From the time that the eq. [11] results were obtained, we were interested in the possibility that sulfonate-stabilized carbanion sulfenylation might be reversible. Reversibility would not be surprising in view of Trost's results showing that carboxylic ester sulfenylation in THF–HMPA is reversible (9). Reversibility of sulfonate ester sulfenylation under our conditions was established by the following results:

Scheme 3 provides a complete proposal for the first sequence of the Trithioorthoformate Reaction and accounts for all of our experimental results. Note that the intermediacy of thiolsulfonates was considered in detail in an earlier paper (2).

The sulfide-sulfonate ester **3** was produced in only 7% yield under our optimized conditions (see eq. [13]). A significant improvement in the yield of **3** was realized when we carried out the following reaction:

[19] 
Methods

Details for ZINDO computations have been given earlier (3, 5).

[18] 
Experimental

General

The ir spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer. Ultraviolet spectra were run on a Beckman DU-2 spectrophotometer. The nmr spectra were obtained on a Varian EM360A instrument using TMS as the internal standard. Melting points were determined on a Gallenkamp MFB-595 capillary melting point apparatus and are uncorrected. Gas–liquid chromatographic analyses were carried out with a He flow rate of 70 mL/min through a column of 8% Carbowax on Chromosorb W. Column temperatures were 130°C for *p*-tolyl mercaptan analysis and 210°C for *p*-tolyl disulfide analysis.

Sodium hydride was purchased as a dry solid (97%). It was repackaged under N_2 into 1-g lots. Sample vials were sealed with beeswax. Sodium hydride for experiments was weighed from the sample vials into flasks that were sealed with ground-glass stoppers.

Standard work-up

The crude reaction mixture was poured into water (400 mL) and 10% HCl (10 mL). The resultant mixture was washed with diethyl ether (3 100-mL aliquots). The combined ether layers were concentrated and the residue poured into water (100 mL). The resultant mixture was extracted with diethyl ether (3 100-mL aliquots). The combined ether layers were washed with 2.5% NaOH (100 mL), dried ($MgSO_4$), and concentrated.

Formation of p-*tolyl ethyl sulfide and trithioorthoformate* ***1*** *at elevated temperature*

A solution of absolute ethanol (0.636 g, 13.8 mmol) in HMPA[7] (10 mL) was added dropwise to a suspension of sodium hydride (0.659 g, 27.4 mmol) in HMPA (50 mL). A solution of *p*-tolyl mercaptan (1.705 g, 13.8 mmol) in HMPA (10 mL) was added dropwise over 5 min. Phenyl methanesulfonate (2.370 g, 13.8 mmol) was added and the reaction mixture maintained at 100–120°C for 2 h.[8] Standard work-up furnished a crude sample.

The crude product was chromatographed on silica gel

[7] HMPA (hexamethylphosphoramide) is toxic and carcinogenic (10).

[8] Upon completion of mixing the reactants, a significant portion of the sodium hydride was still unreacted. The reaction of ethanol with sodium hydride in HMPA is extremely slow, presumably due to the very high pK_a's of simple alcohols in very polar aprotic solvents, e.g., methanol has a pK_a of 29.0 in DMSO (11).

For personal use only.

(200 g) employing chloroform elution (100-mL fractions). Fractions 5–7 were combined to give a mixture of nonpolar compounds (1.635 g).

The nonpolar mixture was chromatographed on silica gel (150 g) employing mixed hexanes for elution (100-mL fractions). Fractions 6–10 were combined and concentrated, affording a mixture of *p*-tolyl ethyl sulfide (0.272 g, 1.78 mmol, 13%) and *p*-tolyl methyl sulfide (0.101 g, 0.73 mmol, 5%). The mixture was analyzed quantitatively by nmr as outlined elsewhere (12). Each component was identified by the addition of authentic material, which induced an increase in intensity for the appropriate signals in the proton nmr of the mixture.

Fractions 22–35 were combined and concentrated, furnishing clean trithioorthoformate **1** (0.708 g, 1.85 mmol, 40%). Chromatographed **1** was shown to be identical to authentic material prepared as described previously (13).

Reaction of phenyl ethanesulfonate and p-*tolyl mercaptide ions*

The reaction "Formation of *p*-tolyl ethyl sulfide and trithioorthoformate **1** at elevated temperature" was rerun on the same scale but phenyl ethanesulfonate (13.8 mmol) was substituted for the methanesulfonate. Standard work-up furnished crude product that showed no trithioorthoformate **1** by nmr or tlc. Column chromatography (200 g silica gel) employing chloroform for elution (30 100-mL fractions) resolved the product mixture. The principal product was *p*-tolyl disulfide (0.835 g, 3.39 mmol) from fractions 5 and 6. No trithioorthoformate **1** was found in any column fractions.

Trithioorthoformate reaction in the presence of phenyl methyl sulfide

The reaction "Formation of *p*-tolyl ethyl sulfide and trithioorthoformate **1** at elevated temperature" was rerun on the same scale but phenyl methyl sulfide (0.865 g, 6.8 mmol) in HMPA[7] (10 mL) was also added. Standard work-up furnished a semicrystalline crude residue. Recrystallization from methanol furnished the trithioorthoformate **1** (0.263 g, 0.68 mmol), which was identical to authentic material by nmr, ir, and mp. The mother-liquor concentrate was chromatographed on silica gel (150 g) employing carbon tetrachloride for elution (100-mL fractions). Fraction 5 furnished *p*-tolyl disulfide (0.242 g, 0.98 mmol). Fraction 6 yielded unchanged phenyl methyl sulfide (0.192 g, 1.5 mmol). Fractions 7–10 were combined and concentrated, giving impure trithioorthoformate **1**. Recrystallization from methanol furnished a crop of clean **1** (0.111 g, 0.29 mmol).

Trithioorthoformate reaction in the presence of bis(thiophenyl)methane

This reaction was carried out in the same manner as "Formation of *p*-tolyl ethyl sulfide and trithioorthoformate **1** at elevated temperature" employing the following chemicals: phenyl methanesulfonate (0.741 g, 4.30 mmol), sodium hydride (0.106 g, 4.41 mmol), *p*-tolyl mercaptan (0.536 g, 4.32 mmol), bis(thiophenyl)methane (0.996 g, 4.29 mmol), and HMPA[7] (40 mL).

Standard work-up furnished crude product (1.193 g), which was chromatographed on silica gel (100 g) employing carbon tetrachloride for elution (100 mL fractions). Fraction 4 gave unchanged bis(thiophenyl)methane (0.353 g, 1.52 mmol). Fractions 5 and 6 were combined, affording bis(thiophenyl)methane (0.333 g, 1.43 mmol) and the trithioorthoformate **1** (0.131 g, 0.34 mmol).

Reaction of aryl methanesulfonates with sodium hydride and p-*tolyl mercaptan in the presence of ethanol*

The series of reactions represented by eq. [6] was set up in HMPA[7] on the same scale as just outlined under "Formation of *p*-tolyl ethyl sulfide and trithioorthoformate **1** at elevated temperature." Reactions were run at ambient temperature. The reaction on *p*-chlorophenyl methanesulfonate was run for 1 h while the others were all run for 2 h.

Column chromatography as described for the previous experiment furnished the trithioorthoformate **1** and *p*-tolyl disulfide. Yields for these products from each aryl methanesulfonate were: sulfonate (% **1**, % disulfide), phenyl methanesulfonate (0, 0), *p*-chlorophenyl methanesulfonate (4, 4), *p*-methylsulfonylphenyl methanesulfonate (30, 10), 2,4,6-tribromophenyl methanesulfonate[9] (0, 63), and *p*-nitrophenyl methanesulfonate[9] (0, 4).

Optimized preparation of the sulfide-sulfonate ester **2** *in HMPA*[7]

The reactions represented by eq. [8] were all conducted in the manner outlined below.

A solution of *p*-tolyl mercaptan (4.254 g, 34.3 mmol) in HMPA[7] (25 mL) was added dropwise to a suspension of sodium hydride (1.651 g, 68.7 mmol) in HMPA[7] (75 mL). Upon completion of the addition, the reaction mixture was stirred at ambient temperature for 5 min. *p*-Chlorophenyl methanesulfonate (2.828 g, 13.7 mmol) was added, and the reaction mixture stirred for 1 h at ambient temperature.

The reaction mixture was subjected to standard work-up. Crude product was chromatographed on silica gel (200 g) employing carbon tetrachloride elution (100-mL fractions). Fractions 7–10 were combined and concentrated, affording clean trithioorthoformate **1** (0.287 g, 0.75 mmol, 5.5%). Fractions 21–45 were combined and concentrated, affording homogeneous sulfide-sulfonate ester **2** (4) (1.221 g, 3.72 mmol, 27%). After collecting 60 fractions of carbon tetrachloride, the eluting solvent was changed to chloroform. Fractions 65–67 were combined to give unchanged *p*-chlorophenyl methanesulfonate (0.195 g, 7%).

Peroxidation of the sulfide–sulfonate ester **2**

A solution of the sulfide–sulfonate ester **2** (0.510 g, 1.55 mmol) in chloroform (50 mL) was cooled in an ice–water bath. *m*-Chloroperoxybenzoic acid (85%, 0.699 g, 3.45 mmol peracid) was added to the reaction mixture in small portions. The ice was allowed to melt and the reaction to return to room temperature. The reaction was stirred for 48 h upon completion of peracid addition.

The reaction mixture was poured into chloroform and the resultant mixture extracted with 2.5% NaOH (3 50-mL portions). Crude sulfone-sulfonate ester was chromatographed on silica gel (50 g) employing 1:1 methylene chloride/carbon tetrachloride for elution (5-mL fractions). Fractions 5–7 were combined and concentrated, furnishing clean sulfone-sulfonate ester (0.384 g, 1.06 mmol, 68%). Recrystallized sul-

[9] See Table 1, footnote *b*.

For personal use only.

fone-sulfonate ester had mp 76.3–77.1°C; ir ($CHCl_3$); 1398, 1340, and 1155 cm^{-1}; nmr ($CDCl_3$) δ: 7.93 (2H, d), 7.43 (2H, d), 7.36 (4H, br s), 4.73 (2H, s), and 2.46 (3H, s); ms *m/e*: M^+ +2, 362 (13%), 360 (29%), 155 (100%), and 91 (57%). Anal. calcd. for $C_{14}H_{13}ClO_5S_2$: C 46.60, H 3.63; found: C 46.97, H 3.40.

Routine preparation of **2**

A solution of *p*-tolyl mercaptan (4.250 g, 34.2 mmol) in dimethyl sulfoxide (DMSO) (25 mL) was added dropwise to a slurry of sodium hydride (1.668 g, 69.5 mmol) in DMSO (75 mL) over 30 min. The reaction mixture was stirred at ambient temperature for 10 min to permit complete evolution of H_2. *p*-Chlorophenyl methanesulfonate (2.824 g, 13.7 mmol) was added and the reaction mixture stirred at ambient temperature for 35 min.[10]

Standard work-up furnished crude product (2.170 g), which was chromatographed on silica gel (220 g) employing carbon tetrachloride elution (20 100-mL fractions) followed by chloroform elution (100-mL fractions). Fractions 25–27 were combined and concentrated, giving clean sulfide-sulfonate ester **2** (1.292 g, 3.93 mmol, 29%).

Reaction of the sulfide-sulfonate ester **2** *with* p-*tolyl mercaptan*

A solution of *p*-tolyl mercaptan (0.943 g, 7.60 mmol) in HMPA[7] (25 mL) was added dropwise to a suspension of sodium hydride (0.368 g, 15.3 mmol) in HMPA[7] (75 mL). The sulfide-sulfonate ester **2** (1.004 g, 3.06 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h 10 min.

Standard work-up with routine column chromatography (80 g silica gel, carbon tetrachloride elution) furnished a mixture of *p*-tolyl disulfide and the trithioorthoformate **1** (0.362 g). Preparative thick-layer chromatography on this mixture (three 20 cm × 20 cm plates, developed 3 times with hexanes) furnished clean **1** (0.181 g, 0.47 mmol, 15%). The initial column also provided unchanged **2** (0.221 g).

Reaction of p-*chlorophenyl methanesulfonate with* p-*tolyl disulfide*

A solution of *p*-tolyl disulfide (3.375 g, 13.7 mmol) in HMPA[7] (10 mL) was added to a suspension of sodium hydride (1.013 g, 42.2 mmol) in HMPA[7] (80 mL). *p*-Chlorophenyl methanesulfonate (2.825 g, 13.7 mmol) was added and the reaction mixture stirred for 1 h 10 min.

Standard work-up furnished a crude mixture (3.424 g). Crude product was chromatographed on silica gel (350 g) employing 0.5% methanol in carbon tetrachloride (40 100-mL fractions) followed by 0.5% methanol in chloroform (100-mL fractions) for elution. Fractions 12 and 13 provided a mixture that was recrystallized from methanol to give the trithioorthoformate **1** (0.502 g). Fractions 14–17 gave clean **1** (0.694 g). Total trithioorthoformate **1** obtained was 3.13 mmol (23%).

Fractions 49–55 were combined, poured into 2.5% NaOH (50 mL), and the resultant mixture was washed with chloroform (3 50-mL aliquots). The organic solution was dried ($MgSO_4$) and concentrated, yielding sulfide-sulfonate ester **2** (0.765 g, 2.33 mmol, 17%).

Reaction of p-*tolyl mercaptide ions with air*

p-Tolyl mercaptan (0.477 g, 3.6 mmol) in HMPA[7] (3 mL) was added to a slurry of sodium hydride (0.155 g, 6.4 mmol) in HMPA[7] (9 mL). The reaction mixture was stirred for 1 h 5 min. Standard work-up afforded a crude residue that contained *p*-tolyl disulfide (0.122 g, 0.49 mmol) as established by gas chromatography.

Reaction of phenyl methanesulfonate and p-*tolyl mercaptan*

A solution of *p*-tolyl mercaptan (4.250 g, 34.2 mmol) in HMPA[7] (25 mL) was added dropwise to a suspension of sodium hydride (1.680 g, 70.0 mmol) in HMPA[7] (75 mL). Phenyl methanesulfonate (2.346 g, 13.6 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h 10 min.

Crude product (1.897 g), obtained by standard work-up, was subjected to column chromatography on silica gel (190 g) employing carbon tetrachloride (60 100-mL fractions) followed by chloroform (100-mL fractions) for elution. Fractions 8 and 9 were combined and concentrated, providing trithioorthoformate **1** (0.463 g, 0.121 mmol, 0.9%). Fractions 38–51 were combined and concentrated, yielding the sulfide-sulfonate ester **3** (4) (0.270 g, 0.918 mmol, 6.7%). Fractions 53–66 were combined and concentrated, furnishing unchanged phenyl methanesulfonate (1.388 g, 59%).

Reaction of phenyl methanesulfonate with p-*tolyl disulfide*

Phenyl methanesulfonate (2.342 g, 13.6 mmol), sodium hydride (0.687 g, 28.6 mmol), and *p*-tolyl disulfide (2.804 g, 11.3 mmol) were reacted and worked-up as described for the reactants under "Reaction of phenyl methanesulfonate and *p*-tolyl mercaptan."

Crude product was chromatographed on silica gel (300 g) employing carbon tetrachloride (150 100-mL fractions) followed by chloroform (100-mL fractions) for elution.

Fractions 11–19 yielded clean trithioorthoformate **1** (1.374 g, 3.59 mmol, 24%).

Fractions 85–113 furnished the sulfide-sulfonate ester **3** (4) (0.266 g, 0.904 mmol, 6.6%).

Fractions 117–162 were combined and added to 2.5% NaOH (50 mL). The resultant mixture was extracted with chloroform (3 50-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated, furnishing phenyl methanesulfonate (0.873 g, 37%).

Preparation of 4-bromophenyl methanesulfonate

Bromophenol was condensed with methanesulfonyl chloride following the procedure described earlier for the preparation of 2,4,6-tribromophenyl methanesulfonate (2). 4-Bromophenyl methanesulfonate had mp 81.9–83.2°C; ir ($CHCl_3$): 1165 and 1360 cm^{-1}; nmr ($CDCl_3$) δ: 7.70 (2H, d, J = 9.5 Hz), 7.20 (2H, d, J = 9.5 Hz), and 3.11 (3H, s); ms *m/e*: M^+ +2, 252 (100%), 250 (88%), 175 (11%), 174 (54%), 173 (73%), 172 (81%), and 171 (55%). Anal. calcd. for $C_7H_7BrO_3S$: C 33.48, H 2.80; found: C33.57, H 2.89.

Reaction of 2,4,6-tribromophenyl methanesulfonate with sodium hydride

A solution of 2,4,6-tribromophenyl methanesulfonate (2)

[10] Reaction time is critical: shorter times prevent accumulation of **2** and longer periods lead to consumption of **2**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

(5.009 g, 12.2 mmol) in HMPA[7] (10 mL) was added dropwise to a slurry of sodium hydride (0.582 g, 24.2 mmol) in HMPA (20 mL). Upon completion of the addition, the reaction mixture was stirred at ambient temperature for 1 h 5 min.

Standard work-up furnished crude material from the organic layer and a solution of aqueous base. The aqueous base was first acidified with concentrated hydrochloric acid, then 10% HCl (100 mL) was added. The aqueous acid solution was extracted with diethyl ether (5 100-mL portions), yielding 2,4,6-tribromophenol (2.825 g, 8.54 mmol, 70%).

The original organic layer was concentrated and chromatographed on silica gel (100 g) employing carbon tetrachloride (31 100-mL fractions) followed by chloroform (100-mL fractions) for elution. Fractions 18–28 were combined and concentrated, furnishing a mixture of the tribromophenyl methanesulfonate and 2,4-dibromophenyl methanesulfonate[11] (0.452 g). Further attempts to resolve this mixture by column chromatography and thick-layer preparative chromatography were unsuccessful. Fractions 33–40 were combined and concentrated, giving clean 4-bromophenyl methanesulfonate (0.142 g, 0.562 mmol, 4.6%). The 4-bromophenyl methanesulfonate so obtained was identical to authentic material by nmr, ir, mp, and mixture mp.

Reaction of 2,4,6-tribromophenyl methanesulfonate with sodium hydride in the presence of 1,3-dinitrobenzene

The reaction described under "Reaction of 2,4,6-tribromophenyl methanesulfonate with sodium hydride" was rerun on the same scale in the presence of 1,3-dinitrobenzene (4.049 g, 24.1 mmol). The same work-up furnished the same yield of tribromophenol and a mixture of neutrals containing 1,3-dinitrobenzene (3.453 g) and 2,4,6-tribromophenyl methanesulfonate (0.906 g). No dibromophenyl or monobromophenyl methanesulfonate was detectable (nmr).

*Reaction of **2** with sodium* p*-tolyl mercaptide in the presence of p-chlorophenol*

A solution of *p*-tolyl mercaptan (0.441 g, 3.55 mmol) in HMPA[7] (10 mL) was added to a slurry of sodium hydride (0.085 g, 3.54 mmol) in HMPA[7] (11 mL) and the reaction mixture stirred at room temperature for 10 min. *p*-Chlorophenol (0.455 g, 3.55 mmol) in HMPA[7] (4 mL) was added. The sulfide-sulfonate ester **2** (1.003 g, 3.05 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h 5 min.

Crude product (1.125 g), obtained by standard work-up, was subjected to column chromatography on silica gel (150 g) employing carbon tetrachloride (67 100-mL fractions) followed by chloroform (100-mL fractions) for elution.

Fractions 4–6 furnished *p*-tolyl disulfide (0.321 g, 1.30 mmol, 73%). Fractions 7–10 yielded trithioorthoformate **1** (0.138 g, 0.361 mmol, 10%). Fractions 39–51 gave unchanged **2** (0.060 g, 6%). Fractions 67–73 furnished *p*-chlorophenyl methanesulfonate (0.326 g, 1.58 mmol, 52%). Recrystallized methanesulfonate was identical to authentic material by mp, mixture mp, ^{1}H nmr, ir, and double spotted tlc.

*Preparation of the sulfide-sulfonate ester **3***

A solution of phenol (0.921 g, 9.79 mmol) in HMPA[7] (8 mL) was added dropwise to a suspension of sodium hydride (0.230 g, 9.58 mmol) in HMPA[7] (5 mL). Upon completion of the addition, the reaction mixture was stirred at ambient temperature for 10 min. Phenyl chloromethanesulfonate (4) (2.014 g, 9.77 mmol) and *p*-tolyl disulfide (1.190 g, 4.83 mmol) were added. The reaction mixture was stirred at ambient temperature for 45 min.

Crude product, obtained by standard work-up, was subjected to column chromatography on silica gel (200 g) employing carbon tetrachloride elution (100-mL fractions). Fractions 107–166 were combined and concentrated, giving the sulfide-sulfonate ester **3** (0.466 g, 1.58 mmol, 16%).

[11] The structural assignment for the dibromomethanesulfonate rests entirely on the proton nmr obtained by subtraction of the tribromomethanesulfonate signals from the ^{1}H nmr of the mixture.

Peroxydation de l'acide linolénique en présence des fibres d'amiante ou de némalite. Résultats préliminaires avec des cellules épithéliales

Germaine Levasseur-Acker, Roger Zalma, Edith Copin, Jeanine Fournier, Henri Pezerat et Roger Jankowski

Résumé : La peroxydation de l'acide linolénique (LH), en milieu aqueux aéré, a été étudiée en présence de fibres de chrysotile (UICC A et B), de crocidolite UICC et de némalite. Des études préliminaires sur la peroxydation des membranes des cellules épithéliales des voies aériennes ont également été réalisées. Les radicaux ($L^{\cdot}$, $LOO^{\cdot}$) issus de la peroxydation sont détectés en RPE à l'aide d'un piégeur de radicaux, le POBN. L'activité de ces minéraux contenant du fer(II) est liée à la formation d'espèces activées de l'oxygène et en particulier de certaines d'entre elles très électrophiles ($^{\cdot}OH$ ou entités perferryles et ferryles). Leur mise en évidence en RPE par l'intermédiaire d'un piégeur de radicaux, le DMPO, est réalisée en absence et en présence de certains complexants du fer(II) tels que les ions phosphate, l'ADP, l'ATP, l'AMP et l'EDTA. La formation et la nature des entités activées de l'oxygène est fonction non seulement de la nature du matériau inorganique mais aussi de la nature des complexants du milieu. L'extrapolation des résultats obtenus à partir de l'acide linolénique à la peroxydation des membranes des cellules épithéliales ne peut se faire directement.

Mots clés : amiante, peroxydation, complexants du fer, espèces activées de l'oxygène, RPE.

Abstract: Linolenic acid (LH) peroxidation in aqueous medium is studied in the presence of fibers of chrysotile (UICC A and B), crocidolite UICC, and némalite. Preliminary studies on the peroxydation of epithelial cell membranes were also performed. Radicals ($L^{\cdot}$, $LOO^{\cdot}$) formed from the peroxidation process are detected by EPR with a spin trapping agent, POBN. The activity of these iron(II)-containing fibers is related to the formation of activated oxygen species, particularly of some highly electrophilic species ($^{\cdot}OH$ or perferryl and ferryl entities). The presence of these species is shown by EPR with a spin trapping agent, DMPO, in the presence or in the absence of certain iron(II) chelators (phosphate ions, ADP, ATP, AMP, EDTA). The formation and the nature of activated oxygen species depend on the nature both of the inorganic material and of the chelator. It is not possible to directly extrapolate the results obtained with linolenic acid to the peroxidation of epithelial cell membranes.

Key words: asbestos, peroxidation, iron chelators, activated oxygen species, EPR.

