
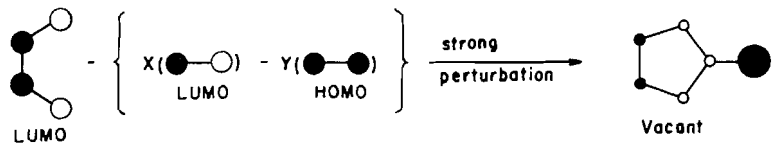
Application of this analysis leads to the following expectation for fulvene's stem-weighted polarizing orbital:

Scheme 7.



The relative magnitude of the coefficients in the stem-weighted polarizing orbital can be anticipated by mixing the stem frontier orbitals together with a weighting that favors the "primary" stem frontier orbital. In general, one can now expect that stem-weighted polarizing orbitals will have coefficients that alternate small, large, small, large ... over the stem portion of the orbital. Precisely this pattern emerges if one tracks the development of stem-weighted orbitals (at the Hückel level) as docking proceeds (see Scheme 8).

Scheme 8.

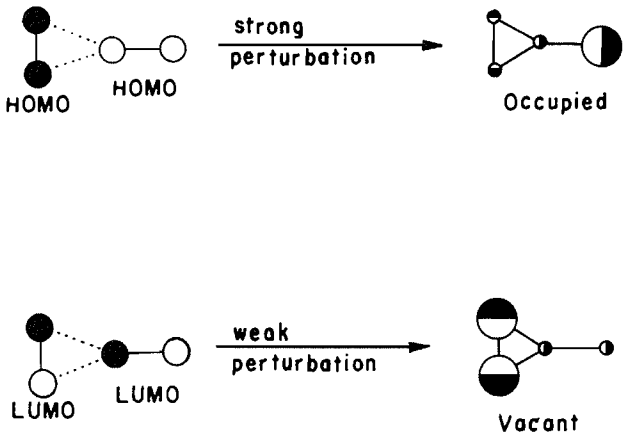
Dynamic polarity analyses: It is now clear that acyclic polyene frontier orbitals can be used to anticipate Hückel polarization for even non-alternant monocyclic singlets. Neither the relative magnitudes of the coefficients in the acyclic polyene frontier orbitals nor the nodal properties of the polarizing orbitals of the monocycle need be known. See Scheme 9 for a representative dynamic polarity analysis.

Scheme 9.

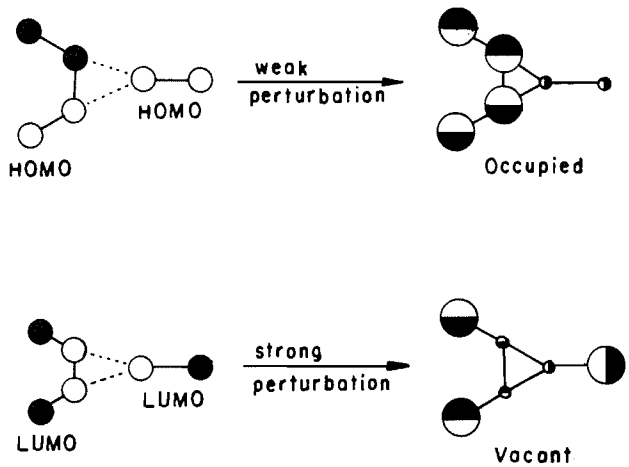


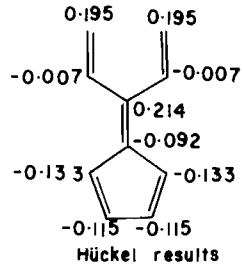
Deducing the polarity of a monocycle requires knowledge of both polarizing orbitals. If they are reverse-polarizing, the monocycle will have moderate polarity. The orientation of the dipole moment will be obvious from the forms of the polarizing orbitals. From Scheme 9, **1** is expected to have its dipole oriented as shown by the dipole arrow accompanying its structure.

Now consider the radialene **4**. Sequential disconnection of each odd substituent with subsequent docking as shown for methylene cyclopropene (Scheme 4) would lead to the conclusion that each exocyclic methylene in **4** has a large coefficient in the stem-weighted polarizing orbital. This analysis leads to the following generalization. *The Odd Substituent Rule: in the stem-weighted polarizing orbital of any fully π-bonded even non-alternant monocycle, all odd substituents are polarized in the same manner.*

Thus, the following dynamic polarity analysis is appropriate for the radialene **4**.

Scheme 10.



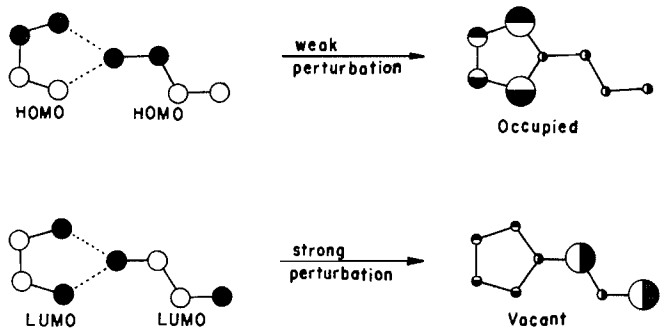


Because the polarizing orbitals for **4** have largest coefficients in common, the orbitals are *not* reverse-polarizing. Therefore, the radialene framework is not significantly polarized. An immediate consequence of the Odd Substituent Rule is that fully π-bonded non-alternant monocycles with one exocyclic double bond are moderately polarized while those with more than one exocyclic π-bond are nonpolar.

(ii) Even substituents

Consider the dynamic polarity analysis of the fulvene relative **5** presented in Scheme 11.

Scheme 11.



In general, the cap coefficients in the cap-weighted molecular orbital (MO) will be smaller than the large coefficients in the stem-weighted MO. All cap coefficients are large in the cap-weighted MO and only half of the stem-weighted coefficients are large in the stem-weighted MO. Consider the effect each type of site would have on a substituent were it to be appended to one of them. The stem atoms that have large coefficients in the stem-weighted polarizing orbital are strongly polarizing (active) and those with small coefficients are nonpolarizing (inactive). The cap atoms have moderate-sized coefficients in the cap-weighted MO and are therefore moderately polarizing (moderately active). The Hückel partial charges for some vinyl-substituted relatives of **5** are shown on **6**, **7**, and **8**. The foregoing discussion leads to the following generalization. *The Building Rule: if a polarized even non-*

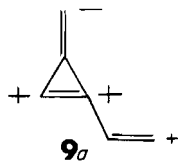
8



9*a*

alternant monocycle is modified by appending an even substituent to an inactive stem atom, the even substituent will not be polarized. An even substituent attached to any cap atom will be weakly polarized. An even substituent attached to an active stem atom will be strongly polarized.

B. Comparison of Hückel and AM1 results

A dynamic polarity analysis leads to the atomic charge distribution for the cap-substituted vinyl methylene cyclopropene shown on structure **9***a*. Hückel and AM1 calculated atomic charges are presented for several non-alternant monocycles as **9***b*, **9***c*, **10***a*, **10***b*, **11***a*, and **11***b*.

Quantitatively, AM1 results for lowest-lying singlet states indicate that fully π-bonded non-alternant monocycles have more weakly polarized frameworks than Hückel results suggest. If polarization is characterized by summing the partial positive charges accruing from the π-system alone, then Hückel polarization is typically about four times larger than AM1 polarization. Compare the Hückel results on **9***b* with the AM1 results on **9***c*.

Qualitatively, AM1 polarization of odd substituents is shorter range, fading faster as one moves through the substituent away from the ring (see **10***a* for Hückel results and **10***b* for AM1 results on the same structure). Even substituents appended to cap sites are always moderately polarized at the Hückel level. At the AM1 level, cap-appended even substituents are very weakly polarized except when attached to three-membered rings. AM1 support for the Building Rule as it applies to stem-appended even substituents is presented on structures **12** and **13**.

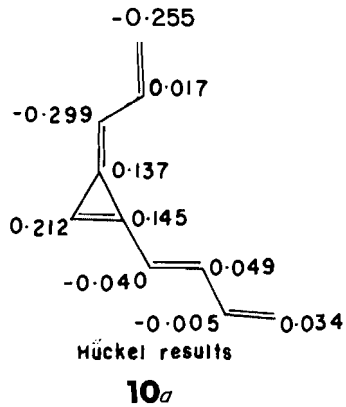
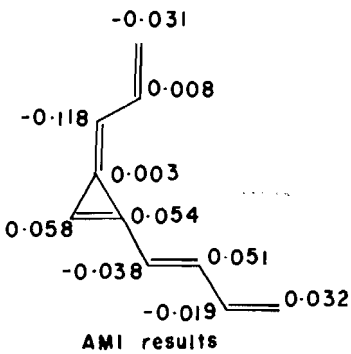
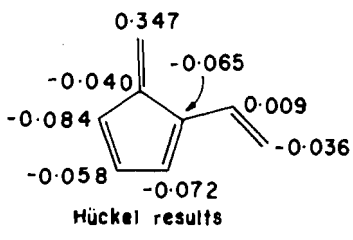
9*c*



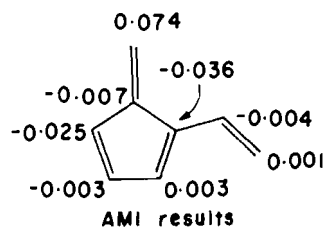
10*a*



10*b*



11*a*



11*b*

C. Very rapid polarity analyses

From the generalizations presented heretofore, it is now possible to carry out extremely rapid "back-of-the-envelope" polarity analyses for non-alternant monocycles. First, if the fully π-bonded even non-alternant monocycle has more than one exocyclic double bond, it is not polarized (Odd Substituent Rule) and is of no interest. Second, for those structures having only one exocyclic double bond, partial charges (*c*) and (*c*′) will develop as shown on **A**. If the ring contains $4J + 3$ carbon atoms, *c* will be positive and *c*′ will be negative. If the ring contains $4J + 1$ carbon atoms, *c* will be negative and *c*′ will be positive. Polarity of even substituents is depicted on **A** (Building Rule).

While many of the compounds that we have examined computationally are not presently known, the three parent compounds have been prepared and their dipole moments

determined experimentally. Methylene cyclopropene has an AM1 dipole moment of 1.20 D and an experimental dipole moment (10) of 1.90 D. Fulvene has an AM1 dipole moment of 0.69 D and an experimental dipole moment (11) of 0.44 D. Heptafulvene has an AM1 dipole moment of 0.36 D and an experimental dipole moment (12) of 0.48 D.

Table 2 presents the relative magnitudes of the coefficients of the polarizing orbitals as deduced from dynamic polarity analyses, consequent charge patterns, and AM1-calculated

charge patterns for a modest selection of fully π-bonded non-alternant monocycles.

As might be expected from the ethylene LUMO coefficients, the cap atoms contained in polarized cyclopropenyl rings have similar AM1-calculated charge densities (see compounds **1** and **9** in Table 2). However, longer acyclic polyenes, e.g., butadiene, have frontier orbitals in which the coefficients of terminal carbon atoms are substantially larger than the coefficients for nonterminal carbon atoms. Thus, an examination of the HOMO of butadiene would lead to the expectation that the terminal cap atoms contained in polarized cyclopentadienyl rings should have much larger charges than nonterminal cap atoms. The AM1 results from compounds **11** and **16** in Table 2 offer support for such an expectation. Tabulated comparisons of dynamic polarity analyses and AM1 π-electron populations for an additional 42 non-alternant monocycles are available as supplementary material.[2]

Conclusions

Dynamic polarity analyses have been defined and developed for fully π-bonded non-alternant monocycles. They have led to a very rapid "back-of-the-envelope" scheme for qualitatively anticipating topologically induced polarity in such monocycles. These "back-of-the-envelope" predictions for charge patterns are in good agreement with AM1 molecular orbital computed polarities. This work provides an effective approach to predicting topologically induced polarity in non-alternant *bicycles* that will be described in due course.

Pyridine hydrobromide perbromide mediated regioselective heterocyclization of *ortho*-cyclohexenyl phenols[1]

Krishna C. Majumdar and Anup K. Kundu

Abstract: A number of 3,4-benzo-9-bromo-2-oxabicyclo[3.3.1]nonanes (**9***a–h*) are synthesized in almost quantitative yields by regioselective heterocyclization of *ortho*-cyclohexenyl phenols (**8***a–h*). The structures of 3,4-benzo-9-bromo-2-oxabicyclo[3.3.1]nonane **9** have been unambiguously settled by the synthesis of 9-chloromercuri-3,4-(4′-methoxybenzo)-2-oxabicyclo[3.3.1]nonane **13**, which has an X-ray determined structure, and by converting **13** to product **9***c* with bromine in sunlight in 45% yield. The 6-chloro-2-cyclohexenenyl phenol **8***i* and 2-cyclohexenyl-4-methyl phenol **8***j* failed to give any cyclic product but instead furnished the ring-brominated products **10***i* and **10***j*, respectively.

Key words: pyridine hydrobromide perbromide, regioselective heterocyclization, *ortho*-cyclohexenyl phenol, oxabicyclo[3.3.1]nonane, 6-*endo* trig.

Résumé : On a synthétisé un certain nombre de 3,4-benzo-9-bromo-2-oxabicyclo[3.3.1]nonanes (**9***a–h*) avec des rendements pratiquement quantitatifs en procédant à l'hétérocyclisation régiosélective d'*ortho*-cyclohexénylphénols (**8***a–h*). On a établi sans ambiguïté la structure du 3,4-benzo-9-bromo-2-oxabicyclo[3.3.1]nonane (**9**) en procédant à la synthèse du 9-chloromercuri-3,4-(4′-methoxybenzo)-2-oxabicyclo[3.3.1]nonane (**13**) dont on a déterminé la structure par diffraction des rayons X et que l'on a transformé en composé **9***c*, avec un rendement de 45%, par réaction du composé **13** avec du brome en présence de lumière solaire. Les 6-chloro-2-cyclohexénenylphénol (**8***i*) et 2-cyclohexényl-4-méthylphénol (**8***j*) ne donnent naissance à aucun produit cyclique; plutôt ils fournissent respectivement les produits bromés sur le cycle **10***i* et **10***j*.

Mots clés : perbromure du bromhydrate de pyridine, hétérocyclisation régiosélective, *ortho*-cyclohexénylphénol, oxabicyclo[3.3.1]nonane, cyclé 6-*endo*.

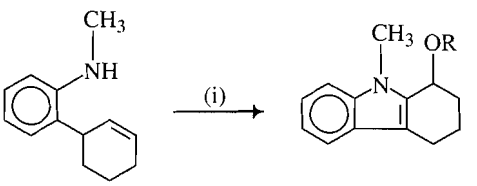
Introduction

We recently reported (1) a one-step mercury(II) mediated regioselective heterocyclization of *ortho*-cyclohexenyl *N*-methylaniline **1** to 1-alkoxy *N*-methyl tetrahydrocarbazole **2** (Scheme 1). This was found to be much simpler than a three-step process we had reported earlier (2) for the cyclization of *ortho*-cyclohexenyl phenols. Our earlier method involved the regioselective cyclization of *ortho*-cyclohexenyl phenols **3** to chromans **6** in 50% overall yield in three steps (3), viz., (*i*) acetylation of the phenolic -OH, (*ii*) addition of bromine to the cyclohexenyl bond, and (*iii*) internal nucleophilic attack at the C3 carbon of the cyclohexenyl side chain in alcoholic potassium hydoxide (Scheme 2). It was necessary to deactivate the phenol ring towards electrophilic attack by acetylation to avoid any ring bromination and as a consequence three steps were necessary to complete the cyclization for the introduction of a bromine in the newly formed pyran ring (Scheme 2). Our recent work on the regioselective synthesis of a number of heterocycles (4) prompted us to search for a simple and efficient reagent for this heterocyclization. We have recently achieved a facile entry to this ring system **6** (5) with the use of a well-known brominating agent, pyridine hydrobromide perbromide, which we report here.

Scheme 1.



1 **2**

The starting materials *ortho*-cyclohexenyl phenols **8***a–j* were prepared (6) by the Claison rearrangement of 3-aryloxy cyclohexenes **7** (Scheme 3).

Results and discussion

ortho-Cyclohexenyl phenyl **8***a* was magnetically stirred with one equivalent of pyridine hydrobromide perbromide in dichloromethane at 0–5°C for 2 h. The reaction was monitored by tlc. A low-melting solid was obtained in 92% yield. Elemental analysis and spectral data indicated this to be 3,4-benzo-9-bromo-2-oxabicyclo[3.3.1]nonane **9***a*. Substrates **8***b–h* successfully underwent cyclization regioselectively to give 3,4-benzo-9-bromo-2-oxabicyclo[3.3.1]nonanes **9***b–h* in 90–96% (isolated) yields (Scheme 4). Altogether 10 different substrates were used for this study. Two substrates (**8***i* and **8***j*) did not give the cyclized product. 6-Chloro-2-cyclohexenyl phenol **8***i* and 2-cyclohexenyl-4-methyl phenol **8***j* furnished ring-brominated products, viz., 4-bromo-6-chloro-2-cyclohexenyl phenol **10***i* and 6-bromo-2-cyclohexenyl-4-methyl phenol **10***j*, respectively, instead of the cyclized product (Scheme 4). At present we do not know why **8***j* should not cyclize. Both 4-methoxy and 4-chloro (**8***c* and **8***d*) do and it is difficult to explain why the electronically intermediate and sterically identical **8***j* should not. The other case that does not cyclize, **8***i*, can perhaps be understood as a steric issue but here too the 2,4-dimethyl compound **8***e* does cyclize satisfactorily. This remains inexplicable.

The formation of product **9** may be explained by the formation of cyclic bromonium ion **11** followed by a 6-"*endo*" cyclization (7) to give **9** (Scheme 5). The cyclization of the proposed bromonium intermediate **11** is facile under such a mild condition perhaps due to favourable juxtaposition of the reacting functionalities to give a stable bicyclic product **9**. The reaction becomes faster in a mixture of solvents, viz., a 1:1 mixture of dichloromethane and methanol. The reaction is complete in 30–40 min instead of 2 h as was required in dichloromethane alone.

The alternative mode of cyclization by a 5-"*exo*"-trig to give **12** is discarded as the products obtained, **9**, remain unaffected when refluxed with potassium cyanide in acetone in presence of potassium iodide (8) or when refluxed with ethanolic potassium hydroxide (9) (12%) for 4 h. An unequivocal proof for the structure of product **9** is provided by means of a transformation route. Compound **8***c* was converted to **13**, the structure of which has been determined by X-ray (10). Compound **13** was then treated with bromine under sunlight to give the product **9***c* in 45% yield (Scheme 6).

The high-field (400 MHz) ^{1}H NMR spectrum of the compound **9***c* showed three lone protons: at δ 4.09–4.17 assignable to proton H_a, at δ 4.75–4.82 assignable to proton H_b, and at δ 3.53–3.59 assignable to proton H_c. The signal at δ 4.09–4.17 due to H_a appeared as a seven-line multiplet; however, careful expansion of the region showed eight lines (ddd, J = 6.86, 4.28, and 10.15 Hz). The signal at δ 4.75–4.82 due to H_b appeared as a triplet, which again on careful expansion appeared as a doublet of doublets with coupling constants J = 6.86 and 6.40 Hz. The signal at δ 3.53–3.59, which initially appeared as an AB quartet, again on careful expansion was found to be a doublet of triplets with coupling constants J = 6.80 and 6.40 Hz. The proton assignments were made from a 2D spectrum and proton decoupling experiments. A Dreiding model of compound **9** can be constructed by 1,3-fusion of the pyran ring in the half-chair conformation with the cyclohexane ring in the chair conformation (distorted) as shown in Fig. 1. However, the coupling constant of 10.15 Hz cannot be explained if the molecule **9***c* attains this conformation. The alternative model that can be constructed, again by 1,3-fusion of the pyran ring in the half-chair form with the cyclohexane ring in the boat (distorted) form, is shown in Fig. 2. The coupling constant J = 10.15 Hz can be explained if the molecule **9** attains this conformation. It may be noted that [3,3,1]bicyclononane is known to be in the chair-boat conformation (11). The 100 MHz ^{1}H NMR spectra of compounds **9***a*, *b*, *d–h* were then compared with the ^{1}H NMR (100 MHz) spectrum of compound **9***c* for which high-field ^{1}H NMR is available. The ^{1}H NMR pattern is found to be similar except for the aromatic region, due to ring substitution.

It is relevant to mention here that on treatment with pyridine hydrobromide perbromide under similar conditions 3-cyclohexenyl-4-hydroxy coumarin **14** afforded only the tribromo derivative **15** (4*b*), and 3-cyclopentenyl-4-hydroxy coumarin **16** furnished the linearly fused furochromone derivative **17** (12).

Pyridine hydrobromine perbromide is a mild reagent and

reacts at a low temperature. It is superior, as in most cases (except in case of **8***i* and **8***j*) it does not seem to affect the aromatic ring of the phenol due to rapid formation of bromonium ion and its cyclization before any ring bromination can take place. Thus deactivation by acetylation is not necessary and the additional base treatment (Step iii) is avoided. Pyridine hydrobromide perbromide had earlier been selectively used

Fig. 1.

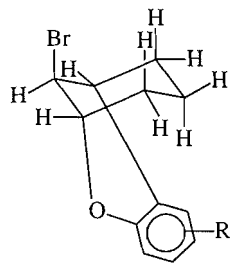

Fig. 2.

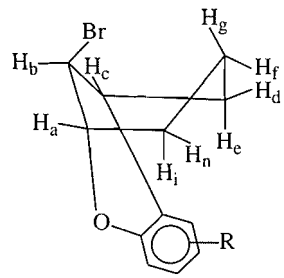

for nuclear bromination of phenols (13). Another method of entry to 3,4-benzo-9-bromo-2-oxabicylo[3.3.1]nonane of the type **9** may involve oxymercuration and replacement of the chloromercury group by bromine, which is a relatively low-yield (10) (overall) process. The methodology presented here is mild, chemoselective, and gives 3,4-benzo-9-bromo-2-oxabicyclo[3.3.1]nonanes in almost quantitative yields.

Experimental

Melting points were determined in a sulphuric acid bath and are uncorrected. UV absorption spectra were recorded in EtOH on a Hitachi 200-20 spectrophotometer (λ_{max} in nm) and IR spectra in KBr discs on a Perkin–Elmer 1330 apparatus (ν_{max} in cm^{-1}). ^1H NMR spectra were run in $CDCl_3$ with $SiMe_4$ as internal standard on a Jeol Fx-100 (100 MHz) instrument at the Indian Institute of Chemical Biology, Calcutta (chemical shifts in δ, ppm). Elemental analyses and mass spectra were recorded by RSIC (CDRI), Lucknow. Silica gel (60–120 mesh) was obtained from Qualigen and aluminium oxide (basic) from SRL. Extracts were dried over anhydrous sodium sulphate.

Preparation of compounds 7*a–j*

Compounds **7***a* (6), **7***c* (10), and **7***g* (2) were prepared according to published procedures.

General procedure for the preparation of compound **7**b, d–f, h–j

A mixture of phenol (0.02 mol), 3-bromocyclohexene (0.02 mol), and anhydrous K_2CO_2 (4 g) was refluxed in dry acetone (100 mL) on a water bath for 10 h. The reaction mixture was then cooled, filtered, and the solvent was removed. The residual mass was extracted with $CHCl_3$ (3 × 50 mL). The $CHCl_3$ extract was washed with potassium hydroxide solution (20%) to remove unreacted phenol, then with brine (3 × 50 mL), and dried (Na_2SO_4). The solvent was removed and the crude mass was chromatographed over aluminium oxide (basic, SRL) using petroleum ether (60–80°C) as eluant to give compounds **7***b*, **7***d–f*, **7***h–j*.

Compound **7**b*:* Viscous oil (89%), UV (EtOH), λ_{max}: 277 (log ϵ 3.10), 226 (log ϵ 3.83) nm; IR (KBr), ν_{max}: 3010, 2940, 1600, 1500, 1380, 1280, 1230, and 1160 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.30 (s, 9H), 1.68–2.08 (m, 6H), 4.68–4.88 (bs, 1H), 5.84–6.08 (m, 2H), 6.80–6.96 (m, 2H), and 7.20–7.40 (m, 2H). Anal. calcd. for $C_{16}H_{22}O$: C 83.48, H 9.56%; found: C 83.25, H 9.45%.

Compound **7**d*:* Viscous oil (88%), UV (EtOH), λ_{max}: 283 (log ϵ 2.99), 230 (log ϵ 3.73) nm; IR (KBr), ν_{max}: 3120, 2936, 1594, 1488, 1235, and 1169 cm^{-1}; ^1H NMR (400 MHz; $CDCl_3$–TMS), δ: 1.50–2.20 (m, 6H), 4.74 (s, 1H), 5.80–5.88 (m, 1H), 5.94–6.01 (m, 1H), 6.80–6.88 (m, 2H), and 7.18–7.28 (m, 2H). Anal. calcd. for $C_{12}H_{13}ClO$: C 69.06, H 6.23%; found: C 69.12, H 6.05%.

Compound **7**e*:* Viscous oil (87%), UV (EtOH), λ_{max}: 279 (log ϵ 3.10), 226 (log ϵ 3.69) nm; IR (KBr), ν_{max}: 3010, 2920, 1600, 1480, 1380, 1240, 1210, and 1120 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.60–2.12 (m, 6H), 2.20 (s, 3H), 2.28 (s, 3H), 4.64–4.92 (bs, 1H), 5.84–6.12 (m, 2H), and 6.72–7.16 (m, 3H). Anal. calcd. for $C_{14}H_{18}O$: C 83.17, H 8.91%; found: C 83.01, H 8.65%.

Compound **7**f*:* Viscous oil (85%), UV (EtOH), λ_{max}: 275 (log ϵ 3.44), 224 (log ϵ 3.70) nm; IR (KBr), ν_{max}: 3010, 2925, 1585, 1450, 1310, 1290, 1150, and 1060 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.64–2.12 (m, 6H), 2.28 (s, 6H), 4.64–4.84 (bs, 1H), 5.84–6.00 (m, 2H), and 6.56 (s, 3H). Anal. calcd. for $C_{14}H_{18}O$: C 83.17, H 8.91%; found: C 83.47, H 9.12%.

Compound **7**h*:* Viscous oil (88%), UV (EtOH), λ_{max}: 208 (log ϵ 3.78), 229 (log ϵ 4.14), 282 (log ϵ 3.13) nm; IR (KBr), ν_{max}: 3120, 2940, 1590, 1490, 1410, 1290, 1245, and 1180 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.54–2.38 (m, 6H), 4.58–4.86 (bs, 1H), 5.70–6.14 (m, 2H), 6.70–6.98 (m, 2H), and 7.28–7.66 (m, 2H). Anal. calcd. for $C_{12}H_{13}BrO$: C 56.91, H 5.13%; found: C 56.82, H 5.31%.

Compound **7**i*:* Viscous oil (82%), UV (EtOH), λ_{max}: 280 (log ϵ 2.63), 205 (log ϵ 3.64) nm; IR (KBr), ν_{max}: 3020, 2930, 1580, 1470, 1440, 1270, 1240, and 1050 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.60–2.56 (m, 6H), 4.60–4.96 (m, 1H), 5.72–6.20 (m, 2H), and 6.76–7.60 (m, 4H). Anal. calcd. for $C_{12}H_{13}ClO$:C 69.06, H 6.23%; found: C 69.48, H 6.35%.

Compound **7**j*:* Viscous oil (90%), UV (EtOH), λ_{max}: 226 (log ϵ 3.77), 280 (log ϵ 2.89) nm; IR (KBr), ν_{max}: 3020, 2930, 1610, 1510, 1395, 1242, 1180, and 1038 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.59–2.19 (m, 6H), 2.28 (s, 3H), 4.63–4.99 (bs, 1H), 5.75–6.15 (m, 2H), and 6.71–7.23 (m, 4H). Anal. calcd. for $C_{13}H_{16}O$:C 82.98, H 8.51%; found: C 82.80, H 8.32%.

Claisen rearrangement of compounds **7**a–j

Compounds **8***a* (6), **8***c* (10), and **8***g* (2) were prepared according to published procedure.

General procedure for the Claisen rearrangement of compounds **7***b*, d–f, h–j

Compound **7***b*, *d–f*, *h–j* (1 g) was refluxed in *N*,*N*-diethylaniline (5 mL) for 16 h. The reaction mixture was cooled and poured into ice-cold dilute (1:1) hydrochloric acid and extracted with $CHCl_3$. The extract was washed with dilute hydrochloric acid, brine, and water and dried (Na_2SO_4). Evaporation gave the crude product, which was chromatographed over aluminium oxide (basic, SRL). Elution of the column with benzene gave compounds **8***b*, *d–f*, *h–j*.

Compound **8**b*:* Gummy mass (87%), UV (EtOH), λ_{max}: 279 (log ϵ 3.50), 223 (log ϵ 3.95) nm; IR (KBr), ν_{max}: 3490, 3018, 2950, 1608, 1449, 1499, 1363, 1266, and 1092 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.30 (s, 9H), 1.60–2.00 (m, 6H), 3.40–3.72 (bs, 1H), 5.28 (s, 1H), 5.76–6.20 (m, 2H), 6.68–6.84 (m, 1H), and 7.08–7.28 (m, 2H). Anal. calcd. for $C_{16}H_{22}O$: C 83.48, H 9.56%; found: C 83.78, H 9.77%.

Compound **8**d*:* Gummy mass (74%), UV (EtOH), λ_{max}: 284 (log ϵ 3.07), 228 (log ϵ 3.84) nm; IR (KBr), ν_{max}: 3400, 3000, 2910, 1580, 1410, 1260, 1210, 1160, and 1110 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.60–2.00 (m, 6H), 3.44–3.68 (bs, 1H), 5.28 (s, 1H), 5.68–5.88 (m, 1H), 6.00–6.20 (m, 1H), 6.68–6.80 (m, 1H), and 7.00–7.20 (m, 2H). Anal. calcd. for $C_{12}H_{13}ClO$: C 69.06, H 6.23%; found: C 69.42, H 6.13%.

Compound **8**e*:* Gummy mass (75%), UV (EtOH), λ_{max}: 280 (log ϵ 3.19), 223 (log ϵ 3.72) nm; IR (KBr), ν_{max}: 3460, 3120, 2910, 1640, 1445, 1400, 1295, 1185, and 1035 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.60–1.96 (m, 6H), 2.16 (s, 3H), 2.20 (s, 3H), 3.36–3.60 (bs, 1H), 5.24 (s, 1H), 5.72–6.16 (m, 2H), 6.76 (s, 1H), and 6.80 (s, 1H). Anal. calcd. for $C_{14}H_{18}O$: C 83.17, H 8.91%; found: C 83.29, H 8.74%.

Compound **8**f*:* Gummy mass (72%), UV (EtOH), λ_{max}: 282 (log ϵ 3.33), 223 (log ϵ 3.91) nm; IR (KBr), ν_{max}: 3464, 3014, 2926, 1621, 1572, 1455, 1283, 1212, 1170, and 1056 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.62–2.04 (m, 6H), 2.22 (s, 3H), 2.26 (s, 3H), 3.60–3.84 (bs, 1H), 5.88–6.28 (m, 3H), and 6.56 (s, 2H). Anal. calcd. for $C_{14}H_{18}O$: C 83.17, H 8.91%; found: C 83.46, H 8.61%.

Compound **8**h*:* Viscous oil (75%), UV (EtOH), λ_{max}: 209 (log ϵ 3.96), 284 (log ϵ 3.27) nm; IR (KBr), ν_{max}: 3445, 3160, 1670, 1405, 1265, 1215, and 1105 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.55–2.35 (m, 6H), 3.35–3.75 (m, 1H), 5.31 (s, 1H), 5.63–5.91 (m, 1H), 5.95–6.27 (m, 1H), and 6.55–7.24 (m, 3H). Anal. calcd. for $C_{12}H_{13}BrO$: C 56.91, H 5.13%; found: C 56.98, H 5.23%.

Compound **8**i*:* Gummy mass (87%), UV (EtOH), λ_{max}: 277 (log ϵ 2.65), 206 (log ϵ 3.92) nm; IR (KBr), ν_{max}: 3520, 3140, 2925, 1595, 1445, 1400, 1325, 1240, 1190, and 1070 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.60–2.28 (m, 6H), 3.64–4.00 (m, 1H), 5.52–5.84 (m, 2H), 5.88–6.12 (m, 1H), 6.84 (t, J = 8 Hz, 1H), and 7.04–7.44 (m, 2H). Anal. calcd. for $C_{12}H_{13}ClO$: C 69.06, H 6.23%; found: C 69.53, H 6.39%.

Compound **8**j*:* Gummy mass (77%), UV (EtOH), λ_{max}: 282

(log ε 3.19), 222 (log ε 3.63) nm; IR (KBr), ν_{max}: 3430, 3010, 2910, 1690, 1610, 1570, 1480, 1440, 1400, 1250, and 1130 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.60–2.16 (m, 6H), 2.24 (s, 3H), 3.36–3.72 (bs, 1H), 5.20 (s, 1H), 5.68–6.20 (m, 2H), and 6.72–7.12 (m, 3H). Anal. calcd. for $C_{13}H_{16}O$: C 82.98, H 8.51%; found: C 82.77, H 8.71%.

General procedure for the cyclization of compounds ***8***a–j

The brominating agent, solid pyridine hydrobromide perbromide (1 mmol), was added to a methylene chloride solution (20 mL) of the compounds ***8****a–j* (1 mmol). The reaction mixture was then stirred for 2 h on a magnetic stirrer at 0–5°C. After completion of the reaction (monitored by tlc), the mixture was washed with 5% $NaHCO_3$ solution (3 × 25 mL) and water (3 × 25 mL), and dried (Na_2SO_4). The residual mass, after removal of the solvent, was subjected to column chromatography over silica gel using petroleum ether (40–60°C) as eluant to give cyclization product ***9****a–h*, but two substrates (***8****i* and ***8****j*) did not give cyclized product. In these cases, ring-brominated products **10***i* and **10***j* were obtained. When the solvent was changed to a 1:1 mixture of dichloromethane and methanol the reaction was complete in 30–40 min.

Compound ***9***a*:* mp 38°C (92%), UV (EtOH), λ_{max}: 280 (log ε 3.54), 223 (log ε 3.77) nm; IR (KBr), ν_{max}: 3040, 2920, 1590, 1465, 1450, 1220, 1200, 1175, and 1105 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.68–2.08 (m, 6H), 3.44–3.74 (dt ≈ q, J = 6.80, 6.40 Hz H_c), 4.08–4.28 (ddd, J = 10.15, 6.86, 4.28 Hz, H_a), 4.72–4.96 (dd ≈ t, J = 6.86, 6.40 Hz, H_b), and 6.80–7.36 (m, 4H); *m/z*: 252, 254 (M^+). Anal. calcd. for $C_{12}H_{13}BrO$: C 56.92, H 5.14%; found: C 57.13, H 5.26%.

Compound ***9***b*:* mp 68°C (93%), UV (EtOH), λ_{max}: 283 (log ε 3.44), 226 (log ε 3.75) nm; IR (KBr), ν_{max}: 3030, 2940, 1600, 1470, 1350, 1250, 1200, 1170, and 1110 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.28 (s, 9H), 1.76–2.16 (m, 6H), 3.42–3.76 (dt ≈ q, J = 6.80, 6.40 Hz, H_c), 4.04–4.36 (ddd, J = 10.15, 6.86, 4.28 Hz, H_a), 4.68–4.94 (dd ≈ t, J = 6.86, 6.40 Hz, H_b), 6.72–6.88 (m, 1H), and 7.12–7.24 (m, 2H); *m/z*: 308, 310 (M^+). Compound ***10***j*:* mp 138°C (90%), UV (EtOH), λ_{max}: 223 (log ε 4.11), 284 (log ε 3.64) nm; IR (Nujol), ν_{max}: 3440, 3120, 1395, 1315, 1230, and 1150 cm^{-1}; ^1H NMR (100 MHz; $CDCl_3$–TMS), δ: 1.48–2.16 (m, 6H), 2.25 (s, 3H), 3.84–4.08 (m, 1H), 4.80–5.08 (m, 2H), 5.52 (s, 1H), 6.84 (s, 1H), and 7.16 (s, 1H). Anal. calcd. for $C_{13}H_{15}BrO$: C 58.42, H 5.61%; found: C 58.59, H 5.80%.

Chloromercuration of compound ***8***c

To a stirred solution of $HgCl_2$ (2 mmol) in water (12 mL) was added ***8****c* (2 mmol) and stirring was continued for 24 h at room temperature, during which time a heavy greyish oil settled down. The supernatant was decanted and a little methanol was added to the oil when a white precipitate was obtained. It was filtered, dried, and recrystallized from chloroform–methanol to obtain **13**. Yield 47%, mp 230°C.

Bromination of compound ***13***

The chloromercurated product **13** (0.4 g) was taken up in chloroform (20 mL) and warmed to 50°C. The solution was then exposed to direct sunlight and a solution of bromine (2 drops) in chloroform (10 mL) added to it with stirring. After the bromine was used up, the mixture was stirred for further a 45 min,

and then cooled in an ice–salt bath for 15 min. The precipitated mercuric bromide was filtered off and the solution was successively washed with saturated aqueous $NaHSO_3$ and salt water, and dried (Na_2SO_4). The solvent was removed to give a highly viscous liquid, which was purified by passing through a silica gel column and eluting the column with petroleum ether (60–80°C). The product was found to be identical with the product **9***c*, mp 64°C, yield (45%).

Attempted dehydrobromination of compound **9**c

A mixture of cyclized product **9***c* (50 mg) and potassium hydroxide (250 mg) in rectified spirit (2 mL) was refluxed on a water bath for 4 h. No change was observed as evidenced from the tlc of the reaction mixture and also from co-tlc with the starting material (**9***c*).

Attempted functionalization of compound **9**a

A mixture of the cyclized product **9***a* (60 mg), powdered potassium cyanide (90 mg), and 5% potassium iodide solution in acetone (2 mL) was stirred and heated under reflux for 12 h. No change was observed when examined by tlc.

Liquid chromatographic analysis and isolation of diastereoisomers obtained by an aldolization reaction

Michel Lafosse, Philippe Morin, Christophe Anceau, Gérard Coudert, Gérald Guillaumet, and Michel Dreux

Abstract: A new route using an aldolization reaction has been investigated in order to synthesize a precursor of pilocarpin, an alkaloid having sympathomimetic properties. To study the stereoselectivity of this route and to propose a mechanism, liquid chromatography has been used to analyse and to isolate each diastereoisomer for a structural determination by NMR. To further investigate the reaction mechanism, seven different aldehydes (or ketones) were used in the aldolization reaction, producing seven different mixtures. This paper describes the improvement of LC conditions with diol- and amino-bonded silica and the nonaqueous mobile phases required for the isolation of each isomer.

Key words: diastereoisomers, pilocarpin precursor, normal phase liquid chromatography, diol- and amino-bonded silicas.

Résumé : On a étudié une nouvelle voie de synthèse, impliquant une aldolisation, d'un précurseur de la pilocarpine, un alcaloïde possédant des propriétés sympathomimétiques. Dans le but d'évaluer la stéréosélectivité de cette voie et d'en proposer un mécanisme, on a utilisé la chromatographie liquide pour analyser et pour isoler chacun des diastéréoisomères dont on a déterminé la structure par RMN. Afin d'étudier le mécanisme réactionnel plus à fond, on a utilisé sept aldéhydes (ou cétones) différents au cours de la réaction d'aldolisation; on a ainsi produit sept mélanges différents. Dans ce travail, on décrit les améliorations des conditions de CL avec des silices liées à des diols et des amines et les phases mobiles non aqueuses nécessaires pour isoler chacun des isomères.

Mots clés : diastéréoisomères, précurseur de la pilocarpine, chromatographie liquide en phase normale, silices liées à des diols et à des amines.

[Traduit par la rédaction]

The synthesis of pilocarpin, an alkaloid with parasympathomimetic properties, was undertaken starting from a retrosynthetic analysis, with the aim of separating this natural molecule into accessible substructures (Fig. 1). The current work concerns the aldolization reaction between a chiral lactone B having a substituent R^4 and an imidazolic aldehyde C in order to obtain the pilocarpin precursor A. Several assumptions can be made about this pilocarpin precursor. Firstly, since in the pilocarpin structure the chiral carbon C2 possesses a well-defined configuration (*S* configuration: see Fig. 1), in the pilocarpin precursor A certain asymmetric carbon atoms (C2, C4, and C6) should also have well-defined configurations. Secondly, carbon C4 should have an *S* configuration in order to direct the aldolization reaction towards a *trans* configuration of C2–C4 as proposed in Fig. 1. Lastly, as carbon C6 has lost its asymmetric character in pilocarpin (Fig. 1), in the precursor it should have an *R* or *S* configuration.

Thus, starting from a chiral lactone B in which the C4 possesses an *S* configuration, we wished to confirm that the aldolization reaction occurred on the least hindered side of the lactone B as predicted by results previously obtained by groups studying alkylation (1–6) or hydroxylation (7), which would have preferentially produced *trans* isomers 2*S* 4*S* 6*R* and (or) 2*S* 4*S* 6*S* (Fig. 1).

To demonstrate the stereoselectivity or nonstereoselectivity of the aldolization reaction and conclude that it can occur preferentially on one side of the lactone B, the composition of the mixture produced by this reaction must be determined by liquid chromatography (LC). Liquid chromatographic analy-

Fig. 1. Scheme of the retrosynthetic analysis of pilocarpin. A = pilocarpin precursor, B = chiral lactone, and C = imidazolic aldehyde. The aldolization reaction between a chiral lactone B and an imidazolic aldehyde C gives the pilocarpin precursor A.

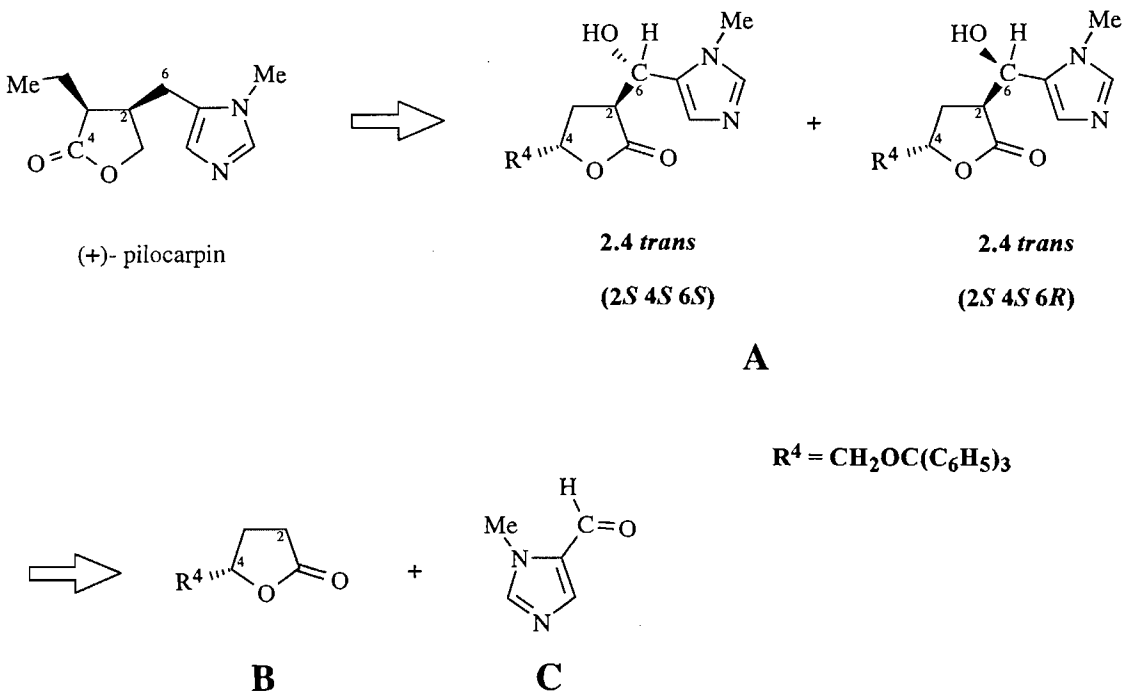

Fig. 2. Diastereoisomer nomenclature of the aldolization reaction products.

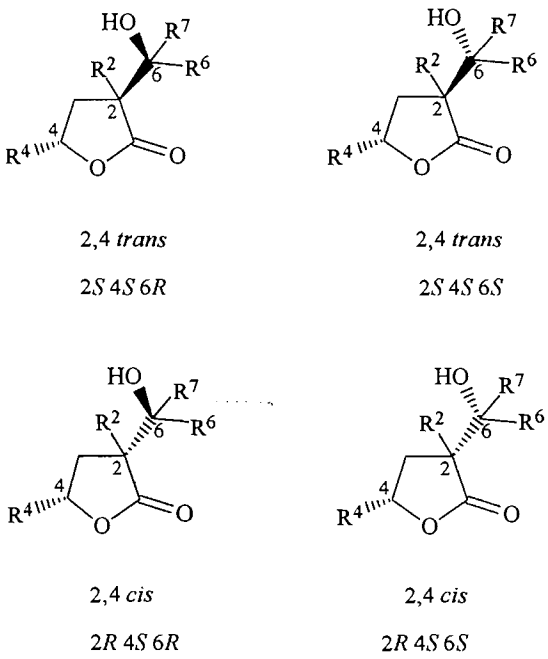

sis must be selective to separate the four diastereoisomers, i.e., one pair of *trans* isomers plus one pair of *cis* isomers (Fig. 2) if the reaction occurred on both sides of the lactone B. The aim of this work is to obtain the best LC conditions required to isolate each pure diastereoisomer in a quantity large enough to carry out its structural determination by ^1H and ^{13}C NMR.

To try to control the formation of *trans* isomers, a general study of the aldolization reaction was carried out using only one chiral lactone with two different substituents R^4 and diverse aldehydes or ketones C as shown in Table 1.

Experimental

Table 1 reports X1 as an isomer mixture containing the pilocarpin precursor A and the other mixtures X2, X3 ...U as instruments that highlight possible orientation effects in the aldolization reaction according to the protecting groups. Different reaction conditions were also tried out (temperature, solvent nature, reaction time ...) in order to determine any tendency towards the formation of single or pairs of compounds among the four diastereoisomers (8). The carbon configuration of different isomers obtained by LC was determined by ^1H and ^{13}C NMR (8, 9).

Chromatography was carried out using a Shimadzu LC 8A pump equipped with a model 7125 injection valve with a 1 mL loop (Rheodyne), a model SPD 6A UV spectrophotometer (Shimadzu) with a preparative cell, and a Shimadzu CR 3A calculator. The solvents were LC grade. In each case the injection solvent was mobile phase or, if the solubility was insufficient, mobile phase with a slightly higher percentage of the strongest solute solvent.

Since preliminary analytical tests by reversed phase LC were unable to show the presence of several diastereoisomers in the precursor compounds of the pilocarpin X1, only normal phase LC with silica and alkane–alcohol mixtures, as shown in the literature (10–13), was considered to separate the diastereoisomers. However, to avoid any difficulty arising from the inconsistency of the adsorbent activity of bare silica, polar-bonded silicas (diol, amino) were used. The following col-

[a] $CH_2OTr = CH_2OC(C_6H_5)_3$

[b] The configuration of C4 is 4*R* and not 4*S*. Change in the R^4 nature justifies the change in the C4 configuration.

umns were used: from Merck, Lichrosorb Diol 7 μm, 250 × 9.4 mm; Lichrospher NH2 5 μm, 250 × 4 mm; and from the laboratoire de Chimie organique at the University of Bordeaux a diamino silica 10 μm, 250 × 4.6 mm (14).

For the capacity factor calculation, the dead volume was determined by UV signal created by an excess of one of the eluent constituents.

Results and discussion

1. Diol-bonded silica as stationary phase

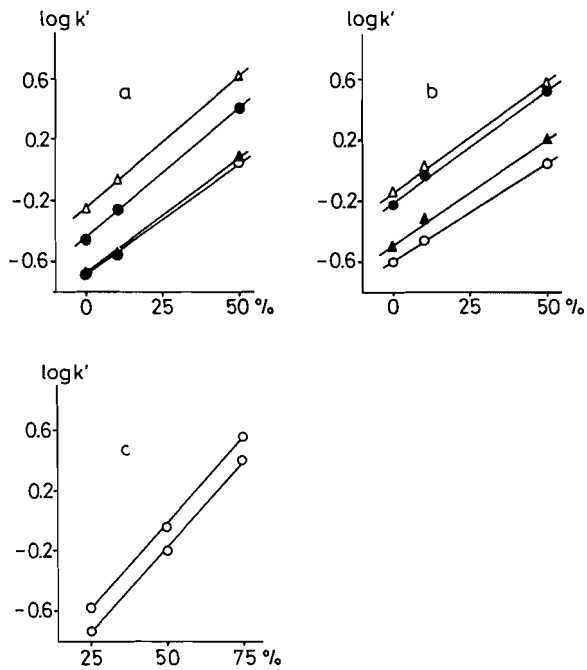
Due to the decreasing efficiency when the amount of injected analyte increases, the selectivity must be enhanced.

As shown in Fig. 3, log *k'* varies linearly versus the percentage of hexane in the hexane–dichloromethane mixture as mobile phase. These curves are nearly parallel, which means that the selectivity between two compounds is nearly constant whatever the mobile phase composition. Mixture Z1 is well separated (Fig. 3c) whatever the dichloromethane content (in a similar manner to the mixture Z2) but the best choice for isolation of each isomer would appear to be the hexane–dichloromethane (50:50, v/v) eluent since (*i*) the analysis time is relatively short, (*ii*) resolution remains high ($R = 3.4$), (*iii*) solubility of the analyte mixture in the eluent is appreciable. So, 1 mL of mixture Z1 at 25 mg/L in a solvent having the same composition as the eluent could be directly chromatographed and yielded each pure isomer.

The diastereoisomers of mixture Y can also be obtained with the same eluent. In this case, obtaining three compounds instead of the four theoretically possible can be explained by kinetic and thermodynamic factors.

Concerning the mixture X2, the first two peaks are not separated on these systems (Fig. 3a), while the four peaks of the mixture X3 are well separated with hexane–dichloromethane

Fig. 3. Variation of the capacity factors *k'* of diastereoisomers as a function of the hexane content in the hexane–dichloromethane mobile phase. Column: Lichrosorb Diol 7 μm (250 × 9.4 mm). Solutes: (a) X2; (b) U; (c) Z1 (see Table 1).



(50:50, v/v). Resolution between two successive peaks is, for the three pairs of isomers, respectively, $R_{1,2} = 2.6$, $R_{2,3} = 7$, and $R_{3,4} = 8.3$. Each isomer of the mixture U can be theoretically isolated (Fig. 3b) but synthetic impurities coelute either with the peak under poor eluent strength or with the first peak under a strong eluent, which requires a second purification in order

			1.36			1.31
	2*R* 4*S* 6*S*	14.7		2*R* 4*S* 6*S*	8.3	

to obtain the individual diastereoisomer. As shown in Table 2, diol-bonded silica as stationary phase resolved only four mixtures (X3, Y, Z1, and Z2). Consequently, amino-bonded silica was used for the remaining three.

2. Amino-bonded silica as stationary phase

This more polar stationary phase requires a stronger organic modifier such as alcohol instead of dichloromethane. But the nature of the alcohol greatly influences retention, as shown in Table 3 and Fig. 4. Hexane modified by 5% ethanol was a stronger eluent than hexane with the same content of methanol. This behaviour is the reverse of that observed in the so-called eluotropic series of alumina or bare silica. It is also observed when comparing the influence of ethanol and isopropanol (Table 3). Moreover, the nature of the alcoholic modifier influences the selectivity. With hexane–ethanol (98:2, v/v) as eluent, selectivity and retention enabled sufficient resolution to obtain each of the four pure diastereoisomers X2 on an analytical column in semi-preparative amounts. The elution order of diastereoisomers X2 is the following: 2*R* 4*S* 6*R*, 2*S* 4*S* 6*S*, 2*S* 4*S* 6*R*, then 2*R* 4*S* 6*S*.

As regards the mixture U, impurities can coelute with one of the peaks whatever the mobile phase. This explains why another modifier was tried: tetrahydrofuran in a ternary eluent with hexane and dichloromethane. This solvent possesses a proton-acceptor character, which is not the case for dichloromethane (dipole–dipole interactions) and the alcohol (proton donor) (15), thus modifying the solvating power of the solute and its adsorption energy. Retention and especially selectivity are greatly improved and in the case of the U mixture enabled isolation of each pure diastereoisomer as shown in Fig. 4.

Concerning the pilocarpin precursor X1 mixture, any one of the previous systems is suitable. A comparison of different commercial aminopropyl-bonded phases (Lichrospher, Zorbax, and Erbasil) shows identical results in separation capabilities whatever the mobile phase composition. However, a diaminopropyl-bonded phase especially designed for hydro-

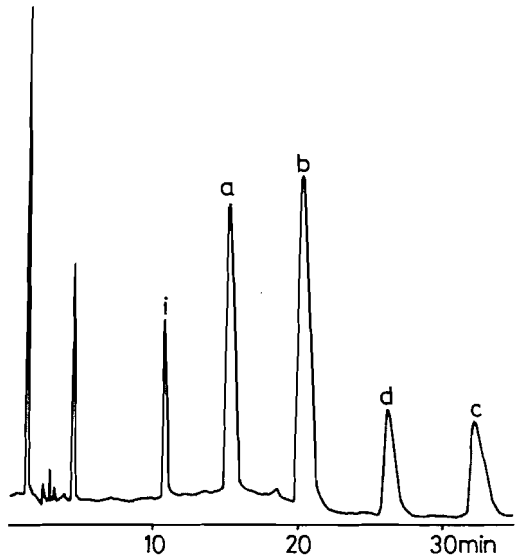
For personal use only.

Fig. 4. Isocratic separation of the U diastereoisomers on amino-bonded silica (Lichrospher NH_2 5 μm, 250 × 4 mm) with a ternary eluent (hexane–dichloromethane–tetrahydrofuran, 60:40:1, v/v/v) at 2 mL min^{-1}. Solutes: (a) 2*S* 4*R* 6*R*; (b) 2*S* 4*R* 6*S*; (c) 2*R* 4*R* 6*R*; (d) 2*R* 4*R* 6*S*; i = impurity.



carbon analysis (16) exhibited better selectivity and resolution. This bonding is much more retentive than the commercial monoaminopropyl bonding and has allowed the use of higher percentages of dichloromethane in ternary eluent (hexane–dichloromethane–methanol, 49:49:2); consequently the solubility of the mixture X1 increases with an increase in dichloromethane content and allows the injection of considerable quantities of solute. The elution order of diastereoisomers is the following: 2*R* 4*S* 6*R*, 2*S* 4*S* 6*S*, 2*S* 4*S* 6*R*, then 2*R* 4*S* 6*S*.

So, LC with polar-bonded silicas (diol and amino) as stationary phase is highly flexible as it allows various mobile phases to be tried and has enabled us to separate and isolate different pure diastereoisomers formed during the aldolization reaction of a multistep analysis. The identification of each isomer by NMR (9) indicates that the reaction is not stereoselective whatever the reaction conditions or the aldolization reagent. These results are negative as regards our initial aim of synthesizing pilocarpin, but they allow us to propose a reaction mechanism (9).

A study of the vacuum pyrolysis of 4-diazo-3-isochromanone with HeI ultraviolet photoelectron spectroscopy

N.H. Werstiuk, J. Ma, C.D. Roy, A.J. Kresge, and E. Jefferson

Abstract: A newly developed ultraviolet photoelectron spectrometer – CO_2 laser instrument that utilizes a 50-W CW laser as a directed heat source was used to study the vacuum pyrolysis of 4-diazo-3-isochromanone (**1**). Analysis of the pyrolysate with ultraviolet photoelectron spectroscopy and photoionization mass spectrometry established that **1** undergoes a facile, unexpected pyrolysis at a laser power level of 26 W yielding N_2, CO, and benzocyclobutenone (**6**). A multistep mechanism beginning with the formation of 4-carbena-3-isochromanone (**2**), which rearranges to oxaketene **3**, can be written for the reaction. If **3** is an intermediate, it must be unusually thermally labile for it readily decarbonylates to 2-carbena-3,4-benzotetrahydrofuran (**4**). The ring opening of **4** into the *ortho*-quininoid ketene **5** and the cyclization of **5** into **6** are possible final steps in the conversion of **1** into **6**.

Key words: vacuum pyrolysis, 4-diazo-3-isochromanone, HeI ultraviolet photoelectron spectroscopy.

Résumé : On a utilisé un nouveau spectromètre photoélectronique ultraviolet – laser au CO_2, qui utilise un laser CW de 50 W comme source dirigée de chaleur, pour étudier la pyrolyse sous vide de la 4-diazo-3-isochromanone (**1**). L'analyse du pyrolysat par spectroscopie photoélectronique et par spectrométrie de masse avec photoionisation a permis d'établir que, sous l'influence d'une puissance laser de 26 W, **1** subit une pyrolyse facile et inattendue qui fournit du N_2, du CO et de la benzocyclobuténone (**6**). Pour cette réaction, on peut proposer un mécanisme en plusieurs étapes qui commence par la formation de la 4-carbéna-3-isochromanone (**2**) qui se réarrange en oxacétène, **3**. Si le composé **3** est un intermédiaire, il doit être exceptionnellement labile vis-à-vis de la chaleur parce qu'il donne facilement une réaction de décarboxylation conduisant au 2-carbéna-3,4-benzotétrahydrofurane (**4**). L'ouverture de cycle du composé **4** en cétène *ortho*-quinonoïde **5** et la cyclisation de cette dernière en **6** sont les étapes finales possibles pour la conversion de **1** en **6**.

Mots clés : pyrolyse sous vide, 4-diazo-3-isochromanone, spectroscopie photoélectronique ultraviolette.

To facilitate the preparation and detection of highly reactive transients in the gas phase, we developed an ultraviolet photoelectron (pe) spectrometer – CW CO_2 laser apparatus and used it successfully to study the vacuum pyrolysis of 6,6-dihalobicyclo[3.1.0]hexanes (1) and 1,2,3-benzotriazines (2). To extend our research to other reactive species, we used this one-of-a-kind instrument to study the vacuum pyrolysis of 4-diazo-3-isochromanone (**1**). We undertook this study (*a*) because **1** is a potential source of two interesting transients, 4-carbena-3-isochromanone (**2**) and its Wolff rearrangement product (3) oxaketene **3**, and (*b*) because there is a lack of information on the vacuum pyrolysis of α-diazocarbonyl compounds in contrast to the substantial body of work documenting the photochemistry of this class of compounds (4–10). We expected that a pe spectroscopic study of **1** would yield information about the stability/reactivity of **2** and oxaketene **3** and provide fundamental information about their electronic structures and bonding. This communication documents the results of our study.

To obtain the pe spectrum of **1**,[2] a 10 mg sample was placed in a bottle-shaped quartz sample tube (1, 2) that was inserted into an electrically heated brass probe tip. Because the source pressure (5×10^{-4} Torr; Torr = 133.3 Pa) was low at ambient temperature, it was necessary to heat the sample tube to a temperature (48°C) slightly below its melting point (this yielded a suitable partial pressure of **1** and avoided the side reactions that occurred in the melt) and to use N_2 as a makeup gas to maintain the source pressure at 7×10^{-3} Torr. In keeping with the results of our previous study (2), this approach allowed us to obtain a spectrum of **1**. As seen in Fig. 1(*a*), the low-IE band of N_2 at 15.6 eV (11) dominates the spectrum of **1** acquired

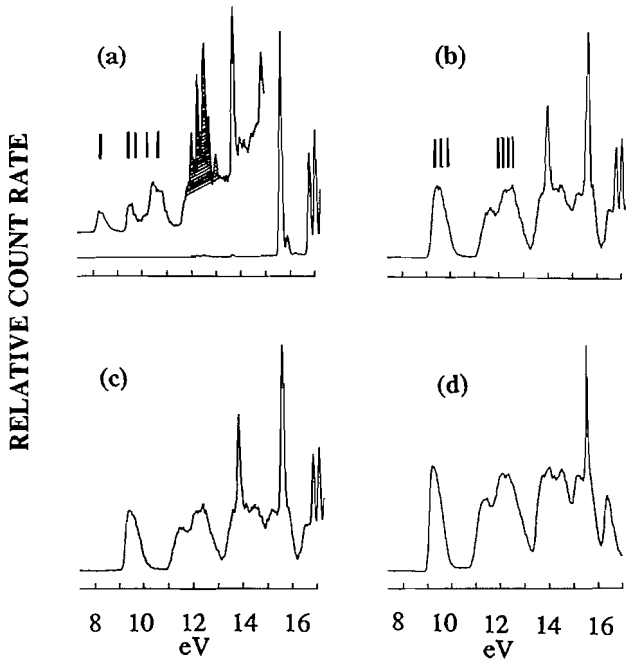
[2] The synthesis (by A.J.K. and E.J.) of **1**, a new compound (mp 48–49°C), was adapted from a procedure used for the synthesis of other α-diazocarbonyl compounds (14). Its spectroscopic properties (ir, nmr, and ms) were entirely in accord with the proposed structure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

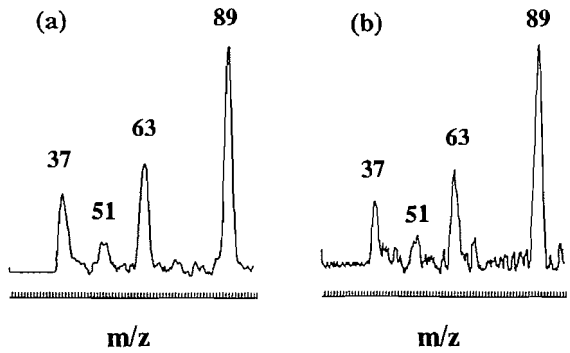
Fig. 1. (*a*) HeI pe spectrum of **1** obtained at a probe temperature of 48°C with N_2 as a make-up gas; (*b*) spectrum of the pyrolysate of **1** obtained at a laser power level of 26 W with no makeup gas; (*c*) spectrum of the pyrolysate of **1** obtained at a laser power of 47 W; (*d*) spectrum of an authentic sample of benzocyclobutenone (**6**) obtained at ambient temperature with N_2 (15.6 eV) as the calibrant.



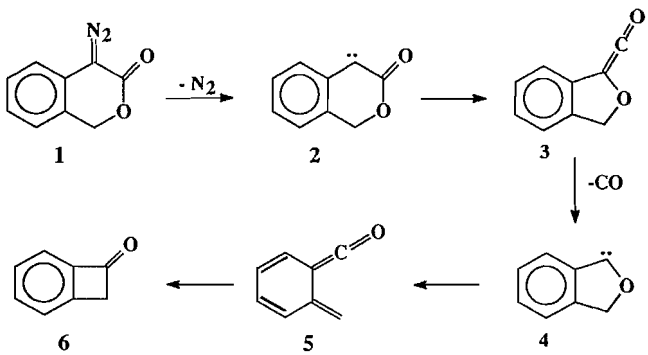
this way. Even so, a vertical expansion of the spectrum[3] between 7 and 14 eV revealed the low-IE bands of **1**. The vertical solid lines on this spectrum show the five lowest ionization energies (8.49, 9.70, 9.93, 10.38, and 10.87 eV) of compound **1** calculated with HAM/3 (12). The equilibrium geometry obtained at the HF/6–31G** level of theory with GAUSSIAN 92 (13) was used in the HAM/3 calculations.

When **1** was pyrolyzed by heating the tip of the sample tube (the hot zone (550 ± 50°C) was 1.5–2 mm in length) at a laser power level of 26 W (1, 2), a different pe spectrum (Fig. 1(*b*)) was obtained. No significant change was seen in the spectrum (Fig. 1(*c*)) when the pyrolysis was carried out at a laser power level of 47 W. While N_2 (identified by the band at 15.6 eV (11)) was expected, we were surprised to find CO (identified by the band at 14.0 eV (11)) as a major product of the reaction because *para*-substituted phenylketenes do not decarbonylate even at laser power levels greater than 40 W.[4] By comparing the calculational IEs (HAM/3//AM1) of possible products (carbene **2**, oxaketene **3**, carbene **4**, the *ortho*-quininoid ketene **5**, and benzocyclobutenone **6**) with the vertical IEs obtained from the pe spectrum of the pyrolysate, we concluded that the

Fig. 2. (*a*) Photoionization mass spectrum of benzocyclobutenone (**6**) obtained at ambient temperature; (*b*) photoionization mass spectrum of the pyrolysate of **1** obtained at a laser power of 26 W.



Scheme 1.



product probably was **6**. We prepared an authentic sample of **6** (16) and obtained its pe spectrum, which is displayed as Fig. 1(*d*). Aside from the peaks arising from CO and N_2, the pe spectra of the pyrolysate (Figs. 1(*b*) and 1(*c*): the vertical lines show the seven lowest IEs 9.64, 9.85, 10.05, 12.25, 12.32, 12.66, and 12.80 eV of **6** calculated with HAM/3//6–31G**)) are virtually identical to the pe spectrum of **6**. We also established that the authentic sample of benzocyclobutenone does not pyrolyze even at the maximum power level (60 W) of the laser. Additional support for **6** as the pyrolysis product was obtained by running the pe spectrometer in its photoionization mass spectrometer mode.[5] The mass spectra of the authentic sample of **6** acquired at ambient temperature and the pyrolysate obtained at a laser power of 26 W are displayed in Fig. 2 as (*a*) and (*b*), respectively. That the mass spectra are virtually identical (**6** does not exhibit a molecular ion under the experimental conditions used in this study) establishes that 4-diazo-3-isochromanone does, in fact, afford benzocyclobutenone in high yield. Even though the intermediates (4-carbena-3-isochromanone (**2**), oxaketene (**3**), 2-carbenatetrahydro-3,4-benzofuran (**4**), and the *ortho*-quininoid ketene (**5**)) shown in Scheme 1 were not detected by pe spectroscopy or mass spec-

[3] The cross-hatched peaks ranging between 12 and 13 eV arise from traces of O_2 (12.1–12.8 eV) and H_2O (12.6 eV) that are present in the source chamber. The band at 13.7 eV, which has a very low intensity relative to the band at 15.6 eV of N_2 in the unexpanded spectrum, arises from ionization by the 537.0 Å line (23.1 eV photons) known to have 2% the intensity of the 584.3 Å line (21.2 eV photons) of the HeI discharge (15).

[4] N.H. Werstiuk, J. Ma (McMaster University), and M. Liu (University of Prince Edward Island); work in progress.

[5] When the pe spectrometer was modified, an 200 amu quadrupole mass spectrometer was interfaced with the source chamber. The pes instrument is switched to the mass spectrometer mode simply by applying a +25 V potential to the upper element of an einzel lens to which a retard potential is applied in the pes mode. This positive potential nudges the ions generated by photoionization through the circular entrance slit of the quadrupole mass spectrometer located 2.5 cm above the upper element of the lens.

trometry, it represents a working hypothesis for the mechanism of the vacuum pyrolysis of **1**. If **3** is an intermediate in the pyrolysis reaction and the source of the CO, then **3** must be unusally thermally labile because *para*-substituted phenylketenes prepared from the corresponding diazoacetophenones by vacuum pyrolysis are stable even at laser power levels beyond 40 W.[4] The enhanced reactivity of **3** must be due largely to the methoxy group, which destabilizes the ketene and stabilizes the carbene. To define the role of **3** in the pyrolysis reaction will necessitate additional studies on its preparation and vacuum pyrolysis. Support that **5** could be an intermediate in the reaction is found in the work of Schiess and Heitzmann (17) who proposed that *ortho*-quininoid ketenes are intermediates in the pyrolytic conversion of *ortho*-alkyl-substituted aromatic acyl halides into benzocyclobutenones at 500–600°C. Whatever intermediates, **2**, **3**, **4**, and **5**, are involved in the pyrolysis of **1**, they must be very short-lived and thermally labile because the pyrolysis hot zone of our apparatus is only 2 mm in length (1, 2). This work also indicates that the preparative-scale vacuum pyrolysis of substituted 4-diazo-3-isochromanones might be a convenient alternate route to substituted benzocyclobutenones.

Micellar properties of two-headed surfactant systems: the disodium 1,2-alkanedisulfates

Ellen K. Comeau, Ellen J. Beck, Jennifer F. Caplan, Calvin V. Howley, and D. Gerrard Marangoni

Abstract: A family of two-headed surfactants, the disodium 1,2-alkanedisulfates, has been synthesized by the addition of chlorosulfonic acid to the corresponding 1,2-alkanediol. The ability of these salts to form micelles in aqueous solution is demonstrated from solution conductance measurements and counterion activity measurements of the sodium ion. The critical micelle concentrations (cmc's) and apparent degrees of counterion binding (β′ values) of these surfactants indicate that the addition of the second headgroup has a profound effect on the micelles formed by the disulfates when compared to their monosulfate analogues.

Key words: surfactants, synthesis, micellization, cmc values, counterion binding.

Résumé : On a synthétisé une famille d'agents de surface à deux têtes, les alcane-1,2-disulfates de disodium, par addition d'acide chlorosulfonique sur les alcane-1,2-diols correspondants. Faisant appel à des mesures de conductivité des solutions et d'activité du contre-ion sodium, on a démontré l'habilité de ces sels à former des micelles en solutions aqueuses. Les concentrations micellaires critiques (cmc) et les degrés apparents de liaison du contre-ion (valeurs β) de ces agents de surface indiquent que, par comparaison avec leurs analogues monosulfates, l'addition d'une deuxième tête a un effet important sur les micelles formées par les disulfates.

Mots clés : agents de surface, synthèse, micellisation, valeurs cmc, liaison de contre-ions.

[Traduit par la rédaction]

Introduction

The application of surfactant technology to a number of industrial and pharmaceutical processes is well known. Recent advances in the understanding of surfactant aggregation in concentrated systems (e.g., emulsions and microemulsions) have led to the use of surfactants in systems such as liquid developers in electronic printing, and in the production of thin insulators, sensors, and magnetic media (1). In view of the increasing and varied number of applications, it is somewhat surprising that the ionic surfactants usually used are long-chain hydrocarbons with typical head groups like sulfate, sulfonate, trimethylammonium, carboxylate, and phosphate, or nonionic surfactants (the alkyl (polyethylene oxide) family) or zwitterionic surfactants (e.g., the betaines). In fact, the bulk of the work in all areas of surfactant technology, including discussions about the driving forces for surfactant aggregation into simple micelles, has been limited to systems similar to those described above. A number of theories of micellization have been proposed (2–5) that describe reasonably the micellization of standard one-headed, one-tailed surfactants containing hydrocarbon, perfluorocarbon, and mixed hydrocarbon–fluorocarbon chains. Recently, the synthesis of novel surfactants, in particular surfactants possessing multiple or unusual headgroups, has been gaining attention in the literature (6–14). As an example, Jobe and Reinsborough (6) have studied the properties of micelles formed by disodium 4-alkyl-3-sulfonatosuccinates (i.e., cmc's, aggregation numbers, and degrees of counterion binding) as a function of the alkyl chain length, using a number of different techniques. These authors concluded that the addition of the second polar head group made it more difficult for the surfactant molecules to cluster together to form micelles; hence, these two-headed surfactants had relatively high cmc's and small aggregation numbers. The degrees of counterion binding appeared to be in the range most often quoted for single-headed surfactants of comparable chain length.

Bolaform surfactants, i.e., surfactants in which the head groups are at both ends of a nonpolar chain, represent another class of two-headed surfactants that has been examined recently in the literature (7–10). Bolaform surfactants differ from single-headed surfactants in that having the hydrophilic head group at both ends of the alkyl chain places significant restrictions on the orientation and packing of the monomers in the micelle. Bolaform surfactants have cmc's that are comparable to single-headed surfactants of half the alkyl chain length (7–10). The surface tension vs. log concentration curves for aqueous solutions of bolaform alkanedisulfates indicate that the cross-sectional area of bolaform sulfate surfactants is about twice as large as the singly charged analogue with the same alkyl chain length. Therefore, bolaform surfac-

tants are proposed to adopt a loop-like configuration at the air–water interface.

It appears that the synthesis and characterization of surfactants having two or more headgroups on adjacent carbon atoms or branched groups at different points of attachment in the alkyl chain have been little investigated in the literature (11–14). We have synthesized a family of surfactants, the disodium 1,2-alkanedisulfates, of medium to long alkyl chain length, and characterized the micelles formed by these surfactants via conductance measurements, counterion activity measurements, and spectroscopic methods. We have compared the properties of the micelles formed by these surfactants to monosulfate surfactants having the same alkyl chain length. As expected, the addition of the second sulfate group affects greatly the properties of the alkanedisulfate micelles, when compared with the well-known alkanesulfate amphiphiles.

The disodium 1,2-alkanedisulfates were synthesized by reacting the corresponding 1,2-alkanediol (Aldrich Chemical Co.) with a 10% molar excess of chlorosulfonic acid in dichloromethane or diethyl ether cooled in an ice bath. The reaction mixture was diluted with an equal volume of cold ethanol or methanol, neutralized with 6 M NaOH, and brought to room temperature and stirred for 2–4 h. The surfactants crystallized from the solvent mixture and were filtered and recrystallized from ethanol or methanol, and washed with a cold methanol–water or ethanol–water mixture. Soxhlet extraction from dichloromethane or diethyl ether was used to rid the surfactant of residual diol. The overall yield of product was about 65–70%. The purified surfactants were characterized by NMR and FT-IR spectroscopy. The presence of residual chloride and sulfate ions in the final product was checked by capillary electrophoresis (Waters Quanta model 4000).

The cmc measurements and estimates of the degree of counterion binding for the disulfate surfactants were obtained via conductance measurements and counterion emf measurements. The conductance measurements were done on a YSI model 32 conductance bridge, using a YSI dip cell (cell constant = 1.0 cm^{-1}). Counterion emf measurements were obtained with a Corning combination sodium electrode connected to a Fisher Accumet pH meter. All measurements were done in a jacketed measuring cell maintained at 25.00 ± 0.02°C with a Haake 4000 temperature bath.

In Fig. 1, we present the FT-IR spectra for the C_{12} diol and the C_{12} disulfate, respectively. The infrared spectrum of the solid diol exhibits two peaks at about 3300 cm^{-1} that are absent in the spectrum of the disulfate surfactant. As well, we note the appearance of a large band in the fingerprint region at about 1200 cm^{-1} in the FT-IR spectrum of the disulfate amphiphile. These changes in the FT-IR spectrum are consistent with those observed when 1-dodecanol is converted to sodium dodecylsulfate (SDS), which is the monosulfate counterpart of this surfactant (15). Therefore, the addition of two sulfonate groups to the starting diol was successful. The presence of residual sodium chloride and sodium sulfate in the purified amphiphiles was confirmed by capillary electrophoresis. The amount of inorganic ion impurities present in the C_{16} disulfate is reduced greatly, but not eliminated completely, when the surfactants were washed with the methanol (ethanol) – water mixtures (Fig. 2). Since the properties of the micelles formed by disulfate surfactants would be affected by the presence of residual inorganic ions, we checked for the presence of chloride and sulfate in highly purified samples of SDS by capillary electrophoresis, and found chloride and sulfate ions present at the ppm level. Given that the aggregation numbers, β′ values, and enthalpy of micellization for our very pure SDS samples were in excellent agreement with the literature values, we feel that the presence of inorganic ions at the same level of concentration will also have a negligible effect on the properties of disulfate micelles. Finally, the amount of sulfate in the final product appears to be slightly larger than the concentration of chloride ion in the final product, which may be due to the well-known hydrolysis of sodium alkanesulfates in aqueous solution (16). It is possible that the rate of hydrolysis of disulfate surfactants is increased over the hydrolysis rate of the monosulfate amphiphiles, due to increased electrostatic interactions between adjacent charged headgroups. We are currently investigating the hydrolysis of a number of sulfate and disulfate surfactants via capillary electrophoresis as a function of pH and temperature in our laboratory.

The cmc values 1,2-alkanedisulfates, obtained from the breaks in the conductance versus concentration or counterion emf vs. log ($C_{surf,t}$) curves, are presented in Table 1 and plotted in Fig. 3 for carbon chain lengths of 10–16. The apparent degrees of counterion binding, the β′ values, obtained from the ratio of slopes method from the conductance or activity measurements, are also presented in Table 1. For comparison, the cmc values of the sodium alkanesulfates are also plotted in Fig. 3 (17–21). It is quite evident that the addition of the second negatively charged headgroup has a profound effect on the cmc values of the disodium 1,2-alkanedisulfates when compared with the sodium alkanesulfates possessing the same number of carbon atoms. Therefore, in agreement with the predictions of Shinoda et al. (17), the disulfate surfactants have higher critical micelle concentrations in water, reflecting a shift in the hydrophilic–lipophilic balance. We note that when we estimate the Gibbs energy of micelle formation, $\Delta_{mic}G^\circ \approx 2RT \ln X_{cmc}$, from the simple pseudo-phase separation model (i.e., ignoring the effects of the counterion dissociation), the difference in $\Delta_{mic}G^\circ$ between the alkanesulfates and the alkanedisulfates of the same alkyl chain length is constant at about 8.3 ± 0.8 kJ/mol (Fig. 4). In fact, the slope of the plot of $\Delta_{mic}G^\circ$ vs. the carbon chain length for the two surfactant families is the same within experimental error. This indicates that the Gibbs transfer energy for the CH_2 from the aqueous phase to the micellar phase is the same for both surfactant families (ca. −3.2 kJ/mol).

The apparent degrees of counterion binding, the β′ values, for disodium alkanedisulfates are lower than those of sodium alkanesulfates of comparable chain length. It should be mentioned, however, that when comparing values of the degree of counterion binding, one should compare values determined via the same method. Therefore, the β′ values that we reported for the sodium alkanesulfates are those obtained by the ratio of slopes method using conductance measurements (18–21). We see from Table 1 that the β′ values for the alkanedisulfates range from 0.26 for 1,2-SDecDS to 0.40 for 1,2-SHDS. The decrease in the β′ values for alkanedisulfate micelles over the alkanesulfate micelles indicates a significant reduction of the surface charge density of the micelle formed by the two-headed surfactants. We note, however, that the measurement of the β′ value via the ratio of slopes method assumes that the molar conductivity of the micelle is a simple function of the

number of dissociated headgroups. Since micelles are compact, highly charged structures, the fraction of charge carried by the two-headed surfactant micelle may be significant, leading to low estimates of the degree of counterion binding. If the counterion binding estimates obtained in this fashion are indeed reasonable, the small β′ values for the disulfate surfactants compared to the monosulfate surfactants suggests that these micelles have much smaller aggregation numbers than the alkanesulfate surfactants of the same chain length. The surface charge density of the disulfate surfactants increases as the surfactant chain length increases, indicating that the aggregation number of disulfate micelles will increase with increasing chain length. The increase in the β′ values for the disulfate micelles with increasing surfactant chain length is comparable to the increase in the apparent counterion binding values observed for the sodium alkanesulfates as a function of the length of the amphiphile chain (Table 1).

In conclusion, cmc's and β′ values for a series of disulfated 1,2-alkanediols indicate that the addition of the second headgroup significantly changes the properties of the micelles formed by the two-headed surfactants, such as the cmc values and the β′ values. We expect that, due to the shift in the hydrophilic–lipophilic balance, other important properties of the surfactant and the micelles will be altered (e.g., surface-tension lowering (12), solubilization of co-surfactants, and aggregation numbers). Kooreman and Engberts (11) have demonstrated that two-headed sulfate surfactants are extremely stable towards precipitation by hard water ions (e.g., Ca^{2+}). All these properties will be the subject of future publications.

Non-equilibrium particle morphology in dispersion-polymerized polystyrene particles[1]

Anthony J. Paine and Richard R. Shivers

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Abstract: The interior particle morphology of dispersion-polymerized polystyrene particles was investigated by freeze fracture TEM (FFTEM) in order to compare the morphology of particles formed under two extreme mechanistic conditions: (*a*) particle growth by scavenging of dead polymer chains formed in solution (which gives rise to large particles of 5–10 μm) and (*b*) particle growth by oligomeric radical capture and polymerization inside the particle (giving rise to small particles of 1 μm or less). Although not generally recognized in the literature, ascribing mechanistic significance to an observed morphology requires a demonstration that the morphology is of the non-equilibrium type, i.e., the morphology depends upon how the particle was formed. An equilibrium morphology, by definition, must be independent of the particle formation route, and therefore carries no mechanistic information. In this case, large PS particles of 6.5 μm were found to have a nodular morphology that was unchanged on heating well above T_g, indicating an equilibrium structure (the nodularity of amorphous polymers is briefly rationalized by comparison with literature results over the past 20 years). On the other hand, small PS particles of 1.3 μm had a pronounced radial structure that could be converted into the nodular morphology by the same heat treatment, or by dissolving and precipitating from a suitable solvent combination. This means that the small particles have a non-equilibrium morphology, from which we may attempt to draw mechanistic inferences consistent with the suspected growth mechanism.

Key words: dispersion-polymerized polystyrene, non-equilibrium polystyrene particle morphology, freeze fracture transmission electron microscopy.

Résumé : On a étudié la morphologie de la particule intérieure d'une dispersion de particules de polystyrène (PS) par la technique de FFTEM dans le but de comparer la morphologie des particules formées sous deux conditions mécanistiques extrêmes : (*a*) croissance des particules par piégeage des chaînes mortes de polymère formées en solution (qui donnent lieu à de grosses particules de 5–10 μm) et (*b*) croissance des particules par une capture d'un radical oligomérique et une polymérisation à l'intérieur de la particule (donnant lieu à de petites particules de 1 μm ou moins). Même si ce fait n'est généralement pas reconnu dans la littérature, l'attribution d'une signification mécanistique à une morphologie observée nécessite une démonstration que la morphologie est d'un type non équilibré, c'est-à-dire que la morphologie dépend de la façon dont la particule s'est formée. Par définition, une morphologie d'équilibre doit être indépendante de la voie de formation de la particule; elle n'a donc aucune signification mécanistique. Dans ce cas, on a trouvé que de grosses particules de PS de 6,5 μm possèdent une morphologie nodulaire qui ne change pas par chauffage à des températures bien supérieures à la T_g; ceci suggère l'existence d'une structure en équilibre (on rationalise brièvement le caractère nodulaire de polymères amorphes par comparaison avec des résultats rapportés dans la littérature au cours des 20 dernières années). Par ailleurs, les petites particules de PS de 1,3 μm possèdent une structure radiale prononcée qui peut être transformée en morphologie nodulaire par le même traitement par la chaleur ou par dissolution et reprécipitation à partir d'une combinaison appropriée de solvants. Ces résultats signifient que les petites particules possèdent une morphologie qui n'est pas équilibrée et on peut essayer d'en tirer des conclusions mécanistiques en accord avec le mécanisme supposé de croissance.

Mots clés : polymérisation d'une dispersion de particules de polystyrène, morphologie d'un type non équilibré, FFTEM.

Introduction

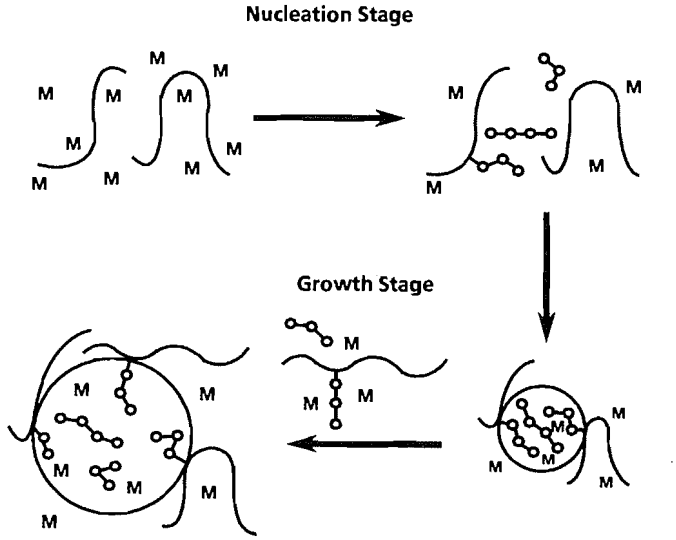
Dispersion polymerization of styrene in polar solvents differs from other types of particle-forming polymerizations, such as suspension or emulsion polymerization. The initial reaction mixture, comprising styrene monomer, steric stabilizer polymer, initiator, and alcohol, is homogeneous. Typical steric stabilizers are alcohol-soluble homopolymers such as hydroxypropyl cellulose (HPC), poly(acrylic acid) (PAA), or poly(*N*-vinylpyrrolidone) (PVP), which graft to the polystyrene as it is formed, although block copolymers and macromers can also be used. Since the initial mixture is homogeneous, the polymerization begins as a solution polymerization. After a short period of time, the homogeneous solution becomes cloudy as the particles nucleate and subsequently grow. Under favourable circumstances, the final particles are monodisperse, in the size range of 1–15 μm.

These reactions have been investigated extensively within Xerox by Lok, Hair, Ober, Paine, and co-workers (1–7), and in the Lehigh University laboratories of Vanderhoff and El-Aasser (8, 9). Figure 1 summarizes the qualitative view of the mechanism of dispersion polymerization, as seen by Ober and Lok (1, 2). When polymerization is initiated, chains of homopolystyrene together with a small amount of graft are formed. The homopolymer is insoluble and precipitates from solution while the graft goes to the particle surface to develop a steric stabilizer layer. Once the particles are formed, the monomer partitions between the particle and continuous phases, and polymerization takes place in both phases, causing the particles to grow. At the end of the reaction the isolated and washed particles have grafted steric stabilizer exclusively on the particle surface. The evidence for this includes transmission electron microscopy (TEM) observation (4), fluorescence quenching studies (3), and X-ray photoelectron spectroscopy (XPS) (7).

An important mechanistic feature is that the balance between the amount of polymerization occurring inside the particles vs. that occurring in the continuous phase depends on the particle size (5, 6). The low-volume fraction of solids after nucleation tends to favour extensive initiation in the continuous phase, rather than in the nuclei. From a consideration of the diffusion constants and chemical kinetics, it can be shown that when the final particle size is large (on the order of 5–10 μm), there are relatively fewer particles, and polymer is primarily formed by termination in solution and accretion of dead polymer onto the nuclei. As a result, the observed molecular weights are low and comparable to those from solution polymerization. On the other hand, when the final particle size is small (on the order of 1 μm), there are many more growing nuclei, and they rapidly scavenge growing oligomer from the continuous phase before it can terminate, and this leads to polymerization inside the particle, with gel-effect-induced increases in the molecular weight. The mechanism for small-particle growth is very similar to that for emulsion polymerization, and leads to comparably high molecular weights.

We became interested in the morphology of dispersion-polymerized particles as a consequence of some earlier work done by one of us with Mitchell Winnik and co-workers on the nonaqueous dispersion polymerization of methyl methacrylate in hydrocarbon solvents (10). Several features of their system were dramatically different from ours. For example, fluorescence quenching studies led them to believe the particle

Fig. 1. Schematic of the mechanism of dispersion polymerization (from Ober and Lok (1, 2)).



structure was of an interpenetrating network of stabilizer throughout the core, while similar measurements (3), together with TEM sectioning and staining results (4), indicated that the stabilizer on the particles that are the subject of this paper was almost exclusively on the surface. The prior authors applied freeze fracture TEM (FFTEM) to several colloidal particles and concluded that the observed structures implied something about the mechanisms of particle nucleation and growth (10, 11). Since our mechanistic study suggested small and large particles grew by different mechanisms, we were anxious to have a look at the freeze fracture morphologies of the polystyrene particles.

Although the explicit objective of the work with Winnik in ref. 10 was to use FFTEM "to obtain new information on the subjects of primary particle formation and monomer–polymer particle growth mechanisms," we were concerned about the morphology–mechanism connection. Although not recognized in that paper, or in the literature in general, ascribing mechanistic significance to an observed morphology requires a demonstration that the morphology is of the non-equilibrium type, i.e., that the morphology depends upon how the particle was formed. The prior work assumed the morphology was non-equilibrium. However, if their observed morphologies were of the equilibrium type (by definition, independent of the particle formation route), they could not possibly carry any mechanistic information.

Thus, the objectives of our study were twofold: (*i*) to compare the morphologies of dispersion-polymerized PS particles formed under the mechanistic extremes; and (*ii*) to critically evaluate whether the observed morphologies could have mechanistic significance.

Experimental section

Particle synthesis and characterization

The details of PVP-stabilized polystyrene particle synthesis were reported earlier (7, 12). Briefly, styrene, AIBN, PVP (mol. wt. 40 000), and optional costabilizer (Triton N-57 (nonylphenol poly(ethylene oxide) from Rohm and Haas) or Aerosol OT-100 (AOT; dioctyl sodium sulfosuccinate from

Table 1. Summary of the synthesis of large and small polystyrene particles by dispersion polymerization.[a]

	Large particles (M137)	Small particles (M87TP)
Synthetic conditions		
PVP (g)	31.3	1.25
Costabilizer (wt/g)	Triton N-57 (31.3)	AOT (0.340)
Solvent (vol/mL)	EtOH (1500.0)	EtOH (56.0)/H_2O (14.0)
Styrene (mL)	500.0	10.0
AIBN (wt% to monomer)	2%	1%
M_w (MWD)	53 500 (3.27)	391 000 (5.04)
Residual sytrene (ppm)	7300	430
Particle size (μm (GSD))	6.35 (1.03)	1.17 (1.16)
Heated sample no.	RS-6	RS-4
Particle size (μm (GSD))	6.3 (1.57)	1.4 (1.41)
Mass fraction original particles	60%	80%

[a]Particle size measurement (volume d_{50} and GSD $\equiv (d_{84}/d_{16})^{1/2}$) by Coulter Multisizer.

American Cyanamid)) were mixed in alcohol, then polymerized at 70°C for 24 h. The resulting latex particles were washed several times with ethanol, then with water, and were freeze-dried. Synthetic conditions, particle size, and molecular weight data are reported in Table 1. ^{13}C NMR indicated that the polymer was atactic in both cases (multiple peaks for the backbone CH_2 groups between 40 and 50 ppm).

Freeze fracture TEM procedure

The details of this procedure were published before in the work with Winnik and co-workers (10). Briefly, particles were suspended at approximately 1% loading in 30% glycerol – 0.1 M sodium cacodylate – 0.01% Triton X-100. A drop of this suspension was frozen in Freon-22 in liquid N_2, then fractured under vacuum at 77 K to give free break through the sample. The surface of the free break was coated with 1–2 nm Pt at a 45° shadowing angle; then 10–30 nm C at 90°. The replica-coated sample was thawed, rinsed in de-ionized water, then soaked 48 h in $CHCl_3$ to dissolve the polystyrene. The replicas were placed on copper TEM grids and examined with a Philips 201 EM. In these micrographs, the white areas correspond to shadows of rough features on the fracture surface that did not receive Pt. Approximately 50–100 micrographs were taken of each sample.

Heating experiment

The particles were suspended at 100 mg loading in 0.5 mL glycerol in a 10 mL test tube. The tubes were capped and placed into an oil bath at 245 ± 5°C for 2 min, then removed and allowed to cool slowly in air at room temperature. The samples were checked for particle coalescence by remeasuring particle size and GSD. The results posted in Table 1 show that fewer than half the original particles coalesced during this procedure.

Precipitation experiment

The procedure was similar to that already published (3, 4). The precipitation of these small particles was difficult because of the high ratio of the molecular weight of the polystyrene to the PVP stabilizer — about 10×, while the process works best at 0.3–3×. A solution of M87TP particles (1.0 g) in dioxane (20 mL) was stirred 3 h, then precipitated with MeOH (250 mL) added at 200 mL min^{-1} with a peristaltic pump. A large lump of coagulum was obtained with only some latex. The experiment was repeated with rapid MeOH addition with a squirt bottle with similar results. A third experiment (0.51 g in 20 mL THF precipitated with 250 mL MeOH added at 10 mL min^{-1}) eliminated the coagulum but gave a high yield of large flocs. The latexes from the three experiments were combined, filtered through a 74 μm filter, washed with MeOH (2 × 50 mL), then with water (2 × 50 mL), and freeze-dried to obtain precipitated particles (217 mg; 9% yield) with volume median diameter 4.6 μm and GSD = 2.7.

Results

The background to FFTEM and the artifact potential from plastic deformation are discussed in depth in the earlier papers with Winnik (10, 11), as well as basic textbooks (13–15) or review articles (16). Briefly, one observes brittle fracture through the centre of the particle, in addition to protrusions and extrusions caused by fractures at the particle surface – matrix interface. For the purposes of this discussion, we selected FFTEM micrographs where the fractures went through the interior of the particle. These were in the vast majority, and permit the discussion to focus on the interior morphology. Plastic deformation artifacts were largely absent.

This investigation focussed on two types of dispersion-polymerized particles: 6.35 μm, "large" particles of low molecular weight typical of considerable solution polymerization and accretion of dead polymer (M 137 in Table 1); and 1.17 μm, "small" particles of high molecular weight typical of extensive radical capture and gel-effect polymerization similar to emulsion polymerization (M87TP in Table 1). Figure 2 shows a typical micrograph from the fractured surface of the small particles. It is remarkably similar to Winnik's earlier samples of poly(methyl methacrylate) (PMMA) (10), and shows the same radial morphology, almost spherulitic. The shadowing shows a highly irregular surface, with some features as much as 100–600 nm high. The thin lines apparently radiating from the centre are typically 200 nm long, but only

Fig. 2. Typical FFTEM of small particles showing the radial structure.

7–8 nm wide, and appear to be made up of little dots. It is not clear whether the dots represent real topology or are a decoration artifact of the platinum coating. However, it may be noteworthy that the width of the lines is comparable to the expected radius of gyration, around 7 nm for polymer of 400 000 molecular weight.

The centers of the small particles appear different from the exterior or shell portion, and appear nodular, like the bulk of the large particles (Fig. 3). The fracture of the larger particles reveals a much different morphology, which appears isotropically nodular. The size of these highly irregular nodules is around 20–60 nm, about 10–25× the radius of gyration of polystyrene of comparable molecular weight, and their size is relatively constant throughout the particles. Thus, in this case, the nodular dimensions do not reflect anticipated polymer dimensions in the amorphous particle. At the particle surface there is only subtle evidence for an intermittent 20–50 nm thick layer where the ruggedness dissipates. Presumably this is the surface graft region, though the visualization of the layer is far less effective than in our prior work where the particles were embedded in epoxy, sectioned, and then stained for TEM to reveal a well-defined surface layer of grafted stabilizer (4).

Thus, comparing Figs. 2 and 3, there is a major difference apparent in the interior morphology of the small and large particles. Both particles were composed of amorphous atactic polystyrene, though it might seem that either size or molecular

weight differences could be the main driver behind the morphological differences.

To evaluate the size and molecular weight effects, and to detect if either or both structures were equilibrium morphologies, the particles were heated well above the glass transition temperature T_g (~100°C) and close to the melting point T_m (~240°C) of polystyrene (17). By using a glycerol dispersion, conditions were found to minimize the amount of inter-particle coalescence, while maximizing the opportunity to rearrange into the lowest energy interior morphology.

As Fig. 4 shows, the large particles were mostly unaffected after heating. The nodule size appears to be about the same, or possibly larger, about 30–100 nm, suggesting that this is an equilibrium structure.

On the other hand, the small particles changed dramatically after heating, as shown in Fig. 5. Their radial structure was converted into the nodular form common for the large particles with a nodule size of about 30–100 nm, very similar to that of the larger particles with molecular weight seven times lower. The particle size is still ~1 μm, yet the morphology appears radically different from that of the original particles, so the morphological differences in these photographs are not a size-dependent artifact. Thus, the heating experiment suggests that (*i*) the nodular structure is thermodynamically preferred, and (*ii*) the small particles were initially formed in a non-equilibrium morphology somehow induced by their synthetic conditions.

It is also interesting to consider the results of precipitation on the non-equilibrium morphology. In earlier work it was noted that dispersion-polymerized particles may be dissolved in a solvent common for the polystyrene and surface graft, and then precipitated into a solvent that is poor for the polystyrene but good for the soluble chains on the graft, to produce new latex particles of very wide size distribution (3, 4, 7). Prior TEM and fluorescence-quenching experiments had suggested the surface stabilizer morphologies of native and precipitated particles were identical. In this particular case, the precipitation of the small particles was difficult because of the high ratio of MW_{PS}/MW_{PVP} (about 10, while the process works best at 0.3–3), with the result that coagulum accounted for 90% of the product. Nevertheless, the precipitated particles from three experiments were combined and subjected to FFTEM to compare the morphology.

Again, Fig. 6 shows that the primary morphology of the precipitated particles was of the nodular type, although some of the very tiny particles may be radial. This may hint at either an artifact or a size dependence to morphology at very small particle sizes. Nevertheless, it is certainly clear that 1 μm particles that were radial in their native state can be precipitated into the nodular morphology, and they account for most of the particulate mass after precipitation.

Discussion

The results show that there appear to be two particle morphologies in these dispersion-polymerized PS particles: nodular and radial. Small particles are formed in the non-equilibrium radial structure as synthesized, but this can be converted into the nodular structure, either by heating or precipitating the particles. Since the large particles have the same type of structure before and after heating, it follows that the nodular structure is the equilibrium structure. We now consider the consequences of the nodular and the radial structures.

Fig. 4. Typical FFTEM of large particles after heating. Note the retention of nodular structure.

Nodular morphology of amorphous polystyrene

Since the nodular structure of the large particles is the equilibrium structure, we can garner no mechanistic information about the particle formation from it. In particular, it says nothing about any accretion mechanism for dead polymer, and nothing about the size of the species accreting onto the particle during its growth. For example, both Winnik (10) and Bassett (18) interpreted the presence of nodules, or a raspberry structure, to an accretion mechanism in particle formation. However, without separate evidence that the morphology was a non-equilibrium structure, their mechanistic inferences must be discounted. It is interesting that there have been a number of reports about nodular structures in amorphous polymers over the past 20 years, though the evidence for nodules in

Fig. 5. Typical FFTEM of small particles after heating. Contrast with Fig. 2 (radial structure).

amorphous polystyrene has not been particularly strong (16, 19–23). The nodules were certainly evident in similar sectioned particles examined by regular TEM (4), where interior features on the order of 50–100 nm seemed to orient in lines parallel to the sectioning knife edge.

In traditional polymer morphology texts, most EM work on polymer fracture is generally at much lower resolution than that shown here (15). Even so, some of the published micrographs hint at a smaller level of structure than is generally discussed.

During the 1970s and early 1980s there was some controversy in the literature over microstructure in amorphous polymers, especially atactic polystyrene (23). Quenching of amorphous polymers (primarily poly(ethylene terephthalate) (PET), but also PS and poly(vinyl chloride)–solvent gels) gave rise to nodular structures of 4–13 nm in diameter and a diffuse electron diffraction ring, indicative of short-range order on this scale. Geil suggested that features less than 5 nm could be instrument artifacts (phase contrast effects that can arise when the replica is slightly out of focus) (16), but features larger than 8 nm were likely real. This caused Geil to conclude that Yeh's original observation (19) about atactic PS with 3.5 nm nodules could be ruled out. Irrespective of that controversy, the nodules observed here are in the 20–100 nm range, much too large to be phase contrast effects.

The nodules arise during either polymerization or cooling because polymer solidification at the glass transition temperature is not a true equilibrium process, unless the cooling rate is infinitely slow. Discontinuous changes in entropy and entropy production during solidification can give rise to dissipative structures like the nodules seen in these micrographs (24, 25). Thus, the nodule structure represents the non-equilibrium structures formed during the solidification process, not the polymerization process. Other symptoms of microstructure in

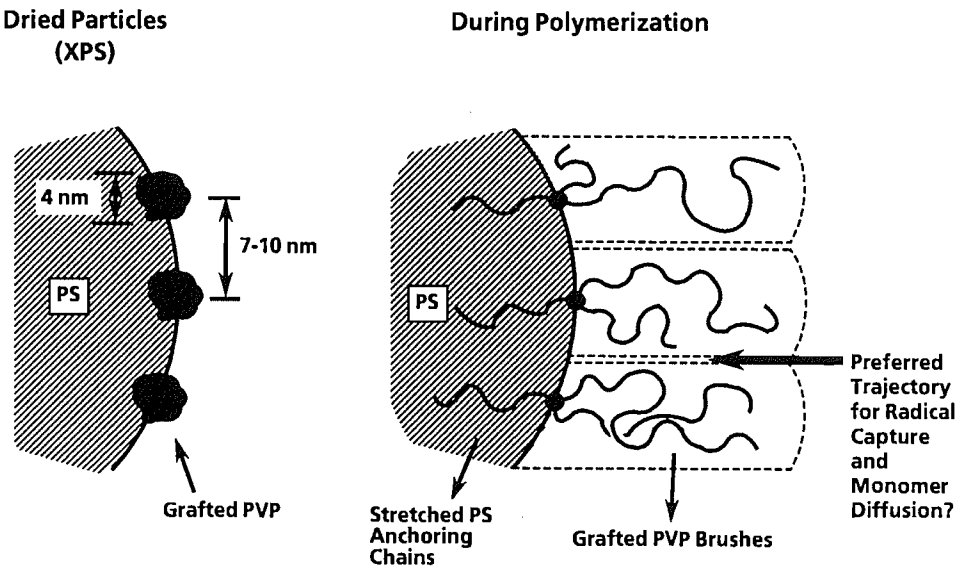
Fig. 7. Hypothetical cause of radial morphology in small PS particles.



amorphous polymers include the well-known densification with time below T_g (26), which presumably reflects the gradual elimination of high-energy boundaries within the sample.

The effect of quenching rate on nodule size has been examined in the literature, but remains confusing. In the case of PET the nodules disappear at high quench rates (23). On the other hand, annealed PS had very fine, nearly invisible nodules, while quenched PS had larger nodules (20 nm) similar to those shown here (27). Correlation lengths of 50–70 nm were obtained by SAXS. In the present dispersion polymerization system the quench during synthesis is expected to occur slowly as the particles gradually consume plasticizing monomer. In the heating experiment, the quench was relatively slow: the tubes were allowed to cool undisturbed in air. Likewise, in the precipitation experiment, there may be sufficient plasticization by dioxane to permit a relatively slow quench.

Radial morphology of dispersion-polymerized polystyrene

To confirm the freeze fracture morphologies, it is quite challenging to find independent corroborative evidence for the morphological change observed in the small particles. Among techniques that might be applied are differential scanning calorimetry (DSC), rheology, NMR, small-angle X-ray scattering, neutron scattering, and accurate density measurement. By definition, the non-equilibrium structure should be a higher energy state than the equilibrium structure,so one might expect some exotherm corresponding to the rearrangement. However, if the rearrangement occurs at or above T_g, or even worse, above T_m, it may not be possible to measure a significant difference between first and second sweeps of the same sample.

The rheology of compressed disks of the particles showed no significant difference between the first and second sweeps, except around the T_g, and that might be due to the plasticization by residual monomer. Differences in morphology might express themselves through the density, and NMR could be a sensitive tool to measure this. However, significant effects would only be observed if a large fraction of the chains experience a local change upon going from one morphology to another. If the changes are at grain boundaries on the 20–100 nm scale, very little measurable difference is expected.

Small-angle X-ray scattering (21) and neutron scattering (28, 29) are possible probes for changes in the size of grains within the amorphous structure. Recently, Gilbert and coworkers carried out small-angle neutron scattering experiments to determine the extent of monomer/polymer spatial inhomogeneities in very small 100 nm emulsion-polymerized polystyrene latex particles (28). They found that surface-anchoring effects of the initiator sulfate groups caused the particles to adopt a core-shell morphology when the radius of gyration of the polymer was less than the particle radius.

It seems likely that during dispersion polymerization, the overall instantaneous monomer content inside the particles is relatively low (despite good thermodynamic driving force from water in the solvent), like the situation in emulsion polymerization. The gel effect suggests the particle interiors are quite viscous. With the dispersion-polymerized particles being very much larger than emulsion-polymerized particles, it is highly probable that the monomer is radially distributed with higher concentrations near the particle surface, where it can be polymerized by incoming captured oligomeric radicals.

In Fig. 7 we propose a possible relationship between the radial morphology and the mechanism of particle growth by radical capture. Previous surface analysis of these same particles in the dry state by X-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass spectrometry (TOF-SIMS) has led to the picture on the left-hand side of Fig. 7 (7). It appears that the collapsed but grafted PVP stabilizer chains occur in surface blobs of approximately 4 nm size, spaced some 7–10 nm apart on the dry particle surface. From this picture, we can infer that during polymerization the grafted chains were acting as stabilizers: random brushes in the compatible aqueous alcohol solvent. Since the radius of gyration of the PVP chains in methanol is about 14 nm (6), they are too close to form mushrooms, and likely prefer brush coils.

We hypothesize that perhaps the brush morphology of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

stabilizer chains in solution results in a preference for radical capture and monomer diffusion toward the particle in the channels between brushes, and away from anchor points. Such a preference might lead to preferred polymerization between anchor points. Since the particles grow with the constant reorganization of the graft to remain on the particle surface, it is also possible that the anchoring chains could become stretched as the growing particle boundary moves outward. Such stretching is more likely when the anchoring chains are of higher molecular weight (i.e., 400 K in the small particles vs. 54 K in the large) and have more entanglements. Perhaps these factors lead to a net orientation of the growing polymer perpendicular to the surface as is ultimately revealed in the FFTEM micrographs in Fig. 2.

It is interesting that the apparent width of the radial structures in Fig. 2 (7 nm) is about the same as the anchor point separation in Fig. 7, and about the same as the radius of gyration of PS of the high molecular weight. This hypothesis is also consistent with the observation of radial structures in emulsion-polymerized PMMA particles (10). In that case the anchoring points are the initiator sulfate groups, which also want to continually reorient to remain on the particle surface during growth. Since the anchoring chains in emulsion polymerization are also of high molecular weight, they may also stretch during growth, rather than remaining as random coils.

At the present time, we view this hypothesis as tentative. Further testing is not a trivial problem. It is not clear how X-ray or neutron scattering could resolve nodular from radial structures. Perhaps the most productive avenue would be to examine the FFTEM morphology of emulsion-polymerized particles from seeded reactions with different molecular weights controlled by chain transfer agent. Using seeded polymerizations should eliminate particle size effects, and the constant solvent (water) leaves only the molecular weight of the anchoring groups as the morphological variable.

Conclusions

The interior morphology of these dispersion-polymerized particles is fascinating, but there are few comparative data available on polymers made by other routes. It seems clear that the large particles are formed in an equilibrium nodular morphology, so the morphology cannot be used to infer anything about mechanism. Thus, there is less mechanistic information available from FFTEM than may have seemed the case to previous investigators (10, 11). On the other hand, the small dispersion-polymerized particles were formed in a radial non-equilibrium morphology that could be converted into the nodular morphology by either heating or precipitation. We have crudely speculated that this morphology might arise from the presence of anchored stabilizer chains on the particle surface that may serve to direct incoming monomer and oligomeric radicals into microscopically oriented channels. A similar mechanism may also prevail in emulsion polymerization. Thus, this work helps to clarify the mechanistic inferences available from FFTEM, and poses some challenging questions yet to be investigated.

Syntheses and interfacial characterization of graft copolymers from styrene and 2-hydroxyethyl methacrylate that comprise either trunks or branches

Hidekazu Yoshida, Shinichi Itsuno, and Koichi Ito

Abstract: Polystyrene (PS) and poly(2-hydroxyethyl methacrylate) (PHEMA) macromonomers with either *p*-vinylbenzyl or methacrylate end groups were prepared by living anionic polymerizations of styrene and 2-(trimethylsilyloxy)ethyl methacrylate, respectively, followed by appropriate end-capping. They were radically copolymerized with 2-hydroxyethyl methacrylate and styrene, respectively, to afford PS-*g*-PHEMA and PHEMA-*g*-PS, having PS trunks with PHEMA branches or the reverse architecture. ^{1}H NMR spectra of the graft copolymers in deuterated methanol showed their micelle formation with PS and PHEMA chains as the core and the shell, respectively. In chloroform the reverse micelles were observed. Contact angle measurements of water on the graft copolymer films revealed that PS chains were generally dominant on the free surface. The films either cast from methanol or after immersion into water, however, were apparently wettable, indicating dominant PHEMA chains on the surface.

Key words: styrene, 2-hydroxyethyl methacrylate, graft copolymer, micelle formation, wettability.

Résumé : On a préparé des macromonomères de polystyrène (PS) et de poly(méthacrylate de 2-hydroxyéthyle) (PHEMA) portant des groupes terminaux *p*-vinylbenzyle ou méthacrylate en procédant à des polymérisations anioniques vivantes respectivement du styrène et du méthacrylate de 2-(triméthylsilyoxy)éthyle, suivies d'une addition appropriée d'un groupe terminal. On les a ensuite copolymérisés d'une façon radicalaire avec du méthacrylate de 2-hydroxyéthyle et du styrène pour obtenir des PS-*g*-PHEMA et PHEMA-*g*-PS respectivement qui possèdent soit des troncs de PS avec des branches de PHEMA soit les architectures inverses. Les spectres RMN du ^{1}H des copolymères greffés déterminés dans le méthanol deutéré présentent des formations de micelles dans lesquelles les chaînes de PS forment le coeur et celles de PHEMA la périphérie. Dans le chloroforme, on observe les micelles inverses. Des mesures des angles de contact de l'eau avec les films de copolymères greffés révèlent que les chaînes de PS sont généralement dominantes sur la surface libre. Toutefois, les films obtenus à partir du méthanol, ou immédiatement après immersion dans l'eau, peuvent apparemment être mouillés; ceci indique que les chaînes PHEMA dominent à la surface.

Mots clés : styrène, méthacrylate de 2-hydroxyméthyle, copolymère greffé, formation de micelle, mouillage.

Introduction

Current progress in macromonomer techniques has made it possible to prepare a variety of well-defined graft copolymers with relatively easy access (1). The technique is based on copolymerization between a given trunk-forming monomer (M_1) and a known, branch-forming macromonomer (M_2) as illustrated in Fig. 1. The trunk/branch composition can be essentially controlled by the feed ratio and the monomer reactivity ratio of M_1 under the usually employed condition of very high molar ratio of M_1 to M_2, i.e., $[M_1]/[M_2] \gg 1$, since the molecular weight of M_2 is usually very high compared with that of M_1. Thus the conventional copolymerization equation (Mayo–Lewis equation) can be approximated as follows.

$$[1] \quad \frac{d[M_1]}{d[M_2]} = \frac{1 + r_1[M_1]/[M_2]}{1 + r_2[M_2]/[M_1]} \cong r_1 \frac{[M_1]}{[M_2]}$$

where $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$ are the monomer reactivity ratios of M_1 and M_2, respectively, and k_{ij} is the propagation rate constant of a propagating chain ending in M_i reacting with a monomer M_j, with i and $j = 1$ or 2.

A number of macromonomers and therefore a much greater number of graft copolymers have been synthesized. Among others, amphiphilic graft copolymers (2) have been our inter-

est because the hydrophilic and hydrophobic chains incorporated into either the trunk or the branch will segregate into the respective microdomains via microphase separation to exert interesting surface- or interface-active behavior. Previously, we reported a graft copolymer, PHEMA-*g*-PS, with poly(2-hydroxyethyl methacrylate) (PHEMA) as the trunk and polystyrene (PS) as the branch, prepared by copolymerization of 2-hydroxyethyl methacrylate (HEMA) and the PS macromonomer with a methacrylate end group (3). The same graft copolymer has been evaluated as a blood-compatible, self-reinforced hydrogel by Yamashita et al. (4). The corresponding block copolymer, PS-*b*-PHEMA, has been established as an excellent antithrombogenic material, most probably as a result of its microphase-separated surface structure (5). Related poly(α-methylstyrene)-*b*-PHEMA have been prepared and examined in terms of the surface properties (6).

Therefore we thought it fundamentally interesting and important to prepare PS-*g*-PHEMA, with PS as the trunk and PHEMA as the branch, in addition to PHEMA-*g*-PS, and to compare their interfacial properties as a function of the composition and the architecture. This paper describes in detail the syntheses of the corresponding PS and PHEMA macromonomers by use of the living anionic polymerization technique as given in Fig. 2, their radical copolymerization reactivities in the preparation of graft copolymers, and micelle formation and wettability of the graft copolymers obtained

Experimental

Materials

All reagents and solvents used for anionic polymerization and end-capping were purified by conventional procedures and finally distilled into ampoules fitted with breakable seals under a vacuum line (10^{-5} Torr; 1 Torr = 133.3 Pa). Styrene, ethylene oxide (EO), methacryloyl chloride (MAC), HEMA, 2,2′-azobisisobutyronitrile (AINBN), benzene, *p*-vinylbenzyl chloride (VBC), tetrahydrofuran (THF), and dimethylformamide (DMF) were purified as described previously (3, 7).

2-(Trimethylsilyloxy)ethyl methacrylate (TMSEMA) was prepared from HEMA and hexamethyldisilazane (8), and finally distilled from a yellow-colored solution containing triethylaluminum before polymerization. *p*-Vinylbenzyl bromide (VBB) was prepared from VBC by reacting with sodium bromide at 60°C for 2 days in benzene and water with tetrabutylammonium bromide as a phase transfer catalyst. Conversion of Cl to Br was 80%, as measured by ^{1}H NMR. The mixture was distilled over calcium hydride into an ampoule. 1,1-Diphenyl-3-methylpentyllithium (DPHLi) was prepared from *s*-butyllithium with 1,1-diphenylethylene in THF at room temperature. Lithium chloride (99.99%, Aldrich) was dried under vacuum at 130°C for 12 h and used as solution in THF.

Preparation of PS macromonomers

PS-VB (Fig. 2) was prepared by the method reported by Asami et al. (9). Living anionic polymerization of styrene with *s*-butyllithium (*s*BuLi) was conducted in benzene at 0°C for 1 h. The resulting red solution was diluted with more than 30 vol.% THF and then terminated by dropping into a THF solution containing excess VBC at 0°C and stirred for 24 h. The macromonomer was isolated by precipitation into methanol, purified by repeated reprecipitations from benzene into methanol, and freeze-dried from benzene. PS-MA was prepared by end-capping with EO, followed by termination with MAC, according to the procedure described before (3), and purified similarly.

The end-group functionality (*f*) of the PS macromonomers was determined as the extent of their incorporation in copolymerization with a large excess of methyl methacrylate (MMA), as evaluated by gel permeation chromatography (GPC) with a UV detector (10). Copolymerization was conducted with 0.1 g of each macromonomer with 1 g of MMA in THF with AIBN (1 wt.%) at 60°C for 3 days.

Preparation of PHEMA macromonomers

Living anionic polymerization of TMSEMA was conducted, as described by Hirao et al. (8), with DPHLi as an initiator in THF, containing excess lithium chloride in some cases, at −78 to −90°C for 30 min. PHEMA-VB was prepared by adding excess VBB–THF solution at −78°C, followed by stirring

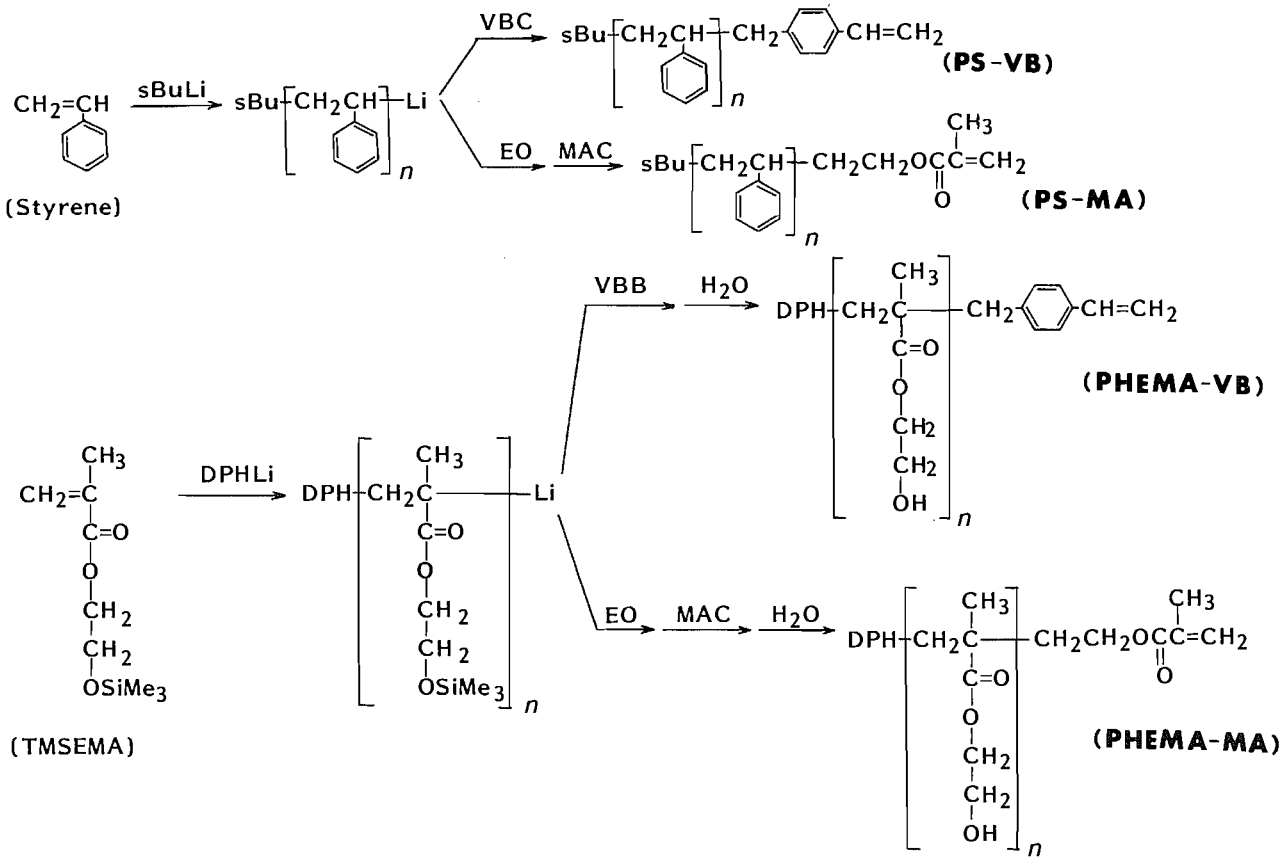
Fig. 2. Preparation of PS and PHEMA macromonomers. DPH = 1,1-diphenyl-3-methylpentyl (diphenylhexyl), VBC = *p*-vinylbenzyl chloride, VBB = *p*-vinylbenzyl bromide, EO = ethylene oxide, MAC = methacryloyl chloride.



for 24 h. After addition of a few drops of 1.2 N aqueous HCl, the solution was evaporated to about one third volume and poured into water to precipitate PHEMA-VB. The macromonomer was reprecipitated three times from methanol into diethyl ether, and dried in vacuo.

PHEMA-MA was prepared by end-capping with EO and termination with MAC, as follows. Excess EO was added at −78°C to the living poly-TMSEMA solution obtained as above, the temperature was allowed to rise very slowly to 0°C over about 10 h, and then excess MAC–THF solution was added and stirred for 24 h at 0°C. The macromonomer was similarly isolated and purified. PHEMA macromonomers were partly benzoylated (8) to be soluble in THF as the eluent for characterization by GPC.

Copolymerization of macromonomers to prepare graft copolymers

Macromonomer and comonomer were weighed into an ampoule with AIBN (2 wt.% to the total monomer) and DMF (20 mL), and sealed after three to four cycles of freeze–thaw under liquid nitrogen. Copolymerization was carried out at 60°C. For evaluation of monomer reactivity ratios (r_1), the copolymerization was stopped before 10% conversion. Usually 5% conversion was attained in 1–3 h. The products were precipitated either into diethyl ether in the case of PS macromonomer or into methanol in the case of PHEMA macromonomer to remove the unreacted monomers.

For preparative isolation of graft copolymers, the copolymerization was conducted for a prolonged time (about 4 days) to 70–80% conversation. The resulting mixture was poured into water. The precipitated polymers were dried in vacuo, dissolved in THF, and repeatedly reprecipitated into methanol–hexane (7/3 v/v) to remove PHEMA macromonomer or homopolymer, and then into diethyl ether – hexane (3/1 v/v) to remove PS macromonomer or homopolymer. The purification was monitored by GPC and thin-layer chromatography (TLC).

Characterization methods

^{1}H NMR spectra were recorded on a JEOL 270 MHz spectrometer (JNM-GX-270), usually in eight scans with a pulse delay time of 30 s. GPC was carried out at 40°C on a JASCO Trirotar III equipped with RI (Shodex SE-11) or UV detector (Uvidec-100-III at 254 nm) with appropriate combination of columns (Shodex A-802 ~ 805). THF was used as an eluent at a flow rate of 1 mL/s and calibration was made with standard polystyrenes. TLC was taken on a silica gel plate with ethyl acetate and methanol as the eluents, which develop selectively the homopolymers, PS and PHEMA, respectively, but not the graft copolymers.

Contact angle of water on the air side of a polymer film was measured at 20°C by a CA-A type apparatus of Kyowa Kagaku Co., Ltd. Polymer films were prepared on clean glass slides by casting from ca. 5 wt.% solutions followed by slow evaporation of the solvent on standing overnight and were finally dried in vacuo at room temperature. A water droplet of

ca. 2 mm diameter was placed on the polymer film and the contact angle was measured in less than 1 min to avoid evaporation or expansion of the droplet. The contact angle was also measured on the film after immersion into water for a given time and immediate wiping off of the free water with a soft tissue.

Results and discussion

Preparation of macromonomers

PS-MA (3, 4, 11) and PS-VB (9) were prepared according to known methods as given in Fig. 2. PHEMA macromonomers were first prepared by living anionic polymerization of the trimethylsilyl-protected monomer (TMSEMA) (8), followed by end-capping with VBB or with EO and MAC. VBB was used instead of VBC because the former was reported to react satisfactorily with the living (meth)acrylate anions (12–14). Figure 3 shows typical ^{1}H NMR spectra.

The results of characterization of the macromonomers are summarized in Table 1. The yield was almost quantitative in each case and the molecular weight could be controlled by the ratio of the monomer to the initiator in feed as expected for the living polymerization. The molecular weight distribution was fairly sharp although, for PHEMA macromonomers, it was found that addition of excess lithium chloride was effective in improving the monodispersity, as reported by Teyssié and coworkers (15) for the anionic polymerization of (meth)acrylates. The advantage of the present method of preparation of PHEMA macromonomers over that of radical chain-transfer polymerization plus end-group transformation (16) is clear in the simplicity, and in the sharp molecular weight distribution attained.

The functionality of the end group (f), however, was not so quantitative but usually in the range of 70–90%. This result appears to come from unexpected terminations that occurred after complete conversion of the monomers between the living polymer anions and some impurities before or during the end-capping reactions, since the molecular weight distribution of the polymers remained, in all cases, fairly sharp. The macromonomers were used as such in the following by considering the functionality in calculating the feed composition.

Copolymerization of the macromonomers and preparation of graft copolymers

The PS and PHEMA macromonomers were copolymerized with HEMA and styrene, respectively, to low conversions to evaluate their copolymerization reactivities. A very large molar excess of the comonomer ($[M_1]/[M_2] > 100$) was used for application of the approximated relation, eq. [1]. The composition of the products after removal of the unreacted mac-

HEMA	PS-VB-1	3600	0.73 ± 0.01	1.37
Styrene	PHEMA-MA-1	2900	1.08 ± 0.08	0.93
Styrene	PHEMA-VB-4	3700	2.92 ± 0.16	0.34

romonomers was determined, as described previously (3), by ^{1}H NMR in a mixed solvent of $CDCl_3$ and CD_3OD (see Fig. 4 for an example). The corresponding monomer reactivity ratio (r_1) was obtained from at least three experiments in each system and found to be independent of the feed composition, as before (3, 7). The results are given in Table 2.

The result that r_1 was considerably higher than unity for the copolymerization of HEMA with PS-MA and that of styrene with PHEMA-VB, in spite of their similar structure in the polymerizing groups, indicates the reduced relative reactivity ($1/r_1 = k_{12}/k_{11}$) of the macromonomer (M_2) as compared to the low molecular weight analog (M_1). This tendency is also apparent in the results for the systems of HEMA with PS-VB and of styrene with PHEMA-MA, because the conventional copolymerization between styrenes and methacrylates is usually of more alternating tendency, with the reactivity ratios around 0.5 (17), as was found for the copolymerization of styrene and HEMA (4). These results support the previous notion (3, 7) that incompatibility between the macromonomer and the growing polymer backbone, i.e., between PS and PHEMA in the present case, appears to interfere thermodynamically with their mutual interpenetration, resulting in the apparently reduced reactivity of the macromonomers, as has been frequently referred to in copolymerization involving macromonomers (18, 19).

Also, interestingly, the values of the reactivity ratios in Table 2 indicate that the copolymerizations of HEMA with PS-VB and of styrene with PHEMA-MA will produce PHEMA-*g*-PS and PS-*g*-PHEMA, respectively, with more azeotropic or more homogeneous compositions than those from the other combinations, HEMA with PS-MA or styrene with PHEMA-VB. This is true at least under the condition where the approximation $[M_1]/[M_2] \gg 1$ holds in the monomer mixture.

The graft copolymers used for interfacial characterization as described below were prepared by prolonged copolymerization to much higher conversions (70–90%). They were, however, purified by repeated precipitations from THF into methanol–hexane and diethyl ether – hexane to remove PHEMA and PS homopolymers, respectively, probably together with any graft copolymers very rich in PHEMA and PS components. The purified graft copolymers were thus isolated to 10–30 wt.% yields. They were confirmed by GPC and TLC to be free of unreacted macromonomers and PHEMA or PS homopolymers. Their compositions were found by ^{1}H NMR to be very close to those in feed, irrespective of the combination of the macromonomer and comonomer, suggesting that the graft copolymers thus isolated are fairly homogeneous in composition.

Micelle formation of the graft copolymers as examined by ^{1}H NMR

As previously reported for PHEMA-*g*-PS copolymers (3), similar micelle formation was observed for the graft copolymers of reverse architecture, PS-*g*-PHEMA. Figure 4 shows the ^{1}H NMR spectra of the graft copolymers obtained by copolymerization of styrene and the macromonomer, PHEMA-MA-1 (M_n = 2900). The sample with PHEMA 62.1 wt.% was apparently soluble in CD_3OD to give a spectrum that showed clearly the peaks due to the PHEMA branches but few peaks due to the PS trunks. On addition of $CDCl_3$ (ca. 30 vol.%), the peaks due to the PS trunks also clearly appeared. This result indicates that the PS chains insoluble in methanol constitute a micelle core that behaves as a rigid "solid" to give peaks too broad to be observed. On the other hand, PHEMA chains are very soluble in methanol to give their own peaks, keeping the solution apparently clear by surrounding the insoluble PS cores. Chloroform, a good solvent for PS chains, destroys the micelle structure in cooperation with methanol, giving rise to a normal spectrum in the mixed solvent.

Exactly the reverse was observed with the sample with 19.8 wt.% PHEMA, which showed only those peaks due to PS trunks in $CDCl_3$, indicating micelle formation with PHEMA branches as the core surrounded by PS trunks. This micelle was destroyed on addition of CD_3OD to give a normal spectrum. These results clearly support micelle formation of the graft copolymers in a selective solvent, as illustrated in Fig. 5. On the other hand, a random copolymer prepared by copolymerization of styrene and HEMA was found to show a normal spectrum even in a single selective solvent (3), indicating that the statistical distribution of styrene and HEMA units with very short sequence lengths prevents micelle formation.

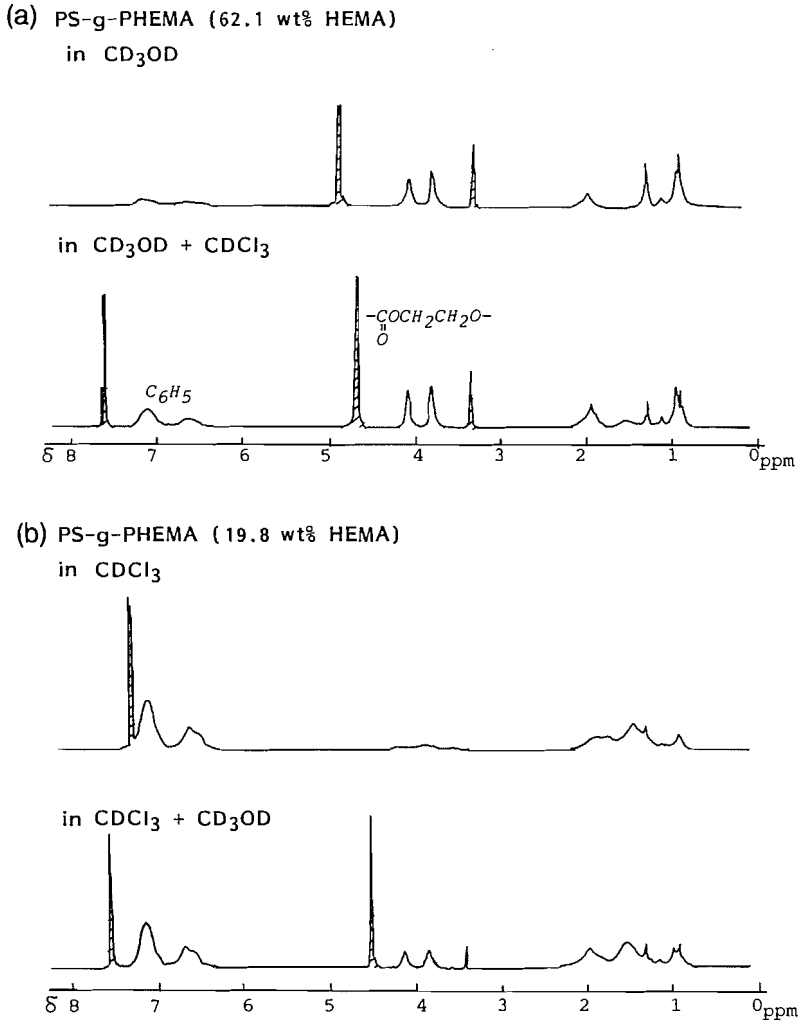
Fig. 4. ^{1}H NMR spectra of graft copolymers. (*a*) PS-*g*-PHEMA (62.1 wt.% HEMA) in CD_3OD and in CD_3OD–$CDCl_3$ (7/3 v/v); (*b*) PS-*g*-PHEMA (19.8 wt.% HEMA) in $CDCl_3$ and in $CDCl_3$–CD_3OD (7/3 v/v). Hatched peaks are due to undeuterated solvents ($CHCl_3$, CH_3OH).



Wettability of graft copolymer films

Surface properties of the graft copolymers were evaluated most conveniently by the measurement of the contact angle of water on polymer films cast from appropriate solvents. Figure 6 shows the effect of the casting solvent on the wettability of the graft copolymers as a function of the composition. As expected, the films cast from DMF and chloroform, which are common and PS-selective solvents, respectively, were found to be nonwettable just like polystyrene, almost independently of the composition and the architecture of the graft copolymers. Thus the PS chains, which have lower surface energy than the PHEMA chains, generally prefer to be exposed to the free surface.

The films cast from methanol, a PHEMA-selective solvent, however, were found to be wettable just like PHEMA homopolymer, again independently of the composition. In accord with the ^{1}H NMR measurement in CD_3OD, the PHEMA chains comprising the micelle shells prefer to selectively cover the surface of the as-cast films. After baking at 150°C, a higher temperature than both T_g's of PS and PHEMA, however, they became nonwettable like polystyrene, as expected thermodynamically as a result of the rearrangement of the surface morphology.

The above observations for the graft copolymers are quite different from those of the random copolymers of styrene and HEMA, which showed, either before or after baking of the films, a smooth change in cos θ with composition (3), indicating the importance of microphase separation of the hydrophobic (PS) and hydrophilic (PHEMA) chains in exerting their interfacial activities. As to the effect of the architecture of the graft copolymers, PS-*g*-PHEMA appeared to be a little more wettable than PHEMA-*g*-PS, as in Fig. 6. The former was also found to be soluble in methanol over a wider composition, even to as low as 30 wt.% PHEMA. Thus the solubility as well as the surface property of a graft copolymer, with a given composition and molecular weight, appear to be more readily controlled by the branches than by the trunks. This may be expected from a geometrical consideration, since the branches may more easily constitute the micelle shells, extending their chains into a medium, than do the trunks, as in Fig. 5.

The usual preference of the PS chains on the film surface, as described above, is also violated when the films are allowed

Fig. 5. Schematic illustration of micelle formation of PS-*g*-PHEMA in selective solvents and its destruction in a common solvent. Solid and broken lines indicate trunk (PS) and branch (PHEMA) chains, respectively.

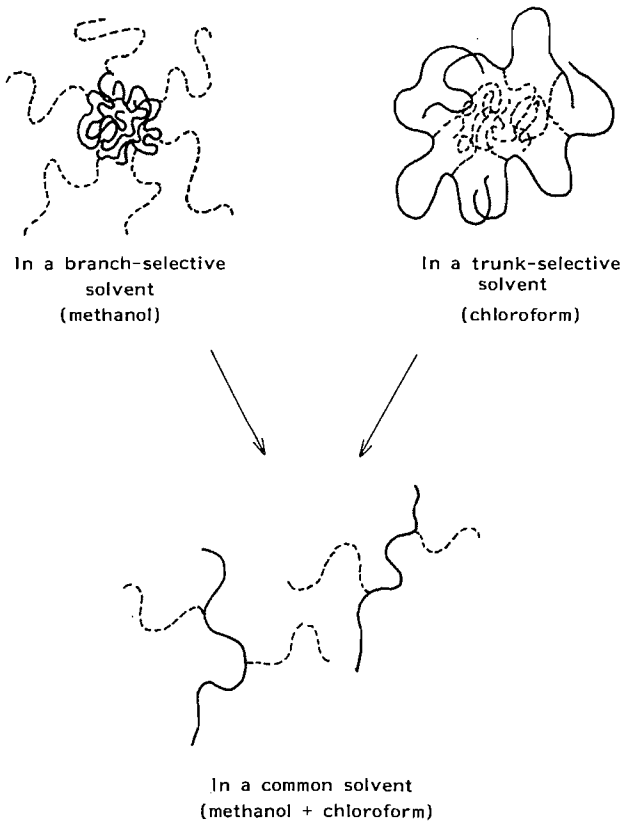

Fig. 6. Contact angle of water on films of PS-*g*-PHEMA (open symbols) and PHEMA-*g*-PS (solid symbols) cast from methanol (□, ■), DMF (○, ●), and chloroform (△, ▲). M_n's of the branches (macromonomers) are in the range of 2500–4700.

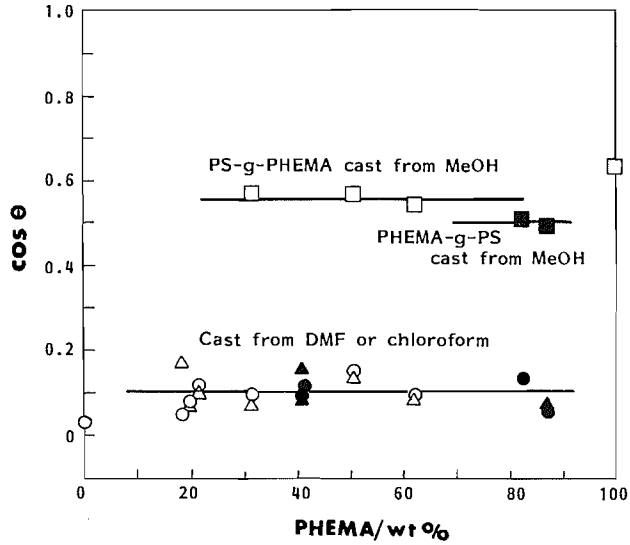

Fig. 7. Change of contact angle of water on graft copolymer films by immersion into water. (*a*) PS-*g*-PHEMA (PS/PHEMA =1/1 w/w); (*b*) PHEMA-q-PS (PHEMA/PS = 1/1 w/w), prepared with M_n of the branches (macromonomers) as indicated.

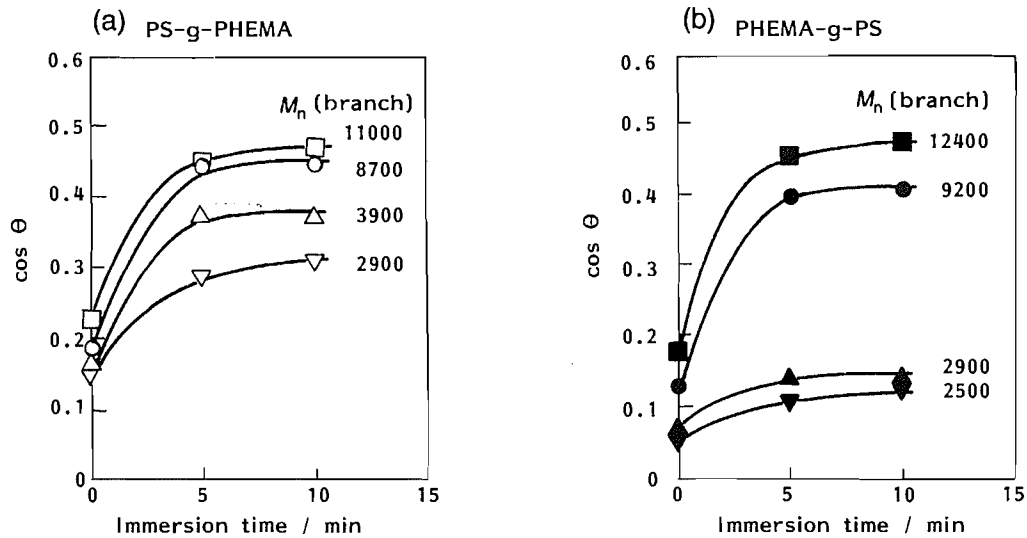

contact with a medium that is selective to PHEMA chains. Figure 7 shows the change in the contact angle on graft copolymer films by immersion into water, indicating clearly the rearrangement of the surface from PS-dominant (nonwettable) to PHEMA-dominant (wettable), particularly for graft copolymers with branches of higher M_n. It also appears that PS-*g*-PHEMA changes a little more rapidly to a more wettable level than its counterpart, PHEMA-*g*-PS, when compared at lower

M_n of the branches. The change of the surface composition and properties of these amphiphilic graft as well as block copolymers, depending on the environment, particularly in contact with water, appears to be an important factor in their usefulness as biocompatible materials (4, 5, 20).

Acknowledgments

This work was undertaken as part of the project, "Syntheses of well-controlled amphiphilic block and graft copolymers and their application to antithrombogenic material," presided over by Prof. S. Nakahama, Tokyo Institute of Technology, and supported by 17th Nissan Science Foundation. Helpful discussions with Prof. S. Nakahama, Dr. A. Hirao, Tokyo Institute of Technology, and Prof. T. Okano, Tokyo Women's Medical College, are gratefully acknowledged.

The role of polymer flexibility on the interaction with surfactant micelles: poly(vinyl alcohol) and sodium dodecyl sulphate aqueous micelle interactions studied by dynamic fluorescence quenching

Jan van Stam, Nadine Wittouck, Mats Almgren, Frans C. De Schryver, and Maria da Graça Miguel

Abstract: The interactions between poly(vinyl alcohol) and the surfactant sodium dodecyl sulphate in aqueous solutions have been investigated by means of static and dynamic fluorescence measurements. By static fluorescence measurements the onset of interaction, the critical aggregation concentration, is determined to be 6.5 mM at 20°C and 7.0 mM at 40°C. By dynamic fluorescence measurements without added quencher the influence on the lifetime of the fluorescent probe, pyrene, by the presence of the polymer is investigated. From measurements with an added quencher, dimethylbenzophenone, the surfactant aggregation numbers of the micellar aggregates formed upon interaction between the surfactant and the polymer and the quenching rate constant are obtained. At the two polymer concentrations, i.e., 0.2% and 2.0%, the surfactant aggregation numbers at low surfactant concentration are very small, but increase rapidly with increasing surfactant concentration. Comparisons are made with results from a system where poly(ethylene oxide) instead of poly(vinyl alcohol) is the polymer.

Key words: dynamic fluorescence quenching, polymer–surfactant interactions, aggregation numbers.

Résumé : Faisant appel à des mesures de fluorescence statique et dynamique, on a examiné les interactions entre l'alcool polyvinylique et l'agent tensioactif dodécylsulfate de sodium, en solutions aqueuses. Sur la base de mesures de fluorescence statique, on a déterminé qu'au début des interactions, la concentration critique d'agrégation est égale à 6,5 mM à 20°C et à 7,0 mM à 40°C. Utilisant des mesures de fluorescence dynamique sans addition de désactivant, on a étudié l'influence du polymère sur le temps de vie de la sonde fluorescente, pyrène. Sur la base de mesures effectuées en présence de diméthylbenzophénone agissant comme désactivant, on a pu déterminer la constante de vitesse de désactivation et les nombres d'agrégation de l'agent tensioactif des agrégats micellaires formés lors de l'interaction entre l'agent tensioactif et le polymère. Aux deux concentrations du polymère, à savoir 0,2 et 2,0%, on réalise que les nombres d'agrégation de l'agent de surface sont très faibles à la faible concentration de l'agent tensioactif, mais qu'ils augmentent rapidement avec une augmentation de la concentration de l'agent tensioactif. On fait des comparaisons avec les résultats obtenus avec un système dans lequel le polymère est du poly(oxyde d'éthylène) au lieu de l'alcool polyvinylique.

1. Introduction

The presence of a nonionic polymer in aqueous solutions of ionic surfactants causes changes in the physical properties of the micellar aggregates formed by the surfactant (1, 2). Such systems are of interest from a fundamental as well as from an applied point of view, polymer–surfactant solutions are for instance used in paints, pharmaceutical drugs, and in systems for enhanced oil recovery.

Among anionic surfactant – polymer systems, sodium dodecyl sulphate (SDS) – poly(ethylene oxide) (PEO) is one of the most studied, both by classical and modern methods (1–20). The system SDS – poly(vinyl alcohol) (PVA), on the other hand, has been studied mainly by classical methods (11, 21–25). These report a behaviour quite similar to that found in the SDS – PEO system, e.g., an onset of interaction below the critical micelle concentration (cmc) and about the same degree of solubilization of hydrophobic species (22*a*, 23). It is also evident that SDS and PVA interact with each other, as solubility and surface tension differ from polymer-free SDS solutions.

In previous reports, the use of the dynamic fluorescence quenching method (DFQ) on the SDS–PEO system (10, 19, 20) was reported. In salt-free systems (10, 19) it was found that the onset of interaction occurred at a concentration lower than the cmc, this concentration referred to as the critical aggregation concentration (cac). Presence of salt (20) lowered the cac due to screening of the electrostatic repulsion between the surfactant headgroups. Further, it was found that at the cac the aggregation number of the micellar-like aggregates formed by the surfactant molecules with the interacting polymer exposed an aggregation number much lower than that found for ordinary SDS micelles, approximately 30[2] as compared to 60. Except for the highest salt concentration, increasing the SDS concentration led to an increase of the aggregation number up to a limiting value, slightly lower than the aggregation number for ordinary micelles. This was explained by a model in which the polymer chain can interact with a certain number of aggregates, depending on the polymer chain length (19). At low polymer concentrations, this number will be reached at the cac, whereas at high polymer concentrations the initial number of aggregates will be lower than at the saturation limit. Upon addition of surfactant there is, initially, primarily an increase in the number of aggregates. As the saturation limit is approached it is mainly the already formed aggregates that grow, possibly in competition with formation of ordinary micelles.

The theories proposed for the interaction between an ionic surfactant and a nonionic polymer (26, 27) point in the same direction as the experimental results, e.g., interaction starts at a cac lower than the cmc and the aggregates formed have a micelle-like structure but with lower aggregation number. The aggregation numbers found, however, in the SDS–PEO system are lower than predicted by theory, and the increase of the aggregation number in this system when more surfactant is added is not explained.

In studies of the interaction between polyelectrolytes and micelles of opposite charge (28, 29), it was found that a flexible polyelectrolyte induced the same lowering of the aggregation number (28) as was found in the SDS–PEO system, while a more rigid polyelectrolyte left the micellar aggregation numbers more or less unchanged (29). It was to investigate whether such a dependence on the polymer flexibility also holds for uncharged systems that we have chosen to study the interaction between SDS and PVA.

In this study, results from static and dynamic fluorescence measurements are reported. From static measurements the cac is obtained. From dynamic fluorescence measurements without added quencher the decay time, τ_0, of the excited probe, pyrene, is obtained, while measurements with dimethylbenzophenone as added fluorescence quencher give the aggregation numbers of the surfactant aggregates and the quenching rate constant k_q.

2. Experimental section

2.1 Materials

Poly(vinyl alcohol) (PVA), 100% hydrolyzed, was from Merck (average molecular weight 115 000) and was used as supplied; c^* was determined as 1.3% w/v (Dr. Fang Liqi, private communication), which means that a 0.2% solution is dilute and a 2% solution is semi-dilute. Pyrene (Aldrich) and dimethylbenzophenone (DMBP) (Aldrich 99%) were recrystallized twice from ethanol. Sodium dodecyl sulphate (SDS) was from BDH, specially pure. Conductivity measurements gave a cmc in accordance with literature (≈8 mM) so no further purification of SDS was done. All solutions were prepared with distilled water. Measurements were performed at two temperatures, 20°C and 40°C. At these two temperatures SDS micelles have approximately the same aggregation number, i.e., 55–65 (19).

The preparation of samples for fluorescence measurements was described earlier (28). The pyrene concentration was kept low enough ($<10^{-5}$ M) to prevent excimer formation. The DMBP concentration was chosen to be less than one DMBP molecule per aggregate.

2.2 Methods

Static fluorescence measurements were used to determine the onset of surfactant aggregation and were carried out on a SPEX Fluorolog 1680 combined with a SPEX spectroscopy laboratory coordinator DM1B. The cell-holder was connected to a standard water-bath. All slits were 0.5 mm.

The ratio between the third and the first vibronic peaks (the III/I ratio) in the pyrene steady-state fluorescence spectrum depends on the polarity of the pyrene microenvironment (30). This can be used to probe surfactant aggregation, as pyrene will be almost exclusively dissolved in the less polar surfactant aggregates as they are formed. We have choosen to set cac

[2] The aggregation number at 9 mM total SDS concentration at 20°C and 0.2% PEO reported in ref. 19 is 26 but should be 34.

equal to the inflection point (the second derivative of a fitted polynomial of order 3 was used to determine the inflection point) obtained when the III/I values are plotted against the SDS concentration.

Dynamic fluorescence decay data were collected with the single photon counting technique. The setup is described elsewhere (28).

3. Theory and data analysis

3.1 Theory

Dynamic fluorescence quenching in microheterogeneous solutions has been well described in the literature (31–38). Under the conditions that the excitation pulse is narrow compared to the fluorescence decay time and no migration of probe or quencher occurs within the time-resolution of the experiment, the interpretation with the Infelta–Tachiya model (39, 40) in a generalized version (41–43) is straightforward.

The fluorescence decay is described (39, 40) by

$$[1] \quad F(t) = A_1 \exp[-A_2 t - A_3\{1-\exp(-A_4 t)\}]$$

where the parameters have the following meaning under the circumstances stated above:

A_1 is the fluorescence intensity at time $t = 0$, i.e., $F(0)$.

A_2 is the decay rate at long times. If there is no exchange of probe or quencher between the micellar phase and the bulk, A_2 will equal the unquenched decay rate k_0, or, equivalently, $1/A_2$ will equal the decay time τ_0 – leading to parallel decays at long times in the logarithmic representation for a set of experiments differing only in quencher concentrations.

A_3 is the average number of quencher molecules per aggregate. With a known amount of bound surfactant molecules and the distribution of quencher between micelles and the bulk phase, the average surfactant aggregation number, $\langle a \rangle$, can be calculated from

$$[2] \quad \langle a \rangle = A_3 S_m / Q_m$$

where S_m is the concentration of bound surfactant (the total surfactant concentration minus the cac or the cmc) and Q_m the concentration of bound quencher (the total quencher concentration minus the amount dissolved in the aqueous sub-phase).

A_4 equals the first-order quenching rate constant k_q for one quencher.

The fluorescence decay time in absence of added quencher, τ_0, was determined in separate experiments. From measurements with added quencher A_2 (eq. [1]) was determined, and the difference between $1/A_2$ and τ_0 is a measure of the condition that the probe and quencher are stationary during the time-window of the experiments. If this difference is close to zero, the quencher does not migrate between micelles or between micelles and the bulk phase. The probe, pyrene, does certainly not migrate under the present conditions, but the quencher, DMBP, has some solubility in the aqueous bulk phase (Dr. Jan Alsins, private communication). It turned out, however, that also the quencher remained in its micelle during the time-window of the measurement.

Nevertheless, the solubility of DMBP in water requires special treatment in order to determine an accurate value of Q_m for use in eqs. [2] and [6], see below.

To determine the distribution constants, K_D, for the distribution of DMBP between the aqueous bulk and the surfactant aggregates,

$$[3] \quad K_D = Q_m/(Q_{aq} S_m)$$

the concentration of DMBP at saturation was determined by absorption measurements (20, 44) for different SDS–PVA solutions at both temperatures. The distribution constant obtained is then used for the determination of Q_m by

$$[4] \quad Q_m = Q_t S_m K_D/(S_m K_D + 1)$$

where Q_t is the total quencher concentration.

The aggregation numbers obtained by eq. [2] should be treated as quencher-averaged aggregation numbers, $\langle a \rangle_q$ (45–47). The $\langle a \rangle_q$ is an apparent property, dependent on Q_m. The weight-averaged aggregation number, $\langle a \rangle_w$, is obtained by extrapolation to zero quencher concentration (45, 46) according to:

$$[5] \quad \langle a \rangle_q = \langle a \rangle_w - 1/2\sigma^2\eta + 1/6\kappa\eta^2 - \ldots$$

where σ^2 is the variance and κ gives the skewness of the size distribution of the system. η is given by

$$[6] \quad \eta = Q_m/S_m$$

It should also be noted here that the solutions were not deoxygenated, which means that the fluorescence decay was quenched by dissolved oxygen. From the measurements it was found that the presence of oxygen only affects the decay time and does not influence the use of eq. [1].

3.2 Data analysis

The computer programs (48) used for estimation of the natural lifetime and the parameters A_1–A_4 in eq. [1] are mainly based on the programs by Löfroth (49). The fitting parameters were obtained by minimizing the global reduced χ_ν^2:

$$[7] \quad \chi_\nu^2 = \left[\sum_{\forall x}\sum_{\forall y} \omega_{xy}(h_{xy}^{obs} - h_{xy}^{calc})^2\right]/\nu$$

where x sums over all experiments and y over the appropriate channels for each experiment. h denotes the observed and calculated fluorescence decay histogram value, respectively, ω is the statistical weight (a Poisson distribution is assumed), and ν represents the degrees of freedom for the entire data surface. The models were fitted under the global analysis approach (49, 50). The fit was considered to be good if $\chi_\nu^2 \leq 1.25$.

4. Results and discussion

4.1 Critical aggregation concentration

The pyrene III/I ratios were obtained from static fluorescence measurements, Fig. 1. At low SDS concentrations, the value is about 0.65, slightly higher than generally expected for pyrene dissolved in water, i.e., 0.55–0.60 (30). The difference is probably due to the presence of PVA, but does not influence the use of the method. This conclusion was further supported by the fact that the decay time for pyrene in aqueous PVA solu-

Fig. 1. Pyrene III/I vibronic peak ratios from static fluorescence measurements in 0.1% PVA at 20°C (open symbols) and at 40°C (filled symbols). Measurements in 0.2% PVA and 2% PVA showed the same behaviour.

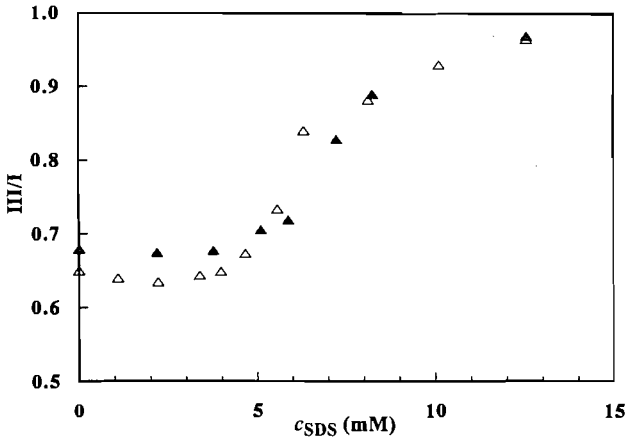

Fig. 2. DMBP distribution constants, k_D, at different SDS concentrations in 0.2% PVA (open symbols) and 2% PVA (filled symbols); circles at 20°C and squares at 40°C. Inserted lines serve as guides for the eye.

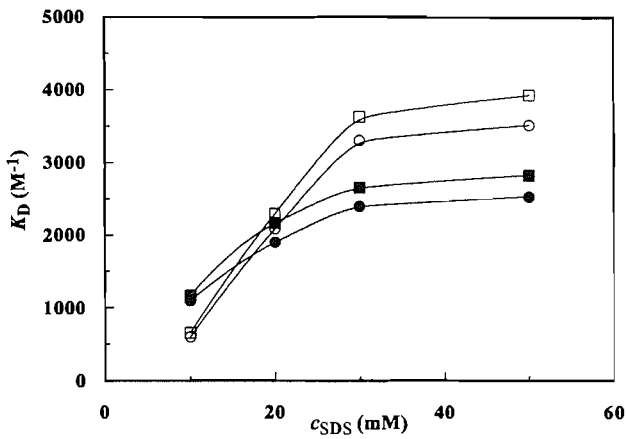

tion was equal to the decay time for pyrene dissolved in pure water. When surfactant aggregation starts, pyrene will be almost exclusively found in the surfactant aggregates, exposing the pyrene molecules to a less polar environment. Consequently, the III/I ratio will show an increase at this point, which was found at a SDS concentration around 5 mM, Fig. 1. The III/I ratio continues to increase up to a limiting value of approximately 0.92, or what is found in pure SDS micelles (30). The steep increase in III/I shows that the aggregation process is highly cooperative in nature, as is ordinary micelle formation. A closer examination of the III/I ratio as a function of SDS concentration yields a cac value of 6.5 mM at 20°C, while it is 7.0 mM at 40°C. The cac in a salt-free SDS–PEO system was found to be 5.5 mM (20)[3] for PEO at 25°C with molecular weights lower than 250 000. Thus, the interaction starts at about the same cac in the present system.

4.2 DMBP distribution between the aqueous and aggregate sub-phases

The K_D values determined at 20°C and 40°C are shown graphically in Fig. 2. The values at the lowest surfactant concentration are the most uncertain: the crossover below 20 mM SDS is an effect of this uncertainty. Nevertheless, the K_D values were used as determined.

The K_D in the present system (approximately 2000 M^{-1} for 20 mM SDS at both PVA concentrations and at both temperatures) is intermediate as compared to the value in polymer-free 20 mM SDS solution, with $K_D \approx 2900\ M^{-1}$ and $\approx 1950\ M^{-1}$ at 20°C and 40°C, respectively (Dr. Jan Alsins, private communication), and the SDS–PEO system, where K_D is $\approx 1600\ M^{-1}$ in 0.2% PEO and $\approx 1900\ M^{-1}$ in 2.0% PEO at both temperatures and 20 mM SDS. This leads to a picture in which the SDS micelle is less altered in size and (or) structure in the SDS–PVA system than in the SDS–PEO system.

Combining eqs. [2] and [4] gives

$$[8] \quad \langle a \rangle = A_3[S_m/Q_t + 1/(Q_t K_D)]$$

from which it follows that an overestimation of K_D leads to an underestimated aggregation number (the product $Q_t K_D$ is, for ordinary micellar solutions in the order of unity).

The aggreation numbers in ref. 19 are in error since K_D-values for pure SDS micelles were used. A recalculation using the correct K_D-values gave small changes of the aggregation numbers at all SDS concentrations except those close to the cac.[2] The overall picture, however, does not change from that given in ref. 19. In all comparisons with the SDS–PEO system, the recalculated aggregation numbers are used.

The water solubility of DMBP also raises the question of whether it affects the photophysical deactivation of the excited probe via quencher migration from the bulk into the surfactant aggregate. Such an effect, if present, should be most pronounced at SDS concentrations close to the cac. At the cac the concentration of aggregates is, roughly, 10^{-4} M, leading to a DMBP bulk-concentration, Q_{aq}, of about 10^{-5} M (assuming one quencher per aggregate on average and 10% dissolved in the aqueous bulk). For a diffusion-limited process one can set the second-order rate constant for migration from the bulk into the aggregates, k_+, to be in the order of $5 \times 10^9\ s^{-1}$ (34), giving the product $k_+ Q_{aq}$ to be about $5 \times 10^4\ s^{-1}$, which should be compared with $k_0\ (=1/\tau_0)$, approximately $4 \times 10^6\ s^{-1}$ in this system, see Table 1. Thus, the effect of quencher migration is only 1% or less of the natural deactivation rate, which is negligible.

4.3 Pyrene fluorescence decay time

The numerical results from the fitting of eq. [1] to the fluorescence decay data and subsequent treatment are compiled in Tables 1 and 2. The pyrene fluorescence decay time, τ_0, Fig. 3, decreases with increasing SDS concentration at the low PVA concentration. If compared with the decay times found in 0.2% PEO (19), one finds an almost identical behaviour at both temperatures and 0.2% PVA concentration. This results in the same picture as proposed earlier (19), with the polymer in close contact with the aggregates causing a steric shielding against penetration, and subsequent quenching, by bulk-dissolved oxygen. As the surfactant concentration increases, this shielding effect decreases due to lower polymer-to-surfactant ratios, and the lifetimes come closer to those found in polymer-free systems.

At 2% polymer concentration, the lifetimes are longer in the SDS–PVA system at the lowest SDS concentration. At this

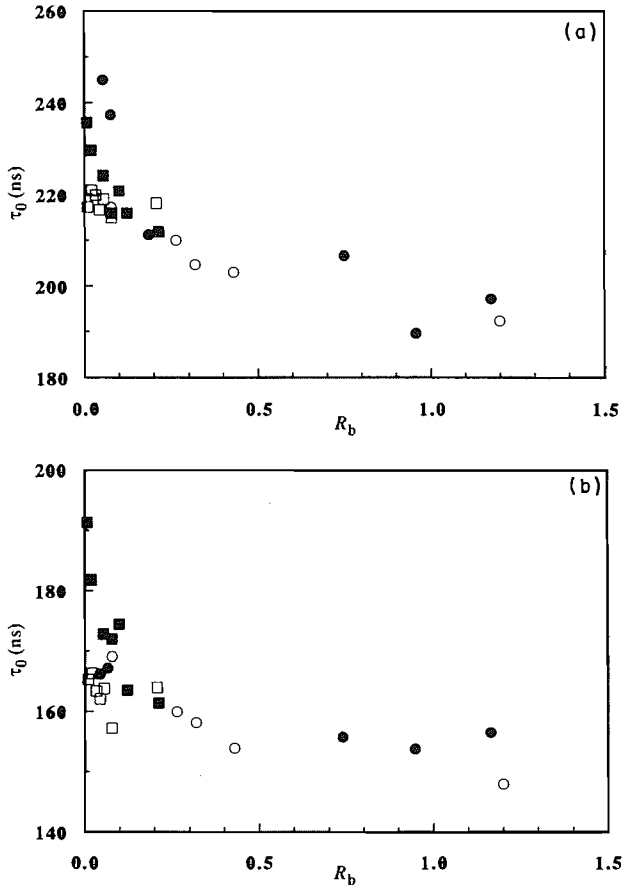
100	0.213	161.4	54.7	5.3

higher polymer concentration the lifetimes do not reach values close to the lifetimes in polymer-free solutions within the concentration range studied. This is due to the much lower ratios of bound surfactant to polymer monomer unit (denoted R_b) in these systems. Increasing the surfactant concentration to raise this ratio will also lead to a higher ionic strength, which would influence both the shape and the size of the micellar aggregates.

Fig. 3. Pyrene fluorescence decay times in PVA solutions (filled symbols) and PEO solutions (open symbols) at 0.2% (circles) and 2.0% (squares) polymer concentration as a function of the ratio R_b (see text for details) at two temperatures: (*a*) 20°C and (*b*) 40°C. Data for the SDS–PEO system are from ref. 19.



4.4 Surfactant aggregation numbers

For determination of the surfactant aggregation numbers, dynamic fluorescence quenching measurements were performed. The fluorescence decays, two typical examples of which are shown in Fig. 4, show well-developed exponential decays at long times. The parallel tails assure that any probe and (or) quencher migration is negligible on this time scale. The determined weight-average aggregation numbers, obtained by the use of eq. [5], are represented graphically in Fig. 5, together with the recalculated (see above) aggregation numbers from ref. 19 for SDS–PEO.

At 0.2% PVA the aggregation numbers as a function of the SDS concentration are initially very small, but increase steeply with increasing surfactant concentration. This aggregation behaviour resembles that of the SDS–PEO system, where a marked decrease in aggregation numbers, by a factor of 2 of those for the ordinary micelles, was found at low surfactant concentrations (19). The aggregation numbers increase more quickly, however, in the present system, Fig. 5.

Fig. 4. The logarithm of the fluorescence intensity versus time from dynamic fluorescence quenching measurements at two temperatures: (*a*) 20°C and (*b*) 40°C. The total SDS concentration is 15 mM and the PVA concentration 0.2%. The DMBP concentrations (total concentration) are from top to bottom: 0, 0.043, 0.085, and 0.126 mM, respectively.

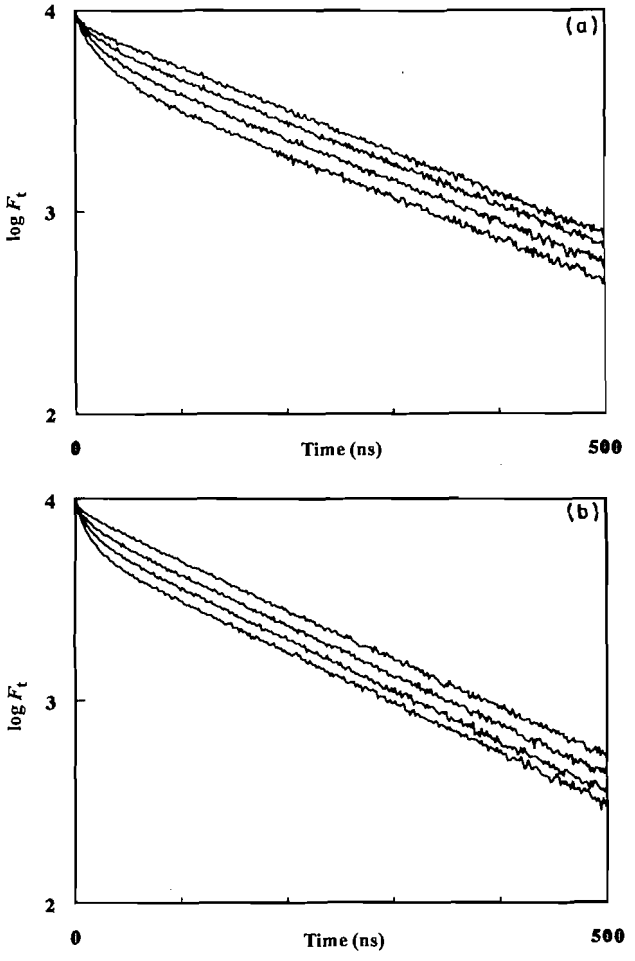

Fig. 5. SDS weight-averaged aggregation numbers for PVA solutions (filled symbols) and PEO solutions (open symbols) at 0.2% (circles) and 2.0% (squares) polymer concentration as a function of the ratio R_b (see text for details) at two temperatures: (*a*) 20°C and (*b*) 40°C. Data for the SDS–PEO system are from ref. 19. The aggregation number for SDS micelles is about 55–65 in this concentration range.

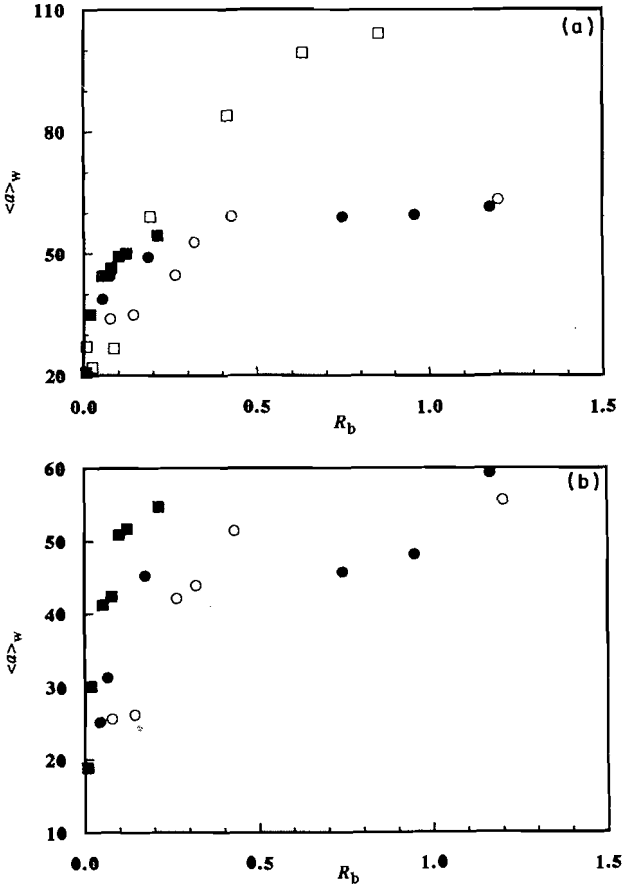

At 2% PVA, the picture is very much the same as for 0.2% PVA. At this higher polymer concentration the surfactant aggregation numbers are also smaller than those for ordinary SDS micelles. Comparing the two surfactant–polymer systems at 2% polymer concentration, one finds that with PVA as polymer approximately 50 mM ($R_b \approx 0.10$) SDS is needed to reach about the same aggregation number as in polymer-free SDS solutions, whereas approximately 100 mM SDS is needed when PEO is the polymer (19). This could be interpreted as a difference in the interaction capability of the two polymers, i.e., that the formation of free aqueous micelles, not interacting with the polymer, starts at a lower R_b when PVA is the polymer. The aggregation numbers determined will in such a case be a weighted average of the aggregation numbers of the aqueous micelle and the aggregate interacting with the polymer (19).

The reason for these differences may be due to the different hydrophobicity of the two polymers. Another parameter of importance is the polymer flexibility: wrapping around small aggregates would be less favourable for a polymer with lower flexibility. In two earlier communications it was found that a stiff polyelectrolyte left the aggregation numbers more or less unaffected (28), while a flexible one caused a decrease in the aggregation numbers (29). In fact, the unperturbed end-to-end distance, $r_0/M^{0.5}$ (r_0 is calculated from the unperturbed mean-square end-to-end distance $\langle r^2 \rangle_0$ and M is the polymer molecular weight), independent of molecular weight, is 0.95 nm for PVA and 0.75 nm for PEO in water (51), showing, along with other macromolecular parameters, that PVA is less flexible than PEO. Furthermore, in a study of the interaction between the cationic surfactant cetyltrimethylammonium chloride (CTAC) and poly(vinyl alcohol-*co*-vinyl acetate) (PVA-Ac), it was concluded that the aggregation numbers were significantly lowered by the presence of the polymer (52). The value of $r_0/M^{0.5}$ for poly(vinyl acetate) (PVAc) is about 0.70 nm (51) and the copolymer PVA-Ac could be expected to be intermediate in flexibility between PVA and PVAc.

Assuming the flexibility to be an important parameter for interactions between an uncharged polymer and SDS micellar aggregates justifies the following description of the SDS–PVA system:

At 0.2% PVA, the polymer interacts with the SDS micelle to form small aggregates at low surfactant concentrations.

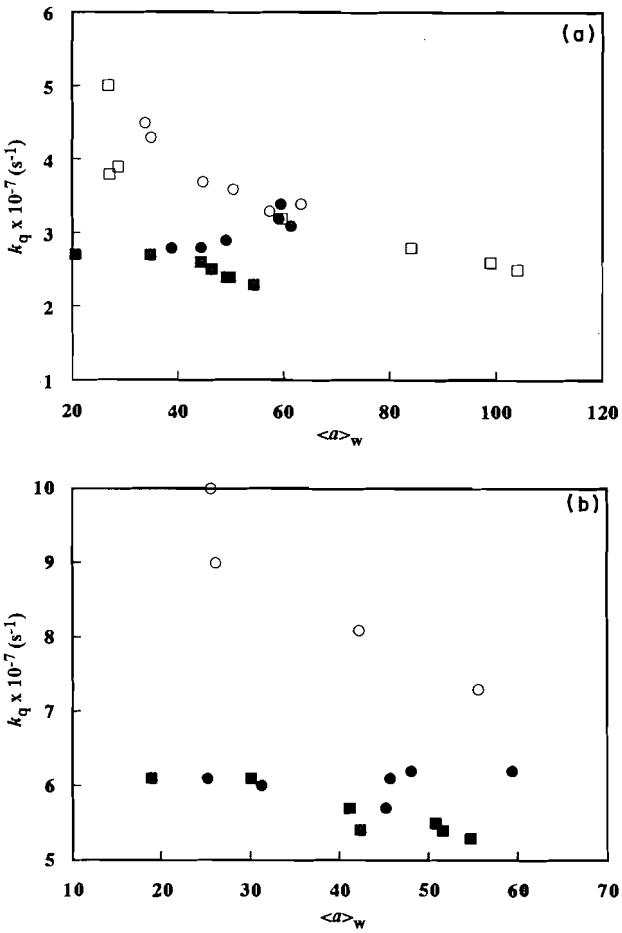
Fig. 6. First-order quenching rate constant k_q for PVA solutions (filled symbols) and PEO solutions (open symbols) at 0.2% (circles) and 2.0% (squares) polymer concentration as a function of the weight-averaged aggregation number $\langle a \rangle_w$ at two temperatures: (*a*) 20°C and (*b*) 40°C. Data for the SDS–PEO system are from ref. 19.



These aggregates grow rapidly when the SDS concentration is increased, possibly due to formation of aqueous SDS micelles not interacting with PVA. The more flexible PEO can wrap around the surfactant aggregate in a more efficient way, and the increase in aggregation number is delayed, as compared to the SDS–PVA system. At higher R_b-values, the two polymers impose the same effect on the SDS aggregation numbers, independent of temperature.

At 2.0% PVA, the results are more or less identical with those obtained at the lower polymer concentration: with increasing surfactant concentration the surfactant aggregation numbers rapidly increase.

4.5 Quenching rate constants

Some reports have paid attention to the fluorescence quenching rate in surfactant–polymer systems (10*a*, 19, 20, 28, 29). The quenching rate constant, k_q, is thought to be inversely proportional to the micellar or aggregate volume, or, equally, to the aggregation number – predicted by theory (53) and experimentally found in systems with small, spherical, micelles, even if in some it has been found to depend on $V^{-1.2}$ (31).

Surprisingly, this does not hold in many surfactant–polymer systems (10*a*, 19, 20, 28, 29). The quenching rate changes much less than the aggregation number, as is also found in the present system, see Fig. 6. There is a slowing down of the quenching rate with increasing aggregation number, but not at all to the extent expected should it be inversely proportional to the aggregation number. Furthermore, k_q is lower in surfactant–polymer systems than in the corresponding surfactant systems. In a discussion of pyrene excimer formation in the SDS–PEO system, Zana et al. (10*a*) proposed a specific interaction between pyrene and PEO. The generality of the effect seems to rule out this proposal, however, and a change in the "microviscosity" due to more rigid packing in the surfactant–polymer aggregate (20) seems to be a more general explanation. This increased viscosity would affect the translational diffusion of the probe and quencher molecules within the aggregates.

In the SDS–PEO system at 20°C, the quenching rate constant is more or less independent of the polymer concentration. The values of k_q at 0.2% PVA fits well into this picture, whereas the quenching rate is significantly lower at the higher PVA concentration. At 40°C this effect is even more pronounced, also at the lower PVA concentration the quenching rate is slowed down with respect to the SDS–PEO system. A reasonable explanation is the small but significant difference in θ temperature between PVA and PEO: in water the θ temperature is about 10°C lower for the former polymer (51). Thus, raising the temperature from 20 to 40°C will change the flexibility and (or) hydrophilicity of PVA as compared to PEO to such an extent that there will be a measurable difference in the quenching rate constant values.

5. Conclusions

The presence of PVA influences the SDS aqueous micellar aggregates and dynamics. The interaction starts at both temperatures at a critical aggregation concentration below the cmc, 6.5 mM at 20°C and 7 mM at 40°C. At 0.2% PVA, the polymer shields the excited probe from oxygen quenching, due to penetration by bulk-dissolved oxygen molecules, to the same extent as does PEO. The aggregation numbers are affected in the same way by the two polymers at the lowest SDS concentrations, but increase more steeply with increasing surfactant concentration when PVA is the polymer due to the less flexible PVA chain as compared to the PEO chain. At 2.0% PVA, the SDS micellar aggregation numbers at low SDS concentrations are also much lower than those found for free SDS micelles and are comparable to those at 0.2% PVA. Increasing the SDS concentration increases the surfactant aggregation numbers rapidly. The results concerning the aggregation numbers are in qualitative accordance with those found in a similar study of the system CTAC–PVA-Ac (52). The small difference in θ temperature in water between PVA and PEO induces a significant difference in the quenching rate constant values: PVA, having a lower θ temperature, affects the micelles more than PEO, leading to a slowing down of the translational diffusion of the dissolved quencher and a lower value for the quenching rate constant.

Azo polymers for reversible optical storage. 8. The effect of polarity of the azobenzene groups

Mei-Sing Ho, A. Natansohn, C. Barrett, and P. Rochon

Abstract: Poly[4′-[[(2-methacryloyloxy)ethyl]ethylamino]azobenzene] (pMAEA) was prepared. Its reversible optical storage properties were studied and compared with the properties of previously reported poly[4-(2-methacryloyloxy)ethylazobenzene] (pMEA) and poly[4-nitrophenyl-4′-[[2-(methacryloyloxy)ethyl]ethylamino]phenyldiazene] (pDR1M). The effect of the dipole moment of the azobenzene moiety on the optical storage properties was studied by comparing the photochemically induced birefringence "writing" and "relaxation" behaviors. The writing and relaxation rates are both in the order pDR1M > pMAEA > pMEA. In addition, pDR1M, which contains donor/acceptor substituents in the azobenzene side chain, exhibits the highest saturation level of optically induced birefringence. The fraction of birefringence conserved after relaxation is lowest for pMEA, which has no donor/acceptor substituents in the azobenzene side chain, and highest for pDR1M.

Key words: polymers, azobenzene type, birefringence, photochemically induced orientation, reversible optical storage.

Résumé : On a preparé le poly[4′-[[(2-méthacryloyloxy)éthyl]éthylamino]azobenzène] (pMAEA). On a étudié ses propriétés d'emmagasinage optique réversible et on les a comparées avec celles des poly[4-(2-méthacryloyloxy)éthylazobenzène] (pMEA) et poly[4-nitrophényl-4′-[[2-(méthacryloyloxy)éthyl]éthylamino]-phényldiazène] (pDR1M). On a étudié l'effet du moment dipolaire de la portion azobenzène sur les propriétés d'emmagasinage optique en comparant les comportements à l'«écriture» et à la «relaxation» de la biréfringence photochimiquement induite. Les vitesses dans les modes écriture et relaxation sont dans chaque cas dans l'ordre pDR1M > pMAEA > pMEA. De plus, le pDR1M, qui contient des substituants donneur/accepteur dans la chaîne latérale, présente le niveau de saturation de biréfringence optiquement induite le plus élevé. La fraction de la biréfringence qui est conservée après relaxation est le plus élevé avec le pDR1M et le plus faible avec le pMEA qui ne porte pas de substituants donneur/accepteur dans la chaîne latérale de l'azobenzène.

Mots clés : polymères, type azobenzène, biréfringence, orientation photochimiquement induite, emmagasinage optique réversible.

[Traduit par la rédaction]

Introduction

Azo polymers are attracting much attention because of their potential use in various optical applications (1). In previous publications, we have demonstrated that stable birefringence can be optically induced in amorphous polymer thin films (2–7). The mechanism postulated for optically induced birefringence is related to the *trans–cis–trans* isomerization of the azobenzene group. A series of *trans–cis–trans* isomerization cycles is accompanied by the movement of the rigid azo groups and eventually creates an excess of azo groups oriented perpendicular to the laser polarization direction. This dichroism produces a measurable birefringence. Circularly polarized light restores the initial disordered state of the azo groups. According to Rau (8), azo compounds can be divided into three classes: azobenzene type, aminoazobenzene type, and pseudo-stibene type. Azobenzenes with electron donor and electron acceptor substituents (pseudo-stilbene type) and aminoazobenzene-type molecules isomerize from the *cis* configuration back to the *trans* configuration very quickly at room temperature. However, the thermal *cis–trans* isomerization in azobenzene-type molecules is relatively slow, and it is even possible to isolate the *cis* isomer.

We are studying various aspects of the mechanism for the optically induced supramolecular organization and structure–properties relationship of the polymers. However, our previous studies have only focused on azo polymers with the pseudo-stilbenes (2–6) and azobenzene (7) type side chain. To have a better understanding of the mechanism and the requirements for achieving optically induced supramolecular orientation, it is important to explore the optical properties of polymers with the aminoazobenzene-type side chain. This paper presents the synthesis of an azo polymer that contains an

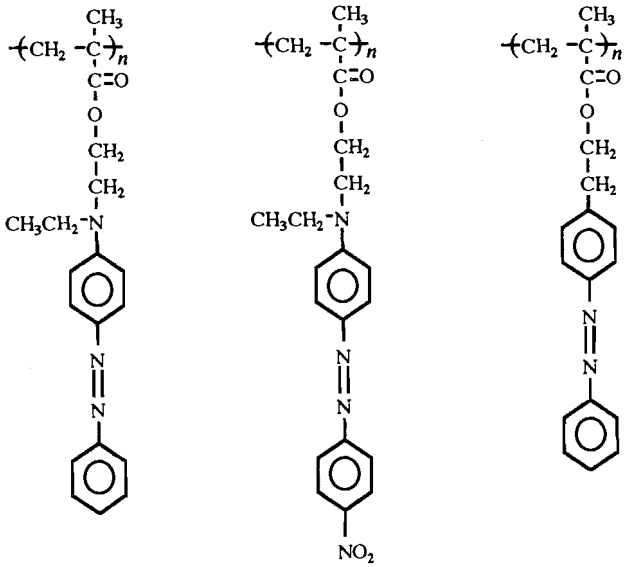
Chart 1.



pMAEA pDR1M pMEA

aminoazobenzene-type group in the side chain. In addition, its optical properties are compared with two structurally similar azo polymers, pMEA (7) and pDR1M (9). The molecular structures of the three polymers compared are presented in Chart 1.

Experimental

The proton spectra were recorded on a Bruker AC-F 200 NMR spectrometer. UV absorption spectra were obtained from a Hewlett Packard 8452A diode array spectrophotometer. The molecular weight was obtained from a Waters Associates liquid chromatograph equipped with μ-Styragel columns and a R401 differential refractometer. The glass transition temperature (T_g) was obtained with a Mettler TA 3000 thermal analysis system equipped with a TC10A TA processor and a DSC30 head.

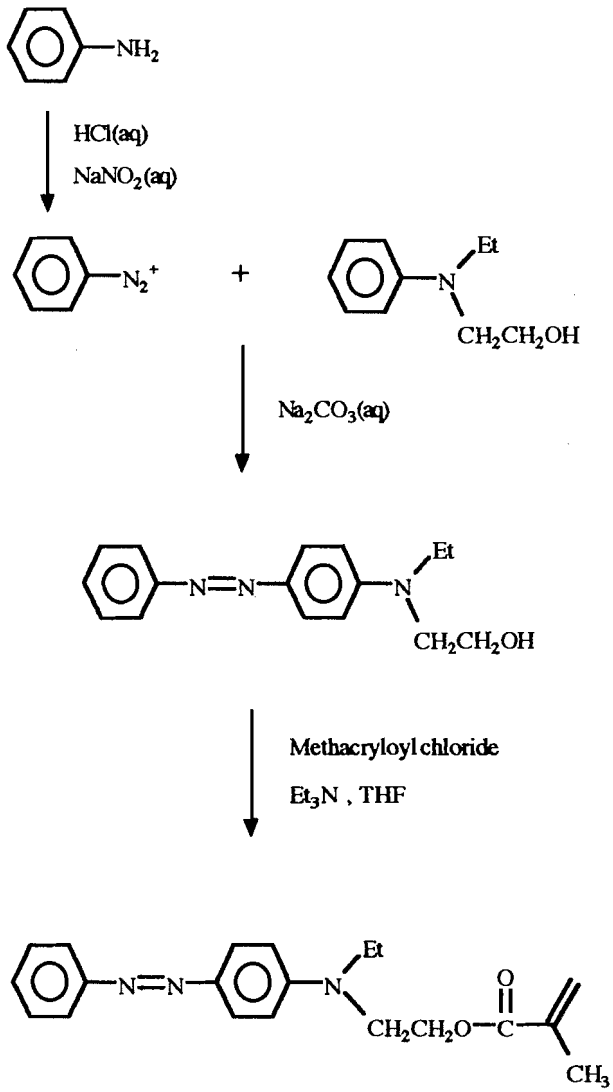
Monomer

4′-[[(2-Methacryloyloxy)ethyl]ethylamino]azobenzene (MAEA)

The monomer was prepared according to the synthetic scheme shown in Scheme 1. 4′-[[(2-Methacryloyloxy)ethyl]-ethylamino]azobenzene was obtained by reacting the corresponding alcohol with methacryloyl chloride. The 4′-[2-(hydroxy)ethyl)ethylamino]azobenzene was prepared by coupling the diazonium salt of aniline with 2-(*N*-ethylanilino)ethanol and the procedure is as follows.

Aniline (2.4 g, 0.025 mol) was dissolved in a solution of concentrated HCl (10 mL) in water (50 mL). The mixture was cooled in an ice bath until the temperature was below 4°C. Then a solution containing sodium nitrite (1.9 g, 0.027 mol) in water (20 mL) was added slowly to the aniline solution. The mixture was allowed to stir in the ice bath for 15 min. The resultant solution, which contained the diazonium salt, was added to a solution of 2-(*N*-ethylanilino)ethanol (4.2 g, 0.025 mol) in glacial acetic acid (10 mL) and water (20 mL). The mixture was stirred for 5 min in the ice bath and aqueous

Scheme 1.



sodium carbonate solution was added to adjust the pH to ~6. The solid was filtered and air dried. The solid was recrystallized from ethanol–water mixture (3/2 by volume). Yield 4.5 g of 4′-[2-(hydroxy)ethyl)ethylamino]azobenzene (68%): mp 119–120°C. ^{1}H NMR($CDCL_3$), δ: 1.24(3H), 1.76(1H), 3.50(2H), 3.60(2H), 3.88(2H), 6.80(2H), 7.50(3H), 7.88(4H). Anal. calcd. for $C_{16}H_{19}N_3O$: C 71.35, H 7.11, N 15.60; found: C 71.53, H 7.29, N 15.58.

A solution of 4′-[2-(hydroxy)ethyl)ethylamino]azobenzene (5.4 g, 0.020 mol) and triethylamine (3.0 mL) was dissolved in THF (80 mL). The solution was kept in an ice bath for 10 min. A solution of distilled methacryloyl chloride (2.3 mL, 0.022 mol) in THF (20 mL) was added slowly to the above mixture. After the addition of methacryloyl chloride, the resultant mixture was stirred at room temperature overnight. The solvent was removed by rotary evaporation and the residue was washed with a solution of sodium carbonate (1.6 g) in water (100 mL). The product was extracted with diethyl ether and the solution was washed with water and dried over anhydrous sodium sulphate. The solvent was removed by rotary evaporation and the residue was purified by column chromatography

over silica gel and eluented with chloroform. Yield 5.0 g (74%) of 4′-[[(2-methacryloyloxy)ethyl]ethylamino]azobenzene as a red viscous liquid. ^{1}H NMR($CDCl_3$), δ: 1.24(3H), 1.95(3H), 3.55(2H), 3.72(2H), 4.38(2H), 5.60(1H), 6.12(1H), 6.80(2H), 7.50(3H), 7.88(4H). Anal. calcd. for $C_{20}H_{23}N_3O_2$: C 71.19, H 6.87, N 12.45; found: C 70.76, H 6.97, N 12.14.

Polymer

The polymerization of MAEA was carried out in dry toluene with 1% weight 2,2'-azobisisobutyronitrile (AIBN) as initiator. The monomer was allowed to polymerize under argon at 60°C for 2 days. The polymerization was stopped by pouring the reaction mixture into methanol. The polymer was redissolved in THF, precipitated again in methanol, and finally dried under vacuum. The yield was 60% and the polymer had a weight-average molecular weight of 41 000 (relative to polystyrene). From the DSC, the glass transition temperature was found to be 104°C for pMAEA. The preparations of pMEA (7) and pDR1M (9) have been reported previously.

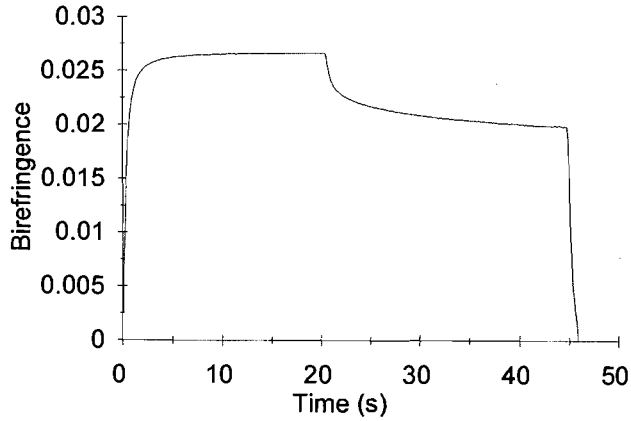
Polymer films and optical studies

Thin films of the polymers were obtained by dissolving the polymers in THF and spin-coating onto clean glass slides. The films were allowed to dry and were subsequently heated above the T_g of the polymers. Relatively homogeneous thin films from 100 to 400 nm thickness were obtained by this procedure. Film thickness was determined by interferometry. Detailed procedures for the measurement of the optically induced birefringence (2–6) and thermal *cis–trans* isomerization rate (10) have been described previously.

Results and discussion

The UV–vis spectra for pMAEA, pDR1M, and pMEA films are shown in Fig. 1. The maximum absorbances (λ_{max}) are 410, 458, and 324 nm for pMAEA, pDR1M, and pMEA, respectively. The UV–vis spectrum of pMEA exhibits a high-intensity band in the UV region and the low-intensity band in the visible region corresponds to the absorption band of the cis isomer. These bands are characteristic for the "azobenzene" type in Rau's classification (8). The UV–vis spectra of pMAEA and pDR1M exhibit high-intensity bands in the visible region, which is characteristic for the "aminoazobenzene" and "pseudo-stilbene" types (8). In addition, the λ_{max} of the polymers suggests that the dipole moments of the *trans* isomers are in the order pDR1M > pMAEA > pMEA. The absorptivity values for pMEA, pMAEA, and pDR1M at 514 nm are 5.8×10^2 cm^{-1}, 3.5×10^3 cm^{-1} and 3.6×10^4 cm^{-1} respectively.

Fig. 2. Write–erase profile of optically induced and erased birefringence of pMAEA with laser beam at 488 nm. Time = 0 s: linearly polarized laser ON; time = 20 s: laser OFF; time = 45 s: circularly polarized laser ON.



For the sake of consistency, a writing laser beam with a wavelength of 514 nm (0.7 W/cm^2) was used to induce birefringence in all the polymer films. Figure 2 shows a typical sequence of inducing and erasing birefringence for pMAEA. Birefringence is induced to a saturated level by a linearly polarized laser beam, and relaxation occurs when the laser beam is turned off at 20 s. As the circularly polarized laser beam is turned on at 45 s, the induced birefringence is "erased." Both pMEA (7) and pDR1M (9) exhibit similar write–erase profiles. The saturation levels of birefringence for pMEA, pMAEA, and pDR1M are 0.012, 0.026, and 0.103, respectively. This result suggests that the saturation level of birefringence follows the order of strength of the dipole moment of the azo group in the polymer. However, it has been observed that a polymer with nitrophenylazocarbazole in the side chain[2] exhibits a saturation level of birefringence as high as 0.09, although its λ_{max} (428 nm) is quite similar to pMAEA. This suggests that not only the dipole moment of the side group but also the presence of the nitro group may be important to achieve high induced birefringence. Since the maximum obtainable birefringence should depend on the interaction between the oriented dipoles (11), the presence of a lateral dipole can stabilize the local orientational ordering induced by the polarized laser beam. In fact, the presence of a terminal nitro group in liquid crystals was found to enhance the layered smectic phase (12).

The growth and relaxation of the optically induced birefringence can be quite well described by the biexponential functions [1] and [2], respectively. In fact, eq. [1] and [2] were found to give good fits to the growth and relaxation of the optically induced birefringence in other polymer systems (9).[2] To study the structural effect on the optical properties, data from the growth and relaxation of the optically induced birefringence were analyzed by eqs. [1] and [2], respectively. The fitting parameters obtained are summarized in Table 1.

[a] $A_n = A/(A + B)$; $B_n = B/(A + B)$.
[b] $C_n = C/(C + D + E)$; $D_n = D/(C + D + E)$; $E_n = E/(C + D + E)$.
[c] Absorptivity at 514 nm.
[d] Thermal *cis–trans* isomerization rate.

$$[1] \quad y = A(1 - \exp(-k_a t)) + B(1 - \exp(-k_b t))$$

$$[2] \quad y = C \exp(-k_c t) + D \exp(-k_d t) + E$$

The writing process involves an initial "fast" response mode and a "slow" response mode. The fast process is associated with the *trans–cis–trans* isomerization rates, with quantum yields, and with the local mobility of the azo group. Therefore, the fast process is controlled by the size of the azo group, the free volume around it, and the strength of the coupling interaction between the azo group and the polymer backbone. The slow process should be associated with the coupling interaction between the azo group and the polymer segments and with the mobility of the polymer segments. The parameter A in eq. [1] represents the contribution of the fast growth component with rate constant k_a. The parameter B represents the contribution of the slow growth component with rate constant k_b. Similarly, the relaxation process can be described by a "fast" mode and a "slow" mode, which are represented by the terms $C \exp(-k_c t)$ and $D \exp(-k_d t)$, respectively, in eq. [2]. In addition, the parameter E represents the induced birefringence conserved after relaxation.

Growth of the optically induced birefringence

Since k_a and k_b in Table 1 represent the rate constants for the fast and slow response modes, it is clear that pMEA has a slower writing response to the writing laser beam than pMAEA and pDR1M. For all three polymers, the parameter A indicates that the fast response mode contribution, which is related to the isomerization and reorientation of the chromophores, is the major component of the optically induced birefringence. The probability of an optical transition from *trans*-azobenzene to *cis*-azobenzene is proportional to $|\mu \cdot \boldsymbol{E}|^2$, where μ is the transition dipole moment and $\boldsymbol{E}$ is the electric field of the laser beam (13). Since the optically induced birefringence is created from the *trans–cis–trans* isomerization and reorientation of the azo moieties, it is expected that the rate of inducing birefringence will depend on the isomerization rate. For the same electric field, azo moieties with larger dipole moments would have a faster *trans–cis* isomerization rate and hence a faster rate of inducing birefringence. In addition, *trans–cis* isomerization rates also depend on the energy absorbed by the polymer film at the irradiation wavelength. The absorptivity of pMEA films at 514 nm is much lower than that of pDR1M and pMAEA, and most of the energy is absorbed by the *cis* isomers. Therefore, the *trans–cis* isomerization rate will be much lower in pMEA than in pDR1M and pMAEA. In spite of the low absorption at 514 nm, using a laser at this wavelength can photochemically activate the *cis–trans* isomerization, which otherwise would be very slow thermally (14) (see also Table 1). Therefore, pMEA can still give a reasonably fast response under these experimental conditions. Although the *trans–cis* and *cis–trans* isomerizations are both photochemically activated at the irradiating wavelength, a slower writing response for pMAEA than for pDR1M is observed. This discrepancy probably comes from the fact that pDR1M has a higher absorptivity and a larger dipole moment than pMAEA. As well as the rate of isomerization, the rate of inducing birefringence should also depend on the molecular associations among the chromophores. The molecular associations should be, in principle, more pronounced for polymers with stronger polar groups. For pDR1M, the donor/acceptor arrangement provides a large dipole, and the intra-chain and inter-chain interactions among these dipoles can create a local ordering that contributes to the observed induced birefringence.

Since it is proposed that the slow component in the writing process is related to the overall motion of the polymer matrix,

Table 2. The weight-average molecular weight (M_w), polydispersity index (M_w/M_n), and glass transition temperatures (T_g) of the polymers investigated.

Polymer	M_w	M_w/M_n	T_g (°C)
pMEA	70 000	2.2	80
pMAEA	41 000	2.2	104
pDR1M	9 000	1.8	116

its magnitude should be affected by the molecular weight and glass transition temperature of the polymer sample. It is expected that the higher the molecular weight and the glass transition temperature of a polymer, the more difficult such motions are. Among the three polymers, pMEA exhibits the lowest glass transition temperature and highest molecular weight (Table 2). Although k_b is not solely determined by the molecular weight, it appears that the high molecular weight of pMEA could be the reason for it having the smallest k_b among the three polymers studied. In spite of having the highest glass transition temperature, pDR1M exhibits the largest k_b. This result suggests that the low molecular weight of pDR1M would facilitate the mobility of the polymer matrix.

Relaxation of the induced birefringence

As shown in Table 1, the relaxation rates (k_c and k_d) also follow the order pDR1M > pMAEA > pMEA. Although the thermal *cis–trans* isomerization is expected to be involved in the relaxation processes, the relaxation rates are much faster than the thermal *cis–trans* isomerization rate for pMEA ($k_i = 1.9 \times 10^{-4}$ s^{-1}) (14). Therefore, the contribution of thermal *cis–trans* isomerization to the relaxation processes should be insignificant for pMEA; in this case the dipole reorientation and the relaxation of the polymer segments would be the major constituents in the relaxation processes. The situation is very different for pDR1M and pMAEA, since both polymers exhibit fast thermal *cis–trans* isomerization rates (Table 1), which would have a significant effect on the observed relaxation rates. In addition to the contribution from thermal *cis–trans* isomerization, one should also consider the effect of molecular association during the dipole reorientation. The effect of molecular association should be more pronounced for the azo group with a stronger dipole. Therefore, the effect of molecular association might account for the difference between the relaxation rates (k_c and k_d) of pMAEA and pDR1M. Similar to the writing process, the slow component in the relaxation process is also related to the overall mobility of the polymer matrix. As pointed out in the previous section, the overall mobility of the polymer matrix would be affected by the glass transition temperature and molecular weight of the polymer. The higher the molecular weight and glass transition temperature of a polymer, the more difficult such motions are. As shown in Table 1, pMEA, which exhibits the lowest glass transition temperature and highest molecular weight, has the smallest k_d among the three polymers. On the other hand, pDR1M, which exhibits the highest glass transition temperature and lowest molecular weight, has the largest k_d. This result agrees with the previous suggestion that the low molecular weight of pDR1M facilitates an increased mobility of the polymer matrix.

The parameter E in eq. [2] is time independent, thus it represents the birefringence conserved in the polymer film after relaxation. It is interesting to note that the fraction of induced birefringence remaining after relaxation is different for every polymer. The fractions of birefringence remaining after relaxation are 0.67, 0.73, and 0.84 for pMEA, pMAEA, and pDR1M, respectively. This result agrees with the suggestion that dipolar interactions are important in stabilizing the local ordering, as discussed in previous section. In addition, the fraction of birefringence remaining increases with the increase in glass transition temperature of the polymer. This observation is reasonable because the orientational ordering conserved in the polymer will depend on the difference between the operating temperature and the glass transition temperature.

Conclusion

The saturated levels of birefringence were found to increase with the increase in dipole moment of the azo moiety in the azo polymers. In addition, the fraction of birefringence conserved after relaxation also follows the same trend as the dipole moment and glass transition temperature. The writing and relaxation behaviors were found to be related to the dipole moment of the azo moiety, the glass transition temperature, and the molecular weight of the polymer. From a practical point of view, the azo moiety with donor/acceptor arrangement (pseudo-stilbene-type azobenzene) gives the best optical properties. The pseudo-stilbene-type azobenzene offers the advantages of fast *trans–cis–trans* isomerization and strong dipolar interactions, which are important for the optically induced ordering and stability.

Abstract: The H/D exchange reactions occurring on collision of protonated alkylbenzenes with C_2H_5OD, CH_3OD, and D_2O at low collision energies in the quadrupole collision cell of a hybrid tandem mass spectrometer have been studied for 22 alkylbenzenes. The exchange reactions with D_2O are much less efficient than the exchange reactions with C_2H_5OD or CH_3OD; this difference is rationalized on energetics grounds. The H/D exchange of the protonated alkylbenzenes with C_2H_5OD or CH_3OD leads, typically, to 40–70% deuterium incorporation in the protonated alkylbenzene and, for most cases, to significant ion signals corresponding to exchange of the added hydrogen and the aromatic hydrogens. Thus, the method is a feasible approach to counting the number of aromatic hydrogens in alkylbenzenes. The extent of exchange decreases with increasing size of the alkyl group in monoalkylbenzenes for reasons that are not readily understood.

Key words: protonated alkylbenzenes, H/D exchange, reactive collisions.

Résumé : On a étudié les réactions d'échange H/D qui se produisent par collision d'alkylbenzènes protonés avec du C_2H_5OD, CH_3OD et D_2O, à de faibles énergies de collision dans la cellule de collision quadripolaire d'un spectromètre de masse hybride à tandem. Les réactions d'échange avec le D_2O sont beaucoup moins efficaces que les réactions d'échange avec le C_2H_5OH ou le CH_3OD; on rationalise cette différence sur la base des énergies. L'échange H/D des alkylbenzènes protonés avec le C_2H_5OD ou le CH_3OD conduit d'une façon typique à une incorporation de 40 à 70% de deutérium et, dans la plupart des cas, à des signaux ioniques significatifs correspondants à l'échange de l'hydrogène additionné et les hydrogènes aromatiques. Ainsi, il est possible d'utiliser cette méthode pour compter le nombre d'hydrogènes aromatiques dans les alkylbenzènes. Pour des raisons qui ne sont pas bien comprises, le taux d'échange diminue avec une augmentation de la grosseur du groupe alkyle des monoalkylbenzènes.

Mots clés : alkylbenzènes protonés, échange H/D, collisions réactives.

Introduction

The exchange of hydrogen for deuterium in organic molecules has been widely used in structural studies by mass spectrometry (1, 2) and in mechanistic studies in gas-phase ion chemistry (3). This exchange has frequently been carried out in solution prior to admission of the sample or in the inlet system when the sample and a deuterium-containing reagent are mixed. Soon after the development of chemical ionization (CI) (4) it was clearly shown (5, 6) that H/D exchange reactions can occur in the ion source of the mass spectrometer under CI conditions. The simplest of these exchange processes involves the exchange of all the labile hydrogens in a molecule using a deuterated reagent gas such as D_2O, CH_3OD, or ND_3 (5–14). It also has been shown that protonated aromatic hydrocarbons exchange the aromatic hydrogens when D_2O, CH_3OD, or C_2H_5OD are used as chemical ionization reagents (15–19) and such exchange reactions have been developed into a method for identifying alkyl aromatic isomers (18, 19).

More recently, there has been an interest in separating the ionization event from the isotopic exchange event using tandem mass spectrometry. In this approach ions produced by any ionization means are mass-selected and react with a deuterium-containing reagent gas at low collision energies in a suitable gas-phase collision cell. Using a triple quadrupole mass spectrometer, Ranasinghe et al. (20) showed that the number of active hydrogens in a variety of aromatic compounds could be determined from the mass shift that occurred when the protonated species, formed by CI, was allowed to collide with ND_3 at low collision energies in the quadrupole collision cell. Dookeran and Harrison (21) have carried out a more detailed study of the H/D exchange reactions of protonated aromatic amines with ND_3 in the quadrupole collision

cell of a hybrid tandem BEqQ (see experimental section) mass spectrometer. The H/D exchange reactions of protonated peptides with ND_3 at low collision energies in the collision cell of a tandem four-sector mass spectrometer have been studied by Cheng and Fenselau (22) while the exchange reactions of protonated peptides with CD_3OD have been investigated by Gard et al. (23) using ion cyclotron resonance (ICR) techniques. The H/D exchange reactions of protonated amino acids and peptides with ND_3 in the quadrupole collision cell of a hybrid tandem mass spectrometer also have been studied (24). Nourse et al. (25) have obtained some distinction among methylguanine isomers from the rate and extent of H/D exchange of mass-selected MH^+ ions with D_2O in a Fourier transform mass spectrometer. In the negative ion mode, Ni and Harrison (26) have shown that the number of enolic hydrogens in enolate ions can be counted from the H/D exchange of the enolate ions with CH_3OD or C_2H_5OD in the quadrupole collision cell of a tandem hybrid BEqQ mass spectrometer. Chan and Enke (27) have shown that the $[M - H]^-$ ions of the three dichlorobenzenes give distinctive H/D exchange patterns on reaction with D_2O or ND_3 in the collision cell of a triple quadrupole mass spectrometer.

Of particular relevance to the present work is the report by Stone (28) of a study of the H/D exchange reactions of protonated aromatic hydrocarbons with D_2O and CD_3OD in the quadrupole collision cell of a triple quadrupole mass spectrometer. In general, rather little exchange was observed, suggesting that the tandem mass spectrometric approach was clearly inferior to the chemical ionization approach (19, 20) to counting hydrogens in aromatic hydrocarbons. The present study presents a detailed study of the H/D exchange reactions of protonated aromatic hydrocarbons with D_2O, CH_3OD, and C_2H_5OD and presents a more optimistic evaluation of the tandem mass spectrometric approach to counting the aromatic hydrogens in alkylbenzenes.

Experimental

All experimental work was carried out using a VG Analytical ZAB-2FQ hybrid BEqQ mass spectrometer, which has been described in detail previously (29). Briefly, this instrument is a reversed-geometry (BE) double-focussing mass spectrometer that is followed by a deceleration lens system, an r.f.-only quadrupole collision cell (q), and a quadrupole mass analyzer (Q). The appropriate MH^+ ions were mass-selected by the BE double-focussing mass spectrometer at 6 keV ion energy, decelerated to a kinetic energy of 3 eV (laboratory scale), and introduced into the quadrupole collision cell, which contained C_2H_5OD, CH_3OD, or D_2O at an indicated pressure of 3×10^{-5} Torr (1 Torr = 133.3 Pa) as read by the ionization gauge attached to the pumping line leading from the quadrupole stage. It is estimated that the actual pressure in the collision cell is 100–1000 times the indicated pressure. The reaction products were analyzed by the final quadrupole mass spectrometer; the resulting mass spectra were accumulated on a multi-channel analyzer with, typically, 25–50 2-s scans being accumulated.

The incident ion kinetic energy and the pressure of reactant gas in the collision cell are the two major parameters that determine the extent of H/D exchange. Earlier studies (21, 24, 26) have shown that incident ion energies in the range of 1–5 eV (laboratory scale) give a reasonable extent of exchange with higher ion energies affording better sensitivity because of greater transmission of the incident ion beam; the present experiments were carried out at 3 eV incident ion energy. The method used to establish this ion energy in a reproducible fashion has been presented in detail previously (21, 26). The rate of H/D exchange of the protonated alkylbenzenes was found to be comparable to that of the enolate ions studied previously (26) with the result that we used the maximum indicated pressures (3×10^{-5} Torr) of deuterated reagent gas that were attainable with the existing experimental configuration. This pressure is about a factor of 10 higher than was used for the exchange of the labile hydrogens of protonated aromatic amines (21) or protonated amino acids (24) with ND_3. Since the ionization cross section is expected to be greatest for C_2H_5OD and least for D_2O (30), the use of the same indicated pressure means that the actual collision cell pressure was least for the alcohol and greatest for D_2O; despite the higher D_2O pressure the exchange with D_2O was the least efficient, as discussed below.

The MH^+ ions of the alkylbenzenes were produced by Brønsted acid chemical ionization using CH_4 as the reagent gas. The EI/CI source was operated in the CI mode at 200°C and an ionizing electron energy of 100 eV. The alkylbenzenes were introduced through a heated inlet system while the CH_4 was introduced through the CI reagent gas inlet. All chemicals were obtained from Aldrich Chemical Co. and were used as received. The listed isotopic purities of the deuterium-containing reagents were D_2O (99.9 at.% D), CH_3OD (99.5 at.% D), and C_2H_5OD (99.5 at.% D).

Results and discussion

The results obtained for the exchange of 22 protonated alkylbenzenes with C_2H_5OD, CH_3OD, and D_2O are presented in Tables 1–3. The final column of each table records the extent of exchange expressed as the percent deuterium incorporation (% D.I.) defined as

$$[1] \quad \%\ \text{D.I.} = \left(\sum_{r=0}^{n-1} r I_r / n \sum_{r=0}^{n-1} I_r \right) \times 100$$

where n is the number of peaks in the cluster (including the unexchanged MH^+ ion) and I_r is the relative intensity for the peak containing r deuterium atoms. The relative ion signals were reproducible to within 10% from day to day.

With either C_2H_5OD or CH_3OD as exchange gas, the extent of exchange was sufficient that, in most cases, one observed an appreciable ion signal corresponding to exchange of the hydrogen added in the ionization step plus all the hydrogens bonded to the aromatic ring. The extent of exchange with D_2O was considerably less; the reasons for this will be discussed below. For the protonated C_4-alkylbenzenes reacting with C_2H_5OD, peaks were observed that suggest exchange of more hydrogens than the aromatic hydrogens and the hydrogen added in the ionization step. Thus, for the protonated diethylbenzenes and methylpropylbenzene, where one would expect $d_5[MH]^+$ as the most highly exchanged ion signal, weak signals were observed that corresponded, nominally, to ions containing six, seven, and eight deuteriums. These appear to be the cluster ions $(C_2H_5OD)_2(C_2H_5OH)H^+$, $(C_2H_5OD)_3H^+$, and

$(C_2H_5OD)_3D^+$, arising either by endothermic proton transfer to C_2H_5OD followed by exchange and clustering at the pressures existing in the collision cell or by the reaction sequence

[2] $ArH^+ + ROD \rightarrow Ar \text{ --- } H^+O(D)R$

[3] $Ar \text{ --- } H^+O(D)R + ROD \rightarrow Ar + (ROD)_2H^+$

followed by further clustering. Both reactions [2] and [3] are likely to be exothermic. For the protonated butylbenzenes it is not clear whether the apparent $d_6[MH]^+$ ion signal is a totally exchanged aromatic species or is an ethanol cluster ion; consequently, this ion signal was not included in the evaluation of the % D.I. values. Similar weak interference ions (not included in the table) were observed in the reaction of protonated toluene with CH_3OD and corresponded to $(CH_3OD)_3H^+$ and $(CH_3OD)_3D^+$ (these species are isobaric with $d_7[MH]^+$ and $d_8[MH]^+$). Such cluster ions were generally observed for both the alcohol systems but only in a limited number of cases do they create uncertainty as to the number of exchangeable hydrogens. As Hawthorne and Miller (18) have noted in CI studies, the use of CH_3OD as the exchange gas gives lower mass cluster ions and affords fewer interferences. Unexpectedly, weak signals corresponding, nominally, to $d_7[MH]^+$ and $d_8[MH]^+$ also were observed in the exchange of the MH^+ ion of toluene, ethylbenzene, and *n*-propylbenzene with C_2H_5OD. The origin of these ion signals is not clear.

The extent of exchange we have observed is considerably greater than that reported by Stone (28). For the reaction of protonated toluene, the protonated xylenes, and protonated mesitylene with CD_3OD, Stone's results correspond to percent deuterium incorporations in the range 6–14% while we observe 60–70% deuterium incorporation on reaction of the protonated species with CH_3OD. Stone also reported that protonated i-propylbenzene was unreactive with CD_3OD while we observe 34% deuterium incorporation on reaction with CH_3OD. With D_2O as the collision gas, Stone's data give 2–4% deuterium incorporation in the protonated xylenes compared to the present values of 30–40%. Since the extent of exchange depends on a number of parameters such as pressure and incident ion energy, the exact origin of these differences is difficult to establish. Stone's results were reported for a nominal collision energy of 0 eV, however, he later noted (private communication, 1993) that it was necessary to apply a bias of +10 V to the quadrupole collision cell to reduce the primary ion beam intensity to zero, indicating that the incident ion energy in the "0" eV collisions was higher than supposed. It has been shown in this laboratory (24, 26) that the extent of deuterium incorporation decreases markedly with increasing incident ion energy and it is likely that the differences between the present data and those of Stone (28) arise, in part, from differences in the incident ion energy.

Hawthorne and Miller (18) have reported a detailed study of the exchange reactions of alkylbenzenes with CH_3OD under chemical ionization (CI) conditions and it is of interest to compare the present results with their data. In their study the MD^+ ion is formed in the initial ionization step and it is this species that subsequently undergoes gas-phase H/D exchange reactions with CH_3OD. From their data one can calculate the percent deuterium incorporation in the MD^+ ion. These % D.I. figures are comparable to ours with two exceptions. Hawthorne and Miller (18) reported that *meta*-substituted alkylbenzenes showed distinctly less exchange than the *ortho* or *para* isomers. Thus, from their data one obtains the following

% D.I. values: *o*-xylene (73), *m*-xylene (58), *p*-xylene (75), 1,2,3-trimethylbenzene (57), 1,2,4-trimethylbenzene (60), mesitylene (29). In contrast, we observe similar extents of exchange for the three xylenes and for the three trimethylbenzenes not only with CH_3OD reagent gas but also with C_2H_5OD and with D_2O as reagent gases.

On the other hand we do observe a significant decrease in the extent of H/D exchange for monoalkylbenzenes as the size of the alkyl group increases. Thus, with C_2H_5OD as the reagent gas, we observe 65% D.I. for protonated toluene, 56% D.I. for protonated ethylbenzene, 40% D.I. for protonated *n*-propylbenzene, 23% D.I. for protonated i-propylbenzene and 24–28% D.I. for the protonated butylbenzenes. A similar decrease with increasing alkyl group size also is observed when CH_3OD is the reagent gas. Such a decrease of extent of exchange with increasing alkyl group size was not observed by Hawthorne and Miller (18) using CH_3OD CI. In their work *n*-hexyl and *n*-pentyl benzene showed similar extents of exchange as the propyl benzenes and all showed a greater extent of exchange than ethylbenzene. The effect of the alkyl group size in the present work is not a mass effect since the protonated trimethylbenzenes and protonated methylethylbenzenes show considerably higher % D.I. values than do the protonated propyl benzenes, while the protonated tetramethylbenzenes and diethylbenzenes show a much greater extent of exchange than do the protonated butylbenzenes. (It might be noted, in passing, that the exchange reactions of protonated *tert*-butylbenzene could not be studied because of the low intensity of MH^+ in the CH_4 CI mass spectrum (31).

There is substantial evidence (17, 32, 33) that H/D exchange occurs by the general mechanism shown in Scheme 1 for a

Scheme 1.

$$MH_n^+ + DOR \rightarrow MH_n^+ \cdots DOR \rightarrow MH_{n-1} \cdots HDOR^+$$

$$\downarrow$$

$$MH_{n-1}D^+ + HOR \leftarrow MH_{n-1}D^+ \cdots HOR$$

species with *n* interchangeable hydrogens interacting with ROD. An essential requirement is that proton transfer from MH_n^+ to ROD be endothermic, otherwise simple proton transfer will occur. A plausible potential energy surface for exchange is shown in Fig. 1. The energy of the intermediate $[MH_{n-1} \cdots HDOR^+]$, relative to the separated species MH_{n-1} + $RODH^+$, is determined by the strength of the ion/neutral interaction. If this interaction energy is less than the difference in the energy between MH_{n-1} + $RODH^+$ and MH_n^+ + ROD, which is given by the difference in proton affinities of MH_{n-1} and ROD, the intermediate $[MH_{n-1} \cdots HDOR^+]$ will not be accessible for thermal energy reactants and H/D exchange will not occur. Table 4 lists the proton affinities of C_2H_5OH, CH_3OH, H_2O, and those alkylbenzenes for which proton affinities have been recorded (34). As these data show, proton transfer from a protonated alkylbenzene to H_2O (D_2O) is 23 kcal mol^{-1} (toluene) to 34 kcal mol^{-1} (mesitylene) endothermic. Since the bonding energy in the $[MH_{n-1} \cdots HD_2O^+]$ complex is likely to be less than 20 kcal mol^{-1}, it is not surprising that H/D exchange of protonated alkylbenzenes with D_2O is inefficient. Only reactants with excess energy should be able to surmount the central energy barrier. On the other hand, proton transfer from protonated alkylbenzenes to CH_3OH (CH_3OD) is 8–19 kcal mol^{-1} endothermic and to C_2H_5OH (C_2H_5OD) is 2–12 kcal mol^{-1} endothermic. Thus, for these systems, the $[MH_{n-1} \cdots HDOR^+]$ complex should be accessible and H/D exchange should occur relatively efficiently.

Fig. 1. Schematic potential energy surface for H/D exchange between MH_n^+ and ROD.

[a]From ref. 34.

The energetics argument cannot rationalize the relatively poorer exchange of the larger monalkylbenzenes. However, to exchange all aromatic hydrogens it is necessary that all ring positions be sampled, either by a hydrogen ring walk (35) in the protonated species or by interaction of the $HDOR^+$ moiety in the intermediate complex with all different positions of the aromatic ring. Although it is known (35) that hydrogen randomization by the ring walk mechanism is relatively facile for protonated benzene, toluene, and the xylenes, it is possible that hydrogen randomization becomes less facile as the size of the alkyl group increases. This could arise if the charge site is localized through ion – induced dipole interactions with the more readily polarized larger alkyl groups. It is not clear why similar effects of alkyl group size were not observed by Hawthorne and Miller.

The reaction of some *endo*-5-acetyl norborn-2-enes with benzene thiol: a thermally induced non-allylic [1,3]-acetyl shift, as anticipated by a photochemical precedent

Johannes Leitich, Ingeborg Heise, and Kurt Schaffner

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Abstract: The thermal reaction of benzene thiol with *rac*-1-(4a*S**,5*R**,8*S**,8a*R**-5,8-methano-1,2,3,4,4a,5,8,8a-octahydro-4a-naphthyl)ethanone (**10***b*), an *endo*-5-acetylnorborn-2-ene with a particularly close distance between one olefinic carbon and the keto carbon, and with its 8a*S** epimer **10***a*, has been investigated. Besides the conventional unrearranged adducts **16***a*, *b* and **17***a*, *b* of the thiol to the C=C bonds of **10***a*, *b*, an adduct **18** was formed from **10***b* that involved a [1,3]-acetyl shift; no other products were formed. The dependence of adduct ratios on thiol concentration is consistent with two competing reactions of an intermediate radical **14***b* formed by addition of thiyl radical to the C=C bond of **10***b*, namely, abstraction of hydrogen from thiol (which is the conventional reaction path) vs. intramolecular attack of the radical on the keto group inducing the [1,3] shift of the latter. This shift constitutes an intramolecular variety of the known alkyl transposition reaction of ketones initiated by a reversible attack of an alkyl radical on a keto carbonyl group to generate an intermediate *tert*-alkoxyl radical; however, it is very much faster than the intermolecular reaction and corresponds to an effective molarity between 10^7 and 10^{10}. These findings have a bearing on the mechanism of photorearrangements homologous to the ODPM (oxa-di-π-methane) photorearrangement, such as ODPE (oxa-di-π-ethane) and higher homologues, in that they support a two-step mechanism involving this type of acyl shift.

Key words: oxadi-π-methane photorearrangement; oxadi-π-ethane photorearrangement; acetyl shift, non-allylic [1,3]; thiol, addition to C=C bonds; norbornenes.

Résumé : On a étudié la réaction thermique du benzènethiol avec le *rac*-1-(4a*S**,5*R**,8*S**,8a*R**-5,8-méthano-1,2,3,4,4a,5,8,8a-octahydro-4a-naphtyl)éthanone (**10***b*), un *endo*-5-acétylnorborn-2-ène comportant une distance particulièrement courte entre le carbone oléfinique et le carbone cétonique, ainsi qu'avec son épimère 8a*S**, **10***a*. En plus des adduits conventionnels non réarrangés (**16***a* et *b* et **17***a* et *b*) du thiol sur les doubles liaisons C=C des produits **10***a* et *b*, il se forme un adduit **18** à partir du produit **10***b* qui implique un déplacement [1,3] d'acétyle; il ne se forme aucun autre produit. La relation entre les rapports d'adduits et la concentration en thiol est en accord avec l'existence de deux réactions en compétition d'un intermédiaire radicalaire **14***b* qui se formerait par l'addition du radical thiyle sur la double liaison C=C du composé **10***b*, à savoir l'enlèvement d'un hydrogène à partir du thiol (qui est le chemin réactionnel normal) vs. une attaque intramoléculaire du radical sur le groupe cétonique induisant un déplacement [1,3] de ce dernier. Ce déplacement constitue une variété intramoléculaire de la réaction de transposition connue des groupes alkyles des cétones initiées par une attaque réversible d'un radical alkyle sur un groupe carbonyle d'une cétone pour générer un intermédiaire radicalaire *tert*-alkoxyle; toutefois, il est beaucoup plus rapide que celui de la réaction intermoléculaire et il correspond à une molarité effective intermédiaire entre 10^7 et 10^{10}. Puisqu'ils offrent un support pour un mécanisme à deux étapes impliquant ce type de déplacements de groupes acyles, les résultats obtenus ont une relation avec le mécanisme des photoréarrangements homologues du photoréarrangement ODPM (oxa-di-π-méthane), comme les réarrangements ODPE (oxa-di-π-éthane) et ceux de leurs homologues supérieurs.

Mots clés : photoréarrangement oxadi-π-méthane, photoréarrangement oxadi-π-éthane, déplacement non allylique [1,3] d'acétyle, addition de thiol sur des liaisons C=C, norbornènes.

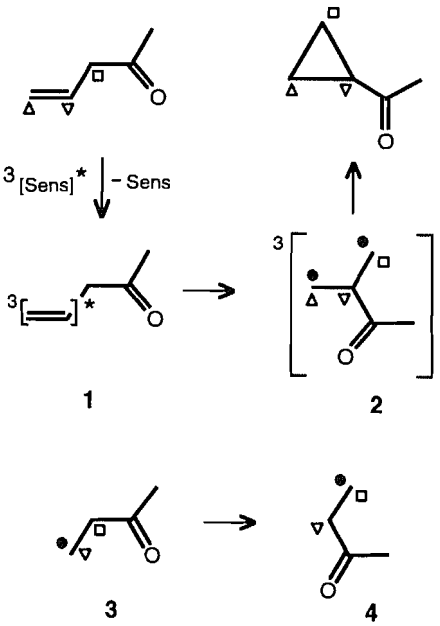
Scheme 1.



Background: ODPM- and free-radical-induced [1,2]-acyl shifts

The rearrangement of many β,γ-unsaturated ketones to give, via [1,2]-migration of an acyl (i.e., alkylketo) moiety, α-cyclopropyl ketones ("oxa-di-π-methane" (ODPM) rearrangement, Scheme 1) is a well-known photoreaction (for reviews, see ref. 1). It is most frequently encountered in triplet sensitization, and in the context of the present work we shall refer to the triplet-sensitized reaction only. Evidence has been obtained for a reactive state **1** that is characterized by $^3(\pi, \pi^*)$ excitation residing predominantly in the olefinic moiety of the unsaturated ketone (2). Stereochemical evidence suggests the intermediacy of the triplet 1,3-diradical **2** (3). In the case of systems with isolated olefinic double bonds, the ODPM rearrangement has been found to be efficient only when the olefinic double bond is part of a ring that constrains the double bond into planarity and thus prevents it from adopting, in its $^3(\pi, \pi^*)$ state, the energetically more favourable and, presumably, shorter lived perpendicular conformation (1).

Recently, Caldwell et al. presented evidence that perpendicular $^3(\pi, \pi^*)$ states of some typical olefins are quite accurately described as 1,2-diradicals (4), in view of both their heats of formation (4*a*) and of their reactivity (4*b*). If an olefinic double bond formed part of a ring that constrained it into planarity, the heat of formation of its triplet state was found to be higher than expected for a 1,2-diradical by several kcal/mol (4*a*) and its reactions faster by one order of magnitude or more (for simplicity, we shall call this difference the "non-perpendicularity effect"), but qualitatively its reactivity still resembled that of a (bi)radical (4*b*). This immediately links the [1,2]-acyl migration step **1** → **2** (ODPM) to the well-known [1,2]-acyl migration **3** → **4**, which is observed in monoradicals derived from dialkyl ketones and for which, in two cases, first-order rate constants and Arrhenius parameters have been measured (5). The step **1** → **2** can thus be viewed as being essentially a migration **3** → **4** with its rate being strongly enhanced by the non-perpendicularity effect.

Norborn-2-en-5-one (**6**) may serve as an example for which both bonds of [1,2]-acyl shifts have been described (Scheme 2). Firstly, **6** gives ODPM efficiently (6). Secondly, the free radical **7** formed by addition of benzene thiyl radical to the C=C bond of **6** gives the free-radical-induced [1,2]-acyl shift. Thiols are known to add across C=C bonds via a free-radical chain mechanism involving reversible addition of a thiyl radical to the C=C bond to give a carbon-centered radical that subsequently abstracts hydrogen from thiol to give the final addition product, thereby regenerating the thiyl radical (7, 8). Thus, norbornene with benzene thiol (PhSH) reacts exothermally after an induction period to form exclusively the *exo* adduct **5** (8, 9). In the case of **6**, reaction with benzene thiol gives, besides the two regioisomeric unrearranged *exo* adducts analogous to **5**, the rearranged adduct **9**, which clearly results from the intermediate **7** by a [1,2]-acyl shift to give **8** before hydrogen abstraction. As the product ratios are independent of thiol concentration (0.1–4.5 M), the establishment of an equilibrium between **7** and **8** before hydrogen abstraction has been inferred (10).

Introduction

We recently described norbornene systems undergoing "oxa-di-π-ethane" (ODPE) photorearrangements (11). These are homologous to the ODPM photorearrangements. They are encountered with γ,δ- rather than β,γ-unsaturated ketones, and they undergo a [1,3]- rather than a [1,2]-acyl migration, leading ultimately to α-cyclobutyl rather than to α-cyclopropyl ketones (**10** → **12**, Scheme 3). The excited state characteristics of the ODPE also resemble those of the ODPM rearrangements in that ODPE occurs preferentially on triplet sensitization of the olefinic double bond, whereas the excitation of the carbonyl group by direct irradiation tends to give rise to a different photochemistry. This led us to conjecture a mechanism of the triplet-sensitized ODPE, shown in Scheme 3, analogous to that of the ODPM rearrangement shown in Scheme 1, and hence led us to formulate the rearrangement step ^{3}**10*** → **11**.

If this conjecture is correct, the monoradical **14** (Scheme 4) formed by addition of benzene thiyl radical to **10** might be expected to show a hitherto unobserved thermal nonallylic [1,3]-acyl migration, for reasons outlined above and in full analogy to the case of **6**. To test this, we chose two substrates, **10***a* and **10***b*, which differ in the stereochemistry of the fusion of a cyclohexane to the norbornene skeleton. Both substrates give ODPE, but **10***b* does so much more efficiently than **10***a* (11). The presumed reason for this is a twofold effect of the *trans* ring fusion in **10***b*: firstly, it exerts an extra strain that is relieved on acetyl migration, and secondly, it places the acetyl group closer to the C=C bond. Thus, the distance between the carbonyl C-atom to which it forms the new bond is 2.8 Å for **10***a* (according to models (12, 13)) but only 2.59 Å for **10***b* (by X-ray crystallography; R. Goddard and C. Krüger, personal communication). In either case, *a* or *b*, the thiol-induced acetyl migration would be anticipated to be much slower than the ODPE-induced migration because the latter would be accelerated by the non-perpendicularity effect.

Results and discussion

Heating a 1:1 molar mixture of **10***a* and benzene thiol, either neat or 0.2 M in acetonitrile and at complete or partial conver-

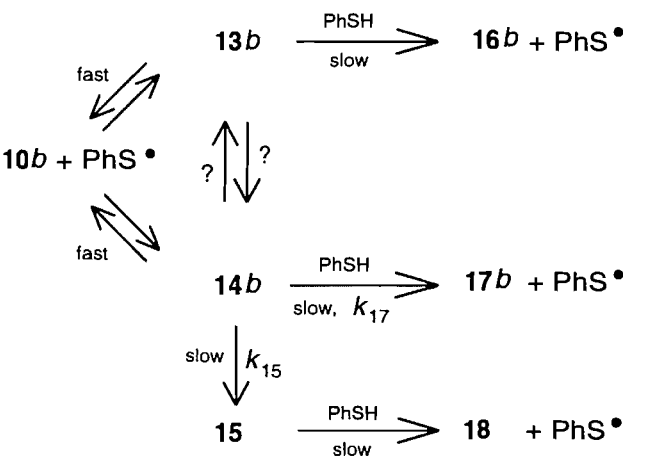
sion, gave a 1:2 mixture of the two unrearranged *exo* addition products **16***a* and **17***a* and no indication of acetyl migration (Scheme 4). With **10***b*, however, a rearranged addition product of structure **18** was obtained, as well as a mixture of the two

Scheme 5.



unrearranged *exo* addition products **16***b* and **17***b*. **18** obviously arose from **14***b* via the anticipated [1,3]-acetyl migration to give the radical **15**, which then abstracted hydrogen from benzene thiol on the *exo* side of the norbornane moiety. The product ratio [**17***b*]/[**18**] varied proportionally to [PhSH] and thus covered a range of 0.1–0.8 (see Table 1). The product ratio [**16***b*]/[**17***b*], on the other hand, did not change significantly with [PhSH] under the same conditions and amounted to 1.97 ± 0.27 (95% probability level). These findings are consistent with a reaction scheme (Scheme 5) that features: (*a*) a competition between the rearrangement **14***b* → **15** and the reaction of **14***b* with PhSH to give **17***b*; (*b*) a fast equilibration between radicals **13***b* and **14***b* before further reaction, probably by fast addition/elimination of PhS˙ (7, 8), although a direct interconversion **13***b* ⇆ **14***b* cannot be ruled out. The irreversibility of the rearrangement **14***b* → **15**, which contrasts to the reversibility **7** ⇆ **8**, is in line with the strain release on going from **14***b* to **15**, and the difference in the rearrangement propensity between *a* and *b* conforms with the relative ODPE behaviour of **10***a* vs. **10***b*.

As can be derived from Scheme 5, the value of 0.28 ± 0.06 M^{-1} for [**17***b*][**18**]$^{-1}$[PhSH]$_{av}^{-1}$ at 60°C (95% probability level; Table 1) can be equated to the ratio of the rate constants, k_{17}/k_{15}, of the two competing reactions of **14***b*. Assuming k_{17} to be equal to the rate constant for hydrogen abstraction from PhSH by isopropyl radical at 60°C, 1.4 × 10^8 M^{-1} s^{-1} (14), one obtains an estimate for k_{15} at 60°C of 5 × 10^8 s^{-1}. The analogous rate constant for **14***a* is estimated at <10^7 s^{-1}. If the first-order decay constant of ^{3}**10***b** to give **10***b* were tentatively

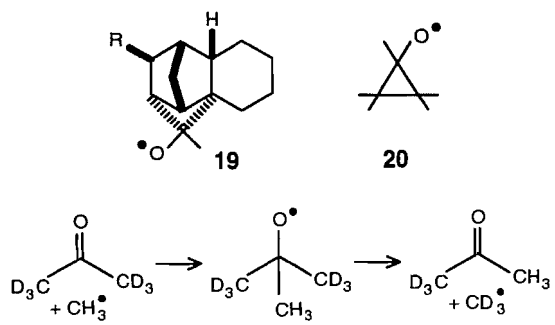
taken to be similar to that of its parent olefin, norbornene, i.e. $(250\ ns)^{-1} = 4 \times 10^6\ s^{-1}$ (15), the value for k_{15} of $5 \times 10^8\ s^{-1}$ could indeed have predicted the highly efficient ODPE rearrangement of ^{3}**10***b** via the mechanism of Scheme 3, even without invoking the acceleration by the non-perpendicularity effect.

One conceivable mechanism for the rearrangement **14***b* → **15** would involve elimination of acetyl radical from **14***b* with simultaneous ring closure to form a cyclopropane, followed by ring-opening attack of the acetyl radical on the cyclopropane, to give **15**. To check this possibility, we studied the behaviour of quadricyclane (tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane, a model compound for the putative cyclopropane intermediate) towards acetyl radical generated from acetaldehyde in a radical chain reaction (16). For conditions under which norbornene cleanly added acetaldehyde in such a radical chain reaction to give *exo*-2-acetyl norbornane (as described previously in ref. 17), quadricyclane remained unchanged. Hence, any reaction of acetyl radical with quadricyclane must be much slower than diffusion controlled. Since our putative cyclopropane intermediate would liberate less strain energy on ring opening than would quadricyclane and hence would be expected to react even less readily with acetyl radical than the latter, this finding effectively rules out the envisaged mechanism for the rearrangement **14***b* → **15** as the reaction products comprise only **16***b*, **17***b*, and **18** but no acetyl-free compound. For the ODPE rearrangement **10** → **12**, also, such a mechanism can be excluded since it would be expected to lead preferentially not to **12** but instead to an isomer of **12** containing a cyclopropane ring. As a consequence, there remains no reasonable mechanism for the rearrangement **14***b* → **15** other than via the bridged structure **19** (Scheme 6; R = PhS); analogously, ^{3}**10***b** → **11***b* must proceed via **19** (R = ·). Thus, the rearrangement **14***b* → **15** is an intramolecular variety of the known free-radical alkyl displacement reaction of ketones (18) of which Scheme 6 shows one example (19).

The rate constant of ca. $5 \times 10^8\ s^{-1}$ at 60°C for **14***b* → **15**, however, is much higher than that of the reaction shown in Scheme 6, $\log_{10}(kMs) = (7.5 \pm 0.5) - (11\ 500 \pm 1100)/4.576T$ (19), which corresponds to a pseudo-first-order rate constant in acetone at 60°C of 0.6–180 s^{-1}. Hence, the effective concentration of **14***b* amounts to an impressive 10^7–10^{10} M. This again emphasizes the importance of a short distance between the bond-forming carbon atoms and (or) of molecular strain acting as a driving force. The role of **19** as an intermediate or a transition state parallels that of **20** (rather than an acyl radical – olefin geminate pair) in the [1,2]-acyl shifts (5*b*) and in the ODPM rearrangements (1). Moreover, one may anticipate [1,*n*]-acyl shifts with $n > 3$ via species homologous to **19** provided the conditions of close distance plus favourable relative orbital orientation plus favourable thermodynamics be fulfilled. Indeed, one case of an "oxa-di-π-propane" photorearrangement, homologous to both ODPM and ODPE and featuring a [1,4]-acyl shift, was described as early as 1977 (20). Molecular models of the unsaturated ketone giving this rearrangement confirm the close distance and favourable orbital orientation between the carbonyl C-atom and the olefinic C-atom to which it forms the new bond; they bring to light a prohibitively unfavourable and inflexible relative orientation (pointing away from each other) of those two orbitals that are to form the second new C—C bond. This argues against the concerted mechanism suggested by Hayakawa et al. (20) but is perfectly in line with a two-step mechanism analogous to Schemes 1 and 3.

Scheme 6.



Elucidation of molecular structures

Of each new compound, the following NMR spectra were obtained: 400 MHz ^{1}H, 100 MHz ^{13}C (Broad Band decoupled

(BB) and Distortionless Enhancement by Polarization Transfer (DEPT)), and $^1H/^{13}C$ Correlation Spectroscopy (CH-COSY). Moreover, $^1H/^1H$ spin–spin decoupling and $^1H/^1H$ NOE (Nuclear Overhauser Effect) experiments were carried out whenever instructive. These NMR spectroscopic data, together with IR, UV, the analytical data, and base-catalyzed H/D exchange experiments, sufficed to derived the complete molecular structures of all new compounds independently of each other. This includes also the compounds mentioned below. The structural work was facilitated by the following empirically established NMR assignments (13, 21): Firstly, one particular NMR pattern common to all new compounds, namely, a CH_2 group showing a geminal $J_{H,H}$ value of 8.5–10.5 Hz, each of the two hydrogen atoms being further coupled weakly (1.4–1.8 Hz) to two methine hydrogen atoms that show a mutual coupling of 1.1–1.7 Hz. This feature is characteristic of the bridge $-CH_a.CH_2.CH_b-$ in norborn(a,e)nes. Secondly, values of 2–5 Hz and 0–1 Hz, respectively, which are characteristic for $^3J_{HH}$ of norborn(a,e)ne bridgehead protons with norborn(a,e)ne *exo* and *endo* protons, respectively. Thirdly, a characteristic long-range coupling of 1.5–3.5 Hz between norborn(a,e)ne *endo* protons and the one norborn(a,e)ne methano-bridge proton that is *anti* relative to them.

The following chemical transformations starting from **18** bear out the molecular structure of **18** as derived spectroscopically.

With stoichiometric amounts of strong base, **18** readily eliminated benzene thiol to give **21** (Scheme 7). This reaction occurred even with the traces of alkali present in commercial silica gel. With less than stoichiometric amounts of strong base, the remaining excess of **18** was recovered unchanged. In contrast to benzene thiol, sodium benzene thiolate in methanol left **10***b* unchanged. The latter two facts preclude the possibility of a catalytic conversion of **10***b* to **21** with benzene thiol plus base.

Compound **21** was also not entirely stable to alkali, but it added methanol under the influence of catalytic amounts of sodium methoxide to give at first a 7:3 equilibrium mixture of **21** and **24**. Much more slowly under the same conditions, this mixture changed into a 7:3:3 equilibrium mixture of **21**, **24**, and **25** (^1H NMR analysis). The latter mixture was also obtained starting from pure **25**. The formation of these secondary products in the preparation of **21** from **18** was avoided by the use of an excess of silver oxide as the base.

Both **23** (obtained by irradiation of **12***b* (11)) and **21** cleanly gave the same product, **22**, on catalytic hydrogenation. Catalytic amounts of sodium methoxide in methanol epimerized **22** to 98% **26**.

In perdeuterio methanol as a solvent, catalytic amounts of sodium methoxide exchanged the α-carbonyl *exo* methine protons of **22** and **24** for deuterons within minutes, whereas the exchange of the corresponding *endo* methine protons of **25** and **26** required many hours. In the case of compound **18**, benzene thiol elimination was even faster than proton exchange, which means that in alkaline media every enolate anion formed eliminated thiolate much faster than it was reprotonated.

Experimental

Instrumentation, general methods, and materials. General remarks

For NMR spectroscopy, the instruments and software were obtained from Bruker GmbH: for quantitative analyses of product mixtures, WH-270; all other measurements on AM-400. All spectra are in $CDCl_3$. In the following, δ values are given relative to internal tetramethylsilane (TMS) and apparent coupling constants are in Hz. "α" and "β" subscripts to H-atoms refer to *syn* and *anti* arrangements, respectively, relative to the norbornane methano bridge, in compliance with existing rules for nomenclature. This bridge is assigned the position number 9. The subscripts "a" and "b" of its H-atoms refer to *anti* and *syn* arrangements, respectively, relative to the unbridged cyclohexane ring. NOE enhancements are not mentioned if found between geminal or strongly coupled vicinal protons. UV spectra (in *n*-hexane) were recorded on an Omega-10 spectrophotometer (Bruins Instruments, Munich). IR spectra were obtained on a Perkin–Elmer 580 spectrophotometer. Electron impact mass spectra were obtained on a Finnigan MAT 8200 instrument using 70 eV electrons. Melting points were determined on a Kofler hot stage and are uncorrected. Elemental analyses were performed by H. Kolbe (formerly: Dornis u. Kolbe), Mülheim a.d. Ruhr. C, H, and S (where applicable) analyses were obtained for all new compounds; the maximum deviation was 0.26%, the average deviation was 0.11%.

Preparative chromatographic separations were carried out over silica gel 0.04–0.063 mm (Merck) with *n*-pentane, followed by *n*-pentane + 1% ether as the eluent. All solvents were technical grade and were redistilled before use. Benzene thiol was a commercial product whose purity, in particular the absence of diphenyl disulfide, was checked by ^1H NMR.

rac-*1-(1*R*,2*S*,4*R*,4a*S*,8a*S*-1,4-Methanodecahydro-2-naphthyl)ethanone (26)*

A solution of 120 mg (62.5 mmol) **22** and 13 mg (24 mmol) sodium methoxide in 4 mL methanol was left at room temperature for 5 days. After addition of water the mixture was extracted five times with diethyl ether. The combined ether layers, after washing with water, drying over anhydrous magnesium sulfate, and evaporation of the solvent, left 121 mg residue, composed, except for traces of ether, of 98% **26** and 2% **22** (^1H NMR analysis). The solution of the residue in *n*-pentane at −70°C deposited a solid, which was collected by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

inverse filtration. It became liquid at room temperature and was distilled (Kugelrohr, 0.1 Torr, bath temperature 80°C) to give 88.6 mg (74%) **26** as a colourless liquid. UV, λ_{max} (log ϵ): 282 (1.50), 291 (sh), 301 (sh), 314 nm (sh). IR (KBr): 1708 cm^{-1}. ^1H NMR: 2.67 (ddd; 8.9, 5.6, 1.2 Hz; exchangeable by D; 2-H), 2.31 (dddd; 4.2, 1.7, 1.5, 1.0 Hz; 1-H), 2.13 (tddd; 2 × 4.2, 1.7, 1.5, 1.0 Hz; 4-H), 2.09 (s; CH_3), 1.80 (tdd; 2 × 11.8, 5.8, 4.2 Hz; 8a-H), 1.69 (tddd; 2 × 11.8, 5.7, 4.2, 1.3 Hz; 4a-H), 1.66 (dddd; 13.0, 5.6, 4.2, 1.3 Hz; *exo*-3-H), 1.57 (ddd; 13.0, 8.9, 2.4 Hz; *endo*-3-H), 1.26 (dt; 9.7, 2 × 1.7 Hz; 9-H_a), 1.22 (dddt; 9.7, 2.4, 2 × 1.5, 1.2 Hz; 9-H_b), ca. 1.65 (5-H_α and 8-H_α), 1.30 (5-H_β and 8-H_β), ca. 1.30 and ca. 1.23 (each 2 H; 6-H and 7-H). NOE enhancements: 1-H/2-H, 1-H/methyl-H, 2-H/8-H_β, 2-H/methyl-H, *endo*-3-H/5-H_β. ^{13}C NMR: 210.5 (C=O), 48.1 (C-2), 44.3 (C-1), 40.6 (C-4), 39.3 (C-8a), 38.0 (C-4a), 37.1 (C-9), 28.6 (methyl-C), 25.4 (C-3), 20.24, 20.22, 20.20, 20.0 (C-5 through C-8). MS, *m/e*: 192 (7%, M^+), 174 (7%), 149 (100%), 67 (99%), 43 (46%).

Product ratios: from weighed amounts of reactants were determined by ^1H NMR, in situ in most cases; e.g., from **10***a* and benzene thiol in CD_3CN; from **18**, **21**, **24**, or **25** with sodium methoxide in CD_3OD.

*Analytical runs with **10**b and varied concentrations of benzene thiol*

For each run, 20 mg (0.105 mmol) **10***b* was placed in an NMR tube. This NMR tube was then equipped with a "Quickfit" glass head that allowed the following operations: Evacuation and filling of the NMR tube with Ar, addition by syringes of a measured volume of acetonitrile-d_3 followed by a measured volume of benzene thiol, and capping the tube, all under a steady slow stream of Ar. The NMR tubes thus prepared (sample volumes ca. 0.5 mL) were heated at 60°C for 2 h and then analyzed by ^1H NMR spectroscopy. The analysis was facilitated by the perfectly isolated signals at δ = 5.98 (**10***b*, 2 H), 4.10 (**18**), 3.94 (-SH), 3.49 (**17***b*), and 3.03 (**16***b*). No compounds besides these five and, in two cases, some diphenyl disulfide (δ = 7.5) were found to be present in any significant amount. Conversions of **10***b* varied (44–75%) since the radical chain reaction depends on adventitious catalysis for its start; this should, however, not affect the product ratios. $[PhSH]_0$ values, i.e., the concentrations of benzene thiol at the beginning of the reaction, were calculated from the volumes of benzene thiol added and its density (1.078 at 20°C); they were checked by ^1H NMR. In the first run, which featured the smallest volume of added PhSH of all runs, a discrepancy was noted and the NMR-based value was preferred over the volume-based one. In the calculations of $[\mathbf{17}b][\mathbf{18}]^{-1}[PhSH]_{av}^{-1}$ (= k_{17}/k_{15}) values (see Scheme 5 and Table 1, fifth column), average benzene thiol concentrations $[PhSH]_{av}$ were used that took into account the consumption of PhSH during reaction. Average values and their confidence limits were obtained from the fifth and sixth columns, respectively, of Table 1.

Free-radical chain addition experiments with aldehydes

Experiments were performed as described in the literature (16, 17) except that di-*tert*-butyl hyponitrite (DBH; 1,2-di-*tert*-butoxydiazene) (22) was used as the free-radical starter since it decomposes at somewhat lower temperature (23) than the commonly used starters (AIBN, diacyl peroxides), which is convenient when working with acetaldehyde (bp 21°C). Sodium hyponitrile was prepared via diazotation of hydroxylamine (24) and converted to silver hyponitrite by combining its aqueous solution with that of silver nitrate and collecting the precipitate; the silver hyponitrite was converted to DBH as described (22). Three vials, each containing a homogeneous mixture of 1 g acetaldehyde, 0.5 g substrate, and 50 mg DBH, degassed and under 1 atm of Ar (1 atm = 101.3 kPa), were left standing together at 20°C. The substrate was norbornene in the first, quadricyclane (purchased from Aldrich, pure according to ^1H NMR) in the second, and a 1:1 mixture of norbornene and quadricyclane in the third vial. After 93 h, in each case the norbornene was quantitatively converted to *exo*-2-acetyl-norbornane (17), identified by ^1H NMR comparison with an authentic sample prepared from 2-acetyl-5-norbornene, *endo,exo* mixture from Aldrich, via catalytic hydrogenation of the *exo* isomer; the quadricyclane, however, had remained entirely unchanged in each case (^1H NMR analysis). A similar reactivity difference was observed at 45°C using pivalaldehyde in place of acetaldehyde.

β-Trichlorosilylstyrene oligomers[1]

Michael A. Brook, Thomas Sebastian, Peter Hülser, Ralf Jüschke, Stefan Wenzel, Jennifer A. Townsend, and Patricia R. Falletta

Abstract: Under cationic conditions using triflic acid as the initiator, it is possible to oligomerize β-trichlorosilylstyrene **2** to low molecular weight oligomers **14** with a maximum degree of polymerization of about 9. Termination of the process was shown to occur by an intramolecular Friedel–Crafts reaction, leading to highly functionalized, indane-terminated oligomers **9**, **12**, etc. At lower temperatures, the reaction is diastereoselective. The oligomerization process was shown to require electron-withdrawing groups on silicon; the replacement of Cl spectator ligands with alkoxy or alkyl groups led to protiodesilylation. The mechanism for formation of the indane-terminated oligomers is discussed.

Key words: cationic polymerization, β-silylstyrene, stereoselective oligomerization, indene termination.

Résumé : Sous des conditions cationiques utilisant de l'acide triflique comme initiateur, il est possible de provoquer une oligomérisation du β-trichlorosilylstyrène, **2**, en oligomères **14** de bas poids moléculaire et comportant un degré maximal de polymérisation d'environ 9. On a montré que le processus de terminaison se produit par une réaction de Friedel–Crafts intramoléculaire conduisant à des oligomères **9**, **12**, etc. se terminant par des indanes hautement fonctionnalisés. À des températures plus basses, la réaction est diastéréosélective. On a montré que le processus d'oligomérisation nécessite la présence de groupes électroattracteurs sur le silicium; le remplacement des coordinateurs Cl agissant comme spectateurs par des groupes alkoxyles ou alkyles conduit à une protiodésilylation. On discute du mécanisme de formation des oligomères se terminant par un indane.

Mots clés : polymérisation cationique, β-silylstyrène, oligomérisation stéréosélective, terminaison par un indène.

[Traduit par le rédaction]

Introduction

Silicones possess very different properties from carbon-based polymers. Typically, they have very low glass transition temperatures (1), are relatively bioinert,[4] hydrophobic (2), and thermally stable. The presence of silicon in an organic polymer conveys some of these special properties to the composite material. Its incorporation into the polymer chain may be done in a variety of ways, including the formation of block copolymers of silicones and polyolefins under anionic (3) or other conditions (4), the use of a silicon-functionalized monomer in which the silicon is distal from the reactive site (e.g., *p*-$Me_3SiC_6H_4CH{=}CH_2$), by post polymerization grafting of a silicon-containing group (5),[5] or, inefficiently, by the direct polymerization of vinylsilanes (6). In most cases, advantage is taken of the fact that reactions at silicon tend to take place under ionic conditions. Thus, any radical processes used for polymerization do not affect the silicon moiety and ionic processes used to modify the silicon do not affect the polymer.[6]

We have been interested for some time in the addition of electrophiles to vinylsilanes. During the course of a study in which the addition of electrophiles to silicon-substituted styrenes was examined, we discovered that the nature of the groups on silicon dramatically affected the reactivity of the molecules (8). For example, although the addition of Friedel–

This paper is dedicated to Professor J.E. (Jim) Guillet in recognition of his contributions to Canadian chemistry.[2]

M.A. Brook,[3] **T. Sebastian, P. Hülser, R. Jüschke, S. Wenzel, J.A. Townsend, and P.R. Falletta.** Department of Chemistry, McMaster University, 1280 Main St. W., Hamilton, ON L8S 4M1, Canada.

[1] Part of the M.Sc. thesis of T.S.

[2] It is a tremendous pleasure to dedicate this paper to Jim Guillet. While an undergraduate, his teaching sparked my interest in polymers. He fostered that interest through his fascinating research activities and was tremendously supportive in my early efforts in polymer chemistry for all of which I am deeply grateful.

[4] This statement has become quite controversial given the current legal situation for manufacturers of silicone breast prostheses. A variety of detrimental aspects of silicones, particularly in their effect on the immune system, have been suggested. Nonetheless, comparable bioinertness has not been observed with other man-made polymers, and silicones remain constituents of pharmaceutical preparations, medical devices (non-implanted), etc.

[5] The introduction of silicon into polymers more commonly involved the radically induced grafting of the above monomers onto an existing polymer chain: Neste Öy produces a "moisture cure" polyethylene in this manner.

[6] It should, however, be noted that alkylsilyl groups (which lead to the first three properties outlined above) can participate in radical reactions via α-SiCH abstraction. These reactions are much less efficient than radical propagation of olefins. Functionalized silicon groups, in which Cl or OR groups are bound to silicon, readily react with water or nucleophiles. See ref. 7.

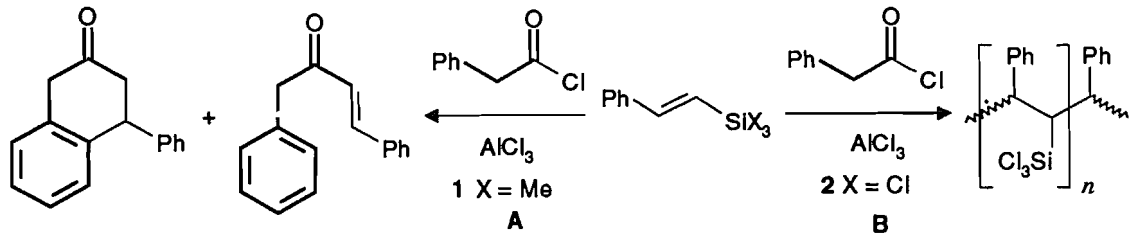
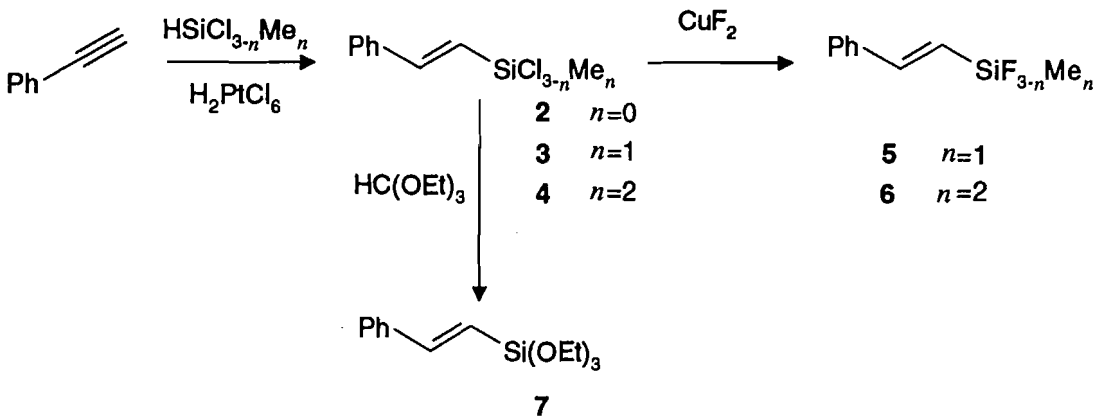
Scheme 1.



Scheme 2.



Crafts acylating agents to trimethylsilylstyrene **1** led to the mixture of addition and elimination products (Scheme 1A)(9, 10), addition of the same electrophile to the trichlorosilyl derivative **2** led to addition products (11) accompanied by a higher molecular weight material that was extremely difficult to characterize (Scheme 1B); elimination products were not observed.

Few polymers are based upon vinylsilanes. Although trichloro-, trimethyl-, and trimethoxyvinylsilane may be radically polymerized to give polymers (6), more highly substituted polymer chains have not been produced by the direct polymerization of vinylsilanes. One notable exception is the work of Weber and Chan who demonstrated that silylated butadienes can be polymerized (12). The difficulty in preparing highly substituted polymers is, of course, a problem that is not limited to vinylsilanes: the polymerization of 1,2-disubstituted olefins is normally difficult.

We have discovered that under cationic conditions, using triflic acid as the cationic initiator, it is possible to cleanly oligomerize β-trichlorosilylstyrene **2** (13). The mechanism of polymer formation and the properties of the resultant silicon-containing oligomers are described in the following sections.

Results and discussion

Preparation

As with many vinylsilanes, the preparative route of choice is hydrosilation of a precursor alkyne. This process, typically catalyzed with transition metal complexes (14), especially those derived from Pt (H_2PtCl_6, Speier's catalyst (15), and $Pt_2(H_2C{=}CHSiMe_2OSiMe_2CH{=}CH_2)_4$, Karstedt's catalyst (16)), is remarkably efficient and highly regio- and stereoselective. The hydrosilation of phenylacetylene with $HSiCl_3$ in the presence of H_2PtCl_6 (17) led to the production of **2** in 95% isolated yield after distillation (Scheme 2). Similarly, using $HSiMe_nCl_{3-n}$ (n = 1, 2) in the presence of H_2PtCl_6, **3** and **4** were cleanly prepared. Fluoro compounds **5** and **6** were synthesized by halide exchange of **2** and **3**, respectively, using CuF_2 (17). The completely methylated compound **1** was prepared by reaction of **2** with MeLi or MeMgBr. The ethoxylated compound **7** was prepared by the reaction of **2** with $HC(OEt)_3$ (18). The materials were purified by distillation.

Oligomerization

It is not possible to polymerize vinylchlorosilanes anionically: initiators such as n-BuLi preferentially react at silicon in an S_N2 fashion (this fact was used to prepare moisture-stable analogues, see below). To establish if **2** would polymerize under radical conditions, it was reacted with di-*tert*-butyl peroxide above the initiator decomposition temperature. It is not surprising that only unreacted starting materials were recovered; as noted above, the radical polymerization of 1,2-disubstituted olefins is generally quite difficult.

Having established that the higher molecular weight materials produced from the electrophilic addition of acylium ions to the styrylsilanes (Scheme 1) were not the result of radical reactions, an attempt was made to establish reproducible cationic conditions under which higher molecular weight materials could be prepared and to determine their structures.

Initiators for cationic polymerization are typically proton sources in which the counterion is non-nucleophilic (19). These can be classified into three groups: carbocationic initiators such as Meerwein's salts, stable cations ($Ph_3C^+X^-$), or Friedel–Crafts acylation reagents; Lewis acids contaminated with traces of water or alcohol (co-catalysts) that form a Brønsted acid in situ; or protonic acids. Initially, the first class of initiators was examined. However, the reaction of **2** with

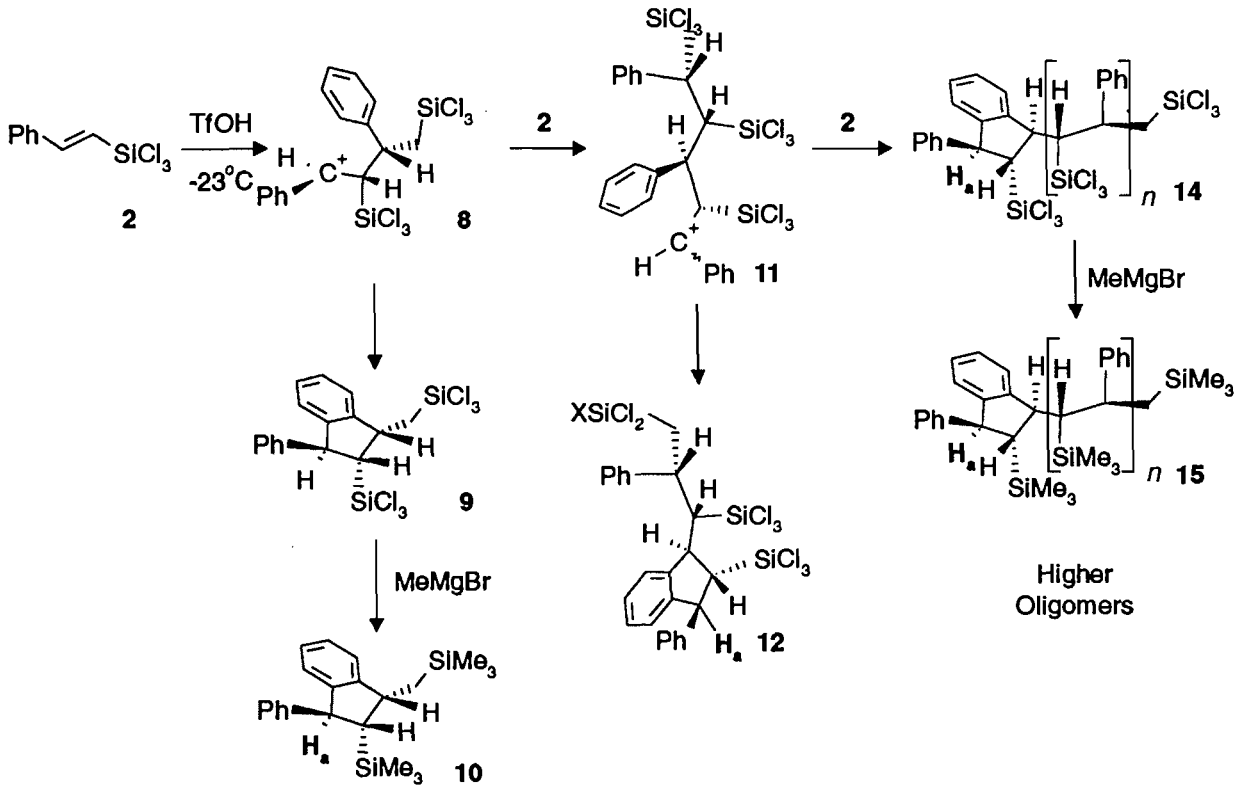
Scheme 3.



$Ph_3C^+BF_4^-$ or CH_3COCl–$AlCl_3$ as initiators[7] led to recovered starting materials or, in the latter case depending on the reaction conditions, an intractable tar. While it proved possible to produce oligomeric mixtures with the second class of initiators including $BF_3{\cdot}Et_2O$, $AlCl_3$, $ZnCl_2$, or $TiCl_4$, with water, EtOH, or MeOH as co-catalysts, these reactions were completely irreproducible. A systematic evaluation of the reaction parameters failed to provide a set of reaction conditions that would always lead to oligomers. The structure of these oligomeric materials was not examined in detail.

The use of strong acids including $HSbCl_6$, H_3PO_4, HBF_4, and HSO_3CF_3 (trifluoromethanesulfonic acid, triflic acid, TfOH) led to oligomeric materials **14** (Scheme 3). Oligomerization was favoured by the stronger acids: weaker acids with more nucleophilic counterions led to other processes including elimination at carbon and nucleophilic substitution at silicon. The only electrophile with which oligomerization was observed reproducibly was triflic acid.

Because of the instability to hydrolysis of the oligomeric products, the reaction mixture was converted to an air-stable mixture by reaction with MeLi or MeMgBr. Separation by flash chromatography and analysis by mass spectrometry allowed confirmation of the molecular weight dispersity of the reaction. The highest oligomer that could be clearly detected was a nonamer. Using GPC calibrated with polystyrene standards, the degree of polymerization of the reaction was shown to be very low (DP ca. 3, M_n 1000), although with rather large error bars given the low molecular weight of the compounds present.

[7] Elizabeth Jefferson and Michael A. Brook, unpublished results.

Solvent effects

Cationic polymerization clearly involves the intermediacy of at least a highly polarized or ionic species. Thus, the reaction outcome should be dependent upon solvent polarity. To examine this question, the reaction was attempted in a series of solvents (Table 1) of differing polarity varying from pentane (Table 3) to acetonitrile; the use of hydroxylic solvents is precluded because they lead to the exchange of functional groups on silicon. The catalyst used for initiation, triflic acid, is not very soluble in the less polar solvents examined (pentane, $HCCl_3$, and H_2CCl_2), and this was also a contributing factor to the reaction outcome. In the event, only in the chlorinated hydrocarbons was it possible to achieve acceptable, reproducible yields of oligomers. In polar solvents, huge amounts of catalyst were required to take the reaction to reasonable degrees of conversion; acetone and DMSO led to polymerization of acetone and of the chlorosilanes (20, 21), respectively.

Concentration effects

Acid and monomer concentration

Oligomerization only occurred with very high concentrations of monomer and, indeed, of initiator. At <5 mol% ratio of TfOH, conversion was incomplete (Table 1).[8] Thus, between 5 and 10 mol% of initiator was added. In the same way that hydroxylic solvents can lead to nucleophilic substitution at silicon (22), we believe that exchange of triflate and chloride can occur at silicon. The impact of such an exchange is the effec-

[8] These reactions were typically run with a saturated solution of triflic acid.

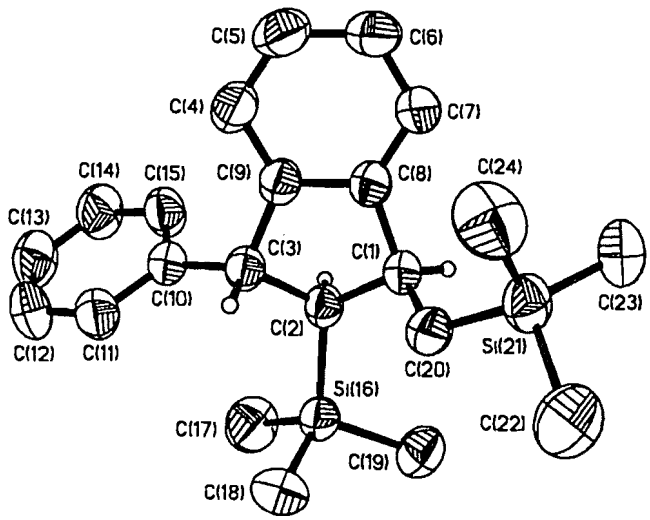
tive removal of acid catalyst from the system. Although the proton concentration is not affected by ligand exchange at silicon, the protons are less reactive; dry HCl bubbled into $CHCl_3$ was not an effective catalyst for the oligomerization of **2**. A large amount of catalyst, when compared to conventional cationic polymerization, was thus required to force the reaction to completion. Any exchange of groups should also have an effect on the rate of polymerization of the styrene, although this has not been established.

In spite of the use of relatively high acid levels, at low monomer concentrations (below 10 mM [**2**] in $HCCl_3$), little reaction was observed; primarily starting materials were recovered at reaction temperatures varying from −60°C to 60°C. The range of concentrations between 8 mM and neat **2** was examined. The molecular weight distributions over this range are given in Table 2.

At the lower concentration range, unless an unduly long reaction time was permitted (≥2 days), a great deal of unreacted starting material accompanied dimer and trimer formation (10). Above a monomer concentration of 4.2 M, higher oligomers accompanied the lower molecular weight species. However, even when the reaction was run neat, higher oligomers remained minor products and the dimer and trimer dominated the reaction mixture. An attempt was made to increase the molecular weight by metering in monomer using a syringe pump during the reaction in order to maximize monomer concentration throughout the reaction. This effort, however, also led primarily to the preparation of low molecular weight materials. Similarly, lowering the reaction temperature, which commonly leads to higher molecular weights in cationic polymerization (19), gave essentially the same molecular weight distribution: at −60°C only a small increase in the trimer/dimer ratio was noted.

Fig. 1. ORTEP representation of **10**, the dimer of **2**.



Product structure and stereochemistry: temperature effects

Although the molecular weight distribution of the oligomer was not found to be highly temperature dependent, the stereochemistry of the products was. Thus, at low temperature only one dimeric product **9** was isolated. It was possible to determine the crystal structure of the methylated dimer **10** prepared from **2**, which showed the presence of an indane group (the ORTEP picture is shown in Fig. 1 (10)). The permethylated trimer **13** (from **12**) was similarly a single compound containing the indane structure although the relative

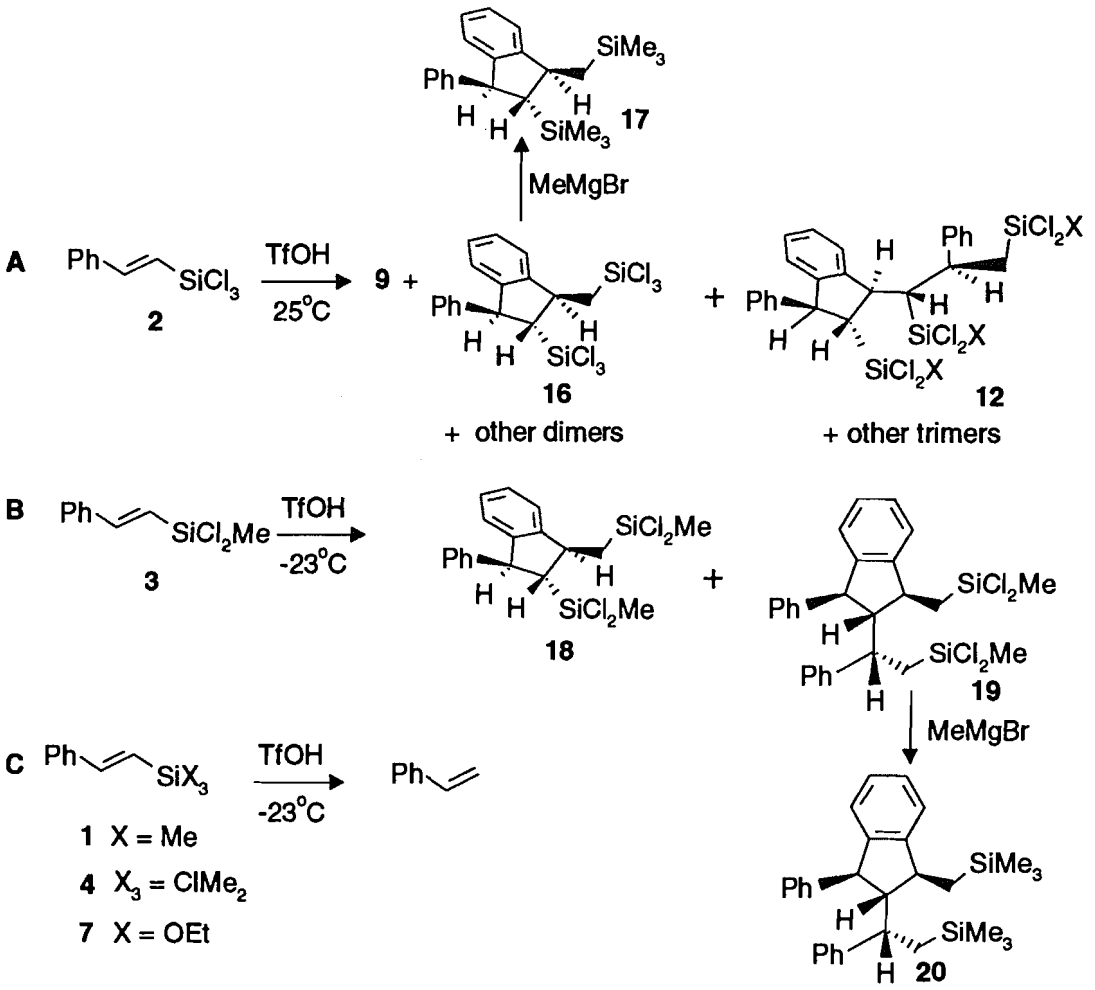
Scheme 5.



stereochemistry of this species was not unambiguously determined. The remaining higher molecular weight isomers were similarly terminated by indanes as clearly determined by the NMR signal for the doubly benzylic proton on the ring.

Performing the reaction at room temperature led to a deterioration of the stereochemical integrity; in addition to the dimeric product **9**, the isomer **18** and one other was produced. Similarly, several isomeric trimers including **12** were observed at higher temperatures (Scheme 5).

Effect of Ligands on Silicon

The degree to which oligomerization took place was highly dependent on the groups on silicon. As the number of Cl groups was reduced and replaced with methyl groups, the degree of protiodesilylation increased. This process, leading to styrene, could be seen from ^{1}H NMR studies of the reaction as it progressed and through the polystyrene that was isolated at the end of the reaction. Thus, with **2** or **5** protiodesilylation was not observed. However, with **3** or **6** ca. 35% protiodesilylation occurred, giving a dimer **18**, a desilylated trimer **19**, and styrene (Scheme 5B); with **4** or **1** (23) the products of the reaction did not contain silicon. Similarly, the exchange of one heteroatom Cl for another, for example, the replacement of $SiCl_3$ in **2** with $Si(OEt)_3$ **7** (18), led exclusively to protiodesilylation (Scheme 5C).

Table 3. Stereoselectivity as a function of reaction temperature and silyl group.[a]

Compound	Solvent	Temperature (°C)	Dimers **9**:**16**:other dimers	Trimers **12**:**19**
2	$CDCl_3$	−55	46:4:0	
2	$CDCl_3$	−23	40:6:0	
2	$CDCl_3$	0	19:9:0	
2	$CDCl_3$	25	11:5:2

6[b]	$CDCl_3$	0	0:6:0	0:16

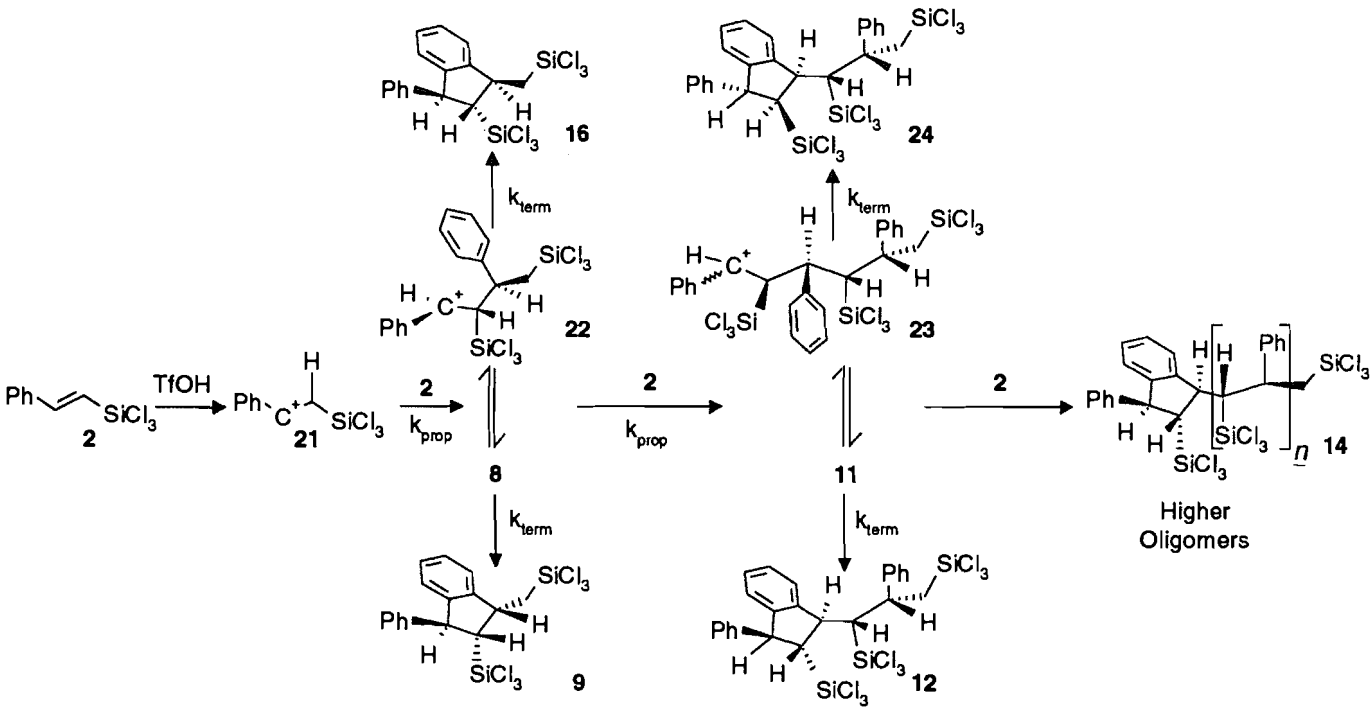
[a]Recovered starting material and higher oligomers account for the remaining product, total = 100%.

[b]The product stereochemistry is that shown for dimers **9**, **18** and trimer **19** in Scheme 5, but with the silyl groups SiF_3 and $SiMeF_2$, respectively.

Mechanism

The mechanism of the oligomerization of **2** and related derivatives is presumably simple electrophilic addition. Electrophilic addition to vinylsilanes usually occurs more efficiently than to normal olefins. The presence of the silyl group nor-

Scheme 6.



mally activates the double bond inductively. In addition, the intermediate cation **21**, formed by the protonation of **2** (Scheme 6), is stabilized through the β-effect by the silyl group (hyperconjugative stabilization of the cation by the Si—C σ-bond (8, 24)); the aryl group provides the most important stabilizing effect. If the β-effect is large (8), the cation will be better stabilized ($SiMe_3$, $SiMe_2Cl$, $Si(OMe)_3$) but will simultaneously be more susceptible to nucleophilic attack giving styrene (Scheme 5C)(23). With a less susceptible leaving group ($SiCl_3$, $SiCl_2Me$) protiodesilylation is avoided and **21** dimerizes to **8** or **22**. This process can be repeated, leading to higher oligomers, or termination can occur *via* an intramolecular Friedel–Crafts reaction, leading to indane-terminated species **14** (25). At low temperature, the stereochemistry of this closure involves attack of the phenyl group on the face of the cation opposite to the face bearing the silicon group (e.g., the dimer cation **8**→**9** and **23**→**24**). At higher temperatures, any stabilization of the cation by the silyl group (β-effect) is overshadowed by rotation and several isomers are produced.

The molecular weight distribution of the oligomerization will reflect the relative rates of the unimolecular termination and the bimolecular propagation reactions k_{term}/k_{prop} (19). As described above, all attempts to favour the bimolecular process by temperature control or control of monomer concentration were relatively unsuccessful; the highest molecular weight oligomer observed was a nonamer. This suggests that the lifetimes of the cations **8** and higher homologues are very low; unless the concentration of monomer **2** is high, deprotonation (**21**→**2**) or Friedel–Crafts termination (**8**→**9**) predominate (Scheme 6).

Utilization of the oligomers

Chlorosilanes are remarkably reactive species. The exposure of these functional groups to almost any nucleophile including hydroxylic species (water, alcohols, acids), amines, carbanions (RMgBr, RLi) etc., leads to substitution reactions at silicon. Indeed, it is this reactivity that is utilized to prepare silicone polymers (1).

The oligomers **14** (Scheme 3) have several special properties. In addition to their diastereoselective synthesis, the materials possess a high degree of functionality on a short chain and are liquids soluble in most solvents (with the exception of water). As with most trifunctional silanes ($RSiCl_3$), hydrolysis of **14** led to a rigid silsesquioxane (Scheme 7A). Films made by the hydrolysis of **14** were very brittle. However, the high degree of functionality on such a short chain might make **14** a useful crosslinking agent for polymers terminated with a functional group that will react with chlorosilanes. Polymers that appear to be suitable include living anionic polymers (26), polyethylene glycols, hydroxy-terminated silicones, etc. (Scheme 7B). Our efforts in these areas will be reported in due course.[9]

Experimental section

Apparatus, materials, and methods

The continuous wave ^1H NMR spectra were recorded on a Varian EM-390 (90 MHz) spectrometer and the Fourier spectra on a Bruker AM-500 (500 MHz) spectrometer or a Bruker AC-200 (200 MHz) spectrometer. ^{13}C (75.6 MHz) and ^{29}Si NMR (59.6 MHz) were performed on a Bruker AC-300 (at 300 MHz for protons). Chemical shifts are reported with respect to tetramethylsilane as standard, set to 0 ppm. Coupling constants (*J*) are recorded in hertz (Hz). The abbrevia-

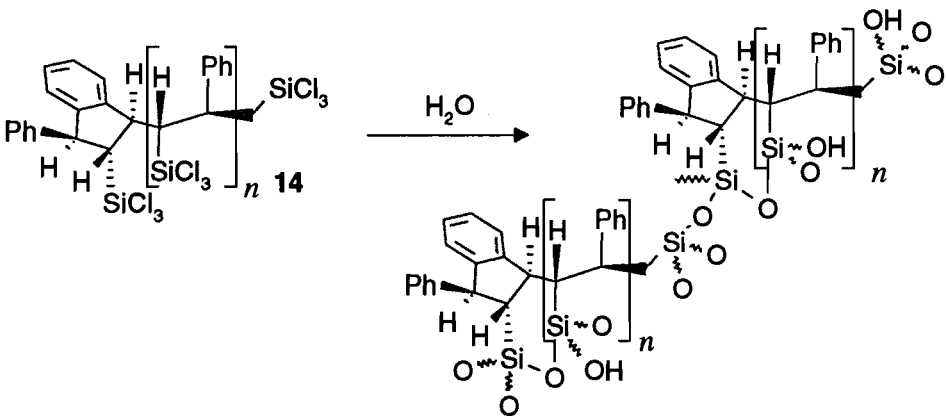
Scheme 7.



tions s = singlet, d = doublet, t = triplet, dd = doublet of doublets, m = multiplet, etc., are used in reporting the spectra.

Electron impact (EI) and chemical ionization (CI, NH_3) mass spectra were recorded at 70 eV with a source temperature of ca. 200°C on a VG analytical ZAB-E mass spectrometer equipped with a VG 11-250 data system. High-resolution mass spectral (HRMS) data were obtained with the VG-ZAB-E instrument by the EI method. Infrared spectra were run on a Perkin Elmer 283 spectrometer and Fourier spectra on a BIO RAD FTS-40 spectrometer, as neat films.

X-ray diffraction data for compound **10** were collected at room temperature on a Nicolet R3/m diffractometer with a Mo tube. The full experimental details have been reported elsewhere (10).

The copolymers were analyzed for the molecular weight distribution using a Waters gel permeation chromatograph equipped with a Waters 410 differential refractive index detector and a Foxboro Miran 1A variable wavelength IR detector to monitor the silicone distribution in copolymers. Narrow molecular weight silicone standards from Scientific Polymer Products (Ontario, N.Y.) were used for calibration of the chromatographic system.

All solvents were thoroughly dried before use. Dichloromethane was distilled over P_2O_5. Diethyl ether, THF, and hexane were distilled over Na–benzophenone. NEt_3 was dried by refluxing with NaOH and distilling over BaO.

Due to the tendency of halo groups on silicon to hydrolyze easily (**CAUTION: hydrolysis leads to production of HCl**), all reactions were carried out in dry apparatus under a nitrogen atmosphere with the use of septa and syringes for the transfer of reagents.

Preparation of 2–7

The hydrosilation of phenylacetylene to give **2–4** (8, 17), the conversion of **2**→**1** and **2**→**7** using MeMgBr (13, 17) and $HC(OEt)_3$ (18), respectively, and the preparation of the fluoro compounds using CuF_2 have also been reported (**2**→**5** and **3**→**6** (8)).

Attempted radical polymerization of 2

To **2** (2.0 g, 8.4 mmol) was added di-*tert*-butylperoxide (2.0 mg, 0.014 mmol, 0.1 wt.%) and the mixture was refluxed for 16 h at 140°C under a N_2 atmosphere. ^1H NMR clearly showed only starting material present in the reaction mixture.

General procedure 1: oligomerization of 2 with triflic acid as catalyst

To a solution of **2** (2.68 g, 11.3 mmol) in $CHCl_3$ (2.5 mL, frequently $CDCl_3$ was used, giving similar results, to facilitate NMR examination of the reaction) cooled to −23°C under a N_2 atmosphere was added triflic acid (0.1 mL, 1.13 mmol, 0.1 wt.%). The solution immediately turned dark red-orange and became viscous. After stirring for 2–4 h, the solution was allowed to warm to room temperature. The solvent could be removed under vacuum to give a quantitative mixture of oligomers. IR (KBr) ν: 3060, 3020, 2900, 1590, 1480, 1440, 1270, 1230, 1175, 1015, 725 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.6–2.7 (5H, m, backbone H's), 3.9–4.8 (<1H, doubly benzylic H_a, see Scheme 6), 7.2 (12 H, m).

General procedure 2: methylation of the oligomers

To facilitate structural characterization, the oligomeric residue (1 g) was diluted with ether (10 mL) cooled to 0°C and an excess of MeMgBr added (10 mL, 2.5 M in Et_2O). The mixture was allowed to warm to room temperature overnight, was quenched with water (20 mL), extracted with ether (3 × 20 mL), and the combined organic fractions dried over $MgSO_4$. The solvents were removed under reduced pressure to give a colourless oil (0.7 g, 93%). GPC (against polystyrene standards): M_n = 425. The compounds were separated (1.4 g) using flash chromatography with hexane as eluent. The major fractions R_f 0.37, 0.23, and 0.17 were isolated.

10: 0.70 g (50%); mp 75°C; IR (KBr pellet) ν: 3070, 3020, 2950, 2900, 1600, 1490, 1470, 1450, 1410, 1250, 1150, 1025, 990, 935, 850, 750, 690, 640 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz) δ: −0.10 (s, 9 H), 0.04 (s, 9 H), 0.91 (dd, 1 H, J = 11.9, 14.2 Hz), 1.02 (dd, 1 H, J = 2.9, 14.2 Hz), 1.89 (dd, 1 H, J = 6.5, 11.5 Hz), 3.52 (ddd, 1 H, J = 2.9, 6.5, 11.9 Hz), 4.39 (d, 1 H, J = 11.5 Hz), 6.76–7.30 (m, 9 H); ^{13}C NMR ($CDCl_3$, 63.9 MHz) δ: −0.83, −0.27, 21.65, 43.13, 49.08, 51.52, 123.40, 124.59, 125.51, 126.09, 126.39, 128.27, 128.90, 144.73, 148.82, 150.20; ^{29}Si NMR ($CDCl_3$ 49.7 MHz) δ: −0.71, 0.27; HRMS (high resolution, EI, *m/z*), calcd. for M^+: 353.2043; found; 352.2030. (m, 1H), 3.41–3.53 (m, 1H), 4.03–4.12 (m, 1H), 4.30–4.38 (m, 1H), 7.0–7.32 (m, 14H); ^{13}C NMR ($CDCl_3$, 75.6 MHz) δ: −1.89–0.99 (m), 14.08, 21–24 (m), 42–52 (m), 123–129 (m), 142–147 (m); ^{29}Si NMR ($CDCl_3$, 59.6 MHz) δ: −0.84–0.59 (m); MS (EI) *m/z*: 704 (M^+, tetramer, (1), 672 (1), 617 (1), 570 (1), 555 (1), 528 (M^+, trimer, 100), 513 (51), 441 (64), 351 (39), 274 (70), 249 (94), 177 (100).

Higher oligomers: 0.4 g (30%); ^1H NMR, ^{13}C NMR, and ^{29}Si NMR were used in conjunction with mass spectroscopy to confirm that this fraction also contained indane-terminated oligomers. Based on the integration of the backbone protons (<3 ppm in ^1H NMR) to the doubly benzylic proton (3–4 ppm), the oligomers in this fraction are estimated to be 4–9 monomer units in length as confirmed by the mass spectrum. ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.90 (m), 0.9–2.0 (m), 3.2–3.6 (m), 3.9 (m), 4.5 (m), 7.1 (m); ^{13}C NMR ($CDCl_3$, 75.6 MHz) δ: −1.2–1.0 (m), 22–34 (m), 42–52 (m), 122–129 (m), 144–149 (m); ^{29}Si NMR ($CDCl_3$, 59.6 MHz) δ: 0.00 (m), 16.9 (m); MS (EI) *m/z*: 1511 (9mer $M^+ - 73(SiMe_3)$), 1335 (8mer $M^+ - 73$), 1159 (7mer $M^+ - 73$), 983 (6mer $M^+ - 73$), 807 (5mer $M^+ - 73$).

Oligomerization of 3 with triflic acid as catalyst

Procedure 1 as above: **3** (2.45 g, 11.3 mmol); triflic acid (0.1 mL, 1.13 mmol, 0.1 wt.%). ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.3 (s); 0.65 (s), 0.7–4.5 (m), 7.4 (m).

Methylation of the oligomers

Procedure 2 as above: oligomeric residue (1 g); MeMgBr added (10 mL, 2.5 M in Et_2O). Yield 0.75 g (92%). ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.1–0.6 (m); 1.3–1.6 (m), 2.6 (m), 3.8 (d, J = 8 Hz), 7.5 (m).

The compounds were separated (1.4 g) using flash chromatography with hexane as eluent. The major fractions R_f 0.37, 0.35, and 0.16 were isolated.

17: 0.32 g, 40%; mp 66°C; IR (KBr pellet) *v*: 3070, 3030, 2960, 2890, 1600, 1495, 1470, 1450, 1405, 1250, 1165, 1130, 1030, 1010, 875, 865, 830, 750, 700, 685 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz) δ: −0.02 (s, 9 H), 0.04 (s, 9 H),1.13 (dd, 1 H, J = 6.6, 15.2 Hz), 1.17 (dd, 1 H, J = 5.2, 15.2 Hz), 1.57 (t, 1 H, J = 8.5 Hz), 3.35 (dd, 1 H, J = 5.2, 6.6 Hz), 4.20 (d, 1 H, J = 8.5 Hz), 6.81–7.30 (m, 9 H); ^{13}C NMR ($CDCl_3$, 63.9 MHz) δ: −1.82, 0.29, 25.00, 42.57, 44.98, 53.08, 123.47, 124.73, 126.08, 126.22, 126.49, 128.27, 128.54, 146.62, 146.82, 150.01; ^{29}Si NMR ($CDCl_3$ 49.7 MHz) δ: −0.29, 2.64; MS (high resolution, EI, *m/z*): calcd. for M+ 353.2043; found: 352.2039. Combustion analysis, calcd. for $C_{22}H_{32}Si_2$: C 74.93, H 9.15, found: C 74.83, H 9.27.

20: 0.15 g, 20%; IR (KBr pellet) *v*: 3060, 3030, 2950, 2920, 2900, 2860, 1600, 1490, 1450, 1415, 1240, 850, 830, 745, 695 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz) δ: −0.28 (s, 9 H), 0.09 (s, 9 H), 0.82 (d, 2 H, J = 6.7 Hz), 1.04 (dd, 1 H, J = 12.1, 14.7 Hz), 1.10 (dd, 1 H, J = 3.3, 14.7 Hz), 2.47 (dt, 1 H, J = 3.6, 5.3 Hz), 2.88 (ddd, 1 H, J = 3.2, 7.1, 11.2 Hz), 3.10 (dt, 1 H, J = 5.5, 6.2 Hz), 4.27 (d, 1 H, J = 5.3 Hz), 6.90–7.27 (m, 14 H); ^{13}C NMR ($CDCl_3$, 63.9 MHz) δ: −1.03, −0.09, 20.50, 25.52, 45.23, 46.45, 54.20, 65.89, 123.90, 125.40, 125.76, 126.22, 126.36, 126.74, 128.19, 128.38, 128.98, 144.95, 146.83, 149.09; ^{29}Si NMR ($CDCl_3$ 49.7 MHz) δ: −0.37, 0.73; HRMS (EI, *m/z*): calcd. for $M^+ - CH_3$: 441.2434; found: 441.2389. Combustion analysis, calcd. for $C_{30}H_{40}Si_2$: C 78.88, H 8.83, found: C 79.28, H 9.03.

The third fraction also comprised higher, indane-terminated oligomers.

Oligomerization of 4–7 with triflic acid as catalyst

Procedure 1 as above: e.g., **7** (4.0 mL, 19.6 mmol); $CDCl_3$ (4 mL); triflic acid (0.3 mL, 3.4 mmol). The residue in all three cases comprised unreacted starting materials, styrene, and polystyrene.

Controlling the oligomerization reaction

Acid concentration (Table 1)

Following General Procedure 1, the sensitivity of the reaction to the acid concentration was examined. The reaction with **2** (2.68 g, 11.3 mmol) was repeated with 10 mol%, 7 mol%, 5 mol%, 4 mol%, and 2 mol% triflic acid. Below 5 mol%, a significant amount of unreacted starting material was observed (>50%). This is attributed to loss of the triflic acid via nucleophilic exchange with Cl at silicon. HCl was shown to be ineffective as a catalyst for the oligomerization of **2**. At 5 mol% triflic acid or higher, the molecular weight distributions, as described above, were identical within experimental error.

Monomer concentration (Table 2)

The oligomerization was run at four different monomer concentrations. General Procedure 1 was followed with two exceptions, the triflic acid was used at 24 mol%; the amount of $CDCl_3$ controlled the monomer concentration (**2** (0.1 g, 0.422 mmol), triflic acid (0.01 mL, 0.1 mmol)) varied from 8.43 mM, 42.15 mM, 4.2 M, and bulk polymerization. The results are incorporated in Table 2. If shorter reaction times were used at the lowest concentration, the dimer was accompanied by unreacted **2**, the concentration of which decreased with increasing reaction time.

Temperature effects (Table 3)

The reaction (General Procedure 1) was examined at several temperatures from −55°C to 25°C. To shorten chain lengths and facilitate characterization of the stereochemical identity of the products much higher initiator concentrations were used (10–20 mol%). The yields reported below (Table 3) were calculated following isolation of the products by flash chromatography. The main change in the product distribution was the deterioration of stereochemical control as the temperature was increased (Table 3). The most convenient temperature that led to high levels of stereocontrol and acceptable conversion rates was −23°C.

Solvent effects (Table 1)

Using General Procedure 1, the oligomerization of **2** was repeated in a series of solvents. The product distributions and yields are shown in Table 1. It was necessary to use huge excesses of triflic acid in some cases to produce polymer; presumably, salting out of the acid reduced its concentration and its acidity was lower in the most polar medium. Methylene chloride and chloroform were judged to be the best solvents for this conversion.

Abstract: One- and two-electron transfer reactions of 3,5-di-*tert*-butylcatechol and the corresponding quinone were studied by fast kinetic spectroscopy coupled with laser photolysis and pulse radiolysis, and by cyclic voltammetry in aqueous solutions. Photoionization of catechol yields the same semiquinone radical as the formate-radical-induced quinone reduction in the pulse radiolysis experiment. The neutral semiquinone radical deprotonates at $pK_r = 6.0 \pm 0.1$, as deduced from the pH induced changes in the radical spectra. The two-electron reduction potentials of quinone and catechol were measured by cyclic voltammetry in aqueous solutions containing 25% methanol in the pH range 3–14. The pH dependence has two linear parts with slopes of 0.056 and 0.03 V/pH, intersecting at $pK_a = 10.0$. This is in excellent agreement with $pK_a = 10.05 \pm 0.05$ obtained spectrophotometrically. The reduction potential of 3,5-di-*tert*-butyl quinone, $E_7 = 0.01 \pm 0.04$ V, was obtained from the one-electron transfer equilibrium of the quinone with the oxygen/superoxide redox couple by pulse radiolysis. The rate constant of the reaction of quinone with the superoxide radical, $k = 1.2 \times 10^9$ M^{-1} s^{-1}, is higher than those of the superoxide reduction by catechols and phenols (typically $\sim 10^5$ M^{-1} s^{-1}); thus, lignin *o*-quinones could be efficient scavengers of superoxide under the conditions relevant for the photo-induced yellowing of lignin-rich paper. The reaction with $O_2^{\cdot-}$ effectively bleaches yellow quinone and generates metastable furanone, which hydrolyses to muconic acid, thus completely eliminating yellow quinone. 3,5-Di-*tert*-butylquinone also undergoes rapid bleaching with ascorbate, $k = 600 \pm 100$ M^{-1} s^{-1}, in methanol. The reaction has a 1:1 stoichiometry and leads to complete reduction of quinone to catechol with concomitant oxidation of ascorbate to dehydroascorbate. This unusual selectivity and the fact that the reaction of the milder oxidant 3,5-di-*tert*-butylquinone is an order of magnitude faster than that of stronger oxidant *p*-benzoquinone ($k = 60 \pm 10$ M^{-1} s^{-1}) suggest that a nucleophilic attack of quinone at the ascorbate double bond initiates the reaction.

Key words: superoxide, lignin, photochemistry, quinone.

Résumé : Faisant appel à voltampérométrie cyclique et à la spectroscopie cinétique rapide couplée à photolyse laser et à la radiolyse pulsée, on a étudié les réactions de transfert d'un et de deux électrons du 3,5-di-*tert*-butylcatéchol et la quinone correspondante, en solutions aqueses. La photoionisation du catéchol fournit le même radical semiquinone que celui produit lors de la réduction radicalaire de la quinone induite par le formiate dans l'expérience de radiolyse pulsée. Sur la base des changements induits de pH dans le spectre radicalaire, le radical semiquinone neutre se déprotone à un $pK_r = 6{,}0 \pm 0{,}1$. On a utilisé la voltampérométrie cyclique pour mesurer les potentiels de réduction à deux electrons quinone/catéchol en solutions aqueuses contenant 25% de méthanol, à des pH allant de 3 à 14. La relation avec le pH présente deux parties linéaires avec des pentes de 0,056 et 0,03 V/pH, avec ordonnée à l'origine de $pK_a = 10{,}0$. Cette valeur est en bon accord avec le $pK_a = 10{,}05 \pm 0{,}05$ obtenu spectrophotographiquement. On a obtenu le potentiel de réduction de la 3,5-di-*tert*-butylquinone, $E_7 = 0{,}01 \pm 0{,}04$ V, à partir de l'équilibre de transfert monoélectronique de la quinone avec le couple redox oxygène/superoxyde par radiolyse pulsée. La constante de vitesse de la réaction de la quinone avec le radical superoxyde, $k = 1{,}2 \times 10^9$ M^{-1} s^{-1}, est plus élevée que celles obtenues pour la réduction des catéchols et de phénols par le superoxyde (d'une façon typique $\sim 10^5$ M^{-1} s^{-1}); le *o*-quinones de la lignine pourraient donc être des pièges efficaces du superoxyde dans des conditions prévalent lors du jaunissement photoinduit du papier riche en lignine. La réaction du $O_2^{\cdot-}$ blanchit efficacement la quinone jaune et génère une furanone métastable qui s'hydrolyse en acide muconique en éliminant complètement le jaune de la quinone. La 3,5-di-*tert*-butylquinone subit aussi un blanchiment avec l'ascorbate dans le méthanol, $k = 600 \pm 100$ M^{-1} s^{-1}. La stoechiométrie de la réaction est 1 : 1 et elle conduit à une réduction complète de la quinone en catéchol avec une oxydation concomitante de l'ascorbate en déhydroascorbate. Cette sélectivité inhabituelle et le fait que la

réaction de l'oxydant plus doux 3,5-di-*tert*-butylquinone soit un ordre de grandeur plus rapide que celle de l'oxydant plus puissant *p*-quinone ($k = 60 \pm 10$ M^{-1} s^{-1}) suggère qu'une attaque nucléophile de la quinone au niveau de la double liaison de l'ascorbate initie la réaction.

