited clean pseudo-first-order kinetics, but in the intermediate pH 2.5–4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

region important deviations from this behaviour were observed due to the interference of PBQ hydrolysis. Attempts to fit the absorbance–time data to a double exponential equation did not give satisfactory results. Therefore, unfortunately, we could not obtain kinetic data in this pH region.

The influence of the acidity on k_{obs} is shown in Fig. 2. In agreement with previous reports (4, 5), we find that above pH 4 the reaction rate is independent of acidity and first order in each of the reagents (Table 2). At 25°C and 20% methanol–water, the overall second-order rate constant has a value of 5.84×10^{-2} M^{-1} s^{-1}, and the activation parameters are $\Delta H^{\neq} = 31 \pm 2$ kJ mol^{-1} and $\Delta S^{\neq} = -181 \pm 6$ J mol^{-1} K^{-1}. Since this reaction was previously investigated by other authors, we have not carried out more extensive studies in this pH region.

The results of the kinetic studies at varying H_2SO_4 and PDS concentrations are collected in Table 3. At fixed $[H_2SO_4]$, k_{obs} increases with [PDS], although plots of k_{obs} vs. [PDS] are curved. Within the range of [PDS], k_{obs} was found to fit the empirical eq. [2].

$$[2] \quad k_{obs} = \frac{a\,[PDS]}{1 + b\,[PDS]}$$

which can be rearranged to give eq. [3].

$$[3] \quad 1/k_{obs} = 1/a\,[PDS] + b/a$$

The linearity of the double reciprocal plots of k_{obs}^{-1} vs. $[PDS]^{-1}$, shown in Fig. 3, confirms the consistency of eq. [2]. The values of the kinetic parameters a and b in eq. [2] collected in Table 4 were obtained from the slopes and intercepts of these plots.

To get a better insight into the reaction mechanism, the effects of Ag^+ ions ($1 \times 10^{-5} - 1 \times 10^{-6}$ M) and allyl alcohol (up to 1% v/v) on the reaction rates were also examined. The former ions are known to be an effective catalyst for radical peroxodisulfate reactions (7, 8), whereas the alcohol is an excellent radical trap (9). Neither of them had a detectable effect on k_{obs} and therefore these results are not reported. This can be taken as evidence for the noninvolvement of radicals in the reaction mechanism. These results, on the other hand, contrast with those reported for the inhibitory effects of allyl alcohol on the reaction rates of this and other related reactions in less acidic media (5, 10). It is also to be noted that the addition of Na_2SO_4 up to 0.1 M did not have an effect on the reaction rates.

Discussion

The results of the product analysis indicate that, under our experimental conditions ([PDS] >> [DPA]), PBQ is the primary detectable reaction product in the oxidation of DPA by PDS. This compound undergoes acid-catalyzed hydrolysis, initially giving *p*-benzoquinone and aniline (6) and further, different, polymeric condensation products. At pH > 4 the hydrolysis of PBQ is very slow and it does not interfere with PBQ formation. However, this hydrolysis is greatly enhanced by acid and at pH < 2.5 PBQ decomposes as it is formed, PBQ formation therefore being the rate-controlling step.

The pH–rate profile of the reaction is complex. As shown in Fig. 2, k_{obs} reaches a maximum value around H_0 1.8, which is flanked by inflection points around H_0 1.3 and pH 2.5, respectively. Before the plateau region at pH > 4 a third inflection point is also expected, but could not be determined due to the previously mentioned kinetic problems. The decrease of k_{obs} at H_0 below the maximum might be clearly imputed to DPA protonation ($pK_a = 0.78$) (3), since the protonated amine is expected to be inert toward oxidation by PDS (2). The further decrease of k_{obs} after the maximum is more difficult to rationalize.

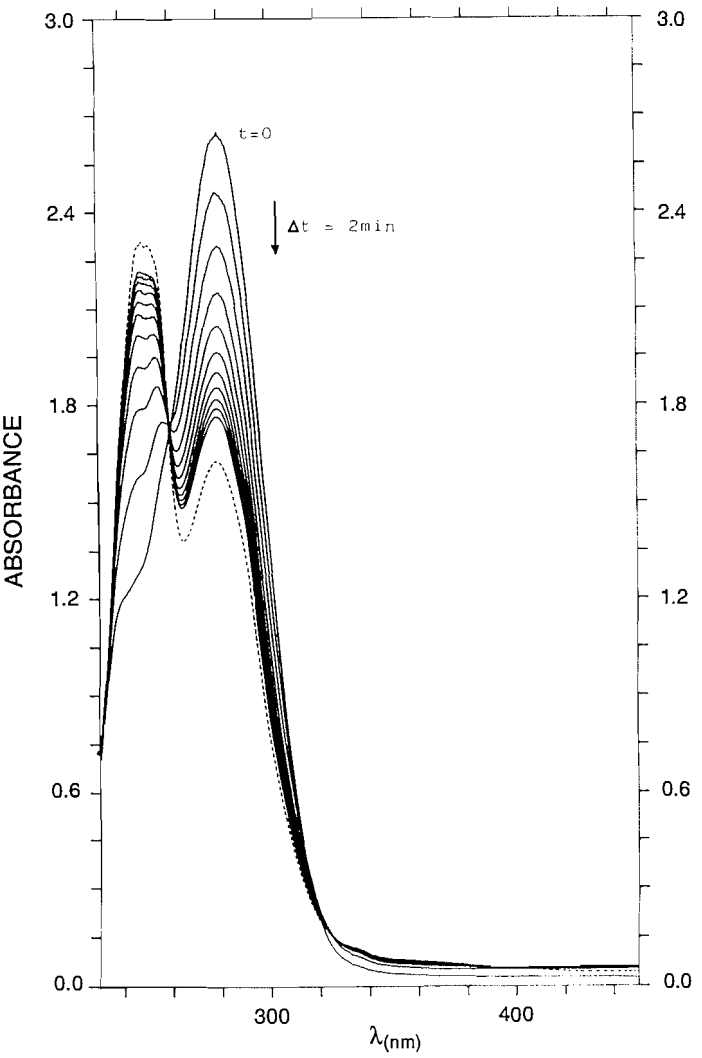

FIG. 1. Spectral changes with time of a reaction mixture ([PDS] = 4×10^{-2} M and [DPA] = 2×10^{-4} M) in 20% v/v methanol–water and 0.02 M H_2SO_4. The dotted line corresponds to the reaction product of a mixture with the same composition, but initially at pH = 5, which at the end of the reaction was acidified until a final H_2SO_4 acid concentration of 0.02 M.

One possible explanation for it might be the PDS protonation ($HS_2O_8^- \rightarrow S_2O_8^{2-} + H^+$), by assuming a greater reactivity for $HS_2O_8^-$ than for $S_2O_8^{2-}$ ions. However, the inflection point in the pH–rate profile at pH ~2.5 is somewhat larger than that expected from the pK_a value of PDS protonation. It has been estimated, although with great uncertainty, to be close to 1 (11). Moreover, PDS protonation equilibria could not explain the further increase of k_{obs} up to the plateau region nor the changeover in the kinetic behaviour of the reaction below pH 2.5 and above pH 4.

Since there are no ionizable functions in the reagents with an expected pK_a value in the vicinity of 3, we then consid-

ered the possible formation of an intermediate having this pK_a value. Thus, the present results of the DPA–PDS reaction can be more easily explained by assuming the formation, in a preequilibrium step, of an intermediate that rearranges to give PBQ. This interpretation also implies, as will be seen below, different rate-controlling steps in the mechanism depending on the protonation state of the intermediate.

The nonlinear form of the rate law [2] obtained in H_2SO_4 media supports the hypothesis of intermediate formation. Furthermore, the existence of an induction period early in the reaction might be taken as evidence that the proposed intermediate is indeed on the reaction coordinate. It can be attributed to the time required for the buildup of the intermediate. In view of the nature of the reagents and

reaction products, we think that diphenylhydroxylamine-*O*-sulfonate (I) is a reasonable structure for the proposed intermediate. Phenylhydroxylamines, on the one hand, are known to have protonation pK_a's close to that expected for the proposed intermediate (12, 13) and, on the other hand, these compounds experience rearrangement reactions to give aminophenols (Bamberger rearrangement) (12, 14) that are structurally related to PBQ. It must be also noted that similar arylhydroxylamine-*O*-sulfonates were recently proposed

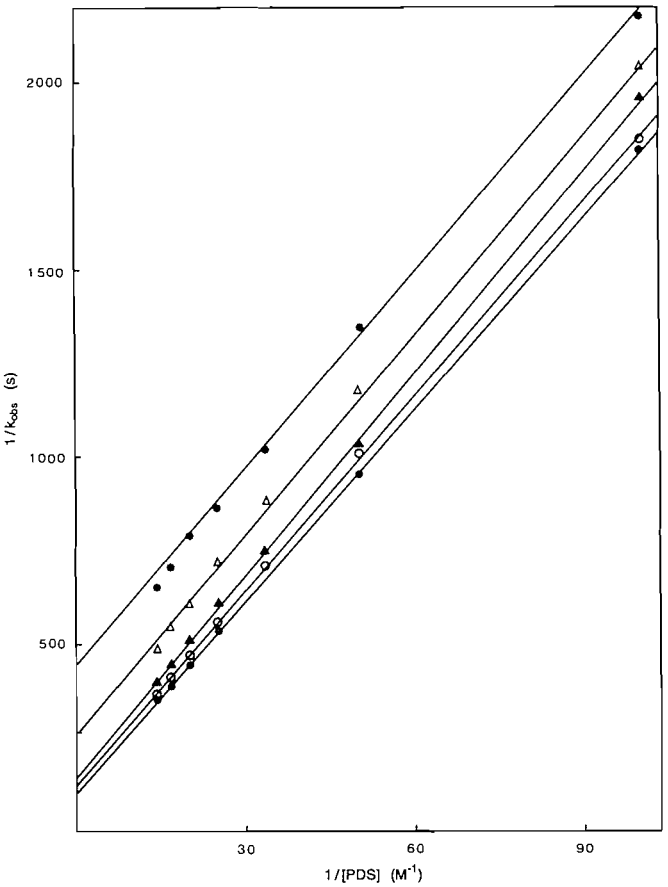

FIG. 3. Plots of k_{obs}^{-1} vs. $[PDS]^{-1}$ for the DPA–PDS reaction in 20% v/v methanol–water media at 25°C. Sulfuric acid concentrations: 2×10^{-2} M (●), 1×10^{-2} M (○), 5×10^{-3} M (▲), 2.5×10^{-3} M (△), and 1×10^{-3} M (*).

as the more probable intermediates in the Boyland–Sims oxidation of aromatic amines by PDS (2, 15).

Scheme 1 outlines a minimal mechanism consistent with the above considerations. Depending on the relative magnitudes of the microscopic constants, this mechanism would give rise to several specific situations, any one of which may occur in the present system.

The rate equation expected from Scheme 1 by assuming the steady-state concentration for the intermediate IH^+ or I is given in eq. [4] where [DPA] is the actual concentration of substrate ($[DPA]_T$ = [DPA] + [I or IH^+]):

$$[4] \quad \text{rate} = \frac{k_1 k_2 [PDS] [DPA]_T}{k_2 + k_{-1} [SO_4^{2-}] + k_1 [PDS]}$$

With [PDS] >> [DPA], the measured first-order rate constant k_{obs} (defined by rate = k_{obs} [DPA]) is given by eq. [5]:

$$[5] \quad k_{obs} = \frac{k_1 k_2 [PDS]}{k_2 + k_{-1} [SO_4^{2-}] + k_1 [PDS]}$$

Equation [5] can be identified with experimental eq. [2] obtained in sulfuric acid media provided that (*i*) $k_{-1} [SO_4^{2-}] << k_2 + k_1 [PDS]$ ($a = k_1^{IH}$ and $b = k_1^{IH}/k_2^{IH}$) or (*ii*) $k_2 << k_{-1} [SO_4^{2-}] + k_1 [PDS]$ ($a = k_2^{IH} K_1^{IH}/[SO_4^{2-}]$ and $b = k_1^{IH}/[SO_4^{2-}]$). Equation [5] predicts a retarding effect of $[SO_4^{2-}]$ ions; therefore, since Na_2SO_4 addition does not affect k_{obs} it may be assumed that situation (*i*) predominates over (*ii*).

25	0.0010	5.56	22.51

A similar dichotomy of mechanistic possibilities can be envisioned to account for the experimental rate law obtained in media of pH > 4; (*i*) the intermediate, I, is formed in a reversible step but $k_2^I >> k_1^I$, k_1^I being, therefore, the rate-limiting step, and (*ii*) the mechanism operates with $k_{-1}^I [SO_4^{2-}] >> k_2^I$, the rate-controlling constant being $k_2^I k_1^I$. In both cases, the intermediate will be in a steady state and its concentration small relative to the reactants, as it is required by the experimental evidence that the intermediate I does not accumulate. A key observation that can help to decide between the two possibilities is the fact, previously pointed out, that k_{obs} has similar values at high sulfuric acid concentration and in acetic acid – acetate buffers of pH > 4. This fact might be taken as evidence that in both cases the rate-limiting attack is the same; i.e., the PDS attack on DPA, k_1.

Bearing in mind the above assumptions, the kinetic data in Tables 2 and 4 can be analyzed to obtain the microscopic constants in Scheme 1, which are presented in Table 5. A perusal of the data in this table reveals the satisfactory correspondence between k_1^{IH} and k_1^I and among their activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$. The low activation enthalpies and the high negative activation entropies, together with the experimental observations that neither radical promoters nor radical traps have influence on the reaction rates, suggest that the formation of the diphenylhydroxylamine intermediate does not involve a radical mechanism. These results strongly support the formation of the intermediate as a polar mechanism involving nucleophilic displacement of the lone pair of the DPA nitrogen atom on the peroxide group of PDS (16).

On the other hand, the simplest mechanistic interpretation for the rearrangement process, k_2, might be the cleavage of the nitrogen–oxygen bond in the intermediate. However, the experimental evidence supported by the pH–rate curve points clearly to the existence of two separate pathways for each of the conjugate acid–base forms IH^+ and I of the intermediate. The more important difference from a kinetic point of view is that the rearrangement of IH^+ might be slower than that of I and, apparently, acid catalyzed. It means, in other words, that IH^+ is more stable to rearrangement than I. This could be related to the zwitterionic structure of IH^+, which would greatly decrease the leaving tendency of the sulfate group.

The acid dependence of k_2^{IH} resembles the Bamberger rearrangement of phenylhydroxylamines to aminophenols (12, 14) and points to a similar mechanism. This mecha-

nism is shown in Scheme 2 and involves the heterolytic cleavage of the N—O bond and the formation of a resonance-stabilized imine ion (14), which reacts with the solvent in fast steps leading to the final product. As in the Bamberger rearrangement, it can be assumed that the reaction proceeds by an S_N1 mechanism and that the active species are not the *N*-protonated ones but the *O*-protonated species (I_OH^+) of the diphenylhydroxylamine sulfate intermediate.

The kinetic rate law previously derived from the Bamberger rearrangement (12, 14) can be adapted to obtain the expression for k_2 in eq. [6]

$$[6] \quad k_2 = \frac{k K_a^N [H^+]}{K_a^O (K_a^N + [H^+])} = \frac{k_N [H^+]}{K_a^N + [H^+]}$$

where $k_N = k K_a^N / K_a^O$, K_a^O and K_a^N being the dissociation constants of the *O*- and *N*-protonated forms of the IH^+ intermediate. As would be expected, the double reciprocal plot of k_2^{-1} vs. $[H^+]^{-1}$ yields a straight line (Fig. 4) from whose slope and intercept the values of 1.1×10^{-2} M^{-1} s^{-1} and 2.4 ± 0.6 can be estimated for k_N and pK_a^N, respectively. These values, as well as the $\Delta H^{\neq}$ value, are of the magnitudes expected for the Bamberger rearrangement (12, 14) of a phenylhydroxylamine derivative. However, the negative activation entropy of −45 ± 25 eu, in the range of the expected value for a bimolecular hydrolysis, is in contrast to the small and usually positive entropies observed for typical unimolecular Bamberger reactions (12). Therefore, although the great uncertainty inherent in the calculation procedure of $\Delta S^{\neq}$ obscures its significance, the possibility of a bimolecular N—O bond cleavage assisted by a water molecule cannot be ruled out.

Because of the lack of kinetic information, the rearrangement mechanism for the unprotonated intermediate I is more difficult to rationalize. However, in spite of the previously assumed differences for the rearrangement reactions of IH^+ and I, their mechanisms are not expected to be very different, since both conjugate species lead to the same rear-

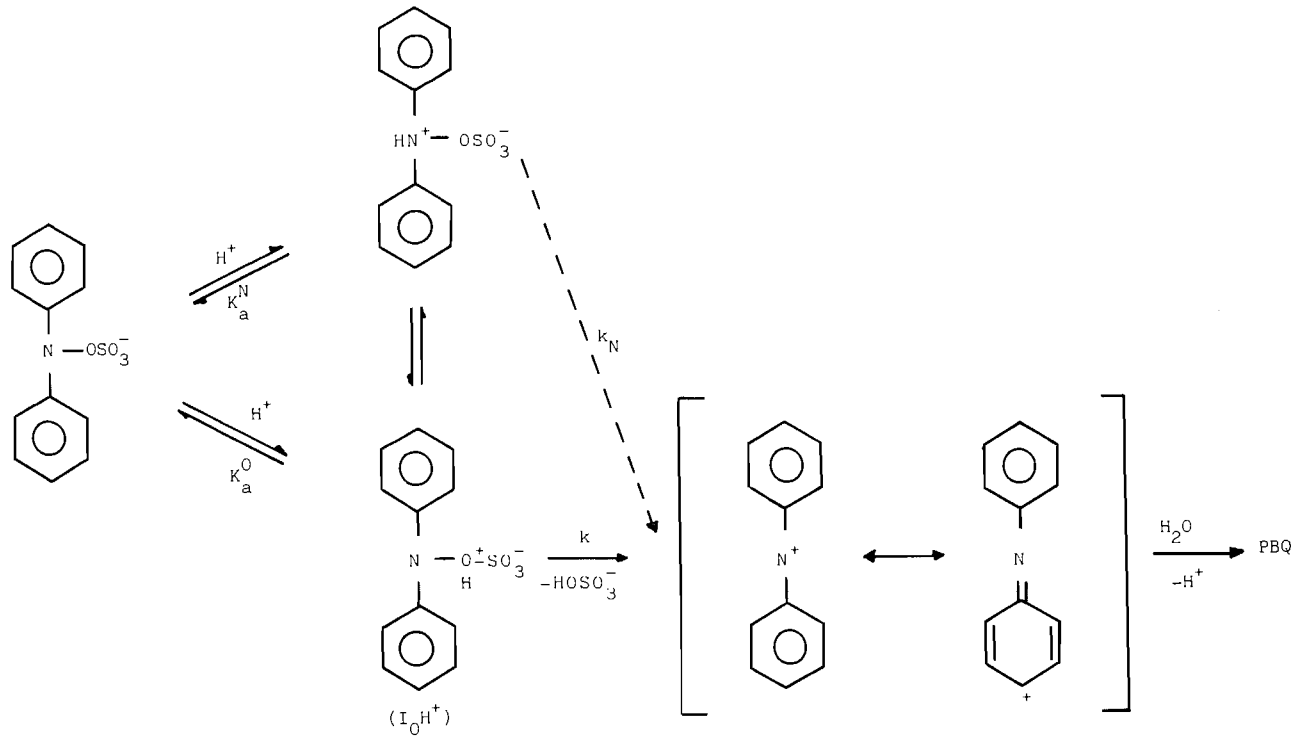

SCHEME 2

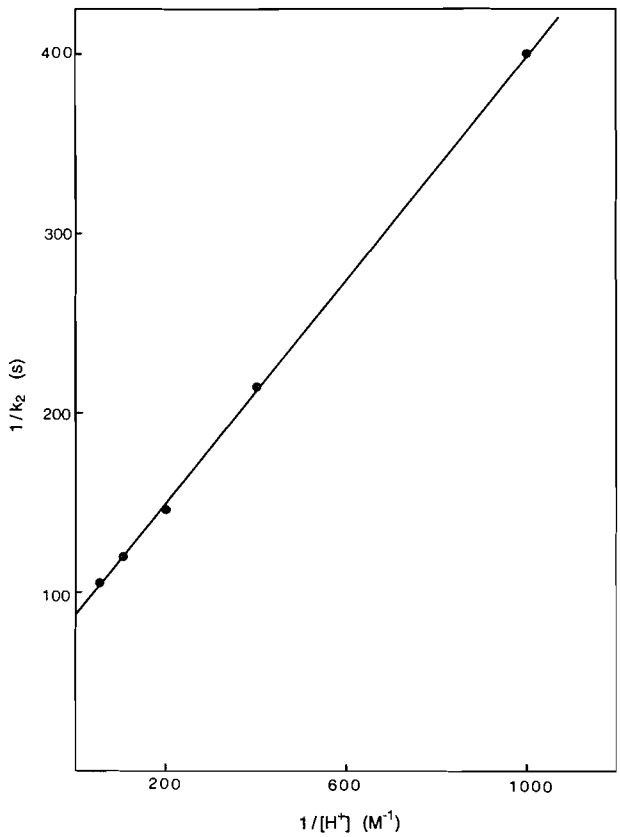

FIG. 4. Plot of k_2^{-1} for the rearrangement of the IH^+ intermediate against $[H^+]^{-1}$ at 25°C.

rangement product. In this sense, the hypothesis that these reaction pathways could be related to the two possible homolytic and heterolytic mechanisms for the N—O cleavage seems to be very attractive. Thus, although for IH^+ the kinetic evidence points to the ionic mechanism depicted in Scheme 2, an alternative radical mechanism for I involving homolytic N—O cleavage is also reasonable. The available trapping data for the reaction in media of pH > 4 could be invoked to support this mechanism. As has been proposed (5, 10), the inhibitory effects of radical traps on the reactions of aromatic amines by PDS involve intermediate radical capture rather than PDS radical reactions. This effect, in turn, may also affect the reaction rates, particularly at high conversion times.

We can now summarize our interpretation of the DPA–PDS reaction mechanism, which has proved to be more puzzling and elusive than we might have conceived at the outset:

1. The reaction of DPA with PDS to give PBQ initially involves the formation of an *N*-diphenylhydroxylamine-*O*-sulfonate intermediate, whose protonation pK_a of 2.4 ± 0.6 has been kinetically estimated. The intermediate further rearranges to give PBQ or, in media of sufficient acidity (pH < 2.5), its hydrolytic decomposition products.

2. The experimental findings strongly suggest that the formation of the proposed intermediate proceeds by a polar mechanism. It involves nucleophilic displacement on the peroxide bond in PDS by the lone electron pair of the DPA nitrogen atom. On the other hand, the intermediate is more stable as a protonated form, IH^+, than as a nonprotonated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

form, I. The zwitterionic structure of IH^+ is apparently responsible for this behaviour.

3. The intermediate rearrangement may be rationalized by a mechanism analogous to that of Bamberger rearrangement of *N*-phenylhydroxylamines to aminophenol, but with separate pathways for each of the acid–base conjugated species IH^+ and I. The latter presumably rearranges via homolytic N—O bond cleavage, the former rearrangement is acid catalyzed and involves an ionic mechanism.

4. The experimental results suggest that, while the rearrangement step may not be rate limiting at pH > 4, it is at least partly limiting at lower pH's. In these more acidic media the intermediate accumulates, being kinetically detectable.

Although we feel that, at present, some aspects of our mechanistic interpretation of the DPA–PDS reaction are rather speculative and therefore should be taken with caution, the interest in the oxidation reactions of aromatic amines by peroxides undoubtedly requires a more extensive experimental effort (including other amines and different peroxides, and medium influence), which will be the subject of future work.

A simple quality test for self-consistent-field atomic orbitals

N. DESMARAIS, G. DANCAUSSE, AND S. FLISZÁR[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received September 15, 1992

N. DESMARAIS, G. DANCAUSSE, and S. FLISZÁR. Can. J. Chem. **71**, 175 (1993).

A quality test is proposed for SCF atomic orbitals, $\phi_i = \Sigma_k c_{ki}\chi_k^{lm}$, approximated as finite linear combinations of suitable basis functions χ_k^{lm}. The key is in a function, readily derived from the Hartree–Fock equation $\hat{F}\phi_i = \varepsilon_i \phi_i$, which is identically zero for true Hartree–Fock spin orbitals and not so for approximate orbitals. In this way, our test measures how closely approximate orbital descriptions approach the true Hartree–Fock limit and thus provides a quality ordering of orbital bases with respect to one another and with respect to that limit, in a scale uniquely defined by the latter. Moreover, this analysis also holds for atomic subspaces of our choice, e.g., the valence region. Examples are offered for representative collections of Slater- and Gaussian-type orbital expansions.

N. DESMARAIS, G. DANCAUSSE et S. FLISZÁR. Can. J. Chem. **71**, 175 (1993).

On propose un critère pour évaluer la qualité des orbitales atomiques, $\phi_i = \Sigma_k c_{ki}\chi_k^{lm}$, décrites par des combinaisons linéraires finies de fonctions de base χ_k^{lm}. La clé est dans une fonction découlant de l'équation de Hartree–Fock $\hat{F}\phi_i = \varepsilon_i \phi_i$, qui est identiquement nulle pour les vraie orbitales de spin Hartree–Fock, mais non nulle autrement. Ceci permet de mesurer comment la description des orbitales leur permet de se rapprocher de la limite exacte de Hartree–Fock et fournit une appréciation de la qualité des bases dans une échelle définie par cette limite. Cette analyse est également possible pour des sous-espaces atomiques, par exemple la région de valence. Les exemples portent sur une série de fonctions gaussiennes et de Slater.

1. Introduction

Here we consider analytic Hartree–Fock–Roothaan self-consistent-field (SCF) atomic orbitals

$$[1] \qquad \phi_i = \sum_k c_{ki}\chi_k^{lm}$$

represented as finite linear combinations of appropriately selected basis functions χ_k^{lm}. Of course, to get true Hartree–Fock orbitals, an infinite set of basis functions should be included in eq. [1]. The question is: how closely do finite expansions approach the true Hartree–Fock limit?

This question is usually answered with the help of comparisons between results obtained from selected truncated expansions and results computed from significantly richer expansions, hoping that the latter adequately mirror the Hartree–Fock limit, which calls for a judgement depending also on the property used in this type of comparisons, the total energy, however, offering the primary guideline. Alternatively, fully numerical Hartree–Fock solutions may serve as reference. Either way, some estimate of the exact Hartree–Fock result is required.

The hierarchy of atomic basis sets is nowadays well established, in essence through the vast experience gathered from a wealth of calculations. Here we submit an objective quality test "measuring" how closely atomic SCF wave functions approach the true Hartree–Fock eigenfunctions. This test is self-contained in that it does not require any a priori knowledge of results (e.g., the energy) obtained at (or at least near) the Hartree–Fock limit. Examples are worked out for representative collections of Slater and Gaussian basis functions.

2. Outline of method

Our quality test is rooted in the partitioning of an atom (or ion) into two regions of space: a spherical inner region of radius r_b, centered at the nucleus, and an outer region, extending from r_b to infinity. The Hartree–Fock equation

$$[2] \qquad \hat{F}\phi_i = \varepsilon_i\phi_i$$

is our starting point. Multiplication from the left by ϕ_i^*, integration from r_b to ∞, and summation over all occupied orbitals i leads to

$$[3] \qquad \sum_i \int_{r_b}^{\infty} \nu_i\phi_i^*\hat{F}\phi_i \, d\boldsymbol{r} = \sum_i \int_{r_b}^{\infty} \nu_i\phi_i^*\varepsilon_i\phi_i \, d\boldsymbol{r}$$

where ν_i is the occupation of the normalized orbital with eigenvalue ε_i. No special meaning is attached to any particular radius r_b defining the boundary surface separating the inner and outer regions: r_b can be chosen at will, whether or not this boundary corresponds to a physically meaningful (1) core-valence separation. We shall learn that the validity of eq. [3] depends on whether or not the ϕ_i's are true Hartree–Fock orbitals: approximate solutions, namely those obtained from truncated expansions, eq. [1], do not satisfy eq. [3]. The difference between the left- and right-hand sides of eq. [3] serves as a quality test for these approximations. The better the basis set, the smaller is this difference for any r_b.

Now we transform eq. [3] into something more practical. Let us begin with its right-hand side. The integral

$$[4] \qquad N_i^v = \nu_i \int_{r_b}^{\infty} \phi_i^*\phi_i \, d\boldsymbol{r}$$

represents the number of electrons of orbital i found in the outer region (which we call for simplicity, but admittedly somewhat sketchily, the valence region; hence the superscript v). Equation [3] thus becomes

$$[5] \qquad \sum_i \int_{r_b}^{\infty} \nu_i\phi_i^*\hat{F}\phi_i \, d\boldsymbol{r} = \sum_i N_i^v\varepsilon_i$$

[1]Author to whom correspondence may be addressed.

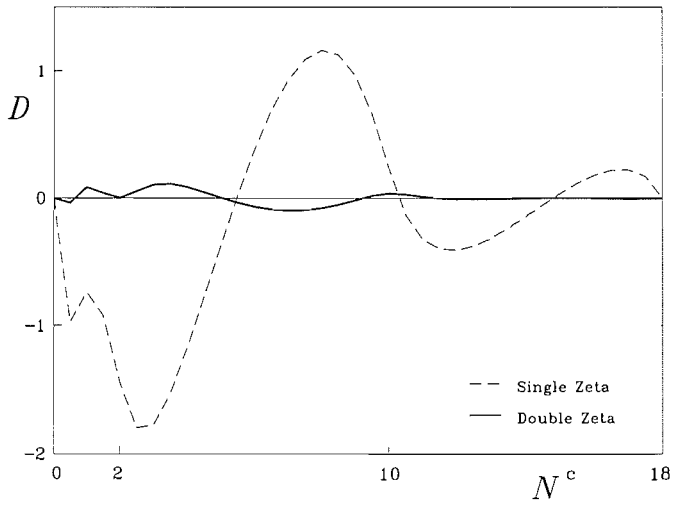

FIG. 1. Argon. Deviations (atomic units) calculated from eq. [12] using the single-ζ and double-ζ Slater bases of Clementi and Roetti (3). The Hartree–Fock limit is represented by the line $D = 0$. $N^c = 0$ and $N^c = 18$ e correspond to $r_b = 0$ and $r_b = \infty$, respectively.

Next, we proceed with the left-hand side of eq. [5]. The evaluation of the monoelectronic integrals occurring in it is straightforward. The nuclear-electronic potential energy of the $\Sigma_i N_i^v$ outer electrons in the field of the nuclear charge Z is

$$[6] \qquad V_{ne}^v = -Z \sum_i \nu_i \int_{r_b}^{\infty} 4\pi r |\phi_i(r)|^2 dr$$

and their kinetic energy is

$$[7] \qquad T^v = \sum_i \nu_i \int_{r_b}^{\infty} \phi_i^* \hat{T} \phi_i d\boldsymbol{r}$$

Now we turn to the bielectronic integrals appearing in the left-hand side of eq. [5]. They require a little attention. Consider the Coulomb operator $\hat{J}_j$ defined by

$$[8] \qquad \hat{J}_j(1)\phi_i(1) = \phi_i(1) \int |\phi_j(2)|^2 \frac{1}{r_{12}} d\tau_2$$

where $d\tau_2 = r_2^2 \sin\theta_2 \, d\theta_2 \, d\varphi_2 \, dr_2$ (with a similar expression for $d\tau_1$). The integral $\int \ldots d\tau_2$ is over all space, but can be separated into two contributions, namely, in short-hand notation,

$$\int_{\tau_2^c} \ldots d\tau_2 + \int_{\tau_2^v} \ldots d\tau_2$$

where the first integral (from 0 to r_b) covers the inner (core) region τ_2^c, whereas the second one (from r_b to ∞) is for the outer (valence) space τ_2^v. Using eq. [8], the integration between r_b and ∞ required by eq. [5] thus gives the following Coulomb repulsion:

$$[9] \qquad \int_{\tau_1^v} \phi_i^*(1)\hat{J}_j(1)\phi_i(1) \, d\tau_1 = \int_{\tau_1^v} \int_{\tau_2^c} \ldots d\tau_2 \, d\tau_1 + \int_{\tau_1^v} \int_{\tau_2^v} \ldots d\tau_2 \, d\tau_1$$

These integrals describe a potential energy of interaction involving the part of electron 1 assigned to the valence space τ^v and a smeared-out electron with density $|\phi_j(2)|^2$. The two terms of the right-hand side of eq. [9] differ from one another because the first integral "sees" only the part of $|\phi_j(2)|^2$ found in the core space τ^c, whereas the second integral concerns only the part of $|\phi_j(2)|^2$ confined within the valence region τ^v.

At last, we can carry out the sum indicated in eq. [5]. This sum also includes a term arising from $\hat{J}_i(2)\phi_j(2)$, whose integral is evaluated as just shown for $\hat{J}_j(1)\phi_i(1)$. As a consequence, the summation over all occupied orbitals counts once again the 1–2 Coulomb interaction confined within the valence space, i.e., the $\int^{\tau_1^v} \int^{\tau_2^v} \ldots d\tau_2 \, d\tau_1$ term already found in eq. [9], and adds the new integral

$$\int_{\tau_1^c} \int_{\tau_2^v} \ldots d\tau_2 \, d\tau_1$$

describing the interaction between the part of electron 2 found in τ^v and the part of electron 1 found in the core region. Briefly, all interactions involving exclusively electron densities assigned to the outer space τ^v are counted twice, whereas the cross interactions between electrons assigned to τ^v and those assigned to τ^c, represented by the appropriate

$$\int_{\tau_1^v} \int_{\tau_2^c} \ldots d\tau_2 \, d\tau_1 + \int_{\tau_1^c} \int_{\tau_2^v} \ldots d\tau_2 \, d\tau_1$$

integrals, are counted only once. The same reasoning applies to the exchange operator

$$\hat{K}_j(1)\phi_i(1) = \phi_j(1) \int \frac{\phi_j^*(2)\phi_i(2)}{r_{12}} d\tau_2$$

and to its integral $\int \ldots d\tau_1$, followed by summation over i. Down the line, taking now all the appropriate Coulomb and exchange integrals into account, it is seen that V_{ee}^{vv} (= electron–electron repulsion involving only the electrons of the outer (valence) region) is counted twice in the left-hand side of eq. [5], whereas V_{ee}^{cv} (= repulsion between the outer (valence) electrons and those of the inner (core) region) is counted only once.

The final result, including now V_{ne}^v and T^v (eqs. [6] and [7], respectively) is thus

$$[10] \qquad \sum_i N_i^v \varepsilon_i = T^v + V_{ne}^v + 2V_{ee}^{vv} + V_{ee}^{cv}$$

The companion formula

$$[11] \qquad \sum_i N_i^c \varepsilon_i = T^c + V_{ne}^c + 2V_{ee}^{cc} + V_{ee}^{cv}$$

where T^c, V_{ne}^c, and V_{ee}^{cc} are the kinetic, the nuclear-electronic, and the interelectronic energies of the $\Sigma_i N_i^c$ core

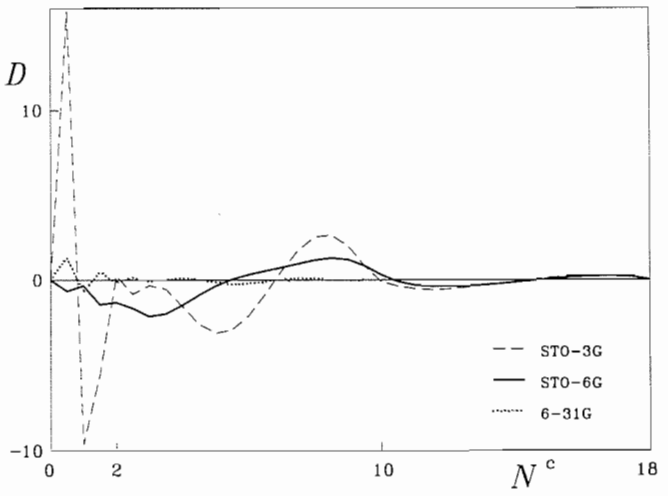

FIG. 2. Argon. Deviations (atomic units) observed for the STO-3G, STO-6G, and 6-31G Gaussian bases of Pople *et al.* (4). The results for STO-4G and STO-5G are intermediate between those shown for the STO-3G and STO-6G bases, namely in the short-range region.

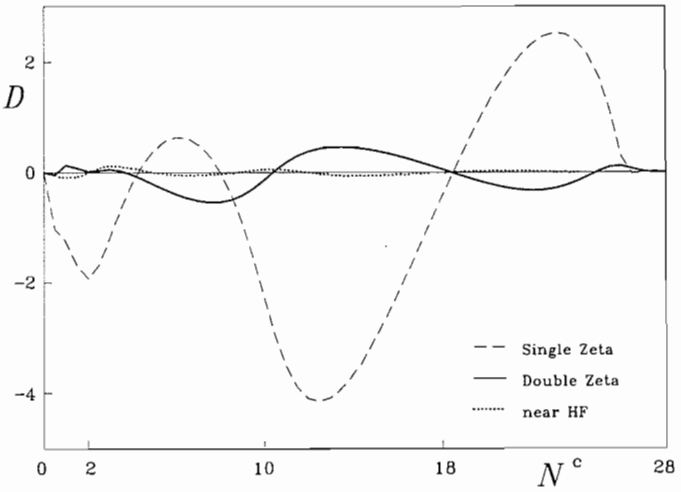

FIG. 3. Nickel. Deviations (atomic units) calculated by means of the Slater bases of ref. 3. The solid line for $D = 0$ represents the Hartree–Fock limit.

electrons, respectively, follows immediately because the individual core and valence terms add up correctly to give the corresponding totals for the entire atom, e.g., $T^{\text{total}} = T^{\text{v}} + T^{\text{c}}$. Remember that all the quantities appearing in eqs. [10] and [11], except ε_i, are functions of r_b, i.e., $N_i^{\text{v}} = N_i^{\text{v}}(r_b)$, $T^{\text{v}} = T^{\text{v}}(r_b)$, etc.

Equation [10] (1) is most convenient for our intended analysis of SCF orbitals, eq. [1]. The first step consists in conventional optimizations of the ϕ_i's (or the selection of the appropriate literature data) and the calculation of the corresponding orbital energies ε_i. The wave functions are used to calculate N_i^{v}, eq. [4], and the sum $\Sigma_i N_i^{\text{v}}\varepsilon_i$ for the r_b of our choice. The V_{ne}^{v} and T^{v} contributions are obtained from eqs. [6] and [7], respectively, and the bielectronic integrals are deduced with the help of the standard expansion of $1/r_{12}$ in terms of spherical harmonics (2) and use of the appropriate limits of integration. The programs were developed both for Slater and Gaussian basis functions.

[a] Misprints were detected in the double-ζ basis of Li reported in ref. 3.

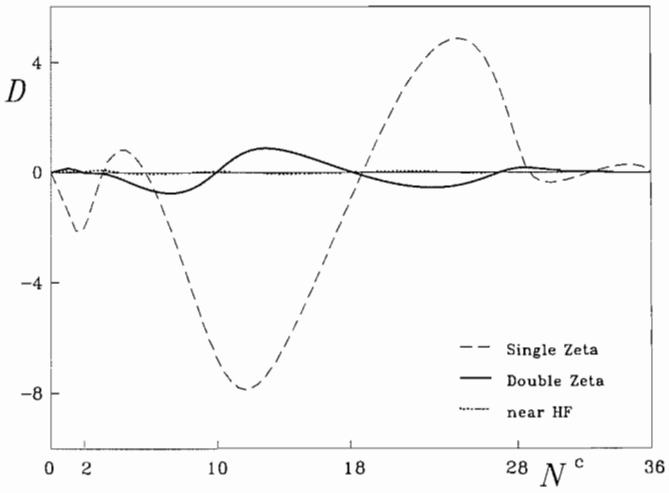

FIG. 4. Krypton. Results (atomic units) obtained with the Slater bases of ref. 3. This example, compared to that given in Fig. 3, illustrates the regularities that are typical for Slater bases.

3. Results

Our results are expressed as the difference, from eq. [10],

$$[12] \quad D = \sum_i N_i^{\text{v}}\varepsilon_i - (T^{\text{v}} + V_{\text{ne}}^{\text{v}} + 2V_{\text{ee}}^{\text{vv}} + V_{\text{ee}}^{\text{cv}})$$

This difference represents what we may call the "noise" of a truncated expansion, with respect to a "base line" that is everywhere identically zero at the true Hartree–Fock limit.

TABLE 2. Quality indices of selected Gaussian-type orbitals, expressed as root-mean-square deviations (atomic units)

6-31G	0.008	0.008	0.008	0.015
Double-ζ	0.009	0.010	0.009	0.013

This difference is a function of r_b. For each r_b, there is one value of N^c, the number of electrons contained within the sphere of radius r_b. The use of $D = D(N^c)$ allows us to scan the entire atom, thus simplifying the presentation of results by avoiding long tails for large r_b's. At the limits $N^c = 0$ and $N^c = N$ = total number of electrons, it is $D(N^c) = 0$ because $N^c = 0$ corresponds to the entire atom, for which the SCF result is correct, while for $N^c = N$ nothing is left in the "outer" region, meaning that all terms of eq. [10] are naught.

Figures 1 and 2 describe argon and indicate how $D(N^c)$ varies with N^c. The results of Fig. 1 were obtained from the single-ζ and double-ζ Slater bases of Clementi and Roetti (3), those of Fig. 2 from selected popular Gaussian bases developed by Pople and co-workers (4). Figures 3 and 4 display Slater basis results for nickel and krypton, respectively. These examples are typical. The results are self explanatory.

Yet, it seems unpractical to present all our results by means of figures, as was done in the preceding examples. A more compact presentation was selected as follows. The deviations $D(N^c)$ were calculated from eq. [12] at intervals spaced[2] by $\Delta N^c = 0.5$ e, starting from $N^c = 0.5$ up to $N^c = N - 0.5$ e. The final result for each basis set is then conveniently given as the root-mean-square (RMS) of these deviations. While some information is lost in this manner, namely as regards the profile of $D(N_c)$ in the various regions of space, the RMS deviations offer a simple quality index for the bases to which they correspond. The results obtained from Slater orbitals (3, 5) are given in Table 1, for the atoms Li–Kr. Table 2 reports the quality indices calculated for a representative collection of well-known Gaussian-type orbitals (4, 6–8).

4. Discussion and conclusions

The quality indices obtained with the single-ζ, double-ζ, and the near Hartree–Fock Slater-type orbitals of Clementi

[2]The selection of $\Delta N^c = 0.5$ e is arbitrary. It is convenient because it describes the profile of $D(N^c)$ vs. N^c with sufficient accuracy to permit meaningful comparisons. Smaller ΔN^c increments were also considered, with an added computational burden, but tests indicated that the usually minor numerical changes do not affect the overall conclusions reached in this work.

and Roetti (3) (Table 1) may serve as a convenient reference.[3] The noise of double-ζ calculations is roughly one tenth that of the single-ζ basis, while in near Hartree–Fock calculations this noise is further reduced by a factor of 10, approximately. Constraints imposed on ζ and the type of expansion to be used for *s*-type orbitals in order to satisfy the cusp condition are included in Malli's bases (5), which is attractive because they give a predominant weight to the description of the charge density at the nucleus. On the whole, these constraints produce a slight deterioration, which, however, seems acceptable.

As regards the familiar Gaussian basis sets of ref. 4 (Table 2), the superiority of the STO-5G and STO-6G sets over STO-3G and STO-4G is seemingly clear-cut. Comparison with Table 1 suggests that the STO-6G basis approaches the quality of a single-ζ Slater basis. The 4-31G basis does not seem to live up to its expectation as a double-ζ basis, which it is by design. We shall return to it a little later. For the first-row atoms, the 6-31G and 6-311G bases, in contrast, tend to approach double-ζ quality. Huzinaga's (10*s*6*p*) basis (6), as well as Dunning's (10*s*6*p*) → [5*s*4*p*] contraction (7), approach this result even better. Interestingly, in contrast with the general trends, with the [5*s*4*p*] basis the noise is systematically somewhat larger, but the energy always slightly better, than what is obtained in Slater double-ζ basis calculations. Finally, van Duijneveldt's (13*s*8*p*) basis (8) leans towards near Hartree–Fock quality.

But this assessment is incomplete. Inspection of Fig. 2 (which is a typical example) shows that the deviations of the STO-3G basis primarily cloud the short-range region. Turning our attention now to the outer atomic regions, beyond a core of 2 electrons, which are of particular interest in molecular problems (bonding, conformational effects, etc.) treated in the LCAO-MO approximation, we ask about the profile of these deviations in the chemically important valence regions. As for the STO-*N*G bases, Table 3 indicates that, for all practical purposes, the quality of the STO-3G and STO-6G expansions is the same, particularly for the first-row elements. It is fair to conclude that, beyond a core of 2 electrons, the profile of STO-*N*G bases is essentially that of single-ζ Slater expansions. It is also clear that in this region the 4-31G and 6-31G bases approach, and that the 6-311G basis surpasses, the quality of double-ζ Slater expansions. Finally, in the valence regions of second-row elements, beyond a core of 10 electrons, all STO-*N*G bases are similar in quality (Table 4), but exhibit a larger noise as the corresponding single-ζ Slater bases. The 6-31G basis, however, comes certainly as close to the true Hartree–Fock result as a double-ζ Slater expansion.

[3]We have examined whether near Hartree–Fock functions given with more significant figures than in ref. 3 would improve on the results of Table 1. This is not the case. We thank Drs. G. Corongiú and E. Clementi for their help in this matter.

All the bases used here as examples are well known, and so are their properties. This has oriented our selection. Therefore, one hardly did expect to learn anything basically new about them. But that was not our intention. The point made here touches the potential of eqs. [3] and [12]: they provide blunt information, unbiased by any a priori knowledge we may have, as to how closely SCF orbital descriptions approach the true Hartree–Fock limit and thus offer a meaningful objective quality ordering of SCF orbital bases with respect to one another and with respect to that limit, in a scale uniquely defined by the latter. In a sense, eq. [12] is but a mechanical device, no replacement for the flair involved in the art of researching good basis functions, yet capable of monitoring and documenting in a simple numerical manner what is otherwise the privilege of intuition supported by vast experience (6, 9). Our approach adds some welcome sharpness from which comparisons between orbital bases should benefit.[4] Extension to molecular LCAO wave functions is in progress.

WILLIAM M. DAVIS, ROBIN G. HICKS, RICHARD T. OAKLEY, BAIYI ZHAO, and NICHOLAS J. TAYLOR. Can. J. Chem. **71**, 180 (1993).

The preparation and crystal and molecular structure of the monofunctional 1,2,3,5-diselenadiazolyl radical [RCN_2Se_2] (R = 3,5-dicyanophenyl) are described. Crystals of [$(CN)_2C_6H_3CN_2Se_2$] are triclinic, space group $P\bar{1}$, a = 7.197(2), b = 10.753(3), c = 13.345(5) Å, α = 88.00(3)°, β = 82.05(2)°, γ = 81.00(2)°, MW = 311.1, Z = 4. The structure consists of stacked arrays of radical dimers laced together by networks of short CN---Se contacts, but the steric bulk of the organic ligand leads to a pairwise aggregation of [CN_2Se_2] columns. These structural features are compared with those observed in related dimers, and the results interpreted in the light of extended Hückel band calculations on a series of model structures. The results provide a qualitative correlation between the size and dimensionality of the intermolecular Se---Se network and the degree of crystal orbital dispersion.

WILLIAM M. DAVIS, ROBIN G. HICKS, RICHARD T. OAKLEY, BAIYI ZHAO et NICHOLAS J. TAYLOR. Can. J. Chem. **71**, 180 (1993).

On a préparé le radical monofonctionnel 1,2,3,5-disélénadiazolyle [RCN_2Se_2]$^{\cdot}$ et on a déterminé ses structures cristalline et moléculaire. Les cristaux du [$(CN)_2C_6H_3CN_2Se_2$] sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 7,197(2), b = 10,753(3) et c = 13,345(5) Å, α = 88,00(3)°, β = 82,05(2)° et γ = 81,00(2)°, PM = 311,1 et Z = 4. La structure consiste en des empilements de dimères de radicaux reliés entre eux par des réseaux de contacts CN · · · Se courts; toutefois, le volume stérique des ligands organiques conduit à une agrégation par paire des colonnes de [CN_2Se_2]. On compare ces caractéristiques structurales avec celles observées dans des dimères apparentés et on interprète les résultats en fonction de calculs étendus de la bande de Hückel sur une série de structures modèles. Les résultats fournissent une corrélation qualitative entre la grosseur et la dimension du réseau Se · · · Se intermoléculaire et le degré de dispersion de l'orbitale cristalline.

[Traduit par la rédaction]

Introduction

We recently reported the preparation and structures of the dimers of several 1,2,3,5-diselenadiazolyl radicals, including the 4- and 3-cyanophenyl derivatives **1** and **2** (1). This work resulted from our interest in the design of low-dimensional molecular conductors from neutral radicals (2). In these systems, as elsewhere (3–5), the nitrile moiety serves as a structure-influencing functional group by interacting with the chalcogen atoms of neighbouring radical dimers; the CN---Se contacts so generated link dimers together in ribbon-like (head-to-tail) networks. In the 4-cyanophenyl dimer, adjacent ribbons run in opposite directions, while in the 3-cyanophenyl system the ribbons stack in nearly vertical arrays. All these structures are characterized by extended lateral Se---Se contacts between adjacent ribbons and, where applicable (i.e., **2**), between stacked dimers. The number and magnitude of both vertical and lateral Se---Se interactions have important effects on crystal orbital dispersion (i.e., bandwidth), and hence electronic properties.

To explore further the relationship between crystal structure, bandwidth, and conductivity we have prepared and structurally characterized the 3,5-dicyanophenyl derivative **3**; the structural results from this and previous work are correlated with extended Hückel band structure calculations.

Results

Preparation of 3

The precursor to **3**, i.e., the corresponding 1,2,3,5-diselenadiazolium cation, was prepared by the condensation of the *N,N*-bis(trimethylsilyl)-*N'*-lithium salt of 3,5-dicyanobenzamidine with selenium dichloride (eq. [1]). Reduction of the cation with a slight excess of triphenylantimony afforded the crude radical **3**, which was purified by vacuum sublimation at 160°C/10^{-3} Torr (1 Torr = 133.3 Pa) to give dark green crystals.

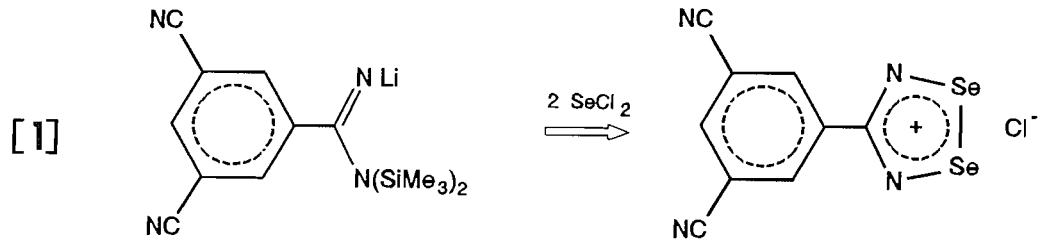

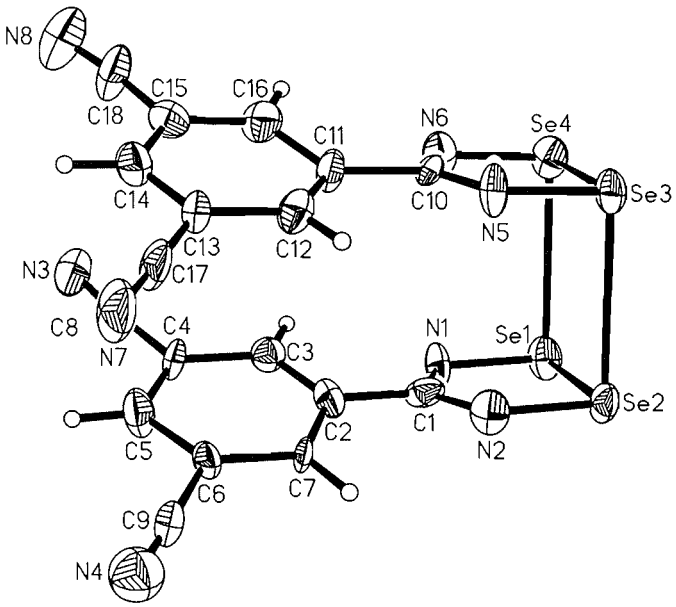

FIG. 1. MOLECULAR PLOT drawing for **3**, showing atom numbering scheme.

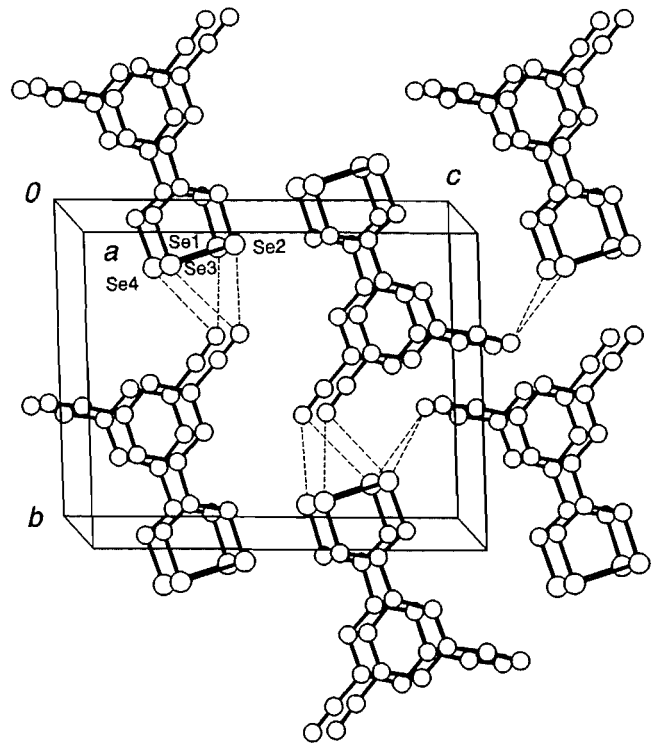

FIG. 2. *yz*-Projection of cell packing in **3**, with Se---NC contacts (dashed lines).

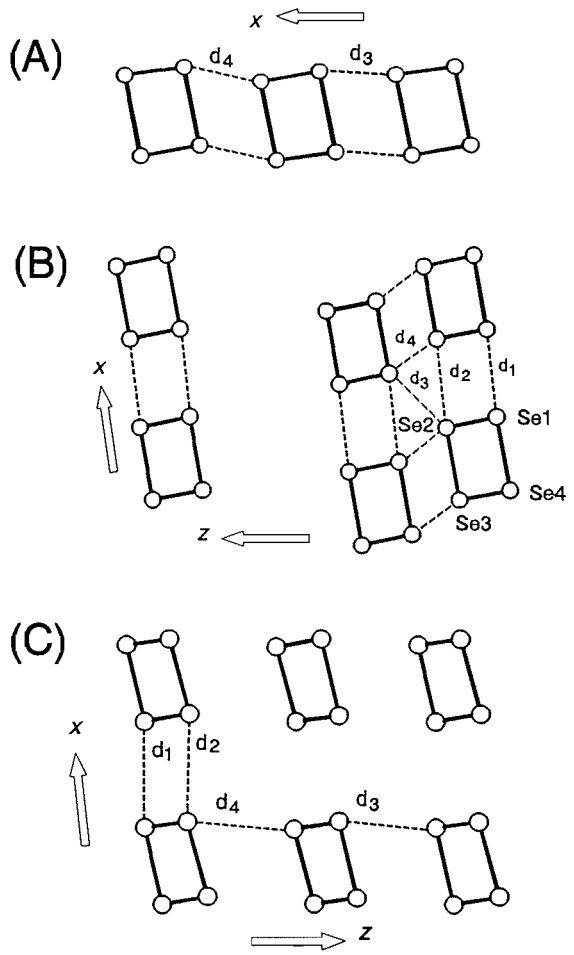

FIG. 3. Stacking of dimer units in **1** (*A*), **3** (*B*), and **2** (*C*), showing lateral and vertical interdimer Se---Se contacts. In **1** there are no vertical contacts, so only one layer is shown.

Crystal structure of **3**

Crystals of **3** belong to the triclinic space group $P\bar{1}$, and consist of radical dimers linked in a cofacial manner through two interannular Se---Se bonds (mean of d_1 and d_2 is 3.239 Å). A drawing of a single dimer unit is shown in Fig. 1. Non-hydrogen coordinates are compiled in Table 1 and internal structural parameters, which are typical for this class of compound, are summarized in Table 2.

The crystal structure of **3** (Fig. 2) consists of rows of radical dimers along *y* linked by CN---Se contacts that are reminiscent of the monocyanophenyl systems. There are also slightly different CN---Se interactions between molecules in adjacent ribbons. The former contacts link a nitrile to two neighbouring selenium atoms within one radical unit (Se1 and Se2 *or* Se3 and Se4), while the latter involve two selenium

[a]Numbers in parentheses are ranges.
[b]Numbers in parentheses are esd's.

atoms spanning a dimer (Se1 and Se4). The ribbons stack along x to produce near-vertical arrays of radical dimers. The two interdimer Se---Se contacts within a stack, d_1 (Se1---Se4′) and d_2 (Se2---Se3′) (mean 4.059 Å), are slightly shorter than those found in **2** (mean 4.15 Å). As Fig. 3*B* illustrates, the dimer stacks exist as isolated pairs spanned by the bulky dicyanophenyl ligand. Consequently, Se---Se interactions between stacks are limited to the pairwise contacts d_3 (Se2---Se2′, 3.716 Å) and d_4 (Se2---Se3′, 3.846 Å).

Band structure of 3

The crystal structure of the diselenadiazolyl dimer reported here is, like those of the cyanophenyl derivatives described earlier, strongly influenced by intermolecular CN---Se interactions, which serve to orient dimer units into ribbons or sheets. In the case of the 4-cyanophenyl compound **1**, the antiparallel arrangement of adjacent ribbons affords only lateral Se---Se contacts between dimer units (Fig. 3*A*), while structures **2** and **3** possess stacked assemblies in which dimer units are connected by vertical as well as lateral Se---Se interdimer contacts (Table 2). In the case of **3** these contacts are only pairwise in nature while in **2** they link dimer units into extended networks. Within the context of the design of molecular species that crystallize in a manner which enhances orbital interactions in a multidimensional manner, the series of cyanophenyl structures now in hand provides an opportunity to probe the extent and consequences of intermolecular Se---Se interactions in a systematic manner. To this end we have carried out extended Hückel band structure calculations on a number of model structures related to **1**, **2**, and **3**.

The density of states (DOS) for the structure of **3** is shown in Fig. 4*B*. Also shown are the corresponding DOS diagrams for two model "fragments" related to **3**. The first (Fig. 4*A*) is for a dicyanobenzene structure in which the organic unit is placed in the same positions as are the dicyanophenyl ligands in the unit cell of **3**. The second fragment (Fig.

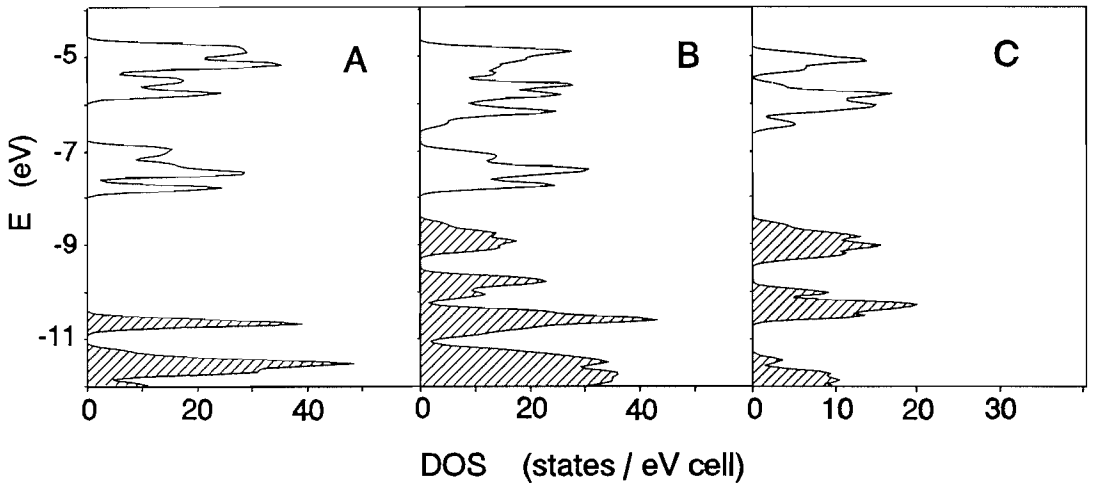

FIG. 4. Density of States (DOS) for (*A*) dicyanobenzene, (*B*) **3**, and (*C*) HCN_2Se_2. The packing pattern is defined by the crystal structure of **3**.

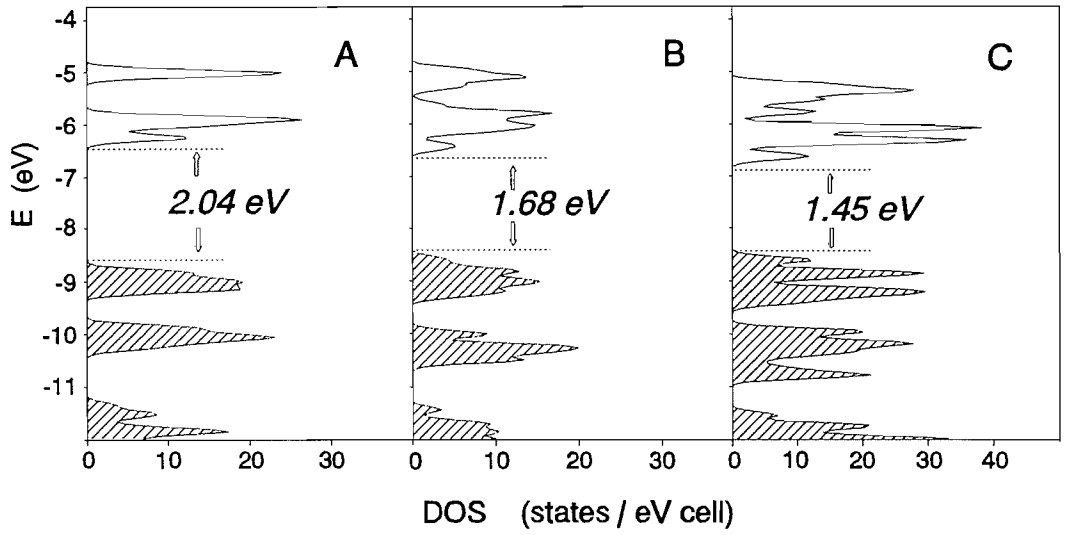

FIG. 5. π-SOMO interactions within and between HCN_2Se_2 radicals, illustrating the development of band-spreading.

4*C*) is HCN_2Se_2, i.e., the basic heterocyclic unit, again located in all the regular positions of the full structure, but with the organic ligand replaced by hydrogen. The combination of the DOS diagrams for the two fragments facilitates a clearer understanding of the origin of the band structure of **3** itself. This approach, i.e., of examining parts of the structure as well as the full structure, is, of course, a routine event in the discussion of molecular electronic structure (6), and was invoked in this case because of the electronic characteristics of the dicyanophenyl group. The low-lying acceptor (vacant) orbitals, which can be loosely described as π^*(CN), generate non-interacting "intruder" states in the full DOS diagram, and can give rise to a false impression of the band gap for the full structure. Correlation of the two fragment DOS diagrams with that of the full structure reveals a relatively clearer picture of the valence and conduction bands associated with the $[HCN_2Se_2]_2$ building blocks. Indeed, insofar as the SOMO orbitals of $[RCN_2Se_2]^{\cdot}$ are nodal at carbon (Fig. 5), it is not surprising that the neither the dispersion nor position of the valence and conduction bands of the model $[HCN_2Se_2]_2$ structure are perturbed by the attachment of the dicyano moiety.

A similar approach, i.e., one using $[HCN_2Se_2]_2$ fragments rather than the full structure, has been applied to analyse the extent of Se---Se interactions in **1** and **2**. The results of these calculations are presented in Fig. 6. Comparison of the dispersion (here approximated by the bandwidth) of the valence and conduction bands from these model systems, and also the valence/conduction band gaps, reveals a satisfying trend that parallels the structural data described above. In **1**, where stacking of dimers is absent, and only lateral interdimer interactions are observed, relatively narrow valence and conduction bands are observed, and the band gap is large. In **3** (Fig. 4*C*), lateral interactions are only pairwise, and band dispersion from such interactions is likely to be small. However, insofar as the structure is stacked, dispersion arising from interactions up and down the stack can be expected to reduce the band gap relative to **1**. For structure **2** extended interactions both within and between columns are observed. Bandwidths accordingly increase, and the va-

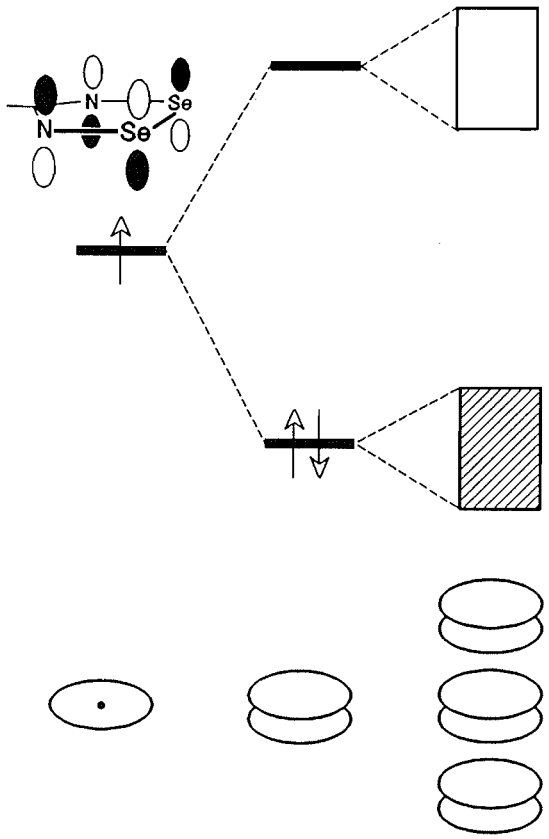

FIG. 6. Density of States (DOS) for HCN_2Se_2 units with packing pattern defined by the crystal structures of **1** (*A*), **3** (*B*), and **2** (*C*).

lence-to-conduction band gap in **2** is less than in either **1** or **3**.

Summary

The three diselenadiazolyl crystal structures under consideration all consist of molecular units, the greater part of which is a cyanoaryl moiety. The heterocyclic radical dimer fragment (i.e., $[\text{-}CN_2Se_2]_2$), which is the "building block" whose solid state properties we wish to probe, constitutes a relatively minor component of the overall molecule. In the polyfunctional diselenadiazolyl radicals we have studied (7–9), the density of the $[\text{-}CN_2Se_2]_2$ blocks within the unit cell is greater, and hence the number and magnitude of the Se---Se contacts is significantly enhanced. As a result of the relatively large size of the organic substituent in the present systems the number and (or) magnitude of significant Se---Se contacts is reduced, and the extent of intermolecular orbital interactions is diminished. Nonetheless the structural differences that are observed along the series **1–3** can be correlated, albeit qualitatively, with band structure calculations on simple model systems related to the three structures.

Insofar as electrical conductivity in these systems can be ascribed to a mechanism involving thermal activation across the valence/conduction band gap, the less extensive solid state networks found in all of **1–3**, and the wider band gaps found for their model counterparts, are all consistent with the poorer conductivity found for these systems compared to the bifunctional compounds previously characterized. Within the group, the relative conductivities appear to be consistent with the trend in the band gaps given above. Both **1** and **3** are insulating, and compound **2** was earlier shown to have a room temperature conductivity near 10^{-9} S cm^{-1}. This value is significantly lower than the conductivities of bifunctional systems.

Experimental

Starting materials and general procedures

1,3,5-Benzenetricarbonyl trichloride, lithium bis(trimethylsilyl)amide, selenium powder, and triphenylantimony were all obtained commercially (Aldrich). 1,3,5-Tricyanobenzene was prepared from the tricarbonyl trichloride according to literature methods (10) and $LiN(SiMe_3)_2$ was converted to its diethyl etherate prior to use. Selenium tetrachloride was prepared by direct oxidation of selenium powder with chlorine (11). Acetonitrile (Fisher HPLC grade) was purified by distillation from P_2O_5, toluene was dried by distillation from sodium, and diethyl ether by distillation from lithium aluminum hydride. All reactions were performed under an atmosphere of nitrogen. Mass spectra (70 eV, EI) were recorded on a Kratos MS890 mass spectrometer. Infrared (CsI optics, Nujol mulls) were obtained on a Nicolet 20SX/C FTIR instrument. Elemental analyses were performed by MHW Laboratories, Phoenix, Arizona.

Preparation of N-*lithio*-N′,N′-*bis(trimethylsilyl)-3,5-dicyanobenzamidine*

This compound was prepared by a modification of the procedure used for tris(trimethylsilyl)amidines (12). A solution of $LiN(SiMe_3)_2 \cdot Et_2O$ (5.60 g, 23.2 mmol) in 50 mL of toluene was added dropwise to a slurry of 1,3,5-tricyanobenzene (3.59 g, 23.4 mmol) in 80 mL of toluene. After stirring for 1 h, the tan-coloured precipitate so produced was filtered, washed with three 20-mL portions of toluene, and pumped to dryness. The *N*-lithiated amidine was obtained in virtually quantitative yield and used in subsequent reactions without further purification.

Preparation of $[3,5\text{-}(CN)_2C_6H_3CN_2Se_2]^{\cdot}$ **3**

Solid *N*-lithio-*N*′,*N*′-bis(trimethylsilyl)-3,5-dicyanobenzamidine (3.21 g, 10.0 mmol) was added to a solution of $SeCl_2$ (generated *in situ* by mixing $SeCl_4$ (2.23 g, 10.0 mmol) and Se powder (0.79 g, 10.0 mmol) in 30 mL of acetonitrile). The mixture was heated to gentle reflux for 1 h, cooled, and filtered to yield crude $[3,5\text{-}(CN)_2C_6H_3CN_2Se_2]^+Cl^-$ as a dark red powder. This solid was slurried in 40 mL of acetonitrile, solid Ph_3Sb (1.80 g, 5.1 mmol) was added, and the mixture was refluxed for 90 min. The resulting dark green solid was filtered, washed with three 10-mL portions of acetonitrile, and dried *in vacuo*. Sublimation of the crude product at 160°C/10^{-3} Torr produced $[3,5\text{-}(CN)_2C_6H_3CN_2Se_2]$ as lustrous metallic green crystals (0.88 g, yield 27%), dec. 280–284°C. IR (2000–200 cm^{-1}): 1465 (vs), 1436 (m), 1377 (s), 1338 (m), 1324 (w), 1214 (m), 1155 (w), 954 (w), 940 (w), 926 (w), 905 (s), 774 (s), 764 (vs), 746 (m), 721 (w), 697 (s), 669 (m), 655 (w), 633 (vs), 616 (w), 545 (s), 471 (w), 390 (s), 291 (s) cm^{-1}. Mass spectrum *m/e*: 327 (M^+, 64%), 174 (Se_2N^+, 100%), 160 (Se_2^+, 30%), 153 ($C_6H_3(CN)_3^+$, 13%), 94 (SeN^+, 11%), 80 (Se^+, 16%). Mass spectral isotope distributions (for selenium) were consistent with the assigned fragments. Anal. calcd. for $C_9H_3N_4Se_2$: C 33.25, H 0.93, N 17.24; found: C 33.27, H 1.08, N 17.13.

X-ray measurements on **3**

X-ray data were collected on a Siemens R3m/V diffractometer at 293 K with monochromated MoK_α (λ = 0.71073 Å) radiation; crystals were mounted on glass fibers with epoxy. The crystals belong to the triclinic space group $P\bar{1}$ and have unit cell parameters a = 7.197(2), b = 10.753(3), c = 13.345(5) Å, α = 88.00(3)°, β = 82.05(2)°, γ = 81.00(2)°, MW = 311.1, Z = 4. Data were collected using a $2\theta/\theta$ method with scan widths from 1.1° below $K_{\alpha 1}$ to 1.1° above $K_{\alpha 2}$. The structure was solved by Patterson and Fourier techniques using Siemens SHELXTL PLUS software and

refined by full-matrix least squares which minimized $\Sigma(F_o - F_c)^2$. The final R and R_w values of 0.0664 and 0.1071 were based respectively on 2186 observed unique data with $F > 6.0\sigma(F)$. Atoms N2 and C3 were refined isotropically due to data-set limitations.[2]

Extended Hückel band calculations

Extended Hückel calculations were performed with the EHMACC suite of programs, using parameters discussed previously (9). The programs were compiled with the NDP Fortran compiler (version 4.0.2) and implemented under DOS 5.0 on a 486/50 personal computer.

Nucleic acid related compounds. 77. 2′,3′-Didehydro-2′,3′-dideoxy-2′(and 3′)-methylnucleosides via [3,3]-sigmatropic rearrangements of 2′(and 3′)-methylene-3′(and 2′)-*O*-thiocarbonyl derivatives and radical reduction of a 2′-chloro-3′-methylene analogue[1]

VINCENTE SAMANO AND MORRIS J. ROBINS[2]
Department of Chemistry, Brigham Young University, Provo, UT 84602, U.S.A.

Received August 11, 1992

VINCENTE SAMANO and MORRIS J. ROBINS. Can. J. Chem. **71**, 186 (1993).

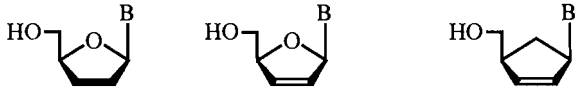
Treatment of 5′-*O*-(*tert*-butyldiphenylsilyl)-2′(and 3′)-deoxy-2′(and 3′)-methyleneuridine (and adenosine) derivatives with phenyl chlorothionocarbonate gave the 3′(and 2′)-*O*-phenoxythiocarbonyl intermediates, which underwent spontaneous [3,3]-sigmatropic rearrangement to give the 2′,3′-didehydro-2′,3′-dideoxy-2′(and 3′)-(phenoxycarbonylthio)methyl analogues. These allylic thioesters were subjected to tributylstannane-mediated hydrodesulfurization and deprotection to give 2′,3′-didehydro-2′,3′-dideoxy-2′(and 3′)-methyluridine (and adenosine). Tributylstannane-mediated hydrodehalogenation of a 2′-chloro-2′,3′-dideoxy-3′-methyleneuridine derivative afforded the 2′,3′-didehydro-2′,3′-dideoxy-3′-methyl product of allylic transposition exclusively.

VINCENTE SAMANO et MORRIS J. ROBINS. Can. J. Chem. **71**, 186 (1993).

Le traitement des dérivés 5′-*O*-(*tert*-butyldiphénylsilyl)-2′(et 3′)-désoxy-2′(et 3′)-méthylèneuridine (et adénosine) avec du chlorothionocarbonate de phényle conduit à des intermédiaires 3′(et 2′)-*O*-phénoxythiocarbonyles qui subissent une transposition sigmatropique-[3,3] spontanée fournissant les analogues 2′,3′-didéhydro-2′,3′-didésoxy-2′(et 3′)-(phénoxycarbonylthio)méthyles. On a soumis ces thioesthers allyliques à une hydrodésulfurisation catalysée par le tributylstannane et à une déprotection conduisant à la 2′,3′-didéhydro-2′,3′-didésoxy-2′ (et 3′)-méthyluridine (et adénosine). L'hydrodéshalogénation, catalysée par le tributylstannane, d'un dérive 2′-chloro-2′,3′-didésoxy-3′-méthylèneuridine conduit uniquement au produit 2′,3′-didéhydro-2′,3′-didésoxy-3′-méthyle provenant de la transposition allylique.
[Traduit par la rédaction]

Introduction

A number of 2′,3′-dideoxynucleoside (**A**) and 2′,3′-unsaturated (2′,3′-didehydro) analogue triphosphates cause selective inhibition of the HIV reverse transcriptase in vitro (1). Potent anti-HIV activity has been reported for the 2′,3′-didehydro-2′,3′-dideoxy analogues of cytidine (2) (**B**), thymidine (3, and references therein) (**C**), and carbocyclic



A **B** B = cytosin-1-yl **C** B = thymin-1-yl **D** B = guanin-9-yl

guanosine (4) (**D**). We have reported 2′(and 3′)-deoxy-2′(and 3′)-methylene (**8** and **1**, respectively) pyrimidine (5*a*) and purine (5*b*) nucleosides and their mechanism-based inhibition of ribonucleotide reductase (6) and *S*-adenosyl-L-homocysteine hydrolase (7). We now describe conversions of **1** and **8** into 2′,3′-didehydro-2′,3′-dideoxy-3′(and 2′)-methyl nucleosides (**7** and **14**) via [3,3]-sigmatropic rearrangements of the 2′(and 3′)-*O*-phenoxythiocarbonyl intermediates **3** and **10**, respectively. The endocyclic alkenes **7** and **14** also are produced exclusively by radical dehalogenation of the allylic chloro derivatives **4** and **12**, respectively. During our investigation, Ueda and co-workers (8) reported obtaining the 2′,3′-didehydro-2′,3′-dideoxy-2′(and 3′)-methyl-5-methyluridines via a similar rearrangement of 2′(and 3′)-deoxy-3′(and 2′)-*O*-(imidazol-1-yl)thiocarbonyl-2′(and 3′)-methylene derivatives. Czernecki *et al.* (9) also prepared 2′,3′-didehydro-2′,3′-dideoxy-3′-methyl-5-methyluridine starting from 1,2-*O*-isopropylidene-α-D-xylofuranose via sugar transformations, coupling, and an analogous rearrangement.

Results and discussion

Protection of the 3′-deoxy-3′-methylene nucleosides **1***a* (5*a*) and **1***b* (5*b*) (Scheme 1) with *tert*-butyldiphenylsilyl (TBDPS) chloride/pyridine (10) gave the 5′-*O*-TBDPS derivatives **2***a* (94%) and **2***b* (95%). Treatment of **2**(*a* and *b*) with phenyl chlorothionocarbonate/DMAP/MeCN (11) at ambient temperature resulted in spontaneous conversion into their 2′,3′-didehydro-2′,3′-dideoxy-3′-(phenoxycarbonylthio)methyl analogues **5***a* (80%) and **5***b* (93%). The ^{1}H NMR spectrum of **5***a* (Table 1) had an olefinic proton peak at δ 6.99 for H2′ and an AB system at δ 3.59, 3.89 (J = 15.6 Hz) for the CH_2S group. Similar ^{1}H NMR data were observed for **5***b*. Precedent for the spontaneous [3,3]-sigmatropic rearrangement of the allylic 2′-*O*-phenoxythiocarbonyl intermediates **3***a,b* (observed at lower temperatures by ^{1}H NMR) was noted with allyl *S*-methyl xanthate in 1909 (12), and the mechanism and synthetic applications have been studied (13, and references therein). Tributyltin hydride-mediated hydrodesulfurization (Bu_3SnH/AIBN/toluene/Δ) of **5***a* and **5***b* gave **6***a* (85%) and **6***b* (90%) exclusively, and deprotection with tetrabutylammonium fluoride in tetrahydrofuran (TBAF/THF) and purification gave crystalline 1-(2,3-dideoxy-3-methyl-β-D-*glycero*-pent-2-enofuranosyl)uracil (2′,3′-didehydro-2′,3′-dideoxy-3′-methyluridine) (**7***a*, 60%) and **7***b* (60%), respectively.

Since these exomethylene allylic thioesters, **5**, with an endocyclic double bond gave only the exomethyl endocyclic alkenes, the 2′-chloro-2′-deoxy derivative **4***a* was prepared to evaluate whether initial generation of a radical

(*a*) TBDPS-Cl/pyridine; (*b*) $SOCl_2$/pyridine; (*c*) PhOC(S)Cl/DMAP; (*d*) Bu_3SnH/AIBN/toluene/100°C; (*e*) Bu_4NF/THF

SCHEME 1

at C2′ would have any effect on product formation. Treatment of **2***a* with thionyl chloride/pyridine/dichloromethane afforded **4***a* (62%) and the cyclonucleoside **15** (14%). O^2,2′-Anhydronucleoside intermediates such as **15** have been identified in various preparations (14) of pyrimidine 2′-deoxy-2′-halonucleosides from 2′-hydroxy precursors. Treatment of **4***a* with Bu_3SnH/AIBN/toluene/Δ gave **6***a* (95%) as the only observed product. Thus, this radical species underwent highly preferential allylic hydrogen transfer at the exocyclic methylene carbon to give the *endo* unsaturated compound, in harmony with the greater thermodynamic stability of 1-methylcyclopentene relative to methylenecyclopentane (15).

The rearrangement/desulfurization/dehalogenation sequence worked equally well with 2′-deoxy-2′-methylene nucleosides. Silylation of **8***a* (5*a*) and **8***b* (5*b*) gave **9***a* (90%) and **9***b* (95%), respectively. Treatment of **9***a* and **9***b* with phenyl chlorothionocarbonate afforded the rearranged products **11***a* (85%) and 9-[5-*O*-(*tert*-butyldiphenylsilyl)-2,3-dideoxy-2-(phenoxycarbonylthio)methyl-β-D-*glycero*-pent-2-enofuranosyl]adenine (**11***b*, 87%). Treatment of **11***a* and **11***b* with Bu_3SnH/AIBN/toluene/Δ gave **13***a* (85%) and **13***b* (84%), which were deprotected to afford **14***a* (95%) and **14***b* (95%), respectively. Compound **14***a* was previously synthesized in low yield from a 2′,3′-didehydro-2′,3′-dideoxy-3′-phenylselenone nucleoside (16).

Treatment of **9***a* with $SOCl_2$/pyridine/CH_2Cl_2 afforded the allylic transposition product **12***a* (89%) in contrast to the results with **2***a* (*vide supra*). Formation of pyrimidine O^2,3′-anhydronucleosides is much less facile than cyclization at the 2′-position (17). Thus, the initially formed 3′-chlorosulfite presumably underwent S_N2' substitution by attack of chloride at the exocyclic 2′-methylene carbon to gave **12***a*. Treatment of **12***a* with Bu_3SnH/AIBN/toluene/Δ again gave the exomethyl endocyclic alkene **13***a* (88%) exclusively.

In summary, we have developed mild conversions of 2′(and 3′)-deoxy-2′(and 3′)-methylenenucleosides into their corresponding 2′,3′-didehydro-2′,3′-dideoxy-2′(and 3′)-methyl analogues via formation of phenyl thionocarbonate esters, spontaneous rearrangement of the latter to allylic thioesters at ambient temperature, and tributylstannane-mediated allylic hydrodesulfurization. We also have demonstrated that the radical-mediated hydrodehalogenations of 5′-*O*-TBDPS-2′-chloromethyl-2′,3′-didehydro-2′,3′-dideoxyuridine and 5′-*O*-TBDPS-2′-chloro-2′,3′-dideoxy-3′-methyleneuridine give the more thermodynamically stable 2′(and 3′)-methyl-2′,3′-didehydro-2′,3′-dideoxyuridine derivatives (exomethyl endocyclic alkenes).

Experimental section

General procedures

Uncorrected melting points were obtained with a capillary melting tube apparatus. Ultraviolet (UV) spectra of MeOH solutions were determined with a Hewlett–Packard 8451A spectrophotometer. ^1H (200 MHz) (Table 1) and ^{13}C (50 MHz) (Table 2) NMR spectra were obtained with a Varian Gemini-200 spectrometer. Low-resolution electron-impact mass spectra (MS) were determined with a Finnigan MAT 8430 spectrometer at 20 eV. Flash evaporations (<35°C bath temperatures) were effected with a rotary evaporator with water aspirator or mechanical oil pump vacuum. Flash chromatography was performed with E. Merck Kieselgel 60, 230–400 mesh. Unless specified otherwise, the solvent for chromatography was hexanes/EtOAc (7:3, v/v). Reagent grade solvents and reagents were distilled prior to use. Pyridine was dried by refluxing with and distillation from CaH_2. MeCN and toluene were distilled from P_4O_{10}. Elemental analyses were determined by M-H-W Laboratories, Phoenix, Ariz.

*1-(5-O-TBDPS-3-deoxy-3-methylene-β-D-*erythro-*pentofuranosyl)uracil* **2**a

Procedure A (10)

TBDPS-Cl (0.40 mL, 0.42 g, 1.56 mmol) was added to a solution of **1***a* (5*a*) (0.25 g, 1.04 mmol) in pyridine (5 mL) and the mixture was stirred at ambient temperature for 18 h. Solvent was evaporated and the residue partitioned between EtOAc (50 mL) and ice-cold 0.01 N HCl/H_2O (30 mL). The aqueous phase was extracted (EtOAc) and the combined organic phase was washed (saturated $NaHCO_3/H_2O$ and brine), dried (Na_2SO_4), and evaporated. The colorless foam (0.55 g) was used without further purification. For characterization, this material was chromatographed (hexane/EtOAc, 1:2) to give **2***a* (0.47 g, 94%) as a colorless solid foam: UV_{max}: 260 nm; MS *m/z*: 420 (10, M − CMe_3 − H), 309 (90, M − CMe_3 − BH), 281 (14, M − CMe_3 − BCHO), 199 (100, Ph_2SiOH).

*9-(5-O-TBDPS-3-deoxy-3-methylene-β-D-*erythro-*pentofuranosyl)adenine* **2**b

Procedure A was applied to **1***b* (5*b*) (0.56 g, 2.13 mmol) to give **2***b* (1.0 g, 95%) as a colorless solid foam: UV_{max}: 260 nm; MS *m/z*: 502 (4, MH^+), 444 (100, M − CMe_3), 309 (18, M − CMe_3 − BH), 199 (75, Ph_2SiOH).

*1-(5-O-TBDPS-2-chloro-2,3-dideoxy-3-methylene-β-D-*erythro-*pentofuranosyl)uracil* **4**a

Procedure B

$SOCl_2$ (37 μL, 60 mg, 0.5 mmol) in CH_2Cl_2 (0.5 mL) was added to **2***a* (50 mg, 0.10 mmol) and pyridine (41 μL, 40 mg, 0.5 mmol) in CH_2Cl_2 (1.5 mL) at 0°C. The mixture was stirred at ambient temperature for 48 h, diluted (CH_2Cl_2, 10 mL), and poured into saturated $NaHCO_3/H_2O$ (5 mL, 0°C). The aqueous phase was extracted (CH_2Cl_2) and the combined organic phase was dried (Na_2SO_4) and evaporated. The residue was chromatographed (hexane/EtOAc, 3:1) to give cyclonucleoside **15** (6.5 mg, 14%) and **4***a* (32 mg, 62%) as a colorless solid foam. **15**: UV_{max}: 306 nm; MS *m/z*: 403 (80, M − CMe_3), 327 (6, M − CMe_3 − Ph), 293 (40, M − CMe_3 − B), 199 (100, Ph_2SiOH). **4***a*: UV_{max}: 259 nm (ε 9000); MS *m/z*: 439 (3, M[^{35}Cl] − CMe_3), 441 (1, M[^{37}Cl] − CMe_3), 403 (40, M − CMe_3 − HCl), 293 (10, M − CMe_3 − Cl − B), 87 (100, M − BCHO − $Ph_2Si(CMe_3)OCH_2$). Anal. calcd. for $C_{26}H_{29}ClN_2O_4Si$: C 62.83, H 5.88, N 5.64; found: C 63.00, H 5.98, N 5.62.

*1-[5-O-TBDPS-2,3-dideoxy-3-(phenoxycarbonylthio)methyl-β-D-*glycero-*pent-2-enofuranosyl]uracil* **5**a

Procedure C (11)

DMAP (0.32 g, 2.7 mmol) was added to a solution of crude **2***a* (0.55 g) in MeCN (25 mL). Phenyl chlorothionocarbonate (0.18 mL, 0.22 g, 1.35 mmol) was added and the mixture was stirred at ambient temperature under N_2 for 18 h. Volatiles were evaporated and the residue was partitioned between EtOAc (50 mL) and brine/H_2O (1:1, 30 mL). The aqueous phase was extracted (EtOAc) and the combined organic phase was washed (saturated $NaHCO_3/H_2O$ and brine), dried (Na_2SO4), and evaporated. Chromatography (hexane/EtOAc, 1:1) gave **5***a* (0.51 g, 80% from **1***a*) as a colorless solid foam: UV_{max}: 260 nm (ε 9700); MS *m/z*: 557 (1, M − CMe_3), 445 (100, M − CMe_3 − BH), 291 (98, M − CMe_3 − BH_2 − PhOCOS). Anal. calcd. for $C_{33}H_{34}N_2O_6SSi$: C 64.47, H 5.57, N 4.56, S 5.22; found: C 64.45, H 5.64, N 4.54, S 5.30.

*9-[5-O-TBDPS-2,3-dideoxy-3-(phenoxycarbonylthio)methyl-β-D-*glycero-*pent-2-enofuranosyl]adenine* **5**b

Procedure C was applied to **2***b* (0.60 g, 1.2 mmol) to give **5***b* (0.70 g, 93%) as slightly colored needles (EtOAc/hexanes): mp 111–112°C; UV_{max}: 260 nm (ε 16 700); MS *m/z*: 580 (10, M −

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

CMe_3), 445 (100, M − CMe_3 − BH). Anal. calcd. for $C_{34}H_{35}N_5O_4SSi$: C 64.03, H 5.53, N 10.98; found: C 63.66, H 5.60, N 10.99.

*1-(5-O-TBDPS-2,3-dideoxy-3-methyl-β-D-*glycero*-pent-2-enofuranosyl)uracil* **6**a

Procedure D

AIBN (0.042 g, 0.25 mmol) and Bu_3SnH (0.56 mL, 0.61 g, 2.1 mmol) were added to a solution of **5***a* (0.43 g, 0.70 mmol) in toluene (20 mL). The solution was deoxygenated (N_2) for 20 min and then heated at 100°C under N_2 for 10 h. Volatiles were evaporated and the residue was chromatographed (hexane/EtOAc, gradient 4:1 → 1:1) to give **6***a* (0.27 g, 85%) as a colorless foam: UV_{max}: 260 nm; MS *m/z*: 293 (100, M − CMe_3 − BH), 199 (90, Ph_2SiOH), 187 (60, M − CMe_3 − BCH_2O − Ph). Analogous treatment of **4***a* (17 mg, 0.034 mmol) gave **6***a* (15 mg, 95%) with identical spectral data.

*9-(5-O-TBDPS-2,3-dideoxy-3-methyl-β-D-*glycero*-pent-2-enofuranosyl)adenine* **6**b

Procedure D was applied to **5***b* (0.44 g, 0.69 mmol) to give **6***b* (0.29 g, 90%) as colorless needles (EtOAc/hexane): mp 121–122°C; UV_{max}: 260 nm; MS *m/z*: 428 (95, M − CMe_3), 293 (100, M − CMe_3 − BH), 187 (90, M − CMe_3 − BCH_2O − Ph).

*1-(2,3-Dideoxy-3-methyl-β-D-*glycero*-pent-2-enofuranosyl)uracil (2',3'-didehydro-2',3-dideoxy-3'-methyluridine)* **7**a

Procedure E

Bu_4NF/THF (1 M; 0.54 mL, 0.54 mmol) was added to a solution of **6***a* (0.25 g, 0.54 mmol) in THF (15 mL) at 0°C. After 1 h at 0°C, the solution was evaporated (<25°C) and the residue was chromatographed (Dowex 50 (Na^+) resin/H_2O; elution with H_2O) to give a colorless residue containing uracil (TLC). Chromatography ($CHCl_3$/EtOH, 47:3) and crystallization (acetone/Et_2O) afforded **7***a* (0.072 g, 60%) as a colorless powder: mp 123–124°C; UV_{max}: 260 nm (ε 9600); MS *m/z*: 112 (100, M − BH). Anal. calcd. for $C_{10}H_{12}N_2O_4$: C 53.57, H 5.39, N 12.49; found: C 53.47, H 5.29, N 12.57.

*9-(2,3-Dideoxy-3-methyl-β-D-*glycero*-pent-2-enofuranosyl)-adenine (2',3'-didehydro-2',3'-dideoxy-3'-methyl-adenosine)* **7**b

Procedure E was applied to **6***b* (0.25 g, 0.51 mmol) with evaporation (<25°C) and direct chromatography ($CHCl_3$/EtOH, 93:7) to give **7***b* (0.075 g, 60%) as a colorless solid: mp 110–112°C; UV_{max}: 260 nm (ε 14 000); MS *m/z*: 248 (30, MH^+), 231 (100, MH − OH). Anal. calcd. for $C_{11}H_{13}N_5O_2 \cdot 0.25$ EtOH: C 53.38, H 5.65, N 27.06; found: C 53.35, H 5.36, N 26.82.

*1-(5-O-TBDPS-2-deoxy-2-methylene-β-D-*erythro*-pentofuranosyl)uracil* **9**a

Procedure A was applied to **8***a* (5*a*) (0.70 g, 2.91 mmol) to give **9***a* (1.25 g, 90%) as colorless prisms (EtOAc/hexane): mp 146–147°C; UV_{max}: 260 nm; MS *m/z*: 421 (96, M − CMe_3), 309 (20, M − CMe_3 − BH), 293 (100, M − CMe_3 − B − OH).

*9-(5-O-TBDPS-2-deoxy-2-methylene-β-D-*erythro*-pentofuranosyl)adenine* **9**b

Procedure A was applied to **8***b* (5*b*) (0.37 g, 1.4 mmol) to give **9***b* (0.66 g, 95%) as a colorless solid foam: UV_{max}: 260 nm; MS *m/z*: 444 (100, M − CMe_3), 309 (8, M − CMe_3 − BH).

*1-[5-O-TBDPS-2,3-dideoxy-2-(phenoxycarbonylthio)methyl-β-D-*glycero*-pent-2-enofuranosyl]uracil* **11**a

Procedure C was applied to **9***a* (0.40 g, 0.84 mmol) to give **11***a* (0.43 g, 85%) as a solid foam: UV_{max}: 260 nm (ε 9000); MS *m/z*: 556 (40, M − CMe_3 − H), 445 (100, M − CMe_3 − BH), 351 (30, M − CMe_3 − BH_2 − PhO), 293 (22, M − CMe_3 − B − PhOCOS). Anal. calcd. for $C_{33}H_{34}N_2O_6SSi$: C 64.47, H 5.57, N 4.56, S 5.22; found: C 64.59, H 5.41, N 4.56, S 5.15.

*9-[5-O-TBDPS-2,3-dideoxy-2-(phenoxycarbonylthio)methyl-β-D-*glycero*-pent-2-enofuranosyl]adenine* **11**b

Procedure C was applied to **9***b* (0.40 g, 0.80 mmol) to give **11***b* (0.34 g, 87%) as a colorless solid foam: UV_{max}: 260 nm (ε 18 000); MS *m/z*: 325 (20, M − CMe_3 − B − PhOCO), 293 (22, M − CMe_3 − B − PhOCOS), 199 (100, Ph_2SiOH). Anal. calcd. for $C_{34}H_{35}N_5O_4SSi$: C 64.03, H 5.53, N 10.98; found: C 64.20, H 5.31, N 10.80.

*1-(5-O-TBDPS-2-chloromethyl-2,3-dideoxy-β-D-*glycero*-pent-2-enofuranosyl)uracil* **12**a

Procedure B was applied to **9***a* (50 mg, 0.10 mmol) to give **12***a* (46 mg, 89%) as a colorless solid foam: UV_{max}: 260 nm (ε 9400); MS *m/z*: 403 (12, M − CMe_3 − HCl), 327 (6, M − CMe_3 − BH), 293 (18, M − CMe_3 − BH − Cl), 199 (100, Ph_2SiOH). Anal. calcd. for $C_{26}H_{29}ClN_2O_4Si$: C 62.83, H 5.88, N 5.64; found: C 62.81, H 5.82, N 5.56.

*1-(5-O-TBDPS-2,3-dideoxy-2-methyl-β-D-*glycero*-pent-2-enofuranosyl)uracil* **13**a

Procedure D was applied to **11***a* (0.30 g, 0.48 mmol) to give **13***a* (0.19 g, 85%) as colorless needles (Et_2O/hexane): mp 146–147°C; UV_{max}: 260 nm; MS *m/z*: 405 (5, M − CMe_3), 293 (100, M − CMe_3 − BH), 187 (60, M − CMe_3 − BCH_2O − Ph). Analogous treatment of **12***a* (36 mg, 0.076 mmol) by procedure D gave **13***a* (29 mg, 88%) with identical spectral data.

*9-(5-O-TBDPS-2,3-dideoxy-2-methyl-β-D-*glycero*-pent-2-enofuranosyl)adenine* **13**b

Procedure D was applied to **11***b* (0.35 g, 0.54 mmol) to give **13***b* (0.22 g, 84%) as a colorless solid (EtOAc/hexane): mp 166–167°C; UV_{max}: 260 nm; MS *m/z*: 428 (8, M − CMe_3), 293 (20, M − CMe_3 − BH), 95 (100, M − BH − $Ph_2Si(CMe_3)O$).

*1-(2,3-Dideoxy-2-methyl-β-D-*glycero*-pent-2-enofuranosyl)uracil (2',3'-didehydro-2',3'-dideoxy-2'-methyluridine)* **14**a *(16)*

Procedure E was applied to **13***a* (0.20 g, 0.43 mmol) to afford **14***a* (0.092 g, 95%) as a solid foam: UV_{max}: 259 nm (ε 9200); MS *m/z*: 224 (2, M^+), 193 (30, M − CH_2O), 113 (100, M − B). Anal. calcd. for $C_{10}H_{12}N_2O_4$: C 53.57, H 5.39, N 12.49; found: C 53.73, H 5.49, N 12.29.

*9-(2,3-Dideoxy-2-methyl-β-D-*glycero*-pent-2-enofuranosyl)-adenine (2',3'-didehydro-2',3'-dideoxy-2'-methyl-adenosine)* **14**b

Procedure E was applied to **13***b* (0.185 g, 0.38 mmol) with evaporation (<25°C) followed directly by chromatography ($CHCl_3$/EtOH, 47:3) to give **14***b* (0.085 g, 91%) as a colorless powder: mp 177–178°C; UV_{max}: 259 nm, (ε 14 000); MS *m/z*: 247 (6, M^+), 217 (10, M − CH_2O), 135 (100, BH), 112 (20, M − BH). Anal. calcd. for $C_{11}H_{13}N_5O_2$: C 53.43, H 5.30, N 28.32; found: C 53.27, H 5.47, N 28.10.

Acknowledgments

We thank the American Cancer Society (Grant No. DHP-34) and Brigham Young University Development Funds for generous support and Mrs. Kathryn M. Rollins for assistance with the manuscript.

Nucleic acid related compounds. 78. Stereocontrolled syntheses of 6′(*E* and *Z*)-halovinyl analogues from uridine-derived vinylsulfones via vinyltin intermediates[1]

STANISLAW F. WNUK AND MORRIS J. ROBINS[2]
Department of Chemistry, Brigham Young University, Provo, UT 84602, U.S.A.

Received August 12, 1992

STANISLAW F. WNUK and MORRIS J. ROBINS. Can. J. Chem. **71**, 192 (1993).

Treatment of the 6′(*E*)-tosylvinyl homonucleoside **1***a* with Bu_3SnH/AIBN/toluene/Δ gave separable mixtures of 6′-vinylstannanes **2***a*(*E*/*Z*) in high yields. Stereospecific halodestannylations with *N*-iodosuccinimide, bromine, and *N*-bromosuccinimide proceeded smoothly to give the 6′(*E* or *Z*)-iodo(and bromo) vinyl compounds with retention of configuration. Chlorine or iodobenzene dichloride effected moderately stereoselective chlorodestannylation. Treatment of **2***a* with NH_4F/MeOH/Δ resulted in carbon–tin bond cleavage to give the free vinyl derivative **4***a*. Aqueous trifluoroacetic acid effected concomitant protiodestannylation and deprotection of **2***a* to give **4***b*. Treatment of **2***a*(*E*) with lead tetraacetate/acetonitrile and deprotection afforded acetylenic derivative **3***b*.

STANISLAW F. WNUK et MORRIS J. ROBINS. Can. J. Chem. **71**, 192 (1993).

Le traitement de l'homonucléoside de 6′(*E*)-tosylvinyle (**1***a*) avec le Bu_3SnH/AIBN/toluène/Δ conduit, avec d'excellents rendements, à des mélanges de 6′-vinylstannanes (**2***a*(*E*/*Z*)) que l'on peut sèparer. Les halodéstannylations stérospécifiques avec de la *N*-iodosuccinimide, du brome ou de la *N*-bromosuccinimide se réalisent facilement et conduisent à des composés 6′(*E* ou *Z*)-iodo(et bromo) vinyliques, avec rétention de configuration. Le chlore ou le dichlorure d'iodobenzène provoquent une chlorodéstannylation modérément stéréosélective. Le traitement du composé **2***a* avec du NH_4F/MeOH/Δ conduit à un clivage de la liaison carbone–étain avec la formation du dérivé vinylique libre **4***a*. L'acide trifluoroacétique aqueux permet d'effectuer la protiodéstannylation concomitante avec la déprotection du composé **2***a* qui fournit le composé **4***b*. Le traitement du composé **2***a*(*E*) avec du tétraacétate de plomb/acétonitrile, suivi d'une déprotection, conduit au dérivé acétylénique **3***b*.

[Traduit par la rédaction]

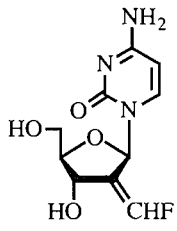
Introduction

Sulfones (1), vinyl sulfones (2), and vinyltin compounds (3) have recently been incorporated into the sugar moiety of nucleosides and used for a variety of transformations (4–8). Chattopadhyaya and co-workers (4) have prepared 1-(2,3-dideoxy-3-(*p*-toluenesulfonyl)-β-D-*glycero*-pent-2-enofuranosyl)uracil (and adenine) and uracil 2′(and 3′)-phenylselenone analogues and utilized these vinyl sulfones and selenones as Michael acceptors for functionalization of the carbohydrate moiety. Barton *et al.* have developed radical-mediated chemistry at C4′ for the stereocontrolled synthesis of chain-lengthened vinyl sulfones (5*a*) and synthesized sinefungin (5*b*) and its uracil analogue (5*c*).

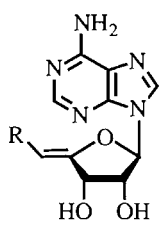
Oxidation of 2′,3′-*O*-isopropylidene nucleosides and treatment of the resulting 5′-aldehydes with (*p*-toluenesulfonylmethylene)triphenylphosphorane afforded the *E*-vinylsulfone **1***a* (6*a*) and its adenine analogue (6*b*). Michael addition of hydrogen, thiomethanol, and ammonia gave 5′-substituted 5′,6′-dideoxy derivatives, but attempted removal of the tosyl group failed (6*a*) or was difficult (6*b*). Detosylation of the adenine analogue of **1***a* was effected via addition of tributylstannyllithium (6*b*).

Horner–Wittig treatment (7) of 2′-ketonucleosides with diethyl fluoro(phenylsulfonyl)methanephosphonate gave fluorovinyl sulfone diastereomers that were separated and converted into fluorovinylstannanes of retained stereochemistry with tributyltin hydride under free radical conditions. Hydrodestannylation with retention occurred upon protiolysis to give the 2′-deoxy-2′-fluoromethylenecytidines (**A**), which are potent inhibitors (7*b*) of ribonucleoside diphosphate reductase. Sulfonate isosteres of nucleoside monophosphates have been synthesized (8) via Horner–Emmons addition of a sulfonate-stabilized reagent to nucleoside 5′-aldehydes (or carbohydrate 3′-ketones) and incorporated into nonionic dinucleotide analogues.

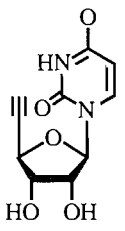
Other Wittig reactions of nucleoside 5′-aldehydes have provided 6′-substituted hexofuranosyl nucleosides (9, 10), and recently the unsubstituted 5′-deoxy-5′-methyleneadenosine (6*b*) and its neplanocin A analogue (11) were prepared by this route. Hydroboration of a 5′-deoxy-5′-



A



B (R = F or Cl)



3*b*

methyleneadenosine derivative gave homoadenosine, 9-(5-deoxy-β-D-*ribo*-hexofuranosyl)adenine (12). Treatment of 5′-aldehydes with (dibromomethylene)triphenylphosphorane gave the 5′-(dibromomethylene)-5′-deoxyuridine and thymine analogues. The uracil compound was converted into acetylenic derivative **3***b* (10). The adenine analogue of **3***b* was prepared recently by analogous approaches and found to be a mechanism-based inhibitor of *S*-adenosyl-L-homocysteine hydrolase (13). The 5′(*Z*)-fluoro(and chloro) 4′,5′-unsaturated adenine nucleosides (**B**) also are potent inhibitors of this enzyme (14). Acetylenic and iodomethylene acyclo adenine analogues have been reported recently (15).

We now describe efficient syntheses of uridine-derived 6′(*E* and *Z*)-vinylstannanes **2***a* via radical-mediated detosylation (16) of vinyl sulfone **1***a*. Protiodestannylation gave

(*a*) Bu_3SnH/AIBN/toluene/Δ; (*b*) $Pb(OAc)_4/CH_3CN$; (*c*) CF_3CO_2H/H_2O; (*d*) NH_4F/MeOH/Δ; (*e*) (Br_2 or NBS/CCl_4/CH_2Cl_2/-40°C; (*f*) (I_2 or NIS)/CCl_4/CH_2Cl_2/-40°C

SCHEME 1

5′-deoxy-5′-methyleneuridine (**4***b*) and oxidative destannylation gave the acetylenic analogue **3***b*. Stereospecific conversion of the **2***a* diastereomers to 6′(*E* and *Z*)-halovinyl derivatives (**5**–**8**) provided convenient access to these 5′-halomethylene analogues, which are difficult to prepare directly.

Results and discussion

The crystalline vinyl sulfone **1***a* was prepared in 85% yield from 2′,3′-*O*-isopropylideneuridine (6*a*). Treatment of **1***a* with Bu_3SnH/AIBN/toluene/Δ gave the 6′-vinylstannanes **2***a* (*E*/*Z*, ~2.8:1; 87%) (Scheme 1). The **2***a*(*E*) ($^3J_{5'-6'}$ = 19.1 Hz) and **2***a*(*Z*) ($^3J_{5'-6'}$ = 12.8 Hz) diastereomers were separated by silica column chromatography. It is noteworthy that no conversion of vinyl sulfone **1***a* to its allylic isomer was observed, since this isomerization had occurred with classical reductive sulfone cleavage methods (6*a*).

Treatment of **2***a* with silica/CH_2Cl_2 (17), CsF/MeOH, or NH_3/MeOH (7*b*) gave the 5′-methylene derivative **4***a* in low yields. However, **4***a* was obtained smoothly (94%) upon treatment of **2***a* with NH_4F/MeOH/Δ, as we recently described for efficient silicon–oxygen bond cleavage (18). Deprotection of **4***a* with aqueous trifluoroacetic acid gave 5′-deoxy-5′-methyleneuridine (**4***b*). Aqueous trifluoroacetic acid effected concomitant protiodestannylation and deprotection of **2***a*(*E*) to give **4***b* (94%). The free 6′-vinylstannane **2***b*(*E*) was obtained (~65%) when unprotected vinyl sulfone **1***b* was treated with Bu_3SnH/AIBN/toluene/*N*,*N*-dimethylacetamide/Δ. Treatment of **2***a*(*E*) with lead tetraacetate (1.25 equiv.) in acetonitrile (19) afforded the acetylenic derivative **3***a* (72%) (plus recovered **2***a*(*E*) (18%)), which was deprotected to give **3***b* (80%).

Bromo(and iodo)destannylation with electrophilic halogen reagents proceeded smoothly to give the 6′-halovinyl derivatives with retention of configuration. Treatment of **2***a*(*E*) with *N*-bromosuccinimide (NBS, 1.02 equiv.) in CCl_4/CH_2Cl_2 (1:1) at −40°C for 10 min gave the 6′(*E*)-bromo derivative **5***a*(*E*). Treatment of **2***a*(*E*) with equimolar bromine also gave **5***a*(*E*) exclusively. Analogous treatment of **2***a*(*Z*) with NBS gave **5***a*(*Z*). The ^{1}H NMR spectra of **5***a*(*E*) and **5***a*(*Z*) had "collapsed" singlet H5′ and H6′ peaks. However, deprotection of **5***a*(*E*) and **5***a*(*Z*) afforded **5***b*(*E*) ($^3J_{6'-5'}$ = 13.5 Hz) and **5***b*(*Z*) ($^3J_{6'-5'}$ = 7.0 Hz), respectively, whose vinyl coupling constants were consistent with the assigned configurations. Analogous treatment of **2***a*(*E*) and **2***a*(*Z*) with *N*-iodosuccinimide (1.03 equiv.) effected iododestannylation to give **6***a*(*E*) and **6***a*(*Z*), which were deprotected to give **6***b*(*E*) (87%) and **6***b*(*Z*) (84%) (two steps), respectively. Stereochemical assignments were in harmony with NMR spectra (Tables 1 and 2).

Treatment of **2***a*(*E*) with *N*-chlorosuccinimide (1–3 equiv.; −40°C–ambient; 15 min – 6 h) in CCl_4/CH_2Cl_2 failed to give the 6′-chloro compounds. Chlorine effected conversions of **2***a*(*E*) to separable mixtures of **7***a*(*E*/*Z*, ~3.2:1; 46%) and the 5,6′-dichloro products **8***a*(*E*/*Z*, ~2.8:1; 33%) (Scheme 2). Similarly, treatment of **2***a*(*Z*) gave **7***a*(*E*/*Z*; ~1:3) plus **8***a*(*E*/*Z*, ~1:3.5) in ~80% combined yields. Lower yields and decreased stereospecificity for chlorodestannylation relative to bromo(and iodo)destannylation reactions have been noted previously (3). Treatment of **2***a*(*E*) and **2***a*(*Z*) with iodobenzene dichloride afforded **7***a*(*E*/*Z*: ~3.3:1 and ~1:3, respectively) in moderate yields without observed formation of the uracil-chlorinated compounds **8**. However, a small quantity of a 6-iodo isomer, **6***b*(*E*), was detected by HPLC (after deprotection) and tentatively identified by ^{1}H NMR comparison. Deprotection, silica column or RP-HPLC separation, and crystallization afforded **7***b*(*E*) and **7***b*(*Z*) (and **8***b*(*E*) and **8***b*(*Z*) when chlorine was used) with NMR data in harmony with the geometric assignments (Tables 1 and 2). ^{13}C NMR peaks for C5′ of the 6′(*E*)-halovinyl derivatives were at lower fields (Δδ 1.81–4.52 ppm) than those of the 6′(*Z*) isomers. Our attempted fluorodestannylation of **2***a*(*E*) with xenon difluoride or *N*-fluoropyridinium triflate (1–2 equiv./CH_2Cl_2/−20°C–ambient/1–6 h) resulted in hydrodestannylation to give the 5′-methylene compound **4***a* in moderate yields. This is consistent with results noted in a very recent report in which the synthesis of vinyl fluorides in low to moderate yields by treatment of vinyl stannanes with xenon difluoride and "silver hexafluorophosphate" was described (20).

In summary, radical-mediated detosylation of the easily accessible 6′(*E*)-vinylsulfone **1***a* with Bu_3SnH/AIBN/toluene/Δ gave separable mixtures of the 6′-vinylstannanes **2***a*(*E*/Z). Stereospecific bromo(and iodo)destannylation proceeded smoothly to give 6′-(bromo or iodo)vinyl derivatives in high yields. Chlorodestannylations proceeded with only moderate stereoselectivity and yields. Attempted fluorodestannylations were not successful. Treatment of the 6′-vinylstannanes with ammonium fluoride in methanol or lead tetraacetate in acetonitrile resulted in carbon–tin bond cleavage to give the unsubstituted-vinyl and acetylenic analogues, respectively.

Experimental section

Uncorrected melting points were determined on a Hoover capillary apparatus. UV spectra of solutions in MeOH were recorded on a Hewlett–Packard 8951A spectrophotometer. ^{1}H (200 MHz) and ^{13}C (50 MHz) NMR spectra were recorded on a Varian

SCHEME 2

Gemini-200 spectrometer in Me_2SO-d_6 unless otherwise noted. Low-resolution mass spectra (MS) were obtained with a Finnigan MAT 8430 instrument. Elemental analyses were determined by M-H-W Laboratories, Phoenix, Ariz. Reagents and solvents were of reagent quality, and solvents were purified and dried before use. "Diffusion crystallization" was performed with the noted solvent combinations as described (21). Thin-layer chromatography (TLC) was performed on Merck Kieselgel 60 F_{254} sheets with: S_1 (Me_2CO/$CHCl_3$, 1:3), S_2 (EtOAc/hexane, 7:3), or S_3 (MeOH/$CHCl_3$, 1:9) with sample observation under 254 nm light. Column chromatography was performed with Merck Kieselgel 60 (230–400 mesh). Preparative and analytical RP-HPLC were performed with a Spectra Physics SP 8800 ternary pump system and Dynamax C_{18} columns.

*1-[6(*E/Z*)-Tributylstannyl-5,6-dideoxy-2,3*-O-*isopropylidene-β-*D*-*ribo-hex-5-enofuranosyl]uracil* **2**a(E/Z)

A suspension of **1***a* (1.63 g, 3.75 mmol) in toluene (30 mL) was deoxygenated (Ar, 30 min) and Bu_3SnH (4.37 g, 4.02 mL, 15 mmol) was added. Deoxygenation was continued for 15 min and AIBN (66 mg, 0.4 mmol) was added. The solution was refluxed for 4 h (TLC (S_{1-3}) showed less polar products and traces of **1***a*), evaporated, and the residue was column chromatographed. Slow elution (EtOAc/hexane, 3:2 → 4:1) gave **2***a*(*E*) (1.23 g, 58%), **2***a* (*E*/*Z*, ~3:2; 0.19 g, 9%), and **2***a*(*Z*) (0.43 g, 20%). Further elution (EtOAc) gave **1***a* (0.11 g, contaminated with by-products). **2***a*(*E*) (white solid dried at 65°C *in vacuo* for 3 days): mp 82–84°C; UV_{max}: 259 nm (ε 9800), UV_{min}: 233 nm (ε 4200); MS *m*/*z*: 513 (100, M − 57, ^{120}Sn), 511 (74, M − 57, ^{118}Sn), 509 (45, M − 57, ^{116}Sn). **2***a*(*Z*) (viscous oil): MS (CI, CH_4) *m*/*z*: 571 (100, MH^+, ^{120}Sn), 569 (72, MH^+, ^{118}Sn), 567 (43, MH^+, ^{116}Sn).

*1-[6(*E*)-Tributylstannyl-5,6-dideoxy-β-*D*-*ribo-*hex-5-enofuranosyl]uracil* **2**b(E)

A suspension of **1***b* (160 mg, 0.41 mmol) in deoxygenated *N,N*-dimethylacetamide/toluene (1:3, 20 mL), Bu_3SnH (477 mg, 0.44 mL, 1.62 mmol), and AIBN (10 mg, 0.0061 mmol) was refluxed for 6 h. Work-up (as described for **2***a*(*E*/*Z*)) and column chromatography (MeOH/$CHCl_3$, 1:25) gave **2***b*(*E*) (141 mg, ~65%; contaminated with by-products) as a viscous oil: MS (CI, CH_4) *m*/*z*: 531 (31, MH^+, ^{120}Sn), 529 (25, MH^+, ^{118}Sn), 527 (15, MH^+, ^{116}Sn), 473 (100, M − 57, ^{120}Sn), 471 (74, M − 57, ^{118}Sn), 469 (50, M − 57, ^{116}Sn).

1-(6-Deoxy-2,3-O-*isopropylidene-β-*D*-*ribo-hex-5-ynofuranosyl)uracil* **3**a

A solution of **2***a*(*E*) (120 mg, 0.21 mmol) in anhydrous CH_3CN (6 mL) under Ar was treated with $Pb(OAc)_4$ (115 mg, 0.26 mM) and stirred at ~0°C (ice-bath) for 1 h and then an additional 2 h at 0°C–ambient (TLC ($S_{2,3}$) showed more polar **3***a* and **2***a*(*E*)). The

mixture was evaporated and the residue was partitioned ($NaHCO_3/H_2O//CHCl_3$). The organic phase was washed ($NaHCO_3/H_2O$ and brine), dried ($MgSO_4$), evaporated, and the residue was column chromatographed (EtOAc) to give **2***a*(*E*) (21 mg, 18%) and **3***a* (42 mg, 72%): MS *m/z*: 263 (24, M − CH_3), 138 (65), 113 (30, BH_2), 80 (100).

*1-(6-Deoxy-β-D-*ribo*-hex-5-ynofuranosyl)uracil* **3**b

A solution of **3***a* (35 mg, 0.12 mmol) in CF_3CO_2H/H_2O (9:1, 5 mL) was stirred at 0°C for 1 h, evaporated, and coevaporated (EtOH). The residue was dissolved (H_2O/MeOH, 4:1; 5 mL), the solution was cooled (ice-bath), and H_2S was gently bubbled through for 30 s. The mixture was filtered through Celite, the filtrate was evaporated, and the residue was column chromatographed (EtOAc → MeOH/EtOAc, 1:9). Diffusion crystallization (EtOH/EtOAc) gave **3***b* (23 mg, 80%): mp 217–218°C (lit. (10) mp 209–211°C); UV_{max}: 261 nm (ε 9600), UV_{min}: 230 nm (ε 2200); MS *m/z*: 238 (M^+, 100).

*1-(5,6-Dideoxy-2,3-*O*-isopropylidene-β-D-*ribo*-hex-5-enofuranosyl)uracil* **4**a

A solution of **2***a* (*E*/*Z*, ~3:2; 0.18 g, 0.32 mmol) and NH_4F (59 mg, 1.6 mmol) in dry MeOH (10 mL) was refluxed for 4 h and evaporated. The white foam was partitioned ($NaHCO_3/H_2O//CHCl_3$) and the organic layer was washed (brine), dried ($MgSO_4$), and evaporated to give **4***a* (97 mg, 108%; contaminated with tin by-products). Column chromatography (EtOAc/hexane, 4:1) gave **4***a* (84 mg, 94%), which failed to crystallize: MS (CI, CH_4) *m/z*: 281 (100, MH^+).

*1-(5,6-Dideoxy-β-D-*ribo*-hex-5-enofuranosyl)uracil (5'-deoxy-5'-methyleneuridine)* **4**b

Method A

A solution of **2***a*(*E*) (91 mg, 0.16 mmol) in CF_3CO_2H/H_2O (9:1, 5 mL) was stirred at ~0°C for 1 h, evaporated, and coevaporated (EtOH). The residue was crystallized (Me_2CO) to give **4***b* (36 mg, 94%): mp 166–167°C; UV_{max}: 261 nm (ε 9800), UV_{min}: 230 nm (ε 2000); MS (CI, CH_4) *m/z*: 241 (18, MH^+), 113 (100, BH_2). Anal. calcd. for $C_{10}H_{12}N_2O_5$ (240.2): C 50.00, H 5.04, N 11.66; found: C 49.90, H 5.18, N 11.66.

Method B

A solution of crude **4***a* (97 mg) in CF_3CO_2H/H_2O (9:1, 5 mL) was stirred at ~0°C for 1 h, evaporated, and coevaporated (EtOH). The residue was chromatographed (Dowex 1 × 2 (OH^-), ~1.0 g of resin; H_2O (~100 mL), MeOH (~100 mL), product eluted with 0.3 M $Et_3NH_2CO_3/H_2O$ (~200 mL)) and the eluate was evaporated followed by additions/evaporations of H_2O (3 × 25 mL) *in vacuo*. The residue was diffusion crystallized (Me_2CO/hexane) to give **4***b* (62 mg, 81% from **2***a*) with identical physical data as in Method A.

*1-[6(*E*)-Bromo-5,6-dideoxy-2,3-*O*-isopropylidene-β-D-*ribo*-hex-5-enofuranosyl]uracil* **5**a(E)

Method A

Bromine (53 mg, 0.33 mmol) in CCl_4 (5 mL) was added dropwise to a stirred solution of **2***a*(*E*) (185 mg, 0.33 mmol) in CH_2Cl_2/CCl_4 (1:1, 15 mL) at ~−50°C. TLC (S_1) indicated that starting material was consumed when the addition of Br_2 was completed. After 5 min the colorless solution was poured into saturated $NaHCO_3/H_2O$ and extracted ($CHCl_3$). The combined organic phase was washed (brine and H_2O), dried ($MgSO_4$), and evaporated to give **5***a*(*E*) (136 mg, 115%; contaminated with tin by-products): mp 149–153°C; MS *m/z*: 360 (20, M^+, ^{81}Br), 358 (21, M^+, ^{79}Br), 112 (100, BH).

Method B

A solution of *N*-bromosuccinimide (37 mg, 0.21 mmol) in CH_2Cl_2/CCl_4 (1:1, 8 mL) was added dropwise to a stirred solution of **2***a*(*E*) (114 mg, 0.2 mmol) in CH_2Cl_2/CCl_4 (1:1, 12 mL) at ~−40°C. After 15 min the mixture was worked up as in Method A and column chromatographed (MeOH/$CHCl_3$, 1:49) to give **5***a*(*E*) (68 mg, 95%).

*1-[6(Z)-Bromo-5,6-dideoxy-2,3-*O*-isopropylidene-β-D-*ribo*-hex-5-enofuranosyl]uracil* **5**a(Z)

Treatment of **2***a*(*Z*) (85 mg, 0.15 mmol) with NBS (28 mg, 0.16 mmol) (as described for **5***a*(*E*), Method B) gave **5***a*(*Z*) (59 mg, 110%; contaminated with tin by-products): mp 167–170°C; MS *m/z*: 360 (34, M^+, ^{81}Br), 358 (35, M^+, ^{79}Br), 112 (100, BH).

*1-[6(*E*)-Bromo-5,6-dideoxy-β-D-*ribo*-hex-5-enofuranosyl]uracil* **5**b(E)

A solution of crude **5***a*(*E*) (136 mg, from Method A) in CF_3CO_2H/H_2O (9:1, 5 mL) was stirred at 0°C for 1 h, evaporated, coevaporated (EtOH), and the residue diffusion crystallized (MeOH/Et_2O) to give **5***b*(*E*) (42 mg). The concentrated mother liquor afforded an additional 41 mg (diffusion crystallization, MeOH/EtOAc//hexane) of **5***b*(*E*) (83 mg, 79% from **2***a*(*E*)) as a white solid: mp 183–184°C; UV_{max}: 261 nm (ε 9200), UV_{min}: 231 nm (ε 1900); MS *m/z*: 320 (8, M^+, ^{81}Br), 318 (8, M^+, ^{79}Br), 190 (52), 188 (53), 162 (54), 160 (52), 141 (90), 113 (100, BH_2). Anal. calcd. for $C_{10}H_{11}BrN_2O_5 \cdot 0.5\ H_2O$ (328.1): C 36.61, H 3.69, N 8.54; found: C 36.85, H 3.80, N 8.34.

*1-[6(Z)-Bromo-5,6-dideoxy-β-D-*ribo*-hex-5-enofuranosyl]uracil* **5**b(Z)

Deprotection of crude **5***a*(*Z*) (59 mg) (as described for **5***b*(*E*)), column chromatography (MeOH/EtOAc; 1:15), and diffusion crystallization (MeOH/EtOAc//hexane) gave **5***b*(*Z*) (39 mg, 81% from **2***a*(*Z*)): mp 194–196°C; UV_{max}: 261 nm (ε 9500), UV_{min}: 231 nm (ε 2000); MS (CI, CH_4) *m/z*: 321 (96, MH^+, ^{81}Br), 319 (100, MH^+, ^{79}Br). Anal. calcd. for $C_{10}H_{11}BrN_2O_5$ (319.1): C 37.64, H 3.47, N 8.78; found: C 37.79, H 3.41, N 8.56.

*1-[5,6-Dideoxy-6(*E*)-iodo-2,3-*O*-isopropylidene-β-D-*ribo*-hex-5-enofuranosyl]uracil* **6**a(E)

A solution of *N*-iodosuccinimide (63 mg, 0.28 mmol) in CH_2Cl_2/CCl_4 (1:1, 10 mL) was added dropwise to a stirred solution of **2***a*(*E*) (142 mg, 0.25 mmol) in CH_2Cl_2/CCl_4 (1:1, 15 mL) at ~−30°C. TLC (S_2) after 25 min indicated complete reaction to give a more polar compound (R_f 0.59; **2***a*(*E*): R_f 0.81). The slightly pink mixture was poured into saturated $NaHCO_3/H_2O$ and extracted ($CHCl_3$). The combined organic phase was washed (very dilute $NaHSO_3/H_2O$ and brine), dried ($MgSO_4$), and evaporated to give **6***a*(*E*) (100 mg, 99%) as a white solid: mp 170–172°C; MS (CI, CH_4) *m/z*: 407 (26, MH^+), 113 (100, BH_2). Treatment of **2***a*(*E*) with I_2 (1.1 equiv.) at ~0°C for 2 h also gave **6***a*(*E*) (85%).

*1-[5,6-Dideoxy-6(Z)-iodo-2,3-*O*-isopropylidene-β-D-*ribo*-hex-5-enofuranosyl]uracil* **6**a(Z)

Treatment of **2***a*(*Z*) (91 mg, 0.16 mmol) with *N*-iodosuccinimide (40 mg, 0.18 mmol) (as described for **6***a*(*E*)) gave **6***a*(*Z*) (63 mg, 97%; TLC (S_2) R_f 0.53, **2***a*(*Z*): R_f 0.75): mp 184–186°C; MS (CI, CH_4) *m/z*: 407 (100, MH^+).

*1-[5,6-Dideoxy-6(*E*)-iodo-β-D-*ribo*-hex-5-enofuranosyl]uracil* **6**b(E)

Deprotection of **6***a*(*E*) (78 mg, 0.19 mmol) (as described for **5***b*(*E*)) gave a colorless solid that was crystallized (MeOH/H_2O, 1:6) to give **6***b*(*E*) (23 mg, 33%) as fine needles. The mother liquor was concentrated and chromatographed ((Dowex 1 × 2 (OH^-) (~2 g of resin); H_2O (100 mL), MeOH (100 mL), product eluted with 0.3 M $Et_3NH_2CO_3/H_2O$ (~300 mL)) and the eluate was evaporated. Additions/evaporations of H_2O (3 × 30 mL) *in vacuo* gave a residue that was crystallized (MeOH/H_2O, 1:12) to give additional **6***b*(*E*) (28 mg; 51 mg, 73%, two crops): mp 202–203°C; UV_{max}: 260 nm (ε 10 500), UV_{min}: 238 (ε 4900); MS (CI, CH_4) *m/z*: 367 (15, MH^+), 239 (32), 113 (100, BH_2). Anal. calcd. for $C_{10}H_{11}IN_2O_5$ (366.1): C 32.81, H 3.03, N 7.65; found: C 33.02, H 3.07, N 7.71.

*1-[5,6-Dideoxy-6(Z)-iodo-β-D-*ribo*-hex-5-enofuranosyl]uracil* **6**b(Z)

Deprotection of **6***a*(*Z*) (61 mg, 0.15 mmol) (as described for **5***b*(*E*)) gave a colorless solid that was column chromatographed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

(MeOH/EtOAc, 1:20) and diffusion crystallized (Me_2CO/hexane) to give **6***b*(*Z*) (39 mg, 71%): mp 203–205°C; UV_{max}: 260 nm (ε 9700), UV_{min}: 237 nm (ε 4400); MS (CI, CH_4) *m/z*: 367 (81, MH^+), 239 (63), 113 (100, BH_2). Anal. calcd. for $C_{10}H_{11}IN_2O_5$ (366.1): C 32.81, H 3.03, N 7.65; found: C 32.79, H 3.09, N 7.71.

1-[6(E/Z)*-Chloro-5,6-dideoxy-2,3*-O-*isopropylidene-β-D*-ribo-*hex-5-enofuranosyl]uracil* **7**a(E/Z) *and 5-chloro-1-[6*(E/Z)*-chloro-5,6-dideoxy-2,3*-O-*isopropylidene-β-D*-ribo-*hex-5-enofuranosyl]uracil* **8**a(E/Z)

Method A

Cl_2 was gently bubbled through a solution of **2***a*(*E*) (285 mg, 0.5 mmol) in CCl_4/CH_2Cl_2 (1:1, 10 mL) at ~−50°C, and stirring was continued at ~−50 to −40°C for 15 min. The solution was washed ($NaHCO_3/H_2O$, dilute $Na_2S_2O_3/H_2O$, and brine), dried ($MgSO_4$), and evaporated. The resulting foam was column chromatographed (EtOAc/hexane, 1:1 → 9:1) to give **8***a*(*E*) (19 mg, 11%; S_2 R_f 0.81), **8***a* (*E/Z*, ~3:2; 38 mg, 22%), **7***a*(*E*) (55 mg, 35%; S_2 R_f 0.48), and **7***a*(*Z*) (17 mg, 11%; S_2 R_f 0.43). **8***a*(*E*): MS (CI, CH_4) *m/z*: 353 (9, MH^+, $^{37}Cl_2$), 351 (50, MH^+, ^{37}Cl, ^{35}Cl), 349 (76, MH^+, $^{35}Cl_2$), 205 (38, M − BH_2, ^{37}Cl), 203 (100, M − BH_2, ^{35}Cl), 149 (18, BH_2, ^{37}Cl), 147 (60, BH_2, ^{35}Cl). **7***a*(*E*): MS *m/z*: 301 (6, M − CH_3, ^{37}Cl), 299 (20, M − CH_3, ^{35}Cl), 144 (100), 138 (62). **7***a*(*Z*): MS (CI, CH_4) *m/z*: 317 (18, MH^+, ^{37}Cl), 315 (53, MH^+, ^{35}Cl), 144 (100), 138 (82).

Product ratios varied in different runs. Treatment of **2***a*(*Z*) under identical conditions gave **7***a*(*E/Z*, ~1:3; 44%) and **8***a*(*E/Z*, ~1:3.5; 36%). Longer reaction times and (or) greater amounts of Cl_2 gave **8***a*(*E/Z*) (~50%).

Method B

$PhICl_2$ (99 mg, 0.36 mM) was added in one portion to a stirred solution of **2***a*(*E*) (171 mg, 0.3 mmol) in CCl_4/CH_2Cl_2 (1:1, 10 mL) at ~−20°C. After 25 min a second portion of $PhICl_2$ (25 mg, 0.09 mM) was added and stirring was continued at ~−20°C for 40 min. Work-up and purification as in Method A gave **7***a*(*E*) (37 mg, 39%) and **7***a*(*Z*) (11 mg, 12%). Analogous treatment of **2***a*(*Z*) with $PhICl_2$ gave **7***a*(*E/Z*, ~1:3: 49%).

1-[6(E)*-Chloro-5,6-dideoxy-β-D*-ribo-*hex-5-enofuranosyl]uracil* **7**b(E)

Deprotection of **7***a*(*E*) (50 mg, 0.16 mmol; from Method A) (as described for **5***b*(*E*)) gave a slightly yellow solid that was column chromatographed (EtOAc/MeOH; 19:1) and diffusion crystallized (MeOH/EtOAc//hexane) to give **7***b*(*E*) (35 mg, 80%): mp 170–172°C (dec.); UV_{max}: 262 nm (ε 10 500), UV_{min}: 229 nm (ε 2000); MS (CI, CH_4) *m/z*: 277 (14, MH^+, ^{37}Cl), 275 (44, MH^+, ^{35}Cl), 113 (100, BH_2). Anal. calcd. for $C_{10}H_{11}ClN_2O_5 \cdot 0.5\ H_2O$ (283.7): C 42.34, H 4.26, N 9.88; found: C 42.66, H 4.55, N 9.49.

Deprotection of **7***a*(*E*) (45 mg, 0.14 mmol; from Method B) (as described for **5***b*(*E*)) and RP-HPLC (preparative column; program: 17% H_2O/CH_3CN for 45 min followed by a gradient of 17–25% for 45 min at 2.7 mL/min) gave **7***b*(*Z*) (2 mg, 5%, R_T = 38 min), **7***b*(*E*) (25 mg, 65%, R_T = 45 min), and **6***b*(*E*) (5 mg, 10%, R_T = 52 min). Compounds **8***b*(*Z*) and **8***b*(*E*) in the same analytical system have R_T = 60 and 67 min, respectively.

1-[6(Z)*-Chloro-5,6-dideoxy-β-D*-ribo-*hex-5-enofuranosyl]uracil* **7**b(Z)

Deprotection of **7***a*(*Z*) (32 mg, 0.1 mmol) (as described for **5***b*(*E*)) gave a slightly yellow solid, which was subjected to RP-HPLC (as described under **7***b*(*E*)) and diffusion crystallized (MeOH/EtOAc//hexane) to give **7***b*(*Z*) (19 mg. 69%): mp 193–194°C; UV_{max}: 261 nm (ε 10 600), UV_{min}: 233 nm (ε 3000); MS *m/z*: 276 (3, M^+, ^{37}Cl), 274 (9, M^+, ^{35}Cl), 113 (100, BH_2). Anal. calcd. for $C_{10}H_{11}ClN_2O_5$ (274.7): C 43.73, H 4.04, N 10.20; found: C 43.85, H 4.15, N 10.12.

5-Chloro-1-[6(E)*-chloro-5,6-dideoxy-β-D*-ribo-*hex-5-enofuranosyl]uracil* **8**b(E)

Deprotection of **8***a*(*E*) (24 mg, 0.07 mmol) (as described for **5***b*(*E*)), column chromatography (EtOAc/MeOH, 19:1), and diffusion crystallization (MeOH/EtOAc//hexane) gave **8***b*(*E*) (15 mg, 70%): mp 198–202°C (dec.); UV_{max}: 275 nm (ε 9800), UV_{min}: 236 nm (ε 1300); MS (CI, CH_4) *m/z*: 313 (0.4, MH^+, $^{37}Cl_2$), 311 (2, MH^+, ^{35}Cl, ^{37}Cl), 309 (3, MH^+, $^{35}Cl_2$), 149 (34, BH_2, ^{37}Cl), 147 (100, BH_2, ^{35}Cl). Anal. calcd. for $C_{10}H_{10}Cl_2N_2O_5$ (309.1): C 38.86, H 3.26, N 9.06; found: C 38.74, H 3.47, N 8.85.

5-Chloro-1-[6(Z)-chloro-5,6-dideoxy-β-D-ribo-*hex-5-enofuranosyl]uracil* **8**b(Z)

Deprotection of **8***a*(*E/Z*, ~1:3.5; 28 mg, 0.08 mmol, from Method A) (as described for **5***b*(*E*)) gave a slightly yellow solid that was purified by RP-HPLC (as described under **7***b*(*E*)) and diffusion crystallized (MeOH/EtOAc//hexane) to give **8***b*(*Z*) (13 mg, 53%; 68% based on **8***a*(*Z*)): mp 148–152°C (dec.); UV_{max}: 274 nm (ε 9600), UV_{min}: 236 nm (ε 1400); MS (CI, CH_4) *m/z*: 313 (1, MH^+, $^{37}Cl_2$), 311 (5, MH^+, $^{35}Cl^{37}Cl$), 309 (8, MH^+, $^{35}Cl_2$), 149 (38, BH_2, ^{37}Cl), 147 (100, BH_2, ^{35}Cl). Anal. calcd. for $C_{10}H_{10}Cl_2N_2O_5$ (309.1): C 38.86, H 3.26, N 9.06; found: C 38.99, H 3.14, N 9.21.

Studies of the synthesis, structure, and reduction of *trans*-dichloro bis(2,3-dihydro-4- and 7-methylbenzo[*b*]thiophene)palladium(II) complexes

PETER D. CLARK,[1] MARTIN J. KIRK, AND MASSOOD PARVEZ

Department of Chemistry, The University of Calgary, 2500 University Drive N.W., Calgary, Alta., Canada T2N 1N4

Received September 19, 1991[2]

PETER D. CLARK, MARTIN J. KIRK, and MASSOOD PARVEZ. Can. J. Chem. **71**, 199 (1993).

trans-Dichlorobis(2,3-dihydro-4- and -7-methylbenzo[*b*]thiophene)palladium(II), **1***b* and **1***c*, have been prepared by reaction of 2,3-dihydro-4- and -7-methylbenzo[*b*]thiophenes with palladium(II) chloride. Both **1***b* and **1***c* exhibit complex ^1H and ^{13}C NMR spectra as a result of inversion of the sulfur-containing ligands. Their structures were confirmed by single crystal X-ray studies. **1***b* crystallized in the triclinic spacegroup $P\bar{1}$ (a = 7.219(2), b = 8.441(5), c = 8.494(7) Å, α = 61.47(5)°, β = 88.85(4)°, γ = 84.40(3)°, and R = 0.067 for 1372 observed of 1760 unique reflections). **1***c* also crystallized in the triclinic space group $P\bar{1}$ (a = 7.730(3), b = 8.056(3), c = 8.516(4) Å, α = 62.87(3)°, β = 82.31(3)°, γ = 88.82(3)°, and R = 0,040 for 1425 observed of 1825 unique reflections). **1***b* and **1***c* and the complex **1***a* (prepared from 2,3-dihydrobenzo[*b*]thiophene) were unstable in the presence of molecular hydrogen at ambient conditions, liberating the parent dihydrobenzothiophenes and forming elemental palladium. **1***a* was also unstable to the organic hydrogen donor tetrahydronaphthalene, again forming Pd and 2,3-dihydrobenzothiophene. Complexes **1***a–c* were shown to promote the shift of CO/H_2O to hydrogen and CO_2 although most of the hydrogen was consumed by the reduction of Pd(II) to Pd^0.

PETER D. CLARK, MARTIN J. KIRK et MASSOOD PARVEZ. Can. J. Chem. **71**, 199 (1993).

On a préparé les *trans*-dichloro(2,3-dihydro-4- et -7-méthylbenzo[*b*]thiophène)palladium(II), **1***b* et **1***c*, par réaction des 2,3-dihydro-4- et -7-méthylbenzo[*b*]thiophènes avec le chlorure de palladium(II). À cause de l'inversion des ligands contenant du soufre, les produits **1***b* et **1***c* présentent tous les deux des spectres RMN du ^1H et du ^{13}C complexes. On a confirmé les structures par des études de rayons-X sur des cristaux uniques. Le composé **1***b* est triclinique, groupe d'espace $P\bar{1}$, avec a = 7,219(2), b = 8,441(5) et c = 8,494(7) Å, α = 61,47(5)°, β = 88,85(4)° et γ = 84,40(3)° et R = 0.067 pour 1372 des 1760 réflexions uniques. Le composé **1***c* est triclinique, groupe d'espace $P\bar{1}$, avec a = 7,730(3), b = 8,056(3) et c = 8,516(4) Å, α = 62,87(3)°, β = 82,31(3)° et γ = 88,82(3)° et R = 0,040 pour 1425 des 1825 réflexions uniques. Les composés **1***b* et **1***c* ainsi que le complexe **1***a* (préparé à partir du 2,3-dihydrobenzo[*b*]thiophène) sont instables en présence d'hydrogène moléculaire, aux conditions ambiantes; ils libèrent alors les dihydrobenzothiophènes fondamentaux et forment du palladium élémentaire. Le composé **1***a* est aussi instable en présence du donneur d'hydrogène, le tétrahydronaphtalène; il conduit encore à la formation de Pd et du 2,3-dihydrobenzothiophène. On a montré que les complexes **1***a–c* facilitent la transformation de CO/H_2O en CO_2, même si la majorité de l'hydrogène est consommée par la réduction du Pd(II) en Pd^0.

[Traduit par la rédaction]

Introduction

We previously (1) reported the preparation and structural determination of *trans*-dichloro bis(2,3-dihydrobenzo[*b*]thiophene)palladium(II) **1***a*, which was of interest regarding mechanisms for the catalytic hydrodesulfurization of benzo[*b*]thiophene (BT) and the reaction of BT with water at elevated temperatures in the presence of aqueous platinum metal species (2). To unambiguously assign the ^1H NMR spectrum of **1***a*, which is complicated by inversion of the sulfur-containing ligand about the sulfur atom, the 4-methyl derivative **1***b* was prepared and reported (1) but was not characterized fully. In this article, we describe the full NMR and single X-ray characterization of **1***b* and also of the 7-methyl derivative **1***c*.

Since these complexes may model intermediates formed during the catalytic hydrodesulfurization of BT and its methyl-substituted derivatives, we investigated their reactions with molecular hydrogen and with the hydrogen donor tetrahydronaphthalene (THN). Reactions of **1***a–c* with THN are of particular interest since one pathway of desulfurization occurs by interaction of sulfur-containing compounds with organic hydrogen donors that act as vehicles for transfer of gas phase hydrogen (3, 4). In addition, it is shown that complexes **1***a–c* catalyze the shift of CO/H_2O to H_2 and CO_2. This chemistry is relevant to the mechanisms proposed for the desulfurization of BT and related sulfur heterocycles using aqueous platinum metal species (1, 2).