Introduction

La toxicité des fibres d'amiante et de némalite a été examinée par de nombreux auteurs. Un certain nombre d'entre eux (1) ont montré que ces matériaux présentant un caractère donneur d'électrons dû à l'existence de sites réducteurs (Fe(II)) sont capables d'activer, en milieu aqueux aéré, l'oxygène moléculaire dissous pour conduire à la formation d'espèces activées de l'oxygène (EAO). Ces sites réducteurs Fe(II) peuvent éventuellement être formés par réduction de sites Fe(III) en présence d'un réducteur. Les espèces activées de l'oxygène, susceptibles de participer à des processus de stress oxydant (2), peuvent être de diverse nature et se différencier par leur pouvoir oxydant. En effet nos études récentes (3, 4) ont permis de distinguer deux sous-ensembles parmi l'ensemble des EAO. Le premier, appelé A*, regroupe des espèces très oxydantes (par exemple des radicaux $^{\cdot}OH$, ou des espèces ferryles $Fe^{IV}{=}O$, et (ou) perferryles $Fe^{V}{=}O$ (5)), capables d'arracher un atome d'hydrogène à une grande variété de molécules cibles (RH) telles le DMSO, l'alcool ou l'anion formiate, pour donner un radical $R^{\cdot}$. Le second sous-ensemble, appelé P*, correspond à des espèces moins électrophiles que les A* (par exemple les entités superoxo Fe^{III}-$O_2^{-\cdot}$ (6)) qui sont incapables d'extraire un atome d'hydrogène aux molécules cibles (RH) citées ci-dessus mais par contre sont aptes à attaquer un

hydrogène plus labile sur un lipide polyinsaturé (LH) et ainsi de déclencher la peroxydation. A fortiori les espèces A* sont aussi capables d'initier la peroxydation des lipides.

Bien que le mécanisme de la peroxydation lipidique apparaisse très complexe, il est généralement admis (7) que la peroxydation s'effectue selon une succession de réactions radicalaires réparties en trois étapes principales : initiation, propagation et terminaison.

Par abstraction d'un atome d'hydrogène la première étape (initiation) conduit à la formation d'un radical L·

$$[1] \quad LH \xrightarrow{-H^{\cdot}} L^{\cdot}$$

La seconde étape (propagation) en milieu aéré, fait apparaître des radicaux peroxyles (LOO·) et des hydroperoxydes :

$$[2] \quad L^{\cdot} + O_2 \longrightarrow LOO^{\cdot}$$

$$[3] \quad LOO^{\cdot} + LH \longrightarrow LOOH + L^{\cdot}$$

La dernière étape (terminaison) correspond à la combinaison des radicaux L· et LOO· pour donner des produits non radicalaires.

La présente étude a pour but de mettre en évidence le rôle des EAO dans l'initiation de la peroxydation de l'acide linolénique, grâce à la détection des radicaux L· ou LOO· formés. Certaines de ces entités activées de l'oxygène (A* et P*) sont dans le cas présent générées par des fibres minérales d'amiante (chrysotile, crocidolite) ou de némalite, matériaux contenant du Fe(II), après réaction avec l'oxygène moléculaire dissous dans un milieu aqueux. Plusieurs types de fer(II) peuvent être à l'origine de l'apparition des EAO (8, 9) : les ions Fe^{2+} liés au réseau solide, les ions Fe^{2+} passés en solution se retrouvant soit à l'état hydraté soit à l'état complexé par des ligands appropriés. La production de ces EAO peut être aussi liée à la présence de fer(III) pouvant présenter les mêmes types de coordination que le fer(II), à condition que les ions Fe^{3+} puissent être préalablement réduits en ions Fe^{2+} par des molécules réductrices telles la NADPH. Les différences de réactivité du fer vis-à-vis de l'oxygène moléculaire sont fonction de ses divers états du cation de transition.

Dans le cadre de l'étude de la peroxydation de l'acide linolénique, nous avons été amenés à étudier l'influence de certaines molécules complexantes susceptibles d'extraire le fer des fibres minérales (10), ce processus pouvant contribuer à la formation de ces espèces A* ou P* en solution. Une étude de la peroxydation des membranes de cellules épithéliales en présence des fibres minérales est également abordée et nous exposerons les résultats préliminaires obtenus avec ou sans ajout de complexants.

Matériaux et méthodes

Fibres minérales

L'étude a porté sur trois échantillons d'amiante qui nous ont été fournis par l'Union Internationale contre le Cancer (UICC) : deux échantillons de chrysotiles A (Rhodésie) et B (Canada) et un échantillon de crocidolite. Nous avons choisi également d'examiner une brucite fibreuse, la némalite, de la mine d'Asbestos (Québec). La némalite est un contaminant fréquent des chrysotiles canadiens (11). La crocidolite et la némalite ont été broyées 2 min à la main dans un mortier en agate juste avant la réalisation des tests.

Réactifs

L'éthylènediamine tétraacétique disodique dihydraté (EDTA, 99%) et quatre nucléotides adényliques ont été utilisés : l'adénosine 5′-diphosphate sodique (ADP, 97%), l'adénosine 5′-monophosphate sodique (AMP, 99%), l'adénosine 5′-triphosphate disodique (ATP, 99%) et la nicotinamide adénine diphosphate tétrasodique (NADPH, 96%). Tous ces réactifs ainsi que l'agent mouillant, le CHAPS ou 3-[(3-cholamidopropyl)-diméthylammoniol]-1-propanesulfonate, le DMPO ou 5-5′-diméthyl-1-pyrroline-*N*-oxyde (99%) et l'acide linolénique ou acide 9-12-15-octadécatriènoïque (98%) viennent de chez Sigma. Le DMPO a été purifié par filtration sur charbon actif suivant la méthode préconisée par Buettner et Oberley (12). Le POBN ou α-(4-pyridyl 1-oxyde)-*N*-*tert*-butylnitrone (99%) provient de chez Jansen Chimica. Le dihydrophosphate de potassium et le monohydrophosphate de potassium permettant de préparer la solution tampon (pH 7,4) et le formiate de sodium proviennent de chez Merck. Le milieu de culture utilisé pour la culture cellulaire est le «Dulbecco modified Eagle's medium» (DME) provenant de chez Gibco. La pronase provient de chez Sigma Chemical Co.

Cultures cellulaires

L'expérimentation a été menée sur des cellules provenant de 15 polypes du nez obtenus par chirurgie chez des sujets atteints de polypose nasale. Dès l'ablation les tissus sont rincés dans le milieu de culture DEM stérile puis incubés pendant 16 h à 4°C dans ce milieu de culture contenant 0,1% de pronase (enzyme protéolytique qui digère les tissus enrobant les cellules, ce qui conduit ainsi à leur dissociation). Les cellules dissociées obtenues sont comptées et mises en culture selon la technique décrite par Levasseur-Acker et al. (13). Lorsque les cultures cellulaires arrivent à confluence (6–8 jours de culture), elles sont utilisées pour le test de peroxydation lipidique.

Test de peroxydation

Le test de peroxydation est effectué dans un réacteur à l'abri de la lumière à 37°C. Les fibres (45 mg) sont mises en suspension dans 2 mL d'une solution aqueuse (tamponnée ou non en milieu phosphate; 0,1 M; pH 7,4) contenant un piégeur de radicaux le POBN (0,1 M). À cette solution sont ajoutés 25 μL d'acide linolénique pur (23 mM) auxquels on additionne, pour faciliter sa mise en suspension, un surfactant, le CHAPS à la concentration de 0,8 mM. Lorsque le test est réalisé en présence des complexants, la quantité ajoutée correspond à des concentrations variant de 1 à environ 7 mM selon la nature du complexant. Des parties aliquotes du milieu réactionnel sont prélevées à des temps déterminés, filtrées et examinées en RPE (Bruker ESP 300 E) afin de mettre en évidence et d'évaluer la quantité d'adduits radicalaires formés. Lorsque le test est effectué sur des cellules, la quantité de fibres est seulement de 20 mg et l'acide linolénique est remplacé par les cellules (1×10^6). Suivant les cas, l'expérience est menée dans le milieu de culture DEM, dans l'eau ou le sérum physiologique (solution saline à 9‰). Le temps de vie des radicaux R· (L· ou LOO·) formés lors de la peroxydation est trop court pour per-

Fig. 1. Spectre RPE de l'adduit radicalaire (POBN,R)˙. Conditions : champ central : 3480 G; fréquence : 9,7693 GHz; puissance : 10 mW; constante de temps: 0,128 s; modulation d'amplitude: 2,043 G; gain : 4×10^4.

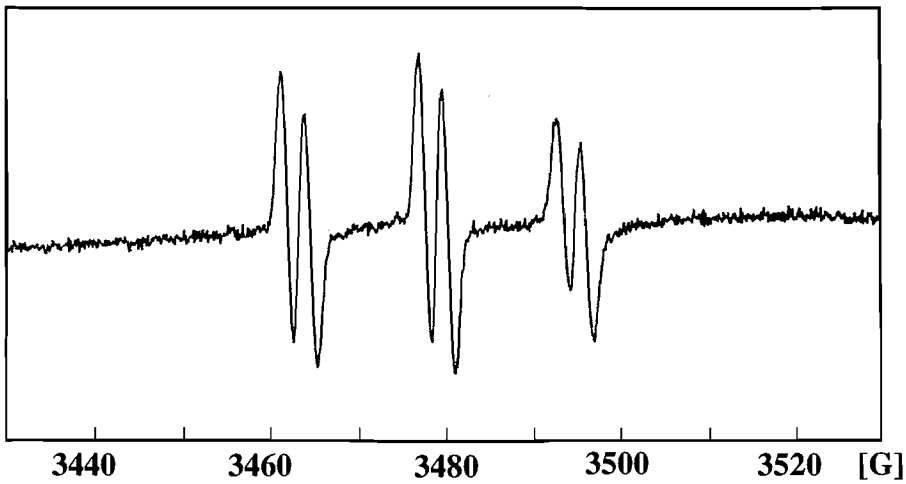

Schéma 1. Formation de l'adduit radicalaire (POBN,R)˙.

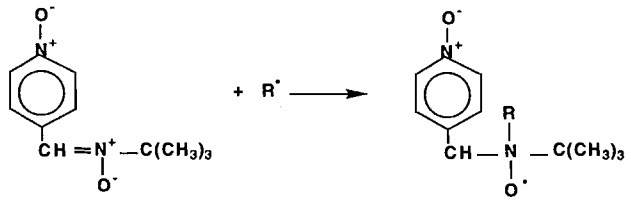

mettre leur étude. C'est la raison pour laquelle on ajoute un piégeur de radicaux le POBN, conduisant à la formation d'un adduit radicalaire suffisamment stable pour être mis en évidence par RPE (Schéma 1).

Cette derniére réaction peut être représentée plus simplement sous la forme :

[4] $\text{POBN} + \text{R}^{\cdot} \longrightarrow (\text{POBN,R})^{\cdot}$

Mise en évidence des entités A*

Certaines espèces oxydantes A*, radicalaires telles ˙OH, peuvent être mises en évidence par RPE en présence d'un piégeur de radicaux, le DMPO (14), grâce à la formation d'un adduit plus stable :

[5] $\text{DMPO} + {}^{\cdot}\text{OH} \longrightarrow (\text{DMPO,OH})^{\cdot}$

D'autres espèces A* telles les entités ferryles, perferryles, etc. ne peuvent être détectées directement par l'intermédiaire du DMPO. Cependant, ces entités oxydantes à l'égal des radicaux ˙OH sont capables d'arracher un atome d'hydrogène à une molécule RH tel l'ion formiate HCO_2^- (15) :

[6] $HCO_2^- + \text{A}^* \longrightarrow CO_2^{-\cdot} + \text{AH}$

Le radical carboxylate $CO_2^{-\cdot}$ en présence de DMPO conduit à la formation d'un adduit radicalaire détecté en RPE.

[7] $CO_2^{-\cdot} + \text{DMPO} \longrightarrow (\text{DMPO,}CO_2^-)^{\cdot}$

Pour la mise en évidence des radicaux ˙OH, 45 mg du solide testé sont mis en suspension dans 2 mL d'une solution aqueuse aérée de DMPO (50 mM). Après incubation à 37°C à l'abri de la lumière pendant des temps déterminés, des parties aliquotes sont prélevées et examinées en RPE. Le même protocole réalisé en présence du formiate de sodium permet de mettre en évidence les adduits radicalaires $(\text{DMPO,}CO_2^-)^{\cdot}$. Les conditions d'obtention et les caractéristiques de ce spectre ainsi que celui de $(\text{DMPO,OH})^{\cdot}$ ont été précédemment détaillées dans diverses études (16).

Les intensités des adduits radicalaires $(\text{POBN,LOO})^{\cdot}$, $(\text{DMPO,}CO_2^-)^{\cdot}$ et $(\text{DMPO,OH})^{\cdot}$ mentionnées dans les tableaux de résultats présentés ci-dessous sont exprimées en unités arbitraires (u.a.).

Résultats et discussion

Les tests de peroxydation de l'acide linolénique réalisés avec chacun des quatre échantillons de fibres minérales en présence de POBN conduit à la formation d'adduits radicalaires $(\text{POBN,R})^{\cdot}$ où R˙ serait LOO˙ plutôt que L˙ en milieu aqueux aéré (17). Le spectre RPE, traduisant la présence de ces adduits, est constitué de 6 raies (Figure 1) et les constantes de couplage évaluées à partir du spectre ont pour valeur a_N = 15,8 G et a_H = 2,8 G. Ces valeurs sont conformes à celles trouvées par Rosen et Rauckman (17).

Les intensités du signal RPE obtenues après piégeage par le POBN des radicaux formés au cours de la peroxydation de l'acide linolénique sont rassemblées dans le tableau 1. On observe pour les quatre matériaux testés que l'intensité des spectres après un temps d'incubation de 30 min varie suivant la nature de la fibre minérale testée et qu'elle est nettement supérieure à celle du contrôle obtenu sans fibres.

L'activité vis-à-vis de la peroxydation de l'acide linolénique est du même ordre pour la némalite et la crocidolite et elle est nettement plus importante que celles des chrysotiles A et B. Le fait que l'activité du chrysotile B soit plus importante que celle de son homologue A peut sans doute s'expliquer par la présence de la némalite dans l'échantillon B. L'activité observée traduit le degré de peroxydation de l'acide linolénique (18) et elle est due aux espèces activées de l'oxygène formées à partir du Fe^{2+} accessible en surface de la fibre minérale et (ou) en solution. Cette activité ne peut être due

[c]Test effectué en absence de fibres minérales.

seulement à des espèces A* puisque le chrysotile A ne conduit qu'à la formation d'une très faible quantité d'adduits radicalaires (DMPO, CO_2^-)· (4, 18), elle serait donc liée à des espèces A* et P*.

Ces premiers résultats permettent d'envisager une possible attaque des membranes cellulaires en milieu biologique selon des mécanismes semblables à ceux de l'oxydation de l'acide linolénique. Le tableau 2 révéle l'intensité du signal (POBN,R)· lors du test de peroxydation des membranes de cellules épithéliales nasales humaines en culture primaire en présence des différentes fibres minérales. Les résultats obtenus sont assez surprenants puisque seule la némalite présente une activité alors que la crocidolite active dans la peroxydation de l'acide linolénique (tableau 1) ne présente alors aucune activité. Ces résultats nous amènent à envisager le rôle de plusieurs facteurs : (*i*) activité oxydante en surface des fibres et (ou) activité en solution; (*ii*) nature des espèces oxydantes A* (·OH et (ou) ferryle et perferryle) et (ou) P* (Fe^{III} superoxo).

Il est à priori probable que l'activité de surface, sur des temps aussi courts qu'une heure, ne permettra que difficilement une interaction entre les entités oxydantes à l'interface fibre–milieu et les zones sensibles des lipides organisés au sein de la double couche des membranes cellulaires. Cette interaction ne peut guère se produire que pendant les processus d'internalisation des particules au sein des cellules, ou suite à la rupture de la membrane (cytotoxicité). Il n'est pas impossible que la différence entre némalite et crocidolite soit due à des cinétiques de ces phénomènes plus rapides avec le premier minéral qu'avec le second.

La nature et la charge des espèces oxydantes en solution vont jouer également un rôle car la diffusion au sein de la double couche des espèces non chargées comme ·OH est probablement plus aisée que celle des ferryles et perferryles, entités existant principalement sous forme anionique (19).

Des études précédentes (20) ayant montré qu'en milieu phosphate aéré la némalite, à la différence de la crocidolite, générait des ·OH en quantité importante, il est plausible de considérer à titre d'hypothèse que cette différence de nature dans les espèces oxydantes formées joue également un rôle dans le phénomène de la peroxydation des membranes cellulaires.

Pour essayer d'approfondir cette interprétation, nous avons étudié plus particulièrement la crocidolite UICC active en présence de l'acide linolénique (tableau 1) mais totalement inactive en présence des cellules épithéliales (tableau 2).

Sachant que l'activité oxydante des fibres minérales étudiées est due à l'accessibilité du fer(II) dans les matériaux (8), nous avons tenté de modifier cette accessibilité par ajout de complexants ce qui a aussi pour conséquence de changer le potentiel rédox du couple Fe^{3+}/Fe^{2+}. Les tests ont été réalisés en présence d'un certain nombre de complexants solubles du fer tels l'AMP, l'ADP, l'ATP, l'EDTA et des ions phosphate, ces derniers pouvant jouer également un rôle important dans le phénomène de lixiviation des fibres minérales (18). En premier lieu, nous avons recherché si les complexants avaient une influence sur la formation des entités hautement électrophiles du type A*. Rappelons que ces entités sont capables en présence de DMPO et d'ions formiate de former des adduits radicalaires (DMPO,CO_2^-)·.

Les résultats obtenus à partir de la crocidolite UICC, préalablement broyée 2 min à la main (tableau 3), montrent l'influence des complexants sur l'intensité du signal de l'adduit radicalaire (DMPO,CO_2^-)·, donc sur l'activité oxydante du matériau suite à la formation d'espèces activées de l'oxygène de type A*.

Par rapport au milieu eau distillée, l'ajout de complexants permet une augmentation de l'intensité du signal et mis à part le cas de l'EDTA, le signal croît avec le temps d'incubation. Il apparaît donc que la présence d'un complexant ou du phosphate dans le milieu favorise la formation d'espèces A*. Cette augmentation pourrait s'expliquer soit par une meilleure accessibilité de l'oxygène aux Fe^{2+} du réseau solide du fait d'une cinétique de lixiviation du solide favorisée par la présence de ces complexants, soit par un renforcement du caractére réducteur du Fe^{2+} à l'état complexé, soit encore par ces deux phénomènes intervenant simultanément. Par ailleurs il est probable que l'encombrement stérique du complexe influence le pouvoir oxydant du système. Dans le cas de l'EDTA, le signal à 60 min n'est pas significatif de toutes les espèces A* formées, car il diminue en fonction du temps d'incubation. Ce phénomène est probablement du à une diminution du temps de vie des adduits radicalaires (DMPO,CO_2^-)·, observé dans le

AMP	1480
ADP	0
ATP	0
Phosphate	0
EDTA	1120
Sans complexant[b]	1830

Conditions expérimentales : 45 mg de crocidolite préalablement broyée 2 min en suspension dans 2 mL d'une solution aqueuse de DMPO (0,05 M). Cette solution contient suivant les cas soit du tampon phosphate pH 7,4 (0,1 M), soit 5 mg de complexant AMP (7,2 mM), ADP (5,8 mM), ATP (4,5 mM), soit 0,75 mg d'EDTA (1 mM).

[a]Intensité exprimée en unités arbitraires (u.a.).

[b]Test effectué en présence de la crocidolite en milieu eau distillée.

cas où des espèces très réductrices sont présentes en solution (21).

Afin d'examiner dans quelle mesure les entités oxydantes présentes en solution aqueuse sont des radicaux $^{\cdot}OH$, les tests ont été refaits en présence de DMPO à partir de la crocidolite en suspension dans l'eau contenant les complexants sans adjonction de formiate de sodium (tableau 4). Les résultats de ce tableau montrent l'influence des complexants sur la formation des radicaux $^{\cdot}OH$ mis en évidence sous la forme de l'adduit radicalaire $(DMPO,OH)^{\cdot}$. On note que le test réalisé avec la crocidolite, sans phosphate et sans complexant, permet la génération de radicaux $^{\cdot}OH$. On remarque aussi que la présence de certains complexants (ATP, ADP) et des ions phosphate ne permet pas la formation de radicaux $^{\cdot}OH$. Il apparaît donc que les radicaux $(DMPO,CO_2^-)^{\cdot}$ observés (tableau 3) sont dus à des mécanismes faisant intervenir des entités

Tableau 5. Intensité du signal $(DMPO,CO_2^-)^{\bullet}$ obtenus à partir de filtrats de suspensions de la crocidolite UICC en présence de complexants.

Complexant	Intensité $(DMPO,CO_2^-)^{\bullet}$[a] après incubation 60 min
AMP	2000
ADP	2400
ATP	3600
Phosphate	0
EDTA	5100
Sans complexant[b]	0

Conditions expérimentales : la solution aqueuse étudiée contient 0,5 mL de filtrat, de la NADPH (1 mM), du formiate de sodium (1M) et du DMPO (0,05 M). Le filtrat est obtenu après 3 h d'incubation de 45 mg de crocidolite broyée dans 1 mL d'une solution contenant suivant les cas soit du tampon phosphate pH 7,4 (0,1 M), soit 5 mg de complexant AMP (7,2 mM), ADP (5,8 mM), ATP (4,5 mM), soit 0,75 mg d'EDTA (1 mM).

[a]Intensité exprimée en unités arbitraires (u.a.).

de type ferryle ou perferryle capables d'arracher un hydrogène à l'ion formiate. Par contre dans les autres cas (AMP, EDTA et sans complexant), l'intensité des signaux $(DMPO, OH)^{\cdot}$ d'une part (tableau 4) et $(DMPO,CO_2^-)^{\cdot}$ d'autre part (tableau 3) montrent que les entités oxydantes A* comportent en grande majorité des espèces oxydantes de type ferryle ou perferryle et pour une partie moindre des radicaux $^{\cdot}OH$. En effet les étalonnages en nombre de radicaux par litre effectués dans nos conditions d'évaluation permettent de considérer que pour une même intensité en unités arbitraires (u.a.) le rapport entre le nombre d'adduits $(DMPO, CO_2^-)^{\cdot}$ et celui des adduits $(DMPO, OH)^{\cdot}$ est approximativement de l'ordre de 2 (20).

Afin d'évaluer l'apport maxima des complexes du fer(II) en solution dans le système réactionnel, nous avons étudié l'oxydation du formiate sur des filtrats issus des suspensions contenant la crocidolite broyée et incubée 3 h avec les différents complexants utilisés ci-dessus. Le fer(II) en solution s'oxydant facilement en fer(III) du fait de la présence de l'oxygène dissous dans le milieu aqueux, il est probable qu'une partie du fer précipite sous forme d'hydroxyde ferrique qui sera éliminé lors de la filtration. En ajoutant au filtrat un réducteur comme la NADPH, le fer(III) complexé pourra éventuellement être réduit à l'état de fer(II) susceptible de former des espèces activées de l'oxygène.

Le test d'oxydation de l'anion formiate sur les filtrats a conduit aux résultats exposés dans le tableau 5. D'après les valeurs de l'intensité du signal de l'adduit radicalaire $(DMPO,CO_2^-)^{\cdot}$, on observe que la présence en solution des complexes du fer et des ligands, AMP, ATP, ADP et EDTA, contribuent à la formation des radicaux $^{\cdot}OH$ et $CO_2^{\cdot -}$. En milieu eau distillée ou en présence de phosphate on n'observe pas de signal $(DMPO,CO_2^-)^{\cdot}$. Deux raisons peuvent expliquer ce fait : en effet, soit l'essentiel du fer oxydé lors des trois heures d'incubation a pu précipiter (par exemple sous forme d'un phosphate de fer(III) insoluble) puis a été éliminé par filtration, soit il est possible que des ligands comme HPO_4^{2-}, $H_2PO_4^-$ ou HCO_2^- confèrent aux ions Fe^{3+} un potentiel rédox qui ne permet pas leur réduction en Fe^{2+} par la NADPH.

L'activité constatée (valeur de 6050 u.a., tableau 3) de la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Tableau 6. Intensité du signal (POBN,R)$^{\cdot}$ lors de la peroxydation de l'acide linolénique en présence de la crocidolite UICC et de différents complexants.