Mots clés : superoxyde, lignine, photochimie, quinone.

[Traduit par la rédaction]

Introduction

Light-induced changes in thermomechanical and chemical pulps are initiated by the excitation of lignin chromophores, whose content may be as high as 23% in bleached pulp (1, 2). Subsequent reactions of excited chromophores lead to the formation of free radicals of phenoxyl, phenacyl, and peroxyl type and, probably, of singlet oxygen. These unstable species undergo complex reactions leaving behind non-radical products, the major classes being quinones, phenol dimers and oligomers, and organic peroxides and hydroperoxides (1). It is noteworthy that most of these "stable" products are extremely photochemically and chemically reactive. For example, organic peroxides and hydroperoxides can be cleaved photochemically or thermally to yield alkoxyl radicals, which could initiate further radical processes, resulting in increased brightness – reversion products. Of particular interest are the formation and the fate of yellow quinones, since they are believed to account for most of the photogenerated yellow color of the pulp.

Quinones may be formed in the oxidation reactions of the *o*-methoxyphenoxyl radicals followed by hydrolysis of the incipient arylmethoxide cation (3, 4). Major methoxyphenols in lignin are 2–methoxy- (vanillin-type) and 2,6-dimethoxyphenol (syringyl-type) (2). The corresponding *ortho*-quinones are unstable in protic solvents, which led us to model their redox properties using more stable 3,5-di-*tert*-butyl-1,2-benzoquinone. It is noteworthy that *o*-quinones are also produced by action of dioxygenase on catechols, which are chromophores in a variety of important biomolecules, such as epinephrine, dihydroxyphenylalanine (DOPA), DOPamine, quercetin, and rutin, and which prompted extensive research of their oxidation (5–10).

Photooxidation of 3,5-di-*tert*-butylcatechol, upon direct excitation (at 280 nm), or via a sensitizer (Rose Bengal), yields a mixture of products (6), among which yellow quinone and colorless 3,5-di-*tert*-butyl-5-(carboxymethyl)-2-furanone were identified by IR and NMR spectroscopy. These results were later revised (5), and an endoperoxide was identified as a major product of singlet oxygen reaction with the catechin derivative. Quinone and 3,5-di-*tert*-butyl-5-(carboxymethyl)-2-furanone (7) were the main products of oxidation of 3,5-di-*tert*-butylcatechol by the superoxide radical in tetrahydrofuran solutions. The formation of furanone from quinone was also demonstrated (7), which led to the conclusion that the superoxide radical reacted with both catechol and quinone, yielding the same semiquinone radical. The semiquinone radical was postulated (7) to react with another superoxide radical to form the furanone. It should be emphasized that the superoxide reaction effectively "bleaches" yellow quinone to a practically non-oxidizable metastable furanone (yields muconic acid upon hydrolysis), which is of interest for the reversal of paper yellowing. The above superoxide reactions are, in fact, one-electron transfer processes, the reaction with catechol being the reduction (superoxide→hydrogen peroxide) and that with quinone the oxidation of the superoxide radical (superoxide→oxygen). However, the kinetics and energetics of these electron transfer processes have yet to be established. We believe that the knowledge of redox characteristics of catechols is important not only for the improvement of the bleaching and yellowing inhibition strategies, since both quinones and catechols are abundant in thermomechanical pulp, but also for the understanding of the mechanisms of action of dioxygenases, where the establishment of the redox equilibria of various oxy species may play a role.

Ascorbate has been proposed as an inhibitor of photoyellowing of thermomechanical pulp (TMP), on the basis of its excellent radical-scavenging properties (1). However, ascorbate has also been shown to react thermally with *p*-quinones (11). It is, therefore, conceivable that it may also react with *o*-quinones (12), converting them to less colored products, thus effectively bleaching the pulp. Although the intermediacy of semiquinone radicals has been demonstrated in the *p*-quinone–ascorbate system (11), actual kinetic data for this two-electron reduction of quinone have not been reported. To establish fully the role of ascorbate in the reversal of yellowing, it is desirable to understand the kinetics and mechanism of the *o*-quinone reduction.

In this study, the redox and acid–base properties of 3,5-di-*tert*-butyl-semiquinone radicals have been studied by laser flash photolysis and pulse radiolysis. The one-electron reduction potential of quinone was determined by pulse radiolysis, whereas the two-electron reduction potential was measured by cyclic voltammetry in aqueous solutions (containing 25% methanol to dissolve the quinone). The redox properties of the quinone are consistent with the rapid oxidation of superoxide. The reaction with ascorbate was studied by UV–VIS and NMR spectroscopy. The implications of these results for the reversal of yellowing of lignin-rich TMP are discussed.

Materials and methods

All chemicals used in this study were of the highest purity commercially available. 3,5-Di-*tert*-butylcatechol, 3,5-di-*tert*-butyl-1,2-benzoquinone, ascorbate, and CD_3OD were Aldrich products; methanol and 2-propanol were Omnisolv grade from BDH; KCl and phosphate buffer were from Fisher or Merck. Water was purified through a Millipore MilliQ system, to a resistance better than 18 MΩ/cm. Solutions were freshly prepared before each experiment. The pH of the solutions was adjusted with NaOH (Merck or Fisher) and $HClO_4$ (Merck or Fisher). The solutions were saturated with high purity gases, N_2, N_2O, O_2, and N_2O:O_2 = 4:1 prior to the experiment.

Laser flash photolysis was performed on a system similar to that described in previous publications (13, 14) . A solution was made to flow from a container through a 7×7 mm^2 Suprasil cell, where it was photolyzed by pulses from a Lumonics EX-510 excimer laser (Kr/F_2/He, 248 nm, ~5 ns). The signal from the photomultiplier was initially captured by a Tektronix

2440 digital oscilloscope interfaced to a Macintosh IIcx computer, which was used for data acquisition and processing. Software for the laser system was written in the LabVIEW Version 2.2 programming environment from National Instruments.

For pulse radiolysis studies (15), we used the 3.0 MeV Van-de-Graaff pulse radiolysis facility at the Max-Planck-Institute für Strahlenchemie, Mülheim, Germany. Absorbed doses were ~20 Gy/pulse for the spectra determination, and ~2–3 Gy/pulse for the kinetic measurements, as determined by thiocyanate dosimetry.

Cyclic voltammetry was performed in the standard electrochemical cell, with glassy carbon as the working electrode, platinum mesh as a counter, and saturated calomel as the reference electrode, controlled from an EG&G Princeton VersaStat potentiostat. To avoid rapid autooxidation of catechol in an oxygen atmosphere, a buffered aqueous solution containing 25% v/v methanol without redox-active solutes was first purged with N_2 for ~20 min. Then catechol and quinone were injected (typically 0.25–1 mL in 82 mL total volume) as concentrated methanol solutions to achieve the desired concentrations in the buffered aqueous–methanol mixture.

The reactions of ascorbate with quinones were monitored by UV–VIS spectroscopy. The methanol solutions of ascorbate and quinone were mixed in a 10×10 mm^2 Suprasil quartz cell and quickly placed in the spectrophotometer. The *p*-benzoquinone–ascorbate reaction was monitored at 320 nm, where pseudo-first-order kinetics were observed for 1 mM *p*-benzoquinone and 0.01–0.25 mM ascorbate. The *o*-quinone (3,5-di-*tert*-butyl-1,2-benzoquinone)–ascorbate reaction was monitored at 400 nm. Pseudo-first-order kinetics could not be achieved under normal experimental conditions, so second-order kinetics were used. The concentrations of quinone and ascorbate were kept equal, and varied over the range 0.3–1.5 mM, and the second-order rate was obtained by extrapolation to the initial absorbance of the solution corrected for dilution due to the mixing of solutes. The identity of the products was investigated by NMR spectroscopy. The ^{13}C NMR spectra were recorded on a Varian Gemini 200 NMR spectrometer in deuterated methanol and D_2O solutions.

Results and discussion

Generation of semiquinone radicals

Semiquinone radicals may in principle be generated from 3,5-di-*tert*-butylcatechol or the corresponding quinone by the following methods: (*a*) by photoionization or chemionization (one-electron oxidation by strong transient oxidants, such as $Br_2^{\bullet-}$, and $^{\bullet}N_3$, radicals) of catechol; (*b*) H-atom abstraction from catechol by alkoxyl or peroxyl radicals generated by photochemical or radiation chemical methods, such as the *tert*-butoxyl radical; (*c*) via the excited triplet state of quinone, which has an n,π^* configuration, and is capable of H-atom abstraction from suitable H-atom donors; and (*d*) one-electron reduction of quinone by strong transient reductants, such as $CO_2^{\bullet-}$, $(CH_3)_2C^{\bullet}OH$.

One-electron oxidation of catechol with strong transient oxidants, although probably fast, $k \sim 10^9$ M^{-1} s^{-1}, might lead to the formation of adducts, as demonstrated (16) in the case of $Br_2^{\bullet-}$ reaction with phloroglucinol. The excited triplet state of 3,5-di-*tert*-butyl-1,2–benzoquinone undergoes rapid ($k \sim 10^6$ M^{-1} s^{-1}) intramolecular deactivation (17), which effectively competes with any intermolecular H-atom transfer and thus limits the use of this method for the generation of semiquinone radicals. Consequently, we used the 248 nm laser photoionization of catechol and the reduction of quinone with the formate radical anion, $CO_2^{\bullet-}$, to generate the semiquinone radicals.

Direct laser photoionization at 248 nm yields the semiquinone radical cation and an electron, eq. [1]. Similar to other semiquinone radicals (18), the radical cation rapidly loses a proton ($pK_r < 2$) to become the neutral radical in the pH range 2–14.

[1] 
[2] 
The quantum yield of photoionization, $\Phi = 0.26 \pm 0.03$, was determined in aqueous solutions at pH 9 ([3,5-di-*tert*-butylcatechol] = 0.3 mM), against the yield of electron in an N_2-saturated aqueous solution of KI ($\Phi = 0.29$) (19). The dependence of the transient optical density at 650 nm (solvated electron) vs. laser power was linear, indicating that the photoionization of 3,5-di-*tert*-butylcatechol is a monophotonic process at this wavelength. Solvated electron is easily scavenged with 2-chloroethanol, which enables the investigation of the spectral, acid–base, and redox properties of semiquinone radicals. The spectrum of the semiquinone radical is presented in Fig. 1.

The formate radical was generated by the pulse radiolysis of an N_2O-saturated aqueous solution of 0.1 M sodium formate and 0.1 mM quinone by the following sequence of reactions (20):

[3] $$H_2O \rightsquigarrow e_{aq}^-, {}^{\bullet}OH, H, H_3O^+, \ldots$$

[4] $$e_{aq}^- + N_2O + H_2O \longrightarrow {}^{\bullet}OH + OH^- + N_2$$
$$k = 9 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$$

[5] $$^{\bullet}OH + HCOO^- \longrightarrow H_2O + CO_2^{\bullet-}$$
$$k = 2.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$$

[6] $$H + HCOO^- \longrightarrow H_2 + CO_2^{\bullet-}$$
$$k \sim 2 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$$

The formate radical is a strong reductant, $E_7 = -2.0$ V (21), and rapidly reduces *o*-quinone.

Depending on the pH of the solution, the semiquinone radical anion formed in reaction (7) may be protonated to the neutral semiquinone radical (vide infra). The absorption spectrum of the semiquinone radical anion obtained upon $CO_2^{\bullet-}$ reaction with quinone is also presented in Fig. 1.

It is obvious from Fig. 1 that both photochemical and radiation chemical methods yield the same semiquinone radical, as expected. The noticeable difference exists in the 370–420

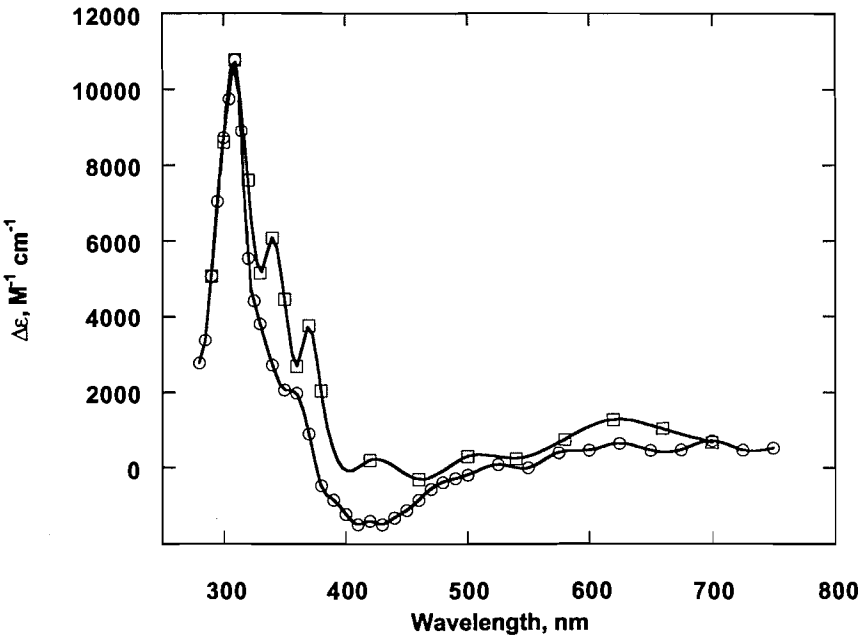
Fig. 1. Absorption spectra of the semiquinone radical anion, obtained by laser photolysis of 0.21 mM 3,5-di-*tert*-butylcatechol in N_2-saturated aqueous solution at pH 7, 20°C, containing 1% 2-chloroethanol to scavenge solvated electrons (–□–) normalized to A_{310} in the pulse radiolysis experiment; and pulse radiolysis of an N_2O-saturated aqueous solution of 35 mM NaOOCH and 0.07 mM 3,5-di-*tert*-butyl-1,2-benzoquinone at pH 7, 20°C (–○–).



[7] $CO_2^{\bullet-}$ +  →  + CO_2

$k = 1.5 \times 10^9\ M^{-1}\ s^{-1}$

nm region, where the negative absorbance in the radiation chemical experiment occurs as a consequence of the bleaching of the parent quinone. The presence of the weak 650 nm band in the spectrum is expected for the *o*-semiquinone radical (22).

The neutral semiquinone radical undergoes deprotonation in neutral and alkaline media, as derived from the pH-dependent spectral changes, Fig. 2.

[8]  $pK_r = 6.0$  + H

The pK_r of the semiquinone radical anion (6.0 ± 0.1) is 4 pH units lower than that of parent catechol (pK_a = 10.05 ± 0.05, determined spectrophotometrically), which is similar to the data previously reported for a series of substituted hydroquinones and corresponding semiquinone radicals (10, 18). Such change in the acidity probably originates from the aromaticity of the semiquinone radical, which facilitates proton loss.

Redox potential of catechol/quinone redox pair

3,5-Di-*tert*-butylcatechol, QH_2, and the corresponding quinone, Q, may exhibit the following acid–base and electron-transfer equilibria in aqueous solutions,

[9] $^{-}Q^{\bullet} + e^- + 2H^+ \longrightarrow QH_2$

[10] $QH_2 \rightleftharpoons QH^- + H^+$ ($pK_a = 10.05$)

[11] $Q + e^- \longrightarrow {}^{-}Q^{\bullet}$

[12] $QH_2 + Q \longrightarrow 2\dot{Q}H$

[8] $^{-}Q^{\bullet} + H^+ \rightleftharpoons {}^{\bullet}QH$ ($pK_a = 6.0$)

Consequently, in the cyclic voltammetry of aqueous solutions the cathodic process is the one-electron reduction of quinone, whereas the anodic process corresponds to the oxidation of catechol. Both processes yield short-lived semiquinone radicals, which are in equilibrium with the parent catechol and quinone. The voltammograms of catechol–quinone mixtures were recorded in aqueous solutions (containing 25% methanol) at various pH in the range from 2 to 14. The standard electrode potential for the two-electron reduction of quinone was measured as a function of the concentrations of catechol and quinone (0.5–2 mM), and calculated according to the Nernst expression (23).

The titration curve of the change of absorbance at 310 nm with the pH is shown as an inset.

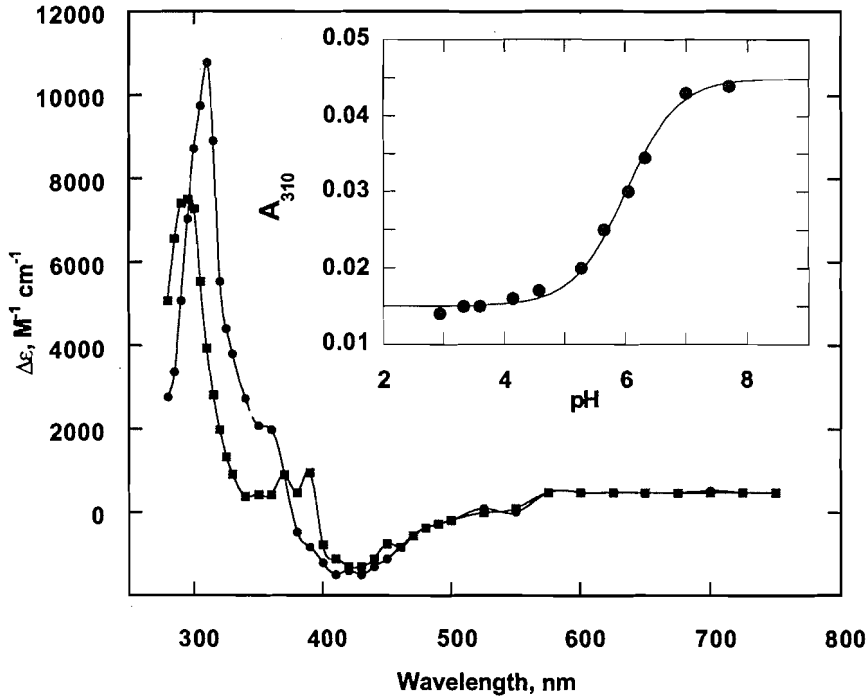

Fig. 3. Two-electron reduction potentials of 3,5-di-*tert*-butyl-1,2-benzoquinone measured at various pH values. Solid lines are best fits to the experimental data.

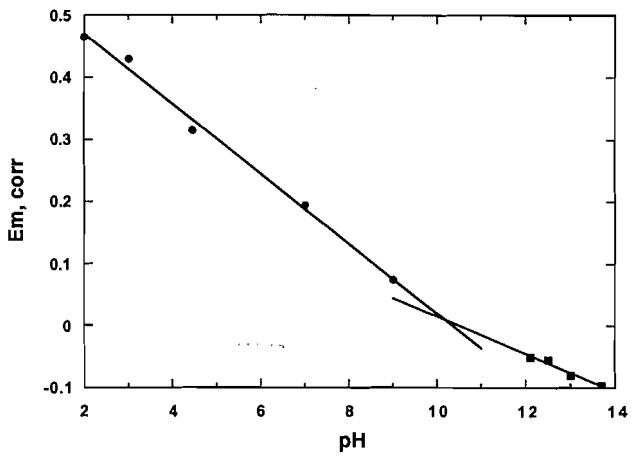

The half-cell reaction is

[13] $Q + 2e + 2H^+ \rightarrow QH_2$

which leads to the following expression for the pH dependence of the reduction potential (24),

[14] $E_m{}^i = E^0(Q/QH_2) + 0.03 \log\{f_Q(a^2H^+/f_{QH_2} + a_H + K_a/f_{QH^-}\}$

where $E_m{}^i$ and $E^0(Q/QH_2)$ represent the standard reduction potentials at pH = i and 0, respectively, and activity coefficients, f_i, are the function of the ionic strength of the solution (21). K_a is the thermodynamic dissociation constant of catechol. The pH dependence of the two-electron reduction potential of 3,5-di-*tert*-butyl-1,2-benzoquinone in 25% methanol – water at 20°C is presented in Fig. 3.

The pH dependence of the reduction potential is consistent with two linear regions with slopes equal to 0.056 and 0.03 V/pH, which means that the half-cell reactions involve QH_2 and QH^- in the respective pH range. The thermodynamic dissociation constant, $pK_a = 10.0$, may be derived from the intersection of the linear segments, in excellent agreement with $pK_a = 10.05 \pm 0.05$, determined spectrophotometrically.

$E^0(Q/QH_2) = 0.58$ V is obtained by extrapolation of the 0.056 V/pH portion of the pH dependence to pH = 0. This value is approximately equal to the standard potential, provided that the activity coefficients of quinone and catechol are equal at pH = 0 (which is a reasonable assumption at 0.1 M ionic strength). $E^0(Q/QH_2) = 0.58$ V is 0.12 V lower than 0.699 V (21) for the 1,4-benzoquinone/hydroquinone couple (which must be lower than the standard potential of the *o*-quinone/catechol couple (10, 18)), as expected from favorable electron-donating properties of the *tert*-butyl group.

The one-electron oxidation potential of 3,5-di-*tert*-butyl-1,2-benzoquinone was also determined by pulse radiolysis of aqueous solutions against the oxygen/superoxide redox couple. At pH 7, the superoxide radical was generated by the formate system (20), and was found to rapidly transfer an electron to quinone to form the semiquinone radical anion, as illustrated in the following reaction,

[15] 
$k_f = (1.2 \pm 0.12) \times 10^9\ M^{-1}\ s^{-1}$ $K_{kin} = 400 \pm 120$; $K_{abs} = 620 \pm 60$
$k_r = (3 \pm 1) \times 10^6\ M^{-1}\ s^{-1}$

[c]This study.

where K_{kin} and K_{abs} are the equilibrium constants determined from kinetic and spectroscopic studies, respectively.

The establishment of the electron transfer equilibrium between the quinone/semiquinone radical and oxygen/superoxide redox couples was monitored at 310 nm, where the difference in extinction coefficients of the semiquinone and superoxide radicals is optimal. The equilibrium constant from equilibrium absorbances, K_{abs}, was derived from the influence of the ratio of concentrations of quinone and oxygen (introduced to the solution as a N_2O:O_2 mixture) on the absorbance at 310 nm. The concentrations of quinone and oxygen were varied from 0.006 to 0.03 mM and from 0.026 to 1.3 mM, respectively. Since both quinone radical anion ($2k \sim 1 \times 10^8$ M^{-1} s^{-1}) and superoxide radical ($2k \sim 1 \times 10^8$ M^{-1} s^{-1}) at ~0.2 mM (1.4 Gy/pulse) do not decay appreciably over the time necessary for the establishment of the redox equilibrium (≤100 μs), the pseudo-first-order rates can be determined with sufficient accuracy. These data are used to evaluate the kinetic parameters of the redox equilibrium.

The redox potential difference between the oxygen/superoxide and quinone/semiquinone redox couples derived from the measured equilibrium constant using the Nernst equation yields $\Delta E = 0.16$ V. Since the reduction potential of oxygen is $E_7 = -0.15$ V (21), the reduction potential of quinone at pH 7 is $E_7(Q/^{\cdot-}Q^{\cdot}) = -0.15 + 0.16 = 0.01 \pm 0.04$ V.

With this value and $E_7(Q/QH_2) = 0.195$ V from cyclic voltammetry, we calculate the one-electron reduction potential of the 3,5-di-*tert*-butylcatechol radicals, $E_7(Q^{\cdot-}, 2H^+/QH_2) = 0.38$ V, and the semiquinone formation constant, $\log K_{f,7} = -6.16$ (see, for example ref. 21). The calculated reduction potential of the catechol radicals is in good agreement with the value of 0.34 V predicted from the Brown substituent constants (25–27). Such low reduction potential means that electron-rich methoxy- and methyl-substituted catechols are very sensitive to oxidation, which converts them to colored quinones.

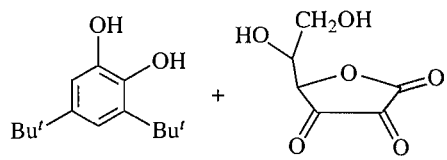
The redox properties of 3,5-di-*tert*-butylquinone favor its reaction with the superoxide radical over the pH range 3–14, which is of significance for the bleaching and yellowing of pulp.[2] The superoxide radical may be generated either thermally from hydrogen peroxide (28, 29) in the peroxide bleaching, or photochemically from singlet oxygen (30–33) in the course of photoyellowing of pulp. Assuming that substituent effects in the catechol derivatives are similar to those in the hydroquinone derivatives, i.e., that the electron-rich substituents make both reduction potential of catechol radical and oxidation potential of quinone more negative, it may be concluded that all lignin-derived *o*-quinones (such as 3-methoxy-1,2-benzoquinone) are expected to be rapidly oxidized by the superoxide radical (see Table 1). On the basis of close to diffusion-controlled rate constants, the reactions of the superoxide radicals with quinones are by far the most efficient route for superoxide disappearance in a system devoid of substantial concentrations of transition metal ions.

[2] Because $pK_a = 4.8$ (27) for the protonation of $O_2^{\cdot-}$ to $HO_2^{\cdot}$, the reactions in acidic media, pH < 4, where $HO_2^{\cdot}$ predominates, may be considerably slower than those in neutral and alkaline media.

Two-electron reduction of quinone by ascorbate

Mixing methanol solutions of ascorbate and 3,5-di-*tert*-butyl-1,2-benzoquinone results in rapid disappearance of the yellow color, which provides a convenient method for monitoring the reaction.

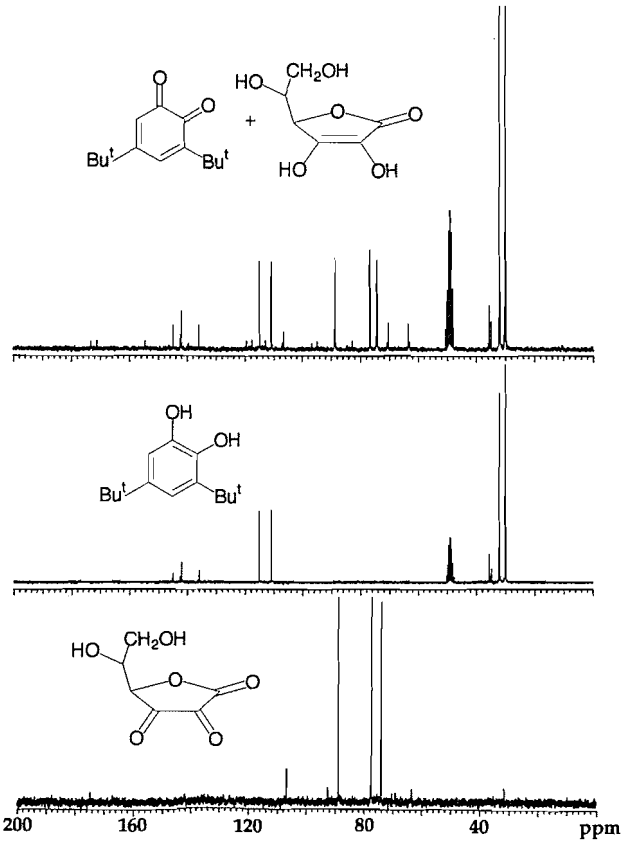
[16] 



The reaction rate constant was derived from the second-order kinetics for various initial concentrations of the quinone and ascorbate as $k = 600 \pm 100$ M^{-1} s^{-1}. The stoichiometry of this reaction appears to be 1:1, as deduced from the variation of the concentrations of both reactants and the measurements of the residual absorbance at 400 nm (data not shown). The identity of the products of the reaction was verified by ^{13}C NMR spectroscopy in CD_3OD. The NMR spectra of reactants and products of the above reaction are presented in Fig. 4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Fig. 4. ^{13}C NMR spectra of methanol-d_4 solutions containing the products of the reaction of 1 M 3,5-di-*tert*-butyl-1,2-benzoquinone and 1 M ascorbate; 1 M 3,5-di-*tert*-butyl catechol; and 1 M dehydroascorbate (in D_2O).



The products of the two-electron reduction of 3,5-di-*tert*-butyl-1,2-benzoquinone by ascorbate are indeed catechol and dehydroascorbate, as may be seen from Fig. 4. Consequently, one mole of the quinone reacts with one mole of ascorbate to produce one mole each of catechol and oxidized ascorbate. This is surprising, considering the reported intermediate formation of free radicals, namely semiquinone and ascorbate radicals, whose reactions must produce a more complicated mixture of products. In an attempt to rationalize these results we investigated the reaction of ascorbate with 1,4-benzoquinone. This reaction was previously shown (11) to involve the intermediacy of semiquinone radicals, and constitutes the two-electron reduction of the quinone to hydroquinone:

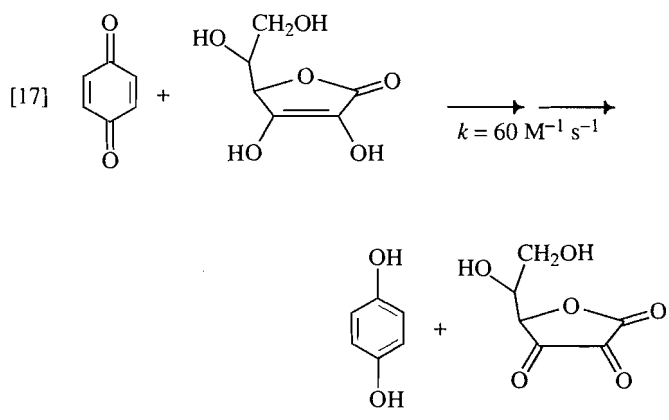


Fig. 5. ^{13}C NMR spectra of methanol-d_4 solutions containing the products of the reaction of 1 M 1,4-benzoquinone and 1 M ascorbate; 1 M hydroquinone; and 1 M dehydroascorbate (in D_2O).

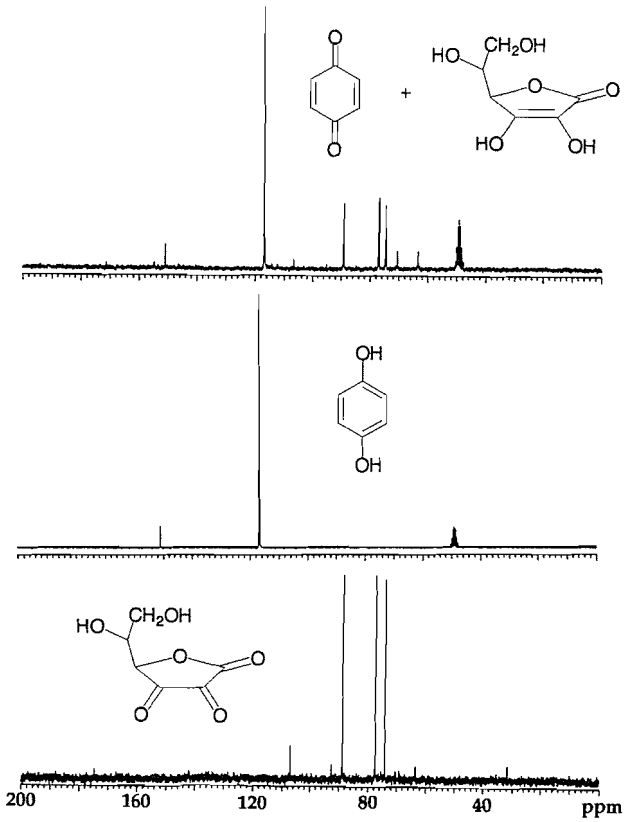

We studied the reaction of *p*-benzoquinone and ascorbate in methanol solutions. Similar to the reaction with *o*-quinone, the final products are fully reduced quinone, hydroquinone, and dehydroascorbate (also confirmed by NMR spectroscopy, see Fig. 5). However, the reaction rate constant is found to be an order of magnitude slower than that with *o*-quinone, $k = 60 \pm 10\ M^{-1}\ s^{-1}$ compared to $600\ M^{-1}\ s^{-1}$. This difference in the rates of the reactions is in contrast the redox properties of the quinones. Namely, *p*-quinone is, by 0.12 V, a stronger oxidant than *o*-quinone, which means that the electron transfer involving *p*-quinone is more exothermic and thus expected to be faster.

Conclusions

o-Semiquinone radical may be produced either by photoionization of 3,5-di-*tert*-butylcatechol or by the reduction of the quinone induced by the radiolytically generated formate radical. $pK_a = 6.0$ is determined from the pH-dependent changes in the semiquinone radical spectra.

The two-electron reduction potential of quinone, $E^{0'} = 0.58$ V, is lower than $E^{0'} = 0.699$ V of the unsubstituted 1,4-benzoquinone (which must be lower than that of *o*-quinone) (10, 18), a consequence of the substituent effect of electron-donating *tert*-butyl groups. Similar two-electron reduction potentials are also expected for other *o*-quinones substituted by electron-rich substituents (for example, $\sigma^+[ortho(OCH_3)] = -0.67$, $\sigma^+[ortho(CH_3)] = -0.27$, should be compared with

$2\sigma^+[meta(C(CH_3)_3)] = -0.14$) (26). The one-electron reduction potential of 3,5-di-*tert*-butyl-1,2–benzoquinone determined by pulse radiolysis at pH 7, $E_7 = 0.01 \pm 0.04$ V, enables calculation of the reduction potential of the corresponding catechol radicals, $E_7 = 0.38$ V, which is lower than $E_7 = 0.53$ V of unsubstituted catechol. Low reduction potential of the catechol radicals, in general (see also refs. (10, 18, 25, 34) means that they are highly sensitive to oxidation.

3,5-di-*tert*-butyl-1,2-benzoquinone and various electron-rich methoxy- and methyl-*o*-quinones appear to be moderately strong oxidants, capable of oxidizing the superoxide radical at any pH. The oxidation of the superoxide radical by the quinones is a very efficient route for the superoxide decay. Since this reaction was shown (7, 9) to decompose yellow quinone to colorless and photoinactive products, it is of relevance for the reversal of photoyellowing of lignin-rich pulp.

Two-electron reduction of the quinones by ascorbate is an efficient bleaching reaction, since it yields colorless products, hydroquinone and dehydroascorbate. This reaction occurs spontaneously in the dark and may contribute to the potential use of ascorbate in the protection of pulp from photo-induced yellowing. However, it should be noted that dihydroxybenzenes are highly oxidizable substrates, whose oxidation ultimately leads to the production of yellow products (quinones and (or) phenol dimers and oligomers). Therefore, in the use of ascorbate as an inhibitor, the reduction of various quinones actually wastes ascorbate, thus diminishing its efficacy.

Acknowledgment

This work was supported by the Natural Sciences and Engineering Research Council of Canada and the Canadian Network of Centers of Excellence through the Mechanical and Thermomechanical Wood Pulps Network. We are grateful to Prof. Steen Steenken of the Max-Planck-Institute für Strahlenchemie who kindly provided access to the pulse radiolysis equipment. Abstract: New mono- and disubstituted cholesteryl derivatives of itaconic acid have been prepared and their thermotropic liquid crystalline behaviour examined. The monosubstituted derivative has been homopolymerized, and also copolymerized with a non-chiral mesogen 4-cyanophenyl-4′-(6-acryloyl oxyhexyloxy) benzoate. Examination of the series of copolymers prepared, using differential scanning calorimetry and hot-stage polarizing microscopy, showed that when the content of the cholesteryl itaconate was high, both a smectic-A phase (S_A) and a cholesteric phase (N*) were present. It was found that the S_A phase could be eliminated by lowering the content of the cholesteryl itaconate in the copolymers, giving samples that displayed only the N* phase over a much wider temperature range. The samples in the N* phase also exhibited selective reflection of visible light that changed from short to long wavelengths as the samples were cooled from the isotropic melt. These colours can be locked into the glassy state of the polymer by quenching below the glass transition temperature, but only if the S_A phase is absent. It was also noted that at high contents of the cholesteryl itaconate the selective reflection appears to occur in the ultraviolet region.

Key words: itaconic acid, copolymers, liquid crystalline polymers, cholesteric phases, selective reflection.

Résumé : On a préparé de nouveaux itaconates de mono- et di-cholestéryle et on a examiné leur comportement comme cristaux liquides thermotropes. On a homopolymérisé l'ester monosubstitué et on l'a aussi copolymérisé avec un mésogène non chiral, le 4′-(6-acryloyloxyhexyloxy)benzoate de 4-cyanophényle. L'examen de la série des copolymères qui ont été préparés en faisant appel à la calorimétrie à balayage différentiel et à la microscopie à plaque chauffante polarisante a permis de montrer que le contenu en itaconate de cholestéryle est élevé et que l'on retrouve une phase smectique-A (S_A) ainsi qu'une phase cholestérique (N*). On a trouvé que la phase S_A peut être éliminée en abaissant le contenu de l'itaconate de cholestéryle dans les échantillons donnant des copolymères qui ne présentent que la phase N* sur une plage plus étendue de température. Les échantillons dans la phase N* présentent aussi une réflexion sélective de la lumière visible qui passe des longueurs d'onde courtes à élevées lorsque les échantillons sont refroidis à partir du produit fondu isotrope. Ces couleurs peuvent être figées dans l'état vitreux du polymère par une trempe à une température inférieure à celle de la transition de la vitre; cette possibilité n'existe que si la phase S_A est présente. On a aussi noté que, si la quantité d'itaconate de cholestéryle est élevée, la réflexion sélective semble se produire dans la région ultraviolette.

Mots clés : acide itaconique, copolymère, polymères cristallines liquides, phases cholestériques, réflexion sélective.

[Traduit par la rédaction]

Introduction

Interest in chiral side-chain liquid crystal polymers has grown rapidly in recent years because of their potential in emerging optical technologies. Many exhibit piezo and pyroelectric effects, some are ferroelectric, and others are capable of selective reflection of electromagnetic radiation, particularly in the visible region (1–4). This latter property can be a function of both structure and temperature and in our own work we have used copolymerization as an additional means of fine tuning this behaviour (5–7). While these previous studies have used the strategy of introducing a chiral centre in the spacer between the mesogen and the chain backbone, this synthetic approach can be simplified by using instead the cholesteryl unit as a natural chiral mesogen and synthesizing monomers with this as a pendant side chain. While this structure tends to be susceptible to oxidative degradation and it is not the ideal unit to use for practical applications, examination of such systems can assist in our understanding of the relationships between copolymer constitution and the resulting optical properties.

Freidzon et al. (8) have observed differences in behaviour when the cholesteryl group is attached to acrylate and methacrylate units. Here we have selected the analogue, itaconic acid, as one monomer unit because it has the additional flexibility of having two functional sites for modification, if that is deemed necessary for further property modification. Both mono- and disubstituted cholesteryl itaconate ester monomers have been synthesized, but only the monosubstituted derivative proved amenable to polymerization reactions. These are structures **1** and **2**, shown below, and the monomer selected for the copolymerization reaction is 4-cyanophenyl-4′-(6-acryloxyhexyloxy) benzoate **3**, which is mesogenic but non-chiral.

Experimental section

Monomer synthesis

The precursor to the preparation of both mono- and disubstituted cholesteryl itaconates was cholesteryl-11-bromo undecanoate, which was synthesized following a route similar to that proposed by Freidzon et al. (9).

Cholesteryl-11-bromo undecanoate

Redistilled and dried triethylamine (4.05 g, 0.04 mol) was added to a solution of cholesterol (11.6 g, 0.03 mol) in anhydrous benzene (150 mL) and the mixture vigorously stirred whilst 10-bromo undecanoyl chloride (11.35 g, 0.04 mol) was added slowly dropwise, at room temperature. The resultant pink-coloured solution was stirred for a further 2 h and then the benzene removed in vacuo. Diethyl ether (200 mL) was added to the mixture along with water (100 mL), the layers were separated, and the organic phase was washed with two further portions of water (2 × 50 mL). The dried ($MgSO_4$) organic phase was reduced to about one quarter of its original volume and poured into a large excess of methanol to precipitate the product which was then collected by filtration. After washing with methanol the product, was dried and analysed for purity by tlc. No further purification was needed. Yield: 14.6 g, 77%; mp 104–106°C (lit. (9) mp 105°C).

1-[1-[Cholesteryloxy)carbonyl]-10-decanyl]-2-methylene-4-methyl butane-1,4-dioate 1

Monomethyl itaconate (6.34 g, 4.4 mmol) from the esterification of methanol with itaconic acid in the presence of acetyl chloride was dissolved in anhydrous methanol (15 mL) and cesium hydroxide (6.74 g, 4.4 mmol) was added. After complete dissolution the methanol was evaporated to give the cesium salt of monomethyl itaconate. Anhydrous DMF (120 mL) was added and the mixture stirred at 50°C for 2 h in the presence of hydroquinone (ca. 0.5 g). Cholesteryl-11-bromo undecanoate (7 g, 1.1 mmol) was then added and the mixture stirred for a further 24 h under nitrogen at 50°C. After cooling, DMF was coevaporated with xylene in vacuo and the residue dissolved in chloroform (200 mL). After washing with water (50 mL) the organic layer was washed with saturated sodium bicarbonate (2 × 50 mL) and then with water (50 mL). The chloroform layer was dried ($MgSO_4$), evaporated, and subjected to column chromatography using silica gel. The bromide starting material was eluted with toluene (R_f = 0.88, toluene) and the desired mixed ester was eluted with a 20% chloroform in toluene mixture (R_f = 0.22, toluene). Yield: 2.27, 74%; mp 14–17°C; ^1H nmr, δ ppm ($CDCl_3$; 90 MHz): 0.5–3.25 (m, 63H) cholesteryl R-H, undecyl $R(CH_2)_8$-COO-, vinyl -CH_2CO_2-; 3.7 (s, 3H) RCO_2CH_3; 4.13 (t, 2H) R-CH_2OCO-; 4.6 (m, 1H); 3α-H; 5.34 (m, 1H) cholesteryl 6-H (olefinic); 5.8 (s, 1H) vinylic H, *trans* to carbonyl; 6.3 (s, 1H) vinylic H, *cis* to carbonyl. Anal. calcd. for $C_{44}H_{72}O_6$ (696 $gmol^{-1}$): C 75.79, H 10.33; found: 76.19, H 10.81%.

Di-[1{(cholesteryloxy)carbonyl}-10-decanyl]-2-methylene butane 1,4-dioate 2

Anhydrous dicesium itaconate (2.6 g, 6.6 mmol) was prepared by dissolving relative amounts of itaconic acid and cesium hydroxide in methanol and evaporating to dryness. (Care must be taken at this point to ensure that the hygroscopic salt remains dry, as this affects the final yield.) The salt was added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

to a solution of cholesteryl-11-bromo undecanoate (9.5 g, 15 mmol) in dry DMF (100 mL) and the heterogeneous mixture stirred at ca. 70°C for 24 h under a blanket of nitrogen. It is important to keep the reaction temperature at 70°C or below to avoid isomerization of the itaconate ester into the citraconate ester. On cooling the reaction mixture, DMF was coevaporated in vacuo with xylene. Chloroform (250 mL) and water (50 mL) were added and the mixture shaken. The organic layer was washed with a further portion of water (50 mL) followed by saturated sodium bicarbonate solution (2 × 50 mL), and finally with water (50 mL). The dried ($MgSO_4$) organic layer was evaporated in vacuo and the crude product purified by column chromatography using silica gel. Unreacted bromide was eluted with toluene ($R_f = 0.88$, toluene) and the desired diester eluted with a 10% chloroform in toluene mixture ($R_f = 0.46$, toluene). Yield: 5.1 g, 63%; mp 38–40°C; ir: $\bar{\nu}$(thin film): 2850, 1720, 1660, 1470, 1395, 1180 cm^{-1}; ^1H nmr, δ ppm ($CDCl_3$; 80 MHz): 0.5–3.25 (m, 124H) cholesteryl R-H, undecyl $R(CH_2)_8COO$-, vinyl-CH_2CO_2-; 4.15 (t, 4H) RCH_2OCO; 4.6 (m, 2H) 3α-H; 5.34 (m, 2H) cholesteryl 6-H (olefinic); 5.8 (s, 1H) vinylic H *trans* to carbonyl; 6.32 (s, 1H) vinylic H *cis* to carbonyl. Anal. calcd. for $C_{81}H_{134}O_8$ (1234 $gmol^{-1}$): C 78.78, H 10.86; found: C 79.98, H 10.96%.

The comonomer 4-cyanophenyl-4′-(6-acryloyloxyhexyloxy) benzoate was prepared using a general procedure outlined by Portugall et al. (10) that was modified in the following three stages.

4-(6-Hydroxyhexyloxy)benzoic acid

4-Hydroxybenzoic acid (25.5 g, 0.185 mol) was dissolved in a mixture of ethanol (65 mL), water (28 mL), potassium hydroxide (27.75 g, 0.49 mol) and a pinch of potassium iodide. 1-Chloro-6-hydroxyhexane (23 g, 0.168 mol), was then added slowly, dropwise, and the mixture refluxed for 20 h. After cooling the mixture, the ethanol was evaporated in vacuo and the residue dissolved in water (200 mL). This aqueous solution was washed with diethyl ether (3 × 50 mL), then adjusted to pH 2 with 2 N HCl and the resultant precipitate collected by filtration. After washing with water and drying, the product was recrystallized from ethanol. Yield: 21.6 g, 54%; mp 139–142°C (lit. (10) mp 139°C).

4-(6-Acryloyloxyhexyloxy) benzoic acid

The alcohol prepared as above (21.6 g, 0.09 mol) was esterified azeotropically with freshly distilled acrylic acid (26 g, 0.36 mol) in benzene (300 mL) using *p*-toluene sulphonic acid (6 g, 0.03 mol) as the catalyst and hydroquinone (2 g, 0.018 mol) as the polymerization inhibitor. Reflux was continued for a further 20 h. On cooling, the reaction mixture was diluted with diethyl ether (1000 mL) and washed carefully with warm water until no more acrylic acid was detected. The organic layer was dried ($MgSO_4$), evaporated, and the crude product recrystallized from isopropanol to afford the liquid crystalline benzoic acid derivative. Yield: 17.6 g, 67%; k $\xrightarrow{86°C}$ N $\xrightarrow{90°C}$ I. Anal. calcd. for $C_{16}H_{20}O_5$ (292 $gmol^{-1}$): C 65.75, H 6.84; found: C 66.22, H 6.99%.

4-Cyanophenyl-4′-(6-acryloyloxyhexyloxy)benzoate 3

The target monomer was prepared by firstly converting the acid into the corresponding acid chloride, then condensing this with *p*-cyanophenol. The acid (17.32 g, 0.059 mol) was stirred with thionyl chloride (35.7 g, 0.3 mol) in the presence of DMF (2 drops) and 2,6-di-*tert*-butyl-4-methyl phenol (4.4 g, 0.02 mol). After ca. 25 min, by which time solution was achieved, the excess thionyl chloride was removed by rotary evaporation and high vacuum (1–2 h). The acid chloride residue was dissolved in anhydrous chloroform (30 mL), then added slowly dropwise into a stirred solution of *p*-cyanophenol (7.03 g, 0.059 mol) and triethylamine (6.07 g, 0.06 mol) in chloroform (20 mL) at 0°C. After the addition the mixture was stirred at room temperature for 24 h and then chloroform (200 mL) added. This solution was washed with water (50 mL) followed by 2 N sodium hydroxide solution (3 × 50 mL) and water (2 × 50 mL). The organic layer was dried ($MgSO_4$), evaporated, then subjected to flash chromatography, using dichloromethane as both the solvent and the eluant. The monomer was finally recrystallized from isopropanol and shown to be pure by tlc. Yield: 16 g, 69%; mp 72–75°C (lit. (10) mp 72°C); ^1H nmr, δ ppm ($CDCl_3$; 90 MHz); 1.2–2.1 (m, 8H) $R(CH_2)_4R$; 4.01–4.13 (overlapping t's, 2 × 2H) $ArOCH_2R$ and RCH_2OCO; 5.63–6.5 (m, 3H) vinylic H; 6.78–8.2 (4 × d, 8H) Ar-H. Anal. calcd. for $C_{23}H_{23}NO_5$ (393 $gmol^{-1}$): C 70.23, H 5.85, N 3.56; found: C 71.15, H 5.97, N 3.61%.

Characterization of liquid crystal behaviour

A hot-stage polarizing microscope was used to identify the mesophases in the samples and the temperature range of stability. Transitions were also located by differential scanning calorimetry (DSC) and the instrument used was a Perkin Elmer DSC2 at a scanning rate of 20°C min^{-1}. Glass transition temperatures (T_g) were recorded as the onset of the baseline shift that occurs during this transition and the mesophase transitions were detected from the presence of small endothermic peaks during the heating cycle or exothermic peaks on cooling.

Copolymerizations

Reactions were carried out under vacuum, using benzene as solvent at a temperature of 60°C, in the presence of the radical initiator 2,2′-azo bisisobutyronitrile (0.5 mol%). For copolymerizations the reaction conversion was restricted to ≤15% to minimize composition drift and the copolymers were isolated by precipitation in methanol, ethanol, or ether. Samples were purified by repeated dissolution–precipitation, then dried in vacuo. Copolymer compositions proved difficult to determine with any accuracy and so the trends in behaviour are expressed in terms of the molar feed composition of the monosubstituted itaconate monomer, f_1.

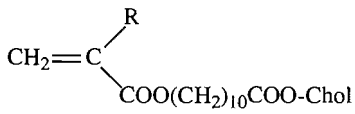
Characterization

Molar masses were measured either by membrane osmometry (Knauer) or by vapour pressure osmometry (Hewlett–Packard 302b).

Results and discussion

The cholesteryl derivatives of itaconic acid **1** and **2** are new compounds, both of which were found to exhibit liquid crystal phases, and their mesogenic characteristics can be compared with other cholesteryl acrylates and methacrylates that have been reported elsewhere (8). The monosubstituted monomer **1** displayed both a smectic A (S_A) phase and a cholesteric phase

Table 1. Comparison of the phase transition temperatures for cholesteryl containing monomers of the general structure



R	Meosphase temperature ranges
H[a]	$k_I \xrightarrow{28} k_{II} \xrightarrow{51} S \xrightarrow{54} N^* \xrightarrow{73} I$

CH_2COOCH_3	$k \xrightarrow{16} S_A \xrightarrow{42} N^* \xrightarrow{54} I$
$CH_2COO(CH_2)_{10}COOChol$	$k \xrightarrow{39} S_A \xrightarrow{65} N^* \xrightarrow{72} I$

k = crystal; I = isotropic liquid
[a]Data from ref. 8.

(N*) in common with the acrylic analogues, and the transition temperatures for each can be compared with reference to Table 1.

While the phases observed are similar in all cases, the temperature at which each appears depends strongly on the substituent on the α-carbon atom. Freidzon et al. (8) reported two crystal phases for the acrylate derivative that then passed into a brief smectic phase (51–54°C), before the appearance of the N* phase as the temperature was raised. For the methacrylate derivative the melting temperature T_m was higher but the clearing temperature T_I was lower, giving a restricted liquid crystal range of only 7°C in total. The itaconate derivatives both exhibited much wider temperature ranges for the liquid crystal phases. Monomer **1** had the lowest T_m, but the S_A phase is now extended over a 26°C range, although T_I is again the lowest in the series. The increased size of the -(-CH_2CO_2-CH_3) side group in **1** appears to destabilize the crystalline order but enhanced the formation of a smectic phase. Monomer **2** also exhibited an extended S_A phase that was stable over 26°C but the added bulk of the second side-chain raises both T_m and T_I, with a concomitant reduction in the range for the N* phase. In both cases the itaconate derivatives have extended S_A phases that appear to be a consequence of the bulky substituents on the α-carbon atom.

Homopolymerization

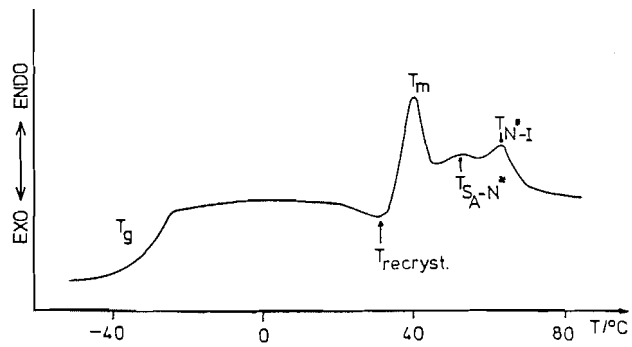
The polymerization of **1** was successful but high molar mass material was difficult to obtain, with typical values of M_n lying around 10^4. Attempts to polymerize **2**, however, were totally unsuccessful and, although conditions were varied, no polymer was formed using radical initiators. Itaconic acid derivatives (11) are known to be more difficult to polymerize than their acrylate or methacrylate counterparts, and it would appear that the steric restrictions imposed by the disubstituted derivative are too great to allow polymer formation.

The polymer (**P1**) of monomer **1** was also found to be a thermotropic liquid crystalline material and passes through the following sequence of phase changes where "g" represents the glassy state:

$$g \xrightarrow{-35°C} k \xrightarrow{41°C} S_A \xrightarrow{52°C} N^* \xrightarrow{64°C} I$$

The DSC trace, shown in Fig. 1, indicates that the sample

Fig. 1. DSC trace for polymer of monomer **1**.



undergoes a cold crystallization followed rapidly by melting at T_m = 41°C, which is much higher than the parent monomer **1**. There are also increases in the $T_{S_A-N^*}$ and T_{N^*-I} transition temperatures for the polymer, which is typical when mesogens are incorporated into a polymer chain and the motional modes are now more restricted.

Liquid crystal textures

Liquid crystal polymers with chiral mesogenic groups, either in the main chain or, more commonly as with the samples reported here, in the side chain, display a cholesteric (or chiral nematic) phase that has special optical properties. The directors of the nematic layers tend to be displaced by a few degrees from those in the adjacent layers, such that they trace out a supermolecular helical structure, formed by the directors twisting regularly about an axis perpendicular to the layers. This chiral perturbation minimizes the energy of the stacked array with each molecule skewed at an average angle $\pm\theta$ with respect to its neighbours above and below. These helical aggregates have dimensions of the order of visible light and exhibit remarkable circular dichroism effects, being able to reflect circularly polarized light of wave length λ_R, selectively. This wavelength is proportional to the pitch p of the helical structure in the liquid crystal phase, i.e.,

$$[1] \quad \lambda_R = \tilde{n}\mathbf{p}$$

where $\tilde{n}$ is the average refractive index of the cholesteric phase.

Examination of the itaconate monomers and polymer, using a hot-stage microscope, showed that on cooling from the isotropic melt all the samples formed a grey-coloured homogeneous planar texture with oily streaks, spontaneously. This is typical of the Granjean texture exhibited by most cholesteric phases and is formed more rapidly in the monomers than the polymer because of the lower viscosity of the former.

On cooling further, selective reflection of visible light was observed with the colours appearing first as blue and changing through the spectrum to red as the transition from the cholesteric to the smectic phase was approached. At this point the planar texture was rapidly transformed into the focal-conic fanned texture typical of a smectic A phase, as shown in Fig. 2.

As the pitch of the helical structure formed can be varied by

altering the temperature, the value of λ_R can also be changed. In the case of the systems studied here, the colour changes indicate that the helix pitch is short at temperatures just below the clearing temperature (characterized by the blue reflection, although the suggestion is that the samples may reflect in the UV initially) and progressively lengthens or unwinds as the temperature drops until it becomes very long and the molecules pass into the more ordered smectic phase.

Copolymers of 1 and 3

We have shown previously (5–7) that copolymerization of a chiral mesogen with a non-chiral mesogen can alter (*a*) the number of liquid crystal phases observed, (*b*) the temperature range over which the liquid crystal phases are stable, and (*c*) can effect some control over the wavelength of the selective reflection. For example, it has been observed (12) that the pitch of the helix in an N* phase is a function of the mole fraction of chiral units X* in the copolymer, i.e.,

$$[2] \quad \lambda_R \alpha {}^{1}/_{X^*}$$

These phenomena were examined here by preparing copolymers of the cholesteric monomer **1** with the non-chiral monomer **3**. Details of the samples and their transition temperatures are given in Table 2. The temperature stability ranges are better represented diagrammatically and are shown plotted as a function of the mole fraction of **1** in the copolymerization feed f_1, in Fig. 3.

The copolymerization reactions were much more facile than the homopolymerization of **1** and average values of M_n for the copolymers were found to be in the region of (2–6) × 10^4. All exhibited glass transition temperatures, T_g, ranging from below to above ambient, indicating that the samples were amorphous with no evidence of the crystallinity observed in the homopolymer **P1**.

Another general observation is that copolymers with lower concentrations of the chiral monomer incorporated in the chain do not display a smectic phase. This is a distinct advantage as it is now possible to freeze a particular reflection colour into the polymer glass, by quenching the copolymer rapidly from the appropriate temperatures in the N* phase. This is not possible, or is extremely difficult, to do if there is an intervening smectic phase, as there is a tendency for the helical structure to unwind rapidly at the transition point between the N* and S_A phases during the cooling cycle.

The samples were examined in some detail using DSC and the hot-stage polarizing microscope. Copolymers **4a** and **4b** with low concentrations of **1** in the chain exhibited only the N* phase. On cooling from the isotropic melt both formed pale blue, homogeneous, planar textures with white oily streaks, characteristic of the cholesteric phase. Slow cooling of sample **4a** gave reflected colour changes in the sequence:

95°C/blue → 64°C/yellow → 40°C/orange

Sample **4b** showed a similar trend but in a different temperature range:

82°C/blue → 68°C/green → 50°C/yellow → 25°C/red-orange

As the alignment of the samples, on cooling from the isotropic

melt, is not perfect, the colours are "grainy," because they are a diffuse mixture of slightly different wavelengths centred on the main reflected wavelength that dominates the sample colour. This is caused by the tilting of the helical aggregates away from the ideal planar state.

The colour changes were found to be reversible on heating and the sequences indicate that the helical structure is unwinding as the temperature is lowered. This is the normally observed trend for both main-chain (13) and side-chain (14) polymers, but the opposite temperature dependence has been known to occur (8). This can be explained by postulating that the temperature dependence of the pitch of the helix is a consequence of two opposing effects. As the temperature rises the system expands and the pitch length increases, but this is offset by an increase in the displacement angle θ between the directors, which leads to a reduction in the pitch (15). In the systems discussed here the latter appears to dominate.

With a further increase in the cholesteric monomer content of the polymer the behaviour of the samples changes. Sample **4c** still exhibits only the one liquid crystal phase, N*, but on cooling from the melt an imperfect grey/blue planar texture was formed that was improved only after annealing the sample for 12 h. The selective reflection was now quite indistinct and was no longer a vivid blue. It was likely that λ_R was now partially displaced into the ultraviolet region and further slow cooling was needed to initiate a change to a pale blue reflection that remained stable until room temperature was reached.

When the content of **1** in the feed exceeded 0.5 mol fraction as for sample **4d**, the smectic-A phase reappeared, which restricted the N* phase to about 11°C. A grey-coloured planar texture formed spontaneously on cooling from above T_I and remained unchanged on further cooling until the N*–S_A transition was approached. Here the so-called pretransitional phenomenon (16) was observed, which is manifest as a rapid series of colour changes through the visible spectrum as the helix unwinds, followed by the transformation into the typical fanned focal-conic texture of the S_A phase. A similar phenomenon was observed on cooling the polymer **P1**.

The relationship expressed in eq. [2] was confirmed by the observations made on these copolymer samples. In the temperature range 60–70°C, for example, the selective reflection colours for **4a**, **4b** and **4c** were green, yellow, and blue, respectively, indicating a move to shorter wavelengths as the content of **1** in the copolymer increased. Thus a greater preponderance of the cholesteric units leads to a shortening of the pitch length of the helical structure in the N* phase with a possible move of the λ_R into the ultraviolet region. Unfortunately, the increased content of **1** also leads to the formation of a smectic phase, which would make it difficult to lock the UV reflecting phase into these polymer glasses.

A stabilized and persistent tetraketene: 1,4-bis(1′,4′-dioxo-3′-trimethylsilyl-2′-buta-1′,3′-dienyl)benzene

Ronghua Liu and Thomas T. Tidwell

Abstract: Reaction of 1,4-bis(trimethylsilylethynyl)benzene with CCl_3COCl and Zn gave 1,4-bis(4′,4′-dichloro-2′-trimethylsilyl-3′-oxo-1′-cyclobutenyl)benzene (**7**), which reacted with concentrated H_2SO_4 at 87°C to give 1,4-bis(2′-trimethylsilyl-3′,4′-dioxo-1′-cyclobutenyl)benzene (**8**). Photolysis of **8** in $CDCl_3$ with 350 nm light gave the bisketene **9**, which on further photolysis formed the title tetraketene **10**, as identified by its spectral properties. Upon heating of **10** the successive closure of the two bisketene moieties, first to give the mono(cyclobutenedione) **9** and then to reform **8** in a slower step, was observed by NMR and UV spectroscopy. Reaction of **10** with MeOH gave the tetraester **11**, which was assigned the *erythro* configuration at each of the succinate moieties.

Key words: ketenes, photolysis, cyclobutenediones, esterification, silicon.

Résumé : La réaction du 1,4-bis(triméthylsilyléthynyl)benzène avec le CCl_3COCl et le Zn conduit au 1,4-bis(4′,4′-dichloro-2′-triméthylsilyl-3′-oxo-1′-cyclobuténynl)benzène (**7**) qui réagit avec du H_2SO_4 à 87°C, pour fournir du 1,4-bis(2′-triméthylsilyl-3′,4′-dioxo-1′-cyclobuténynl)benzène (**8**). La photolyse du composé **8**, dans du $CDCl_3$ à 350 nm, fournit le biscétène **9** qui par photolyse ultérieure forme le tétracétène **10** mentionné dans le titre qui a été identifié par ses propriétés spectrales. Lors du chauffage du composé **10** on a pu observer les cyclisations successives des deux portions biscéténiques qui conduisent en premier lieu à la mono(cyclobutènedione) **9** et qui redonnent le composé **8** lors d'une réaction plus lente. La réaction du composé **10** avec de l'alcool méthylique conduit au tétraester **11** auquel on a attribué la configuration *érythro* pour chacune des portions succinates.

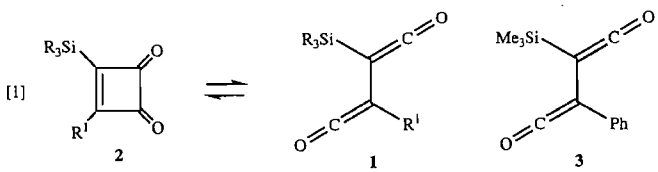
Mots clés : cétènes, photolyse, cyclobutènediones, estérification, silicium.

[Traduit par la rédaction]

Introduction

Ketenes have been actively studied for 90 years (1), and the first bisketene, carbon suboxide (O=C=C=C=O), was reported in 1906 (2*a*). Because of their interesting and potentially useful polyfunctionality, the chemistry of carbon suboxide (2) and other bisketenes (1*e*, 3–5) has been of continued interest. In particular, the potential utility of these materials as polymer intermediates has been widely recognized (4*e*, *f*).

Recently we reported (6) that a variety of long-lived 1,2-bisketenes **1** substituted with stabilizing (7) trialkylsilyl groups (Me_3Si, *t*-$BuMe_2Si$, i-Pr_3Si) may be prepared from photolysis or thermolysis of the corresponding cyclobutenediones (**2**), as shown in eq. [1]. When these bisketenes have two trialkylsilyl substituents they are thermodynamically stable relative to the cyclobutenedione precursors (6*a*, *b*), but in examples substituted with one Me_3Si group and either Ph (**3**) or Me the bisketene is rather long lived at room temperature, but reverts to the more stable cyclobutenedione at measurable rates at higher temperatures (6*c*, *d*).



Bisketenes in which the ketenyl groups are nonadjacent have been prepared and directly observed in only a few cases (1*e*, 4*a*, *b*). 1,2-Bisketenes without stabilizing silyl substituents were previously generated as intermediates that could be detected at low temperatures, or trapped by various reagents (5). Polyketenes may have been generated (8) by photolysis of polycyclobutenediones in a matrix at 30 K, as in the reaction of **4** to give an IR band at 2115 cm^{-1}, possibly due to hexaketene **5** (eq. [2]). Further photolysis led to decarbonylation and possible formation of cyclooctadecanonyne (C_{18}). We now report the preparation and reactivity of a longlived tetraketene stabilized by Me_3Si groups.

Results and discussion

The reaction of trimethylsilylacetylene with 1,4-diiodobenzene in the presence of palladium acetate, copper(I) iodide, and triphenylphosphine gave 1,4-bis(trimethylsilylethy-

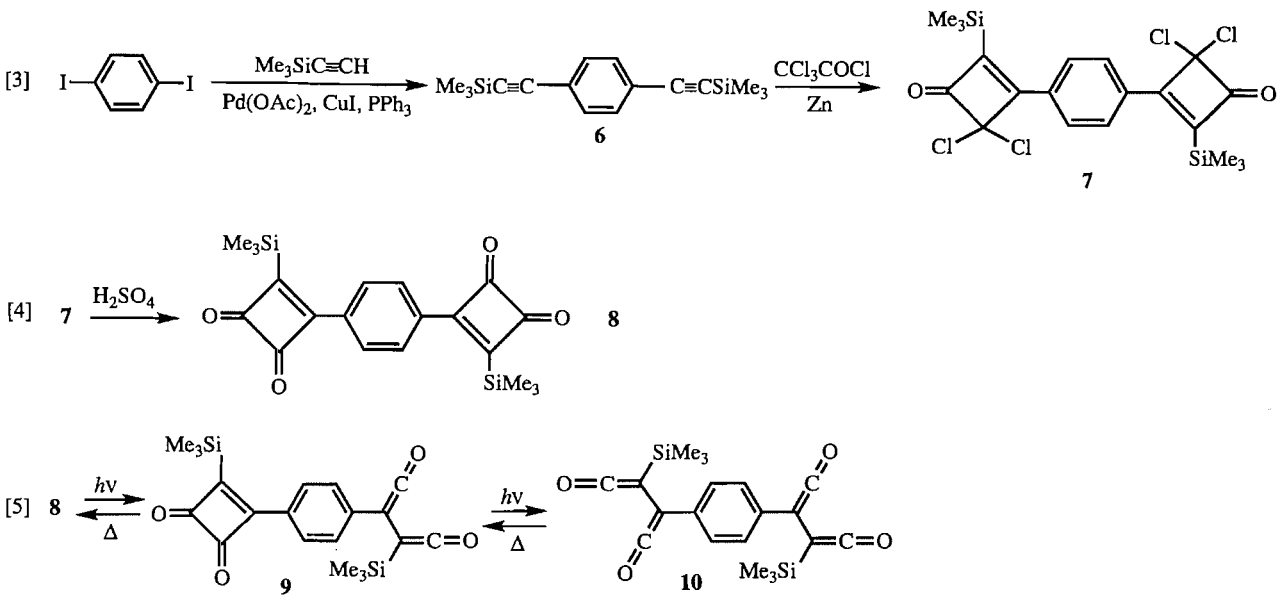
nyl)benzene **6** in 88% yield. This reaction is analogous to a reported preparation of **6** using $Pd(PPh_3)_2Cl_2$ (9*a*). The reaction of **6** with dichloroketene generated from trichloroacetyl chloride and zinc dust, activated by ultrasonic irradiation (9*c*), gave the bis(oxocyclobutenyl)benzene **7** (eq. [3]), together with minor amounts of products of chlorine migration. Reaction of **7** with concentrated H_2SO_4 at 87°C followed by hydrolysis gave the tetraketone **8** (eq. [4]). The structures of **7** and **8** were easily assigned from their characteristic spectral properties, especially their ^1H NMR spectra, which showed only single Me_3Si and aryl resonances for each.

Upon heating of **8** to 100°C in $CDCl_3$ no significant change could be detected in the ^1H NMR spectrum. However, upon photolysis with 350 nm light for 5 min at 25°C there was a color change to a deeper yellow, and the ^1H NMR spectrum indicated the presence of three components assigned (vide infra) as residual tetraketone **8**, the bisketene **9**, and the tetraketene **10**, in a relative ratio of 30:30:40. Upon further photolysis for 1 h the signals due to **8** and **9** each decreased to less than 5% of the total, and 90% of the signals present were assigned to the tetraketene **10**. Upon further photolysis for an additional 15 h further signals appeared, assigned to formation of the alkyne **6** to the extent of about 5%. These photochemical changes correspond to those observed in the photochemical ring opening of the cyclobutenedione **2** (R_3Si = Me_3Si, R^1 = Ph) to form the bisketene **3** (6*c*, *d*), and so the process is assigned as initial photolysis of tetraketone **8** to form the bisketene **9**, which on further photolysis forms the tetraketene structure **10** (eq. [5]). Other evidence for the structure of **10**



includes the ketenyl IR band observed at 2086 cm^{-1}, which is comparable to that at 2084 cm^{-1} for bisketene **3** (6*c*, *d*), and the very distinctive signals in the ^{13}C NMR spectrum at δ 6.9 and 32.8 for the Me_3Si and aryl-substituted ketenyl carbons, as compared to the values for the corresponding carbons of **3** at δ 7.9 and 33.5, respectively.

Upon heating, the reversion of **10** to **8** could be observed by monitoring the disappearance of the UV absorption of **10** at 280 nm, and the increase in absorption at 320 nm. Two separate processes were observed, and these are attributed to the initial conversion of **10** to **9**, and then a slower conversion of **9** to **8**. Upon heating the solution of **10** in $CDCl_3$ for 10 min at 100°C, the signals due to **10** completely disappeared, and the spectra of **9** could be observed, together with those of **8**, in a ratio of 55:45. Spectral features assigned to **9** include the ketenyl IR band at 2101 cm^{-1}, ^1H NMR absorption of the ketenyl and cyclobutenyl $(CH_3)_3Si$ groups at δ 0.24 and 0.47, respectively, and signals for nonequivalent pairs of protons on the aromatic ring at 7.26 and 7.94 (each doublet, J = 8.4 Hz). The kinetics of the thermal conversion of **10** to **9** and then to **8** are under investigation as part of a study of the effect of aryl substituents on the rates of bisketene ring closures.[2]

The appreciable kinetic stability at room temperature of the bisketene **9** and the tetraketene **10** are indicative of significant barriers for the ring closure. Analogous behavior has been previously found experimentally for **3** (6*c*, *d*), and quantitative agreement has been found (6*e*) between the experimental barrier for ring opening of **2** (R = Me, R^1 = Me_3Si) and the theoretically calculated barrier for **2** (R = H, R^1 = SiH_3).

Excess methanol was added, at −78°C, to a solution of the tetraketene **10** generated by photolysis of **8**, and the solution was kept at 0°C for 10 h. By this time the tetraketene had disappeared, and signals attributed to a mixture of the stereomeric tetraesters **11** were observed. The mixture was purified by flash chromatography, and the product had NMR, IR, and mass spectral properties consistent with those expected for **11**.

There are six possible diastereoisomers of **11**, but the ^1H and ^{13}C NMR spectra indicated that a single diastereomer predominated, and the spectra resembled those of the isomer of **12** from the reaction of **3** with MeOH, which has been assigned the *erythro* structure (6*d*). On this basis the structure of the major isomer of **11** is also assigned as being one of the two *erythro*, *erythro* diastereomeric structures of **11**, either the achiral **11B**, or the chiral **11C**, or a mixture of the two, which would be expected to have very similar chromatographic and spectral properties.

The structure assigned (6*d*) as the *erythro* isomer of **12** showed, in the ^1H NMR spectrum ($CDCl_3$), δ: 0.13 (Me_3Si), 3.10 (d, J = 12.4 Hz, C*H*TMS), 3.38 and 3.62 (each OCH_3), 4.02 (d, J = 12.4 Hz, C*H*Ph), and 7.24–7.34 (br s, Ph), while the structure assigned as the *threo* isomer gave an ^1H NMR spectrum ($CDCl_3$), δ: −0.21 (Me_3Si), 2.96 (d, J = 12.4 Hz, C*H*TMS), 3.60 and 3.69 (each OCH_3), 4.09 (d, J = 12.4 Hz, C*H*Ph), and 7.31 (br s, Ph). The major peaks for **11** were δ: 0.11 (Me_3Si), 3.04 (d, J = 12.4 Hz, C*H*TMS), 3.33 and 3.62 (each OCH_3), 4.00 (d, J = 12.4 Hz, C*H*Ph), and 7.27 (s, C_6H_4), and these are in close agreement with the structure assigned as *erythro*-**12**, but not *threo*-**12**.

The six diastereomers of **11** and the respective absolute configurations of the carbons 1–4 are **A** (*R, R, R, R/S, S, S, S*), **B** (*R, S, R, S*; achiral), **C** (*R, S, S, R/S, R, R, S*), **D** (*R, R, R, S/S, S, S, R*), **E** (*R, R, S, S*; achiral), and **F** (*R, S, R, R/S, R, S, S*), and of these **B** and **C** each have two *erythro* side chains.

In the reaction of **3** with MeOH there was a 2/1 preference for the formation of the isomer assigned the *erythro* structure **12** as opposed to the *threo* structure **12**. Experiments are in progress to determine whether this product mixture represents an equilibrium mixture of these two structures.

In summary, photolysis of **8** produces the bisketene **9**, which upon further photolysis forms the tetraketene **10**. Both **9** and **10** are long lived at room temperature and can be directly observed by IR, NMR, and UV spectroscopy. The thermal conversion of **10** to **9**, which then forms **8** in a slower step, is also observable, and reaction of **10** with MeOH leads to the tetraester **11**. The further chemistry of these unique polyfunctional intermediates is being actively explored.

Experimental

General procedures

Most of the reagents and solvents were obtained from Aldrich or BDH. Ether was distilled from sodium–benzophenone. All reactions were carried out in oven-dried glassware and $CDCl_3$, used as a reaction solvent, was dried over 4A molecular sieves. NMR spectra were measured using Varian Germini 200 and XL-400 spectrometers. Infrared spectra were measured using Nicolet DX FT-IR and Perkin–Elmer 882 instruments. Mass spectra were obtained on a VG 70-2505 instrument by Dr. A. Young. The sonicator was a Branson model 1200. The UV absorption data were obtained using a Varian 210 instrument. Photolyses were carried out with a Rayonet RPR-100 photoreactor.

1,4-Bis(trimethylsilylethynyl)benzene (6)

To a 500 mL three-neck flask equipped with a Dry Ice condenser was added successively 250 mL triethylamine, 1,4-diiodobenzene (20.0 g, 0.061 mol), triphenylphosphine (0.65 g, 2.48 mmol), cuprous iodide (0.24 g, 1.26 mmol), (trimethylsilyl)acetylene (14.7 g, 0.15 mol), and palladium(II) acetate (0.32 g, 1.42 mmol), and the reaction mixture was stirred at room temperature for 4 h under nitrogen and then the solvent was removed using the rotary evaporator. The residue was recrystallized from hexanes to afford colorless crystals of **6** (14.5 g, 0.054 mol, 88%), with spectra and melting point consistent with the literature (9*a*).

1,4-Bis(4′,4′-dichloro-2′-trimethylsilyl-3′-oxo-1′-cyclobutenyl) benzene (7)

To a dry, 100 mL round-bottom flask under nitrogen was added zinc dust (13.0, g, 0.2 mol), **6** (2.0 g, 7.4 mmol), and 60 mL anhydrous ether. The flask was then partially submerged

in a sonicator water bath, trichloroacetyl chloride (21.9 g, 0.116 mol) dissolved in 12 mL anhydrous ether was added dropwise over 0.5 h, and the reaction mixture was left under sonication for another 2 h. The product was filtered through Celite to remove unreacted zinc, the Celite was washed with ether, and the solvent was evaporated from the filtrate. The residue was separated by flash chromatography, with elution by 2/3 dichloromethane and hexanes, to give a light yellow solid (1.95 g, 3.96 mmol, 52%), which by ^{1}H NMR was a mixture of **7** and a small amount of an isomeric product of chlorine migration. Pure **7** was obtained by recrystallization from ethyl acetate and hexanes; mp 181.0–182.0°C; IR ($CDCl_3$): 1799 (C=O), 1620 (C=C), 1550 cm^{-1}; ^{1}H NMR ($CDCl_3$), δ: 0.43 (s, 18H, Me_3Si), δ: 8.08 (s, 4H, Ar), ^{13}C NMR ($CDCl_3$), δ: −1.6, 125.6, 130.4 132.0, 157.6, 178.4, 182.3; EIMS, *m/z*: 496, 494, 492, 490 (M^+, 27), 449 (M^+ − CO, CH_3, 15), 149 (M^+ − 4Cl, 2CO, 2TMS, 38); 73 (Me_3Si^+, 100); HRMS, *m/z*, calcd. for $C_{20}H_{22}Cl_4O_2Si_2$: 489.9912; found: 489.9924.

1,4-Bis(2′-trimethylsilyl-3′,4′-dioxo-1′-cyclobutenyl)-benzene (8)

Crude **7** (0.31 g, 0.62 mmol) was dissolved in 10 mL chloroform in a 50 mL round-bottom flask, 10 mL concentrated sulfuric acid was added with magnetic stirring, and the mixture was heated at 87°C for 0.5 h. The reaction mixture was added to 100 mL of ice–water mixture, extracted three times with 20-mL portions of ether, the extracts were washed with three 40-mL portions of water and dried over anhydrous magnesium sulfate, and the solvents were evaporated to give 0.28 g crude tetraketone **8**. Purification by flash chromatography eluted with 30% dichloromethane in hexanes gave pure tetraketone **8** (66 mg, 0.17 mmol, 28%) as a yellow solid, mp 203.0 – 203.5°C; IR ($CDCl_3$): 1732 (s, C=O), 1776 (w, C=O), 1488 (m, C=C) cm^{-1}; UV, λ_{max} (acetonitrile): 320 nm; ^{1}H NMR ($CDCl_3$), δ: 0.50 (s, 18, Me_3Si), 8.10 (s, 4, Ar); ^{13}C NMR ($CDCl_3$), δ: −1.8, 129.8, 132.7, 197.0, 197.5, 199.9, 205.6; EIMS *m/z*: 382 (M^+, 25), 326 (M^+ −2CO, 28), 293 (M^+ − TMS, O, 33); 73 (100, Me_3Si^+); HRMS, *m/z* calcd. for $C_{20}H_{22}O_4Si_2$: 382.1057; found: 382.1047.

1,4-Bis(1′,4′-dioxo-3′-trimethylsilyl-2′-buta-1′,3′-dienyl)benzene (10)

A solution of **8** (0.010 g, 0.03 mmol) in 0.8 mL $CDCl_3$ in an NMR tube was degassed for 15 min, then sealed and photolyzed at 350 nm for 5 min at 25°C. The ^{1}H NMR spectrum revealed the presence of residual **8**, the bisketene **9** (vide infra), and the tetraketene **10** in a relative ratio of 30:30:40. Upon further photolysis for 1 h, the signals due to **8** and **9** each decreased to less than 5% of the total, and 90% of the signals present were assigned to the tetraketene **10**, as identified by its spectral properties: IR ($CDCl_3$): 2086 (C=C=O) cm^{-1}; UV, λ_{max} : 280 nm; ^{1}H NMR ($CDCl_3$), δ: 0.20 (s, 18, Me_3Si), 7.05 (s, 4, Ar); ^{13}C NMR ($CDCl_3$ at −30°C), δ: −0.8, 6.9, 32.8, 124.2, 127.7, 178.0, 203.0. Upon further photolysis the amount of **10** in the sample decreased, and the ^{1}H NMR signal of the alkyne **6** increased.

1-(1′,4′-Dioxo-3′-trimethylsilyl-2′-buta-1′,3′-dienyl)-4-(2′-trimethylsilyl-3′,4′-dioxo-1′-cyclobutenyl)benzene (9)

The sample of **10** obtained above was heated for 10 min at 100°C. The ^{1}H NMR spectrum revealed the absence of **10**, and the presence of **8** and **9** in a ratio of 45:55. The structure of **9** was assigned based on its mode of formation and spectral properties: IR ($CDCl_3$); 2101 cm^{-1}; ^{1}H NMR ($CDCl_3$), δ: 0.24 (s, 9, Me_3Si), 0.47 (s, 9, Me_3Si), 7.26 and 7.94 (each d, 2, J = 8.4 Hz, C_6H_4). Upon further heating for 20 min there was almost complete reformation of **8**, as indicated by ^{1}H NMR.

Reaction of tetraketene 10 with methanol to form esters (11)

Tetraketone **8** (25 mg, 0.065 mmol) in 0.5 mL $CDCl_3$ was photolyzed under 350 nm for 35 min, and then 72 μL (excess) anhydrous methanol was added at −78°C. The NMR tube then was warmed to room temperature and left overnight at 0°C. After purification by radial chromatography using 30/70 ethyl acetate/hexanes, the product was shown by ^{1}H NMR to be a mixture of tetraester stereoisomers. The major isomer gave IR ($CDCl_3$): 1756, 1734 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$), δ: 0.11 (s, 18, Me_3Si), 3.04 (d, 2, J = 12.4 Hz, C*H*TMS), 3.33 and 3.62 (each s, 6, OCH_3), 4.00 (d, 2, J = 12.4 Hz, C*H*Ph), 7.27 (s, 4, Ar); ^{13}C NMR ($CDCl_3$), δ: 2.12, 41.36, 49.40, 50.83, 52.18, 128.08, 138.07, 173.14, 173.16; EIMS, *m/z*: 510 (2, M^+), 495 (67, M^+ − CH_3), 451 (100, M^+ −CO_2Me); HRMS, *m/z* calcd. for $C_{24}H_{38}O_8Si_2$: 510.2105; found: 510.2094.

Fluorescence energy transfer studies in a cross-linked polyurethane network

Jie Yang and Mitchell A. Winnik

Abstract: A series of cross-linked polyurethane samples, labeled with dyes suitable for fluorescence energy transfer experiments, were prepared (donor, phenanthrene; acceptor, anthracene). Fluorescence decay profiles for these samples were measured as a function of acceptor concentration. These decays obey Förster nonradiative energy transfer kinetics, with an energy transfer critical distance (R_0) of 26.7 Å. Fluorescence intensities, calculated from the decays by integrating the decay profiles, also fit the Perrin model, with a quenching radius (R_s) of 25.6 Å. The fluorescence decay profiles were further examined with a distribution analysis method, which also revealed uniformly distributed donors and acceptors in the polymer matrices.

Key words: fluorescence quenching, fluorescence decay, phenanthrene, anthracene, polyurethane.

Résumé : Nous avons préparé une série d'échantillons de polyuréthanes réticulés, marqués de colorants appropriés pour des expériences de transfert d'énergie de fluorescence (donneur : phénanthrène; accepteur : anthracène). Nous avons mesuré les profils de décroissance de la fluorescence en fonction de la concentration d'accepteur. Ces décroissances obéissent à une cinétique de transfert d'énergie non radiative de Förster avec une distance critique de transfert d'énergie (R_0) de 26,7 Å. Les intensités de fluorescence, calculées à partir des décroissances par une intégration des profils de décroissance, s'ajustent aussi au modèle de Perrin, avec un rayon de désactivation (R_s) de 25,6 Å. On a aussi examiné les profils de décroissance à l'aide d'une méthode d'analyse statistique qui a aussi révélé que la distribution des donneurs et des accepteurs est uniforme dans les matrices de polymères.

Mots clés : désactivation de la fluorescence, décroissance de la fluorescence, phénanthrène, anthracène, polyuréthane.

[Traduit par la rédaction]

Introduction

Fluorescence energy transfer is being used increasingly in polymer science, to study various polymer properties (1), such as polymer conformation (2), diffusion (3), and morphology (4). To use this method, polymers are usually labeled with fluorescent dyes, among which the phenanthrene–anthracene pair (Phe, energy transfer donor; An, energy transfer acceptor) have often been employed (2*c*, 3*a*, 4*d*). In both simple and cross-linked polymer films, energy transfer from phenanthrene (donor) to anthracene (acceptor) should occur by the dipole coupling (Förster) mechanism. Direct nonradiative energy transfer (DET) by the Förster mechanism leads to nonexponential fluorescence decay curves (5). The shape of the curve depends upon the detailed description of the donor–acceptor (Phe/An) pair distribution. In films that are not cross-linked, one anticipates a uniform distribution of donors and acceptors. However, for labeled polymers of high molecular weight, the "correlation hole" can perturb the dye distribution (6). Therefore, in cross-linked polymer films, one has to exercise special care to establish whether the cross-linking chemistry perturbs that distribution. Here we examine cross-linked polyurethane films containing covalently bound Phe and An in the polymer backbone. Through careful fluorescence decay measurements, we establish that there is in fact a uniform distribution of donors and acceptors in the system.

In a system with uniformly distributed donors and acceptors in three dimensions, the donor fluorescence intensity decay $I_D(t)$ is described by eq. [1], where τ_0 is the donor fluorescence lifetime in the absence of acceptors, and P is proportional to the acceptor (quencher) concentration [Q] (5, 7):

$$[1] \quad I_D(t) = A \exp\left[-\frac{t}{\tau_0} P\left(\frac{t}{\tau_0}\right)^{0.5}\right]$$

$$[2] \quad P = \gamma \times \frac{4\pi^{3/2} N R_0^3 [Q]}{3000}$$

In eq. [2], γ is an orientation factor, N is Avogadro's number, and R_0 is the Förster critical radius for energy transfer.

The Perrin model (8) is a related but simplified model, which also describes static quenching between randomly distributed and immobile fluorophores and quenchers that are accidentally in proximity. In this model, one presumes that there is instantaneous quenching of an excited donor (D*) by a

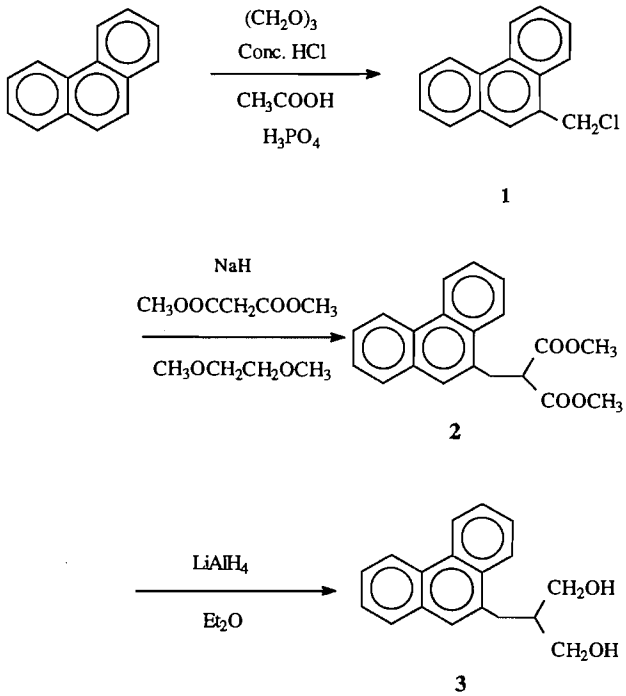
Table 1. Polyurethane sample compositions.

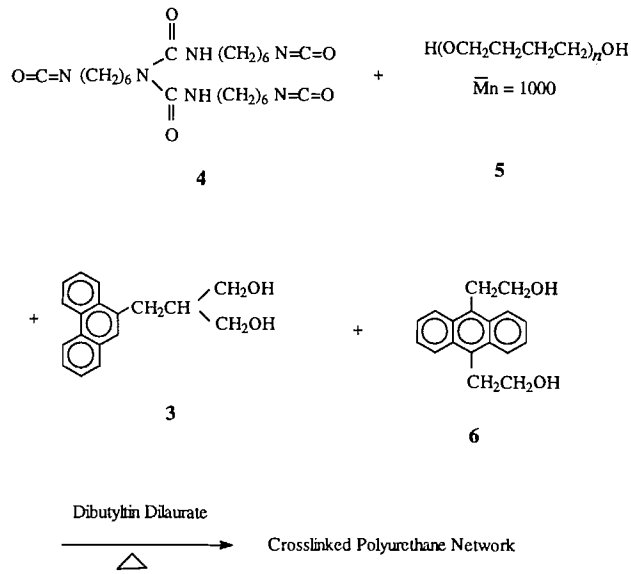
Sample	Polytetramethylene glycol **5** (mg)	Triisocyanate **4** (mg)	Phe-diol **3** (mg)	An-diol **6** (mg)	An/Phe Ratio
PU0	1500	575	0.8	0	0
PU1	1500	575	0.8	0.8	1
PU3	1500	575	0.8	2.4	3
PU6	1500	575	0.8	4.8	6
PU9	1500	575	0.8	7.2	9
PU12	1500	575	0.8	9.6	12

Note: Stock solutions were prepared by dissolving Phe-diol and An-diol in poly(tetramethylene glycol), in order to avoid weighing small amount of fluorescent dyes; see the experimental section for details.

Scheme 1. Synthesis of phenanthrene-diol **3**.



Scheme 2. Preparation of crosslinked polyurethane network labeled with energy transfer donor (Phe) and acceptor (An).



quencher (Q) if this quencher is inside a spherical volume V centered on D*, and there is no quenching when the quencher is outside of this volume. From data plotted according to this model, eq. [3], one can obtain R_s, the radius of the quenching sphere.

$$[3] \quad \ln \frac{F_0}{F} = V[Q] = \frac{4}{3}\pi R_s^3[Q]$$

Here F is the fluorescence intensity in the presence of quenchers, and F_0 is that when [Q] = 0. As originally proposed, the Perrin model predicts that $\tau = \tau_0$ for Q outside of V and $\tau = 0$ for Q inside V.

In this paper, we wish to report the synthesis of a new fluorescent label molecule (phenanthrene-diol **3**, Scheme 1), the preparation of cross-linked polyurethane networks labeled with both phenanthrene and anthracene chromophores (Scheme 2), and the study of fluorescence energy transfer for the above polyurethane samples by fluorescence decay measurements (9).

Results and discussion

1. Polyurethane sample preparation

To prepare labeled polyurethane samples, diol derivatives of the donor and acceptor dyes are needed. The anthracene-diol derivative **6** has been reported previously in the literature. We developed a rather straightforward synthesis of the phenanthrene-diol derivative **3** by the route shown in Scheme 1. These two dyes were then introduced as co-reactants in the polyurethane synthesis.

The cross-linked polyurethane network was formed between a polymer-diol **5** (polytetramethylene glycol) and the triisocyanate **4** (Desmurdo N-100) as shown in Scheme 2. A series of polyurethane samples (PU0 – PU12) were prepared with different anthracene acceptor (**6**) concentrations, while the phenanthrene donor (**3**) concentration was kept constant. The compositions are given in Table 1.

Fig. 1. UV absorption spectrum for sample PU1.

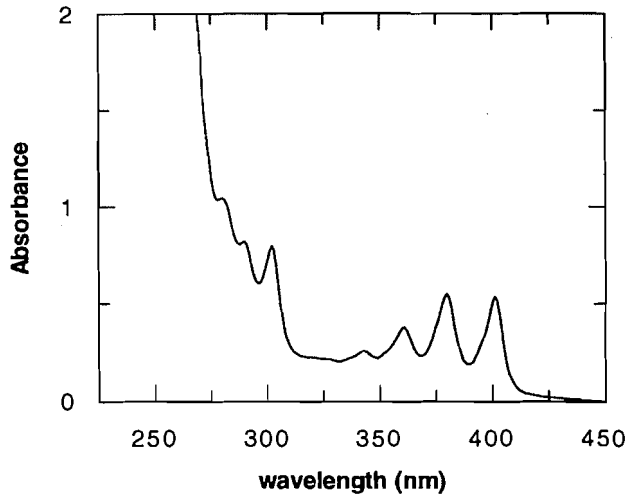

Fig. 2. Fluorescence emission spectrum for sample PU0 (λ_{ex} = 300 nm).

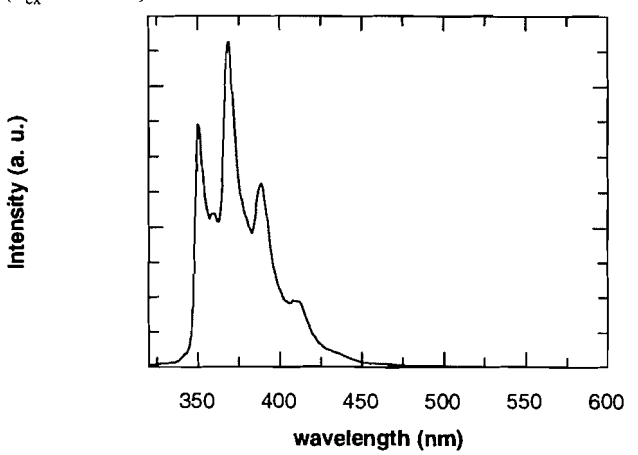

2. Sample characterization

During the preparation of polyurethane samples, an FT-IR spectrometer was used to monitor the monomer **4** consumption at 2270 cm^{-1}. This band disappeared completely after 48 h under the experimental conditions. The above prepared samples were also characterized by UV, fluorescence emission, and fluorescence excitation spectroscopies. The UV absorption spectrum for sample PU1 (An/Phe = 1) is shown in Fig. 1. One can see the characteristic band of phenanthrene at 300 nm, and the typical four vibronic bands for anthracene at 340, 360, 380, and 400 nm, respectively. The fluorescence emission spectrum for sample PU0 (labeled with Phe only) is shown in Fig. 2, which is a typical phenanthrene fluorescence spectrum.

Two fluorescence spectra for sample PU1 (An/Phe = 1) are shown in Fig. 3. This sample is labeled with equal amounts of Phe and An. Excitation of the sample at 360 nm (λ_{ex}) leads to An emission only (Fig. 3*a*), whereas excitation at λ_{ex} = 300 nm gives results in fluorescence from both Phe and An (Fig. 3*b*). One can also see that the Phe emission intensity is very weak, while that from An is strong. This indicates significant fluorescence energy transfer from Phe to An in the sample. The fluorescence excitation spectrum (λ_{em} = 500 nm) for PU1 in Fig. 4 corresponds to the UV absorption bands for anthracene and phenanthrene in the sample.

Fig. 3. Emission spectra for sample PU1: (*a*) λ_{ex} = 360 nm; (*b*) λ_{ex} = 300 nm.

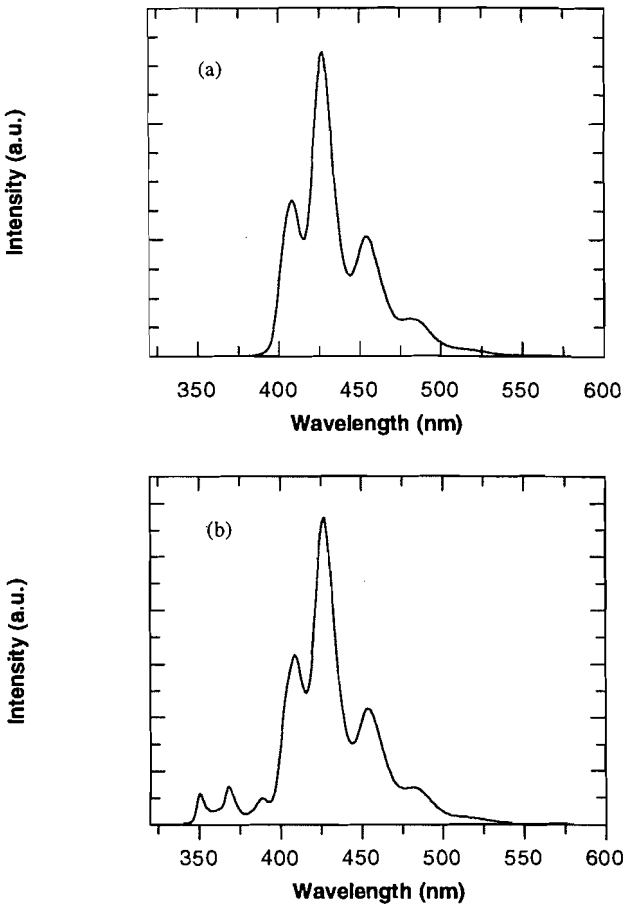

Fig. 4. Excitation spectrum for PU1 (λ_{em} = 500 nm).

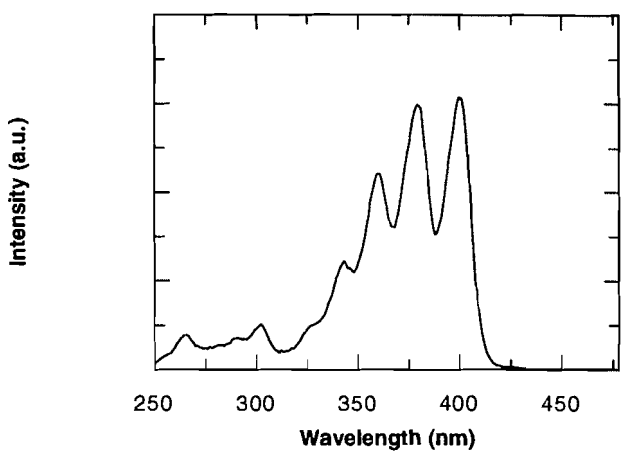

3. Fluorescence decay studies

For each polyurethane sample, fluorescence decay profiles of the energy donor (Phe) were measured using the Time Correlated Single Photon Counting technique. Samples were excited at 300 nm (λ_{ex}), and the fluorescence emission was detected at 366 nm (λ_{em}). Sample PU0 (labeled with only Phe) gives a single exponential decay of the phenanthrene fluorescence (cf. Fig. 5), with a lifetime of 49.7 ns (χ^2 = 1.04).

Fig. 5. Fluorescence decay for sample PU0 and the weighted residuals, for an exponential fit ($\tau_0 = 49.7$ ns, $\chi^2 = 1.04$).

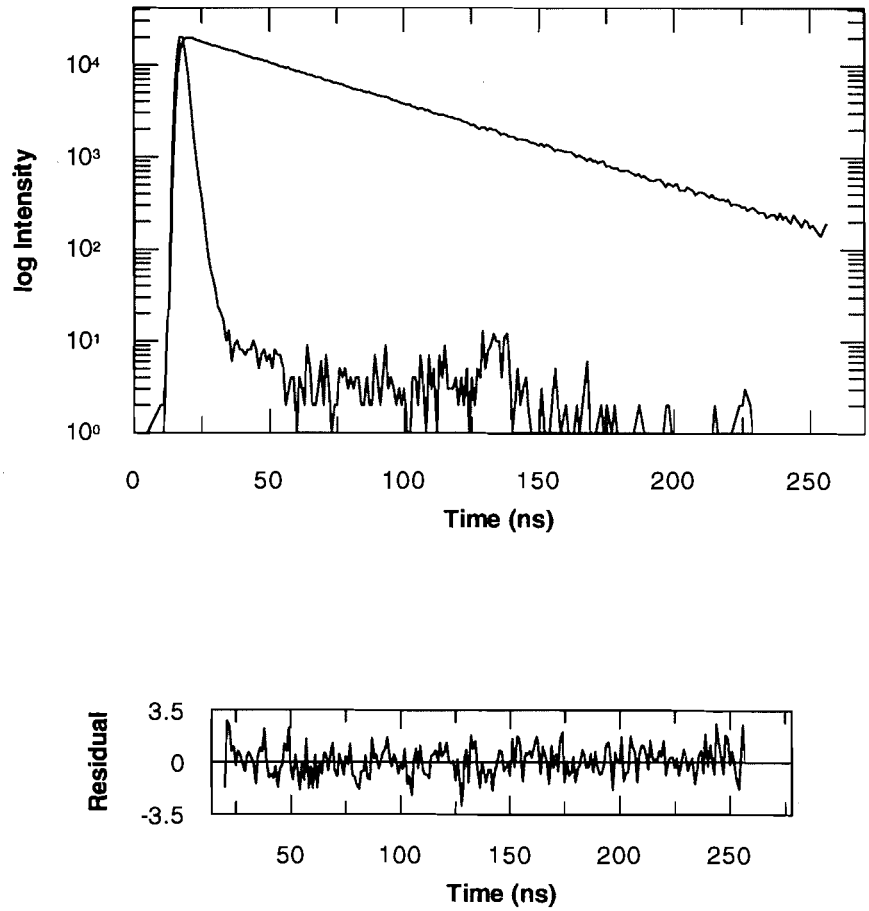

Fig. 6. Fluorescence decay curves for polyurethane samples (from top to bottom: PU0, PU1, PU3, PU6, PU9, PU12).

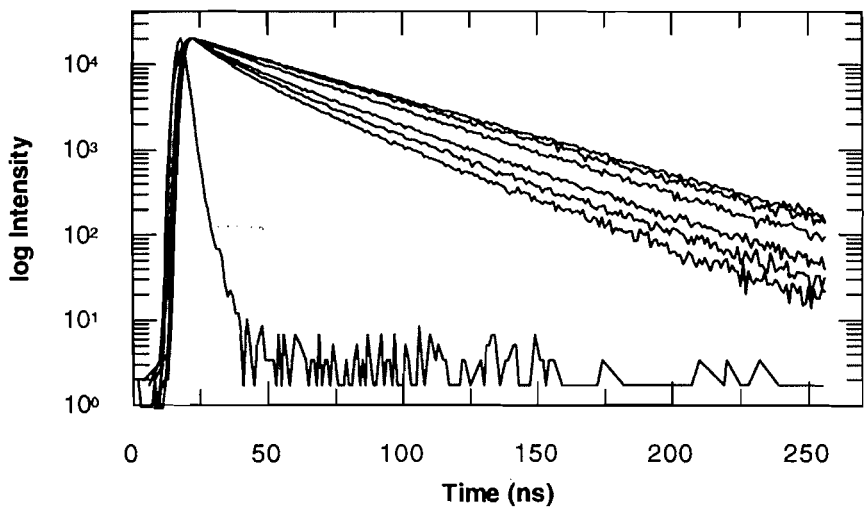

The introduction of acceptors (An) into samples PU1 – PU12 enhances the phenanthrene fluorescence decay rate and makes the decay nonexponential (Fig. 6). With the increase of anthracene concentration, one can see that the curvature of the decay curves increases and that the area under a decay curve decreases. We used the two related models, the Förster energy transfer model and the Perrin static quenching model, to analyze these decay curves. The Förster model is concerned with the shape of the decay curves, and the Perrin model is related to the area under each decay curve.

(a) Data fitting with the Förster energy transfer equation

In the polyurethane samples, the quenching of Phe fluorescence is expected to follow the direct nonradiative energy

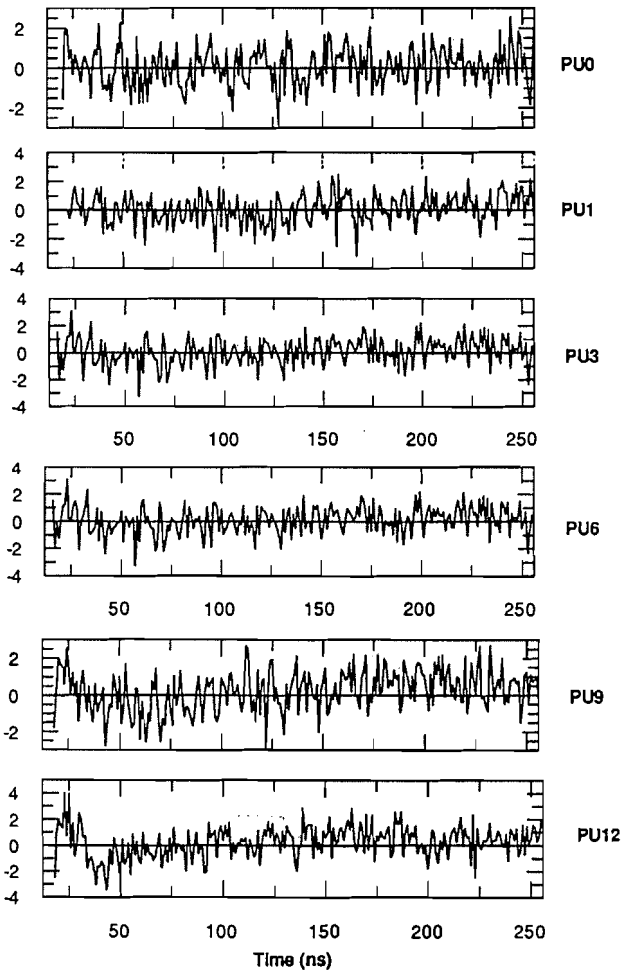
PU12	18.0	1.29	49.7	1.58

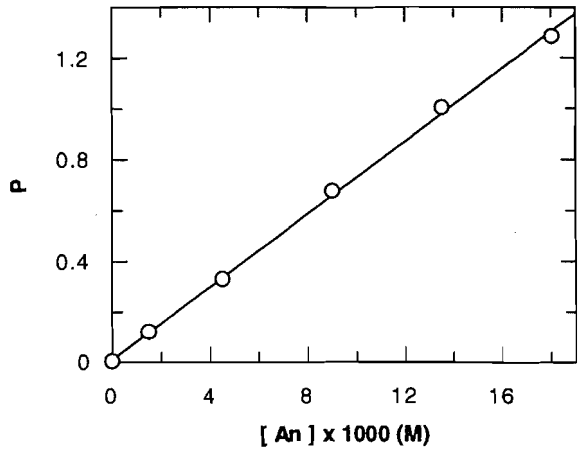
Fig. 7. Weighted residuals from Förster equation fits to the decays shown in Fig. 6.



transfer (DET) mechanism proposed by Förster, in which the Phe fluorescence intensity is described by eq. [1]. The donor fluorescence decay profiles from the samples (Fig. 6) were fitted to eq. [1]. The fitting results are listed in Table 2 and the residuals are given in Fig. 7. Note that this is a two-parameter fit to the data since τ_0 is known independently.

The decay profiles fit well to eq. [1] for samples PU0 – PU6, with acceptable χ^2 and evenly distributed residuals. However,

Fig. 8. Plot of P vs. anthracene concentration for polyurethane samples.



the χ^2 values for PU9 (1.35) and PU12 (1.58) are a little high, and the plot of weighted residuals indicates that the largest deviations occur at early times in the decay. These two samples, consisting of high concentrations of An (acceptor), require longer times to collect the Phe fluorescence data compared with the rest of the polyurethane samples, and this would allow more drift in the lamp profile, which often leads to deviations in the fit at early times of the decay. Overall, the data fitting is reasonably good.

According to the Förster mechanism (5), the parameter P should be linear with the acceptor concentration [An] (cf. eq. [2]). We plot P against [An] in Fig. 8 and obtain a straight line with a slope of 72.4 M^{-1}. This slope contains the Förster energy transfer critical radius R_0, which can be calculated from eq. [2] (5, 7). In a rigid polymer film, the orientation factor $\gamma = 0.8452$ (7), and the critical radius R_0 was calculated to be 26.7 Å. This calculated critical radius R_0 is very close to the R_0 reported for the Phe/An pair in several cases (24.1 Å (4*d*), 25.2 Å (10), and 25.5 Å (11)). From the above analysis, we conclude that nonradiative energy transfer in the polyurethane network obeys the Förster dipole–dipole interaction mechanism (5), which also implies that the fluorescent labels Phe and An are randomly distributed in the cross-linked polyurethane network.

The issue of uniform donor and acceptor distribution in the matrix can be examined more deeply through a *distribution analysis* of the fluorescence decay profiles. The Förster expression (eq. [1]) is derived through an integration over an assumed uniform donor–acceptor distribution. The fluorescence decays previously analyzed in terms of the Förster expression were reanalyzed using the exponential series method (12). In this approach, one fits the decay to a large number of evenly spaced exponential terms and optimizes their coefficients. This approach is often very powerful at identifying multiple distributions of donor decay rates within a sample (3*c*).

Results are shown in Fig. 9. In each case our sample is characterized by an unimodal distribution of acceptors surrounding excited donors. As the acceptor concentration increases, the distribution shifts to the right. The mean acceptor concen-

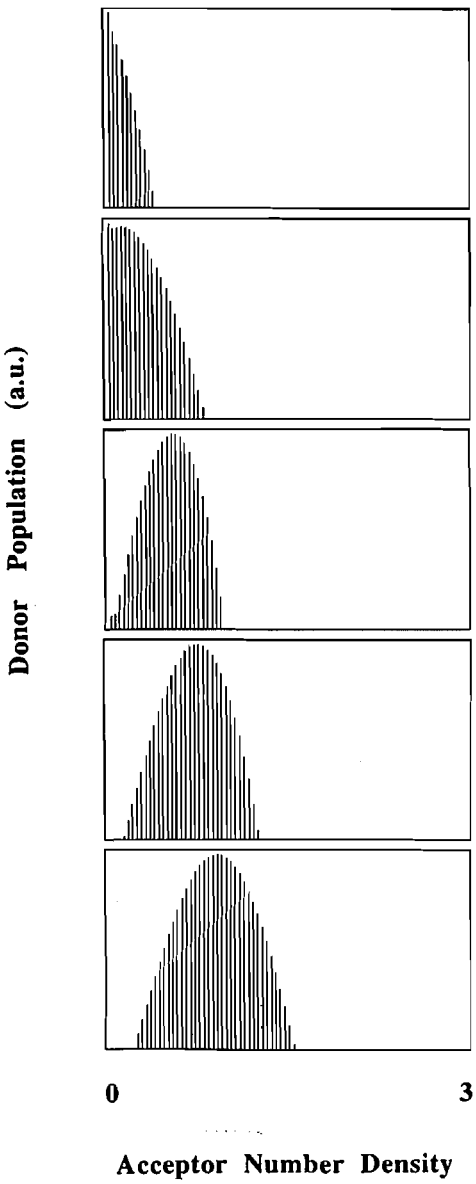
Fig. 9. Acceptor distributions for polyurethane samples. The graph plots relative number of donors undergoing energy transfer on the *y*-axis vs. the number density of acceptors at a distance r/R_0 from the donor. From top to bottom: PU1, PU3, PU6, PU9, PU12. The shaded areas are not normalized.



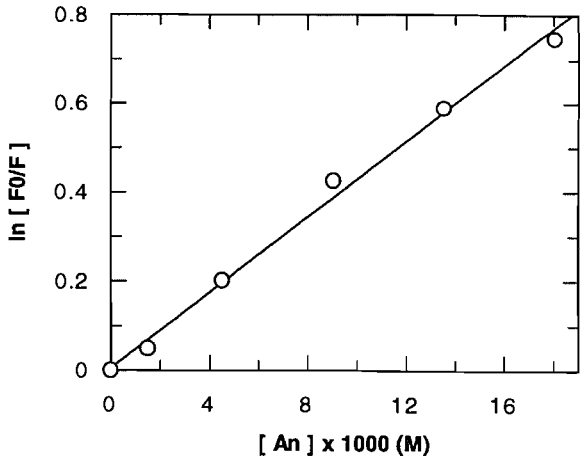
tration calculated from these distributions corresponds to that of the sample itself.

(b) Data fitting with the Perrin model

In fitting the data to the Perrin model (eq. [3]), one needs to know the fluorescence intensities F_0 and F. It is normally very difficult to obtain absolute fluorescence intensities from measurements on film samples by steady-state fluorescence spectroscopy. An alternative is to integrate the normalized intensity decay curves (13, 14), since the fluorescence quantum yield is given by

$$[4] \quad \Phi_f = k_f \int_0^\infty I_D(t)dt$$

Fig. 10. Plot of ln (F_0/F) vs. anthracene concentration for polyurethane samples



where k_f is the radiative rate coefficient for the fluorophore, and Φ_f refers to the fluorescence quantum yield. Thus:

$$[5] \quad \frac{F_0}{F} = \frac{\Phi_f^0}{\Phi_f} = \frac{\int_0^\infty I_D{}^0(t)dt}{\int_0^\infty I_D(t)dt}$$

In our calculations, we fit each decay curve into the sum of two exponential decay terms, and F is giving by eq. [6]. In Fig. 10 we see that the plot of ln (F_0/F) vs. [An] yields a linear fit, with a slope of 42.7 M^{-1}. The Perrin quenching sphere radius R_s was calculated, from eq. [3], to be 25.6 Å.

$$[6] \quad F = \int_0^\infty I_D(t)\,dt = \int_0^\infty (A_1 \exp(-t/\tau_1) + A_2 \exp(-t/\tau_2))dt = A_1\tau_1 + A_2\tau_2$$

Conclusion

In cross-linked polyurethane networks, the fluorescence of covalently bound phenanthrene is quenched by the bound anthracene groups. By analyzing the phenanthrene fluorescence intensity decay profiles, we found that the fluorescence quenching obeys Förster energy transfer kinetics, with R_0 = 26.7 Å. This establishes that these donor and acceptor groups are randomly distributed in the polymer matrix and that the cross-linking chemistry does not perturb their distribution. The fluorescence intensities, obtained by integrating the area under each decay curve, also fit the Perrin model, with a quenching radius R_s of 25.6 Å. The similarity of the two R values serves as a reminder of the similarity of the two models in the case of randomly distributed donor and acceptor pairs in rigid media.

Experimental section

Synthesis of 9-chloromethylphenanthrene (1)

A reported procedure (15) was followed to synthesize compound **1**. A mixture of phenanthrene (35.7 g, 0.20 mol), paraformaldehyde (11 g, 0.37 mol), glacial acetic acid (36 ml), 12 N HCl (110 mL), and 85% phosphoric acid (16.5 mL) was stirred vigorously in a 500 mL round-bottom flask fitted with a reflux condenser. The reaction temperature was controlled at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

85°C for 52 h. This reaction mixture was then poured over 200 mL of crushed ice, and extracted with 3 x 200 mL of diethyl ether. The combined organic layer was washed with water until neutral, dried over magnesium sulfate, and the solvent was removed *in vacuo* to leave 40 g of dark paste. Column chromatography was carried out three times on this dark paste (with pure hexanes as the eluting solvent). 9–Chloromethylphenanthrene (35.0 g, yield 77%) was isolated, with a melting point of 101–102°C (lit. (15) mp 101–102°C). ^{1}H NMR ($CDCl_3$, 200 MHz, δ ppm): 8.55–8.80 (m, 2H, Ar-H), 8.1–8.3 (m, 1H, Ar-H), 7.5–7.95 (m, 6H, Ar-H), 5.05 (s, 2H, CH_2). Mass (*m/e*, peak intensity in parentheses): 228 (M^+ + 2, 14), 226 (M^+, 38), 192 (28), 191 (100), 190 (15), 189 (38).

Synthesis of dimethyl 2-(9-Phenanthrylmethyl) malonate (2)

To a 3–neck, 500 mL round-bottom flask (under nitrogen) was added 2.08 g of NaH (50% content, 43.4 mmol) and 150 mL of dimethoxyethane (dried and distilled over $LiAlH_4$). Dimethyl malonate (5.63 g, 43.4 mmol, Aldrich) in 30 mL of dimethoxyethane was added dropwise. After 15 min, 9–chloromethylphenanthrene (7.0 g, 31 mmol) in 20 mL of dimethoxyethane was added over 10 min. and the resulting solution was heated to 60°C for 4 h. The reaction mixture was then washed with water, extracted with diethyl ether (3 × 80 mL), and the combined organic layer was dried over magnesium sulfate. After evaporating the solvent *in vacuo*, the oily residue **2** (10 g) was obtained, which was used directly in the next step without further purification.

Synthesis of 2-(9-phenanthrylmethyl)-1,3-propanediol (3)

The above 10 g of oily residue **2** was dissolved in 200 mL of anhydrous diethyl ether in a 500 mL round bottom flask. Excess of $LiAlH_4$ (1.5 g) was added to the solution, and the resulting mixture was refluxed for 5 h. Ethanol (20 mL) was cautiously added to the reaction mixture, followed by 150 mL of water. This mixture was extracted with diethyl ether (3 × 100 mL). The combined organic layer was dried over magnesium sulfate, and the solvent was evaporated *in vacuo*. The residue was column chromatographed (20% acetone in hexanes, v/v). 2-(9-Phenanthrylmethyl)-1,3-propanediol (**3**) was isolated in 52% yield (4.3 g, mp 145–146°C). ^{1}H NMR (DMSO-d_6, 200 MHz, δ ppm): 8.7–8.9 (m, 2H, Ar-H), 8.2–8.3 (m, 1H, Ar-H), 7.8–8.0 (m, 1H, Ar-H), 7.5–7.7 (m, 5H, Ar-H), 4.6 (t, 2H, 2OH), 3.4–3.6 (m, 4H, $2OCH_2$), 3.3–3.4 (m, 1H, CH), 3.05–3.15 (d, 2H, CH_2). ^{13}C NMR and APT (DMSO-d_6, 50 MHz, δ ppm):135.47, 131.54, 131.18, 130.55, 129.41, 128.16, 127.48, 127.09, 127.03, 126.65, 126.44, 125.15, 123.67, 122.93, 61.73 (OCH_2), 44.41 (CH), 31.72 (CH_2). Mass (*m/e*, peak intensity in parentheses): 267 (M^+ + 1, 15), 266 (M^+, 53), 217 (41), 192 (100), 191 (99).High resolution mass calculated for $C_{18}H_{18}O_2$: 266.1307, found: 266.1311 .

Synthesis of 9,10-anthracenediethanol (6) (ref. 16)

9,10–Dibromoanthracene (10 g, 30 mmol, Aldrich) and anhydrous diethyl ether (180 mL) were added into a 250 mL, 3–neck round-bottom flask. This mixture was stirred under nitrogen, and cooled to 5°C (ice-water bath). *n*-BuLi (7.5 mL, 75 mmol, 10.0 M hexane solution, Aldrich) was added with a syringe over a period of 10 min and stirred for another 20 min. An excess of ethylene oxide (6.0 g, 136 mmol, Fisher) was added over 10 min. This solution was stirred at 5°C for 1 h, and was allowed to warm up to room temperature. It was then poured over crushed ice (100 mL), and extracted with diethyl ether (100 ml) and chloroform (3 × 100 mL). The combined organic solvents were dried over magnesium sulfate and evaporated *in vacuo*. 9,10–Anthracenediethanol (5.35 g, yield 67%) was obtained after a column chromatograph (30% acetone in hexanes, v/v); mp 224–225°C (lit. (16) mp 221–225°C). ^{1}H NMR (DMSO-d_6, 200 MHz, δ ppm): 8.3–8.5 (m, 4H, Ar-H), 7.5–7.7 (m, 4H, Ar-H), 4.9 (m, 2H, 2OH), 3.8 (m, 8H, $4CH_2$). ^{13}C NMR (DMSO-d_6, 50 MHz, δ ppm): 130.43, 129.81, 125.42 (2C), 62.04 (OCH_2), 31.82 (CH_2). Mass (*m/e*, peak intensity in parentheses): 267 (M^+ + 1, 16), 266 (M^+, 56), 235 (59), 217 (28), 205 (100), 191 (47).

Example of polyurethane sample preparation: PU6 film preparation

(*a*) Stock solution A(6): To a 50 mL Erlenmeyer flask was added polytetramethylene glycol (7.5 g, M_n = 1000, Teracol 1000, Dupont), phenanthrene-diol **3** (4.0 mg), and anthracenediol **6** (24.0 mg). This mixture was then heated to 90°C under nitrogen with stirring to dissolve the two solid diols. This mixture was kept at room temperature in the dark as stock solution A(6).

(*b*) Film casting: Stock solution A(6) (1500 mg) and triisocyanate **4** (Desmurdo N-100, 575 mg, Miles Chem. Co.) were added to a small test tube with stirring. This mixture was subsequently warmed up to 50°C to make a homogeneous solution. Dibutyltin dilaurate (1 μL, Polysciences Inc.) was added afterwards. The resulting viscous liquid was cast onto the surface of quartz plates (1 × 10 × 25 mm). These samples were kept under nitrogen at room temperature for at least 48 h before any testing. The triisocyanate **4** was completely polymerized after 48 h, as was monitored by FT-IR at the wave number of 2270 cm^{-1}.

UV and fluorescence measurements

The UV absorption spectrum was measured with a Perkin–Elmer Lambda 6 spectrometer. Fluorescence spectra were measured with a SPEX Fluorolog 2 instrument equipped with a DMA 3000 data system. Fluorescence decay profiles were measured by the time-correlated single photon counting technique (9) as described previously (3*a*). The excitation wavelength was 300 nm, the emission wavelength was 366 nm, and 20 000 counts were collected in the maximum channel.

Abstract: A recently developed spectroscopic technique was used to determine oxygen diffusion coefficients as a function of temperature for polystyrene and polycarbonate films. Data were recorded at total pressures <300 Torr over the temperature range 5–45°C under conditions in which argon, helium, and nitrogen, respectively, were copenetrants. In all cases, the presence of the additional gas caused an increase in the oxygen diffusion coefficient. Arrhenius plots of the data yield (*a*) a diffusion activation barrier, E_{act}, and (*b*) a diffusion coefficient, D_0, that represents the condition of "barrier-free" gas transport for the temperature domain over which the Arrhenius plot is linear. For all cases examined in both polystyrene and polycarbonate, D_0 increased with an increase in the partial pressure of added gas. In polystyrene, the presence of an additional gas did not change E_{act}. In polycarbonate, E_{act} obtained in the presence of helium and argon likewise did not differ from that obtained in the absence of the copenetrant. When nitrogen was the added gas, however, a larger value of E_{act} was obtained. This latter observation is interpreted to reflect the plasticization of polycarbonate by nitrogen. E_{act} and D_0 data are discussed within the context of a model that distinguishes between dynamic and static elements of free volume in the polymer matrix.

Key words: oxygen diffusion, polystyrene, polycarbonate, activation barrier.

Résumé : On a utilisé une technique spectroscopique développée récemment pour déterminer les coefficients de diffusion de l'oxygène, en fonction de la température, dans des films de polystyrène et de polycarbonate. On a enregistré les données à des pressions totales inférieures à 300 Torr, à des températures allant de 5 à 45°C, dans des conditions telles que l'argon, l'hélium et l'azote sont respectivement des copénétrants. Dans tous les cas, la présence de gaz additionnel provoque une augmentation du coefficient de diffusion de l'oxygène. Les courbes d'Arrhenius des données permettent d'obtenir (*a*) une barrière d'activation à la diffusion, E_{act}, et (*b*) un coefficient de diffusion, D_0, qui représente la condition de transport du gaz « sans barrière » pour le domaine de température pour lequel la courbe d'Arrhenius est linéaire. Pour tous les cas examinés tant dans le polystyrène que le polycarbonate, la valeur de D_0 augmente avec une augmentation de la pression partielle du gaz additionné. Dans le polystyrène, la présence d'un gaz additionnel ne provoque pas de changement dans la valeur de E_{act}. Dans le polycarbonate, les valeurs de E_{act} obtenues en présence d'hélium et d'argon ne diffèrent pas de celles obtenues en l'absence de copénétrant. Toutefois, lorsqu'on ajoute de l'azote comme copénétrant, on obtient une valeur plus élevée pour E_{act}. On interprète cette dernière observation comme un reflet de la plasticisation du polycarbonate par l'azote. On discute des données de E_{act} et de D_0 dans le contexte d'un modèle qui permet de distinguer entre les éléments dynamiques et statiques du volume libre dans la matrice de polymère.

Mots clés : diffusion de l'oxygène, polystyrène, polycarbonate, barrière d'activation.

Introduction

Studies of oxygen diffusion in amorphous organic polymer glasses are important from fundamental and practical perspectives. For those interested in polymer photophysics and photochemistry, such studies are useful because oxygen is an efficient quencher of excited electronic states (1–6). Studies of oxygen diffusion should also be useful for those interested in packaging materials, protective coatings, polymer oxidative degradation, and membranes for gas separation. With respect to the latter, the effect that other gases may have on the oxygen diffusion coefficient is certainly very important.

We recently developed a spectroscopic technique to quantify oxygen diffusion coefficients for polymer films (7). In this method, oxygen *sorption* into the film is followed by monitoring the 1270 nm phosphorescence of singlet oxygen [$O_2(a^1\Delta_g)$

Received March 30, 1995.

$\rightarrow O_2(X^3\Sigma_g^-)]$. Singlet oxygen is produced from ground state oxygen by energy transfer from a photosensitizer dissolved in the polymer. The experiment is performed under conditions in which only one sensitizer state (invariably the triplet) is the singlet oxygen precursor.

$$[1]\quad \text{Sens} \xrightarrow{h\nu} \text{Sens}^* \xrightarrow{O_2(X^3\Sigma_g^-)} O_2(a^1\Delta_g) + \text{Sens}$$

Thus, upon exposure of a polymer film to oxygen, the intensity of singlet oxygen phosphorescence increases as the concentration of $O_2(X^3\Sigma_g^-)$ in the film increases. Although the proportionality constant that relates the photosensitized $O_2(a^1\Delta_g)$ phosphorescence intensity to the amount of sorbed oxygen can be determined in independent control experiments, it is not necessary with this technique to explicitly know the solubility of oxygen in the polymer. Data obtained behave according to eq. [2], in which the amount of $O_2(X^3\Sigma_g^-)$ that has entered the film at time $t(M_t)$, normalized by the amount at time = ∞ (M_∞), is expressed as a function of the film thickness ι and the diffusion coefficient D (7,8).

$$[2]\quad \frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2\pi^2} \exp\left(\frac{-D(2n+1)^2\pi^2 t}{4\iota^2}\right)$$

For films cast onto an oxygen-impermeable substrate, ι is the distance from the front to back surface of the film. For free-standing films, ι is the distance from the film center to a surface. Diffusion coefficients obtained from iterative fits of the data to eq. [2] are independent of (*a*) the film thickness over the range ~15–90 μm, and (*b*) the concentration of the singlet oxygen sensitizer over the range ~$(0.1–1.5) \times 10^{-3}$ M. Furthermore, diffusion coefficients obtained from free-standing films are identical to those recorded from films cast onto a substrate.

We recently used this technique to determine oxygen diffusion coefficients as a function of temperature in polystyrene and polycarbonate films (8). Over comparatively large temperature ranges, the diffusion coefficient behaved according to eq. [3], and we were able to obtain values of E_{act} and D_0 for films under a number of different conditions.

$$[3]\quad D = D_0 \exp(-E_{act}/RT)$$

We discovered that when nitrogen gas is a copenetrant, values of D, D_0 and E_{act} for oxygen diffusion can differ from those obtained in the absence of nitrogen (8). In an attempt to find the origin of this interesting phenomenon, we extended our work to include a study of the effects of helium and argon on D, D_0 and E_{act} for oxygen diffusion. The results of this latter study are presented and discussed in the current paper.

Experimental section

The methods by which we prepare polymer films and quantify oxygen diffusion coefficients have been previously described in detail (7, 8). Briefly, polycarbonate films were prepared by first dissolving the polymer and the sensitizer in CH_2Cl_2 to yield a homogenous mixture. The CH_2Cl_2 was then removed, and the resultant solid pressed between heated platens. Samples prepared for this study were heated at 250°C for 7 min under vacuum and in the absence of an applied load. A 1 metric ton load was then applied and maintained for 3 min on the 250°C sample. Resultant films were removed from the heated press and equilibrated with the ambient atmosphere. Data were recorded from free-standing films. Although attempts were made to prepare polycarbonate films from CH_2Cl_2 solutions by spin-casting, the samples thus obtained were not of the same high optical quality as those obtained by heated pressing (i.e., the cast films were cloudy). Polystyrene films were prepared from benzene solutions by spin-casting onto quartz substrates. Film thicknesses were determined from absorption spectra using the Beer–Lambert law (7). Unless indicated otherwise, all of the experiments were performed under conditions in which the degassed polymer sample was abruptly exposed to an ambient atmosphere containing (*a*) 30 Torr of oxygen (1 Torr = 133.3 Pa), and (*b*) the copenetrant gas at a partial pressure that ranged from 50 to 500 Torr.

Polystyrene (Aldrich) had an average molecular weight of 280 000. Poly(bisphenol A carbonate) (Polysciences, Inc.) had an average molecular weight of 34 000. Helium and argon (Spectra Gases,Inc.) were 99.999% pure. Nitrogen and oxygen (Argyle Medical Supply, Inc.) were 99.95% pure. The singlet oxygen photosensitizer, *meso*-tetraphenylporphine (Porphyrin Products, Inc.) was used as received.

Results

1. Isothermal data

(a) Polystyrene

Oxygen sorption was monitored subsequent to exposure of a degassed 18 μm thick 25°C polystyrene sample to an ambient atmosphere containing only 30 Torr of oxygen. The oxygen diffusion coefficient obtained under these conditions ($(2.0 \pm 0.2) \times 10^{-7}$ cm^2/s) was the same, within experimental error, as that obtained in our earlier studies ($(2.3 \pm 0.3) \times 10^{-7}$ cm^2/s) (7, 8). The same sample was then exposed to an ambient atmosphere containing (*a*) 30 Torr of oxygen, and (*b*) helium, nitrogen, and argon, respectively, at a partial pressure that ranged from 50 to 500 Torr. Oxygen diffusion coefficients D obtained under these conditions are listed in Table 1. For data recorded with added nitrogen, values of D obtained in the present study are slightly larger than those obtained in our earlier work (Table 1) (8). Nevertheless, both nitrogen data sets have common features that are also found with the helium and argon data: (*a*) values of D increase with an increase in the partial pressure of added gas over the range ~30–300 Torr, and (*b*) above ~300 Torr of added gas, further increases in D do not occur with an increase in the partial pressure of added gas. Subsequent to recording the data listed in Table 1, we again recorded a diffusion coefficient of $(2.0 \pm 0.2) \times 10^{-7}$ cm^2/s upon exposure of the same sample to an atmosphere containing only 30 Torr of oxygen.

(b) Polycarbonate

Oxygen sorption was monitored subsequent to exposure of a degassed 50 μm thick 25°C polycarbonate sample to an ambient atmosphere containing only 30 Torr of oxygen. The oxygen diffusion coefficient obtained under these conditions ($(7.0 \pm 0.7) \times 10^{-8}$ cm^2/s) was slightly larger than, but nevertheless similar to, that obtained in our earlier studies ($(5.5 \pm 0.5) \times 10^{-8}$ cm^2/s) (7, 8). The same sample was then exposed to an

[b]From ref. 8.

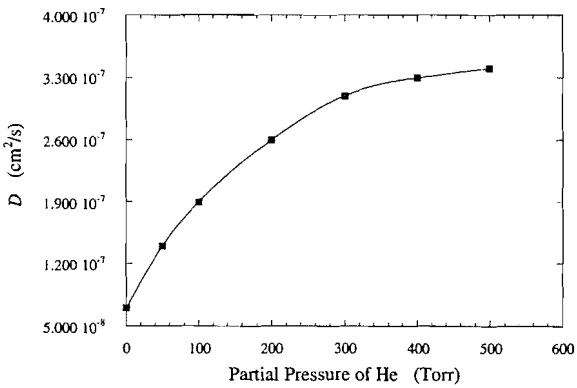
ambient atmosphere containing (*a*) 30 Torr of oxygen, and (*b*) helium, nitrogen, and argon, respectively, at a partial pressure that ranged from 50 to 500 Torr. Oxygen diffusion coefficients obtained under these conditions are listed in Table 2. For data recorded with added nitrogen, values of D obtained in the present study are larger than those obtained in our earlier work (Table 2) (8). As with the polystyrene data discussed above, both nitrogen data sets nevertheless have common features that are also found with the helium and argon data: values of D (*a*) increase with an increase in the partial pressure of added gas, and (*b*) reach a threshold above which further increases in D do not occur with an increase in the partial pressure of added gas. Data from the system in which helium is the added gas are shown in Fig. 1. Subsequent to recording the data listed in Table 2, we again recorded a diffusion coefficient of $(7.0 \pm 0.7) \times 10^{-8}$ cm^2/s upon exposure of the same sample to an atmosphere containing only 30 Torr of oxygen.

Fig. 1. Plot of the oxygen diffusion coefficient as a function of the partial pressure of helium added to the atmosphere surrounding a polycarbonate sample. The data are listed in Table 2. The solid line is a cubic spline fit to the data.



2. Effect of temperature on D

Polymer samples used for the isothermal studies discussed above were not used in the temperature-dependent studies. Rather, fresh samples were prepared. For a given material, all data listed in Tables 3 and 4 were obtained from the same sample. After recording the temperature-dependent data for each of the three copenetrants, we ascertained that D(25°C) for the additive-free material was identical to that initially measured.

(a) Polystyrene

Oxygen sorption was monitored as a function of temperature subsequent to exposure of a 20 μm thick degassed polystyrene sample to an ambient atmosphere containing only 30 Torr of oxygen. The oxygen diffusion coefficient obtained under these conditions at 25°C ($(2.0 \pm 0.2) \times 10^{-7}$ cm^2/s) was the same as that obtained in the isothermal study. Diffusion coefficients recorded at other temperatures were identical to those obtained in our earlier study (Table 3) (8). The sample was then exposed to an ambient atmosphere containing (*a*) 30 Torr of oxygen, and (*b*) helium, nitrogen, and argon, respectively, at partial pressures of both 50 and 100 Torr. Oxygen diffusion coefficients D obtained under these conditions as a function of temperature are listed in Table 3. Plots of ln D *vs.* $1/T$ for these data are shown in Figs. 2–4. The data indicate that, in all cases examined, E_{act} was independent of (*a*) the added copenetrant, and (*b*) the pressure of the ambient atmosphere surrounding the sample. Although D_0 was similarly independent of whether the added copenetrant was He, Ar, or N_2, D_0 did depend on the pressure of the system; as the ambient pressure was increased, D_0 increased.

(b) Polycarbonate

Oxygen sorption was monitored as a function of temperature subsequent to exposure of a 50 μm thick degassed polycarbonate sample to an ambient atmosphere containing only 30 Torr of oxygen. Over the temperature range studied, the oxygen diffusion coefficients obtained in the present study were slightly larger than those obtained in our earlier work (Table 4) (8). Plots of ln D vs. $1/T$ for these two data sets are shown in Fig. 5. The current data yield an E_{act} for oxygen diffusion that is identical to that obtained in our earlier study, and a D_0 value

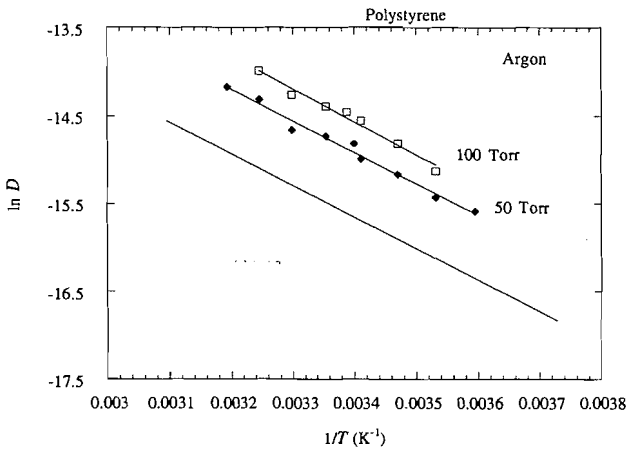
Fig. 2. Plots of ln D vs. $1/T$ for oxygen diffusion coefficients, D, determined in polystyrene. Data shown as filled squares were recorded under conditions in which the polymer film was exposed to an ambient atmosphere containing only 30 Torr of oxygen. The solid line through these data is a linear least-squares fit to data recorded over a wider temperature range than that shown here (see Table 3 and ref. 8). Data recorded under conditions in which the ambient atmosphere contained 100 (●) and 50 (□) Torr, respectively, of nitrogen in addition to 30 Torr of oxygen are also shown. Solid lines are linear least-squares fits to the data.

Data were recorded under conditions in which the ambient atmosphere contained 100 (□) and 50 (◆) Torr, respectively, of argon in addition to 30 Torr of oxygen. Solid lines are linear least-square fits to the data. The linear least-squares fit for data recorded under conditions in which the polymer film was exposed to an ambient atmosphere containing only 30 Torr of oxygen (see Fig. 2) is also shown.



that is only slightly larger than that obtained earlier (the comparatively large error bars on D_0 in the present study reflect the small number of points in the ln D vs. $1/T$ plot).

The sample was then exposed to an ambient atmosphere containing (*a*) 30 Torr of oxygen, and (*b*) helium, nitrogen, and argon, respectively, at partial pressures of both 50 and 100 Torr. Oxygen diffusion coefficients D obtained under these conditions as a function of temperature are listed in Table 4. Plots of ln D *vs.* $1/T$ for these data are shown in Figs. 6–8. The data

shown indicate that, with one exception, the general effects of an added gas on E_{act} and D_0 that were observed with polystyrene also apply to polycarbonate. Specifically, an increase in the pressure of added gas results principally in an increase in D_0. Furthermore, in comparison to the unperturbed system, the addition of either helium or argon does not significantly change E_{act}. When nitrogen is the added copenetrant, however, a larger value of E_{act} is obtained. This increase in the slope of the ln D vs. $1/T$ plot, in turn, results in a comparatively large value of D_0.

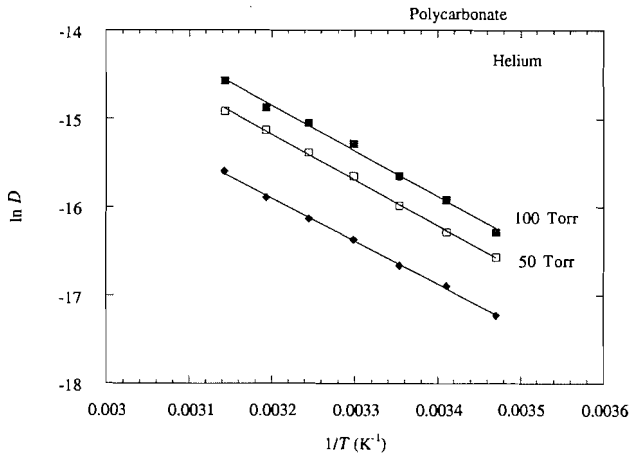
Discussion

1. General background on gas diffusion

Models based on the concept of "free volume" have thus far proven effective in understanding gas mobility in glassy polymers (9–16). From this perspective, gas diffusion is perceived to depend on the presence of spaces in the polymer matrix through which the diffusing molecule can move. We can expand this concept by recognizing that, over a specific temperature range and in a given period of time, these spaces will

Fig. 8. Plots of ln D vs. $1/T$ for oxygen diffusion coefficients, D, determined in polycarbonate. Data were recorded under conditions in which the ambient atmosphere contained 100 (■) and 50 (□) Torr, respectively, of helium in addition to 30 Torr of oxygen. Solid lines are linear least-squares fits to the data. Data recorded under conditions in which the polymer film was exposed to an ambient atmosphere containing only 30 Torr of oxygen (see Fig. 5) are also shown.



be either dynamic or static (8). The former derive from ephemeral cavities created by thermally accessible conformational changes and segmental motions of the macromolecule. In defining a static cavity, we envision spaces in the matrix whose volume is essentially independent of the thermally accessible motions of the macromolecule. When summed over the entire polymer sample, these dynamic and static spaces define an overall free volume characteristic of a particular material at a given temperature.

The notion that a dissolved gas molecule can exist within a cavity in the polymer matrix is a defining feature of the dual-mode sorption model (17–19). In liquids, gas sorption behaves according to Henry's law, in which the mole fraction of a dissolved gas depends linearly on the partial pressure of that gas in the atmosphere surrounding the sample. In amorphous glasses, however, isothermal gas sorption does not often behave according to Henry's law, and a second pressure-dependent term is commonly added to the Henry's law term to account for this deviation. This "Langmuir" term is included to describe a proposed population of gas molecules sorbed in the matrix cavities of the glass. Although exchange between the Henry domain of molecularly dissolved gas and the Langmuir domain of encapsulated gas is proposed to be facile, separate Langmuir (D^L) and Henry (D^H) diffusion coefficients can nevertheless be defined.

The molecular events that define static and dynamic cavities, and hence that control gas diffusion, are thermally activated. Specifically, over limited temperature ranges, the diffusion coefficient D behaves according to eq. [3] (2, 3, 8, 9, 15, 20), which is analogous to the Arrhenius equation. The exponential term thus represents the fraction of diffusing molecules able to surmount a diffusion activation barrier E_{act} at the temperature T. The magnitude of this exponential term ranges from 1.0 at large T to 0 at low T. The activation barrier E_{act} is believed to derive principally from characteristic motions of the macromolecule in a given temperature domain,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

and is thus likely to manifest events that define the dynamic free volume of a material. If ln D varies linearly with $1/T$ over a given temperature range, it is typically concluded that the type of polymer motions and interactions that control gas mobility do not change within this temperature domain (E_{act} is obtained from the slope in a plot of ln D vs. $1/T$). Activation barriers for oxygen diffusion can be compared to barriers for macromolecular motion independently obtained from temperature-dependent NMR or dielectric/mechanical relaxation studies (3, 8).

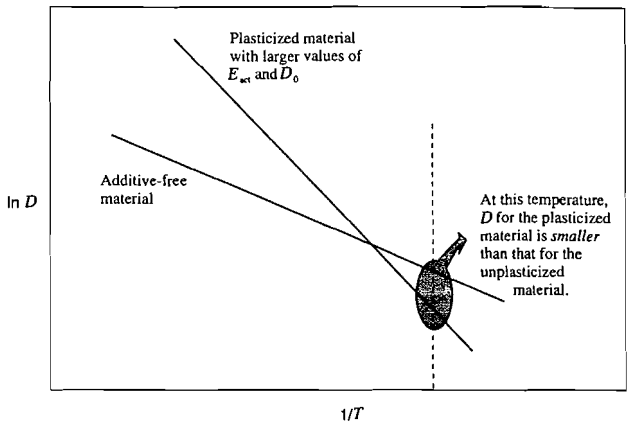
In a plot of ln D vs. $1/T$, D_0 is obtained by extrapolating to $1/T = 0$. At such infinitely high temperatures, gas transport can be considered "barrier-free" (i.e., $\exp(-E_{act}/RT) = 1.0$). This condition corresponds to an 'imaginary' state of the material because the polymer will clearly not remain an amorphous glass at these temperatures. We simply envision a state of the polymer under conditions where all the diffusing molecules are able to surmount the activation barrier E_{act} characteristic of a given temperature domain. From this perspective, D_0 can be considered to reflect the static free volume of the matrix for the temperature domain defined by the ln D vs. $1/T$ plot.

Elements that define a given D_0 and E_{act} clearly pertain only to a specific temperature domain. Successive increases in E_{act} and D_0 for successively higher temperature domains reflect, in part, polymer motions that incorporate increasingly larger segments of the macromolecule. The increase in the number and kind of accessible polymer motions with temperature is often manifested by noticeable morphological changes in the polymer (e.g., glass to rubber transition).

The incorporation of a low molecular weight solute in a solid polymer often perturbs molecular phenomena that influence gas diffusion (8, 13, 19–21). This perturbation may involve (*a*) a filling of voids in the matrix, and (or) (*b*) a change in the intra- and inter-molecular interactions of the macromolecule that influence specific polymer motions. The additive may act either to facilitate or inhibit gas diffusion relative to diffusion in the unperturbed, additive-free material. The addition of these low molecular weight solutes to the polymer is also often manifested in other properties of the material. For example, some additives, called plasticizers, can facilitate motion of larger macromolecular segments and make a rigid polymer more flexible (i.e., the plasticizer lowers T_g). This increase in segmental motion would be reflected in larger values of E_{act} and D_0. Conversely, an antiplasticizer hinders certain motions of the polymer, and is thus expected to yield both a more rigid material and smaller values of E_{act} and D_0. Note that, for a plasticized material in which values of E_{act} and D_0 are larger than E_{act} and D_0 in the unperturbed, additive-free material, plots of ln D vs. $1/T$ for plasticized and additive-free samples may intersect. Thus, at a given temperature, the oxygen diffusion coefficient D for the plasticized polymer can be *smaller* than that found in the additive-free polymer (8). This point is illustrated in Fig. 9.

When transition state theory is applied to the problem of gas diffusion, the terms in eq. [3] take on additional meaning (9). E_{act} will correspond to an activation enthalpy $\Delta H^{\ddagger}$ for diffusion. D_0 will be a function of the activation entropy $\Delta S^{\ddagger}$ for diffusion and a term λ that defines the distance between equilibrium positions for the diffusing molecule in the matrix (eq. [4]).

Fig. 9. Illustration of a phenomenon that can be observed upon the addition of a plasticizer to a given material. Examples of data that behave in this fashion are given in ref. 8.



$$[4] \quad D_0 = \exp \lambda^2 \frac{kT}{h} \exp(\Delta S^{\ddagger}/R)$$

The dependence of D_0 on temperature in eq. [4], however, indicates that transition state theory may not provide a totally accurate model with which the data can be interpreted; plots of ln D vs. $1/T$ are indeed reasonably linear over temperature ranges that can be as large as 80–100°C.

2. The copenetrants nitrogen, helium, and argon

Size

Published data on covalent radii indicate that He, Ar, and N_2 increase in size with the relative ratios of approximately 1:2:3, respectively (22–24). The covalent radius of oxygen does not differ significantly from that of nitrogen.

Diffusion coefficients

Data recorded in 35°C polycarbonate indicate that diffusion coefficients for N_2, Ar, O_2, and He increase with the relative ratios 1:1.8:3.1:360, respectively (25, 26). In 35°C polystyrene, diffusion coefficients for N_2, O_2, and He increase with the relative ratios 1:3.3:312 (14). These data indicate that, upon exposure of a degassed film to a mixture of oxygen and helium, the rate of oxygen incorporation into the film will be significantly slower than the rate of helium incorporation. At the other limit, upon exposure of a degassed film to a mixture of oxygen and nitrogen, oxygen will "precede" nitrogen into the film. Nitrogen will nevertheless be present in the film, particularly near the film surface, while oxygen is still being incorporated from the atmosphere.

3. Effect of added gas on oxygen solubilities

In our experiment, when the polymer sample has reached equilibrium with the ambient atmosphere, the intensity of the singlet oxygen signal will be proportional to the solubility of oxygen in that material. In all experiments, we found that in the presence of added He, Ar, and N_2, the singlet oxygen intensity at equilibrium was ~5–10% larger than that in the absence of the added gas. This systematic change barely exceeds our limits of error in monitoring the singlet oxygen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

intensity. Such a change may indeed derive from an additive-dependent increase in the solubility of oxygen. Although unlikely, we nevertheless cannot presently exclude the possibility that the added gas may increase the rate constant for singlet oxygen phosphorescence, thus giving the appearance of an increase in the amount of oxygen dissolved in the polymer (27, 28). We nevertheless suggest that, under our conditions, additive-dependent changes in the solubility of oxygen are not pronounced. With reference to the discussion in Sect. 5 below, the data certainly do not indicate a copenetrant-induced decrease in the oxygen solubility.

4. Isothermal data

(a) Polystyrene

In the absence of an added copenetrant, the oxygen diffusion coefficient we obtain in 25°C polystyrene agrees with (*a*) our earlier data (8), and (*b*) data published by other investigators (2, 29–31). For diffusion coefficients recorded with nitrogen as a copenetrant, differences between the pressure dependence of our present data and the pressure dependence of data in our previous study (8) likely derive from differences in the respective samples. For example, these polystyrene films were prepared by spin-casting, and differences in the rate of solvent evaporation may have yielded subtle differences in the free volume of the resultant films.

(b) Polycarbonate

In the absence of an added copenetrant, the 25°C diffusion coefficient we obtain in this study ($(7.0 \pm 0.7) \times 10^{-8}$ cm^2/s) is approximately a factor of two larger than that of Muruganandam et al. (25); using Arrhenius parameters reported by the latter, we calculate a value for D(25°C) of 3.9×10^{-8} cm^2/s. For diffusion coefficients recorded with nitrogen as a copenetrant, our present pressure-dependent data are also larger than those recorded in our previous study (8). As with the data recorded in polystyrene, these differences likely derive from differences in the preparation of the respective samples. In this case, our films were prepared by hot-pressing material that had previously been dissolved in CH_2Cl_2 (see Experimental section). Thus, differences in (*a*) the amount of residual CH_2Cl_2 remaining in the material at the time of pressing, and (or) (*b*) the temperature history of the samples may have yielded differences in the free volume of the respective films.

For all data in polystyrene and polycarbonate, values of D (*a*) increased with an increase in the partial pressure of added gas, and (*b*) reached a threshold above which further increases in D did not occur with an increase in the partial pressure of added gas. Within the errors of our measurement, values of D were independent of the specific copenetrant added to the ambient atmosphere. On the basis of the latter observation, these data thus appear to simply reflect a pressure effect on the oxygen diffusion coefficient.

Oxygen diffusion coefficients in polycarbonate and poly(methylmethacrylate) [PMMA] have been observed to increase with an increase in the ambient pressure of oxygen over the range ~50–1000 Torr (32). Similarly, CO_2 diffusion coefficients in PMMA and PMMA blends depend on the CO_2 pressure to which the polymer sample is exposed (33). In the latter experiment, which was performed over the range 1–25 atm (1 atm = 101.3 kPa), pressure-dependent changes in the diffusion coefficient reflect plasicization of the polymer by CO_2. Indeed, plasticization of polymers by high pressures (>1 atm) of CO_2, Ar, and N_2 is a documented phenomenon (34, 35). On the basis of our temperature-dependent data (vide infra), however, we suggest that, with the possible exception of nitrogen added to polycarbonate, the dependence of D on the pressure of added gas shown in Tables 1 and 2 and Fig. 1 does not reflect polymer plasticization.

5. Effect of temperature on D. Values of D_0 and E_{act}

For a given material, temperature-dependent data for each of the three copenetrants were recorded using the same film. Thus, reported values of D_0 and E_{act} do not reflect differences in sample preparation.

(a) Polystyrene

Published data obtained from NMR and mechanical/dielectric relaxation measurements indicate that rotation of the pendant phenyl group in polystyrene is the principal chracteristic motion of the macromolecule in the temperature range −5–85°C (36, 37). Reported values for the activation energy of this process are ~38 kJ/mol (36, 37). The similarity between this value and the E_{act} values obtained for oxygen diffusion (Table 3) indicate that, at these temperatures, phenyl group rotation may create the dynamic cavities in polystyrene that control oxygen transport. In 1974, Guillet and co-workers likewise suggested that the rotation of the pendant phenyl group likely influences oxygen diffusion (3).

The data in Table 3 and Figs. 2–4 indicate that addition of the copenetrant does not affect E_{act}. This general phenomenon was also noted by Barker in the analogous study of the oxygen pressure dependence on oxygen diffusion in PMMA and polycarbonate (32). We conclude from our E_{act} data that, in this temperature domain and at these pressures, added He, Ar, and N_2 do not inflence the motions of polystyrene that define the dynamic free volume. We have indicated that plasticizers can facilitate the motion of different and (or) comparatively larger segments of the macromolecule. Such changes are invariably manifested by an increase in E_{act} (8). It thus appears that under these conditions in polystyrene, He, Ar, and N_2 do not act as a plasticizer.

Addition of the copenetrant, however, influences D_0; D_0 increases with an increase in the pressure of added gas. This same phenomenon was likewise reflected in Barker's ln D vs. $1/T$ plots as the oxygen pressure was increased in PMMA and polycarbonate (32). An interpretation of these D_0 data should also address the isothermal pressure dependence of D shown in Tables 1 and 2 and Fig. 1. (Because E_{act} is independent of pressure, pressure-dependent changes in D reflect changes in D_0.)

From the perspective of transition state theory, the added gas may exert its effect on D_0 via changes in λ and (or) $\Delta S^{\ddagger}$ (eq. [4]). With respect to the latter, the presence of the copenetrant in the cavity through which oxygen is moving is likely to increase the available degrees of freedom, and as a result cause an increase in the activation entropy for diffusion. For a given polymer and copenetrant, the increase in D_0 with an increase in copenetrant pressure corresponds to a $\Delta S^{\ddagger}$ value that becomes increasingly positive. Thus, with an increase in copenetrant pressure, the data reflect a transition state for oxygen propagation that becomes increasingly disordered. It is somewhat more complicated, however, to understand how

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

increases in copenetrant pressure above a threshold of ~200–300 Torr must correspond to a lack of change in $\Delta S^{\ddagger}$.

The copenetrant may also fill voids and thus cause an increase in λ, the "jump distance" between equilibrium oxygen positions in the matrix. However, we again return to the data in Fig. 1 and Tables 1 and 2 and find it difficult to rationalize how an increase in the copenetrant pressure above a threshold of ~200–300 Torr must correspond to a lack of change in λ. These points, coupled with the expected temperature dependence of D_0 shown in eq. [4], indicate that transition state theory is not likely to be an appropriate perspective for the interpretation of our data.

We now consider whether or not our data reflect features of the dual-mode sorption model as described by Koros (17). From this perspective, the copenetrant and oxygen would compete for "Langmuir cavities" in the polymer. In experiments such as ours in which the oxygen partial pressure is held constant and the polymer is not plasticized by the copenetrant, we would expect (*a*) a decrease in the number of oxygen molecules in the Langmuir domain as the added-gas partial pressure is increased, and (*b*) no change in the number of oxygen molecules dissolved in the Henry domain. Thus, as discussed by Koros, displacement of oxygen from the Langmuir domain by added copenetrant should result in a *decrease* in the overall solubility of oxygen in the polymer. This expectation is not supported by our data (vide supra, Sect. 3).

From the perspective of the dual-mode sorption model, overlooking expected changes in oxygen solubility, the observed increase in D with an increase in the copenetrant pressure could reflect displacement of oxygen by the copenetrant from Langmuir sites that hinder the net propagation of oxygen.[2] This interpretation presumes a distribution of Langmuir sites, some of which bind or trap oxygen more effectively than others. An attractive feature of this model is that, under conditions in which the polymer is not plasticized, such traps would eventually all be filled by the copenetrant, thus causing no further changes in D with an increase in copenetrant pressure (Fig. 1 and Tables 1 and 2).

Finally, we have indicated that an increase in D_0 may be interpreted to reflect an increase in the so-called static component of free volume. Thus, our data may reflect an internal pressure-induced expansion of cavities in the polymer that does not substantially perturb the segmental motions that define E_{act}. At these comparatively low pressures, such an expansion would be opposed by a matrix-dependent restoring force that, in turn, could yield data such as those shown in Tables 1 and 2 and Fig. 1. Furthermore, such a pressure-induced increase in static free volume might also result in a slight increase in the solubility of oxygen in the polymer. Solubility data discussed in Sect. 3 are not inconsistent with this expectation. Certainly, additional experiments need to be performed to further test this hypothesis.

(b) Polycarbonate

As discussed with respect to our isothermal data, the differences between our present results and those recorded in our earlier study likely derive from differences in the respective samples. It is interesting to note, particularly in light of the discussion above on pressure-dependent changes in D_0, that plots of ln D vs. $1/T$ generated from different samples yield the same E_{act} but different D_0 values (Fig. 5).

Published data obtained from NMR and mechanical/dielectric relaxation measurements indicate that rotation of the phenyl group in the polycarbonate backbone, along with attendant local segmental conformational changes, is the principal characteristic motion of the macromolecule in the temperature range −5–75°C (2, 36, 38–40). The similarity between reported values for the activation energy of this process (~38–50 kJ/mol) (2, 36, 38–40) and the E_{act} values obtained for oxygen diffusion (Table 4) indicate that, at these temperatures, this motion may create the dynamic cavities in polycarbonate that control oxygen transport.

With respect to the effects of added He and Ar, the discussion above for polystyrene is equally applicable for the polycarbonate data. In particular, the E_{act} data indicate that He and Ar do not act as plasticizers. Data recorded when nitrogen is the copenetrant, however, indicate otherwise. Values of E_{act} obtained at both 100 and 50 Torr of added nitrogen are ~5 kJ/mol larger than values of E_{act} obtained under the other conditions (Table 4). The change in slope of the ln D vs. $1/T$ plot that yields a larger E_{act} also yields larger D_0 values. Thus, in this case, the data are consistent with the added gas acting as a plasticizer.

Conclusions

Over the temperature range ~5–45°C, oxygen diffusion coefficients D for polystyrene and polycarbonate films increase upon the addition of He, Ar, or N_2 as copenetrants. Except for the case of added nitrogen in polycarbonate, this increase in D does not derive from a change in the activation barrier for diffusion. Rather, the increase in D reflects an increase in the parameter D_0, which is the pre-exponential factor in an Arrhenius treatment. These data may reflect a copenetrant pressure-dependent (*a*) expansion of the cavities in the matrix that make up the so-called static free volume, and (or) (*b*) displacement of oxygen from Langmuir "trap" sites that hinder the propagation of oxygen through the matrix.

In polycarbonate, the data indicate that nitrogen acts as a plasticizer. In this case, the added gas causes an increase in both E_{act} and D_0 for oxygen diffusion. These changes are interpreted to reflect nitrogen-dependent increases in the segmental motions that define both dynamic and static elements of free volume in the macromolecule.

Abstract: Phenyl isopropenyl ketone (PIPK) copolymer films were irradiated with a low-pressure mercury lamp, and benzoyl side-chain cleavage and main-chain scission at various temperatures were followed by UV spectral changes and gel permeation chromatography, respectively. Quantum yields of both reactions and the ratio of the latter to the former reaction increased markedly above their glass transition temperatures. The main-chain scission continued to proceed by irradiation even after the side chain ceased to split. These experimental results suggest a new reaction mechanism of photosplitting of the methyl methacrylate ester side chain on the carbon adjacent to the C=C bond followed by β-scission, in addition to the known benzoyl side-chain cleavage followed by β-scission or C=C bond formation. The enhanced quantum yield for the main-chain scission of the PIPK copolymer at 130°C realized sensitivity of 100 mJ/cm^2 as a DUV resist, which was 1200 times as high as that of poly(methyl methacrylate) exposed at room temperature and developed under similar conditions.

Key words: Norrish type I cleavage, β-scission of main chain, temperature dependence, photosplitting of ester side chain, conjugated polymer radical.

Résumé : On a irradié des films de copolymère de phényl(isopropényl)cétone (PIPK) à l'aide d'une lampe au mercure à basse pression et on a observé le clivage de la chaîne latérale benzoyle ainsi que la scission de la chaîne principale, à diverses températures, en faisant appel respectivement aux changements des spectres UV et à la chromatographie par perméation de gel. Les rendements quantiques des deux réactions ainsi que les rapports de la dernière réaction par rapport à la première augmentent d'une façon marquée au-dessus de leur température de transition vitreuse. Sous l'influence de l'irradiation, la scission de la chaîne principale se produit encore même lorsque la chaîne latérale a cessé de se cliver. Ces résultats expérimentaux suggèrent que, en plus du mécanisme connu impliquant un clivage de la chaîne latérale benzoyle, suivi d'une scission-β ou de la formation d'une liaison C=C, il existe un nouveau mécanisme réactionnel pour la réaction de photoclivage de la chaîne latérale du méthacrylate de méthyle; il implique le carbone adjacent de la liaison C=C et il est suivi par une scission-β. Le rendement quantique plus élevé pour la scission de la chaîne principale du copolymère PIPK, à 130°C, a permis d'atteindre une sensibilité de 100 mJ/cm^2 comme résistante DUV; cette valeur est 1200 fois plus élevée que celle du poly(méthacrylate de méthyle) exposé à la température ambiante et développé dans des conditions semblables.

Mots clés : clivage Norrish de type I, scission-β de la chaîne principale, relation avec la température, photoclivage de la chaîne latérale ester, radical polymère conjugé.

Introduction

The continuing increase in the packaging density and shrinkage of the pattern size of electronic devices requires advanced resists that are sensitive to radiation in the deep ultraviolet (DUV, λ = 180–300 nm) region. Isopropenyl ketone polymers represent an important class of positive DUV resists based on main-chain scission. Poly(methyl isopropenyl ketone) (PMIPK) is a commercially available resist, but the sensitivity is not high enough (140 mJ/cm^2 as reported by Nakane et al. (1) and 1000 mJ/cm^2 by Nate and Kobayashi (2)). MacDonald et al. (3) found that the quantum yield of main-chain scission at 313 nm in films of poly(*tert*-butyl isopropenyl ketone) (PTBIPK) is 12 times higher than that of PMIPK, but the high molecular weight polymer was not obtained for investigating the lithographic characteristics.

Another attempt at developing excellent DUV resists

Received March 24, 1995.

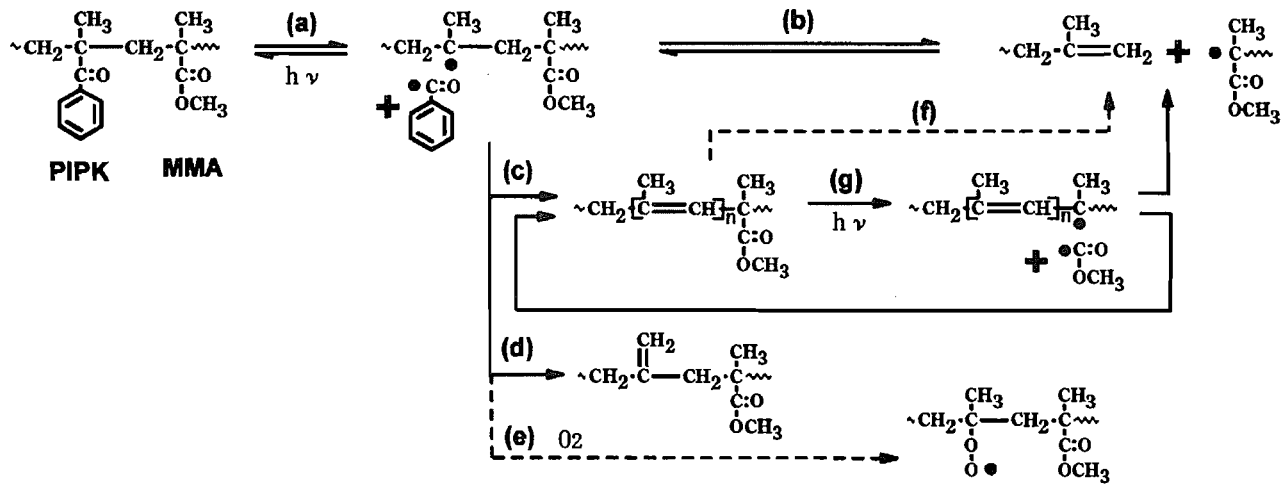
Fig. 1. Degradation scheme of PMMA–PIPK: (*a*) photolysis by Norrish Type I, (*b*) β-scission, (*c*, *d*) hydrogen abstraction, (*e*) auto-oxidation, (*f*) thermal decomposition, and (*g*) photolysis of MMA ester side chain on the carbon adjacent to the C=C bond.



sought to enhance the sensitivity of poly(methyl methacrylate) (PMMA) (700 mJ/cm^2 reported by Lin (4) and 11 000 mJ/cm^2 by Nate et al. (2)) by copolymerizing radiation-active monomers with methyl methacrylate (MMA). Incorporation of 16 mol% of 3-oximino-2-butanone methacrylate (5) and 3 mol% of indenone (6) results in 30 and 35 times increase in the sensitivity, respectively. The benzoyl chromophore of the phenyl isopropenyl ketone (PIPK) unit is highly sensitive to DUV light, and its copolymer with MMA (the copolymer is hereafter designated as PMMA–PIPK) has been reported to be 110 (28 mol% of PIPK) and 350–800 times (6–35 mol% of PIPK) as sensitive as PMMA when irradiated with a Xe–Hg lamp (2) and 254 nm light (7), respectively. In addition, bleaching of the resist film was also observed during DUV irradiation (7), which is preferable for efficient light penetration through the entire film thickness and formation of resist patterns with a steep profile (8).

Photochemistry, as well as photophysics, of solid ketone polymers is well documented in the extensive reviews by Guillet (9, 10): the Norrish type I reaction, the Norrish type II reaction, photoreduction of the carbonyl group, and the formation of cyclobutanol. For polymers with a γ-hydrogen at the carbonyl group (e.g., poly(styrene-*co*-phenyl vinyl ketone) (PS–PVK) and poly(methyl methacrylate-*co*-methyl vinyl ketone) (PMMA–MVK) (11)) where the Norrish type II mechanism is possible, a large increase in the quantum yield of chain scission by the type II mechanism, Φ_{II}, is observed at and above the glass transition temperature, T_g, because this reaction requires a large amount of free volume for the six-membered intermediate. The generality of this effect suggests that even in the solid phase above T_g the conformational freedom of large segments of the polymer chain is comparable to that in solution, and consequently one should expect equivalent chemical reactivity.

On the other hand, methyl isopropenyl ketone (MIPK) copolymers with ethylene or styrene (PE–MIPK or PS–MIPK) degrade mainly by the type I mechanism (12). Cleavage produces a small methyl radical and a polymer radical, and the former has a greater probability of escaping the polymer cage. There is a small but continuous increase in the quantum yield of chain scission, Φ_I, with a temperature increase, but no discontinuous change is observed in the region of T_g, since the process requires a very small volume of activation in order to occur.

PIPK does not homopolymerize by radical polymerization, and the PIPK unit exists in between two MMA units in the copolymer chain (13, 14). PMMA–PIPK, which has no γ-hydrogen, is reported to degrade exclusively by the Norrish type I mechanism involving cleavage of the larger benzoyl moiety, followed by β-scission of the main chain (15, 16) (Fig. 1, a and b). Therefore the bleaching can be ascribed to the hypochromic effect caused by the cleavage and to partial escape of the benzoyl moiety from the polymer matrix. Photosplitting of the ester side chains of PMMA generates polymer radicals, the structure of which is the same as those from PMMA–PIPK involving the benzoyl side-chain cleavage. β-Scission proceeds from only 2.6% of the polymer radicals and most of the radicals form C=C bonds in the main chain or the side chain (17) (Fig. 1, c (n = 1) and d). The fate of the C=C bond still remains to be clarified.

One objective of this paper is to study the temperature dependence of the type I reaction involving benzoyl side-chain cleavage and of the succeeding main-chain scission in the case of PMMA–PIPK. The other is to elucidate the photodegradation mechanism of a promising DUV resist, PMMA–PIPK, and, at the same time, the PMMA standard resist.

Experimental

Materials

PIPK was prepared from propiophenone by the Mannich reaction followed by deamination, and copolymerized with MMA by suspension or bulk polymerization with 2,2′-azobis(isobutyronitrile) (AIBN) as an initiator as described in the previous papers (7, 18). The copolymer was reprecipitated from the benzene–methanol system. The PIPK content in the copolymer was estimated from the absorbance at 280 nm due to n–π^* transition in the UV spectrum in $CHCl_3$, assuming the molar absorptivity was equal to that of propiophenone (7, 14). The content was confirmed further by ^{1}H NMR. Molecular weights were determined by gel permeation chromatography (GPC) in toluene using a Waters type 410 chromatogram

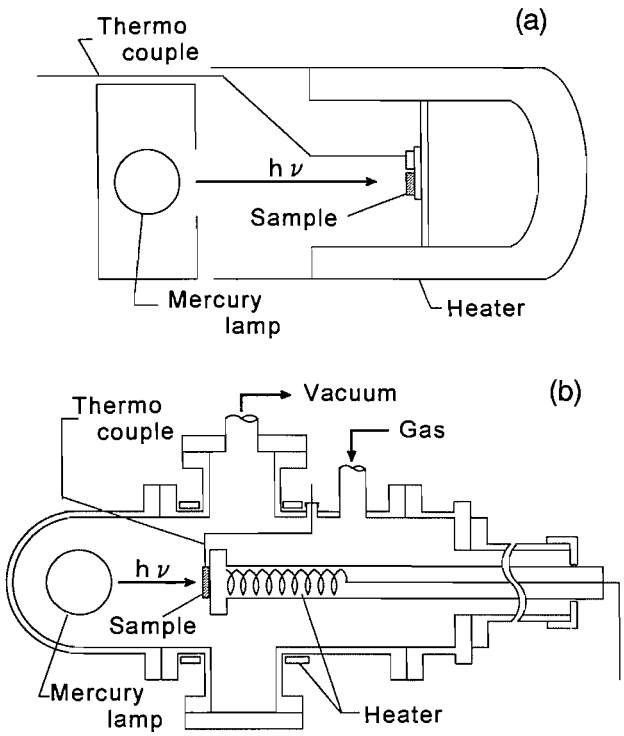
Fig. 2. Schematic diagram of irradiation apparatus with (*a*) 8 W and (*b*) 15 W mercury lamps.



equipped with a Ultrastyryl Gel Linear 10674 column and an RI detector. Polymer data are summarized in Table 1.

Polymer film preparation

PMMA–PIPK and PMMA films were prepared by spin-coating from toluene solutions onto quartz or glass plates, and prebaked in an air-circulating oven at 140°C for 30 min. They were used for UV spectral and resist performance measurements, respectively. Polymer samples for GPC measurements were scratched from the glass plates after irradiation. Polymer films of as similar thickness as possible (500–750 nm) were used for each series of experiments.

DUV irradiation

Low-pressure mercury lamps of 8 W and 15 W without filters were used as the light source, which mainly emits DUV light of wavelength 254 nm. Irradiation in air was performed in the apparatus shown in Fig. 2*a*, while the effects of irradiation atmosphere were studied by using the chamber in Fig. 2*b*. In both cases the sample temperature was monitored with a thermocouple that was fixed on the sample holder. Incident light intensity, I_0, was measured to be 0.11–0.28 mW/cm^2 for PMMA–PIPK or 2.87 mW/cm^2 for PMMA (Apparatus a) and 0.83 mW/cm^2 for PMMA–PIPK (Apparatus b) with an Eppley air-type thermopile.

Measurement of benzoyl group removal

Concentration of remaining benzoyl groups was calculated from the absorbance at 242 nm, and the number of absorbed photons from the absorbance at 254 nm in the UV spectra, where the ε_{242} and ε_{254} values used were 12 700 and 7 600, respectively.

Measurement of main-chain scission

The molecular weights were measured for PMMA–PIPK before and after DUV irradiation at various temperatures using GPC. The number of moles of the main-chain scission, S_n, and quantum yield for main-chain scission, Φ_{cs} (=Φ_I), are calculated by the following equation:

$$\Phi_{cs} = S_n/I_{abs} = (M_{n0}/M_n - 1)m/M_{n0}/I_{abs}$$

where, M_{n0} and M_n are number-averaged molecular weights before and after DUV irradiation, respectively, m is a sample mass, and I_{abs} is the number of moles of photons (in einstein) absorbed by the polymer sample.

Resist performance

A polymer film was irradiated with 254 nm DUV light, developed in methyl isobutyl ketone (MIBK) without agitation at 23°C for 180 s, and rinsed with isopropanol (IPA) for 20 s. These developing conditions were selected to keep thickness reduction of the resist film in the unexposed area smaller than 10% of the initial thickness of the PMMA – PIPK 06b film.

The developed depth, which was the difference in film thickness between the exposed and the unexposed areas, was measured with an interference microscope after evaporating aluminum onto the surface of the specimen. The remaining resist thickness was obtained by reducing the measured depth from the thickness in the unexposed area, normalized to the initial thickness, and plotting against the logarithm of a varying radiation energy (dose) to give the characteristic lithographic curve. The sensitivity was defined as the minimum incident dose (in mJ/cm^2) required for complete removal of the resist film. The contrast, γ, was obtained as the slope of the linear part of the characteristic curve.

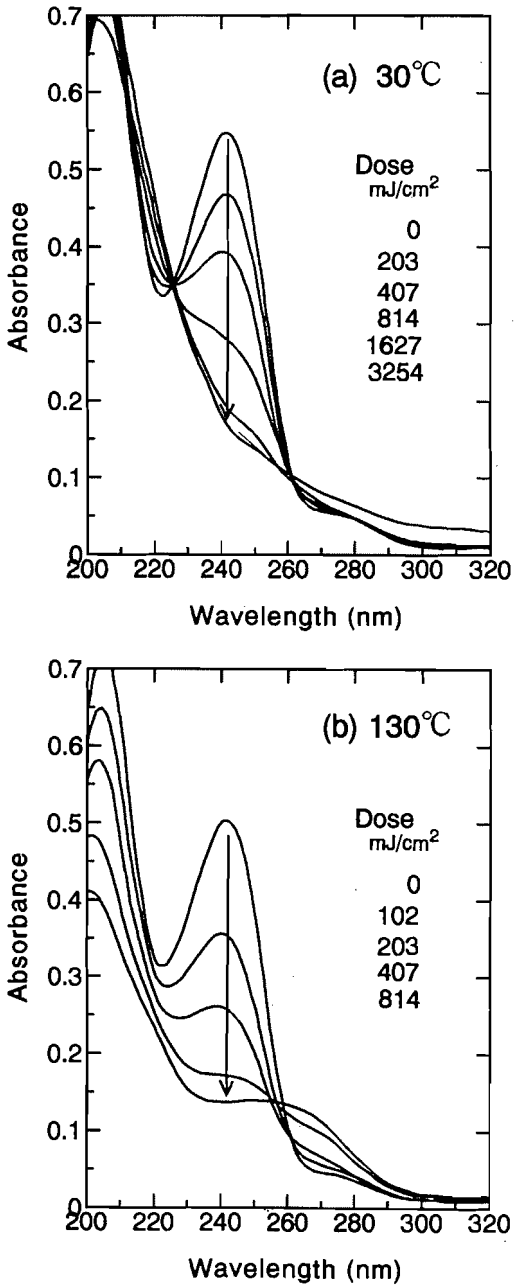
Fig. 3. UV spectra of 750 nm-thick PMMA–PIPK 06a films before and after irradiation (*a*) at 30°C and (*b*) at 130°C.

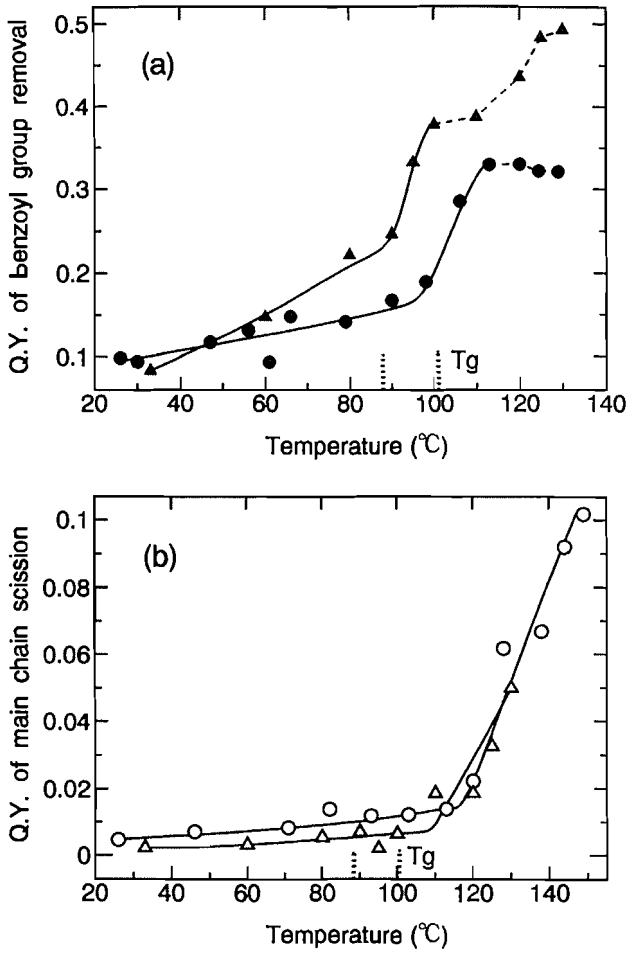


Results and discussion

I-1 Temperature dependence of benzoyl group removal

UV spectral changes were measured for PMMA–PIPK 06a after DUV irradiation at 30°C and 130°C, and are shown in Figs. 3*a* and 3*b*, respectively. PMMA has a weak absorption below 260 nm, which is negligible compared with that of PIPK copolymers (7). The absorption band at 242 nm decreased as the irradiation dose increased, and the copolymer films showed good bleaching characteristics. This is ascribed to cleavage of the benzoyl groups from the PIPK side chain by the Norrish Type I pathway (Fig. 1, a), and, perhaps, to the escape of some of the benzoyl groups from the polymer matrix, as no isosbestic point is observed in Fig. 3*b*. Naito et al. detected the benzoyl moieties as benzaldehyde, with a high yield in DUV photolysis of PMMA–PIPK in dioxane solutions (15). UV absorption remaining after the band at 242 nm ceased to decrease by DUV irradiation was considered to be due to the photoproducts formed by the benzoyl group removal, and calculation of the quantum yield was performed by subtracting the residual UV absorption.

Fig. 4. Temperature dependence of quantum yield for (*a*) benzoyl group removal and (*b*) main-chain scission of PMMA–PIPK 06a films (-●- and -○-) and PMMA–PIPK 35 films (-▲- and -△-).



Quantum yields for the benzoyl group removal were calculated for PMMA–PIPKs 06a and 35 irradiated at various temperatures. They are plotted in Fig. 4*a* as a function of the irradiation temperature. The quantum yield increased abruptly above each T_g of the PMMA–PIPKs, as is observed with the quantum yield for main chain scission of PMMA–MVK by the type II mechanism, Φ_{II} (11). The increase was considered to be caused by a free volume increase above T_g, allowing the benzoyl radical to escape from the side-chain cage, and suppressing the back reaction: the benzoyl radical can be recombined with the polymer radical to again form the PIPK side chain. The activation energies below T_g for PMMA–PIPKs 06a and 35 were found to be 3.9 and 9.0 kJ/mol, respectively, which are a little smaller than the value of 12.5 kJ/mol for PMMA–MVK to form the six-membered intermediate by crankshaft motion of the main chain (11). A similar tempera-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

ture dependence of quantum yield on T_g and other secondary transitions was not found in Norrish type I cleavage of PE–MIPK and PS–MIPK, where smaller CO, $CH_3^{\cdot}$, and $CH_3CO^{\cdot}$ escape with great efficiency through polymeric glassy matrices (12). The dependence was observed in quenching of excited benzophenone in solid PMMA matrix, in which the quenching rate of phosphorescence was controlled by diffusion of benzophenone molecules (19). The activation energy for the carbonyl loss of PS–MIPK is calculated from the data in ref. 12 to be 5.5 kJ/mol between 64 and 104°C, and that for the benzophenone diffusion is reported to be 40 kJ/mol (19). The former is comparable to, but the latter is much larger than, that for benzoyl group removal in the case of PMMA–PIPK.

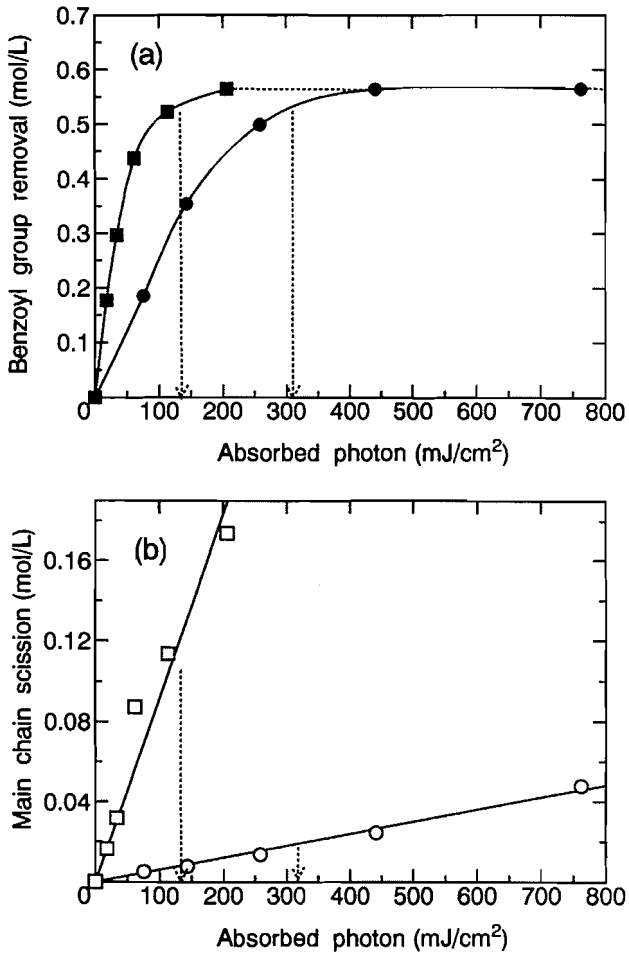
I-2 Temperature dependence of main-chain scission

The polymer radical, which is generated by Norrish type I cleavage, undergoes β-scission of the main chain to reduce the molecular weight (Fig. 1, b) (15). Since Norrish type II elimination scarcely occurs with the ketone polymer that has no γ-hydrogen at the carbonyl group (16), the decrease in the molecular weight is primarily brought about by β-scission through the type I mechanism. Quantum yield for main-chain scission was calculated from the GPC measurement on PMMA–PIPKs 06a and 35 irradiated at various temperatures. They are plotted in Fig. 4*b* as a function of the irradiation temperature. The quantum yield increased markedly at a certain temperature about 20°C higher than each T_g of the PMMA–PIPKs. The increase in the quantum yield was ascribed to a free volume increase, which was necessary for the polymer fragment generated by β-scission to escape from the cage and for suppression of recombination between the fragments to reunite the main chain. Activation energies below and above the critical temperature were 5.9 and 41 kJ/mol for PMMA–PIPK 06a, respectively. As mentioned in Sect. I-1, PS–MIPK degrades mainly by the type I mechanism. The quantum yield for the main-chain scission as well as the loss of carbonyl function does not show a discontinuous change in the region of T_g (12). However, a similar temperature dependence of quantum yield and similar values of activation energy for PMMA–PIPK have been reported, with chain scission and cross-linking between polymer radicals influenced by segment motion of poly(vinyl acetate) (20).

I-3 Correlation between benzoyl group removal and main-chain scission

Benzoyl group removal and main-chain scission in PMMA–PIPK 06a are plotted as a function of absorbed photon in Figs. 5*a* and 5*b*, respectively. When the slope in Fig. 5*b* is compared with that of the initial linear part of the corresponding curve in Fig. 5*a*, it is found that main-chain scission occurs from only 2.5% and 10% of the polymer radicals generated by benzoyl side-chain cleavage at 30°C and 130°C, respectively. The former value, 2.5%, is quite similar to the value of 2.6% observed with main-chain scission of PMMA after the ester side-chain removal (17). Compared with this, the ratio of 10% indicates much enhanced efficiency of main-chain scission at 130°C. As Fig. 5*b* indicates, main-chain scission continues to proceed even after benzoyl group removal reaches a saturated value (see dotted arrows in Fig. 5a), which suggests the possibility of other degradation mechanisms for PMMA–PIPK than the Norrish type I cleavage followed by β-scission (Fig. 1, a and b).

Fig. 5. Photolyses of (*a*) side chain and (*b*) main chain of PMMA–PIPK 06a irradiated at 30°C (-●- and -○-) or 130°C (-■- and -□-) in air.



When PMMA–PIPK is irradiated with 254 nm light, the primary photochemical event is exclusively Norrish type I cleavage of the ketone side chain to form the polymer radical (15, 16). Then, some polymer radicals may undergo β-scission of the main chain, but others may form C=C bonds in the main chain (Fig. 1, c) or in the side chain by hydrogen abstraction (Fig. 1, d) (17), start auto-oxidation with addition of O_2 (Fig. 1, e), or be converted to stable polymer radicals or unstable intermediates from which main-chain scission can occur by post-exposure heating (Fig. 1, f). The probability of main-chain scission via Fig. 1, e and f mechanisms will be discussed next in Sects. I-4 and I-5.

I-4 Influence of ambient atmosphere on main-chain scission

PMMA–PIPK 06b was irradiated at 30°C or 130°C in different atmospheres: O_2, air, and N_2. Benzoyl group removal and main-chain scission are plotted as a function of absorbed photon in Figs. 6*a* and 6*b*, respectively. These figures are quite similar to Figs. 5*a* and 5*b*, regardless of different ambient atmospheres during DUV irradiation.

No increase in main-chain scission at 130°C in O_2 compared with that in air shows negligible contribution of auto-oxidation, which would be initiated by addition of O_2 to the

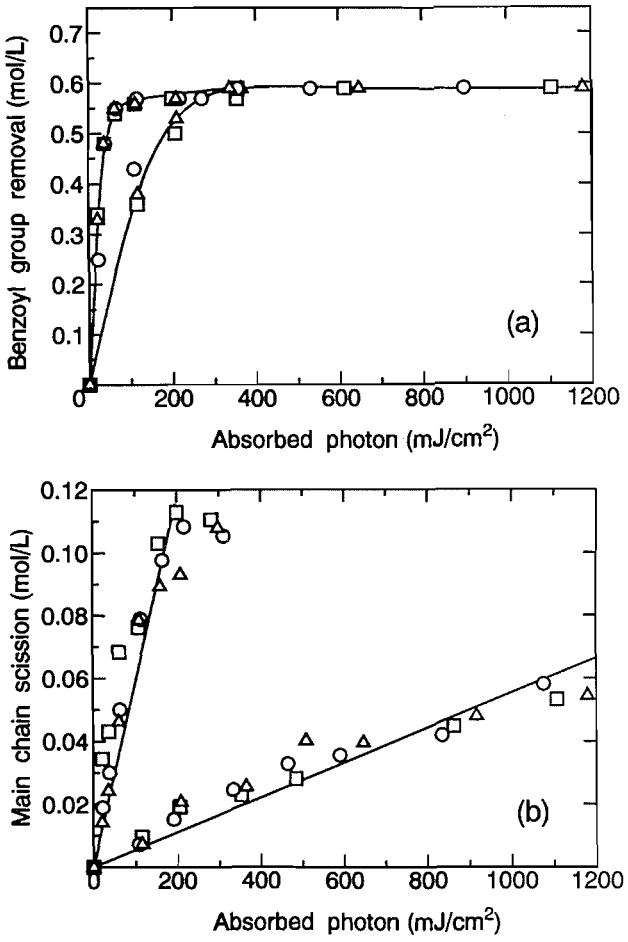
For personal use only.

Fig. 6. Atmospheric influence on photolyses of (*a*) side chain and (*b*) main chain of PMMA–PIPK 06b irradiated at 30°C or 130°C. ○: in air, △: in O_2, and □: in N_2.



polymer radical (Fig. 1, e). No increase in main-chain scission at 30°C in N_2 compared with that in air suggests no detectable quenching of the polymer radical by O_2. These results indicate that ambient atmosphere hardly influences degradation, including auto-oxidation, of PMMA–PIPK in the solid phase, probably due to slow diffusion of the O_2 molecule into the polymer film, as was reported by Kato et al. in a comparison of the photolysis of copolymers of MMA with MIPK in solution and in the solid phase (21, 22).

I-5 Effect of post-exposure heating on main-chain scission

PMMA–PIPK 06b was irradiated at 30°C or 130°C and then heated at 130°C for a period equal to the irradiation. The results are shown in Fig. 7. Heating at 130°C after irradiation at 30°C or 130°C had no effect on further scission of the main chain. Heating at 130°C without irradiation also had no effect. These experiments reveal that although some stable polymer radicals and thermally unstable intermediates may remain in the polymer matrix, the quantities are too small to influence the degradation scheme.

I-6 Photolysis of PMMA at an elevated temperature

Main-chain scission was measured on a PMMA film of the same thickness and had been irradiated or heated under the

Fig. 7. Influence of heating at 130°C on main-chain scission of PMMA- PIPK 06b after irradiation at 30°C (●: with and ○: without heating) or 130°C (■: with and □: without heating). ◆: heated at 130°C without irradiation.

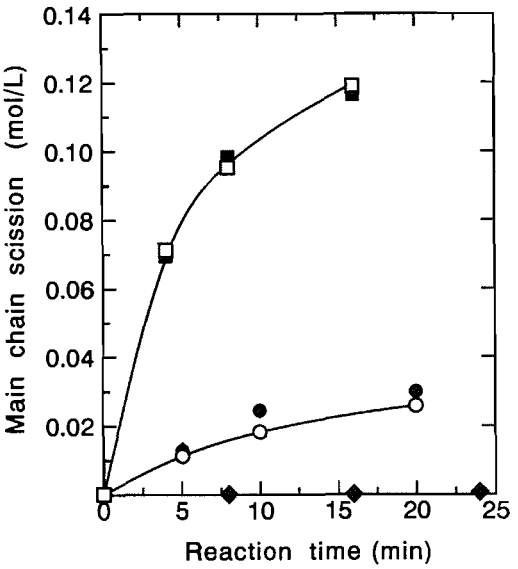


Fig. 8. Main-chain photolyses of PMMA films irradiated at 30°C (○) and 130°C (□). ◆: heated at 130°C without irradiation. (- - -) and (– – –): photolyses for PMMA–PIPK 06b at 30°C and 130°C, respectively.

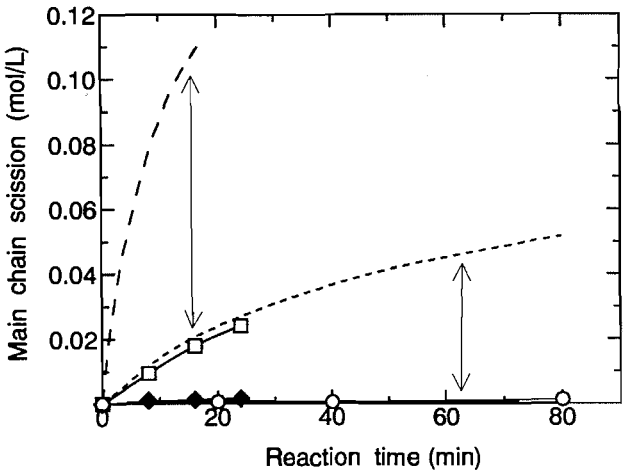
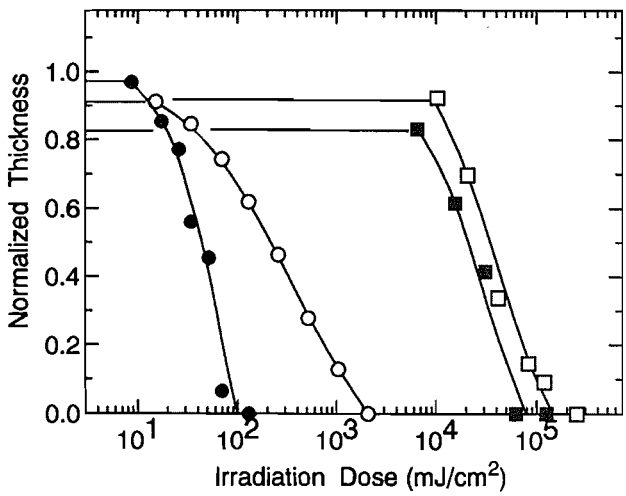


same conditions as a PMMA–PIPK 06b film. The number of main-chain scissions is plotted against irradiation or heating time in Fig. 8. The dashed and broken lines indicate the plots for photolyses of PMMA–PIPK 06b at 30°C and 130°C, respectively. Photolysis of PMMA at 30°C and thermolysis at 130°C were negligibly slow, compared with photolysis of PMMA–PIPK at 30°C. However, PMMA was found to degrade at about 25% of the photolysis rate of PMMA–PIPK 06b by DUV irradiation at 130°C, which is above its T_g.

I-7 Degradation mechanism of PMMA–PIPK and PMMA

Based on the results observed in Sects. I-1–I-6 in addition to those reported in refs. 15, 16, 17, 21, and 22, the primary photochemical event for PMMA–PIPK is Norrish type I cleavage of the phenyl ketone side chain to generate the polymer radical

Fig. 9. Characteristic lithographic curves for PMMA–PIPK films irradiated at 30°C (○) and 130°C (●) and for PMMA irradiated at 30°C (■), developed with MIBK for 180 s. The PMMA film was also developed with MIBK for 90 s (□).



(Fig. 1, a). Then, a small number of the polymer radicals contribute to molecular weight decrease through β-scission (Fig. 1, b), but most of them are stabilized to form C=C bonds by hydrogen abstraction (Fig. 1, c and d).

Since the contributions of auto-oxidation of the polymer radical (Fig. 1, e) and thermal decomposition of stable radicals or unstable intermediates derived from the polymer radical (Fig. 1, f) were found to be small, main-chain scission by DUV irradiation after the benzoyl side chain ceased to split cannot be explained by the known mechanisms of Fig. 1, a–f. The MMA ester side chain on the carbon adjacent to the C=C bond can split to form conjugated polymer radicals (Fig. 1, g) by DUV irradiation more easily than can the intrinsic PMMA ester side chain. Some of the conjugated radicals will contribute to main-chain scission, but others will be stabilized again by further hydrogen abstraction from the main chain or the side chain. UV absorption at 242 nm due to the photoproducts discussed in Sect. I-1 can be ascribed to these conjugated C=C bonds, which were formed by successive photo-splitting of ester groups and hydrogen abstraction (Fig. 1, c ($n \geq 2$)). All these degradation mechanisms except the initial type I cleavage of benzoyl groups hold valid also for PMMA, because the polymer radicals are of exactly the same structure for both PMMA–PIPK and PMMA. The primary photoprocess, which is cleavage of ester groups in the case of PMMA, occurs less readily than that with PMMA–PIPK, but it is likely to be accelerated above the T_g.

II. Resist performance

Characteristic lithographic curves were obtained with polymer films of PMMA–PIPK 06b of ca. 750 nm thickness exposed at 30°C and 130°C, and are shown in Fig. 9. The sensitivity was 1600 and 100 mJ/cm^2, and the contrast was 0.6 and 1.3 at 30°C and 130°C, respectively. In Fig. 4*b*, quantum yields of main-chain scission at 30°C and at 130°C are 0.0029 and 0.036, respectively. The difference in sensitivity is a little larger than that of the quantum yield.

The contrast at 130°C was improved compared with that at 30°C, but little difference of M_w/M_n was observed, by GPC, between PMMA–PIPKs exposed with DUV light of radiation energy at each sensitivity dose at 30°C and at 130°C. In addition to the partial escape of split benzoyl groups observed in the UV spectra with no isosbestic point in Fig. 3*b*, thickness reduction (self-development) was actually detected to be 90 nm during DUV irradiation of 450 mJ/cm^2 at 130°C. Therefore, it is likely that gaseous photoproducts as well as main-chain scission enhanced the dissolution rate of the resist film in the exposed area, and the contrast at 130°C was higher than that at 30°C .

Characteristic curves of PMMA were also obtained with films exposed at 30°C and developed with MIBK for 180 s (the same conditions as for PMMA–PIPK) or developed with MIBK for 90 s (the same conditions as in the previous paper (2), which give a similar ratio of thickness reduction in the unexposed area by wet development). The sensitivities of PMMA–PIPK 06b at 30°C and 130°C were 75 and 1200 times as high as that of PMMA exposed at room temperature and developed under similar conditions. The sensitivity enhancement is ascribed to both efficient absorption of DUV light and high quantum yield for main-chain scission, especially highly effective photosplitting of the benzoyl side chain by the Norrish type I mechanism.

The findings in this study are applicable to actual lithography in the following three patterns:

1. Exposure at a higher temperature than T_g, rather than post-exposure bake, is effective for the increase in quantum yield for main-chain scission. In this case development at a lower temperature than T_g is necessary for preventing the latent image from being smeared.

2. Lowering the T_g of the resist film by incorporation of, or formulation with, plasticizing units will increase the quantum yield. This methodology has already been partially adopted in the molecular design of FBM, poly(1,1,1,2,3,3–hexafluorobutyl methacrylate) (T_g = 50°C) (23).

3. Incorporation of an appropriate substituent on the phenyl ring of PIPK will increase the absorption of DUV radiation and (or) the quantum yield for main-chain scission, and hence the sensitivity. This study will be reported in another contribution by some of the present authors (24).

Conclusion

Temperature dependence of benzoyl side-chain cleavage and main-chain scission of PMMA–PIPK irradiated with DUV light showed a large and discontinuous increase in the quantum yields of the type I mechanism in the region of T_g. The correlation between cleavage and scission revealed a new reaction mechanism of photosplitting of the MMA ester side chain on the carbon adjacent to the C=C bond. This mechanism also holds valid for PMMA.

Efficient DUV absorption and high quantum yield for main-chain scission above T_g realized a sensitivity of 100 mJ/cm^2 for PMMA–PIPK as a DUV resist.

Photomodulation of the hydrophilic properties of acrylic polymers containing side-chain azobenzene chromophores

Nicola Tirelli, Angelina Altomare, Francesco Ciardelli, and Roberto Solaro

Abstract: Partially hydrophilic polymers have been prepared by free-radical copolymerization of *trans*-4-acryloyloxyazobenzene with *N-tert*-butylacrylamide and *N*-isopropylacrylamide. A turbidimetric method has been adapted to investigate the dependence of the polymer hydrophilic–hydrophobic balance on chemical composition and extent of photoisomerization of side-chain azobenzene chromophores. Irradiation at 366 nm of polymer suspension in THF–water induces the isomerization of azobenzene groups from the planar apolar *trans* form to the nonplanar polar *cis* form. Correspondingly, the solution turbidity is appreciably modified. Experimental results are discussed in terms of polymer structural parameters. Suspension stability and the possibility of carrying out photochemical cycles have been also investigated.

Key words: photochromic polymers, photoresponsive polymer, photomodulation of polymer properties, azobenzene-containing polymers, acryloyloxyazobenzene, *N-tert*-butylacrylamide.

Résumé : On a préparé des polymères partiellement hydrophiles par copolymérisation radicalaire du *trans*-4-acryloxyazobenzène avec les *N-tert*-butylacrylamide et *N*-isopropylacrylamide. On a adapté une méthode turbidimétrique pour étudier la dépendance de la balance hydrophile–hydrophobe sur la composition chimique et le degré de photoisomérisation de la chaîne latérale des chromophores azobenzènes. L'irradiation, à 360 nm, d'une suspension de polymère dans un mélange THF–eau induit une isomérisation des groupes azobenzènes de la forme *trans*, plane et apolaire, vers la forme *cis*, non planaire et polaire. D'une façon correspondante, la turbidité de la solution est modifiée d'une façon appréciable. On discute des résultats expérimentaux en fonction des paramètres structuraux du polymère. On a étudié la stabilité de la suspension et la possibilité d'effectuer des cycles photochimiques.

Mots clés : polymères photochromes, polymère photorépondant, photomodulation des propriétés d'un polymère, polymères contenant de l'azobenzène, acryloxyazobenzène, *N-tert*-butylacrylamide.

[Traduit par la rédaction]

Introduction

In recent years increasing attention has been focused on polymeric systems and gels based on *N*-alkylacrylamide, for their well-known properties of thermoreversible swelling or collapse, and for their possible application as drug release systems, chemo-mechanical transducers, sensors, and selective pumps (1–5). Polymer gelation can also be controlled by parameters other than temperature, e.g., pH, ionic strength, and solvent composition (6–8). However, only a few attempts to achieve a *photochemical* control of this transition have been reported so far (9–11).

For some time our research group has been investigating the preparation and the photochromic characterization of synthetic polymers having a hydrocarbon backbone and bearing photoactive moieties, mainly azobenzene groups, in the side chains (12–19). Until now, however, this research has been mainly focused on hydrophobic systems.

In the present paper we report on the results obtained in an investigation of the photomodulation of the hydrophilic–hydrophobic balance of radical copolymers of a photochromic monomer, *trans*-4-acryloyloxyazobenzene (**AAB**), with a hydrophilic monomer, N-*tert*-butylacrylamide (**NTBA**). For comparison, copolymers of **AAB** with *N*-isopropylacrylamide (**NIPA**) have been also studied. Modulation of polymer solubility parameters was carried out by reversible photochemical control of phase segregation.

The choice of the azobenzene chromophore as photochromic group has been suggested because of its stability and the

photoreversibilty of the *trans→cis* isomerization process. Moreover, only the photoinduced change of side-chain polarity can affect polymer solubility. On the contrary, triphenylmethane and spiropyran derivatives are less stable and the charge photogeneration induced by light irradiation gives rise to a significant increase of ionic strength.

Experimental

Polymer synthesis and characterization has been reported in a previous paper (17).

Spectrograde anhydrous THF (Erba) and bidistilled water were used as solvents. UV measurements were performed at 25°C in THF–H_2O in solvent mixtures by a Jasco Uvidec 510 spectrophotometer connected to a microcomputer for automatic collection and processing of experimental data. Microscopy analyses were performed by a Polyvar optical microscope equipped with polarizing filters and a photographic apparatus.

Phase segregation experiments were carried out by repeated additions of a small amount (10–50 μL) of water to a stirred polymer solution in THF while recording the 380 nm optical density. Each addition was limited so as to induce a variation of absorbance lower than 0.04. Subsequent additions were delayed until photometric stabilization.

Photoisomerization experiments were carried out on polymer solutions or suspensions, by using the following experimental setup: the emission from a 150 W high-pressure Hg/Xe lamp, filtered by a 366 nm or 440 nm interference filter (Balzer) having ±5 nm bandwidth, was guided by a 3 mm × 50 cm quartz fibre on top of a magnetically stirred 10 mm quartz cell placed within the UV spectrophotometer. Isomerization kinetics were monitored by measuring the 320 nm absorbance or 380 nm scattering every 5–10 s. About 1000–1500 data points were collected for each photoisomerization experiment.

Results and discussion

Copolymers of acryloyloxyazobenzene (**AAB**) with *N-tert*-butylacrylamide (**NTBA**) and with *N*-isopropylacrylamide (**NIPA**) were prepared by free-radical polymerization in benzene, as reported elsewhere (17). For comparison the corresponding homopolymers were also synthesized. Data relevant to chemical composition and molecular weight of the investigated samples are summarized in Table 1.

Table 1. Characterization of copolymers of 4-acryloyloxyazobenzene (**AAB**) with *N-tert*-butylacrylamide (**NTBA**) and *N*-isopropylacrylamide (**NIPA**).

Sample	Comonomer (type)	**AAB**[a] (mol%)	$\overline{M}_n$[b]	$\overline{M}_w/\overline{M}_n$[b]

[a]Evaluated by ^{1}H NMR.
[b]Evaluated by GPC in THF.

The reactivity ratios obtained for the investigated systems (respectively, $r_{AAB} = 0.66$ and $r_{NIPA} = 0.57$; $r_{AAB} = 0.91$ and $r_{NTBA} = 0.53$) indicate some tendency to an alternating enchainment of monomeric units ($r_{AAB} \times r_{NIPA} = 0.38$; $r_{AAB} \times r_{NTBA} = 0.49$).

On irradiation at 366 nm, corresponding to the $\pi \rightarrow \pi^*$ electronic transition, the intensity of the 320 nm absorbance of copolymer solution in THF shows an exponential decay, and a plot of $\log(A_0 - A_\infty)/(A_t - A_\infty)$, where A_0, A_t, and A_∞ are, respectively, the absorbance at time 0, t, and at the photostationary state, exhibits a linear dependence upon irradiation time, in accordance with the occurrence of a first-order kinetics ($k_i \approx 4\times10^{-4}$ s^{-1}). The occurrence, in the UV spectra of the solutions, of two distinct isosbestic points at about 280 and 380 nm indicates that only two absorbing species, namely, the *trans* and *cis* isomers, are present and that no side reaction occurs. The *trans→cis* photoisomerization process can be reversed either thermally ($k_t \approx 5\times10^{-6}$ s^{-1} at 25°C) or by irradiation at 440 nm ($k'_i \approx 1\times10^{-2}$ s^{-1}), corresponding to the $n \rightarrow \pi^*$ electronic transition.

Polymer precipitation

Hydrophilicity of polymer samples can be ranked by measuring either the precipitation temperature in a given water – organic solvent mixture or the solvent composition at a definite temperature. Both methods decrease the thermodynamic strength of the solvent, thus reducing the solvation of polymer macromolecules. This decrease causes the system to cross binodal or spinodal lines in the phase diagram (20, 21) and formation of metastable polymer solutions or phase separation of polymeric materials is observed. However, to evaluate the possible effect of *trans–cis* photoisomerization, it was necessary that the thermal back-isomerization rate did not change too much in different runs. As a consequence, the temperature was kept constant at 25°C while changing the solvent composition.

Experimentally, the 380 nm absorbance of polymer solutions in THF was monitored while adding increasing amounts of water. The 380 nm wavelength was selected, as neither

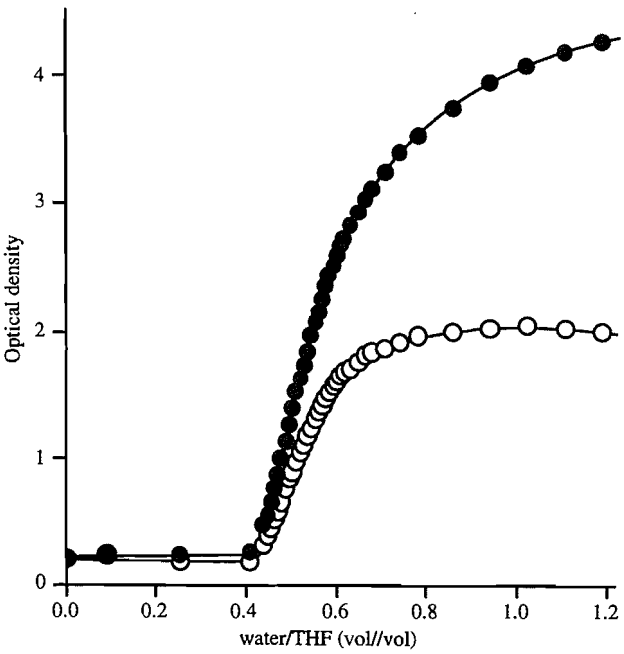

Fig. 2. UV spectra of **AAB/NTBA** copolymer (sample AABA3) at 25°C in water–THF solution at different water contents.

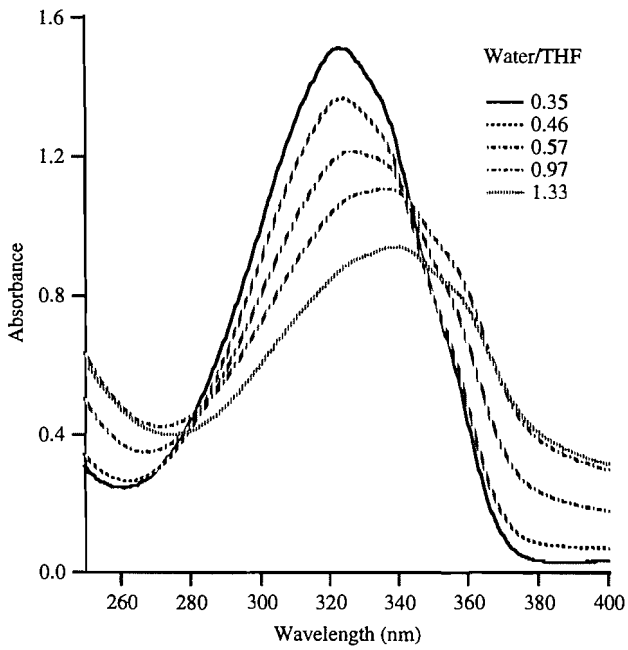

trans- nor *cis*-azobenzene have an appreciable absorption at this wavelength. The recorded variation of the 380 nm absorption could therefore be attributed almost exclusively to the light scattering of the precipitated polymer.

Optical microscopy examination of suspensions gave evidence that polymer microparticles were highly swollen and allowed us to associate the observed increase of light scattering on water addition during the precipitation process to an increase of their average size.

Polymer suspensions thus obtained were characterized by a rather low stability and, on stirring, the spherical polymer microparticles gave rise to multinuclear aggregates. However, addition of 1.0 g/L of sodium dodecylsulfate to polymer solutions noticeably improved the stability of suspensions whose 380 nm scattering remained almost constant over at least 20 h.

For each polymer sample, experiments were carried out using polymer solutions having concentrations between 0.02 and 0.2 g/L. The inflection point of the titration curves and light scattering at complete precipitation, averaged over at least three runs, were recorded as a measure of polymer hydrophilicity (Table 2). To better display the inflection point, measured absorbance values were corrected for the increasing dilution due to water addition (Fig. 1). However, values reported in Table 2 and subsequent figures use uncorrected experimental data.

During the precipitation process, a shift of the maximum of the $\pi \rightarrow \pi^*$ absorption band from 320 to 350 nm was recorded. This effect is too large to be attributed solely to a solvent effect and seems to arise from a modification of the relative intensity of the different components of the band (Fig. 2). However, no sound explanation can be put forward at present.

The starting concentration of polymer solution significantly affected not only the final light scattering but also the position of the inflection point, for polymer samples both in the all-*trans* configuration and at the photostationary state under irradiation at 366 nm (Table 3). This result is not unexpected; in fact, it is known that a larger decrease of the thermodynamic

[a]At the photostationary state under irradiation at 366 nm.

Fig. 3. Dependence of the water/THF ratio at the inflection point on the composition of **AAB/NTBA** (-●-) and **AAB/NIPA** (-■-) copolymers (c = 0.1 g/L) at 25°C.

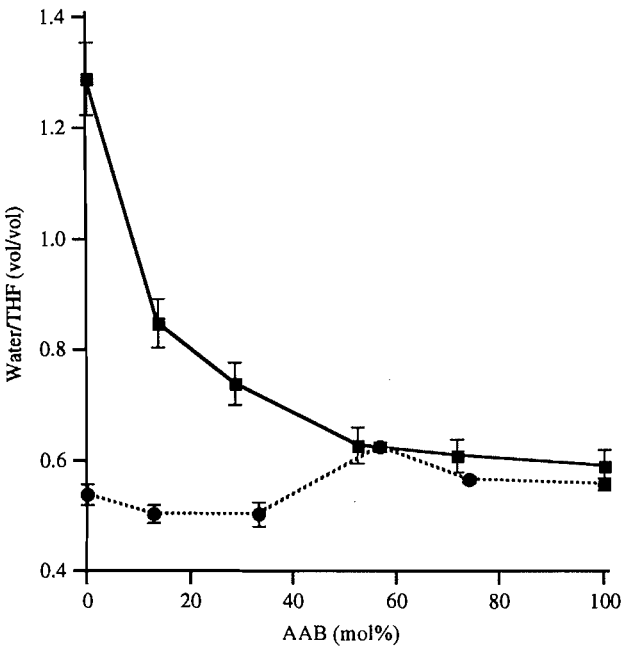

Fig. 4. Dependence of the water/THF ratio at the inflection point on the composition of **AAB/NTBA** copolymers (c = 0.1 g/L) in the all-*trans* configuration (-●-) and at the photostationary state under irradiation at 366 nm (-○-) at 25°C.

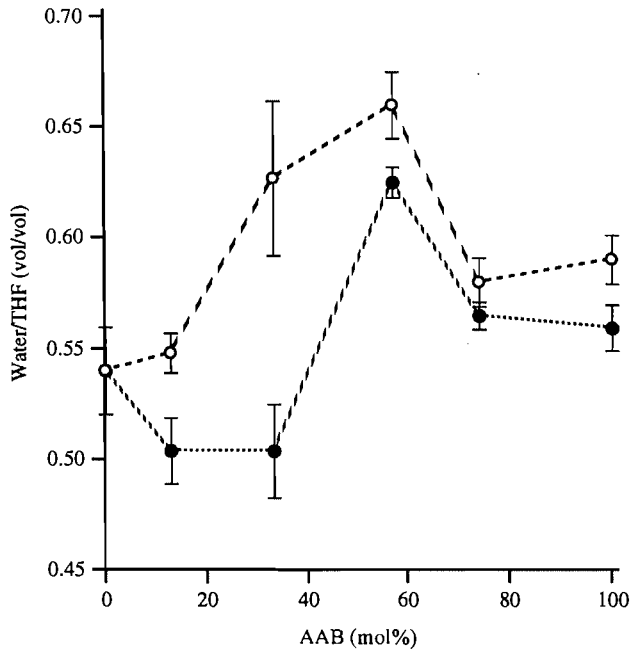

solvent strength is required in order to make more dilute polymer solutions cross binodal and spinodal lines (20). Comparison of the solvent composition at the inflection point for different *trans*-**AAB/NTBA** copolymer samples showed that the water/THF ratio increased from 0.60 to 0.65 on increasing the **NTBA** content from 0 to about 40% and then decreased to about 0.54 (Fig. 3).

On the basis of the expected different hydrophobicity of **AAB** units as compared to **NTBA** units, one should anticipate a monotonic dependence of the amount of water required for polymer precipitation on the chemical composition of the copolymers. The observed trend highlights the complexity of the precipitation process, which is influenced not only by the hydrophilic–hydrophobic balance, but also by molecular weight ($\overline{M}_n$), the polydispersity index ($\overline{M}_w/\overline{M}_n$), and polymer conformation. In particular, it seems reasonable to attribute the observed behavior to the concurrent variation of copolymer hydrophilicity and molecular weight (Table 1) and to some specific interaction between monomeric units.

However, the range of water content at the inflection point spanned by different polymer samples is quite small, indicating that the **AAB** and **NTBA** monomeric units are characterized by rather similar hydrophobicity, thus allowing other minor factors to manifest their effect. To verify this point, copolymers of **AAB** with **NIPA**, a monomer significantly more hydrophilic than **NTBA**, were investigated under the same experimental conditions. As expected, a monotonic increase from 0.6 to 1.7 of the water/THF ratio at the inflection point was observed as the content of **NIPA** units changed from 0 to 100% (Fig. 3).

Photomodulation of polymer suspension properties

Slow addition of water to polymer solutions at the photostationary state under irradiation at 366 nm induced polymer coacervation, analogous to that observed for polymer samples containing azobenzene chromophores in the all-*trans* configuration.

Independent of polymer chemical composition, the inflection point in the precipitation plots of polymer samples having a large content of *cis*-**AAB** units occurred at a larger water/

Fig. 5. Dependence of the 380 nm light scattering at the end point on polymer concentration (sample ABBA3) at 25°C: non-irradiated (-●-), and at the photostationary state under irradiation at 366 nm (-○-).

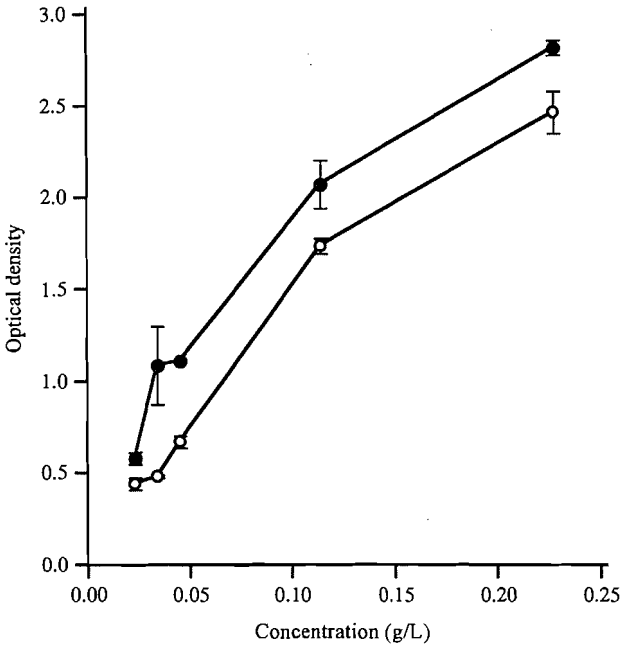

Fig. 6. Dependence of 380 nm light scattering at the end point on the composition of **AAB/NTBA** copolymers (c = 0.069 g/L) at 25°C: non-irradiated (-□-), precipitated at the photostationary state (-●-), and irradiated at 366 nm after precipitation (-○-).

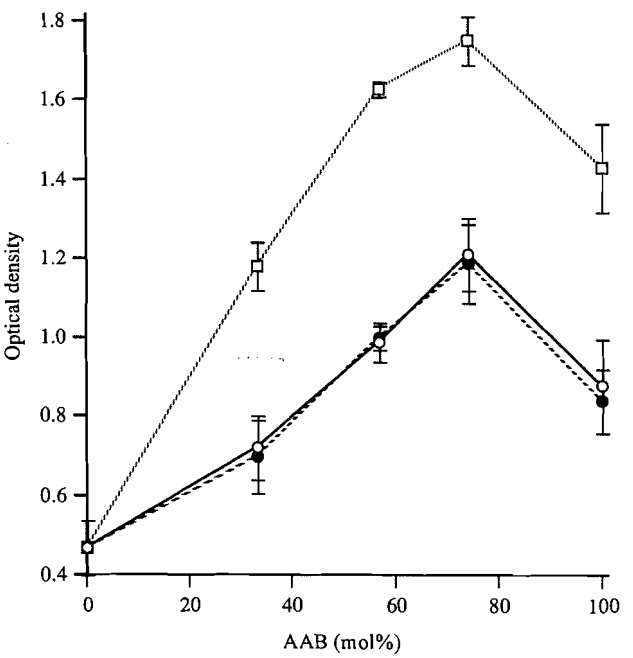
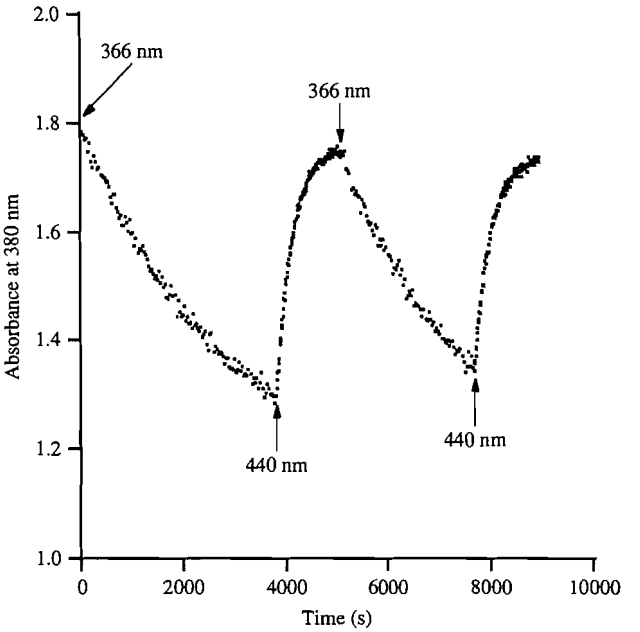


THF ratio than the corresponding all-*trans* samples (Fig. 4). By selecting a suitable solvent composition, photodissolution–photoprecipitation cycles could be effected by successive irradiation at 366 and 440 nm. Taking into account that no modification of polymer molecular weight, polydispersity index, and content and distribution of monomeric co-units occurs on irradiation, the observed trend must be attributed to a variation of the overall polymer hydrophilicity, due to the increasing content of more polar *cis*-chromophores.

Fig. 7. Variation of the light scattering at 380 nm of a polymer suspension by cycling irradiation at 366 and 440 nm (sample ABBA1, c = 0.069 g/L in water–THF at 25°C).



It was observed that in all cases the light scattering of polymer suspensions at the photostationary state was lower than that of the corresponding non-irradiated samples. To avoid possible interference by a partial photodissolution process, the scattering of polymer solutions having different concentrations (Fig. 5) or content of **AAB** units (Fig. 6) was recorded at a water/THF ratio of 1.2, well beyond the end point of both *trans* and *cis* forms. Optical microscopy analysis of polymer suspensions seems to indicate that this effect arises from a decrease of the average size of polymer microparticles, due to their lower extent of swelling. A variation of the particle refraction index cannot, however, be ruled out.

Identical values of light scattering were recorded either by precipitation of solutions at the photostationary state or by irradiation at 366 nm of all-*trans* polymer suspensions (Fig. 6). Photoisomerization of polymer suspensions exhibited first-order kinetics, having rate constants of the same order of magnitude as those measured in solution. This result seems to confirm a significant swelling of polymer particles.

The light scattering of polymer suspensions can be repeatedly cycled between two extreme values by alternate irradiation at 366 and 440 nm (Fig. 7). The different absorbance levels reached during the cyclic switching process depend on the different irradiation times used in the four cycles reported and to some extent on the limited stability of the investigated polymer suspension. This demonstrates the possibility of reversibly photomodulating the scattering of copolymer suspensions, which, at least in principle, could be used as optical switches.

Concluding remarks

Investigation of the precipitation of partially hydrophilic copolymers of acryloyloxyazobenzene with *N-tert*-butylacrylamide by water addition to THF solutions has shown that several structural parameters can contribute to the overall hydrophilic–hydrophobic balance due to the very similar hydrophobicity of the two comonomers. Indeed, in copolymers of **AAB** with *N*-isopropylacrylamide, a more hydrophilic comonomer, only the chemical composition affected the water/THF ratio necessary for polymer precipitation.

Irradiation of polymer suspensions at 366 and 440 nm has demonstrated the possibility of photomodulating both the solubility of polymer samples and the light scattering of polymer suspensions. This last phenomenon is rather large, a 30–50% variation of the 380 nm absorbance being observed. Some information on the photomodulation of polymer solubility is available in the literature (11, 22–25), whereas, to the best of our knowledge, this is the first report on the photomodulation of the light scattering of photochromic polymer suspensions.

In principle, photomodulation of the light scattering of suitable polymer suspensions could be used for the fabrication of optical switches. However, the limited stability of suspensions may prevent their practical application. The possibility of photomodulating the swelling of cross-linked polymers, which are inherently stable, is at present under investigation.

Abstract: The spatial distribution of toluene and THF in the polyester poly(diethylene glycol-*co*-succinic acid) and its Mg^{2+}-containing "telechelic" derivative was described by Kirkwood–Buff–Zimm (KBZ) cluster integrals. The values of KBZ integrals as a function of the volume fraction of solvent in the polymer–solvent systems were obtained from finite concentration inverse gas chromatography measurements utilizing the elution-on-a-plateau technique. The results show that toluene has a higher self-affinity to form clusters in the pure polyester than THF, which is more homogeneously distributed in the polymer. Data for preferential solvation indicate that a segregation of parts of the polymer chains is present in the toluene–polyester system. When metal ions are introduced, the self-affinity of the solvent molecules to gather increases, whereas solvent clusters of toluene form in the free volume, and the gathering of the THF is likely to take place close to the metal ions. Based on the electron donacity values of the various donor groups present in the metal-ion-containing polymer it was assumed that THF in the Mg^{2+}-containing polyester will be bound to the central metal ion while the apolar toluene will participate in the solvation of the apolar parts of the polymer and will be "repelled" from the ion-containing regions. The concentration of these ionic centres, which act as effective cross-links in the coordination polymer, was determined from measurements of thermodynamic activity. A comparison of the experimental and estimated effective cross-link density values indicates a nearly atomic dispersion of Mg^{2+} in the metal-ion-containing polyesters.

Key words: inverse gas chromatography, cluster integrals, solvent partition in polymers, metal-ion-containing polyesters, Flory–Huggins interaction parameter.

Résumé : Utilisant les intégrales d'agrégats de Kirkwood–Buff–Zimm (KBZ), on a décrit la distribution spatiale du toluène et du THF dans le polyester, poly(diéthylène glycol-*co*-acid succinique), et dans son dérivé «téléchélique» contenant du Mg^{2+}. Utilisant la technique d'élution sur un plateau lors de mesures de chromatographie en phase gazeuse inversée, à concentration définie, on a obtenu les valeurs des intégrales de KBZ en fonction de la fraction volumique du solvant dans les systèmes polymère–solvant. Les résultats montrent que le toluène possède une autoaffinité à former des agrégats qui est plus grande dans le polyester pur que celle du THF qui est distribué d'une façon plus homogène dans le polymère. Les données relatives à la solvatation préférentielle indiquent qu'il existe une ségrégation de parties des chaînes de polymère dans le système toluène–polyester. Quand on introduit des ions metalliques, l'autoaffinté des molécules de solvant augmente, alors que les agrégats de solvant du toluène se forment dans le volume libre, et l'agrégation du THF se produit probablement près des ion métalliques. Sur la base des valuers exprimant la facilité à donner des électrons des divers groupes donneurs présents dans le polymère contenant l'ion métallique, on a fait l'hypothèse que le THF présent dans le polyester contenant du Mg^{2+} se lie à l'ion métallique central alors que le toluène qui est apolaire participe à la solvation

Introduction

Novel, high-value-added engineering polymers with targeted properties can either be synthesized from different monomers in various polymerization reactions, or be prepared by chemical or physcial modification of existing polymers. Ionomeric polymers are a good example of chemical modification. A commercially important class of ionomers are ethylene copolymers containing acrylic or methacrylic acid comonomer neutralized by a metal salt (acetate or oxide of Zn, Na, Mg, etc.) (1, 2). The ionic groups act as thermally reversible cross-links. In these polymers, microphase separation, which results in the formation of clusters of the nonpolar hydrocarbon parts of the polymer and the ionic metal carboxylates, can occur (3). The onset of cluster formation may depend on ion concentration; however, this idea is not universally accepted (4). The restricted mobility model of Eisenberg et al. (5) is useful to explain dynamic mechanical and thermal properties of ionomers containing ionic multiplets.

To understand and control structure–property relations of ion-containing coordination polymers, the spatial distribution of the various constituents must be known. One method that could be used to study short-range order in ion-containing coordination polymers is offered by the use of inverse gas chromatography (IGC) (6, 7). The use of IGC for the study of polymers was pioneered, for the most part, by Guillet and coworkers (6–8). The adjective "inverse" indicates that the point of interest is the stationary phase in the chromatographic column that includes the "unknown" sample.

In an IGC experiment a chromatographic column is packed with the polymer sample, which is either in the form of small pieces (with the longest dimension being less than ca. 50 μm) of the polymer sample mixed with chromatographic support or as a thin film coated onto the support. A molecular probe, e.g., solvent vapor, carried by an inert gas, is injected into the column and the retention time of the probe is measured. The retention of the probe in the column is a result of gas–bulk interactions between the molecular probe and the polymer. These interactions include predominantly either absorption or adsorption or both, depending on the experimental conditions. In the limit of decreasing probe concentration, infinite dilution of the probe in the polymer can be approached. Infinite dilution IGC has been used to study a wide range of structural and thermodynamic properties of polymers and polymer–solvent systems. These include determination of degree of crystallinity (9), cross-link density of insoluble networks (10), glass transition and melting temperature (11), thermal transition temperatures of insoluble liquid-crystalline polymers (12), activity coefficients and enthalpies of solution (6), solvent diffusion coefficients (6), surface area measurements (13), etc. The particular advantage of IGC is that it can be used to obtain molecular characteristics of nonsoluble polymers. A sorption equilibrium can also be established in an IGC experiment at a given volume fraction of the probe in the polymer. In this case, the vapor pressure of the probe in the carrier gas is controlled by a saturator condenser at the "inlet" side of the column. The column is purged by a mixture of the carrier gas and the vapor of the probe, which has a vapor pressure adjusted to the value required. This process results in a sorption equilibrium with a constant probe concentration in the polymeric stationary phase. This "plateau" concentration of the probe in the polymer can be perturbed by injecting a small amount of the same solvent probe (elution-on-a-plataeu). This experiment gives information about structure and thermodynamics of the polymer studied at finite (low) concentrations of the probe. The physical basis for "finite concentration" IGC (FCIGC) was developed by Conder and Purnell (14) and was soon adapted by Brockmeier et al. to study polymers (15). In this work we will be concerned with absorption of the molecular probe. In this case the retention volume is independent of the amount of probe injected.

In preliminary studies, we used FCIGC to study the partition of solvent molecules and clustering of polymer segments and solvent molecules in the polymer matrix in various amorphous polymers (16, 17). To quantitatively characterize spatial short-range order we developed an approach to use FCIGC data to obtain cluster integrals and mean cluster size. This work reports results regarding clustering of solvents, network density, and thermodynamic interactions in metal-ion-containing coordination polyesters and their neutral counterparts.

Aliphatic polyesters containing carboxylic chain ends can be modified by introducing oxides of bivalent metals (e.g., MgO, ZnO) that form complexes with functional ~COOH end groups (18, 19). Such metal-ion-containing coordination polyesters represent a special case of ion-containing polymers that has found numerous applications. Physical properties of coordination polyesters, such as glass transition temperature (T_g) (20, 21), melt viscosity (18*b*), and crystalline morphology (18*c*), can be altered in a controlled fashion. For example, the T_g of the metal-ion-containing polyester poly(diethylene glycol-*co*-succinic acid) (PDEG–SA) rises with increasing amount of the metal ions and tends to a constant value that corresponds to the T_g of the polymer with infinitely high molar mass. Further, the heat capacity change measured at T_g decreases and the melt viscosity increases with increasing complex concentration. These results were interpreted by assuming that a dynamic ionic-polar network had formed with the complexes and that, as a result, the chain mobility became restricted and the specific free volume decreased. It was postulated that, depending on the

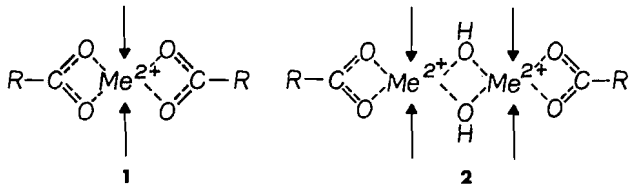
stoichiometry, the following dominating complex species can form (18, 21):



1 2

The arrows in **1** and **2** correspond to empty coordination sites, and can act as "polar cross-linking" sites for different ligands on the neighboring polyester chains (such as donor oxygen atoms of alcoholic OH, COOH, and ester groups) to coordinate the metal ions. Structure **1** is predominant at 0.5 mol MeO/COOH, while **2** dominates at around 1.0 mol MeO/COOH.

In this work our attention focused on the different thermodynamic interactions between polymer–solvent probe and polymer–polymer molecules in a pure polyester of PDEG–SA and its coordination complex formed in reactions with MgO. Also discussed are the Hildebrand solubility parameter for the pure and metal-ion-containing polyesters, preferential solvation and spatial distribution of toluene and tetrahydrofuran (THF) in the polymer, and the average degree of ionic cross-link density in the coordination polyesters.

Experimental

The synthesis and characterization of PDEG–SA and the preparation of the complex with MgO is described in ref. 21. The number-average molar mass of the polymer used in this study was 1060 g/mol, and the polymer contained statistically equal amounts of COOH and OH chain-terminal groups. DEG–SA with Mg^{2+} was obtained by mixing the polymer with MgO at a molar ratio of 0.8 MgO/COOH. The solvent probes used in IGC experiments were analytical grade purchased from Aldrich. All solvents were dried with molecular sieves.

The IGC apparatus was set up exactly as described by Price and Guillet (7). The chromatographic support was Chromosorb G with 60–80 mesh size, dimethyldichlorosilane-treated, acid-washed product from Chromatographic Specialties. Other details of the instrument and the experimental procedures are described in ref. 10.

Infinite dilution IGC

The values of the effective Flory–Huggins χ parameters for solvent probe–polymer interactions were determined from IGC experiments using eq. [45] from ref. 6*a* for 10 different solvent probes at 80°C. Then the expression on the left of eq. [1] was plotted as a function of the known solubility parameter δ_1 of the solvent probes used (22) (the so-called Guillet plot). This yielded a linear relationship with a slope of $2\delta_2/RT$, where δ_2 is the solubility parameter of the polymer sample, V_1 is the molar volume (which we use to approximate the partial molar volume) of the probe, and χ_s is the entropy contribution to χ:

$$[1] \qquad \frac{\delta_1^2}{RT} - \frac{\chi}{V_1} = \frac{2\delta_2}{RT}\delta_1 - \left(\frac{\delta_2^2}{RT} + \frac{\chi_s}{V_1}\right)$$

Cluster integrals from finite concentration IGC

In this section we briefly discuss the definition and physical interpretation of cluster integrals and their determination from FCIGC. A detailed description of this approach is the subject of another paper.[2]

The spatial distribution of solvent molecules in a polymer matrix or the distribution of polymer segments can be described by fluctuations in the corresponding values of the particle number densities. Local deviations from the mean particle number density values can be expressed by G_{ij} Kirkwood–Buff–Zimm (KBZ) integrals (23, 24). In the polymer–solvent system the particle number density of the species "j" ($j = 1$ for solvent, $j = 2$ for polymer segment) is defined by $\rho_j = N_j/V$ with N_j particles in the subsystem with a volume V. The value of the product $\rho_j G_{ij}$ describes the excess (or deficiency) in the average number of j molecules, surrounding a typical molecule of the sort "i" relative to the overall number density of j for the entire system. "Typical" in this context refers to average for i taken over the entire system. The tendency of particles of type j to gather around i-type particles (or particle affinity as it is often referred to), can be described by the value of G_{ij}. To normalize for molecular size effects, it is convenient to introduce the ratio $G_{ij}/\bar{V}_j$ where $\bar{V}_j$ is the partial molar volume of particles j (25, 26). The value of $G_{ij}/\bar{V}_j$ can also be used to characterize preferred spatial gathering of solvent or polymer segments around the specified "partner." At a given volume fraction of the species i, an increase of the value of $G_{ii}/\bar{V}_i$ corresponds to a greater tendency of the i species to form self-clusters. Preferential solvation of i around j can be given by $(G_{ij} - G_{jj})/\bar{V}_j$. A positive value of this expression means favored preferential solvation of j around i (24).

Different experimental techniques, including scattering experiments and thermodynamic measurements, allow us to determine cluster integrals. An excellent example for the thermodynamic approach is given by Ben-Naim (27) who used partial molar volumes, isothermal compressibilities, and partial vapor pressures to obtain $G_{ij}/\bar{V}_j$ values in the water–ethanol system. Scattering experiments were employed by Benoit et al., for example, to study concentration fluctuations in polymer solutions and polymer blends (28).

We used finite concentration IGC to obtain cluster integrals in polymer–solvent systems. Preliminary work has been reported (16, 17), while details of the approach will be described elsewhere.[2]

To obtain the values of the KBZ cluster integrals we first determined the value of the effective Flory–Huggins interaction parameter and its dependence on the volume fraction of the solvent v_1:

$$[2] \qquad \chi = \chi^{\infty} + \beta v_1$$

In eq. [2] we assume a linear dependence of χ on v_1.

In finite concentration IGC experiments, the concentration dependence of the χ parameter is determined by utilizing the elution-on-a-plateau technique. The net retention volume at different concentrations of the solvent probe must be mea-

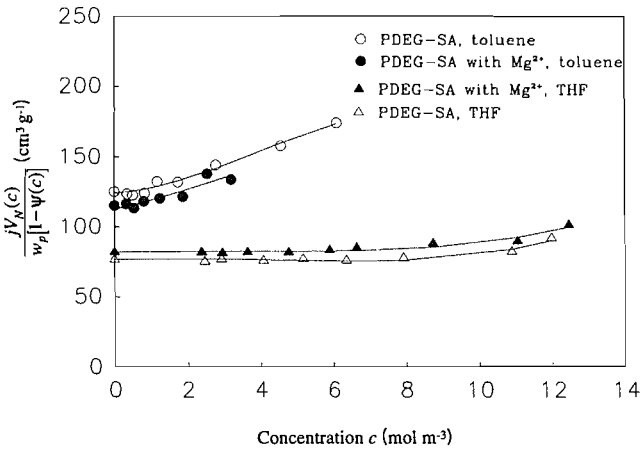
Fig. 1. Plot of $jV_N(c)/[w_p\{1-\psi(c)\}]$ vs. concentration of solvent probe in the mobile phase, c, for the pure polyester PDEG–SA and its metal-ion-containing derivative (see eq. [3] in the text). The data at c = 0 were obtained by infinite dilution IGC.



sured to obtain the volume fraction of the solvent v_1 in the polymer–solvent system.

The concentration of the solvent probe q (number of moles of solvent in 1 g of polymer) in the polymer can be expressed by using the Conder–Purnell treatment (9) with the following expression:

$$[3] \qquad q(c) = (1/w_p)\int_0^c jV_N(c')/[1-\psi(c')]dc'$$

where w_p is the mass of the polymer in the column, c is the concentration of the probe in the mobile phase, j is a correcting factor that accounts for the nonideality and compressibility of the gas phase (there is a pressure gradient along the column), and ψ is the corrected mole fraction of the solvent in the mobile phase (10*b*). Figure 1 shows the reduced retention volume (the function to be integrated in eq. [3]) measured for the polyester samples with and without Mg^{2+} as a function of the concentration of the solvent probes (toluene and THF). The weight fraction of the probe can be obtained from the q value determined from eq. [3]:

$$[4] \qquad w_1 = qM_1/(1+qM_1)$$

where M_1 is the molar mass of the solvent probe. The volume fraction of the probe can be obtained with the density values of the solvent and polymer if one assumes volume additivity during mixing:

$$[5] \qquad v_1 = \frac{w_1/\rho_s}{w_1/\rho_s + (1-w_1)/\rho_p}$$

In eq. [5] ρ_s and ρ_p are the mass density of the solvent and polymer, respectively. In other words, by using eq. [5] we assume that the values of the partial molar volumes in the polymer–solvent system are equal to the corresponding values of the molar volumes in the pure states.

For binary gaseous mixtures (e.g., for the mixture of the vapor of the solvent probe and the carrier gas) the fugacity of the components can be expressed by a virial series. We calculated the thermodynamic activity of the solvent a_1 from the fugacity of the probe f_1, which is controlled by the experiment. The concentration dependence of the χ parameter was then obtained from eq. [6]:

$$[6] \qquad \ln a_1 = \ln(1-v_2) + [1-(1/r)]v_2 + \chi v_2^2$$

where r is a parameter related to the ratio of the partial molar volumes of the polymer $\bar{V}_2$ vs. the solvent $\bar{V}_1$, $r = \bar{V}_2/\bar{V}_1$. For binary systems, the volume fraction of the polymer v_2 is related to the volume fraction of the solvent via $v_2 = 1 - v_1$. The cluster integral can then be obtained by the following equations using the abbreviation $S(0)$ defined as

$$[7] \qquad S(0) = [(1/v_1) + (1/rv_2) - (2\chi^{\infty} + 2\beta - 3v_2\beta)]^{-1}$$

$$[8] \qquad G_{11}/\bar{V}_1 = (1/v_1)[(S(0)/v_1) - 1]$$

$$[9] \qquad \frac{G_{21}-G_{11}}{\bar{V}_1} = \frac{1}{v_1}\left[1 - S(0)\left(\frac{1}{v_1}+\frac{1}{v_2}\right)\right]$$

In eq. [7] $S(0)$ is the scattering structure factor of the system at the limit of zero scattering angle and is related to the concentration–concentration fluctuation (25, 26).

Determination of cross-link density by finite concentration IGC

For cross-linked systems the thermodynamic activity a_1 can be written as

$$[10] \qquad \ln a_1 = \ln(1-v_2) + [1-(1/r)]v_2 + \chi v_2^2 + \rho_p \bar{V}_1 \gamma_e [v_2^{1/3} - (2v_2/\Lambda)]$$

In eq. [10] γ_e is the effective cross-link density and Λ is the functionality of the network (10). The effective cross-link density γ_e is defined as the number of moles of elastically effective cross-linked chains per gram of polymer sample (29).

A comparison of eqs. [6] and [10] shows that the difference between linear polymers and cross-linked systems is described by the fourth term on the right-hand side of eq. [10]. This term, introduced by Flory and Rehner (30), takes into account the change in the free energy due to elastic contributions of the deformed network swollen by the solvent probe. With the χ parameter obtained from FCIGC experiments, we estimated the effective cross-link density of the polar-ionic network of the metal-ion-containing coordination polyesters. Toluene was used as solvent probe in these experiments.

Results and discussion

To study the possible change in the cohesive energy density as a result of complex formation of Mg^{2+} ions with the polymer, infinite dilution IGC experiments were performed.

The Guillet plot of infinite dilution IGC data as described earlier was used to obtain the solubility parameter of the polyester PDEG–SA with and without the carboxylate complexes. The plots of $[(\delta_1^2/RT) - (\chi/V_1)]$ vs. δ_1 for 10 different solvents obtained at 80°C are shown in Fig. 2. The solvents used (listed in increasing order of their Hildebrand solubility parameter δ_1) were *n*-hexane, *n*-octane, cyclohexane, ethyl acetate, toluene, benzene, acetone, propanol, ethanol, and methanol. The value of δ_2 was 10.3 $(\text{cal cm}^{-3})^{1/2}$ within

Fig. 2. Guillet plot of the pure polyester PDEG–SA and its Mg^{2+}-containing derivative as a function of the solubility parameters of the solvents used in infinite dilution IGC.

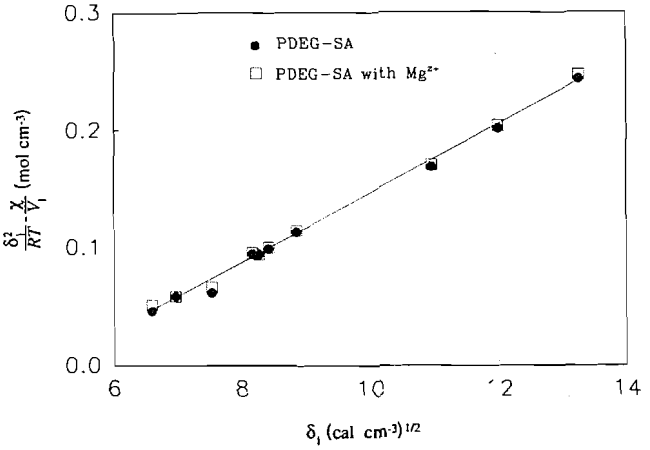

Fig. 3. The effective Flory–Huggins interaction parameter χ vs. the volume fraction of the solvent probes.

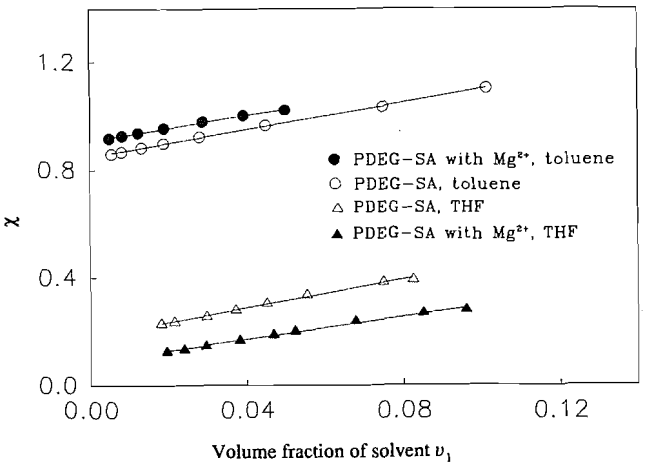

the experimental error of ca. ±0.5 (cal $cm^{-3})^{1/2}$ for both the pure PDEG–SA and the Mg^{2+}-ion-containing coordination polyester. Thus, for the ion concentration utilized in this work, no difference was obtained by infinite dilution IGC for the probe-averaged value of δ_2 between the pure and the Mg^{2+}-containing polymers. It is interesting to mention that pressure–volume–temperature (PVT) phase diagrams can also be used to obtain solubility parameter data (31). PVT experiments were performed on the polymers discussed in this study. Numerical fits of PVT data (32) yielded δ_2 = 15.0 (cal $cm^{-3})^{1/2}$ for the pure DEG–SA and δ_2 = 15.5 (cal $cm^{-3})^{1/2}$ for the metal-ion-containing polymer. This small increase in the solubility parameter, obtained in PVT experiments, only slightly exceeded the estimated error of PVT data, which was ca. ±0.2 (cal $cm^{-3})^{1/2}$. The deviation between IGC and PVT results, however, is far beyond the experimental error. One possible explanation for the unrealistically high δ_2 values obtained in PVT experiments is that the polyester decomposed during the pressurization (pressures up to 200 MPa and temperatures up to 100°C) in the PVT sample cell, which was filled with Hg. This might result in an increase of the absolute value of δ_2 (e.g., δ_2 for ethylene glycol is 14.6 (cal $cm^{-3})^{1/2}$ (33)).

Figure 3 shows the concentration dependence of the χ parameter for the pure polyester DEG–SA with toluene and with THF as well as for the metal-ion-containing polymer with the same two solvents. The corresponding IGC experiments were performed at 75°C. The value of χ is lower for DEG–SA with the polar THF than for the polymer with toluene. This is what one would expect as it is well known that THF is the better solvent for DEG–SA.

For the more polar solvent THF the value of χ becomes smaller if ions are introduced into the polymer. This trend is opposite for the polyester with the significantly less polar toluene, i.e., in this case the χ parameter increases when complexes are formed. Generally, an increase in the χ value corresponds to a poorer solvent–polymer affinity. For the ion-containing polyesters the ligands coordinated to the central metal ion of the complex include ~OH and ester carbonyl groups. These can be replaced by a ligand group with a higher donor strength, such as THF, which results in a strong interaction between the solvent probe and the sample and thus contributes to a decrease in the χ value of THF with the metal-ion-containing polymer.

The strength of coordinate bonds ($-\Delta H$) can be expressed by the "*E* and *C* equation," as follows:

$$[11] \qquad -\Delta H = E_A E_B + C_A C_B$$

where ΔH is the enthalpy of adduct formation, the subscript A refers to acid and B to base, *E* is an empirical parameter related to the tendency of the given species to form electrostatic bonding, and *C* describes the tendency to undergo covalent bonding (34). A quantitative comparison using Table 1 of ref. (34) shows that the expected $-\Delta H$ value of THF is higher than that of representative esters ($CH_3COOC_2H_5$), ketones ($(CH_3)_2CO$), or ethers ($(C_2H_5)_2O$). Thus, the polar solvent THF in the metal-ion-containing polyester will be bound to the central metal ion, while the apolar solvent will participate in the solvation of the apolar parts of the macromolecules and will be "repelled" from the ion-containing regions.

Let us assume that at high temperatures (e.g., 75°C) the association of the ligands having low donor strengths with the metal ions becomes weak. The role of Mg^{2+} would then be to connect only neighboring chains and thus it would increase the effective molar mass (i.e., there are not multifunctional cross-links present). If this metal-ion-containing polymer is cooled to, for example, 40°C, a network can form at the lower temperature with a functionality Λ in eq. [10] greater than 2 (e.g., Λ = 4). By using eq. [10] and calculating the activity difference, $\Delta \ln a_1$, for the two temperatures, the increase of the γ_e value upon cooling can be obtained from the following formula:

$$[12] \qquad \Delta \ln a_1 = \Delta \ln a_{1,L} + \rho_p(T_2)\bar{V}_1(T_2)\gamma_e[v_2^{1/3} - (2v_2/\Lambda)]$$

where $\Delta \ln a_{1,L}$ refers to the difference in the thermodynamic activity for the linear polymer going from T_2 = 75°C to T_2 = 40°C. This approximation yielded γ_e = 9.0 (±1.0) × 10^{-4} mol g^{-1} for the effective cross-link density of the ion-containing polymer with Λ = 4. By assuming that each metal ion acts as a junction point, the calculated γ_e value is 15.1 ×

Fig. 4. The value of the reduced self-cluster integral $G_{11}/\bar{V}_1$ of the solvents toluene and THF (see eq. [8] in the text) as a function of the volume fraction of the solvent probes.

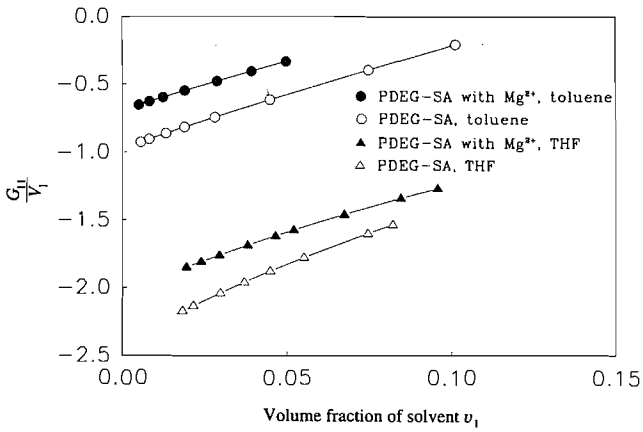

Fig. 5. The value of $(G_{21} - G_{11})/\bar{V}_1$ (preferential solvation, see eq. [9] in the text) as a function of the volume fraction of the solvent probes.

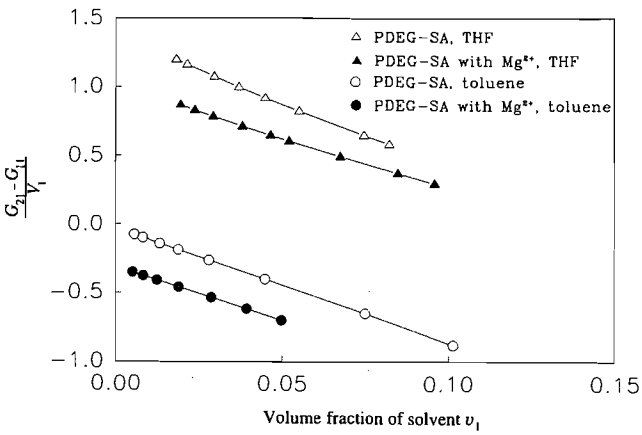

10^{-4} mol g^{-1} for $\Lambda = 4$. A comparison of the experimental and calculated γ_e values gives a strong indication for a nearly atomic dispersion of Mg^{2+} in the metal-ion-containing polymers, that is, it means that the existence of Mg^{2+} clusters with a large number of ions is unlikely in the polyester studied.

The values of the reduced cluster integrals $G_{11}/\bar{V}_1$ and $(G_{21} - G_{11})/\bar{V}_1$ were calculated as a function of the volume fraction of the solvent, as described earlier in the paper. Data obtained for solvent clusters $G_{11}/\bar{V}_1$ are shown in Fig. 4 while results for the combination of the cluster integrals $(G_{21} - G_{11})/\bar{V}_1$ are depicted in Fig. 5.

The value of the solvent self-cluster integral for both the pure polyester and the metal-ion-containing polyester $G_{11}/\bar{V}_1$ is greater for toluene than for THF. This corresponds to a higher self-affinity of toluene molecules to form self-clusters than is the case with THF, which is more homogeneously distributed in the polymer. The preferential solvation of the polymer by the solvent is characterized by $(G_{21} - G_{11})/\bar{V}_1$. As can be seen in Fig. 5, the value of this combination of cluster integrals is higher, and positive, for THF compared with the case for toluene. The positive $(G_{21} - G_{11})/\bar{V}_1$ value for the THF–polyester systems corresponds to stronger specific interaction between the solvent and the polymer than that between the solvent–solvent molecules. The negative $(G_{21} - G_{11})/\bar{V}_1$ values for the toluene-containing polyester systems along with the high $G_{11}/\bar{V}_1$ values correspond to preferential gathering of solvent molecules in the free volume available in the polymer. In the polymer samples probed with toluene, the negative $(G_{21} - G_{11})/\bar{V}_1$ values also indicate that a segregation of the macromolecules is present in the toluene–polyester systems. The value of $G_{11}/\bar{V}_1$ is higher for the ion-containing polyesters than for the neutral polymer for both solvent probes. This corresponds to an increased self-affinity of the solvent molecules to gather when metal ions are introduced. For the apolar toluene this gathering is likely to occur in the free volume (negative $(G_{21} - G_{11})/\bar{V}_1$ values, see Fig. 5). The gathering of THF is likely to take place close to the metal ions. (The corresponding $(G_{21} - G_{11})/\bar{V}_1$ values are positive.)

It is interesting to point out the relative change of the values of $G_{11}/\bar{V}_1$ and the Flory–Huggins χ parameter for the pure polyesters and the polyesters with metal ions. The results shown in Fig. 3 clearly indicate that the value of the χ parameter increases for the polyester–toluene systems when Mg^{2+}-containing complexes are present, while it decreases for the polyester with THF when the metal ions are introduced. On the other hand, $G_{11}/\bar{V}_1$ values show an increase for the metal-ion-containing polymer compared with the pure polyester for both toluene and THF. This trend might seem surprising at first glance. In fact, a detailed analysis of the $G_{11}/\bar{V}_1$ values shows that the differences in the slopes of the χ parameter values as a function of the solvent probe concentration are responsible for this effect. An increase in the χ parameter value at zero solvent concentration (χ^∞ in eq. [2]) with unchanged slope of the χ vs. concentration curve (the value of β in eq. [2]) makes the $G_{11}/\bar{V}_1$ values larger. An increase in the slope β, however, has the opposite effect, that is, it corresponds to a decrease in the value of $G_{11}/\bar{V}_1$ at an unchanged χ^∞ value. As can be seen in Fig. 3, the value of the slope of the χ vs. concentration plots for the pure polyester with THF is significantly higher than the slopes of the three other straight lines. This larger slope value is then the reason for the increase in the $G_{11}/\bar{V}_1$ values of the Mg^{2+}-ion-containing polyester system with THF as solvent probe in spite of the decrease of the corresponding χ^∞ values.

It can be shown (35) that the mean cluster size (MCS) of a solvent cluster is given by:

$$[13] \qquad \text{MCS} = (v_1 G_{11}/\bar{V}_1) + 1$$

The value of MCS (which describes the average number of molecules in a cluster) as a function of solvent probe concentration can be calculated from the concentration dependence of the χ parameter (eq. [2]) by a linear fit to the χ values determined from IGC (see Fig. 3). The χ^∞ and β values in eq. [2] can be used to calculate $G_{11}/\bar{V}_1$, which allows a direct determination of the MCS with the corresponding v_1 values.

Corresponding MCS curves for the polymer systems studied in this work are shown in Fig. 6. The value of the expected mean cluster size for a predominantly entropy-driven solution process with preferential solvent would result in MCS $\cong$ 1, showing that no significant gathering of solvent molecules takes place. Such behavior was observed for

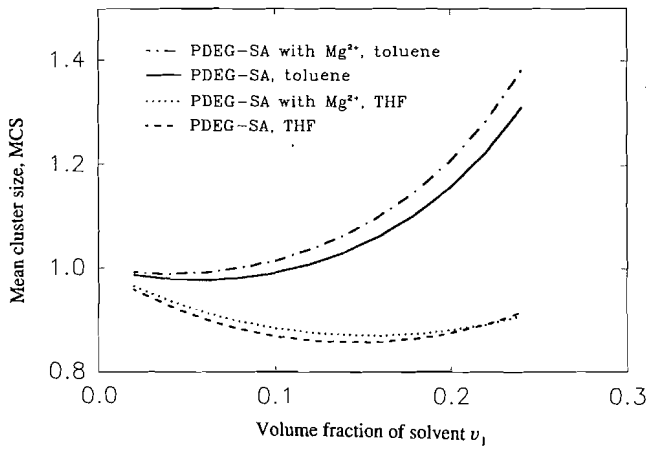
Fig. 6. The mean cluster size, MCS (see eq. [13] in the text), of the solvents toluene and THF, calculated from the concentration dependence of the effective Flory–Huggins interaction parameter χ as a function of the volume fraction of the solvent probes.



the THF–polyester systems, while the toluene–polyester mixtures showed a significant increase of MCS of solvents with increasing toluene concentration (see Fig. 6). This is a result of the congregation of the absorbed solvent molecules in the free volume of the polymer matrix. For such systems, with increasing values of the Flory–Huggins χ parameter, the mean solvent cluster size progressively increases and can tend to infinity if phase separation occurs.

In conclusion, inverse gas chromatography, utilizing the technique of elution-on-a-plateau, was used to study solvent clustering and partition in polyesters of poly(diethylene glycol-*co*-succinic acid) and their complexes with metal ions. IGC allowed us to obtain specific and detailed information concerning spatial distribution of solvents and the thermodynamics of the polyesters and their coordination polymers with Mg^{2+} using a good and a less good solvent.

Acknowledgements

The authors would like to thank Professor J.E. Guillet for directing their interest to inverse gas chromatography studies of polymers. Grateful thanks are due to Ms. Susan Arbuckle for her help with the write-up of this paper. The work was financially supported by the Natural Sciences and Engineering Research Council of Canada, and by the Ontario Centre for Materials Research. G.J.V. would like to take this opportunity to express his sincere appreciation to Professor James Guillet for all of the enlightening discussions, stimulating joint work in many areas of polymer science, collegiality, and last but not least friendship, which made working as a member of the faculty of the Chemistry Department in Toronto a great pleasure. I will miss you, Jim, in my new job! Thank you.

Abstract: The effect of individual transformation products of 2,6-di-*tert*-butyl-4–methylphenol (**1**, BHT), namely, 2,6-di-*tert*-butyl-4-hydroxy-2,5-cyclohexadienone (**3**), 2,6-di-*tert*-butyl-1,4-benzoquinone (**4**), and 3,5,3′,5′-tetra-*tert*-butylstilbenequinone (**5**), in the course of thermal- and photo-degradation of LDPE has been examined. Oxidative DSC studies combined with oxygen uptake measurements, IR spectroscopy data, and embrittlement tests proved to be sufficiently sensitive to detect differences in the stability of the above-mentioned samples. A comparative study revealed a pronounced stabilizing effect of **5** in LDPE thermooxidation at moderate temperatures (90–100°C). The stabilizing action of BHT is due in part at least to its coloured transformation product.

Key words: LDPE, thermooxidation, photooxidation, transformation products of phenolic antioxidants.

Résumé : On a étudié l'effet des produits individuels de transformation du 2,6-di-*tert*-butyl-4-méthylphénol (**1**, BHT), soit les 2,6-di-*tert*-butyl-4-hydroxycyclohexa-2,5-diénone (**3**), 2,6-di-*tert*-butyl-1,4-benzoquinone (**4**) et 3,5,3′,5′-tétra-*tert*-butylstilbènequinone (**5**), sur le cours des dégradations thermiques et photochimiques du LDPE. Des études oxydantes de DSC combinés à des mesures d'absorption d'oxygène, à des données de spectroscopie et à des tests de fragilisation se sont avérées suffisamment sensibles pour détecter des différences de stabilité dans les échantillons mentionnés plus haut. Une étude comparative a permis de mettre en évidence un effet stabilisant important du produit **5** sur la thermooxydation du LDPE à des témperatures modérées (90 à 100°C). L'action stabilisante du BHT est due en partie à son produit de transformation coloré.

Mots clés : LDPE, thermooxydation, photooxydation, produits de transformation d'antioxydants phénoliques.

Introduction

The use of sterically hindered phenols such as 2,6-di-*tert*-butyl-6-methylphenol (BHT, **1**) and octadecyl-3-(3′,5′-di-*tert*-butyl-4′-hydroxyphenyl)propionate (Irganox 1076, **2**) to protect polymers against oxidative degradation is well established. Under atmospheric conditions, they are known to interfere with the chain-propagating step of the polymer oxidation mechanism (postulated originally for hydrocarbons by Bolland and Gee (1, 2)) as they react with the chain-carrying $R^{\bullet}$, $RO^{\bullet}$, and $RO_2^{\bullet}$ radicals; for example,

$$ArOH + RO_2^{\bullet} \rightarrow ArO^{\bullet} + RO_2H$$

Received June 6, 1995.

This paper is dedicated to Professor J.E. (Jim) Guillet in recognition of his contributions to Canadian chemistry.

The resulting, relatively stable radicals $ArO^{\bullet}$ either mesomerize and dimerize, disproportionate, or scavenge other peroxy radicals to form numerous nonradical transformation products (3, 4).

The antioxidant BHT has been used for many years to stabilize polyolefins and polystyrenes during processing, but because of its high volatility is not suitable for long-term ageing stability. However, BHT and its mechanism of activity have been studied extensively (5, 6) as a model for other phenolic stabilizers. Various BHT transformation products resulting from phenoxyl radical decay have been isolated and identified; these are typically unsaturated systems such as the cyclohexadienone (**3**), the benzoquinone (**4**), and stilbenequinone (**5**) (Scheme 1). The last compound is highly coloured ($\varepsilon = 1.1 \times 10^5\ M^{-1}\ cm^{-1}$ at $\lambda = 452$ nm) due to the large number of conjugated double bonds, and is mostly responsible for the yellowing of polymers stabilized with BHT.

Several antioxidant transformation products are reported to have some stabilizing properties. Henman (7) showed that di-*tert*-butylbenzoquinone (**4**) and tetra-*tert*-butylstilbenequinone (**5**) were more effective melt stabilizers for polypropylene than BHT itself, and both compounds were found to retard the oxidation of tetralin and polypropylene (8, 9). A stabilizing effect of both compounds was also found in the thermooxidation and photooxidation of high-impact polystyrene (10). On the other hand Klemchuk and Horng (11) reported that **4** and **5** retained no stabilizing activity in polypropylene oven-aged at 150°C.

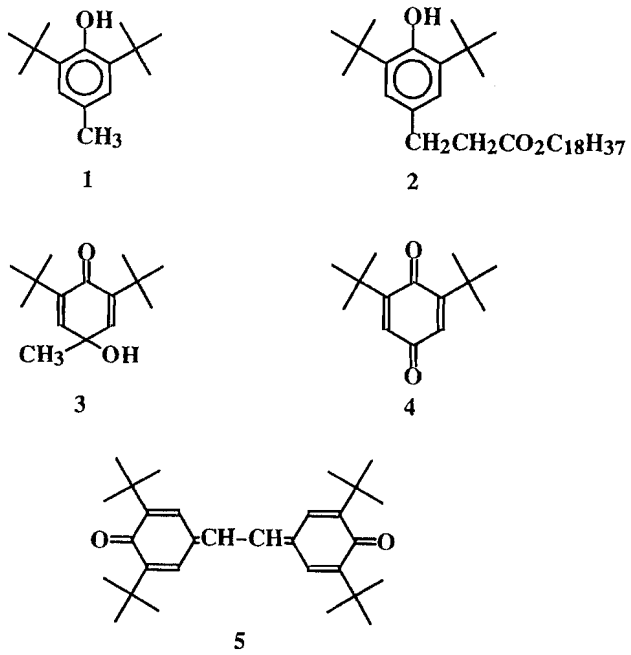
Scheme 1. Structures of phenolic antioxidants and transformation products.



Since relatively little is known about the chemical reactivity and antioxidant mechanism of these compounds, a study was undertaken in which several of the known transformation products of BHT were investigated on their own. To this end, two main approaches were followed: (i) steady-state ageing experiments involving samples of polyethylene doped with the pure transformation products, to determine if stabilization occurs and under what conditions; and (ii) time-resolved experiments using electron pulse radiolysis and laser flash photolysis, to study the elementary reactions of the pure compounds both in nonpolar liquids (as a model for polymers) and in molten polyethylene.

A preliminary report about time-resolved experiments made with the stilbenequinone compound has been given by Brede et al. (12). In the present paper, the results from steady-state ageing experiments are presented.

Results and discussion

Environmental degradation limits the lifetime of articles made from polyolefins. These lifetimes are generally too long to be determined in tests performed under environmental (mild) conditions. As a result, most investigations into the degradation of polyolefins are done under accelerated conditions. Since the degradation mechanism highly depends on the experimental conditions and test methods used, a combination of methods was applied in our degradation study of LDPE containing the additives depicted in Scheme 1.

Thermooxidation

The results of oxygen absorption measurements of doped LDPE samples at a temperature of 180°C are shown in Fig. 1 and Table 1. All samples containing the transformation products **3–5** were comparable to the blank LDPE without additives or rather showed a slight pro-oxidative effect. They retained none of the stabilizing activity of the hindered phenol. Similar results were reported by Klemchuk and Horng (11) for polypropylene oxidation in the presence of stilbene-quinone at 150°C.

Table 1. Oxidation of doped LDPE: the induction periods (IP) from the oxygen absorption measurements in the melt at 180°C; embrittlement times ET_T and ET_P, i.e., ageing up to failure on manual bending of strips at 100°C for the thermooxidation and 40°C for the photooxidation (λ_{max} = 350 nm), respectively. Melting points of virgin LDPE strips (Tm_V) and strips embrittled at 100°C (Tm_E), measured by DSC under N_2 (heating rate 10°C/min)

Additive	IP (min)	ET_T (days)	ET_P (days)	Tm_V (°C)	Tm_E (°C)

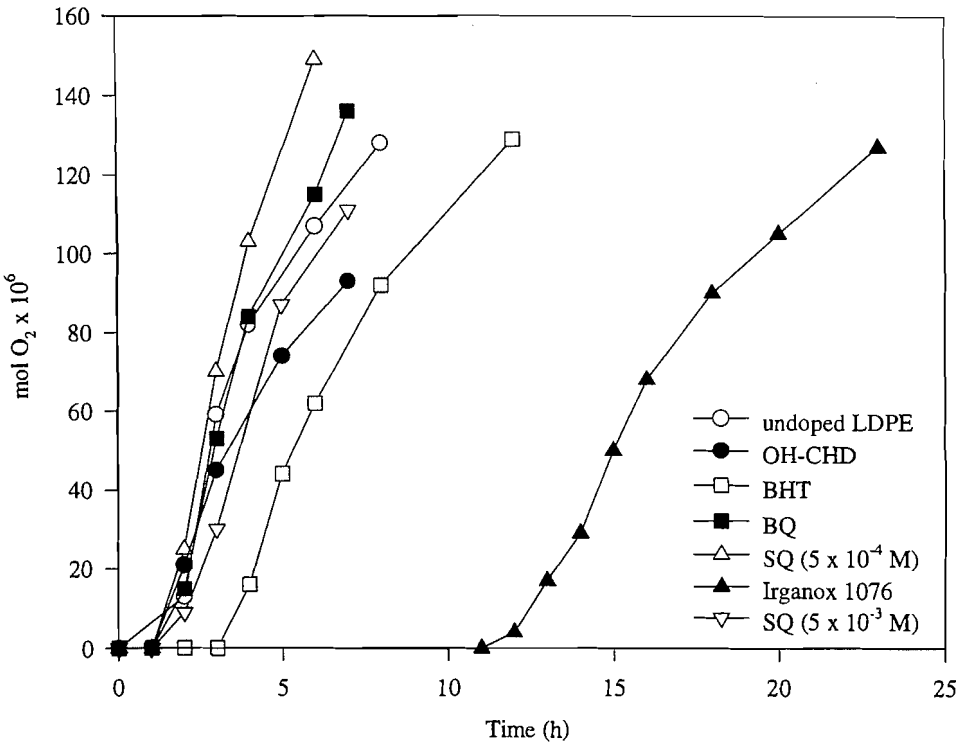
[b]Concentration 5×10^{-3} M.

Even BHT, one of the strongest processing stabilizers, under these experimental conditions (polymer melt at 180°C, pure O_2 atmosphere) represents a relatively weak antioxidant. On the other hand, the oxygen uptake in the presence of Irganox 1076, which is used industrially and was placed in our study as a reference compound, showed a distinct induction period (IP).

In the oxygen uptake method, which is the most direct way to study polymer oxidation, the assumption is implicitly made that the drop of the pressure in a closed system corresponds quantitatively to the consumption of oxygen. The possible formation of gaseous degradation products or volatilization of additives at high temperatures might, however, influence the pressure drop and cause an error in the calculated oxygen uptake value. It is also generally accepted that an ageing test done at temperatures above the melting point of the polymer does not correspond to what is happening in the solid state (13) and has only limited predictive value for the lifetime of an article or for the ranking of stabilizers at service temperatures.

The thermooxidative stability of LDPE films was tested in an air oven at 90°C. The chemical changes accompanying polymer degradation were monitored by means of IR spectroscopy. The course of carbonyl group formation (characterized as the carbonyl index $CI = A_{1720}/A_{720}$) during oven ageing of the doped LDPE films is shown in Fig. 2. In this study, the raw carbonyl index is used as a measure of the extent of degradation and no explicit information is given concerning the composition (i.e., the relative amount of ketones, acids, esters, etc.) contributing to the broad IR absorption band of carbonyls in LDPE-oxidized samples. For detailed information on chemical changes occurring in PE degradation see refs. (14–16). Although such a simple procedure neglects the complex structure of the carbonyl region it nevertheless gives compar-

Fig. 1. Oxygen uptake in the high-temperature oxidation of LDPE doped with compounds **1–5** (OH-CHD = **3**, BQ = **4**, SQ = **5**); sample size 40 mg. For the number codes of the additives see the Experimental.



ative information about the effect of individual additives **1–5** on the course of LDPE degradation.

The results in Fig. 2 indicate an almost identical pattern of changes in both the pure LDPE and LDPE doped with BHT (IP = 7 days); the hydroxycyclohexadienone **3** shows in this group of samples a slightly pro-oxidative effect. The low stabilizing activity of BHT is explained by its high volatility and, consequently, its physical loss from the oven-aged polymer at 90°C. The compatibility of additives with LDPE is generally poorer than for other polyolefins (4). The presence of the benzoquinone (**4**) on the other hand retards the carbonyl formation in LDPE for up to 65 days, while the stilbene-quinone (**5**) completely inhibits chemical changes in LDPE. It is evident that the observed concentration-dependent antioxidant activity of **5** compares well with that of the most effective stabilizer, the commercial Irganox 1076. In the case of **5** the H-donor antioxidant mechanism, characteristic for phenols, is hardly applicable. The oxidation chain-carrying ROO• radicals can possibly add to the system of conjugated double bonds in the stilbene-quinone, in analogy with the scheme proposed by Boozer and Hammond (17) for other conjugated systems.

The chain-breaking acceptor mechanism, in which the chain-carrying radical adds to the inhibitor, is often envisaged for the transformation products of phenols that have a structure of conjugated dienones (i.e., quinone methides, stilbene-quinones, and benzoquinones). The radicals involved in this reaction type are alkyl radicals, which are not particularly effective in hydrogen abstraction from the inhibitor. In the presence of a sufficient amount of oxygen, as in our experiments, these reactions are not very important because the alkyl radicals are transformed very rapidly into peroxy radicals. Only under conditions of oxygen starvation, for example in an extruder, their importance increases and they may even become dominant (4).

Photooxidation

The increase in carbonyl index (CI) was also taken as an indication of the extent of photooxidative degradation in LDPE films. Figure 3 shows the results for doped films after exposure to a light source having its peak emission at 350 nm. In practically all the samples here a gradual and equal increase of CI from the beginning of and throughout the exposure is seen. Only in the case of the stilbene-quinone (**5**) at a higher concentration (5×10^{-3} M) a certain protection (even a slight IP) in the early stages of LDPE photooxidation was observed. Presumably, this effect can be attributed to the filter effect of the highly coloured compound **5** and its subsequent chemical conversion to colorless species, since a bleaching of the sample was observed. Similar behaviour has already been reported for the photooxidation of HIPS (10) containing **5**. Generally, highly conjugated discoloring antioxidant transformation products, and the stilbene-quinone in particular, are very sensitive to UV light and undergo reduction in color during exposure to UV radiation (11), but the reactions involved are not yet known.

In contrast to the thermooxidation results (Fig. 2), none of the antioxidants and BHT transformation products **3–5** acts as effective photostabilizer or as photooinitiator.

While IR measurements provide evidence for the nature and extent of chemical changes occurring during photo- or thermooxidation of LDPE films, they do not provide direct evidence concerning the accompanying changes in the mechanical and thermal properties of the polymer.

Embrittlement tests

The effect of additives **1–5** on changes in the mechanical characteristics of oxidized LDPE was examined. Table 1 depicts the results of the completed embrittlement tests: times to embrittlement (on manual bending at a bending angle 90°) for thermooxidized (ET_T) or photooxidized (ET_P) polymer strips were evaluated. The results in both cases correlate well with the results from the IR measurements. The additives used had no effect on photooxidative changes in LDPE as all UV-irradiated samples failed in the same time interval (after 160 days); the only exception, as before, was the sample with stilbene-quinone (5×10^{-3} M) (Table 1).

In contrast to the photooxidation results, embrittlement times (ET_T) for thermooxidized LDPE strips differ significantly due to the nature of the additives present (Table 1); the pronounced stabilizing ability of **5** and **2**, as in the oven-ageing experiments, was confirmed. However, BHT showed a much better performance than before. The influence of sample thickness seems to be operative as a possible explanation for the difference in stabilizing behaviour of BHT. Even at lower temperatures the physical loss of BHT from LDPE film samples is reported to be very high (4). Additional pressing in the case of preparing 0.1 mm thick films for the oven-ageing study (as compared to strips for embrittlement tests) has certainly also contributed to the volatilization of BHT and thus to its apparent very low antioxidative activity in the oven-aged sample.

This statement is also supported by the results from DSC measurements in air (Table 2). When comparing the additive stabilities of the virgin LDPE strips and films, a certain decrease in the onset temperature of oxidation (T_0) is evident for all additives, but for BHT the effect is greatest. Thus for the efficiency evaluation rating of individual additives the results from the embrittlement test give a more realistic picture.

The temperature T_0 at which the oxidation exotherm first deviates from the baseline has frequently been employed to evaluate the stability of various polymers and to quantify the performance of antioxidants (18–21).

Reviewing the results in Table 2, all virgin additive-containing samples exhibit higher T_0 than pure LDPE and thus display a certain stabilizing or inhibiting effect on polymer autoxidation. This effect is, however, rather small for **3** and **4**; BHT and stilbene-quinone show a more pronounced and comparable influence on T_0, while **2** is again by far the most effective additive. The results in Table 3 reveal clearly a temperature dependence of the inhibiting efficiency of **5**.

In most cases the T_0 values for the doped LDPE samples embrittled in the 100°C thermooxidation approach the T_0 value of the undoped polymer. A shift in the opposite direction was, however, observed for stilbene-quinone (at 5×10^{-3} M) and

Irganox 1076 (Table 2); they both exhibit T_o values even higher than in the respective virgin samples. This finding would suggest that another mechanism than the purely oxidative one can also contribute to the mechanical failure (embrittlement) of the sample. The increased melting points (T_m) of the embrittled samples (Table 1) can serve as an indication for morphology changes taking place during the degradation of LDPE.

Summarizing the results for the influence of individual additives **1**–**5** on the oxidative degradation of LDPE, some points should be mentioned:

Different test methods require different preparation conditions (i.e., films, strips, etc.) and the thermal history may, as in the case of BHT in our study, influence the sample oxidative stability by lowering the additive content in relation to its volatility. Then, conclusions based on the results of single test method could prove to be erroneous.

Since stilbene-quinone itself is a thermally stable compound (mp 312°C), its low stabilizing activity at high temperature must be ascribed to other effects than to its thermal decomposition. The change of the degradation mechanism due to the increase of the temperature well above the LDPE melt-

ing temperature might be one of the reasons for the observed inactivity of **5**. Similarly, hindered amine stabilizers were reported to be effective in polyolefins at temperatures below 100°C while they lost the activity at higher temperatures (around 150°C) (22).

As well as the suggested temperature dependence of the LDPE degradation mechanism, a relative drop of the additive concentration is also to be taken into account when the melting temperature of the semicrystalline polymer is reached. The additive is then homogeneously distributed in the entire melt at a relatively lower concentration than in the solid polymer where the additive is restricted to only the amorphous phase. Thus, the lower concentration may not be sufficient to inhibit the high-temperature degradation processes of the LDPE melt. This hypothesis is further supported by the results in Tables 2 and 3, which clearly reveal a strong concentration dependence of the inhibiting efficiency of **5**.

Of the transformation products studied, stilbene-quinone shows an undisputable stabilizing effect in the thermooxidation of LDPE at moderate temperatures, while at high temperatures and in irradiated samples it is practically inactive.

From the DSC measurements under nitrogen, changes in the phase behaviour taking place during the degradation of the doped LDPE samples are indicated. A detailed study of this phenomenon is under way and will be discussed in detail later on.

Experimental

Materials

The following stabilizers and their transformation products were used: 2,6-di-*tert*-butyl-4-methylphenol (**1**, mp 67°C); octadecyl-3-(3′,5′-di-*tert*-butyl-4′-hydroxyphenyl)propionate (**2**, Irganox 1076, Ciba-Geigy AG, mp 49–50°C); 2,6–di- *tert*-butyl-4-methyl-4-hydroxy-2,5–cyclohexadiene-1-one (**3**, mp 111–112°C) (23); 2,6-di-*tert*-butyl-1,4-benzoquinone (**4**, Fluka AG, mp 63,5°C); 3,5,3′,5′-tetra-*tert*-butyl-stilbene-4,4′-quinone (**5**, mp 312°C) (24).

The additives were melt-blended at 150°C with an unstabilized LDPE (Leuna, AL 21FA, density 0.919, MI 436 K/5 kp = 0.32/10 min). The concentration was 10^{-2} M (mol/kg of polymer) for each additive except **5**, for which 5×10^{-4} and 5×10^{-3} M were used.

Plates 3 mm thick were then compression moulded at 170°C. From these plates strips for the embrittlement tests and films for IR measurements were cut and pressed, respectively.

Methods and measurements

Oxygen uptake experiments were conducted with 40 mg LDPE samples in closed glass vessels under pure oxygen at atmospheric pressure. The oxygen uptake was monitored with a mercury pressure device (25), while the temperature was kept at 180 ± 1°C using an oil block. The induction period (IP) was determined graphically on the plot of oxygen consumption versus time (25).

Polymer films (ca. 0.1 mm thick) were mounted in slide holders and either oven-aged in air at 90°C or photooxidized at 40°C using an Osram L 20 W/73 fluorescent tube with a wavelength range 315–405 nm (λ_{max} = 350 nm) and constant light intensity.

Polymer strips (50 × 3 × 1.7 mm) in glass tubes were placed in a thermostated block and thermooxidized at 100 ± 0.5°C, or directly mounted in the holders of the photooxidation box. The embrittlement tests were performed at room temperature by pulling the strips out of the tube up to one third of their length, and manually bending at a 90° angle over the tube's edge. For these strips (five of each sample) the times to embrittlement were found to have good reproducibility. A similar procedure was also reported by Gugumus (4).

The effect of exposure time on the development of functional groups in the thermo- and photooxidized films was determined by IR spectroscopy on a Perkin Elmer 577 spectrophotometer. An increase of the carbonyl concentration was evaluated as the ratio of the carbonyl group absorbance (A_{1720}) to that of the standard band absorbance (A_{720}), and is defined as the carbonyl index CI (A_{1720}/A_{720}).

The melting and crystallization behavior of LDPE samples was analyzed by differential scanning calorimetry with a Perkin Elmer DSC 7, calibrated with indium prior to use. The thermal transitions in N_2 (30mL/min) were recorded at a heating rate of 10°C/min. DSC in air was used to study the effect of BHT transformation products on the oxidative stability of LDPE. Both the isothermal and the dynamic mode (heating rate 3°C/min) were used to determine the performance of these compounds. A constant flow of air 50 mL/min was kept during the measurements. In the dynamic experiments the temperature T_o for the start of an exothermal reaction is determined, and is referred to as the onset oxidation temperature. The average of two determinations was taken as T_o for the sample. From isothermal DSC runs, performed at 180, 170, and 160°C, the oxidation induction time (OIT) for the onset of the oxidation exotherm was noted.

Conformational dependence of electronic spectra and zero-field splitting parameters in 2-naphthylphenylcarbene

Olivier Parisel, Gaston Berthier, and Eva Migirdicyan

Abstract: Quantum mechanical calculations using ab initio and semi-empirical methods have been carried out for elucidating the electronic structure and geometry of 2-naphthylphenylcarbene conformers. The *Z/cis* conformer has the lowest ground state triplet energy, the lowest triplet–triplet (T_0–T_1) transition energy, as well as the largest zero-field splitting parameter *D*. A clear-cut relationship between the *D* value and the geometry is pointed out.

Key words: carbenes, conformational isomerism, triplet–triplet transitions, CS-INDO/CI calculations, ZFS *D* parameters.

Résumé : Dans le but d'étudier la structure électronique et la géométrie du 2-naphtylphényle carbène, des calculs de chimie quantique (ab initio et semi-empiriques) ont été réalisés sur différents conformères de ce carbène. Le calcul montre que c'est le conformère *Z/cis* qui présente l'énergie minimale dans son état triplet fondamental, l'énergie de transition triplet–triplet (T_0–T_1) la plus faible ainsi que la valeur la plus élevée du paramètre *D* de séparation des sous-niveaux triplets en champ nul. Une relation simple reliant *D* et la géométrie est mise en évidence.

Mots clés : carbènes, isomérie conformationnelle, transitions triplet–triplet, calculs CS-INDO/CI, paramètres *D* de ZFS.

Introduction

The geometry of carbenes has long been a source of concern for spectroscopists as well as for quantum chemists. For many years, the structure of methylene (CH_2) in its triplet ground state was a matter of debate (1). While Foster and Boys (2) predicted a bent equilibrium geometry, Herzberg (3) concluded that the molecule was linear on the basis of his pioneering studies of the electronic spectrum of CH_2. This spectrum was subsequently reinterpreted by Herzberg and Johns (4) in terms of a bent structure of the methylene molecule. The EPR experiments of Wasserman, Yager, and Kuck (5) established that the structure of CH_2 in a Xe matrix at 4.2 K is bent with a bond angle of 136°. Finally, Bunker et al. (6) found that, in the gas phase, the equilibrium bond angle of CH_2 is 134.037° ± 0.045°. This value determined from the IR laser magnetic resonance spectra is in excellent agreement with the ab initio prediction of McLaughlin, Bender, and Schaefer (1, 7) of 134° ± 2° for the equilibrium bond angle of CH_2.

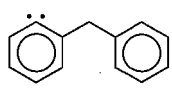
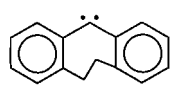
Diphenylcarbene (DPC), like methylene, has a bent triplet ground state that can be either planar or nonplanar according to the mutual orientation of the two phenyl rings. In previous reports (8, 9), it was shown that two distinct fluorescence spectra are emitted from DPC in an *n*-hexane Shpolskii matrix over the temperature range between 4.2 and 77 K: a sharp fluorescence with an origin band at 502.8 nm and a broad blue-shifted fluorescence with λ_{max} = 482 nm. The two fluorescence spectra were attributed to two different conformations of DPC trapped in this Shpolskii matrix. The low-energy sharp fluorescence was attributed to a DPC molecule with a geometry similar to that of dibenzocycloheptadienylidene (DBC), the carbene with the ethano bridge, since DPC and DBC both have their fluorescence origins at 502.8 nm. In this geometry,



DPC



DBC

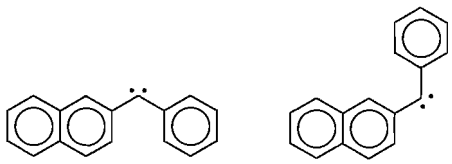
the two aromatic rings of DPC are not too far from being coplanar. The broad blue-shifted fluorescence was attributed to a nonplanar DPC conformer in which the carbenic bond angle is 140° and the dihedral angles between each benzene ring and the average plane are close to 30°. This geometry corresponds to that determined by Anderson and Kohler (10), who used the ENDOR technique for DPC in benzophenone. This implies that DPC has nearly the same geometry in *n*-hexane and in benzophenone, which is consistent with the fact

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

that the broad fluorescence with λ_{max} = 482 nm observed in *n*-hexane is very similar to the broad structureless phonon band with λ_{max} = 476 nm observed in benzophenone (11).

A detailed CS-INDO/CI investigation was performed for three different geometries of DPC including both the above-mentioned structures (9). This theoretical approach is based on a carefully designed multireference perturbation and uses a semi-empirical valence-Hamiltonian specifically developed and parametrized for conformational and spectroscopic problems.

The aim of the present work is to extend the CS-INDO/Cl predictions to the conformers of a larger carbene, the 2-naphthylphenylcarbene (2-NPC). EPR experiments (12) performed with 2-NPC in a 2-methyltetrahydrofuran matrix at 77 K indicate that this carbene has a triplet ground state T_0 like methyl-



E/trans 2-NPC *Z/cis* 2-NPC

ene and DPC. In addition, 2-NPC in this glassy matrix at 77 K can exist in two different conformations, *syn* and *anti*, which have different zero-field splitting (ZFS) parameters in the T_0 ground state. Such a conformational isomerism was first observed in EPR experiments for 1- and 2-naphthylcarbenes (13) and the measured *D* values were assigned to specific conformers on the basis of calculations involving the relationship established between the ZFS parameters *D* and π spin densities in the frame of the point-spin model (14, 15).

The fluorescence spectra of 2-NPC in *n*-hexane and *n*-heptane Shpolskii matrices at 4.2 K are composed of several quasi line spectra with origins shifted by 30–300 cm^{-1} from each other (16). Furthermore, the fluorescence and EPR spectra reveal that there is a light-induced transformation of the conformer emitting at 600.5 nm into the one emitting at 589.5 nm in the *n*-heptane matrix. Based on preliminary estimates of the ZFS parameter *D* (12), these spectra have been attributed to the planar *E/trans* (*syn*) and *Z/cis* (*anti*) conformers of 2-NPC, each one being trapped in several different sites of the matrix (16). To check these interpretations on a theoretical basis, the transition energies and the ZFS parameters *D* of 2-NPC in several geometries have been calculated.

Computational techniques

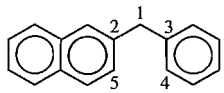
To determine the low-energy triplet and singlet states of the *E/trans* and *Z/cis* conformers of 2-NPC, we performed CS-INDO (Conformational Spectra – Intermediate Neglect of Differential Overlap) quantum mechanical calculations similar to those we successfully applied to DPC. As proven by a large number of applications in the field of photochemistry (17), this method is especially convenient for dealing with problems of conformations of conjugated molecules in their ground states as well as in their excited states. The CI treatment itself is performed using the CIPSI (Configuration Interaction by Perturbative Selected Iterations) procedure, which is a multireference second-order perturbation method involving a variational subspace *S* constructed in an iterative way (18); the selection threshold of the configurations included in subspace *S* according to their first-order contributions in the total wave functions of the different states is about $\eta \approx 0.08$. The starting molecular orbitals were obtained through an open-shell self-consistent field (SCF) treatment of the triplet ground state of DPC, performed using the restricted Hartree–Fock procedure proposed by Nesbet (19).

The parameters required by CS-INDO were taken from our earlier studies on conjugated molecules involving similar (second-order perturbation) CI treatments (20) and were used without any special adjustment for carbenic systems. They are the screening factors $k_{\sigma\sigma}$ (= 1.0), $k\sigma\pi$ (= 0.75), $k_{\pi\pi}$ (= 0.6) determining the values of the resonance integrals in a hybridized valence basis set; in addition, there are *n*-type screening parameters (for the selection criterion of these parameters, see ref. 21) for the electrons originating from the carbenic atom C1, for which we took an sp^3-type hybridization similar to an oxygen atom in a C-O-C group (i.e., $k_{n\sigma} = 0.8$, $k_{nn} = 0.74$, $k_{n\pi} = 0.68$). Note that, in this representation, the atomic functions describing the two unpaired electrons on C1 are the minus (π type) and plus (σ type) combinations of the two sp^3-type orbitals pointing in the plane orthogonal to the C2C1C3 plane; the conventional description in terms of *n* and π_0 orbitals can be restored by simply going back from the hybridized orbital basis to the (s, p_x, p_y, p_z) primitive basis set. The one-center integrals γ_{AA} were given the standard values γ_{HH} = 12.85 eV and γ_{CC} = 10.93 eV, and the two-center integrals γ_{AB} were computed by the Ohno–Klopman formula, a very suitable recipe for CI treatments including polyexcited configurations (22). It has been shown, in particular, that combining polyexcited CI treatments with Ohno–Klopman Coulomb integrals provides good predictions of the triplet state energies (22, 23). All the computations were carried out with our CS-INDO-CIPSI program running on an IBM RISC-SYSTEM/6000 workstation.

As geometry input data, we used idealized bond lengths and bond angles R_{CC} = 1.4 Å, R_{CH} = 1.1 Å, and CCC = HCC = 120°, except for the angle parameters involving the carbenic atom.

(*i*) In a first treatment, planar conformations were assumed for both the *E/trans* and *Z/cis* conformers with an apex angle α equal to 150° taken from the EPR experiments on DPC (24).

(*ii*) A second series of calculations was carried out using partially optimized geometries derived from ab initio ROHF/3-21G treatments. The nonfrozen parameters were the apex angle α and both the dihedral angles Φ_1 (out-of-plane torsion centered on the carbenic atom for the phenyl group) and Φ_2 (rotation angle of the phenyl around the C1C3 bond).



α = (2 1 3)
Φ_1 = (3 1 2 5)
Φ_2 = (4 3 1 2)

(*iii*) Five different geometries were determined for the following fixed values of Φ_1: 0°, 45°, 90°, 135°, and 180°, while allowing α and Φ_2 to vary during the optimization procedure.

(*iv*) A final optimization was performed with α, Φ_1, and Φ_2 varying simultaneously.

The optimized geometries obtained as described above were then used to compute the corresponding vertical transition energies.

The *D* values were determined by the method described in ref. 9 but using integrals $D_{\sigma\pi}^{CC}$ adjusted on the experimental *D* parameter of the DPC molecule (D_{exp} = 0.4050 cm^{-1} (25) and *d* = 0.965 Å). In the present calculations, all the one- and two-center terms have been taken into account.

Results and discussion

1. Ground state energetics

The optimized geometries have been collected in Table 1 together with their corresponding energy: the departure from planarity results in the decrease of the apex angle α from about 150° in planar forms to about 135° in the nonplanar ones. The conformers corresponding to the lowest energies are obtained for Φ_1 = 30.77° or Φ_1 = 153.17°, which gives an overall molecular structure more or less similar to that determined by ENDOR experiments in the case of DPC (10). Between these two conformers, the pseudo-*Z/cis* (Φ_1 = 153.17°) conformer lies 63 cm^{-1} below the pseudo-*E/trans* one (Φ_1 = 30.77°) when using the ROHF/3-21G level of calculation.

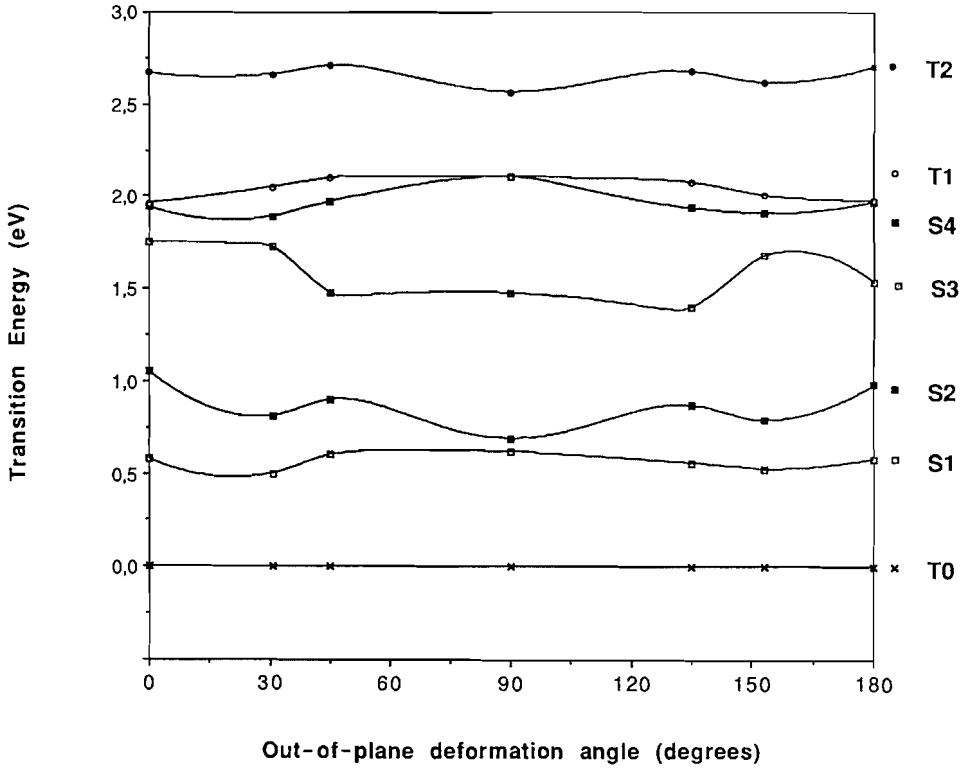
The energy barriers for the conversion of these forms into each other are 395 cm^{-1} (pseudo *E/trans* → pseudo *Z/cis*) and 458 cm^{-1} (pseudo *Z/cis* → pseudo *E/trans*). Our previous experimental results (16) indicated that, in the *n*-heptane Shpolskii matrix, the species fluorescing at 589.5 nm converts thermally at 90 K (corresponding to 60 cm^{-1}) into the species fluorescing at 600.5 nm. Therefore, the actual energy barrier should be smaller than our theoretical SCF value. Increasing the accuracy of the calculated energy barrier would require the consideration of correlation effects and possible matrix effects. Furthermore, the zero-point energy correction for the Φ_1 = 90° conformer is expected to be smaller than the corresponding one in pseudo-planar conformers as a consequence of the lack of conjugation between the two aromatic cycles: this results in a decrease of the energy barrier height.

Nevertheless, these experimental results, coupled to our predictions on absolute energies, suggest that the species emitting at 600.5 nm in the *n*-heptane matrix (and at 600.1 nm in the *n*-hexane matrix) is the pseudo-*Z/cis* conformer while the one emitting at 589.5 nm in the *n*-heptane matrix (and at 588.8 nm in the *n*-hexane matrix) is the pseudo-*E/trans* one.

2. Transition energies of the conformers

The CS-INDO/CIPSI transition energies are listed in Table 2 for the planar conformers and in Table 3 for the nonplanar

Fig. 1. Adiabatic correlation diagram from the planar *E/trans* conformer to the *Z/cis* conformer through nonplanar forms.



ones. The T_0–T_1 transition energies compare favorably with the previous experimental results (16). The comparison between theoretical predictions and experimental results enables us to propose the following assignment:

pseudo-*E/trans*, Φ_1 = 30.77°, $(T_0–T_1)_{calcd}$ = 2.05 eV, $(T_0–T_1)_{exp}$ = 2.11 eV;

pseudo-*Z/cis*, Φ_1 = 153.17°, $(T_0–T_1)_{calcd}$ = 2.01 eV, $(T_0–T_1)_{exp}$ = 2.06 eV.

This assignment is consistent with the ground state energetics discussed above.

The correlation diagram from the planar *E/trans* conformer to the *Z/cis* conformer through nonplanar forms is presented in Fig. 1.

The T_0–T_1 transition energies of 1.96 and 1.98 eV calculated for the planar 2-NPC conformers are lower than the corresponding energy of 2.62 eV computed for the planar (C_{2v}) DPC (9), in good agreement with the expected energy shift for more extended conjugated systems. This indicates that the CS-INDO parameters can be transferred from a medium-size molecule, like DPC, to larger compounds.