Experimental

Materials

Palladium(II) chloride, organic reagents, and general solvents were purchased from standard chemical suppliers and were used as received. 2,3-Dihydro-4- and -7-methyl-BT have been mentioned (5) as by-products of the Lewis acid catalyzed reactions of BT with aromatics but were not isolated and fully characterized. In this study, these compounds were made by oxidation of 4- and 7-methyl-BTs (prepared by the methods of Elvidge and Foster (6) and Kloetzel *et al.* (7) respectively) to the corresponding sulfones with H_2O_2, reduction of the 2,3-bond of the sulfones with H_2 over Pd on carbon, and removal of the sulfone group with $LiAlH_4$. General procedures for these transformations have been described previously (8). The crude dihydro compounds were purified by

column chromatography (hexane/silica) and were isolated as oils with the following characteristics.

*2,3-Dihydro-4-methylbenzo[*b*]thiophene*

Isolated as a pale yellow oil in 13% overall yield from 4-methyl-BT; IR (neat), ν(cm^{-1}): 766 (s), 1454 (s), 1578 (s), 2936 (s), and 3057 (m); ^{1}H NMR δ: 2.47 (s, CH_3), 3.38–3.59 (m, CH_2CH_2), 7.06 (dd, H-6), and 7.23–7.27 (m, H-5 and H-7); ^{13}C NMR δ: 141.24, 138.63, and 134.05 (quaternary carbons), 127.33, 125.42, and 119.51 (unsubst. aromatic C), 34.55 and 32.33 (dihydro carbons), and 19.96 (CH_3). Anal. calcd. for $C_9H_{10}S$: C 72.00, H 6.66, S 21.33%; found: C 71.84, H 6.42, S 21.62%.

*2,3-Dihydro-7-methylbenzo[*b*]thiophene*

Isolated as a pale yellow oil in 21% yield from 7-methyl-BT; IR (neat), ν (cm^{-1}): 768 (s), 1059 (s), 1454 (s), 2876 (s), and 3055 (m); ^{1}H NMR δ: 2.60 (s, CH_3), 3.59 (br s, CH_2CH_2), 7.24 – 7.28 (m, H-4, 5, and 6); ^{13}C NMR δ: 141.28, 139.62, and 131.62 (quaternary carbons), 127.79, 124.15, and 121.58 (unsubst. aromatic C), 36.52 and 32.65 (dihydro carbons), and 20.69 (CH_3). Anal. calcd. for $C_9H_{10}S$: C 72.00, H 6.66, S 21.33%; found: C 71.72, H 6.89, 21.01%.

Preparation of palladium complexes **1**b *and* **1**c

Both **1***b* and **1***c* were prepared by adding either 4- or 7-methyl-dihydro-BT (1.5 g, 10 mmol) to a stirred solution of palladium(II) chloride (0.89 g, 5 mmol) in 90% aqueous ethanol (50 mL) at 50°C. After 1 h, the orange solids that had formed were filtered off and were crystallized from ethanol/chloroform.

trans-*Dichloro bis(2,3-dihydro-4-methylbenzo[*b*]thiophene)palladium(II)* **1***b*[3] was isolated as deep orange plates, 41%, mp > 250°C (dec.); IR (KBr), ν (cm^{-1}): 783 (s), 1265 (m), 1419 (m), 1458 (m), and 2362 (m). ^{13}C NMR†, δ:[4] 20.0 (20.39) (CH_3), 34.25 (34.02), 35.51 (35.04) (dihydro carbons), 125.02 (124.13, 124.49), 129.03 (127.97), 130.28 (130.31) (unsubst. aromatic C), 133.31 (132.84), 135.10 (135.19), and 141.59 (141.81) (quaternary C). Anal. calcd. for $C_{18}H_{20}Cl_2PdS_2$: C 45.25, H 4.19, S 13.41%; found: C 44.97, H 3.99, S 13.48%.

trans-*Dichloro bis(2,3-dihydro-7-methylbenzo[*b*]thiophene)palladium(II)* **1***c*[3] was isolated as deep orange plates, 53%, mp > 250°C (dec.); IR (KBr), ν (cm^{-1}): 785 (s), 1261 (m), 1421 (m), 1458 (m), and 2850 (w). ^{13}C NMR† δ: 21.70 (21.49, 21.63) (CH_3), 36.46 (36.16, 36.21), 40.39 (40.56, 41.06) (dihydro carbons), 122.67 (122.58, 122.63), 128.71 (128.23, 128.30), 129.36 (129.42) (unsubst. aromatic C), 132.88 (132.05, 132.18), 137.48 (137.17, 137.54), and 143.73 (143.42, 143.61) (quaternary C). Anal. calcd. for $C_{18}H_{20}Cl_2PdCl_2$: C 45.25, H 4.19, S 13.41%; found: C 45.01, H, 4.06, S, 13.22%.

X-ray structure determinations of **1**b *and* **1**c

Both crystal structures were determined by the same general procedure. Accurate cell dimensions and crystal orientations of suitable crystals placed in Lindemann glass capillaries were determined on an Enraf–Nonius CAD-4 diffractometer by a least-squares refinement of the setting angles of 25 reflections with θ in the range 10–15°. Intensity data were collected by the $\omega/2\theta$ scan method using variable scan speed (1.27–3.30°/min), scan width (1.00 + 0.35 tan θ)°, and monochromatized Mo Kα radiation in the range $2 < \theta < 25°$ with h 0 to 8, k −10 to 10, and l −10 to 10. Three reflections were monitored every two hours of exposure time and showed insignificant variations. The intensities of 1760 (**1***b*) and 1825 (**1***c*) reflections were measured, of which 1372 (**1***b*) and 1425 (**1***c*) had $I > 3\sigma(I)$, where $\sigma^2 I = S + 2B + [0.04(S - B)]^2$, with S = scan count, and B = time averaged background count extended 25% on each side. Data were corrected for Lorentz, polarization, and absorption effects (DIFABS; Walker and Stuart (9)), correction range being 0.676–1.331 for **1***b* and 0.749–1.395 for **1***c*. Crystal data and experimental details are summarized in Table 1.

Both structures were solved by the heavy-atom method. Refinement of the structures used full-matrix least-squares calculations, initially with isotropic, and finally with anisotropic temperature factors for the non-hydrogen atoms. At intermediate stages in the refinements, difference maps revealed all H-atoms which were included in the subsequent cycles at geometrically idealized positions (C—H, 0.95 Å) and at a fixed overall isotropic temperature factor. Refinements converged with $R = 0.067$ and $wR = 0.074$ for **1***b* and $R = 0.040$ and $wR = 0.040$ for **1***c*. In the refinement cycles, weights were derived from the counting statistics. Scattering factors were those of Cromer and Mann (10) and Stewart *et al.* (11) and allowances were made for anomalous dispersions (12). A difference map calculated at the conclusion of the refinement had no chemically significant features. All computer programs used in this study were part of XTAL 2.6 (13) and Figs. 1 and 2 were plotted using ORTEP II (14). Final values of the refined positional parameters, selected bond lengths, and angles are collected in Tables 2, 3, and 4 respectively.

Supplementary tables of hydrogen atom parameters, non-hydrogen thermal parameters, dihedral angles, and observed and calculated structure factors have been deposited with the National Research Council of Canada.[5]

NMR spectra

Variable temperature proton spectra of **1***b* and **1***c* were recorded on a Bruker AM-400 spectrometer in deuterochloroform solution using solvent resonances as internal references. Probe temperatures were determined by reference to methanol and 1,2-dihydroxyethane chemical shift data. Data are summarized in Tables 5 and 6.

Reactions of **1**a–c *with reducing agents*

(a) Hydrogen

All reactions were done at 20°C and at ambient pressure. Hydrogen was admitted to a flask containing a solution of **1***a* or *b* (100 mg) in toluene or dichloromethane (50 mL) that had previously been flushed with nitrogen and evacuated. Hydrogen was taken up rapidly in stirred solutions for experiments conducted in toluene (uptake complete within 15 min) and at a lesser rate (2–16 h) using dichloromethane. No uptake of hydrogen was observed for reactions with **1***c* unless ethanol was used as solvent. In this case reaction was complete after 16 h. Deposition of a palladium mirror on the surfaces of the glassware and disappearance of the characteristic orange coloration of the complex solutions was observed in all experiments. When uptake of hydrogen was complete, the solutions were analyzed for volatile organic products using GC–MS techniques (see ref. 1 for details of this analysis). In each experiment, the corresponding 2,3-dihydro-BT was observed as the only organic product.

(b) THN

A solution of **1***a*, *b*, or *c* (100 mg) in THN was heated under reflux for 16 h. During this time, black particles (later shown to be palladium) deposited from solution. GC–MS analysis of the solution revealed the presence of the 2,3-dihydro-BT compounds originally present in the complexes and traces of naphthalene.

[3]Note: variable temperature NMR data for **1***b* and **1***c* are given in Tables 5 and 6. s, m, and w denote strong, medium and weak absorptions.

[4]†denotes δ ppm from TMS recorded at 293 K; data in parentheses were recorded at 215 K.

[5]Supplementary tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom parameters and dihedral angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

(c) CO/H$_2$O

A solution of **1***a* (220 mg, 0.49 mmol) in 95% ethanol (150 mL) and distilled water (50 mL) was purged with argon to remove dissolved air. A reservoir of 120 mL (5.35 mmol) of CO was connected to the head space over the orange-colored solution and stirring of the solution was commenced. A black precipitate (shown later to be palladium) was formed almost immediately and the orange color faded to give a colorless solution. Analysis of the head space gas showed that CO_2 (0.08 mmol) had been formed (see Discussion for further details) along with traces of hydrogen.

Analysis of the solution using GC–MS indicated that 2,3-dihydro-BT was the only organic product present. Addition of copper(II) chloride (250 mg) to the solution and admission of air to the apparatus caused the black precipitate to redissolve and, after stirring the reaction mixture for 16 h, the orange color of the complex **1***a* was reestablished. Evaporation of the solvents and extraction of the residue with chloroform enabled re-isolation of **1***a*.

Parallel experiments using either **1***b* or **1***c* gave very similar results.

Results and discussion

*Preparation and NMR spectroscopic characterization of 1*b *and 1*c

Both complexes formed readily at 50°C and were isolated as orange-red solids. Analysis of the crude solids by ^{13}C NMR or by reverse phase HPLC showed that only one product had been formed in each experiment. These results follow the general trend (15, 16) that palladium(II) compounds react with thioethers to produce, predominantly, one compound with square planar geometry (X-ray analysis described later confirmed that both **1***b* and **1***c* have a *trans* square planar configuration).

The ^1H NMR spectra of **1***b* (Table 5) and **1***c* (Table 6) taken at ambient temperature displayed very broad signals in all regions of the spectra, most likely because of inversion of the sulfur-containing ligands. Such inversions are commonplace for metal–thioether complexes and have been examined in detail (15–17). As was the case for the unmethylated complex **1***a* (1), the signal for H-4 of **1***b* is well downfield of that of uncomplexed dihydro-BT, most likely because of close contact with the chlorine substituents (see X-ray discussion). At ambient temperature (295 K), the signal due to H-4 consists of two broad lines (*ortho* coupling to H-5, J = 8 Hz), but the expected *meta* coupling was not observed, probably because of the broad nature of the lines. Only at 210 K did the signals for H-4 become sharp but, at this temperature, the signal was much more complex than was expected for an *ortho–meta* coupled aromatic proton, showing eight partly resolved lines consistent with two *ortho–meta* coupled protons. The dihydro protons of **1***b* (at C-2 and C-3) showed the classic coalesence and sharpening behaviour at high and low temperatures, respectively, associated with a dynamic inversion process. Resonances due to the dihydro protons of **1***b* and **1***c* were shifted significantly (both upfield and downfield) in comparison to the signals for the dihydro protons of uncomplexed dihydro-BT ligands (see data in the experimental section and in Tables 5 and 6). X-ray analysis suggests that these shifts may be due to close contact with the chloro ligands. The signals due to the methyl protons of **1***b* and **1***c* were observed as sharp singlets at 315 K and as broader singlets at 295 K that resolved into two singlets of approximately equal intensity at 215 K. This behaviour was completely reversible with no signs of decomposition over the temperature range 215–328 K.

[a]Estimated standard deviations are given in parentheses.

Overall, the spectra described above can be explained by inversion of the sulfur-containing ligands about the sulfur lone pairs. Since the complexes contain two chiral sulfur centers, the complex signals for H-4 and resolution of the methyl signals at 215 K can be ascribed to the presence of diastereomers, which would be observed when inversion at sulfur ceases. Further evidence for the presence of diastereomers at 215 K was given by the observation that many of the signals in a proton-decoupled ^{13}C NMR spectrum of **1***c* taken at 295 K split into two lines when a spectrum was recorded at 215 K. The inequivalence of NMR signals at low temperatures could also be explained on the basis that structurally different isomers arise as a result of hindered rotation around the Pd—S bond. However, inspection of models does not suggest that any particular rotamer should be favored and thus the low-temperature spectra are most probably explained by the presence of diastereomers. The observation of diastereomers as a result of inversion at sulfur bonded to metal species is well documented (18).

Calculation of thermodynamic parameters for inversion using NMR band shape fitting techniques gave values with unacceptable errors. These inaccuracies likely stem from effects of temperature on chemical shift values of the protons of interest.

X-ray characterization of ***1***b *and* ***1***c

Interatomic distances and bond angles for complexes **1***b* and **1***c* are given in Tables 3 and 4. Each complex has a slightly distorted square planar structure (Cl—Pd—S angles of 95.9(1) and 95.07(7)° for **1***b* and **1***c*, respectively) with the thioether ligands *trans* to each other (Figs. 1 and 2). Pd—S and Pd—Cl bond lengths are very similar to those observed in other Pd–thioether complexes (see ref. 14 for a review of this topic) (Pd—S: 2.318(3) Å for **1***b* and 2.330(1) Å for **1***c*; Pd—Cl: (2.306(4) Å for **1***b* and 2.283(2) Å for **1***b*). Several close contacts exist in each molecule. For **1***b*, through-space distances for Cl—H(21) and Cl—H(71) were 2.747(3) and 3.038(3) Å, respectively. Similar close contacts in solution would explain the downfield shifts observed for these protons in the ^{1}H NMR spectrum. In the 7-methyl complex **1***c*, close contacts were observed for Cl—H(21) (2.840(2) Å) and Cl—H(712) (3.349(2) Å) and again these contacts are useful in rationalizing the proton and carbon chemical shift data.

Reactions of ***1***a–c *with hydrogen and THN*

Since 2,3-dihydro-BT is known to be an intermediate in the catalytic hydrodesulfurization of BT (19–24), it was of interest to determine how the complexes **1***a–c* behaved in the presence of molecular hydrogen or organic donor hydrogen. When a stirred solution of **1***a* in either toluene or dichloromethane was exposed to 1 atmosphere of hydrogen at 20°C (1 atm = 101.3 kPa) there was a rapid uptake of hydrogen and deposition of a palladium mirror on the surface of the apparatus. The reaction was faster in toluene solution but, in either solvent, 2,3-dihydro-BT was the only organic product detected. Similar reactions were noted for the 4- and 7-methyl complexes **1***b* and **1***c* and, in each case, the re-

[c]Two singlets were observed at low temperatures.

spective 2,3-dihydro compounds were the only organic products. All of the reactions were complete within 30 min with the exception of those with **1***c*, which took several hours to go to completion. No reaction was observed when **1***a–c* were treated with the organic hydrogen donor THN at 20°C. However, when **1***a* was heated with THN at 200°C a palladium mirror was deposited in the apparatus and 2,3-dihydro-BT was formed.

Overall, the major process that occurred when complexes **1***a–c* were exposed to hydrogen was reduction of Pd(II) to Pd^0 and subsequent decomposition of the complexes. Since the thioether sulfur is bonded directly to palladium, it might have been expected that the C—S bonds would have been activated sufficiently to have undergone hydrogenolysis, ultimately producing ethylbenzene as a product. However, careful analysis of the reaction solutions showed that this compound was not formed. This observation may have some implication on the mechanism of catalytic hydrodesulfurization of BT since when Pd catalysts (usually in the form of PdS) are used, it is unlikely that desulfurization of intermediate 2,3-dihydro-BT occurs by coordination to palladium compound sites. Perhaps only in hydrogen atmospheres with high partial pressures of H_2S would complexes of the type **1***a–c* be stable. Note, however, that these statements may not apply when other metal sulfides are used in the catalytic hydrodesulfurization of BT. For example, reduction of MoS_2 by hydrogen is probably a more difficult process than would be the case for PdS. (Note: useful and comparative reduction potentials for metal sulfides absorbed on surfaces are not available but some measure of the stability of PdS and MoS_2 can be ascertained from free energy of formation values (25); ΔG_f^0 PdS = −16 kcal/mol and ΔG_f^0 MoS_2 = −54 kcal/mol). In this case, complexation of 2,3-dihydro-BT with MoS_2-like species may be an important step in the desulfurization of the molecule. A useful review of possible mechanisms for the desulfurization of BT has been given by Gates *et al.* (26).

Reactions of **1***a–c with* CO/H_2O

A variety of metal complexes have been shown to catalyze the water gas shift (WGS) of CO/H_2O to CO_2 and H_2 under very moderate conditions (27–36). A useful collation of recent work is given in ref. 36. However, to our knowledge, complexes incorporating organosulfur ligands have not been used to promote this reaction. The only report concerning the effect of sulfur compounds on the WGS is that of King *et al.* (37), which describes the effect of sodium sulfide on the ability of various metal carbonyls to promote the shift reaction. Consequently, it was of interest to determine if the complexes **1***a–c* catalyzed the WGS. Initial experiments showed that exposure of an aqueous ethanolic solution of any of the complexes **1***a–c* at 20°C resulted in a rapid reaction in which CO_2, H_2, Pd^0, and the free dihydro ligand were produced. No evidence for desulfurization of the ligand was obtained. Very little hydrogen was observed but significant quantities of CO_2 were measured. The percentage of CO_2 in the head space was well above atmospheric levels (up to 1.6%) so there was no doubt that it was produced by chemical reaction. However, much less CO_2 was produced in comparison to the amount of complex used in the experiments (on average, about one fifth the amount). The fact that some H_2 was observed suggests that the shift reaction had occurred but it was observed only in trace quantities. The most likely explanation for the low observed yield of H_2 is that much of it was used to produce the elemental palladium formed in the experiment.

For personal use only.

The overall reactions occurring are thus:

$$PdCl_2L_2 + CO + H_2O \rightarrow Pd(II) + 2Cl^- + H_2 + CO_2 + 2L \quad (\mathbf{1}a\text{–}c)$$

$$Pd(II) + H_2 \rightarrow Pd^0 + 2H^+$$

where L is the dihydro ligand.

Since all of the complexes **1***a*–**1***c* were consumed by exposure to excess CO/H_2O, amounts of CO_2 at least equimolar to the amount of complex originally present should have been produced. The lower than expected amount of CO_2 may be explained by a combination of some CO_2 being dissolved in the aqueous media used and by absorption onto the elemental palladium produced during the experiments (no attempts were made to measure these contributions). The fact that any H_2 was observed suggests that 1 mole of these complexes may have produced more than 1 mole of H_2. However, low yields of H_2 and CO_2 (most likely because of absorption of these gases by the elemental palladium) precludes establishment of precise mechanisms.

By applying the $Cu(II)/O_2$ couple used in the Wacker process (38), it was possible to reform the original complexes. Thus, on addition of $Cu(II)Cl_2$ and admission of air to the apparatus, the deposited palladium was redissolved with formation of the original complex. This confirms that hydrogen produced during the shift of CO was used to reduce palladium rather than desulfurize the ligand. Other metal–thioether complexes in which the metal is less easily reduced might be more useful for the shift of CO. These possibilities are under examination.

Phosphonolipids 4. A phosphonic acid analogue of platelet activating factor[1,2]

YUE-JIN LIU, BURTON E. TROPP, AND ROBERT ENGEL[3]

Department of Chemistry and Biochemistry, Queens College of the City University of New York, Flushing, NY 11367, U.S.A.

Received September 4, 1992

YUE-JIN LIU, BURTON E. TROPP, and ROBERT ENGEL. Can. J. Chem. **71**, 206 (1993).

A phosphonic acid analogue of platelet activating factor (PAF) bearing a backbone that is isosteric with and has stereochemistry corresponding to that of natural PAF has been synthesized. The synthesis uses a route maintaining stereochemical integrity.

YUE-JIN LIU, BURTON E. TROPP et ROBERT ENGEL. Can. J. Chem. **71**, 206 (1993).

On a synthétisé un analogue du facteur activant des plaquettes (FAP) contenant de l'acide phosphonique et comportant un squelette isostère et de la même stéréochimie que le FAP naturel. La synthèse fait appel à une route qui préserve l'intégrité stéréochimique.

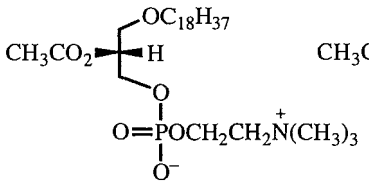
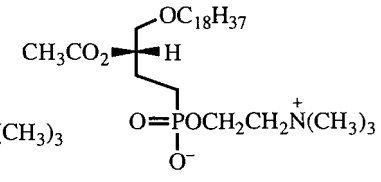
Introduction

Since the discovery (3) of the series of natural ether lipids 1-*O*-alkyl-2-*O*-acetyl-*sn*-glycero-3-phosphorylcholine (**1**), also known by a name describing one of its biological functions, platelet activating factor (PAF), the natural material and structural analogues thereof have been targets of numerous laboratory syntheses (for a review of this area of effort, see ref. 4). These efforts have been stimulated by the particularly intriguing range of biological activities associated with natural PAF (5).

In the continuing efforts of our laboratory toward the preparation and investigation of phosphonic acid analogues of natural phosphate esters, we herein describe the synthesis of a new analogue of **1** which is anticipated to serve as a particularly useful probe of PAF activity. This analogue is one in which are incorporated fundamental structural similarities with **1** while rendering the backbone resistant to hydrolysis at the phosphorus by the incorporation of a carbon–phosphorus bond (6). Specifically, this analogue, illustrated as **2**, bears a backbone that is isosteric with that of **1** and a stereogenic center of the same absolute configuration as found in **1**.



1



2

Results and discussion

The synthesis of **2** is accomplished starting with (*S*)-malic acid as the source of the stereogenic carbon site. The conversion of (*S*)-malic acid into (*S*)-4-benzyloxy-1,2-butanediol is accomplished in five steps as previously reported (7). Continued conversion of the (*S*)-4-benzyloxy-1,2-butanediol into the target material **2** has been accomplished as illustrated in Scheme 1.

The regiospecificity of the tosylation step, and of the alcohol attack of the epoxide by the alcohol in the presence of boron trifluoride etherate, have been established by prior work of this and other laboratories (2, 8, 9). Once acetylation is accomplished, the remainder of the route involves standard procedures for deprotection of the primary hydroxyl group, conversion to the alkyl chloride, phosphonylation via the Arbuzov reaction, and final functionalization. The selective cleavage of the phosphonate methyl ester groups is accomplished under very mild conditions using bromotrimethylsilane followed by work-up with aqueous tetrahydrofuran (10). Esterification of **10** to generate the target choline derivative **2** was accomplished using a technique previously applied for the preparation of choline derivatives (11).

Experimental

General

All chemicals were of reagent quality and were used without further purification with the following exceptions: chloroform was distilled over phosphorus pentoxide; pyridine was dried over calcium hydride and distilled; dimethylformamide (DMF) and methanol were dried over molecular sieves 4A prior to use. (*S*)-4-Benzyloxy-1,2-butanediol and its precursors were prepared as previously described (7). Thin-layer chromatography (TLC) was performed using Polygram Sil N-HR sheets. Silica gel for flash chromatography was from EM Science (230–300 mesh). Infrared spectra were measured using a Perkin–Elmer 1600 FTIR instrument, and ^{1}H and ^{31}P NMR spectra were measured using an IBM-Bruker WP200SY instrument. Optical rotations were measured using a Jasco DIP-140 digital polarimeter. Elemental analyses were performed by Desert Analytics of Tucson, Arizona, and by Schwarzkopf Microanalytical Laboratories of Woodside, New York.

Preparation of (S)-4-benzyloxy-2-hydroxy-1-tosyloxybutane (3)

In a reaction system under a nitrogen atmosphere the (*S*)-4-benzyloxy-1,2-butanediol (4.20 g, 21.4 mmol) was dissolved in a mixture of chloroform (50 mL) and pyridine (3.6 mL) and the resultant mixture was stirred at 0°C for 5 min. After this time there was added *p*-toluenesulfonyl chloride (4.10 g, 21.4 mmol) in chloroform (5 mL) solution over a period of 2 min. The mixture was stirred at 0°C for 2.5 h, after which time the cooling bath was removed and the mixture was stirred for an additional 2 h at ambient temperature. After this time diethyl ether (200 mL) was added with stirring and the mixture was washed with water (2 × 15 mL). The organic layer was dried over anhydrous calcium chloride, fil-

tered, and the volatile materials were evaporated under reduced pressure to give the desired material (7.00 g, 94%), which exhibited a major spot on TLC (R_f 0.80, hexane ethyl acetate 2:1) with a trace of starting material, and IR and ^{1}H NMR spectra in accord with the proposed structure **3**. Owing to its highly reactive nature, the material was not further purified, but used immediately in the continuing reaction. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 3500 (broad), 3050–3150, 2900–2990, 1510, 1470, 1400, 1270, 1180, 1100. The ^{1}H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 1.87, multiplet, 2H; δ 2.34, singlet, 3H; δ 2.98, broad singlet, 1H; δ 3.35–3.85, broad multiplet, 4H; δ 4.00, multiplet, 1H; δ 4.51, doublet, 2H, J = 5 Hz; δ 7.25, broad singlet, 5H; δ 7.60, AA'BB', 4H.

Preparation of (S)-4-benzyloxy-1,2-epoxybutane (4)

(*S*)-4-Benzyloxy-2-hydroxy-1-tosyloxybutane (**3**) (3.5 g, 10.0 mmol) was dissolved in dry methanol (30 mL) and cooled to −10°C, and anhydrous potassium carbonate (1.70 g, 12.3 mmol) was added. The reaction mixture was stirred at −10°C for 3 h and allowed to come to room temperature with stirring for an additional 2 h. After this time diethyl ether (50 mL) was added and the resultant precipitate was removed by filtration through a pad of silica gel. The precipitate was washed with diethyl ether (100 mL) and the combined filtrates were evaporated under reduced pressure. The residue was purified by flash chromatography (20 g, 2 cm diameter) eluted using hexane:chloroform mixtures. The fractions exhibiting R_f 0.70 on TLC (hexane:chloroform 2:1) were combined and evaporated under reduced pressure to give the pure desired material (1.65 g, 98.0%), which exhibited IR and ^{1}H NMR spectra in accord with the proposed structure **4**. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 3010–3050, 2850–2990, 1510, 1480, 1450, 1410, 1350, 1130. The ^{1}H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 1.85, multiplet, 2H; δ 2.51, multiplet, 1H; δ 2.76, multiplet, 1H; δ 3.10, multiplet, 1H; δ 3.62, multiplet, 2H; δ 4.58, singlet, 2H; δ 7.38, broad singlet, 5H. Anal. calcd for $C_{11}H_{14}O_2$: C 74.13%, H 7.92%; found: C 74.49%, H 7.89%. Specific rotation: $[\alpha]_{25}$ = −14.8 (0.08 M, ethanol).

Preparation of (S)-4-benzyloxy-2-hydroxy-1-octadecyloxybutane (5)

In a reaction system under a nitrogen atmosphere a 10% solution of boron trifluoride in methylene chloride (0.5 mL) was added to a mixture of (*S*)-4-benzyloxy-1,2-epoxybutane (**4**) (1.60 g, 9.0 mmol) and 1-octadecanol (2.43 g, 9.0 mmol) in methylene chloride (25 mL) at 0°C. After stirring for 10 min, the reaction mixture was allowed to warm to room temperature and to stir for 24 h. After this time volatile materials were removed under reduced pressure and the residue was purified by flash chromatography (20 g, 2 cm diameter) eluted using hexane:chloroform

mixtures. The fractions exhibiting R_f 0.60 (chloroform:hexane 3:1) were combined and evaporated under reduced pressure to give the pure desired material (3.90 g, 97%), which exhibited IR and ^{1}H NMR spectra in accord with the proposed structure **5**. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 3450 (broad), 3010–3050, 2850–2990, 1480, 1400, 1150. The ^{1}H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 0.91, triplet, 3H, J = 6 Hz; δ 1.12–1.52, broad singlet, 32H; δ 1.80, triplet, J = 6 Hz, 2H; δ 3.25–4.02, broad multiplet, 8H; δ 4.52, singlet, 2H; δ 7.29, singlet 5H. Anal. calcd. for $C_{29}H_{52}O_3$: C 77.62%, H 11.68%; found: C 77.91%, H 11.83%. Specific rotation: $[\alpha]_{25} = -15.7$ (0.022 M, ethanol).

Preparation of (S)-2-acetyloxy-4-benzyloxy-1-octadecyloxybutane (6)

(*S*)-4-Benzyloxy-2-hydroxy-1-octadecyloxybutane (**5**) (3.00 g, 6.68 mmol) was added to a mixture of methylene chloride (15 mL) and acetic anhydride (15 mL). The mixture was stirred at 0°C for 10 min, after which time *p*-(dimethylamino)pyridine (20 mg) was added. The mixture was allowed to warm to room temperature and stirring was continued for 24 h. After this time volatile materials were evaporated under reduced pressure and the liquid residue was purified by flash chromatography (20 g, 2 cm diameter) eluted using hexane: chloroform mixtures. Fractions exhibiting R_f 0.50 (hexane:chloroform 1:1) were combined and evaporated to give the pure desired material (3.20 g, 97%), which exhibited IR and ^{1}H NMR spectra in accord with the proposed structure **6**. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 3010–3050, 2850–2990, 1740, 1480, 1380, 1290, 1100, 1030. The ^{1}H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 0.90, triplet, 3H, J = 6 Hz; δ 1.15–1.55, broad singlet, 32H; δ 1.82, multiplet, 2H; δ 2.09, singlet, 3H; δ 3.25–3.82, broad multiplet, 7H; δ 4.52, singlet, 2H; δ 7.38, singlet, 5H. Anal. calcd. for $C_{31}H_{54}O_4$: C 75.87%, H 11.09%; found: C 75.61%, H 11.12%. Specific rotation: $[\alpha]_{25} = -14.9$ (0.029 M, ethanol)

Preparation of (S)-3-acetyloxy-1-hydroxy-4-octadecyloxybutane (7)

A mixture of (S)-2-acetyloxy-4-benzyloxy-1-octadecyloxybutane (**6**) (2.02 g, 4.11 mmol) was stirred with 95% ethanol (25 mL) and 5% palladium on charcoal (0.51 g) under a hydrogen atmosphere (1 atm (101.3 kPa)) for 20 h at ambient temperature. After this time the mixture was filtered through a pad of silica gel and the solid was washed with ethanol (75 mL). The combined filtrates were evaporated under reduced pressure and the residue was purified by flash chromatography (20 g, 2 cm diameter) eluted using hexane:ethyl acetate mixtures. The fractions exhibiting R_f 0.72 (hexane:ethyl acetate 3:1) were combined and evaporated under reduced pressure to give the pure desired material (1.60 g, 97%), which exhibited IR and ^{1}H NMR spectra in accord with the proposed structure **7**. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 3580 (sharp), 3450 (broad), 2850–2990, 1830, 1740, 1480, 1380, 1110. The ^{1}H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 0.89, triplet, 3H, J = 6 Hz; δ 1.28–1.40, broad singlet, 32H: δ 1.71, multiplet, 2H; δ 2.08, singlet, 3H; δ 2.50, broad singlet, 1H; δ 3.30–3.50, broad multiplet, 5H; δ 4.24, multiplet, 2H. Anal. calcd. for $C_{24}H_{48}O_4$: C 71.95%, H 12.08%; found: C 71.63%, H 12.00%. Specific rotation: $[\alpha]_{25} = -9.5$ (0.26 M, ethanol).

Preparation of (S)-3-acetyloxy-1-chloro-4-octadecyloxybutane (8)

To a solution of (*S*)-3-acetyloxy-1-hydroxy-4-octadecyloxybutane (3.90 g, 9.73 mmol) in methylene chloride (5 mL) and tetrachloromethane (3.24 g, 21.1 mmol) was added dropwise a solution of triphenylphosphine (3.57 g, 9.73 mmol) in methylene chloride (6 mL) over a period of 5 h. After completion of the addition, the reaction mixture was stirred at ambient temperature for an additional 2 h, at which time pentane (40 mL) was added, resulting in the formation of a white precipitate. The precipitate was removed by filtration, washed with pentane (50 mL), and the filtrates were combined and volatile materials were evaporated under reduced pressure. The residue was purified by flash chromatography (20 g, 2 cm diameter) eluted using hexane:ethyl acetate mixtures. The fractions exhibiting R_f 0.80 (hexane:ethyl acetate 5:1) were combined and evaporated under reduced pressure to give the pure desired material (3.62 g, 89%), which exhibited IR and ^{1}H NMR spectra in accord with the proposed structure **8**. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 2850–2990, 1730, 1480, 1360, 1240, 1100, 1040. The ^{1}H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 0.89, triplet, 3H, J = 6 Hz; δ 1.28–1.40, broad singlet, 32H; δ 1.52, multiplet, 2H; δ 2.08, singlet, 3H; δ 3.40–3.60, multiplet, 7H. Anal. calcd. for $C_{24}H_{47}O_3Cl$: C 68.78%, H 11.30%; found: C 68.60%, H 11.20%. Specific rotation: $[\alpha]_{25} = -11.8$ (0.026 M, ethanol).

Preparation of dimethyl (S)-3-acetyloxy-4-octadecyloxybutyl-1-phosphonate (9)

A mixture of (*S*)-3-acetyloxy-1-chloro-4-octadecyloxybutane (**8**) (3.62 g, 8.63 mmol), DMF (10 mL), and trimethyl phosphite (15 g, 120 mmol) was heated at 140°C for 48 h with continual stirring. After that time the volatile materials were evaporated under reduced pressure and the residue was purified by flash chromatography (20 g, 2 cm diameter) eluting with chloroform. In addition to the recovery of unchanged **8** (1.40 g), fractions exhibiting R_f 0.40 (chloroform) were combined and the volatile materials were evaporated to give the pure desired material (2.50 g, 59%), which exhibited IR and ^{1}H NMR spectra in accord with the proposed structure **9**. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 2850–2990, 1740, 1480, 1230, 1040. The ^{1}H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 0.88, triplet, 3H, J = 6 Hz; δ 1.28–1.40, broad singlet, 32H; δ 1.49–1.65, multiplet, 4H; δ 2.08, singlet, 3H; δ 3.35–3.60, multiplet, 5H; δ 3.80, doublet, 6H, J = 12 Hz. Anal. calcd. for $C_{26}H_{53}O_6P$: C 63.39%, H 10.84%; found: C 63.44%, H 10.84%. Specific rotation: $[\alpha]_{25} = -2.7$ (0.021 M, ethanol).

Preparation of (S)-3-acetyloxy-4-octadecyloxybutyl-1-phosphonic acid (10)

To dimethyl (*S*-3-acetyloxy-4-octadecyloxybutyl-1-phosphonate (**9**) (1.50 g, 3.04 mmol) in methylene chloride (5 mL) solution at −10°C under a nitrogen atmosphere was added bromotrimethylsilane (4.0 g, 26 mmol) and the reaction mixture was stirred for 15 min at −10°C and allowed to come to room temperature for 5 min. After that time the volatile materials were evaporated under reduced pressure, a 9:1 THF:water mixture (15 mL) was added, and the mixture was stirred for 20 min. Again the volatile materials were evaporated under reduced pressure. There was thus isolated the pure material (1.28 g, 90%) of mp 65°C, which exhibited IR and ^{1}H NMR spectra in accord with the proposed structure **10**. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 3400 (broad), 2850–2990, 1730, 1480, 1380, 1230, 1040 (broad). The ^{1}H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 0.89, triplet, 3H, J = 6 Hz; δ 1.28–140, broad singlet, 32H; δ 1.49–1.65, multiplet, 4H; δ 2.08, singlet, 3H; δ 3.35–3.60, multiplet, 5H; δ 4.74, broad singlet, 2H. Anal. calcd. for $C_{24}H_{49}O_6P$: C 62.04%, H 10.63%; found: C 62.01%, H 10.85%. Specific rotation: $[\alpha]_{25} = -5.0$ (0.011 M, ethanol).

Preparation of (S)-3-acetyloxy-4-octadecyloxybutyl-1-phosphonylcholine (2)

To a solution of (*S*)-3-acetyloxy-4-octadecyloxybutyl-1-phosphonic acid (**10**) (110 mg, 0.237 mmol) in pyridine (5 mL) under a nitrogen atmosphere was added dry choline tosylate (500 mg, 1.82 mmol) and trichloroacetonitrile (1.00 g, 6.92 mmol). The reaction mixture was stirred for 72 h at 50°C, after which time the volatile materials were evaporated under reduced pressure. Acetonitrile (30 mL) was added to the residue and the solid material was isolated by filtration, purified by dissolution in 9:1 THF:water (10 mL), and passed through an ion exchange column (Amberlite MB-3 resin). From the eluent was isolated the pure target material (50.0 mg, 39%), which exhibited IR and ^{1}H and ^{31}P NMR spectra

in accord with the proposed structure **2**. The IR spectrum (CCl_4) exhibited the following signals (partial) (cm^{-1}): 3400 (broad), 2850–2990, 1730, 1480, 1260 (broad), 1080 (broad). The ^1H NMR spectrum ($CDCl_3$) exhibited the following signals: δ 0.88, triplet, 3H, J = 6 Hz; δ 1.18–1.30, broad singlet, 32H; δ 1.36, singlet, 9H; δ 1.49–1.65, multiplet, 4H; δ 2.08, singlet, 3H; δ 3.20–3.65, multiplet, 9H. The ^{31}P NMR spectrum ($CDCl_3$) exhibited a signal at −30 ppm relative to external 85% H_3PO_4. Anal. calcd. for $C_{29}H_{60}NO_6P$: C 63.36%, H 11.00%; found: C 63.71%, H 11.35%. Specific rotation: $[\alpha]_{25}$ = −6.2 (0.01 M, ethanol).

Reactions of SO_2X mono-substituted arenes with SO_3 in nitromethane: electronic and steric directing effects of the sulfonic acid group and some model substituents[1,2]

HAROLD R. W. ANSINK, ERIK J. DE GRAAF, ERWIN ZELVELDER, AND HANS CERFONTAIN[3]
Laboratory of Organic Chemistry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

Received June 22, 1992

HAROLD R. W. ANSINK, ERIK J. DE GRAAF, ERWIN ZELVELDER, and HANS CERFONTAIN. Can. J. Chem. **71**, 210 (1993).

The sulfonation of benzene-SO_2X (X = CH_3, OCH_3, OH, and Cl) and of 1- and 2-naphthalene-SO_2X (X = CH_3, OCH_3, and Cl) with sulfur trioxide in nitromethane as solvent has been studied. In the benzene series, substitution only occurs at the 3-position irrespective of X; the reaction rates, which are all within the same order of magnitude, are low. Upon sulfonation of the 1-SO_2X-substituted naphthalenes, the main sulfonation product (58–80%) is the 5-sulfonic acid (5-S); in addition, 6-S and small amounts of 3-S and 7-S are formed. Also, the formation of the intermolecular sulfonic anhydride of 1-(methylsulfonyl)naphthalene-5-S is observed. The 2-SO_2X-substituted naphthalenes all yield the 5-S and 8-S in a ratio of ≅4.9. For both the benzene and naphthalene series, insertion of SO_3 between the SO_2 and X moieties of the chlorosulfonyl and methoxysulfonyl substituents proper takes place. In the benzene series these reactions are fast as compared with the actual ring sulfonation, whereas in the naphthalene series they are, in general, relatively slow. In the naphthalene series the mesomeric directing effect of the SO_2X groups is less important than in the benzene series; the "naphthalene α-effect" also plays an important role.

HAROLD R. W. ANSINK, ERIK J. DE GRAAF, ERWIN ZELVELDER et HANS CERFONTAIN. Can. J. Chem. **71**, 210 (1993).

On a étudié la sulfonation des benzène-SO_2X (X = CH_3, OCH_3, OH et Cl) et des naphtalène-1- et 2-SO_2X (X = CH_3, OCH_3, et Cl) par le trioxyde de soufre dans le nitrométhane. En série benzénique, la substitution ne se produit qu'en position 3, quelle que soit la nature de X; les vitesses de réaction, qui sont toutes du même ordre de grandeur, sont faibles. Lors de la sulfonation des naphtalènes substitués en position par un 1-SO_2X, le principal produit de sulfonation (58–80%) est l'acide 5-sulfonique (5-S); de plus, il se forme du 6-S et de faibles quantités des 3-S et 7-S. De plus, on observe la formation de l'anhydride sulfonique intermoléculaire du 1-(méthylsulfonyl)naphthalène-5-S. Les naphtalènes substitués par un 2-SO_2X conduisent tous aux 5-S et 8-S dans un rapport de ≈4,9. Dans les séries benzénique et naphtalénique, il se produit aussi une insertion du SO_3 entre le SO_2 et le X des substituants chlorosulfonyle et methoxysulfonyle. En série benzénique, ces réactions sont rapides comparées aux réactions de sulfonation du cycle; par contre, en série naphtalénique, elles sont en général relativement plus faibles. En série naphtalénique, l'effet mésomérique directeur des groupes SO_2X est moins important qu'en série benzénique; l'effet-α du naphtalène joue toujours un rôle important.

[Traduit par la rédaction]

Introduction

From studies on the sulfonation of methyl- (1) and methoxy-substituted (2) naphthalenes, it emerged that the electronic directing effect of the activating, "*ortho/para*"-directing CH_3 substituent is large and that this effect is even larger for the OCH_3 substituent. The electronic directing effect of the deactivating "*meta*"-directing sulfonic acid group present in the methyl- and methoxy-substituted naphthalenes is not very apparent; the directing effects of the CH_3 and OCH_3 groups are dominant over that of the sulfonic acid substituent in the further sulfonation of the naphthalenemonosulfonic acid products. In contrast, in the benzene series, the electronic directing effect of a sulfonic acid group appears to be large in most cases (3).[4]

We now report on the SO_3 sulfonation behaviour of a number of SO_2X monosubstituted benzenes and naphthalenes with the objective to monitor, for the two arene systems, the relative importance of the inductive and mesomeric effects on the one hand and the steric effects on the other of the SO_2X substituents, as for the sulfonic acid product mixture composition. Sulfonation of naphthalene-1-sulfonic acid in 98.5% H_2SO_4 occurs at the 5- (58%), 6- (32%), and 7-positions (10%), whereas sulfonation of the 2-isomer occurs at the 4- (4%), 5- (74%), 6- and 7- (4% in total), and 8-positions (18%) (5). The positional reactivity orders for naphthalene-1- and 2-sulfonic acid, predicted on the basis of the electron-withdrawing inductive effect (which will be more pronounced in the ring to which the SO_3H group is attached than in the other), and the mesomeric and steric effect of the sulfonic acid group are $2 < 4 < 3 < 5 \cong 7 < 8 < 6$ and $1 < 3 \cong 4 \cong 6 = 8 < 5 = 7$, respectively (6).

Results and discussion

The sulfonation of benzene-SO_2X (X = CH_3, OCH_3, OH, and Cl) and of 1- and 2-naphthalene-SO_2X (X = CH_3, OCH_3, and Cl) with sulfur trioxide in nitromethane as solvent has been studied, the results of which are compiled in Tables 1 and 2. To obtain more concrete information on the course of the substitution, some of the reactions have been monitored by ^1H NMR using $C^2H_3NO_2$ as solvent.

In the benzene series, substitution very predominantly occurs at the 3-position irrespective of the type of X; the reaction rates, which are all within the same order of magnitude, are low. This implies that all four SO_2X substituents studied (*i*) deactivate the phenyl ring and (*ii*) strongly destabilize the σ-complexes leading to *ortho* and *para* substitution. Furthermore, the chlorosulfonyl and methoxysulfonyl

[1]Aromatic Sulfonation part 117. For part 116, see ref. 2.

[2]For reasons of convenience, all sulfo products have been numbered as the substrates.

[4]For instance, 3-methylbenzenesulfonic acid, when dissolved in 118.1% sulfuric acid, is sulfonated at the 5-position, i.e., *meta* to the methyl and sulfonic acid groups, for 69.4% (4).

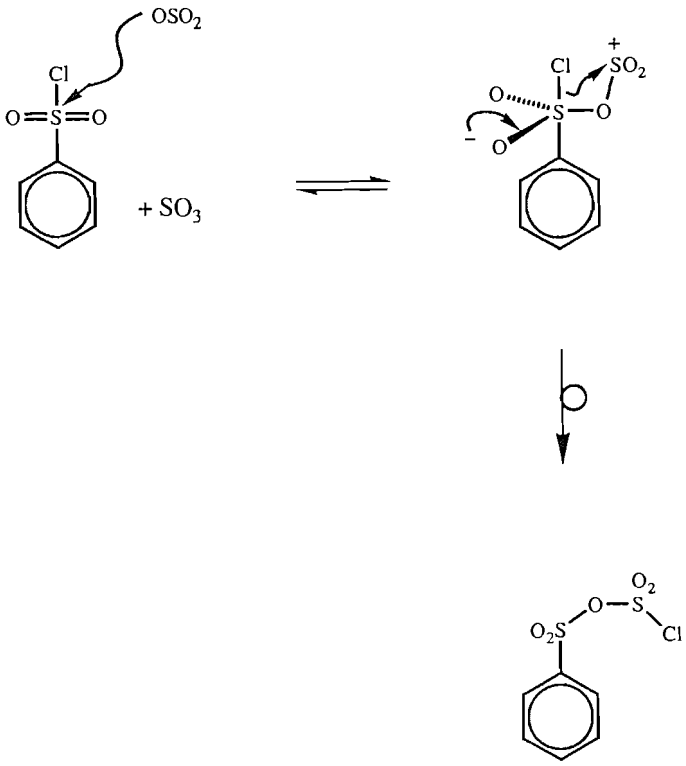
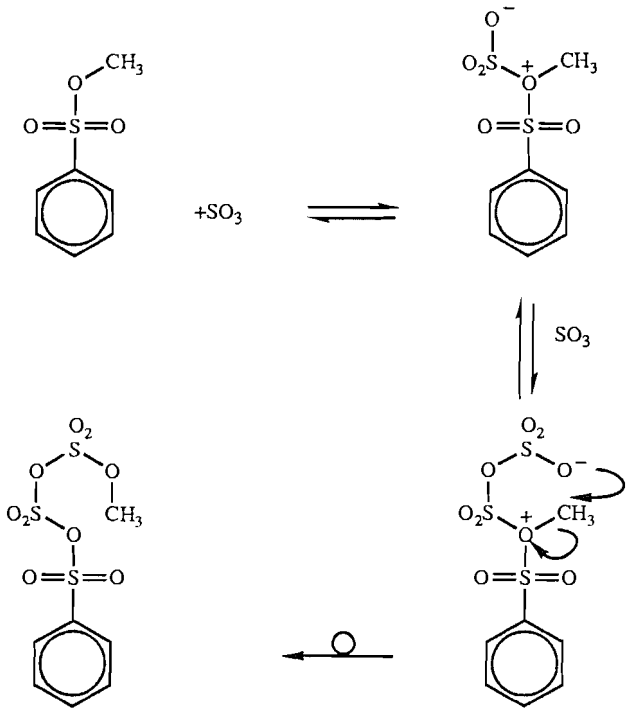


SCHEME 1. Mechanism for the insertion of a SO_3 molecule in between the SO_2 and Cl moieties of (chlorosulfonyl)benzene.



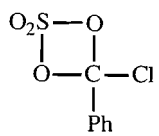
SCHEME 2. Mechanism for the SO_3 insertion in between the SO_2 and OCH_3 moieties of (methoxysulfonyl)benzene.

substituents proper undergo insertion of respectively one and two molecules of SO_3 between the SO_2 and X moieties, reactions that are fast as compared with the actual ring sulfonation. The evidence for these insertions is twofold: first, in the ^1H NMR spectra of the reaction mixtures in fully deuterated nitromethane, signals appear that belong to benzenepyrosulfonic acid rather than to the substrates and, second, after aqueous work-up, potassium benzenesulfonate, containing some dipotassium benzene-1,3-disulfonate, is isolated in all cases. Similar types of SO_3 insertion have been observed for the carbonyl analogues (7, 8) and phenyl methanesulfonates (9). Mechanisms for the insertion of SO_3 between the CO and Cl of the chlorocarbonyl substituent and between the CO and RO of alkoxycarbonyl groups have been proposed (7, 8), with the insertion in the alkoxycarbonyl group being reversible. Mechanisms for the present SO_3 insertions are proposed in Schemes 1[5] and 2[6].

Upon SO_3 sulfonation of the three 1-SO_2X-substituted naphthalenes studied, the 3-, 5-, 6-, and 7-sulfonic acids (3-S, 5-S, 6-S, and 7-S) are formed, of which the 5-S is the major product. A similar product distribution was observed in the sulfuric acid sulfonation of naphthalene-1-S (5). The predominant sulfonation occurs in the ring not containing the (initial) SO_2X substituent. The 5-S is, however, not the main product predicted on the basis of the mesomeric effect of the SO_2X substituents. Apparently, the higher reactivity of the α as compared to the β positions in naphthalenes (the "α-effect") is the dominant factor. Again, sulfodechlorination and sulfodemethylation resulting from SO_3 insertion are the predominant side reactions, although it is not clear at which stage these processes occur. For example, with 1-(methoxysulfonyl)naphthalene, the 5-S derivative was observed in the nitromethane reaction mixture, but only dipotassium naphthalene-1,5-disulfonate is isolated after aqueous alkaline work-up; thus the demethylation had taken place during the alkaline work-up, at least to some extent.

The formation of a substantial amount of the 6-S upon sulfonation of both 1-(methoxysulfonyl)- and 1-(chlorosulfonyl)naphthalene is in contrast to the sulfonation of 1-(methylsulfonyl)naphthalene, for which substrate the amount of 6-S is appreciably smaller. It is thought that the sulfonation σ-complexes for sulfonation at C(3) and C(6) are more stabilized by the chlorosulfonyl and the methoxysulfonyl substituents than by the methylsulfonyl substituent, for the following reason. In the former two σ-complexes, the two carbons adjacent to C(1) are partially positively charged; the electron-rich chlorine atom of the chlorosulfonyl and the methoxy oxygen atom of the methoxysulfonyl substituents are in the vicinity of these two carbons, enabling through-

[5]In the mechanism proposed by Krespan and England (7), the initial step is the electrophilic attack of SO_3 on the carbonyl oxygen; however, we propose that, due to the strong electron-withdrawing power of the chlorine atom, the initial step is *nucleophilic* attack by one of the oxygens of SO_3 on the partially positively charged sulfur atom of the SO_2Cl group, thus avoiding the unlikely four-membered ring intermediate **A** proposed by Krespan and England.



A

[6]A similar mechanism to that in Scheme 2 was proposed for the insertion of SO_3 between the C(sp^2)-bonded oxygen and the sulfur atom of an -OSO_2CH_3 substituent as in 4-(trifluoromethoxy)phenyl methanesulfonate (9*a*) and in dimethyl sulfate (10).

[c]δ relative to virtual internal TMS.

space dipolar stabilization of these σ-complexes (see Fig. 1). As a result, the sulfonation at C(3) and C(6) will be faster than sulfonation at C(5) and C(7) for these two substrates as compared with 1-(methylsulfonyl)naphthalene. In addition, the chloro and methoxy moieties are both electron withdrawing relative to the SO_2 moiety, whereas the methyl group is electron donating. As a result, the sulfonation σ-complexes for sulfonation of 1-(chlorosulfonyl)- and 1-(methoxysulfonyl)naphthalene at the 5- and 7-positions are more destabilized, rendering sulfonation at their 6- and 3-positions relatively more favoured.

The variation in the amounts of 3-, 5-, and especially 6-S formed for X = Cl and OCH_3 upon increasing the relative amount of SO_3 may be explained in terms of the increasing rate of initial complex formation (the first step in Schemes 1 and 2) or SO_3 insertion, thus varying the actual directing effect due to substituent modification. It should, however, be noted that the SO_3-complexed substituents, and the SO_2OSO_2Cl and $SO_2OSO_2OCH_3$ groups resulting from the insertion, will have a similar effect (see Fig. 1) to that originally presented by the SO_2Cl and SO_2OCH_3 groups as they also contain an electron-withdrawing moiety adjacent to the carbon-bonded sulfur atom; thus, the variation will not be very dramatic, as is in fact observed.

Of interest is the conversion of 1-(methylsulfonyl)naphthalene-5-S into its intermolecular anhydride, which is not further sulfonated. Sulfonic anhydride formation is a common secondary reaction in SO_3 sulfonation (11), especially with either substrates of low reactivity, or upon using moderated sulfonating reagents.[7] The ^{1}H NMR absorptions of the aromatic hydrogens are dramatically shifted up-field upon going from the naphthalenesulfonic acid to the corresponding sulfonic anhydride, as is shown in Table 5, as a result of the increase of the electron density due to the proximity of the two naphthalene rings of the sulfonic anhydride.

The formation of a small amount of the 7-S on sulfonation of the 1-SO_2X-naphthalenes with SO_3 is further evidence that the inductive (deactivating) effect is stronger in the ring to which the SO_2X substituent is attached than in the other. The result further compares favourably with the sulfuric acid sulfonation of naphthalene-1-S, which occurs at C(7) for 10% (5).

On sulfonation of the three 2-SO_2X-substituted naphthalenes, the 5-S and 8-S are formed in a ratio of ≅4.9. The 5-S is the product predicted on the basis of the mesomeric and inductive effects of the SO_2X substituents; the formation of ≅17% of the 8-isomer illustrates again the importance of the "α-effect", especially since no β-sulfonation products are observed. Also, the sulfuric acid sulfonation of naphthalene-2-S yields in total only 4% of the 2,6- and 2,7-S_2 (5).

Disulfonation was not observed to occur for any of the substrates, illustrating the large electron-withdrawing effect of both the SO_2X and sulfonic acid substituents. In fact, only when reacting naphthalene with fuming sulfuric acid (containing 105.4% H_2SO_4), naphthalene-1,3,5-, -1,3,6-, and -1,3,7-trisulfonic acid are formed (5).

From the present data it appears that the four SO_2X substituents all behave similarly; the methylsulfonyl substituent seems to be the most suitable model for the sulfonic acid group, as it is stable under both the sulfonation and the aqueous alkaline work-up conditions. The inductive electronic effect diminishes the amount of sulfonation in the ring to which the SO_2X substituent is attached, and the steric effect impedes sulfonation *peri* to an SO_2X group. It appears that the mesomeric directing effect of the SO_2X groups in the naphthalene series is less important than in the benzene series; in addition, the "α-effect" plays an important role.

Experimental

(Chlorosulfonyl)- and (methylsulfonyl)benzene, benzenesulfonic acid, and the (chlorosulfonyl)naphthalenes were obtained commercially and used as such. The methoxysulfonyl derivatives of benzene and naphthalene were synthesized by dissolving the corresponding chlorosulfonyl compounds in methanol. After standing for 8 h, the solvent was removed by vacuum evaporation, the residue dissolved in chloroform, and the resulting solution washed three times with water. After drying over magnesium sulfate and evaporation of the chloroform, the naphthalene products were recrystallized from a 1:1 mixture of diethyl ether and hexane to give 1-(methoxysulfonyl)naphthalene, mp 75°C (lit. (12*a*)

[7]For instance, the sulfonation of 1,7-dimethoxynaphthalene with 4.0 equiv. of SO_3 in $^2H_8$-dioxane yields, as secondary product, the intermolecular anhydride of its 4-S (H.R.W. Ansink, unpublished result).

mp 75°C) and 2-(methoxysulfonyl)naphthalene, mp 54–55°C (lit. (12*b*) mp 53–54°C). The (methylsulfonyl)naphthalenes were synthesized from the corresponding (chlorosulfonyl)naphthalenes following a described procedure (13). The NMR spectra were recorded using Bruker AC-200 and WM-250 spectrometers. The three-dimensional molecular structures were calculated using the Cambridge Scientific Computing "Chem3D plus" package.

Sulfonation procedures

Method A

A solution of the desired amount of SO_3 in 7.0 mL of nitromethane was added to a homogeneous solution of 1.0 mmol of substrate in 7.0 mL of nitromethane at ambient temperature (≅20°C) in an argon atmosphere. After the appropriate reaction time, 1.0 mL of ^1H_2O was added and the mixture heated to 40°C for 30 min to hydrolyze (most of) the anhydrides. The aqueous layer was isolated and extracted at room temperature three times with 1–2 mL of CH_2Cl_2 to remove any unconverted substrate and remaining nitromethane. The residual CH_2Cl_2 was removed by bubbling N_2 through the aqueous solution for 30 min. The aqueous layer was subsequently neutralized with 10% aqueous potassium hydroxide and the water removed by freeze-drying. Subsequently, an ^1H NMR spectrum of the resulting potassium sulfonate salt mixture dissolved in ^2H_2O was recorded for product assignment and the quantitative analysis.

Method B

A solution of the desired amount of SO_3 in 0.5 mL of $C^2H_3NO_2$ was added to a solution of 0.10 mmol of substrate in 0.5 mL of $C^2H_3NO_2$ at ambient temperature under argon. A sample of the resulting homogeneous reaction mixture was then transferred into an NMR tube and subsequently ^1H NMR and (or) ^{13}C NMR spectra were recorded allowing appropriate time intervals. The reaction mixtures thus obtained were worked up with H_2O and subsequently treated as described in method A.

The structural assignments of the sulfo products of the SO_3 sulfonations were made on the basis of the observed ^1H NMR chemical shifts, absorption area ratios, and coupling constants in combination with the shielding parameters of the SO_3^- and SO_3H substituents. The assignments are compiled in Tables 3 and 4. The compositions of the sulfonation reaction mixtures and the sulfonated product mixtures were determined by multicomponent ^1H NMR analysis on the basis of specific absorptions of the various components (14). The chemical shift changes on converting a 1-naphthalenesulfonic acid group into the corresponding intermolecular anhydride are collected in Table 5.

Coincidence electron-scattering experiments: the statistics of coincidence counting

LISA A. GRAHAM, S. J. DESJARDINS, AND A. D. O. BAWAGAN[1]
Ottawa–Carleton Chemistry Institute, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received August 21, 1992

LISA A. GRAHAM, S. J. DESJARDINS, and A. D. O. BAWAGAN. Can. J. Chem. **71**, 216 (1993).

A new coincidence electron-scattering spectrometer for electron momentum spectroscopy (EMS) experiments is described. The new features include the use of a single 360° cylindrical mirror analyzer (CMA) for energy analysis and a coincidence data acquisition system based on a qVt-multichannel analyser and CAMAC electronics. The CMA energy resolution and coincidence time resolution are 0.32 ± 0.03% $\Delta E/E$ fwhm and 3.5 ± 0.5 ns fwhm, respectively. The helium 1*s* orbital binding energy spectrum is obtained at 1000 eV binding energy and 100 eV pass energy, yielding a coincidence binding energy resolution of 1.5 ± 0.2 eV fwhm. The coincidence data analysis procedure that is introduced provides experimental verification of some basic statistics of coincidence counting.

LISA A. GRAHAM, S. J. DESJARDINS et A. D. O. BAWAGAN. Can. J. Chem. **71**, 216 (1993).

On décrit un nouveau spectromètre diffusion des électrons à coïncidence pour des expériences de spectroscopie des moments électroniques. Les nouvelles caractéristiques comprennent l'utilisation d'un analyseur en forme de miroir cylindrique (AMC) de 360° unique pour l'analyse de l'énergie et d'un système à coïncidence d'acquisition de données basé sur un analyseur multicanaux qVt et de l'électronique CAMAC. Les résolutions de l'énergie et du temps de coïncidence par l'AMC sont respectivement de 0,32 ± 0,03% $\Delta E/E$ fwhm et 3,5 ± 0,5 ns fwhm. On a obtenu le spectre d'énergie de liaison de l'orbitale 1*s* de l'hélium à une énergie de liaison de 1000 eV et une énergie de passage de 100 eV qui conduisent à une résolution de la coïncidence de l'énergie de liaison de 1,5 ± 0,2 eV fwhm. La façon d'analyser les données de coïncidence qui est introduite fournit une vérification expérimentale de quelques statistiques fondamentales de la facon de compter les coïncidences.

1. Introduction

A coincidence electron-scattering technique called electron momentum spectroscopy (EMS)[2] has emerged as a unique and powerful spectroscopic technique following the pioneering experimental studies of Amaldi *et al.* (1), Camilloni *et al.* (2), and Weigold *et al.* (3) and the insightful theoretical investigations of Neudatchin *et al.* (4) and Glassgold and Ialongo (5). The theoretical framework, originally developed for (p,2p) reactions, was quickly applied to the analysis of (e,2e) experiments. Initial speculations at that time (4–6) indicated the potential of (e,2e) reactions for probing individual orbital electron momentum distributions (MDs) as well as the investigation of correlation effects in atoms, molecules, and thin films. These speculations were soon verified in several experiments around the world (2, 3, 7–9). Since then several reviews have been published and excellent surveys of the literature (10, 11) can be consulted.

The major experimental observables in an EMS experiment are the binding energy spectrum and the experimental momentum profile (XMP). Since EMS is not energy-limited by resonance light sources (e.g., He I limit is 21.2 eV), it is capable of observing spectra over the complete binding energy range including both the outer valence and the inner valence regions. Electron momentum spectroscopy (EMS) and photoelectron spectroscopy (PES) studies in the inner valence region have shown extra structure to what one would expect from the single-particle picture of ionization and these structures are now attributed to correlation states. The understanding of these correlation (many-body) states as well as the accurate prediction of their transition probabilities is fairly recent (12, 13). Nevertheless, the generally semi-quantitative agreement obtained between the experimental binding energy spectra obtained in EMS and the calculated spectrum is quite impressive. It is clear from the studies conducted so far that the breakdown of the single-particle picture of ionization, especially in the inner valence region, is a general phenomenon (13).

Although EMS and PES both give closely related information regarding the correlation state (satellite) intensities, the two techniques are of an entirely different nature because of the different momentum regions sampled by the techniques. In fact, this difference has been the subject of intense investigation and controversy (14).

Electron momentum spectroscopy is one of the experimental techniques capable of probing atomic and molecular momentum distributions. Other techniques include Compton scattering, high-energy electron scattering, and positron annihilation. In EMS the angular correlation spectra obtained for a particular energy-selected state are called experimental momentum profiles (XMPs). The XMP is a well-defined physical observable within the limits defined by the theory of EMS and is proportional to the spherically averaged orbital momentum distribution. Since EMS is orbital selective, it has a *distinct* advantage compared to Compton scattering and high-energy electron scattering, which are experimental techniques that measure a quantity equal to an integral over the total electron momentum distribution.

With the current improvements in momentum resolution, EMS measurements are now providing a sensitive test of the quality of *ab initio* wavefunctions. Collaborative experimental and theoretical studies (15–18) have led to the development of so-called universal wavefunctions in the sense that they are sufficiently accurate to calculate all electronic properties of the molecule with good precision. As opposed to traditional one-electron properties such as the dipole moment, an increasing amount of evidence (15) indicates that XMPs are even more sensitive to the diffuse region of the orbital electron distribution. In addition, the experimental

investigation of traditional chemical concepts such as inductive effects and hyperconjugation becomes feasible through a comparative study of the outermost valence XMPs of a series of chemically related molecules (19–21).

The present work outlines the construction, calibration, and operation of a new coincidence electron-scattering spectrometer for EMS experiments at Carleton University. The new EMS spectrometer is of a novel design following the early ideas of Cook (22) and Moore *et al.* (8), the ultimate goal being the development of a multichannel EMS spectrometer in the angular plane (ϕ-plane) as opposed to the energy-dispersive plane. Although multichannel EMS spectrometers in the energy-dispersive plane have been utilized extensively in chemical investigations (23), they involve the assembly of several binding energy spectra taken at several azimuthal angles to generate the experimental momentum profiles (XMPs). A multichannel EMS spectrometer in the angular plane will provide the XMPs directly without cumbersome data analysis procedures and is thus of more practical chemical interest. XMPs produced by this type of EMS spectrometer will most likely be less sensitive to instrumental instability because of the shorter data collection times involved.

A further advantage of the present design is the flexibility allowed to perform future (e,3e) triple coincidence experiments, since the larger CMA design would allow the introduction of a third electron energy analyzer (within the inner cylinder) with ease. These (e,3e) experiments are believed (24, 25) to provide a more detailed picture of electron correlations in atoms and molecules.

2. Theoretical background

Electron momentum spectroscopy is based on the (e,2e) reaction,

$$[1] \quad e_0^-(E_0\boldsymbol{p}_0) + M \rightarrow M^+ + e_1^-(E_1\boldsymbol{p}_1) + e_2^-(E_2\boldsymbol{p}_2)$$

where $\boldsymbol{p}_i$, E_i (i = 0, 1, 2) are the momentum and energy of the incoming, scattered, and ejected electrons, respectively. The ion recoil momentum and energy are given by $\boldsymbol{p}_3$ and E_3, respectively. The (e,2e) reaction is also shown in Fig. 1. Early studies (26, 27) have shown that under certain well-defined kinematic conditions the (e,2e) cross section (reaction probability) is largely a measure of the electron momentum distribution of the single-particle orbital from which the electron was ionized or knocked out. It is now established that the necessary conditions are

(*a*) high-impact energy ($E_0 \geq 1000$ eV)
(*b*) symmetric energy sharing ($E_1 = E_2 = E$)
(*c*) large momentum transfer ($|\mathbf{K}| = |\boldsymbol{p}_0 - \boldsymbol{p}_1| \geq 5$ au)
(*d*) non-coplanar ($\theta = 45°$, ϕ = variable)

Under these conditions and within the independent-particle (Hartree–Fock) description of electronic motion, the (e,2e) cross section is given by

$$[2] \quad \sigma_{e,2e} = \text{constant} \cdot (4\pi)^{-1} \int |\psi_j(\mathbf{p})|^2 \, d\hat{p}$$

where $\boldsymbol{p}$ is the momentum of the electron in orbital ψ_j prior to ionization. The momentum distribution is spherically averaged ($d\hat{p}$) to account for the random orientation of the gaseous targets.

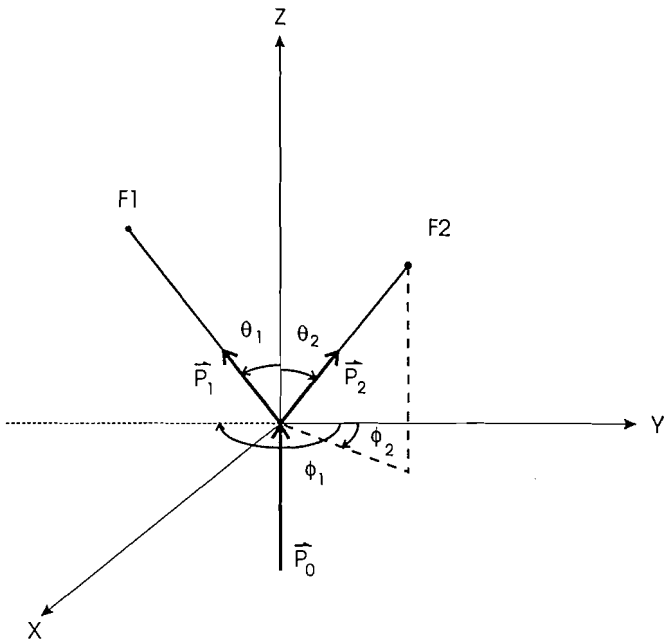

FIG. 1. Vector diagram showing collision geometry for the (e,2e) symmetric non-coplanar scattering kinematics. The experimental parameters are: $\theta_1 = \theta_2 = 45°$, $\phi_1 = 180°$, $\phi_2 = \phi$ = variable.

The expression in eq. [2] follows from energy conservation,

$$[3] \quad E_0 = E_1 + E_2 + E_3 + E_b \sim E_1 + E_2 + E_b$$

and momentum conservation laws,

$$[4] \quad \boldsymbol{p}_0 = \boldsymbol{p}_1 + \boldsymbol{p}_2 + \boldsymbol{p}_3$$

E_3 is the ion recoil energy and is negligible due to the large mass of the ion. E_b is the binding energy (ionization potential) of the orbital electron. The ion recoil momentum, $\boldsymbol{p}_3$ within the conditions (*a*)–(*d*) outlined above is equal in magnitude but opposite in sign to the orbital electron momentum prior to knockout, i.e.,

$$[5] \quad \boldsymbol{p} = -\boldsymbol{p}_3$$

In the symmetric non-coplanar arrangement the magnitude of the orbital electron momentum, $\boldsymbol{p}$, is given by

$$[6] \quad p = p_{\text{nom}} = \{(2p_1 \cos\theta - p_0)^2 + [2p_1 \sin\theta \sin(\phi/2)]^2\}^{1/2}$$

where the scattering angles θ and ϕ are defined in Fig. 1. It should be recognized that eq. [6] is only valid for a *point* source and finite volume effects need to be considered in the assignment of the momentum scale and (or) the incorporation of momentum resolution effects (28–30).

Equation [5] is an approximation that assumes the target to be initially at rest and the ion is a "spectator" in the collision process. The approximations leading to the proportionality relation (eq. [2]) are called the plane wave impulse approximation (PWIA) and the target Hartree–Fock approximation (THFA), both of which were discussed at length in previous publications (26, 27).

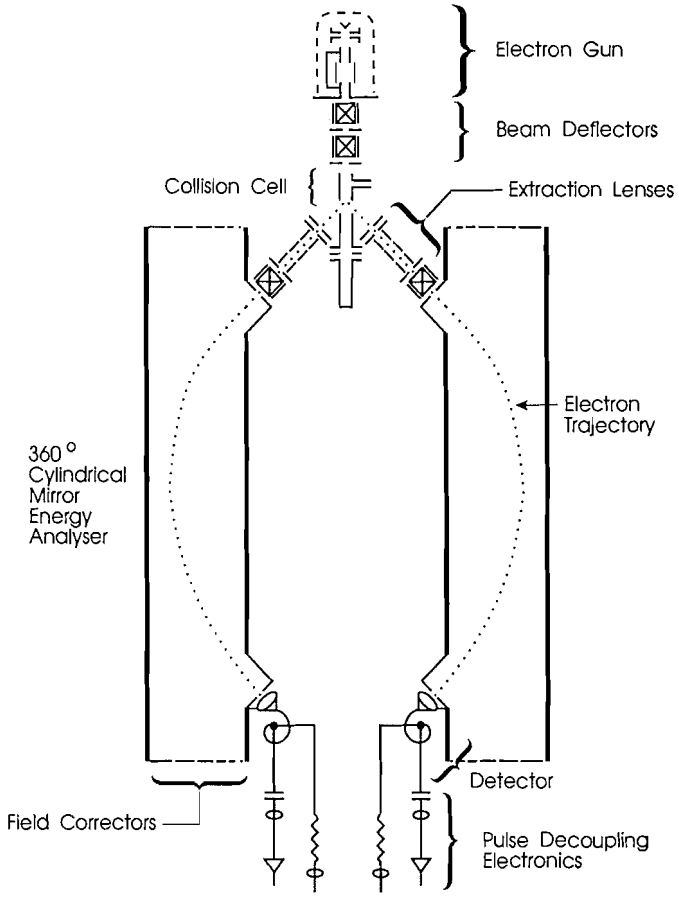

FIG. 2. Illustration of Coincidence Electron Momentum Spectrometer. Note that this illustration is not drawn to scale. Major spectrometer dimensions are indicated in ref. 32.

3. Description of coincidence electron-scattering spectrometer

The coincidence electron-scattering spectrometer for electron momentum spectroscopy (EMS) experiments is shown in Fig. 2. The present EMS spectrometer is of a unique design. It features a *single* 360° cylindrical mirror analyzer (CMA) for the energy analysis of the two outgoing electrons resulting from the (e,2e) reaction (see Fig. 1). A 360° CMA is composed of two concentric cylinders wherein the inner cylinder has entrance and exit slots for the electrons that have to be analysed. Traditionally, most EMS spectrometers have been built with two independent energy analyzers, one for each outgoing electron. In the non-coplanar geometry, one of the energy analyzers is fixed whereas the other is allowed to move (i.e., variable azimuthal angle) to generate the XMP. The present design follows from early ideas (8, 22), where a single energy analyzer is used to select *both* outgoing electrons. With such a design the simultaneous collection of outgoing electrons at several azimuthal angles (ϕ) becomes possible. Thus an experimental momentum profile for an energy-selected molecular orbital can be generated without changing or scanning the azimuthal angles. Clearly, with this kind of design careful calibration studies are necessary to ensure that the collection efficiency across the accessible azimuthal angles is uniform. This requirement places stringent constraints on spectrometer alignment and machining tolerances.

At present, the EMS spectrometer is operated at single-angle mode (i.e., at one fixed azimuthal angle) as a necessary calibration step towards its eventual operation as a multi-angle EMS spectrometer. The spectrometer is described in Sect. 3.1 and preliminary results on the coincidence binding energy spectrum of the He 1*s* orbital are described in Sect. 4.3.

3.1. Physical characteristics of apparatus

Located at the top of the assembly is the electron gun (Cliftronics CE5AH), which uses a thoriated tungsten hairpin filament. The voltage on the filament cathode, which is negative relative to the gas cell (−1000 V), defines the incoming electron impact energy. The filament and its extraction electrodes are housed within a Faraday cage, which is held at large negative potential.

The electron beam passes through a pair of quadrupole beam deflectors for focusing. The electron beam is focused by minimizing the current measured at spray plates 1 and 2 and maximizing the current measured at the Faraday cup. Before reaching the Faraday cup, the electron beam (circular cross section of ~1 mm) passes through a small gas cell where the (e,2e) reaction occurs. The target gas is introduced to the gas cell through a 0.5 mm diameter stainless steel tube. Two sets of three-element cylindrical lenses are used to select those electrons emitted at a 45° polar angle (θ) with respect to the incident beam. These cylindrical lenses are mounted on the legs of a hinge mechanism that rotates about the center axis of the CMA. One leg of the hinge is held stationary while the other hinge can move within a range of azimuthal angles ($-45° \leq \phi \leq +45°$). The angular acceptances of these lenses intersect with the electron beam to define the probed collision volume.

The three-element cylindrical lenses retard and focus the electrons emitted from the collision volume into the CMA for energy analysis. Typically, a 5:1 or 6:1 retarding field is used. In the present application, a 5:1 retarding field is used to retard 500 eV electrons to 100 eV prior to entering the CMA. Thus it is said that the CMA is operating at 100 eV pass energy. Reducing the pass energy to lower values improves the energy resolution up to a point where it is dominated solely by the incoming electron beam energy spread.

The cylindrical mirror analyzer is designed for first-order focusing using the parameters suggested by Risley (31). The base energy resolution R_{base} is given by,

$$[7] \qquad R_{base} = \frac{w_{sz} + w_{ez}}{D}$$

where w_{sz} and w_{ez} are the projections of the source and exit slit widths onto the axis of the analyzer, respectively. D is the linear dispersion of the analyzer. The contributions of angular aberrations to the energy resolution are neglected since these contributions are relatively much smaller in the present application. Using the present experimental parameters,[3] the calculated energy resolution of the present CMA is

$$[8] \qquad R_{base} = \frac{\Delta E_{base}}{E_{pass}} = 0.70\%$$

$$[9] \qquad R_{fwhm} = \frac{\Delta E_{fwhm}}{E_{pass}} = 0.35\%$$

As a result of the high machining tolerances required, both inner and outer cylinders of the CMA are machined from bronze and mounted on high-quality sapphire balls. Concentric rings are placed on the top and bottom ends of the cylinders to correct for fringing field effects. All surfaces traversed by the electron are coated with benzene soot to minimize secondary electron emission. To null the earth's magnetic field, two concentric mu-metal shields (Conetic AA) are placed around the CMA and the electron gun assembly. This reduces the magnetic fields within the CMA to ≤5 mG.

The electrons are detected by identical channel electron multi-

[3]The outer cylinder and inner cylinder radii are 168 and 84 mm, respectively. The entrance and exit aperture diameters are 0.7 and 1.0 mm, respectively. Further details are available in ref. 32.

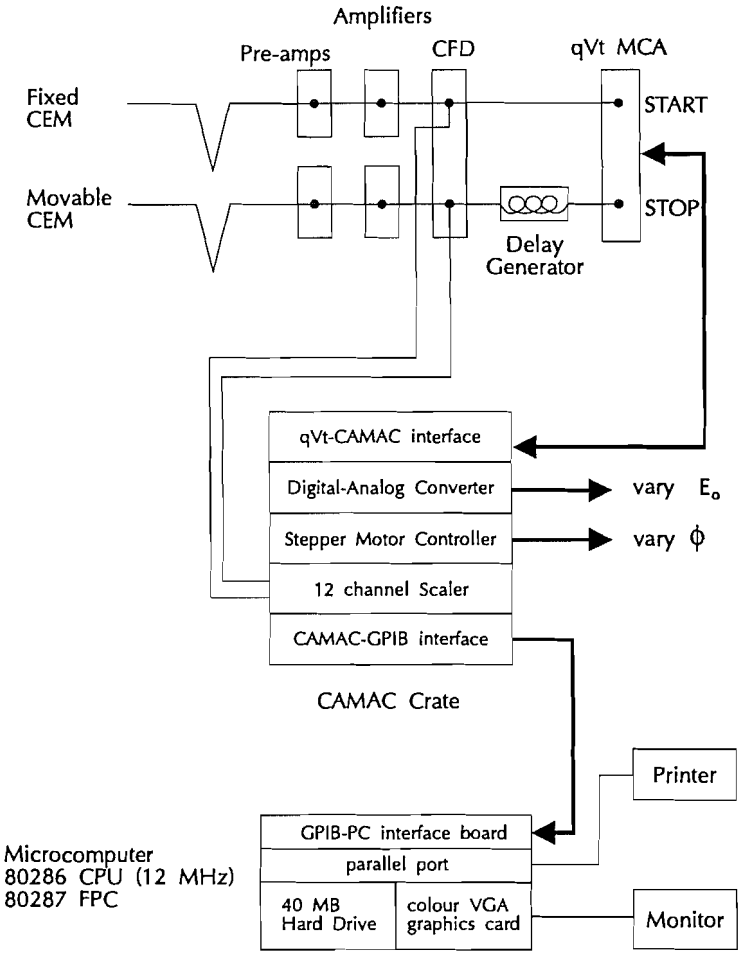

FIG. 3. Schematic diagram of coincidence electronics and computer-controlled data acquisition system.

pliers (Galileo 4318 CEM), which are also located on the same hinge of the corresponding cylindrical lens as shown in Fig. 2. The CEM output pulse is decoupled, amplified, and sent to the coincidence electronics as described in the following section.

The whole coincidence electron-scattering spectrometer is enclosed in a high-vacuum chamber with a base pressure of less than 8×10^{-7} Torr (1 Torr = 133.31 Pa). A baffled oil diffusion pump (Varian VHS 6) with pumping capacity of 2400 L/s is used to maintain this pressure. The diffusion pump is backed by a direct drive roughing pump (Leybold D30A). A second roughing pump is used to evacuate the sample manifold.

3.2. Coincidence timing electronics

Time-correlated pulses are produced by the two electron detectors when the electrons arriving at the detectors arise from the same ionizing event. Electrons that are not from the same ionizing event are also detected, but the time difference between arrival times of these two electrons is randomly distributed. We are interested in distinguishing between the number of true coincidences and the number of random coincidences. The correlated pulses are distinguished by passing one of the CEM pulses through a fixed known time delay and measuring the time delay between the two CEM pulses. Pairs of pulses with a time delay within a certain allowable time spread are considered to be coincident. This time spread is also referred to as the time resolution. Time delays measured outside this range are considered to arise from random events. This classification is accomplished by the coincidence electronics system illustrated in Fig. 3.

The pulses produced by the CEMs are capacitively decoupled and amplified (Ortec 9301, Ortec 474). The amplified pulses are used to trigger the constant fraction discriminators (CFDs, Canberra 2126Q) to produce standard fast timing pulses. These fast timing pulses are then used to trigger the qVt multichannel analyzer (MCA, LeCroy 3001), which measures the time difference between the pulses appearing at its START and STOP inputs. The pulse originating from the fixed detector is used as the START trigger and the pulse originating from the movable detector is passed through a time delay unit (Canberra 2058, τ_d = 32 ns) and used as the STOP trigger. The qVt-MCA is operated in time mode (t) and produces a time spectrum or histogram (counts vs. time difference). At the end of each acquisition time, the time spectrum is transferred from the qVt-MCA to the computer via the qVt-CAMAC interface module (LeCroy 2301).

The time spectrum is a plot of the number of coincidence events occurring with a specific time delay between the two trigger pulses generated by the event, and an example is shown in Fig. 4. The time spectrum can be produced using either the TAC (time to amplitude converter) as used previously (26) or the qVt method (a similar use is outlined in ref. 33) as we have chosen to use. There are advantages and disadvantages as will be explained below. The whole time spectrum is divided into two sections, the coincidence time window and the background time window. The number of true coincidences can therefore be calculated from the number of coincidence counts occurring at both windows and their relative widths.

The ratio of the widths of the coincidence time window to background time window must be known and constant throughout the experiment. In the present qVt method the entire time spectrum is saved at each parameter setting ($E_0 + E_b$ or ϕ), and the data

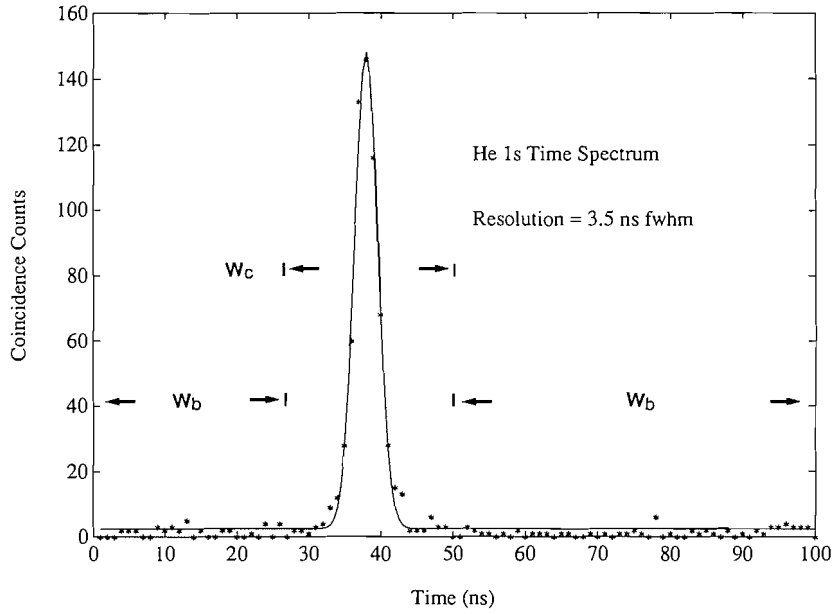

FIG. 4. Typical time delay spectrum observed at $\epsilon \sim \epsilon_b$. The coincidence window and background windows are also indicated. The shift of the peak of the time spectrum from τ_d (32 ns) is due to the inherent time pedestal of the LeCroy qVt. Experimental parameters are: He 1*s* orbital, E_0 = 1000 eV, ϵ = 24.6 eV, E_{pass} = 100 eV.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

analysis is done off-line. The window width ratio is a software parameter that can be chosen to optimize the signal to noise ratio. The window width ratio is therefore known to be constant throughout the data analysis.

In the more popular TAC method, the time difference between the two pulses is converted to a voltage pulse whose amplitude is proportional to the time difference. The TAC output pulse is then connected to two single channel analyzers (SCAs) that count pulses that fall within a specified range of amplitudes. One SCA counts pulses with amplitudes corresponding to the coincidence time window while the second SCA is used to count pulses corresponding to the background time window. The data obtained at each energy parameter are composed of two values, one corresponding to the number of true coincidences plus accidental coincidences and the second value corresponding to the number of random coincidences. The ratio of the coincidence window width and the background window width is determined electronically by the SCAs. Thus in the TAC method this ratio is subject to the temperature and time stability of the electronics (otherwise known as "time walk").

In some cases, elaborate noise veto circuits have to be used with the TAC method to ensure that the pulses being counted arise only from the collision process. If the ambient noise level is high, a significant amount of data collection time is wasted. With the qVt method, the possibility exists for identifying noise interferences that have crept into the data since the full time spectra at different binding energies (or azimuthal angles) are collected. Spurious events occur at specific time delays, often different from τ_d, and can therefore be removed in the data analysis. The recovery of the real coincidence data in the presence of noise interference has recently been demonstrated in our laboratory (32). This is not possible with the TAC method because the counts obtained in the coincidence and background windows are actually *integrated* counts.

3.3 Data acquisition

The binding energy spectrum is a plot of the number of true coincidences versus binding energy ($\varepsilon = E_0 - E_1 - E_2$) with a peak appearing whenever $\varepsilon = E_b$. The impact energy E_0 is scanned using a programmable power supply and a digital to analog converter (Joerger D/A-16). E_1 and E_2 are equivalent and held constant as selected by the CMA.

Rather than using a predetermined, fixed-length, data acquisition time at each energy parameter (or azimuthal angle), the data acquisition time is determined by the sum of the singles count rate of electrons reaching the two detectors. The data acquisition time is determined by counting until a preset number of total singles counts is achieved. Thus the measured true coincidence counts are directly proportional to the EMS triple differential cross section (as defined in eq. [2]) and independent of any fluctuations in incident electron flux and local gas pressure. These fluctuations can be significant especially with the long data collection times (1–4 weeks) characteristic of coincidence-type experiments.

The binding energy spectrum is generated from the time spectra obtained at the different binding energies.[4] First, the coincidence window width (w_c) and background window width (w_b) are assigned. At each binding energy, the total number of counts within the coincidence window (N_c), and the total number of counts in the background window (N_b) are calculated. Within the coincidence window, some of the counts correspond to accidental coincidences (i.e., two electrons from different events arriving at the two detectors at the same time). These counts are subtracted from the total coincidence counts to give the number of true coincidence counts (N_t). The number of true coincidences is therefore given by

$$[10] \quad N_t = N_c - N_b\left(\frac{w_c}{w_b}\right)$$

And the uncertainty of N_t is given by

$$[11] \quad \Delta N_t = (N_c + r^2 N_b)^{1/2}$$

where $r = w_c/w_b$. Statistics can generally be improved by decreasing r and decreasing N_b up to a certain point (33).

A further advantage of having all of the time spectra at different binding energies is that the shape in three dimensions (counts–energy–time) of the coincidence peak may be studied. Any asymmetries in the three-dimensional peak shape would suggest experimental irregularities in timing of the observed coincidences and (or) *new* physical processes in (e,2e) experiments. Verifica-

[4]Likewise, an orbital experimental momentum profile can be generated from the time spectra obtained at different azimuthal angles.

For personal use only.

tion of the randomness of the background at specific binding energies is also possible. Any interferences appearing systematically in the time delay spectra may be dealt with prior to computing the binding energy spectrum.

4. Characterization of EMS spectrometer

4.1. Time resolution

One of the important experimental parameters of an EMS spectrometer is the time resolution. As mentioned in Sect. 3.3, it is necessary to reduce the instrumental time resolution in order to improve the coincidence counting statistics.

The base width of the coincidence peak in the time delay spectrum is generally defined as the time resolution of the system. The analysis of the various contributions to this width as detailed by Volkel and Sandner (33) is used to predict the time resolution of the new EMS spectrometer.

The base width of the coincidence peak is defined as Δt and is the total variation in travel times of both the electrons from collision to detection and any time variations introduced by the signal handling electronics. The width (Δt) is the sum of variations in the total travelling times of both particles.

$$[12] \quad \Delta t = \Delta t_1 + \Delta t_2$$

The contributions to Δt_i ($i = 1, 2$) are as follows:

$$[13] \quad \Delta t_i = \Delta t_{\text{volume}} + \Delta t_{\text{energy}} + \Delta t_{\text{geometric}} + \Delta t_{\text{detector}} + \Delta t_{\text{electronics}}$$

The contribution of Δt_{volume} arises from the time required to travel across the finite collision volume. Assuming a spherical volume, the worst case is that the electron has to traverse the diameter, thus

$$[14] \quad \Delta t_{\text{volume}} = \frac{d}{\sqrt{\frac{2E}{m}}}$$

where d is the diameter of the collision volume (1.0 mm), E is the energy of the electron as it traverses this volume (500 eV), and m is the mass of the electron. Using these values, $\Delta t_{\text{volume}} \approx 80$ ps.

The variation in travelling time due to the finite energy resolution of the energy analyzer is given by

$$[15] \quad \Delta t_{\text{energy}} = \left(\frac{m}{8}\right)^{1/2} \frac{LR}{E^{1/2}}$$

where L is the length of the total flight path from collision point to detector (59.3 cm). The theoretical base resolution of the spectrometer, R, is 0.70% $\Delta E/E$. The energy of the electrons passing through the analyzer, E, is 100 eV. Using these values $\Delta t_{\text{energy}} \approx 150$ ps.

The angular acceptance of the energy analyzer contributes to the time resolution due to the range of allowable launch angles into the energy analyzer. This contribution is given by

$$[16] \quad \Delta t_{\text{geometric}} = \left(\frac{z_0}{\sqrt{\frac{2E}{m}}}\right) \frac{\sin\theta}{\cos^2\theta} \Delta\theta$$

where z_0 is the length of the flight path perpendicular to the electric field in the analyzer (33.6 cm), θ is the polar component of the launch angle (45°), and $\Delta\theta$ is the angular acceptance of the analyzer as defined by the lens apertures (21.74×10^{-3} radians). These values give $\Delta t_{\text{geometric}} \approx$ 720 ps.

The variations in transit time of the charge cloud within the channel electron multiplier are included in $\Delta t_{\text{detector}}$. This transit time variation is on the order of 2 ns (26).

The last contribution is from the time jitter of the electronics and cables used to measure the time difference between the pulses. This was experimentally determined by using a pulse generator and splitting the output to produce two identical pulses. These pulses were connected to the coincidence electronics system instead of the signals from the detectors. The base width of the coincidence peak in the time delay spectrum is a direct measure of $\Delta t_{\text{electronics}}$, which is $\approx$300 ps (35).

Considering the two channels identical, the expected total time resolution of the system is $2\Delta t_1$ or 6.5 ns base width. It is clear from the above estimates that the two largest contributions are from the use of the channel electron multipliers ($\Delta t_{\text{detector}}$) and from the angular acceptance of the energy analyzer ($\Delta t_{\text{geometric}}$). Replacing the CEMs with multichannel plate detectors is expected to reduce $\Delta t_{\text{detector}}$ to 100 ps, giving a predicted lower limit of 2.8 ns (base width).

The experimental time resolution obtained for the present EMS spectrometer is 7 ns base width or 3.5 ns (fwhm) (See Fig. 4). This result is in excellent agreement with the predicted total time resolution ($\Delta t_{\text{base}} = 6.5$ ns).

4.2. CMA energy resolution

Another experimental parameter vital to the performance of an EMS spectrometer is the resolution of its energy analyzer. Energy resolution is defined as the ratio of the energy spread (base width or fwhm) of electrons accepted by the spectrometer to the energy of the electrons as they pass through the spectrometer (see eq. [8]).

Due to the large size of the 360° CMA, possible mechanical misalignments were of main concern. Careful calibration of the CMA deflection voltage and measurement of the energy resolution of the CMA are therefore necessary. The deflection voltage[5] of the CMA determines the electric field between the inner and outer cylinders of the CMA, which determines the energy of the electrons that pass to the detectors. The theoretical deflection voltage V_d required by the CMA for a given pass energy can be calculated from the dimensions of the CMA.

$$[17] \quad V_d = \frac{\ln\left(\frac{b}{a}\right)}{\ln 2.80} E_{\text{pass}}$$

where b is the radius of the outer cylinder, a is the radius of the inner cylinder, and the factor of ln 2.80 is interpolated

[5]Note that in the present design there is only one deflection voltage to focus the two outgoing electrons, in stark contrast to previous EMS designs. A comparison of the experimental and theoretical CMA deflection voltages is therefore a very stringent test of spectrometer alignment.

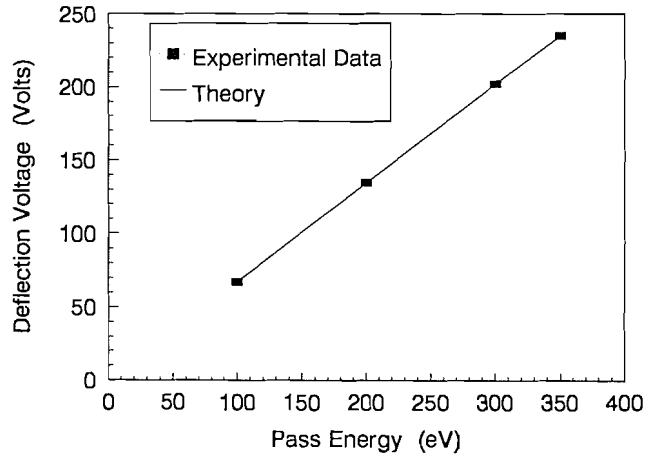

FIG. 5. Calibration of CMA deflection voltage. Scatter of data points for movable and fixed detectors is within the size of the symbols. The solid line is not a fit and indicates the theoretical prediction (eq. [17]).

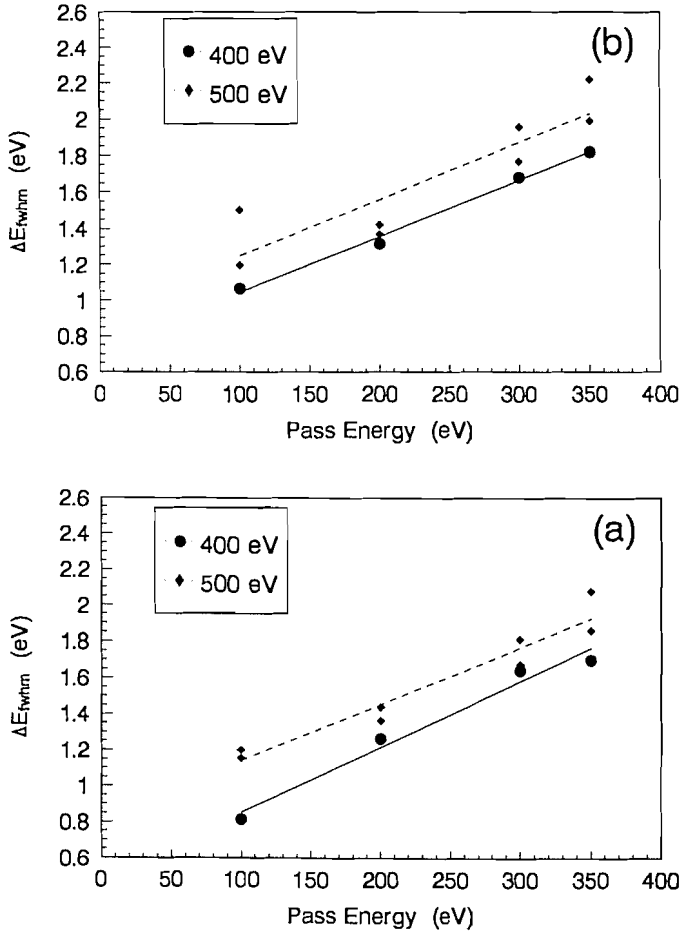

FIG. 6. Determination of experimental energy resolution of CMA. Experimentally measured peak widths obtained from (*a*) movable CEM and (*b*) fixed CEM for the elastic scattering of 400 eV (●) and 500 eV (◆) electrons. The solid and dashed lines are the linear fits to the 400 and 500 eV data, respectively. Note that the relevant curve for the present experiment (E_0 = 1000 eV) is indicated by the 500 eV data (◆).

TABLE 1. Summary of the regression results for determination of the experimental CMA energy resolution

Elastic energy (eV)	Movable R_{fwhm}	Fixed R_{fwhm}	Predicted R_{fwhm}
400	0.00365	0.00310	0.0035
500	0.00314	0.00313	0.0035

from Fig. 4(a) of ref. 31 (with $\theta = 45°$ and $d = 1.0$). The ratio of outer cylinder radius to inner cylinder radius is 2.00.

To calibrate the CMA deflection voltage, elastic scattering experiments at two scattering energies (400 and 500 eV) were done with varying pass energies (100–350 eV) by applying the required retarding voltage to the inner cylinder. The deflection voltage necessary to detect elastically scattered electrons of known kinetic energy (or E_{pass}) was measured. The results of the CMA deflection voltage calibration are shown in Fig. 5. Excellent agreement was obtained between experimental CMA deflection voltages and those predicted by eq. [17]. This result indicates that mechanical misalignments are insignificant.

To experimentally measure the energy resolution of the spectrometer, the full widths at half maximum (ΔE_{fwhm}) of the elastic profiles obtained above were measured for each detector. The energy resolution of the CMA was determined from the slope of a plot of ΔE_{fwhm} versus E_{pass}. These graphs are shown in Fig. 6 for two energies of the elastically scattered electrons (i.e., 400 and 500 eV). The two sets of data points at 500 eV, which represent the actual parameters used in the present experiment, indicate the error limits involved in the measurements of ΔE_{fwhm}. The slope of the regression line obtained from a plot of ΔE_{fwhm} versus E_{pass} is generally associated with the experimental fwhm resolution R_{fwhm} from which the base resolution R_{base} can easily be calculated (31). A summary of the calculated experimental R_{fwhm} for both sections of the CMA and the predicted R_{fwhm} (see Sect. 3.1) are shown in Table 1.

The experimental CMA energy resolution (0.32 ± 0.03% R_{fwhm}) agrees well with the prediction from the design of the CMA (0.35% R_{fwhm}). The results in Table 1 as well as Figs. 5 and 6 clearly indicate that the 360° CMA has been built and assembled to the desired tolerances and is operating at the designed specifications.

4.3. Binding energy spectrum of helium

Coincidence experiments were run at 1000 eV impact energy and $\phi \sim 0°$ using several pass energies from 400 to 100 eV. As expected, energy resolution improved and count rate decreased going from high pass energy to lower pass energies. Figure 7 shows the He 1*s* binding energy spectrum obtained at 100 eV pass energy where the best compromise between energy resolution and coincidence count rate was attained. The background is clearly flat, indicating that the coincidence timing algorithm is functioning as expected. The binding energy peak is Gaussian in shape with a measured coincidence energy resolution of 1.5 ± 0.2 eV fwhm. This resolution is comparable to coincidence energy resolutions obtained in other EMS laboratories (8, 11, 26, 36). Typically, the coincidence energy resolution in an EMS experiment is given (37) by

[18] $$\Delta E_{coinc} = \sqrt{\Delta E^2_{movable} + \Delta E^2_{fixed}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12

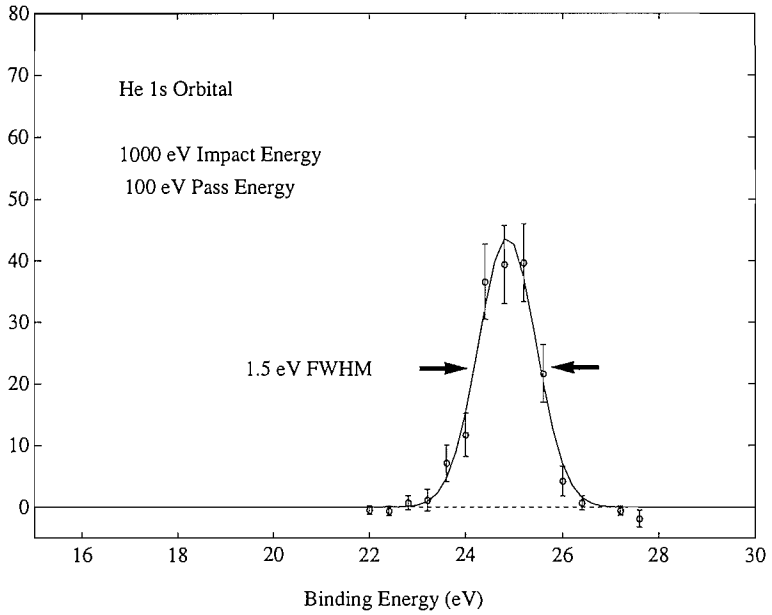

FIG. 7. Binding energy spectrum of helium 1*s* orbital obtained at 1000 eV impact energy, 100 eV pass energy, and $\phi \sim 0°$. Solid line shows Gaussian fit (1.5 ± 0.2 eV fwhm).

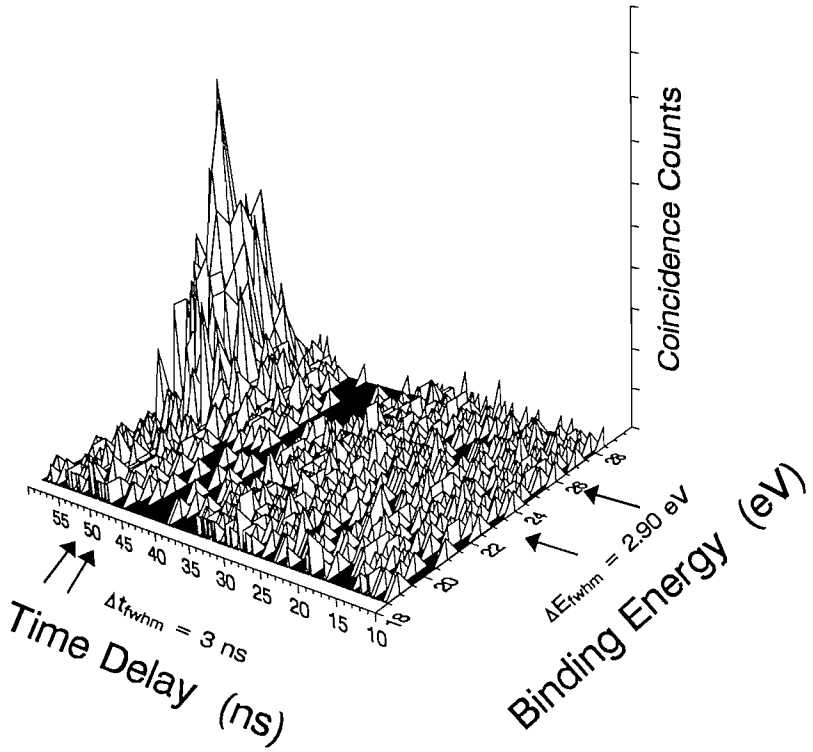

FIG. 8. Three-dimensional surface plot of the He 1*s* (e,2e) binding energy spectrum. Experimental parameters are: E_0 = 1000 eV, E_{pass} = 300 eV, and $\phi \sim 0°$.

where $\Delta E_{movable}$ and ΔE_{fixed} are measured from the elastics experiment described in the previous section.

The measured elastic widths at 100 eV pass energy are 1.0 eV fwhm for both movable and fixed detectors (see Fig. 6), thus the calculated coincidence energy resolution is 1.4 eV fwhm. The measured and calculated coincidence energy resolutions are in reasonable agreement. This suggests that possible misalignments often encountered in 360° cylindrical or spherical analyzers have been dealt with satisfactorily in the present application. This result lends some confidence in future extensions of the coincidence electron-scattering spectrometer to EMS experiments in the multiazimuthal-angle mode.

As discussed earlier, one of the advantages of the present approach to coincidence data collection is the ability to observe the full three-dimensional structure (counts–energy–time) of the coincidence spectra. This is illustrated, for example, in Fig. 8 where the coincidence data were ob-

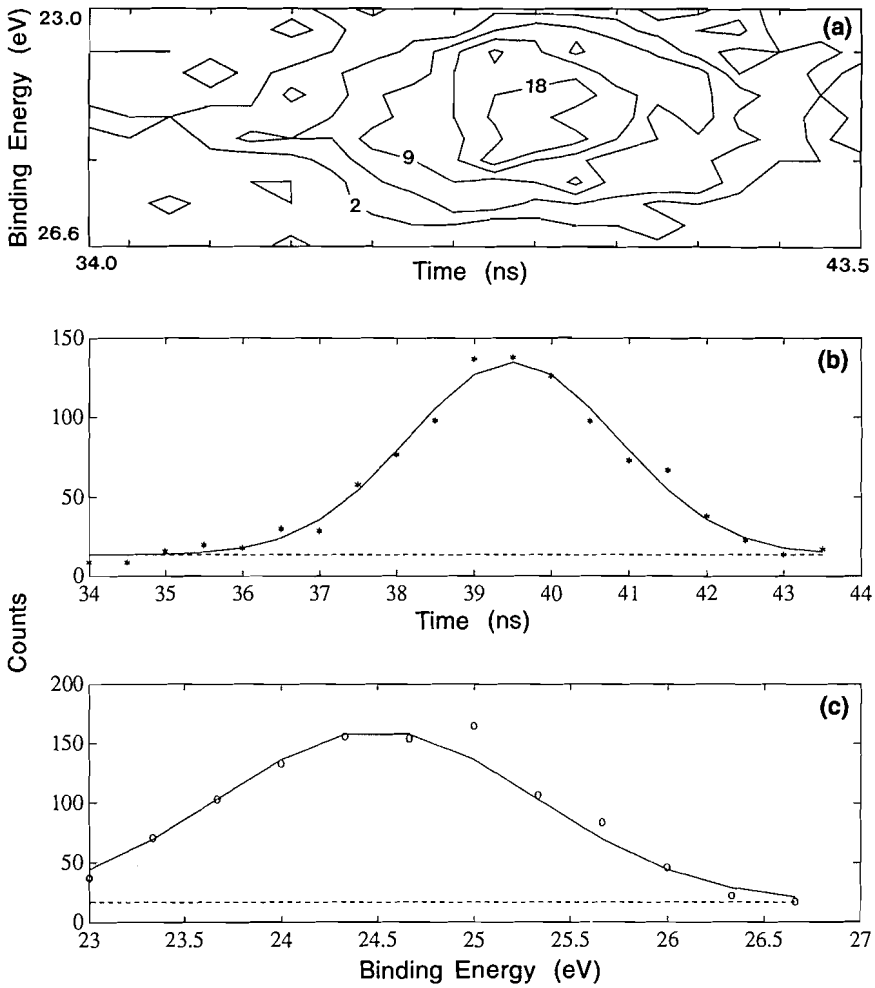

FIG. 9. (*a*) Contour plot of coincidence peak in time delay spectrum of helium 1*s* orbital at E_0 = 1000 eV, E_{pass} = 100 eV, and $\phi \sim 0°$. Contours at 2, 5, 9, 13, and 18 counts. (*b*) Cumulative projection of the coincidence spectrum on the time delay axis. The solid line is a fitted Gaussian curve with 3.5 ns fwhm. (*c*) Cumulative projection of the coincidence spectrum on the binding energy axis. The solid line is a fitted Gaussian curve with 1.9 eV fwhm.

tained at impact energy of 1000 eV + E_b and a pass energy of 300 eV. The high pass energy was necessary to obtain good enough statistics to illustrate the potential of the present approach to a three-dimensional coincidence data analysis. No serious asymmetry is observed in the energy–time plane. The very slight asymmetry at high time delay and the small valley at 40–45 ns are, in fact, artifacts and are not present at lower pass energies (i.e., at 100 eV pass energy, see below).

The distribution of coincidence counts is a function of two variables, namely, the binding energy (E_b) and the time delay (Δt). The most common bivariate distribution (38) is the normal bivariate or normal two-dimensional distribution given by

$$[20]\quad p(E_b, \Delta t) = \frac{1}{2\pi\sigma_{E_b}\sigma_{\Delta t}\sqrt{1-\rho^2}} \exp\left\{-\frac{1}{2(1-\rho^2)}\left[\frac{(E_b-m_{E_b})^2}{\sigma_{E_b}^2} + \frac{(\Delta t-m_{\Delta t})^2}{\sigma_{\Delta t}^2} - \frac{2\rho(E_b-m_{E_b})(\Delta t-m_{\Delta t})}{\sigma_{E_b}\sigma_{\Delta t}}\right]\right\}$$

where m_{E_b}, σ_{E_b}, $m_{\Delta t}$, and $\sigma_{\Delta t}$ are the means and standard deviations of the distributions in E_b and Δt, respectively. ρ is called the "correlation coefficient" for fluctuations in E_b and Δt and is given by

$$[21]\quad \rho = \frac{<(E_b-m_{E_b})(\Delta t-m_{\Delta t})>}{\sigma_{E_b}\sigma_{\Delta t}}$$

ρ measures the degree to which E_b and Δt fluctuate in a mutually dependent manner. If ρ is zero then the normal bivariate distribution (eq. [20]) can be written as a simple product of two one-dimensional normal distributions, i.e., E_b and Δt are statistically independent.

Figure 9*a* shows a contour diagram of the coincidence spectrum as a function of E_b and Δt for the ionization of the helium 1*s* orbital at 1000 eV impact energy and 100 eV pass energy, which are typical EMS operating conditions. The contour diagram (Fig. 9*a*) is clearly Gaussian in shape as can be seen in the cumulative (summed) projections of the

For personal use only.

coincidence spectrum on both the time delay axis (Fig. 9*b*) and the binding energy axis (Fig. 9*c*).[6] This result verifies a well-known fact that in most physical problems wherein several variables contribute to the experimental observable, the resulting experimental distribution is Gaussian or normal. This result is often attributed to the "central limit theorem". However, a less well-studied aspect of coincidence spectra is the correlation coefficient of the bivariate distribution. As mentioned earlier, most of the previously reported EMS experiments do not save the total coincidence spectra, thus an assessment of the correlation coefficient is not possible in these cases. It is generally assumed, however, that $\rho = 0$ and the bivariate distribution is simply a product of two one-dimensional normal distributions in E_b and Δt. The correlation coefficient for the coincidence spectrum shown in Fig. 9*a* is calculated using eq. [21] and is found to be $\rho = +0.05$ with an estimated uncertainty of ± 0.10. This clearly indicates that E_b and Δt are *statistically independent variables*.

Although it is generally assumed that the coincidence spectrum is a function of statistically independent variables (i.e., the binding energy and the time delay), the present study is the first experimental confirmation of this fact, at least for the helium 1*s* (e,2e) coincidence binding energy spectrum. It is, however, of great interest to verify this statistical independence for a wider range of atomic and molecular systems. Although the present results may appear uninteresting, it is not inconceivable to expect some correlation between binding energy and time delay. One can envision a correlation between binding energy and time delay in cases wherein two or more distinct scattering processes lead to final outgoing electron states similar to the final electron states in the (e,2e) reaction. Since the final state of the ion is never observed in an (e,2e) experiment, there are conceivably many other reaction channels than that illustrated in eq. [1] and assumed in the plane wave impulse approximation (PWIA). Several theoretical and experimental studies (26, 27) indicate that within the present experimental conditions (see Sect. 2), the PWIA is a valid representation of the necessarily complex scattering process. In other words, the PWIA assures us that the coincident electron events detected in an (e,2e) or EMS experiment are *dominated* by single, hard, binary-type collisions and consistent with eq. [1]. The fact that the experimental correlation coefficient (ρ) obtained in the present experiment is effectively *zero* can therefore be viewed as further experimental evidence that the PWIA is a valid framework for the interpretation of EMS experiments.

It is likely that the new coincidence data acquisition methods introduced here may find use in the analysis of other forms of (e,2e) experiments than high-energy, symmetric, non-coplanar kinematics. In addition, the measurement of the correlation coefficient (ρ) in (e,2e) experiments where post-collision interaction effects or resonant channel effects have been observed (39) will be most useful.

The acidity constant of fluorene-9-carboxylic acid in aqueous solution. Determination of the pK_a of a sparingly soluble substance

A. J. KRESGE,[1] I. G. POJARLIEFF,[2] AND E. M. RUBINSTEIN
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 3, 1992

A. J. KRESGE, I. G. POJARLIEFF, and E. M. RUBINSTEIN. Can. J. Chem. **71**, 227 (1993).

The acid ionization constant of the carboxylic acid group of fluorene-9-carboxylic acid in aqueous solution at 25°C was determined to be pK_a = 3.61, using a method based upon the increase in solubility of this sparingly soluble substance brought about by its ionization. This corrects an earlier considerably different value of this quantity determined by equating pK_a with the pH measured at half-neutralization. The hazard inherent in the latter method when applied to sparingly soluble substances is discussed.

A. J. KRESGE, I. G. POJARLIEFF et E. M. RUBINSTEIN. Can. J. Chem. **71**, 227 (1993).

Opérant en solution aqueuse, à 25°C, et faisant appel à une méthode basée sur l'augmentation de solubilité de cette substance pratiquement insoluble provoquée par son ionisation, on a déterminé que le pK_a du groupe acide de l'acide fluorène-9-carboxylique est égal à 3,61. Ce résultat corrige une valeur assez différente publiée antérieurement pour cette constante qui avait été déterminée en faisant l'hypothèse que son pK_a est égal au pH mesuré à sa demi-neutralisation. On discute des problèmes potentiels inhérents à cette dernière méthode lorsqu'on l'applique à des produits très peu solubles.

In the course of a study of the keto–enol system of fluorene-9-carboxylic acid,[3] we needed to know the pK_a of the carboxylic acid group of this substance in aqueous solution. A value of this quantity has recently been published (1), but it seemed likely that the method used for its determination could have led to significant error. We have therefore carried out a redetermination.

The previous result (1) was based upon a potentiometric titration whose pH value at half-neutralization was taken to be the pK_a. This method assumes that equal amounts of the ionized and unionized forms of the acid exist in solution when half an equivalent of base has been added, but fluorene-9-carboxylic acid is only sparingly soluble in water, and, at the low concentrations that consequently had to be used, significant further ionization of the acid may have taken place; the assumption upon which this method is based may thus have been invalid. We performed our redetermination with a method that is free of this difficulty, and which, in fact, makes use of the sparing solubility of fluorene-9-carboxylic acid (2).

Consider a saturated solution of a sparingly soluble neutral acid, HA, and its anionic conjugate base, A^-. The concentration of HA species in such a solution will be constant, and equal to its solubility S_0, eq. [1], because HA will be in equilibrium with undissolved acid whose activity is constant. The total solubility of the acid, however, will vary with the extent of ionization of the acid because this solubility, S, is equal to the concentration of both HA and A^- species, eq. [2].

$$[1] \quad [HA] = S_0$$

$$[2] \quad [HA] + [A^-] = S$$

The concentration ionization constant of the acid, Q_a, may consequently be expressed in terms of these solubilities and the concentration of hydrogen ions, as in eq. [3], and Q_a may be determined from a knowledge of these solubilities and $[H^+]$.

$$[3] \quad Q_a = [H^+](S - S_0)/S_0$$

We have measured the solubility of fluorene-9-carboxylic acid in a series of aqueous formic acid buffer solutions of known $[H^+]$ and have then determined Q_a by fitting the data to the hyperbolic form of eq. [3] shown as eq. [4].

$$[4] \quad S = S_0 + Q_a S_0/[H^+]$$

Experimental section

Materials

Fluorene-9-carboxylic acid (Aldrich) was recrystallized from ethanol; mp 230–232°C (lit. (3) mp 232°C). All other materials were best available commercial grades and were used as received.

Solubility determinations

Solubilities of fluorene-9-carboxylic acid were determined by measuring its concentration in saturated solutions spectrophotometrically; the absorption maximum at λ = 265 nm, ε = 19 100 M^{-1} cm^{-1}, was used for this purpose. Preliminary experiments showed that considerable oxidation of fluorene-9-carboxylic acid to fluorenone (3) takes place in the times (ca. 1 day) used to ensure equilibration of dissolved with solid acid, and anaerobic conditions were therefore devised. Samples, 10–15 mg, of powdered fluorene-9-carboxylic acid were placed in 25-mL Erlenmeyer flasks, and these were sealed with serum-cap stoppers and purged with argon for 20 min. Formic acid buffer solutions (10 mL), previously purged with argon for 30 min, were then injected into these flasks, and purging was continued for another 20 min. These solutions were allowed to equilibrate in a Precision Dubnoff metabolic shaking incubator equipped with a shallow shaking bath; shaking was first performed at 37°C for 1–2 h and then at 25.0 ± 0.1°C for 24 h. After this period of time, 1.00-mL samples of the equilibrated solutions were withdrawn using pipettes whose tips were wrapped with cotton wool, and these samples were then quenched in 6.00 mL of a mixture consisting of 2 parts methanol and 3 parts 0.1 M aqueous $HClO_4$. The absorbance at λ = 265 nm

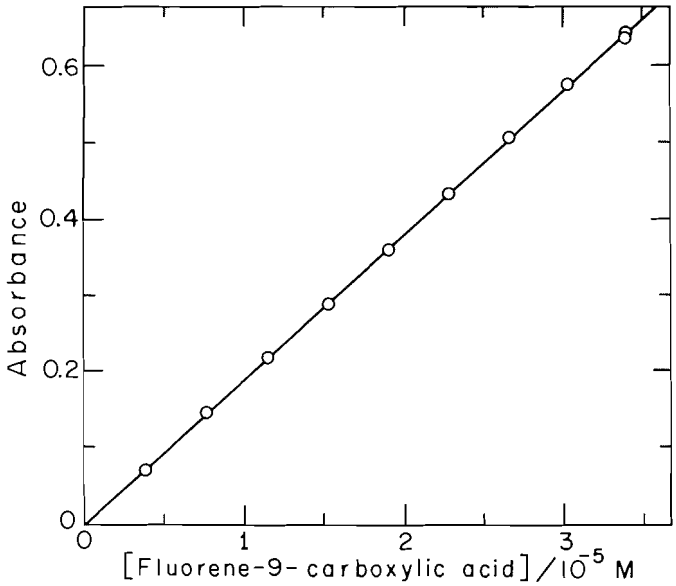

FIG. 1. Beer's Law plot for fluorene-9-carboxylic acid dissolved in the medium used for solubility–absorbance measurements.

TABLE 1. Solubility of fluorene-9-carboxylic acid in aqueous formic acid buffer solutions at 25°C[a]

Buffer ratio[b]	$[H^+]/10^{-4}$ M	$S/10^{-5}$ M
9:1	20.5	7.87
4:1	10.5	8.41
3:1	8.05	9.52
2:1	5.47	10.5
1:1	2.77	14.3
1:2	1.39	23.3
1:3	0.929	30.4
1:4	0.697	40.4
1:5	0.558	48.3

$S/M = (6.33 \pm 0.21) \times 10^{-5} + (2.34 \pm 0.02) \times 10^{-8}/[H^+]$.

[a]Total concentration of buffer = 0.10 M; ionic strength maintained at 0.10 M by adding $NaClO_4$ as required.

[b]Buffer ratio = [acid]: [base].

of these quenched samples was measured with a Cary model 2200 spectrophotometer.

A calibration curve was constructed for the purpose of converting these absorbances into molar concentrations of fluorene-9-carboxylic acid. As Fig. 1 shows, the data obeyed Beer's law accurately: least-squares analysis gave the relationship $A = -(0.85 \pm 2.14) \times 10^{-4} + (1.91 \pm 0.01) \times 10^4 \cdot$ [fluorene-9-carboxylic acid].

Results and discussion

The solubility of fluorene-9-carboxylic acid was measured in nine aqueous formic acid buffer solutions of different buffer ratio and therefore different hydrogen ion concentrations.[4] The data so obtained are summarized in Table 1 and are shown in Fig. 2 plotted according to the relationship of eq. [4]. Nonlinear least-squares fitting of these data to this expression gave $S_0 = (6.33 \pm 0.21) \times 10^{-5}$ M, in good agreement with $S_0 = (6.52 \pm 0.03) \times 10^{-5}$ M measured directly in 0.1 M HCl solution, and $Q_a = (3.70 \pm 0.13) \times 10^{-4}$ M, $pQ_a = 3.43 \pm 0.02$.

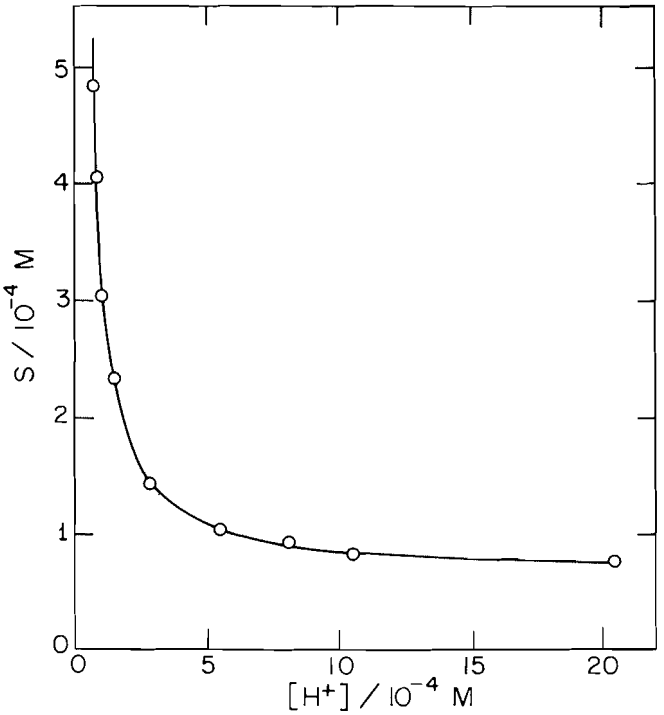

FIG. 2. Solubility of fluorene-9-carboxylic acid in aqueous formic acid buffer solutions plotted according to eq. [4].

This acidity constant is a *concentration quotient*, applicable at the ionic strength of the measurements, μ = 0.10 M. It can be converted into a thermodynamic value, $pK_a = 3.61$, by the use of appropriate activity coefficients (5). This result is considerably less than the value obtained earlier, $pK_a = 4.3$, by equating pK_a with the pH measured at half-neutralization in a potentiometric titration of fluorene-9-carboxylic acid (1).

The difference between this earlier value and the present result can be accounted for in the following way. The previous determination was made by titrating a saturated aqueous solution of fluorene-9-carboxylic acid,[5] (whose stoichiometric concentration of this acid in both forms, HA and A^-, may be estimated as being equal to the saturation solubility of HA (= S_0 as determined in the present work) plus the amount of A^- that would have formed by ionization of HA before the titration had begun. The latter may be calculated as 1.25×10^{-4} M on the basis of the pK_a value (= 3.61) determined here.[6] The total stoichiometric concentration of fluorene-9-carboxylic acid throughout the potentiometric titration was therefore (6.33×10^{-5}) (= S_0) + $(1.25 \times 10^{-4}) = (1.88 \times 10^{-4})$ M. At half-neutralization the stoichiometric concentration of each form, HA and A^-, was half of this, and another calculation using pK_a (= pQ_a) =

[4]Values of $[H^+]$ of these buffers were determined by calculation using the thermodynamic acidity constant of formic acid, $pK_a = 3.75$ (4), and activity coefficients recommended by Bates (5).

[5]E. Krogh, private communication.

[6]This is a good approximation to pQ_a at the very low ionic strength of this solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

3.61 gives $[H^+] = 5.8 \times 10^{-5}$ M for this solution. This corresponds to pH = 4.24, which is very close to the half-neutralization pH (= 4.3) taken to be the pK_a of fluorene-9-carboxylic acid in the earlier work (1).

The difficulty with the earlier work may be understood somewhat more clearly by considering the relationship of eq. [5]. Equating pK_a with pH requires the last term of this

$$[5] \quad pK_a = pH + \log ([HA])/[A^-])$$

expression to be zero, or [HA] to be equal to $[A^-]$, but this will be so at half-neutralization only as long as [HA] is sufficiently large to have been able to provide the H^+ represented by pH, which must have come mainly from ionization of HA, without having significantly reduced the value of [HA]. If [HA] is not large enough, it will be reduced when HA ionizes to furnish the necessary H^+; this will bring about a simultaneous increase in $[A^-]$, and, as a result, [HA] will no longer be equal to $[A^-]$ and pK_a will not be correctly represented by pH. This condition was forced upon the earlier determination of the pK_a of fluorene-9-carboxylic acid by the low solubility of this substance: calculations such as those described in the preceding paragraph give $[HA] = 3.95 \times 10^{-5}$ M and $[A^-] = 15.2 \times 10^{-5}$ M at half-neutralization, which makes $\log ([HA])/[A^-]) = -0.63$ and provides a sizeable difference between pK_a and pH.

In the earlier work, the pK_a of fluorene-9-carboxylic acid was also determined in 20% acetonitrile – 80% water, a solvent that allowed a significantly greater substrate concentration to be used than that employed in pure water. The result obtained, $pK_a = 3.9$, supports the presently determined value for pure water, $pK_a = 3.61$, on the basis of the expectation that pK_a's of neutral acids will increase with decreasing polarity of the solvent (6), but it is inconsistent with the earlier result for pure water, $pK_a = 4.3$.

Organometallic products from the reaction of the isoelectronic $Mn(CO)_5^-$ and $Cr(CO)_4NO^-$ metallate anions with bis-α-bromocyclopropyl ketone

A. P. MASTERS, M. PARVEZ, T. S. SORENSEN,[1] AND F. SUN

Received August 27, 1992

A. P. MASTERS, M. PARVEZ, T. S. SORENSEN, and F. SUN. Can. J. Chem. **71**, 230 (1993).

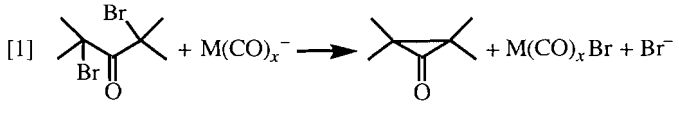
$Mn(CO)_5^-$ and $Cr(CO)_4NO^-$ react with the title ketone to give organometallic products. In the chromium case, a single metallofuran product is produced. In the manganese reaction, one can isolate a series of four complexes, two of which have a structure closely related to the chromium complex. The other two complexes are assigned an acyl manganese structure. The structures of the chromium complex and one of the acyl manganese complexes have been determined by X-ray methods. One finds a distorted octahedral bonding about the metal atom in each case. The chromium complex has bond lengths very similar to those reported for a closely related manganese structure, implying a delocalization of electrons within a metallofuran ring. As expected for this mixed carbonyl nitrosyl complex, the nitrosyl group is positioned *trans* to the oxide bond, representing the weakest and strongest "*trans*-effect" substituents. The acyl manganese structures contain an $Mn(CO)_4$ unit in contrast to the usual $Mn(CO)_5$ acyl complexes, with the $18e^-$ count being provided by an internal chelation with the *n*-electrons of the dicyclopropyl ketone group. The reaction mechanism for the formation of the complexes is postulated to involve initial bromine abstraction (two-electron reduction) by the metallate anion, with the $Cr(CO)_4NO^-$ reaction being much faster compared to $Mn(CO)_5^-$. The resulting organic enolate then "back-reacts" with a carbonyl group of the just-formed metal carbonyl bromide to form a transient anionic Fischer carbene complex. Ultimately this intermediate loses the metal bromide ion with the formation of the neutral complexes.

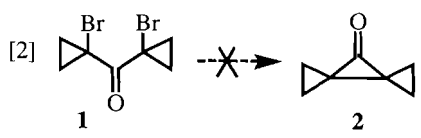
A. P. MASTERS, M. PARVEZ, T. S. SORENSEN et F. SUN. Can. J. Chem. **71**, 230 (1993).

Le $Mn(CO)_5^-$ et le $Cr(CO)_4NO^-$ réagissent avec la cétone mentionnée dans le titre pour donner des produits organométalliques. Dans le cas du dérivé chromé, il se forme un seul produit organofurane. Dans la réaction du dérivé manganique, on peut isoler une série de quatre complexes dont deux ont des structures très apparentées à celle du complexe du chrome. On a attribué une structure acyle de manganèse aux deux autres complexes. On a déterminé la structure du complexe du chrome et de l'un des complexes du manganèse par des méthodes de rayons X. Dans chaque cas, on observe une liaison octaédrique déformée autour de l'atome métallique. Les longueurs des liaisons dans le complexe du chrome sont très semblables à celles rapportées antérieurement pour une structure manganique très apparentée; ce résultat implique qu'il se produit une délocalisation dans le cycle métallofurane. Comme on pouvait s'y attendre pour un complexe mixte de carbonyle et de nitrosyle, le groupe nitrosyle se trouve en position *trans* par rapport à la liaison oxyde; ces substituants présentent en effet les «effets *trans*» les plus faibles et les plus forts. Par opposition à ce que l'on retrouve généralement avec les complexes acyles de $Mn(CO)_5$, les structures d'acyle manganèse comportent une unité $Mn(CO)_4$ dans laquelle les 18 e^- sont fournis par une chélation interne avec les électrons-*n* du groupe dicyclopropylcétone. On suppose que le mécanisme de la réaction conduisant à la formation des complexes implique un enlèvement initial de brome (réduction à deux électrons) par un anion métallate; cette réaction serait beaucoup plus rapide avec le $Cr(CO)_4NO^-$ qu'avec le $Mn(CO)_5^-$. L'énolate organique qui en résulte «réagit en retour» avec un groupe carbonyle du bromure de carbonyle métallique qui vient de se former et conduit à un complexe carbénique anionique de Fischer transitoire. Pour terminer, cet intermédiaire perd un ion bromure métallique avec la formation de complexes neutres.

[Traduit par la rédaction]

The reaction of selected tri- or tetrasubstituted α,α′-dibromo ketones with transition-metal carbonyl (or carbonyl nitrosyl) anions is a recently discovered low-temperature route to solutions of substituted cyclopropanones[2] (eq. [1]).





1 2

However, when this reaction was attempted using bis-α-bromocyclopropyl ketone **1**, in the hopes of preparing the unknown bis-spirocyclic cyclopropanone **2** (eq. [2]), unexpected organometallic products were produced instead.

In an attempt to understand why the eq. [2] reaction was being diverted in this case, we isolated and characterized these organometallic products. From these results, one sees that this study has implications as a variant route to Fischer carbene complexes.

Results

The two metallate anions used in this study were the well-known $Mn(CO)_5^-$ (**3**) and a recently described (1) isoelectronic species $Cr(CO)_4NO^-$ (**4**).

Corresponding to the usual cyclopropanone synthetic procedure, the dibromo ketone **1** in methylene chloride solution was added to a solution of **4** PPN^+ (where PPN^+ denotes $(PPh_3)_2N^+$ monocation) in methylene chloride at −78°C. This solution was stirred at −78°C for 4 h and then stored in a freezer for 48 h. Work-up and chromatography gave a 73% crude yield of a single orange crystalline solid that could be recrystallized from *n*-hexane. The mass spectrum indicated a formula $CrC_{11}H_8BrO_6N$, which corresponds to the elements $Cr(CO)_4NO^-$ (**4**) and $C_7H_8OBr_2$ (**1**) with loss of bromide. The infrared spectrum showed strong

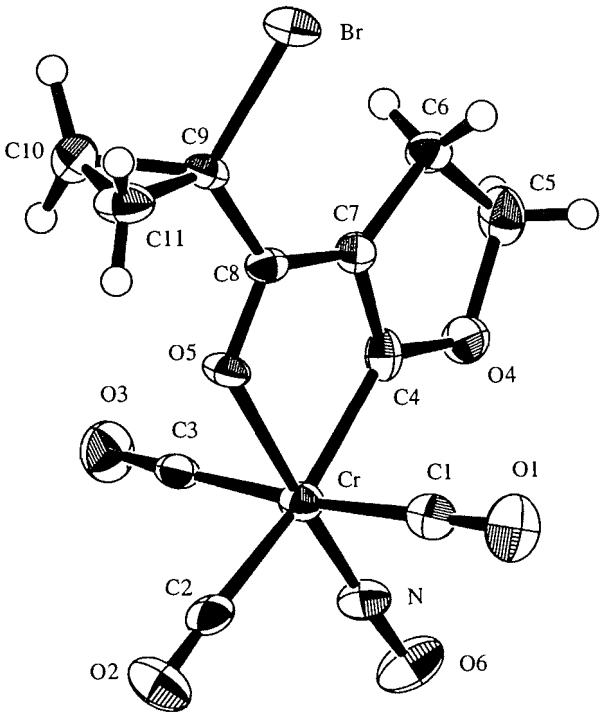

FIG. 1. ORTEP drawing (50% probability level) of the chromium complex **5**.

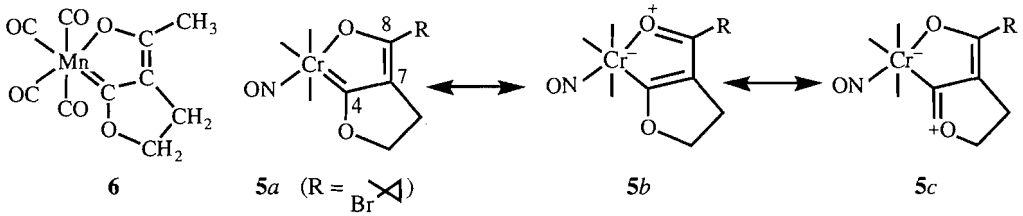
and characteristic M—C≡O and M—N=O stretching frequencies but there was no sign of organic $\rangle$C=O stretching frequencies, although the M—N=O stretch partially obscures this region. The ^{1}H NMR spectrum showed four peak regions of area 2:2:2:2, indicating symmetry in the molecule. Peak regions centered at 3.03 and 5.02 were mutually coupled triplets, J = 9.0 Hz, characteristic of a partial structure -CH_2-CH_2-O-. The other two peak areas, also mutually coupled, were centered at 1.303 and 1.518, similar to the peaks in the starting ketone **1** and therefore indicative of a $\rangle\!\!<^{Br}$ fragment. In the ^{13}C NMR spectrum, peaks at 20.4 and 29.6 (q) also indicate this latter partial structure. Peaks at 26.5 and 83.2 are in agreement with a -CH_2-CH_2-O fragment. The remaining carbons are all quaternary, located at 128.7, 195.1, 215.1, 217.7, and the unusually low field position of 249.7 ppm. The NMR data clearly suggest that one cyclopropyl ring has opened up, but we were inconclusive about the detailed structure of the complex and therefore a single crystal X-ray analysis was carried out.

The ORTEP structure of the complex **5** is shown in Fig. 1, and bond lengths and angles are given in Tables 1 and 2. Complex **5** is remarkably similar in gross structure to a manganese complex **6** reported by Casey *et al.* (2), obtained by a totally unrelated route.

In structure **5**, atoms Cr—O—C8—C7—C4 form a near planar ring typical of delocalized molecular structures. An average of the resonance hybrid structures **5***a* ↔ **5***b* ↔ **5***c* gives the best representation of the actual bond lengths, as previously reported by Casey *et al.* for **6** (2). Structure **5***a* corresponds to a carbene complex, but it also can be described as a metallofuran. As deduced from the NMR data, the molecule would have a plane of symmetry in solution such that both carbons of the cyclopropane ring are equivalent, as are two of the -C≡O ligands. The nitrosyl ligand is positioned *trans* to the oxide ligand, as expected for the strongest and weakest "*trans*-effect" ligands. The M—C≡O unit *trans* to the carbene carbon is not appreciably different from the other M—C≡O bonds.

The most important structural feature of **5** from a mechanistic viewpoint (see later) is that one original -C≡O ligand on the chromium has been transformed into a carbene center.



6 **5***a* (R = $\rangle\!\!<_{Br}$) **5***b* **5***c*

The reaction of the dibromo ketone **1** with $Mn(CO)_5^-$ (**3**) was carried out at an initial mixing temperature of −78°C, using a variety of experimental conditions, since this reaction is much more complex than in the chromium anion case. Four organometallic products can be isolated from the reaction, their relative amounts depending on the stoichiometric ratio of the reactants, the counterion of **3**, and the time–temperature cycle used after the initial −78°C addition. These four products will be arbitrarily referred to as **7***a–d*. When a 2:1 molar ratio of **1**:**3** is used, and when the reaction is worked up rapidly after warming the original solution to ca. 0°C, two products, **7***a* and **7***b*, are mainly present. Compound **7***a* is nearly absent when a 1:1 molar stoichiometry is used, and **7***b* is the major product. If the reactions are left at room temperature before work-up, two new products become dominant. Both of these latter compounds are much more mobile on silica gel TLC development than are **7***a* and **7***b*. In most cases, all four complexes are present to some extent in the mixture and the R_F TLC chromatographic order is **7***d* ⩾ **7***c* > **7***a* > **7***b*, using methylene chloride as the developing solvent. Crystalline samples of all four complexes could be obtained using flash chromatography and preparative TLC techniques. Complexes **7***a–d* are relatively air stable. On standing at room temperature for several months, **7***b* was nearly completely transformed into **7***c*. On melting **7***a* (60°C) a small amount of **7***d* was formed and, even on storage in the freezer for prolonged periods, some **7***a* → **7***d* transformation takes place.

From the NMR spectroscopic data, the structures of complexes **7***c* and **7***d* were obviously very similar to each other, and a comparison with the corresponding data for the chromium complex **5** showed that **7***c* and **7***d* were also closely

[a]Distances are in angstroms. Estimated standard deviations in the least significant figure are given in parentheses.

related in structure to this compound. In Table 3, we show the ^{1}H and ^{13}C NMR assignments for **5** and assignments for **7***c* and **7***d* based on the same gross structure. In particular, one notes the characteristic (3) low-field carbene carbon (^{13}C-4) in all three cases, as well as similar δ values for C7 and C8 in each case. The ^{13}C and ^{1}H data for the -O-CH_2-CH_2- region are also very similar among the three structures. Complexes **7***c* and **7***d* differ only in the H vs. Br substitution at C9. This is of course easily seen in the extra ^{1}H peak present in **7***c*. Mass spectral analysis also confirms these structural assignments, showing a molecular ion *m/z* 304 for **7***c* and 382 (^{79}Br) for **7***d*. The infrared spectra in both cases show no typical $\diagdown\!\!\diagup$C=O stretching frequencies, as was also the case for complex **5**.

Complexes **7***c* and **7***d* are thus virtually identical to the complex **6** prepared by Casey *et al.* (2) (methyl substituent at C8 vs. cyclopropyl (**7***c*) and α-bromocyclopropyl (**7***d*). No ^{13}C NMR spectroscopic data were reported for **6** but the ^{1}H values for the C5 and C6 methylene groups of **6** (4.31 and 3.18 ppm) are modestly similar to the ^{1}H data for **7***c* and **7***d*.

Complexes **7***a* and **7***b* also appear to be related to each other. Mass spectral analysis shows that **7***a* has an identical composition to **7***d* (*m/z* 384), while **7***b* is identical to **7***c* (*m/z*) 304). Like **7***c* and **7***d*, **7***a* and **7***b* appear to differ only in the bromine substitution on the α-position of a cyclopropyl group. In contrast to complexes **7***c* and **7***d*, one sees possible $\diagdown\!\!\diagup$C=O stretching frequencies in the infrared spectra of both **7***a* and **7***b*; for example, **7***b* shows absorptions at 1651 and 1584 cm^{-1}, which may indicate the presence of two carbonyl groups. Another major difference between **7***a*, **7***b* and **7***c*, **7***d* is the absence of the -CH_2-CH_2-O- partial structure. In fact, **7***a* and **7***b* appeared from the ^{1}H and ^{13}C NMR data to have two intact, but chemically different, cyclopropyl rings, with each ring having symmetry such that the two carbons in each ring are equivalent. From the spectroscopic data, an acyl manganese structure seemed possible, with the added requirement that the 18e^- count for an $Mn(CO)_4$ acyl structure would require another 2e^- donor, most probably the lone-pair electrons of the ketonic oxygen.

The suppositions were verified by means of a single crystal X-ray structure of **7***b*. The ORTEP structure is shown in Fig. 2 and selected bond lengths and angles are given in Tables 4 and 5. Although the Mn—O—C6—C8—C5 partial structure contains the same bonded atoms in both **7***b* and **7***c*, in **7***b* the C6—O and C5—O bonds have typical carbonyl bond lengths (1.23 and 1.21 Å, respectively). One also sees two intact cyclopropane rings in this structure.

The geometry associated with the spirocyclopropane moiety in **7***b* deserves special mention. One notes that the C8—C7 and C8—C9 bonds are fairly normal (1.53 Å average), whereas the C7—C9 bond is extremely short (1.42 Å). The C6—C8 bond is also very short (1.44 Å). These features are typical of a bisected cyclopropane in which there is extensive delocalization of the electrons from the cyclopropyl ring into the C6=O6 complexed carbonyl group. A comparison with the recent X-ray data of Childs *et al.* (4) reveals that **7***b* has similar bond lengths to those in protonated methyl cyclopropyl ketone. A comparison of bond lengths is provided in Fig. 3, although one should note that structure **7***b* has relatively large bond-length standard deviations. This delocalization has mechanistic implications (see later). Note also that the second cyclopropyl ring shows much more uniform C—C bond lengths (and the cyclopropane ring in **5** even more so).