Complexant	Intensité du signal (POBN,R)$^{\cdot}$[a] après incubation 30 min
AMP	9100
ADP	9230
ATP	12100
Phosphate	9900
EDTA	22000
Sans complexant[b]	9900

Conditions expérimentales : 45 mg de fibres dans 2 mL d'une solution aqueuse contenant : acide linolénique (23 mM), POBN (0,1 M), CHAPS (0,8 mM) et suivant les cas soit du tampon phosphate pH 7,4 (0,1 M), soit 5 mg de complexant AMP (7,2 mM), ADP (5,8 mM), ATP (4,5 mM), soit 0,75 mg d'EDTA (1 mM).

[a]Intensité exprimée en unités arbitraires (u.a.).

[b]Test effectué en présence de la crocidolite en milieu eau distillée.

crocidolite en suspension en milieu eau distillée en absence de complexant par comparaison à l'inactivité du filtrat correspondant (tableau 5) permet de penser que cette activité est liée à l'apparition de radicaux $^{\cdot}$OH et d'espèces du type ferryle ou perferryle liées au solide. Les radicaux $^{\cdot}$OH ne peuvent être présents dans le filtrat au bout de 3 h d'incubation du fait de leur temps de vie très court (22) et les autres espèces sont probablement éliminées par filtration.

La comparaison des données des tableaux 3 et 5 révèle une activité oxydante en présence de complexant plus faible pour les filtrats que pour les suspensions, bien que l'activité oxydante des filtrats soient dues pour partie à des Fe(III) du solide mis en solution sous forme de complexe puis réduits par la NADPH, processus qui ne joue pas de rôle dans les résultats du tableau 3. Il semble probable que même en présence de complexes la majorité de l'activité oxydante due à la crocidolite apparaît à la surface du solide suite à l'interaction des Fe(II) encore liés au réseau solide avec l'oxygène .

Le tableau 6 répertorie les résultats des tests de peroxydation de l'acide linolénique effectués en présence de crocidolite UICC broyée et de différents complexants. Parmi les complexants seul l'EDTA augmente nettement l'activité, l'ATP donnant une augmentation moins significative. Les autres complexants (AMP, ADP, phosphate) n'ont pas d'influence sur l'activité. Il ne semble pas que l'on puisse établir une corrélation entre l'activité due aux entités oxydantes A* (test d'oxydation de l'anion formiate, tableau 3) et celle mise en évidence au cours de la peroxydation de l'acide linolénique (tableau 6). Il est très probable que les mécanismes de peroxydation de l'acide linolénique dépendent non seulement des espèces A* mais aussi des entités superoxo (P*). On peut envisager aussi l'intervention d'autres facteurs comme, par exemple, l'adsorption de l'acide linolénique sur la surface du solide. Cette adsorption plus ou moins importante suivant la nature du milieu peut perturber les cinétiques de lixivation et les réactions de peroxydation.

À partir de ces données, des tests préliminaires de peroxydation ont été réalisés avec des cellules, en présence de crocidolite broyée et différents complexants. Les résultats obtenus, exprimés par l'intensité des adduits radicalaires (POBN,R)$^{\cdot}$, sont présentés dans le tableau 7. Des tests de contrôle effectués sans cellules en présence du milieu de culture ou de sérum physiologique ou d'eau ne donnent pas de signaux alors que l'on constate la présence de l'adduit radicalaire (POBN,R)$^{\cdot}$ avec l'EDTA et l'ATP dans ces divers milieux. Ce résultat semble conforme à l'activité observée dans le tableau 6 où l'EDTA et l'ATP sont les plus actifs dans la peroxydation de l'acide linolénique. On remarque aussi dans le tableau 7 qu'en présence de l'ATP en milieu tampon phosphate il n'apparaît pas de signal en RPE et qu'en présence de l'AMP et de l'ADP, l'activité de la crocidolite est nulle quelle que soit la nature du milieu étudié (eau ou sérum physiologique en présence de tampon ou non).

Tableau 7. Influence de complexants sur l'intensité du signal (POBN,R)$^{\cdot}$ obtenu à partir de la crocidolite UICC en présence des cellules épithéliales

Complexant	Intensité du signal (POBN,R)$^{\cdot}$[a] 60 min d'incubation	Conditions
EDTA	700	Milieu de culture sans TP
EDTA	960	Milieu eau sans TP
AMP	0	Milieu eau sans TP
ADP	0	Sérum physiologique sans TP
ADP	0	Sérum physiologique avec TP
ATP	840	Milieu de culture sans TP
ATP	0	Sérum physiologique avec TP

Conditions expérimentales : les cellules en culture sont soumises à l'action de 20 mg de fibres mis en suspension dans 2 mL d'une solution aqueuse comprenant éventuellement 0,5 mL de sérum physiologique ou 0,5 mL de milieu de culture. Cette solution contient du POBN (0,1 M) et du CHAPS (0,8 mM) et suivant les cas soit du tampon phosphate (TP) pH 7,4 (0,1 M), soit 5 mg de complexant AMP (7,2 mM), ADP (5,8 mM), ATP (4,5 mM), soit 0,75 mg d'EDTA (1 mM).

[a]Intensité exprimée en unités arbitraires (u.a.).

Conclusion

La présente étude permet de confirmer que les fibres d'amiante et de némalite sont à même de peroxyder les lipides polyinsaturés suite à la formation de diverses espèces activées de l'oxygène (EAO). Dans ce processus de peroxydation la formation d'espèces A* très électrophiles (ferryles, perferryles, $^{\cdot}$OH) joue le rôle principal, mais des EAO du type P* à caractére moins électrophile (Fe^{III} superoxo) peuvent également participer au processus.

Dans le cas de la crocidolite, la présence de complexants dans le milieu permet d'augmenter sensiblement (surtout pour l'EDTA) l'oxydation du formiate par les espèces A*, et la peroxydation de l'acide linolénique (seulement pour l'EDTA et l'ATP) par des espèces A* et P*.

Les espèces A* sont très majoritairement des ferryles et des perferryles dans le cas de la crocidolite, la formation d'·OH n'étant pas favorisée par l'ajout de complexant et même inhibée par la présence de phosphate, d'ADP et d'ATP. Enfin on note que les espèces A*, pour la crocidolite, sont en grande majorité générées à partir de la réaction avec l'oxygène d'entités en surface du solide, même en présence de complexant.

La comparaison de l'activité de divers matériaux dans la peroxydation de l'acide linolénique et dans celle des membranes de cellules en culture, ne révèle pas un strict parallélisme dans la formation des radicaux peroxydes issus des lipides polyinsaturés.

Plusieurs phénomènes peuvent être à l'origine du fait que, dans nos conditions expérimentales, les EAO générées en présence de némalite soient capables de peroxyder les membranes cellulaires alors que celles générées en présence de chrysotile ou de crocidolite ne le permettent pas. La peroxydation des membranes cellulaires va dépendre en effet de l'accessibilité des EAO aux sites sensibles sur les molécules d'acide gras organisées en double-couche. Or cette accessibilité va être fonction de la cinétique de divers phénomènes comme l'internalisation des particules au sein des cellules et la rupture de la membrane cellulaire (cytotoxicité), tous facteurs qui ne dépendent pas uniquement de la production des EAO. Il est bien connu par exemple que la crocidolite est moins cytotoxique que le chrysotile.

De plus il est nécessaire de noter que nous n'avons pas étudié comparativement la némalite et la crocidolite dans le rôle respectif des activités de surface et des activités en solution. L'importance relative de ces deux types d'activité pourrait expliquer la différence constatée entre ces deux matériaux fibreux dans la peroxydation des membranes cellulaires.

Enfin il est possible également que la nature des EAO formées (qui varie en fonction de la nature du solide) joue un rôle dans les différences observées lors de la peroxydation des membranes des cellules. On note par exemple qu'en présence d'ions phosphate la némalite, et non la crocidolite, génère des ·OH, mais la présence d'EDTA peut favoriser la formation de ces radicaux avec la crocidolite, ce qui montre l'importance de la nature du milieu.

La complexité des facteurs conditionnant la vie cellulaire ne permet pas toujours d'extrapoler directement les phénomènes observés dans des milieux chimiques simples aux différents systèmes organisés des milieux biologiques.

Experimental and AM1 calculational studies of the deprotonation of bicyclo[2.2.2]octane-2,5-dione and bicyclo[2.2.2]octane-2,6-dione: a study of homoconjugation, inductive, and steric effects on the rates and diastereoselectivities of α enolization

Nick Henry Werstiuk and Chandra Deo Roy

Abstract: The kinetics of NaOD-catalyzed H/D exchange (enolization) at C3 α to the carbonyl group of bicyclo[2.2.2]octane-2,5-dione (**1**) and bicyclo[2.2.2]octane-2,6-dione (**2**) have been studied in 60:40 (v/v) dioxane–D_2O at 25.0°C. The second-order rate constants for exchange are $(9.7 \pm 1.5) \times 10^{-1}$ and $(3.4 \pm 1.2) \times 10^{-5}$ L mol^{-1} s^{-1} for **1** and **2**, respectively. Thus, **1**, exchanges 76 times faster than bicyclo[2.2.2]octan-2-one (**3**) ($k = (1.27 \pm 0.02) \times 10^{-2}$ L mol^{-1} s^{-1}), but the 2,6-dione **2** unexpectedly is much less reactive (2.7×10^{-3}) than the monoketone. Unlike the large *exo* selectivity of 658 observed in the case of bicyclo[2.2.1]heptan-2-one, small and opposite selectivities, *exo* (1.2) for **1** and *endo* (2.1) for **2**, are found for the isomeric [2.2.2] ketones. The results indicate that the incipient enolate of **1** is stabilized by a polar effect of the β carbonyl group at C5, not by homoconjugation. The source of the surprising low reactivity of **2** is unknown at this stage. The small diastereoselectivities, *exo* (1.2) for **1** and *endo* (2.1) for **2**, correlate with relative energies of the diastereomeric pyramidal enolates calculated with AM1.

Key words: enolization, bicyclo[2.2.2]octane-2,5-dione, bicyclo[2.2.2]octane-2,6-dione, AM1, thermodynamic acidities.

Résumé : Opérant à 25,0°C, dans des solutions 60 : 40 (v/v) de dioxane–D_2O, on a étudié la cinétique de l'échange (énolisation) H/D, catalysé par le NaOD, au niveau du C3 en α du groupe carbonyle de la bicyclo[2.2.2]octane-2,5-dione (**1**) et de la bicyclo[2.2.2]octane-2,6-dione (**2**). Les constantes de vitesse d'échange du deuxième ordre sont de $(9,7 \pm 1,5) \times 10^{-1}$ et $(3,4 \pm 1,2) \times 10^{-5}$ L mol^{-1} s^{-1} respectivement pour **1** et **2**. Le composé **1** s'échange donc 76 fois plus rapidement que la bicyclo[2.2.2]octan-2-one (**3**) ($k = (1,27 \pm 0,02) \times 10^{-2}$ L mol^{-1} s^{-1}; toutefois, la 2,6-dione (**2**) est beaucoup moins réactive ($2,7 \times 10^{-3}$ fois moins réactif) que la monocétone. Par opposition à la forte sélectivité de 658 observée dans le cas de la bicyclo[2.2.1]heptan-2-one, on a observé de faibles sélectivités opposées, *exo* (1.2) pour **1** et *endo* (2.1) pour **2**, pour les cétones [2.2.2] isomères. Les résultats indiquent que l'énolate qui se forme dans le composé **1** est stabilisé par un effet polaire du groupe carbonyle β en C5 et non pas par homoconjugaison. La cause de cette faible réactivité surprenante du composé **2** est pour l'instant inconnue. Les faibles diastéréosélectivités, *exo* (1,2) pour **1** et *endo* (2,1) pour **2**,

Over the past two decades a great deal of research has been carried out on the α and β (homoenolization) enolization of ketones (1–4) to determine the role of various factors such as orbital alignment, steric effects, homoconjugation, and hyperconjugation in determining the kinetic and thermodynamic acidities of this very important class of compounds. Our long-standing interest in this field (5, 6), specifically in establishing how remote polar groups stabilize enolates, and our developing interest in using semiempirical calculations with AM1 to predict and rationalize variations in the kinetic and thermodynamic acidities of carbon and oxygen acids (6–9) motivated us to undertake experimental and computational studies on the isomeric diones bicyclo[2.2.2]octane-2,5-dione (**1**) and bicyclo[2.2.2]octane-2,6-dione (**2**). Because the C3 methylene hydrogens of **1** and **2** are diastereotopic[2] and exhibit distinct ^{1}H nmr resonances (6), which is not the case for bicyclo[2.2.2]octan-2-one, the diastereoselectivities of exchange can be determined in the absence of differential steric effects for *exo* and *endo* approach of the base at C3. This is an important point because it is possible that a differential steric effect between the methano and ethano bridges gives rise to the large *exo* selectivity of 658 found for enolization at C3 of bicyclo[2.2.1]heptan-2-one (5). Our goal was to use the diastereoselectivities of H/D exchange and AM1 calculations to establish the importance of homoconjugative stabilization of an incipient enolate by a carbonyl group located β to the enolizable center as in [2.2.2] ketones. If α enolization at C3 of **1** is assisted by homoconjugation, then the *exo/endo* rate ratio should be substantially greater than 1, a consequence of the fact that *exo* deprotonation leads to development of the back-lobe of a *p*-orbital *syn* to the π-system of the carbonyl group at C5; this is not the case for *endo* deprotonation. On the other hand, if the incipient enolate is stabilized solely by a polar effect and differential steric effects are small or negligible (this also holds for the enolization of **2**) the *exo/endo* diastereoselectivity should be near 1. A study of **1** and **2** also provided us with an opportunity to establish whether AM1 is useful for predicting the relative rates and diastereoselectivities of enolization reactions in solution. In this communication we report the rates and the *exo/endo* preferences for NaOD-catalyzed H/D exchange of **1** and **2** along with the results of an AM1 calculational study.

To check our experimental method, the H/D exchange of bicyclo[2.2.2]octan-2-one (**3**) was studied in 0.04 M NaOD – 60:40 dioxane–D_2O at 25.0°C. The second-order rate constant ($(1.27 \pm 0.02) \times 10^{-2}$ L mol^{-1} s^{-1}) compares reasonably well with the rate constant (3.03×10^{-2} L mol^{-1} s^{-1}) obtained in another study (10), with the difference possibly arising from the fact that slightly different dioxane/D_2O ratios were used in the two studies. Under identical conditions, the 2,5-dione **1** ($k = (9.7 \pm 1.5) \times 10^{-2}$), which we synthesized recently (6), underwent exchange 76 times faster[3] than **3** and 2.8×10^4 times faster than **2** ($k = (3.4 \pm 1.2) \times 10^{-5}$), which was prepared by the method described by Gerlach and Muller (11). Analysis of several incompletely exchanged (30%) samples of **1** with ^{2}H nmr established that exchange of the *exo* hydrogen is preferred by a factor of 1.2. Because the differential steric effect for approach of hydroxide ion *exo* or *endo* at C3 is expected to be small, the results establish that the incipient enolate anion at C3 is stabilized through a polar effect, not by homoconjugation. Unlike **1**, the 2,6-dione **2** is much less reactive (2.7×10^{-3}) than **3**. The low rate of exchange of **2** is not due to a hydroxide ion-depleting ring-opening reaction; **2** was recovered in 80% yield (there was 5.03% H/D exchange at C3(C5)) from a 4 h reaction in 0.04 M NaOD – dioxane–D_2O at 25°C. Some time ago Bartlett and Forrest Woods found that **2** did not give the positive $FeCl_3$ test that is exhibited by enolizable 1,3-diketones, but they did not carry out base-catalyzed H/D exchange studies (12). Our work shows that H/D exchange at the bridgehead carbon C1 does not occur at a detectable rate in a medium that induces rapid H/D exchange of acyclic and monocyclic 1,3-diketones; there is no detectable signal with the chemical shift expected for the bridgehead deuteron in the ^{2}H spectrum of **2**, which was isolated from a 4 h exchange reaction. Under identical conditions, the hydrogens at C3 and C6 of the 2,5-dione **1** are equilibrated with the deuterium pool (97% exchange) within 1 min. The reason for the low reactivity of **2** relative to monoketone **3** is presently unknown. That this low reactivity is not due to the formation of a cyclic hydrate involving the carbonyl groups at C2 and C6 was established by ^{1}H nmr spectroscopy. The exchange solution of **2** exhibits only signals that exactly match the nmr spectrum obtained in $CDCl_3$. Possibly, a through-space interaction of the carbonyl π-systems at C2 and C6, a decrease in the electrophilicity of carbonyl groups, and angle strain resulting from the introduction of a second carbonyl group at C6 combine to

[2] The *exo* hydrogens are *syn* to the ethano bridges of **1** and **2**; the *endo* hydrogens are *anti* to the ethano bridges. As in the case of **1** (6), nuclear Overhauser difference spectroscopy was used to assign the resonances of the C3 *exo* and *endo* hydrogens of **2**.

[3] The exchange solutions (60:40 dioxane–D_2O) were 0.12 M in ketone and 0.02 or 0.04 M in NaOD. Uptake of deuterium was monitored with 200 MHz ^{1}H nmr spectroscopy by integrating the appropriate resonances and using the bridgehead protons as internal standards. In some cases the results were checked mass spectrometrically. Because **1** and **2** exhibited significant variations in the rates of H/D exchange as the base concentration was decreased, we used a one-point kinetic method to obtain the rate constants, which are the mean of three determinations. That the variability in the rate was not due to the intrusion of an acid–base equilibrium involving **1** and its enolate was established by obtaining a 200 MHz ^{1}H nmr spectrum of the exchange solution; within the detection limits of nmr, no signals other than those due to **1** were found in the spectrum.

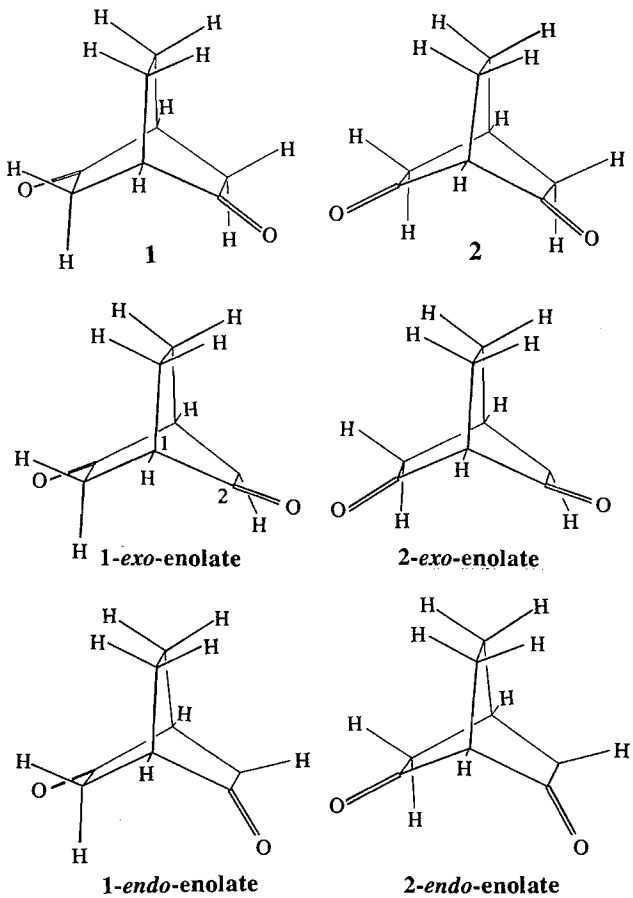
reduce the kinetic acidity of **2**. Additional experimental and computational studies are needed to determine the source(s) of the unexpected low reactivity of **2**. Analysis of partially labelled **2** (6%) with ^2H nmr established that deprotonation at C3 occurs with *an* endo *diastereoselectivity of 2.1.*

Two sets of AM1 calculations (the keyword PRECISE was used to tighten the convergence criteria) were carried out on the 2,5-dione **1**, the 2,6-dione **2**, **3**, and their enolates and the results are given in Tables 1 and 2. The gas phase enthalpies of ionization of **1**, **2**, and **3** calculated from the ΔH_f's of the ketones and their planar enolates are given in Table 1. The geometrical structures of the optimized geometries of **1** and **2** are given in Fig. 1. The AM1-calculated C(3) ΔH_i's (ΔH_i (**1**) − ΔH_i (**3**) = −8.1 kcal/mol), which are a measure of the relative thermodynamic acidities of **1** and **3**, correlate with the kinetic acidities. But **2** is much less reactive kinetically than **3**, not what would be expected on the basis of the calculational ΔH_i's. Yet the calculated ΔH_i of the C1 bridgehead hydrogen of **2** is 18.4 and 26.0 kcal/mol higher than the C3 ΔH_i's of **3** and **1**, respectively, in keeping with the fact that this hydrogen does not undergo H/D exchange under normal enolization conditions (vide supra). Most surprising is the finding that the calculated C1 ΔH_i's of **1** and **2** are virtually identical. That the C1 ΔH_i's of **1** and **2** are 10.7 and 11.0 kcal/mol lower than the C1 ΔH_i of **3** establishes two important points: (*a*) the inductive stabilization of a carbanion by an α carbonyl group is reproduced in the AM1 calculations, and (*b*) α and β carbonyl groups evidently stabilize a bridgehead enolate of a [2.2.2] ketone to the same degree.[4] To establish whether AM1 calculations are useful for estimating the relative reactivities of diastereotopic hydrogens α to a carbonyl group and to provide new insights into the factors that determine the diastereoselectivities, we calculated the ΔH_f's (Table 2) of *exo* and *endo* pyramidal C3 enolates of **1** (**1**-*exo*-enolate and **1**-*endo*-enolate) and **2** (**2**-*exo*-enolate and **2**-*endo*-enolate). The AM1-optimized geometrical structures of the pyramidal enolates obtained by deleting the *exo* or *endo* hydrogens and fixing the H-C3-C2-O torsional angle of the remaining hydrogen at the value calculated for the ketone are displayed in Fig. 1. While

Fig. 1. Displays of AM1-optimized geometrical structures of ketones and pyramidal enolates.



[4] We plan to determine the rates of bridgehead exchange of 3,3,6,6-tetramethylbicyclo[2.2.2]octane-2,5-dione and 3,3,5,5-tetramethylbicyclo[2.2.2]octane-2,6-dione with *t*-BuOK/*t*-BuOD to test the results of the AM1 calculations.

1-*exo*-enolate is slightly more stable than **1**-*endo*-enolate, the order of stability is reversed for the pyramidal enolates derived from **2** (Table 2). Because the transition states for OH^- induced α enolization undoubtedly have pyramidal character, we expected that the experimental diastereoselectivities would correlate with the $\Delta\Delta H_f$'s of the pyramidal enolates. The data given in Table 2 confirm this expectation. We expect that $\Delta\Delta H_f$'s of the pairs of pyramidal enolates will decrease to bring the values in line with the experimental diastereoselectivities as the α carbons approach the triangular planar configuration of the planar enolates. It is also noteworthy that the relative magnitudes of the $\Delta\Delta H_f$'s correlate with the relative magnitudes of the diastereoselectivities. It is possible that better orbital alignment — the *endo* H-C3-C=O torsional angle is 2° larger than the *exo* H-C3-C2-O angle — and a through-space polar effect differentially stabilize the *endo* pyramidal enolate of **2** relative to the *exo* diastereomer. In going from **1** to **1**-*exo*-enolate, C3 bends slightly towards the carbonyl carbon at C5: the C3-C4-C5 angle decreases from 108.6° to 106.9° and the C3,C5 internuclear distance decreases from 2.46 to 2.42 Å. And, there is a surprisingly large increase in the C1—C2 bond lengths when the ketones are converted to the pyramidal enolates (**1**, 1.517 Å; **1**-*exo*-enolate, 1.555 Å; **1**-*endo*-enolate, 1.555 Å; **2**, 1.518 Å; **2**-*exo*-enolate, 1.567 Å; **2**-*endo*-enolate, 1.565 Å). According to the AM1 calculations (Tables 1 and 2), the pyramidal enolates are 9–10 kcal/mol higher in energy than the planar enolates (the *exo* enolates of **1** and **2** by 9.44 and 9.63 kcal/mol, respectively; the *endo* enolates of **1** and **2** by 9.57 and 9.12 kcal/mol, respectively). Even so, there must be a substantial interaction between the anionic carbon and the carbonyl group of the pyramidal enolates because the AM1-calculated enolate C2—C3 bond lengths (**1**-*exo*-enolate, 1.402 Å; **1**-*endo*-enolate, 1.398 Å; **2**-*exo*-enolate, 1.399 Å; **2**-*endo*-enolate, 1.397 Å) are much shorter than the corresponding C—C bonds of **1** and **2** (1.507 and 1.506 Å, respectively).