When aromatic molecules present sparsely spaced electronic levels of a given multiplicity, the vibrational structures of their emission and absorption, or excitation, spectra generally show mirror-image symmetry. In contrast, when the molecules present two close-lying electronic states of different symmetry, the latter can interact vibronically through an inducing mode of appropriate symmetry. In such a case, the vibronic levels of one manifold will be mixed with levels of appropriate symmetry of the other manifold, resulting in level shifts and intensity redistribution. In the case of 2-NPC, the second excited triplet state T_2 is separated from the T_1 state by 0.71 eV (5727 cm^{-1}) for the pseudo-*E/trans* conformer and by 0.72 eV (5808 cm^{-1}) for the pseudo-*Z/cis* conformer. This large separation explains why the quasi line fluorescence spectra of both conformers exhibit mirror-image symmetry with the corresponding excitation spectra, as far as vibrational frequencies up to 1700 cm^{-1} are concerned (16). Such a mirror-image symmetry does not exist for DPC (see Fig. 4 in ref. 9) where the corresponding T_1–T_2 separation is about 0.03 eV (~240 cm^{-1}).

3. ZFS parameter *D*

The computed values for the ZFS parameter $D(T_0)$ in the ground state T_0 and $D(T_1)$ in the first excited state T_1 of 2-NPC in various geometries are gathered in Table 4. It should be noticed that our evaluation of the ZFS parameters assumes that the principal axes of the *D* tensor for the *E/trans* and *Z/cis* 2-NPC conformers in their T_0 state are approximately the same as in DPC and that they are not changed when passing from T_0 to T_1 (25). These *D* values were obtained by considering only the first-order contributions due to the spin–spin interaction between the two unpaired electrons.

Table 4 reveals that the largest $D(T_0)$ values are obtained for the planar conformers of 2-NPC: the $D(T_0)$ and $D(T_1)$ values decrease upon out-of-plane torsion with respect to the Φ_1 dihedral angle. For both states, the minimum is reached at Φ_1 = 90°. In this geometry, the π_0 orbital on the carbenic center remains conjugated with the phenyl ring while the *n* orbital now conjugates with the naphthyl group, unlike the planar conformers for which no conjugation at all occurs between the *n* orbital and the π system of the rings. As a consequence of this increased delocalization effect, the average separation

[b]Only the main configuration of the CI wave function has been retained in the evaluation of the D parameters.

between the π_0 and n unpaired electrons increases, leading to a smaller $D(T_0)$ value.

Furthermore, it is noteworthy that the D values may be fitted with respect to Φ_1 according to eq. [1]:

$$[1] \quad D(T_i) = a_i + b_i \cos^2 \Phi_1 \qquad i = 0, 1$$

For the ground state T_0, $a_0 = 0.272$ cm^{-1} and $b_0 = 0.126$ cm^{-1} with a correlation coefficient $r_0 = 0.92$. For the excited state T_1, $a_1 = 0.0497$ cm^{-1} and $b_1 = 0.0215$ cm^{-1} with a correlation coefficient $r_1 = 0.90$.

Such an equation has to be compared to the Heller–McConnell formula (26), which gives a relationship between carbon spin densities of radicals and EPR coupling constants.

A further refinement in this fitting would include the role of the Φ_2 and α angles. In addition, it might be necessary to use a set of two equations, instead of eq. [1], in order to account for the asymmetry of the molecule, as suggested by Douady et al. (27) for the β hydrogen hyperfine coupling constants. Such a discussion is, however, beyond the scope of this paper. We just want to emphasize that such a relationship could contribute to the determination of the structure of diarylcarbenes when their ZFS parameters are known.

In Table 4, the $D(T_0)$ values are always higher for the *Z/cis* and pseudo-*Z/cis* ($\Phi_1 \geq 90°$) conformers than for the *E/trans* and pseudo-*E/trans* ones ($\Phi_1 \leq 90°$). As a consequence, we assign the compound having the largest experimental $D(T_0)$ value (12, 16) to the pseudo-*Z/cis* conformer of 2-NPC. This attribution is consistent with the fact reported in ref. 16 that the conformer with the largest $D(T_0)$ value fluoresces at the highest wavelength, in agreement with our results on transition energies (see sect. 2). Although the difference between the $D(T_0)$ values of the *Z/cis* (or pseudo-*Z/cis*) and the *E/trans* (or pseudo-*E/trans*) conformers of 2-NPC is small (but significant), this attribution is opposite to the one previously presented in ref. 12 that was based on an erroneous comparison of spin densities, but is consistent with the revised analysis presented in ref. 28.

The electronic structure of the excited T_1 state involves the promotion of the unpaired electron from the π_0 orbital to a π^* orbital. As in the case of DPC (9), this π^* orbital has only a minor contribution from the carbenic $2p\pi$ atomic orbital. Thus the excitation results in a delocalization of the unpaired electron on the rings and in a lack of corresponding spin density on the carbenic center, while retaining the spin density originating from the n unpaired electron. As a consequence, the average separation between the two unpaired electrons is increased relative to the T_0 ground state: the ZFS parameter $D(T_1)$ is then expected to decrease relative to $D(T_0)$, which is in agreement with the values presented in Table 4. However, the electronic distributions are very different in the T_0 and T_1 states, so that our assumption of taking the same principal axes, and consequently the same ordering of the three sublevels $|x\rangle$, $|y\rangle$, and $|z\rangle$, in both states may be questionable. In addition, the contribution of the second-order spin-orbit coupling between singlet and triplet states should be considered. As seen in Table 2, the spin-orbit interaction is likely to particularly affect the $D(T_1)$ value because of the very small separation between the S_4 and T_1 states: ΔE $(S_4–T_1) = 81$ cm^{-1}. Furthermore, this coupling could also induce energy shifts capable of disturbing the ordering of the T_1 sublevels.

Conclusion

In this contribution, three different calculations involving absolute energies, transition energies, and ZFS D parameters have been performed using three different methods for different conformers of the 2-NPC molecule.

Due to the very small differences in the calculated values between the pseudo-*E/trans* and pseudo-*Z/cis* conformers, it might be risky to draw unambiguous conclusions. However, these three different calculations lead to a series of converging results, consistent with the experimental data (16), but in disagreement with the assignment reported in refs. 12 and 16 that has now been found to be erroneous (28): the conformer emitting at 600.5 nm and at 600.1 nm (respectively, in the n-heptane and in the n-hexane matrices) would likely be the pseudo-*Z/cis* conformer with $\Phi_1 \approx 153°$ while the one fluorescing at 589.5 nm and at 588.8 nm (respectively, in the n-heptane and in the n-hexane matrices) would be the pseudo-*E/trans* conformer with $\Phi_1 \approx 31°$. In addition, our calculated D values have demonstrated their dependence on $\cos^2 \Phi_1$, thus establishing a clear-cut relationship between the ZFS parameters and the geometries of diarylcarbenes.

Protected building blocks for luminescent and redox-active dendritic metal complexes. Excited state properties and electrochemical behavior

Alberto Juris, Margherita Venturi, Luca Pontoni, Immaculada Resino Resino, Vincenzo Balzani, Scolastica Serroni, Sebastiano Campagna, and Gianfranco Denti

Abstract: The mononuclear complexes $[Ru(2,3\text{-}Medpp)_3]^{5+}$, $[Ru(2,3\text{-}Medpp)_2(bpy)]^{4+}$, and $[Ru(2,3\text{-}Medpp)(bpy)_2]^{3+}$ and the dinuclear complex $[(2,3\text{-}Medpp)_2Ru(\mu\text{-}2,3\text{-}dpp)Ru(2,3\text{-}Medpp)_2]^{8+}$ (bpy = 2,2′-bipyridine; 2,3-dpp = 2,3-bis(2-pyridyl)pyrazine; 2,3-Medpp$^+$ = monomethylated 2,3-bis(2-pyridyl)pyrazine) have been synthesized. Their absorption spectra, luminescence properties, and electrochemical behavior have been investigated and compared with those of the mononuclear $[Ru(bpy)_3]^{2+}$, $[Ru(2,3\text{-}dpp)_3]^{2+}$, $[Ru(2,3\text{-}dpp)_2(bpy)]^{2+}$, and $[Ru(2,3\text{-}dpp)(bpy)_2]^{2+}$ and the dinuclear $[(bpy)_2Ru(\mu\text{-}2,3\text{-}dpp)Ru(bpy)_2]^{4+}$ parent compounds. The complexes examined are fundamental units in the synthesis of polynuclear metal complexes of dendrimeric structure and nanometer size.

Key words: luminescence, ruthenium complexes, dendrimers, electrochemistry, photochemistry.

Résumé : On a synthétisé les complexes mononucléaires $[Ru(2,3\text{-}Medpp)_3]^{5+}$, $[Ru(2,3\text{-}Medpp)_2(bpy)]^{4+}$ et $[Ru(2,3\text{-}Medpp)(bpy)_2]^{3+}$ et le complexe dinucléaire $[(2,3\text{-}Medpp)_2Ru(\mu\text{-}2,3\text{-}dpp)Ru(2,3\text{-}Medpp)_2]^{8+}$ (bpy = 2,2′-bipyridine; 2,3-dpp = 2,3-bis(2-pyridyl)pyrazine; 2,3-Medpp$^+$ = 2,3-bis(2-pyridyl)pyrazine monométhylé). On a examiné leurs spectres d'absorption, leurs propriétés de luminescence et leurs comportements électrochimiques et on les a comparés aux propriétés correspondantes des complexes parents mononucléaires $[Ru(bpy)_3]^{2+}$, $[Ru(2,3\text{-}dpp)_3]^{2+}$, $[Ru(2,3\text{-}dpp)_2(bpy)]^{2+}$ et $[Ru(2,3\text{-}dpp)(bpy)_2]^{2+}$ et dinucléaire $[(bpy)_2Ru(\mu\text{-}2,3\text{-}dpp)Ru(bpy)_2]^{4+}$. Les complexes étudiés sont les unités fondamentales dans la synthèse de complexes métalliques polynucléaires de structure dendrimérique et de grosseur du nanomètre.

Mots clés: luminescence, complexes du ruthénium, dendrimères, électrochimie, photochimie.

[Traduit par la rédaction]

Introduction

Much attention is currently devoted to the preparation of tree-like structures, also called arborols or dendrimers (1). Particularly interesting are dendrimers that incorporate in their building blocks specific "pieces of information" such as the capability to absorb and emit visible light and to reversibly exchange electrons. Such species could find applications as components in molecular electronics (2) and as photochemical molecular devices (3) for solar energy conversion and information storage (4). Ideal components to build up dendrimers of this type are transition metal complexes (5). In the last few years we have used Ru(II) and Os(II) as metals, 2,3- and 2,5-bis(2-pyridyl)pyrazine (2,3-dpp and 2,5-dpp) as bridging ligands, and 2,2′-bipyridine (bpy) and 2,2′-biquinoline (biq) as terminal ligands and we have developed a synthetic strategy to prepare luminescent and redox-active polynuclear metal complexes of dendrimeric structure, where the desired metals and ligands can be placed in specific sites of the supramolecular structure (6). Species containing 4 (7), 6 (8), 7 (9), 10 (10), 13 (11), and 22 (12) metal-based units have been obtained. Dendrimers containing metal atoms have also been reported by other groups (13).

We report here the synthesis and discuss the absorption spectra, the luminescence properties, and the electrochemical behavior of mono- and dinuclear Ru(II) complexes that contain the 2,3-Medpp$^+$ ligand. In this ligand one of the two chelating sites is temporarily blocked by the presence of a methyl group. For this reason one can refer to 2,3-Medpp$^+$ as a "protected" counterpart of the "deprotected" bis-chelating 2,3-dpp. The novel complexes described in this paper, which

can be viewed as fundamental units of some of our dendrimers, and other related compounds are schematized in Fig. 1. In that figure and throughout the text each compound is designated by a label where the first number indicates the nuclearity, the letters indicate the type (and its lower index the number) of peripheral ligands: deprotected 2,3-dpp ligands (d), protected 2,3-Medpp$^+$ ligands (p), or terminal monochelating ligands (t). Finally, the "prime" notation indicates the presence of labile ligands (Cl^-).

Experimental section

Materials and methods

The preparation of the precursor compounds 2,3-Medpp$^+$ (**p**) (12), $[Ru(2,3\text{-}Medpp)_2Cl_2]^{2+}$ (**1'p$_2$**) (12), and $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (**1't$_2$**) (14), and of compounds $[Ru(2,3\text{-}dpp)(bpy)_2]^{2+}$ (**1d$_1$t$_2$**) (7*b*), $[Ru(2,3\text{-}dpp)_2(bpy)]^{2+}$ (**1d$_2$t$_1$**) (7*b*), and $[Ru(2,3\text{-}dpp)_3]^{2+}$ (**1d$_3$**) (15) has been previously reported.

Equipment

Absorption spectra were obtained at room temperature by means of a Perkin–Elmer λ-6 spectrophotometer. Luminescence spectra were obtained with a Perkin–Elmer LS-50 spectrofluorimeter. Emission quantum yields were measured at room temperature (20°C) with the optically dilute method (16), calibrating the spectrofluorimeter with a standard lamp. $[Ru(bpy)_3]^{2+}$ in aerated aqueous solution was used as a quantum yield standard, assuming a value of 0.028 (17). Emission lifetimes were measured with an Edinburgh 199 single-photon counting device. Electrochemical measurements were carried out in argon-purged acetonitrile solution at room temperature with a PAR 273 multipurpose apparatus interfaced to a PC. The working electrode was a Pt microelectrode or a glassy carbon (8 mm^2, Amel) electrode. The counter electrode was a Pt wire, and the reference electrode was a SCE separated with a fine glass frit. The concentration of the complexes was 5×10^{-4} M. Tetrabutylammonium hexafluorophosphate (0.05 M) was added as supporting electrolyte. Cyclic voltammograms were obtained at sweep rates of 20, 50, 100, and 200 mV/s. For reversible processes, half-wave potentials (vs. SCE) were calculated as an average of the cathodic and anodic peaks. The criteria for reversibility were the separation between cathodic and anodic peaks, the close-to-unity ratio of the intensities of the cathodic and anodic currents, and the constancy of the peak potential on changing scan rate. For irreversible processes, the potential values were evaluated from differential pulse voltammetry (DPV) peaks. The number of exchanged electrons was measured with DPV experiments performed with a scan rate of 20 mV/s, a pulse height of 30 mV, and a duration of 40 ms. The procedure for the calibration of the number of electrons corresponding to the various redox waves has been described in detail (10*b*). Experimental errors in the reported data are as follows: absorption maxima, 2 nm; emission maxima, 5 nm; emission lifetimes, 10%; emission quantum yields, 20%; redox potentials, 20 mV. As far as molar absorption coefficients are concerned, the uncertainty in their absolute values is ~10% because of the very dilute solutions used (10^{-5}–10^{-4} M).

Synthesis of the new complexes

*$[Ru(2,3\text{-}Medpp)(bpy)_2](PF_6)_3$ (**1p$_1$t$_2$**)*

Solid $AgNO_3$ (65 mg, 0.384 mmol) was added to a solution of $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (100 mg, 0.192 mmol) in 1:2 (v/v) H_2O/EtOH (11 mL). The resulting suspension immediately changed color from deep red to orange, with precipitation of AgCl. After 1 h stirring at room temperature, 2,3-Medpp$^+$ (76 mg, 0.192 mmol) was added and the mixture was refluxed for 18 h. After removal of AgCl by repeated centrifugation, the solution was concentrated to 2/3 of its volume. An excess of NH_4PF_6 was added to the mother liquor and the dark red solid so obtained was filtered out. The product was then purified by recrystallization from CH_3CN–EtOH (yield 71%).

*$[Ru(2,3\text{-}Medpp)_2(bpy)](PF_6)_4$ (**1p$_2$t$_1$**)*

Solid $AgNO_3$ (11 mg, 0.062 mmol) was added to a suspension of $[Ru(2,3\text{-}Medpp)_2Cl_2](PF_6)_2$ (20 mg, 0.021 mmol) in 1:2 (v/v) H_2O/EtOH (15 mL). After 2 h stirring at room temperature, bpy (5 mg, 0.032 mmol) was added and the mixture was refluxed for 16 h. After removal of AgCl by repeated centrifugation, the solution was filtered. An excess of NH_4PF_6 was added to the mother liquor and the orange solid so obtained was filtered out. The product was washed repeatedly with diethyl ether to eliminate the excess of the ligand. The compound was dissolved in the minimum volume of CH_3CN and the solution was purified by flash chromatography on Sephadex G-10 and concentrated to a volume of about 2 mL. Addition of 12 mL of diethyl ether caused the precipitation of an orange compound that was separated by filtration (yield 77%).

*$[Ru(2,3\text{-}Medpp)_3](PF_6)_5$ (**1p$_3$**)*

Solid $AgNO_3$ (9.5 mg, 0.055 mmol) was added to a suspension of $[Ru(2,3\text{-}Medpp)_2Cl_2](PF_6)_2$ (26 mg, 0.027 mmol) in 1:2 (v/v) H_2O/EtOH (10 mL) . After stirring for 2 h at room temperature, 2,3-Medpp$^+$ (11 mg, 0.027 mmol) was added and the mixture was refluxed for 6 days, the progress of the reaction being followed by TLC. After removal of AgCl by repeated centrifugation, the solution was filtered, an excess of NH_4PF_6 was added, and the solution was rotary evaporated to dryness. The compound was dissolved in the minimum volume of

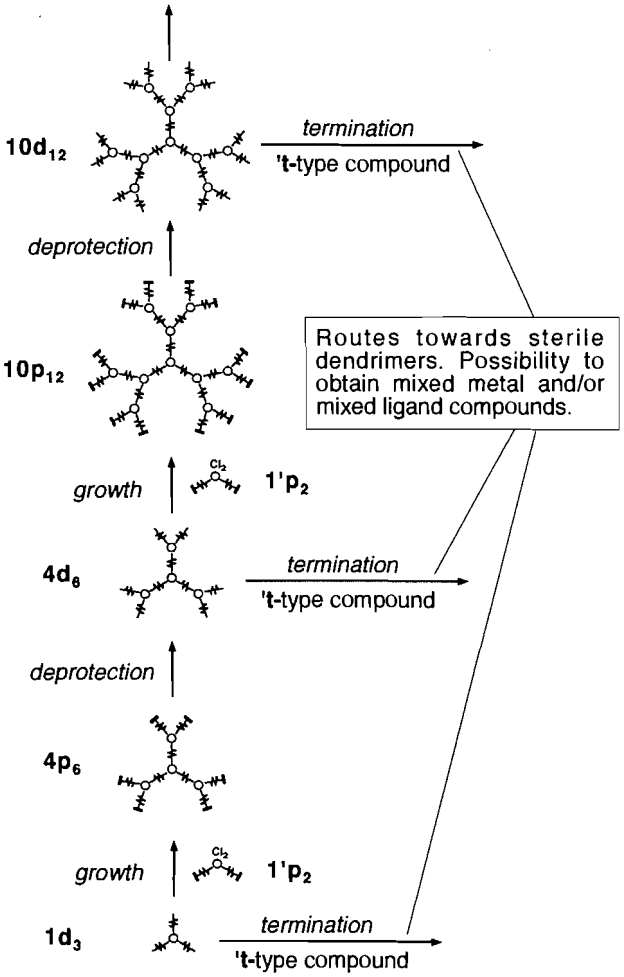
Fig. 2. Procedure for the synthesis of the luminescent and redox-active dendritic metal complexes. For labels of the complexes, see text and Fig. 1.



CH_3CN and the solution was purified by flash chromatography on Sephadex G-10 (1 cm × 20 cm). The first (brown-orange) eluted band contained the required complex. After concentration the product was precipitated by addition of diethyl ether (yield 25%).

*[(2,3-Medpp)$_2$Ru(μ-2,3-dpp)Ru(2,3-Medpp)$_2$](PF$_6$)$_8$ (**2p$_4$**)*
Solid $AgNO_3$ (15 mg, 0.088 mmol) was added to a suspension of [Ru(2,3-Medpp)$_2$Cl$_2$](PF$_6$)$_2$ (42 mg, 0.044 mmol) in 1:2 (v/v) H_2O/EtOH (10 mL) . After stirring for 1 h at room temperature, 2,3-dpp (5 mg, 0.022 mmol) was added and the mixture was refluxed for 15 h, the progress of the reaction being followed by TLC and absorption spectra. After removal of AgCl by repeated centrifugation, the solution was filtered and an excess of NH_4PF_6 was added. The orange solid was filtered and washed with ethanol and diethyl ether. The compound was then dissolved in acetonitrile and after addition of ethanol the solution was concentrated. The precipitate so obtained was filtered and washed with diethyl ether (yield 62%).

Elemental analyses of all the new compounds were consistent with the given formulation.

Results and discussion

The divergent synthetic approach developed to construct our dendrimers is illustrated in Fig. 2. The two key compounds for this synthesis are the [Ru(2,3-dpp)$_3$]$^{2+}$ (**1d$_3$**) and [Ru(2,3-Medpp)$_2$Cl$_2$]$^{2+}$ (**1'p$_2$**) mononuclear species. Reaction of the "complex ligand" **1d$_3$** with the "complex metal" **1'p$_2$** in a 1:3 molecular ratio leads to the tetranuclear complex **4p$_6$** (first generation of our dendrimers), which in its periphery contains six protected chelating sites. Demethylation of **4p$_6$** yields the tetranuclear complex **4d$_6$**, which can play the role of complex ligand. Reaction of **4d$_6$** with the complex metal **1'p$_2$** in 1:6 molecular ratio leads to the decanuclear compound **10p$_{12}$** (second generation of our dendrimers). Deprotection of **10p$_{12}$** leads to the decanuclear complex ligand **10d$_{12}$**, which contains 12 vacant chelating sites. The divergent iterative synthesis has been carried out up to this stage (6*d*). In principle, iteration of this procedure can lead to further generations, but difficulties are expected due to the increasing number of reaction sites (1). The reaction of the complex ligand deprotected species (**d**-family) with complex metal building blocks ('**t**-family, e.g., **1't$_2$**) yields coordinatively saturated (sterile) dendrimers (termination steps, Fig. 2).

As one can see, this synthetic procedure is based on protection–deprotection steps that involve methylation and demethylation of peripheral chelating sites. The study of the properties of methylated building blocks is therefore essential to better characterize the dendrimers.

There are also other important reasons to investigate the excited state and electrochemical properties of the novel complexes. In dendrimer terminology, **1d$_3$** is the core of a tri-dendron (three-branched structure). It could be interesting to develop di-dendron and mono-dendron structures (Fig. 3). In our systems, the cores of such structures are the mononuclear complexes **1d$_2$t$_1$** and **1d$_1$t$_2$**. Another interesting structure is that of a bis di-dendron having as a core the **2d$_4$** (which can be obtained by demethylation of **2p$_4$**). The excited state and electrochemical properties of the core units in such structures cannot be inferred by the properties of the **1d$_2$t$_1$**, **1d$_1$t$_2$**, and **2d$_4$** complexes because the properties of the 2,3-dpp bridging ligand change strongly on coordination of a second metal unit. The methylated **1p$_1$t$_2$**, **1p$_2$t$_1$**, and **2p$_4$** species, which have been investigated in this paper, can be considered much better models for such cores.

Electrochemical behavior

Previous investigations of the free 2,3-dpp and bpy ligands (18) and of their complexes (5–12) have shown that (*i*) the 2,3-dpp ligand is reduced at less negative potentials than bpy; (*ii*) in the complexes, oxidation is metal centered and reduction is ligand centered; (*iii*) metal coordination moves the reduction potentials of the ligands to much less negative values; (*iv*) when 2,3-dpp plays the role of a bridge between two metal ions, its reduction potentials move further towards less negative values.

On the basis of the above results one can expect that (*a*) the reduction potential of 2,3-Medpp$^+$ is less negative than that of 2,3-dpp since methylation is in some way similar to metal coordination; (*b*) when 2,3-dpp is methylated on one side and coordinated to a metal ion on the other side, its behavior should be somewhat similar to that exhibited by bridged 2,3-

dpp in polynuclear metal complexes; however, the methylated and metal-coordinated sites are not equivalent.

The results obtained are gathered in Table 1 and displayed in graphical form in Fig. 4. To facilitate the discussion, previously reported data for compounds of related families are also shown.

Electrochemical oxidation

All the oxidation processes are reversible with ΔE ca. 60 mV. The data reported in Table 1 and Fig. 4 show that on replacing bpy of $[Ru(bpy)_3]^{2+}$ with 2,3-dpp or 2,3-Medpp$^+$, a progressive increase in the potential at which the metal is oxidized occurs. It can also be noted that the displacement caused by 2,3-Medpp$^+$ is larger than that caused by 2,3-dpp. These results can be rationalized by considering that the electron donor power decreases in the series bpy > 2,3-dpp > 2,3-Medpp$^+$. For the dinuclear complex $\mathbf{2p_4}$, one could expect either simultaneous or successive oxidation of the two metal centers, depending on the degree of metal–metal interaction. The observed oxidation wave is monoelectronic, close to the upper limit of the potential window in the solvent used. This suggests that there is a noticeable metal–metal interaction and that the second oxidation process cannot be seen because of experimental limitations.

Electrochemical reduction

Most of the reduction processes exhibit an irreversible character in cyclic voltammetry (CV). The following discussion will therefore be limited to a few considerations based on the observed sequences of the differential pulse voltammetry peaks (Table 1 and Fig. 4).

First of all, one can notice that upon methylation the first three reduction waves of 2,3-dpp are displaced to less negative potentials by as much as 1.1–1.4 V. Metal coordination on 2,3-dpp has a similar, but smaller, effect. Metal coordination on 2,3-Medpp$^+$ has, apparently, an even smaller effect, suggesting that reduction occurs on the methylated pyridine.

From Fig. 4 it is clear that the first reduction process of $\mathbf{1p_1t_2}$ concerns the 2,3-Medpp$^+$ ligand, most likely on the methylated pyridine (see above). The second and third reduction processes occur in the potential range for which 2,3-dpp is reduced in $\mathbf{1d_1t_2}$ (18). Since in $\mathbf{1d_1t_2}$ bpy reduction occurs at more negative potentials (18), the second and third reduction processes of $\mathbf{1p_1t_2}$ can be assigned to the 2,3-Medpp$^+$ ligand. Comparison with the second and third reduction waves of free 2,3-Medpp$^+$ shows that the third wave is much more affected by metal coordination than the second one. Therefore one can conclude that the third reduction process involves the metal-coordinated site more directly. Whereas the fourth reduction wave of $\mathbf{1p_1t_2}$ is difficult to assign, the fifth and the sixth can be attributed to bpy reduction.

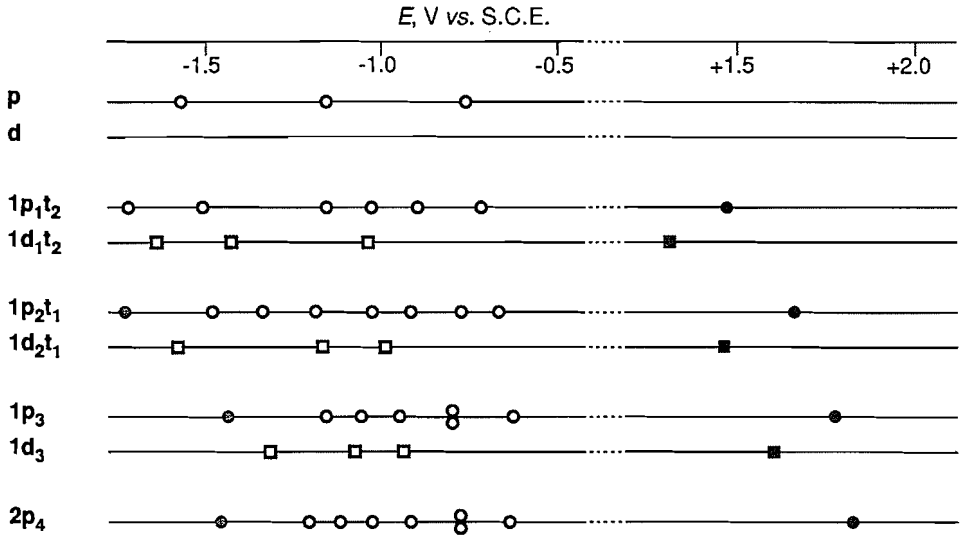
Fig. 4. Schematic comparison of the redox potentials for the new compounds and related parent species (see also Table 1). The greyed circles represent multielectronic processes. Notice that the reductions of **d** occur outside the potential range shown in this figure. For the labels of the compounds, see text and Fig. 1.



For $\mathbf{1p_2t_1}$, where two 2,3-Medpp$^+$ ligands are present, one could assign the first two processes to successive reduction of the two methylated sites. This would imply some interaction between the methylated pyridine moieties. According to this hypothesis the first wave moves slightly to less negative potentials compared with $\mathbf{1p_1t_2}$ because replacement of bpy by 2,3-Medpp$^+$ makes the metal ion more positive. The smaller separation between the two reduction waves compared with $\mathbf{1d_2t_1}$ (18) can be accounted for by the increased distance between the two reduced sites. An alternative interpretation will be given after discussion of $\mathbf{1p_3}$.

For $\mathbf{1p_3}$ the results show that there is a first, monoelectronic, process followed by a two-electron process. An attempt to assign these reduction processes can be based on the following considerations. The metal-coordinated site of 2,3-dpp in $\mathbf{1d_1t_2}$ is 300 mV more difficult to reduce than the methylated site of 2,3-Medpp$^+$ in $\mathbf{1p_1t_2}$ (Table 1). In the latter complex, however, the metal-coordinated site of 2,3-Medpp$^+$, because of its positive charge, is certainly easier to reduce than the metal-coordinated site of 2,3-dpp of the former complex. Furthermore, the difference in the reduction potential between the methylated and metal-coordinated site of 2,3-Medpp$^+$ is expected to decrease substantially along the series $\mathbf{1p_1t_2}$, $\mathbf{1p_2t_1}$, $\mathbf{1p_3}$ because of the increase in the positive charge on the metal, as shown by the parallel displacement to more positive potentials of the (metal-centered) oxidation wave (Table 1, Fig. 4). Therefore in $\mathbf{1p_3}$ the reduction orbitals of the methylated and metal-coordinated sites are likely very close in energy and their relative position can change upon addition of electrons. It should also be noted that for reasons of distance the interaction between the metal-coordinated sites is much stronger than the interaction between the methylated sites. In the light of the above considerations, the reduction pattern of $\mathbf{1p_3}$ could be interpreted as follows. The first reduction process may concern an orbital of the metal-coordinated sites. The second electron would then enter a methylated site, but its presence raises the energy of the orbitals of the metal-coordinated sites, while it does not practically affect the energy of the two other methylated sites. In other words, for the two-electron reduced species the lowest energy orbitals could be those of the three (weakly interacting) methylated sites. As a consequence, the third methylated site would also become available for reduction at the same potential as the second one, accounting for the observed reduction pattern.

Within this scheme, the first two reduction waves of $\mathbf{1p_2t_1}$ can be assigned to a metal-coordinated site and a methylated site, respectively, with a subsequent electron rearrangement to give a species where the two methylated sites are reduced.

The above discussion suggests that detailed assignment of reduction waves occurring at more negative potentials of $\mathbf{1p_2t_1}$ and $\mathbf{1p_3}$ is difficult because several reduction orbitals of different localization, whose energy ordering can change on successive addition of electrons, are present.

The behavior of the dinuclear $\mathbf{2p_4}$ complex is similar to that of $\mathbf{1p_3}$, with the additional complication that two, nonequivalent chelating sites (of bridging and methylated ligands) are present. A tentative interpretation of the first four reduction waves can be given along the same guidelines followed for $\mathbf{1p_3}$. The first reduction process could involve an orbital of the bridging ligand more localized on one of the two metal ions. This would increase in energy the reduction orbitals of the confining methylated sites, leaving unperturbed the energy of the reduction orbitals of the two methylated sites belonging to the other moiety of the complex. The second and third reduction processes could thus involve the latter (non-interacting) sites. The fourth process would then concern a methylated site of the moiety of the reduced metal-coordinated sites. This would probably change the orbital energy ordering, leading to a species where the four electrons are localized on the four methylated sites.

Excited state properties

The absorption and luminescence spectra of compounds $\mathbf{1p_1t_2}$, $\mathbf{1p_2t_1}$, $\mathbf{1p_3}$, and $\mathbf{2p_4}$ are shown in Figs. 5 and 6, respectively. Table 2 shows the wavelengths of the lowest energy absorption maxima, the wavelengths of the maxima of the lumines-

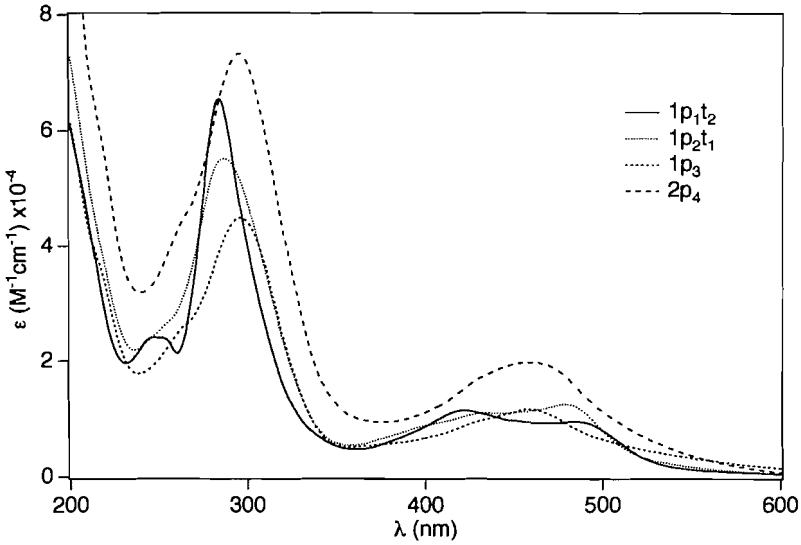

Fig. 6. Luminescence spectra (uncorrected) of the new complexes in acetonitrile fluid solution at room temperature (top) and in MeOH/EtOH 4:1 (v/v) rigid matrix at 77 K (bottom). For abbreviations, see text and Fig. 1.

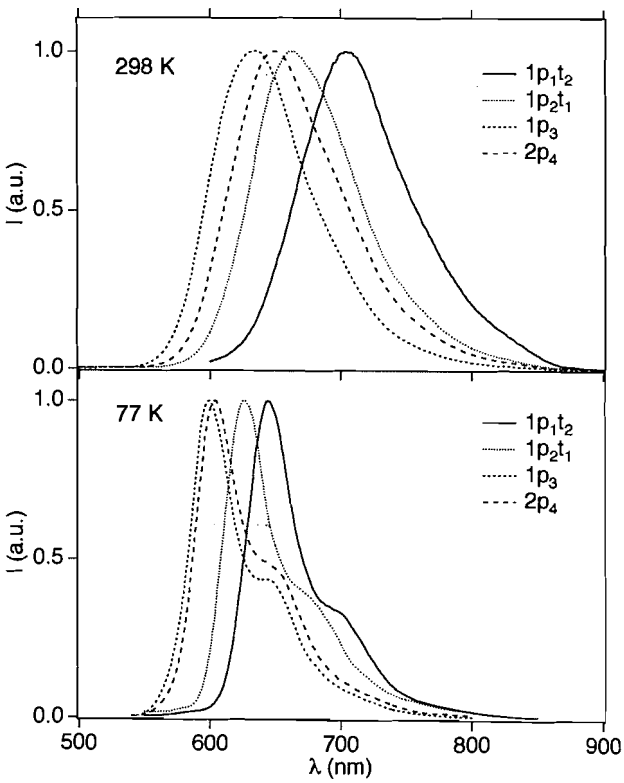

cence bands at 298 and 77 K, the lifetimes of the luminescent excited states at 298 and 77 K, and the luminescence quantum yields at 298 K. The corresponding data for related complexes ($[Ru(bpy)_3]^{2+}$, corresponding mononuclear d-family compounds, and $[(bpy)_2Ru(\mu\text{-}2,3\text{-}dpp)Ru(bpy)_2]^{4+}$ (**2t$_4$**)) are also shown for comparison purposes.

It is well known (5) that in Ru(II)–polypyridine complexes the absorption bands in the visible region are due to spin-allowed transitions from a metal-centered orbital (t_{2g} in octahedral symmetry) to a ligand-centered orbital (π^*). Such transitions are usually called MLCT (metal-to-ligand charge transfer). It is also known that the luminescent excited state is the lowest lying, formally triplet MLCT level, ^{3}MLCT.

It is convenient to compare and discuss the properties of the mononuclear compounds investigated starting from the $[Ru(bpy)_3]^{2+}$ parent complex and observing the effect obtained when one or more bpy ligands are replaced by 2,3-dpp or 2,3-Medpp$^+$ ligands.

Let us first recall the properties of the **1d$_1$t$_2$**, **1d$_2$t$_1$**, and **1d$_3$** complexes. As we have seen above, 2,3-dpp is a worse electron donor and a better electron acceptor than bpy. In particular, its lowest energy π^* orbital lies below that of bpy (6). As a consequence, in **1d$_1$t$_2$** the lowest energy MLCT excited state involves the 2,3-dpp ligand and lies at lower energy than the lowest MLCT level of $[Ru(bpy)_3]^{2+}$. Therefore, the absorption and emission bands of **1d$_1$t$_2$** are red-shifted compared with those of $[Ru(bpy)_3]^{2+}$ (Table 1). Passing to **1d$_2$t$_1$**, and **1d$_3$**, the lowest energy π^* orbital remains that of 2,3-dpp, but the energy of the t_{2g} metal orbital decreases because 2,3-dpp is a worse electron donor than bpy, as also shown by the potentials for the metal oxidation. For this reason, both the absorption and emission maxima move progressively to the blue along the **1d$_1$t$_2$**, **1d$_2$t$_1$**, and **1d$_3$** series. In the last compound, however, the bands are still red shifted compared with $[Ru(bpy)_3]^{2+}$, indicating that the stabilization of the π^* orbital in passing from bpy to 2,3-dpp is not compensated by the corresponding stabilization of the t_{2g} metal orbitals.

Methylation of 2,3-dpp stabilizes the π^* ligand orbital and at the same time reduces the electron-donor power. Therefore in the mixed-ligand **1p$_1$t$_2$** complex the lowest energy MLCT transition involves the 2,3-Medpp$^+$ ligand and the corresponding absorption and emission bands are red shifted with respect to both $[Ru(bpy)_3]^{2+}$ and **1d$_1$t$_2$** (Table 1). On passing to **1p$_2$t$_1$**, and **1p$_3$**, the bands move to the blue for the same reason discussed above.

Comparison between the **1d$_1$t$_2$**, **1d$_2$t$_1$**, and **1d$_3$** compounds

and the corresponding methylated species $\mathbf{1p_1t_2}$, $\mathbf{1p_2t_1}$, and $\mathbf{1p_3}$ shows that the bands of $\mathbf{1p_1t_2}$, are strongly red shifted compared with those of $\mathbf{1d_1t_2}$, and that such a shift decreases (especially as far as the emission bands are concerned) for the second members of the two series and becomes almost negligible for the third members. This behavior is due to the fact that replacing the "ancillary" ligands affects the energy of the t_{2g} metal orbitals more effectively with 2,3-Medpp$^+$ than with 2,3-dpp.

We have seen above that in the mononuclear species replacement of bpy with 2,3-Medpp$^+$ causes a decrease in the energy of the lowest excited state. It is interesting to notice that the opposite effect occurs for the dinuclear species. This different behavior originates from the fact that in $\mathbf{2t_4}$ and $\mathbf{2p_4}$ there is a 2,3-dpp ligand that bridges two metal ions (μ-2,3-dpp). It is well known that coordination to two metal ions lowers considerably the energy of the π^* orbital of 2,3-dpp (6–12), so that the lowest excited state of $\mathbf{2t_4}$ involves charge transfer from the t_{2g} metal orbital to the π^* orbital of the bridging ligand. This, coupled with the presence of strong electron-donating ancillary bpy ligands, accounts for the very low energy of the absorption and emission bands in $\mathbf{2t_4}$. When bpy is replaced by the weaker electron donor 2,3-Medpp$^+$ (i.e., in $\mathbf{2p_4}$), the Ru → μ-2,3-dpp CT transition is displaced to higher energy. The Ru → μ-2,3-dpp level could even move above the Ru → 2,3-Medpp$^+$ level, which in $\mathbf{2p_4}$ is expected to lie at higher energy than in $\mathbf{1p_2t_1}$: the electrochemical results, however, show that the LUMO is centered on μ-2,3-dpp, so that also the luminescent level should involve the bridging ligand.

The data collected in Table 2 show that the luminescence efficiencies and lifetimes for the methylated complexes are in the range expected for Ru(II)–polypyridine complexes. In particular, the excited state lifetimes of $\mathbf{1p_3}$ and $\mathbf{2p_4}$ are very close to that exhibited by $[Ru(bpy)_3]^{2+}$. More generally, within the family of mononuclear methylated compounds one can observe a decrease of the excited state lifetime (both at 77 and 298 K) along the series $\mathbf{1p_3} > \mathbf{1p_2t_1} > \mathbf{1p_1t_2}$. One can notice that the excited state energy also decreases along the series.

It is well known (5) that the ^{3}MLCT luminescent level of Ru(II)–polypyridine complexes can undergo nonradiative deactivation through two different routes: (*i*) direct decay to the ground state, whose rate increases with decreasing energy of the ^{3}MLCT level (energy-gap rule (19)); (*ii*) thermally activated crossing to an upper lying, triplet metal-centered level, ^{3}MC, which is strongly distorted compared to the ground state geometry and therefore undergoes fast deactivation to the ground state. At low temperature (77 K) the second route is certainly frozen so that one expects the rate of radiationless decay to increase with decreasing energy of the ^{3}MLCT level. Using the Φ_{em} and τ values at 298 K (Table 2) it is possible to calculate the radiative (k_r) rate constant by eq. [1].

$$[1] \quad k_r = \Phi_{em}/\tau$$

The nonradiative rate constant (k_{nr}) value at 77 K has been evaluated by eq. [2] using the τ value at 77 K, and with the usual approximation that the k_r value is independent of temperature.

$$[2] \quad k_{nr} = 1/\tau - k_r$$

Figure 7 presents the plot of log k_{nr} vs. emission energy at 77

K, showing that the energy-gap rule is satisfactorily obeyed at low temperature. At room temperature route (*ii*) also becomes important. Quantitative assessments of the relative importance of routes (*i*) and (*ii*) at room temperature are difficult to discuss, since the energy of the upper-lying ^{3}MC state is also expected to change.

Investigation of mesophase transitions in liquid crystals using inverse gas chromatography

Gareth J. Price and Ian M. Shillcock

Abstract: Inverse Gas Chromatography, IGC, has been used to study phase transitions in three low molar mass liquid crystals and one side-chain liquid crystalline polymer. This extension of previous work has shown that transitions between all of the various mesophases can be detected and their temperatures measured with an accuracy and precision comparable to that of more conventional techniques. For one of the compounds, 4,4′-(*n*-hexyloxy)cyanobiphenyl, the kinetics of solidification from the supercooled nematic phase have been measured. The process took place in two stages which could be interpreted in terms of a modified version of the Avrami model of polymer crystallization. An explanation of the results is that the solid support is providing a large number of nucleation sites for the initial part of the solidification, which is completed in a slow, diffusion-limited process. However, further work is required to confirm this mechanism.

Key words: inverse gas chromatography (IGC), liquid crystals, mesophase transitions, activity coefficients, retention volumes.

Résumé : On a utilisé la chromatographie en phase gazeuse inverse (IGC) pour étudier les transitions de phase de trois cristaux liquides de faibles masses molaires et d'un polymère cristal-liquide avec chaîne latérale. Cette extension du travail précédent a permis de démontrer que l'on peut détecter toutes les transitions entre les diverses mésophases et de mesurer leurs températures avec une exactitude et une précision comparables à celles des techniques plus conventionnelles. Pour l'un des composés, le 4,4′-(*n*-hexyloxy)cyanobiphényle, on a mesuré la cinétique de la solidification à partir de la phase nématique surrefroidie. Le processus se produit en deux étapes que l'on peut interpréter en fonction d'une version modifiée du modèle d'Avrami de la cristallisation d'un polymère. On peut expliquer les résultats en supposant que le support solide fournit un grand nombre de sites de nucléation pour la partie initiale de la solidification que est complétée par un processus lent, à diffusion limitée. Toutefois, des travaux ultérieurs seront nécessaires pour confirmer ce mécanisme.

Mots clés : chromatographie gazeuse inverse (IGC), cristaux liquides, coefficients d'activité, volumes de rétention.

Introduction

The use of Inverse Gas Chromatography, IGC, for characterizing structure and interactions in involatile materials was pioneered by Guillet and co-workers in the late 1960s and early 1970s (1–3). The alternative term "molecular probe experiment" (4) more accurately describes the technique. A volatile compound introduced into the carrier gas is used to "probe" the properties of an involatile material packed into the chromatography column. Since its introduction, a large number of materials have been studied by IGC although perhaps the major class has been polymers (5). The basis of the method is the recording, under accurately controlled conditions, of the specific retention volume, $V°_g$, the volume of carrier gas at S.T.P. needed to elute a probe molecule from the column per gram of stationary phase (6). Isothermal operation allows determination of thermodynamic parameters such as activity coefficients and interaction parameters (7–10) in bulk polymers or blends and investigation of the chemical nature of polymeric surfaces (11, 12). The temperature variation of retention, plotted in the form shown schematically in Fig. 1, allows measurement of a range of structural transitions (13–16).

At low temperatures, the probe can only interact with the surface of the glassy polymer (3–5). In general, the retention volume decreases with rising temperature. However, as the temperature passes through the glass transition temperature, T_g, the probe can enter the structure of amorphous regions of the rubbery polymer leading to a deviation from linearity of the retention diagram. The retention volume now rises until all of the amorphous region can be probed and the plot returns to linearity. Crystalline regions of the polymer are impermeable to the probe so that, when melting occurs, the amount of amorphous material and hence the retention volume increases leading to a second transition in the diagram. Above the maximum temperature at which crystalline polymer exists, i.e., the melt-

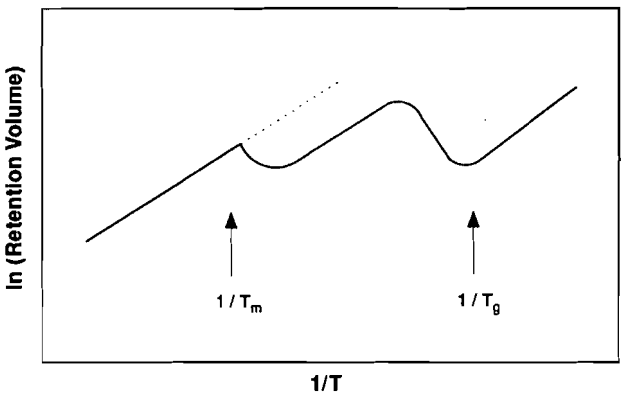
Fig. 1. Schematic retention diagram for a semicrystalline polymer.



ing temperature, T_m, the plot returns to linearity and equilibrium bulk sorption measurements can be made. In some cases, other transitions such as side-group rotations have been associated (14) with other deviations from linearity in the plots.

The difference between the retention volume in the semicrystalline region and that at the same temperature extrapolated from the totally amorphous region (shown by the broken line in Fig. 1) can be used to investigate the amount of crystalline material in polymers. It follows that

$$[1] \quad \text{Crystalline fraction} = \left(1 - \frac{V°_g(\text{experimental})}{V°_g(\text{extrapolated})}\right)$$

This approach has been used to estimate both the degree of crystallinity (3, 4, 15, 16) and, by following retention as a function of time, the rate of crystallization (17) in polymers. The IGC method has the advantage over, for example, density measurements that no properties of the 100% crystalline material are needed. The usual method of interpreting polymer crystallization (18) relies on the Avrami method (19, 20), which relates the volume fraction of crystalline material, V_c to the time, t, by:

$$[2] \quad (1 - V_c) = \exp -(K t^n)$$

where K is effectively a rate constant for the crystallization and the exponent n is an integer representing (21) the sum of the number of dimensions in which crystal growth takes place (1 for rods, 2 for discs, and 3 for spherulites) and the order of the time dependence of the nucleation (0 for instantaneous nucleation and 1 for sporadic growth where the number of nucleation sites varies linearly with time). Hence, n is typically 4 for an ideal spherulitic crystal growth. However, this model is recognised to be somewhat idealized and, in reality, several crystallization mechanisms often operate concurrently leading to the measurement of fractional exponents.

Liquid crystals, and in particular liquid crystal polymers, LCPs, are becoming increasingly important in a number of technologies (22). Liquid crystalline stationary phases are finding increasing use in analytical GC where they allow the separation of closely related isomers (23) on the basis of their molecular shapes. The thermodynamic properties of a small number of these materials have been studied using IGC (24–29). Romansky and Guillet (30) have also studied main-chain liquid crystal polymers and Laub and co-workers (31) have investigated some of the thermodynamic properties of side-chain LCPs from the point of view of their use as analytical stationary phases.

Despite the work described above, there has not been, to our knowledge, a systematic and comprehensive study of the use of IGC to investigate a range of the properties of liquid crystals. The present authors illustrated the potential of IGC for studying these materials in a preliminary study of the transition temperatures in one low molecular weight and one polymeric cyanobiphenyl (32). In this paper, that study is extended to a wider range of mesophase types. In addition, the methods used to investigate crystallinity in polymers have been applied to one of the liquid crystals in order to measure the rate of transition from the mesophase to the solid crystal phase.

Experimental

Differential scanning calorimetry

To give a comparison with the IGC results, the transition temperatures were also measured using a DuPont 9900 calorimeter employing an indium control for calibration. As usual, a small variation of the results obtained at different heating rates was noticed and, to allow accurate values to be recorded in a convenient time, a heating or cooling rate of 5°C min^{-1} was employed. Cycling was commenced at room temperature and the temperature raised to well above the highest transition before cooling at 5°C min^{-1}. Duplicate runs were performed in all cases.

Inverse gas chromatography

Chromatographic measurements were performed on a modified Pye Unicam 204 chromatograph fitted with FID detection and modified by the addition of fittings that allowed the pressure at the inlet to the column to be measured using a mercury manometer. The apparatus conformed in terms of temperature and flow rate stability to the accepted requirements for this type of work.[2] Nitrogen was used as the carrier gas at flow rates between 20 and 80 cm^3 min^{-1}, measured using a soap bubble flow meter. The probe molecules, detailed below, were of analytical grade or better and were obtained from commercial sources. Their retention times were determined by injecting approximately 0.01–0.05 μL from a syringe and recording to ±0.01 min with a Spectra-Physics SP4270 integrator. The mean of at least three readings agreeing to within experimental uncertainty was recorded. No dependence on the amount of probe injected was noted for any system reported here. The column temperature was measured to ±0.1°C using a thermocouple attached to the column that had been calibrated against a Tinsley Type 5840 platinum resistance thermometer. The temperature variation through the oven was less than 0.2°C.

Column preparation

Three low molecular weight liquid crystals were studied along with a side-chain polysiloxane containing a cyanobiphenyl mesogen. They were chosen to demonstrate the applicability of our methods to a number of different mesophases including nematic (N), smectic-A (S_A), smectic-C (S_C), and cholesteric (C) as well as the isotropic (I) and solid crystalline (K) phases.

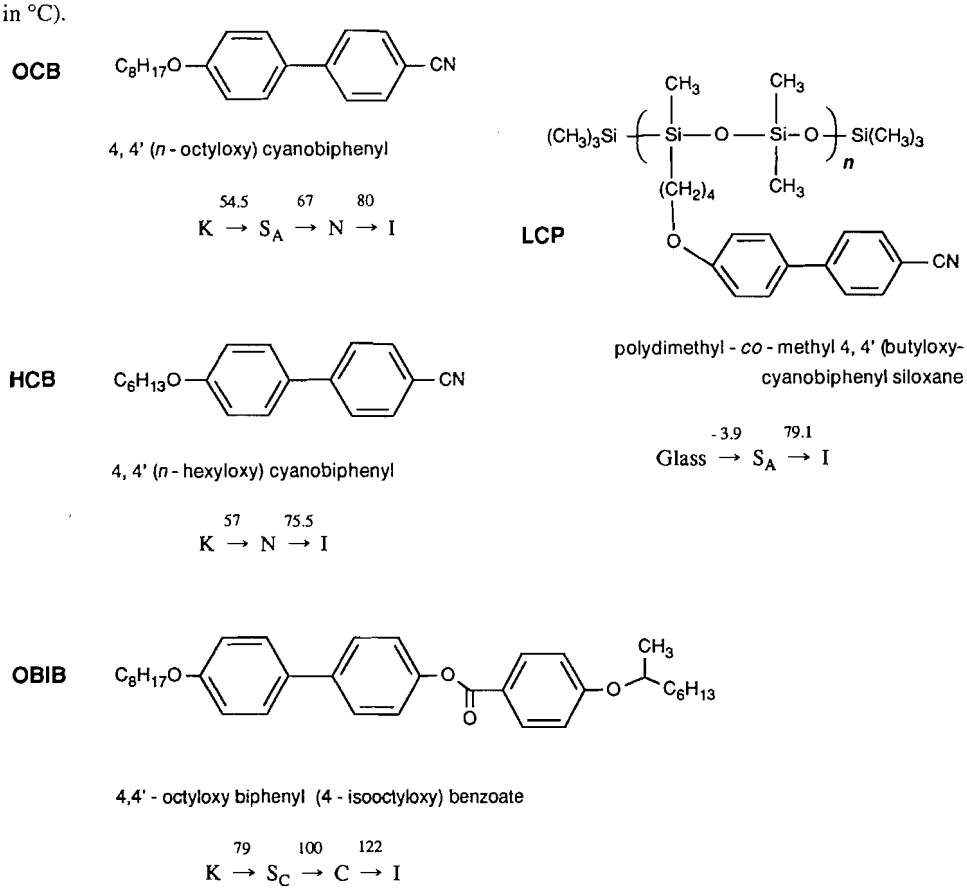
Fig. 2. Structures and expected phase transition of the liquid crystal stationary phases (temperatures in °C).



The structures, along with the manufacturer's reported phase transitions, are shown in Fig. 2. The acronyms which will be used for each of the LCs used are also shown.

The stationary phases were prepared in the usual way by coating the support from a solution of the LC in the minimum amount of chloroform required to completely cover the required mass of solid support. The support (Chromosorb P of 100–120 mesh size) was added to the solution and the chloroform removed slowly under constant agitation in a rotary evaporator. The resulting stationary phase was dried under vacuum to constant weight and a known amount packed into 1/4 in. o.d. copper tubing. The exact amount of liquid crystal on the column was determined by calcination or, for LCP, by exhaustive soxhlet extraction. Loadings in the range of 8–16% by weight were used. Within this range, no significant variation of retention with loading was observed.

Results and discussion

Differential scanning calorimetry

To validate the IGC results, the mesophase transition temperatures were first measured using the conventional technique of DSC. The results are shown in Fig. 3 and the transition temperatures and associated enthalpy changes are listed in Table 1, which shows the average of at least two cycles.

The results show satisfactory agreement with the manufacturer's values with agreement to within ±1°C apart from the polymer LC that would be expected to show larger batch-to-batch variation than the low molar mass versions. As expected, the largest energy changes were associated with the transition to or from the solid crystalline (K) phase since this involved the major realignment on a molecular scale. The transitions at the clearing point (i.e., into the isotropic phase) are also clearly shown but with much lower energy changes associated with the smaller degree of molecular ordering or disordering involved. It is significant that the $S_A \rightarrow N$ transition in OCB was barely discernable while that for $S_C \rightarrow C$ in OBIB was larger than that at the clearing temperature. A considerable hysteresis was observed, particularly around the melting (K) temperature. The shapes of the peaks suggest that this is not solely due to kinetic factors in the calorimetry but indicate a significant degree of supercooling.

The chromatographic measurements described below were performed on liquid crystals coated onto a solid support. It has previously been suggested (33, 34) that the support might alter phase transitions in the thin films of material present on coated supports so that it was important to ensure that this was not the case in our systems. DSC measurements were therefore performed on samples of the coated stationary phases used in the IGC work to evaluate any such effects. The results are shown in Table 2 and show no significant difference from the bulk, unsupported materials except for the supercooling effects in the $N \rightarrow K$ transition measured on cooling the HCB sample, with the transition being depressed by some 3°C. The original behaviour is restored after storage so that it is reasonable to assume that there is a small kinetic effect but no significant

alteration of the mesophase properties by coating onto the support. This is also supported by the results for OCB and LCP.

Inverse gas chromatography

As noted above, the primary measurement (6) in IGC is $V°_g$, given by:

$$[3] \quad V°_g = F(t_r - t_m)/w$$

where t_r and t_m are the retention times of the solvent and an inert marker, respectively, w is the weight of polymer on the column, and F is the flow rate of carrier gas, corrected to S.T.P. The flow rate is calculated from:

$$[4] \quad F = F' \left(\frac{273.2}{T_f}\right)\left(\frac{P_0}{760}\right)\left(\frac{P_0 - P_w}{P_0}\right)\left(\frac{3[(P_i/P_0)^2 - 1]}{2[(P_i/P_0)^3 - 1]}\right)$$

where F' is the flow rate measured at a flowmeter temperature T_f and atmospheric pressure P_0 (measured in Torr; 1 Torr = 133.3 Pa). Thus, the first three terms of eq. [4] represent F' corrected to S.T.P., while the last two account, respectively, for the vapour pressure of water in the flow meter, P_w, and the compressibility of the gas as it passes through the column, P_i being the pressure at the column inlet.

Retention diagrams were recorded for a range of hydrocarbon probes in each of the LCs and examples are shown in Figs. 4–7. For clarity, only a selection of the results is shown. More polar probes such as chloroform are good solvents for the LCs and Braun and Guillet (35) demonstrated that these give less clear transitions in polymer phases due to strong interactions below T_g.

Each of the diagrams displays the same general form as in Fig. 1 and clearly shows the melting transitions in the results recorded on heating the samples. The inter-mesophase transitions are less clear, as would be expected since the differences are due to relatively minor structural changes in the stationary phase compared to the melting. However, it is notable that all of the various mesophase transitions in the accessible temperature range could be seen in the retention diagrams whereas, as noted above, the $S_A \rightarrow N$ transition in OCB could not be detected in the DSC thermograms. It can also be seen in the retention diagrams that, in general, aromatic probes gave much larger increases in $V°_g$ on passing through the transitions, particularly those from the K phase. The increase in $V°_g$ is related to probe interaction with the LC surface below the melting temperature and to probe solubility above it. Related work (36) has shown that the aromatic probes are better solvents for the LCs than aliphatic species.

Figures 4 and 5 clearly show that OCB and HCB form stable, supercooled solids on cooling below the melting point. The large change of retention that occurs on melting is not seen on freezing. However, a small change of retention vol-

ume does occur, shown as N → N′ and S_A → S_A′ in the tables, the prime ′ indicating a supercooled phase. Below this temperature, the linear region of the retention diagram extends well below the equilibrium freezing point. Retention volumes measured in this region remained constant for several days. With OBIB, similar hysteresis was seen but the supercooled phase was only stable for a few degrees below the melting point.

By analogy with crystallization studies in polymers, the transitions were recorded at the highest temperature at which the lower phase exists. These measurements are more clearly

p-Xylene	77.0 ± 0.5	57.6 ± 0.7	57.2 ± 0.2
Cyclohexane	76.9 ± 0.6	57.5 ± 0.4	57.1 ± 0.2
Average	76.7 ± 0.7	57.6 ± 0.5	57.2 ± 0.4

Despite the differences in the degree of change in the retention diagrams, there was no significant probe-to-probe variation in the measured transition temperatures so that it is clear that the probes were not influencing and distorting the structural transitions. Under the conditions used in this work, the probe is at infinite dilution so that it would not be expected to influence the stationary phase. The lack of probe sample size effects would appear to confirm this.

Comparison of the average values shown in Tables 3–6 with the DSC results in Tables 1 and 2 shows excellent agreement to within 1°C. The change in $V°_g$ for LCP takes place over a range of 3–4°C, which is rather wider than seen for the low molar mass LCs, presumably due to the polydispersity of the polymer LC. The precision of the IGC technique is therefore comparable with that of, for example, DSC or polarized microscopy. Clearly, while not as convenient as DSC merely to measure the transition temperatures, IGC could be valuable since a number of other parameters (32, 36) can be measured in the same experiment, amongst which are thermodynamic properties such as activity coefficients that yield information on the interactions between the components in the system. It has previously been shown that deviations occur at the phase transitions in plots of activity coefficient (or their logarithm) versus reciprocal temperature. These results in our systems will be discussed elsewhere (36) but this treatment did not significantly increase the precision of the measurements.

Measurement of crystallization kinetics

The observation of metastable, supercooled phases described above led us to consider the use of IGC to investigate the kinetics of the crystallization to the solid crystal phase. In each of OCB and OBIB, the conversion from supercooled to crystal solid was too rapid to be measured conveniently with our current apparatus. Hence, HCB was used to investigate our method.

For these experiments, the column oven was held for some time in the nematic phase so that a consistent equilibrium value of $V°_g$ was measured. The temperature was then reduced

as rapidly as possible to below the transition temperature and values of V°_g recorded isothermally as a function of time. A plot of the results for the retention of five probes in HCB at 38.5°C is shown in Fig. 9. Several distinct regions can be seen in the curves. After an initial rapid fall in V°_g associated with the equilibration to the lower temperature, the values settled into two distinct regions. The first involved approximately 30–35% of the mass of the HCB and occupied around 8–10 h, after which the remainder of the compound crystallized at a rate that slowed as complete crystallization is approached.

If the values of V°_g at the start, at time t, and at the end of the crystallization process are denoted by $V^\circ_g(0)$, $V^\circ_g(t)$, and $V^\circ_g(\infty)$ respectively, the mass fraction of crystallinity, W_c, at time t is

$$[5] \quad W_c = \frac{V^\circ_g(t) - V^\circ_g(0)}{V^\circ_g(\infty) - V^\circ_g(0)}$$

The results obtained using *n*-heptane as the probe at four different temperatures are shown in Fig. 10. As expected, the solidification process proceeded faster at higher temperatures although there was no significant difference between the results at 43.6°C and those at 38.5°C. The two-stage nature of the solidification is particularly evident in these plots. The probe-to-probe reproducibility is excellent as shown by the results for five probes at 38.5°C shown in Fig. 11, all of which agree to well within experimental uncertainty.

The degree of crystallinity can be used in eq. [2] to calculate the Avrami parameters. Formally, the Avrami treatment refers to the volume fraction of crystallinity whereas IGC yields mass fraction values. However, the difference in density between the two phases will be small (36) so that the approximation has been made that the values will be equivalent. Modification and rearrangement of eq. [2] leads to:

$$[6] \quad \ln(\ln(1 - W_c)) = \ln K + n \ln t$$

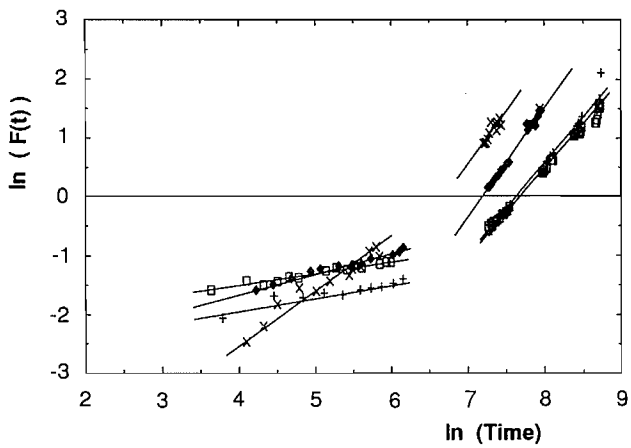
so that K and n can be measured from a suitable plot of the data. The plot of the results for *n*-heptane retention is shown in Fig. 12. While there was significant scatter in some of the results, particularly at early times, some general trends emerge. The data were particularly imprecise as the sample approached total crystallinity so that these data were not included in the analysis.

The two regions of crystallization can clearly be seen in the

Fig. 12. Avrami plot for crystallization of HCB. × 48.7°C; ◆ 46.6°C; + 43.6°C; ■ 38.5°C.



plot with the initial, faster crystallization being complete in approximately 10 h. The results recorded at 48.7°C have a different form from the other three temperatures, although it should be pointed out that there are relatively few data points at longer times due to the higher rate of the process. The reason for this is not clear, as it seems to be sufficiently far away from the equilibrium N → K transition temperature (~57°C) that thermal effects should not be important, but may be related to its proximity to the stable supercooled region. The plots at the other three temperatures showed very similar characteristics. The Avrami constants were calculated by performing a least-squares fit to the results in each of the two regions, the values being shown in Table 7.

The process in Region 1 is several orders of magnitude faster than that in Region 2 as shown by the K_1 and K_2 values, although it should be noted that the units will differ depending on the value of n. There is no clear trend of K_1 or K_2 values with the temperature. It should be noted that K_2 carries a large uncertainty due to the extrapolation of a steep portion of the graph and depends critically on the value of n_2. The values of the exponent, n, are very low compared with previous studies of bulk LCs. For example, Price and co-workers obtained a value of $n = 4$ for the transition to solid of several cholesteryl esters (37–39) while n was found to be 2 for the other transitions. The growth rate of crystalline spherulites was also found to be independent of temperature. Jabarin and Stein (40),

Table 7. Avrami constants for N′ → K transition of HCB.

Temperature (°C)	Region 1[a]		Region 2[a]	
	n_1	K_1/min^{-n}	n_2	K_2/min^{-n}
48.7 ± 0.3	0.80	3.7×10^{-3}	1.7	1.2×10^{-5}
46.6 ± 0.3	0.33	5.3×10^{-2}	1.9	7.0×10^{-7}
43.6 ± 0.4	0.21	9.8×10^{-2}	1.4	2.1×10^{-5}
38.5 ± 0.4	0.22	6.0×10^{-2}	1.6	3.8×10^{-6}

[a]The division between region 1 and region 2 is taken at ln (t/h) = 7.

using light scattering, measured n to be 3 for the I → C transition in cholesteryl myristate, suggesting that the growth involved disk-shaped spherulites. It should also be noted that while the crystallization of most polymers gives n values of 3–4, in a few examples, such as poly(*trans*-butene) and PTFE, results as low as 0.2 have been reported (41). The solidification of some thermotropic copolyesters (42) yielded values from 0.2 to 0.8.

There are two major differences between the current work and previous studies. Firstly, the transition being studied here is from a supercooled, and therefore more viscous, mesophase. Secondly, the HCB is spread as a thin film onto a solid support, which may place restrictions on the spherulite growth.

Chang and Wunderlich (42, 43) suggested that in similar situations, low values of n, even approaching zero, could be obtained. For example, crystallization from a viscous medium where mobility is restricted, described as a "cold crystallization," would restrict the rate of crystallite growth. Also, a situation where a large number of nucleation sites existed originally but decreased with time would add a negative time exponent, denoted a, further reducing n. Another factor is that if the solidification is dominated by a diffusion process, this would involve a t^m dependence of the crystal growth rate where m would normally be 0.5. These factors led Chang and Wunderlich to recast the Avrami equation [6] as:

$$[7] \quad \ln(\ln(1 - W_c)) = \ln K^* + \{n(1 - m) - a\} \ln t$$

Hence, our IGC results can be interpreted in these terms. The solid support would provide a relatively large number of nucleation sites for the early stages of the solidification, at which growth would be restricted due to viscosity and steric factors. The number of sites would reduce as the crystallites coalesced during growth. After this initial stage, crystallization continues in a more conventional 2- or 3-dimensional growth that is diffusion limited (i.e., $n = 3$ or 4). It is tempting to explain the two-stage process in terms of a nucleated solidification onto the support followed by a more conventional "freezing" of the remaining material. Preliminary calculations (36) suggest that the 30–35% of HCB involved in the primary crystallization is approximately that needed to coat the support. However, at this stage, this explanation is rather speculative and more work is necessary to fully elucidate the mechanism of the solidification. However, it is clear that IGC has a significant role to play in this type of work, particularly in systems where the transitions are relatively slow.

Conclusions

It has been shown that IGC can be used to measure the temperatures of a range of mesophase transitions in liquid crystals. It can be applied to a wide range of materials, both low molar mass and polymeric. The accuracy and precision are comparable with other techniques although IGC is slower and less convenient solely to measure the transition temperatures. This disadvantage is outweighed by the ability to measure other data such as thermodynamic activity coefficients and interaction parameters. This work has also demonstrated the potential of IGC as a method of following the kinetics of solidification in suitable mesogenic systems.

Acknowledgements

We are grateful to the Science and Engineering Research Council for the award of a research studentship (to I.M.S.) and particularly to Merck Ltd for providing the liquid crystals used in this work. On a more personal note, I would like to thank Jim Guillet for a stimulating two years spent in his laboratory and for the inspiration needed when starting out on a research career. I am more grateful than I can say!

Solid-state photochemistry of π-conjugated poly(3-alkylthiophenes)

Mohamed S.A. Abdou and Steven Holdcroft

Abstract: Films of poly(3-alkylthiophenes) undergo simultaneous photobleaching, cross-linking, and chain scission when irradiated in air with UV or visible light. The quantum yields of the latter two processes were determined using Chalesby–Pinner theory. Under the irradiation conditions employed the cross-linking density is ~4.5 times greater than the fracture density (chain scission). This corroborates the observation that poly(3-alkylthiophenes) are negative-type photoresists. Although the quantum yield of cross-linking is relatively low, the polymer maintains a relatively high degree of π-conjugation following irradiation. The mechanism of cross-linking and insolubilization proceeds via a classical photooxidation route that is initiated by photolysis of residual iron impurities. Photobleaching involves photosensitization, and reaction of singlet oxygen. $^1O_2$ undergoes a 1,4 Diels–Alder addition to thienyl units which results in a loss of π-conjugation, a blue shift in the absorption spectrum of the polymer, and a decrease in the optical density. Photobleaching, cross-linking, and chain scission are considerably reduced in the absence of oxygen.

Key words: photochemistry, polymers, thin films, degradation, cross-linking.

Résumé : Lorsqu'on les soumet à une irradiation UV ou visible dans l'air, les films de poly(3-alkylthiophènes) subissent des photoblanchiments, des réticulations et des scissions de chaînes simultanés. Utilisant la théorie de Chalesby–Pinner, on a déterminé les rendements quantiques des deux derniers processus. Dans les conditions d'irradiation employées, la densité de la réticulation est environ 4,5 fois plus grande que la densité de fracture (scission des chaînes). Ces résultats corroborent l'observation que les poly (3-alkylthiophènes) sont des photorésistances de type négatif. Même si le rendement quantique de la réticulation est relativement bas, le polymère maintient un degré relativement élevé de conjugaison π après l'irradiation. Le mécanisme de réticulation et d'insolubilisation procède par le biais d'une photooxydation classique qui est initiée par la photolyse d'impuretés ferriques résiduelles. Le photoblanchiment implique une photosensibilitation et la réaction d'un oxygène singulet. Le $^1O_2$ subit une addition-1,4 de Diels–Alder sur les unités thiényles qui provoquent une perte de conjugaison π, un déplacement vers le bleu dans le spectre d'absorption du polymère et une diminution de la densité optique. Les réactions de photoblanchiment, réticulation et scission de chaîne sont fortement réduites en l'absence d'oxygène.

Mots clés : photochimie, polymères, films minces, dégradation, réticulation.

Introduction

The effect of light on π-conjugated polymers plays an important role when they are utilized in specialized technical innovations such as optoelectronic devices, photoconduction (1), electroluminescence (2, 3), photovoltaics (4), and photolithography of semiconducting and electronically conducting polymer *wires* in the design of integrated circuitry and device fabrication (5–8). However, few studies probe the chemical reactions that result from the interaction of light with π-conjugated polymers. Studies of the photochemistry of π-conjugated polymers are thus necessary in order to understand the effect of light on these materials and to improve their properties.

Polyacetylene (PA) was one of the first conjugated organic polymers to undergo photochemical study. It was found that irradiation of the soluble Durham precursor to PA leads to photobleaching and insolubilization of the material (9, 10). The mechanism of photobleaching was explained by invoking reactions of singlet oxygen with the polymer. The origin of singlet oxygen was not discussed.

Photochemically induced insolubilization of another conjugated polymer, poly(*p*-phenylene sulfide) (PPS), has also been examined as a means to photoimage conjugated polymers (11). The technique uses a photooxidant and is based on the solubility difference between exposed (photooxidized) and unexposed (neutral) polymer. A soluble sulfur-phenylated PPS derivative can be employed for this application so that the photoacid generator, a triaryl sulfonium salt, is chemically bound to the polymer backbone (12). A detailed photochemical study of PPS has been performed using oligomers of phenylene sulfide and their halogenated derivatives (13). PPS is photodegraded by UV–VIS light. The reported mechanism of

photodegradation involves homolytic cleavage of the C—S bond via the singlet state to produce thiophenoxy radicals.

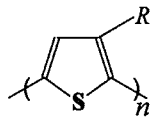
Photochemical reactions of precursors to π-conjugated poly(*p*-phenylene vinylenes) (PPV) have been investigated (14). Precursors derived from 1,4-bis(tetrahydrothiophenium salts) of benzene and its 2,5-derivatives are soluble in organic solvents. Photochemical elimination converts the insulating, soluble, precursor into the insoluble π-conjugated polymer. However, irradiation was performed with a 514 nm Ar^+ laser source, a wavelength at which the polymer films have very low absorption coefficients, and thus no elimination occurs upon direct photolysis even with high exposure doses (~350 W/cm^2). Photosensitizers such as azo-sulfonic dyes enhance the efficiency of photoelimination. Irradiation of the PPV precursor with 488 nm and 254 nm light, wavelengths at which the polymer precursor is highly absorbing, failed to completely convert the precursor to a fully conjugated polymer. Prolonged irradiation resulted in degradation products such as carbonyl and hydroxyl groups (15, 16).

Polyaniline (PANI) has also been subject to photochemical investigation for applications in photolithography (17,18). To date, lithography of such polymers has not been the result of photochemical reaction of PANI but rather photodoping reactions using photoacid generators, e.g., triphenyl sulfonium salts (12, 17). Photogenerated acids are effective dopants (oxidants) of the polymer. Photolithography is achieved because of the differential solubility between the doped and neutral polymer. Other methods used for photoimaging PANI include the reduction of doped polymer films containing semiconductor microparticulates and laser-induced electropolymerization (19, 20). The photochemistry of PANI in its various forms has been studied, e.g., leucoemeraldine, emeraldine base, and emeraldine salt forms (21). Exposure to light degrades the polymer, as manifested by the formation of carbonyl groups and a blue shift in the interband (π–π*) transition. Both of these observations indicate disruption of the conjugated system. The extent of degradation depends on the oxidation state of the material and the wavelength of excitation. The rate decreases with an increase in the doping level of the polymer.

Photolithography of polypyrrole (PPy) has been investigated in a similar manner to PANI, and includes photoelectrochemical polymerization of pyrrole on semiconductor electrodes (21), and photosensitized polymerization using sensitizers and sacrificial oxidizing agents (22). Laser ablation has also been used to image PPy but the technique damages the polymer surrounding the irradiated spot, thus producing patterns of low resolution (23).

Another important class of conjugated polymer are the poly(3-alkylthiophenes) (P3ATs). We have been investigating these systems in order to understand their photochemical degradation, offer rationale strategies for enhancing photostability, and design conjugated materials that act as both photoresists and electronic conductors (5–8, 24). Poly(3-hexylthiophene) degrades in nonaqueous solvents containing dissolved molecular oxygen when irradiated with UV or visible light. Degradation takes the form of both reduced π-conjugation and chain scission. The former manifests itself as photobleaching and is largely the product of photosensitization and reaction of singlet oxygen. Chain scission occurs via the classical route of photooxidation where scission is initiated by photolysis of trace amounts of transition metal salts.

Fig. 1. Chemical structure of poly(3-alkylthiophenes).



R = *hexyl*

The photochemistry of aqueous solutions of water-soluble derivatives of P3ATs containing alkanesulfonate substituents has also been investigated (8). Aqueous solutions of these polymers exhibit a substantial increase in photostability because the lifetime of the reactive intermediate, singlet oxygen, is much lower in aqueous solution.

We have previously shown that films of poly(3-alkylthiophenes) undergo cross-linking, and thus become insoluble in organic solvents when irradiated with UV-VIS light (6*b*). These characteristics make poly(3-alkylthiophenes) interesting candidates for photoresist technology since polymer films can be readily spin-cast onto solid substrates, irradiated through a photomask, and unexposed polymer removed by dissolution to provide a negative photoimage. Oxidation of the cross-linked polymer results in an electronically conducting pattern. In contrast to conventional photolithography, the soluble π-conjugated polymer acts as both the photoresist and the precursor to an electronically conducting pattern. In this paper, we wish to provide the photochemical details of the mechanisms of photo-oxidation, photocross-linking, and insolubilization of this class of polymer in the solid state (Fig. 1).

Experimental

Polymer synthesis

Poly(3-hexylthiophene) (P3HT) was prepared by oxidative coupling using $FeCl_3$ (25). The iron content of the polymer was determined by standard acid digestion procedures followed by atomic absorption analysis (24). The identity of the iron impurities was determined using Mössbauer spectroscopy (24). P3HT containing 1.3 wt.% iron was employed in this study. The molecular weight of the polymer was determined using gel permeation chromatography (26). The polymer possessed a number average molecular weight, M_n, of 10 000 and molecular weight distribution of ~3. The polymer also possessed an HT:HH ratio of 80:20 as determined by ^{1}H NMR (27). Polymer solutions were prepared by dissolving an appropriate amount of solid polymer in toluene, followed by filtration through a 0.2 μm filter to remove insoluble residues. Polymer films were prepared by spin casting. Thin films of polymer (0.1–0.25 μm) were spin-cast (2000–5000 rpm for 30 s) onto glass or quartz slides from dilute solutions of the polymer dissolved in toluene (10 mg/mL). Films were prebaked at 120°C for 30 min. The thicknesses of the polymer films were measured using a profilometer (Tencor Instruments, Alpha-Step 200).

Photolyses

The illumination source was a 150 W mercury lamp (Illumination Industries Ltd.). Irradiation was carried out using a 300 nm cut-off filter unless stated otherwise. The wavelength of irradiation was selected using an appropriate 10 nm bandwidth interference filter or cutoff filters. The temperature of the cell was maintained at 25°C using a cooling block and a circulating water bath. Photolysis was performed in ambient air,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

unless otherwise stated. The intensity of incident light at 435 nm was 1.39 mW/cm^2 as measured by radiometer/photometer (International Light, model L 1350).

Sol fraction (ref. 28)

Thin films of polymer (100 nm) were spin-cast onto quartz slides from dilute solutions of the polymer in toluene (10 mg/mL). After drying, the polymer films were exposed through the quartz. Back-side exposure was performed for evaluation of resist parameters. After irradiation, the soluble fraction was extracted by solvent development using chloroform. The sol fraction, S, was determined by measuring the optical density, OD, of the soluble polymer fraction following irradiation and development. The solubility of the polymer (sol fraction, S) was determined using the following equation (28, 29):

$$[1] \quad S + S^{1/2} = \frac{p_o}{q_o} + \frac{1}{q_o \overline{P}_n} \frac{1}{r}$$

where p_o and q_o represent the fracture and cross-linking densities per unit radiation dose, $\overline{P}_n$ is the number average degree of polymerization, and r is the absorbed irradiation dose. The ratio p_o/q_o indicates the relative amount of scission to cross-linking as a function of irradiation.

Lithographic parameters and quantum yield (ref. 30)

Lithographic parameters were determined from gel dose curves constructed by plotting the residual thickness of the polymer film after solvent development as a function of the energy absorbed by the polymer. The contrast of the photoresist, γ_n, is defined as the rate of insolubilization (or the rate of cross-linking) at a constant input energy. It is calculated using the equation:

$$[2] \quad \gamma_n = \frac{1}{\log D_g^0 - \log D_g^i} = \left[\log \frac{D_g^0}{D_g^i} \right]^{-1}$$

For negative photoresists, D^ig is the minimum radiation dose required to induce a reaction such that an insoluble gel (residue) of polymer remains after development. The sensitivity of the resist is signified by the exposure dose required to yield a particular response in the resist polymer after development. It is most commonly defined as the dose required to leave 50% of the original thickness. D^0g is the dose required to produce 100% gel formation of the original film and was determined by extrapolation of the linear portion of the sensitivity plot to a dose value equivalent to original film thickness, l_o.

The relationship between the quantum yield of cross-linking, Φ_x, and gel dose, r_{gel} is given by

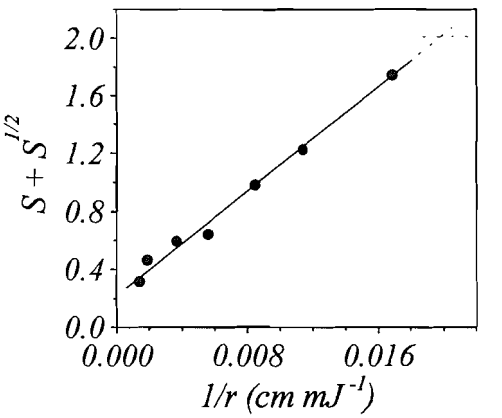
$$[3] \quad r_{gel} = \frac{\rho}{2 \times 2.303 \, M_w \varepsilon M \Phi_x}$$

where ρ is density, M_w is the weight average molecular weight, ε is the extinction coefficient of the chromophore, and M is its molarity in the solid film.

Instrumentation

FTIR spectra were recorded on a Bomem Michelson FTIR (120 series). The polymer samples were prepared by solvent evaporation in the form of thin polymer films on KBr discs. UV–VIS spectra were recorded on a Perkin Elmer Lambda 3A. Measurements were conducted at 25°C. Thin polymer films were prepared by spin coating of polymer solutions onto quartz slides. ^{13}C magic angle spinning/cross polarization (MAS/CP) NMR spectra were obtained using a TT-14 spectrometer modified for solid-state NMR studies. Differential scanning calorimetry (DSC) measurements were performed using a Perkin–Elmer DSC 7 calorimeter. The temperature was scanned over 380°C from −30°C with a heating rate of 5.0°C/min.

Fig. 2. Solubility curve of P3HT following irradiation with 435 nm light.



Results and discussion

Sol–gel properties of poly(3-alkylthiophenes)

Figure 2 shows a solubility plot of poly(3-hexylthiophene) films following irradiation with 435 nm light under ambient conditions. This graph was constructed by plotting the soluble fraction $S + S^{1/2}$ of P3HT films as a function of $1/r$ according to eq. [1]. The intercept of the linear plot at infinite exposure dose provides the ratio of photochain scission to photocross-linking, p_o/q_o. A value of 0.23 was calculated that indicates thin films of P3HT undergo simultaneous cross-linking and chain scission. From this, the crosslinking density, q_o, was found to be ~4.5 times greater than the fracture density, p_o. The energy required for incipient gelation of the polymer, r_{gel}, calculated from extrapolation of the linear plot to a sol fraction $S + S^{1/2} = 2$, was 49 mJ/cm^2, or 1.78×10^{-7} einstein/cm^2. Using eq. [3], the quantum yield of cross-linking, Φ_x, at 435 nm was calculated to be 2.37×10^{-3} mol/einstein^{-1}. Using the ratio p_o/q_o, the quantum yield of main-chain scission, Φ_s, was estimated to be 5.45×10^{-4} mol/einstein. Main-chain scission was indeed observed experimentally as evidenced by a decrease in M_n of the soluble extractable component of the polymer following irradiation and development.

The fact that cross-linking and insolubilization were observed meant the polymer was a suitable candidate for photolithography. The lithographic parameters of P3HT at 435 nm were determined from a sensitivity curve shown in Fig. 3 that was constructed by plotting the remaining thickness of polymer films after solvent development, l/l_o, against exposure dose. The gel content (film thickness) increased with

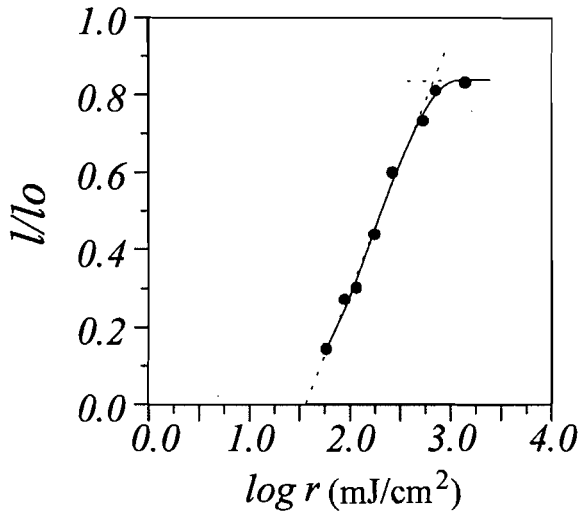
For personal use only.

Fig. 3. Sensitivity plot of P3HT using 435 nm light.



increasing exposure dose until the thickness remaining was similar to the original film thickness. The values of gel dose, r_{gel} (or D_g^i), sensitivity, $D_g^{0.5}$, and contrast, γ, were calculated to be 38, 190 mJ/cm^2, and 0.8, respectively. The gel dose values determined from both the solubility and sensitivity curves are in agreement to within ~25%.

In a previous study, lithographic parameters were investigated using much higher intensity laser light (442 nm He–Cd laser) (6). Lithographic parameters were similarly determined from gel dose curves constructed by plotting the residual thickness of the polymer image deposited on a substrate after solvent development as a function of the exposure dose. The dose of incipient gelation, D_g^i, was found to be 7.7 mJ/cm^2, the sensitivity at 50% gel formation, $D_g^{0.5}$, was 61 mJ/cm^2, and the contrast, γ_n, was 0.7. The discrepancy between values obtained by laser lithography (Cd–He laser irradiation) and conventional photolithography (Hg lamp irradiation) is due to the difference in irradiation intensity.

The effect of irradiation on the conjugation length and conductivity of P3HT was investigated. The change in π-conjugation can be monitored qualitatively by observing the change of optical density of the film with irradiation. Prolonged irradiation of thin films of P3HT at 435 nm in ambient air causes the optical density of the film to decrease. Figure 4 shows a plot of optical density of the polymer film (at λ = 500 nm) against the irradiation dose.

Neutral, undoped polymer film has a strong absorption band at 500 nm, indicating a significant degree of π-conjugation along the polymer backbone. The electronic transition of solid polymer films correlates to an effective conjugation length of ~6 thiophene units (31, 32). Figure 4 shows that the effective conjugation length of the polymer does not change appreciably for irradiation doses <300 mJ/cm^2; above this value the π-conjugation system was visibly disrupted (photobleaching). Photochemical insolubilization requires considerably less energy dosage than 300 mJ/cm^2; thus polymers can be rendered insoluble while maintaining extensive conjugation.

FTIR measurements on thin solid polymer films were used to determine which photochemical processes lead to an insoluble product. Figure 5 shows FTIR spectra of thin films of the

Fig. 4. Relative optical density (λ = 500 nm) of P3HT films versus irradiation dose (irradiation wavelength = 435 nm).

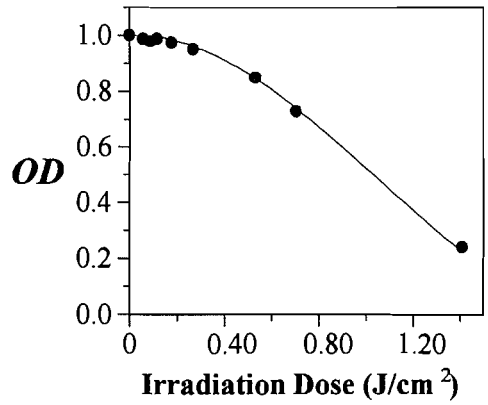


Fig. 5. FTIR spectra of P3HT films before and after 12 h irradiation. Irradiation in air with a polychromatic light (>300 nm).

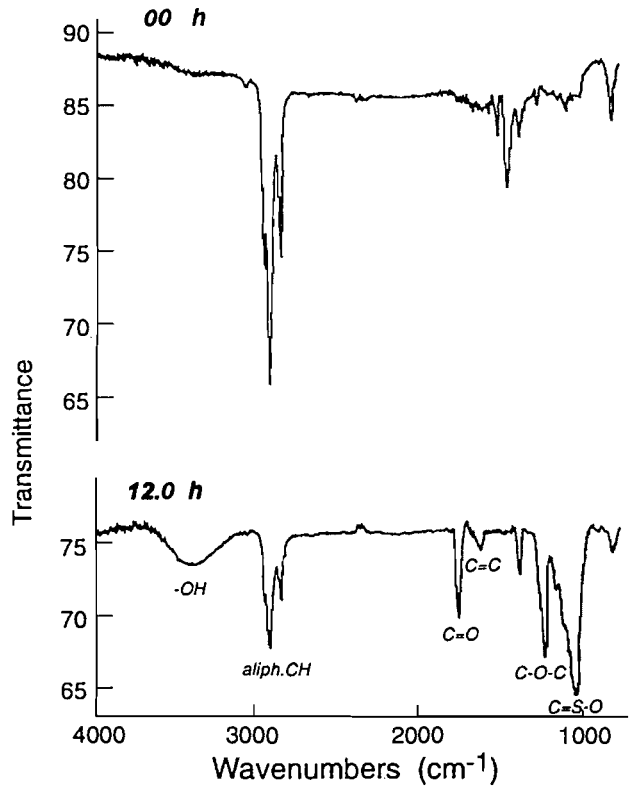

polymer before and after irradiation in air using polychromatic light (>300 nm). The following new IR bands appear in the spectra following irradiation: 3400, 1743, 1610, 1230, and 1045 cm^{-1}. The band at 2962 cm^{-1}, due to C–H stretching in the alkyl chain, decreases with exposure time. Prolonged exposure causes this band to disappear completely. The bands at 1743, 1610, and 1045 cm^{-1} were previously assigned to C=O, C=C, and C=S$^+$-O$^-$ residues and result from a 1,4 Diels–Alder addition of photosensitized singlet oxygen to thienyl moieties in the main chain (5, 24). Kinetic studies (Fig. 6) establish that these absorption bands evolve immediately upon irradiation and that all three bands increase in intensity at

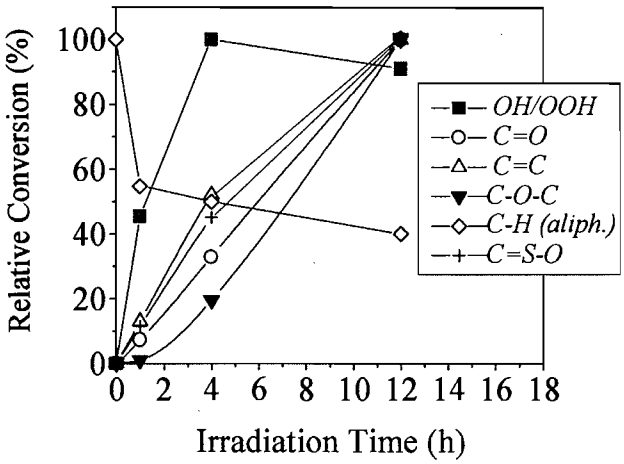
Fig. 6. Time-dependent evolution of functional groups during irradiation. Data obtained from FTIR spectra (see text for details). Irradiation of P3HT in air with polychromatic light (>300 nm).



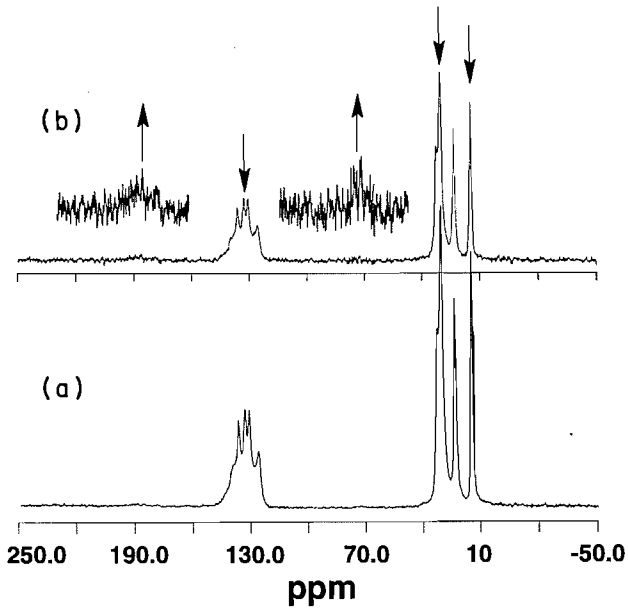
relatively the same rate. This indicates they are products of a common reaction pathway.

Assignment of the IR bands at 3400 cm^{-1} (-OH), and 1230 cm^{-1} (C-O-C, ether linkage) is made by invoking a mechanism of oxidative degradation and cross-linking of the alkyl side chain in analogy to that observed in the photooxidation of polyolefins (33). The mechanism of photooxidation of polyolefins, and presumably of alkyl side chains, begins with an initiation step in which an impurity, usually a transition metal ion, photosensitizes the generation of reactive free radicals. Potential photoinitiators of this process for films of P3HT are residual ferric salts that originate from the ferric chloride used in the polymerization of hexylthiophene. Extensive purification does not remove trace ferric salts. Even polymers purified by repeated recrystallization contain trace iron salts (>0.05 wt.%) (24).

Solid-state NMR was used to provide further information on the chemical changes in the polymer following irradiation. Figure 7 shows the ^{13}C spectra of P3HT before and after irradiation. Noteworthy is the formation of C-O and C=O functionalities as indicated by the NMR signals at ~70 and ~220 ppm, respectively. This was accompanied by a decrease in the carbon signals due to both the alkyl side chains (14–30 ppm) and the thienyl moieties (120–140 ppm). The changes in the NMR spectra of the photolyzed polymers are consistent with assignments made using FTIR data.

In studies of the photochemistry of the polymers in solution, it was found that irradiation causes both photobleaching and chain scission (5, 24). The former involves photosensitization, and reaction of singlet oxygen, while the latter followed a classical photooxidation route. Given this, it is probable that the photobleaching and cross-linking observed for films of P3HT also proceed via two independent reaction pathways. To test this hypothesis, singlet oxygen was generated ex situ, and its effect on cross-linking and photobleaching was examined. The hypochlorite – hydrogen peroxide system was chosen to generate singlet oxygen ($^1O_2$) for these studies since it does not contaminate the test sample with impurities (24). Reaction of thin films of P3HT (~100 nm) with singlet oxygen was monitored over a period of 20 h. The optical density of the film at

Fig. 7. MAS/CP ^{13}C NMR spectra of P3HT: (*a*) pristine polymer, (*b*) after 48 h irradiation. Irradiation in air with a polychromatic light (>300 nm).



500 nm decreased by ~ 20% but the polymer remained soluble. It is noteworthy that, in contrast to this, virtually no change in optical density was observed when the minimum irradiation dose was used to photocross-link the polymer. Thus, photobleaching appears to involve $^1O_2$ whereas cross-linking does not.

FTIR analysis of the polymer following exposure to $^1O_2$ showed strong signals due to sulfine (1090–1020 cm^{-1}), keto (1730 cm^{-1}), and olefinic (1650 cm^{-1}) residues. Notably, no hydroxyl or ether functionalities were observed. Reaction products are consistent with reported mechanisms observed for the reaction of $^1O_2$ with small-molecule thienyls (34, 35) and longer chain thienyls (5, 24). In this mechanism, shown in Scheme 1, $^1O_2$ undergoes a 1,4 Diels–Alder addition with thienyl units. Endoperoxide residues **2** may be envisaged as intermediates in the formation of the sulfine. However, their formation as primary oxygenation products can only be inferred from the photochemical products because endoperoxides derived from heterocyclic 1,4-dienes are generally unstable at room temperature (36) and decompose to form either the sulfine **3** or the *trans*-diketone **4**.

The dominant reaction leading to polymer photobleaching involves photosensitization, and reaction, of singlet oxygen. Photosensitization of singlet oxygen is often the result of triplet–triplet annihilation (Scheme 2).

Singlet oxygen generation via triplet states of polythiophene ($^3P^*$) appears unlikely, given the recent phosphorescence and transient spectroscopic data, which indicate a very low quantum yield ($<10^{-6}$) for triplet formation (37, 38)[2]. An alternative explanation for photosensitization of singlet oxygen is based on dissociation of an excited state charge transfer complex. Recently, it was demonstrated that photogeneration of singlet oxygen in solid films of polystyrene can

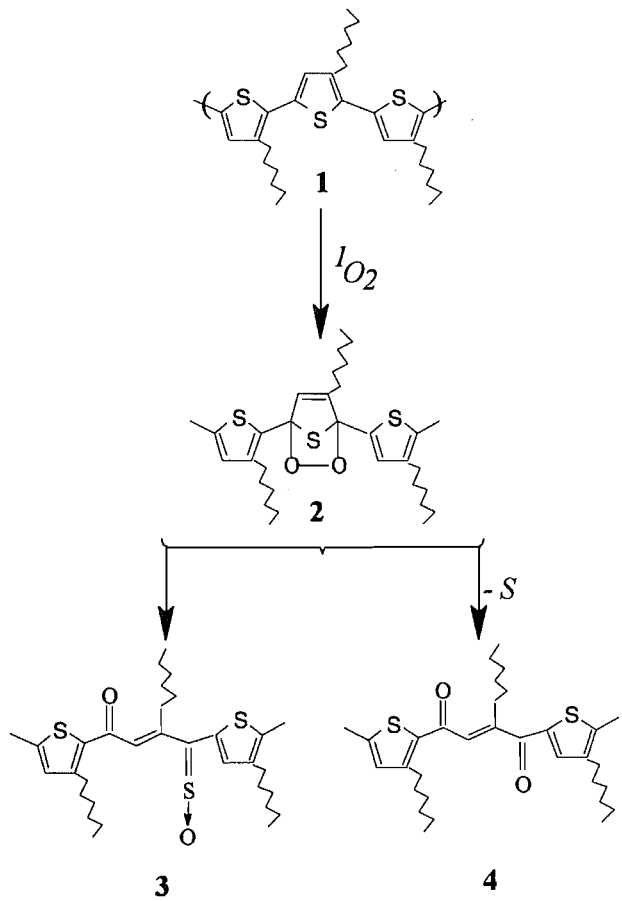
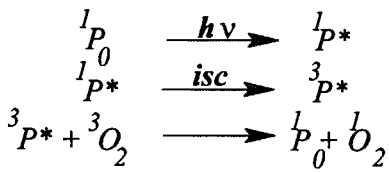
Scheme 1.



Scheme 2.

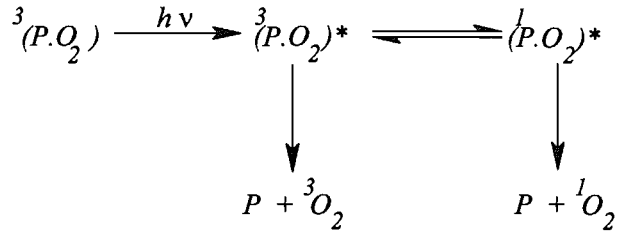


result from irradiation of oxygen–polystyrene charge transfer complexes (39). A similar mechanism can be anticipated for P3ATs. Indeed, the existence of a charge transfer complex formation between oxygen and P3ATs has been recently confirmed using optical and electron spin resonance spectroscopies, and electrical measurements (40). The following is a possible mechanism that describes the photosensitization process (Scheme 3) (41).

In this mechanism, the ground state P3HT·O_2 charge transfer complex (CTC) is a triplet due to multiplicity multiplication of the singlet ground state of P3HT and the triplet nature of molecular oxygen. Excitation of the P3HT·O_2 complex yields a triplet excited state that is close in energy to the excited singlet state (41). Dissociation of the latter is believed to yield singlet oxygen. The formation of $^1O_2$ from ^{3}CTC* is improbable because it is spin forbidden. Further photophysical studies are necessary to clarify this mechanism.

Photoinduced cross-linking appears to involve photooxidation of polymers and is rationalized in terms of a free-radical chain reaction comprising initiation, propagation, and termination steps. It is well documented that photooxidation reactions of saturated polymers such as polyethylene are initiated by photolysis of residual metal catalyst. In the case of P3ATs prepared by oxidative coupling using $FeCl_3$ the impurities are residual ferric salts (24, 42). We have previously shown that interaction of these impurities leads to chain scission in solution (24). The impurities were shown to be octahedral Fe(III) hydroxychloro complexes ($[Fe(H_2O)_4(OH)_2]X$) where X is a chloride or hydroxyl ion. These salts have broad electronic absorptions that extend from the UV to the visible region of the spectrum (~250–450 nm) (43). $Fe^{3+}\cdot X^-$ undergoes photoreduction to yield iron(II) and a free radical X$^\bullet$ according to eq. [4]:

Scheme 3.



[4] $Fe^{3+}\cdot X^- \xrightarrow{h\nu} [Fe^{2+}X^\bullet] \rightarrow Fe^{2+} + X^\bullet$

The resulting radicals (X$^\bullet$) are sufficiently reactive to abstract hydrogen atoms from most hydrocarbons (RH), thus initiating photodegradation reactions (eq. [5]).

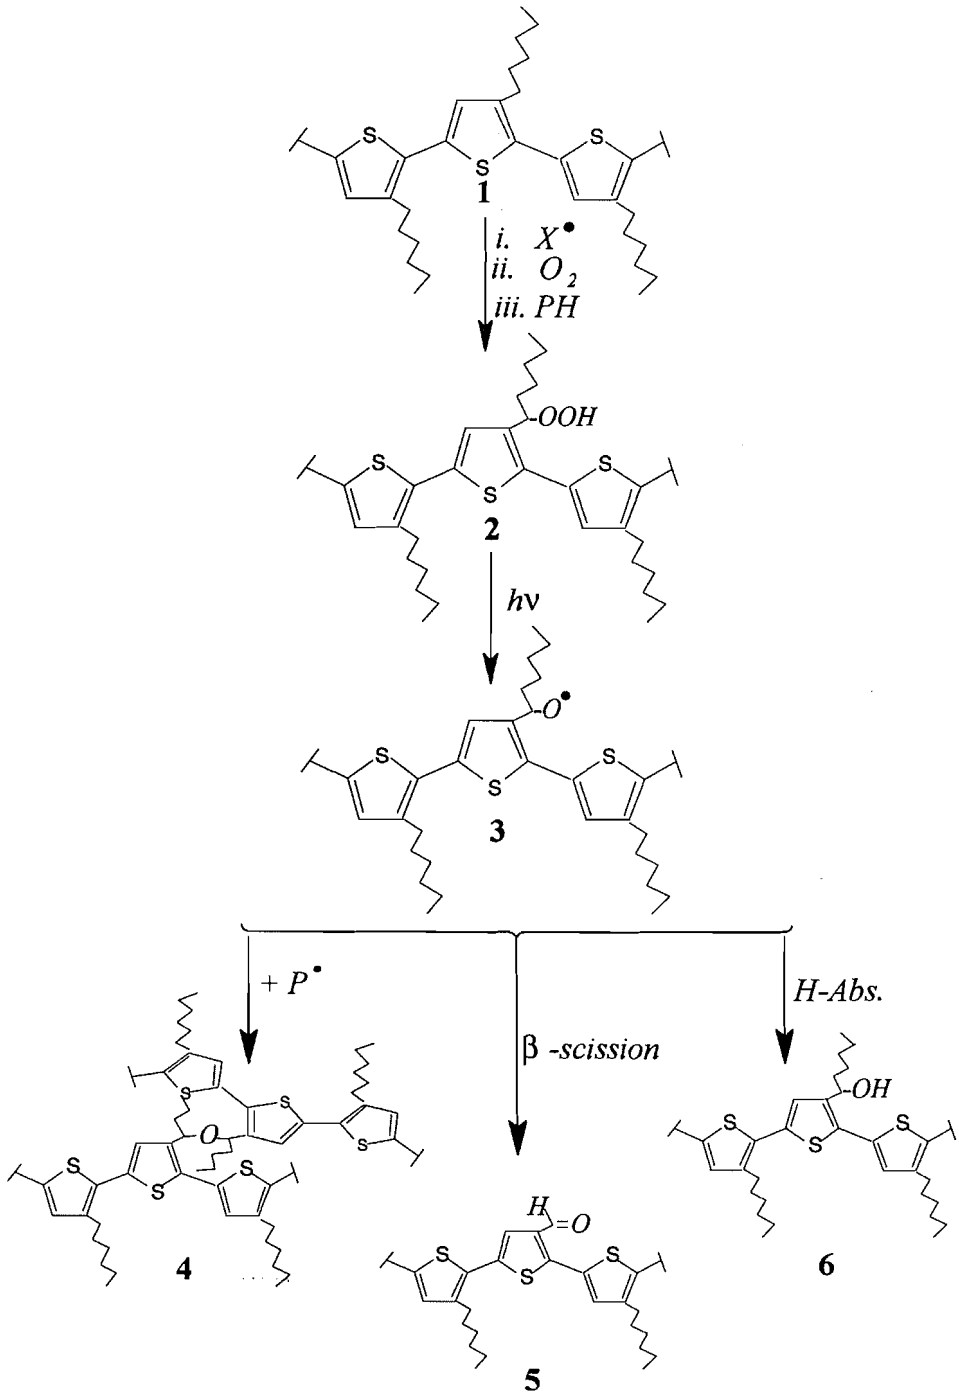
[5] $RH + X^\bullet \rightarrow R^\bullet + HX$

The primary point of H-abstraction from P3HT is the α-carbon atom of the alkyl group due to the lower dissociation energy of the α-C—H bond (44). Abstraction of an H-atom is presumably followed by the addition of oxygen to the polymer-bound radical and the formation of hydroperoxide. The rate of reaction of oxygen with free radicals is known to be diffusion controlled (45). Cleavage of the peroxide by the absorption of light, or by reaction with Fe(II) species, produces alkoxy radicals that can couple with polymer-bound radicals to form ether linkages (Scheme 4). OH radicals are produced in subsequent reactions. These propagate the photoxidation process by participating in additional H-atom abstraction reactions.

FTIR analyses of photolyzed P3HT is consistent with the proposed mechanisms and reveals the formation of ether groups (see Fig. 5). A kinetic study of the evolution of 3400 (-OH/-OOH) and 1230 (C-O-C) cm^{-1} bands (Fig. 6) further supports the proposed mechanism. The IR band at 3400 cm^{-1} reaches steady state after only a relatively short period of irradiation (<4 h). This implies that the rate of formation of these residues is equal to their rate of depletion. This is consistent with initial formation of hydroperoxide and its subsequent photolysis to form alkoxy radicals and OH. An induction period (~2 h) is observed for the formation of the ether band at 1230 cm^{-1}. The ether band then evolves continuously with irradiation and does not reach a steady state value even after 12 h of photolysis. This indicates that formation of the ether

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Scheme 4.



group is the result of a secondary photochemical reaction. This is consistent with the hypothesis that ether linkages form via the free-radical chain reaction.

When thin P3HT films were irradiated in an argon atmosphere, the films remained soluble in toluene and changes in the IR spectra were negligible, even after 24 h of photolysis.

The photochemical mechanism proposed for photooxidation of P3HT involves participation of the alkyl substituents. In the absence of the alkyl side chain one can anticipate that the photochemical properties of polythiophenes will be different. Parallel studies with side-chain-free α-hexathiophene and poly(thiophene) reveal the absence of photooxidation under the same experimental conditions used for P3HT, thus corroborating the hypothesis that alkyl side chains are involved in the photooxidation process. Photobleaching was still observed for these systems, however, since photosensitization and reaction of singlet oxygen are independent of the presence or absence of the alkyl side chain.

The thermal stability of P3ATs was investigated using differential scanning calorimetry (DSC) and FTIR spectroscopy.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

The DSC thermogram of P3HT under N_2 exhibited endothermic transitions at 55°C and 170°C. These transitions are assigned to T_g and T_m, respectively, and are consistent with thermal studies using dynamic mechanical analysis (46, 47) P3ATs underwent thermal decomposition in air at ~250°C. Under an inert atmosphere, the polymer was thermally stable up to 350°C. FTIR was used to provide insight into the mechanism of this process. Films of the polymer heated in vacuo at 200°C for 15 h remained completely soluble in organic solvents and FTIR spectra of the polymer before and after thermal treatment were identical. When polymer films were heated under identical conditions but in the presence of an oxygen atmosphere, the films were rendered insoluble. Films heated in oxygen exhibited almost identical FTIR spectra to those produced by irradiation of poly(3-hexylthiophene) in oxygen, i.e., a decrease in the intensity of the bands at ~2900 cm^{-1} (C-H) and an increase in the bands at 3400 (-OH) and 1230 cm^{-1} (C-O-C) were observed. However, the band at 1045 cm^{-1} due to sulfine ($C{=}S^{+}\text{-}O^{-}$) was absent in the thermally treated sample. This is not surprising since the sulfine residue, a photochemically generated product, arises from singlet oxygen formation. Indeed, photolysis of the thermally treated sample in oxygen generated the sulfine residue. It is evident that the reaction pathway involving singlet oxygen generation and Diels–Alder addition is not required for insolubilization of the polymer. The similarity of the thermal and photochemical products of poly(3-hexylthiophene) in the presence of oxygen implies similar chemical routes. It is well known from studies of polyolefins that thermal treatment in the presence of oxygen results in a free-radical chain reaction initiated by H-abstraction, followed by formation of hydroperoxide, peroxide bond cleavage, and cross-linking via ether bond formation (48). The same chemical events occur in the photooxidative process, the difference being that in one case the initial H-abstraction is thermally driven, while in the other it is photochemically driven.

Conclusions

Films of poly(3-alkylthiophenes) (P3ATs) undergo simultaneous cross-linking and chain scission when irradiated in air with UV or visible light. The mechanism of cross-linking and insolubilization proceeds via free-radical chain reactions that appear to be initiated by photolysis of residual iron impurities. The mechanisms of photocross-linking and insolubilization of poly(3-hexylthiophenes) described in this work are believed applicable to poly(3-alkylthiophenes) in general. It appears that cross-linking requires an α-CH_2 in the 3-position and would preclude poly(3-alkoxythiophenes) from exhibiting cross-linking. However, photobleaching might still occur for these polymers since this occurs via photosensitization and reaction of singlet oxygen.

Poly(3-alkylthiophenes) are thermally stable up to 350°C under inert atmosphere. In air, the material degrades at temperatures above 250°C. Degradation takes the form of autooxidation, which is initiated by residual metal impurities.

Abstract: Benzene derivatives give, in cyclohexane solution, a strongly emitting (Φ_f up to 0.8) excited complex with dibenzoylmethanatoboron difluoride ($DBMBF_2$). The rate constant k_{ex} for the complex formation varies between 3.5×10^9 and 2.6×10^{10} M^{-1} s^{-1} depending on the benzene derivative, and the complex emission can already be detected at very low concentrations of the aromatics. This behaviour is different from that found in acetonitrile where the $DBMBF_2$ emission disappeared completely before the new emission of the complex could be detected. The position of the complex emission and its lifetime depend upon the redox potential of the aromatics: the lower the latter, the longer the lifetime and the more the emission is red-shifted. The monotonous increase of the lifetime and of the fluorescence quantum yield of the emission with the concentration of the aromatics has been interpreted on the basis of an equilibrium between the exciplex and excited $DBMBF_2$. The equilibrium constant varies with the electron-donating property of the aromatics, from 2.7 for benzene to 560 M^{-1} for isodurene. A decrease in the excited complex lifetime or in its fluorescence quantum yield is observed in some cases when the aromatics concentration is close to that of the pure solvent. Such behaviour is believed to arise from a new equilibrium resulting from the interaction of the exciplex with a second molecule of the aromatics to form triplex species. A detailed kinetic study has been undertaken in case of *p*-xylene, and the rate constants of all the processes involved in the double equilibrium have been determined. No basic difference is observed in the rate constant for exciplex formation when a single or double equilibrium is assumed; on the other hand, large discrepancies are found in the exciplex deactivation processes, specially for the back reaction from the exciplex to excited $DBMBF_2$. The equilibrium constants between $DBMBF_2$ and the exciplex, on one hand, and between the latter and the triplex are 56.6 and 0.68 M^{-1}, respectively, when the concentration of *p*-xylene in cyclohexane is 3.3 M.

Key words: fluorescence, exciplex, triplex, dibenzoylmethanatoboron difluoride, kinetics.

Résumé : En solution dans le cyclohexane, les dérivés du benzène donnent un complexe excité fortement émissif (jusqu'à $\Phi_f = 0.8$) avec le difluorure de dibenzoylmethanatobore ($DBMBF_2$). Cette émission de fluorescence est déjà détectable aux faibles concentrations en dérivé du benzène. Ce comportement se distingue de celui observé dans l'acétonitrile où l'émission de $DBMBF_2$ disparait complètement avant que n'apparaisse celle de l'exciplexe. La constante de vitesse de formation de l'exciplexe varie entre $3{,}5 \times 10^9$ et $2{,}6 \times 10^{10}$ M^{-1} s^{-1} suivant l'aromatique. Dans le cyclohexane, le complexe émet à une longueur d'onde d'autant plus grande et sa durée de vie est d'autant plus élevée que le potentiel redox de l'aromatique est faible. L'augmentation régulière de la durée de vie et du rendement quantique de fluorescence de l'exciplexe résulte d'un équilibre entre le $DBMBF_2$ excité et l'exciplexe. La constante de cet équilibre varie de 2,7 à 560 M^{-1}; elle est d'autant plus élevée que le caractère électrodonneur de l'aromatique est grand. Une diminution de la durée de vie, ou du rendement quantique de fluorescence du complexe excité est observée avec certains aromatiques pour des concentrations très élevées. Ce phénomène a été expliqué par l'établissement d'un second équilibre formant un triplexe excité et mettant en jeu deux molécules du dérivé benzénique pour une de $DBMBF_2$. Une étude cinétique détaillée a été

entreprise dans le cas du *p*-xylène et les constantes de vitesse de tous les processus mis en jeu dans le double équilibre ont pu être calculées. On ne trouve pas de différence fondamentale dans la valeur de la constante de formation de l'exciplexe suivant le traitement à un ou à deux équilibres. En revanche, les constantes de vitesse des processus qui désactivent l'exciplexe intermédiaire, en particulier le retour à $DBMBF_2$ excité, diffèrent fortement suivant le traitement. Les constantes d'équilibre, entre $DBMBF_2$ et l'exciplexe d'une part, et entre ce dernier et le triplexe sont respectivement de 56,6 et 0,68 M^{-1} lorsque la concentration en *p*-xylène est 3,3 M.

Mots clés : fluorescence, exciplexe, triplexe, difluorure de dibenzoylméthanatobore, cinétique.

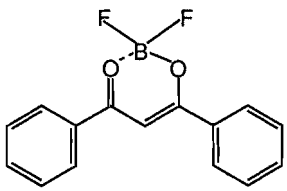
Introduction

Electron transfer constitutes an important chemical process because of its extensions in chemistry and biology. The quenching of the fluorescence of molecules by electron-withdrawing or electron-donating species is well established (1, 2). In some cases this quenching is accompanied by a weak and broad emission at wavelengths longer than the quenched fluorescence (3–5). The influence of the solvent on the course of the electron or charge transfer process has been intensively studied in both its theoretical (6–10) and experimental (11–14) aspects. Ultrafast (up to 10^{13} s^{-1}) electron transfer has been shown to occur between excited dyes and weakly polar electron-donating solvent molecules (15).



Dibenzoylmethanatoboron difluoride

Dibenzoylmethanatoboron difluoride ($DBMBF_2$) exhibits very different photoreaction and photophysical patterns in alkylbenzenes from those in acetonitrile or dichloromethane as solvents (16). $DBMBF_2$ fluoresces with moderate efficiency ($\Phi_f = 0.1$) in acetonitrile solution and its fluorescence has been found (17) to be quenched by alkylbenzenes, presumably through an exciplex formation. In acetonitrile, the quenching by toluene and *p*-xylene as a function of solvent fractions is unusual in that the quenching is straightforward at low concentrations of the quencher, but a strong, broad, structureless and red-shifted fluorescence, attributed to an exciplex, emerges at high mole fractions (>3 mol L^{-1} for toluene and >6 mol L^{-1} for *p*-xylene) of the aromatics, with a lifetime that increases with the proportion of the aromatics in the solvent mixture. In the quenching by benzene, the exciplex begins to emit with a lifetime that increases systematically with the benzene concentration, even at low concentration of the quencher.

A behaviour similar to that observed with benzene in acetonitrile is found with all the benzene derivatives studied (toluene, *m*-xylene, *p*-xylene, mesitylene, and isodurene) when cyclohexane is used as solvent. Then, the exciplex fluorescence quantum yield increases rapidly from $\Phi_f = 0.046$ in cyclohexane to become higher than 0.5 in all cases except isodurene. It is the aim of the present article to introduce a new series of strongly emitting excited complexes and, more specifically, to rationalize the evolution in lifetime and fluorescence quantum yield of the $DBMBF_2$ exciplex as the concentration of the benzene derivative is increased.

Experimental

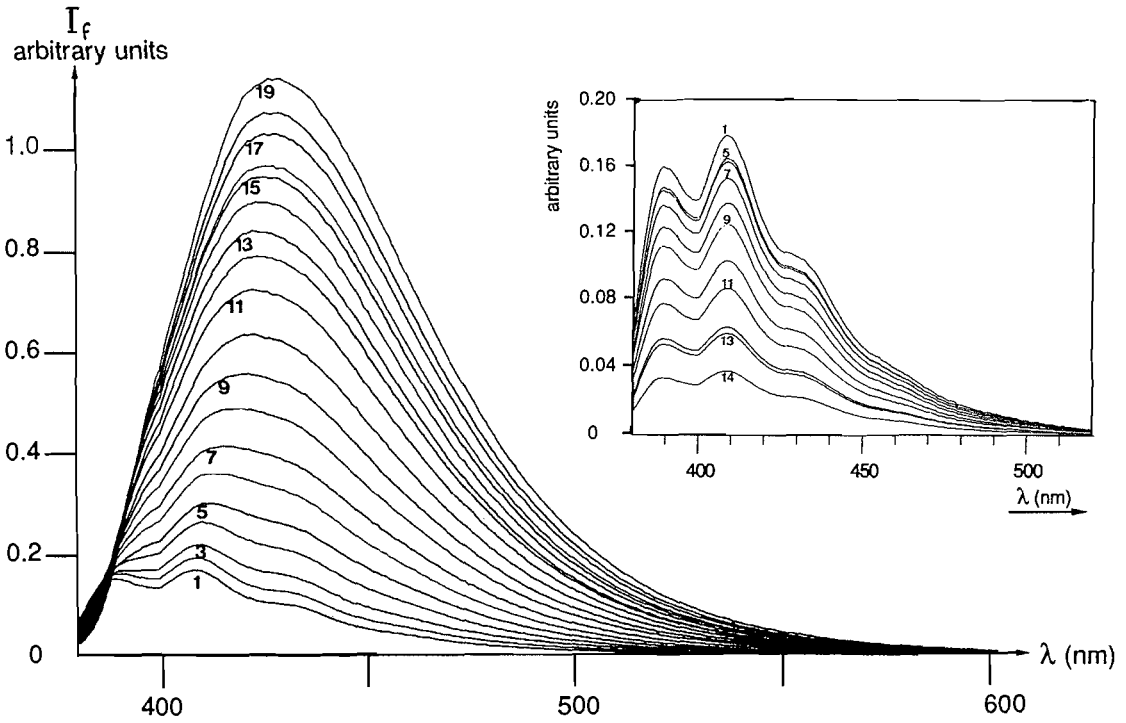
The UV–visible absorption spectra were obtained using a Varian–Cary model 219 apparatus. Fluorescence spectra were recorded with a SLM 8000C spectrofluorimeter equipped with a spectral correction unit by excitation at 389 nm. Fluorescence quantum yields were determined in pure cyclohexane solution, as well as in mixtures with benzene, toluene, *m*-xylene, *p*-xylene, mesitylene, and isodurene. A 10^{-4} mol L^{-1} solution of 5,6,8,9-tetrahydro-7-phenyldibenzo[*c*,*h*]xanthylium perchlorate in dichloromethane solution ($\Phi_f = 0.95$) was taken as secondary actinometer (18). The absolute fluorescence quantum yields are given with less than 10% error but their values relative to each other are estimated with less than 3% error.

Singlet lifetimes longer than 0.8 ns were measured with a frequency-tripled pulsed YAG laser (from B.M. Industries) of 30 ps fwhm. The light was focused through a cylindrical lens onto the sample placed in front of a photodiode. The output from the photodiode was fed into a Tektronix 7912 AD digitized oscilloscope and the data stored in an Apple II+ microcomputer were analyzed directly at any wavelength and compared to several kinetic treatments: mono-exponential with or without a residue, bi-exponential, combination of first and second order decays, ... The final curves were displayed on a Hewlett–Packard model 7470A graphic plotter. For lifetimes higher than 1 ns, the fitting of the curves was obtained with $\sum(y_i - y_{exp})^2$ smaller than 5×10^{-4}. For lifetimes lower than 2 ns, the fluorescence decay is measured with ca. 6% or less error, while for lifetimes higher than 4 ns the decay can be evaluated with less than 3% error. For shorter lived fluorescent species (<800 ps), the same laser was used with a TSN 506 streak-camera having ca. 10 ps time resolution. The fluorescence was focused through an optical coupling on the slit of the streak-camera and the data were transferred to a multichannel analyzer that permitted the accumulation of several decay measurements. In this way, lifetimes of 60 ps (±10%) or more could be handled as described for the data stored in the digitized oscilloscope.

The triplet signal and lifetime were determined using a frequency-doubled pulsed ruby laser (347.5 nm) from JK Laser following the experimental protocol already described (19).

Dibenzoylmethanatoboron difluoride ($DBMBF_2$) was prepared according to known procedures (16). Benzene (Aldrich, spectroscopic grade), toluene (Aldrich, ACS reagent), *m*-xylene (Aldrich, anhydrous), *p*-xylene (Aldrich, HPLC grade), mesitylene (Aldrich, 99% pure), and isodurene (Aldrich, 95+) were used as received.

Fig. 1. Fluorescence emission of the exciplex formed by addition of benzene to the cyclohexane solution of $DBMBF_2$. Benzene concentration (mol L^{-1}): (1) 0; (3) 0.27 M; (5) 0.88 M; (7) 1.68 M; (9) 2.92 M; (11) 4.64 M; (13) 5.78 M; (15) 7.52 M; (17) 9.40 M; (19) pure benzene. Inset: residual $DBMBF_2$ fluorescence spectra obtained by subtraction of the exciplex emission from the total luminescence at the following benzene concentrations (mol L^{-1}, from the upper to the lower curve): (1) 0; (5) 0.88 M; (7) 1.58 M; (9) 2.92 M; (11) 4.65 M; (13) 5.78 M; (14) 6.63 M.



Results and discussion

$DBMBF_2$ absorption and emission

The $DBMBF_2$ absorption band in the aromatic solvents was found identical in overall profile to that of $DBMBF_2$ absorption in cyclohexane but its position (maximum at 368 nm) is slightly red-shifted.

In cyclohexane solution, $DBMBF_2$ showed a fluorescence spectrum with maxima at 389, 409, and 432 nm. Its fluorescence quantum yield, Φ_f^{A0}, in the absence of aromatic quencher in cyclohexane solution and at room temperature (22 ± 1°C), equals 0.046 and its lifetime is 0.14 ns.

Flash photolysis of $DBMBF_2$ in cyclohexane solution gave an O_2 sensitive *T–T* absorption showing a maximum at 740 nm and a triplet yield Φ_T of the order of 0.01. In the absence of O_2, the triplet lifetime is 17.5 μs. The singlet to triplet intersystem crossing could be regarded as a negligible process in the deactivation of singlet excited $DBMBF_2$ to its ground state. Thus, in cyclohexane solution, the radiative and the nonradiative decays are the main deactivation processes of the $DBMBF_2$ singlet excited state. The corresponding rate constants, k_f^A and k_{nrA}, are easily deduced: $k_f^A = \Phi_f^{A0}/\tau_A^0 = 3.3 \times 10^8\ s^{-1}$ and $k_{nrA} = (1 - \Phi_f^{A0} - \Phi_T)/\tau_A^0 = 6.8\ 10^9\ s^{-1}$, respectively.

Quenching of $DBMBF_2$ fluorescence by the aromatics

Addition at room temperature (22 ± 1°C) of small amounts of the benzene derivatives to the cyclohexane solution of $DBMBF_2$ (at a concentration of ca. 3×10^{-5} mol L^{-1}) first modifies slightly the shape of the fluorescence spectrum by changing the relative intensities of the three peaks while the total fluorescence intensity is increased (Fig. 1). Further additions of the aromatics suppress the vibrational structure of the fluorescence, which changes into a new broad emission with a maximum shifted progressively from ca. 420 nm to 427 nm for benzene, 444 nm for toluene, 460 nm for *m*-xylene, 470 nm for *p*-xylene, 472 nm for mesitylene, and to 497 nm for isodurene.

The exciplex emission can be fully characterized in the solutions of pure benzene derivatives. Except with isodurene, the measurement of the quenching process by the aromatics is made difficult because of the overlap of $DBMBF_2$ fluorescence with the exciplex emission. The fluorescence spectra of the exciplexes obtained in the pure benzene derivatives have been taken as reference spectra to isolate the $DBMBF_2$ residual emission profile from the recorded total emission spectra by using the mathematical treatment already described (17). This technique introduces a small error as a result of a small bathochromic shift of the total emission profile at high aromatics concentrations. The quenching of $DBMBF_2$ fluorescence by benzene under steady state conditions is shown in Fig. 1 as an example. Having extracted the residual $DBMBF_2$ fluorescence spectra at various concentrations of the benzene derivative (inset of Fig. 1), the results have been used to evaluate the Stern–Volmer quenching rate constant K_{SV} from the plot of the ratio of the fluorescence in the absence (Φ_f^{A0}) and in the presence (Φ_f^A) of

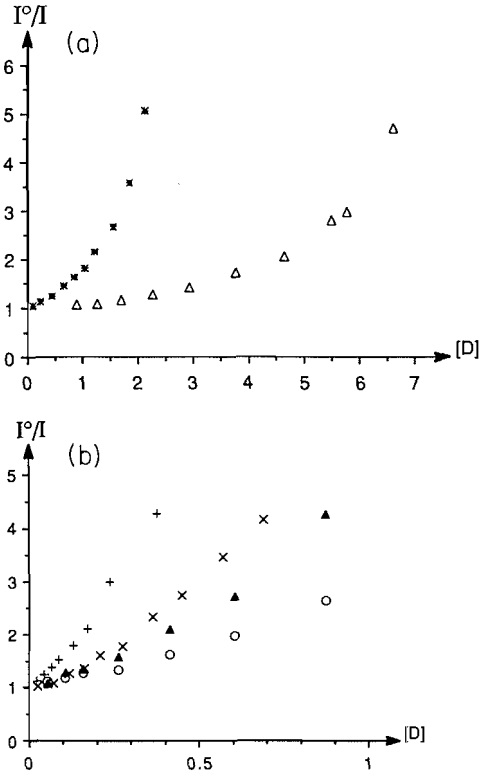
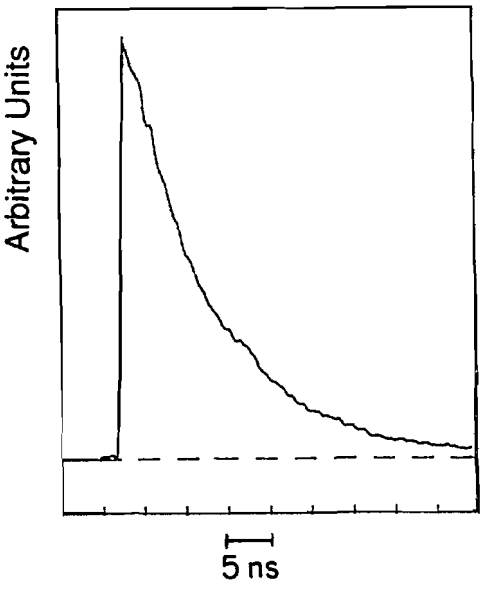
Fig. 2. Stern–Volmer plot of the quenching of $DBMBF_2$ fluorescence in cyclohexane solution ([D] in mol L^{-1}): (*a*) by benzene (△ △ △) and toluene (* * *); (*b*) by *m*-xylene (o o o), *p*-xylene (▲ ▲ ▲), mesitylene (× × ×), and isodurene (+ + +).



quencher vs. the concentration of the quencher. In all cases, the quenching does not give a straight line but shows (Fig. 2) an upward curvature, which occurs already at moderate concentrations of the quencher (ca. 1.5 mol L^{-1} for benzene, 1.0 mol L^{-1} for toluene, 0.5 mol L^{-1} for *m*- and *p*-xylene, 0.4 mol L^{-1} for mesitylene, and 0.2 mol L^{-1} for isodurene) and which, in the absence of any other process, could correspond to a static quenching. The curvature is more pronounced when the electron-donating properties of the aromatics increase (the oxidation potentials versus SCE are 2.38, 2.28, 1.88, 1.77, 1.80, and 1.73 V for benzene (20), toluene (20), *m*-xylene (20, 21), *p*-xylene (21), mesitylene (21), and isodurene (20), respectively). However, no ground state association could be detected in the absorption spectra of the mixture of the two compounds. An attempt to fit the data obtained on the basis of a double equilibrium, one to form a ground state charge transfer complex between $DBMBF_2$ and *p*-xylene and the other between excited $DBMBF_2$ and the exciplex, led to the conclusion that if such a ground state equilibrium does occur, its constant K_0 is lower than 10^{-3}. Evaluation of the K_{SV} constant has been carried out by fitting the experimental data of $\Phi_f^{A^0}/\Phi_f^A$ with a third-degree polynomial of the type $\Phi_f^{A^0}/\Phi_f^A = 1 + ax + bx^2 + cx^3$. The values obtained (Table I) show a monotonous increase of K_{SV} with the electron-donating character of the aromatics (from 0.1 M^{-1} for benzene to 3.4 M^{-1} for isodurene).

Fig. 3. Decay of the full fluorescence of excited $DBMBF_2$ in the presence of 3.27 mol L^{-1} of *p*-xylene in cyclohexane solution (5 ns per division).



Exciplex formation

Addition of the methyl-substituted benzene derivatives to a solution of $DBMBF_2$ in both polar and nonpolar solvents decreases the $DBMBF_2$ fluorescence intensity around 390 and 410 nm and gives rise to a new broad emission at longer wavelengths (from 430 to 495 nm, depending on the aromatics) that decays monoexponentially when analyzed in the nanosecond time range (Fig. 3). This emission increases and is steadily red-shifted as the concentration of the benzene derivative is increased, in agreement with an exciplex formation. The quenching of the singlet excited state of $DBMBF_2$ by 1,3-cyclohexadiene (E_{ox} = 1.58 V/SCE (22)) was reported earlier (23). The transformation of the latter into its radical cation by electron transfer to $DBMBF_2$ has already been reported (23) although no exciplex fluorescence could be observed.[3] Quenching of the fluorescence of $DBMBF_2$ by 1,4-cyclohexadiene (E_{ox} = 1.90 V/SCE (24)), 1,3-cyclooctadiene (E_{ox} = 1.89 V/SCE (25)), and 1-methylcyclohexene (E_{ox} = 1.77 V/SCE (26)) is also observed but, again, no exciplex emission could be detected. On the other hand, pyridine (E_{ox} = 2.12 V/SCE (24)) gives rise to a new emission around 418 nm. Thus, it seems likely that the aromatic π-electron system is needed for the quencher to give a fluorescent exciplex with $DBMBF_2$.

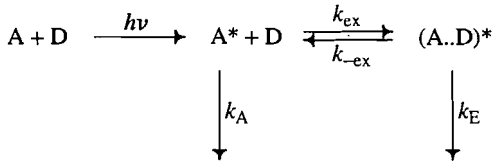
Stabilization of the exciplex, as the number of methyl substituents on the benzene ring increases, can be interpreted in terms of the lowering of the exciplex energy, which is visualized by the red shift of the exciplex emission as the oxidation potential of the aromatics decreases. A concomitant increase of the lifetime of the exciplexes from 2 ns with benzene all the way up to 22.9 ns with isodurene corroborates this stabilization.

Both the exciplex lifetime and fluorescence quantum yield increase progressively as the concentration of the aromatics increases. Such behaviour suggests that the exciplex is

[3] C.I. Johansson, unpublished results (Simon Fraser University).

formed reversibly and can be analyzed within the framework of Scheme 1:

Scheme 1.



where $k_A = k_f^A + k_{nrA}$ and $k_E = k_f^{ex} + k_{nrE}$. A and D represent $DBMBF_2$ and the benzene derivative, respectively. k_f^A and k_{nrA} are the radiative and nonradiative rate constants of excited $DBMBF_2$ in cyclohexane (in the absence of aromatic donor), k_f^{ex} and k_{nrE} being the corresponding rate constants for the $DBMBF_2$ exciplex (A..D)* at the concentration [D] of the aromatics, respectively.

$\tau_A^0 = (k_A)^{-1} = (k_f^A + k_{nrA})^{-1}$ corresponds to the lifetime of A* in the absence of D, while $\tau_{ex} = (k_E + k_{-ex})^{-1}$ is the lifetime of the exciplex at concentration [D] of the aromatic donor. The latter expression is valid because τ_A^0 is small compared to τ_{ex} and, therefore, the dissociation from (A..D)* to A* must be slow enough to be neglected. If the reverse is fast under the condition $\tau_A^0 \gg \tau_{ex}$, then τ_{ex} of the exciplex would be equal to τ_A^0 of $DBMBF_2$.

The decays measured on the ns time scale are all found to be first order at both the short and long wavelengths. However, in the short-wavelength range, where $DBMBF_2$ emits, the decay is found to be second order when analyzing on the picosecond time scale but, 0.42 ns after the laser pulse (after three lifetimes of $DBMBF_2$ fluorescence in the absence of any aromatics), the $DBMBF_2$ emission intensity has decreased by a factor of 20 to become negligible. When the aromatics are present, this intensity is even more reduced after the same time interval due to the quenching process and, even when the two emissions do not overlap, $DBMBF_2$ fluorescence decays in the ns range because of its equilibrium with the exciplex.

Application of the steady state assumption to A* and to (A..D)* under continuous irradiation conditions of the cyclohexane solution of A + D leads to the following expressions for $DBMBF_2$ (Φ_f^A) and exciplex (Φ_f^E) fluorescence quantum yields:

$$[1] \quad \frac{I^0}{[A^*]} = k_A + \frac{k_{ex}k_E[D]}{k_{-ex} + k_E}$$

$$[2] \quad \Phi_f^A = \frac{k_f^A}{k_A + \dfrac{k_{ex}k_E[D]}{k_{-ex} + k_E}}$$

$$[3] \quad \Phi_f^E = \frac{k_f^{ex}k_{ex}[D]}{k_{-ex} + k_E} \times \frac{1}{k_A + \dfrac{k_{ex}k_E[D]}{k_{-ex} + k_E}}$$

Combining expressions [2] and [3] gives

$$[4] \quad \frac{\Phi_f^E}{\Phi_f^A} = \frac{k_f^{ex}k_{ex}[D]}{k_f^A(k_{-ex} + k_E)} = \frac{k_f^{ex}}{k_f^A} k_{ex}\tau_{ex}[D]$$

while relation (2) leads to

$$[5] \quad \frac{\Phi_f^{A0}}{\Phi_f^A} - 1 = \frac{k_{ex}k_E[D]}{k_A(k_{-ex} + k_E)} = K_{SV}[D]$$

Φ_f^{A0}, the fluorescence quantum yield of $DBMBF_2$ in the absence of the aromatic donor D, is measured easily; $(k_A)^{-1}$, which corresponds to the lifetime of $DBMBF_2$ in cyclohexane in the absence of benzene derivative, is known; $(k_{-ex} + k_E)^{-1}$, the lifetime of the exciplex at the concentration [D] of the aromatics, can be measured.

In the pure aromatics solution, the exciplex fluorescence quantum yield is high (see Table 1) and its lifetime τ_{ex} increases with the number of methyl substituents on the benzene ring: e.g., 2.0 ns in benzene, 4.0 ns in toluene, 8.2 ns in *m*-xylene, 14.4 ns in *p*-xylene, 13.6 ns in mesitylene, and 22.9 ns in isodurene. At the same time, the emission maximum undergoes a bathochromic shift increasing with the reduction potential of the donor (see Table 1). The plot of the fluorescence quantum yield versus the concentration of the aromatics shows that all the curves appear (Fig. 4) to have two slopes and to asymptotically approach their maxima at lower concentration with more substituted benzene, and even with benzene, although less pronounced with the latter. The quantum yield even decreases slightly above a certain concentration of the aromatics, as observed for *m*- and *p*-xylene as well as for isodurene. The same phenomenon is also observed when plotting the exciplex lifetime as a function of the aromatics concentration (Fig. 5). But it is only in the case of isodurene that the lifetime of the exciplex reaches a maximum and then decreases. Such behaviour, which may involve an additional deactivation pathway for the exciplex due to the increased benzene derivative concentration, will be discussed later.

As far as we are aware, there exist only few examples in the literature (27) describing exciplex fluorescence quantum yield enhancement of more than one order of magnitude (up to 0.8) with respect to that of the parent compound itself. A red shift by more than 100 nm (>5100 cm^{-1}) of the exciplex emission with respect to the position of the $DBMBF_2$ absorption maximum makes these exciplexes interesting as potential laser dyes.

When plotting the reciprocal of the exciplex fluorescence quantum yield versus the reciprocal of the aromatics concentration (eq. [6]), one can (*i*) get the maximum value reached by this quantum yield when the concentration of the aromatics is infinitive; (*ii*) deduce the ratio k_E/k_f^{ex} from the intercept of the plot:

$$[6] \quad \frac{1}{\Phi_f^{ex}} = \frac{k_E}{k_f^{ex}} + \frac{1}{k_f^{ex}k_{ex}\tau_A^0\tau_{ex}[D]}$$

We already pointed out (vide supra) that the increase of the exciplex (A..D)* lifetime with the concentration of the aromatic (Scheme 1) arises from its equilibrium with the starting excited $DBMBF_2$ (A*). This equilibrium must be strongly displaced toward the exciplex in the pure aromatics and, under such conditions, the quantum yield Φ_{-ex} of the back reaction (A..D)* → A* could be neglected with respect to the quantum yield Φ_E of the intrinsic deactivation of the exciplex, i.e., $k_{-ex} \ll k_E$. This hypothesis agrees with the high values of the exciplex fluorescence quantum yields obtained for all the benzene derivatives studied except isodurene.

Since $\Phi_E = \Phi_{ex}k_E\tau_{ex}$ and $\Phi_f^{ex} = \Phi_{ex}k_f^{ex}\tau_{ex}$, relation [6] indicates that the intercept of the plot of $1/\Phi_f^{ex}$ vs 1/[D] corresponds also to the ratio Φ_E/Φ_f^{ex} at infinite dilution. However,

there is one ambiguity in this plot because the maximum value that the concentration of the aromatics can take is when it constitutes the solvent itself: 11.2 M for benzene, 9.4 M for toluene, 8.2 M for *m*-xylene, 8.1 M for *p*-xylene, 7.2 M for mesitylene, and 6.6 M for isodurene. Because of this ambiguity, two values of the Φ_E/Φ_f^{ex} ratio have been evaluated (see Table 1). One, $(1/\Phi_f^{ex})_\infty$, corresponds to the intercept of the plot, which is obtained using only values of Φ_f^{ex} at low concentrations of the aromatics, thus eliminating any additional processes occurring at high concentrations. The other,

[a]Stern–Volmer constant.
[b]Using the values deduced for the maximum values of Φ_f^{ex} and τ_{ex}.
[c]Equilibrium constant calculated with relation [9].

$(1/\Phi_f^{ex})_{max}$, is based on the fact that the concentration of the quencher cannot be higher than the number of moles of the quencher contained in 1 L of solution; putting the different values of [D]max and the experimental values obtained for $(\tau_{ex})_{max}$ in eq. [6] gives the $(\Phi_f^{ex})_{max}$ values shown in Table 1.

As the intercept corresponds to the Φ_E/Φ_f^{ex} ratio, knowledge of $(\Phi_f^{ex})_{max}$ allows determination of Φ_E (the sum of the intrinsic radiative and nonradiative quantum yields of the exciplex) and of $(\Phi_{nrE})_{max}$. The deactivation rate constants of the exciplex, k_f^{ex} and k_{nrE}, can easily be obtained since the lifetime of the exciplex in the pure benzene derivatives is known, and since the quantum yield Φ_{-ex} for the return of the exciplex to excited $DBMBF_2$ can be ignored.

The calculations were performed using two sets of data. One is deduced from the plot of $1/\Phi_f^{ex}$ versus 1/[D] according to relation [6] while the other set uses the maximum values measured for the exciplex lifetime $(\tau_{ex})_{max}$ and for the fluorescence quantum yield $(\Phi_f^{ex})_{max}$.

The quantum yield for exciplex formation Φ_{ex} can be calculated from the expression $\Phi_f^{ex} = \Phi_{ex} k_f^{ex} \tau_{ex}$ as long as τ_{ex}, Φ_f^{ex}, and k_f^{ex} are known.

Table 1 gives the values of τ_{ex}, Φ_f^{ex}, Φ_{nrE}, and Φ_{ex} calculated in both cases, and of the rate constants k_f^{ex}, k_E, and k_{nrE}.

Once τ_{ex} and Φ_f^{ex} are known, the rate constant for exciplex formation k_{ex} can be obtained from expression [7], which is deduced from eq. [6].

$$[7] \quad k_{ex} = \frac{1}{k_f^{ex} \tau_A^0 \tau_{ex} [D] \left(\frac{1}{\Phi_f^{ex}} - \frac{k_E}{k_f^{ex}} \right)}$$

This has been done at low concentrations (<1 M) of the aromatic donor since k_f^{ex}, τ_A^0, and k_E are already known, while Φ_f^{ex} and τ_{ex} were measured for various concentrations of the aromatics [D].

Toluene is an exception in the series since the plot of $1/\Phi_f^{ex}$ versus 1/[D] gives an intercept smaller than unity, which is meaningless. Therefore the ratio (k_E/k_f^{ex}) used to determine k_{ex} for toluene is the one calculated for $1/\Phi_f^{ex}$ at the concentration of pure toluene, 9.4 mol L^{-1}.

The data given in Table 2 for k_{ex} correspond to the average of the different k_{ex} values determined according to relation [7] for all concentrations <1 M of the aromatics. It can be seen that the value of k_{ex} measured by this method increases regularly with the electron-donating property of the aromatics to become larger than the diffusion rate constant k_{diff} of cyclohexane ($k_{diff} = 6.7 \times 10^9$ L mol^{-1} s^{-1}) for all the aromatics except benzene and toluene. However, with the proportion of the aromatics increasing in the reaction mixture, k_{diff} also increases slightly since it is larger (28) for the aromatics (at least for benzene, $k_{diff} = 1.0 \times 10^{10}$ L mol^{-1} s^{-1}, and for toluene $k_{diff} = 1.1 \times 10^{10}$ L mol^{-1} s^{-1}) than for cyclohexane. So, although the values obtained for k_{ex} must be regarded as an estimate, their increase with the electron-donating properties of the aromatics is a good indication that the process involves the formation of a charged species. That k_{ex} is found to be larger than the diffusion rate constant is evidence of the surrounding of $DBMBF_2$ by several molecules of the benzene derivative at high concentration (>1 M) and, therefore, the involvement of a static quenching process. As already stated, no equilibrium between the two entities and a charge transfer complex seems to be operating in the ground state.

The rate constant k_{-ex} for the back reaction from the exciplex to excited $DBMBF_2$ can be deduced from the rearrangement of the Stern–Volmer constant K_{SV} given in relation [5]:

$$[8] \quad k_{-ex} = k_E \left(\frac{k_{ex} \tau_A^0}{K_{SV}} - 1 \right)$$

The values deduced from this expression can be found in Table 2. They show for all the aromatics used, with the exception of benzene, that the rate constant of the back reaction from the exciplex to the parent excited $DBMBF_2$ is always smaller than that of the complex formation. This also means that the value of the equilibrium constant K_1 existing between (A* + D) and (A..D)* must be important. This constant K_1 as formulated by relation [9] now becomes accessible since the three rate constants k_{ex}, k_{-ex}, and k_E have been calculated.

$$[9] \quad K_1 = \frac{[(A..D)^*]}{[A^*][D]} = \frac{k_{ex}}{k_{-ex} + k_E}$$

The equilibrium constant values obtained for benzene and its five derivatives can be found in Table 2. As can be seen, only with benzene is this constant small due to a non-negligible back reaction from the exciplex to excited $DBMBF_2$.

The value obtained for K_1 increases with the number of

For personal use only.

methyl substituents bound to the aromatics. This behaviour was expected from the steady state fluorescence-quenching experiments; effectively, high concentrations of the aromatics were needed in the case of benzene and toluene, corresponding to the smallest quenching rate constants of the series of compounds, while the quenching already occurred at low concentrations of the good electron-donating aromatics.

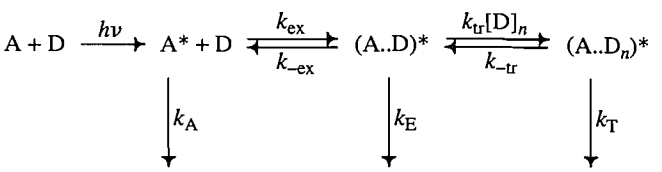
Double equilibrium. Triplex formation

To a first approximation, the equilibrium between A* and (A..D)*, proposed to explain the increase in lifetime of the exciplex as the concentration of the aromatics is increased, is valid for benzene and toluene since the plot of $1/\Phi_f^{ex}$ versus 1/[D] gives almost straight lines. However, for toluene, we already noted that the intercept of this plot has a meaningless value lower than unity.

On the other hand, the plot of the fluorescence quantum yield as a function of the concentration of the aromatics shows curves with at least two slopes, and this is visible even for benzene (Fig. 4). Also, the fluorescence quantum yield of the exciplex, obtained with the xylenes, mesitylene, and isodurene, increases with the proportions of the aromatics in the solvent mixture, reaches a maximum value for a certain concentration of the aromatics, and decreases or remains approximately constant at high concentrations of the aromatics. Similar behaviour was previously found in acetonitrile solution for the exciplex given by $DBMBF_2$ with toluene and *p*-xylene (17). This behaviour could have been taken as an indication that the stabilization of the exciplex depends upon the polarity of the solvent (17). However, here, the dielectric constant of the solvent varies very little between cyclohexane (ε = 2.023) and the aromatics (29): ε = 2.284 for benzene, 2.379 for toluene, 2.374 for *m*-xylene, 2.270 for *p*-xylene, and 2.279 for mesitylene. Furthermore, since the ε values for *p*-xylene and mesitylene are closer to that of cyclohexane than the ε value of benzene, the effect should be more important with benzene than with *p*-xylene. This is not the case, and the formation of the exciplex increases monotonously with the concentration of benzene. Furthermore, the effect should be most pronounced with toluene and with *m*-xylene since they have the highest ε values of the aromatics investigated. Again, this is not the case. Therefore, a solvent effect cannot be a plausible explanation for the observed concentration effect.

An alternative possibility to explain the evolution of the exciplex observed at high concentrations of the benzene derivatives would be the formation of a triplex (and (or) a multiplex) in which two (or more) aromatic donor molecules are associated with $DBMBF_2$. However, since the excited species decays monoexponentially, the triplex (and (or) multiplex) must not only emit in the same region as the exciplex but must also be in equilibrium with the exciplex and have a fluorescence quantum yield different from that of the exciplex. Scheme 2 illustrates such a double equilibrium involving an exciplex and a triplex (or multiplex):

Scheme 2.



k_A and k_E have the same meaning as in Scheme 1; $k_T = k_f^{tr} + k_{nrT}$ represents the intrinsic deactivation rate constant of the triplex (or multiplex) in the absence of back reaction from (A..D_n)* to (A..D)*.

With the hypothesis of a triplex species (n = 2), the regular increase of both Φ_f^{ex} and τ_{ex}, to reach their maximum values in the pure aromatics, means that the triplex has a higher fluorescence quantum yield and a longer lifetime than the exciplex itself (this is observed with benzene, toluene, and mesitylene).

On the other hand, when both the quantum yield and the lifetime of the fluorescence first increase but then decrease at high concentration of the aromatics, as is the particular case with isodurene, two hypotheses can be put forward: (*i*) either the triplex is in equilibrium with the exciplex but has a lower fluorescence efficiency and a shorter lifetime than the exciplex, or (*ii*) the formation of the triplex is less efficient than that of the exciplex and is irreversible.

A third case is found here, with the *m*- and *p*-xylenes, where the lifetime of the complex increases continuously with the concentration of the aromatics while its fluorescence quantum yield first increases and then begins to decrease at high concentrations of the aromatics. Such behaviour can be taken as an indication that the triplex has a longer lifetime but a lower fluorescence quantum yield than the exciplex.

Figures 4 and 5 present the evolution of the fluorescence quantum yield and of the fluorescence lifetime, respectively, as a function of the concentration of the benzene derivatives. They illustrate well the three cases described above.

Yet, the decrease of the lifetime and (or) of the fluorescence quantum yield at high concentrations of the aromatics could be interpreted in terms of quenching of the exciplex by the aromatics and could correspond to triplex formation. Then, both the lifetime and the quantum yield of the exciplex fluorescence should decrease, as found with isodurene. However, such a process cannot be operating with the xylenes since their fluorescence lifetime increases continuously with the concentration of the aromatics. For all the aromatics studied here, the polarity of the solvent mixtures remains practically constant; consequently, no shift of the exciplex emission should occur even at high concentrations of the aromatics if the process involved was a simple quenching of the exciplex. This is not the case, as shown in Fig. 6 with a 13 nm bathochromic shift at high concentrations of *p*-xylene. Similarly, a 10 and 24 nm red shift is observed in the high concentration ranges for mesitylene and isodurene, respectively.

Triplex formation with *p*-xylene

The triplex approach has been undertaken in the case of *p*-xylene because of the high fluorescence quantum yield and the long lifetime observed for the excited complex at the various concentrations in *p*-xylene.

Application of the steady state assumption to A*, (A..D)*, and (A..D_2)* under continuous irradiation of the cyclohexane

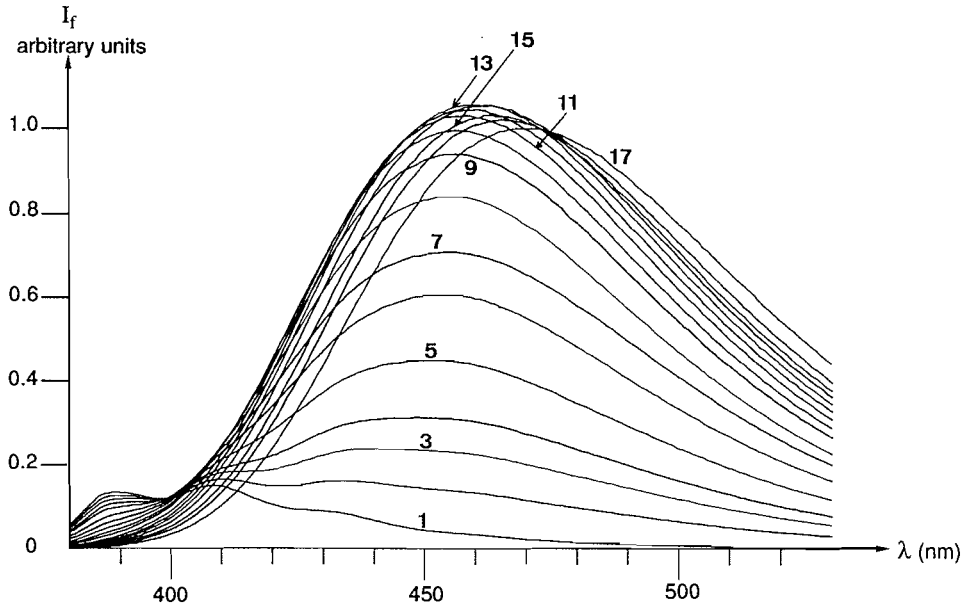
Fig. 6. Fluorescence emission of the exciplex formed by addition of *p*-xylene to the cyclohexane solution of $DBMBF_2$. *p*-xylene concentration (mol L^{-1}): (1) 0; (3) 0.11 M; (5) 0.26 M; (7) 0.61 M; (9) 1.17 M; (11) 2.04 M; (13) 3.27 M; (15) 5.11 M; (17) pure *p*-xylene.



solution of A + D leads to new expressions of the quantum yields as a function of the concentration of D. Thus the Stern–Volmer expression is changed into:

$$\frac{\Phi_f^{A^0}}{\Phi_f^A} - 1 = k_{ex}\tau_A^0[D]\left\{\frac{1}{\tau_E^0\left[(k_{-ex}+k_E)+\dfrac{k_{tr}k_T[D]}{k_{-tr}+k_T}\right]} + \frac{k_{tr}k_T[D]}{(k_{-ex}+k_E)(k_{-tr}+k_T)+k_{tr}k_T[D]}\right\}$$

Incorporation of the equilibrium constant K_2 between the exciplex (A..D)* and the triplex (A..D_2)* species

$$[10]\quad K_2 = \frac{[(A..D)^*]}{[(A..D)^*][D]} = \frac{k_{tr}}{k_{-tr}+k_T}$$

in the above Stern–Volmer expression leads to:

$$[11]\quad \frac{\Phi_f^{A^0}}{\Phi_f^A} = 1 + \frac{k_{ex}\tau_A^0[D]}{\tau_E^0[(k_{-ex}+k_E)+K_2k_T[D]]} + \frac{k_{ex}k_{tr}\tau_A^0[D]^2}{(k_{-ex}+k_E)\left(1+\dfrac{k_{-tr}}{k_T}\right)+k_{tr}[D]}$$

That relation [11] reduces to expression [5] in the absence of triplex formation is readily verified.

Equation [11] can be changed into:

$$[12]\quad \frac{\Phi_f^{A^0}}{\Phi_f^A} = 1 + k_{ex}\tau_A^0[D] - \frac{k_{ex}k_{-ex}[D]}{k_Ak_TK_2\left[\dfrac{k_{-ex}+k_E}{k_TK_2}+[D]\right]}$$

which is of the following form:

$$\frac{\Phi_f^{A^0}}{\Phi_f^A} = 1 + a[D] - \frac{b[D]}{c+[D]}$$

and which can be fitted with the different values of Φ_f^A to obtain the parameter $a = k_{ex}\tau_A^0$, thus permitting the evaluation of k_{ex}. This fit of the Φ_f^A data to expression [12] gives the value 3.9 L mol^{-1} for the $k_{ex}\tau_A^0$ product. Since $\tau_A^0 = 0.14 \times 10^{-9}$ s,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

the rate constant for exciplex formation is $k_{ex} = 27.9 \times 10^9$ L mol^{-1} s^{-1}, a value that is 20% higher than that (23.0×10^9 L mol^{-1} s^{-1}) calculated with the hypothesis of a single equilibrium between A* and (A..D)*.

The expression for $1/\Phi_f^{ex}$, used formerly in the case of a simple equilibrium between A* and (A..D)*, can be reformulated by including the second equilibrium constant K_2 between (A..D)* and (A..D_2)* given by relation [10]. This leads to:

$$[13] \quad \frac{1}{\Phi_f^{ex}} = \frac{k_E}{k_f^{ex}} + \frac{K_2 k_T [D]}{k_f^{ex}} + \frac{K_2 k_T}{k_f^{ex} k_{ex} \tau_A^0} + \frac{k_{-ex} + k_E}{k_f^{ex} k_{ex} \tau_A^0 [D]}$$

As expected, expression [13] is reduced to relation [6] in the absence of the second equilibrium. It can be written in the new form:

$$[14] \quad \frac{1}{\Phi_f^{ex}} = \frac{\frac{K_2 k_T}{k_f^{ex}}[D]^2 + \left(\frac{k_E}{k_f^{ex}} + \frac{k_A K_2 k_T}{k_f^{ex} k_{ex}}\right)[D] + \frac{k_A(k_{-ex} + k_E)}{k_f^{ex} k_{ex}}}{[D]}$$

To evaluate the fluorescence data of both the exciplex and the triplex, we need the expression for the quantum yield of the triplex emission. This is obtained by application of the steady state principle to the reactions of Scheme 2:

$$[15] \quad \frac{1}{\Phi_f^{tr}} = \frac{\frac{k_T}{k_f^{tr}}[D]^2 + \left(\frac{k_E}{k_f^{tr} K_2} + \frac{k_A k_T}{k_f^{tr} k_{ex}}\right)[D] + \frac{k_A(k_{-ex} + k_E)}{k_f^{tr} k_{ex} K_2}}{[D]^2}$$

For simplification, we shall abbreviate the following rate constant expressions: k_T/k_f^{tr} by $X(1)$; $k_T K_2$ by 10^8 $X(2)$; $(k_{-ex} + k_E)$ by 10^8 $X(3)$; k_E/k_f^{ex} by $X(4)$; k_f^{ex} by $10^8 X(5)$; and assign to $k_A/k_{ex} = X(6)$ the reciprocal of the value (3.9 L $\times$ mol^{-1}) obtained from the Stern–Volmer plot.

Relations [14] and [15] can be transformed into eqs. [16] and [17], respectively:

$$[16] \quad \frac{1}{\Phi_f^{ex}} = \frac{\frac{X(2)}{X(5)}[D]^2 + \left(X(4) + \frac{X(2)X(6)}{X(5)}\right)[D] + \frac{X(3)X(6)}{X(5)}}{[D]}$$

and

$$[17] \quad \frac{1}{\Phi_f^{tr}} = \frac{X(1)[D]^2 + \left(X(1)X(6) + \frac{X(1)X(4)X(5)}{X(2)}\right)[D] + \frac{X(3)X(6)}{X(5)}}{[D]^2}$$

The fitting of the curve of the reciprocal of the global fluorescence quantum yield $1/(\Phi_f^{ex} + \Phi_f^{tr})$ vs. the reciprocal of the *p*-xylene concentration has been carried out (Fig. 7) using the Levenberg–Margnardt algorithm given in the IGOR Pro program from Watermetrics. The best fit is obtained for the following values: $X(1) = 2.04$, $X(2) = 0.4$, $X(3) = 3.62$, $X(4) = 1.015$, and $X(5) = 1.18$.

The ratio $k_T/k_f^{tr} = X(1) = 2.04$ is the reciprocal of the triplex intrinsic fluorescence quantum yield in the absence of back reaction to the exciplex. This gives $(\Phi_f^{tr})_0 = 0.49$. Similarly, $k_E/k_f^{ex} = X(4)$ is the reciprocal of the exciplex intrinsic fluorescence quantum yield with no other deactivation than fluorescence and nonradiative decay. Thus, $(\Phi_f^{ex})_0 = 0.98$. The fluorescence rate constant of the exciplex, $k_f^{ex} = 1.18 \times 10^8$ s^{-1}, the intrinsic deactivation process of the exciplex, $k_E = 1.20 \times 10^8$ s^{-1}, and the rate constant for the back reaction from the exciplex to excited $DBMBF_2$, $k_{-ex} = 2.42 \times 10^8$ s^{-1}, are deduced from the values obtained for $X(3)$, $X(4)$, and $(X5)$. The nonradiative deactivation rate constant of the exciplex, $k_{nrE} = 2 \times 10^6$ s^{-1}, and the intrinsic lifetime of the exciplex, $\tau_{ex}^0 = 1/k_E = 8.3$ ns, are easily deduced from the above data.

In pure *p*-xylene solution, the fluorescence quantum yield of the excited complex and its lifetime are 0.59 and 14.4 ns, respectively. Yet, the value obtained from the fit of the curve for the intrinsic fluorescence quantum yield of the triplex is 0.49, that is ca. 20% lower than the measured value. Therefore, even in pure *p*-xylene solution the triplex does revert in part to the exciplex, which fluoresces with an efficiency twice as high as that of the triplex. Consequently, the lifetime of the pure triplex must be higher than the 14.4 ns found in pure *p*-xylene. We have arbitrarily multiplied the measured lifetime by 1.2 and taken $\tau_{tr}^0 = 17$ ns.

Then, $k_T = \frac{1}{\tau_{tr}^0} = 5.9 \times 10^7$ s^{-1} and the value of K_2 is deduced from $X(2) = k_T K_2 = 0.4 \times 10^8$ M^{-1}s^{-1}. This gives $K_2 = 0.68$ M^{-1}. k_f^{tr} is obtained from $X(1)$: $k_f^{tr} = 2.9 \times 10^7$ s^{-1} and this permits the evaluation of $k_{nrT} = 3.0 \times 10^7$ s^{-1} since $k_{nrT} = k_T - k_f^{tr}$.

Access to the constants of the remaining two reactions, the forward and the backward triplex formation from the exciplex, is more complex. They could be reached by neglecting the back reaction from the exciplex to excited $DBMBF_2$, at high *p*-xylene concentrations. This hypothesis is quite reasonable when comparing the rate constant for exciplex formation (27.9×10^9 M^{-1} s^{-1}) with that for the reverse reaction (2.42×10^8 s^{-1}). Then, the only equilibrium to be considered at high *p*-xylene concentrations is the one between the exciplex and the triplex. On this basis, the kinetic treatment used in other cases (30, 31)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

can be applied here. If the exciplex and the triplex have different decays ($\tau_{ex} = 1/\lambda_1$, and $\tau_{tr} = 1/\lambda_2$), they can be described as

$$\lambda_1, \lambda_2 = \frac{1}{2}\left\{(k_{tr}[D] + k_E + k_{-tr} + k_T \pm \sqrt{(k_{tr}[D] + k_E - k_{-tr} - k_T)^2 + 4k_{tr}k_{-tr}[D]}\right\}$$

Since the intrinsic lifetime of the triplex is longer than that of the exciplex, and because the two species are in equilibrium, the λ value to be considered is the one having the minus sign before the square root. Then, the relation to be used (after remodeling the expression under the square root) is

$$\frac{1}{\tau_{tr}} = \lambda_2 = \frac{1}{2}\left\{k_{tr}[D] + k_E + k_{-tr} + k_T - \sqrt{(k_{tr}[D] + k_{-tr})^2 + 2(k_{tr}[D] - k_{-tr})(k_E - k_T) + (k_E - k_T)^2}\right\}$$

For a 3.27 M concentration in *p*-xylene, the lifetime of the excited species is 10.0 ns and the overall fluorescence quantum yield is 0.63. At this concentration, the [triplex]/[exciplex] ratio deduced from relation [10] is 4.1; this means that, under steady state conditions, there is 20% of exciplex for 80% of triplex in the cyclohexane solution that is 3.27 M in *p*-xylene (in pure *p*-xylene, the exciplex represents only 9% and the triplex 91% of the excited species).

The importance of triplex formation implies that k_{tr} [D] is much greater than $(k_{-ex} + k_E) = 3.62 \times 10^8$ s^{-1}. So, since $(k_{tr}[D] + k_{-tr})^2$ is larger than $(k_{-ex} + k_E)^2$, which is equal to 13×10^{16} s^{-2}, it is at least 36 times more important than $(k_E - k_T)^2 = 3.6 \times 10^{14}$ s^{-2}. Consequently, the last factor under the square-root sign in the expression for λ_2 can be neglected in favor of the first factor and, therefore, λ_2 is reduced to

$$[18] \quad \frac{2}{\tau_{tr}} = 2\lambda_2 = k_{tr}[D] + k_{-tr} + k_E + k_T - (k_{tr}[D] + k_{-tr})\sqrt{1 + \frac{2(k_{tr}[D] - k_{-tr})(k_E - k_T)}{(k_{tr}[D] + k_{-tr})^2}}$$

The lifetime of the excited species is known at the different concentrations of *p*-xylene. The other constants k_E and k_T having already been calculated, k_{tr} and k_{-tr} become the only unknown parameters in expression [18]. Similarly, formula [10] gives another relation between the same two rate constants since K_2 and k_T are known. The two expressions [10] and [18] lead to the values $k_{tr} = 2.1 \times 10^9$ M^{-1} s^{-1} and $k_{-tr} = 1.55 \times 10^9$ s^{-1} for the triplex formation rate constant and for that of the reverse reaction, respectively.

Scheme 3 can now summarize the different kinetic data for the double equilibrium between excited $DBMBF_2$, the exciplex (A..D)*, and triplex (A..D_2)* species formed with *p*-xylene in cyclohexane solution:

Scheme 3.

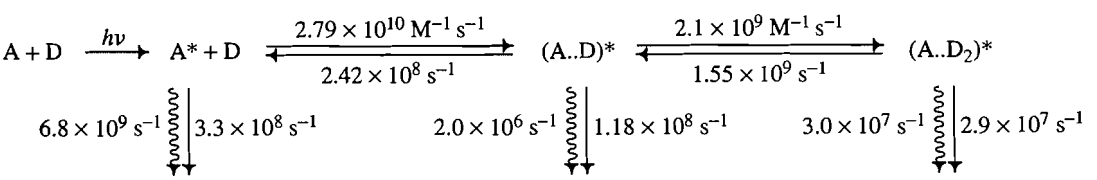

Fig. 7. Plot of the reciprocal of the global fluorescence quantum yield versus the reciprocal of *p*-xylene concentration in cyclohexane solution (× × ×). The points (····) represent the best fit of the calculated curve compared to the experimental values.

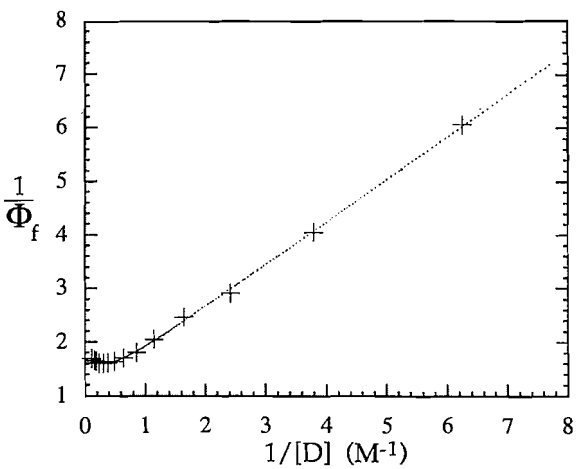

The constant K_1 of the first equilibrium between excited $DBMBF_2$ and the exciplex (A..D)* is

$$[19] \quad K_1 = \frac{[(A..D)^*]}{[A^*][D]} = \frac{k_{ex}}{k_E + k_{-ex} + k_T K_2 [D]}$$

Since k_E, k_{ex}, k_{-ex}, k_T, and K_2 have been calculated in the case of *p*-xylene, the equilibrium constant K_1 becomes accessible. At the concentration 3.27 M in *p*-xylene, K_1 = 56.6 M^{-1}. This value is four times lower than the value (Table 2) obtained when considering a single equilibrium process. Furthermore, the maximum value that can be reached by K_1, at low concentration of *p*-xylene, is of the order of 77 M^{-1}, a value that is still three times lower than that given on the basis of a single equilibrium.

Comparison of the two treatments, the one limited to the exciplex only, and the other that takes into account the formation of the triplex species, shows, in the case of *p*-xylene, that no important difference between the two approaches is reflected in the rate constant for the exciplex formation (2.79 instead of 2.3×10^{10} L mol^{-1} s^{-1}). However, involvement of the triplex species strongly modifies the rate

constant for the back reaction of the exciplex to $DBMBF_2$ (by a factor of 37) and the exciplex fluorescence rate constant only slightly (by a factor of 2).

Indeed, the different possibilities discussed above can explain the various evolutions observed in the lifetime and the fluorescence quantum yield of all the excited species studied. However, they do not completely explain the changes observed from one complex to the other. The increase in the excited species lifetime could be related to the increased electron-donating properties of the aromatics, but the results obtained with isodurene are puzzling since its lifetime, although the longest, as expected, decreases above a certain isodurene concentration (perhaps by formation of a multiplex). On the other hand, the fluorescence quantum yield of the excited species decreases above a certain concentration of the aromatics with the two xylenes and with isodurene but not with mesitylene. Such a difference cannot be related to the reduction potential of the aromatics but possibly to the steric hindrance introduced by the methyl groups in the formation of the complex.[4]

Conclusion

$DBMBF_2$ has been shown to give rise to a series of strongly fluorescent excited complexes with one or two molecules of benzene derivatives. The lifetime and the fluorescence quantum yield of the excited species increase monotonously with the concentration of the benzene derivative, but several of them reach a maximum value that decreases in the high concentration range of the aromatics. The two excited complexes are formed in a double equilibrium with the starting excited $DBMBF_2$. All the rate constants involved in this double equilibrium have been evaluated for the complex given with *p*-xylene.

Synthesis and characterization of a series of poly(α,ω-alkyldiynes) and copoly(α,ω-alkyldiynes)

J.C. Kennedy, J.R. MacCallum, and D.H. MacKerron

Abstract: A series of poly(α,ω-alkyldiynes) and copoly(α,ω-alkyldiynes) were synthesized by catalytic Glaser coupling reactions. Two routes were investigated and developed. These routes were chosen in anticipation that high molar mass, linear and polydisperse, polymers would be achieved. GPC (gel permeation chromatography) curves revealed that this was possible for the majority of polymers synthesized by the first route. However, a wide range of molar masses were obtained by the second route with a significant low molar mass tail present in almost all GPC curves. Very low M_n (number average molar mass) values by GPC gave correspondingly very high M_n values by end-group analysis (EGA). Hence, it was proposed that the low molar mass tail was a consequence of cyclic structures. From these results and observations a mechanism for the polymerization of the α,ω-alkyldiynes was proposed.

Key words: poly(α,ω-alkyldiynes), Glaser coupling, molar mass.

Résumé : On a synthétisé une série de poly(α,ω-alkyldiynes) et de copoly(α,ω-alkyldiynes) par les réactions de couplage catalytique de Glaser. On a étudié et développé deux voies. Ces voies ont été choisies dans le but d'obtenir des polymères linéaires et polydispersés de poids moléculaires élevés. Des courbes de chromatographie par perméation de gel (GPC) ont révélé que ceci est possible pour la majorité des polymères synthétisés par la première voie. Toutefois, la seconde voie a conduit à de grandes variations dans les poids moléculaires et, dans chaque cas, les courbes de GPC ont toutes présentées des traînées avec des quantités importantes de produits de faibles poids moléculaires. Des valeurs très faibles de M_n (valeur moyenne de la masse molaire) par GPC fournissent des valeurs correspondantes élevées de M_n par l'analyse des groupes terminaux (EGA). On suggère donc que les traînées de faible poids moléculaire sont une conséquence de structures cycliques. Sur la base de ces résultats et de l'ensemble des observations, on propose un mécanisme pour la polymérisation des α,ω-alkyldiynes.

Mots clés : poly(α,ω-alkyldiynes), couplage de Glaser, masses molaires.

[Traduit par la rédaction]

Introduction

It has been shown by several workers that α,ω-alkyldiynes can be polymerized through an oxidative "Glaser" coupling reaction catalysed by a complex of a copper salt and *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) (1–6).

This reaction of α,ω-alkyldiynes was first performed by Hay (1) in 1967 when 1,6-heptadiyne, 1,7-octadiyne, and 1,8-nonadiyne were polymerized. Hay's reaction system consisted of 2 g (0.02 mol) Cu(I)Cl, 7 g (0.058 mol) TMEDA, 135 mL pyridine, and 0.05 mol of α,ω-alkyldiyne monomer (a 1:29 molar ratio of Cu(I)Cl to TMEDA was used). The number average molar masses were low, as polymer precipitation was a problem.

To achieve higher molar mass polymers Hay's system was modified by White in 1971 (2). The pyridine solvent used in Hay's system was replaced by 1,2-dichlorobenzene and the catalyst concentration lowered. Previously Hay (1) had employed high catalyst concentrations to achieve rapid polymerization rates before polymer had the chance to precipitate out of solution. With precipitation no longer a problem, catalyst concentrations could be considerably lower with low copper salt concentrations making purification easier. The reaction system employed by White was 0.150 g (0.0015 mol) Cu(1)Cl, 0.23 mL (0.0015 mol) TMEDA, 1.7 mL pyridine in 48 mL 1,2-dichlorobenzene; to this was added 0.0396 mol α,ω-alkyldiyne in 10 mL 1,2-dichlorobenzene (a 1:1 molar ratio of Cu(I)Cl:TMEDA was used). Also, since high monomer concentrations were employed it would seem less likely that the α,ω-alkyldiynes would cyclize on polymerization (7).

In 1989, Butera et al. (3,4) synthesized poly(α,ω-alkyldiynes) using a polymerization procedure based upon that of White's. However, Butera incorporated a polymerization delay time: the reaction was allowed to proceed overnight at

room temperature before the final polymerization temperature was set, then the contents were left to polymerize for the desired time. Butera's system had the added advantage over White's system in that the polymerization delay time had better control over the polydispersity (PDI) of the poly(α,ω-alkyldiynes) formed. Gel permeation chromatography (GPC) traces of the poly(α,ω-alkyldiynes) gave almost ideal polydisperse curves (theoretically, polydispersity being 2). With almost ideal PDI at high molar masses it will be very unlikely that cyclic structures (7) will have formed and the polymer will comprise a distribution of linear molar masses.

A similar approach to the methods adopted above was carried out by Kevelam et al. (5) in 1975. The reaction system chosen for the polymerization work consisted of 0.25 g (1.28×10^{-3} mol) Cu(I)Cl, 0.64 mol of TMEDA, 80 mL pyridine, and 0.0216 mol of 1,8–nonadiyne (a 1:50 molar ratio of Cu(I)Cl to TMEDA was used). The contents were polymerized at 26°C for several hours with low M_n values being obtained by vapour pressure osmometry.

There are several reasons why the molar mass of the poly(1,8-nonadiyne) synthesized by Kevelam was low:

(*i*) polymerisation temperature — higher temperatures are required; (*ii*) solvent — pyridine solvent was used, 1,2-dichlorobenzene is a far superior solvent; (*iii*) cyclic oligomers — the system used by is dilute; therefore there is a tendency for the polymers to cyclize (7); (*iv*) concentration — using a more concentrated system will promote higher molar mass.

An improvement in the polymerization procedure of Kevelam was reported by Knol et al. (6) in 1984. Initially Knol followed the same procedure adopted by Kevelam, but the solvent pyridine was replaced by 1,2-dichlorobenzene. This modified procedure doubled the M_n values obtained by vapour pressure osmometry. Knol further optimized the polymerization conditions by increasing the temperature of polymerization and changing the concentration (a more dilute solution was used). Knol claimed that molar masses (M_n), measured by membrane osmometry, were as high as 20 000. However, with the exclusion of molar mass distribution curves by GPC it is not possible to predict whether cyclic or oligomeric structures form during the polymerization reaction.

Three main differences exist between the polymerization systems optimized by Butera (3,4) and Knol (6). These are (*i*) polymerization delay time — in Butera's route a polymerization delay time was included in the syntheses of the polymers whereas in Knol's route this was excluded and the flask contents were polymerized immediately; (*ii*) copper(I) chloride:TMEDA — in Butera's route the copper(I) chloride:TMEDA ration is 1:1 whereas in Knol's route the copper(I) chloride:TMEDA ratio is 1:50; (*iii*) solvent system — in Butera's route the 1,2-dichlorobenzene: pyridine solvent system is used whereas in Knol's route 1,2-dichlorobenzene solvent is used exclusively.

For the purpose of this study these two routes optimized by Butera and Knol were selected and developed even further for polymerization and copolymerization of a series of α,ω-alkyldiynes.

Butera's route was further developed by varying the polymerization temperature from 60 to 80°C and increasing the time of polymerization by 1. The concentration of the α,ω-alkyldiyne(s) in the polymerization medium was not increased, as polymer precipitation became a major problem. In this study this route will be referred to as *polymerization Route A*.

Knol's route was further developed by varying the polymerization temperature from 40 to 80°C, varying the polymerization time from 6 to 15 h, and increasing the α,ω-alkyldiyne(s) concentration in the polymerization from 0.011 mol dm^{-3} to 0.4 mol dm^{-3}. In this study this route will be referred to as *polymerization Route B*.

The work described in this paper concerns the molar mass characteristics of these polymers. The molar mass characteristics of the polymers synthesized by polymerization Routes A and B are studied by gel permeation chromatography (GPC), end-group analysis (EGA), and ^1H nmr spectroscopy. This gives an indication whether polydisperse linear polymers can by synthesized by both polymerization Routes A and B. From these results a mechanism for the polymerization of α,ω-alkyldiynes for both routes A and B is proposed.

Experimental procedures

Materials

The monomers 1,7-octadiyne, 1,8-nonadiyne, 1,9-decadiyne, 1,10-undecadiyne, and 1,11-dodecadiyne were synthesized from sodium acetylide and the respective α,ω-dibromoalkane by following a literature procedure (8) and were distilled once more prior to use. All other reagents and solvents (Aldrich, high purity) were purified an distilled before use. All glassware was thoroughly dried at 120°C before use.

Synthesis of poly(α,ω-alkyldiynes) and copoly(α,ω-alkyldiynes)

Polymerization, Route A

To a 50 mL wide-mouthed Erlenmeyer flask, equipped with a magnetic stirrer, an oxygen inlet tube, and a thermometer, 20 mL 1,2-dichlorobenzene, 0.71 mL (8.8 mmol) pyridine, 0.096 mL (0.625 mmol) TMEDA, and 0.0625 g (0.625 mmol) copper(I) chloride were added, producing a light green solution. Oxygen was then bubbled through the stirring solution for 40 min (the solution turned dark green shortly after oxygen flow was started). A solution of 0.0165 mol of the chosen α,ω-alkyldiyne(s) in 4 mL of 1,2-dichlorobenzene was then slowly added to the stirring reaction mixture. The reaction was allowed to proceed overnight (with continuous oxygen flow), after which time a milky green suspension was formed. The flask was then placed in an oil bath at temperatures ranging from 70 to 90°C. Upon placing the flask into the oil bath the reaction mixture turned clear and was dark green in colour. The reaction was allowed to polymerize at the desired temperature for 5 h (*an hour more than the polymerization time adopted by Butera et al.* (3, 4). After this time, the flask was removed from the oil bath and allowed to cool (with stirring) for 15 min. The mixture was then added dropwise to a stirred solution of 5 mL concentrated HCl in 250 mL methanol. The resultant precipitate was allowed to stir for 15 min in the methanol–HCl mixture. The precipitate was then dried over a Büchner funnel (with aspiration) and subsequently dissolved in 100 mL of dichloromethane. The polymer was reprecipitated four times, twice in methanol–HCl, then twice in pure methanol, to obtain a white semicrystalline product. The polymer was dried over a Büchner funnel (with aspiration), then

under vacuum at room temperature, and its yield recorded. The polymer was then dissolved in dichloromethane, the solution was filtered using Hyflo-Supercel filtering agent to give a clear solution. The polymer was stored in dichloromethane as a 1% weight/volume solution (the polymer was filtered to remove any low molar mass species that may affect the polydispersity of the polymers and stored in dilute solution because of its photoreactivity in the solid state). A small quantity of this purified polymer was evaporated, dried under vacuum, and then dissolved in deuterochloroform for ^{1}H nmr – end-group analysis (EGA) studies.

Polymerization, Route B

To a 25 mL wide-mouthed Erlenmeyer flask, stirred in an oil bath (temperatures ranging from 70 to 90°C) equipped with a magnetic stirrer, an oxygen inlet tube, and a thermometer were added 10 mL 1,2-dichlorobenzene and 3.8 mL (25 mmol) TMEDA. Once the desired temperature of the solution was reached 0.05 g (0.5 mmol) of copper(I) chloride was added. Oxygen was then bubbled through the stirring solution for 40 min (the solution turned dark green shortly after oxygen flow was started). A solution of 7.45 mmol of the chosen α,ω-alkyldiyne(s) in 5 mL of 1,2-dichlorobenzene was added to the stirring reaction mixture. The reaction mixture was left to polymerize at the desired temperature for the chosen length of time. Then, the flask was removed from the oil bath and allowed to cool (with stirring for 15 min).

Note: The remainder of this procedure is the same as Route A, the only difference being the quantities of acid and solvents used in the work-up. In Route B 2 mL concentrated HCl, 100 mL methanol, and 50 mL of dichloromethane were used.

Molar mass characterization techniques

Gel permeation chromatography (GPC)

Molar mass averages were obtained by using GPC. The GPC analyses were carried out using a MC/GPC/3 series chromatograph (equipped with a Shodex mixed gel column capable of wide molar mass range resolution), using a refractive index detector and chloroform as solvent (1 mL/min at 24°C). All molar masses are reported with respect to polystyrene standards.

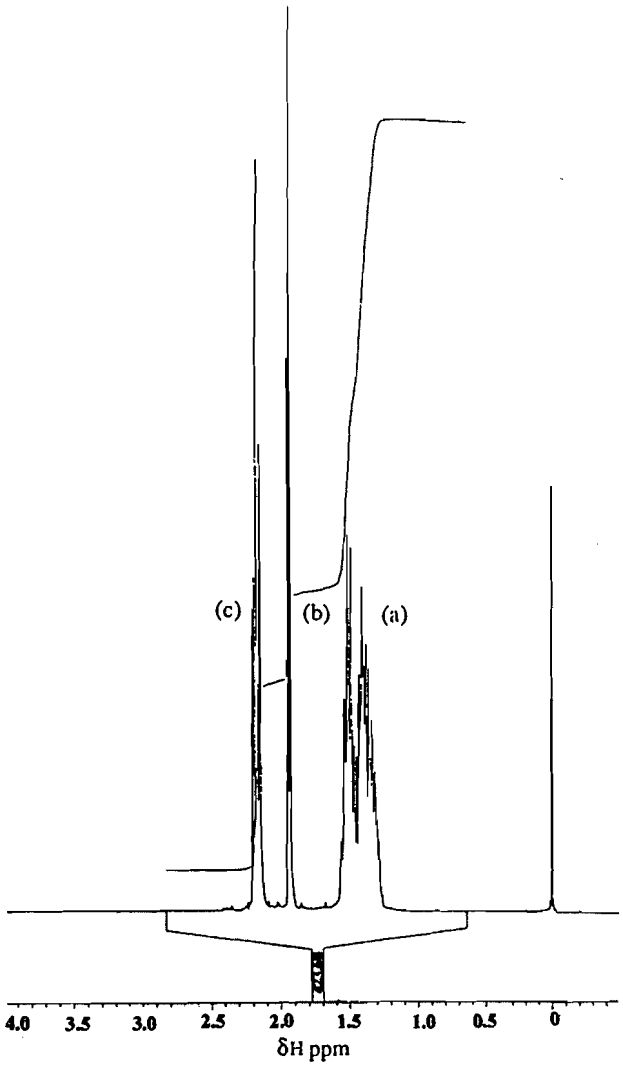
End-group analysis (EGA) by ^{1}H nmr spectroscopy

Number average molar masses (M_n) were obtained by using EGA. All ^{1}H nmr spectra were recorded at 300 MHz on a Brüker AM-300 spectrometer. EGA is limited to linear polymers and the sensitivity of this method decreases rapidly as the chain length increases and the number of end groups drops (i.e., a practical upper limit will restrict what M_n values can be measured). EGA assigns an absolute M_n value for the polymer molar mass, unlike GPC, which assigns an M_n value for the polymer molar mass relative to polystyrene standards.

A typical EGA calculation for the polymer poly(1,10-undecadiyne) is now given. This polymer was synthesized by polymerization route A. The polydispersity index (PDI) of the polymer was almost ideal (i.e., M_w/M_n = 2.09) and the M_n value is high enough to assume a distribution of linear molar masses.

In Fig. 1 the ^{1}H nmr spectrum of 1,10-undecadiyne is shown. The spectrum reveals three peaks: (a) δH = 1.35 ppm

Fig. 1. The ^{1}H nmr spectrum of 1,10-undecadiyne.



(multiplet) — represents ten methylene protons in the middle of the monomer chain; (b) δH = 1.94 ppm (triplet) — represents two terminal alkyne protons at either end of the monomer chain; (c) δH = 2.15 ppm (multiplet) — represents four methylene protons attached to the two terminal alkyne groups. That is, for 1,10-undecadiyne:

$$\underset{(b)}{HC{\equiv}C\text{-}}\underset{(c)}{H_2C\text{-}}\underset{(a)}{(CH_2)_5\text{-}}\underset{(c)}{CH_2\text{-}}\underset{(b)}{C{=}CH}$$

When the monomer is oxidatively polymerized to give a linear structure the signal for the two terminal alkyne end groups (b) at δH = 1.94 ppm decreases in intensity with respect to the two signals (a) and (c) for the methylene protons in the polymer chain. As the molar mass of the polymer increases the signal (b) decreases in intensity. Therefore at high molar masses the signal (b) is broad and indistinguishable with respect to signals (a) and (c) in the ^{1}H nmr spectrum.

This can be shown in Fig. 2 in the ^{1}H nmr spectrum of poly(1,10-undecadiyne). In the ^{1}H nmr spectrum of poly(1,10-undecadiyne) the triplet signal for the two terminal alkyne groups is barely recognizable; therefore integration of the sig-

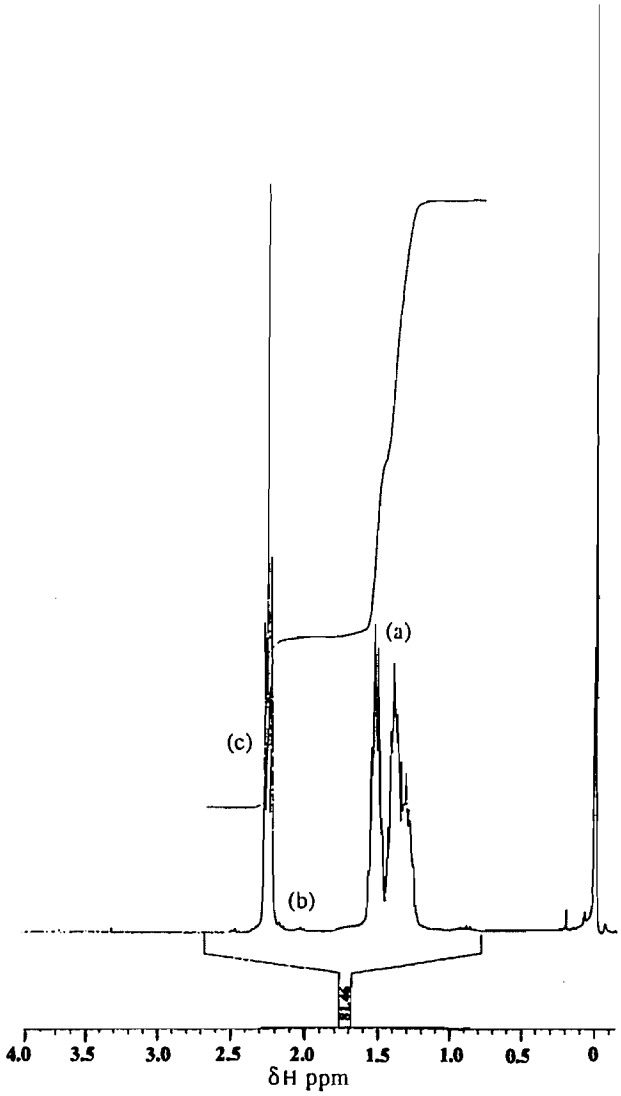
For personal use only.

Fig. 2. The ^{1}H nmr spectrum of poly(1,10-undecadiyne).



nal is not possible. To obtain an M_n value for this polymer, expansion of this peak with respect to either signal (a) or signal (c) is necessary. In all end-group analysis calculations signal (b) was expanded with respect to signal (a).

This was done by expanding the triplet peak (b) for the two terminal alkyne protons by a factor of 8 with respect to the multiplet peak (a) for the $(CH_2)_5$ protons (which occur along the main chain of the linear polymer) so the areas of both peaks can be compared. This is shown in Fig. 3.

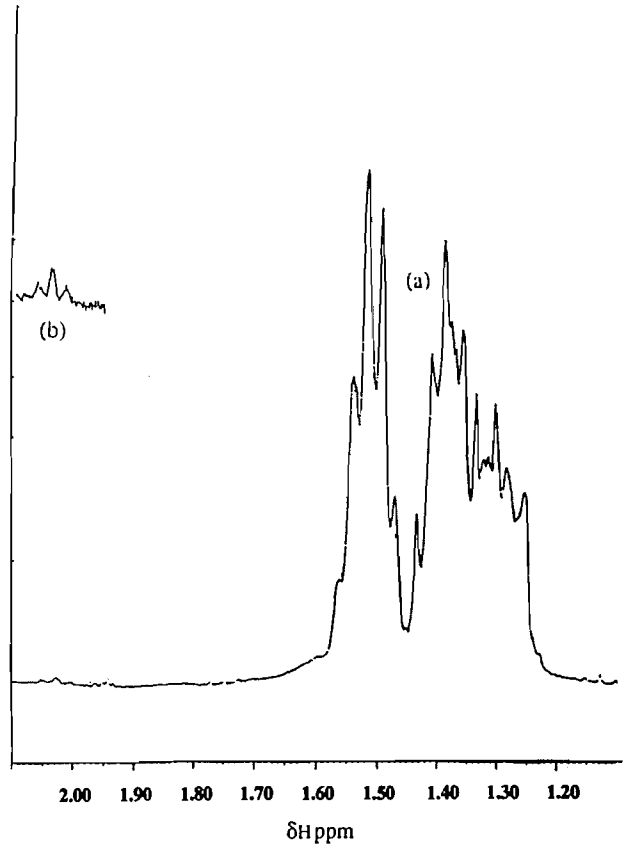
To obtain a value for M_n the areas of the peaks were cut out, weighed, and the following series of arithmetical calculations were performed;

$$H(C{\equiv}C\text{-}H_2C\text{-}\underline{CH_2CH_2CH_2CH_2CH_2}\text{-}CH_2\text{-}C{\equiv}C)_nH$$

(b) (c) (a) (c) (b)

1. Mass of the multiplet peak (a) for $(CH_2)_5$ protons
2. Mass of the triplet peak (b) for two terminal alkyne protons

Fig. 3. Expansion of triplet signal for two terminal alkyne groups (b) by a factor of 8 with respect to the $(CH_2)_5$ protons (a) that occur along the length of the linear polymer chain.



There are ten protons that occur along the main chain of the linear polymer and two terminal alkyne protons at either end of the polymer chain.

To obtain a value for the number of repeat units (n) in the polymer chain, the mass of the multiplet peak (a) for the $(CH_2)_5$ protons must be divided by 5 to give the mass of $-CH_2-$ in the main chain of the linear polymer. The mass of the triplet peak (b) for the terminal alkynes must be divided by 8 to give the mass of HC≡C at either end of the linear polymer chain.

The number of repeat units (n) can be obtained by the following expression:

$$\frac{\text{mass of -CH- in the main chain of the linear polymer}}{\text{mass of HC≡C at either end of the linear polymer chain}}$$

The number of repeat units n is then multiplied by the relative molar mass (r.m.m.) of the repeat unit of poly(1,10-undecadiyne), giving the M_n of the poly(1,10-undecadiyne):

$$M_n = n \times \text{r.m.m.}$$

Errors are bound to arise in the EGA calculation and these include the following.

(*i*) Judgement of where the baseline should be set for the multiplet peak of the methylene protons (when it is cut out) requires consistency.

(*ii*) Also in some cases the triplet peak was poorly resolved. The sensitivity of EGA decreases rapidly as the chain length

increases because the number of end groups drops. Therefore cutting out this peak is difficult and requires careful work with no guarantee of an accurate result for M_n.

However, EGA does have an obvious advantage over GPC (when studying a distribution of linear molar masses exclusively) in that an absolute value is obtained by EGA, whereas in GPCD a value relative to a polystyrene standard is obtained.

Results and discussion

Molar mass results

Polymerization conditions and yields for a range of polymers are shown in Tables 1 and 2.

For the polymers synthesized by **Route A** all polymers, except for poly(1,7-octadiyne), were very soluble in chloroform, dichloromethane, and tetrahydrofuran at room temperature. 1,2-Dichlorobenzene and 1,2-dichloroethane will also dissolve the polymers, but not as readily as the above solvents. Poly(1,7-octadiyne) was insoluble in a range of solvents at room temperature and at elevated temperatures. However, it was sparingly soluble in 1,2-dichlorobenzene at elevated temperatures.

For the polymers synthesized by **Route B** all polymers, except for poly(1,11-dodecadiyne), were very soluble in chloroform, dichloromethane, and tetrahydrofuran at room temperature. 1,2-Dichlorobenzene and 1,2-dichloroethane also dissolve the polymers, but not as readily as the above solvents. Poly(1,11-dodecadiyne) was very soluble in chloroform and methylene chloride at room temperature, but insoluble in tetrahydrofuran at room temperature and only sparingly soluble in 1,2-dichlorobenzene at room temperature.

It was noted that the polymers stored in methylene chloride solution synthesized from **Route B** gave a coloured solution (i.e., yellow/orange/brown) whereas those synthesized from **Route A** were clear when stored in methylene chloride solution.

The molar mass values of the polymers studied by EGA and GPC for both polymerization routes A and B are presented in Tables 3 and 4, respectively.

One GPC curve from polymerization Route A and the majority of the GPC curves from polymerization Route B have a significant low molar mass tail present. It is proposed that this low molar mass tail is not only the consequence of linear oligomeric structures but also low molar mass cyclics formed during the course of the polymerization.

All GPC curves from polymerization Route A, with the exception of polymer A2, poly(1,8-nonadiyne), polymerized for 5 h at 65°C, were Gaussian in shape at high molar masses. The GPC curve for A2 was non-Gaussian in shape with a combination of low and high molar masses, i.e., a large distribution of molar masses with PDI as high as 6.37 (see Table 3). The M_n value obtained by EGA was 15 000 whereas the M_n value obtained by GPC was 5 890. This strongly favours the proposal that low molar mass cyclics contribute to the low molar mass tail. The high value for M_n by EGA suggests that the calculation overestimates the number of methylene pro-

N.B. Refer to Table 2 for polymerization temperature, time, and yield.

tons contributing to the M_n value. *When cyclic structures are present the calculations will involve methylene protons from the linear chains and also methylene protons from the cyclic structures. Therefore these methylene protons will be compared with the terminal protons from the linear chains exclusively as the cyclic structures do not possess end-group protons. Hence an exaggerated M_n value will be obtained by EGA.*

In the majority of cases from polymerization Route B, GPC curves are non-Gaussian in shape with the presence of a low molar mass tail.

PDI values of 4.69 and 5.69 for polymers B1 and B2, respectively, were obtained and results for M_n by EGA and GPC for the individual polymers were comparable. However, polymer B1 produces a higher M_n polymer, indicating that the shorter polymerization time produces higher M_n polymer.

PDI values of 4.22 and 3.24 for polymers B3 and B4, respectively, were obtained. The results for M_n by EGA and GPC or polymer B3 were comparable with values of 11 000 and 9 621. However, results for M_n by EGA and GPC for polymer B4 were not as comparable, values of 10 006 and 7 660 being recorded. Polymer B3 produces a marginally higher M_n polymer, again indicating that the shorter polymerization time produces higher M_n polymer.

For polymer B5, a PDI value of 3.86 was obtained and a high M_n value of 16 700 was obtained by GPC. This high M_n value of GPC gives a fair comparison with the M_n value of 13 788 obtained by EGA. The GPC curve for polymer B6 was Gaussian in shape but comprised low molar masses. A PDI value of 1.66 was obtained and an M_n value of 3 266 was obtained by GPC. However, the very low M_n value of 3 266 obtained by GPC contrasts with the high M_n value of 17 563 measured by EGA (see Table 4). *This strongly suggests that a high percentage of low molar mass cyclics were formed during the course of the polymerization.*

From the results by EGA and GPC the following conclusions are drawn for poly(1,9-decadiyne) polymerized for 15 h:

(*i*) Low polymerization temperatures (40°C) — produces high M_n values with a small percentage of low molar mass material.

(*ii*) Intermediate polymerization temperatures (60°C) — produces very low M_n values by GPC but correspondingly very high M_n values by EGA, suggesting that a high percentage of low molar mass cyclics are formed during the polymerization.

(*iii*) High polymerization temperatures (80°C) — produces intermediate M_n values with a broad distribution of molar masses.

For B8, a PDI value of 3.60 was obtained and an M_n value of 6 988 was obtained by GPC. However, this low value of 6 988 obtained by GPC compares with the M_n value of 12 418 by EGA. This also suggests that a high percentage of low molar mass cyclics are formed during the course of the polymerization.

For B9, a PDI value of 2.85 was obtained and an M_n value of 17 290 was obtained by GPC. This high M_n value compares with an M_n value of 14 453 by EGA.

For B10, a PDI value of 2.15 was obtained and an M_n value

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

of 5 900 was obtained by GPC. This M_n value of 5 900 obtained by GPC compares with the correspondingly high M_n value of 10 043 measured by EGA. Again, this suggests that a high percentage of low molar mass cyclics are formed during the course of the polymerization.

Polymers synthesized by both polymerization routes A and B produces similar material at high molar masses. This was evident after curve idealization work was performed on the majority of polymers produced by polymerization route B and the one polymer from polymerization Route A. Molar mass distribution curves were idealized to represent a Gaussian shape at higher molar masses by outlining a curve inside the authentic GPC molar mass distribution curve and hence eliminating the low molar mass tail. The details of the curve idealization work can be found elsewhere (9).

The next section of this paper discusses the consequence of the low molar mass tail with reference to the cyclization of α,ω-alkyldiynes.

Cyclization of α,ω-alkyldiynes

It is proposed that the low molar mass tail that is present in the GPC curve for poly(1,8-nonadiyne) from polymerization route A and the majority of GPC curves from polymerization route B are not only a consequence of oligomeric linear-type structures, but also of low molar mass cyclic structures formed during the course of the polymerization.

Cyclic structures are greatly favoured using homogeneous, nonaqueous, mildly basic conditions (10). The effect of dilution has not been properly evaluated although it is anticipated that the smaller the concentration of the α,ω-alkyldiyne, the less tendency there will be to form linear oligomeric or polymeric structures.

Previous oxidative coupling work on α,ω-alkyldiynes that cyclize

(A) Using cupric acetate – pyridine system: High-dilution systems will yield increased proportions of the smaller cyclic hydrocarbons (7). Concentrations of ~0.0035 mol dm^{-3} used for tetradeca-1,13-diyne ($HC{\equiv}C\text{-}(CH_2)_{10}\text{-}C{\equiv}CH$) yields cyclic monomer and dimer in 17 and 30% yield, respectively, the yields being improved when the dilution is higher.

Moderate concentration systems yield increased proportions of the higher cyclic hydrocarbons (10, 11). Concentrations of ~0.0075–0.13 mol dm^{-3} were used for monomers of the series $HC{\equiv}C\text{-}(CH_2)_n\text{-}C{\equiv}CH$ (where n = 2–6). On oxidative coupling, cyclic trimers, tetramers, pentamers, hexamers, and heptamers were formed.

(B) Using cuprous chloride (Cu(I)Cl) and oxidant (12–15): High-concentration systems yield predominantly linear dimers and tetramers but in some instances cyclic dimers were formed. Concentrations of ~0.7–1.25 mol dm^{-3} were used for monomers of the series $HC{\equiv}C\text{-}(CH_2)_n\text{-}C{\equiv}CH$ (where n = 2–6). On oxidative coupling it was found that, as well as linear dimers and tetramers being formed, cyclic dimers were formed in the case of 1,6-heptadiyne, 1,7-octadiyne, and 1,8-nonadiyne, but not in the case of 1,5-hexadiyne and 1,9-decadiyne.

From the above observations it is evident that cyclization can occur in both dilute and concentrated medium for (A). It can also occur in a highly concentrated medium for (B) with the α,ω-alkyldiyne monomers 1,6-heptadiyne, 1,7-octadiyne, and 1,8-nonadiyne.

Oxidative coupling work on α,ω-alkyldiynes investigated in this study

In this study polymerization routes A and B both involve cuprous chloride – TMEDA and an oxidant; therefore comparison can be made with (*B*) in previous oxidative coupling work on α,ω-alkyldiynes that cyclize.

As a basis for polymerization, route A, work was carried out with reference to Butera's system (4). In the original study by Butera the α,ω-alkyldiyne concentration employed was 0.665 mol dm^{-3}. There were no reports of a low molar mass tail in the GPC curves for poly(1,6-heptadiyne), poly(1,8-nonadiyne), and poly(1,11-dodecadiyne).

The same α,ω-alkyldiyne concentration of 0.665 mol dm^{-3} was employed for polymerization route A in this present study, with a low molar mass tail being evident in the GPC curve of poly(1,8-nonadiyne).

As a basis for polymerization route B, work was carried out with reference to the systems of Kevelam (5) and Knol (6). In the original study by Kevelam et al. the 1,8-nonadiyne concentration employed was 0.27 mol dm^{-3}. This was modified by Knol et al. with the 1,8-nonadiyne concentration decreased to 0.102 mol dm^{-3}. In both studies no GPC was performed and, therefore, no low molar mass tail could be observed.

In this study the α,ω-alkyldiyne concentration was increased to 0.4 mol dm^{-3} for polymerization route B, with a low molar mass tail being evident for the majority of polymers in their GPC curve.

The two concentrations of 0.665 mol dm^{-3} and 0.40 mol dm^{-3} employed for the α,ω-alkyldiynes in polymerization routes A and B, respectively, lie close to the values employed for the concentration of the α,ω-alkyldiynes for (*B*) in previous oxidative coupling work on α,ω-alkyldiynes that cyclize (i.e., 0.7–1.25 mol dm^{-3}) (12–15).

Reasoning that favours cyclic structures of α,ω-alkyldiynes contributing to the low molar mass tail includes the following.

(*i*) Values of M_n by EGA that are very high compared with their corresponding M_n value by GPC.

(*ii*) In the GPC curves the low molar mass tail elution peak values are ~1200, which can correspond to cyclic pentamer, hexamer, and heptamer as the elution values of the α,ω-alkyldiyne monomers are ~200.

(*iii*) Mildly basic conditions promote cyclization (10). In polymerization route B, the coordinating ligand TMEDA is present in excess.

(*iv*) Moderate concentrations employed with the cupric acetate – pyridine system (~0.075–0.13 mol dm^{-3}) produced higher cyclics, i.e., trimers, tetramers, pentamers, hexamers, and heptamers of the α,ω-alkyldiynes 1,6-heptadiyne, 1,7-octadiyne, 1,8-nonadiyne, and 1,9-decadiyne (10,11). Although in this study systems involved cuprous chloride – TMEDA and oxidant the concentrations employed were also moderate, i.e., 0.665 mol dm^{-3} and 0.4 mol dm^{-3} for polymerization routes A and B, respectively. Therefore it was possible that higher cyclics mentioned above may have formed.

To fully establish whether low molar mass cyclic structures are present, further examination is necessary. If facilities were available a useful analytical tool for analysing fractions of eluant coming off the GPC column would be preparative GPC. An example of this technique was described by Dodgson et al. (16), who separated broad fractions of cyclic and linear poly(dimethylsiloxanes). Although preparative GPC was not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

available, attempts to isolate the cyclic structures by mass spectroscopy were carried out; these were unsuccessful and therefore inconclusive.

However, on the basis of points (*i*) – (*iv*) above, there is evidence that strongly favours the presence of low molar mass cyclic structures in the low molar mass tail of the GPC curves.

Mechanism of oxidative coupling of polymerization routes A and B

From previous studies on the mechanism for the oxidative coupling of reaction of α,ω-alkyldiynes several points were concluded:

(*i*) The cupric ion (copper II) is the actual oxidant (7, 17, 18)

$$2RC{\equiv}CH+Cu^{2+} \rightarrow RC{\equiv}C\text{-}C{\equiv}CR + 2H^{+} + Cu(I)$$

The Cu(I) can then oxidize back to Cu(II) for further coupling.

$$2Cu(I) + 0.5O_2 + H_2O \rightarrow 2Cu(II) + OH^{-}$$

(*ii*) Under acidic conditions the reaction rate increases with increasing Cu(I) concentration (7, 17, 18).

(*iii*) The greater the acidity of the terminal alkyne the faster the reaction rate (7, 18).

(*iv*) The reaction is second order with respect to the concentration of the alkyne (17, 18).

(*v*) A bridged dimeric structure was isolated for the catalyst complex, confirmed by X-ray diffraction studies, and consistent with detailed mechanistic studies (5, 7, 17–19).

(*vi*) Increasing the basicity of ligand, i.e., TMEDA > TEA > py, and the ligand concentration increases the reaction rate (5, 20).

(*vii*) On increasing the polymerization temperature from 26 to 65°C (i.e., Kevelam's (5) and Knol's (6) work) and decreasing the concentration of the α,ω-alkyldiyne, a corresponding increase in reaction rate and molar mass were achieved.

In this present study involving oxidative polymerization routes A and B further observations were made:

(*i*) For Route A: on increasing the polymerization temperature from 60 to 80°C an optimum polymerization temperature of 65°C was established for poly(1,9-decadiyne). An M_n value of 29 300 was achieved.

(*ii*) For Route B: on increasing the polymerization temperature from 40 to 80°C for poly(1,9-decadiyne) the M_n values go through a minimum.

(*iii*) For Route B: on increasing the time for polymerization for both monomers 1,8-nonadiyne and 1,9-decadiyne there is a corresponding decrease in molar mass (M_n).

As previously mentioned, there are three main differences between polymerization routes A and B:

1. Polymerization delay time
2. Cu(I)Cl:TMEDA ratio
3. Solvent system employed

In polymerization route A the Cu(I)Cl:TMEDA ratio is 1:1 with pyridine controlling the basicity of the reaction medium. In polymerization route B the Cu(I)Cl:TMEDA ratio is 1:50 with no pyridine solvent present, therefore the excess TMEDA controls the basicity of the reaction medium. In route A the pyridine solvent is present in 13 molar equivalents more than the Cu(I)Cl and TMEDA molar equivalents. In route B the TMEDA is in excess by 49 molar equivalents. Kevelam has shown that the reaction rate for oxidative coupling increases with increasing ligand concentration and increased basicity of ligand (5). Pyridine has a pK_b of 8.75 (21) and TMEDA has a pK_b of 4.9 (22). Therefore, since TMEDA is present in 3–4 times greater amount than pyridine and it is more basic than pyridine, the rate of oxidative coupling for polymerization route B will be faster than for polymerization route A. The solubility of the bridged dimeric catalytic complex decreases with increasing TMEDA concentration, causing a maximum reaction rate (5). Also, the more basic the ligand, the more it will facilitate the entrance of the acetylenic end group in the bridged dimeric catalytic complex.

However, more importantly, since there is a greater concentration of base in polymerization route B, it is conceivable that the two end-group protons could be removed from an α,ω-alkyldiyne monomer, dimer, trimer, tetramer, pentamer, etc., giving a doubly negatively charged terminal diacetylene, i.e., for the case of the α,ω-alkyldiyne monomer.

When there is a high concentration of these doubly negatively charged terminal diacetylenes present there is a high probability that two of these will coordinate like bidentate ligands to the bridged dimeric catalytic complex; then, on intramolecular oxidative coupling, a cyclized product will form. However, as the reaction proceeds to higher molar mass polymer, cyclization will be less of a problem as linear polymerization is more sterically favourable (23).

A mechanism for the polymerization of the α,ω-alkyldiynes to give both linear and cyclic structures now shown.

Then the catalytic complex reforms:

$$2\ CuCl + 2\ TMEDA + 0.5\ O_2 + H_2O \rightleftharpoons [Complex]$$

This structure can continue to polymerize linearly or to cyclize.

The above mechanism can also be explained for both linear and cyclic routes by way of kinetic expressions (L = ligand, M = monomer, B = base, D = dimer, CD = cyclic dimer).

Linear route

[1] $Cu(I) + L \rightarrow [Cu(I)L]$

[2] $[Cu(I)L] + 0.5\ O_2 + H_2O \rightleftharpoons [Cu_2(II)L_2O_2H_2]^{2+} = [Complex]$

[3] $M + B \rightleftharpoons M^{-} + BH^{+}$

[4] $M^{-} + [Complex] \rightleftharpoons [M{\cdot}Complex] = OH^{-}$

[5] $[M{\cdot}Complex] + [M] \rightleftharpoons [M_2{\cdot}Complex] + OH^{-}$

[6] $[M_2{\cdot}Complex] \rightarrow D + 2[Cu(I)L]$

Then the catalytic complex reforms, i.e.:

$$2[Cu(I)L] + 0.5\ O_2 + H_2O \rightarrow [Complex]$$

and steps [3]–[6] repeat themselves.

Cyclic route

Steps [1] and [2] as above. Then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

Photo-initiated and thermal curing of epoxides by the use of photo-base generators bearing acyloxyimino groups

Ken-ichi Ito, Yoshitaka Shigeru, Yu-uichi Kawata, Katsuhiko Ito, and Masahiro Tsunooka

Abstract: The formation of amines by the photolysis of *O*-acyloximes derived from acetophenone oxime, benzophenone oxime, fluorenone oxime, and 2-acetonaphthone oxime and the curing of epoxides by the resulting amines were investigated. The quantum yields of their photolysis at 366 nm in polystyrene films depend on their structures, and those for bifunctional ones bearing phenyl or naphthyl moieties were found to be very high, at 0.88 and 0.76, respectively. The yields of the resulting amines in polymer matrices were higher than those in solution. The yields for *O*-acyloximes bearing a naphthyl moiety were ca. 90% and higher than for those bearing a phenyl moiety. Although the resulting amines were efficient photo-cross-linkers for poly(glycidyl methacrylate), they were not effective for curing of epoxy resins (oligomers). On the other hand, polymer amines with a glass transition temperature lower than room temperature, which were obtained by the photolysis of copolymers bearing acyloxyimino groups, were found to be effective photo-cross-linkers for the epoxy resins.

Key words: photo-base generator, acyloxyimino group, photo-initiated and thermal curing, poly(glycidyl methacrylate), epoxy resin.

Résumé : On a étudié la formation d'amines par la photolyse d'*O*-acyloximes dérivées des oximes de l'acétophénone, de la benzophénone, de la fluorénone et de l'acéto-2-naphtone et la réaction des amines qui en résultent avec les époxydes. Les rendements quantiques de leurs photolyses à 366 nm, dans des films de polystyrène, dépendent de leurs structures; on a trouvé que ceux des composés bifonctionnels avec des portions phényle ou naphtyle sont très élevés, soit respectivement 0,88 et 0,76. Les rendements des amines qui en résultent dans les matrices de polymère sont plus elevés que ceux en solution. Les rendements pour les *O*-acyloximes portant un groupe naphtyle sont plus élevés (environ 90%) que ceux des acyloximes portant un groupe phényle. Même si les amines qui en résultent sont des photoréticuleurs efficaces pour le poly(méthacrylate de glycidyle), ils ne sont pas efficaces pour la cuisson des résines époxy (oligomères). Par ailleurs, on a trouvé que les amines polymériques, qui se forment par photolyse de copolymères portant des groupes acyloxyimino et qui présentent une température de transition vitreuse inférieure à la température ambiante, sont des photoréticuleurs efficaces pour les résines époxy.

Mots clés : générateur de photobase, groupe acyloxyimino, photoinitiation et cuisson thermique, poly(méthacrylate de glycidyle), résine époxy.

[Traduit par la rédaction]

Introduction

A large number of photo-acid generators such as aromatic diazonium salts and aromatic iodonium salts have been developed and their wide use in the fields of photo-curable coatings (1) and chemically amplified photo-resists (2) investigated. Similarly, although photo-base generators are expected to be promising as photo-cross-linkers for epoxides, used without worrying about corrosive trouble derived from photo-generated acids, only a few articles were published before 1990 concerning photo-base generators and their applications. Kutal and Willson reported that the photolysis of a cobalt–ammine complex led to the formation of ammonia, which induced the cross-linking of a glycidyl methacrylate – ethyl acrylate copolymer upon heating (3). Winkle and Graziano utilized an amine generated by photolysis of an *o*-nitrobenzyl carbamate in a positive photoresist (4). We had also reported that in the photolysis of copolymers of *O*-acryloyl acetophenone oxime (AAPO) with styrene, pendant acyloxyimino (AOI) groups led to pendant amino groups in a good yield (5). Recently, studies on photo-base generators such as *o*-nitrobenzyl carbamates (6) and α,α-dimethyl-3,5-dimethoxybenzyl carbam-

ates (7) have been reported and their utility is gradually being recognized. In particular, applications to microlithography, that is, chemically amplified photo-resists using photo-base generators, have been developed in analogy with those using photo-acid generators. For example, Leung et al. reported the decarboxylation of pendant carboxylic acid groups using photo-generated amines as catalysts (8), and Fréchet et al. (9) and Mckean et al. (10) also used photo-generated amines as catalysts for imidization of polyamic esters. In addition, for application to UV curing, Nishikubo and co-workers (11) utilized amines generated by the photolysis of blocked amines as cross-linkers of epoxy resins or polyurethane oligomers.

In previous articles, we reported that the yields of amines formed by the photolysis of some *O*-acyloximes in polystyrene (PSt) films depended on their structures (12), and these amines were efficient cross-linkers for poly(glycidyl methacrylate) (PGMA) films, but not for epoxy resins (13). In this article, we report various features of *O*-acyloximes as photo-base generators and their applications to photo-initiated and thermal curing of epoxides.

Experimental

Materials

Monofunctional *O*-acyloximes, i.e., *O*-phenylacetyl acetophenone oxime (PaApO), *O*-phenylacetyl 2-acetonaphthone oxime (PaAnO), *O*-phenylacetyl benzophenone oxime (PaBpO), and *O*-phenylacetyl fluorenone oxime (PaFO), and bifunctional *O*-acyloximes, i.e., *O,O′*-succinyl diacetophenone oxime (SDApO) and *O,O′*-succinyl di-2-acetonaphthone oxime (SDAnO), were prepared by a method similar to that described in a previous article (12). Their structures and characteristics are shown in Fig. 1 and Table 1, respectively.

O-Acryloyl acetophenone oxime (AAPO) and *O*-acryloyl 2-acetonaphthone oxime (AANO) were prepared by reaction of the corresponding oximes with acryloyl chloride by a method similar to that described in a previous article (14). Styrene (St) and ethyl acrylate (EA) were purified by distillation under reduced pressure. Copolymers of AAPO or AANO with St or EA were prepared by radical copolymerization in benzene using α,α′-azobisisobutyronitrile (AIBN) as initiator under vacuum at 60°C (5). In the case of the copolymer of molecular weight below 10 000, 0.2 mol% lauryl mercaptan as chain transfer agent was added in the benzene solution. The structures and abbreviations of the copolymers are shown in Fig. 2. The contents of monomeric AAPO and AANO in the copolymers were determined by their elemental analysis carried out on a Yanaco MT-3 CHN corder. Their molecular weights were determined by using GPC (JASCO) in comparison with those of polystyrene standards. Their glass transition temperatures (T_g's) were determined by using DSC (Rigaku DSC 8230). Table 2 shows the polymerization conditions and the characteristics of the copolymers.

Poly(glycidyl methacrylate) ($\overline{M}_n$ = 117 000) was prepared by solution polymerization in benzene using AIBN as initiator under vacuum at 60°C and was purified by reprecipitation of PGMA in tetrahydrofuran (THF) with methanol. Commercial epoxy resins, EPOLIGHT 100MF (trimethylol propane triglycidyl ether, epoxy equivalent: 140) (TMPGE) and EOCN 104S (*o*-cresol novolac epoxy resin, epoxy equivalent: 215) (EOCN) were provided by Kyoueisha Yusi Kagaku Kogyo

Co. Ltd. The structures and the degree of polymerization of epoxy resins are shown in Fig. 3.

Reagent grade benzophenone (BP) was recrystallized from ethanol. Tetrahydrofuran (Reagent grade) was distilled prior to use. 3,5-Dinitrobenzoyl chloride (Tokyo Kasei Co., HPLC labeling grade, mp 67–69°C) (DNBC) was used without further purification. Polystyrene (Katayama Kagaku Kogyo Co., $\overline{M}_n$ = 113 000) was purified by reprecipitation of PSt in THF with methanol. Poly(methyl acrylate) ($\overline{M}_n$ = 129 000) (PMA) was prepared and purified in a similar manner to PGMA.

Photo-irradiation and quantitative analysis of amines or amino groups

The determination of the yield of amines for *O*-acyloximes in polymer films was carried out by a method similar to that described in a previous article (12). That is, polymer films (35–45 μm thick) with 5 wt.% *O*-acyloxime and 10 wt.% BP as sensitizer to the polymer were prepared by casting THF solutions of the polymer and additives on a Petri dish. In the

case of PSt films, they were taken out of the Petri dish after standing overnight in the dark at room temperature and dried under reduced pressure (3 Torr; 1 Torr = 133.3 Pa) overnight at room temperature. These films were irradiated with a high-pressure mercury lamp (Sen Tokusyu Kogen, HL-100, 100 W) without a filter at a distance of 10 cm at room temperature under N_2 for 1 h to photolyze the *O*-acyloximes completely. On the other hand, PMA films were irradiated on a Petri dish in a similar manner as described above because they were too soft to take out of the Petri dish, their T_g being below room temperature. The intensity of the incident light was 4.10 mW/cm^2 at 366 nm. A water-vapor treatment was carried out to completely hydrolyze the photolysates formed by the photolysis of *O*-acyloximes in the irradiated film. That is, the irradiated film was allowed to stand for 10 min in a glass chamber with saturated water vapour at 25°C. Then the polymer films (40–50 mg) were dissolved in THF (2 mL). After the amines in the solution were converted into *N*-3,5-dinitrobenzoylamines (DNBAs) by the reaction with DNBC, the amount of DNBAs in the solution was determined on a HPLC equipped with a UV detector (JASCO 970-UV).

Quantitative analysis of the amines formed in solution was carried out as follows. A benzene solution (3 mL) of an *O*-acyloxime (0.1 mol/L) containing BP (0.1 mol/L) in a quartz cell (1 × 1 × 5 cm) was irradiated under N_2 for 1 h, in a similar manner as described above. After the irradiated benzene solution (0.5 mL) was diluted with THF (19.5 mL), DNBC (ca. 20 mg) was added to a portion (2 mL) of the solution. The very small amount of water in the THF was enough to hydrolyze the photolysates formed by the photolysis of *O*-acyloximes. The amount of amines in the solution was determined on the HPLC in a manner similar to that described above.

Determination of the yield of amino groups for copolymers bearing AOI groups was carried out by a method similar to that described in a previous article (5). That is, the films of copolymers with 10 wt.% BP (ca. 20 μm thick) were irradiated without a filter, in a manner similar to that described above, to photolyze the AOI groups completely; this was confirmed by the disappearance of the absorption of AOI groups at 1760 cm^{-1} in the IR spectrum. After the water-vapour treatment, the irradiated film was dissolved in THF, and the resulting polymer in THF was purified by reprecipitation with methanol 3 times. Then the polymer was dried under reduced pressure (3 Torr) overnight at room temperature. The nitrogen content of the polymer was determined by elemental analysis. The yield of amino groups was calculated from the nitrogen content.

Quantum yield of photolysis of *O*-acyloximes in a polymer matrix

The PSt films (ca. 45 μm thick) containing 5 wt.% *O*-acyloximes and a given amount of BP were irradiated with 366 nm light by use of the high-pressure mercury lamp combined with a filter (Toshiba UV-D1B) at room temperature in air in a similar manner to that described above. The degree of decomposition of the *O*-acyloximes was determined by following the changes in absorbance, at about 1750 cm^{-1}, due to the AOI groups in their IR spectra, which were measured on a IR spectrometer (JASCO IR-810). The quantum yield of photolysis of *O*-acyloximes in PSt films with 366 nm light (ϕ_{366}) was determined as moles of decomposed *O*-acyloximes divided by einsteins of light absorbed by the film (eq. [1]).

$$[1] \quad \phi_{366} = \Delta m/\Delta I_{abs} = \Delta m/[I_0(1 - 10^{-A})tS]$$

where Δm: moles of decomposed *O*-acyloximes (mol); ΔI_{abs}: einsteins of light absorbed by the film (einstein); I_0: intensity of light at 366 nm (einstein cm^{-2} s^{-1}); A: absorbance of the film at 366 nm; S: irradiated area of the film (cm^2); and t: irradiation time (s).

The intensity of the irradiating light was determined by potassium ferrioxalate actinometry (15).

Photo-chemical insolubilization of PGMA films with *O*-acyloximes

The PGMA films (ca. 35 μm thick) with a given mol% *O*-acyloxime and 10 wt.% BP prepared by the casting method were irradiated in a similar manner as that described above, in air for 1 h, followed by the water-vapor treatment. Then the films were heated at 80°C for 1 h on a hot plate. The films (ca. 0.05 g) were immersed in THF (5 mL) for 1 d at room temperature; then the insoluble fractions were separated by centrifugation. The supernatant liquid was next removed and THF (5 mL) was added for washing the insoluble fraction, and the insoluble fraction was again separated by centrifugation. This series of washing operations with THF was repeated 3 times, the supernatants were removed, and then methanol (5 mL) was added for washing the insoluble fraction. This insoluble fraction was separated by centrifugation. After most of the solvent was removed by an aspirator, the insoluble fraction was dried under reduced pressure (3 Torr) at room temperature overnight, and its dry weight determined (13).

Photo-chemical insolubilization of the films composed of copolymers bearing AOI groups and epoxy resins

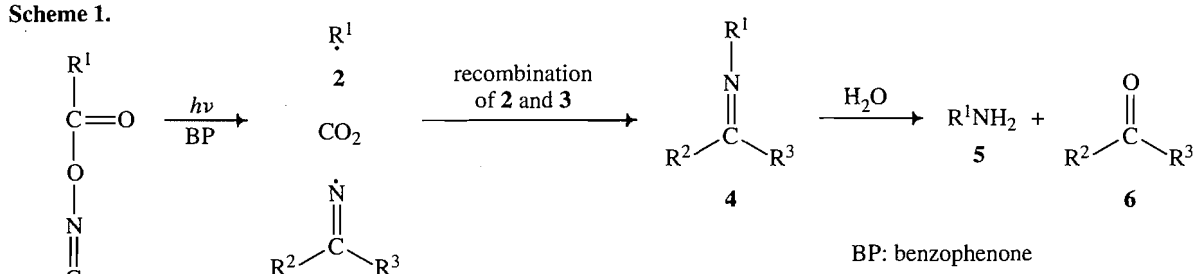
Thin films (ca. 0.15 μm thick) containing a given amount of copolymers bearing AOI groups an epoxy resin, and BP were prepared by casting their THF solutions onto a quartz plate. Each film was irradiated on the quartz plate with the high-pressure mercury lamp at a distance of 7 cm, at room temperature in air, for a given time. Then the irradiated film was heated at a given temperature for a given time. In this case, the water-vapor treatment was not carried out because the insoluble fraction of the film was not changed by this treatment. After the film was immersed in THF for 10 min at room temperature, it was dried under hot air for a few minutes. The insoluble fractions were determined from the difference in thickness of the films before and after the immersion. The thickness of the films was determined by two-beam interferometry with an interference microscope (Nikon OPTIPHOT).

Results and Discussion

Amine formation by the photolysis of *O*-acyloximes

In a previous article (12), we reported that amines are formed in the photolysis of *O*-acyloximes in PSt films as shown in Scheme 1. That is, benzophenone (BP) absorbs UV light and the energy of the excited BP is transferred to the *O*-acyloximes. The decomposition of the excited *O*-acyloxime (**1**) leads to the formation of an alkyl radical (**2**), an imino radical (**3**), and carbon dioxide. Then an azomethine (**4**) is formed by the recombination of 2 and 3, and finally an amine (**5**) and a

Scheme 1.



ketone (**6**) are generated by the hydrolysis of **4**. Most of the intermediary azomethines are considered to be easily hydrolyzed by water vapor in air during irradiation since PGMA films (even ca. 35 μm thick) containing *O*-acyloximes and BP were insolubilized appreciably by heating after irradiation under air without a water-vapor treatment (16). Besides, although imines and azines are obtained from **3** as described in the previous article (12), the yield of the azines was very low and the yield of the imines depended on the structure of the *O*-acyloximes.

Table 3 gives quantum yields of photolysis at 366 nm (ϕ_{366}) for *O*-acyloximes in the presence of 10 wt.% BP. The ϕ_{366} for PaAnO was highest among the monofunctional *O*-acyloximes, at 0.58, and that for PaFO was lowest, at 0.06. Although the triplet energies of the *O*-acyloximes are deduced to be close to triplet energies of the original ketones (17), it is difficult to clarify the relation between the triplet energies and the ϕ_{366} values for each at present. The ϕ_{366} for PaAnO was hardly altered by the change in amount of BP as sensitizer in the range of 5–15 wt.%. This result shows that the decomposition rate is proportional to the amount of BP over this range, and that the efficiency of decomposition based on absorbed light intensity is the same. Interestingly, the ϕ_{366} for the bifunctional *O*-acyloximes, i.e., SDApO and SDAnO, was higher than for the monofunctional *O*-acyloximes. Similar results were observed for the ϕ_{366} of pendant acyloxyimino (AOI) groups in polymers (Table 3).

Table 4 shows the yields of amines based on decomposed *O*-acyloximes. The yields of amines for PaApO and PaAnO in the PSt films were 72% and 89%, respectively, which were ca. 30% higher than those in benzene solutions. This result shows that the recombination of imino and alkyl radicals occurs more effectively in a polymer matrix than in solution. As described in a previous article (12), it is deduced that the movement of *O*-acyloximes is restricted by the PSt main chains since the glass transition temperature (T_g) of PSt containing 5 wt.% *O*-acyloximes and 10 wt.% BP is 54°C, and higher than room temperature. This result suggests that the increase in the yield is due to a cage effect of the polymer matrix.

On the other hand, the yields for PaApO and PaAnO in PMA films were lower than those in PSt films. Since the segment motions in the main chains in the PMA (T_g = 7°C) occur at room temperature, it is deduced that the PMA matrix is not effective for the formation of amine precursors.

The yields of amines for PaAnO and SDAnO in PSt films were ca. 20% higher than those for PaApO and SDApO, respectively. This result suggests that the bulkiness of a naphthyl moiety in PaAnO and SDAnO was advantageous to the formation of amine precursors. Similarly, the yield of amine for PaBpO was high, as well as that for PaAnO or SDAnO. This seems to be due to the bulkiness of AOI groups bearing two phenyl moieties. These results suggest that the bulkiness of the AOI group is important for efficient formation of the amine precursors.

The formation of polymer amines was also similarly investigated. Figure 4 shows the relationship between the yield of amino groups and the content of AAPO or AANO in the copolymers. The results for AAPO copolymers are taken from a previous article (5). In Fig. 4, yields of amino groups for AANO–St's were almost the same as those for AAPO–St's at any content of AANO. This result was different from the result for *O*-acyloximes described above. It seems that, judging from the T_g's of the copolymers, the motions of pendant AOI groups are restricted more strongly by the main chains of the copolymers at room temperature, and that the yields for the two copolymers are almost the same. Here, since an increase in the contents of AANO in the copolymers leads to an

increase in their T_g's, the effect of T_g on the yield was not considered.

Photo-chemical insolubilization of PGMA film with *O*-acyloximes

Table 5 shows the results of insolubilization of PGMA films containing *O*-acyloximes and BP by UV irradiation. The films were irradiated for 1 h in air and then heated at 80°C for 1 h after water-vapor treatment. No insolubilization of the films occurred by the water-vapor treatment and (or) by heating without irradiation. From the results for insoluble fractions of the films, PaAnO was more active than PaApO and a similar relation was observed for bifunctional *O*-acyloximes. However, the bifunctional *O*-acyloximes, SDApO and SDAnO, were more active than the monofunctional ones, PaApO and PaAnO. In Table 4, the yield of benzylamine for PaAnO is higher than that for PaApO. Thus, the order of activity of the monfunctional *O*-acyloximes as photo-cross-linkers is understood to be due to the difference in the yields of amines. Although there is no difference in the yields of amines between monofunctional and bifunctional oximes with the same AOI groups, bifunctional oximes were much more active as photo-cross-linkers than the monfunctional ones. Ethylenediamine and benzylamine are obtained in the photolysis of bi- and monofunctional *O*-acyloximes, respectively. Although the difference in their basicity should be considered, bifunctionality of the resulting amine is thought to be beneficial for cross-linking.

While these results show that the *O*-acyloximes acted as photo-cross-linkers of PGMA, these amines were not efficient cross-linkers for trifunctional epoxy resins such as TMPGE, as described in a previous article (13). We later investigated thermal curing of epoxy resins by polymer amines formed by the photolysis of copolymers bearing AOI groups.

Photo-chemical insolubilization of AAPO copolymer films with TMPGE as a cross-linker

Figure 5 shows the effect of irradiation time and heating temperature on photo-cross-linking of AAPO(34)–St or AAPO(33)–EA films. On heating at 150°C after irradiation, both films were insolubilized rapidly at almost the same rate With lowering of the heating temperature, the insolubilization rate of AAPO(34)–St films fell significantly, while that of AAPO(33)–EA films did so only slightly. To clarify the difference in the photo-cross-linking behavior of these copolymers, effects of miscibility of TMPGE and BP with the copolymers and of the T_g's of the copolymers on the photo-cross-linking were investigated. The miscibility of the copolymers with TMPGE and BP was satisfactory, because only one T_g was observed for each film composed of AAPO–St or AAPO–EA, BP, and TMPGE. The T_g's of AAPO(34)–St and AAPO(33)–EA with 10 wt.% TMPGE and 10 wt.% BP were 68.3 and −11.8°C, respectively.

Figure 6 shows Arrhenius plots of the photo-cross-linking of AAPO(34)–St and AAPO(33)–EA films. The photo-cross-linking rate (κ) was determined as a reciprocal of the time required for insolubilization of 50% of the copolymer film in Fig. 5. The apparent activation energies (E_{act}) of insolubilization for AAPO(34)–St and AAPO(33)–EA films that were calculated from the plot were 64.3 and 21.3 kJ/mol, respectively. The cause of the lowering in E_{act} for AAPO(33)–EA is thought to be due to the difference in energy required for the segmental motion of AAPO(33)–EA, because miscibility of TMPGE with both polymers was good and the T_g of AAPO(33)–EA was considerably lower than that of AAPO(34)–St.

Figure 7 shows the effects of the molecular weights of AAPO copolymer and the heating temperature after irradiation on insoluble fractions of AAPO copolymer films. The films were heated at a given temperature for 10 min after irradiation for 10 min in air.

All AAPO films were cross-linked effectively by TMPGE on heating at 150°C after irradiation, while the proportion of the insoluble fractions was very different at lower temperatures. Insolubilization of AAPO(33)–EA (T_g = 5.1°C, $\overline{M}_n$ = 92 000) films occurred at room temperature and the insoluble fraction of the film reached ca. 50%, while heating at temperatures over 70°C was required for insolubilization of AAPO(34)–St (T_g = 93.3°C, $\overline{M}_n$ = 85 000) films. Since the T_g of AAPO(33)–EA is lower than room temperature, it is deduced that the reaction of amino groups in the copolymer with epoxy groups occurs efficiently at room temperature. Although the T_g's of AAPO(26)–EA (T_g = 0.8°C, $\overline{M}_n$ = 5200)

Fig. 5. Effect of irradiation time and heating temperature on photo-cross-linking[a] of AAPO(34)–St films (*a*) and AAPO(33)–EA films (*b*) with 10 wt.% BP and 10 wt.% TMPGE (ca. 0.15 μm thick): (■) 60°C, (□) 80°C, (●) 100°C, (○) 150°C.

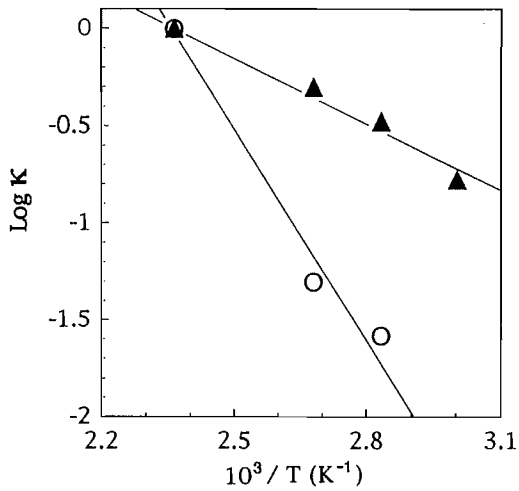

Fig. 7. Effects of molecular weights of AAPO copolymers and heating temperature on insoluble fraction[a] of AAPO copolymer films (ca. 0.15 μm thick): with 10 wt.% BP and 10 wt.% TMPGE: (○) AAPO(33)–EA (M_n = 92 000, T_g = 5.1°C), (●) AAPO(26)–EA (M_n = 5200, T_g = 0.8°C), (□) AAPO(34)–St (M_n = 85 000, T_g = 93.3°C), (■) AAPO(29)–St (M_n = 3300, T_g = 70.2°C).
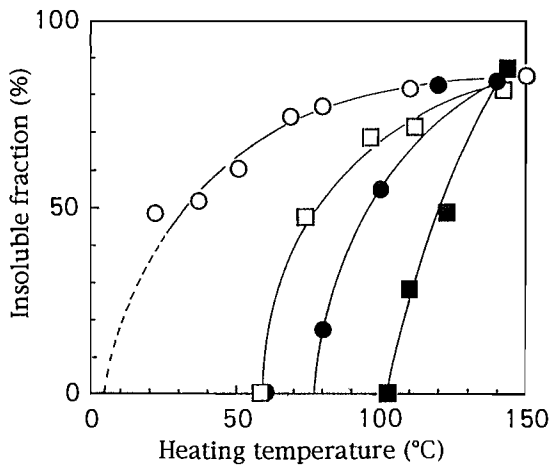
[a]After irradiation for 10 min in air, heated for 10 min.



and AAPO(29)–St (T_g = 70.2°C, $\overline{M}_n$ = 3300) were lower than those of the corresponding copolymers, which had higher molecular weights, the higher temperature for insolubilization of the former two copolymers was needed. It is deduced that the lowering of molecular weights of the copolymers affects the insolubilization more strongly than the lowering of T_g.

Photo-chemical insolubilization of epoxy resin films by use of AAPO or AANO copolymers as photo-cross-linkers

Table 6 shows relations between the ratio of TMPGE and AAPO copolymers in the films and the insoluble fractions. The films were heated at 100°C for 5 min after irradiation for 10 min in air. The insoluble fractions for any copolymer except AAPO(29)–St were highest at 10 wt.% TMPGE. At this wt.%, insoluble fractions for both AAPO(33)–EA and AAPO(34)–St, which had higher molecular weights, were ca. 90%.

The insoluble fractions were lowered with an increase in content of TMPGE. In the case of AAPO copolymers, which had lower molecular weights, the insoluble fractions were lower than those for the copolymers that had higher molecular weights. Especially, AAPO(29)–St films were not insolubilized at any ratio. These results show that AAPO copolymers do not work as photo-cross-linkers for TMPGE at low content.

Table 7 shows the effect on the insoluble fractions of the weight ratio of an epoxy resin with a higher molecular weight, EOCN, to the copolymers. Since only one T_g was observed in any ratio of EOCN and copolymer and the T_g varied with the ratio as shown in Table 8, it is thought that the miscibilities of EOCN with the copolymers were also good. The films were heated at 100°C for 5 min after irradiation for 10 min in air. The insoluble fractions for AAPO(33)–EA and AANO(32)–EA were ca. 80% at any ratio except AANO(32)–EA with 80 wt.% EOCN. This result was very different from the results in

50/50	−3.3	5.1	19.0
80/20	−8.2	−3.0	6.9
100/0	−9.6	−9.6	−9.6

Table 6. Although the films of AAPO(34)–St were also insolubilized even at lower content of the copolymer, the proportion of insoluble fractions of AAPO(34)–St was lower than that of AAPO(33)–EA or AANO(32)–EA. It is thought that the T_g's of their copolymers played an important role in the insolubilization. These results suggest that copolymers bearing AOI groups can be used as effective photo-cross-linkers for epoxy resins by choosing an appropriate combination of epoxy resin and copolymers.

Conclusions

1. The use of *O*-acyloximes and copolymers bearing AOI

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

groups as photo-base generators was verified. This could be applied to photo-initiated curing of epoxides.

2. The yields of amine for *O*-acyloximes bearing a bulky moiety such as a naphthyl group were found to reach ca. 90% in PSt films under N_2.

3. It was found that the T_g of copolymers bearing AOI groups played a very important role in the curing of epoxides when the copolymers were used as photo-cross-linkers.

Chemically modified pullulans II. New hydrophobically substituted derivatives

G. Mocanu, A. Carpov, S. Chapelle, L. Merle, and G. Muller

Abstract: New hydrophobically substituted pullulans were synthesized, such as (*i*) neutral derivatives obtained by direct esterification of pullulan with adenine and thymine butyric acid and (*ii*) ionic derivatives obtained by amidation of carboxymethyl pullulan with aromatic amines (aminopyrene and adenine). Rheological measurements in dilute solutions allowed us to test the influence of the hydrophobic aromatic substituents and of the ionicity of the parent support on the nature of the hydrophobic associations in dilute solutions. The rheological studies on the pullulan derivatives revealed mainly intramolecular hydrophobic associations for both ionic and non-ionic derivatives, suggesting a more compact conformation than that of the precursor.

Key words : hydrophobically modified pullulans, esterification, amidation, condensed aromatic ring, size exclusion chromatography, multi-angle laser light scattering.

Resumé : On a synthétisé de nouveaux pullulanes substitués d'une façon hydrophobe, tels que les dérivés neutres obtenus par estérification directe du pullulane avec l'acide butyrique de l'adénine et de la thymine ainsi que les dérivés ioniques obtenus par amidation du carboxyméthylpullulane avec des amines aromatiques (aminopyrène et adénine). Des mesures rhéologiques en solutions diluées ont permis de vérifier l'influence des substituants aromatiques hydrophobes et du caractère ionique du support parent sur la nature des associations hydrophobes en solutions diluées. Les études rhéologiques sur les dérivés du pullulane ont mis en évidence l'existence d'associations principalement hydrophobes intramoléculaires pour les dérivés aussi bien ioniques que non ioniques; ceci suggère que la conformation est beaucoup plus compacte que celle du précurseur.

Mots clés : pullulanes hydrophobiquement modifiés, estérification, amidation, noyau aromatique condensé, chromatographie par exclusion stérique, diffusion de la lumière laser à angles multiples.

[Traduit par la rédaction]

Introduction

Pullulan is a neutral water-soluble exopolysaccharide with a linear flexible macromolecular chain, formed mainly by α-1,6-linked maltotriose sequences containing α-1,4-linked D-glucose units (pannose) in a 2:1 ratio.

The reactivity of its alcohol groups permits the obtention of a large variety of pullulan derivatives, such as etherified (1), esterified with aliphatic or aromatic acids (2, 3), cationized (5), sulfoalkylated (6), or sulfated (6) pullulans.

Recently, many studies have been devoted to hydrophobically modified water-soluble synthetic polymers (7–9) and natural polysaccharides (10–12). Special concern for such materials may be explained by their interesting properties, leading to their use as tensioactive agents (13), associative thickeners, and support for enzyme immobilization (13) in biotechnology and medicine (14). Hydrophobically modified pullulans have been much less studied. Sunamoto and co-workers have reported the synthesis and properties of palmitoyl (15) and cholesteryl (16) modified pullulan derivatives and their use as host for protein guests (16, 17).

The present paper reports the synthesis, in organic medium, of new hydrophobically modified pullulan derivatives: i.e., non-ionic by esterification with adenine and thymine *n*-butyric acid in the presence of dicyclohexylcarbodiimide, and ionic by amidation of carboxymethyl pullulan with aromatic amines (aminopyrene or adenine).

The choice of nucleic bases and of aminopyrene was made for two reasons: (*i*) introduction of a hydrophobic moiety on the polysaccharide chain, (*ii*) utilization as fluorescent labels for further photophysical measurements.

The rheological behaviour of these derivatives was studied for comparative determination, as a first approach, of the nature of the hydrophobic associations of derivatives of a same precursor.

dicyclohexylcarbodiimide (DDCI) are commercial products from Aldrich.

Dimethylformamide and dimethyl sulfoxide (Prolabo) were freshly distilled on CaH_2 under argon.

Carboxymethyl pullulan (CMPNa), with a degree of substitution DS = 0.88, was a laboratory sample synthesized in Romania according to the procedure reported in a patent (18) and recently characterized (19).

Synthesis of intermediate products

Ethyl-2 (adenine-9-yl) butyrate and its acid (ABA), and ethyl thymine-1-yl butyrate and its acid (TBA) were synthesized following the method described by Overberger and Morishima (20) for propionic adenine derivatives. Thymine-1–yl butyric acid (TBA) was obtained by methanolic alkaline hydrolysis. This milder hydrolysis was preferred to the acidic one (5 N HCl), which leads to complex degradation products.

The purity was checked by ^1H NMR in DMSO-d_6; ABA: aliphatic (CH_2), 4.2 ppm; Ad-NH_2: 7.35 ppm (2H), H_2-H_8Ad: 8.25 ppm, 2H; TBA: CH_3: 1.75 ppm, aliphatic (CH_2): 3.25–4.20 ppm; T-H_2: 7.5 ppm; and mass spectroscopy analysis (in glycerol matrix: ABA, *m/z*, $[MH]^+$: 222; TBA, *m/z*, $[MH]^+$: 213.

Synthesis of pullulan esters

Pullulan adenine-9-yl butyric acid ester (PAE)

Pu (1 g, 6.17 mM) and 0.02 g of *N,N*-dimethylamino pyridine (DMPA) were dissolved in 10 mL of dry DMSO, at room temperature. Separately, 0.681 g (3.08 mM) of ABA was dissolved in 10 mL of DMSO together with 0.634 g (3.08 mM) of *N,N'*-dicyclohexylcarbodiimide, the mixture was stirred for 30 min at room temperature, and then added to the pullulan solution. The reaction was run for 48 h at room temperature under stirring. Then the polymer was precipitated three times by pouring the water solution into ethyl alcohol, was washed with warm alcohol to extract the last traces of adenine physically included in the polymer, and finally the clear aqueous solution was freeze-dried (recovery: 90% of pullulan derivative). Any free adenine can be detected, by checking by UV (TLC eluant: dichloromethane:methanol, 92:8).

The pullulan-containing thymine (PTE) derivatives were obtained in the same way. Table 1 summarizes the different samples obtained.

Table 1. Adenine and thymine ester pullalan derivatives.

Sample	Reagent	Molar ratio reagent per glucose unit	% Content per mole by UV
G3	Adenine-9-butyric acid	0.5/1	4.57
G4	Adenine-9-butyric acid	0.75/1	5.8
G5	Adenine-9-butyric acid	1.2/1	7.05
G6	Thymine-1-yl butyric acid	0.5/1	4.57
G7	Thymine-1-yl butyric acid	0.5/1	4.57

Table 2. Carboxymethyl pullulan containing an amide group.

Sample	Reagent	Molar ratio reagent per glucose unit	% Content per mole	
			by UV	Conductimetry
G9	1-Aminopyrene	0.2/1	4.57	2.05
G10	Adenine	0.4/1	3.4	5.8

Synthesis of pullulans containing amide groups (aminopyrene and adenine)

With 1-aminopyrene (or with adenine): to 1 g (4.71 mM) of CMP (as COOH) (with DS = 0.88) dissolved in 10 mL of dry DMSO was added 0.19 g (0.92 mM) of DDCI under stirring during 30 min. Then, 0.2 g (0.92 mM) of aminopyrene and 0.02 g of DMPA in 10 mL of DMSO were added to the carbodimide preactivated CMP (as COOH), and stirred at room temperature during 48 h. The polymer (sodium salt) was purified as above, neutralized, then dialyzed against water and freeze-dried. Any free aminopyrene can be detected.

Methods

The adenine and thymine contents of the pullulan esters were determined by UV analysis of their aqueous solutions, taking as model samples the butyric esters (ε = 13 900 and 11 600 L mol^{-1} cm^{-1} at 260 and 267 nm, respectively, for N_9-adenine and N_1-thymine *n*-butyl ethyl esters). The results are listed in Table 1.

The degrees of substitution (DS) of the hydrophobic moiety of the carboxymethyl pullulan were established by conductimetric titration in an excess of acid, following the method of Eyler et al. (21) as the difference between the DS of precursor and that of the modified polymer, in good accord with the results obtained from UV analysis for aminopyrene and adenine derivatives, thus confirming the accuracy of the conductimetric method. The contents of CMP are presented in Table 2.

Rheological measurements were performed in dilute solutions with a low-shear 30 Contraves rheometer. Size Exclusion Chromatography (SEC) curves were obtained as described in ref. 19.

NMR spectra were recorded at 323 K, on a Brucker ARX 400 spectrometer equipped with a multinuclear 5 mm probe.

The ^{13}C frequency was 100.62 MHz. An aqueous solution of 2,2,3,3-tetrahydroxide-3–trimethyl silyl propionate (TMSP) was taken as chemical shift reference. Spectra were broad-band decoupled and obtained with nuclear Overhauser enhancement. Sample concentrations were ~20% in D_2O.

Results and discussion

The structures of the synthesized hydrophobically substituted derivatives are presented in Scheme 1.

As seen from the data presented in Table 1, the percentage of the esterification reaction (in the presence of DDCI), due to the weak acidity of ABA or TBA, remains low enough, as less than 10% of the amount of reagent was used.

Because of its low nucleophilicity, the *exo* amino group of adenine is usually attacked only by reactive acid chloride or anhydride. The adenine was grafted to the CMP by the Ad_6NH_2 group, through the anhydride intermediate of CMP (usual mechanism of DDCI), in spite of the very low p*K* value of adenine. Nevertheless, the reaction of amidation is nearly quantitative (Table 2).

Figures 1(*a*) and 1(*b*) show the ^{13}C NMR of CMP and the modified adenine CMP spectrum. The CMP spectrum was assigned on the basis of the known pullulan ^{13}C NMR data (21). The main difference between both spectra is the appearance of a new signal around 80 ppm corresponding to the deshielding of C_6(1-6) by the amide substitution and the broadening of the signals due to the C_6(1-6) (61.5 ppm) and C_4(1-4) (77.1 ppm) non-substituted carbon atoms; this broadening was attributed to an equilibrium between several conformers.

The spectrum of adenine CMP is similar to that of CMP, except that two small new peaks are detected: one at 185.7 ppm corresponding to an amide carbonyl group and the second at 154.5 ppm assigned to the $C_{2'}$ of adenine. The presence of these two peaks bears evidence that CMP was modified via the NH_2 of the adenine. The relative ratio of the amide and the carboxymethyl group peaks was around 3%, in agreement with UV data (although no quantitative inverse gating procedure was used). Let us mention also the presence of six well-resolved α-C_1 anomeric peaks due to the nonequivalence of the six α-glucose units; the quaternary carbon atoms of adenine do not appear.

The plot of reduced viscosity against the concentration of pullulan precursor is compared to those of its nucleic base esters, in dilute 0.1 N NaCl solutions (Fig. 2). The intrinsic viscosities [η] decrease when the content of hydrophobic substituent increases. The change in viscosities can be attributed to the intramolecular interaction. Indeed, we verified that no degradation occurred due to the action of the carbodimide or to the presence of the acid group of the reagents, as checked on pullulan treated either with DCCI or ABA alone. As the [η] values obtained are of the same order as those for the pullulan precursor, it may be assumed that no degradation takes place on the polymeric chain during the reaction. Thus, the polymer coil contraction detected by the viscosimetry change can be attributed to hydrophobic association.

Generally, the introduction of hydrophobic groups will affect the intrinsic viscosity and the Huggins constant *k′* in the classical relation:

$$\eta_{red} = [\eta] + k'[\eta]^2 c$$

For a random coil polymer, a common value of 0.3–0.8 is found for *k′* and values larger than 0.8 indicate association. From data reported in Table 3, it is clear that *k′* is only slightly changed for both modified pullulan derivatives. On the other hand, the viscosity was found to decrease strongly in the case of adenine-containing pullulan, from $[\eta]_0$ = 66 for pullulan itself to 33.5, to 25.5, to 12.5 mL g^{-1} with ABA content increasing from 4.07 to 7.05% (Table 3), in contrast with the value of the intrinsic viscosities of the PTE derivatives (0.98 and 2.19%), which remain very similar to that of the precursor. This viscosity change is correlated with the hydrophobic character of the grafted moiety, which is more pronounced for the adenine group than for the thymine group.

CMP	—	190	0.10
G9(pyr)	2.0	94.3	0.62
G10(ad)	3.4	87.14	0.38

As is well known, adenine and thymine derivatives in solution form a hydrogen bond association, if they are in opposition to each other; however, the amino group of the adenine or the carbonyl group of the thymine can also associate with the hydroxyl group of the sugar moiety. Consequently, if these last interactions take place in a solution of a 1:1 mixture of adenine- and thymine-substituted pullulan solutions, it is possible to have a decrease in $[\eta]$, corresponding to intramolecular association, and an increase in k', the Huggins constant. Plotting the reduced viscosity of a solution of a 1:1 mixture of samples G4 (adenine – butyric acid ester) and G7 (thymine – butyric acid ester) pullulan derivatives versus concentration gave an average $[\eta]$ value that lies between those for the viscosity of the two separate polymer solutions (Fig. 2). These results suggest that the hydrophobic associations are preponderant or stronger than the possible association by hydrogen bonds, even in a solution of polymers containing both adenine and thymine units, probably at too low a content. (Note, however, that if the substitution is more than 5–6%, the modified polysaccharides are not soluble in water.)

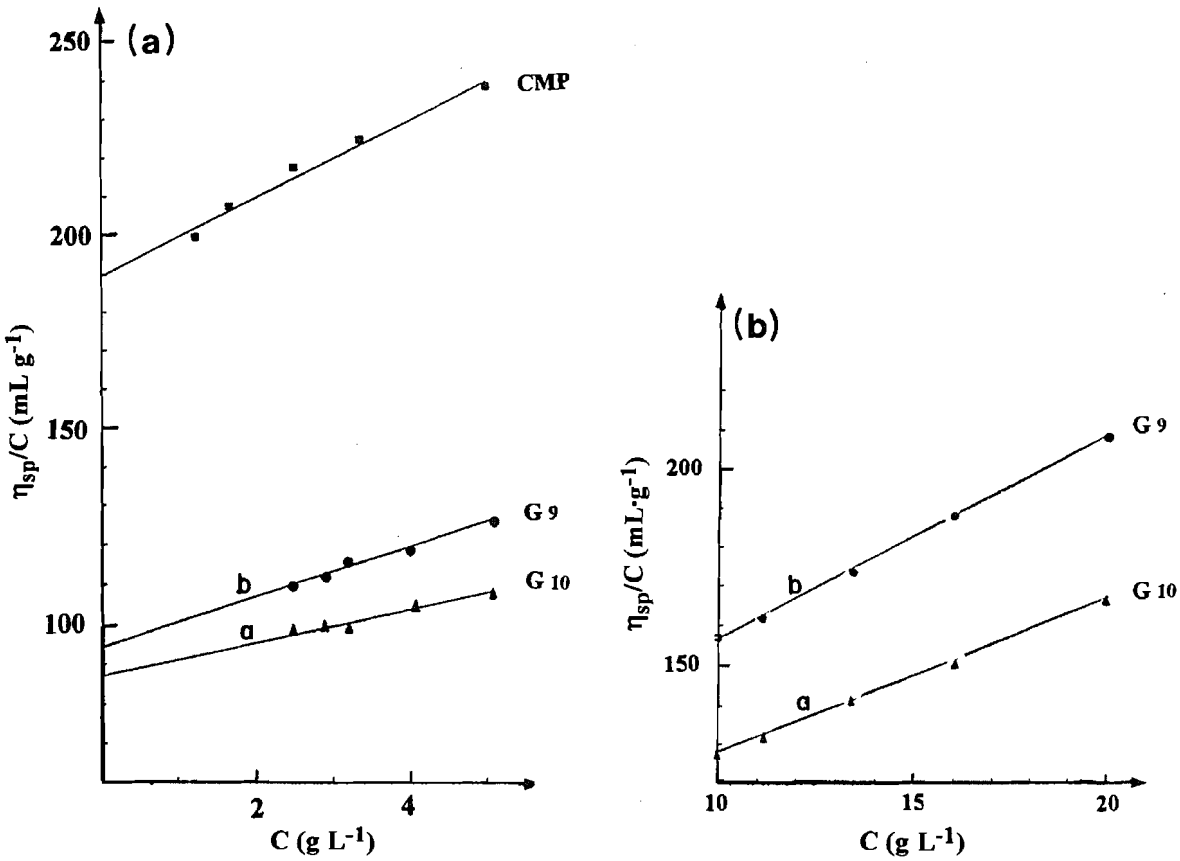
In Table 3 are presented the $[\eta]$ values and k' Huggins constants for the pullulan precursor and its derivatives.

Light scattering measurements performed on sample G4 (pullulan – adenine butyric acid ester, 5.8%) showed a M_W value higher than that of its pullulan precursor ($M_W \sim 3.5 \times 10^5$) and a second virial coefficient A_2 with a negative value ($A_2 \sim -3.7 \times 10^{-3}$ mL mol g^{-2}), which may be attributed to formation of self-aggregates. Later, the same measurement performed after 2 weeks on the same solution showed significant changes of M_W and A_2. This observation suggests the occurrence of an undesirable hydrolysis reaction of ester linkages (as already mentioned for other polysaccharides modified by an ester group), with formation of the parent acid, which in turn can accelerate the degradation of the polysaccharide chain.

Figure 3(*a*) presents the plots of reduced viscosity versus concentration in a dilute concentration of carboxymethyl pullulan and its two amide derivatives (Table 3). As can be seen, the aminopyrene and adenine-CMP derivatives present a similar decrease in $[\eta]$ value, which can be attributed to similar hydrophobic intramolecular interactions of the pyrene (G9) or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Fig. 3. (*a*) Reduced viscosity versus concentration (g L^{-1}) of CMP derivatives, in 0.1 N NaCl: 1, CMP-pullulan; 2, modified (a) with 1-aminopyrene: 1.92% (G_{10}), (b) with adenine: 3.1% (G_9); (*b*) reduced viscosity for G_9 and G_{10} in the semi-dilute concentration domain.



the adenine group (G10). The plots of $[\eta]/c$ versus c remain linear, even in the semi-dilute domain, probably due partly to the high flexibility of the pullulan skeleton but also to the condensed structure of the grafted molecule, both factors favouring the predominance of intramolecular associations. Indeed, for pullulan modified with a linear alkyl chain, we observed the formation of intermolecular hydrophobic associations[2] in the semi-dilute concentration range above approximatively 3.5 g L^{-1}. The great difference between the intrinsic viscosity at the same ionic strength (0.1 N NaCl) between the pullulan and its carboxymethyl derivatives (from $[\eta]_0$ = 66 to 190 mL g^{-1}) is probably the consequence of two additive factors, namely, an electrostatic effect due to the presence of unscreened carboxylic groups at the ionic strength used and a greater rigidity of the polysaccharide chain as a result of the introduction of the carboxymethyl group.

From Size Exclusion Chromatography (SEC) coupled to a multi-angle laser detector as described in ref. 19 (for the experimental procedure and equations used), there has been clear evidence that both CM-aminopyrene and -adenine (G9 and G10) are heterogeneous mixtures of two kinds of polymer populations, corresponding to the large first peak at $M_W \sim 1.3 \times 10^5$, approximately the molecular weight of the CMP precursor (exclusion volume ~29.54 mL), and to the second peak (about 10%) (exclusion volume ~36.54 mL), with a much larger molecular weight ($M_W \sim 1.4 \times 10^6$) (Fig. 4(*b*)), corresponding probably to the aggregate polysaccharide molecule, through the interaction of the bulky hydrophobic pyrene group. (π–π^* interaction). Figure 4(*a*) shows the normal profile of CMP modified by the aminopyrene detected classically (exclusion volume ~34 mL). These aggregates have a more compact conformation than the CMP precursor, which explains the inversion of the exclusion volumes in SEC as already mentioned for self-aggregated polymers like xanthane (22), or for globular proteins.

Conclusions

This paper reports some preliminary results on new hydrophobically modified pullulan derivatives. The aim of this work was to point out the influence of the nature of the hydrophobic aromatic substituent and of the ionicity of the parent precursor on the nature of the associations in the dilute concentration range. The reported data indicate that the introduction of aromatic hydrophobic substituents mainly induce *intramolecular associations* in ionic or non-ionic dilute polymer solutions. This is probably a consequence of the bulkiness of aromatic substituents such as pyrene that favours the establishment of intramolecular associations even in the semi-dilute domain of concentration. The presence of a long spacer chain would seem favourable for the formation of intermolecular interactions, as has been reported with other systems.

New amphiphilic copolymers derived from hydrophobically modified vinyl saccharides

Joachim Klein, Markwart Kunz, and Lutz Guderjahn

Abstract: The synthesis and characterization of new amphiphilic copolymers derived from copolymerization of hydrophobically modified so-called vinyl saccharides with 1-vinyl-2-pyrrolidone are described. The vinyl saccharides were prepared in a two-step synthesis. In the first step hydrophobically modified saccharide derivatives were synthesized without protecting procedures by direct reductive amination of the reducing keto-disaccharide isomaltulose (Palatinose®) with *n*-dodecylamine. In the second step the resulting *N*-dodecylaminopolyols were coupled with allyl glycidyl ether to give polymerizable amphiphilic vinyl saccharides. The copolymerizations with 1-vinyl-2-pyrrolidone were performed as free radical aqueous solution polymerizations. The characterization of the copolymers was carried out by measuring the viscosity and light scattering in water as well as in trichloromethane, in addition to surface tension measurements and solubilization studies. The solution properties of the copolymers in water and trichloromethane differ remarkably. While the values for the intrinsic viscosities in both solvents are comparable, the weight-average molecular weights in water are much higher than those in trichloromethane, indicating the formation of aggregates in aqueous solution. The vinyl pyrrolidone copolymers are also very surface active, lowering the surface tension of water to as low as 30 mN/m. The combination of measurements of surface tensions and solubilization studies indicates that their hydrophobic association behaviour is formally comparable to those of low molecular weight surfactants.

Key words: vinyl saccharides, isomaltulose, hydrophobic association, amphiphilic polymers.

Résumé : On décrit la synthèse et la caractérisation de nouveaux copolymères amphiphiles dérivés d'une copolymérisation de la 1-vinyl-2-pyrrolidone avec des soit disant saccharides vinyliques modifiés d'une façon hydrophobe. Les saccharides vinyliques ont été préparés par une synthèse en deux étapes. Dans la première étape, on a synthétisé les dérivés saccharidiques modifiés d'une façon hydrophobe, sans procédures de protection, en procédant à une amination réductrice du céto-disaccharide réducteur isomaltulose (Palatinose®) avec de la *n*-dodécylamine. Dans la deuxième étape, on a procédé au couplage des *N*-dodécylpolyols ainsi obtenus avec de l'oxyde d'allyle et de glycidyle qui a conduit aux saccharides vinyliques amphiphiles. On a effectué les copolymérisations avec la 1-vinyl-2-pyrrolidone sous la forme de polymérisations radicalaires en solutions aqueuses. La caractérisation des copolymères a été effectuée par la mesure de leur viscosité et de leur diffusion de la lumière en solution dans l'eau ainsi que dans le trichlorométhane; on a aussi fait appel à leurs tensions superficielles et à des études de solubilisation. Les propriétés des copolymères en solution dans l'eau sont très différentes de celles dans le trichlorométhane. Alors que les valeurs des viscosités intrinsèques sont comparables dans les deux solvants, les poids moléculaires moyens dans l'eau sont beaucoup plus élevés que ceux dans le trichlorométhane; ceci indique qu'il y a formation d'agrégats en solution aqueuse. Les copolymères de la vinylpyrrolidone ont une grande influence sur les propriétés de surface; elles diminuent la tension superficielle de l'eau jusqu'à des valeurs aussi basses que 30 mN/m. La combinaison des mesures de tensions de surface et des études de solubilisation indique que leurs comportements d'association hydrophobe sont formellement comparables à ceux d'agents de surface de faibles poids moléculaires.

Mots clés : saccharides vinyliques, isomaltulose, association hydrophobe, polymère amphiphiles.

Introduction

Hydrophobically modified water-soluble polymers, so-called polymeric surfactants, are a particularly interesting class of water-soluble macromolecules. The first report on such polymers was the synthesis of hydrophobically modified poly(vinylpyridine)s (so-called "polysoaps") by Strauss et al. (1, 2).

Recently, interest in hydrophobically modified water-soluble polymers, for both fundamental research and technical application, has increased significantly. Therefore, a wide range of these polymers with various structural concepts and different synthesis approaches have been produced and investigated (3–6).

A rather interesting approach is the synthesis of carbohydrate based amphiphilic polymers, which can be produced by a three-step synthesis, starting from the reductive amination of a reducing carbohydrate, coupling the resulting amino sugar with a polymerizable compound, and finally polymerizing the vinyl saccharide (7).[2]

This paper describes the synthesis of one of these types of amphiphilic polymers, derived from copolymerization of a hydrophobically modified vinyl saccharide and 1-vinyl-2-pyrrolidone, and includes a study of the solution properties in water and trichloromethane, respectively.

Results and discussion

Synthesis of the copolymers

The preparation of vinyl saccharides requires strictly monofunctionalized carbohydrate derivatives. This can be achieved either by the laborious way via protected sugars (8) or by the much easier way, through the reductive amination of reducing carbohydrates (9).

The reductive amination is a two-step reaction; in the first step the aminating agent is added to the reducing saccharide forming "Schiff bases" or osylamines, followed by a heterogeneously catalyzed hydrogenation. Hydrazine and ammonia as aminating agents generally lead to primary aminopolyols, while with alkyl amines secondary aminopolyols are formed (7).

Meanwhile, extensive studies have been done concerning the application of different mono- and disaccharides and varying the aminating agents (10). Due to its stability and selectivity, the reducing keto-disaccharide isomaltulose (6-*O*-(α-D-glucopyranosyl)-D-fructose, Palatinose®)[3] is generally a very interesting starting compound for the synthesis of monoaminopolyols (10). Therefore, isomaltulose was selected as the carbohydrate compound and, in order to produce amphiphilic saccharide derivatives, *n*-dodecylamine was chosen as the aminating agent.[4]

To ensure the preparation of an *n*-dodecylamine-free product suitable for technical applications, without the need for laborious purification steps, amination with *n*-dodecylamine was carried out with a triple molar excess of the saccharide. Normally, for amination with hydrazine or ammonia a large excess of the aminating agent is used.[5] The excess sugar alco-

[2] Generally, saccharide derivatives bearing a polymerizable C=C double bond are called "vinyl saccharides" (see also ref. 9).

hols resulting from hydrogenation of isomaltulose could be removed easily by passing the raw product through a cation exchange column loaded with NH_4^+ ions (11).

As the ^{13}C NMR and mass spectra show, the resulting product is a mixture of three *N*-dodecylaminopolyols resulting from rearrangement or cleavage of isomaltulose. The amounts of the three *N*-dodecylaminopolyols could be determined by HPLC analysis (12). Since it was not possible to separate the three amphiphilic carbohydrates in larger amounts, and the ratio of the different *N*-dodecylaminopolyols was known, the mixture of the reaction was considered to be applicable for a derivatization with allyl glycidyl ether.

Further details concerning the reaction of isomaltulose with *n*-alkyl amines in the presence of Raney nickel will be presented shortly.[6]

Studies about the surface activity of *N*-alkylaminopolyols showed these compounds to be very effective surfactants (13).

The addition of epoxides to amines to form aminocarbinols is a technically widely used method, for example, for the production of fatty amine ethoxylate surfactants (14), and it is suitable for the preparation of vinyl saccharides (11).

The reaction of *N*-dodecylaminopolyols with allyl glycidyl ether was performed with a triple excess of the epoxide component to ensure the complete consumption of the saccharide component. The copolymerizations of **4** with 1-vinyl-2-pyrrolidone were carried out with small molar amounts (1–3%) of the vinyl saccharides. The polymerization reactions were terminated after short reaction times in order to prepare copolymers with randomly distributed monomers (yields 10–20%, cf. Table 3). The structural properties of the three *N*-dodecylaminopolyol-based vinyl saccharides being similar, their polymerization behaviour was assumed to be similar too.

To obtain reliable results from the characterization of the copolymers, it was essential to quantitatively remove residual amphiphilic vinyl saccharide monomers. Therefore, the copolymers were purified by repeated precipitation from cold acetone–methanol mixture and dialysis of the resulting aqueous solutions against deionized water, for several weeks. No signals of any possible residual monomers could be detected in the ^1H NMR spectra.

Solution properties of amphiphilic copolymers

The copolymers derived from amphiphilic vinyl saccharides are, analogously to the corresponding homopolymer poly(vinylpyrrolidone) (PVP), soluble in water as well as in trichloromethane, so that the solution properties of these polymers could be investigated in both solvents.

The values of the intrinsic viscosities [η] of the copolymers in both solvents are rather similar; this is comparable to nonmodified PVP. In the observed concentration range, from 0.1 to 1% (w/w), a linear correlation between η_{sp}/c values and solution concentration could be determined.

The results from light-scattering measurements of the copolymer solutions in both solvents are significantly different. In trichloromethane the apparent weight-average molecular weights ($M_W^{app}(CHCl_3)$) range from about 1.9×10^5 (Copo-2) to 2.9×10^5 g/mol (Copo-1) (cf. Fig. 1*c*). In water the molecular weights ($M_W^{app}(H_2O)$) could be determined to be in the range of $(4.8–11.3) \times 10^6$ g/mol (cf. Figs. 1*a*, 1*b*). Analogous measurements of the corresponding PVP solutions showed only slight differences between both solvents.

The second virial coefficients A_2 are in the range from 5.1 to 17.1 bar cm^6 g^{-2} in water and from 5.4 to 11.7 bar cm^6 g^{-2} in trichloromethane. The corresponding *z*-average of radii of gyration $\langle R_G^2 \rangle_z^{1/2}$ ranges from 120 to 267 nm in water and from 46 to 81 nm in trichloromethane.

The amount of incorporated amphiphilic saccharide units influences the shape of the solvated macromolecules in aqueous solution. The Zimm plots indicate the transition from a rodlike polymer shape (cf. Fig. 1*a*: Copo-1, curvature for $c = 0$ convex downwards) to a more spherical type (cf. Fig. 1*b*: Copo-3, curvature for $c = 0$ convex upwards) with increasing amount of amphiphilic saccharides (15, 16).

Furthermore, compared to nonmodified PVP, the copolymers have very effective surfactant properties, lowering the surface tension of water to less than 30 mN/m, although only small molar amounts of amphiphilic vinyl saccharides were used. The shape of the σ vs. log *c* isotherms of the copolymers

is comparable to that of low molecular weight surfactants (e.g., the monomer unit **4**). The surface tensions reach a constant minimum value at a concentration characteristic of the copolymers, which is similar to the critical micelle concentration, (cmc) of low molecular weight surfactants (17) (cf. Fig. 2*a*). To compare the surface activity of the copolymers with each other as well as with the corresponding vinyl saccharide monomer **4**, it is useful to consider the surface tensions as a function of the concentration of incorporated amphiphilic monomers in the copolymers. In this case, the minimum surface tensions as well as the cmc's of the monomer and the copolymers are nearly equal (cf. Fig. 2*b*).

To obtain additional information concerning the solution properties of the copolymers in water and the question of the existence of a cmc for these polymeric amphiphiles, the solubilization behaviour of eosine in aqueous solution was investigated (18).

Extinctions of the eosine solutions were determined at 515 and 536 nm at various copolymer concentrations. At definite copolymer concentrations, which correlate with the cmc's found by measurement of surface tensions, characteristic changes of slopes of the extinction curves could be observed, indicating the transition from a hydrophilic to a hydrophobic environment of the eosine molecules and offering strong evidence for hydrophobic association (19) (cf. Fig. 3).

Conclusions

It is well known that hydrophobically modified water-soluble polymers associate in aqueous media via their hydrophobic groups (3–6). The properties of such polymers are mainly defined by the number of incorporated hydrophobic groups per molecule.

The solution properties of the vinyl pyrrolidone copolymers of this work can be explained by assuming the formation of aggregates in water via hydrophobic association. The light-scattering studies show that the polymer coils are not associated in trichloromethane. The ratio of the molecular weights determined in water and trichloromethane is therefore a number expressing the average degree of hydrophobic association.

Extensive studies on the surface activity of polymeric surfactants are remarkably rare. Discussions about whether there is a critical concentration of such polymers in water indicating the beginning of the formation of aggregates, similar to the cmc of low molecular weight surfactants, are contradictory (3–6, 18, 20).

Our measurements of surface tensions and solubilization studies show that the aggregation process in water is a function of the number of hydrophobic groups being solvated. This behaviour is therefore comparable to low molecular weight surfactants. The concentration could analogously be described as the "critical aggregation concentration" (cac).

Light-scattering and viscometric studies of the polymer solutions were performed at concentrations higher than the cac, so that these properties of the aggregates were definitely

determined. The results from light-scattering measurements in water correlate with results from the determination of surface tensions and solubilization, showing the formation of large aggregates. Viscometry only shows a slight increase of the size of solvated coils, which could be explained by assuming that light scattering is a method more affected by the formation of a small number of large aggregates than viscometry (21).

[c]Determined by solubilization of eosine (yellow).
[d]According to average weight percent of **4** in the copolymers.

A particular structural feature of amphiphilic vinyl saccharide based systems is the sterically ambitious saccharide unit, which is closely positioned to the hydrophobic alkyl chain (cf. Scheme 3). The formation of "micellar structures" at low polymer concentrations could therefore be affected, resulting in the need for a minimum number of hydrophobic groups to form aggregates, which are determinable by the applied methods. At low concentrations the polymer molecules might preferably be adsorbed at the surface, lowering the surface tension of water significantly. The amphiphilic saccharide units must be concentrated at the surface and the vinyl pyrrolidone units connecting the hydrophobic groups must be turned away to form flexible loops. This behaviour might be responsible for the high surface activity with small molar amounts of hydrophobic groups.

As well, the average number of hydrophobic per polymer molecule in the amphiphilic copolymers N is in the range between $N=25$ (Copo-1) and $N=47$ (Copo-3), which is too small for the formation of intramolecular aggregates. For the average number of low molecular weight surfactant molecules forming micellar structures (e.g., fatty alcohol ethoxylates) N is in the range between $N=100$ (*n*-octyl) and $N=400$ (*n*-dodecyl) (22). The type of micellar structure discussed here therefore requires a larger number of macromolecules, which is confirmed by the results of light-scattering and solubilization studies.

Further statements concerning these aspects, however, will require more detailed investigations of a larger compositional and molecular weight spectrum of these amphiphilic polymers.

mL of a mixture of distilled water and propanol-2 (30/70, v/v) and cooled down to 10°C. Under vigorous stirring, *n*-dodecylamine (Fluka, Neu-Ulm, FRG) (0.461 mol, 86 g), dissolved in 400 mL of a mixture of distilled water and propanol-2 (30/70, v/v) was added slowly. The mixture was stirred for 14 h and filled into a 5 L high-pressure autoclave together with aqueous Raney Nickel suspension (Merck, Darmstadt, FRG) (120 g). The mixture was hydrogenated for 24 h at 50°C, 200 bar (1 bar = 100 kPa), and 1000 rpm. The autoclave was depressurized and the mixture diluted with propanol-2 (500 mL). The catalyst was removed by filtration and the filtrate was passed through a glass column, packed with cation exchanger (IR 120, 20–50 mesh, NH_4^+ form) in order to remove hydrogenation products of **1**. After washing the column bed with 2 L of distilled water, the *N*-dodecylaminopolyols (**2**) were eluted by a mixture of 10% aqueous ammonia and propanol-2 (50/50, v/v). The eluent was removed in vacuo and the product isolated by freeze-drying. Yield: 75% (referred to *n*-dodecylamine) ^{13}C-NMR (75.5 MHz, D_2O/propanol-2-d_8 (70/30, v/v), δ: 14.49 (C-12″), 23.28 (C-11″), 26.75–32.61 (C-10″–C-2″), 48.74 (C-1″), 50.58 (C-1), 61.46 (C-6′), 69.44 (C-6), 69.73–73.95 (C-2–C-5, C-2′–C-5″), 98.99, 99.24 (C-1′). Mass spectra (FAB pos., 3-nitrobenzylalcohol), *m/e*(%): 534 (26, $(M + Na)^+$), 512 (100, $(M + H)^+$), 422 (26, $(GPG + H)^+$), 350 (40, $(M - C_6H_{10}O_5 + H)^+$), 260 (44, $(M - C_6H_{10}O_5 + H)^+$).

Mixture of 1-deoxy-1-*N*-dodecyl-1-*N*-(2-hydroxy-4-oxa-6-heptenyl)-6-*O*-(α-D-glucopyranosyl)-D-mannit resp. -sorbit, 1-deoxy-1-*N*-dodecyl-1-*N*-(2-hydroxy-4-oxa-6-heptenyl)-3-*O*-(α-D-glucopyranosyl)-L-glycerol, and 1-deoxy-1-*N*-dodecyl-1-*N*-(2-hydroxy-4-oxa-6-heptenyl)-D-sorbit (4)

2 (0.03 mol, 15 g) was dispersed in propanol-2 and the suspension cooled down to 0°C. Allyl glycidyl ether (**3**) (Fluka, Neu-Ulm, FRG) (0.09 mol, 10.3 g) was added slowly under vigorous stirring. While being stirred, the mixture was warmed up to room temperature over a period of 14 h. Excess **3** was removed in vacuo, the crude product dissolved in propanol-2, and recrystallized from acetone/diethyl ether (30/70, v/v). Yield: 88%. ^{13}C NMR (100.6 MHz, D_2O/propanol-2-d_8, (70/30, v/v)), δ: 15.72 (C-12″); 24.47 (C-11″); 27.93–33.79 (C-10″–C-2″); 57.38–59.97 (C-1, C-1″, C-7); 62.84 (C-6′); 71.16 (C-6); 69.73–75.35 (C-2–C-5, C-2–C-5′, C-8); 74.95, 74.44 (C-9, C-10), 100.34 (C-1′), 118.93 (C-12); 136.59 (C-11). Mass spectra (FAB neg., glycerol), m/e(%): 625 (37, $(M)^-$), 624 (100, $(M - H)^-$), 510 (20, $M - C_6H_{10}O_2 - H)^-$), 462 (22, $M - C_6H_{10}O_5 - H)^-$).

Synthesis of copolymers

The copolymerizations were carried out in aqueous media employing $(NH_4)_2S_2O_8$ as initiator. The monomers **4** and **5** were dissolved in doubly distilled, filtered, and degassed water and placed in a steel cyclinder under nitrogen atmosphere. Initiator was added as an aqueous solution and the polymerization procedure started by raising the temperature to 60°C. The reactions were stopped after 2 h by purging air through the mixture and pouring the solutions into a large amount of cool acetone/methanol (50/50, v/v). The precipitated polymers were dissolved in water, the precipitation repeated five times, and the polymer solutions dialyzed in special tubes (Reichelt-Chemie-Technik, Heidelberg, Germany, cutoff: 10 000 D) against distilled water for 3 weeks. Finally, the polymers were isolated by freeze-drying.

Characterization of the polymers

Viscometry

Measurements were carried out in doubly distilled water and trichloromethane, respectively, at 25°C in a Ubbelohde capillary viscometer (Schott, Mainz, Germany) and a rotational viscometer (Low Shear LS 100, Contraves, Zürich, Switzerland) at shear rates between 1×10^{-3} and 1 s^{-1}).

Light-scattering measurements

These measurements were performed in doubly distilled water and trichloromethane, respectively, at 25°C employing a wide-angle photo-gonio-diffusometer (model 42 000 "SOFICA," Le Mesnil-Saint Denis, France) with a vertically polarized incident beam of $\lambda_0 = 632.8$ nm from a He-Ne laser at 9 angles between 30° and 135°.

Before measuring, the solutions were carefully filtered through membranes (polycarbonate membranes (Nuclepore, Pleasanton, Calif., U.S.A.) for aqueous solutions and cellulose membranes (Sartorius, Göttingen, Germany) for trichloromethane solutions, respectively). The concentration ranges chosen were fitted to the maximum of the signal intensity.

The refractive index measurements were carried out with a Brice–Phoenix differential refractometer (BP-2000 V, Virtis Co., New York, U.S.A.) at $\lambda = 632.8$ nm and 25°C.

Surface tensions

The measurements of surface tension were carried out at 25°C with an automatic processor–tensiometer (K 12C, Krüss GmbH, Hamburg, Germany) using a platinum plate according to *Wilhelmy* (23). The measurements were stopped, when the

standard deviation(s) of 10 values of surface tension, s_{max}, were 0.01 or lower. The interval between two measurements was 10 min.

Solubilization

The solubilization properties of the amphiphilic copolymers in water were determined by treating aqueous solutions of eosin (yellow) (1×10^{-5} mol/L) with various concentrations of the copolymers (**5**) and measuring the UV absorbance of the solutions at 25°C and $\lambda = 515$ nm and 536 nm, respectively, with a UV photometer (Uvikon 930, Kontron Instruments, Eching, Germany).

Spectral properties of ionic derivatives of pyrene and their aggregates with anionic surfactant and polyelectrolyte

Pavol Hrdlovič, Lubica Horinová, and Štefan Chmela

Abstract: A multifunctional probe based on pyrene, the chloride of the 2,2,6,6-tetramethyl-4-hydroxypiperidinium ester of 4-(1-pyrene)butyric acid, at a concentration of 5×10^{-5} mol dm^{-3} exhibits excimer-like green emission with the maximum at 480 nm in the presence of sodium dodecylsulfate below its critical micelle concentration. A similar effect has been observed for this probe in the presence of the sodium salt of polyacrylic acid in the same concentration range. 1-Pyrenemethylammonium chloride exhibits a broad green excimer-like emission for sodium dodecylsulfate but not for the sodium salt of polyacrylic acid. The quenching constants of the monomeric and excimer-like emissions were determined for acrylamide, 1-oxo-2,2,6,6-tetramethyl-4-hydroxypiperidine, potassium iodide, and copper(II) sulfate, representing neutral, ionic, and free-radical types of quenchers. The rate constants of quenching for N-oxyl radicals indicate that the monomeric emission from both water-soluble probes is diffusion controlled. For other types of quenchers the rate constant of bimolecular quenching is lower. The quenching of the excimer-like emission of an aggregate of the chloride of the 2,2,6,6-tetramethyl-4-hydroxypiperidinium ester of 4-(1-pyrene)butyric acid is less efficient than in the case of 1-pyrenemethylammonium chloride, which indicates a more packed structure of the former aggregate.

Key words: pyrene, ionic derivative, emission, micelle, aggregation, quenching.

Résumé : La sonde multifonctionnelle basée sur le pyrène, le chlorure de l'ester 2,2,6,6-tétraméthyl-4-hydroxypipéridinium de l'acide 4-(1-pyrène)butyrique, à des concentrations de 5×10^{-5} mol dm^{-3}, en présence de dodécylsulfate de sodium à une concentration inférieure à sa concentration micellaire critique, présente une émission verte, semblable à celle d'un excimère, avec un maximum à 480 nm. On a observé un effet semblable avec cette sonde, en présence du sel de sodium de l'acide polyacrylique, à des concentrations semblables. Avec le dodécylsulfate de sodium, le chlorure de 1-pyrèneméthylammonium présente une émission verte large, semblable à celle d'un excimère; il ne la présente pas avec le sel de sodium de l'acide polyacrylique. On a déterminé les constantes de désactivation des émissions de type monomères ou excimères pour l'acrylamide, la 1-oxo-2,2,6,6-tétraméthyl-4-hydroxypipéride, l'iodure de potassium et le sulfate de cuivre(II) qui représentent des désactiveurs de type ionique, neutre et radicalaires. Les constantes de vitesses pour la désactivation des radicaux N-oxyles indiquent que l'émission monomérique provenant des deux sondes solubles dans l'eau sont contrôlées par la diffusion. Pour d'autres types de désactiveurs, la constante de vitesse de la désactivation est plus faible. La désactivation de l'émission semblable à celle d'un excimère d'un agrégat du chlorure de l'ester 2,2,6,6-tétraméthyl-4-hydroxypipéridinium de l'acide 4-(1-pyrène)butyrique est moins efficace que dans le cas du chlorure de 1-pyrèneméthylammonium; ceci indique que la structure du premier agrégat est plus compacte.

Mots clés : pyrène, dérivés ioniques, émission, micelle, agrégation, désactivation.

[Traduit par la rédaction]

Introduction

Fluorescence of hydrophobic, hydrophilic, and amphiphilic probes is widely used for characterization of either a homogeneous or heterogeneous surrounding (1–4). It is advantageous that these probes contain the pyrene moiety as the reporting chromophore (5).

Recently, it was observed that some ionic pyrene derivatives aggregate in the presence of polyelectrolytes and ionic surfactants in concentrations below the critical micelle concentration (cmc) (6–11). The formation of aggregates was observed for sodium salts of 1-pyrenesulfonic and 4-(1-pyrene)butyric acids with cetyltrimethylammonium chloride, 1-pyrenebutyltrimethylammonium chloride with the sodium salt of dodecylsulfate, and certain polyelectrolytes. Absorption, emission, lifetime measurements, and quenching indicate that these aggregates are ground-state complexes (6–11) arising from the ionic and hydrophobic interactions of the above molecules.

In this paper we describe the spectral properties of multifunctional probes derived from pyrene. Besides pyrene as a

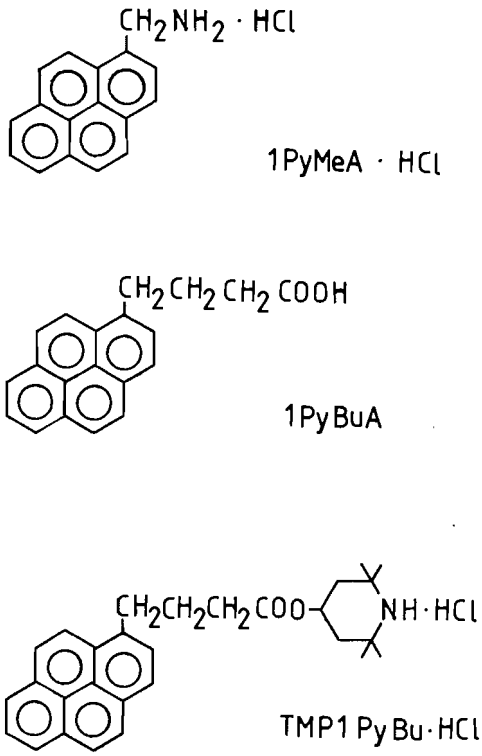
Chart 1. Structures of the fluorescence probes.



chromophore, the probes contain an additional functionality, a sterically hindered amine, which may enter neutralization and oxidation reactions.

The chloride of this probe, at higher concentration in ethanol, exhibits bathochromically shifted emission. In water solution, it exhibits even more bathochromically shifted emission, which appears at low concentration of the probe and in the presence of ionic surfactant or polyelectrolyte.

This paper is aimed at the more detailed characterization of this probe. A comparison of its behaviour with less sterically hindered ammonium chlorides was also made.

Experimental

The structures of the fluorescence probes used in this paper are shown in Chart 1.

The 2,2,6,6-tetramethyl-4-hydroxypiperidinium ester of 4-(1-pyrene)butyric acid (TMP1Py Bu) was prepared by reesterification of the methyl ester of 4-(1-pyrene)butyric acid (mp 43–45°C) with 2,2,6,6-tetramethyl-4-hydroxypiperidine. The reesterification catalyst tetrabutylorthotitanate was added to the stirred solution of reagents after clearing, and the solution was heated under reflux. Viscous liquid was isolated as the product. Attempts to crystallize it from ethanol, *n*-heptane, and diethyl ether were unsuccessful. The absorption spectrum of the product was identical with that of 4-(1-pyrene)butyric acid in ethanol: λ_{max} (ε): 243 nm (4.76), 276 nm (4.60), 342 nm (4.52). Its fluorescence spectrum in ethanol was identical with that of the sodium salt of the parent acid in water: λ_{max}: 377, 398, and 418 nm. ^{1}H NMR, $CDCl_3$, δ: 1.15–1.30 (2H, multiplet, CH_2, 3 + 5 axial H of piperidine ring), 1.15 (6H, singlet, CH_3, 2 + 6 axial H), 1.24 (6H, singlet, CH_3, 2 + 6 equatorial H), 1.87–2.06 (2H, multiplet, CH_2, 3 + 5 equatorial H of piperidine ring), 2.19 (2H, quintet, CH_2, middle group in propylene chain), 2.41 (2H, triplet, CH_2, at pyrene ring), 2.80 (1H, broad singlet, >NH), 3.35 (2H, triplet, CH_2CO-O), 5.15 (1H, multiplet, >CH of piperidine ring), 7.6–8.3 (9H, multiplet, pyrene).

The 2,2,6,6-tetramethyl-4-hydroxypiperidinium ester of 4-(1-pyrene)butyric acid was dissolved in diethyl ether and precipitated with methanol saturated by HCl. The white powder of the chloride of the ester (TMP1PyBu·HCl) was filtered, washed, and dried. It exhibits a rather broad range of mp, 220–230°C. The melting is accompanied by decomposition. The absorption and emission spectra of TMP1PyBu·HCl were the same as those of the parent amine.

4-(1-Pyrene)butyric acid (1PyBuA) was a commercial product (Aldrich-Chemie Steinheim, F.R.G.). For the synthesis of TMP1PyBu·HCl, 4-(1-pyrene)butyric acid was prepared by addition of succinic acid anhydride to pyrene (12) followed by the reduction of 3–(1–pyrenoyl)propanoic acid (13).

1-Pyrenemethylammonium chloride (1PyMeA·HCl) was a commercial product (Aldrich-Chemie, Steinheim, F.R.G.).

1-Oxo-2,2,6,6-tetramethyl-4-hydroxypiperidine (TMPNO) was prepared by standard oxidation of the parent amine (Chemko Strážske, n.e., Slovakia) with *m*-chloroperbenzoic acid.

Sodium dodecylsulfate (SDS), product of Merck (Darmstadt, F.R.G), was used without any further purification. The sodium salt of poly(acrylic acid) (PAANa) DEGAPAS 4104W was the product of Degussa AG (Hanau, F.R.G.).

All other chemicals and solvents were commercial products of Lachema Ltd., Brno, Czech Republic.

Absorption spectra were recorded on SPECORD UV–VIS and M-40 (C. Zeiss, Jena, F.R.G.) spectrometers. Emission spectra were taken on a Perkin–Elmer MPF-4 spectrometer (Perkin–Elmer, Norfolk, Conn., U.S.A.), which was connected through the interface and A/D converter to a microcomputer (14) for data collection, processing, and plotting on an XY 4110 plotter (Laboratorní přístroje, Prague, Czech Republic). The fluorescence lifetime measurements were performed on a LIF 200 (Laser Technik Berlin GmbH., Berlin, F.R.G.), which operates as a stroboscope. The output signal was digitized and transferred to the microcomputer (15). In most cases the decay curves were evaluated by a simple phase-plane method assuming monoexponential decay (16). If the agreement between experimental and calculated curves was not satisfactory, i.e., the standard deviation $G^{1/2} = ((I_{exp} - I_{cal})^2)^{1/2}$ was larger than 5%, the modified method of nonlinear regression by Marquardt (17) was used. When the fluorescence lifetime was substantially longer than 0.5 ns, which corresponds to the half-width of the nitrogen laser pulse, the simple method without deconvolution for fitting of the decay curve to the mono- or biexponential curve was applied (18).

^{1}H NMR spectra were measured on a 300 MHz AM-300 instrument (Bruker, F.R.G.).

Results and discussion

The multifunctional probe combines in one molecule the luminescence properties of the pyrene chromophore with the properties of a sterically hindered amine, which exhibits an acid–base or oxidation–reduction functionality. Such a probe, in which hydrophobic and hydrophilic parts are combined, is also soluble in a larger range of solvents. As the maximum solubility of the TMP1PyBu·HCl probe in water is 0.001 mol

Fig. 1. Emission spectrum of TMP1PyBu·HCl in ethanol at the concentration (1) 4×10^{-5} mol dm^{-3}; (2) 4×10^{-4} mol dm^{-3}; (3) 4×10^{-3} mol dm^{-3}.

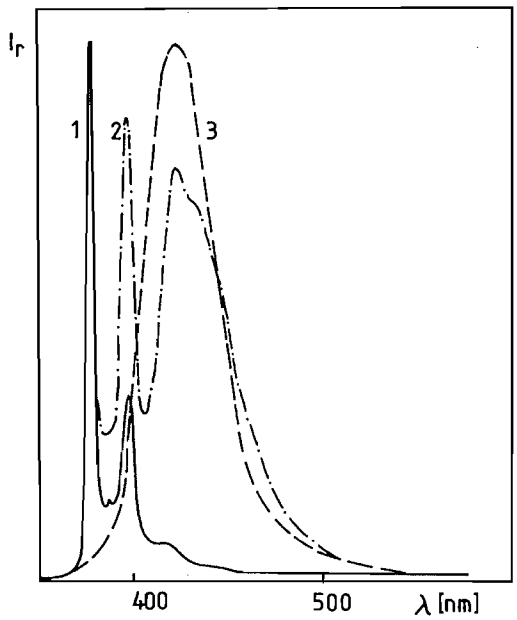

Fig. 2. Emission spectrum of potassium salt of 1PyBuA at the concentration (1) 10^{-4} mol dm^{-3}; (2) 10^{-3} mol dm^{-3}; (3) 10^{-2} mol dm^{-3}.

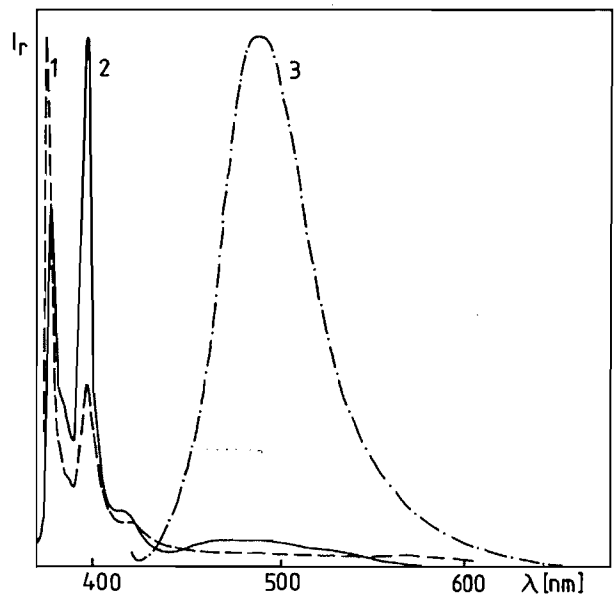
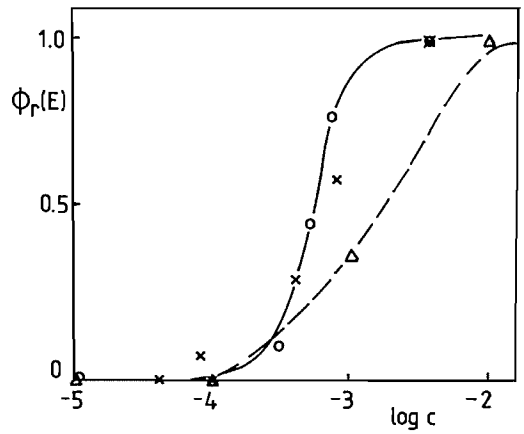


dm^{-3}, the concentration dependence of the fluorescence spectra was investigated in ethanol, which is a protic and polar solvent having properties similar to water.

The emission spectra of unsubstituted 1PyBuA, 1PyMeA·HCl, and TMP1PyBu·HCl are bathochromically shifted when the concentration increases from 10^{-5} up to 4×10^{-3} mol dm^{-3} (Fig. 1). The vibrationally resolved monomer emission with a narrow maximum at 377 nm is transformed gradually to a broad excimer emission, which was observed at 440 nm for TMP1PyBu·HCl and at 480 nm for 1PyMeA·HCl. Formation of excimers appears to be a diffusion-controlled process occurring at concentrations above 10^{-4} mol dm^{-3}. No excimer formation due to increased concentration could be observed under the limited solubility of the above chlorides in water.

Fig. 3. Dependence of relative quantum yield of excimer emission on the concentration of 1PyBuA in ethanol (○), of its potassium salt (Δ), and of TMP1PyBu·HCl in ethanol (x).



The potassium salt of 4-(1-pyrene)butyric acid, which is sufficiently soluble in water, forms the excimer at higher concentrations (Fig. 2). The excimer is characterized by a broad peak with a maximum at 480 nm. This maximum is bathochromically shifted by about 20 nm in comparison with the broad emission of TMP1PyBu·HCl in ethanol. On the other hand, the shift of monomer fluorescence in comparison with the excimer-like emission is more than 110 nm (3205 cm^{-1}). The dependence of the ratio of monomer to excimer-like emission is characterized by a sigmoidal course (Fig. 3). Anions of 4-(1-pyrene)butyric acid in water give less steep plots of the ratio of monomer to excimer-like emission than the chlorides in ethanol. Thus it appears that the ionic repulsion of chlorides in ethanol is weaker than the repulsion of anions of 4-(1-pyrene)butyric acid.