The assignment of the **7***a* structure as the corresponding α-bromocyclopropyl derivative of **7***b* was made by ^{1}H and ^{13}C NMR spectroscopic comparisons, as shown in Table 6. The correspondence of the ^{1}H NMR data between complexes **7***a* and **7***b* is somewhat divergent. For example, the protons on C7—C9 are deshielded in **7***a* by about 0.4 ppm, compared to **7***b*. However, there is generally good agreement in the ^{13}C shifts; for example, C8 is quite similar, as are the low-field C5 acyl carbons and the C6 ketonic carbons. The infrared spectrum of **7***a* shows a peak at 1657 cm^{-1}, close to the 1651 cm^{-1} peak observed for **7***b*. Both are in a position characteristic of the acyl manganese $\diagdown\!\!\diagup$C=O stretching region. However, **7***a* shows only a very broad peak in the 1566 cm^{-1} region (vs. a sharp peak at 1584 cm^{-1} for **7***b*). There have been several *ortho*-acetylarylmanganese tetracarbonyl X-ray structures reported (5, 6), where the internal ketone coordination provides a 2e^- donation. Structure **7***b* is the first manganese acyl complex to show this feature. The Mn - - - O=C$\diagdown\!\!\diagup$ distance is very similar in all of the reported structures, including **7***b*.

Discussion

Mechanism of formation of the complexes

In both the chromium and manganese complexes, an original metal carbonyl group has been transformed into either an acyl (**7***a*, **7***b*) or an oxycarbene fragment (**5**, **7***c*, **7***d*). In the initial reaction of $Cr(CO)_4NO^-$ or $Mn(CO)_5^-$ with dibromo ketone **1**, there is little doubt that the first reaction is the two-electron reductive cleavage of one of the C—Br bonds, forming the organic enolate and either $Cr(CO)_4NOBr$ or $Mn(CO)_5Br$. For example, in the chromium case, one can entirely quench the organometallic reaction by including trimethylsilyl chloride along with **1** in the original addition of **1** to $Cr(CO)_4NO^-$. A good yield of the silyl enol ether **8**

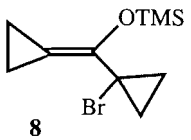
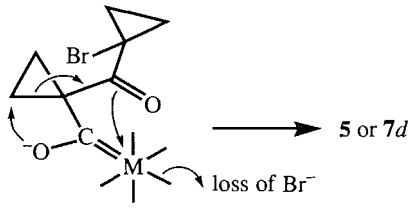
can then be isolated, i.e., this compound is derived from a straightforward reaction between the enolate and the silyl chloride.

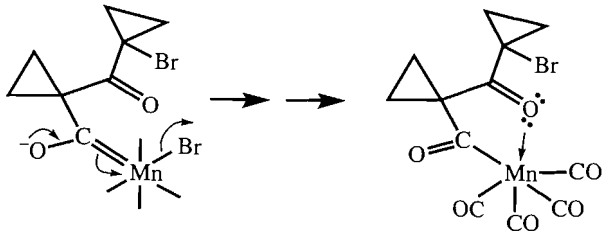


8

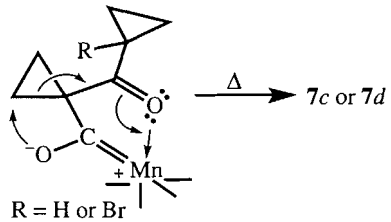
In the absence of such enolate traps, the organic enolate must eventually back-react with the metal carbonyl halide, forming an anionic Fischer carbene complex in each case, as shown:



Attack of the nucleophilic oxycarbene on the cyclopropane ring could then lead to complexes **5** or **7***d*, although the details concerning the timing and stereochemistry of the bromide loss are unknown. In the manganese case, a competing reaction of the carbene complex is the simple loss of bromide, forming an acyl complex, i.e., **7***a*.



The neutral acyl complexes **7***a* and **7***b* are also thermally rearranged to the complexes **7***d* and **7***c*, respectively, but this process appears to be slower than the rate of formation of **7***c* and **7***d* under the original reaction conditions. This arrangement can be pictured as follows:



Thus, it appears that the ring-opened products **7***c* and **7***d* may be formed from either the anionic intermediate (in a relatively rapid reaction) or from the neutral complexes **7***a* and **7***b* (in a slow process).

One major difference between $Cr(CO)_4NO^-$ and $Mn(CO)_5^-$ is that the former is considerably more reactive in reduction of the C—Br functionality. One can demonstrate that $Cr(CO)_4NO^-$ reacts slowly with **1** even at −78°C (loss of the deep red color). In contrast, $Mn(CO)_5^-$ almost certainly requires a much higher temperature for the initial reduction to occur. A consequence of this is that the chromium reactions are well separated, i.e., the $Cr(CO)_4NO^-$ is totally consumed in a stoichiometric reaction to form an enolate and $Cr(CO)_4NOBr$ (the latter is only presumed to be formed here, but it is a detectable product of the normal cyclopropanone-forming reaction of eq. [1]). At a much slower rate, the enolate then back-reacts with $Cr(CO)_4NOBr$ to form the complex. The lack of formation of an acyl complex in the chromium case may indicate that the oxycarbene functionality is more nucleophilic than in the manganese case.

For $Mn(CO)_5^-$, it appears that the reduction of the first C—Br bond in **1** is a rate-determining process. After reduction, a faster reaction leads to organometallic complexes, where the remaining bromine in the complex is more reactive than those in **1**. Thus, one gets debrominated complexes **7***b* and **7***c* after work-up (proton source). Also, leaving the reaction at room temperature prior to work-up increases the amount of **7***c* at the expense of **7***b*, an indication that the cyclopropane ring-opening is slowly taking place at this

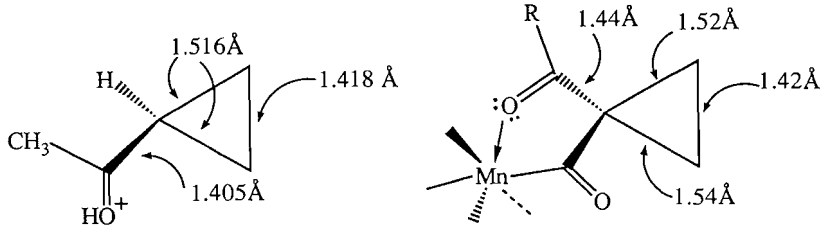

FIG. 3. Comparison of bond lengths for protonated methyl cyclopropyl ketone and complex **7b**.

temperature. Since **7b** and **7c** require two moles of $Mn(CO)_5^-$ in their formation, it is obvious that an initial 1:1 reactant stoichiometry will result in recovered starting dibromo ketone **1**, and this was observed.

One could also explain the formation of acyl products by postulating that $Mn(CO)_5^-$ displaces bromide from **1** in an S_N2 reaction, followed by carbonyl insertion. Although this route is well established with methyl iodide, it is highly unlikely that the tertiary bromines in **1** would undergo such substitution.

Generality of the reactions

The attack of a preformed carbanion on a neutral metal carbonyl is the usual route to transition metal carbenes (7). The unique feature in the present reactions is that one uses the anionic metal complex and an α-bromo carbonyl compound to create the carbanion and a bromo carbonyl metal complex, these then re-reacting by the traditional Fischer route to give an anionic carbene complex intermediate. By having a bromide leaving group on the metal, the reactions leading to the carbene complex are self-quenching after the cyclopropane ring-opening has taken place. Alternatively, if cyclopropane ring-opening does not occur, loss of bromide leads to an acyl complex.

One can note in closing that the failure of eq. [2] in the bis-α-bromocyclopropyl ketone (**1**) case is likely due to the large steric strain involved in forming cyclopropanone **2**, since there is abundant evidence from the structure of the organometallic complexes that the first bromine atom in **1** can be removed without complication.

Experimental

All melting points are uncorrected. NMR spectra were obtained on a Bruker AM-400 (δ values, *J* in Hz). In descriptions of the ^1H NMR spectra, s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, b = broad. Coupling networks were verified using ^1H COSY 2D spectra and ^{13}C multiplicities were determined from DEPT sequences. Mass spectra were determined with a Kratos MS-80. Infrared spectra were obtained using a Mattson 4030 FT-IR spectrometer. Flash chromatography was performed using silica gel (230–400 mesh) with methylene chloride as the eluting solvent. Thin-layer chromatography (TLC) was performed on precoated silica gel 60 F_{254} plates (Merck 5554) and PTLC was performed on 0.5 mm plates (Merck 5774). Tetrahydrofuran was purified by distillation from sodium benzophenone ketyl. Hexane, pentane, and methylene chloride were dried over 3A molecular sieves. Glassware was oven-dried.

Preparation of complex ***5***

In a small Schlenk tube with a septum and stopcock side-arm, under a nitrogen atmosphere and with magnetic bar stirring, a solution of 0.52 g (0.71 mmol) of $PPN^+Cr(CO)_4NO^-$ (1) in 2 mL methylene chloride was prepared and cooled to −78°C. Dibromo ketone **1** (0.1902 g, 0.710 mmol) in 1 mL of methylene chloride was added dropwise via syringe over 1 min and the mixture stirred for 4 h at −78°C. The reaction mixture was then left at ca. −20°C

[a]AA'BB' system.
[b]AA'BB'X system.

for 48 h. Pentane (10 mL) was added and the supernatant decanted (orange). The pentane was evaporated, and the residues redissolved in 2 mL pentane and applied to a flash chromatography column (1 × 15 cm, silica gel). Elution with methylene chloride (orange band) gave 0.197 g of crude **5** (73%). Crystallization from *n*-hexane eventually produced needles suitable for X-ray studies, mp 70–72°C. Infrared (CH_2Cl_2): 2092 (m), 2029 (vs), 1707 (vs). The ^1H and ^{13}C NMR spectral data are listed in Table 3. Mass spectrum (^{79}Br) *m/z*: 382 (M^+), 270 (58), 267 (57), 204 (78), 203 (60), 136 (65), 121 (58), 97 (90).

Preparation of complex 7a

Using the same apparatus described above, bis-α-bromocyclopropyl ketone **1** (213 mg, 0.80 mmol) in 1 mL THF was added dropwise to a solution of $Na^+Mn(CO)_5^-$ (prepared from $Mn_2(CO)_{10}$, 80 mg, 0.20 mmol, with 1% Na/Hg amalgam) in 4 mL THF with stirring at −78°C under nitrogen. The reaction mixture was warmed to 10°C during 3 h. Pentane (5 mL) was added and solution decanted from sludge and evaporated. The residue was chromatographed to give 16.4 mg of *7a* (19% yield based on recovered starting material, 151.2 mg), yellow crystals, mp 58–60°C. Infrared (CCl_4): 2091 (w), 2079 (m), 2002 (s), 1985 (s), 1964 (s), 1657 (w). The ^1H and ^{13}C NMR data are listed in Table 6. Mass spectral fragmentation *m/z*: 382 (1), 354 (4), 336 (3), 298 (1), 270 (5), 242 (23), 162 (38), 134 (62), 79 (100). High-resolution mass spectrum calcd. for $C_{12}H_8O_6MnBr$: 381.8889; found: 381.8885.

Preparation of complex 7b

Using the apparatus described above, $PPN^+Mn(CO)_5^-$ (400 mg, 0.54 mmol) in 2 mL methylene chloride was cooled to −78°C. Under a nitrogen atmosphere, dibromo ketone **1** (144 mg, 0.537 mmol) in 1 mL of methylene chloride was added dropwise via syringe. The reaction mixture was slowly warmed to 0°C and then filtered through a short silica gel column (2 g), using methylene chloride washes. After evaporation of the solvent, the residue was applied to a PTLC plate to give 38 mg of *7b* (23%). The yellow solid was recrystallized from hexane to give crystals suitable for X-ray studies, mp 137–139°C. Infrared (KBr plate): 2079 (m), 1977 (s), 1944 (s), 1626 (m), 1574 (m), 1435 (m). The ^1H and ^{13}C NMR data are listed in Table 6. Mass spectral fragmentation *m/z*: 304 (2), 276 (11), 248 (7), 220 (5), 192 (13), 164 (100), 134 (11), 96 (25), and 55 (66). High-resolution mass spectrum calcd. for $C_{12}H_9MnO_6$: 303.9780; found: 303.9790.

Preparation of complex 7c

Using the same apparatus described above, dibromo ketone **1** (170 mg, 0.64 mmol) in 1 mL THF was added to a solution of $PPN^+Mn(CO)_5^-$ (490 mg, 0.67 mmol) in 2 mL THF at −78°C under a nitrogen atmosphere. The reaction mixture was warmed to 20°C during 3 h and stirred for a further 1 h at 20°C. After the same work-up and separation procedure as described for *7b*, 60 mg of *7c* was obtained (31%), yellow crystals, mp 170°C (dec.). Infrared (CCl_4): 2089 (m), 2052 (m), 2000 (s), 1956 (s), 1491 (m). The ^1H and ^{13}C NMR data are listed in Table 3. Mass spectral fragmentation *m/z*: 304 (55), 248 (28), 220 (65), 192 (100), 164 (55), 138 (40), 96 (91), 55 (93). High-resolution mass spectrum calcd. for $C_{12}H_9MnO_6$: 303.9780; found: 303.9783.

Preparation of complex 7d

The reaction was carried out as for *7a*, using a calculated 1:1 stoichiometry of the reactants. The reaction mixture was allowed to warm to 15°C during 2 h, 5 mL of pentane was then added, and the mixture filtered through a short silica gel column (2 g), which was washed with methylene chloride. The solvent was removed and a PTLC separation gave 11.9 mg (8%) of *7d*, together with 8.7 mg of *7c* and 30 mg of *7b*. The compound forms yellow crystals, mp 58–60°C. Infrared (KBr plate): 2090 (m), 1991 (s), 1938 (s), 1462 (m). The ^1H and ^{13}C NMR data are listed in Table 3. Mass spectral fragmentation *m/z*: 382 (13), 354 (2), 328 (6), 300 (31), 272 (76), 230 (46), 190 (47), 136 (59), 97 (60), 55 (100). High-resolution mass spectrum calcd. for $C_{12}H_8O_6MnBr$: 381.8889; found: 381.8885.

Crystal structure determination of 5

Accurate cell dimensions and a crystal orientation matrix were determined on a Rigaku AFC6S diffractometer by a least-squares

TABLE 7. Crystal data and experimental details for **5**

A. Crystal data

Empirical formula	$C_{11}H_8O_6BrCrN$
Formula weight	368.08
Crystal color, habit	Yellow, plate
Crystal dimensions	0.090 × 0.260 × 0.400
Crystal system	Monoclinic
No. of reflections used for unit cell determination (2θ range)	25 (20.0–30.0°)
Lattice parameters	a = 13.523(3) Å b = 5.845(2) Å c = 18.488(4) Å β = 110.68(2)°
	V = 1367.2(6) Å^3
Space group	$P2_1/c$ (no. 14)
Z value	4
D_{calc}	1.788 g/cm^3
F_{000}	724.00
μ(MoKα)	37.27 cm^{-1}

B. Intensity measurements

Diffractometer	Rigaku AFC6S
Radiation	MoKα (λ = 0.71069 Å) graphite monochromated
Temperature	−103.0°C
Scan type	ω–2θ
Scan rate	4.0°/min (in ω) (3 rescans)
Scan width	(0.94 + 0.35 tan θ)°
$2\theta_{max}$	50.1°
No. of reflections measured	Total: 3194 Unique: 2678 (R_{int} = 0.045)
Corrections	Lorentz, polarization, absorption (trans. factors: 0.5619–0.9997) Decay (0.77% increase)

C. Structure solution and refinement

Structure solution	Heavy-atom method
Refinement	Full-matrix least squares
Anomalous dispersion	All non-hydrogen atoms
No. of observations ($I > 3.00\ \sigma(I)$)	1537
No. of variables	205
Reflection/parameter ratio	7.50
Residuals: R; Rw	0.036; 0.036
Goodness-of-fit indicator	1.73
Max shift/error in final cycle	0.01
Maximum peak in final diff. map	0.45 e/Å^3
Minimum peak in final diff. map	−0.38 e/Å^3

fit of the setting angles of 25 reflections. Crystal data and experimental details are provided in Table 7. Data were corrected for Lorentz, polarization, and empirical absorption effects (8), transmission factors being in the range 0.5619–0.9997.

The structure was solved by the heavy-atom method. Refinement of the structure was by full-matrix least-squares calculations, initially with isotropic and finally with anisotropic temperature factors for the non-hydrogen atoms. At an intermediate stage in the refinement, a difference map revealed maxima consistent with the positions of hydrogen atoms, which were included in the subsequent cycles of refinement with fixed isotropic temperature factors. Refinement converged with R = 0.036 and Rw = 0.036. In the refinement cycles, weights were derived from the counting statistics. Scattering factors were those of Cromer and Waber (9) and Stewart, Davidson, and Simpson (10) and allowance was made for anomalous dispersion (11). A difference map calculated at the conclusion of the refinement had no chemically significant features. All computer programs used in this study were part of teXsan (12) installed on a Silicon Graphics Personal Iris 4D/35 computer and Fig. 1 was plotted using ORTEP II (13). The positional parameters are given in Table 8.[3]

[a] $B(\text{eq}) = \frac{8}{3}\pi^2(U_{11}(aa^*)^2 + U_{22}(bb^*)^2 + U_{33}(bb^*)^2 + 2U_{12}aa^*bb^* \cos\gamma + 2U_{13}aa^*cc^* \cos\beta + 2U_{23}bb^*cc^* \cos\alpha)$.

Crystal structure determination of 7b

Accurate cell dimensions and a crystal orientation matrix were determined on a Rigaku AFC6S diffractometer by a least-squares fit of the setting angles of 15 reflections. Crystal data and experimental details are provided in Table 9. Data were corrected for Lorentz, polarization, and empirical absorption effects (8), transmission factors being in the range 0.776–0.997.

The structure was solved by the heavy-atom method. Refinement of the structure was by full-matrix least-squares calculations allowing anisotropic temperature factors for Mn only; carbon and oxygen atoms were allowed isotropic temperature factors. At an intermediate stage in the refinement, a difference map revealed maxima consistent with the positions of hydrogen atoms, which were included in the subsequent cycles at idealized geometries (C—H, 0.95 Å) with fixed isotropic temperature factors. Refinement converged with R = 0.057 and Rw = 0.045. In the refinement cycles, weights were derived from the counting statistics.

[3] A complete set of structure factor listings, anisotropic thermal parameters, torsional angles, and hydrogen atom parameters is available for **5** and **7b** and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom parameters have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Received August 21, 1991[2]

PHILIP J. DUTTON, THOMAS M. FYLES, VALIA VEETTIL SURESH, FRANK R. FRONCZEK, and RICHARD D. GANDOUR. Can. J. Chem. **71**, 239 (1993).

The solid-state structures of alkali-metal salt complexes of crown ether tetra- and hexa-carboxylic acids (18C6A$_4$ and 18C6A$_6$) have been determined. The sodium salt of 18C6A$_6$ crystallizes as the trihydrate in orthorhombic space group $P2_12_12_1$ (a = 7.6868(12), b = 15.429(3), c = 21.975(2) Å, R = 0.031 for 5192 observed data); the potassium salt of 18C6A$_6$ crystallizes as the the trihydrate in orthorhombic space group $P2_12_12_1$ (a = 7.6711(8), b = 15.709(2), c = 21.966(5) Å, R = 0.035 for 2521 observed data); the thallium(I) salt of 18C6A$_6$ crystallizes as the dihydrate in orthorhombic space group $P2_12_12_1$ (a = 12.0331(10), b = 12.4333(12), c = 17.366(2) Å, R = 0.035 for 4952 observed data); and the cesium salt of 18C6A$_6$ crystallizes as the dihydrate in monoclinic space group $P2_1$ (a = 7.708(3), b = 13.492(2), c = 11.9501(9) Å, β = 94.49(2)°, R = 0.029 for 4480 observed data). The sodium salt of 18C6A$_4$ crystallizes as the dihydrate in monoclinic space group $P2_1$ (a = 11.4368(11), b = 7.7068(11), c = 12.6579(12) Å, β = 98.515(8)°, R = 0.035 for 3000 observed data); the thallium(I) salt of 18C6A$_4$ crystallizes as the dihydrate in monoclinic space group $P2_1$(a = 11.719(2), b = 7.668(2), c = 12.8403(13) Å, β = 99.052(9)°, R = 0.040 for 3981 observed data); and the cesium salt of 18C6A$_4$ crystallizes as the dihydrate in monoclinic space group $P2_1$ (a = 11.787(2), b = 7.637(2), c = 13.001(2) Å, β = 98.705(12)°, R = 0.038 for 3428 observed data). Both chorands exhibit a cooperative relationship of mean cavity radius and guest-ion radius, which closely follows the effective ionic radii of the guests. The hexaacid is a preorganized host for monohydrated cations. It provides a trigonal hydrogen bonding receptor site for the water molecule, and up to nine oxygen donors for cation binding. Guests ranging in size from Na^+ to Cs^+ are accommodated without distortion of the macrocyclic framework. The tetraacid is similarly tolerant of a range of guests, but greater structural reorganization of the ligand is required to optimize contacts with fully dehydrated cations. Skeletal drawings of donor atoms, in conjunction with polar coordinate maps of torsion angles, reveal how the demands of the guest are accommodated by the host.

PHILIP J. DUTTON, THOMAS M. FYLES, VALIA VEETTIL SURESH, FRANK R. FRONCZEK et RICHARD D. GANDOUR. Can. J. Chem. **71**, 239 (1993).

On a déterminé les structures cristallines de complexes de sels de métaux alcalins et d'éthers couronnes tétra- et hexacarboxyliques (18C6A$_4$ et 18C6A$_6$). Le sel de sodium du 18C6A$_6$ cristallise sous la forme d'un trihydrate orthorhombique, groupe d'espace $P2_12_12_1$, avec a = 7,6868(12), b = 15,429(3) et c = 21,975(2) Å et R = 0,031 pour 5192 données observées; le sel de potassium du 18C6A$_6$ cristallise sous la forme d'un trihydrate orthorhombique, groupe d'espace $P2_12_12_1$, avec a = 7,6711(8), b = 15,709(2) et c = 21,966(5) Å et R = 0,035 pour 2521 données observées; le sel de thallium(I) du 18C6A$_6$ cristallise sous la forme d'un dihydrate orthorhombique, groupe d'espace $P2_12_12_1$, avec a = 12,0331(10), b = 12,433(3)(12) et c = 17,366(2) Å et R = 0,035 pour 4952 données observées et le sel de césium du 18C6A$_6$ cristallise sous la forme d'un dihydrate monoclinique, groupe d'espace $P2_1$, avec a = 7,708(3), b = 13,492(2) et c = 11,9501(9) Å, β = 94,49(2)° et R = 0,029 pour 4480 données observées. Le sel de sodium du 18C6A$_4$ cristallise sous la forme d'un dihydrate monoclinique, groupe d'espace $P2_1$, avec a = 11,4368(11), b = 7,7068(11) et c = 12,6579(12) Å, β = 98,515(8)° et R = 0,035 pour 3000 données observées; le sel de thallium(I) du 18C6A$_4$ cristallise sous la forme d'un dihydrate monoclinique, groupe d'espace $P2_1$, avec a = 11,719(2), b = 7,668(2) et c = 12,8403(13) Å, β = 99,052(9)° et R = 0,040 pour 3981 données observées et le sel de césium du 18C6A$_4$ cristallise sous la forme d'un dihydrate monoclinique, groupe d'espace $P2_1$, avec a = 11,787(2), b = 7,637(2) et c = 13,001(2) Å, β = 98,705(12)° et R = 0,038 pour 3428 données observées. Les deux chorands présentent une relation coopérative des rayons moyens de cavité et d'ion invité qui suit de très près celle des rayons ioniques effectifs des invités. L'hexaacide est un hôte préorganisé pour les cations monohydratés. Il fournit aux molécules d'eau un site récepteur pour une liaison hydrogène trigonale et jusqu'à neuf oxygènes donneurs pour des liaisons avec les cations. Les invités dont la taille se situe entre celles du Na^+ et du Cs^+ s'accommodent sans distorsions dans la structure macrocyclique. Le tétraacide tolère aussi une grande variété d'invités; toutefois, une plus grande réorganisation structurale est requise du ligand pour optimiser les contacts avec les cations complètement déshydratés. Des diagrammes du squelette des atomes donneurs utilisés en conjonction avec des cartes en coordonnées polaires des angles de torsion révèlent comment les demandes des invités sont accommodées par l'hôte.

[Traduit par la rédaction]

The search for molecular receptors of the alkali-metal cations has developed from crown ethers via cryptands to spherands (1). Design principles emphasizing ligand cavity size, ligand–cation complementarity, and ligand preorganization have guided syntheses of increasingly complex macrocyclic ligands with highly specific cation binding capabilities (2). Nevertheless, the binding of alkali-metal

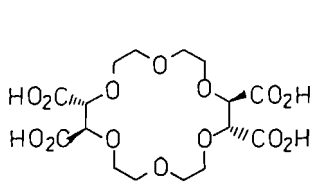
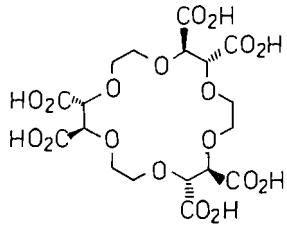
cations in aqueous solution remains largely unexplored. Water binds these cations more tightly than simple crown ethers, cryptand binding requires a basic solution to avoid ligand protonation, and the spherands are insoluble in water. In contrast, polycarboxylate crown ethers derived from *R,R*-(+)-tartaric acid (3, 4) bind cations in acidic aqueous solution with stability constants for alkali-metal cations comparable to those for the cryptands.

The structures of polycarboxylate crown ether complexes with alkali-metal cations have been inferred from stability constant data (3, 5, 7) and from UV and ESR spectral changes (8). Analyses of solid-state structures of several derivatives (6, 9–11) have established the main structural features. In particular, the vicinal carboxylates derived from the tartaro units strongly favour an *anti* conformation. All our structural investigations reveal the same.

The purpose of this study is to reveal the structural details of alkali-metal complexation in water by two polycarboxylate crown ethers, an 18-crown-6 tetraacid ($18C6A_4$) (4) and an 18-crown-6 hexaacid ($18C6A_6$) (3).



$18C6A_4$



$18C6A_6$

We initially compare the coordination geometries of all the complexes about the cation, especially the relationship of cavity sizes to effective ionic radii of the bound cations. Both ligands are multi-armed lariat ethers, and we follow an earlier analysis of the solid-state structures of neutral lariat ether complexes (12). For each complex, we calculate the mean cavity radius by the procedure of Mathieu *et al.*, which averages the differences between the metal–donor distance and the covalent radius of the donor atom for all donors in the ligand (13). We calculate the guest-ion radius, which includes all donors to the cation, in the same manner as effective ionic radii (14, 15). We then compare both the mean cavity radius and the guest-ion radius with the effective radii of the cations for various coordination numbers. The most striking result is that the $18C6A_6$ complexes contain a water molecule and the guest cation. These hosts complex monohydrated cations rather than dehydrated cations.

We next analyze macrocyclic conformations, a fascination since the earliest reports of macrocycle crystal structures (1, 2). How does macrocyclic conformation influence the complexation of an ion? We describe the detailed reorganizations that the different guest ions provoke in the host and the ways in which those reorganizations may be discerned. We use skeletal drawings, which include only the donor atoms of the ligands (12), to reveal the topographies of the donor atoms about the guest cations. We next present the 18 torsion angles of a macrocycle on a polar-coordinate map (16, 17)[3] to reveal how the host forms the cavity. We have recently used these maps to compare solid-state conformations of many 18-crown-6 metal cation complexes (18). We offer this method as an alternative to the torsion-angle-sequence methods of Stoddart (19) and Dale (20). The polar-coordinate maps permit ready visual comparisons among the maps and reveal how bond rotations may interconvert two conformations. Skeletal drawings and polar-coordinate maps provide complementary perspectives on the cooperative interplay of host and guest.

Results

All the salt complexes were formed by simple metathesis reactions of the corresponding metal halide or nitrate and readily crystallized from aqueous solution. Formally, the crystallization generated an equivalent of mineral acid in a strongly acidic solution (3). Large, colourless crystals grew over a period of hours from equimolar mixtures of the ligand ($18C6A_4$ or $18C6A_6$) and cations (Na^+, K^+, Tl^+, Cs^+). The exception was the K^+ complex of $18C6A_4$, which resisted all attempts at crystallization. The corresponding salt complexes of alkaline earth cations failed to crystallize in a form suitable for X-ray analysis; fibrous precipitates immediately formed from mixtures of ligand and salts of the cations (Ca^{2+}, Sr^{2+}, Ba^{2+}). The fibres analyzed as 1:1 complexes.

The structures of seven complexes were determined. For each complex, crystallographic parameters (Tables 1 and 2) and key structural features of the coordination environment of the cation are given (Tables 3 and 4). The structures are illustrated in three ways (Figs. 1–7): a structure with all atoms, a skeletal drawing of all donors to the cation, and a polar-coordinate map of the macrocyclic torsion angles (18). Endocyclic torsion angles are determined with the convention that a positive torsion angle exhibits a clockwise rotation between the front and the rear three atom planes. The macrocycle *bonds* are numbered sequentially: the starting point and direction can be chosen randomly. The torsion angle of each bond is then plotted by bond number on a polar-coordinate system. For 18-crown-6, each bond accounts for 20° (one eighteenth of 360°), and the resultant map is an octadecagon. The torsion angles are plotted from the centre at 0° to the outer edge (360°); negative torsion angles are plotted as 360° plus the negative torsion angles. This plotting convention differs from Ounsworth and Wieler (16), but is useful for crown ethers. It diminishes the small differences about *anti* torsion angles (+175° vs. −175°) and accentuates the equally small differences between *eclipsed* torsion angles (+5° vs. −5°).

Complexes of $18C6A_6^-$

$18C6A_6^- \cdot Na^+$

The Na^+ complex crystallizes from an aqueous 1:1 mixture of the $18C6A_6$ and sodium chloride as the trihydrate (Table 1 and Fig. 1). A water molecule, an oxygen from the carboxylate, and the six macrocyclic oxygens coordinate the Na^+. The macrocyclic oxygens adopt a planar conformation (maximum deviation 0.095(1) Å) with the Na^+ 0.523(1) Å out of this plane, drawn toward the carboxylate. The coordinating water molecule lies above the opposite face of the plane, and hydrogen bonds to three carboxyls of the ligand. The hydrogen bond donor of the ligand utilizes an *anti*

conformation of the carboxylic acid group to form a strong hydrogen bond (2.599(2) Å) with the coordinated water molecule; the other hydrogen bonds to it are longer (2.817(2) and 3.006(2) Å).

$18C6A_6^- \cdot K^+$

The K^+ complex crystallizes from an equimolar mixture of the $18C6A_6$ and potassium chloride in water as the trihydrate (Table 1 and Fig. 2). A water molecule, an oxygen from the carboxylate side arm, an oxygen from a carboxyl side arm, and the six macrocyclic oxygens coordinate the K^+. One of the potential donors, O26, remains uncoordinated to the K^+ at a distance of 3.687(3) Å from the cation. The macrocyclic oxygens adopt a nearly planar conformation (maximum deviation 0.134(2) Å) with the K^+ 0.985(1) Å above this plane on the side of the carboxylate oxygen. On the opposite face, the water molecule is hydrogen bonded to the three carboxyl groups. The hydrogen bond donor of the ligand utilizes an *anti* conformation of the carboxylic acid group to form a strong hydrogen bond (2.592(3) Å) with the coordinated water molecule; the other two hydrogen bonds to it are longer (2.917(4) and 2.994(4) Å).

$18C6A_6^- \cdot Tl^+$

The Tl^+ complex crystallizes from a 1:1 mixture of the $18C6A_6$ and thallium(I) nitrate as the dihydrate (Table 1 and Fig. 3). A water molecule, a carboxylate oxygen, an oxygen from each of two carboxyls, and all six macrocyclic oxygens coordinate the Tl^+. The macrocyclic oxygens adopt a planar conformation (maximum deviation 0.095(5) Å) with the Tl^+ displaced 1.219(1) Å from this plane towards the carboxylate. The water lies below the plane on the opposite face and hydrogen bonds with two carboxyls, O23 (2.667(6) Å) and O35 (2.759(6) Å), and possibly with the third carboxyl O30 (3.096(7) Å). The hydrogen on O23 is in the *anti* conformation.

$18C6A_6^- \cdot Cs^+$

The Cs^+ complex crystallizes from an aqueous solution of the $18C6A_6$ and cesium chloride as the dihydrate (Table 1 and Fig. 4). A water molecule, an oxygen from three intramo-

lecular and two intermolecular carboxyl groups, and the six macrocyclic ether oxygens coordinate the Cs^+. The protonation of the carboxyl groups may be disordered, hence the carboxylate cannot be identified unambiguously. The macrocyclic oxygens adopt a flattened twist-boat conformation with the Cs^+ ion 1.6896(2) Å from their best plane. The Cs^+ and the coordinating water molecule lie on opposite sides of the macrocycle. The water is hydrogen bonded to three carboxyls in a site similar to that in the Na^+, K^+, and Tl^+ complexes. The hydrogen on O23 was not located but is presumed to be in the *anti* conformation as in the other complexes. Like the other complexes, it forms a strong hydrogen bond to the water (2.486(4) Å); the other located hydrogen bonds are longer (2.713(4) and 2.805(4) Å).

Complexes of $18C6A_4^-$

$18C6A_4^+ \cdot Na^+$

The Na^+ complex crystallizes from a mixture of the $18C6A_4$ and 1 equivalent of sodium chloride in water as the dihydrate (Table 2 and Fig. 5). Carbonyl oxygens from two side arms, water, and four ether oxygens ligate the Na^+. The remaining ether oxygens, O4 and O7, reside at 3.074(2) and 3.351(2) Å respectively from the Na^+. The carboxylate group does not participate in the coordination of the cation, but forms two very strong intermolecular hydrogen bonds, 2.490(3) and 2.568(3) Å, with carboxyl groups. The macrocyclic oxygens adopt a flattened twist-boat conformation. The Na^+ lies on one side of the macrocycle, 0.4371(4) Å from the best plane, and the water resides on the opposite side

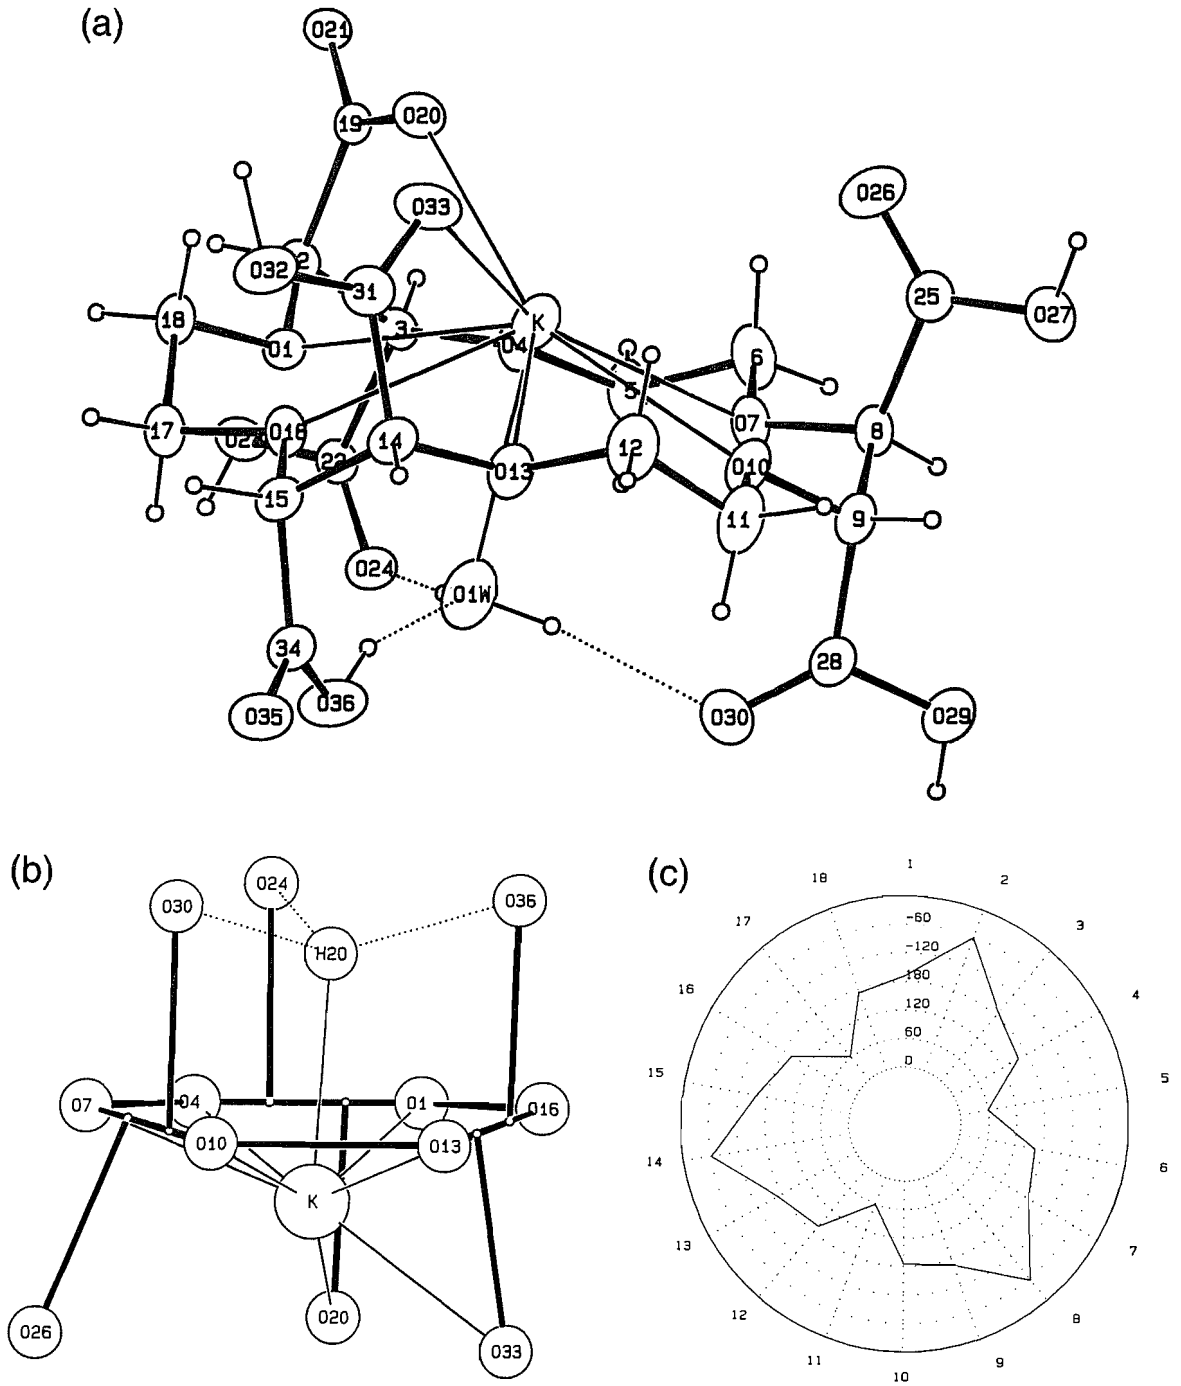

FIG. 2. $18C6A_6^- \cdot K^+$ complex. (*a*) Structure of the complex showing atom numbering, (*b*) skeletal drawing showing donors to the cation, and (*c*) polar coordinate map of macrocyclic torsion angles.

of the macrocycle. The coordinated water molecule has long intramolecular contacts to ether oxygens O7 (2.915(3) Å) and O10 (3.090(3)Å) of the ligand, but forms intermolecular hydrogen bonds to a carboxyl group and to the second water molecule.

$18C6A_4^- \cdot Tl^+$

The Tl^+ complex crystallizes from a mixture of the $18C6A_4$ and thallium nitrate in water, as a hydrate (Table 2 and Fig. 6). The uncertainty in the hydration state results from disorder of the water of crystallization ($x \approx 2$). The Tl^+ is also disordered between two sites with a population ratio of approximately 95:5, separated by 2.36(1) Å. In either site, all six macrocyclic oxygens and an oxygen from each of two side-arm carboxyls coordinate the Tl^+. A coordinated water molecule may lie near the minor Tl′ site. The macrocyclic oxygens adopt a flattened half-chair conformation. The Tl^+ lies 0.9603(1) Å above the best plane of these oxygens.

$18C6A_4^- \cdot Cs^+$

The Cs^+ complex crystallizes from a 1:1 mixture of the $18C6A_4$ and cesium chloride in water as the dihydrate (Table 2 and Fig. 7). All six macrocyclic oxygens, and an oxygen from each of three carboxyls, two intramolecular and one

intermolecular, coordinate the Cs^+. The carboxylic protons were not located, so the carboxylate is not identified. The macrocyclic oxygens adopt a planar conformation with maximum deviation 0.097(4) Å. The Cs^+ lies 1.4463(1) Å above this plane, and a water molecule lies on the other side. This water molecule does not ligate the cation, but hydrogen bonds to O23 and the other water molecule in the structure.

Discussion

Comparison of 18C6A$_6$ complexes

The threefold symmetry of the arrangement of carboxylic acids, which are attached to the two faces of the macrocycle, is optimal for binding monohydrated cations. All $18C6A_6$ complexes contain a water molecule bound to the metal ion. The water forms three hydrogen bonds to three carboxyl groups on one face of the macrocycle. The water forms two OH...O=C hydrogen bonds, both in the preferred *anti* direction of the carbonyl oxygen (21). The water accepts a hydrogen bond from the third carboxylic acid, which is in the more acidic, but less stable, *anti* conformation about C(O)—OH (22). In the Cs^+ complex, the third carboxyl also donates electron density to a Cs^+ in a neighbouring complex. In addition to the water donor, and the six ether oxygens, the metal ions bind to a carboxylate on the opposite face of the macrocycle. The geometry of the ligand enforces the

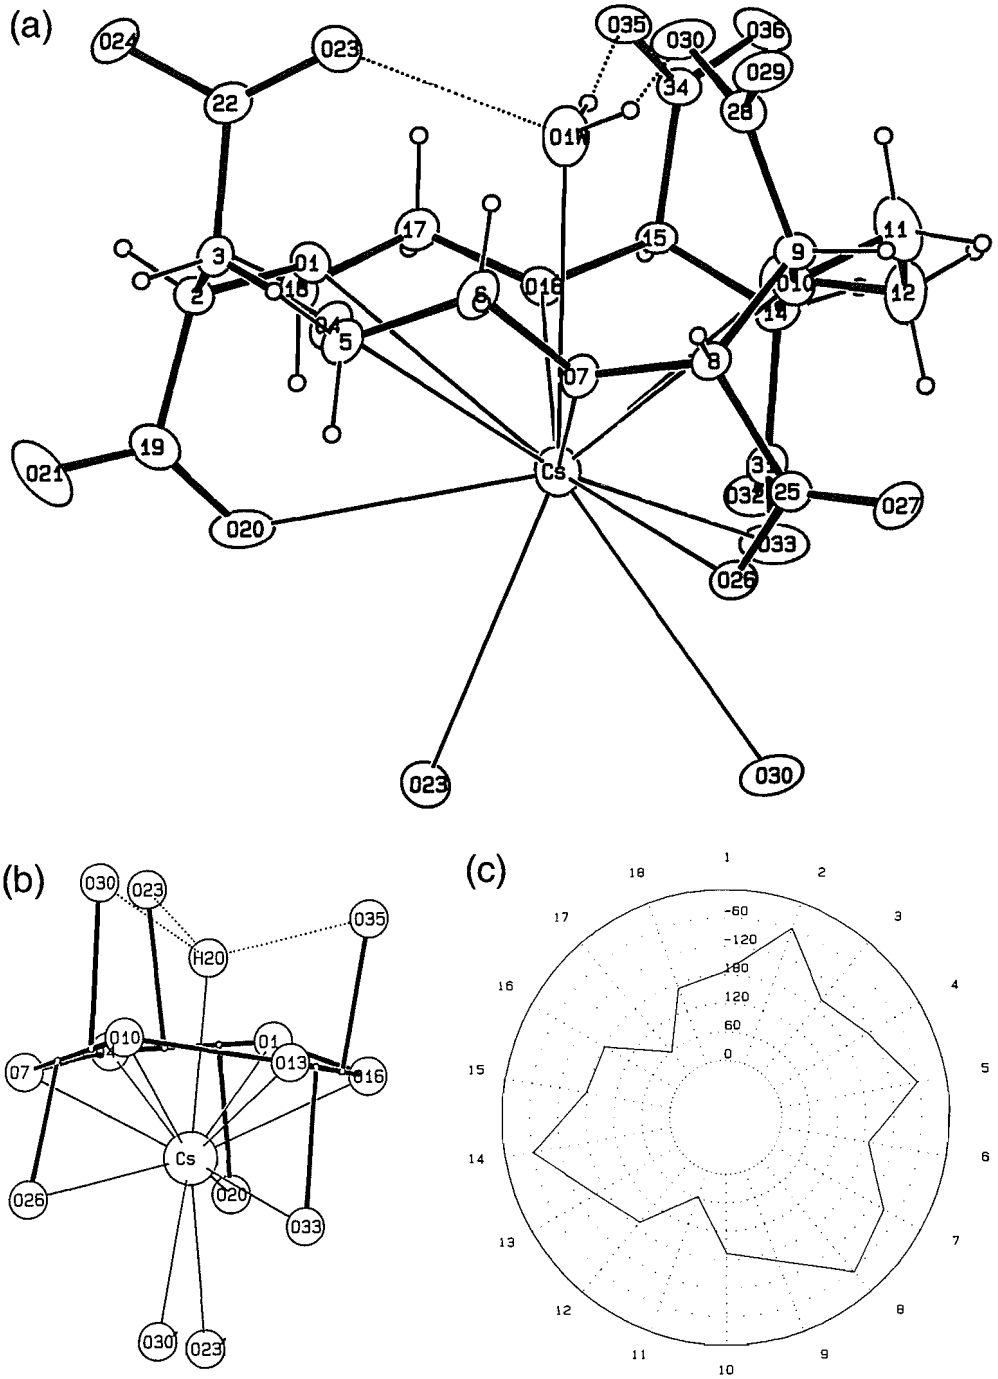

FIG. 4. $18C6A_6^- \cdot Cs^+$ complex. (*a*) Structure of the complex showing atom numbering, (*b*) skeletal drawing showing donors to the cation, and (*c*) polar coordinate map of macrocyclic torsion angles.

less preferred *anti* attachment to the carboxylate for Na^+, K^+, and Tl^+ (23). Cs^+ slightly prefers *direct* and *syn* to *anti* attachment to carboxylate (23). As the size of the cation increases, the remaining two carboxyls donate electron density to the cation. No carboxyls donate to Na^+; one, to K^+; and two, to Tl^+ and Cs^+. Water on one face of the macrocycle and the carboxylate and carboxyls on the other face encapsulate the cations. These complexes resemble bibracchial lariat ether and cryptand complexes (12).

Table 3 summarizes the coordination about each cation. In all cases, the mean cavity radius is the same or slightly larger than the guest ionic radius. This is a minor artifact of calculation because the oxygen radius is a constant (1.4 Å) when calculating the mean cavity radius (13) but increases with increasing coordination number when calculating the guest ionic radius (24). As the ionic size increases, the cation moves away from the mean plane of the macrocyclic oxygens towards the carboxylate. The carboxylate O—M—OH_2 angle also decreases: Na^+(130.0(1)°) > K^+(119.9(1)°) > Tl^+(116.5(1)°) > Cs^+(102.4(1)°). The smaller bite angles involve a nine-atom cycle ($H_2O\cdots$ M$\cdots$O=C-CH-CH-C-O-H$\cdots$), while the larger bite angles involve a 13-atom cycle ($H_2O\cdots M\cdots$O=C-CH-O-CH_2-CH_2-O-CH-C-O-H$\cdots$). In the Na^+ and K^+ complexes, the water

[a]Definitions are: $R = \Sigma \|\|F_o\| - |F_c\|\|/\Sigma |F_o|$; $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2)^{1/2}$; GOF = $[\Sigma w(|F_o| - |F_c|)^2/(N_{obs} - N_{param})]^{1/2}$.

molecule is held further from the mean plane of the macrocyclic oxygens than in the Cs^+ and Tl^+ complexes. The size of the ion dictates the additional number of intramolecular carboxyl donors: zero (Na^+), one (K^+), or two (Tl^+ and Cs^+). Two intermolecular carboxyls bind to the cation in the Cs^+ complex, which has the only nonplanar skeletal arrangement of macrocyclic oxygens (Fig. 4*b*).

Comparison of 18C6A$_4$ complexes

The $18C6A_4$ complexes show greater structural diversity than the $18C6A_6$ complexes (Table 4). Two oxygens from two carboxyls (or one carboxyl and the carboxylate) attached to the same face of the $18C6A_4$ macrocycle bind to the cation. In the Tl^+ and Cs^+ complexes, the carboxylate is unidentified, but in the Na^+ complex, carboxylate does not contact the cation, but forms two strong intermolecular hydrogen bonds to two carboxyls. Both carboxylic oxygens donate electron density from the *anti* direction. Like other lariat ether complexes, the size of the metal ion affects the skeletal arrangement of the macrocyclic oxygens. The Na^+ complex has a twist-boat arrangement (Fig. 5*b*) that is seen in many Na^+ complexes of 18-crown-6 (18). This arrangement places two macrocyclic oxygens outside bonding distance to the Na^+. The skeletal arrangement of the Tl^+ complex is half chair (Fig. 6*b*), and the Cs^+ complex is planar (Fig. 7*b*).

Comparisons of 18C6A$_6$ and 18C6A$_4$ complexes

The similarity in structure of the $18C6A_6$ complexes contrasts the diversity of the $18C6A_4$ complexes. In both series the *R,R*-tartaro units favour an *anti* conformation for the carboxyls. This conformational bias produces a "stiff" torsion angle in the macrocycle, which resists reorganization to accommodate a guest. The $18C6A_4$ ligand (two tartaro units) is more flexible than $18C6A_6$ (three tartaro units). This flexibility in $18C6A_4$ conforms with the variability of the skeletal arrangements of macrocyclic oxygens in the $18C6A_4$ complexes. The $18C6A_4$ complexes resemble lariat ether complexes, but the $18C6A_6$ complexes resemble cryptates (12). The transannular distances among the macrocyclic oxygens suggest that the $18C6A_4$ macrocycle provides an oval

array of six donor atoms, while the $18C6A_6$ cavity is nearly circular.

Na^+ complexes

A comparison of the Na^+ complexes of $18C6A_4$ and $18C6A_6$ shows that hydrogen bonding to the monohydrating water centres the metal ion in the cavity in the latter. In $18C6A_6$, the M^+—O distances for the macrocyclic oxygens vary only 0.23 Å, but in $18C6A_4$ they vary 0.83 Å. The large spread in the latter results in an ambiguous coordination number of the metal. The carboxylate–metal distance is shorter in $18C6A_4$, but the water–metal distance is shorter in $18C6A_6$. Monohydrated Na^+ is the guest in $18C6A_6$, whereas dehydrated Na^+ is the guest in $18C6A_4$. The guest ionic radius in $18C6A_4$ as either a hepta- or a nona-coordinated complex agrees well with the effective ionic radii. The guest ionic radius in the $18C6A_6$ is larger than the effective ionic radius for octacoordinated Na^+. Mean cavity radii are larger than the guest ionic radii because the solvating water in each complex has a shorter M^+—O distance than all other contacts in the ligand, except for carboxylate.

Tl^+ complexes

A comparison of the Tl^+ complexes shows many similarities in Tl^+—O contacts with the ligand, even though $18C6A_6$ binds a monohydrated Tl^+ and $18C6A_4$ binds only the metal ion (major site; the minor site Tl′ may be hydrated). The mean cavity radii are identical in spite of the additional carboxyl donor in $18C6A_6$. The guest ionic radius of $18C6A_6$ is smaller than that of $18C6A_4$ because the M^+—O distance

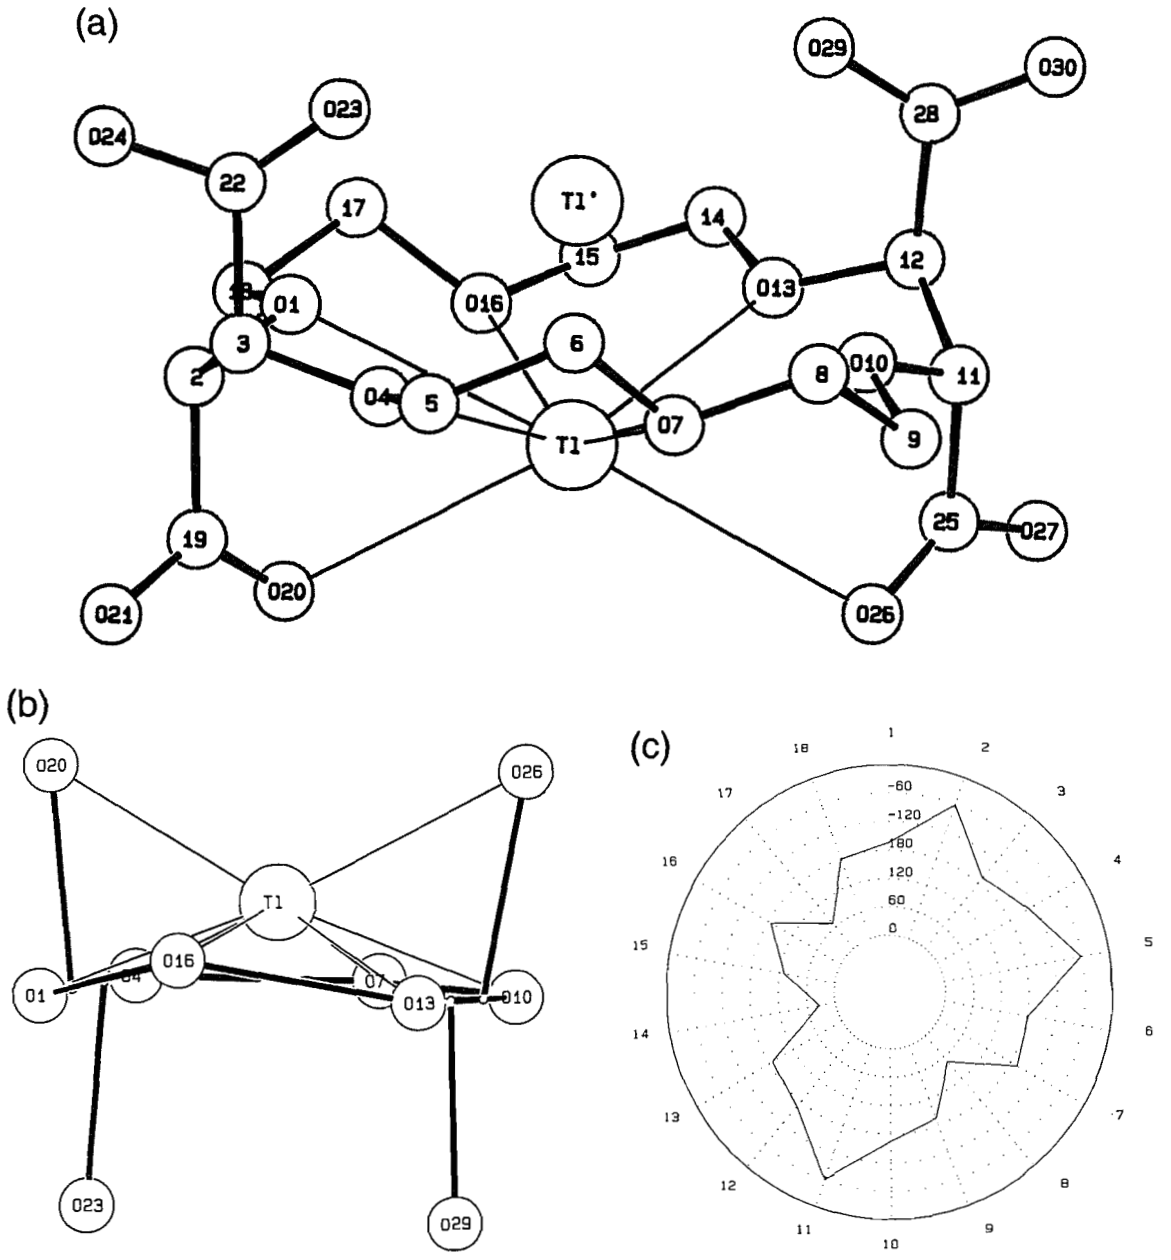

FIG. 6. $18C6A_4^- \cdot Tl^+$ complex. (*a*) Structure of the complex showing atom numbering, (*b*) skeletal drawing showing donors to the cation, and (*c*) polar coordinate map of macrocyclic torsion angles.

for the hydrating water is the shortest contact in the former complex. The close agreement between guest ionic radius in $18C6A_4$ and effective ionic radii for octacoordinated Tl^+ contrasts a similar comparison in $18C6A_6$ with decacoordinated Tl^+.

Cs^+ complexes

The Cs^+ complexes are similar if the two long intercomplex carboxyl contacts in $18C6A_6$ are excluded. Both complexes show close agreement between guest ionic radius and effective ionic radius. The water in the $18C6A_6$ complex has a longer M^+—O distance than any macrocyclic oxygen or intracomplex carboxyl donor. The $18C6A_6$ appears more to act as a host with two loosely coupled guests rather than the tightly coupled guests of the Na^+, K^+, and Tl^+ complexes with this ligand.

Polar maps and skeletal drawings

Clarifying the relationship between macrocyclic conformation and cation binding provides a key to the design of complexing agents with preselected properties. Skeletal drawings focus attention on the topography of the donors of the ligand, revealing the familiar conformations of smaller carbocyclic rings (boat, chair, twist-boat, etc.). The skeletal drawings (Figs. 1*b*–4*b*) reveal a nearly planar array of macrocyclic oxygens in all four $18C6A_6$ complexes. Skeletal drawings of more flexible crown ethers show nonplanar arrangements (12). The conformational restraint of the tartaro units and the three-point binding of the hydrating water partly enforce near planarity of the six macrocyclic oxygens. The rationale for the use of skeletal drawings is that flexible bonds connecting the donors can adjust to give the best arrangement of donors to the cation. If the connecting

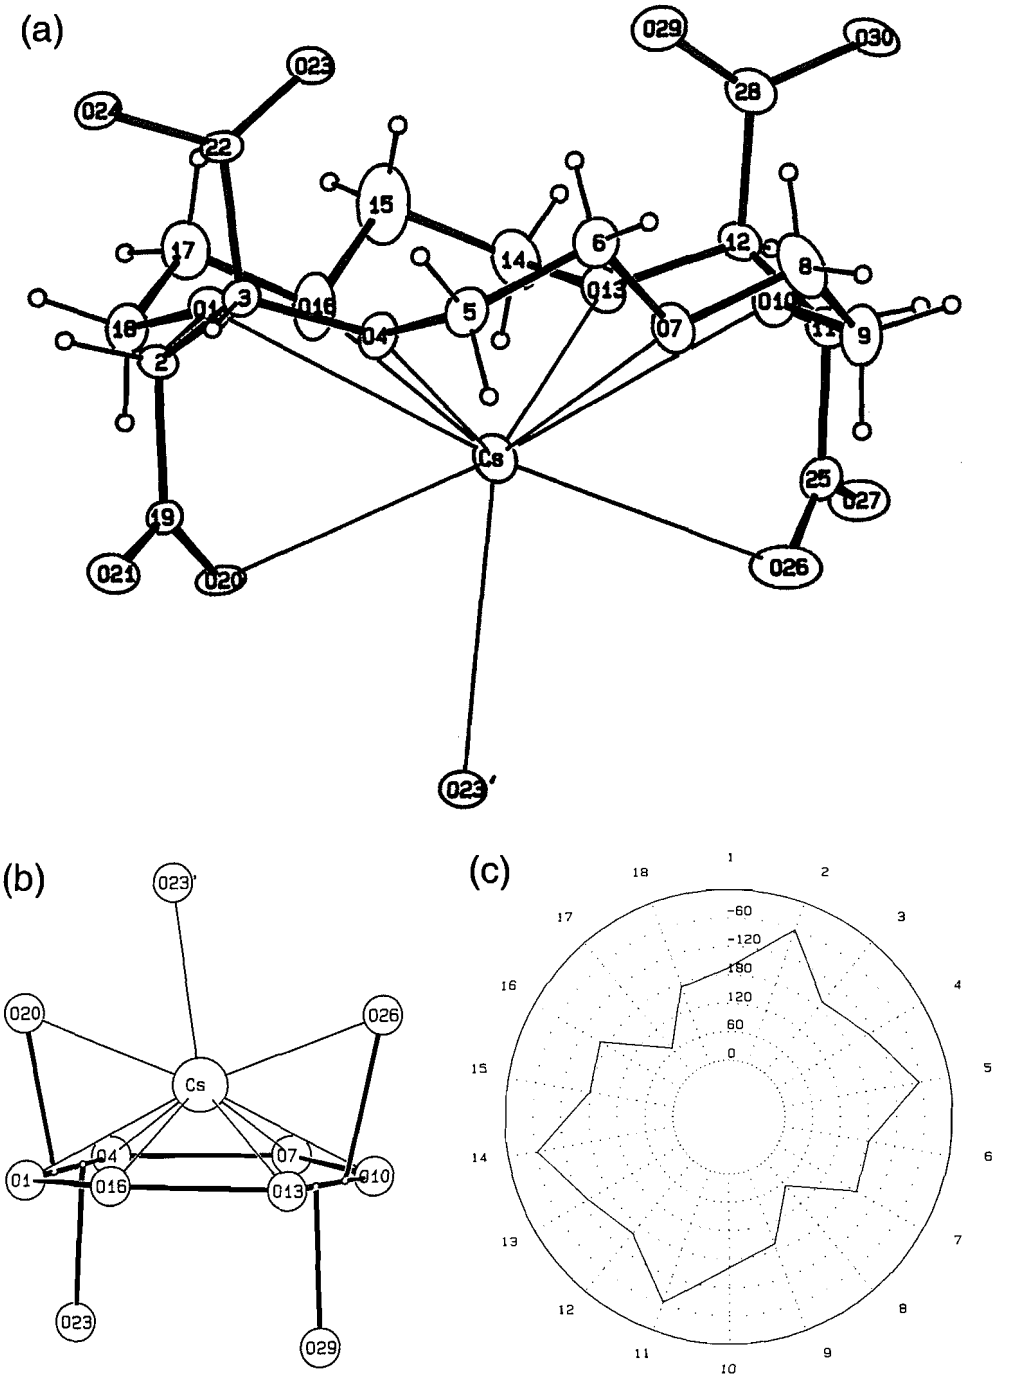

FIG. 7. $18C6A_4^- \cdot Cs^+$ complex. (*a*) Structure of the complex showing atom numbering, (*b*) skeletal drawing showing donors to the cation, and (*c*) polar coordinate map of macrocyclic torsion angles.

bonds are not completely flexible, then there must be a balance between the conformational preference of the host and the optimal donor topography for the guest.

Polar-coordinate maps of macrocyclic torsion angles clearly illustrate the conformations of the macrocycle. For example, compare Figs. 1*c*, 2*c*, and 3*c*. An overlay of the three, Fig. 8, emphasizes the similarity. Now, compare Figs. 1*b*, 2*b*, and 3*b*. All of these skeletal drawings reveal the planar arrangement of the macrocyclic donors. The remaining structure in the series, Fig. 4, has a different skeletal drawing (twist boat) and polar map from the other three $18C6A_6$ complexes. By contrast, the $18C6A_4$ complexes have different polar maps (Figs. 5*c*–7*c*) and skeletal drawings (Figs. 5*b*–7*b*). Polar maps also reflect the difference in symmetry between $18C6A_4$ (twofold) and $18C6A_6$ (threefold) complexes.

Polar-coordinate maps show differences in complexes with similar skeletal drawings. The Na^+ complex of $18C6A_4$ and the Cs^+ complex of $18C6A_6$ have the same skeletal drawing (twist boat). An overlay of the two polar maps, Fig. 9, reveals the similarity. Fifteen of the 18 torsion angles match. One ethylenedioxy unit differs: O4—C5—C6—O7 in $18C6A_4 \cdot Na^+$ and O7—C8—C9—O10 in $18C6A_6 \cdot Cs^+$. In the former, the O—C—C—O torsion angle is *gauche*$^+$

(64.3(3)°) while in the latter it is *gauche*$^-$ (−54.0(3)°). The O7—C8—C9—O10 unit in the Cs^+ complex *cannot* be *gauche*$^+$ as this would place the two tartaro carboxyl carbons in a *gauche* conformation. A similar overlay (not shown) exists between the Cs^+ complex of $18C6A_4$ and the Na^+, K^+, and Tl^+ complexes of $18C6A_6$. All four complexes have planar skeletal drawings.

Polar maps also reveal the rotations required to interconvert conformations. For example, an overlay (Fig. 10) of the polar maps of the Tl^+ and Cs^+ complexes of $18C6A_6$ illustrates that the torsion angles about O4—C5—C6—O7 differ in the two complexes. A "crankshaft" rotation, where C3—O4—C5—C6 goes from about 60° to about −60° and C5—C6—O7—C8 goes from about 60° to about 180°, interconverts the two conformations. The end-to-end distance (C3–C8) is the same in the two complexes, but the motion has altered the positions of the carboxyl side arms. The C3—C22 and C9—C28 bonds, which are nearly parallel in the Tl^+ complex, swivel to close the C22 to C28 gap from 6.480(9) to 5.416(6) Å in the Cs^+ complex. The donor at O7 also moves from a position as the longest of the six macrocyclic oxygen–Tl contacts to the shortest of the six macrocyclic oxygen–Cs contacts.

Ligand preorganization

In the absence of metal ions, both ligands crystallize as hydrates (25). The dihydrate of $18C6A_4$ contains water molecules hydrogen bonded to opposite faces of a nearly planar macrocycle, bridging between the carboxylic acid groups. Overlays of the polar-coordinate maps (18) of the $18C6A_4$ hydrate with any of the salt complexes reveal that major conformational changes must occur during complexation. In each case, the formal result is the displacement of the bridging waters and the reorganization of the macrocycle to optimize the coordination environment.

In striking contrast, the tetrahydrate of $18C6A_6$ undergoes minimal net reorganization during the complexation and crystallization processes. The hydrated ligand complexes a water dimer using a six-point hydrogen bond network (25). Three carboxyl donors accept hydrogen bonds in the preferred *anti* direction. The other three host carboxylic acids donate hydrogen bonds in the less preferred, more acidic, *anti* conformation. Substitution of the donor water of the dimer by the cation, accompanied by ionization of one of the carboxylic acids, produces the structure of a salt complex. The hydrogen-bond-accepting water of the dimer coordinates the cation. Consequently, two carboxyls, which hydrogen bond in *anti* conformations to the hydrogen-bond-donating water of the dimer, become carbonyl oxygen donors in the salt complexes and revert to the more stable *syn* conformation. Remarkably, minimal structural reorganization accompanies the formal H_3O^+-by-cation substitution. The polar-coordinate map of the $18C6A_6$–water–dimer complex (18) directly overlaps the polar maps of the Na^+, K^+, and Tl^+ complexes (Fig. 8).

The $18C6A_6$ ligand in water is a rare example of a *chorand* that is preorganized by solvent. Three effects combine

and reinforce one another: (1) the macrocyclic framework adopts the D_{3d} conformation; (2) the tartaro units adopt preferred *anti* conformations; and (3) a bridging water molecule is held by three hydrogen bonds across one face of the molecule. This combination produces a preorganized cavity, which may be occupied either by a second water molecule or a cation.

Relationship of structure to cation binding in solution

Alkali-metal cations in aqueous solutions bind to $18C6A_6$ up to 10^4-fold more strongly than to the parent, 18-crown-6 (3). This structural study implies that $18C6A_6$ could bind monohydrated cations in water. Is there evidence for such a structure in solution? Perhaps there is. Carboxylate electrostatically enhances the stability of a complex (3). In-

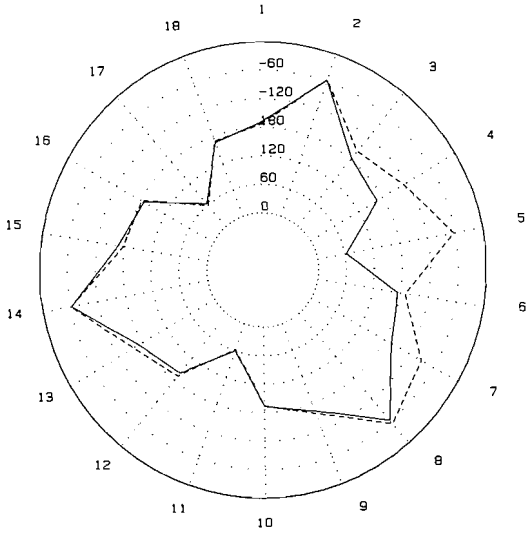

FIG. 10. Overlay of the polar coordinate maps of macrocyclic torsion angles of the Tl^+ (solid) and Cs^+ (dashed) complexes of $18C6A_6$.

creasing the number of carboxylates generally enhances cation binding, but not always. Both the Tl^+ and K^+ complexes of fully deprotonated (6^-) $18C6A_6$ are weaker than the monoprotonated (5^-) forms (3). Such an observation supports the suggestion of monohydrated cations binding to $18C6A_6$ in solution. Optimal binding (three-point attachment) of the water molecule requires at least one carboxyl (protonated carboxylate) to donate a hydrogen bond.

A bound water molecule could enhance complex stability either by preorganizing the ligand, or by altering the energetics of cation desolvation/complex formation. The energy of cation desolvation contributes to the energy of complexation, which can be reduced if a host binds a partly hydrated cation. Dehydration from heptahydrated Na^+ costs 12–16 kJ/mol each for the first five waters[4]. The next water costs 55 kJ/mol and the last 74 kJ/mol. This effect is less with Cs^+ (34 kJ/mol for the last water). Ligand preorganization by bound water or partial cation desolvation have different mechanistic implications, but give the same thermodynamic result. The stability of alkali-metal complexes of $18C6A_6$ results from the host complementing the water–cation guest couple.

Summary

Structural studies of hosts that complex hydrated cations may serve as models of how ions are transported across biological membranes. Carboxylates are frequently located on protein surfaces that contact water. As these studies reveal, a monohydrated sodium or potassium cation could readily move through the 18-crown-6 cavity. Dihydrated cations, if the second water is apical to the first, could conceivably move through as well. Molecular modelling of these complexes may provide further insight into mechanisms of ion transport or confirmation of our speculations about the mechanism of complexation or both.

[4]Experimental data: ref. 26*a*. Computational data: refs. 26 *b–d*.

Experimental

The ligands were prepared and purified as previously described (3, 4). The abbreviations are: $18C6A_6$ = 2*R*,3*R*,8*R*,9*R*,14*R*,15*R*-1,4,7,10,13,16-hexaoxacyclooctadecan-2,3,8,9,14,15-hexacarboxylic acid; $18C6A_4$ = 2*R*,3*R*,11*R*,12*R*-1,4,7,10,13,16-hexaoxacyclooctadecan-2,3,11,12-tetracarboxylic acid. Crystals were grown from aqueous solutions of the ligands (0.5 M) containing an equivalent of the metal halide or nitrate.

Crystal structure determination

Intensity data were collected by ω–2θ scans of variable rate designed to yield measurements of equal relative precision for all significant reflections, using Enraf–Nonius CAD4 diffractometers equipped with Cu Kα (λ = 1.54184 Å) or Mo Kα (λ = 0.71073 Å) radiation and graphite monochromators. Unit-cell dimensions were determined from the setting angles of 25 reflections. A maximum was placed on the scan time spent on any reflection. In several cases more than one unique form of data was collected. Data reduction included correction for absorption by psi scans, background, Lorentz, polarization, and, in several cases, linear intensity decay. Three standard reflections remeasured every 10 000 s monitored the decay. Equivalent data were merged and all reflections having $I > 3\sigma(I)$ were used in the refinements. The structures were solved by heavy atom methods or using coordinates from isomorphous structures. Refinement was carried out by full-matrix least squares minimizing $\Sigma\, w(|F_o|-|F_c|)^2$ with weights $w = \sigma^{-2}(F_o)$, using the Enraf–Nonius SDP programs (27). Scattering factors were those of Cromer and Weber (28), and anomalous coefficients were those of Cromer (29). Except where noted below, non-hydrogen atoms were refined anisotropically, and hydrogen atoms were either located on difference maps and refined isotropically or placed in calculated positions with C—H distance 0.95 Å and $B_{iso} = 1.3B_{eq}$ of the bonded carbon atom. For five of the structures, secondary extinction coefficients, *g*, were refined, where the correction factor $(1 + gI_c)^{-1}$ was applied to F_c. Absolute configuration determinations were attempted, and in all cases, the better refinement agreed with the absolute configuration of the starting materials. Agreement indices for the alternate refinements are given in parentheses in Tables 1 and 2. Crystal and refinement data are given in Table 1 for complexes of $18C6A_6$ and in Table 2 for complexes of $18C6A_4$. Specifics of each refinement are given as follows.[5]

$18C6A_6^- \cdot Na^+$: Two octants of data were collected. All hydrogens were refined.

$18C6A_6^- \cdot K^+$: Isomorphous with the Na^+ complex. Carboxylic acid and water hydrogens refined; all others were fixed.

$18C6A_6^- \cdot Tl^+$: Two octants of data with $\theta < 25°$ were collected. Hydrogen atoms were not refined and those on O2W were not located.

$18C6A_6^- \cdot Cs^+$: One hemisphere of data with $\theta < 25°$ was collected; one quadrant $25° < \theta < 30°$. Carboxylic acid hydrogens and those on uncoordinated water were not located; others were calculated.

$18C6A_4^- \cdot Na^+$: Carboxylic acid and water hydrogens were located and refined; macrocycle hydrogens were fixed. The *B* of one water hydrogen was fixed.

[5]Tables of atomic positional coordinates, hydrogen atom coordinates, anisotropic thermal parameters, bond distances, bond angles, torsion angles, and structure factors have been deposited, and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of atomic parameters, bond distances, and bond angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

$18C6A_4^- \cdot Cs^+$: The carboxylic acid and water hydrogens were not located; others were calculated and fixed.

$18C6A_4^- \cdot Tl^+$: Isomorphous with the Cs^+ complex. One hemisphere of data with $\theta < 25°$was collected; one quadrant $25° < \theta < 33°$. The Tl^+ is disordered between two sites (95:5). Two water molecules with very high thermal parameters were refined isotropically. These and the high thermal parameters of C15 may be indicative of disorder. Residual peaks around the minor Tl site may indicate partial occupancy by additional water. Values in Table 2 assume the dihydrate. Hydrogen atoms were ignored.

L'azote n'est pas le site basique des amides encombrés

CHRISTIAN LAURENCE ET MARYVONNE HELBERT

Reçu le 16 octobre 1992

CHRISTIAN LAURENCE, MARYVONNE HELBERT et ABDELJALIL LACHKAR. Can. J. Chem. **71**, 254 (1993).

L'abaissement de la bande carbonyle dans les complexes du diiode avec les amides encombrés i-PrCON(C_6H_{11})$_2$, *t*-BuCON(C_6H_{11})$_2$ ou *t*-BuCON(i-Pr)$_2$ montre que le site de fixation de diiode reste l'atome d'oxygène du carbonyle. Les donneurs de liaison hydrogène *p*-FC_6H_4OH, $CHCl_3$ ou $CHBr_3$ se fixent également sur l'oxygène du carbonyle. Les seules différences entre ces amides encombrés et les amides non encombrés comme $MeCONMe_2$ résident dans des constantes de complexation plus faibles (par exemple 15 L mol^{-1} pour $MeCONMe_2$–I_2, mais 3 L mol^{-1} pour *t*-BuCON(i-Pr)$_2$) et une stoechiométrie inférieure de complexation (par exemple mélanges de complexe 1 : 1 et 1 : 2 pour *t*-BuCON(C_6H_{11})$_2$, alors que $MeCONMe_2$ forme principalement des complexes 1 : 2).

CHRISTIAN LAURENCE, MARYVONNE HELBERT, and ABDELJALIL LACHKAR. Can. J. Chem. **71**, 254 (1993).

The shift of the carbonyl band of the iodine complexes with the hindered amides i-PrCON(C_6H_{11})$_2$, *t*-BuCON(C_6H_{11})$_2$, and *t*-BuCON(i-Pr$_2$) shows that the iodine interacts with the oxygen atom of the carbonyl group. Hydrogen bond donors, such as *p*-FC_6H_4OH, $CHCl_3$, or $CHBr_3$, also interact with the oxygen atom of the carbonyl group. The only differences between these hindered amides and unhindered amides like $MeCONMe_2$ are the lower complexation constants (15 L mol^{-1} for $MeCONMe_2$–I_2 vs. 3 L mol^{-1} for *t*-BuCON(i-Pr$_2$) and a lower stoichiometry of complexation (for example, a mixture of 1:1 and 1:2 complexes is obtained with *t*-BuCON(C_6H_{11})$_2$ while $MeCONMe_2$ forms mainly 1:2 complexes).

[Journal translation]

Introduction

Alors qu'il est généralement admis que la protonation (1), la liaison hydrogène, ou la fixation d'acides de Lewis (2, 3) s'effectuent pour les amides sur l'oxygène du carbonyle, Guihéneuf *et al.* ont récemment émis dans ce journal (4) l'hypothèse que l'azote pourrait devenir le site basique des amides encombrés. Ils ont en effet observé que les constantes de formation des complexes des amides avec l'acide de Lewis I_2 étaient beaucoup plus élevées avec les amides très encombrés comme *t*-BuCON(C_6H_{11})$_2$ qu' avec les amides comme MeCON(Me)$_2$ et qu'elles se rapprochaient de celles des amines correspondantes. Ils ont expliqué ces observations par une déconjugaison stérique des groupes CO et N(C_6H_{11})$_2$ qui réduit la basicité de l'oxygène et augmente celle de l'azote (4).

Dans ce travail nous examinons cette hypothèse séduisante en étudiant par infrarouge la bande carbonyle des amides encombrés et non encombrés en présence de I_2 et également des donneurs de liaison hydrogène comme le *p*-fluorophénol, le chloroforme et le bromoforme.

Partie expérimentale

Produits

Les amides non encombrés, I_2, le *p*-fluorophénol et les solvants sont des produits commerciaux purifiés par les méthodes usuelles (3). Les amides encombrés ont été préparés par action des amines convenables avec les chlorures d'acide correspondants. Leur pureté a été soigneusement vérifiée par spectroscopie IR.

Mesures spectroscopiques

Les spectres infrarouges ont été enregistrés sur un spectromètre à transformée de Fourier Nicolet 510 M avec une résolution de 1 cm^{-1}. Les cellules utilisées sont en CaF_2 et font 0,5 mm d'épaisseur. Les décompositions mathématiques des massifs complexes ont été effectuées avec le logiciel Spectracalc (Galactic).

Constantes d'équilibre

Les constantes de complexation K_c des équilibres dans l'heptane à 25°C :

$$RCONR'_2 + I_2 \leftrightarrows RCONR'_2 \ldots I_2$$

sont déterminées par infrarouge sur la bande carbonyle des amides. Les constantes des équilibres dans CCl_4 à 25°C :

$$RCONR'_2 + p\text{-}FC_6H_4OH \leftrightarrows p\text{-}FC_6H_4OH \ldots RCONR'_2$$

sont déterminées par infrarouge sur la bande ν(OH) du *p*-fluorophénol (6).

Résultats et discussion

Étude de la bande carbonyle des amides encombrés en présence de diiode dans l'heptane

Dans l'heptane les amides tertiaires présentent vers 1650 cm^{-1} une bande fine et très intense. Ainsi le coefficient d'extinction molaire de la bande à 1659 cm^{-1} de MeCON(C_6H_{11})$_2$ vaut 1380 L mol^{-1} cm^{-1}. Cette bande très caractéristique est principalement due à la vibration de valence de la liaison carbonyle.

Drago *et al.* ont montré que la complexation des amides tertiaires avec le diiode ou le phénol s'accompagnait d'un abaissement de plusieurs dizaines de cm^{-1} de la bande carbonyle et que cet abaissement constituait un argument majeur en faveur d'une fixation de ces acides de Lewis sur l'oxygène du carbonyle (2, 3).

Nous avons étudié la bande carbonyle des amides MeCON(C_6H_{11})$_2$, EtCON(C_6H_{11})$_2$, i-PrCON(C_6H_{11})$_2$, *t*-BuCON(C_6H_{11})$_2$ et *t*-BuCON(i-Pr)$_2$ en solution dans l'heptane en ajoutant des quantités croissantes de diiode jusqu'à saturation. Nous observons, comme sur la figure 1 pour

For personal use only.

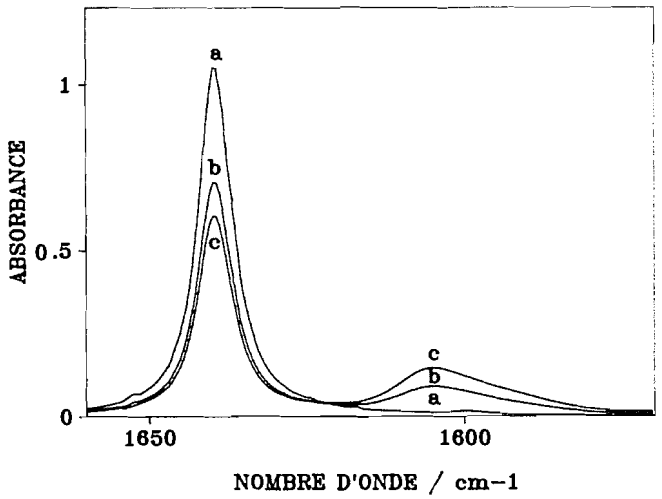

FIG. 1. Spectre IR-TF de *t*-BuCON(C_6H_{11})$_2$ dans l'heptane, seul (*a*) et en équilibre avec son complexe avec le diiode (*b* et *c*); (*a*) *t*-BuCON(C_6H_{11})$_2$ 0,029 M; (*b*) *t*-BuCON(C_6H_{11})$_2$ 0,012 M + I_2 0,027 M; (*c*) *t*-BuCON(C_6H_{11})$_2$ 0,012 M + I_2 à saturation.

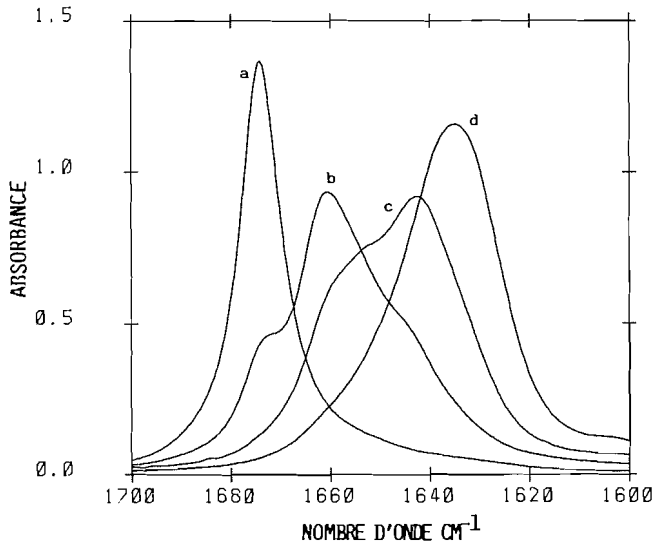

FIG. 2. Spectre IR-TF du *N,N*-diméthylacétamide 0,032 M dans des mélanges chloroforme–hexane; (*a*) fraction molaire *x* de $CHCl_3$ = 0; (*b*) *x* = 0,1; (*c*) *x* = 0,4; (*d*) *x* = 1.

t-BuCON(C_6H_{11})$_2$, que la bande carbonyle de l'amide libre diminue d'intensité et qu'elle est remplacée dans le complexe avec I_2 par une bande plus large aux fréquences plus basses. Ce comportement est caractéristique d'une fixation du diiode sur l'oxygène du carbonyle.

La fixation du diiode sur l'azote de la fonction amide envisagée par Guihéneuf *et al.* devrait s'accompagner de l'apparition d'une bande carbonyle aux fréquences élevées, car alors la participation du doublet de l'azote à la liaison N ... I_2 contrarierait sa conjugaison $n-\pi$ avec le carbonyle. L'examen minutieux, après de nombreuses accumulations spectrales, de solutions heptaniques d'amides saturés en diiode, ne montre aucune nouvelle bande aux fréquences élevées. On peut donc rejeter toute fixation du diiode sur l'azote pour les amides étudiés dans ce travail.

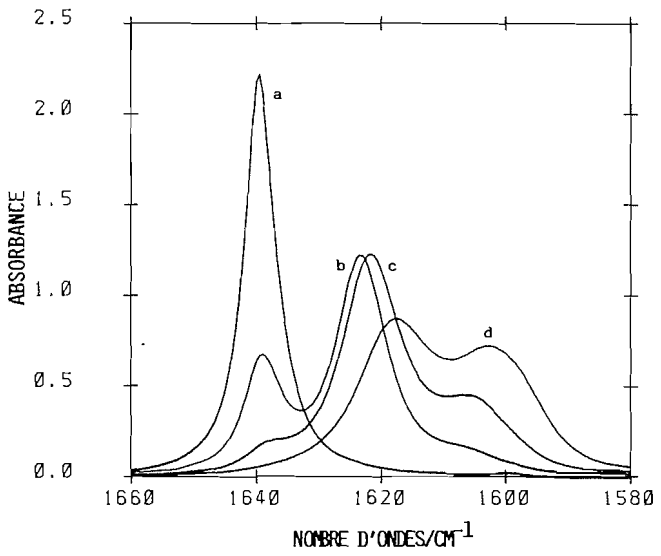

FIG. 3. Spectre IR-TF de *t*-BuCON(C_6H_{11})$_2$ 0,032 M dans des mélanges chloroforme–hexane; (*a*) fraction molaire *x* de $CHCl_3$ = 0; (*b*) *x* = 0,1; (*c*) *x* = 0,4; (*d*) *x* = 1.

Le tableau 1 résume les observations spectrales effectuées dans la région carbonyle, ainsi que la valeur de la constante de complexation K_c. On ne retrouve pas les valeurs très élevées observées par Guihéneuf *et al.* pour i-PrCON(C_6H_{11})$_2$ (1350 L mol^{-1}), *t*-BuCON(C_6H_{11})$_2$ (4300 L mol^{-1}) ou *t*-BuCON(i-Pr)$_2$ (350 L mol^{-1}). Au contraire les constantes K_c diminuent régulièrement dans la série RCON(C_6H_{11})$_2$ de 20 L mol^{-1} pour MeCON(C_6H_{11})$_2$ à 3,5 L mol^{-1} pour *t*-BuCON(C_6H_{11})$_2$ au fur et à mesure que le substituant R sur le carbonyle augmente de volume dans l'ordre Me, Et, i-Pr et *t*-Bu. Ce comportement s'explique bien à partir d'une fixation sur l'oxygène du carbonyle par une augmentation de la tension frontale entre I_2 et le substituant R sur le carbonyle.

Complexes des amides encombrés avec le p*-fluorophénol dans* CCl_4

Le *p*-fluorophénol est un indicateur de référence pour mesurer le pouvoir accepteur de liaison hydrogène des bases (5). Nous avons montré dans un travail précédent (6) que la bande carbonyle des complexes des amides encombrées avec le *p*-fluorophénol est située à une fréquence plus basse ($\Delta\nu$ = 32 cm^{-1} pour *t*-BuCON(C_6H_{11})$_2$) que pour l'amide libre. Ceci caractérise à nouveau une fixation du *p*-fluorophénol sur le groupement carbonyle.

On observe de plus les mêmes effets stériques des substituants alkyles dans les complexes de RCON(C_6H_{11})$_2$ avec le *p*-fluorophénol qu'avec I_2. Les constantes de formation (entre parenthèses en L mol^{-1}) des complexes *p*-fluorophénol–RCON(C_6H_{11})$_2$ diminuent dans l'ordre :

$$\underset{(257)}{\text{MeCON}(C_6H_{11})_2} > \underset{(166)}{\text{EtCON}(C_6H_{11})_2}$$

$$\sim \underset{(174)}{\text{i-PrCON}(C_6H_{11})_2} > \underset{(115)}{t\text{-BuCON}(C_6H_{11})_2}$$

Complexes des amides encombrés avec $CHCl_3$ *et* $CHBr_3$

Le chloroforme est un donneur de liaison hydrogène C—H très utile pour mettre en évidence l'aptitude du groupement

TABLEAU 1. Fréquences carbonyle (cm^{-1}) des amides libres et complexés par I_2 dans l'heptane et constantes de complexation K_c (L mol^{-1})

Amide	ν(CO)libre	ν(CO)complexe	$\Delta\nu^a$	K_c
$MeCON(C_6H_{11})_2$	1659	1603	56	20
$EtCON(C_6H_{11})_2$	1661[b]	1597[c]	64	10
$i\text{-}PrCON(C_6H_{11})_2$	1654[b]	1608[d]	46	4
$t\text{-}BuCON(C_6H_{11})_2$	1640	1606[d]	34	3,5
$t\text{-}BuCON(i\text{-}Pr)_2$	1641	1606[d]	35	3

[a]$\Delta\nu$ = ν(CO)libre − ν(CO)complexe.
[b]Maximum du doublet causé par l'isomérie de rotation autour des liaisons Et—CO et i-Pr—CO.
[c]Une deuxième bande est observée à 1622 cm^{-1} et est attribuée à une résonance de Fermi avec un harmonique ou une combinaison à 1620 cm^{-1}.
[d]Bande dissymétrique.

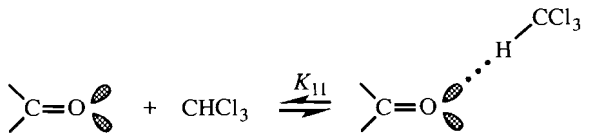
TABLEAU 2. Fréquences carbonyle (cm^{-1}) des amides libres et de leurs complexes 1 : 1 et 1 : 2 avec $CHCl_3$ ou $CHBr_3$ dans l'hexane et pourcentage de complexe 1 : 2 dans $CHCl_3$ ou $CHBr_3$ purs

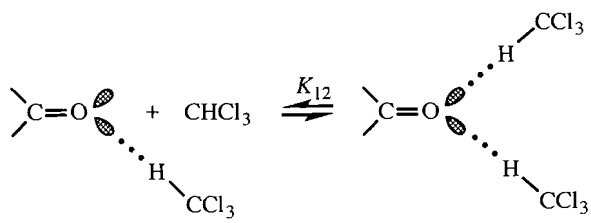
Complexes	ν(CO) libre	ν(CO)[a] 1 : 1	ν(CO)[b] 1 : 2	% de complexe[c] 1 : 2
$MeCONMe_2$–$CHCl_3$	1674	1661	1634	~100
$t\text{-}BuCON(C_6H_{11})_2$–$CHCl_3$	1639	1623	1602	~45
$t\text{-}BuCON(C_6H_{11})_2$–$CHBr_3$	1639	1622	1600	~45

[a]Pour x = 0,1.
[b]Pour x = 1.
[c]En supposant que les coefficients d'extinction molaires des bandes carbonyle des complexes 1 : 1 et 1 : 2 sont voisins.

carbonyle à former des complexes 1 : 2 correspondant à la fixation de deux molécules de $CHCl_3$ sur chacun des doublets libres de l'oxygène du carbonyle (7).

Ainsi pour le *N*,*N*-diméthylacétamide en solution dans des mélanges hexane–$CHCl_3$, l'augmentation progressive de la fraction molaire x de $CHCl_3$ montre la disparition progressive de la bande carbonyle libre (x = 0) à 1674 cm^{-1} au profit d'abord d'un complexe 1 : 1 majoritaire (x = 0,1) à 1661 cm^{-1} puis d'un complexe 1 : 2 majoritaire (x = 0,4) puis unique (x = 1) à 1634 cm^{-1} (figure 2).





Complexe 1 : 2

Les amides encombrées fixent également le chloroforme sur l'oxygène de carbonyle, puisque l'addition croissante de chloroforme ne fait apparaître de nouvelles bandes de complexes amides–$CHCl_3$ qu'aux basses fréquences (figure 3). Cependant la figure 3 montre que pour une fraction molaire x = 0,4 de chloroforme, le complexe 1 : 2 à 1606 cm^{-1} est devenu minoritaire et que même le chloroforme pur (x = 1) ne réussit pas à complexer totalement $t\text{-}BuCON(C_6H_{11})_2$ avec une stoechiométrie 1 : 2.

Il est clair que la constante de formation K_{12} du complexe 1 : 2 est fortement diminuée par l'effet stérique des substituants sur le carbonyle qui encombrent fortement la paire libre qui leur est proche.

Les mêmes observations ont été effectuées avec le bromoforme. L'ensemble de nos observations spectrales sur la complexation des amides avec $CHCl_3$ et $CHBr_3$ est rassemblé dans le tableau 2.

Conclusion

Les résultats précédents montrent que pour les amides encombrés, comme pour les amides non encombrés, la fixation du diiode et des donneurs de liaison hydrogène s'effectue sur l'oxygène et non pas sur l'azote de la fonction amide. Les resultats de Guihéneuf *et al.* ne peuvent alors s'expliquer que par une pureté insuffisante de certains de leurs produits, des résidus de l'amine servant à leur synthèse pouvant être à l'origine du comportement pseudo-amine des amides encombrés.

Stereoselective 1,3-debromination reactions

YINGCHUN LIU, TED S. SORENSEN,[1] AND FANG SUN
The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received September 4, 1992

YINGCHUN LIU, TED S. SORENSEN, and FANG SUN. Can. J. Chem. **71**, 258 (1993).

The metallate, $PPN^+Cr(CO)_4NO^-$, was used for the 1,3-debrominative reductive cyclization of the (±) and *meso* isomers of dimethyl 2,4-dibromoglutarate and dimethyl 2,4-dibromo-2,4-dimethylglutarate. In both (±) isomers, the reaction is stereospecific in giving the *trans* cyclopropane product. In the *meso* case, the reaction is unselective in the first case, but distinctly favors the *cis* cyclopropane isomer in the second set of compounds. This (±) and *meso* pair thus represent the first example of near stereospecificity in the debrominations of both 1,3-dibromo diastereomers. Using an enantiomerically enriched dimethyl 2,4-dibromoglutarate, and determining the absolute stereochemistry of the cyclopropane product, it was found that a strict double inversion (⟋⟍) mechanism is involved in the (±) debromination reaction and presumably also in the near-stereospecific *meso* case reported above.

YINGCHUN LIU, TED S. SORENSEN et FANG SUN. Can. J. Chem. **71**, 258 (1993).

On a utilisé le $PPN^+Cr(CO)_4NO^-$ pour provoquer une cyclisation impliquant une débromation réductrice-1,3 des isomères (±) et *méso* des 2,4-dibromoglutarate de diméthyle et 2,4-dibromo-2,4-diméthylglutarate de diméthyle. Avec les deux isomères (±), la réaction est stéréospécifique et elle conduit au cyclopropane *trans*. Avec les isomères *méso*, la réaction n'est pas sélective dans le premier cas, mais elle favorise nettement le cyclopropane *cis* dans le deuxième ensemble de produits. Cette paire d'isomères (±) et *méso* représente donc le premier exemple approchant la stéréospécificité lors de la débromation des deux diastéréoisomères des dérivés 1,3-dibromo. Utilisant un 2,4-dibromoglutarate de diméthyle énantiomériquement enrichi et déterminant la stéréochimie absolue du cyclopropane obtenu, on a trouvé qu'un mécanisme de double inversion stricte (⟋⟍) est impliqué dans la réaction de débromation du produit (±) et que cette conclusion s'applique probablement au cas pratiquement stéréospécifique rapporté plus haut.

[Traduit par la rédaction]

Introduction

1,3-Dehalogenation reactions leading to cyclopropanes have been known for over a century (1). However, compared to their 1,2-dehalogenation counterparts, their stereochemistry and mechanism have received less attention.

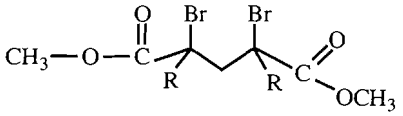
Based on several previous studies, it appears that a ⟋⟍-conformation double inversion mechanism (in the Nickon–Werstiuk terminology (2)) is generally involved, although most authors conclude that the reaction is a two-step process, in many cases involving a carbanion intermediate. Previous reagents used for 1,3-debrominations include reducing metals (Zn (3–5), Zn–Cu (6), Mg (6), Na (7), Li/Hg (8)), phosphines (6), $LiAlH_4$ (6), *n*-BuLi (9), iodide ion (6), thiophenoxide ion (6), and electrochemical $2e^-$ reduction (10–12).

Recent work in this laboratory has shown that metallate carbonyl anions are efficient $2e^-$ reductants of C—Br bonds (13–16). Using the PPN^+ ($\phi_3P{=}N^+{=}P\phi_3$) counterion, these metallate salts are soluble in nonpolar organic solvents such as methylene chloride or THF and are often effective at very sub-ambient temperatures, in contrast to most of the reagents listed above. In a preliminary study of 1,2-debromination reactions, we found the stereospecificity of the well-known *anti* elimination product to be comparable to that obtained from the best of the previously described procedures (17). For example, while many reducing reagents give stereospecific *trans*-alkene formation on debromination of *meso*-1,2-dibromides, in the difficult *cis*-alkene cases, such as the formation of *cis*-stilbene from (±)-1,2-dibromo-1,2-diphenylethane, the resulting stereospecificity is often poor or nonexistent (18, 19). However, use of the PPN^+-$Cr(CO)_4NO^-$ metallate (20) at −78°C gave a 19:1 *cis/trans*-stilbene mixture. Furthermore, both *cis* and *trans*-2-butene were taken through the cycle (bromination–debromination)$_2$ with no detectable loss of stereochemistry.

In this paper, we report a study of the stereochemistry associated with the 1,3-debromination of two 2,4-dibromoglutarate ester systems using the metallate anion $Cr(CO)_4NO^-$. These studies were carried out at a temperature of −78°C, or lower (or higher) in a few cases. We previously worked with several other easily obtained metallate anions, e.g., $Mn(CO)_5^-$ and $Fe(CO)_3NO^-$, but the chromium salt is by far the more reactive in these debromination reactions. By using both the (±) and *meso* isomers in the initial reactions, and by using a single enantiomer in a second-stage investigation, the overall reaction is shown to occur with at least a preference for double inversion at both C—Br centers, with the reaction being stereospecific in the (±)-reactant cases.

Results

The 2,4-dibromoglutarate systems **1** and **2** were used in this study.



1 R = H **1***a* (±); **1***b meso*
2 R = CH_3 **2***a* (±); **2***b meso*

The acids corresponding to compounds **1***a* and **1***b* were prepared as described by Ingold (21), noting the later revision of the original diastereomer assignments (22). Diastereomeric mixtures of **2***a*–**2***b* were prepared using the method of Chan and Wallace (23). The reaction product consisted of nearly equal amounts of the previously unreported diastereomers. Flash chromatography allowed the isolation of the two nearly pure diastereomers as crystalline

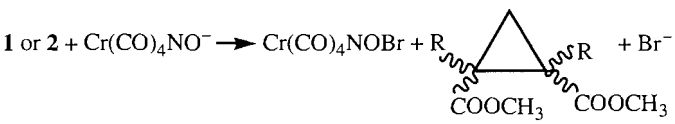
2*b*[a]	−78	CH_2Cl_2	**4***a* (19–25%)	**4***b* (75–81%)
2*b*[a]	−78	THF	**4***a* (10–12%)	**4***b* (88–90%)
2*b*[a]	−95	THF	**4***a* (10–14%)	**4***b* (86–90%)

[a]The data are uncorrected for ca. 2–4% of the (±) isomer as an impurity in the starting material.

compounds. The ^{1}H NMR spectra of **2***a* and **2***b* are distinctive and the assignments unequivocal (an A_2 system for **2***a* and AB for **2***b*, for the H-3 protons).

The reaction of these dibromides with $Cr(CO)_4NO^-$ was carried out on a small scale (0.1–0.4 mmol of dibromide and about a 20% molar excess of the chromium salt). The latter was dissolved in 1 mL of dry methylene chloride under nitrogen, cooled to −78°C or lower, and the dibromide in 1 mL of methylene chloride was added via syringe over about 2 min. All reactions are quite fast and can be monitored visually by noting a marked decrease in the intensity of the deep red color associated with $Cr(CO)_4NO^-$. After work-up (see Experimental), the isolated products were analyzed by ^{1}H NMR spectroscopy and in some cases by GLC. Cyclopropane formation appeared to be the sole reaction product under these experimental conditions. The overall reaction can be written:



3 R = H (*a*) *trans*; (*b*) *cis*
4 R = CH (*a*) *trans*; (*b*) *cis*

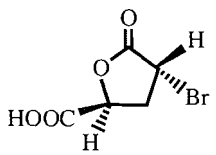
The ^{1}H NMR spectra of all of the possible cyclopropanedicarboxylates have been reported (24, 25), so the ratio of the *cis* and *trans* product isomers was determined by ^{1}H NMR integration, without separation of the *cis* and *trans* diesters in those cases where a mixture was obtained. The experimental results are shown in Table 1.

The results show that the (±) isomers are stereospecifically converted to a *trans*-cyclopropanedicarboxylate. The *meso*-dibromide **2***b* preferentially forms the *cis*-cyclopropanedicarboxylate, while *meso*-dibromide **1***b* forms comparable amounts of both the *cis* and *trans* cyclopropanes.

These results are consistent with a 1,3-debromination mechanism in which both C—Br centers undergo inversion or both involve retention, with the *meso* isomers having some additional mechanistic feature that allows for a further epimerization process.

If one carries out the debromination of either (+)-**1***a* or (−)-**1***a*, then the absolute configuration of the *trans*-cyclopropanedicarboxylate product will differentiate a double inversion (⟋⟍) versus a double retention (∪) mechanism. The optical purity of the product will further offer one a measure of how rigidly the stereochemistry is controlled in the debromination reaction since a *trans* cyclopropane is certainly the thermodynamically stable product (i.e., *trans* > *cis*), but one might conceivably have some loss of optical purity in forming this thermodynamically favourable product.

The preparation of an enantiomer of **1***a* proved somewhat problematic. A literature search revealed that 2,3-dibromosuccinic (26), 2,5-dibromoadipic (27), and 2,6-dibromopimelic acids (27) had long ago been resolved, but 2,4-dibromoglutaric acid was reported (28) to be unstable when the preparation of alkaloidal salts was attempted. We have verified this observation since all attempts to form diastereomeric amine salts produced only the crystalline lactone **5**, even at sub-ambient temperatures (e.g., −78°C), and even under the slightly acidic conditions that prevail when a 1:1 molar ratio of diacid and amine is present. Attempts to effect some kinetic resolution by converting only part of the acid to the lactone using chiral amines was also unsuccessful, as were recrystallizations of the acid from chiral



5 (racemic)

solvents. The formation of enantiomeric mono or diesters, followed by resolution, acid hydrolysis, and re-esterification, was considered, but a more practical approach involving the enzymatic hydrolysis of (±) **1***a* was ultimately found, in which the slower hydrolyzing diester enantiomer could be re-isolated and eventually used directly as a reactant.

Initial efforts using pig liver esterase (PLE) gave enantiomeric excesses of a (−)-diester estimated at 6–10% after 40–60% consumption of the racemic diester, assuming an $[\alpha]_D$ value of ca. −76 for the pure enantiomer of **1***a* (estimated from data for the homologous diacids mentioned above). This poor enantiomeric differentiation fits fairly well with that predicted from the Jones active site model (29) for PLE. Candida cylindracea lipase (CCL) proved superior to PLE, giving enantiomeric excesses of the (−)-diester estimated at 20–50% after 40–80% hydrolysis. With this level of enantiomeric excess, it proved possible to further enrich the material, since it was observed that recrystallization of

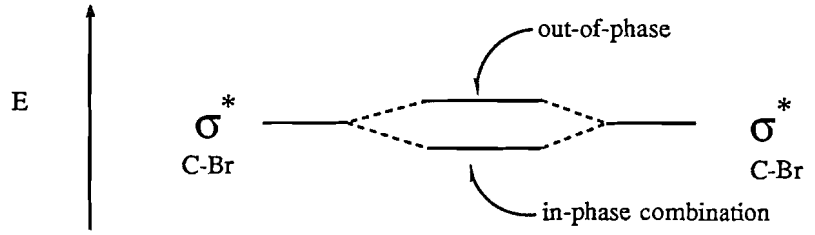
For personal use only.



Note: only a W-conformation of the C-Br bond would allow this possible weak back-lobe interaction. For other conformations, the σ* (C-Br) energy level would apply.

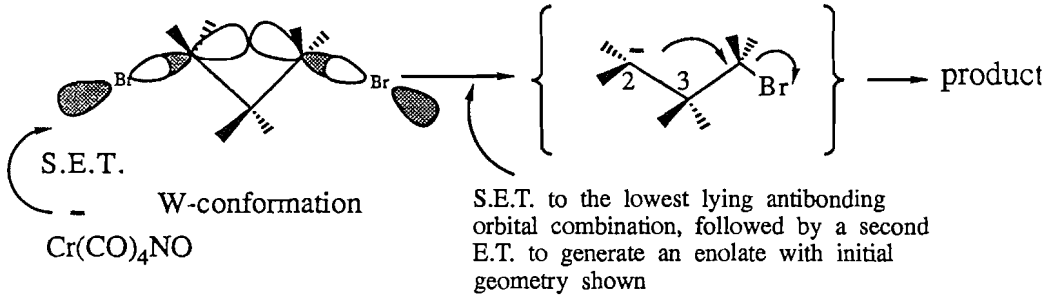


FIG. 1. Proposed mechanistic route for cyclopropane formation.

the diester from hexane preferentially formed crystals of the racemate. After several crystallization crops, a mother liquor diester sample estimated as 85% ee was obtained. Finally, the actual enantiomeric purity was determined by ^{1}H NMR spectroscopy using this diester sample and a chiral shift reagent in deuterocyclohexane solvent, giving a calculated $[\alpha]_D$ of −84, quite close to the estimated value (−76) used in the beginning. The absolute stereochemistry assigned to the laevorotatory diester (2*S*,4*S*) was based on correlations with the known absolute configuration of 2,4-dihydroxyglutaric acid (30) and with the configuration of several mono-α-bromocarboxylic acids or esters.

Reactions of 2*S*,4*S*-**1***a* with $Cr(CO)_4NO^-$, using material that was 78% ee or 34% ee, yielded (+)-dimethyl *trans*-cyclopropanedicarboxylate ((+)-**3***a*) with the same enantiomeric excess, within experimental error, as in the starting material. The $[\alpha]_D$ and absolute configuration of **3***a* are known (31), (+)-**3***a* corresponding to the 1*S*,2*S* configuration. This requires that the 1,3-debromination reaction must have proceeded with strict double inversion.

Discussion

The mechanism by which metallates such as $Cr(CO)_4NO^-$ react with organobromine compounds has not been investigated, although one might anticipate that single electron transfer (S.E.T.) might initially occur, and that this electron transfer would be most facile when the dibromides have already adopted a ⩘ conformation, which allows for back-lobe orbital overlap (an inphase combination of the antibonding C—Br σ*-orbitals that lowers the σ*-orbital energy, see Fig. 1). Independent evidence for a more easily reducible ⩘ conformation of 1,3-dibromides comes from the electrochemical studies of Rifi (10, 32, 33) and the more recent "back-lobe-overlap" concept has been used by a number of authors in discussing dehalogenation reactions. A mechanism for our reactions is pictured in Fig. 1.

We also assume that a second electron transfer occurs before the initially formed radical pair can dissociate. This leads to $Cr(CO)_4NOBr$ and a short-lived enolate intermediate. In the (±) isomers, this enolate has a favorable steric arrangement and *trans*-cyclopropane isomers are generated without any bond-rotation process intervening. In the *meso* isomers, however, an unfavorable geometry can be relieved by a bond rotation (C2—C3 bond), which would necessarily have to be competitive with the actual elimination reaction in order to rationalize our results. The higher specificity observed for **2***b* (vs. **1***b*) is consistent with this picture since there is less driving force for the enolate bond rotation in **2***b* (CH_3 and $COOCH_3$ are somewhat similar in size) and the added methyl group in **2***b* should slightly destabilize the enolate, leading to a more rapid elimination reaction.

In previous work by Fry and Britton (11) on 2,4-dibromopentanes, a ⩘ mechanism has been inferred for the electrochemical reductive cyclization reaction even though the reactions show essentially no stereospecificity (i.e., (±) and *meso* isomers yield nearly the same product mixture). These authors showed, however, that the (+)-dibromide leads to (+)-*trans*-1,2-dimethylcyclopropane (a stereospecific double inversion if one focuses only on this product of the reaction). Schlosser and Fouquet (34) reported similar observations starting with an optically active dibromononane and using lithium amalgam. Bordwell and Jarvis also studied the stereochemistry of the Ramberg–Baeklund reaction (a debromination variant) and provided evidence for a ⩘ double inversion process leading to the episulfone intermediate. Trost *et al.* have shown that (±)- and *meso*-2,4-dibromopentane can be stereoselectively converted to cyclopropanes using *n*-BuLi (*meso* gives mainly *cis*, (±) mainly

trans), but covalently bonded lithium intermediates are likely involved.

We believe that the present study is the first one to show that (±)- and *meso*-1,3-dibromo isomers react with at least some stereospecificity *and* that the double inversion mechanism is operative (exclusively with the (±) isomers).

These results for 1,3-debromination can be compared with those for 1,2-debrominations. The latter reactions are usually thought of as strongly concerted (anti-periplanar E2), but clearly the inability to stereospecifically produce *cis*-stilbene from the (±)-dibromide implies some breakdown in this common assumption. It is very likely that 1,3-debrominations are less strongly controlled by stereoelectronic factors, but use of the $Cr(CO)_4NO^-$ salt in this regard may be of advantage since the resulting reactions occur at quite low temperatures and in quite nonpolar solvents where carbanion intermediates are poorly stabilized.

Experimental

Tetrahydrofuran (THF) was purified by distillation from sodium benzophenone ketyl. Hexane, pentane, methylene chloride, and acetonitrile were dried over 3A molecular sieves. ^1H and ^{13}C NMR spectra were obtained on a Bruker ACE 200 (δ values in $CDCl_3$, *J* in Hz). For ^1H NMR, s = singlet, d = doublet, t = triplet, q = quartet. For ^{13}C NMR, q = quaternary; DEPT 90 and 135 experiments were used to determine multiplicities. Mass spectra were determined on a Kratos MS-80, a VG-7070, or an HP 5971A GC–MS system, using a 12.5 m × 0.20 mm (i.d.) DB-1 capillary column. Other GC data were measured on an HP-5890 instrument using 530-μm columns, OV-1. Optical rotations were determined on a Rudolph Autopol III polarimeter, using 5-cm cells. Flash chromatography was performed using silica gel (230–400 mesh). Glassware was oven-dried.

$PPN^+Cr(CO)_4NO^-$

This salt was prepared as described (20) from $Cr(CO)_6$ and $PPN^+NO_2^-$, carrying out all operations under an inert atmosphere.

(±)-2,4-Dibromoglutaric acid and meso*-2,4-dibromoglutaric acid* were prepared as described by Ingold (21). ^1H NMR spectra were in accord with literature values (22). ^{13}C NMR, (±) isomer: 170.0 (C=O), 44.5 (CH), 39.4 (CH_2); *meso* isomer: 169.8 (C—O), 42.9 (CH), 40.3 (CH_2).

Dimethyl (±)- and meso*-2,4-dibromoglutarates (**1**a and **1**b)* were prepared from the acids using diazomethane (ether solvent). These esters have been previously reported (21). During the esterification, and even on storage, a small amount of the *meso* isomer is isomerized to the (±) isomer. For the reaction results shown in Table 1, a *meso* diester of ca. 97% purity was used. These two esters have mutually well-resolved ^1H and ^{13}C NMR spectra.

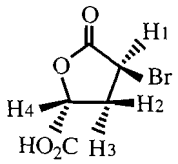
Dimethyl (±)- and meso*-2,4-dibromo-2,4-dimethylglutarates (**2**a and **2**b)*

To a solution of diisopropylamine (3.54 mL, 0.025 mol) in dry THF (15 mL) was added *n*-butyllithium (10 mL, 0.025 mol) at −30°C under argon. After the reaction mixture was stirred at −30°C for 15 min, a solution of dimethyl 2,4-dimethylglutarate (35) in THF (5 mL) was added dropwise at −78°C. After 15 min, chlorotrimethylsilane (3.24 mL, 0.025 mol) was added and the reaction mixture was slowly warmed to room temperature (2 h). The solvent was removed *in vacuo* and the residue was dissolved with 10 mL of hexane and filtered, using a further 5 mL of hexane wash. The solvent was removed *in vacuo* and *N*-bromosuccinimide (13.5 g, 0.030 mol) in 30 mL of dry CH_2Cl_2 was added. After 12 h, the reaction mixture was poured into a mixture of water and CH_2Cl_2, the organic layer was separated from the aqueous layer, and washed successively with saturated $NaHCO_3$ solution, brine, and water. After drying and evaporation, a residue mixture of the title esters was obtained, 2.1 g (62%). GC–MS showed that the ratio of (±) and *meso* isomers was ca. 1.4:1. The isomers were separated on a silica gel column eluted with hexane – ethyl acetate (50:1 v/v) to give the (±) isomer **2***a* (860 mg, crystallized from hexane), mp 63–64°C, and the *meso* isomer **2***b* (220 mg, crystallized from hexane), mp 53–54°C.

For **2***a*, ^1H NMR: 3.80 (6H, s), 3.43 (2H, s), 1.89 (6H, s). ^{13}C NMR: 171.2 (C=O), 56.6 (q), 53.2 (OCH_3), 52.3 (CH_2); 26.9 (CH_3). MS: 317 (3), 315 (6), 313 (3), 267 (45), 265 (45), 235 (100), 233 (97), 126 (92), 153 (62). Anal. calcd. for $C_9H_{14}Br_2O_4$: C 31.23%, H 4.11%; found: C 31.08%, H 3.95%. For **2***b* (ca. 97% purity), ^1H NMR: 3.82 (6H, s), 3.36, 3.25 (2H, AB system, J = 15.1), 1.96 (6H, s). ^{13}C NMR: 171.3 (C=O), 58.2 (q), 53.5 (OCH_3); 51.6 (CH_2), 28.5 (CH_3). The MS fragmentation pattern is the same as for **2***a*. High-resolution MS, calcd. for $C_9H_{14}{}^{79}Br^{81}BrO_4 - OCH_3$: 314.9055; found: 314.9059.

*Isolation of lactone **5***

Treatment of (±)-2,4-dibromoglutaric acid with one equivalent of (−)-brucine ((−)-cinchonidine or (+)-cinchonine led to similar results) in acetone solution led to a gummy precipitate of brucine · HBr. After decanting/filtering, the acetone solvent was evaporated to give a mixture of solid and oil. This mixture was extracted with hot chloroform, and then some of the chloroform was evaporated to yield, on cooling, crystals of the title lactone, mp 121–123°C, after two recrystallizations from chloroform. ^1H NMR:



(±) **-5**

H1, 4.86; H2, 2.85; H3, 3.00; H4, 5.20; J_{12} = 5.5; J_{13} = 7.3; J_{23} = 14.4; J_{24} = 7.1; J_{34} = 7.1. ^{13}C NMR: C2, 38.6; C3, 37.4; C4, 75.3; carbonyls, 170.1, 172.6. MS: 208 (0.24), 163 (49), 165 (47), 135 (11), 137 (10), 85 (100), 107 (28), 109 (26). High-resolution MS, calcd. for $C_5H_5O_4{}^{79}Br$: 207.9371; found: 207.9375.

*Enzymatic hydrolysis of **1**a*

Since the PLE hydrolysis yielded inferior results compared to CCL, only the latter reaction is described in detail. To a 1-L round-bottom flask was added a solution of 1.70 g (5.3 mmol) of **1***a* in 200 mL of methanol. This was followed by the addition of 200 mL of tris buffer solution (pH = 8.5, approximately 0.1 M in buffer) and 0.70 g (490 000–1 050 000 units) of Candida cylindracea lipase (CCL) (Sigma Chemical Co.) The resulting mixture was an opaque suspension since the dibromo ester is not water soluble and the enzyme is probably not very soluble in H_2O–CH_3OH. The reaction mixture was stirred (magnetic bar) at room temperature for 26 h. The reaction solution was then acidified by adding concentrated HCl, and extracted with diethyl ether (4 × 100 mL). The extracts were combined, dried over $CaCl_2$, filtered, and the solvent removed on a Rotovap. An ^1H NMR integration of peaks for the unhydrolyzed diester compared to those for lactone **5** and 2,4-dibromoglutaric acid (no mono-ester was observed, presumably because it is more soluble than the diester and more rapidly hydrolyzed) yielded a 45% hydrolysis conversion, but the actual conversion is probably higher since the material balance was less than the theoretical, due likely to the incomplete extraction of the diacid. The residue was subjected to flash chromatographic separation (4:1 v/v hexane–ether) to give 0.37 g (22% recovery) of the diester, $[\alpha]_D^{20}$ −42 (50% ee). Recrystallization of this material from hexane yielded crystals that were mainly the racemic diester. Two more crops of crystals were obtained by concentration of the mother liquors, but the third crop of crystals had an enantiomeric excess similar to that of the filtrate. The final recovered

material was subject to a bulb-to-bulb distillation purification to give an $[\alpha]_D^{20}$ of 65.5. Using this material in cyclohexane-d_{12} with (−)-[Eu(hfc)] (Aldrich Chemical Co.) and integrating the OCH_3 peaks gave a calculated 78% ee determination. Control experiments were performed on (±)-**1***a* and by using (+)-[Eu(hfc)]. The specific rotation, $[\alpha]_D$, of (−)-**1***a* was calculated to be −84°. Control experiments without the enzymes showed no detectable hydrolysis of the diester.

General preparation of the cyclopropanedicarboxylates

Into a small Schlenk tube fitted with a septum and stopcock sidearm, under a nitrogen atmosphere, and with magnetic bar stirring, a solution of 0.10 g (0.14 mmol) of $PPN^+Cr(CO)_4NO^-$ in 1 mL of solvent (see Table 1) was prepared and cooled to the requisite temperature using an external bath. The dibromo ester (0.12 mmol) in 1 mL of solvent was added over a period of ca. 2 min. From the visual color change (considerable loss of intense red color) the reactions appeared to be over almost immediately at −78°C. The reactions were allowed to warm slowly to room temperature and 10 mL of pentane (or hexane) was added. The solutions were recooled to −78°C and stirred for about 40 min. The solution was filtered from the accumulated precipitate (using a $MgSO_4$ column in some instances) while cold, and the solvent was removed on a Rotovap to yield the crude product. Generally, 80–90% crude yield of the cyclopropanedicarboxylates was obtained in the larger scale runs, and the material was further purified by flash chromatography and (or) bulb-to-bulb distillation in some instances. In some cases, total product yields were determined by ^1H NMR integration using a weighed standard. The ratios of the *cis* and *trans* isomers were based on ^1H NMR integrations. In a few cases, GLC peak areas were also determined and these agreed well with the NMR results.

*Conversion of (−)-(2S,4S)-**1**a into (+)-(1S,2S)-**3**a*

A debromination reaction was carried out with 86.0 mg (0.27 mmol) of **1***a* (78% ee) and 400 mg (0.55 mol, a twofold excess) of the $PPN^+Cr(CO)_4NO^-$. After work-up, the crude product was purified by flash chromatography and the residue, after solvent evaporation, was distilled (bulb-to-bulb), yielding the pure diester **3***a*. This sample had $[\alpha]_D^{20}$ +181, which corresponds to 78% ee. Similar results were obtained using (−)-**1***a* of 34% ee.

Received December 9, 1991[3]

ECKART AHLENSTIEL, WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **71**, 263 (1993).

The syntheses and structures of the bicyclic boron-nitrogen betaines 1-methyl-5-(3-nitrophenyl)-4,6,9-trioxa-1-azonia-5-boratabicyclo[3.3.1]nonane, **7***a*, and 3,3,4-trimethyl-1-(3-nitrophenyl)-2,6,7-trioxa-3-azonia-1-boratabicyclo[2.2.2]-octane, **14***a*, are reported. Crystals of **7***a* are orthorhombic, $a = 20.256(2)$, $b = 37.652(2)$, $c = 6.642(1)$ Å, $Z = 16$, space group $Fdd2$, and those of **14***a* are orthorhombic, $a = 21.402(2)$, $b = 11.334(3)$, $c = 11.248(2)$ Å, $Z = 8$, space group $Pbca$. The structures were solved by direct methods and were refined by full-matrix least-squares procedures to $R = 0.038$ and 0.045 ($R_w = 0.036$ and 0.053) for 975 and 1646 reflections with $I \geq 3\sigma(F^2)$, respectively. The X-ray analyses establish the bicyclo[3.3.1]nonane and bicyclo[2.2.2]octane "cage" structures for **7***a* and **14***a*, respectively. Bond lengths involving the tetrahedral boron atom are (N)O—B = 1.519(5), (C)O—B = 1.444(6) and 1.443(6), C(aryl)—B = 1.602(5) Å for **7***a*; and (N)O—B = 1.530(3), (C)O—B = 1.446(3) and 1.455(3), C(aryl)—B = 1.608(3) Å for **14***a*. Weak C—H···O interactions are the main feature of the crystal packing arrangements of both compounds.

ECKART AHLENSTIEL, WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **71**, 263 (1993).

On a réalisé la synthèse des bétaïnes bicycliques bore/azote, 1-méthyl-5-(3-nitrophényl)-4,6,9-trioxa-1-azonia-5-boratabicyclo[3.3.1]nonane (**7***a*) et 3,3,4-triméthyl-1-(3-nitrophényl)-2,6,7-trioxa-3-azonia-1-boratabicyclo[2.2.2]-octane (**14***a*) et on en a déterminé les structures. Les cristaux du produit **7***a* sont orthorhombiques, groupe d'espace $Fdd2$, avec $a = 20{,}256(2)$, $b = 37{,}652(2)$ et $c = 6{,}642(1)$ Å et $Z = 16$ alors que ceux du composé **14***a* sont orthorhombiques, groupe d'espace $Pbca$, avec $a = 21{,}402(2)$, $b = 11{,}334(3)$ et $c = 11{,}248(2)$ Å et $Z = 8$. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}038$ et 0,045 ($R_w = 0{,}036$ et 0,053) pour respectivement 975 et 1646 réflexions avec $I \geq 3\sigma(F^2)$. Les déterminations par rayons X ont permis de confirmer les structures en formes de "cage" pour les bicyclo[3.3.1]nonane et bicyclo[2.2.2]octane des composés **7***a* et **14***a* respectivement. Les longueurs des liaisons impliquant un atome de bore tétraédrique sont (N)O—B = 1,519(5), (C)O—B = 1,444(6) et 1,443(6) et C(aryl)—B = 1,602(5) Å pour le composé **7***a* et (N)O—B = 1,530(3), (C)O—B = 1,446(3) et 1,455(3) et C(aryl)—B = 1,608(3) Å pour le composé **14***a*. Pour les deux composés, la caractéristique principale de l'entassement du cristal est un ensemble de faibles interactions C—H···O.

[Traduit par la rédaction]

Introduction

The condensation of bis(2-hydroxyethyl)amines **1** and arylboronic acids leads to 1,3-dioxa-6-aza-2-boracyclooctanes **2** that are known to undergo transannular N → B coordination to form the stable bicyclo[3.3.0]octane ring systems **3**. The structure **3** for these materials has been confirmed by chemical and physical investigations (1), including an X-ray crystallographic analysis of the *N*-unsubstituted derivative **3** (R = H, Ar = C_6H_5) (2). Employing the *N*-oxides **4**, obtained by reaction of **1** with hydrogen peroxide (3, 4), the condensation with an arylboronic acid could result in both the eight-membered cyclic arylboronate **5** and the six-membered chelate **6**.[4] Both products (**5** and **6**) could subsequently cyclize to the bridged-ring compound **7**, the *N*-oxide **5** undergoing an intramolecular O → B coordination and the chelate intermediate **6** by further intramolecular condensation.

The bicyclo[3.3.1]nonane ring system **7** has already been postulated for some phenylboronates of this type (4) but has not been established to date. To achieve this goal, at least for the solid state by single-crystal X-ray analysis, we synthesized several 3-nitrophenylboronates **7** (Ar = 3-$NO_2C_6H_4$). The nitrophenyl substituent was expected primarily to enhance the intramolecular O—B coordination by an inductively increased Lewis acidity (5) of the boronate function, but, as a bonus, produced the derivatives **7***a–c* that formed better crystals than did other analogs. The elemental analyses indicate a complete condensation in each case that is also confirmed by infrared and ^{1}H nmr spectra. The tetracoordination at the boron atom, even in $CDCl_3$ solution, can be deduced (6) from the ^{11}B nmr spectra of **7***a* ($\delta(Et_2OBF_3) = 5.4$ ppm) and **7***b* (5.2 ppm). This evidence strongly supports the intramolecular complex **7** rather than the "open" *N*-oxide **5**, but cannot unambiguously rule out

*inter*molecular (polymeric) O—B adducts of **5** or a dimerization product of **5**, like **8**. Similar chemical and spectroscopic features should also be shown by polycondensates of **6** or by the cyclic bis-condensate **9**, which can also be understood as a dimer of **7**. However, the ring sizes of **8** and **9**, and the mass spectral data for **7***a* (EI: 4% M^+; CI: 86% $M^+ + 1$) make these structural alternatives less probable than the monomer **7**. Another isomer of **7** with tetracoordinate boron also had to be considered: the rearrangement product **10** that is conceivable as a result of an intramolecular redox process **7** → **10** causing the oxidation of the boronic acid moiety to a boric acid moiety at the expense of the *N*-oxide function. Comparable findings have been reported for diarylboron chelates of *N*,*N*-dialkyl-*N*-(2-hydroxyalkyl)-amine-*N*-oxides under thermal stress (7, 8). However, a compound of type **10** should be obtainable by condensation of the bis(2-hydroxyethyl)amine **1**, boric acid, and a phenol (Ar-OH). Since we have not yet been able to isolate a crystalline product from this reaction it seemed unlikely that the thermal rearrangement product **10** had been formed. The *N*-methyl derivative **7***a* produced the best crystals for a definitive elucidation of the molecular structure by an X-ray crystallographic analysis.

A problem similar to that detailed above for **7** and its alternatives arises from the condensation of the *N*-oxide **11** with an arylboronic acid. In this case two primary condensates, the six-membered arylboronate **12** and the six-membered chelate **13**, could cyclize to the "cage" compound **14**, either by O → B coordination of the *N*-oxide group to the boronate group in **12**, or by further intramolecular condensation in **13**. In addition to the previously postulated bicyclo[2.2.2]octane ring system **14** (9), possible polyadducts of **12** or the dimer **15**, polycondensates of **13** or the cyclic bis-condensate **16**, and the isomeric rearrangement product **17** had to be considered. The ^{11}B nmr spectra, two of which are reported here,[5] show respective shift values of $\delta(Et_2OBF_3) = 4.0$ and 4.7 ppm for **14***a* (Ar = 3-$NO_2C_6H_4$) and **14***b* (Ar = 4-$CH_3OC_6H_4$). These values are consistent with the presence of a tetracoordinated boron atom (6). Experiments to crystallize a type **17** condensate from the reaction of 2-dimethylamino-2-hydroxymethylpropanol, boric acid, and a phenol have been unsuccessful so far, supporting the

[5] ^{11}B nmr spectra of $CDCl_3$ solutions of **14***a* and **14***b* were determined at 64.21 MHz.

postulated structure **14**. To establish the structure in the solid state an X-ray crystallographic analysis of **14***a* (Ar = 3-$NO_2C_6H_4$), which forms the best crystals, was undertaken.

Boronate matrices have been shown to be very useful for the separation of various polyfunctional biomolecules, metabolites, and xenobiotics (10–12). Since nitrophenylboronate matrices in particular offer enhanced binding of most molecules having an affinity for such matrices (12), the structural elucidation of the nitrophenylboronate complexes in this work should supply valuable information on the chemical binding and geometry of species resulting from the interaction between polyfunctional ligands and boronic acids. There is also great interest in boronate complexes of polyfunctional compounds with respect to the transfer of reporter reagents into living cells in the area of biomedical research (13) and also in the construction of chiral cavities as specific receptor sites (14), broadening the significance of structural investigations of such boronate complexes.

Experimental

*1-Methyl-5-(3-nitrophenyl)-4,6,9-trioxa-1-azonia-5-boratabicyclo[3.3.1]nonane, 7*a

3-Nitrophenylboronic acid (167 mg, 1 mmol) and 1 mmol of the oily crude *N,N*-bis(2-hydroxyethyl)-*N*-methylamine *N*-oxide **4** (R = CH_3), prepared as described previously for similar *N*-oxides (3, 4, 9), were dissolved in 10 mL of ethanol and heated to the boiling point under reflux for 15 min. The solvent was partially distilled off. Crystallization started spontaneously or upon the addition of diethyl ether. Yield: 165 mg (62%), mp 191–193°C (from ethanol/diethyl ether). Infrared (KBr): 1605 (C=C), 1520 (NO_2, asym), 1350 (NO_2, sym) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 3.30 (s, CH_3), 3.65 (t, J = 5 Hz, 2 NCH_2C), 3.9–4.5 (m, 2 OCH_2), 7.40 (t, 5-H of 3-nitrophenyl), 7.80–8.16 (m, 4-H and 6-H of 3-nitrophenyl), 8.40 (d, 2-H of 3-nitrophenyl); ^{11}B nmr (64.2 MHz, $CDCl_3$), δ (Et_2OBF_3): 5.4 ppm ($w_{1/2}$ = 128 Hz). Mass spectrum (EI, 150°C), *m/z*: 266 (4%, M^+), 222 (60%), 144 (100%), 114 (43%); (CI, NH_3, pos., 175°C), *m/z*: 267 (86%, M^+ + 1), 251 (75%), 191 (33%), 118 (100%). Anal. calcd. for $C_{11}H_{15}BN_2O_5$: C 49.66, H 5.68, N 10.53; found: C 49.62, H 5.65, N 10.73.

*1-Butyl-5-(3-nitrophenyl)-4,6,9-trioxa-1-azonia-5-boratabicyclo[3.3.1]nonane, 7*b

3-Nitrophenylboronic acid and *N*-butyl-*N,N*-bis(2-hydroxyethyl)amine *N*-oxide **4** (R = n-C_4H_9) were reacted as described for **7***a*. Yield: 49 mg (16%), mp 128–133°C (from ethanol/diethyl ether). Infrared (KBr): 1605 (C=C), 1520 (NO_2, asym), 1350 (NO_2, sym) cm^{-1}; ^{11}B nmr (64.2 MHz, $CDCl_3$), δ (Et_2OBF_3): 5.2 ppm ($w_{1/2}$ = 170 Hz). Anal. calcd. for $C_{14}H_{21}BN_2O_5$: C 54.57, H 6.87, B 3.51, N 9.09; found: C 54.58, H 7.05, B 3.59, N 9.36.

*1-Cyclohexyl-5-(3-nitrophenyl)-4,6,9-trioxa-1-azonia-5-boratabicyclo[3.3.1]nonane, 7*c

3-Nitrophenylboronic acid and *N*-cyclohexyl-*N,N*-bis(2-hydroxyethyl)amine *N*-oxide **4** (R = C_6H_{11}) were reacted as described for **7***a*. Yield: 200 mg (60%), mp 163–164°C (from ethanol/diethyl ether). Infrared (KBr): 1605 (C=C), 1520 (NO_2, asym), 1350 (NO_2, sym) cm^{-1}. Anal. calcd. for $C_{16}H_{23}BN_2O_5$: C 57.51, H 6.94, B 3.24, N 8.38; found: C 57.08, H 6.92, B 3.18, N 8.29.

3,3,4-Trimethyl-1-(3-nitrophenyl)-2,6,7-trioxa-3-azonia-1-boratabicyclo[2.2.2]octane, ***14***a

This compound was prepared as described previously (9). Additional analytical data: infrared (KBr): 1605 (C=C), 1520 (NO_2, asym), 1350 (NO_2, sym) cm^{-1}; ^1H nmr (90 MHz, DMSO-d_6/

Crystals suitable for X-ray analysis were obtained by repeated, very slow, recrystallization from ethanol.

X-ray crystallographic analyses of 7a *and* **14**a

Crystallographic data for 7*a* and **14***a* appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 40.6–75.9° for 7*a* and 51.9–90.1° for **14***a*. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed linear decays of 7.3% for 7*a* and 5.3% for **14***a*. The data were processed,[6] and corrected for Lorentz and polarization effects, decay, and absorption (empirical, based on azimuthal scans for four reflections).

The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. The central carbon atoms of the three-atom bridges of the bicyclo[3.3.0]nonane skeleton of 7*a* were refined using a split-atom twofold disordered model. The thermal parameters for the remaining atoms of these two -OCC- moieties and the *N*-methyl carbon atom C(5) suggest minor disordering of these atoms as well. The low number of significant data for this non-centrosymmetric structure and the small separation between components preclude a complete resolution of the disorder. The site occupancy factors for the major component atoms (C(2) and C(4)) were refined, the sums of the occupancies at each site being constrained to equal 1.00. The low-occupancy carbon atom C(2A) in 7*a* was refined isotropically and all other non-hydrogen atoms of both structures were refined with anisotropic thermal parameters. The hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, B_H = 1.2 $B_{bonded\ atom}$). Corrections for secondary extinction were applied for both structures, the final values of the extinction coefficients being 1.27 × 10^{-6} for 7*a* and 1.11 × 10^{-6} for **14***a*. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (15). A parallel refinement of the structure of 7*a* having the opposite polarity gave slightly higher residuals, the R and R_w factor ratios being 1.0026 and 1.0028, respectively. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles appear in Tables 2–4, respectively. Hydrogen atom

parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes, and measured and calculated structure factor amplitudes for both structures have been supplied as supplementary material.[7]

[7]Supplementary material mentioned in the text may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom coordinates and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

Results and discussion

The X-ray analyses establish the postulated structures of **7***a* and **14***a* (Fig. 1), both representing examples of bicyclic boron-nitrogen betaines with the anionic borate centre at one of the bridgehead positions and the cationic ammonium nitrogen atoms at the other bridgehead position in **7***a*, and forming part of the bridge itself in **14***a*. Compound **7***a* is a new type of hetero-analog of bicyclo-[3.3.1]nonane (14) containing five hetero atoms in the ring skeleton and bearing substituents at both bridgeheads. As a result of the disordering of the "wing tip" atoms C(2) and C(4) (see experimental section), there are three possible conformations for the bicyclo[3.3.1]nonane skeleton in **7***a*. The most probable conformation (50%, based on the re-

fined site occupancy factors) is the chair–chair arrangement involving the higher-occupancy sites C(2) and C(4). The two possible chair–boat conformations, C(2) and C(4A), C(2A) and C(4), have a combined probability of 44% while the boat–boat form with C(2A) and C(4A) has a 6% probability. For the chair–chair conformation, the O—C—C "wings" appear to be somewhat flattened, probably due to steric repulsions between the *endo* hydrogen atoms at C(2) and C(4). There also appears to be some flattening of the boat components but this may result from errors arising from incomplete modelling of the disorder since the lower-occupancy sites are involved. It is likely that the atoms adjacent to C(2) and C(4) also suffer minor unresolved disorder. In **14***a* the *N*-oxide oxygen–boron coordination (O(1)—B(1)) forces the 1,3-dioxa-2-boracyclohexane ring of the cyclic boronate of type **12** into a somewhat distorted boat conformation.

The tetracoordinated sp^3-boron atoms in both **7***a* and **14***a* show nearly ideal tetrahedral ligand arrangements. Comparable modes of boron coordination have been observed in the intramolecular nitrone adduct **18** (16) and also in a similar cage structure reported for the intramolecular amine *N*-oxide adduct **19** (17). Compound **18** possesses exactly the same heterobicyclo[2.2.2]octane ring system as **14***a*, whereas **19** represents a benzo-fused derivative of an analogous heterobicyclo[3.2.1]octane skeleton. Another related cage structure, containing a tetracoordinated boron atom, has been reported for the bicyclic anion **20** (18).

Within the 1,3-betainic ring segments in **7***a*, **14***a*, **18**, and **19**, the N—O(B) distances in **7***a*, **14***a*, and **19** (17) (1.427(3), 1.425(2), and 1.424(1) Å, respectively) are equal within experimental error and are significantly longer than the N—O bond of 1.352(5) Å in **18** (16), consistent with the retention of some double bond character in the latter case. The (N)O—B bond lengths in **7***a* (1.519(5) Å), **14***a* (1.530(3) Å, and **19** (1.539(2) Å) differ slightly, presumably for steric reasons. The ring system in **7***a* is practically free from angular strain while those in **14***a* and **19** would be expected to have somewhat more strained ring skeletons. The shorter (N)O—B bonds in **7***a* and **14***a* are in accord with the increased Lewis acidity of the boronic acid relative to those in **18** and **19**. The substantially longer (N)O—B bond in **18** (1.601(7) Å) reflects primarily the lower basicity of the azomethine *N*-oxide group compared with that of the amine *N*-oxide group in **14***a*, and perhaps, to a lesser extent, the lower Lewis acidity of the phenylboronic acid relative to that of the 3-nitrophenylboronic acid components of these two compounds.

The B—C(aryl) bond lengths **7***a* (1.602(5) Å) and **14***a* (1.608(3) Å) may be compared with other (sp^3)B—C(aryl) distances that range from 1.581(5) to 1.606(5) Å (19, and references therein). The B—C(aryl) bonds in the present structures are somewhat longer than those in **18**, **19**, and **20** that are all 1.591 (2–8) Å, consistent with stronger binding of the 3-nitrophenylboron moiety to the oxygen atoms of the tridentate ligands. The sums of bond lengths about the boron

atoms in **7*a*** (6.008 Å)[8] and **14*a*** (6.039 Å) are similar to the values reported for **18** (6.101 Å), **19** (6.099 Å), **20** (6.042 Å), and other compounds having the (aryl)CBO_3 ligand set (19, and references therein) and also that reported for the (alkyl)CBO_3 ligand set of a methylboronate-capped tris(dioximate) complex of Tc(III) (6.093 Å) (20). The bond length sum reflects the overall steric strain at the boron centre.

In addition to the compounds **14*a*** (this work) and **18** (16), which represent the first structurally characterized arylboronates having a bicyclo[2.2.2]octane ring system, one other analogous structure, **21**, derived from a tripodal phosphane, has been reported (21). The larger radius of phosphorus relative to that of oxygen gives rise to a substantial distortion of the bicyclo[2.2.2]octane skeleton, most noticeably affecting the bond angles about the boron atom: the O—B—O angles in **14*a*** range from 107.2(2) to 111.1(2)°, whereas the P—B—P angles in **21** are significantly more acute, ranging from 101.3(5) to 104.6(5)°. Bicyclo[2.2.2]octane skeletons have been postulated for the arylboronates of 2,2-bis(hydroxymethyl)propanal and 2,2-bis(hydroxymethyl)-propanamine derivatives, **22** and **23**, that were believed to be at least partially stabilized by intramolecular coordination. Infrared and nmr (22, 23) as well as FAB mass spectroscopic data (24) indicated a boronate cage structure featuring a tetracoordinated boron atom. The structure of **14*a*** provides additional support for the postulated structures **22** and **23**. The bicyclo[3.3.1]nonane and bicyclo[2.2.2]octane ring skeletons found for the two types of compounds studied here appear to be very stable. Several samples of type **7** and **14** compounds have remained unchanged over a period of 20 years, stored under normal atmospheric conditions in the laboratory.

The most notable features of the crystal packing arrangements of both **7*a*** and **14*a*** are pairs of weak intermolecular C—H···O interactions. In **7*a*** these interactions both involve hydrogen atoms bound to *N*-methylene car-

[8]Due to ligand disordering, the O—B distances in **7*a*** may suffer some degree of foreshortening, resulting in a smaller sum than is actually the case. This sum would nonetheless be expected to be smaller than in the more strained compound **14*a***.

bon atoms of the chair forms of the 1-aza-2,4-dioxa-3-boracyclohexane rings and (C)O(B) oxygen atoms of the same rings (C(1)—H(1)···O(2)(1/2 + x, 1/4 − y, 1/4 − z) and C(3)—H(6)···O(3)(1/2 + x, 1/4 − y, 1/4 − z), H···O = 2.33 and 2.42 Å, C···O = 3.297(5) and 3.384(5) Å, C—H···O = 168 and 166°, respectively). In **14***a* the C—H···O interactions involve one of the *N*-methyl groups and oxygen atoms of the nitro group and the 1,3-dioxa-2-boracyclohexane ring (C(6)—H(11)···O(3)(1/2 − x, y − 1/2, z) and C(6)—H(13)···O(5)(1/2 + x, y, 1/2 − z), H···O = 2.48 and 2.54 Å, C···O = 3.440(3) and 3.205(4) Å, C—H···O = 166 and 125°, respectively). The C···O distances are less than or near the sum of the van der Waals radii of a methyl group and an oxygen atom (25).