1994 E.W.R. Steacie Award Lecture Application of natural products chemistry to a biological problem[1]

William A. Ayer

Abstract: Aspen that bear a certain type of black gall have a lower incidence of heartwood rot (caused by the fungus *Phellinus tremulae*) than do nearby non-gall trees. Efforts to determine the chemical nature of this black gall effect are described. The metabolites of some fungi associated with the black gall (*Phoma etheridgei, Stachybotrys cylindrospora*), and of the rotting fungus *Phellinus tremulae*, are described. Extracts of the black gall tissue have a very high concentration of benzoic acid and it is suggested that the benzoic acid may play a role in the protection of the galled trees.

Key words: fungal metabolites, aspen, benzoic acid, salicylic acid, black galls on aspen, *Phellinus tremulae*.

Résumé : Les trembles qui portent un certain type de galle noire sont moins susceptible à la pourriture du coeur du bois (causée par le champignon *Phellinus tremulae*) que les arbres avoisinants ne portant pas de galle. On décrit les efforts faits pour déterminer la nature chimique de cet effet de la galle noire. On décrit les métabolites de quelques champignons associés à la galle noire (*Phoma etheridgei, Strachybotrys cylindrospora*) et du champignon causant la pourriture, le *Phellinus tremulae*. Les extraits du tissu de la galle noire contiennent une grande concentration d'acide benzoïque et on suggère que cet acide peut jouer un rôle dans la protection des arbres qui portent la galle.

Mots clés : métabolites de champignons, tremble, acide benzoïque, acide salicylique, galles noires sur le tremble, *Phellinus tremulae*.

[Traduit par la rédaction]

Introduction

When I entered graduate school at the University of New Brunswick in 1953 the nature of natural products chemistry was quite different from what it is today, both in its methods and in its objectives. It was sufficient then to study a particular compound just because "it was there," and it often took years of painstaking chemical degradation to determine the structure of a relatively small molecule. At the time I started my studies, others in the laboratory began work on the elucidation of the structure of the Lycopodium alkaloid annotinine. In my final year in Fredericton, I was part of the team that arrived at the correct structure, **1**, for this unique 16-carbon alkaloid (1). During this period, U.N.B. acquired its first infrared spectrometer and we began to hear of a new physical method, nuclear magnetic resonance spectroscopy! Nowadays, the determination of the structure of a new natural product often requires only a few days, sometimes only a few hours. By the late 60s it was apparent that if one were to continue with isolation and structure determination studies, there should be a purpose other than the discovery of a new structural class of natural products. The study of the "black gall effect" of aspen will be used to provide an example of how natural products chemistry may be applied to provide knowledge that perhaps will be useful to the forestry sector in our country.

Decay and stain of aspen

Aspen (*Populus tremuloides* Michx.) is the most widely distributed tree species in North America (2). In this country, aspen represents more than one half of the merchantable hardwood timber and 11% of our entire timber resource (3). The utilization of aspen has increased substantially in recent years. The introduction of oriented strand board (OSB), prepared by compacting thin strands of aspen with resins under heat and pressure, and the development of new pulp and paper technologies such as chlorine-free chemothermomechanical pulping (CTMP) have been important factors in the increased use of this previously neglected resource (2, 4). Because of its natural light weight and its colorless, tasteless, and odorless properties, aspen is also used extensively in the production of chopsticks and popsicle sticks (2).

A serious limitation to the utilization of aspen results from the fact that it is very susceptible to decay and stain caused by fungi (5). Heartwood decay, caused by *Phellinus tremulae*, is often present in a high percentage of trees in a mature stand (5). Stored logs of aspen are extremely susceptible to blue stain fungi (6).

Received January 5, 1995.

This lecture is dedicated to Dorothy K. Ayer and to the memory of Rueben Sandin and John Hooz.

It has been discovered that aspen with a certain type of black gall occurring as a stem deformitory have a lower incidence of decay caused by *Ph. tremulae* than do nearby non-gall trees (7). The cause of these galls is still under investigation.[2] This exciting discovery by Hiratsuka, communicated to us several years ago, encouraged us, with the cooperation of Dr. Hiratsuka and his colleagues, and L. Sigler, curator of the University of Alberta Microfungus Herbarium, to examine the chemistry of the black galls, and of fungi associated with the black galls, to see if we could discover a chemical cause of this black gall effect.

Chemistry of the decay fungi and micro-organisms related to the black galls

We have approached this problem in several ways. One approach was to study the chemical constituents of the black galls themselves. Another was to examine the metabolites of fungi associated with the black galls which our collaborators had shown to be antagonistic to the decay-causing *Phellinus tremulae*. It has also been observed (5, 8) that when the decay fungus *Peniophora polygonia* is also present in *Phellinus* infected aspen, there is a sharp demarcation between the *Peniophora* rot and the *Phellinus* rot. This mutual antagonism is also observed in agar cultures (8). Thus the metabolites of the two decay-causing fungi were of interest in an attempt to determine the chemical basis of the antagonism.

The presence of the decay fungus *Ph. tremulae* in aspen can usually be detected by the appearance of the distinctive fruiting bodies, or conks (pictured in ref. 2, p. 75), on the main stem of the tree. The fungus causes rotting of the heartwood of the tree. The rotted heartwood (also shown in ref. 2, p. 75) often has a distinctive odor of wintergreen, due to the presence of methyl salicylate (9). When the fungus is grown in liquid culture on 2% malt extract broth, methyl salicylate is one of the metabolites produced. More interestingly, when the fermentation is carried out in the presence of beads of DIAION HP 20®, a highly porous styrene–divinylbenzene resin useful in removing nonpolar metabolites from aqueous media (10), we isolate not only methyl salicylate, but also its biogenetic precursor, the valence tautomer 2-carbomethoxyoxepin:1-carbomethoxybenzene 1,2 oxide (**2**) (11). In the presence of traces of acid, **2** undergoes facile rearrangement to methyl salicylate. It was suggested some time ago that the biosynthesis of salicylic acid (and methyl salicylate) involves monooxidase oxidation of benzoic acid (methyl benzoate) to the arene oxide followed by NIH shift of the carboxyl or carbomethoxyl group (12), but the arene oxide had not previously been isolated from natural sources. To demonstrate that *Ph. tremulae* could indeed carry out this transformation, we added ^{13}C-carboxyl-labelled benzoic acid to the growing culture and were able to isolate the appropriately labelled oxepin **2** as well as labelled methyl salicylate and labelled methyl benzoate (13). The significance of these observations in relation to the black gall effect will be discussed later. *Phellinus tremulae* also produces a new family of sesquiterpenes, which we call the tremulanes, shown in Fig. 1 (14). The structures were determined by NMR techniques (^{1}H–^{1}H COSY, HMQC, HMBC) and other methods including in the case of tremulenolide A (**3**), X-ray crystallography. Chemical correlations among the tremulenes also played an important role in the structural studies. For example, manganese dioxide oxidation of tremulenediol A (Fig. 1) provided tremulenolide A (**3**). Presumably, oxidation of the diol selectively oxidized the allylic alcohol to provide the α,β-unsaturated aldehyde, which, after hemiacetal formation, gave the allylic hemiacetal, and this in turn was oxidized to the unsaturated lactone **3** (14).

The tremulane (**4**) family does not obey the biogenetic isoprene rule. It is positionally isomeric with the lactarane (**5**) and the recently reported (15) merulane (**6**) perhydroazulene sesquiterpenes. It was, therefore, of interest to study the biosynthesis of this unique sesquiterpene skeleton. *Phellinus tremulae* was cultivated in shake cultures that were periodically supplemented with injections of sodium [1-^{13}C]-, [2-$^{13}C_2$]-, and [1,2-$^{13}C_2$]acetate (16). Since tremulenediol A (Fig. 1) can be isolated in reasonable amounts and is readily puri-

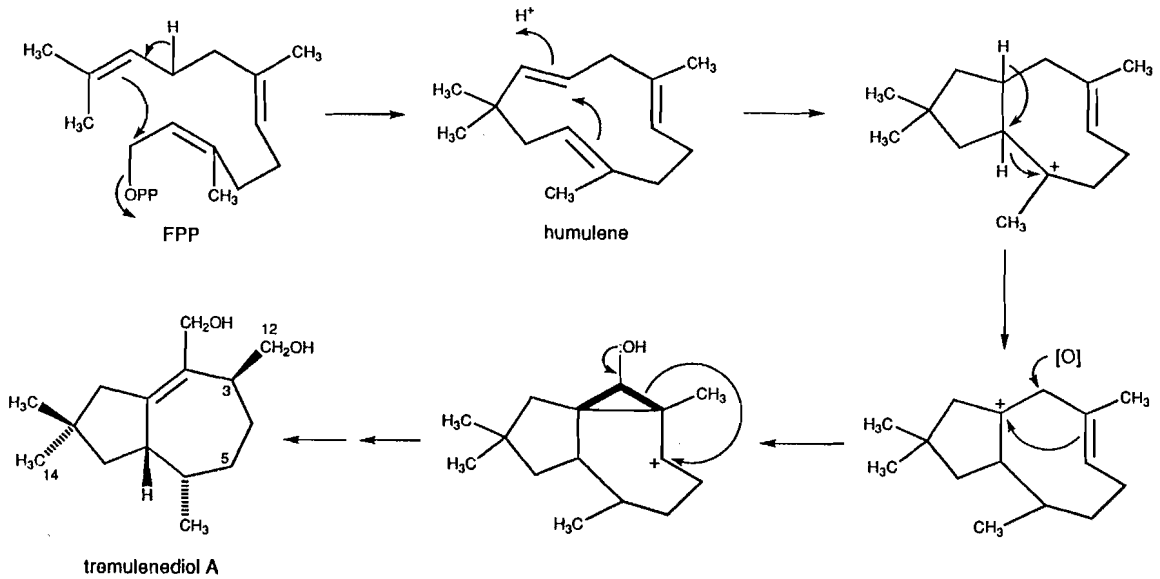
Scheme 1



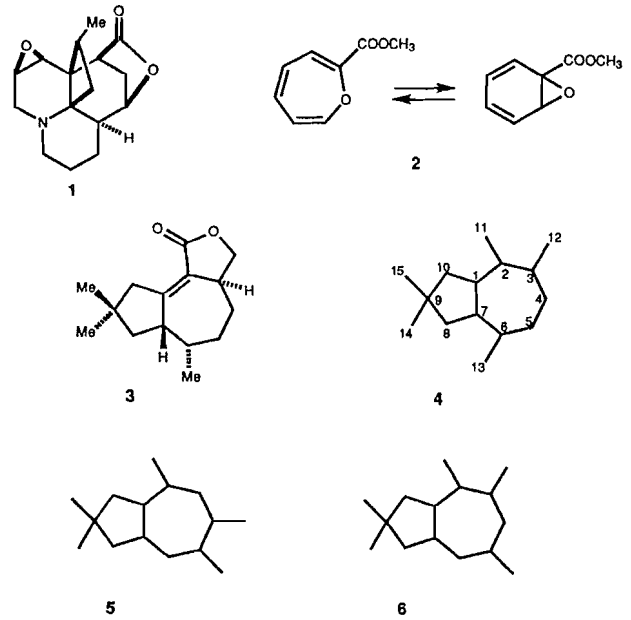


Fig. 2. ^{13}C-acetate labelling results.

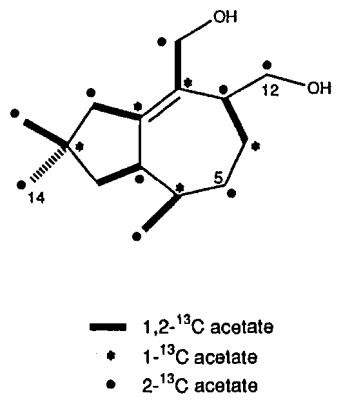

fied as its di-*p*-bromobenzoate, it was chosen for ^{13}C NMR analysis of the labelling patterns. The labelling results are summarized in Fig. 2. A 2D-INADEQUATE experiment on the material from the [1,2-$^{13}C_2$]acetate-labelling experiment clearly confirmed the spin-coupled pairs and showed that carbons 5, 12, and 14 do not give rise to cross peaks. The lactarane skeleton **5** and, presumably, the merulane skeleton **6** are formed from farnesyl pyrophosphate (FPP) via humulene (see Scheme 1) (17). A possible route from FPP, via humulene, to the tremulane skeleton that is in accord with the labelling results is shown in Scheme 1.[3] In order that the C-2 to C-11 bond originate from the same acetate unit, it is necessary that the oxygenated carbon in the cyclopropyl intermediate (Scheme 1) be the group that migrates to C-3, rather than the methyl group. An alternative pathway involving the head-to-tail addition of geranyl pyrophosphate to dimethylallyl pyrophosphate (14, 16) also accounts for the observed labelling pattern, but since we are not aware of any sequiterpenes that are not derived via FPP, we favor the pathway shown in Scheme 1.

None of the metabolites produced by *Ph. tremulae* showed antifungal activity against *Peniophora polygonia*, and we turned our attention to the metabolites of this latter fungus. A number of new drimane sesquiterpenes (e.g., peniopholide (**7**)) as well as some known members of this class were isolated (18), along with a number of benzenoid compounds (19). Bioassays revealed that *Pe. polygonia* also produces some volatile acids and alcohols that inhibit the grown of *Ph. tremulae* (8). These were identified by gas chromatography (gc), gc–ir, and gc–ms (20). The most active of the volatile compounds were 2-phenylethanol and benzoic acid and these proved to be the most active of all the metabolites examined, but complete inhibition required concentrations of 1000 μg/mL. Several commercially available analogs of the aromatic acids were also tested and it was discovered that 4-phenyl-3-butenoic acid (**8**), a known enzyme hydroxylase inhibitor (21),

[3] We thank Professor David Cane for first suggesting this pathway.

causes complete inhibition of the growth of *Ph. tremulae* at 10 μg/mL (20). We conclude that it is *Pe. polygonia* which is responsible for the antagonism observed between the two decay fungi, but that the metabolites are not sufficiently active to be of practical value. However, further testing of compound **8** and analogs thereof is being conducted.

The investigation of the fungi associated with the black galls has led to the isolation of several fungi that are antagonistic to *Ph. tremulae* or to *Ophiostoma crassivaginatum*, the most common of the blue stain fungi that cause stain in stored logs of aspen (6). Among these antagonistic fungi is a newly discovered fungus, *Phoma etheridgei*, which is consistently present on the surface of the galls (22). This fungus shows antagonistic activity against both *Ph. tremulae* and *O. crassivaginata*.

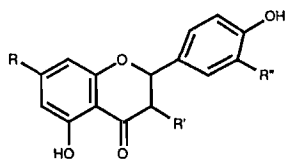
11 R = Ac
12 R = H



13 R = OH, R' = R" = H
14 R = OCH_3, R' = OH, R" = H
15 R = R' = OH, R" = H
16 R = R' = R" = OH

It was difficult to obtain liquid cultures of the *Phoma* species that consistently produced bioactive material until we discovered that spore (pycnidia) suspensions of the fungus should be used as inoculum for the liquid cultures rather than mycelia suspensions (23). Bioassay (against *Ph. tremulae*) -guided separation of the metabolites (again DIAION HP 20® was used to facilitate the isolation process) led to the isolation of a new natural product that we have named phomalone, and which has been shown to possess structure **9** (23). Phomalone is an unusual hexaketide, which labelling studies have shown is derived by condensation of two triketide chains and further elaborated via a cyclopropylcyclohexadienone intermediate such as **10**. Phomalone completely inhibits the growth of *Ph. tremulae* at a concentration of 250 μg/mL, but has no effect at 25 μg/mL. Since phomalone cannot be detected in the tissue of aspen bearing the black galls, it appears unlikely that it is responsible for the black gall effect (23). However, the potential use of *Phoma etheridgei* as a bioprotectant against *Ph. tremulae* is being studied (22).

Other fungi being explored by the forest scientists as possible bioprotectants include two fungi obtained from healthy aspen, *Lecythophora hoffmannii* (24) and *Stachybotrys cylindrospora* (25). The nature of the antifungal agents(s) produced by *L. hoffmannii* has not yet been determined, but we have shown that the compounds responsible for the antifungal activity of *S. cylindrospora* are the trichothecene mycotoxins trichodermin (**11**) and trichodermol (**12**) (26). The known toxicity of the latter type of compound mitigates against use of this fungus as a bioprotectant.

The chemistry of the black galls

We hesitated to begin studying the chemistry of the galls themselves. The wood and bark of aspen had already been examined and a variety of compounds, from triterpenes (27), to glycosides (28), to flavanoids and aromatic acids (29), have been reported. I felt it might be an unrewarding experience to try to sort out the normal products from those induced by the black galls. However, we decided that we would at least extract some sawdust from black gall tissue and compare the bioassay (against *Ph. tremulae*) of the extract with the bioassay of an extract of "clean" aspen from a non-gall healthy tree. We extracted with several solvents, including water, and found that ethyl acetate provided us with the largest amount of extract. The extract was divided into acidic and non-acidic fractions and these were then subjected to bioassay. The acidic portion of the black gall tissue inhibited the growth of *Ph. tremulae* in agar cultures! The extracts from the healthy tissue showed no activity. A similar result was obtained when dichloromethane was the extraction solvent. The aqueous extract gave a faintly positive result.

The acidic portion of the ethyl acetate fraction (5 g of acidic material was obtained from 500 g of air-dried sawdust) was separated into its components by a combination of column chromatography, flash chromatography, and preparative tlc. The major component (0.8 g!) was benzoic acid. Other components identified include *trans*-cinnamic acid, *p*-hydroxybenzoic acid, *p*-hydroxycinnamic acid, and the known flavanoids naringenin (**13**), 7′-methyl-3-hydroxynaringenin (**14**), aromandendrin (**15**), and taxifolin (**16**) (30). Benzoic acid was the only compound that showed activity against *Ph. tremulae* (1000 ppm shows complete inhibition of growth on carrot agar). Benzoic acid is known to have weak antimicrobial activity and is widely used as a food preservative, often in the form of its more soluble sodium salt (31). To determine whether benzoic acid might be acting as the protective agent in the black gall trees, we next studied the benzoic acid level in these trees in an area well removed from the site of the gall. Since dichloromethane is as effective a solvent as ethyl acetate in extracting the benzoic acid from sawdust and it is more volatile, it was chosen as the solvent for the subsequent studies. This has the added advantage that dichloromethane extracts less of the more polar materials present in the wood. As a control, it was necessary to examine the benzoic acid level in healthy, non-galled trees. Sawdust prepared from black gall tissue, from wood removed 25 cm above the gall, and from wood of a healthy tree (the trees were adjacent to one another and harvested on the same day near Blue Ridge, Alberta, in July, 1993) was extracted with dichloromethane. *p*-Toluic acid was added to the sawdust to serve as an internal standard to measure the extraction efficiency. The acids were removed from the dichloromethane by extraction with aqueous sodium

bicarbonate, then back-extracted, after acidification, into dichloromethane. Phenylacetic acid was added to the concentrated extract to serve as a further internal standard. The acids were esterified by addition of diazomethane and the amount of benzoic acid (as methyl benzoate) was determined by gas chromatography, using the methyl *p*-toluate and methyl phenylacetate peaks for comparison. The black gall tissue contained 1700 ppm of benzoic acid, the wood from the gall-bearing tree contained 90 ppm, and the wood from the non-galled tree contained only 14 ppm. Several duplicate experiments were carried out and the results were reproducible to ±5% (30).

Our bioassays on agar plates indicate that the minimum inhibitory concentration (mic) of benzoic acid against *Ph. tremulae* is in the range of 800–1000 ppm; mic values ranging between 120 and 500 ppm are reported against some other fungi (31). It is difficult to quantitatively relate the level of benzoic acid in the tree tissue to that obtained by adding benzoic acid to an agar preparation. It is also known that the antifungal activity of benzoic acid is pH dependent (31). It is clear that further work is necessary before we can state whether or not benzoic acid is responsible for the black gall effect.

I noted earlier that the decay fungus *Ph. tremulae* is capable of transforming benzoic acid to methyl benzoate and methyl salicylate. It has previously been reported that the bark of aspen contains benzoylated and salicyloylated glycosides (32, 33). In recent years it has been established that salicylic acid plays an important role in the induction of systemic acquired resistance (SAR) in many plants (34–36). Salicylic acid (in the form of its glycoside, salicin) was one of the first natural products to be isolated (1828) and its acetyl derivative, aspirin, is the most widely used pharmaceutical product (37). Although the many beneficial effects of salicylic acid in human medicine are well studied and much is known (37), the question as to why plants make salicylic acid has not been widely addressed. It appears that this so-called secondary metabolite plays an important role in defending plants, as well as humans, against disease!

Salicylic acid is produced in plants by the monooxygenase oxidation of benzoic acid (38, 39). Benzoic acid is biosynthesized from phenylalanine via cinnamic acid (38), one of the minor acids isolated from black gall tissue. Salicylic acid was not isolated directly from the black galls but it was detected, along with benzoic acid, in the form of glycosides (which are not soluble in dichloromethane), by extraction with butyl alcohol of the sawdust remaining after dichloromethane extraction and hydrolysis of this extract. It has been suggested that the glycosides provide a mechanism by which plants may store salicylic acid for rapid deployment during SAR (35). It is possible to speculate that the black gall effect may not be directly due to the antifungal activity of benzoic acid, but that the excess benzoic acid serves as a ready precursor of salicylic acid, the SAR signal molecule. In tobacco, it has been demonstrated that the hydroxylase required for the oxidation of benzoic acid to salicylic acid (presumably via the carboxyl form of oxepin **2**) is activated by the pathogen (38).

As mentioned above, *Ph. tremulae* is capable of methylating benzoic acid and then transforming it into methyl salicylate (oil of wintergreen), a molecule that does not induce SAR (34). Analysis of the benzoic acid level in *Phellinus* infected aspen reveals a concentration of benzoic acid intermediate between the healthy trees and the galled trees (30). Thus the methylating ability of *Phellinus* species (40) may be a factor in their ability to successfully invade host plants.

It is clear that much remains to be done in the study of the black gall effect and that the hypotheses advanced herein are only that, hypotheses. I do hope, however, that this lecture does illustrate some of the ways in which natural products chemistry may make some contribution in the study of biological problems.

Acknowledgements

I am deeply indebted to my co-workers and collaborators on the "aspen project" for the support they have provided. In particular, I wish to acknowledge the leading role that Dr. Yasuyuki Hiratsuka of the Northern Forestry Centre in Edmonton has played in this work. Yasu's observation that aspen with black galls seem to be resistant to rot reminds me of Svent-Györgyis' observation on the mark of a great scientist: "to see what everyone sees, to think what no one has thought." Hiratsuka's co-workers, Dr. P. (Chak) Chakravarty and Dr. Leonard Hutchison, contributed much to the project as did Patricia Crane and Gabriele Herger. The insightful comments and critiques of Lynn Sigler of the U. of A. Microfungus Herbarium have been of great value. I am immensely grateful to the members of my own research group who worked so diligently and enthusiastically on this project, and who provided many of the ideas. The details of the work I've discussed are provided in refs. 11, 13, 14, and 16 with Elizabete Cruz (who introduced the use of DIAION HP 20), refs. 18, 19, and 20 with Latchezar Trifonov (who coordinated much of the work), ref. 23 with Luis Jimenez (who persisted with the reluctant *Phoma* species), refs. 25 and 26 with Shichang Miao, and ref. 30 with Gabrielle Pausler (who cheerfully carried out the sawdust extractions). Katarzyna Ptaszynska carried out valuable preliminary studies on *Lecythophora hoffmannii*, a fungus reluctant to provide consistent bioactivity. I would also like to express my appreciation to members of the Chemistry Department staff who have provided strong support over the years, especially Erica Schamedatus, Lois Browne, Tom Nakashima, Alan Hogg, Tony Schnautz, and Avron Levine. It has been a privilege to work with all of these people.