It has recently been observed that the aggregation of some ionic derivatives of pyrene at a low concentration (10^{-5}–10^{-4} mol dm^{-3}) occurs in the presence of ionic surfactants below, or approximately at, the critical micelle concentration. Under these conditions, the dynamic formation of excimers is excluded. The aggregation manifests itself by a red-shifted excimer-like emission at 480 nm. This phenomenon had not previously been observed for chlorides of amines. The positive charge on the TMP1PyBu·HCl molecule is more sterically shielded than in other cationic pyrene probes (6, 8) and on 1PyMeA·HCl it is less shielded. The interaction of the above-mentioned probes with SDS in the concentration range 10^{-5}–10^{-2} mol dm^{-3} was therefore investigated.

As seen from Fig. 4, TMP1PyBu·HCl at the concentration 5×10^{-5} mol dm^{-3} in water solution exhibits monomer fluorescence with a well-resolved vibrational structure dominated by a narrow band at 377 nm. This emission is identical with that of the potassium salt of 1PyBuA. The fluorescence lifetime is 117 ns and its decay corresponds excellently to a monoexponential decay. Addition of anionic surfactant SDS at a concentration above 10^{-4} mol dm^{-3} distinctly changes the spectrum. In the concentration range from 10^{-4} to 10^{-2} mol dm^{-3} a broad

Fig. 4. Emission spectrum of TMP1PyBu·HCl (1) at the concentration 5×10^{-5} mol dm^{-3}; (2) in the presence of SDS (5×10^{-3} mol dm^{-3}).

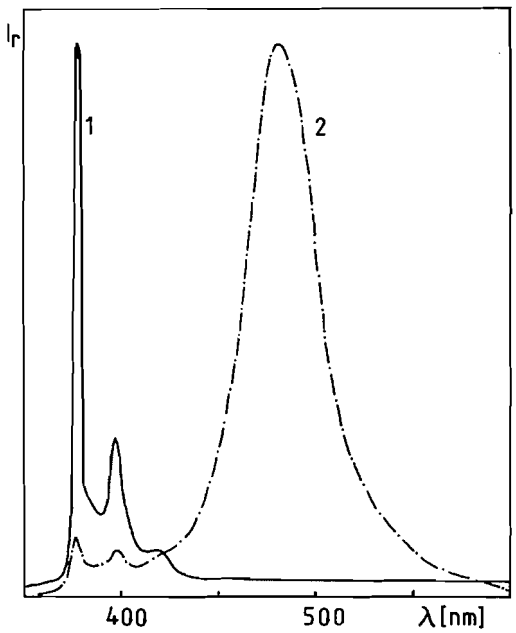

Fig. 5. Emission spectrum of TMP1PyBu·HCl (5×10^{-5} mol dm^{-3}) in the presence of SDS (1) 5×10^{-3} mol dm^{-3}; (2) 9×10^{-2} mol dm^{-3}.

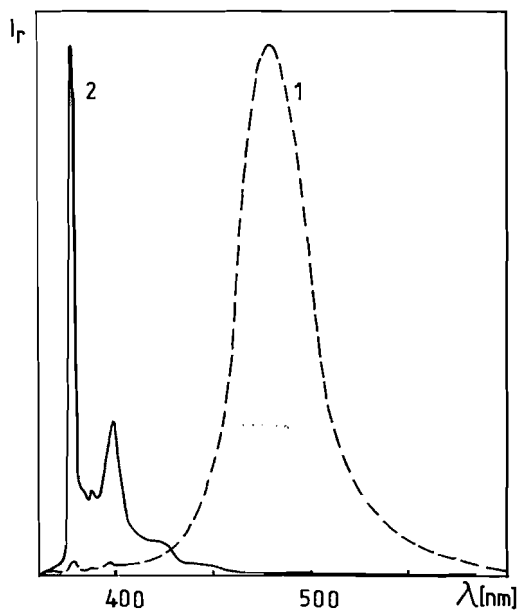

emission without any vibrational structure was observed at 480 nm. Its lifetime is 44 ns. It is shorter than the lifetime of monomer emission. The decay curve of this excimer-like emission does not fit monoexponential decay as well as does the decay curve of monomer emission. The largest deviation from monoexponential decay was observed at the beginning of the process. The excimer-like emission is reduced and monomer emission reappears (Fig. 5) above the cmc (8×10^{-3} mol dm^{-3}). The intensity of monomer fluorescence is slightly lower and its lifetime is slightly shorter.

Fig. 6. Emission spectrum of 1PyMeA·HCl at the concentration 5×10^{-5}mol dm^{-3} at (1) in the presence of 10^{-2} mol dm^{-3} SDS and (2) 5×10^{-3} mol dm^{-3}.

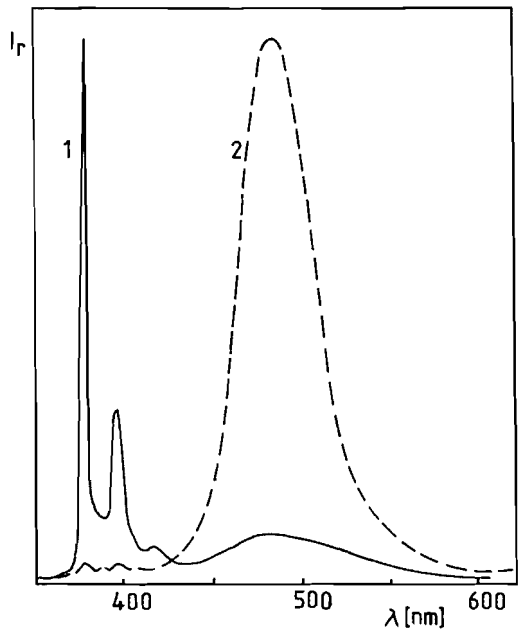

Fig. 7. Absorption spectrum of TMP1PyBu·HCl (1.25×10^{-4} mol dm^{-3}, cuvette thickness 0.1 cm) (1) in water and (2) in the presence of SDS (5×10^{-3} mol dm^{-3}).

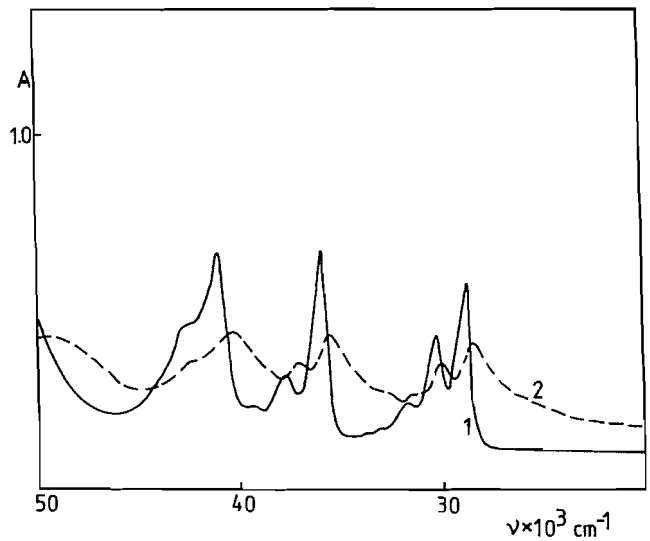

The same effect caused by addition of surfactant was observed for 1PyMeA·HCl. The excimer-like emission (Fig. 6) was observed in a narrower concentration range. The lifetime of monomer fluorescence at a concentration of 5×10^{-5} mol dm^{-3} is slightly longer than in the case of TMP1PyBu·HCl (around 130 ns) and again fits excellently to the monoexponential decay. The lifetime of excimer-like emission is 45 ns, which is the same value as for the emission originating from the aggregate based on TMP1PyBu·HCl with SDS.

The absorption spectra of the aggregate based on TMP1PyBu·HCl with SDS are more diffuse than those with 1PyMeA·HCl. (Fig. 7).

For personal use only.

Fig. 8. Emission spectrum of TMP1PyBu·HCl (5×10^{-5} mol dm^{-3}) in water in the presence of PAANa (1) 10^{-3} mol dm^{-3}; (2) 5×10^{-3} mol dm^{-3}.

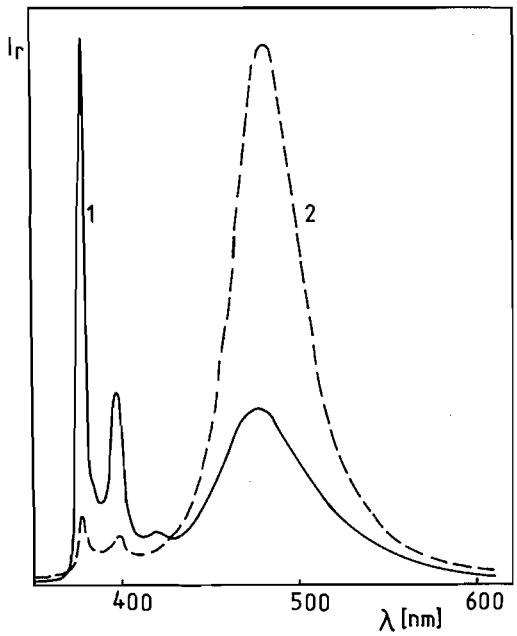

Fig. 9. Dependence of the ratio $I_E//I_M$ for TMP1PyBu·HCl on the concentration of SDS (o) and PAANa (x) and for 1PyMeA on the concentration of SDS (□).

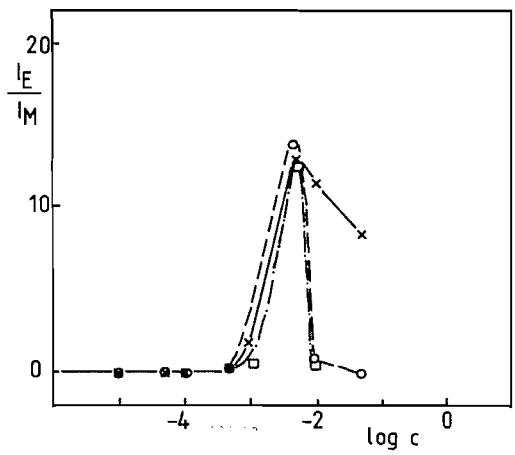
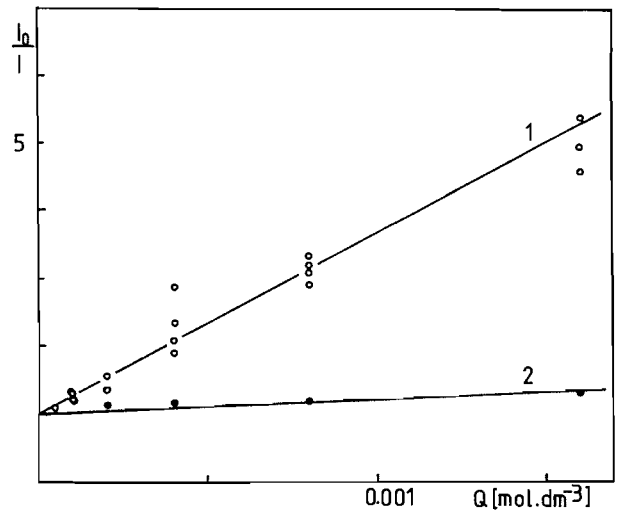


These observations indicate that the excimer-like emission stems from the stable ground-state aggregate (6, 8) formed by two molecules of TMP1PyBu·HCl with the pyrene chromophore in a sandwich-like arrangement and several molecules of surfactants. The hydrophilic anionic part of the surfactant interacts with the cationic part of TMP1PyBu·HCl or 1PyMeA·HCl and the hydrophobic parts, long alkyl chains, stabilize the aggregate. The positive charges are probably on opposite sides.

When the concentration of SDS is higher than the cmc, the aggregates begin to disintegrate. The hydrophobic interactions in the core of a pure SDS micelle repulse the probe in the water phase and the monomer emission reappears. This means that the hydrophobic interactions of the surfactants disturb the fine balance between the hydrophobic interaction of the pyrene

Fig. 10. Stern–Volmer dependence for quenching of TMP1PyBu·HCl emission by free radical 1-oxo-2,2,6,6-tetramethyl-4-hydroxypiperidine (1) at 377 nm and (2) at 480 nm in the presence of SDS (5×10^{-3} mol dm^{-3}).



chromophores and ionic interactions between probe and surfactants.

Similar aggregation effects have been observed between ionic pyrene derivatives and polyelectrolytes (7, 9–11). We have observed, for example, an excimer-like emission for TMP1PyBu·HCl at a concentration of 5×10^{-5} mol dm^{-3} in the presence of PAANa at a concentration above 10^{-3} mol dm^{-3} of AANa structural units (Fig. 8). The mean lifetime of this emission is around 53 ns and the kinetics is better fitted by biexponential than monoexponential decay. It involves a fast decay, $\tau_1 = 13.7$ ns (50%), and a slow decay, $\tau_2 = 62.3$ ns (50%). On the other hand, 1PyMeA exhibits only monomer fluorescence in the same concentration range. The kinetics in the presence of PAANa corresponds to biexponential decay with $\tau_1 = 14.5$ ns (58%) for fast and $\tau_2 = 107.5$ ns (42%) for the slow part with a mean lifetime 92.7 ns.

As shown in Fig. 9, the concentration range for formation of aggregates based on both probes is rather narrow.

The most effective quencher for monomer and excimer emission of both probes is a free radical, 1-oxo-2,2,6,6-tetramethyl-4-hydroxypiperidine (Table 1). The solubility of this free radical in water is sufficient for this type of quenching experiment. The rate constant of quenching of the monomer fluorescence of TMP1PyBu·HCl is about 2.3×10^{10} dm^3 mol^{-1} s^{-1} assuming a lifetime of 117 ns. This indicates that quenching is controlled by diffusion. Quenching of the excimer-like emission of TMMP1PyBu·HCl by a free radical is six times less efficient (Fig. 10). Moreover, quenching of the excimer-like emission of aggregates TMP1PyBu·HCl/PAANa is even less efficient although it is slightly longer-lived.

On the other hand, monomer and excimer-like emissions of 1PyMeA·HCl are quenched in both cases by diffusion-controlled rates. An electron-donating quencher such as acrylamide is quite efficient for the monomer fluorescence of TMP1PyBu·HCl but completely inefficient for the excimer-like emission.

Ions such as I^- or the cation Cu^{2+} are quenchers of the monomer and excimer-like emission of TMP1PyBu·HCl but they are

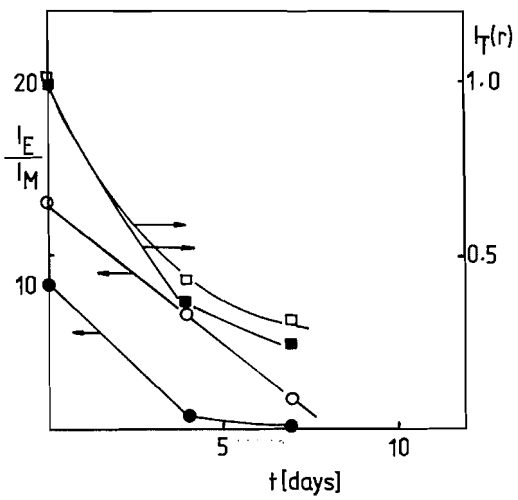
4-hydroxypiperidine	480(SDS)	560	1.24

[a]Wavelength at which K_{sv} was determined.

[b]The value of K_{sv} was determined immediately after addition of quencher. After longer standing at laboratory temperature the white voluminous precipitate starts to fall out.

Fig. 11. Dependence of the ratio I_E/I_M for the aggregate of TMP1PyBu·HCl at the concentration of PAANa 5×10^{-3} mol dm^{-3} (⊗) and 5×10^{-2} mol dm^{-3} (○) on time, and total dependence of I_T for the same aggregate at 5×10^{-3} mol dm^{-3} (□) and 5×10^{-2} mol dm^{-3} (■) on time.



less efficient than N-oxyl radical. Both quenchers are about 10 times more efficient at quenching monomer emission than the excimer-like emission. Although quenching data in these micellar systems may involve considerable error, we should expect that quenching of monomer fluorescence with the I^- anion is more efficient than with the Cu^{2+} cation because TMP1PyBu·HCl has a positive charge. Consequently, K_{sv} for quenching with I^- should be higher than that with Cu^{2+}. In fact, quenching with copper(II) ions is even more efficient. This indicates that the charge of TMP1PyBu·HCl is well shielded from the pyrene chromophore where the fluorescence originates.

In the case of the aggregate TMP1PyBu·HCl/SDS, all types of quenchers are less efficient. This might be explained by the fact that quenchers must overcome a hydrophobic barrier formed by alkyl chains of the anionic surfactants. The least effective quencher in this intrusion seems to be neutral acrylamide. The aggregate with PAANa is even less efficiently quenched.

The aggregate 1PyMeA·HCl/SDS seems to be less packed since monomer and excimer-like emission are quenched by a diffusion-controlled rate.

The charges on aggregates of all types are compensated and therefore both ionic quenchers should be equally effective. Copper(II) is, however, more efficient.

Generally, the aggregates exhibit a low stability. As shown in Fig. 11, the ratio I_E/I_M decreases with time as well as the total emission. After some time a voluminous precipitate begins to form. Addition of I^- anion accelerates this process. Therefore, the quantitative data may include some error because all the factors influencing precipitation are not known. The clear solution after precipitation exhibits only monomer fluorescence of lower intensity.

In conclusion, one can say that the chlorides of pyrene amino derivatives exhibit the same aggregation phenomena as those with alkylammonium functional groups. It has been clearly established that the probe TMP1PyBu·HCl yields more packed aggregates than 1PyMeA·HCl.

Fluorescence spectroscopy of mechanical pulps III: Effect of chlorite delignification

Jennifer A. Olmstead, Jian H. Zhu, and Derek G. Gray

Abstract: Many paper and wood samples fluoresce, but the sources of the emission are not well understood. Fluorescence excitation and emission spectra of paper sheets prepared from thermomechanical pulp (TMP) and bleached chemithermomechanical pulp (BCTMP) showed that the emission from the BCTMP was significantly higher than that from the TMP. Removing almost all of the lignin from both pulps by means of an acid chlorite treatment did not reduce the fluorescence significantly. By means of an approximate correction for changes in sheet reflectivity caused by the chlorite treatment, the fluorescence intensity was found to increase with lignin removal. Clearly, fluorescence is not simply related to lignin content.

Key words: wood pulp, lignin, cellulose, fluorescence spectra, acid chlorite delignification.

Résumé : Plusieurs échantillons de bois et de papier donnent lieu à de la fluorescence, mais les sources de ces émissions ne sont pas bien comprises. Les spectres d'excitation et d'émission de fluorescence de feuilles de papiers préparés à partir de pâte thermomécanique (TMP) et de pâte chimithermomécanique blanchie (BCTMP) ont permis de démontrer que l'émission à partir d'une pâte BCTMP est beaucoup plus importante que celle provenant d'une pâte TMP. L'enlèvement de pratiquement toute la lignine à partir des deux pâtes, par un traitement avec un chlorite acide, ne réduit pas la fluorescence d'une façon significative. En introduisant une correction approximative pour les changements de réflectivité causés par le traitement au chlorite, on a trouvé que l'intensité de la fluorescence augmente avec l'enlèvement de la lignine. Il est évident que la fluorescence n'est pas simplement reliée au contenu en lignine.

Mots clés : pâte de papier, lignine, cellulose, spectre de fluorescence, délignification par du chlorite acide.

1. Introduction

Fluorescence emission has been observed from a wide variety of pulps (1, 2) and lignin components (3, 4). Reductive treatments with compounds such as sodium borohydride result in an apparent increase in fluorescence intensity and a blue shift in emission, whereas oxidative reactions under irradiation with ultraviolet light or treatment with sodium periodate produce decreases and red shifts in emission. Davidson et al. (5) suggested that blue shifts produced in bleached or reduced papers were due to the formation of new products that fluoresce in this shorter wavelength region. Generally, the fluorescence of pulps had been attributed solely to lignin, possibly phenylcoumaran and coniferyl alcohol structures. However, our previous results (6) suggested that cellulose contributes significantly to the fluorescence emission of mechanical pulps, and that lignin or some lignin components must act as an absorbing screen or fluorescence quencher in addition to being a source of fluorescence emission. The results from quantum yield studies of mechanical pulps and cellulose also indicate that fluorescence emission under ultraviolet excitation is decreased in the presence of lignin ($\phi_f = 0.11$ for cellulose vs. $\phi_f = 0.015$ and 0.051 for TMP and peroxide-bleached TMP, respectively) (7).

Recently, Castellan et al. (8, 9) contested these conclusions. Using fluorescent lifetime measurements and fluorescence microscopy, they found that the fluorescence from cellulose sheets and from borohydride-reduced wood sections both underwent bi-exponential decay, but with radically different lifetimes (8), and that fluorescence emission from stone groundwood was stronger than that from cellulose (9). Furthermore, stone groundwood and cellulose behave differently when radiated sequentially with UV and visible light. They also investigated a number of model compounds absorbed on cellulose, and found fluorescence emission maxima of 360 nm for coniferyl alcohol compounds and 400 nm for biphenyl structures. Based on these observed differences between pure cellulose and lignin-containing samples, they concluded that fluorescence of wood sections and papers made from mechanical pulps originated from lignin and not cellulose.

Our original conclusions were that fluorescence of mechanical pulps originates primarily with some (as yet unidentified) source associated with the cellulose, and that screening groups

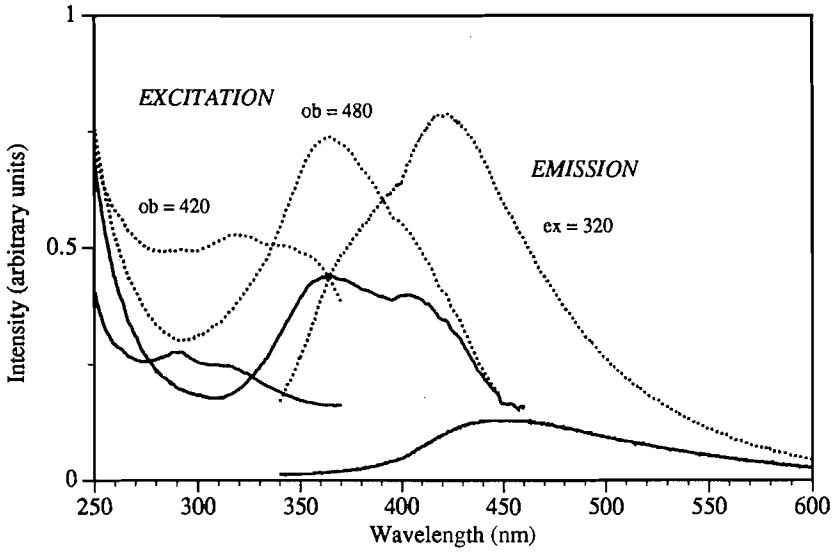
Fig. 1. Fluorescence spectra for TMP (solid lines) and BCTMP (dotted lines). Excitation spectra are observed at 420 and 480 nm; emission spectra are generated with an excitation wavelength of 320 nm.



in lignin tend to absorb this emission. While this may be oversimplified and naive, it does account for many of our observations, and those reported in the literature. In fact, the results reported by Castellan et al. (9) contain elements that support our conclusions: the fact that fluorescence emission of wood sections increased upon borohydride treatment indicates that carbonyl groups present in the sections were screening or otherwise quenching emission. Based on our hypothesis, removal of lignin from a mechanical pulp might result in an increase in fluorescence emission: essentially the chromophore screen affecting the fluorescence would disappear.

To try and distinguish between the possible sources of fluorescence, we here report some further experiments, where we measure the changes in fluorescence from mechanical pulps after acid chlorite delignification. If our hypothesis is correct, removal of the lignin by this selective procedure (10) should increase the fluorescence. Conversely, if lignin is the sole source of the fluorescence, then its removal should lead to the disappearance of the fluorescence.

2. Experimental section

Mechanical pulps used in this study were a black spruce (*picea mariana*) thermomechanical pulp (TMP) and a mixed hardwood peroxide-bleached chemithermomechanical pulp (BCTMP). Pulp samples were subjected to acidic sodium chlorite delignification (11). Lignin contents of all pulps (Klason and acid-soluble lignin) were determined using standard methods (11). Less than 0.1% Klason and 1.5% acid soluble lignin was detected after the chlorite treatment.

Thin sheets (~12 g/m^2) were made from delignified TMP and BCTMP, as well as from the untreated pulps, using the method of Schmidt and Heitner (12). Fluorescence measurements were carried out for all samples using a Spex Fluorolog spectrofluorometer, as previously described (6). Three fluorescence spectra were measured for each pulp: two excitation spectra with observation at 420 and 480 nm, and an emission spectrum with excitation at 320 nm. Each fluorescence spectrum shown in this paper has been averaged over five sets of spectral data taken at different locations on a sheet. UV–visible reflectance and absorption spectra were obtained for the same sheets using a Pye–Unicam PU-3300 spectrophotometer fitted with an integrating sphere, according to Schmidt and Heitner (12).

For comparison, fluorescence spectra were also measured for a delignified pulp to which milled wood lignin had been added. Milled wood lignin was isolated from unbleached softwood using the methods of Brownell (13) and Björkman (14). A dioxane solution of this lignin (0.4%) was added dropwise to delignified unbleached TMP; fluorescence spectra of this sample were measured before and after addition of the lignin, once the dioxane had evaporated. The sheet was left in the sample holder throughout this part of the experiment, to eliminate artifacts caused by variable scattering.

3. Results and discussion

3.1. Comparison of untreated pulps

Fluorescence spectra and reflectance spectra of TMP and BCTMP are presented in Figs. 1 and 2, respectively. A number of differences are evident, which may largely be attributed to bleaching and sulphonation that destroy screening groups (6).

The reflectance of BCTMP is higher over the 300–600 nm range. Accordingly, the absorption coefficient is lower, indicating that fewer absorbing groups in general are present in the BCTMP. The absorption present at 360 nm for TMP disappears in the BCTMP absorption spectrum: Schmidt and Heitner (15) have attributed changes in this region to quinones and coniferaldehyde groups that are consumed in bleaching and sulphonation reactions.

Fluorescence emission observed from BCTMP is higher than from TMP in all spectra obtained (Fig. 1). Excitation and emission spectra both vary with the observation/excitation wavelength. Emission spectra measured with excitation at 320

nm clearly demonstrate the impact of the screening groups in lignin on observed emission. Bleaching and sulphonation reactions both act to decrease the chromophore content of pulps, affecting primarily quinones and coniferaldehyde structures (15). Removal of screening groups, particularly in the 350–500 nm range, increases the amount of observed emission in this region. The same basic principle may help to explain the increase in fluorescence emission of pulps upon borohydride reduction as reported by others (8, 9).

Removal of screening groups via bleaching and sulphonation affects excitation spectra in two ways. Decreasing the screen at the observation wavelength allows for increased apparent emission (as for emission spectra). The removal of screening groups in the excitation range also results in increased emission, since the fluorophores are able to absorb a greater proportion of the incident light. In TMP, at least two broad peaks are visible in the excitation spectrum for emission at 420 nm (wavelength associated mainly with cellulose emission): these occur at 290 and 320 nm. These maxima are both present in the corresponding excitation spectra of BCTMP. Excitation spectra measured with an observation wavelength of 480 nm contain contributions from both cellulose and lignin. Both maxima, at 360 and 410 nm, undergo an increase upon bleaching and sulphonation, due to the reasons outlined above. The relative intensity of the peaks changes as well: in TMP, the maxima are of nearly equal intensity, whereas the peak at 360 nm dominates the spectrum of CTMP.

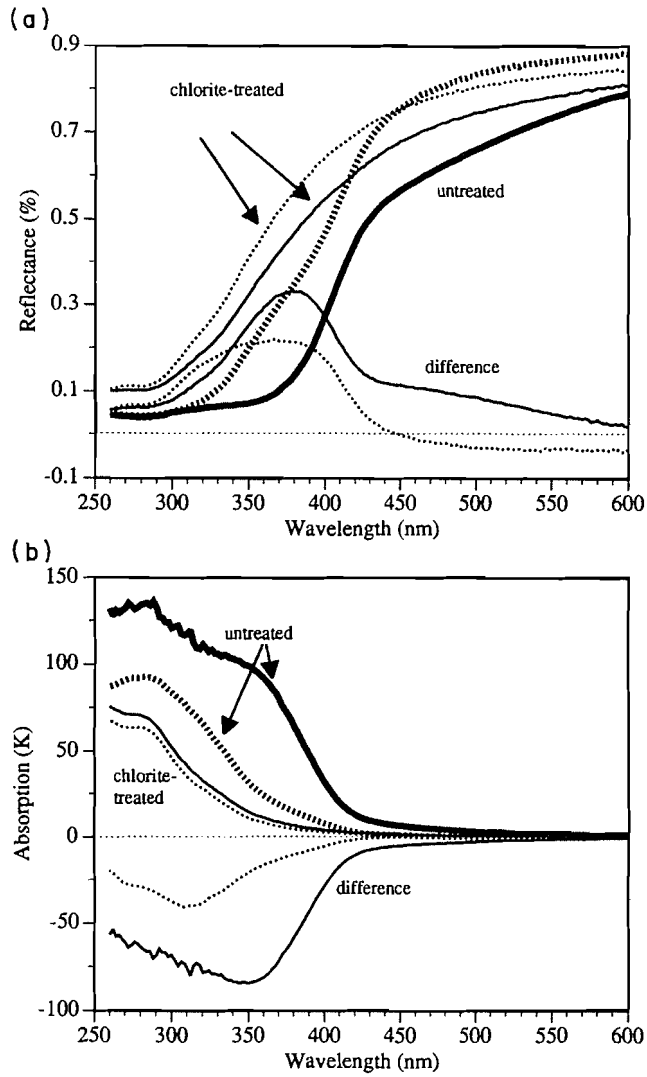
3.2. Effect of chlorite delignification

If lignin is the sole source of fluorescence from mechanical pulps, then delignification, which removes lignin, should produce decreases in fluorescence emission. Acid chlorite treatment of the TMP and CTMP samples removes almost all of the lignin, but the fluorescence signals remain almost constant, or even increase. At the same time, the absorption of the sheets decreases, and the reflectance increases. The emission properties of both pulps (from different sources, under radically different treatments) undergo similar changes during delignification, indicating that these changes are not isolated artifacts.

Absorption and reflectance spectra of untreated and delignified samples are shown in Fig. 2. An increase in reflectance was observed for both pulps upon delignification. Differences in the absorption spectra indicate that several lignin chromophores disappear when lignin is removed. Fewer chromophores are present in the BCTMP before delignification, which would account for the smaller decrease in absorption. Differences in reflectance and absorption spectra in the 350–400 nm region may be attributed to bleaching and (or) sulphonation reactions, which remove coniferaldehyde and other lignin aromatic carbonyl groups that screen emission. The decrease in absorption in the 250–350 nm region must arise from a decrease in aromatic rings (280 nm) and residual carbonyl groups (320 nm) as the lignin is removed.

These changes in reflectance and absorption will change the intensity of light striking the fluorophores in the sheet. To compare intensities of fluorescence before and after delignification, this effect should be considered. A rigorous consideration of the interactions between scattering, absorption, and fluorescence in highly scattering media such as paper is very complex. However, the following approximate approach may be used to correct for the change in reflectance, based on a

Fig. 2. (*a*) Reflectance and (*b*) absorption spectra of pulps before (thick lines) and after delignification (thin lines). Spectra of TMP are solid lines, BCTMP are broken lines. Difference spectra are calculated as (treated) − (untreated), so positive values represent gains, negative values represent losses due to delignification.



method to estimate the fluorescence quantum yields of pulp handsheets (7).

The total fluorescence of the system, I_f, is related to the amount of absorbed light I_{ab} and the quantum yield Φ_f as $I_f = \Phi_f I_{ab}$. The observed fluorescence i_f is a fraction of this,

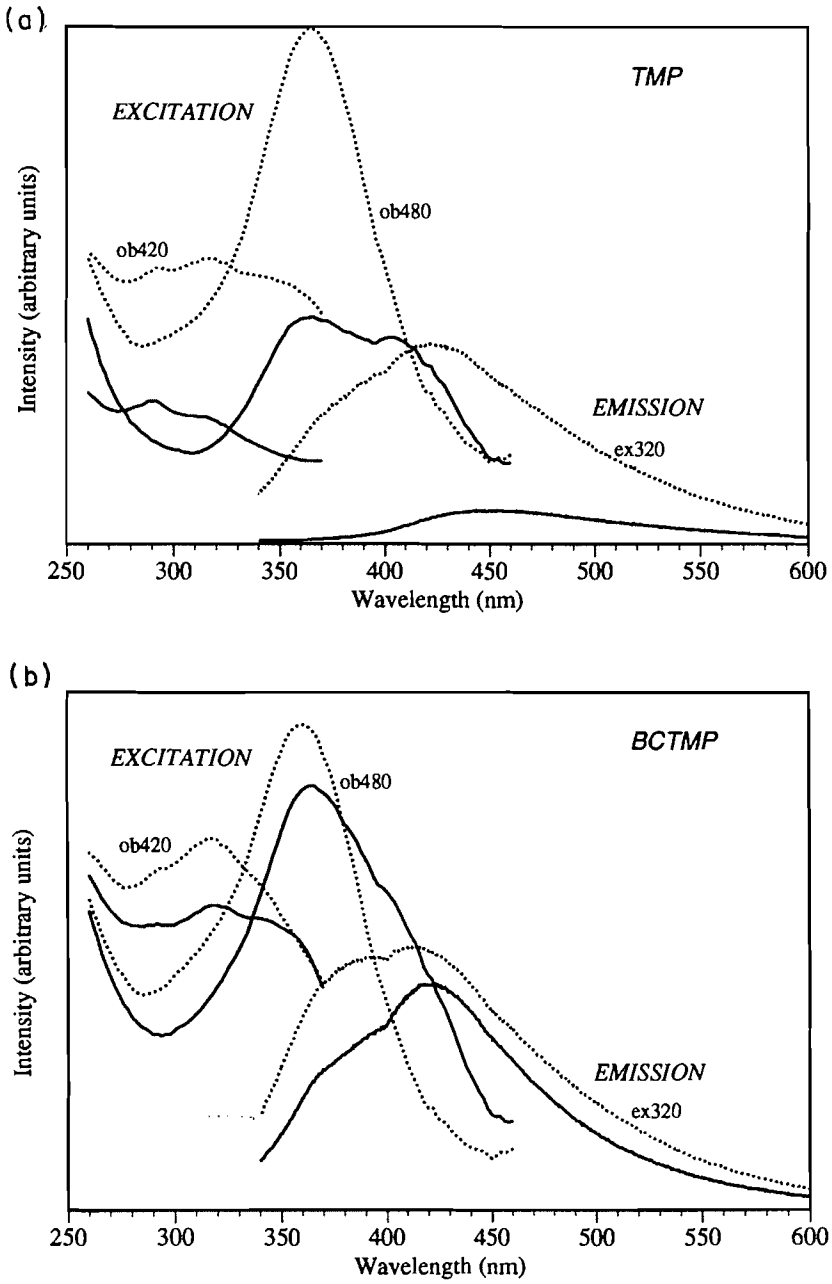
$$[1] \quad i_f = \alpha I_f = \alpha \Phi_f I_{ab}$$

If we assign the constant terms to a single variable, $\alpha\Phi_f = c$. Then $i_f = cI_{ab}$ and $i_f = c(I_{in} - I_{sc})$ where I_{in} is incident intensity and I_{sc} is the intensity of scattered radiation. Thus,

$$[2] \quad i_f = cI_{in}\left(1 - \frac{I_{sc}}{I_{in}}\right)$$

or

Fig. 3. Fluorescence spectra for (*a*) TMP and (*b*) BCTMP sheets. Solid lines: before chlorite treatment; broken lines: after chlorite treatment to remove lignin. Spectra of chlorite-treated pulps have been corrected for differences in sheet reflectance using eq. [5]. Excitation spectra were observed at 420 and 480 nm; emission spectra were generated by excitation with 320 nm light.



[3] $i_f = cI_{in}(1 - R_\infty)$

R_∞ is a measurable quantity. It is the proportion of incident light reflected from an optically thick sample, i.e., $R_\infty = I_{sc}I_{in}/I_{in}$. R_∞ changes with chlorite treatment. The "corrected" fluorescence, or the fluorescence that would have been observed if R_∞ had not changed with chlorite treatment, can be expressed as

[4] $i_f^{cor} = cI_{in}(1 - R_\infty^0)$

where R_∞^0 is the reflectance of the original untreated sample. The corrected spectrum is related to the measured spectrum by combining eqs. [3] and [4], and rearranging:

[5] $$i_f^{cor} = \frac{(1 - R_\infty^0)}{(1 - R_\infty)} i_f$$

Fluorescence spectra for TMP and BCTMP before and after chlorite delignification are shown in Fig. 3. Clearly, the delignification shows an increase in fluorescence. However, the

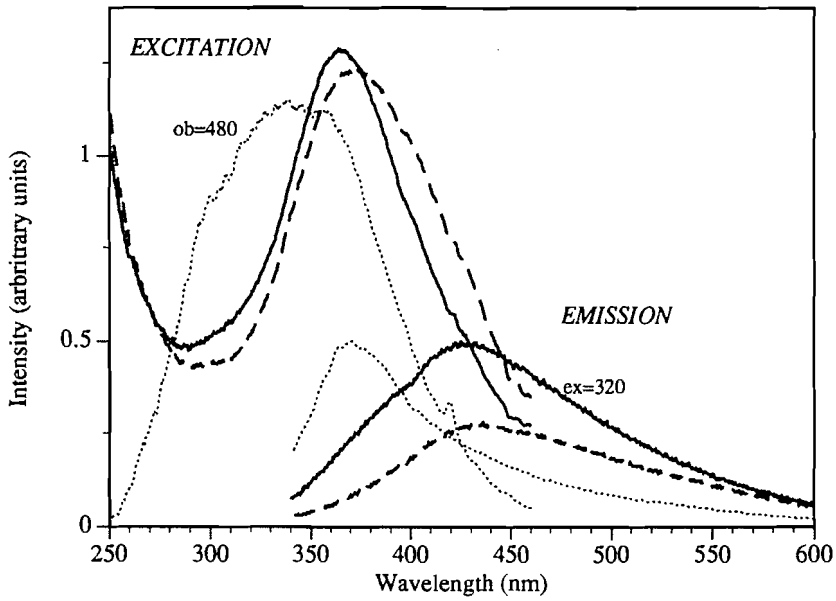
Fig. 4. Fluorescence spectra of delignified TMP before (solid lines) and after (broken lines) loading with milled wood lignin. Fluorescence spectra of a milled-wood lignin – dioxane solution are also shown (thin dotted lines), and are scaled for comparison.



disappearance of some spectral features, most notably a peak in the excitation spectrum at 410 nm (observed at 480 nm), indicates that lignin does make a minor contribution to the total fluorescence emission of mechanical pulps.

3.3. Fluorescence upon addition of milled wood lignin

Since removal of lignin from mechanical pulps causes an apparent increase in emission under excitation at 320 nm, addition of lignin to a delignified pulp should produce the opposite effect. In fact, this is the case, as may be seen in Fig. 4. The fluorescence emission spectrum of chlorite-treated TMP (λ_{ex} = 320 nm) undergoes a decrease when milled wood lignin is added to the sheet. Decreases at 320 and 350 nm and an increase at 415 nm may be observed in the excitation spectrum upon addition of lignin. Most of the changes may again be attributed to absorption of lignin, particularly at emission wavelengths below 430 nm. These changes closely mirror the changes seen during delignification, and provide further evidence as to the role of lignin in mechanical pulp fluorescence. The similarity of the changes seen during delignification and addition of lignin also indicates that the fluorescence properties of pulps are not overly dependent on formal lignin–cellulose bonds present in mechanical pulps: rather, lignin and cellulose act independently.

Concluding remarks

The physical processes involved in fluorescence from scattering media such as paper are complex, and eq. [5] may be an oversimplification. Nevertheless, the basic emission spectra for excitation at 320 nm show no decrease in fluorescence intensity when the lignin content of the TMP and BCTMP pulps was reduced from >25% to <2%. Furthermore, when dioxane lignin was added to the sheets, the fluorescence intensity increased. Thus a primary role of lignin in the photochemistry of mechanical pulps is the screening or quenching of fluorescence; the source of the fluorescence remains an open question.

Acknowledgments

We thank Nazeer Muradali (Paprican) for technical assistance and Dr. John Schmidt (Paprican) for use of the UV–visible spectrophotometer. Samples of milled wood lignin were supplied by Dr. Jiashu Wang (McGill University). Role of the reaction parameters in the direct synthesis of aromatic polyamides

Alberto Mariani, Sabina L.E. Mazzanti, and Saverio Russo

Abstract: A thorough study, devoted to analyzing the role of various reaction parameters in the direct synthesis of poly(*p*-phenylene terephthalamide) and poly(*p*-benzamide), activated by triphenyl phosphite, is described. The effects of temperature, salt type and concentration, amount of triphenyl phosphite and its stepwise introduction, as well as monomer and reagent concentrations, are considered. The inherent viscosity values of the above aromatic polyamides are higher than those reported in the literature for analogous syntheses and are comparable to the values of typical samples obtained by the acyl chloride routes.

Key words: poly(*p*-benzamide), poly(*p*-phenylene terephthalamide), triphenylphosphite, direct synthesis, aromatic polyamides.

Résumé : On décrit une étude complète orientée vers l'analyse du rôle de divers paramètres réactionnels dans la synthèse directe du poly(téréphtalamide de *p*-phénylène) et du poly(*p*-benzamide), activée par le phosphite de triphényle. On a considéré l'effet de la température, du type de sel et de sa concentration, de la quantité de phosphite de triphényle et de son introduction par étape ainsi que des concentrations de monomère et de réactifs. Les valeurs de la viscosité inhérente des polyamides aromatiques mentionnés plus hauts sont plus élevées que celles rapportées dans la littérature pour des synthèses analogues et elles sont comparables aux valeurs d'échantillons typiques obtenus par des voies impliquant les chlorures d'acyles.

Mots clés : poly(*p*-benzamide), poly(téréphtalamide de *p*-phénylène), phosphite de triphényle, synthèse directe, polyamides aromatiques.

[Traduit par la rédaction]

Introduction

In 1974, Yamazaki et al. (1) performed the direct synthesis of aromatic polyamides employing triphenyl phosphite (TPP) as activator. Only low molecular weight *para*-oriented polyamides were obtained with their original method.

In 1982 Higashi et al. (2) found a great improvement of the inherent viscosity (η_{inh}) value of poly(*p*-phenylene terephthalamide) (PPD-T) by adding to the solvent medium a salt mixture composed of $CaCl_2$ and LiCl, instead of LiCl alone, as previously suggested by Yamazaki et al. (3). However, their attempts to also use the double salt system in the synthesis of poly(*p*-benzamide) (PBA) did not provide any η_{inh} improvement. Later on, Preston and co-workers (4, 5) found that the optimum temperature for the direct synthesis of both polymers is 115°C.

Recently we reported that, when very accurate purification procedures are used, the inherent viscosities of PPD-T and PBA can reach rather high values (6). In the case of PPD-T, the η_{inh} value obtained in our laboratory is very close to that of the same polymer synthesized by using terephthaloyl chloride, which is used in all industrial recipes instead of the corresponding diacid.

In the present paper we report a systematic study of the role of several reaction parameters in order to evaluate the best experimental conditions for the direct synthesis of PPD-T and PBA, taken as examples for AA–BB and A–B polyamides, respectively.

In particular, we studied the effect of temperature, salt type and concentration, amount of TPP and its stepwise introduction, under both Yamazaki and Higashi conditions. With the above terms, we designate a reaction medium based on *N*-methyl pyrrolidone (NMP), pyridine (Py), and triphenyl phosphite (TPP), plus lithium chloride or lithium and calcium chlorides, respectively. Within each system, component (including monomer or reactants) concentrations can largely be varied. The slight discrepancy between the optimum η_{inh} values quoted in the present paper (see later) and those found previously (6) is due to minor differences in the purification procedures and polymerization setups.

Experimental section

(a) Materials

NMP (Aldrich) was refluxed under vacuum in the presence of CaH_2 for 8 h and distilled under the same conditions. Then it was refluxed under vacuum in the presence of P_2O_5 for 6 h and dis-

tilled; the treatment was repeated twice. Py (Aldrich) was refluxed under an inert atmosphere in the presence of sodium hydroxide for 6 h and distilled; the treatment was repeated three times. LiCl (Carlo Erba) and $CaCl_2$ (Fluka) were dried for 24 h at 340°C under vacuum. TPP (Aldrich) was purified by fractional distillation under vacuum. The procedure was repeated three times. Diphenyl phosphite (DPP), Aldrich, was purified by fractional distillation under vacuum. The procedure was repeated three times. *p*-Phenylenediamine (PPD), Fluka, was purified by sublimation at reduced pressure. The procedure was repeated three times. Terephthalic acid (TA), Amoco, was dried for 24 h at 80°C under vacuum. *p*-Aminobenzoic acid (pABA), Aldrich, was dried for 24 h at 100°C under vacuum.

(b) Procedure

1. Synthesis of PBA in a solvent medium containing LiCl (so-called Yamazaki conditions)

In a typical run, by operating in a dry-box under inert atmosphere, 10 mL of NMP, 3.3 mL of Py, 1.37 g of pABA, 1.70 mL of TPP, and 0.5 g of LiCl were added to a 50 mL three-neck flask, fitted with an inlet and an outlet for inert gas (in most cases argon) and a magnetic stirrer. Oxygen traces were preliminarily removed from the components mentioned above by several cycles of vacuum and argon. The vessel was placed in a thermostatically controlled oil bath at 115°C. The reaction mixture became a clear gel within 0.5 h. After 4 h of reaction, the polymer obtained was ground in a blender in the presence of methanol. The reaction product was washed with boiling methanol and dried in a vacuum oven for 18 h at 80°C. Polymer yield was determined gravimetrically.

2. Synthesis of PBA in a solvent medium containing LiCl and $CaCl_2$ (so-called Higashi conditions)

NMP (25 mL), Py (5 mL), pABA (1.13 g), TPP (1.30 mL), $CaCl_2$ (1.5 g), and LiCl (0.5 g) were added to the above reaction vessel as described. All polymerization procedures and the operations on the resultant polymer were as mentioned in point 1.

3. Synthesis of PPD-T in a solvent medium containing LiCl (Yamazaki conditions)

In a typical run, 9 mL of NMP, 6 mL of Py, 0.3068 g of TA, 0.1997 g of PPD, 1.11 mL of TPP, and 0.4 g of LiCl were added to the above reaction vessel as described. All polymerization procedures and the operations on the resultant polymer were as mentioned in point 1.

4. Synthesis of PPD-T in a solvent medium containing LiCl and $CaCl_2$ (Higashi conditions)

In a typical run, 12.5 mL of NMP, 2.5 mL of Py, 0.2077 g of TA, 0.1352 g of PPD, 0.72 mL of TPP, 0.75 g of $CaCl_2$, and 0.25 g of LiCl were added to the above reaction vessel as described. All polymerization procedures and the operations on the resultant polymers were as mentioned in point 1 above.

(c) Polymer characterization

Viscosities, expressed as η_{inh}, of polymer solutions (at the concentration of 0.1 g/dL) were determined in 96% H_2SO_4 at 25°C using a Ubbelhode-type viscometer.

Results and discussion

In a recent paper (6) we reported on the critical relevance of high purification methods joined with very accurate polymerization procedures in order to obtain high molecular weight aromatic polyamides. In the present work, a systematic evaluation of various reaction parameters (see below) for both Higashi and Yamazaki conditions is explored, taking into account the aforementioned importance of high purification levels for all reaction components.

Namely, we studied the influence of variables such as TPP/monomer (or reactant) molar ratio, salt type and concentration, reaction temperature, and mode of TPP addition to the reacting mixture, in terms of both polymer yields (which were almost always quantitative) and polymer molecular weights (MW). The latter are hereafter reported in terms of inherent viscosities, i.e., true experimental values, instead of MW data calculated from still controversial [η]–M relationships (7, 8).

The aromatic polyamides considered are PBA and PPD-T.

(a) Effect of the [TPP]/[monomer] or [TPP]/[reactant] ratio

1. [TPP]/[pABA]

We studied the synthesis of PBA prepared under Yamazaki or Higashi conditions and found that the best molar ratio for the synthesis of high molecular weight PBA was, in every case, [TPP]/[pABA] = 0.6. Thus, in Tables 1 (Yamazaki conditions) and 2 (Higashi conditions) are listed the η_{inh} values of PBA synthesized using different ratios of [TPP]/[pABA] (from 0.4 to 1.0). As shown in the tables, the inherent viscosity values decrease rapidly when [TPP]/[pABA] < 0.6, whereas such values for the two systems seems less prone to change at higher ratios.

2. [TPP]/[TA]

Table 3 lists the inherent viscosities of PPD-T synthesized under Yamazaki conditions, varying the molar ratio from 1.3 to 2.3 (a ratio of 2 refers to stoichiometric conditions). As we

[a]Experimental conditions: [TA] = [PPD] = 0.125 mol/L; NMP/Py = 1.5 (v/v); 2.7% LiCl (w/v); T = 115°C.

Table 4. Effect of [TPP]/[TA] ratio in the synthesis of PPD-T (Higashi conditions).[a]

Sample	[TPP]/[TA]	η_{inh} (dL/g)
0.44	2.0	6.84
0.42	2.2	8.15
0.43	2.4	6.89

[a]Experimental conditions: [TA] = [PPD] = 0.083 mol/L; NMP/Py = 5 (v/v); 1.7% LiCl (w/v); 5.0% $CaCl_2$ (w/v); T = 115°C.

can see, the [TPP]/[reactant] ratio in this system seems to be less critical than in the PBA synthesis. Moreover, the inherent viscosity values of the resultant polymers are very low. This is probably due to polymer precipitation during the reaction, which thereafter proceeds in a heterogeneous phase.

The situation is sharply different for polymerization under Higashi conditions, with a total reagent concentration of 0.166 mol/L (Table 4) being used. In these experiments, no precipitation of the polymer is observed and a complete gelation of the reacting mixture appears to take place. Under these conditions, the growth of the polymer chains is surely more extensive than in the previous system.

(b) Effect of salt type and concentration

1. PBA

The types of salt dissolved in the reaction medium and the concentration of salts have been studied in detail. LiCl and $CaCl_2$ have been used alone or mixed together. Table 5, which is based on a [TPP]/[pABA] ratio = 0.6, gives the η_{inh} data obtained using different concentrations of salts.

The values obtained under experimental conditions indicated under footnote *a* are related to a monomer concentration of 0.75 mol/L. The maximum value obtained (η_{inh} = 2.15 dL/g) is higher than the best literature value (5) (η_{inh} = 1.8 dL/g), most probably because of a better purification of reagents and solvents. As can be seen from the table, the highest η_{inh} value for this relatively high monomer concentration corresponds to the synthesis where the largest total salt concentration has been used.

The values obtained under experimental conditions indicated under footnote *b* are related to a lower monomer concentration of 0.27 mol/L. It can be seen that the sample 0.18 has the lowest inherent viscosity. It may therefore be concluded that, in this system, $CaCl_2$ has a negative effect. The highest η_{inh} value (2.19 dL/g) has been obtained when a high salt concentration in the reaction medium, based on LiCl only, has been used.

It is known (3) that the main effect of salts dissolved in the solvent mixture is to increase the solubility of rigid polymer chains, allowing the synthesis to be carried out in a homogeneous phase. We may infer that a high salt concentration has a marked positive effect for systems leading to a high polymer concentration. On the other hand, when the polymer concentration is relatively low, the solubility problems for polyamides are less important, with a scant effect linked to the increase of salt concentration, in particular if $CaCl_2$ is present in the reaction mixture.

2. PPD-T

The nature of the salt is the most important parameter in the synthesis of this polymer. Our study has been focused on a [TPP]/[TA] ratio = 2.

The data obtained from experiments carried out under conditions indicated by footnote *a* in Table 6 are related to some syntheses carried out using a total reagent concentration of 0.25 mol/L. It is clear that the mixed salt system is the worst. In general, the η_{inh} values are very low and there are no big differences among the three values. This result is probably due to polymer precipitation during the synthesis, which makes further polymer growth unfavorable. In the same table, the data obtained from experiments carried out under conditions indicated by footnote *b* are related to syntheses performed at a total reagent concentration equal to 0.166 mol/L. By comparing these latter values with the previous ones, the importance of working with a lower reactant concentration in order to avoid polymer precipitation during the synthesis is clearly evident.

(c) Temperature effect

1. PBA

All above syntheses were made at 115°C, i.e., at the best conditions suggested in the literature (5). We considered it relevant to also check this assumption for the experimental conditions leading to the optimum data of our experiments. Table 7 gives the inherent viscosities of PBA synthesized under the best conditions previously quoted (Table 6), using reaction temperatures in the range of 105 to 120°C. Our data confirm the presence of a maximum value for the reaction at 115°C with η_{inh} = 2.19, as compared to 1.8 dL/g, quoted in the literature (5).

2. PPD-T

Table 8 refers to temperature effects on some syntheses made under Yamazaki conditions at [TPP]/[TA] ratio = 2.0. It is evident that this system is not very sensitive to the variation of temperature. The inherent viscosity values are rather low and almost constant.

More significant in this respect is the Higashi system. The data reported in Table 9 refer to syntheses made at a [TPP]/[TA] ratio of 2.2, which represents the best ratio found for these experimental conditions. The highest value is obtained at 115°C and is equal to 8.15 dL/g, much higher than the best literature value of 6.2 dL/g (5).

It is relevant to observe that the Higashi system is more sensitive to temperature variations than the Yamazaki system. It can also be seen that a dramatic decrease of η_{inh} occurs when

the temperature is increased above the optimum value of 115°C.

(d) Mode of TPP addition

1. PBA

In 1984 Preston and co-workers (5) noticed that a direct synthesis of PBA from the dimer of the pABA, instead of the monomer itself, made it possible to obtain a polymer with a higher inherent viscosity. By this method, PBA with η_{inh} = 4.6 dL/g, as compared to the value of 1.8 dL/g for the polymer synthesized directly from pABA, was obtained and represents the highest value reached so far by the direct synthesis activated with TPP. In our opinion, an alternative and simpler route could produce

Table 10. Effect of TPP stepwise addition in the synthesis of PBA (Yamazaki conditions).[a]

Sample	[TPP]/[pABA]	η_{inh} (dL/g)	Increment (%)
0.13	0.6	2.00	—
0.16[b]	0.6	2.25	13
0.15	1.0	1.26	—
0.17[b]	1.0	2.07	64

[a]Experimental conditions: [pABA] = 0.75 mol/L; NMP/Py = 3 (v/v); 3.7% LiCl (w/v); T = 115°C.
[b]The same as above; stepwise addition of TPP.

Table 11. Effect of TPP stepwise addition in the synthesis of PBA (Higashi conditions).[a]

Sample	[TPP]/[pABA]	η_{inh} (dL/g)	Increment (%)
0.18	0.6	1.53	—
0.37[b]	0.6	1.96	28
0.12	1.0	1.40	—
0.36[b]	1.0	1.77	26

[a]Experimental conditions: [pABA] = 0.27 mol/L; NMP/Py = 5 (v/v); 1.7% LiCl (w/v); 5.0% $CaCl_2$ (w/v); T = 115°C.
[b]The same as above; stepwise addition of TPP.

relatively larger (as compared to the usual procedures) amounts of dimer in situ, by using a stepwise addition of TPP, thus initially activating only part of the carboxylic groups.

In Table 10, data concerning four syntheses made under Yamazaki conditions at a pABA concentration of 0.75 mol/L and two different [TPP]/[pABA] ratios are reported. Relevant improvements of η_{inh}, when TPP is added stepwise, were obtained.

The same conclusion can be reached from the data of Table 11, which refers to four syntheses performed using the more dilute pABA concentration of 0.27 mol/L under Higashi conditions. Also for this system a good improvement of inherent viscosity was found.

On this basis, a comparison between our highest η_{inh} value (sample 0.29 in Table 7), reached using a monomer concentration of 0.27 mol/L and 6.7% LiCl, and the corresponding η_{inh} value obtained from a synthesis made under the same conditions but with stepwise TPP addition, shows that under the latter conditions a further increase of η_{inh} (from 2.19 to 2.35 dL/g) was found. The above value is, probably, the highest η_{inh} obtained so far, when a direct synthesis from pABA is employed.

2. PPD-T

In contrast to PBA, the literature does not report, for the PPD-T synthesis, any improvement for the reaction made starting from the "dimer" (9). Similarly, in our stepwise procedure, no increase of η_{inh} was found.

(e) Use of DPP

As previously indicated, the best [TPP]/[pABA] ratio is 0.6, a rather unusual value if we consider that each TPP molecule activates a carboxylic function, allowing it to react with the amino group. It can be reasonably assumed that DPP, formed as by-product during the reaction, is also able to activate the acidic group. Two attempts of PBA synthesis using DPP instead of TPP, for two different [phosphite]/[pABA] ratios were successful, although they gave rather low η_{inh} values, and fully justify our assumption. Thus, DPP can be considered to promote the reaction between the acid and the amino functions, although with lower efficiency. This may also be due to the presence of high concentrations of phenol not easily removed in our DPP. Phenol may be responsible, in our opinion, for the rather low η_{inh} values obtained ($\leq$0.2 dL/g). Direct evidence of its role was demonstrated by its addition in equimolar amount to the monomer in a typical synthesis of PBA by TPP. The η_{inh} of PBA was lowered from 2.0 to 0.06 dL/g. Literature data on polyamidohydrazides synthesized in the presence of DPP, on the contrary, reveal that the latter is a better reagent than TPP (10).

Conclusions

Direct synthesis appears a very easy and useful method for obtaining, on a laboratory scale, aromatic polyamides characterized by a large range of inherent viscosity values, which depend on the experimental conditions, thoroughly studied in the present work, chosen for their synthesis.

In addition, accurate purification procedures and proper choice of the reaction conditions make it possible to reach quite high polymer molecular weights, close to those obtained by acyl chloride routes.

Advantages of direct synthesis are the ease to carrying it out, the use of relatively stable diacids instead of moisture-

For personal use only.

and temperature-sensitive compounds, such as acyl chlorides, and also the simplicity and low cost of the experimental equipment.

On the contrary, the high concentration of TPP required, as well as the problems connected with its removal from the polyamide, may represent a relevant disadvantage.

Further improvement of the reaction can be envisioned by continually removing the phenol formed as by-product. As a consequence, it would be possible to shift the equilibrium more and more towards the products and avoid the possibility of the phenol reacting with the growing polymer chains.

Mechanical behaviour of polymer mixtures in the phase separation region

V.N. Kuleznev and L.B. Kandyrin

Abstract: The liquid–liquid phase transition triggered by changes in the composition of polymer mixtures in solution or melt is often accompanied by "critical" opalescence, which signals the appearance of a microemulsion in the mixture. The viscosity of the polymer mixture in this region is characterized by a sharp minimum, observed, as a rule, over an extremely narrow range of concentration. Depending on the concentration of the solution, the type of polymer, and the solvent, the viscosity may decrease by a factor of 8–10. On transition from micro- to macro-separation, viscosity rapidly increases back to the original level. Changes in the composition of the mixture can alter the concentration at which phase separation occurs, but the minimum in viscosity invariably corresponds to the moment of phase separation. The critical opalescence region represents the formation of phase particles up to 80–100 nm in size, and this corresponds to the point of viscosity drop. This effect is due to the appearance of thermodynamically stable microemulsions in the polymer mixture, in the region between the binodal and the spinodal in the phase diagram. These emulsions are characterized by lower molecular interaction of incompatible polymers in the highly developed interfacial layer. Extremal changes at the point of phase separation are also observed for other mechanical characteristics of polymer mixtures in solutions or melts, for example, G' and G'' dynamic moduli or complex viscosity η^*.

Key words: polyblends, critical phenomena, viscosity, emulsions, phase separation.

Résumé : Les transitions de phase liquide–liquide provoquées par des changements dans la composition de mélanges de polymères fondus ou en solution sont souvent accompagnées par une opalescence critique qui signale l'apparition d'une microémulsion dans le mélange. La viscosité du mélange de polymère dans cette région est caractérisée par un minimum pointu généralement observé sur une bande extrêmement étroite de concentration. Suivant la concentration de la solution, le type de polymère et le solvant, la viscosité peut diminuer par un facteur allant de 8 à 10. Lors de la transition de la microséparation en macroséparation, la viscosité augmente rapidement pour revenir au niveau original. Des changements dans la composition du mélange peuvent affecter la concentration à laquelle la séparation de phase se produit; toutefois, le minimum de viscosité correspond invariablement au moment de la séparation de phase. La région de l'opalescence critique représente la formation d'une phase de particules dont la grosseur varie de 80 à 100 nm et elle correspond au point de diminution de la viscosité. Cet effet est dû à l'apparition, dans le mélange de polymère, de microémulsions thermodynamiquement stables dans la région entre le binodal et de spinodale du diagramme de phase. Ces émulsions sont caractérisées par une interaction moléculaire plus faible des polymères incompatibles dans la couche interfaciale hautement développée. On a aussi observé des changements extrêmes à ce point de la séparation de phase pour d'autres caractéristiques mécaniques de mélanges de polymères fondus ou en solution, par exemple, pour les modules dynamiques G' et G'' et pour la viscosité complexe η^*.

Mots clés : mélanges complexes, phénomène critique, viscosité, émulsions, séparation de phase.

[Traduit par la rédaction]

During a stay of V. Kuleznev in the laboratory of Jim Guillet in 1965–1966, the idea arose of investigating the influence of butadiene–styrene block copolymers on the compatibility of polystyrene and polybutadiene (PS–PB) in appropriate solvents. Although the work was not concluded, two important experimental facts emerged. The first was that the block copolymers increased the concentration of PS–PB where phase separation occurred, that is, improved the compatibility of these polymers in the solution. The second was that solutions of the block copolymers with sufficiently high molecular weights were turbid and opalescent themselves. This second observation led us to the possibility of employing internal block segregation in block copolymers to form stable microemulsions. Further development of this idea in our laboratory in Moscow demonstrated the possibility of forming stable microemulsions in polymer–polymer mixtures when the stability was provided by "thermodynamics" and not by chemical bonds between the segregated macromolecules.

This paper considers the rheological properties of these unique systems, and is published with deep gratitude to Pro-

fessor Jim Guillet for providing the opportunity for repeatedly working together.

Binary polymer mixtures in solution, melt, or the solid state may be one- or two-phased depending on the temperature, concentration, or composition of the mixture. The binodal that Gibbs described as the boundary of the absolute phase stability (Fig. 1) acts as a barrier between the one- and two-phase regions in the phase diagram. In the immediate vicinity of the binodal, homophasal statistical fluctuations appear in the one-phase system, with their composition and density different from the average (1). When passing through the binodal, the values of these homophasal fluctuations rise to such an extent that they can viewed as seeds of a new phase, i.e., a heterophasal state. This state is maintained up to the spinodal, which Gibbs described as the boundary of the absolute phase instability. Following the transition over the spinodal, two macrophases emerge in the system, taking in some cases a substantial period of time to evolve, particularly if the viscosity of the system is high.

The region bordering the spinodal on the side of either the one-phase or two-phase system is characterized by lower thermodynamic stability. Progressive large-scale fluctuations create a specific granular structure throughout the system. Externally this is indicated by the appearance of critical opalescence. This was first described by Smoluchowski (2), and later quantitatively described for single-component systems by Ornstein and Zernicke (3) and for bi-component systems by Debye (4, 5). The phase separation of mixtures of low molecular weight liguids, as well as polymer–solvent mixtures, occurs sharply due to comparatively high interfacial tension, since the range of critical opalescence is very narrow. On the other hand, the range of large-scale fluctuations is considerably wider for the phase separation of polymer–polymer or polymer–polymer–solvent mixtures. This makes it possible to carry out a detailed study of the physical properties of these systems. Such studies are of considerable interest, since the appearance of large-scale fluctuations near the critical point is accompanied by extreme changes in certain physical properties such as compressibility, thermal expansion, and heat capacity even for mixtures of low molecular weight liquids (6–10). Regrettably, the mechanical properties of polymer mixtures in the critical region have not yet been thoroughly investigated. This is probably due to the fact that the low mutual solubility of most polymers results in a critical point (transition over the binodal) with a concentration of a given component being less than 1%. In consequence there is only a low probability of detection of anomalies caused by changes in the mechanical properties of the polymer mixtures. The results of some investigations have demonstrated that the concentration (or temperature) dependence of the viscosity becomes nonmonotonical at the phase transition point, with an uneven decrease in the viscosity (11–16).

The objective of the experiments described in this paper was to study peculiar changes in the rheological properties of polymer mixtures in solution and in the melt, in the critical area where the mixture goes from the one-phase to the two-phase condition.

Experimental section

The following polymers, all of industrial grade, were employed: polyisoprene (PI-1), Cariflex-JR 500, mol. wt. 9×10^5; polystyrene (PS-1), block polymerized, mol. wt. 2.8×10^5; polymethacrylate (PMMA), suspension polymerized, mol. wt. 2.4×10^5; and their solutions in benzene, decahydronaphthalene, toluene, and other solvents. To study the influence caused by the width of molecular weight distribution, we also analyzed mixtures of polyisoprene (PI-2) and polystyrene (PS-2), each with a narrow MWD (M_w/M_n = 1.05), and their solutions in α-methylnaphthalene.

Polymer mixtures in solution were obtained by mixing equiconcentrated solutions of each polymer in a common solvent. In the case of melt studies, samples were prepared by pressing films obtained from polymer mixtures in a common solvent, followed by evaporation of the solvent in vacuo at a suitable temperature.

One-phase solutions of the polymers were highly stable. Separating solutions of polymer mixtures were thoroughly stirred so as to be homogenized prior to measurement. Time-intensive measurements were conducted, for solutions only, in high-boiling solvents. Good reproducibility was observed in all experiments.

The turbidities of one- and two-phase solutions and films were measured with a photoelectric double-beam turbidmeter with light filters having different pass bands. The known relationship between turbidity and the wavelength of the passing light (17) was used to calculate the size and number of dispersed particles in the sample. The viscosity at a steady flow was measured by a rotation viscosimeter with coaxial cylinders, with various rotation speeds of the inner cylinder.

Dynamical mechanical characteristics of the polymer mixture solutions (G', G'', η^*) were measured by a low-amplitude mechanical spectrometer with coaxial cylinders in the 10^{-2}–10^3 s^{-1} frequency range.

The viscosity of the polymer mixtures in the absence of solvent was measured with a capillary viscosimeter at 170 ± 0.2°C.

Results

The most simple case in studying the phase transition region of solutions of polymer mixtures involves an examination of

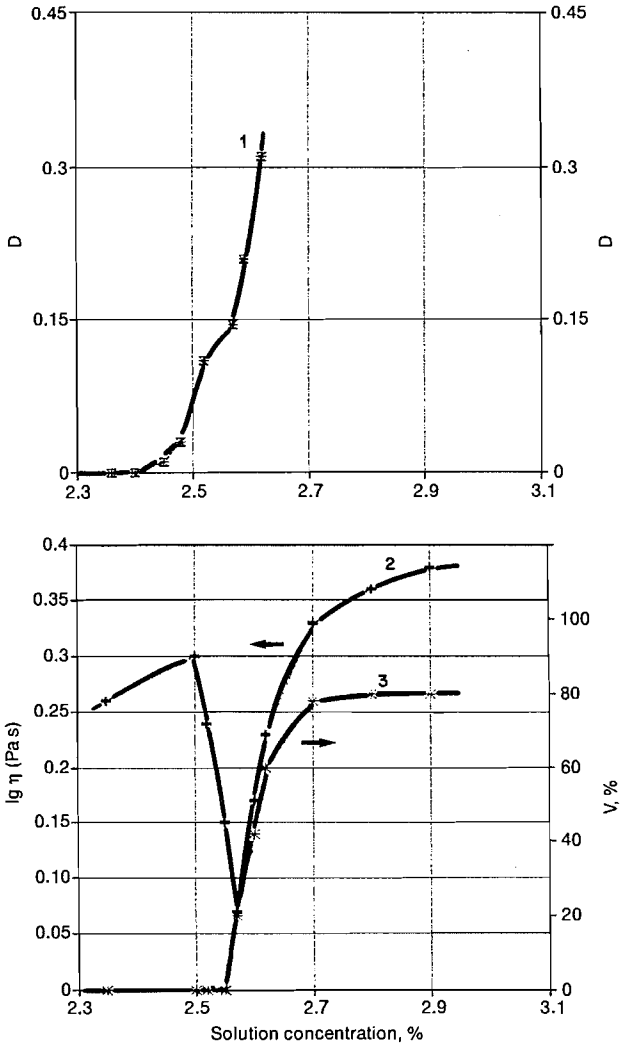
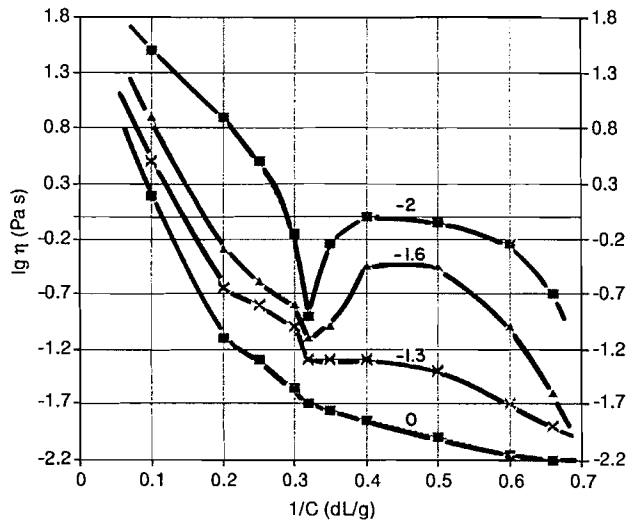
Fig. 2. Concentration dependence of turbidity D (1), viscosity lg η (2), and lower layer volume V (3) for benzene solutions of PI-1–PS-1 mixture (3:7).



the relationship between properties and concentration in the interval that contains the phase separation point. Depending on the concentration of the solution, the ratio of polymers therein, the temperature, and the nature of the polymers and their molecular weight distribution, the position of the phase separation point can shift substantially. Figure 2 illustrates the dependence on concentration of viscosity and turbidity for a solution of PI-1 and PS-1 (3:7 mixture) in benzene. The same figure presents the concentration dependence of the volume of the lower layer (PS) in the separated two-phase mixture. A higher concentration of the solution raises the turbidity near the point of separation. The "critical" opalescence appearing in the solution indicates the formation of concentration and composition fluctuations. This state usually precedes macroseparation of the system. The plateau in the concentration dependence of the turbidity prior to separation can be more or less pronounced, but further increases in solution concentration lead to a sharp increase in turbidity due to macroseparation. It should be mentioned that the plateau representing critical opalescence can be reached from two regions, a dilute one-phase solution or a concentrated two-phase solution. The

Fig. 3. Dependence of viscosity of toluene solutions of PI-1–PS-1 mixture (1:1) on reciprocal value of their concentration. Figures near curves represent logarithms of shear stress used to determine viscosity (Pa).



intensity of critical opalescence (solution turbidity) remains the same and does not change with time. This indicates that the solution structure is in an equilibrium state in the area of critical opalescence.

Analysis of the changes in viscosity near the phase transition point is of considerable interest. With increasing concentration below this point the viscosity increases as expected, but when the region of "critical" opalescence is reached, there is a dramatic decrease. Depending on the concentration of the solution, the type of polymer, and the solvent, the viscosity can drop by a factor of 7–10. This occurs over a very narrow range in concentration in the immediate vicinity of the phase separation point. At the appearance of the first signs of macroseparation, i.e., the appearance of a second macrolayer in the solution, the viscosity then rapidly increases again, returning to a value close to the original. Altering the ratio of polymers in the mixture, or employing a different solvent, changes the concentration at which phase separation occurs. However, the minimum in viscosity invariably coincides with the region of phase separation. An increase in the shear stress (at which the viscosity of the solution is measured) reduces the effect of the diminishing viscosity. At certain, sufficiently high, levels of shear stress, this effect for practical purposes does not occur. Comparing changes in viscosity in the region of phase separation with the reciprocal value of the concentration of the solution results in a dependence (Fig. 3) that resembles to a certain extent the van der Waals isotherm for a real gas. Increases in shear stress can in this case be compared to an increase in temperature, since both factors act to destroy association of like macromolecules in the mixture of incompatible polymers. In other words, the two factors tend to homogenize the system.

The phase separation point can be approached at constant concentration of the mixture by changing the ratio of the polymers in the solution, as illustrated in Fig. 4. In this case also, the critical opalescence appears when approaching points of phase separation, indicating pre-separation fluctuations. The appearance of critical opalescence is also accompanied by a

Fig. 4. Dependence of viscosity lg η (1) and turbidity D (2) of toluene solutions of PI-1–PS-1 mixtures on the ratio of polymer components in the mixture. Solution concentration 2.5%.

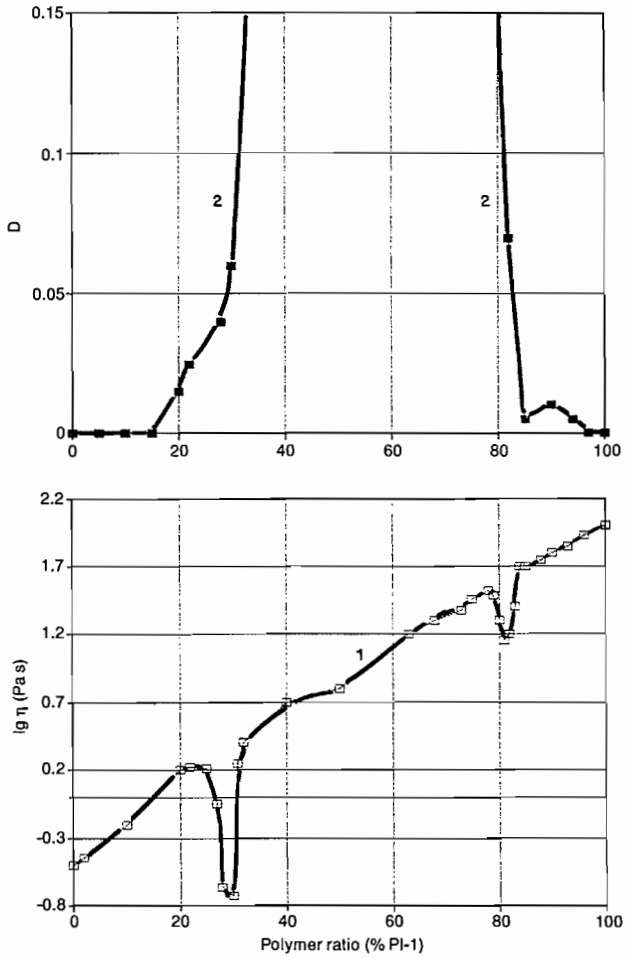

Fig. 5. Dependence of loss modulus G'' on polymer ratio of the mixture of PI-1 and PS-1 solutions in decahydronaphthalene (2), and of the mixture of PI-2 and PS-2 solutions in α-methylnaphthalene (1).

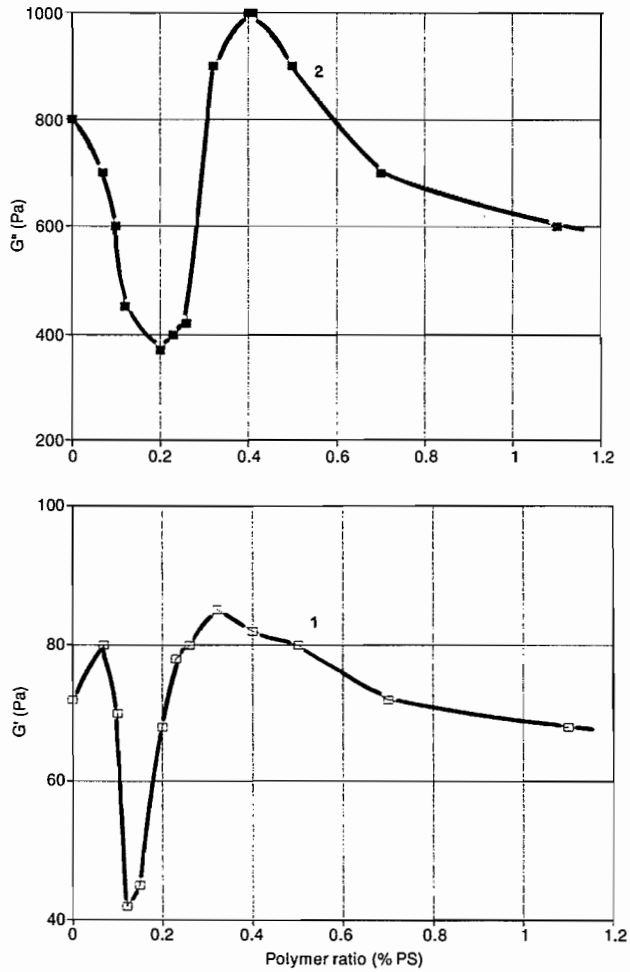

sharp drop in viscosity. It can be noted that the concentration of the solution for the system shown in Fig. 4 is relatively low. The mutual solubility of the components of this system is relatively high, so that a considerable amount of polymer can be added before reaching the separation points. Increasing the concentration of the solution causes the phase separation points to move closer to the Y-axes. In the absence of solvent the solubility of one polymer in another, which corresponds to the points of phase separation, is below 1%.

Extremal changes when reaching the phase separation point occur not only in the viscosity, but also in other mechanical characteristics of mixed polymer solutions. Figure 5 shows the dependence on concentration of the dynamic loss modulus G'', as determined with a low-amplitude mechanical spectrometer for concentrated solutions of PI-1:PS-1 mixtures in decahydronaphthalene. The position of the minimum in G'' corresponds exactly to the region of critical opalescence. To determine the role played by the width of the MWD, we measured the dependence of G'' on polymer ratio for a solution of mixtures of two monodisperse polymers PI-2 and PS-2 in α-methylnaphthalene (curve 1 of Fig. 5). In this case also there was good correspondence between the position of the G'' minimum and the critical opalescence. It can be noted that for the monodisperse mixture, the region that contains the G'' minimum is narrower than that of the mixture of polydisperse polymers. This is understandable, since the mutual polymer solubility depends on the molecular mass. The existence of low molecular weight fractions in polydisperse samples, with a higher mutual solubility than that of high molecular weight fractions, serves to extend the range of concentration that corresponds to the separation region.

A study of the optical characteristics of solutions of the polymer mixtures at different wavelengths of transmitted light, the so-called turbidity spectrum technique (17), made it possible to calculate the sizes and numbers of particles in the disperse phase of the investigated solutions, both in the region of critical opalescence, and probably in the two-phase region. It was found that the region of critical opalescence corresponds to the formation of a maximum number of particles with a size of 80–100 nm (Fig. 6). Further increases in concentration (or changes in composition) that result in rapid phase separation lead to a rapid increase in the sizes of the disperse particles, to 400–500 nm. At the same time, their number decreases proportionally. The total interfacial surface of the system, which is maximum in the region of critical opalescence, is reduced just as quickly. The system becomes unsta-

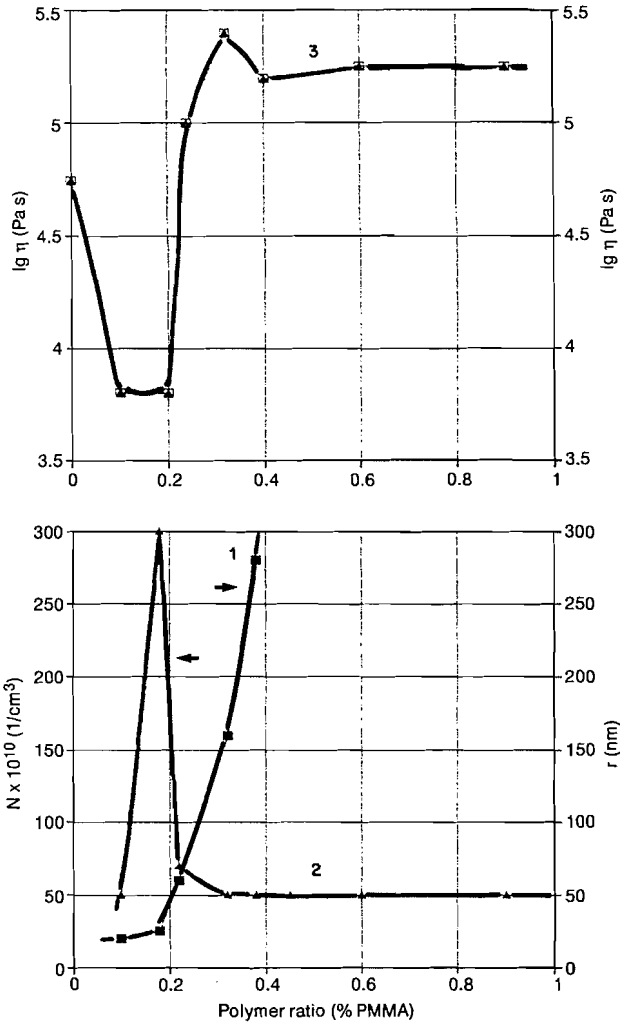
ble, and is separated into two phases with a minimal interfacial surface.

The rapid drop in viscosity in the critical region of phase separation is characteristic not only of polymer mixtures in solution, but also of polymer mixtures in the absence of solvent. In this case, the experimental detection of the effect becomes difficult due to the low mutual solubilities of polymers of high molecular weight at attainable temperatures. Figure 7 illustrates the dependence of turbidity of PS–PMMA films on PMMA content. Film turbidity was determined at temperatures similar to those employed for the determination of rheological properties, 170±0.2°C. As seen in Fig. 7, the range of concentration of PMMA that corresponds to the onset of film turbidity also corresponds to a viscosity drop. Analogous effects were also observed in the study of the rheological properties of the other pairs of polymers in solution or in the melt.

Discussion

To explain the results obtained in this study, it is advisable to discuss the phase structure of mixtures. A two-component mixture is known to exist in both a one-phase state and a two-phase state. The number of phases corresponding to a given composition of the mixture and temperature is determined, according to Gibbs, by binodal and spinodal positions. The region between the binodal and the spinodal is called the metastable region, and corresponds to a situation where the one-phase structure of the system is stable in relation to small changes in thermodynamic parameters but if unstable when nuclei of the second phase appear. Gibbs proposed treating the work needed for the appearance of the critical seed element of the new phase as a measure of the stability of the metastable state. Volmer and Rehbinder showed that is the interfacial tension of the system is sufficiently low, the spontaneous appearance of thermodynamically stable emulsions becomes possible (18, 19). The stability of such emulsions is associated with the excess entropy, and consequently free energy, released by the participation in the Brownian movement of the particles formed in the emulsion (20, 21).

Fig. 7. Dependence of the size (1), number (2) of particles, and viscosity (3) of mixed PS-1–PMMA melt on mixture composition.



Interfacial tension in the polymer–polymer system is very low, especially in the region of formation of the new phase (22). In consequence, there is a high probability of spontaneous formation of emulsions in mixed polymer solutions near the critical point. The experimental detection of critical opalescence in solutions of polymer mixtures (Figs. 2, 4) and melts, together with estimated sizes and numbers of particles in such emulsions (Figs. 6, 7) verifies the above proposition. These emulsions are likely to be in an equilibrium state, since the system fully maintains its structure, in a solution with sufficiently low viscosity, for a year or more. Moreover, the particle sizes in a disperse emulsion, as well as the number of particles, are not altered by moderate heating and cooling. Solutions of polymer mixtures of moderate concentration exhibit little change in the concentration of phase separation on changing the temperature. In consequence, emulsion stability is maintained with increasing temperature (in the absence of diffusion complications) in high molecular weight viscous liquids, and this can be taken as a sign that the system is in an equilibrium state.

The sharp viscosity drop observed in the region of the existence of critical emulsion can be explained as follows. The

interfacial layer that appears on phase separation contains large volumes of substances belonging to both phases. This is because the thickness of the layer and the interfacial surface area, governed by the small sizes and large numbers of particles in the region of phase separation, are great. Insignificant molecular interaction of incompatible polymers in the interfacial layer leads to a decrease in the cohesion energy density of the mixture as a whole (23), which is equivalent to an increase in the concentration of the free volume inside the interfacial layer (24, 25). Such a system should possess low viscosity. Since the appearance of spontaneously formed highly disperse emulsions is characteristic only of a narrow concentration range near the phase separation point, the concentration range showing the drop in viscosity is also narrow. A small increase in concentration of the solution, or a slight alteration in the composition of the mixture, can push the system beyond the limit of emulsion stability. This causes an instant phase separation of the system, an abrupt drop of interfacial area by 2–3 decimal orders, and an immediate growth of viscosity.

Changes in viscosity on appearance of a new phase, or even a simple restructuring of the supermolecular structure, are a common characteristic for even the most diverse systems. Thus in dilute solutions of PS–PMMA mixtures, increasing the concentration of the solution results in a transition from a structure with isolated coils to a structure characterized by dynamic contacts and interpenetration of coils (critical concentration c_1 according to Doty and Steiner (26)). For this polymer mixture in the solution, a slight, but fully reproducible, minimum in the viscosity was observed exactly at the c_1 point (27). Even in a dilute solution of block copolymer, a minimum in viscosity was observed at the moment of transition from a structure of mixed blocks to a structure of segregated blocks, caused by changing temperature (28, 29).

In conclusion, it can be noted that the uneven distribution of free volume in the system near the critical region in, for example, melted polymer mixtures can be maintained at a lower temperature of the mixtures, even below the glass transition point, where the molecular mobility is limited and the system is no longer in an equilibrium state. Such a system can also have anomalous characteristics when its structure remains similar to that of the "critical" emulsion.

Abstract: The influence of sugar residue sequence in partially *N*-acetylated chitosans on relative hydrolysis rate catalyzed by lysozyme was studied. The relative rates were modelled assuming an Arrhenius-type relation for the relative rate constants. The apparent activation energy was assumed to consist of additive contributions from GlcN or GlcNAc residues within the polymer chain interacting with sites A–F of the active cleft of lysozyme. This model accounted well for the relative hydrolysis rates reported for well-defined oligomers. Calculated and experimental data for the dependence of the initial relative hydrolysis rates on fraction of acetylated units, F_A, showed an $F_A^{3,6}$ dependence. A fully water-soluble highly *N*-acetylated chitosan with F_A = 0.68 was depolymerized using lysozyme for further testing of the model. Analyses of the ^{13}C nuclear magnetic resonance spectra of the diad sequences at the new reducing and nonreducing ends formed by lysozyme showed that this enzymatic depolymerization was dominated by chitosan sequences presenting GlcNAc residues to sites C, D, and E of the active cleft. In contrast, there was no selectivity between GlcNAc and GlcN residues interacting with site F. These selectivities were confirmed by the calculated contributions to the apparent activation energy of these sites. The experimentally determined depletion in the diad and triad frequencies of GlcNAc during the course of lysozyme hydrolysis was in good agreement with the model calculations.

Key words: lysozyme, chitosan, chitin, sequence specificity, subsite model.

Résumé : On a étudié l'influence de la séquence des résidus de sucre, dans des chitosanes partiellement *N*-acétylés, sur le vitesses relatives d'hydrolyse par le lysozyme. On a fait un modèle des vitesses relatives en supposant qu'on peut leur appliquer une relation du type d'Arrhenius. On a supposé que l'énergie d'activation apparente est formée de contributions additives des résidus GlcN ou GlcNAc présents dans la chaïne de polymère avec les sites A à F de la cavité du lysozyme. Ce modèle a permis d'expliquer les vitesses d'hydrolyse relatives rapportées pour des oligomères bien définis. Les données calculées et expérimentales concernant la dépendance des vitesses d'hydrolyse relatives initiales sur la fraction d'unités acétylées, F_A, présentent une dépendance $F_A^{3,6}$. Dans le but de vérifier plus à fond le modèle et utilisant le lysozyme, on a dépolymérisé un chitosane *N*-acétylé, complètement soluble dans l'eau et de F_A = 0,68. Des analyses par de la résonance magnétique nucléaire ^{13}C des séquences de diades aux extrémités réductrices et non réductrices formées par le lysozyme ont montré que cette dépolymérisation enzymatique est dominée par des séquences de chitosane présentant des résidus GlcNAc aux sites C, D et E de la cavité active. Par opposition, aucune sélectivité a pu être observée entre les résidus GlcNAc et GlcN qui interagissent avec le site F. On a confirmé ces sélectivités par les contributions calculées à l'énergie apparente d'activation de ces sites. La diminution déterminée expérimentalement dans les fréquences des diades et triades du GlcNAc durant l'hydrolyse par le lysozyme est en bon accord avec les calculs faite avec les modèles.

Mots clés : lysozyme, chitosane, chitine, spécificité séquentielle, modèle d'un sous site.

Introduction

Development and the use of biodegradable polymers require knowledge about the mechanisms of action of enzymes on polymer substrates. Heteropolysaccharides constitute a highly complex field when considered as substrates for polymer-modifying or -cleaving enzymes. Their heterogeneity in chain length, sequence distribution, and the possibility of single-chain and multiple- or multichain enzyme attacks make such a basic enzyme concept as molar substrate concentration difficult to apply. Still, some specificity must be present in the recognition process between the polymeric substrate and the active cleft of the enzyme. This paper considers the influence of the sequential distribution in partially *N*-acetylated chitosans on their enzymatic depolymerization by lysozyme. The primary objective is to explore the influence of sequence distribution on the relative hydrolysis rates, and changes in fractional occurrence of the possible diad and triad combinations due to depolymerization.

Chitosans are made from chitin by *N*-deacetylation under homogeneous or heterogeneous conditions. The resulting polysaccharide consists of 2–acetamido-2–deoxy-β-D-glucopyranose (GlcNAc; **A** unit) and 2–amino-2–deoxy-β-D-glucopyranose (GlcN; **D** unit) connected by (1→4) linkages. It has previously been shown that the sequential arrangement of **A** and **D** residues in the polymer chain is governed by Bernoullian statistics for a range of samples with fraction of acetylated residues, F_A, from 0.01 to 0.5 (1, 2). Lysozyme (EC 3.2.1.17) hydrolyses the β-(1→4) glycosidic linkage in chitin. Depolymerization of chitosans by lysozyme has been studied by various groups because of the large interest in biomedical applications of this polysaccharide. Hirano et al. (3) reported that optimum degradation rates were achieved for chitosans having an F_A of 0.8. However, these data could be difficult to interpret because of differences in solubility as a function of F_A for the chitosans used in that study (4, 5). Nordtveit et al. (4) reported that the initial depolymerization rate of partially *N*-acetylated chitosans catalyzed by lysozyme increases in proportion to F_A raised to the 3.6 power ($F_A^{3.6}$). The interpretation of these observations was made by considering the relative susceptibility of the 64 possible hexamers acting as substrates in a Michaelis–Menten analysis of lysozyme, combined with their relative fraction occurring at different F_A. Furthermore, the rate dependence on substrate and enzyme concentrations followed a Michaelis–Menten type of kinetics.

In this study, a molecular model for quantitative prediction of relative hydrolysis rates by lysozyme for chitosans having different F_A is developed. The model adopted shares many of the features employed in the subsite models of α-amylases acting on linear substrates of the homopolysaccharide α−(1→4)-glucopyranose (6, 7). A crucial difference when comparing lysozyme action on chitosans with α-amylases on amylose-type substrates is the information that can be obtained by studying the depolymerization products. For the binary heteropolysaccharide chitosan, analysis of newly formed end groups and their adjacent neighbours may provide information about subsite specificity that may not be obtained for a hompolysaccharide. As an integrated part of our strategy, we therefore analysed new reducing and nonreducing ends of the lysozyme-depolymerized chitosan using nmr methods.

Molecular model for lysozyme depolymerization of chitosans

The aims of the model were to quantitatively predict relative initial hydrolysis rates for lysozyme-catalyzed depolymerization of chitosans spanning a range of F_A, and to study potential changes in polysaccharide sequence information as a function of degree of depolymerization. The active cleft of lysozyme recognizes six hexose residues at subsites designated A–F. The glycosidic linkage being hydrolysed is located between the sugar residues interacting at sites D and E (Fig. 1). Amano and Ito (8) reported that the relative hydrolysis rates for partially *N*-acetylated oligomers derived from chitosan depend strongly on the acetylation pattern of the oligomers. They also report, by studying the products formed from various oligomers, that more than one binding mode to the active cleft can result in hydrolysis. Their data therefore suggest that the acetylation pattern in chitosan polymers may influence the relative susceptibilities for hydrolysis of the glycosidic linkages within the polymer.

Lysozyme hydrolysis of chitooligomers occurs either by direct hydrolysis of 1:1 substrate-to-enzyme complexes, or 2:1 substrate-to-enzyme complexes, with the relative importance depending on the concentration ratios and degree of polymerization (9, 10). Furthermore, the transglycosylation

pathway becomes increasingly important relative to the hydration and release of degraded products as the molar concentration of nonreducing ends increases (9, 10). In the following it was assumed that lysozyme hydrolysis data used in the model was governed by random, multiple attack of lysozyme, and that the 2:1 substrate-to-enzyme pathway and the transglycosylation were negligible. Omitting the transglycosylation was justified by working with substrate concentrations lower than about 2×10^{-3} M in aqueous solvents, where the hydration and release of products dominate (9). Disregarding the pathway involving 2:1 substrate-to-enzyme complexes was valid at least in the case of polymeric substrates, but also the experimental data reported by Amano and Ito (8) do not appear to involve significant amounts of 2:1 complexes. This indicates that the parameters for the model to be estimated from hydrolysis rates of various chitooligomers, and from the experiments carried out on higher molecular weight material, correspond with respect to the dominating hydrolysis pathways.

The steady-state Michaelis–Menten enzyme kinetics equations for the 64 possible types of hexasaccharides were deduced by Nordtveit et al. (4):

$$[1] \quad V_{tot} = \frac{\Sigma f_i V_f^i}{1 + K_S/[S]}$$

In eq. [1], V_{tot} is the total hydrolysis rate, the summation is over all possible hexasaccharides, f_i and V_f^i are the fraction of hexasaccharide i and associated maximum hydrolysis rate, respectively. K_S is the dissociation constant for all substrate types, and [S] is the total molar substrate concentration. Equation [1] was derived by assuming the dissociation constants for all substrate types were equal. This assumption was based on the experimental finding that the net hydrolysis rate showed a characteristic levelling off as a function of [S] at the same [S] for different F_A (4). The relative rate for lysozyme hydrolysis of chitosans with increasing F_A can then be calculated using eq. [1], provided that all f_i at a given F_A, and their associated V_f^i and K_S, are given. The fractions f_i were calculated using Bernoullian sequence statistics. Substrate saturation was assumed in the calculation, i.e., $K_S/[S] << 1$ in eq. [1].

The hydrolysis rates, V_f^i, for the 64 hexasaccharides were calculated by applying an activation energy, $E_{a(i)}$, to describe the rate-limiting step of the hydrolysis:

$$[2] \quad V_f^i = k \exp(-E_{a(i)}/RT)$$

where k is a constant, R is the molar gas constant, and T the absolute temperature. It was furthermore assumed that the influence of the hexasaccharide acetylation sequence can be represented by additive contributions arising from each of the **A** or **D** residues within a given oligosaccharide interacting with the subsites A–F in the active cleft of lysozyme. Thus, a contribution ΔE_S^T to $E_{a(i)}$ is assigned to each site S, S = A, B, C, D, E, and F, for interaction with residue of type T, T = **A** or **D**, to the apparent activation energy (Table 1). As an example, consider the hexassacharide **ADAAAD** perfectly aligned in the active cleft of lysozyme (Fig. 1). The hydrolysis rate for this hexasaccharide can then be written:

$$[3] \quad V_f^{ADAAAD} = k \exp[-(\Delta E_A^A + \Delta E_B^D + \Delta E_C^A + \Delta E_D^A + \Delta E_E^A + \Delta E_F^D)/RT]$$

It is sufficient to consider only the hexasaccharides for the initial hydrolysis of high molecular weight polymers. But the same formalism was also applied to oligomers not saturating all sites of the active cleft of lysozyme. If the selected bond between the D and E sites indicated unoccupied sites in the active cleft, these were neglected. This description of the relative hydrolysis rates was also limited to oligosaccharides spanning the D–E sites. Oligosaccharides smaller than hexasaccharides were treated by only considering binding modes that span the D–E sites in lysozyme, and that vacant sites did not contribute to the apparant activation energy. In the present description, differences in relative hydrolysis rates arising

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

both from the (microscopic) Michaelis–Menten constants and from the catalytic activities (corresponding to the acceleration factor used by Allen (6)) for different types of chitosan sequences are treated in one term. The motivation for not distinguishing these two possibilities is that binding data for various chitosan sequences have only been determined for a limited number of partly *N*-acetylated trisaccharides (11).

Estimates of values for the various ΔE_S^T were obtained by employing the experimental data reported for relative hydrolysis rates of various tri- and tetrasaccharides (8). These provided 13 equations analogous to eq. [3] for the relative hydrolysis rates with a total of 9 unknowns, ΔE_S^T for T=**A** and **D** and S=C–F, and T=**A** and S=B. These 9 parameters were estimated by minimalization of the sum of the square of residuals between theoretical and reported hydrolysis rates using a Simplex algorithm (12). The equations for the theoretical hydrolysis rates for the various chitooligomers were analogous to eq. [3]. The chitooligomers having more than one productive binding mode were represented by summation over the binding modes, yielding a nonlinear set of equations. Each of the 9 estimated parameters therefore represents a *mean* for the observed hydrolysis rates that includes a given parameter. Estimates for the remaining three contributions to $E_{a(i)}$ were obtained by using the reported relative hydrolysis rates of fully acetylated oligosaccharides to ΔE_A^A (9). Experimental data that can be used to estimate ΔE_A^D and ΔE_B^D are not known, and they were assumed not to influence the relative hydrolysis rates. An estimate of the numerical constant k (eq. [2]) was obtained by assuming a total activation energy of 3 kcal mol^{-1} for the fully acetylated pentamer (9). Note that the *relative* hydrolysis rates V_f^i, however, are independent of this numerical value.

Changes in sequence composition during lysozyme hydrolysis of partially *N*-acetylated chitosans were calculated using a Monte Carlo procedure. First, an ensemble of monodisperse model chitosans with a user selectable F_A and degree of polymerization, DP, was constructed. The sequences of **A** and **D** units in the chains were generated assuming a Bernoullian sequence statistic for the two residues, as previously shown experimentally (1, 2). Furthermore, the lysozyme depolymerization of the reconstructed ensemble was modelled by selecting a linkage at random in a polymer chain for each cycle in the computational procedure. The cycle number was proportional to reaction time with an unknown proportionality constant. Correlation between calculated and experimental data was therefore based on average degree of polymerization to circumvent this limitation.

The selected linkage was assumed to be the one hydrolysed and the adjoining four residues towards the nonreducing end and two residues towards the reducing end were inspected to assign the appropriate hydrolysis rate. No change was introduced to the ensemble if the selected linkage had previously been hydrolysed. The selected linkage was hydrolysed with a relative probability proportional to the relative hydrolysis rate determined by the composition of the hexasaccharide, or shorter oligosaccharide, interacting with the active cleft of lysozyme (eq. [2]). In addition to the relative hydrolysis rates needed for the 64 hexasaccharides, the hydrolysis rates for oligomers with fewer than six residues appearing as a result of multiple cleavages in the same polymer chain, that is, penta-, tetra-, and trisaccharides, were assigned in the same way. These oligomers were assigned with two binding modes spanning the hydrolysis site of the active cleft in lysozyme. Using this approach, a large number of relative hydrolysis constants was needed; these, however, could be reduced to the 12 contributions to the activation energy as described above. The calculated degradation products were characterized with respect to sequential distribution of the ensemble, distribution of degree of polymerization, and chemical composition of free mono-, di-, tri-, and tetrasaccharides.

Materials and methods

Chitosan

Chitin was isolated from shrimp shells. Chitosan was prepared by homogeneous *N*-deacetylation of chitin (13). The chitosan was converted into the chloride salt (chitosan-HCl), filtered and lyophilized. The fraction of *N*-acetylated units was determined by high-field proton nmr spectroscopy (1) to be 68% (F_A = 0.68). The intrinsic viscosity, [η], was determined to 800 mL/g as previously described (14). The number-average molecular weight M_n was estimated from the Mark–Houwink–Sakurada equation (15) as 1.7×10^5 g mol^{-1}.

A lower molecular weight chitosan used for lysozyme depolymerization studies was prepared by depolymerization of chitosan by nitrous acid as previously described (5). The chitosan (F_A = 0.68, M_n = 1.7×10^5 g mol^{-1}) was degraded by 30 mg $NaNO_2$/g chitosan, yielding a sample with intrinsic viscosity of 44 mL/g.

Lysozyme degradation of chitosan

The depolymerized chitosan was used as a substrate for the lysozyme hydrolysis studies. Solutions of chitosan (30 mg) in distilled water (13 mL) were prepared, solid NaCl was added to an ionic strength of 0.05 M, and the pH was adjusted to 4.5. Lysozyme from chicken egg white (Sigma L-6876) was used without further purification. The chitosan–lysozyme solutions were incubated at room temperature for 2 h, lysozyme was (partially) denatured by boiling for 1 h, and the pH subsequently adjusted to 6.5. Lysozyme was still active after this treatment, and in order to fully deactivate the enzyme, 0.3 mL of a mixture of a protease stock solution (3.0 mg α-chymotrypsin (EC 3.4.21.1, Sigma C-4129, type 2), 3.0 mg trypsin (EC 3.4.21.4, Sigma T-8253, type 3 from bovine pancreas), and 3.0 mg NaCl in 2.0 mL distilled water at pH 6.5) was added. The lysozyme–chitosan solutions were incubated for 10 min, the pH was adjusted to 4.5 with HCl, and the solution was lyophilized. Increasing degrees of depolymerization were obtained by employing increasing amounts of lysozyme (1.5, 3.75, and 7.5 mg lysozyme per 30 mg chitosan), corresponding to molar ratios of hexasaccharide units to enzyme of 230, 93, and 46, respectively.

Nuclear magnetic resonance spectroscopy

The number-average degree of polymerization (DP_n) of the lysozyme-degraded chitosans was determined by high-field proton nmr spectroscopy using a JEOL EX-400 (399.65 MHz) spectrometer as previously described (16). The fraction of acetylated units and the diad and triad frequencies were determined by ^{13}C nmr spectroscopy employing a Bruker AM-500 (125.76 MHz) spectrometer (2). The interpretations of the spectra were based on the assignments of carbon resonances

[a]The notation designates the chitooligosaccharides without any linkage illustrations, as used by Amano and Ito (8).

[b]The experimental data for relative hydrolysis rates are those reported (8) in the binding modes specified in their Table 3. The lysozyme hydrolyses were carried out at T = 37°C, 0.04 M ammonium acetate, pH 5.25.

[c]The notation designates the chitooligosaccharides with linkage illustrations in their apparent productive binding modes.

[d]The calculated values were based on the parameter values listed in Table 1.

in the trimer **A-A-A** ($(GlcNAc)_3$ (17)), the trimer **D-D-D** ($(GlcN)_3$ and higher GlcN oligomers (18)), and our previous assignments of ^{13}C nmr spectra (2). Absolute values of ^{13}C chemical shift values are difficult to compare, as the shift values are given relative to different standards and temperatures. However, *relative* shift differences between carbons can be directly compared. The chemical shifts, δ of the resonances for the new nonreducing and reducing ends were assigned based on the similarity of difference in δ of the resonances in central and terminal units of the **A-A-A** and **D-D-D** trisaccharides and that observed. Details of this analysis will be given elsewhere (19).

Results and discussion

Model parameters.

The estimated subsite contributions to the activation energy (E_a) for the relative lysozyme hydrolysis rates of chitooligomers are listed in Table 1. Parameter set I contains the nine estimated values obtained from the oligomer data (8) as explained above. The values range from -2 kcal mol^{-1} for presenting **A** residues to site B, to 8.85 kcal mol^{-1} for presenting **D** residues to site D. The sum of the contributions to E_a from the fully acetylated pentamer spanning subsites B–F was set to 3 kcal mol^{-1} (9), yielding k = 12 544. It should be noted that it is a prerequisite in the model that the chitooligomers should interact with both subsites D and E for the approach to be valid. The interpretation of a negative contribution to E_a in the present model implies that the hydrolysis rate increases when that site is occupied. The parameter values show strong preference for **A** relative to **D** residues in subsites C and E. The relative rate of hydrolysis for chitooligomers presenting **A** residues relative to **D** residues to site D is calculated to 5.6, whereas there is hardly any selectivity in the F-site. Note that these parameter values were derived without any assumptions about relative contributions to the hydrolysis rate arising from different binding modes of a given chitooligosaccharide. The contributions to E_a for the fully acetylated hexamer are negative for interactions at all sites except D, which corresponds to the trend observed for the binding energies to these sites (9).

In Table 2, the calculated rate constants for the chitooligosaccharides are compared with the reported experimental relative hydrolysis rates (8) to test the quality of the best fit. The agreement between the calculated relative hydrolysis rates (eq. [2]) using the estimated contributions to E_a and the experimentally determined relative rates is excellent. The largest deviation is 0.06 for the **DAA** in the DEF binding mode. The selected number of figures included in Table 2 for the relative rates is intended only to show the precision in the fit of the model to the observations, and not to reflect the num-

ber of significant figures. The data (Table 2) also illustrate the approach adopted for the chitooligosaccharides where the net relative rate for more than one productive binding mode was determined experimentally. The net rate was assumed to be equal to the sum of the different binding modes. The estimated values of ΔE_S^T allow direct calculation of the relative rates for different binding modes without any further assumptions. A further aspect of the model is that the relative hydrolysis rates for chitooligosaccharides other than those used in the experimental studies can be predicted.

The good agreement between the experimentally determined relative hydrolysis rates and the best fit of the model shows the quality of the noncooperative additive model. Typical for many recognition processes, e.g., chain pairing or formation of α-helical structures, are their cooperative nature, i.e., that a given state is not independent of other states. Likewise, it could be expected, in the current model, that contributions ΔE_S^T may depend on the type of residue that is interacting in the neighbouring sites. An extension to a cooperative model would be at the expense of an increasing number of parameters. The good agreement between the best fit of the model data and the experimentally determined parameters (Table 2) indicates that it is not necessary to extend the model to include nearest neighbour effects.

The parameter set II (Table 1) is completed for the contributions not directly calculable from the experimental data (8). The values of ΔE_A^A were selected to nearly reproduce the reported increase in relative hydrolysis rates from fully acetylated pentamer to hexamer. The experimental values, however, dictate that the most favorable contribution to E_a arises from interaction in the A-site, and an additional value for this parameter was therefore also selected (Table 1, set III) for further testing. The parameter values for ΔE_A^D and ΔE_B^D were set to zero as a first approximation, since experimental data have not been reported. Parameter set IV was derived from set III by adding 2 kcal mol^{-1} to ΔE_D^D. This is based on the results from the nmr analysis of the new reducing ends introduced by lysozyme hydrolysis of partially *N*-acetylated chitosans (see below) that showed a stronger preference for **A** units relative to **D** units interacting at site D compared to the data of Amano and Ito (8). The fit to the observed relative hydrolysis rate deviates therefore for the **A-D-A-A** and **A-D-A-D** tetrasaccharides using parameter set IV compared to the other parameter sets (Table 2).

Nuclear magnetic resonance spectroscopy

The 125 MHz proton decoupled ^{13}C nmr spectra of the chitosan substrate (F_A = 0.68, DP_n = 30) and the same chitosan extensively hydrolysed (DP_n = 7) by lysozyme are shown in Fig. 2. The selection of the relatively high F_A, intermediate DP_n, substrate for these studies was based on increased sensitivity towards changes in diad and triad frequencies with increasing F_A, and the possibility of determining DP_n directly from the number of reducing ends and of characterizing the diad and triad frequencies of the substrate without depolymerization. From the ^1H nmr spectra of the lysozyme-degraded chitosan (data not shown), it was found that the new reducing ends were exclusively from **A** units, as previously reported for lysozyme hydrolysis of a more deacetylated chitosan sample (16). This interpretation confirms the strong preference for **A** units interacting at site D for hydrolysis to occur. The lysozyme hydrolysis of the partially *N*-acetylated chitosan introduces new reducing and nonreducing end signals, as clearly seen in Fig. 2. Assignments of these end signals were much simplified by the fact that the new reducing ends were exclusively from **A** units (19).

The chemical shift assignments of the spectra are shown in Table 3. The resonances of the α- and β-anomers of C1 are seen at 92.9 and 97.4 ppm, respectively, which represent upfield shifts of 6.2 and 10.7 ppm from the **AA** diad (103.6 ppm). The absence of sequence splitting in the resonances of the α- and β-anomers of C1 suggests that the preceding unit of the reducing **A** units may not be dependent on the composition

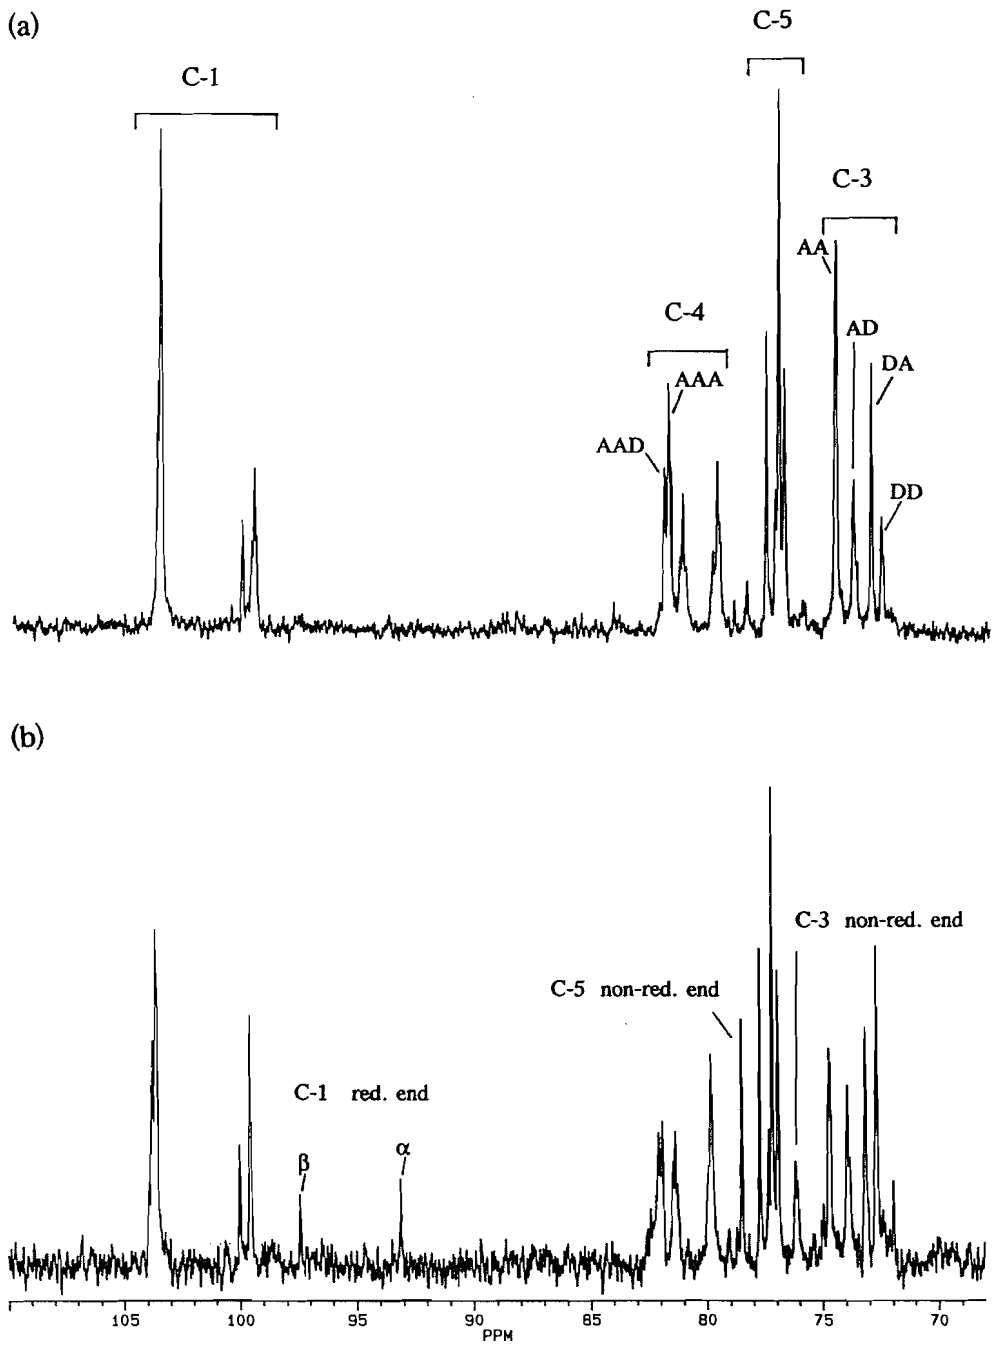
Fig. 2. The ^{13}C nmr spectrum (125 MHz) of a solution of chitosan used as substrate for lysozyme hydrolysis, $DP_n = 30$ (*a*), and a lysozyme-hydrolysed sample with $DP_n = 7$ (*b*), in D_2O at $T = 90°C$.



of the chitosan, i.e., the reducing end is exclusively -**A**-**A** or -**D**-**A**. If this neighbouring unit is an **A**, it implies preference for **A** units interacting at site C of lysozyme for the hydrolysis. This is consistent with the data from hydrolysis of oligomers (8) and is also seen in the estimated parameter values (Table 1). However, the possibility that the C1 anomers are insensitive to the neigbouring unit cannot be excluded. Note also the absence of reducing end resonances from **D** units in the area for these resonances (18), in agreement with the proton nmr spectra (16). However, the C1 resonances were not used for quantification of diad frequencies, because the **AA** and **AD** diads were poorly resolved, and the nonreducing ends were not resolved from the diads.

The finding that F_A was constant during lysozyme depolymerization of the chitosan samples (Table 4) indicates that α-chymotrypsin used to deactivate lysozyme (see Materials and methods) did not hydrolyze the -NH-CO-CH_3 linkage in the chitosan. The observed changes in the diad and triad frequencies arise therefore from differences in hydrolysis rates of the chitooligomers and not from depletion of acetylated units.

Detailed assignments of the diad frequencies and the reducing or nonreducing ends were performed on C3, C4, and C5.

Table 4. Composition and diad and triad frequencies in chitooligomers obtained by lysozyme depolymerization from C3 and C4 resonances determined by ^{13}C nmr spectroscopy.

[a]Substrate for lysozyme hydrolysis prepared by nitrite degradation of the high M_n sample.
[b]Calculated assuming Bernoullian sequence distribution and experimentally determined F_A.

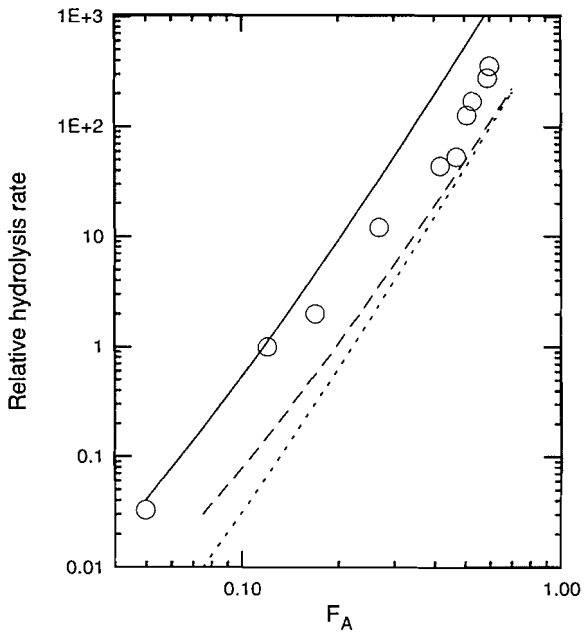
These were carried out to get information on the specificity of the individual sites on lysozyme towards the **A** and **D** units, and to obtain experimental data from diad and triad frequencies that could be compared to the calculated data. The nmr data detailing the analysis of nearest neighbour composition to the new nonreducing and reducing ends will be reported separately (19), but key features relevant for comparison with the calculations are given here. Note that the resonance at ~82 ppm is the **AA** diad from C4, which is further split into two resonance lines, identified with the triads **AAA** (at the lowest ppm value) and **AAD** (2). The **AAA** triad clearly decreases in intensity relative to **AAD** as lysozyme hydrolyses the chitosan (Fig. 2).

The absence of sequence splitting in the resonances of the α- and β-anomers of C3, as for C1, again suggests that the preceding unit of the reducing **A** units is independent of the composition of the chitosan, i.e., site C on lysozyme must bind an **A** unit for hydrolysis to occur. The resonance at ~76 ppm from C3 at the nonreducing end is split into two resonance lines, indicating that this carbon is sensitive to the nearest neighbour, which can be either an **A** or a **D** unit. The intensities of the two resonance lines at 76.1 and 76.0 ppm were found to be identical to the fraction of **A** and **D** units in the chitosan. These two resonances were identified as **AA** (at the higher ppm value) and **AD** (at the lower ppm value) in a separate experiment where a partially *N*-acetylated chitosan with $F_A = 0.5$ was degraded with lysozyme and the two resonances were found to be identical in intensity (data not shown). Because the **A** and **D** units are randomly distributed along the chain and the neighbouring unit to the nonreducing end associates with subsite F for the hydrolysis to occur, these data show that there is no selectivity for **A** or **D** units at site F on lysozyme degrading partially *N*-acetylated chitosans. That the calculated contributions from **A** and **D** units to E_a (Table 1) show no strong preference for either type of residue is in line with this data. The nmr data thus support the model adopted in describing the relative hydrolysis rates. Previous studies of lysozyme-catalyzed transglycosylation reaction at subsites E and F have shown that there is a strong preference for GlcNAc (**A**) at subsite E through its 2-acetamido group while this group is not involved in interactions at subsite F (20), according to our results.

Comparison of observed and calculated relation between initial hydrolysis rates and F_A

Figure 3 shows the calculated initial hydrolysis rate for chitosans having F_A = 0.05–0.7 for the parameter sets II–IV. Sub-

Fig. 3. Calculated relative hydrolysis rates for chitosans versus degree of acetylation, F_A, using parameter set II (———), set III (— — —), and set IV (- - - -) compared with the experimentally determined initial hydrolysis rates (○, (ref. 4)). The units for relative rates are those for the oligosaccharides in the case of the calculated curves (Table 2), and are normalized to a relative rate set to 1 for $F_A = 0.12$ for the experimental data.



strate saturation was further assumed for all 64 hexamers, i.e., $K_S/[S] << 1$ in eq. [1]. These model data were compared with the experimental data for the initial hydrolysis rates reported by Nordtveit et al. (4). The experimentally determined initial hydrolysis rates were reported to depend on F_A raised to the 3.6 power ($F_A^{3.6}$). The calculations show that the relative initial hydrolysis rates versus F_A depend on the parameter set, i.e., on the hydrolysis rate increase of fully acetylated oligomers from tetramers to hexamers. On the other hand, the calculations also show that the relative dependence on F_A is not sensitive to this increase. The reason for this is the relatively small fraction of fully acetylated pentamer or higher oligomer sequences. The results from the nmr data, indicating no selectivity between **A** and **D** units interacting with site F, suggest that the relative hydrolysis rate at the maximum should

For personal use only.

depend on F_A raised to the fifth power (F_A^5) and not the sixth power (F_A^6). Increasing the selectivity for **A** units relative to **D** units in site D (parameter set III compared to IV) yields a stronger dependence on F_A for the lower F_A values (less than about 0.15).

The experimentally determined initial rates show an excellent fit to the calculations when only the dependence on F_A is considered, and the experimental data appear to be more in line with calculations based on parameter sets II and III than on IV. However, since the comparison is based on relative rates, further comparison based on absolute rates is required to discriminate between different parameter sets. Direct comparisons between absolute rates are also difficult because the solution conditions for lysozyme hydrolysis of the chitooligomers, $T = 37°C$, 0.04 M ammonium acetate, pH 5.25 (8), differ from those used for lysozyme hydrolysis of chitosan, T = 20°C, 0.1 M KCl, pH 4.5 (4). This does not invalidate the present calculations discussing relative effects of F_A because the relative dependence of initial hydrolysis rate on F_A has been found to be largely independent of solution ionic strengths and pH (21).

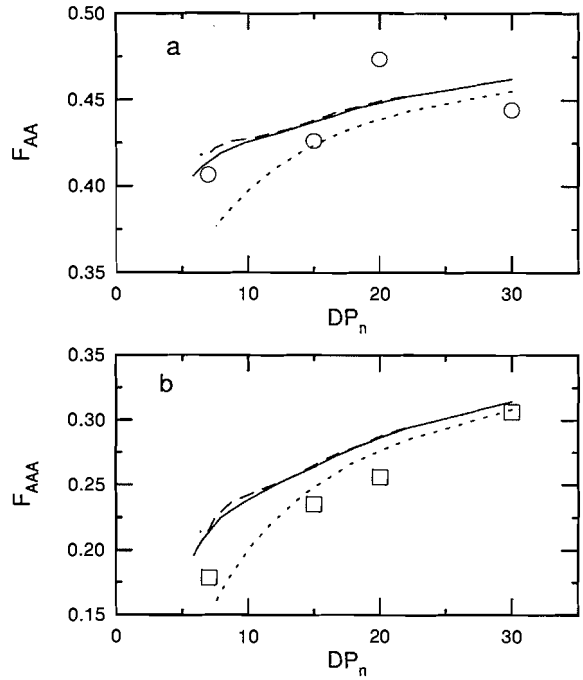
The present model for lysozyme action on chitosans also reproduces the nonlinear time course of lysozyme hydrolysis of partially *N*-acetylated chitosans (data not shown). This is in line with the experimental data (4) and illustrates that lysozyme preferentially hydrolyses the fully acetylated sequences in the polymeric chain.

Comparison of calculated and observed changes in chitosan sequence information

A further interesting aspect of lysozyme hydrolysis of chitosans is the potential change in sequential distribution in the polymeric chain. Since the relative hydrolysis rates show a strong preference for cleavage of the fully acetylated sequences, concomitant decrease in fractions of **AA** diads, F_{AA}, and **AAA** triads, F_{AAA}, is expected as the degradation continues. The Monte Carlo calculations of lysozyme hydrolysis of partially *N*-acetylated chitosans predict changes in the relative amounts of the diads and triads. In particular, the F_{AA} and F_{AAA} are predicted to decrease.

Removal of a diad occurs by direct cleavage of the glycosidic linkage. As an example, consider the tetrameric sequence consisting of four **A** units (-$\mathbf{A_1}$-$\mathbf{A_2}$-$\mathbf{A_3}$-$\mathbf{A_4}$-) numbered 1–4 to illustrate the three diad frequencies in this tetramer sequence ($\mathbf{A_1A_2}$, $\mathbf{A_2A_3}$, and $\mathbf{A_3A_4}$). Cleavage of the glycosidic linkage between $\mathbf{A_2}$ and $\mathbf{A_3}$ removes one of the three diads ($\mathbf{A_2A_3}$). Since this cleavage leads to new nonreducing and reducing ends, it must be taken into account in analysis of the sequence information from the nmr spectra. Since it is likely that the C3 and C4 carbon resonances, which were used to determined the diad frequencies, are most influenced by the preceding residue in the chain (2), we need to consider the three diads $\mathbf{A_1\underline{A}_2}$, $\mathbf{A_2\underline{A}_3}$, and $\mathbf{A_3\underline{A}_4}$, where the underlining means the unit from which the resonance originates. By cleaving the glycosidic linkage between $\mathbf{A_2}$ and $\mathbf{A_3}$, the three diads $\mathbf{A_1\underline{A}_2}$ (with $\mathbf{A_2}$ at the reducing end), $\mathbf{\underline{A}_3A_4}$ (with $\mathbf{A_3}$ at the nonreducing end), and $\mathbf{A_3\underline{A}_4}$ (with $\mathbf{A_3}$ at the nonreducing end) are observed in the nmr spectrum. Either the reducing **or** the nonreducing end should be included in the **AA** diad for correspondence with the calculations. This becomes increasingly more important the lower the DP_n, as is the case for the lysozyme-hydrolysed chitooligomers. Concerning C3, both the reducing and the nonreducing ends are shifted out of the **AA** diad, while for C4 only the β-reducing end is contained in the **AA** diad. The diad frequencies as a function of lysozyme degradation using C3 and C4 have been corrected, and are shown in Table 4.

Fig. 4. Experimentally determined change in fraction of diad frequency F_{AA} (*a*) and triad frequency F_{AAA} (*b*) due to lysozyme depolymerization of a chitosan substrate with $DP_n = 30$, $F_A = 0.68$. Monte Carlo simulated changes in the corresponding diad and triad using parameter set II (———), set III (— — —), and set IV (- - - -) using an ensemble of 1000 chains. Note that increasing extents of lysozyme hydrolysis yielding decreasing DP_n correspond to moving from the right to the left on the *x*-scale.



Comparison of the observed changes in the F_{AA} diads as a result of lysozyme degradation with those calculated using the Monte Carlo approach (Fig. 4*a*) shows that there is good agreement between the relative reduction in this diad fraction betweeen the experiments and the model. Analogously, there is good agreement between the experimentally determined reduction of F_{AAA} and the calculated values (Fig. 4*b*). The predicted decrease in both F_{AA} and F_{AAA} is larger at a given DP_n for parameter set IV than for sets II and III. This is as expected since parameter set IV implies a stronger preference for **A** units at site D. The experimental uncertainty does not, however, allow preference for either parameter set as the best fit.

Conclusions

This is the first study of the lysozyme specificity for GlcN (**D**) and GlcNAc (**A**) at the six possible subsites in the active cleft using a combination of nmr and modelling techniques. This allows us to relate the hydrolysis rates at the polymer level to those for chitooligomers. A molecular model for considering chemical heterogeneity in polysaccharides when they act as enzymatic substrates is proposed. It is assumed that the relative hydrolysis rate for the rate-limiting step in the reaction

can be described by an activation energy. The activation energy was further assumed to consist of additive contributions specific for the type of substrate residue interacting at a given subsite in the active cleft of the enzyme. These contributions reveal selectivities between **A** and **D** residues in sites C–F that were found to be consistent with the terminal sequences for both the reducing and nonreducing ends introduced by lysozyme, as determined by nmr spectroscopy. Using the calculated relative hydrolysis rates for the possible hexasaccharides, good agreement was found between experimental data for initial hydrolysis rates for polymeric chitosan substrates with F_A from 0.04 to 0.60. It was further found that preferential hydrolysis of fully acetylated sequences in a polymeric chitosan substrate yielded depletion of the F_{AA} diad and the F_{AAA} triad that was in quantitative agreement with that predicted using a Monte Carlo calculation. In summary, this study shows that the preferential lysozyme hydrolyses reported for oligomeric substrates are preserved for the polymeric substrate. The general approach of using an activation energy to account for different sequences interacting with the subsites of the enzyme could also be explored for other types of enzymes working on *co*-polymeric substrates. Alginate M- and G-lyase depolymerizing alginates (22–24), β-D-mannanase hydrolysing galactomannan (25), and chitinase/chitosanase depolymerizing chitosan (26) are all examples in this respect.

Luminescence studies of hydrophobically modified, water-soluble polymers. I. Fluorescence anisotropy and spectroscopic investigations of the conformational behaviour of copolymers of acrylic acid and styrene or methyl methacrylate

J.R. Ebdon, B.J. Hunt, D.M. Lucas, I. Soutar, L. Swanson, and A.R. Lane

Abstract: Fluorescence spectroscopy and anisotropy measurements have been used to study a series of styrene – acrylic acid, STY–AA, and methyl methacrylate – acrylic acid, MMA–AA, copolymers in dilute methanolic and aqueous solutions. Copolymerization of either STY or MMA with AA has little effect upon the rate of intramolecular segmental motion in methanol solutions. In aqueous media, intramolecular hydrophobic aggregation occurs and restricts the macromolecular dynamics to an extent dependent upon pH, nature of the comonomer, and copolymer composition. The hydrophobic domains formed in these copolymer systems can solubilize organic guests. In this respect, STY is a more powerful modifier of AA-based polymer behaviours than is MMA. In general, the hydrophobic modification increases the solubilization power of the resultant polymer. Furthermore, the copolymers retain their solubilization capacities to higher values of pH the more hydrophobic the comonomer and the greater its content in the copolymer. The interiors of the hydrophobic aggregates reduce the mobilities of occluded guests: the microviscosities of the domain interiors depend upon the nature of the hydrophobe, pH, and copolymer composition.

Key words: fluorescence, anisotropy, water-soluble polymers, acrylic acid, hydrophobic modification.

Résumé : On a utilisé des mesures d'anisotropie et de spectroscopie de fluorescence pour étudier une série de copolymères de styrène – acide acrylique, STY–AA, et de méthacrylate de méthyle – acide acrylique, MMA–AA, en solutions diluées dans le méthanol et dans l'eau. La copolymérisation du STY ou du MMA avec l'AA n'a que de faibles effets sur la vitesse du mouvement segmental intramoléculaire, en solutions méthanoliques. En milieu aqueux, il se produit une agrégation hydrophobe intramoléculaire et elle restreint la dynamique macromoléculaire qui dépend, jusqu'à un certain point, sur la nature du comonomère et de la composition du copolymère. Les domaines hydrophobes qui se forment dans ces systèmes de copolymères peuvent solubiliser des hôtes organiques. À ce point de vue le STY est un modificateur plus puissant des comportements des polymères basés sur le AA que ceux basés sur le MMA. En général, la modification hydrophobe augmente le pouvoir de solubilisation du polymère qui en résulte. De plus, plus le comonomère est hydrophobe et plus il contient de copolymère, plus les copolymères conservent leurs propriétés de solubilisation à des valeurs élevées de pH. Les intérieurs des agrégats hydrophobes réduisent les mobilités des hôtes occlus : les microviscosités des domaines intérieurs dépendent de la nature de l'hydrophobe, du pH et de la composition en copolymère.

Mots clés : fluorescence, anisotropie, polymères solubles en milieu aqueux, acide acrylique, modification hydrophobe.

Introduction

Water-soluble and water-swellable polymers constitute an important class of materials that finds application in a diverse range of technologies including those concerned with the production of agrochemicals, adhesives, coatings, enhancers for oil recovery, foodstuffs, personal care products, superabsorbants, inks, and coding systems. Consequently, a significant amount of effort has been expended, in recent years, in attempts to better understand the factors that govern the physical behaviour of macromolecules in aqueous media. (For recent overviews, see, for example, refs. 1 and 2).

Certain water-soluble polymers and their hydrophobically modified forms have the ability to solubilize species that would otherwise be sparingly soluble in water. When the hydrophobic pockets formed by such molecules are composed of a significant amount of aromatic material, the polymers have the potential for performance of photochemistry upon occluded guests, which is considerably enhanced by energy transfer from the host macromolecule. The field of "energy-harvesting" water-soluble polymers has been pioneered by Guillet and his co-workers. Guillet has coined the terms "antenna effect" and "photozyme" to describe the energy-channeling process and the "light-harvesting" polymers, respectively.

In the first published example (3) of the antenna effect in aqueous media, it was shown that the transfer of energy from naphthyl species to terminal anthryl groups in an acrylic acid – 1-naphthylmethyl methacrylate copolymer was much more efficient in alkaline aqueous solution than in organic solvents. It was proposed that the hydrophobic naphthyl derivatives formed aggregates in the aqueous medium, thereby enhancing the energy transfer process (3). This report was followed by a series of papers on the antenna effect, initiated in 1982 (4). These seminal publications illustrate the importance of the antenna effect upon the photophysics and photochemistries that occur within the close confines of the hydrophobic domains, which can be created in aqueous polymer solutions. The photocatalytic activity of photozyme systems has been amply illustrated (5–11). The field of photon-harvesting polymers has been the subject of an excellent review (12).

Luminescence spectroscopy has featured prominently in studies of the physical behaviour of water-soluble polymers: techniques employed include those of fluorescence quenching (e.g., refs. 13–20), energy transfer (e.g., refs. 3, 4, 12, 21–23), excimer formation (e.g., refs. 24–32), phosphorescence (19, 33–35), and fluorescence anisotropy (e.g., refs. 13, 36–43). Time-resolved anisotropy measurements, TRAMS, involving labelled polymers, are particularly useful in the study of the conformational behaviour of polymers since they allow direct examination of the segmental dynamics of the macromolecule. (See, for example, refs. 44–46 and references therein.) However, relatively few studies involving TRAMS have been reported on water-soluble polymers (13, 37–43).

In the current article, we report on fluorescence anisotropy studies (both time-resolved and steady state) on the effects of hydrophobic modification (through copolymerization) upon the conformational behaviour of acrylic acid-based polyelectrolytes. The investigations have involved the use of both fluorescent labels and probes. The resultant data are of relevance to considerations of the development of novel polymeric solubilizing media, including photozymes.

Experimental

Materials

Methyl methacrylate (Aldrich) and styrene were freed of inhibitor using 10% NaOH, washed with distilled water until the washings were neutral to litmus, dried (molecular sieve), and distilled under high vacuum. Acrylic and methacrylic acids (Aldrich) were prepolymerized using uv irradiation and fractionally distilled under high vacuum, immediately prior to use. Acenaphthylene (Aldrich, 99%) was purified by multiple recrystallization from ethanol, followed by sublimation under high vacuum. 1-Vinyl naphthalene was synthesized from 1-acetonaphthone (Aldrich) by reduction ($NaBH_4$) to the carbinol followed by dehydration ($KHSO_4$). The monomer was purified by fractional vacuum distillation.

Polymers of acrylic acid (AA) and copolymers of AA with styrene (STY) or methyl methacrylate (MMA) were formed by free radical solution (50 wt.% toluene) polymerization under high vacuum at 60°C using 2,2′-azobisisobutyronitrile (AIBN) as initiator. Polymerizations leading to labelled macromolecules contained 0.5 mol% luminescent monomer (acenaphthylene, ACE, or 1-vinylnaphthalene, VN) in the feed. Polymers were purified by multiple precipitation: at acrylic acid contents $\geq$70 mol% in feed, methanol was used as solvent, diethyl ether as precipitant. At lesser acrylic acid contents, tetrahydrofuran was the solvent with 40/60 petroleum ether as precipitant.

Samples of poly(methacrylic acid), PMAA, were prepared by free radical polymerization in benzene (80 wt.%) at 60°C and purified by multiple precipitation (methanol into diethyl ether).

Instrumentation

Steady state luminescence spectra were recorded using a Perkin–Elmer LS50 spectrometer. Time-resolved fluorescence measurements were made using the technique of time-correlated, single-photon counting (TCSPC). Fluorescence "lifetimes" were determined from decay profiles recorded on an Edinburgh Instruments 199 spectrometer using a thyratron-gated flashlamp (with either H_2 or D_2 as discharge medium). A fast photomultiplier tube (Philips XP2020Q) was used to detect fluorescence, producing an instrument response function of ca. 1.0–1.2 ns (FWHM) dependent, inter alia, upon discharge medium. Corroborative lifetime data were determined by analysis of decay curves recorded in magic angle (54.7° with respect to the plane of vertically polarized excitation) observations of emissions produced using synchrotron radiation (from the Synchrotron Radiation Source, SRS, EPSRC Daresbury Laboratory, Warrington, U.K.). Fluorescence detection at the SRS employed a Philips XP4278b photomultiplier, resulting in an instrument response function of <330 ps (FWHM). Details of the SRS have been previously published (see, for example, refs. 43, 46, 47).

Molar masses and the polydispersities of their distributions were estimated using aqueous size exclusion chromatography (SEC). The SEC system employed incorporated the following components: a Waters Associates model 6000 pump, a Rheodyne injector, and Waters Associates Ultrahydrogel mixed gel (2 × 30 cm) columns. A sample concentration of 0.1% w/v with an injection volume of 100 μL and a flow rate of 0.8 cm^3 s^{-1} was employed for all samples. Data acquisitions and sub-

STY(39)–AA-ACE	54	5.6
STY(33)–AA-VN	50	2.8
STY(44)–AA-VN	32	2.6

[a]AA = acrylic acid; MAA = methacrylic acid; PAA = homopolymer of acrylic acid.

[b]ACE = acenaphthylene; VN = 1-vinylnaphthalene; PAA-ACE = acenaphthylene labelled poly(acrylic acid).

[c]MMA = methyl methacrylate; STY = styrene; MMA(20)–AA = methyl methacrylate – acrylic acid copolymer, containing 20 mol% MMA.

[d]MMA(34)–AA-ACE = acenaphthylene labelled methyl methacrylate – acrylic acid copolymer containing 34 mol% MMA.

sequent analyses were performed using a Polymer laboratories PL data station with associated software. Narrow distribution poly(ethylene oxide) standards were used for column calibration in all instances.

Copolymer compositions were determined from ^{1}H nmr using a JEOL FX-100 spectrometer.

Results and discussion

Polymer characterization

Apparent molar mass data and composition information are listed in Table 1, where D (= $\overline{M}_w/\overline{M}_n$) is the polydispersity.

Aqueous SEC analyses of polymers are prone to distortion of the resultant chromatograms from the elution profiles that would be obtained on the basis of a "pure size exclusion mechanism" through the intervention of interactions between the eluting solute and the gel employed. Polyelectrolyte-gel adsorption can be reduced, in general, by addition of a low molar mass electrolyte to the eluant (see, for example, ref. 48). However, use of 0.1M $NaNO_3$(aq) solution did not effect elution of any of the polymer samples within the range of calibration volumes established using the PEO standards.

Following trials involving a variety of elution media, an elution mixture comprising a solution of $NaNO_3$ (0.1 M) in an aqueous mixture containing 20 wt.% acetonitrile, was used: this eluant produced SEC responses of "normal" elution profile for all polymer samples analysed. However, since the hydrophobically modified forms of the polymers have the greatest potential for interaction with the surfaces within the pores of the gel, the molar mass data must be regarded with caution. The data listed in Table 1 indicate that the *apparent* molar mass of the various polyacids studied in this work decreases, in general, as the intramacromolecular concentration of hydrophobic modifier increases. In addition, the apparent drift to lower molar mass with high hydrophobe content is more evident in the AA copolymers containing styrene as the "modifying comonomer."

Neither observation is unexpected: the more hydrophobic the polymer, the greater will be its tendency to interact with the separating gel. Consequently, the distribution of eluting solutes will be displaced to larger elution volumes and, thence, to lower apparent molar masses. In turn, the molar mass data, recorded in Table 1, must be regarded as approximating to representations of the true distribution of molar masses. The "apparent" values of molar mass listed in Table 1 have to be regarded as lower limits to their "true" values. Within this context, we shall discuss the photophysical and solubilization properties of these systems on the assumption that we are dealing with high molar mass polyacids, whose properties are independent of molar mass.

Time-resolved anisotropy measurements (TRAMS) upon labelled polyacids

TRAMS experiments upon macromolecules bearing luminescent labels are, arguably, *the* most powerful of all the fluorescence methods used in interrogation of the conformational behaviour of polyelectrolytes. TRAMS data report upon the reorientational characteristics of the label, which, in turn, reflect restrictions imposed upon polymer chain mobility as hydrophobically modifying comonomers are added to the water-soluble macromolecule. At low intramolecular concentrations of hydrophobically modifying comonomer, steric constraints upon local segmental mobility will dominate the observed changes in segmental dynamics, which, in turn, should parallel those apparent in solvents other than water. At higher hydrophobic contents, intramolecular aggregation involving the hydrophobic species will occur, resulting in additional restrictions upon segmental mobility. As is demonstrated below, the creation of intramolecular hydrophobic domains in dilute aqueous polymer solutions is the dominant influence in determining the dynamic behaviour of such systems.

The TRAMS experiment, in studies of macromolecular dynamics, employs polarized light to photoselectively excite those labels whose transition vectors for absorption are preferentially aligned, at the moment of absorption, parallel to the (vertical) plane of polarization of the incident radiation. (The probability of absorption falls off as $\cos^2\theta$ where θ is the angle between the molecule's transition vector and the plane of polarization of the excitation.) This creates the necessary anisotropy within an otherwise randomly oriented distribution of chromophores. The extent to which this anisotropy is retained in the fluorescence emitted at any time, t, following excitation, depends upon the extent of chromophore reorientation during this period and is reflected in the difference of the intensities of emission observed in planes parallel ($I_\parallel$) and perpendicular ($I_\perp$) to that of the incoming excitation. Information regarding rotational motion of a fluorescent label (and, thence, regarding the relaxation behaviour of the macromolecule to which it is affixed) may be obtained by analysis of the *observed*, time-dependent anisotropy, $R(t)$, given by

$$[1] \quad R(t) = \frac{I_{\parallel}(t) - I_{\perp}(t)}{I_{\parallel}(t) + 2I_{\perp}(t)} = \frac{D(t)}{S(t)}$$

In the simplest of situations, that of a spherical rotor, the true time dependence, $r(t)$, of the emission anisotropy would be described by a simple exponential function, i.e.,

$$[2] \quad r(t) = r_0 \exp(-t/\tau_c)$$

where τ_c is the parameter of (most) interest, being the rotational correlation time for the motion. r_0 is the intrinsic anisotropy, a fundamental spectroscopic characteristic of the chromophore (related, inter alia, to the relative configuration of the transition vectors for absorption and emission, respectively).

Recovery of relaxation data is not as straightforward as is the case for fluorescence data alone. The severity of the problem depends upon the relative rates of decay of the luminescence and its anisotropy and their relationship to the time scale upon which the pulse from the excitation source distorts the observed decay profiles.

In the case of fluorescence decay data, information regarding the relaxation of the distribution of excited states responsible for the emission can be recovered, in a reasonably direct fashion, in an iterative reconvolution procedure in which the instrument response function (the *observed* excitation profile) is convoluted with a mathematical model (appropriate to "expectation") of the fluorescence response and the resultant "fit" is optimized in comparison with the observed fluorescence profile. In the TRAMS experiment, the finite width of the excitation pulse will distort each of the observed fluorescences, $I_{\parallel}(t)$ and $I_{\perp}(t)$. However, although either of these fluorescence responses (containing information regarding both electronic and reorientational relaxation) is amenable to the "deconvolution" procedure described above, the combination function, $R(t)$, can *not* be treated in this "simple" fashion. Other approaches must be adopted in instances where it is anticipated that failure to deconvolute the anisotropy data might lead to evolution of misleading information regarding the reorientational relaxation process under investigation. Such will always be the case in analysing anisotropy data accrued in the earlier stages of the observed fluorescence responses where the influence of the excitation pulse is significant. The time range over which such distortions of $R(t)$ are apparent will, naturally, depend upon the excitation source and the detection system employed, as revealed in the instrument response function. Under the conditions employed in the current study (cf. "Experimental" above) the instrument response function generated by the SRS exhibits an instrument response function of FWHM <300 ps.

Procedures for ensuring reliable retrieval of rotational relaxation data from TRAMS experiments have been discussed elsewhere (for example, see refs. 45 and 46). In the current study, $R(t)$ has been analysed directly (i.e., without any attempt to account for data distortion by the excitation pulse) and the resultant correlation times, τ_c, compared to those evolved in both impulse reconvolution, IR (49, 50), and autoreconvolution, AR (46, 51), analyses. Each of the latter (IR and AR) forms of approach seeks to "deconvolute" the $R(t)$ data and thereby provides a check upon the reliability of direct analysis of $R(t)$ (46).

A problem that accompanies direct analysis of $R(t)$ is the fact that it is not possible to establish a value for r_0. Consequently, the time from which analysis of $R(t)$ should be initiated is uncertain. As in previous TRAMS studies of polymer relaxation in which we have employed (43, 46) such direct analyses, fitting $R(t)$ has been initiated from a decay channel in which the apparent anisotropy, R, has attained a value corresponding to that "expected" for the chromophore involved, on the basis of both steady-state ("Perrin-plot") (e.g., see ref. 44) and TRAMS (43, 46) studies of the relaxation behaviour of polymers bearing the same labels. This is clearly unsatisfactory in the absence of means of testing the reliability of the direct analysis approach (such as those afforded by the IR (49, 50) and AR (46, 51) approaches). As we have observed previously (46), direct analysis of $R(t)$ data in the absence of such safeguards can be misleading: in particular, the decay of $R(t)$ can appear to be more complex than that of the true anisotropy, $r(t)$. In studies of labelled macromolecules, direct analyses of $R(t)$ can, in turn, appear to imply that a more complex model than is justified should be employed to characterize the polymer relaxation behaviour.

Table 2. Correlation times for segmental motion of hydrophobically modified polymers containing varying amounts of acrylic acid, in methanol, as recovered by DA, IR, and AR analyses.

Polymer	τ_c(DA)/ns	τ_c(IR)/ns	τ_c(AR)/ns
STY(27)–AA-ACE	2.4	2.3	2.0
STY(39)–AA-ACE	2.8	2.9	3.0
STY(33)–AA-VN	1.9	1.8	1.6
STY(44)–AA-VN	2.2	2.1	1.9
MMA(45)–AA-VN	1.5	1.4	1.4

Segmental dynamics of the hydrophobically modified forms of PAA in methanol

Table 2 lists rotational correlation times, obtained using the various analytical approaches and modelling the anisotropy using a function of the form

$$[3] \quad r(t) = r_0 \exp(-t/\tau_c) + r_\infty$$

The anisotropy decays were, in each case, well described by this model function. Furthermore, the resultant values of r_∞, applied as a freely varying parameter, lay close to zero, as is to be expected for rotational relaxation of a chromophore that is not confined within a restricted geometry.

In consideration of these data, it is apparent that

(*i*) the segmental dynamics of the macromolecules depend upon the nature and quantity of the copolymerized hydrophobically modifying monomer. Incorporation of 45 mol% MMA produces a polyelectrolyte with a correlation time for reorientation of its VN label of 1.4 (±0.1) ns, which is similar in magnitude to that of PAA–VN itself (τ_c = 1.2 (±0.1) ns (46)). Incorporation of styrene into the polymer, on the other hand, produces a less flexible polyacid: the greater the styrene content of the copolymer, the longer is the associated correlation time.

In good organic solvents of similar viscosity, the room temperature segmental dynamics of polystyrene and poly(methyl methacrylate) are characterized by correlation times that are both similar to one another (see, for example, ref. 52) and slightly greater than that of PAA in methanol (46). Consequently, as is

For personal use only.

observed in the case of MMA, incorporation of either styrene or MMA in copolymers with AA would not be expected, on steric grounds, to alter the rate of segmental motion to any marked extent. It may then be that the effects induced by the less polar comonomer, styrene, are the results of intramolecular interactions between styryl residues and (or) blocks of styryl species within the polyacid coil. Such effects are enhanced in aqueous media (see below) under conditions in which aggregation occurs to form intramolecular hydrophobic domains.

(*ii*) The values obtained for τ_c at a given styrene content show a dependence upon the label employed: those for ACE-labelled polymers are greater than those of the VN-labelled species. In general, ACE and VN labels produce equivalent information in fluorescence anisotropy determinations of macromolecular relaxation times in dilute fluid solutions. Under certain conditions, notably when segmental motion of the macromolecule becomes hindered, the labels appear to relax at different rates. A recent example of this effect is to be found in a report of TRAMS investigations of the conformational behaviour of PMAA (42): at low pH the relaxation data characteristic of the reorientational motions of the ACE and VN labels are not comparable. A likely explanation is that additional depolarization of the fluorescence from VN occurs as a result of rotation of the label independent of that of the polymer chain. It is possible that a similar effect is being observed in the current work: the motion of the VN might enjoy a degree of decoupling from that of the polymer segments as the motion of the latter becomes more restricted due to interactions between the styryl residues. The effect has also been observed in TRAMS studies of PMAA in methanol using VN and ACE labels (46).

Segmental dynamics of the hydrophobically modified forms of PAA in aqueous media

TRAMS studies of the ACE and VN amphiphilic polyelectrolytes reveal that the relaxation behaviour of these hydrophobically modified polymers is complex. Modelling of $r(t)$ by the functional form represented in eq. [3], although providing fits in DA and IR analyses that could be deemed statistically adequate, resulted in a finite value for r_∞. This gives cause for concern, since there is no reason to suppose that the relaxation of any of these macromolecules in dilute fluid solution *should* be characterized by a residual anisotropy. Furthermore, values of r_0 obtained by IR analysis were less than those expected for ACE or VN labels on the basis of previous TRAMS studies on other macromolecules. In addition, AR analyses indicated that modelling of $r(t)$ by a single exponential function was less than statistically adequate (an observation consistent with the fact that IR analyses in which r_∞, in eq. [3], was fixed at zero did not result in adequate fitting to the data).

These features of the analyses of the TRAMS data are similar to those which we have reported (42) in studying the conformational behaviour of PMAA in acid media. However, in contrast to the latter system, adoption of a dual exponential decay function for $r(t)$ of the form

$$[4] \quad r(t) = A_1 \exp(-t/\tau_{c1}) + A_2 \exp(-t/\tau_{c2}) + r_\infty$$

did not result in "best fits" to the current data in which freely varied r_∞ values converged to negligible proportions. Clearly, the relaxation behaviours of the hydrophobically modified polyacids are at least as complex as that of PMAA.

Fig. 1. Correlation times for intramolecular segmental motion of ACE-labelled PAA and a series of hydrophobically modified AA copolymers. (▽) STY(39)–AA-ACE; (●) STY(27)–AA-ACE; (□) MMA(34)–AA-ACE; (○) PAA-ACE.

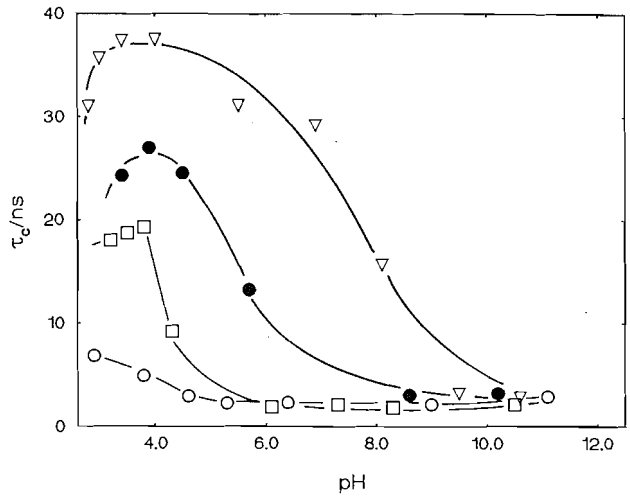

Fig. 2. Correlation times for intramolecular segmental motion of VN-labelled PAA and a series of hydrophobically modified AA copolymers. (□) STY(44)–AA-VN; (▽) STY(33)–AA-VN; (●) MMA(45)–AA-VN; (○) PAA-VN.

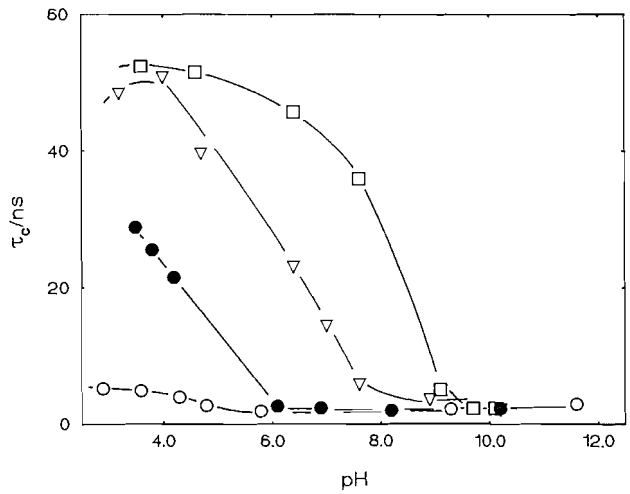

It is likely that the relaxations of each of these hydrophobically modified species are characterized by a broad distribution of relaxation times. TRAMS studies of these and other modified systems continue. However, for the current purposes of examining the effects of incorporation of a modifying comonomer upon the inherent pH-dependent conformational behaviour of the polyacid, single exponential analyses, using eq. [3], suffice in providing a characteristic "average correlation time" for the chain dynamics of a given copolymer at a particular pH. The resultant data are shown in Figs. 1 and 2.

Reference to Figs. 1 and 2 reveals that (*i*) neutralization of PAA is accompanied by a conformational transition in which the segmental mobility of the polyelectrolyte increases over a pH range (from ca. pH 3 to pH 5) such that τ_c decreases from ca. 6 ns for the polyacid to ca 2 ns for the polysalt; and (*ii*) introduction of a hydrophobically modifying comonomer such as MMA or styrene has a marked effect upon the segmental mobility of the acidic forms of the resultant polyelectro-

For personal use only.

lytes: τ_c increases by factors of between ca. 3 and 4 (dependent upon pH and copolymer content) upon incorporation of MMA and between ca. 4 and 9 (again dependent upon pH and degree of hydrophobe loading) for the styrene-containing copolyacids. The magnitude of the effects of the copolymerized hydrophobic species is much greater than would be predicted solely on the grounds of steric constraints upon intramacromolecular mobility (as discussed above) and considerably exceeds those induced by the same amounts of hydrophobic comonomer upon the chain dynamics of the same polyacids when dispersed in dilute methanolic solutions.

In contrast, the presence of the hydrophobic units incorporated in the polymers by copolymerization of MMA or styrene has only a moderate influence upon the intramolecular dynamics of the fully neutralized forms of the modified polyacids: the copolysalts exhibit segmental relaxation rates similar both to one another and to those of the copolymers when dispersed in methanol.

(*iii*) Incorporation of a hydrophobic monomer has a pronounced effect, dependent upon both the polarity of the modifying comonomer and the content of the copolyacid, on the conformational behaviour of the polyelectrolyte. In general, the pH range over which the transition in segmental relaxation dynamics between the acidic form of the water-soluble copolymer and its completely neutralized analogue occurs is both broadened and shifted to higher values of pH. These effects are the result of the formation of hydrophobic domains formed by intramolecular aggregation of the hydrophobic repeat units that result from copolymerization of either MMA or styrene with AA. At lower values of pH, the influence of these intramacromolecular aggregates completely dominates the dynamic aspects of the behaviour of the copolymers in dilute aqueous solutions as is apparent by comparison with the conformational behaviour of PAA itself or, indeed, with the relaxation characteristics of the copolymers in methanol. In the latter solvent, as discussed above, MMA-modified copolymers exhibit segmental relaxations that differ little in rate from those of PAA, whilst those of the styrene-based systems might exhibit relatively minor effects resultant upon aggregation of the copolymerized styryl residues in the macromolecules. Our proposal that the significant differences between the dynamic behaviour of the hydrophobically modified polyacids in aqueous acidic media and that in methanol are the result of domain formation is supported by studies of the solubilization of guest molecules, as discussed below.

(*iv*) The segmental relaxation data of the hydrophobically modified forms of PAA show an *apparent* label dependence in acidic media. In both the styrene and MMA-modified systems there is the implication that, for a given hydrophobe content and a given pH, the apparent rate of segmental relaxation of the hydrophobically modified polyelectrolyte is dependent upon the label (ACE vs. VN) employed. Given the differences between the nature of the way in which each label is attached to the macromolecule, differences in fluorescence anisotropy might be expected. However, the observed trends in τ_c are opposite to those of "intuitive reasoning" based upon the premise that the VN label might experience subsidiary rotational mobility as a result of motion about the bond of attachment to the polymer chain: for a given type of hydrophobic modifier, at a common copolymer content, it would appear that the VN label produces τ_c values for reorientational relaxation that exceed those of the ACE label at similar extents of neutralization of the polyacid. However, it is likely that these trends (which are opposite to those observed in the behaviour of the hydrophobically modified polyelectrolytes in methanol (as described above) *and* PMAA in aqueous media (42)) are artifacts that derive from the complexity of the time dependence of the decay of $r(t)$ and the simplicity of the current "single exponential" approach to analysis of the TRAMS data.

Application of eq. [3] in modelling the anisotropy decay via a single exponential function results, as discussed above, in an average correlation time that we hope is representative of the distribution of reorientational processes of the label, which reduce the relaxation of emission anisotropy to zero. This procedure seems justified, to some extent, by the self-consistent trends that emerge in the τ_c data, for a given label, as both the pH of the medium and the composition of the copolymers are varied. However, fitting to eq. [3] disguises the complexity of the anisotropy relaxation since the longer rotational processes are reflected in the presence of an apparent residual anisotropy, r_∞. Consequently, since the VN label has the potential for loss of anisotropy through motion independent of the polymer chain, which is not enjoyed by the ACE moiety, consistency between the τ_c values obtained using the two different labels should not (necessarily) be expected. In other words, although τ_c will increase as the overall distribution of relaxation processes shifts to longer times, the mode in which τ_c and r_∞ combine to reflect such shifts will not be the same for each label. Allied to this effect is the observation that, in general, direct analysis of the raw anisotropy function (from a point in the decay at which the perturbing influence of the excitation pulse is negligible) tend to produce similar estimates for τ_c (and r_∞) as those furnished by the IR method, in the case of the ACE-labelled copolymers. The VN-labelled species, in contrast, produced marked differences, in some instances, between the τ_c values estimated using the DA and IR methods. (The τ_c data shown in Fig. 2 are those recovered by the IR method of analysis.)

Solubilization studies using luminescent probe molecules

The dramatic changes in τ_c induced by hydrophobic modification, as revealed in TRAMS experiments and described above, are consistent with the supposition that the hydrophobic components of the resultant polyelectrolytes form aggregates within the macromolecular coil. The creation of hydrophobic domains can be tested using luminescent probes since these domains act as solubilizing pockets for organic guests. Furthermore, the photophysical characteristics of the occluded guests can yield information regarding the nature of their host matrix. In the current work, three luminescent guests; pyrene, 9-methylanthracene, and perylene, have been used to probe the interiors of the hydrophobic cavities formed in the styrene- and MMA-modified AA polymers.

Pyrene

Pyrene is one of the most widely used fluorescent probes. Photophysical applications involving pyrene in the study of aqueous polymer solutions and in other organized media have formed the basis of a recent excellent review (29). The fluorescence spectrum of a pyrene probe offers a simple and convenient means of sensing the molecule's local environment (53, 54). In particular, the ratio of the intensities of two specific

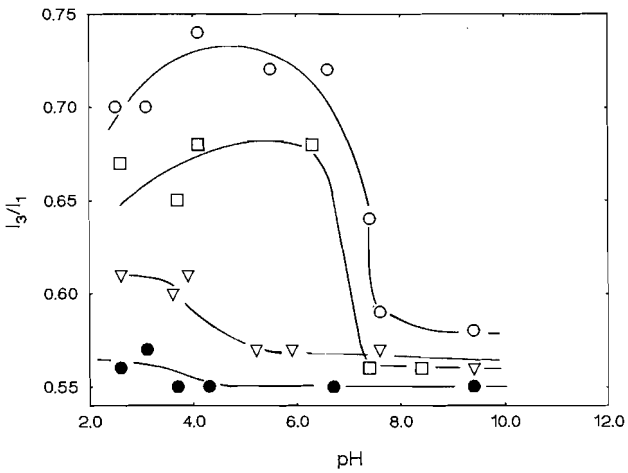
Fig. 3. I_3/I_1 ratios from the fluorescence spectra of pyrene (10^{-6} M) dispersed in various AA-based polymers (10^{-2} wt.%). (○) STY(44)–AA; (□) STY(27)–AA; (▽) MMA(38)–AA; (●) PAA-VN.



vibronic bands (the I_3/I_1 ratio) within the emission spectrum provides a measure of the polarity of the medium in which the pyrene is dissolved (54). This ratio is plotted in Fig. 3 as a function of pH, for pyrene dispersed in dilute (10^{-2} wt.%) solutions of PAA and various hydrophobically modified polyacids. It should be noted that at a pyrene concentration of 10^{-6} M there is no evidence in the fluorescence spectrum for excimer formation in any of the systems studied (including pure water). With reference to Fig. 3, it is apparent that

(*i*) the I_3/I_1 ratio for the PAA solution is virtually independent of pH. If the pyrene is solubilized at all by the polymer, it experiences a microenvironment that is very similar to that of water itself.

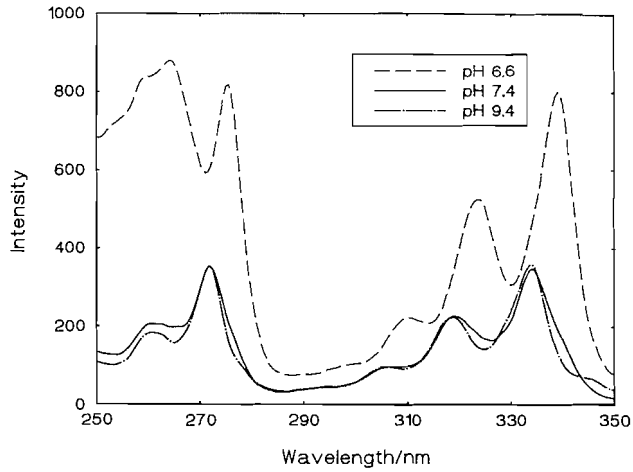
(*ii*) Hydrophobic modification using styrene leads to the generation, at lower pH values, of hydrophobic domains capable of solubilizing pyrene. The hydrophobicity of these domains is considerably enhanced compared to that of PAA itself. Indeed, the I_3/I_1 ratio attained for pyrene solubilized in the polyacid form of the STY(44)–AA copolymer indicates that the solubilization sites afforded to the probe are similar in polarity to those found in certain micellar systems (54). Even at high pH (>8.0) the copolymer creates a microenvironment for the pyrene of lesser polarity than that of the aqueous phase.

(*iii*) The hydrophobicity of the microenvironment afforded to the solubilized guest depends upon the nature of the modifying comonomer. The domains created in MMA–AA copolymers are more polar than those in STY–AA species of a similar (overall) composition.

(*iv*) For a given hydrophobic modifier, the hydrophobicity of the solubilizing domains is dependent upon the composition of the copolymer.

(*v*) The polarity of the microenvironment sensed by the dispersed probe depends upon the pH of the system. The dependence of I_3/I_1 upon pH constitutes a kind of "photophysical titration curve" that allows the effects of neutralization, upon the nature of the intramolecular solubilizing cavities formed in the various polymers, to be examined. The curves reflect the trends apparent in the pH dependencies of the relaxation characteristics of the various polymers (themselves determined

Fig. 4. Excitation spectra for pyrene (10^{-6} M; λ_a = 380 nm) dispersed in STY(44)–AA at various values of pH.



largely by the existence, or otherwise, of intramolecular aggregation). Again, it can be seen that hydrophobic modification shifts the range in pH, over which the change in the conformational behaviour of the polyacid becomes apparent, to higher pH. The greater the mole fraction of hydrophobic comonomer incorporated into the polymer, the greater the shift.

Solubilization of pyrene in the styrene–AA copolymers results in other changes in the probe's spectral characteristics that can be used to detect the presence of intramolecular aggregates. Upon occlusion in a styrene-rich "pocket," both the excitation and emission spectra of the pyrene become red-shifted. The effect is shown, for excitation, in Fig. 4. At low pH (below that of the conformational transition of the copolyacid) the excitation spectra of the solubilized probe exhibit a 0–0 vibronic band for the ($S_1 \leftarrow S_0$) transition that is centred at about 338 nm. At pH values greater than ca. 7 for the STY(44)–AA copolymer, the position of this band moves to higher energy, becoming centred at ca. 333 nm. Similar red shifts in excitation spectra are observed when excimer formation, involving "preassociated" pyrenes, occurs (for example, see ref. 29 and references therein). However, under the conditions employed in the current work, there was no spectral evidence (whether steady state or time-resolved) for excimer formation between the pyrene probes. In this instance, the spectral shifts merely reflect the location of the pyrenes in a solvating medium that consists, largely, of styryl residues. This observation is supported by the facts that

(*i*) similar shifts are induced in the spectra of pyrene when dispersed in toluene as opposed to water.

(*ii*) When the number of solubilizing sites is decreased (by reducing the STY(44)–AA concentration, from 10^{-2} to 10^{-3} wt.%) the pyrene becomes distributed more equally between the aqueous and polymer domains. The effects on the resultant excitation spectra are shown in Fig. 4: at low to intermediate pH, the 0–0 vibronic band peaks at 338 nm but contains a shoulder at 333 nm resultant upon a contribution to the overall spectrum from pyrene molecules dissolved in the bulk aqueous medium and (or) more polar regions within the polymer coils.

(*iii*) In these more dilute (10^{-3} wt.%) polymer solutions, selection of excitation wavelengths in the blue and red edges of the broadened and partially split vibronic bands, respectively, produces emission spectra that differ in I_3/I_1 ratio: the spectrum

produced by excitation into the red edge of a vibronic band (e.g., at 340 nm) has a higher I_3/I_1 ratio than that resultant upon excitation into a blue edge (e.g., at 318 nm). This implies that the distribution of pyrenes excited at 340 nm experiences, on average, a more hydrophobic set of microenvironments than those enjoyed by the excited states created in absorption at 318 nm. The photoselectivity of different distributions of pyrene molecules, within the overall probe population, through variation of excitation wavelength is further demonstrated by the excited state lifetime data discussed below.

The singlet excited state lifetime of pyrene is sensitive to the polarity of its surroundings (55). This effect has been used, for example, in pyrene probe studies of the conformational behaviour of poly(methacrylic acid) (14, 15, 18, 56). In a similar fashion, the fluorescence lifetime can be used to detect the existence of solubilizing cavities within the hydrophobically modified AA copolymers. Representative data are shown in Table 3 for 10^{-6} M pyrene dispersed in 10^{-2} wt.% solutions of various AA-based systems.

With reference to Table 3, it can be noted that

(*i*) the lifetime of pyrene dispersed in the PAA solution, even at low pH, is identical (within experimental error) to that in water (130 ± 5 ns). This supports the conclusions based upon trends in I_3/I_1 ratio that the PAA (if it has *any* solubilization capacity for pyrene, at this concentration) presents the probe with a solvent environment similar to that of the bulk aqueous phase.

(*ii*) At pH values below the conformational transition (as revealed in TRAMS experiments) for each particular macromolecule, the decays of the fluorescence from the pyrene probe become too complex for adequate description in terms of a single exponential function. At pH values higher than that of the conformational transition, the fluorescence decays become simpler and are characterized by a single lifetime of the order of 130 ns. These data are consistent with our belief that, during the conformational transition, the intramolecular hydrophobic aggregates, which characterize the acid form of the polymer, disintegrate. The pyrene is then ejected into the aqueous phase as the polymer loses its capacity for solubilization.

Table 4. Fluorescence decay parameters resultant upon triple exponential fitting to the time-resolved fluorescence of pyrene (10^{-6} M) dispersed in STY(44)–AA (10^{-3} wt.%) at various values of pH.

pH	λ_e/nm	τ_1/ns[a]	τ_2/ns[a]	τ_3/ns	$\langle\tau\rangle$/ns
3.5	318	322 (0.52)	131 (0.44)	26	228
	340	306 (0.68)	117 (0.29)	20	244
6.0	318	321 (0.50)	127 (0.48)	28	223
	340	320 (0.63)	122 (0.35)	16	245
7.2	318	341 (0.39)	133 (0.59)	29	210
	340	354 (0.48)	133 (0.49)	21	236

[a]Figures in parentheses show fractional contribution to overall fluorescence.

(*iii*) The complexities of the fluorescence decays of the pyrene guest, observed at low pH, typify the photophysical behaviour of excited state species, whether probes (14, 15, 18, 19, 56) or labels (15), when enclosed within the hydrophobic domains of water-soluble polymers. Dual exponential analyses of the fluorescence decays obtained from pyrene dispersed in the hydrophobically modified copolyacids result in fits to the observed emissions that are justified on statistical grounds. In most cases, this procedure leads to evolution of a component of the pyrene emission with a lifetime that is close to that obtained for the probe in water or in polymeric dispersion, at high pH. In addition, a longer-lived component is also obtained. It is tempting, following the approach of Thomas and co-workers (14, 15, 18, 56) to ascribe these components to populations of pyrene chromophores solubilized in polar environments (or in the bulk aqueous phase itself) and in hydrophobic domains, respectively. However, as we have discussed previously (19), it is probably an oversimplification to assume that these two populations are sufficiently distinct, within the overall distribution of dispersed probes, to be resolved by such an analysis. It is more likely that the double exponential fitting procedure merely serves to parameterize, in a statistically adequate fashion, the fluorescences emanating from a broad, heterogeneous range of environments. However, these twin parameters, τ_1 and τ_2, and their relative contributions to the overall fluorescence (listed in Table 3) can be used as indicators of the ranges in pH over which hydrophobic domains are generated within the coils of polyelectrolytes. Alternatively, the average fluorescence lifetime, $\langle\tau\rangle$, derived using eq. [5], can be used as a monitor for the regions of pH in which intramolecular aggregates of hydrophobic components of the AA copolymers are present.

$$[5] \quad \langle\tau\rangle = \frac{\sum a_i\tau_i^2}{\sum a_i\tau_i}$$

In eq. [5], τ_i represents the "lifetime" parameters evolved in multiexponential fitting according to eq. [6], where a_i represents the various pre-exponential terms and B is a "background" parameter:

$$[6] \quad i(t) = B + \sum_i a_i \exp(-t/\tau_i)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Clearly, had data been collected at more frequent intervals in pH, a plot of $\langle\tau\rangle$ against pH would have furnished a complementary (but more onerous in construction) "titration curve" to that afforded by I_3/I_1 ratios.

The lifetime data of Table 3 reveal that the copolymer MMA(38)–AA sustains occlusion of pyrene guests at low pH. The pH range over which solubilization is effected, however, is less than that maintained in either STY(27)–AA or STY(44)–AA. These observations are consistent with the findings based upon I_3/I_1 ratios, discussed above.

As the concentration of the AA copolymer is reduced, the number of solubilizing domains available to the probe also decreases. Studies of the fluorescence spectra of the overall pyrene probe distribution revealed (vide supra) a dependence upon excitation wavelength in the more dilute solutions of the copolymeric hosts. These observations are substantiated by time-resolved fluorescence measurements, as discussed below.

When pyrene (10^{-6} M) is dispersed in solutions of STY(44)–AA at a copolymer concentration of 10^{-3} wt.%, the decay data become more complex (in that they require a minimum of three exponential terms to be applied in the model fitting function (eq. [6])) than in dispersions that are an order of magnitude more concentrated. The data from triple exponential fitting of the pyrene fluorescences are listed in Table 4. A dependence upon polymer concentration (by comparison with the data in Table 3), pH, and excitation wavelength is apparent.

The reconvolution analyses consistently retrieve a lifetime component of between ca. 115 and 135 ns. This is, perhaps, not unexpected in these dilute systems since, as argued above, it might be expected that these dispersions will contain a fair proportion of pyrene molecules that are located within the bulk aqueous phase and (or) the more polar interiors of the polymer coil. In this respect, the time-resolved data corroborate those derived from the spectroscopic investigations. Moreover, the proportion of emission associated with this component of the overall fluorescence intensity, increases (*a*) as the pH of the solution increases and (*b*) as the excitation wavelength is changed from 340 nm to 318 nm. (As the excitation and emission spectra indicate (vide supra), excitation at 318 nm preferentially excites pyrene molecules located within the more polar regions of the dispersion. On the other hand, 340 nm radiation, accesses probes located within the more hydrophobic domains). The average lifetime, $\langle\tau\rangle$, also reflects this excitation wavelength dependence.

It is not anticipated that the triple exponential fits accomplish more than mere parameterization of the observed decay profiles: the three resultant "lifetimes" will have little *physical* significance. However, recovery of *one* component of lifetime close to that of pyrene in water may not be entirely fortuitous since a significant population of the pyrenes will be located in aqueous microenvironments. The two parameters recovered would, in combination with this component, serve to characterize the broad distribution of chromophoric environments to be found in these heterogenous systems.

Fluorescence anisotropy measurements, using probe molecules, can be used to investigate the local viscosity that they sense when solubilized in water-soluble polymers (see, for example, ref. 13 and references therein). Values of the reciprocal anisotropy of the steady state fluorescence of pyrene, dispersed in various AA-based matrices, are listed in Table 5. Also included, for comparison, are values of the anisotropy of this probe dispersed in poly(methacrylic acid), PMAA, at low pH. Under these conditions, PMAA is said to "hypercoil" (see, for example, refs. 13 and 42 and references therein). Consequently, the much-studied PMAA system provides a useful reference point for comparison of the emission anisotropies obtained in the hydrophobically modified AA macromolecules.

Table 5. Fluorescence anisotropy data for pyrene dispersed (10^{-6} M) in a variety of polyacids (10^{-2} wt.%).

Polymer	pH	r^{-1}	τ_c/ns[a]	τ_c/ns[b]

[a]Estimated from steady-state data using eq. [7] and $r_0^{-1} = 15$ (see text).
[b]Estimated from TRAMS data via IR analysis (see text).

The steady-state r^{-1} values provide a means of identifying the conditions under which the pyrene probe is, or is not, solubilized by the various polyacids. For example, the fluorescence from the pyrene probe dispersed in PAA at low pH and in MMA(38)–AA at pH 5 is completely (within the accuracy of the experiment) depolarized. This observation is consistent with the I_3/I_1 and fluorescence lifetime data, which indicate that the probe is solubilized to a minimal extent in these media (vide supra). In contrast, at the lower pH value of 3.4, emission from the probe dispersed in MMA(38)–AA exhibits a finite value of r^{-1}. It is interesting that, at this pH, the emission of the pyrene probe, solubilized by this copolymer, is more polarized than that of pyrene solubilized in the PMAA hypercoil.

In the STY–AA systems, the probe's fluorescence is more anisotropic than in any of the other systems. Furthermore, as the pH is increased the fluorescence becomes more depolarized. The pH value at which marked increases in r^{-1} occur in these systems depends upon the styrene content of the copolymer: at high pH the emission becomes completely depolarized. However, at pH values of 5 and 6.2 for the STY(27)–AA and STY(44)–AA systems, respectively, the fluorescence of the pyrene guest exhibits a lesser degree of anisotropy than that obtained in either system, at lower pH. Since both I_3/I_1 and τ data indicate that pyrene is still solubilized at these higher pH values, the r^{-1} data imply that neutralization of the AA derivatives in the copolymers results in a partial expansion of the hydrophobic domains *prior* to the disaggregation that occurs at higher pH (which, in turn, results in complete loss of solubilization capacity for pyrene).

The r^{-1} data are not strictly comparable: r^{-1} depends upon the mobility of the solubilized probe on the time scale imposed by its excited state lifetime. This is expressed by the Perrin equation, as

$$[7] \quad r^{-1} = r_0^{-1}\,(1 + \langle\tau\rangle/\tau_c)$$

(pH = 8.4)	10.9	
(pH = 10.2)	10.9	

[a]Figures in parentheses represent fractional contribution to the total fluorescence.

However, since $\langle\tau\rangle$ for pyrene in the PMAA and the STY–AA systems (at all pH values listed in Table 5) and MMA(38)–AA at pH 3.4 is ca. 300 ns, the r^{-1} data do reflect restrictions that the media impose on the probe's rotational mobility. A more valid comparison of relative mobilities of the probe under the varying conditions employed in this study, would be afforded by examination of the relevant τ_c data. In principle, these can be obtained using eq. [7] *provided* that the intrinsic anisotropy, r_0, is known for the probe, in the medium of interest. Unfortunately, conventional approaches (see, for example, ref. 44) to the determination of r_0 in steady state measurements are not applicable in this instance. (Addition of organic quenchers, to reduce $\langle\tau\rangle$, for example, would disrupt the hydrophobic domains under investigation.)

τ_c data can be obtained using TRAMS (as described above for labelled polymer samples). With appropriate "deconvolution," using the IR approach, estimates of r_0 are also furnished in such experiments. Unfortunately, the period of the electron storage ring, at the SRS Daresbury, is too short to allow TRAMS experiments to be performed upon excited states as long lived as that of pyrene. Lower repetition rates than that of the SRS must be employed. Pulsed laser sources have been used to effect in studies of water-soluble polymers bearing pyrenyl labels (57). In this context, the high stability of the laser source allows data collection to high signal-to-noise ratios, despite the relatively long accumulation times required. Pulsed flashlamps are much more limited, in this respect. Nevertheless, we have performed a limited number of TRAMS experiments, within the current investigation, using a thyratron-gated flashlamp employing D_2 as discharge medium (D_2 produces a more intense excitation flash than H_2). Figure 5 shows typical decay data for pyrene solubilized in STY(44)–AA at pH = 4.0. The data provide a good graphic illustration of the effects of the restrictions imposed upon the rotational tumbling of the pyrene constrained within the hydrophobic cavities of this polymer: covergence of the fluorescence intensity components, $I_\parallel$ and $I_\perp$, requires several hundred nanoseconds to accomplish.

The resultant data were analysed by the IR method, using a single exponential model for $r(t)$. The resultant τ_c values are listed in Table 5. The IR analyses of the various systems resulted in a consistent estimate for r_0^{-1} of 15.5 (± 0.5). This value was used in eq. [7] to estimate τ_c for each of the systems studied using steady state anisotropy determinations. The resultant data are also listed in Table 5. It can be seen that

(*i*) reasonable agreement is achieved between the relaxation data obtained in steady state and time-resolved experiments, given the limitations of the approaches adopted. (The application of a single exponential analytical procedure, for the modelling of $r(t)$, is likely to be an oversimplification, considering the complexities of the polymer dispersions under investigation. However, adoption of a more sophisticated model for the TRAMS data was not considered to be warranted under the resolution obtained using flashlamp excitation.)

(*ii*) The trends apparent in the τ_c values corroborate the observations made earlier on the basis of the steady state r^{-1} data:

(*a*) at low pH, each of the hydrophobically modified systems presents the pyrene guest with an environment that is more restrictive to motion, than that which exists in the hypercoiled form of PMAA. (Caution must be exercised here: a hydrophobic guest has the potential to influence the cavity in which is is occluded. There is spectral evidence[2] that the guest can alter the nature of its solubilizing pocket. It has also been reported that 9-methylanthracene induces production of a proportion of hydrophobic domains in PMAA that is not present in the unperturbed hypercoil (13).)

(*b*) The cavity/pyrene guest combination restricts the rotational freedom of the probe at low pH, to an extent that depends upon the nature of the hydrophobic modifier (i.e., MMA vs. styrene) and the copolymer composition.

(*c*) At pH values less than those associated with loss of solubilization capacity, the STY–AA systems seem to experience a relaxation of the restrictions to rotation of the guest, compared to those imposed in highly acidic media.

9-Methylanthracene

9-Methylanthracene has been a fluorescent reporter upon the conformational behavior of PMAA in aqueous media (13, 39, 58, 59). In particular, it has been reported that the fluorescence characteristics of this probe are sensitive to the viscosity of its microenvironment (60). In pure solvents, the fluorescence decays of 9-methylanthracene are monoexponential and their rates decrease with increasing viscosity (13). However, when solubilized in PMAA the decays become biexponential: it has been reported (13, 39) that a longer-lived component (of lifetime ca. 13 ns) is accompanied, in PMAA solution, by a shorter component of τ around 5–7 ns (dependent upon the tacticity of the PMAA).

Incorporation of 9-methyanthracene (10^{-5} M) into solutions of PMAA and hydrophobically modified forms of AA results in red shifts of both its excitation and emission spectra. The extent of the shift is dependent upon the polymer. Solubilization of the probe in STY(44)–AA at low pH, for example, results in a larger displacement of the spectra to lower energy than when the probe is incorporated in the PMAA hypercoil. The shifts might reflect differences in microviscosity and (or) hydrophobicity of the coil interiors.

Table 6 lists fluorescence liftetime data for the 9-methylanthracene probe dispersed in a variety of solvent media. In

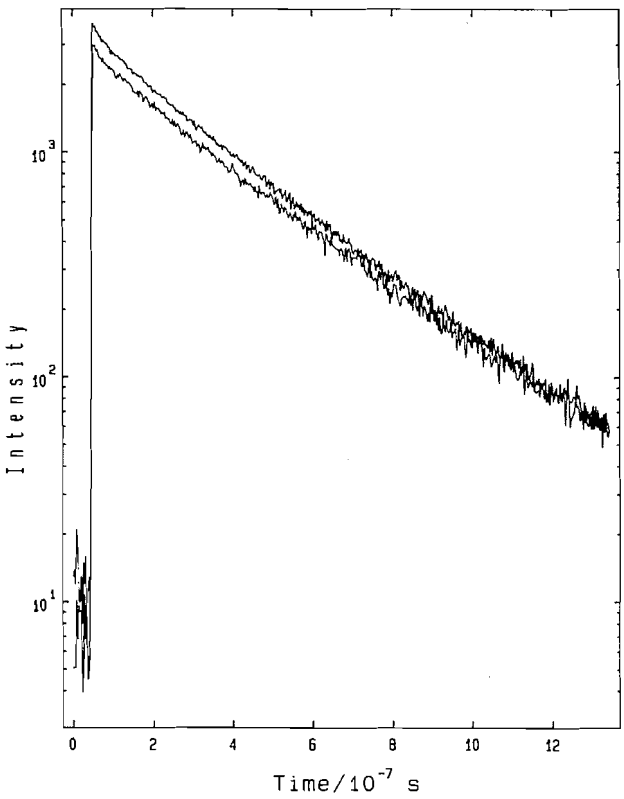
Fig. 5. $I_{\parallel}$ (upper curve) and $I_{\perp}$ decay curves (λ_a = 380 nm), following vertically polarized excitation (λ_e = 340 nm) of pyrene (10^{-6} M) dispersed in STY(44)–AA (10^{-2} wt.%) at pH = 4.0 and 298 K.



accord with previous observations (13, 39) the fluorescence decays become nonexponential when the probe is dispersed in aqueous solutions of polymers. In such systems, double-exponential models of the true decay (of the form of eq. [6], with i = 2) provide statistically adequate fits to the observed fluorescence profile.

The lifetime obtained for 9-methylanthracene in cyclohexane aggrees well with that reported by other workers (13, 39). Comparison of that of 11 ns, obtained in an aqueous medium (saturated solution at 298 K), with those reported by Snare et al. (39) in a variety of solvents over a range of viscosities, reveals that the lifetime of the solute is not determined by solvent viscosity alone.

In PMAA solution, recovery of a lifetime component of ca. 13 ns is consistent with earlier reports (13, 39). However, the lifetime of the second component is somewhat greater than that previously reported (13, 39). (It should be noted that the technique of time-correlated single-photon counting is not particularly well adapted to the recovery of two closely matched decay parameters. However, recovery of a component of magnitude similar to that of the probe in water gives confidence in the dual exponential fitting procedure (deemed both necessary and adequate on the grounds of "goodness of fit").)

The complexities of the fluorescence decays, obtained in the two copolymer systems studied, confirm the existence of solubilizing domains in these species at low pH. The STY(44)–AA system was studied over a range of pH values and the data clearly indicate the extended range of pH over which solubilization of the probe is effected. In this respect, the data support the findings of TRAMS upon the labelled copolymers indicating that this hydrophobically modified polymer does not fully uncoil until a pH of about 8 is attained. At higher values of pH, the fluorescence decay of the probe is monoexponential, showing that it has been ejected into the aqueous phase. In a similar fashion, the simplicity of decay of the probe's fluorescence, characterized by a lifetime of 10.9 (±0.1) ns, confirms that, in the presence of PAA, the probe experiences an environment similar to that of the bulk aqueous phase.

Steady-state fluorescence anisotropy studies of 9-methylanthracene solubilized in PMAA and STY(44)–AA at low pH, provide information that broadly supports our findings, using pyrene as a probe, regarding the relative microviscosities of the two systems. Fluorescence from the probe, solubilized in STY(44)–AA at pH = 4.2, is less depolarized (r^{-1} = 17.4) than that obtained in PMAA at pH = 3.4 (r^{-1} = 20.5). Using $\langle\tau\rangle$ values (based on eq. [5]) and an r_0^{-1} of 10.22 (based upon an estimate of the intrinsic polarization quoted for 9-methylanthracene frozen in a methylcyclohexane low-temperature glass (61)) we arrive at correlation times of ca. 19 and 12 ns, respectively. These data again suggest that rotation of the probe is more restricted in the hydrophobically modified copolymer than in the PMAA hypercoil. (Of interest in this context, it can be noted that Snare et al. (39) have shown that the time-resolved fluorescence anisotropy of 9-methylanthracene solubilized in PMAA may be resolved into two components (of 33 and 11 ns, respectively). The steady-state estimate of τ_c for the same probe in PMAA gives a value that is very close to that of the shorter of the two τ_c values recovered in TRAMS (39).)

Marked differences are apparent in the values of τ_c that result from anisotropy measurements of solubilized 9-methylanthracene and pyrene. These emphasize the fact that measurements of the rotational mobility of a given probe reflect both its intrinsic molar volume *and* the effects that it might induce by "drawing a cloak" of solvating species about itself as it enters the hydrophobic domains within the polymer coils. These observations are further substantiated by luminescence measurements upon solubilized perylene as described below.

Perylene

Fluorescence experiments involving both pyrene and 9-methylanthracene are complicated by the fact that both probes have significant solubility in water (62). Perylene, on the other hand, is soluble only to the extent of about 10^{-9} M in water (62). Consequently, its presence as a solubilized guest in a hydrophobic cavity can be detected, very simply, by the dramatic increase in its fluorescence intensity when compared to that of a saturated solution in water alone. For example, when dispersed in 10^{-2} wt.% solutions of STY(44)–AA at a nominal concentration of 10^{-5} M, solubilization of the probe occurs at pH values of less than ca. 7.5, as indicated by the concomitant appearance of discernible fluorescence.

As a consequence of its short-lived excited state (perylene solubilized in STY(44)–AA, for example, has a fluorescence lifetime of about 6 ns) perylene is not particularly well suited to anisotropy probing of media of very high viscosity. In STY(44)–AA the value of r^{-1}, observed in steady-state experiments, is 4.0. The value of r_0^{-1} for perylene is quoted as being of the order of 2.8 (63). Incorporation of these estimates into eq. [7] yields an estimate of 14 ns for τ_c. This value (subject to some

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

error, due to the assumptions involved) is very similar to that obtained from solubilization of 9-methylanthracene, under similar conditions, and suggests that the interiors of the hydrophobic domains produced in such copolymers are highly viscous.

Conclusions

1. Hydrophobic modification via copolymerization alters the conformational behaviour of polyacrylic acid: (*i*) in acid media, hydrophobic domains, which do not exist in PAA itself, are formed in MMA–AA and STY–AA copolymers; (*ii*) aggregation between hydrophobic components of the modified polyacids can, dependent upon hydrophobe and copolymer composition, markedly affect the segmental dynamics of the macromolecule; (*iii*) the creation of hydrophobic aggregates opposes the Coulombic forces of repulsion between the carboxylate anions formed during neutralization of the polyacid. The net effect is to shift, to higher values, the pH range over which chain expansion occurs, producing the more flexible open coil associated with the polysalt.

2. The hydrophobic domains formed in the AA-based copolymers can solubilize organic guests. It is apparent that (*i*) the microviscosity of the domain interiors is much greater than that of water; (*ii*) the hydrophobicity and microviscosity of the domain interiors depend upon both the nature of the modifying monomer and the composition of the copolymer; (*iii*) dependent upon the nature of the modifying comonomer and the copolymer composition, the hydrophobic aggregates disintegrate at higher pH and the solubilization capacity of the polymer, for organic guests, is lost; (*iv*) at intermediate pH values, such that guest solubilization can still be effected, the hydrophobic pockets of the polymeric host seem to exert lesser constraints upon probe motion than is the case at lower pH values.

Chain exchange kinetics of diblock copolymer micelles studied by nonradiative energy transfer. 1. Experimental design and theory

Guojun Liu

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

Abstract: A fluorescence experiment involving mixing donor-labeled micelles with acceptor-labeled unimers has been designed and a kinetic scheme for describing such an experiment has been proposed. An approximate analytical solution was found for the decrease in the donor fluorescence intensity at time t after sample mixing relative to that at time zero, $I(t)/I(0)$. Treating the data of this decrease in donor fluorescence intensity as a function of time using the derived equation allows the simultaneous determination of the rate constant k_n for unimer incorporation into micelles and the quenching efficiency φ of donor fluorescence by an acceptor in a micelle.

Key words: polymer micelles, dynamics, chain exchange, energy transfer.

Résumé : On a mis au point une expérience de fluorescence impliquant le mélange des micelles contenant un donneur marqué avec des unimères accepteurs marqués et on propose un schéma cinétique pour décrire une telle expérience. On a trouvé une solution analytique approximative pour expliquer la diminution de l'intensité de la fluorescence du donneur à un temps t relatif au temps zéro, $I(t)/I(0)$, du mélange de l'échantillon. Le traitement des données relatives à la diminution de l'intensité de la fluorescence du donneur en fonction du temps en faisant appel à l'équation dérivée permet de déterminer simultanément la constante de vitesse, k_n, pour l'incorporation de l'unimère dans les micelles et pour l'efficacité d'extinction, φ, de la fluorescence d'un donneur par un accepteur dans une micelle.

Mots clés : micelles de polymère, dynamique, échange de chaîne, transfert d'énergie.

[Traduit par la rédaction]

1. Introduction

Due to their potential medical and pharmaceutical applications, block copolymer micelles have attracted much attention in the past decade (1–4). Significant progress has been made in the theoretical (5–12) and experimental (13–19) understanding of the equilibrium properties, such as the size and aggregation number, of micelles. The study of micelle chain exchange dynamics has, however, been relatively rare from either a theoretical (20, 21) or experimental (22–26) point of view.

In a micellar system, chain exchange between a pool of unimers and micelles, the breakdown of larger micelles into smaller ones (fission), and the formation of larger micelles from smaller ones (fusion) may all occur simultaneously (1). Of all the processes, chain exchange, in which a unimer chain U is either dissociated from a micelle M_n with n chains or added to a micelle M_{n-1} with $n-1$ chains, is the most fundamental:

$$[1] \qquad M_n \underset{k_n}{\overset{k_{-n}}{\rightleftharpoons}} M_{n-1} + U$$

where k_n and k_{-n} are the rate constants for chain incorporation into and dissociation from a micelle, respectively. Rate constants k_n and k_{-n} are related, at equilibrium, by

$$[2] \qquad K_n[M_{n-1}][U] = k_{-n}[M_n]$$

where [U] and $[M_n]$ denote the concentrations of U and M_n, respectively.

Halperin and Alexander (20) have recently argued that the chain exchange process is much faster than the micelle fusion and fission processes. The slower fusion rate can be understood as due to the strong repulsion between the coronas of two micelles approaching one another. The fission rate is lower because the simultaneous disentanglement of a few chains or more from the core of a micelle is kinetically unfavorable. Based on the assumption that only one chain is either incorporated into or dissociated from a micelle at a time, Halperin and Alexander derived scaling relations between k_{-n} and polymer structural parameters such as the length of each block of a diblock copolymer.

Due to the dominance of the chain exchange process

in block copolymer micelles, the Aniansson and Wall (A–W) (27) analysis of micelle dynamics, originally developed for small-molecule surfactant micelles, should apply. The A–W theory was formulated to describe a typical perturbation and relaxation experiment. In such an experiment, a miceller system at equilibrium is suddenly subjected to a minor perturbation such as a jump in temperature or pressure. Due to the change in external conditions, the concentration of unimers or micelles or their equivalents should relax after the initial perturbation, according to the A–W theory, to their new equilibrium values with two relaxation times τ_1 and τ_2. In the short-time domain characterized by τ_1, the total number of micelles would remain unchanged while the mass concentrations of micelles and unimers, in terms of grams per litre of solution, adjust so that they attain approximately their equilibrium values. In the second stage characterized by τ_2, micelle disintegration and formation take place. This is accompanied by either growth or reduction in micelle sizes. The A–W theory has been very successful as it relates τ_1 and τ_2 to k_{-n} and to characteristic micellar parameters such as the average aggregation number $\bar{n}$ and the variance σ in $\bar{n}$.

The relaxation kinetics of diblock copolymer micelles studied so far have been found to follow a two-stage mechanism in agreement with the A–W theory. Rate constants such as K_{-n} for diblock micelles have, however, not been reported. The difficulty has been in establishing the equivalence between the experimentally determined τ_1 and τ_2 and those discussed by A–W, owing to complications from the techniques used for monitoring the relaxation of a micellar system.

Light scattering has, for example, been the most popular technique for monitoring micelle relaxation kinetics but the validity of such a usage is questionable. To see the significance of such an experiment, we will first simplify the expression for the scattered light intensity $i_\theta(t)$ by making some assumptions. We assume that the micellar particles are sufficiently small or the scattered light intensity is detected at a small enough angle θ so that the scattering function $P(\theta)$ is approximately 1 (28). We further assume that the micelle solution is dilute, and interparticle interference negligible. Under these conditions, we have

$$[3] \qquad i_\theta(t) \propto \bar{M}_w c_m$$

where $\bar{M}_w$ and c_m are the weight-average molar mass and the mass concentration of micelles, respectively. In the time domain immediately after a perturbation, the number of micelles, according to the A–W analysis, is approximately constant. Any increase in c_m would naturally also lead to an increase in $\bar{M}_w$ of micelles. Thus, $i_\theta(t)$ in this region does not increase linearly but, rather, quadratically with c_m, a situation not addressed by Aniansson and Wall.

In the time domain when micelle size redistribution dominates, c_m is more or less constant but $\bar{M}_w$ varies. Thus, the use of light scattering, in this time domain, is in agreement with the spirit of the Aniansson and Wall discussion. The quadratic c_m dependence in the short-time domain can be accounted for if the initial process is well resolved or decoupled from the micelle size redistribution process characterized by τ_2. In reality, the two processes are coupled. Due to the coupling of these two processes and the different connotations of the scattered light intensity $i_\theta(t)$ in the two regimes, the analysis of $i_\theta(t)$ using

$$[4] \qquad i_\theta(t) = \sum_{i=1}^{2} a_i \exp(-t/\tau_i)$$

where a_i are the amplitude coefficients, will not yield τ_1 and τ_2 values that are the same as the concentration relaxation times for unimers or micelles.

In addition to the aforementioned complication, most of the previous studies were plagued by the use of large perturbations. The use of large perturbations, such as the sudden change in solvent composition (2) or temperature (23) to cause micelle formation from a solution with no micelles, or vice versa, makes the experimental detection of the relaxation process easier but the A–W theory inapplicable.

Fluorescence techniques are ideal for studying chain exchange dynamics as they are sensitive to minor changes in the properties of a system if an experiment is well designed. Wang et al. (24) and Procházka et al. (25) for example, labeled identical diblock copolymers with fluorescence donors and acceptors and prepared micelles from differently labeled chains, respectively. Micelles containing differently labeled chains were then mixed. Due to chain exchange after mixing, donors residing in the same micelles as acceptors may transfer electronic excitation energy to acceptors, via the dipole–dipole energy transfer mechanism (29). Energy transfer decreases the fluorescence intensity of the donor but increases that of the acceptor, although the donor is selectively excited in the process. The beauty about the experiments of Wang et al. and Procházka et al. was that they were carried out near equilibrium conditions, if the donor- and acceptor-labeled chains could be viewed as identical.

The experimental data of Wang et al. and Procházka et al., i.e., the variation in the fluorescence intensity $I(t)$ of the donor as a function of time, have been fitted with a sum of two exponential terms. The difficulty there again lies in relating the τ_1 and τ_2 values recovered to k_{-n}. In this case, $I(t)$ is, by no means, a linear function of a concentration parameter such as the number of acceptor-labeled chains entering a micelle consisting primarily of donor-labeled chains. Instead, $I(t)$ is a complex function of the efficiency of energy migration among donor groups, the number and locations of donors and acceptors in a micelle, and the rate constant for energy transfer, etc. It is not surprising that when attempted by Wang et al., only numerical expressions were found between $I(t)$ and k_{-n}, and the numerical solutions did not explain the experimental data well.

In this paper, I will describe the proper design of the experiment involving mixing donor- and acceptor-labeled chains to enable the unambiguous analysis of fluorescence data to yield rate constant k_n. In Sect. 2, the experimental design and the kinetic model for the experiment will be described, and the approximate solutions for some important equations will be presented. In Sect. 3, errors that may be introduced due to the treatment of experimental data with approximate analytical solutions found in Sect. 2 will be estimated for commonly encountered experimental conditions. Some conclusions will be drawn in Sect. 4.

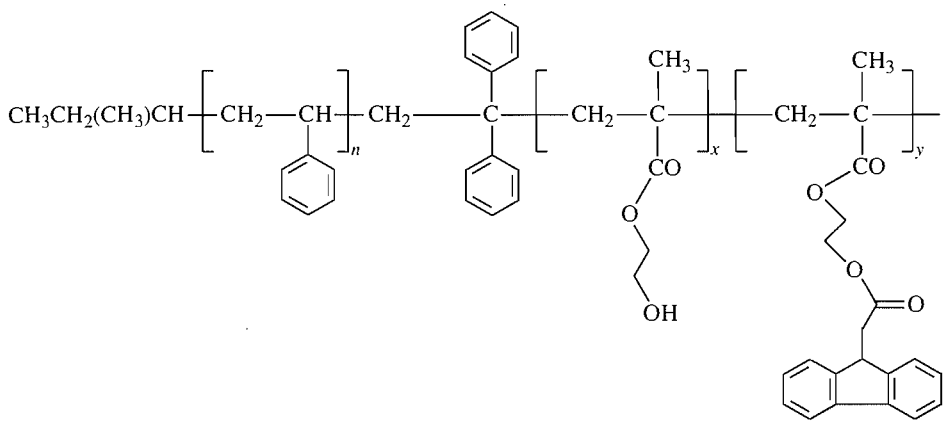
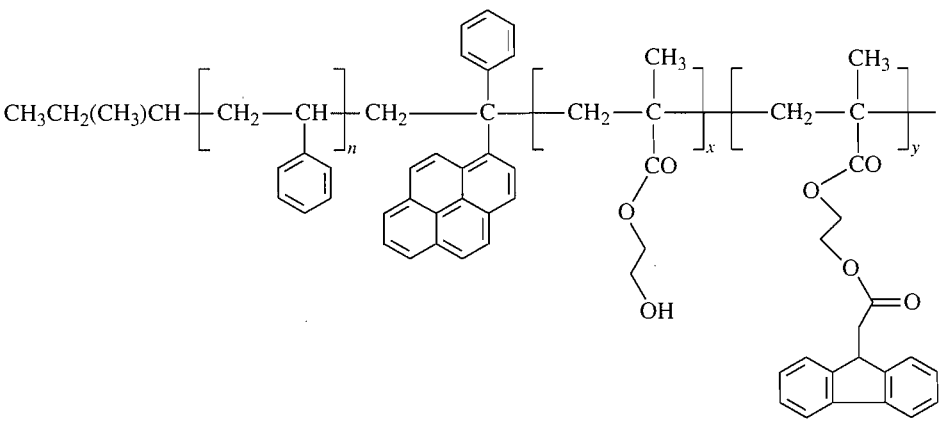
2. Experimental design and theory

Experimental design

I will use fluorene- and pyrene-labeled polystyrene (PS) and poly(2-hydroxylethyl methacrylate) (PHEMA) block copolymers, i.e., PS-*b*-PHEMA-Fl(y), PS-*Py*-PHEMA-Fl(y), which have been synthesized and are currently being studied in my laboratory (30),[2] to illustrate the essential features of such an experiment:



PS-*b*-PHEMA-Fl(y)



PS-*Py*-PHEMA-Fl(y)

The PHEMA blocks of these polymers are labeled by fluorene at a density y typically less than 10% as denoted by the "Fl(y)" suffix. The PS-*Py*-PHEMA polymer is labeled to minimize the structural differences between it and PS-*b*-PHEMA-Fl(y).

A micelle solution will be prepared first from PS-*b*-PHEMA-Fl(y) in a THF-cyclohexane mixture that is selectively poor for the PHEMA block. The molar micelle concentration c_M^0 is tuned using:

$$[5] \qquad c_M^0 = \frac{c - c^*}{\bar{n}}$$

to be close to the critical micelle concentration c^*. In eq. [5], $\bar{n}$ denotes the average micelle aggregation number and c the polymer concentration.

Then, an equal volume of a PS-*Py*-PHEMA-Fl(y) sample at a polymer concentration c_{Py}^0, which is below c^*, e.g. $c_{Py}^0 \approx 0.50c^*$ or $c_{Py}^0 \approx 0.50c_M^0$, is added to the PS-*b*-PHEMA-Fl(y) micelle solution. After mixing, the decrease in the fluorescence intensity of the donor and the increase in that of the acceptor as a function of time will be monitored while exciting the donor group selectively.

Analysis of the experiment

Three important features of the experiment described above are discussed here. First, a unimer solution of PS-*Py*-PHEMA-Fl(y) instead of its micelle solution is mixed with a micelle solution of PS-*b*-PHEMA-Fl(y). This will greatly simplify the kinetic description. Immediately after the mixing, unimer concentration [U] is diluted by a factor of 0.75, since [U] = $0.50c^*$ for the PS-*Py*-PHEMA-Fl(y) solution and [U] = c^* for the PS-*b*-PHEMA-Fl(y) micelle solution. Due to the relatively large negative deviation of [U] from c^*, the system will respond rapidly by dissociating some unimers from the existing micelles until the total unimer concentration is again approximately c^*. This initial adjusting period, characterized by τ_I, is short (20).

After τ_I, the average size of the micelles in the system is

[2] Studies of chain exchange kinetics are currently being performed.

For personal use only.

smaller than their equilibrium size. Micelle size redistribution takes place. In this process, a small number of micelles will disintegrate and the majority will increase their size. It is the kinetics of chain exchange in this long-time domain, between PS-*b*-PHEMA-Fl(y) chains, associated mostly with micelles, and PS-*Py*-PHEMA-Fl(y) chains, existing almost exclusively as unimers, that is the focus of discussion here. Due to the assumption that acceptor-labeled chains initially only exist as unimers, the kinetic scheme here is much simpler than for the case when two micellar solutions are mixed, as one does not need to keep track of micelles consisting dominantly of donor- and acceptor-labeled chains, respectively.

Then, the concentration of PS-*Py*-PHEMA-Fl(y) is lower than c_M^0, e.g., $c_{Py}^0 \approx 0.50c_M^0$. This ensures a low probability of each micelle having more than one quencher. As will be seen later, this condition again greatly simplifies the derivation of the mathematical expressions for the donor and acceptor fluorescene intensities as a function of time.

Thirdly, I have chosen fluorene as the energy donor and pyrene as the acceptor or quencher because fluorene transfer energy to pyrene with a critical energy transfer distance of ~32 Å (31). Also, efficient energy migration among different fluorene groups is possible in a micellar core because the critical energy transfer distance between two fluorene groups is ~22 Å (31). Energy migration increases the effective radius of fluorene fluorescence quenching by pyrene, which ensures that a single pyrene group inside a micelle core will lead to the effective quenching of the fluorescence of fluorene. With the use of fluorene and pyrene, we have determined a quenching efficiency of ~15% for the incorporation of one PS-*Py*-PHEMA-Fl(y) chain into a micelle of PS-*b*-PHEMA-Fl(y), where both samples have 3% of fluorene labeling and an equal number of styrene and HEMA units (i.e., 100), respectively. The average aggregation number for such a micelle has been determined to be around 63 and the hydrodynamic radius to be some 140 Å (30).

General kinetic model

In my treatment, the fastest occurring unimer exchange process is assumed to be mainly responsible for the incorporation of PS-*Py*-PHEMA-Fl(y) into PS-*b*-PHEMA-Fl(y) micelles.

$$[6] \qquad M_n + U \underset{k_{-(n+1)}}{\overset{k_{(n+1)}}{\rightleftharpoons}} M_{n+1}$$

$$[7] \qquad M_n \underset{k_n}{\overset{k_{-n}}{\rightleftharpoons}} M_{n-1} + U$$

$$[8] \qquad M_nPy_i + \wedge\wedge\wedge\wedge\wedge\wedge\wedge Py \underset{[(i+1)/(n+i+1)]k_{-n}}{\overset{k_n}{\rightleftharpoons}} M_nPy_{i+1}$$

where $i = 0, 1, \ldots, m-1$.

In the above equations, U and $\wedge\wedge\wedge\wedge\wedge\wedge\wedge Py$ represent PS-*b*-PHEMA-Fl(y) and PS-*Py*-PHEMA-Fl(y) unimers, respectively; M_n denotes a micelle with n PS-*b*-PHEMA-Fl(y) chains; m stands for the maximal number of PS-*Py*-PHEMA-Fl(y) chains that a micelle can take up. The factor $(i+1)/(n+i+1)$ before k_{-n} in eq. [8] accounts for the fact that every unimer chain, either U or $\wedge\wedge\wedge\wedge\wedge\wedge\wedge Py$, has an equal chance to exit a micelle and that there are only $(i+1)$ $\wedge\wedge\wedge\wedge\wedge\wedge\wedge Py$ out of a total of $(n+i+1)$ chains in a micelle M_nPy_{i+1}.

Since eqs. [6] and [7] do not involve $\wedge\wedge\wedge\wedge\wedge\wedge\wedge Py$ and will not affect the fluorescence properties of the system, I will not consider them any further. I have also assumed that the k_n for PS-*b*-PHEMA-Fl(y) and PS-*Py*-PHEMA-Fl(y) addition to a micelle is the same. So are their k_{-n} values. The last assumption may be validated by synthesizing PS-*b*-PHEMA-Fl(y) and PS-*Py*-PHEMA-Fl(y) polymers with everything identical except the difference in the pyrene label.

From eq. [8] we have the following equations for describing the change in the concentration of micelles of n unimers containing i PS-*Py*-PHEMA-Fl(y) chains:

$$[9] \qquad \frac{d[M_nPy_i]}{dt} = k_n[\sim\sim Py][M_nPy_{i-1}] - \frac{i}{n+i}k_{-n}[M_nPy_i] - k_n[M_nPy_i][\sim\sim Py] + \frac{i+1}{n+i+1}k_{-n}[M_nPy_{i+1}]$$

$$i = 0, 1, 2, \ldots, m$$

In using eq. [9] for $d[M_nPy_0]/dt$ or $d[M_n]/dt$, one should remember $[M_nPy_{-1}] = 0$. For $d[M_nPy_m]/dt$, one resorts to the assumption that a micelle with $(m+1)\wedge\wedge\wedge\wedge\wedge\wedge\wedge Py$ groups does not form.

In using the same rate constant k_n for PS-*Py*-PHEMA-Fl(y) incorporation into a micelle regardless of the i value, I have implicitly assumed that m is small compared to n and the presence of a few PS-*Py*-PHEMA-Fl(y) chains will not significantly perturb the property of a micelle.

Equation [9] is general and applies to micelles of all sizes or of different n. If assuming that n has a very sharp distribution around the average aggregation number $\bar{n}$ and the n independence of k_n and k_{-n}, an approximation used in all previous studies (1, 27), the kinetic equations for the concentrations, $[MPy_i]$, of micelles with i PS-*Py*-PHEMA-Fl(y) chains, i.e., $\sum_n[M_nPy_i]$, are

$$[10] \qquad \frac{d[MPy_i]}{dt} = k_n[\sim\sim Py][MPy_{i-1}] - \frac{i}{\bar{n}+i}k_{-n}[MPy_i] - k_n[MPy_i][\sim\sim Py] + \frac{i+1}{\bar{n}+i+1}k_{-n}[MPy_{i+1}] \qquad i = 0, 1, 2, \ldots, m$$

Again, one is cautioned that $[MPy_{-1}] = 0$ and $[MPy_{m+1}] = 0$ when using eq. [10] for finding $d[M]/dt$ and $d[MPy_m]/dt$, where [M] is the concentration of micelles containing no pyrene at time t.

Due to the nonlinearity of the series of equations denoted by eq. [10], they generally do not give exact analytical solutions for $m > 1$. They can, however, be easily solved numerically.

Kinetic model for the low c_{Py}^0/c_M^0 case

Since c_{Py}^0 has been assumed to be low relative to c_M^0, the probability for the incorporation of two or more PS-*Py*-PHEMA-Fl(y) chains into the same micelle is low and we can use eq. [10] by setting $m = 1$:

$$[11] \qquad \frac{d[MPy]}{dt} = k_n[M][\sim\sim\sim Py] - \frac{1}{\bar{n}+1}k_{-n}[MPy]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

To simplify notation, let:

[12] $x = [\text{MPy}]$

Due to the assumption of no moe than one acceptor per micelle,

[13] $[\text{M}] = c_{\text{M}}^0 - x$

and the concentration of $\wedge\wedge\wedge\wedge\wedge\wedge Py$, [$\sim\sim\sim$ Py], is related to x by

[14] $[\sim\sim\sim \text{Py}] = c_y^0 - x$

where c_y^0 is the initial PS-Py-PHEMA-Fl(y) concentration. Since $\bar{n}$ is typically larger than 50, the second term on the right-hand side of eq. [11] is assumed to be negligible. Inserting eqs. [13] and [14] and neglecting the second term, eq. [11] becomes

[15] $$\frac{dx}{dt} = k_n(c_{\text{M}}^0 - x)(c_y^0 - x)$$

The solution for x from eq. [15] can be found in most physical chemistry textbooks to be

[16] $$x = \frac{c_y^0(1 - e^{-kt})}{1 - \frac{c_y^0}{c_{\text{M}}^0} e^{-kt}}$$

where

[17] $k = (c_{\text{M}}^0 - c_y^0)k_n$

Equation [17] gives $x = 0$ at $t = 0$ and $x = c_y^0$ as $t \rightarrow \infty$. These results are reasonable and suggest the validity of the equation.

Decrease in normalized donor fluorescence intensity as a function of time

Due to the low concentration of polymers existing as unimers, light is mainly absorbed by fluorene dispersed inside the micellar cores and I assume that light is emitted from fluorene or pyrene associated with micelles only. If the efficiency of fluorene fluorescence quenching by a PS-*Py*-PHEMA-Fl(y) chain in a micelle is φ, the fluorescence intensity $I(t)$ of the donor at time t normalized relative to that $I(0)$ at time $t = 0$ should be:

[18] $$\frac{I(t)}{I(0)} = \frac{c_{\text{M}}^0 - \varphi x}{c_{\text{M}}^0}$$

Inserting eq. [16] and simplifying gives:

[19] $$\frac{I(t)}{I(0)} = 1 - \varphi \frac{c_y^0 - c_y^0 e^{-kt}}{c_{\text{M}}^0 - c_y^0 e^{-kt}}$$

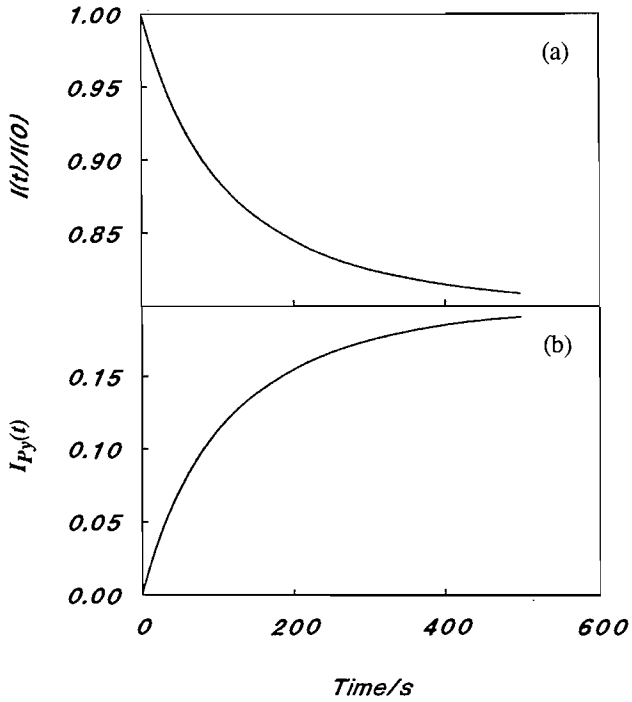
At $t = 0$, eq. [19] gives $I(t)/I(0) = 1$. Extrapolating to infinitely long times, $I(t)/I(0) \rightarrow 1 - \varphi(c_y^0/c_{\text{M}}^0)$. These predictions are intuitively reasonable, suggesting the validity of eq. [19].

Increase in the acceptor fluorescence intensity

After solution mixing, the acceptor fluroescence intensity increases with time. This increase is proportional to the magnitude of x:

[20] $$I_{\text{Py}}(t) \propto \frac{c_y^0(1 - e^{-kt})}{1 - \frac{c_y^0}{c_{\text{M}}^0} e^{-kt}}$$

Fig. 1. Decrease (top graph) in donor fluorescence intensity and increase (bottom graph) in acceptor fluorescence intensity as a function of time after sample mixing. Curves generated from eqs. [24] and [25], respectively, using $k_n = 1.00 \times 10^4$ (M^{-1} s^{-1}), $c_{\text{M}}^0 = 10^{-6}$ M, and $\varphi = 0.400$.



3. Discussion

Equations [19] and [20]

Illustrated in Fig. 1 are solutions for eqs. [19] and [20] using the following parameters: $c_y^0 = 5 \times 10^{-7}$ M, $c_{\text{M}}^0 = 1 \times 10^{-6}$ M, $\varphi = 0.40$, and $k_n = 10^4$ M^{-1} s^{-1}. These curves look very similar in shape to those obtained experimentally by Wang et al. (24) and Procházka et al. (25) and suggest that our theoretical results agree with experimental results, at least qualitatively. We will report the treatment of our own experimental results elsewhere (30).

Both the increase in the fluorescence intensity of the acceptor and the decrease in that of the donor with time can be fitted using eqs. [20] and [19], respectively, to obtain k and thus k_n. The decrease in the fluorescence intensity of the donor with time is, however, richer in information as it can be fitted using eq. [19] to obtain both k_n and φ. Therefore, in this paper I emphasize the treatment of donor decay data.

Accuracy of the no more than one acceptor in one micelle approximation

In my derivation so far, I have assumed each micelle can, at most, contain one acceptor due to the low c_y^0/c_{M}^0 value. In reality, the equilibrium distribution of acceptors inside mi-

Table 1. Variation of $P(i)$ with $\langle s \rangle$ as calculated from the Poisson distribution and from solving eqs. [12]–[14] at $t = 1000$ s setting $m = 10$. The following parameters: $k_n = 1.00 \times 10^4$ (M^{-1} s^{-1}), $k_{-n} = 10^{-2}$ (s^{-1}), $c_M^0 = 10^{-6}$ M, and $\bar{n} = 100$, were used for solving eqs. [12]–[14].

	$\langle s \rangle$					
	0.100		0.500		0.900	
	Poisson	Our approach	Poisson	Our approrach	Poisson	Our approach
$P(0)$	0.905	0.906	0.607	0.604	0.407	0.387
$P(1)$	0.090	0.089	0.303	0.311	0.365	0.398
$P(2)$	0.009	0.004	0.076	0.073	0.165	0.164
$P(3)$	0.000	0.000	0.013	0.011	0.049	0.042
$P(4)$	0.000	0.000	0.002	0.001	0.011	0.008

celles obeys the Poisson distribution. Letting $c_y^0/c_M^0 = \langle s \rangle$, the probability $P(i)$ for a micelle to contain i acceptors is given by:

$$[21] \qquad P(i) = \frac{\langle s \rangle^i}{i!} \exp(-\langle s \rangle)$$

The variation of $P(i)$ with $\langle s \rangle$ for the $\langle s \rangle$ values of 0.100, 0.500, and 0.900 is tabulated in Table 1. Even when $\langle s \rangle$ = 0.50, the probability of finding two or more acceptors in a single micelle is already quite significant. This affects the φ and k_n results recovered by fitting donor fluorescence intensity decay curves using eq. [19]. The error introduced due to the use of eq. [19] for treating experimental data will be examined in this subsection.

The series of equations denoted by eq. [10] can be solved numerically for $[MPy_i]$, the concentrations of micelles with different numbers, i, of acceptors. From known $[MPy_i]$, the relative donor fluorescence intensity at time t can be calculated using:

$$[22] \qquad \frac{I(t)}{I(0)} = 1 - \sum_{i=1}^{\infty} \varphi(i) \frac{[MPy_i]}{c_M^0}$$

where $\varphi(i)$ is the efficiency of donor fluorescence quenching by i acceptor groups residing in a micelle. Due to the small $m/\bar{n}$ ratio, I assume that the rate constant $k_q(i)$ of fluorene fluorescence quenching by pyrene increases with the number i of quenchers in a micelle following:

$$[23] \qquad k_q(i) = ik_q(1)$$

where $k_q(1)$ is the rate constant of fluorescence quenching by one quencher in a micelle.
$\varphi(i)$ is defined by

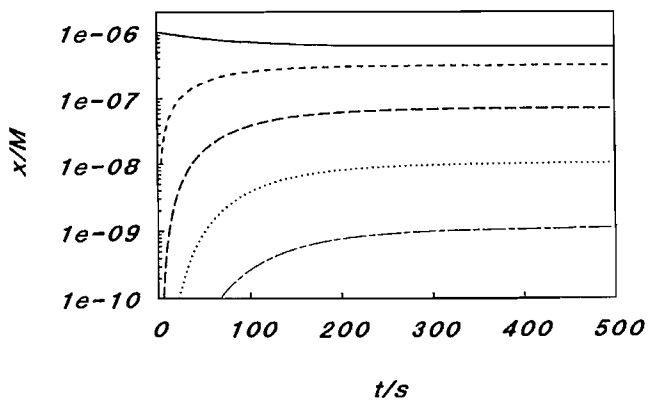
$$[24] \qquad \varphi(i) = \frac{ik_q}{ik_q + 1/\tau_0}$$

where τ_0 is the lifetime of fluorene in the absence of fluorescence quenching by pyrene. For a given $\varphi(1)$ not equal to 1, any other $\varphi(i)$ can be calculated using:

$$[25] \qquad \varphi(i) = \frac{i\varphi(1)/[1 - \varphi(1)]}{i\varphi(1)/[1 - \varphi(1)] + 1}$$

The relative donor fluorescence intensity at time t calculated using eq. [22] and $[MPy_i]$ solved from eq. [10] is the accurate result. The strategy here is to generate donor decay curves from this approach and then to fit the decay curves using eq. [19] to see how the recovered k_n and φ values deviate from k_n and $\varphi(1)$, input to estimate the error involved with the use of eq. [19].

Fig. 2. Variation in $[MPy_i]$ where $i = 0, 1, \ldots, 4$ (from top down as i increases) as a function of time after solution mixing. Curves generated from simultaneous differential equations [12]–[14] by setting $m = 4$, $k_n = 1.00 \times 10^4$ (M^{-1} s^{-1}), $k_{-n} = 10^{-2}$ (s^{-1}), $c_M^0 = 10^{-6}$ M, $c_y^0 = 0.500 \times 10^{-6}$ M, $\bar{n} = 100$, and $\varphi = 0.150$.



The set of curves in Fig. 2 illustrate how $[MPy_i]$, where $i = 0$, 1, 2, 3, and 4, vary with time after sample mixing. The curves were generated using $k_n = 1.00 \times 10^4$ M, $k_{-n} = 10^{-2}$ M, $c_M^0 = 10^{-6}$ M, $c_y^0 = 0.500 \times 10^{-6}$ M, and $\bar{n} = 100$. Initially, only MPy are formed in significant amounts. As time progresses, MPy_2, MPy_3, and then MPy_4 begin to form. At long times, the concentration of each species no longer changes significantly with time, indicating the establishment of acceptor distribution equilibrium. All these behaviors are intuitively expected and thus suggest the validity of our approach.

At sufficiently long times, the solution of eq. [10] gives the equilibrium concentrations of micelles containing varying numbers of PS-*Py*-PHEMA-Fl(y) chains. For a micellar system with $k_n = 1.00 \times 10^4$ M, $k_{-n} = 10^{-2}$ M, $c_M^0 = 10^{-6}$ M, and $\bar{n} = 100$ and varying c_y^0, I have solved $[MPy_i]$

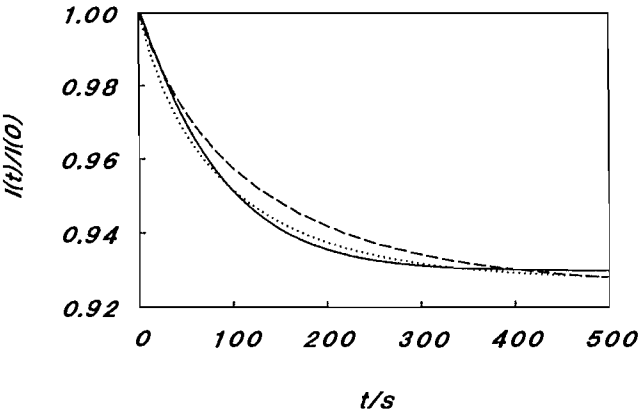
Fig. 3. Comparison of the transient donor intensity decay curve (—) generated using simultaneous differential equations [12]–[14] and eq. [27] with that (- - -) generated using eq. [24]. The shared parameters are $k_n = 1.00\times10^4$ (M^{-1} s^{-1}), $c_M^0 = 10^{-6}$ M, $c_y^0 = 0.500\times10^{-6}$ M, and $\varphi = 0.150$. The solution of the simultaneous differential equations also required the use of $\bar{n} = 100$, and $k_{-n} = 10^{-2}$ (s^{-1}). Also illustrated is the best fit (···) to (—) by eq. [24].



where $i = 0, 1, \ldots,$ and 4 at time $t = 10^3$ s, a sufficiently long time, and used them for calculating $P(i)$ from

$$[26] \qquad P(i) = \frac{[MPy_i]}{\sum_{i=0}^{4}[MPy_i]}$$

The $P(i)$ values calculated are tabulated in Table 1 for comparison with those calculated from the Poisson distribution given by eq. [21]. The superb agreement between these two approaches, particularly at low $\langle s\rangle$ values, confirms the validity of our solutions.

Illustrated in Fig. 3 is the comparison between a transient donor fluorescence intensity decay curve generated using the accurate approach described above from eq. [22] and that generated from eq. [19]. The curves were constructed using $k_n = 1.00 \times 10^4$ M, $c_M^0 = 10^{-6}$ M, $c_y^0 = 0.500 \times 10^{-6}$ M, and $\varphi(1) = 0.150$ in common. The construction of the decay curve from the more accurate approach also used $k_{-n} = 10^{-2}$ M and $\bar{n} = 100$. The $\bar{n}$ value of 100 is typical. The k_n value of 10^{-2} M was calculated from eq. [2] by assuming that $[M_{n-1}] \approx [M_n]$ and $[U] = 10^{-6}$ M. At $\langle s\rangle = 0.500$, substantial differences between results from the two approaches already exist.

At short times, the agreement between the two approaches is good. The slightly lower values of $I(t)/I(0)$ calculated from eq. [19] are due to neglecting, in the approximate approach, the dissociation of PS-*Py*-PHEMA-Fl(y) chains from micelles once they are incorporated into micelles. At intermediate times, the more accurate approach leads to lower $I(t)/I(0)$ values, because the formation of micelles with more than one PS-*Py*-PHEMA-Fl(y) chain is now substantial and these processes lead to the more rapid incorporation of PS-*Py*-PHEMA-Fl(y) chains and thus the more rapid decrease in $I(t)/I(0)$. At long times when the equilibrium quencher distribution is approximately established, lower quenching is obtained again from the more accurate approach. This is because $\varphi(i) < i\varphi(1)$ holds for all $i > 1$ according to eq. [25] and the uniform distribution of quenchers in micelles would lead to more quenching than is the case when quenchers are concentrated in relatively fewer micelles.

Table 2. Errors in recovered φ and k_n due to the use of eq. [24]. Also examined is the effect of $\varphi(1)$ input on the recovered φ and k_n values. Donor fluorescence intensity decay data were generated using eqs. [12]–[14] and [27] by setting $m = 10$, $k_n = 1.00 \times 10^4$ (M^{-1} s^{-1}), $k_{-n} = 10^2$ (s^{-1}), $c_M^0 = 10^{-6}$ M, and $\bar{n} = 100$.

s	φ	$k_n \times 10^{-4}$ (M^{-1} s^{-1})
$\varphi(1) = 0.150$		
0.100	0.147	1.07
0.300	0.145	1.22
0.500	0.146	1.39
0.700	0.147	1.53
0.900	0.152	1.57
$\varphi(1) = 0.300$		
0.100	0.291	1.08
0.500	0.278	1.43
0.900	0.281	1.70
$\varphi(1) = 0.500$		
0.100	0.481	1.08
0.500	0.442	1.49
0.900	0.430	1.84

Also illustrated in Fig. 3 is the best fit to the accurate curve by eq. [19]. The best fit was obtained by minimizing the following function:

$$[27] \qquad \chi^2 = \frac{1}{N}\sum_{i=1}^{N}\frac{[y_{cal}(i) - y_{sim}(i)]^2}{y_{sim}(i)}$$

where N, equal to 250 in this case, is the total number of data points fitted; $y_{sim}(i)$ and $y_{cal}(i)$ are the simulated donor intensity from the more accurate approach and data at time t_i calculated using eq. [19], respectively.

The error involved with the use of eq. [19] for fitting data calculated from the more accurate approach at different $\langle s\rangle$ and $\varphi(1)$ values can be seen from Table 2. As $\langle s\rangle$ increases, the assumption of no more than one quencher per micelle becomes increasingly invalid and it is expected that the error in k_n and φ values recovered will increase.

As input $\varphi(1)$ increases, φ recovered deviates more negatively from $\varphi(1)$. This is reasonable considering that $\varphi(i)$ becomes increasingly smaller than $i\varphi(1)$ for $i > 1$ as $\varphi(1)$ increases. If $\varphi(i)$ values are less than $i\varphi(1)$, it is expected that the quenching efficiency in a system where quenchers are distributed among different micelles according to the Poisson distribution is lower than in a system in which quenchers are uniformly distributed.

Effect of experimental errors on the recovered k_n and φ values

It is assumed, from now on, that all experimental data will be treated using eq. [19] because the error involved with its use can be estimated using Table 2 for cases when $\langle s\rangle \leq 0.900$.

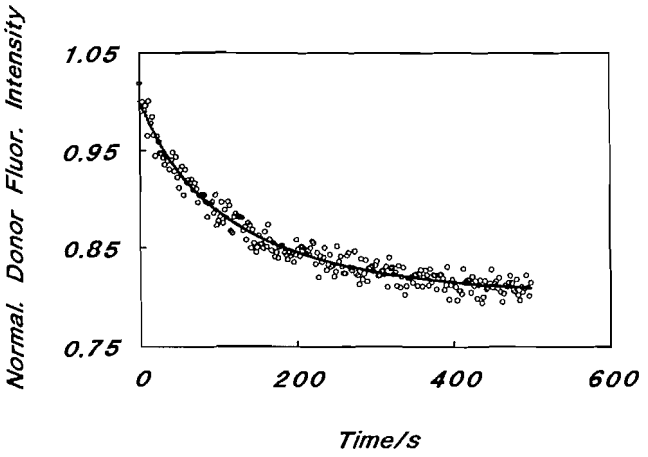
Fig. 4. Best fit (—) by eq. [24] to donor fluorescence intensity decay data (○) at a noise level $er\% = 1\%$. The noise-added data were derived from the curve in Fig. 1*a*.



What are to be examined next are the errors introduced to recovered k_n and φ values due to experimental uncertainties in c_M^0 and c_y^0 values and the statistical error in donor intensity decay data.

To simulate experimental donor fluorescence intensity data, noise has been added to the donor intensity decay curve shown in Fig. 1 using the following formula

$$[28] \qquad \frac{I(t)}{I(0)} = \frac{I(t)}{I(0)}[1 + er\% \times r(t)]$$

where $er\%$ is the average percentage error in the $I(t)/I(0)$ data and $r(t)$ are random numbers generated by an IMSL subroutine supported on our university computer system. The $r(t)$ values obey a Gaussian distribution with a zero mean and a variance of 1. After noise addition with $er\% = 1\%$, the donor decy curves of Fig. 1*a* are now illustrated in Fig. 4 by 250 data points represented by ○'s.

Noise-added curves were fitted using eq. [19] by minimizing χ^2 as defined by eq. [27]. The solid curve in Fig. 4 represents the best fit to the scattered data. Tabulated in the first three rows of Table 3 are φ and k_n values obtained by fitting donor fluorescence intensity decay curves at different noise levels. As noise level or $er\%$ increased, errors in recovered φ and k_n values increased and the errors seem to be smaller than $er\%$ in each case. Actual fluorescence intensity fluctuation should be less than ±1%. The error in recovered φ and k_n values due to fluorescence intensity fluctuation should be negligible.

The error in c_M^0 derives mainly from the uncertainty in the determination of $\bar{n}$. Assuming that a ±5% error is associated with the true c_M^0 values of 1.00×10^{-6} M, the error in recovered φ and k_n due to the wrongly input c_M^0 values of 0.95×10^{-6} and 1.05×10^{-6} M can be seen in Table 3. The relative error in recovered φ and k_n values is comparable with that in c_M^0.

The error in c_y^0 mainly derives from the uncertainty in the determination of the molar mass of PS-*Py*-PHEMA-Fl(y). The deviation in the c_y^0 values determined from the true value of 0.500 caused errors mostly in the recovered φ value. That a positive error in c_y^0 leads to a negative error in φ is expected,

Table 3. Effect on the recovered φ and k_n values of uncertainties in c_M^0 values and statistical errors in donor fluorescence intensity decay data. The true values should be 0.400 and 1.00×10^4 M^{-1} s^{-1}, respectively.

Source of error	φ	$k_n \times 10^{-4}$ (M^{-1} s^{-1})
er (%)		
1.000	0.3984	1.007
2.000	0.3970	1.017
3.000	0.3956	1.030
$c_M^0 \times 10^6$/M		
0.950	0.3803	1.064
1.050	0.4167	0.955
$c_y^0 \times 10^6$/M		
0.48	0.4140	1.003
0.52	0.3840	1.010

as the experimental degree of fluorescence quenching, approximately equal to $\varphi c_y^0/c_M^0$, should not vary with the erroneous assignment of c_y^0.

Other concerns

Other concerns about the validity of our kinetic scheme include the use of a single rate constant k_n for chain incorporation and of a single rate constant k_q for fluorescence quenching. The incorporation of a PS-*Py*-PHEMA-Fl(y) chain into a micelle is a complex process. The chain first of all has to encounter a micelle, squeeze through the corona layer to touch the core, and then the PHEMA block has to creep into the core. Of the three processes, the creeping of the PHEMA block into the core is the likely rate-determining step and k_n would be a measure of how fast this process occurs, as argued by Halperin and Alexander (20).

The quenching of fluorene fluorescence by a pyrene group in a micelle needs to be described by a few rate constants as shown previously by the author (32). After fluorene excitation, energy will be passed around among different fluorene groups due to energy migration until it finally arrives at the pyrene site and gets trapped. The rate constant of fluorescence quenching would depend on where in the core of a micelle, relative to the position of the pyrene trap, a fluorene group is initially excited by light absorption. The quenching rate constant would be larger if the initially excited fluorene group is closer to the pyrene. When we assume a single rate constant, i.e., $k_q(1)$, for fluorescence quenching, we are assuming the use of an average value.

4. Summary

A fluorescence experiment involving mixing donor-labeled micelles with acceptor-labeled unimers has been designed and a kinetic scheme describing such an experiment has been proposed. In the approximate form of this scheme, the concentration of acceptor-labeled unimers has been assumed to be low so that the probability for having micelles with more than one acceptor is negligible. Based on this assumption,

approximate analytical solutions were found for the decrease in the donor fluorescence intensity and the increase in the acceptor fluorescence intensity as a function of time after sample mixing. Treating the decrease in donor fluorescence intensity as a function of time using the derived equation allows the simultaneous determination of the rate constant k_n for unimer incorporation into micelles and the quenching efficiency φ of donor fluorescence by an acceptor in a micelle. Errors in k_n and φ determined due to the assumption of no more than one acceptor per micelle have been estimated for frequently encountered experimental situations by comparing donor fluorescence intensity decay data calculated from our approximate approach and those from a more accurate model. Also examined are possible errors in the determined k_n and φ values due to experimental uncertainties in the micellar concentration c_M^0 and acceptor-labeled chain concentration c_Y^0.

The described experiment is easy to carry out. If successful, it will be the first determination of k_n values for diblock micelles.

Abstract: Contrary to a previous report, it is concluded that formation of methanol adducts to 3-methyl-2-cyclohexenones and of deconjugated enones on irradiation of the enones in acidified solutions proceeds via protonation of the intermediate enone π,π^* triplet excited state and not by protonation of a relatively long-lived ground state *trans*-cyclohexenone. A rate constant for protonation of the triplet state of 3-methyl-2-cyclohexenone by sulfuric acid of 1.7×10^9 M^{-1} s^{-1} was determined by laser flash photolysis in ethyl acetate. Based on quantum efficiencies of product formation, a rate constant of ca. 10^8 M^{-1} s^{-1} was estimated for protonation of the enone triplet by acetic acid, which is too small to cause measurable reduction in the triplet state lifetime in the mM concentration range used in the preparative studies. The intermediate carbocation can be trapped by methanol, or revert to starting enone or the exocyclic deconjugated enone by loss of a proton. Since products revert to starting materials in an acid-catalyzed process, there is an acid concentration at which the yields of products are optimal. This concentration is ca. 6 mM for acetic acid, but is only 0.1 mM for *p*-toluenesulfonic or sulfuric acids. Product formation could be quenched using 1-methylnaphthalene and cyclopentene as triplet quenchers; in the latter case, formation of [2 + 2] photoadducts was observed to compete with formation of methanol adducts. Quenching rate constants were determined by laser flash studies.

Key words: laser flash photolysis, kinetic absorption spectroscopy (KAS), photoacoustic calorimetry (PAC), protonation of triplet states, *trans*-cyclohexenones.

Résumé : Contrairement à ce qui a été publié antérieurement, on montre que la formation d'adduits du méthanol avec les 3-méthylcyclohexén-2-ones et les énones déconjuguées, par irradiation des énones en solutions acidifiées, ne se produisent pas par le biais d'une protonation de l'état fondamental de la *trans*-cyclohexénone qui possède une durée de vie relativement longue. Faisant appel à la photolyse laser éclair dans l'acétate d'éthyle, on a déterminé que la constante de vitesse de protonation de l'état triplet de la 3-méthylcyclohexén-2-one, par de l'acide sulfurique, est de $1{,}7 \times 10^9$ M^{-1} s^{-1}. En se basant sur les efficacités quantiques de formation du produit, on a évalué que la constante de vitesse pour la protonation du triplet de l'énone par l'acide acétique est d'environ 10^8 M^{-1} s^{-1} qui est beaucoup trop faible pour provoquer une réduction mesurable du temps de vie de l'état triplet dans la zone de concentration (mM) utilisé dans les études préparatives. On peut piéger le carbocation intermédiaire par le méthanol ou le laisser retourner à l'énone de départ ou à l'énone exocyclique déconjuguée par perte d'un proton. Puisque les produits retournent aux produits de départ dans un processus acidocatalysé, il existe une concentration d'acide à laquelle les rendements en produits sont optimaux. Cette concentration est d'environ 6 mM pour l'acide acétique, mais elle n'est que de 0,1 mM pour les acides sulfurique et *p*-toluènesulfonique. La formation de produit peut être désactivée par l'utilisation du 1-méthylnaphtalène ou du cyclopentène comme désactivants des triplets; dans le dernier cas, on a observé la formation de photoadduits [2 + 2] qui sont en compétition avec la formation d'adduits du méthanol. On a déterminé les constantes de vitesse de désactivation à l'aide d'études au laser éclair.

Mots clés : photolyse laser éclair, spectroscopie d'absorption cinétique, calorimétrie photoacoustique, protonation des états triplets, *trans*-cyclohexénones.

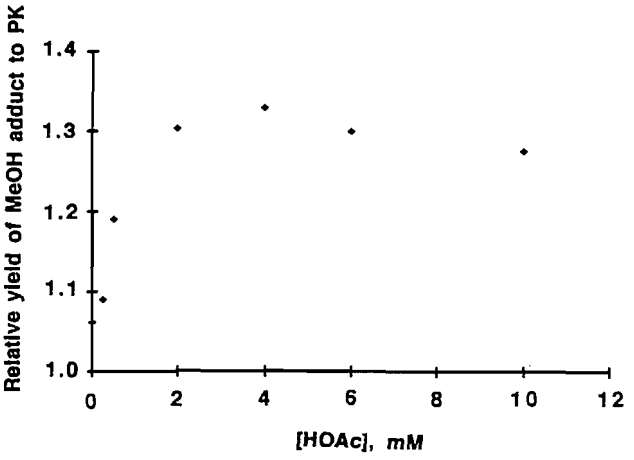
Introduction

It was reported by Rudolph and Weedon (1) that small amounts of acetic acid catalyze the photochemical addition of methanol to isophorone (**1***a*) in benzene or ethyl acetate solvents (see Scheme 1). The limiting quantum yield of this reaction (ϕ ca. 0.04) was reached at ca. 0.004 M acetic acid. The reaction is accompanied by deconjugation to enone **4***a*. Quenching of the reaction by isoprene (a common triplet quencher) gave a linear Stern–Volmer plot, implicating the T_1 state of **1***a* as the reactive intermediate. Formation of neither **3***a* nor **4***a* proceeds efficiently in the absence of acetic acid, or in neat methanol. The mechanism therefore appears to involve interaction of acetic acid with either the T_1 state of **1***a* or a subsequent intermediate to give carbocation **2***a* (or its enol tautomer), which then either deprotonates to give **4***a* or is trapped by methanol to give adduct **3***a*.

Based on an estimated triplet lifetime of 10 ns for **1***a*, Rudolph and Weedon (1) ruled out direct trapping of the triplet by 0.004 M acetic acid, since they estimated that a protonation rate constant of ca. 10^{12} M^{-1} s^{-1} was required, which would be higher than the diffusion-controlled rate. By analogy with the proposed mechanism for acid-catalyzed photochemical reactions of cyclohexenes (2), it was suggested that the reaction intermediate trapped by acetic acid was a ground state *trans* isomer of **1***a* with an estimated lifetime of 1 μs. Although *trans*-cyclohexenones have never been directly observed to date (3), stereochemical data consistent with the intermediacy of a *trans*-cyclic enone have been reported for the photochemical addition of methanol to Pummerer's ketone **5** (a 2-cyclohexenone) (Scheme 2) and for the photochemical addition of nucleophiles to 2-cycloheptenones and 2-cyclooctenones (4, 5). Based on kinetic data, Schuster et al. suggested that photochemical [2 + 2] cycloadditions of 2-cyclohexenones to alkenes might occur in some cases via transient twisted ground state *trans*-2-cyclohexenones (6). In response to the report by Rudolph and Weedon, we now report the results of steady-state and nanosecond flash photolysis studies of isophorone (**1***a*) and 3-methyl-2-cyclohexenone (**1***b*) in neutral and acidic media (7).

Fig. 1. Relative yield of methanol adduct of Pummerer's ketone (compound **6**) in benzene containing 10% methanol as a function of acetic acid concentration.



Results and discussion

A. Continuous irradiations

We first wanted to establish whether Pummerer's ketone (PK, **5**) behaved in a manner similar to that reported by Rudolph and Weedon for isophorone (1). Indeed, irradiation of PK in benzene containing 10% methanol and varying amounts of acetic acid led to a methanol adduct, according to GC–MS analysis, presumably the adduct **6** previously described by Hart and co-workers (4). As shown in Fig. 1, the yield of this adduct peaked at about 4 mM HOAc, consistent with the findings for isophorone (1). Having established this similarity in photochemical behavior, we decided to focus our studies on 3-methyl-2-cyclohexenone (**1***b*), which has been the subject of numerous mechanistic investigations in our laboratory (3, 6, 8–10).

Continuous irradiation of **1***b* in 90:10 ethyl acetate – methanol containing up to 0.008 M acetic acid gave **3***b* and **4***b*. These compounds were characterized by ^{1}H NMR spectroscopy and GC–MS (see Experimental for details). A plot of the yield of these products vs. the concentration of acetic acid is shown in Fig. 2. Analogous to the behavior of isophorone **1***a* and PK (see above), the yields of **3***b* and **4***b* level off at acetic acid concentrations above ca. 0.006 M. This behavior is probably due to the thermal instability of these products, which both undergo acid-catalyzed reversion to the starting material **1***b*. Upon irradiation of **1***b* in ethyl acetate – methanol containing a stronger acid, *p*-toluenesulfonic or sulfuric acid, **3***b* and **4***b* were again obtained, but in this case their yields sharply declined at acid concentrations above 10^{-4} M (Fig. 3).

Fig. 2. Relative yields of methanol adduct of 3-methylcyclohexenone (compound **3***b*,◆) and deconjugated enone (**4***b*,▲) in ethyl acetate containing 10% methanol as a function of acetic acid concentration.

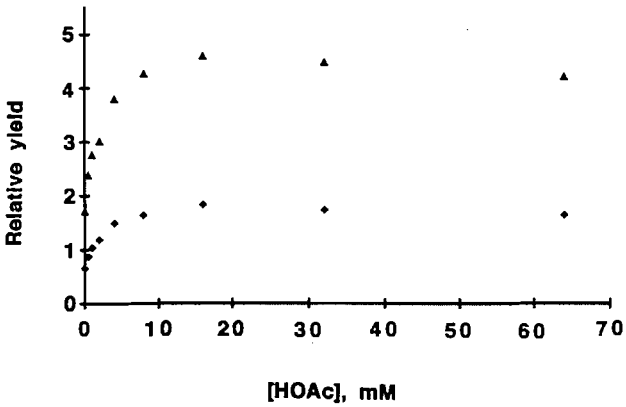

Fig. 3. (*a*) Relative yields of compound **3***b* as a function of the concentration of *p*-toluenesulfonic acid in ethyl acetate solvent. (*b*) Same as (*a*) but using sulfuric acid in place of *p*-toluenesulfonic acid.

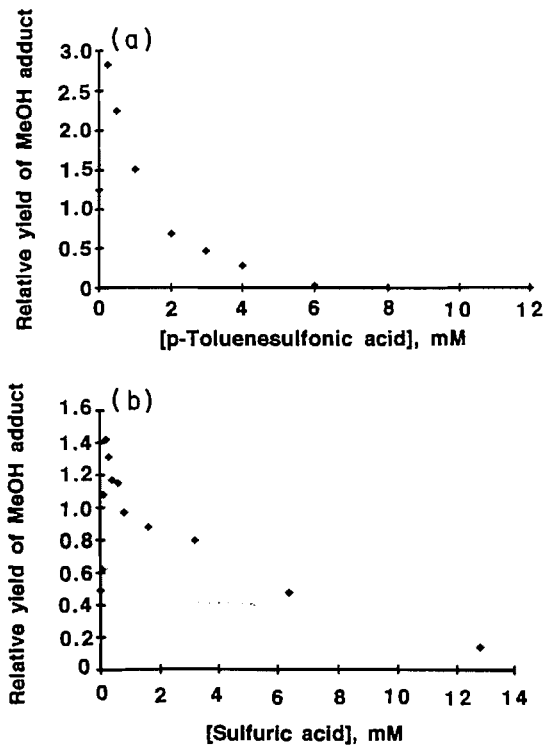
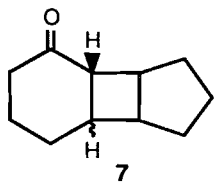


Although linear Stern–Volmer plots were obtained for quenching of both products by the triplet quencher 1-methylnaphthalene (1-MeNA), quantitative data in this system were not very reproducible, probably because of competitive light absorption by the quencher at the concentrations required for these experiments (up to 0.3 M) using broad spectral sources. Better data were obtained under similar reaction conditions using cyclopentene as the triplet quencher. In this case, a reduction in the yields of products **3***b* and **4***b* was observed concomitant with an increase in yields of the well-known [2+2] cycloadducts **7** (see Fig. 4). It is well established (8) that



7

photocycloaddition of enones to alkenes occurs via enone triplet excited states. Thus, the steady-state behavior of **1***b* in acidic methanol, which clearly occurs via triplet states of the enone, closely resembles that previously reported (1) for isophorone (**1***a*).

B. Laser flash photolysis — kinetic absorption spectroscopy

Using both nanosecond kinetic absorption spectroscopy (KAS) (8, 11) and time-resolved photoacoustic calorimetry (PAC) (9), the triplet lifetime of isophorone (**1***a*) in acetonitrile was found to be 79 ns, much higher than previously assumed (1). Thus, direct protonation of triplet excited states of **1***a* by acids is more likely than previously concluded (1). In principle, if the second-order rate constant for protonation of the triplet is sufficiently large, the enone triplet lifetime should decrease as a function of increasing acid concentration. We elected to use enone **1***b*, which, as shown above, behaves similarly to enone **1***a* under the photochemical reaction conditions.

For the laser flash (KAS) studies, **1***b* was excited with a 10 ns pulse of a YAG (355 nm) or nitrogen laser (337 nm). Following excitation, the triplet lifetime (τ_T) was determined from the decay of the transient absorption at 280 nm (8, 11). The values for τ_T measured under different conditions were 78 ± 2 ns in benzene containing up to 2×10^{-3} M HOAc; 73 ± 2 ns in neat EtOAc; 79 ± 2 ns in EtOAc–MeOH 90:10 containing up to 2×10^{-3} M HOAc; and 95 ± 3 ns in MeOH containing up to 7×10^{-3} M HOAc (the indicated errors reflect the 90% confidence limit). (Values of τ_T for enones are consistently higher in methanol than in nonpolar and aprotic polar solvents (3)). Thus, τ_T appears to be independent of the acetic acid concentration within experimental error. However, when acetic acid was replaced by sulfuric acid, direct quenching of the triplet of enone **1***b* in ethyl acetate was observed. From the Stern–Volmer plot shown in Fig. 5, a rate constant of 1.7×10^9 M^{-1} s^{-1} for protonation of the triplet of **1***b* was obtained using eq. [1]. This value can then be used to calculate the quantum yield

$$[1] \quad 1/\tau_{obs} = 1/\tau_0 + k_a[H^+]$$

$$[2] \quad \phi_a = k_a\tau_T[H^+]$$

of protonation of the triplet (ϕ_a) using eq. [2]. Thus, at a sulfuric acid concentration of 10^{-3} M, where τ_T was determined to be 58 ns, ϕ_a is ~0.1. This is slightly greater than the quantum yield of product formation (ϕ = 0.04), suggesting that deprotonation of carbocation **2**b to regenerate the starting material competes with formation of **3***b* and **4***b*.

Based on our value of τ_T for isophorone (**1***a*), the quantum yield reported (1) for formation of photoproducts **3***a* and **4***a* from **1***a* at 4×10^{-3} M acetic acid would require a rate constant k_a for protonation of the enone triplet by acetic acid of ca. 10^8

Fig. 4. (*a*) and (*b*) Relative yields of **3***b* and the *cis*- and *trans*-fused isomers of **7** upon irradiation of **1***b* in ethyl acetate containing 10% methanol and 10 mM acetic acid, as a function of the concentration of added cyclopentene. (*c*) and (*d*) Stern–Volmer plots of the ratio of the yields of **3***b* and **4***b* in the absence and presence of cyclopentene as a function of cyclopentene concentration.

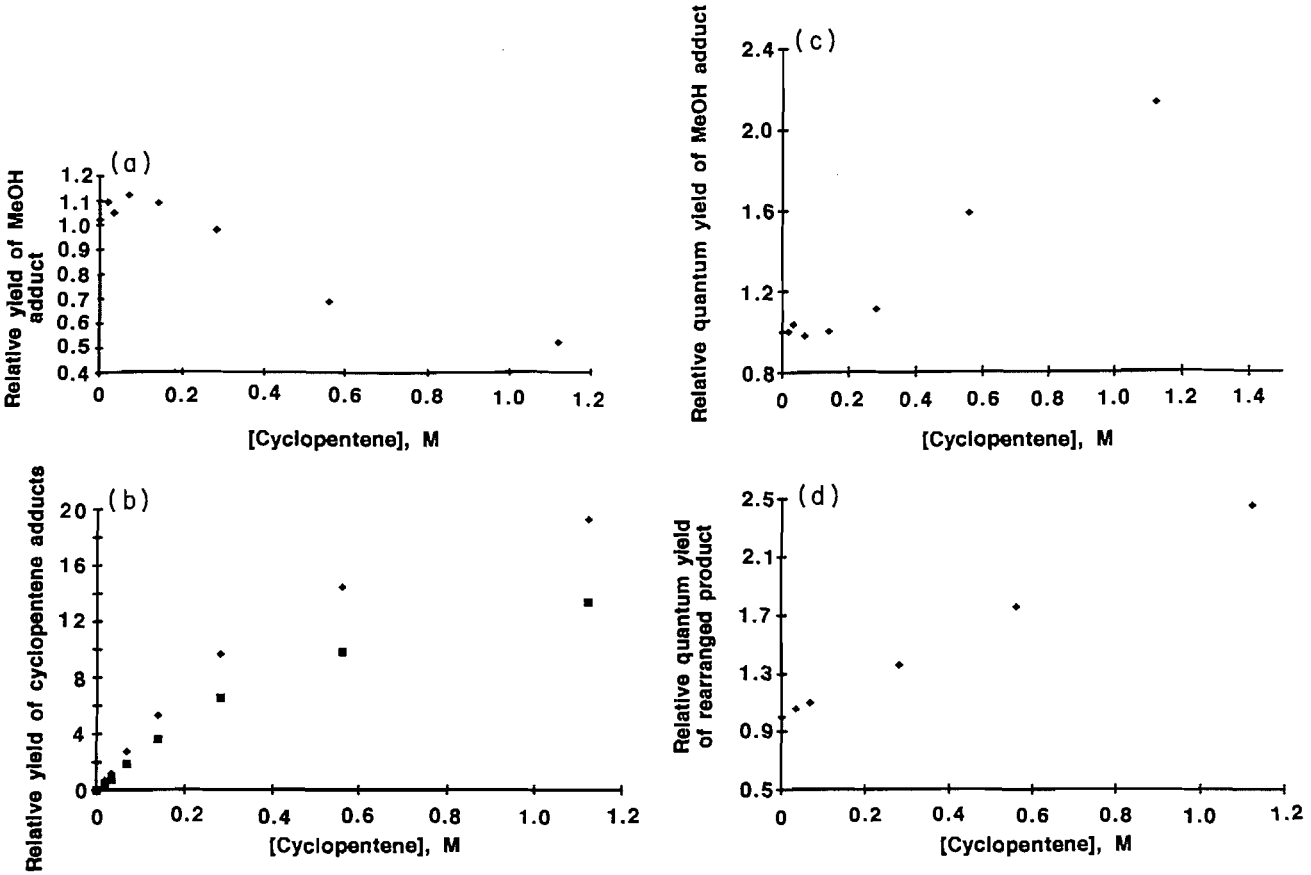


Fig. 5. Inverse triplet lifetime (in s^{-1}) of **1***b* in ethyl acetate as a function of sulfuric acid concentration.

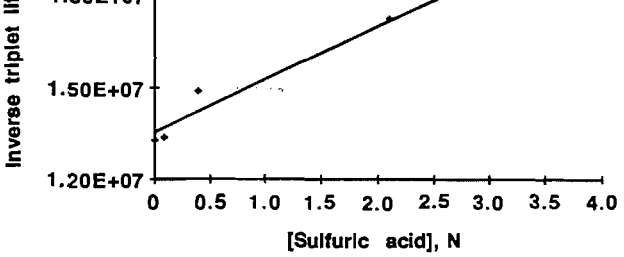

M^{-1} s^{-1} rather than the previous estimate (1) of 10^{12} M^{-1} s^{-1}. This lower value of k_a is realistic given that HOAc is a much weaker acid than H_2SO_4. Using eq. [1] it can be calculated that the reduction in τ_T for **1***b* would be too small to be detected by KAS over the HOAc concentration range (up to 7 mM) utilized in these studies, in accord with our observations.

Rudolph and Weedon (1) reported that the Stern–Volmer slope $k_q\tau_T$ for quenching of deconjugation of **1***a* by isoprene in benzene solvent was 60 M^{-1}, which is consistent with quenching of a triplet state of lifetime about 80 ns since rate constants for triplet energy transfer to acyclic 1,3-dienes in related systems are typically about 10^8 M^{-1} s^{-1} (8). Rudolph and Weedon (1) also showed a plot of the inverse quantum yield for deconjugation of **1***a* in benzene vs. the inverse concentration of acetic acid. Based on the slope and intercept of this plot, assuming a linear correlation, they concluded that the enone triplet state could not be the species undergoing protonation. In addition to their erroneous assumption regarding the rate of decay of the enone triplet, the significant deviation of their data from the assumed straight-line correlation at high acid concentrations was ignored. Given the kinetic and thermodynamic instability of the deconjugation product **4***b* observed in the present study (see Experimental), the validity of the quantum yield data reported for formation of **4***a* in acidic solution as well as the derived kinetic parameters (1) are open to question. In any event, the inconsistency between the kinetic data of Rudolph and Weedon (1) and the results of the present study need to be resolved.

As a check of the steady-state quenching studies discussed earlier, rate constants for quenching of triplet states of **1***b* by both 1-MeNA and cyclopentene were directly measured. Stern–Volmer plots of $(\tau_T)^{-1}$ vs. quencher concentrations in ethyl acetate (in the absence of methanol or acetic acid) afford quenching rate constants of 4.5×10^9 M^{-1} s^{-1} and 5.6×10^6 M^{-1} s^{-1}, respectively (see Figs. 6 and 7). The latter value is within a factor of 3 of that (1.6×10^7 M^{-1} s^{-1}) calculated from

Fig. 6. Inverse triplet lifetime (in s^{-1}) of **1***b* in ethyl acetate in the absence of methanol and acetic acid as a function of 1-methylnaphthalene concentration.

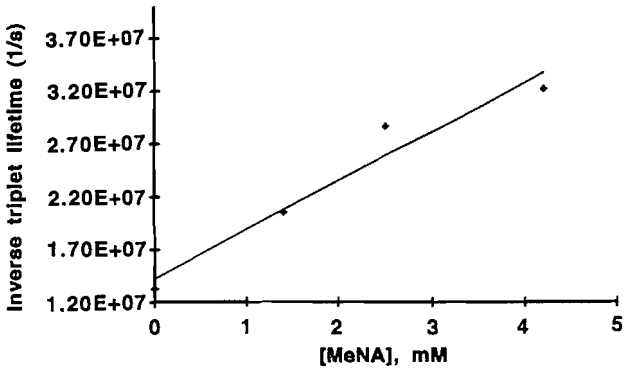

Fig. 7. Same as Fig. 6, but using cyclopentene as the triplet quencher.

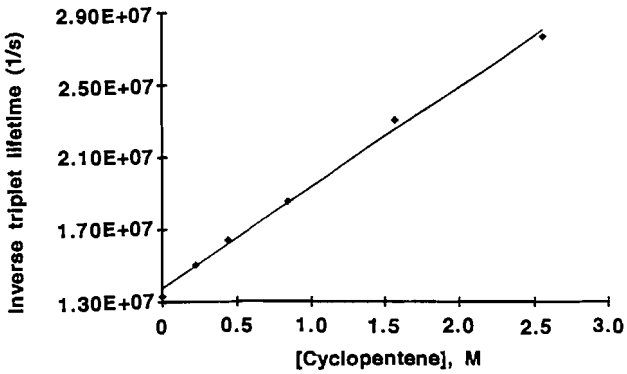

the slope (1.29 M^{-1}) of the steady-state Stern–Volmer plot in Fig. 4*b* under the reaction conditions, assuming a triplet lifetime of 80 ns. However, quenching of product formation by 1-MeNA is not nearly as efficient as expected from the diffusion-controlled triplet quenching rate constant measured by flash photolysis. A likely explanation is that under the steady-state reaction conditions, where 1-MeNA is competing with the enone for light with a broad spectral distribution generated from the Hanovia or Rayonet lamps (see Experimental), 1-MeNA may be acting as both a singlet sensitizer and a triplet quencher. This is not unreasonable since the singlet excited state lifetime of 1-MeNA is nearly 100 ns in polar solvents (12) and diffusion-controlled singlet energy transfer to **1***b* at a concentration of 0.07 M should be an efficient process.

Conclusions

Based on both steady-state and flash kinetic data, we conclude that it is highly probable that the species actually undergoing protonation in these reactions is the enone triplet excited state and not a ground state *trans*-cyclohexenone. The enone triplet in these systems is sufficiently long lived that direct quenching by acids to give the carbocations **2** is a kinetically viable process. Whether protonation of the triplet may be adiabatically reversible under these conditions remains in question. As far as the intermediacy of *trans*-cyclohexenones is concerned, we have repeatedly failed to detect such species on laser flash photolysis of a large number of cyclohexenones (8). Furthermore, PAC data (7, 9) for isophorone, 3-methyl-2-cyclohexenone, and other 2-cyclohexenones rigorously exclude the formation of a high-energy ground state intermediate with a lifetime in the microsecond range and measurable (>0.05) quantum efficiency. That is, intersystem crossing and radiationless decay of the enone triplet accounts for essentially all (>98%) of the energy of the absorbed photon. Substantial heat discrepancies are seen only in cases where bona fide strained ground state *trans* isomers are formed, as with 1-acetylcyclohexene (13). As noted earlier, some inconsistencies between our present data and the earlier report by Rudolph and Weedon (1) remain to be resolved. Theoretical calculations by Johnson[2] indicate that *trans*-2-cyclohexenones indeed appear to lie in a potential minimum on the 2-cyclohexenone ground state energy surface. However, under ambient conditions, the lifetimes of such species are expected to be extremely short, probably on the order of nanoseconds or even less. Thus, we conclude that *trans*-cyclohexenones are not likely intermediates in the photoreactions of cyclohexenones under the acidic conditions described in this paper and in the earlier study (1), and that the only hope of observing such species spectroscopically is by generating them in particularly favorable systems at very low temperatures.

Experimental

A. Laser flash photolysis

General sample preparation

Commercially available 3-methyl-2-cyclohexenone, cyclopentene, and 1-methylnaphthalene were purified by careful distillation. All the solvents employed were either HPLC grade or spectrograde. Sample solutions were prepared by weighing the enone in volumetric flasks followed by addition of the proper amount of other chemicals such as methanol or acetic acid into the flask and adding the solvent to the mark. A pipet was used to transfer solutions to the reaction cells. The optical density of the solutions studied ranged from 0.5 to 1.0 at the excitation wavelength. All samples were purged with either argon or oxygen-free nitrogen for at least 10 min prior to the experiments. Quenchers (either neat or in solution) were added using a microlitre syringe. At Columbia University, data was obtained by averaging 10–30 laser pulses in each measurement depending on the signal-to-noise ratio. At the National Research Council in Ottawa, data from 30–200 laser pulses were averaged.

Apparatus and procedures

The nanosecond laser flash photolysis configurations at Columbia University and at the National Research Council of Canada are very similar, but differ in details such as the type of laser used and in the arrangement of the exciting and analyzing beams. In experiments carried out at Columbia University (14), a Quanta Ray Q-switched Nd-YAG laser was used. After pulse selection, amplification, and frequency conversion, pulses of duration of ca. 6 ns and energies of 2–5 mJ/pulse, which varied less than 10% in intensity at 355 nm, were provided. The exciting and analyzing beams were oriented at

[2] R. Johnson, University of New Hampshire, private communication of unpublished results.

For personal use only.

right angles (crossed-beam arrangement). The analyzing light source was a 150 W xenon lamp (Oriel). The samples (2 mL) were contained in Super cells with a 10 mm optical path.

At the NRC in Ottawa (15), a Molectron UV-24 nitrogen laser, providing pulses of 8–10 ns and energies up to 10 mJ at 337.1 nm, was employed. A crossed-beam arrangement with an angle of 15° was used throughout. The use of this small angle configuration considerably decreases the volume irradiated and is more convenient for lower energy lasers (16). A pulsed 200 W xenon lamp was employed in the monitoring system and a high-intensity B & L monochromator and an RCA-4840 photomultiplier tube were used at the detection end. The photomultiplier response was fed to a 7A16A plug-in used in a R7912-Tektronix transient digitizer that contains a 4K local memory in which each trace was stored. The samples (1 mL) were contained in Suprasil cells made of 7 × 3 mm rectangular tubing (Vitro Dynamics). The temperature of the cell was controlled by a constant-temperature nitrogen flow and was measured with a copper–constantan thermocouple.

At both laboratories, the lifetime of the optically detected transient is determined from the slope of a plot of ln (I/I_0) as a function of time. Although the data collection and analysis were controlled by the computer using programs developed individually in each lab, the baseline and region of the trace to be analyzed is determined manually by the operator. The error in the triplet lifetimes evaluated by the present analyzing method is estimated to be ±10%.

B. Steady-state photolyses

All preparative reactions were done using a Rayonet 350 nm Srinivasan–Griffin photochemical reactor, which has a broad range from 300 to 400 nm, with a maximum at 350 nm, a Hanovia 550 W high-pressure mercury arc lamp, or a Hanovia 450 W medium-pressure mercury arc lamp. The latter two required a water-cooled jacket and the samples were suspended in Pyrex test tubes outside the immersion well. All three reactors were equipped with a merry-go-round rotating turntable for even irradiation of each sample. Samples in Pyrex tubes that filter out light below 280 nm were purged with argon for 10 min prior to irradiation. All reactions were monitored by capillary GC analysis, using either a Hewlett–Packard model 5890 gas chromatograph equipped with a Hewlett–Packard 3396A integrator or a Hewlett–Packard 5710A gas chromatograph equipped with an 18740B capillary column control, 5702A oven temperature programmer, and a 3390A integrator. The same type of capillary column (Alltech, 30 m × 0.25 mm Heliflex, RSL-150) was used throughout. *n*-Dodecane was used as the internal standard. The major products formed in the reaction were analyzed by GC–MS, using a Hewlett–Packard model 5992 GC–MS system equipped with a Hewlett–Packard 20 m × 0.25 mm cross-linked methyl silicone capillary column. Ultraviolet absorption spectra were obtained with a Cary 210 double-beam spectrophotometer.

Preparative cycloaddition of methanol to Pummerer's ketone **5**

Pummerer's ketone (PK) was synthesized and purified as described in the literature (4). A series of benzene solutions containing 0.145 M PK and 10% MeOH and various concentrations of acetic acid were prepared. The final concentrations of acetic acid were 0.0, 0.25, 0.50, 1.00, 2.00, 4.00, 6.00, and 10.00 mM. These solutions in Pyrex tubes were purged with argon for 10 min and irradiated with a Hanovia 450 W lamp for 45 h. One new product was formed in the reaction, which was confirmed by GC–MS to be the PK–methanol adduct. The mass spectrum of the adduct, *m/z* (relative intensity), was 246 (42.7) M^+, 160 (14.9), 159 (79.9), 147 (11.4), 146 (100), 145 (49.0), 115 (15.5), 91 (10.0).

*Optimization of photoaddition of methanol to 3-methyl-2-cyclohexenone (**1**b)*

This experiment was carried out in ethyl acetate solvent with a series of solutions containing 0.145M **1***b*, 10% methanol, and acetic acid concentrations of 0.00, 2.00, 4.00, 8.00, 16.00, 32.00, and 64.00 mM, respectively. The samples were purged with argon for 10 min and then irradiated for 24 h. Several new species appeared on GC analysis, which corresponded to compounds **3***b*, **4***b*, and trace amounts of 3-methyl-3-cyclohexenone (**8**) and enone photodimers. The mass spectra of each component, *m/z* (rel. intensity), were as follows: **3***b*: 142 (10.2) M^+, 110 (11.8), 85 (83.1), 72 (40.6), 54 (100), 42 (86.0); **4***b*: 110 (20.2) M^+, 82 (100), 54 (35.2), 41 (14.5); **8**: 110 (10.3), 82 (20.1), 55 (25.0), 43 (100.0). Similar results were obtained when benzene was employed as the solvent. When sulfuric acid or *p*-toluenesulfonic acid was used as the catalyst, the acid concentrations in the tubes were 0.0, 0.025, 0.05, 0.1, 0.2, 0.4, 0.8, 1.6, 3.2, 6.4, and 12.8 mN, respectively. The results otherwise were similar to those obtained using acetic acid as the catalyst.

*Preparative scale irradiation of 3-methyl-2-cyclohexenone (**1**b) in methanol*

To 335 μL (4.5 mmol) of **1***b* in a 35 mL Pyrex test tube were added 3.1 mL MeOH, 28 mL EtOAc, and lastly 17 μL of HOAc. The final concentrations of **1***b* and HOAc were 0.14 M and 0.01 M, respectively. Each solution was then sealed with a rubber septum and purged with argon for 30 min. Each sample was then irradiated with a 450 W medium-pressure Hg arc lamp fitted with a water-cooled jacket at a distance of about 1 cm from the jacket for 18 h. GC–MS analysis of the irradiated mixture indicated conversion to two major photoproducts. The crude mixture was then washed ($NaHCO_3$, water, and brine), dried over anhydrous $MgSO_4$, gravity filtered, and concentrated in vacuo. When washings were not performed and the sample was concentrated immediately after irradiation, the deconjugated product **4***b* decomposed. The crude ^1H NMR spectrum (200 MHz, $CDCl_3$) of the washed photoproduct indicated the presence of some unreacted **1***b* along with methanol adduct **3***b* ((s, 3.15 ppm, 3H, $-OCH_3$; m, 1.5–2.6 ppm, $-CH_2-$; s, 1.21 ppm, 3H, $-CH_3$), lit. NMR in CCl_4 (17) (s, 3.00 ppm, 3H, $-OCH_3$; m, 1.5–2.5 ppm, 8H, $-CH_2-$; s, 1.15, 3H, $-CH_3$)) and deconjugated product **4***b* (m, 4.77 ppm, 1H, vinyl H, J = ~1 Hz; m, 4.69 ppm, 1H, vinyl H, J = ~1 Hz; d, 3.08 ppm, 2H, allylic H α to the carbonyl, J = 1.14 Hz; m, 1.5–2.5 ppm, $-CH_2-$). Attempts to purify previously uncharacterized **4***b* were not successful since **4***b* slowly decomposed on distillation (55°C, 1.5 Torr; 1 Torr = 133.3 Pa), and completely decomposed on chromatography on silica (1:1 pentane:EtOAc) or activated basic Brockmann 1 alumina (EtOAc). As **4***b* decomposed, the ratio between the ^1H NMR peaks at 4.69 and 4.77 to the allylic proton α to the carbonyl (3.08) remained constant.

Quenching of the photoaddition of methanol to 3-methyl-2-cyclohexenone by cyclopentene

Cyclopentene was added using a microlitre syringe to solutions containing 0.145 M **1***b*, 10% MeOH, and 10 mM HOAc, to give final cyclopentene concentrations of 0.00, 0.020, 0.035, 0.070, 0.14, 0.28, 0.56, and 1.12 M, respectively. The solutions were purged with argon for 10 min, then irradiated through Pyrex using a 350 nm Rayonet Lamp for 17 h, and were then analyzed directly using capillary GC.

Quenching of the photoaddition of methanol to 3-methylcyclohexenone by 1-methylnaphthalene

Benzene solutions were prepared containing 0.07 M **1***b*, 10% MeOH, 10 mM HOAc, and *n*-dodecane as an internal standard for GC analyses. Varying amounts of 1-methylnaphthalene were added to give final concentrations of 0.020, 0.035, 0.070, 0.14, and 0.28 M, respectively. The solutions in Pyrex tubes were purged with argon, irradiated for 20 h using a 550 W Hanovia lamp, and then analyzed for products **3***b* and **4***b* using capillary GC.

Acknowledgments

Studies of the inhibition of autooxidation of polypropylene with 4,4′-bis(2,6-di-*tert*-butylphenol)

E.L. Shanina, G.E. Zaikov, and N.A. Mukmeneva

Abstract: The kinetics of 4,4′-bis(2,6-di-*tert*-butylphenol) (BP) consumption in the oxidation of polypropylene (PP) at 130°C in air has been studied. It is shown that 3,3′,5,5′-tetra-*tert*-butyl-4,4′-diphenoquinone (DPQ) is the main product of conversion of the starting BP. An effect of synergism has been revealed on studying stabilization of PP with BP–DPQ mixtures. The antioxidative activity of BP was compared with that of some other stabilizers.

Key words: polypropylene oxidation, antioxidative activity, 4,4′-bis(2,6-di-*tert*-butylphenol), 3,3′,5,5′-tetra-*tert*-butyl-4,4′-diphenoquinone.

Résumé : On a étudié la cinétique de la consommation du 4,4′-bis(2,6-di-*tert*-butylphénol) (BP) lors de l'oxydation du polypropylène (PP) à 130°C, dans l'air. On montre que le produit principal de la conversion du BP de départ est la 3,3′,5,5′-tétra-*tert*-butyl-4,4′-diphénoquinone (DPQ). On a mis en évidence un effet de synergie lors de l'étude sur la stabilisation du PP par des mélanges de BP-DPQ. On a comparé l'activité antioxydante du BP avec celles d'autres stabilisants.

Mots clés : oxydation du polypropylène, activité antioxydante, 4,4′-bis(2,6-di-*tert*-butylphénol), 3,3′5,5′-tétra-*tert*-butyl-4,4′-diphénoquinone.

[Traduit par la rédaction]

Introduction

In spite of the fact that many new antioxidants and even whole classes of novel compounds with antioxidant activity have been developed, the sterically hindered phenols are still of practical and scientific interest. The careful study of the properties and behavior of such phenols in oxidizable systems suggests that the potential of these compounds is still far from exhausted and further research in this direction promises new prospects. In this connection, it is 4,4′-bis(2,6-di-*tert*-butylphenol) (bisphenol-1, BP-1) that seems to be one of the most promising inhibitors in the class of sterically hindered phenols. Some peculiarities of the inhibition of the autooxidation of solid state isotactic polypropylene (PP) with this particular bisphenol are considered in this work.

Experimental

Thoroughly purified isotactic Moplen grade PP with intrinsic viscosity 1.53 dL/g (decalin, 135°C) and crystallinity of 60% was used in the form of a finely dispersed powder with a particle size $\leq 5 \times 10^{-3}$ cm. Octadecyl 3,5-di-*tert*-butyl-4-hydroxyphenolpropionate (phenol-1) and 2,6-di-*tert*-buty-4-methylphenol (Hinmont, phenol-2) were used as inhibitors without further purification. The initiator, dimethylacetylene carbinol (DAC) was purified by recrystallization from heptane and ethanol. Cumene was purified as described previously (1). Samples of polymer were oxidized at 130°C in air under conditions that excluded the loss of additives due to evaporation. The inhibitor content in the polymer was calculated after its extraction from PP with chlorobenzene and subsequent determination of the induction period for oxidation of the cumene–initiator–inhibitor extract mixture. The procedures for preparing the oxidizing samples, measuring the induction period for oxidation of the polymer in the solid state, and determining the inhibitor concentration were reported in detail previously (2, 3). The concentration of 3,3′,5,5′-tetra-*tert*-butyl-4,4′-diphenoquinone (diphenoquinone, DPQ) in PP was determined spectrophotometrically with a Specord UV–vis instrument after extracting the DPQ from the polymer with heptane. In preliminary tests the DPQ was shown to be the only conversion product of the starting bisphenol-1 that absorbs in the visible region of the spectrum, with an extinction coefficient equal to 8.3×10^4 L mol^{-1} cm^{-1} (heptane, $\lambda = 422$ nm).

The DPQ used was prepared according to the literature procedure (4) by oxidizing 2,6-di-*tert*-butylphenol with molecular oxygen in the presence of the pyridine–CuCl catalytic system. The starting bisphenol-1 was synthesized by the oxidative dehydrogenation of 2,6-di-*tert*-butylphenol with PDQ in the presence of an alkaline catalyst (5).

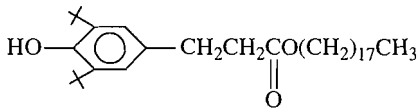
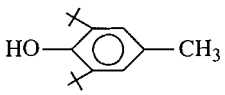
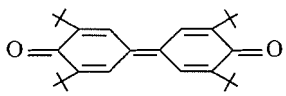
Bisphenol-1 (BP-1)



Phenol-1



Phenol-2



Diphenoquinone (DPQ)

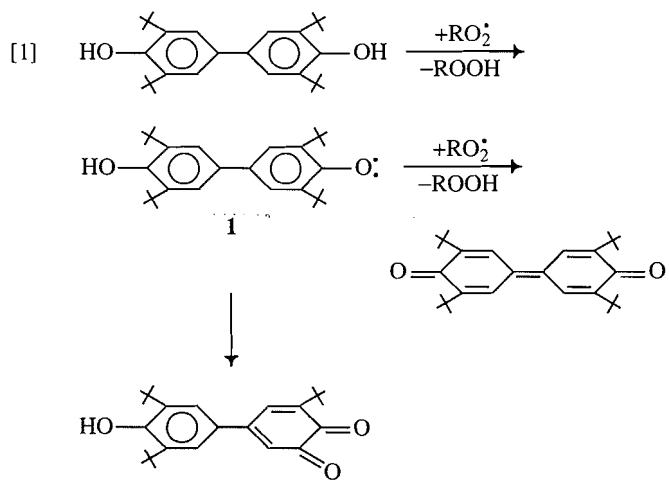
X = *tert*-butyl-$C(CH_3)_3$

Results and discussions

Bisphenol-1 inhibits oxidation of cumene at 60°C, with the inhibition coefficient (f) dependent upon the initiation rate W_{in} as shown below:

$W_{in} \times 10^6$ mol L^{-1} s^{-1}	1.8	0.14	0.17
f	1.8	2.1	2.8

Some of the values exceed those usual for inhibitors of this type. The value of 2 implies ease of quinoid structure formation. The experimental f values under the conditions of the initiated oxidation can be explained by a number of factors. Thus, a hydroxybiphenyloxy radical (**1**) arising from a reaction of bisphenol-1 with a peroxy radical $RO_2^{\bullet}$ may then react with another peroxy radical $RO_2^{\bullet}$ to give either diphenoquinone or the corresponding quinophenol (**2**); the formation of the latter may be accompanied by an enhancement of the inhibition coefficient f.



2

At high initiation rates, however, the inhibition coefficient f may be diminished owing to a reaction of hydroxybiphenyloxy radical with oxygen.

The consumption of bisphenol-1 in the course of oxidation of PP is shown in Fig. 1. The kinetic curve obtained cannot, however, be defined by a simple kinetic equation although, by analogy with other sterically hindered phenols, one can suppose that the initial rate of bisphenol-1 consumption (3.6×10^{-8} mol kg^{-1} s^{-1}) characterizes the rate of its oxidation with atmospheric oxygen (2). Bisphenol-1 is shown to be easily oxidized in air. Even thoroughly purified samples of it may contain a small admixture of diphenoquinone, e.g., up to 0.0015% in BP-1 used in this work, according to spectral data. Though one could assume that such an easily oxidizable inhibitor as bisphenol-1 does not possess a high antioxidative activity, a simple comparison of the gross index, the induction period, for oxidation of PP per se and its mixtures with three different additives (bisphenol-1, phenol-1, and phenol-2) disproves this assumption. At the same initial concentration bisphenol-1 appears to be at least as effective as phenols 1 and

Fig. 1. The kinetics of bisphenol-1 consumption (•) and diphenoquinone accumulation (○) in oxidizing polypropylene (130°C in air).

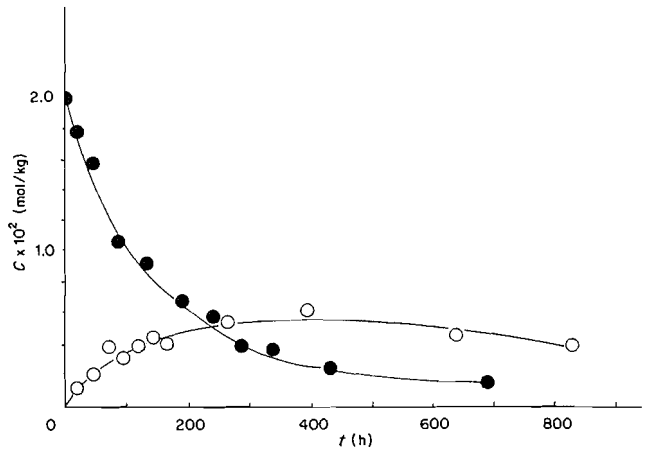


Table 1. The antioxidative efficiency of phenolic inhibitors in the oxidizing solid state of PP (130°C).[a]

Inhibitor (In)	[In] × 10^4 mol/kg	Induction period (h)
Bisphenol-1	5.0	170
Phenol-1	5.0	90[b]
Phenol-2	5.0	90[b]
Bisphenol-1	2.0	20
Phenol-1	2.0	18
—	—	0.5

[a]The phenols used under the conditions of the initiated oxidation (cumene–DAC–phenol–chlorobenzene) differ in value of the stoichiometric initiation coefficient f. However, so long as the f values are unknown, due to the more complex kinetics of the process under the conditions of autooxidation, samples were taken with the same concentration of an inhibitor.

[b]It is of interest to note that under the conditions of the runs described, in which the inhibitor volatility is of no importance, the efficiencies of phenols 1 and 2 are identical.

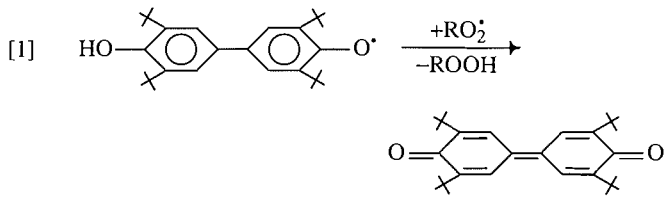
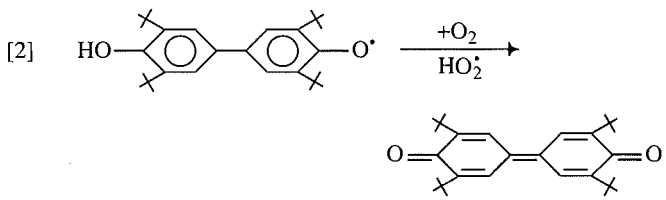
2, respectively (Table 1). In Fig. 1 there is also shown the change in diphenoquinone concentration, the main conversion product in the course of the bisphenol-1 consumption. For example, the initial rate of diphenoquinone accumulation is 1.6×10^{-8} mol kg^{-1} s^{-1}, which is more than twice as small as the rate of bisphenol-1 consumption. It seems quite probable that several processes may contribute to the formation of diphenoquinone.

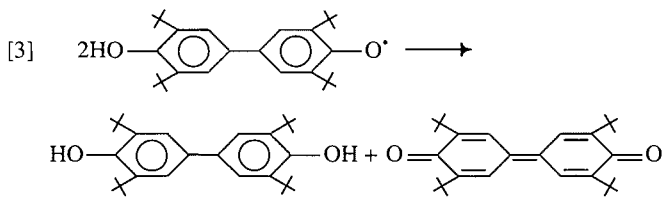
1. A reaction ([1]) of the hydroxybiphenyloxy radicals with peroxy radicals



2. A reaction ([2]) of the hydroxybiphenyloxy radicals with atmospheric oxygen



3. A reaction ([3]) of disproportionation of the hydroxybiphenyloxy radicals



Whereas in the liquid phase the rate constant of this reaction is $\sim 10^6$ L mol^{-1} s^{-1} (6), in the solid state there is a possible leveling of the rate constants and this reaction can play a significant role.

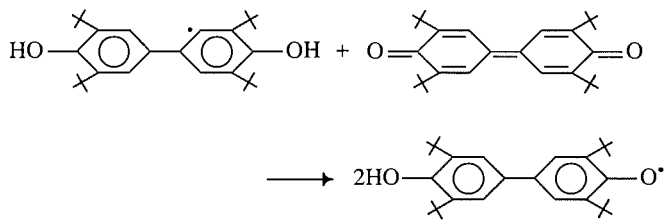
4. Various reactions of quinolide peroxide decomposition

However, the corresponding curve in Fig. 1 shows clearly that diphenoquinone is not only accumulating, but also is consumed in the process of the inhibited oxidation of the polymer, thus appearing as an active intermediate. So the data obtained have led to the necessity of a more detailed study of the role of diphenoquinone in the process of PP oxidation inhibited by bisphenol-1. With this aim in view, a series of tests were carried out to determine the induction periods for the oxidation of PP samples that contain both bisphenol-1 and diphenoquinone in various ratios, with the total concentration being constant. The results are summarized in Table 2.

As apparent from these data, under the conditions of PP autooxidation at 130°C, diphenoquinone acts in fact as an inhibitor, though it is much less effective than bisphenol-1. However, the inhibiting activity of quinones is known to manifest itself, as a rule, under conditions of oxygen deficiency. Hence, insofar as the ratio of concentrations of alkyl and peroxide macroradicals in the oxidizing solid polymer is higher than that, for example, in the liquid phase, the induction period in the tests in which diphenoquinone was added may have been caused by its reaction with alkyl radicals. The bisphenol-1–diphenoquinone mixtures, in which the content of the former exceeds 50%, are protecting the polymer more effectively than bisphenol-1 itself.

Table 2. The antioxidative efficiency of the BP–DPQ mixtures in the process of PP autooxidation.

[BP] × 10^4 mol/kg	[DPQ] × 10^4 mol/kg	Induction period (h)
5.0	—	155
4.0	1.0	220
3.0	2.0	270
2.0	3.0	50
1.0	4.0	25
—	5.0	10



The observed synergism of action of the bisphenol-1–diphenoquinone mixtures may be caused by reaction between the components to produce the hydroxybiphenyloxy radicals. In any case, the synergism of the phenol–quinone mixture in the liquid phase has been interpreted in the same way (7). In terms of the formal kinetics, the above-mentioned reaction between bisphenol-1 and diphenoquinone will not necessarily result in an increase in the antioxidative activity of the mixture, since, instead of a molecule of bisphenol-1 capable of terminating two kinetic chains, there are formed two hydroxybiphenyloxy radicals, each of which is capable of terminating one kinetic chain. However, under the conditions of the autooxidation process, when the initiation rates are low, some side reactions with the participation of both bisphenol-1 and the hydroxybiphenyloxy radicals may also occur along with the "classical" reactions of the inhibited oxidation, thus decreasing values of the stoichiometric inhibition coefficient f. Besides, a certain gain in the antioxidative efficiency can also be attained owing to the possible formation of the additional oxyradicals from the hydroxy groups of various monophenols arising in the process of the inhibited oxidation.

One more mechanism is reported in the literature that seems to be suitable for interpreting the observed syneristic effect, namely, the formation of phenoxyl radicals from reaction of a quinone with hydroperoxide radicals (8). The latter are believed to be generated from hydrogen peroxide derived in its turn by splitting off the hydroperoxide groups from the oxidized polymer. The alternation of a reaction of a hydroperoxide radical with quinone (Q), leading to the formation of a phenoxyl radical (PhO·), and a reaction of the latter with an

alkylperoxide radical ($RO_2^{\bullet}$)of the substrate creates an effect of repeated termination of kinetic oxidation chains:

$$HO_2^{\bullet} \xrightarrow{Q} PhO^{\bullet} \xrightarrow{RO_2^{\bullet}} Q \xrightarrow{HO_2^{\bullet}} PhO^{\bullet} \quad \text{etc.}$$

As a matter of fact, under the conditions of experiments carried out in this work, the polymer is practically not oxidized, and therefore the content of hydrogen peroxide is very low. In this case, however, a reaction [2] of oxidation of the hydroxy-

[2] 
biphenyloxy radicals could serve as an alternative source of the hydroperoxy radicals $HO_2^{\bullet}$

Since this reaction is reversible, at high concentrations of diphenoquinone the equilibrium can be shifted toward the formation of the hydroxybiphenyloxy radicals.

The experimental data obtained appear to be insufficient to solve the problem of the mechanism responsible for the synergistic effect in the PP–bisphenol-1–diphenoquinone system. It should, however, be noted that although reactions which can in principle occur in the autooxidizing polymer, a phenolic inhibition system, have been explored fairly well, a kinetic characterization of the process for individual specific systems appears to present great difficulty. In addition to a large number of reactions with the participation of both the inhibitor and the radical thereof, the situation is complicated by the formation of active molecular conversion products from the initial bisphenol-1. Among them there can be compounds with prooxidative activity (e.g., quinolide peroxides) and the so-called secondary inhibitors of oxidation (e.g., new binuclear phenols, quinones, active radicals thereof, etc.).

The complicated mechanism of the process of inhibited autooxidation of polymers makes it practically impossible to compare the activity of the antioxidant using only one parameter, for example, oxidation with atmospheric oxygen. The PP–bisphenol-1 system gives clear proof of the fact that the easy oxidizability of the inhibitor, decreasing its efficiency, can be compensated for by formation of a new active product, diphenoquinone. The synergistic effect of the mixture of diphenoquinone and the starting bisphenol-1 substantially increases the protection of the polymer against oxidation, producing under the above-mentioned experimental conditions a better result than that obtained with such a widely used inhibitor as phenol-2.

It was also of interest to compare the antioxidative activity of bisphenol-1 with that of structurally similar bisphenol-2 and bisphenol-3. Under the conditions of oxidation at 130°C, the values of the induction period found for the samples containing bisphenol-1, bisphenol-2, or bisphenol-3 appeared to be 100, 45, and 20 h, respectively. Though efficiency of an inhibitor depends upon many factors, it is the synergistic effect of the bisphenol-1–diphenoquinone system that plays the most important role in the case of bisphenol-1. As regards bisphenol-2, it seems possible that a cycle of processes, including formation and conversion of galvinoxyl radical **3**, can occur. In the case of bisphenol-3, an intermediate formation of stilbene quinone **4**, possessing a weak antioxidative activity (9), should also not be discounted.

Energy migration and transfer in styrene-containing polymers with inhibited excimer formation

Kenneth P. Ghiggino, David J. Haines, Trevor A. Smith, and Gerard J. Wilson

Abstract: Steady-state and time-resolved fluorescence spectroscopic techniques have been used to examine energy transfer and the migration of photoexcitation energy in styrene-containing polymer systems in which excimer formation is inhibited. In particular, copolymers of styrene and *p-tert*-butyl styrene with acenaphthylene (ACE) acceptor chromophores have been studied. Energy transfer efficiencies between styrene moieties and ACE chromophores incorporated as in-chain traps have been determined and are higher than predicted for a single-step Förster dipole–dipole energy transfer process. The results are discussed with reference to the possible mechanisms for excitation energy transport in these polymers.

Key words: polystyrene fluorescence, energy migration, energy transfer, excimer.

Résumé : On a utilisé les techniques de spectroscopie de fluorescence à l'état stationnaire et à résolution temporelle pour examiner le transfert d'énergie et la migration de l'énergie de photoexcitation dans des systèmes de polymères contenant du styrène dans lesquels la formation de l'excimère est inhibée. On a étudié en particulier des copolymères du styrène et du *p-tert*-butylstyrène avec de l'acénaphtylène (ACE) comme accepteur de chromophores. On a déterminé les efficacités du transfert d'énergie entre des portions styrène et des chromophores ACE incorporés sous la forme de pièges insérés dans la chaîne et elles sont plus élevées que celles prédites pour un processus de transfert d'énergie dipôle–dipôle de Förster en une seule étape. On discute des résultats en faisant référence aux mécanismes possibles pour le transport de l'énergie d'excitation dans ces polymères.

Mots clés : polystyrène, fluorescence, migration d'énergie, transfert d'énergie, excimère.

Introduction

The close proximity of chromophores along a polymer chain is conducive to the process of migration and trapping of photoexcitation energy. Ng and Guillet (1) and others realized that polymers could act as "antenna" to relocate energy efficiently away from the initial site of light absorption to "trap" moieties where useful sensitized chemistry could occur. The effective absorption cross section of the trap moiety could thus be enhanced considerably. The goal of developing such "light-harvesting" polymers, which can mimic the processes in the photosynthetic apparatus or may be exploited in polymer photodegradation and (or) protection applications, has provided a considerable impetus for polymer photochemistry and photophysics over the past decade (2, 3).

There is now substantial experimental evidence for energy migration and energy transfer occurring in vinyl aromatic polymer systems obtained largely from fluorescence measurements (4). These experiments usually involve the observation of luminescence from a trap following excitation of the polymer chromophores. Alternatively, energy migration among randomly oriented chromophores has been shown to lead to depolarization of the polymer fluorescence following excitation by polarized light. These experiments have been discussed in detail elsewhere. (3, 5, 6) A considerable challenge in polymer photochemistry is to understand the mechanisms by which energy transfer and trapping occur. In a recent paper the possible pathways for energy transport in polymers were discussed from a theoretical viewpoint (7).

Besides energy migration and trapping, there are numerous other factors that can help determine the fate of excitation energy residing in vinyl aromatic polymers following irradiation with light. One such factor is excited-state dimer (excimer) formation, which is a further consequence of the close proximity of the chromophores along the polymer backbone. The formation of excimers is usually undesirable in light-harvesting systems since these species can trap the migrating exciton, thus terminating the energy migration process and

thereby reducing the efficiency of relocation of the excitation energy to the desired site (8). The kinetic behaviour of excimer formation has also proven difficult to model even in comparatively simple systems such as bichromophoric ("model") molecules (9). The additional complexity contributed by the occurrence of excimer formation to the time-resolved fluorescence behaviour observed from polymers has also retarded progress in attempts to elucidate the mechanism and rate of the energy migration/transfer processes in such systems. It is therefore desirable to exclude or at least minimize excimer formation in such studies.

In this work we report experimental studies of energy migration and trapping in polymers containing *p-tert*-butylstyrene in which excimer formation has been inhibited significantly.

Experimental section

Acenaphthene and acenaphthylene (Aldrich) were purified by multiple recrystallization from methanol. Styrene was vacuum distilled prior to use. *para-tert*-Butyl styrene monomer and the corresponding homopolymer (PTBS) were synthesized by Mr Ludger Pille (University of Melbourne). All solvents used for spectroscopic work were free of fluorescent impurities in the spectral regions of interest. Copolymers of styrene and acenaphthylene (PS–ACE) and *p-tert*-butylstyrene and acenaphthylene (PTBS–ACE) were both prepared by free radical copolymerization (using AIBN initiator) under dry nitrogen at 60°C in tetrahydrofuran and heptane solvents, respectively.

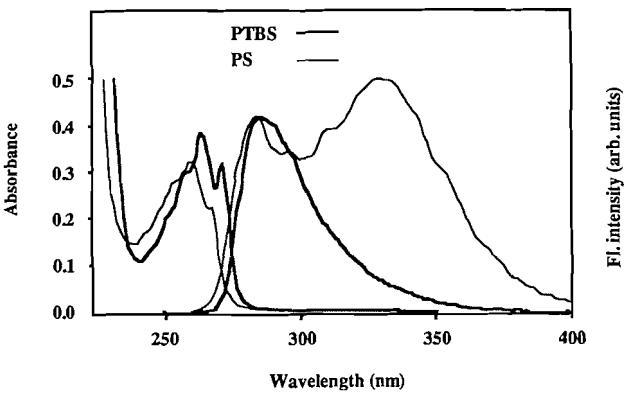
Copolymer compositions were determined by absorption spectroscopy and molecular weights were measured by gel permeation chromatography and light scattering. All spectroscopic measurements were made at room temperature in either dichloromethane (DCM) or dichloroethane (DCE). Polymer solutions were prepared to optical densities of 0.3 or less at 262 nm and degassed via multiple freeze–pump–thaw cycles. The polymer concentration is less than 2.5 μM and interchain interactions during the excited state lifetimes in these systems (<20 ns) can be neglected.

Absorption and fluorescence spectra were recorded using a Hitachi model 150-20 spectrophotometer and a Hitachi model F-4010 fluorimeter, respectively. Molecular weights were determined using a Waters GPC system equipped with microstyrogel columns and calibrated with PS standards. Light scattering was performed using a Wyatt Technology Corporation Dawn-F laser photometer. Fluorescence decay measurements were obtained using the time-correlated single-photon counting technique as described previously (3). The frequency-doubled output of a cavity-dumped Spectra Physics model 3500 dye laser (rhodamine 110 dye) pumped synchronously by a mode-locked Spectra Physics model 2030 argon ion laser was used as the excitation source (instrument response ≈ 80 ps FWHM).

Results and discussion

In previous work on synthetic aromatic polymer systems the amount of excimer formation has been controlled to some extent by (*i*) changing the tacticity of the polymer (10–12), (*ii*) randomly copolymerizing inert "spacer" groups into the polymer (13), (*iii*) preparing copolymers with alternating inert groups (14), (*iv*) sterically hindering excimer formation by attaching bulky groups to the chromophore (15), and (*v*) using chromophores in which excimer formation is inhibited for other reasons (1, 16, 17). The latter two methods are preferred as the other approaches are expected to adversely affect the efficiency of energy migration by increasing the interchromophore separation. We report here recent results obtained using method (*iv*) for styrene-containing polymers.