Dioxirane formation in ozonolysis of *E*- and *Z*-1,2-dimethoxy-1,2-diphenylethene

KARL R. KOPECKY,[1] YU XIE, AND JOSÉ MOLINA[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 6, 1992

KARL R. KOPECKY, YU XIE, and JOSÉ MOLINA. Can. J. Chem. **71**, 272 (1993).

Addition of ozone to *E*- or *Z*-1,2-dimethoxy-1,2-diphenylethene, *E*- or *Z*-**1**, in inert solvents results in formation of ~1 mole of methyl benzoate, ~0.5 and ~0.1 mole of the corresponding oxiranes **2** and dioxetanes **3**, respectively, and 0.03 mole of 3,6-dimethoxy-3,6-diphenyl-1,2,4,5-tetroxane **4** at −20°C. Product distributions vary with starting material, initial concentration, extent of reaction, and temperature. At −70°C ~0.3 mole of *trans*-**2** and 0.2 mole of *cis*- and *trans*-**4** are formed from *E*-**1**. Addition of *E*- or *Z*-**1** to solutions of excess ozone results in formation of up to 0.7 mole of (methoxy)phenyldioxirane **5**, which is a strong, stereospecific epoxidizing agent.

KARL R. KOPECKY, YU XIE et JOSÉ MOLINA. Can. J. Chem. **71**, 272 (1993).

L'addition d'ozone, à −20°C, aux *E*- et *Z*-1,2-diméthoxy-1,2-diphényléthène, *E*- et *Z*-**1**, dans des solvants inertes, conduit à la formation d'environ 1 mole de benzoate de méthyle, d'environ 0,5 et 0,1 mole respectivement des oxiranes (**2**) et dioxétanes (**3**) correspondants et de 0,03 mole de 3,6-diméthoxy-3,6-diphényl-1,2,4,5-tétroxane (**4**). La distribution des produits varie avec la nature du produit de départ, l'avancement de la réaction et la température. À −70°C, le produit *E*-**1** conduit à la formation d'environ 0,3 mole du produit *trans*-**2** et de 0,2 mole des isomères *cis*- et *trans*-**4**. L'addition des composés *E*- ou *Z*-**1** à des solutions contenant de l'ozone en excès conduit à la formation de jusqu'à 0,7 mole du (méthoxy)phényldioxirane (**5**) qui est un puissant agent d'époxydation stéréospécifique.

[Traduit par la rédaction]

Ozonolysis of tetramethoxyethene results in the formation of mainly tetramethoxy-1,2-dioxetane and methyl trimethoxyacetate with relatively little cleavage product, dimethyl carbonate, eq. [1] (1). This unusual result prompted

[1] $(CH_3O)_2C{=}C(OCH_3)_2 \longrightarrow$  $+ CH_3O_2CC(OCH_3)_3 + (CH_3O)_2CO$

~ 35% ~ 40% ~ 20%

a survey of the ozonolysis of other electron-rich alkenes. Luminescent reaction mixtures, indicative of the presence of 1,2-dioxetanes, were formed from *E*- and *Z*-1,2-dimethoxy-1,2-diphenylethene, *E*- and *Z*-**1**. A detailed study of the ozonolysis of these alkenes showed that large amounts of the noncleavage products, 2,3-dimethoxy-2,3-diphenyloxirane **2** and 3,4-dimethoxy-3,4-diphenyl-1,2-dioxetane **3** were formed in addition to the cleavage products, methyl benzoate and 3,6-dimethoxy-3,6-diphenyl-1,2,4,5-tetroxane **4**. Product distributions vary with starting material, temperature, initial concentration, solvent, and extent of reaction. The dioxetanes and oxiranes are formed stereospecifically. At −20°C, **2, 3**, and methyl benzoate are almost the exclusive products, but at −70°C significant amounts of **4** are also produced, especially from *E*-**1**, Table 1.

Small-scale reactions were carried out by delivering measured amounts of ozone from a gas syringe (1) into CD_2Cl_2 solutions of the alkenes in nmr tubes at −20°C or below. The reaction mixtures were analysed by ^1H nmr spectroscopy at −20°C. The ^1H nmr signals of the OCH_3 groups of the various products are well separated and occur at δ (CD_2Cl_2, −20°C): 3.87, methyl benzoate; 3.24, *trans*-**2**; 3.29, *cis*-**2**; 3.06, *trans*-**3**; 3.36, *cis*-**3**; 3.59, *trans*-**4**; and 3.69, *cis*-**4**. The dioxetanes were identified by comparison of ^1H and ^{13}C signals in the nmr spectra of the reaction mixtures with those of authentic *cis*- and *trans*-**3** prepared by singlet oxygen oxidation of *Z*- and *E*-**1** (2). The oxiranes were identified on the basis of their thermal rearrangement at 20°C to 2,2-dimethoxy-1,2-diphenylethanone **5** (3) and their rapid hydrolysis to benzil. Signals at δ 92.64 and δ 92.74 in the ^{13}C nmr spectra of the reaction mixtures were assigned to *trans*- and *cis*-**2**, respectively. All other ^{13}C nmr signals could be assigned to isolable compounds of known structure. Preparative scale ozonolysis of *E*-**1** resulted in isolable (by thick-layer chromatography on silica gel, 10 developments with 2% ethyl acetate in hexane) amounts of *cis*- and *trans*-**4**. It was necessary first to convert *trans*-**2** to benzil and then treat the resulting mixture briefly with hot methanolic hydroxide ion to convert the benzil to benzilic acid anion. The ^1H nmr signal of the OCH_3 groups of the isomer melting at 145–146°C broadened on cooling and was split into two peaks, δ 3.82 and 3.70 at −65°C. The OCH_3 signal of the isomer melting at 113–114°C remained a sharp singlet down to −65°C. These isomers were thus assigned to be *cis*- and *trans*-**4**, respectively. Both isomers were decomposed to methyl benzoate radical cation and its fragmentation products upon electron impact. However, chemical ionization with

$\overset{+}{N}H_4$ afforded the ($M + H^+$) and the $M + \overset{+}{N}H_4$) ions at *m/e* 305 and 322, respectively, from each isomer.

Evidence that the dioxetanes are formed by reaction between singlet oxygen and the alkenes was obtained by carrying out the ozonolysis at −20°C in the presence of some 2,5-dimethylfuran (1). No dioxetane was found although methyl benzoate and oxirane were still formed in similar relative amounts as in the absence of the furan.

At this point it still was not clear how oxirane and singlet oxygen are produced. A possible contribution to oxirane formation from a radical chain oxidation reaction between oxygen and the alkenes (1, 4) could be ruled out. Such a reaction would be unlikely to lead to *cis*-**2** as the only oxirane formed from *Z*-**1**. In fact, when an oxygen-saturated solution of *Z*-**1** containing some di-*tert*-butyl trioxide (5) was allowed to warm slowly from −40° to −20°C a 90:10 mixture of *cis*:*trans*-**2** was formed, along with methyl benzoate, in contrast to the exclusive formation of *cis*-**2** in the ozonolysis reaction.

Attempts to determine whether there is a contribution from a direct reaction between ozone and the alkenes to give oxirane and singlet oxygen (6) resulted in a very enlightening observation. If such a direct reaction occurred, slow addition of alkene to excess ozone should still result in forma-

For personal use only.

tion of large amounts of oxirane. The ^1H nmr spectrum of such a light-yellow ozonolysis reaction mixture from either *E*- or *Z*-**1** at −20°C contained a strong new OCH_3 signal at δ 3.50 (CD_2Cl_2) that decreased slowly in intensity as the signal of the OCH_3 group of methyl benzoate increased in intensity and the yellow color disappeared, when the solution was warmed to 0°C. Relatively much smaller amounts of oxirane and dioxetane were produced than in the normal ozonolyses. Addition at −70°C of *E*- or *Z*-**1** or *E*- or *Z*-2-butene to the reaction mixtures led within a few minutes to the consumption of the new intermediate together with the stereospecific conversion of the alkenes to the corresponding oxiranes. Coincident with the consumption of the intermediate by the alkenes is an equivalent increase in the amount of methyl benzoate and loss of the yellow color. These reactions are strong evidence for the presence of (methoxy)phenyldioxirane **6**. Consistent with this is the presence of a new signal at δ 109.1 in the ^{13}C nmr spectra of reaction mixtures from the inverse ozonolysis of both *E*- and *Z*-**1**. The position of this signal is in the region expected for a carbon atom bound to a phenyl group and three oxygen atoms. The corresponding signal for dimethyldioxirane is at δ 102 (7). Dioxiranes are yellow and are stereospecific epoxidizing agents (7).

The ozonolysis of *E*- and *Z*-**1** thus results in a relatively complex series of reactions, as illustrated in Scheme 1 for *Z*-**1**. There appear to be two initial reactions: one results in formation of oxirane and oxygen, at least some of which must be singlet, the other results in formation of the molozonide. The molozonide fragments in the normal way with formation of methyl benzoate and carbonyl oxide. The latter can either cyclize to dioxirane or dimerize to tetroxane. There must be an energy barrier to cyclization (8), as more tetroxane is formed at −70°C than at −20°C, especially from *E*-**1**. The amount of oxirane formed from the reaction between alkene and dioxirane in the normal ozonolysis reactions is equal to half the moles of methyl benzoate minus the moles of tetroxane. There is always more oxirane than this. The excess must come from the initial reaction between alkene and ozone that also produces oxygen. On this basis the reaction between ozone and *E*-**1** at −20°C results initially in an oxirane:molozonide ratio of about 3:97 and that from *Z*-**1** is about 25:75. Dimerization of the carbonyl oxide to form tetroxane may not be concerted but proceed via a dimeric zwitterion, which could also decompose to form 2 moles of methyl benzoate and oxygen (9). This could be another route to singlet oxygen.

Determination (1) of the stoichiometry of the reaction showed that about 1.4 moles of both *E*- and *Z*-**1** are consumed per mole of ozone at −20°C. This is consistent with the observed product distribution.

This appears to be the first example of dioxirane formation from ozonolysis in solution. Other attempts to find definitive evidence for the presence of dioxiranes from ozonolysis of alkenes or from singlet oxygen oxidation of diazo compounds in solution have been unsuccessful (7, 10).

Use of a laboratory robot for repetitive solution NMR sample preparation

MICHAEL A. JEANNOT AND R. STEPHEN REID[1]

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received June 29, 1992

MICHAEL A. JEANNOT and R. STEPHEN REID. Can. J. Chem. **71**, 275 (1993).

Observing ligand ^{1}H NMR signals while conditions (e.g., analytical concentrations, pH) are changed in an aqueous metal–proton–ligand system is one of the most potent methods of elucidating the precise details of speciation in such systems. Typically this is performed by changing the conditions in a solution reservoir, while withdrawing a sample for NMR analysis at each stage. However, such sample preparation is tedious and time-consuming. We report here studies, using a Mitsubishi RM-101 laboratory robot, of the feasibility of completely automating such a procedure. A simple acid–base study is used to evaluate performance.

MICHAEL A. JEANNOT et R. STEPHEN REID. Can. J. Chem. **71**, 275 (1993).

L'observation des spectres RMN du ^{1}H des ligands en fonction des conditions (concentrations analytiques, pH, etc.) d'un système aqueux métal–proton–ligand est une des méthodes les plus puissantes pour élucider d'une façon précise les détails de la spéciation dans de tels systèmes. D'une façon typique, on effectue ces études en faisant varier les conditions dans un réservoir de la solution, tout en retirant un échantillon pour analyse RMN à chaque étape. Toutefois, la préparation de ces échantillons est laborieuse et elle demande beaucoup de temps. Dans ce travail, on rapporte des études sur la possibilité d'utiliser un robot de laboratoire Mitsubishi RM-101 pour automatiser complètement une telle procédure. On a utilisé une étude acide–base simple pour évaluer la performance.

Introduction

Many methods have been reported in the literature for the determination of metal–ligand speciation data (1, 2). Equilibrium potentiometric studies can yield high-precision complexation constants; however, since potentiometric measurements give no information about the *site* of protonation or deprotonation, a major pitfall is that the data can be fitted to an incorrect model, resulting in statistically valid but chemically meaningless conclusions. By contrast, ^{1}H NMR observation of the ligand in a series of solutions of known proportions of reactants over a range of pH values yields detailed information about the number and type of species present, but gives lower-quality numerical results for the relevant equilibrium constants.

We have found a *combination* of both of these techniques to be a potent method for elucidation of a variety of multi-equilibrium systems (3–7). Details of implementation have been discussed therein; a simple example of the application of NMR studies is given later in this paper (see Performance evaluation).

However, speciation studies of metal–proton–ligand systems using these techniques are hampered by the repetitive, time-consuming nature of the experimental techniques involved in both cases. Development of automated systems, making it possible to collect data without dedicating long hours to manual sample preparation, is therefore a priority. We previously investigated computer-controlled gravimetric titration as a means of automating the potentiometric aspects of the work (8). The possibility of similarly automating the NMR experiments is of obvious interest.

Automatic sample changers for NMR spectrometers, which permit unattended running of multiple samples, have been commercially available for some years; the remaining productivity bottleneck is the preparation of those samples. Here we report preliminary studies of the feasibility of automating the preparation of such samples.

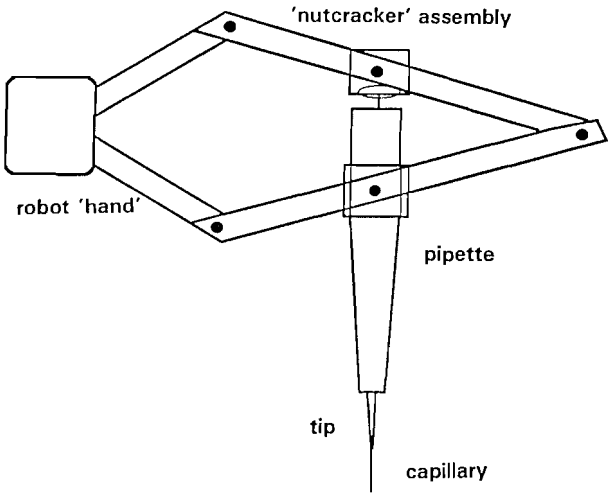

FIG. 1. Robot manipulator for use with automatic pipette.

Experimental

Hardware

A Mitsubishi RM-101 laboratory robot was available for this project. Its basic design is similar to that of a human arm. Control is via six stepping motors: body, shoulder, elbow, wrist (2 motors), and hand. The body motor moves the robot arm around the arc of a circle; full 360-degree coverage is available. The shoulder, elbow, and wrist motors can move the arm up and down over angular ranges roughly similar to a human arm; the wrist can also be used to rotate the hand, again over a 360-degree range. The "hand" has an opposable "finger" and "thumb" and can be opened (about 10 cm maximum separation) and closed.

Delivery of solutions and of samples is accomplished using an automatic plunger-type pipette (Nichiryo, model 5000DG, maximum volume capacity 1 mL). A special adapter for the hand was constructed such that closing the hand motor depresses the plunger of the pipette (see Fig. 1). The mechanism is similar to that of a nutcracker. The pipette is nested near the pivot of the adapter, and the hand squeezes the ends of the "nutcracker." A standard pipette tip was modified to permit entry into a 5 mm o.d. NMR tube

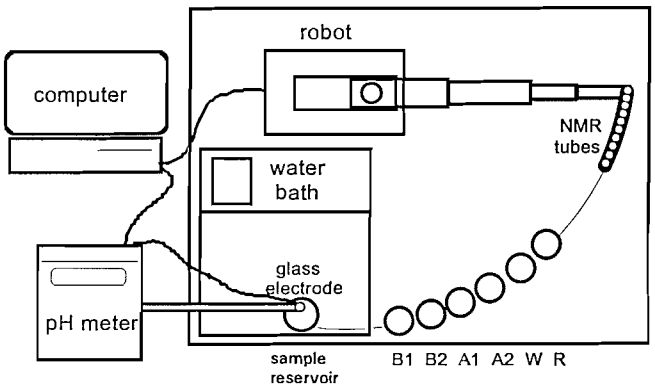

FIG. 2. Layout of apparatus (plan view). Beakers B1, B2, A1, A2, W, and R hold strong base (more and less concentrated), strong acid (more and less concentrated), waste, and rinse water, respectively. See experimental section for further details.

by addition of a glass capillary tube connected with a short length of tubing.

A Fisher Accumet 825 MP pH meter and combination glass electrode were used for pH measurement. The setup was calibrated with standard pH buffers (nominal pH values 4.00 and 7.00), which were periodically standardized against NBS primary standard pH solutions (9). All studies were carried out at 25°C. The temperature was maintained using a water bath equipped with a Haake D1 circulator and a cold-water cooling coil.

The robot, water bath, sample reservoirs, and NMR tubes were secured to a plexiglass sheet (see Fig. 2) The various reservoirs and tubes were placed on the arc of a circle centred on the pivot of the robot body joint. Initially, the joints of the robot arm must be aligned manually to a "home" position (indicated by arrows drawn on the robot body) with the pipette tip 2–5 mm above the centre of the first NMR tube. This is critical for the proper delivery of samples into the tubes; the width of the internal bore of a tube corresponds to only 4–5 steps of the body motor. Initial alignment was performed daily.

Interfacing and software

The robot is interfaced to an AT&T PC6300 8086 microcomputer via a parallel port. Low-level commands are issued by the computer as printer commands; the robot contains a built-in command interpreter. Although the robot is capable of interpreting several different commands, only one of these was used in the control software, the MOVE 1 command. This command simply steps each motor a specified number of steps. (The other commands, such as those to fully open or close the hand, or to adopt a previously defined position, are either not used in this application or, given the "teaching" routine used, offer no advantage over the use of the MOVE 1 command.) The pH meter is interfaced via a serial (RS232C) port; a continuous "print" by the pH meter of the pH reading is polled as required by the controlling software. Control software was written in Turbo Pascal version 5.0. Linear regression and preliminary data analysis were accomplished using QuattroPro on a Dell System 310 80386 microcomputer, and nonlinear least-squares curve fitting using the SigmaPlot scientific graphing software package.

^1H NMR spectroscopic measurements

These were performed on a Bruker AM-300 pulsed Fourier transform NMR spectrometer at an approximate frequency of 300.13 MHz, using a spectral width of 3289 Hz, collecting and transforming 16K points. Sufficient transients were averaged to give a signal-to-noise ratio adequate for precise chemical shift measurement. Typically 16 transients were sufficient. Chemical shifts were measured and are quoted in ppm relative to internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS), positive shifts to high frequency. A binomial composite ('1331') pulse sequence (10) was used to suppress the intense water resonance.

Chemicals and solutions

All chemicals were of reagent grade and were used as received. Buffers for pH calibration, acetic acid, and sodium chloride were obtained from BDH Inc. (Toronto, Ont.), deuterium oxide (99.9% atom *d*) from the Aldrich Chemical Company Inc. (Milwaukee, Wis.), and DSS from Merck, Sharp and Dohme (Kirkland, Que.). For NMR studies, an aqueous solution of 0.02 M acetic acid containing 10% D_2O to provide a lock signal was used. The solution was also 1 mM in DSS (chemical shift reference) and 0.13 M in NaCl (to adjust the ionic strength); 0.05 M and 0.4 M solutions of sodium hydroxide and of hydrochloric acid were used for pH adjustment. Samples were prepared manually at pH < 2 and pH $>$ 12 to obtain the extreme chemical shift values. Finally, samples were prepared from pH 5.75 to 3.75 in 0.20 pH increments, both manually and using the robot. The allowable discrepancy in pH from the target value was set to ± 0.02 pH units.

Results and discussion

Design considerations

Because both the "independent" (pH) and the dependent (chemical shift) variables are measured, the precision with which solutions can be added does not in fact limit the quality of the experiment. (It is not, for instance, essential that samples be withdrawn at *exactly*, say, 0.5 pH unit intervals, only that they be withdrawn at *approximately* that interval and that the pH in each case be *precisely* known.) For this reason, a simple liquid delivery system based on a single automatic pipette was used, as discussed in the experimental section. By use of water rinsing where appropriate (for instance, when switching from acid delivery to sample collection), the possibility of contamination errors due to the use of a single pipette can be minimized.

Control software

The MOVE 1 commands corresponding to basic motions of the robot, such as moving the pipette tip from one station to another or placing it into an NMR tube, were established using a simple "teaching" routine written in Pascal, as follows. The routine generated a MOVE 1 command from a set of instructions given by the operator, and executed that command. By repeated application of the routine, the operator gradually "taught" the desired motion to the robot; the routine then summed the net change in each stepping motor setting, so that in future MOVE 1 could be executed directly, as a single movement, under computer control. For the relatively simple setup described in this paper, this approach allowed rapid "teaching," and obviated the need for detailed consideration of the position of objects or of a choice of coordinate system to work in. The time-consuming implementation of a kinematic transformation was thus also avoided.

For the hand (pipette), the precise relationship between the number of motor steps the hand opens (from the closed position) and the volume taken up by the pipette had to be determined. This was accomplished by a simple gravimetric calibration. Linear regression was performed to obtain the required relationship (see Fig. 3). The minimum volume that can be added from the linear part of the curve is 0.13 mL; the maximum (determined by the design of the pipette holder) is 0.91 mL.

The robot adjusts the pH of the sample by adding acid or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

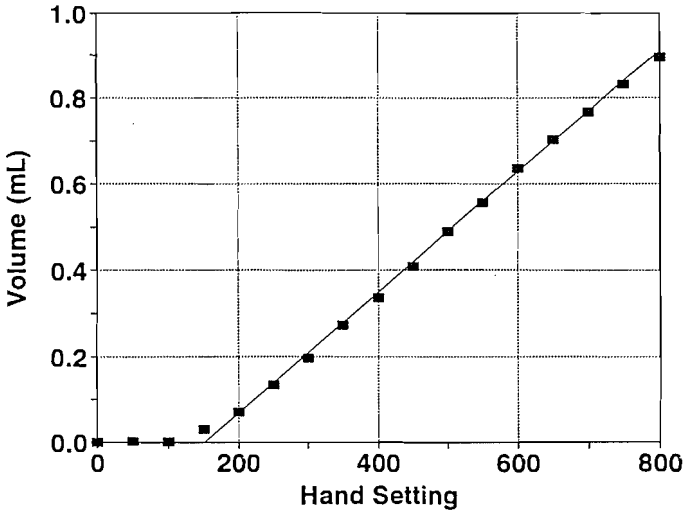

FIG. 3. Pipette calibration (volume delivered as a function of hand stepper motor position). Calibration is linear (correlation coefficient = 0.995) in the range of 0.1–0.9 mL.

base solution using the pipette. Base is used to adjust the pH of the solution upward initially to the highest desired value, acid for the downward adjustment between successive samples, and base also in the case of overshooting the desired pH as adjustment is performed. (Downward pH adjustment is the normal procedure for such studies, since it preserves the ionic strength close to a constant value. For instance, in the sodium acetate – hydrochloric acid titration used in the validation studies, the decline in the moles of acetate ion as the titration proceeds is exactly balanced by the rise in the moles of chloride ion.)

The limited range of volumes of acid the pipette can deliver (0.13–0.91 mL) is a potential problem, since the range of acid volumes necessary in the course of an experiment is likely to be much larger than this. In poorly buffered regions of the titration curve, only very small amounts of acid are required. A single acid solution of sufficiently low concentration to permit 0.13 mL additions near the titration equivalence point would have to be added in unacceptably large volumes in buffered regions of the titration curve. Time-consuming multiple additions would be required and considerable dilution would result. To avoid this problem, two solutions each of acid and base, of differing concentrations, are used. Discussion of the estimation of the optimum concentrations for these solutions lies outside the scope of this paper; typical values are given in the Chemicals section.

Once the pH is within a user-defined tolerance of the nominal target value, the robot withdraws a sample and transfers it to an NMR tube. This process is repeated for the required number of samples. Once a set of operating parameters have been accepted, the system can be left unattended while it prepares the samples.

Control software was written in top-down programming format such that the main loop of the program consists of only a few high-level procedures. Several levels of subroutines are called in turn. A simplified algorithm is as follows:[2]

```
Input parameters (e.g., target pH values)
Read initial pH
Withdraw and deliver first sample
REPEAT:
  Add acid (volume calculation routine)
  REPEAT:
    Read pH meter
    Add acid or base as appropriate (volume
    calculation routine)
  UNTIL pH is within the desired range
  Withdraw and deliver sample
UNTIL pH = lower limit
```

The user has the option of going down by a fixed pH interval between samples, or of entering a list of target pH values. pH data collected during the procedure are stored on disk.

The most difficult part of this procedure is predicting the volume of acid or base solution required to be added in order to change the pH by a given amount. Obviously, this can only be precisely calculated given a detailed knowledge of the equilibria involved — the knowledge the experiment is being performed to elucidate! However, a general prediction method, based on extrapolation of the recent history of the experimental volume added/pH curve, was developed, following the treatment of Smit and Smit (11). It is assumed that small portions of the titration curve may be empirically described by a hyperbolic function defined by the three parameters A, B, and C:

$$[1] \quad \mathrm{pH}(V) = A/(B + V) + C$$

where V is the volume of titrant added. A simple eight-step algorithm can be developed to predict the next volume of acid or base to add in order to reach the next pH value based on the previous three titration points. This algorithm has been incorporated into the control software for the robot.

Performance evaluation

This was accomplished by determination of the pK_a of acetic acid (HA) using both manually and robotically prepared samples. Depending on the pH of the system, varying proportions of HA and the acetate ion A^- will be present at equilibrium. Since the rate of chemical exchange between these two species is rapid on the NMR time scale, the observed methyl proton chemical shift δ_{obs} is the population-weighted average of those of the two species, i.e.,

$$[2] \quad \delta_{obs} = \delta_{HA}\alpha_{HA} + \delta_{A^-}\alpha_{A^-}$$

where δ_i is the chemical shift of a species and α_i its mole fraction. δ_{HA} and δ_{A^-} can be determined at very low and high pH values, respectively. The mole fractions are functions of the hydronium ion concentration[3] and K_a, the acid dissociation constant:

$$[3] \quad \alpha_{HA} = [H_3O^+]/([H_3O^+] + K_a)$$

$$[4] \quad \alpha_{A^-} = K_a/([H_3O^+] + K_a)$$

Samples were prepared over a range of pH values and the resultant chemical shifts measured (see experimental section and Fig. 4 for details). Using the nonlinear least-squares routine Sigmaplot, the value of K_a was refined to obtain the

[2]A copy of the compiled program and a source listing is available from the corresponding author.

[3]Strictly speaking, activity, but we will neglect consideration of activity coefficients here for simplicity, since it is the *comparison* between manually and robotically derived K_a values that is of interest, not the absolute values themselves.

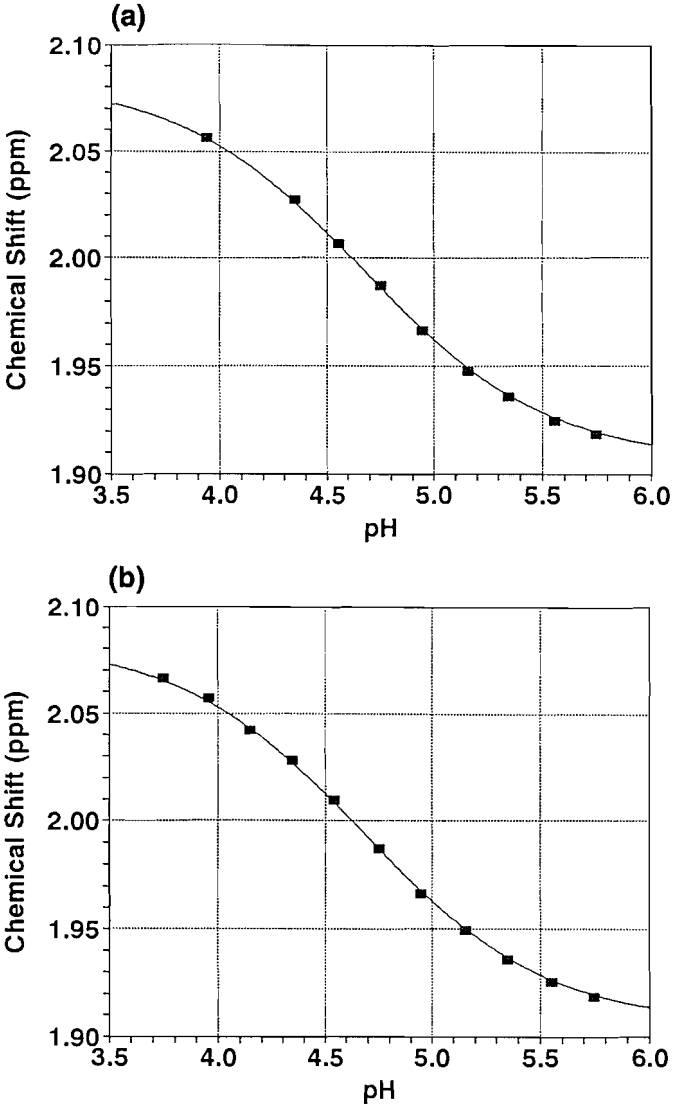

FIG. 4. pH dependence of chemical shift for acetic acid, for (*a*) a set of robotically prepared samples and (*b*) a set of manually prepared samples. The points in each case indicate experimental data and the line the best fit to the model described by eqs. [2], [3], and [4]. See text for further details.

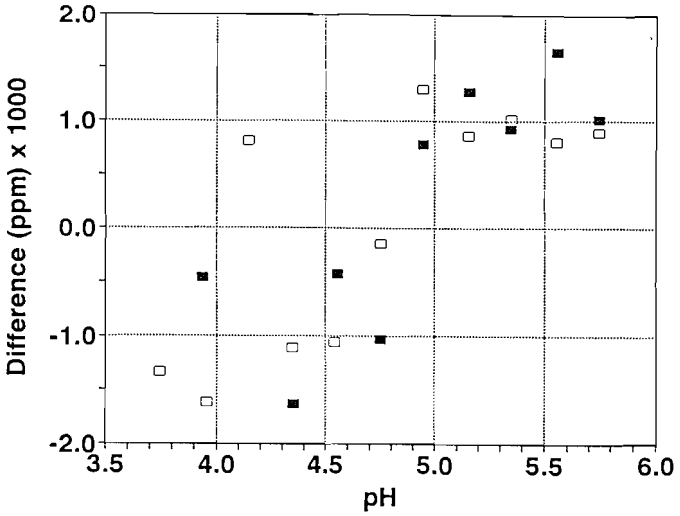

FIG. 5. Differences between experimentally determined chemical shifts and those predicted from the best-fit model for robotically prepared samples (■) and for manually prepared samples (□).

best agreement between experimental and predicted chemical shifts.

Validation results are shown graphically in Fig. 4. The fit, not surprisingly for such a simple equilibrium system, is excellent. A plot of the differences between actual and predicted chemical shifts is given in Fig. 5. A slight systematic trend is apparent. This is probably due to a small error in the pH electrode calibration (slope), to neglect of consideration of activity coefficients, or to an error in one or both of the extreme chemical shift values. Since the frequency difference between points on the digitized NMR spectra is 1.3×10^{-3} ppm, the trend is scarcely significant and further refinement was considered redundant.

A pK_a of 4.669 ± 0.005 (sd) was obtained for the robotically prepared samples, and a pK_a of 4.677 ± 0.005 (sd) was obtained for the manually prepared samples. The standard deviations are based on goodness of fit; allowing for electrode calibration the true standard deviation is approximately 0.02. There is therefore no significant difference between these values.

Overall performance

Typically the setup takes approximately twice as long to prepare a set of samples as an experienced operator would take to perform the job manually; however, the time involved now requires no human intervention, and operator time is freed for other tasks.

The "slack" in the movements of the various joints of the robot does result in some hysteresis effects with respect to volumes of samples delivered to NMR tubes. Although calibration studies (see Fig. 3) indicated that the uncertainty in volume delivered was ±0.01 mL, in practice larger variations in sample volumes were observed. These variations were not normally distributed, and appeared to depend on the recent activities of the arm. In a typical validation run, perhaps two samples were of volume 0.35 mL rather than the expected 0.4 mL. Modern automated NMR spectrometers with computer-controlled shimming facilities can accommodate variations of this magnitude in sample size.

Careful selection of parameters is needed. In particular, the allowable discrepancy between actual and target pH values should not be set too small compared to the pH interval between samples. (This depends upon the titration being performed; typically the discrepancy should be approximately 10% or more of the interval.) If not, although a set of samples will still be prepared, overshooting will occur, resulting in considerable dilution of the reservoir contents during the run. Provided these points are borne in mind, the apparatus performs well.

Acknowledgements

We wish to thank Mr. A. Leyland for assistance in constructing some of the hardware for the system, and Dr. B. Kratochvil for the loan of the robot. EDWARD PIERS, BIK WAH ANISSA YEUNG, and FRASER F. FLEMING. Can. J. Chem. **71**, 280 (1993).

The development of a new, synthetically useful methylenecyclohexane annulation method is described. Transmetallation (MeLi, tetrahydrofuran, −78°C) of 5-chloro-2-trimethylstannyl-1-pentene (**8**) affords the novel bifunctional reagent 5-chloro-2-lithio-1-pentene (**9**), which, at temperatures higher than approximately −50°C, self-destructs to give methylenecyclobutane (**14**). Reagent **9** can be converted into the Grignard reagent **10** and the organocopper(I) species **15**. Conjugate addition of **10** and **15** to a number of cyclic enones (**16–22**), followed by intramolecular alkylation of the resultant adducts (**23–29**), produces the corresponding methylenecyclohexane annulation products (**30–40**).

EDWARD PIERS, BIK WAH ANISSA YEUNG et FRASER F. FLEMING. Can. J. Chem. **71**, 280 (1993).

On décrit le développement d'une nouvelle méthode d'annellation du méthylènecyclohexane qui est utile en synthèse. La transmétallation (MeLi, tétrahydrofurane, −78°C) du 5-chloro-2-triméthylstannylpent-1-ène (**8**) conduit au 5-chloro-2-lithiopent-1-ène (**9**), un nouveau réactif bifonctionnel qui, à des températures plus élevées qu'environ −50°C, s'autodétruit pour donner du méthylènecyclobutane (**14**). On peut transformer le réactif **9** en réactif de Grignard **10** et en l'espèce organocuivrée(I) **15**. L'addition conjuguée des réactifs **10** et **15** à un certain nombre d'énones cycliques (**16–22**), suivie par une alkylation intramoléculaire des adduits qui en résultent (**23–29**), conduit aux produits d'annellation correspondants, soit les méthylènecyclohexanes **30–40**.

[Traduit par la rédaction]

Introduction

A recent paper (1) from this laboratory reported that the novel reagent 4-chloro-2-lithio-1-butene (**2**) can be obtained readily by transmetallation (MeLi, tetrahydrofuran (THF), −78°C) of the vinyl trimethylstannane **1**. Furthermore, it was shown (1) that **2** can be transformed into the lower order heterocuprates **3** and **4** and that the latter substances are effective reagents for the conversion of enones **5** into bicyclic substances of general structure **6**. In these efficient, synthetically useful (1–3) methylenecyclopentane annulation sequences, the conjunctive reagents **3** and **4** serve as synthetic equivalents of the 1-butene d^2,a^4-synthon **7**.

In view of the success derived from the studies summarized above, it was of considerable interest to investigate the transmetallation of 5-chloro-2-trimethylstannyl-1-pentene (**8**), with the aim of determining whether or not the lithio reagent **9**, the corresponding Grignard species **10**, and (or) appropriate copper(I) reagents would serve as stable, viable, bifunctional reagents. We were particularly interested in developing a methylenecyclohexane annulation method shown in general terms by the conversion **5** → **11**. The fact that the methylenecyclohexane moiety is a fairly common structural feature of terpenoid natural products provided additional impetus for developing this new ring-forming method. We report herein the details of this study (4), which showed that **9** and **10**, as well as a related copper(I) reagent, are indeed viable synthetic equivalents of the 1-pentene d^2,a^5-synthon **12**.

Results and discussion

(a) Transmetallation of 5-chloro-2-trimethylstannyl-1-pentene (8). Regarding the stability of 5-chloro-2-lithio-1-pentene (9)

A "large-scale" preparation of the required stannane **8** was achieved, in 68% yield, by reaction of 5-chloro-1-pentyne with $Me_3SnCu \cdot Me_2S$ (**5**) under conditions (THF, −78°C, 6 h) modified from those reported earlier (6). Treatment of **8** with 1.2 equivalents of MeLi in THF at −78°C for 15 min produced a solution of the lithio reagent **9**. Addition of cyclohexanone to this solution, followed by continued stirring for 3 h, appropriate work-up, and product purification, gave the chloro alcohol **13** in 85% yield (Scheme 1, Experiment 1). If the solution of **9** in THF was stirred for an additional 30 min *prior to* addition of cyclohexanone, the yield of **13** was essentially unchanged (84%) (Scheme 1, Experiment 2). Thus, at −78°C in THF, 5-chloro-2-lithio-1-pentene (**9**) is, like its lower homologue **2** (1), a stable reagent.

To obtain additional information regarding the thermal

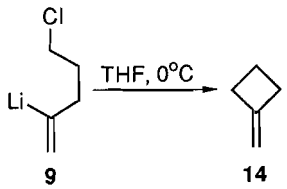
Experiment	Conditions A	Yield of 13(%)
1	--	85
2	-78°C, 30 min	84
3	-63°C, 30 min	76
4	-48°C, 30 min	58
5	-20°C, 30 min	0

SCHEME 1

stability of **9**, Experiments 3–5, Scheme 1, were carried out. The results of these experiments showed that, at −63°C in THF, **9** is still reasonably stable. However, at −48°C, **9** partially decomposes over a period of 30 min and, at −20°C, it completely self-destructs within the same time span. The material isolated from the reaction mixture of Experiment 5, Scheme 1, consisted nearly entirely of one of the starting materials, cyclohexanone.

What is the fate of **9** when a solution of this species is warmed? This question was conveniently answered by means of ^{1}H nmr spectroscopy. A 400 MHz spectrum of an aliquot of a THF solution of **9** that had been warmed to 0°C for 30 min showed, as expected, signals due to Me_4Sn (from transmetallation of **8** with MeLi), Et_2O (from the MeLi solution), and THF. The only other significant signals were obviously due to the presence of methylenecyclobutane (**14**) (7, 8) (eq. [1]). Thus, although the resonance due to the two

[1]



C-3 protons of **14** was hidden under the strong peak for the C-3(C-4) protons of THF, the signals derived from the allylic and olefinic protons of **14** (7, 8) were clearly visible at δ 2.63 (tt, 4H, J = 3, 8 Hz) and 4.61 (quintet, 2H, J = 3 Hz). This experiment was repeated except that, prior to measurement of the ^{1}H nmr spectrum, an internal standard (benzyl benzoate) was added to the reaction mixture. Careful integration of the olefinic protons of **14** and the benzylic protons of benzyl benzoate showed that the conversion of **9** into methylenecyclobutane (**14**) had taken place in essentially quantitative yield. Thus, perhaps not surprisingly, the thermal "decomposition" of 5-chloro-2-lithio-1-pentene (**9**) proceeds via a cyclization process involving elimination of the elements of lithium chloride, accompanied by the formation of the strained carbocycle **14**. It appears that similar cyclizations of analogues of **9** would constitute a useful method for the synthesis of specifically substituted alkylidenecyclobutanes.

(b) Methylenecyclohexane annulations

A number of methods aimed at effecting the conjugate addition of the 2-(5-chloro-1-butenyl) group to cyclic enones were investigated. Eventually, two reasonably effective procedures were found. The first of these (eq. [2], experimental section, general procedure A) involved copper(I)-catalyzed addition of the Grignard reagent **10**, which was readily formed by treatment of a solution of the lithio species **9** with magnesium bromide etherate. The second method (eq. [3], experimental section, general procedure C) was modelled on studies carried out by Noyori and coworkers (9). Addition of a solution of $CuBr \cdot Me_2S$ (1.1 equivalents) and n-Bu_3P (2 equivalents) in Et_2O (−78°C) to a THF solution (−78°C) of the lithio reagent **9** provided a reagent that, for the sake of convenience, may be formulated as shown in **15** (eq. [3]). Reaction of this species with the enone provided the desired conjugate addition product.

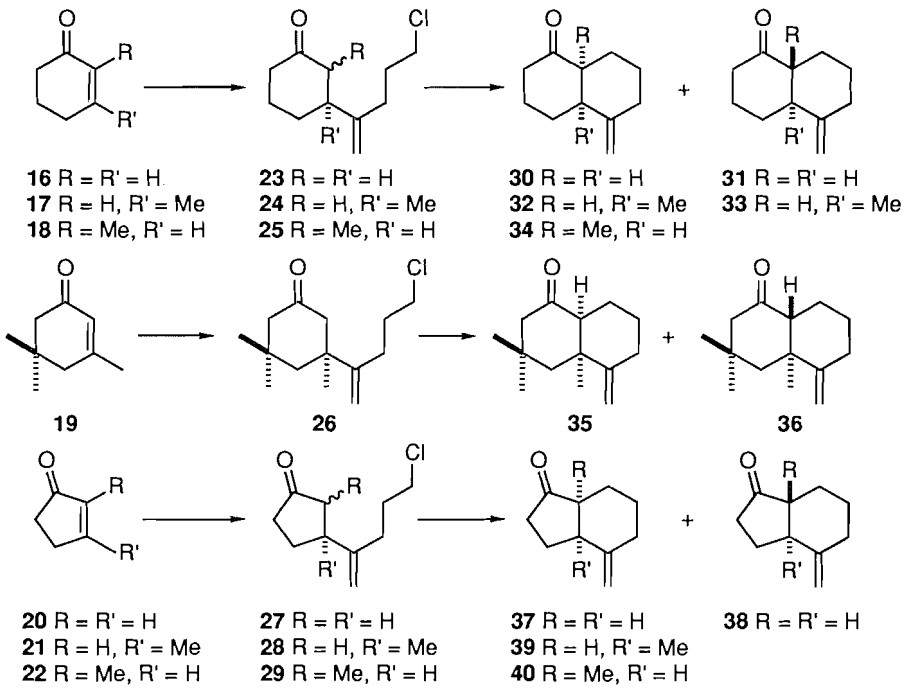

SCHEME 2

TABLE 1. Methylenecyclohexane annulation of cyclic enones

Entry	Enone	Conjugate addition product (procedure,[a] yield (%)[b])	Cyclized product(s)[c] (ratio,[d] yield (%)[b])	Cyclized product(s) (ratio[d] after equilibration[e])
1	**16**	**23** (A, 81; C, 61)	**30**, **31** (1:2, 86)	**30**, **31** (<1:>99)
2	**17**	**24** (B, 37; C, 55)	**32**, **33** (3.5:1, 82)	**32**, **33** (1:2.8)
3	**18**	**25**[f] (B, 56; C, 58)	**34** (—, 78)	
4	**19**	**26** (B, 45; D, 21)	**35**, **36** (8:1, 89)	**35**, **36** (1:2)
5	**20**	**27** (A, 54; C, 65)	**37**, **38** (5:1, 84)	**37**, **38** (5:1)
6	**21**	**28** (B, 54; D, 38)	**39** (—, 83)	(no change)
7	**22**	**29**[f] (B, 33; C, 67)	**40** (—, 90)	

[a]Procedures: A, $CuBr \cdot Me_2S$-catalyzed conjugate addition of the Grignard reagent **10**; B, as procedure A, but in the presence of $BF_3 \cdot Et_2O$; C, conjugate addition of the organocopper(I) reagent **15**; D, as procedure C, but in the presence of $BF_3 \cdot Et_2O$. Details are given in the experimental section of this paper.
[b]Yield of distilled, purified product.
[c]Intramolecular alkylation of the chloro ketones was accomplished with KH in THF.
[d]Ratios were determined by gas–liquid chromatography and (or) by ^1H nmr spectroscopy.
[e]Equilibration was accomplished with NaOMe in refluxing MeOH.
[f]This product consisted of a mixture of epimers.

For enones that are relatively poor substrates for conjugate addition of organocopper(I) reagents, the two procedures (A and C) outlined above were advantageously modified by employing $BF_3 \cdot Et_2O$ (10) to facilitate the process. These methods are designated, respectively, as general procedures B and D (see experimental section).

A number of cyclic enones (**16–22**, see Scheme 2) were subjected to the conjugate addition procedures outlined above and the results are summarized in Table 1. In general, the yields of the addition reactions were satisfactory, but not particularly high. In all cases, the desired chloro ketone could be conveniently purified by a combination of column chromatography on silica gel and distillation. As expected, the products **25** and **29** derived from 2-methyl-2-cyclohexen-1-one (**18**) and the corresponding cyclopentenone **22** (Table 1, entries 3 and 7) consisted of mixtures of epimers. In each case, the ratio of the diastereomeric products varied somewhat from experiment to experiment.

The originally envisaged methylenecyclohexane annulation sequences were completed by carrying out the intramolecular alkylation of each of the chloro ketones **23–29** with excess potassium hydride in dry THF at room temperature. In all cases studied, the yields of the cyclized products were excellent and the desired substances could be obtained in pure form by direct distillation of the crude products.

On the basis of literature reports (11, 12), the *cis*-fused bicyclic ketones would be expected to be the kinetically favored cyclization products. Indeed, in each of the two cases in which subsequent equilibration was not possible (Table 1, entries 3 and 7), a single *cis*-fused annulation product was formed in high yield. The relative configurations of these products (**34**, **40**) were confirmed by ^1H nmr nuclear

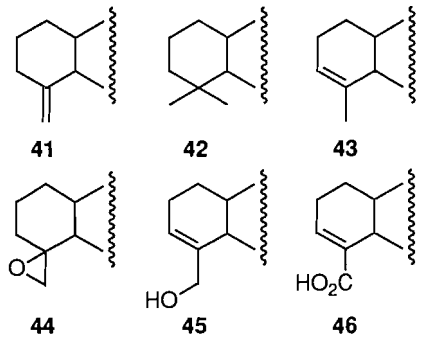
Overhauser enhancement (nOe) difference experiments. Thus, irradiation at δ 1.10 (three-proton singlet, angular Me signal) in the spectrum of **34** caused enhancement of the resonance (δ 2.25) due to the angular proton. In similar fashion, the resonance (δ 2.49) due to the angular proton in the spectrum of product **40** was enhanced when irradiation was carried out at δ 1.04 (angular Me signal).

During the potassium hydride-induced ring closure of the chloro ketones **23**, **24**, and **26** to produce the corresponding 7-methylenebicyclo[4.4.0]decan-2-ones, the initially formed *cis*-fused products underwent varying degrees of epimerization. Thus, cyclization of **23** produced a mixture in which the *trans*-fused product predominated (Table 1, entry 1), while, in the product mixtures derived from cyclization of substrates **24** and **26**, the *cis*-fused ketones were the major products (Table 1, entries 2 and 4). In each of these cases, the bicyclic products were subjected to equilibration with sodium methoxide in refluxing methanol and the equilibrium ratios were determined (Table 1). Not unexpectedly, the equilibrium between *cis*- (**30**) and *trans*-7-methylenebicyclo[4.4.0]decan-2-one (**31**) favored exclusively the *trans* isomer **31** (Table 1, entry 1). On the other hand, equilbration of the more highly substituted 7-methylenebicyclo[4.4.0]decan-2-ones (**32** ⇌ **33**, **35** ⇌ **36**) gave mixtures in which the *trans* isomers **33** and **36** were only marginally favored (Table 1, entries 2 and 4).

Intramolecular alkylation of the chloro ketone **27** produced a 5:1 mixture of *cis*- (**37**) and *trans*-2-methylenebicyclo[4.3.0]nonan-7-one (**38**). Equilibration (NaOMe, MeOH) of this mixture produced no change, while similar treatment of a pure sample of **37** also furnished a mixture of **37** and **38** in a ratio of 5:1. Thus, the *cis* isomer **37** is somewhat more stable than its *trans* counterpart **38**.

Ring closure of the chloro ketone **28** afforded exclusively *cis*-1-methyl-2-methylenebicyclo[4.3.0]nonan-7-one (**39**). Attempted equilibration of this material produced no detectable amount of the corresponding *trans*-fused isomer.[2]



Conclusion

The methylenecyclohexane substructure **41**, as well as, for example, functionalized cyclohexane units represented in general terms by structural formulas **42–46** are quite commonly found in members of the terpenoid family of natural products. It is evident that compounds possessing the part structure **41** should serve as effective synthetic precursors for substances containing the structural features shown in **42–46**. Consequently, the concise methylenecyclohexane annulation method developed in this study should find use in organic synthesis. The details of a number of recent applications will be reported in the near future.[3]

Experimental

General information

Distillation temperatures, which refer to short-path (Kugelrohr) distillations, and melting points are uncorrected. Infrared (ir) spectra were recorded on Perkin–Elmer models 710B or 1710 spectrometers. Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (nmr) spectra were recorded on $CDCl_3$ solutions. Resonance positions are given in parts per million (ppm, δ) relative to the signal for Me_4Si (δ = 0). High-resolution mass spectra were recorded with a Kratos MS-50 mass spectrometer. Gas–liquid chromatography (glc) was performed with gas chromatographs equipped with 12.5 m × 0.21 mm fused silica columns coated with cross-linked OV-210 or SE-54. Analytical thin-layer chromatography was done with commercial aluminum-backed silica gel plates (E. Merck, Type 5554). Column chromatography was carried out with 70–230 mesh silica gel (E. Merck). Reagents and solvents were purified and dried using standard methods.

Aqueous NH_4Cl–NH_4OH (pH 8) was prepared by addition of ~50 mL of aqueous ammonium hydroxide (58%) to 1 L of saturated aqueous ammonium chloride.

Note: Unless otherwise indicated, all reactions were carried out under an atmosphere of dry argon using oven- or flame-dried glassware.

Note: Unless otherwise noted, all substances for which high-resolution mass measurements are given exhibited clean ^{1}H nmr spectra and showed one spot on tlc analysis and essentially one peak on glc analyses.

5-Chloro-2-trimethylstannyl-1-pentene (8)

To a cold (−78°C), stirred solution of $Me_3SnCu \cdot Me_2S$ (5) (38.3 mmol) in dry THF (250 mL) was added 5-chloro-1-pentyne (3.2 mL, 30.2 mmol) and the resultant mixture was stirred at −78°C for 6 h. Acetic acid (3 mL), methanol (3 mL), aqueous NH_4Cl–NH_4OH(pH 8) (200 mL), and diethyl ether (100 mL) were added sequentially. The vigorously stirred mixture was opened to the atmosphere and was allowed to warm to room temperature. The phases were separated and the deep-blue aqueous layer was extracted twice with diethyl ether. The combined organic extracts were washed twice with aqueous NH_4Cl–NH_4OH (pH 8), and then were dried ($MgSO_4$) and concentrated. Column chromatography (450 g silica gel, petroleum ether) of the remaining material, followed by distillation (80–85°C/25 Torr (1 Torr = 133.3 Pa)) of the acquired oil, gave 5.5 g (68%) of the chloro trimethylstannane **8**, a colorless oil that exhibited spectra identical with those recorded previously (6).

Preparation of 5-chloro-2-lithio-1-pentene (9)

To a cold (−78°C), stirred solution of 5-chloro-2-trimethylstannyl-1-pentene (**8**) (1.0 equiv.) in dry THF (~1 mL per 0.1 mmol of **8**) was added a solution of methyllithium (~1.2 equiv.) in diethyl ether. The colorless solution was stirred at −78°C for 15 min before being used.

Experiments to determine the stability of 9. Reactions of 9 with cyclohexanone

Four separate solutions of 5-chloro-2-lithio-1-pentene (**9**) (0.37 mmol) in dry THF (4 mL), each prepared as described above, were stirred at −78, −63, −48, and −20°C for 30 min (experiments A, B, C, and D, respectively). The solutions derived from experiments B–D were recooled to −78°C. Cyclohexanone

[2]Treatment of the **39** with NaOMe–MeOD gave the expected (*cis*-fused) trideuterio ketone. Molecular mechanics calculations (Chem 3D Plus,™ Version 3.0, Cambridge Scientific Computing, Inc., 1991) indicate that **39** is approximately 3 kcal/mol more stable than the corresponding *trans*-fused isomer. We are grateful to Mr. Jacques Roberge for his assistance in performing these calculations.

[3]For preliminary reports, see refs. 13–15.

(43 μL, 0.41 mmol) was added to each solution and, in each case, the mixture was stirred at −78°C for 3 h. Saturated aqueous NH_4Cl (5 mL) and diethyl ether (10 mL) were added to each reaction mixture, which was then allowed to warm to room temperature. In each case, the phases were separated, the organic solution was washed with saturated aqueous NH_4Cl (2 × 5 mL), and then was dried ($MgSO_4$) and concentrated. Column chromatography (5 g silica gel, 3:2 petroleum ether – diethyl ether) of each of the crude products obtained from experiments A, B, and C, followed by distillation (110–115°C/0.2 Torr) of each of the acquired liquids, provided 64 mg (84%), 57 mg (76%), and 44 mg (58%) of 1-[5-chloro-2-(1-pentenyl)]cyclohexanol (**13**), respectively. The chloro alcohol **13**, a colorless oil, displayed ir (neat): 3431, 3094, 1639, 902 cm^{-1}; ^1H nmr (400 MHz) δ: 1.12–1.30 (m, 2H), 1.50–1.70 (m, 9H), 1.98 (quintet, 2H, J = 7 Hz), 2.24 (t, 2H, J = 7 Hz), 3.36 (t, 2H, J = 7 Hz), 4.82, 5.14 (s, s, 1H each). Exact Mass calcd. for $C_{11}H_{19}{}^{35}ClO$: 202.1124; found: 202.1130.

Analysis (glc, ^1H nmr) of the crude product obtained from experiment D showed that it contained none of the chloro alcohol **13**, but consisted nearly entirely of cyclohexanone.

Cyclization of ***9****. Formation of methylenecyclobutane (****14****)*

A solution of 5-chloro-2-lithio-1-pentene (**9**) (0.43 mmol) in dry THF (4.3 mL) at −78°C, prepared as described above, was allowed to warm to 0°C for 30 min. Benzyl benzoate (80 μL, 0.42 mmol) was added and, after the mixture had been stirred thoroughly, a 50 μL aliquot was removed and dissolved in $CDCl_3$ for ^1H nmr analysis. The ^1H nmr spectrum (400 MHz) showed, in addition to signals due to Me_4Sn, Et_2O (from the MeLi solution used to prepare **9**), and THF, essentially only resonances derived from $PhCO_2CH_2Ph$ and methylenecyclobutane (**14**) (8). The resonance for the C-3 protons of **14** was buried under the signal due to the C-3 + C-4 protons of THF. The four allylic protons of **14** gave rise to a tt (J = 3, 8 Hz) at δ 2.63, while the olefinic protons produced a quintet (J = 3 Hz) at δ 4.61. Careful integration of the signals due to the olefinic protons of **14** and the benzylic protons of benzyl benzoate showed that the conversion of **9** into **14** had taken place quantitatively.

General procedure A. CuBr · Me_2S-catalyzed conjugate addition of the Grignard reagent ***10*** *to enones*

To a cold (−78°C), stirred solution of 5-chloro-2-lithio-1-pentene (**9**) (1.0 equiv.) in dry THF (~1.0 mL per 0.1 mmol of **9**) was added, in one portion, solid magnesium bromide etherate (~1.2 equiv.). The milky solution was stirred at −78°C for 20 min. Solid CuBr · Me_2S complex (~0.25 equiv.) and the enone (1.0 equiv.) were added sequentially and the resultant yellow mixture was stirred at −78°C for 3 h. Aqueous NH_4Cl–NH_4OH (pH 8) (~1.25 mL per 0.1 mmol of enone substrate) and Et_2O (~2.5 mL per 0.1 mmol of enone substrate) were added, the rapidly stirred mixture was opened to the atmosphere, and then was allowed to warm to room temperature. The blue aqueous layer was separated and washed twice with Et_2O. The combined Et_2O solutions were washed twice with aqueous NH_4Cl–NH_4OH (pH 8), dried ($MgSO_4$), and concentrated. The residual material was purified by column chromatography on silica gel (~5 g per 100 mg of crude product, 3:1 petroleum ether – Et_2O) and distillation.

General procedure B. CuBr · Me_2S-catalyzed conjugate addition of the Grignard reagent ***10*** *to enones, in the presence of $BF_3 \cdot Et_2O$*

This procedure was essentially identical with that described above, except that $BF_3 \cdot Et_2O$ (~1.2 equiv.) was added to the reaction mixture immediately after addition of the enone substrate.

General procedure C. Conjugate addition of the organocopper(I) reagent ***15*** *to enones*

Solid CuBr · Me_2S complex (1.1 equiv.) was added to a stirred solution of n-Bu_3P (2.0 equiv.) in dry Et_2O (~1.0 mL per 0.1 mmol of CuBr · Me_2S). After the mixture had been stirred at room temperature for 10 min, all of the solid had dissolved. The solution was cooled to −78°C and then was transferred via cannulation to a cold (−78°C), stirred solution of **9** (1.0 equiv.) in dry THF (~1.0 mL per 0.1 mmol of **9**). The light-yellow solution was stirred at −78°C for 20 min. The enone (1.0 equiv.) was added and the bright-yellow solution was stirred at −78°C for 1 h and at −48°C for 2 h. Work-up as described in general procedure A (*vide supra*) and purification of the crude material by column chromatography on silica gel (~5 g per 100 mg of crude oil, 20:1 to 7:1 petroleum ether – Et_2O) and distillation gave the desired product.

General procedure D. Conjugate addition of the organocopper(I) reagent ***15*** *to enones, in the presence of $BF_3 \cdot Et_2O$*

This procedure was identical with general procedure C, except that $BF_3 \cdot Et_2O$ (1.2 equiv.) was added to the reaction mixture immediately after the enone had been added.

The following compounds were prepared by use of the general procedures described above. The specific procedure employed and the yields obtained are indicated in Table 1.

*3-[2-(5-Chloro-1-pentenyl)]cyclohexanone (****23****)*

Distillation temperature: 82–85°C/0.2 Torr; ir (neat): 3050, 1700, 1630, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.52–1.74 (m, 2H), 1.85–2.00 (m, 3H), 2.02–2.14 (m, 1H), 2.15–2.24 (t, 2H, J = 7.0 Hz), 2.24–2.49 (m, 5H), 3.54 (t, 2H, J = 7.0 Hz), 4.85 (br s, 2H). Exact Mass calcd. for $C_{11}H_{17}{}^{35}ClO$: 200.0969; found: 200.0963.

*3-[2-(5-Chloro-1-pentenyl)]-3-methylcyclohexanone (****24****)*

Distillation temperature: 85–90°C/0.2 Torr; ir (neat): 3050, 1700, 1620, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.11 (s, 3H), 1.57–1.67 (m, 1H), 1.67–1.80 (m, 1H), 1.80–1.90 (m, 1H), 1.90–2.10 (m, 3H), 2.10–2.36 (m, 5H), 2.60 (br d, 1H, J = 14 Hz), 3.59 (t, 2H, J = 7.0 Hz), 4.87, 4.93 (s, s, 1H each). Exact Mass calcd. for $C_{12}H_{19}{}^{35}ClO$: 214.1126; found: 241.1119.

*3-[2-(5-Chloro-1-pentenyl)]-2-methylcyclohexanone (****25****)*

This material (distillation temperature 93–98°C/0.2 Torr) was shown by gas–liquid chromatographic analysis to consist of a mixture of two diastereomers in a ratio of ~12:1; ir (neat): 3070, 1700, 1635, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95, 1.00 (d, d, 3H total, ratio ~1:12, J = 7.0 Hz in each case), 1.65–1.80 (m, 2H), 1.80–1.97 (m, 3H), 2.21–2.32 (m, 1H), 2.44–2.60 (m, 2H), 2.60–2.70 (m, 1H), 3.55 (t, 2H, J = 7.0 Hz), 4.75, 4.98 (br s, br s, ~0.9 H each), 4.86, 4.89 (br s, br s, ~0.1 H each). In a decoupling experiment, irradiation at δ 1.00 caused the signal at δ 2.60–2.70 to collapse to a d (J = 7.0 Hz). Exact Mass calcd. for $C_{12}H_{19}{}^{35}ClO$: 214.1126; found: 214.1124.

*3-[2-(5-Chloro-1-pentenyl)]-3,5,5-trimethylcyclohexanone (****26****)*

Distillation temperature 82–86°C/0.2 Torr; ir (neat): 3070, 1700, 1630, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 0.97, 1.04, 1.16 (s, s, s, 3H each), 1.58 (d, 1H, J = 14 Hz), 1.90–2.05 (m, 3H), 2.13–2.25 (m, 5H), 2.76 (d, 1H, J = 14 Hz), 3.59 (t, 2H, J = 7.0 Hz). 4.81, 5.04 (br s, br s, 1H each). Exact Mass calcd. for $C_{14}H_{23}{}^{35}ClO$: 242.1437; found: 242.1436.

*3-[2-(5-Chloro-1-pentenyl)]cyclopentanone (****27****)*

Distillation temperature 90–95°C/0.5 Torr; ir (neat): 3050, 1735, 1630, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.72–1.86 (m, 1H), 1.93–2.01 (quintet, 2H, J = 7.0 Hz), 2.08–2.32 (m, 5H), 2.34–2.50 (m, 2H), 2.89 (m, 1H), 3.58 (t, 2H, J = 7.0 Hz), 4.86 (br s, 2H). Exact Mass calcd. for $C_{10}H_{15}{}^{35}ClO$: 186.0812; found: 186.0815.

*3-[2-(5-Chloro-1-pentenyl)]-3-methylcyclopentanone (****28****)*

Distillation temperature 76–85°C/0.2 Torr; ir (neat): 3070, 1730, 1630, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.20 (s, 3H), 1.85–2.50 (m, 10H), 3.59 (t, 2H, J = 7.0 Hz), 4.82 (br s, 1H), 4.88 (s, 1H). Exact Mass calcd. for $C_{11}H_{17}{}^{35}ClO$: 200.0969; found: 200.0969.

*3-[2-(5-Chloro-1-pentenyl)]-2-methylcyclopentanone (****29****)*

Analysis (glc) showed that this material (distillation temperature 90–95°C/0.2 Torr) consisted of a mixture of two diastereomers in a ratio of ~4:1; ir (neat): 3060, 1730, 1635, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.05, 0.88 (d, d, 3H total, ratio ~4:1, J =

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

7.0 Hz in each case), 1.60–2.50 (m, ~9.25H), 2.78–2.88 (m, ~0.75H), 3.52–3.63 (m, 2H), 4.78, 4.94 (s, s, ~0.75H each), 4.89–4.92 (m, ~0.5H). Exact Mass calcd. for $C_{11}H_{17}{}^{35}ClO$: 200.0969; found: 200.0975.

General procedure E. Cyclization of chloro ketones

To a stirred solution of KH (~2.5 equiv.) in dry THF (~1 mL per mmol of KH) was added a solution of the chloro ketone (1.0 equiv.) in THF (~1 mL per 0.1 mmol of substrate) and the resultant yellow solution was stirred at room temperature for 2 h. Saturated aqueous NH_4Cl and Et_2O (~2.5 and 5 mL, respectively, per 0.1 mmol of chloro ketone substrate) were added. The aqueous phase was separated and extracted twice with Et_2O. The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Distillation of the residual oil provided the product(s).

General procedure F. Equilibration of bicyclic ketones

To a stirred solution of NaOMe (4.0 equiv.) in dry MeOH (1.25 mL per mmol of NaOMe) was added a solution of the bicyclic ketone (1.0 equiv.) in dry MeOH (0.5 mL per 0.1 mmol of substrate) and the mixture was refluxed for 18 h. Saturated NH_4Cl and Et_2O (3 and 6 mL, respectively, per 0.1 mmol of substrate) were added. The aqueous layer was separated and extracted twice with Et_2O. The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. The makeup of the crude product was determined by gas–liquid chromatographic analysis or by ^1H nmr spectroscopy. Distillation provided the product(s).

The following compounds were prepared by use of general procedure E. Those substances that contained an angular proton adjacent to the carbonyl group were subjected to equilibration (general procedure F). The results of these experiments are summarized in Table 1.

cis- *and* trans-*7-Methylenebicyclo[4.4.0]decan-2-one (30, 31)*

Cyclization of the chloro ketone **23** (44 mg) provided 31 mg (86%) of a mixture of **30** and **31** (distillation temperature 100–120°C/33 Torr, ratio 1:2, respectively, by ^1H nmr spectroscopy). Column chromatography (10 g silica gel, 12:1 petroleum ether – Et_2O) of this mixture afforded 8 mg of the *cis* isomer **30**, a colorless oil, and 17 mg of the *trans* compound **31**, a white solid.

Compound **30** exhibited ir (neat): 3040, 1700, 1630, 895, cm^{-1}; ^1H nmr (400 MHz) δ: 1.31–1.45 (m, 1H), 1.45–1.64 (m, 2H), 1.64–1.79 (m, 1H), 1.79–1.94 (m, 2H), 2.00–2.19 (m, 3H), 2.19–2.30 (m, 2H), 2.36–2.55 (m, 2H), 2.63–2.72 (m, 1H), 4.66 (t, 1H, J = 1.5 Hz), 4.69 (s, 1H). Exact Mass calcd. for $C_{11}H_{16}O$: 164.1202; found: 164.1205.

The *trans* isomer **31** displayed mp 28–29°C (from petroleum ether); ir ($CHCl_3$): 1700, 1635, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.20–1.36 (m, 1H), 1.36–1.52 (m, 1H), 1.60–1.78 (m, 2H), 1.83–2.09 (m, 6H), 2.09–2.21 (m, 1H), 2.23–2.45 (m, 3H), 4.69, 4.75 (s, s, 1H each); ^{13}C nmr (20 MHz) δ: 25.0, 25.3, 26.3, 27.6, 35.8, 41.3, 48.1, 55.5, 75.4, 77.0, 78.6, 105.7, 151.6, 212.5. Exact Mass calcd. for $C_{11}H_{16}O$: 164.1202; found: 164.1202.

Equilibration (general procedure F) of a 1:2 mixture of **30** and **31**, as well as of samples of pure **30** and **31**, gave, in each case, the crystalline *trans*-fused ketone **31** as the only product.

cis- *and* trans-*6-Methyl-7-methylenebicyclo[4.4.0]decan-2-one (32, 33)*

Distillation (100–113°C/33 Torr) of the crude product derived from cyclization of the chloro ketone **24** (22 mg) produced 15 mg (82%) of a mixture of **32** and **33**, in a ratio of 3.5:1, respectively (analysis by glc). Column chromatography of this material on silica gel impregnated with 25% silver nitrate (6 g, 25:1 petroleum ether – Et_2O), followed by distillation of the acquired materials, gave 5 mg of the *cis* isomer **32**, 5 mg of a mixture of **32** and **33**, and 2 mg of the *trans* isomer **33**.

Compound **32** showed ir (neat): 3060, 1700, 1630, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.17 (s, 3H), 1.28–1.47 (m, 2H), 1.61–1.70 (m, 1H), 1.75–2.05 (m, 4H), 2.15 (dd, 1H, J = 10, 4 Hz), 2.18–2.40 (m, 4H), 2.43–2.53 (m, 1H), 4.73 (s, 1H), 4.76 (br s, 1H). In a nOe difference experiment, irradiation at δ1.17 caused enhancement of the signals at δ 2.15 (angular proton) and 4.73. Exact Mass calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1359.

Compound **33** exhibited ir (neat): 3060, 1700, 1630, 895 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95 (s, 3H), 1.20–1.35 (m, 1H), 1.50–1.75 (m, 2H), 1.84–2.40 (m, 10H), 4.70–4.76 (m, 2H). Exact Mass calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1355.

Equilibration of small samples of each of the pure ketones **32** (11 mg) and **33** (15 mg) gave, in each case, a clean mixture of the two ketones **32** and **33**, in a ratio of 1:2.8 (analysis by glc).

cis-*1-Methyl-7-methylenebicyclo[4.4.0]decan-2-one (34)*

This material (15 mg, colorless oil, distillation temperature 85–92°C/22 Torr) was obtained in 78% yield as the only product from cyclization of the chloro ketone **25** (22 mg). Compound **34** exhibited ir (neat): 3050, 1695, 1635, 895 cm^{-1}; ^1H nmr (400 MHz) δ: 1.10 (s, 3H), 1.19–1.28 (m, 1H), 1.55–1.76 (m, 4H), 1.98–2.37 (m, 7H, including a dd, J = 12, 6 Hz, at 2.25), 2.55–2.67 (m, 1H), 4.69 (t, 1H, J = 1.5 Hz), 4.72 (t, 1H, J = 2 Hz). In a nOe difference experiment, irradiation of δ 1.10 caused enhancement of the resonance at δ 2.25 (angular proton). Exact Mass calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1357.

cis- *and* trans-*4.4.6-Trimethyl-7-methylenebicyclo[4.4.0]-decan-2-one (35, 36)*

Cyclization of the chloro ketone **26** (77 mg) provided 58 mg (89%) of a mixture of the bicyclic ketones **35** and **36** (distillation temperature 70–86°C/24 Torr, ratio 8:1, respectively, by glc analysis). Column chromatography of this material on silica gel impregnated with 25% silver nitrate (12 g, 25:1 petroleum ether – Et_2O) gave 6 mg of the *cis* isomer **35** (a white solid) and 46 mg of a mixture of **35** and **36**.

Compound **35** displayed mp 56–56.5°C (from petroleum ether); ir ($CHCl_3$): 3070, 1690, 1620, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.05, 1.06, 1.26 (s, s, s, 3H each), 1.33 (d, 1H, J = 15 Hz), 1.43 (m, 1H), 1.63–1.76 (m, 2H), 1.92–2.03 (m, 1H), 2.08 (ddd, 1H, J = 14, 1.5, 1.5 Hz), 2.13 (dd, 1H, J = 8, 4.5 Hz), 2.23–2.37 (m, 3H), 2.43 (d, 1H, J = 14 Hz), 4.77 (q, 1H, J = 1.5 Hz), 4.80 (br s, 1H). In a nOe difference experiment, irradiation at δ 1.26 (angular Me group) caused enhancement of the signals at δ 1.06, 2.13 (angular proton), and 4.80. Exact Mass calcd. for $C_{14}H_{22}O$: 206.1672; found: 206.1680.

Equilibration of a sample (54 mg) of an 8:1 mixture of **35** and **36** provided 50 mg (92%) of a mixture of these substances (ratio 1:2, respectively, analysis by glc). Column chromatography of this material on silica gel impregnated with 25% silver nitrate (12 g, 90:1 to 20:1 petroleum ether – Et_2O) gave 11 mg of **35**, 16 mg of a mixture of **35** and **36**, and 17 mg of the *trans*-fused ketone **36** (colorless oil, distillation temperature 72–79°C/24 Torr).

Compound **36** exhibited ir (neat): 3060, 1700, 1623, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.04, 1.10, 1.14, (s, s, s, 3H each), 1.19–1.34 (m, 1H), 1.49–1.72 (m, 2H), 1.76–1.91 (m, 2H), 2.01 (d, 1H, J = 13.5 Hz), 2.08–2.20 (m, 2H), 2.20–2.43 (m, 3H), 4.70, 4.73 (br s, br s, 1H each). Exact Mass calcd. for $C_{14}H_{22}O$: 206.1671; found: 206.1675.

cis- *and* trans-*2-Methylenebicyclo[4.3.0]nonan-7-one (37, 38)*

Ring closure of the chloro ketone **27** (37 mg) produced 25 mg (84%) of a colorless oil (distillation temperature 70–85°C/23 Torr) that consisted of a mixture of the bicyclic ketones **37** and **38** in a ratio of ~5:1, respectively (analysis by glc). Column chromatography of this mixture on silica gel impregnated with 25% silver nitrate (6 g, 20:1 petroleum ether – Et_2O) gave 4 mg of the *cis*-fused ketone **37** and 11 mg of a mixture of **37** and **38**.

Compound **37** exhibited ir (neat): 3050, 1730, 1635, 895 cm^{-1}; ^1H nmr (400 MHz) δ: 1.42–1.60 (m, 2H), 1.62–1.80 (m, 2H), 1.85–1.97 (m, 1H), 2.05–2.14 (m, 1H), 2.15–2.37 (m, 3H), 2.37–2.41 (m, 2H), 2.95 (dt, 1H, J = 7.0, 7.0 Hz), 4.79 (s, 1H), 4.80 (br s, 1H). In a nOe difference experiment, irradiation at δ 2.95 (angular allylic proton) caused enhancement of the resonances at

δ 4.79 and 2.37–2.41. Exact Mass calcd. for $C_{10}H_{14}O$: 150.1046; found: 150.1039.

The ^1H nmr spectrum of the mixture of **37** and **38** showed that the alkene protons of the *trans*-fused isomer **38** resonate at δ 4.66 (s) and 4.77 (br s).

Equilibration of a sample (15 mg) of a mixture of **37** and **38** (84.16, respectively), as well as of a sample (15 mg) of pure **37**, produced, in each case, a mixture of **37** and **38** in a ratio of ~5:1, respectively (analyses by glc).

cis-*1-Methyl-2-methylenebicyclo[4.3.0]nonan-7-one (39)*

Cyclization of the chloro ketone **28** (33 mg) gave 22 mg (83%) of a colorless oil (distillation temperature 72–76°C/23 Torr) that, on the basis of analyses by glc and ^1H nmr spectroscopy, consisted of a single compound, the *cis*-fused ketone **39**. This substance displayed ir (neat): 3070, 1735, 1635, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.15–1.30 (m, 1H), 1.34 (s, 3H), 1.50–1.61 (m, 3H), 1.97–2.10 (m, 2H), 2.10–2.33 (m, 4H), 2.45 (m, 1H), 4.77, 4.81 (s, s, 1H each). Exact Mass calcd. for $C_{11}H_{16}O$: 164.1202; found: 164.1208.

Attempted equilibration of a sample (11 mg) of **39** gave only the starting material.

cis-*6-Methyl-2-methylenebicyclo[4.3.0]nonan-7-one (40)*

Cyclization of the chloro ketone **29** (37 mg) afforded 27 mg (90%) of the *cis*-fused bicyclic ketone **40**, a colorless oil (distillation temperature 68–73°C/23 Torr) that exhibited ir (neat): 3050, 1730, 1635, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 1.04 (s, 3H), 1.18–1.27 (m, 1H), 1.43–1.56 (m, 2H), 1.60–1.72 (m, 1H), 1.83–1.95 (m, 1H), 1.98–2.12 (m, 1H), 2.12–2.28 (m, 3H), 2.43–2.55 (m, 2H), 4.76–4.83 (m, 2H). In a nOe difference experiment, irradiation at δ 1.04 caused enhancement of the signal at δ 2.49 (dd, J = 12, 8 Hz, angular proton). Exact Mass calcd. for $C_{11}H_{16}O$: 164.1202; found: 164.1205.

Received September 18, 1992

JEAN-PAUL JAY-GERIN, THOMAS GOULET, and ISABELLE BILLARD. Can. J. Chem. **71**, 287 (1993).

The correlation between the thermal electron mobility, μ_e, the radiation-induced free-ion yield G_{fi} at zero applied electric field, and the most probable thermalization distance b of secondary electrons, is examined for 52 different pure nonpolar dielectric liquids for which data have been reported in the literature. It is shown that, in liquids for which $\mu_e > 10^{-1}$ cm^2 V^{-1} s^{-1}, the variation of G_{fi} with μ_e is well represented by a relation of the type $G_{fi} \propto (\mu_e)^n$, where $n \approx 0.31$. The connection between G_{fi} and μ_e can be described through the product $\varepsilon_s b$, where ε_s is the static dielectric constant of the intervening liquid. In particular, $1/\varepsilon_s b$ is shown to correlate with both μ_e and G_{fi}. Analysis of these correlations allows us to estimate an upper limit of μ_e that can be attained in a room-temperature dielectric liquid, information of utmost importance from the point of view of application to liquid ionization detectors.

JEAN-PAUL JAY-GERIN, THOMAS GOULET et ISABELLE BILLARD. Can. J. Chem. **71**, 287 (1993).

On a évalué la corrélation entre la mobilité des électrons thermiques, μ_e, le rendement G_{fi} en ions libres induit par la radiation à champ électrique appliqué nul et la distance de thermalisation b la plus probable des électrons secondaires de 52 liquides diélectriques non polaires purs différents pour lesquels des données ont été rapportées dans la littérature. On démontre que, dans les liquides pour lesquels $\mu_e > 10^{-1}$ cm^2 V^{-1} s^{-1}, la variation de G_{fi} en fonction de μ_e est bien représentée par une relation du type $G_{fi} \propto (\mu_e)^n$ où $n \approx 0{,}31$. On peut décrire la correspondance entre G_{fi} et μ_e par le produit $\varepsilon_s b$ où ε_s est la constante diélectrique statique du liquide intervenant. En particulier, on a démontré qu'il existe une corrélation entre $1/\varepsilon_s b$ et μ_e ainsi que G_{fi}. Une analyse de ces corrélations nous permet d'évaluer la limite supérieure de μ_e qui peut être atteinte dans un liquide diélectrique à la température ambiante; cette information est d'importance capitale dans l'application aux détecteurs liquides à ionisation.

For personal use only.

The electrical properties of nonpolar dielectric liquids have been actively studied for several decades (for recent reviews, see ref. 1). In particular, electron transport in room-temperature liquids exhibiting high values of the electron mobility has attracted considerable attention in recent years, since these liquids are potential candidates for use in a variety of applications, including liquid ionization detectors (2–5), pulsed-power switches (6), X-ray tomography (7), and high-precision radiotherapy dosimetry (8).

Experimental data on thermal electron mobility μ_e and radiation-induced free-ion yield $G_{fi}(E)$ (measured as a function of applied electric field strength E) are now available in many dielectric liquids (9–14). It is found that μ_e can change by orders of magnitude from one liquid to another, depending strongly on the shape of the constituent molecules. In fact, electron mobilities tend to increase with the degree of sphericity of the molecules (13, 15, 16). Values of μ_e have also been found to correlate with those of G_{fi} at $E = 0$ for liquids of high electron mobilities (5, 17). Despite theoretical efforts (18–20), this correlation remains incompletely understood. Also closely related to the mobility is b, the most probable distance that a secondary electron travels away from its parent ion during its thermalization in the liquid. Values of b are obtained from fitting the field dependence of the experimentally measured yields $G_{fi}(E)$, using various forms of the extended Onsager model (5, 13, 21–25). In fact, there is a correlation between values of b and μ_e in different liquids, the trend being for b to increase with μ_e (13, 26, 27). This correlation is well documented and has been explained on the basis that electrons ejected initially with excess kinetic energy travel the major part of their thermalization distance while having energies of only a few tenths of an electronvolt above thermal (13, 28–31).

In this work, we present a compilation of experimental data available in the literature on the electron mobility, the most probable electron thermalization distance, and the radiolytic zero-field free-ion yield (hereafter simply denoted G_{fi}, for convenience) for a variety of nonpolar liquids, in an attempt to characterize further the interrelationship between these quantities. Values of μ_e, b, and G_{fi} for 52 pure liquids (4, 5, 7, 9, 10, 13, 22, 23, 25–27, 32–57) at room temperature are collected in Table 1, along with the values of the corresponding static dielectric constant ε_s.

In Fig. 1, values of G_{fi} are plotted against log μ_e for all the considered liquids. As we can see, G_{fi} is nearly constant (~0.1 molecule/100 eV) in the range $\mu_e \sim 10^{-2}$–10^{-1} cm^2 V^{-1} s^{-1},[1] whereas it increases with μ_e in higher electron-mobility liquids. Since we are interested by the correlation between G_{fi} and μ_e, we will thus only consider in the following the first 35 liquids of Table 1, for which $\mu_e > 10^{-1}$ cm^2 V^{-1} s^{-1}. A double logarithmic plot of G_{fi} against μ_e is shown in Fig. 2 to examine more quantitatively the re-

[1]Electron mobilities less than 10^{-2} cm^2 V^{-1} s^{-1} are in general observed in polar liquids. The lower mobilities in these liquids are attributed to electron solvation processes; electron migration occurs by an ion-like mechanism rather than by transport through the conduction band (see, for example, refs. 13 and 58.

TABLE 1. Thermal electron mobility (μ_e), most probable electron thermalization distance (b), and free-ion yield (G_{fi}) in various dielectric liquids of static dielectric constant ε_s[a]

[a]Selected values are for room temperature, unless otherwise mentioned. The different liquids are listed in the order of decreasing μ_e.
[b]Values at zero applied electric field strength. Note that G_{fi} is defined as the number of free-ion pairs formed per 100 eV of energy absorbed by the irradiated liquid. Data obtained with low-LET radiations such as γ or X rays, or megavolt electron beams.
[c]Many of the data on ε_s are from ref. 66.
[d]Used in Figs. 1–4.

lationship between those two quantities. A linear correlation is obtained, indicating that the variation of G_{fi} with μ_e can be expressed as

$$[1] \quad G_{fi} = \alpha(\mu_e)^n$$

A least-squares fit of eq. [1] to the log G_{fi} vs. log μ_e data of Fig. 2 (with μ_e in $cm^2\ V^{-1}\ s^{-1}$ and G_{fi} in molecule/100 eV) yields

$$[2] \quad \alpha = 0.21\ (\pm 0.02) \quad \text{and} \quad n = 0.31\ (\pm 0.05)$$

where the values in parentheses indicate the 95% confidence intervals of the estimated parameters calculated using Student's t statistics. The straight line shown in Fig. 2 is calculated from eq. [1] with those parameter values. For the sake of comparison, $G_{fi}(\mu_e)$ data points (13, 16, 59–62) corresponding to low-temperature liquids, namely, liquefied methane and rare gases (see Table 1), are also included in Fig. 2. Rather surprisingly, we note that the fitted line, when extrapolated to higher μ_e and G_{fi} values, also gives a reasonable description of these latter points. This suggests that a general relationship could exist between G_{fi} and μ_e for all dielectric liquids for which $\mu_e > 10^{-1}\ cm^2\ V^{-1}\ s^{-1}$. The physical meaning of the exponent n is not a priori obvious. It is interesting to note, however, that $n \sim 1/3$, which could be indicative that the observed $G_{fi}(\mu_e)$ relationship rests on simple theoretical grounds.

The connection between G_{fi} and μ_e may be seen through the most probable thermalization distance b. This naturally follows from the fact that, on the one hand, liquids with a high μ_e also exhibit a large value of b (13, 26, 27), and that, on the other hand, Onsager's recombination theory (5, 13, 21–25) predicts that high-yield liquids are characterized by high b values. More specifically, the Onsager theory states that in the absence of a collecting electric field, the probability P that an ion pair thermalized at separation r will diffuse apart to become free ions is related to the electron thermalization-distance distribution function $F_b(r)$ by

$$[3] \quad P = \frac{G_{fi}}{G_{tot}} = \int_0^\infty F_b(r) \exp\left[-\frac{e^2}{4\pi\varepsilon_0\varepsilon_s k_B T r}\right] dr$$

where e is the electron charge, ε_0 is the permittivity of vacuum, k_B is Boltzmann's constant, T is the absolute temperature, and G_{tot} is the number of ion pairs initially formed per 100 eV of energy absorbed by the medium.

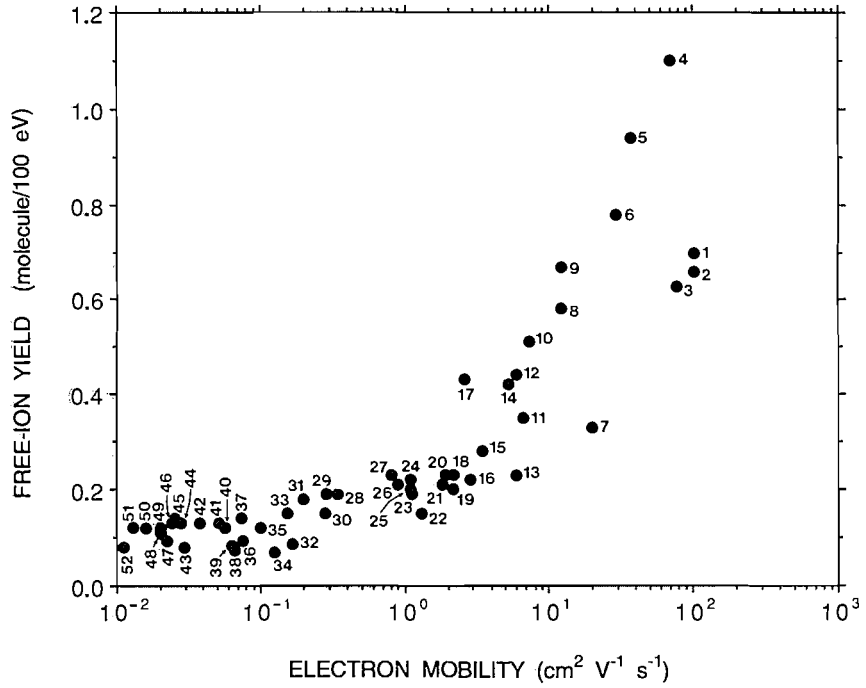

FIG. 1. Free-ion yield G_{fi} as a function of thermal electron mobility μ_e for a variety of pure nonpolar dielectric liquids at room temperature (●). The number for each point refers to the serial number of the liquid in Table 1.

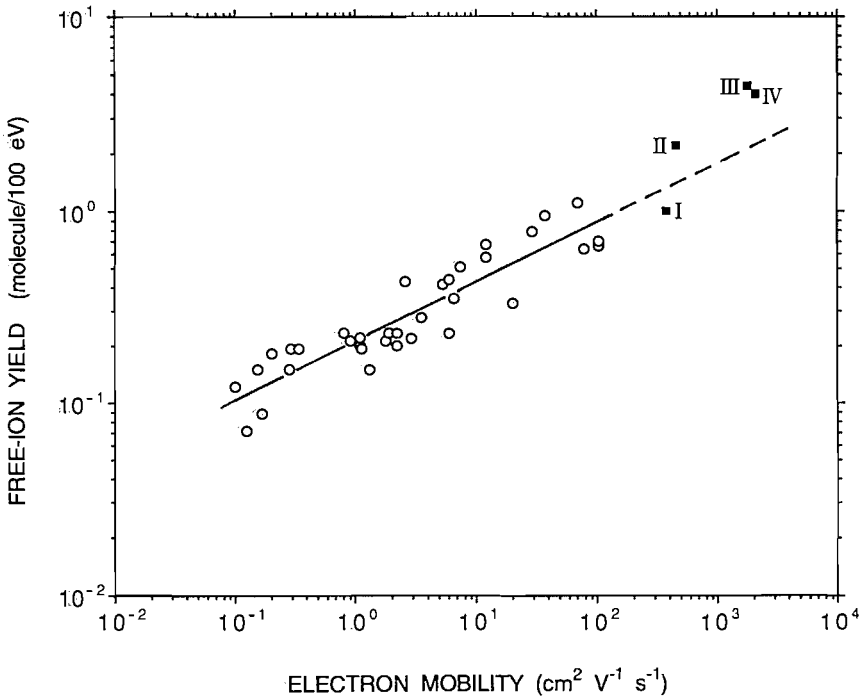

FIG. 2. Double logarithmic plot of free-ion yield against the mobility of thermal electrons for the first 35 liquids listed in Table 1 for which $\mu_e > 10^{-1}$ cm^2 V^{-1} s^{-1} at room temperature (○). The straight line was obtained with eq. [1], using the values of α and n in eq. [2]. The $G_{fi}(\mu_e)$ data points for liquid methane at 122 K, argon at 95 K, xenon at 164 K, and krypton at 129 K (■), included for comparison, are denoted by the numbers I–IV, respectively (see Table 1). The dashed line is an extrapolation of the fitted straight line to higher G_{fi} and μ_e values.

To examine the relationship between G_{fi}, b, and ε_s, a semilog plot of G_{fi} against $1/\varepsilon_s b$ is shown in Fig. 3. A good linear correlation is obtained, indicating that the variation of G_{fi} can be described by a simple equation of the form

$$[4] \quad G_{fi} = G_\infty \exp(-B/\varepsilon_s b)$$

which includes the essential elements of eq. [3]. A least-squares fit of eq. [4] to the log G_{fi} vs. $1/\varepsilon_s b$ data yields

$$[5] \quad G_\infty = 2.1\ (\pm 0.3)\ \text{molecule/100 eV}$$

and $B = 324\ (\pm 22)$ Å

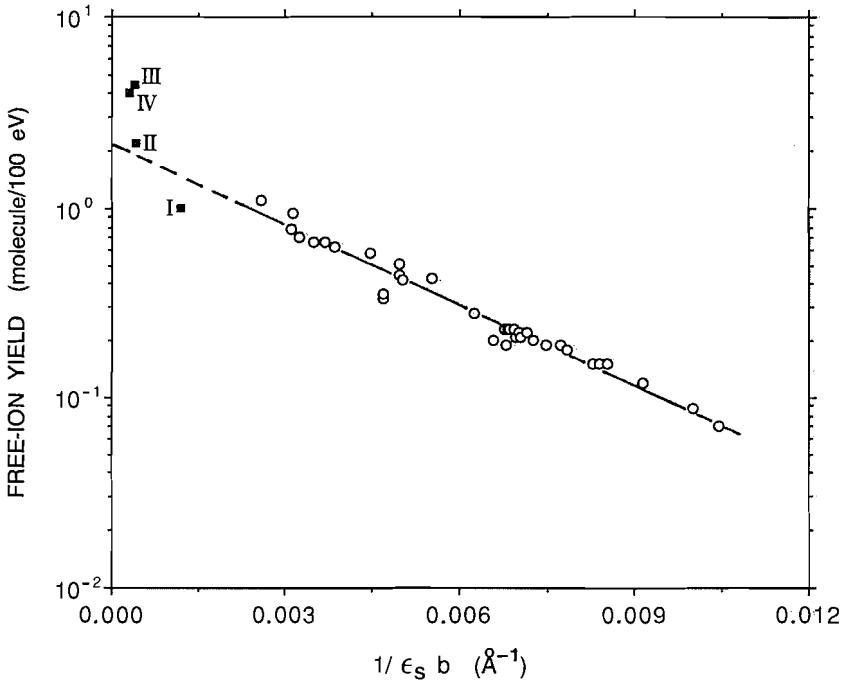

FIG. 3. Plot of the free-ion yield G_{fi} as a function of $1/\varepsilon_s b$ for the same liquids as those in Fig. 2 (○). The straight line was obtained with eq. [4], using the values of G_∞ and B in eq. [5]. The dashed line is an extrapolation of the fitted straight line to $1/\varepsilon_s b \rightarrow 0$. The corresponding data points for liquid methane at 122 K, argon at 95 K, xenon at 164 K, and krypton at 129 K (■), denoted by the numbers I–IV, respectively (see Table 1), are included for comparison.

for the parameters and their 95% confidence intervals (values in parentheses). The solid line shown in Fig. 3 is calculated from eq. [4] with these parameter values. The low-temperature $G_{fi}(1/\varepsilon_s b)$ data points corresponding to liquefied methane and rare gases (see Table 1) are also included in Fig. 3 for comparison. Extrapolation of the fitted line to $1/\varepsilon_s b \rightarrow 0$ passes again through these latter points, but the dispersion is rather large. No indication can be seen here of the existence of anomalous behavior in the variation of G_{fi} with $1/\varepsilon_s b$ in going from the region of electron mobilities considered in this study to higher μ_e values. This does not preclude, however, the breakdown of the Onsager theory that has been predicted for high-electron-mobility liquids (63) since all the b values reported here were obtained with the explicit assumption that this theory remains applicable.

One should note that G_∞, the limiting value of G_{fi} as $1/\varepsilon_s b \rightarrow 0$, cannot be interpreted as the average value of G_{tot} for the various liquids considered. Similarly, B does not represent the term $e^2/4\pi\varepsilon_0 k_B T$ (equal to 560.7 Å at T = 298 K) that appears in the Onsager recombination model (see eq. [3]) (5, 13, 21–25). In fact, eq. [4] is purely empirical and does not attempt to account for the actual electron thermalization-distance distribution function $F_b(r)$ (which peaks at $r = b$) for each liquid. In that sense, the quality of the fit obtained is somewhat surprising, but makes this simple empirical relation quite useful.

If we use eq. [3] with the well-known distribution function YGP (consisting of a three-dimensional Gaussian function extended to larger r values by the addition of a power function tail (13, 50)) in a nonlinear least-squares fit to the $G_{fi}(1/\varepsilon_s b)$ data of Table 1, we find an average total ionization yield $\bar{G}_{tot}$ = 3.7 (±0.5). This value is significantly lower than the commonly accepted gas-phase G_{tot} value of 4.3 molecule/100 eV (64), which has been used in the literature for a variety of hydrocarbon liquids (13, 65). Interestingly, a "universal" value of G_{tot} of 4.3 has also been questioned recently by Holroyd *et al.* (5). In fact, these authors concluded from their analyses of free-ion yields in several room-temperature tetraalkyl liquids containing silicon, germanium, or tin atoms, that G_{tot} values close to 3 ion pairs per 100 eV deposited seemed more appropriate than values near 4 (5).

Combining eqs. [1] and [4] readily yields

$$[6] \quad 1/\varepsilon_s b = C - D \ln \mu_e$$

in agreement with the linear correlation that one can see in the plot of $1/\varepsilon_s b$ against log μ_e of Fig. 4. The best fit to the data (with b in Å and μ_e in $cm^2\ V^{-1}\ s^{-1}$) is obtained with $C = (7.2 \pm 0.3) \times 10^{-3}\ Å^{-1}$ and $D = (9.6 \pm 1.2) \times 10^{-4}\ Å^{-1}$. The extrapolation of the fitted straight line to $1/\varepsilon_s b \rightarrow 0$ again provides a reasonable description (within the statistical uncertainties) of the corresponding $1/\varepsilon_s b(\mu_e)$ data points for liquefied methane and rare gases.

A few words should finally be said about the physical significance of $(\mu_e)_\infty = \exp(C/D) = 1800\ (\pm 1580)\ cm^2\ V^{-1}\ s^{-1}$, the extrapolated value of the fitted straight line in Fig. 4 to $1/\varepsilon_s b \rightarrow 0$. $(\mu_e)_\infty$ appears as an upper limiting value of the mobility of an excess electron in an "ideal" room-temperature liquid in which the most probable thermalization distance would be infinity. A knowledge of $(\mu_e)_\infty$ is therefore of utmost importance from the point of view of application to liquid ionization detectors since it gives us an estimate of the upper limit of μ_e that it is possible to attain in a dielectric liquid at room temperature.

In conclusion, we have presented as complete a compilation as possible of literature values of thermal electron mobilities, radiolytic free-ion yields, and thermalization distances of secondary electrons in a variety of pure non-

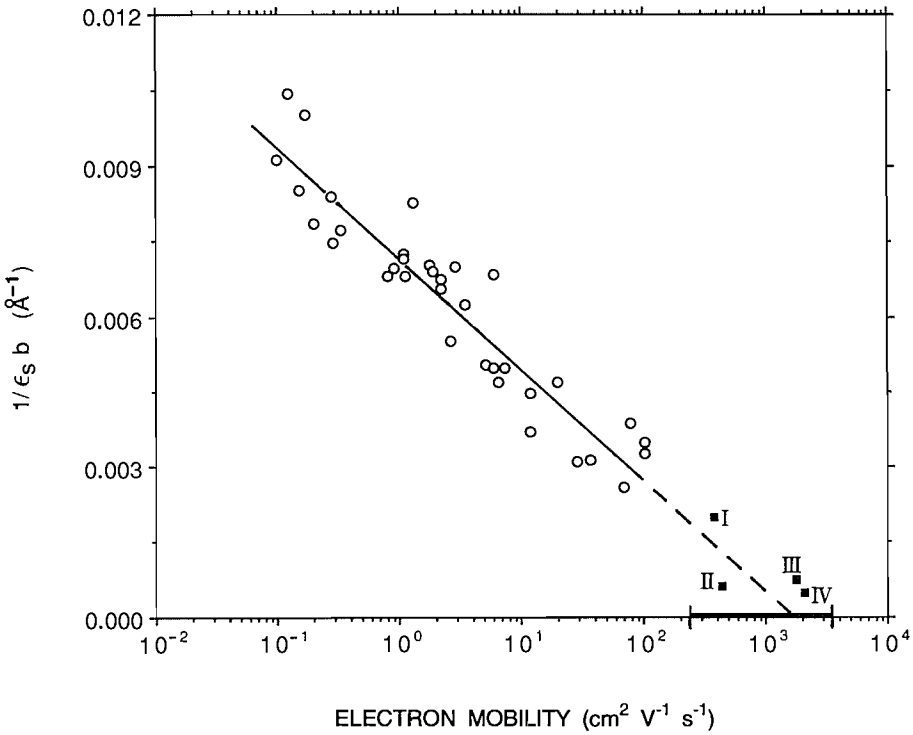

FIG. 4. Plot of $1/\varepsilon_s b$ as a function of the thermal electron mobility μ_e for the same liquids as those in Fig. 2 (○). The straight line was obtained with eq. [6], using the values $C = 7.2 \times 10^{-3}$ Å^{-1} and $D = 9.6 \times 10^{-4}$ Å^{-1}. The dashed line is an extrapolation of the fitted straight line to $1/\varepsilon_s b \rightarrow 0$. The error bar on $(\mu_e)_\infty$ at $1/\varepsilon_s b = 0$ indicates the 95% confidence interval on this parameter. The data points for liquid methane at 122 K, argon at 95 K, xenon at 164 K, and krypton at 129 K (■), denoted by the numbers I–IV, respectively (see Table 1), are included for comparison.

polar liquids at room temperature. On this basis, we have quantitatively described certain correlations that exist between these values. We hope that the present results will contribute to favor further developments of a coherent theory of electron transport and geminate ion–electron recombination in dielectric liquids.

Processus élémentaires en solution : Apports et limites de la théorie du complexe activé dans le cas d'un prééquilibre rapide d'échange protonique entre réactifs

B. SOLASTIOUK, A. MERLIN ET X. DEGLISE[1]

Université de Nancy I, Laboratoire de photochimie appliquée (Unité associée au Centre nationale de la recherche scientifique n° 328), Boîte Postale n° 239, 54506 Vandoeuvre les Nancy CEDEX, France

Reçu le 15 juillet 1992

B. SOLASTIOUK, A. MERLIN et X. DEGLISE. Can. J. Chem. **71**, 294 (1993).

L'étude cinétique des réactions de N-chloration en milieu aqueux de différentes molécules azotées (amines secondaires, imides, acide cyanurique . . .) nous a montré que le comportement acido-basique faible en solution aqueuse des réactifs implique, du fait d'un échange rapide de proton, une indétermination sur le mécanisme exact de chloration. Nous avons généralisé ce résultat à des réactifs de charge quelconque susceptibles d'échanger rapidement un proton. Cette généralisation nous a montré que ce sont les hypothèses de la théorie de l'état de transition qui imposent cette indétermination.

B. SOLASTIOUK, A. MERLIN, and X. DEGLISE. Can. J. Chem. **71**, 294 (1993).

The kinetic study of N-chlorination reactions in the aqueous phase of different nitrogenized molecules (secondary amines, imides, cyanuric acid, etc . . .) shows that the correct chlorination mechanism has not yet been determined because fast proton exchange causes weak acido-basic behaviour of the reagents in aqueous solution. We extended this result to reagents of any charge capable of fast proton exchange. This generalization demonstrates that the indeterminate nature of the mechanism is imposed by the hypotheses of transition state theory.

Introduction

Nous intéressant à l'étude cinétique des réactions de N-chloration en milieu aqueux de différentes fonctions azotées (amines secondaires, succinimide et triazine trione) et des réactions d'hydrolyse des dérivés N-chlorés correspondants, il nous est apparu que le comportement acido-basique faible du chlore et de molécules azotées en solution aqueuse implique, du fait d'un échange rapide de proton,

$$HOCl \leftrightarrows ClO^- + H^+ \text{ pour le chlore}$$

et

$$R_3NH^+ \leftrightarrows R_3N + H^+ \text{ pour les molécules azotées}$$

une indétermination sur le mécanisme exact de la réaction de chloration (1–3).

Dans le cas où la réaction peut concerner les formes acides et basiques de façon croisée, par exemple pour une amine secondaire :

$$R_2NH + ClOH \rightarrow \text{produits}$$

ou

$$R_2NH^+ + ClO^- \rightarrow \text{produits}$$

ces deux mécanismes (pourtant ionique pour l'un ou moléculaire pour l'autre) rendent compte du point de vue théorique de tout résultat expérimental qu'il s'agisse des influences du pH ou de la force ionique sur ces coefficients d'activité qui sont des effets classiquement utilisés en cinétique homogène en solution.

Ce phénomène a déjà été noté par Morris et Weil (4) à propos également de la cinétique de réactions de N-chloration et analysé par Pearson pour la réaction de conversion de cyanate d'ammonium en urée (5–7) où, de façon analogue, les deux mécanismes :

$$NH_3 + CNOH \rightarrow CO(NH_2)_2$$

ou

$$NH_4^+ + CNO^- \rightarrow CO(NH_2)_2$$

sont cinétiquement indiscernables.

Notre objectif est de généraliser ce résultat, a priori surprenant, à des réactifs de charge quelconque susceptibles d'échanger rapidement un proton et de montrer que les hypothèses de l'état de transition imposent cette indétermination.

Constantes de vitesse expérimentales

Hypothèses et expressions générales

Considérons une réaction en solution aqueuse du type :

$$AX + B \underset{V_b}{\overset{V_f}{\rightleftharpoons}} \text{produits}$$

où X représente un atome ou un groupe d'atomes. Les produits peuvent être du type A + XB (substitution, cas de la N-chloration) ou du type A × B (addition, cas de la conversion cyanate d'ammonium-urée), la nature de ces produits n'ayant pas d'influence sur le raisonnement qui suit.

Nous supposons d'une part que la réaction est étudiée suffisamment loin de son état d'équilibre pour que la vitesse de retour V_b soit négligeable devant celle du sens direct V_f et d'autre part qu'il a été observé un ordre 1 par rapport à chacun des réactifs AX et B. Le processus limitant du mécanisme est soit bimoléculaire soit monomoléculaire avec un intermédiaire (C) en équilibre rapide avec AX et B :

$$AX + B \leftrightarrows C^{\neq} \rightarrow \text{produits}$$

$$AX + B \leftrightarrows C \leftrightarrows C^{\neq} \rightarrow \text{produits}$$

Le fait de considérer le cas d'une processus élémentaire limitant bimoléculaire ne nuit en rien à la généralisation des résultats; en effet, supposer un intermédiaire réactionnel en équilibre rapide avec les réactifs d'une part et le composé activé d'autre part n'influe pas sur le raisonnement que nous allons développer.

AX et B possèdent de plus propriétés acido-basiques et se répartissent selon le pH en espèces protonées ou non selon les équilibres suivants :

$$HAX^{(Z_{AX})} \leftrightarrows AX^{(Z_{AX}-1)} + H^+ \qquad (K_a^{AX})$$

$$HB^{(Z_B+1)} \leftrightarrows B^{(Z_B)} + H^+ \qquad (K_a^{B})$$

Les charges Z_i des espèces correspondantes sont quelconques, positives, négatives ou nulles.

Nous admettrons que ces équilibres sont rapides devant la cinétique de la réaction étudiée.

Dans ces conditions sont conservés, quelque soit l'avancement de la réaction, les lois d'action de masse et les bilans suivants :

[1] $$C_{AX} = [HAX] + [AX]$$

avec C_{AX} : concentration totale de AX.

[2] $$C_B = [BH] + [B]$$

avec C_B : concentration totale de B.

[3] $$K_a^{AX} = \frac{(AX)(H^+)}{(HAX)} = \frac{[AX](H^+)}{[HAX]} \frac{f_{(AX)}}{f_{(HAX)}}$$

[4] $$K_a^{B} = \frac{(B)(H^+)}{(BH)} = \frac{[B](H^+)}{[BH]} \frac{f_{(B)}}{f_{(BH)}}$$

Les concentrations molaires courantes de chaque espèce s'écrivent donc à tout instant de la réaction :

[5] $$[HAX] = \frac{(H^+) f_{(AX)}}{(H^+) f_{(AX)} + K_a^{AX} f_{(HAX)}} C_{AX}$$

[6] $$[AX] = \frac{K_a^{AX} f_{(HAX)}}{(H^+) f_{(AX)} + K_a^{AX} f_{(HAX)}} C_{AX}$$

[7] $$[BH] = \frac{(H^+) f_{(B)}}{(H^+) f_{(B)} + K_a^{B} f_{(BH)}} C_B$$

[8] $$[B] = \frac{K_a^{B} f_{(BH)}}{(H^+) f_{(B)} + K_a^{B} f_{(BH)}} C_B$$

L'expérimentation en cinétique doit, à partir de la mesure d'une vitesse globale $V_{(observée)}$, conduire, par une méthode quelconque, à la détermination d'une constante de vitesse expérimentale $k^{(exp)}$ à partir de la relation :

[9] $$V_{(observée)} = k^{(exp)} C_{AX} C_B = -\frac{d C_{AX}}{dt} = -\frac{d C_B}{dt}$$

Cette relation s'applique à une expérience menée dans un réacteur fermé, isotherme, isochore et parfaitement agité.

La constante de vitesse ainsi déterminée dépend de tous les paramètres expérimentaux (pH, température, force ionique . . .) auxquels la réaction est sensible.

Pour remonter au mécanisme de la réaction et à une constante de vitesse qui ne dépende que de la température, il faut, à partir de l'inventaire de tous les mécanismes possibles, comparer les variations de la constante de vitesse expérimentale $k^{(exp)}$ aux variations attendues dans l'hypothèse de l'un ou l'autre des mécanismes.

Dans notre cas, compte tenu de la bimolécularité de la réaction et sans tenter de décrire les états de solvatation des réactifs, quatre mécanismes différents sont envisageables :

$$\mathcal{P}_1 : HAX^{(Z_{AX})} + B^{(Z_B)} \xrightarrow{k_1} \text{produits}$$

$$\mathcal{P}_2 : AX^{(Z_{AX}-1)} + HB^{(Z_B+1)} \xrightarrow{k_2} \text{produits}$$

$$\mathcal{P}_3 : HAX^{(Z_{AX})} + HB^{(Z_B+1)} \xrightarrow{k_3} \text{produits}$$

$$\mathcal{P}_4 : AX^{(Z_{AX}-1)} + B^{(Z_B)} \xrightarrow{k_4} \text{produits}$$

En faisant l'hypothèse de la participation exclusive d'un seul de ces mécanismes, l'expression de la vitesse devient pour chacune des hypothèses :

[10] $$\mathcal{P}_1 : V_{(observée)} = k^{(exp)} C_{AX} C_B = k_1[HAX^{(Z_{AX})}] [B^{(Z_B)}]$$

[11] $$\mathcal{P}_2 : V_{(observée)} = k^{(exp)} C_{AX} C_B = k_2[AX^{(Z_{AX}-1)}] [HB^{(Z_B+1)}]$$

[12] $$\mathcal{P}_3 : V_{(observée)} = k^{(exp)} C_{AX} C_B = k_3[HAX^{(Z_{AX})}] [HB^{(Z_B+1)}]$$

[13] $$\mathcal{P}_4 : V_{(observée)} = k^{(exp)} C_{AX} C_B = k_4[AX^{(Z_{AX}-1)}] [B^{(Z_B)}]$$

avec pour une solution réelle :

[14] $$k_i = k_i^0 \frac{f_{(AX)} f_{(B)}}{f_i^{\neq}}$$

k_i^0 est la constante de vitesse dans des conditions où les coefficients d'activité (f_i) sont égaux à 1. $f_i^{\neq}$ exprime le coefficient d'activité du complexe activé du processus $\mathcal{P}_i$.

À partir des relations [5]–[14], nous obtenons quatre expressions théoriques de la constante de vitesse expérimentale :

[15] $$\mathcal{P}_1 : k^{(exp)} = k_1^0 \frac{K_a^{B}}{f_1^{\neq}} \left[\frac{(H^+) f_{(AX)} f_{(HAX)} f_{(B)} f_{(BH)}}{\mathcal{A}}\right]$$

[16] $$\mathcal{P}_2 : k^{(exp)} = k_2^0 \frac{K_a^{AX}}{f_2^{\neq}} \left[\frac{(H^+) f_{(AX)} f_{(HAX)} f_{(B)} f_{(BH)}}{\mathcal{A}}\right]$$

[17] $$\mathcal{P}_3 : k^{(exp)} = k_3^0 \frac{1}{f_3^{\neq}} \left[\frac{(H^+)^2 f_{(AX)} f_{(HAX)} f_{(B)} f_{(BH)}}{\mathcal{A}}\right]$$

[18] $$\mathcal{P}_4 : k^{(exp)} = k_4^0 \frac{K_a^{AX} K_a^{B}}{f_4^{\neq}} \left[\frac{f_{(AX)} f_{(HAX)} f_{(B)} f_{(BH)}}{\mathcal{A}}\right]$$

avec

$$\mathcal{A} = [(H^+) f_{(AX)} + K_a^{AX} f_{(HAX)}] [(H^+) f_{(B)} + K_a^{B} f_{(BH)}]$$

La figure 1 représente ces fonctions sur le domaine de pH des solutions aqueuses avec des paramètres arbitraires.

Il apparaît clairement que si les processus $\mathcal{P}_3$ et $\mathcal{P}_4$ sont facilement discernables par une simple étude de l'influence du pH sur la constante de vitesse expérimentale, il n'en est pas de même pour les processus $\mathcal{P}_1$ et $\mathcal{P}_2$ dont les variations théoriques de la constante de vitesse en fonction du pH sont strictement identiques à coefficients d'activité constants. Ce second cas est observé par les réactions de N-chloration d'amines (2) ou d'isomérisation du cyanate d'alkylammonium en phase aqueuse (5).

En milieu neutre et basique, les variations de la constante de vitesse expérimentale de chloration de la diéthylamine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

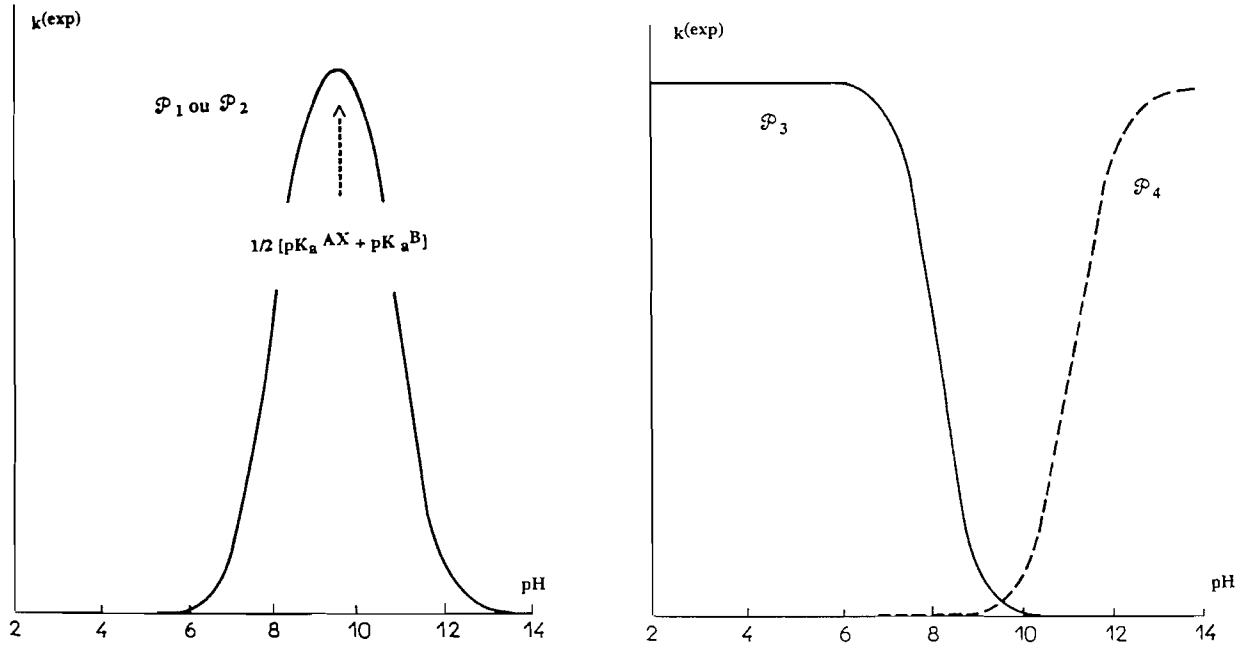

FIG. 1. Variations théoriques de la constante de vitesse expérimentale pour chaque processus en fonction du pH.

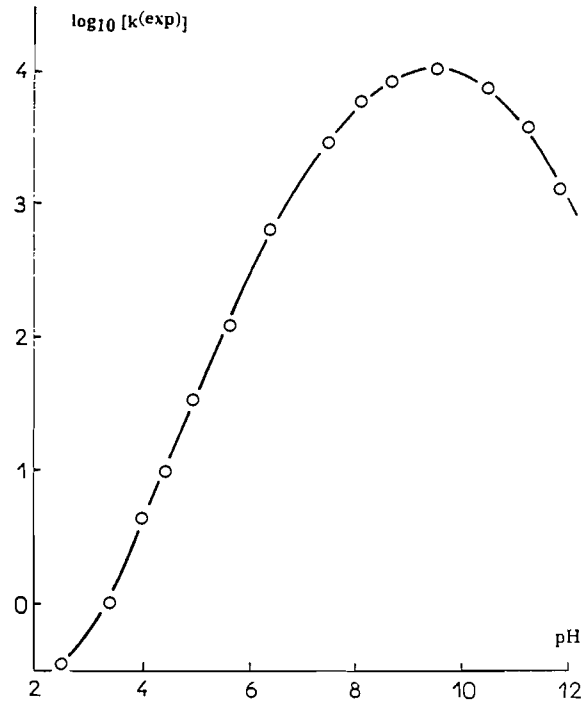

FIG. 2. Variation de la constante de vitesse expérimentale de la *N*-chloration de la diéthylamine.

(figure 2) montrent que ces cinétiques correspondent au cas $\mathcal{P}_1$ et $\mathcal{P}_2$ avec les deux processus équivalents :

$$R_2NH + ClOH \xrightarrow{k_1} \text{produits}$$

$$R_2NH_2^+ + ClO^- \xrightarrow{k_2} \text{produits}$$

En milieu acide, nous observons une chloration par le chlore moléculaire. Une étude spécifique de cette réaction a montré que cette cinétique est limitée par la diffusion des réactifs et se fait sur l'amine non protonée (2) :

$$R_2NH + Cl_2 \xrightarrow{k_{Cl_2}} R_2NCl + H^+ + Cl^-$$

Formes limites et effets de la force ionique

Dans la mesure où l'effet de pH ne permet pas de différencier les processus $\mathcal{P}_1$ et $\mathcal{P}_2$, il semble logique, dans ce but, d'étudier l'effet de la force ionique du milieu sur la vitesse de réaction.

Pour ces processus, en posant :

$$[19] \quad W = \frac{(H^+) f_{(AX)} f_{(HAX)} f_{(B)} f_{(BH)}}{\mathcal{A}}$$

nous obtenons pour $\mathcal{P}_1$:

$$[20] \quad k^{(exp)} = k_1^0 \frac{K_a^B}{f_1^{\neq}} W$$

pour $\mathcal{P}_2$:

$$[21] \quad k^{(exp)} = k_2^0 \frac{K_a^{AX}}{f_2^{\neq}} W$$

Les constantes de vitesse k_i^0 et d'équilibre K_a ne dépendent que de la température. Ainsi, une différence observable sur les constantes de vitesse expérimentale $k^{(exp)}$ à température constante obtenue pour une variation des paramètres ne peut provenir que d'un comportement différent de la valeur du coefficient d'activité du complexe activé de chacun des processus.

En fait, ceux-ci sont constitués du même nombre d'atomes et portent la même charge :

$$\mathcal{P}_1 : HAX^{(Z_{AX})} + B^{(Z_B)} \leftrightarrows (HAX...B)^{(Z_1^{\neq})} \rightarrow \text{produits}$$

$$\mathcal{P}_2 : AX^{(Z_{AX}-1)} + HB^{(Z_B+1)} \leftrightarrows (AX...BH)^{(Z_2^{\neq})} \rightarrow \text{produits}$$

$$Z_2^{\neq} = (Z_{AX} - 1) + (Z_B + 1) = Z_{AX} + Z_B = Z_1^{\neq}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

Dans ces conditions, il est difficile d'attendre une influence différente du milieu sur la valeur du coefficient d'activité de l'un ou l'autre de ces complexes activés.

Même s'il ne permet pas de différencier ces deux processus, l'effet de la force ionique sur les constantes de vitesse expérimentales est intéressant à analyser, en particulier en milieu fortement acide ou basique où les expressions de ces constantes prennent des formes simplifiées (tableau 1).

Ces formes limites sont représentées par des droites de pente +1 en milieu acide et −1 en milieu basique en portant $\log_{10}(k^{(exp)})$ en fonction du pH (figure 3).

Dans les domaines de concentration et de force ionique où la loi de Debye–Hückel peut être appliquée, les coefficients d'activité se déduisent de la relation $\log_{10}(f) = -\alpha Z^2\sqrt{I}$ avec I la force ionique du milieu et $\alpha \approx 0{,}5$ pour l'eau à 298 K. Nous avons alors pour toutes les espèces en présence :

$$\log_{10}[f_{(HAX)}] = -\alpha(Z_{AX})^2\sqrt{I}$$

$$\log_{10}[f_{(AX)}] = -\alpha(Z_{AX} - 1)^2\sqrt{I}$$

$$\log_{10}[f_{(B)}] = -\alpha(Z_B)^2\sqrt{I}$$

$$\log_{10}[f_{(BH)}] = -\alpha(Z_B + 1)^2\sqrt{I}$$

et pour les complexes activés :

$$\log_{10}(f_1^{\neq}) = \log_{10}(f_2^{\neq}) = -\alpha(Z_{AX} + Z_B)^2\sqrt{I}$$

On en déduit les expressions suivantes de la constante de vitesse, en milieu acide :

$$\log_{10}(k^{(exp)}) = C^{te} - \alpha[1 + 2Z_B - 2Z_{AX}Z_B]\sqrt{I}$$

en milieu basique :

$$\log_{10}(k^{(exp)}) = C^{te} - \alpha[1 - 2Z_{AX} - 2Z_{AX}Z_B]\sqrt{I}$$

qui sont valables pour les deux processus $\mathcal{P}_1$ et $\mathcal{P}_2$.

Pour $Z_{AX} = Z_B = 0$ (par exemple $\mathcal{P}_1$: ClOH + R_2 NH et $\mathcal{P}_2$: ClO^- + $R_2NH_2^+$), la pente attendue de la droite représentant la variation de $\log_{10}(k^{(exp)})$ en fonction de $\sqrt{I}$ est de $-\alpha$ pour $\mathcal{P}_1$ et $\mathcal{P}_2$ alors que, si l'on ne tient compte que de l'effet de sel primaire, elle devrait être de $2\alpha Z_{AX}Z_B$ donc nulle pour $\mathcal{P}_1$ et de -2α pour $\mathcal{P}_2$. En effet, dans ce dernier cas, on ne prend plus en compte les propriétés acido-basiques des espèces AX et B. D'après les relations [10], [11] et [14], on aura, pour $\mathcal{P}_1$:

$$k^{(exp)} = k_1^0 \frac{f_{(HAX)}f_{(B)}}{f_1^{\neq}}$$

soit

$$\log_{10}(k^{(exp)} = C^{te} + 2\alpha Z_{AX}Z_B\sqrt{I}$$

pour $\mathcal{P}_2$:

$$k^{(exp)} = k_2^0 \frac{f_{(AX)}f_{(BH)}}{f_2^{\neq}}$$

soit

$$\log_{10}(k^{(exp)}) = C^{te} + 2\alpha(Z_{AX} - 1)\,(ZB + 1)\sqrt{I}$$

Le raisonnement précédent montre que l'analyse des variations des constantes expérimentales en fonction des paramètres du milieu ne permet pas de différencier les processus du type $\mathcal{P}_1$ et $\mathcal{P}_2$.

Pour poursuivre plus loin une tentative de différenciation de ces processus, il nous faut exprimer les constantes de vitesse absolues (k_i^0) dans les hypothèses de la théorie du complexe activé.

Utilisation de la théorie du complexe active

Pour qu'une réaction qui n'est pas limitée par la diffusion ait lieu de part et d'autre d'un processus élémentaire, on doit supposer qu'il existe une configuration correspondant au point d'énergie maximum entre l'état de réactif et l'état de produit.

La théorie du complexe activé prête à cet état transitoire les propriétés thermodynamiques d'une molécule normale. Sa concentration, par exemple, peut être calculée par la thermodynamique statistique. On suppose de plus que la vitesse de réaction est égale au produit de cette concentration $C^{\neq}$ par sa fréquence de dissociation $\nu^{\neq}$ (8).

Formellement, ces hypothèses ne s'appliquent qu'à l'équilibre entre réactifs et produits mais son extension à des systèmes hors équilibre n'est généralement pas remise en cause.

À l'équilibre entre réactifs et produits, la concentration en complexe activé est constante.

Dans ces conditions, en reprenant le formalisme utilisé par Hall (9) et en notant $C_f^{\neq}$ la concentration en complexe provenant des réactifs et p_f la probabilité qu'ont ceux-ci de reformer les réactifs, une fraction $\frac{1}{1 + p_f}$ donne les produits alors qu'une fraction $\frac{p_f}{1 + p_f}$ reforme les réactifs. Alors la vitesse dans le sens direct s'écrit :

$$[22] \quad V_f = \nu^{\neq}\left(\frac{1 - p_f}{1 + p_f}\right) C_f^{\neq}$$

De la même façon, en indiçant par b les valeurs symétriques concernant le sens direct de la réaction :

$$[23] \quad V_b = \nu^{\neq}\left(\frac{1 - p_b}{1 + p_b}\right) C^{\neq}$$

À l'équilibre, $V_f = V_b$ et comme $C^{\neq} = C_f^{\neq} = C_b^{\neq}$, on en déduit l'équation de la vitesse :

$$[24] \quad V_f = \kappa\,\nu^{\neq}\frac{C^{\neq}}{2}$$

où

$$\kappa = \frac{(1 - p_f)\,(1 - p_b)}{1 - p_f p_b}$$

est le coefficient de transmission du processus.

On admet en solution réelle que la concentration en complexe activé dépend d'une constante d'équilibre soit, pour une réaction bimoléculaire du type qui nous intéresse (8, 9) :

$$[25] \quad K^{\neq} = \frac{a^{\neq}}{(AX)\,(B)} = \frac{C^{\neq}}{[AX]\,[B]}\frac{f^{\neq}}{f_{(AX)}f_{(B)}}$$

TABLEAU 1. Formes limites des constantes de vitesse expérimentales en milieu fortement acide ou basique

	Milieu acide	Milieu basique
$\mathcal{P}_1$	$k^{(exp)} = k_1^0 \frac{K_a^B}{(H^+)} \frac{f_{(HAX)} f_{(BH)}}{f_1^{\neq}}$	$k^{(exp)} = k_1^0 \frac{(H^+)}{K_a^{AX}} \frac{f_{(AX)} f_{(B)}}{f_1^{\neq}}$
$\mathcal{P}_2$	$k^{(exp)} = k_2^0 \frac{K_a^{AX}}{(H^+)} \frac{f_{(HAX)} f_{(BH)}}{f_2^{\neq}}$	$k^{(exp)} = k_2^0 \frac{(H^+)}{K_a^B} \frac{f_{(AX)} f_{(B)}}{f_2^{\neq}}$

où $a^{\neq}$ est l'activité du complexe activé. L'utilisation d'une telle constante d'équilibre sous-entend que le complexe activé est normalement solvaté donc que la réorganisation du solvant autour du complexe en collision est rapide par rapport à la durée du processus.

À partir de l'expression de $C^{\neq}$ déduite de la relation [25], la vitesse de réaction devient :

$$[26] \quad V_f = \kappa \frac{\nu^{\neq}}{2} K^{\neq} \frac{f_{(AX)} f_{(B)}}{f^{\neq}} [AX] [B]$$

Par identification à la relation [14], k^0 prend la forme :

$$[27] \quad k^0 = \kappa \frac{\nu^{\neq}}{2} K^{\neq}$$

Dans le cas AX + B, il est habituel de considérer la fréquence de dissociation du complexe activé comme le rapport d'une vitesse moyenne (v) de déplacement de X sur une coordonnée privilégiée de l'espace des configurations dite coordonnée de réaction et d'une longueur δ définissant le complexe activé sur cette coordonnée. Par définition du complexe activé, sur cette longueur δ, X n'est soumis à aucun grandient de potentiel et ne possède qu'une énergie de translation. Dans cette situation, on assimile X à une molécule de gaz parfait et on peut donc lui attribuer une vitesse moyenne calculée par la théorie cinétique :

$$v = \sqrt{\frac{2k_B T}{\pi m}} \qquad (k_B \text{ constante de Boltzmann})$$

ainsi qu'une fonction de partition de translation :

$$Q^x_{trans} = \frac{\delta}{h} \sqrt{2 \pi m k_B T}$$

Il en découle l'expression habituelle de k^0 :

$$k^0 = \kappa \frac{k_B T}{h} K^* \text{ avec } K^* = \frac{K^{\neq}}{Q^x_{trans}}$$

K^* ne représente pas, au contraire de $K^{\neq}$, une valeur thermodynamique «normale».

À partir des relations [15], [16] et [27], nous obtenons les expressions des constantes de vitesse expérimentales pour les processus $\mathcal{P}_1$ et $\mathcal{P}_2$:

$$\mathcal{P}_1 : \quad k^{(exp)} = \frac{k_1}{2} \frac{\nu_1^{\neq}}{f_1^{\neq}} K_1^{\neq} K_a^B W$$

$$\mathcal{P}_2 : \quad k^{(exp)} = \frac{k_2}{2} \frac{\nu_2^{\neq}}{f_2^{\neq}} K_2^{\neq} K_a^{AX} W$$

En exprimant les constantes d'équilibre en fonction des activités des espèces, le rapport des produits $K_1^{\neq} K_a^B$ et $K_2^{\neq} K_a^{AX}$ apparaît comme égal au rapport des activités des complexes activés donc à une constante d'équilibre $K_{12}^{\neq}$:

$$[28] \quad \frac{K_1^{\neq} K_a^B}{K_2^{\neq} K_a^{AX}} = \frac{a_1^{\neq}}{a_2^{\neq}} = K_{12}^{\neq}$$

Ceci découle de nos hypothèses car, si l'on veut comparer les vitesses dues respectivement à $\mathcal{P}_1$ et $\mathcal{P}_2$, il faut admettre un triple équilibre :

$$(B...HAX)^{\neq} \leftrightarrows B + HAX \leftrightarrows BH + AX \leftrightarrows (BH...AX)^{\neq}$$

et donc indirectement un équilibre entre les deux complexes activés.

On aura donc égalité de leurs potentiels chimiques :

$$\mu_1^{\neq} = \mu_2^{\neq}$$

soit :

$$\mu_1^{0\neq} + RT \ln(a_1^{\neq}) = \mu_2^{0\neq} + RT \ln(a_2^{\neq})$$

La relation [28] devient alors :

$$K_{12}^{\neq} = \frac{K_1^{\neq} K_a^B}{K_2^{\neq} K_a^{AX}} = \exp\left(\frac{\mu_2^{0\neq} - \mu_1^{0\neq}}{RT}\right)$$

En admettant $\nu_1^{\neq} = \nu_2^{\neq}$ et $\kappa_1 = \kappa_2$ ou que ces valeurs sont proportionnelles d'un facteur β qui ne dépend pas du milieu $\kappa_2 \nu_2^{\neq} = \beta \kappa_1 \nu_1^{\neq}$, nous avons (avec $\beta = 1$) :

$$\mathcal{P}_1 : \quad k^{(exp)} = k_1^0 \frac{K_a^B}{f_1^{\neq}} W$$

$$\mathcal{P}_2 : \quad k^{(exp)} = k_1^0 \frac{K_a^B}{f_2^{\neq}} W \exp\left(\frac{\mu_2^{0\neq} - \mu_1^{0\neq}}{RT}\right)$$

soit :

$$[29] \quad k_{(\mathcal{P}_1)}(exp) = k_{(\mathcal{P}_2)}(exp) K_{12}^{\neq}$$

Il existe donc un facteur de proportionnalité entre les deux constantes de vitesse qui ne dépend que des énergies standards des complexes activés. Dans ces conditions, seul un effet comme celui du solvant qui pourrait avoir une influence différente sur ces niveaux selon le processus et la nature du complexe activé correspondant peut être envisagé pour différencier $\mathcal{P}_1$ de $\mathcal{P}_2$.

La relation [29] montre que toute différence d'effet attendue dans l'une ou l'autre de ces hypothèses ne peut se mesurer que par les potentiels standards des complexes activés. Pour dire si la réaction se fait par l'un ou l'autre des processus, il faut que ces potentiels soient nettement différents (un seul des processus participe à la réaction). Pour le prouver, il faut trouver un paramètre qui agisse théoriquement différemment sur les énergies libres standards de ces états. Ceci implique de faire d'abord une hypothèse sur la structure des complexes activés ce qui peut être délicat en solution.

Effet de solvant

L'effet de solvant sur les vitesses de réaction (12) est décrit à partir de l'expression de la variation d'énergie libre pour amener une sphère de rayon r contenant des charges à répartition non uniforme (possédant un moment dipolaire ρ)

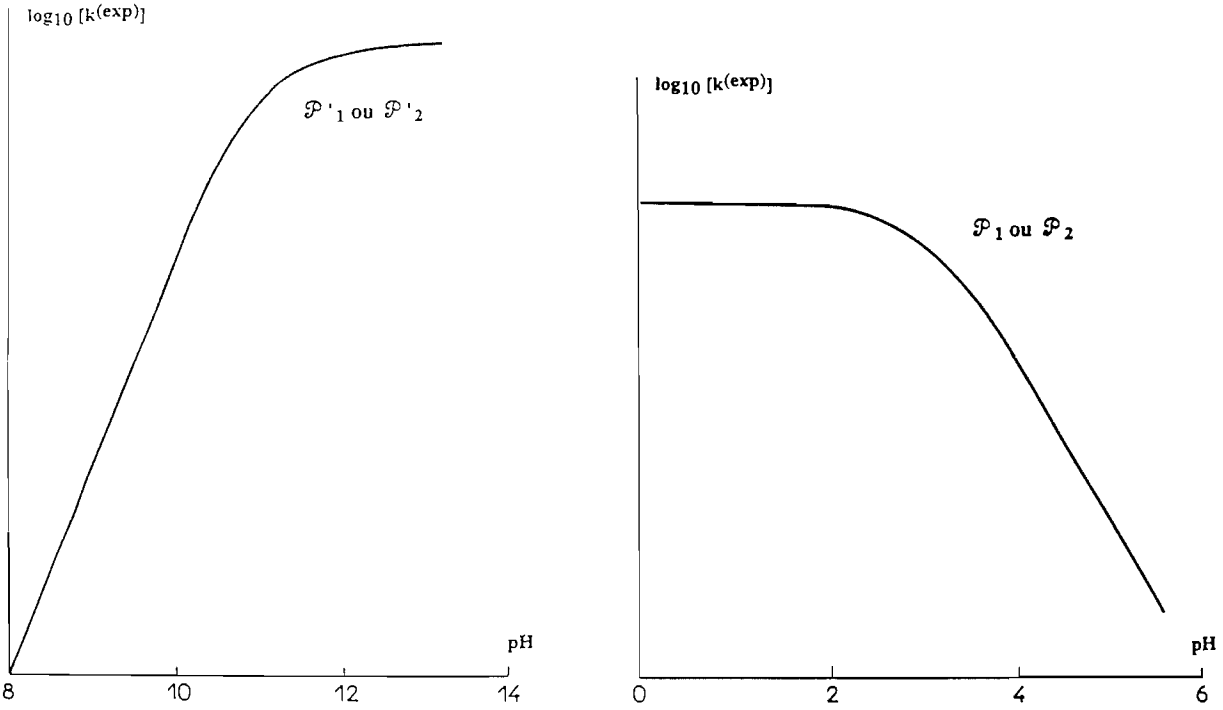

FIG. 3. Variations théoriques du logarithme décimal de la constante de vitesse expérimentale pour chaque processus en fonction du pH.

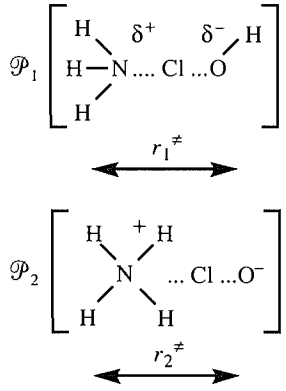
d'un milieu de constante diélectrique égal à 1 dans un milieu de constante diélectrique ε.

$$\Delta G = \frac{z^2 e^2}{2r}\left(\frac{1}{\varepsilon} - 1\right) + \frac{3\rho^3}{8r^3}\left(\frac{1-\varepsilon}{1+\varepsilon}\right)$$

Pour les deux complexes activés $z^{\neq} = z_{AX} + z_B$, leurs rayons sont du même ordre de grandeur ($r_1^{\neq} = r_2^{\neq}$). Quant à leurs moments dipolaires, si l'on prend comme exemple la N-chloration de l'ammoniac NH_3 :



du fait de la structure proche des complexes activés, ceux-ci sont nécessairement de même grandeur ($\rho_1^{\neq} \approx \rho_2^{\neq}$). On peut donc admettre que la variation d'energie libre due au passage d'un solvant (S) à un solvant (S') est quasiment égale pour les deux complexes activés :

$$\Delta G_1^{\neq 0}(S \rightarrow S') = \Delta G_2^{\neq 0}(S \rightarrow S')$$

et donc :

[30] $$K_{12(S)}^{\neq} = K_{12(S')}^{\neq}$$

Cet exemple montre qu'il est extrêmement peu probable de trouver un cas où l'effet de solvant puisse jouer de façon suffisamment différente et mesurable sur deux complexes activés dont la nature ne diffère que de la position d'un proton. Néanmoins, un tel cas ne peut être généralisé et cet effet ne peut être analysé qu'au cas par cas. Dans des situations favorables, il permet en théorie de tirer des conclusions mais cela ne peut être que dans les hypothèses décrites précédemment. Une analyse partielle peut conduire à des déductions erronées comme l'a montré Pearson et Frost (5) à propos d'études sur la réaction de conversion du cyanate d'ammonium en urée.

Les relations [29] et [30] indiquent que ces constantes de vitesse expérimentales pour l'un ou l'autre des processus sont proportionnelles d'un terme ne dépendant pas des conditions expérimentales. Dans les hypothèses de la théorie du complexe activé, ces deux processus nous apparaissent comme indiscernables par l'analyse formelle des effets du milieu sur la cinétique de réaction.

Approche du mécanisme par corrélation entre reactions similaires

Il est possible par comparaison de deux séries de réactions voisines, dont l'une ne présente pas d'ambiguïté de mécanisme, d'obtenir des indications sur la nature des mécanismes dans l'autre série. Jensen (6), par exemple, a pu corréler de façon évidente les constantes de vitesse de réactions d'amines avec l'acide cyanique et celles des mêmes amines avec le dioxyde de carbone pour former des carbamates (réaction qui ne présente pas d'ambiguïté de mécanisme; l'hydratation de CO_2 étant lente par rapport à celle-ci).

$$R\,NH_2 + CO_2 \xrightarrow{k_{CO_2}} R\,NH\,CO_2H$$

$$R\,NH_2 + CNOH \xrightarrow{k_{CNOH}} R\,NH\,CO\,NH_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

avec

$$\log_{10}(k_{CNOH}/1\ M^{-1}\ s^{-1}) = \log_{10}(k_{CO_2}/1\ M^{-1}\ s^{-1}) - 1{,}08$$

alors qu'il n'existe pas de corrélation pour les valeurs de constantes de vitesse calculées dans l'hypothèse du processus :

$$R\,NH_2^+ + CNO^- \xrightarrow{k_{CNO^-}} R\,NH\,CO\,NH_2$$

Pour les N-chlorations, le fait qu'en présence de dichlore (Cl_2), nous ayons (2) :

$$R_2NH + Cl_2 \xrightarrow{k_{Cl_2}} R_2N\,Cl + H^+ + Cl^-$$

permet de penser que le mécanisme le plus probable pour la chloration par l'acide hypochloreux est

$$R_2NH + Cl\,OH \xrightarrow{k_{ClOH}} R_2N\,Cl + H_2O$$

Il n'est malheureusement pas possible de corréler les valeurs de k_{Cl_2} et de k_{ClOH}, la chloration des amines par Cl_2 en milieu aqueux présentant une cinétique limitée par la diffusion (2, 13).

De plus, contrairement au cas des réactions des amines avec CNOH, les constantes de vitesse de N-chloration sont directement liées au pK_a de l'amine. La relation liant k_{ClOH} à k_{ClO^-} étant

$$k_{ClOH} = \frac{K_2}{K_a} k_{ClO^-}$$

toute corrélation concernant l'une des constantes de vitesse sera aussi valable pour l'autre.

Ces comparaisons, ou des hypothèses sur la structure la plus probable d'un complexe activé, ne donnent que des indications et ne constituent pas des preuves irréfutables sur la nature du processus élémentaire limitant.

Cas particulier de l'hydrolyse

Les réactions d'hydrolyse de composés acides ou bases faibles représentent un cas particulier du type de réaction présenté précédemment. Deux cas sont possibles :
Hydrolyse «acide» :

$$SH + H_2O \leftrightarrows S^- + H_3O^+$$

$\mathcal{P}_1$: $S^- + H_3O^+ \rightarrow$ produits

$\mathcal{P}_2$: $SH + H_2O \rightarrow$ produits

Hydrolyse «basique» :

$$S^- + H_2O \leftrightarrows SH + OH^-$$

$\mathcal{P}'_1$: $S^- + H_2O \rightarrow$ produits

$\mathcal{P}'_2$: $SH + OH^- \rightarrow$ produits

Dans le premier cas, les vitesses s'expriment selon le processus envisagé :

$$[31] \quad v = k_1^0 \frac{f_{(H)} f_{(S^-)}}{f_1^0} [S^-]\,[H_3O^+]$$

$$[32] \quad v = k_2^0 \frac{f_{(H_2O)} f_{(HS)}}{f_2^{\neq}} [SH]\,[H_2O]$$

En appliquant les principes définis précédemment, nous obtenons les constantes de vitesse expérimentales :

$$[33] \quad \mathcal{P}_1 : \quad k^{(exp)} = k_1^0 \frac{k_a^S}{f_1^{\neq}} \left(\frac{(H^+) f_{(S^-)} f_{(SH)}}{[(H^+) f_{(S^-)} + K_a^S f_{(SH)}]} \right)$$

$$[34] \quad \mathcal{P}_2 : \quad k^{(exp)} = k_2^0 \frac{(H_2O)}{f_2^{\neq}} \left(\frac{(H^+) f_{(S^-)} f_{(SH)}}{[(H^+) f_{(S^-)} + K_a^S f_{(SH)}]} \right)$$

Pour le milieu basique :

$$[35] \quad v = k_1'^0 \frac{f_{(H_2O)} f_{(S^-)}}{f_1^{\neq}} [S^-]\,[H_2O]$$

$$[36] \quad v = k_2'^0 \frac{f_{(OH^-)} f_{(SH)}}{f_2^{\neq}} [SH]\,[OH^-]$$

Soit, en posant $K_W = (H_3O^+)\,(OH^-)$:

$$[37] \quad \mathcal{P}'_1 : \quad k^{(exp)} = k_1'^0 \frac{(H_2O) K_a^S}{f_1'^{\neq}} \left(\frac{f_{(S^-)} f_{(SH)}}{[(H^+) f_{(S^-)} + K_a^S f_{(SH)}]} \right)$$

$$[38] \quad \mathcal{P}'_2 : \quad k^{(exp)} = k_2'^0 \frac{K_W}{f_2'^{\neq}} \left(\frac{f_{(S^-)} f_{(SH)}}{[(H^+) f_{(S^-)} + K_a^S f_{(SH)}]} \right)$$

L'activité de l'eau est équivalente à la constante d'acidité du proton solvaté :

$$H_2O + H_3O^+ \leftrightarrows H_3O^+ + H_2O$$

soit avec les conventions habituelles :

$$H_3O^+ \leftrightarrows H_2O + H^+$$

et

$$K_a^{H_2O} = \frac{(H^+)\,(H_2O)}{(H_3O^+)} = (H_2O)$$

Cette valeur est généralement sous-entendue sous celle de k^0 (en milieu tamponné, ces cinétiques sont du pseudo-premier ordre par rapport à S).

La figure 4 montre les variations de ces constantes de vitesse en fonction du pH.