The financial assistance of the Natural Sciences and Engineering Research Council in the form of operating grants (W.A.A.) and a Strategic Grant (with Y. Hiratsuka and L. Sigler) is gratefully acknowledged.

Abstract: The ^{1}H NMR signals of the Ru(III) species present in solution are considerably broadened and shifted by paramagnetism, but they can be used to follow chloride displacement in the *trans*-$[RuCl_4Im_2]^-$ ion. This anion remains predominant for several hours at room temperature in D_2O, but its signals are progressively replaced by those of a monoaqua $[RuCl_3(D_2O)Im_2]$ complex. Over a period of days, two new sets of peaks appear, corresponding to two isomers of $[RuCl_2(D_2O)_2Im_2]^+$. The same behaviour is observed for the 1-methyl- and 4-methylimidazole analogues. These reactions can be driven backwards by addition of KCl, but $[RuCl_4Im_2]^-$ is not quantitatively regenerated in solution even for 6 M NaCl. Within several months, the $[RuCl_2(D_2O)_2Im_2]^+$ isomers further aquate to a single species $[RuCl(D_2O)_3Im_2]^{2+}$. In CD_3OD, displacement of the first chloride of $[RuCl_4Im_2]^-$ takes place faster, over several hours, but substitution stops at the $[RuCl_3(CD_3OD)Im_2]$ stage. In DMSO, substitution occurs very slowly. The $[RuCl_3(DMSO)Im_2]$:$[RuCl_4Im_2]^-$ mixture (1:2) obtained after 12 days starts to show very slow reduction to two Ru(II) species, one of which precipitates as yellow crystals. From X-ray diffraction work (monoclinic, $P2_1/n$, $a = 9.951$, $b = 8.564$, $c = 10.527$ Å, $\beta = 92.95°$, $R = 0.033$), the compound was identified as $[RuCl_2(DMSO\text{-}d_6)_2Im_2]$, where the metal has a *trans-trans-trans* coordination and the DMSO ligands are S-bonded.

Key words: paramagnetic ruthenium anion, solvolysis, chloro complexes.

Résumé : Les signaux RMN ^{1}H des espèces de Ru(III) présentes en solution sont fortement élargis et déplacés par le paramagnétisme, mais on peut les utiliser pour suivre le déplacement des chlorures dans l'ion *trans*-$[RuCl_4Im_2]^-$. Cet anion demeure prédominant durant quelques heures à température ambiante dans D_2O, mais ses signaux sont progressivement remplacés par ceux du complexe monoaqua $[RuCl_3(D_2O)Im_2]$. Sur une période de quelques jours apparaissent deux séries de nouveaux pics correspondant à deux isomères de $[RuCl_2(D_2O)_2Im_2]^+$. On observe le même comportement pour les complexes analogues du 1-methyl- et du 4-methylimidazole. On peut déplacer l'équilibre en sens inverse par addition de KCl, mais $[RuCl_4Im_2]^-$ n'est pas regénéré quantitativement en solution même pour 6 M NaCl. En quelques mois, les isomères de $[RuCl_2(D_2O)_2Im_2]^+$ subissent une aquation supplémentaire pour donner l'unique espèce $[RuCl(D_2O)_3Im_2]^{2+}$. Dans CD_3OD, le déplacement du premier chlorure de $[RuCl_4Im_2]^-$ se produit plus rapidement, en quelques heures, mais la substitution s'arrête à l'étape de $[RuCl_3(CD_3OD)Im_2]$. Dans DMSO, la substitution a lieu très lentement. Dans le mélange $[RuCl_3(DMSO)Im_2]$:$[RuCl_4Im_2]^-$ (1:2) obtenu après 12 jours commence une très lente réduction en deux espèces de Ru(II), dont l'une précipite sous forme de cristaux jaunes. Au moyen d'une étude par diffraction des rayons X (monoclinique, $P2_1/n$, $a = 9{,}951$, $b = 8{,}564$, $c = 10{,}527$ Å, $\beta = 92{,}95°$, $R = 0{,}033$), ce composé a été identifié comme étant $[RuCl_2(DMSO\text{-}d_6)_2Im_2]$, où le métal possède une coordination *trans-trans-trans* et les ligands DMSO sont liés par le soufre.

Mots clés : paramagnétisme, ruthénium, solvolyse, complexes chloro.

Introduction

Several ruthenium complexes have attracted attention as potential non-platinum antitumour agents (1, 2). To this series were recently added chloro-ruthenium(III) complexes with imidazoles and related N-heterocyclic ligands, whose promising antitumour properties are presently being evaluated (3). Considering that related ruthenium(II) compounds with nitroimidazoles are known to be efficient radiosensitizers (4, 5), it appears that important chemotherapeutic applications are to be associated with ruthenium–imidazole systems.

The chloro-Ru(III)-imidazole compounds have been well characterized as solids (6, 7), but their behaviour in solution is complicated. A good understanding of solution chemistry is important, first, to identify the species actually responsible for

the therapeutic activity. In addition, the presence of imidazole makes these compounds attractive as models to unravel complex processes involving metallobiomolecules, where the imidazole unit is present as such in the histidine residue or as one of the purine rings in nucleic acids.

The binding of (ImH)[$RuCl_4Im_2$] (**1**) to biological substrates has been shown to take place slowly, over several hours, in fresh aqueous solutions (8, 9), suggesting that a chloro ligand must first be replaced by water, as in the case of $PtCl_2(NH_3)_2$. Other Ru(III) systems have, so far, been considered as substitution inert in physiological conditions (10), and activation by in situ reduction to a more labile Ru(II) species has been assumed to take place (11). This Ru(II) species would then be able to interact with the target molecules after dissociation of a Cl^- ligand, a step considered to be of paramount importance. This mechanism has been proposed to explain the radiosensitizer ability of [$RuCl_2(4\text{-}NO_2Im)_2(DMSO)_2$] (5), where a Cl^- ligand is quickly released and replaced by a water molecule in aqueous medium. Therefore, whether interactions with biomolecules involve the Ru(III) centre itself or a reduced Ru(II) species is still unclear, but the presence of a readily displaced aqua ligand in the active species seems to be widely accepted.

The solution chemistry of Ru(III) compounds is still difficult to study, because NMR techniques are not routinely applicable to such paramagnetic species: the unpaired electron in these low-spin d^5 complexes causes line broadening and large chemical shifts, making spectra difficult to obtain and interpret (12). When this work was undertaken, ^1H NMR spectra had been reported for aqueous solutions of [$Ru(NH_3)_5Im]Cl_3$, used as a model for ruthenium–histidyl protein complexes (13). More recently, the spectra of (ImH)[$RuCl_4Im_2$] in DMSO (10) and of Na[$RuCl_4$(DMSO)Im] in D_2O (14) were reported.

In the present paper, ^1H NMR spectroscopy is used to follow the behaviour of (ImH)[$RuCl_4Im_2$] and the analogues with 1-MeIm and 4(5)-MeIm[2] in three solvents. Very recently, on the basis of HPLC and other experiments, Keppler et al. (3) gave a description of the earlier aquation steps for the Im complex, which are generally in good agreement with our results described here.

Experimental

Instruments and reactants

^1H NMR spectra were recorded on Varian XL-300 or Bruker AMX-300 spectrometers. No particular precautions were taken to protect the solutions from the atmosphere. Sweep-widths of 50 or 100 kHz were used at pulse rates of 0.04 s. The peaks were referenced to residual solvent peaks (D_2O, δ = 4.80; CD_3OD, δ = 3.30; $(CD_3)_2SO$, δ = 2.50 ppm) and given with respect to Me_4Si, downfield being positive. Infrared spectra (4000–220 cm^{-1}) were recorded on a Perkin–Elmer 1600 FTIR apparatus as either KBr or CsI pellets.

The imidazole ligands were used as received from Aldrich. $RuCl_3 \cdot 3H_2O$ (Aldrich) was "activated" by refluxing in an ethanol – aqueous HCl mixture for several hours prior to each synthesis.

Preparative work

The (LH)[$RuCl_4L_2$] compounds were prepared by variations of known methods (6, 7). Pure samples were found to be obtained only if acidity, temperature, and reaction time were carefully controlled. Activation of $RuCl_3$ was necessary, but various procedures commonly used in the literature were equally efficient. The reactions proceeded normally with HCl ~1 M. In the absence of acid, extremely insoluble green products precipitated, which remain uncharacterized, but are thought to be chloride-bridged polymeric materials of the type described earlier (15).

(ImH)[$RuCl_4Im_2$], 1

Commercial $RuCl_3$ (0.94 g) was dissolved in a mixture of concentrated HCl (2 mL), H_2O (12 mL), and EtOH (12 mL). This solution was refluxed for 3 h at which time its volume was reduced by half. It was filtered while hot and added to a solution of imidazole (3.0 g) in 6 N HCl (5 mL). The mixture was heated gently for 15 min and allowed to cool. Within 24 h, an orange powder had precipitated, which was filtered, washed with copious amounts of cold methanol, then dried under high vacuum. Yield: 10–20%.

The red-brown powder often contained red crystals, whose cell parameters and space group are those of (ImH)[$RuCl_4Im_2$] (6). The powder and the crystals gave identical IR spectra, where the low-frequency bands (cm^{-1}) correspond with those reported: 334 (s), 294 (w), 249 (m). The ^1H spectra of fresh solutions showed a single set of signals with the expected intensity ratio for ImH^+ and [$RuCl_4Im_2$]$^-$. The samples were free of $(ImH)_2$[$RuCl_5Im$], as evidenced from the absence of the characteristic signals for this species (−27.0, −15.2, and −6.7 ppm) (16).

(4-MeImH)[$RuCl_4$(5-MeIm)$_2$], 2

A solution containing concentrated HCl (2.1 mL), EtOH (24 mL), water (24 mL), and $RuCl_3$ (0.95 g) was refluxed for 2.5 h. The volume was reduced to 8 mL and cooled to room temperature. To this solution was added 4-MeIm (2.1 g) in 6 M HCl (2.5 mL). The resulting solution was stirred for 5 min and then held at 8°C for 4 days, at which time a red powder appeared. This solid was filtered and washed with EtOH. Yield: 20%. IR (cm^{-1}): 385 (w), 335 (m), 314 (s), 290 (vs), 274 (sh). The ^1H spectra of fresh solutions showed a single set of signals with the expected intensities (see next section). Anal. calcd. for $C_{12}H_{19}Cl_4N_6Ru$: C 29.40, H 3.91, N 17.14, Cl 28.93; found: C 29.79, H 4.01, N 17.06, Cl 29.09.

(1-MeImH)[$RuCl_4$(1-MeIm)$_2$]·H_2O, 3

This complex was prepared similarly to the 4-MeIm product and isolated as the monohydrate. Yield: 20%. IR (cm^{-1}): 398 (w), 350 (vw), 319 (vs), 280 (m), 268 (m), 254 (w), 248 (w).

[2] Conventional ring numbering starting with the N-H(R) position is used. The two tautomeric forms are designated as 4-MeIm (4-methyl-1*H*-imidazole) and 5-MeIm (5-methyl-1*H*-imidazole), respectively. The equilibrium mixture is represented by 4(5)-MeIm.

Fresh solutions showed a single set of ^{1}H NMR signals with the expected intensities (see next section). Anal. calcd. for $C_{12}H_{21}Cl_4N_6ORu$: C 28.36, H 4.16, N 16.54, Cl 27.90; found: C 28.45, H 3.99, N 16.38, Cl 28.00.

trans,trans,trans-*[$RuCl_2$(DMSO-d_6)$_2Im_2$]*

Complex **1** (37 mg) was dissolved in DMSO-d_6 (3 mL) and acetone (25 mL) was added. This solution was heated gently for 15 min. The initial orange-yellow precipitate of **1** was filtered and the mother liquor was allowed to rest. In 2 days, the product precipitated as elongated yellow crystals, whose X-ray structure has been determined. Low-frequency IR data (cm^{-1}): 392 (s), 362 (m), 351 (s), 302 (vw), 279 (vw), 248 (w), 241 (m).

Crystal structure of $[RuCl_2(DMSO\text{-}d_6)_2Im_2]$

X-ray diffraction data were obtained with an Enraf–Nonius CAD-4 diffractometer. A reduced cell was determined from 25 reflections on a rotation photograph and final cell parameters were calculated by least-squares refinement on 25 higher angle reflections ($20° < \theta < 25°$) obtained from a quick pre-collection. The Niggli parameters clearly identified a monoclinic reduced cell. Space group $P2_1/n$ was determined unambiguously from the systematic absences (h0l, $l \neq 2n$; 0k0, $k \neq 2n$) in the intensity data set. Crystal data are given in Table 1.

Four standards were used to monitor intensity every hour and orientation every 200 measurements. Variations remained within ±2.0% during data collection. A whole sphere of data (6331 reflections) was collected by the ω/2θ scan technique. They were averaged to 1693 independent hk$l$ and hk$\bar{l}$ reflections, of which 1450 where above background ($I > 2.5\ \sigma_I$). The usual corrections for the effects of Lorentz and polarization were finally applied.

From the Patterson map, the Ru atom was found to lie on a crystallographic inversion centre and the origin was arbitrarily chosen. The remaining atoms were located from structure-factor and ΔF calculations. The structure was refined on $|F|$ by full-matrix least squares. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with individual weights w based on counting statistics ($w = 1/[\sigma^2(F_o) + 0.00005\ F_o{}^2]$). All non-hydrogen atoms were refined anisotropically. The hydrogens were fixed at idealized positions (C(N)—H = 0.95 Å, U_{iso} = 0.075 Å^2). The general background in the final ΔF map was below ±0.3 e Å^{-3}. A few residuals of ±|0.9–1.2| e Å^{-3} remained near the Ru atom. The refined coordinates of the non-hydrogen atoms are given in Table 2. The temperature factors are available as supplementary material.[3] All calculations were done with the NRCVAX package (17).

Preliminary crystallographic results on (ImH)[$RuCl_4Im_2$]·2DMSO

The orthorhombic crystals ($Pbcm$, a = 7.873(2), b = 15.404(6), c = 19.913(4) Å, Z = 4) were obtained by adding acetone to a fresh solution of **1** in DMSO at 5°C (see text). Most of them were twinned. Intensities were collected on two apparently good specimens, as for the previous structure, but at −100°C. The data set used consisted of 2352 independent hk$l$ reflections, of which 1278 with $I > 3\ \sigma_I$ were retained and corrected for Lorentz and polarization effects. The Ru atom was readily found from the Patterson map. The remaining non-hydrogen atoms in the ImH^+ and $[RuCl_4Im_2]^-$ ions were located in the next ΔF map. Peaks for lattice solvent molecules were then found, but they defined a highly disordered DMSO molecule, in which the oxygen atom and the methyl groups could not be distinguished. These atomic positions were refined isotropically to R = 0.114. Small electron density residuals in the solvent region suggested partial replacement of DMSO by acetone in the structure. A similar problem has been encountered for related compounds (14). The coordinates and interatomic distances are given as supplementary material.[3] So far, we have been unable to grow better crystals. Despite the crystallographic disorder encountered, the presence of ImH^+ and $[RuCl_4Im_2]^-$ in this crystal is unambiguously established.

[3] The supplementary material includes four sets of ^{1}H NMR spectra, a table of data for the equilibrium constants, complete crystallographic data (anisotropic temperature factors, hydrogen coordinates, least-squares plane calculations, geometry of hydrogen bonds) for $[RuCl_2(DMSO\text{-}d_6)_2Im_2]$, and partial crystallographic data (coordinates and geometry) for (ImH)[$RuCl_4Im_2$]·2DMSO (12 pages). Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen coordinates, and distances and angles for $[RuCl_2(DMSO\text{-}d_6)_2Im_2]$, have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Results

Aqueous solutions of $(ImH)[RuCl_4Im_2]$, 1

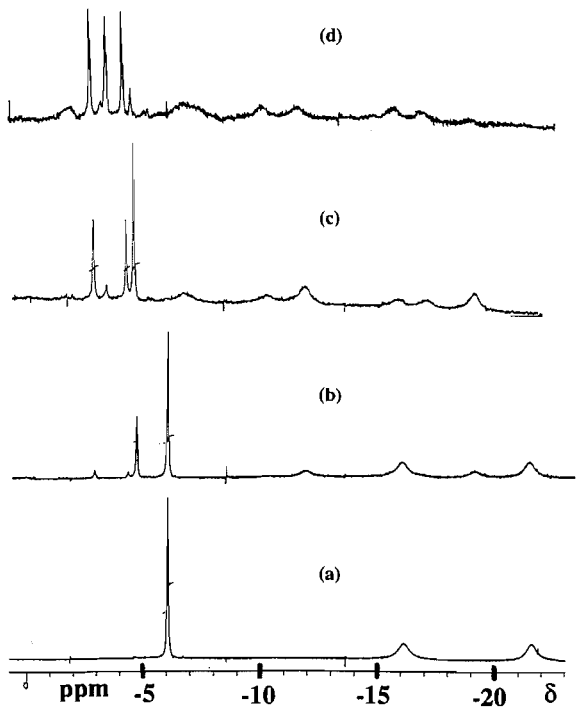
The red complex **1** could be obtained, as described earlier (6), by reacting commercial $RuCl_3$ with several equivalents of imidazole in ethanol–HCl. The cell parameters of the crystals matched perfectly those already reported, as did the ν(Ru–Cl) (334 and 294 cm^{-1}) and ν(Ru–N) (249 cm^{-1}) IR bands. Splitting (614/622 and 1046/1063 cm^{-1}) due to the presence of both imidazolium counterion and coordinated imidazole (18) was also noted. Although the samples appeared to be pure from these criteria, the ^1H NMR spectra of fresh D_2O solutions often showed small spurious peaks, which were eventually found to be predominant in fresh solutions of $(ImH)_2[RuCl_5Im]$ (16). Starting materials free of $(ImH)_2$ $[RuCl_5Im]$ could be obtained by carefully adjusting heating, acidity, and reaction time (see experimental section).

Complex **1** is quite soluble in water and ^1H spectra could be recorded in spite of paramagnetism. Coordinated imidazole gives rise to three broad, but well-defined, peaks (Fig. 1*a* and Table 3), shifted to very high field by coordination to the paramagnetic Ru(III) centre. Two extra peaks are found in the normal region, at 7.4 (H2) and 8.6 ppm (H4/H5), for the imidazolium counterion. The N-H protons are seen for neither the coordinated ligand nor the imidazolium ion, due to rapid exchange with D_2O. As in the case of $[Ru(NH_3)_5Im]Cl_3$ (13), the relatively narrow signal of coordinated imidazole at -5.7 ppm is assigned to H5, that is, the proton furthest away from the metal centre. The peaks at -16.0 and -21.4 ppm are assigned to H4 and H2, respectively, on the basis of data from reactions using C2-deuterated imidazole, to be published later (16).

This spectrum is consistent with the *trans*-$[RuCl_4Im_2]^-$ structure determined for the solid (6), in that a single set of peaks is seen for the two equivalent coordinated imidazoles. However, the *cis* isomer and aquation products could produce a similar spectrum. As a check, complex **1** was dissolved in water and acetone was added after 15 min. The IR spectrum of the precipitate was superimposable with that of **1** and its ^1H NMR spectrum showed only the original set of peaks, thereby making the possibility of isomerization, aquation, or imidazole loss during this period of time very unlikely.

Over a period of several hours, the signals of $[RuCl_4Im_2]^-$ decreased, while a set of peaks appeared for a new complex

Fig. 1. ^1H NMR spectra of complex **1** in D_2O immediately after dissolution *(a)*, after 22 h *(b)*, after 21 days *(c)*, and after 8.5 months *(d)*. Sharp peaks at 7.4 and 8.6 ppm for the ImH^+ ion not shown.



1a[4] (Fig. 1*b*). Both imidazole ligands should be retained, since the Ru—N bond with N-heterocycles is usually regarded as kinetically inert (19). Therefore, this single set of three peaks is attributable to two equivalent coordinated imidazole ligands. The narrowest peak (–4.7 ppm) is assigned to the remote H5 proton, whereas the other two broad peaks (–19.2 and –12.0 ppm) are assigned to the H2 and H4 protons, respectively, from deuteration experiments.

This new species is either *cis*-$[RuCl_4Im_2]^-$ or a $[RuCl_3$-

[4] This and all other "aqua" species discussed in this paper can behave as weak acids and they exist at equilibrium as a mixture of the Ru-OH and Ru-OH_2 forms.

1a1

(D_2O)Im_2] molecule, resulting from the substitution of a chloro ligand by water. The latter possibility is preferred on the basis of experiments in the presence of KCl described below. There exist three possible isomers of [$RuCl_3(D_2O)Im_2$], but only **1a** and **1a1** are consistent with the presence of a single set of NMR signals for coordinated imidazole. No direct evidence for a particular geometry could be obtained. Addition of acetone at this or a later stage gave no precipitate. When the solvent was removed in vacuo at ~60°C, only (ImH)[$RuCl_4Im_2$] (**1**) was obtained. Solubility was not high enough to obtain good solution Raman data. Considering that the conversion of **1a** leads only to **1** when solvent is removed or KCl is added and that no extra signals are detected for a hypothetical *cis*-[$RuCl_4Im_2$]$^-$ species, for instance, the *trans* form **1a** is preferred. Keppler et al. (3) monitored the appearance of this species by HPLC and they also proposed the *trans* structure, which has been observed in the crystal structure of the related [$RuCl_3(H_2O)$(1-methylindazole)$_2$] complex.

After several days, the spectrum (Fig. 1*c*) contains two new sets of three peaks associated with coordinated imidazole (Table 3). Those at −16.0, −6.9, −3.1 ppm are assigned to one type of Im ligands and those at −17.1, −10.4, −4.4 ppm to another type, although some of the signals could be interchanged, since both sets have the same intensity and grow at the same rate. They likely correspond to new substitution products [$RuCl_2(D_2O)_2Im_2$]$^+$, of which two isomers **1b1** (*trans,cis,cis*) and **1b2** (*trans,trans,trans*) contain *trans* imidazoles (Scheme 1).[5] Formation of two species at the same rate is surprising, but a similar case has recently been found with a Ru(III) complex of 9-methylhypoxanthine (20). Keppler et al. (3) noted the formation of a diaqua species, but stereoisomers were not mentioned. These authors also found that **1a** is attacked by free imidazole to generate *mer*-[$RuCl_3Im_3$]. The latter species, which contains two nonequivalent coordinated imidazoles in a 2:1 ratio, is not detected in our conditions.

Over a period of months, a new species **1c** progressively

[5] **Noted added in proof:** The first two aquation steps in Scheme 1 have also been observed for (ImH)[$RuCl_4Im_2$](**1**) in a very recent study by Dhubhgaail et al.(41).

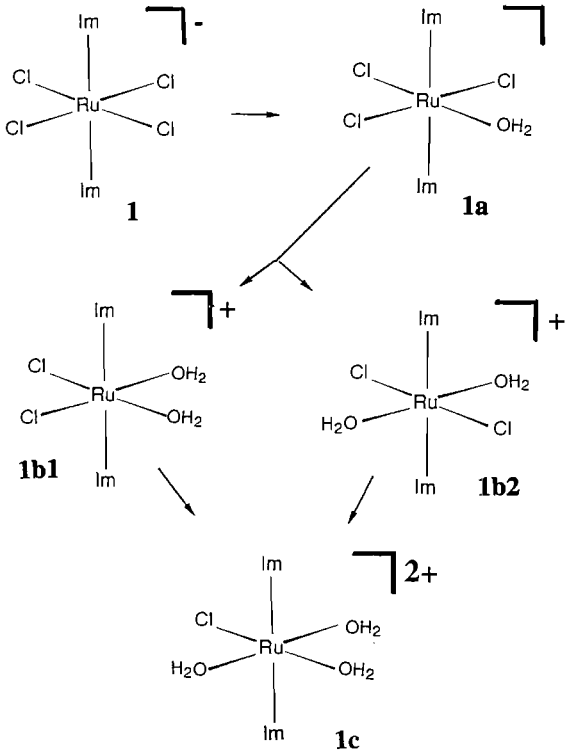
Scheme 1



appears. After 8.5 months (Fig. 1*d*), **1a**, **1b1**, and **1b2** are still present, but **1c** accounts for ~30% of the intensity in the paramagnetic region. Complex **1c** gives a sharp H5 signal at −3.7 ppm. The corresponding signals for H2 and H4 probably occur at −7.0 and −11.7. The new species **1c** containing only one type of imidazole should be $[RuCl(D_2O)_3Im_2]^{2+}$, produced by further aquation of both **1b1** and **1b2**. In the meantime, some decomposition has occurred, producing a few black particles and a small amount of Ru(II) species giving sharp low-intensity peaks in the diamagnetic region.