Fig. 1. UV absorption spectra and steady-state fluorescence spectra (λ_{ex} = 260 nm) of PTBS (thick line) and PS (thin line) at 20°C in dilute, degassed dichloroethane.



The photophysical behaviour of polystyrene has been studied in detail by numerous authors; however, there is still some debate regarding the occurrence and extent of energy migration in this polymer (18, 19). Furthermore, if energy migration does occur in this polymer, contradictions exist in the literature as to the mechanism (resonance or exchange) by which it occurs (18, 20). Excimer fluorescence is readily observable in PS at room temperature and the complexity introduced by excimer formation may be a factor contributing to the apparent confusion relating to the question of energy migration in PS. In an effort to study energy transfer and migration in styrene-containing polymers without the complication of excimer formation, we have examined polymers containing the *p-tert*-butylstyrene (TBS) group in which excimer formation between adjacent chromophores is hindered by the steric constraints of the bulky *tert*-butyl groups on the chromophores, while maintaining the close average interchromophore separation required for facile energy migration assuming a dipole–dipole mechanism.

The absorption and fluorescence spectra of the poly(*p-tert*-butylstyrene) homopolymer (PTBS) and poly(styrene) (PS) in dilute degassed solutions of 1,2-dichloroethane are given in Fig. 1. The absence of a clear emission band at 330 nm in the case of PTBS indicates that excimer formation has been efficiently suppressed as compared with PS. It is assumed that the bulky *tert*-butyl groups do not allow the close approach of the chromophoric units to form the usual planar "sandwich" excimer configuration in which the rings are typically 3–3.5 Å apart (21).

Having demonstrated that there are few, if any, excimer sites present in this polymer, polymers containing the TBS and energy acceptor groups would appear to be suitable candidates for the investigation of energy migration. To this end polymers containing styrene or TBS along with the acenaphthyl chromophore were synthesized and characterized as described in the Experimental section. The physical properties of the

Table 1. Physical properties of copolymers.

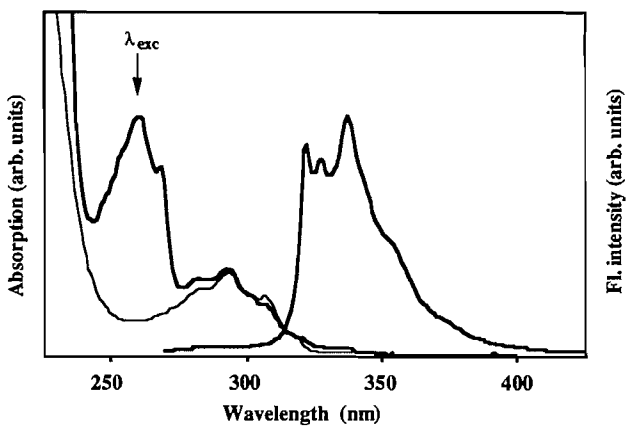
Copolymer	M_n	S:ACE	M_w	R_g (nm)	$V_h \times 10^{22}$ (dm^3)
PS–ACE	29 200	64 : 1	45 300	7[a]	7.5
PTBS–ACE	88 100	203 : 1	160 000	10 ± 3[b]	21.4

Abbreviations: S:ACE = styrene:acenaphthylene ratio calculated using M_n (the number average molecular weight). R_g = radius of gyration. V_h = hydrodynamic volume.

[a]Calculated using classical Flory theory (35). Mark–Houwink parameters: $K_w = 21.0 \times 10^{-3}$ cm^3 g^{-1} and $a = 0.66$ for atactic PS in dichloroethane at 25°C (36).

[b]Measured using light scattering (37).

Fig. 2. Emission (λ_{ex} = 262 nm) and fluorescence excitation spectra (λ_{obs} = 350 nm) of PS–ACE at 20°C in dilute, degassed dichloroethane solution. The normalized absorption spectrum of PACE (light line) is included for reference.



polymers used are collected in Table 1. The ratios of donor (styrene or *tert*-butylstyrene) to acceptor (acenaphthylene) chromophore in the copolymers were determined by absorption spectroscopy using poly(acenaphthylene) (PACE) as a reference compound. This also permitted determination of the relative absorptions due to each species at a given wavelength.

The hydrodynamic volume (V_h) of a single polymer coil can be calculated using the radius of gyration (R_g) and eq. [1] assuming a random coil, where ξ is a numerical factor (assumed to be 0.8).

$$[1] \quad V_h = \frac{4}{3}\pi\xi^3 R_g^3$$

The emission and fluorescence excitation spectra of radically prepared PS–ACE copolymer are shown in Fig. 2 from which it is clear that excitation of the styrene (donor) chromophores results in a fluorescence spectrum that is dominated by acenaphthylene (trap) emission.

It is possible to calculate the theoretical transfer efficiency from a styrene or *tert*–butylstyrene donor to an acenaphthylene acceptor (Eff_{th}) assuming electronic energy transfer occurs via a single-step Förster-type mechanism (22, 23), eq. [2].

$$[2] \quad Eff_{th} = \pi^{1/2}\gamma \exp(\gamma^2)[1-\mathrm{erf}(\gamma)]$$

where $\gamma = C/C_0$, C is the effective acceptor concentration within the volume of the polymer coil, and C_0 is the Förster critical transfer concentration given by eq. [3].

$$[3] \quad C_0 = \frac{3000}{2\pi^{3/2}NR_0^3} \qquad (\mathrm{mol\ dm^{-3}})$$

In eq. [3] N is Avogadro's number and R_0 (cm) is the Förster critical transfer distance, the donor–acceptor separation at which there is equal probability of excitation transfer and spontaneous deactivation. The expression for R_0 is given by eq. [4].

$$[4] \quad R_0^6 = \frac{9000\ln(10)\kappa^2\Phi_d}{128\pi^5 n^4 N}\int_0 \frac{F_d(\bar{\nu})\varepsilon_a(\bar{\nu})}{\bar{\nu}^4}\,d\bar{\nu} \qquad (\mathrm{cm^6})$$

Here, κ^2 is an orientation factor that, for a random distribution of transition dipoles, has a value of 2/3, Φ_d is the quantum yield of fluorescence from the donor in the absence of acceptor, n is the refractive index of the solvent, and the integral term, designated J, is a measure of the degree of spectral overlap between the absorption spectrum of the acceptor ($\varepsilon_a(\bar{\nu})$ is the extinction coefficient of the acceptor at wavenumber, $\bar{\nu}$), and the unit area normalized fluorescence emission spectrum of the donor, $F_d(\bar{\nu})$.

Figures 3 and 4 show the overlap of the donor emission and acceptor absorption spectra for PS–PS and PTBS–PTBS self-transfer, and PS–ACE and PTBS–ACE energy transfer. The resultant values for spectral overlap integral term, J, along with the corresponding R_0 and C_0 values are given in Table 2.

From the data presented in Table 2, a beneficial effect of *tert*-butyl substitution, from the point of view of dipole–dipole energy transfer, is the almost doubling of the R_0 value for self-transfer in PTBS compared with PS. This is due to the fourfold increase in the Φ_{fl} (PTBS = 0.12, PS = 0.03) and the absence of much long-wavelength emission in PTBS compared with PS. It has been suggested (24) that using an R_0 calculated from PS is inappropriate because of the presence of excimers acting as traps, and that the R_0 for PS should be close to that for isopropylbenzene (6.47 Å) (25). This being the case, the R_0 for PTBS calculated in this work still indicates that self-transfer should be more prevalent in this polymer than in PS.

It is instructive at this point to compare the R_0 values calculated from the photophysical properties of the chromophores with the actual average interchromophore separation. A value of 6.63 Å has been determined for the latter from X-ray analysis of crystalline isotactic PS (26), while MM2 minimization of a *trans-gauche* diad in PTBS suggests an interchromophore separation of 6.6 Å. Using 6.6 Å as a typical interchromophore separation for these polymers and assuming a random distribution of transition dipoles, it can be seen by inspection of eq. [5] describing the rate of donor–acceptor transfer, that for R_0 = 6.47 Å, the rate of self-transfer in PS via a resonance mecha-

Fig. 3. Overlap of absorption and emission spectra for self-transfer in PS (upper) and PTBS (lower), respectively.

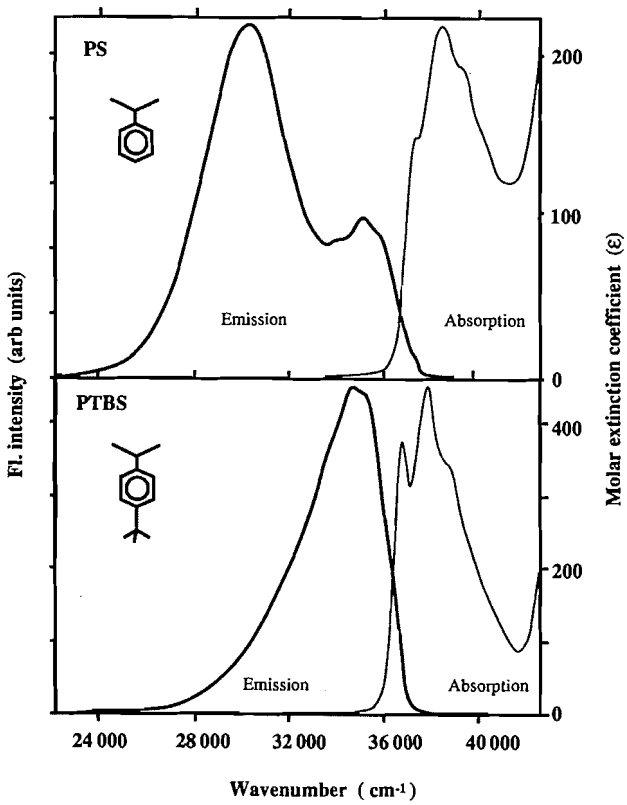

Fig. 4. Overlap of acenaphthene absorption spectrum and the PS (upper) and PTBS (lower) emission spectra, respectively.

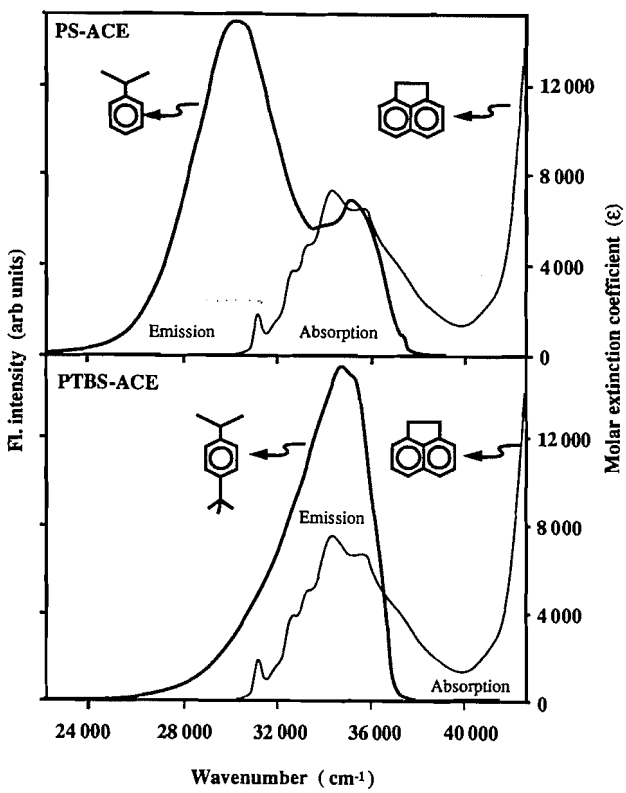

nism must be quite close to the fluorescence rate of the unquenched donor ($1/\tau_D$), with the rate being slightly greater for PTBS self-transfer.

$$[5] \quad k_{DA}(R) = \frac{3\kappa^2}{2\tau_D}\left(\frac{R_0}{R}\right)^6$$

In eq. [5] τ_D is the donor lifetime in the absence of energy transfer, R is the intermolecular separation, and the other terms have been defined previously. Using ethylbenzene (τ_D = 13 ns) (27) as a model compound for PS results in a Förster transfer rate of 7×10^7 s^{-1} (or ~14 ns per hop). In the case of PTBS a model compound is not yet available but, using a donor lifetime of 10 ns estimated from the homopolymer decay, a rate of 2×10^8 s^{-1} (~5 ns per hop) is obtained. It should be emphasized that these hopping rates will depend strongly on the dynamic interchromophore separations, which can be smaller and larger than those determined from energy-minimized and crystal structures. Nevertheless the above considerations suggest that singlet energy migration would not be expected to be facile in these polymers if the transfer is via a series of Förster hops. At the typical interchromophore separations in these systems (~ 5–7 Å) it is possible that orbital overlap effects (e.g., exchange interactions) are important. Using Monte Carlo simulations, Blonski and Sienicki (20) have suggested that exchange interactions are responsible for the energy migration process in PS. Recent work in this laboratory has shown that a combination of Coulombic (dipole–dipole) and exchange interactions can lead to a rate of energy transfer substantially higher than that expected by a purely dipole–dipole mechanism (28). In addition, the possibilities of overlap-dependent energy transfer induced by superexchange interactions through the polymer backbone connecting the chromophores has recently been proposed (7).

We now turn our attention to the steady-state sensitization results. It is clear from eq. [2] that calculation of the theoretical transfer efficiency requires knowledge of the effective local acceptor concentration (C_{eff}) in the polymer volume. The average number of acceptor molecules per chain can be determined by a combination of absorption and molecular weight measurements and C_{eff} is then obtained from the the number of acceptor molecules per chain and the hydrodynamic volume (V_h; see Table 1).

Table 3 lists the relevant energy transfer data for the PS–ACE and PTBS–ACE systems, including the effective acceptor concentration (C_{eff}), the critical transfer concentration (C_0) (see Table 2), the theoretical transfer efficiency (Eff_{Th}) (calculated using eq. [2]), and the experimentally determined transfer efficiency (Eff_{Exp}).

The efficiency of acenaphthylene sensitization was determined from comparison of excitation and absorption spectra as described elsewhere (29). This method does not require evaluation of the fluorescence quantum yield of the donor or acceptor. The fluorescence and fluorescence excitation spectra for a PS–ACE sample with absorbances at 262 nm (PS and ACE excited) and 295 nm (ACE only excited) of 0.268 and 0.096, respectively, are shown in Fig. 2. For 262 nm excitation (donor region) the intensity of ACE emission expected for 0% energy transfer is evaluated from the fraction of light absorbed by the ACE at 262 nm and the emission yield determined by exciting ACE alone at 295 nm. The intensity of ACE emission expected

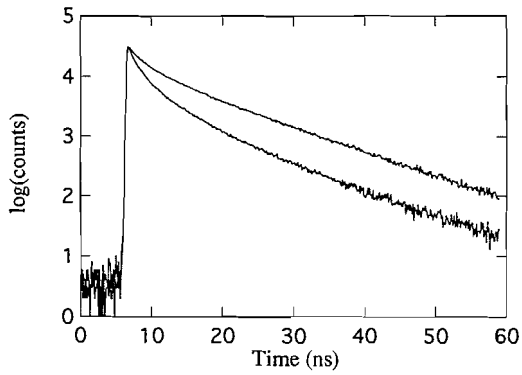
for 100% energy transfer from the donor to the acceptor is determined by assuming all light absorbed by the polymer at 262 nm is emitted from the acceptor. Comparison of the actual intensity measured with that expected for 0% and 100% energy transfer enabled extraction of the experimental transfer efficiency. These values are also listed in Table 3 along with the corresponding single-step theoretical transfer efficiencies.

From the data presented in Table 3 it is apparent that for both PS–ACE and PTBS–ACE the experimentally determined energy transfer efficiency far exceeds that calculated assuming a single-step Förster-type mechanism. This suggests that photon-harvesting effects are indeed operating. However, as discussed above, it is unlikely that energy migration is occurring via a purely Coulombic dipole–dipole mechanism.

For PTBS–ACE the donor:acceptor ratio is approximately 203:1 and this gives rise to an observed energy transfer efficiency to the ACE trap of 21%. For PS–ACE the ratio is only 64:1, i.e., the excitation has to travel only about one third as far before it encounters a trap, yet the energy transfer efficiency in PS–ACE has increased to only 31%. This result is not too surprising when one considers that there are approximately seven to nine excimer-forming sites at room temperature in a polymer chain of this length (30, 31) as well as the four to five ACE traps per PS chain. While excimers may be able to participate in energy transfer to ACE, they will also limit the energy migration length and provide additional deactivation pathways for excitation energy in the polymer thus decreasing the overall transfer efficiency.

Time-resolved data show that in all cases the fluorescence decay from the monomer emission region cannot be described adequately by a single exponential decay function. Whilst this is not unusual for homopolymers with excimer-forming sites such as PS, the reasons for the observed non-exponentiality of the PTBS homopolymer fluorescence decay (Fig. 5) are not clear. Monte Carlo calculations have shown that the presence of any energy trapping site will introduce non-exponentiality to fluorescence decays (3), which may indicate that excimer formation might not be completely inhibited within this polymer. However, for the copolymers the dominant cause of the observed non-exponentiality is almost certainly the presence

Fig. 5. Fluorescence decays of PTBS homopolymer (upper trace) and PTBS–ACE (lower trace) following excitation at 273 nm.



of the ACE trap. One noteworthy feature of the time-resolved data from the PS–ACE and PTBS–ACE polymers is the absence of any rise time of the trap fluorescence observable within the time resolution of our detection system (≈80 ps). Attempts to recover the experimentally observed trap rise time using numerical simulation of single-step time-dependent Förster theory have, to date, been unsuccessful. In all cases the predicted trap rise time is at least an order of magnitude slower than that observed experimentally. We take this as further evidence that, in addition to single-step, dipole–dipole energy transfer, mechanisms may be operative that enhance the rate of energy trapping in these polymers. Previous estimations of the singlet energy migration coefficient in polystyrene of about 10^{-8} m^2/s^{-1} from trapping and quenching data are also consistent with high migration efficiencies (32, 33).

Time-resolved fluorescence anisotropy measurements have the most potential to yield quantitative information with respect to the existence and rate of excitation transport (34). Such measurements on the polymers under discussion in this paper are currently in progress but the results will be reported elsewhere.

Conclusions

In the work reported here the formation of excimers in sty-

rene-based polymers has been restricted by attaching a *tert*-butyl group at the *para* position. Qualitative considerations on the basis of donor:trap ratios indicate that the efficiency of energy transfer to an acenaphthylene trap incorporated onto the polymer chain is greater in PTBS–ACE than in PS–ACE where the competition from excimers hinders energy migration. The observed efficiency is greater than can be rationalized in terms of a single-step Förster transfer from excited donor to acenaphthylene acceptor, providing evidence for down-chain energy migration. Consideration of the parameters involved in self-transfer via a series of dipole–dipole hops and the rapid (undetectable) rise times observed for the acceptor suggest Förster transfer is not the dominant process for energy migration in these polymers and other mechanisms enhancing energy transfer are operative.

Luminescence measurements of oxygen permeation and oxygen diffusion in thin polymer films

Ahmad Yekta, Zahra Masoumi, and Mitchell A. Winnik

Abstract: A new method is developed for analyzing the diffusion of oxygen in thin polymer films via fluorescence quenching measurements. We begin by reviewing previous methods, all of which involve approximations, for the measurement of permeability and diffusion coefficient by luminescence quenching; their shortcomings are clarified. An exact analytic theory is developed that successfully couples Fick's laws of diffusion to the Stern–Volmer equation of intensity quenching. Various modes of experimentation with polymeric films are considered. The equations we derive make the unexpected prediction that the rate of emission intensity decay when O_2 diffuses into a polymer film is much faster than the rate of emission intensity enhancement when O_2 diffuses out of the same film, even when the molecular diffusivity remains unchanged. Experiments show that this is indeed the observed behaviour.

Key words: diffusion coefficient, oxygen permeability, polymers, quenching, luminescence quenching, Fick's laws, Stern–Volmer equation.

Résumé : Faisant appel à des mesures de décroissance de la fluorescence, on a mis au point une nouvelle méthode pour analyser la diffusion de l'oxygène dans des films minces de polymère. On passe en revue les méthodes décrites antérieurement pour la mesure de la perméabilité et du coefficient de diffusion par décroissance de la luminescence; toutes ces méthodes impliquent des approximations et on a clarifié leurs limitations. On a mis au point une théorie analytique exacte qui relie avec succès les lois de diffusion de Fick avec l'équation de Stern–Volmer de la décroissance de l'intensité. On considère divers modes d'expérimentation avec des films polymériques. Les équations que l'on a dérivées permettent de faire la prédiction inattendue que la vitesse de décroissance de l'intensité de l'émission, lorsque du O_2 diffuse dans un film de polymère, est beaucoup plus rapide que la vitesse d'augmentation de l'intensité de l'émission lorsque le O_2 diffuse du même film, même lorsque la diffusivité moléculaire demeure la même. Les expériences montrent que le comportement observé correspond à cette prédiction.

Mots clés : coefficient de diffusion, perméabilité à l'oxygène, polymères, décroissance, décroissance de la luminescence, lois de Fick, équation de Stern–Volmer.

[Traduit par la réduction]

Introduction

Oxygen diffusivity in polymers is most commonly determined by measuring the rate of oxygen permeation across a membrane. One exposes one side of the polymer film to oxygen at time zero and measures the flux of oxygen across the film as a function of time. Knowing the dimensions of the film and the partial pressure of oxygen on the high-pressure side, one can calculate the diffusion coefficient and the permeability from the flux (1). The diffusion coefficient D_{O_2} is determined from the kinetics of the approach of the O_2 flux to its steady-state value, and at steady state, the flux measures the permeability P_{O_2}, which is equal to the product of the oxygen solubility in the film (S_{O_2}) and D_{O_2}.

It is not always convenient to determine D_{O_2} and S_{O_2} in this way, particularly where it is difficult to prepare free-standing films. Because oxygen is such a powerful quencher of fluorescence and phosphorescence, there is a natural attraction to using this property to determine these values. Unfortunately, the approaches that satisfy diffusion equations in a rigorous way have been cumbersome from the point of view of experimental detail. On the other hand, experiments that are easy to carry out do not conform to geometries where it has been possible to evaluate rigorously the coupling between the diffusion equation and the luminescence quenching kinetics.

This is a topic that has long been of interest to J. E. Guillet. He has worked in the area and has published two key reviews on this topic (2, 3). Here we would like to present a rigorous theoretical solution to the simplest way of measuring oxygen diffusion in polymer thin films by luminescence quenching. We believe that it is fitting that we publish this work in a journal issue dedicated to Professor Guillet.

Received March 30, 1995.

This paper is dedicated to Professor J.E. (Jim) Guillet in recognition of his contributions to Canadian chemistry.

From a historical point of view, one of the first approaches to measuring luminescence quenching in polymers involved a polymer rod of large diameter (i.e., cm) containing a uniform distribution of dye molecules (4, 5). All oxygen is removed from the rod under vacuum, rendering the entire rod brightly fluorescent or phosphorescent. At $t = 0$, the rod is exposed to air and illuminated at one end. As O_2 penetrates into the rod, it quenches emission from nearby dye molecules, forming a dark cylindrical shell at the periphery of the rod. The thickness of this dark shell grows with increasing diffusion time. One lays a ruler across the end of the rod and tries to measure the thickness of the bright circle and dark outer ring as a function of time. Because diffusion occurs on the scale of centimeters, the experiment takes a long time (weeks to months). Measuring the appropriate distances accurately is not easy, and the analysis ignores oxygen diffusion into the rod ends.

Another approach due to Cox also looks at large samples (6). Here one constructs a square cell with centimeter-scale height. The cell is filled with a polymer containing the dye and all oxygen is removed. Cox irradiated a thin (1 mm) middle cross section of the cell, and then allowed oxygen to diffuse into the cell from the top. As the oxygen concentration profile propagates through the illuminated middle slice, the emission intensity is quenched. Note that because of the experimental design, with the plane of the slice perpendicular to the propagation direction of the O_2 profile, there will at all times be a nearly uniform O_2 concentration in the plane of the illumination. There are a number of technical difficulties involved with this experiment, particularly ones of alignment of the illuminated plane, focus of the collection optics, and the long time scale of the experiment. Nevertheless, for this geometry as well as the cylindrical geometry described above, rigorous application of Fick's laws of diffusion is possible.

From the point of experimental ease, what one would like to be able to do is to spread a thin film (1–100 μm) containing the dye on a flat substrate, and mount it in a fluorescence spectrometer in a cell with a controlled atmosphere. At $t = 0$, one could pass air or oxygen into the cell and measure the time profile of the decay of the emission intensity (on the order of minutes), or flush nitrogen into the cell containing air and observe the growing-in of the emission intensity as oxygen diffuses out of the film. From an analytical point of view one would like to have a relationship that connects the measurable intensity-versus-time profiles to the diffusivity of the penetrating quencher.

The Guillet group was one of the first to report experiments involving oxygen diffusion into dye-doped polymer films (7, 8). They calculated diffusion coefficients from their data, but in their data analysis they made simplifying assumptions about the connection between the oxygen diffusion and the extent of luminescence quenching in the film. They used Fick's laws to calculate the amount of oxygen that had entered into the film at time t, but to calculate the amount of quenching they assumed that this amount could be treated as an effective average uniform concentration over the sample thickness. This neglects the details of the concentration profile of quencher in the film and introduces an error into the calculated diffusion coefficient value.

We have been able to derive an exact expression relating the concentration profile to the fluorescence quenching. The equations we derive make the unexpected prediction that the rate of emission intensity decay when O_2 diffuses into a thin polymer film is much faster than the rate of emission intensity increase when O_2 diffuses out of the same film. Experiments show that this is indeed the observed behavior. Values of D_{O_2} and P_{O_2}can now be obtained with accuracy and with excellent precision.

Experimental

Fluorescence measurements employed a SPEX Fluorolog 2 with a DM3000 data system, operated in the time-base mode. Polymer films were prepared by either casting onto quartz plates or onto a Teflon surface. In the latter case, the films could be peeled off after drying to yield free-standing films. The film was then mounted in a sample chamber (3 cm^3) through which various gases could be passed at a controlled rate. The cell and the details of polymer film preparation will be described in more detail in a future publication. The flow rates were about 150 cm^3/s so that the gas in the chamber could be replaced every 20 ms. The polymers, silicone resin solutions EXP-36-X20 and GP-197, were obtained from Genesee Polymers, Flint, Mich. The dye, platinum octaethylporphine (Porphyrin Products, Logan, Utah), was dissolved in 1,1,1-trichloroethane (Caledon) to give a 100 ppm stock solution. An aliquot of the dye solution was added to that of the resin so that the dye concentration in the dry resin would be ca. 10 ppm. Samples were excited at 534 nm, and emission was monitored at 646 nm.

Computer programs for simulation and data analysis were written in Quick-basic. The summation expressing $\rho(x, t)$ (cf. eq. [9]) converges rapidly except for very short times. Even for times as short as $Dt/L^2 = 0.001$, 60 summation terms are sufficient to give an accuracy better than 1 in 10^6. The integration in eq. [9] was performed by dividing the range into 100 segments and employing the Simpson algorithm. Data fits were performed by inputting the experimental value of B and adjusting D/L^2 as a parameter, requiring that the half-way points (between maximum and minimum intensities) of theory and experiment overlap. More sophisticated analysis requiring minimization of χ^2 criteria can be performed, but will not be considered here.

Previous analyses of oxygen quenching in thin films

Equilibrium state measurements

Experiments have been reported in which the oxygen concentration in the film has been allowed to come to equilibrium. Under these circumstances, the quencher concentration should be macroscopically uniform throughout the sample, at its equilibrium solubility limit, Q_{eq}. Within the context of the underlying assumptions, this type of experiment yields the quencher permeability in the matrix. One typically measures the fluorescence or phosphorescence intensity of the polymer film in the absence of oxygen (I^0), and compares it to the corresponding intensity after equilibration (I_{eq}) with an external atmosphere containing oxygen with a partial pressure of p_Q. To analyze the data one assumes a Stern–Volmer (SV) type of relation, eq [1], where k_q represents the bimolecular rate constant of quenching, modeled after kinetics of quenching in fluid media, and τ^0 is the unquenched fluorescence or phosphorescence lifetime.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

$$[1a]\quad \frac{\tau^0}{\langle\tau_{eq}\rangle} = \frac{I^0}{I_{eq}} = 1 + k_q\tau^0 Q_{eq}$$

One feature of these experiments that remains unresolved is that while the unquenched decay profile of the dye is often exponential, and thus characterized by a well-defined τ^0 value, these decays become non-exponential when oxygen is present (9–11). The Stern–Volmer equation is derived from assumptions that lead to the prediction that $I^0/I_{eq} = \tau^0/\tau_{eq}$. Since the decay in the presence of quencher is not exponential, this poses a problem in the assumption of SV kinetics since τ_{eq} is not defined. One can either ignore the problem by examining intensities only, or sidestep the issue by replacing τ_{eq} with its mean value $\langle\tau_{eq}\rangle$ calculated from the decay profile. While the former approach is more common, when decay profiles are measured, one often finds that $I^0/I_{eq} = \tau^0/\langle\tau_{eq}\rangle$. That is, for low concentrations of Q_{eq}, the SV relation [1] is usually obeyed, even when the sample shows nonexponential decays of luminescence.

For oxygen, in terms of its external partial pressure p_Q, the equilibrium solubility Q_{eq} is proportional to p_Q (Henry's law) in the range of low to moderate pressures (1), i.e. $Q_{eq} = Sp_Q$, where S is the Henry's law constant of the gas solubility.[2] In this case eq. [1*a*] reduces to

$$[1b]\quad \frac{\tau^0}{\langle\tau_{eq}\rangle} = \frac{I^0}{I_{eq}} = 1 + (k_q\tau^0 S)\,p_Q$$

By varying the external pressure of the gas, and each time allowing for equilibration, one obtains a linear plot of eq. [1*b*]. From the slope and the knowledge of τ^0 one then calculates the product k_qS.

The rate coefficient k_q is related to the diffusivity of the quencher. For fluid media,

$$[2]\quad k_q = \alpha k_{diff}$$

where α is the probability of quenching in an encounter complex of the excited state/quencher, and k_{diff} is the diffusion-controlled rate constant of the formation of the encounter pair. The diffusional encounter theory of Smoluchowski (3, 12) provides a direct proportionality relation between k_{diff} and the diffusion coefficient D.

$$[3]\quad k_{diff} = 4\pi\sigma N_A D$$

where σ is the diameter of the encounter complex (about 10 Å), and N_A is Avogadro's number. Substitution in eq. [1*b*] yields

$$[4]\quad \frac{\tau^0}{\langle\tau_{eq}\rangle} = \frac{I^0}{I_{eq}} = 1 + (4\pi\sigma N_A\alpha\tau^0)(D\,S)p_Q$$

where the product (DS) equals the permeability (P) of the quencher. Thus following the above assumptions equilibrium state measurements allow for the determination of the permeability of oxygen in polymeric samples.

There are three types of uncertainties in this kind of analysis. The first is the questionable applicability of the kinetics of fluid media to rigid polymeric media with possible domains of microscopic inhomogeneities. Second is the magnitude of σ in eq. [3], and the last concerns the magnitude of α in eq. [2]. In principle these parameters should be determined independently, but in fact their values remain ambiguous. For example, while some authors (13, 14) have assumed α to be unity, Guillet and Andrews (8) argue that for phosphorescence quenching by O_2 (a ground state triplet), spin statistics imply that α is at most 1/9, and probably less because of electronic overlap considerations.

Jones (13) studied O_2 quenching of the phosphorescence lifetime of naphthalene solubilized in poly(methyl methacrylate) (PMMA) and fitted the data to eq. [4]. With the assumption that $\alpha = 1$, $\sigma = 10$ Å, the authors calculate for the oxygen permeability at room temperature, $P = (1.1 \pm 0.2) \times 10^{-17}$ $cm^2 \cdot s^{-1}$ $(mole/cm^3) \cdot (mm\ Hg)^{-1}$. This can be converted to the usual units[2] $P_{O_2} = 1.8 \times 10^{-15}$, which compares unfavourably with the two reported classical measurement (15, 16) values of 2.9×10^{-14}, and 1.2×10^{-14} (34°C), respectively. Only with the Guillet presumption of $\alpha = 1/9$ do we get an acceptable agreement with the classical measurements.

For oxygen in polystyrene we can compare data of steady-state fluorescence quenching from the studies of Nowakowska et al. (14). These workers measured I^0/I_{eq} as a function of oxygen pressure for the three different fluorescent probes, naphthalene, triphenylene, and perylene, solubilized in polystyrene. Here the excited states are singlet and their $\alpha = 1$, $\sigma =$ 11 Å assumption is more reasonable. From their data for the plot of eq. [3] we calculate[2] oxygen permeabilities in polystyrene of 3.8×10^{-13}, 3.7×10^{-13}, and 6.3×10^{-13}, respectively, for the three dyes. These values can be compared with the classically measured (15) value of 1.9×10^{-13}.

Transient measurements

Guillet (2, 3, 7, 8) and co-workers and MacCallum and Rudkin (17) extended this kind of analysis to transient measurements on thin polymer films. In these experiments, they measured the rate of decrease of luminescence intensity from the dye-doped film following exposure of the film to oxygen. The challenge in these experiments is to relate the decrease in emission intensity to the Fickian diffusion of oxygen into the film. In their analysis, these workers invoked two types of simplifying assumptions. First, they used the sample-width-averaged, time-dependent concentration of oxygen in the sample to relate $I(t)$ to the quencher concentration. Second, they employed asymptotic solutions to diffusion equations, which could be evaluated analytically. Thus to analyze their data, Guillet and Andrews used the long-time behavior ($t \to \infty$) of the Fick's law solution for the mean oxygen concentration (8), whereas MacCallum and Rudkin (17) used the corresponding short-time ($t \to 0$) behaviour (see Appendix A).

A novel advance in the area of transient measurements of

---

[2] The units for S are usually expressed as cm^3 (gas at STP)/cm^3 polymer/Pa of the external pressure. On this basis, permeability would have units of

$$P = \frac{(\text{quantity of permeant}) \cdot (\text{film thickness})}{(\text{film area}) \cdot (\text{time}) \cdot (\text{pressure drop across the film})}$$

$$= \frac{cm^3(\text{gas at STP})\ cm}{cm^2 \cdot s \cdot Pa} = DS$$

oxygen diffusion was made when Gao, Ogilby and co-workers (18, 19) developed a technique for directly monitoring the O_2 uptake. In this technique, as the external pressure of O_2 evolves, one irradiates (visible light) the polymer film containing a sensitizer dye. Simultaneously, one observes the near-infrared (1270 nm) phosphorescence of excited singlet molecular oxygen, which is generated when ground state O_2 (a triplet state) interacts with the excited dye. For sufficiently low concentrations of dissolved O_2, the intensity of the 1270 nm signal is linearly proportional to the total O_2 uptake of the sample, and can be related to the diffusivity via a Fick's law solution of the total uptake. This technique is promising and we believe that the data analysis can be extended to regimes of higher oxygen pressure by taking an approach very similar to the one being developed in this writing.

Our major contribution in this paper is to extend these works by providing an exact derivation of the expected behaviour of $I(t)$ for all time t, and employing numerical methods, both to simulate and to analyze real experimental data. While the older experiments dealt with only one experimental situation, a thin polymer film on a solid substrate exposed at $t = 0$ to oxygen, there are in fact four different types of experiments that one can carry out. These provide four different sets of boundary conditions for solutions to the diffusion equations and thus four independent ways of evaluating the connection between experiment and data analysis. For oxygen diffusion *into* a sample, one can examine both substrate-supported and free-standing films (in-diffusion from both sides). For oxygen diffusion out of a sample (I increases from I_{eq} to I^0), one also can compare free standing and substrate-supported films.

Although the present model deals with situations where the lumophore is imbedded in the polymer film, thereby limiting application to optically transparent films, luminescence methodology can also be applied to nontransparent films. Lu and Weiss (20) have recently shown that one can extend the experiments for cases in which it is difficult to observe fluorescence from the film itself. In a modification of the Lu–Weiss approach, the nontransparent film containing the quencher is immersed in a transparent liquid containing the fluorophore. As the quencher diffuses out of the film, it quenches fluorescence emanating from the solution.

Transient measurements of oxygen diffusion

Assumptions of the model

The most convenient shape of a polymeric sample for diffusion studies is that of a thin film that can be modeled by a rectangular sheet of *uniform* thickness L, and infinite extension (relative to L). The mathematical description of diffusion normal to the plane of the film is that of one-dimensional diffusion. We assume that the *immobile* luminescent dye is *uniformly* distributed throughout the film. The samples are illuminated continuously with excitation light of constant intensity. The experiments involve quenchers diffusing into (or out of) the sample, with a concurrent decrease (or increase) of the detected luminescence intensity, $I(t)$. For simplicity we consider cases where the quencher concentration (Q) changes between the values of zero and Q_{eq} (equilibrium solubility of the penetrant), corresponding to the measurable intensities I^0 and I_{eq}, respectively. The required change is brought about by an abrupt variation of the external concentration (or pressure) of the quencher between zero and some required external equilibrium value. During the time the sample evolves from one equilibrium state to another, the quencher concentration at various depths in the film changes with time with a concentration profile expressed by $Q(x, t)$ while, over this time, the external quencher concentration is kept constant (i.e., in contact with a large reservoir).

At any time t, the instantaneous elemental luminescence intensity ($\delta I(x, t)$) emanating from an infinitesimally thin layer of the sample, between x and $x + dx$, is given by a Stern–Volmer (SV) type relation

$$[5a] \quad \frac{\delta I^0}{\delta I(x, t)} = 1 + AQ(x, t); \qquad \delta I^0 = I^0 dx$$

$$[5b] \quad \delta I(x, t) = \frac{I^0 dx}{1 + AQ(x, t)}$$

where $Q(x, t)$ is the quencher concentration at position x and time t; I^0 is the observable total luminescence intensity of the sample in the absence of quenchers, and the proportionality constant A^{-1} can be identified as the equilibrated quencher concentration ($Q_{1/2}$) capable of reducing I^0 to $I^0/2$. The elemental intensities cannot be measured. What is measured is the sum total of the elemental intensities. It follows that when the emission intensity is compared between the two equilibrium states of the sample, one has

$$[6] \quad \frac{I^0}{I_{eq}} = 1 + AQ_{eq}$$

which can be used to substantiate the validity of eq. [6]. Equation [6] and [1] are functionally equivalent and we can identify the constant A as $k_q\tau^0$. Such equivalence is, however, not necessary because no mechanistic relation is being assumed.

There are a number of technical issues that need to be satisfied in this type of experiment. First, it is important that the optical density (OD) of the sample at the wavelength of excitation be small (OD < 0.1) and that the film be transparent. These conditions imply that the excitation light will penetrate into the film with nearly uniform intensity. Second, the lifetime (τ^0) of the excited lumophore (in the absence of quenchers) should be at least two orders of magnitude shorter than the time scale of quencher diffusion across the film thickness. That is,

$$[7] \quad \tau^0 < 10^{-2} (L^2/D)$$

An order of magnitude estimate of the value of L^2/D can be obtained from the time that is taken for the signal to reach halfway between I^0, and I_{eq} in an experiment where the quencher *diffuses out* of the film. Under these conditions, although the evolving system is not at a true steady state, at any point in the sample, the excited-state concentration can be evaluated through the application of (pseudo) steady-state approximations that lead to SV-type equations. This condition is easily satisfied for a variety of systems.

Finally, the film thickness L must be sufficiently small that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

the optical detection system picks up elements of intensity from all points along the excitation path in the sample with an equal weight. In practice, most samples will have (and should have) $L < 1$ mm. Therefore, this requirement is satisfied by all commercial luminescence instrumentation systems having a light-collecting element more than 10 cm away from the sample. One way to check that this condition is satisfied is to see whether the observed $I(t)$ time profiles are identical when viewed from the front face and from the back side of the excitation area. This assumption may not be valid, for instance, if an optical fiber close to the sample is used to pick up the emission.

Development of the model

We assume that Fick's laws of diffusion apply, and that D is a constant throughout the sample. Thus

$$[8a] \quad \frac{\partial Q(x,t)}{\partial t} = D\frac{\partial^2 Q(x,t)}{\partial x^2}$$

For simplicity of notation, we define a dimensionless concentration profile and obtain

$$[8b] \quad \rho(x,t) \equiv Q(x,t)/Q_{eq}$$

$$[8c] \quad \frac{\partial \rho(x,t)}{\partial t} = D\frac{\partial^2 \rho(x,t)}{\partial x^2}$$

The boundary conditions for solving eq. [8] are described later. The observable intensity is related to the solution of eq. [8] by summing the elemental intensities defined in eq. [5*b*]. From the these requirements, it follows that

$$[9a] \quad I(t) = \frac{I^0}{L}\int_0^L \frac{dx}{1 + B\rho(x,t)}$$

$$[9b] \quad B \equiv AQ_{eq} = \left(\frac{I^0}{I_{eq}} - 1\right)$$

The analytical behaviour of $I(t)$ is not trivial and in fact we shall show surprising differences between diffuse-in and diffuse-out experiments. Note that the rate of intensity decay depends upon Q_{eq}, a feature not taken into account in previous analyses of this type of experiment. The direct measurement of the equilibrium penetrant solubility is, however, not necessary. The constant B in eq. [9*a*] is related to the measurable intensity ratio I^0/I_{eq} as indicated in eq. [9*b*], and serves as an input parameter for the data analysis procedure. One then has to evaluate numerically the integral in eq. [9*a*], employing $\rho(x, t)$ obtained as a solution to eq. [8*c*], to obtain the best value of D/L^2 as a fitting parameter.

We draw attention to the fact that B is a parameter expressing the sensitivity of the system to quenching (quenching efficiency) that is independent of the sample size. For the samples we have encountered, values of B range between 0.1 and several hundreds, depending on the type of polymer in use and also on the oxygen pressure applied. In practice, values of B lower than 0.5 are not desirable because the overall signal variation will approach the instrumental noise level, while very high values of B imply there may be little signal to measure when the system approaches saturation with the quencher. In theory, however, one has a good control over the value of B. On the basis of our earlier discussions we can identify B with $k_q\tau^0 Q_{eq}$, which is roughly proportional to the diffusion coefficient D. While the value of k_q is determined by the size of the diffusing quencher and the type of polymeric matrix involved, can be varied greatly by going from fluorescent to phosphorescent probes. Also, the value of quencher solubility Q_{eq} can be easily controlled by varying the external pressure (concentration) of the equilibrating quencher. Further discussion on the properties of $I(t)$ are given after we consider the various possible types of experimentation.

There are four distinct experiments that one can carry out to obtain independent measures of oxygen diffusion D_{O_2} in a polymer film, that correspond to four different boundary conditions for solving eq. [8]. One pair of experiments refers to a polymer film mounted on an impermeable substrate (e.g., quartz) so that oxygen diffusion can occur across only one film surface. For a free-standing film, the second pair of experiments involves oxygen diffusion across both surfaces. Within each sample geometry, one can follow the increase in $I(t)$ as oxygen diffuses into the film, or one can follow the increase in $I(t)$ as oxygen diffuses out of the film. In Figs. 1*a* and 1*b* we show the two sample geometries, where the penetrant in Fig. 1*a* has started to diffuse into a film previously devoid of Q from one side of exposure. Figure 1*b* depicts the case for two sides of exposure. The excitation light enters the film along the x axis. Regions of lower quencher concentration will yield higher emission intensities.

For evaluation of the diffusion equation, we set one face of exposure at $x = 0$. If the sample has two faces of exposure, these are located at $x = 0$, and $x = L$. The boundary conditions needed for the solution of $\rho(x, t)$ from eq. [8*c*] are determined by the direction of net quencher flow, and the number of exposed sample faces. The information needed is the initially uniform concentration in the sample, $\rho(x, 0)$, the concentration of quencher dissolved at the surface(s) of exposure, and the locus x^* of zero flux in the sample. That is,

$$[10] \quad D\left.\frac{\partial \rho(x,t)}{\partial x}\right]_{x=x^*} = 0$$

In analysis of diffusion problems, one commonly assumes that the infinitesimally thin layer at the exposed surface achieves its equilibrium concentration of sorbant Q_{eq} instantaneously. Therefore $\rho(x, t)$ at the exposed face is equal to unity as soon as the surface partial pressure of oxygen p_{O_2} has a finite non zero value, as for "diffuse-in" experiments, and $\rho(x, t)$ at the exposed face is equal to zero when $p_{O_2} = 0$, as for "diffuse-out" experiments. Table 1 summarizes the boundary conditions for the four possible modes of experimentation, along with the corresponding solutions to eq. [8*c*].

The solutions to $\rho(x, t)$ can be found by reference to texts (21) dealing with the mathematics of diffusion, and are given in Table 1 in terms of the family of terms in the expression [11]

$$[11] \quad F(x,t,L) = \frac{4}{\pi}\sum_{n=\text{odd}}^{\infty}\frac{1}{n}\exp\{-n^2\pi^2 Dt/L^2\}\sin(n\pi x/L)$$

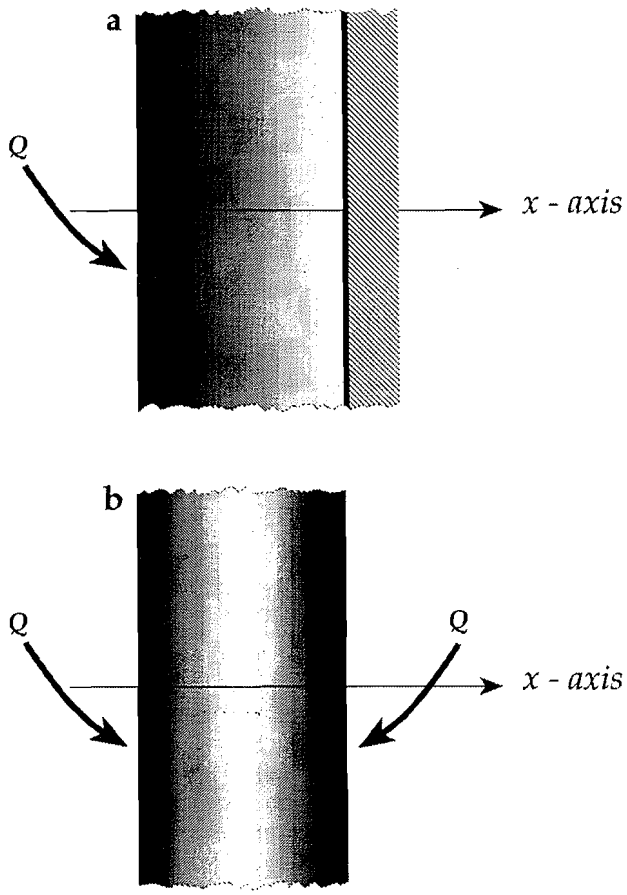
Table 1. Boundary conditions and functional forms for the solutions of eq. [8], $\rho(x, t)$, for the two different pairs of experiments.

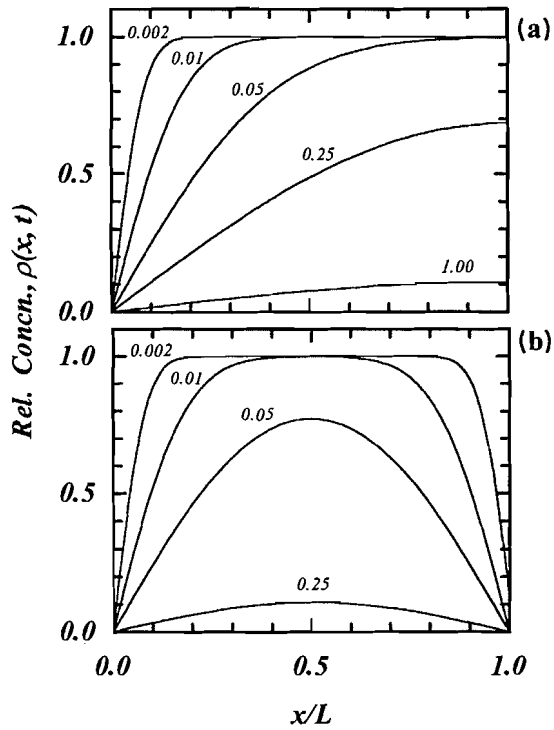
	Diffuse-out experiments		Diffuse-in experiments	
	$x = 0$ face	$x = 0, L$ faces	$x = 0, L$ faces	$x = 0$ face
$\rho(x, 0)$	1	1	0	0
ρ(exposure, t)	0	0	1	1
Zero flux, $x^* =$	L	$L/2$	$L/2$	L
$\rho(x, t)$	$F(x, t, 2L)$	Eq. (11), $F(x, t, L)$	$1 - F(x, t, L)$	$1 - F(x, t, 2L)$

Fig. 1. Schematic representation of quencher Q in in-diffusion experiments where the film sample is either supported on a substrate with only one face of exposure (*a*), or free standing and with two faces of exposure (*b*). Excitation light enters the sample along the x axis. The degree of shading represents the quencher concentration profile, while the degree of whiteness at various values of x represents the relative luminescence intensity emanating from those points.



Concentration profiles calculated in this way for diffuse-out experiments are shown in Fig. 2 for various values of reduced time Dt/L^2. Two features of these profiles are noteworthy. First, for a given direction of net flow, a sample of thickness L with one side of exposure shows an evolution of the concentration profile that is identical to that of a sample of thickness $2L$ with two sides of exposure. That is, for the evolution of $Q(x, t)$, doubling the number of exposure sides is equivalent to halving the film thickness. It is important to recognize, however, that because of the way $Q(x, t)$ enters into eq. [9], this statement is *not* true for the evolution of the $I(t)$ time profiles.

Fig. 2. Calculated relative concentration profiles from films initially equilibrated with O_2, and then p_{O_2} is reduced to zero at $t = 0$: (*a*) one side of exposure, (*b*) two sides of exposure. Calculations employ $\rho(x, t)$ functions defined in Table 1. Adjacent to each profile is a number indicating the reduced diffusion time as the ratio Dt/L^2. Corresponding in-diffusion profiles can be calculated from the relation $\rho_{in}(x, t) = [1 - \rho_{out}(x, t)]$.



Second, as seen in Table 1, for a fixed sample thickness and exposure side, the concentration profiles of the in-flow and out-flow experiments are related by the simple expression that they add up to Q_{eq}. However, as we shall see, depending on the quenching efficiency (value of B in eq. [9*b*]), the time profiles $I(t)$ can be drastically different. This will have important implications in the design of experiments and analysis of the data.

Simulated luminescence data

In a typical experiment, a polymer film is mounted in the sample chamber of a fluorescence spectrometer in a cell that allows control of the surrounding atmosphere. One flushes the

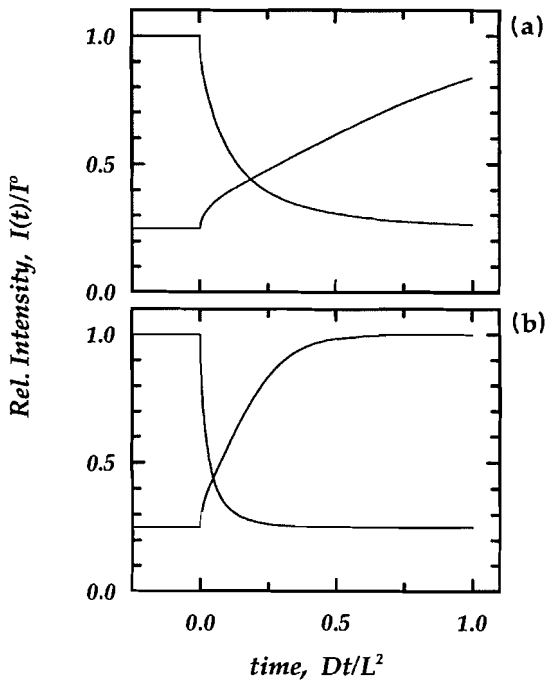
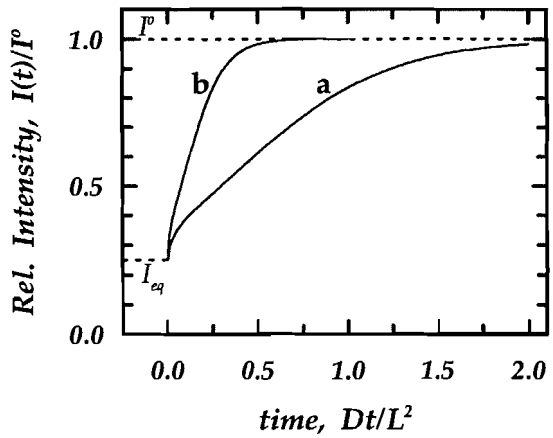
Fig. 3. Simulated (eq. [9], Table 1) luminescence intensity vs. time transient profiles for a sample film of thickness L and quenching sensitivity $I^0/I_{eq} = 4$ ($B = 3$); (*a*) exposure on one side, (*b*) exposure on two sides. Rising transients correspond to out-diffusion experiments where the sample is initially equilibrated with some external partial pressure of O_2, p_{O_2}, and at time $t = 0$ the system is flushed with N_2. Decaying transients correspond to in-diffusion experiments where the sample is free of any dissolved oxygen, and at time $t = 0$ the system is flushed with an excess of gas of external partial pressure of O_2, p_{O_2}. Notice that the absolute magnitude of the initial slopes for the decaying transients are larger by about $(I^0/I_{eq})^2 \approx 16$ times, when compared to the rising transients.



cell with a gas like nitrogen or argon until oxygen has been removed completely from the film, and the emission intensity holds steady at its most intense value. At this point, one has $Q = 0$, inside and outside of the sample, and $I = I^0$. At time zero, the sample is at once exposed to a *fixed* external partial pressure of oxygen. In the sample, $Q(x, t)$ increases to its final uniform equilibrium value, Q_{eq}, and concurrently the measured intensity drops to its final value I_{eq}. One now has one data set to be analyzed. The same sample is now ready for an out-diffusion experiment. That is, the external concentration (pressure) of oxygen is at once brought to zero (e.g., flushing with N_2). There is a net diffusion of quenchers out of the sample, until $Q = 0$ everywhere in the sample. The measured intensity increases concurrently from I_{eq} to I^0. Furthermore, the final intensity values are the same, whether one has one or two sides of the film exposed to the outside atmosphere, since Q_{eq} is the same in both experiments. All simulations satisfy the expression $I^0/I_{eq} = 1 + AQ_{eq}$, which is, of course, a consequence of our assumption of the SV quenching relation.

Examples of these experiments, employing simulated data according to eq. [9], are shown in Fig. 3*a* for a single exposure face, whereas Fig. 3*b* describes the system with two exposure faces. In this simulation the value of the intensity ratio I_{eq}/I^0 is arbitrarily chosen to be 0.25 ($B = 3$). Examples for other

Fig. 4. The same simulated out-diffusion experiment as in Fig. 3, but examined on a longer time scale.



choices of B will be given when we compare theory with experimental data. Figure 4 shows the quencher out-diffusion simulations of Fig. 3 on a longer time scale. It is clear that equilibrium is approached more rapidly for two-face exposure than for diffusion across a single film surface. Significantly, in both examples we see that the time profiles for the in-diffusion experiment are very different than those for the out-diffusion experiment. They have different shapes, and they seem to require different amounts of time to come to equilibrium. Note that there is no difference in the diffusion coefficient of the penetrant into and out of the film. Rather, this result indicates that the oxygen concentration profile couples to the emission quenching process in very different ways in the two experiments.

Previous considerations of transient oxygen-quenching experiments treated the quencher concentration at time t as being uniformly distributed in the film. Such models fail to predict the difference between experiments in which the quencher diffuses into the film and those in which it diffuses out of the film. There are other differences as well between the exact analysis presented here and those involving asymptotic solutions to the diffusion equation. In Fig. 5 we compare the analysis of simulated data for two cases in which oxygen is allowed to diffuse into a luminescent polymer film. In the first case, at equilibrium, $I_{eq}/I^0 = 0.67$, whereas in the second case, $I_{eq}/I^0 = 0.25$. Analysis of the data according to the MacCallum expression (eq. [A3], Appendix) generates the two dotted lines, which lie significantly below the solid lines representing the exact solution to the quenching data. The shape of the Guillet expression (eq. [A4]) has no dependence on I_{eq}/I^0, and for both experiments yields the broken line in Fig. 5. The simplifying assumptions made in both of these analyses of the quenching-coupled-to-diffusion experiment, unfortunately, lead to significant errors.

Experimental data

In Fig. 6, we show plots of experimental data for oxygen diffusion into an uncured silicone epoxy resin film, 745 μm thick, containing 50 ppm platinum octaethylporphine as the luminescent dye. Two pairs of curves are displayed. One shows a rapid decrease in emission intensity after exposure of the deoxygenated film to air at 1.0 atm (101.3 kPa). The sec-

For personal use only.

Fig. 5. Comparison of results obtained by fitting simulated data to eqs. [A3] and [A4] with those obtained using eq. [9]. Solid lines refer to the exact calculations (eq. [9]) of $I(t)/I^0$ for I_{eq}/I^0 equal to 0.67 and 0.25. Dotted traces refer to the same data analyzed according to the MacCallum formulation (eq. [A3]) The broken line refers to the data as analyzed with the Guillet formulation (eq. [A4]) where the transient decay shape has no dependence on the value of I_{eq}.

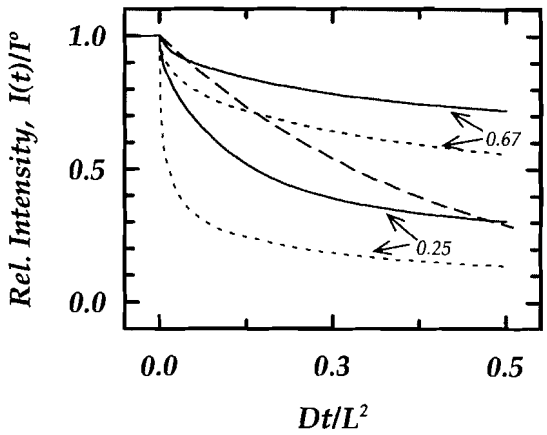

Fig. 6. Analysis of experimental data for a film (L = 745 μm) of Genesee silicone epoxy resin EXP-36-X20 containing 50 ppm of platinum octaethylporphine (λ_{ex} = 534 nm, λ_{em} = 646 nm). The solid lines represent experimental data. In the out-diffusion experiment, the sample, initially equilibrated with air, is at once flushed with N_2. Following the leveling off of the rising transient, I^0/I_{eq} = 9.15. In the in-diffusion experiment, the sample initially equilibrated with N_2 is at once flushed with air. Here I^0/I_{eq} = 9.76. Broken lines refer to theoretical fits of the data, using eq. [9] and Table 1, with $D = 1.0 \times 10^{-5}$ cm^2 s^{-1} (rising transient), and $D = 1.2 \times 10^{-5}$ cm^2 s^{-1} (decaying transient). The inset displays details of the transients on a shorter time scale.

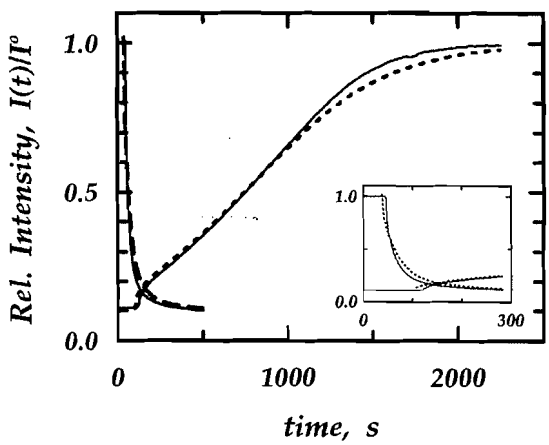
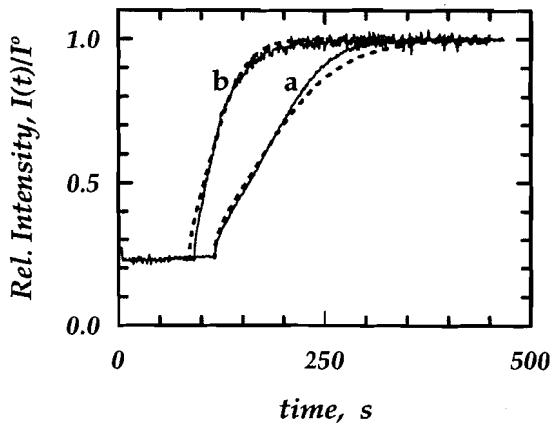


ond curve shows the much slower increase in the emission intensity following complete removal of oxygen from the external atmosphere. The dashed lines in Fig. 6 represent the best theoretical fits to the data employing eq. [9]. For the rising transient, we obtained a value of $D_{O_2} = 1.0 \times 10^{-5}$ cm^2 s^{-1}, whereas for the decaying transient, the best-fit value is $D_{O_2} = 1.2 \times 10^{-5}$ cm^2 s^{-1}. The insert shows the comparison between

Fig. 7. Analysis out-diffusion experimental data for two different films of Genesee silicone resin GP-197 containing 150 ppm of platinum octaethylporphine (λ_{ex} = 534 nm, λ_{em} = 646 nm). The solid lines represent experimental data. Curve (*a*) refers to a film of L = 80 μm supported on a glass substrate. Curve (*b*) refers to a free-standing film with two sides of exposure and L = 112 μm. Broken lines refer to theoretical fits obtained using eq. [9] and Table 1, for (*a*) with $D = 6.0 \times 10^{-7}$ cm^2 s^{-1} and I^0/I_{eq} = 4.20; and for (*b*) with $D = 5.4 \times 10^{-7}$ cm^2 s^{-1} and I^0/I_{eq} = 4.34.



the experimental and best-fit (theoretical) data on an expanded time scale.

A second experiment is shown in Fig. 7 for a different silicone resin. Here we compare diffusion-out experiments for a substrate-supported film (a) of thickness L = 80 μm with (b) a free-standing film of thickness L = 112 μm. Fits to the data yield $D_{O_2} = 6.0 \times 10^{-7}$ cm^2 s^{-1} for the former case and $D_{O_2} = 5.4 \times 10^{-7}$ cm^2 s^{-1} for the latter. While there are small deviations between the experimental and fitted data, which may be related to non-uniformity of film thickness, the fit is on the whole very good and, most important, it accommodates and confirms the most surprising feature of the model, namely, that the rate of intensity decay for diffusion of oxygen into the sample is more rapid than the rate of intensity growth for oxygen diffusion out of the film.

Conclusion

Luminescence quenching experiments employing a fluorescence spectrometer operated in the time base mode with steady illumination of a sample can provide precise values (±10–15%) of the diffusion constant for oxygen into and out of thin polymer films, provided that the data are analyzed by taking into account the time evolution of the concentration profile of oxygen as a quencher in the system. The model predicts, and experiments show, that the rate of intensity decrease is much faster for oxygen diffusing into the film than the rate of intensity increase for oxygen diffusion out of the film.

Appendix A

Previous analyses of the transient in-diffusion of oxygen experiment invoke the assumption that at every instant of time the observed luminescence intensity $I(t)$ is related to the mean concentration of quencher $\langle Q_q(t)\rangle$ through a SV-type of relation. Therefore, for quencher in-diffusion through one face of exposure, one would have

$$[A1] \quad \frac{I^0}{I(t)} = 1 + A\langle Q(t)\rangle$$

where A is some proportionality constant. The mean concentration of quencher $\langle Q_q(t)\rangle$ is found from a Fick's law solution of the system for the quencher concentration profiles $Q(x, t)$ and is given by

$$[A2] \quad \langle Q_q(t)\rangle = \frac{1}{L}\int_0^L Q(x,t)\,dx = Q_{eq}\left[1 - \frac{8}{\pi^2}\sum_{n=\text{odd}}^{\infty}\frac{1}{n^2}\exp\{-n^2\pi^2 Dt/4L^2\}\right]$$

For very short times $\langle Q_q(t)\rangle$ approximates as $4(Dt/\pi L^2)^{1/2}$, while for longer times only the first exponential term of eq. [A2] is needed. Such considerations lead to the suggestions

$$[A3] \quad I(t)_{t\to 0} = \frac{I^0}{1 + \frac{4B}{\pi^{1/2}}(Dt/L^2)^{1/2}}$$

$$[A4] \quad I(t)_{t\to 0} \sim \exp(-Dt/4L^2)$$

where the constant B is defined by eq. [9*b*].

Pyrene-labeled amphiphilic poly-(*N*-isopropylacrylamides) prepared by using a lipophilic radical initiator: synthesis, solution properties in water, and interactions with liposomes

Abstract: Fluorescently labeled amphiphilic poly-(*N*-isopropylacrylamides) (PNIPAM) substituted with a *N*-[4-(1-pyrenyl)butyl]-*N*-*n*-octadecyl group at the chain end were prepared by free-radical polymerization in dioxane of *N*-isopropylacrylamide (NIPAM) using 4,4′-azobis{4-cyano-*N*,*N*-[4-(1-pyrenyl)butyl]-*n*-octadecyl}pentanamide as the initiator. The solution properties of the polymers in water were studied as a function of polymer concentration and temperature. Quasi-elastic light-scattering measurements and fluorescence experiments monitoring the pyrene excimer and pyrene monomer emissions revealed the presence of multimolecular polymeric micelles below the lower critical solution temperature (LCST) of PNIPAM. These underwent partial, reversible reorganization as they were heated above the LCST. The interactions of the pyrene-labeled amphiphilic PNIPAM with dimyristoylphosphatidylcholine (DMPC) liposomes have been examined in water at 25°C. From fluorescence experiments it was established that the polymeric micelles are disrupted irreversibly upon contact with the liposomes. The anchoring of the polymer chains occurs by insertion of their hydrophobic tail within the phospholipidic bilayer, as evidenced from a large decrease of the pyrene excimer emission relative to pyrene monomer emission. The copolymers remained anchored within the bilayer as the temperature of the copolymer–liposome suspension was raised above the LCST of PNIPAM.

Key words: liposome, poly-(*N*-isopropylacrylamide), fluorescence, micelles.

Résumé : On a préparé des poly-(*N*-isopropylacrylamides) (PNIPAM) amphiphiles, substitués par un groupe *N*-[4-(1-pyrényl)butyl]-*N*-*n*-octadécyle au bout de la chaîne et marqués pour la fluorescence, en effectuant une polymérisation radicalaire, dans le dioxane, du *N*-isopropylacrylamide (NIPAM) à l'aide du 4,4′-azobis{4-cyano-*N*,*N*-[4-(1-pyrényl)butyl]-*n*-octadécyl}pentanamide comme initiateur. On a étudié les propriétés des polymères en solution en fonction de la concentration du polymère et de la température. Des mesures de diffusion quasi-élastique de la lumière et de fluorescence impliquant l'examen de l'évolution des émissions de l'excimère du pyrène et du pyrène monomère ont permis de mettre en évidence la présence de micelles polymériques multimoléculaires à des températures inférieures à la température critique la plus basse de la solution (LCST) de PNIPAM. Lorsqu'on les chauffe au-dessus de la LCST, ces micelles subissent des réorganisations partielles et réversibles. Opérant dans l'eau, à 25°C, on a étudié les interactions du PNIPAM amphiphile marqué au pyrène avec les liposomes dimyristoylphosphatidylcholine (DMPC). Sur la base des expériences de fluorescence, on a établi que les micelles polymériques sont détruites au contact des liposomes. L'ancrage des chaînes de polymère se produit par une insertion de leur queue hydrophobe dans la bicouche phospholipidique, cette conclusion est basée sur une diminution importante de l'émission de l'excimère du pyrène par rapport à l'émission du monomère du pyrène. Les copolymères restent ancrés dans la bicouche même lorsqu'on augmente la température de la suspension copolymère–liposome au-dessus de la LCST du PNIPAM.

Mots clés : liposome, poly-(*N*-isopropylacrylamide), fluorescence, micelles.

Introduction

A drug may appear extremely promising on the basis of testing protocols carried out in vitro; however, its effectiveness in vivo is often stifled by the complex nature of living organisms. The main problems involved in the effective administration of highly potent drugs can be summarized in two points: drugs are rapidly cleared from the blood system, hence they do not have a sufficiently long residence time to act on target tissues, and many drugs are toxic not only to malignant cells but also to healthy cells in the body. Such unfavorable circumstances may be alleviated significantly through the use of drug delivery systems. These are composite materials in which a drug is integrated within another phase that, ideally, carries the drug to a specific, targeted site within the body and also controls the rate of drug release. Liposomes, which consist of a spherical bilayer membrane capturing a pool of water in their center, have attracted considerable interest as delivery systems. The practical value of liposomes derives from two unique properties: (*i*) their ability to entrap either water-soluble materials in the internal water reservoir or liposoluble compounds in their lipid bilayer; and (*ii*) their compatibility with natural membranes, making them safe for medical applications.

Even with the advantages of facile production, biocompatibility, and capacity to encapsulate a wide variety of molecules, early liposome-based drug delivery systems performed rather poorly. The problems were traced primarily to the rapid uptake of the liposomes in the reticulo-endothelial system (RES). Liposomes in the blood stream are quickly labeled by opsonins present in blood plasma. These proteins are part of the defense mechanism signalling to phagocytes the presence in the blood of foreign substances (1). Adsorption of opsonins on the surface of liposomes triggers their removal from the blood and a subsequent increase of their concentration in the RES. It was quickly recognized that surface modification of the liposomes that would mimic the surfaces of cells would prevent the immune system from attacking liposomes, hence increasing their residence time in blood. Allen and Chong discovered that surface sialic acid, in the form of gangliosides, serves as an effective surface modifier, inducing significant prolongation of the liposome circulation half-life (2). Sterically stabilized liposomes (S-liposomes) are now produced industrially under the trade name "Stealth Liposomes" and are employed in drug delivery systems targeted at tumor cells. In this case the stabilization of the liposomes is achieved by incorporation of polyethylene glycol derivatives within the outer liposome surface. The current understanding of the reason behind the increased half-life of S-liposomes is the inhibition of opsonization by plasma proteins due to the presence of polyethylene glycol chains anchored on the outer liposome surface.

While polyethylene glycol coated liposomes have been especially successful in improving the performance of liposome-based drug delivery systems (3, 4), other polymer coatings have been investigated and have met with some level of success. Sunamoto et al. pioneered the use of polysaccharide derivatives, such as amylopectin and mannan (5). They showed that coating the outer surface of liposomes with polysaccharides produced vesicles that are much more stable, not only under laboratory conditions, but also in vivo (6). A range of biocompatible synthetic polymers, either neutral or charged, have also been studied with regard to their role in imparting structural stability to liposomes (7). Several recent studies have demonstrated that the polymer coatings may not only play a passive protective role, but may in fact participate in the drug release process by responding to some external stimulus (8). We (9–11) and others (12, 13) have explored the use of hydrophobically modified poly-(*N*-isopropylacrylamides) (HM-PNIPAM) as liposome stabilizers. The polymers employed consist of a neutral hydrophilic chain made up of *N*-isopropylacrylamide units to which were attached at random a few octadecyl chains (9, 12) or phosphatidylethanolamine moieties (13). The alkyl substituents are known to interact strongly with lipid bilayers (14) and thus can serve as anchors for the polymer onto the liposomes. PNIPAM is very soluble in cold water, but its solution undergoes phase separation as it is warmed up past a critical temperature (32°C), the lower critical solution temperature or LCST (15, 16). Detailed investigations of this phase transition have established that at the LCST the PNIPAM chains undergo a collapse from hydrated extended coils to hydrophobic globules, which aggregate and form a separate phase (17). This temperature sensitivity of the polymer chain was used to simulate the dynamics of cell membranes, by anchoring the polymer onto liposomes and subjecting the systems to repeated heating-cooling cycles in temperature domains including the polymer LCST (9–11).

We observed recently that certain PNIPAM grafted surfaces resist protein adsorption in physiological environment (18), via a mechanism akin to that put forward to account for the protective effect of polyethylene glycol chains. Thus we set about to investigate the preparation of PNIPAM-stabilized liposomes and to test their effectiveness in drug delivery systems capable of preventing the adsorption of opsonins. We chose to employ HM-PNIPAM in which the octadecyl chains are incorporated as end groups, rather than as grafts randomly distributed along the polymer chain. This strategy should permit a finer control over the PNIPAM chain density on the liposome outer surface. The interactions between liposomes and the HM-PNIPAM were established by monitoring the photophysical properties of fluorescently labeled polymers in which a pyrenyl group was incorporated as part of the hydrophobic end moiety. The polymers were obtained by free-radical polymerization of *N*-isopropylacrylamide using a pyrenyl-substituted lipophilic initiator. The synthesis, characterization, and solution properties of the polymers are presented here. Special emphasis will be given to results obtained from fluorescence techniques. Evidence is given for the formation of polymeric micelles in aqueous solutions below and above the lower critical temperature. We then report a series of spectroscopic measurements aimed at assessing the interactions of dimyristoylphosphatidylcholine (DMPC) liposomes and the pyrene end-labeled polymers. The effect of polymer concentration, relative to liposome concentration, and the influence of changes in solution temperature are examined in detail.

Experimental

Materials and instrumentation

Water was deionized with a Barnstead NANOpure water purification system. Reagent grade solvents were used in all

Fig. 1. Synthetic scheme for the preparation of the polymerization initiator Py-ODA (**3**); (a): $CHCl_3$–THF.

syntheses. Dioxane was purified by distillation from sodium under nitrogen. *N*-isopropylacrylamide (NIPAM, Eastman Kodak Chemicals) was purified by recrystallization from toluene/hexane 10/1 v/v. Dimyristoylphosphatidylcholine (DMPC, 99%, synthetic grade) was purchased from Sigma Chemicals. 4-(1-Pyrene)butyric acid was obtained from Aldrich Chemical Co. Stearylamine and carbonyldiimidazole were obtained from Wako Chemicals. Disuccinimidyl 4,4′-azobis(cyanovaleric acid) (**2**, Fig. 1) was prepared as described previously (19). Proton NMR spectra were recorded for $CDCl_3$ solutions of the polymers at ambient temperature on a Bruker 200 MHz spectrometer. Gel permeation chromatography (GPC) was performed with a Waters 590 programmable HPLC system equipped with a Waters 410 differential refractometer and three Ultrastyragel polystyrene columns (eluent: THF, flow rate: 1.0 mL min^{-1}). The weight and number average molecular weights were determined from a calibration curve established with polystyrene standards. Thin-layer chromatography (TLC) was performed with silica gel coated glass plates obtained from Whatman. UV spectra were measured using a Hewlett Packard 8452A photodiode array spectrometer equipped with a Hewlett Packard 89090A temperature controller and operated under the HP ChemStation Windows-based software. Steady-state fluorescence spectra were recorded on a SPEX Fluorolog 212 spectrometer operated by the DM3000F data system. Temperature control of the samples was achieved using a water-jacketed cell holder connected to a Neslab circulating bath. The temperature of the sample fluid was measured with a thermocouple immersed in a water-filled cuvette placed in one of the four cell holders. Liposome and polymeric micelle sizes were determined by quasi-elastic light-scattering (QELS) measurements at a fixed 90° scattering angle with a NICOMP 370 Submicron Particle Sizer or a Brookhaven Instrument Corp. model BI-9000AT correlator equipped with a Lexel (25 mW) argon ion laser operating at 514.5 nm. Data analysis was performed with the software provided by the manufacturers. Liposomes were obtained by extrusion using a LiposoFast Large system (Avestin Inc. Ottawa, Canada) connected to a nitrogen cylinder.

Syntheses

N-*[4-(1-Pyrenyl)butyl]*-N-n-*octadecylamine* ***1***

4-(1-Pyrenyl)butyric acid (4.31 g, 15 mmol), stearylamine (4.58 g, 17 mmol), and carbonyldiimidazole (2.98 g, 18.4 mmol) were dissolved in an anhydrous mixture of THF/DMF (1:1 v:v, 20 mL) at room temperature. The mixture was stirred overnight. The solvent was evaporated, yielding an oily residue. This was triturated vigorously with MeOH. A brown-colored paste was obtained (6.02 g, 11.1 mmol). A solution of this paste in dry THF (100 mL) was poured in a three-necked flask equipped with a condenser. $LiAlH_4$ (6.32 g, 166 mmol) was added slowly. The reaction mixture was stirred at 50°C overnight. After dropwise addition of water (10 mL) the precipitate was treated with THF and diethyl ether to extract the desired product. Evaporation of the combined extracts yielded *N*-[4-(1-pyrenyl)butyl]-*N*-*n*-octadecylamine (14.34 g, 74.8%) as a light-brown solid.

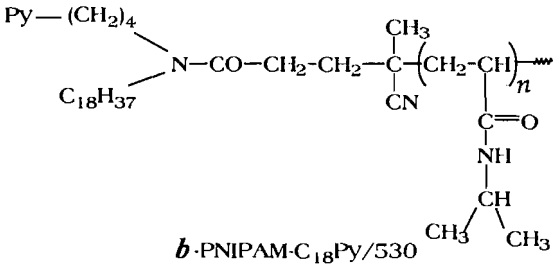
*4,4′-Azobis{4-cyano-*N,N-*[4-(1-pyrenyl)butyl]*-n-*octadecyl]-pentanamide (PyODA)* ***3*** *(Fig. 1)*

A solution of disuccinimidyl 4,4′-bis(4-cyanovalerate) (**2**, 1.59 g, 3.35 mmol) in THF (20 mL) was added to a solution of *N*-[4-(1-pyrenyl)butyl]-*N*-*n*-octadecylamine (**1**, 3.52 g, 6.7 mmol) in chloroform (40 mL). The mixture was stirred at room temperature overnight. The solvent was evaporated in vacuo at room temperature, yielding an oily material. The residue was dissolved in chloroform (50 mL). It was washed twice with a 5% sodium bicarbonate solution (50 mL) and twice with water (50 mL). The organic phase was dried with anhydrous Na_2SO_4, filtered, and evaporated. The product was purified by chromatography on silica gel eluted with ethanol. A final precipitation from acetonitrile yielded the initiator PyODA **3** (530 mg, 0.41 mmol, 12.2% yield relative to disuccinimidyl 4,4′-bis(4-cyanovalerate)); IR: 3041 (C-H aromatic), 2926, 2854 (ν_{as} and ν_s CH_2), 2239 (-CN stretching), 1627 (C=O stretching, tertiary amide), 1605, 1491 (aromatic), 1460 ($\delta_s$aliphatic CH_2) cm^{-1}.

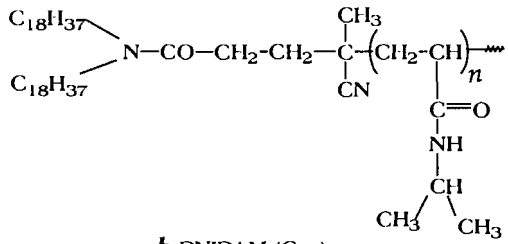
b-*PNIPAM-(C_{18}Py)/530 (Fig. 2)*

NIPAM (4.42 mmol, 0.5 g) and PyODA (0.03 mmol, 40 mg)

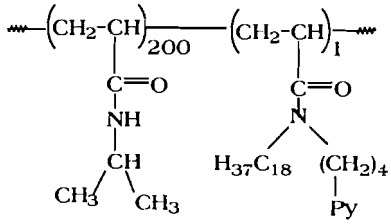
Fig. 2. Chemical structures of the polymers described in this study.



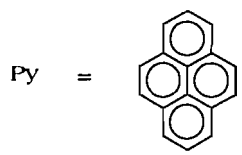
b-PNIPAM-C_{18}Py/530



b-PNIPAM-$(C_{18})_2$



b-PNIPAM-C_{18}Py/200



were dissolved in dioxane (5 mL). The solution was degassed by bubbling N_2 for 10 min. It was heated to 70°C for 17 h. The polymer was recovered by precipitation in hexane (50 mL). It was dissolved in THF (1 mL) and reprecipitated into diethyl ether (200 mL). The polymer was separated by filtration and dried in vacuo at 40°C for 24 h (320 mg).

b-*PNIPAM-(C_{18}Py)/910 (Fig. 2)*

This polymer was prepared by the same procedure, starting with NIPAM (0.026 mol, 3.0 g) and PyODA (0.13 mmol, 170 mg) and yielding 2.72 g of purified polymer.

Cloud point measurements

Cloud points were determined by spectrophotometric detection of the changes in turbidity (λ = 390 nm) of aqueous polymer solutions (0.26 g L^{-1}) heated at a constant rate (0.2°C min^{-1}) in a magnetically stirred UV cell. The value reported is the temperature at which turbidity of the solution appears upon heating.

Fluorescence measurements

Slit widths were set at 1 nm for both excitation and emission monochromators. For the emission spectra the excitation wavelength was set at 346 nm and the emission range was 370–600 nm. Excitation scans were measured between 280 and 360 nm with emission being monitored at 378 and 472 nm. Excitation spectra were measured in the ratio mode, while emission spectra were not corrected. The excimer-to-monomer emission intensity (I_E/I_M) ratios were calculated by taking the ratio of the emission intensity at 472 nm to the half-sum of the emission intensities at 398 and 378 nm after subtraction of the excimer contribution. For the studies at different temperatures, measurements were repeated until no change in consecutive spectra was observed, to ensure that an equilibrium had been reached. Time-based fluorescence scans were performed with excitation at 346 nm and emission at 378 nm to monitor the increase in monomer emission over a period of 3–5 h.

Solutions for spectroscopic analysis

Polymer solutions in water were prepared at room temperature from an aqueous concentrated stock solution of polymer. The stock solution (6.0 g L^{-1}) was diluted in water to the desired concentration (usually 0.26 g L^{-1}). In the preparation of polymer–liposome mixtures, the stock polymer solution was added to a freshly prepared liposome suspension to gain the desired polymer concentration (0.26 g L^{-1}). The liposome concentration was only slightly lowered, since a very small volume of the concentrated polymer stock was required to reach the proper concentration, e.g., the phospholipid concentration changed from 1.0 to 0.96 g L^{-1}. Polymer–liposome mixtures were allowed to equilibrate for 3–4 h prior to measurements, unless otherwise specified. Solutions in methanol were degassed by vigorous bubbling with solvent-saturated argon for 1 min prior to fluorescence analysis. Aqueous solutions were not degassed.

Liposome preparation

DMPC (approximately 10 mg) was weighed out in a vial and dissolved in a minimal amount of chloroform. The chloroform was evaporated, with a stream of nitrogen, in such a way as to form a thin film of phospholipid on the walls of the vial. The vial was evaporated further under vacuum (water aspirator) for 2 h at room temperature. Deionized water was added to the vial, causing the phospholipid film to disperse in the water. This suspension was subjected to 10 consecutive freeze–thaw cycles. The resulting suspension was passed 15 times through a polycarbonate membrane, 0.1 μm pore size, housed in a Liposofast Large apparatus. Nitrogen (20–60 psi; 1 psi = 6.9 kPa) was used to force the suspension through the membrane. The diameters of the liposomes obtained ranged from 140 to 160 nm. All liposome suspensions were stored under refrigeration and used within a day after preparation.

Results and discussion

Synthesis and characterization of the copolymers

The polymerizations were accomplished in dioxane solutions, starting with two different molar ratios of *N*-isopropylacryl-

amide and initiator, PyODA, leading to two polymer samples with slightly different physical properties (Table 1). Several precipitations with THF (solvent) – diethyl ether (non-solvent) were performed to purify the polymers. The absence of low molecular weight fluorescent impurities was ascertained by TLC analysis using 254 and 340 nm illumination to detect the pyrene chromophore. Of particular importance to the experiments described here is the absence of low molecular weight pyrene derivatives, since they may affect the spectroscopic measurements aimed at characterizing the polymer properties. Polymers with reasonably high molecular weights and broad molecular weight distributions were obtained in all cases. The average numbers of monomer units per pyrene end group were determined by UV analysis of polymer solutions in methanol, using *N*-[4-(1-pyrenyl)butyl]-*N*-*n*-octadecylacrylamide (ε_{341} (MeOH) = 34 900) (20), as model compound. Numbers of NIPAM units per pyrenyl group of 530 and 910 were calculated for polymers prepared with initial monomer/initiator ratios of 147 and 200, respectively. Consistent with our previous nomenclature we designate these polymers as *b*-PNIPAM-C_{18}Py/530 and *b*-PNIPAM-C_{18}Py/910 (Fig. 2). The number of monomer units per polymer end group was confirmed by an analysis of the ^{1}H NMR spectroscopy. The ratio of isopropyl to C_{18} groups was calculated from the area of the singlet at 3.97 ppm, due to the resonance of the isopropylidene proton of the monomer unit and the area of the triplet centered at 0.85 ppm, attributed to the resonance of the terminal methyl protons of the octadecyl chain. The number of monomer units per polymer end group calculated from either NMR or UV data should correspond to the degree of polymerization of the polymers, assuming that termination occurred by disproportionation and chain transfer (21). From the data presented it is not possible to assert that some polymers do not carry pyrenyl groups at both chain ends. The assumption that substitution occurred at only one end of each macromolecule is based on mechanistic considerations and on supportive evidence from an earlier investigation of NIPAM polymerization initiated with the dioctadecyl analogue of PyODA (22).

Properties of the copolymers in water. Evidence for micelle formation

The polymers were soluble in water at or below room temperature. Optically clear aqueous solutions of polymer concentrations as high as 6.0 g L^{-1} were prepared with no difficulty. As expected, the aqueous solutions became turbid when heated, signaling the occurrence of a lower critical solution temperature (LCST). This temperature (32.2 °C) is identical to that of PNIPAM (15) (Table 2). This may seem surprising, since as a rule the LCST of a polymer in water decreases with increasing hydrophobicity (23). This trend was observed in a previous study of the block copolymers *b*-PNIPAM-$(C_{18})_2$/280 and *b*-PNIPAM-$(C_{18})_2$/540 (20) (Table 2). It suggests that the hydrophobic substituents are not exposed to water, but rather form a micellar structure protected from water by the PNIPAM chains and therefore do not make a hydrophobic contribution to the LCST.

The formation of such micellar structures in aqueous solutions of *b*-PNIPAM-C_{18}Py/530 was confirmed by quasi-elastic light-scattering measurements (QELS). The experiments were carried out at a fixed angle (90°) with solutions (0.3 g L^{-1}) of the copolymers kept at 25°C. Strong signals were detected, indicating the presence of polymeric micelles, in contrast to the case of homopolymer (PNIPAM) solutions, which gave no detectable response. The sizes of the polymeric

micelles are reported as effective diameter, d, determined by a cumulant analysis of the data (Table 2). From the calculated polydispersity values it is apparent that there is a broad distribution of micelle sizes. The sizes were insensitive to changes in temperature below the LCST (32.2°C). At 35°C, intermicellar aggregation took place, as indicated by an increase in the average diameter of the polymeric micelles from 44 nm at 25°C to 70 nm at 35°C. These larger polymeric micelles were stable for several hours at 35°C, implying that no further aggregation took place. Upon cooling below the LCST the solutions recovered their optical clarity. QELS measurements on these solutions revealed the presence of micelles of the same average size as those observed in the solutions before the heating–cooling cycle. The formation of the polymeric micelles and their microscopic structure are dictated by the action of two competing forces: (*a*) the hydrophobic forces (for reviews, see ref. 24) on the alkyl-pyrenyl groups in water that sequester them in the aggregate center and (*b*) the excluded volume repulsion between the polymers that limits the aggregate size. The balance of these two forces is expected to depend not only on the molecular architecture of the copolymers but also on the application of external stimuli, such as changes in temperature and in solvent composition. Micellar structures exist in water and also in water–alcohol mixtures within a narrow composition range.[2] Polymeric micelles do not form in methanol or in tetrahydrofuran. In these solvents no signal was detected by QELS analysis of polymer solutions ranging in concentration from 1 g L^{-1} to 6 g L^{-1}.

Characterization of the hydrophobic clusters by fluorescence spectroscopy

Emission spectra of the polymer *b*-PNIPAM-C_{18}Py/530 in water and in methanol are shown in Fig. 3. The emission of the polymer in water is dominated by a broad signal centered at 472 nm attributed to pyrene excimers (intensity I_E). The much weaker contribution of isolated excited pyrene ("monomer" emission, intensity I_M) is also detected, with the [0,0] band located at 378 nm. In a methanolic solution the polymer exhibits a much stronger emission due to excited isolated pyrene chromophores. The excimer emission, while still detectable, is very weak (I_E/I_M = 0.15). The contrast of the two spectra provides vivid evidence of the differences in the microstructure of the aqueous and the methanolic polymer solutions. The fact that pyrene excimer emission is very strong from aqueous polymer solutions implies that the pyrene groups are in close spatial proximity, incorporated within hydrophobic clusters. In methanol the polymer chains are isolated from each other and free to diffuse. Pyrene excimer emission can occur when a pyrene chromophore in its excited state comes into close proximity of a ground-state pyrene. Since each polymer chain carries only one chromophore, intrapolymeric excimer formation is precluded. As a consequence, the excimer contribution is much weaker than in the related case of the randomly substituted copolymer PNIPAM-C_{18}/200 (20), where excimer formation can take place by interaction of pyrenes attached to the same macromolecule.

Concentration studies confirm this description and emphasize the differences between the polymeric solutions in the two solvents. The ratio I_E/I_M measured from methanolic solutions

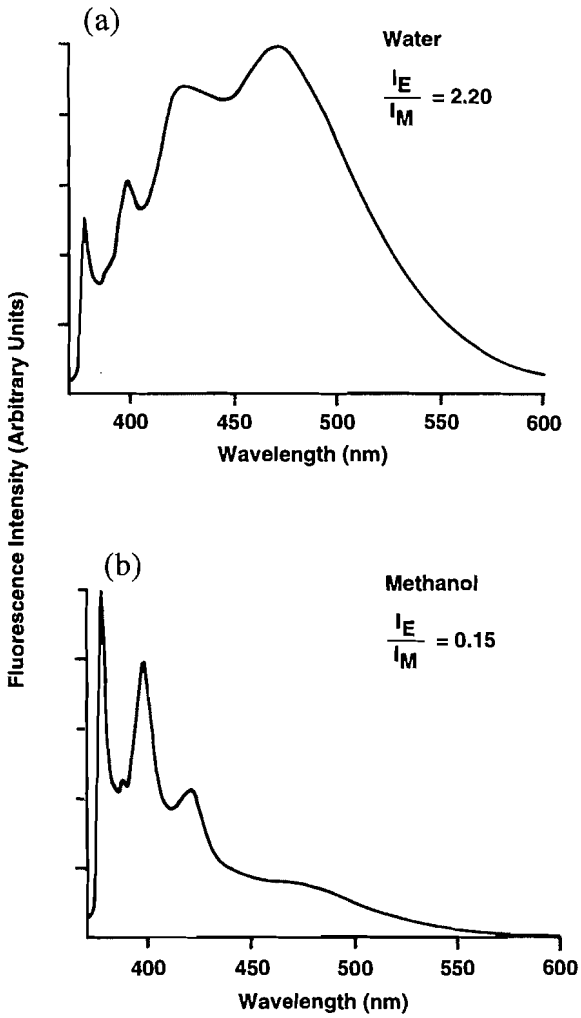
Fig. 3. Fluorescence spectra of pyrene-labeled poly(*N*-isopropylacrylamide) (*b*-PNIPAM-C_{18}Py/530, 0.26 g L^{-1}) (*a*) in water and (*b*) in methanol. Excitation wavelength: 346 nm.



decreases with polymer concentration. Only pyrene monomer emission is observed when the polymer concentration is 0.03 g L^{-1} or lower. The ratio I_E/I_M measured from aqueous solutions was insensitive to changes in polymer concentrations ranging from 0.03 to 2 g L^{-1}, implying that the hydrophobic aggregates form at polymer concentrations as low as 0.03 g L^{-1}, the limit of detection of our instrument. An interesting spectroscopic point needs to be clarified. It concerns the exact nature of the pyrene excimer: is it a diffusion-controlled dynamic excimer, or does it originate from preformed ground-state pyrene aggregates, a frequent occurrence in aqueous solutions of pyrene-labeled polymers (25)? A comparison of the UV absorption spectra and of the excitation spectra monitored for the excimer and monomer emissions points to the existence of ground-state pyrene aggregates. The following observations in particular are significant: (*i*) the excitation spectra for the monomer and excimer emissions from aqueous polymer solutions are clearly different. The general features of the spectra are similar, but the former is blue-shifted by 2 nm; (*ii*) the widths of the bands in the two spectra differ, with extensive band broadening in the case of the spectrum monitored for the excimer; (*iii*) the UV spectra of the polymer in water have

maxima at 346 nm, compared to 342 nm in methanol; and (*iv*) the UV spectra of the polymer in water exhibit a hypochromic effect accompanied by peak broadening. Relative measures of these effects are given by the peak-to-valley ratios P_M and P_E for the (0,0) transition in the excitation spectra viewed at the monomer emission and at the excimer emission, respectively, and $\Delta\lambda = \lambda_{max}$(excimer) $- \lambda_{max}$(monomer) (Table 3). This question will be addressed in more detail by carrying out time-dependent fluorescence measurements.

When a solution of *b*-PNIPAM-C_{18}Py/530 in water was heated from 15 to 45°C, several spectroscopic events occurred (Fig. 4). The ratio I_E/I_M increased slightly to reach a maximum value of 2.20 at 30°C. Then it decreased sharply to reach a value of 0.75 at 45°C. The midpoint of the transition was 32°C (Fig. 5). These changes were reversible: upon cooling of the solution, the ratio I_E/I_M increased to reach a value slightly higher than the value recorded before the heating–cooling cycle. A hysteresis in the temperature profile was observed, indicating that the time scale of polymer reorganization is rather long and that equilibrium was not achieved in scans performed at an approximate cooling or heating rate of 0.5°C min^{-1}. The initial I_E/I_M ratio was recovered when solutions car-

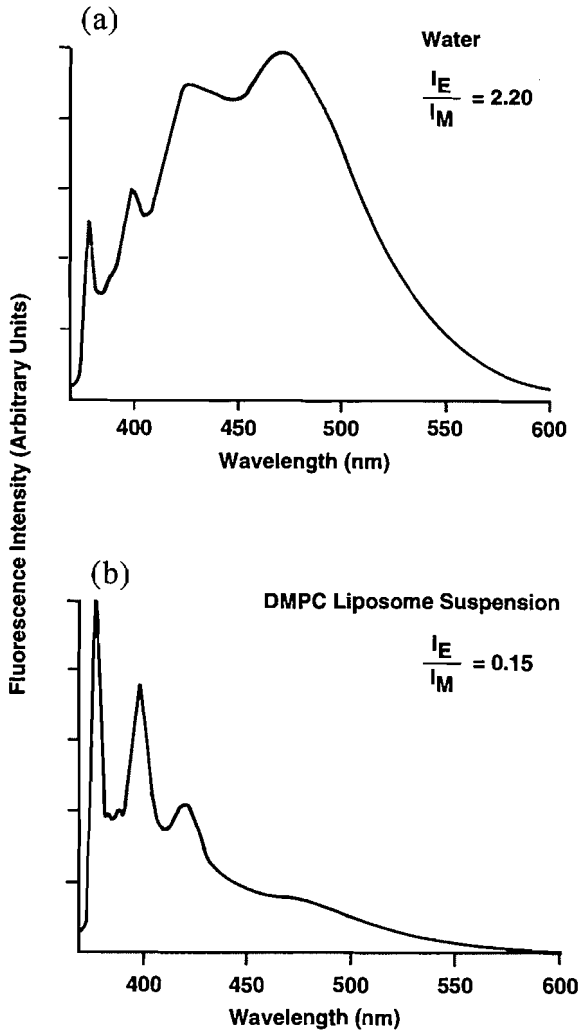
Dimyristoylphosphatidylcholine (DMPC)

ried through one heating–cooling cycle were kept at room temperature for 24 h. The decrease of I_E/I_M observed for *b*-PNIPAM-C_{18}Py/530 solutions above the LCST reflects a strong enhancement of the pyrene monomer, rather than a decrease in the pyrene excimer emission (see Fig. 4). This increase in total emission intensity is indicative of the occurrence of a significant level of pyrene self-quenching in cold solutions.

From the changes with temperature of the pyrene emission we conclude that at the LCST the morphology of the original polymeric micelles is disrupted to a small but significant extent. The temperature-induced collapse of the PNIPAM chains triggers a reorganization of the hydrophobic core such that a large fraction of the thermodynamically unstable pyrene aggregates falls apart. The original micelles conserve the over-

Fig. 7. Fluorescence spectra of *b*-PNIPAM-C_{18}Py/530 (0.26 g L^{-1}) (*a*) in water and (*b*) in the presence of DMPC liposomes; temperature 25°C; equilibrium time: 3 h; excitation wavelength: 346 nm.

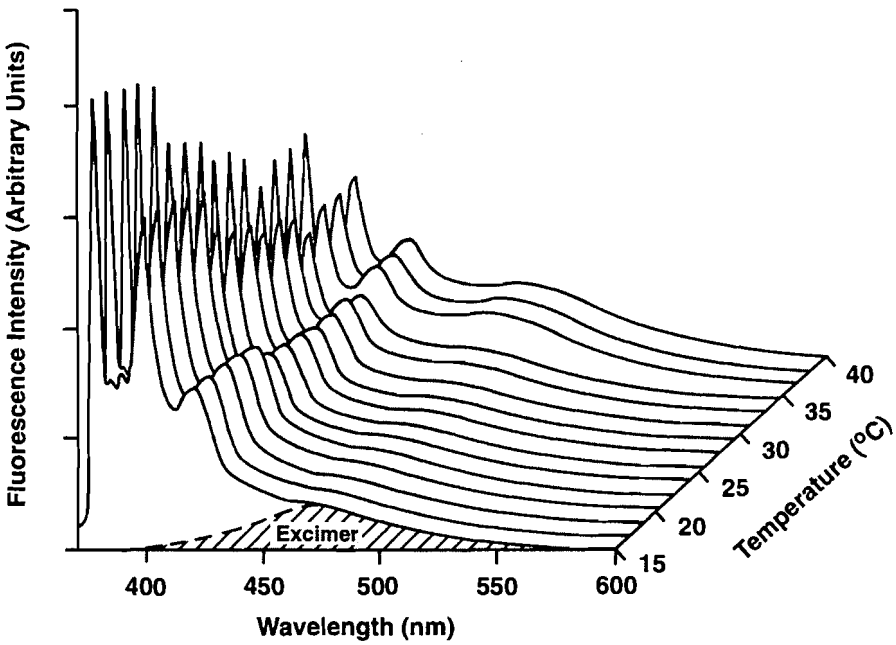


all morphology they adopted in the solutions below the LCST, as indicated by QELS measurements. Viewed at the molecular level this phase separation process differs in several key aspects from that occurring in solutions of the randomly alkylated amphiphilic polymers. In solutions of these polymers phase separation results in a disruption of the hydrophobic clusters formed below the LCST and a more isotropic distribution of the pyrenyl-octadecyl chains within the polymer-rich phase (20).

Interaction of the polymers and liposomes

Dimyristoylphosphatidylcholine (DMPC) (Fig. 6) liposomes were prepared by dispersion of the phospholipid in water and subsequent extrusion of the suspension through a polycarbonate membrane of 0.1 μm average pore size. Under these conditions unilamellar vesicles form predominantly (26, 27). The liposome diameters, measured by QELS, ranged from 140 to 160 nm in all the preparations. The structure and fluidity of lipidic bilayers exhibit a well-documented temperature dependence (28). Below a characteristic temperature, T_C, the phase transition temperature, the lipo-

Fig. 8. Fluorescence spectra of *b*-PNIPAM-C_{18}Py/530 (0.26 g L^{-1}) in the presence of DMPC liposomes measured at several temperatures between 15 and 40°C. Excitation wavelength: 346 nm.



some bilayer exists in the solid-analogous phase in which the alkyl groups are crystallized in an all-*trans* configuration. As the temperature is raised above the T_C the bilayer passes from this tightly ordered "solid" phase to a liquid-crystal phase, where freedom of motion of individual chains is higher. The alkyl groups are able to adopt conformations other than the all-*trans* configuration and to undergo rotational movements. This tends to create void volumes and to allow lateral diffusion within the plane of the membrane. The phase transition temperature of DMPC liposomes, 23°C (29), is such that the experiments carried out at room temperature and above monitor the interactions of the polymers and a fluid membrane.

Another important consideration in the design of the experiments has to do with the relative concentrations of polymers and liposomes in the samples under study. Most experiments described here were performed with a lipid concentration of 1 g L^{-1} and a polymer concentration of 0.26 g L^{-1}. Under these conditions, assuming that all the liposomes are unilamellar and that each liposome (diameter: 150 nm) contains about 182 000 phospholipids (30), there are approximately 260 polymer chains for each liposome.

The addition of a solution of *b*-PNIPAM-Py-C_{18}/530 to DMPC liposomes triggered remarkable changes in the emission of the labeled polymer (Fig. 7). Most noticeable was a sharp decrease in the pyrene excimer emission, relative to pyrene monomer emission. The ratio I_E/I_M dropped from a value of 2.20 for the polymer in water to ca. 0.15 in the presence of liposomes. The spectral changes, however, were not instantaneous. The equilibration time required was found to be on the order of 3–5 h, depending on the relative concentrations of polymer and liposomes. This was observed from time-based fluorescence scans that monitored the increase in monomer emission as a function of time. The decrease in pyrene excimer emission is diagnostic of the disruption of the hydrophobic clusters into which the pyrene groups were accommodated in close proximity within the polymeric micelles formed by the HM-PNIPAM in water. In the system liposome–HM-PNIPAM the pyrene emission originates primarily from pyrenes unable to get into close proximity. This observation is taken as a strong indication of the insertion of the hydrophobic polymer tail of *b*-PNIPAM-C_{18}Py/530 within the lipid bilayer, thus generating "stabilized liposomes" (Fig. 9).

Next we monitored the effects of changes in temperature on the stability of the polymer–liposome association. As the temperature of a liposome–polymer suspension in water was increased above LCST, it was found that the I_E/I_M ratio increased marginally, from 0.2 to ca. 0.4. This small change reflects an increase of the excimer emission intensity at the expense of pyrene monomer emission (Fig. 8). Several possible explanations for this increase exist. It is likely that as the polymer chains collapse at the LCST, some chains are pulled away from the lipidic bilayer due to steric factors. They may then aggregate into polymeric micelles in the surrounding solvent. There was no visual indication of macroscopic polymeric aggregation. However, on the basis of the evidence gathered to date, some degree of disintegration of the liposome–polymer system cannot be dismissed. Another interpretation of the increase in pyrene excimer emission is that, during the process of contraction, several polymer chains become tangled and pull the pyrenes closer together, with concomitant increase in excimer emission. This mechanism was proposed to account for the increase in excimer emission intensity observed in the case of the interaction of DMPC liposomes with the randomly grafted polymer PNIPAM-C_{18}Py/200, the "molecular accordion" (9).

Conclusions

Pyrene end-labeled poly-(*N*-isopropylacrylamides) prepared with the lipophilic initiator PyODA form micelles in water, with a hydrophobic core consisting of octadecyl chains and pyrene groups and a loose corona of solvated PNIPAM chains. The pyrene groups in the core are placed in close proximity, as evidenced by the strong contribution of pyrene excimers to the total pyrene emission and implied by the significant quenching of the pyrene emission. When placed in contact with liposomes, the polymeric micelles are disrupted irreversibly. The polymer chains reorganize on the liposome surface in a slow process that results in a separation of the octadecyl–pyrenyl groups previously held in close contact within the core of the micelles. The hydrophobic tails of the polymers insert themselves within the fluid lipidic bilayer, creating "stabilized liposomes" consisting of vesicles decorated with hydrated PNIPAM chains extending in the aqueous environment. The effectiveness of the PNIPAM chains in preventing protein adsorption will be studied next, with the design of novel drug release systems as an ultimate objective.

Acknowledgments

F.M.W. and A. A. thank the Natural Sciences and Engineering Research Council of Canada for financial support, Mr. A. Davidson and Ms. L. Lee for their assistance in the preparation of polymer samples, and Mr. H. Ketelson for performing light-scattering measurements.

It is a pleasure for us to dedicate this publication to Professor Jim Guillet. Indeed the 1968 article in the Journal of Macromolecular Science (ref. 15 of this manuscript), authored by Heskins and Guillet, is quoted in nearly every paper dealing with poly-(*N*-isopropylacrylamide). But even more to the credit of Jim Guillet, it is his enthusiasm and his willingness to share his experience with PNIPAM that has triggered many a scientist to employ the unusual properties of PNIPAM in "intelligent devices." Thank you, Jim.

Abstract: Complexes of polyionene and anionic dyes and surfactant were prepared by exchange reaction of counterions in the parent polymer. Fluorescence studies were conducted to observe some characteristic behaviour of these complexes in water. Polyionenes with aromatic hydrocarbons adopt an open conformation and there is no evidence for interpolymer interactions. On the contrary, polyionenes with long aliphatic counterions easily form microdomains in aqueous solution due to hydrophobic interaction as evidenced by an increase in excimer emission. Microdomains have an interpolymer nature, as confirmed by measurements of energy transfer from naphthalene to pyrene moieties. Polyionenes with SDS counterions interact with external surfactant molecules and form polymer–surfactant aggregates. Electrostatic repulsions between aggregates dominate on hydrophobic interaction between polymer chains and are responsible for conformational changes.

Key words: hydrophobically modified polymers, surfactants, complexation, fluorescence, nonradiative energy transfer.

Résumé : On a préparé des complexes de polyionènes, de colorants anioniques et d'agents de surface en procédant à l'échange de contre-ions dans le polymère fondamental. On a effectué des études de fluorescence pour observer quelques-uns des comportements caractéristiques de ces complexes dans l'eau. Les polyionènes, avec les hydrocarbures aromatiques, adoptent une conformation ouverte et on n'a pas relevé des données pouvant suggérer l'existence d'interactions interpolymères. Tel qu'on a pu le mettre en évidence par une augmentation de l'émission excimère, les polyionènes et les contre-ions aliphatiques longs, en solutions aqueuses, donnent au contraire facilement lieu à la formation de microdomaines à cause de l'interaction hydrophobe. Tel que confirmé par des mesures de transfert d'énergie des portions naphtalènes aux portions pyrènes, les microdomaines ont une nature interpolymérique. Les polyionènes et les contre-ions SDS interagissent avec des molécules externes d'agent de surface et ils forment des agrégats polymère – agents de surface. Les répulsions électrostatiques entre les agrégats dominent l'interaction hydrophobe entre les chaînes de polymères et elles sont responsables des changements conformationnels.

Mots clés : polymères hydrophobiquement modifiés, agents de surface, complexation, fluorescence, transfert non radiatif d'énergie.

Introduction

The importance of aqueous systems composed of water-soluble polymers and low molecular weight surfactants for technological applications has encouraged the synthesis of new types of hydrophobically modified polymers. Hydrophobic functionalization is usually achieved by introducing aliphatic or condensed hydrocarbon residues of different length or size to given parts of a macromolecule to enhance the strength of polymer–surfactant interactions. Attention has been attracted to neutral water-soluble polymers such as poly(ethylene oxide) (1) or poly(acrylamide)s (2, 3) and to polyelectrolytes, i.e., charged polymers showing amphiphilic properties (4, 5).

Hydrophobically modified water-soluble synthetic polyelectrolytes bearing charges on their side groups, such as polycarboxylic acid (4), poly(sodium acrylate)s (6), cellulose derivatives (7), or poly(*N*-vinylpyridinium bromide) (8) and related polymers have been the systems more recently investigated, mainly by fluorescence techniques. Up to this time, however, little work has been done in the field of aliphatic ionenes in solution, this being one of the simplest ion-containing polymers (9). To this class of polycations belong polymers with ammonium or sulfonium groups in the main chain. Solid state ionenes with low charge density, i.e., with long alkylene chain length in the repeat unit, can form high quality amorphous solids, so their bulk properties have been the subject of

detailed studies (10). By the proper choice of low molecular weight counterions, which balance the charges on the N^+ or S^+ cation, one can tailor the thermal, optical, electrical, and related properties of solid polyionenes. On the other hand, the conformation of polyionenes in solution can be controlled by different charge density on the polymer chain or by counterions of different hydrophobicity. The preparation of starting polyionene followed by the exchange of bromide anions is an easy procedure and provides a convenient way to prepare a broad class of ionenes with different aggregation properties.

We recently reported preliminary investigations on polyionene, of the general chemical formula presented in Scheme 1, having the spiropyrane group as counterion (11). The results indicated that such solution properties of the photochrome–ionene complex as the kinetics of photochromic reaction were affected by the hydrophobic part of the polymer and a Coulombic interaction with quaternary ammonium ions. The present paper is devoted to further study of polyionene systems in water solution complexed with salts of pyrene and naphthalene chromophores and with anionic surfactant. For such "hydrophobically functionalized Coulombic composites," characteristic of various hydrophobicities, the polymer chain conformation in water was modified to influence the photophysical properties of these systems. The hydrophobic nature of ionenes was investigated by means of spectrofluorometry using the fluorescence properties of the pyrene counterions. This label is commonly used for the study of microheterogeneous systems (4, 5). Our results show that the photophysical properties of pyrene related to the conformational behaviour of polyionene in solution are complex and depend strongly on the hydrophobic nature of the counterions. The structure–property relationship of polyionene solutions indicates that the system investigated, characterized by relatively low ion concentration, could be considered as ionomers rather than as polyelectrolyte (12).

Experimental

The parent polyionene (Scheme 1) having relatively high molecular weight (200 repeating units in the main chain structure) was synthesized by reacting alkenediamines with dibromoalkanes following the Menschutkin reaction and procedures

Table 1. The investigated molecular composites of polyionene and chromophore–surfactant complexes.

Counterion X^- 10%	Counterion Y^- 90%	Abbreviation
$PySO_3^-$	BF_4^-	I–Py
NSO_3^-	BF_4^-	I–N
$PySO_3^-$	SDS	I–Py–SDS
NSO_3^-	SDS	I–N–SDS
$PySO_3^-$	NSO_3^-I–Py–N	

that have been described by Rembaum et al. (13). It has uniform distribution of the length of the alkylene units between the N^+ atoms (m = 10, n = 10). 1-Pyrenesulfonic acid (Py), 1-naphthalenesulfonic acid (N) prepared as the sodium salt, and sodium dodecyl sulfate (SDS) were commercial products of fluorescence grade from Aldrich and were used as received. The exchange of bromide counterions in the parent polycation with anionic fluorophores, surfactant, and with tetrafluoroborates (to lower hygroscopicity of the solid samples) was carried out in water at 30°C by the same method as reported previously (13,14). Thus integral-type complexes, i.e., with cationic sites on the main chain of polyionene and $PySO_3^-$, NSO_3^-, SDS, or BF_4^- residues of well-defined composition, were obtained. Low molar concentration of the ionic group (below 9%) along the aliphatic chain of the polyionene and large size of counterions lead to its low solubility in water solution.

The polycations investigated are presented, with their abbreviations, in Scheme 1 and in Table 1. The content of aromatic anion in the polyionene was 10 mol% with respect to the N^+-charged groups. Thus the chromophore loadings on the copolymer could be considered as high. The complementary concentrations of SDS, NSO_3^-, or BF_4^- ions were 90 mol%. The polyionenes were dissolved in dipolar aprotic solvents of high polarity, e.g., DMF or DMSO. For all measurements we used triply distilled ion-exchanged water.

All polymers obtained were poorly soluble in water but polyionenes with an anionic surfactant displayed the highest solubility. In our experiments a small volume of concentrated solution of polyionene complexes in *N,N*-dimethylformamide (DMF), generally 1×10^{-1} M, was added to the water solution. The mixture was shaken and degassed by bubbling with nitrogen for 10 min. The fluorescence properties of the samples showed no time-dependent changes during the measurements. In all sample solutions, the polyionene concentration was 3×10^{-4} M of monomer units.

Photostationary fluorescence and excitation spectra were measured with a Perkin–Elmer LS-50 luminescence spectrometer equipped with the front face accessory. The excitation wavelengths were 280 and 340 nm for naphthalene and pyrene, respectively. All the measurements were carried out at room temperature in a quartz cell of 2 mm thickness.

Results and discussion

Fluorescence of pyrene is widely used for the polarity study of microheterogeneous systems. It readily forms excimers and is an energy acceptor via nonradiative energy transfer (NRET) from the naphthalene or fluorene chromophore; thus one could expect to detect its emission behavior depending on the nature

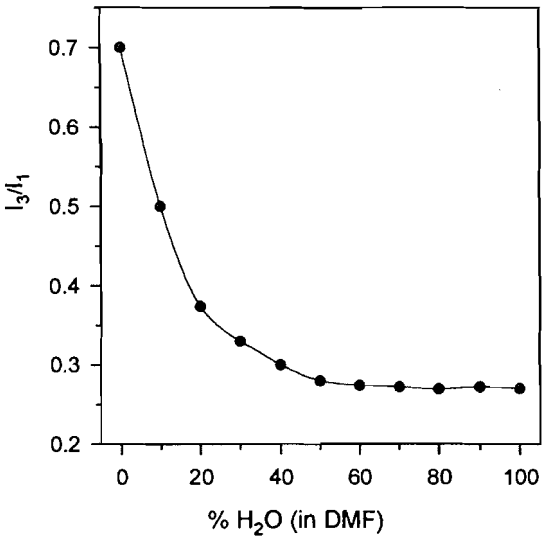
Fig. 1. Plot of I_3/I_1 for $PySO_3Na$ emission as a function of water content in various DMF– H_2O mixtures.



of the local environment (4, 5). The steady-state emission spectrum of pyrene provides three parameters, the ratio, I_3/I_1, of the intensities of the third to first vibronic bands, and the ratio, I_E/I_M, of the excimer emission relative to the monomer emission. The changes in the ratios I_E/I_M and I_3/I_1 are then used to determine the critical aggregation concentration (cac) or to detect the presence of hydrophobic microdomains for the polymers in solution (4).

In unsubstituted pyrene, a polarity-dependent emission band is correlated with vibronic coupling. The intermolecular processes responsible for vibronic coupling are solvent dipole – solute induced dipole moment interactions that distort nuclear vibrations of b_{3g} symmetry (15). Usually, for unsymmetrically substituted pyrene, the immediate environment has little influence on vibronic coupling since the substituent itself breaks the vibronic symmetry. In the case of noncomplexed $PySO_3Na$ chromophore, the fluorescence spectrum depends markedly on solvent polarity. In Fig. 1 we plotted values of I_3/I_1 as a function of water content in binary mixtures of DMF and H_2O. On going from neat DMF ($\varepsilon = 37.6$) to pure water ($\varepsilon = 80.4$) the values change from 0.7 to as low as 0.27. The same dependence with an identical plot of I_3/I_1 vs. $\%H_2O$ content was obtained for I–Py samples. When the ionic surfactant SDS is added to the water solution of $PySO_3Na$ no changes occur either in the monomeric or the excimeric part of the emission. The fluorescence independence of SDS concentration was observed over the range from 10^{-5} to 5×10^{-2} M, i.e., well below the critical micelle concentration (cmc) of SDS. This means that nonbonded dyes are not sequestered by the hydrophobic core of the micelles, probably because of its good solubility in water.

Figure 2 compares the fluorescence spectra of I–Py–SDS and I–Py in aqueous solution at room temperature. The fluorescence spectra depend on the polyionene composition. No changes were observed in the monomer part of the pyrene emission spectrum for either sample while for the copolymer with SDS counterions, as well as a strong monomer fluorescence I_M, a characteristic structureless excimer emission band I_E appears, with a maximum at about 480 nm.

Fig. 2. Normalized fluorescence spectra of I–Py (broken line) and I–Py–SDS (solid line) in water.

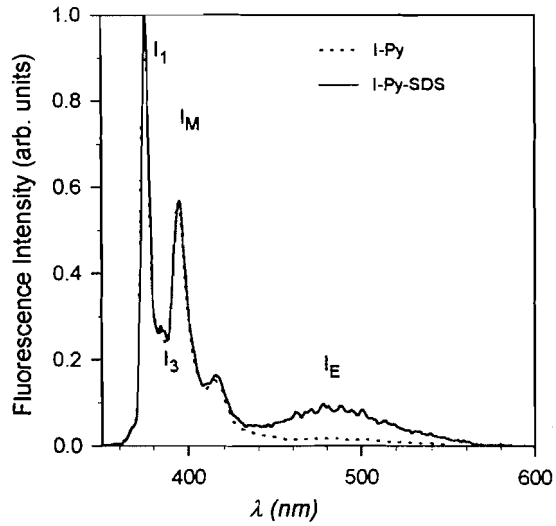


Fig. 3. Excimer-to-monomer intensity ratio I_E/I_M and the ratio of vibronic band intensities I_3/I_1 for pyrene in water solution at different polyionene concentrations.

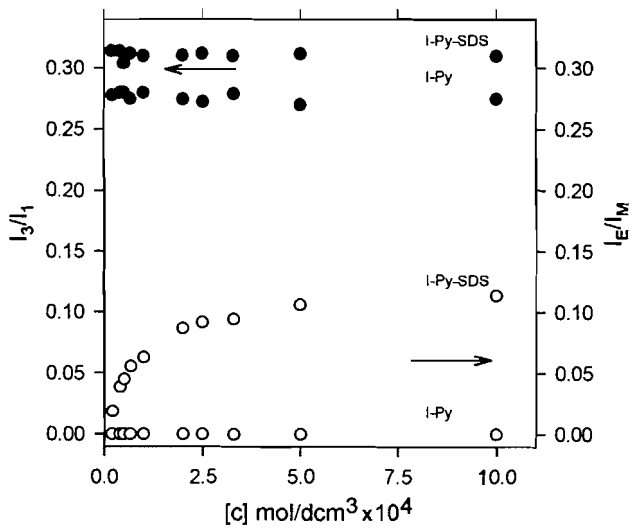

Figure 3 presents the plots of the ratios I_3/I_1 and I_E/I_M as a function of I–Py–SDS concentration in water solution. For comparison on the same plot, we show the fluorescence parameters of I–Py samples. The values of both parameters are constant upon increasing polyionene concentration: I_3/I_1 achieved the value of 0.27 while excimer emission was not detected in the range of concentration examined. In the case of I–Py–SDS samples, the ratio I_3/I_1 of pyrene fluorescence was estimated to be 0.31 and also shows fixed values vs. concentration. On the other hand, values of the excimer-to-monomer intensity ratio I_E/I_M increase continuously until a certain critical concentration equal to 3×10^{-4} M is reached and then they remain constant upon further increase of the I–Py–SDS concentration. This type of behaviour is connected with excimer formation and suggests its interchain origin. For I–Py the content of the hydrophobic pyrene units, although high (9 mol%), is not sufficient to form hydrophobic aggregates in aqueous solution.

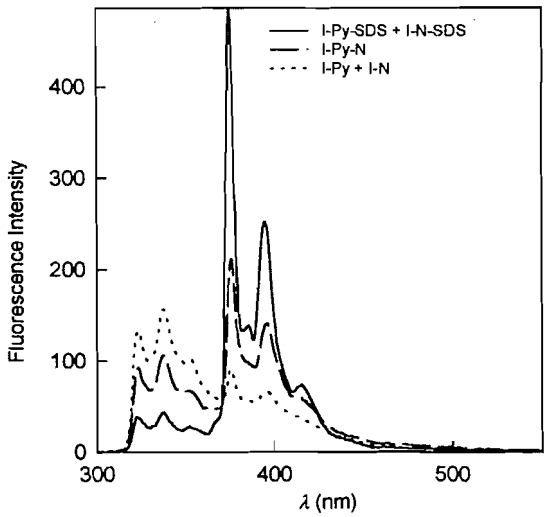
Fig. 4. Steady-state fluorescence emission spectra of polyionenes excited at 290 nm in aqueous solution: (*a*) I–N–Py; (*b*) mixture of I–N and I–Py; (*c*) mixture of I–N–SDS and I–Py–SDS.

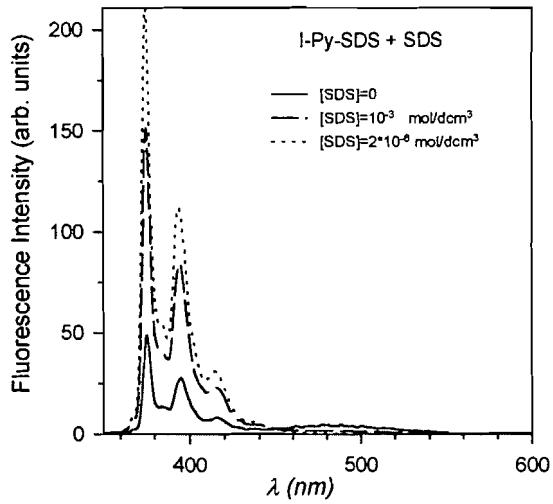


The established values of vibronic band intensities I_3/I_1 for both ionenes are understandable because the pyrene residue is confined to strong Coulombic interaction from charged N^+ groups on the polymer chain and the presence of hydrophobic domains has little influence on I_3/I_1 behaviour in water solution. The solvation of salt groups was found to be dependent on the dielectric constant (ε) of the solvent: dipolar molecules of DMF solvate SO_3^- ions in another way than do H_2O molecules. For higher ε (in water) the Coulombic interaction between ions is reduced and the effect of vibronic coupling on the vibronic structure of the emission band is influenced mainly by substituent interactions and not by solvent molecules as is normally observed.

Both polyionenes were poorly soluble in water; however, I-Py gives a transparent solution whereas the I–Py–SDS sample is turbid. This suggests that the differences in photophysical behaviour of I–Py and I–Py–SDS could arise from different polymer conformations. The question is whether polyionene forms aggregates because of self-organization of the hydrophobic groups and whether the hydrophobic aggregation has an intramolecular or intermolecular character. Comparative studies can provide some evidence of fluorescence on the association of I–Py–SDS polyionene with additional surfactant molecules, and from the nonradiative energy transfer (NRET) phenomena between naphthalene and pyrene groups in polyionenes of different counterion composition: singly labelled (I–Py, I–N, I–Py–SDS, I–N–SDS) and doubly labelled (I–Py–N).

The efficiency of NRET between donor (naphthalene) and acceptor (pyrene) depends on their separation distance and their relative orientation. NRET is particularly useful for estimation of polymer chain dimensions in solution or distances between macromolecules smaller than 100 Å. In the glassy state I–Py–N shows an efficient "antenna" effect in the energy transfer from naphthalene to pyrene groups (14). For such high efficiency to be possible, most of the $PySO_3^-$ groups must exist

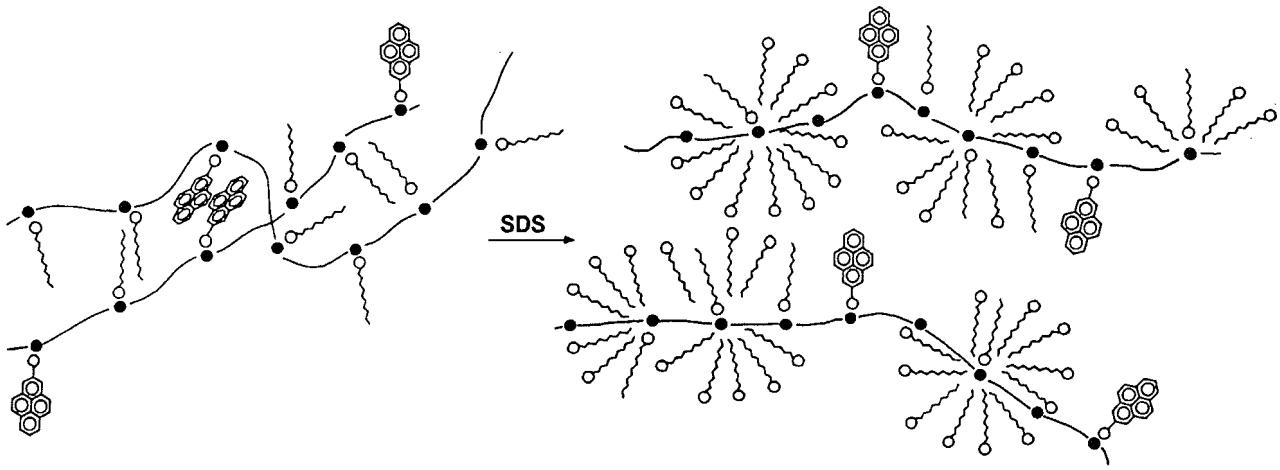
Fig. 5. Fluorescence spectra of I–Py–SDS in the presence of varying concentrations of SDS.



within a distance from the NSO_3^- groups of less than the Förster radius R_0 (28.64 Å), defined as a distance at which there is a 0.5 probability for the NRET mechanism of deactivation of the donor excited state (16). Figure 4 shows the structured fluorescence spectra of pyrene and naphthalene on excitation of the naphthalene chromophores at 290 nm for ionenes with different counterions. All the observed emission spectra show pyrene fluorescence; however, in aqueous solution the extent of energy transfer is much lower than for the glassy state, where the NRET is complete. This emission is also lower than the fluorescence intensity observed on direct excitation of the Py moieties. For the mixture of singly labelled polyionenes with naphthalene (I–N) and pyrene residues (I–Py), naphthalene predominates in the steady-state emission spectra, which implies that the mean interpolymer distances must be larger than R_0 and the chains do not form aggregates. It is evident from Fig. 5 that the presence of SDS counterions on the polyionene chain enhances energy transfer efficiency, resulting in a change in polymer aggregation. Moreover, the observed lack of an excimer band can be exclusively accounted for by the interpolymer association of I–Py–SDS and I–N–SDS.

Further evidence for formation of polyionene complexes can be derived from the interaction of I–Py–SDS with additional surfactant molecules. Figure 5 compares fluorescence spectra of I–Py–SDS in the presence of varying concentrations of SDS. The intensity of excimer emission decreases progressively with increasing [SDS], while monomer emission increases. Simultaneously with the fluorescence changes, one can observe a decrease of apparent light scattering from the samples. The aqueous solution of I–Py–SDS is turbid. In composition with additional SDS molecules at low surfactant concentration (below cmc) the sample becomes less turbid. Then, above the cmc it is completely transparent. Thus the suppression of the excimer emission may be attributed to compartmentalization of the $PySO_3^-$ counterions by external SDS molecules and changes in polymer chain conformation due to the formation of polyionene–surfactant complexes. A schematic representation of the micellization of I–Py–SDS

Fig. 6. Proposed conformation of I–Py–SDS in aqueous solution and an illustration of a local aggregate structure of I–Py–SDS and SDS. Solid lines and filled circles represent polyionene with N^+ ions, open circles represent polar heads in $PySO_3^-$ counterion and in SDS surfactant.



induced by the addition of SDS to the solution is shown in Fig. 6.

In the polyionene aggregate several SDS and $PySO_3^-$ groups (from different chains) participate in the complexes. Addition of external SDS surfactant molecules leads to rearrangement of the coil structure. They bind by hydrophobic interaction to SDS counterions in I–Py–SDS chains. We rather excluded the possibility that they can be attracted by Coulombic interaction to N^+-charged groups in the vicinity of $PySO_3^-$, SDS, or BF_4^- counterions. An increase in SDS concentration above the cmc leads to changes in polyionene coil structure: the chains are more separated from each other and more expanded due to repulsive interactions between SDS micelles bound to the polyionene chain, as illustrated in Fig. 6. On this basis, we consider that polyionene complexes with excess surfactant are not compact. The behaviour in water solution of I–Py–SDS exhibits a more pronounced tendency to interchain aggregation. Separation of pyrene groups by SDS micelles is expected to be the mechanism responsible for increasing monomer fluorescence intensity. Adsorption of anionic surfactant on hydrophobically modified ionenes leads to decreasing excimer formation due to the expansion and (or) separation of the polymer chains: greater concentration of SDS increases hydrophobic interactions between nonpolar fragments of polyionene chains and the surfactant counterions and enhances the repulsive forces between SDS micelles. For I–Py samples the changes in fluorescence spectra are small and even at higher SDS concentration the fluorescence remains unchanged.

Conclusions

In the study presented, we have hydrophobically modified ionene polymers in a way other than through formation of covalent bonds. Polyionenes with pyrene and naphthalene counterions are not able to form stable aggregates in aqueous solution even at relatively high molar concentration, contrary to polyelectrolytes with long aliphatic counterions. This confirms that the hydrophobicity of alkanes is much stronger than that of aromatic hydrocarbons (4). Hydrophobic domains are efficiently formed for I–Py–SDS samples and have an interpolymer nature, as evidenced by measurements of the extent of energy transfer from naphthalene to pyrene in mixtures of polyionenes of different composition. I–Py accepts an extended conformation whereas I–Py–SDS is in a coiled interpolymer conformation as demonstrated by polyionene interactions with external surfactant molecules. The interaction of I–Py–SDS with excess of surfactant leads to formation of polymer–surfactant aggregates. SDS counterions facilitate association of excess surfactant with the ionene chain. It was found that the conformation of I–Py–SDS/SDS is more open than in the case of I–Py or I–Py/SDS systems. The difference is considered to derive from the nature of the interaction between aromatic and aliphatic hydrocarbons.

It is hoped that further studies with polycations of different charge density in the main chain may elucidate the relationship between the structure of polyionene complexes and their association properties in water.

Photochemistry of nonconjugated diketones: internal self-quenching and energy transfer

Peter J. Wagner and Harlan W. Frerking, Jr.

Abstract: The triplet state behavior of nine α,ω-dibenzoylalkanes indicates the occurrence of a rapid quenching interaction between the two carbonyl groups. This quenching is fastest ($k = 3 \times 10^7$ s^{-1}) in dibenzoylbutane, is slightly slower ($\sim 10^7$ s^{-1}) in dibenzoylethane, dibenzoylpentane, and 2,2-dibenzoylpropane, but is absent in 1,3-dibenzoylpropane. It also occurs in several "mixed" 1,4-diaroylbutanes incorporating *p*-ethylbenzoyl or *p*-methoxybenzoyl chromophores This internal self-quenching is interpreted as the intramolecular counterpart of the well-known bimolecular self-quenching of aryl ketones, although no exact mechanism can be proposed. Such internal quenching does not occur as rapidly, if at all, in three "turned around" diketones: δ-(*p*-acetylphenyl)valerophenone, δ-(*p*-acetylphenoxy)valerophenone, and γ-(*p*-acetylphenoxy)butyrophenone. This fact, together with the varying rates of internal self-quenching in the dibenzoylalkanes, indicates the necessity for a very specific and close orientation of the two carbonyl groups for self-quenching. In the mixed diketones containing a *p*-alkylbenzoyl group, triplet excitation appears to be fully equilibrated between the two chromophores. However, in those containing a *p*-methoxybenzoyl group, excitation does not fully equilibrate before triplet decay, as evidenced by different quenching efficiencies for products from the two carbonyls. Analysis indicates intramolecular energy transfer rate constants $\leq 10^8$ s^{-1}. These are sufficiently lower than in other bichromophoric systems to suggest relatively slow energy hopping in the polymers of phenyl vinyl ketone.

Key words: nonconjugated diketones, dibenzoylalkanes, self-quenching, energy transfer, triplet ketones.

Résumé : Le comportement de l'état triplet de neuf α,ω-dibenzoylalcanes indique qu'il se produit une rapide interaction de désactivation entre les deux groupes carbonyles. Cette désactivation se fait le plus rapidement ($k = 3 \times 10^7$ s^{-1}) dans le dibenzoylbutane; elle est légèrement plus lente ($\sim 10^7$ s^{-1}) dans les dibenzoyléthane, dibenzoylpentane et 2,2-dibenzoylpropane, mais elle est totalement absente dans le 1,3-dibenzoylpropane. Elle se produit aussi dans plusieurs 1,4-diaroylbutanes « mixtes » qui incorporent les chromophores *p*-éthylbenzoyle ou *p*-méthoxybenzoyle. On interprète cette autodésactivation interne comme la contrepartie intramoléculaire de l'autodésactivation bimoléculaire bien connue des arylcétones, même si aucun mécanisme exact a été proposé. Si elles se produisent, de telles désactivations internes ne se produisent pas non plus rapidement dans les trois dicétones « qui sont retournées » : δ-(*p*-acétylphényl)valérophénone, δ-(*p*-acétylphénoxy)valérophénone et γ-(*p*-acétylphénoxy)butyrophénone. Ce fait, pris avec les vitesses variables de l'autodésactivation interne dans les dibenzoylalcanes, indique qu'il est nécessaire d'avoir une orientation spécifique et rapprochée des deux groupes carbonyles pour obtenir de l'autodésactivation. Dans les cas des dicétones mixtes contenant un groupe *p*-alkylbenzoyle, il semble que l'excitation triplet est complètement équilibrée entre les deux chromophores. Toutefois, dans celles qui contiennent un groupe *p*-méthoxybenzoyle, il semble, sur la base des efficacités de désactivation différentes pour les produits des deux carbonyles, que l'excitation ne s'équilibre pas avant la décroissance du triplet. Une analyse indique que les constantes de vitesse pour le transfert intramoléculaire de l'énergie sont $\leq 10^8$ s^{-1}. Ces valeurs sont suffisamment plus faibles que celles dans les systèmes bichromophores pour suggérer que, dans les polymères de la phényl vinyl cétone, le transfert d'énergie par sauts est relativement lent.

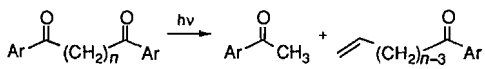
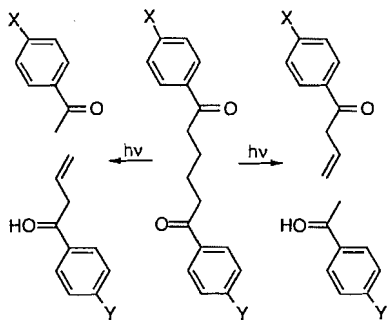
Introduction

Two decades ago, when we published a systematic study of the Norrish type II photoreactions of γ- and δ-substituted alkyl phenyl ketones (1), we noted that 1,4-dibenzoylbutane reacts in only half the quantum yield observed for similar monoketones (2). Later it became apparent that triplet aryl ketones undergo often efficient self-quenching by their ground state molecules (3, 4). Therefore it seemed likely that dibenzoylbutane undergoes the same reaction in an internal fashion. More recently, however, several studies on 1,3-dibenzoylpropanes (5, 6) and on poly(phenyl vinyl ketone) (7–9) suggest that no such internal self-quenching occurs in the triplet states of these molecules and that triplet energy transfer between equivalent chromophores is very efficient. Singer et al. have discussed several geometric approaches that might lead to self-quenching (4). Because of our interest in intramolecular energy transfer in ketones (10) and diketones (11), we decided to investigate the behavior of several dibenzoylalkanes to verify the difference between dibenzoylpropane and -butane and to better define the geometric requirements for self-quenching. In the process we were led to delve more completely into the kinetics of reversible triplet energy transfer (12), a topic that will be addressed briefly in this paper and more thoroughly in a forthcoming paper.





Experimental section

Materials

Solvents

Benzene and pyridine were purified as in earlier work. Ethanol and dioxane were purified as recommended by Riddick (13). Methylcyclohexane (Eastman) was stirred with sulfuric acid until further portions remained colorless, then washed, dried, and distilled. Cyclohexane (Matheson, Coleman, and Bell, spectrograde) was recrystallized twice from itself. 2-Methyltetrahydrofuran was purified by the procedure of Gordon and Ford (14). Gold label Aldrich 2-methylbutane was used as received.

Internal standards

Tetradecane, hexadecane, and octadecane were all available from earlier studies. Di-*n*-ethyl and di-*n*-butyl phthalate were used as received from Aldrich. Di-*n*-propyl phthalate was prepared by treatment of phthalic anhydride with 1-propanol and distillation, bp 128°C (1.2 Torr; 1 Torr = 133.3 Pa).

Quenchers

trans-Stilbene was used as received from J.T. Baker. *cis*-1,3-Pentadiene (Chemical Samples Co.) was used as received. 2,5-Dimethyl-2,4-hexadiene (Chemical Samples Co.) was allowed to sublime in the refrigerator.

Ketones

Acetophenone, valerophenone, *p*-methoxyacetophenone, and *p*-methoxyvalerophenone were all available from earlier studies.

The following ketones were all synthesized. Their melting points (uncorrected) were measured on a Thomas–Hoover Unimelt capillary apparatus. IR spectra were recorded on a Perkin–Elmer 237B; UV, in benzene on a Cary 17 spectrometer, ^{1}H NMR, in $CDCl_3$ on a Varian T-60 or Gemini 300; ^{13}C NMR, in $CDCl_3$ on a Varian CFT-20; mass spectra, at 70 eV on a Hitachi RMU-6. All products were checked for purity by GC analysis and by the lack of extraneous peaks in their NMR spectra.

2,2-Dimethyl-1,3-diphenylpropan-1,3-dione was prepared by Smedley's procedure (15) in 25% yield. Dimethylmalonic acid (Aldrich, 25 g) was treated with excess thionyl chloride. The crude acid chloride was then treated with excess benzene and $AlCl_3$. After normal work-up the crude diketone was recrystallized from ethanol to yield white crystals, mp (dec.) 97.2°C (lit. (15) mp 99°C); IR ($CHCl_3$): 1670 cm^{-1}; UV λ_{max} (n,π^*): 320 nm; ^{1}H NMR δ: 1.6 (s, 6H), 7.30 (tt, 4H, J = 7, 2 Hz), 7.41 (tt, 2H, J = 7, 2 Hz), 7.82 (dd, 4H, J = 7 Hz); ^{13}C NMR δ: 25.14, 59.32, 128.36, 128.95, 132.69, 200.01; MS *m/z*: 252, 147, 105 (base), 77.

1,4-Diphenylbutane-1,4-dione was prepared by Becker's procedure of irradiating acetophenone (450 mL) with phenol and silica gel (16). After three recrystallizations from ethanol the dione was isolated in 5% yield as white crystals, mp 145°C (lit. (16) mp 144–145°C; IR ($CHCl_3$): 1690 cm^{-1}; UV λ_{max} (n,π^*): 313 nm; ^{1}H NMR δ: 3.39 (s, 4H, CH_2), 7.43 (tt, 4H, J = 7.0, 2.0 Hz), 7.54 (tt, 2H, J = 7.0, 2.0 Hz), 8.02 (dd, 4H, J = 7, 2 Hz); ^{13}C NMR δ: 32.4, 127.9, 128.4, 132.9, 136.7, 198.4; MS *m/z*: 238, 220, 133, 105 (base), 77.

1,5-Diphenylpentane-1,5-dione was prepared by Friedel–Crafts acylation of benzene with glutaryl chloride and aluminum chloride. It was purified by six recrystallizations from ethanol–water as white crystals, mp 64.2°C (lit. (17) mp 66.7°C, (6) mp 65°C); IR ($CHCl_3$) 1690 cm^{-1}; UV λ_{max} (n,π^*): 317 nm; ^{1}H NMR δ: 2.15 (quin, 2H, J = 7 Hz), 3.00 (t, 4H, J = 7 Hz), 7.43 (tt, 4H, J = 7.0, 2.0 Hz), 7.54 (tt, 2H, J = 7.0, 2.0 Hz), 7.92 (dd, 4H, J = 7, 2 Hz); ^{13}C NMR δ: 18.45, 37.2, 127.7, 128.2, 132.7, 136.6, 199.4; MS *m/z*: 252, 147, 133, 120, 105 (base), 77.

1,6-Diphenylhexane-1,6-dione was prepared by the Friedel–Crafts acylation of benzene with adipoyl chloride. It was purified by four recrystallizations from ethanol–water as white crystals, mp 106°C (lit. (18) mp 106–108°C); IR ($CHCl_3$): 1690 cm^{-1}; UV λ_{max} (n,π^*): 319 nm; ^{1}H NMR δ: 1.80 (tt, 4H, J = 7, 3 Hz), 2.95 (t, 4H, J = 7 Hz), 7.43 (tt, 4H, J = 7, 2 Hz), 7.54 (tt, 2H, J = 7, 2 Hz), 7.92 (dd, 4H, J = 7, 2 Hz); ^{13}C NMR δ: 23.5, 38.0, 127.6, 128,2, 132.5, 136.6, 199.45; MS *m/z*: 266, 248, 147, 146, 120, 105, 77 (base).

1,7-Diphenylheptane-1,7-dione was prepared by Friedel–Crafts acylation of benzene with pimeloyl chloride. It was purified by five recrystallizations from ethanol–water as white

For personal use only.

crystals, mp 65.5–66°C (lit. (18) mp 67–68°C); IR ($CHCl_3$): 1690 cm^{-1}; UV λ_{max} (n,π^*): 318 nm; ^1H NMR δ: 1.70 (quin, 2H, J = 7 Hz), (tt, 4H, J = 7, 6 Hz), 2.95 (t, 4H, J = 6 Hz), 7.43 (tt, 4H, J = 7, 2 Hz), 7.54 (tt, 2H, J = 7, 2 Hz), 7.92 (dd, 4H, J = 7, 2 Hz); ^{13}C NMR δ: 23.5, 28.4, 37.7, 127.45, 128.0, 132.3, 136.4, 199.4; MS *m/z*: 280, 175, 161, 160, 146, 133, 120 (base), 105, 77.

*1,6-Bis-(*p*-ethylphenyl)hexane-1,6-dione*: Ethylbenzene was acylated with adipoyl chloride and $AlCl_3$. Normal work-up gave crude product in 25% yield. Two recrystallizations from ethanol–water gave white crystals, mp 96.2°C; IR ($CHCl_3$): 1685 cm^{-1}; UV λ_{max} (n,π^*): 318 nm; ^1H NMR δ: 1.22 (t, 6H, J = 7.6 Hz), 1.80 (tt, 4H, J = 7, 3 Hz), 2.70 (quart, 4H, J = 7.6 Hz), 2.99 (tt, 4H, J = 7, 3 Hz), 7.18 (d, 4H, J = 8 Hz), 7.82 (d, 4H, J = 8 Hz); ^{13}C NMR δ: 14.7, 23.7, 28.5, 37.9, 127.6, 127.85, 134.4, 149.3, 199.1; MS *m/z*: 322, 174, 161, 148, 145, 133 (base), 105.

*1,6-Bis-(*p*-methoxyphenyl)hexane-1,6-dione*: Adiponitrile (5.4 g) was added dropwise over 0.5 h to a 50 mL ether solution of the Grignard reagent prepared from 41 g *p*-bromoanisole and 4.8 g magnesium. Another 50 mL ether was added and the solution was refluxed for 4 h. The cooled solution was added slowly to excess HCl and ice. The resulting precipitate was not soluble in dilute aqueous HCl or in chloroform. After being heated, the aqueous portion provided very little product. The original precipitate was treated with hot 5 N HCl for 2 h. The cooled heterogeneous mixture was extracted with chloroform, with most of the remaining solid dissolving. Normal work-up provided 12 g of tan solid. Recrystallization from ethanol provided white crystals, mp 141.5–142.5°C; IR (KBr): 3000, 2951, 2938, 1671, 1599, 1254, 1169, 972, 833, 605 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.78 (tt, 4H, J = 7, 3 Hz), 2.95 (tt, 4H, J = 7, 3 Hz), 6.90 (d, 4H, J = 9 Hz), 7.91 (d, 4H, J = 9 Hz); ^{13}C NMR ($CDCl_3$) δ: 24.26, 38.05, 55.51, 113.64, 130.01, 130.26, 163.31, 198.65; MS *m/z*: 326, 176, 150, 135 (base).

*1-Phenyl-6-(*p*-methoxyphenyl)hexane-1,6-dione*: Reaction of phenyl magnesium bromide with γ-chlorobutyronitrile afforded γ-chlorobutyrophenone (1). Its ethylene glycol ketal was prepared in routine fashion. The ketal was added dropwise over 15 min to a stirred solution of 1.4 g NaCN in 10 mL DMSO held at 90–95°C during the addition. The solution was then heated for 6 h at 125°C. The cooled solution was added to 50 mL of dilute aqueous $NaHCO_3$. Extraction into ether and solvent evaporation left 5 g (82%) of crude cyanoketal. This was added to the Grignard reagent prepared from 17 g *p*-bromoanisole in 30 mL ether. After 1 h reflux, the cooled solution was added to excess HCl–ice. The resulting aqueous layer was washed with ether, then heated on a steam bath. A solid separated; the entire mixture was extracted with chloroform. Normal work-up gave 2 g of off-white solid (30%). Recrystallization from hexane, then from methanol–hexane, gave white crystals, mp 111–112.5°C; IR (KBr): 1680, 1669, 1601, 1254, 1160, 1170 cm^{-1}; ^1H NMR (CDCl3) δ: 1.81 (tt, 4H, J = 7, 3 Hz), 2.96 (tt, 2H, J = 7, 3 Hz), 3.01 (tt, 2H, J = 7, 3 Hz), 6.91 (d, 2H, J = 8.9 Hz), 7.43 (t, 2H, J = 7 Hz), 7.53 (tt, 1H, J = 7, 2 Hz), 7.92 (d, 2H, J = 8.9 Hz), 7.935 (dd, 2H, J = 7 Hz); ^{13}C NMR ($CDCl_3$) δ: 23.84, 24.00, 37.93, 38.30, 55.33, 113.57, 127.90, 128.46, 129.92, 130.17, 132.84, 136.83, 163.25, 198.47, 199.92; MS *m/z*: 296, 176, 150, 146, 135 (base), 105.

Methyl 5-benzoylpentanoate was prepared by Friedel–Crafts acylation of benzene with the acid chloride of adipic acid monomethyl ester (prepared from adipic acid monomethyl ester by treatment with excess thionyl chloride), as described by Kemppainen (19). IR (neat): 1750, 1690, 1600, 1450 cm^{-1}; ^1H NMR (CCl_4) δ: 1.60 (m, 4H), 2.20 (t, 2H, J = 6 Hz), 2.75 (t, 2H, J = 6 Hz), 3.40 (s, 3H) 7.25 (t, 2H, J = 7 Hz), 7.45 (tt, 1H, J = 7, 2 Hz), 7.85 (dd, 2H, J = 7, 2 Hz).

*1-Phenyl-6-(*p*-ethylphenyl)hexane-1,6-dione*: Methyl 5-benzoylpentanoate was hydrolyzed with aqueous sodium hydroxide. The resulting acid was recrystallized once from ethanol–water and then treated with excess thionyl chloride at room temperature for 2 h. The crude acid chloride so obtained (9 g) was dissolved in 15 mL CH_2Cl_2 and added dropwise to 16.5 g $AlCl_3$ in 20 mL CH_2Cl_2 at 0°C; 5 g ethylbenzene was then added. The mixture was stirred at room temperature for 2.5 h and then poured onto 200 g of ice. Normal work-up furnished 8.8 g (75%) of brown solid. Recrystallization from ethanol–water gave white crystals, mp 77.5–78°C. IR (CCl_4): 1690, 1605 cm^{-1}; UV λ_{max} (n,π^*): 317 nm; ^1H NMR (CCl_4) δ: 1.20 (t, 3H, J = 7 Hz), 1.75 (m, 4H), 2.65 (quin, 2H, J = 7 Hz), 2.85 (m, 4H), 7.28 (d, 2H, J = 8 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.54 (tt, 1H, J = 7, 2 Hz), 7.82 (d, 2H, J = 8 Hz), 7.94 (dd, 2H, J = 7, 2 Hz); MS *m/z*: 294, 276, 174, 148, 146, 133 (base),105.

1,5-Diphenylpentan-1-one was prepared in 23% yield by the general procedure of Stork and Dowd (20). The cyclohexylimine of acetophenone was treated with ethyl magnesium bromide in THF and then with 3-bromo-1-phenylpropane (Aldrich). After normal work-up the crude oil was vacuum distilled and the fraction boiling between 133 and 142°C (0.025 Torr) collected. It was recrystallized six times from ethanol–water as white crystals, mp 44.5°C (lit. (21) mp 47°C); IR (CCl_4): 1695, 1450 cm^{-1}; UV λ_{max} (n,π^*): 319 nm; ^1H NMR δ: 1.65 (m, 4H), 2.73 (t, 2H, J = 6 Hz), 2.90 (t, 2H, J = 6 Hz), 7.15 (m, 5H), 7.43 (tt, 2H, J = 7, 2 Hz), 7.53 (tt, 1H, J = 7, 2 Hz), 7.94 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR δ: 23.7, 30.75, 35.5, 38.0, 125.4, 127.7, 128.2, 132.5, 136.8, 141.9, 199.7; MS *m/z*: 238, 148, 133, 120, 118, 117, 105 (base), 91, 77.

*1-Phenyl-5-(*p*-acetylphenyl)pentan-1-one*: Acetyl chloride (3.6 g) was mixed with 15.2 g $AlCl_3$ in 35 mL methylene chloride at 0°C; 9.0 g of 1,5–diphenylpentan-1-one in 10 mL CH_2Cl_2 was added dropwise; the mixture was stirred at room temperature for 2 h. Normal work-up provided 10.4 g (94%) of crude solid. Four recrystallizations from methanol–water gave white crystals, mp 64.5°C; IR ($CHCl_3$): 1695, 1610 cm^{-1}; UV λ_{max} (n,π^*): 317 nm; ^1H NMR δ: 1.75 (m, 4H), 2.56 (s, 3H), 2.73 (t, 2H, J = 7 Hz), 3.00 (t, 2H, J = 7 Hz), 7.28 (d, 2H, J = 8 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.53 (tt, 1H, J = 7, 2 Hz), 7.87 (d, 2H, J = 8 Hz), 7.94 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR δ: 23.55, 26.1, 30.3, 35.44, 37.9, 127.6, 128.2, 132.6, 134.8, 136.7, 147.7, 199.5; MS *m/z*: 280, 162, 160 (base), 133, 120, 105.

*1-Phenyl-5-(*p*-valerylphenyl)pentan-1-one* was prepared as was the *p*-acetyl compound except that valeryl chloride was used. Crude product was recrystallized five times from methanol to give white crystals, mp 60.2°C; IR (CCl_4): 1695, 1610 cm^{-1}; UV λ_{max} (n,π^*): 320 nm; ^1H NMR δ: 1.0 (t, 3H, J = 7

For personal use only.

Hz), 1.7 (m, 8H), 2.75 (t, 2H, J = 7 Hz), 3.00 (t, 2H, J = 7 Hz), 7.18 (d, 2H, J = 8 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.55 (tt, 1H, J = 7, 2 Hz), 7.82 (d, 2H, J = 8 Hz), 7.94 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR δ: 13.7, 22.2, 23.6, 26.4, 30.4, 35.5, 37.95, 127.8, 128.0, 128.3, 132.7, 134.8, 136.8, 147.5, 199.7, 199.8; MS *m/z*: 322, 280, 265 (base), 202, 167, 161, 160, 147, 133, 131, 120, 105.

4-Phenoxy-1-phenylbutane-1-one was prepared by a procedure similar to that described by Kalir and Balderman (22). *O*-(Tetrahydropyran-2-yl)mandelonitrile was treated with sodium hydride in DMSO under nitrogen; 1-bromo-3-phenoxypropane was added and the mixture stirred for 1 day and then acidified. Normal extraction and work-up provided pale yellow crystals in 97% yield. Three recrystallizations from ethanol gave white crystals, mp 62°C (lit. (1) mp 62.5–63.5°C); IR ($CHCl_3$): 1695, 1603 cm^{-1}; UV λ_{max} (n,π^*): 316 nm; ^{1}H NMR δ: 2.25 (tt, 2H, J = 7, 6 Hz), 3.15 (t, 2H, J = 7 Hz), 4.05 (t, 2H, J = 6 Hz), 7.0 (dd, 2H, J = 9, 2 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.54 (tt, 1H, J = 7, 2 Hz), 7.92 (dd, 2H, J = 7. 2 Hz); ^{13}C NMR δ: 23.5, 34.6, 66.5, 114.2, 120.4, 127.7, 128.2, 1219.1, 132.7, 136.6, 158.6, 199.1; MS *m/z*: 240, 147 (base), 120, 105.

*4-(*p*-Acetylphenoxy)-1-phenylbutan-1-one* was prepared by Friedel–Crafts acetylation of 4-phenoxybutyrophenone; white crystals were obtained after work-up and recrystallization from ethanol, mp 92°C; IR ($CHCl_3$): 1690, 1605 cm^{-1}; UV λ_{max} (n,π^*): 316 nm; ^{1}H NMR δ: 2.25 (tt, 2H, J = 6, 7 Hz), 2.40 (s, 3H), 3.19 (t, 2H, J = 7 Hz), 4.11 (t, 2H, J = 6 Hz), 6.89 (d, 2H, J = 9 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.54 (tt, 1H, J = 7, 2 Hz), 7.89 (d, 2H, J = 9 Hz), 7.96 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR δ: 23.5, 26.1, 34.5, 67.1, 114.0, 127.8, 128.5, 130.2, 130.4, 133.0, 135.6, 162.7, 196.5, 199.0; MS *m/z*: 282, 163, 147 (base), 120, 105.

*4-(*p*-Valerylphenoxy)-1-phenylbutan-1-one* was prepared in 87% yield by the same procedure as followed for the *p*-acetyl homologue above, except for the use of valeryl chloride. It was purified by two recrystallizations from ethanol as white crystals, mp 116°C. IR ($CHCl_3$): 1690, 1603 cm^{-1}; UV λ_{max} (n,π^*): 316 nm ; ^{1}H NMR δ: 1.00 (t, 3H, J = 7 Hz), 1.6 (m, 4H), 2.25 (tt, 2H, J = 7, 6 Hz), 2.85 (t, 2H, J = 7 Hz), 3.15 (t, 2H, J = 7 Hz), 4.10 (t, 2H, J = 6 Hz), 6.85 (d, 2H, J = 4 Hz), 7.35 (m, 3H), 7.85 (d, 2H, J = 9 Hz), 7.96 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR δ: 13.7, 22.3, 23.4, 26.5, 34.5, 37.8, 67.0, 113.9, 127.8, 128.4, 130.1, 132.9, 136.7, 162.4, 198.9, 199.05; MS *m/z*: 324, 282, 267, 205, 177, 148 (base), 121, 120, 105.

*4-(*p*-Cyanophenoxy)-1-phenylbutan-1-one* was prepared by S_N2 displacement on γ-iodobutyrophenone. Benzene was acylated with 35 g 4-chlorobutyryl chloride and 36 g $AlCl_3$ and furnished a 95% yield of crude 4-chloro-1-phenylbutan-1-one. Distillation provided a 70% yield of pure ketone, bp 100–103°C at 0.55 Torr (lit. (23) bp 126–129°C at 5 Torr); IR (neat): 1690, 1600 cm^{-1}; ^{1}H NMR (CCl_4) δ: 2.15 (quin, 2H, J = 7 Hz), 3.05 (t, 2H, J = 7 Hz), 3.55 (t, 2H, J = 7 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.54 (tt, 1H, J = 7, 2 Hz), 7.92 (dd, 2H, J = 7, 2 Hz).

A mixture of 43 g chloroketone and 75 g sodium iodide in 500 mL 2-butanone was refluxed for 2 h. After the solvent was removed, the resulting sludge was taken up in a mixture of 500 mL ether and 500 mL water. The ether layer was separated, washed, and distilled, leaving 51 g (78%) of crude 4-iodoketone as an oil. IR (neat): 1690, 1230, 745, 695 cm^{-1}; ^{1}H NMR δ: 2.2 (m, 2H), 3.0 (t, 2H, J = 3 Hz), 3.3 (t, 2H), 7.35 (m, 3H), 7.85 (m, 2H). The 4-iodo-1-phenylbutan-1-one was converted to its ethylene glycol ketal by reflux in a Dean–Stark apparatus. Normal work-up provided a 93% yield of ketal as an oil: ^{1}H NMR δ: 1.9 (t, 2H), 3.0–4.0 (m, 8H), 7.25 (m, 5H).

To 300 mL of DMSO containing 4.6 g sodium under nitrogen, 23.8 g 4-cyanophenol in 300 mL DMSO was added dropwise; the resulting mixture was stirred until all the sodium had dissolved. The iodoketone ketal (54 g) in 300 mL DMSO was then added dropwise over 6 h and let stir another 24 h. The mixture was heated to 60°C for 1 h. Water was added to the cooled mixture, which was then extracted with four 500 mL portions of ether. Normal work-up and solvent removal left 33 g (73%) of a light brown solid. Two recrystallizations from ethanol gave 4-(*p*-cyanophenoxy)-1-phenylbutan-1-one as white crystals, mp 117°C. IR ($CHCl_3$): 2210, 1690, 1515, 1260, 1175 cm^{-1}; UV λ_{max} (n,π^*): 316 nm; ^{1}H NMR δ: 2.2 (quin, 2H, J = 3 Hz), 3.15 (t, 2H, J = 3 Hz), 4.05 (t, 2H, J = 3 Hz), 6.85 (d, 2H, J = 9 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.54 (tt, 1H, J = 7, 2 Hz), 7.75 (d, 2H, J = 9 Hz), 7.96 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR δ: 23.2, 34.25, 67.1, 103.6, 114.9, 118.9, 127.7, 128.3, 132.9, 133.6, 136.5, 161.9, 198.8; MS *m/z*: 265, 147 (base), 120, 105, 77.

5–Phenoxy-1-phenylpentan-1-one: This ketone was prepared by two methods. The first involved treatment of 5-iodo-1-phenylpentan-1-one with the sodium salt of phenol. Normal work-up gave a complex mixture from which 12 g of desired product (21%) was isolated by chromatography through 3 lb alumina. The eluting solvent was continuously varied from hexane to ethyl acetate, with chloroform providing the product fraction. The ketone was also prepared in 39% yield from 25 g *O*-(tetrahydropyran-2–yl)mandelonitrile and 25 g 1-bromo-4-phenoxybutane by the procedure described above for the 4-phenoxy ketone. In both cases, three recrystallizations from ethanol provided white crystals, mp 68.7–69.0°C; IR ($CHCl_3$): 1690, 1603 cm^{-1}; UV λ_{max} (n,π^*): 318 nm; ^{1}H NMR δ: 1.95 (m, 4H), 3.0 (t, 2H, J = 7 Hz), 3.95 (t, 2H, J = 6 Hz), 6.85 (d, 2H, J = 9 Hz), 7.20 (m, 5H), 7.85 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR δ: 20.7, 28.6, 37.9, 67.3, 114.3, 120.4, 127.8, 128.4, 129.2, 132.7, 136.8, 158.8, 199.6; MS *m/z*: 254, 161, 131, 105 (base), 94, 91, 77.

*5-(*p*-Acetylphenoxy)-1-phenylpentan-1-one*: A 5 g portion of the above ketone was subjected to Friedel–Crafts acetylation as described above for the analogous butanone. Recrystallization from ethanol gave white crystals, mp 125.2–125.5°C. IR ($CHCl_3$): 1685, 1603, 1175 cm^{-1}; UV λ_{max} (n,π^*): 317 nm; ^{1}H NMR δ: 1.9 (m, 4H), 2.50 (s, 3H), 3.11 (t, 2H, J = 7 Hz), 4.11 (t, 2H, J = 6 Hz), 6.89 (d, 2H, J = 9 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.54 (tt, 1H, J = 7, 2 Hz), 7.89 (d, 2H, J = 9 Hz), 7.96 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR 20.6, 26.05, 28.4, 37.7, 67.7, 113.9, 127.8, 128.4, 130.05, 130.4, 132.8, 136.7, 162.7, 196.5, 199.5; MS *m/z*: 296, 161 (base), 149, 120, 105, 77.

*5-(*p*-Valerylphenoxy)-1-phenylpentan-1-one* was prepared in 82% yield from 5 g 1,5-diphenyl-1-pentanone by the Friedel–Crafts reaction just described for the acetyl derivative. Recrystallization from ethanol provided white crystals, mp 111.7–112.0°C; IR ($CHCl_3$): 1690, 1600, 1515, 1175 cm^{-1}; UV λ_{max} 317 nm; ^{1}H NMR δ: 1.0 (t, 3H, J = 3 Hz), 1.2–2.0 (m, 8H), 3.11 (t, 2H, J = 7 Hz), 4.20 (t, 2H, J = 6 Hz), 6.95 (d, 2H, J = 9 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.54 (tt, 1H, J = 7, 2 Hz),

7.85 (d, 2H, J = 9 Hz), 7.96 (dd, 2H, J = 7, 2 Hz); ^{13}C NMR δ: 13.77, 20.61, 22.33, 26.59, 28.48, 37.80, 67.69, 113.84, 128.37, 129.94, 130.06, 132.79, 136.75, 162.53, 199.02, 199.63; MS *m/z*: 338, 296, 281, 177, 162, 161 (base), 147, 121, 120, 105.

*5-(*p*-Cyanophenoxy)-1-phenylpentan-1-one* was prepared in 70% yield from 11 g of 5-iodo-1-phenylpentan-1-one and 9.1 g 4-cyanophenol as described above for the homologous butanone. Six recrystallizations from ethanol gave white crystals, mp 96.2–96.5°C; IR: 2215, 1690, 1605, 1175 cm^{-1}; UV λ_{max} (n,π^*): 318 nm; ^{1}H NMR δ: 1.9 (m, 4H), 3.05 (t, 2H, J = 7 Hz), 4.0 (t, 2H, J = 6 Hz), 6.95 (d, 2H, J = 9 Hz), 7.43 (tt, 2H, J = 7, 2 Hz), 7.54 (tt, 1H, J = 7, 2 Hz), 7.75 (d, 2H, J = 9 Hz), 7.96 (dd, 2H, J = 7, 2 Hz)); ^{13}C NMR δ: 20.5, 28.3, 37.7, 103.6, 115.0, 127.75, 128.1, 128.4, 132.8, 133.7, 136.7, 162.05, 199.4; MS *m/z*: 279, 162, 161 (base) 143, 133, 132, 120, 119, 105 (base), 102.

p-*Ethylvalerophenone*: Friedel–Crafts acylation of ethylbenzene with valeryl chloride gave an oil that was purified by repeated vacuum distillation, bp 93°C (0.35 Torr) (lit. (24) bp 169–171°C at 32 Torr). GC analysis indicated 99.15% *para* isomer, 0.84% *ortho* isomer, and 0.01% unknown impurity. IR (neat): 1690, 1605 cm^{-1}; UV λ_{max} (n,π^*): 309 nm; ^{1}H NMR δ: 1.10 (t, 3H, J = 7 Hz), 1.25 (t, 3H, J = 7 Hz), 1.4–1.7 (m, 4H), 2.65 (quart, 2H, J = 7 Hz), 2.65 (t, 2H, J = 7 Hz), 7.28 (d, 2H, J = 8 Hz), 7.87 (d, 2H, J = 8 Hz); ^{13}C NMR δ: 13.6, 14.85, 22.2, 26.35, 28.6, 37.9, 127.7, 128.0, 134.6, 149.4, 199.8; MS *m/z*: 190, 161, 148, 133 (base), 105.

p-*Ethylacetophenone*: Friedel–Crafts acetylation of excess ethylbenzene gave a liquid, bp 50.5–51°C (0.1 Torr) (lit. (25) bp 125°C at 20 Torr). GC analysis indicated 0.85% *ortho* isomer. IR (neat): 1690,1605 cm^{-1}; UV λ_{max} (n,π^*): 309 nm; ^{1}H NMR (CCl_4) δ: 1.25 (t, 3H, J = 7 Hz), 2.45 (s, 3H), 2.65 (quart, 2H, J = 7 Hz), 7.10 (d, 2H, J = 8 Hz), 7.70 (d, 2H, J = 8 Hz); MS *m/z*: 148, 133 (base), 105.

Procedures

Product identification

Acetophenone and its *p*-ethyl and *p*-methoxy derivatives were identified by their characteristic GC retention times. The same was true for propene, which produces a sharp peak well before the solvents. It could be analyzed quantitatively by keeping the samples in an ice bath before analysis; its peak intensity was calibrated for Stern–Volmer plots by equating its yield to that of the nonvolatile acetophenone. The several ω-(*p*-acetylphenyl) diketones were themselves products from the *p*-valerylphenyl diketones. The various vinyl ketone products also formed by type II photoelimination were apparent in GC peaks comparable in size to those of the acetophenones, although their structures were not routinely verified. Likewise, in all cases small GC peaks were observed with retention times, relative to starting diketone, characteristic of cyclobutanols.

Product formation from the diketones was determined by a representative analysis of just one, 5-(*p*-acetylphenyl)-1-phenylpentan-1-one. A 2 g sample in 450 mL benzene under nitrogen was irradiated in an immersion well with a quartz-filtered 450-W Hanovia mercury arc. After 6 h no diketone was detectable by HPLC. Removal of solvent left 2 g of oil, which was dissolved in a few mL of hexane and chromatographed through 65 g of Mallinkrodt Silicar CC-7 silica gel. The column was eluted with hexane mixed with increasing proportions of methylene chloride and then with increasing proportions of ethyl acetate. Acetophenone and *p*-allylacetophenone eluted in the range 40:60 to 80:20 CH_2Cl_2:hexane; their structures were determined by comparison to authentic samples. The fraction eluting at 20:80 ethyl acetate:CH_2Cl_2 was found to be a single compound assigned as *cis*-1-phenyl-2-(*p*-acetylphenyl)methylcyclobutanol. Evaporation of solvent left 0.21 g of oil: IR ($CHCl_3$): 3580, 3475, 1690, 1605, 1275, 1185 cm^{-1}; UV λ_{max} (CH_2Cl_2): 254 nm (ε = 15 000); ^{1}H NMR δ: 1.5 (m, 1H), 2.0 (m, 2H), 2.2 (d, 1H, J = 2 Hz), 2.4 (s, 3H), 2.95 (m, 4H), 7.15 (m, 3H), 7.65 (m, 2H); MS *m/z*: 280, 252, 237, 161, 145, 134, 122, 121 (base), 120, 107, 106, 105. Earlier and later fractions contained another 0.08 g. The fractions that eluted at 40% ethyl acetate yielded 0.074 g analyzed as 93% of one compound; it was assigned as the *trans* cyclobutanol; IR ($CHCl_3$): 3580, 3450, 1690, 1605, 1275, 1185 cm^{-1}; UV λ_{max} (CH_2Cl_2): 254 nm (ε = 9500); ^{1}H NMR δ: 1.2–3.0 (m, 11H), 6.8–7.75 (m, 9H); MS *m/z*: 280, 252, 237, 161, 145, 134, 120 (base), 115, 105. Another 0.14 g was contained in earlier fractions.

Spectroscopy

Phosphorescence spectra were taken on a Perkin–Elmer MPF-44A spectrophotometer equipped with a differential corrected spectrum unit and a Hitachi phosphorescence accessory. Samples, typically 10^{-3}–10^{-4} M in 5 mm quartz tubes, were held in a quartz Dewar containing liquid nitrogen.

Steady state photokinetics

As in previous work (1), samples were prepared in volumetric glassware; 2.8 mL aliquots were transferred into constricted 13 × 100 mm Pyrex or Kimax culture tubes, which were then subjected to three freeze–pump–thaw cycles at high vacuum before being sealed. All samples in a given experiment were irradiated in parallel on a "merry-go-round" apparatus (26) set in a room temperature water bath. Light was provided by a 450-W Hanovia mercury arc housed in an immersion well inside a Vycor vessel containing a basic solution 0.002 M in potassium chromate to isolate the 313 nm emission band. Samples were analyzed either by GC or HPLC, with response factors for products and standards calibrated with authentic samples. Both long-chain alkanes and long-chain alkyl benzoates were used as internal standards.

Results

The dibenzoylalkanes shown in Scheme 1, with from one to five intervening carbons, were prepared by standard methods. Dibenzoylmethane could not be studied because of the preponderance of the enol form, so 2,2-dibenzoylpropane **2,2Bz$_2$Pr** was studied instead. Neither this compound nor 1,2-dibenzoylethane **12Bz$_2$Et** underwent any measurable photodegradation after prolonged irradiation. Both diketones did sensitize the *cis–trans* isomerization of 1,3-pentadiene and of stilbene. Figure 1 shows the sensitization plots obtained, from which $k_q\tau$ and Φ_{isc} values were extracted (27). The Φ_{isc} values for a few other ketones were obtained by measuring the

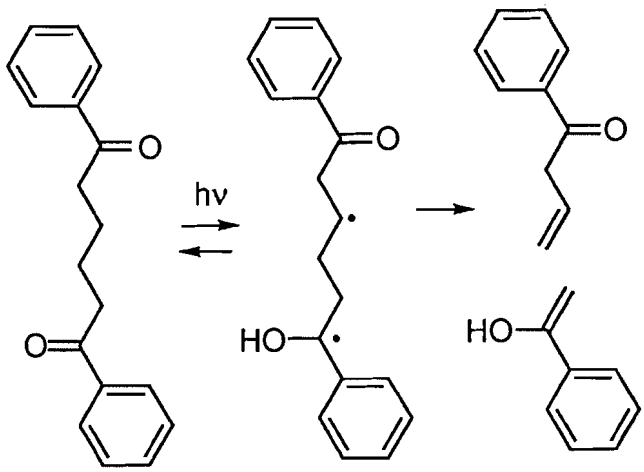
extent of isomerization of a single high concentration of pentadiene.

Dibenzoylpropane, -butane, and -pentane all undergo Norrish type II photoelimination. Quantum yields of acetophenone formation were determined for degassed benzene solutions containing 0.01 M diketone and various concentrations of dioxane. Comparable valerophenone solutions were irradiated simultaneously as actinometers (28). The values so measured were reproducible within ±5%. For the first two diketones quantum yields reached maximum levels at 4–5 M dioxane; but for **1,5Bz$_2$Pn** they get even higher in *tert*-butyl alcohol. The maximum and minimum values are recorded in Table 1. Benzoylalkenes accompany the acetophenone; they were not measured directly, but peaks of the appropriate size and retention time were noted during GC analysis. In the case of dibenzoylpropane **1,3Bz$_2$Pr**, the coproduct is phenyl vinyl ketone, an excellent triplet quencher (9). Acetophenone quantum yields decreased with increasing conversion as shown in Fig. 2 (28). Table 2 contains the values extrapolated to zero conversion, as determined from plots of reciprocal quantum yields, one of which is included in Fig. 2. Diketone disappearance quantum yields were also measured in pure benzene, in the presence of 4.5 M dioxane or 1 M pyridine, and in *tert*-butyl alcohol. In most cases disappearance yields were 15 ± 5% higher than acetophenone yields (29). GC peaks corresponding to the expected minor cyclobutanol coproducts were observed but not measured quantitatively except for dibenzoylbutane **1,4Bz$_2$Bu**, where $\Phi_{CB} = 0.05$ in benzene, and for dibenzoylpentane **1,5Bz$_2$Pn**, where $\Phi_{CB} = 0.14$ in *tert*-butyl alcohol. The chemical yields of cyclobutanol were in the 10 ± 5% range for the other diketones studied.



Triplet lifetimes were measured by standard quenching techniques. Degassed benzene solutions containing 0.01 M diketone and varying concentrations of 2,5-dimethyl-2,4-hexadiene were irradiated to ~5% conversion. Stern–Volmer plots were linear with the slopes listed as $k_q\tau$ values in Table 1. The value for dibenzoylpropane was corrected upward for product quenching from the data in Fig. 2, by multiplying the observed slope by Φ^{0conv}/Φ_{obs} as described earlier (28).

The same measurements were performed on two groups of unsymmetric diketones: diaroylbutanes with different *para* substituents; and ones in which one benzoyl group is turned around. Scheme 2 depicts these compounds and their abbreviations. Proper interpretation of their behavior necessitated study of the *p,p'*-disubstituted 1,4-dibenzoylbutanes shown in Scheme 1 and the model monoketones shown in Scheme 2. Table 2 lists steady state quantum yields and $k_q\tau$ values, some of which were reported much earlier (1). As with the symmetric diketones, acetophenones were the major products

and **δVaPhOVP**, type II reaction of the valeryl group was detected both by appearance of the homologous acetylketones and by measurement of propene formation. Triplet lifetimes of the different δ-phenoxyvalerophenones were confirmed by flash kinetics. For the *p*-methoxybenzoyl groups of **δAcPhOVP** and **δVaPhOVP**, these were 500 and 450 ns, respectively.

Spectroscopy

UV spectra of the various diketones were measured in benzene; phosphorescence spectra, in 2-methyltetrahydrofuran at 77 K. Table 3 contains all the relevant data, including extinction coefficients at 313 nm, where the compounds were irradiated. **1,3Bz$_2$Pr**, **1,4Bz$_2$Bu**, and **1,5Bz$_2$Pn** behave just like valerophenone in absorption. Their emission spectra nearly duplicate the characteristic n,π^* spectrum of valerophenone, with 0–0 bands at 385 ± 1 nm (74.3 kcal/mol). **1,2Bz$_2$Et** and **2,2Bz$_2$Pr** show the same emission spectra but have larger extinction coefficients at 313 nm, respectively. Likewise, **1,4EtBz$_2$Bu** and **1,4An$_2$Bu** mimic the behavior of *p*-ethyl- and *p*-methoxyvalerophenone in both absorption and emission, the latter occurring at lower energy and showing broader structure, as expected for systems with π,π^* lowest triplets. The various ω-substituted alkanophenone model monoketones have spectra like that of valerophenone.

Discussion

The diketones that we have studied are divided into symmetric and unsymmetric categories because intramolecular energy transfer affects the kinetics for the two quite differently. Each symmetric diketone has two identical chromophores, either of which can be excited with equal probability. After excitation of one of the carbonyls, energy transfer will eventually equilibrate the excitation such that each carbonyl is excited for exactly half the time on a given molecule. In contrast, the absorption ratio for the unsymmetric diketones with two different chromophores need not be 50:50 and can vary with wavelength. Since the two chromophores have different triplet energies, rates of internal energy transfer are not equal and define a distribution of interconverting triplets that begins equal to the ratio of extinction coefficients and rapidly establishes an equilibrium that is not 50:50. Inasmuch as triplet excitation equilibrates between the two chromophores before significant decay occurs, both chromophores will show the same equilibrium lifetime, as defined by eq. [1], where $1/\tau^0$ represents the sum of all unimolecular and pseudo-first-order decay rate constants for a given carbonyl triplet *exclusive of its rate of energy transfer to the other* and the χ's reflect the fractional population of triplet excitation on each chromophore (27). In that case the same triplet lifetime is measured no matter which chromophore is monitored for both steady state Stern-Volmer quenching studies and direct flash kinetic detection of triplet decay. If the two chromophores are not completely equilibrated, because natural decay is competitive with energy transfer, then the kinetics become complicated; Stern–Volmer plots diverge and curve in opposite directions (27). This situation is discussed more fully below.

$$[1] \quad 1/\tau_{eq} = \chi_{Bz}/\tau^0_{Bz} + \chi_{RBz}/\tau^0_{RBz}$$

For the symmetric diketones, separate τ's and χ's cannot be distinguished, since energy transfer is degenerate. The unexcited benzoyl group effectively behaves merely as an electron-withdrawing substituent in its effect on the reactivity of the excited benzoyl. For the unsymmetric diketones, the apparent rate constants for excited state decay of each chromophore are different from those intrinsic to the chromophore, depending also on rate constants for triplet energy transfer and relative extinction coefficients β.

Derivation of triplet decay rate constants

Tables 4 and 5 contain rate constants for hydrogen abstraction and radiationless decay of all the monoketones and symmetric diketones studied; Table 6 contains apparent rate constants for the unsymmetric diketones. These are all derived from the

reciprocal triplet lifetimes contained in the $k_q\tau$ values, with k_q equaling 6×10^9 M^{-1} s^{-1} in benzene (31). Rate constants $k_{\gamma-H}$ for γ-hydrogen abstraction equal Φ^{max}/τ, where Φ^{max} is either the maximum quantum yield for acetophenone formation in Lewis base solvents, multiplied by 1.1 to take into account cyclobutanol formation, or the maximum disappearance quantum yield. For most of the model phenyl ketones this value is 1 and no other triplet decay occurs (1). For *para*-substituted phenyl ketones, however, π,π* triplets usually lie below the reactive *n*,π* triplets (32); this situation reduces reactivity sufficiently that some quenching by solvent or impurities occurs, such that $1/\tau > k_{\gamma-H}$ (33). Such is the case for the *p*-alkyl and *p*-alkoxy ketone chromophores that occur in many of the diketones in Tables 4 and 5; we lump all decay other than γ-hydrogen abstraction into k_d by equating it to $1/\tau - k_{\gamma-H}$.

To detect any internal self-quenching, we must properly dissect these k_d values into competing chemical and physical decay modes. It is well established that both Norrish type I cleavage and bimolecular hydrogen abstraction are too slow to compete with γ-hydrogen abstraction in such triplet alkanophenones (34). Only three other forms of triplet decay normally need be considered:

(*i*) Quenching by benzene is known to involve charge transfer (4, 35) and has an observed rate of $(1–10) \times 10^5$ s^{-1} (4). This process is competitive only for very long-lived triplets and may contribute to k_d for *p*-alkoxyphenyl ketones (33).

(*ii*) Bimolecular rate constants for self-quenching by ground state ketone have been measured in the $10^6–10^8$ M^{-1} s^{-1} range (4). For the *p*-alkoxyphenyl ketones at ketone concentrations 0.01–0.1 M, this process would have a rate of $10^6–10^7$ s^{-1} (36).

(*iii*) For the δ-phenylvalerophenones, significant δ-hydrogen abstraction should compete, on the order of 15–20%. The normal 20/1 γ/δ rate ratio is lowered by inductive deactivation of the γ-hydrogens (1) and by conjugative activation of the δ-hydrogens, as occurs with δ-alkoxy groups (30). The same effect probably occurs to a lesser extent in the δ-phenoxyvalerophenones.

The k_H value calculated for **δPhVP** just from type II products leaves a k_d value that undoubtedly represents entirely δ-hydrogen abstraction. This fact cannot be gleaned just from product yields, since the 1,5-biradicals produced by δ-hydrogen abstraction seem to cyclize very inefficiently (30). Thus there is no reason to suggest the occurrence of internal self-quenching by the δ-phenyl group, such as is very rapid ($k \sim 10^9$ s^{-1}) with β-phenyl ketones (37). We have verified independently that γ-phenylbutyrophenone undergoes γ-hydrogen abstraction in 100% quantum efficiency.[3] This finding limits the rate of internal quenching by a γ-phenyl to $<5 \times 10^7$ s^{-1} and suggests an even lower rate for a δ-phenyl.

Rate constants for γ-hydrogen abstraction in symmetric diketones

We are the third group to measure the triplet lifetime of **13Bz$_2$Pr** by steady state Stern–Volmer quenching with similar results, the other groups reporting $k_q\tau$ values ~180 M^{-1} (5, 6). Scaiano's group also did a laser flash measurement by sensitizing formation of triplet naphthalene and obtained a value of 260 M^{-1} (6). Thus $1/\tau$ values have ranged from 2.3×10 to 4.0×10^7 s^{-1}, with different measures being taken to correct for quenching by acrylophenone product. We have measured a 100% quantum yield for product formation from **13Bz$_2$Pr**, and Scaiano's group has reported a comparably high value for the homolog 1,3–dibenzoylbutane (6). Consequently γ-hydrogen abstraction is concluded to represent the entirety of triplet decay. The monoketone model, **γEstBP**, has a considerably longer triplet lifetime. As we pointed out originally (1), the ester function appears to deactivate γ C—H bonds inductively without providing much conjugative activation. It appears that the benzoyl group does provide enough conjugative stabilization of the developing γ-radical site to increase the inductively depressed rate of reaction some 3-fold. It is important to point out here that the conversion dependence of quantum yields for **13Bz$_2$Pr** is relatively small compared to that of **γEstBP** (28). This fact corroborates the shorter triplet lifetime of the diketone relative to the ketoester.

Table 5 contains "expected" $k_{\gamma-H}$ values based on the well-known (1) large inductive effects of γ and δ substituents. Table 4 summarizes the kinetic behavior of those model monoketones needed to predict the behavior of individual ketone units in these diketones. The excellent Hammett correlation of such substituent effects on triplet reactivity (1) allows calculation of "expected" rate constants for new compounds; those for the diaroylbutanes and **15Bz$_2$Pn** were calculated by using the same σ_I value for benzoyl as for other carbonyl groups, 0.30, and the measured ρ_δ and ρ values of −1.85 and −0.76, respectively. The close agreement between expected and measured $k_{\gamma-H}$ values provides a good test for the accuracy of values based on quantum yields.

Self quenching in the α,ω-diaroylalkanes

As Tables 4 and 5 indicate, none of the dibenzoylalkanes is expected to undergo any physical decay, whereas the bisethyl- and -dimethoxybenzoylalkanes should undergo some slow physical decay, probably bimolecular quenching. However, except for **1,3Bz$_2$Pr**, all of these diaroylalkanes have k_d values $\geq 10^7$ s^{-1}. Since all other modes of decay have been ruled out, we must conclude that they all undergo internal self-quenching, the intramolecular equivalent of the bimolecular self-quenching known for phenyl ketones. We emphasize that our conclusion of significant self-quenching for the diaroylbutanes is based on low quantum yield measurements that have been reproduced by three separate students (2, 11) and thus seem reliable.

The observed order of k_{sq} values is unusual, with perhaps the most intriguing question being why no internal quenching occurs in triplet **1,3Bz$_2$Pr**. Apart from imposing a mechanistic puzzle, this result is very important in terms of the work on energy transfer in polymers based on phenyl vinyl ketone. The many examples of highly efficient energy transfer to trapping agents in these polymers could not exist if 1,3-dibenzoylalkane subunits underwent rapid self-quenching.

We shall discuss possible mechanisms for this quenching effect after we have analyzed the behavior of the unsymmetric diketones. These were chosen for study only after we were convinced that the symmetric diketones undergo significant internal quenching. An obvious structural parameter that can be modified is the orientation between the benzoyl groups allowed by the tether connecting them. Thus the γ- and δ-acylphenyl and -acylphenoxy ketones have one of the two

benzoyl groups turned around so that it must orient itself differently in relation to the other benzoyl group when the tether coils enough for them to interact.

Rate constants for γ-hydrogen abstraction in unsymmetric diketones

All of the diketones in Table 6 have one benzoyl group and either a *p*-alkylbenzoyl group or a *p*-alkoxybenzoyl group. In all cases the energy of the benzoyl n,π^* triplet is higher than that of the π,π^* triplet of the *p*-substituted benzoyl group. Therefore the equilibrium distribution of excitation favors the substituted benzoyl groups, leaving $\chi_{Bz} < 0.5$. The table lists "model" rather than "expected" k_H and k_d values, since all observed rate constants are altered by internal energy transfer. Equation [2], a corollary of eq. [1], describes the observed rate constant for reaction when triplet excitation is equilibrated between two nonequivalent chromophores. The observed rate constant is the normal (model) rate constant for a chromophore weighted by the fractional distribution of excitation on that chromophore. Thus k_H/k_{model} should equal χ for each chromophore, although the measurements are more precise for the benzoyl group. Interestingly, k_H and k_{model} are nearly equal for reaction of the substituted benzoyl chromophore in each diketone, reflecting the fact that most of the excitation resides on that chromophore.

$$[2] \quad k_H^{obs} = \chi_{Bz} k_{model}$$

Figures 3 and 4 display the quenching plots for the two diketones with one *p*-alkylbenzoyl chromophore. For **1Bz4EtBzBu**, acetophenone and *p*-ethylacetophenone formation are quenched with the same efficiency. Likewise, for **δVaPhVP**, acetophenone and propene are quenched with equal efficiency. In each diketone the two chromophores have identical triplet lifetimes, so excitation equilibrates between them before they decay. These equilibrium lifetimes are intermediate between those of the monoketone models. Figure 4 also shows the behavior of **δAcPhVP**. Reaction of its benzoyl group is quenched more readily than is the case for the valeryl homolog, which has a shorter overall lifetime because of reaction by the valeryl group.

The k_H/k_{model} value for **1Bz4EtBzBu** suggests a χ_{Bz} value of 3/8. This value means that the lowest triplets of the two chromophores are very close in energy, so that transfer of triplet excitation has nearly the same rate in both directions. No direct model for the δ-(*p*-acylphenyl)valerophenones was studied, but a model k_H value of half that for **δPhVP** itself was estimated based on the effects of a cyano group on **δPhOVP**; this value is consistent with a χ_{Bz} value of 3/8. No appreciable physical decay occurs in the monoketone models for **1Bz4EtBzBu**, which itself shows a significant k_d value that we ascribe to self-quenching, just as in **1,4Bz$_2$Bu**. In contrast, the two δ-(*p*-acylphenyl)valerophenones have k_d values comparable to those for **δPhVP**, which is attributed in all three to δ-hydrogen abstraction. There is no need to invoke any internal self-quenching.

The same conclusion about self-quenching can be drawn from the kinetics of the other three diketones, none of which appear to have fully equilibrated triplets. Equation [5] below describes how the quantum yield of acetophenone formation and thus the observed k_H value depends on both kinetics and relative absorption (β's) in such cases. For **1Bz4AnBu**, k_d is much larger than any physical decay rates of the model monoketones, so self-quenching is indicated. The turned-around analogs all have k_d values no larger than the monoketone models and are concluded not to undergo any internal self-quenching. In these ketones the k_H/k_{model} values suggest χ_{Bz} values of 0.1, which translates into a 9/1 ratio for energy transfer rates.

Scheme 3 shows why the χ_{Bz} values for the diketones are larger than would be anticipated from the χ^{n,π^*} values of the model *p*-substituted monoketones, which are 0.12 and 0.01 for *p*-alkyl and *p*-methoxy, respectively (33). Electron-donating groups raise n,π^* energies as well as lower π,π^* energies, so the energy gap ΔE_{ex} between the lowest triplets of two chromophores is lower than the $n,\pi^* - \pi,\pi^*$ energy gap ΔE_{in} in the *p*-substituted chromophore (11).

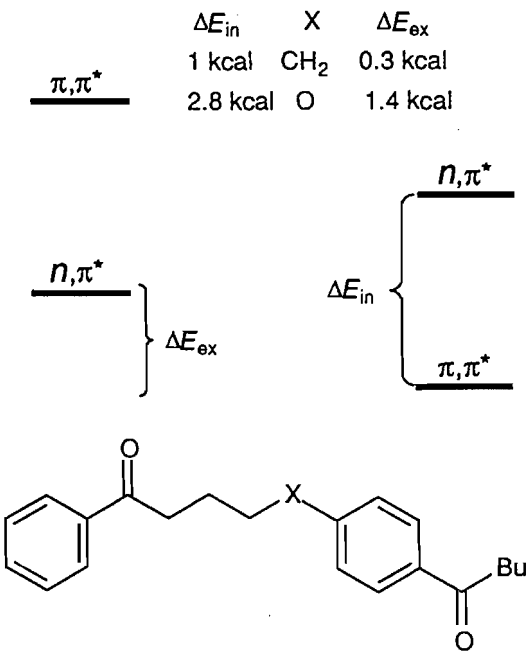
Scheme 3.



Structural dependence of k_{sq}

The rate constants for this internal self-quenching show three distinct variations:

1. Only the α,ω-diaroylalkanes display this form of internal quenching. Since the π systems of the turned-around diketones are as close to each other as they are in the α,ω-diaroylalkanes, we conclude that close contact between the carbonyl groups is required.

2. In the 1,4-diaroylbutanes, k_{sq} decreases as the π,π* triplet becomes lower in energy than the *n*,π* triplet. This behavior parallels the corresponding drops in observed rate constants for *n*,π* reactions (33, 38) and strongly suggests that the self-quenching involves mainly the *n*,π* triplet. This conclusion reinforces the first one. The relative ordering is opposite to that reported for bimolecular self quenching, where the order is π,π* *p*-methoxyacetophenone (36) > *n*,π* benzophenone (4). It already has been concluded that bimolecular self-quenching can occur by more than one mechanism (5). Apparently the tether prevents the two benzoyl groups from attaining whatever orientation favors rapid quenching of π,π* triplets.

3. In the α,ω-diaroylalkanes, the fastest rate occurs for a four-carbon tether, which is not unusual in organic chemistry, but the lack of reaction for the three-atom tether is surprising. Apparently a very specific orientation of the two carbonyls is required for this quenching interaction, one that is not possible with the three-atom tether and that becomes less likely for tethers longer than four atoms. At this point we cannot suggest a more exact description of the interaction, except that it must provide a path for radiationless decay. The most likely possibilities are some form of excimer interaction or a chemical reaction such as revertible radical addition. Since internal excimer formation is usually favored by three-carbon tethers and since it has been shown that rates for hydrogen abstraction in 2,4-dibenzoylpentanes are very sensitive to conformation (5), a radical reaction-like process may seem favored, although radical additions to carbonyls work well for three-atom tethers (39).

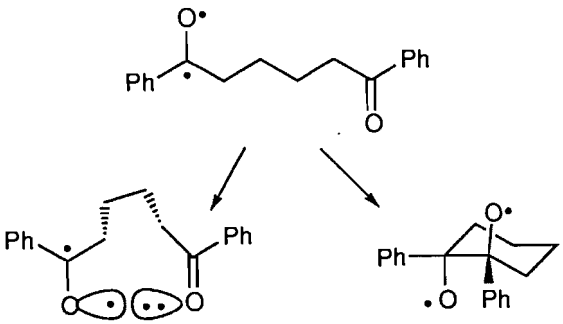


Fig. 5. Stern–Volmer plots for quenching by 2,5-dimethyl-2,4-hexadiene of acetophenone formation from (- - -) **γPhOBP**, (■) **γ(CNPhO)BP**, (▲) **δ(AcPhO)BP**, and (○) **γ(VaPhO)BP**; (. . . .) of *p*-methoxyacetophenone formation from **pMeOVP**; and (●) of propene formation from **γ(VaPhO)BP**.

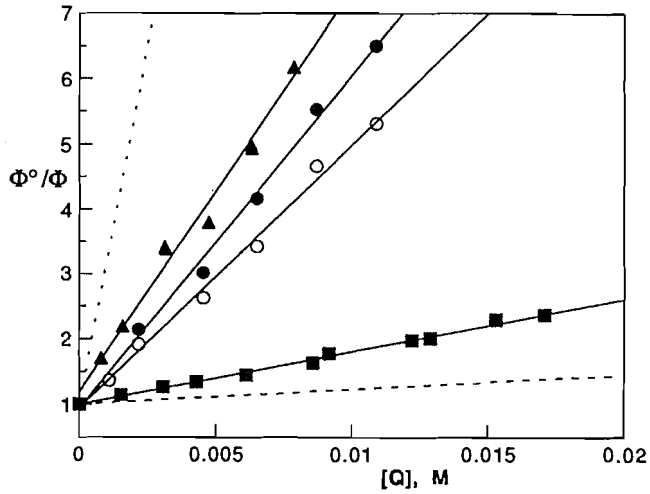

4. The electronic spectra of the 1,1- and 1,2-dibenzoylalkanes, especially the former, with its nonunity intersystem crossing yield, suggest some direct mixing of the chromophores. Their relatively high k_{sq} values may indicate a mechanism different from that in **1,4Bz$_2$Bu**.

Rates of intramolecular energy transfer

When we first studied **1Bz4AnBu** and noted similar $k_q\tau$ values for quenching reaction from both chromophores (11), we treated the system as if it were fully equilibrated, even though the two $k_q\tau$ values differed by more than normal experimental error. Figure 5 shows the quenching behavior for the various γ-(acylphenoxy)butyrophenones and their models. Acetophenone and propene are formed from the two different chromophores of **γVaPhOBP** and are not quenched with the same efficiency. Plots of **δVaPhOVP** and its models look very similar. Having now found two more examples of diketones in which the benzoyl and alkoxybenzoyl chromophores are not quenched equally, we can analyze all three cases with the complete equation that describes quenching of two partially equilibrating chromophores. Scheme 4 displays the reactions that determine the extent of excitation interconversion in one representative diketone. Equations [3] and [4] describe how quantum yields and Stern–Volmer plots depend on the various kinetic parameters (27). Equation [3] is given in two forms: the general one where subscripts u and r distinguish the unre-

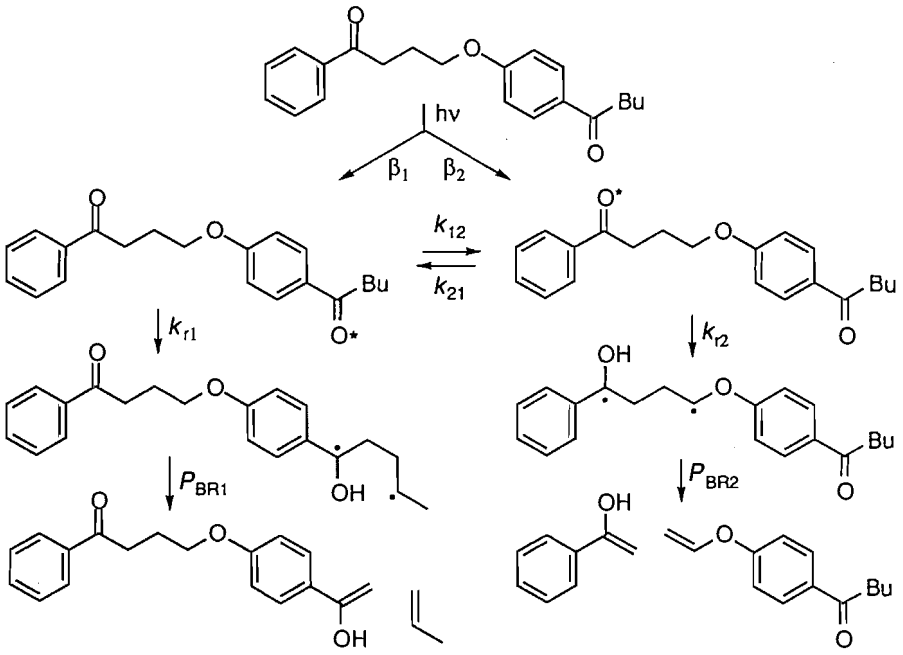
For personal use only.

Scheme 4.



acting and reacting chromophores, and one specific to acetophenone formation from the benzoyl chromophore. In Eq. [4] the numerator is basically the product of two Stern–Volmer expressions divided by D, which equals 1 when no state interconversion occurs and approaches zero as equilibration becomes complete. The denominator, which handles quenching of interconversion and includes the fraction of light β absorbed by each chromophore, differs for products formed from each state. The β's are determined by the extinction coefficients of the two chromophores: $\beta_1 = 1 - \beta_2 = \varepsilon_1/(\varepsilon_1 + \varepsilon_2)$. All the rate constants except for k_{12} and k_{21} can be estimated closely from the kinetics of the model monoketones or symmetric diketones. The τ values are dominated by k_r (= $k_{\gamma\text{-H}}$) and k_{12} or k_{21} values in these diketones, where physical decay reactions are slow. The χ_{Bz} values gleaned from quantum yields furnish the k_{21}/k_{12} values, which are 5/3 and 9/1.

[3] $$\Phi_r = P_{BR}k_r\tau_r(\beta_r + \beta_u k_{ur}\tau_u)D^{-1}$$
$$\Phi_{AP} = P_{BR}k_H\tau_{Bz}[\beta_{Bz} + \beta_{RBz}k_{12}\tau_{RBz}]/(1 - k_{12}\tau_{RBz}k_{21}\tau_{Bz})$$

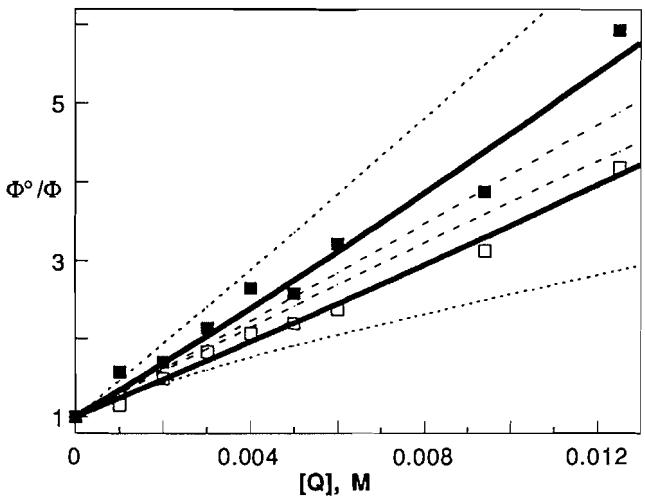
[4] $$\Phi^0/\Phi = \frac{1 + (k_q\tau_1 + k_q\tau_2)[Q]D^{-1} + k_q^2\tau_1\tau_2[Q]^2D^{-1}}{1 + \beta_r k_q\tau_u[Q](\beta_r + \beta_u k_{ur}\tau_u)^{-1}}$$

[5] $$D = 1 - k_{12}\tau_1\, k_{21}\tau_2$$

Figures 6 and 7 show the best fit of the data for two of the diketones to eqs. [3] and [4]. The benzoyl chromophore is always state 2; the *p*-alkoxybenzoyl, state 1; $1/\tau_r = 1/\tau_r^0 + k_{ru}$; $1/\tau_u = 1/\tau_u^0 + k_{ur}$.

For **1Bz4AnBu**, the following values were used: $k_q = 6 \times 10^9$ for each state; $1/\tau_2' = 7 \times 10^7$; $1/\tau_1' = 1 \times 10^7$; $P_{BR2}k_{r2} = 3 \times 10^7$; $P_{BR1}k_{r1} = 2 \times 10^5$; $\beta_2 = 0.3$; $\beta_1 = 0.7$; $k_{21} = 1 \times 10^8$; $k_{12} = 2 \times 10^7$. With these parameters, $D = 0.61$, and the predicted quantum yield ratio of 0.21/0.01 matches that actually measured. The dotted and dashed lines in Figs. [6] and [7] represent 5-fold changes in the energy transfer rate constants

Fig. 6. Stern–Volmer quenching of **1Bz4AnBu** by 2,5-dimethyl-2,4-hexadiene: (□) acetophenone formation; (■) *p*-methoxyacetophenone formation. Calculated plots: (——) $k_{21} = 1 \times 10^8$ s^{-1}; (— — —) $k_{21} = 5 \times 10^8$ s^{-1}; (- - - -) $k_{21} = 2 \times 10^7$ s^{-1}.



and show just how sensitive such plots are to these values. Thus the not-quite-equal slopes for the experimental data indicate two triplets that are about 2/3 equilibrated. Decreasing D to 0.2 (90% interconversion) brings the two plots within experimental error of each other, whereas increasing it to 0.98 (15% interconversion) causes the plots to diverge sharply.

For **δVaPhOVP**, the following values predict the experimental data in Fig. 7: $k_q = 6 \times 10^9$ for each state; $1/\tau_2' = 2 \times 10^7$; $1/\tau_1' = 3 \times 10^6$; $P_{BR2}k_{r2} = 1 \times 10^7$; $P_{BR1}k_{r1} = 2 \times 10^5$; $\beta_2 = 0.25$; $\beta_1 = 0.75$; $k_{21} = 7 \times 10^7$; $k_{12} = 7 \times 10^6$. With these parameters, $D = 0.46$, which represents 70% interconversion, and the quantum yield ratio is 0.22/0.08, the same as that measured. The 450 ns triplet lifetime measured by flash kinetics corrob-

Fig. 7. Stern–Volmer plots for quenching of **δVaPhOVP** by 2,5-dimethyl-2,4-hexadiene: (○) acetophenone formation; (●) propene formation. (——) $k_{21} = 7 \times 10^7$ s^{-1}; (— — —) $k_{21} = 3.4 \times 10^8$ s^{-1}; (- - - -) $k_{21} = 1.4 \times 10^7$ s^{-1}.

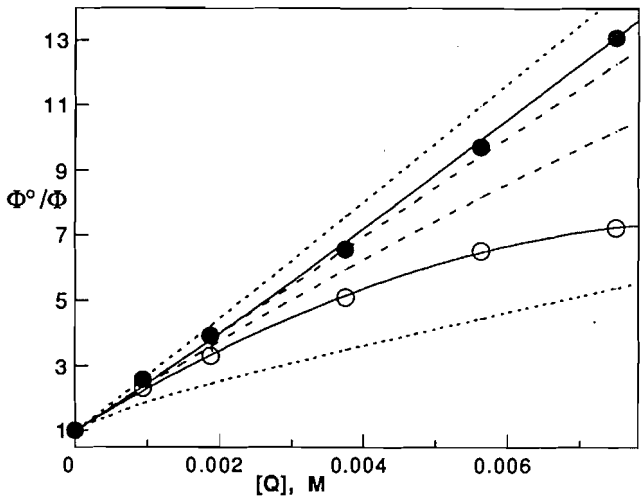

Fig. 8. Calculated Stern–Volmer plots for quenching of acetophenone (bottom 3) and propiophenone (top 3) formation from 1,3-dibenzoylbutane in benzene. (——) plots reported in ref. 6, $k_{21} = 3 \times 10^7$ s^{-1}, $D = 0.98$; (— — —) $k_{21} = 1.5 \times 10^8$ s^{-1}, $D = 0.81$; (- - - -) $k_{21} = 6 \times 10^6$ s^{-1}, $D = 0.998$.

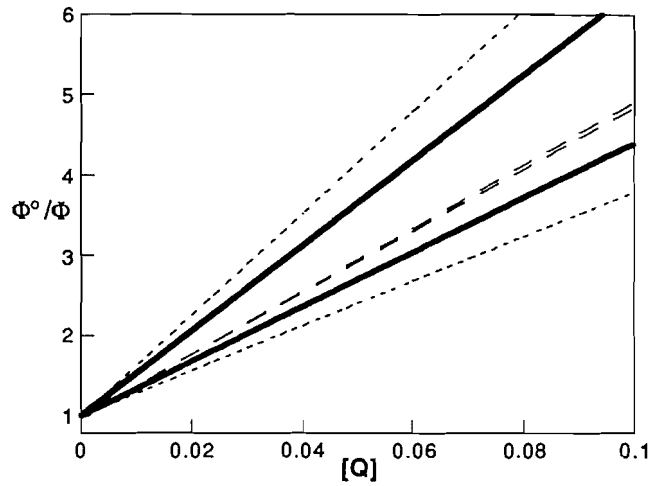

orates the conclusion that near-equilibrium conditions obtain. Again, the calculated plots for faster and slower energy transfer rates indicate how little leeway there is in estimating such rate constants from the experimental data.

The rate constants for exothermic energy transfer from benzoyl to alkoxybenzoyl group near 10^8 s^{-1} are only 1/10 the $\sim 10^9$ M^{-1} s^{-1} value for bimolecular energy transfer between phenyl alkyl ketones (28, 40). This amounts to an unusually low effective molarity of only 0.1 M for two "reactants" separated by a flexible four-atom link. A similar analysis of **γVaPhOBP** provides a set of energy transfer rate constants five times larger than those for **δVaPhOVP**, exactly the kind of distance dependence on energy transfer that one would expect (10, 12, 41). Moreover, it appears that the turned-around diketone with four atoms between the benzoyl group and the alkoxybenzoyl benzene ring undergoes energy transfer somewhat faster than the 1-benzoyl-4-anisyl system. Both comparisons reinforce the notion that the α,ω-dibenzoyl structure can inhibit formation of the best orientation for orbital overlap of the two benzoyl groups.

Postscript

The relatively low rate constants for $n,\pi^* \rightarrow n,\pi^*$ triplet energy transfer are well established (42). Therefore we must emphasize that the exothermic rate constants that we have estimated represent $n,\pi^* \rightarrow \pi,\pi^*$ energy transfer, which usually is faster (43).The conclusion that energy transfer in these diketones is relatively slow reopens the question as to its rapidity in 1,3-dibenzoylpropane structures. As just mentioned, we would normally expect that shortening the connecting tether by one carbon would increase energy transfer rate constants 5- to 10-fold. That would leave a rate constant of no more than 10^9 s^{-1} in **1,3Bz$_2$Pr**. However, we wonder whether the conformational constraints that reverse the normal rate ratio for self-quenching may also apply to energy transfer. In their study of 1,3-dibenzoylbutane, Scaiano and co-workers found unequal $k_q\tau$ values for quenching of acetophenone and propiophenone formation in benzene (6). Assuming internal energy transfer so rapid as to assure equilibration, they speculated at length about a cause for the difference without posing a solid explanation. We have made a much fuller study of the quenching of unsymmetric diketones that will soon be published and we find that solvent changes can greatly affect the degree of curvature and divergence shown in plots such as Figs. 5–7. Consequently we offer Fig. 8 as a *possible* explanation for the behavior of the 1,3–dibenzoylbutane. If energy transfer is much slower than assumed, just as is self-quenching, then the decay rate constants expected for this compound would predict that the two Stern–Volmer plots diverge exactly as was observed. (The analysis assumes that a-alkylation slightly enhances extinction coefficients, as Lewis has reported (40), and also raises the triplet energy slightly.) We do not at this point maintain this suggestion as fact, just as an interesting possibility, and offer it to emphasize how many factors must be balanced in a thorough analysis of the quenching behavior of bichromophoric systems. In particular, it is important to note that internal energy transfer rates of only 10^8 s^{-1} would be sufficient to make the system behave as though it were fully equilibrated. Therefore the observation of the same $k_{q\tau}$ values for the two chromophores in such diketones (6) cannot be used as evidence for energy transfer rates any faster than 10^8 s^{-1} in 1,3-dibenzoyl units of either diketones or polymers.

Acknowledgment

This work was supported by continuing grants from the National Science Foundation. We thank Dr. Anna Gudmundsdottir for measuring some NMR spectra to update those originally taken on low-resolution machines.

This paper is submitted in recognition of Professor James Guillet's singular fusion of photochemical and polymer research, in which he has applied photochemical knowledge to fashion useful polymeric materials and fashioned unique polymer structures to develop new photochemical knowledge and methodology.

Solvent effect on the photophysics of bisphenol-A-based polycarbonate and diphenylcarbonate

Charles E. Hoyle, Isaac B. Rufus, and Himanshu Shah

Abstract: Polycarbonate and diphenylcarbonate exhibit an anomalous fluorescence emission with peak maximum around 350 nm in polar solvents that may be attributed to the association of diarylcarbonate moieties in a polar solvent cage. The red-shifted emission is attributed to intermolecular interactions in polar solvents and intramolecular interactions in polycarbonate. The photophysical behavior of polycarbonate and diphenylcarbonate is different from that of 1,3-diphenylpropane where a red-shifted emission is due to excimers formed by phenyl groups separated by three carbon atoms and is independent of the polarity of the solvent.

Key words: diphenylcarbonate, polycarbonate, aggregates, photophysics.

Résumé : Le polycarbonate et le carbone de phényle présentent tous les deux une émission de fluorescence anormale, avec un maximum autour de 350 nm dans des solvants polaires, qui peut être attribuée à l'association des portions de carbonate de diaryle dans une cage de solvant polaire. On attribue le déplacement vers le rouge de l'émission à des interactions intramoléculaires dans les solvants polaires et à des interactions intramoléculaires dans le polycarbonate. Le comportement photophysique du polycarbonate et du carbonate de diphényle est différent de celui du 1,3-diphénylpropane pour lequel le déplacement de l'émission vers le rouge est causé par les excimères formés par les groupes phényles séparés par trois atomes de carbone et il est indépendant de la polarité du solvant.

Mots clés : carbonate de diphényle, polycarbonate, agrégats, photophysique.

1. Introduction

Polycarbonate has many attributes that contribute to its use in a variety of applications. Unfortunately, it degrades upon exposure to sunlight, necessitating an understanding of polycarbonate photochemistry and photophysics. Even though the photodegradation of polycarbonate has been studied for several decades, there are few papers (1–3) on the photophysics of polycarbonate and corresponding models, none of which reports on solvent effects. In contrast, there are numerous reports on the effects of solvent polarity on the photophysical behavior of polystyrene (4, 5), and Hirayama (5) reported that the intramolecular excimers of 1,3-diphenyl alkanes, which are models for the polystyrene repeat unit, are not influenced by solvent polarity.

1,3-Diaryl systems containing hetero atoms like O, N, and S are of particular interest for photophysical studies since they occur as repeat units in important polymers, i.e., polycarbonate. There is a question of whether 1,3-diphenyl systems with hetero atoms will behave in a manner similar to that of 1,3-diphenyl alkanes. It has previously been reported that both 1,3-diphenylcarbonate (DPC) and polycarbonate exhibit primarily monomer emission with a peak maximum around 300 nm (3, 6–8) in a relatively nonpolar solvent such as dichloromethane. In this paper, we report on the effect of solvent polarity on the photophysical behavior of DPC and polycarbonate, both of which contain 1,3-diaryl repeat units separated by a bridging system with hetero atoms incorporated.

2. Experimental details

Diphenylcarbonate (99%, Aldrich) was sublimed three times. Phenylbenzoate (99%, Aldrich), phenylacetate (99%, Aldrich), 1,3-diphenyl acetone (99%, Aldrich), ethylene glycol (spectrophotometric grade, 99+%, Aldrich), and 1,3-diphenylpropane (TCI, 99%) were used as received. Spectrophotometric grade dichloromethane, methanol, acetonitrile, cyclohexane, 1,4-dioxane, dichloroethane, tetrahydrofuran, isopropanol, and isobutanol were used as received from Burdick and Jackson. The polycarbonate sample, Lexan-140, was received from GE plastics and used after two reprecipitations.

UV-visible absorption spectra were obtained on a Perkin–Elmer Lambda-6 spectrophotometer and fluorescence spectral measurements were made on a SPEX Fluorolog-2 spectrophotometer. Fluorescence emission spectra were recorded without emission correction unless otherwise mentioned. Fluorescence lifetime measurements were measured with time-correlated single-photon counting instruments from Photochemical Research Associates and Edinburgh Analytical Instruments.

3. Results and discussion

3.1 Photophysics of DPC

The polarity of the solvent has only a very modest hypsochromic effect on the UV absorption spectral maximum of DPC (Fig. 1), suggesting that the spectrum with peak maximum around ~257 nm is due to a π,π^* transition. In addition to the shift of the peak absorption maximum to slightly higher energies in polar solvents, there is a very weak absorption band in polar solvents, at wavelengths greater than 280 nm extending to around 300 – 310 nm. Surprisingly, the fluorescence spectrum of DPC is quite different in polar and nonpolar solvents as can be seen by comparing the results in Fig. 2 in methanol and dichloromethane. In methanol, DPC shows a bimodal spectrum with two emission peaks, one at 300 nm and another at 350 nm, when excited at 270 nm (Fig. 2a). In the relatively (compared to methanol) nonpolar solvent dichloromethane, DPC has only one emission peak with a maximum at 300 nm (Fig. 2d). To show that no reaction occurs between methanol and DPC, the solvent from the methanol solution was evaporated and the DPC residue redissolved in dichloromethane. The fluorescence spectrum of DPC redissolved in dichloromethane exhibits only one emission peak at 300 nm (Fig. 2b), indicating that the 350 nm emission peak is not due to a chemical reaction between methanol and DPC, a photochemical reaction product produced in the fluorimeter, or an impurity. To further illustrate this point, dichloromethane from the redissolved solution of DPC was evaporated and the residue redissolved in methanol a second time. Again the fluorescence spectrum of the solution of DPC in methanol (Fig. 2c) is identical to the fluorescence emission spectrum of the fresh solution of DPC in methanol (Fig. 2a), confirming that the 350 nm emission is not from an impurity. We have found in general that, in polar solvents, DPC exhibits a 350 nm emission in addition to the 300 nm emission (Table 1), while in relatively nonpolar solvents like cyclohexane and tetrahydrofuran, DPC exhibits only one emission band with peak maximum around 300 nm (Table 1). (It should be noted that a hydrolysis product of DPC and hence a suspect impurity, phenol, does not show any fluorescence emission peak at 350 nm in any of the polar solvents in Table 1.) While in methanol the I_{350}/I_{300} ratio decreases with a decrease in the concentration of DPC (Fig. 3), concentrated solutions of DPC in dichloromethane, DPC in a PMMA matrix (up to 30 wt.% loading), and DPC crystals do

Fig. 3. Fluorescence emission spectra of DPC in methanol as a function of concentration: (a) 5×10^{-3} M ($I_{350}/I_{300} = 1.46$), (b) 2×10^{-3} M ($I_{350}/I_{300} = 0.86$), and (c) 5×10^{-4} M ($I_{350}/I_{300} = 0.34$). $\lambda_{EX} = 270$ nm.

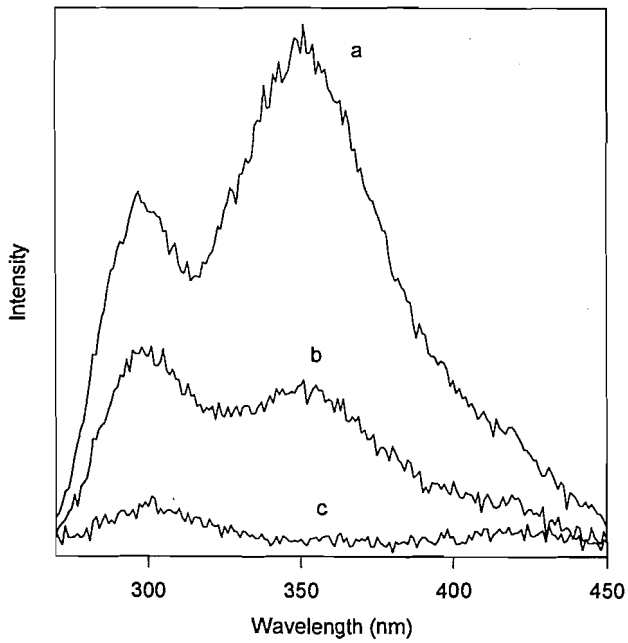

Fig. 4. Fluorescence excitation spectra of DPC (2×10^{-3} M) in methanol: (a) $\lambda_{EM} = 300$ nm and (b) $\lambda_{EM} = 350$ nm.

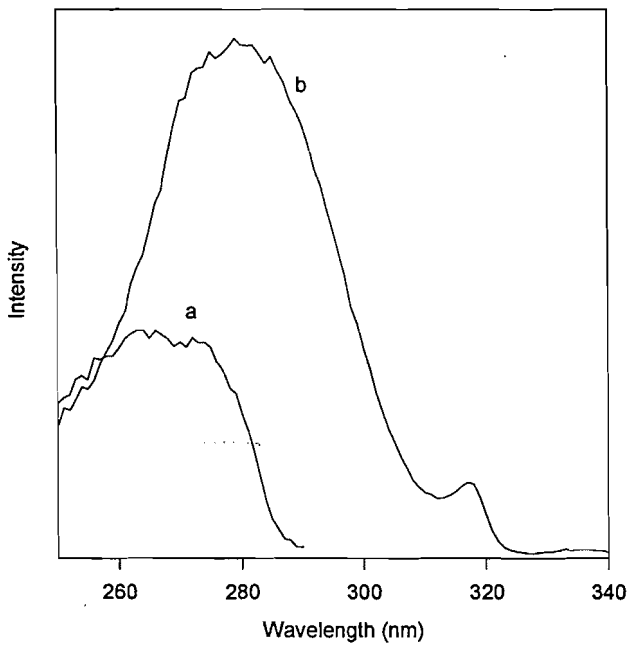
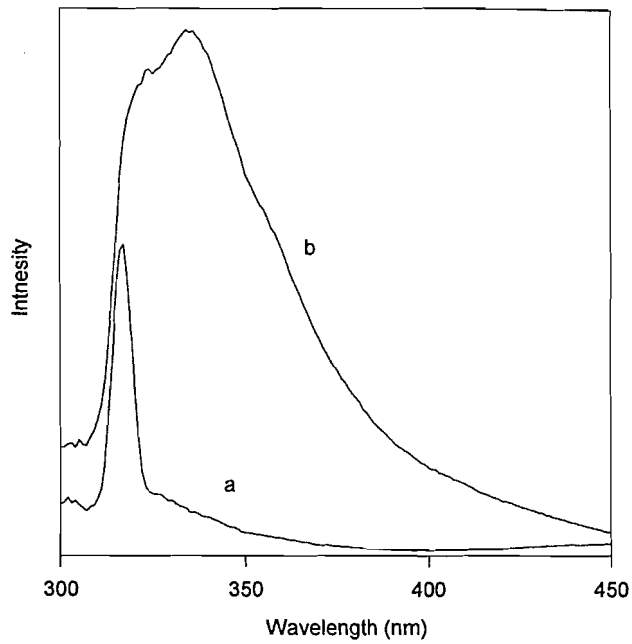


not exhibit any fluorescence with an emission peak around 350 nm, but exhibit only the normal emission (peak maximum near 300 nm) from the excited singlet state. The above observations suggest that the 350 nm emission arises from intermolecular interactions between diphenylcarbonate molecules in polar solvents and is not the result of an intramolecular interaction. The excitation scan for the 300 nm emission peak in methanol (Fig. 4a) is essentially identical to the UV absorption spectrum

Fig. 5. Fluorescence emission spectra of DPC (5×10^{-3} M): (a) in cyclohexane and (b) in methanol. $\lambda_{EX} = 290$ nm.



of DPC, indicating that the 300 nm emission arises from direct excitation of DPC. The excitation scan for the 350 nm emission peak (Fig. 4b) is shifted to lower energy than that for the 300 nm emission peak, indicating that the 350 nm emission may be due to some type of solvent-induced aggregate formation. When excited at shorter wavelengths where excitation of single chromophores no doubt occurs, the 350 nm emission may be due to preformed excimers or excited aggregates.

When DPC in polar solvents is excited at 290 nm, a fluorescence emission peak is observed at 350 nm (e.g., Fig. 5) that is not observed in nonpolar solvents, providing additional support that DPC may form aggregates in polar solvents. Since polar solvents form strong solvent cages (9), it is not totally unexpected that DPC might easily aggregate in such polar solvents. Addition of 1% (v/v) water to anhydrous acetonitrile (~0.001 wt.% water) does not increase the intensity of the 350 nm emission peak significantly (figure not shown), suggesting that the 350 nm fluorescence emission peak of DPC observed in polar solvents is probably not due to the presence of large amounts of water in these solvents. However, we cannot totally rule out the role of trace amounts of water in contributing to the red-shifted emission found in polar solvents since there was a trace amount of water present initially even in the purported anhydrous acetonitrile.

For comparison with DPC, we consider 1,3-diphenylpropane, which exhibits fluorescence with emission peak maxima at 300 and 350 nm in dichloromethane (Fig. 6) as reported by Hirayama (5). We have confirmed the report by Hirayama (5) that the fluorescence spectrum of 1,3-diphenylpropane is independent of the chromophore concentration and the solvent polarity (Fig. 6), i.e., the 350 nm peak is observed in both polar and nonpolar solvents. The excitation scans for 1,3-diphenylpropane of the 300 and 350 nm emission peaks are identical in polar and nonpolar solvents (Fig. 7). These obser-

Fig. 6. Fluorescence emission spectra of 1,3-diphenylpropane: (a) 5×10^{-3} M in dichloromethane ($I_{340}/I_{295} = 2.75$), (b) 5×10^{-4} M in dichloromethane ($I_{340}/I_{295} = 2.72$), and (c) 5×10^{-4} M in methanol. $\lambda_{EX} = 260$ nm.

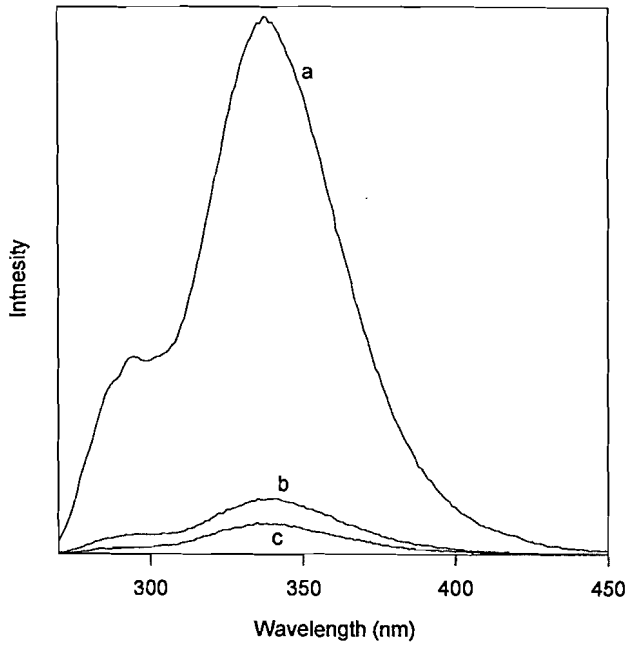

Fig. 7. Fluorescence excitation spectra of 1,3-diphenylpropane (5×10^{-4} M): (a) in methanol ($\lambda_{EM} = 300$ nm), (b) in dichloromethane ($\lambda_{EM} = 300$ nm), (c) in methanol ($\lambda_{EM} = 350$ nm), and (d) in dichloromethane ($\lambda_{EM} = 350$ nm).

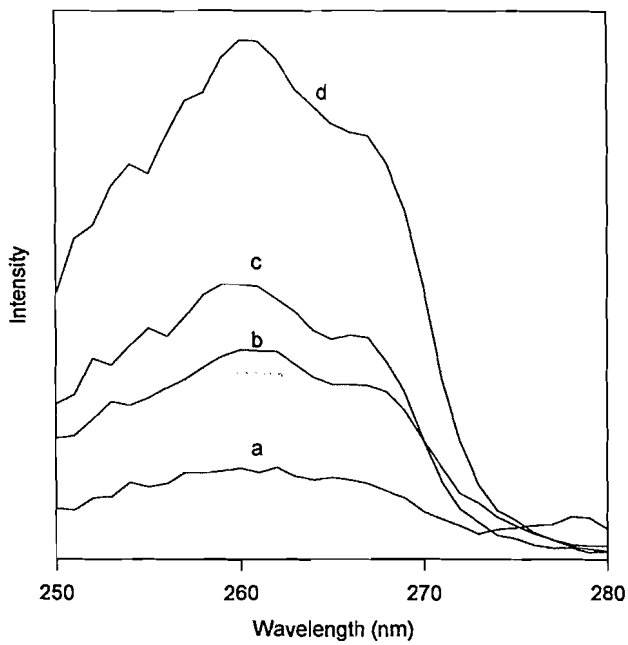


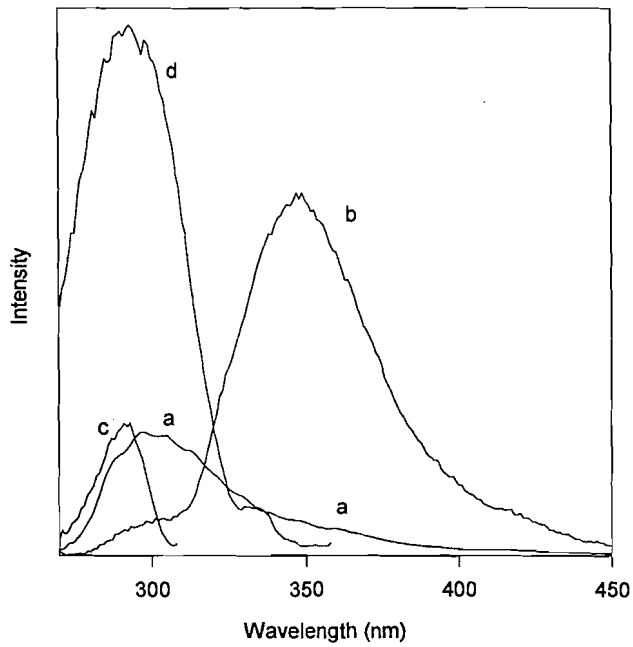
vations suggest that 1,3-diphenylpropane forms an intramolecular excimer in both nonpolar and polar solvents, but that little or no aggregation occurs, whereas DPC probably forms some type of fluorescent aggregates at higher concentrations in polar solvents.

In addition to the results for 1,3-diphenylpropane, we found that 1,3-diphenylacetone does not show any solvent-dependent fluorescence emission, but rather exhibits two emission peaks, one at 300 nm and another at 340 nm, which are not affected by concentration or by the polarity of the solvent. Apparently the polarity of the solvent plays an important role only when the carbonyl group is connected to the phenyl groups via oxygen.

Table 2. Fluorescence lifetime data on DPC.

Solvent	λ_{EX}/nm	λ_{EM}/nm	τ_1/ns	τ_2/ns
Cyclohexane	260	290	1.78	—
Methanol	260	290	0.96	3.40
Methanol	260	340	0.42	3.80

Fig. 8. Fluorescence excitation and emission spectra of phenylacetate: (a) 1×10^{-2} M in cyclohexane ($\lambda_{EX} = 260$ nm), (b) 1×10^{-3} M in acetonitrile ($\lambda_{EX} = 260$ nm), (c) 1×10^{-3} M in acetonitrile ($\lambda_{EM} = 300$ nm), and (d) 1×10^{-3} M in acetonitrile ($\lambda_{EM} = 350$ nm).



Fluorescence lifetime studies (Table 2) show that the decay curve of the unassociated DPC (in cyclohexane) is single exponential with a lifetime of 1.78 ns. In methanol, the decay of fluorescence at 290 nm can be described by the sum of two exponential functions with 35% contribution from a longer lived component (3.40 ns) and 65% contribution from a short-lived component (0.96 ns). When the fluorescence decay is monitored at 340 nm, the fraction (87%) of the longer lived component (3.80 ns) is higher than that (13%) of the short-lived component (0.42 ns). Although no conclusive assignments can be made, the long-lived component may be from a preformed excimer or aggregate and the shorter lived component from a single excited monomer species. The decrease in lifetime of the purported monomer emission (compared to cyclohexane) in methanol could be a solvent polarity effect, self-quenching, or a combination of both.

Phenylacetate behaves quite similarly to DPC. In cyclohexane, phenylacetate exhibits only one fluorescence emission peak at 300 nm (Fig. 8a), whereas in acetonitrile phenylacetate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Fig. 9. Fluorescence emission spectra of phenylacetate as a function of concentration in acetonitrile: (a) 1×10^{-4} M ($I_{360}/I_{300} = 1.9$), (b) 5×10^{-4} M ($I_{360}/I_{300} = 3.7$), and (c) 1×10^{-3} M ($I_{360}/I_{300} = 14.8$). $\lambda_{EX} = 280$ nm.

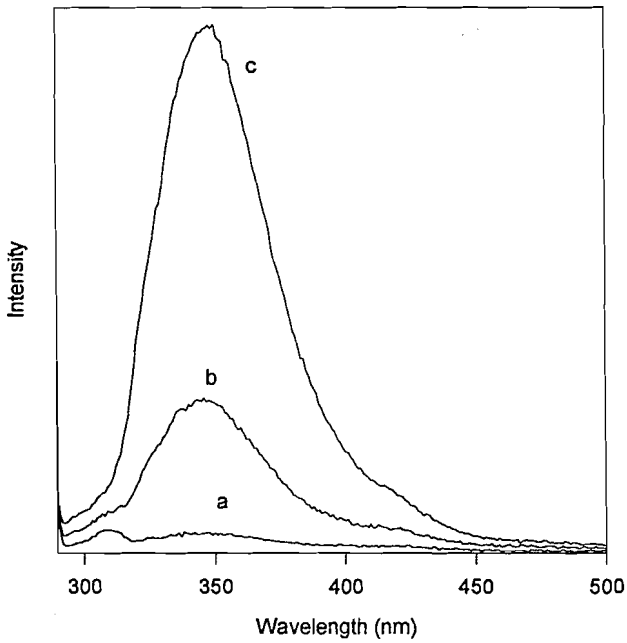


Fig. 10. Fluorescence emission spectra of polycarbonate (0.1 mg/mL): (a) in a mixture of 25% methanol and 75% dichloromethane, (b) solvent mixture evaporated from (a) and the residue redissolved in dichloromethane, and (c) in fresh dichloromethane. $\lambda_{EX} = 270$ nm.

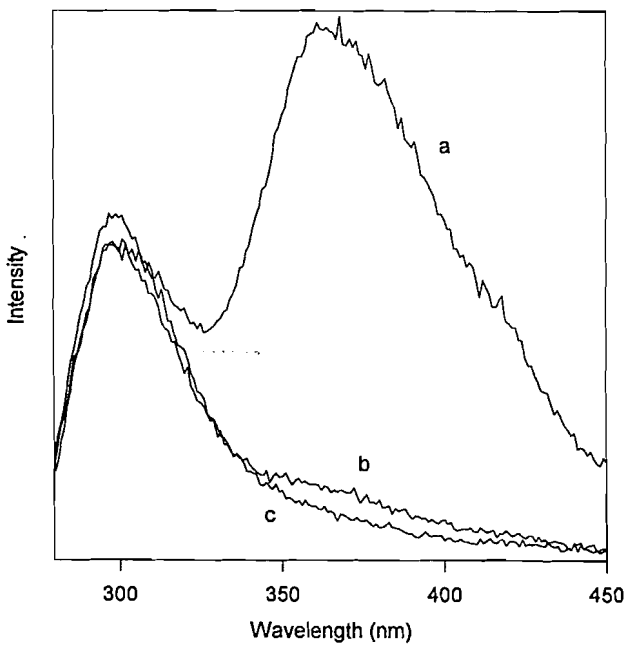
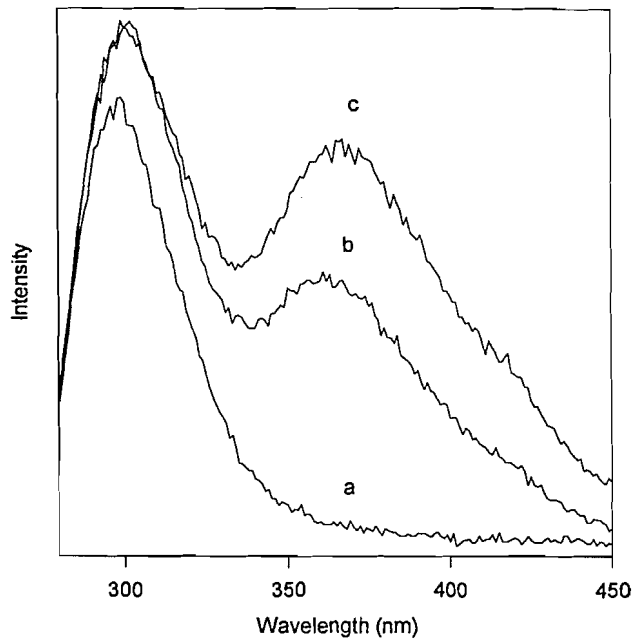


has a strong fluorescence with emission peak at 350 nm and a weak emission with peak maximum around 300 nm (Fig. 8b). This corroborates our previous observation that the 350 nm emission observed in the case of DPC is not due to a 1,3 intramolecular interaction. As observed for DPC, the excitation scan of the 350 nm fluorescence emission peak of phenylacetate is also red-shifted compared to that of the 300 nm fluorescence emission peak (Fig. 8 c and d), indicating that the 350 nm emission peak may well be from an aggregate when excited at longer wavelengths. In addition, the ratio of the intensity of the 350 nm peak to that of the 300 nm emission peak appears to decrease with decrease in concentration (difficult to assess absolutely due to low intensity of emission with peak maximum at ~300 nm), suggesting that for phenylacetate the 350 nm emission is also due to intermolecular association in polar solvents (Fig. 9).

Fig. 11. Fluorescence emission spectra of polycarbonate (0.1 mg/mL): (a) in dichloromethane, (b) in 25% acetonitrile and 75% dichloromethane mixture, and (c) in 50% acetonitrile and 50% dichloromethane mixture. $\lambda_{EX} = 265$ nm.



3.2 Photophysics of polycarbonate

Having analyzed the fluorescence of DPC, which is a model for the repeat units of polycarbonate, we next extend our study to polycarbonate. In addition to polarity effects, in the case of polycarbonate the solubility parameter must also be considered, i.e., dichloromethane is a good solvent for polycarbonate, while methanol and acetonitrile are non-solvents for polycarbonate. Mixtures of dichloromethane and methanol and dichloromethane and acetonitrile are thus relatively poor solvents for polycarbonate. In a mixture of dichloromethane(75%, v/v) and methanol (25%, v/v), polycarbonate exhibits two emission peaks, one at 300 nm and another at 360 nm upon excitation at 270 nm (Fig. 10a). When the methanol and dichloromethane mixture was evaporated and the residue (polycarbonate) redissolved in dichloromethane, the resultant fluorescence spectra showed only one emission peak around 300 nm (Fig. 10b), essentially that observed for the fresh sample (Fig. 10c). These results clearly show that the 360 nm emission is not due to a reaction product or an impurity. In a mixture of dichloromethane and acetonitrile, polycarbonate also exhibits an emission with peak maximum around 360 nm in addition to the regular emission at 300 nm (Fig. 11). The intensity of the 360 nm emission peak increases as the fraction of acetonitrile

Fig. 12. Fluorescence excitation spectra of polycarbonate (0.1 mg/mL) in a mixture of 25% acetonitrile and 75% dichloromethane: (a) λ_{EM} = 305 nm and (b) λ_{EM} = 365 nm.

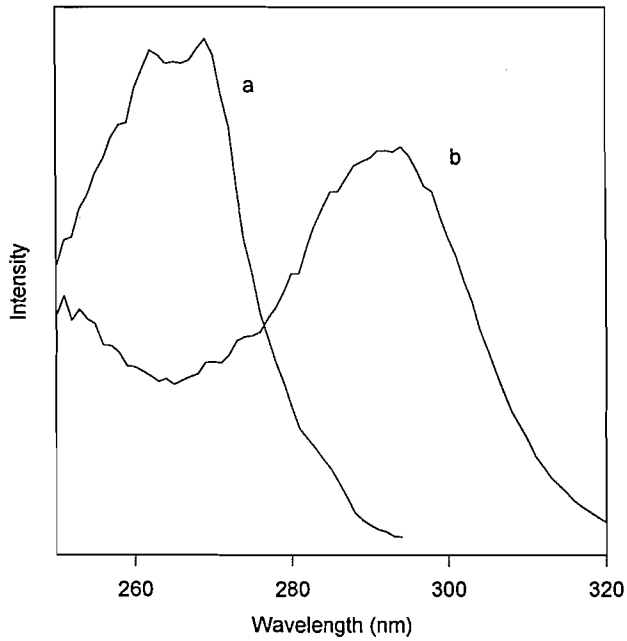

Fig. 13. Fluorescence emission spectra (emission corrected) of polycarbonate (0.1 mg/mL): (a) in dichloromethane (solubility parameter of 9.7 $(cal/cc)^{1/2}$), (b) in a mixture of 53% cyclohexane and 47% dichloromethane (solubility parameter of 8.4 $(cal/cc)^{1/2}$), and (c) in a mixture of 27% methanol and 73% dichloromethane (solubility parameter of 11.0 $(cal/cc)^{1/2}$). λ_{EX} = 270 nm.

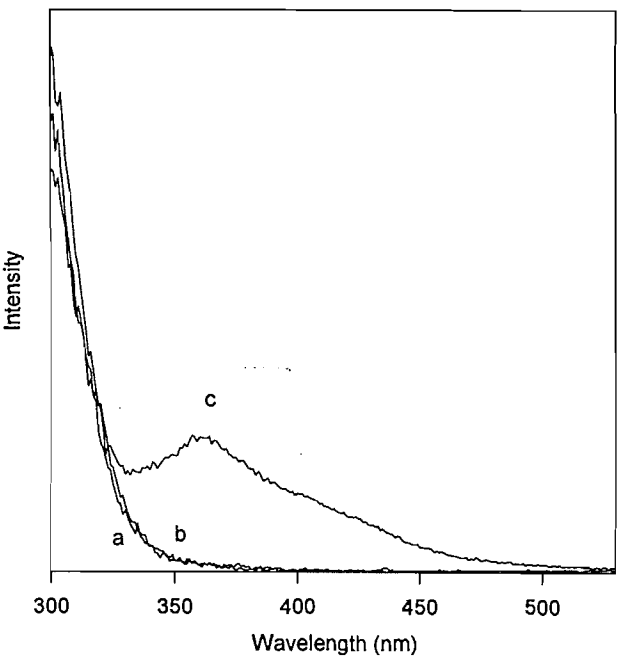
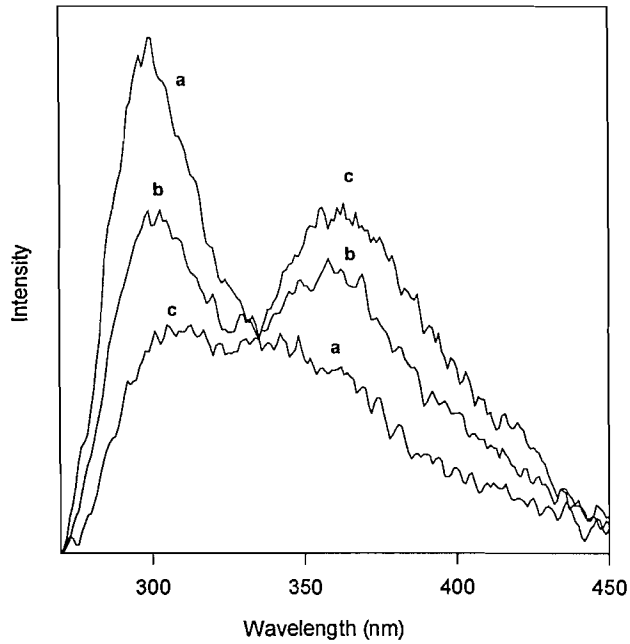


increases in the dichloromethane–acetonitrile mixture (Fig. 11). Likewise, in a dichloromethane–methanol mixture, as the fraction of methanol increases, the intensity of the 360 nm emission peak also increases (not shown). The excitation scan of the 360 nm emission peak extends to longer wavelengths compared to that recorded for the 300 nm emission peak of polycarbonate

Fig. 14. Fluorescence emission spectra of polycarbonate (0.1 mg/mL/75% dichloroethane and 25% methanol mixture) as a function of temperature: (a) 4°C, (b) 24°C, and (c) 60°C. λ_{EX} = 260 nm.



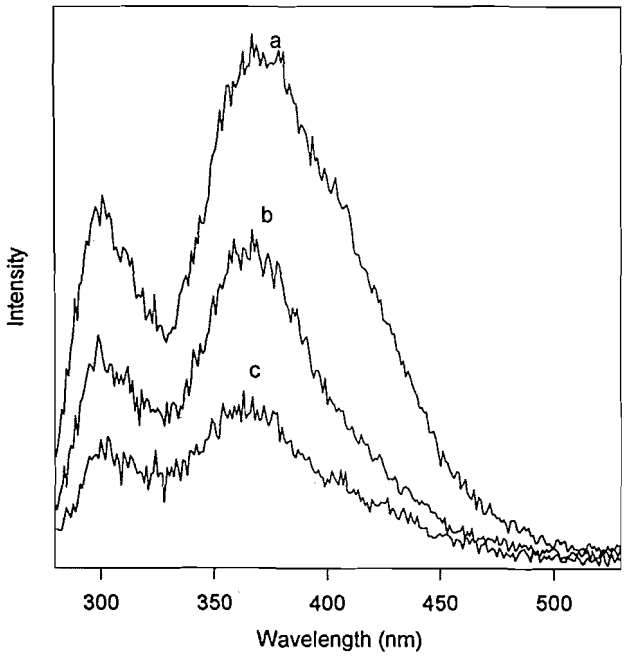
in both mixtures of dichloromethane and acetonitrile (Fig. 12) and dichloromethane and methanol (not shown), indicating that the 360 nm emission, at least when excited above 280 nm, probably results from an aggregate absorption. In contrast to these observations, when a polycarbonate solution in pure dichloromethane is excited at 290 nm, no red-shifted fluorescence emission peak can be observed.

To check whether the 360 nm emission of polycarbonate is dependent on the thermodynamic quality (good/poor) of the solvent, or simply the solvent polarity as was found for the model DPC, fluorescence spectra of a given concentration of polycarbonate were recorded as a function of the solubility parameter of the solvent mixture comprised of dichloromethane and either a nonpolar poor solvent or a polar poor solvent. When the solubility parameter of the solvent (9.7 for dichloromethane) is decreased by 1.3 units (i.e., 47% dichloromethane plus 53% cyclohexane) the fluorescence emission spectrum of polycarbonate does not change (Fig. 13). However, when the solubility parameter of the solvent is increased by 1.3 units (i.e., 27% methanol plus 73% dichloromethane) the emission with peak maximum at 360 nm is observed (Fig. 13c). These observations indicate that the 360 nm emission is independent of the thermodynamic goodness/poorness of the solvent, but highly dependent upon the polarity of the solvent.

3.3 Effect of temperature on the fluorescence spectra of polycarbonate in a mixture of dichloroethane and methanol

Normally the intensity of the fluorescence emission peak of aggregates (dimers) decreases with an increase in temperature as a result of dissociation at higher temperatures (10). In the present case, the I_{360}/I_{300} ratio increases as the temperature is increased (Fig. 14). The effects of variation of temperature are reversible (figures not shown). We cannot explain the origin

Fig. 15. Fluorescence emission spectra of polycarbonate in a mixture of 27% methanol and 73% dichloromethane as a function of concentration: (a) 0.10 mg/mL (I_{360}/I_{301} = 1.35), (b) 0.05 mg/mL (I_{360}/I_{301} = 1.48), and (c) 0.02 mg/mL(I_{360}/I_{301} = 1.30). λ_{EX} = 270 nm.



of the temperature effect in Fig. 14 at present. However, we note that such a temperature effect has also been observed for poly(ethylene terephthalate) (11–15), another main-chain polymer.

3.4 Effect of concentration on the ratio of the emission intensity at 360 nm to that at 300 nm (I_{360}/I_{300}) for polycarbonate in methanol–dichloromethane solvent mixtures

As suggested previously, the red-shifted emission with peak maximum at 350 nm emission peak in the case of DPC arises from intermolecular interactions in polar solvent cages. In the case of polycarbonate, the I_{360}/I_{300} ratio decreases negligibly upon dilution (Fig. 15). Apparently the 360 nm emission (peak maximum) of polycarbonate in a mixture of dichloromethane and methanol is due to intramolecular aggregation (at least when excited at longer wavelengths) in a strong polar solvent cage. This is in contrast to the 350 nm emission (peak maximum) in the case of DPC and phenylacetate that results primarily from an intermolecular process in each case.

4. Conclusions

A polar solvent induced red-shifted fluorescence emission from polycarbonate, DPC, and phenylacetate has been identified. In the case of DPC and phenylacetate it is suggested that the red-shifted emission results mainly from intermolecular aggregation, while in the case of polycarbonate it is largely due to intramolecular aggregation within a strong polar solvent cage. Diphenylcarbonate, phenylacetate, and polycarbonate behave much differently than other 1,3 systems such as 1,3-diphenylpropane and polystyrene, which exhibit intramolecular excimer formations and are not influenced greatly by solvent polarity.

Abstract: The silicon-bridged [1]ferrocenophane Fe(η-$C_5H_3SiMe_3)_2(SiMe_2)$ (**5**) was synthesized via the reaction of Li_2[Fe(η-$C_5H_3SiMe_3)_2$]·tmeda (tmeda = tetramethylethylenediamine) with Me_2SiCl_2 in hexanes. The disilane-bridged [2]ferrocenophane Fe(η-$C_5H_3SiMe_3)_2(Si_2Me_4)$ (**7**) was prepared using a similar route from the disilane $ClMe_2SiSiMe_2Cl$. Despite the presence of sterically demanding $SiMe_3$ substituents on the cyclopentadienyl rings, compound **5** was found to undergo thermal ring-opening polymerization at 170°C to produce very soluble, high molecular weight poly(ferrocenylsilane) **6** with $M_w = 1.4 \times 10^5$, $M_n = 8.4 \times 10^4$. However, the [2]ferrocenophane **7** was found to be resistant to thermal ring-opening polymerization even at 350°C and decomposed above 380°C. A single-crystal X-ray diffraction study of **7** revealed that the steric interactions between the bulky $SiMe_3$ groups are relieved by a significant twisting of the disilane bridge with respect to the plane defined by the centroids of the cyclopentadienyl ligands and the metal atom. The angle between the planes of the cyclopentadienyl rings in **7** was found to be 5.4(6)°, slightly greater than that in the non-silylated analogue Fe(η-$C_5H_4)_2(Si_2Me_4)$ (**4***a*) (4.19(2)°), and dramatically less than the corresponding tilt angle of the strained, polymerizable, silicon-bridged [1]ferrocenophane Fe(η-$C_5H_4)_2(SiMe_2)$ (**1**) (20.8(5)°). The length of the Si—Si bond in **7** (2.342(3) Å) was found to be close to the sum of the covalent radii (2.34 Å). Crystals of **7** are monoclinic, space group *C*2/*c*, with $a = 23.689(3)$ Å, $b = 11.174(1)$ Å, $c = 31.027(3)$ Å, $\beta = 109.16(1)°$, $V = 7758(2)$ Å^3, and $Z = 12$.

Key words: ring-opening polymerization, ferrocenophane, organometallic polymers.

Résumé : On a synthétisé le [1]ferrocénophane ponté par un silicium, Fe(η-$C_5H_3SiMe_3)_2(SiMe_2)$ (**5**), par une réaction du Li_2[Fe(η-$C_5H_3SiMe_3)_2$]·tmeda (tmeda = tétraméthyléthylènediamine) avec du Me_2SiCl_2 dans de l'hexane. On a préparé le [2]ferrocénophane ponté par deux silanes, Fe(η-$C_5H_3SiMe_3)_2(Si_2Me_4)$ (**7**), faisant appel à une voie semblable à partir du disilane $ClMe_2SiSiMe_2Cl$. Malgré la présence sur les noyaux cyclopentadiényles de substituants $SiMe_3$ ayant une demande stérique importante, on a trouvé que le composé **5** subit une polymérisation thermique par ouverture de cycle à 170°C qui conduit au poly(ferrocénylsilane) **6** très soluble et de poids moléculaire élevé avec $M_w = 1{,}4 \times 10^5$, $M_n = 8{,}4 \times 10^4$. Toutefois, on a trouvé que le [2]ferrocénophane **7** est résistant à une polymérisation thermique par ouverture de cycle, même à 350°C, et qu'il se décompose à 380°C. Une étude de diffraction des rayons X par un cristal unique du composé **7** montre que les interactions stériques entre les groupes $SiMe_3$ stériquement encombrants sont apaisées par une déformation importante du pont disilane par rapport au plan défini par les centroïdes des coordinats cyclopentadiényles et de l'atome de métal. On a trouvé que l'angle entre les plans des noyaux cyclopentadiényles du composé **7** est de 5,4(6)°, ce qui est légèrement supérieur à la valeur de 4,19(2)° observée dans l'analogue non silylé Fe(η-$C_5H_4)_2(Si_2Me_4)$ (**4***a*) et de beaucoup inférieure à celle observée (20,8(5)°) dans [1]ferrocénophane ponté par un silicium, polymérisable et tendu Fe(η-$C_5H_4)_2(SiMe_2)$ (**1**). On a trouvé que la longueur de la liaison Si—Si dans le composé **7** (2,342(3) Å) se rapproche de la somme de rayons covalents (2,34 Å). Les cristaux du composé **7**

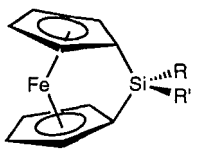
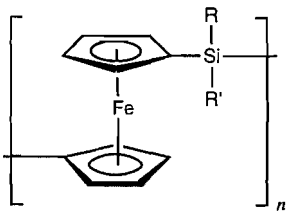
High polymers in which transition metals are incorporated directly into the main chain are attractive synthetic targets due to their unusual physical and chemical properties. Such materials are expected to possess an interesting and potentially useful range of electronic, magnetic, and optical characteristics that are not readily achieved using traditional organic polymers (1–4). However, for the most part, progress in this area has been limited by the synthetic challenge of obtaining high molecular weight, well-defined polymers (4).



1

R, R' = H, alkyl, aryl



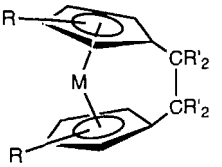
2

R, R' = H, alkyl, aryl

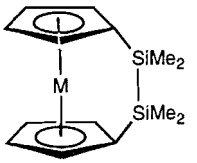
In 1992, we reported the synthesis of soluble, high molecular weight poly(ferrocenylsilanes) (**2**) via the thermal ring-opening polymerization (ROP) of silicon-bridged [1]ferrocenophanes (**1**) (5). More recently, we have demonstrated that living ROP can also be achieved in solution at room temperature in the presence of anionic initiators (6). This has provided access to poly(ferrocenylsilanes) with controlled molecular weights as well as to block copolymers (7). In addition, random copolymers are accessible via thermal copolymerization of different monomers (8). We have also shown that ROP is catalyzed in solution by certain transition metal complexes (9) and that the ROP route can be extended to other strained [*n*]metallocenophanes; thus, polymers such as poly(ferrocenylgermanes) and poly(ferrocenylethylenes) have been prepared from germanium-bridged [1]ferrocenophanes and hydrocarbon-bridged [2]ferrocenophanes, respectively (10–17). Crystallographic studies have revealed that these polymerizable monomers possess ring-tilted structures in which the planes of the cyclopentadienyl ligands are tilted by angles of up to 31° (17). By contrast, in ferrocene the cyclopentadienyl rings are planar. The apparent strain in these highly ring-tilted molecules is believed to provide the driving force for their facile thermal ROP.

Although the ROP strategy has been successfully applied to [2]metallocenophanes **3***a*–**3***c* with a hydrocarbon bridge, the analogues **4***a* and **4***b* with a disilane bridge possess only modest tilt angles (**4***a*, 4.19(2)°; **4***b*, 7.8(5)°) and are resistant to ROP, presumably as a result of their significantly less strained structures (13, 18).

The rationale behind the work described in this paper was as follows. Firstly, it is known that the presence of sterically demanding substituents generally hinders the formation of high molecular weight polymers via ROP. For example, Compton and Rauchfuss have reported that the desulfurization of [3]trithiaferrocenophanes with phosphines yields polymers with ferrocene and disulfido units in the backbone (19). The molecular weights of the polymers formed when an *n*-butyl substituent is present on the cyclopentadienyl rings (M_n = ca. 100 000) are much higher than when bulkier *tert*-butyl substituents are attached (M_n = ca. 3000). It was therefore of interest



3*a* M = Fe, R = H, R' = H
3*b* M = Fe, R = Me, R' = H
3*c* M = Ru, R = H, R' = H
3*d* M = Fe, R = H, R' = Me



4*a* M = Fe
4*b* M = Ru

to examine if significantly lower molecular weight products would be generated by the ROP of [1]ferrocenophanes incorporating bulky substituents. Isolation of low molecular weight poly(ferrocenylsilanes) would allow end-group analysis and might yield useful information on the thermal ROP mechanism. Secondly, we felt that polymerization of disilane-bridged [2]ferrocenophanes might even be facilitated if sterically demanding substituents, such as trimethylsilyl groups, were present on the cyclopentadienyl rings. Thus, the preference for these bulky substituents to minimize steric interactions with one another might provide an additional driving force for ROP. Thirdly, we have previously shown that a *trans* zigzag conformation is likely for the high polymer **2** (R = R' = Me) in ordered regions in the solid state (20). The presence of bulky trimethylsilyl substituents might be expected to impart unusual conformational properties to the macromolecules both in the solid state and solution which would influence the interactions between the transition metal centers that dominate the electrochemical behaviour (4).

In this paper, we describe our studies on the influence of trimethylsilyl groups on the thermal polymerization behaviour of silicon-bridged [1]- and [2]ferrocenophanes.

Results and discussion

Synthesis of the bis(trimethylsilyl)-substituted, silicon-bridged [1]ferrocenophane 5

The dilithiation of bis(trimethylsilyl)ferrocene was previously shown to be regio- and stereoselective by Silver and coworkers (21). Thus, reaction of this species with *n*BuLi·tmeda

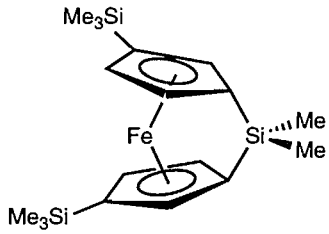
(tmeda = tetramethylethylenediamine) followed by Ph_2PCl yielded 1,1′-bis(diphenylphosphino)-3,3′-bis(trimethylsilyl)-ferrocene. This regio- and stereoselectivity was viewed to be attractive as the formation of more well-defined ferrocenophane monomers and corresponding polymers rather than mixtures of isomers would be anticipated.



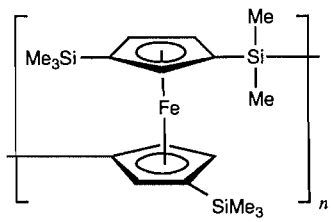
5

The silicon-bridged [1]ferrocenophane **5** was prepared via the reaction of the dilithium salt $Li_2[Fe(\eta\text{-}C_5H_3SiMe_3)_2]\cdot$tmeda with dichlorodimethylsilane (22). The synthesis and isolation of the dilithium salt was achieved by reacting dilithioferrocene with 2 equivalents of chlorotrimethylsilane, purification of the bis(trimethylsilyl)ferrocene by vacuum distillation, deprotonation of the product with 2 equivalents of *n*-BuLi in the presence of tmeda, followed by recrystallization from hexanes at −78°C. The final product (**5**) was purified by vacuum distillation (80°C, 0.005 Torr; 1 Torr = 133.3 Pa) as a red-orange liquid.

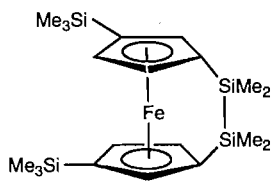
The purified silicon-bridged [1]ferrocenophane **5** was characterized by ^1H, ^{13}C, and ^{29}Si NMR as well as by mass spectrometry, and the data were consistent with the assigned 1,1′-3,3′-substituted structure. In particular, the ^{13}C NMR chemical shift of the ipso carbons of the cyclopentadienyl groups attached to the $SiMe_2$ bridge (36.9 ppm) showed the characteristic upfield shift compared to the other cyclopentadienyl carbons (22). This upfield shift is a well-established trend for strained, ring-tilted main group element-bridged [1]ferrocenophanes and is probably indicative of increased sp^3 character for the ipso carbon bonded to the bridging silicon in comparison with ipso carbons in unbridged, substituted ferrocenes (22, 23). Interestingly, all the other cyclopentadienyl ^{13}C NMR resonances are located further downfield than the resonances reported for other symmetrically substituted, silicon-bridged [1]ferrocenophanes (e.g., **1**). The ^1H NMR revealed two pseudo quartets and a pseudo triplet in the cyclopentadienyl region, characteristic of an $A_2B_2C_2$ spin system. The ^{29}Si NMR spectrum of **5** showed two singlet resonances at −3.3 and −5.4 ppm, of relative intensity 1:2, which were assigned to the $SiMe_2$ bridge and the two equivalent trimethylsilyl groups, respectively. The mass spectrum of **5** showed a molecular ion at *m/e* 386 as the most abundant peak.

Thermal ROP of the bis(trimethylsilyl)-substituted, silicon-bridged [1]ferrocenophane 5

When **5** was heated in an evacuated Pyrex tube for 3 h at 170°C the tube contents became more viscous and then immobile. The poly(ferrocenylsilane) **6**, a red-orange powder, was isolated by dissolution in THF followed by precipitation into methanol. GPC analysis revealed that the polymer was of high molecular weight (M_w = 140 000) with a relatively narrow weight distribution (M_w/M_n = 1.7). The results of multinuclear NMR studies were consistent with the assigned structure. A single, broad ^1H NMR resonance was found in the cyclopentadienyl region. In addition, broad resonances for the protons from the bridging $SiMe_2$ and pendant $SiMe_3$ groups were observed. The ^{29}Si NMR spectrum for **6** revealed two broad resonances (−5.9 ppm, $SiMe_2$; −2.5 ppm, $SiMe_3$) that are found upfield with respect to the monomer **5**. The ^{13}C NMR resonance attributable to the (C_{ipso}−$SiMe_2$) ipso carbons was shifted to a more conventional region associated with cyclopentadienyl carbons in unbridged, substituted ferrocenes compared to that in **5**. This indicated that the strain of the ring-tilted monomer **5** was relieved by ROP to yield polymer **6** in which the cyclopentadienyl ligands were approximately parallel. The polymer formed air-stable, amber, free-standing, brittle films, which were cast from a solution of **6** in toluene via slow solvent evaporation. The polymer was shown to be extremely soluble, even in nonpolar solvents such as hexanes.



6



7

Synthesis of the bis(trimethylsilyl)-substituted, disilane-bridged [2]ferrocenophane 7

The disilane-bridged [2]ferrocenophane **7** was synthesized in a similar manner to the [1]ferrocenophane **5** by employing 1,2-dichloro-1,1,2,2-tetramethyldisilane in the place of dichlorodimethylsilane. Compound **7** was isolated by vacuum distillation (120°C, 0.05 Torr) as reddish-orange crystals of low melting point. Multinuclear NMR studies were consistent with the assigned structure. The ^{29}Si NMR spectrum revealed two resonances: one corresponding to the $SiMe_3$ substitutents (−9.7 ppm) and the other to the bridging $SiMe_2$ groups (−4.0 ppm). In sharp contrast to **5**, the ^{13}C NMR resonances associated with the cyclopentadienyl carbons bonded to the bridging disilane unit occur at 76.0 ppm. This is consistent with a much less tilted and strained structure for **7** than is the case for **5**. One interesting feature of the ^1H NMR of **7** was the presence of *three* resonances in the region for methyl groups bonded to silicon. The resonance at 0.28 ppm (singlet, 18H) was attributed to the protons in the two $SiMe_3$ groups. The other two resonances (multiplets at 0.45 ppm and 0.25 ppm, 6H for each) were assigned to inequivalent methyl groups bonded to the bridging silicons. In addition, two resonances were detected in the methyl region of the ^{13}C NMR spectrum of **7**. This situation was in contrast with that for the [1]ferrocenophane **5** where the methyl substituents at the bridging silicon atom were found to be equivalent. To examine in detail the effects the bulky $SiMe_3$ groups would have on the structure of the disilane-bridged [2]ferrocenophane ***4a*** (13), compound **7** was studied by single-crystal X-ray diffraction.

X-ray structure of 7

Reddish-orange, X-ray diffraction-quality crystals of **7** were isolated from a vacuum distillation. Figure 1 shows two alternative views of **7** (molecule B) A summary of cell constants and data collection parameters is included in Table 1 and the

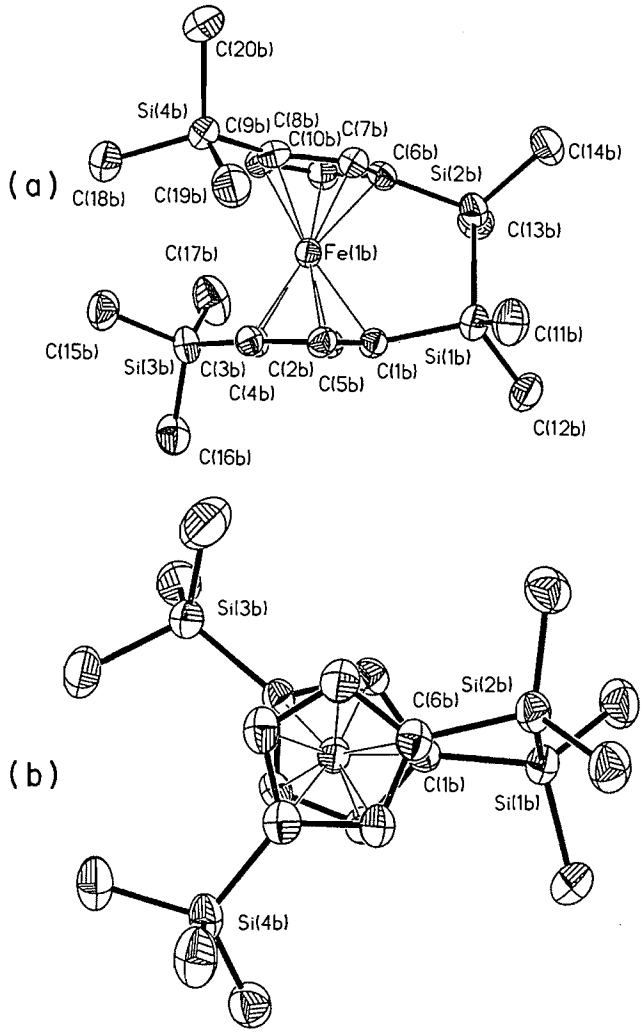
Fig. 1. (*a*) Molecular structure of **7** (molecule B) (vibrational ellipsoids at the 25% probability level). (*b*) Alternate view of **7** (vibrational ellipsoids at the 25% probability level).



fractional coordinates and important bond lengths and angles are listed in Tables 2 and 3. A summary of important structural features is presented in Table 4. Compound **7** crystallizes in space group *C*2/*c* with $Z = 12$. Hence there are two independent molecules in the structure. One of these molecules (molecule A) has twofold crystallographic symmetry with the Fe atom on a special position. The presence of a C2 axis leads to the inequivalent methyl groups on the bridging silicon atoms. All bond lengths and angles quoted within the text for **7** are for molecule B. Molecules A and B were not found to possess significantly different geometrical parameters with the exception of the C(ipso)-Si-Si-C(ipso) torsion angle.

A comparison of the structural features of **7** with those of the strained monomer **1** (13) and the relatively strain-free species **4***a* (13) is informative and suggests that **7** is relatively unstrained. The dihedral angle between the planes of the cyclopentadienyl rings is 5.9(6)°, only slightly greater than for **4***a* (4.19(2)°) and is dramatically smaller than for **1** (20.8(5)°). Also, the angle β between the plane of the cyclopentadienyl rings and the bridging silicon – ipso carbon bond is 12.6(4)°

compared to 10.8(3)° for **4***a*. The corresponding value in **1** is much greater (37.0(6)°) and suggests significantly less strain in both **7** and **4***a*. The twist angle for **7** (22.9(8)°) is significantly greater than in **4***a* (8.4(4)°) and is attributable to the unfavourable steric interactions between the two $SiMe_3$ groups. The twist angle for **4***a* is comparable to the corresponding angle in **3***d* (24) (8.9(13)°) whereas virtually no twisting occurs with the disilane-bridged [2]ruthenocenophane **4***b* (18) (0.2(5)°). The twisting of the bridge in **7** as well as the bulkiness of the $SiMe_3$ groups, also results in a significantly increased staggering of the cyclopentadienyl rings such that the stagger angle of 17.7(8)° is much greater than those found in either **4***a* (6.0(1)°) or **4***b* (rings are virtually eclipsed, 0.6(7)°). The larger Ru atom of **4***b* leads to an elongated Si—Si bond (2.370(2) Å) in comparison to **7** where the Si—Si bond length (2.349(3) Å) is similar to that found for **4***a* (2.3535(9) Å) and is close to the average for a typical Si—Si bond length (2.34 Å).

Thermal polymerization behaviour of the bis(trimethylsilyl)-substituted, disilane-bridged [2]ferrocenophane 7

In contrast to the [1]ferrocenophane **5**, when the [2]ferrocenophane **7** was heated in a sealed, evacuated tube at 350°C for 24 h, no increase in melt viscosity was observed. Furthermore, analysis of the contents of the tube by ^{1}H NMR revealed only the presence of **7** and no high molecular weight material ($M_w >$ 1000) was detected by GPC. Similarly, a sample of compound **7** was heated from 380 to 420°C over a span of about 2 h and

[a]Equivalent isotropic *U* defined as one third of the trace of the orthogonalized U_{ij} tensor.

another sample heated at about 160°C over a span of 20 h in the presence of the anionic initiator, potassium trimethylsilanoate, $K[OSiMe_3]$.[2] In both cases, no oligomeric or polymeric material could be detected by either GPC or mass spectrometry. ^1H NMR for the sample heated in the presence of $K[OSiMe_3]$ revealed only the presence of unreacted **7** whereas ^1H NMR of the sample heated over the range from 380 to 420°C showed both the presence of unreacted **7** and very broad resonances in both the cyclopentadienyl region and the SiMe region that were assigned to unidentified decomposition products.

Summary

The introduction of sterically demanding trimethylsilyl substituents to the cyclopentadienyl rings does not significantly affect the polymerizability of silicon-bridged [1]ferrocenophanes. A high molecular weight poly(ferrocenylsilane) was still formed via the ROP of **5** at elevated temperatures. The presence of these bulky ligands has some significant effects on the structure of disilane-bridged [2]ferrocenophanes with an increase in both the tilt angle and the degree of twisting of the disilane bridge. However, these distortions were found to be insufficient to allow ROP, and **7** was found to be stable to 380°C.

We are now studying in detail the properties of the poly(ferrocenylsilane) **6** and related polymers with bulky side groups. Our results will be reported in the near future.

Experimental section

All chemicals unless otherwise noted were purchased from

[2] Anionic ROP has been shown to occur for a number of silicon-containing ring systems. See, for example: refs. 6 and 25.

Aldrich Chemicals Co. 1,2-Dichloro-1,1,2,2,-tetramethyldisilane (26) and dilithioferrocene (27) were synthesized using literature methods. All silanes were distilled and stored under nitrogen. Ferrocene was purified via Soxhlet extraction using hexanes. All syntheses were carried out under an atmosphere of prepurified nitrogen using either standard Schlenk techniques or an inert-atmosphere drybox (Vacuum Atmospheres). Solvents used in these syntheses were dried by standard methods, distilled, and stored under nitrogen.

The 200 or 400 MHz ^{1}H NMR spectra were recorded on a Varian Gemini 200 and a Varian XL 400 spectrometer, respectively. The 100.5 MHz ^{13}C NMR and 79.5 MHz ^{29}Si NMR spectra were recorded on the Varian XL 400 spectrometer. The ^{29}Si NMR data were acquired in a proton-decoupled mode using a DEPT pulse sequence with $^{2}J_{Si-H} = 6.7$ Hz. The ^{13}C NMR data were acquired in a proton-decoupled mode using an APT pulse sequence. Mass spectra were obtained with the use of a VG 70-250S mass spectrometer operating in an electron impact (EI) mode. Elemental analyses were performed by the Canadian Microanalytical Service Ltd., Delta, B.C.

Molecular weights were estimated by gel permeation chromatography (GPC) using a Waters Associates liquid chromatograph equipped with a 510 HPLC pump, U6K injector, ultrastyragel columns with a pore size between 10^3 to 10^5

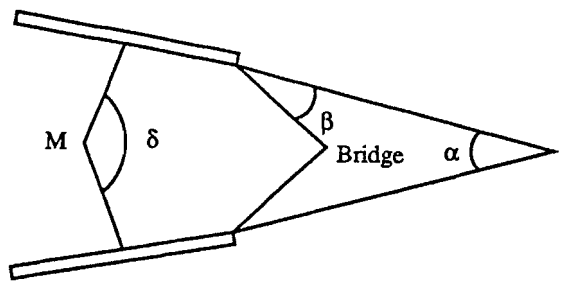
[a]The displacement of the iron atom from the line joining the two centroids of the cyclopentadienyl rings.

[b]The angle(s) between the planes of the cyclopentadienyl ligands and the C(Cp)—E bonds (where E = bridging atom).

[c]The angle(s) between the plane defined by the centroids of the cyclopentadienyl ligands and the metal atom and the E—E bond (where E = bridging atom).

[d]The first line represents the value for molecule A and the second line is for molecule B.

Fig. 2. Distortions in metallocenophanes defining angles α, β, and δ.



Angstroms, and a Waters 410 differential refractometer. A flow rate of 1.0 mL/min was used and samples were dissolved in a solution of 0.1% tetra-*n*-butylammonium bromide in THF. Polystyrene standards were used for calibration purposes.

Synthesis of dilithio-1,1′-bis(trimethylsilyl)-ferrocene·tmeda

The synthesis of dilithio-1,1′-bis(trimethylsilyl)ferrocene was a modification of a literature method (21, 28).

Dilithioferrocene·tmeda (25.0 g, 79.6 mmol) was suspended in 180 mL of freshly distilled diethyl ether. Chlorotrimethylsilane (20.1 mL, 159.2 mmol) was added dropwise to the above solution with stirring at 0°C using an ice–water bath. The reaction mixture was allowed to warm up to room temperature and stir overnight. Unreacted dilithioferrocene was separated from the reaction mixture by cannulation of the solution through a filter frit. The solvent was removed under high vacuum before subliming to remove any ferrocene. The resultant bright red oil was further purified by distillation under high vacuum (80°C, 0.05 Torr). Yield of 1, 1′-bis(trimethylsilyl)ferrocene: 19.8 g (75%).

The distilled 1,1′-bis(trimethylsilyl)ferrocene was then dissolved in 100 mL of freshly distilled hexanes. Butyllithium in hexanes (75 mL, 120 mmol) and TMEDA (14.0 mL, 120 mmol) were added dropwise to the solution at room temperature with stirring. The solution was allowed to warm up to room temperature and stirred overnight. The product was precipitated from hexanes at −78°C as a reddish-orange solid that was isolated by cannulation of the suspension onto a filter frit at −78°C. Yield (based on 1,1′-bis(trimethylsilyl)ferrocene): 7.1 g (26%).

Synthesis of 1,1′-bis(trimethylsilyl)-ferrocendiyldimethylsilane (5)

Dilithio-1,1′-bis(trimethylsilyl)ferrocene·tmeda (2.00 g, 4.37 mmol) was suspended in 100 mL of freshly distilled hexanes and cooled down to −78°C. To this stirred suspension was added 0.6 mL (4.95 mmol) of freshly distilled dichlorodimethylsilane. The mixture was allowed to warm up to room temperature and stir overnight. This solution was filtered through a filter frit and the solvent removed under high vacuum. The moisture-sensitive product was then isolated as a red-orange liquid by high-vacuum distillation (88°C, 0.005 Torr). Yield: 0.95 g (56%). For **5**: ^{29}Si NMR (C_6D_6) δ: −3.3 (s, $SiMe_2$, 1Si), −5.4 (s, $SiMe_3$, 2Si) ppm; ^{13}C NMR (C_6D_6) δ: 82.9 (η-C_5H_3), 82.7 (η-C_5H_3, C-$SiMe_3$), 80.4 (η-C_5H_3), 77.4 (η-C_5H_3), 36.9 (η-C_5H_3, C-Si), 0.34 (-$SiMe_3$), −3.0 (-$SiMe_2$) ppm; ^{1}H NMR (C_6D_6) δ: 4.39 (m, 2H, Cp), 4.13 (m, 2H, Cp), 4.03 (m, 2H, Cp), 0.40 (s, 6H, $SiMe_2$), 0.24 (s, 18H, $SiMe_3$) ppm; MS (EI, 70 eV) *m/z* (%): 386 (100, M^+), 371 (26, $M^+ - CH_3$), 357 (5, $M^+ - CH_3 - CH_2$).

Thermal ring-opening polymerization of 5

A 0.35 g (0.91 mmol) sample of **5** was sealed in an evacuated Pyrex glass tube and heated at 170°C for 3 h. The resultant polymer **6** was dissolved in THF and precipitated dropwise into methanol. The polymer was isolated as a red-orange powder. Yield: 0.19 g (54%). For **6**: ^{29}Si NMR (C_6D_6) δ: −5.9 (br

s, $SiMe_2$, 1Si), −2.5 (s, $SiMe_3$, 2Si) ppm; ^{13}C NMR (C_6D_6) δ: 79.5 (Cp), 77.0 (Cp), 76.2 (Cp), 76.2 (br s, Cp, C-Si), 74.7 (Cp), 1.1 (-$SiMe_3$), 0.25 (-$SiMe_2$) ppm; ^1H NMR (C_6D_6) δ: 4.30 (br s, 6H, Cp), 0.75 (br s, 6H, $SiMe_2$), 0.32 (br s, 18H, $SiMe_3$) ppm. Anal. calcd.: C 55.9, H 7.8; found: C 55.2, H 7.6. GPC: $M_w = 1.4 \times 10^5$, $M_n = 8.4 \times 10^4$, polydispersity (M_w/M_n) = 1.7.

Synthesis of 1,1′-bis(trimethylsilyl)ferrocendiyl-(1,1,2,2)-tetramethyldisilane (7)

Dilithio-1,1′-bis(trimethylsilyl)ferrocene·tmeda (1.65 g, 3.60 mmol) was dissolved in 80 mL of freshly distilled hexanes and cooled to −78°C in a Dry Ice – acetone slurry. 1,2-Dichloro-1,1,2,2-tetramethyldisilane (0.7 mL, 3.74 mmol) was added dropwise with stirring. The reaction mixture was allowed to warm up to room temperature and stir overnight. The solution was then filtered through a filter frit and the solvent removed under high vacuum. The product **7** was isolated as a red-orange liquid by high-vacuum distillation (120°C, 0.05 Torr). Yield: 0.75 g (47%). For **7**: ^{29}Si NMR ($CDCl_3$) δ: −4.0 ($SiMe_2$), −9.7 ($SiMe_3$) ppm; ^{13}C NMR ($CDCl_3$) δ: 78.3 (Cp), 77.4 (Cp), 76.8 (ipso C, -$SiMe_3$), 76.0 (ipso C, -$SiMe_2$-), 75.4 (Cp), 0.1 ($SiMe_3$), −0.1 ($SiMe_2$), −3.8 ($SiMe_2$) ppm; ^1H NMR ($CDCl_3$) δ: 4.6 (m, 2H, Cp), 4.5 (m, 2H, Cp), 4.0 (m, 2H, Cp), 0.45 (s, 6H, -$SiMe_2$-), 0.28 (s, 18H, $SiMe_3$-), 0.25 (s, 6H, -$SiMe_2$-) ppm; MS (EI, 70 meV) *m/z* (rel. intensity): 444 (100, M^+), 429 (18, M^+ − Me), 386 (6, M^+ − $SiMe_2$), 371 (15, M^+ − $SiMe_3$). Anal. calcd.: C 54.1, H 8.1; found: C 53.8, H 8.2.

Attempted thermal ROP of 7

A 0.10 g (0.22 mmol) sample of **7** was sealed in an evacuated Pyrex glass tube and heated at 350°C for 24 h. A second sample (0.22 g, 0.50 mmol) was sealed in an evacuated Pyrex glass tube and heated (*i*) at 380°C for 30 min, (*ii*) at 390°C for 30 min, (*iii*) at 400°C for 30 min, (*iv*) at 410°C for 30 min and (*v*) at 420°C for 30 min. A third sample (0.30 g, 0.68 mmol) was sealed in an evacuated Pyrex glass tube in the presence of a trace amount of K[$OSiMe_3$] and heated at 140°C for 2 h, at 160°C for 14 h, and then at 180°C for 2 h. All samples were dissolved in THF and precipitated dropwise into methanol. Subsequent analysis of the first two samples revealed only **7** (^1H NMR) and small molecules (GPC). The third sample was a dark reddish-brown viscous liquid that was mostly soluble in THF (the insoluble product was a black precipitate). Analysis by ^1H NMR showed only **7** and unidentified products (broad resonances from 4.0 to 4.4 ppm (cyclopentadienyl region) and from 0.0 to 0.4 ppm (Si-Me region)). Analysis by GPC and mass spectrometry revealed only small molecules.

X-ray structure determination technique

Intensity data were collected on an Enraf–Nonius CAD4 diffractometer at low temperature (185 K) using graphite monochromated Mo Kα radiation, λ = 0.710 73 Å. The ω-scan technique was used with variable scan speeds. The intensities of three standard reflections, which were measured every 2 h, indicated no decay. The data were corrected for Lorentz and polarization effects and also for absorption (using ψ-scan data). The structures were solved by direct methods (29). Non-hydrogen atoms were refined with anisotropic thermal parameters by full-matrix least squares to minimize $\Sigma w(F_o - F_o)^2$, where $w^{-1} = \sigma_2(F_o) + g(F_o)^2$. The hydrogen atoms were included in calculated positions with C—H = 0.96 Å. Crystal data, data collection, and least-squares parameters are listed in Table 1.[3] All calculations were performed and structural diagrams created using SHELXTL PC (29) on a 486 personal computer.

Radical-induced degradation of a lignin model compound. Decomposition of 1-phenyl-2-phenoxyethanol[1]

Y. Huang, D. Pagé, D.D.M. Wayner, and P. Mulder

Abstract: Reaction of 1-phenyl-2-phenoxyethanol (**1**) with thermally or photochemically generated *tert*-butoxyl radicals leads, via the intermediate ketyl radical, to the formation of the corresponding ketone, α-phenoxyacetophenone (**4**), as the only product at low conversion under an inert atmosphere. An approximately twofold increase in the product yield is observed when the reactions are carried out under oxygen. Under the photochemical conditions it is shown that **4** is the primary product and that acetophenone and phenol are formed as a result of secondary photolysis of **4**. These data suggest that the rate constant for fragmentation of the ketyl radical derived from **1** is on the order of 10 s^{-1} at 298 K and contradict a report in the literature that suggests a rate constant of $>10^6$ s^{-1}. The relevance of this study to the photodegradation of lignin and consequent photoyellowing is discussed and a revised mechanism for the photoyellowing of pulp is proposed.

Key words: ketyl radical, photochemical degradation, thermal degradation, lignin.

Résumé : Lorsqu'on effectue la réaction du 1-phényl-2-phénoxyéthanol (**1**) avec des radicaus *tert*-butoxyles générés thermiquement ou photochimiquement à de faibles taux de conversion, sous une atmosphère inerte, le seul produit à se former, par le biais du radical cétyle intermédiaire, est la cétone correspondante, α-phénoxy-acétophénone (**4**). Lorsqu'on effectue la réaction sous une atmosphère d'oxygène, le rendement en produit est approximativement doublé. Dans des conditions photochimiques, il a été démontré que **4** est le produit primaire et que de l'acétophénone et du phénol se forment par le biais d'une photolyse secondaire de **4**. Ces données suggèrent que la constante de vitesse de fragmentation du radical cétyle dérivé de **1** est de l'ordre de 10 s^{-1}, à 298 K, et elles sont en contradiction avec des données de la littérature qui suggèrent que la constante de vitesse est $>10^6$ s^{-1}. On discute de l'intérêt de cette étude pour la photodégradation de la lignine et jaunissement photochimique qui en découle et on propose un mécanisme révisé pour jaunissement de la pulpe.

Mots clés : radical cétyle, dégradation photochimique, dégradation thérmique, lignine.

[Traduit par la rédaction]

Introduction

The chemical and photochemical processes leading to the yellowing of mechanical pulps have been the subject of numerous investigations (1–3). In general, it is agreed that phenoxyl radicals generated from the degradation of lignin are important intermediates whose subsequent oxidation leads to the formation of products that absorb well into the visible. Several photochemical routes to phenoxyl radicals have been proposed (Scheme 1). While much attention had been given to paths A and B, Schmidt and Heitner (4) showed that the extent of yellowing was far greater than expected on the basis of the quantities of ketone and phenolic residues in lignin-rich papers. They proposed that up to 70% of the photogenerated chromophores were generated via path C in which ketyl radicals, generated from β-guaiacoxybenzyl alcohols, underwent fragmentation to give the phenoxyl radical directly and a substituted acetophenone (via the initally formed enol).

While the formation and reactivity of phenoxyl radicals in the lignin matrix is not well understood, a number of photochemical studies (5–12) using model compounds in solution or adsorbed on solid supports have provided some insights into the factors influencing all of the proposed mechanisms. In one of these studies (7) it was suggested that the fragmentation of 1-phenyl-2-phenoxyethanol-1-yl radical (**1**˙) formed from the reaction of photogenerated *tert*-butoxyl radicals with 1-phenyl-2-phenoxyethanol (**1**, eqs. [1], [2]) undergoes rapid fragmentation to yield phenoxyl radical and acetophenone (**2**, eq. [3]) thus giving kinetic support to the ketyl radical mechanism (path C). To better understand the dynamics of the formation and reaction of **1**˙, we have studied the radical-induced thermal and photochemical decomposition of **1** in acetonitrile and benzene. The thermal and photochemical experiments are similar in that *tert*-butoxyl radicals are the abstracting species.

Results

Thermal decomposition of 1 in the presence of di-*tert*-butylhyponitrite (BONNOB)

In BONNOB–acetonitrile (10 mol%), the decomposition of 1-phenyl-2-phenoxyethanol (**1**, 0.2 M)) at 60°C for 5 h (ca. 5 half-lives) yields only one product, α-phenoxyacetophenone (**4**, see Table 1) in approximately 6% yield (ca. 34% based on BONNOB after taking into account the expected cage effect of 12% (13)). In the presence of oxygen, the yield of **4** is higher (about 17%, 97% based on BONNOB). No acetophenone or phenol was formed. At higher stoichiometric ratios of BONNOB (50 mol%) under argon, the yield of **4** increased to 18% (20% based on BONNOB). At higher conversion, under oxygen, the mass balance was lower and a yield of **4** of 27% (32% based on BONNOB) was obtained.

Products obtained at 120°C using di-*tert*-butyl peroxide as initiator are shown in Table 2. In this case **4**, acetophenone (**2**), and phenol (**3**) are formed as products (the yields of **2** and **3** are

[b]0.025 M.

equal). In these high-temperature experiments the mass balances were poor and account for only about half of the total mass. The remainder of the mass appears to be an intractable tar. At this temperature, in the absence of di-*tert*-butyl peroxide, the starting compound is stable for the duration of the experiment (Table 2, entry 1).

Photochemical decomposition of 1 in the presence of di-*tert*-butylperoxide (DTBP)

These irradiations were carried out as described by Scaiano et al. (7). A solution of DTBP/benzene (2:1) containing **1** was irradiated for 4 h at 350 nm (Rayonet reactor, 30°C) to give a light yellow solution. The results are shown in Table 3. α-Phenoxyacetophenone (**4**) was formed as the predominant product with yields of 31% under argon (entry 1) and 39% under oxygen (entry 2). Small amounts of acetophenone and phenol were produced under both argon and oxygen. Triplet sensitization by anthracene gave similar results (entries 3 and 4). Although the energy transfer to DTBP is slow (14), absorption by anthracene prevents secondary photolysis of the primary products. The mass balance obtained under argon was generally better than that obtained under oxygen (the solutions under oxygen also were more highly coloured). Similar experiments carried out in acetonitrile are shown in Table 4 and are essentially the same as those obtained using benzene.

Compound **4** was irradiated in both benzene and acetonitrile, under argon, to determine its stability under our conditions. These results are summarized in Table 5. In benzene, after 4 h irradiation at 350 nm, acetophenone (**2**) and phenol (**3**) were formed with yields of 1.1% and 2.9%, respectively. However, at 300 nm, a small amount of new product was observed by GC–MS and HPLC, which corresponds in mass to the dimer (**5**) that is formed, presumably, by dimerization of the phenacyl radical. In acetonitrile, **4** appears to be photostable after irradiation for 4 h with only a trace of the dimer observed. After prolonged irradiation (18 h) some acetophenone and phenol were observed. Addition of thiophenol to the irradiation mixture (as a hydrogen atom donor) suppresses the dimer formation and improves the yield of acetophenone. These results are consistent with previously reported photochemical behaviour of **4** (15).

Laser flash photolysis

The rate constant for reaction of *tert*-butoxyl radicals with **1** was reported to be 2×10^6 M^{-1} s^{-1} using a benzhydrol probe method in benzene (7). We have determined a rate constant for reaction of the cumyloxyl radical of 1.5×10^6 M^{-1} s^{-1} using direct detection of the decay of the cumyloxyl radical, generated from photolysis of dicumyl peroxide as described by Avila, Lusztyk, and Ingold (16). In our experiments, the plot of the experimental first-order rate constant versus the concentration of **1** had a downward curvature at high concentration of **1**. The slope of this line at low concentrations (<0.3 M) was equal to the rate constant for the bimolecular hydrogen atom abstraction. At high concentrations, the limiting slope is about one third that at low concentration. Nevertheless, the agreement between the two sets of results is considered to be adequate. Spectroscopic results indicated a long-lived residual signal with shoulders at ca. 440 and 400 nm and an apparent maximum near 330 nm, after the cumyloxyl radical had completely disappeared. The residual signal between 350 and 500 nm was found to be completely quenched in the presence of oxygen.

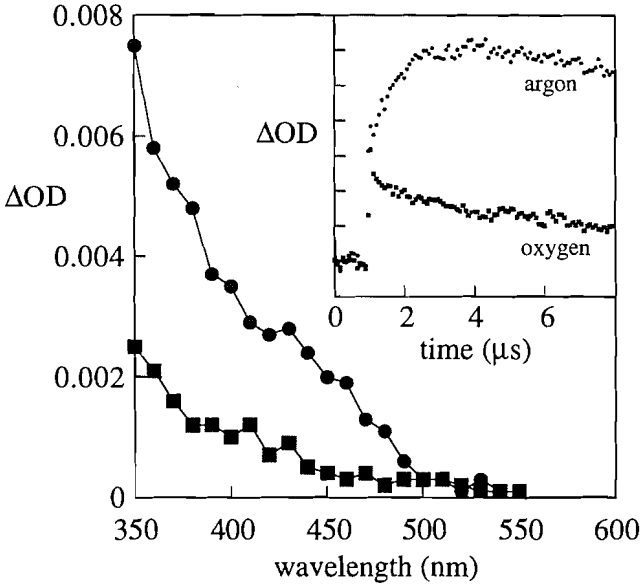
Fig. 1. Transient absorption spectrum recorded 6 μs following 308 nm laser excitation of a solution containing **1** (0.5 M) and di-*tert*-butyl peroxide (0.2 M) in acetonitrile solution under argon (●) and under oxygen (■). The inset shows the temporal evolution of the signal at 440 nm under argon and under oxygen (same symbols), which has been tentatively assigned to the ketyl radical derived from **1**.



Irradiation of DTBP in acetonitrile (308 nm) in the presence of **1** gave a similar residual spectrum, in this case unobscured by the competitive absorption of the alkoxyl radical (Fig. 1). A clear growth of the signal at 440 nm was now observed and, as in the previous case, the residual spectrum was completely quenched by oxygen (see inset, Fig. 1). An absorption previously assigned to phenoxyl radical (7) was not observed. The long-lived signal at 440 nm has been tentatively assigned to the ketyl radical derived from **1** (see below).

ESR measurements

Several attempts were made to record the ESR spectrum of **1**˙. A mixture containing 0.1 M **1** in DTBP/benzene (9:1 v/v) was photolyzed in a 6 mm diameter quartz tube in an ESR cavity. A weak spectrum, which was clearly a mixture of radicals, was obtained from which definitive identification of **1**˙ was not possible. The use of partially deuterated **1** ($PhCHOHCD_2OPh$) resulted in a similar mixture of radicals without affecting the overall spectral width (which implies that abstraction from the methylene does not contribute significantly to the observed spectrum). Under the same conditions, using 1-phenylethanol instead of **1**, the corresponding ketyl radical spectrum was clearly evident as the major contributor to the spectrum.

Discussion

Thermochemical considerations

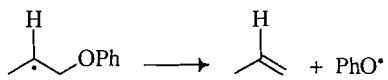
Estimation of the thermochemistry of reaction [3] provides a reasonable starting point to understanding the kinetics. The fragmentation of a similar radical, 2-phenoxy-1-phenylpropyl (reaction [4]), has been reported by Franz and co-workers (17). The corresponding rate constant was shown to follow a temperature dependence given by $\log (k_4) = 13.4 - 18/2.303RT$ (in kcal mol^{-1}), leading to $k_4 = 3$, 39, and 2460 s^{-1} at 30, 60 and 120°C, respectively. Since the overall enthalpy change, $\Delta H°_4$, is 12 kcal mol^{-1}, an activation energy of ca. 6 kcal mol^{-1} for the addition of phenoxyl radical to β-methylstyrene was derived.

[4] $PhC\dot{H}(Me)OPh \rightarrow PhCH{=}CHMe + PhO\cdot$

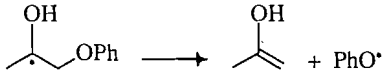
To use the data for reaction [4] to assess ΔH_3, the effect on the thermochemistry upon removal of the β-methyl group and replacement of the benzylic hydrogen by a hydroxyl group must be estimated. According to standard group additivity rules $\Delta\Delta H°_f(PhC(H_2)CH_3 \rightarrow PhC(H)(OH)CH_3)$ can be evaluated to be −41 kcal mol^{-1}, leading to a value of $\Delta H°_f$ (**1**) of −39 kcal mol^{-1}. The strength of the benzylic C—H bond is lowered as a result of the additional stabilization by the OH group. Although the amount of experimental data is limited, a difference of 7 kcal mol^{-1} for the C—H bond in CH_3CH_2–H and $CH_3CH(OH)$-H represents an upper limit leading to a value of $\Delta H°_f(PhC\dot{}(OH)CH_2OPh)$ of −12 kcal mol^{-1}. In reaction [3] the enol of acetophenone is formed. Using a group increment derived from group additivities and experimental data (18, 19) $\Delta\Delta H°_f(CH_3C(H){=}CH_2 \rightarrow CH_3C(OH){=}CH_2) =$ −47 kcal mol^{-1}, a value of $\Delta H°_f(PHC(OH){=}CH_2)$ of −12 kcal mol^{-1} is obtained. Thus, a value of ΔH_3 of 12 kcal mol^{-1} is obtained and (assuming $\log A = 13.4$ and $E_a = \Delta H + 6$ kcal mol^{-1} (17)) rate contants at 30, 60, and 120°C of 2.6, 38, and 2400 s^{-1}, respectively, are predicted.

Alternatively, $\Delta H°_f(PhCH_2CH_2OPh)$ can be estimated from group additivities to be 2 kcal mol^{-1} and the C—H bond energy to be ca. 86 kcal mol^{-1} (20); a value of $\Delta H°_f(PhC\dot{H}CH_2OPh) = 36$ kcal mol^{-1} is obtained. An assessment of the effect of the hydroxyl group can be made since it is possible to quantify the thermochemisty of reactions [5] and [6] using known bond energies (21) and heats of formation of enols (18, 19) to give $\Delta H_5 = 3.0$ and $\Delta H_6 = 3.2$ kcal mol^{-1}. This demonstrates that the hydroxyl group has a negligible effect on the thermochemistry. Therefore, it is expected that the thermochemistry of fragmentation of 2-phenoxy-1-phenylethyl radical, reaction [7], should be the same as reaction [3], leading to $\Delta H_3 = 11$ kcal mol^{-1}. Thus, two independent thermochemical assessments of reaction [3] give the same result.

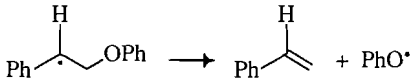
[5]



$\Delta H°_f$/kcal mol^{-1} 13.2 4.8 11.4



[6] $\Delta H°_f$/kcal mol^{-1} −31.8 −40 11.4



[7] $\Delta H°_f$/kcal mol^{-1} 35.8 35.3 11.4

It is important to comment on the selectivity of reaction [2] especially in light of the inability to observe **1**˙ by ESR spec-

For personal use only.

troscopy. The observed rate constant, k_2, of 1.5×10^6 M^{-1} s^{-1} in DTBP/benzene (1:9, v/v) represents the sum of the reactivities at all sites. The extent to which abstraction from the methylene contributes can be estimated by the reactivity of the *tert*-butoxyl radical towards 2,3-dihydro-1,4-benzodioxane, which was measured to be 3.3×10^5 M^{-1} s^{-1} (per molecule) in DTBP/benzene (1:2, v/v). Since the solvent effect on the rate constants is small, the contribution to the overall rate constant from methylene abstraction should be ca. 1.7×10^5 M^{-1} s^{-1} (ca. 10% of the overall reaction). However, one should keep in mind that the radicals (or mixture of radicals) observed by ESR spectroscopy are not necessarily those generated most efficiently but those that are most persistent (22). Since the rate constants were determined at 20°C and since the selectivity is expected to be temperature dependent, the contribution from methylene abstraction should increase to ca. 15% at 60°C and 25% at 120°C. In addition to only moderate selectivity in reaction [2], radical generation by secondary photolysis of products as described above also is likely to contribute to the complex ESR spectrum observed.

The data present above are not consistent with the rapid ($>10^6$ s^{-1}) fragmentation of **1**˙ as reported by Scaiano et al. (7), who also used reaction [2] as a source of the radical. The approximate twofold increase in the yield of the ketone **4** upon introduction of oxygen is consistent with a mechanism in which direct reaction with oxygen (reaction [8]) competes with the bimolecular disproportionation of **1**˙ to give one equivalent of **1** and one of **4** (reaction [9]). In the presence of oxygen all of the ketyl radicals are trapped by reaction [8] and subsequently tranformed into **4**. The slightly higher than twofold increase in the yield of **4** in the presence of oxygen may be indicative of a small amount of autoxidation under oxygen (presumably via the hydroperoxyl radical). Given that the average steady state concentration of radicals under these conditions at 60°C is on the order of 10^{-8} M, and assuming a value of $2k_9$ of 5×10^9 M^{-1} s^{-1} (23), an upper limit of $k_3 < 0.1k_9$ of only 6 s^{-1} for reaction [3] at 60°C is obtained.[3] Since the rate constant is expected to decrease by about a factor of 10 at room temperature, an upper limit for k_3 of only ca. 1 s^{-1} is derived. This value is consistent with the thermochemical estimates described above, which can only be expected to have order of magnitude precision.