Contrairement aux cas précédents, ces courbes ne présentent pas de maximum mais là aussi, il persiste une indétermination du mécanisme réel. Ces exemples de réaction de ce type sont nombreux. Ainsi, au cas acide, correspondent les hydrolyses des amides (de pK_a suffisamment élevé) avec, comme prééquilibre :

$$R\,CO\,NH_3^+ + H_2O \leftrightarrows R\,CO\,NH_2 + H_3O^+$$

En milieu basique, nous avons rencontré cette situation (10) à propos de l'hydrolyse du dérivé monochloré de l'acide cyanurique (H_3Cy) avec l'équilibre d'échange protonique. Deux processus sont possibles :

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

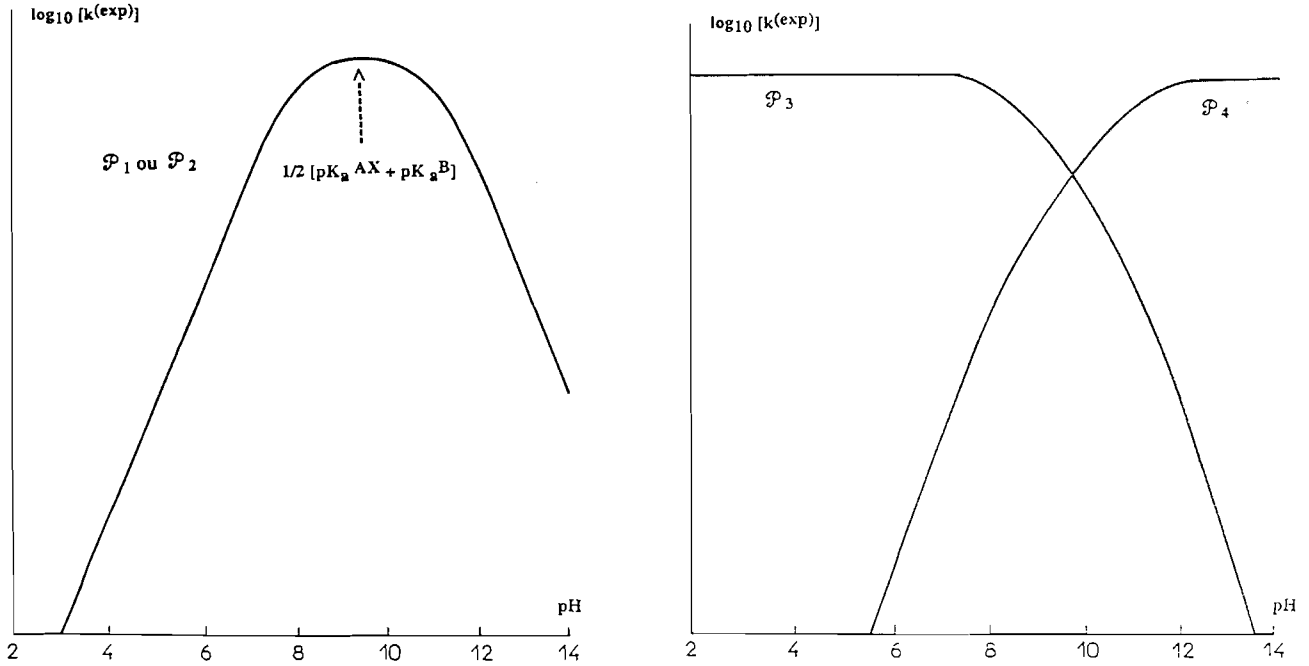


FIG. 4. Variations du logarithme de la constante de vitesse expérimentale de l'hydrolyse de bases ou d'acides faibles en fonction du pH.

$$\mathcal{P}_1 : \quad Cy\,Cl\,H^- + OH^- \rightarrow Cy\,H_2^- + ClO^-$$

$$\mathcal{P}_2 : \quad Cy\,Cl^{2-} + H_2O \rightarrow Cy\,H_2^- + ClO^-$$

avec ici une totale ambiguïté puisque les deux processus sont imaginables du point de vue de la structure du complexe activé.

Indétermination ou équivalence?

Les raisonnements précédents reposent sur l'hypothèse que les processus $\mathcal{P}_1$ et $\mathcal{P}_2$ sont élémentaires. En fait, en solution, la notion de processus élémentaire est moins facilement définie qu'en phase gazeuse. L'effet cage par exemple impose un état physique supplémentaire des réactifs. Pour une réaction limitée cinétiquement par cette barrière, l'étape de diffusion et de formation des paires solvatées n'est pas limitante et n'a pas d'influence sur la cinétique de réaction.

L'existence d'une paire solvatée a une influence si l'on admet le modèle proposé par Bell (11) pour le mécanisme d'échange de proton pour un équilibre acido-basique :

$$HAX + B \underset{k_{ba}}{\overset{k_{ab}}{\rightleftarrows}} HAX\,B \underset{k_{cb}}{\overset{k_{bc}}{\rightleftarrows}} AX\,BH \underset{k_{dc}}{\overset{k_{cd}}{\rightleftarrows}} AX + BH$$

où le signe barre symbolise les espèces réunies dans une même cage de solvant. On admet que $k_{ba} < k_{bc}$ et $k_{cd} < k_{cb}$ ce qui signifie que le proton s'échange de nombreuses fois entre les deux espèces avant que le phénomène de difffusion n'intervienne. Si la fréquence de cet échange est élevée par rapport à la vitesse de diffusion des réactifs, c'est que la quasi-totalité des collisions dans la cage de solvant le provoque, alors que le processus d'échange de X est moins fréquent (cinétique limitée par la barrière).

Ainsi, à l'échelle de temps du processus étudié, la position du proton sur AX ou sur B dans la paire solvatée serait indépendante de l'origine de celle-ci (AXH + B ou AX + BH).

Dans une telle optique, si l'on prend comme exemple la N-chloration des amines, en admettant, comme c'est probable, que l'étape limitante de la cinétique est l'attaque nucléophile de l'amine non protonée sur ClOH, nous avons le schéma réactionnel suivant :

$$ClOH + R_2NH \leftrightarrows \overline{ClOH\,R_2NH} \leftrightarrows [H\,R_2N \ldots Cl - OH]^{\neq} \xrightarrow[V_f]{}$$

$$\Updownarrow$$

$$ClO^- + R_2NH_2^+ \leftrightarrows \overline{ClO^-\,R_2NH_2^+}$$

Il apparaît équivalent d'écrire la vitesse en fonction des concentrations de ClO^- et $R_2NH_2^+$ ou ClOH et R_2NH, expressions globales qui cachent la nature de l'acte élémentaire limitant.

Conclusions

Les succès de la théorie du complexe activé en solution sont liés aux hypothèses thermodynamiques qu'elle implique. Le principe de l'état final et initial permet d'écrire toute cinétique comme pour les réactions en phase gazeuse :

$$A + B \leftrightarrows AB^{\neq} \rightarrow \text{produits}$$

En général cette simplification est utile et permet une analyse simple des réactions en solution mais elle cache la réalité physique de la suite de processus qui peuvent intervenir en solution.

Une analyse plus fine des réactions en solution pose un certain nombre de problèmes (14) que l'on peut difficilement résoudre. Néanmoins, la théorie du complexe activé reste, pour l'expérimentateur, un outil puissant pour l'ana-

lyse et la prévision des cinétiques en phase liquide. Il apparaît cependant nécessaire d'en connaître les limites en particulier pour interpréter les phénomènes expérimentaux.

Ab initio study of the structure of the hydrogen maleate anion

MIGUEL A. RÍOS AND JESÚS RODRÍGUEZ[1]

Departamento de Química Física, Facultade de Química, Universidade de Santiago, 15706 Santiago de Compostela, Galicia, Spain

Received September 28, 1992

MIGUEL A. RÍOS and JESÚS RODRÍGUEZ. Can. J. Chem. **71**, 303 (1993).

The hydrogen maleate ion was studied by *ab initio* methods with complete optimization at the 3-21G, 6-31G, 6-31G**, and 6-31+G(2*d*,1*p*) levels. To study the influence of electron correlation, MP2 calculations have been done for the 6-31G** geometry. All calculations at the HF level predicted an asymmetric hydrogen bond with a double minimum potential governing transfer between the two equivalent structures. Moreover, both asymmetry and proton transfer barrier increase systematically with the power of the basis set used, with calculated barrier heights of 0.12 (3-21G), 1.59 (6-31G), 1.64 (6-31G**), and 2.00 kcal/mol (6-31+G). Only the introduction of the electron correlation at the MP2 level seems to predict a single minimum potential.

MIGUEL A. RÍOS et JESÚS RODRÍGUEZ. Can. J. Chem. **71**, 303 (1993).

On a étudié l'ion maléate d'hydrogène par des méthodes *ab initio* des optimisations complètes, aux niveaux 3-21G, 6-31G, 6-31G** et 6-31+G(2*d*,1*p*). Afin d'étudier l'influence de la corrélation électronique, on a effectué des calculs MP2 sur la géométrie 6-31G**. Tous les calculs au niveau HF prédisent une liaison hydrogène asymètrique pour laquelle le transfert entre les deux structures équivalentes implique un double minimum de potentiel. De plus, l'asymétrie et la barrière au transfert de proton augmentent tous les deux systématiquement avec la puissance de l'ensemble de base utilisé; les hauteurs calculées de la barrière sont 0,12 (3-21G), 1,59 (6-31G), 1,64 (6-31G**) et 2,00 kcal/mol (6-31+G). Seule l'introduction d'une corrélation électronique au niveau MP2 semble prédire un seul minimum du potentiel.

[Traduit par la rédaction]

Introduction

One of the fundamental issues when studying intramolecular hydrogen bonds is to determine whether the potential energy surface governing the motion of the hydrogen atom has just a single minimum (*a*) or two distinct minima (*b*):

X--H--X X-H---X ⇌ X---H-X

(*a*) (*b*)

Assuming that the two electronegative atoms are identical (which implies that the molecular fragments linked by the hydrogen bond are identical), then in the former case the two X—H distances will be equal.

In the double-minimum case there will generally be two distinct asymmetric structures that, depending on the characteristics of the potential surface, may or may not be interconverted by intramolecular proton transfer. When the double-minimum surface is completely symmetric, proton transfer does take place (in fact tunnelling through the potential barrier is observed (see, for example, refs. 1 and 2)) but even a small energy difference between the two tautomers can hinder or totally prevent proton transfer, leading to one tautomer predominating over the other (3).

The hydrogen bond is asymmetric in most of the compounds showing this kind of interaction. However, the hydrogen maleate and hydrogen phthalate anions (Fig. 1) have usually been considered as paradigms of symmetric hydrogen bonding (for review, see ref. 4), and for the former this notion has been supported experimentally by X-ray (5) and neutron diffraction (6) studies (which, while not locating the position of the hydrogen atom, have shown that the heavy atom skeleton is symmetric, implying that the hydrogen bond also should be symmetric) and by nmr experiments (7, 8). Even for the asymmetric chloro hydrogen maleate, practically equal OH distances (1.206 and 1.199 Å) have been found (9). Recently, there have been reports that the position of the hydrogen atom in hydrogen maleate is in fact not totally symmetric (10–14), the reported asymmetry, however, being slight: Table 1 lists the hydrogen bond geometries determined by X-ray and neutron diffraction studies using the potassium (5, 6, 9), sodium (10), calcium (11), zinc (12), lithium (12), and magnesium (13) salts of hydrogen maleate. The greatest asymmetry in the hydrogen bond (Δ_{OH} = 0.288 Å, the difference between the two OH distances) is found in the sodium salt. The differences among the studies must evidently depend on the different cations present, and in some cases on the presence of water molecules in the crystal lattice. In all cases the crystal environment affects the position of the hydrogen atom more than it does the heavy skeleton, which is never very asymmetric: even in the salt with greatest Δ_{OH}, "equivalent" bond lengths differ by less than 0.03 Å and "equivalent" angles by much less than 1°. The reported O---O distances are all very similar, ranging between 2.403 and 2.445 Å. Although these data are for crystals rather than the free anion, they suggest that any asymmetry in the hydrogen bond of the latter cannot be very pronounced. Theoretical 4-21G level calculations with complete geometry optimization (13) do not

contradict the above conclusion, the predicted OH distances (1.080 and 1.365 Å) yielding a value of Δ_{OH} of 0.285 Å, which is within the experimental range. Also *ab initio* vibrational analysis (15) suggested a low barrier height for the proton potential. However, 4-31G level calculations (16) indicate that both the heavy skeleton and the hydrogen bond of the free anion are clearly asymmetric, with OH distances of 1.017 and 1.464 Å (Δ_{OH} = 0.447 Å).

To obtain a clearer picture of the situation, we have now used a number of basis sets of differing complexity for *ab initio* geometrical optimizations of the hydrogen maleate anion and investigation of the potential curve governing proton transfer and the transition state.

Computation

All calculations were performed at the HF level, with complete geometry optimizations. The basis sets 3-21G (17), 6-31G (18), 6-31G** (19), and 6-31+G(2*d*,1*p*) (20) were used; the last includes the next diffuse functions: 2*d* functions on heavy atoms (scaled up and down by a factor of 2 from the standard single-*d* value), *p*-functions on hydrogen, and a set of diffuse *sp* functions on heavy atoms. Moreover, single-point MP2 calculations were carried out for the HF/6-31G** optimized geometries. Computations were performed with the GAUSSIAN 88 program (21).

Results and discussion

Table 2 shows the optimized geometric parameters of the anion as calculated using the basis sets mentioned above. All the optimized structures are planar, showing C_S symmetry. Data of this table show that a slight asymmetry in the molecular skeleton gives rise to a clear asymmetry in the O--H--O fragment.

The salient feature of Table 2 is the systematic increase in the asymmetry of the hydrogen bond with the complexity of the basis set used: Δ_{OH} is given as 0.234 Å by 3-21G,

0.447 Å by 4-31G (ref. 15), 0.467 Å by 6-31G, 0.417 Å by 6-31G**, and 0.495 Å by 6-31+G(2*d*,1*p*). Only 3-21G calculations predict a slightly asymmetric hydrogen bond, the larger asymmetry corresponding to the calculations including diffuse functions (which in principle should give accurate results for anions). Although to make an accurate comparison it would be necessary to dispose of experimental data in the gaseous phase, according to the crystallographic data reviewed above the hydrogen bond seems to be symmetric or nearly symmetric. Only the value of Δ_{OH} predicted using 3-21G is within the experimental range; all the others are considerable greater.

The O---O distance also increases systematically with the size and complexity of the basis, and it is again 3-21G that gives the only value in the experimental range, 2.40–2.44 Å (7–13).

The hydrogen maleate anion is not the only species for which the above trend has been observed. Similar results have been reported for malonaldehyde (22–24) and for salicylaldehyde and its derivatives (25, 26), for which the best Hartree–Fock predictions of the characteristics of the hydrogen bond are likewise provided by 3-21G, and for which increasing the power of the basis set again systematically increases the O---O distance, causing it and the rest the hydrogen bond geometry to deviate from the experimental value.

The angle OHO formed by the hydrogen bond is almost linear according to the experimental data, with values in the neighbourhood of 175°. This feature is adequately predicted by all the theoretical calculations, although the predicted angles are slightly narrower.

It is not only regarding the hydrogen bond that the 3-21G optimized geometry is more symmetric than the others; the experimental finding that the rest of the anion is very close to exact symmetry is likewise best predicted by 3-21G. The greatest discrepancy between the 3-21G and experimental geometries concerns the angles C3—C2—O1 and C4—C5—O6, for which the 3-21G values are rather smaller; the O---O distance is, however, not affected because the narrowing of angles C3—C2—O1 and C4—C5—O6 is compensated by a slight widening of the C2—C3—C4 and C5—C4—C3 angles. Similarly, the above-mentioned narrowing of the OHO angle is compensated by the widening of the two COH angles.

In malonaldehyde (24), salicylaldehyde (25, 26), and tropolone (27), intramolecular hydrogen bonding favours the existence of a "pseudoaromatic" ring in which the difference in length between the single and double bonds is considerably less than usual. For the hydrogen maleate anion, this phenomenon is supported by neither the experimental nor the theoretical data: two of the C—C bonds have lengths of around 1.5 Å, i.e., in the normal range for a single bond, while C3—C4 is clearly a typical double bond. π-Delocalization is thus practically limited to the O—C—O regions.

All the basis sets used lead to the prediction of an asymmetric structure, so that there are two C_S related tautomers that in principle are interconvertible by intramolecular proton transfer. Assuming C_{2v} symmetry, we optimized the corresponding transition state using each of the basis sets, obtaining barrier heights of 0.12 (3-21G), 1.37 (4-31G, ref. 15), 1.59 (6-31G), 1.64 (6-31G**), and 2.00 (6-31+G(2*d*,1*p*)) kcal/mol. Improving the basis set thus raises the potential barrier, which is in keeping with the increased asymmetry of the more stable structure.

To illustrate the effect of electron correlation, MP2 calculations were performed. The MP2/6-31G**//HF/6-31G** energies of the C_S and C_{2v} geometries were −453.51352 and −453.51459 au respectively. The C_{2v} geometry is thus 0.7 kcal/mol more stable than the C_S geometry, supporting the hypothesis of a single minimum potential energy curve, contrary to the findings from HF calculations.

Table 3 shows the geometries of the calculated transition states. Contrary to the trend exhibited by the C_S tautomer, the O---O distance decreases as the basis set improves. The difference between the O---O distances of the C_S (minimum) and C_{2v} (transition state) structures, $\Delta(O---O)_{C_S\text{-}C_{2v}}$, is, however, found to increase as the basis set improves. This can be related to the increase in the asymmetry of the C_S form, and results in an increase in the separation between the minimum and the transition state, i.e., an increase in the breadth of the potential barrier. Improving the basis set therefore tends to establish a potential with two minima that are increasingly deep and increasingly farther apart. The potential calculated using 3-21G has practically a single minimum, the

height of the barrier being only 0.12 kcal/mol (much less than the thermal energy) and the C_S and C_{2V} structures being very close.

Conclusions

Our results show that for hydrogen maleate anion, calculations at the HF level predict an asymmetric structure for the hydrogen bond. Moreover, the improvement of the basis set systematically increases the asymmetry and the height barrier for the motion of the hydrogen atom between the two oxygen atoms. However, MP2 single-point calculations seem to predict a single minimum potential. This trend has been already reported for other compounds, therefore it could be generalizable to compounds with similar kinds of intramolecular hydrogen bond. As a result of this trend, the acceptable behaviour of the 3-21G calculations (which give a very slight asymmetry and a potential curve virtually with a single minimum) seems to be due to mutual cancellation of errors.

Reactions of Ni(II) and its complexes with free radicals derived from thymine

S. CHAKRABARTI, P. C. MANDAL, AND S. N. BHATTACHARYYA[1]

Nuclear Chemistry Division, Saha Institute of Nuclear Physics, 1/AF, Bidhannagar, Calcutta-700064, India

Received February 20, 1992[2]

S. CHAKRABARTI, P. C. MANDAL, and S. N. BHATTACHARYYA. Can. J. Chem. **71**, 307 (1993).

The effects of nickel(II) ions and its complexes on the products arising from the γ-radiolysis of thymine were studied. The decomposition of the pyrimidine base and formation of different radiolytic products indicate that nickel(II) ions or its complexes have little effect on the radiosensitivity of thymine. The transient hydroxyl adduct of thymine reacts with Ni(II) with the formation of a complex having a nickel–carbon bond. The rate constants for the reactions are of the order of 10^6 dm^3 mol^{-1} s^{-1}. Possible mechanisms for the formation of different products in the radiolysis of thymine in the presence of nickel(II) compounds are discussed.

S. CHAKRABARTI, P. C. MANDAL et S. N. BHATTACHARYYA. Can. J. Chem. **71**, 307 (1993).

On a étudié l'influence des ions du nickel(II) et de ses complexes sur les produits provenant de la radiolyse γ de la thymine. La décomposition de la pyrimidine et la formation de divers produits radiolytiques indiquent que les ions nickel(II) ou ses complexes n'ont que peu d'effet sur la radiosensibilité de la thymine. L'adduit hydroxylé transitoire de la thymine réagit avec le Ni(II) avec formation d'un complexe comportant une liaison nickel–carbone. Les constantes de vitesse pour les réactions sont de l'ordre de 10^6 dm^3 mol^{-1} s^{-1}. On discute des mécanismes possibles pour la formation des divers produits de radiolyse de la thymine en présence de composés du nickel(II).

[Traduit par la rédaction]

Introduction

In connection with studies on the effects of transition metal ions on the radiosensitivity of nucleic acid components, the effects of Cu(II) and Fe(III) ions on the radiation-induced degradation of thymine were investigated earlier in dilute aqueous solutions (1–3). It was observed that both Cu(II) and Fe(III), whether present as simple salts or as complexed ions, could enhance the radiation-induced degradation of the nucleic acid base. The increased radiosensitivity of thymine depends on the reactivity of transient adducts of thymine, e.g., TOH$^\cdot$, TH$^\cdot$, T$^-$, and UCH$_2^\cdot$ (where both T and UCH$_3$ represent thymine), with the metal ions. This reactivity was earlier reported to be dependent on the one-electron reduction potential of the metal ion couple ($M^{n+}/M^{(n-1)+}$) and on the redox properties of the transient radicals of thymine. The one-electron reduction potential of Ni^{2+}/Ni^{1+} ($E_0 = -2.7$ V) (4) is much lower than that of Cu^{2+}/Cu^{1+} ($E_0 = 0.16$ V) (5) or Fe^{3+}/Fe^{2+} ($E_0 = 0.77$ V) (5). Hence it is very difficult to reduce Ni^{2+}. It is also very difficult to oxidize Ni^{2+} in its complex with EDTA (E_0(Ni(III)EDTA/Ni(II)EDTA) = 1.9 V) (6). Although the redox properties of the reducing or oxidizing thymine adducts are too weak to cause reductive or oxidative interaction with Ni^{2+} or its complexes, some of the nickel(II) complexes have been found to be radiosensitizing (7). Hence a detailed study of the effects of Ni(II) ions/complexes on the radiosensitivity of molecules like thymine may shed light on the reactivity of the thymine transients with the Ni^{2+} ions. The present investigation describes the results of studies on the reaction of Ni(II) ions and their complexes with transient thyminyl radicals. The rate constants for the reactions were studied using flash photolysis whereas the stable products arising from the degradation of thymine were ascertained in steady-state radiolysis experiments.

Experimental

Materials

Thymine (Koch Light) was recrystallized three times from triply distilled water. 2-^{14}C-thymine was procured from BARC, Bombay. The nickel(II) complexes of EDTA, NTA, and IDA were prepared by the usual methods as described earlier (8–10). EDTA, NTA, and IDA represent ethylenediamine tetraacetic acid, nitrilotriacetic acid, and iminodiacetic acid, respectively. All other chemicals and reagents were of analytical reagent grade. Nitrous oxide and argon gas were of extra pure grade.

γ-Irradiation

γ-Irradiation was carried out with ^{60}Co γ-rays. The dose rate (10.4 Gy/min) was measured by Fricke dosimeter taking $G(Fe^{3+})$ = 15.5. (1 G unit = 1.036×10^{-7} mol J^{-1}.)

Analysis

The products of radiolysis arising from the degradation of thymine were measured after separation by bidimensional thin-layer chromatography using the solvent systems chloroform:methanol:water (4:2:1) and ethyl acetate:isopropanol:water (75:16:9) as described earlier (3). Since the Ni(II) complexes and most of the products of radiolysis (except 5-hydroxymethyluracil, which, however, is only present in insignificant amounts) do not absorb at the wavelengths where thymine absorbs, they can also be measured using spectrophotometry. Formaldehyde was measured by the chromotropic acid method (11) and glyoxalic acid by its reaction with 2,4-dinitrophenylhydrazine (12).

Flash photolysis

Kinetics for the decay of the transient thyminyl radicals (TH$^\cdot$ and TOH$^\cdot$) in the presence of various nickel(II) compounds were studied by flash photolysis. The flash photolysis apparatus (model KN-020) was supplied by Applied Photophysics Ltd. The path length of the photolysis cell is 10 cm. Two flash lamps (LR 16) connected in series were operated at 15 kV, which gives a light flash of 10 μs duration (FWHM). The digitized transient signal from the oscilloscope (Iwatsu TS-8123) was fed into a PC through a GPIB interface and the absorption vs. time data were analysed for first-order and second-order fits by least-squares methods.

Results and discussion

Reaction between TOH$^\cdot$ and Ni(II) compounds

Flash photolytic study

TOH$^\cdot$ was generated by the flash photolysis of an aqueous deaerated solution of 2×10^{-3} mol dm^{-3} thymine (T) in the

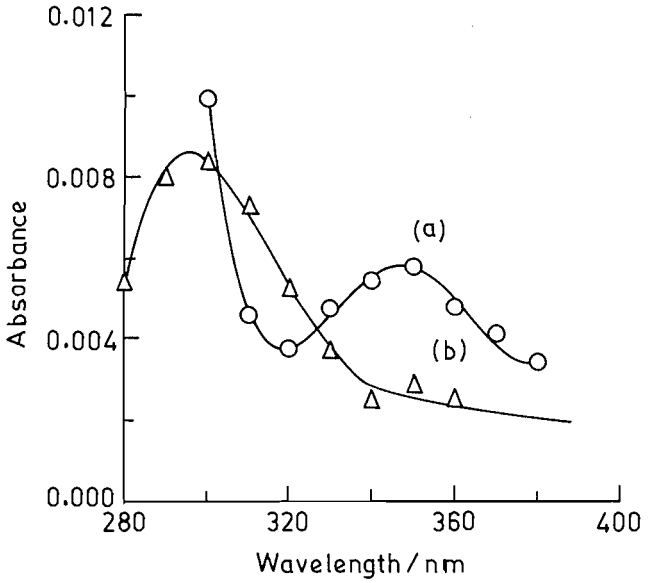

FIG. 1. (*a*) Transient spectrum of TOH$^{\bullet}$ obtained 200 μs after the flash in the flash photolysis of 2×10^{-3} mol dm^{-3} thymine and 10^{-2} mol dm^{-3} H_2O_2 in the presence of 10^{-5} mol dm^{-3} Ni(II)EDTA under deaerated conditions at neutral pH. (*b*) The absorption spectrum of the products formed after the reaction of TOH$^{\bullet}$ with Ni(II)EDTA. The spectrum was taken 5 ms after the flash.

presence of 10^{-2} mol dm^{-3} H_2O_2. When light is absorbed by H_2O_2, the OH$^{\bullet}$ radical is produced.

$$[1] \quad H_2O_2 \xrightarrow{h\nu} 2OH^{\bullet}$$

This OH radical then undergoes reactions [2] and (predominantly) [3] ($k_2 = 2 \times 10^7$ dm^3 mol^{-1} s^{-1} and $k_3 = 6.4 \times 10^9$ dm^3 mol^{-1} s^{-1}) (13).

$$[2] \quad OH^{\bullet} + H_2O_2 \xrightarrow{k_2} H_2O + HO_2^{\bullet}$$

$$[3] \quad T + OH^{\bullet} \xrightarrow{k_3} TOH^{\bullet}$$

Figure 1*a* shows that the spectrum of transients formed 200 μs after the flash is very similar to that of TOH$^{\bullet}$ reported earlier (14). OH$^{\bullet}$ adds to thymine, producing C_5-OH and C_6-OH adducts, which have similar absorption spectra but different absorption maxima (15). Contrary to the uracil system where the C_5-UOH adduct (82%) predominates over the C_6-UOH adduct (18%) (15), in the case of thymine the C_6-TOH adduct is formed in 30% yield and C_5-TOH adduct in 60% yield. The observed spectrum was found to be similar to the composite spectrum of both OH adducts of 1,3-dimethylthymine reported earlier by Deeble and von Sonntag (16).

The absorption spectrum of the product formed after the reaction of TOH$^{\bullet}$ with Ni(II)EDTA is shown in Fig. 1*b*. The uv part of the spectrum is very similar to that of Ni(III)EDTA formed by oxidation of the Ni(II)EDTA complex to the Ni(III) state (17). It can be surmised that TOH$^{\bullet}$ radicals formed in reaction [3] are reacting with Ni(II)EDTA, forming Ni(III)EDTA or a species having similar absorption. Note that the C_5-OH adduct of thymine is known to be reducing while the C_6-OH adduct is oxidizing (18). However, consideration of the redox potentials of Ni(II)/Ni(I) (4) and Ni(III)/Ni(II) (6) indicates that oxidation of C_5-TOH$^{\bullet}$ (19) and reduction of C_6-TOH$^{\bullet}$ (20) by Ni(II) compounds is unlikely.

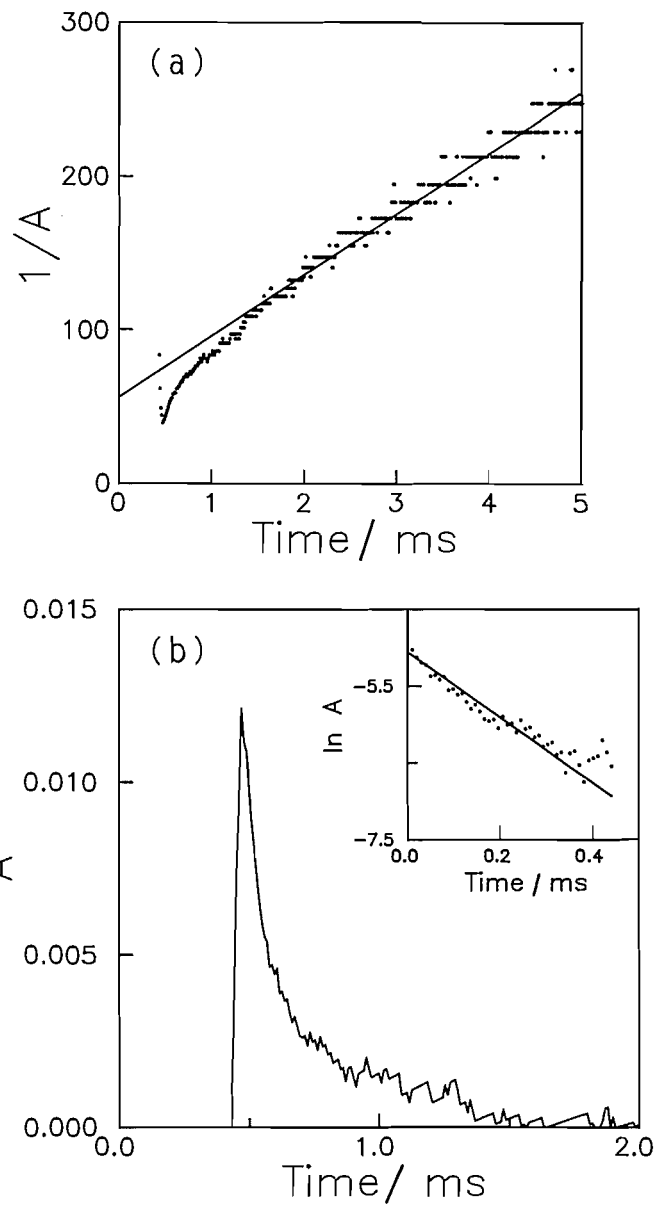

FIG. 2. (*a*) Second-order kinetic fitting of the absorbance (*A*) vs. time data for the decay of TOH$^{\bullet}$ formed by the photolysis of deaerated solutions of 2×10^{-3} mol dm^{-3} thymine and 10^{-2} mol dm^{-3} H_2O_2 in the presence of 4×10^{-4} mol dm^{-3} $NiSO_4$. (*b*) *A* vs. time curve for the decay of TOH$^{\bullet}$ at 360 nm after subtracting the contribution for the second-order component from the absorbance–time data. Inset: fitting of the data by an integrated equation based on first-order kinetics.

When the decay of TOH at 360 nm was followed in the presence of Ni(II)EDTA or other Ni(II) complexes, the absorbance did not show first-order or second-order decay but was best described as due to concurrent pseudo-first-order and second-order processes (Fig. 2). An apparent second-order rate constant was determined by plotting $1/A$ vs. time. Its value ($\sim 10^9$ dm^3 mol^{-1} s^{-1}) was found to be that observed for bimolecular TOH$^{\bullet}$ decay in the absence of metal

ions (21). Subtraction of this slow second-order component yielded a fast exponential decay of TOH in the presence of Ni(II) compounds. The corresponding second-order rate constants, k, were determined from the observed dependence of the pseudo-first-order rate constants on the concentrations of Ni(II) compounds. A typical plot is shown in Fig. 3 and the relevant rate constants are listed in Table 1. This plot shows a large intercept, a behaviour typical for an equilibrium where the slope represents the rate constant for the forward reaction. These data can thus be interpreted as due to complex formation between $TOH^{\bullet}$ and Ni(II) compounds.

[4] $TOH^{\bullet} + Ni(II)EDTA \rightleftarrows TOH\text{--}NiEDTA$

Such a complex might contain a nickel–carbon bond. Formation of a metal–carbon bond has been reported in the reactions of some alcohol radicals with metal ions (22–24). The complexes containing a Ni—C bond are rather long lived (25) and the absorption spectrum observed 5 ms after the flash (spectrum (*b*) in Fig. 1) is probably due to such a species.

γ-Radiolytic study

In γ-irradiated dilute aqueous solutions, the OH radical formed in the radiolysis of water reacts with thymine, forming TOH radicals (reaction [3]) (15). However, when Ni(II) ions are present they compete with thymine for primary radicals, depending upon the respective concentrations and rate constants (13).

The absence of a dependence of the decomposition of thymine, G(-T), on the concentration of $NiSO_4$ in the γ-radiolysis of 2×10^{-3} mol dm^{-3} thymine in N_2O-saturated solution is shown in Fig. 4. The base decomposition yields, G(-T), determined under different conditions are tabulated in Table 2. From Table 2 and Fig. 4, it is evident that the Ni(II) ions have no influence on the radiosensitivity of thymine. The study was extended to various Ni(II) complexes of aminopolycarboxylic acids, the resulting G(-T) values also being shown in Table 2. It follows that the G(-T) values observed with Ni(II) complexes are comparable to those obtained with $NiSO_4$. Analysis of the products arising from the degradation of thymine in the presence of Ni(II) ions and their complexes showed that they are similar to those obtained without Ni(II) compounds (Table 3).

The observed G(-T) values in N_2O-saturated solution were nearly double those observed under argon-saturated conditions (Table 2). In N_2O-saturated solution e_{aq}^- formed in the radiolytic system is converted to an equivalent amount of OH radical.

[5] $e_{aq}^- + N_2O \rightarrow OH^{\bullet} + OH^- + N_2$

Hence it can be argued that the base degradation is primarily due to the reaction of TOH radicals. This was verified by carrying out the radiolysis in the presence of 0.4 mol dm^{-3} *tert*-butyl alcohol under N_2O-saturated conditions where G(-T) values were negligibly small.

From these observations one can conclude that the degradation of thymine is due to OH radicals only. It must be pointed out that the electron adduct of thymine, T^-, must be present in appreciable amount under argon-saturated conditions. Why the disappearance of T^- does not lead to degradation of thymine is not immediately clear.

[a]Yields were determined spectrophotometrically. Error in the estimation of yields of various products is ±10%.
[b]A: in the absence, and C, E, and G: in the presence of $NiSO_4$, Ni(II)EDTA, and Ni(II)IDA, respectively, under argon-saturated conditions. B: in the absence, and D, F, and H: in the presence of $NiSO_4$, Ni(II)EDTA, and Ni(II)IDA, respectively, under N_2O-saturated conditions.
[c]Values in parentheses are those obtained spectrophotometrically.

When thymine is irradiated in N_2O-saturated solutions in the presence of Ni(II) aminopolycarboxylates, formation of carbonyl compounds, such as formaldehyde and glyoxalic acid, was observed; the yields are shown in Table 2. In argon-saturated solutions these yields are much lower. No carbonyl products were observed when the radiolysis was carried out in the presence of $NiSO_4$ or in the absence of any metal ion, or in aerated solutions. Thus it appears that the carbonyl products arise from degradation of the aminopolycarboxylate ligand in the complex. In this context a possible contribution of C_5-TOH$^\bullet$ to the formation of carbonyl compounds by abstracting hydrogen from the nickel complexes was checked, since the reducing C_5-OH adduct of uracil or thymine has been reported (26, 27) to abstract hydrogen from polyuridylic or polythymidylic acid. However, the absence of carbonyl compounds during radiolysis of dihydrothymine (where mainly reducing radical C_5-TH is formed) in the presence of Ni(II)EDTA in N_2O-saturated solution indicates that in our system no such abstraction of hydrogen from the ligands of nickel complexes takes place. The degradation of the ligand therefore may be thought of as arising from the interaction between C_6-TOH$^\bullet$ and Ni(II) complexes.

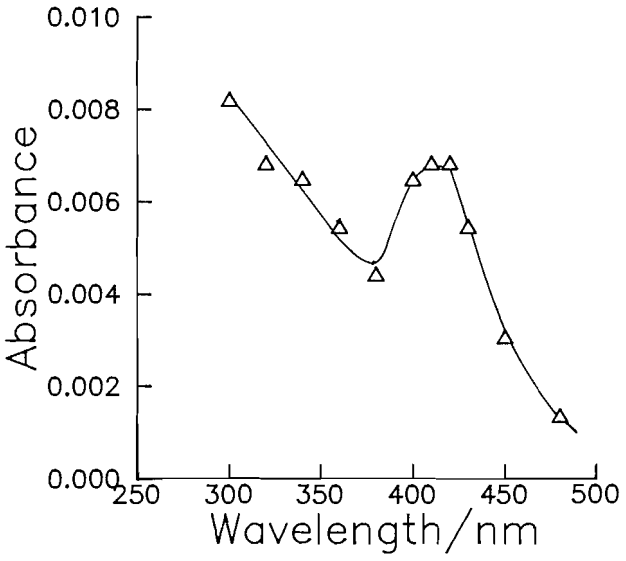

FIG. 5. Absorption spectrum of TH radical formed after flash photolysis of an aqueous solution containing 10^{-3} mol dm^{-3} dihydrothymine and 10^{-2} mol dm^{-3} hydrogen peroxide under argon saturated conditions.

It was reported earlier (28) that the C_6-OH adduct of uracil oxidizes the Ni(II) aminopolycarboxylates to Ni(III) species, which then give rise to carbonyl products arising from the degradation of ligands by Ni(III) in the complexes. But as discussed earlier, the C_6-OH adduct of thymine does not oxidize Ni(II) to Ni(III); rather, it seems to form a complex having a Ni—C bond that exists in equilibrium with the reactants.

Thus from the flash photolytic as well as γ-radiolysis experiments of thymine in the presence of Ni(II) it is quite clear that the electron transfer reaction, which leads to the enhanced oxidation of the C_5-TOH radical with previously studied metal ions such as Cu(II) (1, 2) or Fe(III) (3), does not occur in the nickel system.

Reactions of TH$^{\bullet}$ and Ni(II) compounds

Flash photolytic study

TH radicals were generated through reactions of 10^{-3} mol dm^{-3} dihydrothymine (TH_2) with OH$^{\bullet}$ radicals produced by flash photolysis of 10^{-2} mol dm^{-3} H_2O_2 under deaerated conditions. The rate constant (29) for the reaction of OH$^{\bullet}$ with TH_2 is $\sim 1 \times 10^9$ dm^3 mol^{-1} s^{-1}. Hence under these conditions all the OH radicals would react with TH_2 to give TH$^{\bullet}$.

[6] $TH_2 + OH^{\bullet} \rightarrow TH^{\bullet} + H_2O$

Figure 5 shows that the spectrum of the transient obtained during flash photolysis under argon-saturated conditions is similar to the spectrum of the TH$^{\bullet}$ radical produced by pulse radiolysis (30). Ni(II) compounds increase the decay rate of the absorption peak at 420 nm. The absorption data were fitted in a similar way as those in Fig. 2. From the variation of the pseudo-first-order rate constants with the concentration of the Ni(II), the second-order rate constants for the reactions of TH$^{\bullet}$ with Ni(II) compounds shown in Table 1 were determined.

The plot of the variation of the Ni(II) concentration with k_{obs} shows an intercept (plot not shown), indicating that the TH radical forms a complex with the Ni(II) ions. The TH radical formed by OH attack on dihydrothymine is a reducing species (31–33), but its redox potential is not high enough to reduce Ni(II) to Ni(I) (19). Hence it can be assumed that the intermediate Ni(II)–TH complex does not undergo electron transfer but stabilizes through some bimolecular process (30).

γ-Radiolytic study

H and e_{aq}^- formed in the γ-irradiated deaerated dilute aqueous solution react with thymine, forming TH and T^- radicals (15, 34).

[7] $T + H \rightarrow TH^{\bullet}$

$k_7 = 5.7 \times 10^8$ dm^3 mol^{-1} s^{-1} (13)

The addition of hydrogen atom occurs mainly (60%) at the C(6) position of the thymine ring (15, 35).

[8] $T + e_{aq}^- \rightarrow T^-$

$k_8 = 1.8 \times 10^{10}$ dm^3 mol^{-1} s^{-1} (13)

T^- cannot reduce Ni(II) to Ni(I), since the redox potential of T^- is only in the order of −1.0 V (36) while that of the Ni(II)/Ni(I) equals −2.7 V. The electron adduct of thymine, T^-, protonates at oxygen to form mainly the reducing C_4-TOH radical (37). The protonation in neutral solution is relatively slow ($k < 2 \times 10^{-4}$ s^{-1}) (15) but the protonation by H^+ is quite fast ($k = 2.6 \times 10^{10}$ dm^3 mol^{-1} s^{-1}) (38). A slower protonation at the C_6 position occurs in the presence of phosphate buffer, producing oxidizing C_6-TH$^{\bullet}$ ($k = 3.7 \times 10^6$ dm^3 mol^{-1} s^{-1}) (38). The protonated form of the electron adduct of thymine, T^-, is, however, ultimately converted to the oxidizing C_6-TH radical (36). H and e_{aq}^- adducts of thymine therefore lead to C_5 and C_6-TH adducts. The former is reducing but its redox potential is not sufficiently high to reduce Ni(II) to Ni(I) (19). Thus when dihydrothymine is radiolysed in the presence and in the absence of various Ni(II) compounds under N_2O-saturated conditions, the amount of thymine generated ($G(T) \simeq 1.35 \pm 0.15$) from TH was found to be identical under all conditions. The C_6-TH radical is oxidizing (18), but the C_6-TH adduct has a much lower oxidative power (39) than the corresponding C_6-TOH radical. Hence it can be presumed that the C_6-TH radical does not oxidize Ni(II) to Ni(III) species and probably disappears through bimolecular decay ($2k_{TH+TH} = 10^9$ dm^3 mol^{-1} s^{-1}) (30).

Radiolysis of thymine in the presence of Ni(II) in an aerated medium

In an aerated medium the decomposition of thymine takes place only due to OH radicals, because hydrated electrons and H atoms are converted to unreactive O_2^- and HO_2, respectively.

[9] $e_{aq}^- + O_2 \rightarrow O_2^-$

$k_9 = 1.9 \times 10^{10}$ dm^3 mol^{-1} s^{-1} (13)

[10] $H + O_2 \rightarrow HO_2$

$k_{10} = 2.1 \times 10^{10}$ dm^3 mol^{-1} s^{-1} (13)

In fact, the observed yield of thymine decomposition in the presence of Ni(II) compounds closely resembles $G_{OH} \sim 2.7$ (Table 2). Since no carbonyl compounds are formed during the radiolysis of thymine in presence of nickel(II) complexes in aerated medium, the TOH radicals do not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

undergo reaction with Ni(II) ions, but react with molecular oxygen to give peroxy radicals that ultimately give rise to thymine degradation products.

It can therefore be concluded that, unlike the case of Cu(II) and Fe(III), no electron transfer from the hydroxyl radical adduct of thymine to Ni(II) occurs, in conformity with the redox potentials of the metal ions.

MAHMOUD KOREK and HAFEZ KOBEISSI. Can. J. Chem. **71**, 313 (1993).

The determination of the centrifugal distortion constants (CDC) of a diatomic molecule is sought for high orders. When the vibrational energy $e_0 = E_v$ is known for a vibrational level v, the use of Rayleigh–Schrödinger perturbation theory gives the rotational constant $e_1 = B_v = \langle\Phi_0 R\Phi_0\rangle$ (with $R = 1/r^2$), and the CDC $e_2 = -D_v = \langle\Phi_0 R\Phi_1\rangle$, $e_3 = H_v = \langle\Phi_0 R\Phi_2\rangle$, ..., $e_n = \langle\Phi_0 R\Phi_{n-1}\rangle$, ... where $\Phi_n(r)$ is the solution of the nth rotational Schrödinger equation. The problem of the determination of a function Φ_n is solved by deriving exact analytical expressions for the initial values $\Phi_n(r_0)$ and $\Phi_n'(r_0)$ at an arbitrary "origin" r_0, the determination of any $\Phi_n(r)$ becoming as easy as that of $\Phi_0(r)$ when e_0 is known; that of e_n becomes as easy as that of $e_1 = B_v = \langle\Phi_0 R\Phi_0\rangle$. The application of the present formulation to the model Lennard–Jones potential function allows the numerical computation of D_v, H_v, L_v, M_v, N_v, O_v, P_v, Q_v for low and high v; the CDC beyond M_v are given for the first time; higher order CDC may be reached. The results for the four lowest order constants are in good agreement with those from previously confirmed methods. Appropriate tests for all orders show that the present method provides an elegant and competitive solution to the diatomic CDC problem even for large orders and high levels (near dissociation). Similar good results are obtained for an RKR potential of the $XO_g^+-I_2$ state bounded by 109 levels.

MAHMOUD KOREK et HAFEZ KOBEISSI. Can. J. Chem. **71**, 313 (1993).

On a cherché à déterminer les constantes de distorsion de centrifugation (CDC) d'une molécule diatomique, aux ordres élevés. Lorsqu'on connait l'énergie de vibration $e_0 = E_v$ d'un niveau de vibration v, l'utilisation de la théorie des perturbations de Rayleigh–Schrödinger fournit la constante rotationnelle $e_1 = B_v = \langle\Phi_0 R\Phi_0\rangle$ (avec $R = 1/r^2$) et les CDC $e_2 = -D_v = \langle\Phi_0 R\Phi_1\rangle$, $e_3 = H_v = \langle\Phi_0 R\Phi_2\rangle$, ..., $e_n = \langle\Phi_0 R\Phi_{n-1}\rangle$, dans lesquelles $\Phi_n(r)$ est la solution de la $n^{\text{ième}}$ équation rotationnelle de Schrödinger. On a résolu le problème de la détermination d'une fonction Φ_n en dérivant les expressions analytiques exactes pour les valeurs initiales $\Phi_n(r_0)$ et $\Phi_n'(r_0)$ à une «origine» arbitraire, r_0: la détermination de chacune des $\Phi_n(r)$ devient aussi facile que celle de $\Phi_0(r)$ lorsqu'on connait e_0 et celle de e_n devient aussi facile que celle de $e_1 = B_v = \langle\Phi_0 R\Phi_0\rangle$. L'application de cette formulation à la fonction de potentiel modèle de Lennard–Jones permet de faire des calculs numériques de D_v, H_v, L_v, M_v, N_v, O_v, P_v et Q_v pour des valeurs tant élevées que basses de v. On rapporte pour la première fois des valeurs des CDC au-delà de M_v; on pourrait atteindre des ordres plus élevés. Les résultats obtenus pour les quatre constantes les plus basses sont en bon accord avec celles obtenues antérieurement avec des méthodes confirmées. Des essais appropriés effectués pour tous les ordres démontrent que la méthode rapportée ici présente une solution élégante et compétitive pour la solution du problème des CDC de molécules diatomiques, même pour des ordres et des niveaux élevés (près de la dissociation). On a aussi obtenu de bons résultats pour un potentiel RKR d'un état $XO_g^+-I_2$ délimité par 109 niveaux.

[Traduit par la rédaction]

1. Introduction

The centrifugal distortion constants (CDC) D_v, H_v, L_v, . . ., (1) are usually needed, together with the vibrational energy E_v and the rotational constant B_v, to describe the state of a diatomic molecule characterized by the vibrational quantum number v.

By using a perturbation approach, Hutson (2) elaborated an algorithm to compute the constants $e_1 = B_v$, $e_2 = -D_v$, $e_3 = H_v$, $e_4 = L_v$, $e_5 = M_v$, when v and $e_0 = E_v$ are given. These are given by the expressions:

$$[1.1] \quad e_1 = B_v = \langle\Phi_0 R\Phi_0\rangle$$

$$[1.2] \quad e_2 = -D_v = \langle\Phi_0 R\Phi_1\rangle$$

$$[1.3] \quad e_3 = H_v = \langle\Phi_1|R - e_1|\Phi_1\rangle$$

$$[1.4] \quad e_4 = L_v = \langle\Phi_1|R - e_1|\Phi_2\rangle - e_2\langle\Phi_1\Phi_1\rangle$$

$$[1.5] \quad e_5 = M_v = \langle\Phi_2|R - e_1|\Phi_2\rangle - 2e_2\langle\Phi_1\Phi_2\rangle - e_3\langle\Phi_1\Phi_1\rangle$$

where Φ_0, Φ_1, Φ_2 are the successive solutions of the equations

$$\Phi_0'' + (e_0 - U)\Phi_0 = 0$$

$$\Phi_1'' + (e_0 - U)\Phi_1 = -(e_1 - R)\Phi_0$$

$$\Phi_2'' + (e_0 - U)\Phi_2 = -(e_1 - R)\Phi_1 - e_2\Phi_0$$

with $R = 1/r^2$, r the internuclear variable, and $U(r)$ the potential characterizing the molecule in a given electronic state.

Other recent works presented improvements (3, 4), or alternatives (5, 6), over Hutson's method.

In all these works, the computed CDC were limited to $e_5 = M_v$, i.e., to "low-order" distortion constants. The main reason for this limitation is the common belief that "there is little need for the higher order CDC" (3). A second reason

is that the algorithm presented by Hutson was not extended to higher orders ($e_6 = N_v$, $e_7 = O_v$, ...).

However, in a recent publication (4), Coxon noticed for some diatomic hydrides that when the dissociation limit is approached by increasing v, constants beyond $e_5 = M_v$ appear to be needed, and that "the perturbation in the wavefunction needs to be calculated to approximately fourth order to provide agreement within the experimental uncertainties" (4). In a more recent work (7), Coxon asserts: "Additional constants beyond M_v are required to describe the high rotational levels of high v. A computational algorithm for this purpose has not yet been developed".

The aim of the present work is to make use of the compact form $e_n = \langle \Phi_0 R \Phi_{n-1} \rangle$ of a CDC of any order n (Sect. 2), where Φ_n is the solution of the differential equation $\Phi_n'' + f(r)\Phi_n = s(r)$, $f(r)$ and $s(r)$ are given, as well as the initial values $\Phi_n(r_0)$ and $\Phi_n'(r_0)$ at an arbitrary origin r_0 (Sect. 3). In Sect. 4 we show that one simple routine is sufficient to compute $e_1 = B_v$, up to $e_6 = N_v$, $e_7 = O_v$, etc. Thus higher order CDC are computed as easily as their low-order counterparts.

2. Theory

Within the framework of the vibrating rotator model, the vibrational–rotational motion of the diatomic molecule is governed by the radial Schrödinger equation

$$[2] \qquad \psi_{v\lambda}'' + (E_{v\lambda} - U - \lambda R)\psi_{v\lambda} = 0$$

where $\lambda = J(J+1)$, J is the rotational quantum number, and $\lambda R(r) = \lambda / r^2$ is the rotational contribution to the potential $U(r)$ (1).

According to the Rayleigh–Schrödinger perturbation theory (8), $\lambda R(r)$ may be considered as a perturbation; $E_{v\lambda}$ and $\psi_{v\lambda}(r)$ are expanded in powers of λ,

$$[3] \qquad E_{v\lambda} = \sum_{n=0}^{\infty} e_n \lambda^n$$

$$[4] \qquad \psi_{v\lambda} = \sum_{n=0}^{\infty} \Phi_n(r) \lambda^n$$

where $\Phi_0(r)$ is the solution of the "vibrational" Schrödinger equation

$$[5] \qquad \Phi_0'' + (e_0 - U)\Phi_0 = 0$$

and $\Phi_n(r)$ are the solutions of the "rotational Schrödinger equations" (2–9):

$$[6.1] \qquad \Phi_1'' + (e_0 - U)\Phi_1 = -(e_1 - R)\Phi_0$$

$$[6.2] \qquad \Phi_2'' + (e_0 - U)\Phi_2 = -(e_1 - R)\Phi_1 - e_2\Phi_0$$

$$[6.n] \qquad \Phi_n'' + (e_0 - U)\Phi_n = -(e_1 - R)\Phi_{n-1} - \sum_{m=2}^{n} e_m \Phi_{n-m}$$

By making use of the well-known properties of $\Phi_n(r)$ (continuity at any r, boundary conditions similar to those of the vibrational wavefunction $\psi_v = \Phi_0$ (2–9)), one can derive the expressions [1] found by Hutson (2), or the expressions

$$[7.1] \qquad e_1 = \langle \Phi_0 R \Phi_0 \rangle$$

$$[7.2] \qquad e_2 = \langle \Phi_0 R \bar{\Phi}_1 \rangle - e_1 \langle \Phi_0 \bar{\Phi}_1 \rangle$$

$$[7.3] \qquad e_3 = \langle \Phi_0 R \bar{\Phi}_2 \rangle - e_1 \langle \Phi_0 \bar{\Phi}_2 \rangle - e_2 \langle \Phi_0 \bar{\Phi}_1 \rangle$$

$$[7.n] \qquad e_n = \langle \Phi_0 R \bar{\Phi}_{n-1} \rangle - \sum_{m=1}^{n-1} e_m \langle \Phi_0 \bar{\Phi}_{n-m} \rangle$$

---

as presented in a recent work (6). Φ_n and $\bar{\Phi}_n$ are both solutions of eq. [6.n], but Φ_n is, as taken by Hutson (2), orthogonal to Φ_0, while $\bar{\Phi}_n$ is free from this constraint (6).

In theory, expressions [7] differ from expressions [1] only in minor details: (*i*) eqs. [7] have a more compact form; (*ii*) up to e_5, eqs. [1] and eqs. [7] are "identical"; (*iii*) eqs. [1] give e_5 in terms of Φ_0, Φ_1, Φ_2 only, while eqs. [7] give e_5 in terms of Φ_0, $\bar{\Phi}_1$ up to $\bar{\Phi}_4$; (*iv*) eqs. [7] provide an extension to any order n (>5).

In practice, the computation of e_1–e_5 is quite different by using eqs. [7] or eqs. [1]. Details of the two algorithms are already known (2, 6), and we note here only that Hutson (2) used a matrix method to integrate eqs. [5], [6.1], and [6.2] all together, while Kobeissi *et al.* (6) repeated the same routine for eqs. [5], [6.1], [6.2], [6.3], . . . successively, till the required order.

Another approach giving more compact (and more elegant) expressions is one that requires $\bar{\Phi}_n$ orthogonal to Φ_0 ($n > 0$) in eqs. [7]; one then obtains

$$[8.1] \qquad e_1 = \langle \Phi_0 R \Phi_0 \rangle$$

$$[8.2] \qquad e_2 = \langle \Phi_0 R \bar{\Phi}_1 \rangle$$

$$[8.3] \qquad e_3 = \langle \Phi_0 R \bar{\Phi}_2 \rangle$$

$$[8.n] \qquad e_n = \langle \Phi_0 R \bar{\Phi}_{n-1} \rangle$$

The computation of e_n is here too reduced to that of $\Phi_n(r)$, i.e., to that of the numerical integration of the "rotational Schrödinger equations" [6]. These equations, as well as eq. [5], are all of the form

$$[9] \qquad y'' + f(r)y = s(r)$$

where only $s(r)$ changes from one equation to another. For given $f(r)$ ($f(r) = e_0 - U(r)$) and $s(r)$, the solution $y(r)$ is easily obtained by standard techniques, provided the initial values $y(r_0)$ and $y'(r_0)$ (at a given point r_0) are known. This "initial value" problem is treated in the next section.

3. The Φ_n initial values

We write eq. [6.n] in the form

$$[10] \qquad \Phi_n'' + f\Phi_n = s_n$$

where $f = e_0 - U$ and

$$[11] \qquad s_n = R\Phi_{n-1} - \sum_{m=1}^{n} e_m \Phi_{n-m}$$

The coefficient $f(r)$ is given, while $s_n(r)$ is deduced from the successive integration of eq. [10] with increasing values of n.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

For the numerical integration of eq. [10] one may use the boundary conditions for $\Phi_n(r)$ (and for $\Phi_n'(r)$)

[12] $\Phi_n(0) = 0$

[12′] $\Phi_n(r) \to 0 \quad \text{as} \quad r \to \infty$

and proceed as follows.

We begin the integration at a starting point $r_s \sim 0$, where we take $\Phi_n(r_s) = 0$ and $\Phi'(r_s) = c$ (a small arbitrary constant). As is usual in such problems, eq. [10] is replaced by a convenient difference equation (that of Numerov (10), for example); we step on towards infinity and stop at a (final) point $r_f \sim \infty$ according to a convenient numerical criterion to detect the numerical convergence of $\Phi_n(r)$ at infinity (11).

An alternative to this simple method is one inspired by the Cooley algorithm (12) used for the vibrational eigenvalue problem. It is sufficient to start at "convenient" r_s and r_f, and to integrate simultaneously in opposite directions, till an arbitrary point r_0 ($r_s < r_0 < r_f$), where the solution $\Phi_n(r)$ is reached.

These two procedures are simple, yet they suffer from a well-known weakness (2, 3, 6, 11) described by Tellinghuisen (3) as "nuisance instabilities in the non-classical regions". These instabilities appear mainly for high v.

We already showed (6) that these instabilities are removed by using exact initial values of Φ_n at an arbitrary "origin" r_0 located in the classical region. In this previous work $\Phi_n(r_0)$ and $\Phi_n'(r_0)$ were derived for the solution $\bar{\Phi}_n(r)$ appearing in eqs. [7]. We extend this work to the present case, i.e., to the function $\Phi_n(r)$ (orthogonal to $\Phi_0(r)$) appearing in eqs. [8] adopted here for the expressions of e_n.

We multiply eq. [10] by Φ_0 and integrate between r_0 and ∞; we obtain, by making use of eq. [5],

$$\int_{r_0}^{\infty} (\Phi_n'' \Phi_0 - \Phi_n \Phi_0'') \, dr = \int_{r_0}^{\infty} s_n(r)\Phi_0(r) \, dr$$

We then make use of the boundary conditions for Φ_0 and Φ_n at $r \sim \infty$, and find

[13] $$\Phi_n'(r_0)\Phi_0(r_0) - \Phi_n(r_0)\Phi_0'(r_0) = -\int_{r_0}^{\infty} s_n(r)\,\Phi_0(r)dr$$

When $e_0 = E_v$ is given, $\Phi_0(r_0)$ and $\Phi_0'(r_0)$ are well determined by the canonical functions methods (13). Equation [13] gives the exact value of $\Phi_n'(r_0)$ for an arbitrary given value of $\Phi_n(r_0)$. Note that this expression for $\Phi_n'(r_0)$ implies the Φ_n boundary condition at infinity, and that a similar one,

[13′] $$\Phi_n'(r_0)\Phi_0(r_0) - \Phi_n(r_0)\Phi_0'(r_0) = \int_0^{r_0} s_n(r)\Phi_0(r)dr$$

implies the Φ_n boundary condition at $r = 0$. Note also that one may take $r_0 = \infty$ in eq. [13′], or $r_0 = 0$ in eq. [13], and get

[14] $$\int_0^{\infty} s_n(r)\Phi_0(r) \, dr = 0$$

Substituting for s_n from eq. [11], and taking account of the orthogonality of the functions Φ_n ($n > 0$) with Φ_0, one can verify that eq. [14] leads to eq. [8.n].

The last point in this treatment is to specify $\Phi_0(r_0)$ for the "orthogonal" $\Phi_n(r)$ (verifying the condition $\langle\Phi_0\Phi_n\rangle = 0$). This can be done by considering again a function $\bar{\Phi}_n(r)$, with an arbitrary $\bar{\Phi}_n(r_0)$, and by noticing that the "orthogonal" Φ_n is related to $\bar{\Phi}_n$ by the relation (2)

[15] $$\Phi_n(r) = \bar{\Phi}_n(r) + c_n\Phi_0(r)$$

where the condition $\langle\Phi_0\Phi_n\rangle = 0$ gives for c_n

[16] $$c_n = -\langle\Phi_0\bar{\Phi}_n\rangle$$

Thus the initial values at r_0 of the "orthogonal" Φ_n are

[17] $$\Phi_n(r_0) = \bar{\Phi}_n(r_0) - \langle\Phi_0\bar{\Phi}_n\rangle\Phi_0(r_0)$$

[18] $$\Phi_n'(r_0)\Phi_0(r_0) = \Phi_n(r_0)\Phi_0'(r_0) + \int_0^{r_0} s_n(r)\Phi_0(r) \, dr$$

Since $\bar{\Phi}_n(r_0)$ is taken arbitrarily, we may take

[19] $$\bar{\Phi}_n(r_0) = 0, \; \bar{\Phi}_n'(r_0)\Phi_0(r_0) = \int_0^{r_0} s_n(r)\Phi_0(r) \, dr$$

[19′] $$\Phi_n(r_0) = -\langle\Phi_0\bar{\Phi}_n\rangle\Phi_0(r_0)$$
$$\Phi_n'(r_0) = \bar{\Phi}_n'(r_0) - \langle\Phi_0\bar{\Phi}_n\rangle\Phi_0'(r_0)$$

4. The numerical treatment

In the previous section we adopted for the CDC e_{n+1}, the expression $e_{n+1} = \langle\Phi_0 R\Phi_n\rangle$, and showed that Φ_n is the solution of the equation $\Phi_n'' + f\Phi_n = s_n$ (f and s_n are known), orthogonal to Φ_0, and having the initial values given by eqs. [19] and [19′].

Apparently, one faces an "initial value problem" for the computation of Φ_n: it is first necessary to compute $\bar{\Phi}_n(r)$ (with $\bar{\Phi}_n(r_0) = 0$ and $\Phi_0'(r_0) = \int_0^{r_0} s_n\Phi_0 \, dr/\Phi_0(r_0)$) and then to deduce the Φ_n initial values (eq. [19′]), implying the computation of the integral $\langle\Phi_0\bar{\Phi}_n\rangle$. In fact, this preliminary work may be avoided by proceeding as follows:

The equation $\Phi_n'' + f\Phi_n = s_n$ is integrated for the "arbitrary solution" $\bar{\Phi}_n$, the integral $\langle\Phi_0\bar{\Phi}_n\rangle$ being obtained in the same run, as well as the Φ_n initial values ($\Phi_n(r_0) = -\langle\Phi_0\bar{\Phi}_n\rangle\Phi_0(r_0)$ and $\Phi_n'(r_0) = \bar{\Phi}_n'(r_0) - \langle\Phi_0\bar{\Phi}_n\rangle\Phi_0'(r_0)$).

By making use of the relation $\Phi_n = \bar{\Phi}_n - \langle\Phi_0\bar{\Phi}_n\rangle\Phi_0$, e_{n+1} becomes

[20] $$e_{n+1} = \langle\Phi_0 R\Phi_n\rangle = \langle\Phi_0 R\bar{\Phi}_n\rangle - \langle\Phi_0\bar{\Phi}_n\rangle\langle\Phi_0 R\Phi_0\rangle$$

Thus the integration of the equation $\Phi_n'' + f\Phi_n = s_n$ for the "arbitrary solution" $\bar{\Phi}_n$ allows one to find e_{n+1} along with the Φ_n initial values, these being necessary to compute s_{n+1} appearing in the next equation $\Phi_{n+1}'' + f\Phi_{n+1} = s_{n+1}$, which is used to compute e_{n+2}.

Thus the CDC e_{n+1} is given by eq. [20], in which $\bar{\Phi}_n$ is an "arbitrary" solution" of the corresponding rotational Schrödinger equation (i.e., arbitrary initial value $\bar{\Phi}_n(r_0)$). In this computation of $\bar{\Phi}_n$, the functions Φ_i ($1 \leqq i \leqq n-1$) appearing in s_n are taken orthogonal to Φ_0, i.e., the appropriate $\Phi_i(r_0)$ and $\Phi_i'(r_0)$ are used.

According to this outline, and once $e_0 = E_v$ is given, the description of the computation of e_1, e_2, . . . may be presented as follows:

(*i*) The initial values $\Phi_0(r_0)$ and $\Phi_0'(r_0)$ (then $\Phi_0(r)$) can be obtained by using the "canonical functions" method as out-

lined in the appendix of ref. 6. The rotational constant $e_1 = \langle\Phi_0 R\Phi_0\rangle$ is deduced, as well as the $\bar{\Phi}_1(r)$ initial values, i.e., $\Phi_1(r_0) = 0$, $\bar{\Phi}_1'(r_0) = \int_0^{r_0} s_1(r)\Phi_0(r)\,dr/\Phi_0(r_0)$ (eq. [19]) with $s_1(r) = (R - e_1)\Phi_0$.

(*ii*) The initial values $\bar{\Phi}_1(r_0)$ and $\bar{\Phi}_1'(r_0)$ being in hand, $\bar{\Phi}_1(r)$ is deduced from eq. [6.1], as well as $c_1 = -\langle\Phi_0\bar{\Phi}_1\rangle$, $e_2 = \langle\Phi_0 R\Phi_1\rangle + c_1 e_1$, $\Phi_1(r) = c_1\Phi_0(r_0)$, $\Phi_0'(r_0) = \bar{\Phi}_1'(r_0) + c_1\Phi_1'(r_0)$ (eq. [19′]), $\Phi_2'(r_0) = \int_0^{r_0} s_2(r)\Phi_0(r)\,dr/\Phi_0(r_0)$, and $\Phi_2(r_0) = 0$ with $s_2(r) = (R - e_1)\Phi_1 - e_2\Phi_0$. Note that, in s_2, Φ_1 is the "orthogonal function".

(*iii*) As in (*ii*), the initial values $\bar{\Phi}_2(r_0)$ and $\bar{\Phi}_2'(r)$ allow the computation of $\Phi_2(r)$ (eq. [6.2]), $c_2 = -\langle\Phi_0\bar{\Phi}_2\rangle$ and $e_3 = \langle\Phi_0 R\bar{\Phi}_2\rangle + c_2 e_2$, $\Phi_2(r_0) = c_2\Phi_0(r_0)$, $\Phi_2'(r_0) = \bar{\Phi}_2'(r) + c_2\Phi_0'(r_0)$, $\bar{\Phi}_3(r_0) = 0$, $\Phi_3'(r_0)\int_0^{r_0} s_3(r)\Phi_0(r)\,dr/\Phi_0(r_0)$.

(*iv*) . . . and so on . . .

According to this procedure the computation of one CDC requires: (*i*) the integration of one linear second-order differential equation (with given coefficients and given initial values); (*ii*) the computation of simple integrals of the types $\int_0^{r_0}\Phi_n\Phi_0\,dr$, $\int_0^{r_0}\Phi_n R\Phi_0\,dr$ (used for the $\bar{\Phi}_{n+1}$ initial values).

We deduce that one simple routine is needed: the numerical integration of the equation $y'' + fy = s$, and the numerical computation of simple integrals of the form $I = \int_0^a y(r)g(r)\,dr$ ($a = r_0$, or ∞, $g(r)$ stands for Φ_0 or $R\Phi_0$). This routine is repeated when the order n of e_n increases, and is exactly the same for low or for higher orders.

The method was tested for the commonly used Lennard–Jones model potential and for the Rydberg–Klein–Rees (RKR) potential of the XO state of I_2. In Table 1 we give the low order CDC ($e_2 = -D_v$, $e_3 = H_v$, $e_4 = L_v$, $e_5 = M_v$) for the Lennard–Jones potential; these values have been computed previously (2, 3, 5, 6). In Table 2 we give the higher order CDC ($e_6 = N_v$, $e_7 = O_v$, $e_8 = P_v$, $e_9 = Q_v$), which are reported here for the first time. Similarly Tables 3 and 4 are presented for the XO–I_2 potential constructed by Martin *et al.* (15). The results of Table 3 may be compared to other previous results (14, 15), whereas those in Table 4 are new.

5. Discussion

By comparing the results of Table 1 with those of our previous work (6), we find an agreement to seven significant figures or better; the same result holds in the comparison of the results of Table 3 with those of ref. 14. The previous results were critically tested and showed high accuracy (6, 14). We consider this agreement as a confirmation of the validity of the results of Tables 1 and 3.

Since the results in Tables 2 and 4 are published here for the first time, no comparison with other results is available. However, we may assume that the higher order CDC of Tables 2 and 4 are as accurate as the low-order CDC of Tables 1 and 3, since they are obtained by using the same routine and the same highly accurate numerical techniques (the details may be found in ref. 6).

Moreover we applied the "continuity test" to all the CDC computed here (for the Lennard–Jones potential). This is, for e_1, for example,

TABLE 5. Variation of the "continuity index" $\Delta_n = f(e_n)$ when the parameter e_n takes the values $e_n = e_n^* + kh_n$, where e_n^* is the computed CDC given in Tables 1 and 2; $k = 0, \pm1, \pm2$; h_n is an arbitrary step-size. The values are given for $v = 12$. All values are dimensionless.

n	$e_n^* - 2h_n$	$e_n^* - h_n$	e_n^*	$e_n^* + h_n$	$e_n^* + 2h_n$	h_n
2	−5.21(−12)[a]	−2.60(−12)	−1.15(−15)	2.60(−12)	5.21(−12)	10^{20}
3	−5.65(−13)	−2.82(−13)	6.96(−16)	2.83(−13)	5.66(−13)	10^{23}
4	6.22(−14)	3.13(−14)	3.72(−16)	−3.05(−14)	−6.14(−14)	10^{27}
5	−6.77(−13)	−3.39(−13)	−7.85(−16)	3.37(−13)	6.74(−13)	10^{30}
6	7.27(−14)	3.61(−14)	−8.45(−16)	−3.80(−14)	−7.50(−14)	10^{34}
7	−8.02(−14)	−3.98(−14)	3.38(−16)	4.07(−14)	8.09(−14)	10^{36}
8	8.83(−14)	4.44(−14)	−7.21(−16)	−4.33(−14)	−8.72(−14)	10^{40}
9	−9.61(−14)	−4.82(−14)	−2.55(−16)	4.76(−14)	9.55(−14)	10^{43}

[a]Number between parentheses stands for a multiplicative power of 10.

$$\Delta_1(e_1) = (l_1^+ - l_1^-)/(l_1^+ + l_1^-)$$

where, according to eqs. [13] and [13′]

$$l_1^+ = \left[\Phi_1(r_0) - \int_{r_0}^{\infty} s_1(r)\Phi_0(r)\,dr\right] \Big/ \Phi_0(r_0) = \Phi_1'(r_0)|_{r>r_0}$$

$$l_1^- = \left[\Phi_1(r_0) + \int_{0}^{r_0} s_1(r)\Phi_0(r)\,dr\right] \Big/ \Phi_0(r_0) = \Phi_1'(r_0)|_{r<r_0}$$

with $s_1(r) = (R - e_1)\Phi_0(r)$. We know that $l_1^+ = l_1^-$ only when e_1 is the "exact" constant, say e_1^*, otherwise $l_1^+ \neq l_1^-$ and $\Delta_1(e_1) \neq 0$. Thus the quantity $\Delta_1(e_1)$ is an index measuring the "numerical" continuity (or discontinuity) of the function $\Phi_1(r)$ at r_0.

In Table 5 we give the results of the "continuity test" (for $v = 12$, for example) for all the CDC given in Table 1 (low order) and in Table 2 (high order). The index $\Delta_n(e_n)$ is computed for several values of e_n given by: $e_n = e_n^* + kh_n$, where e_n^* is the computed CDC (Tables 1 or 2), k is an integer (positive or negative), h_n is a convenient step.

The results of Table 5 show that for all values of n, the computed CDC, e_n^*, gives the "best" continuity index Δ_n, i.e., that closest to zero. This provides strong evidence for our assumption that the higher-order CDC are as accurate as the low-order values.

6. Conclusion

The problem of the determination of the diatomic centrifugal distortion constants for large orders was considered.

By using a non-conventional version of perturbation theory, we see that the CDC given by the expression $e_n = \langle\Phi_0 R \Phi_{n-1}\rangle$ is easily computed, for any order n, by using a simple method for the computation of the functions Φ_n, as successive solutions of the "rotational Schrödinger equations". This is done by taking Φ_n orthogonal to Φ_0 (the vibrational wavefunction), and by deriving exact values of $\Phi_n(r_0)$ and $\Phi_n'(r_0)$, the initial values of Φ_n at an arbitrary point r_0.

The numerical application of the present method to the model Lennard–Jones potential allowed us to obtain the same CDC for low orders (D_v, H_v, L_v, M_v) as already calculated by other methods, as well as for large orders (N_v, O_v, P_v, Q_v) given here for the first time. We believe that larger order CDC may be obtained, if needed, in the same manner. A similar application to the RKR potential of the XO_g^+ state of I_2 is presented for several vibrational levels up to dissociation.

Charge transfer complexes of Schiff bases derived from 2-aminobenzothiazole with some acidic and nonacidic acceptors

AMANY M. A. IBRAHIM
Department of Chemistry, Faculty of Science, University of Ain Shams, Cairo, Egypt

Received September 18, 1992

AMANY M. A. IBRAHIM. Can. J. Chem. **71**, 318 (1993).

When Schiff bases derived from 2-aminobenzothiazole were reacted with di- and trinitrobenzene derivatives as acidic and nonacidic acceptors in the ratio of 1:1, stable coloured charge transfer complexes (CTC's) were obtained. The structure and stoichiometry of the CTC's were studied by elemental analysis as well as by electronic absorption and infrared and nuclear magnetic resonance spectra. The CTC's derived from nonacidic acceptors were stabilized via intermolecular $\pi-\pi^*$ and $n-\pi^*$ transitions while those derived from acidic acceptors were formed by intermolecular $\pi-\pi^*$ transitions and a proton transfer stabilized by resonance. The ionization potentials of the Schiff bases and the electron affinities of the nitrobenzene derivatives were calculated.

AMANY M. A. IBRAHIM. Can. J. Chem. **71**, 318 (1993).

Lorsqu'on fait réagir des bases de Schiff du 2-aminobenzothiazole avec une mole de dérivés du di- et du trinitrobenzène agissant comme accepteurs acides et non acides, on obtient des CTC's colorés stables. On a étudié la structure et la stoechiométrie des CTC's par le biais d'analyses élémentaires ainsi que par leurs spectres infrarouge, résonance magnétique nucléaire et d'absorption électronique. Les CTC's dérivés d'accepteurs non acides sont stabilisés par des transitions intermoléculaires $\pi-\pi^*$ et $n-\pi^*$ alors que ceux dérivés des accepteurs acides se forment par des transitions intermoléculaires $\pi-\pi^*$ et un transfert de proton stabilisé par résonance. On a calculé les potentiels d'ionisation des bases de Schiff et les affinités électroniques des dérivés du nitrobenzène.

[Traduit par la rédaction]

Introduction

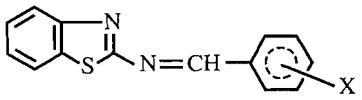
A lot of interest in molecular charge transfer complexes (CTC's) has stemmed from their technological potential. The most important applications of charge transfer complexes are the adsorption of electron acceptors on metal oxides to characterize the electron donor properties of these metal oxides (1–3), their use in current-controlled electrically switched memory (4, 5), the determination of critical micelle concentrations (6), their use as conducting single crystals in the microcircuitry of electronic devices (7, 8), as components of solar cells (9) and in the printing industry (10), and in applications making use of their high electrical conductivity (11, 12).

The present work is devoted to the study of CTC's of Schiff bases derived from 2-aminobenzothiazole with some di- and trinitrobenzene derivatives. The choice of Schiff bases as donors was mainly because they contain the azomethine group, the same group that occurs in rhodopsin, the visual pigment extracted from rod cells (13), while pyridoxal forms Schiff bases with various amino compounds found in the cell, including natural substrates of many B_6 enzymes (14). The CTC's of aromatic nitro compounds have been studied with various aromatic donor compounds (15–18), while few studies have been concerned with CTC's of benzylidene derivatives (19, 20). On the other hand, the behaviour of Schiff bases as donors towards acceptors other than the aromatic nitro compounds was the subject of several investigations (21–23). This study was also extended to investigate the stoichiometry and the structure of the molecular complexes and to identify the types of bonding contributing to their formation.

Experimental

Reagents and preparation of Schiff bases

The Schiff bases (**I–IX**) having the general structure:



where X = H (**I**), *p*-$N(CH_3)_2$ (**II**), *p*-OCH_3 (**III**), *p*-OH (**IV**), *o*-OH (**V**), *p*-Cl (**VI**), *m*-Cl (**VII**), *p*-Br (**VIII**), and *p*-NO_2 (**IX**), were prepared using the method described by Vogel (24). The products were recrystallized several times from ethanol and dried under vacuum. Their purity was checked by thin-layer chromatography, elemental analysis, ir spectra, and melting points, Table 1.

The acceptors used in the present investigation are 1,3-dinitrobenzene (**1**), 3,4-dinitrotoluene (**2**), 2,4-dinitrophenol (**3**), 3,4-dinitrobenzoic acid (**4**), 3,5-dinitrobenzoic acid (**5**), 3,5-dinitrosalicylic acid (**6**), picric acid (**7**), and trinitrobenzene (**8**). Unless otherwise stated, all the chemicals and solvents used in this investigation were of the purest grade and purchased from either BDH (England) or Aldrich Chemical Company, Inc. (U.S.A.).

Preparation of the CTC's

The CTC's were prepared by mixing a saturated solution of Schiff base (0.01 mol dm^{-3} in ethanol) with a similar solution of the acceptor at 40°C. The solid CTC's were separated at once or after cooling and then filtered off and recrystallized from ethanol. Insoluble CTC's were purified by heating them with ethanol several times to remove any contaminants. The complexes were filtered off, dried in vacuum, and preserved in closed tubes over $CaCl_2$. The purity and stoichiometry of the CTC's were checked by thin-layer chromatography, mp (95–205°C), colour (yellow, greenish yellow, orange, brown, or reddish brown), elemental analysis (C,H,N, and S content), and ir and nmr spectra. The data revealed that the Schiff bases (**I–IX**) give mainly 1:1 CTC's with di- and trinitrobenzene derivatives (**1–8**), Table 2.

Instruments

The working procedure and instruments used for electronic absorption, and for the ir and ^1H nmr spectra were as described previously (15). The electronic absorption and ir spectra were measured in Nujol mulls and as KBr discs, respectively. The ^1H nmr spectra were obtained using DMSO-d_6 as solvent and TMS as internal standard.

Results and discussion

Electronic absorption spectra

The electronic absorption spectra of the CTC's include, in addition to the absorption bands of the Schiff bases and nitrobenzene derivatives, one more band in the case of CTC's derived from acidic acceptors (**3–7**) and two more bands for CTC's derived from nonacidic acceptors (**1**, **2**, and **8**), Fig. 1 and Tables 3 and 4. The first band displays relatively high absorbance and appears as a broad shoulder at 340–460 nm, interacting with the long wavelength band of the Schiff base, which suffers a blue shift on complex formation. The second band observed in the spectra of CTC's derived from nonacidic acceptors appears as a very shallow broad absorption at 420–470 nm and disappears on adding few drops of HCl, Fig. 1. The two bands belong to intermolecular CT of the $\pi-\pi^*$ and $n-\pi^*$ type transitions, respectively.

The spectra reveal a blue shift for the long wavelength band of the Schiff bases at 340–415 nm due to $\pi-\pi^*$ intramolecular CT within the benzylidine moiety (25) and a red shift for the ^1L_a and ^1L_b bands of the nitrobenzene derivatives (26). Thus, the nonacidic acceptors interact with Schiff bases **I–IX** through $\pi-\pi^*$ transitions from the HOMO of the benzal ring to the LUMO of the nitrobenzene molecule, in addition to $n-\pi^*$ transitions from the nitrogen atom of the azomethine group or of the $-N(CH_3)_2$ group in the case of Schiff base **II**. Donation from the benzal ring rather than the benzothiazole moiety is supported by the linear free energy relationship (LFER) between λ_{CT} ($\pi-\pi^*$) and Hammett σ-constants, Fig. 2. The magnitude of the shift to longer wavelength is larger in the case of electron-donating substituents than in the case of electron-acceptor substituents, while with λ_{CT} ($n-\pi^*$) a straight line is observed.

π-Donation from the benzal ring is further supported by calculating the ionization potential of the HOMO of the Schiff bases using the equation given by Briegleb (27):

$$[1] \quad I_p = 5.11 + 0.701\, h\nu_D$$

where $h\nu_D$ is the energy of the band at 340–415 nm of the Schiff bases. This band suffers a red shift on increasing the electron-donating or -accepting character of the substituent, Fig. 2. The ionization potential values of Schiff bases, Table 3, are lower than those of benzothiazole (8.58 eV), 2-aminobenzothiazole (8.64 eV) (15), or thiazole and 2-aminothiazole (9.50 and 8.45 eV, respectively) (28). Also, for one and the same donor, the variation of λ_{CT} ($\pi-\pi^*$) with the electron affinity values of di- and trinitrobenzene derivatives, Table 4, is given by broken or straight lines with positive slopes, Fig. 3. These electron affinity values were calculated using eq. [2]:

$$[2] \quad h\nu_1 - h\nu_2 = E_{A_2} - E_{A_1}$$

where $h\nu_1$ and $h\nu_2$ are the energies of the two acceptors **1** and **2** having electron affinities E_{A_1} and E_{A_2}, respectively (27), and using the reported available E_A values of acceptors **1**, **2**, and **8** (27, 29). The broken lines indicate that there are other factors, in addition to the conventional factors, affecting the stability of the CTC's. In this case, they are mainly proton transfer from the acidic acceptors to the basic center of the Schiff bases and the symmetry properties that affect the molecular orientations of the acceptor and the donor to form segregated or mixed stakes (30).

The calculated values of the energy of the CT band, using the relation given by Briegleb *et al.* (31),

$$[3] \quad E_{CT} = I_p - E_A + C_1 + \frac{C_2}{I_p - E_A + C_1}$$

where C_1 and C_2 are constants for a given acceptor (27, 31), are equal to (2.70–3.85 eV) and in good agreement with the experimental values (2.69–3.65 eV), thus supporting the intermolecular CT nature of the first band.

On the other hand, the acidic acceptors interact with Schiff bases through π–π^* transitions, as indicated by the presence of the intermolecular CT band. The absence of the band due to n–π^* transitions reveals that the n–π^* interaction is absent due to blocking of the lone pair of electrons on the nitrogen atom by the proton transferred from the hydroxy or the carboxy group to the basic centre of the Schiff base.

The structure of the CTC's, the infrared and nuclear magnetic resonance spectra

The characteristic ir bands of Schiff bases due to $\nu_{C=N}$ at 1650–1638 cm^{-1}, $\nu_{CH=N}$ and $\gamma_{CH=N}$ at 3030 and 1010 cm^{-1}, respectively, and ν_{C-N} at 1250 cm^{-1} exhibit shifts to lower frequencies on CTC formation. Also, the ν_{asym} of the NO_2 group of acceptors appearing as a group of bands at 1550, 1540, and 1530 cm^{-1} and the ν_{sym} NO_2 band at 1340–1350 cm^{-1} are shifted to lower frequencies due to the increased polarization of the nitro group. On the other hand, the ν_{CH} and γ_{CH} of the acceptors are shifted to higher frequencies, supporting the intermolecular π–π^* interaction between the Schiff bases as donors and the nitrobenzene derivatives as acceptors. This is further supported by the ^1H nmr spectra of the CTC's, Table 5, which show that the resonances due to the Schiff base moieties are shifted downfield, whereas the resonances due to the acceptors are moved to a higher field. The indication from the electronic spectra that the π-donation comes from the benzal ring rather than the benzothiazole moiety is also confirmed by the large magnitude of the shift of the ν_{CH} and γ_{CH} ir bands, as well as the nmr signals around 7.30 ppm of the benzal ring of the CTC's relative to those of the Schiff bases, compared to those of the benzothiazole moiety.

In the case of nonacidic acceptors, the n–π^* transitions play an important role, in addition to the intermolecular π–π^* transitions, for stabilizing the CTC's. A large shift to lower frequencies was observed for the $\nu_{CH=N}$ and $\nu_{C=N}$ ir bands of CTC's (from 3030 to 3010 cm^{-1} and from 1650–1638 to 1640–1625 cm^{-1}, respectively) relative to those of the Schiff bases. Also, the proton chemical shifts of the azomethine group at 9.65–10.45 ppm, which vary linearly with the Hammett σ-constants, Fig. 2, suffer a downfield shift in the nmr spectra of the CTC's, Table 5. This indicates the participation of the lone pair of electrons of the azomethine group

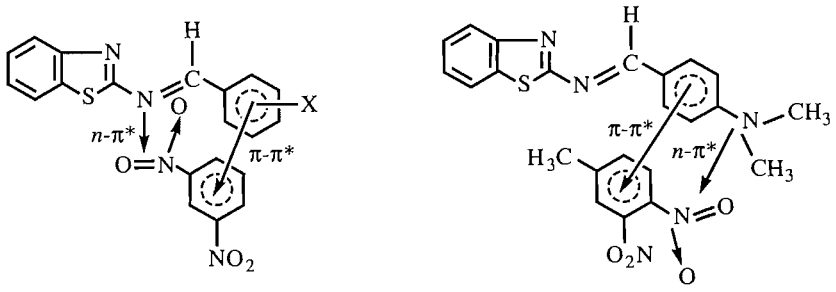
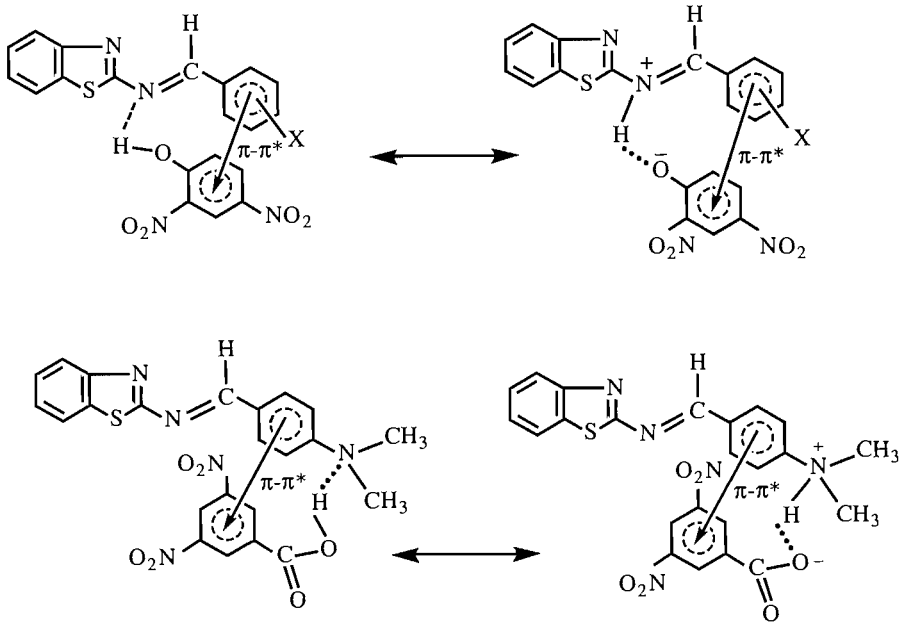
in complex formation. On the other hand, the *n*-donation in CTC's derived from Schiff base **II** comes from the -N(CH$_3$)$_2$ group, as implied by the shifts of the ir bands due to ν_{CH_3} from 2960 to 2945 cm^{-1} and δ_{CH_3} from 1460 to 1450 cm^{-1}, as well as the downfield shift of the strong singlet of the methyl protons from 3.0 to 3.25 ppm on CTC formation, Scheme 1. The interaction between the acidic acceptors (**3–7**) and Schiff bases is achieved by intermolecular $\pi-\pi^*$ transitions



SCHEME 1



SCHEME 2

and proton transfer, Scheme 2. Proton transfer from the hydroxy or carboxy group to the basic centre of the Schiff base can be concluded by the presence of the ν^{+}_{NH} and δ^{+}_{NH} bands at 3220 and 1640 cm^{-1}, respectively, and the ν_{COO^-} band at 1610 cm^{-1} in addition to the bands due to ν_{OH} and $\nu_{C=O}$ at 2560 and 1700 cm^{-1}, respectively, with a relatively weak intensity and a shift to lower frequencies. The ^1H nmr spectra of the CTC's show that the signal due to the hydroxy and carboxy groups disappears, or in some cases appears as a weak broad signal at variable positions, Table 5. The spectra reveal a new broad signal, in the 5.50–9.60 ppm region, which disappears on deuteration. This new signal could be due to the protonation of the basic center of the Schiff base. In these CTC's the n–π^* transitions seem to be ruled out and complete permanent proton transfer is not believed to occur; rather, partial protonation stabilized by resonance seems to be the convenient route to complex formation, Scheme 2.

J. C. GARD, Y. MUGNIER, Y. HUANG, and J. LESSARD. Can. J. Chem. **71**, 325 (1993).

In tetrahydrofuran, with tetrabutylammonium hexafluorophosphate as supporting electrolyte, 4-nitrobenzophenone is reduced to the radical anion and, at a more negative potential, to the dianion. These two species are stable even on the time scale of electrolysis. In the presence of proton donors of increasing strength, the dianion is protonated to $ArNO_2H^-$ but the radical anion is protonated to $ArNO_2H^{\cdot}$ only with the strongest acids. These species react further and the different mechanisms are discussed.

J. C. GARD, Y. MUGNIER, Y. HUANG et J. LESSARD. Can. J. Chem. **71**, 325 (1993).

Dans du tétrahydrofurane contenant de l'hexafluorophosphate de tétrabutylammonium comme électrolyte-support, la 4-nitrobenzophénone est d'abord réduite en son radical anion et, à un potentiel plus négatif, au dianion. Ces deux espèces sont stables à l'échelle de temps d'une électrolyse. En présence de donneurs de protons d'acidités différentes, le dianion est toujours protoné pour donner $ArNO_2H^-$ tandis que le radical anion n'est protoné que par les acides les plus forts pour donner $ArNO_2H^{\cdot}$. Les mécanismes des réactions subséquentes de ces deux intermédiaires sont discutés.

Introduction

The electrochemical behavior of aromatic nitro compounds and more particularly of nitrobenzene has been extensively studied in aqueous or in aprotic medium (see refs. 1–10 for reviews). In aprotic solvents such as DMF (11) and in liquid ammonia (12), nitrobenzene is reduced reversibly to the anion radical and, at a more negative potential, to the dianion. In liquid ammonia, on the coulometric time scale, the dianion reacts slowly with the solvent; in the presence of isopropyl alcohol, the dianion of nitrobenzene is protonated and then rapidly eliminates a hydroxyl ion to give nitrosobenzene.

In this paper, we report the results of an investigation of the electrochemical behavior of 4-nitrobenzophenone (**1**) in tetrahydrofuran (THF). Due to the presence of two electron-withdrawing groups, the anionic species generated should be less basic than in the case of nitrobenzene, and we have examined the reactivity of these anionic species towards proton donors of increasing strength.

Experimental

Tetrahydrofuran was purified by distillation from sodium benzophenone ketyl under argon. The supporting electrolyte was tetrabutylammonium hexafluorophosphate (0.2 M) in all cases; the salt (Fluka) was recrystallized twice from ethanol, then dried and deoxygenated before use. 4-Nitrobenzophenone, fluorene, diethyl malonate, phenol, and benzoic acid were all commercial products.

Apparatus and general procedures

All the experiments were carried out under an atmosphere of argon using Schlenck techniques. In voltammetry, the working electrode was a platinum disc (diameter: 1.2 mm) and for the controlled potential electrolyses, a platinum grid. In each case the reference electrode was a saturated calomel electrode (sce) separated from the solution by a sintered glass disc. The auxiliary electrode was a platinum wire. For thin-layer cyclic voltammetry (tlcv), the platinum disc electrode was lowered until it came into contact with the flat floor of the electrolytic cell so that only a thin layer of solution existed between them. The reagents (4-nitrobenzophenone and proton donors) in THF solution were added with a syringe previously purged with argon. For the rotating disc experiments, a three-electrode Tacussel Tipol polarograph was used. The cyclic voltammetry experiments were conducted with a Tacussel UAP4 unit connected to a Tektronix 5115 oscilloscope or a Sefram TGM 164 X-Y recorder. The macroelectrolyses were carried out with an Amel 552 potentiostat equipped with a Tacussel IG5 integrator.

Results and discussion

In THF with Bu_4NPF_6 as supporting electrolyte, the voltammogram of **1** ($ArNO_2$) on a Pt rotating disc electrode (rde) shows two reduction waves A and B (Fig. 1*a*); the second wave is smaller than the first because the diffusing species is $ArNO_2^{\cdot-}$, which has a smaller diffusion coefficient than $ArNO_2$. The half-wave potentials are respectively −1.0 and −1.6 V vs. sce. The cyclic voltammogram (Fig. 2) shows the two corresponding reversible systems of peaks, A/A′ and B/B′, which correspond to the redox reactions [1] and [2] respectively. No modification of the cyclic voltammogram was observed within the temperature range −30°C to 25°C.

$$[1] \quad ArNO_2 \overset{+e^-}{\rightleftharpoons} ArNO_2^{\cdot-} \qquad A/A'$$

$$[2] \quad ArNO_2^{\cdot-} \overset{+e^-}{\rightleftharpoons} ArNO_2^{2-} \qquad B/B'$$

The electrolysis of **1** at −1.2 V (plateau of wave A) and at 0°C consumed one equivalent of electrons. The rde voltammogram of the green electrolysis solution (Fig. 1*b*) exhibited the oxidation wave A′ and a reduction wave at a lower cathodic potential than the initial wave B; these two waves have nearly the same height but are smaller than the

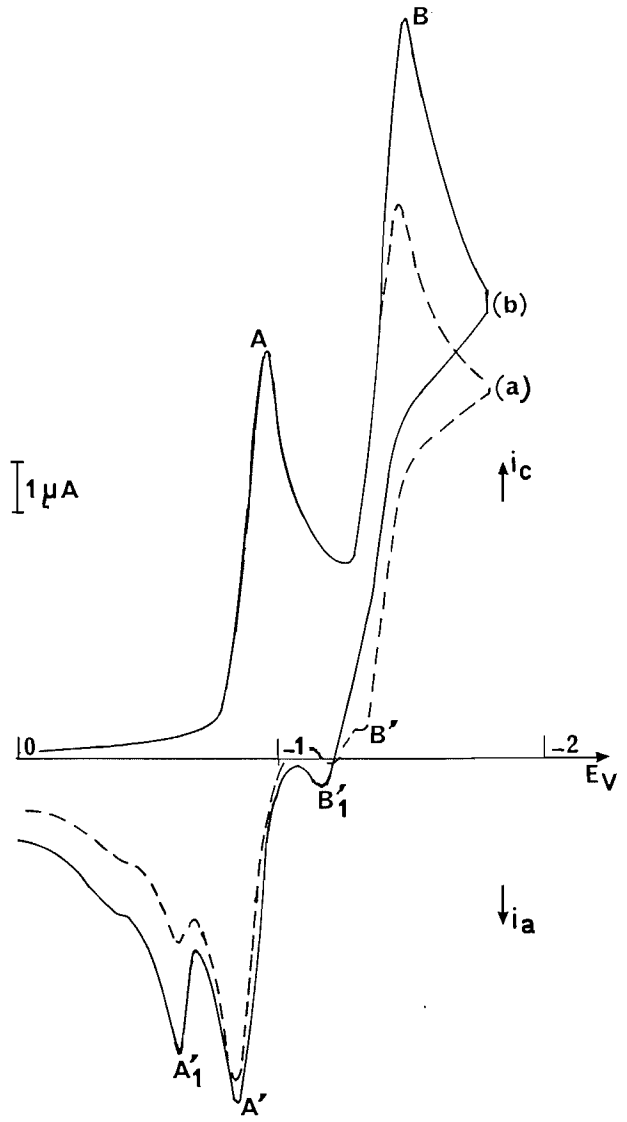

FIG. 5. Cyclic voltammograms of **1** in THF (*a*) in the presence of two equivalents of FlH_2; (*b*) after addition of 10 equivalents of FlH_2. Starting potential 0 V. Sweep rate 0.05 V s^{-1}.

initial waves A and B. The electron spin resonance (esr) spectrum of the electrolysis solution showed the signals characteristic of the anion radical $ArNO_2^{\cdot-}$ (13). There was no starting product left: absence of the $\nu_{(C=O)}$ band at 1670 cm^{-1}. The anion radical was stable in the electrolysis medium since no modification of the rde voltammogram occurred when the temperature was increased from 0 to 30°C. The one-electron oxidation at −0.8 V (plateau of wave A′) gave back the initial voltammogram. Further reduction of the

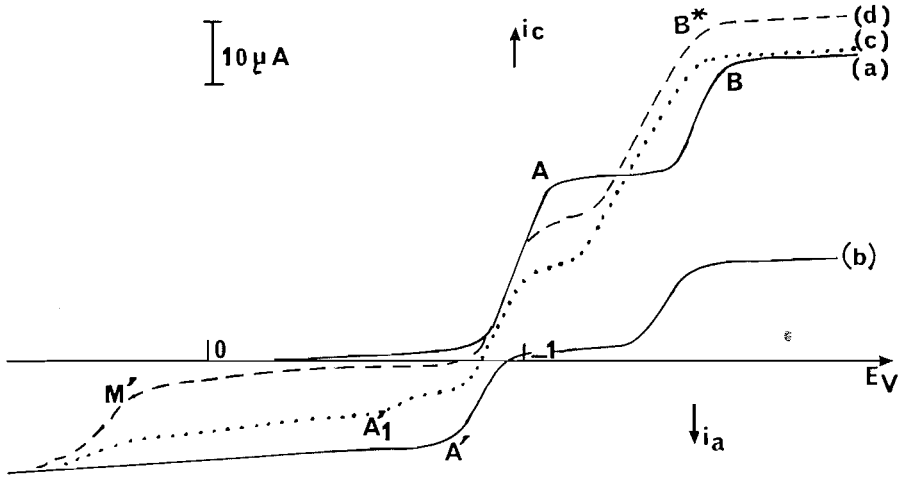

FIG. 8. Rotating disk electrode voltammograms of **1** in THF on platinum electrode (*a*) before electrolysis; (*b*) after one-electron reduction at −1.2 V; (*c*) immediately after addition of one equivalent of diethyl malonate; (*d*) after heating at 50°C.

radical anion at −1.7 V (plateau of the second wave B) and at 0°C consumed one equivalent of electrons. The rde voltammogram of the resulting green solution showed two oxidation waves B′ and A′ of equal height (Fig. 1*c*) corresponding to the oxidation of the dianion to $ArNO_2^{\cdot-}$ and of $ArNO_2^{\cdot-}$ to $ArNO_2$ respectively. The same voltammogram was obtained when a two-electron reduction of **1** was performed directly at −1.7 V. No signal was detected by esr spectroscopy and the band at 1670 cm^{-1} was absent in the ir spectrum. The dianion was stable at 0°C in the electrolysis medium since no modification of the rde voltammogram occurred after several hours. A two-electron oxidation at +0.75 V (plateau of wave A′) gave back the initial voltammogram.

Behavior with added proton donors

The various proton donors studied and their pK_a values in DMSO are shown in Table 1.

Water

No modification in the cyclic voltammogram of **1** occurs when one equivalent of water is added. In the presence of an excess of water, system A/A′ is not modified when the scan is reversed after peak A. In thin-layer voltammetry, two new oxidation peaks B'_1 and A'_1 appear when the potential scan is reversed after peak B (Fig. 3); in the second scan, two other reduction peaks A_1 and B_1 are obtained. This shows that $ArNO_2^{\cdot-}$ does not react with water on the time scale of cyclic voltammetry whereas $ArNO_2^{2-}$ reacts slowly. So we have examined the reactivity of the electrogenerated dianion towards water. Figure 4 shows the rde voltammogram of the dianion $ArNO_2^{2-}$ at room temperature (two oxidation waves B′ and A′). When water (7 equiv.) is added to the solution, reduction wave B appears immediately (Fig. 4*b*). The height of wave B increases and the oxidation wave A'_1 becomes well defined when the proportion of water increases (Fig. 4*c*) or when the solution is stored under argon. This suggests that wave A'_1 corresponds to the oxidation of $ArNO_2^{\cdot-}$ and wave B to the reduction of $ArNO_2^{\cdot-}$. The formation of $ArNO^{\cdot-}$ can be accounted for by reactions [3] (AH = H_2O) – [5]. The systems A_1/A'_1 and B_1/B'_1 of Fig. 3 correspond to the redox reactions [6] and [7].

$$[3]\quad ArNO_2^{2-} + AH \xrightarrow[\text{slow}]{} ArN(O)OH^-$$

$$[4]\quad ArN(O)OH^- \xrightarrow[\text{fast}]{} ArNO + OH^-$$

$$[5]\quad ArNO + ArNO_2^{2-} \rightarrow ArNO^{\cdot-} + ArNO_2^{\cdot-}$$

$$[6]\quad ArNO \overset{e^-}{\rightleftharpoons} ArNO^{\cdot-} \qquad A_1/A'_1$$

$$[7]\quad ArNO^{\cdot-} \overset{e^-}{\rightleftharpoons} ArNO^{2-} \qquad B_1/B'_1$$

Fluorene

Figure 5 shows the cyclic voltammogram of **1** in the presence of two and 10 equivalents of fluorene (FlH_2). The dianion $ArNO_2^{2-}$ reacts more rapidly with fluorene than with water to give ArNO (reactions [3] (AH = FlH_2) and [4]). By adding an excess of FlH_2 to the electrogenerated radical anion $ArNO_2^{\cdot-}$, no modification of the rde voltammogram was observed even at 50°C thus showing that $ArNO_2^{\cdot-}$ is not basic enough to react with FlH_2.

Phenol and diethyl malonate

The thin-layer voltammogram of **1** in the presence of one equivalent of phenol (Fig. 6) exhibits the reduction peaks A and B, a new reduction peak B_2, and the four oxidation peaks B′, A′, A'_1, and P′. We have verified that peak P′ corresponds to the oxidation of PhO^- (in THF, PhONa is oxidized at the potential of peak P′). When increasing the concentration of PhOH, the height of peaks A and B_2 increases and peak B_2 is shifted towards a less negative potential. Peak B_2 corresponds to the reduction of $ArNO_2^{\cdot-}$ followed by the fast protonation of the electrogenerated dianion (EC process) yielding ArNO, which is immediately reduced first to $ArNO^{\cdot-}$ (oxidation peak A'_1), then to $ArNO^{2-}$. The fact that peak B'_1 due to the oxidation of the dianion $ArNO^{2-}$ is absent suggests that its protonation by phenol must be very fast;[2] $ArNO^{2-}$ should be a stronger base than $ArNO_2^{2-}$, the oxidation peak of which, peak B′, is present.

The influence of added diethyl malonate on the electro-

[2]Alternatively, according to a referee's suggestion, the absence of peak B'_1, although peak A'_1 due to the oxidation of $ArNO_2^{\cdot-}$ is present, could be explained by the relative rates of formation of ArNO and the comproportionation reaction $ArNO^{2-} + ArNO \rightarrow 2ArNO^{\cdot-}$.

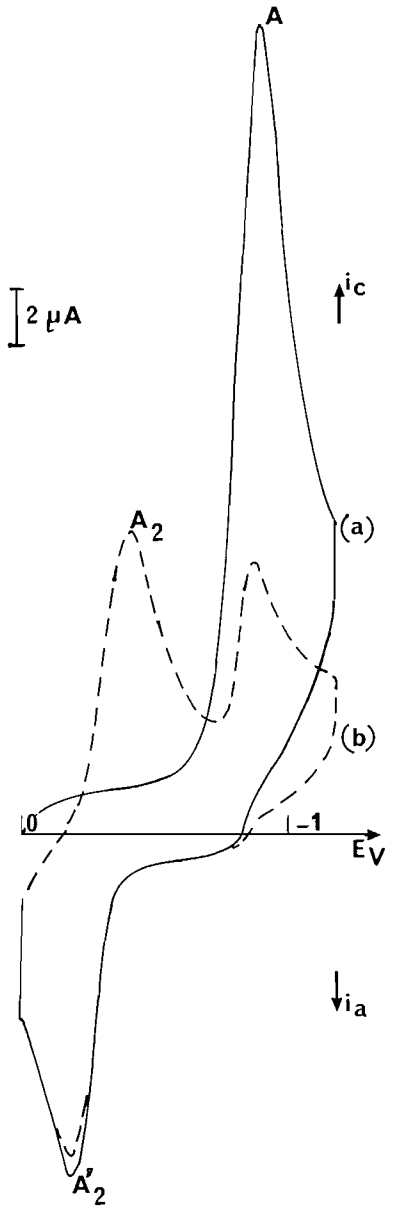

FIG. 9. Thin-layer voltammograms of **1** in THF in the presence of one equivalent of benzoic acid. Starting potential 0 V; sweep rate 0.02 V s^{-1}. (*a*) First scan; (*b*) second scan.

chemical behavior of **1** is shown in Fig. 7. Upon the addition of one equivalent of diethyl malonate, the height of peak B increases, the reduction peak B_2 appears, the oxidation peak B'_1 is absent as in the presence of phenol, and four oxidation peaks B′, A′, A'_1, and M′ are observed (Fig. 7*b*). Peak M′ corresponds to the oxidation of the malonate anion. With two equivalents of diethyl malonate, peaks B and B′ disappear, the height of peak B_2 increases, and that of peak A′ decreases (Fig. 7*c*). The radical anion $ArNO_2^{\cdot-}$ is relatively stable and the dianion $ArNO_2^{2-}$ reacts rapidly with diethyl malonate on the time scale of cyclic voltammetry. However, when adding one equivalent of diethyl malonate to the electrogenerated green solution of the anion radical $ArNO_2^{\cdot-}$, the oxidation waves A'_1 and M′ appear and **1** is regenerated as shown by waves A and B* (ill-defined wave). When this solution is heated at 50°C, the oxidation wave A'_1 disappears. The above results can be explained by reactions [8]–[11]. First, the radical anion is protonated (eq. [8]). Then the protonated anion radical leads to the starting material and the dihydroxylamine derivative $ArNO_2H_2$ by disproportionation (reaction [9]). The loss of water (eq. [10]) or hydroxide ion (eq. [4]) gives ArNO, which is then reduced by $ArNO_2^{\cdot-}$ to $ArNO^{\cdot-}$ (eq. [11]). Peak A'_1 corresponds to the oxidation of $ArNO^{\cdot-}$. Upon heating, $ArNO^{\cdot-}$ probably gives the azoxy derivative according to a process (eq. [12]) similar to the formation of azoxybenzene from the nitrosobenzene radical anion (18); ArN(O)NAr is probably reduced at the potential of wave B* (see Fig. 8).

[8] $ArNO_2^{\cdot-} + AH \rightarrow ArNO_2H^{\cdot} + A^-$

[9] $2ARNO_2H^{\cdot} \rightarrow ArNO_2 + ArNO_2H_2$

[10] $ArNO_2H_2 \rightarrow ArNO + H_2O$

[11] $ArNO + ArNO_2^{\cdot-} \rightarrow ArNO^{\cdot-} + ArNO_2$

[12] $2ArNO^{\cdot-} + 2AH \rightarrow ArN(O)NAr + 2A^- + H_2O$

The decrease in height of wave A is in keeping with the mechanism proposed, to which corresponds the global reaction [13] that shows that two thirds of the initial $ArNO_2$ is regenerated.

[13] $6ArNO_2 + 6AH + 6e^- \rightarrow 4ArNO_2 + ArN(O)NAr + 6A^- + 3H_2O$

Benzoic acid

Upon the addition of one equivalent of benzoic acid, in thin-layer voltammetry, the reduction peak A becomes higher, an oxidation peak A'_2 appears, and, during the second scan, reduction peak A_2 is observed (Fig. 9). ArNHOH is obtained from a four-electron reduction of $ArNO_2$, leading to anionic species ($ArNO_2^{\cdot-}$, $ArNHO_2^-$, $ArNO^{\cdot-}$, $ArNHO^-$) that are quickly protonated in the presence of benzoic acid. Peak A'_2 corresponds to the oxidation of the hydroxylamine derivative in the presence of electrogenerated $PhCO_2^-$ according to the global reaction [14]. Peak A_2 corresponds to the reduction of the nitroso derivative under the influence of benzoic acid (eq. [15]).

[14] $ArNHOH - 2e^- + 2PhCO_2^- \rightarrow ArNO + 2PhCO_2H$

[15] $ArNO + 2e^- + 2PhCO_2H \rightarrow ArNHOH + 2PhCO_2^-$

After a four-electron reduction of **1** at −1.1 V in the presence of six equivalents of $PhCO_2H$, the hydroxylamine ArNHOH was obtained in a nearly quantitative yield as determined by polarography (the height of wave A'_2 being twice as small as the initial reduction wave).

Conclusion

We have shown that, on the time scale of voltammetry, the radical anion $ArNO^{\cdot-}$ is stable in the presence of water or fluorene, but is slowly protonated by phenol or diethyl malonate. In the presence of benzoic acid, $ArNO_2^{\cdot-}$ is rapidly protonated and further reductions and protonations give the hydroxylamine. The anion radical of the nitroso derivative was formed by adding water to the electrogenerated dianion $ArNO_2^{2-}$ (eqs. [3]–[5]). A disproportionation reaction of $ArNO_2H^{\cdot}$ (eq. [9]) was observed when diethyl malonate was added to the electrogenerated anion radical $ArNO_2^{\cdot-}$.

Received July 10, 1992

MARTIN K. EHLERT, ALAN STORR, ROBERT C. THOMPSON, FREDERICK W. B. EINSTEIN, and RAYMOND J. BATCHELOR. Can. J. Chem. **71**, 331 (1993).

Room temperature and low-temperature (110–140 K) powder diffractograms have been obtained for the polymeric compounds $[Cu(4\text{-}Xpz)_2]_x$ (where X = H, CH_3, Cl, and Br), and values of the unit cell parameters (orthorhombic, space group *Ibam*) *a*, *b*, and *c* have been obtained at both high and low temperatures. A single crystal X-ray diffraction study of the X = H compound at 116 K was completed and the results compared with a published study done at room temperature. The structures of these complexes involve extended chains of pyrazolate-bridged copper ions extending along the *c* crystallographic axis. The X-ray studies indicate little change in the *c* parameter with decreasing temperature and small but significant changes in the *a* or *b* parameters reflecting changes in interchain packing. This study permits some evaluation of how structural parameters are affected by these variations in interchain packing and how these variations may be affecting the magnitude of magnetic exchange in the compounds.

MARTIN K. EHLERT, ALAN STORR, ROBERT C. THOMPSON, FREDERICK W. B. EINSTEIN et RAYMOND J. BATCHELOR. Can. J. Chem. **71**, 331 (1993).

On a déterminé les spectres de diffraction, à la température ambiante et à basse température (110–140 K), de poudres polymériques des composés $[Cu(4\text{-}Xpz)_2]_x$ (dans lesquels X = H, CH_3, Cl et Br) et on a déterminé les paramètres *a*, *b* et *c* de la maille (orthorhombique, groupe d'espace *Ibam*) aux températures tant élevée que basses. On a réalisé une analyse complète de la diffraction des rayons X, à 116 K, par un cristal unique du composé où X = H et on a comparé les résultats obtenus avec ceux rapportés dans la littérature pour une étude faite à la température ambiante. Les structures de ces complexes impliquent de longues chaînes d'ions cuivres reliés par des ponts pyrazolates et s'étendant le long de l'axe cristallographique *c*. Les études de rayons X indiquent qu'un abaissement de la température ne provoque que peu de changements dans le paramétre *c*; on observe toutefois de faibles changements significatifs dans les paramètres de *a* ou de *b* qui sont le reflet de changements dans l'empilement interchaîne. Cette étude permet d'évaluer la façon dont les paramètres structuraux sont affectés par ces variations dans l'empilement interchaîne et comment ces variations peuvent affecter l'amplitude de l'échange magnétique de ces composés.

Introduction

Binary copper(II) pyrazolates and substituted pyrazolates adopt structures in which copper ions are doubly bridged by pyrazolate ligands to form extended linear chain polymers (1–3). The compounds show relatively strong antiferromagnetic coupling with values of *J*, the exchange coupling constant, in the range -58 to -105 cm^{-1} (3). The shortest intrachain copper–copper separations in these compounds are of the order of 3.9 Å, too large for direct metal–metal interactions and requiring therefore a ligand-mediated mechanism for exchange (4). A comparison of magnetic and structural parameters between these compounds has revealed that relatively small differences in structural parameters involving the bridging ligands lead to small but significant differences in the magnitude of the exchange (2). The magnetic characterization of these complexes involves the measurement of magnetic susceptibilities over a wide temperature range (2–300 K) and the possibility that minor structural changes with temperature could be occurring in these systems with consequent effects on their magnetic properties prompted the current investigation.

Some evidence for structural change in pyrazolates of copper(II), on cooling, is already available. Several of these polymers exhibit thermochromism and two compounds, $[Cu(4\text{-}Clpz)_2]_x$ (green form) and $[Cu(4\text{-}Brpz)_2]_x$ (where pz = pyrazolate), show discontinuities in their magnetic susceptibility versus temperature plots (2). Accordingly, we have recorded the X-ray powder diffraction patterns of the compounds $[Cu(4\text{-}Xpz)_2]_x$, where X = H, CH_3, Cl, and Br, at room temperature and at low temperature (~110–140 K). We have also completed a single crystal X-ray diffraction study of $[Cu(4\text{-}Hpz)_2]_x$ at 116 K for comparison with the published study (1) done at room temperature.

Experimental

Descriptions of the preparations of the compounds were given previously (2, 3). The powder diffractograms were recorded using a Rigaku Rotaflex rotating anode X-ray diffractometer (graphite monochromator, CuK_α radiation). Low-temperature measurements on this instrument were achieved by equipping the diffractometer with a custom-designed copper cold stage cooled with liquid nitrogen. The samples were deposited as an octane slurry on a glass slide that was mounted on the cold stage. Temperatures were measured using a copper–constantan thermocouple and a Fluke 8120A digital voltmeter. The thermocouple was imbedded in the copper cold stage immediately behind the sample slide.

Unit cell parameters for these compounds derived from powder diffractograms were obtained by least-squares refinement of diffraction peaks to which Miller indices could be unambiguously assigned. For the $[Cu(4\text{-}Xpz)_2]_x$ compounds, the temperature, the

H(1)	0.165 (3)	0.1404 (25)	0.262 (3)	1.34
H(2)	0.024 (4)	0.232 (3)	0	1.50

[a]B_{eq} is the mean of the principal axes of the thermal ellipsoid (in the case of the H atoms B_{eq} is the assigned B_{iso}).

number of powder diffraction data observed, and the number of data used in least-squares refinement (in parentheses) are as follows: X = H: 298 K, 22(18); 110 K, 20(13); X = CH_3: 298 K, 26(21); 109 K, 25(18); X = Cl: 298 K, 36(18); 110 K, 30(25); X = Br: 298 K, 23(15); 140 K 38(20).

The low-temperature single crystal X-ray diffraction study of $[Cu(4\text{-}Hpz)_2]_x$ was done using an Enraf–Nonius CAD-4F diffractometer (graphite monochromatized MoK_α radiation) equipped with an in-house modified low-temperature attachment. A crystal, mounted on a Pyrex filament with epoxy resin as adhesive, was cooled to 116 K. The unit cell was determined from 25 well-centred reflections in the range $38° \leq 2\theta \leq 50°$. Two intensity standards were measured hourly and showed no systematic variations in intensity throughout data acquisition ($2\theta_{max} = 70°$). The data were corrected empirically for the effects of absorption (5). Data reduction included corrections for Lorentz and polarization effects.

The room temperature and this low-temperature study lead to isostructural models (1). Parameters included in the final refinement were coordinates for all atoms and anisotropic thermal parameters for the non-hydrogen atoms. The hydrogen atoms were assigned isotropic temperature factors dependent on the thermal parameters of the carbon atoms to which they were bonded. A weighting scheme, based on counting statistics, was applied such that $\langle w(|F_o| - |F_c|)^2 \rangle$ was approximately constant as a function of either $|F_o|$ or $(\sin\theta)/\lambda$. Final full-matrix least-squares refinement of 33 parameters from 643 observations ($I_o \geq 2.5\sigma(I_o)$) converged at $R_F = 0.027$.

The NRCVAX (6) system of crystallographic programs was used for data reduction and structure refinement. Complex scattering factors for neutral atoms (7) were used in the calculations. All computations were performed with a MicroVax-II computer.

The final atomic coordinates are listed in Table 1, and the unit cell parameters (116 K) are included in Table 2. Supplementary material is available, including experimental details, anisotropic thermal parameters, and observed and calculated structure factors.[2]

Results and discussion

The $[Cu(4\text{-}Xpz)_2]_x$ compounds[3] are orthorhombic, space group *Ibam*; values of the cell parameters are given in Table 2. Comparisons between cell parameters determined by the single crystal and powder methods at equivalent temperatures reveal that most agree to within 3σ, with the largest deviation 6σ. The crystal structures reveal chains of pyrazolate-bridged copper ions extending along the *c* axis (1, 2). Changing the temperature would be expected to have the largest effect on the interchain interactions and hence more effect on the *a* and *b* lattice constants than on *c*. Consistent with this, the cell parameter *c* shows the smallest change on cooling in all four compounds (Table 2), ranging from no change in the X = CH_3 compound to a change of 10σ in the X = H derivative. On the basis of the change in the other two cell parameters the four compounds fall into two groups. The X = H and CH_3 compounds exhibit significant decreases in the *b* parameter on cooling, 77σ and 26σ, respectively. These compounds also show smaller changes in *a* on cooling. For X = H, *a* decreases by 24σ while for X = CH_3 it increases by 3σ. For the other derivatives it is the *a* parameter that is most affected by changing the temperature. For X = Cl and Br the *a* parameter decreases by 49σ and 38σ, respectively, on cooling. On lowering the temperature the *b* parameter shows small increases of 7σ and 6σ, respectively, for X = Cl and Br.

A comparison of the low-temperature single crystal X-ray diffraction study of $[Cu(4\text{-}Hpz)_2]_x$ done here with the previous room temperature study (1) shows how bonding parameters in this compound are affected by changing the temperature. The study also provides some insight into how temperature-induced changes in bond angles and lengths are related to changes in lattice constants in these compounds. Values of selected bond distances and angles are given in Tables 3 and 4. Bond distances are virtually unaffected by the temperature change; the largest change involves the C(1)—C(2) distance, which increases by 0.015 Å or ~4σ on cooling. (These could of course be partially accounted for by thermal motion.) All other changes are smaller and no particular significance can be attached to changes in these bond distances. Bond angles involving only the pyrazolate ligand atoms are also not affected significantly by the temperature change. Some angles involving copper show small, barely significant, changes, notably the N—Cu—N^d angle, which decreases by 0.50° (4.5σ), and the C(1)—N—Cu angle, which also decreases by 0.50° (3.5σ). These changes in angles are necessarily tied to more significant changes in pyrazolate ring dihedral angles (*vide infra*). The most significant changes are seen in the dihedral angle between fused $Cu(N—N)_2Cu$ and N_2C_3 rings and the dihedral angle between consecutive $Cu(N—N)_2Cu$ planes. These are the angles labelled α and β, respectively, in Fig. 5 of ref. 2. The angle α increases from 9.10(3)° to 9.87(5)° (13σ) on cooling while β increases from 126.10(3)° to 127.62(3)° (38σ) on cooling.

Changes in the α and β dihedral angles would be expected to affect the dimensions of the polymer perpendicular to the chain direction and therefore the interchain packing and the *a* and *b* cell parameters. The net effect of the increase of 0.77° in α and 1.5° in β on the dimensions of the polymer chain perpendicular to the chain axis can be seen by examining the changes in the *x* and *y* atomic coordinates of C(1) and C(2) on cooling. These represent an increase of the *x* component of Cu.....C by 0.008 and 0.018 Å, respectively, and a decrease of the *y* component by 0.015 and 0.009 Å, respectively. In effect, on cooling, the polymer chains become slightly compressed along *y* and elongated

along *x*. As might be anticipated, these changes in the dimensions of the chains perpendicular to the chain axis coincide with changes in chain packing as evidenced by changes in the *a* and *b* unit cell parameters. Specifically, in this case, chain packing becomes more efficient with a decrease in *b* by 0.232(3) Å and a much smaller decrease in *a* by 0.047(2) Å. This latter decrease could arise solely because of decreased thermal motion. It should be noted that there appears to be no simple correlation between the nature of the chain distortion and the effect on individual cell parameters. Hence, while the compression in *y* coincides with a decrease in *b*, the elongation in *x* also coincides with a decrease, albeit very small, in the relevant cell parameter *a*.

Although low-temperature single crystal X-ray diffraction studies are not available for the other three compounds studied here, the changes in their unit cell parameters on cooling, as measured by the powder method, are considered here in relation to possible change in the α and β dihedral angles. The *a* and *b* parameters of the X = CH_3 compound change on cooling in a manner similar to that observed for the X = H compound, although the changes are smaller. In this case the change in *a* is not significant. Such changes would be consistent with small α and β dihedral angle changes like those observed for X = H. The changes in the cell parameters for the X = Cl and Br compounds are very different from those observed for the other two compounds. For these halogen derivatives it is the *a* parameter that decreases significantly on cooling while the *b* parameter shows a small but significant increase (rather than the expected decrease due to thermal effects). The analysis of the X = H compound showed that it is not possible to predict the nature of the distortion perpendicular to the chain axis solely on the basis of the changes in *a* and *b*. Nevertheless the clear difference in the changes in the cell parameters for the two groups of compounds strongly suggests, although it certainly does not prove, that the distortions taking place are fundamentally different. It is possible that in the case of the halogen derivatives the chains are compressed along *x* and elongated along *y*, opposite to the distortion seen in the X = H compound. This form of distortion for the halogen complexes could arise from a decrease in the β dihedral angle and (or) an increase in α.

We turn now to a discussion of how these structural changes might be expected to affect the magnetic properties of these compounds. It was argued previously (2) that the strength of magnetic coupling might be expected to in-

crease with increasing β and decreasing α. For the X = H compound α and β both increase on cooling. The counter-complimentary effect of these changes probably results in no significant change in the strength of the magnetic coupling on cooling and probably accounts for the fact that the magnetic data for this compound were reasonably well fitted to a model for exchange employing a single J value for the whole temperature region studied (2–300 K). For the X = CH_3 compound similar, probably smaller, changes are suggested in the α and β angles and, consistent with this, the magnetic data for this compound were also reasonably well fitted to a single J model (2). If our conclusion is correct, i.e., that the change on cooling in the a and b cell parameters of the X = Cl and Br compounds is a consequence of a decrease in β and (or) an increase in α, then the magnetic anomalies observed in these systems are readily understood. As discussed previously (2), such changes in the dihedral angles should result in a decrease in the magnitude of exchange coupling. This could account for the poor fit of the 2–300 K magnetic data for these compounds and, more importantly, would explain the discontinuity in the χ_M vs. T plots (2).

In summary, these studies have shown that in copper(II) pyrazolate extended-chain polymers interchain distances may be affected by changes in temperature. This appears to have little effect on intrachain bond lengths and angles but may significantly alter the dihedral angle between fused $Cu(N—N)_2Cu$ and N_2C_3 rings and the dihedral angle between consecutive $Cu(N—N)_2Cu$ planes. Previous studies indicated that changes in these dihedral angles may measurably alter the magnitude of the exchange coupling. Hence the assumption of a single exchange coupling constant value, J, valid over a wide range of temperatures, in the magnetic modelling of these systems may not be totally correct. Such structural effects may contribute to the variation in the quality of fit between experiment and theory for different compounds (2, 3). They also provide an explanation for features such as the discontinuities observed in the χ_M vs. T plots for $[Cu(4\text{-}Clpz)_2]_x$ and $[Cu(4\text{-}Brpz)_2]_x$ (2). Finally, the difficulty in fitting the low-temperature magnetic data for some compounds, which has been ascribed to inadequacies in modelling paramagnetic impurity in the sample (2, 3), may be due at least in part to these structural effects.

Ab initio studies on the reaction $SN^+ + SNS^+ \rightarrow S_3N_2^{2+}$

F. GREIN

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received October 22, 1992

F. GREIN. Can. J. Chem. **71**, 335 (1993).

The reaction $SN^+ + SNS^+ \rightarrow S_3N_2^{2+}$ has been studied by *ab initio* SCF methods. Geometry optimizations with the 3-21G(*) basis set were followed by 6-31G* single-point calculations. The barrier of $S_3N_2^{2+}$ to dissociation is 10.9 kcal/mol with 3-21G(*), and 19.7 kcal/mol with the (single-point) 6-31G* basis set. The transition structure is cyclic (C_s), and is similar to the optimized C_{2v} structure of $S_3N_2^{2+}$. The relative orientation of the two approaching cations is governed by electrostatic forces rather than electronic (frontier orbital) effects. The product lies 99.3 (3-21G(*)) and 95.2 (6-31G*) kcal/mol higher than the reactants.

F. GREIN. Can. J. Chem. **71**, 335 (1993).

Faisant appel à des méthodes *ab initio* en champ auto-cohérent, on a étudié la réaction $SN^+ + SNS^+ \rightarrow S_3N_2^{2+}$. Après avoir effectué des optimisations de la géométrie à l'aide de l'ensemble 3-21G(*), on a effectué des calculs 6-31G* en point unique. La barrière à la dissociation de l'ion $S_3N_2^{2+}$ est égale à 10,9 kcal/mol lorsqu'on utilise l'ensemble 3-21G(*) alors qu'elle est égale à 19,7 kcal/mol avec l'ensemble 6-31G* (point unique). La structure de transition est cyclique (C_s) et elle est semblable à la structure C_{2v} optimisée de l'ion $S_3N_2^{2+}$. L'orientation relative des deux cations qui s'approchent est plutôt déterminée par des forces électrostatiques que des effects électroniques (orbitales frontières). Suivant les ensembles utilisés, l'énergie du produit est 99,3 (3-21G(*)) et 95,2 (6-31G*) plus élevée que celle des réactifs.

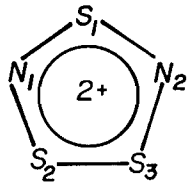
[Traduit par la rédaction]

Introduction

$S_3N_2^{2+}$, in the form of the heterocycle $\overline{SNSNS}^{2+}$, structure **1**, has recently been characterized by Passmore and coworkers (1). Crystalline material of $S_3N_2^{2+}(AsF_6^-)_2$ is formed by the symmetry-allowed cycloaddition reaction

[1] $SNS^+ + SN^+ \rightarrow \overline{SNSNS}^{2+}$

Although in the gas phase $S_3N_2^{2+}$ is about 100 kcal/mol less stable than the reactants $SNS^+ + SN^+$, in the solid state it is stabilized by the large difference in crystal lattice energy between $S_3N_2(AsF_6)_2$ (355.5 kcal/mol) and $SNAsF_6 + SNSAsF_6$ (253.6 kcal/mol), as estimated in ref. 1. In solution, **1** decomposes back to $SNS^+ + SN^+$.



1

C_{2v} *min.*

Geometry optimizations at the 6-31G* level on **1**, as well as on SNS^+ and SN^+, have previously been reported by us (1) and by Gimarc and Warren (2). The results are summarized in Table 1. The optimized geometry of **1**, shown in Fig. 1*a*, is remarkably close to the structure found by X-ray crystallography (1), also given in Table 1.

The detailed mechanism of reaction [1], which is highly endothermic in the gas phase but exothermic in the solid state, is of interest. For this reason, the path of reaction [1] (obviously restricted to the gas phase) has been followed by *ab initio* studies.

SNS^+ is a three-atom, four-electron π system, and is similar to 1,3-dipoles (3). Both the π_g-HOMO and the π_u-LUMO of SNS^+ have suitable symmetry to interact with the π^*-LUMO and the π-HOMO of SN^+, respectively. Since HOMO(SNS^+) and LUMO(SN^+) lie closer in energy than the opposite pair of frontier orbitals, the cycloaddition reaction [1] can be seen as proceeding from the HOMO of SNS^+ to the LUMO of SN^+. It therefore resembles "type I" cycloadditions as classified by Sustmann (in ref. 3). Mulliken charges, to be given later, will confirm this predicted charge transfer from SNS^+ to SN^+.

Since the LUMO of SN^+ has a larger orbital coefficient on S than on N, an initial approach of SNS^+ to SN^+ via the terminal sulfur atoms, $S^{(+)}NS^{(+)}\cdots S^+N$, is expected if the approach is orbital controlled. However, the positive charge of each reactant is mainly located on the sulfur atoms, causing strong electrostatic repulsion of the sulfurs. Based on electrostatic arguments one therefore predicts as initial approach $S^{(+)}NS^{(+)}\cdots NS^+$ or a T-shaped version with the two nitrogens being closest.

In performing the reaction path calculations, both approaches, the orbital-controlled and the electrostatic repulsion-controlled one, have been considered. The cycloaddition reaction prefers the latter approach, as will be shown.

A well-studied example in the literature of a dictation reaction is the dissociation

$$CH_4^{2+} \rightarrow CH_3^+ + H^+$$

which is calculated to be exothermic by about 100 kcal/mol, and has a barrier to dissociation of about 17 kcal/mol (4, 5).

Methods

Geometry optimizations on the supermolecule $SNS^+ \cdot SN^+$ were performed with the GAUSSIAN 86 program (6) using the 3-21G(*) basis set. Here, polarization functions are added to the S, but not to the N atoms. The geometries of $S_3N_2^{2+}$, SNS^+, and SN^+ were reoptimized using this smaller basis set, and the results, also given in Table 1 and Fig. 1*b*, show that the optimized geometry parameters, as well as energy differences, are close to the 6-31G* results. The S—N distances differ by less than 0.01 Å, while the S—S distance differs by about 0.06 Å.

Due to the large number of geometries that had to be studied (see

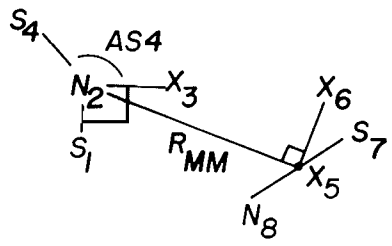
below), use of a basis set larger than 3-21G(*) for the bulk of the calculations would have made the computations prohibitively expensive.

The procedure for obtaining the transition structure (TS) was complicated because no single internal coordinate could serve as reaction coordinate, in the sense that varying such a coordinate from large to small values would bring the system smoothly from the separated reactants over the transition structure to the product. The procedure used will be outlined in the next section. Planar symmetry (C_s) was maintained throughout the reaction path.

Procedure and results

Midpoint approach

The distance between the midpoints of SNS^+ and SN^+, called R_{MM}, was taken as the initial reaction coordinate (see structure **2**). The potential curve with respect to R_{MM} is shown



2

in Fig. 2. According to the classification presented in the Introduction, this choice of reaction path allows the molecule to orient itself under the influence of electrostatic forces (as well as frontier orbital interactions). It is more flexible than the S—S approach to be discussed in the next section.

For R_{MM} values above 3 Å, the supermolecule forms a C_{2v} structure, **3** (Scheme 1), with the two nitrogens facing each other. This can be ascribed to minimization of the electro-

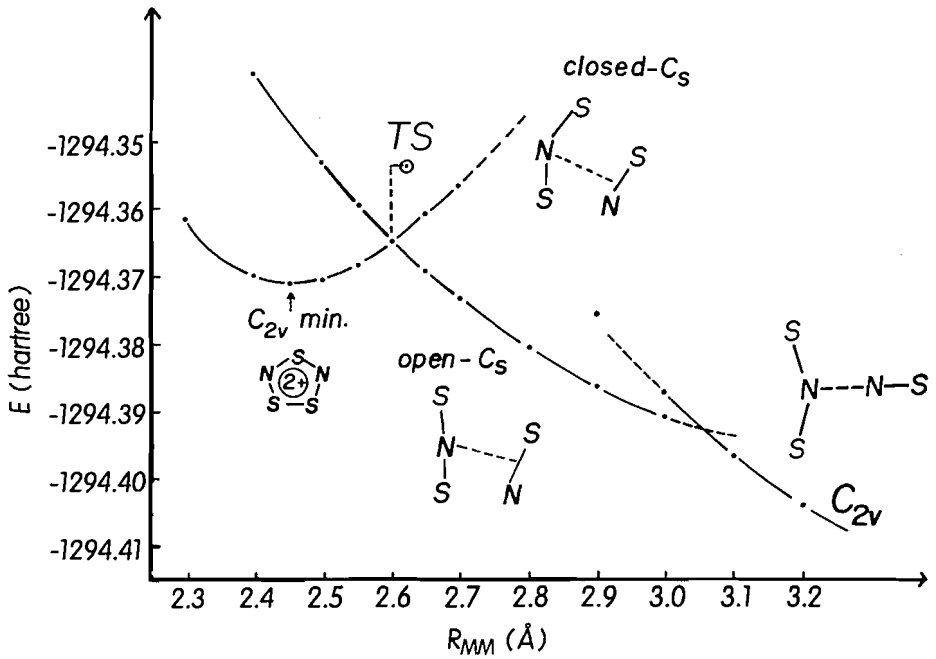


FIG. 2. Minimum energy path for reaction $SNS^+ + SN^+ \rightarrow S_3N_2^{2+}$, using R_{MM} (as defined in structure **2**) as reaction coordinate.

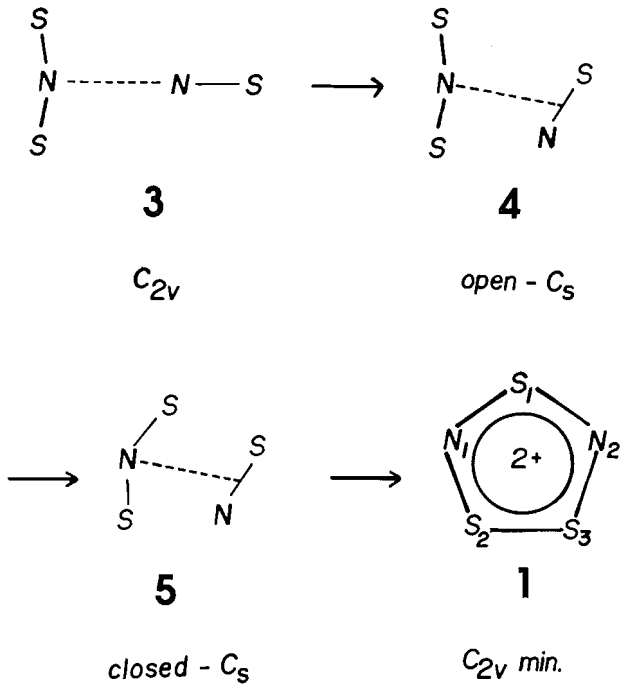

SCHEME 1

static repulsion between SNS^+ and SN^+ since the two nitrogens carry the least positive charge. At R_{MM} = 3 Å it is possible to optimize both a C_{2v} and a C_s structure. The latter, shown in **4** for about 3 Å, has slightly lower energy. It will be designated as the "open-C_s" structure, as contrasted to the "closed-C_s" structure **5** to become important at smaller values of R_{MM}. Figure 2 shows that the C_{2v} and open-C_s curves cross around 3.05 Å.

As R_{MM} decreases, the open-C_s energy increases, until the open-C_s curve crosses the closed-C_s curve around 2.6 Å. In the vicinity of 2.6 Å, both an open-C_s and a closed-C_s structure can be optimized. For example, at 2.55 Å the two structures differ in energy by 5.57 kcal/mol, with the closed-C_s being more stable. With further lowering of R_{MM}, the closed-C_s energy decreases, until it reaches a minimum of C_{2v} symmetry, corresponding to the most stable structure of $S_3N_2^{2+}$, as found earlier. Open and closed C_s energies for selected values of R_{MM} around 2.6 Å are given in Table 2. There is no change of electronic configuration when going from the open-C_s to the closed-C_s structure.

TABLE 2. Relative energies ΔE (in kcal/mol) for the reaction $SNS^+ + SN^+ \rightarrow S_3N_2^{2+}$. See structure **2** for definition of R_{MM}

R_{MM} (Å)	ΔE closed-C_s	ΔE open-C_s
2.152[a]	0	—

2.7	8.70	−1.54
2.8	—	−5.97

[a] C_{2v} symmetry.

At, or close to, 2.6 Å the lowest-energy structure changes abruptly (when seen as function of R_{MM}) from open to closed-C_s. It is obvious that in a smooth structural change, e.g., by varying the angle AS4 in **2** from the open to the closed value, the energy has to go over a barrier. With this in mind, AS4 was chosen as the second reaction coordinate. Keeping R_{MM} at a fixed value, e.g., 2.6 Å, and varying AS4, all other geometry parameters were optimized. As shown in Fig. 3, for R_{MM} at 2.6 Å a maximum is obtained for AS4 = 60°, 7.2 kcal/mol above the closed-C_s energy at 2.6 Å. The potential curves for closing the molecule at 2.5 and 2.7 Å are also shown in Fig. 3. The maximum shifts to 70° and 50°, respectively, and is higher in energy than for R_{MM} = 2.6 Å.

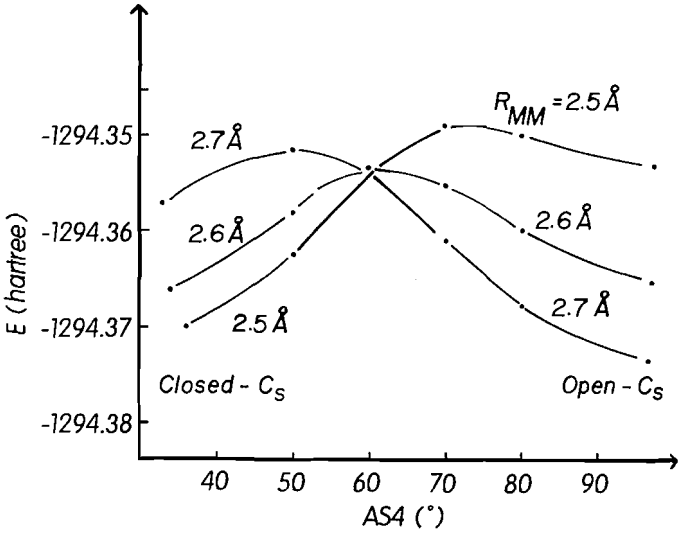

FIG. 3. Potential energies of $S_3N_2^{2+}$, for transition from open to closed C_s structure, as function of angle AS4 (as defined in structure **2**). The distances labeling each curve are the R_{MM} parameters.

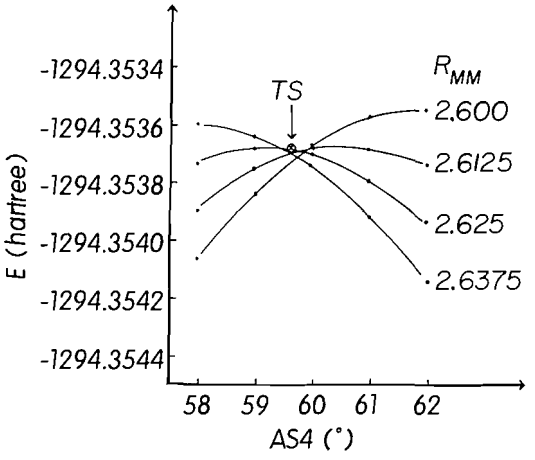

FIG. 4. Refined potential energies as function of angle AS4.

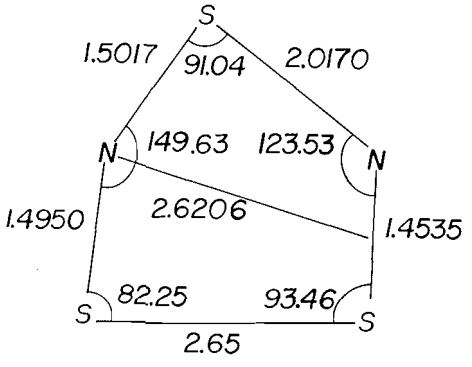

FIG. 5. Optimized geometry of transition structure of $S_3N_2^{2+}$.

A series of calculations for a grid of R_{MM}/AS4 values, with R_{MM} close to 2.6 Å and AS4 close to 60°, was performed in order to refine the potential curves for ring closure and to locate the transition structure. In Fig. 4, potential curves are shown for R_{MM} between 2.6 and 2.6375 Å, and AS4 angles

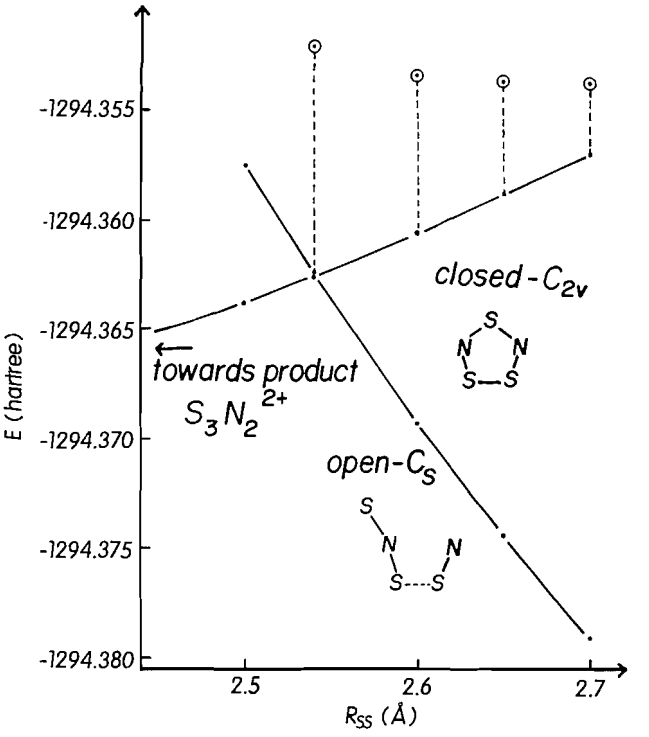

FIG. 6. Minimum energy path for reaction $SNS^+ + SN^+ \rightarrow S_3N_2^{2+}$, using R_{SS} (structure **6**) as reaction coordinate.