A comment should be made here concerning the control of pH in these experiments. Buffers were not used, in order to prevent any interference by coordination of the buffer material to the metal centre over the long periods of time the systems were monitored. The pH of a fresh 0.01 M solution of **1** decreased from 5.0 to ~3.2 during the first few days and then remained constant indefinitely. Thus, the system buffered itself to ~3.2 as the initial aquation process was taking place. Since N-H groups of coordinated imidazole are very weakly acidic (pK_a of 8.9 for $[Ru(NH_3)_5Im]^{3+}$) (21), this acidity must originate from partial conversion of coordinated water molecules into hydroxo groups. The proportions of the Ru-OH_2 and Ru-OH forms cannot be established at the present time, since the two forms are in fast exchange on the NMR time scale and individual pK_a values were not determined. From the observed pH, the behavior of the **1a+1b1+1b2** mixture can be regarded as similar to that of a weak acid of pK_a ~4.4, which is consistent with the acidities found for related aqua-Ru(III) species (5, 22).

Methylated imidazoles

Literature methods, adjusted as above for complex **1**, were used to prepare the analogues with 1-MeIm and 4(5)-MeIm. Both complexes showed the usual ν(Ru–Cl) and ν(Ru–N) absorptions (6) at ~317(s)/~285(m) and ~250(w) cm^{-1}, respectively. In both cases, extra bands appear for the methyl groups. For (1-MeImH)$[RuCl_4(1\text{-MeIm})_2]$, a weak band at 398 cm^{-1} probably originates from the δ(N–CH_3) mode in the coordinated ligand, which is known to shift from 355 cm^{-1} in free 1-MeIm to ~385 cm^{-1} in $CuCl_2(1\text{-MeIm})_2$ (23) and $[ReO_2(1\text{-MeIm})_4]^+$ (24). Since this vibration is not sensitive to protonation (25), the very weak component at ~350 cm^{-1} should be due to the $(1\text{-MeImH})^+$ counter ion. In the 4(5)-MeIm compound, the low-frequency ν(Ru–Cl) band at 290 cm^{-1} should include a contribution of the γ(C–CH_3) mode, which occurs at this frequency for the $[ReO_2L_4]^+$ complex (24) and the protonated form (25). The δ(C–CH_3) mode of the 4-MeImH^+ ion shows at 335 cm^{-1}, where it is expected, whereas the weak peak at 385 cm^{-1} is likely due to the same mode shifted from ~350 cm^{-1} by coordination as in the previous case.

The aqueous solution chemistry of (4-MeImH)$[RuCl_4(5\text{-MeIm})_2]$ (**2**) and (1-MeImH)$[RuCl_4(1\text{-MeIm})_2]$ (**3**) mimics that of complex **1** exactly as described above: the same pattern and progression was seen in the NMR spectra over a period of weeks (Figs. S1-1 and S1-2).[3] The chemical shifts are listed in Table 3. The absence of extra sets of peaks for the 4(5)-MeIm system is interesting, since it shows that the ligand is always coordinated as the same tautomer, that is, the 5-MeIm form found in the solid state (6).

Reaction of 1 in the presence of KCl

A fresh solution of complex **1** (0.015 M) in the presence of 0.12 M KCl gave the same spectrum as in pure D_2O and the subsequent steps leading to **1a**, **1b1**, and **1b2** were not inhibited by KCl. They took place along exactly the same pattern, at a slightly slower rate than in the absence of KCl, but the **(1b1+1b2)/1a** ratio after 2 weeks was somewhat lower than in the KCl-free solution after the same time. As expected, this ratio progressively decreased as the KCl (or NaCl) concentration increased to 1.5 M and 6 M.

The reaction is reversible and can be driven in the opposite direction by increasing the chloride concentration. When KCl was added to an aged KCl-free solution or the KCl concentration was increased in an equilibrated solution, the final mixture was the same as when all the KCl had been added to the fresh solution. From a set of four solutions containing **1** (0.005–0.015 M) and NaCl (1–6.3 M) under equilibrium conditions, an "apparent" constant K_1, valid at the equilibrium pH of 3.2, could be determined for the first aquation step (eq. [1]) (Table S1-1).[3] Equilibrium constants for the next steps could not be obtained, because months are sometimes needed to reach equilibrium and, by that time, side reactions have occurred.

[1] $\mathbf{1} \rightleftharpoons \mathbf{1a} + Cl^-$

$K_1 = [\mathbf{1a}][Cl^-]/[\mathbf{1}] = 3.4 \pm 0.4\ M^{-1}$

Thus, as mentioned earlier (10), no appreciable change is noted in physiological saline solution after 1 h, but, a few hours after dissolution, aquation of **1** has taken place to a significant extent and it cannot be prevented even in 6 M NaCl. Reversibility to Cl^- supports the above interpretation in terms of successive aquation reactions with Cl^- displacement, thereby ruling out simple isomerization.

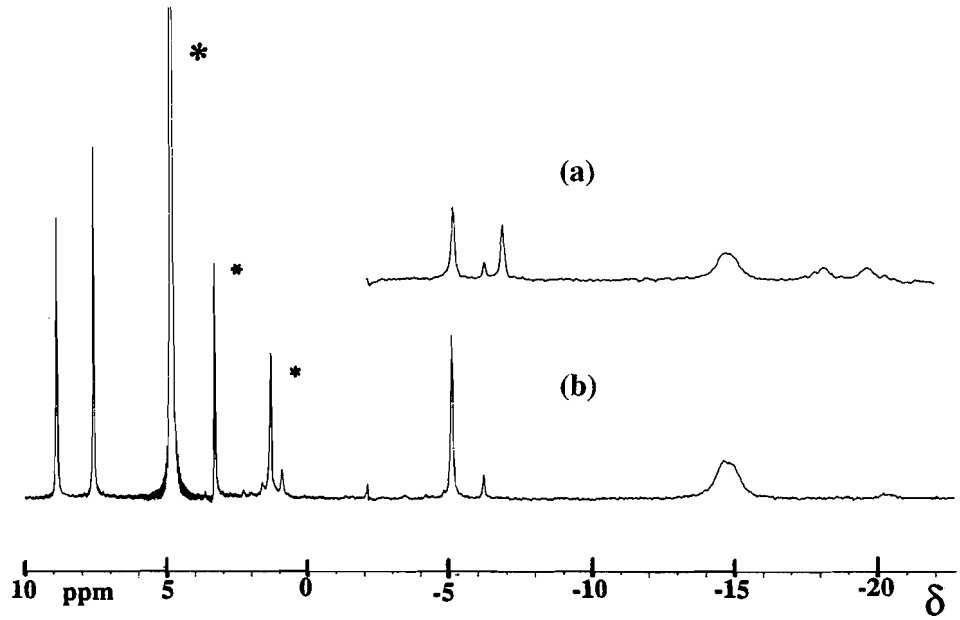
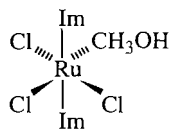
Fig. 2. ^{1}H NMR spectra of complex **1** in CD_3OD solution immediately after dissolution *(a)* and after 24 h *(b)*; * = solvent, water, and impurity (~1 ppm).

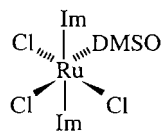


Solutions of 1 in CD_3OD

Besides the sharp signals at 8.9 and 7.6 ppm for the imidazolium ion, two unequal sets of high-field imidazole peaks are initially observed at room temperature (Fig. 2 and Table 3), corresponding to two species each containing equivalent imidazole ligands. One species is derived from the other, as evidenced from one set (−5.1, −14.7, and −14.4 ppm) increasing with time at the expense of the other (−6.9, −18.1, and −19.6 ppm). For the earlier peaks, the chemical shifts are not very different from those of **1** in water and they are assigned to $[RuCl_4Im_2]^-$. By analogy with water solutions, the other set of peaks is assumed to be due to the monosolvent species $[RuCl_3(CD_3OD)Im_2]$, **1d**, corresponding to the monoaqua complex **1a**. Examples of Ru(III) complexes containing coordinated methanol are known (20, 26).



1d



1e

Conversion into **1d** was complete within 24 h at room temperature and the spectrum remained unchanged over a period of several days. At low temperature, conversion was much slower. A solution of **1** was prepared at −50°C and spectra were taken as it was progressively allowed to warm up to 40°C over a period of 4 h. The signals showed a regular downfield shift with temperature (Fig. S1-3), as commonly found in paramagnetic systems (12), but signal correspondence with earlier results was readily made via the spectrum at 25°C. The fresh solution at −50°C showed only the peaks for **1**. The second species **1d** began to appear at 0°C and, as the solution was heated up further to 40°C, it kept growing while **1** disappeared. After allowing the reaction to go to completion (1 day), cooling this sample down to 0°C did not regenerate **1**. Therefore, higher temperature increased the rate of conversion, but did not affect appreciably the equilibrium position.

When the solution of **1** was left at room temperature for 7 days, two very weak peaks (<5%) appeared at −6 and −8 ppm, respectively. They increased only very slowly during the next 2 weeks, while the colour of the solution changed from yellow to dark orange because of decomposition to unidentified products. Therefore, any subsequent reaction is slow at this temperature in methanol.

Attempts were made to isolate solids from fresh or aged solutions. Adding acetone gave no precipitate. When the solvent was removed in vacuo at room temperature or by mild heating, reconversion to **1** took place, even if the solution had aged for several days. The ^{1}H NMR spectra both in D_2O and in CD_3OD were identical with those initially found for **1** in these solvents.

Thus, solvolysis in methanol is faster than in water, but it stops at an earlier stage: conversion of **1d** into a $[RuCl_2(CD_3OD)_2Im_2]^+$ species similar to **1b** could not be observed.

Solutions of 1 in DMSO

The ^{1}H NMR spectrum of **1** in DMSO has been reported, but has been neither thoroughly analyzed, nor fully assigned (10). Figure 3*a* shows three imidazolium peaks with the expected 2:1:2 ratio: 14.3 ppm (N-H), 9.1 ppm (H2), and 7.7 ppm (H4/H5). Four peaks attributed to coordinated imidazole are assigned by analogy to the spectrum in D_2O: −7.6 ppm (narrowest, H5), −2.6 ppm (N-H, not seen in D_2O), −17.2 ppm (H4), and −18.5 ppm (H2).

To make sure that the initial species was the unchanged $[RuCl_4Im_2]^-$ ion, a solution of **1** was prepared at −5°C and its ^{1}H NMR spectrum was recorded at this temperature, where any solvolysis or isomerization processes should be retarded, as noted in CD_3OD. Spectra were also taken while the temper-

ature was raised over a period of 4 h to 25°C by steps of 5°. The peaks showed the regular shift as temperature increased, typical of this paramagnetic system, but the same single set of peaks was seen at all temperatures (Fig. S1-4).[3] An orange-brown powder precipitated when acetone was added to a fresh solution. Single crystals of the same material appeared within several hours when a layer of acetone was poured onto the solution and the system was left at 5°C. They were shown by X-ray diffraction (see experimental section) to be $(ImH)[RuCl_4Im_2]\cdot$ 2DMSO containing the same *trans*-$[RuCl_4Im_2]^-$ and ImH^+ ions as the solvent-free crystals (6). When lattice solvent was removed by extensive pumping in high vacuum, both the powder and the crystals gave the same IR spectrum and the same ^{1}H NMR spectra in DMSO-d_6 and D_2O, which were also identical with those of the starting material **1**. Therefore, the species initially present in DMSO is *trans*-$[RuCl_4Im_2]^-$.

This species has a good kinetic stability, since it remains dominant for several days at room temperature. After 6 days (Fig. 3*b*), it still accounts for 75% of the spectral intensity. A new species **1e** gives peaks (20%) in the paramagnetic region, at −13.5 (H4) and 0.6 ppm (probably N-H). Its H5 resonance likely contributes to the peak of **1** at −17.2 ppm, which has become stronger than the −18.5 ppm component. According to the integration, the N-H resonance of **1** at −2.6 ppm includes a contribution from **1e** (probably H2). This new product **1e** is believed to be $[RuCl_3(DMSO)Im_2]$, where a Cl^- ligand has been substituted by a probably S-bonded DMSO molecule. This species is assumed to be similar to the corresponding $[RuCl_3(D_2O)Im_2]$ complex **1a** formed in water. The spectrum also shows very small peaks (< 5%) for the imidazole protons of a diamagnetic species **1f** at 12.5 (well resolved, N-H), 8.05, 7.41, and 7.13 ppm (tails of strong imidazolium peaks at 7.7 ppm). Any DMSO present in the complex would not be detected, since the reaction takes place in DMSO-d_6.

After 12 days, **1** and **1e** represent 51 and 25% of the intensity, respectively. The contribution of **1f** has increased to 15%, whereas another diamagnetic species **1g** (δ 12.9 (N-H), 8.25, 7.45, and 7.28 ppm), barely visible in the previous spectrum, has become more significant (9%). Within ~2 weeks, yellow crystals of *trans,trans,trans*-$[RuCl_2(DMSO)_2Im_2]$ (see X-ray diffraction work below) became visible. The peaks due to both Ru(III) products were still present over many weeks, indicating that the overall conversion to the diamagnetic products **1f** and **1g** is very slow. The crystals did not redissolve readily in DMSO: stirring for 1–2 weeks gave a solution whose very weak ^{1}H NMR signals matched exactly those of **1g**.

These observations can be reasonably explained by the fol-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

lowing pathway. The first step would be a reduction of $[RuCl_3(DMSO)Im_2]$ (**1e**) to $[RuCl_3(DMSO)Im_2]^-$ (which would be **1f**), followed by substitution of a Cl^- ligand by DMSO to give $[RuCl_2(DMSO)_2Im_2]$ (to be labelled **1g**), which would then crystallize out. Reduction of Ru(III) to Ru(II) in DMSO is well documented: $[RuCl_2(DMSO)_4]$ is thought to be formed via $[RuCl_4(DMSO)_2]^-$ and $[RuCl_3(DMSO)_3]$, reduction being effected by the solvent itself oxidizing to the sulfone (27). Reduction of Ru(III) to Ru(II) is known to take place readily when more than one π-accepting sulfoxide ligand is coordinated, and the complex becomes increasingly reducible with each new DMSO ligand introduced in the coordination sphere. Owing to the large *trans* effect of DMSO, the Cl^- ligand displaced in $[RuCl_3(DMSO)Im_2]^-$ should be *trans* to the DMSO already present, leading to the *trans-trans-trans* geometry observed in the solid.

An alternate scenario cannot be totally ruled out. Compound **1e** could first undergo a second solvolysis and form $[RuCl_2(DMSO)_2Im_2]^+$, which would be immediately reduced to $[RuCl_2(DMSO)_2Im_2]$ (which would be **1f**) crystallizing out slowly. Several possibilities would then exist for the other diamagnetic species **1g** derived from **1f**: further solvolysis to $[RuCl(DMSO)_3Im_2]^+$, isomerization to a species with imidazoles and (or) DMSO in *cis* arrangements (a geometry reported to be more stable for $RuCl_2(DMSO)_4$) (28)), or even aquation with water slowly leaking into the NMR tube. This pathway is believed to be less likely, since unusual dissolution kinetics would have to be assumed to explain that the above saturated solution of the crystals in DMSO gives no ^1H NMR signals for $[RuCl_2(DMSO)_2Im_2]$ itself, but only those of the derived species. Furthermore, $[RuCl_2(DMSO)_2Im_2]^+$would have to reduce so quickly as to not be detected in solution: reduction is much slower in related systems (27).

The crystals of *trans,trans,trans*-$[RuCl_2(DMSO)_2Im_2]$ are not very soluble in D_2O. Overnight stirring gives a solution whose NMR spectrum shows imidazole peaks at 7.26, 7.30, and 8.04 ppm, in the range previously published for Ru(II)–imidazole complexes (29). The DMSO resonance expected at 2.7–3.4 ppm is not visible because the sample has been obtained from DMSO-d_6. No peaks are seen outside the 0–10 ppm range, thus confirming the absence of Ru(III) products here. The species actually present in solution is probably not intact $[RuCl_2(DMSO)_2Im_2]$, but the aquation product $[RuCl(H_2O)(DMSO)_2Im_2]^+$, since aquation is relatively fast for similar systems containing *trans* DMSO (5, 29).

Crystal structure of $[RuCl_2(DMSO\text{-}d_6)_2Im_2]$

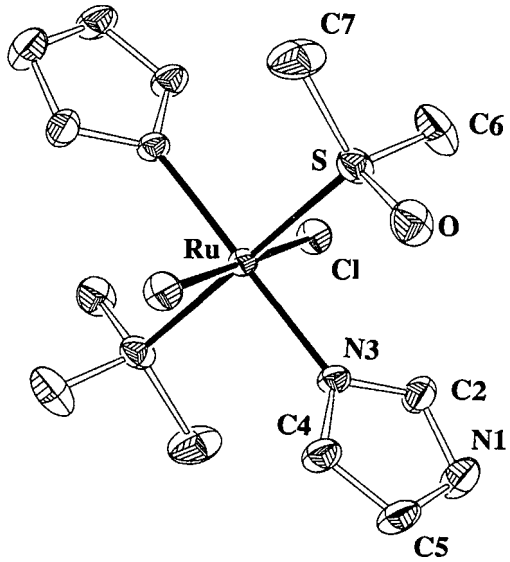
$(ImH)[RuCl_4Im_2]$ (**1**) was dissolved in a DMSO-d_6–acetone mixture by gently heating for 15 min. The yellow rectangular prisms, which were used for X-ray work, appeared within 2 days. The same crystals were obtained only after several weeks from pure DMSO solution.

The unit cell contains two approximately octahedral *trans,trans,trans*-$[RuCl_2(DMSO)_2Im_2]$ molecules (Fig. 4). Related $RuCl_2(DMSO)_2L_2$ complexes have been isolated from reaction of *cis*-$RuCl_2(DMSO)_4$ with 1-MeIm or 2-MeIm, but they are believed to be of the all-*cis* configuration (30).[6]

Since the metal is sitting on crystallographic inversion centres, all *trans* angles in the present compound are within 2.5°

[6] Also, B.R. James, private communication.

Fig. 4. ORTEP drawing of *trans,trans,trans*-$[RuCl_2(DMSO)_2Im_2]$. The Ru atom occupies a crystallographic inversion centre. Ellipsoids correspond to 50% probability. Hydrogens are omitted for simplicity.



of the ideal 90° value (Table 4). DMSO is S-bonded and its Ru—S bond length (2.290(1) Å) is slightly shorter than observed in $RuX_2(DMSO)_4$ (2.353(1) Å for X = Cl (31), 2.352(2) Å for X = Br (28)), probably because two of the DMSO ligands are replaced here by less sterically demanding imidazoles. Our Ru—Cl distance (2.416(1) Å) compares well with those found for mutually *trans* Ru—Cl bonds in Ru(II) compounds (2.40–2.43 Å) (28, 29, 31), this bond being ~0.06 Å shorter in Ru(III) compounds (6, 27, 31, 32). The Ru-N distance of 2.105(4) Å is somewhat longer than found in the $[RuCl_4Im_2]^-$ ion (2.079(3) Å), which reflects the change in oxidation state and greater steric demand of DMSO. The geometry of the DMSO and imidazole ligands is normal. The imidazole ring is planar within 0.005 Å (1σ), but the Ru—N bond does not lie exactly in this plane (Ru-to-plane distance = 0.056(8) Å).

Each imidazole N-H proton forms a bifurcated hydrogen bond with a chlorine and a DMSO oxygen of a neighbouring molecule in the unit cell (Fig. 5). The N···Cl and N···O separations (3.323(4) and 2.790(6) Å, respectively) are typical of these types of interactions (33). The molecule participates in four such hydrogen bonds as donor or as acceptor. Other intermolecular contacts correspond to normal van der Waals interactions.

The infrared spectrum of *trans,trans,trans*-$[RuCl_2(DMSO)_2Im_2]$ is distinctly different from those of the complexes discussed above. Peak doubling due to the presence of both coordinated and protonated imidazoles is no longer present. The ν(S–O) mode of DMSO is identified at 1057 cm^{-1}, in agreement with S-bonding (27, 31). A hydrogen-bonded ν(N–H) band is also seen at 3242 cm^{-1}. In the 600–200 cm^{-1} region, the spectrum is assigned with the aid of data for Ru(III) compounds (6) and the related Ru(II) complex *trans,cis,cis*-$[RuCl_2(DMSO)_2Im_2]$ (29). The Ru–N and Ru–S stretching modes are assigned at 240 and 392 cm^{-1}, respec-

tively, whereas the ν(Ru–Cl) bands at 351 and 362 cm^{-1} occur at relatively high frequency.

Discussion

Solvolysis of $[RuCl_4Im_2]^-$ could be followed by means of ^1H NMR spectroscopy in water, methanol, and DMSO, in spite of the presence of the paramagnetic Ru(III) centre. The imidazole peaks are broad but not exaggeratedly so, the various resonances are spread over a large but limited range, and the chemical shifts of the various species are sufficiently different to allow the appearance and disappearance of successive species to be followed. The present complexes make a homogeneous series and the signals are found to undergo regular downfield shifts as the Cl^- ligands are successively replaced by solvent molecules.

The initial species observed in the NMR spectra has half-lives of 1–2 h in CD_3OD, ~3 days in D_2O, and ~2 weeks in DMSO. Ru(III) complexes are generally regarded as kinetically inert, especially compared to the Ru(II) analogues (19). However, chloride-rich systems are expected to react relatively quickly, since the low position of Cl^- in the spectrochemical series decreases the barrier for substitution (34). For instance, $[RuCl_6]^{3-}$ and $[RuCl_5(H_2O)]^{2-}$, which are thermodynamically stable only at very high Cl^- concentrations, aquate in seconds when dissolved in H_2O (35). Considering that these species are very labile, it was first checked that the complex initially observed in our NMR spectra was still the $[RuCl_4Im_2]^-$ ion present in the solid. This was confirmed by reprecipitation from solution in which later signals had not yet appeared. In the three solvents, the precipitate obtained was the initial $(ImH)[RuCl_4Im_2]$ salt (isolated as a solvate for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

DMSO), thereby confirming that chloride is not lost instantaneously in these solvents.

Our results in D_2O indicate that replacing two water molecules by imidazole in the coordination sphere does not drastically affect the behaviour of the remaining coordinated chlorides. Indeed, from the equilibrium constants available (35, 36), it can be predicted that a solution $[RuCl_6]^{3-}$ should undergo successive aquation reactions and, at the concentration level used for our NMR work ($\sim 5\times10^{-3}$ M), $[RuCl(H_2O)_5]^{2+}$ should be the major component at equilibrium. The rate of aquation decreases regularly as chlorides are displaced: $[RuCl_4(H_2O)_2]^-$ (for which kinetic data are still missing) should aquate relatively quickly; the half-life of $[RuCl_3(H_2O)_3]$ has been found to be ~45 days and that of $[RuCl(H_2O)_5]^{2+}$ has been estimated to be >1 year (35). A similar pattern is found here for the Im system: the half-lives increase regularly from $[RuCl_4Im_2]^-$ (~3 days) to $[RuCl_3(H_2O)Im_2]$ (~21 days) to $[RuCl_2(H_2O)_2Im_2]^+$ (~4 months), and the final product is again the monochloro ion $[RuCl(H_2O)_3Im_2]^{2+}$. For the first aquation process, the rate observed here corresponds well with that reported by Keppler et al. (3), who related the slow binding to biological substrates in fresh solutions of (ImH)$[RuCl_4Im_2]$ to the formation of the monoaqua species, which would actually be the active form.