[8] 
[9] $$2\,\mathbf{1}^{\cdot} \longrightarrow \mathbf{1} + \mathbf{4}$$

An interesting aspect of the reactivity of **1**˙ is the apparent lack of combination of ketyl radicals to form a pinacol. There is considerable literature concerning combination versus disproportionation of alkyl and benzylic radicals (24). In these cases combination is often preferred even though the products tend to be sterically hindered. On the other hand, Fischer and co-workers studied the self-reaction of 2-propanol-2-yl and concluded from CIDNP polarization patterns that 80% of the ketyl radical reacted by disproportionation while only 20% reacted by combination (23). Thus, it is difficult to predict a priori the fraction of combination. However, it has been pointed out[4] that the concentration of oxygen in argon-saturated solutions may be has high as 10^{-7} M. Since the average radical concentrations are on the order of 10^{-8} M, it is likely that the disproportionation between two ketyl radicals will not occur and that the apparent disproportionation is mediated by oxygen (eqs. [8] and [10]). Given this possibility and assuming $k_{10} = 5 \times 10^9$ M^{-1} s^{-1}, the upper limit for reaction [3] should be raised to $k_3 < 0.1k_8[O_2] = 50$ s^{-1} at 60°C, which is more in line with the thermochemical prediction of 38 s^{-1} at this temperature. This slightly revised mechanism would also explain the absence of pinacol in all of these reactions.

[10] $$\mathbf{1}^{\cdot} + HO_2^{\cdot} \rightarrow \mathbf{1} + O_2$$

At higher temperatures there is evidence for the fragmentation and chain decomposition of **1** via reactions [3] and [11]. At 120°C the half-life of DTBP is some 15 h yet after only 5 h a significant fraction of the starting material has reacted and, for the first time, acetophenone and phenol are observed. The increased importance of reaction [3] at the higher temperature simply reflects the fact that the disproportionation is nearly activationless.

[11] $$PhO^{\cdot} + \mathbf{1} \rightarrow PhOH + \mathbf{1}^{\cdot}$$

The observation of **4** from the photo-induced decomposition had not been previously reported (7). However, in light of the data above, it is clear that **4** is, indeed, the primary photoproduct and the acetophenone and phenol are formed in these reactions as a result of secondary photolysis. Our proposed mechanism also is consistent with the observed kinetics and spectra from laser flash photolysis. Although too weak to make an unequivocal assignment, it is likely that the long-lived, broad transient observed between 350 and 500 nm that is quenched by oxygen is actually the ketyl radical, **1**˙ (Fig. 1).

Given the sluggishness of reaction [3] it may be necessary to modify the current mechanism for photoyellowing of pulp. An alternative is presented in Scheme 2 in which both the unimolecular fragmentation of the ketyl radical and its reaction with oxygen may occur. Although the fragmentation of the ketyl radicals from lignin itself is expected to be faster, under conditions in a rigid matrix where reaction [3] can be reversible, reaction of the radical with oxygen may play an important role. This reaction, in which the acetophenone moiety is generated by autoxidation of the benzylic alcohol groups, leads to a greater fraction of the photoyellowing occurring via Path A. The revised mechanism in Scheme 2 is consistent with the observation of Schmidt and Heitner (3) that the carbonyl content of the pulp increases upon irradiation. It also is consistent with the general conclusion that these groups are the major source of long-wavelength chromophores in pulp (4). A consequence of this mechanism is that it may be practical to consider inhibitors of photoyellowing based on the trapping and (or) repair of ketyl radicals generated in environments inaccessible to oxygen. Studies of the thermal decomposition of other model compounds more structurally relevant to lignin are underway.

[3] The factor of 0.1 represents the detection limit of the HPLC analysis. If reaction [3] were faster, we would expect to detect both acetophenone and phenol.

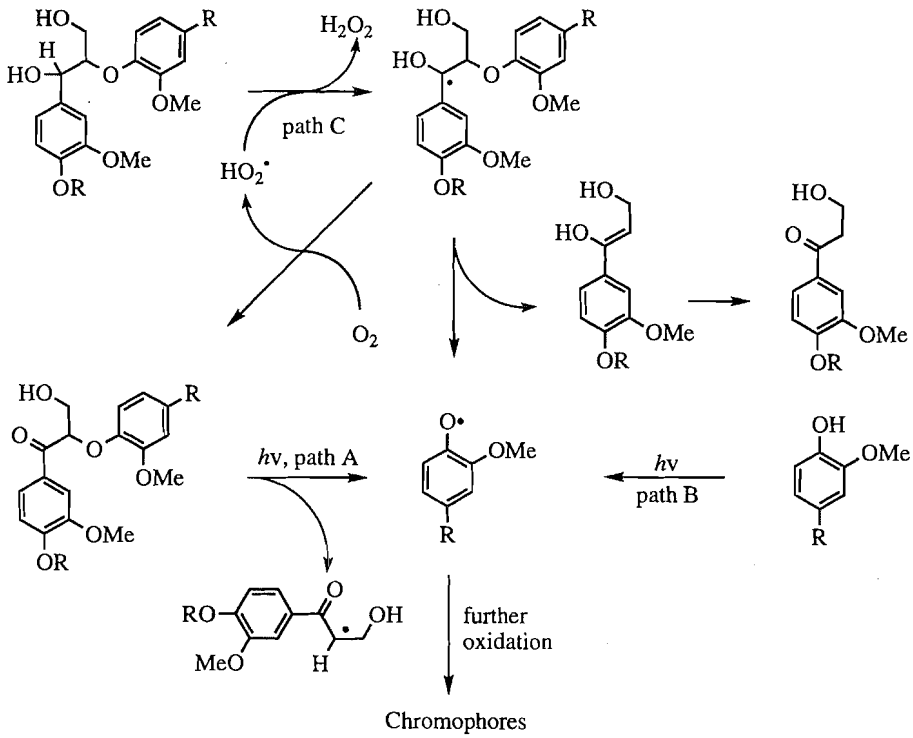
Scheme 2. Revised mechanism for photoyellowing of mechanical pulps.



Experimental

Chemicals

Acetonitrile was distilled before use. Di-*tert*-butyl peroxide was purified on an alumina column. Di-*tert*-butyl hyponitrite was prepared as described by Mendenhall (25). Other chemicals were used as received.

α-Phenoxyacetophenone was prepared by reaction of phenol (1.2 equiv.), potassium carbonate (1.2 equiv.), and 2-bromoacetophenone (1.0 equiv.) in dry acetone at room temperature (about 20 h). The product was recrystallized twice from ethanol.

1-Phenyl-2-phenoxyethanol was prepared by reduction of α-phenoxyacetophenone with $LiAlH_4$ (1.1 equiv.) in anhydrous ether. The solution was refluxed for 1 h and then quenched with a saturated NH_4Cl solution. The product was recrystallized twice from pentane.

Deuterated 1-phenyl-2-phenoxyethanol (**1**-d_2) was prepared from the α-phenoxyacetophenone-d_2, which was, itself, prepared by reaction of α-phenoxyacetophenone with potassium hydroxide and D_2O in 1,4-dioxane. The detailed procedure is given in ref. 6. ^1H NMR analysis indicated that 95% of α-protons of the α-phenoxyacetophenone had been exchanged.

Thermal decomposition of 1-phenyl-2-phenoxyethanol

The reaction mixture contained 1.0 mL acetonitrile with 50 mg of **1** and 20 mg (50 mol%) or 4 mg (10 mol%) of di-*tert*-butyl hyponitrite. The solutions were purged with argon or oxygen for 15 min and were then heated in a constant-temperature bath (60 ± 0.5°C) for 5 h. The resulting solution was quantitatively analyzed by HPLC using benzophenone as an internal standard. For the reactions under oxygen, oxygen was continuously passed over the solution during the reaction. Reactions carried out at 120°C were performed in Pyrex tubes containing 0.5 mL of solution (25 mg of **1** and 3.5 mg (10 mol%) of di-*tert*-butyl peroxide) and were degassed and sealed under vacuum with three freeze–pump–thaw cycles. The products were quantified by HPLC using an internal standard (benzophenone) and calibration curves based on authentic samples of reactants and products.

Photochemical degradations

Irradiations were performed in a Rayonet® reactor with 12-RPR-3000 or 12-RPR-3500 lamps. A 1.0 mL solution containing 50 mg of **1** or **4** and any other additives were syringed into 7 mm × 7mm laser tubes. The solutions were purged with argon or oxygen for 15 min before irradiation.

Laser Flash Photolysis

This instrument has been described in detail elsewhere (26). Nanosecond transient absorption spectra were obtained using a flow system to ensure the presence of unphotolyzed substrate for each laser pulse. Rate constants were obtained using static 7 × 7 mm^2 quartz cells. A Lumonics model EX530 eximer laser (308 nm; ≤40 mJ/pulse; ≈8 ns/pulse) was used as the laser excitation source.

Abstract: The effect of neutralization on the micellization of polystyrene-*b*-poly(acrylic acid) (PS-*b*-PAA) was investigated by static light scattering (SLS) and small-angle X-ray scattering (SAXS). The block copolymers, present initially in single chain form in either dioxane or benzene–methanol (90/10 (v/v)), were neutralized to different degrees by the addition of cesium hydroxide dissolved in methanol. The solutions were simultaneously monitored by SLS. It was found that micelle formation began near 5% neutralization. The normalized scattered light intensity at 90° (I_{90}/c) increased dramatically in the neutralization range between ca. 10 and 60%. For neutralization degrees between 60 and ca. 100%, I_{90}/c did not change significantly with a further increase in the percent of neutralization. In the second part of the study, two block copolymers, PS(600)-*b*-PAA(34) and PS(600)-*b*-PAA(45) (the number of monomer units is given in parentheses), were prepared from benzene–methanol (90/10 (v/v)) with different degrees of neutralization: 5, 25, 60, 100, and 150%. The resulting solutions were freeze-dried and the dried samples were redissolved in toluene. These samples were investigated by SLS and SAXS. By SLS, the aggregation numbers (f) were found to be the same between 5 and 60% neutralization. An increase in f was observed in going from 60 to 100%; i.e., f increased from 82 to 92 for PS(600)-*b*-PAA(34), and from 79 to 110 for PS(600)-*b*-PAA(45). The f values for the two block copolymers at 150% neutralization were found to be the same as those for 100% neutralization. The core radii values (R_{core}) were measured for the neutralized PS(600)-*b*-PAA(45) samples at 0.05 g/mL in toluene by SAXS. The R_{core} values increased from 5 to 60% neutralization, remained constant from 60 to 100%, and increased again in the range from 100 to 150%. The results are explained by dynamic considerations. For low percent neutralization, between 5 and 60%, the micelles and single chains are proposed to be in a dynamic equilibrium state. For higher percent neutralization, between 60 and 100%, the dynamics are probably much slower.

Key words: block copolymers, micelles, ionomers, light scattering, small angle X-ray scattering (or SAXS).

Résumé : Faisant appel à la diffusion statique de la lumière (SLS) et la diffusion des rayons X à petit angle (SAXS), on a étudié l'effet de la neutralisation sur la micellisation du polystyrène-*b*-poly(acide acrylique) (PS-*b*-PAA). Les copolymères à blocs, qui sont présents initialement sous la forme d'une chaîne simple dans le dioxane ou dans un mélange benzène–méthanol (90/10 (v/v)), se neutralisent à des degrés divers par l'addition d'hydroxyde de césium dissous dans le méthanol. On a examiné les solutions simultanément par SLS. On a trouvé que la formation de micelles commence près d'environ 5% de neutralisation. L'intensité normalisée de la lumière diffusée à 90° (I_{90}/c) augmente d'une façon dramatique dans la plage de neutralisation allant d'environ 10 à 60%. Pour des degrés de neutralisation variant de 60 à environ 100%, le I_{90}/c ne varie pas beaucoup avec les augmentations du pourcentage de neutralisation. Dans la deuxième partie de cette étude, on a préparé deux copolymères à bloc PS(600)-*b*-PAA(34) et PS(600)-*b*-PAA(45) (le nombre d'unités de monomères est donné entre parenthèse), à partir de solutions dans un mélange benzène–méthanol (90/10 (v/v)) et avec des degrés de neutralisations de 5, 25, 60, 100 et 150%. On a séché les solutions obtenues à froid et on a redissous les échantillons secs dans du toluène. On a étudié ces échantillons par SLS et par SAXS. Par SLS, on a trouvé que les nombres d'agrégation (f) sont les mêmes pour des neutralisations allant de 5 à 60%. On a observé une augmentation dans la valeur de f en passant de 60 à 100%, c'est-à-dire que la valeur de f est passée de 82 à 92 pour le PS(600)-*b*-PAA(34), et de 79 à 110 pour le PS(600)-*b*-PAA(45). Dans le cas de chacun des copolymères à bloc, on a trouvé que la valeur de f est la même à 150% de neutralisation qu'à 100%. Utilisant le SAXS, on a mesuré les valeurs des rayons de coeur (R_{core}) d'échantillons de PS(600)-*b*-PAA(45) à 0,05 g/mL, dans le

toluène. Ces valeurs augmentent pour des degrés de neutralisation allant de 5 à 60% et elles demeurent constantes de 60 à 100%; elles augmentent de nouveau de 100 à 150%. On explique les résultats par des considérations dynamiques. À des pourcentages de neutralisation faibles (de 5 à 60%), on suggère que les micelles et les chaînes isolées sont dans un état d'équilibre dynamique. À un degré plus élevé de neutralisation (de 60 à 100%), les dynamiques sont probablement beaucoup plus lentes.

[Traduit par la rédaction]

1. Introduction

Block copolymers tend to form micellar structures when dissolved in a solvent that is selective for one of the blocks. Increasing interest has focused on the formation and characterization of these micelles, and the phenomenon has been reviewed (1–5). Recently, considerable research has been performed on nonionic block copolymers that micellize in aqueous media (6–12) or in organic solvents (13–17). Research on the micellization of ionic block copolymers, as compared to that on nonionic block copolymers, is more scarce. Ionic block copolymers, due to their amphiphilic nature, are able to form either polyelectrolyte or ionomer micelles, depending on the nature of the solvent. For instance, in an aqueous environment, polyelectrolyte micelles are formed with a hydrophobic core and a charged ionic corona. Several studies have focused on the characterization of these micelles (4, 18–20). In organic solvents, ionomer micelles are formed with an ionic core and a nonionic corona. The latter micelle structure will be the focus of the present paper.

The association of block ionomers composed of lightly sulfonated polystyrene-*b*-poly(*tert*-butylstyrene) (PS-*b*-P*t*-BS) copolymers has been investigated in polar (21, 22) and nonpolar solvents (23). In polar solvents it was found that the sulfonated block copolymers formed micelles with a charged sulfonated polystyrene corona surrounding an insoluble P*t*-BS core at room temperature (21, 22). At higher temperatures it was found that charged monomolecular micelles were present (21). The aggregation behavior of the block copolymer with 2.3 mol% sulfonation was also investigated in cumene. In this solvent, reverse micelles, in which the sulfonated PS formed the micelle cores were observed. It was found by static and dynamic light scattering (SLS, DLS) that single chains and reverse aggregates coexisted (23). Due to the polydispersity in the degree of sulfonation, the aggregates were found to be formed by copolymer chains of higher ionic contents. This result was similar to that obtained from the aggregation of polystyrene-*b*-poly(metal methylacrylate) (PS-*b*-PMtMA) (24).

Block ionomer micelles that are composed of a nonionic corona of polystyrene and an ionic core of either neutralized poly(methacrylic acid) or poly(acrylic acid), or quaternized poly(4-vinylpyridine), have been extensively studied in this laboratory by several techniques (24–32).[3] It was shown that block ionomer micelles composed of PS-*b*-PMtMA form very stable micelles (24). A systematic study investigated the dependence of the block copolymer composition on the micellar characteristics by size exclusion chromatography (SEC) (24), DLS (25), and viscometry (25). The method of micelle preparation was found to significantly influence the micelle characteristics (25). For instance, the neutralization medium had an effect on the hydrodynamic radius (R_h) of the micelles. The block copolymer neutralized in benzene–methanol was found to have a larger R_h than that in dioxane. It should be noted that both solvents dissolved the acid copolymer as single chains. Also, it was found that neutralized samples that were recovered by freeze-drying and redissolved had a larger aggregation number (f) and R_h than those that were formed directly upon neutralization (25).

Block copolymers of polystyrene-*b*-poly(sodium acrylate) (PS-*b*-PANa) were also investigated by SEC, and it was found that micellization can occur for ionic block lengths as short as three units (26). The critical micelle concentration (cmc) values for a series of PS(660)-*b*-PANa(x), where x ranged from 2.6 to 14 units, were determined by SLS. The cmc values for these micelles were found to be of the order of 10^{-8} M (27). The analysis of the cmc by SLS was based on a recent micellization model that accounts for the polydispersity of the insoluble block length (28). In a study by ^{2}H NMR, the dynamics of PS chains in micelle corona for reverse ionomer micelles were investigated (29). The PS segments near the core were observed to have a restricted mobility compared to those further from the core or to single chains in solution.

The micellization of block ionomer micelles has also been investigated by small-angle X-ray scattering (SAXS) in the solid state and in solution (30–32).[3] An increasing degree of organization in solutions of reverse micelles, formed by polystyrene-*b*-poly(cesium methacrylate) (PS-*b*-PMACs) and polystyrene-*b*-poly(cesium acrylate) (PS-*b*-PACs) in toluene, was observed in the concentration range of 0.01 to 0.1 g/mL.[3] The core radii (R_{core}), calculated aggregation numbers, and surface areas per chain for the reverse ionomer micelles were also fitted to the predictions of the star model (30, 31). It was also found that the ionic core radii of several ionomer micelles were the same in the solid state as in solution (toluene).[3] This result showed that, once micellization occurs, the morphology of the micelles in solution is retained upon solvent evaporation. Also, the micelle cores of the reverse ionomers in toluene would be expected to be solvent free. The chain extension of the block forming the core was also investigated in the solid state (30). The effect of the ionic chain polydispersity on the size of the spherical ionic microdomains was examined for polystyrene-*b*-poly(4-vinylpyridinium methyl iodide) (PS-*b*-P4VPMeI) and PS-*b*-PACs (32). It was found that the polydispersity effect depended on the conditions of sample preparation.

The purpose of the present paper is to investigate the effect of different degrees of neutralization on the micellar properties of polystyrene-*b*-poly(acrylic acid). The samples were measured by using two complementary scattering techniques,

static light scattering and small-angle X-ray scattering. Information on the weight average molecular weight, radius of gyration, second virial coefficient, and core radius was obtained by these two methods in combination. This paper will first discuss the neutralization of the acid copolymer with cesium hydroxide as a function of the solvent and the ionic block length. The results on samples prepared with different degrees of neutralization as investigated by SLS and SAXS will then be presented and discussed.

2. Experimental

Materials

The block copolymers, polystyrene-*b*-poly(acrylic acid), were prepared by sequential anionic polymerization; the details are given in ref. 26. For convenience, a summary of the synthesis will be given here. The copolymers were synthesized by sequential anionic copolymerization of the styrene monomer followed by *tert*-butyl acrylate. The initiator was the reaction product of *sec*-butyllithium with a few drops of α-methylstyrene. The polymerization was carried out in tetrahydrofuran (THF) at −78°C under an atmosphere of nitrogen. The apparatus employed for the polymerization allowed the withdrawal of the reaction mixture in the course of the synthesis. Therefore, for a given constant polystyrene block length, a series of diblocks was obtained with poly(*tert*-butyl acrylate) segments of different lengths. Aliquots of the reaction mixtures were withdrawn for characterization after the polystyrene block was formed and every time following addition of the second monomer. Polystyrene-*b*-poly(acrylic acid) (PS-*b*-PAA) was obtained by acid-catalyzed hydrolysis of the *tert*-butyl acrylate segments in toluene at 80°C using *p*-toluenesulfonic acid as the catalyst. The PS-*b*-PAA was recovered and purified by repeated precipitation in cold methanol. The samples were then dried in a vacuum oven at 50°C for 48 h. The composition of the copolymers was determined by either FT-IR using copolymers in the ester form or by titration of the acid. The molecular weight of the polystyrene block was determined with a precision of ±5% by size exclusion chromatography in THF using narrow molecular weight polystyrene standards. The polydispersity index of the PS block was 1.10.

For neutralization of PS-*b*-PAA, a known amount of the dried copolymer was dissolved in benzene–methanol (90/10 (v/v)) at a concentration of 2% (w/w). The acid samples were neutralized by dropwise addition of CsOH in methanol to the solutions. For two block copolymers, PS(600)-*b*-PAA(34) and PS(600)-*b*-PAA(45), samples with different degrees of neutralization were prepared, i.e., 5, 25, 60, 100, and 150%, by addition of different amounts of CsOH–methanol. The solutions were stirred for 1–2 h, and the diblock ionomers were recovered by freeze-drying. The samples were then further dried at 60°C for 48 h under vacuum. Abbreviations are used to indicate the copolymer composition; for example, PS(600)-*b*-PACs(34) represents a polystyrene chain of 600 units joined to a poly(cesium acrylate) chain of 34 units; PAA denotes poly(acrylic acid).

Sample preparation for SLS

Three PS-*b*-PAA block copolymers, PS(600)-*b*-PAA(45), PS(600)-*b*-PAA(34), and PS(600)-*b*-PAA(13), were prepared by dissolving the copolymer either in dioxane or in a benzene–methanol mixture (90/10 (v/v)). The initial concentrations of the solutions depended on the block copolymer composition, and they ranged from ca. 2.5×10^{-3} to 6×10^{-3} g/g. The solvent and polymer solutions were filtered through 0.2 and 0.45 μm PTFE filters, respectively, into scintillation vials, which were used for the light scattering measurements. Titration curves were obtained by adding dropwise a predetermined amount of CsOH–methanol to the PS-*b*-PAA block copolymer solutions. The concentration of CsOH used was 1.0, 0.44, and 0.18 M for PAA block lengths of 45, 34, and 13 units, respectively. The amounts of CsOH–methanol added did not represent a significant volume as compared to the total volume of the solution. For instance, to achieve 100% degree of neutralization of PS(600)-*b*-PAA(45) in dioxane (10 mL), 144 μL of CsOH–methanol was required. This amount of CsOH–methanol represents ca. 1.4% of the total volume. It should be noted that these values are given for illustrative purposes only, since the actual solution volume is changing during the course of the measurement, as will be explained below. After each addition of CsOH–methanol, the solutions were stirred for ca. 10 min and the scattered light intensity was measured five times; the average value was used. Typical average percent error in the scattered intensity at 90° was ca. 3%. For higher degrees of neutralization, the scattered intensity increased above the detection limit of the detectors, and thus the polymer solutions were diluted by the addition of solvent. For the two samples PS(600)-*b*-PAA(45) and PS(600)-*b*-PAA(34), which were prepared with specific degrees of neutralization (5, 25, 60, 100, 150%), the weight average molecular weight (M_w), radius of gyration (R_g), and second virial coefficient (A_2) were determined by constructing a Zimm plot. A minimum of four concentrations were used for each Zimm plot analysis.

Static light-scattering and specific refractive index increment (d*n*/d*c*) measurement

Light-scattering experiments were performed using a DAWN-F multiangle laser photometer (Wyatt Technology, Santa Barbara, Calif.) at 25°C, which operates at 15 angles, from 26° to 137°, and is equipped with a He-Ne laser (632.8 nm). Data acquisition and analysis utilized the DawnF and SkorF softwares, respectively. Zimm plots were processed with Aurora software. The specific refractive index increments (d*n*/d*c*) were determined using the Wyatt/Optilab 903 interferometric refractometer and accompanying software (Dndc 2.01) at a wavelength of 630 nm. The cell constant was determined by calibration with different concentrations of sodium chloride (99.999%, Aldrich) solutions. Eight to ten concentrations were measured for each d*n*/d*c* determination. The d*n*/d*c* values were obtained from the slope of a plot of refractive index versus polymer concentration. The d*n*/d*c* values for PS-*b*-PAA and PS-*b*-PACs were found to be 0.110 mL/g, which is the same as the literature values for polystyrene in toluene (33). It should be noted that, in general, for block copolymers with different refractive indices, an apparent weight average molecular weight ($M_{w,app}$) is obtained by SLS (34). However, in the present case, $M_{w,app}$ is close to the true M_w values since the refractive index increments of the block copolymers and of the soluble block in toluene were the same. This result is probably due to the small weight fraction of the insoluble block.

Sample preparation for SAXS

Micellar solutions were obtained by dissolving the freeze-dried powder in toluene at a concentration of 5% (0.05 g/mL). For the SAXS experiment, the solution was enclosed in a 1.5 mm thick cell with Kapton® windows. The SAXS measurements were carried out at room temperature.

SAXS measurement

The small-angle X-ray scattering experiments were performed at the D22 station of the LURE-DCI synchrotron radiation source (Orsay, France). A description of the spectrometer has been published elsewhere (35) It is a specialized spectrometer equipped with double crystal, fixed exit, monochromator providing a beam of a narrow energy range tunable from 4 to 15 keV (3–0.8 Å). The size of the beam at the sample was about 1 mm^2. The scattered X-rays were detected with a Xe-CO_2 gas-filled, one-dimensional position sensitive detector with a resolution of 217 μm. Samples were studied in the angular q range from 0.006 $Å^{-1}$ to 0.30 $Å^{-1}$ ($q = 4\pi \sin\theta / \lambda$, where θ is one half the scattering angle, and λ is the X-ray wavelength). The resulting scattering intensities were corrected for the incident beam decay, sample thickness, and transmission. The background scattering from the solvent was also subtracted. The q resolution is of the order of 0.003 $Å^{-1}$.

3. Results and discussion

The Results and discussion section is divided into three parts. In the first part, the effect of neutralization on the micellization of PS-*b*-PAA is discussed qualitatively. Neutralization was followed in two different solvents, dioxane and a benzene–methanol mixture for three different block copolymers. The aim was to examine the effect that increasing degree of neutralization has on the solvent quality for the block copolymer, in particular for the block forming the micelle core. In the second and third parts, more quantitative results are presented that were obtained by SLS and SAXS, respectively. The samples investigated were prepared with specific degrees of neutralization and measured in toluene, which is a nonsolvent for PAA and PACs.

3.1. Titration of PS-*b*-PAA with CsOH–MeOH

Figure 1 summarizes some of the results obtained in this study for the titration of PS(600)-*b*-PAA(45) as well as the results for this sample with different degrees of neutralization. The aggregation numbers (f) (Fig. 1*a*) and core radii (R_{core}) (Fig. 1*b*) will be discussed in Sects. 3.2 and 3.3. First, a typical titration curve obtained for PS(600)-*b*-PAA(45) dissolved in dioxane, which is given in Fig. 1*b*, will be addressed. For this sample, the scattered intensity at 90° was normalized to the polymer concentration and measured as a function of the percent neutralization of the PAA chains with CsOH–methanol. It should be noted that PS-*b*-PAA in dioxane is present as single chains, since the solvent is good for both blocks. However, upon neutralization, the solubility of the partially neutralized PAA block decreases, and thus the chains associate to form the micelle core.

It is interesting to establish at which percent neutralization of the PAA chains micellization starts from a solution of single chains. This value can be determined by examining the inset of Fig. 1*b*, which shows the normalized scattered intensity (I_{90}/c) as a function of the percent neutralization near the origin of the plot. It was found that I_{90}/c was constant below ca. 5% neutralization, after which the value began to increase. Thus, micellization occurred in the block copolymer when ca. 2 of the 45 PAA units per chain (i.e., ca. 5%) were converted to the salt form.

Fig. 1. Summary of results for PS(600)-*b*-PAA(45) as a function of percent neutralization; (*a*) aggregation numbers (f) for freeze-dried samples measured in toluene; (*b*) core radii (R_{core}) for freeze-dried samples measured in toluene (▲) and scattered light intensity at 90° normalized to polymer concentration (I_{90}/c) as a function of the percent neutralization with CsOH–methanol measured in dioxane (○). The inset shows I_{90}/c for low percent of neutralization. The lines are shown as a guide for the eye.

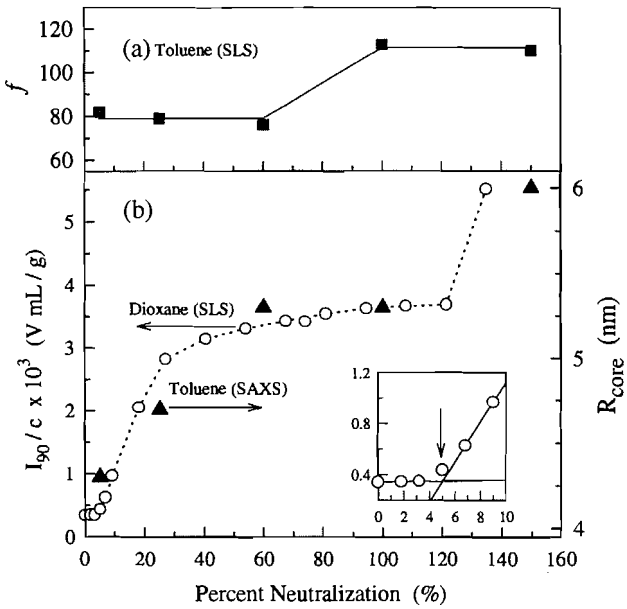

Fig. 2. Scattered light intensity at 90° normalized to polymer concentration (I_{90}/c) as a function of the percent neutralization with CsOH–methanol in benzene–methanol (90/10 (v/v)) for PS(600)-*b*-PAA(34) (●) and PS(600)-*b*-PAA(13) (▲). The lines are shown as a guide for the eye.

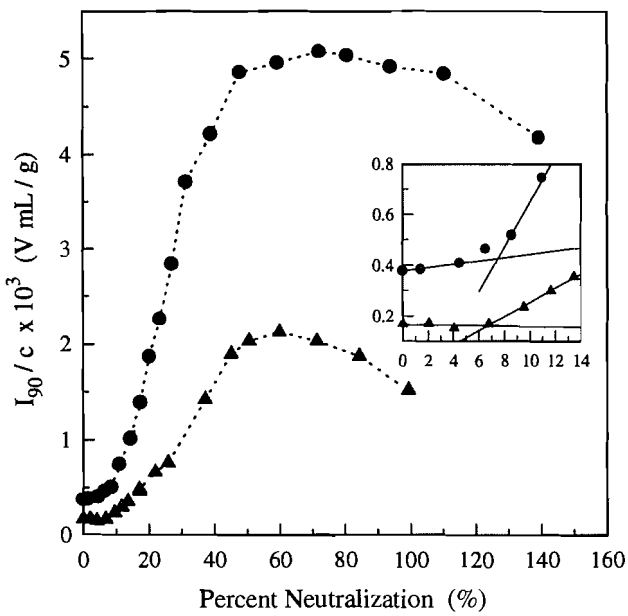

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

A similar titration was performed for PS(600)-*b*-PAA(13) and PS(600)-*b*-PAA(34) in benzene–methanol (90/10 (v/v)), with the results shown in Fig. 2. In this solvent mixture, the block copolymers are also initially present as single chains. The titration curve will be discussed in greater detail later in this section. It should be noted that the first increase in I_{90}/c also occurred at low degrees of neutralization for both block copolymers, specifically at ca. 7% (see inset of Fig. 2). This value was found to be independent of the PAA block length.

Once micellization has begun, it is of interest to examine the effects of further addition of CsOH–methanol on I_{90}/c. For PS(600)-*b*-PAA(45) in dioxane (Fig. 1*b*), it was observed that above 5%, I_{90}/c increased rapidly with increasing degree of neutralization. For instance, between 10 and 60% neutralization, the normalized scattered intensity increased by a factor of ca. 6. A further increase in the degree of neutralization resulted in a less dramatic increase in the scattered intensity. For instance, from 60 to 100% neutralization, the scattered intensity increased by only 10%. However, at 135% neutralization, I_{90}/c increased significantly. This latter increase may arise from the solubilization of the excess neutralizing agent, CsOH, in the micelle core, and will be discussed in Sect. 3.3.

The shape of the titration curve can give information on the solvent environment for the block copolymer with increasing degree of neutralization. First, it should be noted that for low degrees of neutralization, the micelle cores are expected to be swollen with dioxane and methanol. This occurs because the core is composed of PAA chains that are only partially neutralized. The dioxane and methanol would preferentially solvate the unneutralized sections of the PAA block while the block copolymer is in the micellar form. However, as the percent neutralization increases, the high ionic content of the core is expected to create an unfavorable environment for dioxane and methanol. As a result, these solvents would be expelled progressively from the micelle core. Consequently, it can be suggested that the micelle cores are more swollen at low degrees of neutralization than those at higher degrees.

For low degrees of neutralization, the cmc values would be expected to decrease with increasing neutralization. This aspect can be understood because increasing the degree of neutralization results in an increase in the number of ionic groups per chain, and the association of ionic chains would be expected to be stronger than that of acid chains. Also, as a result of the increase in the number or concentration of ionic groups, the solvent quality for the core decreases. Therefore, micelles would form at a lower concentration. Since the cmc decreases, the increase in I_{90}/c at low degrees of neutralization can be attributed, in part, to an increase in the number of the micelles.

To relate I_{90}/c to the weight average molecular weight (M_w) of the particles, M_w was evaluated for PS(600)-*b*-PAA(45) in dioxane for two degrees of neutralization, 7 and 50%. These measurements were performed by taking the samples that had been measured for the titration curve (Fig. 1*b*) and diluting them with dioxane to obtain different concentrations. The results for these samples at different concentrations were represented as Zimm plots. The M_w values for the 7 and 50% neutralized samples were determined to be 1.6×10^5 and 9.3×10^5 g/mol, respectively. Thus, M_w increases by a factor of ca. 6 in this neutralization range.

The effect of using benzene–methanol (90/10 (v/v)) as the solvent medium for the neutralization process was investigated. As noted previously, for this solvent composition, the acid block copolymer is present as single chains, since benzene and methanol are good solvents for the PS and the PAA blocks, respectively. Thus, at low degrees of neutralization it would be expected that methanol would solvate the unneutralized sections of the PAA block, in the same manner as dioxane and methanol discussed previously. Figure 2 illustrates the results obtained for two block copolymers, PS(600)-*b*-PAA(34) and PS(600)-*b*-PAA(13). The shape of the titration curve was similar to that of PS(600)-*b*-PAA(45) dissolved in dioxane (Fig. 1*b*). However, for higher degrees of neutralization, i.e., above ca. 100% for PS(600)-*b*-PAA(34) and above ca. 80% for PS(600)-*b*-PAA(13), further increase in the percent neutralization resulted in a slight decrease of I_{90}/c. At this point, the reason for the slight decrease is not fully understood.

3.2. SLS results on freeze-dried samples

To relate the normalized scattered intensities as a function of the percent neutralization to the actual changes in the micelle aggregation numbers and sizes, samples for PS(600)-*b*-PAA(34) and PS(600)-*b*-PAA(45) with different degrees of neutralization, i.e., 5, 25, 60, 100, and 150%, were prepared and investigated. The PS-*b*-PAA copolymers were dissolved in benzene–methanol (90/10 (v/v)) and CsOH–methanol was added dropwise in order to obtain micelles that have a low polydispersity in core sizes. The neutralized samples, which were recovered by freeze-drying, consisted of micellar structures that were simply redissolved in toluene, a selective solvent for PS, and then characterized by SLS and SAXS. Thus, complications arising from the penetration of solvent in the micelle core are avoided.

The results for the SLS measurements of the copolymers dissolved in toluene are given in Table 1. The aggregation numbers (f) were determined from the ratio of M_w of the micelles to that of a single chain. It should be recalled that the acid form of the block copolymer aggregates in toluene. It was found for PS(600)-*b*-PAA(34) that the aggregation numbers (f) increased from 63 to 80, in going from 0% to 5% neutralization. Thus, the incorporation of just a few ionic groups along the PAA chain affects the micellization significantly. The aggregation numbers for 5, 25, and 60% neutralization were essentially constant at a value of ca. 82 ± 3. A significant increase in f was observed between 60 and 100% neutralization, i.e., from 81 to 92. The same trends in f were observed for PS(600)-*b*-PAA(45). For instance, f was ca. 79 ± 2 for the samples at 5, 25, and 60%, and f increased from 76 to 110 between 60 and 100%. Also, the f values for both copolymer samples were measured for 150% neutralization and were found to be the same as those for 100% neutralization. This result shows that there is no effect on f for neutralization levels above the stoichiometric amount. The results for PS(600)-*b*-PAA(45) are illustrated in Fig. 1*a*.

The trends in the aggregation numbers with increasing percent neutralization can be examined by speculating on the dynamics of the block copolymer in the neutralization medium. The aggregation numbers fall into three regions, depending on the percent neutralization, i.e., between 5 and 60%, between 60 and 100%, and between 100 and 150% (Fig. 1*a*). The region between 5 and 60% will be considered first. In the previous section, it was suggested that, for low degrees of neutralization, the single chains and micelles were in a

Table 1. Results for different percent neutralization for PS-*b*-PAA in toluene.

Percent neutralization (%)	$M_w \times 10^{-6}$ (g mol^{-1})	f	R_g (nm)	$A_2 \times 10^5$ (mL mol g^{-2})	R_{core} (nm)

150	7.9	110	29	0.42	6.0

dynamic equilibrium state due to the solubilization of solvent in the micelle cores. As a result, micelle formation was expected to occur under equilibrium conditions. In this study, the aggregation numbers of the micelles recovered by freeze-drying from this dynamic state were found to be independent of the degree of neutralization. The freeze-dried samples, which were redissolved in toluene, would be expected to exist in a much less mobile state than those in benzene–methanol. This can be anticipated, since toluene is a nonsolvent for the PAA block, and thus the micelle cores would not be swollen with solvent in contrast to the situation with methanol. Therefore, significant rearrangement of the micelles in the toluene solutions would not occur.

The dynamics of the system for the second region, ranging from 60 to 100%, are believed to be considerably reduced compared to those for the lower degrees of neutralization. This can be understood by considering that an increase in the degree of neutralization of the core-forming block reduces its solubility, resulting in micelle formation. As a result of the decreased solubility, the unfavorable solvent is progressively expelled from the core. This process increases the glass transition temperature (T_g) of the core, resulting in a decreased mobility in the core. In fact, when the temperature of measurement is below the T_g, the micelle core can be considered as "frozen." As a result of some or all of these factors, the aggregation numbers for the redissolved freeze-dried samples were found to increase with increasing percent neutralization between 60 and 100%.

In the third region, for degrees of neutralization between 100 and 150%, the aggregation numbers were the same as those at 100%. This result was expected, since a further increase in the neutralization above 100% would not change the ionic nature of the block copolymers appreciably.

The radius of gyration (R_g) and second virial coefficient (A_2) values determined by SLS for PS(600)-*b*-PAA(34) and PS(600)-*b*-PAA(45) are given in Table 1. For both block copolymers, it was found that the R_g values were essentially constant for the neutralization range of 0–60%, and increased slightly for the samples at 100 and 150% neutralization. For instance, for PS(600)-*b*-PAA(34), the average R_g value for the samples at 0–60% neutralization was 26 ± 1 nm, and that for PS(600)-*b*-PAA(45) for the samples at 5–60% was 24 nm. For 100 and 150% neutralization, the R_g values for both samples were only slightly higher than those at lower degrees of neutralization, with a value of ca. 30 nm. The A_2 values did not exhibit any specific trends with the percent neutralization.

3.3. SAXS results on freeze-dried samples

The core sizes for the neutralized PS(600)-*b*-PAA(45) samples were measured by SAXS. In general, for an assembly of scattering particles, the scattered intensity (I(q)) is the product of the particle shape factor (P(q)) and the structure factor (S(q)), which characterize the spatial correlation of the scatterers (36, 37). Since it is a product of two functions, it is often difficult to separate one from the other experimentally. In the present system, since the sizes of the spheres are so much smaller than the characteristic distances between them, and since the contrast between the two media is substantial, the attribution is unambiguous.

The SAXS profiles showed a pronounced shape factor peak for samples at and above 5% neutralization. However, for the acid diblock, PS(600)-*b*-PAA(45), no shape factor features were observed due to the low contrast between the PAA and PS blocks. From the position of the minima of the shape factor, one can calculate the radius of the cores (R_{core}). A detailed description of the data analysis has been published elsewhere (31).

The core radii were found to increase with increasing percent neutralization from 5% to 60%; they remained constant from 60% to 100% neutralization and increased at 150% neutralization. The R_{core} values are summarized in Table 1. The trends in R_{core} with increasing degree of neutralization were similar to those of the I_{90}/c values for PS(600)-*b*-PAA(45) in dioxane. The results are compared in Fig. 1*b*. From the R_{core} values, it can be suggested that micelles begin to form between 0 and 5% neutralization, and that the cores continue to grow in size until 60% of the acid is neutralized. The initial growth in R_{core} accompanies the replacement of the protons in the acid diblock by the Cs^+ ions, which are larger in size than the protons. The fact that R_{core} remained constant between 60 and 100% neutralization suggests that a preferred core size for the micelle has been attained. At 150% neutralization, the

For personal use only.

extra neutralizing agent enters the core in which the medium is already highly polar, thus increasing the core size. The solubilization of the excess cesium hydroxide in the micelle cores was also found to occur in PS(600)-*b*-PAA(45) neutralized in dioxane (Fig. 1*b*). The solubilization of excess neutralizing agent in or near the ionic cores has also been suggested for many random (38) and telechelics ionomers (39).

4. Summary

It was found that when single chains of PS-*b*-PAA were neutralized, they started to form micelles near 5% neutralization. The onset of micellization was almost identical for samples having a PS length of 600 units and PAA lengths of 45, 34, and 13 units. It was found that I_{90}/c increased for the block copolymers significantly in the range of 10–60% neutralization. For neutralization levels between 60 and 100%, the normalized scattered intensity did not change significantly with a further increase in the degree of neutralization. For higher degrees of neutralization the solvent media were found to affect the I_{90}/c values, with an increase for dioxane, but a decrease for benzene–methanol solvents.

The block copolymers PS(600)-*b*-PAA(34) and PS(600)-*b*-PAA(45) neutralized with different degrees in benzene–methanol (90/10 (v/v)), freeze-dried, and redissolved in toluene were studied by SLS and SAXS. The results fell into three regions, depending on the percent neutralization. In the first region, for degrees of neutralization between 5 and 60%, the micelle cores were expected to be swollen with solvent during the neutralization in benzene–methanol, and the association that occurs would likely be dynamic. It was found that the f values were constant, and the aggregation numbers did not depend on the percent of neutralization. The R_{core} values in this range increased due to the replacement of the protons with the Cs^+ ions, which are larger in size. In the second region, for degrees of neutralization between 60 to 100%, dynamics are expected to be much slower. In that range, the f values were found to increase with increasing percent neutralization and the R_{core} was found to be constant. The two results would suggest that the density of the micelle core increases in this range. Finally, at degrees of neutralization between 100 and 150%, the f values were constant, showing no further dependence of the aggregation on the percent of neutralization. On the other hand, R_{core} increased due to the solubilization of the excess neutralizing agent into the ionic cores.

Acknowledgments

The authors would like to thank Dr. Sunil K. Varshney who synthesized the block copolymers in connection with another project as well as Dr. Joon-Seop Kim and Mr. Matthew Moffitt for very useful discussions. Abstract: Small-angle X-ray scattering (SAXS) and solid state CPMAS ^{13}C NMR were used to describe the crystalline morphology of a series of bacterially produced poly(β-hydroxybutyrate-*co*-β-hydroxyvalerate) copolymers containing random distributions of 3-hydroxybutyrate (3HB) and 3-hydroxyvalerate (3HV). Modeling of SAXS results showed that the morphology of this isodimorphic system is better described by two phases, crystalline and amorphous, having defects within each domain. This is in contrast to a model with a large interfacial region between phases. For the 3HV composition range 0–27 mol%, the polymer crystallizes in a poly(β-hydroxybutyrate)-type crystalline lattice. Solid state NMR results showed that there is significant incorporation of the 3HV minor component into the poly(β-hydroxybutyrate) crystalline phase over this composition range . The ratio of the 3HV content in the crystalline phase relative to the overall 3HV content is not linear, but increases with increasing 3HV. For the 21 and 27% 3HV samples, the 3HV content in the crystalline phase is as much as 2/3 of the overall 3HV content. Inclusion of 3HV is correlated to an increase in crystalline disorder (as measured by SAXS), implying that it is easier to accommodate the bulkier 3HV comonomer into a crystalline region that already contains defects.

Key words: bacterial polyesters, poly(3-hydroxyalkanates), small-angle X-ray scattering, solid state NMR, cocrystallization.

Résumé : On a utilisé la diffraction des rayons X à de petits angles (SAXS) et la RMN du ^{13}C CPMAS à l'état solide pour décrire la morphologie cristalline d'une série de copolymères poly(β-hydroxybutyrate-*co*-β-hydroxyvalérate) produits par une voie bactérienne et contenant des distributions au hasard de 3-hydroxybutyrate (3HB) et de 3-hydroxyvalérate (3HV). Un modelage des résultats SAXS a montré que la meilleure façon de décrire la morphologie de ce système isodimorphique est à l'aide de deux phases, l'une cristalline et l'autre amorphe, ayant des défauts dans chaque domaine. Pour une composition de 3HV allant de 0 à 27 mol%, le polymère cristallise dans une réseau cristallin du type poly(β-hydroxybutyrate). Les résultats de la RMN à l'état solide ont montré que, sur cette plage de composition, il se produit une incorporation importante du composant mineur du 3HV dans la phase cristalline du poly(β-hydroxybutyrate). Le rapport de la quantité de 3HV contenue dans la phase cristalline par rapport à la quantité totale de 3HV n'est pas linéaire; il augmente avec une augmentation du 3HV. Pour les échantillons contenant 21 et 27% de 3HV, la quantité de 3HV contenue dans la phase cristalline représente pratiquement les 2/3 de la quantité totale de 3HV. Il existe une corrélation entre l'inclusion du 3HV et l'augmentation du désordre cristallin (tel que mesuré par SAXS); ceci implique qu'il est plus facile d'accommoder le gros comonomère 3HV dans une région cristalline qui contient déjà des défauts.

Mots clés : polyesters bacteriens, poly(3-hydroxyalcanoates), diffusion rayons-X aux petits angles, RMN de l'état solide, cocristallisation.

Introduction

Poly(β-hydroxybutyrate), PHB, and its random copolymers with 3-hydroxyvalerate, P(3HB-*co*-3HV) are bacterially produced biodegradable thermoplastics (1–3). They have found a market niche as biodegradable packaging materials and surgical implants due, in part, to properties imparted by their unique crystallization behaviour (4, 5). PHB is a highly stereoregular polymer that crystallizes rapidly into large crystallites (6). Consequently, the homopolymer tends to have problems with embrittlement and aging. Random copolymers of P(3HB-*co*-3HV) exhibit significant improvements in mechanical and thermal properties (2) due to their "less perfect" crystalline morphology . Even though P(3HB-*co*-3HV) random copolymers have the same high crystallinity as the PHB homopolymers, they exhibit greater ductility and lower melting temperatures than PHB.

In general, the crystalline morphology of random copolymers lies between two extremes represented by (*i*) complete exclusion of the noncrystallizable "other" comonomer from the crystalline phase (7) and (*ii*) uniform inclusion of both comonomers (8). P(3HB-*co*-3HV) are remarkable in that they are isodimorphic; i.e., both the 3HV and 3HB comonomers are included in the crystalline phases (5). Thus, the crystalline morphology is clearly not described by the exclusion model, a conclusion that was drawn from observations that both the PHB and PHV homopolymers crystallize in similar 2_1 helix structures, that the degree of crystallinity for the P(3HB-*co*-3HV) copolymers remains high (>60%) over the full copolymer composition range, and that the X-ray and electron diffraction patterns of the 3HB- or 3HV-rich copolymers vary little with copolymer composition.

There is increasing evidence, however, that the cocrystallization of both comonomers is not uniform, and that there is selective partitioning of comonomers between crystalline and amorphous phases (4, 9–11). Partitioning must alter the dynamics of crystallization, with ramifications such as altering the number of defects in the crystalline phase, and changing the crystalline domain sizes. Changes in the crystalline morphology are likely to change end-use properties such as film ductility and susceptibility to biodegradation.

In this report we relate the degree of cocrystallization to the crystalline morphology of random copolymers of P(3HB-*co*-3HV) for compositions of 0–27% 3HV. Over this composition range, P(3HB-*co*-3HV) crystallizes in a PHB-type crystal lattice. This means we will be looking at the inclusion of the bulkier 3HV group into the PHB-type crystal lattice. Partitioning of comonomers will be quantified using solid state ^{13}C NMR, while the crystalline morphology will be described using results from X-ray scattering.

Experimental

Samples of P(3HB-*co*-3HV) were produced by pilot-scale batch fermentations of *Alcaligenes eutrophus* and kindly provided by Imperial Chemical Industries (ICI), U.K.[3] Molecular weights of these isotactic random copolymers ranged from 200 to 400k. The as-received samples had been originally precipitated from chloroform solution using methanol, which effectively "erased" the thermal history. For studies on the effect of crystallization temperature, samples were melt-pressed at 10°C above their melting temperature using a Carver press at 17.2 MPa for 4 min in a nitrogen environment. Immediately following pressing, samples were quenched in liquid nitrogen and immediately placed in a vacuum oven at a specific crystallization temperature, T_c. Samples were maintained at T_c until they reached an equilibrium degree of crystallinity as measured by wide angle X-ray diffraction. Equilibrium crystallinity was 60–65% for all samples studied, although achieving this took as long as 500 h for the 17 and 21% 3HV samples. Differential scanning calorimetry data were recorded using a Perkin–Elmer DSC-2C.

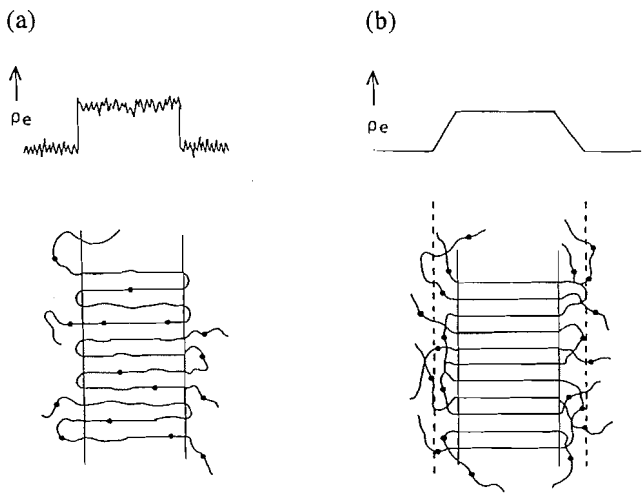
X-ray measurements were made on a Phillips powder diffractometer model PW 1710 equipped with a pulse height analyzer using nickel-filtered Cu K_α radiation ($\lambda = 1.54$ Å) passed through a graphite monochromator. The degree of crystallinity was calculated from wide-angle diffracted intensity (2θ = 10°–40°) using Ruland's method (12). The amorphous scattering component was estimated by measuring the scattering curve from a 21% 3HV sample immediately after quenching in liquid nitrogen. Small-angle X-ray scattering (SAXS) data were collected using a Kratky camera mounted on the same X-ray source, and using a proportional counter 20 cm from the source. Slit-smearing and Lorentz factor corrections (12) were made by multiplying the observed intensity, I, by the scattering vector, $s = 2 \sin \theta/\lambda$.

The NMR spectrometer used for ^{13}C spectroscopy is noncommercial and operates at 2.35 T (25.193 MHz for ^{13}C nuclei). Cross polarization (CP) techniques along with high power decoupling and magic angle spinning (MAS) were combined (13) to produce CPMAS spectra. The nutation frequencies corresponding to the rf field strengths were 66 and 69 kHz for carbons and protons, respectively.

The ^{13}C NMR technique isolates the spectra corresponding to the crystalline and amorphous phases of each sample, as described previously (9, 14). It is based on a simple model that the solid is made up of two phases, crystalline and amorphous, a model that will be tested by the SAXS measurements. In brief, the ^{13}C NMR method consists of taking spectra at different proton spin locking (SL) times prior to cross polarization. During SL, relaxation of polarization takes place more rapidly in the amorphous phase than in the crystalline region due to the greater mobility of carbons in the amorphous phase. Consequently, as the spin lock time increases, the fraction of the total spectral intensity arising from the crystalline regions will increase. By varying the spin lock time, one can recognize the spectral features of the crystalline and amorphous phases, respectively, and isolate the spectra corresponding to each of the two phases. These spectra are isolated by taking linear combinations of experimental spectra acquired with two different SL times. The criteria for isolation of the linear combination spectrum of the crystalline region is that no region of negative intensity is allowed. This approach is successful when net proton polarization gradients are insignificant on distance scales of the monomers and when the time scale of spin diffusion averaging over the domain size of each phase exceeds the time scale of the shorter $T_{1\rho}{}^H$, the rotating frame relaxation time. These conditions have been met for the

[3] Certain commercial material and equipment are identified in this paper in order to specify adequately the experimental procedure. This in no way implies endorsement or recommendation by the National Institute of Standards and Technology.

Fig. 1. Schematic representations and corresponding density profiles of two models of the lamellar morphology of semicrystalline random copolymers. In (*a*), the sharp boundary model, interfaces between domains are sharp with defects or density fluctuations within both domains (defects are represented by circles). In the three-phase diffuse boundary model (*b*) there is a significant interfacial region with an increasing number of defects away from the crystalline core.



P(3HB-*co*-3HV) samples used in this study (14) since the crystalline and amorphous domains are large relative to the monomer size. Moreover, since the shorter $T_{1\rho}{}^{H}$ is approximately 6 ms for these samples, spin diffusion rates imply that overall repeat distances should exceed 6 nm for the experiment to work. In our samples, overall repeat distances were in the range 8–20 nm.

Results and discussion

Small-angle X-ray scattering

It is generally accepted that homopolymers crystallize from the melt into some form of chain-folded lamellar morphology. For random copolymers, this morphology varies not only with the crystallization and annealing conditions, but also with the copolymer composition and the degree of partitioning. Thus, before quantifying the extent of partitioning and discussing its effect on the semicrystalline morphology of melt-crystallized P(3HB-*co*-3HV) random copolymers, we will first use SAXS to determine if a two-phase lamellar model is appropriate to describe this system.

The X-ray scattering intensity from a semicrystalline polymer depends on the electron density differences between domains. Figure 1 is a schematic representation of two models that can be used to describe inclusion of defects into a lamellar crystal along with their respective electron density profiles. In the sharp boundary model (Fig. 1*a*), defects are uniformly spread over two distinct domains, with the corresponding electron density profiles changing sharply at the phase boundary. In the diffuse boundary model, three domains are present: a crystalline and amorphous phase, and a third interfacial region consisting of an increasing number of defects nearer the amorphous domain boundary. The corresponding electron density model is assumed uniform in the crystalline and amorphous phases with a linear density variation in the interfacial region.

The two models outlined in Fig. 1 can be distinguished using SAXS by considering deviations to Porod's law. According to Porod behaviour (15, 16), the *slit-smeared* intensity, I, from an ideal two-phase system with sharp boundaries varies at intermediate angles with the scattering vector s ($s = 2 \sin \theta/\lambda$ such that $I \propto I/s^3$. Ruland (15) and Vonk (16) have shown that deviations from ideal Porod-type behaviour for lamellar structures alter this behaviour such that

$$[1] \quad Is^3 = K_s + \Phi s^3$$

for the sharp boundary model and

$$[2] \quad Is^3 = K_s + \Phi s^2$$

for the (three-phase) diffuse interface model, where K_s is proportional to the electron density difference between phases and Φ is an indication of the interface thickness in eq. [2] and of the density fluctuations within phases in eq. [1]. Accordingly, the diffuse boundary model can be distinguished from the sharp boundary model by plotting Is^3 versus either s^2 or s^3, which should be linear for the appropriate model.

In Fig. 2 the slit-smeared intensity obtained for the 21% 3HV copolymer sample quench-crystallized at 60°C is multiplied by s^3 and plotted against s^3 (Fig. 2*a*) and s^2 (Fig. 2*b*). In Fig. 2*b*, the diffuse boundary model is shown to be clearly inappropriate, not only due to the relative nonlinearity of the data in the Porod region, but also due to the physically unrealistic negative y-axis intercept derived from the best fit through the data. In contrast, when the data are plotted according to the sharp boundary model (Fig. 2*a*; eq. [1]), there is a clear linearity of the data and physically reasonable intercepts.

There is a systematic trend in the shape of the intensity curves with respect to the copolymer composition. In Fig. 3 the slit-smeared intensity data obtained from a series of copolymer samples differing in 3HV composition are plotted according to eq. [1] (samples were crystallized at 60°C from a quenched state). With increasing copolymer composition there is a corresponding increase in the slope, Φ, and a decrease in the intercept, K_s. Noting that K_s is proportional to the density differences between phases and that Φ reflects the fluctuations within a phase (15, 16), the trend in Fig. 3 can be interpreted as an increase in disorder within one or both phases of the sample and a decrease in density difference between phases as the 3HV content increases. Mitomo et al. (17) reported that the total (macroscopic) density of P(3HB-*co*-3HV) copolymers decreases with increasing 3HV content. Their reported explanation, that density decreases due to a decrease in the degree of crystallinity, is at odds with the wide-angle X-ray diffraction evidence showing crystallinity consistently >60% over the 0–21% 3HV composition range. An alternative explanation for the trend in Fig. 3 consistent with high crystallinity is that, with increasing overall 3HV composition, comonomers of 3HV are included increasingly more in the PHB-type crystal. Increased cocrystallization of the energetically less favourable comonomer in the lattice causes defects in the crystalline phase and lowers the apparent overall density. In this picture the increase in Φ is primarily due to a greater number of defects (or density fluctuations) in the crystalline phase rather than in the noncrystalline phase. To investigate this further we sought to quantify the degree of

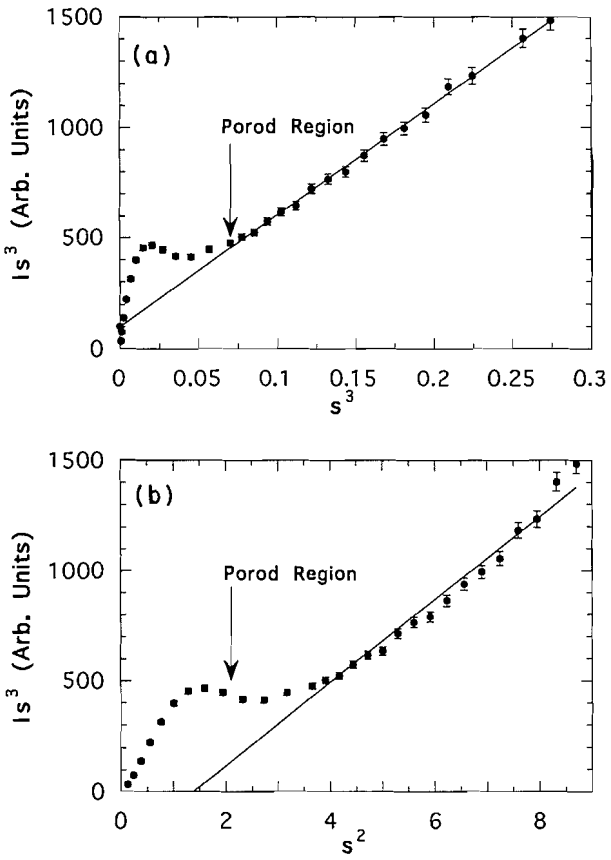
Fig. 2. The observed slit-smeared SAXS data obtained from the 21% 3HV sample of P(3HB-*co*-3HV) random copolymers plotted according to (*a*) the sharp boundary model and (*b*) the diffuse boundary model. The failure of the diffuse boundary model to describe the data is indicated by nonlinearity in the high angle "Porod region" of the data (which is data at angles higher than the one marked with an arrow) and by the physically unrealistic negative *y*-intercept. The sharp boundary model corresponds to a better description of the SAXS data.

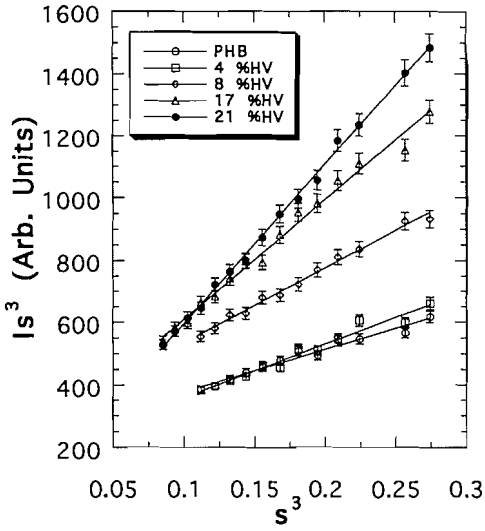


cocrystallization (i.e., the mole fraction of 3HV groups in the PHB-type crystalline phase) and thus correlate the degree of cocrystallization with the relative crystalline disorder.

NMR analysis

The NMR method is exemplified by the spectra from the 21% 3HV as-received sample shown in Fig. 4. Spectrum 4A is the experimental CPMAS spectrum taken with 1 μs SL and 0.7 ms CP time. Since this spectrum is similar to previously published CPMAS data (5, 10, 11), the assignment of carbon resonances from Bluhm et al. (5) were used and are included in the figure. Spectrum 4B is an experimental spectrum taken at the longer SL time of 15 ms, but using the same CP time. To generate the spectra 4C and 4D, representing the crystalline and noncrystalline phases, respectively, we generated linear combinations of spectra 4A and 4B. The details of generating the crystalline and amorphous spectra have been outlined in a previous paper (9, 14). Separation of spectra is based on differences in molecular mobility between the crystalline and amorphous phases in these samples, which means relaxation takes place more rapidly in the amorphous domain than in the crystalline phase.

Fig. 3. The measured slit-smeared SAXS data from samples of P(3HB-*co*-3HV) of compositions 0, 4, 8, 17, and 21% 3HV plotted according to the sharp boundary model. The clear increase of the slope as a function of 3HV composition is indicative of a greater number of fluctuations or defects within the crystalline and amorphous phases. We attribute increased fluctuations to an increase in the number of defects in the crystalline phase as a result of cocrystallization.



Another assertion that allows a separation of crystalline and amorphous spectra is that, due to spin diffusion, the proton polarization level for a minority species, like 3HV, in the crystalline phase will be very similar to that of its neighbouring 3HB crystalline comonomer. Spectra 4C and 4D are produced by assuming (*i*) that the sharper features at a given resonance correspond to the crystalline phase and (*ii*) that the polarization of an amorphous entity will relax more rapidly during SL than a corresponding crystalline group. For P(3HB-*co*-3HV) there is no ambiguity in separating the crystalline and amorphous spectral features since the linewidths of the carbons in the crystalline phase are quite narrow and there are clear changes in relative peak heights between crystalline and amorphous features at different SL times. Scaling in Fig. 4 is chosen so that A or B is the sum of C and D. As a final check, the apparent crystallinity of this sample is 0.60 according to the NMR analysis, which is very consistent with the measured X-ray crystallinities.

The degree of cocrystallization was readily calculated from spectrum 4C by integrating the two OCH peaks, V3 and B3, after lineshape deconvolution. Cocrystallization was quite considerable; for the sample with an overall 3HV mole fraction of 0.21 the 3HV mole fraction in the crystalline phase proved to be 0.119 ± 0.011. Using the method illustrated in Fig. 4, we generated crystalline spectra for five other P(3HB-*co*-3HV) samples: 0, 4, 8, 17, and 27% 3HV. The results derived from these spectra are plotted in Fig. 5, a plot of the measured composition of 3HV in the crystalline region as a function of the total 3HV composition.

Several conclusions can be drawn from the results in Fig. 5. First, a significant number of 3HV residues are included in the crystalline phase for each of the samples. The partitioning of the 3HV comonomers, however, is not linear. Any linear fit to

Fig. 4. The 25MHz CPMAS solid state ^{13}C NMR spectra associated with the 21% 3HV sample. Spectra A and B are experimental data with 1 μs SL and 15 ms SL times, respectively, but a common cross polarization process after spin locking. Spectra C and D correspond to the crystalline and noncrystalline phases, respectively. These latter spectra are different linear combinations of spectra A and B. The sum of C and D is exactly spectrum A. The resonance assignments of the 3HB and 3HV comonomers are represented in the spectra as indicated by the B and V labels, respectively.

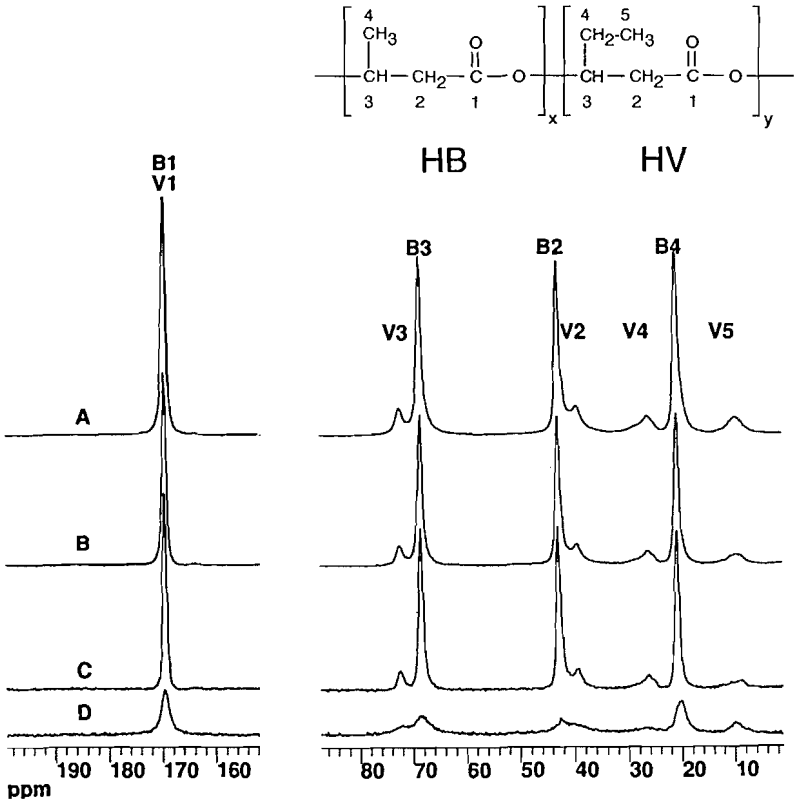

Fig. 5. A plot of the mol% 3HV in the crystalline phase (circles; using the first *y*-axis) as a function of the overall 3HV content. The best-fit curve is quadratic in the overall 3HV content, and is strictly an empirical fit. The disorder parameter derived from SAXS (open diamonds; second *y*-axis) has been normalized to map onto the same *y*-axis and shows the correlation between the inclusion of 3HV comonomers and the relative disorder in the sample.

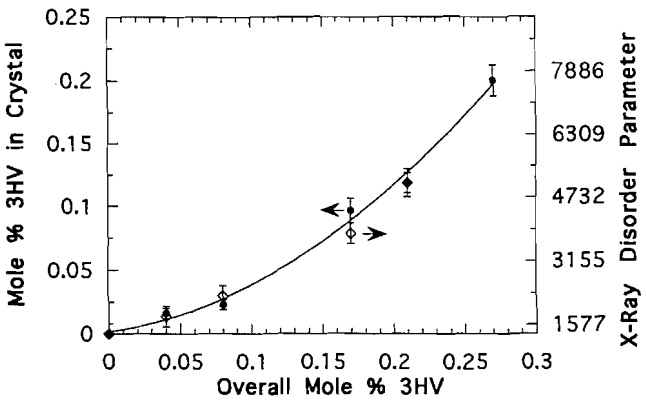

these data would fall outside of experimental error. Instead of linear partitioning, there is a greater tendency to exclude 3HV at low overall 3HV content. For example, for the 4% 3HV sample, the ratio of included 3HV to total 3HV content is less than 0.4. In contrast, for the 21 and 27% samples, the ratio of included to overall 3HV content is ~2/3. The curve in Fig. 5 is an empirical best-fit quadratic in the overall mol% 3HV, which is constrained to pass through the origin and is included to "guide the eye." (This is not necessarily the true functional form of this relationship.) Finally, there is a correlation between the disorder parameter measured by X-ray (Φ from eq. [1]) and the degree of cocrystallization. The disorder parameter, after appropriate normalization onto the *y*-axis, has also been plotted in Fig. 5 as a function of 3HV. The functional form of Φ corresponds to the results from NMR. Clearly, as the relative number of defects in the crystalline phase increases there is a greater tendency to include the larger 3HV residues. This is reasonable considering that it should be easier to add the excess volume of the 3HV group into an already imperfect lattice. At low 3HV compositions, cocrystallization would mean inclusion into a relatively defect-free lattice, which appears to be less favourable.

The NMR results presented here are similar in a general sense to previous solid state NMR studies on P(3HB-*co*-3HV) cocrystallization (10, 11). Both previous studies, which were based on lineshape deconvolution, also reported significant inclusion of 3HV in the PHB-type lattice. In the present NMR study, which we feel is based on fewer assumptions than the two previous studies, we calculate a higher degree of cocrystallization. For example, Kamiya et al. (10) saw no 3HV incorporation until the 3HV content was above 18 mol%.

It could be argued that the differences between the previously reported degrees of partitioning and our present results are due to thermal history. To test this we determined the degree of partitioning for a 27% 3HV sample before and after annealing at 84°C for 18 h. The measured 3HV content in the crystalline phase decreased only marginally from 0.200 to 0.184. In a more extensive test, the crystalline order was measured for a wide range of samples using the SAXS disorder parameter (Φ from eq. [1]) at crystallization temperatures ranging from 30 to 120°C (data not shown). In general, there was little significant change in relative order for a given copolymer sample as a function of T_c. There was, however, some increase in order for the 17% and 21% 3HV samples crystallized within 5°C of their respective melting temperatures. At first glance it is reasonable to assume that the degree of cocrystallization for random copolymers will decrease for crystallization nearer the melting temperature. The argument would be that partitioning is governed by the kinetics of crystallization. The decrease in the rate of crystallization obtained nearer the melting temperature allows more time to exclude the energetically less favoured stems with higher 3HV content from the crystalline phase, resulting in fewer defects.

It is interesting to speculate, however, on why varying the thermal history does not have a more profound effect on the measured degree of cocrystallization (or the disorder parameter). First, the picture of crystallization described in the previous paragraph is simplistic in that it ignores chain connectivity and entropic issues. If we use the argument that annealing "pushes" portions of a crystalline stem rich in defects out of the crystalline phase, it must push that group toward the interface between the crystalline and amorphous phases. This interface, however, is already crowded, considering that this is a region where density considerations cause many chains to fold tightly on themselves (18). Such crowding must prevent any significant buildup of the relatively bulkier 3HV groups in this interfacial area. Another argument that counters the idea that annealing "irons out" defects is the previously reported (19, 20) observation that, at a given crystallization temperature, the crystalline stem length (or lamellar long period) increases with increasing 3HV content. For example, at a constant crystallization temperature of 115°C, the long period measured by SAXS for the 21% 3HV copolymer (with a melting temperature of 118°C) is 22 nm, whereas for PHB (with a melting temperature of 180°C) the long period is 11.4 nm. Presumably, the long period increases with 3HV due to a smaller undercooling, i.e., the T_c is closer to the melting temperature. With increasing crystalline stem length, there is a greater probability that the average composition in the crystalline phase is closer to the overall 3HV composition. Finally, with crystallinities of $\geq$60%, with crystalline stem lengths of more than 10 nm (encompassing more than 40 monomers within each stem), and with sharp boundaries between phases, it is hard to imagine from statistics alone any two-phase crystalline structure without significant cocrystallization.

Summary

This study has shown that the morphology of melt-crystallized P(3HB-*co*-3HV) random copolymers is well described by a two-phase model consisting of two distinct domains (crystalline and amorphous) with density fluctuations or "defects" within each domain. Based on a two-phase model, CPMAS ^{13}C NMR has been used to quantify the degree of cocrystallization of 3HV in the PHB-type crystal structure. For samples with a 3HV composition in the range 0–27%, a significant fraction of 3HV residues are incorporated into the crystalline phase, especially for samples richer in defects. For the 21 and 27% 3HV samples, the 3HV content in the crystalline phase reaches 2/3 of the overall 3HV content. The ratio of the 3HV content in the crystalline phase relative to the overall 3HV content increases with increasing 3HV, and is correlated to an increase in crystalline disorder (as measured by SAXS). This supports arguments that inclusion of the "other" comonomer is accompanied by formation of a defect in the crystal, and that it is easier to accommodate a defect in a crystal structure already containing defects. Finally, based on the length of crystalline stems in the lamellar domain, the high degree of crystallinity (>60%), and on the limitations of chain connectivity during crystallization, one can argue that thermal history has a limited affect on the extent of cocrystallization for P(3HB-*co*-3HV).

Abstract: Steady-state and time-resolved fluorescence spectroscopy of the homopolymers and di- and triblock copolymers of 2-naphthylethylisocyanide (**7**), 9-anthrylethylisocyanide (**10**), and 2-phenanthrylethylisocyanide (**11**) exhibit emission from the isolated chromophores, i.e., naphthyl, anthryl, or phenanthryl, upon excitation at 284 or 354 nm. The absence of excimer emission in the fluorescence spectra of all these homopolymers is indicative of a rigid polymeric backbone. Fluorescence quenching in diblock copolymers containing a dimethylaniline donor block and a naphthalene or anthracene acceptor block takes place through directional energy migration to the acceptor–quencher interface. The migrating excited state is then quenched at the interface either by photoinduced electron transfer in the anthracene–dimethylaniline diblock copolymer or by exciplex formation in the naphthalene–dimethylaniline diblock copolymer. Upon incorporation of an intervening block derived from pentamethylphenylethylisocyanide **8**, exciplex formation is suppressed in the related triblock copolymer. Transient absorption spectra of this family of di- and triblock copolymers reveal the formation of radical ion pairs, with a lifetime of 1.1 μs in the anthracene–dimethylaniline diblock copolymer.

Key words: electron transfer, energy migration, excimer emission, polyisocyanides, block copolymers.

Résumé : La spectroscopie de fluorescence en état stationnaire et résolue dans le temps, appliquée aux homopolymères et aux copolymères à deux et à trois blocs des isocyanures de 2-naphtyléthyle (**7**), de 9-anthryléthyle (**10**) et de 2-phénanthryléthyle (**11**) présente des émissions provenant des chromophores isolées, c'est-à-dire du naphtyle, de l'anthryle ou du phénanthryle lorsqu'on les excite à 284 ou à 354 nm. L'absence d'une émission de l'excimère dans les spectres de fluorescence de chacun de ces homopolymères indique que le squelette est rigide. La dégénérescence de la fluorescence dans les copolymères à deux blocs, contenant un bloc donneur diméthylaniline et un bloc accepteur naphtalène ou anthracène, se produit par une migration directionnelle de l'énergie à l'interface accepteur–désactiveur. L'état excité qui migre est alors désactivé à l'interface par un transfert d'électron photoinduit dans le copolymère à deux blocs anthracène–diméthylaniline ou par la formation du exciplexe dans le copolymère à deux blocs naphtalène–diméthylaniline. Lors de l'incorporation d'un bloc intermédiaire dérivé de l'isocyanure de pentaméthylphényléthyle, **8**, la formation de l'exciplexe est supprimée dans le copolymère à trois blocs apparenté. Les spectres d'absorption des espèces transitoires de cette famille de copolymères à deux et à trois blocs révèlent qu'il y a formation de paires d'ions radicaux dont le temps de vie est 1,1 μs dans le copolymère à deux blocs anthracène–diméthylaniline.

Mots clés : transfert d'électron, migration d'énergie, émission de l'excimère, polyisocyanures, copolymères à blocs.

Introduction

The construction of synthetic chromophore- and quencher-labeled polymers for highly efficient light harvesting remains an elusive, but important, goal (1–4). When such polymers incorporate an energetically graded series of photosensitizers or redox relays, unidirectional electron transfer and (or) energy migration over extended distances can be achieved (1, 3). These systems must include: (*i*) synthetic control of the orientation and spacing of the absorbers, relays, and quenchers; (*ii*) a means of identifying the mode and rate of energy and electron transfer within a homopolymeric block (through-space or through-bond); (*iii*) a means of optimizing energy or electron transfer across the interface between blocks; (*iv*) a mechanism for the prevention of energy-wasting back electron transfer and its consequent charge recombination; and (*v*)

Synthesis of cyclic and acyclic imides, sulfonimides, and *N*-carbobenzyloxyamides by ketene trapping

David I. MaGee, Mahesh Ramaseshan, and James D. Leach

Abstract: A convenient and general method for the synthesis of cyclic and acyclic imides, sulfonimides, and *N*-benzyloxycarbonyl amides via the inter- and intramolecular trapping of ketenes has been developed. Heating the corresponding amido, sulfonamido, and carbamamido ethyl ethynyl ethers at 150°C for 3 h produced the desired compounds in good to excellent yields.

Key words: ketenes, imides, sulfonimides, *N*-benzyloxycarbonyl amides.

Résumé : On a mis au point une méthode générale et appropriée de synthèse d'imides cycliques et aliphatiques, de sulfonimides et d'amides de *N*-benzoyloxycarbonyles qui fait appel à un piégeage inter- et intramoléculaire de cétènes. Si l'on chauffe les oxydes d'éthynyle et d'amido-, de sulfamido- et carbamidoéthyles à 150°C, pendant 3 h, on obtient les produits désirés avec des rendements qui varient de bons à excellents.

Mots clés : cétènes, imides, sulfonimides, amides de *N*-benzoyloxycarbonyles.

Introduction

Cyclic imides and their N-derivatives are an important class of compounds found in interesting natural products such as Showdomycin (1), Sesbanimides (2, 3), bengamides and isobengamides (4), as well as in many interesting unnatural products (4). Cyclic imides have also gained attractive use as intermediates for the synthesis of alkaloids (5–7) and other natural products (8, 9).

In recent years the use and synthesis of imides have received considerable attention (10, 11), however, most studies have been limited to succinimide- and phthalimide-derived compounds. Recently we demonstrated the synthetic utility of the intramolecular trapping of *in situ* generated ketenes as a general method for the efficient formation of lactones (12) and lactams (13). Encouraged by these results, we envisaged the possible utility of this method for the construction of cyclic and acyclic imides, sulfonimides, and *N*-alkoxycarbonyl amides, Scheme 1. Ficini (14) and later Arens and co-workers (15, 16) showed that heating ethyl alkynyl ethers at temperatures above 120°C caused them to undergo a retro-ene reaction to generate a ketene and ethylene, with the ketene being trapped with various added amine and alcohol nucleophiles. Surprisingly, the only related examples we could find of a ketene being trapped with nitrogen nucleophiles other than amines were by Dunbar and White (17) and Rice et al. (18); however, in both studies only ketene itself was used, and with a limited number of amide nucleophiles. Endeavors to utilize our methodology for the synthesis of cyclic and acyclic imides as well as sulfonimides and *N*-benzyloxycarbonyl amides are described herein.

Results and discussion

The cyclization precursors shown in Table 1 were prepared according to standard procedures and, except for entries 8 and 9, are outlined in schemes 2 and 3. Alkynyl ether **29** (13) was constructed according to the following protocol: (*i*) treatment of 1-*tert*-butyldimethylsiloxy-2-propynyl lithium (19) with 2 equivalents of 1,4-dibromobutane (THF, HMPA, room temperature (RT), 86%); (*ii*) substitution of the bromide with 1.2 equivalents of 1-ethoxy ethynyl lithium (THF, HMPA, 0°C–

RT, 82%) (20); (*iii*) deprotection of the silyl ether (TBAF, THF, 92%) (21); (*iv*) mesylation (*n*BuLi, MsCl, THF, 86%); (*v*) bromide formation (NaBr, acetone, 77%); and (*vi*) displacement of the halide with benzamide (KOH, DMSO, 94%) (22), Scheme 4.

Compound **31** was generated in a straightforward manner by alkylation of 1-bromododecane with 1-ethoxy ethynyl lithium (THF, HMPA, 95%), Scheme 5. **Note:** *All of the alkynyl ether compounds are extremely acid and thermally labile, and in our hands decompose readily on standing at room temperature over a period of a few days. Once prepared they should be used immediately, or they can be stored for 2–3 weeks with no significant decomposition in benzene under* N_2 *at* $-10°C$.

Each of the alkynyl ether substrates was then heated at 150°C in refluxing xylenes for 3 h to effect cyclization, except entry 9 where the alkynyl ether was refluxed for 3 h in the presence of 2 equivalents of benzamide, Table 1.

Several points are worth noting about Table 1. First, *sterically hindered or unhindered amides cyclize to give the imide products in good to excellent yields. Five- to eight-membered rings are formed with equal ease* (entries 1–5); of particular note is entry 5 where a fully saturated eight-membered ring is generated. This contrasts with the difficulties encountered by other cyclization methods in related systems (23, 24). Ether protecting groups are unaffected by the reaction conditions (TBS in entries 2, 3, 6, and 7, and MOM (25)), and in one case regiospecific cyclization was accomplished in the presence of a free alcohol (entry 1). Poor nitrogen nucleophiles such as sulfonamides and carbamates also undergo the cyclization with proficiency equal to their amide analogues (entries 6 and 7). Unsymmetrical acyclic imides can be formed easily and efficiently (entry 9).

Efforts to extend this methodology to include substrates that would produce larger than eight-membered rings met with no success. For instance, when alkynyl ether **29** was subjected to our cyclization protocol only unidentifiable products were obtained (entry 8). Attempts to effect successful cyclization using high-dilution syringe pump addition with or without 10 equivalents of tri-*n*-butylamine (12) also proved fruitless.

The reasons for this failure are not readily apparent; however, it could be due to the reduced nucleophilicity of the nitrogen and the increased entropic and enthalpic factors associated with constructing these rings that chemistry other than the desired cyclization occurs. For example in entry 8, if the competition between O- and N-cyclization becomes important due to ease and rate of cyclization, then production of the undesired 12-membered imino ether heterocycle would predominate. The formation of this type of product under the reaction conditions could then very easily result in other unwanted chemistry.

To explore whether this was in fact the problem, three other substrates were examined, Scheme 6. It was expected that carbamate **41** and sulfonamide **42** should not suffer this difficulty, so that cyclization may proceed normally. In amide **43** it was felt that on going to a larger ring system the propensity for O- versus N-cyclization should be more or less identical so the normal cyclization product should reappear, albeit in diminished yields compared to our previous examples. However, when compounds **41**–**43** were heated to 150°C in xylenes for 3 h, myriad unidentifiable products were obtained in each case. The reason for this still eludes us; clearly, all the factors that prevent efficient cyclization in these systems are not yet known.

In summary, we have demonstrated the feasibility of utilizing in situ generated ketenes for the construction of acyclic imides as well as small and medium ring imides, sulfonimides, and *N*-carbobenzyloxyamides. Studies designed to utilize this methodology for the synthesis of biologically important natural products as well as to investigate the chemistry of these compounds are now in progress.

Experimental

All commercial reagents were purchased from Aldrich Chemicals (Milwaukee) and used without any further purification. Reaction solvents were dried according to established procedures (26). All reactions were performed in oven-dried glassware (120°C) under an inert atmosphere of nitrogen unless otherwise stated. Reaction temperatures refer to external baths. Alcohols **1** (27), **2** (28), **3** (29), and **4** (30) were prepared and used according to literature procedures.

Column chromatography was carried out according to the procedure of Still et al (31) using Merck silica gel (230–400 mesh). Thin-layer chromatographic analyses were performed on Merck F_{254} 0.25 mm plates. Infrared (IR) spectra were recorded on a Bruker IFS25 FTIR and are reported in wave numbers (cm^{-1}). Mass spectra were recorded on a Kratos MS50TC and were recorded in FAB or high-resolution EI modes. All ^1H nuclear magnetic resonance (NMR) spectra were recorded on an XL200 (200 MHz) spectrometer with chemical shifts reported in ppm (δ) with tetramethylsilane as an internal standard. Coupling constants (*J*) are reported in Hz. All ^{13}C nuclear magnetic resonance spectra were recorded on a Unity 400 (400 MHz) spectrometer.

General procedure for the preparation of aldehydes 5–8

Preparation of *N*-(4-ethoxy-2-hydroxy-1,1-dimethylbut-3-ynyl)benzamide 9

Ethyl ethynyl ether (0.98 mL, 10 mmol) and THF (10 mL) were placed in a 50 mL RBF. The solution was cooled to 0°C and, after addition of *n*-BuLi (3.71 mL, 9.4 mmol), was stirred for 30 min; then aldehyde **5** (900 mg, 4.7 mmol) was syringed into the solution in one portion. After 1 h the reaction was quenched with pH 10 NH_4Cl (10 mL), extracted into Et_2O (20 mL), dried (K_2CO_3), and the solvent evaporated in vacuo. The crude product was purified by silica gel chromatography (3:1 hexane – ethyl acetate) to provide **9** as a chromatographically pure colourless oil (965 mg, 79%). IR ($CHCl_3$): 3406 (br), 3388 (br), 3287 (br), 2985 (st), 2260 (st), 1654 (st). ^{1}H NMR ($CDCl_3$): 7.66–7.36 (m, 5H), 6.23 (s, 1H), 4.36 (s, 1H), 4.0 (q, 2H, J = 7.0), 1.50 (s, 6H), 1.23 (t, 3H, J = 7.0). ^{13}C NMR ($CDCl_3$): 168.5 (1C), 134.9 (1C), 131.5 (1C), 128.5 (2C), 126.9 (2C), 94.0 (1C), 74.5 (1C), 69.9 (1C), 59.0 (1C), 36.9 (1C), 25.0 (1C), 23.3 (1C), 14.2 (1C). FABMS (NOBA): (m^+ + H) 262 (100).

Preparation of *N*-(5-ethoxy-3-hydroxypent-4-ynyl)-benzamide 10

To a 10 mL RBF cooled to −78°C were successively added ethyl ethynyl ether (0.25 mL, 1.29 mmol), THF (2 mL), and *n*-BuLi (0.27 mL, 0.68 mmol). After 10 min, aldehyde **6** (60 mg, 0.34 mmol) in THF (3 mL) was added and the solution was stirred at this temperature for 30 min. Following quenching with pH 10 NH_4Cl (10 mL), the solution was diluted with Et_2O (10 mL), the layers separated, the organic phase dried (K_2CO_3), and the solvent evaporated in vacuo. The reddish brown crude product **10** (67 mg, 80%) was used directly in the next reaction without further purification. IR ($CDCl_3$): 3381 (br), 3368 (br), 2980 (st), 2270 (st), 1651 (st), 1537 (st). ^{1}H NMR ($CDCl_3$): 7.78–7.46 (m, 5H), 7.10 (s, 1H), 4.63 (m, 1H), 4.08 (q, 2H, J = 7.0), 3.85 (m, 2H), 1.97 (m, 2H), 1.37 (t, 2H, J = 7.0). ^{13}C NMR ($CDCl_3$): 167.8 (1C), 134.4 (1C), 131.4 (1C), 128.5 (2C), 126.9 (2C), 94.2 (1C), 74.7 (1C), 61.0 (1C), 38.7 (1C), 37.6 (1C), 37.0 (1C), 14.3 (1C). FABMS (NOBA): (m^+ + H) 248 (40).

Preparation of 5-(benzyloxycarbonylamino)-1-ethoxypent-1-yne-3-ol 11

Ethyl ethynyl ether (0.68 mL, 7.0 mmol) in THF (5 mL) was placed in a 50 mL RBF. The solution was cooled to −78°C, *n*-BuLi (4.3 mL, 6.9 mmol) was added, and, after stirring for 10 min, aldehyde **7** (650 mg, 3.14 mmol) in THF (5 mL) was syringed in. Stirring of the mixture was continued for an additional 30 min before quenching with 10 mL of pH 10 NH_4Cl solution. The product was extracted into Et_2O (20 mL) and dried (K_2CO_3), the solvent was evaporated in vacuo, and the brown oil was purified by silica gel chromatography (1:1 hexane – ethyl acetate) to give **11** as a chromatographically pure colourless oil (530 mg, 61%). IR ($CHCl_3$): 3305 (st), 3299 (br), 3278 (br), 2260 (st), 1658 (st), 1435 (w). ^{1}H NMR ($CDCl_3$): 7.34 (m, 5H), 5.09 (s, 2H), 4.23 (m, 1H), 4.09 (q, 2H, J = 7.0), 3.74 (m, 2H), 1.84 (m, 2H), 1.34 (t, 3H, J = 7.0). ^{13}C NMR ($CDCl_3$): 156.8 (1C), 136.5 (1C), 128.5 (2C), 128.3 (1C), 128.1 (2C), 94.0 (1C), 74.7 (1C), 66.7 (1C), 60.4 (1C), 38.9 (1C), 38.2 (1C), 37.7 (1C), 14.3 (1C). FABMS (NOBA): (m^+ + H) 278 (15).

Preparation of *N*-(5-ethoxy-3-hydroxypent-4-ynyl)-benzene sulfonamide 12

A 25 mL RBF was cooled to −78°C and THF (5 mL), ethyl ethynyl ether (0.49 mL, 5.0 mmol), and *n*-BuLi (3.0 mL, 4.5 mmol) were successively added. After 30 min aldehyde **8** (442 mg, 2.08 mmol) in THF (3 mL) was added and the solution was stirred at this temperature for 30 min before warming to room temperature and quenching with pH 10 NH_4Cl (10 mL). Extraction with Et_2O (20 mL), drying (K_2CO_3), evaporation of the solvent, and purification of the crude oil by SiO_2 chromatography (2:1 hexane – ethyl acetate) gave alcohol **12** as a chromatographically pure colourless oil (296 mg, 50%). IR ($CHCl_3$): 3331 (br), 3305 (br), 3287 (br), 2264 (st), 1345 (st), 1163 (w). ^{1}H NMR ($CDCl_3$): 7.87–7.51 (m, 5H), 5.32 (s, 1H), 4.66 (t, 1H, J = 5.0), 4.06 (q, 2H, J = 7.0), 3.27 (m, 2H), 1.74 (m, 2H), 1.31 (t, 3H, J = 7.0). ^{13}C NMR ($CDCl_3$): 139.9 (1C), 132.5 (1C), 129.1 (2C), 127.0 (2C), 94.5 (1C), 74.8 (1C), 61.2 (1C), 40.4 (1C), 38.4 (1C), 36.9 (1C), 14.3 (1C). FABMS (NOBA): (m^+) 283 (6).

Preparation of *N*-(2-*tert*-butyldimethylsiloxy-4-ethoxy-1,1-dimethylbut-3-ynyl)benzamide 13

Alcohol **9** (56 mg, 0.21 mmol), CH_2Cl_2 (5 mL), imidazole (16 mg, 0.23 mmol), and *tert*-butyldimethylsilyl chloride (35 mg, 0.23 mmol) were placed in a 10 mL RBF. The reaction mixture was stirred at room temperature for 12 h, the solids were filtered off, and the filtrate was evaporated in vacuo. Purification by silica gel chromatography (5:1 hexane – ethyl acetate)

generated TBS ether **13** as a chromatographically pure colourless oil (75 mg, 93%). IR ($CHCl_3$): 2985 (st), 2260 (st), 1654 (st), 1435 (w). ^1H NMR ($CDCl_3$): 7.60–7.25 (m, 5H), 6.28 (s, 1H), 4.41 (s, 1H), 4.02 (q, 2H, J = 7.1), 1.53 (s, 6H), 1.25 (t, 3H, J = 7.1), 0.88 (s, 9H), 0.08 (s, 6H). ^{13}C NMR ($CDCl_3$): 167.0 (1C), 136.0 (1C), 131.0 (1C), 128.4 (2C), 126.7 (2C), 94.4 (1C), 74.4 (1C), 69.1 (1C), 58.1 (1C), 37.1 (1C), 25.8 (1C), 22.9 (1C), 22.3 (1C), 18.1 (1C), 14.4 (1C), −3.8 (1C), −4.2 (1C). FABMS (NOBA): (m^+ + H) 376 (22).

Preparation of *N*-(3-*tert*-butyldimethylsiloxy-5-ethoxypent-4-ynyl)benzamide 14

Alcohol **10** (67 mg, 0.27 mmol), THF (5 mL), imidazole (19.4 mg, 0.28 mmol), and *tert*-butyldimethylsilyl chloride (43 mg, 0.28 mmol) were placed in a 10 mL RBF. The reaction mixture was stirred at room temperature for 12 h, the solids were filtered off, and the filtrate was evaporated in vacuo. Purification by silica gel chromatography (3:1 hexane – ethyl acetate) generated TBS ether **14** as a chromatographically pure colourless oil (60 mg, 62%). IR ($CHCl_3$): 3350 (st), 2900 (st), 2260 (st), 1725 (st), 1650 (st). ^1H NMR ($CDCl_3$): 7.76–7.38 (m, 5H), 4.68 (m, 2H), 4.07 (q, 2H, J = 7.0), 3.66 (q, 2H, J = 6.1), 1.93 (m, 2H), 1.37 (t, 2H, J = 7.0), 0.87 (s, 9H), 0.07 (s, 6H). ^{13}C NMR ($CDCl_3$): 167.4 (1C), 135.0 (1C), 131.1 (1C), 128.4 (2C), 126.9 (2C), 94.2 (1C), 74.5 (1C), 62.7 (1C), 38.7 (1C), 37.4 (1C), 37.1 (1C), 25.9 (3C), 18.2 (1C), 14.4 (1C). FABMS (NOBA): (m^+ + H) 362 (18).

Preparation of 5-(benzyloxycarbonylamino)-3-*tert*-butyldimethylsiloxy-1-ethoxypent-1-yne 15

To a 10 mL RBF containing alcohol **11** (522 mg, 1.89 mmol) and THF (5 mL) were added *tert*-butyldimethylsilyl chloride (422 mg, 2.8 mmol) and imidazole (204 mg, 3.0 mmol). After stirring at room temperature for 12 h the solids were filtered off and the filtrate was evaporated in vacuo. Purification by silica gel chromatography (8:1 hexane – ethyl acetate) gave **15** as a chromatographically pure colourless oil (610 mg, 83%). IR (neat): 2956 (m), 2857 (m), 2264 (st), 1730 (st), 1696 (st). ^1H NMR ($CDCl_3$): 7.31 (m, 5H), 5.40 (bs, 1H), 5.12 (s, 2H), 4.54 (t, 1H, J = 4.8), 4.06 (q, 2H, J = 7.0), 3.39 (m, 2H), 1.82 (m, 2H), 1.32 (t, 3H, J = 7.0), 0.87 (s, 9H), 0.14 (s, 3H), 0.10 (s, 3H). ^{13}C NMR ($CDCl_3$): 156.3 (1C), 136.8 (1C), 128.4 (2C), 127.9 (2C), 127.2 (1C), 93.9 (1C), 74.4 (1C), 66.4 (1C), 62.1 (1C), 39.0 (1C), 38.2 (1C), 38.1 (1C), 25.8 (1C), 18.1 (1C), 14.4 (1C), −4.8 (1C), −5.2 (1C). FABMS (NOBA): (m^+ + H) 392 (19).

Preparation of *N*-(3-*tert*-butyldimethylsiloxy-5-ethoxypent-4-ynyl)benzene sulfonamide 16

Alcohol **12** (235 mg, 0.83 mmol), THF (6 mL), *tert*- butyldimethylsilyl chloride (188 mg, 1.25 mmol), and imidazole (102 mg, 1.5 mmol) were placed in a 25 mL RBF. The reaction mixture was stirred for 12 h at room temperature, the solids were filtered off, and the filtrate was evaporated in vacuo. Purification of the crude product by silica gel chromatography (3:1 hexane – ethyl acetate) gave sulfonamide **16** as a pure colourless oil (85 mg, 26%). IR ($CHCl_3$): 3320 (br), 3285 (br), 2957 (br), 2895 (br), 2263 (st), 1344 (st), 1160 (st). ^1H NMR ($CDCl_3$): 7.87–7.54 (m, 5H), 5.48 (s, 1H), 4.55 (t, 1H, J = 5.0), 4.0 (q, 2H, J = 7.0), 3.21 (m, 2H), 1.72 (m, 2H), 1.31 (t, 3H, J = 7.0), 0.87 (s, 9H), 0.06 (s, 6H). ^{13}C NMR ($CDCl_3$): 135.0 (1C), 131.1 (1C), 128.4 (2C), 126.9 (2C), 94.2 (1C), 74.5 (1C), 62.7 (1C), 38.9 (1C), 37.4 (1C), 37.1 (1C), 25.9 (3C), 18.2 (1C), 14.4 (1C), −4.6 (1C), −5.1(1C). FABMS (NOBA): (m^+ + H) 398 (21).

Preparation of 6-bromo-1-ethoxyhex-1-yne 19

To a 25 mL RBF cooled to 0°C were successively added diethylamine (0.29 mL, 2.8 mmol), THF (5 mL), and *n*-BuLi (1.7 mL, 2.8 mmol). After 15 min chloroacetaldehyde diethyl acetal (0.14 mL, 0.93 mmol) was added, followed 2 h later by 1,4-dibromobutane (200 mg, 0.93 mmol) in HMPA (6 mL). After agitating the reaction mixture at 0°C for 2 h and at room temperature for 12 h it was quenched with pH 10 NH_4Cl (10 mL), diluted with Et_2O (20 mL), and washed with H_2O (2 × 20 mL). The organic phase was separated, dried (K_2CO_3), evaporated in vacuo, and the crude product was purified by silica gel chromatography (50:1 hexane – ethyl acetate) to produce bromide **19** as a chromatographically pure colourless oil (150 mg, 79%). IR ($CHCl_3$): 2983 (st), 2856 (st), 2268 (st), 1320 (st). ^1H NMR ($CDCl_3$): 4.0 (q, 2H, J = 7.0), 3.45 (t, 2H, J = 6.7), 2.11 (m, 2H), 1.47 (m, 4H), 1.34 (t, 3H, J = 7.0). ^{13}C NMR ($CDCl_3$): 89.8 (1C), 73.9 (1C), 36.5 (1C), 33.5 (1C), 31.7 (1C), 28.0 (1C), 16.5 (1C), 14.4 (1C).

Preparation of 7-bromo-1-ethoxyhept-1-yne 20

A 100 mL RBF was cooled to 0°C and successively charged with diethylamine (1.4 mL, 13.5 mmol), THF (10 mL), and *n*-BuLi (8.4 mL, 13.5 mmol); the mixture was stirred for 30 min, and then treated with chloroacetaldehyde diethyl acetal (0.65 mL, 4.35 mmol). After 2 h 1,5-dibromopentane (0.6 mL, 4.35 mmol) in HMPA (10 mL) was added and stirring was continued at 0°C for 2 h and at room temperature for 12 h. Quenching with pH 10 NH_4Cl (10 mL), dilution with Et_2O (20 mL), washing with H_2O (2 × 20 mL), drying (K_2CO_3), and evaporation of the solvent in vacuo gave a dark oil. The crude product was purified on silica gel chromatography (50:1 hexane – ethyl acetate) to give bromide **20** as a chromatographically pure colourless oil (800 mg, 84%). IR ($CHCl_3$): 2981 (st), 2856 (st), 2270 (st), 1423 (w). ^1H NMR ($CDCl_3$): 4.0 (q, 2H, J = 7.0), 3.51 (t, 2H, J = 6.8), 2.11 (m, 2H), 1.47 (m, 6H), 1.34 (t, 3H, J = 7.0). ^{13}C NMR ($CDCl_3$): 89.5 (1C), 73.9 (1C), 45.0 (1C), 36.9 (1C), 32.2 (1C), 28.9 (1C), 26.0 (1C), 17.1 (1C), 14.3 (1C).

Preparation of *N*-(6-ethoxyhex-5-ynyl)benzamide 21

DMSO (2 mL) and powdered KOH (123 mg, 2.2 mmol) were placed in a 10 mL RBF. After 10 min benzamide (242 mg, 2 mmol) and bromide **19** (111 mg, 0.55 mmol) were added and stirring was continued for 30 min. The reaction mixture was poured into H_2O (10 mL) and extracted with CH_2Cl_2 (3 × 5 mL). The combined organic extracts were washed with H_2O (3 × 10 mL), dried (K_2CO_3), and the solvent was evaporated in vacuo. Purification by silica gel chromatography (2:1 hexane – ethyl acetate) furnished amide **21** (90 mg, 67%) as a chromatographically pure pale yellow oil. IR (neat): 3390 (m), 2912 (st), 2270 (st), 1648 (st), 1450 (m). ^1H NMR ($CDCl_3$): 7.78–7.45 (m, 5H), 6.31 (s, 1H), 4.03 (q, 2H, J = 7.0), 3.45 (q, 2H, J = 6.6), 2.19 (t, 2H, J = 6.1), 1.72–1.58 (m, 4H), 1.37 (t, 3H, J = 7.0). ^{13}C NMR ($CDCl_3$): 167.5 (1C), 134.8 (1C), 131.3 (1C), 128.5 (2C), 126.8 (2C), 89.7 (1C), 73.9 (1C), 39.6 (1C), 36.7 (1C), 28.7 (1C), 27.0 (1C), 17.0 (1C), 14.4 (1C). FABMS (glycerol): (m^+ + H) 246 (84).

Preparation of *N*-(7-ethoxyhept-6-ynyl)benzamide 22

Powdered KOH (1.54 g, 27.6 mmol) and DMSO (15 mL) were stirred for 15 min in a 50 mL RBF, then benzamide (2.6 g, 21.5 mmol) followed by bromide **20** (1 g, 4.6 mmol) in 5 mL of DMSO were added and stirring was continued for 30 min. The solution was poured into H_2O (20 mL) and extracted with CH_2Cl_2 (3 × 10 mL). The combined organic extracts were washed with H_2O (3 × 10 mL), dried (K_2CO_3), and the solvent was evaporated. Purification by silica gel chromatography (2:1 hexane – ethyl acetate) gave amide **22** as a chromatographically pure colourless oil (950 mg, 80%). IR ($CHCl_3$): 3340 (m), 2933 (st), 2264 (st), 1651 (st), 1430 (st), 1287 (st). ^{1}H NMR ($CDCl_3$): 7.78–7.45 (m, 5H), 6.12 (s, 1H), 4.0 (q, 2H, J = 7.0), 3.46 (q, 2H, J = 6.5), 2.13 (m, 2H), 1.49 (m, 6H), 1.34 (t, 3H, J = 7.0). ^{13}C NMR ($CDCl_3$): 167.5 (1C), 134.7 (1C), 131.2 (1C), 128.4 (2C), 126.8 (2C), 89.5 (1C), 73.8 (1C), 39.9 (1C), 36.9 (1C), 29.2 (1C), 29.1 (1C), 26.0 (1C), 17.0 (1C), 14.3 (1C). FABMS (NOBA): (m^+) 259 (100).

Preparation of 1-ethoxytetradec-1-yne 31

A 25 mL RBF was charged with ethyl alkynyl ether (0.1 mL, 0.45 mmol) and THF (5 mL), cooled to −78°C and *n*BuLi (0.16 mL, 0.4 mmol) was added dropwise to the mixture. After stirring for 30 min 1-bromododecane **30** (100 mg, 0.4 mmol) in THF (2 mL) and HMPA (5 mL) were added, the cold bath was removed, and the reaction mixture stirred at room temperature overnight, diluted with Et_2O (30 mL), and quenched with pH 10 NH_4Cl (10 mL). The ether layer was separated, washed with H_2O (2 × 20 mL), brine (2 × 20 mL), dried (K_2CO_3), and then evaporated. The oily residue was purified by silica gel chromatography (60:1 hexane – ethyl acetate) to furnish **31** as a chromatographically pure colourless oil (53 mg, 55%). IR ($CHCl_3$): 2960 (st), 2926 (br), 2260 (st), 1453 (m), 1103 (m). ^{1}H NMR ($CDCl_3$): 4.02 (q, 2H, J = 7.1), 3.41 (t, 2H, J = 6.8), 2.11 (p, 2H, J = 6.7), 1.88 (p, 2H, J = 6.6), 1.34 (t, 3H, J = 7.1), 1.53–1.21 (m, 14H). ^{13}C NMR ($CDCl_3$): 89.3 (1C), 73.8 (1C), 37.4 (1C), 31.9 (1C), 29.8 (1C), 29.7 (1C), 29.6 (2C), 29.6 (1C), 29.4 (1C), 29.2 (1C), 28.8 (1C), 22.7 (1C), 17.2 (1C), 14.4 (1C), 14.1 (1C). FABMS (NOBA): ($2m^+$ + H) 477 (100), (m^+ + H) 237 (10).

Preparation of 1-benzoyl-5,5-dimethyl-4-hydroxylpyrrolidin-2-one 32

To refluxing (150°C) xylenes (15 mL) in a base-washed 100 mL RBF was added amide **9** (25 mg, 0.096 mmol) in xylenes (5 mL) dropwise over 10 min. The solution was kept at reflux for 3 h, cooled to room temperature, and the solvent was evaporated in vacuo. Purification by silica gel chromatography (2:1 hexane – ethyl acetate) furnished imide **32** as a chromatographically pure colourless oil (20 mg, 86%). IR ($CHCl_3$): 3499 (br), 3485 (br), 3444 (br), 1698 (m), 1661 (m), 1651 (m), 1315 (m). ^{1}H NMR ($CDCl_3$): 7.68–7.25 (m, 5H), 4.03 (dd, 1H, J = 3.1, 6.0), 2.86 (dd,1H, J = 6.0, 18.4), 2.45 (dd, 1H, J = 3.1, 18.4), 1.50 (s, 3H), 1.49 (s, 3H). ^{13}C NMR ($CDCl_3$): 173.6 (1C), 171.9 (1C), 136.1 (1C), 132.3 (1C), 128.9 (2C), 128.1 (2C), 73.2 (1C), 66.7 (1C), 39.5 (1C), 24.6 (1C), 19.6 (1C). HRMS (m^+/z) found: 233.1053; calcd.: 233.1052.

Preparation of 1-benzoyl-3-(*tert*-butyldimethylsiloxy)-5,5-dimethylpyrrolidin-2-one 33

To refluxing (150°C) xylenes (15 mL) in a base-washed 100 mL RBF was added amide **13** (25 mg, 0.096 mmol) in xylenes (5 mL) dropwise over 10 min. The solution was kept at reflux for 3 h, cooled to room temperature, and the solvent was evaporated in vacuo. The residue was purified by silica gel chromatography (2:1 hexane – ethyl acetate) to furnish imide **33** as a chromatographically pure colourless oil (20 mg, 75%). IR ($CHCl_3$): 2954 (m), 2929 (m), 1742 (st), 1681 (st), 1145 (st). ^{1}H NMR ($CDCl_3$): 7.62–7.38 (m, 5H), 4.00 (dd, 1H, J = 4.6, 5.1), 2.82 (dd, 1H, J = 5.1, 17.6), 2.45 (dd, 1H, J = 4.6, 17.6), 1.51 (s, 3H), 1.48 (s, 3H), 0.93 (s, 9H), 0.11 (s, 6H). ^{13}C NMR ($CDCl_3$): 173.3 (1C), 171.9 (1C), 135.7 (1C), 132.2 (1C), 128.9 (2C), 128.1 (2C), 73.9 (1C), 67.2 (1C), 40.2 (1C), 25.7 (3C), 24.7 (1C), 20.1 (1C), 18.0 (1C), −4.6 (1C), −5.0 (1C). HRMS (m^+/z − $C(CH_3)_3$) found: 290.1219; calcd.: 290.1213.

Preparation of 1-benzoyl-4-(*tert*-butyldimethylsiloxy)-piperidin-2-one 34

A base-washed 100 mL RBF containing xylenes (50 mL) was brought to reflux (150°C) and amide **14** (100 mg, 0.28 mmol) in xylenes (10 mL) was added dropwise over 10 min. After complete addition and heating for 2 h, the mixture was cooled to room temperature, and the solvent evaporated in vacuo. Purification by silica gel chromatography (5:1 hexane – ethyl acetate) generated imide **34** as a chromatographically pure pale white waxy solid (73 mg, 79%). IR ($CHCl_3$): 2956 (st), 2929 (st), 1694 (st), 1667 (st), 1471 (m). ^{1}H NMR ($CDCl_3$): 7.58–7.40 (m, 5H), 4.33 (m, 1H), 3.78 (m, 2H), 2.74 (dd, 1H, J = 4.1, 16.4), 2.59 (dd, 1H, J = 4.8, 16.4), 2.10 (m, 2H), 0.90 (s, 9H), 0.01 (s, 6H). ^{13}C NMR ($CDCl_3$): 174.2 (1C), 172.1 (1C), 136.1 (1C), 131.5 (1C), 128.1 (2C), 128.0 (2C), 65.5 (1C), 43.8 (1C), 41.5 (1C), 31.1 (1C), 25.7 (3C), 18.0 (1C), 0.01 (2C). HRMS (m^+/z − $C(CH_3)_3$) found: 276.1062; calcd.: 276.1056.

Preparation of 1-benzoylazepan-2-one 35

A base-washed 50 mL RBF was charged with xylenes (20 mL) and brought to reflux (150°C). To this solution was added amide **21** (30 mg, 0.12 mmol) in xylenes (5 mL) dropwise over 10 min and, after complete addition the solution was heated for an additional 2 h. Upon cooling to room temperature and evaporation of solvent the residue was purified by silica gel chromatography (3:1 hexane – ethyl acetate) to produce imide **35** as a chromatographically pure colourless oil (17.8 mg, 68%). IR ($CHCl_3$): 2929 (m), 2800 (w), 1699 (st), 1694 (st), 1674 (st), 1440 (m). ^{1}H NMR ($CDCl_3$): 7.51 (m, 5H), 3.97 (m, 2H), 2.70 (m, 2H), 1.83 (m, 6H). ^{13}C NMR ($CDCl_3$): 177.5 (1C), 174.1 (1C), 136.6 (1C), 131.3 (1C), 128.1 (2C), 127.7 (2C), 45.2 (1C), 38.9 (1C), 29.7 (1C), 29.2 (1C), 23.8 (1C). HRMS (m^+/z) found: 217.1097; calcd.: 217.1103.

Preparation of 1-benzoylazocan-2-one 36

A 50 mL RBF charged with xylenes (20 mL) was brought to reflux (150°C) and amide **22** (50 mg, 0.19 mmol) in xylenes (5 mL) was added dropwise over 10 min. Following complete addition, the solution was refluxed for 3 h, cooled to room temperature, and the solvent was evaporated. The residue was purified by silica gel chromatography (2:1 hexane – ethyl acetate) to furnish imide **36** as a chromatographically pure colourless oil (25.7 mg, 58%). IR ($CHCl_3$): 2924 (m), 2760 (w), 1694 (st), 1668 (st), 1440 (m). ^{1}H NMR ($CDCl_3$): 7.48 (m, 5H), 3.98

(dd, 2H, J = 5.8, 6.0), 2.65 (dd, 2H, J = 5.9, 6.6), 1.90–1.61 (m, 8H). ^{13}C NMR ($CDCl_3$): 178.8 (1C), 174.1 (1C), 136.4 (1C), 131.1 (1C), 128.0 (2C), 127.7 (2C), 44.8 (1C), 35.8 (1C), 30.5 (1C), 28.9 (1C), 26.2 (1C), 23.7 (6C). HRMS (m^+/z) found: 231.1259; calcd.: 231.1260.

Preparation of 1-(benzyloxycarbonyl)-4-(*tert*-butyldimethylsiloxy)-piperidin-2-one 37

A base-washed 100 mL RBF containing xylenes (20 mL) was brought to reflux (150°C) and carbamate **15** (25 mg, 0.064 mmol) in xylenes (5 mL) was added dropwise over 10 min. After complete addition the reaction mixture was refluxed for 3 h, cooled to room temperature, the solvent evaporated, and the crude product purified by silica gel chromatography (7:1 hexane – ethyl acetate) to furnish **37** as a chromatographically pure pale yellow oil (20.2 mg, 87%). IR ($CHCl_3$): 2956 (st), 2928 (st), 2856 (m), 1777 (m), 1716 (st), 1471 (m). ^{1}H NMR ($CDCl_3$): 7.34 (m, 5H), 5.21 (s, 2H), 4.12 (m, 1H), 3.67 (t, 2H, J = 5.4), 2.57 (dd, 1H, J = 4.0, 17.4), 2.45 (dd, 1H, J = 4.2, 17.3), 1.83 (m, 2H), 0.80 (s, 9H), 0.071 (s, 6H). ^{13}C NMR ($CDCl_3$): 169.6 (1C), 154.1 (1C), 135.4 (1C), 128.5 (2C), 128.3 (1C), 128.0 (2C), 68.5 (1C), 64.8 (1C), 44.3 (1C), 42.2 (1C), 31.2 (1C), 25.7 (3C), 18.0 (1C), 1.0 (2C). HRMS (m^+/z – $C(CH_3)_3$) found: 306.1170; calcd.: 306.1162.

Preparation of 1-(benzenesulfonyl)-4-(*tert*-butyldimethylsiloxy)-piperidin-2-one 38

A 100 mL RBF containing xylenes (25 mL) was brought to reflux (150°C) and sulfonamide **16** (40 mg, 0.10 mmol) in xylenes (5 mL) was added dropwise over 10 min. After 3 h the reaction mixture was cooled to room temperature, the solvent evaporated, and the residue purified by silica gel chromatography (2:1 hexane – ethyl acetate) to furnish sulfonimide **38** as a chromatographically pure colourless oil (28.3 mg, 76%). IR ($CHCl_3$): 2957 (st), 2903 (w), 2856 (m), 1683 (st), 1344 (m). ^{1}H NMR ($CDCl_3$): 8.02–7.57 (m, 5H), 4.12 (m, 1H), 4.06 (m, 2H), 2.54 (dd, 1H, J = 3.8, 17.3), 2.44 (dd, 1H, J = 4.1, 17.2), 1.97 (m, 2H), 0.78 (s, 9H), 0.026 (s, 6H). ^{13}C NMR ($CDCl_3$): 168.9 (1C), 138.9 (1C), 133.6 (1C), 128.6 (2C), 128.4 (2C), 64.1 (1C), 43.2 (1C), 42.4 (1C), 30.9 (1C), 25.6 (3C), 17.8 (1C), 1.0 (2C). HRMS (m^+/z – $C(CH_3)_3$) found: 312.0713; calcd.: 312.0727.

Preparation of *N*-tetradecanoylbenzamide 40

A 100 mL RBF containing xylenes (25 mL) and benzamide (80 mg, 0.66 mmol) was brought to reflux (150°C) and alkynyl ether **31** (78 mg, 0.33 mmol) in xylenes (5 mL) was added dropwise over 25 min. The solution was refluxed for 3 h, cooled to room temperature, the solvent evaporated, and the residue purified by silica gel chromatography (2:1 hexane – ethyl acetate) to furnish imide **40** as a chromatographically pure colorless oil (104 mg, 95%). IR ($CHCl_3$): 3405 (w), 3394 (w), 2953 (s), 2916 (s), 1699 (m), 1677 (s), 1470 (m). ^{1}H NMR ($CDCl_3$): 8.60 (s, 1H), 7.83 (m, 2H), 7.54 (m, 3H), 3.00 (t, 2H, J = 7.2), 1.72–1.35 (m, 25H). ^{13}C NMR ($CDCl_3$): 176.0 (1C), 165.3 (1C), 133.2 (1C), 132.9 (1C), 129.0 (2C), 127.5 (2C), 37.5 (1C), 31.9 (1C), 29.7 (2C), 29.6 (1C), 29.6 (1C), 29.5 (1C), 29.4 (1C), 29.3 (1C), 29.2 (1C), 24.1 (1C), 22.7 (1C), 14.1 (1C). HRMS (m^+/z) found: 331.2502; calcd.: 331.2512.

Unusual polyketides from the wood-decay fungus *Sistotrema raduloides*

Albert K. Amegadzie, William A. Ayer, and Lynne Sigler

Abstract: The metabolites of the wood rot decay fungus *Sistotrema raduloides* (P. Karst) Donk have been investigated and a new type of norpentaketide has been discovered. The compounds sistodiolynne (**1**), sistolynone (**5**), and sistopyrone (**6**) represent new carbon skeletons among natural products. The compounds are very unstable and readily polymerize in the presence of air to give black insoluble material. It has been shown by ^{13}C NMR labelling experiments that they arise from five acetate units, and that a methyl carbon of one of the acetate units is lost during the biosynthesis. The structures were determined by spectroscopy methods, mainly NMR, and the absolute configuration of sistodiolynne was established by circular dichroism methods.

Key words: fungal metabolites, *Sistotrema raduloides*, norpentaketides, biosynthetic studies, polyacetylenes.

Résumé : On a étudié les métabolites du champignon *Sistotrema raduloides* (P. Karst) Donk de la pourriture du bois et on a découvert un nouveau type de norpentacétide. Les composés sistodiolynne (**1**), sistolynone (**5**) et sistopyrone (**6**) correspondent à de nouveaux squellettes carbonés des produits naturels. Les composés sont très instables et ils se polymérisent facilement en présence d'air pour donner des matériaux noirs qui sont insolubles. On a montré par des expériences de marquage en RMN du ^{13}C qu'ils proviennent de cinq unités acétates et qu'un carbone de méthyle de l'une des unités acétates est perdue au cours de la biosynthèse. On a déterminé les structures par des méthodes spectroscopiques, principalement la RMN, et on a déterminé la configuration absolue de la sistodiolynne par des méthodes de dichroïsme circulaire.

Mots clés : métabolites de champignons, *Sistotrema raduloides*, norpentacétides, études biosynthétiques, polyacétylènes.

[Traduit par la rédaction]

Introduction

The wood-decay fungus *Sistotrema raduloides* (P. Karst) Donk was recovered from indoor air during a study to evaluate building air quality of a museum in San Juan, Puerto Rico.[2] A member of the Corticiaceae (Basidiomycotina) having a widespread distribution in temperate areas, *S. raduloides* is known to cause white rot decay of both angiospermous and gymnospermous wood (1). On agar media of various kinds, the Puerto Rican isolate[3] was observed to form flaky carbonaceous deposits especially when the mycelium came into contact with glass surfaces. In this study we examined the metabolites produced when the fungus is grown in liquid still culture on Sabouraud dextrose medium. The metabolites proved to be very sensitive to air, forming an insoluble black polymer when exposed to the atmosphere in the absence of solvent. The structures of three of the air-sensitive metabolites are described, and the biosynthetic pathway by which they may be produced from acetate units is discussed.

Received July 4, 1995.

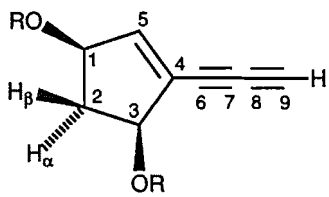
[2] The fungus is further described in the Experimental.

[3] We thank Dr. B. Bolanos, School of Medicine, University of Puerto Rico, San Juan, for bringing the isolate to our attention.

Results and discussion

Sistotrema raduloides was grown in still culture on Sabouraud dextrose broth at room temperature for 5 weeks. The mycelium was then separated from the culture broth by filtration and the filtrate was concentrated and extracted, first with CH_2Cl_2, then with ethyl acetate. In the initial experiment, the extracts were dried (Na_2SO_4) and concentrated to dryness under reduced pressure to give brown oils. On standing open to the atmosphere, the oils rapidly (ca. 2 min) solidified to a black amorphous solid. This material could not be dissolved in organic solvents or water. In subsequent experiments, the crude extracts were not concentrated to dryness but were kept as much as possible in a small volume of the extracting solvent under an inert atmosphere.

Sistodiolynne (**1**) was purified by preparative TLC. To



1 R = H
1a R = Ac

avoid polymerization the compound was eluted directly from the plate with acetone-d_6 and the solution was used for NMR measurements. The HREIMS was obtained by placing a drop

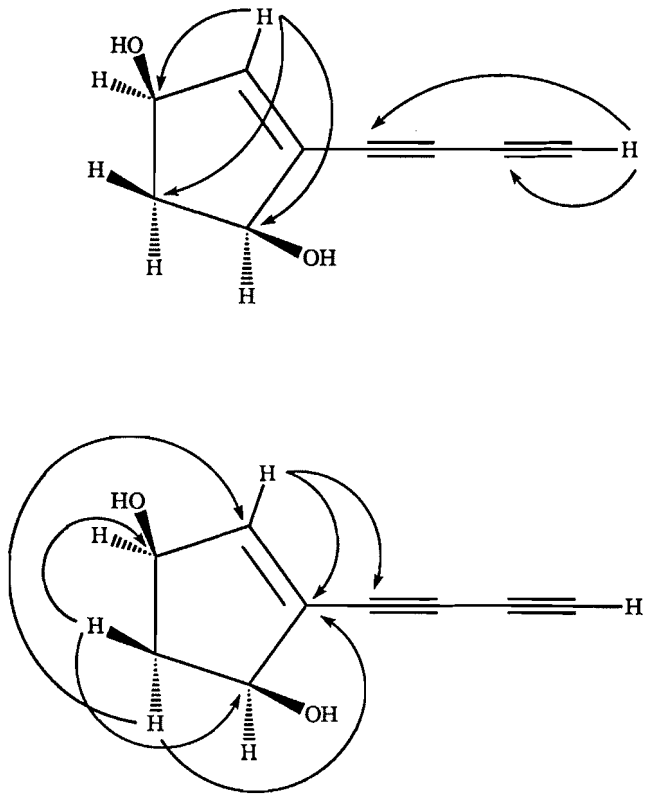
OH-1			C-9	74.1, d
-$COCH_3$		2.08, 2.02 (singlets)		

of the solution directly on the probe and determining the spectrum immediately. The spectrum indicates a molecular formula $C_9H_8O_2$. Peaks at $M^+ - 1$ and $M^+ - 18$ indicate the presence of hydroxyl group(s). The FTIR spectrum (thin film after evaporation of solvent) shows broad hydroxyl absorption centered around 3500 cm^{-1}, with a sharp absorption band protruding at 3287 cm^{-1}. This latter absorption, coupled with absorption at 2230 and 2050 cm^{-1}, is indicative of a terminal and a non-terminal alkyne (2). The ^{13}C NMR spectrum shows four signals in the *sp* carbon region, at 76.9, 74.1, 72.0, and 68.4, consistent with the presence of two triple bonds. A *J*-compensated APT spectrum revealed that the carbon at δ 74.1 carries a hydrogen. The UV spectrum shows absorption bands at 252 and 310 nm, the latter the more intense. This is consistent with the presence of a conjugated endiyne (ref. 2, pp. 3–21).

The ^{1}H NMR spectrum shows signals for all eight hydrogens (Table 1) and the ^{13}C NMR shows the nine carbons (Table 1). The sole methylene carbon, located at δ 44.7, was shown in an HETCOR (3) experiment to correlate to the protons at 2.74 (ddd, J = 13.5, 7.0, 7.0) and 1.50 (ddd, J = 13.5, 6.0, 6.0). These protons are coupled to the protons at δ 4.62 and 4.55, which are attached to the carbons at δ 73.4 and 76.1, respectively. This results in the sequencing of carbons 1, 2, and 3, with the hydroxyl groups assigned as *cis* because of the large chemical shift between the protons of the methylene group. It has been shown that in such *cis* 4-cyclopenten-1,3-diols, the hydrogen *syn* to the hydroxyl groups is upfield of the *anti* proton (4, 5). In confirmation of this, nOe enhancements of H-1α (7.5%) and H-3α (7.5%) were observed when the H-2α signal is irradiated, and no enhancement was seen when H-2β is irradiated. The HMBC spectrum shows that the alkenic hydrogen is correlated with the other alkenic carbon and with the alkynic carbon at δ 76.9, confirming that the trisubstituted double bond is in conjugation with the carbon–carbon triple bonds, as implied by the UV spectrum. Correlated of the alkynic H (δ 3.30) with this same carbon (δ 76.9) as well as with C-8 (δ 68.4) completes the connectivity of the endiyne system. The HMBC correlations are shown in Fig. 1. Since sistodiolynne must be monocyclic, structure **1** is assigned.

Acetylation of sistodiolynne (**1**) provided the diacetyl derivative **1***a* as an unstable oil. The HREIMS confirmed the molecular formula and, as shown in Table 1, the ^{1}H NMR spectrum is in good agreement with structure **1***a*.

Fig. 1. Significant HMBC correlations of sistodiolynne (**1**).



Catalytic hydrogenation (Pd–C, EtOAc) of sistodiolynne (**1**) provides a mixture of the saturated stereoisomers **2** and **3** that proved to be much more stable than sistodiolynne. However, they could not be separated by chromatography, but the derived di-*p*-bromobenzoates **2***a* and **3***a* were separable by preparative TLC. The isomer **2***a* was the major component

For personal use only.

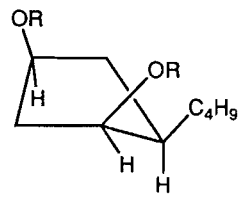
(perhaps due to coordination of the catalyst with the hydroxyl groups), although **3***a* crystallized more readily. The HREIMS of **2***a* and **3***a* are very similar with each showing a molecular ion at *m/z* 522 ($C_{23}H_{24}O_4Br_2$). Loss of two molecules of *p*-bromobenzoic acid gives rise to a base peak at *m/z* 122 (C_9H_{14}). The ^{1}H NMR spectra of **2***a* and **3***a* are also very similar (see Experimental). The methylene hydrogens at C-2 and C-5 were identified by their different *geminal* couplings and by the ^{1}H–^{1}H COSY spectrum of **3***a*. The ^{13}C NMR (APT) spectra each show three methine carbons, two of which are oxygenated, five methylene carbons, and one methyl carbon. The complete ^{13}C NMR signal assignments were made by comparing the results of an HMQC experiment with the ^{13}C NMR spectra of **2***a* and **3***a* obtained during the ^{13}C-labelling experiments described later.

The stereochemistry of the butyl group in **2***a* and **3***a* is assigned on the basis of the chemical shift difference of H-3 in **2***a* and **3***a*. An alkyl group *vicinal* to the carbinyl proton is expected to make an upfield shift if it is *syn* to the carbinyl proton relative to when it is *anti* (6). In addition, irradiation of H-5α (δ 2.6) in **3***a* causes enhancement of H-1α (12%) and H-4 (14%). Similarly, irradiation of H-4 enhances the signal for H-3α by 15%.

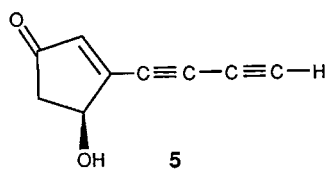
The circular dichroism (CD) spectrum of **3***a* shows the first Cotton effect (negative) at 251 nm and the second (positive) at 231 nm. If we assume that the cyclopentane ring exists predominantly in the envelope conformation with the large butyl group in the equatorial lip position as depicted in **4**, a negative



4 R = *p*-BrC_6H_4CO

chirality (7) exists between the chromophoric groups and the absolute configuration is as depicted in the structural formulae. MM2 calculations indicate that the conformation shown in **4** is the energy minimum (8).

Sistolynone (**5**) was isolated as an unstable oil by preparative TLC. The compound was washed from the adsorbent with deuterated chloroform and was not evaporated to dryness in order to prevent decomposition. This compound was less polar (higher R_f) than sistodiolynne (**1**). The molecular formula



5

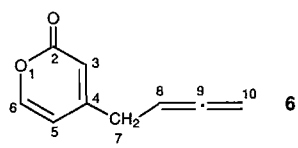
$C_9H_6O_2$ was determined by HREIMS, which indicated a molecular ion peak at *m/z* 146. The peak at *m/z* 118 represents loss of CO, suggesting the presence of a carbonyl group. A strong absorption band at 1710 cm^{-1} in the IR spectrum and a signal in the ^{13}C NMR (APT) spectrum at δ 204.4 confirm the presence of a ketonic carbonyl functionality. The position of this signal suggests an α,β-unsaturated five-membered ring ketone (9). The band at 3389 cm^{-1} is strong evidence for a hydroxyl group, and bands at 3284 and 2204 cm^{-1} indicate a terminal alkyne group.

A singlet at δ 2.9 in the ^{1}H NMR spectrum was easily recognized as the CH of a terminal alkyne. A methylene pair is evident from signals at δ 2.8 and 2.4 (J_{gem} = 18.6 Hz), the chemical shifts and the magnitude of the coupling constant suggesting that they are attached to the carbon α to the carbonyl group. The proton signal at δ 5.0 (dddd, J = 6.5, 5.0, 2.5, 1.0 Hz) is vicinally coupled to this methylene pair by 6.5 and 2.5 Hz and by 5.0 and 1.0 Hz to protons at δ 2.3 and 6.4, respectively. The signal at δ 2.3 disappears when D_2O is added to the sample, indicating that it is a hydroxyl hydrogen. The ^{13}C NMR spectrum is very straightforward and contains nine signals, three of which appear in the region of C≡C at δ 89.8, 68.2, and 66.8. This suggests the presence of a dialkyne system by analogy to the spectra observed for **1**. The terminal alkyne CH at δ 78.3 was distinguished from the rest of the signals by a *J*-compensated APT spectrum.

Based on all the spectral data discussed above, structure **5** is proposed for sistolynone. The small quantity of sistolynone obtained precluded other correlation experiments and derivatization.

Sistopyrone (**6**) also was obtained as an unstable oil by preparative TLC. The HREIMS spectrum displays a molecular ion peak at *m/z* 148, establishing $C_9H_8O_2$ as the molecular formula. The strong absorption at 1725 cm^{-1} in the FTIR spectrum suggests a carbonyl group. The ^{1}H NMR spectrum displays a total of six signals, three of which appear in the olefinic region between δ 7.41 and 6.18. The proton at δ 6.18 (H-3, ddd, J = 2.0, 1.0, 1.0 Hz) is coupled to protons at 7.41 (H-6, dd, J = 5.2, 1.0 Hz), 6.12 (H-5, dd, J = 5.2, 1.0 Hz), and 3.12 (2H, H-7, dtd, J = 7.0, 2.9, 1.0 Hz). The chemical shifts and coupling constants displayed by these olefinic protons, in addition to signals at δ 162.2 (s), 156.8 (s), 150.7 (d), 113.7 (d), and 108.0 (d) in the ^{13}C NMR spectrum, suggest a pyrone ring substituted at the 4-position (10, 11). HMQC correlations confirm the assignments for the partial structure mentioned above.

Infrared bands at 1955 and 853 cm^{-1} are indicative of an allene group (-HC=C=CH_2) (12). Signals at δ 209.7 (s), 85.5 (d), and 76.3 (t) are consistent with this functionality (12). The remaining signals in the ^{1}H NMR spectrum are a one-proton signal at δ 5.15 (qn, J = 7.0 Hz) and a two-proton signal at δ 4.79 (dt, J = 6.7, 2.9 Hz). Decoupling experiments provide confir-



6

matory information concerning the allene group. In particular, the irradiation of the signal at δ 3.12 (dtd, 7.0, 2.9, 1.0 Hz) results in the collapse of signals at δ 6.18, 5.15, and 4.79. The signal at δ 5.15 becomes a triplet with J = 6.7 Hz, coupling only to the signal at δ 4.79. It became evident at this point that the signal at δ 5.15 is in fact an overlapping pair of triplets rather than a quintet. Structure **6** is consistent with these data. Lack of material precluded further experimentation.

Biosynthesis

The metabolites of *S. raduloides* represent a new structural

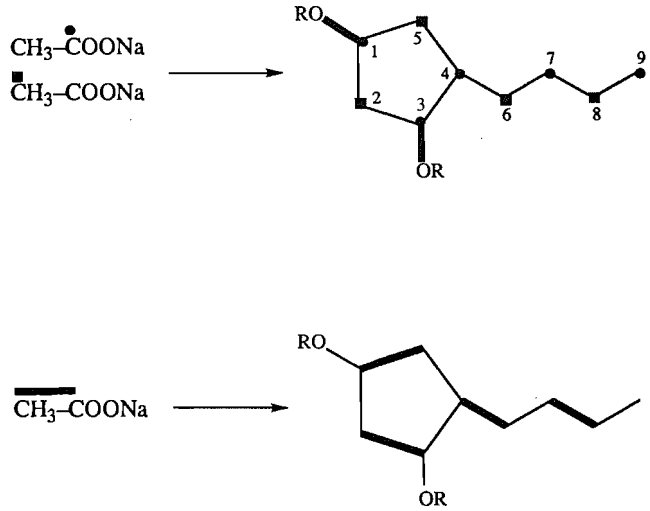
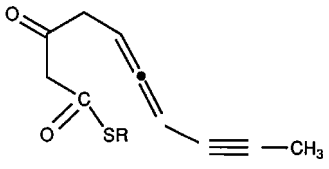
Fig. 2. Acetate labelling patterns in sistodiolynne (**1**).



type of natural product. We have been unable to locate a compound in the literature with this carbon skeleton. The unbranched nature of the carbon skeletons in sistodiolynne (**1**) and sistolynone (**5**), along with the endiyne unit, suggest a polyketide origin. Liquid cultures of the fungus were grown in the presence of [1-^{13}C], [2-^{13}C], and [1,2-$^{13}C_2$] sodium acetate. Since the compounds are unstable, the labelled metabolites were reduced and transformed to the *p*-bromobenzoates in order to study the incorporation pattern. In the case of both di-*p*-bromoacetates, carbons 1, 3, 4, 7, and 9 were enhanced in the [1-^{13}C]acetate experiment and carbons 2, 5, 6, and 8 in the [2-^{13}C] case (illustrated in Fig. 2 for compound **1**). In the case of the C-1 labelling, the signals for C-3 and C-4 show some coupling, indicating that a significant number of molecules incorporating two labelled acetate units were present. In the case of the [1,2-C_2] acetate, C-9 appeared as an enhanced singlet, while all the other signals appeared as doublets. This implies that the compounds are norpentaketides, in which the methyl carbon of one of the acetate units has been lost (see Fig. 2). A 2D-INADEQUATE experiment on **2***a* obtained from the [1,2-$^{13}C_2$]acetate confirmed the spin-coupled carbons and firmly identified the carbon pairs as: C-1, C-5; C-2, C-3; C-4, C-6; and C-7, C-8 (see Experimental).

Most natural polyacetylenes are acetate derived, many by degradation of oleic acid (14). Loss of the terminal methyl via the sequence -CH_3 → CH_2OH → -CHO → -COOH and decarboxylation to yield the terminal acetylene is well documented (2, 14). One possible pathway is illustrated in Scheme 1 in which we use the carboxyl labelled case for illustrative purposes. The intermediate **7** may be derived from five acetate units or by degradation of oleic acid. Ring closure, adjustment of the oxidation level, and loss of the terminal methyl via oxidation and decarboxylation leads to sistodiolynne (**1**). An alternative scheme



8

involving contraction of a six-membered ring derived from the tautomeric (with **7**) allene **8** is discussed in ref. 15.

The ^{13}C-labelling pattern established for sistopyrone is shown in Fig. 3 and suggests that it is derived by oxidative ring expansion of the sistodiolynne skeleton. Scheme 2 depicts a possible biogenetic pathway from sistolynone (**5**) to sistopyrone involving a Baeyer–Villager oxidation, dehydration, adjustment of side-chain oxidation level, and tautomerization to the allene. Again we choose the [1-^{13}C]acetate labelled case for illustrative purposes. As in the case of sistodiolynne, the signals for C-3 and C-4 appear as doublets, flanking a central singlet, indicating that these two carbons arise from acetate carbonyls.

The insoluble black polymeric material resulting when the crude extracts were exposed to oxygen was subjected to combustion analysis and shows an approximate empirical formula C_3H_2O that is not consistent with any of the individual compounds isolated, but suggestive of a general oxidative polymerization. We conclude that the graphite-like particles observed on solid agar media result from polymerization of the polyacetylenes produced by the fungus. The polymer was not investigated further. The instability of the compounds also precluded any investigation of biological activity.

Experimental

General methods

HREIMS were recorded on a Kratos AEI MS-50 mass spectrometer. FTIR spectra were recorded on a Nicolet 7199 FTIR and Nicolet MX-1 FTIR. NMR (^{1}H and ^{13}C) were obtained on a Varian Unity-500 spectrometer and Bruker WH-300, WM-360, and WH-400 spectrometers. NOE experiments were determined in the difference mode. The following 2D experiments, COSY, HMQC, and HMBC, were obtained on a Varian Unity-500 spectrometer. INADEQUATE was performed using a Bruker WH-300 spectromter. UV spectra were determined on a Hewlett Packard 8450A diode array spectrophotometer. Optical rotations were determined using a Perkin Elmer 241 polarimeter. Circular dichroism (CD) spectra were measured using a Jasco SS-20-2 spectropolarimeter. Preparative thin-layer chromatography (PTLC) was performed on E. Merck precoated 20 × 20 glass plates of silica gel 60 F-254. Hexanes refer to light petroleum (bp 60–68°C). All solvents were distilled prior to use.

Description of the fungus

In culture, *Sistotrema raduloides* (UAMH 7326) is moderately slow growing, reaching the edge of the petri dish in 4 or 5 weeks. It forms a dense, moderately thick, felty mat of mycelium. On 2% malt extract agar, UAMH 7326 developed a lattice-like network of reddish brown hyphal tufts that was associated with droplets of clear or amber liquid. On malt and other media such as cornmeal agar, the isolate formed yellowish to reddish brown sclerotia. Microscopic features of the fungus were observed in slide culture preparations in which the fungus is inoculated onto a block of cereal agar placed between two sterile glass coverslips. Microscopic preparations are made when the mycelium of the fungus grows onto the glass surfaces (16). Flaky black deposits were noticed on the glass coverslips and on the surface of colonies grown on various media when growth was examined under a dissecting microscope. These deposits were detected easily in UAMH 7326, but observed sparsely only in two of five other isolates of *S. raduloides*.

Microscopically, the isolate from air samples in Puerto Rico

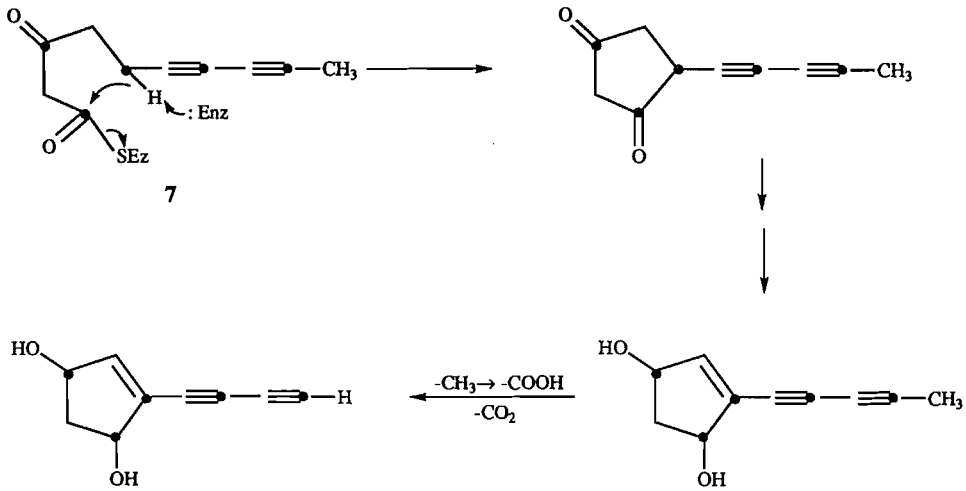
Scheme 1.



Scheme 2.

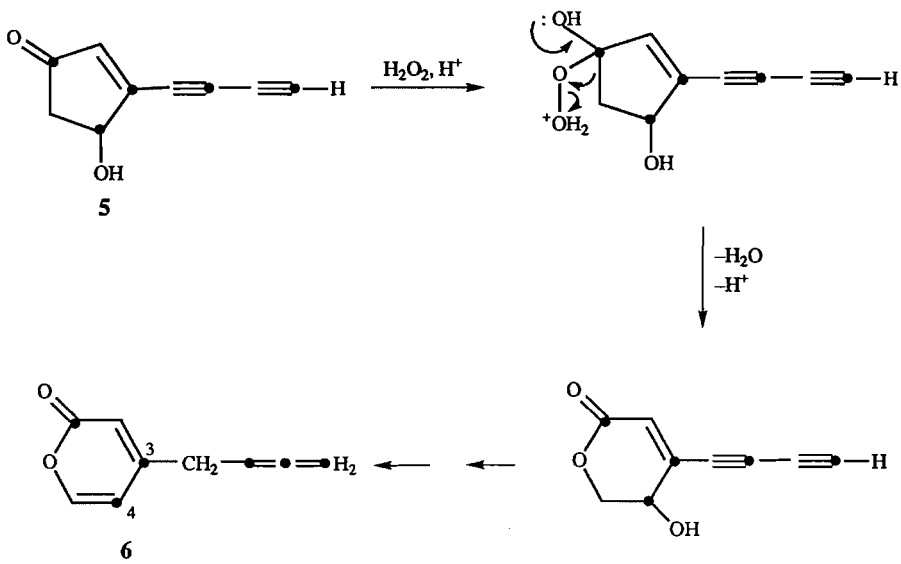


Fig. 3. Acetate labelling patterns in sistopyrone (**6**).

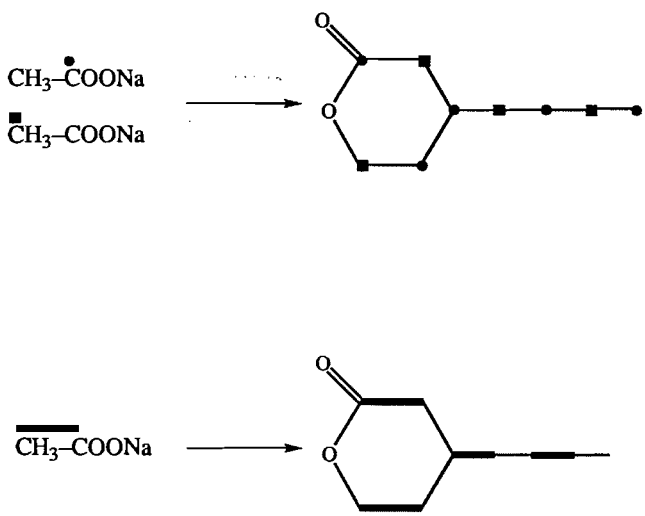

resembled other isolates of *S. raduloides* in forming conidia and yellowish-brown sclerotia having short spinelike appendages, but it lacked clamp connections. A characteristic feature of *S. raduloides*, as noted by others (1, 17, 18), is the formation of hyaline, thin-walled, pyriform (tear-drop) or obovate (egg-shaped) conidia having a flat basal scar. A single conidium forms at the end of a lateral branch and this branch proliferates sympodially to form additional short, blunt, branches, each of which forms a conidium. The entire structure may be simple with two to six conidia or the conidiophore may proliferate to form a small cluster of conidia. Detachment of the mature conidium leaves a truncate scar.

Where a fungus has more than one distinctive stage in its life cycle, it has been common practice to name both states. The solitary blastic conidia borne sympodially on blunt denticles are unusual among the Corticiaceae but this asexual stage has not previously been connected to a genus of Hyphomycetes. *Dexhowardia* Taylor (19) was described for a single species *Dexhowardia tetraspora* Taylor for a fungus suspected to have basidiomycetous affinity, and which lacked

For personal use only.

clamp connections, and formed conidia on blunt denticles in the manner of *S. raduloides*. A further report on the biology of *S. raduloides* and its possible connection with *Dexhowardia* will be submitted to a mycological journal by L.S.

Growth of *Sistotrema raduloides* and isolation of the metabolites

Sistotrema raduloides strain UAMH 7326 was grown on Sabouraud dextrose agar (20 g/L) and the mycelial suspension was used to inoculate five 4-L Erlenmeyer flasks, each containing 2 L of Sabouraud dextrose broth (15 g in 1 L of redistilled water). The cultures were grown as still cultures at room temperature for 5 weeks. The culture broth was separated from the mycelium by filtration and the volume reduced under vacuum to ca. 400 mL. The concentrated broth was first extracted with methylene chloride and then with ethyl acetate. The organic layers were dried separately with anhydrous sodium sulphate, filtered, and concentrated to small volume under reduced pressure. Polymerization occurred if the solvent was completely removed. The methylene chloride extract was separated by preparative TLC and gave compounds **1**, **5**, and **6**. The ethyl acetate extract gave mainly compound **1**.

Labelling experiments

Liquid cultures were prepared as described above. A solution of [1-^{13}C] sodium acetate (5 mL, 0.2 mol/L) was added under sterile conditions 3 days after inoculation of the fungus. Four further additions were made at 2 day intervals, and the culture was allowed to grow for 5 weeks. The same procedure was followed using [2-^{13}C] sodium acetate and [1,2-^{13}C] sodium acetate. The isolation procedure was the same as described above.

*Sistodiolynne (**1**)*

(−)1*R*,3*S*-4-Butadiynyl-4-cyclopentene-1,3-diol, **1**, was isolated as an unstable colorless oil; TLC: R_f 0.18 (CH_2Cl_2:CH_3OH, 19:1); UV (MeOH): 310, 252 nm; FTIR ($CDCl_3$, cast): 3544 (br, OH), 3287 (≡C-H), 2230 (C≡C) cm^{-1}; ^{1}H NMR (acetone-d_6) δ: 6.30 (1H, dd, J = 2.0, 1.0 Hz, H-5), 4.70 (1H, d, J = 6.5 Hz, OH-1β), 4.62 (1H, bdd, H-1α), 4.55 (1H, m, H-3α), 4.48 (1H, d, J = 6.5 Hz, OH-3β), 3.30 (1H, s, H-9), 2.74 (1H, ddd, J = 13.4, 7.0, 7.0 Hz, H-2α), 1.50 (1H, ddd, J = 13.5, 6.2, 6.2 Hz, H-2β); ^{13}C NMR (acetone-d_6) δ: 146.7 (C-5, d), 129.8 (C-4, s), 76.9 (C-6, s), 76.1 (C-1, d), 74.1 (C-9, d), 73.4 (C-3, d), 72.0 (C-7, s), 68.4 (C-8, s), 44.7 (C-2, t); HREIMS (probe 100°C), *m/z* calcd. for $C_9H_8O_2$ (M^+): 148.0509; found: 148.0524, 147 ($C_9H_7O_2$, 25%), 130 (C_9H_6O, 10%), 119 (C_8H_7O, 49%), 102 (C_8H_6, 62%), 76 (C_6H_4, 89%), 74 (C_6H_2, 53%).

*O,O-Diacetylsistodiolynne (**1**a)*

Treatment of sistodiolynne (3–4 mg, estimated) in CH_2Cl_2 with acetic anhydride (0.2 mL) and pyridine (1.0 mL) for 12 h, followed by removal of the solvents under vacuum, gave an oil, which was purified by preparative TLC using 5% MeOH in CH_2Cl_2 and was eluted from the plate with deuterated chloroform; TLC: R_f 0.72; FTIR ($CDCl_3$, cast): 3251 (≡C-H), 1737)-COO-) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 6.44 (1H, bd, J = 2.2 Hz, H-5), 5.60 (2H, m, H-1α3α), 2.95 (1H, ddd, J = 14.6m 6.7, 6.7 Hz, H-2α), 2.50 (1H, s, H-9), 2.08 (3H, s, OAc), 2.02 (3H, s, OAc), 1.75 (1H, ddd, J = 14.6, 4.2, 4.2 Hz, H-2β); HREIMS (probe 100°C) *m/z* calcd. for $C_{13}H_{12}O_4$ (M^+): 232.0736; found: 232.0730, (5%), 172 ($C_{11}H_8O_2$, 11%), 130 (C_9H_6O, 100%), 102 (C_8H_6, 34%).

Reduction and *p*-bromobenzoylation of sistodiolynne (**1**)

Catalytic hydrogenation (Pd–C, EtOAc, 40 psi (1 psi = 6.9 kPa)) of **1** provided a mixture of the saturated isomers (**2***a* and **3***b*), which were not separable by TLC. The mixture was treated with *p*-Br-BzCl (40 mg) and pyridine (2 mL) in CH_2Cl_2 with stirring at room temperature for 24 h. The resulting mixture was concentrated under vacuum to dryness. Separation of the di-*p*-bromobenzoate derivatives (**2***a* and **3***a*) was achieved by preparative TLC (5% EtOAc in hexanes, developed several times).

*Compound **2**a*

(−)1*S*,3*S*-Di-*p*-bromobenzoyloxy-4*S*-butylcyclopentane, **2***a*, was isolated as a yellowish sticky solid that could not be crystallized. TLC: R_f 0.31 (hexane:EtOAc, 9:1); FTIR (CH_2Cl_2, cast), 2957, 2955 (C-H), 1717 (-COO-) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.9 (4H, m), 7.5 (4H, m), 5.4 (1H, m), 5.1 (1H, ddd, J = 7.2, 4.4, 3.8 Hz), 2.6 (1H, ddd, J = 15.5, 7.5, 7.2 Hz), 2.5 (1H, m), 2.3 (1H, dddd, J = 14.0, 7.6, 2.1, 2.1 Hz), 2.1 (1H, bd, J = 15.5 Hz), 1.7 (1H, ddd, J = 14.0, 9.3, 5.8 Hz), 1.6–1.3 (6H, m), 0.9 (3H, t, J = 6.7 Hz); ^{13}C NMR ($CDCl_3$) δ: 165.6 (2C, s), 131.7 (4C, d), 131.1 (4C, d), 129.3 (2C, s), 128.1 (2C, s), 80.5 (C-3, d), 75.6 (C-1, d), 44.0 (C-4, d), 38.9 (C-2, t), 37.5 (C-5, t), 33.1 (C-6, t), 30.1 (C-7, t), 22.8 (C-8, t), 14.0 (C-9, q); HMQC (125, 500 MHz) δ: 80.5 ⇔ 5.1; 75.6 ⇔ 5.4; 44.0 ⇔ 2.5; 38.9 ⇔ 2.6, 2.1; 37.5 ⇔ 2.3, 1.7; 33.1 ⇔ 1.6, 1.3; 30.1 ⇔ 1.3; 22.8 ⇔ 1.3; 14.0 ⇔ 0.9; HREIMS (probe 150°), *m/z* calcd. for $C_{23}H_{24}O_4{}^{79}Br^{81}Br$ (M^+ + 2): 524.0021; found: 524.0001 (2%), 522 (M^+, $C_{23}H_{24}O_4{}^{79}Br_2$, 1%), 322 ($C_{16}H_{19}O_2{}^{79}Br$, 3%), 122 ($C_9H_{14}$, 100%), 80 ($C_6H_8$, 48%).

*Compound **3**a*

(−)1*S*,3*S*-Di-*p*-bromobenzoyloxy-4*R*-butylcyclopentane, **3***a*, was recrystallized from hexane to give fine white needles, mp 110–111°C; TLC: R_f 0.27 (hexane:EtOAc, 9:1); $[\alpha]_D{}^{24}$ −14 (*c* 0.004, hexanes); CD, $\Delta\epsilon_{241}$: −3.6 (*c* 8.8 × 10^{-4}, hexanes); FTIR (CH_2Cl_2 cast) similar to **2***a*; ^{1}H NMR ($CDCl_3$) δ: 7.9 (2H, J = 9.0 Hz), 7.8 (2H, d, J = 9.0 Hz), 7.6 (2H, J = 9.0 Hz), 7.5 (2H, J = 9.0 Hz), 5.5 (1H, dddd, J = 10.0, 7.5, 5.0, 2.5 Hz), 5.4 (1H, bdd, J = 5.0, 4.1 Hz), 2.6 (1H, ddd, J = 13.7, 7.5, 7.0 Hz), 2.4 (1H, ddd, J = 15.5, 8.0, 5.0 Hz), 2.2 (1H, bd, J = 15.5 Hz), 2.0–2.1 (1H, m), 1.8 (1H, ddd, J = 13.7, 10.0, 5.2 Hz), 1.6–1.3 (6H, m), 0.9 (3H, m); ^{1}H–^{1}H COSY ($CDCl_3$) δ: 5.5 (H-1α) ⇒ 2.6 (H-5α), 2.4 (H-2α), 2.2 (H-2β), 1.8 (H-5β); 5.4 (H-3α) ⇒ 2.4 (H-2α), 2.2 (H-2β), 2.1 (H-4α); 2.6 (H-5α) ⇒ 5.5 (H-1α), 2.1 (H-4α), 1.8 (H-5β); 2.4 (H-2α) ⇒ 5.5 (H-1α), 5.4 (H-3α), 2.2 (H-2β); 2.2 (H-2β) ⇒ 5.5 (H-1α), 5.4 (H-3α), 2.4 (H-2α), 1.8 (H-5β); 2.1 (H-4α) ⇒ 5.4 (H-3O), 2.6 (H-5α), 1.8 (H-5β), 1.6–1.3 (H-6); 1.8 (H-5β) ⇒ 5.5 (H-1α), 2.6 (H-5α), 2.1 (H-4α); 1.6 (H-6α) ⇒ 2.1 (H-4α), 1.3 (H-6β), 1.5–1.3 (H-6, 7); differential nOe: H-4α to H-3α 15%, H-2α 10%, H-5α 7%, H-6α 7%; H-5α to H-5β 34%, H-4α 14%, H-1α 12%; ^{13}C NMR ($CDCl_3$) δ: 165.5 (1C, s), 165.4 (1C, s), 131.8 (2C, d), 131.6 (2C, d), 131.1 (2C, d), 131.0 (2C, d), 129.5 (1C, s), 129.3 (1C, s), 128.1 (2C, s), 76.8 (C-3, d), 75.0 (C-1, d), 43.6 (C-4, d), 39.8 (C-2, t), 37.7 (C-5, t), 30.4 (C-7, t), 29.1 (C-6, t), 22.8 (C-8, t), 14.0 (C-9, q), HMQC (125, 500 MHz) δ: 76.8 ⇔ 5.4; 75.0 ⇔ 5.5; 43.6 ⇔ 2.1; 39.8 ⇔ 2.4, 2.2; 37.7 ⇔

Optical absorption spectra of solvated electrons in 1-butylamine–water mixed solvents

Yixing Zhao and Gordon R. Freeman

Abstract: The optical absorption spectra of e_s^- in 1-butylamine–water mixed solvents increase smoothly in energy and intensity as the water content is increased, with the exception of a small decrease in intensity on going from 95 to 100 mol% water. At 298 K the value of $G\epsilon_{max}$ increases from 1.42×10^{-21} m^2/16 aJ (8.6×10^3 e_s^- L/100 eV mol cm) in pure 1-butylamine to 8.3×10^{-21} m^2/16 aJ (50×10^3 e_s^- L/100 eV mol cm) in pure water, and the value of E_{Amax} increases from 115 zJ (0.72 eV) to 278 zJ (1.74 eV). In the pure amine, if $G(e_s^-) = 0.27$, then $\epsilon_{max} = 5.3 \times 10^{-21}$ m^2/e_s^- (3200 m^2/mol). The solvent composition dependences of $G\epsilon_{max}$ and E_{Amax} indicate little selective solvation of e_s^- by water; this might be due to relatively "ideal" mixing of water and amine in the binary solvents. The temperature coefficient $-dE_{Amax}/dT = 0.43$ zJ/K in pure 1-butylamine, 0.47 in pure water, and has a minimum of 0.27 in the 50:50 mixture.

Key words: 1-butylamine–water mixed solvents, optical absorption spectra, solvated electron, temperature dependence.

Résumé : Dans des solvants mixtes 1-butylamine–eau, les spectres d'absorption optique des e_s^- augmentent en façon monotone, tant en énergie qu'en intensité, avec une augmentation de la quantité d'eau, à l'exception d'une légère diminution en passant de 95 à 100% d'eau. À 298 K, la valeur du $G\epsilon_{max}$ augmente de $1{,}42 \times 10^{-21}$ m^2/16 aJ ($8{,}6 \times 10^3$ e_s^- L/100 eV mol cm) dans la 1-butylamine pure à $8{,}3 \times 10^{-21}$ m^2/16 aJ (50×10^3 e_s^- L/100 eV mol cm) dans l'eau pure et les valeurs de E_{Amax} augmentent de 115 zJ (0,72 eV) à 278 zJ (1,74 eV). Dans l'amine pure, si $G(e_s^-) = 0{,}27$, alors $\epsilon_{max} = 5{,}3 \times 10^{-21}$ m^2/e_s^- (3200 m^2/mol). Les dépendances de $G\epsilon_{max}$ et de E_{Amax} avec la composition du solvant indiquent qu'il se produit très peu de solvatation spécifique des e_s^- par l'eau; ceci peut être causé par le mélange relativement «idéal» de l'eau et de l'amine dans les solvants binaires. Le coefficient de température $-dE_{Amax}/dT = 0{,}43$ zJ/K dans la 1-butylamine pure, 0,47 dans l'eau pure et elle passe par un minimum de 0,27 à un mélange 50 : 50.

Mots clés : solvants mixtes 1-butylamine–eau, spectres d'absorption optique, électron solvaté, dépendance sur la température.

Introduction

An excess electron in a polar liquid can occupy a localized state as a result of its interaction with a certain number of neighboring molecules of the solvent. When this interaction leads to a thermally relaxed state of the electron with respect to the medium, the electron is called a solvated electron, e_s^- (1, 2).

The energy levels of e_s^-, as reflected by the energy of the optical absorption maximum E_{Amax}, are determined as much by details of the liquid structure as by the dielectric constant or the molecular dipole moment (3–5). The solvated electron in water has an intense optical absorption band in the visible region, with a peak at 715 nm, which corresponds to E_{Amax} = 277 zJ (6),[2] and $G\epsilon_{max} = 8.3 \times 10^{-21}$ m^2/16 aJ (5.0×10^4 e_s^- L/100 eV mol cm) (7, 8) at 298 K.

The values of E_{Amax} are similar in pure *n*-alcohols and water (9–11). However, there is a marked dependence of E_{Amax} on the composition of alcohol–water mixed solvents (10). The values of E_{Amax} in amines are much smaller than that in water (4, 12). It is therefore interesting to discover the composition dependence of e_s^- spectra in 1-butylamine–water mixed solvents. Data are reported in this paper.

Experimental

Materials

1-Butylamine (Fluka, >98%) was treated for 24 h with potassium and sodium alloy under UHP argon (99.999%, Liquid Carbonic Canada Ltd.) at 330 K, to remove electron scavengers. Fractional distillation was as reported in ref. 13; spectroscopic analysis was not done. The water content, measured by Karl–Fisher titration, was 0.09 mol%. The solvated electron half-life of pure 1-butylamine after a 100 ns pulse of 340 fJ (2.1 MeV) electrons (4 J/kg) at 298 K was about 4 μs. The

purification of water and the half-life of solvated electrons in water were as in ref. 14.

Techniques

The optical system, irradiation facilities, the silicon detector for wavelengths <1050 nm (14), the dosimetry (10), and the calculation of $G\epsilon_{max}$ (15) were described in the references cited. Bauch and Lomb monochromator gratings 1350 (No. 33-86-02) for 400–800 nm, 1350 (No. 33-86-03) for 700–1200 nm, and high-intensity monochromator (No. 33-86-78) for 1100–2600 nm were used in the measurements. Corning filters were placed in front of the monochromator to eliminate higher order light interference: CS 4-97 for 400–500 nm, CS 3-72 for 500–650 nm, CS 2-58 for 650–1050 nm, LL-1000 for 1050–1800 nm, and RL-1500 for 1800–2600 nm.

For the measurement of absorbance at wavelengths >1050 nm, an InSb infrared detector (model I935-IS) was used and is sensitive from 1050 to 2600 nm. The 3–97% response time of the detector, amplifier, and transient digitizer (Tekronix R7912) was 35 ns. The signal-to-noise ratio of the differential amplifier (Tektronix 7A13) was increased by using the 5 MHz filter, which gave a system response time of 96 ns.

Sample preparation was similar to that reported in ref. 14. Spectrosil optical cells were used: 10 mm pathlength for pure water to 70 mol% water, and 5 mm path for 50 mol% water to pure 1-butylamine.

Briefly, each 100 ns pulse of 340 fJ (2.1 MeV) electrons delivered about 4 Gy to the sample.

Physical properties

The normal freezing point of 1-butylamine is 224 K, and the normal boiling point is 351 K. The liquid is completely miscible with water.

The optical absorption spectra were measured at the following compsitions in mol% water: 0.0, 10.0, 30.0, 50.0, 70.0, 90.0, 95.0, 99.0 and 100.0. The densities and viscosities of the mixed solvent (16), except for 95.0 and 99.0 mol% water, are listed in Table 1. The relative permittivity of water at 298 K is 78.4 (17), and that of 1-butylamine is 4.78 (18).

Results and discussion

Absorbance and shape of e_s^- optical spectra at 298 K: solvent dependence

The optical spectra of e_s^- in 1-butylamine–water mixed solvents at 298 K are shown in Fig. 1. The spectra have no fine structure.

As the amount of water is increased in 1-butylamine the optical absorption band changes (Figs. 1–3, Table 1): (*i*) E_{Amax} increases; (*ii*) $G\epsilon_{max}$ increases; (*iii*) the band becomes narrower ($W_{1/2}$ decreases), except at >90 mol% water where the band broadens slightly.

The shift of E_{Amax} with water content in 1-butylamine (Fig. 2) is much closer to linear than is that in 1- or *tert*-butyl alcohol–water mixed solvents (Fig. 2 and ref. 10). This indicates that the amine–water solvents are less structured than are alcohol–water solvents. The spectra in 1-butanol–water and *tert*-butanol–water shift greatly with the addition of 10 mol% of water to the alcohol, which indicates that 10 mol% of water in the alcohols produces a particular structure (molecular packing) that affects the electron trap. This type of structure evidently does not occur in 1-butylamine–water mixed solvents. Hydrogen bonds in RNH_2 are weaker than those in ROH,

because the dipole moment of N–H is smaller than that of O–H (19), so the former liquids are less ordered (20).

The change of viscosity with water content in *t*-BuOH (ref. 21 and broken curve in Fig. 2) also indicates that a particular liquid structure exists at 10 mol% water, whereas there is no evidence for such a structure near 10 mol% water in 1-butylamine (+ curve in Fig. 2).

In view of the greater polarity of water than of 1-butylamine, one might have expected electrons to be more selectively solvated by water than is indicated by the gradual increases of E_{Amax} and $G\epsilon_{max}$ with water content (Figs. 2 and

3). Many years ago we began the study of electron spectra and reactivities in alcohol–water mixed solvents expecting to find subtle changes and, instead, found large, structured changes. We have now begun the study of electron behavior in amine–water solvents, and expected much larger solvent-composition effects than we have observed. It seems that water and 1-butylamine form relatively ideal solutions; this might be related to the fact that 1-butylamine and water are completely miscible, whereas 1-butyl alcohol and water are not.

However, the effect of solvent composition on e_s^- may not be as ideal as it appears in the change of E_{Amax}. The half-life of e_s^- changes markedly with the composition of 1-butylamine–water mixtures (Table 2). As water is added to 1-butylamine, $t_{1/2}$ changes from 3 μs in pure butylamine to the minimum value of 0.5 μs in 50 mol% butylamine; then, when the 1-butylamine is decreased to 1 mol%, $t_{1/2}$ reaches the maximum value of 16 μs, a bit higher than that in pure water. This

incidates that the solvent structure in the region of 50 mol% 1-butylamine is different from those of the two extremities.

The value of $G\epsilon_{max}$ increases at 298 K from 1.42×10^{-21} m^2/16 aJ (8.6×10^3 e_s^- L/100 eV mol cm) in pure 1-butylamine to 8.3×10^{-21} m^2/16 aJ (50×10^3 e_s^- L/100 eV mol cm) in pure water (Table 1). The value in water agrees with that previously reported (6, 8).

The yield $G(e_s^-)$ in water at 298 K is 2.7 ent/16 aJ (6), and $\epsilon_{max} = 3.1 \times 10^{-21}$ m^2/e_s^- (1860 m^2/mol). In 1-butylamine at room temperature $G(e_s^-) = 0.27$ (22), which indicates $\epsilon_{max} = 5.3 \times 10^{-21}$ m^2/e_s^- (3200 m^2/mol).

The observed e_s^- are free ions. The low yield of e_s^- in 1-butylamine compared to that in water correlates (23, 24) with the lower value of the dielectric permittivity in the former than in the latter, 4.78 (18) and 78.4 (17), respectively.

Composition dependence of E_r, E_b, $W_{1/2}$, and asymmetry W_b/W_r at 298 K

Several parameters are used to describe the characteristics of the optical spectrum of e_s^-. E_r and E_b are the energies on the low-energy (red) and high-energy (blue) sides of the band at half the maximum absorbance. The width of the band at half height $W_{1/2}$ is divided at E_{Amax} into W_b (high-energy side) and W_r (low-energy side). The asymmetry of the band is represented by W_b/W_r. In Fig. 3 the values of E_r, E_b, $W_{1/2}$, and W_b/W_r are plotted against composition of 1-butylamine–water mixtures at 298 K. The values of E_r could only be obtained in pure butylamine and 10 mol% water near their freezing points, around 225 K.

The value of E_r (Fig. 3) increases smoothly from 1-butylamine to water, similar to the change of E_{Amax} (Fig. 2). However, there is a big jump in E_b from pure butylamine to 10 mol% water, and then E_b increases gently as more water is added.

The optical absorption at λ <1000 nm (E >200 zJ) had a long-lived tail that extended more than 100 μs (Fig. 4 and Table 2). The long-lived entity has not been identified. The absorbance due to e_s^- is taken as the portion above the long-lived tail. The tail decreases with increase of water content and increase of temperature (Fig. 4). The unidentified entity is only stable at low temperature and in an adequate amine environment.

The band asymmetry W_b/W_r increases from 2.3 in pure 1-butylamine to 2.8 in 10 mol% water, then decreases as more water is added, reaching a minimum of 1.26 at 70 mol%, and then increases slightly to 1.53 in pure water (Table 1 and Fig. 3). Thus the solvent composition has a more complex influence on the band asymmetry than on E_{Amax}.

Temperature effect on the optical spectra of e_s^-

Figure 4 shows the optical spectra of e_s^- in pure 1-butylamine to 50 mol% water at different temperatures. As the temperature is decreased the values of $G\epsilon_{max}$ and E_{Amax} increase.

The temperature coefficient of E_{Amax} has a minimum in 50 mol% water (Figs. 5 and 6). The e_s^- half-life also has a minimum at 50 mol% water (Table 2). These facts are probably related to the solvent structure, but we have no specific suggestion to offer.

Unusual behavior of the conductivity of $LiNO_3$ in *tert*-butanol: ion clustering or ion-pair aggregation

Yixing Zhao and Gordon R. Freeman

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Abstract: The electrical conductance of $LiNO_3$ in *tert*-butanol–water mixed solvents changes gradually from "normal" in pure water to "abnormal" in pure *tert*-butanol. In water the measured specific conductance increases with increase of temperature, and in *tert*-butanol the conductance *decreases* with increase of temperature. In pure *tert*-butanol, the electrical conductances of NH_4ClO_4 and $LiClO_4$ increase with the salt concentration and temperature at lower temperatures, but decrease at higher temperatures. The molar conductivity $\Lambda_0(10^{-4}$ S m^2 mol$^{-1})$ in *tert*-butanol at 300 K is 5.0 for NH_4ClO_4 and 4.0 for $LiClO_4$. Both activation energies E_{Λ_0} are 17 kJ mol^{-1}, which gives an unusual correlation between Λ_0 and viscosity η(mPa s): $\Lambda_0 \propto \eta^{-0.4}$. The values of Λ_0 for NH_4NO_3 and $LiNO_3$ in *tert*-butanol could not be measured, because ion aggregation is significant even at the lowest concentrations required to obtain conductances sufficiently above that of the solvent. The measured temperature coefficient of $LiNO_3$ conductance in *tert*-butanol is negative. Ion clustering of nitrate salts is attributed to poor solvation of the planar NO_3^- ions by the globular *tert*-butanol molecules. Ion aggregation in *tert*-butanol increases with increasing T, due to the relatively rapid decrease of the value of ϵT. Corrections are listed for reaction kinetics parameters for nitrate salts in pure *tert*-butanol solvent reported in Can. J. Chem. **73**, 392 (1995).

Key words: *tert*-butanol, ion-pair aggregation, lithium nitrate, electrical conductance, solvent effects.

Résumé : Dans des solvants mixtes *tert*-butanol–eau, la conductivité électrique du $LiNO_3$ passe graduellement de «normale» dans l'eau à «anormale» dans le *tert*-butanol pur. Dans l'eau, la conductivité spécifique mesurée augmente avec une augmentation de la température alors que, dans le *tert*-butanol, la conductivité *diminue* avec une augmentation de la température. Dans le *tert*-butanol, aux basses températures, les conductivités électriques du NH_4ClO_4 et du $LiClO_4$ augmentent avec une augmentation de la concentration et de la température alors que, à des températures plus élevées, elles diminuent. La conductivité molaire, $\Lambda_0(10^{-4}$ S m^2 mol$^{-1})$, dans le *tert*-butanol, à 300 K, est égale à 5,0 pour le NH_4ClO_4 et à 4,0 pour le $LiClO_4$. Les deux énergies d'activation, E_{Λ_0}, sont égales à 17 kJ mol^{-1}; ceci conduit à une corrélation inhabituelle entre Λ_0 et la viscosité, η (mPa s): $\Lambda_0 \propto \eta^{-0,4}$. Il n'a pas été possible de mesurer les valeurs de Λ_0 pour le NH_4NO_3 et le $LiNO_3$ dans le *tert*-butanol parce que l'agrégation des ions est suffisamment importante, même aux plus faibles concentrations requises pour obtenir des conductivités qui soient suffisamment plus élevées que celle du solvant. Le coefficient de température mesuré pour la conductivité du $LiNO_3$ dans le *tert*-butanol est négatif. On attribue la formation d'agrégats ioniques dans les sels nitriques à une mauvaise solvatation des ions NO_3^- planaires par les molécules globulaires de *tert*-butanol. L'agrégation dans le *tert*-butanol augmente avec une augmentation de la température et ceci est causé par la diminution relativement rapide de la valeur ϵT. On présente une liste de corrections pour les paramètres cinétiques de réactions des nitrates, dans le *tert*-butanol pur agissant comme solvant, qui ont été rapportés dans la Can. J. Chem. **73**, 392 (1995).

Mots clés : *tert*-butanol, agrégation des paires des ions, $LiNO_3$, conductivité électrique, effets de solvant.

[Traduit par la rédaction]

Introduction

The molar electric conductivity of an electrolyte solution decreases as the concentration of electrolyte is increased. The decrease in dilute solutions in hydroxylic solvents is attributed to the ionic atmosphere effect (1, 2) or the formation of ion pairs (3, 4). The formation of ion pairs Li_s^+, $NO_{3,s}^-$, where the subscript s represents "solvated," in different alcohols has been reported for pure propanols (5), 2-butanol (4), 1-hexanol, 1-octanol, and 1-decanol (6). However, there has been no report about the molar conductivity of lithium nitrate in *tert*-butanol. In connection with the study of the reactivity of solvated electrons e_s^- with nitrate ions (7), the electric conductances of lithium nitrate, ammonium nitrate, lithium perchlorate, and ammonium perchlorate were measured in the whole range of *tert*-butanol–water mixtures.

Unusual behavior was found for lithium nitrate in pure *tert*-butanol. It appears to be related to the aggregation of ion pairs found for lithium salts in aprotic solvents (8, 9). The conductance data are presented in this paper.

Experimental

The conductance measurement technique was the same as that reported in ref. 10, except that for the measurements of the

four salts in 10 mol% water and in pure *tert*-butanol, a freshly made solution was used for each temperature to minimize the formation of impurities during heating.

Results and discussion

Conductance of $LiNO_3$: "normal" in water, "abnormal" in *tert*-butanol

The dependences of specific conductance on the concentration of $LiNO_3$ in water – *tert*-butanol mixed solvents at different temperatures are plotted in Figs. 1 and 2. In 100–70 mol% water solvents the conductance increases linearly with the increase of $LiNO_3$ concentration over the range used (Fig. 1). However, as the water content of the solvent is further decreased, the conductance becomes sublinear with concentration (Fig. 2). In 100–30 mol% water the conductance increases monotonically with temperature. However, in 10 mol% water the conductance *decreases* at $T > 320$ K (Fig. 2). In pure *tert*-butanol, as the temperature is increased the conductance decreases monotonically (Fig. 2).

Figures 1 and 2 show the gradual transition of conductance behavior of $LiNO_3$ as the *tert*-butanol content of the solvent is increased. When the lines are gently sublinear, we used initial slopes of the curves to estimate the limiting molar conductivity Λ_0. For severely bent curves the values estimated in this way are too small to be Λ_0.

Comparison of molar conductivities of salts in *tert*-butanol

The measured specific conductances of four salts in *tert*-butanol are shown in Fig. 3. We see again the change from "normal" to "abnormal" behavior. For NH_4ClO_4 and $LiClO_4$, the specific conductance increases linearly with increase of concentration at temperatures around 300 K. However, as the temperature is increased the lines become sublinear, and the specific conductance *decreases* at higher temperatures. This behavior is more marked for the NH_4NO_3 solution. The concentration and temperature at which the line becomes sublinear decrease from NH_4ClO_4 to $LiClO_4$ to NH_4NO_3 (Fig. 3). The conductance of $LiNO_3$ in *tert*-butanol is so low that we could not measure it at the low concentrations used for the other salts. At the higher concentrations used (Fig. 3), the conductance at a given concentration decreases monotonically with increasing temperature.

[e]In *tert*-butanol, from "initial slopes" of the plots in Fig. 4. The values for the nitrates are not Λ_0.

Figure 4 shows the Arrhenius plots of Λ_0 (for straight lines) and initial slopes (for curves, marked*) in *tert*-butanol. A linear Arrhenius plot is obtained for NH_4ClO_4 in the temperature range measured. However, it would likely be bent at higher temperatures. The ionic atmosphere effect calculated from the Debye–Hückel equation (1) is negligible at these concentrations (3% at the highest concentration used). For $LiClO_4$ the line bends at 328 K, and for NH_4NO_3 it seems to have bent at about 300 K. The Arrhenius activation energies obtained at lower temperatures for NH_4ClO_4 and $LiClO_4$ (Fig. 4) are 17 kJ mol^{-1}. The mean Arrhenius activation energy of fluidity ($1/\eta$) of *tert*-butanol (11) below 318 K (Fig. 4) is 38 kJ mol^{-1}. This indicates that the correlation between molar conductivities of the two salts and the viscosity η of pure *tert*-butanol is $\Lambda_0 \propto \eta^{-n}$, with $n \approx 0.4$, which is unusual and does not follow Walden's rule, $n = 1$ (1). The conductances of many salts (Table 1) in water (12) and pure 1- and 2-propanol solvents (13), and in 1- (10), iso- (12), and 2-butanol (4) approximately follow Walden's rule. However, for $LiNO_3$ in iso- (12) and 2-butanol (4), they deviate significantly from Walden's rule, with n = 0.7–0.8. More study is needed to understand the behavior of salt conduction in these solvents.

For NH_4NO_3, the apparent activation energy calculated from 300 to 308 K is 14 kJ mol^{-1}, and is nearly zero between 308 and 328 K (Fig. 4). This seems to indicate that clusters of nitrate and ammonium ions form in *tert*-butanol solvent at higher temperatures.

For $LiNO_3$, the Arrhenius plot has a negative slope at T >308 K (Fig. 4). The value of the initial conductance slope at 299 K (Fig. 3) is 0.5×10^{-4} S m^2 mol^{-1}, which is much lower than the molar conductivities of the other three salts at the same temperature (Table 2). We conclude that Li^+ and NO_3^- ions have a strong tendency to form multi-ion clusters in *tert*-butanol.

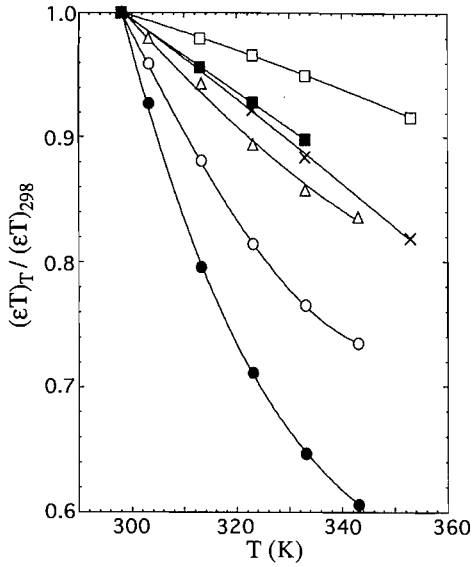
Fig. 5. Temperature dependence of ϵT of some solvents, normalized to the values at 298 K (ref. 16): □, water; ■, ethanol; ×, 1-propanol; ●, *tert*-butanol; ○, 10 mol% water in *tert*-butanol; △, 30 mol% water in *tert*-butanol.



Comparing the molar conductivities with physical parameters (14) of the four salts (Table 2), the conductivities correlate inversely with the molar density and lattice energy of the crystalline salts. The molar density and lattice energy reflect the ability of the ions to pack together. NH_4ClO_4 has the lowest molar density and lattice energy, and the highest molar conductivity (Table 2). The values for $LiClO_4$ and NH_4NO_3 are in the middle (but their relative order is reversed). $LiNO_3$ has the highest molar density and lattice energy, and the lowest molar conductivity. $LiNO_3$ is the smallest molecule, with ionic radii (15) $R_{Li^+} = 74$ pm and $R_{NO_3^-} = 189$ pm; NH_4ClO_4 is the largest molecule, with ionic radii (15) $R_{NH_4^+} = 146$ pm and $R_{ClO_4^-} = 200$ pm.

The approximate inverse relationships between the molar conductivity and the molar density and lattice energy of the salts indicate the extent of formation of ion clusters in *tert*-butanol. The *tert*-butanol molecules are globular; the planar NO_3^- ions would fit less well than the globular ClO_4^- ions into the liquid structure, so NO_3^- might be less tightly solvated than is ClO_4^- in *tert*-butanol. The solvent has a low relative permittivity ($\epsilon = 12.4$ at 298 K) (16), so the Coulombic attraction between oppositely charged ions is greater than in solvents with higher permittivities. These factors might explain the reversal of the electrolyte conductivity/crystal lattice energy orders of $LiClO_4$ and NH_4NO_3. We attribute the low observed conductivity of $LiNO_3$ solutions to the formation of ion clusters, mainly larger than pairs.

In aprotic solvents such as tetrahydrofuran, diethyl ether, pyridine, and diethyl carbonate, the salts LiNCS and LiBr form ion pairs that can agglomerate (8, 9). For example, the following species have been detected by various spectroscopic methods (8, 9):

[1] $Li_s^+ + NCS_s^- \rightleftharpoons LiNCS_s$

[2] $2\,LiNCS_s \rightleftharpoons (LiNCS)_{2,s}$

Table 3. Λ_0[a] of salts in *tert*-butanol at different temperatures.

	Λ_0 (300 K)	Λ_0 (308 K)	E_{Λ_0} (kJ mol^{-1})
NH_4ClO_4[b]	5.0	6.0	17
$LiClO_4$[b]	4.0	4.6	17
NH_4NO_3[c]	~5		
$LiNO_3$[c]	~4		

[a] 10^{-4} S m^2 mol^{-1}.
[b] Measured values.
[c] Estimated values, see text.

[3] $2\,(LiNCS)_{2,s} \rightleftharpoons (LiNCS)_{4,s}$

The trimer $(LiNCS)_{3,s}$ was not detected. The tetramer has a cubane-like structure. The species LiNCS is strongly polar, but the dimer and tetramer are nonpolar. The pairing and agglomeration reactions are entropy driven; each step involves partial desolvation of the species (9).

We suggest that, while *tert*-butanol is a protic solvent, the globular alkyl group hinders it from efficiently solvating Li^+ and NO_3^- ions.

The reason for the unusual temperature dependence of salt conductance in *tert*-butanol is that the product of the relative permittivity and temperature ϵT *decreases* rapidly as the temperature is increased. Ion association constants vary inversely as the product ϵT (17).

The value of ϵT for hydroxylic solvents decreases with increasing T, but the relative decrease is much faster for *tert*-butanol than for water and other simple alcohols (Fig. 5). Values (16) of ϵT normalized to that at 298 K are plotted in Fig. 5 for water, ethanol, 1-propanol, and *tert*-butanol, as well as for 10% and 30% water in *tert*-butanol. The behavior of ϵT for the 30 mol% water solvent is close to that of 1-propanol, and the conductance behavior of $LiNO_3$ in this mixed solvent is not excessively abnormal (Fig. 2).

Estimate of Λ_0 for $(NH_{4,s}^+ + NO_{3,s}^-)$ and $(Li_s^+ + NO_{3,s}^-)$ in *tert*-butanol

The initial slope method and attempts to fit the data to the Debye–Onsager (1, 2) and ion association (3, 4) models gave unreasonably low values of Λ_0 for the two nitrate salts. More complex models (18) have too many adjustable parameters for our purpose.

We suspect that the planar NO_3^- ions are not well solvated by the globular *tert*-butanol molecules, and that this makes the nitrate salts susceptible to ion clustering, or aggregation of ion pairs as in aprotic solvents (9). However, for the analysis of reaction rate constants (7) we need values of Λ_0. An indirect method of estimation has therefore been used.

The ratio of Λ_0 values for $NH_4ClO_4/LiClO_4$ equals 1.3 in both water and *tert*-butanol (Table 1). In water the values of Λ_0 for the two ammonium salts are equal, and those of the two lithium salts are equal (Table 1), so the same is assumed to be true in *tert*-butanol. We thereby arrive at the Λ_0 values listed in Table 3.

Corrections to parameter values in ref. 7

The values of some of the kinetics parameters estimated for

Table 4. Corrected parameter values for pure *tert*-butanol solvent in ref. 7.

Parameter	Location[a]	$LiNO_3$		NH_4NO_3	
		Old	New	Old	New
Λ_0 (10^{-4} S m^2 mol^{-1})	T2, F8	1.9	4	2.4	5

Radiolysis studies on the corrosion inhibitors 1-hexyn-3-ol, cinnamonitrile, and 1,3-diethyl-2-thiourea

A.J. Elliot, M.P. Chenier, and D.C. Ouellette

Abstract: In this publication we report: (*i*) the rate constants for reaction of the hydrated electron with 1-hexyn-3-ol ($(8.6 \pm 0.3) \times 10^8$ dm^3 mol^{-1} s^{-1} at 18°C), cinnamonitrile ($(2.3 \pm 0.2) \times 10^{10}$ dm^3 mol^{-1} s^{-1} at 20°C), and 1,3-diethyl-2-thiourea ($(3.5 \pm 0.3) \times 10^8$ dm^3 mol^{-1} s^{-1} at 22°C). For cinnamonitrile and diethylthiourea, the temperature dependence up to 200°C and 150°C, respectively, is also reported; (*ii*) the rate constants for the reaction of the hydroxyl radical with 1-hexyn-3-ol ($(5.5 \pm 0.5) \times 10^9$ dm^3 mol^{-1} s^{-1} at 20°C), cinnamonitrile ($(9.2 \pm 0.3) \times 10^9$ dm^3 mol^{-1} s^{-1} at 21°C), and diethylthiourea ($(8.0 \pm 0.8) \times 10^8$ dm^3 mol^{-1} s^{-1} at 22°C). For cinnamonitrile, the temperature dependence up to 200°C is also reported; (*iii*) the rate constant for the hydrogen atom reacting with 1-hexyn-3-ol ($(4.3 \pm 0.4) \times 10^9$ dm^3 mol^{-1} s^{-1} at 20°C).

Key words: radiolysis, corrosion inhibitors, rate constants.

Résumé : Dans ce travail, on rapporte : (*i*) les constantes de vitesse des réactions de l'électron hydraté avec l'hex-1-hexyn-3-ol ($(8,6 \pm 0,3) \times 10^8$ dm^3 mol^{-1} s^{-1} à 18°C), le cinnamonitrile ($(2,3 \pm 0,2) \times 10^{10}$ dm^3 mol^{-1} s^{-1}, à 20°C) et avec la 1,3-diéthyl-2-thiourée ($(3,5 \pm 0,3) \times 10^8$ dm^3 mol^{-1} s^{-1}, à 22°C). Pour le cinnamonitrile et pour la diéthylthiourée, on a aussi déterminé la dépendance des vitesses de réaction sur la température jusqu'à 200°C et 150°C, respectivement; (*ii*) les constantes de vitesse de la réaction du radical hydroxyle avec l'hex-1-yn-3-ol ($(5,5 \pm 0,5) \times 10^9$ dm^3 mol^{-1} s^{-1}, à 20°C), le cinnamonitrile ($(9,2 \pm 0,3) \times 10^9$ dm^3 mol^{-1} s^{-1}, à 21°C), et avec la 1,3-diéthyl-2-thiourée ($(8,0 \pm 0,8) \times 10^8$ dm^3 mol^{-1} s^{-1}, à 22°C). Pour le cinnamonitrile, on a aussi déterminé la dépendance de la vitesse de la réaction avec la température jusqu'à 200°C; (*iii*) la constante de la vitesse de réaction de l'atome d'hydrogène avec l'hex-1-yn-3-ol ($(4,3 \pm 0,4) \times 10^9$ dm^3 mol^{-1} s^{-1}, à 20°C).

Mots clés : radiolyse, inhibiteurs de corrosion, constantes de vitesse.

[Traduit par la rédaction]

Introduction

Radioisotopes, such as ^{60}Co, are incorporated in the iron oxide surface of the carbon-steel pipework of the primary heat transport system in a nuclear reactor, and the ensuing radiation fields are of concern during maintenance procedures (1). Decontamination solutions are used to dissolve the iron oxide layer by solubilizing the iron (e.g., as an ethylenediamine tetraacetic acid (EDTA) complex); the radioisotopes are also released at this stage (2). In the case of the CAN-DECON™ process, the decontamination formulation developed by AECL, the EDTA is then regenerated by removing the iron on an ion-exchange column. However, this ion-exchange resin, which also absorbs the radioisotopes released during the oxide dissolution, has to be disposed of following the decontamination. One means of minimizing the generation of ion-exchange waste is to add a corrosion inhibitor to the decontamination formulation in order to minimize the corrosion of the bare carbon-steel pipework exposed after the oxide has been removed. This corrosion, while generally not important from a plant integrity viewpoint, does generate extra soluble iron, which in turn generates more ion-exchange waste. Over the years, there has been an emphasis on finding corrosion inhibitors that are halide and sulphur free to minimize corrosion to I-600 and I-800 alloys during subsequent reactor operations by residues containing chlorine or sulphur.

Based on general radiation chemistry experience, the corrosion inhibitors screened thus far for potential use in decontamination formulations should be degraded preferentially to the organic acids. During a full system decontamination, dose rates in the range of 200–1200 Gy h^{-1} are expected, depending on the time after reactor shutdown, and whether the reactor is fuelled or defuelled. A study of the radiolytic degradation of selected inhibitors has been undertaken to predict their radiolytic degradation during a reactor decontamination. In this publication, some aspects are described of the radiation chemistry of three corrosion inhibitors: 1-hexyn-3-ol, cinnamonitrile, and 1,3-diethyl-2-thiourea.

Experimental

All chemicals were used as supplied. The inhibitors studied, with their sources are 1-hexyn-3-ol (Alfa Products), cinnamonitrile (Aldrich), and 1,3-diethyl-2-thiourea (Fisher Scientific). The other chemicals were AR grade or better. All solutions were prepared in high-purity water that had been distilled once, passed through a Millipore Milli-Q system, and then redistilled from alkaline permanganate. In most of the experiments reported here, the solutions were saturated with the appropriate gas by the syringe-bubbler technique; for some of the γ-radiolysis experiments, the solutions were degassed by freeze–pump–thaw cycles on a vacuum line and then sealed in Pyrex ampoules.

The experimental arrangements for the pulse radiolysis studies have been described in earlier publications (3, 4). A 0.5 μs pulse length was used for these experiments and the dosimeter was an oxygen-saturated KSCN solution (0.01 mol dm^{-3}) where the $G\epsilon_{475}$ value of 2.39×10^{-4} was used. G is defined as the number of species formed per 100 eV (1 eV is equivalent to 1.602×10^{-19} J) and the molar extinction coefficient, ϵ_{475}, is expressed in units of $dm^3\ mol^{-1}\ cm^{-1}$. Where required, density corrections were made for dosimetry.

For all steady-state radiolysis studies, the solutions were irradiated at room temperature in a GAMMACELL at a dose rate of about 1.2 Gy s^{-1}. The dose rate was determined by the Fricke dosimeter (5).

Results and discussion

Radiolysis studies of 1-hexyn-3-ol

The rate constants of the reactions of the hydrated electron, hydroxyl radical, and hydrogen atom with 1-hexyl-3-ol were measured using pulse radiolysis techniques. As 1-hexyn-3-ol is quite volatile and is partially stripped from solution during bubbling, even when the gas is passed through a prebubbler filled with the same solution, its concentration was determined by measuring its absorbance at 237 nm using ϵ_{237} of 445 $dm^3\ mol^{-1}\ cm^{-1}$.

Only weak optical transients were observed in the 350–720 nm range when deoxygenated 10^{-3} mol dm^{-3} 1-hexyn-3-ol solutions were pulse irradiated. This is consistent with the observations of Anderson and Schulte-Frohlinde (6), who studied acetylene solutions using pulse radiolysis; the only significant absorption they observed was in the 200–320 nm range.

The rate constant of $(8.6 \pm 0.3) \times 10^8$ $dm^3\ mol^{-1}\ s^{-1}$ (18°C) was measured for the reaction of the hydrated electron (e_{aq}^-) with 1-hexyn-3-ol (reaction [1]) from the first-order decay of the hydrated electron, as monitored by its absorption at 720 nm in deoxygenated solutions containing 6.8×10^{-4} mol dm^{-3} and 1.6×10^{-3} mol dm^{-3} 1-hexyn-3-ol:

[1] $e_{aq}^- + CH{\equiv}C\text{-}CHOH\text{-}(CH_2)_2\text{-}CH_3 \rightarrow (CH{\equiv}C\text{-}CHOH\text{-}(CH_2)_2\text{-}CH_3)^-$

The rate constant of $(5.5 \pm 0.5) \times 10^9$ $dm^3\ mol^{-1}\ s^{-1}$ (20°C) for the reaction of the hydroxyl radical with 1-hexyn-3-ol (reaction [2]) was measured by competition kinetics in both aerated and N_2O-saturated solutions (natural pH) containing $(1–8) \times 10^{-3}$ mol dm^{-3} KSCN and $(0–2) \times 10^{-3}$ mol dm^{-3} 1-hexyn-3-ol:

[2] $OH + CH{\equiv}C\text{-}CHOH\text{-}(CH_2)_2\text{-}CH_3 \rightarrow$ products

The competition was followed by measuring the absorbance of $(SCN)_2^-$ at 475 nm; the rate constant for reaction [3] was taken to be 1.1×10^{10} $dm^3\ mol^{-1}\ s^{-1}$ (7):

[3] $OH + SCN^- (+SCN^-) \rightarrow (SCN)_2^- + OH^-$

In the N_2O-saturated solutions, corrections were made for the scavenging of the hydrated electron by 1-hexyn-3-ol (reaction [1]) in competition with reaction [4]:

[4] $e_{aq}^- + N_2O (+H_2O) \rightarrow OH + OH^- + N_2$

$k_4 = 9.1 \times 10^9$ $dm^3\ mol^{-1}\ s^{-1}$ (ref. 7)

The rate constant for the reaction of hydrogen atoms with 1-hexyn-3-ol (reaction [5]) was measured to be $(4.3 \pm 0.4) \times 10^9$ $dm^3\ mol^{-1}\ s^{-1}$ at 20°C by competition kinetics in deoxygenated 5×10^{-4} mol dm^{-3} ferricyanide ion (pH 1.8) solutions containing $(0–4.9) \times 10^{-4}$ mol dm^{-3} 1-hexyn-3-ol. The competition was monitored by the depletion of the ferricyanide ion absorption at 420 nm, assuming that the rate constant for hydrogen atoms reacting with ferricyanide ion (reaction [6]) was 5.8×10^9 $dm^3\ mol^{-1}\ s^{-1}$ (8):

[5] $H + CH{\equiv}C\text{-}CHOH\text{-}(CH_2)_2\text{-}CH_3 \rightarrow$ products

[6] $H + Fe(CN)_6^{3-} \rightarrow Fe(CN)_6^{4-}$

On a longer time scale, after reactions [5] and [6] were complete, further ferricyanide ion was reduced to ferrocyanide ion by the free radical products formed from reaction of the hydroxyl radical and hydrogen atom. A rate constant of 1.7×10^8 $dm^3\ mol^{-1}\ s^{-1}$ was measured for this reduction. While this rate constant is about an order of magnitude slower than that normally associated with the reduction of ferricyanide by simple α-hydroxy radicals as derived from 2-propanol, etc., it is still much faster than that of a β-hydroxy radical (e.g., $^{\bullet}CH_2CH_2OH$) (9). This suggests that the radicals are probably α-hydroxy radicals, a point that will be returned to later.

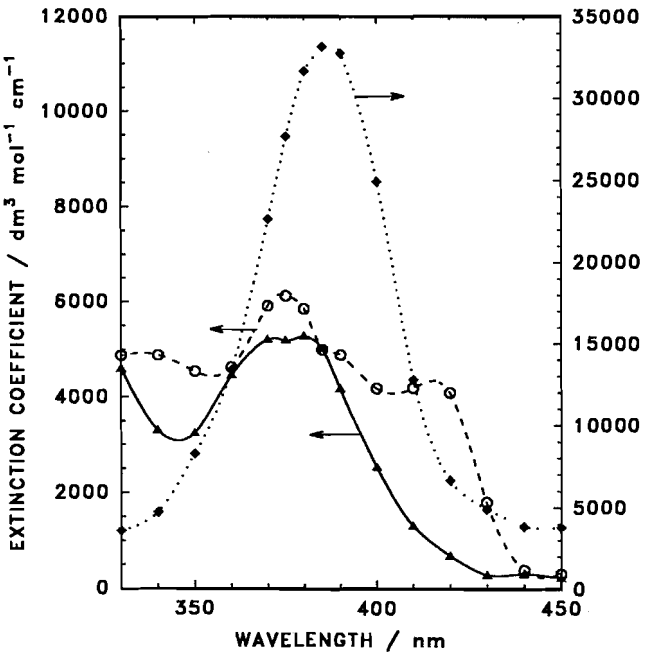
It is interesting to compare the rate constant for reaction of the hydrated electron with 1-hexyn-3-ol, $CH{\equiv}C\text{-}CHOH\text{-}(CH_2)_2\text{-}CH_3$ (8.6×10^8 $dm^3\ mol^{-1}\ s^{-1}$) to that of the electron reaction with acetylene, $CH{\equiv}CH$ (2.0×10^7 $dm^3\ mol^{-1}\ s^{-1}$) (6), and with propargyl alcohol, $CH{\equiv}C\text{-}CH_2OH$, of 2.1×10^8 $dm^3\ mol^{-1}\ s^{-1}$ (10). Substitution of the acetylene group greatly affects the rate of reaction towards the hydrated electron. However, there is no significant difference between the reaction rates of the hydroxyl radical and hydrogen atom with acetylene, 4.5×10^9 and 2.3×10^9 $dm^3\ mol^{-1}\ s^{-1}$ (6), respectively, and those with 1-hexyn-3-ol.

Some γ-radiolysis studies of 1-hexyn-3-ol were made to measure the loss of starting material. N_2O-saturated and deoxygenated solutions containing 10^{-3} mol dm^{-3} 1-hexyn-3-ol at natural pH were γ-irradiated and analyzed using UV spectroscopy. The UV spectrum of 1-hexyn-3-ol has a single absorption at 235 nm associated with an electronic transition in the acetylene group. As such, this method of analysis reflects only what has happened to this acetylene group; reactions occurring at the other end of the molecule are not monitored.

In deoxygenated solutions, G(acetylene loss) of ca. 50 was measured. This high G-value was confirmed by high-pressure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Fig. 1. The spectra calculated (see text) for the transient formed from cinnamonitrile by reaction of the hydrated electron (◆), the hydroxyl radical (▲), and the hydrogen atom (○). Dose per pulse was about 5 Gy.



liquid chromatography; analysis of two samples gave *G*-values of the loss of 1-hexyn-3-ol of 40 and 100. For N_2O-saturated solutions, *G*(acetylene loss) was near 20. A deoxygenated solution at pH 2.6 was also studied and *G*(acetylene loss) was ca. 14.

The above results indicate that the hydrated electron reacts with the acetylene group (reaction [1]) to form a radical anion, which initiates a small chain polymerization reaction. The hydroxyl radical and the hydrogen atom also appear to initiate small chain reactions. Both presumably can add to the acetylene group; however, both can also abstract the hydrogen at carbon-3 (reaction [7]) to form an α-hydroxy radical:

[7] $OH,H + CH{\equiv}C\text{-}CHOH\text{-}(CH_2)_2\text{-}CH_3 \rightarrow CH{\equiv}C\text{-}\dot{C}OH\text{-}(CH_2)_2\text{-}CH_3 + H_2O, H_2$

Evidence for reaction [7] comes from pulse radiolysis experiments, where the *G*-value for ferricyanide reduction in pH 1.8 solutions from the radicals formed in reactions [2] and [5] was about 70% of the yield of hydroxyl and hydrogen atoms. Addition of the hydroxyl radical or the hydrogen atom to the acetylene triple bond will produce a β- or γ-hydroxy radical, either of which are anticipated to be much poorer reducing agents for ferricyanide.

Radiolysis studies of cinnamonitrile

As will be described later, the rate constants for the reaction of the hydrated electron (reaction [8]) and the hydroxyl radical (reaction [9]) with cinnamonitrile are $(2.3 \pm 0.2) \times 10^{10}$(20°C) and $(9.2 \pm 0.3) \times 10^9$ dm^3 mol^{-1} s^{-1} (21°C), respectively. To determine the absorption characteristics of the transients formed from reaction of the hydrated electron, the hydroxyl radical, and the hydrogen atom with cinnamonitrile, the spectra were recorded from a helium-purged 10^{-3} mol dm^{-3} cinnamonitrile solution at pH ~9 (10^{-3} mol dm^{-3} borate) and at pH 1 (0.1 mol dm^{-3} $HClO_4$), and from a N_2O-saturated 10^{-4} mol dm^{-3} cinnamonitrile solution at pH ~9 (10^{-3} mol dm^{-3} borate). The spectra of the transient species are shown in Fig. 1. The extinction coefficients were calculated from the $G\epsilon$ values observed by assuming a *G*(H) of 0.55 (5) and a *G*(OH) of 5.6 in the N_2O-saturated solution (taken from Fig. 4 in ref. 11 and adjusting the result by 1.06 to allow for the difference in $G\epsilon$ used for dosimetry in the two laboratories), a *G*(OH) of 2.72, a *G*(H) of 0.55, and a $G(e_{aq}^-)$ of 2.76 in the helium-saturated solution at pH ~9 (12), and a *G*(OH) of 2.81 and *G*(H) of 3.55 in 0.1 mol dm^{-3} $HClO_4$ (5).

The spectrum of the electron adduct has a maximum extinction coefficient of 33 300 dm^3 mol^{-1} cm^{-1} near 385 nm. The extinction coefficient of the radical anion formed in eq. [8] is similar in magnitude to that of cinnamamide (13) and cinnamic acid (14).

[8] $e_{eq}^- + C_6H_5\text{-}CH{=}CH\text{-}CN \rightarrow (C_6H_5\text{-}CH{=}CH\text{-}CN)^{\cdot -}$

The latter two radical anions undergo acid–base equilibria: cinnamamide (pK_a = 7.2) (13) and cinnamic acid (pK_a = 5.6 and 11.6) (14). Although no pH studies were done in this study, the extinction coefficients at natural pH and at pH~9 were the same, within experimental error, suggesting that the radical anion probably does not have a pK_a near pH 9. This radical anion decayed by first-order kinetics with a rate constant of 1.3×10^5 s^{-1} (24°C) in solutions at natural pH and with a rate constant of 1.8×10^5 s^{-1} (24°C) in solutions buffered with 10^{-3} mol dm^{-3} borate. The transient species formed from reaction of the hydroxyl radical (reaction [9]) did not decay significantly in the time period of the decay of the radical anion.

[9*a*] $OH + C_6H_5\text{-}CH{=}CH\text{-}CN \rightarrow (HO\text{-}C_6H_4)\text{-}CH{=}CH\text{-}CN$

[9*b*] $OH + C_6H_5\text{-}CH{=}CH\text{-}CN \rightarrow C_6H_5\text{-}\dot{C}H\text{-}CHOH\text{-}CN$

The spectrum arising from the reaction of the hydroxyl radical has a maximum extinction coefficient of 5200 dm^3 mol^{-1} cm^{-1} near 375 nm. The hydroxyl radical can react either with the aromatic ring of cinnamonitrile to form cyclohexadienyl radicals (reaction [9*a*]) or with the olefinic group (reaction [9*b*]). The peak observed at 375 nm arises primarily from the cyclohexadienyl radicals; the benzyl radical formed in reaction [9*b*] absorbs near 310–330 nm (15), but we did not record the spectrum in the region. The spectrum of the species formed from the hydroxyl radical reaction is very similar to that observed by Bobrowski and Raghaven (15) for cinnamic acid, suggesting that only 30% of the hydroxyl radicals are reacting by reaction [9*a*] to form the cyclohexadienyl radical.

The spectrum from the transients arising from reaction of the hydrogen atom has a maximum extinction coefficient of 6100 dm^3 mol^{-1} cm^{-1} near 375 nm, and also has a shoulder at 425 nm. This can be interpreted as arising from a mixture of benzyl and cyclohexadienyl radicals that are produced from the hydrogen atom reacting with the ring and the side chain (15). This spectrum is similar in shape, but is slightly more intense than that observed for reaction of the hydrogen atom with cinnamic acid (15).

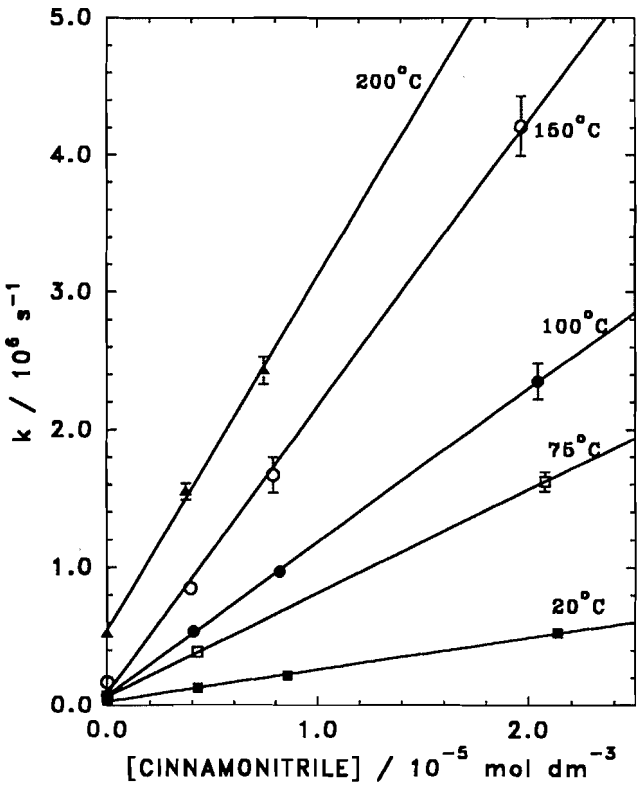
Fig. 2. The first-order rate constant for the reaction of the hydrated electron with cinnamonitrile as a function of temperature.

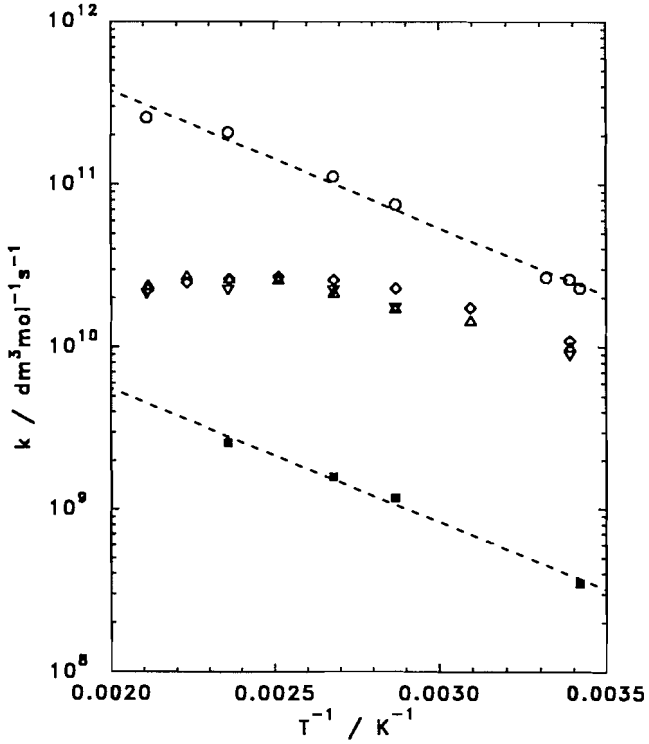


Thermal decomposition studies carried out by us in aqueous solutions indicated that cinnamonitrile was relatively stable at 200°C; i.e., only 10% decomposed in 45 min. This encouraged us to study the rate constant for reaction of the hydrated electron and the hydroxyl radical with cinnamonitrile as a function of temperature. Figure 2 shows the first-order rate constants for decay of the hydrated electron (measured at λ_{max}) as a function of the cinnamonitrile concentration for temperatures up to 200°C. These helium-saturated solutions were buffered with 10^{-3} mol dm^{-3} borate ions. The rate constants for reaction [8] are summarized by the Arrhenius plot in Fig. 3. The room temperature value is near to that expected for a diffusion-controlled reaction, and the line through the date is an Arrhenius fit with an activation energy of 16.1 kJ mol^{-1}. For a truly diffusion-controlled reaction, an activation energy nearer ~20 kJ mol^{-1} would be expected, based on the Smoluchowski equation (16):

$$k_{diff} = 4\pi\,(D_e + D_c)(r_e + r_c)\,N_0\,1000\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$$

where D_e and D_c are the diffusion coefficients and r_e and r_c are the reaction radii for the hydrated electron and cinnamonitrile, respectively. At room temperature, D_e is probably 5 to 10 times larger than D_c (17); furthermore, the temperature dependence of D_e (E_a = 20.75 kJ mol^{-1} (18)) is greater than D_c, which probably has the same dependence as self-diffusion in water (E_a = 15–16 kJ mol^{-1} (17)). As can be seen, the temperature dependence of the reaction is dominated by the diffusion of the hydrated electron in water.

Fig. 3. An Arrhenius plot of the rate constant for reaction of the hydrated electron with cinnamonitrile (○) and diethythiourea (■) and the rate constants observed for the reaction of the hydroxyl radical with cinnamonitrile at 4.5×10^{-5} mol dm^{-3} (◇), 5.3×10^{-5} mol dm^{-3} (▽), and 7.8×10^{-5} mol dm^{-3} (△). All solution were buffered with 10^{-3} mol dm^{-3} borate buffer. The broken lines are the Arrhenius fits to the data.



The rate constant for the reaction of the hydroxyl radical with cinnamonitrile was measured by following the first-order buildup of the absorption at 380 nm in N_2O-saturated solutions. Where appropriate, corrections for the decay of the species formed had to be made using the kinetic package FACSIMILE (19). These results are summarized in Fig. 3. While the rate constant observed at 21°C, $(9.2 \pm 0.3) \times 10^9$ dm^3 mol^{-1} s^{-1}, is close to that expected for diffusion control at room temperature, the temperature dependence of the rate constant is considerably less than that expected for diffusion control; obviously, the reaction is being controlled by the activation energy associated with the individual steps in the overall chemical reaction. Similar temperature dependences for reaction of hydroxyl radicals with aromatic compounds have recently been reported and discussed (20).

Only a few γ-radiolysis studies were undertaken . The *G*-value for cyanide ion formation was measured to be 0.10 ± 0.01 and 0.20 ± 0.02, respectively, for helium- and N_2O-saturated solutions containing 4×10^{-4} mol dm^{-3} cinnamonitrile. This suggests that cyanide is a minor product formed by the reaction of the hydroxyl radical. Based on the loss of the cinnamonitrile absorption at 275 nm, the *G*-values for cinnamonitrile loss measured in a 4×10^{-4} mol dm^{-3} cinnamonitrile solutions saturated with helium at natural pH and at pH 2 were the same, namely 4.4 ± 0.1; for a N_2O-saturated solution it was 4.0 and for a O_2-saturated solution it was 2.0. This is consistent with the efficient reactions of the hydrated electron,

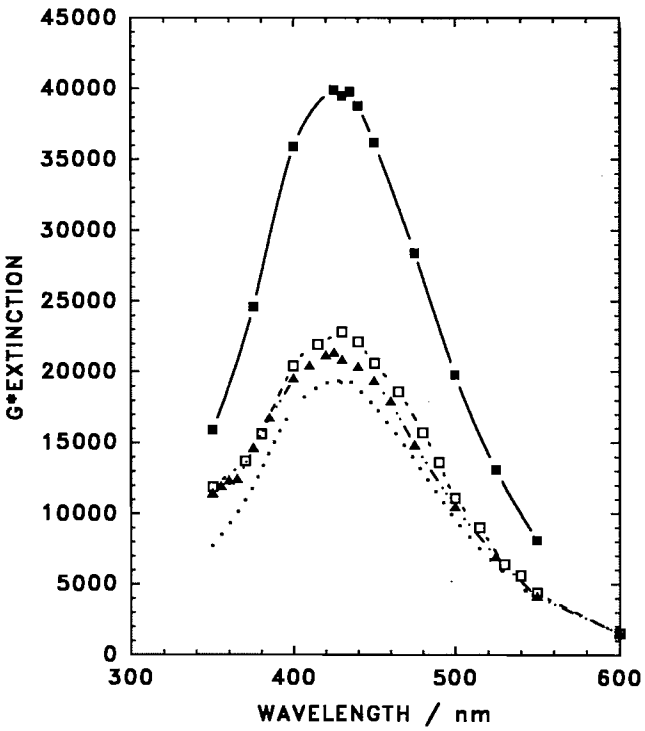
Fig. 4. The spectra observed after pulsing a N_2O-saturated 2×10^{-3} mol dm^{-3} diethylthiourea solution (■) at pH 9, a helium-saturated 2×10^{-2} mol dm^{-3} diethylthiourea solution (▲) at pH 9, and a helium-saturated 2×10^{-2} mol dm^{-3} diethylthiourea solution (□) at pH 1. The dose per pulse was about 6 Gy. The dotted spectrum is the N_2O-saturated 2×10^{-3} mol dm^{-3} diethylthiourea solution scaled by 2.72/5.6 (see text).



hydroxyl radical, and hydrogen atom with cinnamonitrile, but it also indicates that no chain reaction was initiated and that the superoxide ion, O_2^-, does not react significantly with cinnamonitrile.

Radiolysis studies of diethylthiourea

Figure 4 shows the spectra obtained from a pulse-irradiated, N_2O-saturated 2×10^{-3} mol dm^{-3} diethylthiourea solution (10^{-3} mol dm^{-3} borate buffer), a helium-saturated 2×10^{-2} mol dm^{-3} diethylthiourea solution (10^{-3} mol dm^{-3} borate buffer), and a helium-saturated 2×10^{-2} mol dm^{-3} diethylthiourea solution (pH 1 with $HClO_4$). The dotted line in Fig. 4 is the spectrum of the hydroxyl radical induced transient in a helium-saturated solution (assuming $G(OH) = 2.72$), calculated from the spectrum for a N_2O-saturated solution ($G(OH) = 5.6$). The difference between the dotted spectrum and the two spectra from helium-saturated solutions represents the spectra from the transient products of the reaction of the hydrated electron and hydrogen with diethylthiourea. As can be seen, the transients formed from the hydrated electron and the hydrogen atom only absorb slightly in the wavelength range studied. This is consistent with the recent publication by Dey et al. (21). The hydroxyl radical induced spectrum has a maximum extinction coefficient of 7100 dm^3 mol^{-1} cm^{-1} near 425 nm. The rate constant for the reaction of the hydroxyl radical with diethylthiourea was found to be $(8.0 \pm 0.8) \times 10^8$ dm^3 mol^{-1} s^{-1} at 22°C, measured from the buildup of the absorption at 425 nm. While the rate constant is in agreement with that reported recently (21), our extinction coefficient is 25% higher. This rate constant is comparible to that of the ketone analogue, diethylketone (7).

Tests on the thermal stability of aqueous solutions of diethylthiourea indicate that about 20% of the diethylthiourea decomposes at 180°C in about 10 min. Much faster decompositions were observed at 200°C. The rate of reaction of the hydrated electron with diethylthiourea (reaction [10]) was followed up to 150°C, and the results are summarized in Fig. 3.

[10] $e_{aq}^- + (C_2H_5NH)_2C{=}S \rightarrow ((C_2H_5NH)_2C{=}S)^{\cdot -}$

The rate constant at 22°C is $(3.5 \pm 0.3) \times 10^8$ dm^3 mol^{-1} s^{-1}, about two orders of magnitude below that expected if the reaction was diffusion controlled. Interestingly, the activation energy for the reaction (15.8 kJ mol^{-1}) is similar to that for the hydrated electron reaction with cinnamonitrile, as seen in Fig. 3. This rate is about an order of magnitude less than that for thiourea, suggesting that there may be some steric hinderance by the ethyl groups for the reaction with the hydrated electron in diethyl thiourea. The value of 5×10^8 dm^3 mol^{-1} s^{-1} reported in ref. 21 for k_{10} is slightly higher than that reported here.

The rate of reaction of the hydroxyl radical could not be measured at higher temperatures, because the product(s) formed decayed far too rapidly to estimate the first-order build-up rate constant.

Some preliminary steady-state γ-radiolysis studies were undertaken to measure the loss of diethylthiourea; however, monitoring its absorption near 240 nm was not practical, as it appeared that products were formed that absorbed in the same spectral region. All that could be said is that the G(diethylthiourea loss) was >0.6 and >0.9, respectively, for N_2O- and helium-saturated solutions containing 10^{-5} mol dm^{-3} diethylthiourea at natural pH. These low G-values may also be, in part, a result of products being formed from diethylthiourea that are more reactive towards the hydrated electron and hydroxyl radical than the parent compound.

Conclusions

The rate data collected in this paper support the concept that, in general, corrosion inhibitors react rapidly with the free radical species formed in the radiolysis of water. When corrosion inhibitors are used in reactor decontamination formulations, they will generally be depleted preferentially compared to the organic acids. In any full-system field application of the decontamination formulation, the operators will have to be prepared to add more inhibitors as they are radiolytically destroyed.

Comportement photochimique du 4-nitrosophénol en solution aqueuse

Jean-François Pilichowski, Pierre Boule et Jean-Philippe Billard

Résumé : En milieu acide (pH ≈ 1) le 4-nitrosophénol irradié entre 296 et 366 nm se transforme majoritairement (75–80%) en benzoquinone. Le rendement quantique de cette réaction dépend de la longueur d'onde : il est environ 6 fois plus élevé à 365 nm qu'à $\lambda \leq 313$ nm. Ce phénomène est attribué à un équilibre tautomérique entre les formes nitroso et quinone monooxime, la première étant photochimiquement beaucoup plus réactive que la seconde. Dans l'eau distillée non tamponnée (pH = 5–6), il apparaît une espèce intermédiaire qui présente en CLHP un temps de rétention voisin de celui de la benzoquinone et dont le maximum d'absorption est situé à 235 nm. La transformation de cet intermédiaire est accélérée en milieu acide.

Mots clés : photochimie, 4-nitrosophénol, effet de longueur d'onde.

Abstract: In acidic medium (pH ≈ 1) 4-nitrosophenol irradiated in the range 296–366 nm is mainly transformed into benzoquinone (75–80%). The quantum yield of this reaction is wavelength dependent: it is about 6 times higher at 365 nm than at $\lambda \leq 313$ nm. This phenomenon is attributed to an equilibrium between two tautomeric forms, nitroso and quinone monooxime, the former being much more photoreactive than the latter. In unbuffered aqueous solution (pH = 5–6) the formation of an intermediate is observed. Its HPLC retention time is just a little shorter than that of benzoquinone and the maximum of its absorption band is located at 235 nm. The rate of transformation of this intermediate increases with decreasing pH.

Key words: photochemistry, 4-nitrosophenol, wavelength effect.

Introduction

Les nitrosophénols sont des composés dont le comportement photochimique a été très peu étudié. Le 4-nitrosophénol en particulier peut pourtant apparaître, en solution aqueuse, soit dans la photolyse du 4-nitrophénol (1), soit par excitation des ions nitrate (2, 3) ou nitrite en présence de phénol (3). À forte concentration en ions nitrite, la réaction devient même spécifique. Le but de ce travail est d'une part, de déterminer l'influence de différents paramètres (pH, longueur d'onde, oxygénation) sur la vitesse de phototransformation du 4-nitrosophénol et d'autre part, d'analyser les produits formés dans le but de prévoir le devenir de ce composé dans l'environnement.

Partie expérimentale

Le 4-nitrosophénol commercial (Aldrich) a été purifié par cristallisation fractionnée dans un mélange hexane–éther. Une chromatographie de contrôle (gel de silice sur couche mince) a permis de s'assurer de la pureté du produit. L'analyse CLHP et la RMN du proton ont confirmé l'efficacité de cette purification. La *p*-benzoquinone, Merck *for synthesis*, a été purifiée par sublimation. Elle a été obtenue sous forme de cristaux jaune clair.

Reçu le 19 mai 1995.

[1] Auteur à qui la correspondance doit être adressée. Téléphone : (33) 73 40 71 76. Télécopieur : (33) 73 40 77 00.

Les spectres UV–visible ont été enregistrés sur Cary 118 ou Cary 3 (Varian).

L'irradiation monochromatique des solutions a été réalisée grâce à un monochromateur Bausch et Lomb équipé d'une lampe à vapeur de mercure très haute pression de type HBO 200 W ou USH 200 DP.

Les intensités de lumière ont été évaluées par actinométrie chimique au ferrioxalate de potassium ou à l'Aberchrome 540 (en n'utilisant qu'une fois les solutions) (4).

Les solutions ont été analysées par CLHP sur colonne inverse C_{18} 250 mm × 4 mm en utilisant des mélanges eau–méthanol comme éluant.

Résultats

Propriétés spectrophotométriques du 4-nitrosophénol

Le spectre UV–visible du 4-nitrosophénol en solution aqueuse, dont les caractéristiques sont données dans le tableau 1, permet d'évaluer son pK_a à 6,2 (figure 1). Ce résultat est en bon accord avec les valeurs données dans la littérature, 6,2 (7) et 6,5 (8). On peut noter que le 4-nitrosophénol est plus acide que le 4-nitrophénol ($pK_a \approx 7$ à 25°C (9)).

Tautomérie

En faisant réagir l'acide nitreux sur le phénol, on obtient de façon très majoritaire le 4-nitrosophénol (**I**). Par action de l'hydroxylamine sur la *p*-benzoquinone, il se forme de la *p*-quinone monooxime (**II**). Dans certaines conditions expérimentales, ces deux produits peuvent être obtenus, séparément, sous forme cristalline (6). Par contre, en solution, chacune des espèces évolue vers un mélange unique qui correspond à une tautomérie :

[I] [II]

Une analyse par RMN, dans des conditions rigoureusement anhydres, a permis d'observer expérimentalement cet équilibre dans différents solvants (10).

[II] / [I] = 83/17 dans le dioxanne, l'éthanol, l'éther

[II] / [I] = 75/25 dans l'acétone

Par contre, à notre connaissance, il n'existe pas de données relatives aux solutions aqueuses, mais on peut supposer un comportement analogue en solution acide. En milieu basique, par contre, chacune des deux formes conduit aux formes déprotonées, mésomères d'une espèce unique.

Évolution photochimique

Des solutions acides (pH de l'ordre de 1) ou basiques (pH > 9) aérées ou désoxygénées de concentration comprise entre 10^{-4} et 10^{-3} mol L^{-1} ont été irradiées à différentes longueurs d'onde. Il a été vérifié préalablement que ces solutions sont stables pendant plusieurs jours, en absence de lumière.

En solution basique, l'évolution photochimique à 365 nm est extrêmement lente. Le rendement quantique de disparition peut être estimé inférieur à 10^{-6}. Par contre, l'évolution en milieu acide peut être suivie par spectrophotométrie UV et par chromatographie CLHP. Quelle que soit la longueur d'onde d'irradiation (313, 334 ou 365 nm) d'une solution aérée 10^{-3} mol L^{-1}, on constate la formation très largement majoritaire d'un produit qui a été identifié à la *p*-benzoquinone grâce à son spectre UV (figure 2) et à son temps de rétention en CLHP. La *p*-benzoquinone représente environ 75–80% de la transformation. La formation d'une très faible quantité de 4-nitrophénol a également été observée lors d'irradiations longues (>50% de disparition).

L'oxygène n'a pas d'influence appréciable sur la vitesse de transformation, ni sur la formation de la benzoquinone. Il en est de même de l'addition de faibles quantités (≤5%) de méthanol à la solution. Par contre, le rendement quantique de la réaction dépend beaucoup de la longueur d'onde, comme cela apparaît dans le tableau 2 : il est environ 6 fois plus élevé à 365 nm qu'à $\lambda \leq 313$ nm.

En milieu faiblement acide (solution aqueuse non tamponnée; pH ≈ 5), il apparaît initialement un composé intermédiaire (X) dont le maximum d'absorption est situé à 235 nm (figure 4) et dont le temps de rétention en CLHP est légèrement plus faible que celui de la benzoquinone BQ (figure 3). Ce composé disparaît avec formation de benzoquinone (figure 3), la vitesse de transformation augmentant avec la diminution du pH. À température ambiante, la durée de cette transformation varie de 1 à 2 min à pH = 1, jusqu'à plusieurs heures en milieu neutre.

Après irradiation d'une solution dégazée, jusqu'à un avancement de l'ordre de 50%, la formation d'azote a pu être mise en évidence par spectrométrie de masse de la phase gazeuse. Une légère augmentation de pression a aussi pu être observée (en plaçant le réacteur dans un mélange glace–eau pour fixer la pression de vapeur d'eau).

Discussion

Effet de longueur d'onde

Les différentes longueurs d'onde utilisées correspondent apparemment à la même bande d'absorption dont la maximum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

Fig. 3. Chromatogramme CLHP d'une solution non tamponnée de 4-nitrosophénol 10^{-3} M irradiée à 365 nm. Eluant MeOH/H_2O 40:60; détection à 270 nm. BQ : *p*-benzoquinone, X : intermédiaire. (*a*) Quelques minutes après l'irradiation; (*b*) environ 15 min plus tard; (*c*) après 4 h.

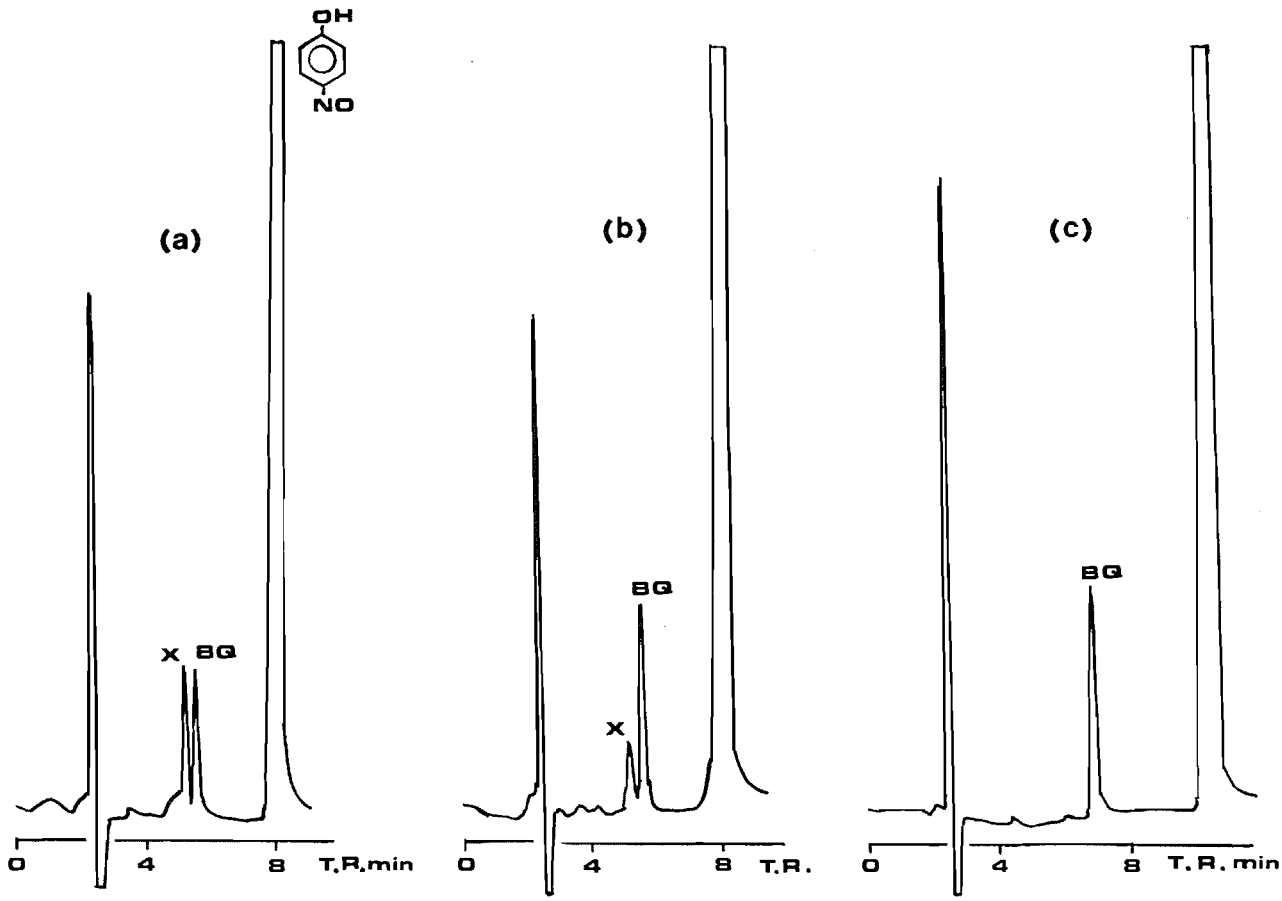

Fig. 4. Spectre UV obtenu sur un détecteur à barrette de diodes du produit X qui se forme avant la *p*-benzoquinone.

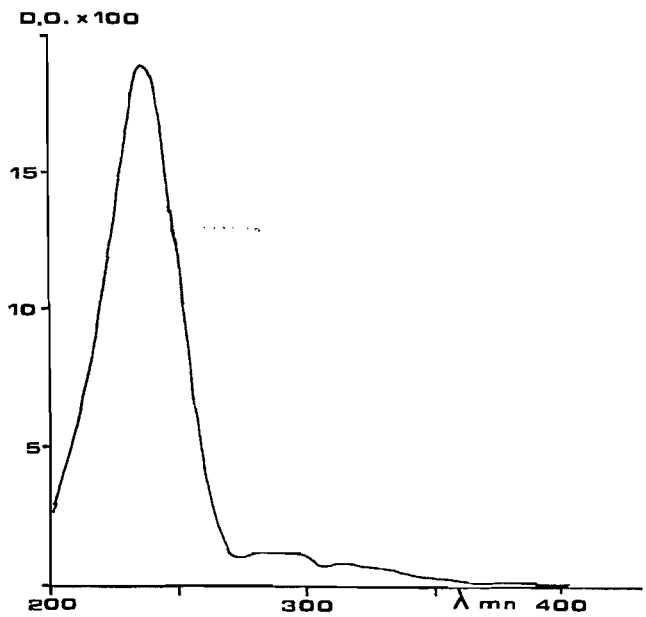

est situé à 300 nm. Le fait que le rendement quantique de la phototransformation décroisse avec la longueur d'onde entre 365 et 313 nm peut être attribué à l'existence de l'équilibre tautomérique signalé, la forme absorbant à plus grande longueur d'onde étant beaucoup plus réactive que l'autre. La bande d'absorption observée correspondrait alors à la superposition des bandes de chacun des deux tautomères. N'ayant pas directement accès aux propriétés spectrophotométriques des deux formes, nous nous sommes reportés aux données de la littérature relatives à des composés comparables sur le plan structural. Les spectres UV–visible du *p*-nitrosoanisole et de la *p*-benzoquinone monooxime méthyl éther présentent des maximums situés respectivement à 333 et 313 nm, avec des coefficients d'extinction molaires voisins (11). Par analogie, on peut supposer que la forme nitroso du 4-nitrosophénol absorbe à plus grande longueur d'onde que la forme quinone-oxime (environ entre 315 et 400 nm). La photoréactivité de la première serait donc 6–7 fois plus élevée que celle de la deuxième. Un phénomène analogue a été signalé dans le cas du 3-chloro-4-nitrosophénol (12).

Mécanisme de la réaction

Le temps de rétention CLHP et le spectre UV de l'intermédiaire mis en jeu lors de la photolyse du 4-nitrosophénol permettent de penser qu'il s'agit d'une espèce de structure voisine de la benzoquinone, cet intermédiaire se transformant rapidement en benzoquinone en milieu acide. Cette réaction pourrait être expliquée par la formation intermédiaire de 4-hydroxyamino-2,5-cyclohexadiénone qui proviendrait de l'hydrolyse de la forme quinonoxime. Cependant, ce mécanisme est incompatible avec l'effet de longueur d'onde observé. Par contre, le passage par une forme oxaziridine a

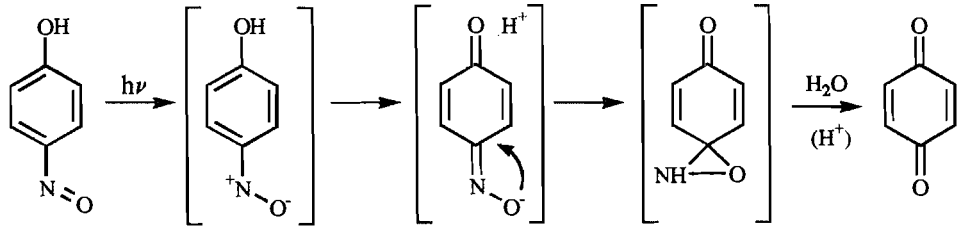
déjà été signalé dans la photolyse des nitrones (13, 14), des aldoximes et cétoximes (13, 15). Par analogie avec le mécanisme suggéré par Isawa et al. (14), la formation d'oxaziridine peut être expliquée par une polarisation de la liaison N—O à l'état excité. On peut donc proposer le mécanisme suivant :



La formation d'azote ne peut se produire que dans une étape ultérieure. Elle pourrait, par exemple, faire intervenir la formation d'un dérivé de l'hydroxylamine, difficile à mettre en évidence.

Protonation of porphocyanine — a new expanded tetrapyrrolic macrocycle

Lily Yun Xie and David Dolphin

Abstract: The porphocyanine nucleus contains six nitrogen atoms, four of which are theoretically capable of accepting a proton in acidic solution. However, only the monoprotonated and diprotonated forms have been observed. These two forms were characterized by their visible and fluorescence spectra. pK_a values of 6.0 ± 0.1 and 4.4 ± 0.1 were determined by spectrophotometric titration. The monoprotonated monocationic form can be observed in methanol.

Key words: porphocyanine, protonation, octaethylporphocyanine, octaethylporphyrin.

Résumé : Le noyau porphocyanine contient six atomes d'azote, dont quatre sont en théorie capables d'accepter un proton d'une solution acide. Toutefois, on n'a observé que les formes mono- et diprotonées. On a caractérisé ces deux formes par leurs spectres visible et de fluorescence. Faisant appel à un titrage spectrophotométrique, on a déterminé que les valeurs de pK_a sont respectivement de 6,0 ± 0,1 et 4,4 ± 0,1. On peut observer la forme monocationique monoprotonée dans le méthanol.

Mots clés : porphocyanine, protonation, octaéthylporphocyanine, octaéthylporphyrine.

We recently communicated the synthesis and characterization of a new class of tetrapyrrolic macrocycles, porphocyanines **1** (1–3), and showed that these compounds were capable of catalyzing the photosensitized oxidation of cholesterol (3). They are potential photosensitizers for photodynamic therapy for cancer treatment because they offer long-wavelength absorption between 795 and 810 nm in their free base form, which would in principle confer superior tissue penetration to visible light than is the case with existing drugs. It is important to know the nature of the ionic species of a photosensitizer in solution as a function of pH (4), since it is known that the longest wavelength absorption and fluorescence emission are affected by protonation of the porphocyanine nucleus, which contains four potential sites for protonation. Furthermore, protonation of porphocyanine might effect biodistribution of the photosensitizer in vivo (4–7) Finally, the pK_a data of porphocyanines are valuable in understanding the reactivity and aromaticity of this new macrocycle.

It is of interest to compare the protonation properties of the porphocyanine with those of porphyrin (**2**), azaporphyrin (**3**), sapphyrin (**4**), and phthalocyanine (**5**). Several techniques have been used in the measurement of pK_a values of porphyrins and related compounds taking account of their poor solubility in water, i.e., potentiometric titration in glacial acetic acid, and spectrophotometric titration in nitrobenzene and in aqueous detergent solutions (7–9). The pK_a value of sapphyrin was, however, recently estimated using a spectrophotometric method in a biphasic system (10).

Experimental

Octaethylporphocyanine (H_2P) was prepared according to the procedure described previously (1) and was dissolved in dichloromethane. The absorbance changes at specific wavelengths were monitored upon mixing a CH_2Cl_2 solution of octaethylporphocyanine (3.5×10^{-4} M) and a pH-adjusted aqueous NaCl solution ($[Cl^-]_{total}$ = 0.1 M). Electronic spectra were recorded on a Hewlett–Packard 8452A diode array spectrophotometer. The pH values were recorded on a Fisher Accumet pH meter model 210 with a glass combination electrode (Fisher Scientific). The pH meter was calibrated at 25°C with standard buffer solutions for pH 4.00 and 7.00 prior to the pH measurements. Fluorescence emission spectra were measured on an Aminco Bowman Series 2 luminescence spectrometer using a flash lamp as the excitation source. Solutions of porphocyanine were handled under dim light to avoid photodegradation.

Results and discussion

Because of the poor water solubility of octaethylporphocyanine, we attempted to solubilize the material in 2.5% sodium dodecyl sulphate (SDS) solution in order to obtain the pK_a values in a solvent system that simulates the experimental conditions used in our photodynamic bioassay experiments (liposomal formulations). The solubility of octaethylporphocyanine can be enhanced by addition of 0.1 N HCl solution but, unfortunately, the amount of octaethylporphocyanine that went into the detergent solution was still insufficient to allow a meaningful analysis of the spectral changes in the regions of interest. Moreover, octaethylporphocyanine was found to behave differently in 2.5% SDS solution and organic solvents. In SDS solution only the dication was observed between pH 2 and 5 and, as the pH increased, the 748 nm band (of the dication) decreased and eventually disappeared with no formation of new bands. That is, neither the monocation nor free base were observed in SDS solution even though octaethylporphocyanine exhibits very distinct absorption bands for both the dication and free base in dichloromethane, with their longest wavelength bands appearing more than 50 nm apart. Thus we employed a biphasic spectrophotometric titration method previously used for estimating the pK_a's of sapphyrin **4** (10).

In the aqueous dichloromethane system, octaethylporphocyanine was well behaved as a function of $[H^+]$. At low pH (below 4), two isosbestic points were observed at 729 and 754 nm in the 720–820 nm region (Fig. 1), indicating that within this pH range only two species, dication and monocation, are dominant. At high pH (above 6), two isosbestic points were also obtained, at 732 and 778 nm (Fig. 2), indicating that within this pH range only monocation and free base are present in significant concentrations. The fluorescence emission spectra of the different forms of octaethylporphocyanine were recorded; three species fluoresce, at 751, 764, and 802 nm, respectively. At low pH, only two peaks (751 and 764 nm) were observed in the fluorescence emission spectrum, consistent with the isosbestic points seen in the optical absorption spectrum (Fig. 1), whereas at high pH, two peaks (764 and 802 nm) were observed, consistent with the isosbestic points in Fig. 2. It was clear that throughout the titration there were only three species, free base, monocation, and dication, present in solution. Two equivalents of HCl will protonate the free base to give the spectrum of the dication, which remains the same upon addition of further equivalents of acids (eqs. [1] and [2]).

$$[1]\quad H_2P + H^+ \overset{K_3}{\longleftrightarrow} H_3P^+$$

$$[2]\quad H_3P^+ + H^+ \overset{K_4}{\longleftrightarrow} H_4P^{2+}$$

The dication spectrum remains unchanged even in the concentrated H_2SO_4. It is well known in the literature that the protonation of phthalocyanine (**5**) occurs at the methine azo groups rather than in the centre of the molecule (11). Very little is known about the protonation behavior of azaporphyrins (**3**) (see ref. 11, p. 75, and ref. 12). However, it was shown previously that protonation of the internal nitrogen in azaetioporphyrin preceded the protonation of the methine bridging nitrogen that had an estimated pK value of ca. −3.3 (13). Despite the fact that porphocyanine contains two imine linkages in the macrocycle, we believe that it behaves more like azaporphyrin than phthalocyanine. Protonations of porphocyanine have thus been assigned to the inner pyrrolinene nitrogens (Scheme 1) and further protonation of imine nitrogen was not observed even in concentrated sulphuric acid. The

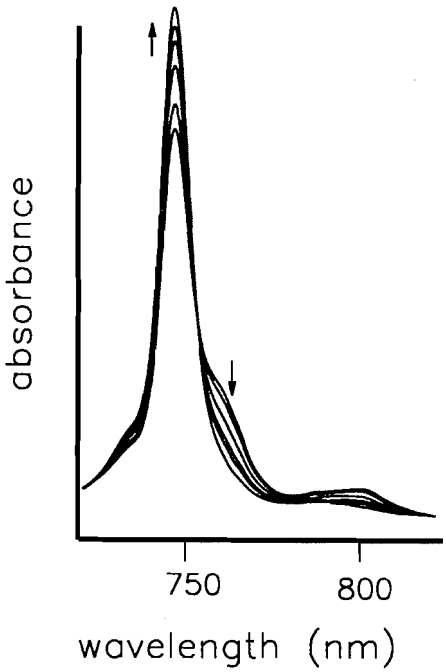

Fig. 2. Absorption spectra of octaethylporphocyanine in dichloromethane equilibrated with 0.1 M NaCl solutions from pH 7.2 to 5.4 at 22°C. Two isosbestic points at 732 and 778 nm were observed.

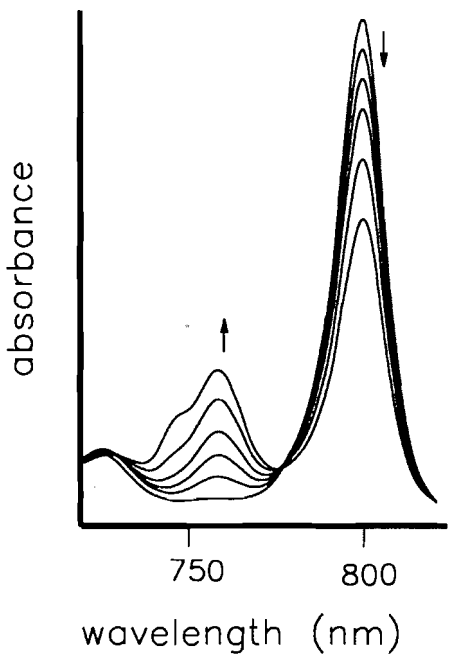
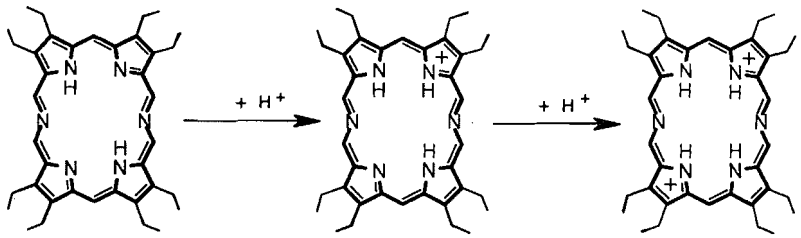


Scheme 1.



weak basicity of the imine nitrogens was also reflected in the inability of these atoms to coordinate with zinc (1).

Using the absorbance changes at high pH at 798 nm from Fig. 2, K_3 could be obtained from the following eq. [3] (14)

$$[3] \quad \frac{1}{A_0 - A} = \frac{K_3}{A_0 - A_1} \cdot \frac{1}{[H^+]} + \frac{1}{A_0 - A_1}$$

where A_0 and A_1 are the absorbances of the pure free base and pure monocation of the octaethylporphocyanine at 798 nm, and A is that of a mixture of monocation and free base at this specific wavelength. The data for the pH values and absorbances necessary for the calculation of K_3 are given in Table 1. The value of K_3 was calculated from the linear relationship between $1/(A_0 - A)$ and $1/[H^+]$ to be approximately $(1.1 \pm 0.1) \times 10^{-6}$, corresponding to a pK_3 of 6.0 ± 0.1 (Fig. 3). The absorbance and $[H^+]$ relationship for the calculation of K_4 can be easily derived as follows:[2]

$$[4] \quad \frac{1}{A_\infty - A} = \frac{[H^+]}{(A_\infty - A_2)K_4} + \frac{1}{A_\infty - A_2}$$

where A_∞ and A_2 are the absorbances of the dication and monocation forms of octaethylporphocyanine at 748 nm, and A is that of a mixture of monocation and dication at this specific wavelength. Using the absorbance changes from Fig. 1 at low pH at 748 nm (Table 2), K_4 can be obtained from the linear relationship between $1/(A_\infty - A)$ and $[H^+]$ (Fig. 4) according to eq. [4]. K_4 was found to be $\sim(4.2 \pm 0.1) \times 10^{-5}$, corresponding to a pK_4 of 4.4 ± 0.1.

A distribution diagram was calculated based on the pK values determined here (Fig. 5). It is clear that the concentration of free base is insignificant below pH 4.0 and that the concentration of dication is negligible above pH 6. Thus the spectrum of monocation in dichloromethane was obtained by subtracting the spectrum of free base from the actual spectrum at pH 6.1. The longest visible absorptions for the three individual species appear distinctly at 748, 760, and 798 nm, respectively. This calculated spectrum of the monocation was found to be the same as the spectrum obtained in methanol. Normally porphyrins form dications on treatment with acids and the intermediate monocationic species are rarely present by

[2] Since $A_2 = \varepsilon_{H_3P^+}cl$, $A_\infty = \varepsilon_{H_4P^{2+}}cl$, and $A = \varepsilon_{H_3P^+}[H_3P^+]l + \varepsilon_{H_4P^{2+}}[H_4P^{2+}]l$, where $c = [H_3P^+] + [H_4P^{2+}]$, it is readily shown from eq. [2] that

$$\frac{A - A_2}{A_\infty - A} = \frac{[H_4P^{2+}]}{[H_3P^+]} = \frac{[H^+]}{K_4}$$

Therefore,

$$\frac{A_\infty - A_2}{A_\infty - A} = \frac{[H^+]}{K_4} + 1$$

Rearranging this equation affords eq. [4].

Table 1. Change of absorbances as a function of $[H^+]$ for pH 6.10–7.20 at 798 nm in CH_2Cl_2–H_2O at 22°C.

A_{798}	$1/(A_0 - A)_{798}$	pH	$1/[H^+]$
0.923	22.2	7.20	1.58×10^7

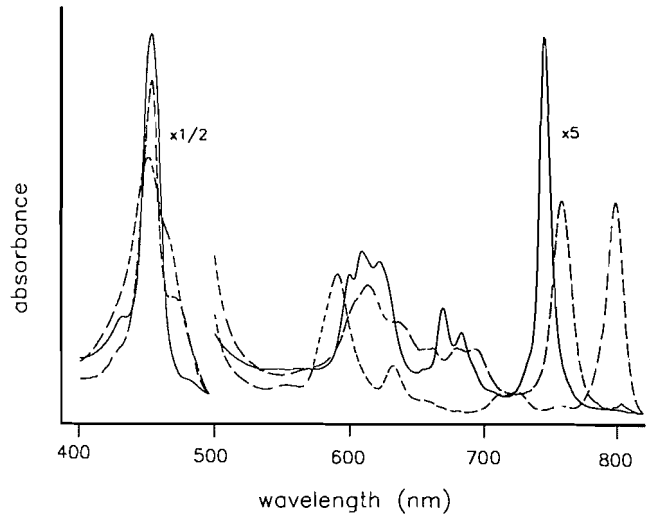
themselves either in solution or the solid state. A crystal structure of octaethylporphyrin monocation (15) and spectral investigation of this monocationic species (16) and that of a tetraphenylporphyrin derivative (17) are among the few such examples in the literature. The fact that octaethylporphocyanine exists as a monocation in a polar organic solvent like methanol indicates that the stability of the monocationic form may result from a nondistorted structure. Distortion of monocationic forms in both tetraphenylporphyrin and octaalkylporphyrin may explain why monocations are rarely observed. In the case of porphyrins the second protonation is normally easier than the first, and only under special conditions can the monocations be observed (8, 18). Porphocyanine, on the other hand, does not seem to need to distort to accommodate a proton, as is seen in the X-ray crystal structure of the zinc derivative where two protons are easily accommodated by two adjacent pyrroles without any distortion from planarity (1). This could, at least in part, be attributed to the observation of a single monocationic species in methanol. It is worth noting that in methanol, addition of HCl led to the formation of dication but addition of NaOH bleached the compound. Thus the free base spectra in methanol was obtained in the presence of

Fig. 6. Optical spectra of porphocyanine in methanol in the presence of triethylamine (-···-), in the presence of HCl (—), and in neat methanol (---).



triethylamine. In acetic acid, octaethylporphocyanine is present as the dication whereas octaethylporphyrin exists as the monocationic form (13). The optical spectra of free base, monocation, and dication of octaethylporphocyanine in methanol are presented in Fig. 6.

The pK_3 and pK_4 values of octaethylporphyrin were determined to be 6.1 and 4.6 in nitrobenzene–$HClO_4$ (19). It is difficult to make a comparison between data determined by different methods; however, we tentatively draw the conclusion that the protonation behavior of porphocyanine is similar to that of porphyrins, with pK_3 and pK_4 differing by about two pK units. We feel that the only proper comparison can be made between porphyocyanine **1** and sapphyin **4** where pK_a values were measured under similar conditions. Octaethylporphocyanine is much less basic than 3,8,12,13,17,22-hexaethyl-2,7,18,23-tetramethylsapphyrin with pK_3 and pK_4 values of 9.5 and 3.5 (10). Attempts by us to determine the pK's of octaethylporphyrin in the same biphasic solvent system were unsuccessful.

Iron porphyrin catalyzed oxidation of lignin model compounds: oxidation of phenylpropane and phenylpropene model compounds

Futong Cui and David Dolphin

Abstract: The oxidation of 1-(4-ethoxy-3-methoxyphenyl)propane (**2**) and 1-(4-ethoxy-3-methoxyphenyl)propene (**3**) by *meso*-tetra(2,6-dichloro-3-sulphonatophenyl)porphyrin iron chloride (TDCSPPFeCl, **1**) and *tert*-butylhydroperoxide (*t*-BuOOH) are discussed. In addition to a C_α-hydroxylation product, demethoxylation and direct aromatic ring cleavage products were found in the oxidation of **2**. When **3** was oxidized by **1** and *t*-BuOOH in aqueous acetonitrile, an acetonitrile-incorporated product was found. A mechanism for the oxidation of **3** is proposed.

Key words: lignin, ligninase, iron porphyrin, model, degradation.

Résumé : On discute de l'oxydation du 1-(4-éthoxy-3-méthoxyphényl)propane (**2**) et du 1-(4-éthoxy-3-méthoxyphényl)propène (**3**) par du chlorure de *meso*-tétra(2,6-dichloro-3-sulfatophényl)porphyrine fer (**1**) et l'hydroperoxyde de *tert*-butyle (*t*-BuOOH). En plus d'un produit d'hydroxylation en C_α, l'oxydation du produit **2** a conduit à des produits de déméthoxylation et de clivage direct du noyau aromatique. Lors de l'oxydation du composé **3** par le composé **1** et le *t*-BuOOH, en solution aqueuse d'acétonitrile, on a observé la formation d'un produit incorporant de l'acétonitrile. On propose un mécanisme pour l'oxydation du produit **3**.

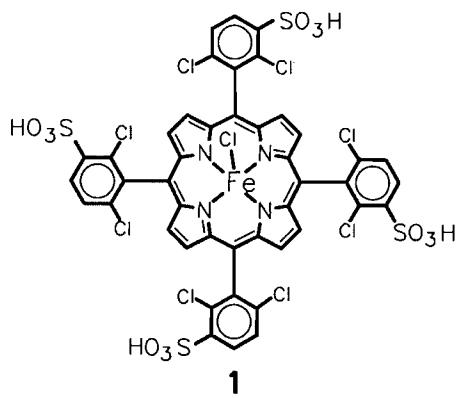
Introduction

Lignin is an aromatic, heterogeneous biopolymer composed of phenylpropanoid units, which are interconnected by C—C and C—O bonds. It occurs widely in plants in the form of lignocellulose (the complex of lignin and cellulose and hemicelluloses), the predominant land-produced biomass. Lignin is among the most persistent carbon–oxygen polymers in nature. Because of the close association of lignin and cellulose, lignin acts as a barrier to the biodegradation of lignocellulose. Lignin-degrading enzymes, lignin peroxidases (1, 2) and Mn(II)-dependent peroxidases (3), have been isolated from the most studied lignin-degrading white rot fungus, Basidiomyce *Phanerochaete chrysosporium*. Lignin peroxidases have been shown capable of catalyzing a variety of degradations and transformations of lignin model compounds (4), including C_α—C_β cleavage of β-O-4 and β-1 dimers (1, 2), β-O-4 cleavage of β-O-4 dimers (5), C_α oxidation (6) and benzylic methylene hydroxylation (7) (C_α hydroxylation), C_α—C_β double bond hydroxylation (2), and aromatic ring cleavage of veratryl alcohol (8) and β-O-4 dimers (9). Iron porphyrins have been used as lignin peroxidase models and shown able to catalyze C_α—C_β cleavage



1

(10–14), C_α oxidation (10, 12, 13), and aromatic ring cleavage reactions (15). We report in this paper the C_α hydroxylation of the phenylpropane model compound, the C_α—C_β double bond hydroxylation (glycol formation) of the phenylpropene model compound, along with other reactions of the two model compounds catalyzed by *meso*-tetra-(2,6-dichloro-3–sulfonatophenyl)porphyrin iron chloride (**1**, TDCSPPFeCl). Related water-soluble metalloporphyrins have also been used by Labat and Meunier (16).

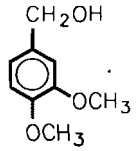
Results and discussion

Tien and Kirk (7) first found that lignin peroxidase catalyzed the hydroxylation of the benzylic methylene group of 2-(3,4-dimethoxyphenyl)ethanol to give 3,4-dimethoxyphenylglycol, which was then further oxidized at the C_α position. Renganathan et al. (17, 18) also reported the C_α hydroxylation of 4-ethoxy-3-methoxyphenylpropane by lignin peroxidase. In addition to the C_α hydroxylation product (**4**) found earlier (17, 18), oxidation of 1-(4-ethoxy-3-methoxyphenyl)propane (**2**) by TDCSPPFeCl and *t*-BuOOH in air at room temperature also gave **5**, **6**, and **7** as major products (Scheme 1). Small amounts of other unidentified products were found by TLC and GC analysis.

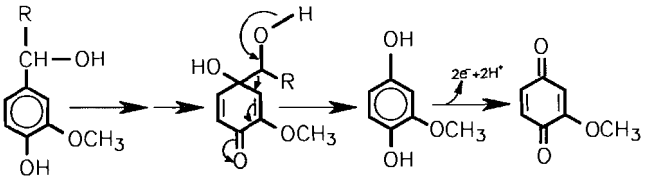
The formation of 2-ethoxy-5-propyl-2,5-cyclohexadien-1,4-dione (**5**) is not unexpected since a similar product, 2-hydroxymethyl-5-methoxy-2,5-cyclohexadien-1,4-dione, was found during the oxidation of veratryl alcohol by both lignin peroxidase (19) and by iron porphyrins (14).



veratryl alcohol

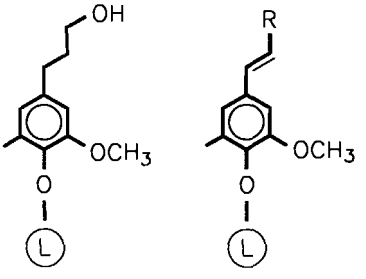
A muconate was first found in the oxidation of a β-O-4 dimer by lignin peroxidase (20). Direct ring cleavage products from the oxidation of veratryl acetate (14) and from veratryl methyl ether (21) have also been reported. The formation of **6** shows that ring cleavage is also an important reaction of the substituted phenylpropane substructure (**8**) of lignin. Phenyl–alkyl cleavage has been found in the oxidation of veratryl alcohol and derivatives by lignin peroxidase (19, 21–23) and by biomimetic systems (14). A mechanism for the phenyl–alkyl cleavage of phenolic model compounds has been proposed (24) as shown in Scheme 2. Formation of **10** results from two one-electron oxidations of **8**. Oxidation of **2** (Scheme 3) gave compound **7**, which is an analog of intermediate **10**, and the characterization of **10** supports the proposed cleavage mechanism (24). Phenyl–alkyl cleavage of **7** did not occur because of the absence of a hydroxy group at the C_α position.

Scheme 2.



9 10

The alkoxy-substituted phenylpropane substructure (**8**) has been suggested as a chain terminus of lignin (25). The relation between C_α hydroxylation of this substructure and lignin biodegradation has not been established (7, 17, 18). Leisola et al. (19, 23) have suggested a pathway of lignin biodegradation that involves the release of low molecular weight quinones and ring cleavage products from the chain terminii of lignin. The quinones and ring cleavage products so released are finally metabolized to carbon dioxide by the fungus, *P. chrysosporium* (23). According to Leisola's hypothesis (19, 23), demethoxylation and aromatic ring cleavage of **2** to give **5** and

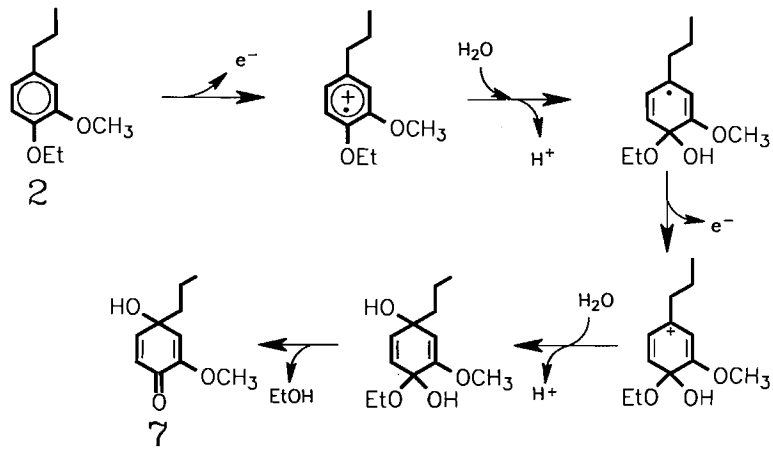


8 **11**

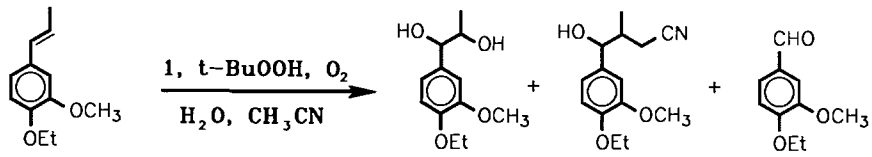
R=CH_2OH or CHO

6 are more important degradative reactions for lignin biodegradation than the C_α hydroxylation. It is possible that the C_α hydroxylation product **4** or its C_α-carbonyl analog cannot be metabolized directly, since it has been demonstrated that veratryl alcohol and its C_α oxidation product (veratraldehyde) are not directly metabolized (23).

Scheme 3.



Scheme 4.



Alkoxy-substituted phenylpropene substructures (**11**) are also found in the lignin chain terminii (25). Diol formation was reported to be the first step in the biodegradation by *P. chrysosporium* culture of lignin model compounds containing this substructure (26–29). 1-(4-Ethoxy-3-methoxyphenyl)propene (**3**) has been used as a model compound for this substructure of lignin. Lignin peroxidase (2, 17, 30) was shown to be able to catalyze the hydroxylation of **3** to give 1-(4-ethoxy-3-methoxyphenyl)-1,2-propanediol (**12**). The oxygen of the 2-hydroxy group of **12** was later shown to be from molecular oxygen (31). TDCSPPFeCl (1) was found to closely mimic lignin peroxidase in the oxidation of **3**. When **3** was oxidized by TDCSPPFeCl and *t*-BuOOH in aqueous acetonitrile in air, 4-ethoxy-3-methoxybenzaldehyde, the diol **12**, and the solvent-incorporated product 4-hydroxy-4-(4-ethoxy-3-methoxyphenyl)-3-methylbutyronitrile (**13**) were obtained (Scheme 4).

Cytochromes P-450 (32), which are monooxygenases and function by activating molecular oxygen, are able to catalyze diol formation from alkenes via an epoxide intermediate. Lignin peroxidases are peroxidases (7, 17, 33–35) having peroxidase and haloperoxidase activity (36). No monooxygenase activity of lignin peroxidase has been reported so far. Because of the great chemical diversity of lignin structure, diol formation from lignin via an epoxide intermediate is unlikely since the substrate needs to approach the active site of cytochromes P-450 closely for direct oxygen atom transfer and epoxide formation to occur. The ability of the ligninolytic culture of *P. chrysosporium* to metabolize lindane (1,2,3,4,5,6-hexachlorocyclohexane) to carbon dioxide (37) suggests the presence of enzymic activity other than that of peroxidases, though it is still not clear which enzyme(s) is responsible for lindane degradation.

While no direct evidence is available to exclude the epoxide pathway of diol formation, the formation of **13** from the oxidation of **3** certainly suggests radical formation as at least one of the pathways. Scheme 5 illustrates a pathway for the formation of **12** and **13**. One-electron oxidation of **3** gives the cation radical. Attack at the cation radical by water gives the C_β-centred radical, coupling of which with oxygen or a further one-electron oxidation followed by reaction with water gives the diol **12**. Coupling of the C_β-centred radical with acetonitrile radical gives **13**. In addition, when **3** was oxidized under oxygen (bubbling oxygen through the reaction mixture), little **13** was detected, probably because of the competitive coupling of molecular oxygen with the C_β-centred radical.

In conclusion, although **8** and **11** substructures might be present in lignin in small amounts, we believe that the reactions of the phenylpropane and phenylpropene model compounds described above are important for lignin biodegradation since the two substructures are mostly located at the chain terminal from where lignin biodegradation most probably begins.

Experimental

NMR spectra were recorded on a Varian XL 300 or a Bruker WH 400 spectrometer using tetramethylsilane as an internal standard. Low-resolution mass spectra (LRMS) were recorded on an AEI MS9 spectrometer and high-resolution mass spectra (HRMS) were recorded on a KRATOS MS50 spectrometer. An HP 5890A gas chromatograph equipped with a 25 m HP17 capillary column was used for the GC analyses. Product yield was calculated based on GC peak area percentage of the total product peak area. Delsi Nermag R10–10C/Kratos MS80RFA instruments were used for the GCMS analyses. Infrared spectra were obtained on a Perkin–Elmer 1710 Fourier transform spectrometer. Preparative thin-layer chromatography (TLC) was performed on a model 7924T chromatotron (Harrison

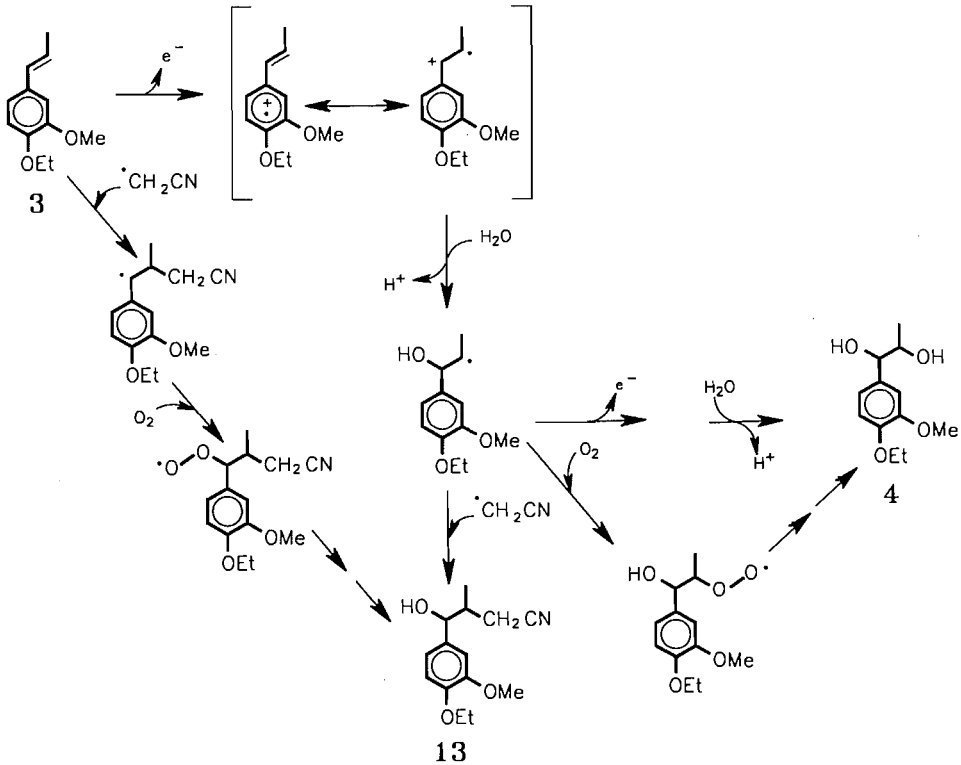
Scheme 5.



Research) using silica gel 60 PF_{254} as absorbent. Merck precoated silica gel 60 PF_{254} TLC plate (0.2 mm) was used for analytical purposes. *t*-BuOOH, eugenol, and isoeugenol were from Aldrich.

Syntheses of model compounds

Compound **2** and **3** were synthesized following reported procedures (38, 39).

Oxidation of 1-(4-ethoxy-3-methoxyphenyl)propane (2) and 1-(4-ethoxy-3-methoxyphenyl)propane (3)

Compound **2** (0.25 mmol) was reacted with *t*-BuOOH (1.25 mmol) and TDCSPPFeCl (0.5 μmol in 500 μL of water) in 20 mL of 1:1 acetonitrile/pH 3 phosphate buffer (0.1 M) at room temperature in air for 3 h. Unreacted *t*-BuOOH was decomposed by adding solid potassium iodide. The solution was then extracted with ethyl acetate (3 × 10 mL). The iodine in the extract was removed by washing with aqueous sodium thiosulphate. The organic extract was dried over sodium sulphate, filtered, and evaporated. One fifth of the residue was acetylated with excess acetic anhydride/pyridine (1:1) and analyzed by GC and GCMS. The rest was separated on a chromatotron as previously described (16). Compounds **5**, **6**, and **7** were obtained in 23, 18, and 20% yields, respectively.

The oxidation of **3** was carried out in the same manner as for **2**, except that the reaction time was 2 h, to give 4-ethoxy-3-methoxybenzaldehyde (20%), **12** (33%), and **13** (18%). When the reaction was carried out for 3 h or longer, 4-ethoxy-3-methoxybenzaldehyde was the major product.

1-(4-Ethoxy-3-methoxyphenyl)propanol (**4**) was obtained in a 20% yield and identified as its acetate; MS: 252, 192, 131, 164, 163, 149, 133, 131, 107, 103, 91, 79, 77.

2-Ethoxy-5-propyl-2,5-cyclohexadien-1,4-dione (**5**): ^{1}H NMR ($CDCl_3$) δ: 0.97 (3H, t, J = 8 Hz), 1.47 (3H, t, J = 7 Hz), 1.51–1.57 (2H, m), 2.41 (2H, m), 4.01 (2H, q, J = 7 Hz), 5.90 (1H, s), 6.49 (1H, s, br). MS *m/z* (%): 194 (4.0), 179 (3.7), 167 (4.1), 166 (5.1), 165 (8.4), 151 (34.8), 150 (23.7), 149 (32.6), 69 (100.0), 67 (22.3), 57 (25.6), 55 (23.4), 53 (28.0), 44 (20.6), 43 (34.4), 41 (30.0). Exact Mass calcd. for $C_{11}H_{14}O_3$: 194.0939; found (HRMS): 194.0934.

Compound **6**: ^{1}H NMR ($CDCl_3$) δ: 0.3 (3H, t, J = 7 Hz), 1.26 (3H, t, J = 7 Hz), 1.44–1.57 (2H, m), 2.39 (2H, t, J = 7 Hz), 3.67 (3H, s), 4.34 (2H, q, J = 7 Hz), 5.76 (1H, s, br), 5.88 (1H, d, J = 12 Hz), 7.05 (1H, dd, J_1 = 12 Hz, J_2 = 1–2 Hz). MS *m/z* (%): 226 (2.74), 211 (1.10), 195 (4.73), 194 (2.27), 181 (9.78), 167 (71.67), 153 (100.0), 149 (10.12), 139 (75.41). Exact Mass calcd. for $C_{12}H_{18}O_4$: 226.1200; found (HRMS): 226.1204.

4-Hydroxy-2-methoxy-4-propyl-2,5-cyclohexadien-1-one (**7**) (40): FTIR (KBr pellet) (cm^{-1}): 3436, 1672, 1645, 1214. ^{1}H NMR ($CDCl_3$) δ: 0.94 (3H, t, J = 8 Hz), 1.26–1.36 (2H, m), 1.76–1.81 (2H, m), 1.92 (1H, s, exchangeable), 3.69 (3H, s), 5.72 (1H, d, J = 2–3 Hz), 6.20 (1H, d, J = 10 Hz), 6.83 (1H, dd, J_1 = 2–3 Hz, J_2 = 10 Hz). MS *m/z* (%): 182 (13.9), 166 (21.8), 140 (22.8), 139 (100.0), 111 (39.3), 94 (29.41), 93 (33.3), 81 (26.7), 79 (32.0), 77 (46.0), 69 (88.0), 68 (29.3), 67 (25.5), 66 (28.9), 65 (68.4), 55 (85.5), 53 (53.4), 52 (26.6), 51 (47.6). Exact Mass calcd. for $C_{10}H_{14}O_3$: 182.0939; found (HRMS): 182.0942.

1-(4-Ethoxy-3-methoxyphenyl)-1,2-propandiol (**12**) (30) (isolated as its diacetate): ^{1}H NMR ($CDCl_3$) δ: 1.08 (3H, d, J = 7 Hz), 1.45 (3H, t, J = 7 Hz), 2.05 (3H, s), 2.07 (3H, s), 3.89 (3H,

Abstract: Our study of the photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction has been extended to include alk-4-enols. Irradiation of acetonitrile solutions of the alk-4-enols, 6-methyl-5-hepten-2-ol (**16**) and 5-methyl-5-hexen-2-ol (**17**), and the aromatic, 1,4-dicyanobenzene (**1**), leads to cyclized 1:1 (alk-4-enol:aromatic) adducts. The addition of biphenyl (**5**) to the irradiation mixture, serving as a codonor, increases the yields and the efficiency of formation of the adducts. The structures assigned to the products, *trans*-2-(isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran (**18**, 29%) and *cis*-2-(isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran (**19**, 24%) from **16** (reaction [5]), and *r*-2-(methyl 4-cyanophenyl)-2,*t*-5-dimethyltetrahydrofuran (**20**, 13%), *r*-2-(methyl 4-cyanophenyl)-2,*c*-5-dimethyltetrahydrofuran (**21**, 7%), *r*-3-(4-cyanophenyl)-3,*t*-6-dimethyltetrahydropyran (**22**, 11%), and *r*-3-(4-cyanophenyl)-3,*c*-6-dimethyltetrahydropyran (**23**, 2%), from **17** (reaction [6]), rests mainly upon analysis of the ^{1}H and ^{13}C nuclear magnetic resonance spectra. The structures of **19**, **22**, and **23** were firmly established by X-ray crystallography. The observed ratio of regioisomers indicates a strong preference for 1,5-*exo-trig*, relative to 1,6-*endo-trig*, cyclization of the intermediate alk-4-enol radical cation. The mechanistic implication of these results is discussed.

Key words: photoinduced electron transfer, radical ions, cyclization of radical cations, intramolecular reactions of radical cations.

Résumé : Notre étude de la réaction de substitution aromatique avec combinaison de nucléophile et d'oléfine a été étendue de façon à inclure les alc-4-énols. L'irradiation de solutions dans l'acétonitrile des alc-4-énols, 6-méthylhept-5-én-2-ol (**16**) et 5-méthylhept-5-én-2-ol (**17**), et du 1,4-dicyanobenzène (**1**) conduit à des adduits 1 : 1 cyclisés (alc-4-énol : aromatique). L'addition de biphényle (**5**, qui agit comme codonneur) au milieu d'irradiation augmente les rendements et l'efficacité de la formation des adduits. Les structures ont été principalement assignées sur la base de l'analyse de leurs spectres RMN du ^{1}H et du ^{13}C : *trans*-2-(isopropyl 4-cyanophényl)-5-méthyltétrahydrofurane (**18**, 29%) et *cis*-2-(isopropyl 4-cyanophényl)-5-méthyl-tétrahydrofurane (**19**, 24%) (à partir du produit **16**, réaction [5]) et *r*-2-(méthyl 4-cyanophényl)-2,*t*-5-diméthyltétrahydrofurane (**20**, 13%), *r*-2-(méthyl 4-cyanophényl)-2,*c*-5-diméthyltétrahydrofurane (**21**, 7%), *r*-3-(4-cyanophényl)-3,*t*-6-diméthyltétrahydrofurane (**22**, 11%), *r*-3-(4-cyanophényl)-3,*c*-6-diméthyltétrahydrofurane (**23**, 2%) (à partir du produit **17**, réaction [6]). Les structures des composés **19**, **22** et **23** ont été confirmées par diffraction des rayons X. Les rapports de régioisomères observés indiquent que, pour la cyclisation du cation radical alc-4-énol intermédiaire, il existe une forte préférence pour une cyclisation 1,5-*exo-trig* par rapport à une cyclisation 1,6-*endo-trig*. On discute des implications mécanistiques de ces résultats.

Mots clés : transfert d'électron photoinduit, ions radicaux, cyclisation de cations radicaux, réactions intramoléculaires de cations radicaux.

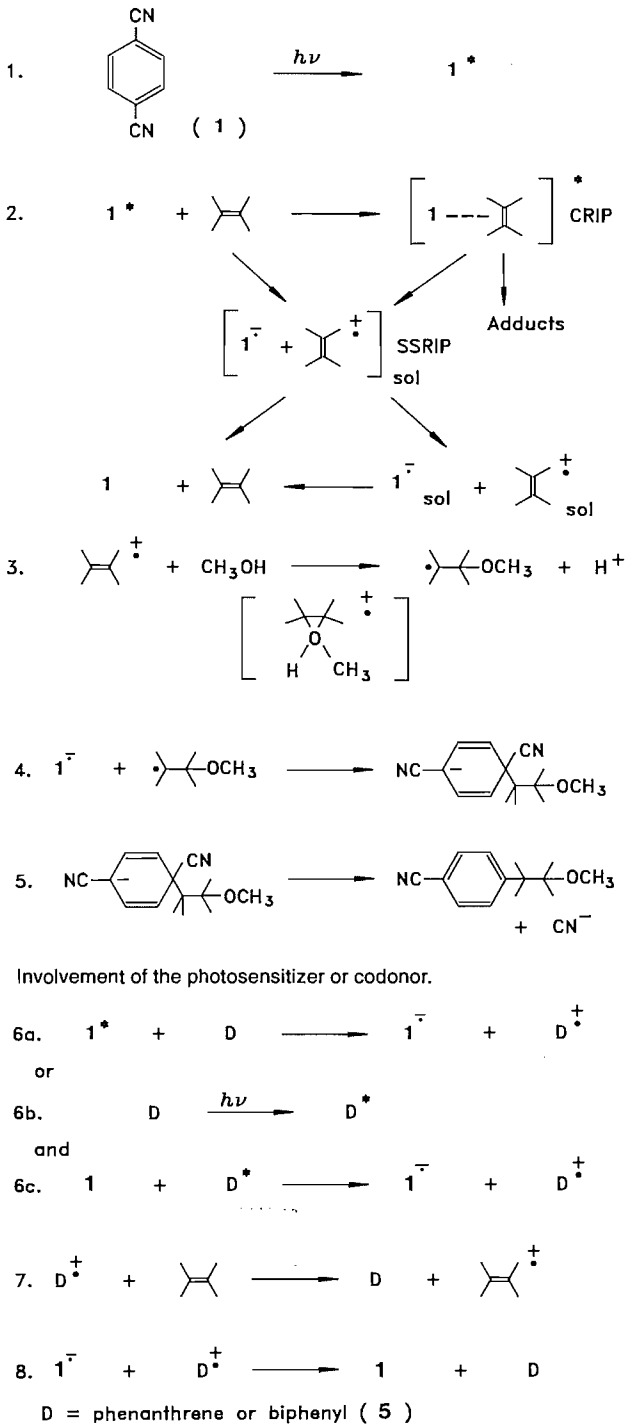
Scheme 1

Mechanism for formation of photo–NOCAS products.



Involvement of the photosensitizer or codonor.

Introduction

Initial studies of the photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction involved the combination of a nucleophile (usually an alcohol), simple mono-olefins, and an electron-withdrawing substituted aromatic (1, 3). One of the first examples combined methanol, 2-methylpropene (**2**), and 1,4-dicyanobenzene (**1**) (reaction [1]) (3). Subsequent studies have confirmed the proposed mechanism (Scheme 1). Firstly, photoinduced single electron transfer occurs from the olefin to the singlet excited state of **1** (Scheme 1, steps 1 and 2) (1, 3). The resulting olefin radical cation is then attacked by the nucleophile (methanol) to give the β-alkoxy alkyl radical (step 3). This radical couples with the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\cdot}$) at an *ipso* position (step 4), followed by loss of cyanide ion and rearomatization (step 5). Addition of a codonor, biphenyl (**5**), to the photo-NOCAS reaction has been shown to increase the efficiency of product formation (Scheme 1, steps 6 and 7) (1, 3). This increase in efficiency is thought to be due to a smaller energy of reorganization for the biphenyl (**5**) – 1,4-dicyanobenzene (**1**) radical-ion pair than for the olefin – 1,4-dicyanobenzene (**1**) radical-ion pair, resulting in an increase in the efficiency of solvent separation of the radical ions from the initially formed geminate radical-ion pair (SSRIP) (3). Subsequent studies have therefore generally included biphenyl (**5**), serving as a codonor, along with the nucleophile, the olefin, and the aromatic.

A variety of substituted olefins have been examined and the regio- and stereoselectivity of the reaction have been established. From the first examples, the regiochemistry of the reaction has been described as *anti*-Markovnikov. That is, the nucleophile (methanol) becomes attached to the olefinic double bond at the least substituted carbon. Results reported here, for the archetypical example of a trisubstituted olefin, 2-methyl-2-butene (**6**), are consistent with this generalization (reaction [2]).

Recently, the scope of this study was extended to include dienes, both conjugated and nonconjugated (1). Nonconjugated 1,5- and 1,6-dienes have been shown to undergo intramolecular cyclization at the radical cation stage, before reaction with the nucleophile, to yield products resulting from substitution of the aromatic with a saturated six- and (or) seven-membered ring (reactions [3] and [4]). The observation of these diene-cyclized products stimulated this study, to further extend the reaction to alk-4-enols. Intramolecular addition could occur, formation of the alkenol radical cation followed by attack of the hydroxyl group, to yield 1,5-*exo-trig* and (or) 1,6-*endo-trig* cyclized product(s).

Rules for cyclization of the common intermediates (carbocations, carbanions, and radicals) are already well understood (4, 5). From the results of the photo-NOCAS reaction involving the cyclization of the unconjugated dienes and the cyclization of the alk-4-enols we can now begin to define rules for cyclization of radical cations.

Results

An acetonitrile–methanol (3:1) solution of 2-methyl-2-butene (**6**), 1,4-dicyanobenzene (**1**), and biphenyl (**5**) was irradiated (reaction [2]). Progress of the reaction was monitored by capillary column gas chromatography with a flame ionization detector (gc/fid). The first indication of the structure of the products was obtained from a gas chromatograph equipped with a mass selective detector (gc/ms). Products were isolated by medium-pressure liquid column chromatography (mplc) on silica gel. Yields were based upon the amount of 1,4-dicyanobenzene (**1**) consumed; the olefin was present in excess. Two 1:1:1 (nucleophile:olefin:aromatic) photo-NOCAS adducts (**7** and **8**) were obtained in high yield (70%

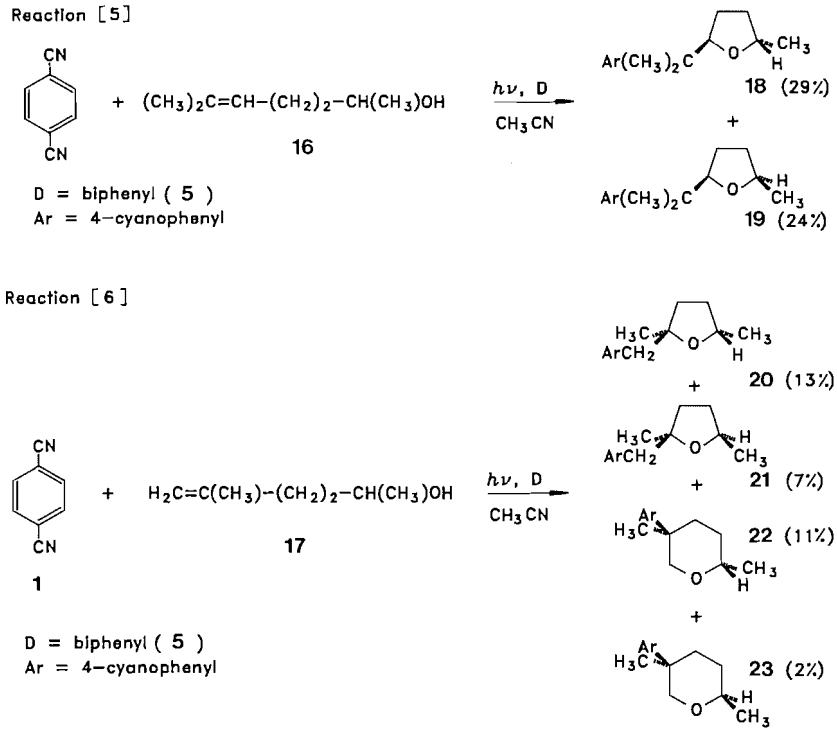
isolated). The mass spectrum of the major adduct (**7**, 87%) has the base peak at 59 *m/z* (C_3H_7O) and the second largest peak at 145 *m/z* (cyanophenylpropyl). For the minor adduct (**8**, 13%), analogous fragments occur at 73 *m/z* (C_4H_9O) and 130 *m/z* (cyanophenylethyl). The ratio of products was determined from the integrated peak area in the gc/fid of the reaction mixture. The adducts were isolated by medium-pressure liquid column chromatography (mplc) and the ratio of the isolated products is in good agreement with the gc/fid results. The structural assignments rest firmly upon an analysis of the ^1H and ^{13}C nmr spectra.

The alk-4-enols chosen for study were (±) 6-methyl-5-hepten-2-ol (**16**) and (±) 5-methyl-5-hexen-2-ol (**17**). When acetonitrile solutions of the alk-4-enol, 1,4-dicyanobenzene (**1**), and biphenyl (**5**) were irradiated with a medium-pressure mercury vapour lamp through Pyrex, the products were cyclized 1:1 (alk-4-enol:**1**) photo-NOCAS adducts. Structural assignments were based primarily upon detailed analysis of ^1H and ^{13}C nmr spectra and, for three of the products (**19**, **22**, and **23**), structures were firmly established by X-ray crystallography.[3]

Irradiation of an acetonitrile solution of 6-methyl-5-hepten-2-ol (**16**), 1,4-dicyanobenzene (**1**), and biphenyl (**5**) gave *trans*-2-(isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran (**18**, 29%) and *cis*-2-(isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran (**19**, 24%) (reaction [5]). Both **18** and **19** result from intramolecular 1,5-*exo-trig* cyclization; no product indicative of 1,6-*endo-trig* cyclization was detected.

[3] Data for **22** and **23** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6. Details of data collection, structural analysis and refinement, and tables of interatomic distances and bond angles have also been deposited with the Cambridge Crystallographic Data Centre and may be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.



Four photo-NOCAS adducts resulted from irradiation of an acetonitrile solution of 5-methyl-5-hexen-2-ol (**17**), 1,4-dicyanobenzene (**1**), and biphenyl (**5**). The structures and yields of these products were: *r*-2-(methyl 4-cyanophenyl)-2,*t*-5-dimethyltetrahydrofuran (**20**, 13%), *r*-2-(methyl 4-cyanophenyl)-2,*c*-5-dimethyltetrahydrofuran (**21**, 7%), *r*-3-(4-cyanophenyl)-3,*t*-6-dimethyltetrahydropyran (**22**, 11%), and *r*-3-(4-cyanophenyl)-3,*c*-6-dimethyltetrahydropyran (**23**, 2%) (reaction [6]). Compounds **20** and **21** result from 1,5-*exo-trig* cyclization; their combined yield makes this the major (60%) mode of cyclization. Compounds **22** and **23** result from 1,6-*endo-trig* cyclization.

Structural assignments

The initial structural assignments for **7** and **8**, based upon the fragmentation pattern in their mass spectra, were confirmed by ^{1}H and ^{13}C nmr spectroscopy. Adduct **7** was identified as the *anti*-Markovnikov product, 2-(4-cyanophenyl)-3-methoxy-2-methylbutane. The aliphatic region of the ^{1}H nmr spectrum shows a doublet (0.92 ppm) corresponding to a methyl group adjacent to a methine group. The proton of the methine group produces a quartet (3.30 ppm). This low-field quartet is indicative of a methine group adjacent to an oxygen. Protons adjacent to oxygen generally occur at lower field (3.2–3.7 ppm) than those adjacent to the 4-cyanophenyl group (2.4–3.0 ppm) (1, 3). A singlet (3.24 ppm) represents the methoxy methyl group and the typical AA′XX′ pattern in the aromatic region of the ^{1}H nmr spectrum is indicative of the 4-cyanophenyl group. Further support for the *anti*-Markovnikov orientation was provided by the ^{13}C nmr spectrum. A singlet (43.10 ppm) representing an aryl-substituted quaternary carbon is observed, along with a doublet (84.28 ppm) indicating a methine carbon bonded to a methoxy group.

Compound **8** was identified as the Markovnikov product, 3-(4-cyanophenyl)-2-methoxy-2-methylbutane. Compound **8** shows characteristic patterns similar to those of **7**. A distinctive feature in the ^{1}H nmr spectra is the appearance of a quartet (2.90 ppm) at higher field for **8**, as opposed to the quartet (3.30 ppm) at lower field for **7**, indicating the methine group is aryl substituted (**8**) rather than methoxy substituted (**7**). In the ^{13}C nmr spectrum, there is a doublet (48.96 ppm) at higher field for **8**, as opposed to the doublet (84.28 ppm) at lower field that appears in the spectrum of **7**. Again, this supports a methine group aryl substituted in **8** rather than methoxy substituted as in **7**.

Compound **19** was identified as *cis*-2-(isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran. The presence of three methyl groups, one of which is adjacent to a methine, is indicated by two singlets and a doublet (J = 6.1 Hz) in the aliphatic region of the ^{1}H nmr spectrum. A high-field multiplet represents the four hydrogens of the methylene groups on the tetrahydrofuran ring. A low-field multiplet at 3.91 ppm shows a methine group, adjacent to an oxygen, and substituted with an alkyl-aryl group. Another low-field multiplet appears at 3.92 ppm with one of its couplings being 6.1 Hz. This represents the methine group, adjacent to an oxygen, and substituted by a methyl group. An AA′XX′ pattern in the aromatic region is indicative of a 4-cyanophenyl group. The ^{13}C nmr spectrum of **19** indicates a quaternary carbon, substituted by two methyl groups and an aryl group (41.53 ppm), and two doublets (75.53 and 86.50 ppm) for two methine groups bonded to oxygen. The *cis* configuration, as well as the overall structure of **19**, was firmly established by X-ray diffraction of a single crystal (Fig. 1).

Compound **18** was identified as *trans*-2-(isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran, the configurational isomer of **19**. The mass spectrum and the ^{1}H and ^{13}C nmr spectra of **18** are very similar to those of the *cis* isomer.

Adduct **20** was identified as *r*-2-(methyl 4-cyanophenyl)-2,*t*-5-dimethyltetrahydrofuran. The ^{1}H nmr spectrum exhibits

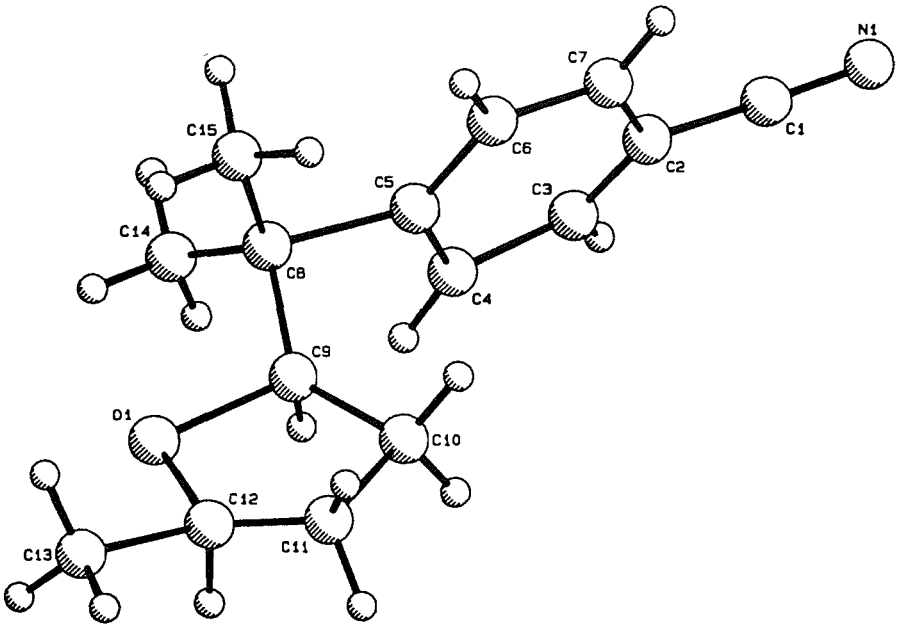
Fig. 1. X-ray structure for *cis*-2-(isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran (**19**); details in the experimental section.



a singlet and a doublet (J = 6.1 Hz) in the aliphatic region, indicative of two methyl groups, one of which is adjacent to a methine group. Two high-field multiplets represent two methylene groups of the tetrahydrofuran ring. Two lower field doublets (2.79 and 2.86 ppm, J = 13.3 Hz) represent the methylene group substituted with the aryl group. At 3.90 ppm, another multiplet appears with one of its couplings being J = 6.1 Hz. This represents the methine group adjacent to an oxygen and substituted by a methyl group. An AA′XX′ pattern in the aromatic region is indicative of the 4-cyanophenyl group. The ^{13}C nmr spectrum of **20** indicates a methylene group (46.92 ppm) substituted by an aryl group and a doublet and a singlet (75.27 and 82.42 ppm, respectively) indicate a methine group and a quaternary carbon bonded to oxygen. The *cis* configuration of the methyl groups, as well as the overall structure of **20**, was established by the observed nuclear Overhauser enhancement (NOE). When the low-field multiplet (3.90 ppm) due to the proton adjacent to the oxygen was irradiated, a strong NOE was observed in the signal due to the protons in the aromatic region. No NOE was observed in the signal due to the methylene protons (2.79 and 2.86 ppm). This is consistent with the assigned structure since the methine proton is significantly closer to the aromatic protons (AA′) than to the methylene group.

Compound **21**, *r*-2-(methyl 4-cyanophenyl)-2,*c*-5-dimethyltetrahydrofuran, was identified as the configurational isomer of **20**. The ^1H and ^{13}C nmr spectra are very similar to those of **20**. The NOE experiment, irradiation of the low-field (4.06 ppm) multiplet due to the methine group, showed no enhancement in the signals due to the aromatic protons or to the methylene group (2.78 and 2.86 ppm).

Compound **23** was identified as *r*-3-(4-cyanophenyl)-3,*c*-6-dimethyltetrahydropyran. The ^1H nmr spectrum exhibits a singlet and a doublet (J = 6.1 Hz) in the aliphatic region, indicative of two methyl groups, one of which is adjacent to a methine group. Four high-field multiplets represent the two adjacent methylene groups on the tetrahydropyran ring. A low-field doublet (3.43 ppm, J = 12.2 Hz) and a low-field doublet of doublets (4.33 ppm, J = 12.2 Hz, J = 3.0 Hz) represent the methylene group adjacent to the oxygen and the stereogenic carbon, aryl and methyl substituted. Another multiplet appears at 3.47 ppm, exhibiting a coupling of J = 6.1 Hz. This represents the methine group adjacent to the oxygen and substituted by a methyl group. The AA′BB′ pattern in the aromatic region is indicative of the 4-cyanophenyl group. The ^{13}C nmr spectrum of **23** indicates a quaternary carbon substituted by an aryl group (38.04 ppm) and a doublet and a triplet (74.19 and 75.22 ppm, respectively) for methine and methylene groups bonded to oxygen. The quaternary aryl carbon, cyano substituted, was observed at 109.47 ppm, a cyano group at 119.16 ppm, two types of CH groups in the aromatic region (128.10 and 131.98 ppm), and the quaternary aryl carbon, alkyl substituted, as a singlet at 152.37 ppm. The *trans* configuration of methyl groups, as well as the overall structure of **23**, was firmly established by X-ray crystallography (Fig. 2). In the crystal, the aryl group attached to C-3 is axial and the methyl group attached to C-6 is equatorial. Molecular mechanics calculations (MMX) also indicate that this conformer is more stable (15 kJ/mol) than the alternative chair conformer with both methyl groups axial.

Compound **22**, *r*-3-(4-cyanophenyl)-3,*t*-6-dimethyltetrahydropyran, is the configurational isomer of **23**. The ^1H and ^{13}C nmr spectra of **22** are very similar to those of **23**; in this case the protons of the 4-cyanophenyl group show up as a distinct AA′XX′ pattern in the ^1H nmr spectrum. The overall structure of **22** was further confirmed by X-ray analysis (Fig. 3). In the crystal of this isomer, both the aryl group attached to C-3 and the methyl group attached to C-6 are equatorial. Again, molecular mechanics calculations (MMX) indicate that this conformer is more stable (6.2 kJ/mol) than the alternative chair conformer.

Table 1. The oxidation potentials of the alkenes and the calculated free energy change (ΔG_{et}) for the electron transfer process from the alkene to the electronic excited singlet state of the acceptor, 1,4-dicyanobenzene (**1**).

Alkene	$E_{1/2}^{ox}$ (V)[a]	ΔG_{et} (kJ/mol)[b]
2-Methyl-2-butene (**6**)	2.03	−57.8
6-Methyl-5-hepten-2-ol (**16**)	2.00	−60.7
5-Methyl-5-hexen-2-ol (**17**)	2.40	−22.1

[a]Oxidation potentials were measured at a platinum electrode relative to the saturated calomel electrode (SCE) using tetraethylammonium perchlorate (0.1 M TEAP) as the electrolyte in acetonitrile. The anodic waves were irreversible; the half-wave potentials were estimated by subtracting 0.028 V from the peak potentials (7).

[b]Based upon the Weller equation (6); $E_{0,0}$(**1**) 408.4 kJ/mol, $E_{1/2}^{red}$(**1**) −1.66 V, the Coulombic attraction term was taken to be 5.4 kJ/mol (*3a*).

Discussion

The initial steps in the proposed mechanism for the photo-NOCAS reaction involve excitation of the electron acceptor, 1,4-dicyanobenzene (**1**), followed by single electron transfer from the donor, the alkene (Scheme 1, steps 1 and 2). The ΔG_{et} for this process, calculated by the Weller equation (ref. 6):

$$\Delta G_{et} = F[E_{1/2}^{ox}(D) - E_{1/2}^{red}(A) - e/\varepsilon\alpha] - E_{0,0}(A)$$

is exergonic by more than 20 kJ/mol for each of the alk-4-enols studied (**16** and **17**) (Table 1); thus, this electron transfer process is expected to occur at the diffusion-controlled rate (6).

Photo-NOCAS adducts were formed upon irradiation of acetonitrile solutions of **1** and the alk-4-enols **16** and **17**; however, addition of a codonor, biphenyl (**5**), to the irradiation mixtures increases the efficiency of the reactions and the yields of adducts (Scheme 1, steps 6–8) (1).

The regiochemistry of the reaction is determined by initial attack of the nucleophile upon the radical cation of the olefin (Scheme 1, step 3) (1, 3). The selectivity of the intermolecular reaction is well established. The ratio of adducts obtained from 2-methylpropene (**2**) (reaction [1]) illustrates a preference (26:1) for nucleophilic attack at the primary carbon relative to attack at the tertiary carbon. The ratio of products from 2-methyl-2-butene (**6**) is 6:1 in favour of attack at the secondary relative to the tertiary carbon (reaction [2]). The same selectivity (6:1) was observed previously for the reaction involving 1-methylcyclohexene (3).