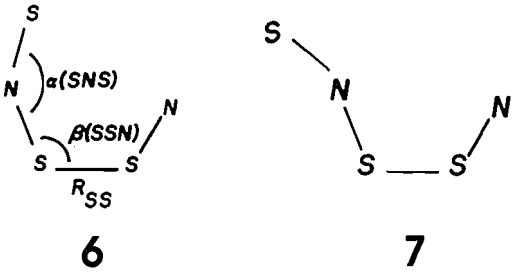
from 58° to 62°. The lowest barrier now occurs between 2.6125 Å (~60.5°) and 2.625 Å (~59°). Further refinement leads to a TS with R_{MM} = 2.620625 Å and AS4 = 59.625°, having an energy 7.19 kcal/mol above the closed-C_s energy at 2.6 Å, and 10.92 kcal/mol above the C_{2v} minimum product structure. The geometry of this transition structure is shown in Fig. 5.

S—S approach

Both HOMO of SNS^+ and LUMO of SN^+ are π^*-type orbitals. The HOMO of SNS^+ has, for symmetry reasons, no atomic orbital on N. The LUMO of SN^+ is more pronounced on S than N. Using frontier orbital arguments only, one would expect that the two cations approach each other via the terminal sulfur atoms. Accordingly, another series of



calculations was performed to find the reaction pathway and transition state of reaction [1]. Now the initial reaction coordinate was chosen to be R_{SS}, the distance between the terminal S atoms of SNS^+ and SN^+ (structure **6**).

At large R_{SS} values, a T-shaped C_{2v} structure, as discussed above, has (for a given R_{SS}) a higher energy than the open-C_s structure **7**. As shown in Fig. 6, the open-C_s energy increases as R_{SS} decreases, and a crossing occurs around 2.54 Å with a closed-C_{2v} structure (and probably also a closed-C_s structure). The closed-C_s curve reaches a mini-

TABLE 3. Mulliken charges for atoms of $SNS^+ + SN^+$. For numbering of atoms see structure **2**

2.152, $-C_{2v}$	1.223	−0.467	0.856	1.612	0.856	−0.467	0.389

mum at R_{SS} = 2.152 Å for the product $S_3N_2^{2+}$. At the crossing point an abrupt change from open-C_s to cyclic C_{2v} occurs, and a second reaction coordinate had to be chosen. For a selected value of R_{SS}, the angle α(SNS) (**6**) was varied from the open-C_s to the closed-C_{2v} value. The energy maximum for a given R_{SS} is indicated in Fig. 6 by a vertical bar. It is seen that the transition structure lies between R_{SS} = 2.65 and 2.70 Å. A third reaction coordinate was needed for which the angle β(SSN) (**6**) was chosen. Finally, the TS was located at R_{SS} = 2.65 Å, α = 149.73°, and β = 82.25°, 10.92 kcal/mol above the C_{2v} minimum. The transition structures obtained by the two methods are (fortunately) identical.

The last-described procedure, which starts with R_{SS} instead of R_{MM} as the initial reaction coordinate, suffers from the same problem as the first method, namely, that there is no suitable single reaction coordinate. It is actually more complicated, since energies over a three-dimensional rather than a two-dimensional grid of geometry parameters had to be evaluated. The choice of R_{SS} led to a nonsymmetrical separation of the product into reactants, whereas the midpoint-to-midpoint approach shows $S_3N_2^{2+}$ to separate into $SNS^+ + SN^+$ having T-shaped C_{2v} symmetry.

Discussion

The transition structure of eq. [1] was found by calculating the energies in a two-dimensional (or three-dimensional) grid. A transition state optimization was not possible since the minimum energy path cannot be described as a function of any one internal coordinate as defined here, but goes diagonally through a grid involving distances and angles. For the same reason, frequency calculations at the TS could not be performed. Due to the low level of basis set used in the optimizations, zero point energy corrections were not found to be helpful. It is intended to carry out 6-31G* geometry optimization if and when better computing resources become available.

All optimizations were performed on planar $S_3N_2^{2+}$. A nonplanar TS cannot be ruled out. It could further lower the energy barrier. Exploratory calculations on nonplanar structures close to the TS were performed. While by no means conclusive, they showed in each case a preference (lower energy) for the planar structure.

The energy of the TS lies 10.9 kcal/mol above the optimized $S_3N_2^{2+}$ structure, and 110.2 kcal/mol above the energy of the reactants $SNS^+ + SN^+$. Single point 6-31G* calculations at the optimized 3-21G(*) geometries of the product and the TS led to an energy difference of 19.7 kcal/mol. However, due to the lack of 6-31G* geometry optimization of the TS, the above number is not considered to be as trustworthy as the 3-21G(*) value.

The transition structure, Fig. 5, is basically cyclic. The SNS^+ and SN^+ units are clearly discernible. Within the SNS^+ unit the bond distances are slightly longer than in free SNS^+ (by about 0.02 Å), whereas the bond angle has changed from 180° to 149.7°. For SN^+ the bond distance is about 0.05 Å larger than in free SN^+. The distances separating SNS^+ and SN^+ are large, 2.65 Å for S—S and 2.02 Å for N—S. The major structural change seen in the TS relative to the reactants is the bending of SNS^+.

At large distances, SNS^+, essentially linear, stands at right angles to SN^+, with the nitrogens, the least positive elements, facing each other. The reasons for this geometry are purely electrostatic. As the distance between the two units decreases, the T-shaped C_{2v} configuration cannot be maintained, and the open-C_s structure, with the two terminal S atoms pointing away from each other, results. Around R_{MM} = 2.6206 Å, the value for the TS (R_{TS}), the open-C_s structure has to become cyclic, which is accomplished by bending SNS^+ towards SN^+. At R_{MM} values below R_{TS}, the supermolecule moves towards the product $S_3N_2^{2+}$, having C_{2v} symmetry.

Using frontier orbital arguments, and neglecting electrostatic repulsions, an initial approach of one of the terminal S atoms of SNS^+ to the S atom of SN^+ would have been predicted. The calculated energies and geometries show that electrostatic repulsions play a more important role than electronic efforts at least in the initial approach of two cations.

In Table 3, the Mulliken charges are given for some typical values of R_{MM}, starting with the C_{2v} structure at 3.5 Å, going to the C_{2v} and open-C_s structures at 3 Å, the open-C_s structure at 2.8 Å, the transition structure, and finally the C_{2v} product. Consistent with frontier orbital arguments, the positive charge on SNS^+ (HOMO) increases, whereas it decreases on SN^+ (LUMO) as one moves from the reactants towards the product. An astonishing amount of charge (0.6 units in the Mulliken picture) is transferred from SNS^+ to SN^+.

Looking at the internal charge distribution, at large separation SN^+ has all positive charge located on S, whereas SNS^+ has N negative (−0.313), and each S therefore positive by more than 0.5 charge units. At the minimum of $S_3N_2^{2+}$, the N's are even more negative. Starting again from the reactants, N2 and N8 (**2**) become more negative, the charge on N2 going from −0.313 to −0.467, and on N8 from 0 to −0.467. Therefore, the S atoms together have to become more positive. S1 and S4, originally associated with SNS^+, go from 0.657 to 1.223 for S1, and from 0.657 to 0.856 for S4. On the other hand, S7 (of SN^+) started out with a charge of 1, and goes to 0.856, becoming thereby less positive.

Considering that the geometrical structures change several times when going from reactants to product (C_{2v} reactants, open-C_s, closed-C_s, C_{2v} product), the charges vary smoothly over the reaction path. The dominant feature of reaction [1], as far as charges are concerned, is the gradual accumulation of negative charge on the nitrogens, and the associated depletion of electrons from the sulfurs. The pattern of sulfur charges is consistent with the S...F cation–anion contacts in the crystal, as reported by Passmore and co-workers (7). S1 has the strongest contact (0.62 valence units, calculated charge of 1.223) while the base sulfur atoms have contacts of 0.5 valence units (charge of 0.856).

In an experimental study on cycloadditions of SNS^+ to alkynes, nitriles, and thiazyl halides, Parsons *et al.* (8) state that, at least for the nitrile cycloadditions, steric factors are found to be unimportant, implying "a highly asynchronous, early transition state." The gas-phase reaction $SNS^+ + SN^+$ is also asynchronous, but has a late transition state in agreement with Hammond's postulate, since the reactants are at much lower energy than the product. The TS itself looks like a slightly distorted blown-up version of the product. Due to the large electrostatic repulsion between the two fragments, a late transition state is expected for the gas phase reaction.

Summary and conclusion

Due to the strong Coulomb repulsions, the formation of the dictation $S_3N_2^{2+}$ from two cations SN^+ and SNS^+ is expected and found to be highly endothermic with an energy of 95–99 kcal/mol, depending on basis set. The barrier to dissociation of $S_3N_2^{2+}$ is calculated to be 10.9 kcal/mol.

$S_3N_2^{2+}$ is known in crystal form as $S_3N_2(AsF_6)_2$ but dissociates in solution, and does not exist in the gas phase.

The transition structure looks similar to the $S_3N_2^{2+}$ product, as expected from Hammond's postulate. The dissociation of $S_3N_2^{2+}$ occurs via distortion from the C_{2v} minimum to a closed-C_s structure, further by ring-opening to an open-C_s structure, and finally at large distances to a symmetric C_{2v} structure, with a T-shaped $SNS^+...NS^+$ having the two nitrogen atoms face each other. The electrostatic interaction between the two cations, rather than frontier orbital considerations, dominate the reaction path.

The cation SNS^+ has been found to undergo many novel chemical reactions, and further theoretical work on reactions of SNS^+ with other systems is of interest.

Acknowledgements

The author is much indebted to Jack Passmore for suggesting this project and for his continuous support and interest in this work. Special thanks go to Simon Parsons for carefully reading the manuscript and for making valuable suggestions towards its improvement. Robert Mawhinney is thanked for drawing several of the structures.

Financial support by the Natural Sciences and Engineering Research Council of Canada (NSERC) and allocation of computing resources by the University of New Brunswick are gratefully acknowledged.

Newly available and highly accurate oscillator strength data, extending over the continuous energy range from the first excitation threshold to 200 eV, are used together with mixture rule estimates and other photoabsorption data to construct a refined dipole oscillator strength distribution to infinite photon energy using Thomas–Reiche–Kuhn sum rule and molar refractivity constraints. This constrained dipole oscillator strength distribution has been used to calculate a wide range of related dipole properties (S_k, k = 2, 1, 0, −1/2, −1, −3/2, −2, −5/2, −3, −4, −5, −6, −8, −10, −12; L_k and I_k, k = 2, 1, 0, −1, −2). The theoretical analysis and associated consistency checks support the high accuracy of the newly available absolute oscillator strengths for the photoabsorption of NH_3.

GORDON R. BURTON, WING FAT CHAN, GLYN COOPER, C. E. BRION, ASHOK KUMAR et WILLIAM J. MEATH. Can. J. Chem. **71**, 341 (1993).

Faisant appel à la règle des sommes de Thomas–Reiche–Kuhn et à des contraintes de réfractivité molaire, et utilisant une combinaison de nouvelles données très précises relatives à la force d'oscillateur dipolaire couvrant l'ensemble continue des énergies allant du seuil de la première excitation jusqu'à 200 eV avec des évaluations de la règle de mélange et d'autres données de photoabsorption, on a construit une distribution raffinée de la force d'oscillateur dipolaire jusqu'à une énergie photonique infinie. On a utilisé cette distribution de la force d'oscillateur dipolaire pour calculer un grand ensemble de propriétés dipolaires apparentées (S_k, k = 2, 1, 0, −1/2, −1, −3/2, −2, −5/2, −3, −4, −5, −6, −8, −10 et −12; L_k et k = 2, 1, 0, −1 et −2). L'analyse théorique et des vérifications de la cohérence associée supportent la grande exactitude des nouvelles forces absolues d'oscillateurs dipolaires pour la photoabsorption du NH_3.

1. Introduction and background

Ammonia has been observed in the interstellar medium, molecular clouds (1, 2), and in the atmospheres of Saturn and Jupiter (3) and is of importance in photochemistry, being a low-energy source of NH_2 and NH radicals (4). Therefore the absolute photoabsorption oscillator strengths (cross sections) for NH_3 over the entire electromagnetic spectrum, and the related dipole properties, are of interest to astrophysicists and others wishing to model the interaction of energetic radiation and particles with this molecule. There is also considerable interest in the possibility of using additivity concepts and mixture rules to estimate the quantitative aspects of the interaction of energetic electromagnetic radiation with large and complex molecules and to evaluate the properties of these molecules from those of smaller, related species (5–9). Therefore the present analysis for NH_3 will be used to provide a foundation that will be extended in subsequent work[4] to include the absolute photoabsorption oscillator strength distributions and dipole properties for monomethylamine (methanamine), dimethylamine (*N*-methylmethanamine), trimethylamine (*N*,*N*-dimethylmethanamine), and also the higher *n*-alkylamines. By comparing the oscillator strength distributions and dipole properties of ammonia and the methylamines an indication of the effect on the oscillator strength distribution, and the dipole properties, of adding methyl or amino groups to larger molecules can be assessed.

The discrete region of the valence-shell photoabsorption spectrum of ammonia has been the subject of numerous experimental studies, presumably owing to the wealth of spectral features below the first ionization threshold. The earliest experiments used photographic techniques and were performed primarily to determine the energy positions of the various observed electronic, vibrational, and rotational transitions rather than transition probabilities. A variety of experiments using conventional light sources or synchrotron radiation have been aimed at also obtaining absolute photoabsorption cross-section data for the valence shell of ammonia (11–28). Electron-impact based techniques have also proved useful in determining the optical oscillator strengths for the photoabsorption of the lowest energy transition in NH_3, by the tedious method of extrapolation of a series of generalized oscillator strength measurements for each transition to zero momentum transfer (29). Absolute total photoabsorption and also partial photoionization oscillator strengths (cross sections) for molecular and dissociative photoionization of NH_3, as well as for the production of electronic states of ions, have been obtained directly over wide energy ranges in the VUV and soft X-ray region at low

resolution by the techniques of dipole (e,e), (e,e+ion), and (e,2e) spectroscopy, respectively (30–32). These dipole techniques, using the broad spectral range and constant flux of the virtual photon field created by a fast inelastically scattered electron, at negligible momentum transfer, provide a direct route to obtaining reliable absolute optical oscillator strengths for photoabsorption and photoionization processes over wide energy ranges up to several hundreds of electron volts (27, 33, 34). In these dipole experiments (27, 33) the absolute photoabsorption oscillator strength scale has usually been established using a valence-shell adapted Thomas–Reiche–Kuhn (TRK) sum rule with allowance for the Pauli-excluded transitions from inner shells to the already occupied valence orbitals. This method of establishing the absolute scale avoids difficulties such as determinations of absolute target density and photon flux that are required in traditional optical methods for absolute cross-section scale determinations. These fast electron impact techniques have proven to be an extremely viable and completely independent alternative to direct optical methods for the measurement of photoabsorption oscillator strengths in the VUV and soft X-ray regions (27). In particular, the problems of contributions from higher-order electromagnetic radiation, which can occur with monochromated synchrotron radiation, are avoided and measurements can be obtained at a constant energy resolution over a wide spectral range. Furthermore, since the electron impact process is non-resonant, and because no logarithmic transform is involved, the high-resolution optical oscillator strength spectrum determined with dipole (e,e) spectroscopy in the region of discrete excitation will be free of the "line-saturation" (i.e., bandwidth) effects that can often seriously perturb intensities obtained in discrete photoabsorption spectra using Beer–Lambert Law techniques (35, 36).

The reliable direct experimental determination or *ab initio* calculation of most of the dipole properties for molecules the size of NH_3 is not at present feasible. However, these properties can be evaluated if globally reliable molecular dipole oscillator strength distributions (DOSDs) are available for all values of the excitation energy from the electronic photoabsorption threshold to very high energy. Such DOSDs can be constructed, by using quantum mechanical constraint techniques (37–42), if sufficient photoabsorption oscillator strength (cross section) and accurate molar refractivity data are available for the molecules of interest. Using this approach a constrained DOSD can be constructed and used to reliably compute a wide variety of dipole properties (43, 44) including the mean excitation energies, and other dipole properties associated with the Lamb shift, and with the straggling, stopping, and total inelastic scattering of fast charged particles in matter (7, 8, 44). Nitrogen-containing organic compounds are of importance in the latter context because of their occurrence in molecules of biological and radiological interest. The presently determined DOSD and dipole properties of ammonia, and the subsequent studies of the methylamines,[4] will provide a fundamental foundation for the investigation of the interaction of larger nitrogen-containing molecules with energetic electromagnetic radiation at UV and X-ray energies.

The constrained least-squares method used here to construct the DOSD, and to evaluate the dipole properties, for ammonia was previously used with considerable success for a variety of molecules (37, 38, 45–51). The previous DOSD studies of NH_3 (37) were, of course, based on the then available absolute photoabsorption oscillator strength data. While they were reasonably successful, the results were limited by inconsistencies between, and the limited energy ranges of, the various available oscillator strength data sets; for details see ref. 37. Recent DOSD analyses,[5] which served as a preliminary basis for the study reported here, have confirmed the inconsistencies and limitations of the currently available absolute photoabsorption oscillator strength data for ammonia and indicated the need for new comprehensive measurements over as wide an energy range as possible. New measurements should also include the valence-shell discrete excitation spectrum at high resolution since no reliable continuous absolute data set is available throughout this low-energy region.

In this paper we make a constrained DOSD analysis of new high- and low-resolution measurements of the absolute oscillator strengths for NH_3 over the entire energy range from the first excitation threshold to 200 eV. A detailed account of the experimental data, including extensive tabular data, together with a spectral analysis of these comprehensive measurements, is to be published elsewhere.[6] The low- and high-resolution oscillator strength data measurements are presented in Fig. 1 and, as integrals over suitable energy blocks, in Table 1. They are used together with molar refractivity data (54–56) to obtain constrained DOSDs, which in turn are used to calculate results of improved reliability for a wide variety of the dipole properties of NH_3. The relatively recent oscillator strength data of Samson *et al.* (26), for 11.07–150 eV, are also included explicitly in the DOSD analysis for NH_3. However, it should be noted that the latter data (26) do not include the discrete excitation region below the first ionization potential. The results obtained in the present work provide updated values of the dipole properties of ammonia, relative to those reported earlier by Zeiss *et al.* (37), and provide the most reliable values yet available for many of the dipole properties of NH_3.

2. Experimental details and results

The dipole (e,e) spectrometers and procedures used to determine the absolute photoabsorption oscillator strengths (cross sections) at both low resolution (~1 eV fwhm) and at high resolution (0.048 eV) have been described previously (36, 57–63, and footnote 6), so only a brief description of the methods will be given. The low resolution (LR) measurements of ammonia were made using an unmonochromated, high incident energy (8000 eV), electron beam in an electron energy-loss spectrometer. The absolute photoabsorption oscillator strengths were obtained by Bethe–Born conversion and valence-shell TRK sum-rule normalization of the background-subtracted electron energy-loss spectrum obtained at a mean scattering angle of zero degrees (acceptance angle of 1.4×10^{-4} sr) (57). The data were obtained from the electronic excitation threshold at 5.5–200 eV. The relative valence-shell optical oscillator strength spectrum was

[5]A. Kumar, W. J. Meath, G. R. Burton, G. Cooper, W. F. Chan, and C. E. Brion. Unpublished work.

[6]G. R. Burton, W. F. Chan, G. Cooper, and C. E. Brion. To be published.

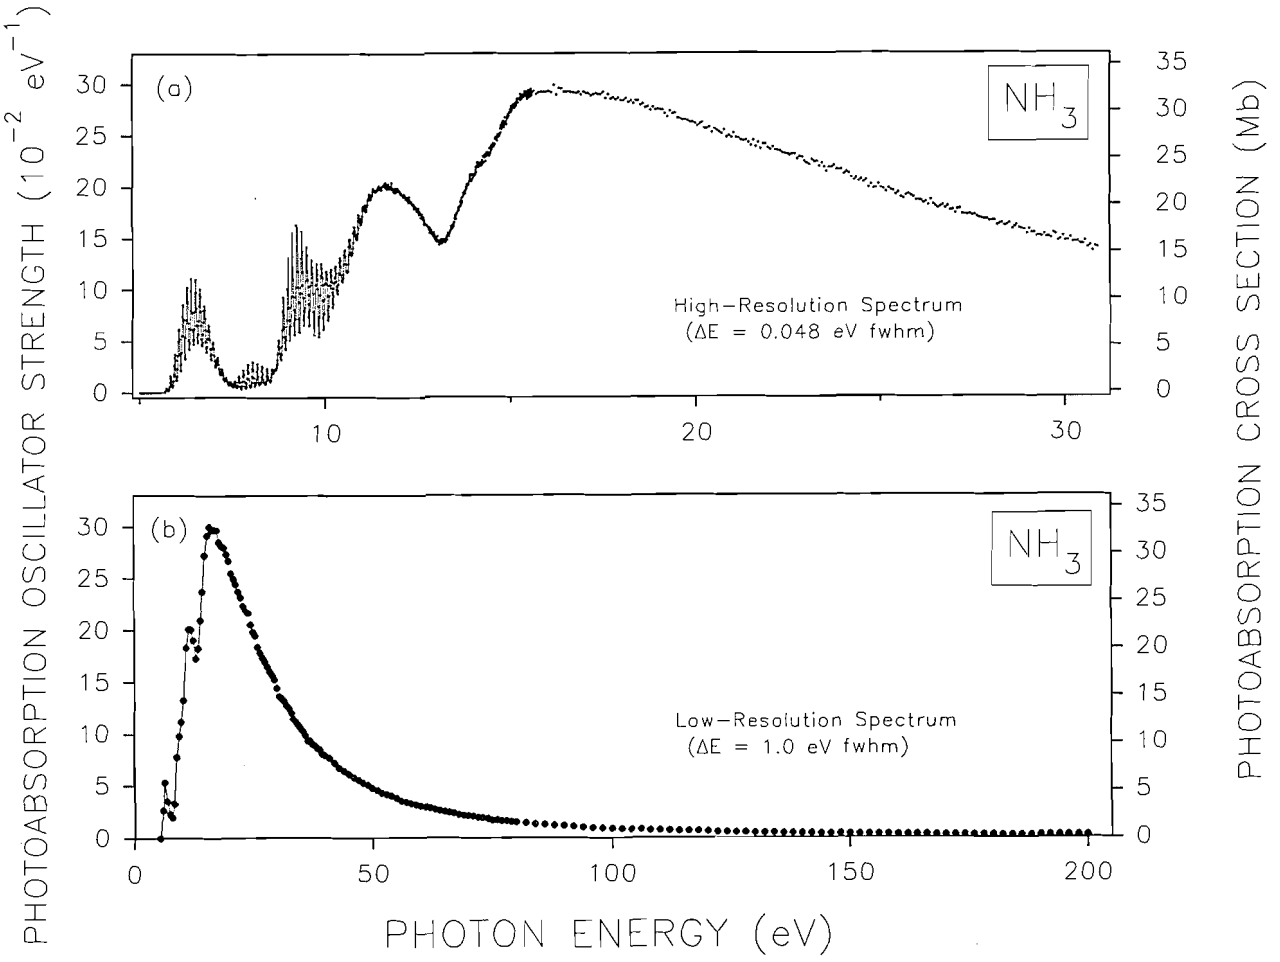

FIG. 1. Absolute photoabsorption oscillator strengths for ammonia: (*a*) the valence-shell region from 5 to 31 eV measured at high resolution (0.048 eV fwhm); (*b*) the valence-shell region from 5.5 to 200 eV measured at low resolution (~1 eV fwhm). These data were determined using dipole (e,e) spectroscopy (see footnote 6 for details).

placed on an absolute scale by first fitting a curve to the high-energy tail from 90 to 200 eV. Using this curve there is estimated to be 4.5% of the total valence-shell oscillator strength above 200 eV. The fitted curve was then extrapolated to infinity and the total area under the whole spectrum was normalized to 8.13. The same value was used to normalize the previously reported low-resolution dipole (e,e) data of Wight *et al.* (31). The value 8.13 corresponds to the eight valence-shell electrons in NH_3 plus a small estimated contribution of 0.13 to account for Pauli-excluded transitions from the nitrogen 1*s* shell to the already occupied valence orbitals (64).[7]

The high-resolution (HR) measurements for ammonia were obtained using a high-resolution electron energy-loss spectrometer, with an incident electron energy of 3000 eV (61). This instrument was recently calibrated to obtain the appropriate Bethe–Born conversion factor so as to be able to produce relative optical oscillator strength distributions from the background-subtracted, zero degree electron energy-loss spectrum (36, 63). The relative oscillator strength spectrum was put on an absolute scale by single point normalization to the presently reported low-resolution photoabsorption oscillator strength spectrum (see above) in the smooth continuum region. The reliability of the presently used dipole (e,e) techniques has been confirmed by the excellent agreement between the previously measured oscillator strengths and high-level *ab initio* calculations for He (36) and H_2 (62).

The sample of ammonia used in this work was obtained from a Matheson lecture bottle and was of a minimum stated purity of 99.99%. The gas sample was used without further purification and no impurity peaks could be detected in the high-resolution electron energy-loss spectrum.

The newly measured absolute differential photoabsorption oscillator strength data for NH_3, obtained as described above, are presented in Fig. 1. Figure 1*a* shows the high-resolution spectrum from 5 to 31 eV at a resolution of 0.048 eV fwhm. The figure gives a detailed and accurate view of the highly structured portion of the differential oscillator strength spectrum in the vibrationally resolved pre-edge region of discrete excitation. The low-resolution spectrum in Fig. 1*b* provides a global view of the absolute photoabsorption oscillator strength distribution from 5 to 200 eV at a resolution of 1 eV fwhm. At this modest resolution the pre-edge excitation region is only partially re-

solved and thus cannot provide accurate *differential* oscillator strength information. However, the integrated oscillator strength over the entire discrete excitation region is consistent with the high-resolution data. In the smooth continuum region the high- and low-resolution differential oscillator strength distributions exhibit the same shape and can thus be compared directly. The overall consistency of the newly reported high- and low-resolution valence-shell oscillator strength measurements can be seen from Fig. 2 where the complete data sets are conveniently displayed in a single diagram on a wavelength scale (Å).

3. Constrained dipole oscillator strength distributions and related properties

3.1. Computational methods

The dipole oscillator strength distribution (DOSD) for a molecule is given by the molecular differential dipole oscillator strength, (df/dE), as a function of photon energy E, from the photoabsorption threshold, E_0, to very high energy. Many important molecular dipole properties (37, 43, 44) can be evaluated if the DOSD for the given molecule is available. Those of particular interest for this paper include the dipole oscillator strength sums S_k, the analogous logarithmic dipole sums L_k, and the related mean excitation energies I_k, defined by

$$[1] \quad S_k = \int_{E_0}^{\infty} \left(\frac{E}{E_H}\right)^k \left(\frac{df}{dE}\right) dE$$

$$[2] \quad L_k = \int_{E_0}^{\infty} \left(\frac{E}{E_H}\right)^k \left(\frac{df}{dE}\right) \ln(E) dE$$

$$[3] \quad I_k = E_H \exp\left[L_k/S_k\right]$$

where E_0 is the electronic absorption threshold for the molecule, and E_H is 27.212 eV (the Hartree unit of energy). The index k can take many different values (e.g., k = 5/2, 2, 1, 0, −1/2, −1, −3/2, −2, −3, −4, ...) and each choice corresponds to a different molecular property with respect to eqs. [1]–[3]. For example, $\alpha_d = a_0^3 S_{-2}$ is the static dipole polarizability of the molecule, where a_0 is the Bohr radius. A further example is the Thomas–Reiche–Kuhn (TRK) sum rule, $S_0 = N$, where N is the total number of electrons in the atom or molecule being studied. Furthermore, the mean excitation energies I_k, for k = 1, 0, and −1, are the average

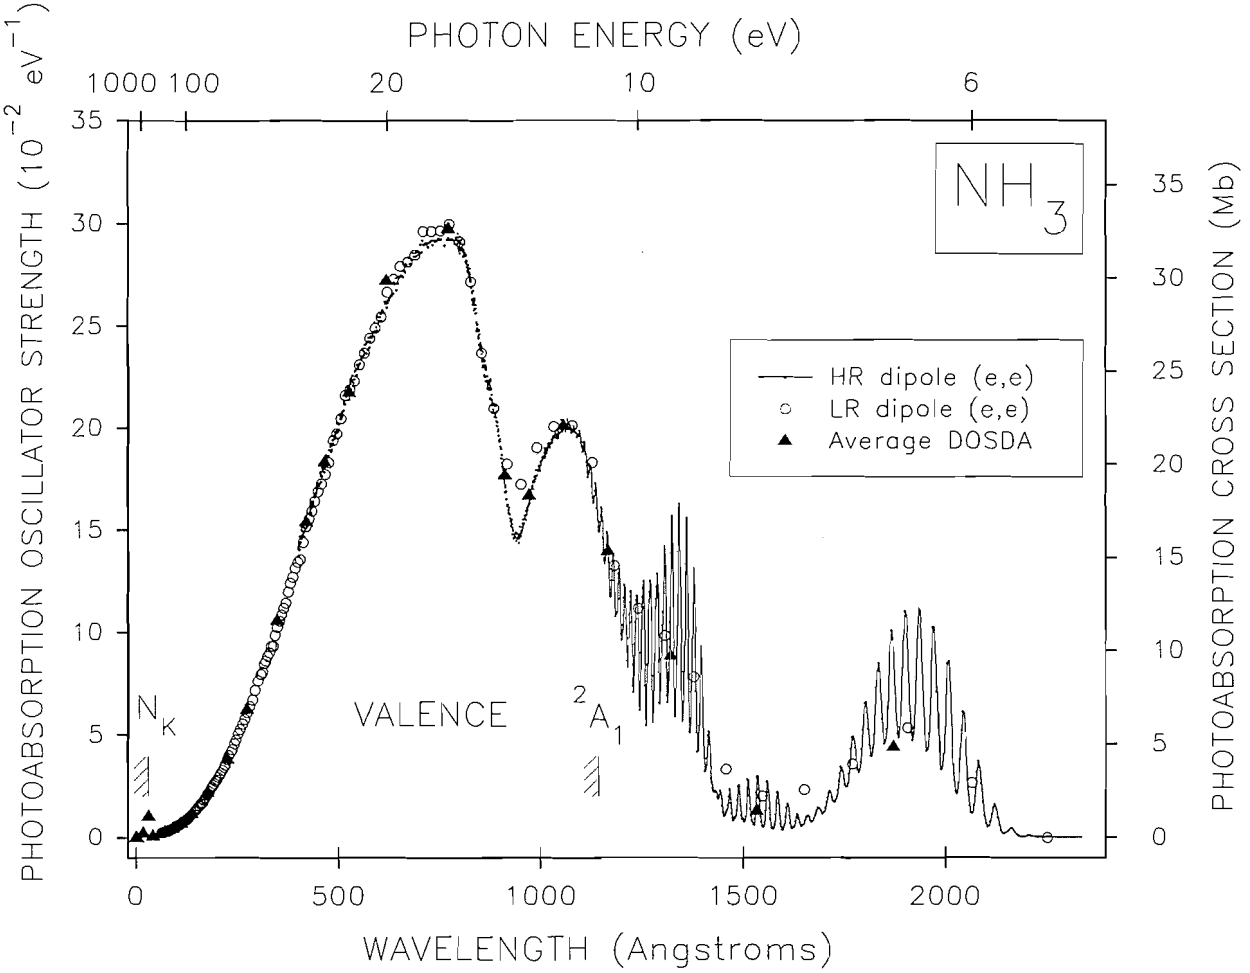

FIG. 2. Absolute experimental low-resolution (~1 eV fwhm) and high-resolution (0.048 eV fwhm) photoabsorption data for NH_3 as a function of wavelength. The hatched lines indicate the positions of the lowest energy valence-shell vertical ionization potential (VIP) and the nitrogen K-shell VIP. The average constrained DOSD data points, calculated for each energy block in the valence- and nitrogen K-shell regions, are taken from DOSD A (Table 1). The energy position of each of these data points is the midpoint of the energy region over which the particular integrated oscillatory strength value was determined and the associated differential oscillator strength value for these data points is the integrated oscillator strength value divided by the width of the energy region.

energies associated with straggling, stopping, and total inelastic cross sections for fast charged particles in matter, respectively. Another important property related to molecular DOSDs is the molar refractivity, R_λ, of a dilute molecular gas. R_λ is related to the refractive index, $n(\lambda)$, and the dynamic dipole polarizability, $\alpha(\lambda)$, of the gas at wavelength λ by

$$[4]\quad R_\lambda = \frac{1}{\rho}\left[\frac{n^2(\lambda)-1}{n^2(\lambda)+2}\right] = \frac{4\pi}{3}\mathcal{N}(E_H)^2 a_0^3 \int_{E_0}^{\infty} \frac{(df/dE)}{E^2-(hc/\lambda)^2}\,dE = \frac{4\pi}{3}\mathcal{N}\,\alpha(\lambda)$$

where ρ is the molar density of the gas, h is Planck's constant, $\mathcal{N}$ is Avogadro's number, and c is the speed of light (42, 43, 66).

The constrained least-squares methods used to construct the DOSD for a given molecule, from an initial data base of (df/dE) versus E values, have been discussed and applied in the literature previously (37, 38). In summary, the excitation energies for the molecule are divided into N_0 energy regions from threshold to very large values of E. The initial differential dipole oscillator strength data for the ith spectral region are modified according to

$$[5]\quad (df/dE)^i_{mod} = (1+a_i)(df/dE)^i_{initial}, \qquad i = 1, 2, \ldots, N_0$$

such that the total modified DOSD satisfies constraints through the choice of the $\{a_i\}$. The constraints used in the present work are the molar refractivity, R_λ, for two well-spaced (47, 49) λ values, and the TRK sum rule, S_0.

A DOSD can be constructed for each initial data base for a given molecule. The amount of modification of the initial (df/dE) versus E data that is required to satisfy the constraints can be represented by the standard deviation (STD) defined by

$$[6]\quad (\mathrm{STD}) = \left[\sum_{i=1}^{N_0}(a_i-\bar{a})^2/N_0\right]^{1/2}$$

where $\bar{a}$ is the mean of the a_i values.

Each adopted DOSD is represented by a set of data points, E_l and $(df/dE)_l$, for $l = 1, 2, \ldots, N_p >> N_0$, and a set of interpolating functions to connect the points; $N_p = 2538$ for ammonia. For very high photon energies, i.e., $E \geq 10^9$ eV, the (df/dE) are represented by the Born dipole formula (67), $AE^{-3.5}$. The dipole properties represented in eqs. [1]–[4] are readily evaluated using this representation of the DOSDs.

3.2. Dipole oscillator strength distribution of ammonia

A DOSD for NH_3 was constructed some time ago (1977) by Zeiss *et al.* (37) who employed methods that are the precursor to those used in this paper. Such photoabsorption, or equivalent data, as were available at the time were considered. However, because of substantial disagreements amongst the available experimental data sets, and due to the lack of NH_3 data for higher photon energies, the DOSD was based on the (H_2, N_2) mixture rule above 33 eV. It was noted (37) that the dipole oscillator strength (DOS) data (4–100 eV) of Van der Wiel and Brion (30) generally agreed with the mixture rule values to within 10%. In this section we construct new DOSDs for NH_3 based on new NH_3 oscillator strength data (see refs. 26 and 68 and the present new experimental work) that has become available since the original DOSD work on ammonia (37) was carried out. We then compare the dipole properties obtained from the resulting constrained DOSDs with those (37) evaluated from the DOSD of Zeiss *et al.* (37). The sources of DOS data discussed and analyzed in ref. 37 are not considered explicitly in the construction of the DOSD for NH_3 reported below. The data subsequently reported by Wight *et al.* (31) over the range 10–60 eV are also not considered explicitly in what follows since it is now apparent that adequate background subtraction procedures were not employed. This was confirmed by preliminary work (see footnote 5), which indicated that the data of Wight *et al.* (31) are too high relative to the new (background-subtracted) measurements reported in Sect. 2.

The following experimental dipole oscillator strength data are considered for the construction of the DOSDs for NH_3: 5.685–30.88 eV (high-resolution data of Sect. 2); 5.685–200 eV (low-resolution data of Sect. 2); 11.07–150.0 eV (Samson *et al.* (26)); 400–425 eV (Akimov *et al.* (68)). This experimental molecular NH_3 data is augmented by employing the following mixture rule, particularly for photon energies $E \geq 150$ eV,

$$[7] \quad (df/dE)(NH_3) = \frac{1}{2}(df/dE)(N_2) + \frac{3}{2}(df/dE)(H_2)$$

The input for this mixture rule uses the recommended N_2 and H_2 DOSDs of Zeiss *et al.* (37).

To construct the DOSD, the photoabsorption spectrum is divided into 26 energy intervals as suggested by the structure of the spectrum and by the photon energy regions corresponding to the various sources of DOS input data. The integrated DOSs for each individual source, and for each relevant energy interval, are given in Table 1, which also contains the analogous results calculated from the adopted DOSD of Zeiss *et al.* (37). The constraints used for constructing the DOSDs for NH_3 from the initial DOS input data are provided by $S_0 = 10$ and by the experimental molar refractivity data of Frivold *et al.* (54) and Friberg (55) at $\lambda = 2753$ Å and $\lambda = 5462$ Å, respectively. These are the same constraints as employed by Zeiss *et al.* (37).

We have constructed three new DOSDs by taking the following combinations of the initial dipole oscillator strength data:

DOSDA : 5.685–30.88 eV (present high-resolution data); 30.88–200 eV (present low-resolution data); 400–425 eV (Akimov *et al.* (68)); all other energy regions (mixture rule).

DOSDB : 5.685–200 eV (present low-resolution data); then as in DOSDA.

DOSDC : 11.07–150 eV (Samson *et al.* (26)); then as in DOSDA.

Each of these initial DOSDs was modified, through requiring the constraints to be satisfied, by using the constrained least-squares procedure discussed earlier. The values of the standard deviation (STD), see eq. [6], for the resulting distributions are 2.68, 0.90, and 2.19, respectively. The STDs for all three DOSDs compare favorably with those for many other DOSDs constructed using the methods employed here.

The constraints used to construct the DOSDs involve integrals over the DOSDs, weighted by simple functions of E, and therefore are effective in a "global" sense over a range of photon energies (46). The constraints used are sensitive to different ranges of photon energies (7, 47, 49). For example, the energy region 5.685–50.0 eV yields ~98% of the molar refractivity constraints while ~100% of S_0 is due to the energy region 5.685–10^4 eV with ~92% arising from the 11.07–10^3 eV region. Therefore the constrained DOSDs are generally reliable in the sense of yielding accurate results for various related dipole properties, but not in the sense of providing accurate DOS values at specific local energies or over narrow energy regions (46). In the present context, while the smaller values of STD imply that less modification of the initial DOS data is required to satisfy the constraints, this cannot be used to discriminate between the input data since the STDs are all small. The difference between the STDs for DOSDA and DOSDB is essentially due to the energy region 5.685–7.563 eV, which contributes only ~1% of S_0 and ~10% of the molar refractivity constraints. The integrated oscillator strengths corresponding to all the input data, and to the constrained DOSDs A, B, and C, are compared in Table 1, which also contains the corresponding previously unpublished results obtained from the recommended DOSD (STD = 2.64) of Zeiss *et al.* (37).

For common energy regions above 11.07 eV, the integrated DOSs obtained directly from the presently reported high- and low-resolution data (estimated error ±5%) agree with each other, and are in essential agreement with those obtained from the data of Samson *et al.* (26) (estimated error ±3%), to within their combined experimental errors. Exceptions are the results obtained from the data of Samson *et al.* (26) for 11.07–12.40 eV and 124.4–150 eV, which are ~12% and ~15% higher and lower, respectively, than the present experimental work over the same energy ranges. For photon energies below 11.07 eV our high- and low-resolution integrated oscillator strengths also agree well with each other except apparently in the 7.563–8.590 eV region where the low-resolution data are larger by a factor of two. Of course in this narrow energy range the low-resolution data are not realistic, since the fine structure (Fig. 1*a*) in the discrete excitation region cannot be resolved. Thus local oscillator strength values in the discrete region of the low-resolution spectrum where sharp structures exist are likely to be severely modified by the "filling in of valleys" and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

"clipping of peaks" that occurs at low resolution. However, the *integrated* oscillator strengths over the entire discrete region, obtained from the two sets of measurements at high and low resolution, may be compared with each other. For example, over the energy range 5.685–13.08 eV the high- and low-resolution integrated oscillator strengths are 0.7125 and 0.7580, respectively; the corresponding results from 5.685–30.88 eV are 4.649 and 4.728.

The integrated oscillator strengths obtained from the constrained DOSDs generally agree to within the estimated experimental error with the corresponding integrated DOSs obtained from the experimental NH_3 data. The largest difference (~11%) occurs in the 5.685–7.563 eV region for DOSDs A and C. Also the raw mixture data, used to construct the constrained DOSDs for most energies greater than 200 eV, are only modified by a few percent by the constraint procedures. Furthermore, the raw mixture data predict results for the integrated oscillator strengths between 150 and 200 eV that differ by only ~6% from the values obtained from the constrained DOSDs. The integrated oscillator strengths for the constrained DOSDs A, B, and C agree very well over the whole energy domain with the largest disagreements being ~12% between DOSDs A and C and DOSDB for 5.685–7.563 eV and ~11% and 15% between DOSDs A and B and DOSDC for 11.07–12.40 eV and 124.4–150 eV, respectively. The oscillator strength input used to construct the adopted DOSD of Zeiss *et al.* (37) differs significantly from that used to obtain the constrained DOSDs A, B, and C for the energy regions 5.685–150 eV and 400–425 eV and this results in the differences that occur between the relevant integrated oscillator strengths in Table 1.

The photoabsorption cross sections reported by Akimov *et al.* (68) in the K-edge region exhibit a structure with four peaks occurring at photon energies of 400.9, 402.4, 403.6, and 404.5 eV and the cross sections at these energies are 1.398, 4.025, 1.525, and 1.751 Mb (10^{-18} cm^2), respectively. The use of the mixture rule, which was based on atomic nitrogen data at high energies, in this energy region yields a single absorption edge at E = 401.5 eV (i.e., the K-edge of N) with a cross section of 0.7670 Mb; the K-edge of N is very close to the average (401.6 eV) of the energies associated with the two most significant absorption peaks in the molecular K-edge measurements. The mixture rule absorption maximum is about five times smaller than the highest molecular K-edge maximum (68). For the energy region 400–425 eV, around the K-edge, the integrated DOSs for the mixture rule data and the data reported by Akimov *et al.* (68) are 1.543(−1) and 2.610(−1), respectively. However, at 400 eV, and for $E \geq 420$ eV, the mixture rule and molecular DOSs agree to within 10 and 20% respectively; the estimated experimental error in the molecular cross section of Akimov *et al.* (68) is about 15%.

The disagreement between the mixture rule and the ammonia experimental data at, and close to, the K-edge reflects the very different photoabsorption effects occurring in atomic nitrogen and NH_3 at these photon energies. An analogous effect has also been discussed by Kumar and Meath (49) for the L_1 absorption of HCl (see also Eberhardt *et al.* (69) and Yates *et al.* (9)). In general, mixture rules, which are based on additivity principles (5–8), work reasonably well for photon energies greater than about 60 eV and become more reliable for high photon energies, except near photoabsorption edges where significant deviations from additivity can occur due to specific molecular effects; examples can be taken from Table 1 and refs. 38 and 45–50.

The averaged oscillator strength results obtained from constrained DOSDA, calculated for each energy block in Table 1, are compared with the initial high- and low-resolution valence-shell oscillator strengths in a global perspective over the entire spectral range in Fig. 2. Figure 3 provides an alternative representation of the integrated DOSDA (Table 1) on a linear scale in the region below 200 eV. These figures show that the *averaged* constrained DOSD data provide an effective representation of the experimental data from 5.685 to 200 eV.

3.3. *Dipole properties for ammonia*

The results for the S_k, $-12 \leq k \leq 2$, and the L_k and I_k, for $-2 \leq k \leq 2$, evaluated by using the constrained DOSDs A and B, and the initial DOSDA, are compared with the results of Zeiss *et al.* (37) in Table 2. The results for the constrained DOSDC are not included in the table since they differ insignificantly from those of constrained DOSDA and DOSDB. The dipole properties obtained from the constrained DOSDs agree very well with each other and certainly to well within the estimated errors in the present results for the dipole properties (these are discussed later in this section). Nominally we choose the results for the dipole properties obtained from constrained DOSDA as recommended values since they are derived using spectroscopically more reliable oscillator strength input data, especially in the low-photon-energy region of the NH_3 photoabsorption spectrum. The results for the molar refractivity of NH_3 evaluated using constrained DOSDA are compared with experiment (54–56) in Table 3 as a function of wavelength; analogous results were not obtained in ref. 37. It is clear that the calculated results for R_λ are in excellent agreement with experiment with the maximum discrepancy being only ~0.07%. The dipole property S_{-2} is related to the static dipole polarizability, which in turn is proportional to R_∞. Our recommended result of S_{-2} = 14.56 can be compared with values obtained from refractivity measurements (70), 14.57, and from dielectric constant measurements (71, 72), 14.71 and 14.2.

The results for the dipole properties (Table 2) evaluated using the initial (unmodified) DOSDA, leading to our constrained DOSDA for NH_3, agree reasonably well with the recommended properties, which indicates the high quality of the input DOSs. The effect of applying the constraint procedure is only 0.3% for S_2, ~1% for S_1, ~2% for S_0, and increases as k decreases, to ~3.5% for S_{-1}, ~4.5% for S_{-2}, and ~9.5% for S_{-12}. For the L_k the differences are ≤1% for $k \geq 0$ and ~7% for $k = -1$ and -2. Berkowitz (73) analyzed the absolute photoabsorption data available before 1979 for NH_3 and used atomic additivity (Henke *et al.* (74)) to extend the molecular data for $E \geq 62$ eV. The dipole sums so obtained are S_0 = 9.38, S_{-1} = 8.70, and S_{-2} = 14.04, which are ~6.2, 6.6, and 3.6% lower than our recommended values. Samson *et al.* (26) obtained S_0 = 9.78 by combining their DOS data from 11 to 150 eV with that used by Berkowitz below 11 eV and above 150 eV.

Our recommended results for the dipole properties of NH_3 (Table 2) generally agree with the results of Zeiss *et al.* (37) to within their estimated errors; this is partly due to the use of the same constraints in the construction of the corre-

For personal use only.

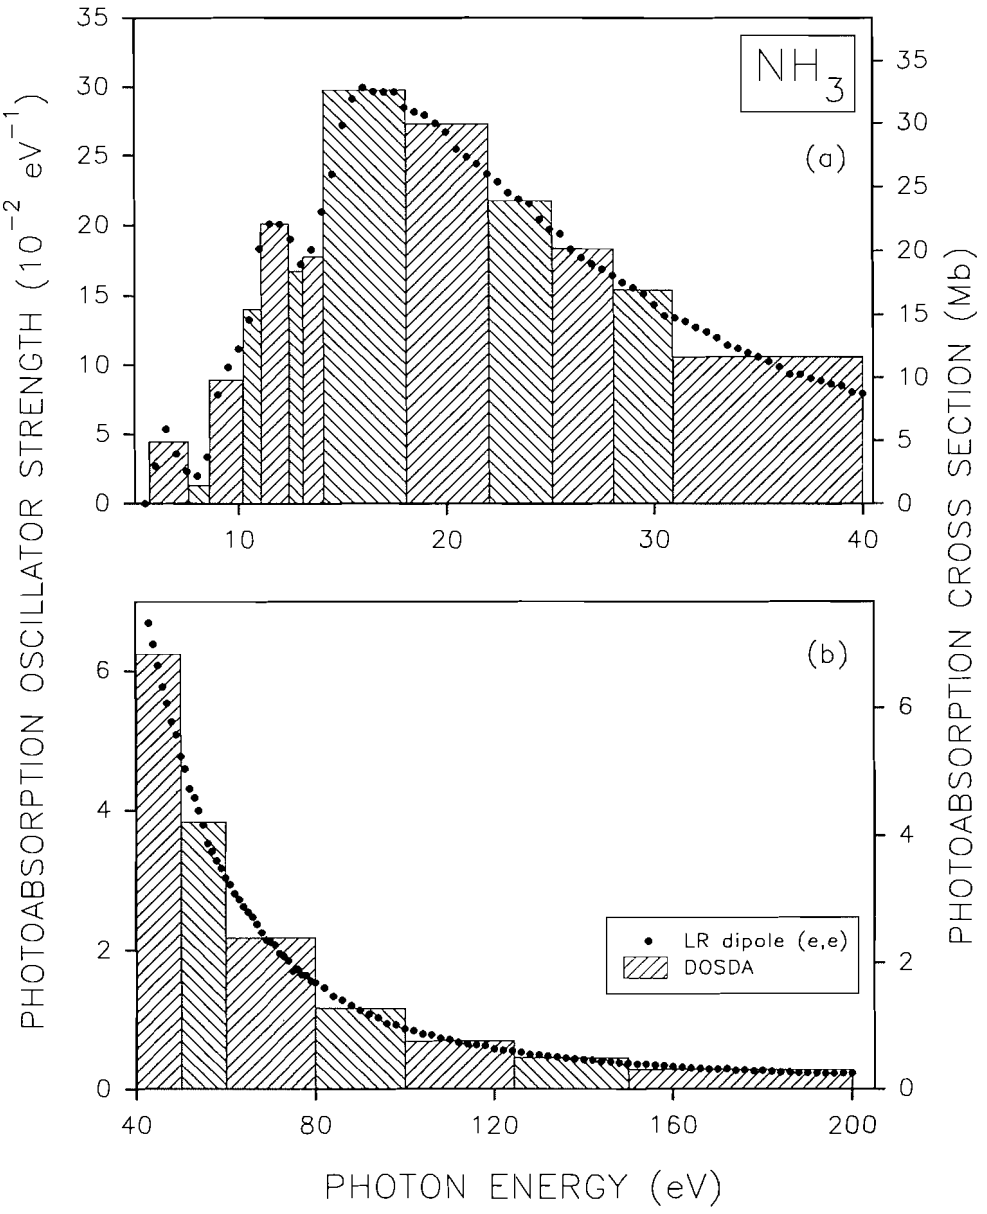

FIG. 3. Absolute experimental low-resolution (~1 eV fwhm) oscillator strengths (filled circles) and constrained DOSD A results (hatched blocks): (*a*) 5.5–40 eV; (*b*) 40–200 eV. Each integrated oscillator strength value (Table 1) is represented by a hatched block with a base that spans the energy range over which the value was determined and with an area equal to the integrated oscillator strength value.

sponding DOSDs. For the S_k the discrepancies are ~2.3% for $k = 1$, ≤0.5% for $k = 2$ and $-12 \leq k \leq 0$; for I_k they are ≤2% for all k. Error estimates were not given for the L_k in ref. 37; the differences in the two sets of values are ≤1% for $k = 2$, -1, -2, and ~2.5% for $k = 1$ and 0, respectively.

There are a number of *ab initio* calculations available for the electronic static dipole polarizability, $\alpha(\lambda = \infty) = a_0^3 S_{-2}$, of NH_3. A coupled Hartree–Fock calculation (75), using an extended complete neglect of differential overlap (CNDO) basis set, yielded $S_{-2} = 15.39$ while a value of $S_{-2} = 13.43$ was obtained (76) using an CNDO/2-FPP (finite perturbation plus polarization) approach. There are also *ab initio* calculations at the SCF level and these correspond to Hartree–Fock, $S_{-2} = 12.71$ (77), coupled Hartree–Fock, $S_{-2} = 12.90$ (78) and 12.80 (79), time-dependent coupled Hartree–Fock, $S_{-2} = 12.95$ (80) and derivative Hartree–Fock, $S_{-2} = 12.83$ (81), treatments. These results do not include the small vibrational averaging effect and are much smaller than the present recommended result of $S_{-2} = 14.56$. Only the calculations of Werner and Meyer (82) include vibrational averaging effects. Their pseudo natural orbital configuration interaction and coupled electron pair approximation results are $S_{-2} = 14.55$ and 14.96, respectively; the former is in excellent agreement with the present recommended result, the latter is ~2.5% higher. Diercksen and Sadlej (10) have used fourth-order many-body perturbation theory to compute S_{-2} and their result, including the vibrational averaging correction (0.26) evaluated by Werner and Meyer (82), is 14.63. Correlation contributions to S_{-2} have also been considered by Maroulis (52) and by Wormer and Hettema (53) using many-body perturbation theory meth-

TABLE 2. The dipole sums S_k, logarithmic dipole sums L_k, and mean excitation energies I_k for NH_3 calculated from various DOSDs. The previously reported results of Zeiss *et al.* (37) are shown for comparison. The values obtained from the constrained DOSDA are recommended.

ods and these calculations yield values of 14.01 and 14.136, respectively.

Reinsch (65) has computed the dynamic polarizability $\alpha(\lambda)$, see eq. [4], of NH_3 for $\lambda = \infty$ and $2278.2 \leq \lambda \leq 9112.7$ Å, using a time-dependent Hartree–Fock approach and the basis set B of Warner and Meyer (82). The values obtained by Reinsch (65) for $\lambda = \infty$ and $\lambda = 9112.7$ Å are ~5% lower than the present results obtained using constrained DOSDA and the discrepancy increases to ~20% at $\lambda = 2278.2$ Å.

3.4. *The reliability of calculated dipole properties*

The uncertainties in our recommended values of the dipole properties of ammonia can be estimated by employing procedures discussed previously (37, 38, 49). The approach is to compare the adopted results with those derived from alternative DOSDs satisfying the same constraints. The uncertainty estimates thus obtained are less reliable for those properties that do not depend significantly on the spectral regions that dominate the constraints, namely, the properties corresponding to $k = 2$, and to a lesser extent $k = 1$ and $k < -4$. A detailed discussion of the photon energy dependence of the dipole properties can be found in refs. 7, 47, and 49. For $k \geq 1$, the uncertainties in the dipole properties are influenced by the uncertainties in the very high energy DOS data used in constructing the DOSD, which are generally a few percent.

Using the results for various alternate DOSDs constructed for NH_3 (this work, ref. 37, and footnote 5) we es-

For personal use only.

timate the uncertainties in the recommended results for the dipole properties to be ≤3% for S_2, S_1, L_2, L_1, and I_2, ≤1% for S_k, $0 \leq k \leq -5$, and for L_2, I_{-1}, and I_{-2}, ≤1–2% for S_k, $-6 \leq k \leq -10$, L_{-1} and I_1, and ~3–4% for S_{-12}. The uncertainty of ~3% in L_0, and hence in I_0, is relatively high because of a partial cancellation (49) between the positive and negative parts of L_0; for NH_3, L_0 ($E \leq E_H$) ~ −1.9 while $L_0(E \geq E_H) \sim 8.4$. The uncertainties in the recommended results for the dipole properties of NH_3 are also based on the assumption that the molar refractivities, used as constraints in the construction of the DOSDs, have experimental errors associated with accurate measurements, namely, a few tenths of a percent.

The application of the constrained DOSD method to NH_3 results in relatively little modification of the high- and low-resolution oscillator strength data of this work, or of the data of Samson *et al.* (26). These three measurements are in close agreement over most of their common energy regions. The high quality of the experimental DOSD data used to construct the ammonia DOSDs is further exemplified by the comparison, made earlier, of the dipole properties obtained from the initial DOSDA with those from the constrained DOSDA. Relative to many other applications of the constrained DOSD method, very little modification of the initial data is required to satisfy the constraints, and the differences between the two sets of dipole properties, see Table 2, are relatively small. The recommended dipole properties of this paper, as obtained from constrained DOSDA, show only small differences from the results of the original calculations of Zeiss *et al.* (37). However, the values obtained here are to be (nominally) preferred since they are based on newer, more reliable DOS input data, which span a much wider energy range than the data available to Zeiss *et al.* (37). On the other hand, the integrated oscillator strengths for DOSDA and constrained DOSDA are clearly preferred relative to those obtained from the recommended DOSD of ref. 37. The excellent agreement between our recommended dipole properties and those of ref. 37 is a good example of the usefulness of the constrained DOSD approach for evaluating molecular *properties*. Very similar properties are obtained from different sets of DOS input data provided that they are in agreement by ~10–20%. For example, the recommended DOSD of Zeiss *et al.* (37) was based on the mixture rule DOS data for photon energies above 33 eV, which are significantly different from the other input DOS data considered here for 30.88–100 eV.

The dimerization of triquinacene ($C_{10}H_{10}$) to dodecahedrane ($C_{20}H_{20}$) has been a goal of organic chemists for more than three decades. An attempted synthesis of dodecahedrane from triquinacene using high pressure and near-UV radiation was not successful, but both hydrocarbons survived the 15 GPa treatment. There is no evidence for a pressure-induced transition in either of the materials. The results of high-pressure Raman spectroscopic investigations to 20 GPa on triquinacene and dodecahedrane are reported. Liquid triquinacene crystallizes near 0.2 GPa at 295 K and the Raman peaks associated with the molecular modes sharpen strikingly. In the crystal the external mode peaks exhibit a large pressure dependence, as expected, but the surprising fact is that the C—H stretching modes behave likewise. In dodecahedrane a similar effect is observed for the C—H stretching modes, but no external mode peaks are observed. The Raman data on dodecahedrane are compared with earlier results and calculations, which support the I_h symmetry for the molecule and an fcc lattice for the crystal.

S. H. BERTZ, G. A. KOUROUKLIS, A. JAYARAMAN, G. LANNOYE et J. M. COOK. Can. J. Chem. **71**, 352 (1993).

La dimérisation du triquinacène ($C_{10}H_{10}$) en dodécaédrane ($C_{20}H_{20}$) a été un des objectifs des chimistes organiciens depuis plus de trois décennies. Un essai de synthèse du dodécaédrane à partir du triquinacène en faisant appel à une radiation du proche UV, à haute pression, n'a pas été couronné de succès; toutefois, les deux hydrocarbures ont survécu au traitement à 20 GPa. On n'a pas de données suggérant une transition induite par la pression de ces composés. On rapporte les résultats d'études par spectroscopie Raman à haute pression, allant jusqu'à 15 GPa, du triquinacène et du dodécaédrane. Le triquinacène liquide cristallise à 295 K, à 0,2 GPa, et les bandes Raman associées avec les modes moléculaires sont fortement affinées. Dans le cristal, comme on pouvait s'y attendre, les bandes du mode externe varient beaucoup en fonction de la pression; toutefois, il est surprenant de réaliser que les modes d'élongation C—H se comportent de la même manière. Dans le dodécaédrane, on observe un effet similaire pour les modes de vibration C—H; toutefois, on n'observe aucune bande du mode externe. On compare les données Raman relatives au dodécaédrane avec les résultats obtenus antérieurement ainsi qu'avec des calculs qui supportent la symétrie I_h pour la molécule et un réseau fcc pour le cristal.

Introduction

Triquinacene is a $C_{10}H_{10}$ hydrocarbon with C_{3v} symmetry, consisting of three multiply fused cyclopentene rings in a unique cup-shaped geometry (1). It is a liquid at room temperature but freezes to a clear crystalline solid at about 18°C. The crystal structure of triquinacene has been determined (2) to be in space group $R\bar{3}$ with six molecules per hexagonal unit cell (a = 7.272(5) Å and c = 23.557(13) Å). The molecules in the crystal are arranged in layers perpendicular to the c-axis, and contacts between molecules are top-to-top (convex faces) and bottom-to-bottom (concave faces) in alternate layers. The molecules are not juxtaposed; they are shifted in the plane perpendicular to the c-axis.

Our interest in triquinacene was stimulated by the expectation that application of high pressure on a triquinacene crystal might lead to a direct synthesis of dodecahedrane by the dimerization of bottom-to-bottom pairs of molecules. For this reaction to take place the two molecules have to move a small amount for proper overlap, and the six double bonds have to open and fuse into six new single bonds (Scheme 1). In fact, attempts to synthesize dodecahedrane by application of 5 GPa (1 GPa = 10 kbar) pressure on a *para*-triquinacenophane by Roberts, Srivastava, and le Noble (3) were unsuccessful. However, we thought we could use much higher pressures with the diamond cell and also use photochemistry, since the concerted 12-electron π-bond rearrangement of two triquinacenes to dodecahedrane is photochemically allowed by the Woodward–Hoffmann rules (4).

Pressurization of triquinacene to nearly 20 GPa in a diamond cell and exposure to 248 and 308 nm ultraviolet radiation at 5 GPa failed to produce any detectable dodecahedrane. In the process we studied the effect of pressure on the Raman modes of both triquinacene and dodecahedrane in order to characterize these two unique molecules. We believe that our high-pressure Raman results are of interest to those in the areas of high-pressure Raman scattering and high-pressure organic chemistry.

Experimental procedures

High pressure was generated in a gasketed diamond anvil cell (5) and triquinacene liquid was introduced directly via syringe into the gasket hole, which also contained a ruby chip for pressure calibration (6). Dodecahedrane is a solid at room temperature and argon was employed as the pressure medium for high-pressure Raman

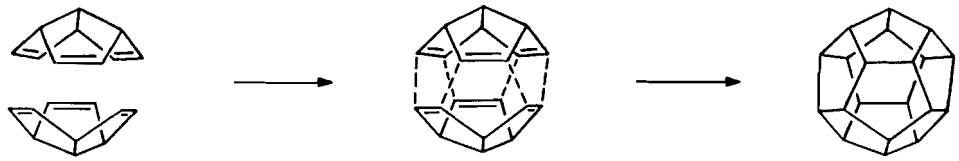

SCHEME 1

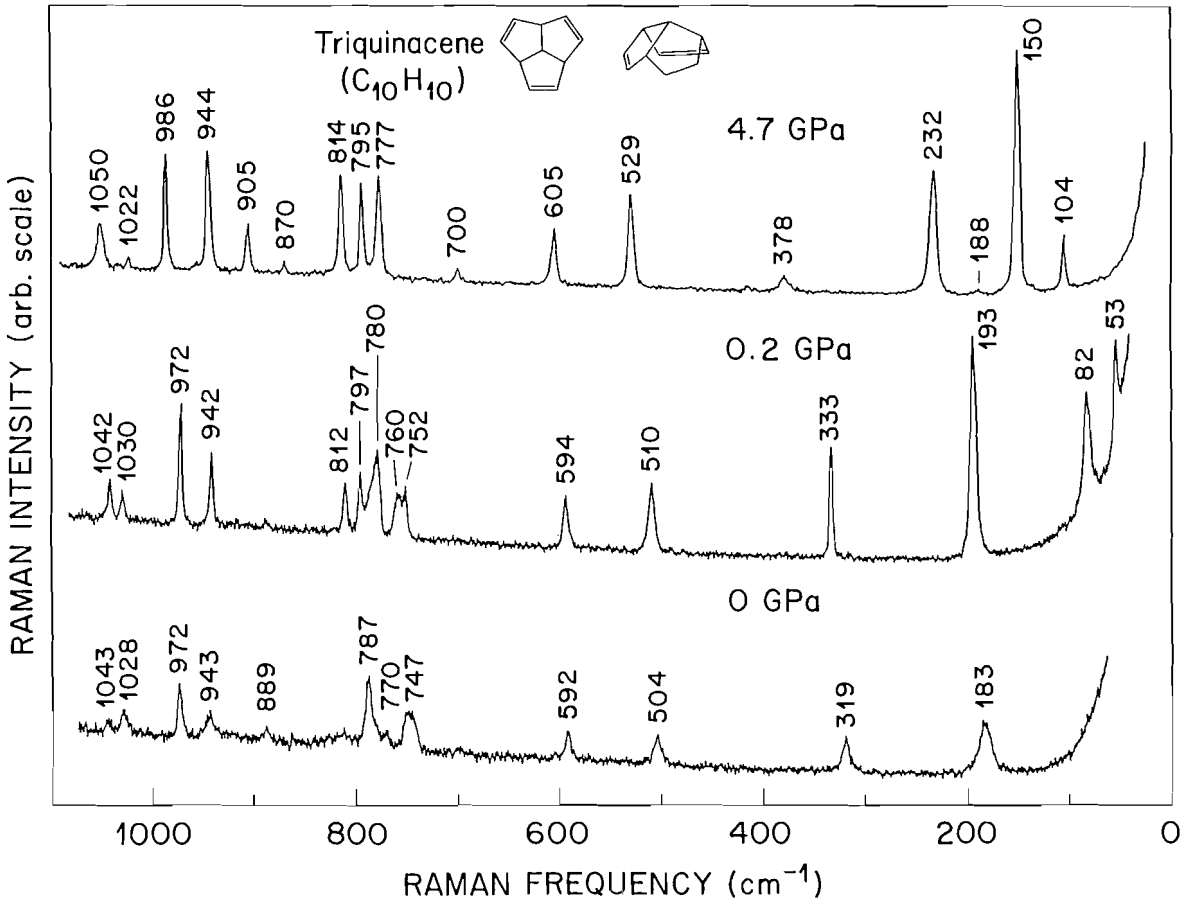

FIG. 1. Raman spectra of liquid (0 GPa) and solid triquinacene at 0.2 and 4.7 GPa in the 0–1100 cm^{-1} region. Raman peaks narrow and become intense in passing from the liquid to the crystalline state.

studies of this material. Raman spectra of samples in the diamond cell were recorded in the back-scattering geometry using a Spex double monochromator equipped with a conventional photon-counting system. For excitation the 488- or the 514.5-nm laser lines from an argon-ion laser were used at a power level of 40–60 mW. All the spectra were recorded at room temperature (~25°C). After each high-pressure experiment, the material in the cell was removed via syringe with ~2–4 μL of benzene and analyzed by GC–MS on a Finnigan 8230 high-resolution mass spectrometer interfaced with a Varian 3400 capillary GC, using on-column injection of the entire sample. A J&W Scientific DB-1 GC column (15 m, 0.32 mm i.d., 0.25 μm film) was used with the following temperature program: 50°C/3 min followed by a 30°C/min ramp to 320°C. Photolyses were carried out at 248 and 308 nm with KrF (Lumonics Hyperex 460) and XeCl (Lambda Physik EMG 201 MSC) lasers, respectively.

Results

Figures 1 and 2 show the Raman spectra of both liquid (0 GPa) and crystalline (0.2 and 4.7 GPa) triquinacene. The liquid sample crystallizes between 0.1 and 0.2 GPa pressure. By slow application of pressure the crystal growth can be controlled and watched through a microscope, and crystals with well-formed facets can be grown. It was also found that the hole in the gasket can be filled with a single crystal by manipulating the pressure on the sample while crystallization is in progress.

All the Raman peaks become much narrower for the triquinacene crystal and, further, two external modes of the molecule appear in the low-frequency end of the spectrum at 53 and 82 cm^{-1}. The observed Raman peaks and their intensities are presented in Table 1 for both the liquid and crystalline triquinacene (near 0.2 GPa). In general, the frequencies of the Raman peaks increase upon crystallization, with two exceptions: 1121 → 1113 cm^{-1} and 1280 → 1270 cm^{-1}. The highest frequency Raman peak of the liquid at 3054 cm^{-1} is quite broad, but in the crystal it becomes a sharp double peak with frequencies of 3063 and 3050 cm^{-1}. These peaks are assigned to vinylic and aliphatic C—H stretching, respectively.

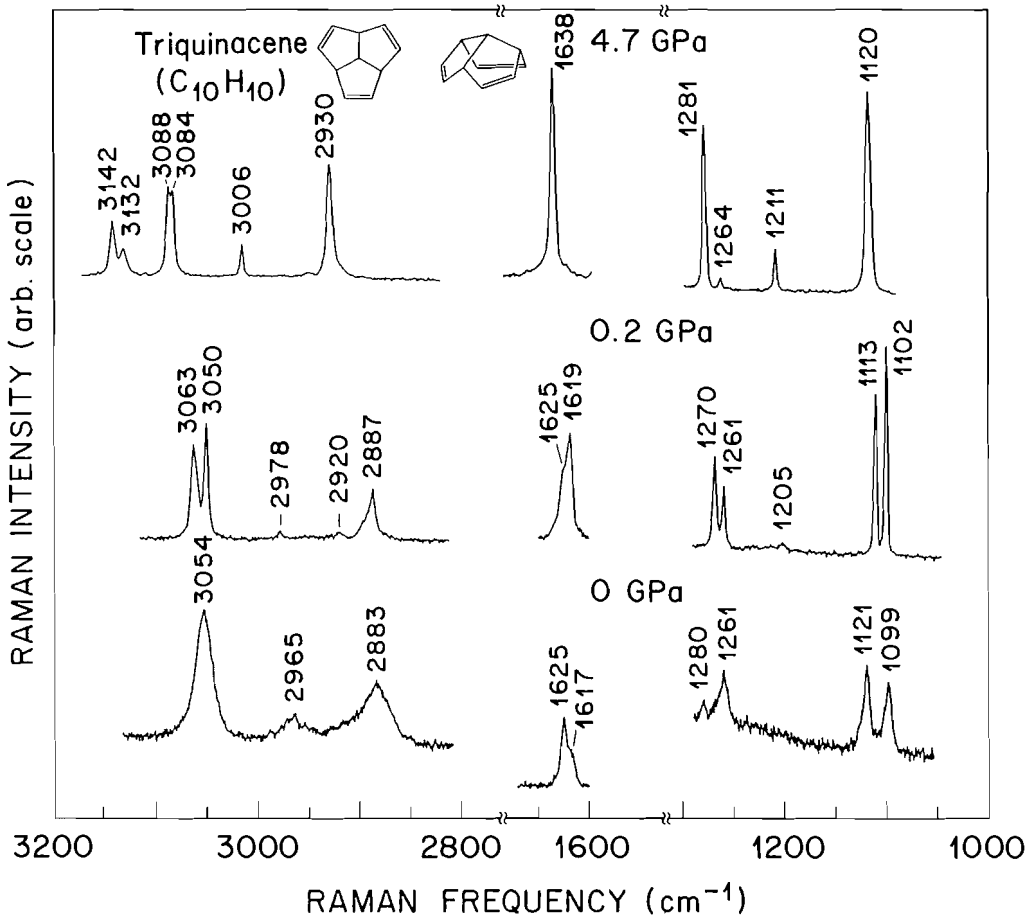

FIG. 2. Raman spectra of liquid (0 GPa) and solid triquinacene at 0.2 and 4.7 GPa in the 1000–3200 cm^{-1} region. Note the narrowing of the Raman peaks and the intensity changes upon crystallization. Some peaks show splittings.

The pressure dependence of the Raman modes is presented in Figs. 3 and 4. With increasing pressure the frequencies of almost all the Raman peaks of the crystal increase. The peak at 3063 cm^{-1} (see Fig. 2, 0.2 GPa spectrum) shifts anomalously and splits (compare the 0.2 and 4.7 GPa spectra in Fig. 2). The 3050 cm^{-1} peak also splits. At pressures higher than 6 GPa the Raman peaks are broadened, presumably due to nonhydrostatic pressure distribution.

The crystalline sample of dodecahedrane was strongly luminescent; however, we were able to record several Raman peaks over the luminescence background with the 514.5-nm laser line excitation. The observed peaks are listed in Table 2 along with the previously reported Raman lines (7). The pressure dependence of the modes is shown in Fig. 5. The strongest and sharpest peak in the Raman spectrum of dodecahedrane is at 679 cm^{-1} at ambient pressure. We assign this peak to a "breathing" mode of the molecule.

Discussion

The synthesis of dodecahedrane is a classic problem in organic chemistry. The successful synthesis (8*a*) in 23 steps by Paquette *et al.* in 1982 has been acclaimed as a great achievement.[4] Our expectation that pressure (up to 17 GPa) with or without photochemistry (248 and 308 nm, 5 GPa) could lead to a direct synthesis of dodecahedrane from triquinacene (1*a*, 1*b*, 9) was not realized.[5] Triquinacene has a negligible extinction coefficient beyond 230 nm (1*a*); nevertheless, we felt photolysis with the high photon flux of eximer lasers might result in a measurable amount of product. The diamonds we used did not transmit light at 222 nm (KrCl laser).

Our high-pressure Raman data on both triquinacene and dodecahedrane reveal some interesting features. We have not been able to find any published account of the Raman spectrum of triquinacene; consequently, this study appears to be the first. We will not present a detailed analysis of the spectra from the point of view of symmetry and the possible vibrational modes of the molecule, as this would be a complicated task. Rather, we identify the group frequencies and comment upon their behavior.

Firstly, the Raman peaks in the liquid spectra of triquinacene are broad, and all of them become strikingly narrower upon crystallization. In the liquid the molecules can have subtle conformational differences. Such a state can give rise to chemical environments that differ from one molecule to another, resulting in a spread of force constants and a corresponding spread in the frequencies of the stretching and

[4]For another successful route see ref. 8*b*.

[5]Small amounts of several triquinacene dimers were observed by GC–MS at retention times less than that of authentic dodecahedrane on a boiling point column.

TABLE 1. Triquinacene Raman frequencies

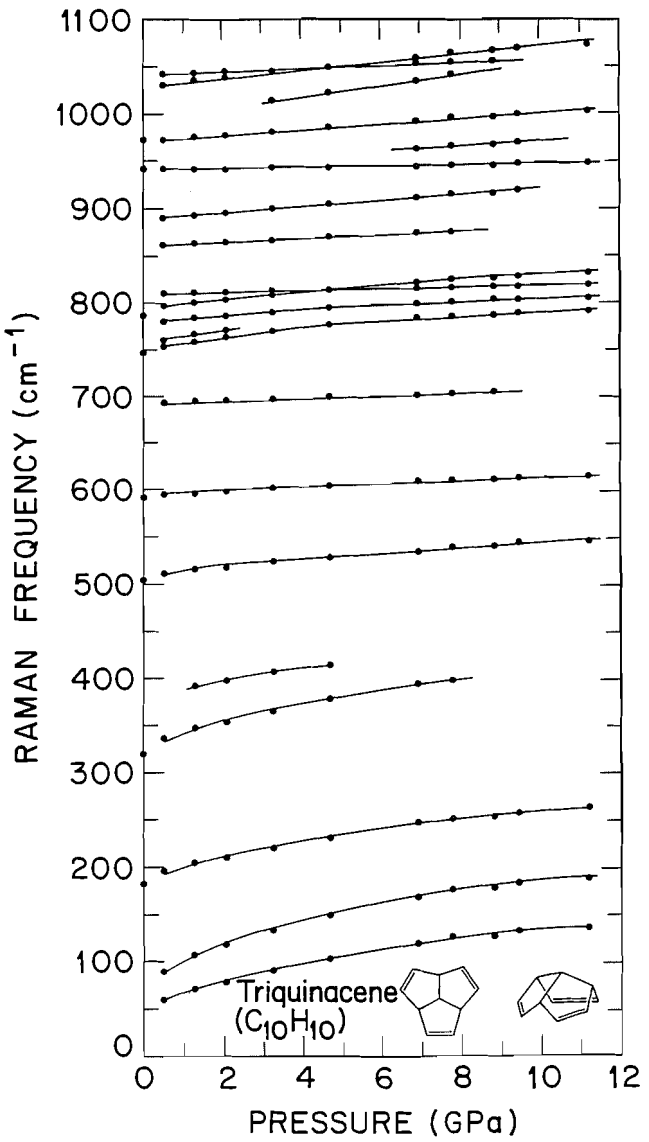

FIG. 3. Pressure dependence of the Raman peaks of triquinacene (see also Fig. 4).

bending modes of the molecule. In the crystal, only a small number of conformations — sometimes just one — are possible, leading to narrower Raman frequencies.

We have indicated in Table 1 the types of stretching modes that can be expected for triquinacene, and many bending modes are evidently possible. The two strong low-frequency peaks at 53 and 82 cm^{-1} are the lattice modes and, as expected of an organic system, they show a strong pressure dependence. There are two mode crossing situations involving the 797 and 812 cm^{-1} modes and the 1030 and 1042 cm^{-1} modes. No phase transition is indicated in our studies up to 11 GPa. A surprising result is that the two high-frequency C—H stretching modes at 3050 and 3063 cm^{-1} exhibit a large pressure dependence. Usually these are relatively insensitive to pressure in an organic crystal.

Dodecahedrane has been described as a beautiful molecule with I_h symmetry (10). It is a highly stable hydrocarbon (8). In Table 2 we have compared our Raman data with Raman peaks reported in an earlier study (8*a*) as well as with the theoretically calculated frequencies (10). In our studies up to 10 GPa there is no evidence for any phase transition and, surprisingly, the high-frequency vibrations (2988 and 2962 cm^{-1}) show a large increase in frequency with pressure. These are assigned to the C—H stretching and bending modes, respectively. There were doubts whether dodecahedrane would form a crystalline lattice; however, a recent X-ray diffraction study has shown that it does crystallize and that the unit cell is face-centered cubic (*FM* 3) (11). For an fcc lattice no Raman-active lattice mode is expected.

Summary and conclusions

We were not successful in synthesizing dodecahedrane from triquinacene by application of pressures up to 17 GPa. Also, exposure to near-UV radiation while the sample was under pressure was ineffective. We find a remarkable narrowing of all the Raman peaks of triquinacene in going from the liquid to the crystalline state. The large changes in the C—H frequencies with pressure in both triquinacene and dodecahedrane is a surprising result. The dodecahedrane molecule is believed to possess I_h symmetry and the crystal the fcc arrangement. The Raman peaks are consistent with these features.

JUAN M. FERNÁNDEZ-G., RAÚL G. ENRÍQUEZ, AMALIA TOBÓN-CERVANTES, MARGARITA I. BERNAL-URUCHURTU, RENÉ VILLENA-I., WILLIAM F. REYNOLDS, and JI-PING YANG. **71**, 358 (1993).

The crystal structures of *N*,*N*′-di(2-acetylcyclohexenyl)ethylenediamine (L_1) and its copper(II) complex, which crystallizes with one solvent molecule of chloroform ($Cu(L_1\text{-}2H) \cdot CHCl_3$), were determined. Crystallographic details are as follows: L_1 is monoclinic, space group $P2_1/c$, with a = 8.280(2), b = 11.692(2), and c = 9.355(2) Å, β = 114.10(2)°, V = 826.7(3) Å^3, Z = 2; ρ_c = 1.22 g cm^{-3}, μ(Cu Kα) = 5.93 cm^{-1}, with the final residual indices of R = 0.046 and R_w = 0.070 for 991 unique reflections. $Cu(L_1\text{-}2H) \cdot CHCl_3$ is triclinic, space group $P\bar{1}$, with a = 11.121(3), b = 11.713(3), and c = 8.974(2) Å, α = 99.35(2)°, β = 110.83(2)°, γ = 82.33(2)°, V = 1074(1) Å^3, Z = 2; ρ_c = 1.50 g cm^{-3}, μ(Cu Kα) = 50.74 cm^{-1}, with the final residual indices of R = 0.048 and R_w = 0.077 for 2369 unique reflections. The X-ray diffraction study shows that in the crystal state the ligand L_1 is in the methylketone–cyclohexanonenamine isomeric form. For the copper complex $Cu(L_1\text{-}2H) \cdot CHCl_3$, the geometry around the metal atom is distorted square planar, and the angle between the chelate ring planes in the complex is 15.1°. An NMR study shows that L_1 in solution has the same structure as that observed in the solid state by X-ray diffraction.

JUAN M. FERNÁNDEZ-G., RAÚL G. ENRÍQUEZ, AMALIA TOBÓN-CERVANTES, MARGARITA I. BERNAL-URUCHURTU, RENÉ VILLENA-I., WILLIAM F. REYNOLDS et JI-PING YANG. **71**, 358 (1993).

On a déterminé les structures cristallines de la *N*,*N*-di(2-acétylcyclohexényl)éthylènediamine (L_1) et de son complexe avec le cuivre(II) qui cristallisent avec une molécule de solvant (chloroforme) ($Cu(L_1\text{-}2H) \cdot CHCl_3$). Les détails cristallographiques sont les suivants : L_1 est monoclinique, groupe d'espace $P2_1/c$, avec a = 8,280(2), b = 11,692(2) et c = 9,355(2) Å, β = 114,10(2)°, V = 826,7(3) Å^3, Z = 2; ρ_c = 1.22 g cm^{-3}, μ(Cu K$_\alpha$) = 5,93 cm^{-1}, R = 0,046 et R_w = 0,070 pour 991 réflexions uniques alors que $Cu(L_1\text{-}2H) \cdot CHCl_3$ est triclinique, groupe d'espace $P\bar{1}$, avec a = 11,121(3), b = 11,713(3) et c = 8,974(2) Å, α = 99,35(2)°, β = 110,83(2)°, γ = 82,33(2)°, V = 1074(1) Å^3, Z = 2; ρ_c = 1,50 g cm^{-3}, μ(Cu K$_\alpha$) = 50,74 cm^{-1}, R = 0,048 et R_w = 0,077 pour 2369 réflexions uniques. L'étude de diffraction des rayons-X montre que, à l'état cristallin, le ligand L_1 est dans la forme isomère méthylcétone–cyclohexanoneamine. Pour le complexe cuivrique $Cu(L_1\text{-}2H) \cdot CHCl_3$, la géométrie autour de l'atome métallique est plan carré déformé et l'angle entre les plans des cycles du chélate est égal à 15,1°. Une étude par RMN montre que, en solution, le ligand L_1 possède la même structure que celle observée à l'état solide par diffraction des rayons X.

[Traduit par la rédaction]

Introduction

With the aim of obtaining a tricyclic compound derived from "cyclam" (1,4,8,11-tetrazaacyclotetradecane), in which the 6–7 and 12–13 positions are shared with cyclohexane rings and having a methyl radical on the 5,14 positions, we prepared the Schiff base *N*,*N*′-di(2-acetylcyclohexenyl)-ethylenediamine (L_1) and its corresponding copper(II) complex ($Cu(L_1\text{-}2H)$), as possible intermediates for that macrocycle. Both the ligand and its copper complex were already reported by Moss and Robinson in 1973 (1). They proposed that the condensation site between ethylenediamine and the β-diketone occurred at the side-chain carbonyl group of the cyclohexane ring (Fig. 1). In agreement with this consideration, it has been accepted that polyamines condense very readily at the carbonyl carbon of an acetyl group whether it be a diketone or a triketone (2). However, a careful inspection of the mass spectrum of L_1 suggested to us that its structure might be wrongly assigned because of the presence of a fragment ion of m/e 43 with relative intensity of 42%, indicating that a methyl ketone group might be present in the ligand. This observation prompted us to establish unambiguously the structure of L_1 by an X-ray diffraction single crystal determination.

In this paper, we describe the crystal and molecular structures of the Schiff base ligand L_1 and its corresponding copper(II) complex $Cu(L_1\text{-}2H) \cdot CHCl_3$, in order to elucidate the conformation and structure of this ligand and to examine the conformational differences between it and its copper complex. Finally, ^{1}H and ^{13}C nmr analyses were also carried out to make an unambiguous assignment of signals and to confirm that the solution and crystal structures of the ligand were identical.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected; 2-acetylcyclohexanone, ethylenediamine, and copper acetate dihydrate were from Aldrich. The ir spectra were recorded on a Perkin–Elmer model 203-B spectrometer. The ^{1}H and ^{13}C nmr spectra and COSY, APT, HETCOR, FLOCK spectra were obtained on a Varian XL-400 spectrometer using $CDCl_3$ or a 1:1 mixture of $CDCl_3$ and C_6D_6, and TMS as internal standard. spectra were obtained on a Hewlett–Packard instrument model 5985, operating at an ionizing potential of 70 eV.

The ligand was prepared as previously described (1) as very pale yellow crystals from hexane–dichloromethane, mp 139–141°C (lit. (1) mp 142–142.5°C).

The complex was obtained as follows: to a stirred solution of 0.304 g (1 mmol) of the Schiff base in dry methanol (100 mL) was added a solution of 2.5 g (30.48 mmol) of sodium acetate in water (25 mL) followed by 0.200 g (1 mmol) of copper(II) acetate monohydrate in water (25 mL). The resulting solution was stirred for 15 min after which time deep red–purple crystals formed, mp 197–199°C (lit. (1) mp 202–204°C).

The ir spectra were in agreement with those reported by Moss and Robinson; the mass spectrum of L_1 showed the following fragments: m/e (relative intensity) 304(13) M^+, 165(17), 152(100), 138(24), 110(10), 69 (5), 43(42). The mass spectrum of $Cu(L_1\text{-}2H)$ showed the molecular ion with the characteristic isotopic contribution of the copper atom: 367(25.6) [M^+ + 2], 365(56) M^+, 216(38.5), 214(100), 150(72), 138(10), 136 (5), 43(37).

Single crystals of L_1 were grown by slow evaporation of an ethyl acetate – hexane mixture while those of $Cu(L_1\text{-}2H)$ were grown by diffusion of ethyl acetate into a chloroform solution. However, the shining dark-red crystals of the complex decompose in the solid state to an opaque solid over the course of 3 h after removal from solution, probably due to loss of the crystallization solvent. Consequently, to avoid decomposition, all the faces of freshly cropped suitable crystals were covered with epoxy resin.

The data for the two compounds were collected on a Nicolet R3m four-circle diffractometer with graphite monochromated CuKα radiation (λ = 1.54178 Å) using an ω-scan mode with variable scan rate from 4 to 30 deg/min and a scan width of 1.0°. Crystal data and additional data collection parameters are given in Table 1. Cell dimensions for L_1 and $Cu(L_1\text{-}2H) \cdot CHCl_3$ were determined by least squares from 25 reflections (11.7° < 2θ < 29.58° and 7.7° < 2θ < 26.55°, respectively). Corrections were applied for Lorentz and polarization effects. Data for $Cu(L_1\text{-}2H) \cdot CHCl_3$ were corrected for absorption using the Ψ scan method.

The structures were solved by direct methods and subsequent use of Fourier difference maps. They were refined by the full-matrix least-squares method using anisotropic thermal parameters for all non-hydrogen atoms. The H atoms of the CH_2 and CH_3 groups were allowed to ride on bonded C atoms with a fixed isotropic temperature factor, U = 0.06 Å^2. The H atoms bonded to N atoms were found from a difference Fourier map at an advanced stage of anisotropic refinement and their coordinates refined. For L_1, the function minimized was $\Sigma w|\Delta F|^2$ with a weighting scheme $w = [\sigma^2(F_o) + G(F_o)^2]^{-1}$, where σ is the esd, based on counting statistics, and G an adjustable variable, final G = 0.00633. The final R and R_w were 0.046 and 0.070 (where $R_w = \Sigma w^{1/2}||F_o| - |F_c||/\Sigma w^{1/2}(|F_o|)]$. For $Cu(L_1\text{-}2H) \cdot CHCl_3$, the function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with a weighting scheme $w = 1/\sigma^2(F)$ based on counting statistics, including a factor (p = 0.09) to downweight the intense reflexions. The final R and R_w were 0.048 and 0.077.

The largest peaks in the final difference map for L_1 and $Cu(L_1\text{-}2H) \cdot CHCl_3$ were 0.75 and 0.17 e/Å^3, respectively.

The atomic scattering factors were taken from International Tables for X-ray Crystallography (3). Solution and refinement of L_1 were carried out using SHELTXL (4) on a Nova 4S computer while $Cu(L_1\text{-}2H) \cdot CHCl_3$ was solved and refined on a Vax station ILI using the TEXSAN–TEXRAY structure analysis package (5).

Results and discussion

Final positional parameters for compounds L_1 and $Cu(L_1\text{-}2H) \cdot CHCl_3$ are given in Table 2, while Table 3 contains selected bond lengths and bond angles.[2] The molecular structures of the compounds, including atom-numbering schemes, are illustrated in Figs. 2 and 3, respectively.

The X-ray structure determination of L_1 (Fig. 2) shows unequivocally that the structure is the result of a nucleophilic attack on the carbonyl of the cyclohexanone ring, which eliminates the structure shown in Fig. 1. In the crystalline state, L_1 is composed of two $C_9H_{14}NO$ halves, which are related to each other by a crystallographic center of inversion as shown in Fig. 2. The ligand is found in the tautomeric enamine–ketone form with an N—H distance of 0.84(2) Å, which is similar to the values observed for other N—H bonds in related compounds (6, 7). The corresponding O · · · · H distance is 1.91(2) Å and the O · · · · H—N angle is 138.8°. Bond lengths in the molecule suggest an electronic delocalization in the N(1)—C(1)—C(2)—C(7)—O(1) bonds. The C(1)—N(1) distance (1.346(3) Å) is slightly longer but in the same range as the C—N distance observed in *N,N'*-ethylenebis(acetylacetoneimine) [en(acacH)$_2$] (7) (mean, 1.331(3) Å), the C(7)—O(1) bond length (1.258(3) Å) is similar to the value observed for the corresponding C=O bond (mean, 1.243(4) Å) in the same compound, and the C(1)—C(2) and C(2)—C(7) bonds have similar lengths (1.394(3) and 1.427(2) Å) to the corresponding C—C bonds in en(acacH)$_2$ (1.393(5) and 1.440(6) Å). In L_1 the torsion angles around the C(1)—N(1)—C(9)—C(9a), C(9)—C(9a), and C(9)—C(9a)—N(1a)—C(1a) bonds are −92.3, 180, and 92.3°, respectively.

The X-ray diffraction analysis of $Cu(L_1\text{-}2H) \cdot CHCl_3$ shows the copper to be four-coordinate and to be involved in a slightly distorted square planar structure. As expected, the ligand undergoes changes upon coordination similar to those found in similar complexes (7–10) and follows the same trend as that observed in the latter complexes, i.e., shortening of the C(1)—N(1) and C(2)—C(7) bonds and a lengthening of the C(7)—O(1) and C(1)—C(2) bonds (see Table 3), which is the result of a greater conjugation in the chelate rings of the metal complex. The chloroform molecules are not interacting directly with the metal atom, but the hydrogen atom of the chloroform does make a close approach, 2.380 and 2.477 Å, to the O(1a) and O(1b) atoms while the carbon atom of chloroform is, respectively, 3.235(6) and 3.294(5) Å from the same oxygen atoms. The angle between the two coordination chelate planes defined by O(1b)—Cu—N(1b) and O(1a)—Cu—N(1a) is 15.1°.

The solution structure of the ligand, L_1, and the ^1H and ^{13}C nmr spectral assignments were confirmed by a series of one-dimensional (^1H, ^{13}C, APT) and two-dimensional (HETCOR, FLOCK, and COSY) nmr experiments. The experiments were carried out in both $CDCl_3$ and a 1:1 mixture of $CDCl_3$ and C_6D_6. The latter solution was required because the two sets of allylic methylene proton signals overlapped in $CDCl_3$,

as did the other two ring-proton methylene signals (H:3 and H:4). Spectral assignments are summarized in Table 4. The key observation was provided by a FLOCK experiment that determines *n*-bond $^{13}C—^1H$ (n = 2 or 3) (11). In this experiment the methyl ^1H singlet (H-8) showed cross peaks with a carbonyl ^{13}C signal at δ 196 ppm and an olefinic carbon at δ 101 ppm. This confirms the proposed structure with the acetyl group unreacted. With the alternative structure reported by Moss and Robinson, one would expect methyl ^1H cross peaks to the two olefinic carbons but none to the carbonyl carbon.

As previously reported (1), the CH_2–CH_2 bridge appeared as a distorted triplet with approximately 2:1:2 peak intensities. This collapsed to a singlet when the broad peak at δ 11.55 ppm was irradiated. The presence of coupling to the N-H proton confirms that L_1 exists in solution as the N-H (enamine) tautomer rather than the alternative O-H (imine) tautomer (see Fig. 4). This was also observed in the solid state.

The unusual appearance of the methylene envelope can be attributed to virtual coupling. The HN—CH_2—CH_2—NH unit forms an AA′A″A‴XX′ spin system. Since the four methylene protons are strongly coupled, they appear to be coupled almost equally to both NH protons, even though the four-bond coupling is actually near zero.

Based on the X-ray diffraction data and the nmr data, there can be no doubt that L_1 has the structure **1** shown in Fig. 4. Because of the limited data reported in the earlier publication of Moss and Robinson (1), it is impossible to determine whether, as they claimed, they actually synthesized and isolated the isomer corresponding to the reaction of diami-

noethane with the acetyl group of 2-acetylcyclohexanone or whether they isolated L_1 but misassigned its structure. Their assignment was entirely based on mass spectral fragmentation patterns that, with the exception of the peak at m/e 43, corresponded closely to those we observed for L_1. We previously demonstrated that use of mass spectral fragmentation patterns can lead to errors in structural assignments (12). To better understand the reactivity of 2-ketocycloalkanones with diaminoalkanes, we are undertaking a more systematic investigation of this reaction.

The chemistry of 5β,6β-epoxy-4,4-dimethylcholest-1-en-3-one. Approaches to the synthesis of 1α,5α-cyclosteroids. Part II[1]

PARIS E. GEORGHIOU[2] AND YI REN
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada, A1B 3X7

Received September 24, 1992

PARIS E. GEORGHIOU and YI REN. Can. J. Chem. **71**, 364 (1993).

Epoxidation of 4,4-dimethylcholesta-1,5-dien-3-one (**9**) with MCPBA gives a mixture of the corresponding epimeric 5α,6α and 5β,6β epoxides. The major product is the 5β,6β epimer **6**, in contradiction to what has been reported by others. The unambiguous assignment of the structures of these epoxides is based upon NMR NOED experiments. The chemistry of the 5β,6β epoxide is described in the context of unsuccessful attempts at synthesizing the corresponding 1α,5α cyclosteroids. Reductive methods using lithium – liquid ammonia, lithium–ethylamine, or tri-*n*-butyl- or triphenyltin–AIBN gave products in which the α,β-unsaturated carbonyl system and the epoxide were reduced. When **6** was treated with BF_3·etherate a *B*-nor derivative **27** was formed, presumably via a pinacol-type rearrangement.

PARIS E. GEORGHIOU et YI REN. Can. J. Chem. **71**, 364 (1993).

L'époxydation de la 4,4-diméthylcholesta-1,5-dièn-3-one (**9**) par l'AMCPB conduit à un mélange des époxydes épimères correspondants 5α,6α et 5β,6β. Contrairement à ce qui a été rapporté par d'autres, le produit majeur est l'épimère 5β,6β (**6**). L'attribution non-ambiguë des structures de ces époxydes est basée sur des expériences de RMN «NOED». On décrit la chimie de l'époxyde 5β,6β dans le contexte d'essais infructueux de synthèse des 1α,5α cyclostéroïdes correspondants. Les réductions à l'aide de lithium – ammoniac liquide, de lithium–èthylamine ou des tri-*n*-butyl- ou triphényl-étain–AIBN conduisent à des produits dans lesquels le système carbonyle α,β-insaturé et l'èpoxyde sont réduits. Le traitement du produit **6** par du BF_3·ether conduit à la formaton du dérivé *B*-nor **27**, probablement par un réarrangement de type pinacolique.

[Traduit par la rédaction]

Introduction

The 1α,5α cyclocholesterols are relatively rare. Laing and Sykes (1, 2) reported the synthesis of 1α,5α-cyclocholest-2-ene (**1**), and 3β-acetoxy-1α,5α-cyclocholestan-6-one (**2**) (3). The synthesis of **2** could not, however, be duplicated (4). Christensen and Reusch (5) synthesized 1-hydroxy-1α,5α-cyclocholestan-7-one (**3**) via lithium – liquid ammonia reduction of cholest-5-ene-1,7-dione. More recently we succeeded in synthesizing 4,4-dimethyl-1α,5α-cyclocholestane-3,7-dione (**4**) via an intramolecular reductive coupling of the *bis*-α,β-unsaturated diketone **5** (6).

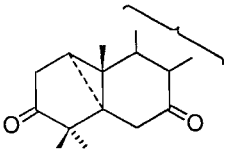
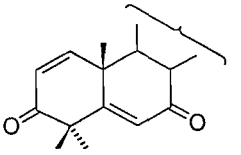
3



4



5

5β,6β-Epoxy-4,4-dimethylcholest-1-en-3-one (**6**) can be envisioned as a potential precursor for the synthesis of the cyclosteroid **7**. As depicted in Scheme 1, **7** could in principle be formed via an intramolecular ring opening of the epoxy group by the intermediate dianion **8** generated by metal – liquid ammonia reduction (7). We were unable to synthesize **7** but the results of our experiments on the chemistry of **6** form the subject of this paper.

Results and discussion

4,4-Dimethylcholesta-1,5-dien-3-one (8) (**9**) was prepared by benzeneselenenic anhydride (8) oxidation of 4,4-dimethylcholest-5-en-3-one (**10**). Reaction of **9** with

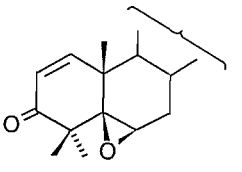
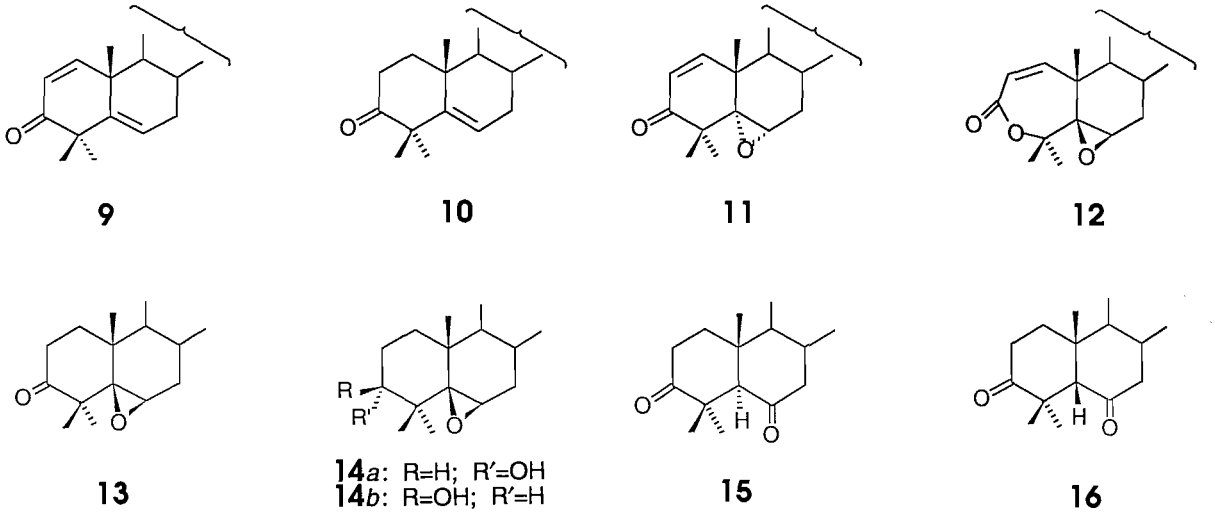
SCHEME 1

m-chloroperoxybenzoic acid (MCPBA) in refluxing dichloromethane solution for 4 h gave a mixture of the 5β,6β and 5α,6α epoxides, **6** and **11**, respectively, and a small amount (12%) of the epoxy-lactone **12**. The mixture comprised the major product **6** (71%) and the 5α,6α epoxide **11** (only 9%). The assignment of structures to the epimeric epoxides was initially based on the observations of Cross (9) and Halsall *et al.* (10) of the C-6 proton chemical shift values of other 5β,6β and 5α,6α epoxides. The major product had the lower field chemical shift value for the C-6 proton and was assigned structure **6**. Nuclear Overhauser effect difference (NOED) experiments on both epoxides were in agreement with this assignment. Separate, selective irradiation of both the α and β C-4 methyl groups of the 5α,6α epoxide at δ 0.93 and 1.36, respectively, each enhanced the C-6 proton signal at δ 3.10 (16% and 3%, respectively). By contrast, only when the α C-4 methyl group of the 5β,6β epoxide at δ 0.94 was irradiated was there any enhancement of the C-6 proton signal at δ 3.32 (20%). No corresponding enhancement was observed when the β C-4 methyl group at δ 1.33 on **6** was irradiated.



6

Brynjolffssen *et al.* (11) reported obtaining a 60% yield of **11** when they treated **9** with MCPBA in refluxing dichloromethane. The melting point and NMR data of what they presumed to be the 5α,6α epoxide were identical with our data for **6**. In addition to our NOE data, direct proof by X-ray crystallographic analysis was obtained. Although both **6** and **11** were crystalline, only crystals of **11** were suitable for X-ray crystallography. The structure obtained[3] confirmed our original assignment that **11** was indeed that 5α,6α epoxide and that the assignment of Brynjolffssen *et al.* was incorrect. Using their conditions **11** was obtained only as a minor product. The major product was different from the expected 5β,6β epoxide **6**. Spectral and mass data of this compound were consistent with it being the epoxy-lactone **12**. Compound **12** is most likely formed by a Baeyer–Villager oxidation of **6** since the MCPBA used is in excess.



9 **10** **11** **12**

13 **14***a*: R=H; R'=OH **14***b*: R=OH; R'=H **15** **16**

Epoxide **6** was reacted with lithium in liquid ammonia under several different conditions, each giving the same results. These were mixtures that could be separated by flash chromatography to afford 5β,β-epoxy-4,4-dimethylcholestan-3-one (**13**), and a mixture of the corresponding epimeric 3α and 3β alcohols **14***a* and **14***b*. Reaction of **6** with ytterbium in liquid ammonia (12) gave the same results as were found with lithium in liquid ammonia. Thus, although the α,β-unsaturated carbonyl system could be reduced, presumably via the dicarbanion **8**, cyclization to **7** via transannular opening of the epoxide did not occur.

The desired intramolecular cyclization can be envisioned as an example of a favoured 3-*exo-tet* or 5-*exo-tet* ring closure (13). It is possible, however, that cyclization did not occur because pyramidalization of the carbanion at C-1 was preferentially formed on the β-face as a result of interactions (14) with the σ-framework.

Reductions employing sodium or lithium in ethylamine can yield different results than when they are employed in liquid ammonia (15, 16). Hallsworth and Henbest (16) found that the course of reductive ring opening of 5β,6β-epoxycholestane could be altered when ethylamine was used with

[3]X-ray crystallographic analysis on **11** confirmed the assigned structure (P. E. Georghiou, Y. Ren, and J. N. Bridson, unpublished data).

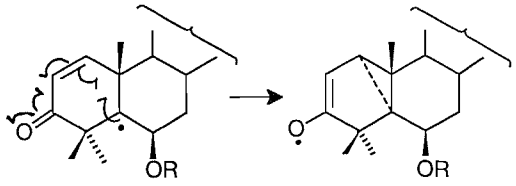
18

SCHEME 2

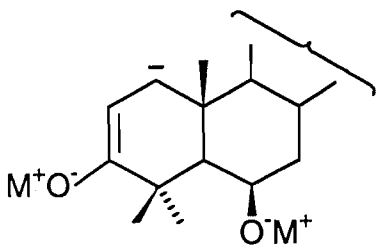


SCHEME 3

lithium. They proposed that the C-5 carbanion was formed directly by the reductive ring opening of the epoxide under these conditions.

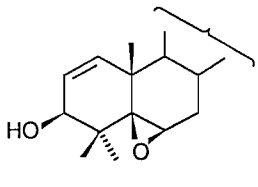
Epoxide **6** was therefore treated with lithium in ethylamine at 0°C. A more complex mixture was obtained than those from the corresponding lithium – liquid ammonia reductions. The mixture could be simplified considerably by oxidation with pyridinium chlorochromate (PCC) to afford only three compounds, none, however, being the desired cyclosteroid. The compounds identified were the C-5 epimeric 4,4-dimethylcholestane-3,6-diones (**15**, **16**) and 4,4-dimethylcholest-5-en-3-one (**10**). The 5α dione **15** was the major product (50%). The 5β dione **16** was obtained in 32% yield. Thus, both the α,β-unsaturated carbonyl system and the epoxide were reduced under these conditions.

The complex mixture that was initially formed resulted from the fact that a new stereogenic centre at C-3 is produced and two of the existing ones at C-5 and C-6 are modified during the reduction. PCC oxidation removed the two stereogenic centres at C-3 and C-6 by converting the epimeric alcohols into the corresponding ketones. That **10** was obtained indicated that an elimination of the epoxy oxygen had also occurred during this reaction. Hallsworth and Henbest (17) reported an analogous finding with 5β,6β-epoxycholesterol under similar conditions. In our case, reduction of the epoxide ring was observed but it is likely that the α,β-unsaturated ketone was reduced more rapidly, thereby precluding the intramolecular Michael addition of a C-5 carbanion. Carbanion formation at C-5 would not be inhibited as was presumed to have been the case with 5β,6β-epoxycholesterol (17) because the enolate oxyanion at C-3 of the intermediate **17** is sufficiently distant from C-5. However, it is recognized that the desired cyclization in this case would have required a type of ring closure that can be viewed as being both a disfavoured 5-*endo-trig* and a favoured 3-*exo-trig* type.

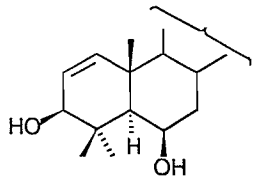


17

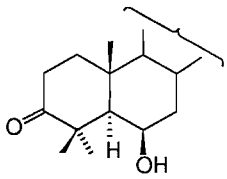
Triphenyltin hydride (TPTH) and tri-*n*-butyltin hydride (TBTH) reduce α,β-unsaturated ketones via a radical mechanism (18, 19). It was therefore of interest to determine whether a radical-induced intramolecular cyclization (20) could be effected with our system via a tin enolate radical **18** (see Scheme 2). When a dilute solution of **6** was treated with TPTH and azobisisobutyronitrile (AIBN), a mixture of four compounds was obtained. The major product surprisingly was the epoxide **19** (76%), followed by the keto-epoxide **13** (14%) and small amounts (3 and 4%, respectively) of the corresponding epoxide ring-opened products, the dihydroxy **20** and the hydroxy-ketone **21**. The fact that **20** and **21** were obtained, albeit in small amounts, indicated that the epoxide ring could be opened by TPTH/AIBN.



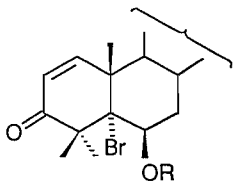
19



20



21



22 R = H
23 R = Ac

Since we were unable to effect transannular cyclization using reductive methods on the α,β-unsaturated ketone-epoxide **6**, we explored the potential for a more typical radical cyclization–coupling (21) route as depicted in Scheme 3. Reaction of **6** with HBr in acetic acid gave the bromohydrin **22**, its corresponding acetate **23**, and the 6α-bromo-5β-hydroxy bromohydrin **24**. Since the bromohydrins were unstable the crude bromohydrin mixture was isolated and, without purification, was treated with TBTH/AIBN in dilute refluxing benzene. The resulting product mixture consisted of three compounds whose spectral properties are consistent with the structures **21**, **25**, and **26**, and an unstable fourth compound that could not be characterized. The major product (48%) was identical with **21**, indicating that the bromine atom of the bromohydrin could indeed be removed by TPTH to afford a radical at C-5 but that it did not add internally to the α,β-unsaturated ketone at C-1—C-3. It is possible that the α,β-unsaturated ketone was reduced first. However, as **25** and **26** were also isolated, this could imply that radical formation occurred at C-5 from bromohydrin **21** and at C-6 from bromohydrin **24**, respectively, whilst the α,β-unsaturated ketone was still present. Cycli-

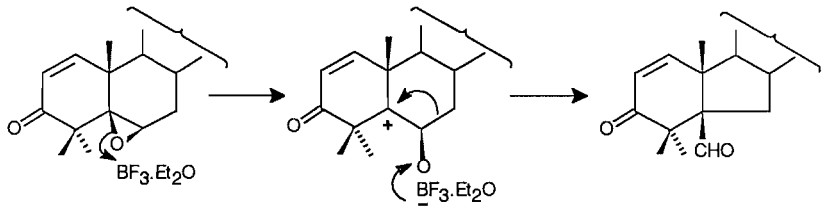
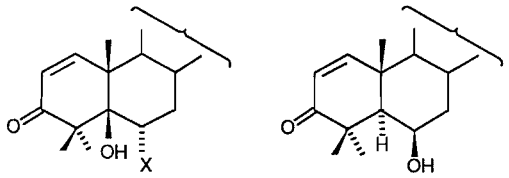


SCHEME 4

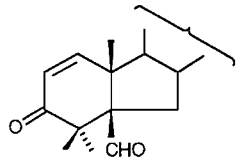
zation could apparently not be effected under these conditions either, for similar reasons to those proposed above for **17**. Compound **26** was presumably formed from **24**, which would have been formed as the minor product of the HBr-induced ring opening of **6**. Compound **26** was found to be inert to PCC oxidation, confirming the presence of a tertiary hydroxy group. It is interesting that when the 5β,6β epoxide group was present as in **6**, the major product of TPTH reduction was that in which the C-3 carbonyl group was reduced. Without the epoxide group present, however, normal reduction of the carbon–carbon double bond was preferred.

The reaction of **6** with BF_3·etherate was also examined during the course of our investigations. A mixture of several compounds was obtained, the major one (77%) being the *B*-nor-enone-5β aldehyde **27** presumably formed via a pinacol-type rearrangement. A similar *B*-nor keto-aldehyde was obtained by Halsall *et al.* (10) and Blunt *et al.* (23) with

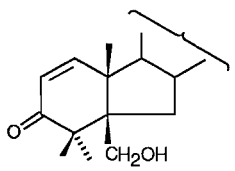


24 X=Br
26 X=H

25



27



28

5β,6β-epoxy-4,4-dimethylcholestan-3-one **13**. These authors, however, did not unambiguously assign the stereochemistry to the aldehyde at C-5.

Since the crystals of **27** that were obtained were not suitable for X-ray crystallography, NOED experiments on **27** were undertaken. Irradiation of the signal due to the aldehyde proton at δ 9.57 enhanced the signals due to both the C-19 methyl and the β C-4 methyl groups by 1%. This evidence ruled out the possibility of an α configuration for the aldehyde group since in this case only the 4α-methyl could be expected to be positively enhanced. However, since the C-19 and β C-4 methyl signals overlap and only a small NOED was observed, the aldehyde **27** was selectively reduced with $NaBH_4$ to the corresponding carbinol **28**. NOED experiments on **28** confirmed the structure assigned. Irradiation of the signal due to the methylene protons of the carbinol group at δ 3.71 enhanced the signals due to the C-19 methyl group at δ 1.21 and the β C-4 methyl group at δ 1.09 by 1.7 and 2.3%, respectively. A likely mechanism for the formation of **27** can be envisioned in Scheme 4, and is in agreement with the mechanism proposed by Blunt *et al.* (23).

In summary, we have shown that epoxidation of 4,4-dimethylcholesta-1,5-dien-3-one with MCPBA leads to the formation of 5β,6β epoxide **6** as the major product. This is in contrast to what was previously reported by others. We were unable to transform this epoxide into the corresponding 1α,5α cyclosteroid **7** using several alternative reductive methods. It is likely that the α,β-unsaturated carbonyl system undergoes reduction more rapidly than intramolecular cyclization occurs, or that the cyclization is reversible, favouring the uncyclized carbanion **8**, or radical **18**.

Experimental

Melting points (mp) were determined on a Fisher–Johns apparatus and are uncorrected. Infrared (IR) spectra were recorded on a Mattson Polaris FT instrument. Mass spectral (MS) data were from a V.G. Micromass 7070HS instrument. ^{1}H NMR spectra were recorded with a GE GN-300NB spectrometer at 300 MHz. ^{13}C NMR spectra were recorded with the same instrument at 75.47 MHz. The solvents used are noted in the experimental details. Proton nuclear Overhauser effect difference (NOED) spectra were obtained from zero-filled 32K data tables to which a 1–2 Hz exponential line-broadening function had been applied. A set of four "dummy" scans was employed to equilibrate the spins prior to data acquisition. No relaxation delay was applied between successive scans of a given frequency. Ultraviolet (UV) spectra were determined on a Unicam SP.800 ultraviolet spectrophotometer. Microanalyses were performed by the Canadian Microanalytical Service Ltd., Delta, B.C.

5β,6β-Epoxy-4,4-dimethylcholest-1-en-3-one (6) and 5α,6α-epoxy-4,4-dimethylcholest-1-en-3-one (11)

A solution of dienone **9** (8) (1.05 g, 2.55 mmol) in 20 mL CH_2Cl_2 was refluxed under argon. *m*-Chloroperoxybenzoic acid, 50–60% (865 mg, 2.76 mmol), in 20 mL CH_2Cl_2 was added dropwise over 0.5 h. The mixture was stirred at reflux for 4 h. The solution was extracted with ether (×4) and the combined organic layers were washed with 10% $NaHCO_3$ (×3) and saturated NaCl (×4), dried ($MgSO_4$), and concentrated. Chromatography (10% benzene in hexane over aluminium oxide, Grade III) yielded the lactone **12** (142 mg, 12%), 5β,6β epoxide **6** (776 mg, 71%), and 5α,6α epoxide **11** (99 mg, 9%). For **6**, mp 101–102°C; $\nu_{max}(CCl_4)/cm^{-1}$: 1687 (α,β-unsaturated ketone); δ_H (300 MHz; $CDCl_3$): 0.67(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.86(3H, d, J = 6.6 Hz, 27-Me), 0.90(3H, d, J = 6.5 Hz, 21-Me), 1.77–1.90(1H, m), 0.94(3H, s, 4α-Me), 1.27(3H, s, 19-Me), 1.33(3H, s, 4β-Me), 2.01(1H, dt, J = 3.4, 12.7 Hz), 2.14(1H, ddd, J = 2.2, 4.3, 14.9 Hz, 7-H), 3.32(1H, s, 6-H), 5.93(1H, d, J = 10.5 Hz, 2-H), 6.90(1H, d, J = 10.5 Hz, 1-H); *m/z*(%): 426(65, M^+), 398(25), 383(15), 356(10), 339(4), 295(5), 247(17), 161(19), 136(82), 107(58), 81(61), 43(100). Anal. calcd. for $C_{29}H_{46}O_2$: C 81.63; H, 10.87%; found C 81.79 H 10.44%. For α-epoxide **11**, mp 132.0–

135.0°C; $\nu_{max}(CCl_4)/cm^{-1}$: 1681(α,β-unsaturated ketone); δ_H(300 MHz; $CDCl_3$): 0.65(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.86(3H, d, J = 6.6 Hz, 27-Me), 0.90(3H, d, J = 6.6 Hz, 21-Me), 0.93(3H, s, 4α-Me), 1.31(3H, s, 19-Me), 1.36(3H, s, 4β-Me), 3.10(1H, d, J = 3.6 Hz, 6-H), 6.00(1H, d, J = 10.3 Hz, 2-H), 7.11(1H, d, J = 10.3 Hz, 1-H); m/z(%): 426(21, M^+), 411(9), 383(13), 365(4), 343(3), 300(3), 275(10), 247(15), 43(100). Anal. calcd. for $C_{29}H_{46}O_2$: C 81.63; H, 10.87%; found C 81.69 H 10.79%.

*5β,6β-Epoxy-4,4-dimethyl-4-oxa-*A*-homocholest-1-en-3-one lactone (**12**)*

A solution of dienone **9** (51 mg, 0.12 mmol) in 10 mL CH_2Cl_2 was refluxed under argon. *m*-Chloroperoxybenzoic acid, 50–60% (300 mg, ca. 0.96 mmol), in 10 mL CH_2Cl_2 was added dropwise over 0.5 h. The mixture was stirred at reflux for 12 h. The solution was extracted with ether (×4) and the combined organic layers were washed with 10% $NaHCO_3$ (×3) and saturated NaCl (×4), dried ($MgSO_4$), and concentrated. Chromatography (10% benzene in hexane over aluminium oxide) yielded the lactone **12** (27 mg, 48%), and a mixture containing 5α,6α epoxide **11** (6 mg, 12%). For lactone **12**, mp 177.5–178.5°C; $\nu_{max}(CCl_4)/cm^{-1}$: 1754 (ε-lactone); δ_H(300 MHz; $CDCl_3$): 0.64(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.86(3H, d, J = 6.6 Hz, 27-Me), 0.89(3H, d, J = 6.6 Hz, 21-Me), 1.19(3H, s, Me), 1.31(3H, s, Me), 1.40(3H, s, Me), 1.77–1.90(1H, m), 1.98(1H, dt, J = 3.4, 12.6 Hz), 2.13(1H, dt, J = 3.2, 14.0 Hz, 7-H), 3.20(1H, br d, J = 1.9 Hz, 6-H), 5.19(1H, d, J = 7.3 Hz, 2-H), 6.26(1H, d, J = 7.3 Hz, 1-H); m/z(%): 442(1, M^+), 427(3), 399(13), 371(10), 353(2), 329(3), 287(3), 262(7), 175(6), 153(25), 123(40), 43(100). Anal. calcd. for $C_{29}H_{46}O_3$: C 78.68; H, 10.47%; found C 78.24 H 10.09%.

*5β,6β-Epoxy-4,4-dimethylcholestan-3-one (**13**)*

Freshly condensed ammonia (30 mL, dried over sodium at −78°C) was allowed to distill into a stirring suspension of lithium (20 mg, 2.9 mmol) in anhydrous THF (5 mL) at −78°C and the stirring continued until the metal had dissolved. A solution of 5β,6β epoxide (**6**) (190 mg, 0.45 mmol) in anhydrous THF (5 mL) was added dropwise over 1 h and the solution stirred at −78°C for another 1 h. Sufficient NH_4Cl was added to discharge the blue colour and the ammonia was allowed to evaporate. Upon the addition of 30 mL of ether and 20 mL of water the aqueous layer was extracted with ether. The combined ether solutions were washed, dried, and evaporated as usual. Chromatography of the residue and gradient elution with hexane – ethyl acetate yielded 5β,6β-epoxy-4,4-dimethylcholestan-3-one (**13**) (124 mg, 65%) and a mixture of the corresponding epimeric 3α and 3β alcohols **14*a***, **14*b*** (48 mg, 25%). For compound **13**, mp 197.0–198.0°C (needles from hexane–methanol (lit. (10) mp 197–200°C); $\nu_{max}(CCl_4)/cm^{-1}$: 1716 (saturated ketone); δ_H(300 MHz; $CDCl_3$): 0.64(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.87(3H, d, J = 6.6 Hz, 27-Me), 0.87(3H, s, Me), 0.89(3H, s, Me), 0.90(3H, d, J = 6.4 Hz, 21-Me), 1.21(3H, s, Me), 1.78–1.90(1H, m), 1.98(1H, dt, J = 3.4, 12.5 Hz), 2.01–2.06(2H, m), 2.15(1H, dt, J = 3.2, 14.2 Hz, 7-H), 2.40–2.58(2H, m), 3.07(1H, s, 6-H); m/z(%): 428(32, M^+), 400(15), 385(10), 343(14), 330(9), 301(2), 273(4), 247(9), 137(100), 107(47), 81(50), 55(94).

*PCC oxidation of **14**a and **14**b*

The mixture of the epimeric 3α and 3β alcohols **14*a*** and **14*b*** (40 mg, 0.09 mmol) was suspended in anhydrous CH_2Cl_2 (10 mL) and pyridinium chlorochromate (41 mg, 0.19 mmol) was added in one portion to the stirred solution. After 2 h the reaction solution was put on the top of a short silica gel column and was washed by a sufficient amount of ether. Evaporation of the ether yielded 5β,6β-epoxy-4,4-dimethylcholestan-3-one (**13**) (34 mg, 84%).

*Hydrogenation of 5β,6β epoxide **6***

To a solution of 5β,6β epoxide **6** (51 mg, 0.12 mmol) in ethyl acetate (100 mL) was added Pd–C (5%, 15 mg) and the mixture stirred under a H_2 atmosphere (1 atm; (= 101.3 kPa)) for 2 h. The reaction solution was applied onto a silica gel column and eluted with sufficient ether. Evaporation of the ether gave 5β,6β-epoxy-4,4-dimethylcholestan-3-one (**13**) in quantitative yield.

*Reaction of **6** with lithium–ethylamine*

Lithium (108 mg, 15.5 mmol) was added to a solution of 5β,6β epoxide **6** (200 mg, 0.47 mmol) in ethylamine (anhydrous, 99%, 15 mL) with stirring at 0°C. The mixture was stirred at 0°C for 1.5 h and then moist ether was added to discharge the blue colour. After the addition of 30 mL of ether and 20 mL of water the aqueous layer was extracted with ether. The combined ether solutions were washed, dried, and evaporated as usual. Thin-layer chromatography (TLC) showed the residue to be a complex mixture that was difficult to separate. The crude residue was suspended in CH_2Cl_2 (10 mL) and PCC (700 mg, 3.25 mmol) and CH_3COONa (200 mg, 2.44 mmol) were added together in one portion to the stirred solution. After 2 h the reaction mixture was placed directly onto a short silica gel column and was eluted with ether. Evaporation of the ether yielded a mixture of three major products. Silica gel chromatography using a gradient solvent system of hexane – ethyl acetate gave 4,4-dimethylcholest-5-en-3-one (**10**) (21 mg, 11%), 4,4-dimethyl-5α-cholestane-3,6-dione (**15**) (100 mg, 50%), and 4,4-dimethyl-5β-cholestane-3,6-dione (**16**) (65 mg, 32%). For **15**, mp 139.5–140.5°C (plates from acetone–methanol) (lit. (10) mp 141–142°C); $\nu_{max}(CCl_4)/cm^{-1}$: 1714 (saturated ketones); δ_H(300 MHz; $CDCl_3$): 0.68(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.87(3H, d, J = 6.6 Hz, 27-Me), 0.91(3H, d, J = 6.5 Hz, 21-Me), 1.12(3H, s, Me), 1.13(3H, s, Me), 1.50(3H, s, Me), 1.95(1H, t, J = 12.5 Hz, 7α-H), 2.22(1H, ddd, J = 2.8, 4.2, 14.4 Hz, 2α-H), 2.31(1H, dd, J = 4.2, 12.5 Hz, 7β-H), 2.40(1H, s, 5-H), 2.81(1H, dt, J = 5.9, 14.6 Hz, 2β-H); m/z(%): 428 (37, M^+), 413(9), 400(3), 371(35), 315(9), 273(11), 262(4), 231(9), 165(40), 137(67), 43(100). For **16**, mp 118–119°C (lit. (10) mp 112–114°C); $\nu_{max}(CCl_4)/cm^{-1}$: 1707 (saturated ketones); δ_H(300 MHz; $CDCl_3$): 0.67(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.87(3H, d, J = 6.6 Hz, 27-Me), 0.91(3H, d, J = 6.5 Hz, 21-Me), 0.96(3H, s, Me), 1.15(3H, s, Me), 1.17(3H, s, Me), 1.93–2.09(3H, mm), 2.38(1H, d, J = 1.5 Hz, 5-H), 2.44(1H, t, J = 4.2 Hz), 2.50(1H, dd, J = 1.7, 4.2 Hz). m/z(%): 428(17, M^+), 400(5), 373(2), 331(100), 302(3), 273(10), 247(8), 191(15), 83(62), 43(74).

*Epimerization of **16** to **15***

To a solution of **16** (20 mg) in dry methanol (50 mL) was added sodium and and the mixture was stirred at room temperature for 3 h. Water (10 mL) was added in to quench the reaction. The solution was extracted with ether and the combined ether layers were washed, dried, and evaporated to gave the 5α epimer **15** in quantitative yield.

*Reaction of 5β,6β epoxide **6** with triphenyltin hydride*

A solution of 5β,6β epoxide **6** (113 mg, 0.265 mmol) in dry benzene (50 mL) was refluxed under argon while triphenyltin hydride (TPTH) (435 mg, 1.24 mmol) and a trace amount of AIBN (7 mg, 0.04 mmol) in dry benzene (30 mL) was added dropwise over 20 h. The mixture was stirred at reflux for 50 h. A small amount of water was then added to quench the reaction. The residue obtained after evaporating the solvent was placed directly onto a silica gel column. Elution, first with pure benzene, removed the TPTH derivatives completely. Subsequent elution using a hexane – ethyl acetate gradient solvent system gave, in the following order: 5β,6β-epoxy-4,4-dimethylcholestan-3-one (**13**) (15 mg, 14%); 6β-hydroxy-4,4-dimethylcholestan-3-one (**21**) (5 mg, 4%); 3β-hydroxy-5β,6β-epoxy-4,4-dimethylcholest-1-ene (**19**) (87 mg, 76%); and 3β,6β-dihydroxy-4,4-dimethylcholest-1-ene (**20**) (3 mg, 3%). For **19**, mp 158.0–159.0°C; $\nu_{max}(CCl_4)/cm^{-1}$: 3632, 3611 (O-H); δ_H(300 MHz; $CDCl_3$): 0.63(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.86(3H, d, J = 6.8 Hz, 27-Me), 0.88(3H, s, Me), 1.02(3H, s, Me), 1.08(3H, s, Me), 1.76–1.88(1H, m), 1.96(1H, dt, J = 3.4, 12.6 Hz), 2.14(1H, ddd, J = 2.1, 4.4,

14.8 Hz, 7-H), 3.28(1H, s, 6-H), 4.08(1H, s, 3-H), 5.50(1H, dd, J = 1.4, 10.4 Hz, 2-H), 5.87(1H, dd, J = 2.5, 10.4 Hz); m/z(%): 428(9, M^+), 410(8), 395(4), 360(7), 331(3), 273(2), 227(3), 175(7), 121(43), 95(52), 43(100). Anal. calcd. for $C_{29}H_{48}O_2$: C 81.25, H 11.29%; found: C 81.37, H 11.18%. For **20**, $\nu_{max}(CCl_4)/cm^{-1}$: 3624 (two free O-H); δ_H(300 MHz; $CDCl_3$): 0.70(3H, s, 18-Me), 0.86(3H, d, J = 6.6Hz, 26-Me), 0.86(3H, d, J = 6.6 Hz, 27-Me), 0.91(3H, d, J = 6.5 Hz, 21-Me), 1.09(3H, s, Me), 1.14(3H, s, Me), 1.28(3H, s, Me), 1.76(1H, s, 5α-H), 1.78–1.83(2H, m), 2.01(1H, dt, J = 3.4, 12.6 Hz), 3.81(1H, d, J = 8.2 Hz, 3-H), 4.41(1H, s, 6-H), 5.36(1H, dd, J = 1.6, 10.4 Hz, 1-H), 5.74(1H, dd, J = 2.3, 10.4 Hz, 2-H). For **21**, mp 152.5–153.5°C; $\nu_{max}(CCl_4)/cm^{-1}$: 3621(free O-H), 1707(saturated ketone); δ_H(300 MHz, $CDCl_3$): 0.71(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.87(3H, d, J = 6.6 Hz, 27-Me), 0.91(3H, d, J = 6.5 Hz, 21-Me), 1.15(3H, s, Me), 1.38(3H, s, Me), 1.43(3H, s, Me), 1.68(1H, s), 1.75–1.86(3H, mm), 1.95(1H, ddd, J = 3.0, 6.0, 13.1 Hz), 2.01(1H, dt, J = 3.3, 12.8 Hz), 2.26(1H, ddd, J = 3.0, 4.6, 14.9 Hz, 2-H), 2.76(1H, dt, J = 6.0, 14.6, 14.6 Hz, 2-H), 4.34(1H, s, 6-H); m/z(%): 430(4, M^+), 412(18), 397(4), 357(4), 327(3), 257(12), 187(17), 145(15), 107(27), 81(36), 43(100). Anal. calcd. for $C_{29}H_{50}O_2$: C 80.87, H 11.70%; found: C 81.00, H 11.54%.

Sodium borohydride reduction of 5β,6β epoxide ***6***

To a solution of **6** (100 mg, 0.24 mmol) in methanol (30 mL) was added $NaBH_4$ (53 mg, 1.4 mmol) and $CeCl_3 \cdot 7H_2O$ (100 mg, 0.27 mmol). The mixture was stirred at room temperature for 45 min before a small amount of water was added to quench the reaction. The mixture was extracted with ether and the combined ether layers were washed, dried, and evaporated as usual. Silica gel chromatography of the residue and elution with a hexane – ethyl acetate gradient solvent system yielded 3β-hydroxy-5β,6β-epoxy-4,4-dimethylcholest-1-ene (**19**) (89 mg, 87%).

PCC oxidation of hydroxy-ketone ***21***

To a solution of 6β-hydroxy-4,4-dimethylcholestan-3-one (**21**) (10 mg, 0.024 mmol) in anhydrous CH_2Cl_2 (10 mL) was added PCC (10 mg, 0.049 mmol) in one portion and the mixture was stirred at room temperature for 2 h. The reaction solution was placed onto a silica gel column and was eluted with ether. Evaporation of the ether yielded 4,4-dimethyl-5α-cholestane-3,6-dione (**15**) (9 mg, 92%).

Preparation of bromohydrin acetate ***23***

To a solution of **6** (100 mg, 0.24 mmol) in dry glacial acetic acid (10 mL) with stirring at 10°C was added a solution of hydrogen bromide (3.7%) in acetic acid (9 mL, 0.41 mmol) by syringe over 30 min. After stirring at 10°C for 8 h, the reaction mixture was poured onto ice-water and extracted with ether. The combined ether layers were washed, dried, and evaporated as usual. Silica gel chromatography of the residue and elution with a hexane – ethyl acetate gradient solvent system afforded **6** (89 mg, 85%), bromohydrin acetate **23** (13 mg, 10%), and a compound (5 mg) whose structure was not determined. For **23**, mp 180–182°C (needles from acetone–water); $\nu_{max}(CCl_4)/cm^{-1}$: 1747(ester carbonyl), 1692(α,β-unsaturated ketone); δ_H(300 MHz, $CDCl_3$): 0.73(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.87(3H, d, J = 6.6 Hz, 27-Me), 0.92(3H, d, J = 6.5 Hz, 21-Me), 1.45(3H, s, Me), 1.52(3H, s, Me), 1.69(3H, s, Me), 2.09(1H, dt, J = 3.3, 12.8 Hz), 2.14(3H, s, acetate methyl), 2.20–2.34(2H, m), 5.59(1H, br s, 6-H), 5.94(1H, d, J = 10.3 Hz, 2-H), 6.83(1H, d, J = 10.5 Hz, 1-H); m/z(%): 426(2, M^+-Br,CH_3CO), 410(7), 408(8), 395(3), 393 (6), 367(3), 365(5), 339(5), 337(2), 149(11), 147(8), 81(38), 79(24), 43(100).

In-situ *reaction of* ***21*** *with triphenyltin hydride*

To a solution of **6** (100 mg, 0.24 mmol) in dry glacial acetic acid (10 mL) with stirring at 10°C was added a solution of hydrogen bromide (3.7%) in glacial acetic acid (0.8 mL, 0.37 mmol) by syringe over 30 min. After stirring at 10°C for 90 min, the reaction mixture was poured onto ice-water. The precipitate was filtered and washed with ice-water to remove all traces of acetic acid. The colourless residue was vacuum-dried and then was dissolved in dry benzene (50 mL) and refluxed. Tri-*n*-butyltin hydride (TBTH) (97%, 0.06 mLl, 0.22 mmol) in dry benzene (10 mL), and a catalytic amount of AIBN were then added dropwise over 1 h. The mixture was stirred at reflux for 2 h. A small amount of water was added to the reaction solution to quench the reaction. The residue after evaporation of the solvent was placed directly onto a silica gel column. Elution, first with pure benzene removed the TBTH derivatives. Subsequent elution with the hexane – ethyl acetate gradient solvent system gave 6β-hydroxy-4,4-dimethylcholestan-3-one (**21**) (49 mg, 48%), 6β-hydroxy-4,4-dimethyl-5α-cholest-1-en-3-one (**25**) (3 mg, 3%), 5β-hydroxy-4,4-dimethylcholest-1-en-3-one (**26**) (18 mg, 18%), and an unstable compound (17 mg, 17%). For **25**, $\nu_{max}(CCl_4)/cm^{-1}$: 3622 (free O-H), 1676 (α,β-unsaturated ketone); δ_H(300 MHz, $CDCl_3$): 0.74(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.87(3H, d, J = 6.6 Hz, 27-Me), 0.92(3H, d, J = 6.5 Hz, 21-Me), 1.22(3H, s, Me), 1.39(3H, s, Me), 1.41(3H, s, Me), 1.64(1H, d, J = 1.4 Hz, 5-H), 1.77–1.90(2H, m), 2.07(1H, dt, J = 3.3, 3.3, 12.9 Hz, 8-H), 4.40(1H, s, 6-H), 5.82(1H, d, J = 10.3 Hz, 2-H), 6.97(1H, d, J = 10.3 Hz, 1-H). For **26**, $\nu_{max}(CCl_4)/cm^{-1}$: 3626(free O-H), 1686(α,β-unsaturated ketone); δ_H(300 MHz, $CDCl_3$): 0.70(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.86(3H, d, J = 6.6 Hz, 27-Me), 0.91(3H, d, J = 6.5 Hz, 21-Me), 1.22(3H, s, Me), 1.30(3H, s, Me), 1.37(3H, s, Me), 2.03(1H, dt, J = 3.3, 12.9 Hz), 2.14(1H, ddd, J = 2.1, 4.5, 14.1 Hz), 5.88(1H, d, J = 10.5 Hz, 2-H), 6.56(1H, d, J = 10.4 Hz, 1-H).

*4,4-Dimethyl-3-oxo-*B*-norcholest-1-ene-5-carboxaldehyde (27)*

To a solution of **6** (110 mg, 0.26 mmol) in dry benzene (5 mL) with stirring at room temperature was added boron trifluoride etherate (0.1 mL, 0.8 mmol) by syringe. After stirring at room temperature for 30 min, the reaction mixture was quenched by pouring into $NaHCO_3$ solution (3%) and extracted with ether. The combined ether extracts were washed, dried, and evaporated as usual. Silica gel chromatography using the hexane – ethyl acetate gradient solvent system yielded the *B*-nor aldehyde **27** (86 mg, 77%), and two other products that could not be characterized due to their instability. For **27**, mp 103.5–104.5°C (plates from ethanol–water); $\nu_{max}(CCl_4)/cm^{-1}$: 1729 (aldehyde), 1688 (α,β-unsaturated ketone); δ_H(300 MHz, $CDCl_3$): 0.64(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.86(3H, d, J = 6.6 Hz, 27-Me), 0.91(3H, d, J = 6.5 Hz, 21-Me), 1.04(3H, s, 4β-Me), 1.04(3H, s, 19-Me), 1.11(1H, dd, J = 11.2, 13.0 Hz, 7-H), 1.17(3H, s, 4α-Me), 1.83–1.90(1H, m), 2.04(1H, dt, J = 2.8, 12.9 Hz), 2.41(1H, dd, J = 7.0, 13.0 Hz, 7-H), 5.94(1H, d, J = 10.2 Hz, 2-H), 6.63(1H, d, J = 10.2 Hz, 1-H), 9.57(1H, s, 6-H); HRMS for $C_{29}H_{46}O_2$, calcd.: 426.3495; found: 426.3495; m/z(%): 426(7, M+), 397(7), 356(5), 313(3), 261(9), 243(3), 149(35), 43(100). Anal. calcd. for $C_{29}H_{46}O_2$: C 81.63, H 10.87%; found: C 81.51, H 10.78%.

Sodium borohydride reduction of 27

To a solution of the *B*-nor aldehyde **27** (51 mg, 0.12 mmol) and $CeCl_3 \cdot 7H_2O$ (56 mg, 0.15 mmol) was added $NaBH_4$ in small portions over 4 h until the starting material almost disappeared according to TLC. The reaction mixture was stirred at room temperature for an additional hour before a small amount of water was added to quench the reaction. The reaction mixture was extracted with ether and the combined ether layers were washed, dried, and evaporated as usual. Chromatography of the residue and elution with the hexane – ethyl acetate gradient solvent system gave 5β-hydroxymethyl-4,4-dimethyl-*B*-norcholest-1-en-3-one (**28**) (45 mg, 88%). For **28**, mp 150–151°C; $\nu_{max}(CCl_4)/cm^{-1}$: 3630 (free O-H), 3493 (intermolecular and weakly bonded O-H), 1685

(α,β-unsaturated ketone); δ_H(300 MHz, $CDCl_3$): 0.66(3H, s, 18-Me), 0.86(3H, d, J = 6.6 Hz, 26-Me), 0.87(3H, d, J = 6.6 Hz, 27-Me), 0.92(3H, d, J = 6.5 Hz, 21-Me), 1.09(3H, s, 4β-Me), 1.12–1.16(1H, m, 7α-H), 1.21(3H, s, 19-Me), 1.22(3H, s, 4α-Me), 1.35(1H, br s, 7β-H), 1.65–1.75(1H, m), 1.81–1.93(1H, m), 2.04(1H, dt, J = 3.2, 12.8 Hz, 12β-H), 3.71(2H, br s, 6-methylene), 5.82(1H, d, J = 10.2 Hz, 2-H), 6.54(1H, d, J = 10.2 Hz, 1-H); m/z(%): 428(23.6, M^+), 413(8), 410(7), 398(14), 397(34), 385(7), 358(22), 261(12), 166(14), 149(43), 121(66), 43(100). Anal. calcd. for $C_{29}H_{48}O_2$: C 81.25, H 11.29%; found: C 81.05; H 11.17%.

Acknowledgements

The authors wish to express their sincerest appreciation to Dr. C. R. Jablonski and Ms. N. Brunet for their generous contributions in the form of numerous high-quality high-resolution nmr spectra. We thank Dr. D. J. Burnell for many suggestions and for his ongoing encouragement, Dr. B. Gregory and Ms. M. Baggs for their mass spectral contributions, and Dr. J. N. Bridson for X-ray crystallographic analyses. Électrodes à membrane indicatrices de surfactifs cationiques. Variation des propriétés électriques de la membrane en fonction de sa composition

M. P. GLOTON, M. TURMINE, A. MAYAFFRE ET P. LETELLIER[1]

Laboratoire d'energétique et réactivité aux interfaces, Université Pierre et Marie Curie, boîte 39, 4 place Jussieu, 75252 Paris, France

Reçu le 23 mars 1992[2]

M. P. GLOTON, M. TURMINE, A. MAYAFFRE et P. LETELLIER. Can. J. Chem. **71**, 371 (1993).

Les électrodes membranaires indicatrices d'ions amphiphiles cationiques utilisent le plus souvent comme capteur de potentiel une membrane spécifique constituée d'un mélange de polymère tel que le PVC, d'un plastifiant et d'un transporteur de l'ion amphiphile. Pour un polymère donné, il existe un grand nombre de plastifiants pouvant convenir à la préparation de membranes spécifiques. Nous avons exploré ce domaine, en préparant différentes membranes à partir de deux polymères (PVC : haut et bas poids moléculaire), de quatre plastifiants utilisés en diverses proportions, et d'un transporteur de l'ion dodécyltriméthylammonium. Ces membranes ont été montées sur des corps d'électrode et utilisées comme électrode spécifique. Nous montrons que tous les mélanges entre ces constituants ne permettent pas la réalisation d'électrodes spécifiques. Peu, en fait, permettent d'obtenir une réponse «nernstienne». Ainsi, les mélanges les plus riches en polymère sont hétérogènes; les réponses de l'électrode ne sont pas reproductibles d'un échantillon à l'autre d'un même mélange. L'introduction d'un modèle de transport des ions à travers la membrane qui suppose une diffusion par transporteur pour l'ion amphiphile et une diffusion non spécifique du sel par les défauts créés par l'hétérogénéité du support permet de rendre compte, de manière qualitative, de la variation de la pente de réponse de l'électrode avec la composition de la membrane.

M. P. GLOTON, M. TURMINE, A. MAYAFFRE, and P. LETELLIER. Can. J. Chem. **71**, 371 (1993).

Amphiphilic-cation-specific electrodes most often use, as captor of potential, a specific membrane composed of a mixture of a polymer such as PVC, a plasticizer, and a carrier of the amphiphilic ion. For a given polymer, various plasticizers can be used to make "plastisols" that can be suitable for the preparation of specific membranes. We prepared different membranes using two polymers (PVC: high and low molecular weight), four plasticizers in various proportions, and a carrier of the dodecyltrimethylammonium ion. These membranes were mounted on an electrode support and used as ion-selective electrodes. We show that none of these component mixtures can allow the design of specific electrodes. Only a few of them give a "Nernstian" response. Thus, the mixtures rich in polymer lead to heterogeneous plastisols; the electrode responses cannot be reproduced with different samples of the same mixture. We use a model of ion transport through the membrane that assumes a diffusion by carrier for the amphiphilic ion and nonspecific diffusion of the salt through the flaws created by the heterogeneity of the plastisols. The introduction of this model allows us to explain qualitatively the variation of the slope of the electrode response with the membrane composition.