Although the composition of the various species in solution has been identified, their stereochemistry is less certain. For instance, the *cis,fac*-$[RuCl_3(H_2O)Im_2]$ isomer would also be consistent with the single set of resonances observed for **1a**, whereas the two equal sets of signals, assigned to different isomers **1b1** and **1b2**, could also arise from nonequivalent imidazoles in the *cis,cis,cis*-$[RuCl_2(H_2O)_2Im_2]$ isomer. Such possibilities cannot be ruled out, but their formation in the **1**–**1a**–**1b** interconversion sequence, which is reversible to Cl^-, would imply that a change of configuration takes place quantitatively and reversibly at one step. This model appears to be unlikely, considering that equilibrium and kinetic data on the chloro-aqua system indicate that both isomers of $[RuCl_3(H_2O)_3]$ and of $[RuCl_2(H_2O)_4]^+$ have comparable stabilities and are not quickly interconverted (35). Unfortunately, we were unable to isolate the solvolyzed Ru(III) compounds as solids. Only in the case of DMSO was it possible to isolate suitable crystals of a final Ru(II) product, in which the *trans* imidazole arrangement present in the starting product was found to have been retained.

Aquation under nonbasic conditions is generally assumed to occur by a predominantly dissociative mechanism, which is thought to be followed in the case of $[Ru(NH_3)_5Cl]^{2+}$ (37). Relatively slow solvolysis observed for the related $[RuCl_4(5\text{-nitroimidazole})_2]^-$ ion (38), where the nitro group reduces electron density at the Ru(III) centre, would be consistent with this assumption. A dissociative process normally takes place via a five-coordinate intermediate, and a square-pyramidal intermediate is predicted for the present low-spin d^5 system since the loss of ligand–field stabilization is less than for a trigonal-bipyramidal intermediate (39). A square-pyramidal transition state should lead to retention of configuration, which is what is suggested by our study.

All species observed contain two coordinated imidazole ligands. No evidence for significant loss of coordinated imidazole could be obtained: none of the signal sets found for species derived from $[RuCl_5Im]^{2-}$ (16) were observed here and the imidazolium resonances did not show the shifts and (or) intensity changes expected if imidazole was liberated. Similarly, there is no evidence for the formation of the *mer*-$[RuCl_3Im_3]$ complex reported by Keppler et al. (3) to form concurrently with $[RuCl_2(H_2O)_2Im_2]^+$. This tris-imidazole complex would contain two nonequivalent Im ligands and give rise to two sets of signals (2:1 ratio). However, this complex has recently been detected during reactions run in the presence of excess imidazole (16). The absence of this species here could be ascribed to our relatively low pH. Our experiments were carried out without buffer and the pH was found to stabilize to ~3.2 early in the aquation process. Therefore, at this pH, imidazole is actually quenched in the protonated form (pK_a ~7) (40), making the amount of neutral Im ligand available to attack on the Ru(III) centre very small. Buffered solutions of higher pH, such as those used by Keppler (pH = 7.0–7.4, carbonate buffer) should provide more favourable conditions for the appearance of this compound.

Family-independent relationships between computed molecular surface quantities and solute hydrogen bond acidity/basicity and solute-induced methanol O–H infrared frequency shifts

Helena Hagelin, Jane S. Murray, Tore Brinck, Michel Berthelot, and Peter Politzer

Abstract: Family-independent relationships between computed molecular surface properties and solute hydrogen bond acidity/basicity and solute-induced methanol O–H infrared frequency shifts are presented. The molecular surface quantities, computed at the ab initio HF/6-31G* level, are primarily related to the electrostatic potential of the molecule, but also include the average local ionization energy on its surface.

Key words: hydrogen bond acidity/basicity, O–H frequency shifts, molecular electrostatic potential.

Résumé : On présente des relations indépendantes des familles entre d'une part les propriétés de surface moléculaire calculées et d'autre part l'acidité/basicité de la liaison hydrogène du soluté et les déplacements induits par le soluté de la fréquence infrarouge du O–H. Les quantités de surface moléculaire, calculées ab initio au niveau HF/6-31G*, sont principalement reliées au potentiel électrostatique de la molécule; elles comprennent toutefois la moyenne de l'énergie d'ionisation locale sur sa surface.

Mots clés : l'acidité/basicité de la liaison hydrogène, déplacements de la fréquence du O–H, potentiel électrostatique de la molécule.

Introduction

In view of the well-established importance of the electrostatic component in hydrogen bonding (1–6), it is not surprising that the molecular electrostatic potential $V(\boldsymbol{r})$ has been found to be an effective means for analyzing and correlating such interactions (2, 7–9). In particular, we have shown that the hydrogen-bond-accepting tendencies (basicities) of solutes and solvents can be related to the most negative values of their electrostatic potentials, V_{min} (10, 11). Analogously, good relationships exist between solute and solvent hydrogen-bond-donating tendencies (acidities) and the most positive values of the potential on their molecular surfaces, $V_{S,max}$ (11, 12). However, these correlations are family dependent; different types of compounds (e.g., alcohols, azines, ethers, etc.) must be treated separately.

Our present objective is to demonstrate that this family dependence can be eliminated by improving the quality of the wave functions used to compute the electrostatic potential and, in the case of hydrogen bond acceptor molecules, by using surface electrostatic potential minima instead of spatial minima. We will also show that a general representation of the infrared O–H frequency shift, $\Delta\nu_{OH}$, which occurs when hydrogen bond acceptors complex with methanol, can be obtained using our General Interaction Properties Function (GIPF) approach (13, 14).

The GIPF provides a unified approach to correlating and predicting a variety of physicochemical properties that reflect molecular interactions (13, 14). The procedure involves representing each property in terms of some subset of a group of computed molecular quantities. Each resulting relationship is viewed as a special case of the GIPF described by eq. [1]:

$$[1] \qquad \text{Property} = f[\text{area}, \bar{I}_{S,min}, V_{S,max}, V_{S,min}, V_{min}, \Pi, \sigma^2_{tot}, \nu]$$

The quantities in brackets in eq. [1] are measures of various aspects of a molecule's interactive behavior; except for

surface area and $\bar{I}_{S,min}$, they are defined in terms of the electrostatic potential $V(\boldsymbol{r})$. The quantities relevant to the present study will be introduced and discussed in the next section.

Methods and procedures

The electrostatic potential $V(\boldsymbol{r})$ created in the space around a molecule by its nuclei and electrons is an effective tool for interpreting and predicting chemical reactive behavior, and has been found to be particularly well suited for the analysis of noncovalent interactions such as hydrogen bonding (9, 15–19). $V(\boldsymbol{r})$ is defined rigorously by eq. [2],

$$[2] \qquad V(\boldsymbol{r}) = \sum_{A} \frac{Z_A}{|\boldsymbol{R}_A - \boldsymbol{r}|} - \int \frac{\rho(\boldsymbol{r}')d\boldsymbol{r}'}{|\boldsymbol{r}' - \boldsymbol{r}|}$$

where Z_A is the charge on nucleus A, located at $\boldsymbol{R}_A$, and $\rho(\boldsymbol{r})$ is the molecular electronic density function. The sign of $V(\boldsymbol{r})$ in any particular region depends upon whether the effects of the nuclei or the electrons are dominant there. An approaching electrophile, such as a hydrogen to be donated in a hydrogen bond, will initially be attracted to those regions where $V(\boldsymbol{r})$ is negative, and particularly to the points where $V(\boldsymbol{r})$ has its most negative values (the local minima, V_{min}).

The use of the electrostatic potential to predict sites susceptible to nucleophilic attack is not as straightforward as for electrophilic attack, due to the fact that $V(\boldsymbol{r})$ maxima are found only at the positions of the nuclei (20). These reflect the magnitudes of the nuclear charges and cannot be assumed to indicate relative reactivities toward nucleophiles. However, we have demonstrated that the electrostatic potential maxima on the molecular surface ($V_{S,max}$), which are significantly removed from the nuclei, do reflect relative affinities for nucleophiles (12, 21, 22), and identify hydrogen-bond-accepting atoms.

The average local ionization energy, $\bar{I}(\boldsymbol{r})$, is defined in eq. [3] (23):

$$[3] \qquad \bar{I}(\boldsymbol{r}) = \sum_{i} \frac{\rho_i(\boldsymbol{r})|\varepsilon_i|}{\rho(\boldsymbol{r})}$$

$\rho_i(\boldsymbol{r})$ is the electronic density of the ith molecular orbital at the point $\boldsymbol{r}$, ε_i is its orbital energy, and $\rho(\boldsymbol{r})$ is the total electronic density function. We interpret $\bar{I}(\boldsymbol{r})$ as the energy required, on average, to remove an electron from a point $\boldsymbol{r}$ in the space of an atom or molecule (23–26). In particular, we have found that the positions where $\bar{I}(\boldsymbol{r})$ has its lowest values on the molecular surface, the $\bar{I}_{S,min}$, are indicative of the sites that are most susceptible to charge transfer with electrophiles (23, 24, 26). For example, for a group of 40 anionic conjugate bases of carbon, oxygen, and nitrogen acids, we have shown that a very good correlation exists between the measured pK_a of the acid and the calcuated $\bar{I}_{S,min}$ of the conjugate base (24).

In accordance with the suggestion of Bader et al. (27), we define the molecular surface as the 0.001 au contour of the electronic density. Our surface areas are obtained by means of grids of equidistant points, converted to units of Å^2.

Four of the quantities in eq. [1] are site-specific: $\bar{I}_{S,min}$, $V_{S,max}$, $V_{S,min}$, and V_{min}. They are indicative of the tendencies for charge transfer ($\bar{I}_{S,min}$) or electrostatic interaction ($V_{S,max}$, $V_{S,min}$, and V_{min}) occurring at specific points. (Note that $V_{S,min}$ refers to minima on the molecular surface, while the V_{min} can be anywhere in the space of the molecule.)

The other four quantities in eq. [1] are global: area, Π, σ^2_{tot}, and ν. These are representative of the entire molecular surface. Π, σ^2_{tot}, and ν are statistically based quantities, which we introduced in earlier work in an effort to develop quantitative measures of key aspects of the overall surface potentials of molecules (13, 14, 28–34). Π, as expressed by eq. [4], is the average deviation of the electrostatic potential on the molecular surface. $V(\boldsymbol{r}_i)$ is the value of $V(\boldsymbol{r})$ at point $\boldsymbol{r}_i$ on the surface, and $\bar{V}_S$ is the average value of the potential on the surface:

$$[4] \qquad \Pi = \frac{1}{n}\sum_{i=1}^{n} |V(\boldsymbol{r}_i) - \bar{V}_S|$$

$$\bar{V}_S = \frac{1}{n}\sum_{i=1}^{n} V(\boldsymbol{r}_i)$$

Π can be viewed as a measure of the local polarity that is present in a molecule, even one having zero dipole moment. We have demonstrated its relationship to several empirical polarity/polarizability parameters and also to the dielectric constant (13, 28). The values of Π for organic molecules typically fall in the range from 2 to 15 kcal/mol (13, 28, 29).

The other global quantities in eq. [1] are σ^2_{tot}, which is the total variance of the electrostatic potential on the molecular surface, and ν, an electrostatic balance parameter. These do not enter into the present analysis, and accordingly will not be discussed further. Applications of these quantities are described in detail elsewhere (13, 14, 29–34).

In this work, GAUSSIAN 88 (35) was used to optimize geometries and to compute $\rho(\boldsymbol{r})$ and $V(\boldsymbol{r})$. All of this was done at the HF/6-31G* level. While all of the quantities in eq. [1] were computed for each molecule of interest, only the four site-specific properties ($\bar{I}_{S,min}$, $V_{S,max}$, $V_{S,min}$, and V_{min}) and one global property, Π, are needed for the correlations presented in this article. These relationships were developed using the SAS statistical analysis program.[2]

Results

In developing our earlier correlations between hydrogen bond acidity and $V_{S,max}$ (11, 12) and between hydrogen bond basicity and V_{min} (10, 11), we used experimentally derived measures of relative hydrogen-bonding tendencies. For solvents, these are the solvatochromic parameters α and β for acidity and basicity, respectively, obtained from linear solvation energy relationships (36). For solutes, the corresponding parameters are α_2^H for acidity and β_2^H for basicity, which were defined to be linearly related to the equilibrium constants for forming 1:1 complexes between the solute molecule and a given reference hydrogen bond donor or acceptor, in CCl_4 (37–39). In this study, we have focused on α_2^H and β_2^H, since these are currently more frequently used than α and β.

Hydrogen bond acidity

We computed the quantities in our GIPF (eq. [1]) for a group of 18 hydrogen-bond-donating molecules of a variety of types, including CH, NH, and OH donors. These com-

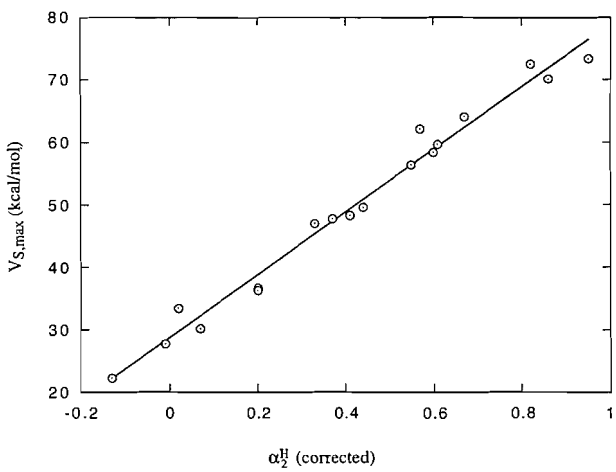
[a]The α_2^H values were obtained by R.W. Taft. A statistical correction has been applied to some of the α_2^H values, as indicated by parentheses.

Fig. 1. Plot of experimentally derived α_2^H (corrected) versus calculated $V_{S,max}$ for the molecules in Table 1. The linear correlation coefficient is 0.991.



pounds are listed in Table 1 along with their experimentally derived but statistically corrected[3] α_2^H values and our calculated $V_{S,max}$. We found that at the HF/6-31G* level, the key variable correlating with α_2^H is $V_{S,max}$, which is invariably associated with the hydrogen(s) to be donated in the hydrogen bond. No other quantity, site-specific or global, is needed to obtain a family-independent relationship with α_2^H.

[3] The statistical correction to α_2^H is applied to those molecules having N similar hydrogens available for hydrogen bonding. α_2^H is defined by: $\alpha_2^H = (\log K_a + 1.1)/4.636$, where K_a is the equilibrium constant for a 1:1 complex of the donor and a reference acceptor. Then $K_a = \sum_{i=1}^{N} K_{ai} = NK'_a$, where K'_a is the corrected value. Accordingly, $\log K_a = \log N + \log K'_a$ and α_2^H (corrected) $= \alpha_2^H - (\log N)/4.636$.

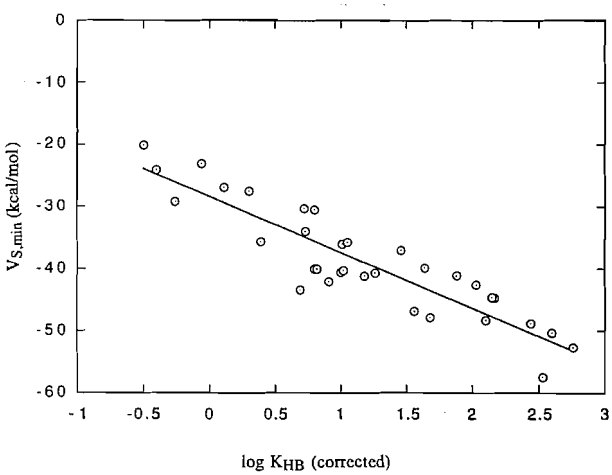
[a]The experimentally determined $\Delta\nu_{OH}$ values were obtained from M. Berthelot.

Fig. 2. Plot of experimentally determined log K_{HB} (corrected) versus calculated $V_{S,min}$ for the molecules in Table 2. The linear correlation coefficient is 0.902.



the acceptors with *p*-fluorophenol. We are using K_{HB} rather than β_2^H because the data, listed in Table 2, are from several different sources and accordingly it seemed preferable to use the actual measured quantity (K_{HB}) rather than one defined in terms of it (β_2^H).

As in the case of the hydrogen bond acidity correlations, we have listed the statistically corrected[4] values of log K_{HB} in Table 2, along with the calculated $V_{S,min}$ for each molecule. Only four acceptors need statistical corrections; these are $(CH_3CH_2S)_2$, dithiane, dioxane, and pyrimidine. These each have two identical hydrogen-bond-accepting heteroatoms per molecule.

Upon applying SAS to the data set of corrected log K_{HB} values, we find a reasonable linear relationship between $V_{S,min}$

[4] The statistical correction to log K_{HB} is applied to those molecules having N indistinguishable atoms that can accept a hydrogen bond. Then $K_{HB} = \sum_{i=1}^{N} K_{HBi} = NK'_{HB}$ where K'_{HB} is the corrected value, and log K'_{HB} = log K'_{HB} − log N.

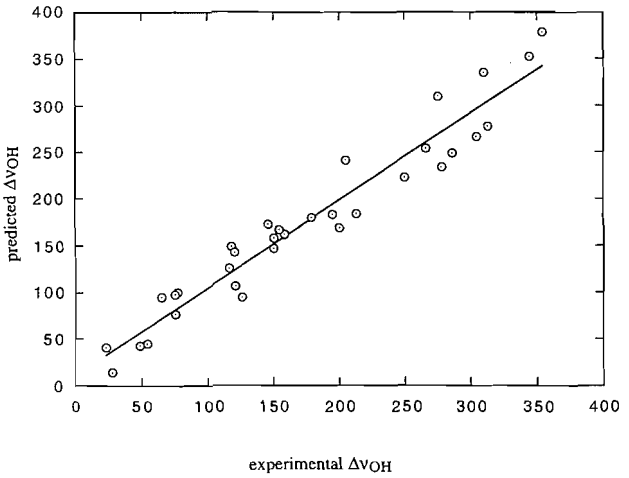
Fig. 3. Plot of experimentally determined versus predicted $\Delta\nu_{OH}$ values for the molecules in Table 3. The linear correlation coefficient is 0.966.



and log K_{HB}, given in eq. [6] and Fig. 2.

$$[6] \qquad \log K_{HB}(\text{corrected}) = -9.030 \times 10^{-2}\, V_{S,min} - 2.341$$

The correlation coefficient and standard deviation are 0.902 and 0.39, respectively. This correlation is of lower quality than that between α_2^H and $V_{S,max}$. This may be due in part to the fact that $V_{S,max}$ is always on a hydrogen, while $V_{S,min}$ is on a variety of acceptor heteroatoms.

Methanol infrared O–H frequency shift

Berthelot and Laurence have developed an experimentally accessible means of quantitating hydrogen-bond-accepting tendencies through the measurement of the IR frequency shift of the methanol O–H peak when the hydrogen is complexed with a hydrogen-bond-accepting molecule (40–46). This O–H frequency shift is designated $\Delta\nu_{OH}$.

Table 3 lists 33 molecules with their experimentally determined $\Delta\nu_{OH}$ values[5] and some calculated quantities: V_{min}, $\bar{I}_{S,min}$, and Π. The molecules in Table 3 represent a variety of types of compounds, including some with second-row hydrogen-bond-accepting atoms.

We have found a good three-parameter correlation, given in eq. [7], between $\Delta\nu_{OH}$ and the quantities V_{min}, $\bar{I}_{S,min}$, and Π. The linear correlation coefficient is 0.966 and the standard deviation is 26 cm^{-1}. Figure 3 presents a plot of experimentally determined $\Delta\nu_{OH}$ values vs. those predicted from eq. [7]. The dominant term in eq. [7] is V_{min}, followed by $\bar{I}_{S,min}$ and Π.

$$[7] \qquad \Delta\nu_{OH} = -5.427\, V_{min} - 25.48\, \bar{I}_{S,min} - 7.113\, \Pi + 268.3$$

In looking back at eq. [6], it is interesting to point out that the addition of either $\bar{I}_{S,min}$ and (or) Π does not statistically improve the quality of the log K_{HB} versus $V_{S,min}$ relationship. That eqs. [6] and [7] are indeed different is consistent with the known lack of family-independent correlation between log K_{HB} and $\Delta\nu_{OH}$.

[5] M. Berthelot, private communication.

Summary and conclusion

We have demonstrated that family-independent correlations can be obtained for solute hydrogen bond acidity and basicity, as quantitated by α_2^H and log K_{HB}, respectively, and for the methanol infrared O–H frequency shift, $\Delta\nu_{OH}$, that occurs upon the complexation of methanol with hydrogen-bond-accepting molecules. Our results show that α_2^H and log K_{HB} can be well represented by an electrostatic potential term alone, $V_{S,max}$ and $V_{S,min}$, respectively. $\Delta\nu_{OH}$, on the other hand, requires a term reflecting charge transfer contributions as well as electrostatic potential terms.

Condensation reactions between vanadate and small functionalized peptides in aqueous solution

Alan S. Tracey, Jaswinder S. Jaswal, Fikile Nxumalo, and Sarah J. Angus-Dunne

Abstract: The role that histidyl, seryl, tyrosyl, and other side chains of small peptides play in the formation of vanadate complexes has been investigated using ^{1}H, ^{13}C, and ^{51}V nuclear magnetic resonance spectroscopy. Formation constants of product complexes in aqueous solution have been determined and the influence of pH on the equilibria established. The results revealed that, in histidine-containing compounds, the protonation state of the imidazole ring of the free ligand strongly influences product formation. The results unequivocally showed that no vanadium-to-imidazole bond was formed for any of the histidine-containing complexes studied. However, imidazole and other aromatic side-chain residues have an effect on product stability via their influence on the protonation state (pK_a) of the products. Aliphatic side-chains, such as those in asparagine or glutamate, do not appear to play a significant role in the formation of products. This is not true, however, of serine or threonine where the side-chains readily generate vanadium–oxygen bonds.

Key words: vanadate, vanadium, 51-V NMR, peptides, complexes, aqueous equilibria.

Résumé : Utilisant la RMN du ^{1}H, du ^{13}C et du ^{51}V, on a étudié le rôle joué par des chaînes latérales histidyle, séryle, tyrosyle et autres de petits peptides dans la formation de complexes du vanadate. On a déterminé les constantes de formation des complexes en solution aqueuse et on a établi l'influence du pH sur l'équilibre. Les résultats révèlent que, dans les composés contenant de l'histidine, l'état de protonation du noyau imidazole du coordinat libre influence fortement la formation du produit. Les résultats montrent sans équivoque qu'il ne se forme pas de liaison vanadium–imidazole dans aucun des complexes étudiés contenant de l'histidine. Toutefois, à cause de leur influence sur l'état de protonation (pK_a) des produits, l'imidazole et d'autres résidus aromatiques dans les chaînes latérales ont un effet sur la stabilité des produits. Les chaînes latérales aliphatiques, telles que celles rencontrées dans l'asparagine ou le glutamate, ne semblent pas jouer de rôle significatif dans la formation des produits. Toutefois, ceci n'est pas vrai pour la sérine ou la thréonine avec lesquelles les chaînes latérales génèrent facilement des liaisons vanadium–oxygène.

Mots clés : vanadate, vanadium, RMN du ^{51}V, peptides, complexes, équilibre aqueux.

[Traduit par la rédaction]

Introduction

The past few years have seen a remarkable surge of interest in the aqueous chemistry of the oxovanadium(V) ion, vanadate. In large part, this interest has been generated because vanadate can influence the function of a large number of phosphate-utilizing enzymes by entering directly into metabolic processes (for recent reviews of much of the chemistry and biochemistry of vanadate the readers are referred to the two compendiums, refs. 1 and 2). In addition to this, vanadium is contained in the prosthetic group of some nitrogen-fixing enzymes (3–5) and in a number of haloperoxidases of marine algae (6–8).

Much of the metabolism of phosphate involves tyrosyl, histidyl, seryl, or other residues in the active site of the protein. It is of interest, therefore, to develop an understanding of the interactions between the side-chain substituents and vanadate.

Recent studies have revealed some of the chemistry associated with the reactions between vanadate and amino acids or peptides (9–12). This work has been limited in scope, in part because of the complexity of the interactions involved, particularly when the peptides contain functionalized side chains. The involvement of histidine in complex formation with vanadate has been studied (13), as has that of asparagine (11), tyrosine (14), aspartic acid (9, 15), and serine (11).