The intramolecular reaction of 6-methyl-5-hepten-2-ol (**16**) demonstrates a clear preference for 1,5-*exo-trig* relative to 1,6-*endo-trig* cyclization; no product having a tetrahydropyran ring was detected (reaction [5]). This preference for 1,5-*exo-trig* cyclization is even more evident in the reactivity of 5-methyl-5-hexen-2-ol (**17**) (reaction [6]). The normal intermolecular preference for nucleophilic attack at the primary over tertiary carbon (26:1) is now dominated by the preference (1.5:1) for 1,5-*exo-trig* over 1,6-*endo-trig* cyclization.

Reaction of the nucleophile (methanol) with the alkene radical cation is clearly more complex than illustrated in Scheme 1, step 3. The initial formation of an encounter complex may

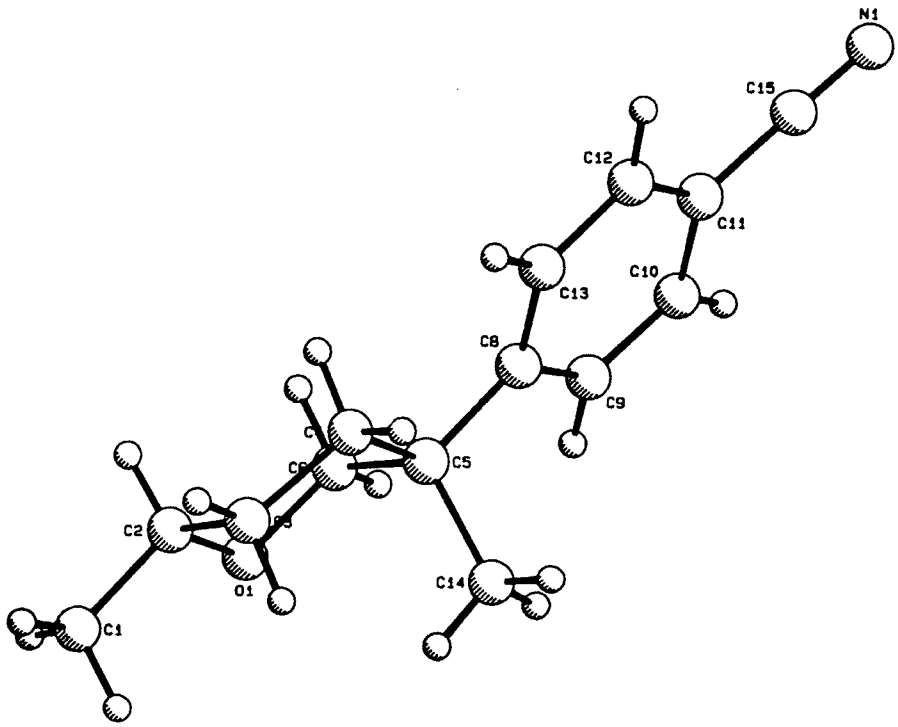
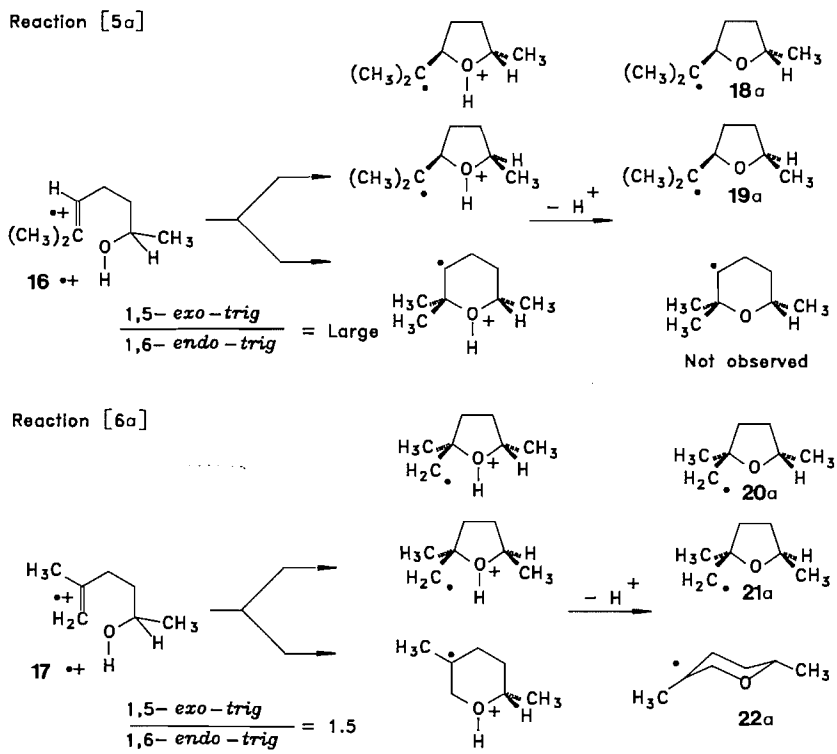
Fig. 3. X-ray structure for *r*-3-(4-cyanophenyl)-3, *t*-6-dimethyltetrahydropyran (**22**) (see footnote 3).





be followed by formation of a bridged radical cation intermediate, which proceeds on to distonic radical cations with alternative carbon–oxygen bond formation. Deprotonation from the oxygen of the distonic radical cations gives the alternative β-alkoxy radicals (reactions [5*a*] and [6*a*]). Presumably, all of the steps preceding formation of the β-alkoxy radicals are reversible. There is no reason, a priori, to presume that the primary β-alkoxy radical intermediates leading to the major products, the tetrahydrofurans (**20**, **21**), are more stable than the tertiary β-alkoxy radical leading to the tetrahydropyrans (**22**, **23**). This deduction is supported by the results of calculations (molecular mechanics (MMX) and semi-empirical

Table 2. Calculated and observed differences in energy (kJ/mol) between the intermediates **21***a*, **20***a*, and **22***a*.

Pyran (**22***a*)	−200.62	38.45		

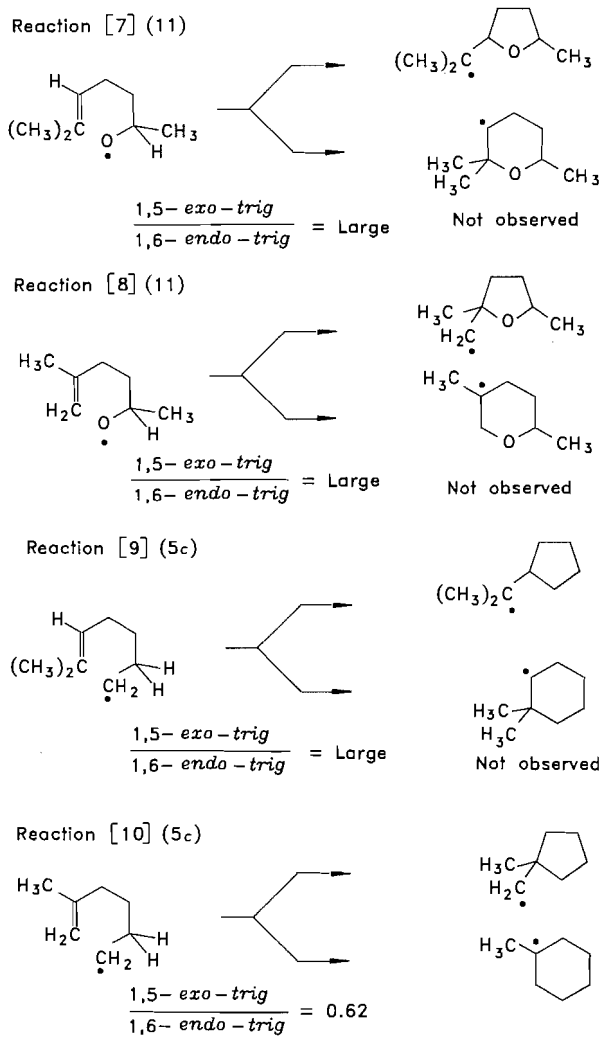
[a]The calculated difference in activation energy (kJ/mol) derived from the observed product ratio.

(AM1)) that indicate that the tertiary β-alkoxy radical (**22***a*) is, in fact, significantly more stable than the primary β-alkoxy radicals (**20***a* and **21***a*) (Table 2). The observed product ratios from the intramolecular cyclizations lead to the conclusion that the regiochemistry is kinetically, not thermodynamically, controlled.

The ratio of stereoisomers obtained is also of interest. The stereochemistry of the tetrahydrofurans (**20** and **21**) is determined during the cyclization step (Scheme 1, step 3, reaction [6*a*]). The ratio of these products follows the relative energy of the intermediate radicals (**20***a* and **21***a*) (Table 2). Since formation of the intermediate radicals is not reversible, it is interesting to note that the ratio of the rates of formation of these intermediates parallels their relative thermodynamic stability.

The stereochemistry of the tetrahydropyrans (**22** and **23**) is determined during the coupling of the dimethyltetrahydropyranyl radical (**22***a*) with the 1,4-dicyanobenzene radical-anion (**1**$^{-\bullet}$) (Scheme 1, step 4). The product ratio indicates a distinct preference (**22/23** = 5.5) for radical–radical-anion coupling from the equatorial position of the pseudo-chair conformation of the radical, with the 2-methyl group in the equatorial position (**22***a*). The calculations (AM1) indicate the radical centre is essentially planar (dihedral angle = 178°). This is consistent with expectations based on the reactivity of alkyl-substituted cyclohexyl radicals (8). Diastereofacial selectivity is dependent upon the size of the reactant (**1**$^{-\bullet}$); equatorial attack is preferred with more bulky reactants. Furthermore, the axial methyl at C-3 of a tetrahydropyran is less hindered than an axial methyl on cyclohexane.

The first set of general rules for predicting the relative facility of ring forming reactions was adumbrated by J.E. Baldwin (4). The rules pertaining to the cyclization of radical intermediates were greatly expanded by Beckwith et al. (5). Several examples of the cyclization of alkenols, involving a wide variety of mechanisms, have been reported (9–26). There are, however, few reported examples of cyclization involving the alkenol radical cation, generated by photoinduced single electron transfer, and these examples have been limited to 1,1-diaryl substituted alkenes (9, 10). With these 1,1-diaryl alkenes, examples of cyclization proceeding 1,5-*exo*-, 1,6-*exo*-, and 1,7-*exo-trig* were observed; however, in all of these cases the regiochemistry of the reaction is dominated by preferred formation of the significantly more stable bis-benzylic radical. Furthermore, the intermediate β-alkoxy bis-benzylic radical is generally reduced, by back electron transfer from the acceptor radical anion, and the resulting anion is protonated; photo-NOCAS products were not observed (9, 10).



The preference for cyclization by the 1,5-*exo-trig* pathway, observed in reactions [5] and [6], is consistent with the previous explanation based upon **approach vector analysis** (4). The favoured transition state incorporates the oxygen and the alkene carbon atoms at the vertices of an obtuse triangle orthogonal to the nodal plane of the π-system. There is convincing evidence that the alkene radical cation maintains the planar structure of the alkene (27). At the transition state, the positive charge will be largely associated with the oxygen, and attached atoms, while the spin density will be borne by the carbon(s), and attached atoms, of the alkene. The structure of the transition state, for the cyclization of the alkenol radical cation, will be similar to that for the cyclization of an alkoxy radical and alkyl radical and it is interesting to compare/contrast these reactions (reactions [7] and [8] (11), and [9] and [10] (5*c*)).

The alkoxy radicals were generated by photolysis of the nitrites (11). In both cases (reactions [7] and [8]) cyclization occurs exclusively by the 1,5-*exo-trig* mode (ca. 60% yield of tetrahydrofuran products); no products resulting from 1,6-*endo-trig* cyclization were observed.

The alkyl radicals were generated by treatment of the halo compounds with Bu_3SnH (reactions [9] and [10]) (5*c*). The cyclization of the 6-methyl-5-heptenyl radical is essentially regiospecific, 1,5-*exo-trig* (reaction [9]). Cyclization of the 5-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

methyl-5-hexenyl radical is not regiospecific; both 1,5-*exo-trig* and 1,6-*endo-trig* cyclization occur; in fact, 1,6-*endo-trig* is favoured.

The explanation given for the differences in reactivity between the alkoxy and alkyl radical cyclization (reactions [8] and [10]) is based upon differences in C—O versus C—C bond lengths. The shorter C—O bond lengths enhance the regiospecificity (and rate) of cyclization of the alkoxy radical (*5a*). The regiochemistry of the cyclization of the 5-methyl-5-hexen-2-ol radical cation ($\mathbf{17}^{+\bullet}$), to give the distonic radical cations (reaction [6a]), more closely resembles the alkyl radical than the alkoxy radical cyclizations, even though the same radicals (**20***a*, **21***a*) are ultimately formed. The same explanation can be applied; the C—O bonds of the intermediate distonic radical cations are longer that the C—O bonds of an ether. Consequently, the tether is long enough to allow 1,6-*endo-trig* cyclization (reaction [6]).

These reactions, cyclization of radical cation intermediates, will have synthetic utility.

Experimental

General information

The ^{1}H and ^{13}C nmr spectra were obtained from a Bruker 250 MSL spectrometer. Spectra were recorded in parts per million and frequencies are relative to tetramethylsilane. Infrared spectra (ir) were recorded on a Nicolet 205 FTIR or on an air-purged Perkin–Elmer 180 grating IR spectrometer and frequencies are reported in wave numbers (cm^{-1}). Elemental analyses were performed by Canadian Microanalytical Service Ltd., B.C. Melting points were determined using a Cybron Corporation Thermolyne apparatus with a digital thermocouple and are corrected. Progress of the reactions was followed by gas chromatography using a Hewlett–Packard (HP) 5890 gas chromatograph with a DB-1701 fused silica WCOT column (20 m × 0.25 mm, 0.4-μm film thickness) and a flame ionization detector (gc/fid). An HP 3392A integrator was interfaced with the gc/fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33-μm film thickness) interfaced with an HP 5970 mass selective detector (gc/ms) was also used for product analyses. Mass spectra are reported as *m/z* (relative intensity). Separation of product mixtures was generally carried out using preparative medium-pressure liquid chromatography (mplc), a 2.5 cm × 1 m column packed with thin-layer chromatography (tlc) grade silica gel (without binder) (cat. no. 7747 Merck) at a pressure of 15 psi using helium (1 psi = 6.9 kPa). Connected to the mplc was a UV spectrophotometer – fraction collector that collects ca. 10 mL fractions.

Materials

Acetonitrile (Fisher ACS grade) was distilled twice, first from sodium hydride and then from phosphorus pentoxide. It was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), fractionally distilled (under nitrogen), and stored over molecular sieves (3 Å) (*28a*). Methanol was distilled from magnesium turnings and then stored over molecular sieves (4 Å). 1,4-Dicyanobenzene (**1**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized three times from water and then dried in a vacuum oven for 15 h, 70°C, 0.25 Torr (1 Torr = 133.3 Pa). (±) 6-Methyl-5-hepten-2-ol, 99% (**16**) and (±) 5-methyl-5-hexen-2-one, 99% (**17**) were obtained from the Aldrich Chemical Co. Sodium borohydride, reagent grade, was obtained from Caledon Laboratory Ltd. Biphenyl (**5**) (Eastman Kodak Co.) was recrystallized from methanol.

Irradiations

Irradiations were generally carried out on solutions of acetonitrile with 1,4-dicyanobenzene (**1**), the alk-4-enol, and biphenyl (**5**), a codonor. Solutions were irradiated in either 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, which were degassed by nitrogen ebullition. These samples were irradiated at 10°C using a CGE 1-kW or a Hanovia 450-W medium-pressure mercury vapour lamp contained in a water-cooled quartz immersion well.

Electrochemical measurements

Cyclic voltammetry was used to obtain the oxidation potential of the alk-4-enols. The apparatus has been described (*28b*). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (sce), which was connected to the solution (TEAP 0.1 M, acetonitrile) through a Luggin capillary. The alk-4-enols were purified by prep/gc using a 0.95 cm × 350 cm aluminum column packed with 40% SE-30 on Chromosorb W 60/80 NAW. The alk-4-enol concentration was ca. 0.005 M. Since the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (7).

Formation of the methanol, 2-methyl-2-butene (6), 1,4-dicyanobenzene (1) photo-NOCAS adducts 7 and 8: reaction [2]

A solution of 2-methyl-2-butene (**6**) (2.7 g, 4.1 mL, 0.038 mol), 1,4-dicyanobenzene (**1**) (2.5 g, 0.019 mol), and biphenyl (**5**) (1.6 g, 0.010 mol) in acetonitrile–methanol (3:1, 160 mL) was degassed by nitrogen ebullition for 5 min and irradiated for 24 h using a 1-kW lamp at 10°C. The solvent was removed to yield a crude photolysate. **1** was totally consumed in the reaction. The crude photolysate was separated by chromatography (mplc) using a linear solvent gradient (hexanes – 5% diethyl ether, 95% hexanes). Products eluted in the order **7**, then **8**.

2-(4-Cyanophenyl)-3-methoxy-2-methylbutane (7)

The yield of **7** was 60%: infrared (Nicolet 205) ν: 2978(s), 2934(s), 2883(m), 2822(m), 2228(s), 1607(m), 1506(w), 1466(m), 1398(w), 1372(m), 1193(w), 1162(w), 1111(s), 1096(s), 1026(w), 840(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 0.92 (d, 3H, $^3J_{3-4}$ = 6.1 Hz, CH_3 (4-H)), 1.31 (s, 3H, CH_3), 1.33 (s, 3H, CH_3), 3.24 (s, 3H, OCH_3), 3.30 (q, 1H, $^3J_{3-4}$ = 6.1 Hz, OCH (3-H)), 7.50 (d, 2H, $^3J_{2'-3'}$ = 8.5 Hz, $^3J_{5'-6'}$ = 8.5 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.58 (d, 2H, $^3J_{2'-3'}$ = 8.5 Hz, $^3J_{5'-6'}$ = 8.5 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 13.72 (q), 24.14 (q), 24.55 (q), 43.10 (s, quaternary carbon, aryl substituted), 57.59 (q, OCH_3), 84.28 (d, OCH),

Formation of the 6-methyl-5-hepten-2-ol (16) and 1,4-dicyanobenzene (1) photo-NOCAS adducts 18 and 19: reaction [5]

A solution of 6-methyl-5-hepten-2-ol (**16**) (4.1 g, 4.9 mL, 0.032 mol), 1,4-dicyanobenzene (**1**) (2.1 g, 0.016 mol), and biphenyl (**5**) (2.5 g, 0.016 mol) in 160 mL of acetonitrile was degassed with nitrogen and irradiated for 117 h using a 450-W lamp. The crude photolysate was separated by chromatography (mplc) using a linear solvent gradient of hexanes – 1% ethyl acetate, 99% hexanes. Products were eluted in the order **18**, then **19**.

trans-*2-(Isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran (**18**)*

The yield of **18** was 29%; infrared (PE-180) ν: 2971(s), 2931(m), 2871(m), 2231(s), 1601(m), 1501(m), 1456(w), 1401(w), 1071(s), 1001(m), 976(m), 851(w), 816(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.18 (d, 3H, $^3J_{5-6}$ = 6.1 Hz, CH_3 (6-H)), 1.32 (s, 3H, CH_3), 1.36 (s, 3H, CH_3), 1.37 (m, 2H, H's on methylene groups of ring (3- or 4-H)), 1.77 (m, 2H, H's on methylene groups of ring (3- or 4-H)), 3.81 (m, 1H, $^3J_{4-5}$ = 6.0 Hz, $^3J_{4-5}$ = 6.0 Hz, $^3J_{5-6}$ = 6.1 Hz, H on methine group, methyl substituted (5-H)), 4.08 (m, 1H, $^3J_{2-3}$ = 6.4 Hz, $^3J_{2-3}$ = 8.5 Hz, H on methine group, alkyl-aryl substituted (2-H)), 7.54 (d, 2H, $^3J_{2'-3'}$ = 8.9 Hz, $^3J_{5'-6'}$ = 8.9 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.59 (d, 2H, $^3J_{2'-3'}$ = 8.9 Hz, $^3J_{5'-6'}$ = 8.9 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 21.15 (q), 24.81 (q), 24.99 (q), 28.21 (t), 34.12 (t), 42.20 (s, quaternary carbon, methyl and aryl substituted), 76.02 (d, CH adjacent to oxygen), 86.20 (d, CH adjacent to oxygen), 109.64 (s, quaternary aryl carbon, cyano substituted), 119.21 (s, CN), 128.01 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.56 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 152.63 (s, quaternary carbon, alkyl substituted); ms *m/z*: 55(4), 57(17), 67(19), 77(4), 85(100), 86(5), 115(5), 116(19), 128(4), 130(11), 142(5), 144(10), 145(11), 157(5). Anal. calcd. for $C_{15}H_{19}NO$: C 78.56, H 8.35, N 6.11; found: C 78.20, H 7.89, N 6.12. (The elemental analysis was obtained on a 50/50 mixture of isomers **18** and **19**).

cis-*2-(Isopropyl 4-cyanophenyl)-5-methyltetrahydrofuran (**19**)*

The yield of **19** was 24%; infrared (PE-180) ν: 2971(s), 2931(m), 2871(m), 2231(s), 1611(m), 1512(m), 1461(m), 1401(m), 1381(m), 1091(s), 1011(m), 821(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.11 (d, 3H, $^3J_{5-6}$ = 6.1 Hz, CH_3 (6-H)), 1.32 (s, 3H, CH_3), 1.33 (s, 3H, CH_3), 1.40–1.90 (m, 4H, H's on methylene groups of ring (3- or 4-H)), 3.91 (m, 1H, $^3J_{2-3}$ = 7.4 Hz, $^3J_{2-3}$ = 7.4 Hz, H on methine group, alkyl-aryl substituted (2-H)), 3.92 (m, 1H, $^3J_{4-5}$ = 5.8 Hz, $^3J_{4-5}$ = 6.4 Hz, $^3J_{5-6}$ = 6.1 Hz, H on methine group, methyl substituted (5-H)), 7.54 (d, 2H, $^3J_{2'-3'}$ = 8.9 Hz, $^3J_{5'-6'}$ = 8.9 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.59 (d, 2H, $^3J_{2'-3}$ = 8.9 Hz, $^3J_{5'-6'}$ = 8.9 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 20.87 (q), 24.68 (q), 24.93 (q), 27.01 (t), 32.90 (t), 41.53 (s, quaternary carbon, methyl and aryl substituted), 75.53 (d, CH adjacent to oxygen), 86.50 (d, CH adjacent to oxygen), 109.66 (s, quaternary aryl carbon, cyano substituted), 119.16 (s, CN), 128.03 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.45 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 152.64 (s, quaternary carbon, alkyl substituted); ms *m/z*: 57(15), 67(15), 85(100), 86(4), 103(3), 104(3), 115(4), 116(16), 130(8), 142(6), 143(2), 144(8), 145(8), 157(3), 200(2). Anal. calcd. for $C_{15}H_{19}NO$: C 78.56, H 8.35, N 6.11; found: C 78.20, H 7.89, N 6.12. (The elemental analysis was obtained on a 50/50 mixture of isomers **18** and **19**). X-ray data: the crystals are monoclinic, space group $P2_1/a$, Z = 4, a = 10.908 (3) Å, b = 7.761 (3) Å, c = 15.708 (3) Å, β = 97.05 (1)°, P_c = 1.154 g/cm^3, μ = 0.669 cm^{-1}, λ = 0.70926 Å. Data are insufficient (only 264 reflections above $I > 1\sigma$); however, the model obtained after isotropic refinement is consistent with the assigned structure (**19**) (Fig. 1).

Preparation of 5-methyl-5-hexen-2-ol (17)

5-Methyl-5-hexen-2-one (6.7 g, 0.06 mol) was dissolved in 50 mL of 95% ethanol and the solution was stirred while sodium borohydride (1.0 g, 0.03 mol) was added slowly. The reaction mixture was left to stir overnight. The mixture was extracted with dichloromethane and the extract was dried over magnesium sulphate. The mixture was filtered and the solvent was removed on a rotary evaporator. The residue was distilled at atmospheric pressure to yield 4.6 g (67%) of the alcohol **17** (bp 156–157°C). The ^{1}H nmr spectrum was similar to that reported in the literature (22, 29). ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.20 (d, 3H, $^3J_{1-2}$ = 6.1 Hz, CH_3 (1-H)), 1.59 (m, 2H, CH_2), 1.74 (s, 3H, CH_3), 1.75 (br s, 1H, OH), 2.10 (m, 2H, CH_2), 3.80 (m, 1H, $^3J_{1-2}$ = 6.1 Hz, H on methine group,

For personal use only.

hydroxyl substituted (2-H)), 4.72 (br s, 2H, vinyl methylene); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 22.44 (q), 23.46 (q), 34.14 (t), 37.02 (t), 67.93 (d), 110.05 (t, vinyl methylene), 145.81 (s, vinyl quaternary carbon).

Formation of the 5-methyl-5-hexen-2-ol (17) and 1,4-dicyanobenzene (1) photo-NOCAS adducts 20–23: reaction [6]

A solution of 5-methyl-5-hexen-2-ol (**17**) (2.1 g, 0.018 mol), 1,4-dicyanobenzene (**1**) (1.0 g, 0.0078 mol), and biphenyl (**5**) (1.2 g, 0.0078 mol), in 80 mL of acetonitrile was degassed with nitrogen and irradiated for 139 h using a 1-kW lamp. The crude photolysate was separated by chromatography (mplc) using a linear solvent gradient of hexanes – 10% diethyl ether, 90% hexanes. Products were eluted in the order **23**, **20**, and **21** (together), then **22**. Separation of **20** and **21** was achieved by rechromatographing the mixture, using a linear solvent gradient of hexanes – 1% diethyl ether, 99% hexanes.

r-*2-(Methyl 4-cyanophenyl)-2,*t-*5-dimethyltetrahydrofuran (20)*

The yield of **20** was 13%: the melting point was 42–43°C; infrared (PE-180) ν: 2970(s), 2930(m), 2871(m), 2227(s), 1608(m), 1506(w), 1454(m), 1415(w), 1379(m), 1175(w), 1086(s), 960(w), 853(w); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.18 (s, 3H, CH_3), 1.22 (d, 3H, $^3J_{5-6}$ = 6.1 Hz, CH_3 (6-H)), 1.56 (m, 1H, H on methylene groups of ring (3- or 4-H)), 1.70–1.95 (m, 3H, H's on methylene groups of ring (3- or 4-H)), 2.79 (d, 1H, $^3J_{1-1'}$ = 13.3 Hz, H on methylene group, aryl substituted (1-H)), 2.86 (d, 1H, $^3J_{1-1'}$ = 13.3 Hz, H on methylene group, aryl substituted (1′-H)), 3.92 (m, 1H, $^3J_{5-6}$ = 6.1 Hz, H on methine group, methyl substituted (5-H)), 7.34 (d, 2H, $^3J_{2'-3'}$ = 8.4 Hz, $^3J_{5'-6'}$ = 8.4 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.56 (d, 2H, $^3J_{2'-3'}$ = 8.4 Hz, $^3J_{5'-6'}$ = 8.4 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{1}H NOE: Irradiation of the methine group at 3.90 ppm produced a NOE at 7.34–7.56 ppm. No enhancement was observed in the signal due to the methylene group 2.79 and 2.86 ppm ; ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 21.69 (q), 27.95 (q), 33.45 (t), 37.02 (t), 46.92 (t, CH_2, aryl substituted), 75.27 (d, CH adjacent to oxygen), 82.42 (s, quaternary carbon adjacent to oxygen), 109.84 (s, quaternary aryl carbon, cyano substituted), 119.09 (s, CN), 131.16 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.55 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 144.22 (s, quaternary carbon, alkyl substituted); ms *m/z*: 51(4), 53(4), 56(5), 63(6), 89(19), 90(6), 99(100), 100(6), 116(25), 117(19), 173(5). Anal. calcd. for $C_{14}H_{17}NO$: C 78.10, H 7.96, N 6.51; found: C 77.90, H 7.94, N 6.52. (The elemental analysis was obtained using a 50/50 mixture of isomers **20** and **21**.)

r-*2-(Methyl 4-cyanophenyl)-2,*c-*5-dimethyltetrahydrofuran (21)*

The yield of **21** was 7%; infrared (PE-180) ν: 2969(s), 2928(m), 2871(m), 2227(s), 1608(m), 1507(w), 1455(m), 1414(w), 1374(m), 1243(w), 1176(w), 1117(m), 1089 (s), 962(w), 953(w), 885(w), 848(w), 824(w); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.14 (d, 3H, $^3J_{5-6}$ = 6.1 Hz, CH_3 (6-H)), 1.19 (s, 3H, CH_3), 1.02–1.27 (m, 1H, H on methylene groups of ring (3- or 4-H)), 1.62–1.96 (m, 3H, H's on methylene groups of ring (3- or 4-H)), 2.78 (d, 1H, $^3J_{1-1'}$ = 13.4 Hz, H on methylene group, aryl substituted (1-H)), 2.86 (d, 1H, $^3J_{1-1'}$ = 13.4 Hz, H on methylene group, aryl substituted (1′-H)), 4.06 (m, 1H, $^3J_{5-6}$ = 6.1 Hz, H on methine group, methyl substituted (5-H)), 7.36 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.56 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to cyano substituted aryl carbon (3′-H, 5′-H)); ^{1}H NOE: Irradiation of the methine group at 4.06 ppm produced no NOE at 7.36–7.56 ppm or at 2.78 and 2.86 ppm; ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 21.18 (q), 27.22 (q), 33.69 (t), 36.84 (t), 48.07 (t, CH_2, aryl substituted), 74.77 (d, CH adjacent to oxygen), 82.46 (s, quaternary carbon adjacent to oxygen), 109.98 (s, quaternary aryl carbon, cyano substituted), 119.22 (s, CN), 131.45 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.47 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 144.16 (s, quaternary carbon, alkyl substituted); ms *m/z*: 51(4), 53(4), 55(13), 56(6), 63(7), 89(15), 99(100), 100(7), 115(4), 116(29), 117(18), 156(4), 160(4), 173(6). Proton dissociation of aqueous organic acids studied by multivariate chemometrics

Roberto Aruga

Abstract: Thermodynamic data of proton dissociation of 75 organic acids belonging to four classes (protonated amines, aliphatic carboxylic acids, benzoic acids, phenols) have been processed by multivariate chemometric techniques. The variables consist of conventional thermodynamic quantities (Gibbs function, enthalpy, entropy) and of partial components of these quantities (internal and external, electrostatic and nonelectrostatic components). The above data refer to the aqueous medium, at 25°C and $I = 0$ mol dm^{-3}. The Gibbs function of deprotonation in the gas phase and the Hammett σ constant have also been considered. Multivariate techniques include Principal Component Analysis, Factor Analysis, and feature selection. Factor Analysis and related concepts have proved to be useful in defining the causes of differences in acid strengths and their respective importance.

Key words: acid dissociation data, chemometrics of; chemometrics of acid dissociation data; factor analysis of acid dissociation data; principal component analysis of acid dissociation data; thermodynamics of acid dissociation.

Résumé : On a examiné les données thermodynamiques de la dissociation protonique de 75 acides organiques appartenant à quatre classes (les amines protonées, les acides carboxyliques aliphatiques, les acides benzoïques et les phénols) à l'aide de techniques chimiométriques à plusieurs variables. Les variables incluent les quantités thermodynamiques conventionnelles (fonction de Gibbs, enthalpie et entropie) et les composantes partielles de ces quantités (composantes internes et externes, électrostatiques et non électrostatiques). Les données ci-dessus se réfèrent à un milieu aqueux, à 25°C et $I = 0$ mol dm^{-3}. On a aussi considéré la fonction de Gibbs de la déprotonation en phase gazeuse et la constante σ de Hammett. Les techniques à variables multiples comprennent l'analyse des composantes principales, l'analyse factorielle et la caractéristique de sélection. L'analyse factorielle et les concepts apparentés se sont avérés utiles pour définir les causes des différences dans les forces des acides et leurs importances respectives.

Mots clés : chimiométrie, données de dissociation acide, analyse factorielle, analyse des composantes principales, thermodynamique de la dissociation acide.

[Traduit par la rédaction]

Introduction

The study of the causes of differences in acid strengths in aqueous solution has passed through various stages in the last decades.

The traditional concept, according to which differences in acid strengths are mainly attributable to molecular properties of acids (e.g., polarization of the O—H bond, electronic structure of the anion, etc.) began to be criticized around 1960, when, as well as pK_a data, accurate values of enthalpy and entropy of deprotonation in aqueous solution were supplied by direct calorimetric techniques (1, 2). On the basis of calorimetric results, the importance of environmental effects (i.e., solute–solvent and solvent–solvent interactions) was pointed out.

Later, these studies were mainly carried on in the direction of a splitting up of conventional thermodynamic quantities into partial components, each of them being related to particular (e.g., molecular or environmental) effects.

The studies of Hepler and co-workers (3, 4) should be cited first in this field. Two components of thermodynamic quantities, one called internal, the other external, were proposed by Hepler, with reference to a proton exchange reaction between an aromatic substituted acid and the corresponding unsubstituted acid.

Nancollas, on the other hand (5), on the basis of previous studies of Gurney (6), proposed a splitting up of conventional thermodynamic quantities into an electrostatic (or long-range) and a nonelectrostatic (or short-range) contribution. These studies, on the whole, helped to clarify further particular questions related to proton–ligand and metal–ligand equilibria in solution.

Considering now the number of conventional (or global) and partial thermodynamic quantities available, it should be of

interest to study the processes of proton dissociation[2] in solution in a more general way, by using simultaneously all the above-cited parameters and the information content of each of them.

A problem of this kind, involving the simultaneous treatment of many variables, can be handled in a suitable way by the use of multivariate statistical techniques. Although these techniques have frequently been applied to analytical chemical data in recent years (e.g., to clinical and food data), and also to data of preparative and pharmaceutical organic chemistry, they have seldom been used for problems related to solution equilibria (7–9). Indeed, the methods of data interpretation normally used in the field of thermodynamics of solution equilibria consist, in general, of an univariate examination of tables of experimental results, and of a visual inspection of bidimensional (i.e., two-variable) plots. Obviously, in the presence of a considerable number of variables and objects (the latter are the acids, in this case) a univariate examination of the data becomes difficult and may lead to predominantly qualitative and rather uncertain conclusions.

Another problem concerns the actual reliability and usefulness of partial components of the thermodynamic quantities, especially the above-cited electrostatic and nonelectrostatic contributions. Chemometric techniques (and, in particular, feature selection methods) could be useful in clarifying these points.

On the basis of the above considerations, thermodynamic data of proton dissociation of 75 organic acids have been processed, in this work, by multivariate chemometric techniques. The acids belong to the following four categories: protonated amines, aliphatic carboxylic acids, benzoic acids, and phenols. Sets from 7 to 10 thermodynamic variables have been considered, the Hammett σ constant included (for a description of all the variables see the following section).

It must be noted that other thermodynamic variables that are coming into use (e.g., molar volume variation, molar compressibility, expansibility, specific heat variation, etc.) do not yet provide a sufficient number of accurate experimental data to justify their inclusion in this study.

Experimental data and parameters

The 75 acids studied here belong to the following four classes: protonated amines (symbol: A; 26 species investigated), aliphatic carboxylic acids (symbol: C; 10 species); benzoic acids (symbol: B; 19 species); phenols (symbol: P; 20 species). All the acid species are synthetically collected in the following list. *Class A*: ammonia, amines: methyl, ethyl, *n*-propyl, i-propyl, i-butyl, *sec*-butyl, *tert*-butyl, cyclohexyl, dimethyl, diethyl, di-*n*-propyl, di-i-propyl, di-*n*-butyl, di-*sec*-butyl, trimethyl, triethyl, tri-*n*-propyl; pyrrolidine, pyrrolidine-1-methyl; piperidine, piperidine-1-methyl; morpholine; piperazine; aniline; pyridine. *Class C*: formic acid; acetic acid; substituted acetic acids: fluoro, difluoro, trifluoro, bromo, chloro, dichloro; propanoic acid; butanoic acid. *Class B*: benzoic acid; substituted benzoic acids: 3-fluoro, 2-chloro, 3-chloro, 4-chloro, 3-hydroxy, 2-methoxy, 3-methoxy, 4-methoxy, 2-methyl, 3-methyl, 4-methyl, 3-cyano, 4-cyano, 2-amino, 3-amino, 4-amino, 3-nitro, 4-nitro. *Class P*: phenol; substituted phenols: 2-fluoro, 3-fluoro, 4-fluoro, 2-chloro, 3-chloro, 3-hydroxy, 2-methoxy, 3-methoxy, 4-methoxy, 4-formyl (CHO), 2-methyl, 3-methyl, 4-methyl, 2-cyano, 3-cyano, 4-cyano, 2-nitro, 3-nitro, 4-nitro.

In some instances the acid species are indicated one by one by means of a symbol (e.g., in Fig. 1). Each individual symbol consists of the symbol of the corresponding class followed by the serial number in the class, in accord with the above list. For example: symbol A2 indicates methylamine.

Among the variables considered here, there are, first, the usual three fundamental quantities of proton dissociation: ΔG^0, ΔH^0, ΔS^0. Entropy was obtained by: $\Delta G^0 = \Delta H^0 - T\Delta S^0$. As regards enthalpy, taking into account the generally greater accuracy of direct calorimetric values in comparison with those obtained from the variation of the equilibrium constant with temperature (10), calorimetric ΔH^0 values were preferred. For 10 acids only, because calorimetric data were unavailable, enthalpy values determined from the variation of equilibrium constants with temperature were used. The latter values have been considered reliable, as they refer to sufficiently wide temperature ranges.

The values of the above parameters were taken from the literature (11); some calorimetric enthalpy values for phenols obtained previously in this laboratory (12) were also taken into account. The parameters always refer to the aqueous medium, at $T = 25°C$ and $I = 0$ mol dm^{-3}. In only two cases ΔG^0 and ΔH^0 had to be corrected to $I = 0$. The Gibbs function was corrected by Davies' equation:

$$[1] \quad -\log \gamma_i = Az_i^2[I^{1/2}/(1 + I^{1/2}) - 0.2\, I]$$

where γ_i is the activity coefficient of the ith ionic species, A is 0.509 for water at 25°C, z_i is the ionic charge, and I the ionic strength.

The enthalpy values were corrected to $I = 0$ mol dm^{-3} by using (13, 14):

$$[2] \quad \Delta H_I^0 = \Delta H_{I'}^0 + RT^2 \Sigma \nu_i \partial(\ln \gamma_i)/\partial T$$

$$[3] \quad \Sigma \nu_i \partial(\ln \gamma_i)/\partial T = -3/2[(1/D)(\partial D/\partial T) + 1/T]$$

where ν_i is the number of moles of the species i, and D is the dielectric constant of the solvent. The values of R, D, and $\partial D/\partial T$ are those reported by Harned and Owen (15).

Electrostatic and nonelectrostatic contributions of Gibbs function and enthalpy have also been considered (ΔG_{el}, ΔG_{non}, ΔH_{el}, ΔH_{non}, respectively). A short account of their significance is given here; fuller details and the equations for their calculation have been reported and discussed previously (16–18). The electrostatic contribution represents long-range electrostatic interactions, which are affected by the dielectric nature of the solvent and by the temperature. Therefore, this part is determined by solute–solute electrostatic bonds and by long-range solute–solvent interactions. The nonelectrostatic contribution is determined by all the short-range factors, independent of dielectric constant and temperature. Thus it is mainly determined by solute–solute covalent bonds and by

[2] As some acids considered here (i.e., protonated amines) dissociate without giving rise to new ionic charges (nonionogenic decomposition), the more general term "acid dissociation" (or "proton dissociation") has been preferred in this text to the term "acid ionization."

solute–solvent contact interactions (i.e., solvation interactions) (16). The nonelectrostatic part includes also the so-called cratic (or translational) contribution (6, 19). The cratic part of the Gibbs function is equal to $nRT \ln M_S$, where n is the number of moles of the reagents minus the moles of the products, R is the gas constant, T is the absolute temperature and M_S is the concentration of the solvent in mol dm^{-3}. Therefore, the cratic contribution (which is an entropy contribution) is constant for all the equilibria studied here and does not affect the differences and correlations between the above thermodynamic quantities. Moreover, taking into account that the difference between ΔG_{non} and ΔH_{non} is constant, as it is equal to the cratic part (18, 19), the following three quantities have been considered in this study: ΔG_{el}, ΔG_{non}, and ΔH_{el}. They were calculated by means of equations published previously (17, 18).

Enthalpy of proton dissociation in aqueous solution, following the treatment of Hepler (3, 4), can also be considered in terms of "internal" and "external" (or environmental) contributions. The former are related to intrinsic effects, i.e., to different conformations between the acid molecule and its anion. The latter are related to interactions between solute particles and the surrounding medium and to other external effects. Calculation of internal and external contributions is possible for symmetrical (or exchange) reactions of the following type:

[4] $HS + R^- \rightleftarrows S^- + HR$

where HR is an acid taken as reference, and HS is the corresponding substituted acid, with a structure similar to HR. For this kind of symmetrical reaction the following may be written: $\Delta H^0_{sym} = \Delta H_{int} + \Delta H_{ext}$. The enthalpy for reaction [4] is obtainable from the corresponding quantities of proton dissociation: $\Delta H^0_{sym} = \Delta H^0(HS) - \Delta H^0(HR)$. Moreover, it may be demonstrated (4) that: $\Delta H_{int} = \Delta H^0_{sym} - \beta \Delta S^0_{sym}$. Knowing the quantities for reaction [4], this relation allows one to obtain, with sufficient accuracy, both the internal and external enthalpy contributions. Numerous correlations from experimental data, for phenols and other aromatic acids at 25°C, are consistent with $\beta = 280$ K (4).

In accord with the above considerations, values of ΔH_{int} and ΔH_{ext} were obtained only for aromatic acids B and P. For

For personal use only.

the same classes the values of the Hammett σ constant for each substituent (20) were also considered.

With the aim of a more complete investigation of deprotonation processes, the Gibbs function values of proton dissociation in the gas phase were also considered for all the acids. The values were taken from the review of Ritchie (21) and refer to 25°C.

In conclusion, the variables considered here are the following (the symbol used for each of them in the Discussion and in the figures is also indicated). For classes A, C, B, P (75 acids): the usual set of three conventional thermodynamic quantities of proton dissociation ($-\Delta G^0$, $-\Delta H^0$, ΔS^0; symbols: *G*, *H*, *S*, respectively); electrostatic and nonelectrostatic contributions ($-\Delta G_{el}$, $-\Delta G_{non}$, $-\Delta H_{el}$; symbols: *GE*, *GN*, *HE*); Gibbs function of proton dissociation in the gas phase ($-\Delta G^0_{gas}$; symbol: *GG*). For classes B and P (39 acids), in addition to the seven variables of the preceding list: internal and external contributions of enthalpy ($-\Delta H_{int}$, $-\Delta H_{ext}$; symbols: *HI*, *HX*); Hammett σ constant (symbol: *HM*). All the variables refer to 25°C and, for the aqueous phase, to $I = 0$ mol dm^{-3}. The sign has been fixed so that the more favourable a parameter is to proton dissociation, the more positive it is, and vice versa. The values of the thermodynamic variables have been arbitrarily collected in Table 1, and appear as the mean and the standard deviation for each class. Hammett σ constants are listed in Table 2.

Statistical treatment of the data

A preliminary step of the treatment consisted of the normalization (or standardization) of the raw data, to avoid misclassification due to the different order of magnitude and range of variation of the variables. Autoscaling, or t-transform, was used for this purpose. The values of each variable, after this scaling procedure, are characterized by zero as the mean value and by unit variance (22).

As they are coming into widespread use, only a brief account will be given of the chemometric techniques used here, together with references to specific works for fuller details. The programs contained in the statistical package PARVUS (23) were used in the calculations.

Principal Component Analysis (PCA), from an *n*-dimensional space corresponding to *n* measured variables, displays objects in a reduced space by finding a direction (first principal component, or first eigenvector) that best preserves the original variance. This corresponds to calculating a new variable as a weighted linear combination of the original ones. A second eigenvector is then chosen among all directions orthogonal to the first, so that maximum preservation of the residual variance can be obtained, and so on. Just two (or three) principal components are sufficient, in some cases, for a projection of the original hyperspace on to two (or three) dimensions, without excessive loss of information (22). This fact makes it possible to represent objects (acids in this case) and the corresponding homogeneous categories by means of only one diagram (namely, the diagram of the scores of objects on principal components). It must be stressed that the above-defined principal components have only a mathematical (and not physical) significance, as they only identify directions of largest dispersion of the data. The program EIGEN obtains the above new variables from the matrix of covariances and calculates eigenvectors by the method of Malinowski (24).

Factor Analysis (FA) was performed by a previous evaluation of principal components and by their rotation, in order to find the directions of variance corresponding to significant physical factors. The rotation was carried out by the Varimax method (Eigenvalue Weighted Varimax). The number of significant factors was found by two methods, i.e., by the average variance method and by double cross validation (24). The significant physical factors determined by Factor Analysis should be considered as a set of a few causes that explains the whole set of experimental variables. A corresponding group of experimental variables is associated with each factor. The variables of each group are collected with the factor representing them and, of course, they are correlated with each other. The correlation of a certain factor with each experimental variable is expressed by the loading. Therefore the matrix of loadings, which is obtained by Factor Analysis, allows one to determine the group of experimental variables best correlated with each single factor and, in consequence, to point out the nature of the factor itself. The importance of each factor is expressed in terms of the corresponding fraction of the total variance.

Selection of variables was also carried out. It gives a sequence of variables on the basis of their information content (i.e., on the basis of their ability to discriminate objects belonging to different classes). The method used here classifies variables on the basis of the corresponding Fisher weight (or F-ratio) (25). The value of the Fisher weight for each variable is the average of the values of all possible pairs of categories into which the objects have been subdivided.

Discussion

A Principal Component Analysis (PCA) was carried out, first, on the four classes of acids and on the corresponding seven variables (matrix 75 × 7; see Experimental data and parameters).

PCA identifies two principal components strongly prevailing over the others as regards the information content. They represent 98.6% of the total variance. The third principal component has a variance of only 0.1, i.e., much less than 1, which is the variance of the autoscaled original variables. This means, in the first place, that bidimensional representations of the scores of objects (i.e., acids) on the two first principal components represent a good approximation to the actual disposition in the seven original dimensions (see the preceding section). Secondly, it can be concluded that the global structure of the data is determined by two physical factors. The scores of the 75 acids on the first two eigenvectors are represented in Fig. 1.

Three fairly sharp clusters of acids appear in the figure: a first for class A, a second for P, with an evident linear structure, and a third deriving from classes C and B superimposed. The association between C and B leads one to conclude that, from a thermodynamic point of view, the common carboxylic nature of these acids prevails over the aliphatic and aromatic nature. It is worth mentioning, as regards class A, the lonely position (and then a different thermodynamic behaviour) of A25 and A26 (aniline and pyridine, respectively) in comparison with other members of the class.

The problem of correlations between variables was then investigated; it allows one to study the general physical factors

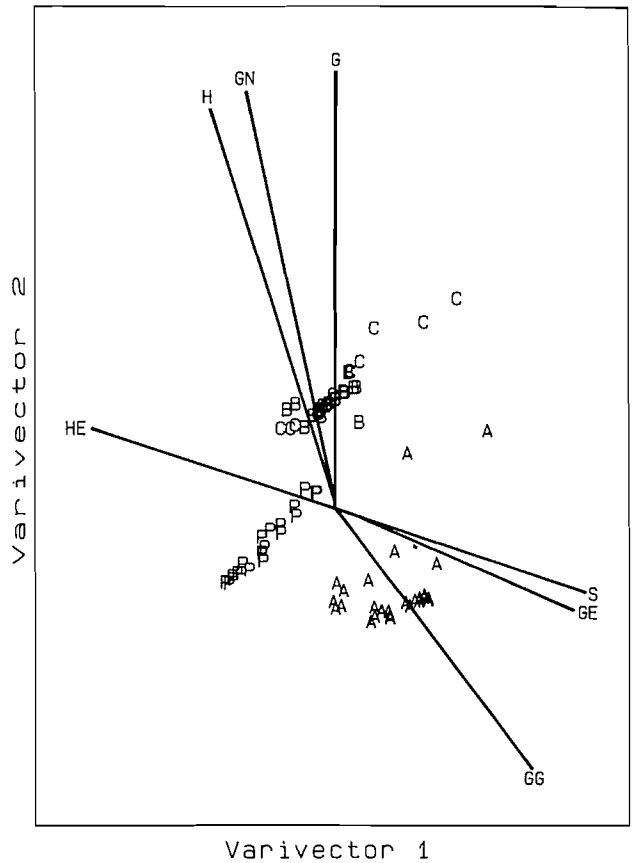
that determine differences in acid strengths. For this purpose, a Factor Analysis was carried out on the same autoscaled matrix (75 × 7), together with an examination of the correlation coefficient matrix. Considering that there are two significant factors present (see above), the values of the loadings of the seven variables on the factors, after Variamax rotation, are reported in Table 3.

Fig. 2. Representation of the scores of 75 acids belonging to four (A, C, B, P) and of the loadings of seven thermodynamic variables on the axes of two Varimax-rotated factors (varivectors).



The loading values show a high correlation of *S*, *GE*, and *HE* with factor *F*1 (correlation is negative for *HE*), and of *G*, *H*, *GN* with *F*2. Considering the nature of the correlated variables, the former factor can be defined as "electrostatic," the latter as "nonelectrostatic." They account for 73% and 25% of the total variance, respectively. The angle between the two rotated eigenvectors is 61°, in accordance with a partial correlation between factors. The corresponding correlation coefficient matrix (Table 4) confirms the presence of the same clusters of mutually correlated variables.

An evident representation of these clusters of mutually correlated variables is given by the loadings in Fig. 2 (parallel or antiparallel loadings indicate a positive or negative correlation; orthogonal loadings a lack of correlation).

Anticorrelation between *S* and *HE* can be justified by taking into account that the aqueous solvent structuring process caused by an ionogenic proton dissociation (*S* unfavourable) gives rise to an electrostatic bond formation between the solvent molecules (*HE* favourable).

Correlations between variables were also studied for classes B and P only (39 acids), in order that all 10 variables could be included in the data treatment (see Table 1). A Principal Component Analysis carried out on the autoscaled (39 × 10) matrix shows that the three first eigenvectors account for 96.7% of the total variance (59.4%, 31.2%, and 6.1%, respectively). As concerns a possible presence of a third significant factor, the average variance method does not give, in this instance, as

clear an indication as in the previous case. Several tests were therefore carried out with the method of double cross validation, using different numbers of random and diagonal cancellation groups. This test shows the presence of three significant factors at 95% confidence level. A subsequent Varimax rotation of the three eigenvectors gives the loadings of the 10 variables collated in Table 5.

The values in this table confirm the presence of two factors (electrostatic and nonelectrostatic, respectively) that have already been pointed out on the (75 × 7) matrix. They appear to be correlated with the same groups of variables as before. These factors, for the sake of brevity, can be indicated as F_{el} and F_{non}. The third factor (*F*3) appears highly and positively correlated with variable *HI* and with the Hammett σ constant (*HM*). Therefore *F*3 may represent the causes related to "internal" molecular effects, which depend on different electronic structures between an acid and its conjugate base and on other electronic effects. In the same manner, the correlation coefficient matrix (Table 6) shows a fairly high and positive correlation ($r = 0.80$) between *HI* and *HM*.

Therefore the internal contribution of enthalpy proves to be in agreement with the nature previously attributed to it (3). Considering now that Nancollas's nonelectrostatic contribution includes all effects the nature of which is not electrostatic or long-range, the internal contribution proposed by Hepler is likely to represent a part of the former. In other words, the two treatments appear to be complementary, in the sense that Hepler's concept of the internal part of enthalpy, being very specific, allows one to study the corresponding factor that otherwise could remain undefined. It must be noted, on the contrary, that the external contribution of enthalpy (*HX*), as it includes all the effects alien to *HI*, appears to be neither very specific nor significant.

Simultaneous examination of the scores of acids and of the loadings of variables on the factors was also done. The more positive the score of an acid species on the direction of a variable loading, the more favourable is that variable to the dissociation of the acid, and vice versa. The processing of the (75 × 7) matrix, which refers to the four classes of acids and to seven variables, is reported here by way of example. The corresponding scores and loadings on the two significant factors defined above are represented in Fig. 2.

As regards the direction of variance of F_{el}, which coincides with the direction of the loadings of *S*, *GE*, and *HE*, it can be noted that class A lies in a more favourable position than the other classes, with reference to *S* and *GE* (i.e., it has more positive scores on F_{el}), while the contrary occurs on *HE*. This can be easily justified by taking into account the explanation of the anticorrelation between *S* and *HE* reported above, and considering also that proton dissociation is not ionogenic for class A, while it is ionogenic for the other classes.

Class A, moreover, shows stronger acidity than the other classes in the gas phase (variable *GG* more favourable, i.e., more positive scores of class A on variable *GG*; Fig. 2). Considering the fairly high positive correlation of *GG* with *S* (Fig. 2 and Table 4) and of *GG* with the electrostatic factor (Table 3), the conclusion can be drawn that the stronger acidity of class A in the gas phase is mainly due to factor F_{el}. Since among the general effects related to F_{el} (see above) only solute–solute electrostatic interactions exist in the gase phase, it can be concluded that these interactions are responsible for the stronger acidity of class A in the gas phase. In this case, too, the nature of the proton dissociation process (ionogenic for C, B, P, nonionogenic for A) plays a leading role.

On the other hand, Fig. 2 shows that the order of acid strength of class A and of the other classes is reversed in the aqueous phase. In fact, considering that variable *G* is the fundamental measure of aqueous acid strength, class A shows in Fig. 2 a less favourable position on the direction of the loading of variable *G* in comparison with the other classes (this fact is also pointed out by the anticorrelation between *G* and *GG*: $r = -0.51$, see Table 4). As variable *G* is strongly correlated with F_{non} (see Table 3, where F_{non} is indicated as F_2), it could be concluded that the different series of acidities in water in comparison with those in the gas phase is caused by the solvent, which acts through a short-range nonelectrostatic factor (F_{non}), and not through a long-range factor. This con-

firms the leading role of solvation in determining different series of acid strengths in the aqueous phase in comparison with the gas phase.

The lonely position pointed out for pyridine and aniline in comparison with the other amines (see above) is attributable to a more favourable value of variable *G* (Fig. 2), i.e., to a greater acid strength. This fact is obviously related to the aromatic nature of pyridine and aniline.

Data-processing procedures similar to those reported in the preceding discussion have also been carried out on every single class. Although this kind of investigation can be useful in the study of the thermodynamic behaviour of each class of acids and of each acid within the class, for the sake of brevity some of the conclusions obtained for class P only are reported here.

The cluster of class P shows a linear structure in Fig. 1. The significance of such a structure is more precisely defined by the following results, referring to 10 variables: (*i*) all the possible pairs between the 10 variables show significant linear correlation at 95% level of confidence; (*ii*) Factor Analysis identifies one significant factor only, accounting for 90% of the total variance. Consequently, the three general acidity factors indicated above come together into a unique factor, through which all the variables concordantly determine different acidities for phenols. As concerns the other classes (A, C, B), Factor Analysis indicates the presence of at least a second significant direction of variance (i.e., two factors at least), in agreement with a less linear structure of the corresponding clusters (Fig. 1).

It can now be noted, from a general point of view, that the problem investigated in the preceding discussion (i.e., the causes of *differences* in acid strengths) is distinct from the problem of the causes that determine the proton dissociation of a certain acid, or of a class of acids. The latter point can be cleared up in a simple way by means of a comparison between two components of the Gibbs function, for example, between the enthalpy and entropy contributions, or between *GE* and *GN* (see Table 1).

Finally, the discriminating ability of variables has been evaluated, by means of Fisher weight calculations. On the basis of the clusters of Fig. 1, three classes have been considered, namely: A, P, (C + D), and the group of the first seven variables of Table 1. The following sequence of variables, in order of decreasing discriminating ability, was obtained:

[5] $GG >> GN > H > G >> GE, HE, S$

It can be observed, first, that variable *GG* shows the highest discriminating ability, while the differentiation of acidities in water (variable *G*) is much less. Therefore these results seem to confirm the presence of a "levelling" effect exerted by the aqueous solvent, as was suggested previously (21). Electrostatic contributions (*GE*, *HE*) and the variable correlated to them (*S*) show the lowest discriminating ability. It is also worth mentioning that the highest discriminant ability among the variables referring to the aqueous medium is shown by a partial component (*GN*); its discriminating ability is then greater than that of conventional quantities (*G*, *H*, *S*). This fact points out the usefulness of the partial components of thermodynamic quantities proposed by Nancollas.

Conclusions

The well-known benefits of multivariate versus traditional methods are also confirmed in the case of thermodynamic data of proton dissociation, as regards both an immediate data representation and interpretation, and the attainment of certain conclusions not easily obtainable in any other way.

Among the latter conclusions, those obtained by means of Factor Analysis seem worth mentioning. Factor Analysis points out, on the basis of 10 experimental variables, three causes of different aqueous acid strength. These causes, ordered on the basis of decreasing importance (i.e., of decreasing percent variance) are the following. 1. A main factor (59.4% of the total variance), correlated with *S*, *GE*, *HE*, of electrostatic, long-range nature. 2. A factor correlated with *GN*, *G*, *H*, of nonelectrostatic, short-range nature (31.2% of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

the total variance). 3. A minor factor (6.1%) correlated with *HI* and *HM*, of internal electronic nature.

On the other hand, the following facts are also pointed out in the Discussion: (*i*) variable *G* (which is connected with pK_H, and then represents the fundamental measure of aqueous acid strength) is correlated with nonelectrostatic factor F_{non}; (*ii*) feature selection (see relation [5]) attributes to the three nonelectrostatic variables a discriminating ability greater than that of electrostatic variables; in other words, relation [5] could be synthetically indicated as: $F_{non} > F_{el}$. Therefore, on the basis of the latter points, factor F_{non} appears to be the most important in determining different acid strengths in aqueous medium. This seems to contradict the results of Factor Analysis. Factor Analysis, indeed, gives a simple explanation of this fact. More precisely, it can be seen in Fig. 2 (or in Table 4) that variables *G*, *H*, *GN* are positively and mutually correlated while, within the electrostatic factor, *HE* is strongly anticorrelated with *S* and *GE*. It can then be concluded that the differences in aqueous acid strength observed by the experimenter are mainly caused by the nonelectrostatic, short-range factor, and Factor Analysis shows that this is due to a simple counterbalancing effect between *S* and *HE* that makes less important the actual influence of the long-range factor.

The concept of factor also permits one to show that the greater acidity in the gas phase of protonated amines as compared with the other classes is attributable to their respective nonionogenic and ionogenic nature, which acts through the long-range factor, while, on the other hand, the reverse order of acidities in water is due to solvation effects (short-range factor).

Photochemistry of *N*-(pyrimidin-2-one-4-yl)pyridinium derivatives. The ring contraction of pyrimidinone into imidazolinone

Grażyna Wenska, Bohdan Skalski, Stefan Paszyc, and Zofia Gdaniec

Abstract: Photochemical reactions ($\lambda > 300$ nm) of *N*-(1-methylpyrimidin-2-one)- and *N*-(1,5-dimethylpyrimidin-2-one)pyridinium chlorides were studied in deoxygenated aqueous solution at various pH's. Only the former compound was found to be reactive under these conditions to give pyrimidine ring contraction photoproducts 1-methyl-4-imidazolin-2-one and 1-methyl-4-imidazolin-2-one-5-carboxyaldehyde, with pH-dependent chemical yields. The photochemical pyrimidine ring contraction reaction does not occur for other photochemically reactive pyrimidin-2-ones bearing 3-methylimidazolium-1,1,2,4-triazol-1-yl, or imidazol-1-yl as substituents at the C-4 position. The suggested mechanism of the reaction involves the addition of water to the pyrimidinone part of the *N*-(1-methylpyrimidin-2-one)pyridinium salt in the excited triplet state as the primary photochemical step. Addition of alcohol to the pyridinium ring was found to be the major reaction under irradiation of *N*-(1-methylpyrimidin-2-one-4-yl)pyridinium chloride in methanol.

Key words: photochemistry, *N*-(pyrimidin-2-one-4-yl)pyridinium compounds, pyrimidine ring contraction, 1-substituted-4-imidazolin-2-ones, 4-imidazolin-2-one-5-carboxyaldehydes.

Résumé : Opérant à divers pH, dans des solutions désoxygénées, on a étudié les réactions photochimiques ($\lambda >$ 300 nm) des chlorures de *N*-(1-méthylpyrimidin-2-one)- et de *N*-(1,5-diméthylpyrimidin-2-one)pyridinium. On a trouvé que, dans ces conditions, le premier composé est le seul à fournir des photoproduits résultant d'une contraction du noyau pyrimidine, soit la 1-méthyl-4-imidazolin-2-one et le 1-méthyl-4-imidazolin-2-one 5-carboxyaldéhyde avec des rendements qui varient avec le pH. La réaction photochimique de contraction du noyau pyrimidine ne se produit pas avec les autres pyrimidin-2-ones photochimiquement réactives portant des substituants 3-méthylimidazolium-1,1,2,4-triazol-1-yle ou imidazol-1-yle en position C-4. Le mécanisme suggéré pour la réaction implique que, dans l'étape photochimique primaire, il y a addition d'eau à la portion pyrimidinone du sel *N*-(1-méthylpyrimidin-2-one)pyridinium dans l'état excité triplet. Lors de l'irradiation du chlorure de *N*-(1-méthylpyrimidin-2-one-4-yl)pyridinium dans le méthanol, on observe que l'addition d'alcool est la réaction principale.

Mots clés : photochimie, composés *N*-(pyrimidin-2-one-4-yl)pyridinium, contraction du noyau pyrimidine, 4-imidazolin-2-ones substituées en position 1, 4-imidazolin-2-one-5-carboxaldéhydes.

[Traduit par la rédaction)

Introduction

Common purine and pyrimidine nucleosides such as guanosine, inosine, thymidine, and uridine can be easily and efficiently converted to the corresponding, fluorescent *N*-(purin-6-yl)- and *N*-(pyrimidin-2-one-4-yl)pyridinium chlorides (1). Some of these derivatives can be incorporated into synthetic oligodeoxynucleotides and used for further, postsynthetic modifications (2, 3). Both purinyl- and pyrimidynyl-pyridinium compounds exhibit significant absorption in the near-UV region ($\lambda > 300$ nm) where common nucleic acid bases are transparent (4) and thus provide the opportunity for their selective excitation in oligonucleotide chains. The photophysical and photochemical properties of *N*-(purin-6-yl)pyridinium salts have been studied extensively over the last several years (5, 6). Some of them were shown to be useful as fluorescent markers in nucleic acids (2, 7) or as efficient acceptors in photochemically induced electron transfer processes (6, 8). In contrast to the purine derivatives, the pyrimidinyl-pyridinium salts have received little attention so far. As a continuation of our interest in this group of modified nucleobases we reported previously on the photophysical properties of pyridinium salts derived from uridine and thymidine (9). It was shown that the lowest energy electronic transition in these compounds is

associated with a significant charge shift from the pyrimidinyl to the pyridinium moiety, and that the short-lived excited singlet state is deactivated mainly via a nonradiative process.

In the present work we report on the photochemical reactivity of pyridinium salts **1***a*,*b* derived from 1-methyluracil and tri-*O*-acetyluridine as well as structurally related compounds bearing heterocyclic substituents other than pyridine at the C-4 position of the pyrimidine ring.

Results and discussion

Photochemistry of 1*a*,*b* in aqueous solutions

An aqueous solution of **1***a* was irradiated with near-UV light (λ > 300 nm) in the absence of oxygen. As seen in Fig. 1, irradiation results in a gradual disappearance of the absorption band with a maximum at λ = 330 nm, characteristic of *N*-(pyrimidin-2-one-4-yl)pyridinium cations (9), with concomitant formation of a new absorption band at λ = 280 nm. HPLC analysis of the irradiated solution (Fig. 2) revealed the presence of three main photoproducts: **2***a*, **3***a*, and **4**, besides the unreacted starting material. Photoproduct **4** was identified as pyridine whereas the structures of **2***a* and **3***a* were assigned as 1-methyl-4-imidazolin-2-one and 1-methyl-4-imidazolin-2-one-5-carboxyaldehyde, respectively (Scheme 1), based on their spectral and elemental analysis data (vide infra). The chemical yields of the imidazolinone photoproducts depend on the pH of the irradiated solutions (cf. Table 1). The aldehyde **3***a* is the major product when irradiation is performed in water (pH 6.5) and the ratio **3***a*/**2***a* increases significantly when the irradiation of **1***a* is performed in slightly basic solution (0.002 M sodium bicarbonate, pH ~8.2). Because of the chemical instability of pyrimidynyl-pyridinium salts at pH > 9 (due to base-induced pyridinium ring opening (1)), the irradiation of **1***a* was not carried out in more basic solution. Prolonged irradiation of **1***a* reduces the yield of **3***a* (Table 1). In a separate experiment it was found that **3***a* undergoes slow degradation under irradiation with Pyrex filtered light; however, **2***a* was not found among the photoproducts.

In the case of pyridinium salt **1***b* derived from 2',3',5'-tri-*O*-acetyluridine, which is less resistant towards bases than **1***a*,

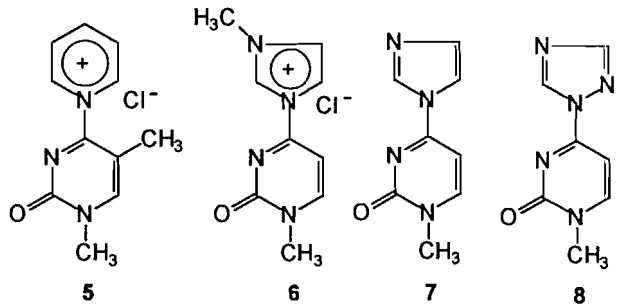
Scheme 2.



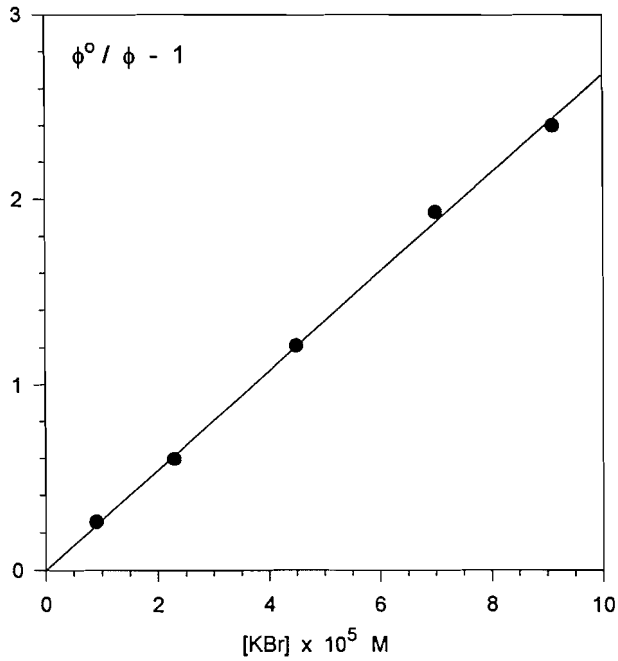
irradiation was performed in aqueous solution at pH 6.5. The expected photoproducts **2***b* and **3***b* were obtained in moderate yields (Scheme 1, Table 1). During the work-up of the irradiated solution of **1***b* in a preparative scale experiment, both photoproducts, **2***b* and **3***b*, were found to undergo partial deacetylation. Therefore they were fully deprotected and characterized as **2***c* and **3***c* (cf. Scheme 1 and Experimental).

The susceptibility to photochemical ring contraction has also been tested for the structurally related *N*-(1,5-dimethylpyrimidin-2-one-4-yl)pyridinium chloride, **5**, and compounds **6**, **7**, and **8** (Scheme 2) bearing 3-methylimidazolium-1, imidazol-1-yl, and 1,2,4-triazol-1-yl substituents at the C-4 position of the pyrimidine ring, respectively. Under the irradiation conditions used for the transformation of **1***a*, compound **5** appeared to be photochemically stable and the estimated quantum yield of its disappearance did not exceed 10^{-4}, whereas in the case of photochemically reactive **6**, **7**, and **8**, no appropriate ring contraction products (**2***a* and **3***a*) could be detected (HPLC) in photolyzed solutions.

The mechanism of the photochemical ring contraction of **1***a,b* is not yet completely clear, but we propose that the addition of a water molecule to the pyrimidinone part of the molecule in the excited triplet state is the primary photochemical event and is followed by a dark transformation of the resulting, unstable, intermediate into **2***a,b* and **3***a,b*. The following observations support the above suggestion.

(*i*) Pyridinium salts **1***a,b* are essentially stable ($\varphi < 10^{-4}$) during irradiation in dry acetonitrile under otherwise identical conditions.

Fig. 3. Stern–Volmer plot for quenching of the photochemical reaction of **1***a* by NaBr.



(*ii*) The photochemical reaction of **1***a* in water is quenched efficiently by bromide ions. Figure 3 shows the relevant Stern–Volmer plot. From the slope of this plot ($K_{sv} = k_q\tau$ = 26 600 $dm^3\ mol^{-1}$) an approximate value of 2.6×10^{-5} s for the lifetime of the reactive species is obtained, assuming $k_q \approx k_{diff} \approx 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$. This value is three orders of magnitude greater than the lifetime of the excited singlet state of **1***a* ($\tau = 0.8$ ns (9)), indicating the involvement of an excited triplet state in the photochemical reaction. The lifetimes of triplet excited pyridinium cations in the purine series have been reported to be in the microsecond region (8).

(*iii*) The quantum yield of disappearance of **1***a* remains constant ($\varphi = 0.05 \pm 0.01$) over the entire pH range studied (pH

2.0–8.5) whereas, as mentioned above (cf. Table 1), the relative amounts of **2***a* and **3***a* are pH dependent. This suggests that the formation of these two photoproducts occurs via pH-controlled transformations of a common, thermally unstable, intermediate formed by the initial photoaddition of water to **1***a*.

Examples of photochemically induced transformations of pyrimidines into imidazoles have been reported (10–13). Pyrimidine 1-oxides give low yields of 5-acetyl imidazoles (10) via oxazirines. 5-Diazouracil undergoes ring contraction to 4-imidazoline-2-one-carboxylate via a carbene-type intermediate upon irradiation in methanol saturated with HCl (11, 12). The synthetic procedures leading to imidazolin-2-one-4- and 5-carboxylic acids and carboxylates have been reported (12, 14); however, to our knowledge, the synthesis of aldehydes **3***a,b* has not been previously described.

Identification of photoproducts 2*a,c* and 3*a,c*

The structure of photoproduct **2***a* was established mainly on the basis of its ^{1}H NMR spectrum and an elemental analysis, and was confirmed by comparison of its spectral data and chromatographic (HPLC) mobility with those of an authentic sample synthesized according to a known procedure (15). The ^{1}H NMR spectrum of **2***a* measured in D_2O shows two doublets at 6.51 and 6.38 ppm (J = 3.1 Hz) corresponding to HC=CH protons of the imidazole ring. Two sets of signals having similar chemical shifts and coupling constants appear in the spectrum of **2***c*, which is the nucleoside analog of **2***a*. The remaining resonances in the ^{1}H NMR spectrum of **2***c* correspond to ribose protons. The ^{1}H and ^{13}C NMR signals of **2***c*, as well as those of other photoproducts, were assigned based on chemical shift arguments and by analysis of homo (^{1}H–^{1}H) and hetero (^{1}H–^{13}C) two-dimensional COSY spectra. These assignments are presented in Tables 2 and 3. Contrary to aldehydes **3***a,c* but in agreement with the proposed structures, imidazolin-2-ones **2***a,c* do not show UV absorptions at λ > 240 nm.

The proposed structures of photoproducts **3***a* and **3***c* are consistent with both their ^{1}H and ^{13}C NMR spectra. The ^{1}H NMR spectrum of **3***a* consists of two singlets at 9.18 and 7.56 ppm corresponding to CHO and H-4 protons, respectively, and one singlet at 3.42 ppm, corresponding to NCH_3 protons (Scheme 2, Table 2). An unequivocal assignment of the site of attachment of the formyl group was deduced from the results of a long-range ^{1}H–^{13}C heteronuclear chemical shift correlation experiment. In the 2-D spectrum both quaternary carbon atoms (δ = 155.6 ppm and δ = 125.6 ppm) show cross peaks with N-CH_3 protons. This observation clearly points to the 5-carboxyaldehyde, **3***a*, and excludes the isomeric 1-methyl-4-imidazolin-2-one-4-carboxyaldehyde structure. As might be expected, the UV absorption spectra of **3***a* and **3***c* are pH dependent owing to their ground state prototropic equilibria (cf. Fig. 4). The relevant ground state ionization constants, pK, obtained from the spectrophotometric titration curves are equal to 9.3 and 8.8 for **3***a* and **3***c*, respectively. Upon prolonged storage in the presence of atmospheric oxygen in aqueous solution, **3***a* undergoes a slow oxidation to 1-methyl-4-imidazolin-2-one-5-carboxylic acid, which has been identified by comparison (HPLC and UV spectra) with an authentic sample prepared by condensation of *N*-methylurea with tartaric acid in fuming sulfuric acid (14). It has been shown that the UV spectra are of diagnostic value in distinguishing between the isomeric imidazolin-2-ones having carboxylic substituents located at the C-4 or C-5 positions of the imidazole ring (14).

It is interesting to note that a positional isomer of **3***c* having an aldehyde function at C-4 is an aglycone of the naturally occurring antibiotic nikkomycin X (16).

The photochemistry of 1*a* in methanol

The addition of a solvent molecule is the main reaction during the irradiation (λ > 300 nm) of **1***a* in deoxygenated methanol.

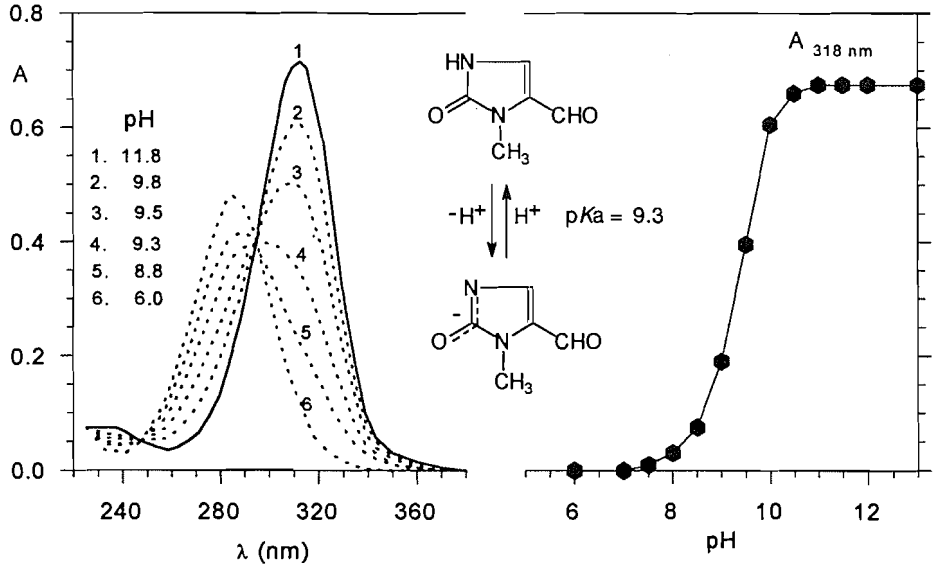
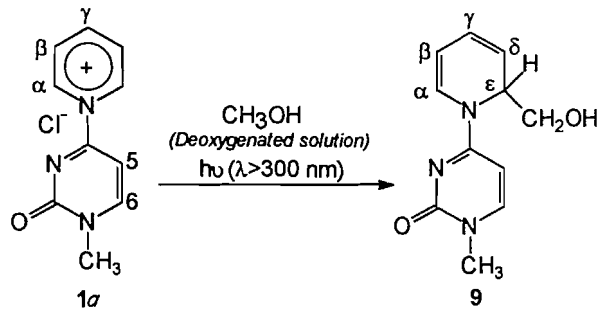
Fig. 4. The pH dependence of the UV absorption spectrum and the relevant spectrophotometric titration curve for the ground state prototropic equilibrium of **3***a*.



Scheme 3.



The addition occurs at the C-α position of the pyridinium residue leading to the dihydropyridine-type adduct **9** (Scheme 3). The quantum yield for conversion of substrate is 0.01. The mechanism of the reaction is most likely similar to that previously reported for the photochemical addition of electron donors such as alcohols, ethers, and amines to various *N*-alkyl-, *N*-alkenyl-, and *N*-heteroaromatic-pyridinium salts (17). The respective dihydropyridine-type photoadducts are formed by the initial electron transfer from the donor to the excited pyridinium salts, followed by coupling of the resulting radicals (17).

Identification of photoproduct 9

As is characteristic of the dihydropyridine structure, photoproduct **9** exhibits an intense absorption in the UV spectrum with a maximum at 335 nm (18). In the ^{1}H NMR spectrum of **9** recorded at room temperature, pyridine α and ε protons give rise to very broad signals at 6.51 and 5.67 ppm, respectively (Scheme 3, and Experimental). Lowering the temperature to 253 K results in sharpening of the signals and reveals their multiplet structure. This behaviour of the ^{1}H NMR spectrum is due to hindered rotation around the inter-ring bond caused by the presence of the *ortho* hydroxymethylene group in photoadduct **9**.

Experimental

General

^{1}H and ^{13}C NMR

Varian Unity 300 (300 MHz for ^{1}H); solvents: D_2O or $CDCl_3$ with dioxane or TMS as an internal reference, respectively; all chemical shifts converted to TMS scale (dioxane ^{1}H δ = 3.71 ppm; dioxane ^{13}C δ = 67.4 ppm).

UV

Perkin–Elmer Lambda-17 spectrophotometer.

Elemental analysis

Perkin–Elmer 2400 CHN analyzer.

Thin-layer chromatography (TLC)

Silica gel 60 F_{254} plates (Merck); solvent systems: A: $CHCl_3$–CH_3OH (5:1; v/v); B: $CHCl_3$–CH_3OH (10:1; v/v).

HPLC

Waters 600E; detection: Waters 991 photodiode-array UV–VIS detector; columns: Nova Pak C-18, 8 × 100 mm and Delta Pak C-4, 4.9 × 250 mm (analytical) and Nova Pak C-18, 25 × 100 mm (semipreparative); mobile phases: A: water; B: 50% acetonitrile, 50% water; C: 0.1 M ammonium acetate; D: 50% 0.1 M ammonium acetate, 50% acetonitrile.

Pyridinium salts **1***a, b* and **5**, and 4-substituted pyrimidin-2-ones **6–8** were synthesized as described previously (1*b, d*). 1-Methyl-4-imidazolin-2-one (15) and 1-methyl-4-imidazolin-2-one-5-carboxylic acid (14) were synthesized according to published procedures.

Analytical scale irradiations

The samples of aqueous solutions ($c = 1.6 \times 10^{-3}$ M) of **1***a, b* and **5–8** were placed in a 1 cm path length cell, deoxygenated, and irradiated on an optical bench with a high-pressure mercury lamp (HBO 200, Narva) through a Pyrex filter. Progress

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

of the reaction was monitored by UV spectroscopy and HPLC. The analytical HPLC was performed on a C-18 column eluted with 100%A (6 min) – 90%C/10%D (1 min) – 50%C/50%D (4 min) in the case of **1***a*, and a C-4 column eluted isocratically with a mixture of 70%C/30%D in the case of **1***b*. The results of chromatographic analyses obtained for the irradiations of **1***a, b* in aqueous solutions are collected in Table 1. The reaction quantum yields, φ, were measured for 313 nm excitation (Zeiss interference filter) using 2-hexanone as an actinometer (19).

General procedure for preparative irradiations

A concentrated aqueous solution (20 mL) containing 3.2 mmol of **1***a, b* was added to 2000 mL of the appropriate solvent (water, 0.002 M sodium bicarbonate, or methanol). Portions (60 mL) of the solutions ($c = 1.6 \times 10^{-3}$ M) were irradiated under an argon atmosphere with an immersion high-pressure mercury lamp (Original Hanau) through a Pyrex filter. The photolyzed solutions were collected and concentrated under reduced pressure. Irradiations were continued up to ca. 70% conversion of the substrate. Chemical yields of the photoproducts are given relative to the amount of substrate that reacted.

Isolation of photoproducts 2*a* and 3*a*

Photoproduct **2***a* was isolated from the irradiated aqueous solution of **1***a* by preparative HPLC (90%A/10%B). Fractions containing **2***a* were evaporated to give 37 mg of colourless solid (17% yield). UV (H_2O), λ_{max}: <220 nm. The ^{1}H NMR spectrum of the photoproduct is in agreement with that reported for 1-methyl-4-imidazolin-2-one (15).

Preparative scale synthesis of **3***a* was performed by irradiation of **1***a* in 0.002 M aqueous sodium bicarbonate. The desired photoproduct was separated from the irradiated mixture by preparative TLC using solvent system A and then subjected to further purification by means of preparative HPLC (90%A/10%B). Evaporation of the solvent gave 155 mg of colorless solid (55% yield). UV (H_2O), λ_{max} (nm) (ε (M^{-1}, cm^{-1})): 286.5 (13 300), (pH 1) 287 (13 600), (pH 12) 312.5 (20 300). ^{1}H and ^{13}C NMR data: Tables 2 and 3. Anal. calcd. for $C_5H_6N_2O_2$: C 47.62, N 22.21, H 4.79; found: C 47.01, N 22.09, H 4.71.

Isolation of photoproducts 2*c* and 3*c*

Leaving the irradiated solutions of **1***c* for several days at room temperature resulted in a partial deacetylation of photoproducts **2***b* and **3***b*, as indicated by HPLC and ^{1}H NMR analyses. Treatment of the mixture with diluted aqueous ammonia over 24 h at room temperature gave the fully deprotected nucleosides **2***c* and **3***c*, which were separated by preparative HPLC (0.005 M aqueous $HClO_4$). The appropriate fractions were collected, neutralized with Dowex-1 resin (HCO_3^-), and evaporated to dryness to give **2***c* (135 mg, 28% yield) and **3***c* (164 mg, 30% yield) as white powders.

2*c*: UV (H_2O), λ_{max}: <220 nm. ^{1}H and ^{13}C NMR data: Tables 2 and 3. Anal. calcd. for $C_8H_{12}N_2O_5$: C 44.45, H 5.59, N 12.96; found: C 44.37, H 5.54, N 12.87.

3*c*: UV (H_2O), λ_{max} (nm) (ε (M^{-1}, cm^{-1})): 283 (13 000), (pH 1) 283 (13 000), (pH 12) 311.5 (21 000). ^{1}H and ^{13}C NMR data: Tables 2 and 3. Anal. calcd. for $C_9H_{12}N_2O_6$: C 44.27, H 4.95, N 11.47; found: C 44.03, H 4.85, N 11.35.

Isolation of photoproduct 9

HPLC analysis (conditions as for irradiation of **1***a* in water) of the methanolic solution of **1***a* irradiated to 68% conversion revealed the presence of only one major photoproduct. Preparative TLC of the concentrated, irradiated solution using solvent system B followed by further purification on HPLC (75%A/25%B) gave an analytically pure sample (83 mg) of **9**, a white solid. Yield: 17% on the isolated product (50%–HPLC). UV (H_2O), λ_{max} (nm) (ε (M^{-1}, cm^{-1})): 283 (4060), 335 (13 900). ^{1}H NMR ($CDCl_3$, 293 K) δ ppm: 7.41 (d, J = 7.3 Hz, 1, H-6), 6.51 (br s, 1, H-α), 6.08 (dd, 1, H-γ), 6.01 (d, J = 7.3 Hz, H-5), 5.67 (br s, 1, H-ε), 5.61 (m, 1, H-δ), 5.51 (m, 1, H-β), 3.71–3.66 (m, 2, CH_2), 3.48 (br s, 1, OH), 3.48 (s, 3, N-CH_3). ^{1}H NMR ($CDCl_3$, 253 K) δ ppm: 7.47 (d, J = 7.3 Hz, 1, H-6), 6.49 (d, J = 7.47 Hz, 1, H-α), 6.10 (dd, 1, H-γ), 6.03 (d, J = 7.3 Hz, H-5), 5.73 (m, 1, H-ε), 5.62 (m, 1, H-δ), 5.56 (m, 1, H-β), 3.84 (s br, 1, OH), 3.71 (m, 2, CH_2) , 3.50 (s, 3, N-CH_3). ^{13}C NMR ($CDCl_3$, 293 K) δ ppm: 163.23 (C-4), 156.15 (C-2), 146.92 (C-6), 123.98 (C-α), 123.06 (C-γ), 121.12 (C-δ), 109.00 (C-β), 92.19 (C-5), 63.64 (CH_2), 54.16 (C-ε), 37.93 (N-CH_3). Anal. calcd. for $C_{11}H_{13}N_3O_2$: C 60.26, H 5.98, N 19.16; found: C 60.08, H 5.90, N 19.07.

Synthesis of steroidal [4,6-*b*,*c*]-benzothiazepines, a new class of aromatase inhibitor

Herbert L. Holland, Sudalaiyandi Kumaresan, and Gingipalli Lakshmaiah

Abstract: Several steroidal [4,6-*b*,*c*]benzothiazepines have been prepared via base-catalyzed Michael addition of 2-aminothiophenol to 3β,17β-diacetoxyandrost-4-en-6-one. The product of this reaction has the 4β,5α stereochemistry, but cyclizes to a benzothiazepine with the steroidal 4β,5β configuration, confirmed by X-ray crystallographic analysis. 2-Aminothiophenol reacts with 3β,17β-diacetoxyandrost-4-en-6-one under acidic conditions to give a steroidal 6-spiro-benzothiazole. An androst-4-ene-3,17-dione-based [4,6]benzothiazepine has been shown to be a moderate competitive inhibitor of the human placental aromatase enzyme with $IC_{50} = 42.3$ μM.

Key words: steroid, aromatase, benzothiazepine.

Résumé : On a préparé plusieurs [4,6-*b*,*c*]benzothiazépines stéroïdales par le biais d'une addition du 2-aminothiophénol sur la 3β,17β-diacétoxyandrost-4-én-6-one. Le produit possède une stéréochimie 4β,5α, mais il se cyclise en une benzothiazépine de configuration stéroïdale 4β,5β qui a été confirmée par diffraction des rayons X. Dans des conditions acides, le 2-aminothiophénol réagit avec la 3β,17β-diacétoxyandrost-4-én-6-one pour donner un 6-spiro-benzothiazole. Il a été démontré qu'une [4,6]benzothiazépine basée sur une androst-4-én-3,17-dione est un inhibiteur modérément compétitif de l'enzyme aromatase du placenta humain; $IC_{50} = 42,3$ μM.

Mots clés : stéroïde, aromatase, benzothiazépine.

[Traduit par la rédaction]

The enzyme aromatase (estrogen synthetase), responsible for the production of the estrogen hormones in human females, is currently of interest in view of its role as a possible regulator in the etiology of breast cancer (1). Of the many steroids that have been examined for their potential as aromatase inhibitors (1), two of the most potent are the 4-enol **1** (2) and the 6-oxime **2** (3, 4). These observations, together with a demonstration of the importance of the Δ^4-3-keto unit and substitution at C-4 and C-6 in the development of efficient steroidal aromatase inhibitors (4, 5), suggested that a steroid such as **3**, carrying the [4,6]benzothiazepine unit, might function as an efficient aromatase inhibitor.

The reactions between 2-aminothiophenol and 3β-acetoxy-Δ^4-6-ketosteroids with the stigmastane (6) and cholestane (7) skeletons (Scheme 1) have been reported to produce the corresponding 4α-substituted-5α-steroids, **4**. We have applied this reaction to the synthesis of **3** as outlined in Scheme 2, starting from 3β,17β-diacetoxyandrost-4-en-6-one (**5**), whose preparation we have previously described (3). When performed under acid-catalyzed conditions as described (6), addition of

3

2-aminothiophenol to the ketone **5** gave only the spiro(benzothiazole) steroid **6** in 68% isolated yield. We were not able to isolate the expected product, benzothiazepine **8**, from this reaction. The structure of **6** follows from spectral data reported in the Experimental section and in Table 1, the significant nmr resonances being those associated with carbons 4–6. The configuration of **6** at C-6 has not been determined.

Reaction between ketone **5** and 2-aminothiophenol occurred to give the Michael addition product, 5α steroid **7**, in 87% yield

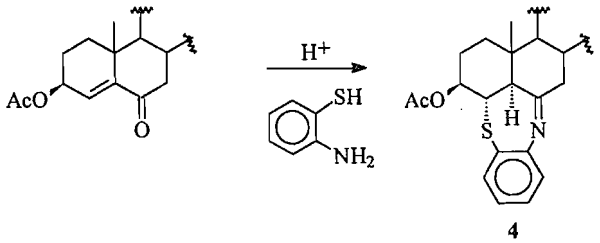
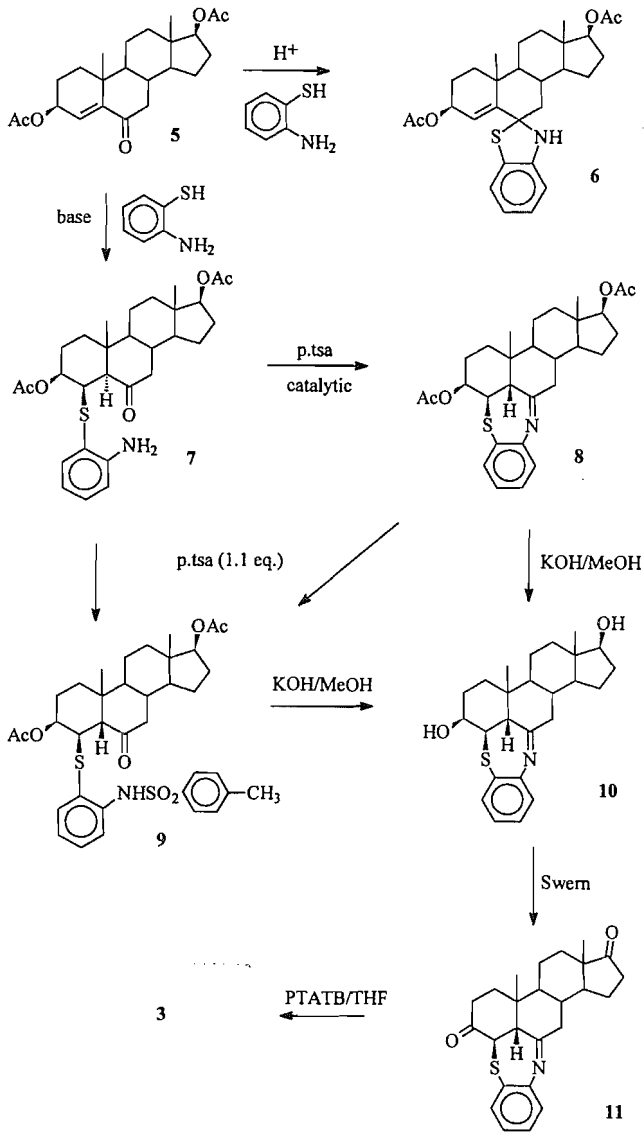


Scheme 2.



when carried out using basic catalysis. The stereochemistry of **7** at C-4, together with that of the AB ring junction, was confirmed as follows. That **7** is a 5α steroid follows clearly from its ^{13}C nmr spectrum (Table 1), with shifts for C-9 and C-19 being diagnostic of this stereochemistry (8, 9). The 4β configuration is then indicated by the ^{13}C resonance position of C-2, which shows a γ-*gauche* upfield shift of −3.5 ppm from the position of C-2 in corresponding C-4-unsubstituted steroids (9); the C-19 resonance position (3.6 ppm downfield from that of corresponding C-4-unsubstituted steroids (9)); and the appearance of the C-4 hydrogen resonance at δ 4.06 ppm as narrow doublet of doublets (J = 3.8 and 3.2 Hz), indicating the presence of only axial–equatorial couplings to hydrogens at C-3 and C-5. Michael addition to **5** from the axial (4β) side is predictable on stereoelectronic grounds (10) and is in accord with literature precedent (11): the 4α stereochemistry assigned earlier to similar products was based on "expectation" and is not substantiated by spectral data (7).

The addition product **7** is converted in high yield (91%) to the benzothiazepine **8** on treatment with a catalytic amount of *p*-toluenesulfonic (p.tsa) acid in refluxing benzene. It is clear from nmr analysis that **8**, and the subsequently derived intermediates **9–11**, possess the 5β configuration. This conclusion follows from the ^{13}C nmr data presented in Table 1, particularly the characteristic shifts for C-9 and C-19 (9), and the observation that the C-4 hydrogen resonance now appears at δ 4.01 ppm as a doublet of doublets with J = 12.9 and 2.5 Hz (in **8**, for example) caused by diaxial, and axial–equatorial couplings to hydrogens at C-5 and C-3, respectively. Proton nmr resonances at C-3, -4, and -5 were assigned in compounds **7–11** by ^1H–^1H COSY experiments, and the associated carbon resonances then assigned by SFORD spectra. In view of its unusual origin, this stereochemical analysis was confirmed by X-ray structure determination of the hydrolysis product, diol **10**, which is presented in Fig. 1.[2]

The formation of benzothiazepine **8** with 4β, 5β stereochemistry is at variance with the results of Mushfiq et al. depicted in Scheme 1 (6, 7), but their reported proton nmr data (6), in particular the assignment of the C-4 hydrogen at δ 2.8 ppm, do not support either their proposed structure or its 4α,5α stereochemistry. Condensation of **7** to a product with 5β stereochemistry is apparently thermodynamically driven. MM2 energy calculations on minimized structures using the Alchemy© or Hyperchem© modelling programmes indicate that **8** is more stable than the corresponding 5α isomer by 15.0 kcal/mol, the difference being associated entirely with angle and torsion strain. This assumption is strengthened by the isolation of the 5β sulfonamide **9** on treatment of **7** with larger amounts of p.tsa; this latter product was also obtained from **8** on further acid treatment, suggesting that formation of **9** from **7** proceeds via the benzothiazepine **8**. A possible route for the conversion of **8** to **9** in the presence of a larger amount of p.tsa may involve the acid-catalyzed addition of p.tsa across the C=N bond, followed by ring opening and O to N migration of the *p*-toluenesulfonyl group.

The diol **10**, obtained by hydrolysis of **8** or from cyclization of **9** under basic conditions, was converted in 90% yield by low-temperature Swern oxidation to the dione **11**. The latter then afforded benzothiazepine **3** on treatment with phenyl trimethyl ammonium tribromide. The target steroid **3** had an IC_{50} value of 42.3 μM when tested against human placental aromatase using 2.5 μM testosterone as substrate,[3] making it a moderately effective inhibitor of this enzyme. In spite of the importance of substitution at C-6 in the design of effective aromatase inhibitor (4), the recent suggestion (5) that the

enzyme's active site possesses limited accessible volume in the C-6 region may account for the lack of high inhibitory activity of benzothiazepine **3**.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage. The nmr spectra were recorded at 200 MHz (routine ^1H) or 50 MHz (routine ^{13}C) with a Bruker AC200 spectrometer using $CDCl_3$ as solvent and $CHCl_3$ or TMS as internal standard. Proton signals were assigned from ^1H–^1H COSY data and carbon signals from a combination of JMOD and SFORD spectra. Mass spectra were obtained with a Kratos 1S instrument operating in EI mode. Thin-layer chromatography was performed on Merck silica gel 60F-254 and flash column chromatography used silica gel, 230–400 mesh. Microanalyses were performed by Guelph Chemical Laboratories, Guelph, Ontario.

X-ray structure determination was carried out with a 0.64 × 0.39 × 0.51 mm crystal on a Nonius diffractometer using the θ/2θ scan mode. Crystal data: $C_{25}H_{33}NO_2S$; FW 411.60; orthorhombic $P2_12_12_1$, a = 12.1438(13), b = 13.2605(19), c = 13.9445(12) Å, V = 2245.5(4) Å^3, Z = 4, ρ_c 1.218 g cm^{-3}, μ = 0.16 mm^{-1} (20°C, MoKα_1, λ = 0.70930 Å), $2\theta_{max}$ = 44.9°; 1688 unique reflections were obtained and the last least-squares cycle was calculated with 62 atoms, 263 parameters, and 1460 observed reflection ($I > 2\sigma_I$) out of 1688 total reflections; R = 0.036, R_w = 0.037. Details of the X-ray measurements and tables of data have been deposited as supplementary material.[4]

(3) (1.164 g, 0.3 mmol), 2-aminothiophenol (0.414 g, 3.3 mmol), dry methanol (8 mL), and 2 drops of concentrated HCl was refluxed under an argon atmosphere for 90 min. The mixture was then cooled in ice, and the precipitated solid collected by filtration and washed with cold methanol (2 mL). The resulting colourless solid (1.01 g) was crystallized from methanol–chloroform to yield **6**, mp 178–179°C; ^{1}H nmr included signals at δ: 0.85 (3H, s, 18-H), 1.27 (3H, s, 19-H), 2.03 (6H, s, OAc), 2.51 (1H, dd, J = 2.5, 12 Hz, 7-H), 3.88 (1H, s, exchanges D_2O, NH), 4.57 (1H, t, J = 8.8 Hz, 17-H), 5.34 (1H, d of t, J = 2.5, 9 Hz, 3-H), 6.15 (1H, s, 4-H), and 6.57–6.96 (4H, m, Ar-H) ppm; ms *m/z*(%): 495 (M^+, 7), 435(100), 420(42), 346(5), 241(27). Anal. calcd. for $C_{29}H_{37}NO_4S$: C 70.27, H 7.52, N 2.83, S 6.47%; found: C 70.04, H 7.92, N 3.11, S 6.44%.

3β,17β-Diacetoxy-4β-(2-aminothiophenyl)-5α-androstan-6-one, 7

Androst-4-ene-3β,17β-diol-6-one diacetate (**5**) (3) (0.582 g, 1.5 mmol) was added to a solution of 2-aminothiophenol (0.207 g, 1.66 mmol) in dry methanol in which a catalytic amount of sodium had been dissolved. The resulting mixture was refluxed under argon for 90 min, cooled in ice, and the precipitated solid was collected by filtration, washed with cold methanol, and crystallized from methanol–chloroform to give **7** (0.675 g, 87%), mp 190°C (sharp); ^{1}H nmr included signals at δ: 0.80 (3H, s, 18-H), 1.07 (3H, s, 19-H), 1.51 (3H, s, OAc), 2.05 (3H, s, OAc), 4.05 (1H, dd, J = 3.8, 3.2 Hz, 4-H), 4.6–4.8 (2H, m, 3- and 17-H), 5.30 (2H, s, exchanges D_2O, NH_2), 6.60 (2H, m, Ar-H), 7.04 (1H, t, Ar-H), and 7.54 (1H, d, Ar-H) ppm; ms *m/z*(%) 513(M^+, 2.5), 435(3.5), 388(7.5), 346(100), 328(17), 313(57). Anal. calcd. for $C_{29}H_{39}NO_5S$: C 67.81, H 7.65, N 2.73, S 6.24%; found: C 67.42, H 7.78, N 3.24, S 6.52%.

2′3′-Dihydro-3β,17β-diacetoxy-5β-androstano[4β,6-*b*,*c*]-1′,5′-benzothiazepine, 8

A solution of **7** (0.400 g, 0.78 mmol) and a catalytic amount of *p*-toluene sulfonic acid in dry benzene (30 mL) was refluxed for 3 h using a Dean–Stark trap. The solution was then cooled, ether (50 mL) added, and the solution was washed with water, followed by saturated aqueous sodium bicarbonate, water, and then dried over magnesium sulfate. Evaporation afforded a yellow solid that was crystallized from benzene–hexane to give 0.350 g (91%) of colourless **8**, mp 270°C (sharp); ^{1}H nmr included signals at δ: 0.81 and 0.83 (each 3H, s, 18- and 19-H), 2.0 and 2.05 (each 3H, s, OAc), 4.02 (1H, dd, J = 2.5, 12.9 Hz, 4-H), 4.65 (1H, t, J = 8.5 Hz, 17-H), 5.1 (1H, br s, 3-H), 7.0–7.4 (4H, m, Ar-H) ppm; ms *m/z*(%): 495(M^+, 100), 435(7.5), 215(43). Anal. calcd. for $C_{29}H_{37}NO_4S$: C 70.27, H 7.52, N 2.83, S 6.47%; found: C 69.74, H 7.83, N 2.97, S 6.48%.

3β,17β-Diacetoxy-4β-(2-[*p*-tolylsulfonylamino]thiophenyl)-5β-androstan-6-one, 9

(a) From 3β,17β-diacetoxy-4β-(2-aminothiophenyl)-5α-androstan-6-one (7)

A mixture of the adduct **7** (0.400 g, 0.78 mmol), *p*-toluenesulfonic acid monohydrate (0.163 g, 0.86 mmol), and benzene (25 mL) was refluxed in a Dean–Stark apparatus for 2.5 h. Chloroform (20 mL) was then added, and the resulting solution was washed with water, aqueous sodium bicarbonate, dried, and evaporated to give 0.300 g (58%) of **9**, crystallized from chloroform – petroleum ether, mp 243°C (sharp); ^{1}H nmr included signals at δ: 0.77 and 0.87 (each 3H, s, 18- and 19-H), 1.94 and 2.06 (each 3H, s, OAc), 2.36 (3H, s, Ar-CH_3), 3.70 (1H, dd, J = 2.6, 12.6 Hz, 5-H), 4.35 (1H, dd, J = 2.6, 12.6 Hz, 4-H), 4.56 (1H, t, J = 8.8 Hz, 17-H), 5.10 (1H, br s, 3-H), and 7.16–7.96 (8H, m, Ar-H) ppm; ms *m/z*(%): 495 (M − p.tsa, 100), 453(3.5), 435(10). Anal. calcd. for $C_{36}H_{45}NO_7S_2$: C 64.74, H 6.79, N 2.10, S 9.60%; found: C 64.63, H 6.99, N 2.19, S 9.76%.

(b) From 2′,3′-dihydro-3β,17β-diacetoxy-5β-androstano[4β,6-b,c]-1′,5′-benzothiazepine (8)

A mixture of the benzothiazepine **8** (0.040 g, 0.06 mmol), *p*-toluenesulfonic acid monohydrate (0.017 g, 0.09 mmol), and dry benzene was refluxed for 2.5 h. Chloroform (10 mL) was then added, and the solution was washed with water, aqueous sodium bicarbonate, dried, and evaporated to give **9** (0.040 g), identical in all respects with the sample prepared in (*a*).

2′,3′-Dihydro-3β,17β-dihydroxy-5β-androstano[4β,6-*b*,*c*]-1′,5′-benzothiazepine, 10

(a) From 2′,3′-dihydro-3β,17β-diacetoxy-5β-androstano[4β,6-b,c]-1′,5′-benzothiazepine (8)

A solution of the diacetate **8** (0.100 g, 0.15 mmol) in dry methanol (3 mL) containing KOH (0.100 g) was stirred at room temperature for 24 h. The solvent was removed by evaporation, ice-water (5 mL) was added to the residue, and the mixture stirred for 10 min. The resulting solid was collected by filtration and dried to yield 0.076 g (92%) of **10**, crystallized from methanol–chloroform, mp 262–264°C; ^{1}H nmr included signals at δ 0.77 and 0.80 (each 3H, s, 18- and 19-H), 3.70 (1H, t, 17-H), 3.86 (1H, br s, 3-H), 4.07 (1H, dd, J = 2.5, 12.6 Hz, 4-H), and 7.03–7.55 (4H, m, Ar-H) ppm; ms *m/z*(%): 411 (M^+, 100), 258(16), 162(15), 149(23). Anal. calcd. for $C_{25}H_{33}NO_2S$: C 72.95, H 8.08, N 3.40%; found: C 72.84, H 7.94, N 3.44%.

(b) From 3β,17β-Diacetoxy-4β-(2-[p-tolylsulfonyl-amino]thiophenyl)-5β-androstan-6-one (9)

Treatment of **9** (1.00 g) by the procedure described in (*a*) resulted in the formation of 0.59 g (96%) of **10**, identical in all respects with the sample described above.

2′,3′-Dihydro-3,17-diketo-5β-androstano[4β,6-*b*,*c*]-1′,5′-benzothiazepine, 11

A solution of dimethyl sulfoxide (18 mg) in dichloromethane (0.5 mL) was added dropwise at −65°C under an argon atmosphere to a solution of oxalyl chloride (13.5 mg) in dichloromethane (0.30 mL), and the resulting mixture stirred for 10 min at that temperature. A suspension of the diol **10** (20 mg, 0.05 mmol) in dichloromethane was then added over a period of 10 min; the mixture was stirred for 1 h at −65°C and then quenched by the addition of triethylamine (49.2 mg). The solution was allowed to reach room temperature, water (2 mL) was added, and the mixture was then extracted with dichloromethane. The extract was washed with water followed by saturated NaCl, dried, and evaporated to give a residue that on chromatography (hexane–acetone, eluting with 12% acetone

in hexane) gave the title product (18 mg, 90%), mp 231–233°C; ^{1}H nmr included signals at δ: 0.87 and 0.95 (each 3H, s, 18- and 19-H), 4.45 (1H, d, J = 14 Hz, 4-H), and 7.0–7.62 (4H, m, Ar-H) ppm; ms *m/z*(%): 407 (M^+, 34), 373(36), 358(52), 299(35), 243(35), 215(100). Anal. calcd. for $C_{25}H_{29}NO_2S$: C 73.67, H 7.17, N 3.44%; found: C 73.78, H 7.23, N 3.44%.

3,17-Diketo-androsteno[4,6-*b*,*c*]-1′,5′-benzothiazepine, 3

A solution of phenyl trimethyl ammonium tribromide (73 mg, 0.194 mmol) in dry THF (1.5 mL) was added at −2°C to a stirred solution of the diketone **11** (80 mg, 0.196 mmol) in dry THF over a period of 10 min, and the mixture stirred at this temperature for 2 h. The mixture was then extracted into dichloromethane, and the extract was washed with water followed by saturated NaCl, dried, and evaporated. The residue was chromatographed using hexane–acetone, the product (45 mg, 57%) being eluted with 10% acetone – hexane, mp 242–244°C; ^{1}H nmr included signals at δ: 0.95 (6H, s, 18- and 19-H) and 7.03–7.45 (4H, m, Ar-H) ppm; ms *m/z*(%): 405 (M^+, 10), 373(68), 358(100), 344(12), 316(16). Anal. calcd. for $C_{25}H_{27}NO_2S$: C 74.04, H 6.71, N 3.45%; found: C 74.03, H 6.64, N 3.43%.

Acknowledgements

We are grateful to Professor Ling-Kang Liu of the Institute of Chemistry, Academia Sinica, Taiwan, for carrying out the X-ray structure determination, and to Drs. V.C.O. Njar and P. Dorfmüller of the Department of Pharmaceutical Chemistry, Universität des Saarlandes, Germany, for the aromatase enzyme inhibition study. We are also grateful to Mr. T. Jones (Brock University) for assistance with the acquisition of spectral data. Financial support was provided by the Natural Sciences and Engineering Research Council of Canada.

Synthesis of the carbocyclic analog of uridine 5′-(α-D-galactopyranosyl diphosphate) (UDP-Gal) as an inhibitor of β(1 → 4)-galactosyltransferase

Hideya Yuasa, Monica M. Palcic, and Ole Hindsgaul

Abstract: Uridine 5′-(5a-carba-α-D-galactopyranosyl diphosphate), the carbocyclic analog of UDP-galactose where the ring oxygen of the galactose residue is replaced by a methylene group, was chemically synthesized as a potential inhibitor of galactosyltransferases. It was found to be a competitive inhibitor of UDP-galactose:*N*-acetylglucosamine β(1 → 4)-galactosyltransferase from bovine milk (EC 2.4.1.22) with a K_i value of 58 μM, similar to the K_m value for UDP-galactose (25 μM).

Key words: carbocycles, UDP-5a-carbagalactose, galactosyltransferase, glycosyltransferase inhibitor.

Résumé : La 5′-(5a-carba-α-D-galactopyranosyl diphosphate) uridine, l'analogue carbocyclique de la UDP-galactose dans laquelle l'atome d'oxygène du résidu galactose a été remplacé par un groupe méthylène, a été synthétisée chimiquement comme un inhibiteur potentiel des galactosyltransférases. On a trouvé qu'elle est un inhibiteur compétitif de la UDP-galactose : *N*-acétylglucosamine β(1 → 4)-galactosyltransférase du lait bovin (EC 2.4.1.22) avec une valeur K_i de 58 μM, semblable à la valeur K_m de la UDP-galactose (25 μM).

Mots clés : carboxycles, UDP-5a-carbagalactose, galactosyltransférase, inhibiteur de glycosyltransférase.

[Traduit par la rédaction]

Introduction

Galactosyltransferases (Gal-T) catalyze the transfer of galactose from uridine 5′-diphosphate galactose (UDP-Gal, **1**) to growing oligosaccharide chains. Recent studies have revealed that a number of diseases are accompanied by structural changes of cell surface glycoconjugates; some of these structural changes are due to a change in Gal-T activity (1). For example, the down-regulation of Gal-T has been observed in multiple myeloma (2) and rheumatoid arthritis (3), while the up-regulation has been suggested for some liver diseases (4) and for Burkitt's lymphoma (5). Inhibitors of Gal-T could be important research tools since they might be able to regulate Gal-T activity, thereby clarifying the role of this enzyme in aberrant glycosylation. In the long term, small-molecule glycosyltransferase inhibitors may serve as drugs because they may be able to alter cell-surface glycosylation by decreasing galactosylation.

The unreactive sugar nucleotide analogs **2** (6) and **3** (7), which differ from UDP-Gal (**1**) in the diphosphate portion, have been synthesized previously and their K_i values were estimated to be 97 and 165 μM, respectively. The K_i (32 μM) of UDP is reported to be considerably lower (8), suggesting that an intact diphosphate grouping is preferred for binding. We therefore decided to synthesize the carbocyclic analog **4** of UDP-Gal, an analog expected to be unreactive while retaining an unmodified diphosphate linkage. The analog **4** might also be an inhibitor of UDP-Gal binding proteins such as the UDP-Gal transporter protein. A mutant of a cancer cell line lacking UDP-Gal transport protein does not metastasize (9).

During the course of this study, Toyokuni's group reported the synthesis of the carbocylic analog of guanosine 5′-(β-L-fucopyranosyl diphosphate) (GDP-Fuc) as an inhibitor of fucosyltransferases (FucT) and showed that the inhibitor binds to FucT comparably to GDP-Fuc (10). Here we report the synthesis of **4** and its inhibitory effect toward β(1 → 4)-Gal-T.

Results and discussion

Although two groups have reported the syntheses of 5a-carba-α-D-galactopyranose (11), the procedures used appeared cumbersome in view of the selective protection of hydroxyls required for UDP incorporation at OH-1. We therefore decided to employ the Ferrier reaction in the key step as has been frequently used in the synthesis of carbocycles (for example, see ref. 12). Initial attempts to use the Ferrier reaction for the synthesis of methyl 2,3,4-tri-*O*-acetyl-6-deoxy-α-L-*arabino*-hex-5-enopyranoside resulted in decomposition, so we elected to use benzyl groups for hydroxyl protection. Methyl 2,3,4-tri-*O*-benzyl-β-D-galactopyranoside **5** (13), obtainable in three steps from methyl β-D-galactopyranoside, was the starting material (Scheme 1).

Received August 1, 1995.

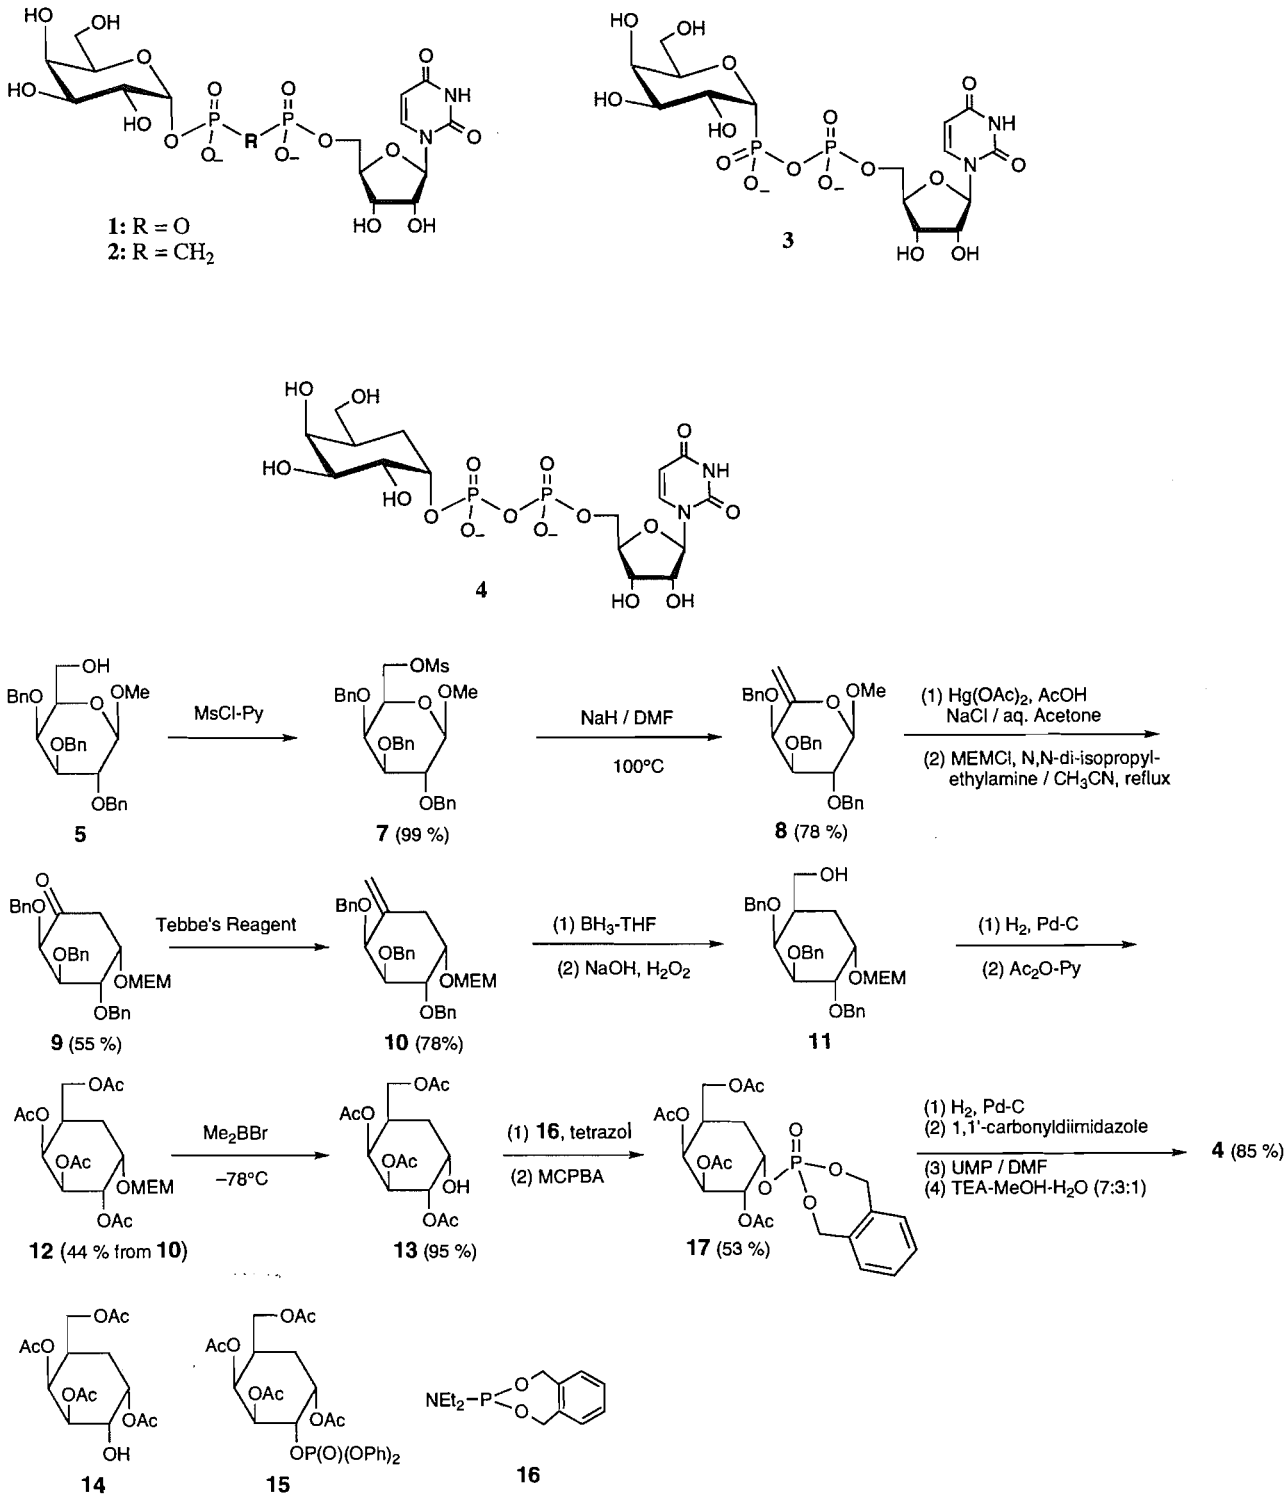
Scheme 1.



Attempts to introduce reactive leaving groups such as iodide and trifluoromethanesulfonate, for the purpose of producing alkene **8**, resulted instead in cyclization between O-3 and C-6 to give the 3,6-anhydro-sugar **6**, presumably through the mechanism shown in Scheme 2. The mesylate **7**, however, was readily prepared and reacted smoothly with sodium hydride to give **8**.

Application of the Ferrier reaction to **8** was successful and protection of the resultant hydroxyl group as the methoxyethoxymethyl (MEM) ether afforded the cyclohexanone **9**. Conversion of the carbonyl group of **9** into the required exocyclic methylene group was achieved with Tebbe's reagent (14) to give the methylenecyclohexane **10**. Attempted Wittig reaction of **9** with methylenetriphenylphosphorane gave only decomposition products.

The hydroboration of **10** gave a complex mixture contain-

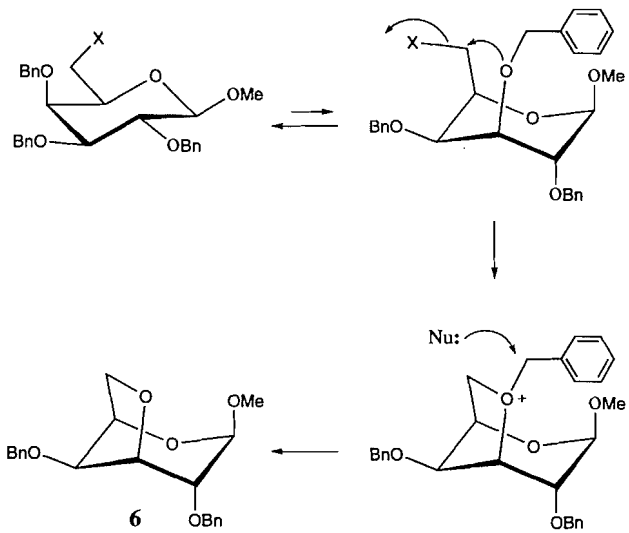
Scheme 2.



ing **11**, which was converted to **12** by hydrogenation (H_2, Pd/C) and acetylation. The coupling constants of the ring protons of **12** ($J_{1,2}$ 3.0, $J_{2,3}$ 11.0, $J_{3,4}$ 3.0, $J_{4,5}$ ~0 Hz) are consistent with the $^4C_1$ conformation. The C-5 epimer would not be expected to adopt this $^4C_1$ conformation. Common reagents used for deprotection of the MEM group in **12**, e.g., $ZnBr_2$ and $TiCl_4$, were unsuccessful, but dimethylboron bromide, developed by Guindon et al. (15), gave a high yield of the deprotected alcohol **13**.

Phosphorylation of the hydroxyl group in **13** was first attempted using diphenylphosphorochloridate and *n*-butyllithium. However, migration of the acetyl group from O-2 to O-1 was the major reaction yielding **14** (12%) and the 2-O-phosphorylated compound **15** (51%). Even pyridine as a solvent was sufficient to cause this migration so a milder method of phosphorylation was required. We therefore employed phosphitylation (16) with 2-dimethylamino-5,6-benzo-1,3-dioxa-2-phosphepane **16** followed by oxidation with *m*-chloroperoxybenzoic acid (MCPBA) to give the desired phosphate **17**. Removal of the benzyl esters of the phosphate by hydrogenation, activation with 1,1′-carbonyldiimidazole, coupling with uridine monophosphate (UMP), and de-O-acetylation then yielded the title compound **4**, which was purified by ion-exchange chromatography.

The K_i value of **4** toward UDP-galactose:N-acetylglucosamine β(1 → 4)-galactosyltransferase from bovine milk (EC 2.4.1.22) was determined to be 58 μM using a previously reported radiochemical "Sep-Pak" assay (17) with 8-methoxycarbonyloctyl 2-acetamido-2-deoxy-β-D-glucopyranoside as the acceptor. This value is essentially the same as the K_m value determined for UDP-Gal (25 μM) under the same experimental conditions, and the same as the K_i value for UDP-5′-thiogalactose (ref. 18, and unpublished data). To confirm that transfer of "carba-Gal" did not occur, a preparative synthesis was attempted using 20 units of Gal-T, 4.4 mg of compound **4**, and 1.6 mg of acceptor for 5 days at room temperature. No product formation was detected by ^1H NMR spectroscopy. Compound **4** was assumed to be stable under these conditions since UDP-Gal has been successfully used in such long incubations, but this issue was not specifically addressed in this work. Certainly, it is stable in the shorter incubations or unusual kinetic behaviour would have been observed. Under these conditions, less than 1 min would be required for complete galactosylation using the natural donor, UDP-Gal. From these results, the conclusions are that the ring oxygen of galactose is not essential for recognition of UDP-Gal by the enzyme but is essential for transfer to occur. This is consistent with the generally accepted mechanism for glycosyl transfer that involves an oxocarbonium ion-like transition state (19).

Experimental

All solvents and reagents used were reagent grade and, in cases where further purification was required, standard procedures (20) were followed. All solid reactants for moisture-sensitive reactions were dried overnight over phosphorus pentoxide under high vacuum prior to use. Solution transfers where anhydrous conditions were required were done under dry nitrogen using syringes. Molecular sieves were purchased from BDH chemicals. Thin-layer chromatograms (TLC) were performed on precoated silica gel 60-F254 plates (E. Merck, Darmstadt) and visualized by quenching of fluorescence and (or) by charring after spraying with 5% sulfuric acid in ethanol. For silica gel chromatography 40–63 μm (400–230 mesh) silica gel 60 (E. Merck No. 9385) and distilled solvents were used, and the ratio of silica gel to compound was in the range 50:1–100:1. Water was evaporated under the vacuum of an oil pump using a rotary evaporator equipped with a condenser containing acetone and Dry Ice. Organic solvents were removed on a rotary evaporator under the vacuum of a water aspirator with bath temperatures of 40°C or lower. Elemental analyses were performed by the Analytical Service Laboratory of the Chemistry Department.

Proton nuclear magnetic resonance (^1H NMR) spectra were recorded at 300 MHz (Bruker AM-300) with internal tetramethylsilane (δ 0 in $CDCl_3$) or external acetone (δ 2.225 in D_2O) at ambient temperature. Carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra were recorded at 75 MHz (Bruker AM-300) with either internal tetramethylsilane (δ 0 in $CDCl_3$) or external 1,4-dioxane (δ 67.4 in D_2O) as the reference standard. Phosphorus-31 nuclear magnetic resonance (^{31}P NMR) spectra were recorded at 108 MHz (Bruker AM-200) with external H_3PO_4 (85%) (δ 0 in D_2O) as the reference standard. The chemical shifts at lower field, relative to external H_3PO_4, are expressed as positive numbers while those at higher field are expressed as negative numbers. Optical rotations were determined on a Perkin–Elmer 241 polarimeter in a 1 dm cell at ambient temperature (23 ± 1°C).

Methyl 2,3,4-tri-*O*-benzyl-6-*O*-methanesulfonyl-β-D-galactopyranoside (7)

A solution of methyl 2,3,4-tri-*O*-benzyl-β-D-galactopyranoside (**5**, 0.488 g, 1.05 mmol) and methanesulfonyl chloride (0.12 mL, 1.55 mmol) in pyridine (10 mL) was kept at room temperature for 2.5 h. Water was added to the reaction mixture, which was then extracted with CH_2Cl_2. The organic layer was washed with aqueous $NaHCO_3$ and concentrated. The residue was chromatographed on silica gel (hexane – ethyl acetate 3:1) to give **7** (0.563 g, 99%) as a white solid: $[\alpha]_D$ −14.2 (*c* 1.5, $CHCl_3$); R_f 0.38 (2:1 hexane – ethyl acetate). ^1H NMR ($CDCl_3$) δ: 7.4–7.25 (m, 15H, Ar), 5.00, 4.62 (each d, 2H, J_{gem} 11.5 Hz, $PhCH_2$), 4.90, 4.75 (each d, 2H, J_{gem} 11.0 Hz,

$PhCH_2$), 4.86, 4.74 (each d, 2H, J_{gem} 12.0 Hz, $PhCH_2$), 4.33 (dd, 1H, $J_{5,6a}$ 7.0, $J_{6a,6b}$ 10.8 Hz, H-6a), 4.29 (d, 1H, $J_{1,2}$ 7.5 Hz, H-1), 4.06 (dd, 1H, $J_{5,6b}$ 5.3 Hz, H-6b), 3.82 (dd, 1H, $J_{2,3}$ 9.5 Hz, H-2), (m, 1H, H-4), 3.65 (ddd, H-1, $J_{4,5}$ 1.0 Hz, H-5), 3.55 (d, 1H, $J_{3,4}$ 3.0 Hz, H-3), 3.55 (s, 3H, OCH_3), 2.93 (s, 3H, SO_2CH_3). Anal. calcd. for $C_{29}H_{34}O_8S$: C 64.19, H 6.32, S 5.91; found: C 63.97, H 6.30, S 6.27.

Methyl 2,3,4-tri-*O*-benzyl-6-deoxy-α-L-*arabino*-hex-5-enopyranoside (8)

A mixture of **7** (0.362 g, 0.667 mmol) and 50% NaH (75 mg, 1.6 mmol, from which the oil was removed by washing with hexane prior to use) in DMF (8 mL) was stirred for 2 h at 100°C. After cooling, ice-water was added and the mixture was extracted with Et_2O. The organic layer was dried over $MgSO_4$ and concentrated. The residue was chromatographed on silica gel (hexane – ethyl acetate 13:1) to give **8** (0.232 g, 78%) as a syrup: $[\alpha]_D$ −9.0 (*c* 2.0, $CHCl_3$); R_f 0.33 (10:1 hexane – ethyl acetate). ^1H NMR ($CDCl_3$) δ: 7.45–7.25 (m, 15H, Ar), 4.85–4.75 (m, 4H, 2 × $PhCH_2$), 4.62 (s, 2H, $PhCH_2$), 4.46, 4.44 (each d, 2H, J_{gem} 6.0 Hz, C=CH_2), 4.43 (d, 1H, $J_{1,2}$ 7.0 Hz, H-1), 4.02 (d, 1H, $J_{3,4}$ 3.2 Hz, H-4), 3.99 (dd, 1H, $J_{2,3}$ 9.5 Hz, H-2), 3.62 (s, 3H, OCH_3), 3.56 (dd, 1H, H-3). Anal. calcd. for $C_{28}H_{30}$plain$6O_5$: C 75.31, H 6.77; found: C 75.12, H 6.82.

(2*R*)-2,3/4,5-2,3,4-Tribenzyloxy-5-methoxyethoxymethoxycyclohexanone (9)

Enolate **8** (0.591 g, 1.32 mmol) and mercury(II) acetate (0.758 g, 2.38 mmol) were heated to reflux in 40% aqueous acetone (28 mL) containing acetic acid (1%) for 1 h. NaCl (0.758 g, 13 mmol) was added, and the mixture was heated for a further 20 min. After cooling, the mixture was concentrated, and the residue was partitioned between CH_2Cl_2 and water. The organic layer was dried over $MgSO_4$ and concentrated. The residue was chromatographed on silica gel (hexane – acetyl acetate 5:2) to give a mixture of (2*R*)-2,3/4,5-2,3,4-tribenzyloxy-5-hydroxycyclohexanone and unknown compounds as a syrup (0.615 g). A mixture of this syrup, 2-methoxyethoxymethyl chloride (0.78 mL, 6.83 mmol), and *N*,*N*-diisopropylethylamine (1.10 mL, 7.85 mmol) in CH_3CN (12 mL) was refluxed for 2 h. The mixture was concentrated and chromatographed on silica gel (hexane – ethyl acetate 3:1–5:2) to give **9** (0.376 g, 55%; R_f 0.39, 2:1 *n*-hexane – ethyl acetate) as a syrup and a mixture of unknown compounds (87 mg; R_f 0.29, the same solvent as above).

9: $[\alpha]_D$ +59.8 (*c* 1.2, $CHCl_3$); ^1H NMR ($CDCl_3$) δ: 7.4–7.15 (m, 15H, Ar), 4.83, 4.42 (each d, 2H, J_{gem} 12.5 Hz, $PhCH_2$), 4.75, 4.55 (each d, 2H, J_{gem} 12.5 Hz, $PhCH_2$), 4.72, 4.54 (each d, 2H, J_{gem} 12.0 Hz, $PhCH_2$), 4.71 (s, 2H, OCH_2O), 4.37 (dd, 1H, $J_{2,3}$ 3.0, $J_{2.6a}$ 0.5 Hz, H-2), 4.27 (ddd, 1H, $J_{4,5}$ 3.0, $J_{5,6a}$ 10.0, $J_{5.6b}$ 6.0 Hz, H-5), 3.99 (dd, 1H, $J_{3,4}$ 5.0 Hz, H-3), 3.95 (ddd, 1H, $J_{4,6b}$ 1.0 Hz, H-4), 3.69–3.64, 3.54–3.49 (each m, 4H, OCH_2CH_2O), 3.37 (s, 3H, OCH_3), 2.80 (ddd, 1H, $J_{6a,6b}$ 13.2 Hz, H-6a), 2.73 (ddd, 1H, H-6b); ^{13}C NMR δ: 204.6 (C-1), 138.1, 137.9, 128.4, 128.3, 127.9, 127.8, 127.7 (Ar), 94.6 (OCH_2O), 81.5, 77.9, 76.9, 73.8 (C-2, C-3, C-4, C-5), 73.5, 72.6, 71.7 ($PhCH_2$), 67.2 (OCH_2), 59.1 (OCH_3), 42.6 (C-6). Anal. calcd. for $C_{31}H_{36}O_7$: C 71.52, H 6.97; found: C 71.52, H 6.94.

(1*S*)-1,2/3,4-2,3,4-Tribenzyloxy-1-methoxyethoxymethoxy-5-methylenecyclohexane (10)

To a stirred solution of **9** (0.749 g, 1.44 mmol) in toluene–THF (9/3 mL/mL) containing pyridine (7 μL) was slowly added a 2 M solution of Tebbe's reagent ($Cp_2TiCH_2AlClMe_2$) in toluene (3.08 mL, 6.16 mmol) at −40°C. After stirring for 0.5 h at −40°C, the temperature was slowly increased to room temperature over 1.5 h. After addition of 0.3 M NaOH (0.1 mL) (gas was evolved), Et_2O and $MgSO_4$ were added to the reaction mixture. Insoluble material was removed by filtration with Celite and the filtrate was concentrated. The residue was chromatographed on silica gel (hexane – ethyl acetate 5:2) to give **10** (0.585 g, 78%) as a syrup: $[\alpha]_D$ +5.5 (*c* 1.5, $CHCl_3$); R_f 0.53 (2:1 *n*-hexane – ethyl acetate). ^1H NMR ($CDCl_3$) δ: 7.4–7.25 (m, 15H, Ar), 5.03 (d, 2H, C=CH_2), 4.81–4.34 (m, 8H, 3 × $PhCH_2$ and OCH_2O), 4.12 (m, 2H, H-1 and H-4), 3.98 (dd, 1H, $J_{1,2}$ 3.0, $J_{2,3}$ 9.0 Hz, H-2), 3.83 (dd, 1H, $J_{3,4}$ 3.5 Hz, H-3), 3.70, 3.50 (each m, 4H, OCH_2CH_2O), 3.38 (s, 3H, OCH_3), 2.5–2.35 (m, 2H, H-6a and H-6b), ^{13}C NMR δ: 141.2 (C-5), 139.0, 138.5 (C=CH_2 and Ar), 128.3, 128.2, 127.8, 127.7, 127.4, 127.3 (Ar), 94.8 (OCH_2O), 78.9, 78.7, 73.6 (C-1, C-2, C-3, C-4), 73.3, 72.6, 71.7 ($PhCH_2$), 69.7, 66.9 (OCH_2CH_2O), 59.0 (OCH_3), 33.9 (C-6). Anal. calcd. for $C_{32}H_{38}O_6$: C 74.11, H 7.38; found: C 73.72, H 7.49.

(1*S*)-1,2/3,5-2,3,4-Tribenzyloxy-5-hydroxymethyl-1-methoxyethoxymethoxycyclohexane (11)

To a stirred solution of **10** (1.205 g, 2.32 mmol) in THF (23 mL) was slowly added a 1 M solution of BH_3–THF complex (2.63 mL) at 0°C. The reaction mixture was allowed to warm to 20°C and stirred for 17 h. EtOH (4.8 mL) was added to the mixture at 0°C followed by 3 M NaOH (8.1 mL) and 30% H_2O_2 (4.8 mL) and the mixture was stirred for 5 h at room temperature. After addition of 1 M NaOH, the mixture was extracted three times with Et_2O. The combined organic layers were concentrated and the residue chromatographed on silica gel (hexane – ethyl acetate 1:1) to give **11**, contaminated with unknown impurities (0.940 g; R_f 0.25, 1:1 hexane – ethyl acetate), as a syrup, which was used for the next reaction without further purification.

(1*S*)-1,2/3,4,5-2,3,4-Triacetoxy-5-acetoxymethyl-1-methoxyethoxymethoxycyclohexane (12)

Syrupy **11** (0.94 g), described above, in MeOH (50 mL) was stirred under H_2 (1 atm = 101.3 kPa) in the presence of 5% Pd/C (0.882 g) for 5 h at room temperature, then filtered, and concentrated. The residue was chromatographed on silica gel (CH_2Cl_2–MeOH 8:1). The fractions containing the major product (R_f 0.22, 8:1 CH_2Cl_2–MeOH) were collected and concentrated to give a white solid (0.350 g), which was acetylated with acetic anhydride (3 mL) and pyridine (3 mL). The product obtained after evaporation and aqueous extraction was chromatographed on silica gel (hexane – ethyl acetate 1:1) to give **12** (0.444 g, 44% from **10**) as a syrup: $[\alpha]_D$ +38.9 (*c* 1.1, $CHCl_3$); R_f 0.27 (1:1 hexane – ethyl acetate). ^1H NMR ($CDCl_3$) δ: 5.54 (bs, 1H, H-4), 5.30 (dd, 1H, $J_{2,3}$ 11.0, $J_{3,4}$ 3.0 Hz, H-3), 5.14 (dd, 1H, $J_{1,2}$ 3.0 Hz, H-2), 4.78, 4.74 (each d, 2H, J_{gem} 7.5 Hz, OCH_2O), 4.22 (m, 1H, H-1), 3.96 (dd, 1H, J_{gem} 11.0, J_{vic} 9.5 Hz, C*H*HOAc), 3.87 (dd, 1H, J_{vic} 6.0 Hz, CH*H*OAc), 3.72, 3.54 (each m, 4H, OCH_2CH_2O), 3.38 (s, 3H, OCH_3), 2.51 (m, 1H, H-5), 2.10, 2.06, 2.04, 1.98 (each s, each 3H, OAc), 1.85 (ddt, 1H, $J_{5,6e}$ 3.8, $J_{4,6e}$ 1.5, $J_{6a,6e}$ 1.40 Hz, H-6e), 1.63 (m, 1H, H-6a). Anal. calcd. for $C_{19}H_{30}O_{11}$: C 52.53, H 6.96; found: C 52.45, H 7.04.

(1*S*)-1,2/3,4,5-2,3,4-Triacetoxy-5-acetoxymethyl-1-hydroxycyclohexane (13)

To a stirred solution of **12** (0.165 g, 0.38 mmol) in CH_2Cl_2 (5 mL) was added bromo dimethylborane (0.13 mL, 1.33 mmol) at −78°C. After 1 h, the mixture was diluted with CH_2Cl_2, washed with aqueous $NaHCO_3$, and concentrated. The residue was chromatographed on silica gel (hexane – ethyl acetate 1:1) to give **13** (0.125 g, 95%) as a syrup: $[\alpha]_D$ +35.3 (*c* 0.8, $CHCl_3$); R_f 0.5 (1:2 benzene – acetate). ^1H NMR ($CDCl_3$) δ: 5.54 (bs, 1H, H-4), 5.31 (dd, 1H, $J_{2,3}$ 10.5, $J_{3,4}$ 3.0 Hz, H-3), 5.19 (dd, 1H, $J_{1,2}$ 3.0 Hz, H-2), 4.26 (m, 1H, H-1), 3.98 (dd, 1H, J_{gem} 11.0, J_{vic} 9.0 Hz, C*H*HOAc), 3.87 (dd, 1H, J_{vic} 6.0 Hz, CH*H*OAc), 2.60 (m, 1H, H-5), 2.11 (s, 6H, 2 × Ac), 2.04, 1.99 (each s, each 3H, Ac), 1.83 (ddt, 1H, $J_{5,6e} = J_{6e,1}$ 4.0, $J_{4,6e}$ 1.5, $J_{6a,6b}$ 14.0 Hz, H-6e), 1.70 (m, 1H, H-6a). Anal. calcd. for $C_{15}H_{22}O_9$: 52.02, H 6.40; found: C 51.83, H 6.62.

(1*S*)-1,2/3,4,5-2,3,4-Triacetoxy-5-acetoxymethyl-1-(2-oxo-5,6-benzo-1,3,2-dioxaphosphep-2-yloxy)-cyclohexane (17)

To a solution of **13** (165 mg, 0.476 mmol) and tetrazole (107 mg, 1.53 mmol) in CH_2Cl_2 (3 mL) was added 2-dimethylamino-5,6-benzo-1,3-dioxa-2-phosphepane **15** (180 mg, 0.752 mmol) and the mixture was stirred at room temperature for 2 h. The reaction mixture was then cooled to −40°C and the solution of MCPBA (208 mg) in CH_2Cl_2 (3 mL) was added. The stirring was continued for 10 min at −40°C and for another 40 min at 0°C. The reaction mixture was diluted with CH_2Cl_2 and washed consecutively with aqueous $NaHSO_4$ and aqueous $NaHCO_3$. The organic layer was dried over $MgSO_4$ and concentrated. The residue was chromatographed on silica gel (hexane – ethyl acetate 1:2) to give **17** (147 mg, 53%) as a foam: $[\alpha]_D$ +53.6 (*c* 0.8, $CHCl_3$); R_f 0.17 (1:2 hexane – ethyl acetate). ^1H NMR ($CDCl_3$) δ: 7.4–7.25 (m, 4H, Ar), 5.57 (m, 1H, H-4), 5.4–5.1 (m, 7H, H-2, H-3, 2 × $ArCH_2$), 4.00 (dd, 1H, J_{gem} 11.5, J_{vic} 9.5 Hz, C*H*HOAc), 3.88 (dd, 1H, J_{vic} 6.0 Hz, CH*H*OAc), 2.12 (s, 6H, 2 × Ac), 2.06, 2.01 (each s, each 3H, Ac), 1.81 (m, 1H, H-6a), 1.62 (m, 1H, H-6b); ^{13}C NMR δ: 170.7, 170.3, 170.2, 170.0 ($COCH_3$), 135.0, 134.9, 129.2, 128.8, 128.75 (Ar), 74.7 (d, $J_{C\text{-}1,P}$ 5.3 Hz, C-1), 69.5, (d, $J_{C\text{-}2,P}$ 3.8 Hz, C-2), 69.2, 68.1 (C-3, C-4), 68.6, 68.5 (2 × $ArCH_2$), 62.7 (CH_2OAc), 32.7 (C-5), 28.0 (C-6), 20.9, 20.7 ($COCH_3$); ^{31}P NMR δ: −0.15. Anal. calcd. for $C_{23}H_{29}O_{12}P$: C 52.28, H 5.53; found: 52.16, H 5.62.

Uridine 5′-(5a-carba-α-D-galactopyranosyl diphosphate) (4)

A solution of **17** (54 mg, 0.102 mmol) in MeOH (4 mL) was stirred under H_2 (1 atm) in the presence of 5% Pd/C (24 mg) for 2 h at room temperature, then filtered and concentrated to give a syrup (R_f 0.70, 60:35:1 dichloromethane–methanol–water), which was dissolved in dry acetone (2 mL) and 1,1′-carbonyldiimidazole (50 mg, 0.246 mmol) was added. The mixture was stirred for 18 h at room temperature. When the reaction was complete, as monitored by TLC (the imidazolide has R_f 0.25, 3:1 $CHCl_3$–MeOH), MeOH (5 μL) was added and stirring continued for a further 20 min. The mixture was concentrated and dried over phosphorus pentoxide in vacuo for 6 h. Meanwhile, uridine 5′-monophosphate disodium salt (74 mg, 0.20 mmol) was passed slowly through a column of Dowex 50 × 8 (H^+) resin and the column was thoroughly washed with water. The eluate was concentrated and trioctylamine (94 μL, 2.15 mmol) was added. The mixture was coevaporated three times with DMF and a solution of the imidazolide in DMF (2.5 mL) was added. The mixture was stirred for 18 h at room temperature and monitored by TLC (the pyrophosphate coupling product has R_f 0.17, 60:40:3 CH_2Cl_2–MeOH–water). The solvent was evaporated and MeOH (3.5 mL), water (1.5 mL), and triethylamine (0.5 mL) were added. After 7 h, the reaction mixture was slowly passed through a column of Dowex 1 × 2-200 (3 × 12 cm, HCO_3^-) and the column was washed with 40 mM ammonium bicarbonate. The product was then eluted using a linear gradient from 40 to 700 mM ammonium bicarbonate (1.1 L) at 23°C. The column was at 23°C at a flow rate of 1.6 mL/min. Each fraction (12 mL) was monitored by UV absorption at 280 nm. Fractions of the product were pooled and concentrated. The residue was dissolved into water and remaining ammonium bicarbonate was removed by adding Dowex 50 × 8 (H^+) until the pH became less than 7.0 (CO_2 gas was evolved). After removing the resin by filtration, the filtrate was concentrated to 5 mL, passed through a Millex-SR 2 μM filter, and lyophilized to give **4** (49 mg, 85%) as a white solid: R_f 0.33 (7:3:1 i-propanol–water – conc. ammonium hydroxide). ^1H NMR (D_2O) δ: 7.97 (d, 1H, $J_{5,6}$ 8.3 Hz, H-6), 5.99 (d, 1H, $J_{1',2'}$ 3.0 Hz, H-1′), 5.98 (d, 1H, H-5), 4.62 (m, 1H, H-1″), 4.09 (m, 1H, H-4″), 3.78 (dd, 1H, $J_{2'',3''}$ 10.5, $J_{3'',4''}$ 3.0 Hz, H-3″), 3.68 (dt, $J_{1'',2''} = J_{2'',P}$ 3.0 Hz, H-2″), 3.62 (dd, 1H, $J_{5'',6a''}$ 8.0, $J_{6a'',6b''}$ 11.5 Hz, H-6a″), 3.52 (d, 1H, $J_{5'',6b''}$ 6.5 Hz, H-6b″), 2.14 (m, 1H, H-5″), 1.94, 1.55 (each m, 2H, ring methylene); ^{13}C NMR δ: 167.1 (C-4), 152.7 (C-2), 142.5 (C-6), 103.5 (C-5), 89.3 (C-1′), 84.1 (d, $J_{C\text{-}4',P}$ 8.4 Hz, C-4′), 76.5 (d, $J_{C\text{-}1'',P}$ 5.5 Hz, C-1″), 74.6, 72.4, 70.6, 70.5 (C-2′, C-3′, C-3″, C-4″), 65.7 (d, $J_{C\text{-}5',P}$ 5.5 Hz, C-5′), 63.2 (C-6″), 37.1 (C-5″), 27.7 (ring methylene of carbagalactose); ^{31}P NMR δ: −10.8 (d, $J_{P,P}$ 20.6 Hz, P attached to uridine), −11.2 (d, P attached to carbagalactose).

Inhibitory assay

Bovine milk β(1 → 4) galactosyltransferase was isolated by chromatography on UDP-hexanolamine and α-lactalbumin Sepharose (21, 22). Kinetic studies were carried out, as previously described (17), in 0.5 mL plastic microcentrifuge tubes that contained 420 μM 8-methoxycarbonyloctyl 2-acetamido-2-deoxy-β-D-glucopyranoside acceptor, 76 000 dpm of UDP-6[^{3}H] Gal, 0.01–1.1 mM UDP-Gal, 0.5 micro-units of enzyme, 250 mM NaCl, 8 mM $MnCl_2$, and 80 mM sodium cacodylate buffer, pH 7.5, in a total volume of 55 μL. After incubation for 20 min at 37°C, the samples were diluted to 500 μL with water and applied to C-18 reverse-phase cartridges. The cartridges were washed with 50–70 mL of water to removed unreacted donor and then the radiolabelled product eluted with 5 mL of methanol into 20 mL plastic scintillation vials. Ecolite (+) cocktail (10 mL) was added to the vials and the amount of product formed was quantitated by counting in a Beckman LS 1801 scintillation counter. Data were analyzed using nonlinear regression analysis of the Michaelis–Menten equation with Sigma Plot to give a K_m for the donor UDP-Gal of 25 μM under these conditions. The K_i for compound **3** was estimated by carrying out kinetic measurements with same range of donor concentrations with 100 μM of **3** added to all of the assay mixtures. Compound **3** was a competitive inhibitor of the galactosyltransferase with a K_i of 58 μM using the equa-

tion $K_m(app) = K_m(1 + [I]/[K_i]$ where $K_m = K_m$ for UDP-Gal, $K_m(app)$ is the K_m in the presence of inhibitor, and [I] is the inhibitor concentration (100 μMm).

No product was formed in incubations that contained 20 units of galactosyltransferase in 1.0 mL of 100 mM sodium cacodylate buffer, pH 7.5, 4.4 mg of compound **3**, and 1.6 mg of 8-methoxycarbonyl octyl 2-acetamido-2-deoxy-β-D-glucopyranoside acceptor after 5 days of reaction at ambient temperature. Only unreacted acceptor was re-isolated on Sep Pak cartridges as evidenced by ^{1}H NMR spectroscopy.

A deuterium NMR study of guest molecular dynamics of acetone in two organic inclusion compounds

Paul S. Sidhu, Jason Bell, Glenn H. Penner, and Kenneth R. Jeffrey

Abstract: Deuterium nuclear magnetic resonance (NMR) spectra and spin-lattice relaxation times (T_1) are used to investigate the dynamics of the guest molecule, acetone, in tris(5-acetyl-3-thienyl)methane (TATM) and cyclotriveratrylene (CTV) inclusion compounds. ^{13}C CPMAS powder NMR spectra were obtained for each clathrate, to verify inclusion. In acetone: TATM, the guest molecule is undergoing twofold reorientation about the CO bond, exchanging the two methyl groups. An activation energy of 20.8 (±1.4) kJ/mol, for the two-site jump motion, was found, independently, from deuterium NMR spectra and T_1 measurements. Acetone in CTV performs the same type of motion as acetone in TATM. Activation energies of 25.0 (±3.2) kJ/mol and 24.1 (±0.5) kJ/mol were determined using the same two techniques. In both inclusion compounds, the rate of methyl rotation within the acetone molecule is greater than 10^8 Hz even at the lowest temperature measured (84 K). Analytical expressions for the spin-lattice relaxation time (T_1), for a twofold jump, were derived. Calculated values of the effective quadrupolar coupling constant and T_{1min} for the guests agree very well with the experimental data. The 84 K spectrum of acetone:TATM unexpectedly shows some asymmetry, the origin of which is discussed. Finally, these two clathrates are compared to the recently examined acetone:tri-*ortho*-thymotide inclusion compound.

Key words: inclusion compounds, deuterium NMR, solid state NMR spectroscopy, molecular dynamics.

Résumé : On a utilisé les spectres de résonance magnétique nucléaire (RMN) et les temps de relaxation spin-réseau (T_1) du deutérium pour étudier la dynamique de la molécule invitée, l'acétone, dans les composés d'inclusion tris(5-acétyl-3-thiényl)méthane (TATM) et du cyclotrivératrylène (CTV). On a déterminé les spectres RMN CPMAS du ^{13}C de chacun des clathrates pour s'assurer de l'inclusion. Dans l'acétone : TATM, la molécule incluse subit une réorientation binaire autour de la liaison CO qui permet d'échanger les deux groupes méthyles. On a déterminé de façons indépendantes, par les spectres RMN du deutérium ainsi que par les mesures de T_1, que l'énergie d'activation est égale à 20,8 (±1,4) kJ mol^{-1} pour le mouvement de saut des deux sites. L'acétone dans le CTV est soumise au même type de mouvement que l'acétone dans le TATM. Les énergies d'activation mesurées par les deux techniques sont respectivement de 25,0 (±3,2) kJ mol^{-1} et de 24,1 (±0,5) kJ mol^{-1}. Dans les deux composés d'inclusion, la vitesse de rotation du groupe méthyle de la molécule d'acétone dépasse les 10^8 Hz, même pour la température de mesure la plus basse (84 K). On a dérivé les expressions analytiques du temps de relaxation spin-réseau (T_1) de l'échange binaire. Les valeurs calculées pour la constante de couplage quadripolaire effective et pour le T_{1min} pour les invitées sont en bon accord avec les valeurs expérimentales. Il est surprenant que le spectre de l'acétone : TATM, à 84 K, présente une certaine symétrie dont on discute l'origine. Enfin, on compare ces deux clathrates au produit d'inclusion acétone : tri-*ortho*-thymotide qui a été examiné récemment.

Mots clés : composés d'inclusion, RMN du deutérium, spectroscopie RMN à l'état solide, dynamique moléculaire.

Introduction

In recent years, deuterium NMR spectroscopy has emerged as a very important technique for the study of anisotropic molecular motion in solids (1–3). Motion with reorientational rates in the range of 10^3–10^8 Hz may be examined by an analysis of the ^2H NMR powder lineshape (4). For faster

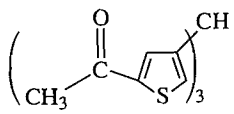
motions, an analysis of the deuterium spin-lattice relaxation time as a function of temperature may be used to extract quantitative information regarding the molecular motion (5). Deuterium NMR spectroscopy has developed into an excellent probe for the study of dynamic processes (6–8), because of the development of computer programs (9–12) capable of simulating deuterium NMR spectra as a function of reorientational rate, molecular geometry, and dynamic model, along with the availability of selectively deuterated molecules (13).

It is generally known that in many inclusion compounds, the relatively weak van der Waals interaction between host and guest affords the enclathrated moiety a large degree of motional freedom (14). Determination of the dynamics of a guest molecule provides insight into the guest–host interaction (15–18). For example, the potential for free rotation is undoubtedly hindered in inclusion compounds where the guest–host interaction involves hydrogen bonds. In addition, X-ray crystallographic data can assist in providing insight into the shape and size of the cavity formed by the host (19–22). We have chosen to study the dynamics of acetone enclathrated by two hosts, tris(5-acetyl-3-thienyl)methane, and cyclotriveratrylene. Both compounds are known to form inclusion compounds with a wide variety of fairly small guest molecules (23, 24).

Tris(5-acetyl-3-thienyl)methane (TATM), **1**, was first synthesized by Yakubov et al., in 1973, from 2-acetyl thiophene and chloroform in the presence of excess aluminum chloride. It was also noted that TATM forms inclusion compounds on recrystallization from various solvents (25).

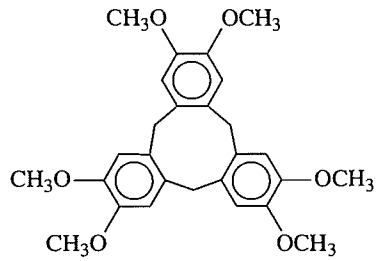


1

In 1977, Bin Din and Meth Cohn found that TATM forms 2:1 host:guest clathrates with a wide variety of organic compounds (23). The guest molecules reside in cavities formed by the TATM molecules. Furthermore, their study, at least to that point in time, failed to reveal a solvent that was not incorporated. Although the pure host compound melts at about 55°C, TATM inclusion compounds generally melt at temperatures above 100°C.

Recently, four crystal structures of TATM with various guests have been reported (26–29). In the presence of guest molecules, the TATM molecules generally form a triclinic lattice in which there is only one guest molecule per unit cell. In addition, the inability to precisely identify the positions of the guest's atom led to the conclusion that the guest molecules are disordered (30). Hydrogen bonds are absent in the ethanol:TATM inclusion compound. Finally, the TATM molecules were seen to form cavities of different sizes and shapes, depending on the guest molecule (26–29).

Turning our attention to cyclotriveratrylene (CTV), **2**, this compound was first obtained in 1915 by reaction between formaldehyde and veratrole (31) and was originally considered to be a cyclic hexamer (32). However, it was later shown by various experiments (33–35) to be a trimer $(C_9H_{12}O_2)_3$ possessing a rigid crown C_{3v} conformation (36).



2

Inclusion compounds of cyclotriveratrylene were first reported in 1931 (37), but were studied in greater detail by Caglioti et al. some 25 years later (24). The crystal structure of the CTV:benzene:water inclusion compound shows that the CTV molecules form channels by stacking on top of one another, with the two guests residing in the channels surrounded by four stacks of CTV molecules. The water molecules form hydrogen bonds with the methoxy oxygen atoms of the host (38). An attempt to form a CTV:toluene clathrate gave water as the only guest with a CTV:H_2O ratio of about 1:0.16. A combined crystal structure and IR study was interpreted as indicating weak hydrogen bonding between water and the methoxy oxygens of CTV (39). As pointed out by Burlinson and Ripmeester, the ability of CTV to form inclusion compounds often depends critically on the presence or absence of water (40). Zhang and Atwood exploited this to prepare crystals of pure CTV (41). One common feature of these studies is that the CTV molecules stack along the crystallographic *b*-axis, and that the *b*-axis value changes little from guest to guest whereas the *a* and *c* axes depend strongly on the size of the guest molecule. An exception to this is the recent structure of $(C_{60})_{1.5}$(CTV)$(\text{toluene})_{0.5}$ where the C_{60} and CTV molecules form a ball and socket structure, nearly doubling the *b*-axis value (42).

Theoretical background

Solid state deuterium NMR spectroscopy is one of the principal techniques used to study guest motion in inclusion compounds. Deuterium is a quadrupolar nucleus and, as such, the interaction between the quadrupole moment of the nucleus and the electric field gradient of the surrounding charge distribution gives rise to a quadrupolar coupling, which is the major perturbation on the nuclear Zeeman interaction. In organic compounds, the electric field gradient arises primarily from the electronic structure of the C—D bond. In solution, rapid isotropic tumbling averages the quadrupolar coupling to zero, but in powders it gives rise to very broad spectra, yielding a superposition of signals for each possible orientation of the C—D bond with respect to the applied magnetic field. For a spin = 1 nucleus, there are two NMR transitions, resulting in a symmetric powder pattern spectrum.

There are two quantities that may be defined to describe the appearance of a ^2H NMR powder spectrum. The quadrupolar coupling constant characterizes the width.

$$[1] \qquad \chi = 2/3\,\Delta\nu_{zz}$$

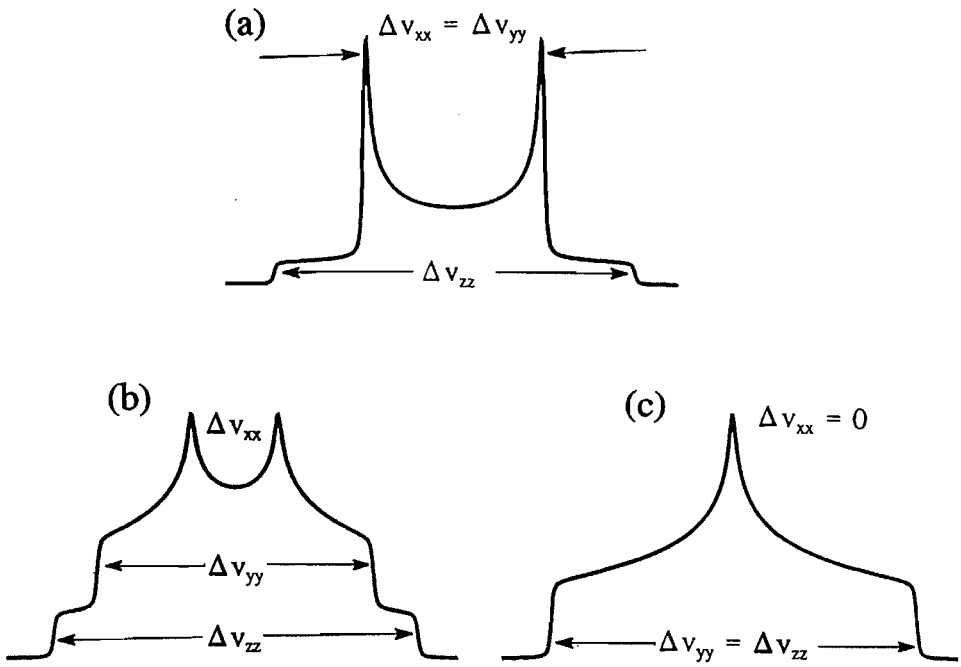
Fig. 1. Three (spin = 1) NMR powder pattern spectra. (a) $\eta = 0$; (b) $\eta = 0.5$; (c) $\eta = 1.0$.



The asymmetry parameter defines the shape.

$$[2] \qquad \eta = \frac{\Delta\nu_{yy} - \Delta\nu_{xx}}{\Delta\nu_{zz}}$$

$\Delta\nu_{xx}$, $\Delta\nu_{yy}$, and $\Delta\nu_{zz}$ are the three splittings observed in a deuterium powder pattern spectrum (see Fig. 1).

Molecular motion has two general effects on the shape of the deuterium powder pattern. It narrows the powder signal, and may change the signal shape. In the case of ^2H quadrupolar coupling, reorientational rates of less than 10^3 Hz have no averaging effect, while motions with rates greater than 10^8 Hz are in the fast rate limit.

The simplest type of motion involves exchange of a deuterium nucleus between three or more equivalent sites. In the fast rate limit, the asymmetry parameter averages to zero, and the spectrum is compressed by a factor of $1/2(3\cos^2\theta - 1)$, where θ is the angle between the X—D bond and the rotation axis. In between the two extremes, a slow evolution of the spectrum from one form to the other is observed. Examples include three-site exchange of the deuterons in a methyl group ($\theta = 70.5°$) and in-plane six-site exchange of the deuterons on a benzene ring ($\theta = 90°$).

An example of asymmetric motion is exchange of a deuteron between only two equivalent sites. When $k > 10^8$ Hz, a non-zero asymmetry parameter is observed. An example is the two-site exchange of the *ortho* and *meta* deuterons of a monosubstituted benzene ring ($\theta = 60°$). The asymmetry parameter η and the quadrupolar coupling constant χ in the averaged spectrum depend on the angle θ for the motion involved (43).

Enclathrated guest molecules often undergo a precessional type of motion, which can be thought of as rotation of the principal symmetry axis on a cone that may have a circular or elliptical shape. This type of motion has a very small activation energy, and is usually only encountered in the fast rate limit at working temperatures. The motion can most simply be broken down into two components: precession on a circular cone and a two-site libration (44).

A further complicating factor in considering the motion of guest molecules is the possibility of unequal populations of the sites taken up by the exchanging deuterium nucleus. Since this leads to more or less preferred orientations for the guest, it introduces asymmetry into the powder spectrum. The justification for unequal populations can be either a non-uniform guest–host interaction, or a situation in which a rotation axis is not a symmetry axis.

Experimental

TATM was prepared according to the method of Yakubov et al. (25). 2-Acetyl thiophene and chloroform (6.2 equivalents) were refluxed for 24 h, in the presence of excess aluminum chloride (2.5 equivalents). After refluxing, 10% HCl was added to dissolve remaining $AlCl_3$. The TATM was then extracted with chloroform, and the organic phase was washed with saturated NaCl aqueous solution. The organic phase was then dried and filtered, and excess $CHCl_3$ was removed by rotary evaporation. The resulting plaque was recrystallized from ethanol. Finally, heating under vacuum for 12 h at 130°C removed enclathrated ethanol. The resulting solid was ground to yield an orange powder that had a broad melting point range of 52°–58°C. The purity was confirmed by solution NMR.

Cyclotriveratrylene was prepared according to the method of Oliverio and Casinovi (45). Cold (5°C) 70% H_2SO_4 (125 mL) was added to cold veratrole (1,2-dimethoxybenzene) (35 g), and the mixture was then cooled to 5°C. Over approximately 90 min, 10 g of 37% formaldehyde was added without letting the temperature rise above 10°C. This mixture was stirred for 0.5 h at 5°C, then finally poured onto 40 g of crushed ice. On standing overnight, a white solid sepa-

For personal use only.

rated from solution. The resulting mixture was extracted into diethyl ether. There were three layers; the middle one contained crude product. The top two layers were decanted off and filtered. The crude product was then recrystallized from ethanol (1–1.5 L). A pink-grey solid (4.4 g), with melting point 226–227°C was obtained. The purity was verified by solution NMR.

The inclusion compounds were prepared by dissolving approximately 200 mg of host solid in 2–3 mL perdeuterated acetone (Aldrich), followed by slow evaporation. Verification of inclusion was done by acquiring ^{13}C CPMAS powder spectra of isotopically normal inclusion compounds. To determine guest:host stoichiometry, integrals of the peaks in the ^{1}H solution NMR spectra of the unenriched clathrate dissolved in $CDCl_3$ were determined. These spectra also showed that no water was present in either of the two isotopically enriched samples. Powder samples were packed in 5 mm o.d. NMR tubes that had been cut to lengths of 2–3 cm.

Deuterium NMR spectra were obtained at 44.7 MHz on a home-built spectrometer using the quadrupolar echo pulse sequence (46): $(\pi/2)_x$–τ_Q–$(\pi/2)_y$–τ_Q–acquire. The length of the $\pi/2$ pulse was approximately 3.5 μs. At each temperature, the echo signals were collected using a τ_Q value of 50 μs. The echo signals were Fourier transformed to obtain the deuterium NMR spectra. The temperature was controlled by flowing nitrogen gas through liquid nitrogen and then through the sample chamber, in combination with an electric heater and a thermocouple. The temperature was stable to within ±0.5 K during the course of each measurement.

The deuterium T_1 data were acquired using an inversion–recovery pulse sequence modified for quadrupolar nuclei: $(\pi)_x$–τ–$(\pi/2)_{\pm x}$–τ_Q–$(\pi/2)_y$–τ_Q–acquire. Typically, 12 values of τ were used to determine T_1 at each temperature. The pulse spacing, τ_Q, for the T_1 determination was 50 μs. The time between repetitions of the pulse sequence was always greater than $5T_1$. The data were fit using a nonlinear least-squares algorithm employing an exponential fitting function to obtain the relevant relaxation time parameters. The amplitude of the signal at each pulse spacing was determined from the echo integral.

^{13}C CPMAS NMR spectra were recorded on a Bruker ASX 200 spectrometer at a frequency of 50.3 MHz. The ^{13}C $\pi/2$ pulses were 4.0 μs, and cross-polarization times of 3 ms were used. Typically 100–150 transients were accumulated, and the recycle delay was 5 s. The samples were spun at 5 kHz, using a 5 mm Bruker MAS probe. The chemical shifts were referenced to the low-frequency signal of adamantane (29.5 ppm) and, following acquisition, an exponential apodization of 10 Hz was applied before the Fourier transform.

Lineshape simulations of quadrupolar echo spectra were carried out by standard methods using the program MXQET (9). Simulated spectra were visually matched to experimental lineshapes. Analysis of the T_1 data was done using the BPP spectral density function (47). The T_1 data were fit to equations of the following type (using K, τ_∞ and E_a as fitting parameters):

$$[3] \qquad \frac{1}{T_1} = K\left[\frac{\tau_c}{1+\omega_0^2\tau_c^2} + \frac{4\tau_c}{1+4\omega_0^2\tau_c^2}\right]$$

$$[4] \qquad \tau_c = \tau_\infty \exp(-E_a/RT)$$

In these equations, τ_c is interpreted as the correlation time for the motion, τ_∞ is the correlation time at infinite temperature, and ω_0 is the Larmor precession frequency. K is a constant that depends on the static quadrupolar coupling constant and the mode of molecular reorientation, while E_a is the activation energy for the motion of interest.

Results and discussion

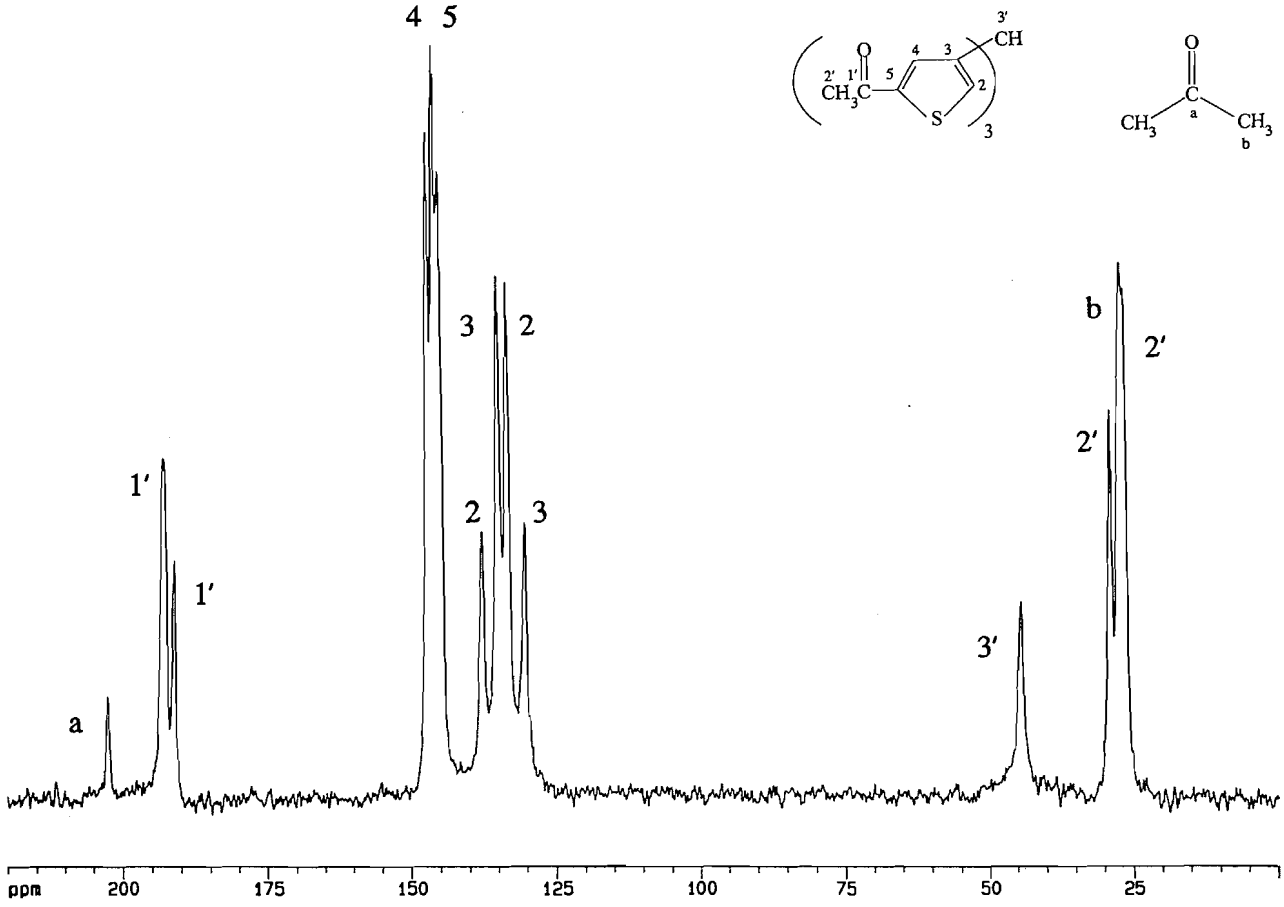
Acetone in TATM

The ^{13}C CPMAS spectrum of the acetone:TATM inclusion compound is presented in Fig. 2. The signals were assigned using ^{13}C chemical shift correlation tables (48). The acetone CH_3 signal is located at 29.2 ppm, while the carbonyl peak appears at 202.6 ppm. The multiplicity of the TATM carbons is two, one strong and one weak signal for each carbon. This may originate from the fact that in the four crystal structures done on TATM inclusion compounds (26–29), two of the three thienyl rings of each TATM molecule participate in forming the cavity in which the guest resides, while the third thienyl ring does not. Thus, the two thienyl rings forming the cavity give rise to the strong signals, while the corresponding weak signals, of approximately 50% intensity, arise from the nonparticipating TATM thienyl ring. This is supported by the observation that the methane CH carbon gives only one signal, as there is only one methane carbon in each TATM molecule.

The deuterium NMR powder spectra of acetone-d_6 in the TATM inclusion compound are presented in Fig. 3, along with simulations. The acetone:TATM complex is characterized by a rapid rate ($k > 10^8$ Hz) of methyl rotation at all temperatures studied (142–273 K), because of its very low activation energy (2–5 kJ/mol) (49–51) and the fact that the 142 K spectrum is narrowed by at least a factor of three over the static spectrum. On top of this motion, there is exchange of the two methyl groups about the CO bond, the molecular C_2 axis. The rate of this motion is in the intermediate exchange region in the temperature range studied. Changes in the rate of this motion give rise to changes in the shape of the experimentally observed spectra. By fitting the simulations to their corresponding experimental spectra, it was possible to extract rates for the exchange between methyl groups as a function of temperature (see Fig. 3). A plot of ln k vs. $1000/T$ (k = rate of motion) gave an activation energy of 20.8 (±1.4) kJ/mol for methyl group exchange (see Fig. 4). In addition, in the simulations, it was necessary to employ a CD_3-C-CD_3 bond angle of 123° (±2°) to make a match to the experimental spectra. From microwave data, the angle in the gas phase is 116° (52, 53).

The profile of ^{2}H spin-lattice relaxation times for acetone:TATM, as a function of temperature, is presented in Fig. 5. Changes in T_1 in this temperature range result from changes in the rate of the above-mentioned twofold flips. By fitting the experimental data to eqs. [3] and [4], an activation energy of 20.8 (±0.5) kJ/mol for the C_2 exchange was determined. Note that this is the same value deduced from our spectral simulations. The constant K (see eq. [3]) was found to be 3.3×10^9 s^{-2}, and τ_∞ was determined as 2.03×10^{-13} s. Using these values of τ_∞ and E_a in eq. [4] and the fact that the jump rate $k = (2\tau_c)^{-1}$ for the twofold reorientation, it is possible to compare the rates of reorientation determined from the T_1 analysis with those found from sim-

Fig. 2. ^{13}C CPMAS powder spectrum of the acetone/TATM inclusion compound (spin rate = 5 kHz).



ulation of ^2H spectra. The two methods give the same results within experimental error. In addition, it can be seen that the two lowest temperature points in Fig. 5 fall below the fitted curve. This suggests the presence of a second T_1 minimum at much lower temperatures that can be associated with rotation of the methyl groups.

Analytical expressions for the deuterium spin-lattice relaxation time, for a two-site jump model, were derived from the following general equations (5):

$$[5] \qquad \frac{1}{T_1} = \frac{\chi^2}{3}[J_1(\omega_0) + 4J_2(2\omega_0)]$$

$$[6] \qquad \chi = \frac{6\pi e^2 qQ}{4h}$$

The quadrupolar coupling constant is defined as χ, with eq and eQ representing the electric field gradient of the surrounding charge distribution and the nuclear quadrupolar moment, respectively. The spectral density functions J_1 and J_2 are defined with respect to the direction of the applied field. For two-site jump motion about a z axis fixed in the crystal with the angle between the two sites being 2θ, the expression for T_1 is given by

$$[7] \qquad \frac{1}{T_1} = \frac{9}{160}\left(\frac{2\pi e^2 qQ}{h}\right)^2 \sin^2 2\theta[J_1'(\omega_0) + 4J_2'(2\omega_0)]$$

Now J_1' and J_2' are defined with respect to the crystal axis. Therefore, the constant K in eq. [3] is equal to

$$[8] \qquad K = \frac{9}{160}\chi^2 4\pi^2(\sin^2 2\theta)$$

In addition, the spin-lattice relaxation time minimum is determined to be:

$$[9] \qquad \frac{1}{T_{1\min}} = \frac{9}{160}\left(\frac{2\pi e^2 qQ}{h}\right)^2 \sin^2 2\theta\left(\frac{1.42}{\omega_0}\right)$$

From the value of K, determined from the T_1 fit (3.3×10^9 s^{-2}), and the angle 2θ (123°), found from simulations, we calculated the effective quadrupolar coupling constant to be approximately 46 (±1) kHz. This compares with an observed χ_{eff} of 45 (±1) kHz at 273 K (found from ^2H spectra). The T_1 minimum occurs at approximately 270 K. This quadrupolar coupling constant is averaged by methyl rotation and the librational motion, but not by the twofold flip.

The experimental value of the ^2H spin-lattice relaxation time at the T_1 minimum, for acetone-d_6 in TATM, is about 60 ms. From eq. [9], using χ_{eff} of 45 kHz at the T_1 minimum and a spectrometer frequency of 44.669 MHz, we calculate that the ^2H T_1 minimum should be approximately 62 ms. The agreement here is apparently very good. The same calculations are performed for acetone:CTV in the next section.

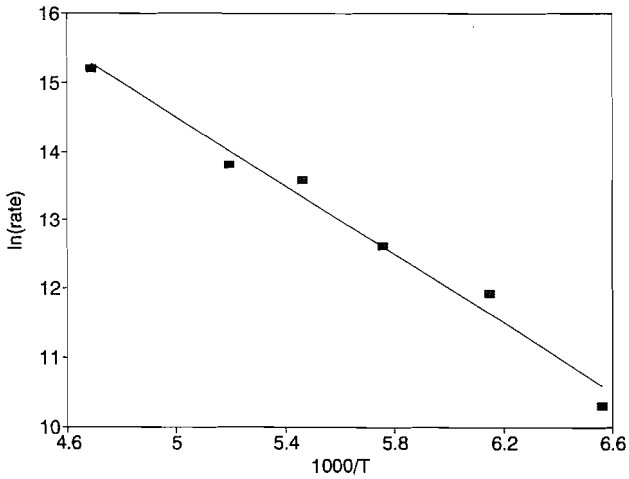

Fig. 5. Deuterium spin-lattice relaxation times, as a function of reciprocal temperature, for the acetone-d_6:TATM inclusion compound.

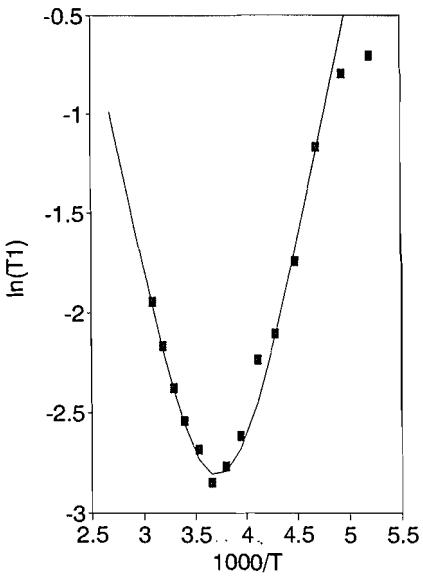
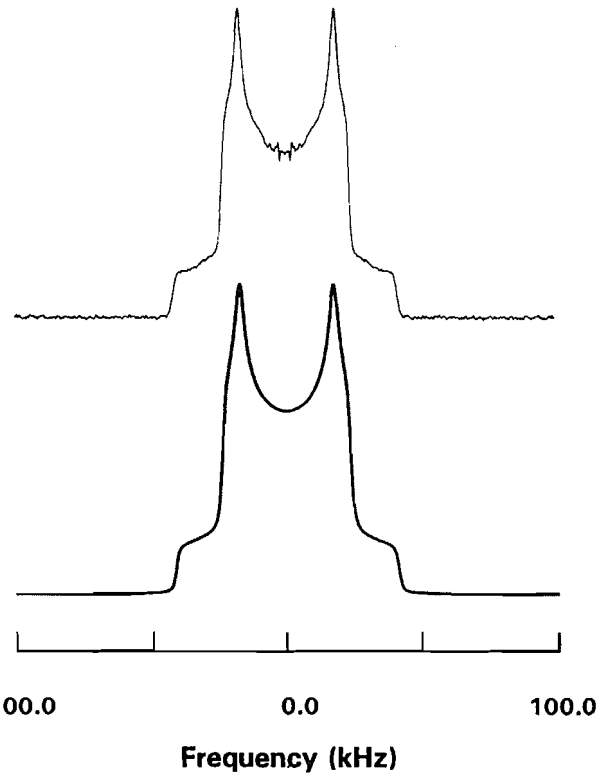


Finally, a third form of motion, precession on a cone, is present. This was deduced from the fact that the lineshapes were too narrow. The two previously described motional mechanisms cannot account for the observed spectral width. In the simulations, precession of the C_2 axis on a circular cone was assumed. However, since acetone is not an axially symmetric molecule, one would expect the precession to be much more asymmetric (i.e., elliptical). However, introducing elliptical precession in this case would overcomplicate the motional model. Elliptical precession might be considered because the spectrum at 142.5 K shows some asymmetry (i.e., $\eta > 0$). This is because precession of an elliptical nature introduces asymmetry into the spectrum, whereas circular precession does not. From the spectral simulation, the

Fig. 6. Deuterium powder spectrum of acetone-d_6:TATM, at 84 K, along with its simulation (below), as discussed in the text.



half angle of precession at this temperature is 16.9°. Facey et al. argue that their 77 K spectrum of acetone in tri-*ortho*-thymotide shows asymmetry because the three sites visited by the methyl deuterons are inequivalent, as they are adjacent to a carbonyl group (54). Possible explanations for this behaviour include a difference in the static quadrupole coupling constant for one of the three deuterons due to the perturbation of the electric field gradient by the electronegative carbonyl group (55), or a slight deviation in the projected angle of 120° between two of the deuterons (56). Facey's argument is valid, because the width of the 77 K spectrum is characteristic of no precession being present ($\chi = 57$ kHz). In our case, the conflict was resolved by obtaining a ^2H powder spectrum at 84 K. In Fig. 6, this spectrum is shown along with a simulation discussed below. The effective quadrupole coupling constant, averaged only by fast methyl rotation, was found to be 55.5 kHz at this temperature. Thus the corresponding static quadrupole coupling constant is approximately three times χ_{eff}, or 166.4 kHz. Since static quadrupole coupling constants of aliphatic deuterons are usually in the range 165–175 kHz, we would propose that there is very little motional averaging (i.e., wobble of the symmetry axis), other than methyl rotation, at this temperature. Yet the spectrum shows a considerable amount of asymmetry ($\eta = 0.14$). This implies that the asymmetry does not come from elliptical precession. Indeed, we were successfully able to simulate this spectrum (Fig. 6) by changing the projected angle between the two methyl deuterons, which are not parallel to the CO bond, from 120° to 124°. These calculations are outlined in more detail in ref. 56.

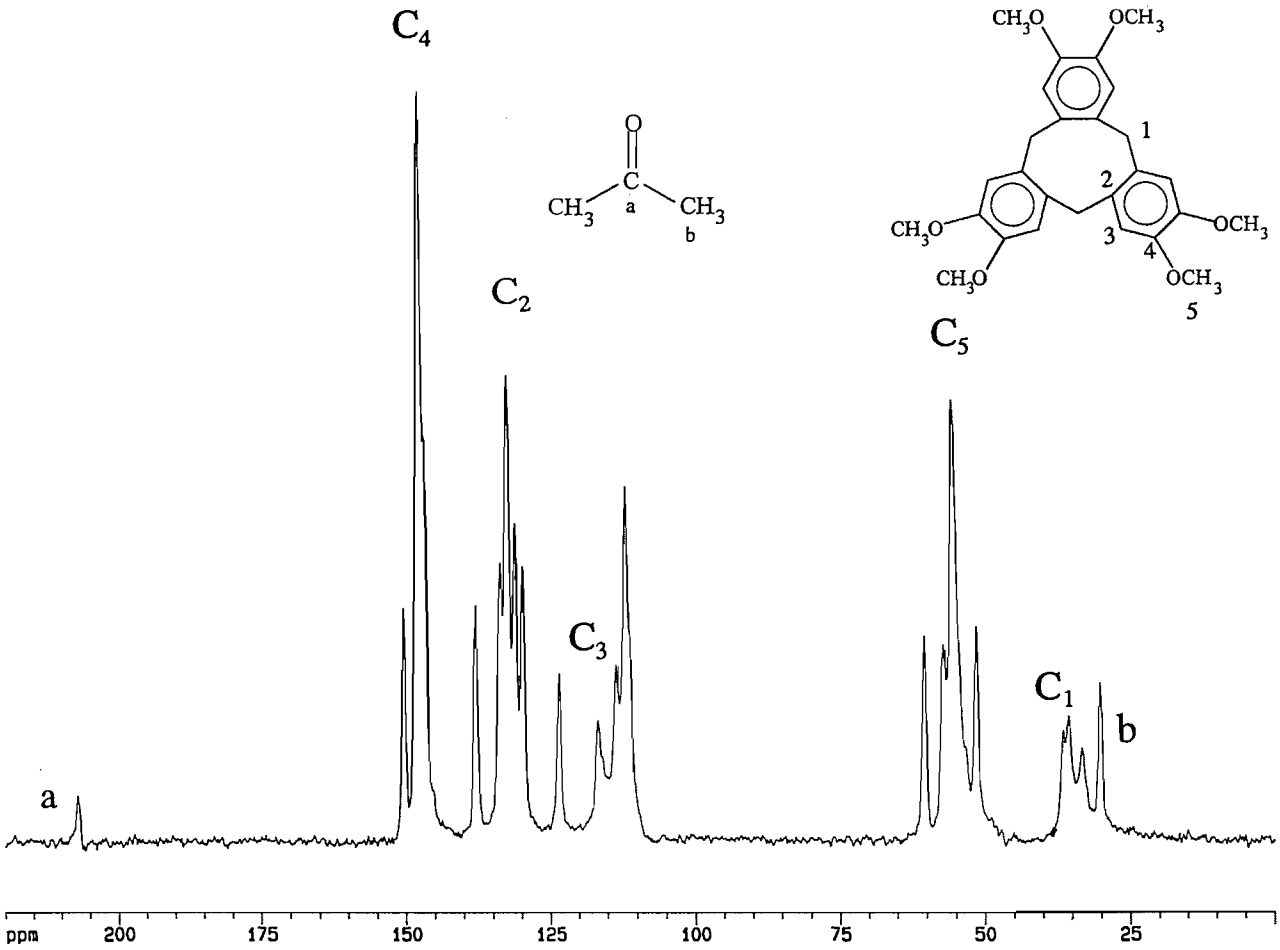
Fig. 7. ^{13}C CPMAS powder spectrum of the acetone:CTV inclusion compound (spin rate = 5 kHz).



Acetone in cyclotriveratrylene

The ^{13}C CPMAS spectrum of the acetone:CTV inclusion compound is presented in Fig. 7. Again, the ^{13}C shifts were assigned using chemical shift correlation tables (48). Burlinson and Ripmeester characterized CTV inclusion compounds by means of solid state ^{13}C NMR in 1984 (40). They distinguished two ^{13}C spectra for the acetone:CTV clathrate, based on the method of preparation. Our spectrum most closely corresponds to the one that has a lower acetone content. Burlinson and Ripmeester concluded that, in this case, a clathrate with a significant number of vacancies in the channel could very well give a spectrum different in appearance from that for an inclusion compound with completely filled channels. This could very well be the reason why the ^{2}H spectra of acetone:CTV shows so much more line broadening than the same guest in TATM. Some acetone molecules might be surrounded by empty cavities, while other guests may interact primarily with neighboring filled cavities. Other possible origins of line broadening are discussed in the next paragraph. Note that the multiplicity of each signal is six. This implies, for example, that the six methoxy CH_3 carbons are all magnetically inequivalent in the solid; the same applies to the other four carbons. In solution, there are only five singlets in the ^{13}C spectrum, suggesting a high degree of symmetry that is lost in the solid. From ^{1}H solution spectra, we found a 1:1 host:guest ratio.

The deuterium NMR spectra of acetone-d_6 in CTV, along with their simulations, are presented in Fig. 8. Note the general similarity, apart from greater line broadening, with the spectra of acetone:TATM. Perhaps the greater line broadening is due to a distribution of rates for the two-site jump of the acetone molecule, or possibly the result of an increased dipolar interaction between the acetone guest and the protons of the CTV host (relative to TATM). The line broadening applied to the acetone:CTV simulations at the lowest temperatures was 5.0 kHz, whereas the corresponding line broadening for acetone:TATM was 1.5 kHz. The similarity in spectra indicate that the same general type of motion is occurring. Again, methyl C_3 rotation is proceeding at a rate greater than 10^8 Hz at all temperatures studied. The twofold flipping rate between methyl groups is in the intermediate exchange region. The rate of this motion, at each temperature, is labelled on each pair of spectra in Fig. 8. From the plot of ln k vs. $1000/T$ (Fig. 9), an activation energy of 25.0 (±3.2) kJ/mol for the methyl group exchange was determined. From the simulations, the CD_3-C-CD_3 angle was 120° (±2°).

The acetone:CTV ^{2}H spin-lattice relaxation data are presented in Fig. 10. From the best-fit curve, the activation en-

Fig. 9. Graph of ln k vs. 1000/T for the twofold flip of the acetone molecule in the CTV lattice. The solid line is a least-squares fit to the data. From the slope of the line, an activation energy of 24.1 kJ/mol was determined.

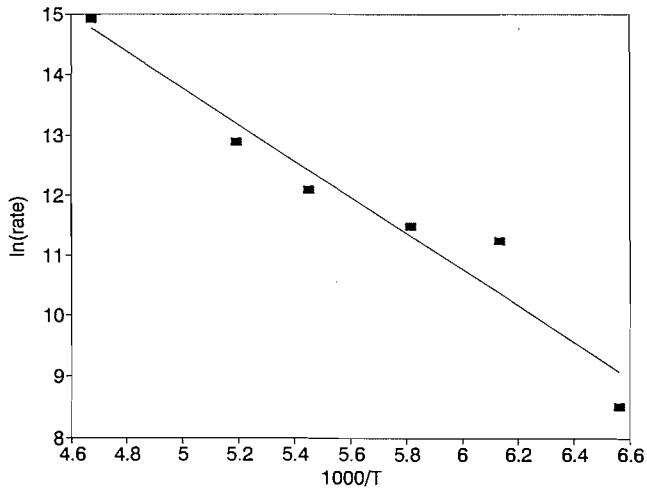

Fig. 10. Deuterium spin-lattice relaxation times, as a function of temperature, for the acetone-d_6:CTV inclusion compound.

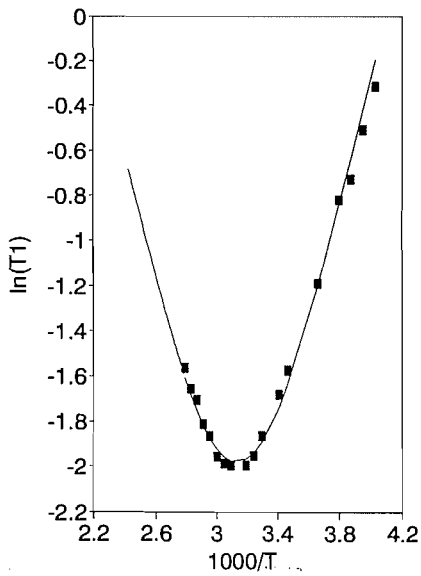


ergy for the methyl group exchange is 24.1 (±0.5) kJ/mol. The average activation energy (from the two determinations) is 24.5 kJ/mol. The constant K (see eq. [3]) was determined to be 1.4×10^9 s^{-2}. The correlation time at infinite temperature was found to be 2.49×10^{-13} s. Note that knowledge of the activation energy and τ_∞ allow the calculation of a motional rate at any temperature, according to eq. [4]. Such a comparison shows that the reorientational rates determined from the spectra and T_1 are the same within experimental error.

The same T_1 calculations performed on acetone:TATM can also be done in this case. The angle between the two deuterons is 120°, and $K = 1.4 \times 10^9$. This gives, from eq. [8], an effective quadrupolar coupling constant of 29 kHz. The experimentally determined value of χ_{eff}, at 298 K, is 33.6 kHz.

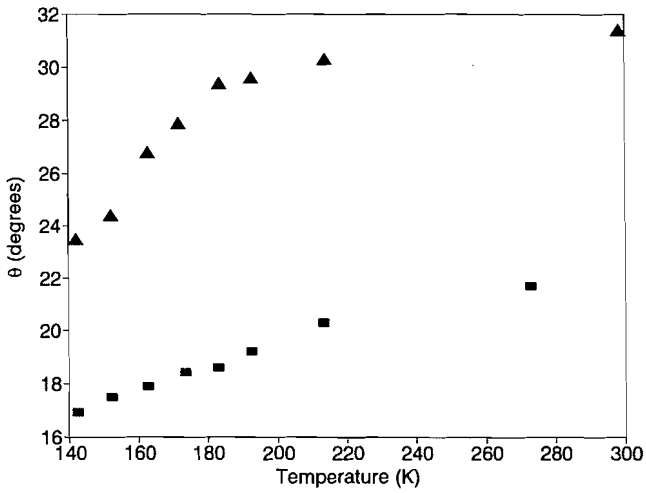
The value of T_1 at the spin-lattice relaxation time minimum is approximately 130 ms. Employing eq. [9], we calculate that the value of T_{1min} should be about 105 ms. Note that the value of T_{1min} for acetone:TATM (60 ms) is smaller than that for acetone:CTV. One might assume that if the same motion is occurring, then the values of T_1 at the relaxation minima should be approximately equal. Considering the difference in 2θ (3°), and the estimated error associated with each angle (±2°, see discussion below), the difference seems too small to reliably assign this to the disparity in T_{1min}. It is possible that the variation comes from a difference in the effective quadrupolar coupling constant. Indeed, as discussed below, acetone in CTV shows much more motional (wobbing) averaging than acetone in TATM; this manifests itself as a reduction in χ_{eff}, for the CTV guest compared to the TATM guest. As χ_{eff} is smaller for acetone:CTV, then from eq. [9] one would expect T_{1min} (acetone:CTV) to be larger than T_{1min} (acetone:TATM), which is exactly what is observed experimentally.

Considering the point just made about the difference between the two C-C-C bond angles, and the error associated with them, it may be instructive to briefly consider the origin of the estimated error in 2θ. The dependence of the asymmetry parameter, for the ^{2}H spectrum (in the fast rate limit), on the value of θ is fairly marked (43). However, we have not considered another possible contributing factor to the asymmetry parameter. It also depends on the anisotropy of the librational motion, which both acetone:TATM and acetone:CTV experience to some degree (see discussion below). As the fast rate limit spectrum of acetone in CTV ($\eta = 0.58$) shows more asymmetry than that corresponding to acetone in TATM ($\eta = 0.50$), this difference may indeed arise from the fact that acetone:CTV shows more anisotropy in its librational motion than acetone:TATM. However, distinguishing this possibility from the proposed difference in 2θ would be a problem more suited for an X-ray crystallographic study.

Regarding a basis for the difference between the proposed C-C-C bond angles of acetone in these two inclusion compounds with that reported in the gas phase (116°) (52, 53), it seems that a likely possibility may be the interaction between the atoms of the host molecule and the acetone guest. Rotational barriers in the gas phase are generally insignificant (joule per mole range) in comparison to the same in solids (approximately 100 to 1000 times greater). In the gas, the interactions are primarily intramolecular, while in these inclusion compounds and other solids, stronger intermolecular forces dominate, giving higher rotational activation energies. These differing interactions may also give rise to the slight difference in molecular geometry between the two phases.

Finally, as was the case in acetone:TATM, a precessional motion of the acetone molecule in the CTV lattice is present. The degree of this vibrational motion, for both acetone inclusion compounds, is presented in Fig. 11. By comparing the data obtained from simulations for each clathrate, it can be seen that the magnitude of the precession is much greater in acetone:CTV. This suggests that the guest–host interaction is greater in acetone:TATM than in acetone:CTV, possibly because the TATM cavity is smaller. Note that the spectrum at lowest temperature (142 K) shows only a small amount

Fig. 11. Graph of the half-angle precession, as a function of temperature, for the acetone:TATM (squares) and acetone:CTV (triangles) inclusion compounds.



of asymmetry. This suggests that the precession on a cone is axially symmetric (circular), or that the three sites visited by the deuterons during methyl group rotation are equivalent. On the other hand, it may be that it is harder to recognize the asymmetry because the line broadening is greater than in acetone:TATM.

In their study of acetone:tri-*o*-thymotide (TOT), Facey et al. determined an activation energy of 13.6 kJ/mol, from spin-lattice relaxation data (54), for acetone's C_2 jump. This activation energy is significantly smaller than either of the values determined for the two current acetone inclusion compounds, suggesting that the cavity occupied by acetone in TOT is larger than those in acetone:TATM or acetone:CTV.

Another motional characteristic that can be used to provide information on the guest–host interaction is the averaging of the quadrupolar coupling constant. At 152.3 K, χ_{eff} for acetone:TATM is 49.0 kHz, for acetone:CTV it is 42.2 kHz, while for acetone:TOT, χ_{eff} is only 27.3 kHz at 156 K (54). This suggests that the strength of interaction between host and guest is strongest for acetone:TATM, intermediate for acetone:CTV, and weakest for acetone:TOT. This topic is pursued in the next paragraph.

It is interesting to compare the three hosts that enclathrate acetone (TATM, CTV, and TOT). Of the three, TATM is the most efficient at enclosing the guest molecule, because of the high activation energy for the twofold flip and the relatively small magnitude of precession (compared to CTV). It may be proposed that the TATM molecules have a high affinity for the guest molecules, based on the four crystal structures obtained for TATM inclusion compounds (26–29), and our experience with the same host. In contrast, from the crystal structures of CTV clathrates (38–42), it was observed that the cyclotriveratrylene host molecules preferred to associate with one another rather than with the guest molecules. This is also reflected in the fact that the precession of acetone in CTV is of greater magnitude than acetone in TATM. In comparison to tri-*o*-thymotide, which is a three-membered macrocycle of the same dimensions as CTV, it was seen that eight TOT molecules form a relatively large cavity in which the acetone guest resides (54). This is accompanied by an activation energy for the twofold jump that is almost half of that in TATM or CTV. Thus, it is possible to compare host molecule efficiency by studying a series of inclusion compounds with the same guest molecule.

Summary

In conclusion, it can be seen that deuterium NMR spectroscopy is a powerful technique for the investigation of guest molecule dynamics in solid inclusion compounds. Rather than the typical study of a series of guests in a particular host system, we have chosen to examine the dynamics of one guest in two quite different hosts and to compare these with a third, previously reported, acetone clathrate. Acetone requires similar activation energies for the two-site methyl group exchange in TATM and CTV (20.8 kJ/mol and 24.5 kJ/mol, respectively). These values are significantly larger than that for acetone:tri-*o*-thymotide (13.6 kJ/mol), which, along with the magnitude of the precessional motion, allows one to envisage the strength of interaction between host and guest.

^{1}H nuclear magnetic resonance and molecular orbital studies of 2-formylstyrene. Three significant nonplanar conformers at 300 K

Ted Schaefer, Scott Kroeker, and David M. McKinnon

Abstract: The ^{1}H nuclear magnetic resonance spectra of 2-formylstyrene, from dilute solutions in CS_2–C_6D_{12} and acetone-d_6, are analyzed to yield precise chemical shifts and spin–spin coupling constants. The long-range coupling constants imply a conformational distribution in which the O-*trans* conformer is 55% abundant in both polar and nonpolar environments. They also imply that the vinyl group, on average, is twisted out of the aromatic plane to a much larger extent than in styrene. The 6-31G* basis set gives an ab initio potential for the torsion of the vinyl moiety with a relatively deep minimum at 38° out-of-plane, for the O-*cis* conformer. For the O-*trans* conformer, two minima are found, one at 45° and another at 129.6°. Essentially the same potential is obtained with the 6-31G** basis. The latter corresponds to a close approach of the hydrogen atom of the formyl group and π orbitals or the β-carbon atom of the olefinic side chain. This local minimum is interesting in terms of a hypothesis used to explain the photochemistry of the molecule. The long-range coupling constants are consistent with the conformational properties calculated for the free molecule; they also indicate no significant difference between the conformational behaviour of the molecule in the two solvents. A proximate coupling constant of −0.16 Hz exists between the formyl and methine (α) protons. The latter is strongly deshielded in the presence of the formyl group, so that it becomes even less shielded than some of the aromatic protons.

Key words: ^{1}H NMR, 2-formylstyrene (*o*-vinylbenzaldehyde); long-range spin–spin coupling constants, 2-formylstyrene; conformations, three nonplanar of 2-formylstyrene; molecular orbital calculations, conformations of 2-formylstyrene.

Résumé : Dans le but d'obtenir des déplacements chimiques et des constantes de couplage spin–spin précis, on a analysé les spectres RMN du ^{1}H de solutions diluées du 2-formylstyrène dans du CS_2–C_6D_{12} et de l'acétone-d_6. Les constantes de couplage à longue distance impliquent l'existence d'une distribution conformationnelle dans laquelle l'abondance du conformère O-*trans* est égale à 55% dans les environnements tant polaires que non polaires. Elles impliquent aussi que, en moyenne, le déplacement du groupe vinyle, par rapport au plan aromatique, est beaucoup plus prononcé que dans le styrène. Des calculs ab initio à l'aide d'un ensemble de base 6-31G* permettent d'évaluer le potentiel de torsion de la portion vinylique et d'établir que, pour le conformère O-*cis*, il existe un puits de potentiel relativement profond pour un décalage de 38° par rapport au plan aromatique. Pour le conformère O-*trans*, on a trouvé deux minima, un à 45° et l'autre à 129,6°. On obtient essentiellement le même potentiel avec un ensemble 6-31G**. Ce dernier correspond à un grand rapprochement de l'atome d'hydrogène du groupe formyle et des orbitales π de l'atome de carbone β de la chaîne latérale oléfinique. Ce minimum local est intéressant en termes d'une hypothèse utilisée pour expliquer la photochimie de la molécule. Les constantes de couplage à longue distance sont en accord avec les propriétés conformationnelles calculées pour la molécule libre; elles indiquent aussi qu'il n'y a pas de différences importantes entre le comportement conformationnel de la molécule dans les deux solvants. Il existe une constante de couplage à courte distance de −0,16 Hz, entre les protons du formyle et du méthine (α). Ce dernier est fortement déblindé en présence du groupe formyle; il devient donc encore moins blindé que certains protons aromatiques.

Mots clés : RMN du ^{1}H, 2-formylstyrène (*o*-vinylbenzaldéhyde); constantes de couplage à longue distance, 2-formylstyrène; trois conformations non planaires de 2-formylstyrène; calculs d'orbitales moléculaires, conformations de 2-formylstyrène.

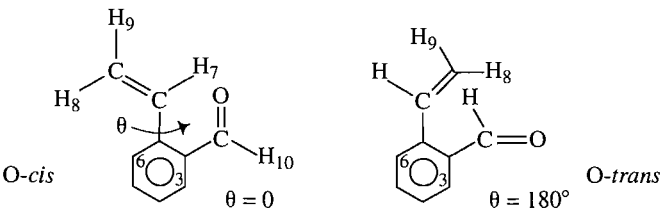
Introduction

The title molecule, 2-formylstyrene (*o*-vinylbenzaldehyde), is of interest to photochemists because two chromophores are present in conjugation (1). Apparently (1), irradiation of an assumed O-*cis*-conformer, **A**, leads to the slow formation of a spiro triene, leading to further reaction, while the putative O-*trans* conformer, **B**, undergoes a fast 1,5-hydrogen shift under irradiation to produce a methyl group at the β-carbon atom (transfer of the formyl hydrogen atom).



A **B**

The purpose of the present report is not to comment in detail on the photochemistry, but to describe a molecular orbital and ^{1}H nmr investigation of the conformational properties of 2-formylstyrene. Interatomic distances in the planar conformers, even for θ = 0, imply substantial steric strain and, therefore, that conformers characterized by θ > 0 are likely, the torsional barrier of the vinyl being much smaller than that of the formyl group. Many of the long-range coupling constants between vinyl or formyl protons and the aromatic protons depend on conformation and on torsion angles in known ways (2–5). Hence their measurement and interpretation in terms of O-*cis* and O-*trans* orientations, together with nonzero values of θ (see **A**), is informative. The molecular orbital calculations, which can approximately reproduce the torsional potential in styrene (6–11), are a valuable aid to such an interpretation. It turns out that computations predict nearly equal energies of the O-*cis* and O-*trans* conformations for the free molecule, together with three nonplanar minima in the torsion angle, θ, two of these belonging to the O-*trans* molecule. The long-range spin–spin coupling constants, derived for 2-formylstyrene in polar and nonpolar solvents, are consistent with the existence of three significant conformers at 300 K. One of these conformers has a close approach of the formyl hydrogen to the π orbitals of the vinyl substituent, possibly conducive to a fast (1) 1,5-hydrogen shift in the electronically excited state.

Experimental

2-Formylstyrene was prepared from *N*-2-phenethylformamide, as described (12). Dilute solutions in CS_2–C_6D_{12} and acetone-d_6 (see Table 1 for details) were filtered into 5 mm o.d. nmr samples tubes, which were then degassed by five cycles of the freeze–pump–thaw procedure and flame-sealed to produce reasonably symmetric tops.

The ^{1}H nmr spectra were obtained using a Bruker AM 300 spectrometer at a probe temperature of 300 K. Typically, the homogeneity of the external magnetic field was monitored and refined every eight scans by shimming on the free induction decay (FID) of internal tetramethylsilane. For high-resolution spectra, 32 FIDS were recorded, using acquisition times of 30 s for the CS_2–C_6D_{12} solution and 41 s for the acetone-d_6 solution. The resulting digital resolution is 0.017 and 0.012 Hz/point, respectively. After zero-filling to twice the original data set and multiplying FIDS by standard resolution enhancement functions, Fourier transformation produced frequency domain spectra with the linewidths less than 30 mHz for the acetone solution and about 40 mHz for the CS_2–C_6D_{12} solution.

Molecular orbital computations of the conformational behaviour of the side chains in 2-formylstyrene utilized the 6-31G* basis functions (13) and the computer program GAUSSIAN 92 (14). The energy of the molecule was calculated at intervals of 15° or less in the vinyl torsion angle, θ, for conformers **A** and **B**. During these optimizations, other bond lengths and angles were allowed to vary, with the constraint that the nuclei of the aromatic and formyl moieties were confined to a plane. For full geometry optimizations at local energy minima, and for θ values of 75° or greater in conformer

B, the twist angle of the formyl group was allowed to relax. Computations with the basis set 6-31G** gave potential energy profiles essentially equal to those obtained with the 6-31G* basis. INDO MO FPT (15, 16) calculations of some long-range proton–proton coupling constants employed the 6-31G* geometries.

Results and discussion

Spectral analyses

The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (17), extensively altered by R. Sebastian. The chemical shifts and coupling constants are found in Tables 1 and 2.

Figure 1 displays a congested spectral region of the ^{1}H nmr spectrum of the acetone-d_6 solution. The spectral extent of ca. 19 Hz contains transitions from H-5 and H-7. The simulated spectrum assumes a linewidth of 0.025 Hz. While the congruence of the two spectra is imperfect, it is in our opinion sufficient to validate those spectral parameters pertinent to the conformational deductions described below. As one more example, Fig. 2 shows the spectrum of the formyl proton that, again imperfect, allows the conclusion that $^5J_{7,10}$ is negative.

The theoretical conformational properties

The 6-31G* energies for various torsion angles, θ, of the vinyl group (see structures **A** and **B**) are given in Table 3. The barrier to internal rotation in benzaldehyde is calculated as 37.5 kJ/mol with the 6-31G* basis (18), rather higher[2] than, for example, the free energy of activation of 32.2(6) kJ/mol in solution (19–21). In contrast, the 6-31G* barrier for styrene is only 12.0 kJ/mol (11) while, experimentally, the internal barrier height is 12.8(6) or 13.8(7) kJ/mol (twofold component) with a fourfold component of −3.3 kJ/mol (6, 7), yielding a very flat potential near θ = 0°. On the basis of these barriers, it is expected that steric strain will force the vinyl group out of the ring plane. The relative energies in Table 3 confirm these expectations, implying that the conformational properties of 2-formylstyrene can be discussed in terms of O-*cis* and O-*trans* conformers, each with potential for the out-of-plane excursion of the vinyl group. Figure 3 gives a plot of the energies as a function of θ.

The planar conformers (θ = 0 in Fig. 3) are stabilized by the π,π conjugational energies and are both destabilized by the energies due to repulsion between the *ortho* C—H and β-CH bonds. To a first approximation, therefore, the energy difference of 3.3 kJ/mol between the planar conformers corresponds to the difference in energy between the H,H and H,O repulsions of the α-CH bond of the vinyl group and the bonds in the formyl fragment. The H,O interaction must be repulsive because otherwise the planar form of **A** would be stable, as in styrene. The stable form of **A**, however, corresponds to a θ of 38°, representing a compromise between the loss of some π,π conjugation and a decrease in the two repulsions amounting to 4.0 kJ/mol (see Table 3). The twofold, conjugational, component of the 6-31G* barrier in sytrene is 12.0 kJ/mol. If the conjugational energy in 2-formylstyrene is very similar in magnitude, then about 4.5 kJ/mol of it would be lost at θ = 38°. Further analysis of the energies of **A** is not feasible, so it cannot be said whether an attractive H,O interaction exists at the twist angle of 38°. The H_α,O distance is somewhat less than 2.4 Å, very like the computed H,O distances[3] in the hydrogen-bonded complexes between water and some fluoromethanes (23). The high energy of **A** at θ = 90° is about 4.7 kJ/mol larger than that expected from the complete loss of π,π conjugation, very likely because of repulsion between the 2*p* orbital on C-α and the C=O bond

[2] There is a controversy concerning the internal barrier for the free molecule (22). However, it is agreed that the barrier in solution is not less than 27 kJ/mol, so that large out-of-plane deviations of the carbonyl group are not expected at 300 K except for θ values other than 90° in **B**. These conformers involve steric congestion in the sidechains.

[3] In 2-hydroxylbenzaldehyde, a molecule with a strong intramolecular hydrogen bond, perhaps as large as 29 kJ/mol (24, 25), the microwave spectrum of the vapor corresponds to a H,O distance of 1.76 ± 0.01 Å (26).

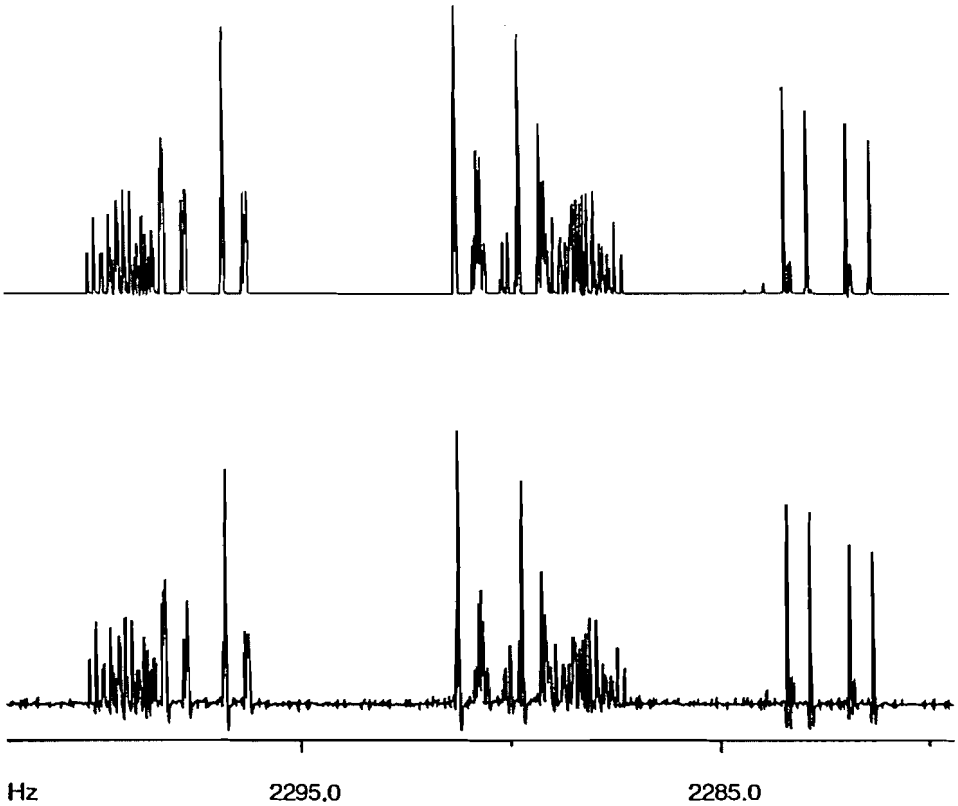
Fig. 1. A span of 18.7 Hz in the ^{1}H nmr spectrum of 2-formylstyrene is displayed for a 4.4 mol% solution in acetone-d_6 at 300 MHz and 300 K. The congestion arises because of overlap between the transitions of the α proton of the vinyl group, H-7, and of the ring proton, H-5. The simulated spectrum uses the spectral parameters found in Table 1.



(reminiscent of the situation in 2-alkylthiobenzaldehydes (27), in which only the O-*trans* conformer occurs when the 3*p* orbital on sulfur is twisted into the molecular plane).

For conformer **B** the lowest energy occurs at θ = 45°, so that H,H repulsion between the α-CH and the formyl C—H bonds in the planar form is substantial. A local maximum at θ = 90° is 11.0 kJ/mol lower in energy than for **A**, and therefore about 6.3 kJ/mol lower than expected for complete loss of π conjugational energy, suggesting an incipient C—H···π hydrogen bond involving the formyl hydrogen and the π system of the vinyl group. As θ increases beyond 90°, the π conjugational energy again increases, contributing to a decrease in total energy. At θ = 129.6°, corresponding to the local minimum, the H,Cβ distance is 2.68 Å. Beyond θ = 129.6° repulsion between the β-CH and formyl C—H bonds becomes dominant. Consequently a local minimum near 129.6° occurs and may well be favorable for the fast 1,5-hydrogen shift from formyl to vinyl fragments, postulated (1) for the electronically excited state. The H_{10},H_8 distance is less than 2.6 Å at θ = 129.6°. Alternatively, the C—H bond of the formyl group is reasonably well placed to interact with the 2*p* orbitals of the double bond in the side chain: the hydrogen atom lies some 2.7 Å above the midpoint of the C=C bond and about 0.5 Å from the normal to the vinyl plane.

Given the potential energies in Table 3, it is of interest whether they are consistent with the long-range coupling constants in Table 2. Those involving the vinyl protons would sample the two energy profiles in Fig. 3 as given by a Boltzmann weighting. The long-range coupling constants over five bonds to the formyl proton are excellent measures of the proportions of **A** and **B** (25, 28, 29).

Long-range coupling constants

(a) The proportions of A and B

It has been established (25, 28, 29) that the ratio of ^5J(H-*m*, CHO), the coupling constant between the formyl proton and a ring proton placed *meta* to the formyl group, to the sum of the two such coupling constants in a benzaldehyde derivative is a good measure of the conformational bias of the formyl group. As applied to 2-formylstyrene, one has $^5J_{6,10}/(^5J_{4,10} + {}^5J_{6,10}) = 0.363/(0.363 + 0.444) = 0.45$ as the fractional population of conformer **A**. The values of the coupling constants in Table 2 are only slightly different in the polar and nonpolar solutions, so that their mean has been used above, implying also that these solvents do not alter the proportions of **A** and **B**.

It is interesting that the 6-31G* energies in Table 3 have **A** as 0.31 kJ/mol less stable than **B**. If this is also true at 300 K, then one has the theoretical fractional population of **A** as 0.47. Of course, this conclusion is only valid if corrections for zero-point energies, thermal energies, and entropies, as well as solvent effects, combine in such a way as to yield a free energy difference essentially unchanged from the energy difference in Table 3. The long-range coupling constants for the formyl proton indicate that such is indeed the case, and shall be assumed in further discussion.

For personal use only.

Fig. 2. A span of 4.0 Hz from the ^{1}H nmr region in Fig. 1 is displayed in detail. The simulated spectrum has a linewidth at half-height of 0.03 Hz. The agreement between simulation and experiment, while not perfect, is sufficient for the purpose to which the underlying coupling constants are put in the text.

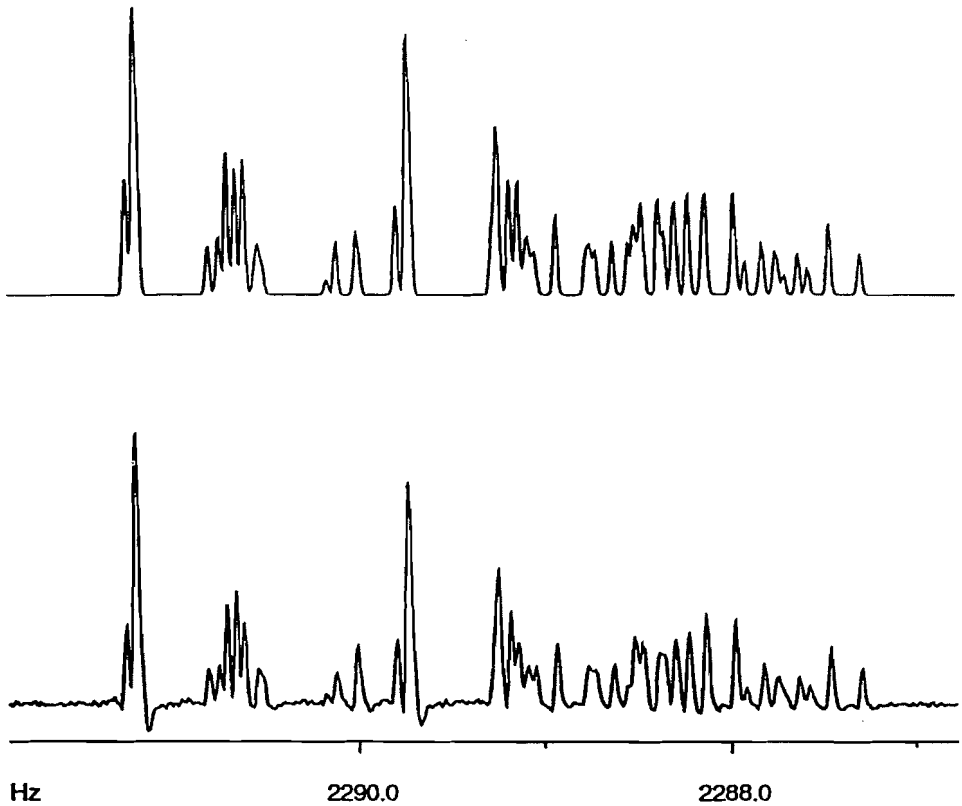

Fig. 3. The potential energy diagram for 2-formylstyrene, as given by 6-31G* molecular orbital computations, refers to the O-*cis* (**A**) and O-*trans* (**B**) conformers. The angle θ is zero if the α C—H bond of the vinyl group lies *cis* to the formyl group in the planar molecule. In the congested region, θ > 105° for **B**, the formyl group twists substantially away from the aromatic plane (see Table 3).

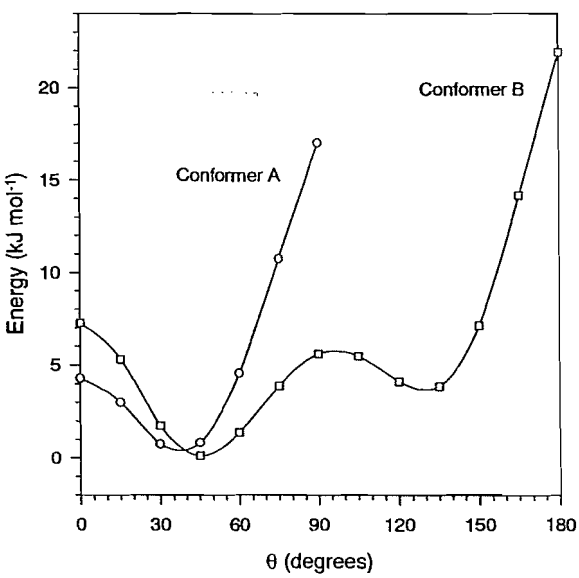

Furthermore, the potential energy curves in Fig. 3 imply various probabilities for the angles θ at a given temperature. The C—H bonds of the vinyl group sample various values of θ and, in so doing, cause the long-range coupling constants of their protons to vary because they are functions of θ. If the functionality is known, then the potential curves will predict the values of the coupling constants.

(b) Computation of $^6J_{47}$

Theoretically and experimentally (2–5), $^6J_{47}$ in styrene is a function of $\sin^2\theta$. We calculate the expectation value of $\sin^2\theta$ as

$$\langle \sin^2 \theta \rangle = \Sigma\, p_i \sin^2 \theta$$

where

$$p_i = \frac{\exp(-E_i/R)}{\Sigma \exp(-E_i/RT)}$$

The probability, p_i, at a given θ, is obtained from the energies, E_i at that θ, as found in Table 3. At 300 K, $\langle \sin^2\theta \rangle$ is then[4] 0.450.

[4] If a 3-site calculation is performed, using the three minima in Fig. 3, one finds $\langle \sin^2\theta \rangle$ as 0.456 at 300 K. This computation assumes the experimental populations of **A** and **B**; the theoretical populations of **A** and **B** entail a $\langle \sin^2\theta \rangle$ of 0.454.

[a]A θ of zero corresponds to a conformation in which the vinyl group lies in the aromatic plane and the α C—H bond points towards the formyl group (see structure **A** in the text).

[b]The total energy is −420.310 715 a.u. The C=O bond of the formyl group twists out of plane by 0.1°.

[c]The total energy is −420.310 833 a.u. The angle of twist of the formyl group is 3°.

[d]This minimum in the energy for the O-*trans* conformer lies 0.31 kJ/mol below the minimum for the O-*cis* conformer.

[e]The numbers in parentheses give the torsion angle of the formyl group. A positive number means that the α and formyl C—H bonds both lie below the aromatic plane.

In studies of various styrene derivatives (3, 4) it was found[5] that $^6J_{47}$ could be written as $-0.149\cos^2\theta - 0.597\sin^2\theta$. This relationship then has $^6J_{47}$ as −0.351 Hz for 2-formylstyrene, to be compared with −0.349(6) Hz, the mean of the two values in Table 2. The mean is used because, in our opinion, the present model is hardly precise enough to corroborate the existence of different potentials in the two solvents. The approach used for $^6J_{47}$ is now applied to other coupling constants of the vinyl protons.

(c) Computation of $^5J_{37}$ and $^5J_{57}$

Odd though it appears, $^5J_{37}$ in styrene and some of its derivatives is reproduced by $A\langle\sin^2(\theta/2)\rangle$; where $\langle\sin^2(\theta/2)\rangle$ is 0.5 for an evenfold potential. Thus, for acetone-d_6 solutions of styrene (30) and 2,6-dichlorostyrene (measured in this laboratory) $^5J_{37} = {}^5J_{57}$ is 0.368(s) Hz and 0.391(1) Hz, respectively. The corresponding values of $^6J_{47}$ are −0.227(2) Hz and −0.540(2) Hz, implying that $\langle\sin^2\theta\rangle$ is very different for the two compounds. In 2-fluorostyrene, $^5J_{37} + {}^5J_{57}$ is 0.758(4) Hz, independent of the polarity of the solvents (4). From Table 2, this sum is 0.750(2) Hz in CS_2–C_6D_{12} and 0.761(2) Hz in acetone-d_6 for 2-formylstyrene. A final datum is the 0.372(1) Hz for $^5J_{3,7}$ in β,β-dibromo-2,6-dichlorostyrene, both in acetone-d_6 and in CD_2Cl_2–CCl_4 solutions at 296 K (5). It seems that a term in $\sin^2\theta$, due to a σ,π mechanism (2), is very small.

From these considerations, we can write $^5J_{37} = 0.755\sin^2(\theta/2)$. The energies in Table 3 yield $\langle\sin^2(\theta/2)\rangle$ as 0.214 and hence predict $^5J_{37}$ as 0.162 Hz and thus $^5J_{57}$ as 0.755 − 0.162 or 0.593 Hz. Of course, the ^5J numbers would also be consistent with two conformers having θ as zero; such a situation is contradicted by models, $^6J_{47}$, and, naturally, by the theoretical computations.

(d) Computation of $^4J_{67}$

$^4J_{67}$ has been assessed as $-0.476\cos^2\theta - 0.759\sin^2\theta$ in styrene and some methyl derivatives (3). This assessment predicts $^4J_{67}$ as −0.603 Hz in 2-formylstyrene, 5% lower in magnitude than the −0.637(2) Hz in Table 2. The term in $\cos^2\theta$ represents π electron spin correlation across the partial double bond.

(e) Coupling constants between ring and β protons, H-8 and H-9

It was postulated (3) that $^7J_{48}$ and $^7J_{49}$ follow $0.300\cos^2\theta + 0.065\sin^2\theta$, with perhaps a small additional term contributing as much as 0.04 Hz to $^7J_{49}$ (2, 3). A $\langle\sin^2\theta\rangle$ of 0.450 for 2-formylstyrene yields 0.194 Hz for $^4J_{48}$ and $^4J_{49}$, midway between the measurements of 0.182(2) Hz for $^7J_{48}$ and 0.211(7) Hz for $^7J_{49}$ in Table 2. In styrene (30), $^7J_{48}$ and $^7J_{49}$ are 0.237(3) and 0.281(3) Hz, respectively, reflecting the larger value of $\cos^2\theta$ in the parent compound (lower θ values).

In styrene, $^6J_{38}$ and $^6J_{39}$ are interesting because they are not detected (30). $^6J_{39}$ is calculated by INDO (2) as +0.12 Hz at θ = 0° ("all-*trans*") and as +0.07 Hz at θ = 90°. At θ = 180°, however, corresponding to $^6J_{59}$ in **A**, its value is −0.18 Hz. In styrene, of course, one measures the mean of $^6J_{39}$ and $^5J_{59}$, accounting for their absence. Write $^6J_{59}$ as $-0.10\cos^2\theta + 0.14\sin^2(\theta/2)$. The first term corresponds to the π electron component, which decreases in magnitude as spin correlation is lost with an increase in θ to 90°. The second term represents a rare (2, 4) positive σ electron contribution with a maximum in the all-*trans* arrangement of the intervening bonds. The discussion of the internal potential for styrene in solution (3) has $\langle\cos^2\theta\rangle$ as 0.825 and $\langle\sin^2(\theta/2)\rangle$ is 0.5 for an evenfold potential, so that this expression yields $^6J_{39} = {}^6J_{59}$ as −0.012 Hz, in satisfactory congruence with experiment. For 2-formylstyrene, $\langle\sin^2(\theta/2)\rangle$ is 0.786 for $^6J_{39}$ and 0.214 for $^6J_{59}$ (see above); also, $\langle\cos^2\theta\rangle$ is predicted as 0.550 from the computed potential. Hence $^6J_{39}$ is calculated as +0.055 Hz and $^6J_{59}$ as −0.025 Hz, again in reasonable agreement with the +0.052 and −0.022(6) Hz in Table 2. In 3-fluorostyrene, however, $^5J_{59}$ is +0.06 Hz (4). All methods agree that the *cis* conformer, which favors a positive $^6J_{59}$, is most abundant (4, 31–34). Yet $\langle\cos^2\theta\rangle$ is not smaller than in styrene (4), so that the expression above cannot reproduce $^6J_{59}$: the conformational dependence of $^6J_{39}$ or $^6J_{59}$ needs more study.

Turning to $^6J_{38}$ and $^6J_{58}$, they are calculated as -0.19_5 Hz in the planar form of styrene and −0.14 Hz in the perpendicular conformer by INDO MO FPT methods (2). These numbers imply a π electron part, proportional to $\cos^2\theta$, and a σ,π contribution in $\sin^2\theta$, increasing in magnitude as the π electron

[5] Another relationship (5), developed using data from β,β-dibromo-2,6-dichlorostyrene and 3,5-dichlorostyrene, is $-0.130\cos^2\theta - 0.800\sin^2\theta$. One then has $^6J_{47}$ in 2-formylstyrene as −0.440 Hz. The relationship used above (3, 4) was designed to reproduce spectral data for styrene itself.

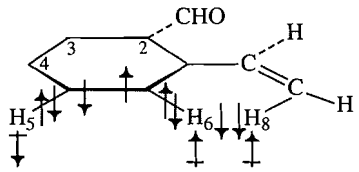
component fades. The finite σ,π component is in line with the −0.1 Hz found in 2,6-dichlorostyrene (2). But, since $^6J_{38}$ is not detected in styrene, another, positive component presumably exists, neglected by the INDO parameterization, and active most prominently at small torsion angles, θ. A speculative mechanism invokes the through-space, or proximate, interaction between the β-CH and the *ortho* C—H bonds, postulated for styrene (2). In all known cases (2, 35–42) such an interaction leads to a negative coupling constant between the protons, as indicated in **C** by the parallel crossed arrows for H-6 and



C

H-8. Schematically, the repulsive overlap of the 1*s* orbitals centered on these protons is consistent with a parallel-spin preference of the electrons in these orbitals. Given this situation, the spin correlation in the σ bonds of the aromatic ring, determined by the Pauli principle and Hund's rule, then leads to the spin state of the proton in H-5 as in **C** and hence a positive contribution to $^6J_{58}$ (see also **A**). At what θ value the proximate interaction is maximized is uncertain, it being very sensitive to interatomic distance and the mutual arrangement of the C—H bonds. In styrene, $^5J_{28} = {}^5J_{68}$ is not seen, presumably because the negative proximate component cancels the expected positive coupling components, σ and π, expected over five bonds. In 2-formylstyrene, $^5J_{68}$, not having a large σ contribution from a mainly *trans* pathway, is −0.132(5) Hz (Table 2), suggesting that the through-space mechanism also operates at substantial θ values corresponding to H_6,H_8 distances of 2.4–2.5 Å. The spin correlation proposed in **C** is consistent with the small magnitude of $^6J_{58}$ in 2-formylstyrene, acting to cancel the negative π and σ,π interactions. These are as large for $^6J_{38}$ as for $^6J_{58}$ and dominate the −0.084(3) Hz measured for $^6J_{38}$. Parenthetically, the present rationalization is consonant with the magnitudes (signs unknown) of $^6J_{58}$ and (or) $^6J_{38}$ in 2-fluoro- and 3-fluorostyrene (4).

The proximate nature of $^5J_{68}$ is mentioned above. As to $^5J_{69}$, one has $(^5J_{29} + {}^5J_{69})/2$ as 0.158(2) Hz in styrene (30), similar to the numbers for some *meta*- and *para*-substituted derivatives (2–4). The negative, proximate contribution to $^5J_{68} = {}^5J_{28}$ is not present in $^5J_{29} = {}^5J_{69}$. Valence-bond theory (2) suggests a π electron term, 0.59 $\cos^2\theta$, for $^5J_{69}$, while the INDO MO FPT procedure (2) has the coupling as 0.20 Hz at θ = 0° (see **A**) and 0.50 Hz at θ = 180°. These numbers imply a σ electron component of appreciable magnitude. However, INDO also calculates $^5J_{69}$ as 0.33 Hz at θ = 90°. In fact, $^5J_{69}$ is 0.047(3) Hz in 2-formylstyrene and, because $\langle\cos^2\theta\rangle$ is apparently equal to 0.550 and θ values nearer 180° are inappreciable, it appears that both methods strongly overestimate the π and σ electron components. In 2-fluorostyrene, $^5J_{69}$ is 0.084(2) Hz (4), corresponding to a larger $\langle\cos^2\theta\rangle$. A parameterization of the θ dependence of $^5J_{29}$ must await further experimental data.

(f) Coupling constants between olefinic protons and the formyl proton

$^5J_{7,10}$ is −0.163(1) Hz and is most likely a proximate coupling constant, similar in nature to the −0.38(1) Hz determined for the coupling constant between the formyl and methine protons in 2-formylisopropylbenzene (42). Such coupling constants are very sensitive to interatomic distance (43, 44). In the isopropylbenzene derivative, the experimental and theoretical evidence (42) is that the methine C—H bond is rather closely confined to the aromatic plane. In consequence, its hydrogen atom approaches that of the formyl C—H bond rather more closely on average than for the analogous interaction in 2-formylstyrene. The O-*trans* populations in the two compounds are almost equal.

CNDO/2 MO FPT computations of $^5J_{7,10}$ in 2-formylstyrene, employing the 6-31G* geometries, were used instead of the INDO formulation because both methods give very similar values for proximate contributions, while the latter strongly overestimates the σ electron component of a five-bond coupling constant in benzene derivatives. For planar **B**, in which H-7 and H-10 approach to within 1.95 Å in the 6-31G* geometry, $^5J_{7,10}$ is computed as −0.31 Hz, implying a negative proximate coupling, as expected. As θ increases (Fig. 3), the computed magnitude decreases. For **A**, $^5J_{7,10}$ is computed as small and positive, less than 0.1 Hz at θ = 0 and becoming negligible for θ = 60°. The potential energy curve in Fig. 3, applied as a weighting function to the computed values, yields $^5J_{7,10}$ as −0.08 Hz. In view of the high sensitivity of the proximate component to internuclear distance, this result may be considered as satisfactory in comparison with the experimental value of −0.16 Hz.

Intragroup coupling constants

The changes in ^2J_g, ^3J_c, and ^3J_t in 2-formylstyrene, caused by the polar solvent (Table 1), are parallel to those measured in 2-fluorostyrene (4). The same can be said for the coupling constants between ring protons in these two compounds and also for 2-formylisopropylbenzene (42). Such small changes, also measured for monosubstituted benzenes in this laboratory, follow patterns to a large extent independent of the nature of the substituent and are certainly not artifacts of the spectral analytical procedures.

The proton chemical shifts

Table 4 contains the δ values for the protons of benzaldehyde, styrene, and 2-formylstyrene dissolved in acetone-d_6. To within the uncertainties caused by differing concentrations, the ring proton shifts in 2-formylstyrene are nearly reproduced by an additive scheme. This result is reasonable in that the formyl group in 2-formylstyrene has almost the equal O-*cis* and O-*trans* populations experienced by the protons in benzaldehyde. Further, the computed potential suggests only small overall deviations from coplanarity of the formyl group, consistent with very similar conjugative shifts caused by this substituent in the parent compound and its derivatives and also with the ^6J(H-*para*, CHO) values in the two compounds. The perturbations of the proton chemical shifts in benzene by the vinyl group are relatively small (Table 4). At the *para* position an increased screening of 0.12(1) ppm occurs (π donor). If the *para* proton shift goes as $\cos^2\theta$ and $\langle\cos^2\theta\rangle$ is 0.825 for styrene (3) and 0.537 for 2-formylstyrene, then for the latter one expects a deviation of 0.04 ppm from additivity (larger δ value) at H-4; one measures 0.03(1) ppm. At H-5, the shift of which is dominated by the electron-withdrawing formyl

Table 4. Chemical shifts (δ values) of benzaldehyde, styrene, and 2-formylstyrene in acetone-d_6 solution.

			2-Formylstyrene

[b]For a 16 mol% solution in acetone-d_6 (30).

[c]For a 4.4 mol% solution in acetone-d_6 (Table 1).

[d]The δ values for C_6H_6 are 7.324 for a 16 mol% solution in acetone-d_6 and 7.349 for a 2.5 mol% solution (4). This column assumes the mean of the two numbers.

[e]In ppm (δ values) relative to internal TMS at 300 K; 298 K for styrene.

group, the deviation is negative by 0.02(1) ppm. It does appear that the ring proton chemical shifts in 2-formylstyrene are consistent with the conformational distribution assumed in the above discussion of the long-range coupling constants.

Perhaps the most striking chemical shift in Table 4 is that of H-7 in 2-formylstyrene. At 7.67 ppm, this proton is deshielded by 0.95 ppm in the presence of the formyl group. Because H-7 is characterized by larger θ values than in the parent compound, which would *decrease* its δ value arising from the diamagnetic anisotropy of the benzene ring, the 0.95 ppm must be due to perturbations by the proximate formyl group. A simple interpretation holds that repulsion by the C—H bond in **B**, and by the C=O bonds in **A**, of the α olefinic C—H bond, the main origin of the out-of-plane twist of the vinyl group, is also the concomitant cause of the descreening of H-7. Numerous examples (46–50) exist of significant deshielding of protons in steric proximity to other groups.[6] At the small interatomic distances applicable to the conformation of Fig. 3, it would be bootless to attempt a dissection of the 0.95 ppm into contributions such as those from the anisotropy of the carbonyl group or from the mean-square electric fields due to the lone-pair electrons on oxygen. It may be noted that in 2-fluorostyrene, for which there is no indication of nonplanarity of the vinyl group significantly larger than that in styrene (4), H-7 is deshielded by only 0.16 ppm relative to styrene. In summary, the large shift experienced by H-7 in 2-formylstyrene is consistent with the conformational distribution of the vinyl group in Fig. 3.

While the large chemical shift of H-7, induced by the presence of the formyl group, is reasonably attributed to proximity effects, the much smaller shifts induced at H-8 and H-9 likely include electric field and mesomeric shifts similar to those characterized for a series of 4-X-styrenes (52), as well as small changes in shielding due to a reduction in the descreening caused by the diamagnetic anisotropy of the benzene ring. Disentanglement of the various shift contributions could only proceed with data from a series of 2-X-styrenes. It is noteworthy that the δ values of H-8 and H-9 in 2-fluorostyrene are 5.88 and 5.39, not strikingly different from those for the title compound. Yet fluorine and the formyl group are characterized by contrasting mesomeric parameters.

The formyl proton is deshielded by 0.25 ppm by the vinyl moiety (Table 4), a minimum value for a proximity shift because in **B** the two local minima are such (Fig. 3) that, in sum, a shielding (49) should occur by the magnetic anisotropy of the C—C olefinic bond.

[6] For some current examples of descreening of protons caused by "proximity effects" see ref. 51.

Summary

The ^{1}H nmr spectral parameters of 2-formylstyrene show that the population of the O-*cis* and O-*trans* conformers are almost equal in both CS_2–C_6D_{12} and acetone-d_6 solutions; the formyl and phenyl groups are roughly coplanar. The theoretical torsional potential for the vinyl group has a minimum at a torsion angle of 38° for the O-*cis* conformer, whereas minima occur at 45° and at 129.6° in the O-*trans* conformer. The long-range coupling constants for the vinyl protons in both solutions are consistent with the theoretical potential. The existence is predicted of a conformer in which the hydrogen atom of the formyl group closely approaches the β-carbon centre of the vinyl group, thereby facilitating a 1,5-hydrogen shift postulated to occur under irradiation. Hydrogen atom transfers during irradiation can be very sensitive to interatomic distances (53).

Abstract: The preparations of four calix[4]resorcinarene esters and two calix[4]resorcinarene amides are reported. The logarithms of association constants have been determined by the picrate extraction method for a variety of metal cations, including alkali metal, alkaline earth, lanthanum, and silver cations. Strong binding toward silver ion, and selectivity amongst the alkaline earth cations, was observed for the octa-α-(diethyl acetamide) **3***c*. Flattened cone conformations have been established for both *C*-undecylcalix[4]resorcinarene octa-α-(methyl acetate), **3***a*, and octa-α-(diethyl acetamide), **3***c*, in chloroform solutions at 200 K. Dynamic nuclear magnetic resonance was used to identify rapid conformational interconversions of both **3***a* and **3***c* corresponding to pseudorotation between flattened cone conformations. The silver complex of **3***c* also exhibits pseudorotation; however, the activation barrier was observed to increase from 42 kJ mol^{-1} in the free ligand to 49 kJ mol^{-1} in the complex. The NMR data indicate that the metal cation binding occurs in a symmetrical fashion using two pairs of binding sites that are disposed across the macrocyclic ring from one another. Considering these data it is concluded that four carbonyl functions are involved in the binding of a metal cation in a 1:1 complex with the ligand.

Key words: resorcinarene, picrate, association constant, dynamic NMR, pseudorotation.

Résumé : On a préparé quatre esters calix[4]résorcinarènes et deux amides calix[4]résorcinarènes. Faisant appel à la méthode d'extraction du picrate, on a déterminé les logarithmes des constantes d'association d'une variété de cations métalliques, y compris ceux de l'argent, des métaux alcalins et alcalino-terreux et de la série des lanthanides. Avec l'octa-α-(diéthyl acétamide), **3***c*, on a observé que les ions de l'argent sont fortement fixés et qu'il existe une grande sélectivité parmi les cations des alcalino-terreux. On a établi que, en solutions dans le chloroforme à 200 K, le *C*-undécylcalix[4]résorcinarène octa-α-(acétate de méthyle), **3***a*, ainsi que l'octa-α-(diéthyl acétamide), **3***c*, ont tous les deux des conformations coniques aplaties. On a utilisé la résonance magnétique nucléaire dynamique pour identifier les interconversions conformationnelles rapides des deux composés **3***a* et **3***c* qui correspondent à la pseudorotation entre des conformations coniques aplaties. Le complexe de l'argent avec le composé **3***c* présente aussi de la pseudorotation; toutefois, on a observé que la barrière d'activation augmente de 42 kJ mol^{-1} dans le coordinat libre à 49 kJ mol^{-1} dans le complexe. Le données de la RMN indiquent que le cation métallique se fixe d'une façon symétrique en utilisant deux paires de sites de fixation disposés l'un en face de l'autre de chaque côté du macrocycle. Sur la base de ces données, on en conclut que les quatre fonctions carbonyles sont impliquées dans la fixation d'un cation métallique dans un complexe 1 : 1 avec le coordinat.

Mots clés : résorcinarène, picrate, constante d'association, RMN dynamique, pseudorotation.

[Traduit par la rédaction]

Introduction

Calixarenes have been extensively studied and used in a variety of industrial and commercial processes and products (1). The closely related calix[4]resorcinarenes are the products of the acid-catalyzed condensation of resorcinol and various aldehydes, whose major structural feature is composed of four resorcinol units in a cyclic tetramer as shown in Scheme 1. This class of compounds has been used elegantly by Cram et al. in the development of the carcerands and hemicarcerands (2). Recently, Aoyama and co-workers have shown the extensive complexation properties that calix[4]resorcinarenes exhibit toward sugars and alcohols (3, 4).

There are many areas of calixresorcinarene chemistry that have not been explored. In this work, we report the synthesis and properties of octafunctionalized calix[4]resorcinarenes that have been used to extract a variety of cationic picrates from aqueous solutions.

Dynamic nuclear magnetic resonance (DNMR) experiments have been carried out on **3***a*, **3***c*, and **3***c*·Ag^+. In each case, a single conformation at the low-temperature limit was identified and the conformational energy barrier to pseudoro-

tation was determined. The symmetry of the ligand and the characteristics of the DNMR spectra also allowed the determination of the mode of complexation of silver cation.

Experimental

Materials

Reagents were used as purchased except for tetrahydrofuran (THF), which was distilled from potassium and benzophenone under an N_2 atmosphere. *C*-Undecylcalix[4]resorcinarenes, **1** and **2** (4, 5) and 2-bromo-*N,N*-diethylacetamide (6) were prepared as previously described. Nuclear magnetic resonance spectra were run on a Bruker AC300 spectrometer at 300.1 MHz for ^1H, and at 75.5 MHz for ^{13}C and DEPT 135 pulse sequencing. DEPT experiments are noted by the multiplicity in brackets within the ^{13}C data. The AC300 was equipped with a Bruker VT1000 variable temperature unit. The chemical shifts are reported in parts per million with the solvent signal used as the standard relative to Me_4Si. Protons exchangeable with D_2O are noted as "D_2O ex." in the ^1H data. Fourier Transform infrared spectra were collected on a Nicolet 5DX spectrometer. Liquid samples were studied as neat films on potassium bromide plates and solid samples were run as potassium bromide pellets. The melting points were determined on a Fisher–Johns hot plate melting point apparatus and are not corrected. Elemental analysis determinations were performed by either M-H-W Laboratories, Phoenix, Arizona, or Galbraith Laboratories, Knoxville, Tennessee. Column chromatography was performed using Merck silica gel 60 (70–230 mesh) and thin-layer chromatography using Merck aluminum-backed 0.2 mm silica gel plates with 254 nm indicator.

Synthesis

C-Heptylcalix[4]resorcinarene, 2

C-Heptylcalix[4]resorcinarene was prepared following Aoyama's method (4). The product was obtained as a light tan powder after repeated recrystallizations from methanol and water (yield 83%); mp > 300°C. IR (cm^{-1}): 3294 br s, 3044 w, 2926 s, 2856 s, 1618 m, 1501 m, 1447 m, 1294 m, 1183 m. ^1H NMR (CD_3OD): 7.17 (s, 1H), 6.21 (s, 1H), 4.26 (t, 1H, 7.7 Hz), 2.16 (m, 2H), 1.31 (br s, 10H), 0.93 (t, 3H, 6.4 Hz). ^{13}C NMR (CD_2Cl_2): 150.5, 150.3, 124.8 (br), 123.8 (br) , 102.8 (br), 33.2, 33.15, 31.9, 29.6, 29.4, 28.1, 22.7, 14.1. ^{13}C NMR (CD_3OD): 152.9, 125.5, 124.6, 104.0, 35.0, 34.6, 33.1, 302.8, 30.5, 29.2, 23.8, 14.6.

General procedures for the functionalization of calix[4]resorcinarenes

Functionalization of the calix[4]resorcinarenes was carried out following the procedure of Ungaro and co-workers (7) except that the functionalization was carried out in 100% THF.

*C-Undecylcalix[4]resorcinarene octa-α-(methyl acetate), 3*a

The crude yellow solid (5.0 g) obtained from the reaction mixture was recrystallized from methanol to obtain a light yellow powder (1.26 g, 0.75 mmol, 68%, R_f = 0.26, 5:1 petroleum ether – ethyl acetate); mp 92–94°C. IR (cm^{-1}): 2922 s, 2852 m, 1762 s, 1732 m, 1616 m, 1587 m, 1505 s, 1306 m, 1228 m, 1202 m, 1166 m, 1124 m. ^1H NMR ($CDCl_3$): 6.58 (s, 1H), 6.19 (s, 1H), 4.56 (t, 1H, 7.2 Hz), 4.25 (s, 4H), 3.73 (s, 6H), 1.81 (br, 2H), 1.21 (br, 18H), 0.84 (t, 3H, 6.9 Hz). ^{13}C NMR ($CDCl_3$): 169.8 (s), 154.4 (s), 128.5 (s), 126.5 (d), 100.7 (s), 67.1 (t), 51.9 (q), 35.7 (d), 34.5 (t), 31.9 (t), 29.99 (t), 29.88 (t), 29.77 (t, CH_2), 29.70 (t), 29.4 (t), 28.1 (t), 22.7 (t), 14.1 (q). Anal. calcd. for $C_{96}H_{144}O_{24}$: C 68.55%, H 8.63%; found: C 68.60%, H 8.85%.

*C-Undecylcalix[4]resorcinarene octa-α-(*tert*-butyl acetate), 3*b

The crude oil (12.5 g) was chromatographed on silica gel (5:1 petroleum ether – ethyl acetate). A yellow solid (1.79 g, 0.89 mmol, 60%, R_f = 0.31, 5:1 petroleum ether – ethyl acetate) was obtained upon evaporation and evacuation; mp 50–53°C. IR (cm^{-1}): 2927 s, 1760 s, 1730 s, 1650 s, 1507 s, 1158 s. ^1H NMR ($CDCl_3$): 6.55 (s, 1H), 6.16 (s, 1H), 4.54 (t, 1H, 7.2 Hz), 4.12 (s, 4H), 1.79 (br, 2H), 1.43 (s, 18H), 1.20 (br s, 18H), 0.84 (t, 3H, 6.8 Hz). ^{13}C NMR ($CDCl_3$): 168.5, 154.5, 128.1, 126.4, 100.5, 81.5, 67.6, 35.7, 34.5, 31.9, 30.0, 29.9, 29.8 (2 × CH_2), 29.7, 29.4, 28.1 (CH_3 and CH_2 superimposed), 22.7, 14.1. Anal. calcd. for $C_{120}H_{192}O_{24}$: C 71.39%, H 9.59%; found: C 71.19%, H 9.53%.

*C-Undecylcalix[4]resorcinarene octa-α-(*N,N*-diethyl acetamide), 3*c

The crude oil (16.7 g) was chromatographed on silica gel (0–50% methanol in ethyl acetate). The product was evacuated for 24 h to obtain a white powder (1.71 g, 0.85 mmol, 85%, R_f = 0.23, ethyl acetate); mp 56–59°C. IR (cm^{-1}): 2972 s, 2928 s, 2858 m, 1640 vs, 1457 s, 1438 s, 1298 m, 1108 m. ^1H NMR ($CDCl_3$): 6.73 (s, 1H), 6.42 (s, 1H), 4.57 (t, 1H, 7.2 Hz), 4.42 (s, 4H), 3.30 (m, 8H), 1.77 (br, 2H), 1.21 (br, 18H), 1.06 (t, 6H, 6.9 Hz), 0.83 (t, 3H, 6.7 Hz). ^{13}C NMR ($CDCl_3$): 167.5 (s), 154.5 (s), 126.5 (s), 126.4 (d), 99.2 (d), 69.1 (t), 41.4 (t), 40.0 (t), 35.6 (d), 35.1 (t), 31.9 (t), 30.1 (t), 29.88 (t), 29.83 (t), 29.77 (t), 29.69 (t), 29.4 (t), 28.4 (t), 22.7 (t), 14.3 (q), 14.1 (q), 12.9(q). Anal. calcd. for $C_{120}H_{200}N_8O_{16}$: C 71.67%, H 10.03%, N 5.57%; found: C 71.55%, H 10.03%, N 5.69%.

*C-Heptylcalix[4]resorcinarene octa-α-(methyl acetate), 4*a

The crude solid (1.24 g) was recrystallized from methanol to obtain a light yellow powder (0.47 g, 0.32 mmol, 87%, R_f = 0.22, 5:1 petroleum ether – ethyl acetate); mp 101–102°C. IR

Determination of association constants

The association constants of **3***a–c* and **4***a–c* with ammonium and metal cations were determined using the picrate extraction method as described both by Cram and co-workers (8) and Chandler et al. (9). Picrate salts were prepared as previously described (10, 11) and the distribution constant of each picrate salt was determined by extraction of the salt from an aqueous solution (10.0 mL) to chloroform (25.0 mL) in a separatory funnel. The organic and aqueous phases were allowed to separate for 20 min and the chloroform layer was carefully separated. The residue after evaporation of the solvent was quantitatively transferred to a 1.00 mL volumetric flask and diluted with spectrophotometric grade acetonitrile. The extinction and distribution coefficients of the picrate salts were in agreement with literature values (8, 9). The distribution coefficient of the previously unreported lanthanum picrate was 0.126 dm^9 mol^{-3} and the extinction coefficient was 27 300 dm^3 mol^{-1} cm^{-1} based upon the concentration of $La(OC_6H_2(NO_2)_3)$. The concentrations of the picrate salts in the extraction experiments were determined by measurement of the absorbance at λ_{max} (380 nm).

During the extraction procedure 200 μL of host solution (approximately 7.00×10^{-2} M) in deuterated chloroform and 2.00 or 3.00 mL aliquots of picrate salt solution (approximately 1.00×10^{-2} M, or a water blank) were stirred vigorously for 24 h at 25.0 ± 0.1°C. An aliquot of the organic phase was diluted with spectral grade acetonitrile and the absorption of each acetonitrile solution was determined against a suitable blank at 380 nm to calculate the concentration of picrate salt in the organic phase.

The standard deviations in Table 1 were determined from at least four independent experiments. Initial experiments were repeated as many as 10 times to ensure sufficient control over experimental error. In later experiments, the determinations were performed in duplicate or triplicate. In those cases the range from highest to lowest value is reported.

General derivation of the K_a expression

Cram and co-workers (12) and Chandler (9) derived expres-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

sions for the association constants of mono- and di-valent cations with host molecules in organic solvents. The expressions for K_a differ due to the change in the order of picrate concentration as a result of the requirement for electroneutrality of charge in the extraction. The general expression for the association constant of any metal ion in a two-phase extraction experiment is reported here in order to apply the equation to the extraction equilibria for the trivalent lanthanum cation. The reported expression holds for cases where the concentration of metal ion is determined by the extent that the counterion is coextracted.

The extraction equilibrium [1] is governed by the extraction constant K_e, eq. [2], and the distribution constant K_d, [3]. The host and the undissociated guest salt in equilibria are represented by (H) and (GX_n). The subscripts on the expressions indicate the solvents in which the species are dissolved. The terms for the dissociated guest ion and its counterion are given by (G^{n+}) and (X^-). The expressions for the concentration equilibrium constants, K_a, K_e, and K_d, are shown in eqs [4], [5], and [6], respectively. Concentrations of species are given in square brackets and subscripts refer to solvent as described above.

[1] $$(H)_{CDCl_3} + (GX_n)_{CDCl_3} \rightleftharpoons (H{\cdot}GX_n)_{CDCl_3} \qquad K_a$$

[2] $$(H)_{CDCl_3} + (G^{n+})_{H_2O} + n(X^-)_{H_2O} \rightleftharpoons (H{\cdot}GX_n)_{CDCl_3} \qquad K_e$$

[3] $$(G^{n+})_{H_2O} + n(X^-)_{H_2O} \rightleftharpoons (GX_n)_{CDCl_3} \qquad K_d$$

[4] $$K_a = \frac{[H{\cdot}GX_n]_{CDCl_3}}{[H]_{CDCl_3}[GX_n]_{CDCl_3}}$$

[5] $$K_e = \frac{[H{\cdot}GX_n]_{CDCl_3}}{[H]_{CDCl_3}[G^{n+}]_{H_2O}[X^-]^n_{H_2O}}$$

[6] $$K_d = \frac{[GX_n]_{CDCl_3}}{[G^{n+}]_{H_2O}[X^-]^n_{H_2O}}$$

Following the previous derivations (9, 12), the concentration of the picrate anion can be described in terms of the metal ion concentration, eq. [7]. The expression for K_e is therefore given by eq. [8].

[7] $$[X^-] = n[G^{n+}]_{H_2O}$$

[8] $$K_e = \frac{[H{\cdot}GX_n]_{CDCl_3}}{[H]_{CDCl_3}[G^{n+}]_{H_2O}(n[G^{n+}]_{H_2O})^n} = \frac{[H{\cdot}GX_n]_{CDCl_3}}{[H_i]_{CDCl_3}(n^n)([G^{n+}]_{H_2O})^{n+1}}$$

The fraction of host associated with metal cation, R, is given by eq. [9]. The concentration of host–guest complex in the organic phase can be expressed in terms of the initial concentrations of the host ($[H]_i$) and R. The concentration of guest remaining in the aqueous phase ($[G^{n+}]_{H_2O}$) can be expressed in terms of $[H]_i$ and the initial concentration of undissociated guest salt ($[GX_n]_{i,H_2O}$), eq. [10]. Therefore the general form of the expression for K_a is given by expression [11].

[9] $$R = \frac{[H{\cdot}GX_n]_{CDCl_3}}{[H]_{i,CDCl_3}}$$

[10] $$[G^{n+}] = [GX_{ni}]_{H_2O} - \left(\frac{V_{CDCl_3}}{V_{H_2O}}\right)R[H_i]_{CDCl_3}$$

[11] $$K_a = \frac{K_e}{K_d} = \frac{R[H_i]_{CDCl_3}}{n^n[H]_{i,CDCl_3}K_d\left([GX_{ni}]_{H_2O} - R\left(\frac{V_{CDCl_3}}{V_{H_2O}}\right)[H_i]_{CDCl_3}\right)^{n+1}}$$

Variable temperature NMR

Compounds **3***a* and **3***c* were examined by dynamic nuclear magnetic resonance techniques in deuterochloroform and deuterodichloromethane solutions. Spectra were collected at 10 K intervals from 300 K to just above the freezing point of the solutions.

Solutions of **3***c*·$AgNO_3$ in deuterochloroform or dichloromethane were prepared by extraction of silver ion from saturated aqueous solutions of $AgNO_3$. Variable temperature spectra were collected as described above.

Results and discussion

Synthesis

The parent calix[4]resorcinarenes, **1** and **2**, were prepared following Aoyama's procedure (4). A modification of Ungaro's procedure (7) was used to functionalize **1** and **2** to obtain the octa-α-(methyl acetates), **3***a* and **4***a*, octa-α-(*tert*-butyl acetates), **3***b* and **4***b*, and the octa-α-(diethyl acetamides), **3***c* and **4***c*. The etherification reaction was carried out in 100% THF rather than a THF–DMF mixture to simplify the purification. Yields of the long-chain calixresorcinarenes were unaffected by this change. The yields of the octasubstitution reactions compare favorably with the yields reported for tetrasubstitution of calix[4]arenes. Yields of esters reported in the literature range from 68 to 88% (7, 13, 14). The yield of octa-α-(diethyl amide) was found to be higher than the yield of the esters, which is also in agreement with the literature (15).

Complexation

The association of compounds **3***a–c* and **4***a–c* with metal cationic guests in $CHCl_3$ was studied using the picrate extraction method. Using the assumptions that Chandler et al. (9) and Cram and co-workers (8) identified for alkaline earth and alkali metal cations, respectively, a general expression for the association constant was derived in order to study the trivalent lanthanum cation. The expression that was derived specifically for the trivalent cation case fits the general form of the equation, as do the expressions of Cram and Chandler for the monovalent and divalent cations, respectively.

The logarithms of the association constants (log β) for the six calix[4]resorcinarenes with a variety of metal cations are given in Table 1. A comparison of the log β values for the undecyl calix[4]resorcinarenes **3***a–c* and the heptylcalix[4]resorcinarenes **4***a–c* reveals that the alkyl chain length has little effect on the alkali metal binding constants, as would be expected. Amongst compounds **4***a–c*, only **4***b* was exam-

For personal use only.

ined for binding toward ammonium ions, and the log β's observed were within one standard deviation of the values observed for **3***b*. Subsequent studies of the binding of **4***a–c* toward cations other than the alkali metals and ammonium ions were not carried out since differences in cation binding between compounds **3** and **4** were not expected. The differences in chain length may cause changes in physical properties that would be observed in the formation of Langmuir or Langmuir–Blodgett films.

In comparing the resorcinarenes to the literature, the *R* value proves to be useful, since some literature data is reported as "extraction percent." The *R* values of the esters **3***a* and **3***b* were all <2%, indicating that these compounds exhibit low extractability toward all the cations studied. In contrast, the amide **3***c* exhibits much higher extractability. The *R* values for **3***c* with the metal cations in this study were as follows: Na^+, 7%; K^+, 22%; Rb^+, 13%; Cs^+, 11%; Ag^+, 75%; Mg^{2+}, 2%; Ca^{2+}, 25%; Ba^{2+}, 47%; and La^{3+}, 65%.

The strength of binding toward metal ions was observed to increase as the carbonyl functionality of the binding site was changed from methyl ester to *tert*-butyl ester to amide. The octaamide is the strongest complexing agent due to the nature of the amide carbonyl, which has the highest electron density on the carbonyl oxygen. The *tert*-butyl ester is intermediate in binding strength as a result of the greater electron donation from the *tert*-butyl group than that from the methyl group. Chang and Cho have reported similar results with calixarene derivatives (16). The calix[4]resorcinarenes behave more like the larger calix[6]- and calix[8]-arenes, but exhibit greater selectivity amongst the group IIa metal cations than do the calix[*n*]arene analogues. Compound **3***c* was selective across the group IIa cations whereas the calix[*n*]arenes were not. Calix[4]- and calix[6]-arene amides were not observed to differentiate between Ca^{2+} and Ba^{2+}, and the calix[8]arene did not differentiate between Mg^{2+} and Ca^{2+}(16, 17).

It was observed that **3***a–c* and **4***b* were able to interact with the hydrogen-bonding ammonium cations. Ammonium ion had a higher association constant with the hosts than the bulky *tert*-butyl ammonium ion due to the steric effect of the bulky alkyl group.

The size selectivity toward guest ions was evaluated using Shannon's definition (18) of cation radii rather than the standard Pauling definition. Pauling radii were defined using 6-coordinate systems based upon expandable donors in contrast to Shannon radii that were defined on the basis that O^{2-} in oxide crystals is clearly of a fixed size and that cation radii change with increasing coordination number. Since the actual coordination in solution is unknown, the discussion below is based upon hexacoordinate systems; however, the arguments hold for other coordinate systems.

No metal cation studied exhibited an *R* value greater than unity, which suggests that the assumption of a 1:1 cation–ligand complex was reasonable. If a 2:1 cation–ligand complex was possible, silver cation should show this stoichiometry as it was found to have the highest R value. Nuclear magnetic resonance experiments indicate that the stoichiometry of the **3***c*·Ag^+ complex is 1:1 and there was no reason to suspect that other metal cations would exhibit different behaviour.

The increase in log β with charge is linear over the series Na^+, Ca^{2+}, and La^{3+} (6-coordinate radii 1.02, 1.00, and 1.03 Å, respectively) (18) for **3***b* and **3***c*. The change in the log β with charge is greater in **3***c* than in **3***b* due to the greater relative electrostatic effects in the amide compared with the ester.

It was observed that amongst the alkali metal cations there is little selectivity exhibited by the hosts **3***a–c* and **4***a–c*. This behaviour, and the magnitude of the binding constants, is similar to that observed in the large-ring calix[*n*]arene esters and amides ($n > 4$). Ligands **3***a* and **3***b* show similar interactions with the singly charged silver cation as do the alkali metal cations; however, ligand **3***c* shows a high affinity for the soft silver ion with respect to the other singly charged ions. The magnitude of the binding constants of **3***c* toward sodium, potassium, and silver cations (1.02, 1.38, and 1.15 Å, respectively) (18) suggests that size selectivity was not of primary importance. The changes in the behaviour of the octaamide compared with the ester are attributed to a balance of hard and soft acid–base relationships with the guest cation. The Bu_4-C[4]A-$(OCH_2CONEt_2)_4$ host studied by Vicens (17) shows a similar binding constant toward silver as **3***c*; however, no selectivity between sodium ion and the silver cation was observed, indicating that size selectivity was of more importance in the calix[4]arene case. The selectivity of **3***c* toward the alkaline earth cations is not likely due to cation size since no size selectivity was observed among the alkali metal ions. The source of the selectivity is probably due to a combination of the large electrostatic interaction, as a result of cation charge, coupled with the hard/soft character of the metal cations. It is apparent that there is an electrostatic binding effect as a result of the change in surface charge on the cation.

Nuclear magnetic resonance

Variable temperature NMR studies were carried out on the free ligands 3*a* and 3*c* in $CDCl_3$ and CD_2Cl_2 to probe the conformations of the hosts. The spectra obtained from CD_2Cl_2 solutions are shown in Figs. 1 and 2. Complete separation of signals in $CDCl_3$ as the temperature was lowered was not observed due to the solvent freezing point limit. This problem was avoided in CD_2Cl_2 where the aromatic protons of 3*c* at 190 K were clearly separated into four signals. Based upon simple chemical shift calculations and shielding arguments, the signals were assigned as: $\delta H_l = 7.07$, $\delta H_{l'} = 5.84$, $\delta H_{u'} = 6.01$, and $\delta H_u = 5.91$ ppm, where H_l and $H_{l'}$ correspond to two different lower or small-rim protons and H_u and $H_{u'}$ correspond to two large or upper rim protons. Two coalescences were observed at 208 K and 224 K for the upper rim protons (H_u and $H_{u'}$) and the lower rim protons (H_l and $H_{l'}$), respectively.

In the cone or 1,3-alternate conformations,[3] only two aromatic proton signals would be expected, whereas the chair conformation would exhibit six aromatic signals. The NMR data clearly show that the free ligands are in flattened cone conformations in chloroform or dichloromethane solution.

Other areas of the spectrum are consistent with this conformational assignment and variable temperature effects were also observed. Using data from the $\mathbf{H_u}$, $\mathbf{H_l}$, OCH_2CO, NCH_2CH_3, and Ar_2CHCH_2R regions and determining $\Delta G^{\ddagger}$ from the coalescence temperatures (20), it was found

[3] Gutsche (ref. 1, p. 89) defines the nomenclature based on the [1.1.1.1]metacyclophane system. Alternative nomenclature (cone = crown; flattened cone = boat; 1,3-alternate = saddle; flattened partial cone = chair) has been suggested by Högberg (ref. 19).

Fig. 1. Variable temperature ^{1}H NMR study of **3***a*.

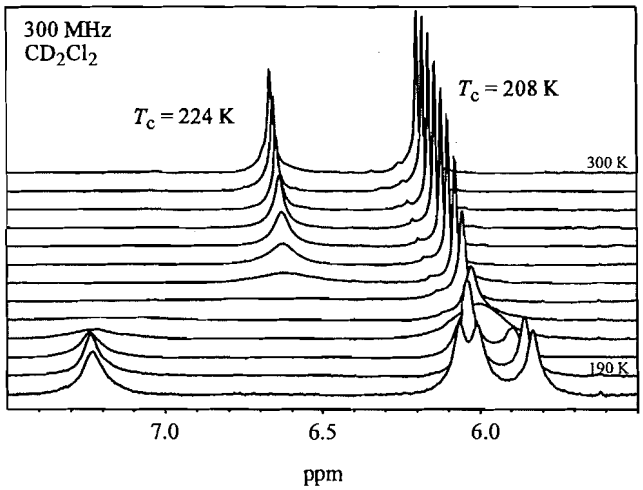

Fig. 2. Variable temperature ^{1}H NMR study of **3***c*.

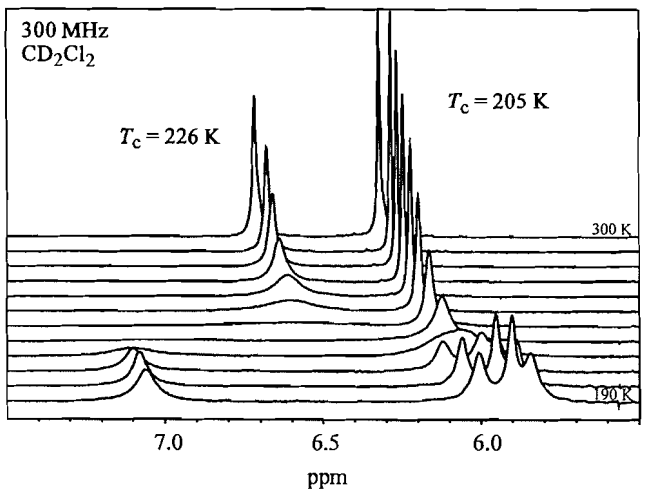
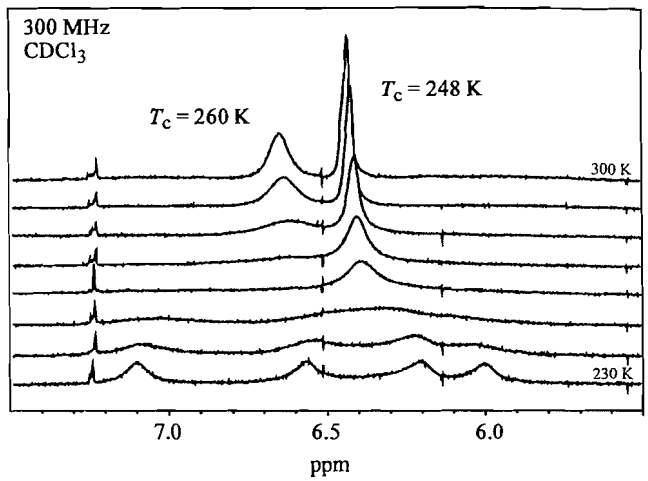


that the average barrier to pseudorotation in **3***c* was 42.3 kJ mol^{-1} (σ = 0.05). A similar analysis of **3***a* finds the average barrier to rotation to be 42.1 kJ mol^{-1} (σ = 0.11). The "exact" temperatures of coalescence reported in the figures were the nearest unit temperatures that resulted in calculated free energies of activation in agreement with all other regions of the spectrum. The data obtained in CD_2Cl_2 solution are in complete agreement with the data obtained in $CDCl_3$.

It is interesting to note that in the ^{13}C spectrum of *C*-heptylcalix[4]resorcinarene, **2**, dissolved in CD_2Cl_2, effects of the conformational interconversion were also observed. The lowest field aromatic signal was clearly split into two, while other aromatic signals were broadened. Variable temperature ^{13}C spectra were not collected for this compound; however, we have noted similar effects in other resorcinarenes and have found that the activation parameters determined from ^{13}C experiments agree well with the activation parameters obtained from ^{1}H NMR experiments. In CD_3OD as solvent, compound **2** was clearly in rapid exchange and only the averaged aromatic signals were observed.

The free energies of activation determined for **3***a* and **3***c* are 20 to 40 kJ mol^{-1} *lower* than those observed for esters of *C*-aryl- and *C*-methyl-calix[4]resorcinarenes, which range from

Fig. 3. Variable temperature ^{1}H NMR study of the **3***c*·$AgNO_3$ complex prepared by extraction of $AgNO_3$ from saturated aqueous solution to $CDCl_3$.

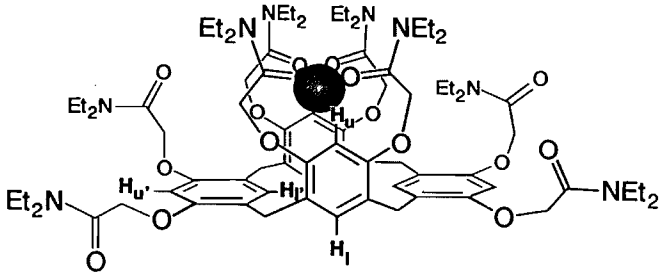


60 to 80 kJ mol^{-1} (19, 21). Two factors may be playing a role in apparent decrease of the activation barrier. The dipole–dipole interaction of the pendant carbonyl functions in the transition state must be different in **3***a* and **3***c* than in the acetate and propionate esters studied by Högberg, which could lower the activation barrier. This hypothesis is supported by preliminary data on Me_4-C[4]R-$(OCH_2CO_2Me)_8$, which has an activation barrier of 53 kJ mol^{-1} (P.J.D., unpublished) compared to 60.3 kJ mol^{-1} (21) for the octaacetate. An increase in the absolute free energy of the flattened cone conformation with respect to the cone conformation (transition state) would account for the missing 10–30 kJ mol^{-1}. The energy for this increase may be due to the "tail wagging the dog" in which thermal motion of the long alkyl tails transfers energy to the calixresorcinarene ring system.

Compound **3***c* was used to extract Ag^+ from an aqueous solution of silver nitrate into $CDCl_3$. The organic phase was examined by variable temperature ^{1}H NMR from 220 to 300 K. As with uncomplexed **3***a* and **3***c*, there are temperature-dependent changes in many areas of the spectrum. Figure 3 shows the aromatic regions of the spectra over the temperature range studied. Two coalescences are observed at 248 K (upper rim protons, H_u and $H_{u'}$, see Fig 4) and 260 K (lower rim protons, H_l and $H_{l'}$) and in the slow exchange regime the aromatic protons separate to four lines, indicating that the conformation of the ligand bound to silver ion is flattened cone. In addition, the symmetry of the proton NMR spectra at all temperatures clearly indicates that the silver ion is symmetrically bound by the ligand. The silver ion is therefore bound by the four carbonyl lone pairs from resorcinol units disposed *across* the calix[4]resorcinarene ring from one another. There is a possibility that the ether oxygens participate in binding but no specific evidence for this type of interaction was observed. No signals were observed due to the unbound host in the slow-exchange regime. Similar behaviour was observed for the **3***c*·Ag^+ complex in a CD_2Cl_2 solution. Considering the spectra, it is concluded that **3***c*·Ag^+ 1:1 complexes are present in both chloroform and dichloromethane solutions. These data support the assumption of a 1:1 complex made for the derivation of the K_a expression.

The free energies of activation determined from $\mathbf{H_l}$ and $\mathbf{H_u}$

Fig. 4. Conformation of the $3c \cdot Ag^+$ complex.



protons in $CDCl_3$ and CD_2Cl_2 were 49.1 and 49.2 kJ mol^{-1}, respectively. Other regions of the spectrum that showed variable temperature effects include the CH_2N and OCH_2CO protons. Using all coalescing signals, in both $CDCl_3$ and CD_2Cl_2 solutions, the free energy of activation for decomplexation of the silver complex of **3***c* was found to be 49.2 kJ mol^{-1} ($\sigma = 0.2$ kJ mol^{-1}).

Conclusion

It has been shown that the calix[4]resorcinarene ligands are capable of binding metal cations and that the octaamide **3***c* shows excellent potential as a selective ligand for soft polarizable cations such as Ag^+ and Ba^{2+}. The amide **3***c* exhibits extraction properties comparable with related calix[4]arenes but contrasting in selectivity. The flexibility of the ligands is apparent from both the DMR studies and from the ability of the ligands to bind both large and small metal cations. Ligands **3***a* and **3***c* were observed to be equilibrating rapidly at room temperature between the two possible flattened cone conformations with an activation barrier to the pseudorotation of 42 kJ mol^{-1} in both species. In the presence of the silver cation 1:1 complex, this barrier was increased due to the decomplexation of cation that was required before pseudorotation could occur. The activation barrier to decomplexation of silver cation from **3***c* was found to be 49 kJ mol^{-1}.

Synthesis, NMR and ultraviolet spectroscopy of [10](*N*6,9)-6-aminopurinophane; calculation of the chemical shifts in the [*n*](*N*6,9)-6-aminopurinophane series

Alfredo Capretta and Russell A. Bell

Abstract: [10](*N*6,9)-6-Aminopurinophane was prepared via a Mitsunobu reaction involving 6-chloropurine and 10-azido-1-decanol. Reduction of the azido moiety to an amine allowed for subsequent cyclization to the cyclophane. *N*6-Nonyladenine, 9-nonyladenine, and *N*6,9-dinonyladenine were also prepared using the established chemistry. Heating the [10](*N*6,9)-6-aminopurinophane to 90°C allowed for a complete assignment of the proton and carbon spectra, while cooling the sample to −77°C revealed additional isomers likely due to the *anti–syn* isomerization about the N6—C6 bond. A variable temperature proton NMR study revealed a $\Delta G_c^{\ddagger}$ of 59.4 ± 5.5 kJ mol^{-1} associated with the interchange between the two major conformers. The ultraviolet spectra of the [*n*](*N*6,9)-6-aminopurinophane series show a bathochromic shift and a hypochromic effect in the transitions as the methylene chain length decreases (i.e., n = 10 to 9 to 8). The aminopurinophanes are used to assess the relative merits of a semi-empirical model that allows for the calculation of the chemical shifts of the methylene bridge protons.

Key words: synthesis of heterocyclophanes, variable temperature NMR, cyclophane conformational analysis, ultraviolet spectroscopy, calculation of chemical shift.

Résumé : On a préparé le [10](*N*6,9)-6-aminopurinophane via une réaction de Mitsunobu impliquant la 6-chloropurine et le 10-azidodécan-1-ol. La réduction de la portion azido en amine a permis de réaliser la cyclisation subséquente en cyclophane. On a aussi préparé les *N*6-nonyladénine, 9-nonyladénine et *N*6,9-dinonyladénine utilisant des méthodes chimiques bien établies. Par chauffage du [10](*N*6,9)-6-aminopurinophane à 90°C, on a pu faire une attribution complète des spectres RMN du proton et du carbone alors que son refroidissement à −77°C a révélé la présence d'isomères additionnels qui sont probablement dus à une isomérisation *anti–syn* autour de la liaison N6—C6. Une étude des spectres RMN du proton à température variable a permis d'établir qu'un $\Delta G_c^{\ddagger}$ de 39,4 ± 5,5 kJ mol^{-1} est associé à l'interconversion entre les deux conformères principaux. Les spectres ultraviolets de la série des [*n*](*N*6,9)-6-aminopurinophanes montrent qu'une diminution de la chaîne méthylénique (lorsque n passe de 10, à 9 et à 8) est associée à un déplacement bathochrome et à un effet hypochrome dans les transitions. On a utilisé les aminopurinophanes pour évaluer les mérites relatifs d'un modèle semi-empirique qui permet de calculer les déplacements chimiques des protons des ponts méthylènes.

Mots clés : synthèse d'hétérocyclophanes, RMN à température variable, analyse conformationnelle des cyclophanes, spectroscopie ultraviolette, calcul des déplacements chimiques.

[Traduit par la rédaction]

Introduction

The shift to lower frequency of the heterobase protons in certain oligonucleotides is a well-documented phenomenon (1). Adjacent bases in a nucleotide strand are separated by as little as 3.4 Å and, at this proximity, can exert pronounced diamagnetic shielding on their neighbours. A detailed knowledge of the spatial distribution of the total diamagnetic shielding anisotropy about these purine and pyrimidine systems could aid in the assignment of the heterobase protons in the ^{1}H NMR spectra of large oligomers. Furthermore, this information could prove valuable in the study of the conformational properties of specific sequences.

[*n*]-Cyclophanes provide an unusual perspective of the diamagnetic shielding about aromatic systems. Unlike the methylene protons of an ordinary aliphatic chain (typically having chemical shifts around 1.3 ppm), the signals from the bridge protons of a cyclophane can assume a wide range of values (often between 3 and −1 ppm). For example, the chemical shifts of the bridge protons in [10]-paracyclophane ranged from 2.62 to 0.51 ppm (2). Work on other heteroaromatic sys-

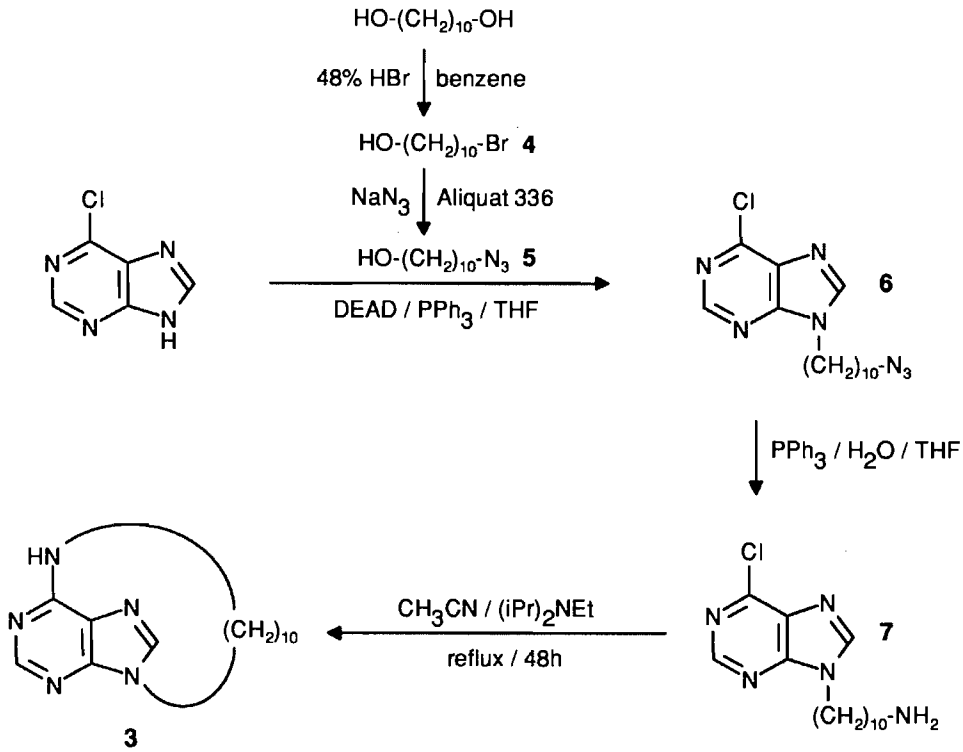
Scheme 1.



tems also shows similar dispersion of signals from the aliphatic chain protons (3).

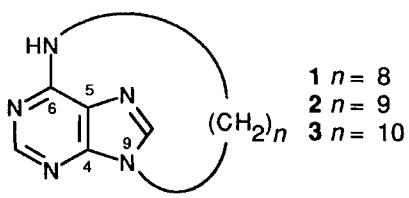
Rather than dismiss these spectra as curiosities, they may be exploited in the study of magnetic anisotropy. Allowing an aliphatic chain to pass over the aromatic plane of a heterobase enables the methylene protons to act as "reporter" groups of the magnetic environment of the system. Ultimately, the proton chemical shifts can furnish values for the spatial definition of the diamagnetic susceptibility anisotropy around these aromatic systems and supply a viable means of appraising the theoretical calculations.

As part of a continuing effort to map the magnetic environment about adenine, the present work describes the synthesis of [10](*N*6,9)-6-aminopurinophane and a number of alkylated adenine derivatives. The NMR and UV spectra of these molecules are examined in order to provide some insight into the conformational and fluxional properties of these cyclophanes. Finally, the aminopurinophanes are used to assess the relative merits of a semi-empirical model that allows for the calculation of the chemical shifts of the methylene bridge protons.

Results and discussion

Synthesis

While many of the successful elements used in the syntheses of the octamethylene (4) and nonamethylene analogues (5), **1** and **2**, respectively, were implemented in the preparation of



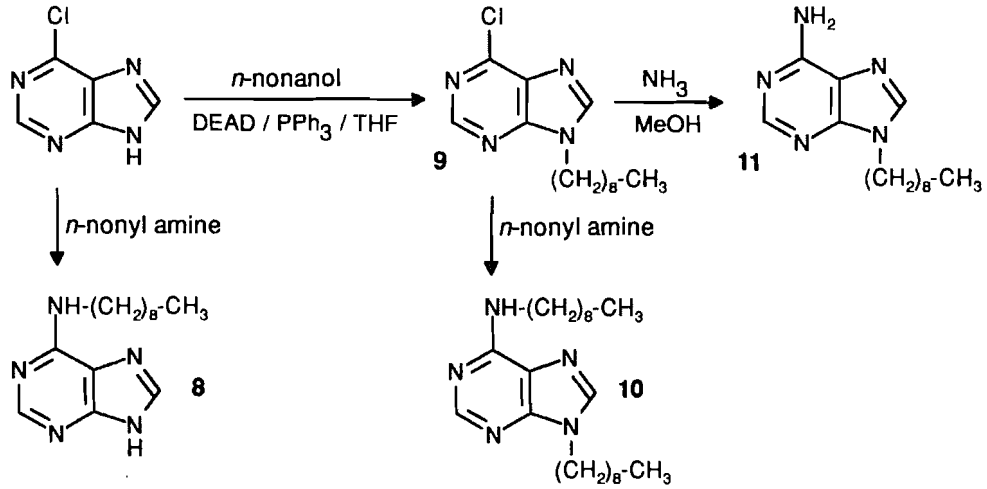
1 *n* = 8
2 *n* = 9
3 *n* = 10

[10](*N*6,9)-6-aminopurinophane **3**, a new preparation for the requisite azido-alcohol was developed. Although the method of Castro and co-workers in (6) for preparing azido-alcohols worked well in the synthesis of **2**, the price of hexamethylphosphorous triamide (HMPT) coupled with the diminished yields upon the "scaling-up" of the reaction prompted the search for a new preparative route to 10-azido-1-decanol (see Scheme 1, **5**). Kang, Kim, and Moon describe a simple method for the preparation of ω-bromo-alcohols from α,ω-diols (7). Refluxing a mixture of an aliphatic diol with an equivalent of aqueous hydrogen bromide (48%) in benzene using a Dean–Stark apparatus provided high yields of the monobromo-alcohol. Treating **4** with aqueous sodium azide in the presence of Aliquat 336 (primarily tricaprylmethylammonium chloride) then yielded the desired ω-azido-alcohol **5** (8). Ultimately, the implementation of this two-step procedure allowed for efficient access to large quantities of pure, low-cost azido-alcohols.

Attachment of the methylene bridge to the purine was then achieved using the protocol described previously (5). As shown in Scheme 1, a Mitsunobu reaction involving 6-chloropurine and 10-azido-1-decanol allows for alkylation at N9 to yield **6**. Following the reduction of the azide **6** to the amine **7**, nucleophilic attack at C6 resulted in the formation of the cyclophane **3**. As expected, the ^{1}H NMR spectrum of [10](*N*6,9)-6-aminopurinophane **3** was comparable to those of the other purine cyclophanes, although complicated to a greater extent by the presence of the additional methylene proton resonances and exchange processes (*vide infra*).

A number of alkylated adenines (to be used as standard compounds in the UV and NMR spectroscopy studies) were also prepared using much of the same chemistry as their cyclized counterparts (see Scheme 2). Dissolving 6-chloropurine in a solution of excess *n*-nonyl amine in acetonitrile readily provided *N*6-amininonyl-purine **8** in 83% yield. The

Scheme 2.



indispensable Mitsunobu reaction allowed for the synthesis of 6-chloro-9-nonyl purine **9**, which could then either be treated with *n*-nonyl amine to yield the *N*6,*N*9-dialkylated purine **10** or dissolved in methanolic ammonia to prepare 9-nonyladenine **11**.

NMR spectroscopy

The exceedingly cluttered ^{1}H NMR spectrum of [10](*N*6,9)-6-aminopurinophane at 25°C was further complicated by extensive broadening of resonances (Fig. 1, spectrum (*b*)). This was not unexpected since conformation flexibility of the aliphatic chain in the [*n*](*N*6,9)-6-aminopurinophanes should increase with each additional methylene. Within this exchange regime, attempts to assign the spectra using the regular 2D NMR experiments failed due to the lack of correlations. Note, for example, that one of the C1′ protons is not seen (highlighted by the arrow in Fig. 1, spectrum (*b*)) until the sample is warmed up to 90°C (see arrow in Fig. 1, spectrum (*a*)). At this elevated temperature, the spectrum showed a marked improvement with many of the signals sharpening and the appearance of some fine structure. Proton assignments were made possible through the application at 90°C of a 2D ^{13}C–^{1}H heteronuclear shift correlated spectrum and a 2D-COSY spectrum and appear in Table 1.

The NMR work carried out at lower temperatures revealed that [10](*N*6,9)-6-aminopurinophane could adopt a number of conformations; for example, at −77°C (Fig. 1, spectrum (*c*)), the multiple signals within the aromatic region revealed the presence of multiple conformations. The two major forms likely arise from the *anti–syn* isomerization about the N6—C6 bond and may be compared with those seen in the low temperature [9](*N*6,9)-6-aminopurinophane NMR spectrum (5). The *anti* conformer is preferred by approximately 4:1 over the *syn* orientation. Each of the *anti/syn* forms showed the presence of additional chain conformers, some with intensities comparable to the minor *syn* isomer, and their presence made it impractical to use simple intensity techniques to assign signals.

A variable temperature NMR study was undertaken to provide the activation parameters associated with the interchange between the major conformers. The low-field signals (H8) were the focus of the line shape analysis (9) and were monitored from −77°C to 30°C. Coalescence of the lines occurred at −20°C and the $\Delta G_c^{\ddagger}$ at this temperature was determined to be 59.4 ± 5.5 kJ mol^{-1}. With a number of minor conformers coalescing about the peaks of interest, the accurate matching of simulated spectra with the actual peaks became difficult and is reflected in the rather large error associated with the activation parameter.

Table 1. ^{1}H and ^{13}C NMR assignments of [10](*N*6,9)-6-aminopurinophane at 90°C (ppm).

	^{13}C	^{1}H	
C1′	42.2	3.79	4.43
C2′	31.5	1.54	1.73
C3′	29.6	1.24	1.41
C4′	29.0	0.96	1.32
C5′	28.1	0.61	0.77
C6′	28.9	1.11	1.18
C7′	28.9	0.30	0.59
C8′	25.8	1.12	1.21
C9′	29.1	1.64	2.04
C10′	44.7	3.96	4.57

Reitz et al. (10) have reported the barrier for rotation about the C6–N6 bond for a number of substituted adenine examples of about 54.0 kJ mol^{-1}, while [9](*N*6,9)-6-aminopurinophane showed a Gibbs' energy of activation of 50.2 kJ mol^{-1} (5). The higher $\Delta G_c^{\ddagger}$ for the decamethylene cyclophane is likely due to a combination of two effects. Unlike the H6-N6-C1′ fragment in the C9 homolog that is twisted about the C6—N6 bond, the longer chain length of the decamethylene cyclophane may allow this fragment to assume a more planar geometry. The barrier for rotation in [10](*N*6,9)-6-aminopurinophane, therefore, is likely to be more in keeping with the Reitz examples wherein the N6 nitrogens assume a more sp^2-like hybridization.

Ultraviolet spectroscopy

Conformational studies on the [10](*N*6,9)-6-aminopurinophane proved frustrating. Crystals suitable for X-ray analysis could not be obtained despite attempts to recrystallize from a variety of solvents. Crystals grown from toluene

Fig. 1. ^{1}H NMR spectra of [10](*N*6,9)-6-aminopurinophane, **3**, in deuterochloroform at (*a*) 90°C, (*b*) 25°C, and (*c*) −77°C.

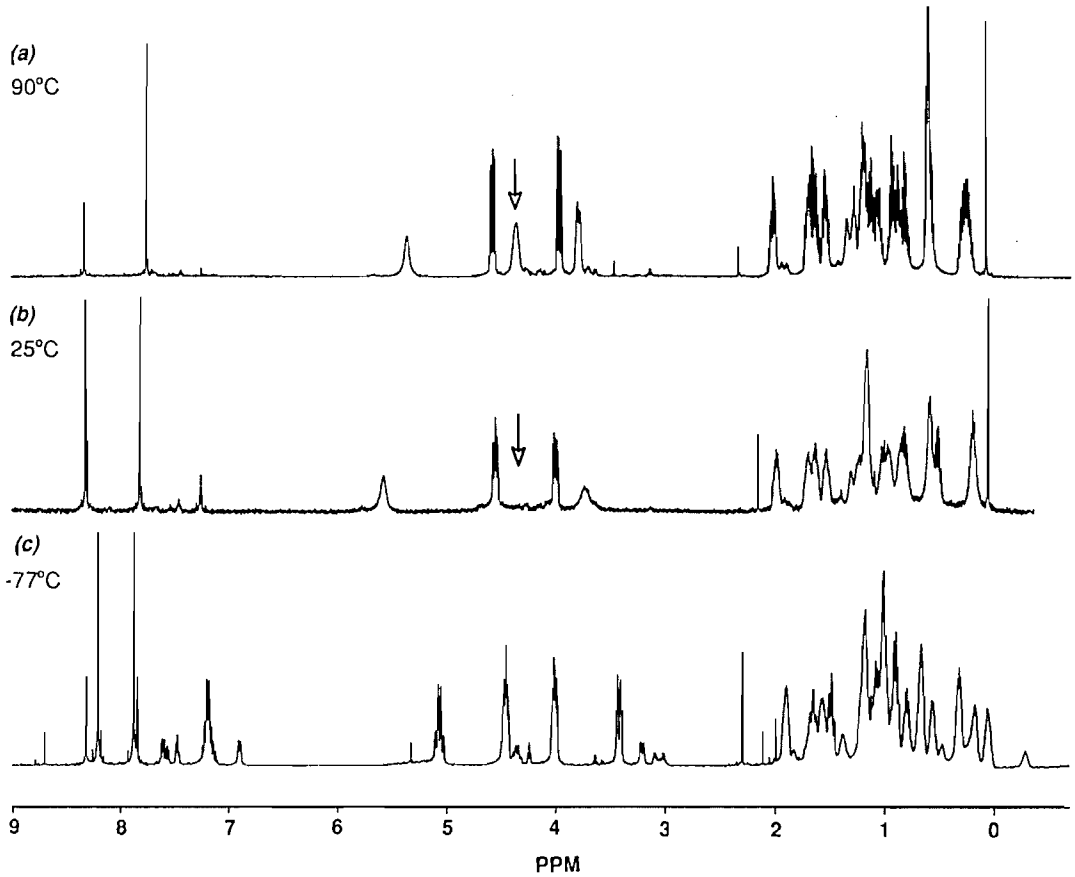

Table 2. Ultraviolet spectra of alkyl adenines and [*n*]-(*N*6,9)-6-aminopurinophanes.

Compound	λ_{max} (nm)	
Adenine	207	261
11	206	261
8	210	269
10	209	269
1	218 (ε 15 200)	278 (ε 13 100)
2	216 (ε 15 500)	276 (ε 13 500)
3	213 (ε 16 200)	273 (ε 13 800)

appeared normal but did not diffract. The computer modelling exercises undertaken were not as conclusive as in the octamethylene and nonamethylene cyclophane cases (5). The conformational freedom conferred by the additional methylene in [10](*N*6,9)-6-aminopurinophane allowed the chain to adopt a number of geometries very similar in energy and, as a result, many conformations were obtained with different structures but similar energies.

Ultraviolet spectroscopy performed on the purinophanes and the series of substituted adenines afforded some insight into the structural characteristics of these molecules. The spectra were recorded using absolute methanol as the solvent and the results are presented in Table 2. The spectra are characterized by two transitions. Alkylation at N9 in adenine seemed to have little effect on the appearance of the spectrum with the absorptions of N9-nonyladenine effectively unchanged from those of adenine. On the other hand, substitution at N6 seemed to have a major effect on the low-energy transition (269 nm in *N*6-nonyladenine compared to 261 nm in adenine) and a marginal effect on the high-energy transition. The low-energy transition, therefore, results from the excitation of an electron from the N6 lone pair in a nonbonding molecular orbital to an unoccupied π^* molecular orbital; while the high-energy transition was a result of a $\pi \rightarrow \pi^*$ excitation.

The cyclophane series of UV spectra were markedly different from that of the *N*6,*N*9-dinonyladenine standard. The bathochromic shift as the methylene chain length decreased had been observed previously in the UV spectroscopy of cyclophanes (11). The shift for the $\pi \rightarrow \pi^*$ transition in cyclophane spectra had been ascribed to the bending of the aromatic plane. The smaller the bridging chain, the greater the deformation of the purine π-system. This distortion raises the energy of the associated molecular orbital and reduces the energy difference between the π and the π^* states. The $n \rightarrow \pi^*$ transition is also a reflection of the cyclophane geometry. Studies have shown (12) that the highest energy absorption for N-substituted anilines occurs when the lone pair on the exocyclic nitrogen is conjugated with the aromatic ring (i.e., the C-NH_2 atoms all lie in the same plane). Twisting the lone pair out of this orientation results in a bathochromic shift. The situation is similar for the purinophanes. The maximum transition energy is required when the N6 lone pair is aligned with the aromatic purine system. Altering the electronic character of N6 by sub-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

stitution or, more dramatically, by twisting the lone pair out of conjugation, as in the cyclophane series, raises the energy of the nonbonding molecular orbital. In essence, the greater the degree of bending and twisting, the less energy is required to induce a transition. These same structural features manifest themselves in a hyperchromic effect seen throughout the series as the chain length increases.

Some of the decamethylene cyclophane structural attributes can now be deduced. The relief of strain that the C-10 chain provides enables the purine ring to adopt a more planar geometry than in the C-8 and C-9 analogs as evidenced by the $\pi \rightarrow \pi^*$ transition. The UV spectra also imply that the degree twisting of N6 in [10]-purinophane is less severe than in the other cases. This lends further support to the statements made in the dynamic NMR study that implicated the relative planarity of the H6-N6-C1′ fragment as a major contributor to the activation energy.