Introduction

La mise en oeuvre des électrodes membranaires indicatrices d'agents tensio-actifs cationiques, anioniques et neutres a fait l'objet depuis quelques années de nombreuses études et il est décrit, dans la littérature, différentes manières de réaliser des membranes spécifiques aux amphiphiles (1–6). Le plus souvent, ces membranes sont réalisées à partir d'un mélange de polymère et de plastifiant que l'on convient de nommer «plastisol» (7–17). La présence d'un transporteur de l'ion à doser confère à la membrane sa sélectivité.

On peut constater en consultant la littérature sur ce sujet, qu'en général, la nature des constituants de la membrane et les compositions proposées par les différents auteurs sont relativement proches les unes des autres, sans doute parce que de tels systèmes fournissent des réponses de potentiel tout à fait convenables pour la majorité des applications envisagées. Il nous a cependant semblé intéressant d'examiner les réponses électriques de membranes contenant d'autres mélanges de plasifiant et de polymère et en diverses proportions. Il existe en effet, pour un polymère donné, comme le chlorure de polyvinyl, PVC, un grand nombre de plastifiants qui conduisent à des supports «solides» sur une gamme très étendue de composition, le plus souvent entre 0 et 90% en masse de plastifiant.

L'étude suivante concerne donc les mélanges entre deux polymères, les PVC haut et bas poids moléculaire, et quatre plastifiants différents pour diverses compositions. Nous exposerons tout d'abord les techniques opératoires mises en oeuvre.

I. Techniques expérimentales

I-1. Les solvants

L'eau est de qualité ultrapure. Le méthanol de même que le tétrahydrofuranne utilisé comme solvant du PVC sont des produits Merck.

I-2. Les gels de polymère

Le polymère

Nous avons utilisé deux types de polymères présentant des propriétés chimiques proches : (*i*) le PVC haut poids moléculaire (PVC-hpm) de masse molaire supérieure à 1 500 000 g mol^{-1} et (*ii*) le PVC bas poids moléculaire (PVC-bpm) dont la masse molaire est de 48 000 g mol^{-1}.

Le plastifiant

C'est un solvant organique qui confère au polymère sa malléabilité. Quatre plastifiants (Fluka) ont été utilisés pour la fabrication des supports : le dinonylphtalate (DNP) de formule $C_{26}H_{42}O_4$; le nitrophényloctyléther (NPOE) de formule $C_{24}H_{21}O_3N$; le dioctyladipate (DOA) de formule $C_{22}H_{42}O_4$; le dioctylsébacate (DOS) de formule $C_{26}H_{50}O_4$.

Préparation de la membrane

La membrane sélective. Elle est constituée d'un mélange entre un polymère et un plastifiant (plastisol). L'ajout d'un transporteur

du cation amphiphile à basse concentration lui donne ses propriétés de sélectivité :

Nous avons utilisé comme cation amphiphile le dodécyltriméthylammonium que nous conviendrons de noter DTA^+. La valeur de la concentration micellaire critique de cet agent tensio-actif dans l'eau est égale à $1{,}6 \times 10^{-2}$ mol L^{-1} à 298 K. Le tétraphénylborure de DTA^+ (ϕ_4B^-,DTA^+) insoluble dans l'eau est, en revanche, soluble dans les solvants organiques. Ce sel est introduit à la même concentration dans toutes les membranes préparées. Il est plus ou moins dissocié dans la matrice selon la nature du plastifiant. L'ion ϕ_4B^- assure le transport de DTA^+ dans la membrane.

Préparation des membranes. (*a*) On mélange en proportions variables du PVC et du plastifiant (masse totale environ 2 g) dans 10 mL de tétrahydrofuranne, THF. À 3 mL de cette solution, on ajoute 0,2 mL d'une solution du transporteur ($DTAB\phi_4$) dans le THF à une concentration de 10^{-2} mol L^{-1}. On dépose ce mélange dans un cristallisoir à fond plat de 25 cm^2 de surface et on laisse évaporer le solvant pendant 12 h à la température ambiante. Avant évaporation du THF, la concentration de transporteur dans la membrane est égale à $6{,}25 \times 10^{-4}$ mol L^{-1}.

(*b*) On prépare le sel du transporteur de la manière suivante : on mélange 5×10^{-3} mol de chacun des deux sels (DTABr et $NaB\phi_4$) dans 50 mL de dichlorométhane. Après 3–4 h d'agitation, ce mélange est filtré sur papier et on obtient un filtrat limpide dont le solvant est évaporé sous hotte. Les cristaux résultants sont lavés à l'eau puis recristallisés deux fois dans un mélange d'éther et de quelques gouttes de méthanol. Cette membrane, d'une épaisseur moyenne de 0,2 mm, constitue le capteur de potentiel de l'électrode (18).

I-3. Le montage électrochimique

L'électrode de mesure

La membrane est découpée à l'emporte-pièce et collée à l'extrémité d'un tube de verre qui constitue le corps de l'électrode. Une électrode à calomel protégée par un pont agar-agar de la diffusion de l'agent tensio-actif constitue la référence interne de l'électrode. Le liquide de remplissage est une solution aqueuse de DTABr à une concentration inférieure à la concentration micellaire critique (cmc).

L'électrode de référence

Les électrodes de référence sont des électrodes à calomel saturées en KCl, protégées de la diffusion des cations amphiphiles par une solution de KCl de concentration égale à 2 mol L^{-1} gélifiée par de l'agar-agar, contenue dans un capillaire de Téflon. Il est très important pour obtenir des mesures reproductibles de renouveler souvent la jonction au cours des manipulations, la diffusion des cations amphiphiles étant très rapide.

La chaîne électrochimique

Toutes les mesures sont effectuées en utilisant la même chaîne électrochimique schématisée ci-dessous :

référence : calomel | solution interne | membrane | solution de mesure | référence : calomel

Étalonnage des électrodes

Les variations de concentration de DTA^+ dans la solution de mesure sont obtenues par une méthode d'ajouts. Chaque étalonnage est effectué sur plusieurs échantillons d'une même préparation de membrane.

II. Étude électrochimique

II-1. Comportement électrochimique des plastisols

Le fonctionnement des électrodes spécifiques membranaires repose sur la mesure d'un potentiel intermembranaire que s'établit de part et d'autre d'une interface séparant deux phases contenant des électrolytes de concentrations et parfois de nature différentes. Lorsque par exemple cette interface sépare deux solutions, 1 et 2, d'un même sel M^+X^- aux concentrations respectives C_1 et C_2, dans deux solvants identiques, il s'établit une différence de potentiel entre les deux compartiments égale à $\Delta\phi$ tel que :

$$[1] \qquad \Delta\phi = (1 - 2t^+)\frac{RT}{F}\ln\frac{C_2}{C_1}$$

où t^+ est le nombre de transport du cation.

Si l'on interpose entre les deux solutions une membrane sélective au cation M^+ ($t^+ = 1$), la différence de potentiel prend la forme :

$$[2] \qquad \Delta\phi = \frac{RT}{F}\ln\frac{C_2}{C_1}$$

La différence de potentiel aux bornes de la pile suivante,

Reference calomel, KCl sat.	solution interne $M^+ : C_1$ constante	Membrane	solution de mesure $M^+ : C_2$ variable	Reference calomel, KCl sat.
$\phi 1$	ϕ sol. 1	ϕ m	ϕ sol. 2	$\phi 2$

s'écrit :

$$\Delta E = \phi 1 - \phi 2 = \phi 1 - \phi \text{ sol. } 1 + \phi \text{ sol. } 1 - \phi \text{ m} + \phi \text{ m} - \phi \text{ sol. } 2 + \phi \text{ sol. } 2 - \phi 2$$

On peut supposer que les deux différences de potentiel ϕ 1 $-$ ϕ sol. 1 et ϕ 2 $-$ ϕ sol. 2 correspondantes aux électrodes à calomel sont constantes. L'expression de la f.e.m. de la pile se résume alors en :

$$[3] \qquad \Delta E = \text{constante} + \phi \text{ sol. } 1 - \phi \text{ sol. } 2 = \text{constante} - \Delta\phi = \text{constante}' + \frac{RT}{F}\ln C_2$$

ΔE varie linéairement avec $\ln C_2$ avec, à 25°C, une pente de 59 mV/dec (pente dite nernstienne).

II-2. Résultats expérimentaux

Avant de présenter l'ensemble des résultats obtenus avec les deux polymères et les quatre plastifiants pour différentes compositions de plastisols, nous avons décrit ci-dessous le comportement d'une électrode réputée pour bien fonctionner, afin de disposer d'un élément de comparaison permettant de juger du comportement des autres électrodes.

Comportement de comparaison : la membrane PVC-hpm 20% | DNP 80%

Un grand nombre d'électrodes indicatrices de surfactifs cationiques proposées dans la littérature utilisent une mem-

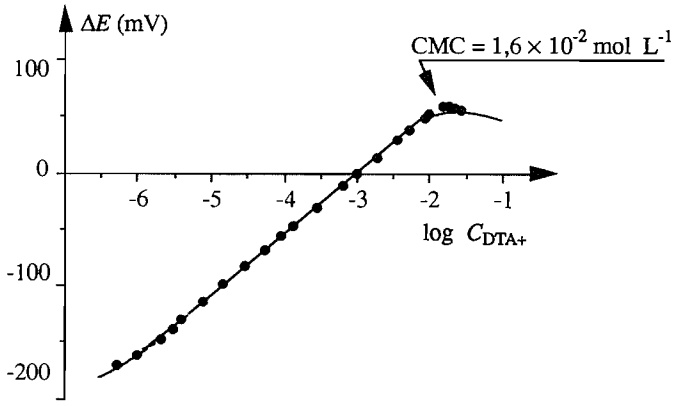

FIG. 1. Comportement de l'électrode de comparaison indicatrice de DTA^+ utilisant une membrane d'un plastisol contenant du DNP 80% – PVC-hpm 20%.

TABLEAU 1. Caractéristiques électrochimiques des électrodes à membranes réalisées avec le mélange PVC-hpm–plastifiant. Les membranes hétérogènes sont signalées par la lettre H

Pourcentage en plastifiant	Pente ±1 (mV/dec)			
	NPOE	DOS	DOA	DNP
80	59	59	60	59
60	58	55	54	52
50	57	49	47	45
45	—	H	H	31
40	55	H	H	H
30	56	H	H	H
25	32	H	H	H

TABLEAU 2. Caractéristiques électrochimiques des électrodes à membranes réalisées avec le mélange PVC-bpm–plastifiant. Les membranes hétérogènes sont signalées par la lettre H

Pourcentage en plastifiant	Pente ±1 (mV/dec)			
	NPOE	DOS	DOA	DNP
80	60	58	59	60
60	57	56	57	60
50	54	54	54	57
40	50	51	44	34
30	49	H	H	H
20	44	H	H	H

brane de PVC-hpm contenant 80% en masse de DNP comme capteur de potentiel (4, 5, 9, 19–23). L'excellente réponse aux agents tensio-actifs cationiques des électrodes sélectives réalisées à partir de cette membrane a pu être vérifiée au laboratoire (18). Une courbe d'étalonnage obtenue avec le DTA^+ est représentée sur la figure 1.

Les électrodes fabriquées à l'aide de cette membrane présentent une cassure très nette au niveau de la cmc. La réponse de l'électrode est linéaire entre la cmc et une concentration en surfactif de l'ordre de 10^{-6} mol L^{-1}. La valeur de la pente de la droite, déterminée par une régression linéaire à partir d'une cinquantaine de points, est égale à la valeur théorique de 59 ± 1 mV/dec. La stabilité des mesures est de ±0,5 mV.

Nous avons caractérisé les autres membranes par les valeurs des pentes des parties linéaires relatives aux concentrations inférieures à la cmc. Ces valeurs sont également déterminées au moyen d'une régression linéaire portant sur une cinquantaine de points.

II-2-1. Plastisols à base de PVC haut poids moléculaire
Mélanges PVC-hpm–plastifiant

Nous avons regroupé dans le tableau 1, les valeurs des pentes des droites caractéristiques des différentes membranes.

Plastifiant : NPOE. On constate qu'entre 80 et 50% en masse de NPOE, la réponse de l'électrode est pratiquement nernstienne. Lorsque la teneur en plastifiant devient inférieure à 30%, on observe une brusque diminution de la valeur de la pente.

Pour des pourcentages encore inférieurs (10 et 20% en NPOE), les mesures deviennent très instables et les valeurs des pentes des parties linéaires diffèrent selon l'échantillon de membrane prélevé. Il apparaît à l'évidence qu'en dessous de 30% les *plastisols sont hétérogènes.*

Plastifiants : DOS, DOA, DNP. Contrairement au cas des mélanges avec le NPOE, on constate que la valeur de la pente de l'électrode diminue dès que le pourcentage en plastifiant devient inférieur à 80%. Seul ce dernier pourcentage pour les trois plastifiants conduit à une pente nersnstienne de l'électrode.

Pour des membranes contenant moins de 40% de ces plastifiants la valeur de la pente dépend de l'échantillon de membrane prélevé. Ces membranes sont hétérogènes.

II-2-2. Plastisols à base de PVC bas poids moléculaire

Nous avons regroupé dans le tableau 2, les valeurs des pentes des droites caractéristiques des différentes membranes.

Mélanges PVC-bpm–plastifiant

Plastifiant : NPOE, DOS, DOA. En ce qui concerne le NPOE, contrairement aux plastisols de ce même plastifiant préparés avec du PVC haut poids moléculaire, on constate que la pente de l'électrode diminue dès que la composition en plastifiant devient inférieure à 80%.

La membrane contenant 10% en NPOE donne des réponses électrochimiques différentes selon l'échantillon utilisé. Ces compositions conduisent à des plastisols hétérogènes. On retrouve un comportement identique pour les deux autres plastifiants.

Plastifiant : DNP. On retrouve, avec ce plastisol, un comportement proche de celui que nous avons observé pour le PVC-hpm et le NPOE, mais sur un domaine de composition plus étroit. Entre 80 et 50% la pente de l'électrode est pratiquement nernstienne.

En revanche pour des compositions inférieures à 30%, les valeurs de pente diffèrent selon l'échantillon utilisé. Ces membranes sont hétérogènes.

Discussion

Les mesures précédentes[3] montrent que l'on dispose en fait d'un nombre restreint de plastisols permettant de fabriquer des électrodes sélectives aux agents tensio-actifs cationiques dont les valeurs des pentes sont égales à 59 mV/dec.

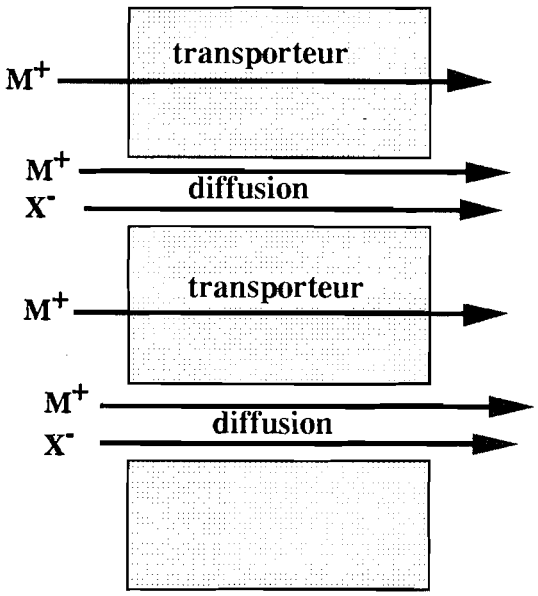

FIG. 2. Modèle de membrane «mosaïque» pour rendre compte du comportement des membranes de plastisol dans le domaine hétérogène.

Ce sont tous des mélanges relativement riches en plastifiant.

En fait, le choix d'un plastisol particulier pour fabriquer une électrode dépend essentiellement de l'utilisation que l'on projette d'en faire, des milieux d'études et des propriétés mécaniques recherchées pour le plastisol. Ainsi, les mélanges PVC-hpm–NPOE constituent un excellent choix pour la réalisation de membranes si l'on ne considère que le large domaine de composition conduisant à des pentes nernstiennes. Ils possèdent, en revanche, l'inconvénient de conduire à des électrodes dont la réponse électrique est fortement influencée par le pH de la solution, ce qui n'est pas le cas des autres plastisols (18); les membranes au NPOE sont donc essentiellement utilisables pour des études à acidité contrôlée de la solution.

Il apparaît ainsi que l'importance du domaine de composition conduisant à une réponse nernstienne n'est pas le seul critère de choix.

Les résultats précédents sont également intéressants sur un tout autre plan. Le fait que, pour certains domaines de composition, la valeur de la pente de l'électrode devient inférieure à la valeur théorique signifie que le nombre de transport des anions dans les plastisols cesse d'être nul (cf. sect. II-1). Ce comportement implique un mode de transport différent de l'amphiphile dans la membrane. Cette conclusion peut être étayée par la constatation que les plastisols de faible teneur en plastifiant sont hétérogènes, ce qui suppose au sein de la structure membranaire la présence de défauts. Cette propriété a déjà été évoquée dans la littérature (24), où l'existence d'agrégats de PVC dans certains plastisols a été montrée.

La création de défauts au sein du support conduit inévitablement à un régime de diffusion hétérogène. Sous l'effet de son gradient de potentiel électrochimique, le transfert de l'ion M^+ peut se réaliser par l'intermédiaire du transporteur, l'ion tétraphénylborure (transport sélectif), mais aussi par diffusion, associé à X^- (transport non-sélectif), en empruntant les chemins ménagés par les défauts du support.

On peut rendre compte de ce comportement en modélisant la membrane de plastisol sous la forme d'une membrane «mosaïque» résultant de la juxtaposition de domaines possédant des propriétés différentes de transfert. On considèrera ainsi, que la membrane est constituée de deux domaines interpénétrés :

(*i*) parfaitement sélectif à l'ion M^+. On conviendra d'appeler θ le rapport de l'aire de ce domaine sur l'aire totale. Le transfert du cation se réalise par l'intermédiaire du transporteur. On conviendra de noter la mobilité de M^+, ω_{mt}. Le flux de cation est alors J_{mt}.

(*ii*) parfaitement non sélectif. M^+ et X^- diffusent dans les chemins ménagés au sein du support par les défauts ou les «volumes libres». Le rapport de l'aire de ce domaine sur l'aire totale est $1 - \theta$. On conviendra de noter les mobilités de M^+ et de X^-, respectivement ω_{md} et ω_{xd}. Les flux respectifs sont J_{md} et J_{xd}.

Le modèle est schématisé sur la figure 2.

On peut alors écrire les flux des deux ions à travers la membrane en tenant compte des deux modes de transfert :
Pour M^+ :

$$[4] \quad Jm = \theta J_{mt} + (1 - \theta) J_{md}$$

Pour X^- :

$$[4'] \quad Jx = (1 - \theta) J_{xd}$$

Chaque flux répond à l'équation suivante :

$$[5] \quad J_{mt} = -\frac{1}{T} \omega_{mt} \text{ grad } \tilde{\mu}_M$$

$$[5'] \quad J_{md} = -\frac{1}{T} \omega_{md} \text{ grad } \tilde{\mu}_M$$

$$[5''] \quad J_{xd} = -\frac{1}{T} \omega_{xd} \text{ grad } \tilde{\mu}_X$$

où $\tilde{\mu}_M$ et $\tilde{\mu}_X$ sont les potentiels électrochimiques de M^+ et de X^-. Le respect de l'électroneutralité lors du transfert permet d'écrire :

$$[6] \quad [\theta \omega_{mt} + (1 - \theta) \omega_{md}] \text{ grad } \tilde{\mu}_M = (1 - \theta) \omega_{xd} \text{ grad } \tilde{\mu}_X$$

À partir de l'expression du potentiel électrochimique des espèces,

$$\tilde{\mu}_i = \mu i + zi F \phi$$

où ϕ est le potentiel de la phase qui contient i, zi la valence algébrique de i, et F le faraday, on établit la relation :

$$[7] \quad F \, d\phi \, [\theta\omega_{mt} + (1 - \theta) (\omega_{md} + \omega_{xd})] = (1 - \theta) \omega_{xd} d\mu_X - [\theta\omega_{mt} + (1 - \theta)\omega_{md}] \, d\mu_M$$

Pour les solutions diluées, on peut indentifier les nombres qui mesurent les concentrations et les activités. Les concentrations en M^+ et X^- sont égales à C, la concentration de MX.

En développant les expressions des potentiels chimiques, on obtient la relation différentielle :

$$[8] \quad d\phi = \frac{RT}{F} \frac{(1 - \theta) (\omega_{xd} - \omega_{md}) - \theta\omega_{mt}}{(1 - \theta) (\omega_{md} + \omega_{xd}) + \theta\omega_{mt}} d \ln C$$

Une fois intégrée entre les compartiments 1 et 2, dans lesquelles les concentrations de MX sont respectivement C_1 et C_2, on établit que la différence de potentiel transmembranaire s'écrit sous la forme :

$$[9] \quad \Delta\phi = \phi 2 - \phi 1 = \frac{RT}{F} \frac{(1-\theta)(\omega_{xd} - \omega_{md}) - \theta\omega_{mt}}{(1-\theta)(\omega_{md} + \omega_{xd}) + \theta\omega_{mt}} \ln \frac{C_2}{C_1}$$

Si l'on introduit le nombre de transport de M^+ dans la phase membranaire, tel que

$$t_m = \frac{\omega_{md}}{\omega_{md} + \omega_{xd}}$$

on peut alors écrite la relation précédente sous la forme :

$$[10] \quad \Delta\phi = \phi 2 - \phi 1 = \frac{RT}{F} \left[\frac{2}{\frac{1}{1-t_m} + \left(\frac{\theta}{1-\theta}\right)\frac{\omega_{mt}}{\omega_{xd}}} - 1 \right] \ln \frac{C_2}{C_1}$$

La différence de potentiel aux bornes de la pile est alors de la forme :

$$[11] \quad \Delta E = \text{constante} + \frac{RT}{F} \left[1 - \frac{2}{\frac{1}{1-t_m} + \left(\frac{\theta}{1-\theta}\right)\frac{\omega_{mt}}{\omega_{xd}}} \right] \ln C_2$$

On conviendra d'appeler $\frac{RT}{F}\alpha$ le terme prélogarithmique

$$\Delta E = \text{constante} + \frac{RT}{F}\alpha \ln C_2$$

On constate ainsi que la pente de la droite de réponse de l'électrode est liée aux valeurs de trois paramètres :

(*i*) le nombre de transport de l'anion caractéristique du phénomène de diffusion passive à travers les défauts du support;

(*ii*) le rapport $r = \omega_{mt}/\omega_{xd}$ entre la mobilité du cation lorsqu'il est associé au transporteur et la mobilité de l'anion pour la partie diffusive du transport;

(*iii*) le rapport des aires associées aux deux phénomènes de transport.

Les deux premiers paramètres sont caractéristiques de la nature de la membrane et des propriétés du transporteur vis-à-vis de l'amphiphile. Le troisième est directement lié à la composition du support. On peut en effet supposer en considérant les résultats expérimentaux que la quantité de défauts de la membrane s'accroît lorsque la concentration en plastifiant diminue. Ceci implique que θ et la proportion de plastifiant sont deux paramètres qui varient dans le même sens.

Nous avons reporté sur la figure 3, à titre d'illustration, les variations de α en fonction de θ pour différentes valeurs de r. Nous avons retenu pour t_m la valeur de 0,3 qui caractérise le transport de l'ion amphiphile dans l'eau en présence de l'anion bromure (18). Ce choix est purement formel et n'a

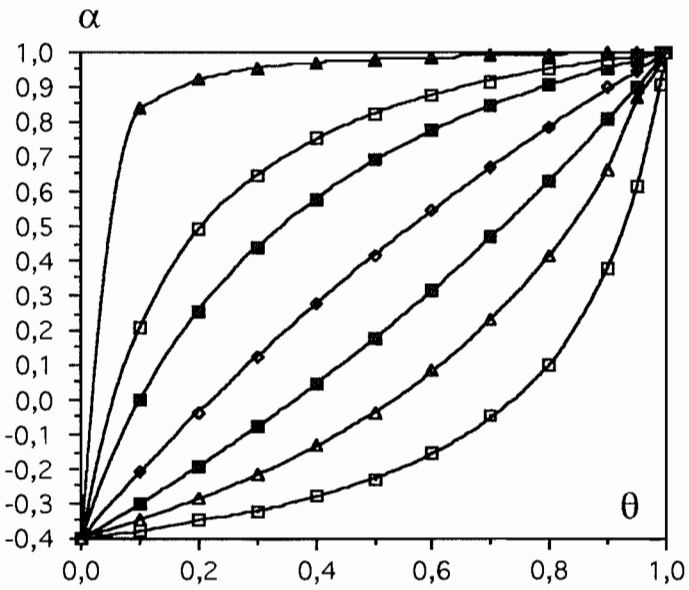

FIG. 3. Variation du paramètre α en fonction de la contribution θ (transfert par transporteur) au transport de M^+ à travers la membrane. De bas en haut : ⊡ $r = 0{,}2$; △ $r = 0{,}5$; ■ $r = 1$; ◇ $r = 2$; ■ $r = 5$; □ $r = 10$; ▲ $r = 100$.

que peu d'importance dans l'analyse suivante qui reste essentiellement qualitative.

Lorsque le rapport r est très grand, c'est-à-dire lorsque la mobilité de l'anion est faible (cf $r = 100$), l'électrode possède une réponse nernstienne sur un très large domaine de composition. Ce comportement correspond tout à fait au cas des plastisols PVC-hpm–NPOE et PVC-bpm–DNP dont on peut donc supposer, soit qu'ils possèdent peu de défauts (θ petit), soit que la mobilité de X^- (ω_{xd}) y est faible.

Pour des valeurs de r plus petites, de l'ordre de 5 à 10, qui supposent qu'une partie non négligeable du transport de M^+ s'effectue par diffusion libre, on retrouve le comportement observé pour l'ensemble des autres plastisols, c'est-à-dire une diminution de la valeur de la pente de l'électrode dès que le milieu s'appauvrit en plastifiant.

Nous avons également reporté sur la figure 3 les comportements limites correspondant au cas où le transfert de M^+ s'effectue essentiellement par diffusion libre $r = 0$; on retrouve bien entendu le cas de la jonction libre.

Bien qu'interprété de manière essentiellement qualitative, ce modèle rend bien compte de la diminution de la pente de l'électrode en supposant l'existence de micro-hétérogénéités permettant une diffusion des sels à travers la membrane.

Conclusion

L'étude présentée avait pour objectif d'explorer les propriétés de différents plastisols en vue de leur utilisation comme capteurs de potentiel. Les résultats obtenus montrent, qu'en fait, peu de plastisols, préparés à température ambiante, conduisent à des milieux homogènes permettant la réalisation d'électrodes sélectives aux surfactifs cationiques possédant une pente nernstienne. Les meilleurs résultants sont toujours obtenus avec les gels les plus riches en plastifiant (60–80%), dans des zones de composition où le support présente des propriétés proches de celles des membranes liquides. Dès que l'on enrichit le milieu en po-

For personal use only.

lymère, on crée des défauts dans la membrane par lesquels vont pouvoir diffuser les ions. La membrane perd alors sa sélectivité assurée par le transporteur.

Les caractéristiques des électrodes obtenues avec les différents plastisols montrent que l'emploi du PVC-bpm est intéressant. Ce polymère permet de réaliser des membranes homogènes possédant d'excellentes réponses sélectives aux ions amphiphiles, dans des domaines de composition en plastifiant beaucoup plus larges que ceux permis par le PVC-hpm. En particulier, les mélanges PVC-bpm–DNP constituent un bon choix.

Cette étude élargit ainsi grandement les possibilités d'utilisation des plastisols pour la réalisation d'électrodes membranaires sélectives.

Characterization of the 2,2′-bipyridine chelates of lanthanum(III) in acetonitrile. A ^{1}H, ^{13}C, ^{17}O, and ^{139}La NMR study

MONIQUE FRÉCHETTE

Ottawa–Carleton Chemistry Institute, University of Ottawa Campus, Ottawa, Ont., Canada K1N 6N5

Received July 7, 1992

MONIQUE FRÉCHETTE. Can. J. Chem. **71**, 377 (1993).

We have investigated the reaction between $La(NO_3)_3 \cdot 6H_2O$ and 2,2′-bipyridine (bipy) in acetonitrile by means of ^{139}La, ^{17}O, ^{13}C, and ^{1}H NMR spectroscopy. The ^{139}La spectra show up to three different sites with variable intensities attributed to solvated La(III) ions and to two complex species with one or two bipy moieties in the La(III) coordination sphere. ^{17}O NMR indicates that during the complexation reaction, the coordinated water is totally displaced from the coordination sphere whereas the nitrate groups remain coordinated. Proton NMR data confirm the water expulsion. In addition, the proton chemical shifts of bipy, in comparison with the ^{13}C NMR data, clearly show an anisotropic shielding when two bipy are coordinated to La(III). Therefore, the two bipy molecules are in close proximity in the coordination sphere. From the NMR results it has been shown that, during the complexation process, five different La(III) species are formed: $[La(NO_3)_3(CH_3CN)_4]$, $[La(NO_3)_3(CH_3CN)_3(H_2O)]$, $[La(NO_3)_3(bipy)(CH_3CN)_2]$, $[La(NO_3)_3(bipy)(CH_3CN)(H_2O)]$, and $[La(NO_3)_3(bipy)_2]$. Each La(III) complex has a coordination member of 10, with NO_3^- and bipy acting as chelating ligands. Furthermore, the structure of the $La(NO_3)_3(bipy)_2$ complex in solution shows similarities with the solid state compound. Finally, comparisons are made with the La(III) complexes previously obtained with 1,10-phenanthroline.

MONIQUE FRÉCHETTE. Can. J. Chem. **71**, 377 (1993).

On a étudié par RMN du ^{139}La, ^{17}O, ^{13}C et ^{1}H la réaction entre $La(NO_3)_3 \cdot 6H_2O$ et la bipyridine-2,2′ (bipy) en milieu acétonitrile. Les spectres de ^{139}La indiquent la présence de trois sites différents dont les intensités varient avec des quantités croissantes de bipy. Ces sites correspondent aux ions solvatés La(III) ainsi qu'à deux espèces complexes avec une et deux molécules de bipy appartenant à la sphère de coordination du La(III). La RMN de ^{17}O montre que l'eau initialement coordinée aux ions La(III) est complètement expulsée lors de la complexation alors que les nitrates restent coordinés. La RMN du proton confirme l'expulsion de l'eau et indique la présence d'une contribution anisotropique lorsque deux bipy sont coordinées; les deux molécules de bipy sont donc à proximité dans la sphère de coordination. En combinant l'ensemble des résultats de RMN, on a pu démontrer que cinq espèces différentes de La(III) sont formées : $[La(NO_3)_3(CH_3CN)_4]$, $[La(NO_3)_3(CH_3CN)_3(H_2O)]$, $[La(NO_3)_3(bipy)(CH_3CN)_2]$, $[La(NO_3)_3(bipy)(CH_3CN)(H_2O)]$ et $[La(NO_3)_3(bipy)_2]$. Chaque ion La(III) a une coordination de 10 avec NO_3^- et bipy agissant comme ligands chélatants. De plus, la structure du complexe $La(NO_3)_3(bipy)_2$ en solution montre des similarités avec le complexe isolé à l'état solide. Enfin, des comparaisons sont faites avec les complexes des ions La(III) précédemment obtenus avec la phénanthroline-1,10.

Introduction

The existence of stable lanthanide(III) complexes, having only nitrogens as coordinating centers, was proved previously (1–3). Such complexes were observed with macrocyclic N-donor ligands (3, 4) and aliphatic amines (5–8), as well as with aromatic and heterocyclic amines (9–11) in organic solvents of low donicity number. In these media, the competing strength of the solvent molecules for the coordination sites on the Ln(III) ions is significantly decreased in comparison with water or other highly basic solvents, improving the chances for the formation of the corresponding amino complexes.

Although the choice of the solvent plays a crucial role in the amino complex stabilization, the type of anion associated with the Ln(III) ions also has a decisive effect on the stability and stoichiometric composition of the resulting amino complexes. Anions can form, to varying degrees, inner sphere complexes with the Ln(III) ions and then act as additional competitors (2, 6, 12, 13).

In a stepwise attempt to characterize and understand the amino Ln(III) complexes in solution, we recently reported a multi-NMR analysis that successfully gave structural and thermodynamic information about the mono- and bis-phen complexes obtained from the reaction of $La(NO_3)_3 \cdot 6H_2O$ and 1,10-phenanthroline (phen) in CH_3CN (14). In the present paper, 2,2′-bipyridine (bipy) is used instead of phen in the complexation reaction. Bipy has a more flexible structure than phen with the possibility that the two pyridyl rings rotate along the C(2)—C(2′) bond. Therefore, interesting differences in the complex stability and in the stoichiometric composition of the species present in solution can be observed.

Until now, nothing has been reported about the bipy complexes of La(III) in solution and only a little is known about the bipy complexes of some other rare earths in water and methanol (15, 16). The solid bipy complexes have been investigated a little more fully. The mixed $La(NO_3)_3(bipy)_2$ crystal was fully studied by Al-Karaghouli and Wood (17), and Sinha characterized some bipy complexes of rare earths from their infrared, fluorescence, and reflection spectra (18, 19).

In the course of this investigation, the ^{139}La, ^{17}O, ^{13}C, and ^{1}H NMR properties of CH_3CN solutions containing bipy and $La(NO_3)_3 \cdot 6H_2O$ are reported and analyzed. The nature of the interactions between the La(III) ions and the various potentially coordinating compounds in solution are discussed and compared with those recently obtained for the phen complexes of La(III) in the same medium (14).

Experimental section

Materials and samples

$La(NO_3)_3 \cdot 6H_2O$ (Aldrich, 99.99%) was kept in a desiccator over Drierite and used as received. 2,2′-Bipyridine (Aldrich, 99+%) was recrystallized in hexane, vaccum dried (44°C) over P_2O_5 for at least

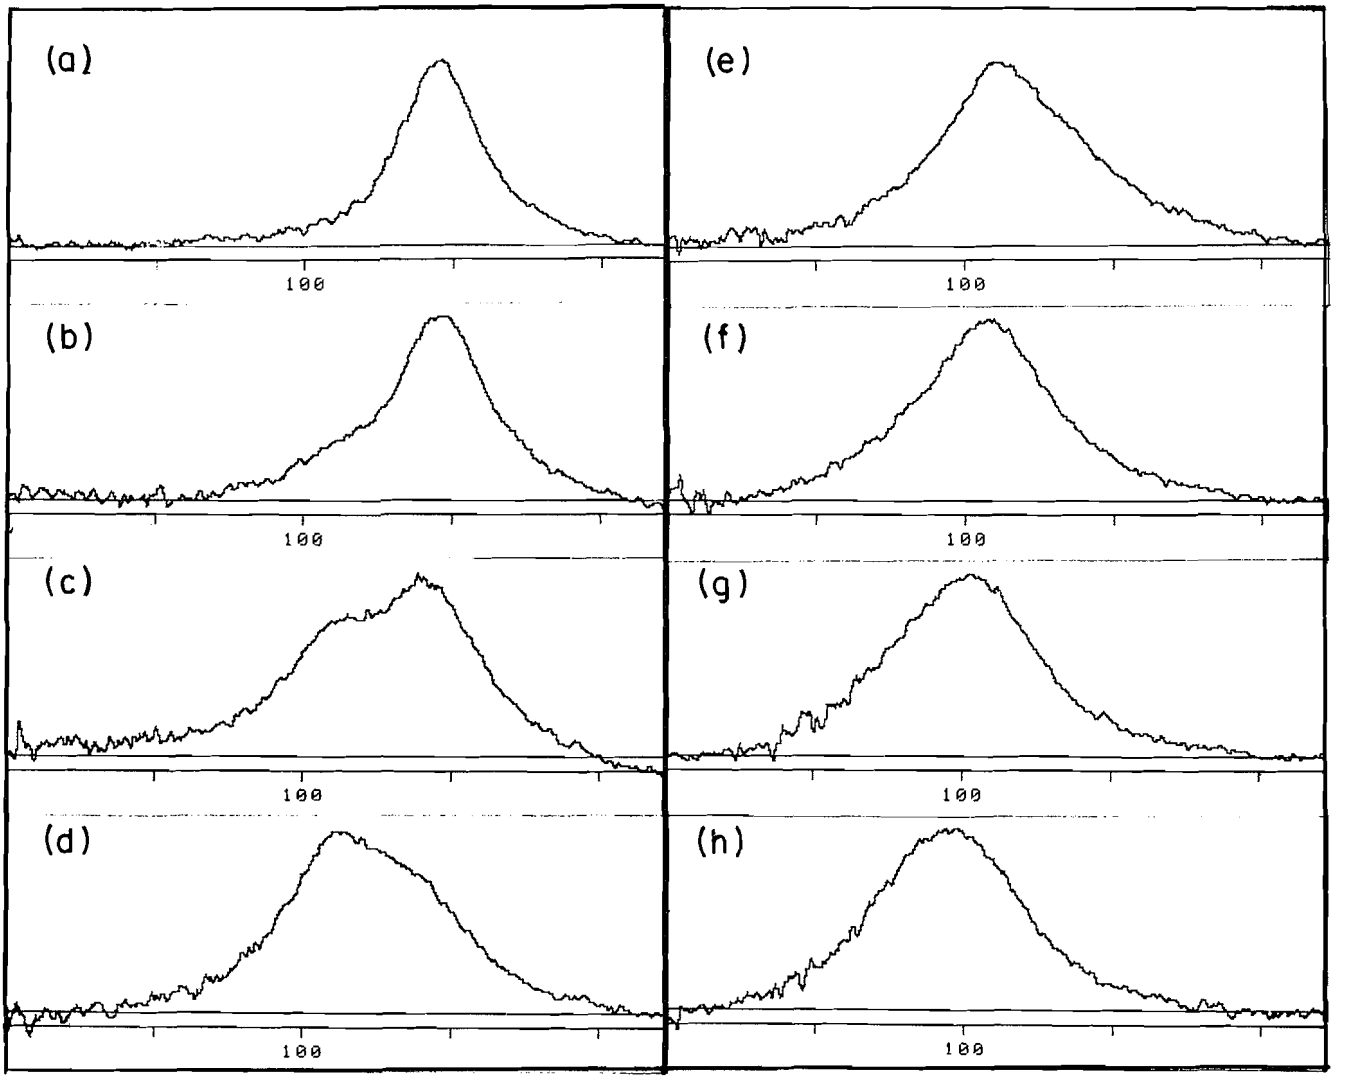

FIG. 1. ^{139}La NMR spectra, at 42.37 MHz, of $La(NO_3)_3 \cdot 6H_2O$ in CH_3CN in the presence of increasing concentration of bipy; $\rho = [bipy]_0/[La(III)]_0$ with $[La(III)]_0 = 5.14 \times 10^{-3}$ M. (*a*) $\rho = 0$, (*b*) $\rho = 0.25$, (*c*) $\rho = 0.50$, (*d*) $\rho = 0.75$, (*e*) $\rho = 1.01$, (*f*) $\rho = 1.26$, (*g*) $\rho = 1.51$, (*h*) $\rho = 1.76$.

20 h, and kept in a desiccator over Drierite. Acetonitrile (CH_3CN) (BDH) was dried as previously described (14). Acetonitrile-d_3 (Aldrich, 99% D) was used as received.

The NMR samples were prepared as previously reported (14). Most of the spectra recorded were of freshly prepared samples because precipitation occurred on standing, especially if $\rho = [bipy]_0/[La(III)]_0 > 1.0$.

NMR measurements

^{139}La, ^{17}O, ^{13}C, and ^1H NMR spectra were recorded at 25.0 ± 0.5°C on a Varian XL-300 spectrometer using resonance frequencies of 42.37, 40.66, 75.43, and 299.94 MHz, respectively. No lock was used (except for proton NMR), the field drift being negligible. The experimental conditions and references used were fully described in a previous paper (14).

The ^{139}La spectral lineshapes, showing the superposition of two or three Lorentzian signals, were decomposed by using a curve-fitting program. From 22 different NMR samples, 35 La NMR spectra were recorded and 62 decompositions were performed. Intensities (I), linewidths ($\upsilon_{1/2}$), and chemical shifts (δ) characterizing the decomposed Lorentzian lines were also derived from that analysis. Because of residual baseline distortions and large linewidth values, non-negligible errors are associated with the I, $\upsilon_{1/2}$, and δ values. Indeed, it was observed that small variations in the phase parameters LP and RP led in some cases to dramatic changes in I, $\upsilon_{1/2}$, and δ even if very good curve fittings were obtained.

The ^{17}O NMR nitrate signal of the $La(NO_3)_3 \cdot 6H_2O$ solutions was only visible at higher concentrations after overnight accumulations. The nitrate resonance of the CH_3CN solutions saturated with KNO_3 and NH_4NO_3 needed at least 36 h to be observable.

Results

^{139}La NMR data

The ^{139}La NMR spectra of $La(NO_3)_3 \cdot 6H_2O$ in CH_3CN were recorded in the presence of increasing amounts of bipy so that $0 < \rho = [bipy]_0/[La(III)]_0 < 1.8$ with $[La(III)]_0 = 5.14 \times 10^{-3}$ M (see Fig. 1). In the presence of bipy, the ^{139}La NMR spectra of the solutions show a single Lorentzian line characterized by a chemical shift (δ) of 9 ± 2 ppm and a linewidth value ($\upsilon_{1/2}$) of 2.75 ± 0.10 kHz, in excellent agreement with the values previously reported (14).

In adding bipy to the La(III) solutions, the ^{139}La spectral lineshapes first show an additional site appearing downfield (82 ± 6 ppm) and associated with the 1:1 complex formation, $La(bipy)^{3+}$ (s) ($\rho < 0.75$). Then for larger bipy concentrations ($\rho > 0.88$), the ^{139}La spectra clearly indicate

steadily faster exchange conditions and the presence of a third ^{139}La site, again more downfield (150 ppm). The result is increasingly broad and deshielded non-Lorentzian spectral lines. Finally for ρ = 1.76, the ^{139}La resonances merge in a Lorentzian signal whose corresponding chemical shift is 110 ppm. This signal appears at a weight-averaged position between the δ values characterizing $La(bipy)^{3+}$ (s) and $La(bipy)^{3+}$ (s).

The ^{139}La NMR lineshapes resulting from the overlap of two or three Lorentzian signals were decomposed by using a curve-fitting program in order to find out the respective spectral contributions and characteristics of each species. Although large errors are possible, particularly regarding the intensities (*I*) and linewidths ($\upsilon_{1/2}$) (see experimental part), fair chemical shift values (δ) were obtained. Data are summarized in Table 1.

^{17}O NMR data

The ^{17}O NMR spectra of 5.24×10^{-3} M and 2.62×10^{-2} M $La(NO_3)_3 \cdot 6H_2O$ in CH_3CN were recorded with increasing concentrations of bipy. As $[bipy]_0$ increases, the water peak appears as a well-resolved triplet (20) steadily resonating at lower frequencies and gradually drawing nearer to the chemical shift of free water in CH_3CN (Fig. 2). This behaviour clearly indicates the presence of free and coordinated water in solution under fast exchange conditions according to the ^{17}O NMR time scale. Data also show that coordinated water is expelled from the coordination sphere of La(III) during the complexation.

The ^{17}O NMR spectra of 2.62×10^{-2} M $La(NO_3)_3 \cdot 6H_2O$ solutions in CH_3CN also show a broad signal associated with the NO_3^- resonance. Its chemical shift and linewidth of 426 ± 2 ppm and 1.3 ± 0.2 kHz, respectively, remain unchanged with the addition of bipy, indicating no change in the nature of the interactions of the NO_3^- species in the medium. Comparison with the ^{17}O NMR properties of free NO_3^- obtained from saturated solutions of KNO_3 and NH_4NO_3 in CH_3CN (see Table 2) reveals identical chemical shift values (426 ± 3 ppm) for both the coordinated and free NO_3^- species. However, a much narrower linewidth value (0.15 kHz instead of 1.3 kHz) is associated with free NO_3^- (Table 2). This linewidth difference does indicate that the three nitrate groups are initially coordinated to La(III) and are not displaced during the complexation with bipy.

No nitrate NMR signal was observable with the 5.24×10^{-3} M $La(NO_3)_3 \cdot 6H_2O$ solutions after an overnight accumulation due to the low natural abundance of ^{17}O and the large NO_3^- linewidth.

^{13}C NMR data

The ^{13}C NMR spectra of 1.26×10^{-2} M bipy solutions were recorded with increasing concentrations of $La(NO_3)_3 \cdot 6H_2O$ in CH_3CN so that $R = [La(III)]_0/[bipy]_0 < 3.7$. All ^{13}C NMR spectra consist, as expected, of five resonance lines whose observed chemical shift (δ) results from fast exchange conditions on the ^{13}C NMR time scale. The carbon assignment is in agreement with the study of Marker *et al.* (21).

The variation of the ^{13}C chemical shifts as a function of *R* (Fig. 3) indicates the formation of $La(bipy)_2^{3+}$ (s) because of plateaus when $R = 0.5$. For $R > 0.5$, no additional ^{13}C NMR shifts were observed, indicating the absence of additional bipy sites. However, the ^{139}La NMR data clearly show the formation of $La(bipy)^{3+}$ (s). Consequently, we do con-

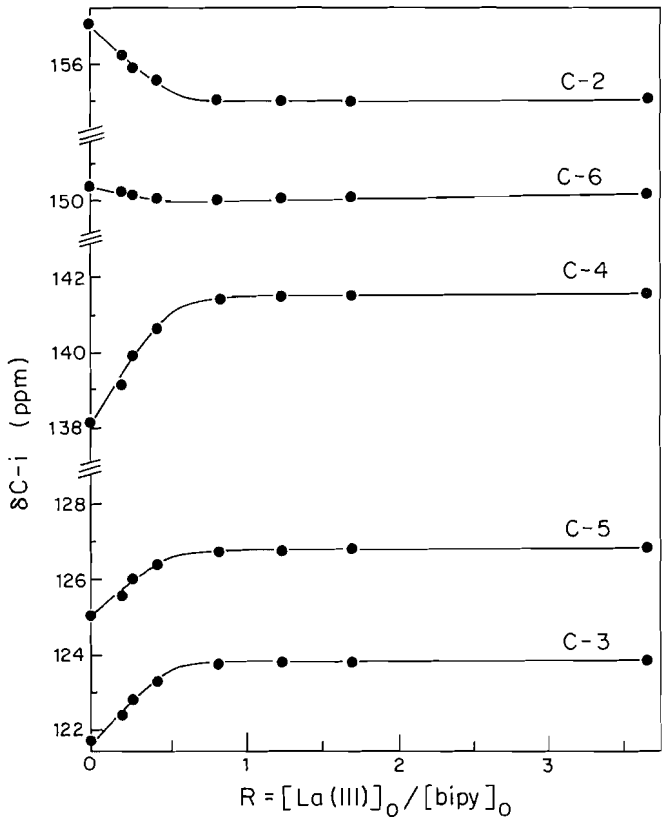

FIG. 3. ^{13}C NMR chemical shifts of bipy in CH_3CN in the presence of increasing concentration of $La(NO_3)_3 \cdot 6H_2O$. $R = [La(III)]_0/[bipy]_0$ with $[bipy]_0 = 1.27 \times 10^{-2}$ M.

clude that the chemical shifts of the coordinated bipy in both $La(bipy)^{3+}$ (s) and $La(bipy)_2^{3+}$ (s) are identical. Similar behaviour was previously observed for the complexation of La(III) with phen under identical experimental conditions (14). The ^{13}C NMR spectral data of free and coordinated bipy are summarized in Table 3.

^1H NMR data

Figure 4 shows the ^1H NMR chemical shifts of bipy (2.63×10^{-3} M) (δH_i) and H_2O) (δH_2O) in CD_3CN in the presence of increasing amounts of $La(NO_3)_3 \cdot 6H_2O$ so that $R < 4.0$. Our proton assignment for the uncomplexed bipy agrees with literature data (22). Both bipy and H_2O are in fast exchange on the ^1H NMR time scale so that their observed δ values appear at weight-averaged positions between those characterizing the free and coordinated ligands.

For $0 < R < 0.4$, the $La(bipy)_2^{3+}$ (s) complex is exclusively present and water-free. Indeed, δH_2O is constant at 2.22 ± 0.01 ppm and very close to the value obtained for the residual H_2O ($H_2O(f)$) in the bipy solution for which $R = 0$ and $\delta H_2O(f) = 2.21$ ppm. For $R > 0.4$, δH_2O appears increasingly downfield, in agreement with the formation of $La(bipy)^{3+}$ (s) and La^{3+} (s), which both have coordinated H_2O.

The ^1H NMR titration curves of bipy with increasing La(III) concentrations differ greatly from the corresponding ^{13}C NMR curves. The ^1H NMR curves, especially those of H-3, H-4, and H-5, reach a plateau around $R = 1.0$ rather than for $R = 0.5$ as observed by ^{13}C NMR, suggesting that only the $La(bipy)^{3+}$ (s) species is formed. For H-6, the sigmoid titration curve can only be explained by the successive formation of $La(bipy)_2^{3+}$ (s) and $La(bipy)^{3+}$ (s) if different δH_i values characterized the coordinated bipy in each complex.

[a]Chemical shifts: deviation better than ±0.03 ppm.
[b]The chemical shifts of complexed bipy in the 1:1 and 1:2 complexes are undistinguishable.

The differences between the ^{13}C and ^1H titration curves are attributed to an anisotropic contribution that is only experimentally observable by using ^1H NMR. Indeed, as previously reported for the complexation of La(III) with phen (14), Ru(II) with polypyridines (23), and Ln(III) with alkyl-substituted bipyridines (24), the protons of bipy in the 1:2 complex can interact with the aromatic system of the other coordinated bipy. These interactions are a source of high-field shift and when present, as suspected here in $La(bipy)_2^{3+}$ (s), lead to lower δH_i values. Consequently, the ^1H NMR titration curves show various patterns that depend on the magnitude of these anisotropic contributions as well as on the magnitude of the coordination shifts.

The δH_i values for free bipy and coordinated bipy in $La(bipy)^{3+}$ (s), $\delta H_i(f)$ and $\delta H_i(1:1)$, respectively, were determined from the titration curves for $R = 0$ and for $R > 2.0$. δH_i of bipy in $La(bipy)_2^{3+}$ (s), $\delta H_i(1:2)$, were calculated from eq. [1] for $R = 0.156$ and 0.312 because, according to the δH_2O values, only the uncomplexed bipy and the $La(bipy)_2^{3+}$ (s) species are present in solution.

$$[1] \quad \delta H_i = X(1:2)\delta H_i(1:2) + X(f)\delta H_i(f)$$

$X(1:2)$ and $X(f)$ are, respectively, the populations of the coordinated and free bipy. Then, the anisotropic contributions, σ(ani), were estimated from eq. [2].

$$[2] \quad \sigma_i(ani) = \delta H_i(1:2) - \delta H_i(1:1)$$

These ^1H NMR data are given in Table 3.

Discussion

The ^{139}La NMR data (Table 1) indicate a constant downfield shift of 70 ppm for each bipy molecule added in the coordination sphere of La(III). As suggested in previous work (14, 25, 26), such steady chemical shift variations are observed when the same molecules are expelled from the co-

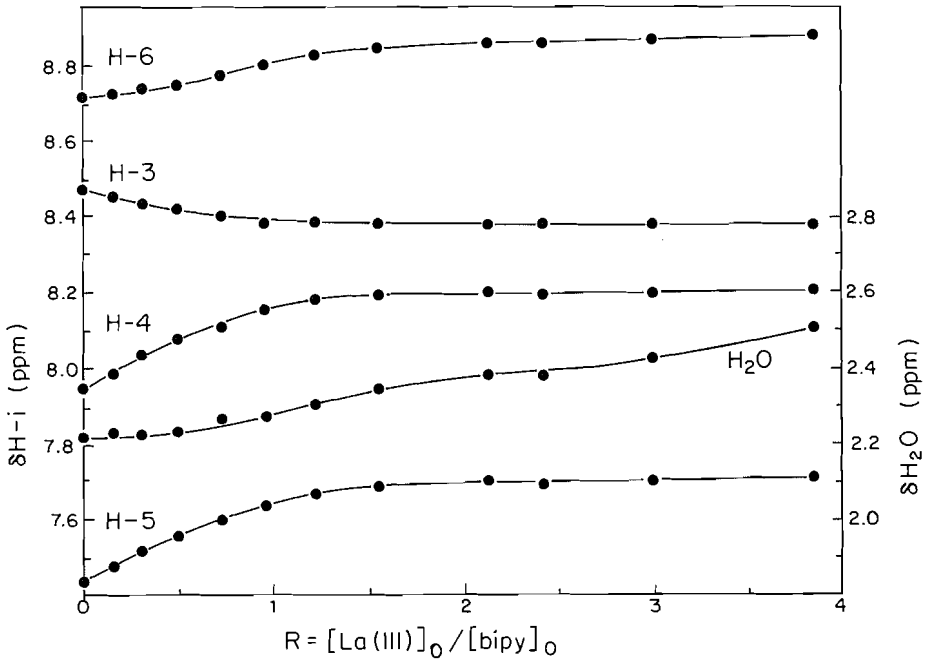

FIG. 4. ^{1}H NMR chemical shifts of bipy and H_2O in CH_3CN in the presence of increasing concentration of $La(NO_3)_3 \cdot 6H_2O$. R = $[La(III)]_0/[bipy]_0$ with $[bipy]_0 = 2.63 \times 10^{-3}$ M.

ordination sphere of La(III) with successive additions of the new ligand. In the present case, CH_3CN and H_2O are the species simultaneously expelled from the coordination sphere of La(III) as a result of the addition of bipy.

The constant downfield shift variation suggests that the coordination number of the La(III) species remains unchanged during the course of the complexation. This is hypothesized according to a study of Evans and Missen (26) that reported a dramatic break in the direction of the ^{139}La chemical shift variation when increasing amounts NO_3^- were added to $La(ClO_4)_3$ in CH_3CN. The break, which occurred with the addition of 4 to 5 NO_3^- molecules, was attributed to a change in the coordination number (C.N.) of La(III), the small size of NO_3^- favouring a higher C.N. value. No such variations are usually observed when C.N. is supposedly unchanged, as clearly indicated by the stepwise addition of H_2O, ethylenediamine, and diethylenetriamine to $La(ClO_4)_3$ solutions in CH_3CN (26).

The results reported in Table 1 also show a marked similarity between the ^{139}La chemical shifts of the bipy complexes of La(III) with those obtained with phen under the same experimental conditions. This similarity strongly suggests that the nature of the interactions between La(III) and the ligand as well as the stoichiometry of the La(III) species are identical with both bipy and phen.

The $\upsilon_{1/2}$ values reported for the bipy complexes of La(III) are quite large in comparison to the corresponding values reported for the phen chelates. Indeed, the similarity of the phen and bipy complexes in solution and in the solid state (14, 17) suggests that the $\upsilon_{1/2}$ values should decrease with the successive complexation of La(III) with bipy, resulting in greater electronic symmetries at the ^{139}La nuclei (14). Considering the present results, the anticipated decrease in the $\upsilon_{1/2}$ values may be obscured by the line broadening contribution, which is a result of the moderate exchange rate of the bipy moieties between the different ^{139}La sites.

The ^{17}O chemical shifts of the free and coordinated NO_3^- are very similar (426 ± 2 ppm). However, their respective $\upsilon_{1/2}$ values are adequate indicators of the behaviour of the NO_3^- counterions during the complexation process. The linewidth values of NO_3^- remain constant at 1.3 ± 0.2 kHz, but are much broader than the corresponding $\upsilon_{1/2}$ value characterizing the free NO_3^- (0.15 ± 0.01 kHz). Therefore we must conclude that the three nitrate groups remain coordinated to La(III) all along the complexation. The presence of the three NO_3^- groups in the La(III) coordination sphere is in agreement with the ^{139}La NMR study of Evans and Missen (26) and the calorimetric works of Forsberg and co-workers using more basic N-donor chelating ligands (6–8).

In comparison to NO_3^-, the H_2O initially coordinated to La(III) is expelled with the addition of bipy. The amount of coordinated water should be very low because in quintupling $[La(III)]_0$ (see Table 2), the ^{17}O chemical shift of water is dramatically changed. According to the thermodynamics of equilibrium, this important variation of the water chemical shifts can only occur if less than one molecule of water is coordinated. This low content in coordinated H_2O has been mathematically proved and will be reported in another paper[1] (the populations of La(III) ions having coordinated water are 24 ± 6% and 60 ± 13% if $[La(III)]_0$ are 5.24×10^{-3} M and 2.62×10^{-3} M, respectively).

When bipy is added to the La(III) solution, the water expulsion causes decreases in the H_2O resonating frequency. For ρ values higher than 1.3, data indicate that some water is still coordinated (see Fig. 2). Therefore the inner coordination sphere of $La(bipy)^{3+}$ (s) must contain coordinated water as well because no more uncomplexed La(III) ions are present in these solutions according to the ^{139}La NMR data. Finally, the $La(bipy)_2^{3+}$ (s) species should be water-free be-

cause, in the presence of large quantities of bipy ($\rho = 2.4$), the ^{17}O chemical shift of free water in CH_3CN has almost been reached. Proton NMR data also confirm the water expulsion because for R values lower than 0.4 the ^1H NMR water shift is identical to the chemical shift of residual water in the bipy solution. The complete expulsion of water from the coordination sphere of the La(III) ions when the $La(bipy)_2^{3+}$ (s) species is exclusively present in solution is in agreement with previous results obtained with phen (14) and with the X-ray crystallographic analysis of $La(bipy)_2(NO_3)_3$ (17). Therefore, according to the ^{17}O and ^1H water chemical shifts, the $La(bipy)_2^{3+}$ (s) is anhydrous whereas H_2O is present in both La^{3+} (s) and $La(bipy)^{3+}$ (s).

Results in Table 2 also show discrepancies of 0.87 and 0.72 ppm between the chemical shift of water dissolved in acetonitrile and the values obtained from the saturated solutions of NH_4NO_3 and KNO_3, respectively. These discrepancies are a likely result of specific interactions between H_2O and NO_3^-, K^+, or NH_4^+.

A description of the La(III) species present in solution during the complexation process is possible by using a combination of the ^{139}La and ^{17}O NMR data.

We confirm the existence of the water-free bis(bipy)La(III) species as $[La(NO_3)_3(bipy)_2]$. The coordination number is 10 with two chelating bipy and three bidentate NO_3^-, just as found for the crystalline complex (17). The main evidence for a C.N. of 10 is (1) the high similarity between the bis(bipy) complex in solution and in the solid state, and (2) the constant downfield shift variation of the ^{139}La NMR signals, with the addition of each bipy then suggesting no variation of the C.N. value. Although the expulsion of H_2O has been proved by ^{17}O and ^1H NMR data, no direct information was obtained for the expulsion of CH_3CN. However, because H_2O is a very good competitor with respect to CH_3CN (despite the huge difference in their concentrations) and because the bis(bipy)La(III) complex is water-free, the CH_3CN molecules should also be absent from the La(III) coordination sphere.

The two other species, La^{3+} (s) and $La(bipy)^{3+}$ (s), are better described by an equilibrium between an aquo and a water-free species because of the low degree of participation of water in the inner sphere of La(III). For each species, the coordination number should be 10 because no change in the C.N. value is expected according to the ^{139}La NMR results. Therefore, because the three NO_3^- are also coordinated, the resulting molecular formulae are $[La(NO_3)_3(CH_3CN)_4]$ in equilibrium with $[La(NO_3)_3(CH_3CN)_3(H_2O)]$ for La^{3+} (s), and $[La(NO_3)_3(bipy)(CH_3CN)_2]$ in equilibrium with $[La(NO_3)_3(bipy)(CH_3CN)(H_2O)]$ for $La(bipy)^{3+}$ (s).

The ^{13}C NMR data do not allow the differentiation of bipy in the 1:1 and 1:2 complexes and only show two different bipy sites associated with the free and coordinated bipy. In comparison, ^1H NMR data are more sensitive to the molecular structures of the La(III) species, and bipy in the 1:1 and 1:2 complexes can be differentiated. Bipy in the 1:1 complex is not subject to special perturbing influences other than the deshielding (shielding for H-3) expected from the electron-withdrawing inductive effect of coordination. However, protons of bipy in the 1:2 complex are subject to an additional high-field shift caused by interaction of its protons with the aromatic system of the other coordinated bipy. Consequently, information about the three-dimensional structure of the chelates can be obtained from ^1H NMR data.

If it is assumed that a similar structure is adopted by $[La(NO_3)_3(bipy)]_2$ in solution and in the solid state (17), the two halves of the bipy ligand are not magnetically equivalent. One pyridine ring is influenced by the adjacent bipy moieties due to the partial superposition of two bipy while the other pyridine only behaves as in $La(bipy)^{3+}$ (s). According to our ^1H NMR data in solution, we do have an anisotropic contribution but no inequivalence of the proton resonance is observed. This suggests an intramolecular configurational equilibrium between a species, analogous to that depicted for $[La(NO_3)_3(bipy)_2]$ in the solid state (17) and its mirror image. The inequivalence should be associated with a rapid exchange of configuration as previously reported for the alkyl-substituted bipyridine complexes of lanthanides (24). According to these facts, we believe that the three-dimensional structures of the 1:2 complex in solution and in the solid state are very close, in agreement with the results previously reported for $[La(NO_3)_3(phen)_2]$ (14).

Because of large errors in the determination of the populations of the La(III) species from the ^{139}La NMR spectra, the apparent constants of stability of the $La(bipy)^{3+}$ (s) and $La(bipy)_2^{3+}$ (s) complexes were not calculated. However, the general trend of the results indicates that these complex species are slightly less stable than the corresponding La–phen complexes (14). Furthermore, results clearly indicate that the bipy moieties are exchanged more rapidly than are the phen from one ^{139}La site to another.

In conclusion, the present results demonstrate the efficiency with which a multi-NMR analysis can establish the behaviour of chelates towards La(III) ions in solution. This multi-NMR study not only indicated the presence of interactions between La(III) and bipy but also provided the number and type of coordinates as well as the possible molecular geometry. Obviously, many more different La(III) species were identified in solution than those isolated in the solid state. Further work is presently in progress in the hope of collecting data with different nitrogen donor ligands that are potentially able to displace the nitrate groups from the coordination sphere and to change the coordination number.

Activity coefficients of $NaNO_3$ in (Mg, Ca, Sr, and Ba)$(NO_3)_2$ + H_2O systems at 298 K by EMF methods

STEPHEN N. SMITH, S. SARADA,[2] AND RAMAMURTHY PALEPU[1]

Department of Chemistry, University College of Cape Breton, Sydney, N.S., Canada B1P 6L2

Received September 3, 1992

STEPHEN N. SMITH, S. SARADA, and RAMAMURTHY PALEPU. Can. J. Chem. **71**, 384 (1993).

The activity coefficients of $NaNO_3$ in $Mg(NO_3)_2$, $Ca(NO_3)_2$, $Sr(NO_3)_2$, and Ba $(NO_3)_2$ were determined at constant total ionic strength of 0.1, 0.5, 0.75, 1.0, 1.5, and 2.0 mol kg^{-1} at 298 K using EMF methods. The experimental activity coefficients were analyzed using four different formalisms, namely, Reilly–Wood–Robinson, Scatchard, Pitzer, and Harned equations, and the interaction parameters were evaluated. Excess Gibbs free energy of mixing and trace activity coefficients were calculated and the results are discussed.

STEPHEN N. SMITH, S. SARADA et RAMAMURTHY PALEPU. Can. J. Chem. **71**, 384 (1993).

Opérant à 298 K, et faisant appel à des méthodes de FÉM, on a déterminé les coefficients d'activité du $NaNO_3$ dans les sels suivants : $Mg(NO_3)_2$, $Ca(NO_3)_2$, $Sr(NO_3)_2$ et $Ba(NO_3)_2$ à des forces ioniques totales constantes de 0,1, 0,5, 0,75,1,0, 1,5 et 2,0 mol kg^{-1}. On a analysé les coefficients d'activité expérimentaux à l'aide de quatre formalismes, soit les équations de Reilly–Wood–Robinson, Scatchard, Pitzer et Harned et on a évalué les paramètres d'interaction. On a calculé l'énergie libre de mélange de Gibbs en excès et les coefficients d'activité de trace et on discute des résultats.

Thermodynamic properties of multicomponent electrolyte mixtures in water have received considerable attention in the literature (1–5). Such solutions are found to be important in various geological, biological, and industrial processes. Knowledge of the value of the activity coefficient of each component in the mixture is essential. Ion selective electrodes (ISE) have been used extensively in the determination of activity coefficients of multicomponent electrolyte systems (6). However, very few studies have been made using the ion-exchange base nitrate ISE in the determination of activity coefficients (7). In the present study, the activity coefficients of $NaNO_3$ in ternary mixtures of $NaNO_3$ + $M(NO_3)_2$ + H_2O where M = Mg, Ca, Sr, and Ba were determined at 298 K and total ionic strengths of 0.1, 0.5, 1.0, 1.5, and 2.0 molal.

Experimental

Analytical grades of sodium, calcium, magnesium, strontium, and barium nitrates (either Baker Analyzed or B.D.H.) were used without further purification. All solutions were prepared by using distilled water that was passed through a NANO pure (Barnstead) ion-exchange apparatus.

The cell used consisted of a Ross sodium glass ISE (model 84-11) and an Orion nitrate ion-exchange ISE (model 93-07) immersed in a mixture of $NaNO_3$ and $M(NO_3)_2$ solution in a double-walled cell. The solutions were stirred at a constant rate with an air-driven magnetic stirrer and the temperature was maintained at 25.0 ± 0.1°C. The cell arrangement is as follows:

Na ion selective electrode	$NaNO_3$ (m_A) + $M(NO_3)_2$ (m_B)	NO_3 ion selective electrode

where m_A and m_B are the molalities of $NaNO_3$ and $M(NO_3)_2$ solutions, respectively. The emf values were recorded using an Accumet 925 pH meter (Fisher) after adding aliquots of m_B to m_A or vice versa at regular intervals. The accuracy of the emf measurements was ±0.1 mV. The potential of the cell was observed to be stable to within ±0.5 mV for periods of time from 0.5 to 1 h. A titration procedure was used to alter the composition of the mixture, so that the cell was undisturbed during the experimentation. Two sets of potential measurements were made at each ionic strength to test the reproducibility and accuracy of the measurements. In the first set, the potentials were measured by taking a $NaNO_3$ solution and using a $M(NO_3)_2$ solution as titrant, and in the second set the order was reversed. In the central region of composition the two runs overlap and this is used as a test for the reproducibility of the data.

Results and discussion

The potentials of the cell in the $NaNO_3$ + $M(NO_3)_2$ mixtures are described by the equation:

$$[1] \quad E_{cell} = E^0 + K \log [a_{Na} a_{NO_3} + K' a_M^{1/2} a_{NO_3}]$$

where K' is the selectivity coefficient of the Na ISE for M^{2+} ions and K is the Nernstian slope.

At each ionic strength, the emf values of the cell were first measured with pure $NaNO_3$ solution in order to calibrate the electrodes. The values of E^0 and K were determined by plotting the cell emf values against log a_{NaNO_3}. The values of the activity coefficients of $NaNO_3$ were taken from N.B.S. data (8). The emf of pure $M(NO_3)_2$ solutions were then measured to evaluate the selective coefficient (K') values. The values of K' were found to be in the range of 10^{-5}–10^{-4} at all the ionic strengths studied. The term $K'(\sqrt{a_M})a_{NO_3}$ in eq. [1] can be neglected and the equation is modified as follows:

$$[2] \quad E_{cell} = E^0 + K \log [a_{Na} a_{NO_3}]$$

By substituting $m_+\gamma_+$ for a_{Na} and $m_-\gamma_-$ for a_{NO_3}, eq. [2] can be rearranged as follows:

$$[3] \quad \gamma_\pm^2 = \frac{1}{m_{Na} m_{NO_3}} [10^{(E_{cell} - E^0)/K}]$$

The mean activity coefficient values[3] of $NaNO_3$ in the mix-

tures at various ionic strengths were obtained by substituting the values of E_{cell}, E^0, and K into eq. [3]. A typical plot of $\gamma_\pm$ for $NaNO_3$ in $NaNO_3 + Ca(NO_3)_2$ as a function of the ionic strength fraction y_B where

$$[4] \quad y_B = \frac{3m_B}{m_A + 3m_B}$$

is presented in Fig. 1. The activity coefficient data were fitted to the Harned equation (9) in the following form:

$$[5] \quad \log \gamma_A = \log \gamma_A^0 - \alpha_{AB} y_B - \beta_{AB} y_B^2$$

where γ_A^0 is the activity coefficient of pure A at the same ionic strength and α_{AB} and β_{AB} are the Harned coefficients, calculated using regression methods. The values of α_{AB} and β_{AB}, along with the root-mean-square deviations, are listed in Table 1. The fact that quadratic terms are needed to fit the experimental data indicates the importance of cation–cation and ternary interactions.

The activity coefficient data were analyzed further using the following three equations available in the literature: (1) The Reilly, Wood, and Robinson (R.W.R.) treatment (10, 11), which expresses the activity coefficient of $NaNO_3$ in ternary mixtures as

$$[6] \quad \log \gamma_A = \log \gamma_A^0 - \frac{1}{2 \ln 10}[(2\phi_A^0 - \phi_B^0 - 1)y_B - (g_0 I + 2g_1 I^2 + g_0' I^2)y_B + (3g_1 + g_0')I^2 y_B^2]$$

where g_0 is identified with binary interaction parameters and g_0' represents the change in the value of g_0 with ionic strength. (2) The Scatchard equation (12, 13) for the activity coefficients of $NaNO_3$ in $M(NO_3)_2$ solutions can be written as

$$[7] \quad \log \gamma_A = \log \gamma_A^0 + \frac{1}{2 \ln 10}\left[(\phi_B^0 - 2\phi_A^0 + 1)y_B + (b^{0,1} I + b^{0,2} I^2 + b^{0,3} I^3)y_B + (b^{1,2} I^2 + b^{1,3} I^3)y_B - \left(0.5 b^{0,2} I^2 + \left(\frac{2}{3}\right) b^{0,3} I^3\right) y_B^2\right]$$

where $b^{0,1}$ can be identified with interactions between ions of the same charge, and $b^{0,2}$ with the ternary interactions. In the present study the higher order parameters $b^{1,2}$ and $b^{1,3}$ were set equal to zero. The Scatchard equation uses different coefficients of $\sqrt{I}$ to account for the different distances of closest approach for the solute components. (3) The Pitzer treatment (14–16), which contains fewer adjustable parameters even after the inclusion of the higher order interaction terms of E_θ and E_θ'. The relevant Pitzer equation for $\gamma_\pm$ of $NaNO_3$ is given by:

$$[8] \quad \ln \gamma_A = \ln \gamma_A^0 - \frac{4}{3} I y_B B_{NaNO_3} + \frac{I y_B}{3} B_{M(NO_3)_2} + \frac{I^2}{18}(7y_B^2 - 30y_B) C^\phi_{NaNO_3} + \frac{I^2 y_B}{3\sqrt{2}} \frac{(1 - y_B)}{3} C^\phi_{M(NO_3)_2} + \frac{I y_B}{3} \theta_{Na-M} + \frac{I^2 y_B}{3} \frac{(1 - 2y_B)}{3} \Psi_{Na-M-NO_3} + \frac{I^2 y_B}{3}(y_B - 4) B'_{NaNO_3} + \frac{I^2 y_B}{3} \frac{(1 - y_B)}{3} B'_{M(NO_3)_2} + \frac{I^2 y_B}{3}(1 - y_B) \theta'_{Na-M}$$

where $\theta_{NaM} = S_{\theta_{NaM}} + E_\theta$ and $\theta'_{NaM} = E'_{\theta_{NaM}}$. The value of S_θ represents the binary interaction between ions of the same charge,

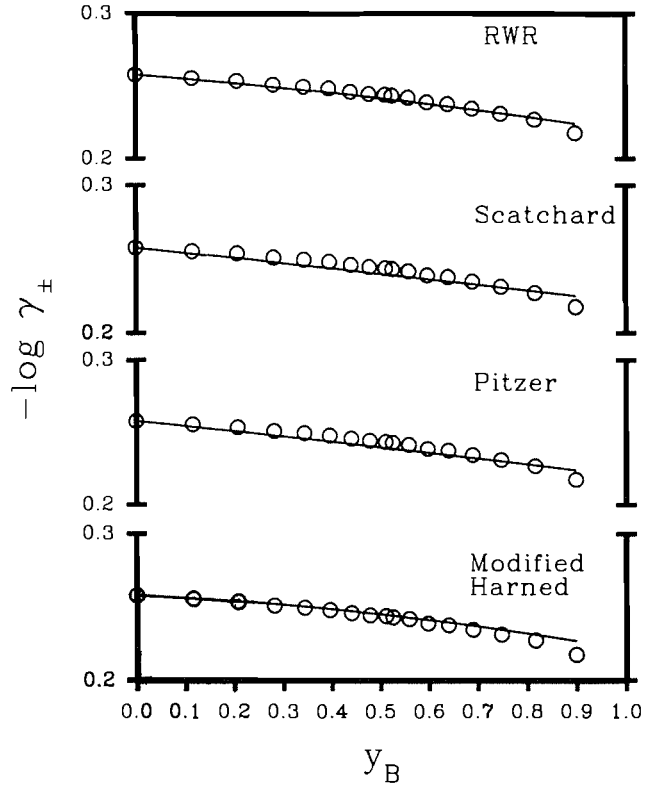

FIG. 2. Plot of log $\gamma_{\pm}$ ($NaNO_3$) vs. y_B at I = 1.0 for ternary mixtures of $NaNO_3$ + $Ca(NO_3)_2$ + H_2O using eqs. [6]–[9].

Ψ represents the ternary interactions, and all other terms have their usual significance. All the data required for the analysis using the Pitzer equation were taken from the work of Kim and Frederick (17).

The experimental activity coefficient data were fitted with a single nonlinear least-squares program and solved for values of the interaction parameters. The interaction parameters along with the RMSD are presented in Table 2. The experimental data were also analyzed using a modified Harned equation of the form (18)

$$[9] \quad \log \gamma_A = \log \gamma_A^0 - \alpha'_{AB} I y_B - \beta'_{AB} I y_B^2$$

The values of α'_{AB} and β'_{AB} are also included in Table 2. The binary interaction parameters $b^{0,1}$, g_0, S_0, and α'_{AB} obtained by solving these equations are of the same sign in all cases except for g_0 in the $NaNO_3$ + $Ba(NO_3)_2$ + H_2O system. In Fig. 2, the experimental activity coefficients of $NaNO_3$ in the mixture $NaNO_3$ + $Ca(NO_3)_2$ + H_2O at I = 1.0 are plotted against y_B and the continuous curves were generated with the

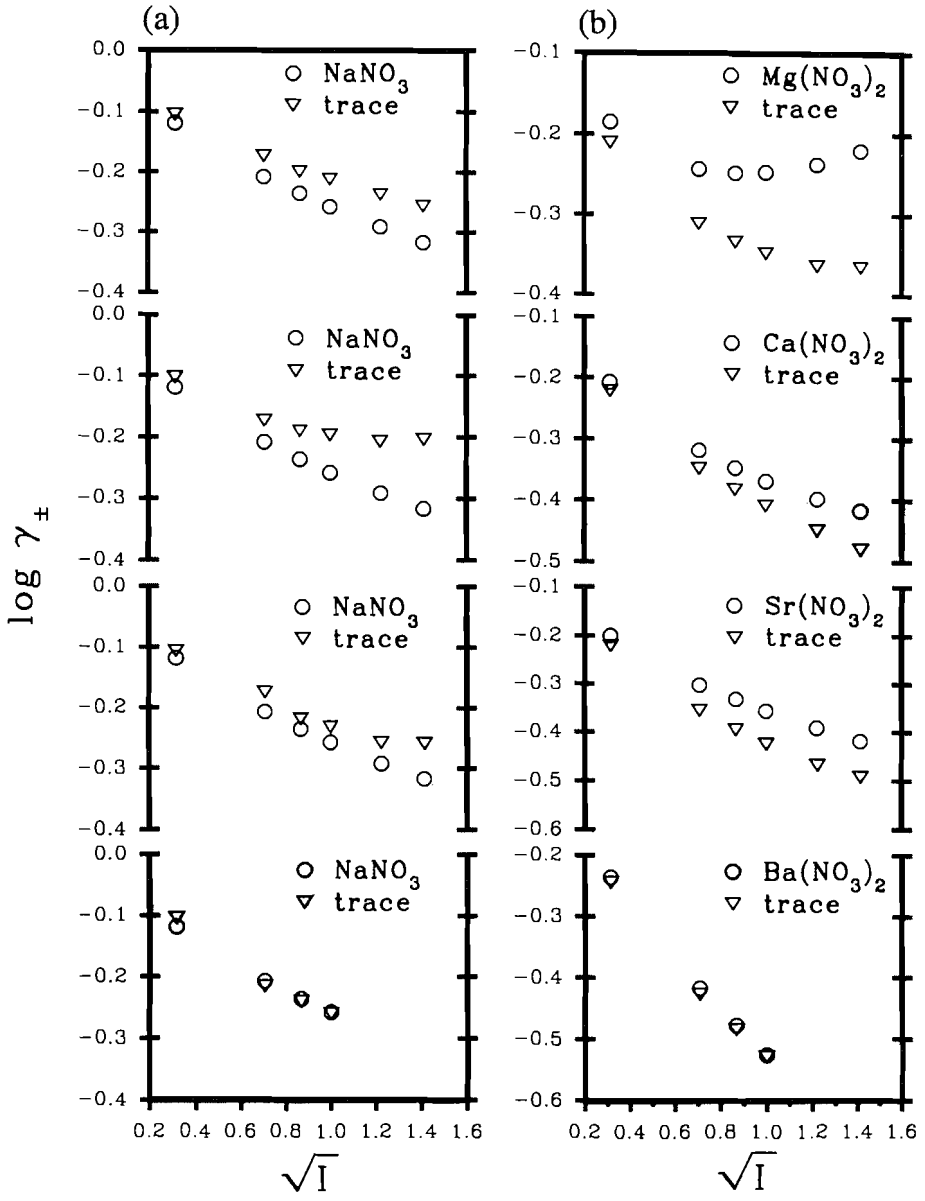

FIG. 4. Plots of log γ^{trace} vs. $\sqrt{I}$. (*a*) $NaNO_3$. (*b*) $M(NO_3)_2$.

aid of the values of the binary coefficients in Table 2. It is apparent that the figure shows good agreement between the R.W.R., Scatchard, Pitzer, and modified Harned treatments and the experimental data. By comparing the coefficients of y_B in the equations of Pitzer, Scatchard, and R.W.R. with the Harned equation, one can calculate α_{AB} and β_{AB} from the values of the interaction parameters in Table 2. The calculated values agree well with the values in Table 1 only at $I \geq 1.5$. At lower ionic strengths the agreement is poor and improves when interaction parameters are obtained by solving these equations individually at each ionic strength.

Values of the Gibbs energy of mixing ($\Delta_m G^E$) were calculated from the experimentally determined activity coefficients and the calculated osmotic coefficients from the Pitzer parameters, using the following equation:

$$[10] \quad \Delta_m G^E = Y_A[\ln(\gamma_A/\gamma_A^0) + (\phi_A - \phi_m)] + Y_B[\ln(\gamma_B/\gamma_B^0) + (\phi_B - \phi_m)]$$

$$[11] \quad Y_A = \nu_A y_A m_A RT \quad \text{and} \quad Y_B = \nu_B y_B m_B RT$$

where ϕ_A and ϕ_B are the osmotic coefficients of the pure components at the same ionic strength as the mixture. The values of ϕ_m and γ_B at various ionic strengths were calculated according to Pitzer equation (14–16). The values of $\Delta_m G^E$ were found to be negative for all the systems except $Ba(NO_3)_2$. Also the values of $\Delta_m G^E$ decrease with increasing ionic strength (Fig. 3*a*) and at a given ionic strength the $\Delta_m G^E$ values varies in the order $Ba(NO_3)_2 > Sr(NO_3)_2 > Ca(NO_3)_2 > Mg(NO_3)_2$ (Fig. 3*b*). The positive $\Delta_m G^E$ on mixing AX and BX_2 solutions implies that replacing A–A and B–B interactions produces an increase in the free energy of the system. This suggests that such replacements will take place less frequently than expected on a purely random basis (19). A negative $\Delta_m G^E$ would require that formation of A–B pairs be more favoured than would be expected from statistical encounters (19). Our results indicate that formation of A–B pairs is definitely favoured at higher ionic

strengths in all the mixtures except for the $Ba(NO_3)_2$ system.

These excess Gibbs energies were fitted to the Friedman (20) equation, which is applicable to a mixture of two electrolytes with a common ion.

$$[12] \quad \Delta_m G^E = I^2 RT y_B (1 - y_B)[g_0 + (1 - 2y_B)g_1]$$

The Friedman coefficients were obtained by solving eq. [12] and the parameters are listed in Table 3. The continuous curves in Figs. 3*a* and *b* were generated with the aid of these parameters. These g_0 and g_1 coefficients represent the changes in the configuration and environments of ion pairs and ion triplets in the solution and are therefore sensitive to both the total salt concentration and composition. As indicated in Fig. 3*a*, $\Delta_m G^E$ changes markedly with ionic strength and this is reflected in the g_0 parameters. All the curves were fairly symmetrical and this is reflected in the g_1 parameter.

The trace activity coefficients of $NaNO_3$ and $M(NO_3)_2$ in the mixtures were calculated using eqs. [13] and [14];

$$[13] \quad \log \gamma^{trace}_{NaNO_3} = \log \gamma^{0}_{NaNO_3} - \alpha_{AB} - \beta_{AB}$$

$$[14] \quad \log \gamma^{trace}_{M(NO_3)_2} = \log \gamma^{0}_{M(NO_3)_2} - \alpha_{BA} - \beta_{BA}$$

and presented in Figs. 4*a* and *b*. Trace activity coefficient values facilitate a more detailed comparison of the effect of one electrolyte on the other in the mixture (21, 22). In ternary mixtures of the $NaNO_3 + M(NO_3)_2 + H_2O$ systems the relative values of log γ^{trace} to the log γ values of the pure salt depend upon two major factors: (1) ion–ion interactions and (2) ion–solvent interactions. An increase in ion–ion interaction causes a fall in log γ whereas an increase in ion–solvent interaction results in a rise in log γ. Examination of Figs. 4*a* and *b* indicates that ion–solvent interactions play a major role in the case of $NaNO_3$ in the presence of $M(NO_3)_2$ (Fig. 4*a*), resulting in an increase in log γ^{trace} above the values for the pure $NaNO_3$. In the case of activity coefficients of $M(NO_3)_2$ in the presence of $NaNO_3$, ion–ion interactions dominate over the ion–solvent interactions, resulting in a decrease in log γ^{trace} below the curves for the pure $M(NO_3)_2$ (Fig. 4*b*). These effects are more pronounced in the mixtures of Mg and Ca nitrates with $NaNO_3$ and minimal in the barium nitrate with $NaNO_3$ mixtures.

The application of molecular mechanics calculations to the study of solid state organic photoconductors has been investigated. Using X-ray crystallographic information for a series of four *N,N'*-dialkylperylene pigments, **1**–**4**, lattices of these molecules were modelled using the Dreiding force field. Comparison of the resulting lattices with the experimental data demonstrated that both molecular and physical features of the perylenes could be accurately reproduced in these calculations. When systematic deviations in molecular geometry occurred, these errors could be attributed to the generic nature of the force field. We have extended the computational studies to the problem of polymorphism since this is known to have a profound effect on photoconduction. To model enthalpic polymorphs of *N,N'*-dimethylperylene, **1**, the symmetry relationships and atomic coordinates from the crystal structure of *N,N'*-di-*n*-pentylperylene, **4**, were utilized. By truncating the pentyl substituents to methyl groups and applying external stresses to the resulting lattice during minimization it was possible to identify two likely polymorphs of **1**. The inclusion of Gasteiger's partial equalization of orbital electronegativity (PEOE) charges on the perylenes was not found to be beneficial in locating suitable polymorphs. These computational methods have been successful in modelling perylene pigments in the solid state and have been shown to be useful in investigating polymorphism.

ANDREW J. MCKERROW, ERWIN BUNCEL et PETER M. KAZMAIER. Can J. Chem. **71**, 390 (1993).

On a évalué la possibilité d'utiliser des calculs de mécanique moléculaire pour l'étude de photoconducteurs organiques à l'état solide. Utilisant des informations cristallographiques obtenues par diffraction des rayons X pour une série de quatre pigments *N,N'*-dialkylpérylène, **1**–**4**, et faisant appel au champ de force de Dreiding, on a développé un modèle de ces molécules. Une comparaison des réseaux qui en résultent avec les données expérimentales démontre que ces calculs permettent de reproduire fidèlement les caractéristiques tant moléculaires que physiques des pérylènes. Lorsque des déviations systématiques dans la géométrie moléculaire se produisent, on peut attribuer ces erreurs à la nature générique du champ de force. Sachant que le polymorphisme affecte profondément la photoconduction, on a examiné le polymorphisme du pérylène par des méthodes de calcul. Comme modèle du polymorphisme enthalpique du *N,N'*-diméthylpérylène, **1**, on a utilisé les relations de symétrie et les coordonnées atomiques de la structure cristalline du *N,N'*-di-*n*-pentylpérylène, **4**. En tronquant les substituants pentyles en méthyles et en appliquant des stress externes au réseau qui en résulte durant la minimisation, il a été possible d'identifier deux polymorphes possibles du composé **1**. On n'a pas trouvé que l'inclusion de charges PEOE de Gasteiger sur les pérylènes avait des effets bénéfiques pour détecter des polymorphes appropriés. On a utilisé ces méthodes de calcul avec succès dans le modelage de pigments du pérylène à l'état solide et on a montré qu'elles sont utiles dans l'étude du polymorphisme.

[Traduit par la rédaction]

Introduction

The study of organic molecules in the solid state has traditionally utilized X-ray crystallography as a means to obtained detailed information concerning molecular structure, i.e., bond lengths, angles, and conformations. Increasingly, the study of organic solids has been directed wards understanding the factors controlling the packing of molecules in the crystalline state. The nature of this packing is of interest as an example of a highly specific recognition phenomenon, as well as in situations in which the chemical and physical properties of the organic compounds are affected by the nature of the solid state packing. Examples of the former are found in investigations of the intermolecular interactions that occur in the crystalline state as these studies can yield insights into the nature of similar interactions in biological systems (1). Effects due to solid state packing are significant in the design of organic molecules with nonlinear optical properties (2), therapeutic drugs (3), and organic photoconductors.

Our interest in the organic solid state results from studies of organic photoconductors. Previous investigations have demonstrated that photoconduction in organic materials is dependent on molecular properties such as fluorescence quantum yield (4). Further studies from our laboratories have shown that photosensitivity is also strongly dependent on interactions that occur in the solid state (5). This is clearly illustrated in the study by Weigl *et al.* in which different photosensitivities were associated with the α, β, and *x* polymorphs of metal-free phthalocyanine (6).

From these examples it is clear that efforts directed towards the development of organic compounds for applications such as photoconduction must not only be concerned with the molecular characteristics of these materials, but also with their solid state properties.

Molecular modelling of photoreceptor pigments presents problems endemic to the pigment area as a whole. Photogenerator pigments by design are very insoluble so it is very difficult, if not impossible, to obtain single crystal X-ray diffraction information on most systems. Furthermore, the chemist designing new pigment structures would like to

predict the effect of molecular changes on the packing of the pigment in the solid state; thus the force field and software program must perform equally effectively at the molecular level as well as on the aggregate or crystal lattice level of calculation. Finally, the coupling of the calculation to readily available information such as X-ray powder diffraction must eventually be achieved.

Our strategy is to start with a generic force field capable of predicting the molecular structure and demonstrate that it can be used to reproduce the lattice and crystal parameters on a known series of photogenerator pigments where single crystal X-ray data are available. Having demonstrated the efficacy of the force field, one could then calculate a series of polymorphs for a particular compound and use this structural information to calculate a series of X-ray powder diffraction spectra. Once these are in hand, the experimental exploration of the relationship between the barriers to polymorphic interconversion and the energy window of polymorph stability could be explored. Our focus in this paper will be on the first two of these objectives, that is to say, the qualification of the force field and the calculation of polymorph energies and geometries.

Of the computational methods which we examined for modelling organic molecules in the solid state, calculations based on the atom–atom potential method (7) were one possibility. These empirical intermolecular force fields are used to calculate crystal packing energies and have been used to predict crystal structures for low-polarity organic compounds (8). This method, however, was shown to be unsuccessful in modelling crystals featuring heteroatoms (9). As organic photoconductors generally incorporate heteroatoms in the molecular framework, an alternative modelling technique was necessary.

Molecular mechanics force fields are routinely used in the study of organic molecules, yet their application to crystalline photoconductors has in the past been limited. With traditional force fields the treatment of molecules with unusual functionality has required considerable effort in order to parametrize the force field to model this functionality. Application of a suitable force field to the study of crystalline systems has been further hindered by difficulties in efficiently calculating the large number of nonbonded interactions occurring in such systems. The recent development of the Dreiding force field has provided possible solutions to these limitations.

The Dreiding force field models molecular structures using parameters that are based on hybridization considerations (10). Although this is not anticipated to be as accurate as customized force fields, the Dreiding method is ideal for studying molecules with non-routine functionality, as compound-specific parametrization is not necessary. The application of this force field to modelling crystalline systems has been rendered computationally feasible through the development of an accuracy-controlled accelerated convergence method for aiding in the calculation of nonbonded interactions (11).

As the Dreiding force field was not previously used to study crystalline organic photoconductors, our initial studies focused on determining if both molecular and physical features of a series of four *N,N'*-dialkylperylene-3,4:9,10-bis(dicarboximide) pigments, **1–4**, could be accurately modelled with this method. This computational approach was subsequently used, in conjunction with crystallographic data, in the search for likely enthalpic polymorphs of *N,N'*-dimethylperylene, **1** (12).[2]

Force field validation — calculations

Hädicke and Graser carried out an X-ray structural analysis of a series of photoconductive *N,N'*-dialkyl perylene-3,4:9,10-bis(dicarboximide) pigments (13). Their data for the perylenes **1–4** was hence chosen in this work as a starting point for investigating the ability of the Dreiding force field to model crystalline systems.

For each of the perylenes **1–4**, Hädicke and Graser's coordinates of the atoms in the asymmetric unit were used to construct an unit cell according to the symmetry operations dictated by the experimentally determined space group. As the hydrogen atom positions were not available from Hädicke and Graser's study, these atoms were explicitly added to the pigment molecules using default carbon–hydrogen bond lengths and angles from the Dreiding force field. Periodic boundary conditions were imposed on all faces of the unit cell in order to model an infinite crystalline environment.

As with other molecular mechanics force fields, the Dreiding method calculates potential energy on the basis of molecular geometry and this energy comprises contributions from bonded and nonbonded interactions. In our studies it was anticipated that evaluation of the electrostatic contribution to the nonbonded interactions could cause problems due to difficulties in accurately determining atomic charges on large molecular systems. To gauge the impact of these interactions on our investigations, parallel studies were carried out in which electrostatic terms were either evaluated based on atomic charges derived from the partial equalization of orbital electronegativity (PEOE) charging scheme of Gasteiger and Marsili (14), or these interactions were omitted.

In minimizing the energy of the lattices generated for perylenes **1–4**, all atoms in the lattice were free to adjust and a cutoff function was used in calculating the nonbonded intereactions so as to exclude interactions between atoms separated by more than 9.25 Å. Studies were carried out in which the unit cell parameters were either allowed to optimize or they were fixed at the experimental values. In both cases, the conjugate gradient method was used to minimize the total energy until the RMS force per degree of freedom

was less than 0.16 kcal mol^{-1}. All calculations were carried out on a Silicon Graphics 4D25 workstation using version 2.10 of the Polygraf Polymer Simulation Program.[3]

Force field validation — discussion

A summary of Hädicke and Graser's crystallographic data for compounds **1–4** is given in Table 1. Changes in the perylene alkyl substituents that are minor on a molecular basis lead to major changes in the nature of the crystal packing. The dimethyl, di-*n*-butyl, and di-*n*-pentylperpylenes crystallized with one half of a molecule in the asymmetric unit, while the di-*n*-propylperylene crystallized with two half molecules in the asymmetric unit that differ from each other in conformation. These differences in crystal packing reinforce the notion that it can be misleading to predict solid state packings based on similarities in molecular structure.

A comparison between the minimized lattices and Hädicke and Graser's experimental lattices was carried out in order to evaluate the accuracy of the Dreiding force field in modelling molecular structure. For perylenes **1–4**, molecules were extracted from both the minimized and experimental lattices so that bond lengths, angles, and torsion angles could be compared. The RMS errors in these molecular structural parameters were found to be small in studies including and excluding electrostatic interactions, Table 2. The magnitude of the errors in Table 2 was similar to that reported in Dreiding modelling studies of a series of 76 organic compounds (10).

Further examination of these deviations revealed that the force field could accurately reproduce the perylene carbon skeleton, with the exception of bonds between carbon and nitrogen. The carbon–nitrogen bonds were consistently 5–6% shorter than the literature values and this systematic error was attributed to the generic nature of the Dreiding parameters. As previously mentioned, with the Dreiding method geometric parameters and force constants are selected solely on the basis of the hybridization state of atoms. Using this generic approach it is possible to study molecules, such as perylene dicarboximides, that contain non-routine functionality without having to initially parametrize the force field for such functionality. It is hence inferred that the errors in carbon–nitrogen bond lengths were a direct manifestation of employing such a generic approach, as the default resonant nitrogen parameters used in the perylene studies imparted too much double bond character to all imide nitrogen–carbon bonds.

Optimization of the unit cell parameters in these modelling calculations led to only small deviations from the experimental unit cell parameters, Table 3. The minimized unit cells of the *N,N'*-dialkylperylenes **1–4** are shown in Figs. 1–4. Comparison of the optimized lattices with perylenes minimized in fixed unit cells showed that the former were more stable by 1.88–6.58 kcal mol^{-1}. This energy decrease appeared to be the result of compensatory motion in the lattice as in each case the increase in stability was accompanied by a slight increase in unit cell volume, 1.3–3.8%. The inclusion of electrostatic interactions led to a similar conclusion but the degree of stabilization in the optimized lattices decreased slightly, 1.41–6.29 kcal mol^{-1}.

Based on these results it was concluded that the Dreiding force field could accurately model both molecular and crystalline features of perylenes **1–4**.

Studies of polymorphism — calculations

A central difficulty in the development of novel organic photoconductors is the occurrence of polymorphism in the solid state. Variations in intermolecular interactions that occur in polymorphic forms of these materials are observed to affect their photoconductive properties. As experimental studies of polymorphism with most photoconductive dyes and pigments are difficult, we sought to study this phenomenon using our computational methods.

Polymorphism in organic solids can be the result of entropic and (or) enthalpic factors (ref. 9, pp. 285–299). Variations in crystal packing that result from disorder, i.e., entropic polymorphism, cannot easily be investigated with the computational methods used in this study due to the symmetry constraints that are imposed when generating the unit cell. Crystalline forms of compounds that are characterized by different periodic packings and stabilities are known as enthalpic polymorphs. If crystallographic information was available concerning enthalpic polymorphs of perylenes, the Dreiding modelling techniques could be used to study them and characterize their relative stabilities. As

[a]These polymorphs can be compared with the minimized monoclinic $P2_1/c$ polymorph, which had an energy of 72.84 kcal mol^{-1} and a density of 1.533 g cm^{-3}.

such information has apparently not been reported, we sought to locate enthalpic polymorphs of perylenes computationally for comparison with the experimentally observed crystal forms.

Our strategy for studying polymorphism in perylenes is based on the following suppositions. Perylenes have very high lattice energy dictated primarily by the interaction of the aromatic rings in the solid state. In one well-studied system, several polymorphs were identified by X-ray powder diffraction but the structure could not be assigned because X-ray powder diffraction alone provides insufficient information to completely determine the structure (5).

In the work of Graser and Hädicke many perylenes are reported that differ only in the substituent on the side chain. It is not clear if the single crystals that were isolated are the thermodynamically favoured polymorphs or if they are produced by kinetic control. Nevertheless it seems to be a rea-

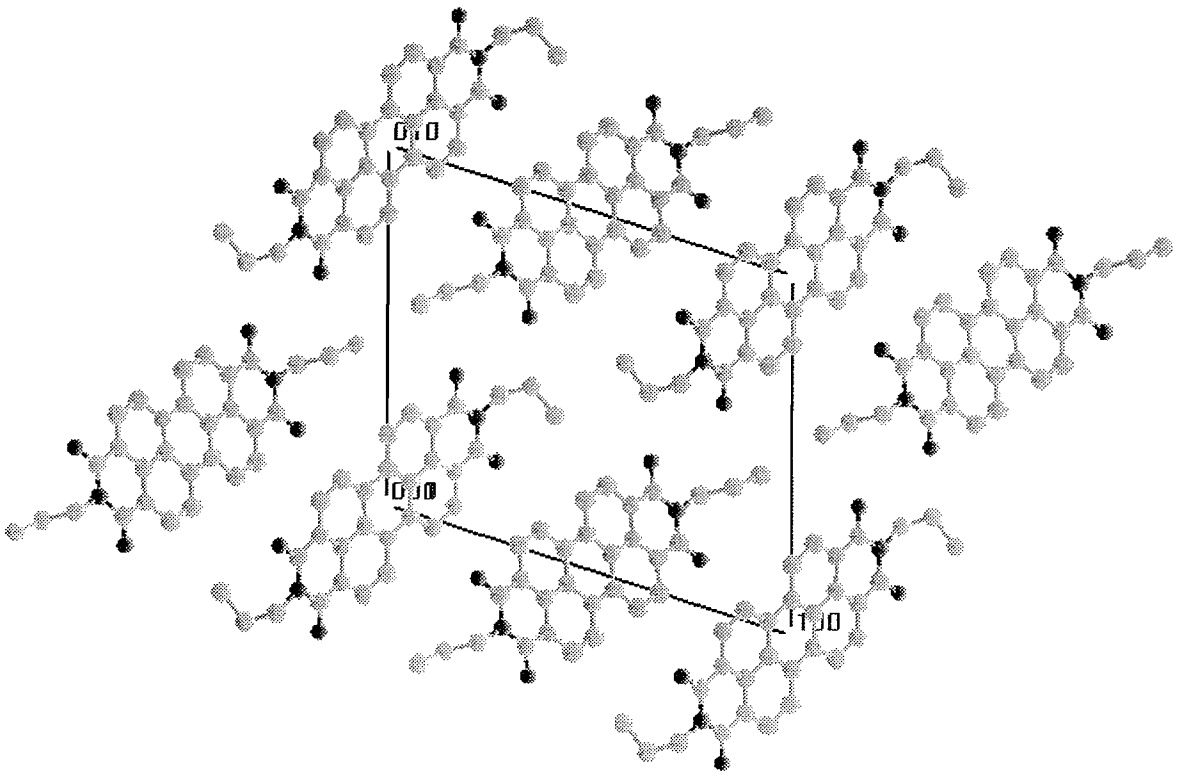

FIG. 2. Minimized unit cell of *N,N'*-di-*n*-propylperylene, **2**, (projection along the *c* axis).

sonable assumption that, for a single compound, all these crystal packings represent a polymorphic packing arrangement for that compound and the side chains act to modify the relative thermodynamic stability of the polymorph. If this assumption is correct, then one could use this experimental series of crystal packings to act as a template for the optimization of the pigment system to a new polymorphic arrangement without having to grapple with the enormous number of degrees of freedom and the many local minima inherent in an optimization without any symmetry constraints.

N,N'-Dimethylperylene, **1**, was chosen as a model compound for these studies as its *N*-alkyl substituents lack the conformational freedom of pigments **2**–**4** that can lead to entropic polymorphism. Furthermore, we have endeavoured to identify polymorphs of *N,N'*-dimethylperylene that occur in triclinic $P\bar{1}$ lattices, as these represent one of the simplest packing motifs for molecular crystals, with only one perylene molecule per unit cell. To simplify this modelling process we used crystallographic data from one of the perylenes that had been found to crystallize in a $P\bar{1}$ lattice. Specifically, the atomic coordinates and symmetry relationships of *N,N'*-di-*n*-pentylperylene, **4**, were used to model theoretical $P\bar{1}$ polymorphs of *N,N'*-dimethylperylene.

The coordinates for the atoms in the asymmetric unit of *N,N'*-di-*n*-pentylperylene, **4**, were edited so as to truncate the alkyl chains to methyl groups. A unit cell was constructed based on the original unit cell parameters with an inversion centre characteristic of the $P\bar{1}$ space group. Periodic boundary conditions were imposed to simulate a crystalline environment. Energy minimizations of this lattice, either with or without electrostatic interactions, yielded high-energy polymorphs with unrealistic densities. For these calculations to be successful it would have been necessary for molecules in the lattice to be drawn together to remove the considerable void volume in the unit cell. This process would presumably have resulted from attractive interactions modelled by the nonbonded component of the Dreiding force field. At the large interatomic separations found in the truncated lattice these interactions were not found to vary markedly on optimization of the atomic positions. This observation supports the supposition that the packing energy is to a large extent governed by the packing of the aromatic nucleus and that the complexity of the aromatic system leads to multiple local minima. The lack of a driving force that would lead to crystal annealing resulted in the system minimizing into unacceptable local minima.

An attractive concept for overcoming this multiple minima problem takes advantage of the shape of the van der Waals potential. Lattices that contain a large void volume are in a regime where the forces that would reduce the void volume are weak while the barriers to reorganization are relatively high because of the strong interaction of the planar pi (π) moieties. On the other hand, if the system could be over-compressed onto the steep portion of the van der Waals repulsion curve, this high potential energy would be sufficient to drive the packing to a minimum that has little if any void volume left. To state it another way, all of the high-energy local minima occur on the low-density side of the minimized structure because the van der Waals attractions at these distances are weak enough to allow these false minima to exist.

Thus, application of external stresses to the initial triclinic *N,N'*-dimethylperylene unit cell during the energy minimizations was an approach that was investigated as a means of annealing the lattice. Direct and shear stresses were

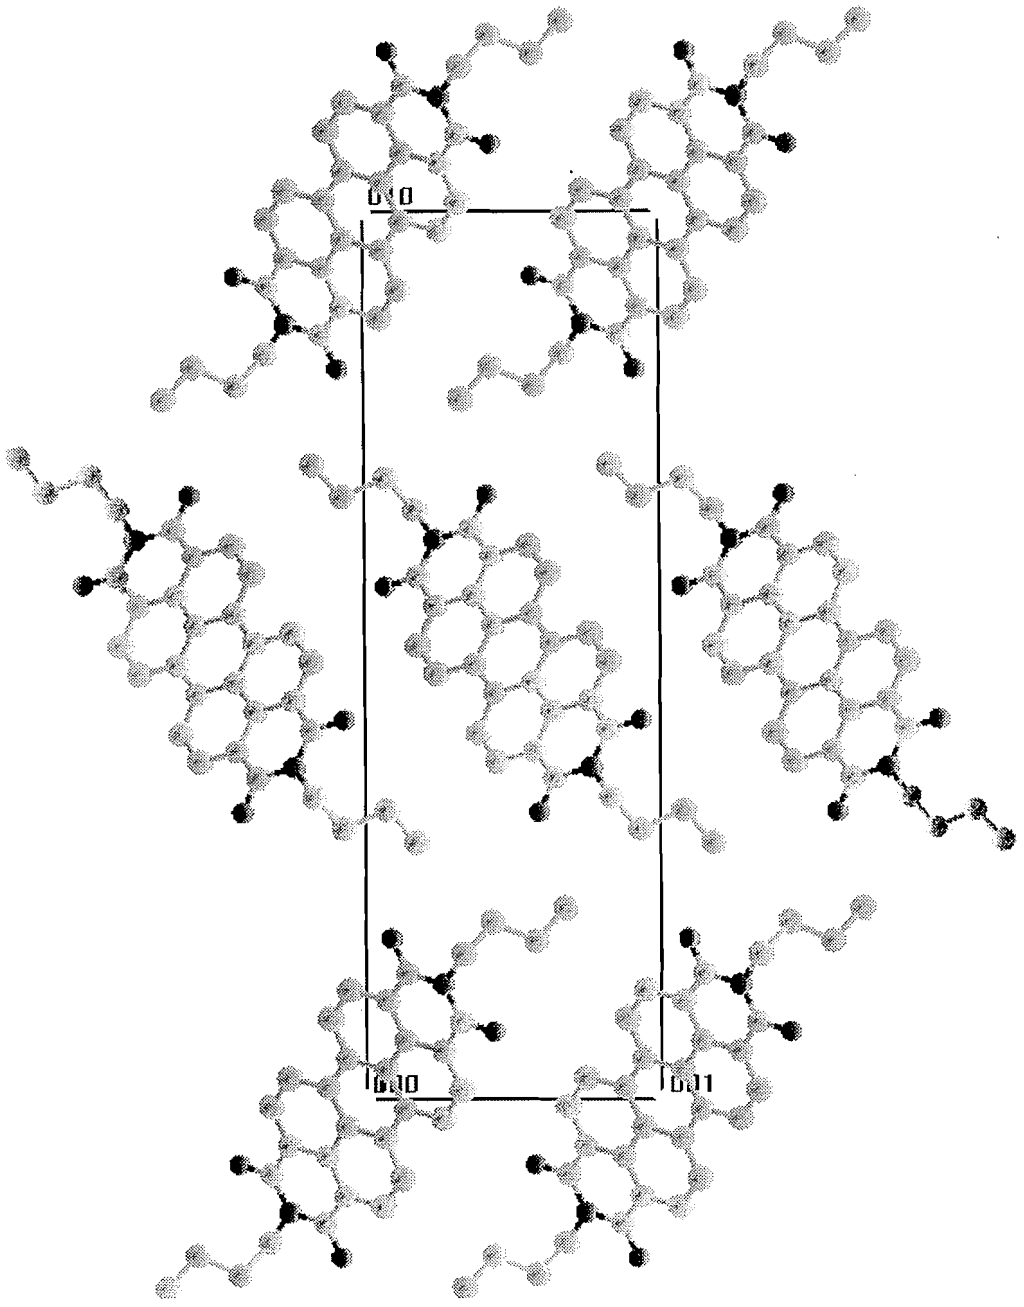

FIG. 3. Minimized unit cell of *N,N'*-di-*n*-butylperylene, **3**, (projection along the *a* axis).

applied to the three faces of the unit cell using either compressive or expansive stresses of 1 GPa during the energy minimizations. These calculations were interrupted after 1000 cycles and the resulting lattices minimized *without any external stresses being applied*. Once again, two sets of calculations were carried out in which electrostatic interactions were either included based on PEOE charge estimates, or these interactions were omitted.

The densities and energies of the lattices generated in these stressed-minimization studies are presented in Table 4 for calculations carried out with PEOE charges. The corresponding information for studies without charges is presented in Table 5. Based on a comparison of these data with the properties of the monoclinic *N,N'*-dimethylperylene, two likely theoretical triclinic polymorphs of this compound have been identified.

Studies of polymorphism — discussion

In the studies incorporating charges, the stressed-minimization procedure did not locate theoretical triclinic polymorphs of *N,N'*-dimethylperylene with densities and energies that compared favourably with the experimentally observed monoclinic polymorph (Table 4). Continued minimization of the stressed lattices beyond 1000 cycles did not significantly increase the density of the polymorphs.

The failure to locate a reasonable triclinic polymorph of *N,N'*-dimethylperylene may be due to limitations in facets of our computational method. Gasteiger's PEOE charging scheme is solely dependent on topology and, as a result, the static atomic charges are not affected by the immediate chemical environment. In crystalline systems it is anticipated that a dynamic charging scheme that was influenced

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12

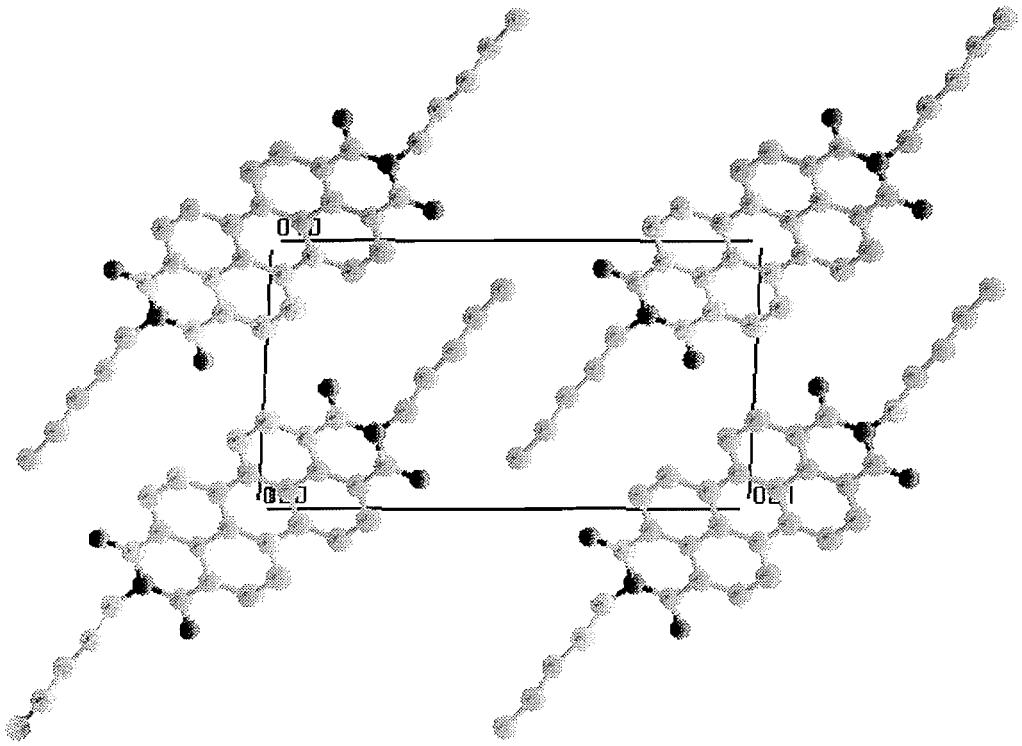

FIG. 4. Minimized unit cell of *N,N'*-di-*n*-pentylperylene, **4**, (projection along the *a* axis).

TABLE 6. Packing characteristics of minimized *N,N'*-dimethylperylene

Polymorph	Monoclinic	Triclinic *X*	Triclinic *Z*
Surface area (Å^2)	493.3	334.0	317.6
Molecular volume (Å^3)	595.5	319.1	317.9
Unit cell volume (Å^3)	906.4	470.6	471.3
Packing coefficient (C_K)	0.657	0.678	0.674

by neighbouring molecules would be better for modelling the annealing process examined in the polymorphism studies. Such a charging scheme has in fact been developed (15) and would be useful to apply in future studies.

Analysis of the lattices generated without PEOE charges revealed situations in which the coupling of energy minimization with the application of external stresses yielded reasonable triclinic *P*1 polymorphs of *N,N'*-dimethylperylene (Table 5). The application of direct compressive stresses to either the X or Z faces of the unit cell yielded polymorphs, hereafter referred to as the Triclinic **X** and Triclinic **Z** polymorphs, respectively, with calculated densities of 1.476 and 1.474 g cm^{-3}, respectively. These values compare favourably with the experimentally observed density of 1.533 g cm^{-3} for the monoclinic polymorph and are well within the range of densities observed for perylenes in general (1.33–1.62 g cm^{-3}). The minimized energies of these theoretical triclinic polymorphs also compare favourably with the energy of the minimized monoclinic polymorph *N,N'*-dimethylperylene. On visual examination the Triclinic **X** and Triclinic **Z** polymorphs appear to be almost identical (Fig. 5). The observation that none of the local minima generated in Table 5 simultaneously combines energies that are too high and densities that are too high validates the supposition that the local minima lie on the *low density side* of the energy hyperspace.

Using a uniform finite element analysis (16) it was possible to calculate the molecular volumes and surface areas of the contents in the minimized monoclinic unit cell and the two hypothetical triclinic *N,N'*-dimethylperylene unit cells (Table 6). The ratio of the molecular volume to the unit cell volume per molecule is known as the Kitaigorodskii packing coefficient, C_K, and for most close-packed organic compounds it is found to be in the range 0.65–0.75 (17). The Kitaigorodsky packing coefficients for the Triclinic **X** and Triclinic **Z** polymorphs lie within this range and compare favourably with the experimental monoclinic polymorph, indicating that all three are close-packed systems.

Conclusions

The study of organic molecules in the solid state is useful in situations in which intermolecular interactions are likely to have an impact on the physical and chemical properties of the compound. As a class, photoconductors are known to be highly dependent on such interactions and therefore our modelling studies have focused on the solid state.

It has been found in this work that the Dreiding force field, as incorporated in Polygraf, can successfully perform molecular mechanics calculations on crystalline solids. Our studies using the solved crystal structures of a series of four *N,N'*-dialkylperylenes, **1**–**4**, verified that this method could

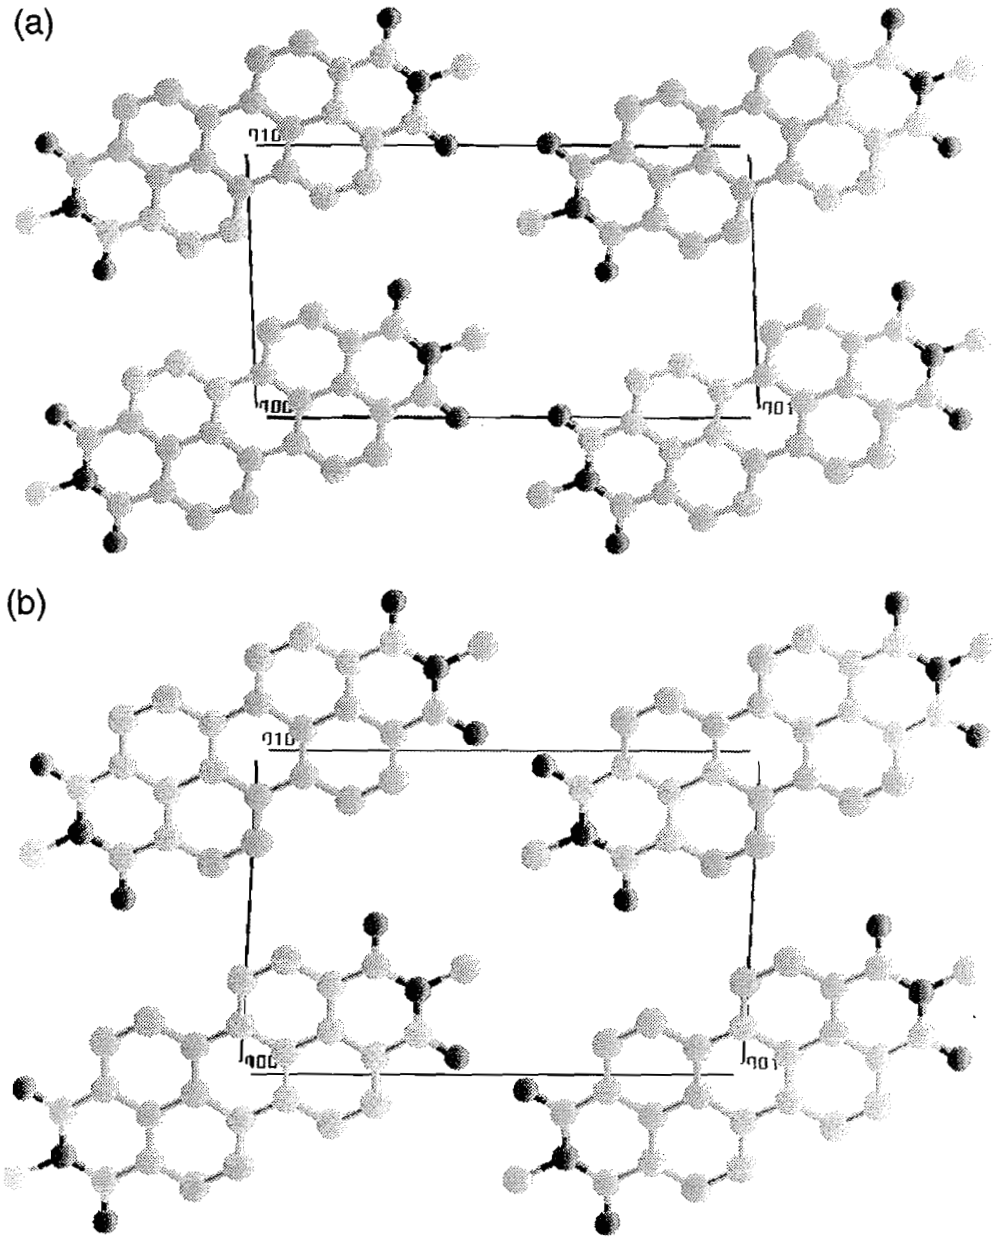

FIG. 5. (*a*) Minimized unit cell for the Triclinic **X** polymorph and (*b*) minimized unit cell for the Triclinic **Z** polymorph (both projections along the *a* axis).

reproduce accurately most molecular features of the perylenes and their unit cell parameters. Where this method was found to deviate from molecular geometries, the discrepancies were attributed to the generic nature of the force field.

Polymorphism is of importance in the study of materials where solid state packing is likely to affect properties such as photosensitivity. As part of our efforts to gain insights into this phenomenon, we have examined polymorphism in perylenes with the Dreiding force field. Using existing crystallographic information we carried out energy minimizations on lattices that were subjected to external stresses. Studies in which atomic charges were included did not yield chemically reasonable perylene polymorphs and this failure is believed to be related to limitations in the charging scheme. In studies in which these charges were omitted it was possible to generate two theoretical enthalpic polymorphs of *N*,*N*′-dimethylperylene, **1**, with reasonable chemical properties and packing parameters.

Preparation and characterization of the osmium cluster complexes $H_2Os_3(CO)_8L(EtFcPCMe)$ (L = CO or PEt_2Fc) and $H_2Os_3(CO)_8[(\eta\text{-}C_5H_3PEt_2)Fe(\eta\text{-}C_5H_4)]$

Received July 7, 1992

WILLIAM R. CULLEN, STEVEN J. RETTIG, and TU CAI ZHENG. Can. J. Chem. **71**, 399 (1993).

Thermolysis of $Os_3(CO)_{11}(PEt_2Fc)$ (Fc = $(\eta\text{-}C_5H_4)Fe(\eta\text{-}C_5H_5)$) in octane for 8 h affords $H_2Os_3(CO)_9(EtFcPCMe)$, **10**, and $H_2Os_3(CO)_8[(\eta\text{-}C_5H_3PEt_2)Fe(\eta\text{-}C_5H_4)]$, **9***e*, in 15 and 65% yield, respectively. Heating $Os_3(CO)_{12}$ and PEt_2Fc in 1:2 molar ratio in xylene for 10 h gives two isomers of $H_2Os_3(CO)_8(PEt_2Fc)(EtFcPCMe)$, **11**, in about 40% yield. Two crystalline modifications of the complex **9***e* have been obtained from the same solvent: **9***e*A, triclinic, a = 15.653(1), b = 15.799(1), c = 11.257(1) Å, α = 90.388(7)°, β = 109.740(6)°, γ = 82.445(6)°, Z = 4 (two molecules per asymmetric unit), space group $P\bar{1}$; and **9***e*B, monoclinic, a = 9.889(2), b = 13.632(3), c = 18.927(4) Å, β = 97.36(2)°, Z = 4, space group $P2_1/n$. The structures were solved by heavy atom methods and were refined by full-matrix least-squares procedures to R = 0.033 and 0.037 for 8131 and 5145 reflections with $I \geq 3\sigma(I)$, respectively.

WILLIAM R. CULLEN, STEVEN J. RETTIG et TU CAI ZHENG. Can. J. Chem. **71**, 399 (1993).

La thermolyse du $Os_3(CO)_{11}(PEt_2Fc)$(Fc = $(\eta\text{-}C_5H_4)Fe(\eta\text{-}C_5H_5)$) dans de l'octane pendant 8 h conduit au $H_2Os_3(CO)_9(EtFcPCMe)$ (**10**) et au $H_2Os_3(CO)_8[(\eta\text{-}C_5H_3PEt_2)Fe(\eta\text{-}C_5H_4)]$ (**9***e*) avec des rendements respectifs de 15 et 65%. Le chauffage du $Os_3(CO)_{12}$ avec du PEt_2Fc, dans un rapport molaire de 1 : 2, dans du xylène pendant 10 h conduit à deux isomères du $H_2Os_3(CO)_8(PEt_2Fc)(EtFcPCMe)$ (**11**) avec un rendement d'environ 40%. On a obtenu les deux formes cristallines du complexe **9***e* à partir du même solvant : **9***e*A est triclinique avec a = 15,653(1), b = 15,799(1) et c = 11,257(1) Å, α = 90,388(7)°, β = 109,740(6)° et γ = 82,445(6)°, Z = 4 (deux molécules par unité asymétrique) et groupe d'espace $P\bar{1}$ alors que **9***e*B est monoclinique avec a = 9,889(2), b = 13,642(3) et c = 18,927(4) Å, β = 97,36(2)°, Z = 4 et groupe d'espace $P2_1/n$. On a résolu les structures par les méthodes des atomes lourds et on les a affinées par les méthodes des moindres carrés jusqu'à des valeurs de R de 0,033 et 0,037 pour respectivement 8131 et 5145 réflexions avec $I \geq 3\sigma(I)$.

[Traduit par la rédaction]

Introduction

Thermolysis of the triruthenium and triosmium cluster complexes $M_3(CO)_{12-n}L_n$ (M = Ru or Os, L = monodentate tertiary phosphine or arsine, n = 1, 2, 3, L = bidentate di(tertiary phosphine), n = 2, 4) generally leads to oxidative cleavages of C—H and (or) C—P(As) bonds (1–23). The ease of both these reactions generally follows the order $sp > sp^2 > sp^3$ for hybridization at carbon atoms (1–3). Thus thermolysis of $Os_3(CO)_{11}(PMePh_2)$ results in aryl C—H and C—P cleavage to give $HOs_3(CO)_9(PMePhC_6H_4)$, **1**, $Os_3(CO)_{10}(PMeC_6H_4)$, **2**, and $Os_3(CO)_9(PMe)(C_6H_4)$, **3** (17, 18, 23). Similarly $Os_3(CO)_{11}(PMe_2Ph)$ affords $HOs_3(CO)_9(PMe_2)(C_6H_4)$, **4**, as a result of one aryl C—H and one aryl C—P bond cleavage (12). Thermolysis of $Os_3(CO)_{11}(PMe_3)$ results in double alkyl C—H oxidative addition from one methyl group to form $H_2Os_3(CO)_9(Me_2PCH)$, **5***a* (15). Complexes of ethylphosphines PEt_xPh_{3-x} (x = 1–3) generally behave similarly, but the pyrolysis of $Os_3(CO)_{11}(PEt_2Ph)$ afforded a complex **6** resulting from two alkyl C—H bond cleavages and one aryl C—P cleavage (Scheme 1) (16). The

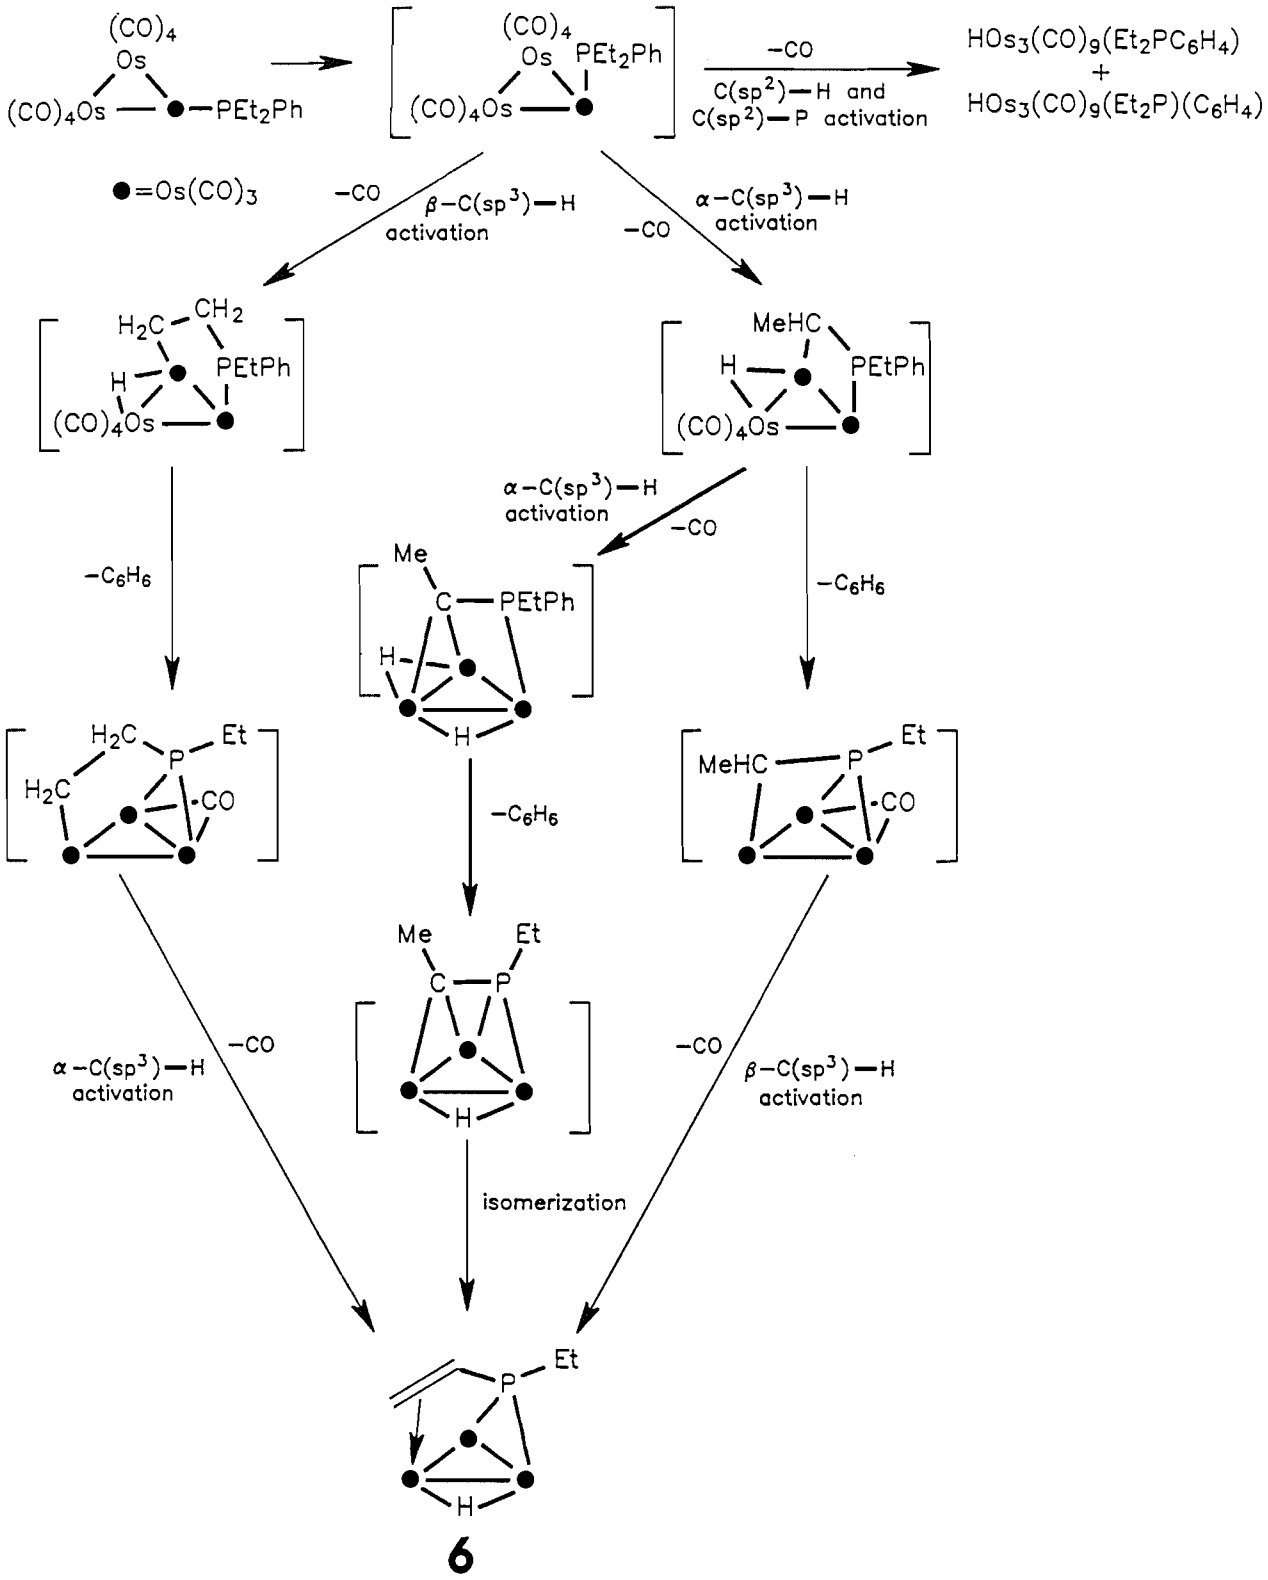

SCHEME 1. Plausible reaction pathways leading to complex **6**.

formation of **6** possibly involves one alkyl α-C—H cleavage to yield $HOs_3(CO)_{10}(EtPPhCHCH_3)$ as the first step. However, instead of undergoing a further alkyl α-C—H cleavage to yield a complex $H_2Os_3(CO)_9(EtPPhCCH_3)$, analogous to **5**, a reductive elimination of benzene occurs to give $Os_3(CO)_{10}(EtPCHCH_3)$, enabling a second alkyl C—H bond cleavage to take place at the β carbon to give the isolated product **6**. This reaction sequence is summarized in Scheme 1. Two plausible alternative sequences, one involving double α-C—H activation and the other β-C—H activation of an ethyl group are also presented in the scheme.

In our recent investigations of the thermolytic reactions of

ferrocenylphosphine-substituted Ru_3 and Os_3 carbonyl-cluster complexes, we characterized a number of novel complexes such as the ferrocyne derivative **7** in addition to an extensive range of compounds such as **8** and **9***a–d* that contain strong Fe→Os interactions (8–10, 20, 21, 24–26). Previously known compounds that show Fe→M bonding of this type were confined to M = group 10 or 11 metals (27–30). We expect to discover an interesting chemistry of these cluster compounds once high-yield routes are available for their preparation, and the work presented in the present paper is directed towards this objective.

The pyrolysis of $Os_3(CO)_{11}(PFcPr^i_2)$ affords at least five products including **9***d* as a result of extensive C—H and C—P cleavages (ref. 25 and footnote 2). The pyrolysis of alkyl-bis(ferrocenyl)phosphine complexes such as $Os_3(CO)_{11}$-$(PEtFc_2)$ affords even more complicated mixtures.[2] On this basis we expected that the pyrolysis of $Os_3(CO)_{11}(PEt_2Fc)$ should afford **9***e* in high yield because complications resulting from the presence of a second Fc group are avoided and

[a] $B_{eq} = (8/3)\ \pi^2 \Sigma \Sigma\ U_{ij} a_i^* a_j^* (a_i \cdot a_j)$.

alkyl β-C—H and P—C cleavage are minimized. We have realized this expectation with the isolation of $H_2Os_3(CO)_8[(\eta\text{-}C_5H_3PEt_2)Fe(\eta\text{-}C_5H_4)]$, ***9e***, in 65% yield. Two other complexes are also described.

Experimental

All reactions were carried out under an argon atmosphere. Solvents were distilled prior to use. Thermolysis reaction was carried out in a flask fitted with a bubbler. ^{31}P and ^1H NMR chemical shifts are given in ppm from 85% H_3PO_4 and TMS, respectively, and NMR spectra were recorded in $CDCl_3$ by using Bruker AC-200 or Varian XL-300 spectrometers. Mass spectra were obtained on a Kratos MS-50 (EI) or an AEI MS-9 (FAB) spectrometer. Elemental analysis were performed by Mr. Peter Borda of this department. Diethylchlorophosphine was purchased from Strem Chemicals Inc. and *n*-butyllithium (1.6 M, hexanes) was obtained from Aldrich Chemical Co.

Preparation of diethylferrocenylphosphine, PEt_2Fc

Ferrocene (5.2 g, 0.028 mol) in diethyl ether (20 mL) was placed in a Schlenk tube equipped with a magnetic stirrer. To the stirred suspension was added *n*-butyllithium (12.8 mL, 0.02 mol) and the solution was left stirring for 60 h. After cooling the reaction mixture in a Dry Ice – acetone bath, diethylchlorophosphine (2.0 g, 0.016 mol) was added dropwise. The reaction mixture was allowed to warm slowly to room temperature and was left stirring for a further 2 h. Water (20 mL) was added to the solution; the oganic layer was separated, reduced in volume by using a rotary evaporator, and pumped to dryness. The residue was chromatographed on silica gel (20:1 petroleum ether:diethyl ether as eluent) and the pure product eluted in the second band. It was obtained in 30% yield (1.3 g) as a reddish yellow oil. $^{31}P\{^1H\}$ NMR δ: 26.1. ^1H NMR δ: 4.28 (m, 2H), 4.20 (m, 2H), 4.10 (s, 5H), 1.58 (m, 4H), 1.04 (td, 6H, J_{P-H} = 20.0 Hz). Mass spectrum (EI), *m/e* (relative intensity): 274(P^+, 40.6), 245(23.9), 218(13.6), 217(100.0), 186(19.8),

151(11.2), 121(90.0), 56(18.9). Anal. calcd. for $C_4H_{19}FeP$: C 61.20, H 6.86; found: C 61.34, H 6.99.

Preparation of $Os_3(CO)_{11}(PEt_2Fc)$

The preparation is based on a literature method (31) but does not involve the isolation of $Os_3(CO)_{11}(MeCN)$. To triosmium dodecacarbonyl (454 mg, 0.5 mol) in dichloromethane (40 mL) in a two-necked flask was added acetonitrile (2 mL, excess) and trimethylamine oxide (38 mg, 0.5 mmol). After stirring the mixture for 2 h, the phosphine PEt_2Fc (137 mg, 0.50 mmol) dissolved in a small amount of dichloromethane was added. After a further 2 h at 20°C, the solvent was removed *in vacuo* and the residue was applied to a column for chromatographic separation (SiO_2, 3:1 petroleum ether:CH_2Cl_2 as eluent). Pure product eluted in the second band; the first contained unreacted $Os_3(CO)_{12}$. Solvent removal afforded orange crystalline $Os_3(CO)_{11}(PEt_2Fc)$ in 80% yield (460 mg). $P\{^1H\}$ NMR δ: −17.0. ^1H NMR δ: 4.50 (m, 2H), 4.30 (m, 7H), 2.24 (m, 4H), 1.10 (td, 6H, J_{P-H} = 24.1 Hz). Mass spectrum (FAB), *m/e*: 1154 (P^+, base peak), 1126, 1098, 1070, 1042, 1014, 984, 955, 928. Anal. calcd. for $C_{25}H_{19}FeO_{11}Os_3P$: C 26.36, H 1,80; found: C 26.05, H 1.66.

*Thermolysis of $Os_3(CO)_{11}(PEt_2Fc)$ and preparation of **9**e and **10***

$Os_3(CO)_{11}(PEt_2Fc)$ (100 mg, 0.086 mmol) in octane (30 mL) was refluxed for 8 h. TLC monitoring of the reaction mixture in association with $^{31}P\{^1H\}$ NMR studies revealed one major product, one in medium quantity, and three in trace quantities. Some starting material was also present. The residue was chromatographed on a silica gel column with 3:1 petroleum ether:CH_2Cl_2 as eluent. The first minor band contained $Os_3(CO)_{12}$, the second contained complex **10** (15 mg, 15%), the third band was $Os_3(CO)_{11}(PEt_2Fc)$, and the fourth orange band proved to be complex **9*e*** (64 mg, 65%). **10**, $^{31}P\{^1H\}$ NMR δ: −50.9. ^1H NMR δ: 4.50 (m, 1H), 4.38 (m, 2H), 4.20 (m, 1H), 4.16 (s, 5H), 2.88 (m, 1H), 2.52 (m, 1H), 2.24 (d, 3H, J_{P-H} = 24.2 Hz), 1.50 (td, 3H, J_{P-H} = 24.0 Hz), −15.1 (d, 1H, J_{P-H} = 11.1 Hz), −19.6 (d, 1H, J_{P-H} = 12.4 Hz). Mass spectrum (FAB), *m/e*: 1096 (P^+, base peak), 1068, 1040, 1012, 983, 955, 927, 913, 899, 883, 876, 854, 841, 827, 813. Anal. calcd. for $C_{23}H_{19}FeO_9Os_3P$: C 25.19, H 1.75; found: C 25.40, H 1.72. **9*e***, $^{31}P\{^1H\}$ NMR δ: −22.7. ^1H NMR δ: 5.16 (m, 1H), 5.02 (m, 1H), 4.70 (m, 1H), 4.18 (m, 2H), 4.06 (m, 1H), 3.06 (m, 1H), 2.16 (m, 1H), 1.86 (m, 2H), 1.28 (m, 1H), 0.90–1.04 (bm, 6H), −12.2 (d, 1H, J_{P-H} = 4.5 Hz), −17.4 (d, 1H, J_{P-H} = 11.0 Hz). Mass spectrum (FAB), *m/e*: 1068 (P^+), 1040, 1012 (base peak), 984, 956, 928, 900, 870, 840, 812. Anal. calcd. for $C_{22}H_{19}FeO_8Os_3P$: C 24.72, H 1.79; found: C 24.99, H 1.92.

*Thermolysis of $Os_3(CO)_{12}$ with PEt_2Fc and preparation of **11***

Triosmium dodecacarbonyl (272 mg, 0.30 mmol) and diethylferrocenylphosphine (160 mg, 0.60 mmol) in *p*-xylene (40 mL) were refluxed for 10 h. The solvent was removed *in vacuo* and the residue chromatographed on a silica column by using 3:1 petroleum ether:CH_2Cl_2 as eluent. The first fraction contained unreacted $Os_3(CO)_{12}$, the second one contained mainly **11*a*** together with some **11*b*** (**11*a***:**11*b*** > 20:1), and the third one contained almost equal amounts of **11*a*** and **11*b***. The two isomers were separated by careful repeated chromatography. **11*a***, $^{31}P\{^1H\}$ NMR δ: −24.6, −62.7. ^1H NMR δ: 4.49 (m, 3H), 4.34 (m, 1H), 4.28 (m, 4H), 4.23 (s, 5H), 4.17 (s, 5H), 2.97 (m, 1H), 2.72 (m, 1H), 2.42 (dd, 3H, J_1 = 18 Hz, J_2 = 5 Hz), 2.20 (bm, 4H), 1.57 (m, 3H), 1.25 (bm, 6H), −14.82 (pt, 1H, $J_1 = J_2$ = 9.9 Hz), −20.42 (pt, 1H, $J_1 = J_2$ = 11.0 Hz). Mass spectrum (FAB), *m/e*: 1342 (P^+), 1314, 1286 (base peak), 1258, 1230, 1200, 1172, 1142. Anal. calcd. for $C_{36}H_{38}Fe_2O_8Os_3P_2$: C 32.20, H 2.85; found: C 31.85, H 2.70. **11*b***, $^{31}P\{^1H\}$ NMR δ: −25.8, −62.1. ^1H NMR δ: 4.5–4.3 (m, 8H), 4.28 (s, 5H), 4.22 (s, 5H), 2.83 (m, 1H), 2.72 (m, 1H), 2.55 (dd, 3H, J_1 = 18 Hz, J_2 = 5 Hz), 2.20 (bm, 4H), 1.57 (m, 3H), 1.25 (bm, 6H), −15.13 (pt, 1H, $J_1 = J_2$ = 10.0 Hz), −20.60 (dd, 1H, J_1 = 11.0 Hz, J_2 = 8.8 Hz). Anal. calcd. for $C_{36}H_{38}Fe_2O_8Os_3P_2$: C 32.30, H 2.85; found: C 32.02, H. 2.74.

*Crystal structure determination of **9**e*

Suitable crystals for X-ray diffraction studies were obtained by evaporation of the solvent from the appropriate chromatographic fraction. Two different forms of crystals were found and both were subjected to crystallographic analyses.

Crystallographic data for the two crystal forms of $\{\mu_3:\eta^4\text{-}[(\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_3)]P(C_2H_5)_2\text{-}Fe,P,C,C,\}(\mu\text{-}H)_2Os_3(CO)_8$, **9*e***, appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 37.2–44.1° for **9*e***A and 35.0–44.6° for **9*e***B. The intensities of three standard relections, measured every 200 reflections throughout the data collections, remained constant for both data sets. The data were processed (32) and corrected for Lorentz and polarization effects, and for absorption (empirical, based on azimuthal scans for four reflections).

Both structures were solved by heavy atom methods, the coordinates of the Os and Fe atoms being determined from the Patterson functions and those of the remaining non-hydrogen atoms from subsequent difference Fourier syntheses. The structure analysis of **9*e***A was initiated in the centrosymmetric space group $P\bar{1}$, this choice being confirmed by the subsequent successful solution and refinement of the structure. All non-hydrogen atoms of both com-

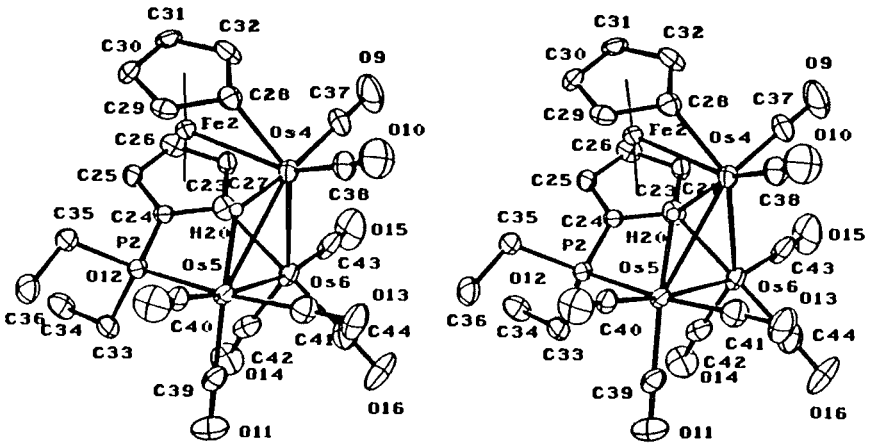

FIG. 1. Stereo ORTEP diagram of 9*e*A.

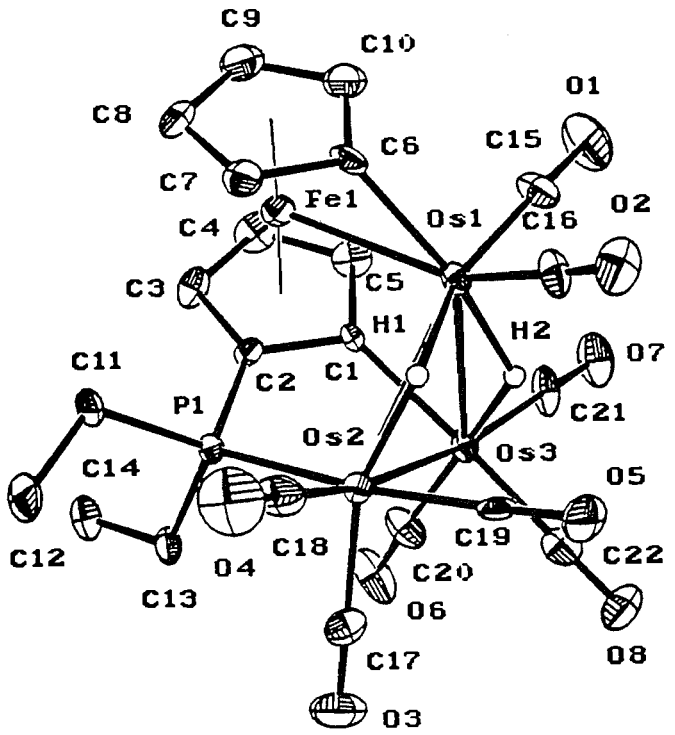

FIG. 2. ORTEP diagram of 9*e*B.

plexes were refined with anisotropic thermal parameters. The metal hydride atoms in both crystal forms, except for one of those associated with the Os(4) molecule in 9*e*A, were included in difference map positions but were not refined. All other hydrogen atoms were fixed in idealized positions (methyl groups staggered, C—H = 0.98 Å, $B_H = 1.2\ B_{\text{bonded atom}}$). Corrections for secondary extinction were applied, the final values of the extinction coefficient being 1.68×10^{-7} for 9*e*A and 2.17×10^{-7} for 9*e*B. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (33). Final atomic coordinates and equivalent isotropic thermal parameters, selected bond lengths, and selected bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, complete tables of bond lengths and bond angles, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes are included as supplementary material.[3]

Results and discussion

The complex $Os_3(CO)_{11}(PEt_2Fc)$ is readily prepared via the reaction of $Os_3(CO)_{11}(MeCN)$ with the phosphine PEt_2Fc. The analytical and spectroscopic results support the formulation of this new ligand and its complex.

When $Os_3(CO)_{11}(PEt_2Fc)$ is heated in refluxing octane for 8 h, two main products **9***e* and **10** can be isolated in 65 and 15% yields, respectively. The molecular formula $H_2Os_3(CO)_8[(C_5H_3PEt_2)Fe(C_5H_4)]$ is established for **9***e* on the basis of the spectroscopic and analytical data and by comparing these with those of **9***a–d*. The $^{31}P\{^1H\}$ NMR resonance of **9***e* at −22.7 ppm is only 5.7 ppm shifted from that of the parent complex $Os_3(CO)_{11}(PEt_2Fc)$, while two hydrides are clearly derived from the ferrocenyl moiety. The structure of **9***e* is confirmed by an X-ray diffraction study. Interestingly, two different forms of crystals of **9***e* were found and they were obtained from the same solvent. A stereoview of 9*e*A from the triclinic system and an ORTEP diagram of 9*e*B from the monoclinic system are shown in Figs. 1 and 2, respectively. Since the structure and bonding parameters of the two molecules are very close, metrical remarks will be confined to the structure 9*e*B from the monoclinic system.

The structure of **9***e* is very similar to those of **9***a–d* previously described (20, 25). It consists of a triangular array of three osmium atoms with one face capped by an axial phosphine and a doubly metalated ferrocenyl moiety. Both

[3]Hydrogen atom parameters, anisotropic thermal parameters, complete tables of bond lengths and bond angles, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor structure amplitudes for 9*e*A and 9*e*B are available as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Hydrogen atom parameters and complete tables of bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Os(2) and Os(3) are bound to three terminal carbonyls and Os(1) to two. The Os—Os bonds show large variations with Os(1)—Os(2) at 3.0765(9) Å being the longest and Os(1)—Os(3) at 2.8274(7) Å the shortest; the remaining Os(2)—Os(3) bond is of intermediate length, 2.8754(8) Å. The longest and shortest Os—Os bonds are each bridged by a hydride, which was located but not refined. One ortho- and one heteroannular C—H bond of the ferocenyl group is cleaved and one Fe→Os bond is established in forming **9*e***. The Fe→Os bond length, 2.826(2) Å, is similar to that found for the other compounds **9** (20, 25).

The C(1)—Os(3) and C(6)—Os(1) distances at 2.168(8) and 2.08(1) Å, respectively, are typical of carbon–osmium σ-bonds, but there is probably also some interaction between C(1) and Os(1) since this distance of 2.584(9) Å is not extreme. The C(1)—C(5) plane, Cp(1), makes an angle of 78.62° with the Os_3 plane. The two Cp rings have a very small ring tilt angle of 1.44° despite the C—Os and Fe→Os

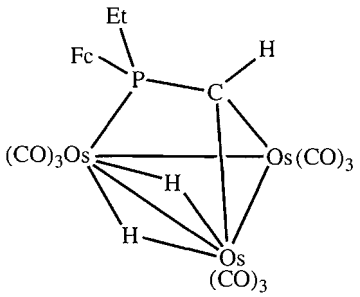
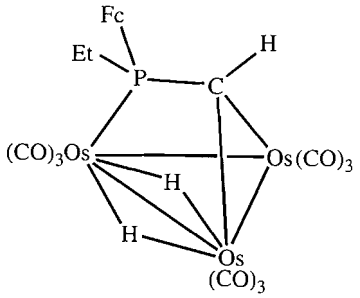
(D)

bonding interactions, and the rings are slightly staggered with the torsion angle C(1)Os(3)Os(1)C(6) being 12.1(4)°. P(1) is almost coplanar with Cp(1) (0.0118 Å away) and, as for the other structures **9** (20, 25), the Fe(1)—C(1) bond at 2.120(8) Å is slightly longer than the other four (avg. 2.044 Å) in Cp(1), while the Fe(1)—C(6) bond at 1.95(1) Å is slightly shorter than the other four (avg. 2.063 Å) in Cp(2). Carbonyl C—Os and C—O bond distances are not unusual and all Os—C—O vectors are close to linear.



10*a*



10*b*

The mass spectrum of **10** suggests the loss of two carbonyls from the parent complex and the analytical data are consistent with this formulation. The $^{31}P\{^1H\}$ NMR resonance at −50.9 ppm indicates that the C—P bonds remain intact. The ^1H NMR spectrum clearly establishes that the two hydrides are derived from the α position of one ethyl group. Generally the spectrum of **10** is very similar to that of $H_2Os_3(CO)_9(Et_2PCMe)$, **5*b*** (15). However, the two hydride signals in **10** are sharp and well separated at room temperature, indicating that the hydride exchange found in **5*b*** is largely suppressed in **10**. The resonances of the two α-hydrogen atoms of the PEt group of **10** are non-equivalent since the P atom is chiral and they are shifted downfield from those in $Os_3(CO)_{11}(PEt_2Fc)$. The methyl attached to the methylene carbon has a chemical shift of 2.24 ppm, a downfield shift of 1.14 ppm from that in the parent complex.

The structure of **10** is not obvious. Table 5 lists the chemical shifts and coupling constants of the hydride resonances for complexes **5**, **10**, **11**, **12**, **13**, and also **9*e***. It seems reasonable to assume that all these complexes, except **9*e***, have a similar hydride arrangement.

For complex **5*a*** four types of hydride arrangements may be considered. Type (C) is symmetrical for **5*a*** and is not consistent with the inequivalency of the two hydrides. Type (D) is not consistent with the almost equal J_{P-H} couplings since one hydride is three bonds and the other two bonds away from the P atom. Support for this statement is provided by complex **9*e*** for which hydrides were located in the crystal structure. This complex shows a coupling of ca. 4 Hz for the hydride that is three bonds away from the P atom and a coupling of ca. 12 Hz for the one that is two bonds away. Type (B) is inconsistent with the fact that the two methyl groups in **5*a*** are found to be inequivalent; two methyl resonances are seen in the ^1H NMR spectrum (15). Moreover the hydride–phosphorus couplings observed for **5*a***, Table 5, are much larger than the ca. 4 Hz expected for a three-bond coupling. Therefore, although Deeming and Underhill (15) favour a type (D) structure for **5**, we prefer a type (A) hydride arrangement as this structure seems to be more consistent with the NMR data. Such a double hydride bridge is

TABLE 5. Hydride NMR resonances for complexes **5**, **10**, **11**, **12**, **13**, and **9*e***

Compound	Hydride chemical shifts and coupling constants	
$H_2Os_3(CO)_9(PMe_2CH)$ **5*a***	−15.75, J = 10.8	−20.08, J = 6.2
$H_2Os_3(CO)_9(PEt_2CMe)$ **5*b***	−15.19, J = 9.4	−20.05, J = 8.0
$H_2Os_3(CO)_8(PMe_3)$ (PMe_2CH) **12*a***	−15.68, J = 11.2, 11.2	−20.44, J = 12.0, 8.0
$H_2Os_3(CO)_8(PMe_3)$ (PMe_2CH) **12*b***	−16.06, J = 11.2, 11.2	−19.25, J = 24.7, 8.9
$H_2Os_3(CO)_8(PEt_3)$ (PEt_2CMe) **13**	−15.30, J = 10.0, 10.0	−20.75, J = 11.0, 9.0
10	−15.13, J = 9.6	−19.72, J = 10.0
11*a*	−14.82, J = 9.9, 9.9	−20.42, J = 11.0, 11.0
11*b*	−15.13, J = 10.0, 10.0	−20.60, J = 11.0, 8.8
9*e*	−12.22, J = 4.4	−17.39, J = 11.4

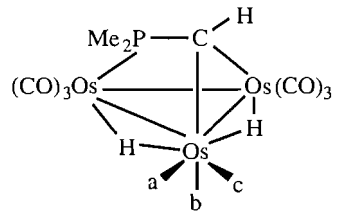
known and the magnitude of the difference of hydride chemical shifts is not unreasonable (35).

If complex **10** has the same hydride arrangement as **5**, two isomers are possible depending on whether the hydrides are *syn* to the Fc group or to the Et group. It is possible that **10** is a mixture of these rapidly interconverting isomers, but we prefer to believe that it has a structure with two hydrides *syn* either to the Fc or to the Et group, with the latter being more likely since the hydride chemical shifts and couplings are close to those of **5*b***. However, there is no rational explanation to account for the absence of the other isomer.

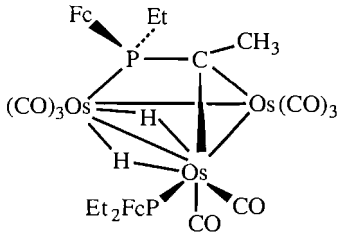
The relative yields of **9*e*** and **10** suggest that C—H activation of the ferrocenyl moiety is easier than that of the ethyl, and that ferrocenyl and ethyl C—P cleavages are not as facile as phenyl C—P cleavage, as we surmised earlier (20). The good yield of **9*e*** obtained from $Os_3(CO)_{11}(PEt_2Fc)$ will allow its chemistry to be explored in future work. However, because of the ready formation of the complexes **9**, as yet unknown, but plausible, ferrocyne complexes such as $HOs_3(CO)_9(\mu\text{-}PR_2)[\mu_3\text{-}(C_5H_3)Fe(C_5H_5)]$ (R = alkyl, cf. **4** (12, 16, 34)) might have to be prepared by routes other than the pyrolysis of $Os_3(CO)_{11}(PFcR_2)$.

When $Os_3(CO)_{12}$ is refluxed in *p*-xylene with PEt_2Fc in 1:2 molar ratio, only one major product, **11**, is formed. This can be isolated as two isomeric forms **11*a*** and **11*b***. The spectroscopic and analytical data for **11** establish the formulation as $H_2Os_3(CO)_8(PEt_2Fc)(PEtFcCMe)$. These data are similar to those reported for $H_2Os_3(CO)_8(PMe_3)(PMe_2CH)$ **12** and $H_2Os_3(CO)_8(PEt_3)(PEt_2CMe)$ **13**.

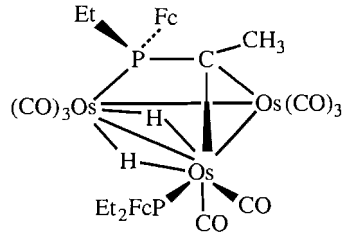
From Table 5 it is clear that both complexes **11*a*** and **11*b***, which contain two phosphine moieties, are very similar to **12*a*** and **13**, but not to **12*b***. Complexes **12*a*** and **12*b*** interconvert in solution. Deeming and Underhill (15) considered three possible coordination sites for the PMe_3 ligand as shown, and suggested that the two isomers differ in the sites occupied by the phosphine PMe_3, a–c.



12



11*a*



11*b*

In solution, **11*a*** and **11*b*** do not equilibrate over several weeks at room temperature, indicating that they do not differ in the site of PEt_2Fc substitution. Since the hydrides

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

couple to two phosphorus atoms approximately equally, the PEt_2Fc ligand must be bonded to the osmium atom that is bridged by the two hydrides. One of the possible structures is shown in **11**. It should be noted that both the P and the C atoms in **11** are chiral, thus two diastereomers result, and these account nicely for the two isomers obtained.

JEAN F. KLEIN, JEAN CLAUDE POMMELET, JOSSELIN CHUCHE, JOSÉ ELGUERO, PILAR GOYA, and ANA MARTINEZ. Can. J. Chem. **71**, 410 (1993).

A novel synthesis of the pyrazole ring involving SO_2 extrusion by flow vacuum pyrolysis in the 1,2,6-thiadiazine 1,1-dioxide system is described. The reaction has potential industrial significance for routes to pyrazoles or functionalized pyrazoles that do not involve hydrazines.

JEAN F. KLEIN, JEAN CLAUDE POMMELET, JOSSELIN CHUCHE, JOSÉ ELGUERO, PILAR GOYA et ANA MARTINEZ. Can. J. Chem. **71**, 410 (1993).

On décrit une nouvelle synthèse du noyau de pyrazole faisant appel à l'extrusion de SO_2 au moyen de la pyrolyse éclair à partir de 1,1-dioxydes de 1,2,6-thiadiazines. Cette méthode a un possible intérêt industriel pour la préparation de pyrazoles ou des pyrazoles fonctionalisés en évitant l'usage d'hydrazines.

Introduction

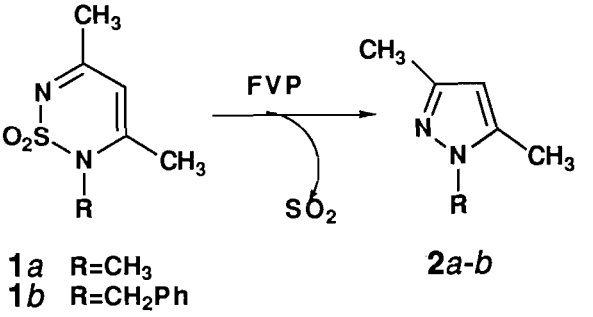
Heterocyclic compounds containing the N-SO_2-N moiety, such as 1,2,6-thiadiazine 1,1-dioxides and fused systems, have been the subject of different studies concerning their biological and physico-chemical aspects (1). We now wish to report their use for the synthesis of pyrazoles through a novel thermal extrusion of the SO_2 group. The N—N bond formation by extrusion of small stable fragments such as sulphur or sulphur monoxide from this heterocycle has already been described, but all attempts to eliminate the SO_2 moiety adjacent to two nitrogen atoms have up to now failed (2) (for a recent review on extrusion of SO_2 from heterocyclic compounds see ref. 3).

In the present case a flow vacuum pyrolysis technique (4) was applied successfully to the synthesis of pyrazoles from 1,2,6-thiadiazine 1,1-dioxides. The starting thiadiazine 1,1-dioxides are readily available by reactions involving condensation of sulfamides with suitable three-carbon fragments (1). On the other hand, the corresponding N-S-N and N-SO-N bridged derivatives are much more difficult to prepare.

Results and discussion

Flow vacuum pyrolysis (5) of *N*-alkyl derivatives **1***a* and **1***b* carried out in C_6D_6 afforded pyrazoles **2***a* and **2***b* as a result of the extrusion of an SO_2 molecule, in yields that increased with temperature (Scheme 1, Table 1). Thermolysis of **1***a* (700°C) and **1***b* (650°C) began at a temperature of 550–600°C and was complete by 650–700°C. A preparative thermolysis carried out in benzene solutions of **1***a* and **1***b* allowed the isolation of **2***a* and **2***b* in 66 and 47% yield, respectively.

Thiadiazine **1***c* showed a completely different thermal behaviour. Thermolysis began at a lower temperature and, at 500°C, 45% of the starting material had already disappeared. This reaction was more complicated and in the crude reaction product, besides unchanged thiadiazine **1***c*, three new products could be identified by NMR: pyrazole **2***c*, thiadiazine **1***d*, and cyclohexene. By 600°C, all the starting material had completely disappeared. A preparative thermolysis of **1***c*, carried out at this temperature, afforded compounds **2***c* and **1***d* (which were separated by silica gel chromatography) in 50 and 35% yield, respectively.



SCHEME 1

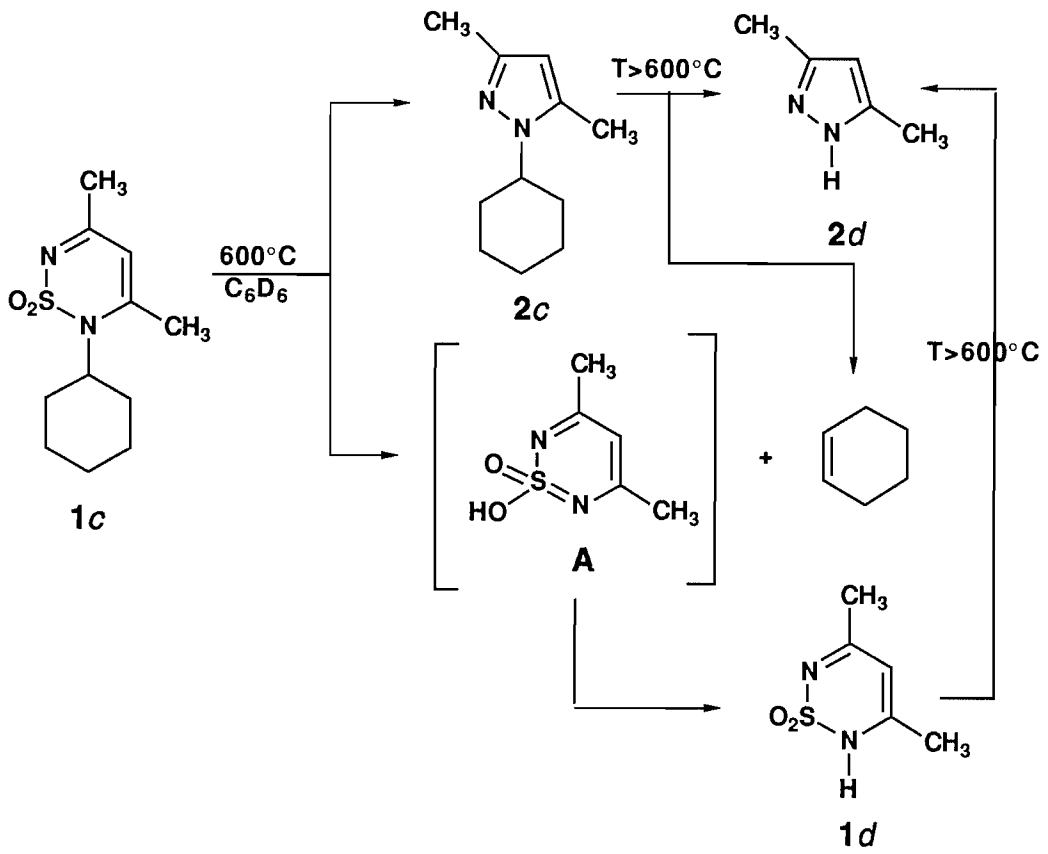
TABLE 1. Thermolysis of **1***a* and **1***b*

T (°C)	**1***a* (%)	**2***a* (%)	**1***b* (%)	**2***b* (%)
550	—	—	100	0
600	80	20	55	45
650	92	8	0	100
700	0	100	—	—

Two competitive reactions occur in the thermolysis of **1***c*: (*i*) an SO_2 elimination similar to that of **1***a* and **1***b*; (*ii*) an elimination of cyclohexene from **1***c*. At this point, it should be mentioned that cyclohexene could also result from the pyrolysis of **2***c*, since it has been shown (6) that *N*-alkyl pyrazoles bearing at least two carbon atoms on the alkyl chain afford alkenes by thermolysis.

To verify this hypothesis, thermolysis of **2***c* was carried out at 600°C under the same conditions. Since at this temperature only traces of cyclohexene and pyrazole **2***d* were

[1]Authors to whom correspondence may be addressed.



SCHEME 2

observed, it can be concluded that cyclohexene is formed essentially from **1***c*. However, at higher temperatures, there is a considerable increase of pyrolysis products (cyclohexene, **2***d*, and **2***c* in a 2:2:1 ratio at 700°C).

To complete this study, the thermal behaviour of **1***d*, which is also capable of losing an SO_2 molecule to afford pyrazole **2***d*, has been investigated. At 600°C, compound **1***d* remained practically unchanged and only traces of pyrazole **2***d* could be detected. At higher temperatures, the reaction became more complicated; at 630°C a considerable increase of **2***d* was observed, together with the appearance of several unidentified products. At 700°C, thiadiazine **1***d* had completely disappeared.

All the experimental results observed in the thermolysis of **1***c* are gathered in Scheme 2. It should be mentioned that the formation of **1***d* is likely to occur through a retroene type reaction (4) with the participation of the S=O double bond to give cyclohexene and the precursor **A** shown in Scheme 2.

The structures of all the products were established by comparison of the NMR data (^1H and ^{13}C) with authentic samples of the corresponding pyrazoles prepared by standard procedures (7).

Conclusions

This unambiguous synthesis of pyrazoles by SO_2 extrusion from 1,2,6-thiadiazine 1,1-dioxides could be very useful to introduce substituents in the five-membered aromatic ring, considering the different reactivity of the two heterocycles, and especially that referring to the 4-position (1).

Experimental

^1H and ^{13}C NMR spectra were recorded on a Bruker AC 250F spectrometer operating at 250 and 60 MHz, respectively, with TMS as internal standard.

Synthesis and characterization of thiadiazines and pyrazoles

Most compounds described in this work were already known (8): **1***a*, **1***b*, **1***d*, **2***a*, **2***b*, and **2***d*.

1-Cyclohexyl-3,5-dimethyl-1,2,6-thiadiazine 1,1-dioxide **1***c*

A solution of cyclohexylsulfamide (1.1 g, 0.011 mol) in ethanol (50 mL) was saturated with hydrogen chloride and then acetylacetone was added. The reaction mixture was refluxed for 4 h, the solvent evaporated *in vacuo*, and the residue recrystallized from water to give 1.8 g (67%) of **1***c*; mp 106–108°C; ^1H NMR ($CDCl_3$) δ: 5.65 (s, 1H, CH-4), 4.01 (m, 1H, -CH-N), 2.27 (s, 3H, CH_3-3), 2.1 (s, 3H, CH_3-5), 1.96–1.21 (m, 10H, CH_2); ^{13}C NMR ($CDCl_3$) δ: 172.74 (C-5), 157.81 (C-3), 103.91 (C-4), 61.62 (CH), 31.88 (CH_2), 26.96 (CH_2), 25.43 (CH_3-5), 25.27 (CH_2) 22.32 (CH_3-3). Anal. calcd. for $C_{11}H_{18}N_2O_2S$: C 54.54, H 7.43, N 11.57, S 13.22; found: C 54.61, H 7.79, N 11.32, S 13.17.

Flow pyrolysis of thiadiazines **1***a–c. General procedure*

Thermolyses were performed in the gas phase by passing the product through a 750 × 18 mm vertical quartz column heated by an electric Hermann–Moritz oven. The column was filled with small quartz cylinders (5 × 0.2 mm) and was connected to the pumping system ($p = 10^{-2}$ Torr; 1 Torr = 133.3 Pa).

In preparative thermolyses, the derivatives **1***a–c* (500 mg) were dissolved in benzene (25 mL) and introduced into the column dropwise. The emergent vapors were collected in a receiver cooled with liquid nitrogen. The solvent was evaporated under reduced pressure and the residue was chromatographed on a silica gel column using chloroform as eluent.

In analytical runs, thermolyses of **1***a–d* and **2***c* (50 mg) at var-

Received October 1, 1992

STANISLAS CZERNECKI, LAURENCE MULARD, JEAN-MARC VALÉRY, and ALAIN COMMERÇON. Can. J. Chem. **71**, 413 (1993).

Based on the mechanism of action of ribonucleoside diphosphate reductase (RDPR), a new class of nucleosides that may act as inhibitors of this enzyme was designed. Starting from uridine, a 2′-deoxy-2′-spirocyclopropyl derivative of cytosine was prepared. The key step of the synthesis is the condensation of diazomethane with a suitably protected 2′-methylene nucleoside. Light-induced nitrogen extrusion affords the cyclopropane ring.

STANISLAS CZERNECKI, LAURENCE MULARD, JEAN-MARC VALÉRY et ALAIN COMMERÇON. Can. J. Chem. **71**, 413 (1993).

En se basant sur le mécanisme d'action de la réductase du diphosphate de ribonucléoside (RDPR), on a mis au point une nouvelle classe de nucléosides qui peuvent agir comme inhibiteurs de cet enzyme. Utilisant l'uridine comme produit de départ, on a préparé un dérivé 2′-désoxy-2′-spirocyclopropylé de la cytosine. L'étape clé de la synthèse est la condensation du diazométhane avec un 2′-méthylène nucléoside protégé d'une façon appropriée. Sous l'influence de la lumière, il y a extrusion d'azote et formation du noyau cyclopropane.

Ribonucleoside diphosphate reductase (RDPR) is a key enzyme in the *de novo* production of deoxynucleoside precursors for DNA synthesis and is tightly linked to neoplastic transformation and progression (1). Accordingly, RDPR appears as a very attractive target for new anticancer agents and much research has been aimed at better understanding its mechanism of action (2) and at devising selective inhibitors (3). Among them, 2′-deoxy-2′-halogenated cytidine derivatives such as 2′-deoxy-2′,2′-difluorocytidine (4) and 2′-deoxy-2′-methylidenecytidine (5) are the more promising.

Since the extensive study of the molecular mechanism of this enzyme by Stubbe *et al.* (2*a*), a tyrosinyl radical is suspected to be the initiator of the enzymatic reaction by abstraction of H-3′. The resulting radical then undergoes a series of transformations to afford the 2′-deoxynucleotide with concomitant regeneration of the tyrosinyl radical.

We thought that it could be possible to design inhibitors utilizing this radical processing.[2] Since radical rearrangements involving β-scission of a cyclopropylmethyl moiety are known to be extremely rapid, they were used as mechanistic probes in reaction pathways implicating radical intermediates (7). Consequently, we decided to prepare a nucleoside derivative bearing a cyclopropyl ring at C-2′ that may act as an in vivo irreversible inhibitor of RDPR. Since the more active inhibitors are found in the cytidine series, 2′-deoxy-2′-spirocyclopropyl cytidine was chosen as target molecule.

The 3′,5′-*O*-protected derivative **1** (8) was smoothly oxidized by the pyridinium dichromate (PDC) – acetic acid reagent (9). This system, which requires only 1.5 molar equivalent of chromium species, was found to be superior to other reagents widely used for the oxidation of nucleosides (10). Further Wittig reaction on the 2′-keto nucleoside **2** was conducted with triphenylmethylene phosphorane generated from methyltriphenyl phosphonium iodide and *sec*-butyllithium in THF at −78°C to −30°C. This technique avoids the use of DMSO as in the procedure of Sano *et al.* (11) and compares favorably with the "salt-free" conditions successfully employed by Samano and Robins (10). Thus we were able to obtain the 2′-deoxy-2′-methylene uridine derivative **3***a* in 70% yield from uridine.

Despite numerous attempts, the samarium-promoted cyclopropanation reaction failed both on the free and on the protected methylene nucleoside although this method had been claimed to work well on various allylic alcohols (12). Deoxyspirocyclopropyl pentoses have previously been prepared by cycloaddition of diazomethane followed by photoinduced nitrogen extrusion from the resulting isomeric spiropyrazolines (13).

Treatment of compound **3***a* by diazomethane in ether at ambient temperature resulted only in the formation of uracil-methylated nucleosides **4** and **5**, together with a very small amount of presumed spiropyrazolines, and this whatever the excess of diazomethane was. Cyclopropanation of allyloxy- and allylamino derivatives was recently carried out with diazomethane in the presence of bisbenzonitrile dichloropalladium (14). Treatment of **3***a* under these conditions afforded **4** and **5** (90:10) together with unreacted starting material.

Nevertheless, we decided to carry out this experiment on the uracil-protected methylene nucleoside **6***b*. The 4-*O*-ethyl protection was chosen because this group could be further replaced by 4-amino, thus leading to cytosine-1-yl derivatives (15). Insufficient stability of the TPDS group during the nucleophilic displacement of the unstable 4-*O*-tosyl derivative (16) required the use of another protective group before activation and transformation at the 4-position of the uracil

residue (See Scheme 1). Diacetylated 2′-deoxy-2′-methylene derivative **3***b* was efficiently prepared from **3***a* (92%), and transformed into **6***a* (72% yield), which was further acetylated in nearly quantitative yield to get the soluble derivative **6***b*.

Treatment of **6***b* with excess diazomethane in ether for 16 h at ambient temperature gave a separable mixture of isomeric 2′-deoxy-2′-spiropyrazoline derivatives **7** (59%) and **8** (15%). The stereochemistry of the major compound **7** (2′*R*) was deduced from variable temperature ^{1}H NMR experiments, which demonstrated restricted rotation of the uracil residue around the glycosidic bond at ambient temperature due to the steric hindrance of the methylene groups of the pyrazoline ring, resulting in low resolution of the signals. At 50°C, a well-resolved spectrum was obtained, indicating the restoration of free rotation of the base. Such a phenomenon was not observed for the minor isomer **8**. Moreover, diazomethane approach from the less-hindered α side of **6***b* seems to be favored, as was previously noticed for the dihydroxylation of the double bond (11).

Exposure of neat **7** and **8** (or their mixture) to daylight during ca. 1 week resulted in the formation of **9***a* by extrusion of nitrogen. The structure of **9***a* was confirmed by mass spectroscopy and the appearance of signals of the cyclopropyl ring between 0.5 and 1 ppm in the ^{1}H NMR spectrum.

Treatment of **9***a* by a methanolic solution of ammonia at room temperature afforded the deacetylated 2′-spirocyclopropyl-2′-deoxyuridine derivative **9***b*. The target molecule **9***c* was obtained by treatment of **9***a* with the same solution at 100°C.

The biological evaluation of this compound is in progress (Dr. F. Lavelle, Rhône-Poulenc Rorer).

Experimental

Microanalyses were performed at the Service de Microanalyse de l'Université Pierre et Marie Curie. Melting points were determined with a Thomas–Hoover apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 polarimeter. The ^{1}H NMR spectra were recorded on a Bruker AM-250 spectrometer with TMS as internal standard. Reactions were monitored by analytical TLC using 2×5 cm precoated aluminum plates and silica gel 60 F_{254} (Merck), and detection by UV light and charring with H_2SO_4. For column chromatography, Merck silica gel 60 (230–400 mesh) and anhydrous solvents were used. Solvents and reagents were purified and dried by standard procedures.

*2′-Keto-3′,5′-*O*-(1,1,3,3-tetraisopropyldisiloxane-1,3-diyl)-β-*D*-uridine (2)*

To a stirred mixture of **1** (8) (4.86 g, 10 mmol), pyridinium dichromate (5.65 g, 15 mmol), and 4 Å molecular sieves (8 g) in CH_2Cl_2 (50 mL), acetic acid (1 mL, 1.75 mmol) is added. Stirring in continued at room temperature for 18 h. Celite (5 g) is added and the mixture is filtered and the solvent evaporated under reduced pressure. To the residue is added a large volume of Et_2O (100 mL) to precipitate most of the chromium salts. The ether solution is dried and slowly filtered through a column containing silica gel and Florisil (1:1). After evaporation pure **2** is obtained (4.11 g, 85%); mp 78–80°C; $[\alpha]_D^{20}$ −25.2 (*c* = 1, $CHCl_3$). Anal. calcd. for $C_{21}H_{36}N_2O_7Si_2$ (484,68): C 52.07, H 7.44, N 5.78; found: C 52.45 H 7.60 N 5.43. The ^{1}H NMR data of **2** are identical with the reported values (17).

*2′-Deoxy-2′-methylene-3′,5′-di-*O*-(1,1,3,3-tetraisopropyldisiloxane-1,3-diyl)-β-*D*-uridine (3a)*

Under a pressure of argon, *sec*-butyllithium in hexane (1.4 N, 6.45 mL, 9 mmol) is added to a suspension of triphenylmethyl phosphonium iodide (4.54 g, 11.2 mmol) in THF (20 mL) cooled at −78°C. The homogeneous orange solution is allowed to warm to −30°C and a solution of **2** (2.17 g, 4.5 mmol) in THF (7 mL) is transferred to this mixture under a pressure of argon. After warming to room temperature, stirring is continued for 24 h. THF is evaporated and replaced by CH_2Cl_2 (250 mL), water is added (20 mL), and the solution is neutralized with a cooled solution of 2% HCl. The organic layer is washed with H_2O (20 mL), 5% aqueous $NaHCO_3$ (20 mL), H_2O to neutrality, and brine (10 mL). After drying (Na_2SO_4), the solvent is evaporated *in vacuo* to give **3***a* (2.0 g), which is chromatographed on a silica gel column. Elution with light petroleum ether – ethyl acetate (7:3) affords pure **3***a* (1.78 g, 82%); mp 174–176°C (lit. (11) mp 130–133°C); $[\alpha]_D^{20}$ +26 (*c* = 1, $CHCl_3$).

*3′,5′-Di-*O*-acetyl-2′-deoxy-2′-methylene-β-*D*-uridine (3b)*

A 1 M solution of Bu_4N^+, F^- in THF (11.12 mL, 11.12 mmol) containing **3***a* (2.68 g, 5.56 mmol) is stirred at room temperature for 15 min. THF is evaporated *in vacuo* and acetonitrile (5 mL), Et_3N (7.7 mL, 56 mmol), and, after cooling at 0°C, acetic anhydride (2.62 mL, 55.6 mmol) are added to the reaction mixture. After evaporation to dryness, the residue is partitioned between AcOEt (50 mL) and aqueous $NaHCO_3$ (10 mL), water, and brine (10 mL). After drying (Na_2SO_4), the solvent is evaporated and the crude product is chromatographed. Elution with AcOEt – pet. ether (4:6) affords pure **3***b* (1.68 g, 92%); $[\alpha]_D^{20}$ −32.6 (*c* = 0.65, MeOH). ^{1}H NMR ($CDCl_3$) δ: 9.48 (br s, 1H, H-3), 7.24 (d, 1H, $J_{5,6}$ = 8.6 Hz, H-6), 6.73 (br s, 1H, H-1′), 5.78 (d, 1H, H-5), 5.64 (br s, 2H, methylene), 5.36 (br s, 1H, H-3′), 4.33 (m, 1H, $J_{5',5''}$ = 12.2 Hz, H-5′,H-5″), 4.2 (m, 1H, $J_{4',5'}$ = 4.2 Hz, $J_{4',5'}$ = 3.9 Hz, H-4′), 2.14 (s, 3H, CH_3CO), 2.03 (s, 3H, CH_3CO). Anal. calcd. for $C_{14}H_{16}N_2O_7$ (324.28): C 51.85, H 4.94, N 8.64; found: C 51.77, H 5.01, N 8.53.

*1-(2-Deoxy-2-methylene-*erythro*-β-*D*-pentofuranosyl)-4-*O*-ethyluracil (6a)*

A suspension of K_2CO_3 (590 mg, 5.9 mmol) in a solution of **3***b* (1.29 g, 3.93 mmol) and *p*-toluenesulfonyl chloride (900 mg, 4.72 mmol) in CH_3CN (15 mL) is heated at 85°C for 2 h. After cooling, the solvent is evaporated *in vacuo* and the residue is treated with NaOEt (1.5 M, 26 mL, 40 mmol) in EtOH (20 mL). The solid is filtered off and washed with EtOH. The ethanolic solution is neutralized with Amberlite IRN-77 (H^+ form). After filtration and evaporation of the solvent, the solid obtained is chromatographed. Elution with $CHCl_3$–methanol (9:1) affords pure **6***a*; yield: 640 mg (60%); mp 115–116°C; $[\alpha]_D^{20}$ +24.7 (*c* = 0.7, CH_3OH). ^{1}H NMR (DMSO-*d*6) δ: 7.9 (d, 1H, $J_{5,6}$ = 7.6 Hz, H-6), 651 (s, 1H, H-1′), 6.02 (d, 1H, H-5), 5.68 (d, 1H, $J_{3',OH}$ = 6.4 Hz, 3′-OH), 5.35 (s, 1H, H-2′), 5.24 (s, 1H, H-2″), 5.06 (t, 1H, $J_{6',OH}$ = $J_{6'',OH}$ = 5.1 Hz, 5′-OH), 4.52 (dd, 1H, $J_{3',4'}$ = 6.8 Hz, H-3′), 4.27 (9, 2H, *J* = 7 Hz, O-CH_2), 3.67 (m, 1H, H-4′), 3.71 (d, 1H, $J_{5',5''}$ = 12.4 Hz, H-5′), 3.57 (d, 1H, H-5″), 1.25 (t, 3H, CH_3).

*1-(3′,5′-Di-*O*-acetyl-2′-deoxy-2′-methylene-*erythro*-β-*D*-pentofuranosyl)-4-*O*-ethyl-uracil (6b)*

A solution of **6***a* (269 mg, 1 mmol) and acetic anhydride (570 mL, 6 mmol) in anhydrous pyridine (5 mL) is stirred at room temperature for 16 h. Solvent is evaporated and the residue is partitioned between $CHCl_3$ (50 mL) and water (10 mL). The organic layer is washed successively with 5% HCl (5 mL) and water, dried (Na_2SO_4), filtered, and evaporated. Compound **6***b* (360 mg, 100%) is homogeneous in TLC (R_f 0.62, $CHCl_3$–MeOH, 95:5; R_f 0.51, AcOEt – pet. ether, 7:3) and is characterized as follows. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.5 (d, 1H, $J_{5,6}$ = 8 Hz, H-6), 6.9 (br s, 1H, H-1′), 5.92 (d, 1H, $J_{5,6}$ = 8 Hz, H-5), 5.68 (m, 1H, $J_{3',4'}$ = 5 Hz, H-3′), 5.6 (br s, 1H, H-2″a), 5.38 (br s, 1H, H-2″b), 4.48 (q, 2H, CH_2O ethyl), 4.38 (d, 2H, H-5′, H-5″), 4.24 (dd, 1H, $J_{4',5'}$ = 5 Hz, H-4′), 2.18 (s, 3H, CH_3CO-), 2.10 (s, 3H, CH_3CO-), 1.38 (t, 3H, CH_3 ethyl). MS (EI) *m/z*: 352 ($M^{+\cdot}$), 293 ($M^{+\cdot}$ −OAc), 227. ($M^{+\cdot}$ −BH^+). Anal. calcd. for $C_{16}H_{20}N_2O_7$ (352.34): C 54.54, H 5.72, N 7.94; found: C 54.71, H 5.65, N 7.80.

*1-[3',5'-Di-*O*-acetyl-2'-deoxy-2'-(*S*)-spiro-4"-(1"-pyrazoline)-*erythro-*β-*D*-pentofuranosyl]-4-*O*-ethyl-uracil (**7**) and its 2'-(*R*) epimer (**8**)*

Compound **6** (100 mg, 0.28 mmol) is reacted with an excess of a solution of diazomethane in diethyl ether (4 equiv., 5 mL). Completion of the reaction is indicated by TLC ($CHCl_3$–MeOH, 98:2) and the mixture is chromatographed after evaporation *in vacuo*. Elution with $CHCl_3$–MeOH (98:2) affords **7** and **8**; yield: 82 mg (74%). The two epimers can be separated with AcOEt – pet. ether (120:130) as eluent and are characterized as follows:

Compound **7**, 2'-(*S*): ^{1}H NMR (400 MHz, $CDCl_3$, 50°C) δ: 7.9 (d, 1H, $J_{5,6}$ = 8 Hz, H-6), 6.04 (br s, 1H, H-1'), 5.96 (d, 1H, H-5), 5.52 (d, 1H, $J_{3',4'}$ = 9 Hz, H-3'), 5.0 (dd, 1H, $J_{4',5'}$ = $J_{4',5'}$ = 3 Hz, H-4'), 4.45–4.7 (m, 6H, CH_2-O, CH_2-N, H-5', H-5"), 2.20 (s, 3H, CH_3CO-), 2.05 (CH_3CO-), 1.62 and 1.42 (m, 2H, CH_2 pyrazoline), 1.39 (t, 3H, J = 7 Hz, CH_2- ethyl).

Compound **8**, 2'-(*R*): ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.88 (d, 1H, $J_{5,6}$ = 8 Hz, H-6), 6.6 (s, 1H, H-1'), 5.9 (d, 1H, H-5), 5.08 (d, 1H, $J_{3',4'}$ = 4 Hz, H-3'), 4.72 (dd, 1H, $J_{5',5''}$ = 12 Hz, $J_{5',4'}$ = 8 Hz, H-5'), 4.64 (dd, 1H, $J_{4'5''}$ = 4 Hz, H-5"), 4.4–4.52 (m, 5H, CH_2-O ethyl, CH_2-N, H-4'), 2.22 (m, 1H, H-4"a pyrazoline), 2.20 (s, 3H, CH_3CO-), 2.19 (s, 3H, CH_3CO-), 1.78 (m, 1H, H-4" pyrazoline). MS (Cl, NH_3) *m/z*: 395 (M+1).

*1-(3',5'-Di-*O*-acetyl-2'-deoxy-2',2'-spirocyclopropyl-*erythro-β-*D*-pentofuranosyl)-4-*O*-ethyl-uracul (**9**a)*

Compounds **7** and **8** (82 mg, 0.21 mmol) are exposed to sunlight in a round-bottom flask for several days (ca. 1 week). The transformation works better without any solvent, but is also effected in chloroform solution and exposure to a tungsten-filament lamp. Completion of nitrogen extrusion is indicated by TLC ($CHCl_3$–MeOH, 95:5); the resulting product is chromatographed on a silica gel column. Elution with AcOEt – pet. ether (1:1) affords pure **9***a*; yield: 43 mg (65%). ^{1}H NMR (400 MHz) $CDCl_3$) δ: 7.76 (d, 1H, $J_{5,6}$ = 8 Hz, H-6), 6.60 (s, 1H, H-1'), 5.95 (d, 1H, H-5), 4.92 (d, 1H, $J_{3',4'}$ = 3 Hz, H-3'), 4.32–4.50 (m, 1H, CH_2O, H-4', H-5', and H-5"), 2.17 (s, 3H, CH_3CO-), 2.16 (s, 3H, CH_3CO-), 1.38 (t, 3H, CH_3-CH_2), 1.06, 0.78, and 0.56 (3m, 2H, 1H, and 1H, cyclopropane). MS(EI) *m/z*: 366 (M^+), 307 ($M^{+\bullet}$ – OAc), 227 ($M^{+\bullet}$ – BH^+). Anal. calcd. for $C_{17}H_{20}N_2O_7$ (364.32): C 56.04, H 5.53, N 7.68; found: C 56.12, H 5.50, N 7.59.

*1-(2'-Deoxy-2'-spirocyclopropyl-*erythro-β-*D*-pentofuranosyl)-4-*O*-ethyl-uracil (**9**b)*

Compound **9***a* (50 mg, 0.13 mmol) is dissolved in methanol presaturated with ammonia (5 mL). After 24 h at room temperature, the solvent is evaporated and the residue purified by flash chromatography using chloroform–methanol (19:1) as eluent. Yield: 36 mg (69%) as a colorless syrup. ^{1}H NMR (DMSO-d_6) δ: 8.24 (d, 1H, $J_{5,6}$ = 7.39 Hz, H-6), 6.04 (d, 1H, H-5), 6.00 (s, 1H, H-1'), 5.19 (d, 1H, $J_{H,OH}$ = 5.84 Hz, 3'-OH), 5.10 (t, 1H, $J_{H,OH}$ = 5.34 Hz, 5'-OH), 4.27 (q, 2H, J = 7.05 Hz, -OCH_2), 4.05 ("t", 1H, $J_{3',4'}$ = 6.05 Hz, H-3'), 3.58–3.83 (m, 3H, H-4', H-5', H-5"), 1.27 (t, 3H, CH_3), 1.03, 0.58, and 0.47 (3m, 1H, 1H, and 2H, cyclopropane). MS (CI/NH_3) *m/z*: 300 (M+18), 283 (M+1).

*2'-Deoxy-2'-spirocyclopropyl cytidine (**9**c)*

Compound **9***a* (180 mg, 0.49 mmol) is dissolved in methanol presaturated with ammonia (40 mL). The mixture is heated in a stainless steel bomb at 100°C for 6 h. The solvent is evaporated and the residue purified as above with chloroform–methanol (2.6:1) as eluent. Yield: 76 mg (61%) as an amorphous solid. ^{1}H NMR (DMSO-d_6) δ: 7.77 (d, 1H, $J_{5,6}$ = 7.37 Hz, H-6), 6.00 (s, 1H, H-1'), 5.72 (d, 1H, H-5), 5.13 (d, 1H, $J_{H,OH}$ = 5.83 Hz, 3'-OH), 4.99 (t, 1H, $J_{H,OH}$ = 5.24 Hz, 5'-OH), 3.97 ("t", 1H, $J_{3',4'}$ = 5.84 Hz, H-3'), 3.72–3.56 (m, 3H, H-4', H-5', H-5"), 0.98 and 0.46 (2m, 1H and 3H, cyclopropane). MS (CI/NH_3) *m/z*: 271 (M+18), 254 (M+1).

A deuterium NMR study of molecular dynamics and geometry in two classes of onium salts: $(CH_3)_3E^+X^-$ and $C_6H_5M(CH_3)_3{}^+I^-$

GLENN H. PENNER,[1] JAMES M. POLSON,[2] STEPHEN I. DALEMAN,[3] AND KARA REID[3]

Received August 6, 1992

GLENN H. PENNER, JAMES M. POLSON, STEPHEN I. DALEMAN, and KARA REID. Can. J. Chem. **71**, 417 (1993).

Deuterium NMR measurements are reported for two types of onium salts: $(CH_3)_3E^+I^-$, where E = O (counterion is BF_4^-), S, Se, or Te, and $C_6H_5M(CH_3)_3{}^+I^-$, where M = N, P, or As. Within each class of compounds the activation energy for rotation of the trimethyl groups about the C_3' axis increases with increasing size of the central atom. In the first class of compounds the C—E—C bond angle decreases with the size of the atom E. In addition the magnitude of the quadrupolar coupling constant, χ, varies with E, ranging from 160 kHz for E = O to 190 kHz for E = Te. This is in qualitative agreement with molecular orbital calculations of the electric field gradients. At low temperatures the ^2H NMR spectrum of $C_6H_5N(CH_3)_3{}^+I^-$ can only be rationalized with a model in which trimethyl rotation is faster than methyl rotation. The ^2H NMR of ring (predominantly *ortho* and *para*)-deuterated $C_6H_5N(CH_3)_3{}^+I^-$ is consistent with rapid n-site ($n \geq 3$) rotation of the phenyl ring above 390 K. Below 390 K spectra characteristic of two-site, 180°, flips of the phenyl ring are observed. Below 280 K the motion of the phenyl ring is in the rigid lattice limit.

GLENN H. PENNER, JAMES M. POLSON, STEPHEN I. DALEMAN et KARA REID. Can. J. Chem. **71**, 417 (1993).

On a effectué des mesures de RMN du deutérium pour deux types de sels onium : $(CH_3)_3E^+I^-$ dans lesquels E = O (le contre-ion est le BF_4^-), S, Se ou Te, et $C_6H_5M(CH_3)_3$ dans lesquels M = N, P ou As. Dans chacune de ces classes de composés, l'énergie d'activation de la rotation des groupes méthyles autour de l'axe C_3' augmente avec une augmentation de la taille de l'atome central. Dans la première classe de composés, l'angle de la liaison C—E—C augmente avec une augmentation de la taille de l'atome E. De plus, l'amplitude de la constante de couplage quadripolaire, χ, varie avec E; elle varie de 160 kHz pour E = O à 190 kHz pour E = Te. Ce résultat est en accord qualitatif avec les calculs d'orbitales moléculaires des gradients des champs électriques. À basses températures, on ne peut rationaliser les spectres RMN du ^2H du $C_6H_5N(CH_3)_3{}^+I^-$ qu'à l'aide d'un modèle dans lequel la rotation de triméthyle est plus rapide que celle du méthyle. Le spectre RMN du ^2H du cycle $C_6H_5N(CH_3)_3{}^+I^-$ deutéré (principalement en *ortho* et *para*) est en accord avec la rotation rapide de n-sites ($n \geq 3$) du cycle phényle à des températures supérieures à 390 K. À des températures inférieures à 390 K, on observe des spectres caractéristiques de rotations rapides des noyaux phényles sur deux sites, 180°. En-dessous de 280 K, les déplacements du noyau phényle se font dans les limites d'un réseau rigide.

Introduction

An important application of solid state NMR spectroscopy is in the study of molecular dynamics. A detailed analysis of NMR spectral lineshapes at different temperatures can provide information on the type of motion and on the energetics of that motion. For powdered samples the change in lineshape is most sensitive to the exchange rate of the dynamic process when this rate is comparable to the inhomogeneous linewidth.

Deuterium (^2H) NMR spectroscopy has developed rapidly as a tool for examining dynamic processes in solids (1–3). It is often relatively easy to introduce ^2H into a variety of molecular systems (4), and ^2H NMR techniques can be used to study molecular dynamics with exchange rates, k, ranging from 10^{-2} to 10^9 s^{-1} (1). The molecular motions of numerous solid trimethyl systems of the type $(CH_3)_3M$, where M is CSH (5), CBr (6), CCl, Cl, CCHO (7), NH^+, $NCH_3{}^+$ (8, 9), $S{=}O^+$ (10), N (11), and CC_6H_5 (12), have been studied by deuterium NMR spectroscopy.

Solid state deuterium NMR spectral lineshapes are dominated by the quadrupolar interaction. The quadrupolar interaction is due to the coupling between the deuterium quadrupole moment, eQ, and the electric field gradient, eq_{zz}, at the deuteron. Two measurable parameters are obtained from the deuterium NMR lineshape: the deuterium quadrupole coupling, $\chi = e^2q_{zz}Q/h$, and the asymmetry parameter, η. The asymmetry parameter is defined as the difference between the other two principle components (eq_{xx}, eq_{yy}) of the electric field gradient tensor, V, (eq. [1] in the principal axis system of the tensor) and has absolute values between 0 and 1.

$$[1] \quad V = \begin{bmatrix} eq_{xx} & 0 & 0 \\ 0 & eq_{yy} & 0 \\ 0 & 0 & eq_{zz} \end{bmatrix}$$

The ^2H NMR spectra of a powder sample containing static C—D bonds is characterized by three separations, $\Delta\nu_{11}$, $\Delta\nu_{22}$, and $\Delta\nu_{33}$, as shown in Figs. 1*a* and 1*b*. These are related to χ and η according to eqs. [2] and [3].

$$[2a] \quad \Delta\nu_{11} = \frac{3}{4}\chi(1 - \eta)$$

$$[2b] \quad \Delta\nu_{22} = \frac{3}{4}\chi(1 + \eta)$$

$$[2c] \quad \Delta\nu_{33} = \frac{3}{2}\chi$$

$$[3] \quad \eta = \frac{\Delta\nu_{22} - \Delta\nu_{11}}{\Delta\nu_{33}}$$

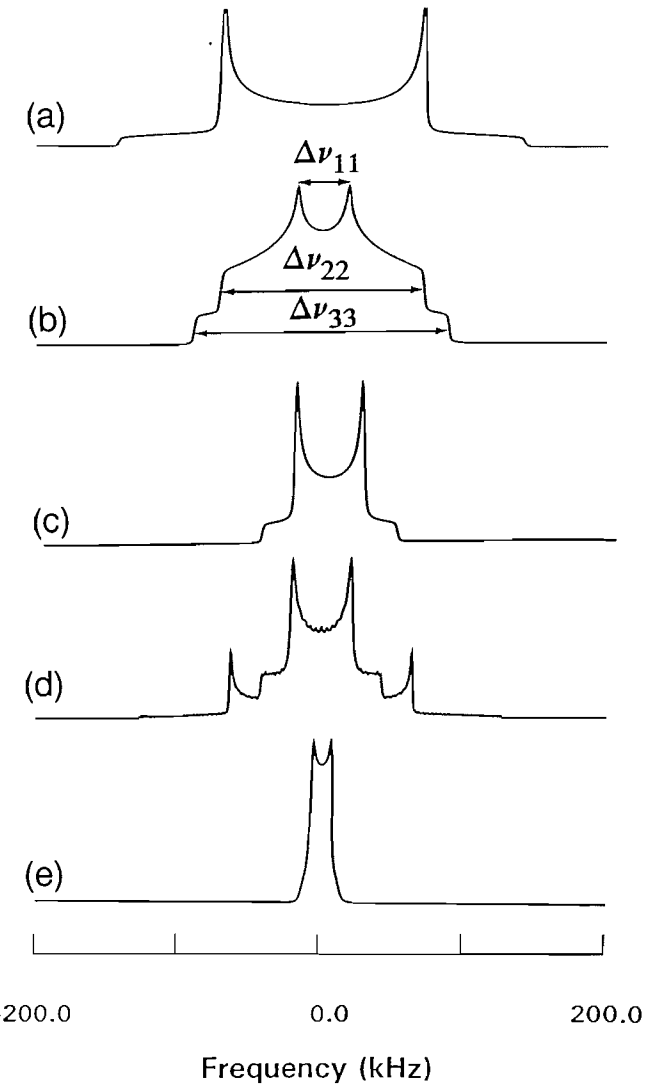

FIG. 1. Calculated deuterium NMR spectra. (*a*) χ = 190 kHz and η = 0.05; typical for a static phenyl ring deuteron. (*b*) χ = 190 kHz and η = 0.05 with rapid 180° flips of the phenyl ring yielding χ_{eff} = 114 kHz and η_{eff} = 0.6 for *ortho* and *meta* deuterons. (*c*) χ = 175 kHz and η = 0 with rapid 3-fold exchange of the methyl deuterons yielding χ_{eff} = 58 kHz and η_{eff} = 0.0. Tetrahedral geometry is assumed for the methyl carbon. (*d*) Same parameters as (*c*) with additional exchange between the three methyl groups of a trimethyl group; tetrahedral methyl and trimethyl geometries are assumed. (*e*) Same parameters as (*c*) but with slow methyl rotation and rapid trimethyl rotation.

Typically η = 0 for methyl deuterons and the spectrum is characterized by a quadrupolar splitting $\Delta\nu$ of $3\chi/4$ and an outer separation of $3\chi/2$. The value of χ normally lies between 160 and 180 kHz, for methyl deuterons (13).

Molecular reorientation in systems of the type $(CH_3)_3M$ usually consists of three-site exchange between the C—D bonds of the methyl groups, often referred to as C_3 rotation, and three-site exchange between the methyl groups, referred to as C_3' rotation.

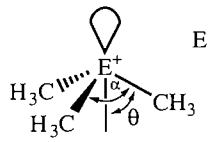
Rapid ($k > 10^7$ s^{-1}) methyl rotation reduces $\Delta\nu$ by a factor of $\frac{1}{2}(3\cos^2\theta_{CD} - 1)$, where θ_{CD} is the angle between the C—D bonds and the rotational axis, and additional rapid trimethyl rotation ($k' > 10^7$ s^{-1}) further reduces $\Delta\nu$ by a factor of $\frac{1}{2}(3\cos^2\theta_{MC} - 1)$ where θ_{MC} is the angle between the M—C bonds and the C_3' rotational axis. Therefore rapid methyl and trimethyl rotation reduces $\Delta\nu$ according to eq. [4].

$$[4] \qquad \Delta\nu = \frac{3}{16}\chi\,(3\cos^2\theta_{CD} - 1)(3\cos^2\theta_{MC} - 1)$$

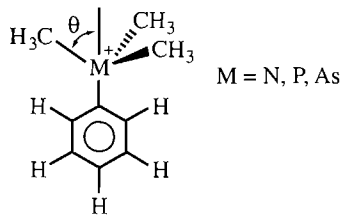
Typical spectra for methyl deuterons undergoing rapid C_3 and for trimethyl deuterons undergoing rapid C_3 plus C_3' rotation are shown in Figs. 1*c* and 1*d*, respectively. If C_3' rotation is fast while C_3 rotation is slow ($k < 10^3$ s^{-1}) the orientation of one C—D bond in each methyl group will not change with respect to the C_3 axis while the other two experience a three-site exchange. The resulting spectrum is simulated in Fig. 1*e*. Spectra for intermediate exchange rates (10^3–10^6 s^{-1}) are more complex in appearance but the lineshapes can be simulated if the correct geometry (θ_{CD} and θ_{MC}) and exchange rates (k and k') are provided (14, 15).

We have undertaken a deuterium NMR study of the methyl and trimethyl rotational dynamics in two classes of solid onium salts:

1. The series of cations $(CH_3)_3E^+$ where E is Te, Se, S, or O (compounds **1**, **2**, **3**, and **4**); and where the counterion is I^-; except for **4** where Y^- is BF_4^-.



2. The series of cations $C_6H_5M(CH_3)_3{}^+I^-$, where M = N, P, or As (compounds **5**, **6**, and **7**).



In addition, since **7** was easily deuterated in the phenyl ring positions, the dynamics of the phenyl ring were also studied by ^{2}H NMR. It is worth noting at this point that whereas the geometry about M in **5**, **6**, and **7** is expected to be tetrahedral or nearly tetrahedral, the structure of the $(CH_3)_3E^+$ cation changes significantly with E (16–19).

Experimental

Deuterated samples of trimethyltelluronium-d_3 iodide, trimethylselenonium-d_3 iodide, and trimethylsulfonium-d_9 iodide were synthesized according to eq. [5] by direct addition of iodomethane-d_3 to dimethyltelluride, dimethylselenide, and dimethylsulfide-d_6, respectively (19).

$$[5] \qquad (CH_3)_2\,E + CH_3\,I \rightarrow (CH_3)_3E^+I^-$$

Trimethyloxonium-d_3 tetrafluoroborate was prepared by condensation of excess dimethyl ether into a suspension of silver tetrafluoroborate in an iodomethane-d_3/dichloromethane solution at −78°C (20). The reaction mixture was allowed to warm to room temperature, under an inert nitrogen atmosphere, and any remaining iodomethane, dimethyl ether, or solvent was removed under vacuum.

$$[6] \qquad (CH_3)_2O + CH_3\,I \xrightarrow{AgBF_4} (CH_3)_3O^+\,BF_4^- + AgI$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

No attempt was made to separate the oxonium salt from the silver iodide. Methyl-deuterated samples of phenyltrimethylammonium-d_3 iodide, phenyltrimethylphosphonium-d_3 iodide, and phenyltrimethylarsonium-d_3 iodide were prepared by addition of iodomethane-d_3 to dimethylaniline, dimethylphenylphosphine, and dimethylphenylarsine, respectively.

[7] $C_6H_5M(CH_3)_2 + CH_3I \rightarrow C_6H_5M(CH_3)_3{}^+I^-$

Phenyl-ring-deuterated **7** was prepared by refluxing dimethylaniline in a 35% DCl/D_2O solution overnight. The product was neutralized with $NaOD/D_2O$ solution and extracted with ether. This was methylated by the above-mentioned procedure. The product is deuterated predominantly in the *ortho* and *para* positions. The samples were ground and sealed in 7 mm (300 mg) or 8 mm (500 mg) o.d. tubes. The oxonium sample was ground and sealed in a dry box under an argon atmosphere. Sample purity was checked by high-resolution solution (solvent: D_2O) ^1H (**1**, **2**, **5**–**7**) and ^{13}C (**3**, **4**) NMR spectroscopy.

Deuterium NMR spectra were obtained at 30.7 MHz on a Bruker CXP-200 or at 41.3 MHz on a home-built spectrometer. Spectra at liquid nitrogen temperature (77 K) were obtained on a Bruker CXP-200 using a home-built probe. The small size of the liquid nitrogen reservoir and potential for damage to the magnet severely limited the total collection time for each spectrum. Spectra were obtained by using the quadrupolar echo (21) pulse sequence: $(\pi/2)_x$–τ_Q–$(\pi/2)_y$–τ_Q-acquire, followed by Fourier transformation. Typically the length of the $\pi/2$ pulse was 3.5–4.0 μs and a τ_Q value of 40 μs was used.

Lineshape simulations of the spectra, partially narrowed by molecular motion, were simulated by standard methods using the program MXQET (15). These computations employed an IBM 3081-K mainframe. Simulated spectra were visually matched to experimental lineshapes. Molecular orbital calculations employed the Gaussian 90 program (22) on a Silicon Graphics Power Series 8 computer.

Results and discussion

Trimethyltelluronium iodide-d_3 ***(1)***

At temperatures between 77 and 423 K the ^2H spectrum of **1** is consistent with that expected for C_3 rotation of the methyl groups. There is no evidence for C_3' rotation in this temperature range. The observed quadrupolar splitting in this temperature range is 47.5 ± 0.5 kHz and, if the methyl groups are assumed to have a tetrahedral geometry, this corresponds to a χ value of 190 ± 2 kHz.

An X-ray diffraction study of **1** indicates that the iodide anions are situated in such a way that secondary bonding may occur between tellurium and the iodine (19). Tellurium ··· iodine secondary bonding has also been reported for β-dimethyltellurium di-iodide, $[Me_3Te]^+$ $[MeTeI_4]^-$ (23). The secondary Te ··· I contacts are approximately *trans* to the Te—C bonds. The existence of these secondary bonds would significantly hinder any C_3' rotation of the cation. Secondary Te ··· X bonds in $Me_3TeCl{\cdot}H_2O$, Me_3TeCl, Me_3TeBr, and Me_3TeI are responsible for scalar ^{125}Te—X *J*-coupling (X = ^{35}Cl, $^{79/81}Br$, ^{127}I) in the ^{125}Te CP/MAS spectra (19), although the internuclear distances are large enough that no dipolar coupling is observed in the static ^{125}Te powder spectra.

Trimethylselenonium iodide-d_3 ***(2)***

Deuterium NMR spectra were obtained for **2** in the temperature range 292–378 K. At the lowest temperature the cation is experiencing only C_3 rotation. Assuming a tetrahedral geometry for each methyl group, the quadrupolar splitting of 45.0 kHz corresponds to a χ value of 180.0 kHz. At temperatures above 378 K the cation is undergoing fast C_3 and C_3' rotation. The reduction in $\Delta\nu$ due to C_3' rotation corresponds to a θ_{SeC} angle of 62.0 ± 0.5°. The polar angle, θ_{EC}, between the E—C bonds and the C_3' rotational axis is related to the C—E—C bond angle, α, by eq. [8],

[8] $\cos(\alpha) = \cos^2(\theta) + \sin^2(\theta)\cos(\phi)$

where φ is the projection angle of the C—E—C bonds onto a plane perpendicular to the C_3' rotational axis.

For all the onium cations considered here, φ = 120°. Then

[9] $\alpha = \cos^{-1}[\cos^2(\theta_{EC}) - 0.5\sin^2(\theta_{EC})]$

The bond angle α is calculated to be 99.8 ± 0.5°, which is in good agreement with the X-ray diffraction crystal structure value of 98.5 ± 1° (18).

Now that the quadrupolar coupling constant, χ, and the polar angle, θ_{SeC}, have been determined from the lowest and highest temperature spectra, respectively, the only parameter that must be varied in order to match simulated and experimental spectra in the intermediate temperature region is the rate constant, k'. The best-fit simulations of spectra for the intermediate C_3' exchanges rates, together with the observed spectra, are shown in Fig. 2. The resulting eight $\ln k'$ versus $1/T$ points were fit to a straight line. The activation energy for C_3' exchange between methyl groups is 78 ± 3 kJ/mol.

The ability of the $(CH_3)_3Se^+$ cation to undergo C_3' rotation at lower temperatures than the $(CH_3)_3Te^+$ ion is a result of the weaker Se···I interaction in $(CH_3)_3SeI$ compared to three relatively strong Te···I interactions in $(CH_3)_3TeI$. The reported linebroadening in the ^{77}Se CP/MAS spectra of $(CH_3)_3SeI$ due to ^{77}Se-^{127}I *J*-coupling is much less severe than that due to ^{125}Te-^{127}I *J*-coupling in $(CH_3)_3TeI$ (19); this implies a weaker Se···I interaction in $(CH_3)_3SeI$.

Trimethylsulfonium iodide-d_9 ***(3)***

Deuterium NMR spectra of solid **3** were obtained at temperatures between 247 and 323 K. At 247 K and below, only methyl rotation is narrowing the lineshape and the measured $\Delta\nu$ value is 43.3 kHz. This yields a quadrupolar coupling constant, χ, of 173 kHz. The spectra at 323 K and above display fast C_3 and C_3' rotation. Assuming a tetrahedral geometry for the methyl groups, the best simulation of the spectrum at 323 K gives a polar angle, θ_{SC}, of 65.0 ± 0.5. The corresponding C—S—C bond angle is 103.4 ± 0.5°. This is in excellent agreement with the crystal structure value of 103 ± 1° (16). Simulations of the spectra in the intermediate exchange regime are shown, together with the experimental spectra, in Fig. 3. An Arrhenius plot of $\ln k'$ versus $1/T$ yields an activation energy of 65 ± 3 kJ/mol for C_3' cation rotation.

Trimethyloxonium-d_3 *tetrafluoroborate* ***(4)***

At temperatures above 240 K the ^2H spectrum of solid **4** is a smooth Lorentzian-like peak of half-maximum width 50 Hz. At lower temperatures a broad component appears. The lineshape of this broad component is consistent with the spectrum expected for fast C_3 and C_3' rotation. The quadrupolar splitting is 15 kHz. The lineshape of the broad component begins to change at 186 K and continues to change as the temperature is lowered. The narrow component begins to broaden at 157 K and by 138 K appears to contribute very little to the overall spectral intensity. The broad component of the ^2H spectrum could be successfully simu-

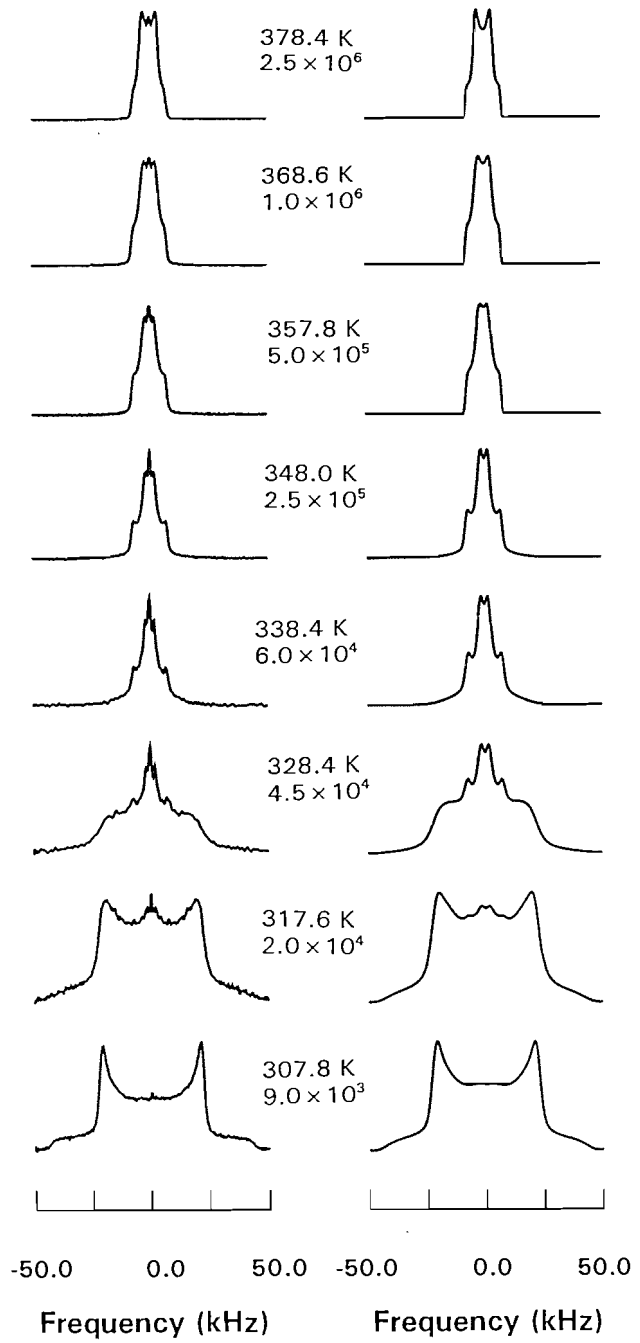

FIG. 2. Deuterium NMR spectra for trimethylselenium-d_3 iodide at various temperatures together with the best-fit simulated spectra.

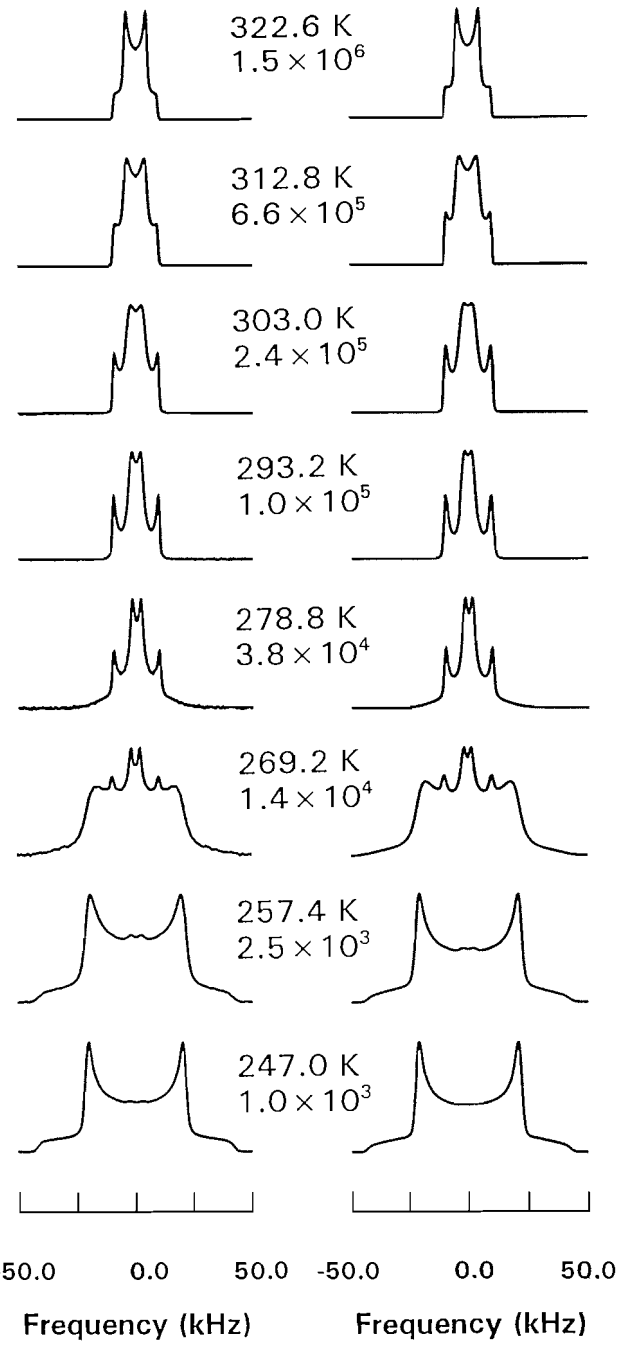

FIG. 3. Deuterium NMR spectra for trimethylsulfonium-d_9 iodide at various temperatures together with the best-fit simulated spectra.

lated using trimethyl rotational rates ranging from 1×10^3 s^{-1} at 119 K to 1.5×10^6 s^{-1} at 186 K. Simulated and experimental spectra are shown in Fig. 4. To satisfactorily simulate the spectrum at 119 K a methyl rotational rate of 4×10^6 s^{-1} was employed. At temperatures above 119 K the methyl C_3 rotation is in the fast exchange limit and the spectral lineshape is independent of the methyl exchange rate. The spectra were simulated with a χ value of 160 kHz and an angle, θ_{OC}, of 73.5°; the methyl groups were assumed to be tetrahedral ($\theta_{CD} = 70.5°$). An X-ray crystal structure is not available for **4** although a C—O—C bond angle of 112.7 ± 2.5° has been found for $(CH_3CH_2)_3O^+PF_6^-$ (16). This is in close agreement with our value of 112.2 ± 1.0°. An Arrhenius plot of the C_3' rotational rates of the oxonium cation versus inverse temperature gave an activation energy of 31 ± 2 kJ/mol.

It is evident that the sample of **4** consists of two components. We have identified one component as due to the oxonium cation undergoing varying rates of methyl rotation and trimethyl rotation below 240 K. The component that remains narrow over a larger temperature range is either a coexisting phase of **4** or an impurity. The ^{13}C spectrum of the solid showed only one resonance of peak width 800 Hz (8 ppm). Two possible impurities, due to the hydrolysis of

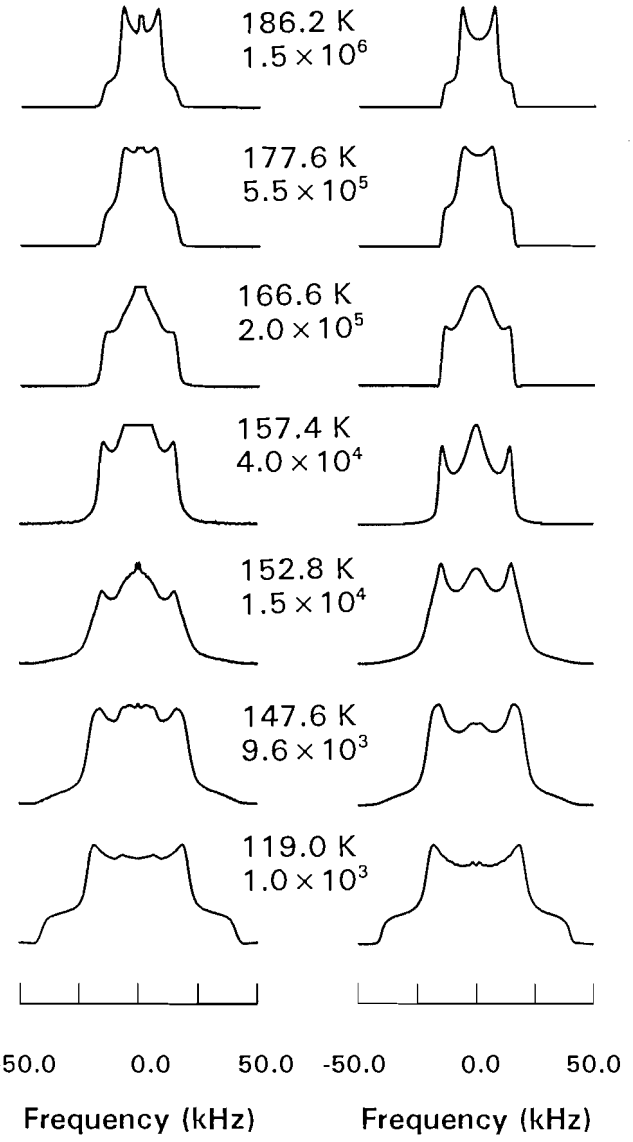

FIG. 4. Deuterium NMR spectra for trimethyloxonium-d_3 tetrafluoroborate at various temperatures. Simulations of the broad component are shown on the right-hand side.

4, are dimethyl ether and methanol. These impurities have ^{13}C chemical shifts that are easily resolved from that for **4**: ($\delta((CH_3)_3O^+)$ = 79 ppm, $\delta((CH_3)_2O)$ = 60 ppm, and $\delta(CH_3OH)$ = 49 ppm. We therefore suggest that some of the trimethyloxonium cations in solid $(CH_3)_3O^+BF_4^-$ can exist in a motionally different regime. Figure 5 shows a spectrum of **4** at 77 K. The spectrum consists of a component with a quadrupolar splitting of 40.5 ± 2 kHz and a component with a splitting of 124 ± 6 kHz, suggesting that at 77 K one component is in the rigid lattice limit and the other is undergoing C_3 rotation.

Oxonium cations may also undergo inversion about the oxygen atom. Rapid inversion would introduce a non-zero asymmetry ($\eta > 0$) and reduce the effective quadrupolar coupling constant. These effects are not observed in the broad component of the deuterium NMR spectrum of **4**. The high-temperature narrow component is likely due to isotropic random reorientation of the trimethyloxonium cation; additional inversion will not change the spectral lineshape. Molecular orbital calculations at the MP2/6-31G** level yield an inversion barrier of 20.9 kJ/mol. The only reported inversion barrier for an oxonium salt in solution is that for **8**. A proton dynamic NMR study of **8** yields an inversion barrier of 42 ± 8 kJ/mol (24). These values suggest that for the broad component the inversion barrier in the solid is higher than those for the gas or solution phases.

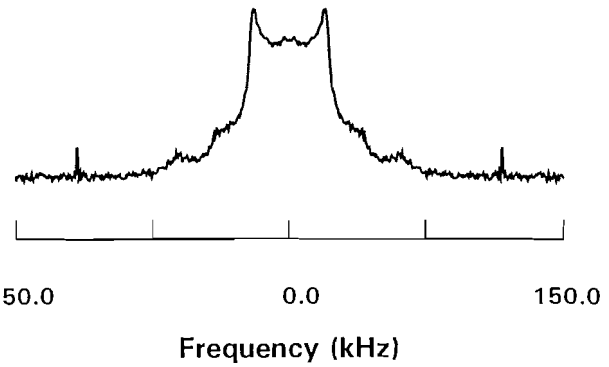

FIG. 5. The deuterium NMR spectrum of trimethyloxonium-d_3 tetrafluoroborate at 77 K.

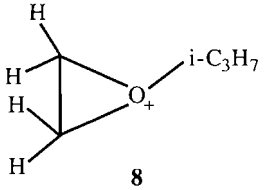

8

Variation of χ in the series $(CH_3)E^+$

The deuterium quadrupolar coupling constant, χ, in the series $(CH_3)_3E^+$ shows a rather significant change with atom E. The value increases steadily from 160 kHz for E = O to 190 kHz for E = Te. Molecular orbital calculations of the electric field gradient, q_{zz}, at the deuterium sites can provide theoretical χ values if the nuclear quadrupolar moment, Q, is known. Equation [10] relates the three quantities,

$$[10] \quad \chi = 235Q\,q_{zz}$$

where q_{zz} is in atomic units, Q has units of 10^{-28} m^2, and χ has units of MHz. Molecular orbital calculations of χ using the STO-3G* basis set are given in Table 1. Although the χ values are not quantitatively reproduced, the trend of decreasing χ with decreasing size of the E-atom is apparant. It has been shown that χ values calculated with large basis sets (e.g., 6-31G*) and at levels where second-order correlation effects are taken into account (e.g., MP2 or CI) are in good aggreement with those obtained from gas phase experiments (e.g., microwave spectroscopy) (25–27). The large size of the Se and Te atoms has restricted our calculations to the STO-3G* basis; therefore electron correlation effects are not taken into account. Also, our experiments were carried out in the solid state. Nevertheless, a qualitative comparison between experiment and theoretical calculation can be made. There are two factors that can affect χ in molecules of the type $(CH_3)_3E^+$: the size of the central atom and the molecular geometry about the central atom. To test the first effect, q_{zz} was calculated for oxygen and sulfur central atoms with the angle θ_{EC} held at 65°. The value of χ increased from 196.7 kHz (E = O) to 199.3 kHz (E = S).

TABLE 1. Activation energies for C_3' motion, bond angles, and deuterium quadrupolar coupling constants for various $(CH_3)_3E^+$ salts

Variable	$(CH_3)_3TeI$	$(CH_3)_3SeI$	$(CH_3)_3SI$	$(CH_3)_3OBF_4$
E_a (kJ/mol)	—	78 ± 3	65 ± 3	31 ± 2
θ_{EC} (deg)	—	62.0 ± 0.5	65.0 ± 0.5	73.5 ± 1.0
α_{EC} (deg)	—	99.8 ± 0.5	103.4 ± 0.5	112.2 ± 1.0
$\alpha_{X\text{-}ray}$	94.2 ± 0.1	98.5 ± 1	103 ± 1	112.7 ± 2.5[a]
χ_{obs} (kHz)	190 ± 2	180 ± 2	173 ± 2	160 ± 2
χ_{MO} (kHz)	203.5	201.8	200.8	196.7

[a]For triethyloxonium hexafluorophosphate (16).

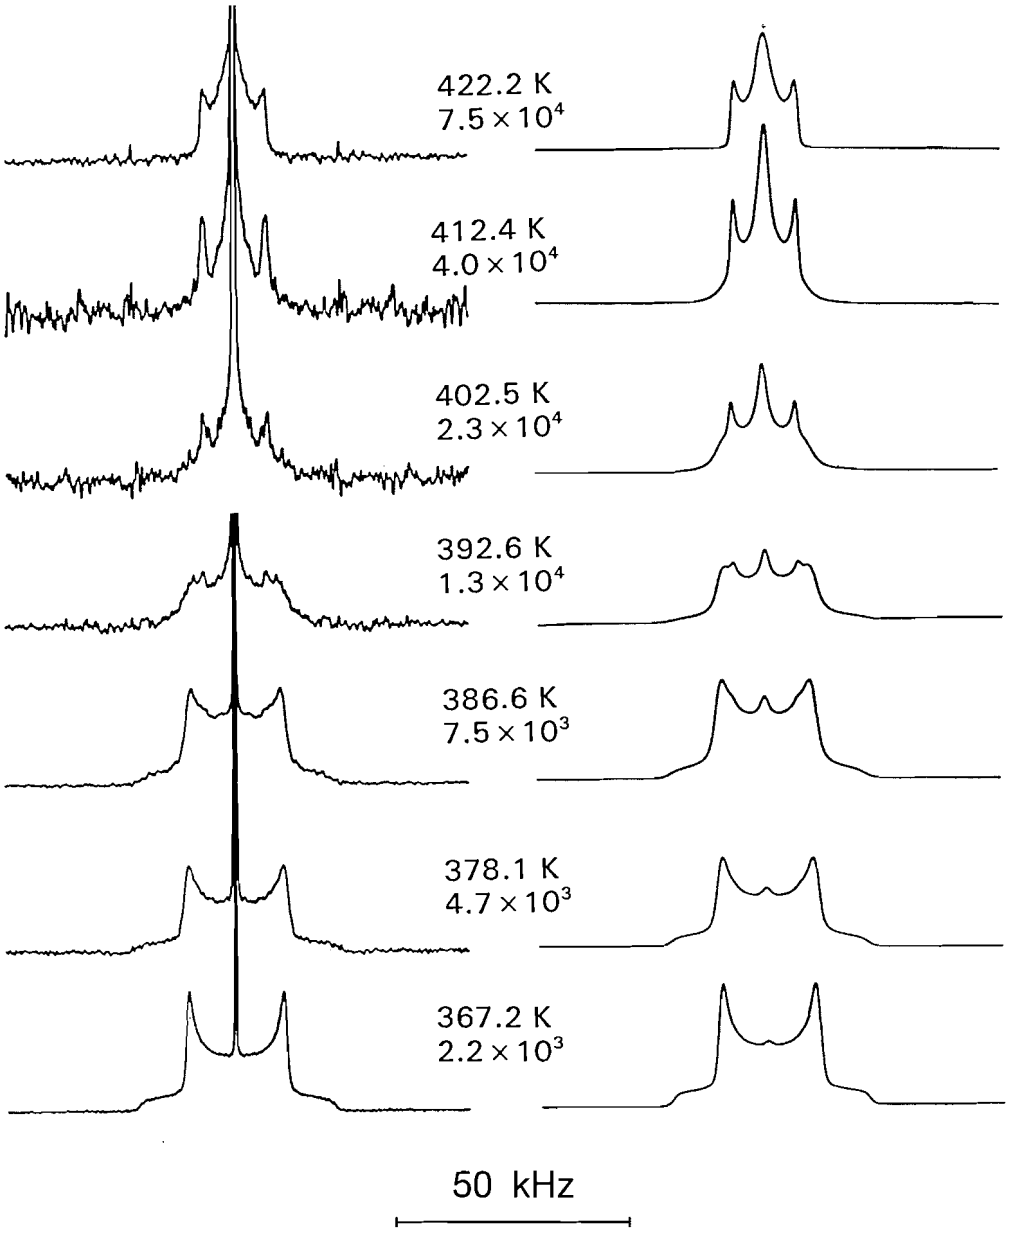

FIG. 6. Deuterium NMR spectra for phenyltrimethylarsoniun-d_3 iodide at various temperatures together with simulated spectra.

Calculations of χ for both the oxygen and sulfur compounds were performed while varying θ_{EC} from 90° to 45°. For both molecules the magnitude of q_{zz} and hence χ increased. These calculations suggest that as one descends group VIB the increasing size of the E-atom and the decreasing angle θ_{EC} each yield an increase in the quadrupolar coupling constant for the methyl deuterons. One factor that cannot be assessed by standard molecular orbital calculations is the intermolecular

contribution to χ due to the neighboring atoms in the crystalline material. To our knowledge the χ value of 190 kHz for **1** is the largest reported for a methyl deuteron.

Phenyltrimethylarsonium-d_3 *iodide (**5**)*

The ^{2}H NMR lineshapes for **5** are shown in Fig. 6. At temperatures below 367 K there is only evidence of methyl rotation. At higher temperatures the lineshape changes in a way characteristic of that expected for intermediate C_3' rotational rates. It is evident that even at the highest attainable temperature (422 K) the trimethyl rotation is not in the fast exchange limit. The central component, which increases in intensity with increasing temperature, is due to decomposition products. Despite relatively poor signal to noise, the lineshape could be simulated with χ = 59 kHz, θ_{As-C} = 70.5, and trimethyl exchange rates between 2.2 kHz (367 K) and 75 kHz (422 K). Simulations are also shown in Fig. 6. The Arrhenius activation energy for reorientation of the $(CH_3)_3As$ group is 96.6 ± 4.6 kJ/mol.

Phenyltrimethylphosphonium-d_3 *iodide (**6**)*

The ^{2}H NMR spectra of **6** are displayed in Fig. 7. The appearance of the spectra below 345 K is consistent with rapid rotation of the methyl groups. Attempts were made to simulate the higher temperature, intermediate C_3' exchange, spectra by varying only k'. Although the general lineshapes could be simulated, the experimental linewidth became progressively narrower with increasing temperature. The reduction of linewidth with increasing temperature is due to a third reorientational motion of the methyl deuterons. This motion is likely a wobbling of the phenyltrimethylphosphonium cation, with the amplitude of the motion increasing with temperature. At the highest attainable temperature (432 K) the trimethyl rotation is not yet in the fast exchange regime. The wobbling motion is taken into account in the simulations by simply reducing the effective quadrupolar coupling constant as the temperature increases. A precessional wobble has been used to explain the decrease in χ_{eff} with increasing temperature for deuterated CH_3NH_3 cations

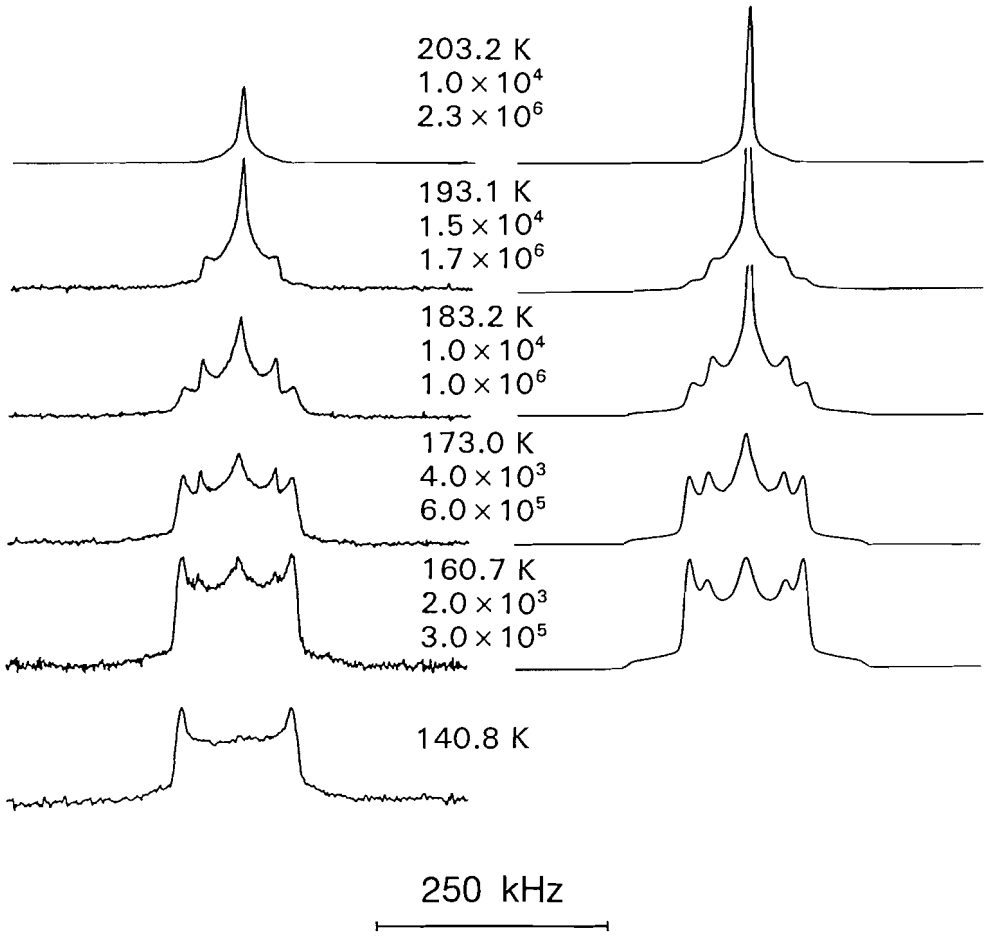

FIG. 8. Deuterium NMR spectra for phenyltrimethyl ammonium-d_3 iodide at various temperatures together with simulated spectra.

in methylammonium salts (28, 29). At temperatures between 343 and 432 K effective χ values ranging from 159 to 146 kHz were employed. The activation energy for trimethyl rotation in **6** is 84.3 ± 0.6 kJ/mol.

Phenyltrimethylammonium-d_3 *iodide (7)*

At temperatures above 300 K the ^{2}H NMR series of **7** indicate that the trimethylammonium group is undergoing both fast methyl and trimethyl rotation. The quadrupolar splitting is about 11 kHz. At temperatures below 150 K both methyl and trimethyl rotation are in the rigid lattice limit. The quadrupolar splitting is 128 ± 5 kHz, yielding a χ value of 171 ± 7 kHz. Therefore, if the geometries about the methyl carbons and ammonium nitrogen are tetrahedral, fast C_3 and C_3' rotation should yield quadrupolar splitting of 14 kHz. This is larger than the observed value of 11 kHz. The observed splitting does not decrease with an increase with temperature; therefore a temperature-dependent wobbling motion similar to that proposed for the phosphonium cation is unlikely. The alternative explanation is a distortion of either the methyl groups or the trimethylammonium group from tetrahedral geometries. A crystal structure is available for phenyltrimethylammonium chloride; the average C(1)—N—CH_3 bond angle, θ_{NC}, is 110.8° (30). If tetrahedral methyl groups are assumed, then eq. [4] yields a reduction of about 1 kHz in $\Delta\nu$. The deviation may be larger for **7**, the iodide salt. An average bond angle, θ_{NC}, of 113.5° is required to give a splitting of 11 kHz. The N—C—H bond angles of the methyl groups, θ_{CD}, may also be greater than 109.5°, yielding a decrease in $\Delta\nu$. The crystal structure of the chloride salt does not provide accurate positions for the methyl hydrogens.

As the temperature of the sample is lowered, the sharp peaks (which define the quadrupolar splitting) become less well defined and, by 233 K, have vanished completely leaving only a smooth Lorentzian-like curve with a width at half maximum of ≈8 kHz. A broad component of low intensity appears at 203 K. As the temperature is further lowered the intensity of the broad component increases at the expense of that of the narrow peak and, by 140 K, the spectrum indicates that the rigid lattice limit has been reached. The spectra for temperatures between 140 and 203 K are shown in Fig. 8. The spectra shown in Fig. 8 are typical of those expected when C_3 and C_3' rotation are of comparable rate (11). Previous work by Ripmeester and Ratcliffe (8, 9) demonstrated that, in trimethyl and tetramethylammonium salts, both C_3' and C_3 rotation may be in the intermediate exchange region at low temperatures. It was also shown that in some $(CH_3)_3CX$ systems C_3' rotation is rapid at low temperatures, whereas C_3 rotation is slow (7, 12). In principle it should be possible to reproduce the spectra shown in Fig. 7, given the correct geometry for the trimethylammonium group (θ_{MC} and θ_{CD}) and the correct combination of k and k'. Any simulations that resembled the observed spectra required that k' be larger than k. Unfortunately these simulations yield a central peak that is too intense. Adjusting the angle θ_{NC}, such that the 11 kHz splitting is reproduced at

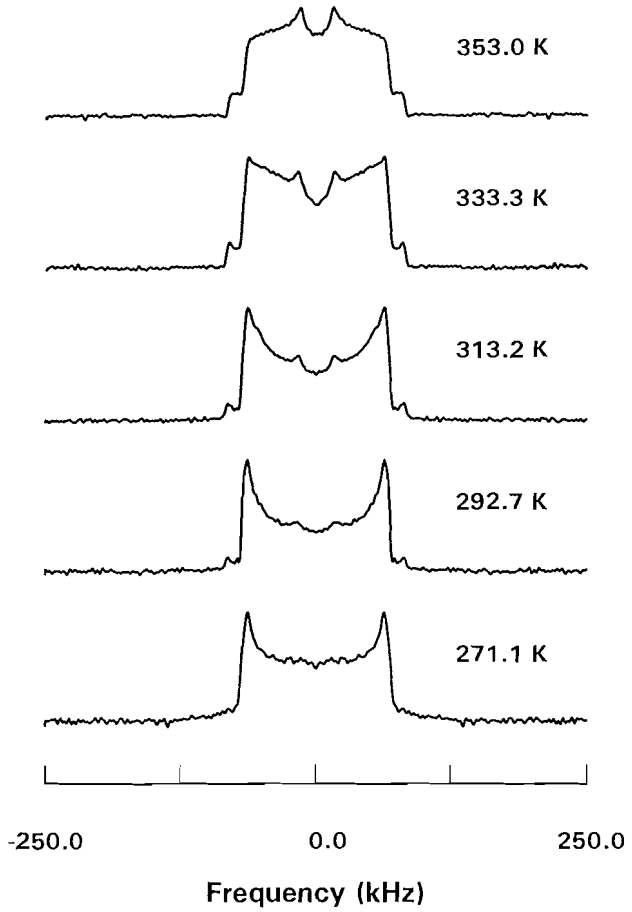

FIG. 9. Low-temperature deuterium NMR spectra for ring-deuterated phenyl-d_3-trimethyl ammonium iodide.

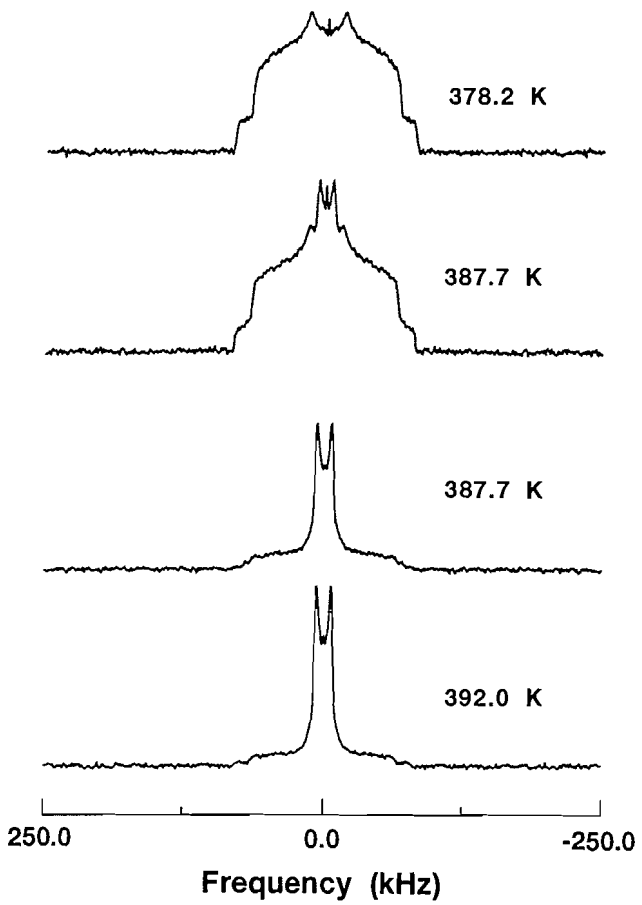

FIG. 10. Deuterium NMR spectra for ring-deuterated phenyl-d_3-trimethyl ammonium iodide near the transition temperature.

higher temperatures, yields some improvement in the fit of the broad component, although the narrow resonance is still too intense. The best-fit simulations are also displayed in Fig. 8. A less significant improvement in the simulations is obtained if one of the methyl groups is allowed to be rotationally inequivalent. With both models k' was required to be about two orders of magnitude greater than k. The former model gave activation energies for methyl and trimethyl rotation of 18.8 ± 1.5 and 13.3 ± 0.4 kJ/mol, respectively. The error quoted is simply the standard deviation obtained from a least-squares fit to the equation $\ln k = E_a/RT + \ln k_0$ and does not reflect the uncertainty associated with the flexibility in the combinations of k and k' that gave reasonable simulated spectra. A satisfactory analysis of the ^2H spectra of methyl-deuterated **7** may well require that the angle θ_{CD} as well as the rotational rates differ for each of the three methyl groups. Analysis of such a nine-site dynamic system (7 variables, with χ and methyl geometry fixed) would be too time consuming and has not been undertaken.

Phenyl-d_3 *trimethylammonium iodide (7)*

The ^2H spectra for **7** deuterated in the *ortho* and *para* positions are shown in Figs. 9 and 10. The lowest temperature spectrum (271 K) is consistent with a rigid phenyl ring. As the temperature is increased the lineshape changes and takes on the appearance of that expected for a superposition of the spectrum for the *para* deuteron, which is not reorienting, and the spectrum for the *ortho* deuterons, which are undergoing two-site exchange. The spectral lineshape changes as the rate of ring reorientation increases with increasing temperature. By about 378 K the rate of ring flipping is in the fast exchange limit. At higher temperature (388 K) a doublet with a splitting of 16 kHz begins to appear. After an additional 15 min at 388 K the broad signal is nearly gone and the intensity of the doublet has increased. After heating the sample to 392 K (the upper temperature limit for our spectrometer) the relative intensity of the narrow doublet has further increased. The appearance of a narrow doublet with a quadrupolar splitting of 16 kHz suggests that the sample goes through a transition to a phase in which the phenyl ring is jumping between n ($n \geq 3$) equivalent sites. Molecular

reorientation has been studied in a large number of solid ammonium salts (8, 9, 28, 29, 31–39). Ratcliffe and Dunell have used proton spin-lattice relaxation times to investigate the reorientation motion of the $-NH_3^+$ and phenyl moieties in solid anilinium chloride, bromide, iodide, and sulphate salts (40). In an ^{123}I NQR study of $C_6H_6NH_3^+I^-$ Fecher and Weiss suggest the possibility of phenyl ring motion (41).

Although there have been numerous investigations of trimethyl rotation by ^1H and ^2H NMR spectroscopy, very few activation energies are reported. There are a number of reasons for this, the most serious being the difficulty in separating contributions to T_1, second moment, or lineshape due to methyl and trimethyl rotation when the two motions have similar activation energies. In some cases additional motions (5–7, 8, 9) make the analysis difficult. A number of investigations were reported before computer lineshape simulation programs capable of reproducing intermediate exchange rate spectra were commonly available. Activation energies for C_3' rotation in several trimethyl compounds are given in Table 2.

Rotation of trimethyl groups can be influenced by a number of intermolecular interactions such as secondary bonding, hydrogen bonding, and the relative proximity and orientation of adjacent molecules (crystal packing). It is extremely difficult to predict the influence of each of these factors without good crystal structures. For example, the extent of secondary bonding influences the trimethyl rotation in $(CH_3)_3E^+$ cations, whereas it is unclear what factors contribute to the hindered rotation for $(CH_3)_3MC_6H_5^+$ cations.

In this study, deuterium NMR spectral lineshape techniques were employed to determine the dynamics of trimethyl groups in $(CH_3)_3E^+$ and $(CH_3)_3MC_6H_5^+$ cations. It is shown that for the former the C—E—C bond angle decreases and the magnitude of the quadrupolar coupling constant increases. For both series of compounds the lineshape analyses show that the trimethyl rotational barrier increases with size of the central atom, E or M. Trimethyl rotation is slower and has a higher activation energy than methyl rotation for all compounds except $(CH_3)_3NC_6H_5^+$.

Preparation and reactions of bromo-2-nitro- and bromo-2-aminoimidazoles

SALIM F. FARAH AND ROBERT A. MCCLELLAND[1]
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 23, 1992

SALIM F. FARAH and ROBERT A. MCCLELLAND. Can. J. Chem. **71**, 427 (1993).

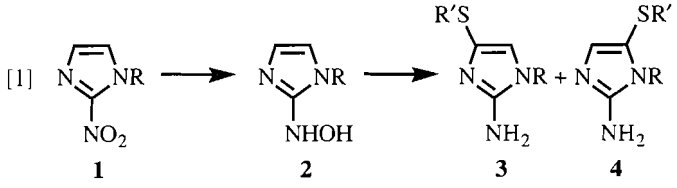
Treatment of 1-methyl-2-nitroimidazole with bromine in water resulted in rapid dibromination to give 4,5-dibromo-1-methyl-2-nitroimidazole. In dioxane, the bromination was slower, and could be controlled to give 4-bromo-1-methyl-2-nitroimidazole **5** and 5-bromo-1-methyl-2-nitroimidazole **6** in a 4:1 ratio. In an attempt to displace the bromine, the monobromo compounds were treated with cysteamine hydrochloride. In each case the nitro group was displaced instead, the 4-bromo **5** resulting in 2-[(2-aminoethyl)thio]-4-bromo-1-methylimidazole **9** as sole product, and the 5-bromo **6** giving two products identified as the monosubstituted 2-[(2-aminoethyl)thio]-5-bromo-1-methylimidazole **13** and the disubstituted 2,5-bis[2-(aminoethyl)thio]-1-methylimidazole **12**. The latter product forms by further reaction of the former and was the sole material observed at long reaction times. A fraction of **12** may also originate from an initial displacement of bromine giving 5-[(2-aminoethyl)thio]-1-methyl-2-nitroimidazole **14**, although this cannot be observed due to a rapid further displacement of its nitro group. The bromonitroimidazoles **5** and **6** were reduced to 4-bromo-2-amino-1-methylimidazole **25** and 5-bromo-2-amino-1-methylimidazole **26** with Zn/HCl. On reflux in water, in the presence or absence of cysteamine hydrochloride, these undergo a protodebromination resulting in the same product, 2-amino-1-methylimidazole **17**. In D_2O the 4-bromo isomer was demonstrated to react specifically to give 2-amino-4-deuterio-1-methylimidazole **27**. Attempted preparation of the bromoaminoimidazoles **25** and **26** by bromination of 2-amino-1-methylimidazole in water resulted in the clean formation of *cis* and *trans* 2-amino-4,5-dihydro-4,5-dihydroxyimidazolium ions **18**.

SALIM F. FARAH et ROBERT A. MCCLELLAND. Can. J. Chem. **71**, 427 (1993).

Le traitement du 1-méthyl-2-nitroimidazole avec du brome dans l'eau conduit à une dibromation rapide, avec formation du 4,5-dibromo-1-méthyl-2-nitroimidazole. Dans le dioxane, la bromation est plus lente et elle peut être contrôlée pour conduire à la formation des 4-bromo- (**5**) et 5-bromo- (**6**) 1-méthyl-2-nitroimidazoles, dans un rapport de 4 : 1. Dans un effort pour déplacer le brome, on a traité les composés monobromés avec de chlorhydrate de la cystéinamine. Dans chaque cas, c'est plutôt le groupe nitro qui a été déplacé; le dérivé 4-bromé (**5**) conduit uniquement au 2-[(2-aminoéthyl)thio]-4-bromo-1-méthylimidazole (**9**) alors que le composé 5-bromé (**6**) fournit deux produits identifiés comme le 2-[(2-aminoéthyl)thio]-5-bromo-1-méthylimidazole (**13**) monosubstitué et le 2,5-bis-[2-(aminoéthyl)thio]-1-méthylimidazole (**12**) disubstitué. Ce dernier composé se forme par réaction ultérieure du premier; il est le seul produit à se former après des temps de réactions prolongés. Une partie du composé **12** peut aussi provenir d'un déplacement initial du brome conduisant au 5-[(2-aminoéthyl)thio]-1-méthyl-2-imidazole (**14**); toutefois, on ne peut pas observer sa formation à cause de la substitution rapide du groupe nitro. On a réduit les bromonitroimidazoles **5** et **6** avec du Zn/HCl et on a obtenu les 4-bromo- (**25**) et 5-bromo- (**26**) 2-amino-1-méthylimidazoles. Par reflux dans de l'eau, en présence ou en l'absence du chlorhydrate de cystéinamine, ces composés subissent tous les deux une protodébromation conduisant au même composé, le 2-amino-1-méthylimidazole (**17**). Dans le D_2O, il a été démontré que l'isomère 4-bromé réagit spécifiquement pour donner le 2-amino-4-deutéro-1-méthylimidzole (**27**). Des essais de préparation des bromoaminoimidazoles **25** et **26** par bromation du 2-amino-1-méthylimidazole dans l'eau à conduit à la formation propre des ions 2-amino-4,5-dihydro-4,5-dihydroxyimidazolium *cis* et *trans* (**18**).

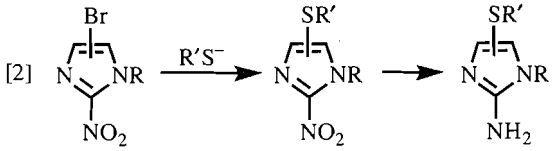
[Traduit par la rédaction]

As part of a program of study of the reduction products of 2-nitroimidazoles (1), we desired independent routes to imidazole derivatives of the structure **3** and **4**.



Such compounds have been characterized in mixtures after the reduction of the 2-nitroimidazole misonidazole (**1**, R = $CH_2CHOHCH_2OCH_3$) following treatment with the thiol glutathione (γ-glutamylcysteinylglycine) (2, 3). They are also observed by reacting an isolated sample of the product of four-electron reduction, the 2-hydroxylaminoimidazole **2**, with thiols such as cysteamine and glutathione (4–6). Misonidazole depletes intracellular glutathione selectively under hypoxic conditions (7), and this chemistry provides a model for the effect. Indeed, the formation of the adducts **3** and **4** has been implicated in biological systems (8–10). There are, however, uncertainties that would be answered through the availability of pure authentic material, particularly with respect to the exact structures of these adducts (11), and to the structures of the metabolites that are being observed in cells.

As an initial approach to these compounds we envisaged the reaction of bromo-2-nitroimidazoles with an appropriate thiol, to be followed by reduction of the nitro group to the amine.



Nitro groups situated at positions 4 and 5 of an imidazole are known to activate adjacent halogens to nucleophilic

substitution (12–15), and there is a recent example, the conversion of 4,5-dibromo-1-methyl-2-nitroimidazole to 4-bromo-5-morphilino-1-methyl-2-nitroimidazole (16), that offers precedent in the case of a 2-nitro compound. This plan obviously required a convenient route to the bromonitroimidazoles. An examination of the literature revealed a 4-bromo derivative of misonidazole (**4**, R = CH_2CHOH-CH_2OCH_3), prepared by bromination of the parent nitro compound with Br_2 in dioxane (17), and, more recently, 4-bromo-1-methyl-2-nitroimidazole, prepared by treatment of the nitro compound with *N*-bromosuccinimide (NBS) in dioxane (16). Neither of these studies mentioned the presence of the 5-bromo isomer, although the latter did prepare 4,5-dibromo-1-methyl-2-nitroimidazole. This was achieved by methylation of the N1-unsubstituted compound, as obtained by NBS treatment of azomycin (**1**, R = H), a reaction that could not be stopped at the monobromo stage.

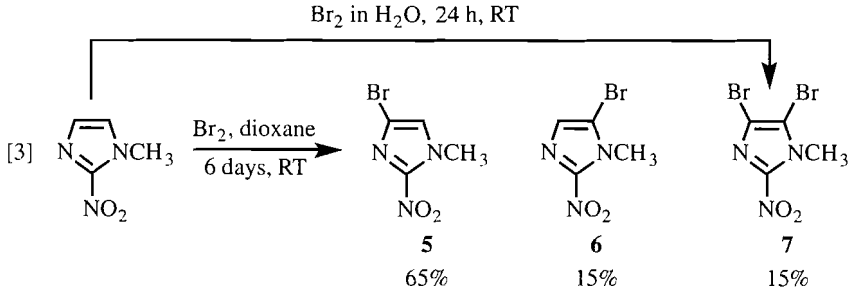
In this paper we report conditions where both 4-bromo and 5-bromo isomers of 1-methyl-2-nitroimidazole are obtained from the bromination of the nitro compound. We further describe the outcome of the treatment of these compounds with the thiol cysteamine. This reaction disappointingly proceeds with displacement of the nitro group rather than the halogen. We also report further novel results encountered in our examination of these systems: a protodebromination of 4-bromo- and 5-bromo-2-aminoimidazoles that offers a convenient route to specifically deuterated 2-aminoimidazoles, and an attempted bromination of a 2-aminoimidazole that leads to 4,5-dihydro-4,5-dihydroxyimidazolium ions.

Results and discussion

4-Bromo- and 5-bromo-1-methyl-2-nitroimidazoles

Our route to these compounds involved the reaction of molecular bromine with 1-methyl-2-nitroimidazole. In water the reaction was very fast, and although the monobromo derivatives are presumably intermediate, the reaction could not be stopped at this stage, the product even with stoichiometric amounts of bromine being the dibromo compound plus unreacted starting material. Use of excess bromine did, however, provide the 4,5-dibromo derivative in good yield in a single reaction step.

Reaction in 1,4-dioxane was slower, and by monitoring the products by ^1H NMR, the monobromo species could be observed to form as intermediates, followed by their subsequent conversion to the dibromide that had been previously characterized from the aqueous reaction. Moreover, it was clear from the NMR spectra taken at intermediate stages that two monosubstituted products were forming, in that two singlets could be observed in the aromatic region. Separate methyl signals corresponding to these isomers could also be observed, along with the methyl signal of the dibromide. Optimal conditions for the preparation of the monobromides were found to be 6 days at room temperature, at which time the product mixture corresponded to that given below, with 5% unreacted starting material also present. At this point the products could be separated to obtain pure samples of the two monobromo compounds.



The isomers were distinguished by the patterns of C4 and C5 in their ^1H-coupled ^{13}C NMR spectra. With the major product, the signals for these two carbons were at 114.2 and 128.4 ppm (in acetone-d_6), with the former splitting into a doublet with J = 9 Hz in the ^1H-coupled spectrum, and the latter a doublet of quartets with J = 200 and 5 Hz. The former signal can be assigned to the carbon bearing the bromine, with the small splitting arising from coupling with the proton on the adjacent carbon. The large splitting for the signal at 128.3 ppm indicates that this is the carbon bearing the remaining hydrogen. The further smaller splitting into the quartet represents long-range coupling with the N-methyl protons, indicating that this carbon is C5. Thus, this compound must be the 4-bromo isomer. The minor product had signals at 129.4 and 112.3 ppm, the former splitting into a clean doublet with J = 193 Hz, the latter, a doublet of quartets with J = 14 and 4 Hz. Thus, the carbon bearing the hydrogen is again at lower field as in the major isomer, but now there is no long-range coupling to the methyl protons. Such coupling is exhibited by the carbon bearing the bromine. In consequence, this isomer can be assigned the 5-bromo structure.

Reaction of bromo-1-methyl-2-nitroimidazoles with cysteamine

The bromonitroimidazoles were treated with cysteamine, employing a weakly acidic aqueous solution (pH 5.5) to minimize the direct hydrolysis that occurs in more basic solution (18–22). With 4-bromo-1-methyl-2-nitroimidazole the reaction produced a single new compound, whose ^1H NMR spectrum showed a singlet in the aromatic region corresponding to the ring hydrogen, the N-CH_3 singlet, plus a pair of triplets near 3 ppm associated with a cysteamine substituent. Integration of these peaks indicated that this was a product of monosubstitution. The mass spectrum, however, showed the characteristic doubling of peaks associated with the presence of a bromine atom, with molecular ions at m/e 235/237 indicating that it is the nitro group that has been displaced. The UV spectrum offered further corroboration of this assignment. 2-Nitroimidazoles such as the starting

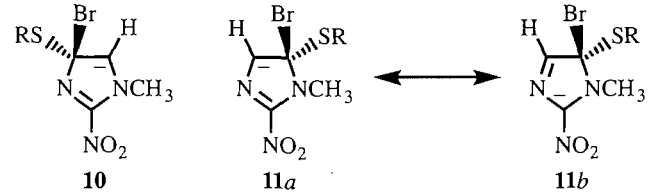
[4] 
material (λ_{max} = 340 nm) typically absorb above 300 nm. With the product the λ_{max} had been reduced to 240 nm.

Treatment of misonidazole with cysteamine, under conditions similar to those of the present study, was previously found to lead to nucleophilic substitution of the 2-nitro group (22).[2]

[5] 
With the 4-bromo-2-nitro compound, the reaction obviously followed the same course. Although there is an additional leaving group, reaction still occurs at the 2-position. This is perhaps not surprising, since the intermediate **10** formed by addition of a nucleophile at the 4-position does not have the negative charge directly conjugated with the nitro group.



With the 5-bromo isomer, such conjugation does exist (see **11***b*), leading to the anticipation of bromine displacement. The reaction proved to be more complex than in the case of 4-bromo, in that two new products appeared on treatment with cysteamine. These products were characterized by two new singlets at δ 7.88 and 7.59, downfield from the aromatic peak for the starting material at 7.37 ppm. Corresponding peaks for the N-CH_3 group could also be observed, at 4.12 ppm for the starting material, and 3.98 and 3.92 ppm for the products with aromatic signals at 7.88 and 7.59 ppm, respectively. With time, it became apparent that the product with the signals at lower field was unstable, being converted into the product with the higher field signals such that at long reaction times the latter became the only species present. A sample was isolated and the NMR and mass spectra indicated a disubstituted compound **12** with both nitro and bromo groups displaced by cysteamine. The other product, which must then be monosubstituted, could not be isolated in pure form. A mass spectrum recorded on a mixture indicated that it still retained its bromine, with peaks at *m/e* 235/237 consistent with a product **13** (Scheme 1) where the nitro group had been displaced.

Thus, both 4-bromo- and 5-bromo-2-nitroimidazoles undergo nucleophilic displacement of the nitro group at the C2 position rather than at C4 or C5. This can be explained by a greater electrophilicity at C2, due to the presence of the powerful electron-withdrawing nitro group coupled with the two electronegative nitrogens of the imidazole ring. The further reaction of the monosubstituted adduct **13** with the 5-bromo substituent can be rationalized in terms of the sulfur located at C2 stabilizing the anionic intermediate, as in **15**. As noted above, such a resonance contributor cannot be written for the 4-bromo analog.

Interestingly, the disubstituted **12** formed in significant amounts (25–30% of total **12** + **13**) even at short reaction times, that is, under conditions where there would be little formation of this product from the monosubstituted **13**. Thus, it appears that some of the disubstituted **12** is an immediate product of the reaction of cysteamine with the bromonitroimidazole **6**. This can arise if a portion of the initial substitution actually occurs through displacement of the bromo group giving the desired product **14**, followed by the rapid reaction of this with a second equivalent of cysteamine. The conversion of **14** to **12** couples the electrophilicity of C2 in a 2-nitroimidazole with sulfur stabilization of the anionic intermediate (as in **16**). This process, therefore, is expected to be fast relative to the other displacements that occur in this system.

Bromination of 2-amino-1-methylimidazole

Having observed a displacement of a 5-bromo substituent in the conversion of **13** to **12**, we turned to the possibility

[2]This study also established that, under some conditions, the substitution can also occur via an electron transfer pathway.

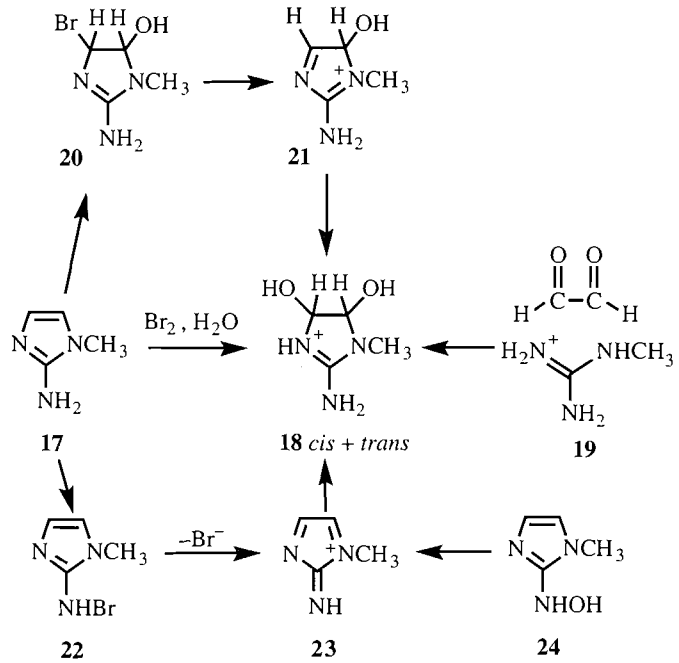


SCHEME 2

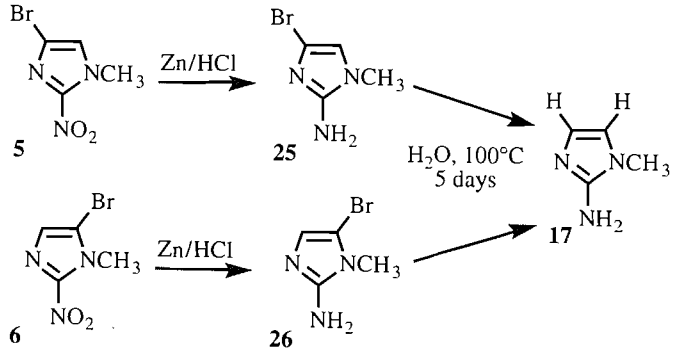
of directly reacting a bromo-2-aminoimidazole with a thiol. Our initial approach to the required starting material involved the bromination of the readily available 2-amino-1-methylimidazole **17**. To our surprise this reaction in water proceeded cleanly to give products that we had previously characterized following the reaction of glyoxal and the methylguanidinium ion **19** (4, 23, 24), a *cis*:*trans* mixture of the 2-amino-4,5-dihydro-4,5-dihydroxy-1-methylimidazolium ion **18**.

This unusual reaction can be explained (Scheme 2) by the formal addition of BrOH across C4,C5 to produce **20** (or its isomer with the bromine at C5), whose bromine would be labile to water displacement because of the presence of the ring nitrogens (see **21**). Imidazoles lacking a 2-NH_2 group, however, give substitution products upon bromination (see above and refs. 16, 25, 26), suggesting that the external amino substituent in **17** may play a direct role. *N*-Bromination, for example, results in an *N*-bromoimidazole **22**, where loss of bromide would lead to the cation **23** and hence to **18**. The cation **23** has previously been implicated as an intermediate in the aqueous decomposition of the imidazole-2-hydroxylamine **24**, a reaction where **18** is also the product (4, 6, 23).

Preparation and reaction of bromo-2-aminoimidazoles

With the failure to obtain samples by direct bromination, we turned to reduction of the previously prepared **5** and **6**. Flockhart *et al.* have reported the catalytic six-electron hydrogenation of misonidazole over Adam's catalyst (27). Similar reactions with **5** and **6** failed, as indicated by no uptake of hydrogen and unchanged NMR spectra. Misonidazole was verified to be reduced to the corresponding amine under the same conditions. Hydrogenation of **5** and **6** using Pd/charcoal in methanol also failed. Finally, we turned to reduction with Zn/HCl and this was successful.

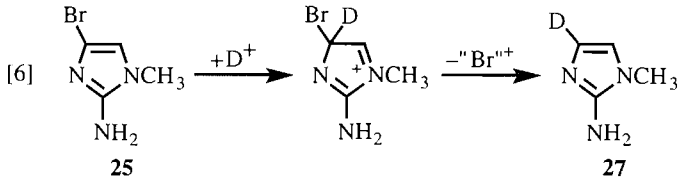
Attempted displacement of the bromine in the reduction products **25** and **26** with cysteamine hydrochloride, however, did not work. Refluxing in water did result in loss of



SCHEME 3

bromine, but to our surprise the two bromoaminoimidazoles gave the same product, with an NMR spectrum identical to that of 2-amino-1-methylimidazole **17** (Scheme 3). The same reaction product was obtained under identical conditions even in the absence of thiol.

The implication of these experiments is that bromine exchanges with the protons from the solvent, presumably by electrophilic substitution into the electron-rich imidazole.



This reaction results in release of an electrophilic bromine. In the case of the reaction with the thiols present this would be taken up by oxidizing these species to disulfides, as is observed. The fate of the bromine in the reaction without the thiol was not determined.

To verify the location of the incoming hydrogen, the displacement with the 4-bromo derivative **25** was carried out in refluxing D_2O. This resulted in a product with deuterium at a single ring position, as evident from the appearance of one singlet at 6.77 ppm in the ^1H NMR spectrum in water. The ^1H-decoupled ^{13}C NMR spectrum showed signals at 149.1, 120.3, 114.9 (and 34.7 ppm for CH_3), with the signal at 114.9 ppm appearing as a weak triplet and representing the carbon bearing the deuterium. In the ^1H-coupled spectrum the signal at 120.3 for the carbon bearing the hydrogen appeared as a doublet. This showed further small splitting into quartets due to long-range coupling with the N-methyl, demonstrating that this carbon was C5 and that the product therefore was the 4-deuterio derivative **27**.

Experimental section

4,5-Dibromo-1-methyl-2-nitroimidazole (7)

1-Methyl-2-nitroimidazole (18, 19) (0.5 g) was dissolved in 150 mL of water and 3 mL of bromine was added with vigorous stirring. The resulting solution was left standing in the dark overnight, at which time the unreacted bromine was driven out of the solution by bubbling with air. Water was removed, and the resulting yellow solid was chromatographed on silica gel (200 mesh) using a mixture of 1:2 ethyl acetate: *n*-hexane. The solvents were evaporated to yield 0.57 g (70%) of product as yellow needles, mp 144–145°C (lit. (5) mp 143–145°C); ^1H NMR (DMSO-d_6) δ: 4.15 (s).

*4-Bromo-1-methyl-2-nitroimidazole (**5**) and 5-bromo-1-methylimidazole (**6**)*

1-Methyl-2-nitroimidazole (0.5 g) was dissolved in 70 mL of 1,4-dioxane and 1 mL of bromine was added with vigorous stirring. The mixture was left standing at room temperature, with the progress being monitored by withdrawing small aliquots, evaporating the solvent, and recording a ^{1}H NMR spectrum in DMSO-d_6. The mixture was characterized by doublets at 7.12 and 7.62 ppm due to starting material, singlets at 7.83 and 7.40 ppm due to the monobromo products, and a cluster of four singlets near 4 ppm due to the methyl groups of these three species, plus the dibromo isomer. After 6 days, 95% of starting material was consumed with minimal formation of dibromide, and the reaction was stopped by evaporating the excess bromine and solvent. To ensure removal of all the Br_2, the resulting oil was twice dissolved in 100 mL of fresh 1,4-dioxane, followed by evaporation. The material so obtained was chromatographed on silica gel (200 mesh) using 2:3 (v:v) ethyl acetate:hexane as eluant. An initial fraction containing the dibromide was discarded. The two monobromo compounds, which were not separated on this column, were collected together as a second fraction. After solvent removal, these were separated on preparative thin-layer chromatography plates (alumina GF, 2 mm thickness) eluted with 1:1 ethyl acetate:hexane. The solids obtained after evaporation of the solvent were recrystallized from water to yield pale yellow needles of the products.

4-Bromo-1-methyl-2-nitroimidazole (0.43 g, 65%): mp 139–141°C (lit. (5) mp 142–144°C); R_f in 1:1 ethyl acetate:hexane, 0.47. ^{1}H NMR (DMSO-d_6) δ: 7.83 (s, 1 H), 3.94 (s, 3 H). MS (EI, methanol): 206/204 (100), 176/174 (79), 160/158 (19), 137/135 (36), 119/117 (20), 80 (60). Anal. calcd. for $C_4H_4N_3O_2Br$: C 23.32, H 1.96, N 20.40, Br 38.79; found: C 23.26, H 2.03, N 20.07, Br 39.03.

5-Bromo-1-methyl-2-nitroimidazole (0.12 g, 15%): mp 117–119°C; R_f in 1:1 ethyl acetate:hexane, 0.31. ^{1}H NMR (DMSO-d_6) δ: 7.40 (s, 1 H), 4.22 (s, 3 H). MS (EI, methanol): 206/204 (56), 176/174 (38), 160/158 (9), 135/133 (76), 121/119 (26), 80 (100). Anal. calcd. for $C_4H_4N_3O_2Br$: C 23.32, H 1.96, N 20.40, Br 38.79; found: C 23.51, H 2.13, N 20.27, Br 38.93.

*Reaction of 4-bromo-1-methyl-2-nitroimidazole (**5**) with cysteamine 2-[(2-Aminoethyl)thio]-4-bromo-1-methylimidazole (**8**)*

To a suspension of 0.1 g of 4-bromo-1-methyl-2-nitroimidazole in 100 mL of oxygen-free water at pH 5.5 was added 1.1 g of cysteamine hydrochloride. The mixture was refluxed for 2 days, at which time the solution was cooled and water removed by lyophilization. The resulting oil was taken up in 100 mL of 3 M NaOH, followed by extraction with 2 × 100 mL of chloroform. The combined chloroform layers were exhaustively washed with 7 × 200 mL of 0.5 M NaOH to effect the complete removal of cysteamine, followed by 3 × 150 mL of distilled water. After drying ($MgSO_4$) and filtration, the solvent was evacuated to give a yellow liquid: ^{1}H NMR ($CDCl_3$) δ: 7.62 (s, 1H), 3.93 (s, 3H), 3.28 (t, 2H, J = 9 Hz), 3.12 (t, 2H, J = 9 Hz). MS (EI, neat): 235/237 (12), 105/207 (76), 175/177 (55), 134/136 (100), 80 (66). HRMS m/e: 235.1430 ($C_6H_{10}{}^{79}BrNS_3$ requires 235.1438).

*Reaction of 5-bromo-1-methyl-2-nitroimidazole (**6**) with cysteamine*

5-Bromo-1-methyl-2-nitroimidazole (0.1 g) was treated with varying amounts of cysteamine hydrochloride as described above. The course of the reaction was monitored by periodically withdrawing a small sample, removing water by lyophilization, dissolving in D_2O, and recording 200 MHz ^{1}H NMR spectra. In an experiment with a 10-fold excess of cysteamine, reaction had gone to completion after refluxing for 10 days, producing a single species that was isolated as described in the previous paragraph. This product had spectra consistent with 2,5-bis[2-(aminoethyl)thio]-1-methylimidazole **12**: ^{1}H NMR (D_2O) δ: 7.58 (s, 1H), 3.92 (s, 3H), 3.40 (two overlapping t's, 6H), 3.09 (t, 6H, J = 9 Hz). HRMS m/e: 212.1577 ($C_8H_{16}N_4S_2$ requires 212.1565). The initial product could not be isolated in pure form. After 6 days of refluxing with a sevenfold excess of cysteamine, a time sufficient for complete disappearance of the NMR signals of the starting material, a 1:3 mixture of monosubstituted:disubstituted compounds was obtained. A mass spectrum of this mixture showed peaks at m/e 235/237 consistent with 2-[(2-aminoethyl)thio]-5-bromo-1-methylimidazole **13** as the structure of the monosubstituted product.

Reaction of 2-amino-1-methylimidazolium chloride with bromine in water

Bromine was slowly added to a solution of 2-amino-1-methylimidazolium chloride (28) (1 g) in 200 mL of water. The bromine color was immediately discharged during this addition, which was continued until a faint orange color persisted. The solvent and excess bromine were removed by evaporation under reduced pressure and lyophilization, the resulting solid was taken up in 35 mL methanol, and then precipitated by addition of 350 mL of ice-cold diethyl ether. After filtration, the ^{1}H NMR spectrum was recorded in D_2O. The only signals observed corresponded to those of a 1:5 *cis*:*trans* ratio of **18**: *cis* **18**, δ 5.37 (d, 1H, J = 5.8 Hz), 5.23 (d, 1H, J = 5.8 Hz), 2.99 (s, 3H) and *trans* **18**, δ 5.18 (d, 1H, J = 0.8 Hz), 5.04 (d, 1H, J = 0.8 Hz), 3.03 (s, 3H). A sample of **18** prepared by the reaction of glyoxal and methylguanidinium chloride (23) was added to the NMR tube to establish the exact correspondence of the signals from the two preparations.

Preparation and reactions of bromoaminoimidazoles

4-Bromo-1-methyl-2-nitroimidazole **5** (0.2 g) and 5-bromo-1-methyl-2-nitroimidazole **6** (50 mg) were dissolved in 100 mL of 0.1 M HCl and zinc dust (1 g) added. The suspension was stirred for 1 h, solids separated by filtration, and the water removed by lyophilization. NMR spectra recorded in D_2O showed the presence of two singlets in a 1:3 ratio in each case, 2-amino-4-bromo-1-methylimidazole hydrochloride at δ 6.79 (1H), 3.51 (3H); 2-amino-5-bromo-1-methylimidazole hydrochloride at δ 6.81 (1H), 3.49 (3H).

These two products were refluxed in water, with and without cysteamine hydrochloride, for 2–5 days. The solvent was removed by lyophilization and NMR spectra recorded in D_2O. Both isomers produced the same product, showing a 2H doublet of doublets with δ 6.83 and δ 6.77, and a 3H singlet at δ 3.53. The identity of the two products was further indicated by the absence of any change in the ^{1}H NMR spectra when the two were mixed together. Addition of authentic 2-amino-1-methylimidazolium chloride also resulted in superimposable peaks.

Received October 21, 1992

S. SUBRAMANIAN and MICHAEL J. ZAWOROTKO. Can. J. Chem. **71**, 433 (1993).

$FeCl_2$ or $FeCl_3$ react with cyclam (cyclam = 1,4,8,11-tetraazacyclotetradecane) in an acidic medium (4 M HCl) to afford dark orange-red plates of $[H_4(cyclam)][FeCl_5(OH_2)](Cl)_2$ (**1**). **1** crystallizes in a polar space group (orthorhombic, $Pc2_1b$) with a = 10.7730(6), b = 13.3418(10), c = 14.4564(10) Å, V = 2077.84(24) Å^3, and D_{calc} = 1.68 g cm^{-3} for Z = 4. Final values of R = 0.031 and Rw = 0.034 were obtained for 1950 independent observed ($I > 3\sigma(I)$) reflections. Cyclam reacts with neat trifluoroacetic acid to afford a colourless salt, $[H_4(cyclam)][CF_3COO]_4$ (**2**). **2** crystallizes in a centric space group (monoclinic, $P2_1/c$), with a = 8.7442(11), b = 10.5121(11), c = 15.2469(20) Å, β = 102.526(15)°, V = 1368.1(3) Å^3, and D_{calc} = 1.593 g cm^{-3} for Z = 2. Final values of R = 0.059 and Rw = 0.067 were obtained for 1336 independent observed ($I > 3\sigma(I)$) reflections. Extensive interionic hydrogen bonding between the cyclam cations, which adopt exodentate conformations, and anions results in network polymeric hydrogen bonding (1-D for **1**, 2-D for **2**). The networking in **1** is intrinsically polar because one chloride anion and the $[FeCl_5(OH_2)]^{2-}$ complex anion are involved in networking between the $H_4(cyclam)^{4+}$ cations. The implications of the crystal structures are discussed from the perspective of rational design of polar solids.

S. SUBRAMANIAN et MICHAEL J. ZAWOROTKO. Can. J. Chem. **71**, 433 (1993).

En milieu acide (4 M HCl), le $FeCl_2$ ou le $FeCl_3$ réagissent avec le cyclame (cyclame = 1,4,8,11-tétraazacyclotétradécane) pour conduire à des plaques rouge-orange foncé de $[H_4(cyclame)][FeCl_6(OH_2)](Cl)_2$ (**1**). Le composé **1** cristallise dans un groupe d'espace polaire (orthorhombique, $Pc2_1b$) avec a = 10,7730(6), b = 13,3418(10) et c = 14,4564(10) Å, V = 2077,84(24) Å^3 et D_{calc} = 1,68 g cm^{-3} pour Z = 4. On a obtenu les valeurs finales de R = 0,031 et R_w = 0,034 pour 1950 réflexions indépendantes observées avec $I = \geq 3\sigma(I)$. Le cyclame réagit aussi avec l'acide trifluoroacétique pur pour conduire à un sel incolore de $[H_4(cyclame)][CF_3COO]_4$ (**2**). Le sel **2** cristallise dans un groupe d'espace centré (monoclinique, $P2_1/c$) avec a = 8,7442(11), b = 10.5121(11) et c = 15,2469(20) Å, β = 102,526(15)°, V = 1368,1(3) Å^3 et D_{calc} = 1,593 g cm^{-3} pour Z = 2. On a obtenu les valeurs finales de R = 0,059 et R_w = 0,067 pour 1336 réflexions indépendantes observées avec $I \geq 3\sigma(I)$. Des liaisons hydrogènes interioniques importantes entre les anions et les cations du cyclame, qui adoptent des conformations exocoordinés, conduisent à l'existence de réseaux de liaisons hydrogènes polymériques (1-D pour **1** et 2-D pour **2**). Le réseau que l'on peut observer dans **1** est intrinsèquement polaire parce qu'un anion chlorure et l'anion complexe $[FeCl_5(OH_2)]^{2-}$ sont impliqués dans le réseau entre les cations $H_4(cyclame)^{4+}$. On discute des implications des structures cristallines dans la perspective de la création rationnelle de solides polaries.

Introduction

Rational design of solids, crystal engineering, is an aspect of chemistry that is of growing interest to synthetic and materials chemists (2). A particularly topical application of crystal engineering concerns design and preparation of solids that exhibit second-order nonlinear optical properties such as second harmonic generation, SHG (2–5). An important criterion for construction of such materials is that they crystallize in a noncentrosymmetric or polar space group (2–6). In this context, the importance of intermolecular network hydrogen bonding cannot be overemphasized. The prototypal inorganic SHG-active solid, KH_2PO_4, is a three-dimensional diamondoid solid that becomes SHG active when the hydrogen bonds align at low temperatures (7). Organic cation $H_2PO_4^-$ analogues are also SHG active (8). Furthermore, analysis of crystallographic databases has recently revealed that there is strong correlation between whether or not a solid is a polymeric network and space group centrosymmetry (6). Therefore, although it is now realized that SHG activity is possible in as wide an array of materials as KH_2PO_4, organics (e.g., polarizable donor–acceptor compounds such as *p*-nitroaniline), and organometallics (e.g., ferrocene derivatives, acetylides), the necessity for crystallizing in a polar space group remains. Moieties that are capable of engaging in network hydrogen bonding are therefore of more than passing interest since they are likely to be predisposed towards polar space groups.

Polyazamacrocyclic molecules have been primarily a subject of interest for their coordination properties (9). In a macrocyclic ligand such as cyclam (1,4,8,11-tetraazacyclotetradecane) the nitrogen atoms typically adopt an endodentate conformation and are therefore oriented for complexation of metal ions within the macrocyclic cavity. Thus, the chemistry of cyclam itself is rather dominated by cation complexation and formation of discrete molecules and ions (10–12). Nevertheless, polyazamacrocyclic ligands and their complexes are capable of forming ordered solids, but not as a direct result of the ligand engaging in intermolecular interactions (13–16). The protonated polyammonium derivatives of cyclam are known but have received much less attention, although complexation of anions by polyammonium and macrocyclic cations has been of interest from structural (17–20), photochemical (21), and analytical (22) perspectives. In this contribution we present the first crystal structures of compounds containing the fully protonated form of cyclam, $[H_4(cyclam)]^{4+}$, a moiety that we expect to be

TABLE 1. Crystal data and summary of intensity data collection and structure refinement for compounds **1** and **2**

Parameter	Compound	
	$FeCl_7ON_4C_{10}H_{30}$, **1**	$F_{12}O_8N_4C_{18}H_{28}$, **2**
Color	Orange red	Colorless
Formula wt.	526.4	656.4
Crystal system	Orthorhombic	Monoclinic
Space group	$Pc2_1b$	$P2_1/c$
Temp. °C	17	17
Cell constants[a]		
a, Å	10.7730(06)	8.7442(11)
b, Å	13.3418(10)	10.5121(11)
c, Å	14.4564(10)	15.2469(20)
β, °		102.526(15)
Cell volume, Å^3	2077.84(24)	1368.1(3)
F(000)	1088	672
Z	4	2
D_{calc}, g cm^{-3}	1.68	1.59
μ_{calc}, cm^{-1}	16.4	1.9
Scan type	ω/2θ	ω/2θ
Radiation	Graphite Monochromated MoK_α (λ = 0.70930Å)	
Max. crystal dimensions, mm	0.15 × 0.85 × 0.85	0.20 × 0.50 × 0.50
Scan width	0.80 + 0.35 tan θ	0.80 + 0.35 tan θ
Transmission range	0.697, 0.999	0.775, 1.000
Decay of standards	±2%	±2%
Reflections measured	3195	1860
2θ range, °	2–50	2–45
Unique reflections	2253	1787
Reflections observed[b]	1950	1336
Computer programs[c]	NRCVAX (ref. 23)	NRCVAX (ref. 23)
Structure solution	Direct	Direct
Number parameters	208	244
Weight modifier, k	0.00001	0.00005
G.O.F.	3.26	4.65
R_f	0.031	0.059
R_w	0.034	0.067
Final diff. map(max) (e/Å^3)	0.41	0.26

[a]Least-squares refinement of $((\sin\theta)/\lambda)^2$ for 24 reflections $\theta > 16°$.
[b]$I > 3.0\sigma(I)$. Corrections: Lorentz-polarization and absorption (empirical psi scan).