Calculation of the chemical shifts in the [*n*]-(*N*6,9)-6-aminopurinophane series

Theoretical models aimed at determining the anisotropy of the molecular diamagnetic susceptibility of the purine system have been developed, adopting either a semi-empirical or quantum mechanical approach (13). The [*n*]-(*N*6,9)-6-aminopurinophane series can be used to assess these theoretical models in much the same way that the examination of the proton chemical shifts of [10]-paracyclophane provided a method of complimenting and assessing the calculated shielding anisotropy of benzene (2). In this previous work, calculated proton chemical shifts for the cyclophane were a composite of a standard methylene shift (14) and a contribution to the total shielding from ring currents and local atomic magnetic anisotropies. With the geometry of the cyclophane provided by a molecular model, estimates of the ring current effect were made using the "free electron" model of Waugh and Fessenden (15) while the local atomic contributions to the diamagnetic anisotropy were evaluated using the method developed by Barfield et al. (16). The same semi-empirical approach used successfully in the [10]-paracyclophane study has been applied to the purinophane system and its assessment appears below.[2] Preliminary work, which considered only ring current contributions to the total shielding, resulted in marginally acceptable values for the chemical shifts (17). It would seem necessary, therefore, to include local anisotropy contributions in the calculations.

While a discussion of the theories behind these calculations is beyond the scope of this present work (interested readers are directed towards references listed in the previous paragraph), some mention of the various components of the calculation is necessary. The standard chemical shift reference chosen was based on the work of Burke and Lauterbur who determined the typical value for the methylene shifts of large cycloalkanes averaged to 1.30 ppm (14). Any deviation from this value by a bridge methylene proton will be ascribed to ring current and local anisotropy effects.

Two ring currents were calculated: one resulting from each of the constituent five- and six-membered rings. Studies using CNDO/2 and MNDO methods to determine the ratio of π-electrons for each ring (18) showed that the pyrimidine and the imidazole rings should be allotted 5.275 and 4.881 electrons, respectively. However, varying the number of electrons circulating in each of the current loops resulted in the best chemical shift values when 6 electrons were used in the pyrimidine ring and 4 used for the imidazole moiety. Carbon atoms 4 and 5 are common to both the imidazole and pyrimidine rings and, as a result, two ring current contributions were calculated and an average was taken.

Our work has shown that introducing a loop separation into the ring current calculation results in very small changes in the chemical shift and does not improve the correlation between predicted and observed chemical shifts. Agarwal et al. (2) also found the best correlation was obtained without invoking a loop separation. As a result, a zero loop separation was used in the present calculation.

Implementation of the semi-empirical model required a knowledge of the purinophane's molecular structure as well as the principal values and directions of the magnetic shielding tensors (σ_{11}, σ_{22}, σ_{33}) of the constituent atoms of the aromatic system. The principal values of shielding tensors for each atom in the purine and pyrimidine bases have been determined computationally by Schindler (19). The conformational details required were provided by the crystal structure of [8]-(*N*6,9)-6-aminopurinophane (4) whose positional parameters were converted to orthogonal angstrom coordinates.[3]

It is worth pointing out that a number of approximations were introduced in an effort to simplify the calculations. The geometry of the adenine moiety was assumed to be planar for the ring current contribution to the chemical shift. In fact, the torsional angles C6-C5-C4-N9 (169.2°) and N7-C5-C4-N3 (176.3°) of [8]-(*N*6,9)-6-aminopurinophane, determined by diffraction studies, confirm the nonplanarity of the adenine moiety (4). The asymmetric nature of adenine also results in an irregular alignment of the shielding tensor values with respect to the molecular geometry (19), although these are not large differences. Forcing the σ_{11}, σ_{22}, and σ_{33} values to lie along more " convenient" molecular axes greatly simplifies the calculation of the local anisotropy contributions while introducing another source of error.

When the observed chemical shifts of the bridging methylene protons in [8]-(*N*6,9)-6-aminopurinophane (taken at 25°C)[4] are plotted against those predicted by the semi-empirical model, a good correlation is evident (Fig. 2). Inductively transmitted substituent effects from N6 and N9 are largely responsible for the deshielding of the protons on C1′ and C8′ and, therefore, for the purposes of comparison, these values have been omitted. It should be borne in mind that long-range inductive effects may after C2′ and C7′ proton resonances as well. If one looks at the differences in chemical shifts between the geminal protons on each methylene, the predicted values seem to follow the same general trend seen experimentally.

[2] The program used to calculate the chemical shifts in the [*n*](*N*6,9)-6-aminopurinophane series has been deposited as Supplementary Material, which can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6.

[3] The development of the model and the refinement of the calculations centered on the octamethylene purine cyclophane whose properties were most clearly defined.

[4] Inspection of the NMR spectra and structural data of [8](*N*6,9)-6-aminopurinophane have revealed an error in the labelling of the methylene bridge protons. The *pro-R* and *pro-S* designations for the geminal proton pairs at C3′, C5′, and C6′ have been switched.

Fig. 2. Plot of the predicted vs. observed chemical shifts for [8]-(*N*6,9)-6-aminopurinophane (from spectra at 25°C).

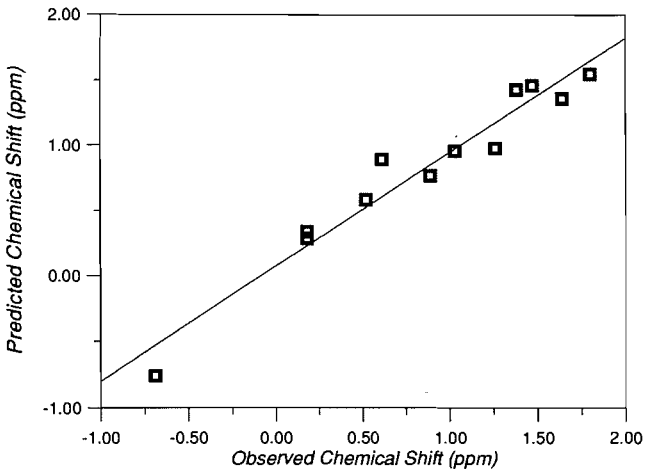

Fig. 3. Plot of the predicted vs. observed chemical shifts for *anti*-[9]-(*N*6,9)-6-aminopurinophane (from spectra at −59.5°C).

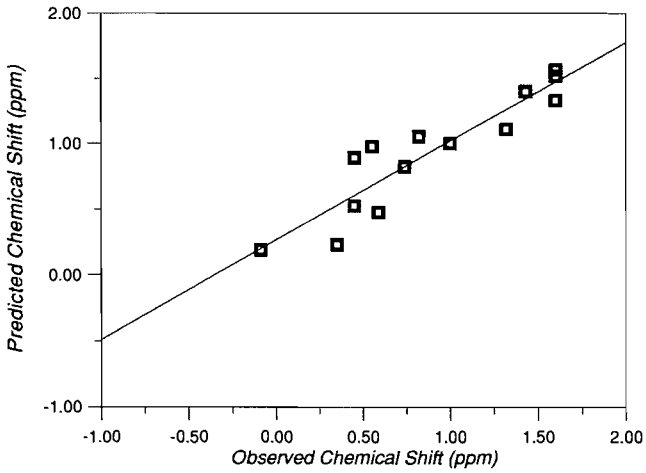
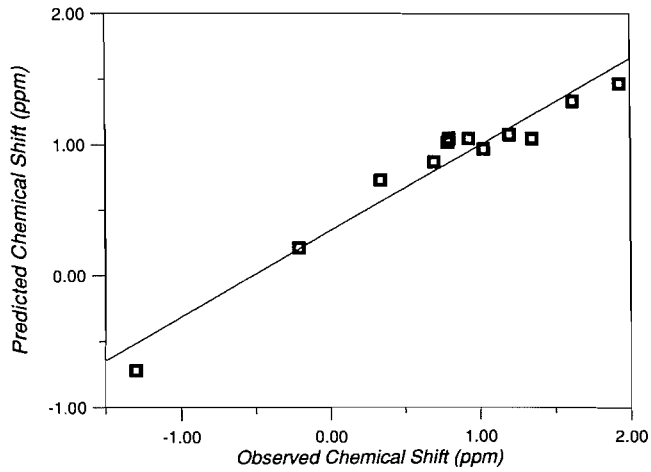


Linear regression analysis on the plot of observed chemical shifts against the predicted values, yields a least-squares correlation coefficient, *r*, of 0.9719.

The semi-empirical model was then modified so as to be utilized for the assignment of the nonamethylene homolog. Using the crystal structure geometry for the *anti* conformer and the computer generated molecular model (**9***b*, see ref. 5) for the *syn* conformation, the predicted chemical shifts were calculated and the values presented in a plot of the experimental (taken at −59.5°C) versus the calculated chemical shifts. For the *anti* case (see Fig. 3), omitting the protons on C1′ and C9′, a linear regression analysis of the data yielded a correlation coefficient of 0.9177. The data for the *syn* conformation of [9](*N*6,9)-6-aminopurinophane is a shown in Fig. 4 and linear regression analysis of this plot yields at least-squares correlation coefficient of 0.9715.

Overall, the chemical shift calculations of the purinophanes illustrate two important points. Firstly, in both the [8]- and [9]-(*N*6,9)-6-aminopurinophane cases, the results generated compare relatively well with the observed ^{1}H NMR resonances despite the approximations made to simplify the procedure.

Fig. 4. Plot of the predicted vs. observed chemical shifts for *syn*-[9]-(*N*6,9)-6-aminopurinophane (from spectra at −59.5°C).



While its absolute predictive ability is limited, the calculations based on the semi-empirical model are relatively simple to set up and evaluate. Secondly, and perhaps more importantly, this exercise has demonstrated the usefulness of the aminopurinophanes in the assessment of a particular chemical shift calculation procedure. It is hoped that these cyclophanes may soon be applied to determine the relative merits of a more sophisticated, ab initio approach. The individual gauges for atoms in molecules (IGAIM) system being developed by Keith and Bader shows promise (20) and, although still in its formative stages, the purinophane series would be an ideal candidate for study using this new methodology.

Experimental methods

Melting points were recorded on a Gallenkamp capillary tube melting point apparatus and are uncorrected. Proton magnetic resonance (^{1}H NMR) spectra were recorded on a Bruker AC-200 or a Bruker AM-500 spectrometer with chloroform-*d* as the solvent unless otherwise noted. Unless specified, the internal references were tetramethylsilane (TMS) or chloroform. The abbreviations (s) = single, (d) = doublet, (t) = triplet, (q) = quartet, (m) = multiplet, and (br) = broad are used in the description of the spin–spin splitting pattern present in the spectra. The natural abundance carbon-13 magnetic resonance (^{13}C NMR) were recorded on a AM-500 (at 125.776 MHz) or AC-200 (at 50.324 MHz) instrument using chloroform-*d* as the solvent and internal reference unless otherwise noted. All ^{13}C spectra were broad-band decoupled. Low-resolution mass spectra (MS) and high-resolution mass spectra (HRMS) were obtained on either a VG Micromass 7070F or a VG ZAB-E mass spectrometer with samples being introduced through a direct inlet system. Ions were generated using electron impact (EI). Infrared spectra (IR) were recorded on a Perkin–Elmer 283 spectrometer. IR samples were run as neat liquids using NaCl windows or, if solid, as KBr pellets. The symbols (s) = strong and (br) broad were used in the recording of the IR data to indicate the intensity of the recorded bands. Ultraviolet (UV) spectra were recorded on a Perkin–Elmer Lambda 9 UV/VIS/NIR spectrophotometer.

Tetrahydrofuran (THF) was dried by refluxing and distilling from sodium and benzophenone under dry nitrogen. THF

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

was collected from the distillation apparatus as required. Acetonitrile was distilled from P_2O_5 followed by distillation from CaH_2, discarding the first 5% and the last 10%. The NMR solvent chloroform-*d* was stored over molecular sieves (4Å) prior to use.

Unless specified, column chromatography was performed by the "flash" method of Still, Kahn, and Mitra (21). The silica gel used for column chromatography (5.0% of 100 mesh up; 47.6% of 100–200 mesh and 47.4% of 200 mesh down) was purchased from Terochem. Silica gel 60 F_{254} (E. Merck Co.) plates of 0.2 mm thickness were used for analytical thin-layer chromatography (TLC). Visualization was achieved using a UV lamp at 254 nm or via treatment of the TLC with either a molybdic acid spray (20 g of molybdic acid and 15 g of ceric sulphate dissolved in 1 litre of 10% sulphuric acid) or a ninhydrin spray (0.2% ninhydrin in ethanol) followed by heating.

Synthesis of 10-bromo-1-decanol, 4

The procedure used was that of Kang, Kim and Moon (7). To a solution of 1,10-decanediol (17.4 g, 100 mmol) in benzene (200 mL) stirred in a 500 mL round bottom flask equipped with a Dean–Stark trap and a condenser was added hydrobromic acid (48%, 12.5 mL, 110 mmol). The reaction was left to stirr at reflux for 28 h during which time the water trapped was periodically drained. The mixture was washed with 6 N NaOH solution (100 mL), 10% HCl (100 mL), water (2 × 200 mL), and saturated NaCl solution (150 mL). The organic layer was dried with anhydrous magnesium sulphate, evaporated under reduced pressure, and the residue purified via distillation. The yield was 80% (18.9 g, 80 mmol). The compound showed bp 110°C/0.2 Torr (lit. (7) bp 125–127°C/3 Torr (1 Torr = 133.3 Pa)); ^{1}H NMR (200 MHz), δ: 1.23 (m, 12H, $(CH_2)_6$), 1.45 (m, 2H, CH_2-CH_2-OH), 1.78 (m, 2H, CH_2-CH_2-Br), 3.34 (t, 2H, *J* = 6.8 Hz, CH_2-Br), and 3.53 (t, 2H, *J* = 6.5 Hz, CH_2-OH); ^{13}C NMR (50 MHz), δ: 25.58, 27.98, 28.58, 29.21, 29.23, 29.33, 32.51, 32.64, 33.90 (CH_2-Br), 62.58 (CH_2-OH); MS[EI], *m/z* (RI%): 237 $[M + 1]^+$ (18), 221 (63), 190 (100), 177 (44); HRMS: Exact Mass calcd. for $C_{10}H_{22}BrO$ $[M + 1]^+$: 237.0854; found: 237.0863.

Synthesis of 10-azido-1-decanol, 5

The procedure was a modification of that used by Reeves and Bahr (8). 10-Bromo-1-decanol (10.0 g, 42.3 mmol) was added to a stirred solution of 25% aqueous sodium azide (10.25 g in 40 mL of water). Aliquat 336 (1.62 g, 4 mmol) was added the mixture heated to 100°C. After 30 h, the reaction was cooled and the phases separated. The 10-azidodecanol was purified via distillation. Yield 87% (7.3 g, 36.9 mmol). The compound showed bp 103°C/0.3 Torr; IR, ν_{max}: 3360 (br, OH), 2095 (s, N_3) cm^{-1}; ^{1}H NMR (200 MHz), δ: 1.24 (m, 12H, $(CH_2)_6$), 1.53 (m, 4H, CH_2-CH_2-OH and CH_2-CH_2-N_3), 3.19 (t, 2H, *J* = 6.8 Hz, CH_2-N_3), and 3.54 (t, 2H, *J* = 6.6 Hz, CH_2-OH); ^{13}C NMR (50 MHz), δ: 25.58, 26.52, 28.65, 28.96, 29.24, 29.33 (CH_2-CH_2-N_3), 32.56 (CH_2-CH_2-OH), 51.29 (CH_2-N_3), 62.62 (CH_2-OH).

Synthesis of 6-chloro-9-(10-azidodecyl)purine, 6

The procedure used was similar to that of Iwakawa et al. (22). To a mixture of 6-chloropurine (4.77 g, 30.86 mmol), triphenylphosphine (8.09 g, 30.84 mmol), and diethyl azidocarboxylate (6.64 g, 6 mL, 30.81 mmol) in 120 mL of dry THF was added a solution of 10-azidodecanol (6.00 g, 30.15 mmol) in 40 mL of THF. The solution was allowed to stir at room temperature for 48 h at which time the reaction mixture was concentrated under reduced pressure. The residue was chromatographed on silica gel using chloroform as the eluent, yielding a viscous yellow oil. TLC of the product with 5% methanol in chloroform gave R_f = 0.62. The yield was 32% (3.31 g, 9.88 mmol). The compound showed ^{1}H NMR (200 MHz), δ: 1.25 (m, 12H, $(CH_2)_6$), 1.57 (m, 2H, CH_2-CH_2-N_3), 1.94 (m, 2H, CH_2-CH_2-N9), 3.23 (t, 2H, *J* = 6.8 Hz, CH_2-N_3), 4.27 (t, 2H, *J* = 7.3 Hz, CH_2-N9), 8.14 (s, 1H, H2), 8.74 (s, 1H, H8); MS [EI], m/z (RI%): 336 $[M + 1]^+$ (100), 295 (6), 265 (10), 209 (18), 115 (23); HRMS: Exact Mass calcd. for $C_{15}H_{23}N_7Cl$ $[M + 1]^+$: 336.1703; found: 336.1714.

Synthesis of 6-chloro-9-(10-aminodecyl)purine, 7

The procedure used was similar to that of Vaultier and coworkers (23). To 6-chloro-9-(10-azidodecyl)purine (1.0 g, 2.99 mmol) in 3 mL of THF was added triphenylphosphine (783 mg, 2.99 mmol), water (80 μL, 4.50 mmol), and a boiling chip. The evolution of N_2 began immediately. The mixture was left standing at room temperature for 18 h. TLC of the reaction mixture showed the complete disappearance of the azide starting material and the appearance of a ninhydrin positive spot on the baseline. The solution was then concentrated, redissolved in 50 mL of chloroform, and extracted with three 20 mL portions of 0.01 M HCl. The combined aqueous solutions were adjusted to pH 8 with 1 M NaOH and extracted with three 30 mL portions of chloroform. These combined organic solutions were dried over anhydrous sodium sulphate and evaporated under reduced pressure. The product was subjected immediately to cyclization conditions.

Synthesis of [10](*N*6,9)-6-aminopurinophane, 3

6-Chloro-9-(10-aminodecyl)purine (700 mg, 2.27 mmol) was dissolved in 50 mL acetonitrile. Diisopropylethylamine (2 mL, 11.48 mmol) was added and the solution diluted with an additional 450 mL of acetonitrile. The reaction was left stirring at 60°C for 48 h at which time the solution was evaporated and the resultant residue was chromatographed on silica gel using 5% methanol in chloroform. TLC of the product in 10% in chloroform gave R_f = 0.50. The yield was 37% (229 mg, 0.84 mmol). The compound showed UV, λ_{max} (methanol): 273 nm (ε 13 800), 213 nm (ε 16 200); ^{1}H NMR (500 MHz at 90°C; sealed tube with $CDCl_3$), δ: 0.30 (m, 1H, C7′H), 0.59 (m, 1H, C7′H), 0.61 (m, 1H, C5′H), 0.77 (m, 1H, C5′H), 0.96 (m, 1H, C4′H), 1.11 (m, 1H, C6′H), 1.12 (m, 1H, C8′H), 1.18 (m, 1H, C6′H), 1.21 (m, 1H, C8′H), 1.24 (m, 1H, C3′H), 1.32 (m, 1H, C4′H), 1.41 (m, 1H, C3′H), 1.54 (m, 1H, C2′H), 1.64 (m, 1H, C9′H), 1.73 (m, 1H, C2′H), 2.04 (m, 1H, C9′H), 3.79 (m, 1H, C1′H), 3.96 (m, 1H, C10′H), 4.34 (m, 1H, C1′H), 4.57 (m, 1H, C10′H), 5.3 (br, 1H, NH), 7.8 (s, 1H, H2), and 8.2 (s, 1H, H8); ^{13}C NMR (125 MHz), δ: 25.8 (C8′), 28.1 (C5′), 28.9 (C7′), 28.9 (C6′), 29.0 (C4′), 29.1 (C9′), 29.6 (C3′), 31.5 (C2′), 42.2 (C1′), 44.7 (C10′), 124.1 (C5), 146.9 (C8), 155.3 (C2), 159.7 (C6); MS [EI], *m/z* (RI%): 273 $[M]^+$ (100), 244 (7), 230 (23), 216 (12), 176 (15), 148 (29), 120 (13), 84 (38); HRMS: Exact Mass calcd. for $C_{15}H_{23}N_5$: 273.1953; found: 273.1945.

Synthesis of *N*6-nonyladenine, 8

6-Chloropurine (1 g, 6.47 mmol) was dissolved in a solution of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

1-nonylamine (2.78 g, 3.56 mL, 19.41 mmol) in 25 mL of acetonitrile and allowed to stir at room temperature for 48 h. The solution was concentrated under reduced pressure and chromatographed on silica gel using 5% methanol in chloroform as the eluent. The alkylated purine was recrystallized from toluene. TLC using 10% methanol in chloroform showed the desired product with R_f = 0.36. The yield was 83% (1.40 g, 5.37 mmol). The compound showed mp 162–164°C; UV, λ_{max} (methanol): 210 nm, 269 nm; ^{1}H NMR (500 MHz), δ: 0.86 (t, 3H, J = 6.7 Hz, CH_3), 1.25 (m, 8H, CH_3-(CH_2)$_4$), 1.34 (m, 2H, NH-(CH_2)$_3$-CH_2), 1.43 (m, 2H, NH-(CH_2)$_2$-CH_2), 1.71 (m, 2H, NH-CH_2-CH_2), 3.66 (br, 2H, NH-CH_2), 6.16 (br, 1H, NH), 7.97 (s, 1H, H2), 8.43 (s, 1H, H8); ^{13}C NMR (125 MHz), δ: 14.04 (CH_3), 22.61 (CH_2-CH_3), 26.91, 29.21, 29.33, 29.48, 29.68, 31.82, 40.85 (NH-CH_2), 137.94 (C8), 152.24 (C2); MS [EI], *m/z* (RI%): 261 [M]$^+$ (47), 246 (6), 232 (12), 218 (20), 204 (43), 190 (70), 176 (36), 162 (39), 149 (100), 135 (88), 108 (27), 94 (7), 67 (13), 55 (27); HRMS: Exact Mass calcd. for $C_{14}H_{23}N_5$: 261.1953; found: 261.1963.

Synthesis of 6-chloro-9-nonyl purine, 9

The procedure used was similar to that of Iwakawa et al. (22). To a mixture of 6-chloropurine (4.77 g, 30.86 mmol), triphenylphosphine (8.09 g, 30.84 mmol), and diethyl azidocarboxylate (6.64 g, 6 mL, 30.81 mmol) in 120 mL of dry THF was added a solution of 1-nonanol (4.35 g, 5.26 mL, 30.15 mmol) in 40 mL of THF. The solution was allowed to stir at room temperature for 48 h, at which time the reaction mixture was concentrated under reduced pressure. The residue was chromatographed on silica gel using chloroform as the eluent. TLC of the product with 5% methanol in chloroform gave R = 0.75. The yield was 80% (6.75 g, 24.12 mmol). The compound showed ^{1}H NMR (200 MHz(, δ: 0.85 (t, 3H, J = 6.7 Hz, CH_3), 1.23 (m, 12H, (CH_2)$_6$-CH_3), 1.90 (m, 2H, N9-CH_2-CH_2), 4.24 (t, 2H, J = 7.3 Hz, N9-CH_2), 8.12 (s, 1H, H2), 8.72 (s, 1H, H8).

Synthesis of *N*6, *N*9-Dinonyladenine, 10

6-Chloro-9-nonyl-purine (1 g, 3.57 mmol) was dissolved in a solution of 1-nonyl amine (1.53 g, 2 mL, 10.71 mmol) in 25 mL of acetonitrile and allowed to stir at room temperature for 48 h. The solution was concentrated under reduced pressure and chromatographed on silica gel using ethyl acetate as the eluent. TLC using ethyl acetate showed the desired product with R_f = 0.73. The yield was 62% (857 mg, 2.21 mmol). The compound showed UV, λ_{max} (methanol): 209 nm, 269 nm; ^{1}H NMR (500 MHz), δ: 0.76 (t, 6H, J = 6.8 Hz, 2 × CH_3), 1.14 (m, 16H), 1.21 (m, 4H), 1.29 (m, 2H), 1.56 (m, 2H), 1.78 (m, 2H), 3.54 (br, 2H, NH-CH_2), 4.07 (t, 2H, J = 7.3 Hz, N9-CH_2), 6.14 (s, 1H, NH), 7.63 (s, 1H, H2), 8.30 (s, 1H, H8); ^{13}C NMR (125 MHz), δ: 13.80, 22.41, 26.48, 26.77, 28.88, 28.96, 29.06, 29.12, 29.12, 29.33, 29.62, 29.95, 31.60, 31.66, 40.57, 43.66, 119.99 (C5), 139.25 (C8), 148.77 (C4), 152.97 (C2), 154.90 (C6); MS [EI], *m/z* (RI%): 387 [M]$^+$ (100), 371 (73), 358 (58), 344 (44), 330 (60), 316 (96), 302 (39), 288 (95); HRMS: Exact Mass calcd. for $C_{23}H_{41}N_5$: 387.3362; found: 387.3370.

Synthesis of 9-nonyladenine, 11

6-Chloro-9-nonyl-purine (1 g, 3.57 mmol) was dissolved in 50 mL of saturated methanolic ammonia and left to stir for 30 days. The solvent was removed under reduced pressure and the residue chromatographed on silica gel using 5% methanol in chloroform as the eluent. The alkylated purine was recrystallized from toluene. TLC using 10% methanol in chloroform showed the desired product having R_f = 0.44. The yield was 25% (232 mg, 0.89 mmol). The compound showed mp 121–126°C UV, λ_{max} (methanol): 206 nm, 261 nm. ^{1}H NMR (500 MHz), δ: 0.84 (t, 3H, J = 6.8 Hz, CH_3), 1.22 (m, 8H, CH_3-(CH_2)$_4$), 1.30 (m, 4H, N9-CH_2-CH_2-(CH_2)$_2$), 1.87 (m, 2H, N9-CH_2-CH_2), 4.16 (t, 2H, J = 7.3 Hz, N9-CH_2), 5.90 (s, 2H, NH_2), 7.77 (s, 1H, H2), 8.35 (s, 1H, H8); ^{13}C NMR (125 MHz), δ: 14.02 (CH_3), 22.58 (CH_3-CH_2), 26.58, 26.63, 29.01, 29.11, 29.33, 30.06, 31.75, 43.95 (N9-CH_2), 119.71 (C5), 140.43 (C8), 152.85 (C2), 155.47 (C6); MS [EI], *m/z* (RI%): 261 [M]$^+$ (10), 245 (6), 190 (10), 177 (10), 162 (26), 148 (100), 135 (82), 119 (19), 93 (8), 55 (11); HRMS: Exact Mass calcd. for $C_{14}H_{23}N_5$: 261.1953; found 261.1958.

Attachment of $C_5Me_4HSi(Me_2)NH$-*t*-C_4H_9 to yttrium via amine elimination. X-ray structure of [(η^5-C_5Me_4)$Si(Me_2)$-η^1-N-*t*-C_4H_9]$YN(SiMe_3)_2$

Ying Mu, Warren E. Piers, Mary-Anne MacDonald, and Michael J. Zaworotko

Abstract: Reaction of the homoleptic yttrium amido complex $Y[N(SiMe_3)_2]_3$ with $C_5Me_4HSiMe_2N(H)$-*t*-C_4H_9, Cp*HSiNHR, at 100°C resulted in elimination of 2 equivalents of $HN(SiMe_3)_2$ and attachment of the Cp-amido donor to yttrium. The product $(Cp^*SiNR)YN(SiMe_3)_2$, **1**, was isolated in 40% yield and was characterized crystallographically (triclinic, space group $P\bar{1}$, a = 8.9759(23) Å, b = 9.504(7) Å, c = 18.294(6) Å, V = 1423.4(12) Å^3, Z = 2, R = 0.061, R_w = 0.053). Metrical parameters associated with the $N(SiMe_3)_2$ ligand were suggestive of weak β-SiC agostic interactions that stabilize the electron-deficient yttrium center. Alkylation of **1** resulted in unstable alkyl derivatives that could not be isolated.

Key words: cyclopentadienyl-amido, amine elimination, yttrium complex.

Résumé : La réaction du complexe homoleptique amido yttrium, $Y[N(SiMe_3)_2]_3$ avec du $C_5Me_4HSiMe_2N(H)$-*t*-C_4H_9, Cp*HSiNHR, à 100°C, conduit à une élimination de 2 équivalents de $HN(SiMe_3)_2$ et à un attachement du donneur Cp-amido à l'yttrium. On a isolé le produit $(Cp^*SiNR)YN(SiMe_3)_2$, **1**, avec un rendement de 40% et on l'a cristallisé par cristallographie (triclinique, groupe d'espace $P\bar{1}$, a = 8,9759(23), b = 9,504(7) et c = 18,294(6) Å, V = 1423,4(12) Å^3, Z = 2, R = 0,061 et R_w = 0,053). Les paramètres métriques associés au coordinat $N(SiMe_3)_2$ suggèrent la présence d'interactions agostiques β-SiC faibles qui stabilisent le centre yttrium qui est électrodéficient. L'alkylation du composé **1** conduit à des dérivés alkyles instables qui n'ont pas pu être isolés.

Mots clés : cyclopentadiényl-amido, élimination d'amine, complexe d'yttrium.

Introduction

The use of "constrained geometry" Cp-amido type ligand arrays in homogeneous Ziegler Natta olefin polymerization catalysts has allowed for production of polymers with different properties and applications than those produced from bis-cyclopentadienyl stabilized catalyst precursors (1). In the Cp-amido ligand family one of the cyclopentadienyl donors from the classical "bent" metallocene bis-cyclopentadienyl ligand arrangement is replaced by an amido donor that is linked to the other cyclopentadienyl ligand, usually by a dimethyl silyl bridge (2). In addition to having two fewer electrons than a bis-cyclopentadienyl array, the chelating nature of the Cp-amido ligands serves to constrain the ancillary ligand set, opening up the geometry about the reactive metal center.

Traditional protocols for attachment of Cp-amido type ligands ("CpSiNR") to early transition metals using dilithio salts of the ligands and the transition metal chlorides are often fraught with disadvantages. In some instances, the protonated ligands are prone to Si—N bond cleavage upon treatment with alkyllithium reagents, leading to low yields of the dilithium salts required for attachment to the transition metal. Yields of these salt elimination reactions can also be highly variable and sensitive to reaction conditions. Furthermore, and this is particularly applicable when M is a group-3 metal, purification of the resulting (CpSiNR)MCl complex can be tedious owing to the difficulty in complete removal of the eliminated salt or the coordinated THF ligands that solubilize the halide starting materials (2*b*).

To circumvent some of these problems Teuben and coworkers (3) drew upon some chemistry originally reported by Chandra and Lappert in the late 1960s (4) that involved amine elimination from metal amides as a means for attaching cyclopentadienyl donors to early transition metals. High-yielding

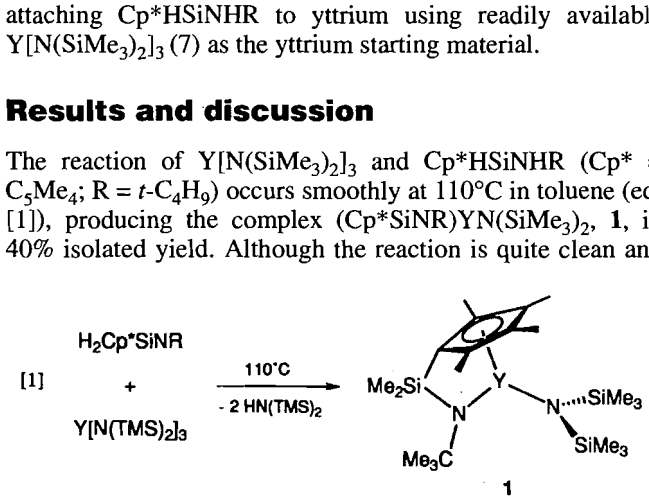
aminolysis reactions between M(NMe_2)$_4$ (M = Zr, Hf) and the ligand $C_5H_5CH_2CH_2CH_2N(H)Me$ were observed (3), producing bis-dimethylamido complexes of this ligand that could be subsequently converted to dichlorides. The generality and utility of this amine elimination strategy for catalyst synthesis is still being mapped out but results so far are clearly promising. For example, Jordan and co-workers (5) have shown that Brintzinger type *ansa*-metallocenes are accessible via this methodology and work from our laboratories indicates that the method is a viable alternative in cases where dilithio salts of ligands are inaccessible and (or) unstable (6).

Some of the problems outlined above were certainly encountered in the reported synthesis of [(Cp*SiNR)ScCl]$_n$, a precursor for hydrocarbyl derivatives with intriguing olefin chemistry (2*b*). We were interested in synthesizing derivatives of yttrium containing ligands of this general type but anticipated that the problems associated with using traditional methods of ligand attachment would be exacerbated in the chemistry of the larger metal. We thus sought a THF and salt-free route and have explored Teuben methodology as a possible alternative. As the chemistry described herein demonstrates, the amine elimination reaction is an effective means of attaching Cp*HSiNHR to yttrium using readily available Y[$N(SiMe_3)_2$]$_3$ (7) as the yttrium starting material.

Results and discussion

The reaction of Y[$N(SiMe_3)_2$]$_3$ and Cp*HSiNHR (Cp* = C_5Me_4; R = *t*-C_4H_9) occurs smoothly at 110°C in toluene (eq. [1]), producing the complex (Cp*SiNR)YN($SiMe_3$)$_2$, **1**, in 40% isolated yield. Although the reaction is quite clean and



1

proceeds nearly quantitatively to **1**, the compound's high solubility in hexanes is responsible for the relatively poor isolated yield. To drive the reaction to completion, it was necessary to periodically remove the eliminated HN($SiMe_3$)$_2$ from the system by evacuating the vessel to dryness, reintroducing solvent, and continuing heating. Other homoleptic amides of yttrium (8) did not prove effective as starting materials for this reaction due primarily, we believe, to the oligomeric nature of such complexes containing smaller amide ligands, such as N(i-C_3H_7)$_2$. Thus, although a more volatile amine product HNR_2 may have been desirable, the N($SiMe_3$)$_2$ group proved to be the best compromise between volatility and steric bulk for this application.

Although the precise structure of Y[$N(SiMe_3)_2$]$_3$ has not been determined, closely related derivatives have been structurally characterized (9) and were found to deviate slightly from trigonal planarity. In all likelihood Y[$N(SiMe_3)_2$]$_3$ is isostructural. ^{1}H NMR experiments monitoring the reaction shown in eq. [1] suggested that it began at room temperature as evidenced by significant quantities of free HN($SiMe_3$)$_2$. Peaks attributable to **1** were not observed until heating commenced, driving the reaction forward. Thus a likely first step in the reaction of Y[$N(SiMe_3)_2$]$_3$ with Cp*HSiNHR involves approach of the sterically more accessible amine proton of the ligand along the more open vacant axial site towards the pyramidalized yttrium center. Amine–amine exchange anchors the Cp*SiNR ligand to the metal and aids in attachment of the cyclopentadienyl moiety to the metal via the chelate effect. That this reaction path is operative is supported by the observation that successful reaction between Cp*H and Y[$N(SiMe_3)_2$]$_3$ required a temperature of 120°C (10) before any reaction was observed.

Clear, white crystals of **1** suitable for X-ray analysis were grown from hexanes; an ORTEP diagram of the molecular structure of **1** is shown in Fig. 1. Crystal data are reported in Table 1, interatomic distances and angles are given in Table 2, and atomic parameters for the heavy atoms are given in Table 3.

The steric requirements of the ligand ensemble in **1** are sufficient to impose mononuclearity on the complex, which can be viewed as assuming a trigonal planar geometry at the yttrium center. The RMS deviation from the least-squares plane fitted to the Cp centroid (Cp_{cent}), Y, N(1), and N(2) is only 0.012 Å. The sum of the angles between yttrium and these vertices is 359.9° although each is necessarily distorted

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

from the ideal 120° due to the chelating nature of the Cp*SiNR ligand. Thus, the Cp_{cent}-Y-N(1) angle is 97.7°, while the bis-trimethylsilylamido ligand is placed so as to minimize steric repulsions between the $SiMe_3$ groups and the methyl groups of the Cp ring (Cp_{cent}-Y-N(2) = 136.6°) and the *tert*-butyl moiety (N(1)-Y-N(2) = 126.6(3)°).

The range of Cp carbon–Y distances of 2.535(9)–2.665(11) Å observed for **1** is on the short end of the "normal" range found in various other structurally characterized complexes of yttrium-containing cyclopentadienyl ligands (11, 12). The Y—N(1) distance of 2.184(7) Å in **1** is short in comparison to Y—N bond lengths in other yttrium silylamide complexes while the Y—N(2) length of 2.255(8) Å is closer to Y—N bond lengths in the two crystallographically distinct molecules in each of Cp*$_2$YN($SiMe_3$)$_2$ (11) (2.274(5) and 2.253(5) Å), and (R)-Me_2SiCp″[(−)-menthylCp]YN($SiMe_3$)$_2$ (12) (2.281(8) and 2.211(8) Å). The shortness of the Y—N bonds in these previously characterized complexes compared to predicted values of ≈2.36 Å (13) was rationalized on the basis of dative π-bonding between the nitrogen lone pair in the unhybridized p-orbital perpendicular to the plane bisecting the Cp donors and an empty orbital of b_1 symmetry that is slightly higher in energy than the in-plane trio of metallocene orbitals usually employed in ligand bonding (14). If one defines the Y–Cp_{cent} vector in **1** as the z-axis, strong π-bonding between Y and N(1) would be expected due to the availability of the metal-based d_{xy} orbital for interaction with the lone pair occupying the N p-orbital since the Cp_{cent}-Y–N(1) angle is only slightly greater than 90° (97.7°). Given the orientation of the N($SiMe_3$)$_2$ ligand with respect to the above-defined coordinate, the nature of the π interaction between Y and N(2) is more difficult to rationalize on a qualitative basis but is clearly significant, as evidenced by the Y—N(2) bond length and the trigonal planar geometry about N(2).

Formally **1** has a maximum electron count of 14 electrons, counting the two amido ligands as contributing four electrons each. The yttrium center should therefore be quite electron deficient. One mechanism by which complexes of this type alleviate electron deficiency is via β-SiC agostic interactions (15, 16). Usually, such interactions skew the N($SiMe_3$)$_2$ ligand in such a way as to bend one of the $SiMe_3$ groups toward the metal center, affording a Ln-N-βSi angle of between 105° and 109° and bringing one of the β-C atoms into close proximity of the metal center (typically 2.88–2.98 Å) (11, 12). As such, the symmetrical metrical parameters observed in the N($SiMe_3$)$_2$ ligand in **1** argue against the presence of any agostic interactions. On the other hand, the C_s symmetry of **1** makes possible a degenerate interaction between the electron-deficient yttrium center and *both* $SiMe_3$ groups. In support of this notion, the $SiMe_3$ groups on the N($SiMe_3$)$_2$ ligand in **1** are eclipsed such that both C(22) and C(32) come into close prox-

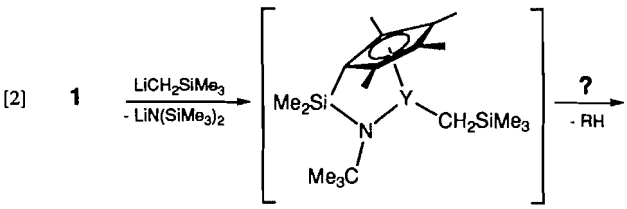
For personal use only.

imity of the yttrium center (Y···C(22) = 3.03 Å; Y···C(32) = 3.05 Å). Also, the two Y-N(2)-Si angles of 111.1(4)°, for Si(2), and 112.1(4)°, for Si(3), are smaller than expected, while the Si(2)-N(2)-Si(3) angle is 136.7(5)°. These values are significantly different from corresponding data (118.4(6), 121.7(6), and 119.9(7)°, respectively) found in a more electron-rich yttrium silylamide containing a 4,13-diaza-18-crown-6 ligand (17) in which the $SiMe_3$ groups assume a more staggered geometry.

Alkylation of **1** with $LiCH_2SiMe_3$ proceeded with selective displacement of the $N(SiMe_3)_2$ ligand (as evidenced by the loss of $LiN(SiMe_3)_2$, ^1H NMR = 0.112 ppm in C_6D_6) but the alkyl complex presumed to be product was not isolable due to thermal instability (eq. [2]). The nature of the organometallic decomposition product(s) was not clear but the presence of ≈1



equivalent of RH in the product mixture was consistent with a product mixture resulting from σ-bond metathesis with ligand or solvent C—H(D) bonds. This is not entirely unexpected since the resulting alkyl complex would be a formally 12-electron complex and therefore extremely electron deficient and reactive. Previously reported scandium congeners were also highly reactive but could be stabilized by PMe_3 (2). This strategy was not successful in this chemistry; alkylation of **1** in the presence of excess PMe_3 led to an intractable mixture from which no well-defined products were isolated.

The amine elimination method is an effective means of attaching Cp-amido type ligands to yttrium. However, at least with the specific ligand employed here, the resulting amide complexes are less amenable to subsequent conversion to catalytically more important alkyl derivatives than their group-4 counterparts. This is, however, likely a function of the Cp*SiNR ligand employed, which does not appear to be sterically bulky enough to prevent facile σ-bond metathesis decomposition pathways in the desired alkyl complexes.

Experimental section

General

General laboratory procedures have been described in detail elsewhere (6). Materials were purchased from Aldrich and used as received. Cp*HSiNHR was prepared using the literature procedure (2*b*) while $Y[N(SiMe_3)_2]_3$ was synthesized by a slightly modified procedure as follows: 1.953 g of YCl_3 (10.0 mmol) and 5.030 g of $LiN(SiMe_3)_2$ (30.0 mmol) were combined with 50 mL of toluene at −78°C. The mixture was allowed to warm to room temperature first, then stirred at 90°C for 3 days. Toluene was removed and the residue was extracted with 50 mL of hexane. The extract was reduced in volume to about 10 mL and cooled to −78°C to let the product crystallize. The crystalline product was collected on a frit, washed with cold hexane, and dried under vacuum; 5.30 g of $Y[N(SiMe_3)_2]_3$ (9.30 mmol, 93.0%) was obtained. ^1H NMR (C_6D_6, ppm): 0.28.

Synthesis of (Cp*SiNR)YN(SiMe$_3$)$_2$, 1

Cp*HSiNHR (0.800 g, 3.18 mmol) was added to a solution of $Y[N(SiMe_3)_2]_3$ (1.600 g, 2.80 mmol) in 10 mL of toluene. The mixture was stirred at 110°C for 4 days. The reaction was pumped to dryness every 24 h to remove the free amine ($HN(SiMe_3)_2$) released from the reaction after which the residue was redissolved in toluene and heating was resumed. After the $Y[N(SiMe_3)_2]_3$ had been totally consumed, toluene was removed and the crude product purified by crystallization from hexane at −78°C; 0.555 g of pure product (1.11 mmol, 40%) was obtained. ^1H NMR (C_6D_6, ppm): 2.10 (6H, CpCH_3), 1.97 (6H, CpCH_3), 1.28 (9H, NC(CH_3)$_3$), 0.72 (6H, Si(CH_3)$_2$), 0.04 (18H, NSi(CH_3)$_3$); $^{13}C\{^1H\}$ NMR(C_6D_6, ppm): 128.4, 124.8 (*C*CH_3), 110.7 (Si-*C*), 53.2 (N*C*(CH_3)$_3$), 36.5 (NC(*C*H_3)$_3$), 14.1, 11.3 (C*C*H_3), 8.2 (Si(*C*H_3)$_2$), 3.0 (NSi(*C*H_3)$_3$)). Anal. calcd. for $C_{21}H_{45}N_2Si_3Y$: C 50.57, H 9.09, N 5.62; found: C 50.50, H 8.47, N 5.16.

Attempted alkylation of (Cp*SiNR)YN(SiMe$_3$)$_2$, 1

(Cp*SiNR)YN($SiMe_3$)$_2$ (100 mg, 0.201 mmol) and $LiCH_2SiMe_3$ (19 mg, 0.202 mmol) were placed in a 50 mL round-bottomed flask. Hexanes (≈20 mL) were condensed into the flask at −78°C. The mixture was allowed to warm to room temperature and stirred for 1 h. Solvent was removed under vacuum to leave a pale-yellow residue. ^1H NMR spectroscopy indicated the presence of $LiN(SiMe_3)_2$ and a complex set of signals for yttrium-containing products. When carried out in an NMR tube (20 mg **1**, 4 mg $LiCH_2SiMe_3$, C_6D_6) almost 1 equivalent of $SiMe_4$ was observed. When the preparative scale reaction described above was performed in the presence of an excess of PMe_3 (≈1 mL), similar results obtained.

X-ray structure of (Cp*SiNR)YN(SiMe$_3$)$_2$, 1

Single crystals were mounted in thin-walled glass capillaries and placed on an Enraf Nonius CAD-4 diffractometer. Unit-cell dimensions were determined via least-squares refinement of the setting angles of 24 high-angle reflections and intensity data were collected using the ω–2θ scan mode. Data were corrected for Lorentz, polarization, and absorption effects but not for extinction. Pertinent data collection and structure refinement parameters are presented in Table 1. The structure was solved using direct methods and all non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were located via difference Fourier map inspection (D_{C-H} = 1.08 Å), given isotropic temperature factors based upon the atom to which they are bonded, and fixed during least-squares refinement. A weighting scheme based upon counting statistics was used with the weight modifier k in kF_o^2 being determined via evaluation of variation in the standard reflections that were collected during the course of data collection. Neutral atom scattering factors were taken from *International tables for X-ray crystallography* (18). Values of R and R_w are given by $R = (F_o - F_c)/EF_o$ and $R_w = [E(w(F_o - F_c))^2/E(wF_o^2)]^{1/2}$. All crystallographic calculations were conducted with the PC version of the NRCVAX program package (19) locally implemented on an IBM compatible 80486 computer. Anisotropic thermal param-

eters and hydrogen atom parameters are available as supplementary material.[2]

A cycloaddition approach to tricyclic taxoid skeletons

Yee-Fung Lu and Alex G. Fallis

Abstract: A cycloaddition approach to the functionalized tricyclo[9.3.1.$0^{3,8}$]pentadecene skeleton contained in Taxol® is described. The cyclohexenone **13** was converted as illustrated to the nitrile-aldehyde **24** to which the diene and acetylenic side chains were attached by sequential nucleophilic additions. Removal of the trimethylsilyl protecting group and Dess–Martin oxidation afforded the triene **35**. Microwave-assisted thermal cyclization stereoselectively generated the tricyclic ketone **36** whose structure was further established by conversion to the aromatic system **37** upon treatment with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). An epoxidation sequence was developed to introduce the epimeric C13 alcohol **47** as required for this cycloaddition strategy. Alternatively, an allylic oxidation (CrO_3, 3,5-dimethylpyrazole) afforded the C13 ketone **49**.

Key words: Taxol®, Diels–Alder, synthesis, diterpene, alkaloid.

Résumé : On décrit une approche, impliquant une cycloaddition, au squelette du tricyclo[3.3.1.$0^{3,8}$]pentadécène fonctionnalisé contenu dans le Taxol®. Tel que représenté dans le diagramme 1, on transforme la cyclohexénone **13** en nitrile-aldéhyde **24** auquel on attache les chaînes latérales diénique et acétylénique par une séquence d'additions nucléophiles. Après enlèvement du groupe protecteur triméthylsilyle et oxydation de Dess–Martin, on a obtenu le triène **35**. Une cyclisation thermique sous l'effet de micro-ondes a fourni stéréosélectivement la cétone **36** dont la structure a été reconfirmée par conversion en système aromatique **37** par traitement avec de la 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). On a développé une séquence d'époxydations (diagramme 2) qui permet d'introduire l'alcool épimère en C_{13} (**47**) qui est requis par cette stratégie de cycloaddition. D'une manière alternative, une oxydation allylique (CrO_3, 3,5-diméthylpyrazole) a fourni la cétone en C_{13}, **49**.

Mots clés : Taxol®, Diels–Alder, synthèse, diterphène, alcaloïde.

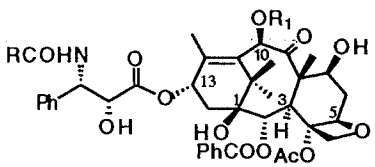
Introduction

The potent antitumor agent paclitaxel (Taxol,® **1**) was approved for the treatment of ovarian and breast cancer in 1993. This was more than 20 years after its structure was initially reported (1), and more than 30 years after its cytotoxicity was first detected. The medicinal potential for the taxoid family is further illustrated by the fact that a semi-synthetic analog, docetaxel (Taxotere,® **2**), is in final clinical trials and also



1 Taxol® R = Ph, R_1 = Ac
2 Taxotere® R = tBuO, R_1 = H

shows considerable therapeutic promise (2) (approved in Canada in September 1995). These compounds belong to a new class of antitumor drugs that interfere with the normal microtubule–tubulin cascade prior to cell division (3). This novel mode of action, plus the significant synthetic challenge presented by the sterically congested multicyclic structure, has stimulated worldwide interest in these molecules (4). Recently two groups reported total syntheses of taxol itself (5, 6). In spite of this success much remains to be investigated and over the next decade it is likely that simpler analogues with a better therapeutic profile will be synthesized and become useful pharmaceutical products. They will thus follow the path from natural products to medicine established earlier for penicillins, tetracyclines, etc., a path that depends upon improved knowledge of structure–activity relationships, the development of efficient synthetic and (or) semi-synthetic routes to the functionalized tricyclo[9.3.1.$0^{3,8}$]pentadecene nucleus, and the development of medicinally interesting analogs that possess a better therapeutic profile than paclitaxel itself.

Thus, synthetic interest int his area continues unabated and several recent reviews summarize the progress that is being achieved and the diversity of synthetic approaches that are under development (4). In this paper we describe an intramolecular Diels–Alder approach that proceeds in the left-to-right direction (ring A to BC). Commencing with a ring A cyclohexene building block, the sequence relies on a cycloaddition reaction to construct the B and C rings simultaneously. This strategy is hlghly convergent, and leads to the functionalized

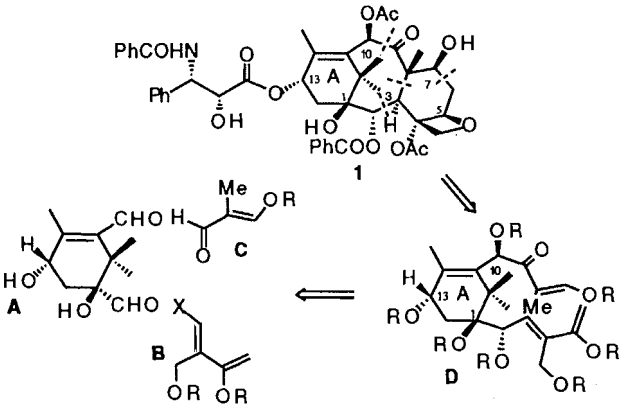
Scheme 1. Convergent ring C Diels–Alder approach.



tricyclo[9.3.1.$0^{3,8}$]pentadecene skeleton in which the C2 epimer controls the adduct stereochemistry.

Synthetic strategy

In a retrosynthetic sense removal of the ring D oxetane followed by a double disconnection between C6—C7 and C3—C8 in ring C suggests a precursor related to the tetraene **D** (Scheme 1). In principle this intermediate could contain the majority of the Taxol® oxygen substituents, although in practice the use of less substituted systems may be more prudent. Construction of **D** may be envisaged in a direct manner from further disconnections between C2—C3 and C9—C10. In total, this leads to a highly convergent approach to the taxane nucleus from a suitably functionalized ring A synthon in the form of a masked dialdehyde synthon related to **A**, followed by attachment of the lower diene and upper dienophile units **B** and **C**, respectively. Subsequently, intramolecular Diels–Alder cycloaddition could afford the carbocyclic nucleus. However, several additional aspects must also be considered for this approach to have a reasonable chance of success.

Other research groups have also examined the potential utility of an intramolecular [4+2] cycloaddition to generate the tricyclic skeleton. In independent studies, Bonnert and Jenkins (7) as well as Shea and co-workers (8) generated the A ring with the bridgehead double bond in place, as illustrated in general terms in Scheme 2. Unfortunately, a recent study reported that the *gem* dimethyl bridge in the adduct does not have the correct orientation in a more highly functionalized example (i.e., epimeric at C1) (9), and a related bis-normethyl system behaved similarly (10). The C ring had been constructed previously from a bicyclo[2.2.2]octene precursor by Sakan and Craven (11). It was assumed that the rigid geometry imparted by this bicyclic framework was required to hold the diene in an axial orientation. This allows the close proximity of the reactive components in order to achieve the proper alignment for the cyclization transition state and overcome the entropic difficulties associated with a conformationally mobile ring system such as a cyclohexene. In addition, the formation of sterically congested cyclooctanes via [4+2] cycloadditions is known to be difficult (12). However, it was not clear whether the one-carbon bridge between the C13 center and the C17 methyl group is essential for a successful intramolecular cyclization in this series.

The conformer population in cyclohexenes is known to vary with the substitution pattern (13). Thus, the potential 1,3-diax-

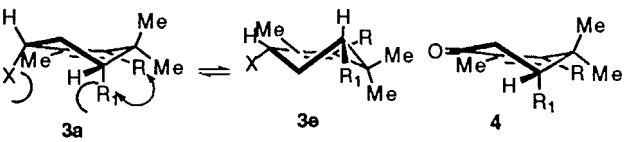
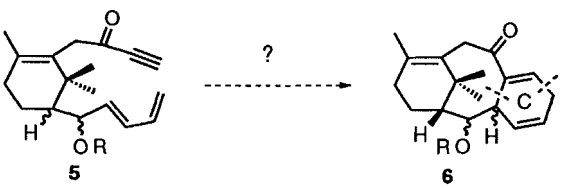


Scheme 4. Ring C construction with acetylenic dienophile.



ial interaction (C—X versus C—R_1) in **3a** (Scheme 3) must be overcome if the reactive components represented by R and R_1 are to cyclize, since the equatorial conformer **3e** does not allow the two side chains to interact significantly. However, this limitation should not cause undue difficulty provided the reactive conformer makes up a reasonable percentage of the equilibrium mixture at the temperature selected. In addition, it will help if the cyclization step is sufficiently rapid that few collisions are required. When X = H the 1,3-interaction should be relatively minor and this will disappear entirely if a cyclohexenone such as **4** is employed. Nevertheless, there is a limitation to this approach for the total synthesis. The natural α orientation of the C13 ester side chain will increase the nonbonded interactions in the required conformer **3a** (X = OR). Thus for the Diels–Alder step to proceed, either the unnatural C13 epimer or the C13 ketone may have to be employed and the synthon **A** modified accordingly (Scheme 1). Consistent with this analysis, molecular mechanics calculations[2] indicated that 1,2,3,3,4-pentamethylcyclohexene preferred a conformation related to **3a** in which a slight twist minimized any 1,3-methyl-hydrogen interference. Therefore, additional ring constructions should not be required to access the transition state geometry for ring C directly when the diene and dienophile are attached to a cyclohexene. To further encourage the cycloaddition, the rotational parameters normally encountered with olefinic partners were minimized by selecting an acetylenic dienophile as illustrated in **5** (Scheme 4). Inherent in the transformation **5** to adduct **6** are several additional questions that require solution. These include the π-facial selectivity of

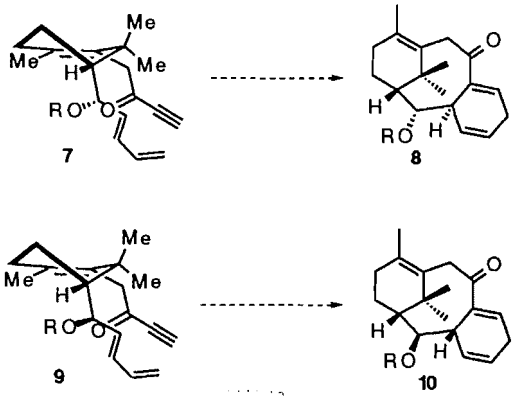
Scheme 5. Transition states for C_2 epimers.



the cycloaddition and the influence of the C2 substituent on the transition states. These considerations are illustrated in Scheme 5 for the transition states of the C2 epimers **7** and **9**. This suggests that the orientation of this C2 group will determine the facial preference of the cycloaddition and hence the resultant stereochemistry of C3 in the adduct. The validity of these analyses have been demonstrated below by the synthesis of the tricyclic taxane nucleus **36** and the related aromatic system **37** (preliminary communication, ref. 14).

Results and discussion

To ascertain the practicality of this plan the carbonyl groups in Hagemann's ester (**11**) were reduced with DIBAL (diisobutylaluminum hydride) in benzene (Chart 1), the allylic alcohol oxidized with DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone), and the remaining primary alcohol protected as a *tert*-butyldimethylsilyl ether to afford the cyclohexenone **13** (15). Treatment of cyclohexenone **13** with methylmagnesium bromide in the presence of cuprous iodide, followed by the addition of methylorthoformate mediated by boron trifluoride etherate, afforded the keto-acetal **14** in 59% yield (Chart 1). Alternatively this compound was prepared in a two-step

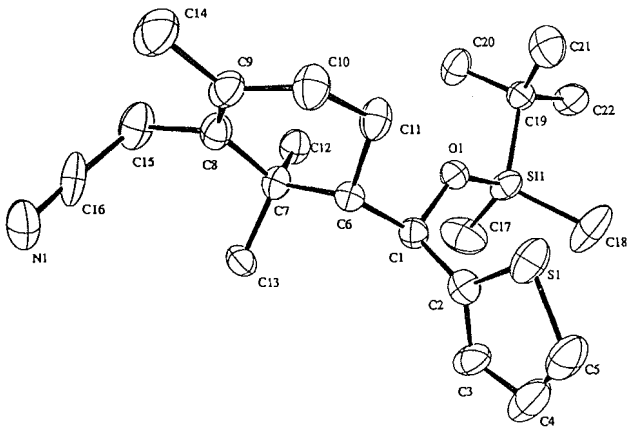
Fig. 1. A view of 1-(2-thiophenyl)methyl-2-cyanomethyl-1,3,3-trimethylcyclohexene (**30**).

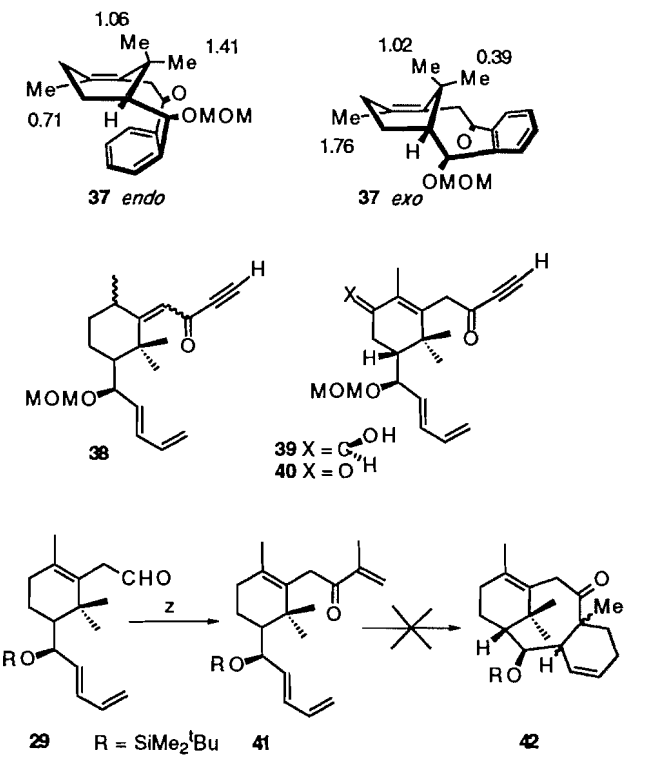


sequence via the intermediacy of the trimethylsilyl enol ether **17** and methylorthoformate in the presence of titanium tetrachloride. Addition of methyllithium to the carbonyl group in **14** allowed preparation of the tertiary alcohol **15**, or it could be alkylated directly in the presence of added HMPA (hexamethylphosphoramide) to give the trimethoxy ether **16**. Trimethylsilyliodide generated in situ (16) released the aldehyde function (i.e., **19**) so that direct treatment with base led to elimination of methoxide ion and the formation of the cyclohexene aldehyde **20** in 70% overall yield from **16**.

Reduction of aldehyde **20** ($NaBH_4$, $CeCl_3$, 70%) provided the alcohol **21** accompanied by a small amount of the less substituted endocyclic isomer (ratio 12:1). Alternatively, this alcohol could be prepared directly from **16** by sequential treatment with trimethylsilyl chloride, sodium iodide, sodium methoxide, and sodium borohydride – cerium trichloride. Chain extension to the nitrile **22** was accomplished by cyanide displacement (NaCN, methyl pyrrolidinone, 75%) of the primary bromide generated from the alcohol upon treatment with Ph_3PBr_2, Et_3N in CH_2Cl_2 at −78°C for 1 h. Removal of the silyl protecting group with fluoride ion (n-Bu_4NF, THF, 21°C, 3 h, 98%) followed by Swern oxidation (DMSO, $(COCl)_2$, Et_3N, CH_2Cl_2, −78°C, 94%) afforded the aldehyde **24**. The required nucleophilic diene unit was prepared by transmetallation of E-1,3-(1-tributylstannyl)butadiene (17) with n-BuLi and added to the aldehyde **24** (THF, −78°C, 0.5 h, 96%). From direct analysis of the resulting secondary alcohol (6:1 diastereomer ratio) it was not possible to determine which of the isomers corresponded to the Taxol® stereochemistry at C2. The stereochemistry was determined by condensation of 2-lithiothiophene with aldehyde **24**, followed by silylation with tert-butyldimethylsilyl chloride, to give the crystalline derivative **30**. X-ray determination showed the major isomer to have the opposite stereochemistry (C1—C2) to Taxol® as shown (Fig. 1). Alcohol **25** was assigned the same relative stereochemistry by analogy and comparison of spectral data and, as outlined, this isomer was used for subsequent experiments.

The secondary alcohol in **25** was protected as either a methoxymethyl ether (MOMCl, $(iPr)_2EtN$, CH_2Cl_2, 90%) or, alternatively a *tert*-butyldimethylsilyl ether to afford **26** and **27**, respectively. Diisobutylaluminum hydride reduction of the nitrile group in these compounds provided the corresponding aldehydes **28 and 29**. In a parallel, but independent, manner, these aldehydes were treated with lithium trimethylsilylacetylide (HCCTMS, n-BuLi, THF, −78°C, 95%) and then transformed into the desired ketones by oxidation either before or after removal of the trimethylsilyl group. These apparently straightforward operations were surprisingly challenging. Removal of the trimethylsilyl group from the acetylenic ketones proved very difficult in contrast to the ease with which this bond cleavage was affected on the acetylenic alcohol. Thus it was important to remove the trimethylsilyl group (KOH, MeOH, CH_2Cl_2, 21°C, 99%) at the alcohol stage on compound **33**. Only the Dass–Martin periodinane oxidation method (18), of several examined, generated the required ketone **35** in reasonable yield (55%). Attempted cycloadditions with ketones **31**, **32**, and the ketone derived from **33** all failed under the various conditions examined.

Fortunately, cyclization of ketone **35** could be affected by heating a 0.05 M toluene solution containing 1% mol-equiv. hydroquinone in a sealed glass tube in a modified microwave oven (19) for 10 h to afford the tricyclic system **36** stereoselectively in yields of 30–40%. This major adduct arose via the preferred transition state in which the nonbonded interactions were minimized due to the alignment of the dienophile under the triene remote from the MOM substituent as illustrated in **35**. This pattern of π-facial selectivity was consistent with related intermolecular cycloadditions involving acetylenes and acylic dienes (20) and implies that with the "natural" C2 stereochemistry the preferred geometry will resemble **7** and should provide the relative stereochemistry illustrated in **8** as required for Taxol® itself. The structural assignment of the adduct **36** was further established on the basis of its ^1H NMR spectrum, in which the C3 proton appeared at δ 2.95 as a doublet of doublets (J = 5.6, 9.6 Hz) due to coupling with the adjacent vinylic C4 and secondary C2 hydrogens.[3] Confirmation



[3] In addition to adduct **36**, the minor adduct epimeric at C3 was also formed (5–7%). This arose from the approach of the addends from the opposite face.

of the tricyclo[9.3.1.$0^{3,8}$]pentadecatriene skeleton was provided by the conversion of **36**, upon treatment with DDQ in refluxing benzene, to the aromatic ketone **37**. In keeping with related literature examples, this material existed as a mixture of exo and endo isomers (~1:1) (21) in which the vinyl methyl signal appeared at 0.71 (endo) or 1.76 (exo) depending upon the orientation of the benzene ring.

Unfortunately, it was not possible to catalyze the cycloaddition with Lewis acids, due to the ease with which the cyclohexene double bond migrated into conjugation with the acetylenic ketone and afforded the complex mixture of isomers represented by **38**. These components accounted for some of the uncyclized material in the thermal reaction. It is anticipated that, with the C13 ketone in place as in ketone **43** (Taxol® numbering), the cyclohexenone will help suppress this tendency for bond migration, flatten the ring, and reduce the axial interaction, and should lead to improved yields. Alternatively, the epi-C13 alcohol **39** is a potential Diels–Alder precursor, and a route to a suitable ring A building block is described below.

The direct introduction of the C8-methyl was also examined. Thus vinyl anion addition to aldehyde **29**, followed by Swern oxidation, afforded **41**. Unfortunately, this material could not be induced to undergo an intramolecular cycloaddition. The failure of the attempted cyclizations with **32** and **41** appears to be a consequence of the large protecting group attached to the C2 alcohol. Thus nonbonded interactions between this substituent and the germinal methyls inhibit attainment of the requisite geometry for cycloaddition. It remains to be established whether adducts of type **42** can be generated if different protecting groups and stereochemical combinations are employed.

An important feature of taxol itself is the C13 oxygen side chain. The requisite oxygen may be installed directly by allylic oxidation as illustrated by the **22** to **49** conversion (Chart 2). It is of interest that in spite of modest yields the reaction is clean and yields are 65–70% based on the recovered starting material. In addition, no oxygen was introduced at the position corresponding to C10 in Taxol® (6, 22, 23). A suitable synthon for the epimeric C13 alcohol (**47**) was prepared from the acetal **15**. Dehydration of this material was affected with thionyl chloride and pyridine to provide **43** and the major isomer **44** with the endocyclic double bond (1:3). This is a consequence of the relative stereochemistry in **15** and the favorable trans diaxial elimination that arises from the preferred conformation **50**. Thus the axial proton adjacent to the germinal methyl groups (H_a) is in a sterically encumbered environment and elimination from the other side (H_b) or the methyl group is more facile. The major isomer **44** was treated with acid to hydrolyze the acetal to give **45**, and oxidation of **45** with dioxirane provided the epoxide **46**, with the oxirane trans to the bulky silyl ether. Treatment with sodium methoxide in refluxing methanol installed the double bond and generated the secondary alcohol **47**, which was characterized as the silyl derivative **48**. This provided a direct route to epi-C13 precursors as required, based on the stereochemical analysis in the introduction. Stork and co-workers (24) have developed a different preparation of epimeric C13 ring A alcohol intermediates.

In conclusion, a carefully designed [4+2] cycloaddition strategy with an acetylenic dienophile can be employed to generate the substituted taxane nucleus directly, with good stereochemical control, in a convergent manner from a functionalized

Chart 2. Oxygen introduction at C13.

cyclohexene substrate. We are currently extending these results toward the total synthesis of Taxol® and the preparation of therapeutically promising analogs, using more highly oxygenated precursors, in which the C13 ketone and "natural" C2 epimer are expected to facilitate and control the cyclization.

Experimental section

Melting points were determined in capillary tubes with a Thomas–Hoover Unit-Melt apparatus and are uncorrected. Infrared (IR) spectra were recorded on a Perkin–Elmer 783 spectrometer or a Bomem MB 100 FTIR spectrometer. Proton magnetic resonance spectra (^{1}H NMR) were measured at 60 MHz with a Varian spectrometer or at 200 MHz with a Varian Gemini spectrometer or at 300 MHz with a Varian XL-300 spectrometer in deuterochloroform unless otherwise stated. Carbon magnetic resonance spectra (^{13}C NMR) were measured at 50 MHz (Varian Gemini) or at 75 MHz (Varian XL-300). Chemical shifts are reported in ppm downfield from tetramethylsilane (δ scale). The multiplicity, number of protons, and coupling constants are indicated in parentheses. Mass spectra (MS) were determined on a VG micromass 7070 HS instrument using an ionization energy of 70 eV. Gas chromatograph – mass spectral (GC–MS) analyses were determined on a Hewlett–Packard 5890 Series II gas chromatograph – 5971A Mass Selective Detector equipped with a 12.5 m capillary column (0.2 mm i.d.) coated with cross-linked dimethylsilicone (0.33 μm). Elemental analyses were conducted by M-H-W Laboratories, Phoenix, Ariz. Analytical thin-layer chromatography (TLC) employed commer-

cial aluminum sheets precoated (0.2 mm layer thickness) with silica gel 60 F_{254} (E. Merck). Flash column chromatography using E. Merck silica gel 60 (70–230 or 230–400 mesh) was employed for all column chromatography. The purity of all title compounds was judged to be >95% as determined by a combination of GC—MS, ^{1}H NMR, and ^{13}C NMR analyses.

Petroleum ether refers to a fraction with boiling range 30–60°C. Anhydrous diethyl ether (ether) and diisopropylamine were obtained by distillation from $LiAlH_4$ and anhydrous tetrahydrofuran (THF) from potassium–benzophenone. Absolute methanol and ethanol were dried by distillation from magnesium. Dry benzene, dimethylformamide (DMF), and carbon tetrachloride (CCl_4) were prepared by distillation from phosphorus pentoxide. Anhydrous hexamethylphosphoramide (HMPA) was obtained by distillation from calcium hydride, and acetone was dried by distillation from anhydrous K_2CO_3. Dioxane was distilled from $LiAlH_4$ and stored over Linde type 4A molecular sieves. CuI (99.99%, Aldrich) was purified by repeated Soxhlet extraction with THF and dried (80°C) under vacuum for 7 h. Solutions in organic solvents were dried over anhydrous magnesium sulfate or anhydrous sodium sulfate and stripped of solvents with a Büchi rotatory evaporator connected to a water aspirator. Unless otherwise stated, all reactions were conducted under at atmosphere of dry nitrogen in flame-dried flasks equipped with a magnetic stirring bar and rubber septa.

X-ray measurements were made on a Rigaku diffractometer with Mo Kα radiation at −158°C using the ω–2θ technique to a maximum 2θ value of 46.9. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement using the setting angles of 25 reflections in the range $40 < 2\theta < 47$ corresponding to an orthorombic cell for compound **30** ($C_{22}H_{35}NOSSi$) with dimensions $a = 22.055$, $b = 9.031$, $c = 23.593$ Å. For $Z = 8$ and FW = 389.67, the calculated density is 1.102 g/cm^3. Based on the systematic absences, the space group was *Pbcn*. The data (3479 reflections) were collected for Lorentz and polarization effects (25). The structure was solved by direct methods all atoms refined except hydrogen. The hydrogen atoms were calculated by assuming a distance of 1.07 Å. The final cycle of full-matrix least-squares refinement was based on 1852 observed reflections ($I > 2.5\ \sigma(I)$) and 236 variable parameters using weights based on counting statistics. The maximum and minimum peaks on the final differences Fourier map were 0.55 and −0.47 e/Å^3, respectively. All calculations were performed using the NRCVAX crystallographic software package (26).[4]

4-Hydroxymethyl-3-methyl-2-cyclohexene-1-ol

Diisobutylaluminium hydride (1 M solution in toluene, Aldirch, 16.5 mL, 16.5 mmol) was added dropwise to a cold (0°C) solution of Hagemann's ester **11** (1.0 g, 5.5 mmol, Aldrich) in benzene (5 mL) and the mixture stirred at 0°C for 2 h, followed by a further hour at 21°C. The aluminum salts were decomposed at 0°C by dropwise addition of excess methanol (20 mL). The resulting white precipitate was removed by filtration and washed several times with hot methanol. The combined filtrate and washings were evaporated to give a thick oil plus a gel-like precipitate that was removed by a second filtration. The crude product was chromatographed (acetone/petroleum ether; 1:1) to afford the diol (770 mg, 98%). In subsequent experiments the initial product was used directly. IR (neat): 3350, 1660 cm^{-1}; ^{1}H NMR (200 MHz) δ: 5.65 (m, 1H), 4.16 (br s, 1H), 3.79 (m, 2H), 1.79 (s, 3H), 2.15 (m, 1H), 1.5–2 (m, 6H). ^{13}C NMR (50.3 MHz) δ: 136.8, 127.7, 65.3, 63.2, 41.4, 30.6, 29.3, 21.4. HRMS calcd. for $C_8H_{12}O$ ($M^+ - H_2O$): 124.0888; found: 124.0890.

4-Hydroxymethyl-3-methyl-2-cyclohexen-1-one (12)

The diol above (3.80 g, 26.8 mmol) was dissolved in dry dioxane (10 mL) and a dioxane solution of dichlorodicyanoquinone (7.92 g, 34.9 mmol, Aldrich) was added dropwise by syringe. The reaction was stirred at 21°C overnight (23 h, reaction complete by TLC). The reaction was concentrated, diluted with ether, filtered through Celite, and washed several times with ether until the washings were colourless. Concentration of the crude filtrate and chromatography (20% acetone – petroleum ether) on alumina (basic or neutral) gave the ketone **12** (3.5 g, 92%). IR (neat): 3300, 1665 cm^{-1}; ^{1}H NMR (200 MHz) δ: 5.92 (s, 1H), 3.79 (m, 2H), 1.98 (s, 3H); ^{13}C (50.3 MHz) δ: 199.5, 162.1, 128.5, 70.0, 42.1, 34.2, 24.9, 22.7. Anal. calcd. for $C_8H_{12}O_2$: C 68.54, H 8.62; found: C 67.91, H 8.70.

4-(*tert*-Butyldimethylsilyloxy)methyl-3-methyl-2-cyclohexen-1-one (13)

The alcohol **12** (0.97 g, 6.8 mmol) was dissolved in DMF (2 mL), imidazole (1.16 g, 17.0 mmol) and *tert*-butyldimethylsilyl chloride (1.23 g, 8.18 mmol, Aldrich) were added, and the mixture was stirred overnight (23 h) at 21°C. The reaction was diluted with ether and the combined organic extracts were washed with small portions of water (2 × 2 mL) and brine, dried, filtered, and concentrated. Chromatography (ethyl acetate/petroleum ether; 1:20) gave **13** (1.7 g, 98%). IR (neat): 1675 cm^{-1}; ^{1}H NMR (200 MHz) δ: 0.02 (s, 6H), 0.85 (s, 9H), 2.02 (m, 2H), 2.39 (m, 3H), 3.72 (d, 2H, $J = 5.5$ Hz), 5.87 (s, 1H); ^{13}C NMR (50.3 MHz) δ: −5,3 (2C), 17.8, 22.7, 25.1, 25.5 (3C), 34,3, 42.7, 63.3, 128.1, 162.5, 199.4. HRMS calcd. for $C_{10}H_{17}O_2Si$ ($M^+ - C_4H_9$): 197.0998; found: 197.1013. Anal. calcd. for $C_{14}H_{26}O_2Si$: C 66.08, H 10.3; found: C 65.91, H 9.51.

4-(*tert*-Butyldimethylsilyloxy)methyl-3,3-dimethyl-2-formyl(dimethylacetal)cyclohexanone (14)

A solution of methyl magnesium bromide (5.14 mL, 7.71 mmol, 1.5 M) in toluene – direthyl ether was added to a cold (0°C), stirred suspension of cuprous iodide (100 mg, 0.52 mmol) in dry diethyl ether (50 mL). After the reaction mixture had been stirred at 0°C for 10 min, a solution of the enone **13** (1.31 g, 5.14 mmol) in dry diethyl ether (2 mL) was added dropwise. The resulting light yellow mixture was stirred at 0°C for 30 min and then cooled to −78°C. Trimethyl orthoformate (5.62 mL, 51.4 mmol) and boron trifluoride etherate

[4] Tables of atomic parameters, anisotropic temperature factors, bond lengths and angles, and torsion angles have been deposited and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6. The tables of atomic parameters and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

(3.16 mL, 25.7 mmol) were syringed sequentially into the cold reaction mixture. After stirring for 5 min at −78°C, the solution was warmed to 0°C for 2 h. Saturated ammonium chloride solution was added and the mixture was extracted with diethyl ether. The combined ether extracts were washed with brine, dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 3:1) to afford 1.05 g (59%) of the ketal **14**. IR (neat): 2970, 1720, 1475, 1120, 880, 780 cm^{-1}; ^1H NMR (200 MHz) δ: 0.02 (s, 6H), 0.78 (s, 3H), 0.86 (s, 9H), 1.04 (s, 3H), 1.45–1.70 (m, 1H), 2.00–2.60 (m, 5H), 3.27 (s, 3H), 3.29 (s, 3H), 3.42 (t, 1H, J = 10 Hz), 3.85 (dd, 1H, J = 4, 10 Hz), 4.71 (d, 1H, J = 7 Hz); ^{13}C NMR (50.3 MHz) δ: −5.7 (2C), 17.9, 22.9, 25.6 (3C), 25.9, 26.0, 38.1, 40.0, 43.2, 52.6, 53.1, 63.3, 64.7, 101.9, 210.6; HRMS calcd. for $C_{14}H_{27}O_4Si$ ($M^+ - C_4H_9$): 287.1679; found: 287.1680. Anal. calcd. for $C_{18}H_{36}O_4Si$: C 62.75, H 10.53; found: C 62.83, H 10.43.

Minor products from this reaction were
*4-(*tert*-Butyldimethylsilyloxy)methyl-3,3-dimethylcyclohexanone*: IR (neat): 2960, 1720, 1475, 1260, 1105, 840, 780 cm^{-1}; ^1H NMR (200 MHz) δ: 0.03 (s, 6 H), 0.81 (s, 3H), 0.87 (s, 9H), 1.05 (s, 3H), 1.55–1.84 (m, 2H), 2.02–2.41 (m, 5H), 3.45 (dd, 1H. J = 7.8, 10 Hz), 3.82 (dd, 1H, J = 3.8, 10 Hz); ^{13}C NMR δ: 212.0, 63.3, 55.1, 47.0, 40.0, 37.2, 30.3, 25.6, 25.4, 22.0, 18.3, −5.7; HRMS calcd. for $C_{15}H_{30}O_2Si$ ($M^+ - C_4H_9$): 213.1310; found: 213.1266.
*4-(*tert*-Butyldimethylsilyloxy)methyl-1-(dimethoxy)oxy-3,3-dimethylcyclohex-1-ene* (**18**): IR (neat): 2960, 1600, 1480, 1100, 840, 780 cm^{-1}; ^1H NMR (200 MHx) δ: 0.03 (s, 6H), 0.82 (s, 3H), 0.88 (s, 9H), 1.06 (s, 3H), 1.35–1.50 (m, 2H), 1.80–1.95 (m, 1H), 2.05–2.15 (m, 2H), 3.34 (s and overlapping dd, 7H), 3.74 (dd, 1H, J = 4, 10 Hz), 4.62 (s, 1H), 5.35 (s, 1H).

Alternative preparation of 14 via 4-(*tert*-butyldimethylsilyloxy)methyl-3,3-dimethyl-1-trimethylsilyloxycyclohex-1-ene (17)

A solution of methyl magnesium bromide (0.48 mL, 0.072 mmol, 1.5 M) in toluene – diethyl ether was added to a cold (0°C), stirred suspension of cuprous iodide (0.01 g), in dry diethyl ether (4 mL). After stirring the reaction for 10 min at 0°C, a solution of enone **13** (0.122 g, 0.48 mmol) in dry diethyl ether (1 mL) was added dropwise. After 30 min at 0°C, triethyl amine (0.20 mL, 1.43 mmol) and trimethylsilyl chloride (0.12 mL, 0.95 mmol) were added sequentially. The reaction was stirred for 1 h at 0°C, warmed to 21°C, and stirring was continued for a further 4 h. A few drops of aqueous saturated ammonium chloride were added and the solution filtered through a short column of sand (1 g). The filtrate was concentrated, chromatographed on Florisil (petroleum ether/ether; 30:1), and the eluent concentrated to afford the enol silyl ether **17** (0.117 g, 71%). IR (neat): 2930, 1250 cm^{-1}; ^1H NMR (200 MHz) δ: 0.01 (s, 6H), 0.14 (s, 9H), 0.78 (s, 3H), 0.86 (s, 9H), 1.02 (s, 3H), 1.37–1.42 (m, 2H), 1.83–1.92 (m, 1H), 1.93–1.96 (m, 2H), 3.30 (dd, 1H, J = 8.7, 9.2 Hz), 3.72 (dd, 1H, J = 3.8, 9.9 Hz), 4.54 (br s, 1H); HRMS calcd. for $C_{18}H_{38}O_2Si_2$ (M^+ − Me): 327.2186; found: 327.2184.

Trimethyl orthoformate (0.78 mL, 7.10 mmol) and titanium tetrachloride (0.20 mL, 1.80 mmol) were syringed sequentially into a cold (−78°C), stirred solution of enolsilyl ether (0.229 g, 0.670 mmol) in dry dichloromethane (7 mL). The reaction mixture was stirred at 0°C for 1 h. Saturated ammonium chloride solution was added and the mixture was extracted thoroughly with diethyl ether. The combined ether extracts were washed (saturated $NaHCO_3$ solution, brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 3:1) to afford 0.126 g (55%) of the ketal **14**.

1-Hydroxy-2-formyl(dimethylacetal)1,3,3-trimethyl-4-*tert*-butyldimethylsilyloxycyclohexane (15)

A 1.5 M solution of methylmagnesium bromide (2.0 mL, 3.0 mmol) in toluene – diethyl ether was added dropwise to a cold (0°C), stirred solution of the ketone **14** (0.713 g, 2.07 mmol) in dry diethyl ether (10 mL). The resulting mixture was stirred at 0°C for 10 min and then warmed to 21°C for 30 min. Saturated aqueous ammonium chloride solution was added and the mixture was extracted thoroughly with diethyl ether. The combined ether extracts were washed with brine and dried. Removal of the solvent afforded 0.708 g (95%) of the alcohol **15**. IR (neat): 3560, 2960, 1090, 840, 780 cm^{-1}; ^1H NMR (200 MHz) δ: 0.01 (s, 6H), 0.86 (s, 9H), 1.00 (s, 3H), 1.15 (s, 3H), 1.29 (s, 3H), 1.30–1.65 (m, 4H), 1.90–2.10 (m, 2H), 3.34 (s, 3H), 3.47 (s, 3H), 3.55–3.75 (m, 2H), 3.98 (br s, 1H), 4.43 (s, 1H); ^{13}C NMR (50.3 MHz) δ: −5.8, −5.7, 17.9, 19.6, 25.7 (3C), 26.2, 28.4, 31.6, 34.6, 35.9, 47.4, 51.3, 55.8, 56.7, 62.2, 72.0, 109.6. Anal. calcd. for $C_{19}H_{40}O_4Si$: C 63.28, H 11.18; found: C 63.34, H 11.1.

1-Methoxy-2-formyl(dimethylacetal)-1,3,3-trimethyl-4-*tert*-butyldimethylsilyloxycyclohexane (16)

A solution of methyllithium (7.90 mL, 11.1 mmol, 1.4 M) in diethyl ether was added dropwise to a cold (0°C), stirred solution of the acetal **14** (2.50 g, 7.26 mmol) in dry diethyl ether (35 mL). After the reaction mixture has been stirred at 0°C for 30 min, hexamethylphosphoramide (2.52 mL, 14.5 mmol) and methyl iodide (1.80 mL, 28.9 mmol) were added sequentially. The resulting mixture was stirred at 0°C for 1 h and warmed to room temperature overnight (16 h). Water was added and the mixture was extracted thoroughly with diethyl ether. The combined ether extracts were washed (saturated sodium bicarbonate, water, and brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 9:1) to afford 2.07 g (76%) of the trimethoxy compound **16** and 0.418 g (16%) of the alcohol **15** (see below). IR (neat): 2950, 1470, 1260, 1200, 1080, 840, 780 cm^{-1}; ^1H NMR (200 MHz) δ: 0.00 (s, 6H), 0.85 (s, 9H), 1.00 (s, 3H), 1.18 (s, 3H), 1.19 (s, 3H), 1.30–1.80 (m, 6H), 3.10 (s, 3H), 3.32 (s, 3H), 3.36 (s, 3H), 3.54 (t, 1H, J = 10 Hz), 3.73 (dd, 1H, J = 10, 5 Hz), 4.65 (d, 1H, J = 4 Hz); ^{13}C NMR (50.3 MHz) δ: −5.7, −5.6, 18.0, 18.5, 25.0, 25.7 (3C), 26.4, 28.7, 28.9, 35.5, 47.8, 48.7, 54.7, 56.1, 61.2, 75.8, 108.4. Anal. calcd. for $C_{20}H_{42}O_4Si$: C 64.12, H 11.30; found: C 64.19, H 11.47.

Methyllithium (9.34 mL, 13.08 mmol) was added to a solution of **15** (3.0 g, 8.7 mmol) in ether (50 mL) at 0°C. HMPA (3.03 mL, 17.44 mmol) was added, followed by MeI (1.08 mL, 17.4 mmol), the reaction mixture was allowed to warm to 22°C, and stirring was continued overnight. The reaction was quenched with water and washed several times with saturated aqueous NH_4Cl solution, dried, and concentrated. Chromatography (5% Et_2O – petroleum ether) gave **16** in 94% yield.

2-Formyl-1,3,3-trimethyl-4-*tert*-butyldimethylsilyloxymethycyclohex-2-ene (20)

Method I

Propylene was bubbled through a solution of **16** (650 mg, 1.7 mmol) in CH_2Cl_2 (3 mL) at 21°C. NaI (279 mg, 1.86 mmol) was added, followed by trimethylsilyl chloride (0.24 mL, 1.86 mmol), and stirring was continued for 5 min. The reaction was quenched with water, and washed with water, aqueous 6% $Na_2S_2O_4$, and brine. The organic layer was concentrated to give the product **19**, which was directly dissolved in MeOH, and NaOMe (91.3 mg, 1.69 mmol) added. The reaction was heated under reflux for 30 min. The mixture was concentrated, ether added, the ether extracts washed with water, brine, and dried. Concentration followed by chromatography (5% Et_2O – petroleum ether) gave **20** (350 mg, 70% from **16**).

Method II

An aqueous 15% H_2SO_4 solution (1.2 mL) was added with continuous stirring to a suspension of silica gel (70–230 mesh, 12 g) in CH_2Cl_2 (15 mL). After 3 min, the aqueous phase disappeared, a solution of **16** (1.1 g, 2.9 mmol) in CH_2Cl_2 (2 mL) was added, and stirring continued at 21°C for 2 min during which time the reaction was completed. $NaHCO_3$ (0.1 g) was then added and stirring continued for 5 min, followed by filtration of the reaction mixture through a small plug of $MgSO_4$. Concentration gave the aldehyde **19**, which was used directly for the next step. NaOMe (140 mg, 2.6 mmol) was added to a solution of the aldehyde (876 mg, 2.6 mL) in MeOH (10 mL). The mixture was refluxed for 8 h, concentrated, ether added, and the ether extracts washed with water and brine, and dried. Concentration and chromatography (5% Et_2O – petroleum ether) gave the aldehyde **20** (846 mg) in 96% yield. IR (neat): 2921, 1698 cm^{-1}; ^1H NMR (200 MHz) δ: 0.01 (s, 6H), 0.85 (s, 9H), 1.01 (s, 3H), 1.30 (s, 3H), 1.36–1.20 (m, 2H), 1.84–1.87 (m, 1H), 2.02 (s, 3H), 2.10–2.20 (m, 2H), 3.33 (dd, 1H, J = 8.75, 10 Hz), 3.83 (dd, 1H, J = 3.65, 10 Hz), 10.62 (s, 1H); ^{13}C NMR δ: 192.3 (conjugated CHO), 156.3, 140.4, 62.9, 47.8, 35.3, 34.6, 26.3, 25.9, 21.4, 20.7, 19.4, 18.0, −5.3; HRMS calcd. for $C_{13}H_{23}O_2Si$ ($M^+ - C_4H_9$): 239.1467; found: 239.1466.

Method III

Hydrogen fluoride (1 mL, 50% solution) was added to a stirred solution of hydroxy-acetal **15** (0.40 g, 1.11 mmol) in acetonitrile (10 mL). The resulting mixture was refluxed for 15 min in a preheated oil bath. The solution was cooled and a saturated aqueous solution of sodium bicarbonate was added. Acetonitrile was removed under reduced pressure and the aqueous solution was extracted with dichloromethane. The combined organic extracts were washed (water, brine) and dried. Concentration afforded the aldehyde-alcohol. *tert*-Butyldimethylsilyl chloride (0.200 g, 1.33 mmol) was added to a stirred solution of the aldehyde-alcohol and imidazole (0.190 g, 2.79 mmol) in dry dichloromethane (10 mL). The resulting solution was stirred at 21°C for 16 h. Aqueous ammonium chloride solution (10%) was added and the mixture was extracted thoroughly with dichloromethane. The combined organic extracts were washed (water, brine), and dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 9:1) to afford 0.15 g (45%) of the aldehyde **20**.

2-Hydroxymethyl-1,3,3-trimethyl-4-*tert*-butyldimethylsilyloxymethyclohex-1-ene (21)

Treatment of the acetal **16** (1.34 g, 3.56 mmol) as described in Method I above; dry dichloromethane (35 mL), trimethylsilyl chloride (0.68 mL, 5.35 mmol), sodium iodide (0.80 g, 5.33 mmol), followed by sodium methoxide (0.19 g, 3.52 mmol) and methanol (10 mL) afforded the crude aldehyde **20**. Cerium(III) chloride heptahydrate (1.33 g, 3.57 mmol) and sodium borohydride (0.135 g, 3.56 mmol) were added slowly and the mixture was stirred at 21°C for 1 h. Water was added and the methanol was removed from the mixture under reduced pressure. Diethyl ether and 5% hydrochloric acid were added and the resulting solution extracted with diethyl ether. The combined ether extracts were washed (water, brine), dried, and concentrated. This material consisted of two alcohols (12:1 ratio), which were separated by chromatography (petroleum ether/diethyl ether; 9:1) to afford 0.745 g (70%) of alcohol **21** as a white solid and 0.070 g (6.5%) of the positional isomer (data below), as a colorless oil. **21**plainc: mp 53.5–55°C; IR ($CHCl_3$): 3620, 2960, 1260, 1090, 840 cm^{-1}; ^1H NMR (200 MHz) δ: 0.01 (s, 6H), 0.84 (s, 3H), 0.86 (s, 9H), 1.11 (s, 3H), 1.20–1.55 (m, 3H), 1.73 (s, 3H), 1.75–1.90 (m, 1H), 1.95–2.05 (m, 2H), 3.33 (dd, 1H, J = 10, 8.5 Hz), 3.75 (dd, 1H, J = 10, 3.9 Hz), 4.05 (d, 1H, J = 12 Hz), 4.13 (d, 1H, J = 12 Hz); ^{13}C NMR (75 MHz) δ: −5.3 (2C), 18.3, 19.7, 21.5, 22.3, 25.9 (3C), 27.1, 31.6, 36.3, 47.0, 58.8, 63.8, 133.9, 137.8. Anal. calcd. for $C_{17}H_{34}O_2Si$: C 68.39, H 11.48; found: C 68.50, H 11.26.

Alternatively, diisobutylaluminum hydride (1 M solution in toluene, 53.6 μL, 0.08 mmol) was added to a solution of the aldehyde **20** (20 mg, 0.07 mmol) in toluene (1.5 mL) at −78°C and the mixture stirred for 1.5 h at −78°C. The reaction was warmed to 0°C and MeOH was added until a white precipitate formed. The crude product was filtered through Celite and washed free of remaining product with hot MeOH. Concentration gave **21** (20 mg, 99%).

*1,5,5-Trimethyl-4-*tert*-butyldimethylsiloxy)methyl-6-hydroxymethylcyclohexene*: IR (neat): 3382, 2917, 1086, 843, 776 cm^{-1}; ^1H NMR (200 MHz) δ: 0.00 (s, 6H), 0.79 (s, 3H), 0.85 (s, 9H), 1.00–1.05 (m, 1H), 1.04 (s, 3H), 1.15–1.25 (m, 1H), 1.50–1.60 (m, 1H), 1.70 (s, 3H), 1.75–2.00 (m, 1H), 2.10–2.28 (m, 1H), 3.30–3.55 (m, 2H), 3.65–3.80 (m, 2H), 5.50–5.65 (m, 1H); HRMS calcd. for $C_{13}H_{23}OSi$($M^+ - C_4H_9$): 224.1463; found: 224.1463.

2-Cyanomethyl-2,3,3-trimethyl-4-*tert*-butyldimethylsilyloxymethylcyclohexene (22)

Bromine (0.011 mL, 0.218 mmol) was added dropwise to a stirred solution of triphenylphosphine (0.57 g, 0.217 mmol) in dry methylene chloride (2 mL). Triethylamine (0.11 mL, 0.789 mmol) was added to the reaction mixture. After stirring at 21°C for 10 min, the resulting light yellow solution was cooled to −78°C. A solution of the alcohol **21** (59.3 mg, 0.198 mmol) in methylene chloride (1 mL) was added dropwise and the reaction mixture was allowed to stir for 1 h at −78°C. Petroleum ether was added and the precipitate was removed via filtration under reduced pressure. Concentration of the petroleum ether fractions precipitated additional triphenylphosphine oxide. Subsequent filtration and concentration provided a quantitative yield of the allylic bromide. IR (neat):

2917, 1466, 1253, 1093, 844, 776 cm^{-1}; ^1H NMR (200 MHz) δ: 0.02 (s, 6H), 0.85 (s, 9H), 0.91 (s, 3H), 1.19 (s, 3H), 1.19 (s, 3H), 1.30–1.50 (m, 2H), 1.73 (s, 3H), 1.75–1.85 (m, 1H), 2.00–2.10 (m, 2H), 3.33 (t, J = 8 Hz, 1H), 3.75 (dd, J = 8, 6 Hz, 1H), 4.01 (d, J = 10 Hz, 1H), 4.09 (d, J = 10 Hz, 1H). Sodium cyanide (19.0 mg, 0.397 mmol) was added to a solution of this allylic bromide in dry *N*-methyl pyrrolidinone (2 mL). The reaction mixture was stirred at 21°C for 1.5 h, pour into water, and extracted with diethyl ether. The combined ether extracts were washed (brine), dried, and concentrated. The crude product was chromatographed (petroleum ether/diethyl ether; 9:1) to afford 45.0 mg (75%) of the nitrile **22** IR (neat): 2960, 2260, 1550, 1260, 1100, 840, 780 cm^{-1}; ^1H NMR (200 MHz) δ: 0.02 (s, 6H), 0.84 (s, 3H), 0.86 (s, 9H), 1.12 (s, 3H), 1.30–1.50 (m, 2H), 1.70 (s, 3H), 1.71–1.85 (m, 1H), 1.95–2.05 (m, 2H), 2.94 (br s, 2H), 3.35 (dd, 1H, J = 10, 8.2 Hz), 3.73 (dd, 1H, J = 10, 4.2 Hz); ^{13}C NMR (50.3 MHz) δ: −5.6 (2C), 15.8, 18.0, 20.0, 21.2, 21.3, 25.7 (3C), 26.4, 31.5, 37.0, 46.5, 63.5, 119.2, 127.5, 134.0; HRMS calcd. for $C_{14}H_{24}ONSi$ ($M^+ - C_4H_9$): 250.1627; found: 250.1654.

2-Cyanomethyl-1,3,3-trimethyl-4-hydroxycyclohexene (23)

A solution of compound **22** (1.00 g, 3.25 mmol) in dry THF (20 mL) was cooled to 0°C and a 1 M solution of tetra-*n*-butyl ammonium fluoride (6.50 mL, 6.50 mmol) and added dropwise. The mixture was warmed to 21°C for 4 h. Water was added and the resultant mixture was extracted with diethyl ether. The combined ether extracts were washed (brine, water), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 3:1) to afford 0.620 g (98%) of the alcohol **23**. IR (neat): 3405, 2924, 2246, 1465, 1030 cm^{-1}; ^1H NMR (200 MHz) δ: 0.85 (s, 3H), 1.13 (s, 3H), 1.30–1.55 (m, 3H), 1.71 (s, 3H), 1.80–1.92 (m, 1H), 2.00–2.10 (m, 2H), 2.95 (s, 2H), 3.39 (dd, 1H, J = 11, 8 Hz), 3.83 (dd, 1H, J = 11, 4 Hz); addition of D_2) simplified multiplet at δ 1.30–1.55; ^{13}C NMR (50.3 MHz) δ: 15.8, 19.9, 21.2 (2C), 26.3, 31.4, 36.9, 46.8, 63.3, 119.1, 127.4, 134.0; HRMS calcd. for $C_{12}H_{19}ON$: 193.1467; found: 193.1466. Anal. calcd. for $C_{12}H_{19}ON$: C 74.57, H 9.91; found: C 74.16, H 9.71.

2-Cyanomethyl-4-formyl-1,3,3-trimethylcyclohexene (24)

Oxalyl chloride (0.310 mL, 3.55 mmol) was added to a cold (−78°C), stirred solution of dry dimethyl sulfoxide (0.250 mL, 3.52 mmol) in dry dichloromethane (25 mL). The reaction mixture was stirred at −78°C for 15 min, a solution of **23** (620 mg, 3.21 mmol) in dry dichloromethane (2 mL) was added dropwise, and the resulting mixture stirred for 15 min. Dry triethylamine (1.78 mL, 12.7 mmol) was added and the solution stirred at −78°C for a further 5 min and then at 21°C for 30 min. Saturated aqueous ammonium chloride solution was added and the mixture was extracted with dichloromethane. The combined organic extract were washed with brine, dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 1:1) to afford 579 mg (94%) of the aldehyde **24**. IR (neat): 2934, 2734, 2244, 1718, 1464 cm^{-1}; ^1H NMR (200 MHz) δ: 1.05 (s, 3H), 1.28 (s, 3H), 1.73 (s, 3H), 1.60–2.00 (m, 2H), 2.04–2.14 (m, 2H), 2.23 (dt, 1H, J = 11, 3 Hz), 3.00 (AB, 2H, J = 19 Hz), 9.83 (d, 1H, J = 5 Hz); ^{13}C NMR (50.3 MHz) δ: 15.7, 19.1, 20.0, 22.5, 26.7, 30.8, 36.9, 56.7, 118.6, 126.9, 133.8, 204.7; HRMS calcd. for $C_{12}H_{17}ON$: 191.1310; found: 191.1313.

2-Cyanomethyl-1,3,3-trimethyl-4-(1-hydroxy-2,4-pentadienyl)cyclohexene (25)

A solution of *n*-butyllithium (0.40 mL, 1.00 mmol, 2.5 M) in hexane was added dropwise to a cold (−78°C), stirred solution of (E)-1-tri-*n*-butylstannyl-1,3-butadiene (373 mg, 1.08 mmol) in dry THF (9 mL). After the reaction mixture had been stirred at −78°C for 10 min, a solution of aldehyde **24** (173 mg, 0.90 mmol) in dry THF (1 mL) was added dropwise. The resulting mixture was stirred at −78°C for 30 min. Water was added and the mixture warmed to 21°C and extracted with diethyl ether. The combined ether extracts were washed with brine, dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 1:1) to afford 213 mg (96%) of the alcohols as colorless oils (ratio 6:1). Further chromatography afforded the major isomer **25**. IR (neat): 3461, 2927, 2245, 1463, 1007 cm^{-1}; ^1H NMR (200 MHz) δ: 1.02 (s, 3H), 1.11 (s, 3H), 1.20–1.68 (m, 4H), 1.69 (s, 3H), 1.90–2.10 (m, 2H), 3.00 (AB, 2H, J = 19 Hz), 4.48 (t, 1H, J = 4 Hz), 5.06 (d, 1H, J = 8 Hz), 5.20 (d, 1H, J = 16 Hz), 5.74 (dd, 1H, J = 16, 4 Hz), 6.10–6.44 (m, 2H); ^{13}C NMR (50.3 MHz) δ: 16.1, 17.4, 19.9, 21.8, 26.3, 32.4, 38.3, 49.6, 70.4, 117.1, 119.1, 127.8, 130.1, 133.8, 136.3, 137.3; HRMS calcd. for $C_{16}H_{23}ON$: 245.1780; found: 245.1760.

2-Cyanomethyl-4-(1-methoxymethyloxy-2,4-pentadienyl)-1,3,3-trimethyl-2-cyanomethylcyclohexene (26)

Chloromethyl methyl ether (0.11 mL, 1.45 mmol) was added to a cold (0°C) solution of the alcohol **25** (301 mg, 1.23 mmol) and diisopropylethylamine (0.58 mL, 3.04 mmol) in dry dichloromethane (15 mL). The resulting solution was stirred at 0°C for 5 min and warmed to 21°C for 16 h. Aqueous ammonium chloride solution (10%) was added and the mixture was extracted with dichloromethane. The combined organic extracts were washed with brine, dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 4:1) to afford 321 mg (90%) of the nitrile **26**, as a slightly reddish oil. IR (neat): 2924, 2245, 1602, 1028, 914, 733 cm^{-1}; ^1H NMR (200 MHz) δ: 1.00 (s, 3H), 1.12 (s, 3H), 1.70 (s, 3H), 1.30–1.80 (m, 3H), 1.95–2.05 (m, 2H), 2.95 (AB, 2H, J = 19 Hz), 3.34 (s, 3H), 4.24 (br d, 1H, J = 10 Hz), 4.46 (d, 1H, J = 8 Hz), 4.65 (d, 1H, J = 8 Hz), 5.10 (br d, 1H, J = 18 Hz), 5.17 (dd, 1H J = 18, 2 Hz), 5.63 (dd, 1H, J = 18, 10 Hz), 6.05–6.42 (m, 2H); ^{13}C NMR (75 MHz) δ: 16.4, 18.8, 20.1, 21.5, 26.6, 32.9, 38.5, 50.1, 56.4, 76.0, 94.4, 117.5, 119.1, 127.9, 132.3, 133.7, 134.0, 136.2; HRMS calcd. for $C_{18}H_{27}O_2N$: 289.2042; found: 289.2032. Anal. calcd. for $C_{18}H_{27}O_2N$: C 74.70, H 9.40, O 11.06; found: C 74.62, H 8.92, O 11.56.

2-Cyanomethyl-1,3,3-trimethyl-4-(1-*tert*-butyldimethylsilyloxy-2,4-pentadienyl)-cyclohexene (27)

To a solution of alcohol **25** (213 mg, 8.70 mmol) in dry DMF (5 mL) was added sequentially *tert*-butyldimethylchlorosilane (170 mg, 1.13 mmol, Aldrich) and 4-(N,N-dimethylamino)pyridine (270 mg, 2.21 mmol). The resulting solution was stirred at 21°C for 3 days. Water was added, the mixture was extracted with diethyl ether, and the combined extracts were washed with brine, dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 19.1) to afford **27** (254 mg, 81%). IR (neat): 2925, 2245, 1603, 1114, 1068, 1006, 838, 774 cm^{-1}; ^1H NMR (200 MHz): δ −0.06 (s, 3H), 0.00 (s, 3H), 0.83 (s, 9H), 0.95 (s, 3H), 1.09 (s,

3H), 1.3–1.4 (m, 1H), 1.50–1.70 (m, 2H), 1.68 (s, 3H), 1.95–2.1 (m, 2H), 2.98 (AB, 2H, J = 19 Hz), 4.37 (d, 1H, J = 8 Hz), 5.07 (d, 1H, J = 10 Hz), 5.16 (d, 1H, J = 16 Hz), 5.75 (dd, 1H, J = 10, 16 Hz), 5.98–6.40 (m, 2H): ^{13}C NMR (75 MHz) δ: −4.8, −3.0, 16.3, 18.1, 18.7, 20.2, 22.2, 25.9 (3C), 26.6, 32.9, 38.5, 51.7, 72.6, 116.9, 119.2, 127.9, 129.9, 133.7, 136.5, 137.9; HRMS calcd. for $C_{18}H_{28}ONSi$ ($M^+ - C_4H_9$): 302.1940; found: 302.64. Anal. calcd. for $C_{22}H_{37}ONSi$: C 73.47, H 10.37, N 3.89; found: C 73.44, H 9.95, N 3.85.

2-Formylmethyl-1,3,3-trimethyl-4-(1-*tert*-methoxymethyloxy-2,4-pentadienyl)cyclohexene (28)

A solution of diisobutylaluminum hydride (1.5 M, 0.71 mL, 1.06 mmol) in toluene was added dropwise to a cold (−78°C), stirred solution of the nitrile **26** (207 mg, 0.715 mmol) in dry dichloromethane (10 mL). The resulting mixture was stirred at −78°C for 1 h and warmed to 0°C for another hour. Saturated ammonium chloride solution was added and the mixture was stirred at 21°C for 30 min. The resulting solution was extracted with dichloromethane. The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 4:1) to afford 147 mg (70%) of the aldehyde **28**. IR (neat): 2915, 2717, 1721, 1029 cm^{-1}; ^{1}H NMR (200 MHz) δ: 0.97 (s, 3H), 1.00 (s, 3H), 1.54 (s, 3H), 1.40–1.85 (m, 3H), 1.90–2.10 (m, 2H), 3.07 (br s, 2H), 3.34 (s, 3H), 4.25 (br d, 1H, J = 8 Hz), 4.47 (d, 1H, J = 7 Hz), 4.65 (d, 1H, J = 7 Hz), 5.00–5.25 (m, 2H), 5.65 (dd, 1H, J = 14, 8 Hz), 6.00–6.44 (m, 2H), 9.48 (t, 1H, J = 2 Hz); ^{13}C NMR (75 MHz) δ: 18.9, 20.3, 21.7, 26.7, 33.0, 38.3, 43.8, 50.3, 56.4, 76.1, 94.4, 117.4, 129.1, 132.1, 132.5, 134.3, 136.2, 201.3; HRMS calcd. for $C_{18}H_{28}O_3$: 292.2038; found: 292.2052.

2-Formylmethyl-1,3,3-trimethyl-4-(1-*tert*-butyldimethylsilyloxy-2,4-pentadienyl)cyclohexene (29)

A solution of diisobutylaluminum hydride (1.0 M, 0.26 mL, 0.260 mmol) in toluene was added dropwise to a cold (−78°C), stirred solution of the nitrile **27** (72 mg, 0.201 mmol) in dry dichloromethane (5 mL). The reaction was stirred at −78°C for 2 h followed by 2 h at 0°C. Water was added and the mixture was stirred at 21°C for 30 min. The resulting solution was extracted with dichloromethane and the combined organic extracts were washed with brine, dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 9:1) to give aldehyde **29** (66.3 mg, 91%). IR (neat): 2946, 2713, 1723, 1648, 1252, 1066, 1004, 838, 775 cm^{-1}; ^{1}H NMR (200 MHz) δ: −0.05 (s, 3H), 0.00 (s, 3H), 1.10–1.40 (m, 2H), 1.50)\(s, 3H), 1.60–1.75 (m, 1H), 1.80–2.10 (m, 3H), 3.08 (br s, 2H), 4.38 (d, 1H, J = 10 Hz), 5.05 (d, 1H, J = 10 Hz), 5.15 (d, 1H, J = 20 Hz), 5.78 (dd, 1H, J = 10, 20 Hz), 5.95–6.40 (m, 1H), 9.47 (t, 1H, J = 4 Hz); HRMS calcd. for $C_{18}H_{29}O_2Si$ ($M^+ - C_4H_9$): 305.1937; found: 305.1958.

1-(2-Thiophenyl)methyl-2-cyanomethyl-1,3,3-trimethylcyclohexene (30)

A solution of *n*-butyllithium (0.52 mL, 1.30 mmol, 2.5 M) in hexane was added dropwise to a cold (−78°C), stirred solution of thiophene (0.114 mL, 1.42 mmol) in of dry THF (10 mL). After the reaction mixture had been stirred at −78°C for 15 min, a solution of the aldehyde **24** (0.227 g, 1.19 mmol) in dry THF (1 mL) was added dropwise. The resulting orange mixture was stirred at −78°C for 30 min. Water was added and the mixture was extracted with diethyl ether. The combined ether extracts were washed with brine, dried, and concentrated. The residual oil was chromatographed using radial chromatography (petroleum ether/diethyl ether; 2:1.5). Concentration of the appropriate fractions afforded 0.226 g (69%) of the major isomer and 0.0464 g (14%) of the minor isomer. Minor isomer, IR (neat): 3450, 2929, 2247, 1425, 1038 cm^{-1}; ^{1}H NMR (200 MHz) δ: 1.06 (s, 3H), 1.07–1.37 (m, 2H), 1.39 (s, 3H), 1.69 (s, 3H), 1.6–2.10 (m, 4H), 2.99 (br s, 2H), 4.87 (br d, 1H, J = 9 Hz), 6.9–7.0 (m, 2H), 7.2–7.28 (m, 1H); ^{13}C NMR (50.3 MHz) δ: 16.2, 20.0, 20.2, 22.5, 27.5, 32.1, 38.9, 51.0, 72.7, 119.3, 125.2, 125.3, 126.4, 128.6, 133.5, 149.0; HRMS calcd. for $C_{1621}ONS$: 275.1319; found: 275.1316.

Major isomer, IR (neat): 3458, 2918, 2247, 1376, 1110, 1045, 706 cm^{-1}; ^{1}H NMR (200 MHz) δ: 1.10 (s, 3H), 1.20 (s, 3H), 1.71 (s, 3H), 1.5–1.7 (m, 2H), 1.88 (d, 1H, J = 5.5 Hz), 1.95–2.10 (m, 2H), 2.99 (AB, 2H, J = 19 Hz), 5.28 (d, 1H, J = 5.5 Hz), 6.88–7.0 (m, 2H), 7.15–7.25 (m, 1H); ^{13}C NMR (50.3 MHz) δ: 16.1, 17.3, 20.0, 21.8, 26.3, 32.4, 38.5, 52.3, 69.2, 119.1, 122.7, 123.9, 126.8, 127.6, 134.1, 150.3; HRMS calcd. for $C_{16}H_{19}NS$ ($M^+ - H_2O$): 257.1238; found: 257.1238.

tert-Butyldimethylsilyl chloride (0.130 g, 0.862 mmol) was added to a stirred solution of silver perchlorate (0.160 g, 0.772 mmol) in dry acetonitrile (5 mL). The resultant white suspension was stirred at 21°C for 15 min. Pyridine (0.23 mL, 2.84 mmol) and a solution of the major alcohol (0.154 g, 0.561 mmol) were added sequentially and the mixture was stirred overnight at 21°C. Diethyl ether was added and the solids were removed by filtration. The ether filtrate was washed (5% aqueous sodium bicarbonate solution, brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 9:1 initially followed by petroleum ether/diethyl ether; 3:1) to afford 0.157 g (72%) of the silyl ether **30** and also 0.0154 g (10%) of the starting alcohol. The product **30** was recrystallized from petroleum ether/diethyl ether (1.1) to give colourless needles, mp 113–114°C. IR (KBr): 2945, 2244, 1109, 1072, 831, 744 cm^{-1}; ^{1}H NMR (200 MHz) δ: −0.36 (s, 3H), 0.03 (s, 3H), 0.84 (s, 9H), 1.01 (s, 3H), 1.12 (s, 3H), 1.45–1.70 (m, 1H), 1.68 (s, 3H), 1.90–2.10 (m, 1H), 2.95 (AB, 2H, J = 18 Hz), 5.18 (br s, 1H), 6.8–6.9 (m, 2H), 7.1–7.18 (m, 1H); ^{13}C NMR (75 MHz) δ: −4.87, −4.23, 16.5, 18.5, 20.0, 21.8, 25.9 (3C), 26.6, 30.6, 32.9, 38.8, 54.2, 69.7, 119.0, 123.1, 123.6, 125.7, 127.5, 133.8, 150.4; HRMS calcd. for $C_{18}H_{26}ONSSi$ ($M^+ - C_4H_9$): 332.1504; found: 332.1496.

4-(1-*tert*-butyldimethylsilyloxy-2,4-pentadienyl)-1,3,3-trimethyl-2-(2-oxo-4-trimethylsilyl-3-butynyl)cyclohexene (31)

A solution of *n*-butyllithium (1.50 mL, 3.75 mmol, 2.5 M) in hexane was added dropwise to a cold (−78°C), stirred, solution of (trimethylsilyl)acetylene (0.53 mL, 3.75 mmol) in dry THF (30 mL). After stirring at −78°C for 10 min, a solution of the aldehyde **29** (0.450 g, 1.24 mmol) in dry THF (5 mL) was added dropwise. The resulting mixture was stirred at −78°C for 1 h and at 0°C for a further hour. Water was added and the mixture was warmed to 21°C and extracted with diethyl ether. The combined ether extracts were washed with brine and dried. Concentration of the organic material afforded 186 mg (93%) of the acetylenic alcohol, which was used directly.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Oxalyl chloride (0.017 mL, 0.194 mmol) was added to a cold (−78°C), stirred, solution of dry dimethyl sulfoxide (0.014 mL, 0.197 mmol) in dry dichloromethane (5 mL). After the reaction mixture had been stirred at −78°C for 15 min, a solution of the acetylenic alcohol (0.0766 g, 0.166 mmol) in dry dichloromethane (1 mL) was added dropwise and the resulting mixture was stirred for 15 min. Dry trimethylamine (0.10 mL, 0.717 mmol) was added, the solution was stirred at −78°C for 5 min, and at 21°C for 30 min. Water was added and the mixture was extracted with dichloromethane. The combined organic extracts were washed with brine, dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 19:1) to afford 0.029 g (38%) of the ketone **31**. IR (neat): 2947, 2151, 1676, 1253, 1090, 851, 772 cm^{-1}; ^1H NMR (200 MHz) δ: −0.05 (s, 3H), 0.00 (s, 3H), 0.19 (s, 9H), 0.84 (s, 9H), 0.92 (s, 3H), 0.95 (s, 3H), 1.15 (s, 3H), 1–1.7 (m, 3H), 1.9–2.10 (m, 2H), 3.24 (br s, 2H), 4.37 (d, 1H, J = 7 Hz), 5.03 (br d, 1H, J = 8 Hz), 5.17 (br d, 1H, J = 18 Hz), 5.75 (dd, 1H, J = 10, 18 Hz), 6.03 (dd, 1H, J = 10, 18 Hz), 6.28 (dd, 1H, J = 10, 18 Hz); HRMS calcd. for $C_{23}H_{31}O_2Si_2$ ($M^+ - C_4H)_9$: 2332; found: 401.2340.

Alternative oxidation: pyridinium dichromate (0.080 g, 0.213 mmol) was added to a stirred solution of the acetylenic alcohol (0.036 g, 0.0793 mmol) in dry dichloromethane (5 mL). The resulting mixture was stirred at room temperature for 4 h. The solid was removed by filtration through a sintered glass funnel under aspirator pressure and was washed thoroughly with diethyl ether. The ether filtrates were concentrated to provided a tan oil. This residual oil was chromatographed (petroleum ether/diethyl ether; 40:1) to afford 0.010 g (26%) of the ketone **31**.

4-(1-*tert*-Butyldimethylsilyloxy-2,4-pentadienyl)-1,3,3-trimethyl-2-(2-oxo-3-butynyl)cyclohexene (32)

A solution of potassium hydroxide (0.200 g, 3.57 mmol) in methanol (5 mL) was added to a stirred solution of the acetylenic alcohol (0.531 mg, 1.15 mmol) (prepared as described above) in dichloromethane (5 mL). The resulting mixture was stirred for 3 h at 21°C. The organic solvent was removed under reduced pressure to provide yellow oil. A mixture of diethyl ether/water (1:1) was added and the solution was extracted thoroughly with diethyl ether. The combined ether extracts were washed with brine and dried. Concentration of the organic material afforded a quantitative yield of the deprotected acetylenic alcohol.

Dess–Martin periodinane (1.00 g, 1.71 mmol) was added to a solution of the deprotected acetylenic alcohol in dry dichloromethane (15 mL). The resulting bright yellow solution was stirred at 21°C for 2 h. Dilute aqueous sodium hydroxide solution (10 mL, 10%) was added and the mixture was stirred for a further 10 min. The solution was extracted with diethyl ether. The combined organic extracts were washed (10% sodium hydroxide solution, water, brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 9:1) to afford 0.133 g (30%) of the ketone **32**. IR (neat): 3266, 2918, 2091, 1684, 839, 775 cm^{-1}; ^1H NMR (200 MHz) δ: −0.05 (s, 3H), 0.01 (s, 3H), 0.85 (s, 9H), 0.99 (s, 3H), 1.01 (s, 3H), 1.34–1.46 (m, 1H), 1.51 (s, 3H), 1.55–1.75 (m, 2H), 1.90–2.25 (m, 3H), 3.21 (s, 1H), 3.30 (d, 1H, J = 16 Hz), 3.42 (d, 1H, J = 16 Hz), 4.36 (br s, 1H), 5.05 (d, 1H, J = 10 Hz), 5.17 (d, 1H, J = 16 Hz), 5.72 (dd, 1H, J = 16.6 Hz); HRMS calcd. for $C_{29}H_{38}O_2Si$: 382.2641; found: 386.2649.

2-(2-Hydroxy-4-trimethylsilyl-3-butynyl)-4-(1-methoxymethyloxy-2,4-pentadienyl)-1,3,3-trimethylcyclohexene (33)

Addition of lithium trimethylacetylide to the aldehyde **29** (147 mg, 0.5.04 mmol) was conducted as described above to afford 186 mg (95%) of the alcohol **33**. IR (neat): 3415, 2918, 2170, 1648, 1045, 871 cm^{-1}; ^1H NMR (200 MHz) δ: 0.13 (s, 9H), 1.03 (br s, 3H), 1.07 (br s, 3H), 1.67 (br s, 3H), 1.00–1.80 (m, 5H), 1.90–2.10 (m, 2H), 2.48–2.60 (m, 1H), 3.34 (br s, 3H), 4.20–4.32 (m, 1H), 4.40–4.52 (m, 2H), 4.60–4.70 (m, 1H), 5.06 (br d, 1H, J = 20 Hz), 5.18 (br d, 1H, J = 20 Hz), 5.55–5.75 (m, 1H), 6.05–6.45 (m, 2H); MS (CI): 329 ($MH^+ - C_2H_6O_2$).

2-(2-Hydroxy-3-butynyl)-4-(1-methoxymethyloxy-2,4-pentadienyl)-1,3,3-trimethylcyclohexene (34)

A solution of potassium hydroxide (250 mg, 4.46 mmol) in methanol (5 mL) was added to a stirred solution of the alcohol **33** (471 mg, 1.21 mmol) in dichloromethane (5 mL). The resulting mixture was stirred for 3 h at 21°C. The organic solvent was removed under reduced pressure to provide a yellow oil. A mixture of diethyl ether/water (1:1) was added and the solution was extracted with diethyl ether. The combined ether extracts were washed with brine and dried. Concentration afforded a quantitative yield of alcohols **34**. IR (neat): 3431, 3300, 2926, 2112, 1647, 1027 cm^{-1}; ^1H NMR (200 MHz) δ: 1.03 (s, 3H), 1.06 (br s, 3H), 1.68 (br s, 3H), 0.8–1.8 (m, 7H), 1.90–2.05 (m, 2H), 2.44 (dd, 1H, J = 8, 2 Hz), 2.50–2.60 (m, 1H), 3.33 (br s, 3H), 4.26 (br d, 1H, J = 10 Hz), 4.46 (br d, 1H, J = 8 Hz), 4.62 (br d, 1H, J = 8 Hz), 4.62 (br d, 1H, J = 8 Hz), 5.09 (br d, 1H, J = 20 Hz), 5.15 (br d, 1H, J = 20 Hz), 5.63 (dd, 1H, J = 16, 8 Hz), 5.95–6.45 (m, 1H); ^{13}C NMR (50.3 MHz): ~3:2 diastereoisomer mixture, major isomer, most signals doubled, δ: 18.7, 21.1, 22.7, 27.3, 32.8, 36.8, 38.3, 50.3, 56.2, 62.1, 72.5, 76.1, 85.4, 94.2, 117.2, 131.9, 132.9, 134.2, 134.3, 136.1; MS (CI): 257 ($MH^+ - C_2H_6O_2$).

4-(1-Methoxymethyloxy-2,4-pentadienyl)-1,3,3-trimethyl-2-(2-oxo-3-butynyl)cyclohexene (35)

Dess–Martin periodinane (997 mg, 1.71 mmol) was added to a solution of the alcohol **34** (384 mg, 1.21 mmol) in dry dichloromethane (10 mL). The resulting bright yellow solution was stirred at 21°C for 1 h. Diethyl ether (20 mL) and aqueous sodium hydroxide solution (10 mL, 10%) were added and the mixture was stirred for a further 10 min. The solution was extracted with diethyl ether. The combined organic extracts were washed (10% sodium hydroxide solution, water, brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 6:1) to afford 210 mg (55%) of the ketone **35**. IR (neat): 3252, 2918, 2089, 1681, 1074, 913 cm^{-1}; ^1H NMR (200 MHz) δ: 0.95 (s, 3H), 0.96 (s, 3H), 1.51 (s, 3H), 1.40–1.80 (m, 4H), 1.90–2.10 (m, 2H), 3.16 (s, 1H), 3.30 (br s, 2H), 3.34 (s, 3H), 4.23 (d, 1H, J = 8 Hz), 4.46 (d, 1H, J = 6.6 Hz), 4.64 (d, 1H, J = 6.6 Hz), 5.08 (d, 1H, J = 18 Hz), 5.15 (dd, 1H, J = 18, 2 Hz), 5.64 (dd, 1H, J = 15, 8 Hz), 6.05–6.40 (m, 1H); ^{13}C NMR (50.3 MHz) δ: 18.9, 20.8, 22.0, 26.6, 32.9, 38.2, 45.3, 50.1, 56.4, 76.2, 78.3, 81.7, 94.4, 117.3, 129.7, 132.8, 134.4, 136.3, 186.0; MS (CI): 317 (MH^+).

(1*R**,2*S**,3*S**)-2-Methoxymethyloxy-9-oxo-12,15,15-trimethyltricyclo[9.3.1.$0^{3,8}$]pentadeca-4,7,11-triene (36)

A solution of the acetylenic ketone **35** (0.121 g, 0.382 mmol)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

in dry toluene (25 mL) containing hydroquinone (0.01 g, 0.09 mmol) was placed in a thick-walled Pyrex pressure tube equipped with a threaded plastic cap. The top of the tube extended through a small hole in the top of the microwave oven. Argon was bubbled through the solution for 10 min and the vessel sealed. The diameter of the even opening is less than 3 cm and is shielded to minimize microwave leakage. The base of the tube inside the microwave oven was surrounded by a beaker of damp (H_2O) vermiculite to facilitate heat transfer. A commercial oven was used (Toshiba model ERF-6630C (720 W) at a power setting of 500 W in which the magnetron was tuned to the water frequency (2450 MHz). The reaction was conducted behind a shield in a fume hood. The reaction was heated for 12 × 0.5 h intervals, after which the tube was allowed to return to room temperature between each session and fresh moist vermiculite added to the beaker. The tube was cooled, solvent evaporated, and the residual oil chromatographed (petroleum ether/diethyl ether; 3:1) to afford the adduct **36** (0.041 g, 34%). (Unfortunately, the minor adduct, epimeric at C3, could not be fully characterized.) IR (neat): 2920, 1694, 1148, 1033, 919 cm^{-1}; ^1H NMR (200 MHz) δ: 1.04 (s, 3H), 1.50–2.30 (m, 4H), 2.50–2.60 (m, 1H), 2.60–2.70 (m, 1H), 2.71–2.85 (m, 1H), 2.95 (dd, 1H, J = 9.6, 5.6 Hz), 3.30 (br s, 2H), 3.32 (br s, 3H), 3.4–3.70 (m, 1H), 4.53 (br s, 2H), 5.5–6.1 (m, 3H); HRMS calcd. for $C_{20}H_{28}O_3$: 316.2040; found: 316.2061.

(1*R,2*S**)-3,4-Benzo-2-methoxymethyloxy-9-oxo-12,15,15-trimethyltricyclo[9.31.0^{3,8}]pentadec-11-ene (37) (*endo/exo* mixture, ~1:1)**

Dichlorodicyanoquinone (0.049 g, 0.216 mmol) was added to the diene (0.034 g, 0.108 mmol) dissolved in dry benzene (5 mL). The stirred reaction was refluxed for 2 h. The mixture was then cooled to 21°C and the solvent removed under aspirator pressure. The residual oil was chromatographed (petroleum ether/diethyl ether; 3:1) to afford 0.023 g (69%) of the mixture of aromatic products **37**. IR (neat): 2919, 1695, 1452, 1031, 923 cm^{-1}; ^1H NMR (200 MHz) δ: 0.39 (s, 3H), 0.71 (s, 3H), 1.02 (s, 3H), 1.06 (s, 3H), 1.41 (s, 3H), 0.8–1.70 (m, 4H), 1.76 (s, 3H), 1.90–2.50 (m, 6H), 3.20 (br s, 3H), 3.35 (br s, 3H), 3.25–3.65 (m, 3H), 3.59 (d, 1H, J = 12 Hz), 4.02 (d, 1H, J = 9.6 Hz), 4.09 (d, 1H, J = 6 Hz), 4.27 (d, 1H, J = 6 Hz), 4.30 (d, 1H, J = 6 Hz), 4.40 (d, 1H, J = 6 Hz), 4.49 (d, 1H, J = 3 Hz), 7.00–7.60 (m, 8H); ^{13}C NMR (75 MHz) δ: 20.17, 20.58, 20.78, 21.58, 26.77, 27.78, 27.81, 28.81, 30.25, 30.47, 37.22, 38.72, 46.98, 47.45, 49.09, 53.78, 55.39, 56.46, 78.85, 86.32, 93.40, 95.02, 125.64, 126.18, 126.31, 127.29, 127.84, 127.92, 128.30, 129.24, 129.43, 129.58, 134.52, 135.85, 137.86, 138.50, 140.91, 143.38, 200.95, 209.43; HRMS calcd. for $C_{20}H_{26}O_3$: 314.1882; found: 314.1883.

4-(1-*tert*-Butyldimethylsilyloxy-2,4-pentadienyl)-1,3,3-trimethyl-2-(2-oxo-3-methyl-3-butenyl)cyclohexene (41)

A solution of *tert*-butyllithium (0.35 mL, 0.60 mmol, 1.7 M) in pentane was added dropwise to a cold (−78°C), stirred solution of 2-bromopropene (0.05 mL, 0.62 mmol) in of dry THF (2 mL). After the reaction was stirred at −78°C for 5 min, a solution of the aldehyde **29** (0.09 g, 0.25 mmol) in dry THF (1 mL) was added dropwise. The resulting mixture was stirred at −78°C for 30 min and warmed to 21°C. Ammonium chloride solution (saturated) was added and the mixture was extracted with diethyl ether. The combined ether extracts were washed (water, brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 9:1) to afford 0.072 g (72%) of the alcohol, which was used directly.

Oxalyl chloride (0.014 mL, 0.160 mmol) was added to a cold (−78°C), stirred solution of dry dimethyl sulfoxide (0.0136 mL, 0.192 mmol) in dry dichloromethane (3 mL). After the reaction was stirred at −78°C for 15 min, a solution of the above alcohol (0.0519 g, 0.128 mmol) in dry dichloromethane (1 mL) was added dropwise and the resulting mixture stirred for a further 15 min. Dry triethylamine (0.070 mL, 0.502 mmol) was added and the solution was stirred at −78°C for 5 min and at 21°C for a further 30 min. Saturated aqueous ammonium chloride solution was added and the mixture was extracted with dichloromethane. The combined organic extracts were washed (water, brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 15:1) to afford 0.045 g (88%) of the enone **41**. IR (neat): 2923, 1686, 1463, 1335, 1064, 1003, 837, 774 cm^{-1}; ^1H NMR (200 MHz) δ: −0.06 (s, 3H), −0.01 (s, 3H), 0.83 (s, 9H), 0.86 (s, 3H), 0.87 (s, 3H), 1–1.5 (m, 1H), 1.39 (s, 3H), 1.5–1.8 (m, 2H), 1.86 (s, 3H), 1.90–2.20 (m, 2H), 3.40 (AB, 2H, J = 20 Hz), 4.36 (d, 1H, J = 7.4 Hz), 5.02 (d, 1H, J = 10 Hz), 5.11 (d, 1H, J = 17 Hz), 5.71 (bs s, 1H), 5.99 (br s, 1H), 5.70–6.40 (m, 3H). HRMS calcd. for $C_{21}H_{33}O_2Si$ (M^+ − $C_4H)_9$: 345.2250; found: 345.2250.

5-(*tert*-Butyldimethylsilyloxy)methyl-3-formyl(dimethylacetal)-2,4,4-trimethylcyclohexene (44)

Thionyl chloride (0.070 mL, 0.960 mmol) was syringed into a cold (0°C), stirred solution of the alcohol **15** (0.174 g, 0.485 mmol) and dry pyridine (0.078 mL, 0.964 mmol) in dry dichloromethane (5 mL). The reaction was warmed to 0°C for 1 h and to 21°C for 30 min. Saturated sodium bicarbonate solution was added and the mixture was extracted with dichloromethane. The combined organic extracts were washed (water, brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 9:1) to afford 0.132 g (80%) of a 3:1 mixture of the olefin acetals **44** and **43**. Compound **44**: IR (neat): 2914, 1090, 842, 775 cm^{-1}; ^1H NMR (200 MHz) δ: 0.01 (s, 6H), 0.79 (s, 3H), 0.85 (s, 9H), 1.00 (s, 3H), 1.00–1.50 (m, 1H), 1.77 (d, 3H, J = 1 Hz), 1.50–2.00 (m, 2H), 2.05–2.30 (m, 1H) 3.34 (s, 3H), 3.37 (s, 3.20–3.40 (m, 1H), 3.71 (dd, 1H, J = 5, 10 Hz), 4.29 (d, 1H, J = 4 Hz), 5.44–5.52 (br s, 1H); ^{13}C NMR (50.3 MHz) δ: −5.3 (2C), 18.2, 23.4, 25.9 (3C), 26.3, 27.5, 33.6, 39.9, 55.0, 55.2, 56.7, 64.2, 108.2, 123.0, 131.8; HRMS calcd. for $C_{19}H_{38}O_3Si$ (M^+ − MeOH): 310.2328; found: 310.2307.

5-(*tert*-Butyldimethylsilyloxy)methyl-3-formyl-2,4,4-trimethylcyclohexene (45)

Saturated oxalic acid solution (2 mL) and a drop of glacial acetic acid were added to a solution of **44** (0.056 g, 0.164 mmol) in diethyl ether (2 mL). The reaction was refluxed for 2 h, then cooled to 21°C. Water was added and the mixture was extracted with diethyl ether. The organic extracts were washed (water, brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 9:1) to afford 0.0411 g (85%) of the aldehyde **45**. IR (neat): 2940, 1724, 1200, 1080, 840, 780 cm^{-1}; ^1H NMR (200 MHz) δ: 0.01 (s, 3H), 0.86 (s, 9H), 1.04 (s, 3H), 1.58 (s, 3H), 1.70–2.00 (m,

For personal use only.

2H), 2.10–2.40 (m, 2H) 3.30–3.50 (m, 1H) 3.78 (dd, 1H, $J = 4$, 10 Hz), 5.73 (br s, 1H), 9.54 (d, 1H, $J = 4$ Hz). HRMS calcd. for $C_{13}H_{23}O_2Si$ ($M^+ - C_4H_9$): 239.1468; found: 239.1469.

5-(*tert*-Butyldimethylsilyloxy)methyl-1,2-epoxy-3-formyl-2,4,4-trimethylcyclohexane (46)

A solution of freshly prepared dimethyloxirane (excess) in acetone (25 mL) was added dropwise to a cold (−4°C), stirred solution of aldehyde **45** (0.184 g, 0.622 mmol) in acetone (5 mL). After stirring at −4°C for 1 h, the reaction mixture was warmed to 21°C. Concentration of the mixture provided a residual oil that was chromatographed (petroleum ether/diethyl ether; 9:1) to afford 0.150 g (77%) of the epoxide **46**. IR (neat): 2946, 2742, 1720, 1467, 1100, 842, 778 cm^{-1}; ^1H NMR (200 MHz) δ: −0.00 (s, 6H), 0.85 (s, 9H), 0.89 (s, 3H), 0.93 (s, 3H), 1.32 (s, 3H), 1.70–1.90 (m, 2H), 1.98 (d, 1H, $J = 4.6$ Hz), 2.06–2.28 (m, 1H), 3.12 (t, 1H, $J = 1.6$ Hz), 3.51 (dd, 1H, $J = 10.4$, 5.6 Hz), 3.63 (dd, 1H, $J = 10.4$, 4 Hz), 9.66 (d, 1H, $J = 4.6$ Hz); ^{13}C NMR (50.3 MHz) δ: −5.5 (2C), 18.2, 23.4, 24.7, 24.8, 25.7, 25.8 (3C), 32.8, 37.2, 57.4, 58.5, 62.0, 63.1, 203.3. HRMS calcd. for $C_{13}H_{23}O_3Si$ ($M^+ - C_4H_9$): 255.1416; found: 255.1424.

5-(*tert*-Butyldimethylsilyloxy)methyl-3-formyl-2,4,4-trimethylclohex-2-en-1-ol (47)

Sodium methoxide (0.031 g, 0.574 mmol) was added to the epoxide **46** (0.15 g, 0.481 mmol) and methanol (10 mL). The reaction mixture was stirred under reflux for 3 h, then cooled to 21°C. Water was added and the solvent was removed. The residual oil was chromatographed (petroleum ether/diethyl ether; 3:1, then the petroleum ether/diethyl ether; 1:1). Concentration of the appropriate fractions afforded 0.0989 g (66%) of the alcohol **47**. IR (neat): 3402, 2942, 2761, 1673, 1254, 1094, 842, 777 cm^{-1}; ^1H NMR (200 MHz) δ: 0.02 (s, 6H), 0.86 (s, 9H), 1.02 (s, 3H), 1.27 (s, 3H), 1.5–1.80 (m, 3H), 1.80–2.0 (m, 1H), 2.17 (s, 3H), 3.39 (dd, 1H, $J = 10$, 8 Hz), 3.78 (dd, 1H, $J = 10$, 4 Hz), 3.95–4.10 (m, 1H), 10.11 (s, 1H); ^{13}C NMR (75 MHz) δ: −5.5, −5.4, 16.9, 18.2, 20.3, 35.92 (3C), 26.4, 30.3, 36.0, 42.3, 62.9, 69.7, 141.9, 151.1, 194.0. HRMS calcd. for $C_{17}H_{32}O_3Si$: 312.2120; found: 312.2110.

1-(*tert*-Butyldimethylsilyloxy)-5-(*tert*-butyldimethylsilyloxy)methyl-3-formyl-2,4,4-trimethylcyclohex-2-ene (48)

tert-Butyldimethylsilyl chloride (0.057 g, 0.378 mmol) was added to a stirred solution of the alcohol **47** (0.099 g, 0.317 mmol) and imidazole (0.53 g, 0.778 mmol) in dry dichloromethane (10 mL). The resultant solution was stirred at 21°C for 16 h. Water was added and the mixture was extracted with dichloromethane. The combined organic extracts were washed with brine, dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 19:1). Concentration of the appropriate fractions afforded 0.123 g (91%) of the silyl ether **48**. IR (neat): 2912, 2762, 1681, 1467, 1254, 1079, 841, 777 cm^{-1}; ^1H NMR (200 MHz) δ: 0.02 (s, 6H), 0.10 (s, 6H), 0.87 (s, 9H), 0.88 (s, 9H), 1.0 (s, 3H), 1.27 (s, 3H), 1.45–1.63 (m, 1H), 1.66–1.82 (m, 1H), 1.90 (dt, 1H, $J = 2$, 12 Hz), 2.08 (s, 3H), 3.33 (dd, 1H, $J = 10$, 12 Hz), 3.76 (dd, 1H, $J = 10$, 4 Hz), 4.02 (t, 1H, $J = 4$ Hz), 10.10 (s, 1H); ^1H NMR ($CDCl_3$, 50.3 MHz) δ: −5.39, −5.35, −4.67, −4.14, 16.82, 18.1, 18.4, 20.5, 25.8 (3C), 26.0 (3C), 26.5, 30.4, 35.7, 42.3, 63.1, 70.1, 141.0, 152.9, 194.1. HRMS calcd. for $C_{23}H_{46}O_3Si_2$: 426.2985; found: 426.2988.

5-(*tert*-Butyldimethylsilyloxy)methyl-2,4,4-trimethyl-3-cyanomethyl-2-cyclohexen-1-one (49)

3,5-Dimethylaminopyridine (0.33 g, 3.43 mmol) was added to a cold (−4°C) suspension of chromium trioxide (0.35 g, 3.50 mmol) in dry dichloromethane (4 mL). the reaction mixture was stirred at 0°C for 20 min and a solution of nitrile **22** (0.450 g, 0.146 mmol) was added. The resulting red-brown solution was stirred at −4°C for 1 h and warmed to 21°C for 16 h. Dilute sodium hydroxide (6 M, 1 mL) was added and the mixture was stirred at 21°C for 20 min. Water (5 mL) and dichloromethane (10 mL) were added and the resulting solution extracted thoroughly with dichloromethane. The combined organic extracts were washed (water, 10% HCl, and brine), dried, and concentrated. The residual oil was chromatographed (petroleum ether/diethyl ether; 1:1) to afford recovered **22** (40–50%) and 0.144 g (31%) of the enone **49**, mp 75–77°C. IR (neat): 2946, 2250, 1669, 1093, 846, 776 cm^{-1}; ^1H NMR (200 MHz) : 0.00 (s, 6H), 0.84 (s, 9H), 1.11 (s, 3H), 1.29 (s, 3H), 1.86 (s, 3H), 1.9–2.10 (m, 1H), 2.42 (dd, 1H, $J = 18$, 11 Hz), 2.65 (dd, 1H, $J = 18$, 5 Hz), 3.18 (br s, 2H), 3.57 (dd, 1H, $J = 10.2$, 6.4 Hz), 3.72 (dd, 1H, $J = 10.2$, 4.6 Hz); ^{13}C NMR (75 MHz) δ: −5.6, 11.8, 17.8, 18.2, 20.9, 25.8, 26.3, 37.1, 38.8, 45.8, 63.1, 116.4, 134.7, 150.6, 197.4. HRMS calcd. for $C_{17}H_{28}O_2Si$ (M^+ − Me): 306.1889; found: 306.1861.

Acknowledgment

We are grateful to Dr. C. Bensimon for the X-ray analysis, Dr. T. Wong for additional spectral data, and to the Natural Sciences and Engineering Research Council of Canada, Merck–Frosst Canada Ltd., Rhône-Poulenc Rorer, and the Canadian Breast Cancer Research Initiative for financial support of this research and to the referees for their helpful comments.

Taxamycins: a new enediyne family with synthetic and biological potential

Yee-Fung Lu, Curtis W. Harwig, and Alex G. Fallis

Abstract: The Pd(0) based synthesis of two disilyl synthons (Z-1-trimethylsilyl-6-*tert*-butyldiphenylsilylhex-3-ene-1,5-diyne (**18**) and Z-1-trimethylsilyl-6-triisopropylsilylhex-3-ene-1,5-diyne (**19**)) and the selective removal of the trimethylsilyl group (K_2CO_3, MeOH) to afford **24** and **25** is described. These building blocks are employed in the construction of the taxamycin-12 compound **38** (16,17,18-trimethyl-2-methyloxymethoxy-9-hydroxybicyclo[9.3.1]pentadec-5-ene-3,7-diyne). The final ring closure to the 12-membered ring utilizes an intramolecular Cr–Ni mediated condensation of the iodoalkyne **37** (1,3,3-trimethyl-2-(2-oxoethyl)-4-(Z-1-methyloxymethoxy-7-iodohept-4-ene-2,6-diynyl)cyclohexene).

Key words: cancer, enediynes, synthesis, Pd(0) coupling.

Résumé : On décrit la synthèse, basée sur l'utilisation du Pd(0), de deux synthons disilyés (Z-1-triméthylsilyl-6-*tert*-butyldiphénylsilylhex-3-ène-1,5-diyne (**18**) et Z-1-triméthylsilyl-6-triisopropylsilylhex-3-ène-1,5-diyne (**19**)) et l'enlèvement sélectif du groupe triméthylsilyle (K_2CO_3, MeOH) pour conduire aux composés **24** et **25**. On a utilisé ces blocs pour la préparation du composé **38** (16,17,18-triméthyl-2-méthyloxyméthoxy-9-hydroxybicyclo[9.3.1]pentadéc-5-ène-3,5-diyne), un dérive de la taxamycine-12. La cyclisation finale du cycle à 12 chaînons fait appel à une condensation de l'iodoalcyne **37** (1,3,3-triméthyl-2-(2-oxoéthyl)-4-(Z-1-méthyloxyméthoxy-7-iodohept-4-ène-2,6-diynyl)cyclohexène) aidée par du Cr–Ni.

Mots clés : cancer, ènediynes, synthèse, couplage Pd(0).

[Traduit par la rédaction]

Introduction

Historically, medicinal leads have arisen from novel structures provided by nature. Frequently, it is not the natural products themselves that become drugs but modified forms of the original structure so that the actual therapeutic agents have improved biological activity. These changes minimize side effects, improve efficacy, and simplify the synthetic and manufacturing steps. The penicillins and tetracyclines provide well-known examples. In the antitumor cancer chemotherapy field, two quite different classes of natural products, the enediynes and taxoids, are receiving intense worldwide attention. The enediyne family forms an important new class of antitumor antibiotics that destroy cells by DNA cleavage. Compounds such as esperamicin A (**1**) (1) and calicheamicin γ_1 (**2**) (2) have generated widespread interest due to their novel mechanism of DNA cleavage (3) and the synthetic challenge these structures represent. Consequently, considerable effort is being devoted both to the synthesis of the natural products themselves (4) and a variety of structural analogues (5). (Esperamicin A_1 is currently in clinical trials in North America and Europe.)

Received June 5, 1995.

In a similar manner, the potent antitumor agent paclitaxel (Taxol,® **1**) (6) and the related analog, docetaxel (Taxotere,® **2**) (7) have proven therapeutic utility as summarized in the preceding paper. These structures have also stimulated significant research interest due to their complex structure and novel mode of action with tubulin (8). The number of new biologically active analogues is growing rapidly and a better understanding of the key structure–activity relationships is slowly emerging (9). It has been established that in certain cases the paclitaxel side chain may be attached to modified nuclei with retention of respectable tubulin activity (10). Consequently, we have designed a new family of potentially biologically active agents called taxamycins and wish to report the synthesis of the parent nucleus **38** (preliminary communication, ref. 11).

Structures **5** and **6** are representative of the parent taxamycin-12 ring system (where the number represents the size of the ring containing the enediyne unit). Structure **7** summarizes some other members of this new family but many variations are possible depending upon the ring sizes and substitution patterns. It is anticipated that with suitable functionality in place these compounds will associate with tubulin in the cell. Equipped with an appropriate cycloaromatization trigger, they should aromatize and result in DNA or related damage by hydrogen abstraction. This will depend in part on the ring size, strain, and separation of the acetylenic termini.

The sequence by which DNA cleavage occurs in the esperamicin–calicheamicin duet involves nucleophilic attack on the trisulfide followed by conjugate addition. This reaction brings the two acetylene termini into bonding distance and

Bergman cyclization (12) ensues to form a *para*-benzyne intermediate. Preferential abstraction of the C5′ hydrogen from the deoxyribose followed by oxygenation and reduction generates a hemi-acetal, which collapses to the aldehyde causing the strand to break. Related analogs have been shown recently to exert similar effects and for some systems the aromatization sequence may be initiated by thiolate (13). These dynemicin models displayed considerable in vivo potency and activity. Similarly, a synthetic calicheamicin displayed good potency against several cancers including breast and ovarian cancers, areas where taxoids are also most effective (14). This emphasizes the medicinal potential of the molecules we intend to synthesize. They may be viewed as doubly armed warheads in the fight for control and destruction of cancerous cells.

The taxamycins are also of interest for their synthetic versatility both for the construction of aromatic systems in a direct fashion and for the capture of the *para*-benzyne intermediate to functionalize the benzenoid system under neutral conditions (15). This potential is summarized in Scheme 1 by the implicit conversion of **8** to **9**. In the cell, DNA damage should occur, while in the laboratory *para* functionalization may generate **10** for taxoid synthesis. Several approaches for the total synthesis of taxol utilize benzenoid intermediates for the preparation of the C ring (16) and some recent ring C aromatic systems have displayed interesting biological activity (10*c*). The synthesis of the taxamycin-12 **38** has been examined in order to investigate these various possibilities, including the synthetic utility of the Bergman cycloaromatization in these large rings and the factors responsible for biradical formation in this series.

Results and discussion

The initial synthetic approach envisaged the use of the protected diol acetylene **14**, which was prepared from the ring A synthon, aldehyde **11**, described in the preceding paper (Chart 1). This aldehyde **11** was condensed with the lithium trimethylsilylacetylide to afford **12** as a mixture of diastereomers (1:1). The trimethylsilyl group was removed with KOH at room temperature (21°C) and the secondary alcohol protected as its MOM ether. Unfortunately, under various conditions the

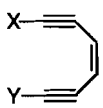
(a) HCCTMS, ^{n}BuLi, THF, −78–21°C, 1.5 h, 93%; (b) KOH, MeOH/CH_2Cl_2 (1:1), 21°C, 4 h, 90%; (c) MOMCl, $EtN^i(Pr)_2$, CH_2Cl_2, 21°C, 16 h, 70%; (d) ClCH=CHCCTMS, $Pd(Ph_3P)_4$, ^{n}BuNH$_2$, CuI, Et_2O, 21°C, 16 h, 95%.

Pd(0)–CuI mediated coupling failed to give the desired enediyne and afforded the dimer **15** (95%) instead. Competitive dimerizations have also interfered with other enediyne syntheses (17). To circumvent this problem a versatile approach based on preconstructed enediyne building blocks was selected. These compounds **17**–**19** should suffice for a variety of objectives.

The use of the dilithio salts derived from **16** to insert the enediyne chromophore was examined previously with variable results and requires the handling of a very volatile precursor (18). Our initial attempts to prepare systems such as **17** with different elements, for example silicon and tin, at the terminal acetylenes were disappointing. It is well established that



16 X = Y = H
17 X = Me_3Si, Y = Me_3Sn
18 X = Me_3Si, Y = ^{t}BuPh$_2$Si
19 X = Me_3Si, Y = ^{i}Pr$_3$Si

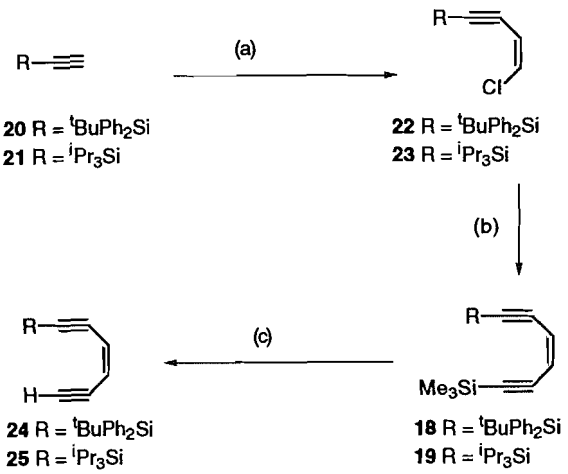
Chart 2. Synthesis of enediyne synthons.

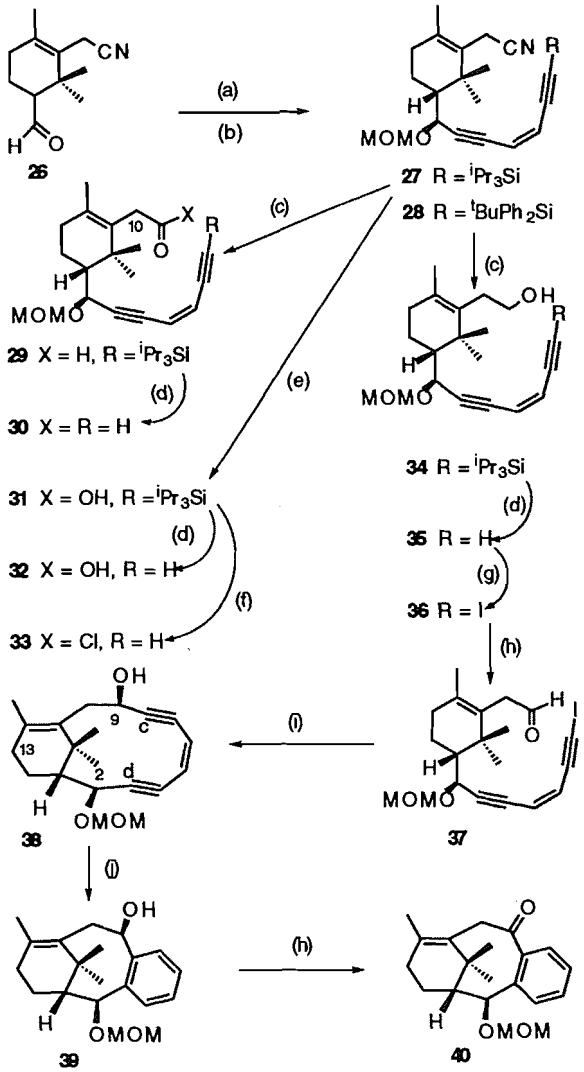


(a) ClCH=CHCl, $Pd(Ph_3P)_4$, $^nBuNH_2$, CuI, Et_2O, 21°C, 15 h, 83–95%; (b) HCCTMS, $Pd(Ph_3P)_4$, $^nBuNH_2$, CuI, Et_2O, 21°C, 16 h, 64–78%; (c) K_2CO_3, MeOH, C_6H_6, 21°C, 2 h, 90–95%.

the rates of base-induced cleavage of silylalkynes depend upon the relative steric bulk of the groups involved. (Relative rates: Et_3Si (1), Ph_3Si (12), $EtMe_2Si$ (49), Me_3Si (277) (ref. 19).) This should allow selective protection and release of the appropriate silyl group at the terminus of interest. Thus the synthesis of two suitable building blocks, Z-1-trimethylsilyl-6-*tert*-butyldiphenylsilyhex-3-ene-1,5-diyne (**18**) and Z-1-trimethylsilyl-6-triisopropylsilylhex-3-ene-1,5-diyne (**19**) was examined. As outlined in Chart 2, these compounds were prepared by repetitive Pd(0) based coupling followed by removal of the trimethylsilyl group in K_2CO_3–methanol. The triisopropyl system **25** has proven more useful than **24**. This is a consequence of the bulk and polarity of *tert*-butyldiphenylsilyl fluoride and the difficulty encountered upon chromatographic separation (silica gel) of this material from the enediyne-alcohol product in some cases. Schreiber and co-workers (20) have used a related compound, 1-*tert*-hexyldimethylsilylhex-1,5-diyne-3-ene, to introduce the enediyne unit.

For the synthesis of the model taxamycin system, the cyanoaldehyde **26** was prepared from Hagemann's ester as described in the preceding paper for the synthesis of the taxane nucleus by an intramolecular Diels–Alder approach (21). The lithium acetylide derived from **25** was condensed with **26** (Chart 3) to afford a 4:1 mixture of alcohol diastereomers. Protection of the secondary hydroxyl of the major diastereomer as its monomethyl ether proceeded slowly but smoothly to give **27** (98%). Diisobutylaluminum hydride reduction of the nitrile function in **27** could be terminated at the aldehyde stage to generate **29** directly or could be reduced further with additional reagent to generate the primary alcohol **34**. A variety of methods have been examined for the intramolecular ring closure of medium-sized cyclic enediynes, particularly for 10-membered rings that mimic calicheamicin and esperamicin. These include ring contraction of a cyclic ether by [2,3]-Wittig rearrangement (5*e*), Nicholas-type cyclization of η^2-dicobalthexacarbonyl complexed propargylic cations with Lewis acid (5*d*), direct condensation of the acetylenic anion with an aldehyde (18*a*, 22), fluoride-induced desilylation–condensation (17*a*, 23), and chromium(II)-mediated coupling of an iodoacetylene and an aldehyde (24).

Chart 3. Synthesis of the taxamycin-12 compound **40**.



(a) **24** or **25**, ^{n}BuLI, THF, −78–0°C, 1 h, 94%; (b) MOMCl, $EtN^i(Pr)_2$, CH_2Cl_2, 21°C, 16 h, 98%; (c) DIBAL-H, CH_2Cl_2, −78–0°C, 2 h, 66%; (d) $^nBu_4NF$, THF, −78°C, 2 h, 86%; (e) DIBAL-H, CH_2Cl_2, −78°C, 1 h, aq NH_4Cl; ^{t}BuOH/CH_2Cl_2 (2:1), $NaClO_2$, NaH_2PO_4, 30% H_2O_2, 21°C, 16 h, 74%; (f) $(COCl_2)$, THF, 21°C, 2 h; (d); (g) morpholine, I_2, C_6H_6, 40°C, 2 h, 86%; (h) PDC, CH_2Cl_2, 21°C, 16 h, 82%; (i) $CrCl_2$, $NiCl_2$ (cat.), THF, 21°C, 4 h, 60%; (j) sealed tube, microwave, 4 h; (h) PDC, CH_2Cl_2, 21°C, 6 h.

In spite of the success of fluoride-mediated desilylation – intramolecular condensation of silyl acetylenes with aldehydes in other systems, this direct, concurrent desilylation–cyclization with **29** to **38** did not occur under a variety of conditions. Completely anhydrous fluoride sources such as tretrabutylammonium difluorotriphenylstannate (25) also suppressed desilylation. Thus it proved most efficient to prepare **30** directly with tetrabutylammonium fluoride CsF in THF. Similarly the direct anionic condensation was unsatisfactory,

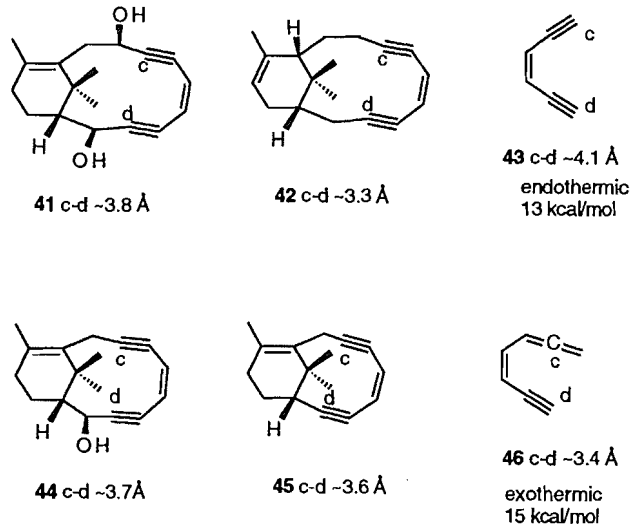
including the use of $Sn(OTf)_2$ and 1,8-bis(dimethylamino)naphthalene (26). A complication in the present example is the fact that the ring size is larger (12-membered) than any of the reported cases. In addition, the C10 hydrogens (Taxol® numbering) are both allylic and adjacent to the aldehyde so their acidity is higher than that of the acetylene proton. In an attempt to overcome these difficulties the acid chloride **33** was prepared from the corresponding carboxylic acid **31**. This was obtained from the nitrile **27** by diisobutylaluminum hydride reduction followed by sodium chloride – hydrogen peroxide oxidation (27). Unfortunately, treatment of the acid chloride under various conditions, including Pd(0) or base, was unsuccessful. In the latter case it was anticipated that ketene formation would be competitive with acetylene anion formation and the corresponding flattening of the reactive components would bring them closer together to encourage addition. In simple systems we have developed a procedure to add lithium acetylides to dimethoxy acetals in the presence of zinc chloride and boron trifluoride etherate.[2] Unfortunately, except for model aldehydes, the yields with these silyl-substituted enediynes have been poor (10–15%). In the case of aldehyde **30** attempts to form the dimethoxy acetal with cerium trichloride or other catalysts failed.

In view of the success of the $CrCl_2$–$NiCl_2$ based coupling of iodoacetylenes with aldehydes to form smaller enediyne ring systems, this approach was examined next. Desilylation of **34** with tretrabutylammonium fluoride in THF and conversion of the resulting alkyne **35** into the alkynyliodide **36** was accomplished with morpholine and iodine (86%). The primary alcohol was oxidized to the aldehyde **37** with pyridinium dichromate (82%). The desired ring closure was effected smoothly with the nickel-catalyzed chromium-based procedure to provide the bicyclo[9.3.1]pentadecadienediyne system **38** in 60% isolated yield. Recent studies (28) have used THF as the solvent and found that the yields for 10-membered rings were almost as high in the absence of $NiCl_2$. A single diastereomer of **38** was formed. Based on molecular models, preferential attack from the bottom (si face) was anticipated and thus it seems likely the new secondary alcohol at C9 is *syn* relative to the C2 MOM group. This stereochemical result is consistent with related intramolecular cases in which the same stereochemical preference was observed for closure to 10-membered rings (22*c*).

The cycloaromatization of **38** was examined to ascertain the potential for direct entry to aromatic taxanes without triggering devices or saturation of the cyclohexene double bond. Thus **38** was heated for 4 h in a sealed tube in toluene in a microwave oven. The crude alcohol **39** was oxidized directly with pyridinium dichromate to provide the aromatic ketone **40** (5% from **38**) prepared previously by a Diels–Alder-aromatization route (preceding paper). Clearly this is not a viable synthetic route to aromatic taxanes at present. Molecular mechanics calculations indicated that the c–d distance in **41** is ~3.8 Å and thus this separation is significantly larger than the separation of ~3.1 Å required for spontaneous cyclization. This separation is less than the simplest enediyne system **43** (*cis*-3-hexene-1,5-diyne) with a separation of approximately 4.1 Å, which underwent cycloaromatization – ring opening above 200°C with low efficiency. Recent calculations have determined that this reaction is endothermic by 13 kcal/mol. In contrast, the related allene system **46**, with a c–d separation of ~3.4 Å in the most favorable conformation for cyclization, closes much more readily and is exothermic by 15 kcal/mol (29). Literature examples display this same relative ease of cyclization (17*b*). As summarized in Chart 4, the lower taxamycin homologues **44** and **45** reduce the c–d separation by approximately 0.1 Å. Isomerization of the double bond away from the bridgehead as in **42** results in a 0.5 Å improvement. These features suggest that synthetic modifications to this family will in the future yield useful synthons that cycloaromatize more easily.

Chart 4. Calculation summary of c–d separations.



In conclusion, the directness of this approach to enediyne systems, using the disilyl-enediyne unit **19** followed by an intramolecular Ni–Cr mediated coupling, should prove beneficial for a variety of synthetic objectives. These include the cycloaromatization of more highly functionalized skeletons to aromatic taxoids and the synthesis of ring-contracted taxamycin-10 nuclei that should mimic their esperamicin and calicheamicin relatives.

hyde **11** (140 mg, 0.451 mmol) in dry THF (2 mL) was added dropwise and the resulting mixture was stirred at −78°C for 1 h. Saturated aqueous ammonium chloride solution was added and the mixture was warmed to 21°C (room temperature) and extracted with diethyl ether. The combined ether extracts were washed with brine and dried. Concentration of the organic material afforded 171 mg (93%) of the alcohol **12** (1:1 ratio). IR (neat): 3384, 2921, 2171, 1462, 1253, 844 cm^{-1}; ^1H NMR (200 MHz) δ: 0.00 (br s, 6H), 0.15 (br s, 9H), 0.86 (br s, 12H), 1.08 (br s, 3H), 1.10–1.60 (m, 1H), 1.69 (br s, 3H), 1.70–1.89 (m, 2H), 1.90–2.05 (m, 2H), 2.52 (br d, 2H, J = 6 Hz), 3.34 (br s, 1H, J = 10 Hz), 3.75 (br dd, 1H, J = 10, 3 Hz), 4.40–4.55 (m, 1H); MS (CI): 409 (MH^+, $C_{23}H_{44}O_2Si_2$).

4-*tert*-Butyldimethylsilyloxymethyl-1,3,3-trimethyl-2-(2-hydroxy-3-butynyl)cyclohexene (13)

A solution of potassium hydroxide (200 mg, 3.57 mmol) in methanol (5 mL) was added to a stirred solution of the alcohol **12** (171 mg, 0.419 mmol) in dichloromethane (5 mL). The resulting mixture was stirred for 4 h at 21°C. The organic solvent was removed under reduced pressure to provide a yellow oil. A mixture of diethyl ether/water (1:1) was added and the solution was extracted with diethyl ether. The combined ether extracts were washed with brine and dried. Concentration afforded alcohol **13**, 126 mg (90%, 1:1 ratio). IR (neat): 3400, 3307, 2917, 1466, 1254, 1069, 843, 776 cm^{-1}; ^1H NMR (200 MHz) δ: 0.016 (br s, 12H), 0.86 (br s, 18H), 0.88 (br s, 6H), 1.07 (br s, 6H), 1.69 (br s, 6H), 0.9–2.0 (m, 13H), 2.4–2.6 (m, 4H), 3.34 (br t, 2H, J = 10 Hz), 3.69–3.80 (m, 2H), 4.49 (br t, 2H, J = 8 Hz); MS (CI): 337 (MH^+, $C_{20}H_{36}O_2Si$).

4-*tert*-Butyldimethylsilyloxymethyl-1,3,3-trimethyl-2-(2-methoxymethylether-3-butynyl)cyclohexene (14)

Chloromethyl methyl ether (0.043 mL, 0.566 mmol, Aldrich) was added to a cold (0°C) solution of the alcohol **13** (0.126 g, 0.376 mmol) and diisopropylethylamine (0.100 mL, 0.574 mmol) in dry dichloromethane (5 mL) and the solution stirred at 21°C for 16 h. Additional chloromethyl methyl ether (0.0285 mL, 0.376 mmol) and diisopropylethylamine (0.065 mL, 0.375 mmol) were added and the mixture was stirred for another 16 h. Water was added and the mixture was extracted thoroughly with dichloromethane. The combined organic extracts were washed with brine, dried, and concentrated. Chromatography of the residual oil (20:1; petroleum ether/diethyl ether) afforded 0.099 g (70%) of the ether **14** (1:1 ratio). IR (neat): 3301, 2925, 2113, 1465, 1090 cm^{-1}; ^1H NMR (200 MHz) δ: 0.02 (br s, 12H), 0.87 (br s, 18H), 1.07 (br s, 6H), 1.53 (br s, 6H), 1.67 (br s, 6H), 1.2–2.0 (m, 12H), 2.3–2.4 (m, 2H), 2.52 (br d, 4H, J = 8 Hz), 3.29 (s, 3H), 3.32 (s, 3H), 3.3–3.4 (m, 2H), 3.7–3.8 (m, 2H), 4.38–4.55 (m, 4H), 4.86 (d, 1H, J = 6 Hz), 4.89 (d, 1H, J = 6 Hz); MS (CI): 381 (MH^+, $C_{22}H_{40}O_3Si$). Anal. calcd. for $C_{22}H_{40}O_3Si$: C 69.42, H 10.59; found: C 69.48, H 10.59.

Bis-4-*tert*-butyldimethylsilyloxymethyl-1,3,3-trimethyl-2-(2-methoxymethylether-3-butynyl)cyclohexene (15)

An anhydrous ether solution (50 mL) containing the chloride **22** (0.082 g, 0.517 mmol), acetylene **14** (0.666 g, 0.174 mmol), *n*-butylamine (0.034 mL, 0.343 mmol), tetrakistriphenylphosphine palladium (0.010 g, 0.009 mmol, Aldrich), and cuprous iodide (0.002 g, 0.010 mmol) was stirred at 21°C for 16 h. Concentration followed by chromatography (9:1; petroleum ether/diethyl ether) afforded the dimer **15**, 0.061 g (69%, 1:1 ratio. IR (neat): 2919, 2157, 1467, 1253, 1095, 1028, 848 cm^{-1}; ^1H NMR (200 MHz) δ: 0.17 (br s, 24H), 0.20 (br s, 36H), 0.86 (br s, 24H), 1.05–1.98 (m, 8H), 1.53 (s, 24H), 2.52 (br d, 8H, J ~ 8 Hz), 3.28 (s, 12H), 3.31 (s, 12H), 3.41 (m, 4H), 3.75 (d m, 4H), 4.48 (m, 8H), 4.85 (m, 4H).

***Z*-1-Chloro-4-triisopropylsilylbutene-3-yne (23)**

An anhydrous diethyl ether solution (50 mL) containing triisopropyl acetylene (1.98 g, 10.8 mmol, Aldrich), 1,2-*cis*-dichloroethylene (1.63 mL, 21.0 mmol, Aldrich), *n*-butylamine (2.10 mL, 21.6 mmol), tetrakistriphenylphosphine palladium (0.376 g, 0.30 mmol, Aldrich), and cuprous iodide (0.061 g, 0.30 mmol) were stirred at 21°C for 15 h. The reaction mixture was concentrated and chromatographed (silica gel, petroleum ether) to provide the eneyne **23** (2.17 g, 83%). IR (neat): 2945, 2154, 1463, 882, 671 cm^{-1}; ^1H NMR (200 MHz) δ: 1.06 (s, 3H), 1.08 (s, 18H), 5.88 (d, 1H, J = 7.4 Hz), 6.37 (d, 1H, J = 7.4 Hz); ^{13}C NMR (50 MHz) δ: 11.2 (3C), 18.6 (6C), 100.1, 100.7, 112.3, 129.2; HRMS (EI) calcd. for $C_{13}H_{23}SiCl$: 242.1257; found: 242.1285.

***Z*-1-Trimethylsilyl-6-triisopropylsilylhex-3-ene-1,5-diyne (19)**

An anhydrous ether solution (50 mL), containing the chloride **23** (1.96 g, 8.07 mmol), trimethylsilyl acetylene (2.27 mL, 223 mmol), *n*-butylamine (1.60 mL, 16.2 mmol), tetrakistriphenylphosphine palladium (0.280 g, 0.242 mmol, Aldrich), and cuprous iodide (0.046 g, 0.241 mmol) was stirred at 21°C for 16 h. The brown residue obtained upon concentration under reduced pressure was chromatographed (petroleum ether) to afford enediyne **19** (1.91 g, 78%). IR (neat): 2948, 2153, 2121, 1250, 1069, 848 cm^{-1}; ^1H NMR (200 MHz) δ: 0.17 (s, 9H), 1.04–1.10 (br s, 21H), 5.83 (s, 2H); ^{13}C NMR δ: 0.22 (3C), 11.2 (3C), 18.7 (6C), 99.8, 101.9, 102.9, 103.8, 120.0, 120.4; HRMS (EI) calcd. for $C_{18}H_{32}Si_2$: 304.2042; found: 304.2032.

***Z*-1-Triisopropylsilylhex-3-ene-1,5-diyne (25)**

Potassium carbonate (0.11 g, 0.80 mmol) was added to a benzene/methanol solution (1:1, 10 mL) containing **19** (0.217 g, 0.713 mmol) and the resulting mixture stirred at 21°C for 2 h. The solvent was removed, water added, and the mixture extracted thoroughly with diethyl ether. The combined ether extracts were washed with brine, dried, filtered, and concentrated to give **25** (0.157 g, 95%). IR (neat): 3303, 2945, 2149, 1463, 1049, 882, 746 cm^{-1}; ^1H NMR (200 MHz) δ: 1.0–1.1 (br s, 21H), 3.29 (dd, 1H, J = 0.8, 2.2 Hz), 5.79 (dd, 1H, J = 2.2, 11 Hz), 5.93 (dd, 1H, J = 0.8, 11 Hz); ^{13}C NMR (50 MHz) δ: 11.2 (3C), 18.6 (3C), 80.8, 84.8, 100.1, 103.3, 119.3, 121.9; HRMS (EI) calcd. for $C_{15}H_{24}Si$: 189.1099; found: 189.1100.

***tert*-Butyldiphenylsilylacetylene (20)**

tert-Butyldiphenylsilyl chloride (1.45 mL, 5.57 mmol, Aldrich) was added to a cold (0°C), stirred solution of lithium acetylide – ethylene diamine complex (0.618 g, 6.70 mmol) in anhydrous THF (30 mL). The resultant solution was stirred at 0°C for 1 h and warmed to 21°C for 16 h. Water was added slowly and the mixture was extracted thoroughly with diethyl ether. The combined organic extracts were washed with brine,

For personal use only.

dried ($MgSO_4$), and concentrated. The residual oil was recrystallized from petroleum ether/diethyl ether (1:1), to provide **20** (1.15 g, 65%): IR (KBr): 3266, 2943, 2034 cm^{-1}; ^1H NMR (200 MHz) δ: 1.08 (s, 9H), 2.69 (s, 1H), 7.30–7.40 (m, 6H), 7.70–7.80 (m, 4H); ^{13}C NMR δ: 18.4, 27.0 (3C), 85.4, 97.3, 127.8 (4C), 129.7 (2C), 132.7 (2C), 135.6 (4C); HRMS (EI) calcd. for $C_{18}H_{20}Si$: 264.1334; found: 264.1343.

Z-1-Trimethylsilyl-6-*tert*-butyldiphenylsilylhex-3-ene-1,5-diyne (18)

Copper(I) iodide (0.017 g, 0.089 mmol) was added to a stirred anhydrous diethyl ether solution (20 mL) containing the acetylene **20** (0.776 g, 2.94 mmol), *n*-butylamine (0.58 mL, 5.86 mmol), *cis*-1,2-dichloroethylene (0.44 mL, 5.83 mmol), and $Pd(Ph_3P)_4$ (0.10 g, 0.0865 mmol, Aldrich). The greenish reaction mixture was stirred at 21°C for 16 h and the resultant brownish mixture concentrated. The residual oil was chromatographed (3:1, petroleum ether/diethyl ether) to afford 0.871 g of the vinyl chloride **22** as a yellowish oil that was used directly in the next reaction. ^1H NMR (200 MHz) δ: 1.10 (s, 9H), 6.02 (d, 1H, J = 8 Hz), 6.50 (d, 1H, J = 8 Hz), 7.30–7.40 (m, 6H), 7.70–7.90 (m, 4H).

Copper(I) iodide (0.007 mmol) was added to a stirred, anhydrous, diethyl ether solution (20 mL) containing trimethylsilylacetylene (0.750 mL, 5.31 mmol), *n*-butylamine (0.53 mL, 5.36 mmol), $Pd(Ph_3P)_4$ (0.07 g, 0.060 mmol), and the vinyl chloride **22**. The reaction mixture was stirred at 21°C for 16 h and then concentrated. The black residual oil was chromatographed (petroleum ether) to afford 0.665 g (64%) of the enediyne **18**. IR (neat): 2948, 2154, 2122, 1428, 1109, 1070, 843, 700 cm^{-1}; ^1H NMR (200 MHz) δ: 0.13 (s, 9H), 1.10 (s, 9H), 5.94 (s, 2H) 7.30–7.40 (m, 6H), 7.70–7.80 (m, 4H); HRMS (EI) calcd. for $C_{21}H_{21}Si_2$ (M^+ − *tert*-butyl): 329.1181; found: 329.1163.

Z-1-*tert*-Butyldiphenylsilylhex-3-ene-1,5-diyne (24)

A benzene solution (5 mL) of **18** (0.662 g, 1.71 mmol) was added to a stirred solution of potassium bicarbonate (0.260 g, 1.88 mmol) in methanol (10 mL). The reaction mixture was stirred at 21°C for 3 h and then concentrated. Water was added and the mixture was extracted thoroughly with diethyl ether. The combined ether extracts were washed with brine, dried ($MgSO_4$), and concentrated to give 0.508 g (94%) of the enediyne **24**. IR (neat): 3293, 2944, 2152, 1428, 1187, 1051 cm^{-1}; ^1H NMR (200 MHz) δ: 1.10 (s, 9H), 3.38 (d, 1H, J = 4 Hz), 5.92 (dd, 1H, J = 4, 10 Hz), 6.05 (d, 1H, J = 10 Hz), 7.30–7.45 (m, 6H), 7.75–7.90 (m, 4H); HRMS (EI) calcd. for $C_{18}H_{13}Si$(M^+ − *tert*-butyl): 257.0787; found: 257.0792.

1,3,3-Trimethyl-2-cyanomethyl-4-(*Z*-1-methyloxymethoxy-7-triisopropylsilylhept-4-ene-2,6-diynyl)cyclohexene (27)

A solution of *n*-butyllithium (1.45 mL, 3.62 mmol, 2.5 M) in hexane was added dropwise to a cold (−78°C), stirred solution of the enediyne **25** (0.837 g, 3.61 mmol) in dry THF (30 mL). After stirring at −78°C for 15 min, a solution of (1,3,3-trimethyl-2-cyanomethyl-4-formyl)cyclohexene (**26**) (0.541 g, 2.83 mmol) in dry THF (5 mL) was added dropwise. The reaction was stirred at −78°C for further 1 h, warmed to 0°C for an additional hour, and water added. The mixture was warmed to room temperature and extracted thoroughly with diethyl ether. The combined ether extracts were washed with brine, dried ($MgSO_4$), and concentrated. The residual oil was chromatographed (5:1, petroleum ether/diethyl ether) to afford 1.13 g (94%) of the alcohol (4:1 epimeric ratio). Major diastereomer, IR (neat): 3450, 2914, 2247, 2140, 1462, 1018, 883, 669 cm^{-1}; ^1H NMR (300 MHz) δ: 1.02 (s, 3H), 1.06 (br s, 3H), 1.08 (br s, 18H), 1.15 (s, 3H), 1.59 (d, 1H, J = 4 Hz), 1.62–1.69 (m, 2H), 1.72 (s, 3H), 1.84–1.94 (m, 1H), 2.01–2.15 (m, 2H), 2.97 (AB, 2H, J = 12 Hz), 4.82 (br d, 1H, J = 4 Hz), 5.83 (br s, 2H); ^{13}C NMR (75 MHz) δ: 11.21 (3C), 16.25, 18.64 (3C), 18.83, 20.17, 21.17, 26.67, 32.42, 38.27, 50.89, 62.92, 82.19, 98.55, 99.70, 103.6, 118.9, 119.4, 120.0, 127.6, 133.8; HRMS (EI) calcd. for $C_{24}H_{34}ONSi$ (M^+ − isopropyl): 280.2410; found: 280.2424.

Chloromethyl methyl ether (0.23 mL, 3.03 mmol, Aldrich) was added to a cold (0°C) dichloromethane solution (25 mL) of the alcohol (0.863 g, 2.04 mmol) and diisopropylethylamine (0.71 mL, 4.07 mmol). The resultant solution was stirred at 0°C for 10 min and warmed to 21°C for 16 h. Water was added and the mixture was extracted thoroughly with diethyl ether. The combined organic extracts were washed sequentially with aqueous 10% HCl, water, brine, dried, filtered, and concentrated to provide the ether **27** (0.934 g, 98%). IR (neat): 2913, 2247, 2140, 1455, 1066, 883, 667 cm^{-1}; ^1H NMR (200 MHz) δ: 1.02 (s, 3H), 1.06 (s, 21H), 1.16 (s, 3H), 1.71 (s, 3H), 1.59 (d, 1H, J = 4 Hz), 1.60–1.80 (m, 2H), 1.85–2.00 (m, 1H), 2.00–2.15 (m, 2H), 2.96 (br s, 2H), 3.36 (s, 3H), 4.52 (d, 1H, J = 6.6 Hz), 4.73 (br s, 1H), 4.95 (d, 1H, J = 6.6 Hz), 5.83 (s, 2H); ^{13}C NMR (50 MHz) δ: 11.2 (3C), 16.3, 18.6 (6C), 19.8, 20.2, 22.1, 26.8, 32.7, 38.3, 50.3, 56.6, 66.7, 83.0, 94.7, 96.4, 99.5, 103.6, 119.0, 119.4, 119.6, 129.5, 133.8; HRMS (EI) calcd. for $C_{26}H_{38}O_2NSi$ (M^+ − isopropyl): 424.2671; found: 424.2655. Anal. calcd. for $C_{29}H_{45}O_2NSi$: C 74.46, H 9.70; found: C 74.43, H 9.88.

1,3,3-Trimethyl-2-cyanomethyl)-4-(*Z*-1-methyloxymethoxy-7-*tert*-butyldiphenylsilylhept-4-ene-2,6-diynyl)cyclohexene (28)

A solution of *n*-butyllithium (0.21 mL, 0.53 mmol, 2.5 M) in hexane was added dropwise to a cold (−78°C), stirred solution of the enediyne **24** (0.162 g, 0.517 mmol) in dry THF (8 mL). The black solution was stirred at −78°C for 15 min and a solution of (1,3,3-trimethy-2-cyanomethyl-4-formyl)cyclohexene (**26**) (0.090 g, 0.471 mmol) in dry THF (2 mL) was added dropwise. The reaction was stirred at −78°C for 1 h further, warmed to 0°C for an additional hour, and water added. The mixture was warmed to 21°C and extracted thoroughly with diethyl ether. The combined ether extracts were washed with brine, dried, and concentrated. The residual black oil was chromatographed (3:1, petroleum ether/diethyl ether) to afford 0.205 g (85%) of the alcohol (3:1 epimeric ratio). Major diastereomer, IR (neat): 3454, 2918, 2247, 2144, 1026 cm^{-1}; ^1H NMR (200 MHz) δ: 0.90 (s, 3H), 1.02 (s, 3H), 1.06 (s, 9H), 1.62 (s, 3H), 0.8–2.10 (m, 5H), 2.7–3.05 (m, 2H), 3.30 (s, 3H), 4.40 (d, 1H, J = 6.7 Hz), 4.75 (br d, 1H, J = 8 Hz), 4.93 (d, 1H, J = 6.7 Hz), 5.96 (br s, 2H), 7.3–7.4 (m, 6H), 7.7–7.85 (m, 4H).

Chloromethyl methyl ether (0.072 mL, 0.948 mmol, Aldrich) was added to a cold (0°C) dichloromethane solution (6 mL) of the alcohol (0.321 g, 0.636 mmol) and diisopropylethylamine (0.27 mL, 1.55 mmol). The resultant solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

stirred at 0°C for 10 min and warmed to 21°C for 16 h. Water was added and the mixture was extracted thoroughly with dichloromethane. The combined organic extracts were washed sequentially with aqueous 10% HCl, water, brine, dried, filtered, concentrated, and chromatographed (3:1, petroleum ether/diethyl ether) to provide the ether **28** (0.271 g, 78%). IR (neat): 2913, 2247, 2140, 1455, 1066, 883, 667 cm^{-1}; ^1H NMR (200 MHz) δ: 0.95 (s, 3H), 1.07 (s, 3H), 1.08 (s, 9H), 1.54 (s, 3H), 1.5–1.9 (m, 5H), 2.89 (AB, 2H, $J \sim 18$ Hz), 3.30 (s, 3H), 4.40 (d, 1H, $J = 6.7$ Hz), 4.70 (br s, 1H), 4.91 (d, 1H, $J = 6.7$ Hz), 5.96 (br s, 2H), 7.3–7.42 (m, 6H), 7.75–7.82 (m, 4H); ^{13}C NMR (50 MHz) δ: 16.3, 18.7, 19.9, 20.2, 22.1, 26.8, 27.1 (3C), 32.5, 38.2, 50.2, 56.6, 66.7, 83.0, 94.7, 97.8, 97.9, 105.6, 119.0, 119.3, 120.6, 120.7, 127.3, 127.8 (4C), 129.6 (2C), 132.9, 133.8; HRMS (EI) calcd. for $C_{32}H_{34}O_2NSi$: 492.2358; found: 492.2349.

1,3,3-Trimethyl-2-(2-oxoethyl)-4-(*Z*-1-methyloxymethoxy-7-triisopropylsilylhept-4-ene-2,6-diynyl)cyclohexene (29)

A toluene solution of diisobutylaluminum hydride (1 M, 0.58 mL, 0.58 mmol, Aldrich) was added dropwise to a cold (−78°C), stirred solution of the nitrile **27** (0.136 g, 0.291 mmol) in dry dichloromethane (5 mL). The reaction was stirred at −78°C for 1 h and warmed to 0°C for an additional hour. Dilute HCl (aqueous 5%) was added, the mixture was stirred at 21°C for 30 min, and the solution was extracted thoroughly with diethyl ether. The combined organic extracts were washed with water, brine, dried, filtered, and concentrated and the residual oil was chromatographed (3:1, petroleum ether/diethyl ether) to afford 0.091 g (66%) of the aldehyde **29**. IR (neat): 2914, 2718, 2141, 1723, 1463, 1029, 883 cm^{-1}; ^1H NMR (200 MHz) δ: 0.98 (s, 3H), 1.06 (s, 24H), 1.55 (s, 3H), 1.60–1.84 (m, 2H), 1.85–2.00 (m, 1H), 2.00–2.20 (m, 2H), 3.07 (br s, 1H), 3.35 (br s, 1H), 3.36 (br s, 3H), 4.53 (d, 1H, $J =$ 8 Hz), 4.73 (br s, 1H), 4.95 (d, 1H, $J = 8$ Hz), 5.82 (br s, 2H), 9.47 (t, 1H, $J = 1.5$ Hz); ^{13}C NMR (75 MHz) δ: 11.3 (3C), 18.7 (6C), 20.1, 22.3, 27.1, 32.9, 43.8, 50.7, 56.6, 66.9, 82.8, 93.7, 94.7, 96.7, 99.4, 103.5, 119.4, 128.7, 132.5, 201.0; HRMS (EI) calcd. for $C_{27}H_{41}O_2Si$ (M^+ − isopropyl): 425.2876; found: 425.2877.

1,3,3-Trimethyl-2-(2-oxoethyl)-4-(*Z*-1-methyloxymethoxyhept-4-ene-2,6-diynyl)cyclohexene (30)

A dry THF solution (6 mL) of the silyl acetylene **29** (0.038 g, 0.107 mmol) was cooled to −78°C and then a 1 M solution of *n*-tetrabutyl ammonium fluoride (0.11 mL, 0.11 mmol) added dropwise. The reaction was stirred at −78°C for 2 h, water was added, and the resultant solution was extracted thoroughly with diethyl ether. The combined ether extracts were washed with brine, dried ($MgSO_4$), filtered, and concentrated and the residual oil was chromatographed (3:1, petroleum ether/diethyl ether) to give 0.027 g (86%) of the acetylene **30**. IR (neat): 3275, 2918, 2720, 2094, 1720, 1462, 1150, 1000 cm^{-1}; ^1H NMR (200 MHz) δ: 0.99 (s, 3H), 1.07 (s, 3H), 1.55 (s, 3H), 1.0–2.2 (m, 5H), 3.07 (br s, 2H), 3.28 (br s, 1H), 3.38 (s, 3H), 4.57 (d, 1H, $J = 6.5$ Hz), 4.73 (br s, 1H), 5.02 (d, 1H, $J = 6.5$ Hz), 5.76 (br d, 1H, $J = 10$ Hz), 5.90 (d, 1H, $J = 10$ Hz), 5.90 (d, 1H, $J = 10$ Hz), 9.49 (t, 1H, $J = 2$ Hz); HRMS (EI) calcd. for $C_{18}H_{21}I_2$ ($M^+ - CH_3OCH_2$): 269.1541; found: 269.1530.

1,3,3-Trimethyl-2-(2-carboxyethyl)-4-(*Z*-1-methyloxymethoxy-7-triisopropylsilylhept-4-ene-2,6-diynyl)cyclohexene (31)

Diisobutylaluminum hydride (0.350 mL, 0.525 mmol, 1 M in toluene) was added dropwise to a cold (−78°C), stirred solution of the nitrile **27** (0.171 g, 0.366 mmol) in dry dichloromethane (10 mL). The resulting mixture was stirred at −78°C for 1 h. Saturated aqueous ammonium chloride was added; the mixture was stirred at room temperature for 30 min and extracted thoroughly with dichloromethane. The combined organic extracts were washed (water, brine), dried, and concentrated. Sodium chlorite (0.060 g, 0.663 mmol) was added to a solution (2:1, *tert*-butanol/dichloromethane, 15 mL) of the aldehyde **29**, aqueous NaH_2PO_4 (0.10 g in 2 mL), and 30% H_2O_2 (0.12 mL, 1.06 mmol). The mixture was stirred at 21°C for 16 h and concentrated. 10% HCl was added and the resulting mixture was extracted thoroughly with diethyl ether. The combined ether extracts were washed (water, 6% sodium thiosulphate solution, and brine), dried, and concentrated. Flash chromatography (1:1, petroleum ether/diethyl ether; then 2:1, petroleum ether/diethyl ether) afforded 0.140 g (74%) of the acid **31**. IR (neat): 2924, 2703, 2141, 2103, 1711, 1463, 1028 cm^{-1}; ^1H NMR (200 MHz) δ: 1.01 (s, 3H), 1.06 (s, 3H), 1.07 (br s, 20H), 1.59 (s, 3H), 1.5–2.15 (m, 6H), 3.10 (s, 2H), 3.37 (s, 3H), 4.52 (d, 1H, $J = 6.7$ Hz), 4.78 (br s, 1H), 4.97 (d, 1H, $J = 6.7$ Hz), 5.83 (br s, 2H), 10.0 (br s, 1H); ^{13}C NMR (75 MHz) δ: 11.3 (3C), 18.5, 18.6 (6C), 19.9, 20.5, 22.6, 27.1, 32.4, 33.7, 37.9, 50.1, 56.7, 67.1, 83.2, 94.8, 96.5, 99.5, 103.6, 119.5, 119.5, 130.1, 132.9, 176.0.

1,3,3-Trimethyl-2-(2-carboxyethyl)-4-(*Z*-1-methyloxymethoxyhept-4-ene-2,6-diynyl)cyclohexene (32)

A solution of the silyl acetylene **27** (0.084 g, 0.162 mmol) in dry THF (5 mL) was cooled to −78°C and *n*-tetrabutyl ammonium fluoride (0.32 mL, 0.32 mmol, 1 M THF) was added dropwise. The mixture was stirred at −78°C for 5 h, quenched with water, and extracted thoroughly with diethyl ether. The combined ether extracts were washed (10% HCl, brine), dried, concentrated, and chromatographed (3:1 petroleum ether/diethyl ether, then 1:1 petroleum ether/diethyl ether) to provide **32**, 0.0410 g (77%). IR (neat): 3281, 2929, 2094, 1714, 1464, 1151, 1029 cm^{-1}; ^1H NMR (200 MHz) δ: 0.87 (s, 3H), 1.08 (s, 3H), 1.59 (s, 3H), 1.5–2.30 (m, 5H), 1.58 (s, 3H), 3.08 (br s, 2H), 3.28 (d, 1H, $J = 2.2$ Hz), 3.37 (s, 3H), 4.55 (d, 1H, $J = 6.7$ Hz), 4.74 (br s, 1H), 5.01 (d, 1H, $J = 6.7$ Hz), 5.76 (dd, 1H, $J = 10.9$, 2.2 Hz), 5.88 (d, 1H, $J = 10.9$ Hz), 10.50 (br s, 1H).

1,3,3-Trimethyl-2-(2-hydroxymethyl)-4-(*Z*-1-methyloxymethoxy-7-triisopropylsilylhept-4-ene-2,6-diynyl)cyclohexene (34)

A toluene solution of diisobutylaluminum hydride (1.5 M, 0.55 mL, 0.825 mmol, Aldrich) was added dropwise to a cold (−78°C), stirred solution of the nitrile **27** (0.351 g, 0.752 mmol) in dry dichloromethane (10 mL). The resulting mixture was stirred at −78°C for 1 h and warmed to 0°C for an additional hour. Dilute HCl (aqueous 5%) was added and the mixture was stirred at 21°C for 30 min. The solution was extracted thoroughly with dichloromethane. The combined organic

For personal use only.

extracts were washed with water, brine, dried ($MgSO_4$), filtered, and concentrated and the residual oil was filtered through a short column of neutral alumina to afford the aldehyde **29**. This material was dissolved in dry dichloromethane (10 mL) and the reduction procedure repeated (diisobutylaluminum hydride, 1.5 M, 0.55 mL, 0.825 mmol). Chromatography (silica gel; 3:1, petroleum ether/diethyl ether) of the resulting oil provided the alcohol **34** (0.180 g, 51%). IR (neat): 3348, 2913, 2141, 1461, 1028 cm^{-1}; ^1H NMR (200 MHz) δ: 1.00 (s, 3H), 1.06 (br s, 24H), 1.1–1.4 (m, 2H), 1.62 (s, 3H), 1.5–2.1 (m, 4H), 2.32 (br t, 2H, J = 8 Hz), 3.36 (s, 3H), 3.58 (br q, 2H, J = 8 Hz), 4.52 (d, 1H, J = 6.6 Hz), 4.77 (br s, 1H), 4.94 (d, 1H, J = 6.6 Hz), 5.81 (br s, 2H); ^{13}C NMR (50 MHz) δ: 11.2 (3C), 18.6 (6C), 19.9, 20.3, 22.9, 27.3, 32.2, 32.6, 38.1, 50.8, 56.5, 62.4, 66.9, 82.7, 94.7, 97.0, 99.3, 103.6, 119.4, 119.5, 129.6, 132.8, 201.0; HRMS (EI) calcd. for $C_{29}H_{48}O_3Si$: 472.3373; found: 472.3426.

1,3,3-Trimethyl-2-(2-hydroxymethyl)-4-(*Z*-1-methyloxymethoxyhept-4-ene-2,6-diynyl)cyclohexene (35)

A dry THF solution (10 mL) of the silyl acetylenic alcohol **34** (0.130 g, 0.275 mmol) was cooled to −78°C and then a 1 M solution of *n*-tetrabutyl ammonium fluoride (0.55 mL, 0.540 mmol) was added dropwise. The reaction was stirred at −78°C for 1 h, warmed to 0°C, water was added, and the resultant solution was extracted thoroughly with diethyl ether. The combined ether extracts were washed with brine, dried ($MgSO_4$), filtered, and concentrated and the residual oil was chromatographed (1:1, petroleum ether/diethyl ether) to give 0.079 g (91%) of the acetylene **35**. IR (neat): 3366, 3286, 2921, 2094, 1459, 1150, 1029 cm^{-1}; ^1H NMR (200 MHz) δ: 0.99 (s, 3H), 1.09 (s, 3H), 1.60 (s, 3H), 1.5–2.0 (m, 6H), 2.30 (br t, 2H, J = 8 Hz), 3.27 (d, 1H, J = 1 Hz), 3.36 (s, 3H), 3.55 (t, 2H, J = 8 Hz), 4.54 (d, 1H, J = 6.8 Hz), 4.71 (br s, 1H), 4.99 (d, 1H, J = 6.8 Hz), 5.75 (dd, 1H, J = 11, 2.2 Hz), 5.88 (dt, 1H, J = 11. 0.5 Hz); HRMS (EI) calcd. for $C_{18}H_{21}O_2$ ($M^+ - CH_3OCH_2$): 269.1541; found: 269.1530.

1,3,3-Trimethyl-2-(2-hydroxymethyl)-4-(*Z*-1-methyloxymethoxy-7-iodohept-4-ene-2,6-diynyl)cyclohexene (36)

Freshly dried morpholine (0.29 g, 3.31 mmol) and iodine (0.11 g, 0.433 mmol) were added sequentially to the acetylene **35** (0.070 g, 0.222 mmol) dissolved in dry benzene (10 mL) in a round-bottom flask (25 mL) equipped with a condenser. The reaction mixture was heated and stirred at ~40°C for 3 h. The mixture was then cooled to 21°C and aqueous sodium thiosulphate solution (6%) added. The resulting mixture was extracted thoroughly with diethyl ether. The combined organic extracts were washed with brine, dried, filtered, concentrated, and chromatographed (1:1, petroleum ether/diethyl ether) to afford the iodoalcohol **36** (0.084 g, 86%). IR (neat): 3376, 2927, 2247, 2153, 1029, 914 cm^{-1}; ^1H NMR (200 MHz) δ: 1.02 (s, 3H), 1.13 (s, 3H), 1.1–2.1 (m, 6H), 1.63 (s, 3H), 2.34 (br t, 2H, J = 8 Hz), 3.38 (s, 3H), 3.60 (br t, 2H, J = 8 Hz), 4.58 (d, 1H, J = 6.3 Hz), 4.73 (br s, 1H), 5.00 (d, 1H, J = 6.3 Hz), 5.78 (dd, 1H, J = 10, 1 Hz), 5.89 (d, 1H, J = 10 Hz); ^{13}C NMR (50 MHz) δ: 20.2, 20.4, 22.8, 27.5, 32.3, 32.8, 38.2, 50.9, 56.6, 62.5, 67.0, 82.5, 91.7, 94.7, 97.4, 119.6, 119.8, 121.7, 129.7, 132.8.

1,3,3-Trimethyl-2-(2-oxoethyl)-4-(*Z*-1-methyloxymethoxy-7-iodohept-4-ene-3,6-diynyl)cyclohexene (37)

Pyridinium dichromate (0.136 g, 0.359 mmol) was added to a stirred solution of the alcohol **36** (0.080 g, 0.181 mmol) in dry dichloromethane (10 mL). The resulting mixture was stirred at 21°C for 16 h. The reaction mixture was filtered through a sintered glass funnel under aspirator pressure and the collected precipitate washed thoroughly with diethyl ether. The ether filtrates were concentrated to provide a brownish oil that was purified by chromatography (3:1, petroleum ether/diethyl ether) to afford the aldehyde **37** (0.065 g, 82%). IR (neat): 2924, 2721, 2251, 2154, 1718, 1042, 1021 cm^{-1}; ^1H NMR (200 MHz) δ: 1.00 (s, 3H), 1.08 (s, 3H), 1.0–2.2 (m, 5H), 1.55 (s, 3H), 3.08 (br s, 2H), 3.39 (s, 3H), 4.58 (d, 1H, J = 7 Hz), 4.73 (br s, 1H), 5.00 (d, 1H, J = 7 Hz), 5.77 (dd, 1H, J = 9, 1.5 Hz), 5.91 (d, 1H, J = 9 Hz), 9.48 (t, 1H, J = 2.3 Hz); ^{13}C NMR (50 MHz) δ: 20.4, 22.3, 27.1, 29.7, 33.0, 38.1, 43.8, 50.7, 56.6, 66.9, 82.7, 91.7, 94.7, 97.2, 119.9, 121.7, 128.8, 131.6, 132.7, 201.2; HRMS (EI) calcd. for $C_{18}H_{20}O_2$ ($M^+ - CH_3OCH_2$): 395.0467; found: 395.0501.

16,17,18-Trimethyl-2-methyloxymethoxy-9-hydroxybicyclo[9.3.1]pentadec-5-ene-3,7-diyne (38)

Nickel(II) chloride (0.012 g, 0.096 mmol) and chromium(II) chloride (0.170 g, 1.38 mmol) were added to a stirred solution of the aldehyde **37** (0.061 g, 0.138 mmol) in dry THF (20 mL). The resulting mixture was stirred at 21°C for 4 h, water was added, and the mixture was extracted thoroughly with diethyl ether. The combined organic extracts were washed with brine, dried ($MgSO_4$), filtered, concentrated, and chromatographed (3:1, petroleum ether/diethyl ether, then 1:1, petroleum ether/diethyl ether) to the cyclic enediyne **38** (0.026 g, 60%). IR (neat): 3380, 2924, 2204, 1029 cm^{-1}; ^1H NMR (200 MHz) δ: 1.10 (s, 3H), 1.29 (s, 3H), 1.5–2.1 (m, 5H), 1.64 (s, 3H), 2.3–2.7 (m, 3H), 3.35 (s, 3H), 4.50 (d, 1H, J = 6.8 Hz), 4.59 (br s, 1H), 4.89 (d, 1H, J = 6.8 Hz), 5.02–5.18 (m, 1H), 5.78 (br s, 2H); ^{13}C NMR (50 MHz) δ: 21.0, 25.1, 25.3, 29.4, 32.0, 36.7, 37.2, 49.1, 55.6, 63.5, 70.1, 82.8, 84.9, 93.3, 95.4, 98.4, 120.7, 121.2, 131.1, 132.5; HRMS (EI) calcd. for $C_{18}H_{21}O_2$ ($M^+ - CH_3OCH_2$): 269.1542; found: 269.1541.

3,4,5,6,7,8-Hexadehydro-2*a*-methoxymethyl-9-oxo-12,15,15-trimethyltricyclo[9.3.1.$0^{3,8}$]pentadec-11-ene (40)

The alcohol **38** (0.015 g, 0.05 mmol) in dry toluene (10 mL) containing 1,4-cyclohexadiene (0.5 mL) was placed in a thick-walled Pyrex pressure tube equipped with a threaded plastic cap. The top of the tube extended through a small hole in the tope of the microwave oven. Argon was bubbled through the solution for 10 min and the vessel sealed. The diameter of the oven opening is less than 3 cm and is shielded to minimize microwave leakage. The base of the tube inside the microwave oven was surrounded by a beaker of damp (H_2O) vermiculite to facilitate heat transfer. A commercial oven was used (Toshiba model ERF-6630C (720 W)) at a power setting of 500 W in which the magnetron was tuned to the water frequency (2450 MHz). The reaction was conducted behind a shield in a fume hood. The reaction was heated for eight 0.5 h intervals in which the tube was allowed to return to room temperature between each session and fresh moist vermiculite was

added to the beaker. The tube was cooled, solvent was evaporated, and the residual oil chromatographed (petroleum ether/diethyl ether, 3:1) to generate the alcohol, which was used directly. Alcohol **39** was dissolved in CH_2Cl_2, pyridinium dichromate (0.10 g) was added, and the reaction was stirred at 21°C for 6 h. After filtration through a sintered glass funnel under reduced pressure (water aspirator) the solution was concentrated and chromatographed (petroleum ether/diethyl ether, 3:1) to afford 0.001 g (6%) of ketone **40**. Identified by spectral comparison (NMR, IR, MS) with an authentic sample (preceding paper).

Acknowledgment

We are grateful to the Natural Sciences and Engineering Research Council of Canada, to Merck-Frosst Canada Ltd. and Rhône-Poulenc Rorer for financial support of this research, and to Torcan Chemical Ltd. for a gift of trimethylsilylacetylene. We thank the referees for their comments.

Abstract: A pair of laminar, premixed, CH_4–O_2 flames above 2000 K at atmospheric pressure, one fuel-rich (FR) and the other fuel-lean (FL), were doped with $\sim 10^{-6}$ mol fraction of the second-row transition metals Y, Zr, Nb, and Mo. Since these hydrocarbon flames contain natural ionization, metallic ions were produced in the flames by the chemical ionization (CI) of metallic neutral species, primarily by H_3O^+ and OH^- as CI sources. Both positive and negative ions of the metals were observed as profiles of ion concentration versus distance along the flame axis by sampling the flames through a nozzle into a mass spectrometer. For yttrium, the observed ions include the $YO^+{\cdot}nH_2O$ (n = 0–3) series, and $Y(OH)_4^-$. With zirconium, they include the $ZrO(OH)^+{\cdot}nH_2O$ (n = 0–2) series, and $ZrO(OH)_3^-$. Those observed with niobium were the cations $Nb(OH)_3^+$ and $Nb(OH)_4^+$, and the single anion $NbO_2(OH)_2^-$. For molybdenum, they include the cations $MoO(OH)_2^+$ and $MoO(OH)_3^+$, and the anions MoO_3^- and $MoO_3(OH)^-$. Not every ion was observed in each flame; the FL flame tended to favour the ions in higher oxidation states. Also, flame ions in higher oxidation states were emphasized for these second-row transition metals compared with their first-row counterparts. Some ions written as members of hydrate series may have structures different from those of simple hydrates; e.g., $YO^+{\cdot}H_2O = Y(OH)_2^+$ and $ZrO(OH)^+{\cdot}H_2O = Zr(OH)_3^+$, etc. The ion chemistry for the production of these ions by CI in flames is discussed in detail.

Key words: transition metals, ions, flame, gas phase, negative ions.

Résumé : Une paire de flammes laminaires prémélangées de CH_4–O_2, l'une riche en carburant (FR) et l'autre déficiente en carburant (FL), ont été dopées par des métaux de transition de la deuxième période, Y, Zr, Nb et Mo (fraction molaire d'environ 10^{-6}), à des températures supérieures à 2000 K et à la pression atmosphérique. Puisque ces flammes d'hydrocarbures comportent des ionisations naturelles, les ions métalliques ont été produits dans les flammes par l'ionisation chimique (IC) des espèces métalliques neutres, principalement par des sources d'IC de H_3O^+ et OH^-. On a observé les ions tant positifs que négatifs des métaux sous la forme de profiles de la concentration ionique en fonction de la distance le long de l'axe de la flamme par le biais d'un échantillonnage des flammes à travers la tuyère dans un spectromètre de masse. Pour l'yttrium, les ions observés incluent ceux de la série $YO^+{\cdot}nH_2O$ (n = 0–3) et $Y(OH)_4^-$. Avec le zirconium, ils comportent ceux de la série $ZrO(OH)^+{\cdot}nH_2O$ (n = 0–2) et $ZrO(OH)_3^-$. Avec le niobium, on a observé les cations $Nb(OH)_3^+$ et $Nb(OH)_4^+$ ainsi qu'un seul anion, le $NbO_2(OH)_2^-$. Pour le molybdène, ils comportent les cations $MoO(OH)_2^+$ et $MoO(OH)_3^+$ ainsi que les anions MoO_3^- ainsi que $MoO_3(OH)^-$. Tous ces anions n'ont pas été observés dans toutes les flammes; avec les flammes FL, on observe principalement les ions des états d'oxydation les plus élevés. On a aussi observé que les états d'oxydation les plus élevés sont plus favorisés dans les flammes des métaux de transition de la deuxième période par rapport à leurs équivalents de la première période. Quelques-uns des ions pour lesquels des structures hydrates ont été proposées pourraient posséder des structures différentes, comme $YO^+{\cdot}H_2O = Y(OH)_2^+$ et $ZrO(OH)^+{\cdot}H_2O = Zr(OH)_3^+$. On discute en détail de la chimie ionique conduisant à la production de ces ions par IC dans des flammes.

Mots clés : métaux de transition, flammes, phase gazeuse, ions négatifs.

Introduction

A few years ago, we studied the cation chemistry of the first row of 10 transition metals Sc–Zn in a premixed, fuel-rich, CH_4–O_2 flame (1, 2). The metals were introduced at a concentration of $\sim 10^{-6}$ mol fraction, and ions were produced by chemical ionization (CI) of metallic flame species by H_3O^+, which occurs naturally in any hydrocarbon flame. Metallic ions were observed by sampling the flame through a nozzle into a mass spectrometer. More recently, we observed the positive flame ionization of the group 3 metals Sc, Y, and La in H_2–O_2–Ar flames of both fuel-rich (FR) and fuel-lean (FL) composition that contain essentially no natural ionization (3). The CI of metallic species by H_3O^+ was also studied, where the H_3O^+ reagent was generated by adding 0.2 mol% of CH_4 to the hydrogen premixed flame gas. The objective of the present study was to extend this work to include further second-row transition metals Zr, Nb, and Mo as well as Y for comparison with the flame-ion chemistry of their first-row counterparts.

Much of the gas-phase organometallic ion chemistry that has been carried out at room temperature is not really applicable to flames because metal–carbon bond formation is not observed. Apart from atomic cations A^+, metallic flame ions exhibit metal–oxygen bonds almost exclusively, although AH^+ has been observed for Mn (2), Fe, Co, and Ni (1). For the second-row transition metals, Armentrout and co-workers (4, 5) have measured the bond dissociation energies $D(A^+ - H)$ to be 259±4 (Y), 230±13 (Zr), 226±13 (Nb), and 176±13 (Mo) kcal mol^{-1}. From gas-phase solvation studies with water, Wilson and Buckner (6) observed the ion series $YO^+ \cdot nH_2O$ ($n = 0$–3) in which the third solvent molecule attaches more rapidly than the second, i.e., to form $Y(OH)_2(H_2O)_2^+$ with $n = 3$. Similarly, Nb^+ with water follows the reaction sequence $Nb^+ \rightarrow NbO^+ \rightarrow NbO_2^+ \rightarrow NbO_2^+ \cdot nH_2O$ ($n = 0$–3) in which the second solvent molecule attaches more rapidly than the first; the ion can be interpreted as $ONb(OH)_2(H_2O)^+$ with $n = 2$. The negative molybdenum ions $HMoO_4^-$ and MoO_3^- were detected in H_2–O_2–N_2 flames seeded with potassium by Jensen and Miller (7), who determined approximate values for the corresponding electron affinities to be $EA(HMoO_4) = 410$ and $EA(MoO_3) = 249$ kJ mol^{-1}; a more recent value is $EA(MoO_3) = 277 \pm 19$ kJ mol^{-1} (8).

For the present study, a pair of CH_4–O_2 flames, one FR and the other FL (i.e., oxygen-rich), were doped with $\sim 10^{-6}$ mol fraction of Y, Zr, Nb, and Mo. Both metallic cations and anions, formed by CI of metallic flame neutrals reacting with natural flame ions (primarily H_3O^+ and OH^-), were observed as profiles of ion concentration versus distance along the flame axis by sampling the flame through a nozzle into a mass spectrometer. The addition of an FL flame for this work was intended to enhance anion formation for these heavier transition metals.

Experimental

These experiments employed small, conical, premixed, CH_4–O_2 flames ~4–5 mm high at atmospheric pressure whose bulk characteristics are given in Table 1. They were stabilized on a simple, tubular, quartz burner surrounded by a flowing argon shield to minimize the entrainment of atmospheric air. The transition metals Y, Zr, Nb, and Mo were introduced as an aerosol by spraying a 0.25 M (molar) aqueous solution of the metallic chloride using a pneumatic atomizer (9). The salts were obtained from the Aldrich Chemical Company (the stated purity is given in parentheses): $YCl_3 \cdot 6H_2O$ (99.9%); $ZrCl_5$ (99.5%); $NbCl_5$ (99%); and $MoCl_5$ (98%). The atomizer was operated by a flow rate of 1 standard cm^3 s^{-1} using part of the flame's oxygen supply, with one exception; with the molybdenum solution, part of the methane supply was employed instead to minimize the rapid oxidation of $MoCl_5$. This technique introduced nearly 1 ppm (9×10^{-7}, or $\sim 10^{-6}$ mol fraction) of metal into the burnt gas of the flame. The undoped flames had a bluish colour, which was more distinct in the FR than in the FL case. The addition of Y coloured the FR flame red but the colour was not noticeable in the FL flame. The addition of Nb gave the appearance of yellowish-orange streaks or lines in both flames. No change in colour was observed in either flame with the addition of Zr or Mo.

Table 1. Bulk characteristics of the CH_4–O_2 flames.

Parameter / flame	Fuel-rich	Fuel-lean
Equivalence ratio ϕ	2.25	0.219
Unburnt gas flow rate (cm^3 s^{-1})	16.43	17.35
CH_4/O_2	1.13/1	1/9.15

H	0.008 2495	0.000 1484
OH	0.000 7485	0.011 4172
O	0.000 0099	0.003 2108

The flame-ion mass spectrometer has been described in detail (10), and only a brief description will be given here. The burner is mounted on a motor-driven carriage, and the flame axis is accurately aligned with the mass spectrometer's sampling nozzle of diameter ca. 0.15 mm. Ions in the sampled flame gas are formed into a beam by an ion lens, and pass through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions are detected with a parallel-plate Faraday collector connected to an electrometer having a grid-leak resistance of 10^{10} Ω. Ion signals in the figures below are given in volts, corresponding to the collected ion current passing through 10^{10} Ω. Positive or negative ions can be detected by reversing the polarity on all electrodes. In addition to individual ionic species, total positive ions (TPI) or total negative ions (TNI) are measured by removing the d.c. voltages applied to the quadrupole rods. Data are presented as profiles of ion signal versus distance z along the flame axis. A relatively sharp minimum in the pressure profile of the sampled gas provides a reproducible origin ($z = 0$) *in the flame* for the distance scale. It corresponds approximately to the downstream edge at the tip of the flame's bright luminous reaction zone. The pressure is measured with an ionization gauge mounted on the wall of the chamber housing the mass filter.

Some ion signals can be distorted during sampling by the

Fig 1. Total positive ion (TPI) profiles along the flame axis z of the fuel-rich (FR) and fuel-lean (FL) flames. The reaction zone is located upstream of $z = 0$ (negative z).

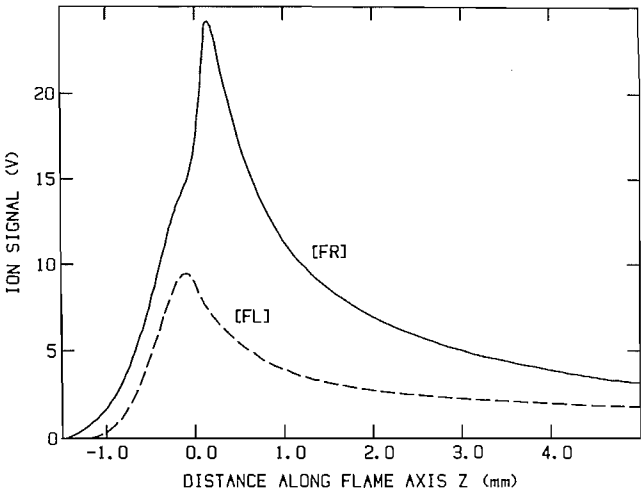

Fig 2. Total negative ion (TNI) profiles along the flame axis z of the fuel-rich (FR) and fuel-lean (FL) flames. The reaction zone is located upstream of $z = 0$ (negative z).

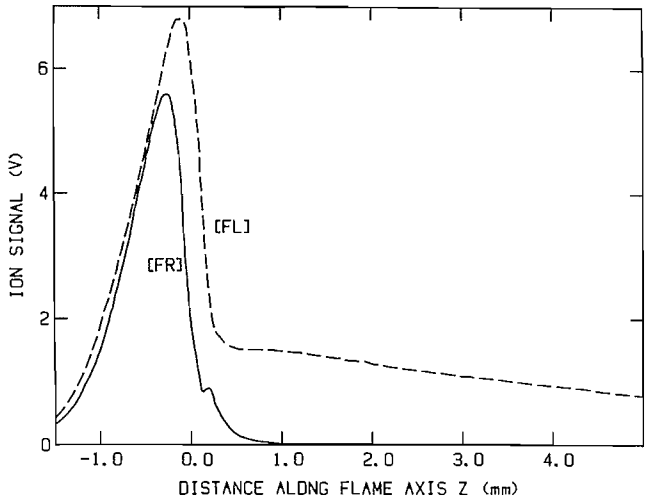

mass spectrometer. The flame gas cools in passing through the thermal boundary layer surrounding the sampling orifice (11), and during the expansion to supersonic velocity that occurs for a few orifice diameters downstream of the nozzle throat (12). A fast ionic equilibrium having a relaxation time comparable to the sampling time (~1 μs) can shift to enhance the product ion in the exothermic direction. A common example in flames is the enhanced formation of H_3O^+ hydrates. Thus, it should be remembered that the measured signal magnitudes can correspond to a temperature several hundred degrees cooler than the actual temperature of the flame.

Results and discussion

Reagent ions for chemical ionization (CI)

Any hydrocarbon flame contains natural ionization initiated by the chemi-ionization reaction (13, 14)

[1] $CH + O \rightarrow HCO^+ + e^-$

Although HCO^+ may undergo a variety of proton transfer reactions in the flame reaction zone, downstream in the burnt-gas region where water is the major product of relatively high proton affinity, the cation chemistry is dominated by H_3O^+ (15)

[2] $HCO^+ + H_2O \rightleftarrows H_3O^+ + CO$

which serves as the major positive reagent ion for CI of flame additives. Similarly, the natural anion chemistry stems from the free electrons e^- produced in reaction [1], initially by three-body attachment to O_2 oxidant molecules (16)

[3] $e^- + O_2 + M \rightleftarrows O_2^- + M$

where M is a third body. The O_2^- ions then charge transfer to other flame neutrals of higher electron affinity including the radicals OH and O

[4] $O_2^- + OH,O \rightleftarrows OH^-,O^- + O_2$

Although other anions are also formed, OH^- and O^- are major reagent anions for CI because they are strong bases, capable of abstracting protons from a variety of flame neutrals including additives; alternatively, these anions can undergo addition reactions with neutral flame species.

Concentration profiles of the total positive ions (TPI) versus distance z along the flame axis are shown in Fig. 1 for the FR and FL flames. The cations reach a maximum concentration near $z = 0$ on the flame axis, and are dominated by H_3O^+ downstream in the burnt gas where the signal decreases steadily by electron–ion recombination (17)

[5] $H_3O^+ + e^- \rightarrow H + H + OH$, or $H + H_2O$

In the FR flame, the peak concentration is approximately 10^{-8} mol fraction or 3×10^{10} ions cm^{-3}, and is about 1/3 that value or 1×10^{10} ions cm^{-3} in the FL flame (16). The total negative ions (TNI), whose profiles are shown in Fig. 2, maximize in the flame reaction zone upstream ($z < 0$). In the FR flame, the TNI signal disappears just downstream of $z = 0$, primarily by associative electron detachment reactions of any general anion X^- with H atoms (18)

[6] $X^- + H \rightleftarrows e^- + HX$

because [H] is large in the burnt gas of the FR flame. In contrast, the peak TNI signal in the FL flame decreases downstream of $z = 0$ but persists throughout the burnt gas where [H] is lower in the FL case. In summary, H_3O^+ is the major cation and OH^- (which exceeds O^-) the major anion to act as CI reagents for additives introduced into this pair of FR and FL methane–oxygen flames. The four metals Y, Zr, Nb, and Mo will be discussed in turn beginning with the cation chemistry, followed by the anion chemistry.

Yttrium ion chemistry

Since Y is a group 3 metal with electron configuration $5s^24d^1$, its chemistry should be dominated by the +3 oxidation state, leading to neutral compounds in flames such as the oxide hydroxide OYOH and the trihydroxide $Y(OH)_3$. However, the

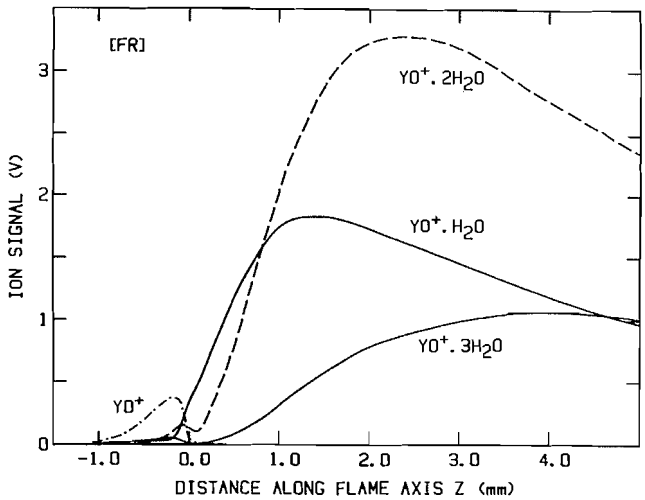

Fig. 4. Axial profiles of yttrium positive ions observed in the fuel-lean (FL) flame.

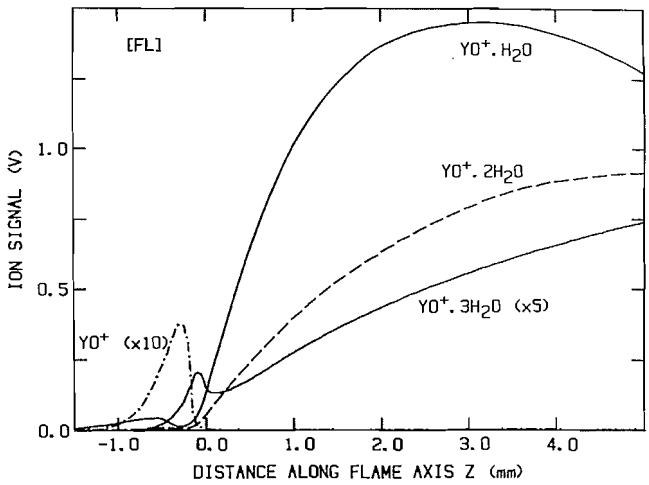

monoxide YO is known to have a very strong bond energy with D(YO) = 7.41 eV, and a rather low ionization energy IE(YO) = 5.85 eV because it is an odd-electron species (19). The YO and OYOH neutrals are expected to be linked in flames by the balanced reaction

[7] $YO + H_2O \rightleftarrows OYOH + H$

such that YO is dominant in FR flames where [H] is large; OYOH might have a comparable concentration in FL flames. In our previous study of group 3 metals in H_2–O_2–Ar flames that contain essentially no natural ionization, it was proposed that yttrium is ionized by the thermal (collisional) ionization of YO and (or) the chemi-ionization of OYOH reacting with H (3). In the present study, the emphasis is placed on CI processes that were considered previously (3), primarily for La, and will only be briefly summarized here for Y.

Figures 3 and 4 give profiles along the flame axis for all of the Y ions that were detected in the FR and FL flames, respectively. As for Sc and La (2, 3), the ions can be represented by a hydrated oxide ion series $YO^+{\cdot}nH_2O$ (n = 0–3) although the ion structures may not be simple hydrates; e.g., $YO^+{\cdot}H_2O$ is equivalent to $Y(OH)_2^+$, and $YO^+{\cdot}2H_2O$ to $Y(OH)_3H^+$ (the protonated trihydroxide), etc. Under normal operating conditions of the mass spectrometer, the YO^+ ion signal was small, and confined to the flame reaction zone ($z < 0$); the other ion signals were larger and persisted throughout the burnt gas. The largest signal was observed for n = 1 in the FL case, but for n = 2 in the FR flame although the latter has the higher temperature. The production of these ions by CI can be explained by proton transfer of H_3O^+ to the oxide hydroxide

[8] $H_3O^+ + OYOH \rightleftarrows H_2O + Y(OH)_2^+$ or $YO^+{\cdot}H_2O$

followed by hydration, or dehydration via the back reactions

[9] $YO^+{\cdot}nH_2O + H_2O + M \rightleftarrows YO^+{\cdot}(n+1)H_2O + M$; n = 0–2

Similarly, if the neutral trihydroxide were to exist in flames to any extent, proton transfer would lead directly to the dihydrate

[10] $H_3O^+ + Y(OH)_3 \rightleftarrows H_2O + Y(OH)_3H^+$ or $Y(OH)_2(H_2O)^+$ or $YO^+{\cdot}2H_2O$

with a planar trigonal structure. The third hydrate $YO^+{\cdot}3H_2O$ written as $Y(OH)_2(H_2O)_2^+$ with four ligands might have a tetrahedral structure with an electron octet around the central Y atom. In these and subsequent reactions, the double arrow denotes that the reaction proceeds in both directions. A balanced reaction indicative of true equilibrium at constant temperature would require that the ratio of the two ion currents remain constant. This situation is approached, for example, well downstream in Fig. 3 for the first two hydrate profiles, but the third hydrate grows as the first two decline. That could occur if the third hydrate is formed from the second in a slow three-body process. Alternatively, the growth would be favoured if the flame cools downstream, perhaps due to entrainment of the surrounding atmosphere, since the reactions [9] will be exothermic to the right.

The various electrodes of the ion lens were normally tuned to maximize the TPI signal. Under these conditions, the profile signal for the nude YO^+ ion was largely confined to the flame reaction zone. However, when the voltage on the single lens element immediately in front of the mass filter was increased, a considerable YO^+ signal was observed downstream as shown in Fig. 5 for the FL flame; the same behaviour is observed in the FR case. Presumably, acceleration of the ions by the high lens voltage promotes collision-induced dissociation (CID) of the higher hydrates with molecules of the background gas by the back reactions [−9] to enhance the YO^+ signal.

Only one anion corresponding to $Y(OH)_4^-$ at 157 u was observed in both the FR and FL flames as shown in Fig. 6. The major FR signal occurred in the reaction zone whereas the FL signal maximized downstream, in keeping with the notion that a major loss mechanism for these anions is associative detachment with H as in reaction [6]. Since $Y(OH)_4^-$ is equivalent to $YO(OH)_2^-{\cdot}H_2O = YO_2^-{\cdot}2H_2O$, the ion could be produced by proton abstraction from OYOH by OH^-

[11] $OH^- + OYOH \rightleftarrows YO_2^- + H_2O$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12

Fig. 5. Axial YO^+ profiles measured in the fuel-lean (FL) flame with the ion lens elements operating at normal voltages (solid line), and with a lens element at high voltage (broken line) to promote collision-induced dissociation (CID) of the YO^+ hydrates.

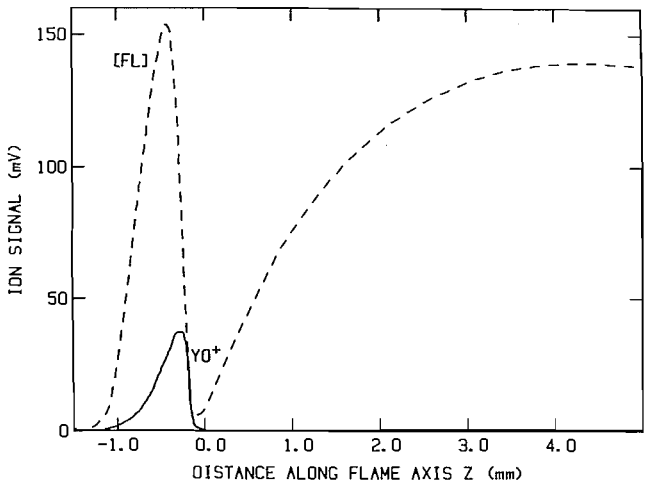

Fig. 6. Axial profiles of metallic negative ions of yttrium, zirconium, and niobium observed in both the fuel-rich (FR) and fuel-lean (FL) flames.

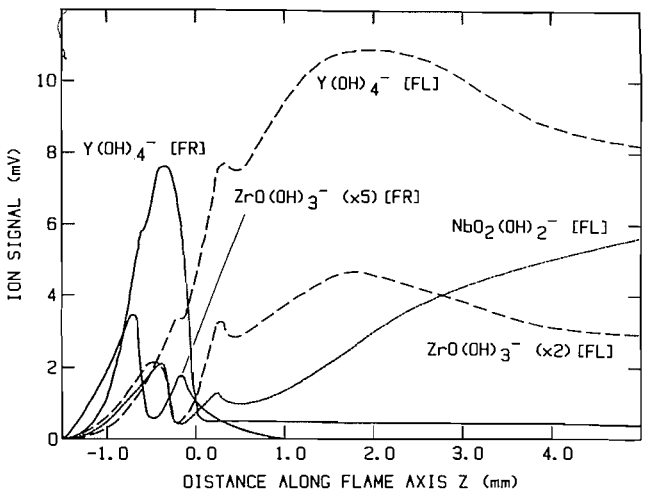

with subsequent hydration, or a one-step addition reaction of OH^- to the oxide hydroxide

[12] $OH^- + OYOH + M \rightleftarrows YO(OH)_2^- + M$

with one further hydration step to give $Y(OH)_4^-$. It is not clear whether reactions such as [12] proceed by a two-body mechanism, or involve a third body M.

Zirconium ion chemistry

The $5s^24d^2$ electron configuration of Zr might suggest a dominant +4 oxidation state although, like Ti, other oxidation states are known, including the +2 state. Generally, the higher oxidation states are more stable for the heavier transition metals (20). The +4 and +2 states would give rise to the neutral oxides ZrO_2 and ZrO, respectively. Neutral hydroxides such as $Zr(OH)_4$ and $Zr(OH)_2$, and a mixed oxide hydroxide $ZrO(OH)_2$, are also possible. Of the five natural isotopes of

Fig. 7. Axial profiles of zirconium positive ions observed in the fuel-rich (FR) flame.

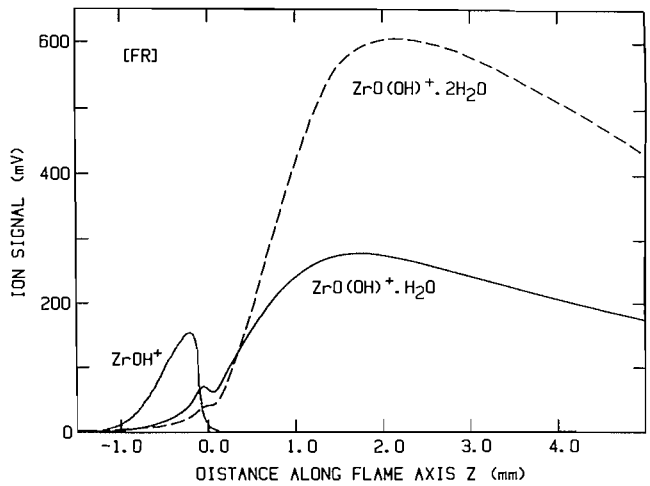

Fig. 8. Axial profiles of zirconium positive ions observed in the fuel-lean (FL) flame.

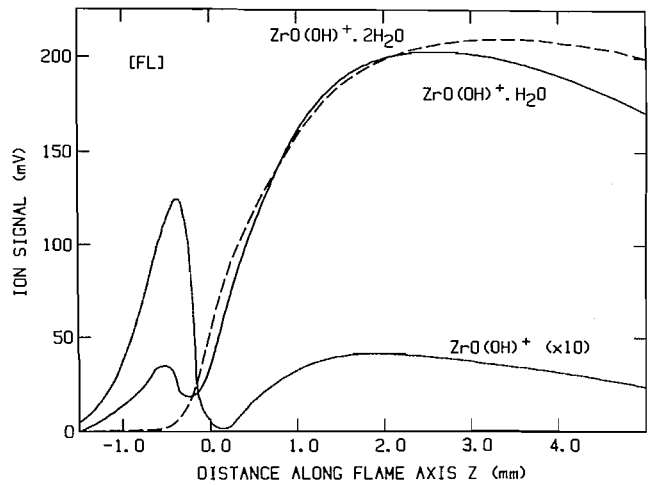


zirconium, ^{90}Zr has the lowest mass and the highest natural abundance of 51.9%; the mass spectral profiles were recorded for this single isotope.

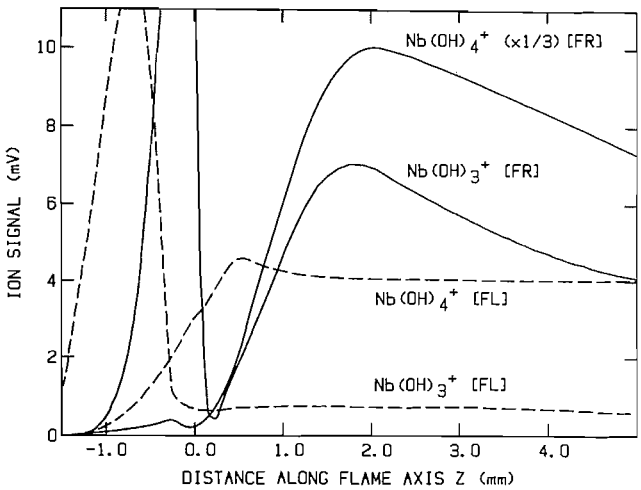
Profiles for the detectable Zr cations are shown in Fig. 7 for the FR flame and in Fig. 8 for the FL flame. With one exception, the cations can be represented by members of a $ZrO(OH)^+ \cdot nH_2O$ series (n = 0–2) in both flames; the $ZrO(OH)^+$ ion signal with $n = 0$ in the FR flame was detected, but was too small to record as a profile. For all of these profiles, the peaks occurring upstream in the flame reaction zone ($z < 0$) are mainly due to natural $C_xH_yO_z^+$ ions at the same mass number; contributions from metallic ions, if present, are very small. The one exception was the detection of $ZrOH^+$ at 107 u in the reaction zone of the FR flame only.

The production of the cation series can occur by proton transfer to ZrO_2

[13] $H_3O^+ + ZrO_2 \rightleftarrows H_2O + ZrO(OH)^+$ or $OZrOH^+$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 46.23.64.124 on 09/08/12
For personal use only.

Fig. 9. Axial profiles of niobium positive ions observed in both the fuel-rich (FR) and fuel-lean (FL) flames.



with subsequent hydration/dehydration equilibria

[14] $ZrO(OH)^+ \cdot nH_2O + H_2O + M \rightleftarrows ZrO(OH)^+ \cdot (n+1)H_2O + M;\ n = 0,1$

Note that the first hydrate with $n = 1$ is equivalent to $Zr(OH)_3^+$ with a possible planar trigonal structure. The second hydrate with $n = 2$ amounts to $Zr(OH)_3(H_2O)^+$, which might be tetrahedral with an electron octet around Zr; it could form directly by proton transfer to neutral $Zr(OH)_4$. Similarly, the $ZrOH^+$ ion, presumably in the +2 oxidation state ($OZrH^+$ in the +4 state is unlikely), can arise by proton transfer to the monoxide ZrO

[15] $H_3O^+ + ZrO \rightleftarrows ZrOH^+ + H_2O$

The ion was not detected in the FL flame; with excess oxygen present, [ZrO] will decrease in favour of increased $[ZrO_2]$.

With regard to the anion chemistry, the same $ZrO(OH)_3^-$ ion was detected in both flames, as shown in Fig. 6. The FR profile is confined to a region in and around the reaction zone, whereas the FL profile persists throughout the burnt gas. Logical production mechanisms include proton abstraction from the tetrahydroxide

[16] $OH^- + Zr(OH)_4 \rightleftarrows ZrO(OH)_3^- + H_2$

or OH^- addition to the mixed oxide dihydroxide

[17] $OH^- + ZrO(OH)_2 + M \rightleftarrows ZrO(OH)_3^- + M$

The disappearance of the anion downstream in the FR flame is probably not surprising; increased [H] will increase the loss rate by associative electron detachment

[18] $ZrO(OH)_3^- + H \rightleftarrows Zr(OH)_4 + e^-$

Reactions such as [18] reinforce the notion that the H atom is a very general and efficient "electron detacher."

Niobium ion chemistry

Niobium adds one more electron for a $5s^14d^4$ configuration with the possibility of a maximum +5 oxidation state that could give rise to such neutral compounds as $NbO_2(OH)$ or $NbO(OH)_3$. However, niobium shows little cationic behaviour in solution although multiple oxidation states are known, including +2, +3, +4, as well as +5 (20). Only the ^{93}Nb isotope occurs naturally with an abundance of 100%.

Small signals of the same two tetra- and trihydroxide cations were observed in both flames with $[Nb(OH)_4^+] > [Nb(OH)_3^+]$, and only in the downstream region. This is another example of the trend, for the heavier transition metals, towards a tendency for the higher oxidation state to be dominant (20). The profiles are shown in Fig. 9; the profile peaks in the reaction zone are due to natural $C_xH_yO_z^+$ ions at the same mass numbers, and not metallic cations. The $Nb(OH)_4^+$ ion could be formed directly by proton transfer to $NbO(OH)_3$

[19] $H_3O^+ + NbO(OH)_3 \rightleftarrows Nb(OH)_4^+ + H_2O$

However, $Nb(OH)_4^+$ is equivalent to the hydrates $NbO(OH)_2^+ \cdot H_2O = NbO_2^+ \cdot 2H_2O$. An alternative mechanism might be proton transfer

[20] $H_3O^+ + NbO_2(OH) \rightleftarrows NbO(OH)_2^+ + H_2O$

followed by hydration

[21] $NbO(OH)_2^+ + H_2O + M \rightleftarrows M + NbO(OH)_2^+ \cdot H_2O$ or $Nb(OH)_4^+$

Note that the +5 oxidation state is emphasized throughout. In a very similar manner, the trihydroxide ion can be produced starting with NbO_2

[22] $H_3O^+ + NbO_2 \rightleftarrows NbO(OH)^+ + H_2O$

[23] $NbO(OH)^+ + H_2O + M \rightleftarrows M + NbO(OH)^+ \cdot H_2O$ or $Nb(OH)_3^+$

In this case, the +4 oxidation state is emphasized throughout. The prominence of $Nb(OH)_3^+$ is somewhat surprising because it is a radical cation. A similar situation was encountered previously in flames with $V(OH)_3^+$ and also $Ti(H_2O)_3^+$, both radical cations (2). Perhaps the stability of these ions against chemical attack in the burnt-gas region is attributable to their high degree of symmetry, whether pyramidal or planar trigonal. It is conceivable that the reaction sequences [20] + [21] or [22] + [23] might take place in a single step. Also, the similar shapes of the pair of cation profiles in either flame suggest that the hydroxide ions might be linked by a balanced reaction such as

[24] $Nb(OH)_3^+ + H_2O \rightleftarrows Nb(OH)_4^+ + H$

Only one niobium anion $NbO_2(OH)_2^-$ was detected, and only in the FL flame in the downstream region as shown in Fig. 6. The same dichotomy exists for the production mechanism already encountered for both Y and Zr; namely, either proton transfer to OH^-

[25] $OH^- + NbO(OH)_3 \rightleftarrows NbO_2(OH)_2^- + H_2O$

Fig. 10. Axial profiles of molybdenum positive ions observed in both the fuel-rich (FR) and fuel-lean (FL) flames.

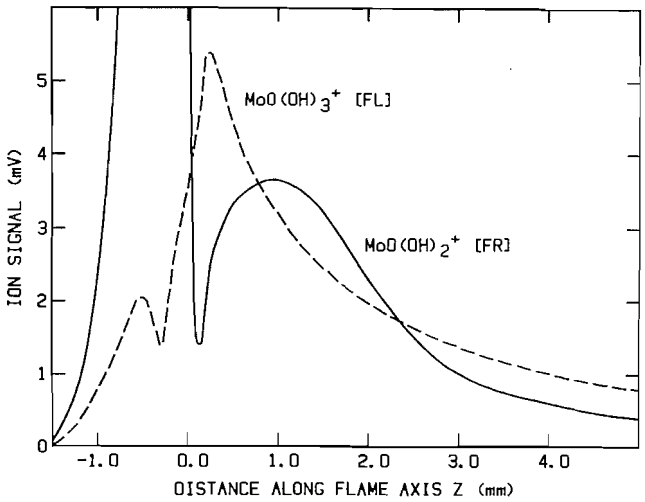

Fig. 11. Axial profiles of moybdenum negative ions observed in both the fuel-rich (FR) and fuel-lean (FL) flames.

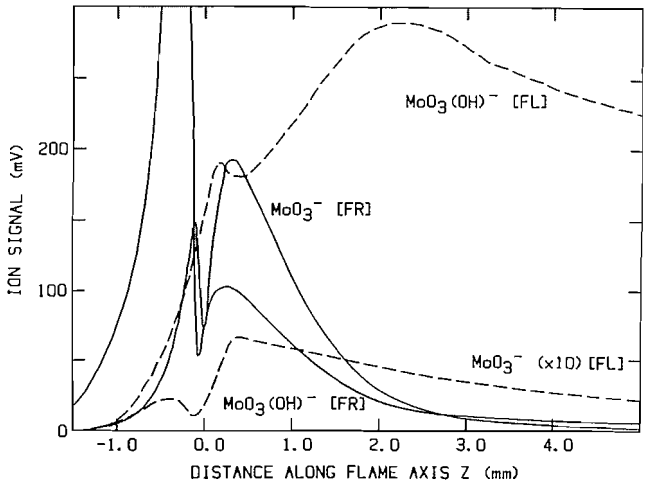

or OH^- addition

[26] $OH^- + NbO_2(OH) + M \rightleftarrows NbO_2(OH)_2^- + M$

The lack of detectable anions in the burnt-gas region of the FR flame is not surprising if the likely anions were to contain OH groups that are prime candidates for associative detachment with H atoms.

Molybdenum ion chemistry

Molybdenum has a $5s^14d^5$ electron configuration, and exhibits a wide variety of stereochemistries and oxidation states from +1 to +6 (20). It is inert to oxygen at ordinary temperatures, but at red heat it combines readily to give trioxides. If the higher oxidation states are favoured, some of the mixed oxide hydroxides such as $MoO_2(OH)_2$ and $MoO_2(OH)$ might be present in flames in addition to MoO_3. The element is difficult to work with mass-spectrometrically because it has seven isotopes with appreciable natural abundances (each >9.1%); flame ions were observed using the major ^{98}Mo isotope of abundance 24.1%.

Very small signals of just two cations were observed, whose axial concentration profiles are given in Fig. 10. They correspond to $MoO(OH)_2^+$ in the FR flame at 148 u in the +5 oxidation state, and $MoO(OH)_3^+$ in the FL flame at 165 u in the +6 state. In this case, it is convenient to discuss the cation production mechanism beginning with the FL flame in which neutral molybdenum is likely to be highly oxidized to the trioxide MoO_3. Proton transfer to MoO_3

[27] $H_3O^+ + MoO_3 \rightleftarrows H_2O + MoO_3H^+$ or $MoO_2(OH)^+$

followed by hydration

[28] $MoO_2(OH)^+ + H_2O + M \rightleftarrows M + MoO_2(OH)^+\cdot H_2O$ or $MoO(OH)_3^+$

yields the observed FL ion. In the presence of high [H] typical of the FR flame, a balanced reaction

[29] $MoO(OH)_3^+ + H \rightleftarrows H_2O + MoO(OH)_2^+$

would yield the observed FR ion $MoO(OH)_2^+$ when the equilibrium is far to the right. The dominance of this ion in the FR flame is somewhat surprising because it is a radical cation. Alternatively, proton transfer to $MoO_2(OH)$ in the +5 oxidation state

[30] $H_3O^+ + MoO_2(OH) \rightleftarrows H_2O + MoO(OH)_2^+$

yields the FR ion directly. In their study of *fuel-rich* H_2–O_2–N_2 flames seeded with potassium to which molybdenum compounds were added, Jensen and Miller (7) assume that the neutral reaction

[31] $MoO_3 + H_2O \rightleftarrows H_2MoO_4$ or $MoO_2(OH)_2$

is balanced. Proton transfer to this neutral product in the +6 oxidation state

[32] $H_3O^+ + MoO_2(OH)_2 \rightleftarrows H_2O + MoO(OH)_3^+$

yields our FL cation directly, but it was not observed in our FR flame. If molybdenum neutrals in the +5 oxidation state (which would be odd-electron species) do not exist in flames, our FR $MoO(OH)_2^+$ cation must be produced by hydroxyl extraction from $MoO(OH)_3^+$ via reaction [29] in which a change of oxidation number is involved.

The same two molybdenum anions $MoO_3(OH)^-$ and MoO_3^- found by Jensen and Miller (7) in their H_2–O_2–N_2 flames, all of them FR, were also observed in both of our FR and FL CH_4–O_2 flames; axial concentration profiles are given in Fig. 11. In our case, the Mo anion signals are much larger than those observed with Y, Zr, and Nb, suggesting that a different type of mechanism may be operative. Jensen and Miller postulated a production mechanism involving dissociative electron attachment

[33] $e^- + MoO_2(OH)_2 \rightleftarrows MoO_3(OH)^- + H$

Table 2. Peak values and properties of metallic positive and negative ions observed for the second-row transition metals Y, Zr, Nb, and Mo in both the fuel-rich (FR) and fuel-lean (FL) flames.

	^{89}Y	100.0	^{90}Zr	51.9	^{93}Nb	100.0	^{92}Mo	14.8
			^{91}Zr	11.2			^{94}Mo	9.3
			^{92}Zr	17.1			^{95}Mo	15.9
			^{94}Zr	17.5			^{96}Mo	16.7
			^{96}Zr	2.8			^{97}Mo	9.6
							^{98}Mo	24.1
							^{100}Mo	9.6

[a]The measured isotopic ion signals have been corrected to account for 100% natural abundance.
[b]The peak ion signal occurred upstream in the flame reaction zone ($z < 0$).
[c]The maximum ion signal occurred at $z = 5$ mm downstream.

followed by the balanced reaction

[34] $MoO_3(OH)^- + H \rightleftarrows MoO_3^- + H_2O$

This mechanism adequately explains the main features of the profiles shown in Fig. 9. In the FL flame, a low [H] value is consistent with higher anion signals overall from reaction [33]; also, a relatively large value of the ratio $[MoO_3(OH)^-]/[MoO_3^-] \propto [H_2O]/[H]$ is consistent with reaction [34]. From Table 1, the $[H_2O]/[H]$ ratio is 1280 in the FL flame, and 27.7 in the FR flame at equilibrium; i.e., a factor of 46.2 greater in the FL case. This agrees with the $[MoO_3(OH)^-]/[MoO_3^-]$ ratio measured in Fig. 9 at $z = 4$ mm downstream; the ratio is a factor of 47 greater in the FL flame than in the FR one. Coming out of the reaction zone of either flame and proceeding downstream ($z > 0$), the anion ratio increases; this is consistent with the realistic expectation that the $[H_2O]/[H]$ ratio increases downstream since $[H_2O]$ rises and [H] falls towards their equilibrium values. Of course, other production mechanisms are possible. For example, proton transfer to OH^- from neutral $MoO_2(OH)_2$ in the +6 oxidation state or from $MoO_2(OH)$ in the +5 state

[35] $OH^- + MoO_2(OH)_2 \rightleftarrows MoO_3(OH)^- + H_2O$

[36] $OH^- + MoO_2(OH) \rightleftarrows MoO_3^- + H_2O$

produces the corresponding anions in the +6 and +5 states, respectively. For both the cations and anions of molybdenum, it is noteworthy and consistent that the higher +6 oxidation state is emphasized for the more oxidizing atmosphere of the FL flame; the presence of the lower +5 state is more evident in the more reducing environment of the FR flame.

Summary and conclusions

A summary of all the cations and anions for each of the four second-row transition metals Y, Zr, Nb, and Mo observed in the pair of FR and FL CH_4–O_2 flames is given in Table 2, together with the oxidation numbers exhibited and the natural abundances of the metallic isotopes. Several general conclusions can be drawn from this work, particularly in regard to comparisons with the lighter first-row transition metals Sc, Ti, V, and Cr (2) from corresponding chemical groups; in the latter case, however, only cations were studied and only in the FR flame.

1. In general, the second-row metals tend to exhibit higher oxidation numbers, and the range of oxidation states is more restricted than with the first-row metals. The $AO^+ \cdot nH_2O$ cation series in the +3 state was dominant for both Sc and Y, although Sc also showed small signals of some $A^+ \cdot nH_2O$ ions in the +1 state. The Ti cations showed the full range of ion series (for brevity, the "$\cdot nH_2O$" hydrate series designation will be left out) including the A^+ series (+1 oxidation state), AOH^+ (+2), AO^+ (+3), and $AO(OH)^+$ (+4) series, with about 94% of the ion signals in the first two series; in contrast, nearly all the cations observed for Zr were $AO(OH)^+$ (+4) ions. A similar range of four cation series was observed for V with about 81% of the ions in the third AO^+ (+3) series, whereas the Nb cations were confined to the fourth $AO(OH)^+$ (+4) and a new AO_2^+ series (i.e., $A(OH)_4^+$ ions, +5 state). For Cr, about 99% of the cations were A^+ (+1) ions, compared with the observed pair of Mo cations $AO(OH)_2^+$ (+5) and $AO(OH)_3^+$ (+6). Thus, the trends towards higher and fewer oxidation states for second-row compared with first-row metallic cations is well established.

2. The second-row anions exhibit essentially the same oxidation numbers as the cations under similar flame conditions.

3. Ions in the higher oxidation state tend to be emphasized in the fuel-lean (FL) flame compared with the fuel-rich (FR) flame where, relatively, the lower oxidation state may be favoured. This trend is probably not surprising; the FL flame is a more oxidizing medium than the more reducing atmosphere of the FR flame.

4. At the relatively high temperatures of these flame studies, a large fraction of the observed ions appear to have four ligands around the central metal atom, suggestive of tetrahedral structures. The Y cations are exceptional, but the assumed $Y(OH)_4^-$ structure with four ligands for the anions is consistent.

5. It had been noted previously for the first-row transition metals (2) that radical cations seem to be stabilized by a high degree of structural symmetry; e.g., $Ti^+ \cdot 3H_2O$ and $V(OH)_3^+$. Further examples from the second-row metals include: $Nb(OH)_3^+$, the counterpart to vanadium; $MoO(OH)_2^+$, the only molybdenum cation observed in the FR flame, where the symmetry is less evident; and MoO_3^-, a radical anion that is dominant in the FR flame.

6. The formation mechanism for these ions by chemical ionization (CI) in CH_4–O_2 flames, which contain a high level of natural ionization, is dominated by proton transfer from H_3O^+ downstream in the case of the cations. For anion formation, the logical CI reagent is OH^-, capable of producing proton transfer in reaction with flame neutrals by proton abstraction because OH^- is a strong base. However, a dilemma exists for some of the anions because they could also be formed by addition reactions of OH^- to different neutral species.

7. Compared with similar studies of first-row transition metals (1, 2), the metallic ion signals obtained with the second-row transition metals using the same mass spectrometer under very similar conditions tend to be very small; the problem is exacerbated for Zr and Mo because the signal is spread out over a rather large number of isotopes. However, the detection of oxygenated anions provides a promising new dimension for possible exploitation in the future.

Rhenium and technetium complexes from pentadentate (N_3O_2) and tetradentate (N_2O_2) Schiff base ligands

Hongyan Luo, Shuang Liu, Steven J. Rettig, and Chris Orvig

Abstract: The rhenium(V) and technetium(V) complexes: [ReO(apa)], [{ReO(epa)}$_2$O], and [TcOCl(epa)] have been prepared from a potentially pentadentate N_3O_2 ligand, *N,N'*-3-azapentane-1,5-diylbis(3-(1-iminoethyl)-6-methyl-2*H*-pyran-2,4(3*H*)-dione) (H_3apa), or a potentially tetradentate N_2O_2 ligand, *N,N'*-ethylene-diylbis(3-(1-iminoethyl)-6-methyl-2*H*-pyran-2,4(3*H*)-dione) (H_2epa). The N_2O_2 complexes were synthesized in low yields. There was also evidence indicating that H_2ppa, *N,N'*-propylene-diylbis(3-(1-iminoethyl)-6-methyl-2*H*-pyran-2,4(3*H*)-dione), hydrolyzed in the course of coordination, forms a rhenium complex of the bidentate monoprotic (O,O) dehydroacetate (dha$^-$), [Re(dha)Cl$_2$(OPPh$_3$)(PPh$_3$)]·EtOH. The structure of this complex was determined by X-ray crystallography. Crystals of [Re(dha)Cl$_2$(OPPh$_3$)(PPh$_3$)]·EtOH ($C_{44}H_{37}Cl_2O_5P_2Re \cdot C_2H_6O$) are monoclinic, a = 11.064(2), b = 24.167(2), c = 16.6687(8) Å, β = 98.779(7)°, Z = 4, space group $P2_1/c$. The structure was solved by the Patterson method and refined by full-matrix least-squares procedures to R = 0.030 and R_w = 0.025 for 6942 reflections with $I \geq 3\sigma(F^2)$.

Key words: dehydroacetic acetate based Schiff base ligands, rhenium, technetium, N_3O_2 Schiff base, N_2O_2 Schiff base, oxygen transfer.

Résumé : On a préparé les complexes du rhénium(V) et du technicium(V) : [ReO(apa)], [{ReO(epa)$_2$O] et [TcOCl(epa)] à partir d'un coordinat potentiellement pentadentate, N_3O_2, la *N,N'*-3-azapentane-1,5-diylbis(3-(1-iminoéthyle)-6-méthyl-2*H*-pyrane-2,4(3*H*)-dione) (H_3apa) ou d'un coordinat potentiellement tétradentate, N_2O_2, la *N,N'*-éthylènediylbis(3-(1-iminoéthyle)-6-méthyl-2*H*-pyrane-2,4(3*H*)-dione) (H_2epa). Les complexes du N_2O_2 ont été synthétisés avec des faibles rendements. On a obtenu des résultats qui suggèrent que le H_2ppa, la *N,N'*-propylènediylbis(3-(1-iminoéthyle)-6-méthyl-2*H*-pyrane-2,4(3*H*)-dione), s'hydrolyse au cours de la coordination et qu'il y a formation d'un complexe du rhénium du déhydroacétate (dha$^-$) monoprotique bidentate (O,O), [Re(dha)Cl$_2$(OPPh$_3$)(PPh$_3$)]·EtOH. On a déterminé la structure de ce complexe par diffraction des rayons X. Les cristaux du [Re(dha)Cl$_2$(OPPh$_3$)(PPh$_3$)]·EtOH ($C_{44}H_{37}Cl_2O_5P_2Re \cdot C_2H_6O$) sont monocliniques, groupe d'espace $P2_1/c$, avec a = 11,064(2), b = 24,167(2) et c = 16,6687(8) Å, β = 98,779(7)° et Z = 4. La structure a été résolue par la méthode de Patterson et elle a été affinée par la méthode des moindres carrés, matrice complète, jusqu'à des valeurs de R = 0,30 et R_w = 0,025 pour 6942 réflexions avec $I \geq 3\sigma(F^2)$.

Mots clés : coordinats formés de bases de Schiff dérivées de l'acétate déhydroacétique, rhénium, technicium, base de Schiff N_3O_2, base de Schiff N_2O_2, transfert d'oxygène.

[Traduit par la rédaction]

Introduction

In searching for new chelates from which to form stable Re/Tc complexes, in addition to the bidentate monoprotic ligands (1, 2), we have recently focussed on some pentadentate (3) and tetradentate Schiff base ligands. Coordination of these multidentate Schiff bases can result in the formation of numerous chelate rings, which may be useful in stabilizing Re/Tc complexes for use as radiopharmaceuticals.

Received July 15, 1995.

The ease of synthesis of multidentate Schiff base ligands has led to extensive investigation of their coordination chemistry with Tc (4) and with many other metal centers (5). Some Re/Tc complexes of tetradentate (6–9) and pentadentate (10, 11) Schiff base ligands have been studied. Most of the ligands are derived from salicylaldehyde; thus they have the disadvantage of producing lipophilic Tc complexes that tend to localize preferentially in the liver (4). To avoid this problem, we have prepared a dha (i.e., dehydroacetic acid, 3-acetyl-6-methyl-2*H*-pyran-2,4(3*H*)-dione)-based, potentially pentadentate (N_3O_2) ligand, H_3apa (3), that contains both lipophilic hydrocarbon chains and polar carbonyl groups (Scheme 1). With H_3apa, one neutral oxotechnetium(V) complex was synthesized in good yield (3); thus the feasibility of Tc(V) complexes of H_3apa has led us to further investigate Re/Tc coordination chemistry with this ligand and with other dha-based, N_2O_2 Schiff base ligands (H_2epa and H_2ppa, Scheme

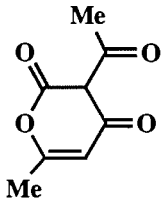
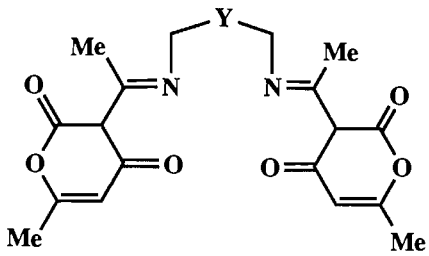
Scheme 1. dha and dha-based Schiff base ligands.



Dehydroacetic acid (dha)



H_3apa = (dha)$_2$dien, Y = CH_2NHCH_2
H_2epa = (dha)$_2$en, Y = none
H_2ppa = (dha)$_2$pn, Y = CH_2

1). The N_3O_2 ligand H_3apa and the N_2O_2 ligands H_2epa and H_2ppa are derived from the condensation of 2 equivalents of dehydroacetic acid (dha) and 1 equivalent of diamine, i.e., diethylenetriamine (dien), ethylenediamine (en), or propylenediamine (pn), respectively. This paper summarizes the attempts to synthesize new Re/Tc complexes of the dha-based Schiff base ligands.

Experimental

Materials

$[NH_4][^{99}TcO_4]$ was obtained from the Du Pont Merck Pharmaceutical Company. Dehydroacetic acid, diethylenetriamine, ethylenediamine, and propylenediamine (all from Aldrich) were used without further purification. $[(n\text{-}Bu)_4N][TcOCl_4]$ (12) $[ReOCl_3(PPh_3)_2]$ (13), $[ReCl_4(PPh_3)_2]$ (14), and H_3apa (3) were prepared according to published procedures.

Caution! ^{99}Tc is a low-energy (0.292 MeV) β^- emitter with a half-life of 2.12×10^5 years. All manipulations of solutions and solids were performed in a laboratory approved for the handling of low-level radioisotopes, and normal safety procedures must be used at all times to prevent contamination.

Instrumentation

^{1}H NMR spectra were recorded on a Bruker AC-200E (^{1}H, ^{1}H–^{1}H COSY, 200 MHz), or a Bruker WH-400 (^{1}H–^{1}H COSY) spectrometer. Chemical shifts are reported as δ in ppm referenced to external TMS: δ (multiplicity, coupling constant, number of hydrogen nuclei, *assignment*). Mass spectra were obtained with either a Kratos MS 50 (electron impact ionization, EIMS) or a Kratos Concept II H32Q instrument (Cs^+-LSIMS with positive or negative ion detection). Infrared spectra were recorded as KBr pellets in the range 4000–400 cm^{-1} on a Perkin–Elmer PE 783 spectrophotometer previously calibrated against the spectrum of polystyrene. Analyses for C, H, N were performed by Mr. Peter Borda (for ligands and the Re complexes) in this department or by Canadian Microanalytical Services Ltd. (for the Tc compound).

N,N′-*Ethylene-diylbis(3-(1-iminoethyl)-6-methyl-2H-pyran-2,4(3H)-dione) (H_2epa)*

This was prepared from the condensation reaction of dha and en, via a similar procedure as that for H_3apa (3). IR (cm^{-1}, KBr disk): 3600–3300 ($\nu_{O\text{-}H}$); 3000–2800 ($\nu_{C\text{-}H}$); 1710, 1660, 1580 (all vs, mixed $\nu_{C=O}$ and $\nu_{C=C}$). ^{1}H NMR ($CDCl_3$): 14.6 (br s, 2H, O*H*), 5.60 (s, 2H, ring-*H*), 3.77 (d, 4H, imine-CH_2), 2.58 (s, 6H, imine-CH_3), 2.12 (s, 6H, ring-CH_3). EIMS; *m/z*: 360 (molecular ion $[C_{18}H_{20}N_2O_6]^+$). Anal. calcd. (found) for $C_{18}H_{20}N_2O_6$: C 59.97 (60.02), H 5.60 (5.70), N 7.78 (7.77).

N,N′-*Propylene-diylbis(3-(1-iminoethyl)-6-methyl-2H-pyran-2,4(3H)-dione) methanol hemisolvate (H_2ppa·0.5MeOH)*

This was prepared from the condensation reaction of dha and pn, via a similar procedure as that for H_3apa (3). IR (cm^{-1}, KBr disk): 3600–3300 ($\nu_{O\text{-}H}$); 3000–2800 ($\nu_{C\text{-}H}$); 1700, 1655, 1580 (all vs, mixed $\nu_{C=O}$ and $\nu_{C=C}$). ^{1}H NMR ($CDCl_3$): 14.4 (br s, 2H, O*H*), 5.60 (s, 2H, ring-*H*), 3.60 (q, 4H, imine-CH_2), 3.40 (s, ~1.5H, CH_3OH), 2.57 (s, 6H, imine-CH_3), 2.00 (m, 8H, central-CH_2 and ring-CH_3). EIMS; *m/z*: 374 (molecular ion $[C_{19}H_{22}N_2O_6]^+$). Anal. calcd. (found) for $C_{19.5}H_{24}N_2O_{6.5}$: C 59.99 (60.00), H 6.20 (6.16), N 7.18 (7.22).

[ReO(apa)]

Method A: To a mixture of $[ReOCl_3(PPh_3)_2]$ (167 mg, 0.200 mmol) and H_3apa (103 mg, 0.256 mmol) was added 6 mL of ethanol. A green solution resulted after boiling. Six drops of triethylamine were added, and the solution was refluxed for a further 30 min. The solution was kept overnight at −4°C, and the resulting brownish green precipitate was filtered off. The precipitate was recrystallized from acetone; brownish green crystals deposited as the solvent evaporated. These were collected by filtration, washed with diethyl ether, and dried in air to yield 85.8 mg (71% based on Re). The product is soluble in chloroform and dichloromethane, but insoluble in diethyl ether and water. IR (cm^{-1}, KBr disk): 1710, 1660, 1644, 1570, 1540 (all vs, mixed $\nu_{C=O}$ and $\nu_{C=C}$), 945 (s, $\nu_{Re=O}$). ^{1}H NMR (500 MHz, $CDCl_3$): 5.73 (d, ^4J = 0.9 Hz; 1H, ring-*H*), 5.05 (d, ^4J = 0.8 Hz; 1H, ring-*H*′),[2] 5.03 (dd, ^2J = 11.6, ^3J = 4.4 Hz, 1H, amido-$CH'_aH'_e$),[3] 4.77 (dd, ^2J = 12.8, ^3J = 6.0 Hz, 1H, amido-CH_aH_e), 4.33 (dd, ^2J = 12.5, ^3J = 6.9 Hz, 1H, amido-CH_eH_a), 4.09 (dd, ^2J = 12.2, ^3J = 5.8 Hz, 1H, amido-$CH'_eH'_a$), 4.07 (m, 1H, imino-CH_aH_e), 3.96 (dt, ^2J = 11.5, ^3J = 5.8 Hz, 1H, imino-$CH'_aH'_e$), 3.82 (dt, ^2J = 12.2, ^3J = 4.6 Hz, 1H, imino-$CH'_eH'_a$), 3.51 (m, 1H, imino-CH_eH_a), 3.04 (s, 3H, imino-CH_3), 2.91 (s, 3H, imino-CH'_3), 2.13 (d, ^4J = 0.8 Hz, 3H, ring-CH_3), 1.98 (d, J = 0.7 Hz, 3H, ring-CH'_3). LSIMS; *m/z*: 604 ([ReO(apa)+1]$^+$). Anal. calcd. (found) for $C_{20}H_{22}N_3O_7Re$: C 39.86 (39.91), H 3.68 (3.75), N 6.97 (6.77).

Method B: To $[ReCl_4(PPh_3)_2]$ (168 mg, 0.197 mmol) and H_3apa (86 mg, 0.21 mmol) was added 7 mL of ethanol. Fourteen drops of triethylamine were added, and the mixture was refluxed for 2.5 h. The dark brown solution was clarified by filtration and the solvent allowed to slowly evaporate at room temperature. Brown crystals were collected and found to be identical to the product obtained via Method A (yield 37 mg; 31% based on Re).

[{ReO(epa)}$_2$O]

To a mixture of [$ReOCl_3(PPh_3)_2$] (166 mg, 0.200 mmol), H_2epa (81.7 mg, 0.23 mmol), and Na_2CO_3 (70 mg, 0.66 mmol) was added 30 mL of ethanol. The mixture was refluxed for 3 h, resulting in a grey-green solution and white precipitate. A green precipitate was deposited on the white precipitate while filtering. The precipitate mixture was recrystallized from acetone–chloroform solution; green crystals and white crystals (dha, presumably from hydrolysis of H_2epa) deposited as the solvents evaporated. The green crystals (15 mg) were mechanically separated from the white crystals after being dried in air (13% based on Re). The product is soluble in chloroform and dichloromethane, but insoluble in diethyl ether and water. IR (cm^{-1}, KBr disk): 675 (s, $\nu_{Re\text{-}O}$). ^1H NMR ($CDCl_3$): 5.95 (s, 2H, ring-*H*), 4.14 (m, 2H, ethylene-*H*), 3.90 (m, 2H, ethylene-*H*), 2.72 (s, 6H, imino-CH_3), 2.28 (s, 6H, ring-CH_3). LSIMS; *m/z*: 561 ([ReO(epa) + 1]$^+$), 1137 ([{ReO(epa)}$_2$O] + 1]$^+$). Anal. calcd. (found) for $C_{36}H_{36}N_4O_{15}Re_2$: C 38.03 (38.10), H 3.19 (3.36), N 4.93 (4.75).

[TcOCl(epa)]·0.5H_2O

To a mixture of [$(n\text{-}Bu)_4N$][$TcOCl_4$] (49.7 mg, 0.10 mmol) and H_2epa (40.1 mg, 0.11 mmol) was added 25 mL ethanol. The suspension became clear after refluxing for 1 h. The solution was refluxed for an additional 2 h. The green-yellow solution was then kept at −4°C for several days. A brown precipitate was filtered out, washed with Et_2O, and dried in air to yield 12 mg (23% based on Tc). The product is slightly soluble in ethanol, chloroform, and dichloromethane, and insoluble in Et_2O and H_2O. IR (cm^{-1}, KBr disk): 960 (w, $\nu_{Tc=O}$). LSIMS; *m/z*: 473 ([TcO(epa)]$^+$). Anal. calcd. (found) for $C_{18}H_{19}ClN_2O_{7.5}Tc$: C 41.76 (41.89), H 3.70 (3.81), N 5.41 (5.58).

[Re(dha)Cl_2(OPPh$_3$)(PPh$_3$)]·EtOH

To a mixture of [$ReOCl_3(PPh_3)_2$] (84.5 mg, 0.10 mmol) and H_2ppa (39.1 mg, 0.10 mmol) was added 25 mL of ethanol. The suspension was refluxed overnight. The solution was clarified by filtration, then held at −4°C. Red crystals (X-ray quality) deposited from the solution. The supernatant solution was removed, then the crystals were washed with diethyl ether and dried in air. The product is soluble in chloroform and dichloromethane, and slightly soluble in diethyl ether. IR (cm^{-1}, KBr disk): 695 (s).

X-ray crystallographic analysis of [Re(dha)Cl_2(OPPh$_3$)(PPh$_3$)]·EtOH

Crystallographic data for [Re(dha)Cl_2(OPPh$_3$)(PPh$_3$)]·EtOH appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 25.6°–30.0° (Rigaku AFC6S diffractometer). The intensities of three standard reflections, measured every hour of X-ray exposure time throughout the data collection, decayed linearly by 2.1%. The data were processed,[4] and corrected for Lorentz and polarization effects, decay, and absorption (empirical, based on azimuthal scans for three reflections).

Table 1. Crystallographic data.[a]

Compound	[Re(dha)Cl_2(OPPh$_3$)(PPh$_3$)]·EtOH
Formula	$C_{44}H_{37}Cl_2O_5P_2Re\cdot C_2H_6O$
fw	1010.90

V, Å^3	4405.0(6)
Z	4
ρ_{calc}, g/cm^3	1.524
F(000)	2024
T	21°C
λ (Å)	0.71 069
$2\theta_{max}$, deg	60
Total reflections	13 756
Total unique reflections	13 144
Reflections with $I \geq 3\sigma(F^2)$	6942
No. of variables	514
R	0.030
R_w	0.025
gof	1.42
Max Δ/σ (final cycle)	0.001
Residual density e/Å^3	−0.68 to 0.48 (both near Re)

[a] $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o|-|F_c|)^2/(m-n)]^{1/2}$. Values given for *R*, R_w, and gof are based on those reflections with $I \geq 3\sigma(F^2)$.

The structure was solved by the Patterson method, the coordinates of the Re atom being determined from the Patterson function and those of the remaining non-hydrogen atoms from subsequent difference Fourier syntheses. The asymmetric unit consists of one metal complex and one molecule of ethanol. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in calculated positions (orientations based on difference map peaks, C—H = 0.98 Å, O—H = 0.92 Å, $B_H = 1.2\ B_{bonded\ atom}$). No correction for secondary extinction was necessary. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International tables for X-ray crystallography (15). Final atomic coordinates and equivalent isotropic thermal parameters, selected bond lengths, and selected bond angles appear in Tables 2–4, respectively. The molecule is shown in Fig. 1. Hydrogen atom parameters, anisotropic thermal parameters, complete tables of bond lengths and angles, torsion angles, intermolecular

[2] Joined at the amido N atom, the two halves of the bound apa^{3-} are chemically nonequivalent with one enolic oxygen donor remaining in the equatorial plane and the other oxygen donor in the apical position (*trans* to Re=O). Thus, the corresponding half of the ligand is referred to as "equatorial" or "apical" (arbitrary), related to the Re=O unit, and the hydrogen nuclei are designated as *H* for that of the "equatorial" half, or as *H'* for that of the "apical" half. Please refer to the geometry of the complex [ReO(apa)] (Scheme 2).

[3] In the chelate ring, the methylene hydrogens are designated as H_e or H_a to refer its (pseudo)equatorial or (pseudo)axial position relative to the ring conformation. Please refer to the ring conformation (Fig. 2).

Results and discussion

Ligands

The N_2O_2 Schiff base ligands, H_2epa and H_2ppa, were prepared in a manner similar to that for the N_3O_2 Schiff base ligand, H_3apa (3), i.e., the Schiff base condensation of ethylenediamine (en) or propylenediamine (pn), with 2 equivalents of dehydroacetic acid (dha). Each of these potentially tetradentate ligands contains an N_2O_2 donor set that may form three chelate rings. As in H_3apa, the infrared spectra of the free ligands show very broad O–H stretching vibrations at 3500 cm^{-1}, suggesting that the molecule probably exists mainly as the imine-enol form. This is also supported by the enol ^{1}H NMR signal, which lies downfield ($\delta > 14$ ppm, as a broad singlet) due to intramolecular hydrogen bonding (16*a*).

Synthesis of complexes

[TcO(apa)] was synthesized via both the ligand exchange route and the reduction–coordination route in moderate yields (49% and 54%, respectively) (3). [ReO(apa)] was prepared from the reaction of $[ReOCl_3(PPh_3)_2]$ or $[ReCl_4(PPh_3)_2]$ with H_3apa in ethanol in the presence of excess triethylamine. Scheme 2 describes the overall results of the synthetic studies. With an N_3O_2 Schiff base ligand H_3L, [MOL] was the only product (3, 10, 11). Upon coordination, the central amine group becomes more acidic due to the strongly electrophilic character of the $[M{=}O]^{3+}$ core, and is deprotonated to give a neutral metal(V) complex. The formation of a Re(V) product from the reaction of $[ReCl_4(PPh_3)_2]$ and H_3apa resulted from aerial oxidation. Oxotechnetium(V) complexes have been

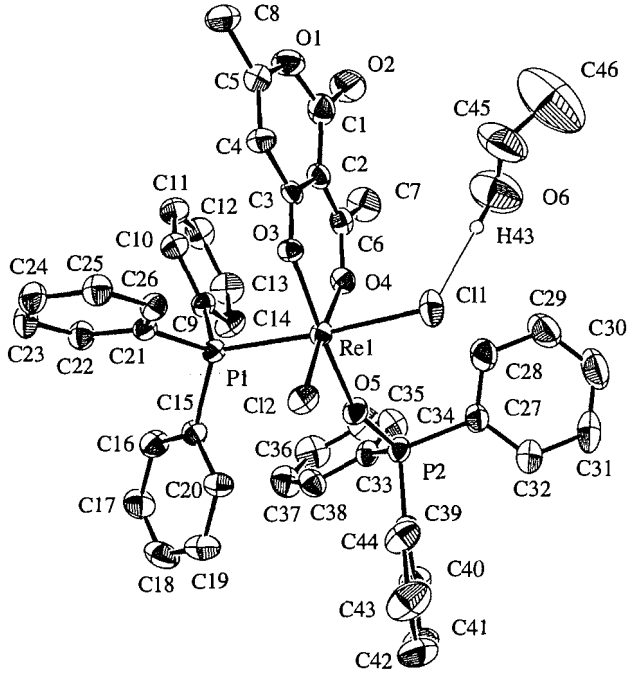
Fig. 1. ORTEP drawing of $[Re(dha)Cl_2(OPPh_3)(PPh_3)]\cdot EtOH$; 33% probability ellipsoids are shown for the non-hydrogen atoms.



shown to form in a similar fashion from the reactions of $[TcCl_4(PPh_3)_2]$ and some N_2S_2 ligands (17).

In contrast to the N_3O_2 ligand H_3apa, the coordination of the N_2O_2 Schiff base ligands to Tc(V) and Re(V) metal centres was found to be much less favorable, and more complicated. The reaction of H_2epa with $[ReOCl_3(PPh_3)_2]$ produced the dinuclear complex $[\{ReO(epa)\}_2O]$ in low yield, and attempts to increase this yield failed. The reaction of H_2epa with $[TcOCl_4]^-$ gave the complex [TcOCl(epa)], also in low yield. It is common for the yields of tetradentate N_2O_2 Schiff base metal complexes to be low (7). The low yields in our reactions with H_2epa may be due to the diversity of the possible products (vide infra). In addition, the desired Schiff base complexes may be difficult to isolate due to reduction of the metal center (in the presence of PPh_3) and (or) hydrolysis of the Schiff base ligand during the reactions, as was seen for H_2ppa (vide infra).

Comparison of N_3O_2 and N_2O_2 ligands

It was reported that substitution reactions on to the TcO^{3+} core with N_2O_2 Schiff base ligands might lead to three types of complex, $[TcOX(N_2O_2)]$, $[\{TcO(N_2O_2)\}_2O]$, and $[TcO(OH_2)(N_2O_2)]^+$(7, 9), in addition to an isolable intermediate $[TcOCl_2(\underline{ON}\text{-}NO)]^-$ (7). Bandoli et al. assumed that all types of the complex are formed but that the isolated product is the most stable (7); this assumption is supported by other investigations wherein several bands were observed when the reaction mixture was loaded onto a column (9). Product purification is the crucial step in most of the N_2O_2 cases; chromatography is often required (8, 9). On the other hand, an N_2O_2 Schiff base ligand was found to form a $[MO(N_2O_2)]$ complex in the only mode for the five donor atoms to surround the M=O core, that in which the ligand is completely coordinated and there is only one complex (two enantiomers) that can be formed (3, 10, 11). This sole pathway in formation of the complex rationalizes the higher yield in synthesis for N_3O_2 vs. N_2O_2 ligands.

It should also be mentioned that all the donor atoms in the N_2O_2 Schiff base complexes were found in the equatorial (relative to M=O) plane, in contrast with the behavior of the bidentate NO Schiff base ligands in the oxo complexes (7). Two NO Schiff base molecules in $[MOX(NO)_2]$ are never found to be coplanar, i.e., one NO bidentate ligand chelates in the plane equatorial to, the other in the plane axial to, the M=O unit with the anionic donor atom *trans* to M=O. This non-coplanar configuration is thus considered thermodynamically more stable than a coplanar configuration (10, 11). Based on their observations and other results, Refosco et al. (11) and Tisato et al. (10) have concluded that tetradentate N_2O_2 Schiff base ligands could form a twisted configuration only when there are five or more atoms in the central chain between the two imine N donor atoms. The inability to adopt the thermodynamically more favored twisted configuration dictates the inherent instability of the N_2O_2 complexes, and therefore the low yield in the synthesis. Meanwhile, side reactions, such as reduction of the metal centers and (or) hydrolysis of the bound ligands, are enhanced, as observed. In the N_3O_2 complexes, such a twisted configuration is feasible, as is seen in all three solved structures (3, 10, 11); high bond strains have not been found in the constructed models of such a configuration (11).

The N_3O_2 Schiff base complexes result from the only coordination mode for the five donor atoms in surrounding the M=O core in a more stable configuration without high strain. In contrast, the N_2O_2 Schiff base complexes are a much less stable configuration with a significant *trans* influence, when

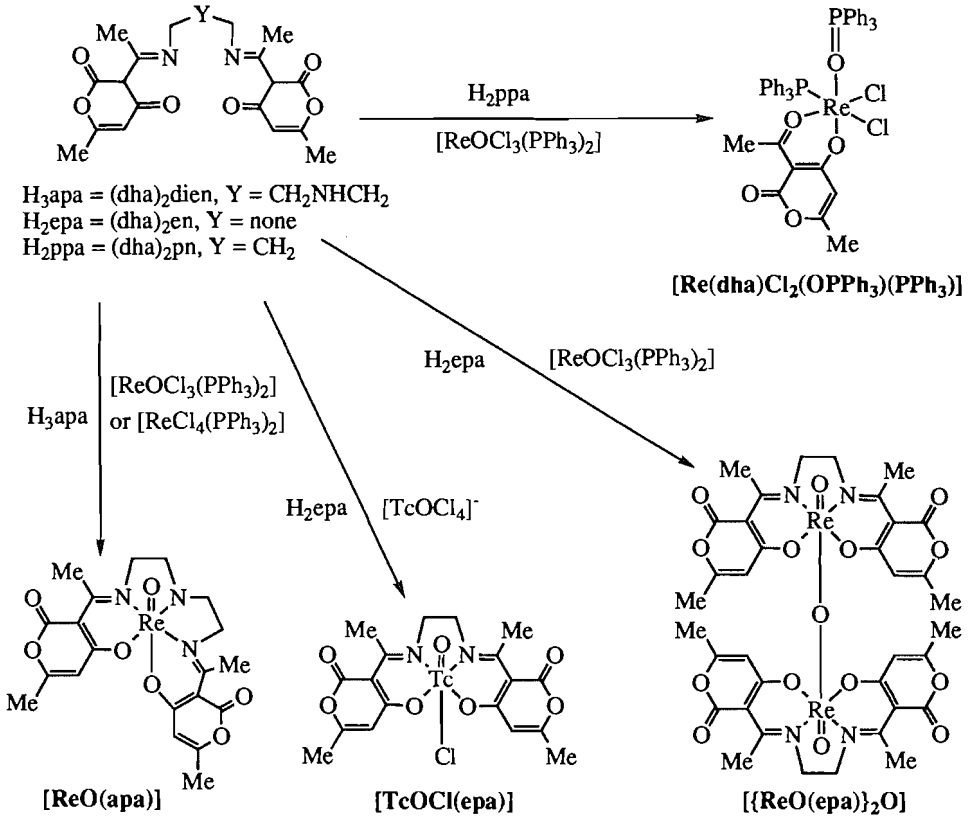
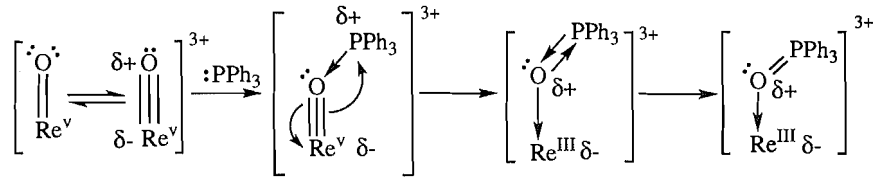
Scheme 2.



Scheme 3.



the four donor atoms of the ligand are bound to the metal in the equatorial plane and the oxo atom occupies the apical position. There are usually many anionic species competing for the sixth coordination site that is *trans* to, and labilized by, the M=O group (*trans* effect). Metal-enhanced hydrolysis of the N_2O_2 Schiff base ligands seriously hampers the synthesis of the complexes (vide infra).

Formation of $[Re(OPPh_3)(dha)(PPh_3)Cl_2]\cdot EtOH$

The trials with $[ReOCl_3(PPh_3)_2]$ and H_2ppa in ethanol resulted in an unexpected Re complex, with one PPh_3 migrating to the oxo oxygen, with the resultant vacant site filled, and with one chloro ligand being replaced by two oxygen donor atoms of dehydroacetate. The Re center is formally reduced to an oxidation state of three (Scheme 3). The $Re{=}O^{3+}$ core is known to react with phosphines and other oxygen acceptors, yielding Re(III) complexes and phosphine oxides (18*a*, 19, 20). In examining the $Re^{V}O + X = Re^{III} + XO$ transformation, Conry and Mayer observed that oxygen atoms were transferred to the substrate X when the X—O bond strength exceeded 127 kcal mol^{-1} (X = PMe_3 or PPh_3), and the reverse reaction proceeded when the bond strength fell below 110 kcal/mol (21). Thus, the fact that the isolated complex is intermediate between the extremes of the expected oxygen transfer indicates that the oxygen transfer is not only related to the O—X bond energy, but also to the ancillary ligands. Jurisson et al. observed that the reactions of acetylacetone-based Schiff base complexes $[TcO(N_2O_2)(H_2O)]^+$ and 3 equivalents of phosphines PR_3 yielded Tc(III) complexes $[Tc(PR_3)_2(N_2O_2)]$ with the N_2O_2 Schiff base intact (8).

The bound dha^- is obviously the hydrolyzed product of the original Schiff base. The ligated Schiff bases are known to be susceptible to metal-enhanced hydrolysis, as is known with some lanthanide complexes (22). The hydrolysis of Schiff bases coordinated to Tc(V) is important in the development of ^{99m}Tc radiopharmaceuticals. While this hydrolysis may be detrimental in many cases, it is postulated also to be advantageous in the design of ^{99m}Tc radiopharmaceuticals that would decompose under certain conditions in vivo (23). Thus it is necessary to characterize the decomposed products. The isola-

tion of this reduced and hydrolyzed Re species demonstrates one aspect of the decomposition.

Characterization

N_3O_2 complexes

The infrared spectrum of [ReO(apa)] exhibits an $\nu_{Re=O}$ vibration at 945, higher than the $\nu_{Tc=O}$ band at 915 in [TcO(apa)]; both are in the expected range for six-coordinated oxo complexes (18*b*). The $\nu_{Tc=O}$ absorption is usually found at lower frequencies than $\nu_{Re=O}$ in analogous oxometal complexes (18*b*). LSIMS of the complex showed a molecular ion peak at *m/z* 603, confirming that the complex is monomeric [ReO(apa)]. The stoichiometry of $[C_{20}H_{22}N_3O_7Re]$ for the complex was confirmed by elemental analysis and is consistent with the [TcO(apa)] complex, the structure of which has been determined by X-ray diffraction methods (3).

N_2O_2 complexes

The N_2O_2 donor set is found in the equatorial plane relative to the Tc=O group in all three possible types of complexes (vide supra) (7, 9). The infrared spectrum of $[\{ReO(epa)\}_2O]$ exhibits two ν_{Re-O} vibrations at 675 and 645 cm^{-1}, agreeing with the literature values of ν_{M-O} for other $[\{MO(N_2O_2)\}_2O]$ (M = Tc, Re) complexes (6, 7, 24, 25). No absorption bands could be assigned to $\nu_{Re=O}$; the two weak absorption bands at 950 and 910 cm^{-1} coincide with two moderate bands of the free ligands. A similar phenomenon was observed for other $[\{MO(N_2O_2)\}_2O]$ complexes, and was not rationalized: there was no absorption that could be attributed to $\nu_{Tc=O}$ in an N_2O_2 Schiff base complex (7) or an N_2O_2 amine phenol complex (25); the $\nu_{Re=O}$ bands were found in only moderate or weak intensity for two N_2O_2 amine phenol complexes (24). LSIMS shows $[ReO(epa)+1]^+$ and $[\{ReO(epa)_2O+1]^+$ at *m/z* 561 and 1037, respectively, suggesting that the complex is dinuclear with an oxygen atom bridging two ReO(epa) units. For [TcOCl(epa)], a weak IR absorption is present around 960 cm^{-1} and is tentatively assigned to the Tc=O stretching vibration, and the *m/z* values corresponding to $[TcO(epa)]^+$ and $[Tc(epa)]^+$ are shown in the LSIMS, indicating a mononuclear oxo complex. The absence of the molecular ion in the mass spectrum may be explained by a Tc—Cl bond weakened by the *trans* influence of the oxo group. In a similar complex, $[TcO\{(sal)_2en\}Cl]$, this *trans* influence was found to weaken the Tc—Cl bond significantly (9). The stoichiometry for $[\{ReO(epa)\}_2O]$ and $[TcOCl(epa)]\cdot 0.5H_2O$ was confirmed by elemental analyses.

^{1}H NMR studies

[ReO(apa)]

The resonances in the ^{1}H NMR spectrum (500 MHz) of [ReO(apa)] were assigned on the basis of the ^{1}H–^{1}H COSY (400 MHz, Fig. 2), and by comparison with the ^{1}H NMR spectra for H_3apa and [TcO(apa)] (3). [ReO(apa)] presented a spectrum similar to that of [TcO(apa)], except that resonances for the eight hydrogen nuclei of the two NCH_2CH_2N units were more distinguishable from one another. Thus it is possible to make a full assignment for the Re complex.

For the free ligand, the seven types of resonances were assignable to enol H (14.00 ppm), ring H (5.50 ppm), imine CH_2 (3.48 ppm), amine CH_2 (2.92 ppm), imine CH_3 (2.56 ppm), ring CH_3 (2.00 ppm), and amine NH (1.45 ppm), in order of increasing field (3). As in [TcO(apa)], upon coordination, the resonances corresponding to the enol H and amine NH disappeared due to deprotonation. Furthermore, the symmetry of the ligand is lost upon coordination; the two halves of the bound ligand, defined by the central nitrogen atom, became nonequivalent (as in [TcO(apa)]), as did the remaining hydrogens. The two halves were arbitrarily designated as "apical" and "equatorial", depending on the binding site of the enolate oxygen donor (Scheme 2, vide infra). Thus two sets of the ring H, imine CH_3, and ring CH_3 hydrogen nuclei were observed, and were assigned to the two arms based on the fact that the signals of nuclei (*H*) of the equatorial portion are more deshielded than those (*H'*) of the apical.[6] The ^{1}H–^{1}H COSY of this complex shows the correlation between the ring H and ring CH_3 of either the upfield or downfield set, or of the assumed equatorial or apical arm. The same two sets of signals were also observed in the ^{1}H NMR spectrum of [TcO(apa)], which is known to have two nonequivalent halves of the bound ligand. Obviously, a similar geometry to that of [TcO(apa)] holds true for [ReO(apa)].

The resonances for the two NCH_2CH_2N units fall almost into eight distinguishable multiplets when observed at 500 MHz, indicating the nonequivalence of the two units. These hydrogens were assigned based on ^{1}H–^{1}H COSY (Fig. 2) and on their similarity to the spectrum of [TcO(apa)]. The eight hydrogen signals were easily grouped into two sets corresponding to the two NCH_2CH_2N units. Two of the four H signals in each unit, each appearing as a doublet-of-doublets, were assigned to the pseudo-equatorial *H* nuclei (26), as only these two could define a dihedral angle of close to 90° (Fig. 2).[7] This assignment was supported by the fact that ring hydrogen atoms in pseudo-axial environments are usually more shielded than those in pseudo-equatorial environments (16*b*). The other two in each unit were more complicated, either doublets-of-triplets or multiplets, due to unequal coupling to three hydrogen nuclei. This assignment is consistent with that of [TcO(apa)], which was based on ^{1}H–^{1}H COSY, APT, and ^{1}H–^{13}C heteronuclear correlation spectra and those of the free ligand (3).

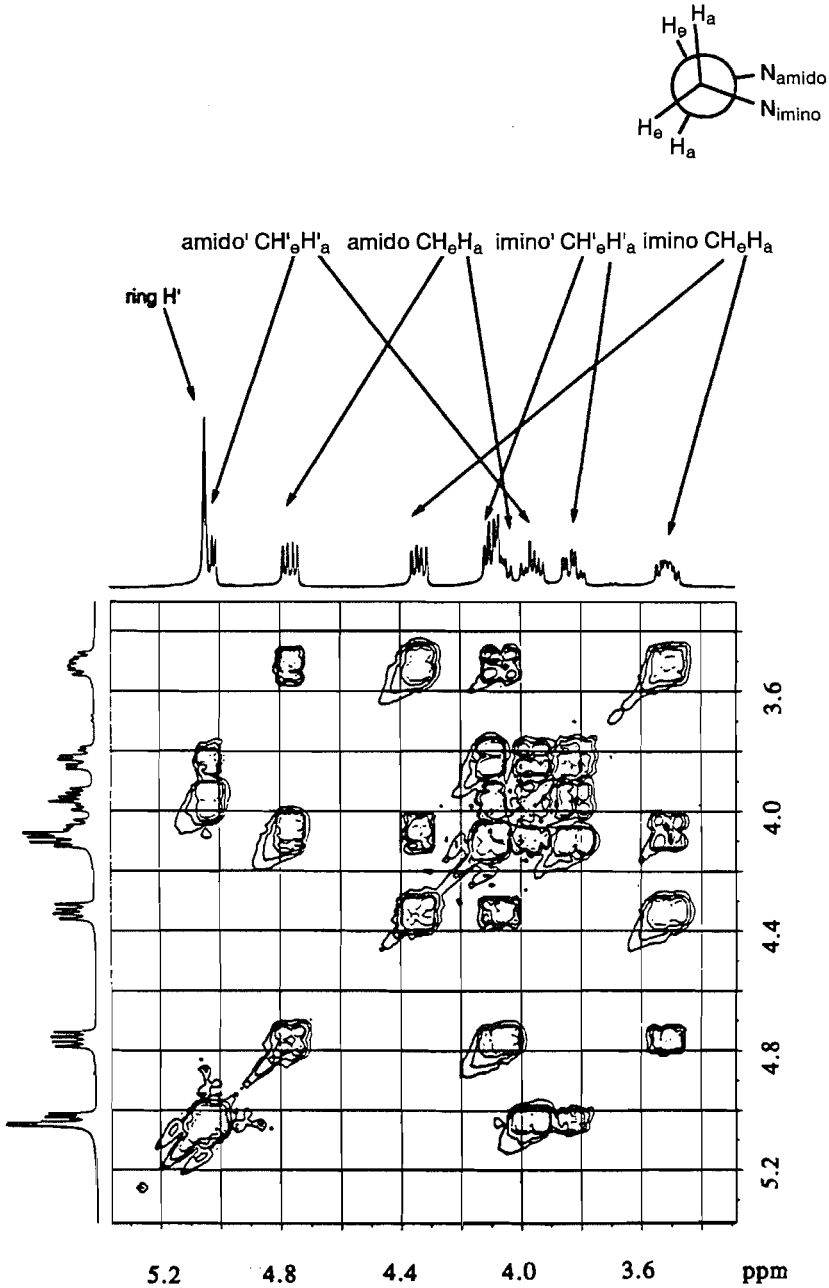
$[\{ReO(epa)\}_2O]$

The ^{1}H NMR spectrum was easily assigned by comparison to that of the free ligand. For the free ligand, the five types of resonances were assigned to enol H (14.6 ppm), ring H (5.60 ppm), imine CH_2 (3.77 ppm), imine CH_3 (2.58 ppm), ring CH_3 (2.12 ppm). As expected, upon coordination the resonance of the enol *H* disappeared while all other hydrogen resonances were shifted downfield from those of H_2epa. The ring H (5.95 ppm), imino CH_3 (2.72 ppm), and ring CH_3 (2.28 ppm) of the two halves of the ligands are indistinguishable, reflecting a symmetric molecule. The hydrogen resonances for the NCH_2CH_2N unit were split into two symmetrical multiplets, as an AA′BB′ system (Fig. 3). The ^{1}H NMR results suggest a

[6] As in $[MOXL_2]$, where the two bidentate L ligands are each bound equatorially and axially, the hydrogens in the equatorial ligand are usually more deshielded than those in the axial ligand (1, 2, 11).

[7] According to the Karplus Equation (27): $^3J = 4.2 - 0.5\cos\theta - 4.5\cos 2\theta$, a very small coupling constant (less than 1 Hz) is expected when θ is close to 90°.

Fig. 2. Ethylene hydrogen region of the ^1H–^1H COSY spectrum for [ReO(apa)].



structure for the complex with coplanar coordinated ligands, consistent with a proposed dinuclear structure with C_i symmetry (known for other dinuclear Re(V) or Tc(V) complexes with two N_2O_2 ligands (6, 7, 24, 25)).

Structure of [Re(dha)Cl_2($OPPh_3$)(PPh_3)]·EtOH

The ORTEP drawing of the complex is illustrated in Fig. 1. The unit cell contains four discrete [Re(dha)Cl_2($OPPh_3$)-(PPh_3)]·EtOH molecules (two of each enantiomer), each of which has the Re(III) center coordinated by the two O donor atoms of the dha^- ligand, two Cl donor atoms, one triphenylphosphine P donor atom, and one triphenylphosphine oxide O donor atom. The coordination geometry is a distorted octahedron with the enolic oxygen of the dha^- located in the position *trans* to the Re-O=PPh_3 unit and the remaining donor atoms occupying equatorial sites relative to the O=PPh_3 group, such that the two chloro ligands are *cis* to each other. The distortion from an ideal octahedron is mainly caused by the variety of the donor atoms and their requirements (Table 3). In the absence of the sterically demanding oxo group, all the *cis* angles are close to 90°, within deviations of less than 4° (Table 4).

The Re—Cl(1) bond that is *trans* to the phosphine P is long (2.430(1) Å), while the Re—Cl(2) *cis* to the phosphine P is normal (2.362(1) Å) in comparison with the Re—Cl distances of 2.35 and 2.36 Å in *trans*-(P,P)-[$ReCl_3(PPh_3)_2(CH_3CN)$] (28), indicating that the phosphine P exerts a significant *trans* influence. The Re—P distance (2.404(1) Å) is short in com-

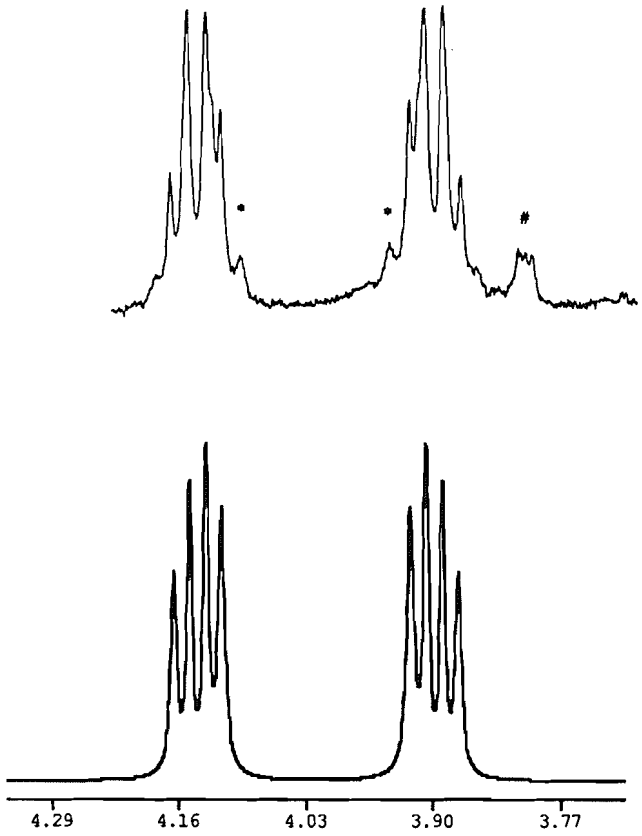
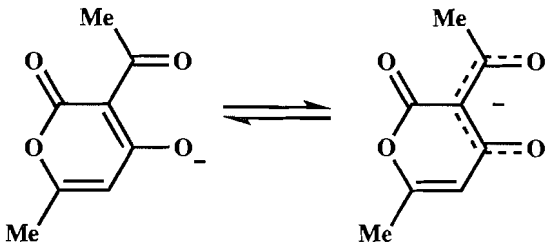
Fig. 3. Ethylene hydrogen region of the ^1H NMR spectrum (top) and a computer-simulated AA'BB' system ($\delta_A = 4.14$, $\delta_B = 3.90$; $J_{AB} = 13.2$, $J_{AB'} = 6.5$) for $[\{ReO(epa)\}_2O]$ (bottom). * = unidentified species; # = impurities.



Scheme 4.



parison to the Re—P bonds of 2.47 and 2.48 Å in *trans*-(P,P)-$[ReCl_3(PPh_3)_2(CH_3CN)]$. This can be explained by the absence of a *trans* influence attributable to this PPh_3 group in $[Re(dha)Cl_2(OPPh_3)(PPh_3)]$. The two Re—O bonds are both close to the lengths found for other Re—O single bonds (29), with Re—O(3) = 1.987(2) Å, and Re—O(4) = 2.016(3) Å, indicating that the two oxygen donor atoms are involved in π-delocalization within the ligand (Scheme 4); in fact, an averaging of bond lengths is seen for this chelate ring (Table 3). The Re to phosphine oxide oxygen distance is longer (2.051(2) Å), but still comparable to the Re—O single bond (29). In contrast, the same oxygen is strongly bound to the phosphorus (O—P = 1.502(3) Å), only about 0.02 Å longer than the values found in the unligated $OPPh_3$ (O—P = 1.483(2) Å) (30), where the P—O is believed to be multiply bound (31). The maintenance of the multiple character of the P—O bond suggests that the O—Re is a coordinate bond (a typical P—O single bond is 1.60 Å (31)). Given the bonding features, it is analogous to a Re(III) complex of phosphine oxide.

In conclusion, the N_3O_2 dehydroacetic acid based Schiff base ligand precursor H_3apa has greater potential for use in radiopharmaceutical studies than its N_2O_2 Schiff base analogues, as stable oxotechnetium and oxorhenium complexes of H_3apa can be prepared in good yields. Complexes of N_2O_2 Schiff bases can be obtained ($[MO(N_2O_2)X]$, $[\{MO(N_2O_2)\}_2O]$, etc., Scheme 2); however, their formation is much less favorable, due to a variety of reaction pathways and a less stable coordination configuration. This severely limits the use of these tetradentate ligands in the design of radiopharmaceuticals.

Acknowledgments

We wish to thank the Natural Sciences and Engineering Research Council of Canada and the British Columbia Health Research Foundation for operating grants, the Du Pont Merck Pharmaceutical Company for support and NH_4TcO_4, Johnson Matthey, Inc. for NH_4ReO_4, and Professor J. Trotter for the very kind use of his crystallographic facilities.