In this study, the reaction of a number of di- and tripeptides with vanadate is reported. In one series of reactants, at least one amino acid residue of the peptide had a functionalized side chain. In a second series, both amino acid residues in a number of dipeptides were functionalized. A previous report detailed the interactions between vanadate and peptides with no func-

tionalized side chains (11) and that information is necessary for understanding these more complex systems.

Experimental

Materials

The peptides used in this study were obtained from Sigma Chemical Company. In some cases the purity of the peptides was checked by ^{1}H NMR spectroscopy but all were used as supplied. The buffer *N*-(2-hydroxyethyl)piperazine-*N'*-ethane sulfonic acid (HEPES) was purchased from Boehringer Mannheim GmbH and used as provided, as was the vanadium pentoxide (99.99%) purchased from Aldrich Chemical Company.

Ligands

The pK_a values for a number of ligands were required. They were obtained by a sequential titration of the particular dipeptide, first from a pH 13.5 solution with HCl until well below the pK_a (pH 2), then with NaOH until back to pH 13.5. The pK_a values were taken from the titration curve of pH vs. volume of added acid or base. The values obtained were as follows: for terminal NH_3–hisser 8.0; hisgly 8.1; glyhis 8.1: for imidazolium–hisser 7.0; hisgly 6.6; glyhis 7.0. The pK_a values for trptrp (7.7), trptyr (8.1), and tyrgly (8.1) were taken from ref. 16.

Solutions

Stock solutions of sodium vanadate were prepared in distilled water by adding 0.5 mol equivalent of V_2O_5 to a 1.0 M solution of NaOH and stirring until the solution became colourless (generally overnight). The concentration was adjusted to provide a 0.1 M stock solution.

1.0 M HEPES and 2.0 M KCl stock solutions were individually prepared in distilled water. Stock solutions of 0.05–0.08 M tryptophyltryptophan and tryptophyltyrosine were prepared by warming the appropriate amounts of dipeptide in distilled water. The peptides, tyrosylglycine, glycylhistidylglycine, tryptophylglycylglycine, and N-CBz-histidylglycine were weighed and added directly to the sample solutions. The remaining stock solutions were prepared at concentrations varying from 0.06 to 0.3 M, depending on the solubility, in distilled water.

The final solutions were prepared by adjusting the pH of the stock solutions to appropriate values so that, on combining them into the final solution, the pH was not less than 6.2. The volume was adjusted to near the final volume; the pH was then adjusted upward with NaOH to the desired value and final volume adjustments made. This procedure prevented the formation of decavanadate. The final solutions contained 20 mM HEPES buffer and the appropriate amounts of vanadate and peptide, and the ionic strength was 1.0 M with KCl. Freshly opened standard buffers at pH 4.0 and pH 10.0 were used for pH calibration.

For ^{1}H and ^{13}C NMR spectroscopic studies of the histidylserine–vanadate equilibria, the solutions were prepared in D_2O and pD adjustments made using DCl or NaOD.

Equilibration of the reactant solutions frequently required many hours. Solutions were normally allowed to stand 1 day at room temperature before obtaining the final NMR spectra. Spectra were again obtained after several additional days to ensure all systems had been in equilibria. Rates of equilibration were found to vary for different peptides but no detailed kinetic study was made.

Spectroscopy

All NMR spectra were obtained from a Bruker AMX-400 NMR spectrometer operating at ambient temperature (21 ± 1°C). ^{51}V chemical shifts are given relative to an external $VOCl_3$ reference at 0.0 ppm. Base-line corrections were applied to all spectra before integrals were obtained.

Methods

The equilibrium equations, derived on the basis of concentration and pH studies, were put into the appropriate linear form, as outlined in the text, and the results were analyzed using standard least-squares techniques. The quoted errors are for the 95% confidence level.

Results and discussion

In this study, the reactions of vanadate with six dipeptides (glyhis, hisgly, hisser, pheglu, tyrgly, and trptyr) were selected for detailed analysis. Extensive concentration and pH studies were carried out for these systems. An additional 14 peptides were studied in a more cursory fashion at pH 7.0.

Glycylhistidine

In the initial studies with glycylhistidine, the total vanadate concentration was maintained at 3.0 mM and the glycylhistidine concentration was varied from 10 to 50 mM. For the 40 mM peptide concentration, additional spectra were obtained for 5.0 and 7.0 mM total vanadate. Under these conditions a single product signal, at −511 ppm, was observed. This signal is close to that (−519 ppm) previously reported for the product of the condensation with alanylhistidine (13). To ascertain the stoichiometry of this product, it is first necessary to know whether additional products are formed.

In addition to the major product, there is possibly a product arising from condensation at the terminal NH_2 group that gives overlapping signals with monomeric vanadate, perhaps because of rapid exchange. To investigate this possibility it is necessary to consider the predominant oligomerization reactions of vanadate as expressed in eqs. [1]–[3]. It frequently happens that the tetramer, V_4, gives a well-defined NMR signal and therefore provides a useful reference for defining the concentration of the vanadate monomer.

$$[1] \quad 2V_1 \underset{}{\overset{K_{12}}{\rightleftharpoons}} V_2, \qquad [V_1]^2K_{12} = [V_2]$$

$$[2] \quad 4V_1 \underset{}{\overset{K_{14}}{\rightleftharpoons}} V_4, \qquad [V_1]^4K_{14} = [V_4]$$

$$[3] \quad 5V_1 \underset{}{\overset{K_{15}}{\rightleftharpoons}} V_5, \qquad [V_1]^5K_{15} = [V_5]$$

The formation of the rapidly exchanging product is written as eq. [4], where V_1 is monomeric vanadate, P is the peptide, and VP is the product. K_{14} and K_1 can be determined simultaneously by combining eq. [2] with eq. [4] and rearranging to give eq. [5]

[4] $V_1 + P \underset{}{\overset{K_1}{\rightleftharpoons}} VP, \qquad [V_1][P]K_1 = [VP]$

[5] $$\frac{[V_1] + [VP]}{[V_4]^{1/4}} = K_{14}^{-1/4} + K_1 K_{14}^{-1/4}[P]$$

When the data were plotted, a linear relationship was obtained but the slope of the line was indistinguishable from zero. From the scatter in the points it was estimated that K_1 was not larger than about 1 M^{-1}. Reported values of K_1 for other dipeptides under similar conditions are about 0.4 M^{-1} (11). From the *Y*-intercept, a value of $(2.1 \pm 0.3) \times 10^{10}$ M^{-3} was calculated for K_{14}. This value is very close to those previously reported for the formation of the vanadate tetramer at this pH (17).

Initial studies of the data for the −511 ppm product suggested that this product contained a single glycylhistidine and a single vanadate and was formed as described by eq. [4]. Figure 1 shows the results of plotting the experimental data. The good linear relationship that was obtained yielded a formation constant of $(1.01 \pm 0.06) \times 10^2$ M^{-1} for K_1. The absence of upward curvature in the experimental data indicated that the −511 ppm NMR signal was not a composite signal deriving from products of VP and V_2P stoichiometry in the fashion recently reported for the −519 ppm product formed from the reaction of alanylhistidine with vanadate (13). However, reanalysis of the alanylhistidine data given in Tables 2 and 3 of ref. 13, according to eq. [4], gave two excellent linear relationships with no upward curvature, as shown in Figs. 2*A* and 2*B*, respectively. There is no indication, from these graphs, that a V_2P product is formed. Earlier studies of other peptides also provided no evidence for formation of a V_2P product (11). It is not impossible that such products are formed; however, the information presently available does not provide evidence for the occurrence of such a product under the conditions of these various studies. The monopeptide monovanadium product, VP, is the only discernible product.

In previous studies of peptidovanadate complex formation it was found that the products giving rise to ^{51}V NMR signals near −510 ppm were formed from $VO_4H_2^-$ and the neutral (zwitterionic) peptide without gaining or losing a proton at pH 7. The products, however, had pK_a values near 10 (11). This value differs considerably from those of the uncomplexed peptides (see experimental section). When an attempt was made to analyze the results of the pH variation study of the glycylhistidine system (pH 6.52–9.61) it was found that the pK_a values both of the terminal nitrogen and of the imidazole nitrogen had to be considered in order to interpret the results. This indicated very clearly that the imidazole ring played an important role in the complexation reaction.

From the pK_a values for the terminal amino group and the imidazole ring of glycylhistidine (see experimental section), the concentration of the positively charged dipeptide can be calculated for all the pH values of this study. As a consequence, product formation can be written according to the top line of eq. [6]. However, a plot of [VP] vs. $[VO_4H_2^-][P^+]$ was not linear as expected. This demonstrated that
it was necessary to consider the pH dependence of the charge state of the product, as in the completed eq. [6]. The concentration of $VO_4H_2^-(V_1^-)$ for this equation is given directly by its pK_{a2} (=8.2) and the pH of the individual solutions. Equation

Fig. 1. A graphical representation of the formation of the −511 ppm product of the reaction of glycylhistidine with vanadate. Conditions of the experiments: pH, 7.0; HEPES buffer, 20 mM; ionic strength, 1.0 M with KCl; variable total glycylhistidine concentration, 10–50 mM; variable total vanadate concentration, 3.0–7.0 mM.

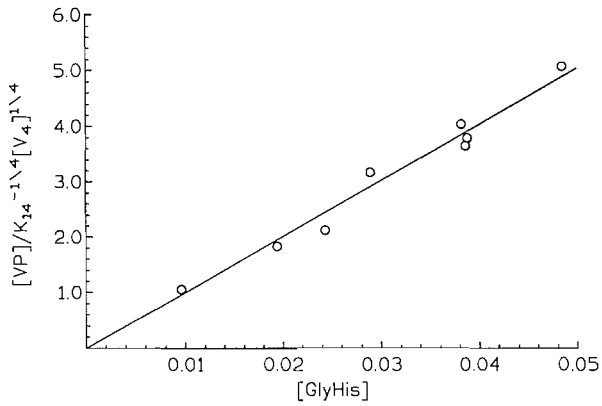

Fig. 2. The formation of the −519 ppm product of the reaction of alanylhistidine with vanadate is shown. The data are (*A*) from Table 2 and (*B*) from Table 3 of ref. 13. For these experiments the total vanadate concentration was varied between 1 and 17 mM and the total peptide concentration between 1 and 52 mM. The data were obtained at pH 7.2 under conditions of 0.2 M ionic strength with NaCl.

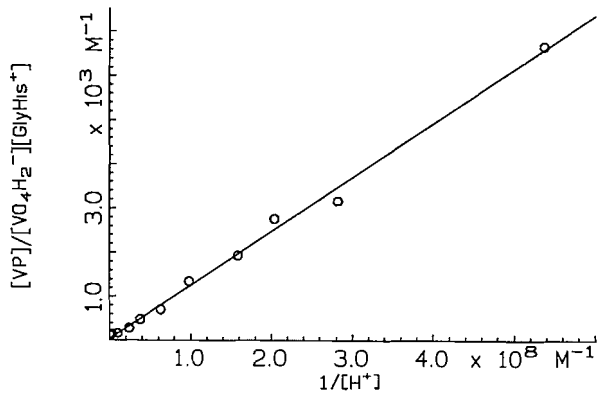
Fig. 3. The formation of the −511 ppm products ([VP] = [VP^0] + [VP^-]) of the reaction of monoanionic vanadate with cationic glycylhistidine is shown as a function of the inverse of the hydrogen ion concentration. The upward slope of the line is consistent with a pK_a for the product. The conditions of the experiments were as follows: total vanadate, 3.0 mM; total glycylhistidine, 40 mM; HEPES buffer, 20 mM; KCl, 1.0 M; pH, variable, pH 6.52–8.73.



[6] $VO_4H_2^- + P^+ \overset{K_2'}{\rightleftharpoons} VP$

$VP \overset{K_a}{\rightleftharpoons} H^+ + VP^{1-}$

[6] can then be reformulated in linear form as eq. [7] where a plot of 1/[H^+] vs. the term on the left of eq. [7] should give a line of slope, $K_2'K_a$, and intercept, K_2'.

$$[7] \qquad \frac{([VP^0] + [VP^-])}{[VO_4H_2^-][P^+]} = K_2'\left(1 + \frac{K_a}{[H^+]}\right)$$

The experimental results are displayed in Fig. 3. Although the slope is well determined, the *Y*-intercept, and therefore K_2' (= 29 ± 66 M^{-1}), is not very well defined because its value is small compared to the scatter in the experimentally determined *Y*-values, which range from 140 to 6700 M^{-1}.

Further information can be gleaned from the experimental results by reformulating eq. [6] as eq. [8] to give eq. [9], then replotting the data. The slope and intercept from this plot gave values

$VP \overset{K_a}{\rightleftharpoons} H^+ + VP^-$

[8] $VO_4H_2^- + P^+ \overset{K_2''}{\rightleftharpoons} VP^- + H^+$

$$[9] \qquad \frac{([VP^0] + [VP^-])[H^+]}{[VO_4H_2^-][P^+]} = K_2'' + [H^+]K_2''/K_a$$

of (1.1 ± 0.2) × 10^{-5} for K_2'' and a pK_a of about 7 (Table 1). This pK_a value, although not well defined, is similar to that of the imidazole ring in glycylhistidine and its value seemingly suggests that the imidazole ring is directly involved in product stability. If the pK_a value is correctly attributed, its occurrence means that no vanadium–imidazole nitrogen bond is formed. If the imidazole ring is not directly involved in product stability, the formation constant of the product would not be sensitive to the overall charge state of the product unless the pK_a that is measured does not arise from loss of a proton from the imidazole but rather from the vanadate core. In two cases where the peptides have no aromatic side chains, the products have a pK_a of about 9 or 10 (11). No evidence for loss of an additional proton from VP^- at the high pH values of this study was obtained.

Histidylglycine

The reactions of histidylglycine are not very different from those of glycylhistidine and again only one product was observed. This product gave a ^{51}V NMR signal at −513 ppm and is formed with a formation constant of 67 ± 4 M^{-1} at pH 7.0.

The pH variation study clearly showed that here, as for glycylhistidine, it was necessary to consider the product charge state when interpreting the results of the experiments. When the results were plotted according to eq. [9], a value of (2.0 ± 0.3) × 10^{-5} was obtained for K_2'' and a value of 6.7 for the pK_a of the product. As for glycylhistidine, the pK_a was not well determined, but its value supports the previous suggestion that there is no bond formed from the vanadium to the imidazole nitrogen of the histidine side chain. The value for K_2'', in this case, is twice that for the glycylhistidine ligand. This indicates the presence of slightly more favourable interactions leading to product stability but the difference is not large.

Neither N-CBz-histidylglycine (30 mM) nor glycyclglycylhistidine (60 mM) gave significant amounts of any product. This suggests that vanadium – imidazole nitrogen bonds are not easily formed in this type of complex. Either of the above ligands could complex in a tridentate fashion without requiring a terminal amino group adjacent to the peptide nitrogen and the terminal carboxylate group but such products were not observed.

The complexes observed here are, apparently, not very different from those formed with simpler dipeptides such as glycylglycine where complexation requires the N-terminal amino group, the N-H of the peptide linkage, and a terminal unprotected carboxylate group (9, 11).

Histidylserine

At pH 7.0, the major product of the reaction gave a vanadium NMR signal at −517 ppm. A second product with a ^{51}V chemical shift of −503 ppm was also formed, but at a low relative concentration of about 5% of that of the major product. The formation constant for the major product, as described by eq. [4], was (3.2 ± 0.2) × 10^2 M^{-1} while that of the minor product was (0.2 ± 0.1) × 10^2 M^{-1}, both for pH 7.0.

When the pH variation study was carried out, it became obvious that the two products had a different proton stoichiometry. The −503 ppm product became increasingly favoured relative to the −517 ppm product with increase in pH. This behaviour is similar to that previously reported for glycylserine (11) and is ascribed to the involvement of the terminal carboxylate in complex formation for the −517 ppm product and the hydroxyl group of the hydroxymethyl of

Table 1. ^{51}V chemical shifts and the formation constants for the products of the equilibrium reactions between vanadate and a number of simple peptides.[a]

Peptide	^{51}V Chemical Shift (ppm)	K_1 (pH 7.0) (M^{-1})	K_2'' (variable pH)	pK_a[b]
Formation constants from concentration and pH variation studies				
GlyHis	−511	101 ± 6	$(1.1 \pm 0.2) \times 10^{-5}$	7.0 ± 0.2
HisGly	−513	67 ± 4	$(2.0 \pm 0.3) \times 10^{-5}$	6.7 ± 0.3
HisSer[c]	−517	320 ± 20	$(1.5 \pm 0.4) \times 10^{-5}$	7.5 ± 0.2
HisSer[c]	−503	20 ± 10	$(4.8 \pm 1.9) \times 10^{-5}$	7.8 ± 0.2
Formation constants from spectra obtained at pH 7.0				
GlyThr[d]	−511	28		
GlyThr[d]	−497	17		
GlyGlu	−508	23		
GluGlu	−516	45		
GluLys	−513	93		
AlaHis[e]	−519	270 ± 10		
No products were observed, under the reaction conditions, with up to 30 mM N-CBz-HisGly, 60 mM GlyHisGly, 100 mM GlyGlySar				

[a]All formation constants were obtained for aqueous solutions with 20 mM HEPES buffer and an ionic strength of 1.0 M maintained with KCl.

[b]The pK_a values are for the product complexes and were determined from the variation of the product formation constant as a function of pH.

[c,d]The −517,−511 ppm signals arise from reaction at the carboxylate group; the −503,−497 ppm signals from reaction involving the hydroxyl group of the side chain. The formation constants of the −517,−503 ppm and −511,−497 ppm pairs should not be compared as they are for different types of equilibrium reactions.

[e]The formation constant is for pH 7.2 and 0.2 M NaCl, calculated from the data in Table 2 of ref. 13 as discussed in the text.

For personal use only.

serine for the −503 ppm product. The loss of a proton from the hydroxyl group in the second case means there is no difference in charge state at the vanadium nucleus of the two products; both can be designated as VP^-. Overall, then, the −517 ppm product is a complex that can take up, but not release, a proton as described by eq. [8]. The −503 ppm product is also ionizable but, since the loss of the initial proton is from the CH_2OH group when the product is formed, this complex can lose, but not gain, an additional proton. Equation [10] describes this latter type of behaviour.

$$[10] \quad VO_4H_2^- + P^+ \underset{}{\overset{K_2'''}{\rightleftharpoons}} VP^- + H^+$$

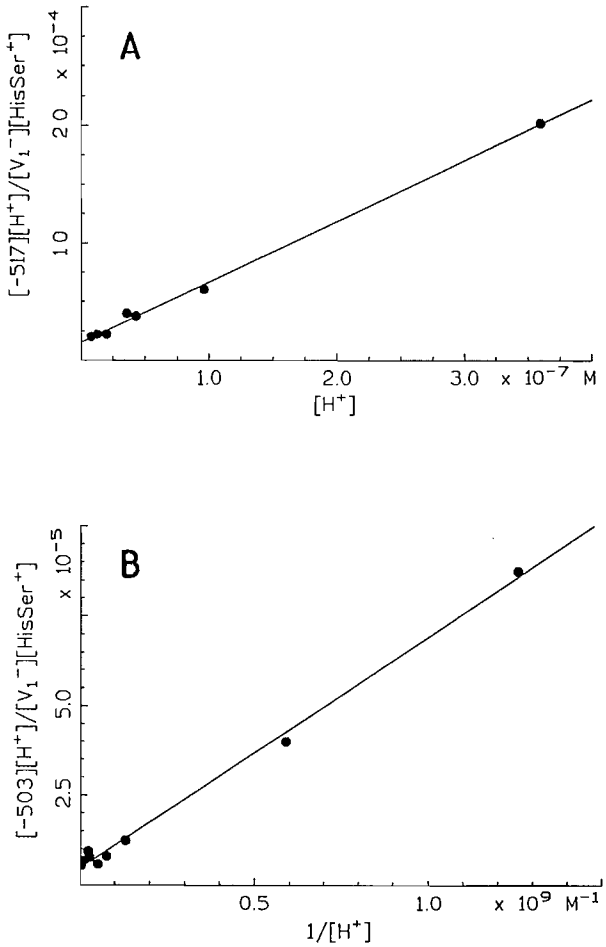
$$K_a \Big\| \Big\downarrow H^+$$

$$VP^{2-}$$

Figure 4*A* shows a plot of the experimental results for the −517 ppm product according to eq. [9]. The graph is similar to those obtained for glycylhistidine and for histidylglycine. The intercept gave a value of $(1.5 \pm 0.4) \times 10^{-5}$ for K_2''. The upward slope of this graph is consistent with a pK_a for the product ($pK_a = 7.5$). Figure 4*B* shows a similar plot, but based on eq. [10], for the −503 ppm product. The intercept, $K_2''' = (4.8 \pm 1.9) \times 10^{-6}$, gives the formation constant for the monoanionic product. This value is about a factor of 10 larger than the analogous value for glycylserine (11). In the case of glycylserine, a third component was observed and assigned to an isomeric product of reaction at the hydroxyl group. A third product was not observed here. This is consistent with the previous assignment, since in the present case steric interactions involving the imidazole ring could selectively discriminate against one of the isomers. Proton NMR spectra from D_2O solution also showed that there was formation of only two products.

The upward slope of the graph shown in Fig. 4*B* arises because of the pK_a of the −503 ppm product ($pK_a = 7.8$). The pK_a values for the −517 and −503 ppm products, 7.5 and 7.8 (Table 1), respectively, are significantly larger than those of the histidine in the free ligand, $pK_a = 7.0$ (experimental section). It was possible to show that a proton was being lost from the imidazole ring by carrying out a pD variation study in D_2O solution. This study revealed an almost identical pD dependence of the histidyl ^1H NMR signals from the histidylserine ligand and the −517 ppm product complex, suggesting an insignificant difference in pK_a between the imidazole in the product and in the free ligand. Over the pD range of 6.22–8.49, the C1 proton of the imidazole ring (see Scheme 1) of the free ligand underwent a chemical shift change of −0.57 ppm, while the chemical shift of the corresponding imidazole proton in the product changed in a corresponding manner by −0.53 ppm. These results clearly showed that the imidazole ring was not complexed and, in addition, indicated that the pK_a measured from the pH dependence of the formation constant of the product is not the same parameter as the pK_a of the imidazole ring. This means, therefore, that at the vanadium centre

Fig. 4. The dependence on hydrogen ion concentration of the formation of the two major products of the reaction of histidylserine with vanadate is shown. *A* is consistent with the uptake of a single proton by a −517 ppm monoanionic product with increasingly acidic conditions. *B* indicates the loss of a proton from a −503 ppm monoanionic product under increasingly basic conditions. The conditions of the experiments were as follows: total vanadate, 3.0 mm; total histidylserine, 9.0 mM; KCl, 1.0 M; HEPES buffer, 20 mM; pH variable, pH 6.45–9.46.

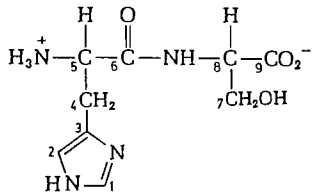


the charge state remains constant at −1 as the product is formed. Clearly, however, an additional proton can be given up from the vanadium centre and, of course, also from imidazolium but in independent reactions.

Additional information about the product complexes was obtained from ^{13}C NMR spectra. Table 2 gives the carbon chemical shifts, for both the ligand and the product complexes, for a selection of pD values. The coordination-induced shifts are also given.

The −517 ppm product, the product favoured by lower pH, shows significant coordination shifts only for the backbone carbons. This is consistent with a tridentate complexation involving the terminal nitrogen, terminal carboxyl, and peptidp nitrogen as proposed earlier for simpler peptides with nonfunctionalized side chains (9, 11). For the −503 ppm product there is a large complexation shift for the carbon of the serine hydroxymethyl group. This supports the pH study that revealed the loss of a single proton as this product is formed. In

Scheme 1



this case a $-CH_2O^-$ rather than a $-CO_2^-$ is the ligating group. No large coordination shifts were observed for the imidazole carbons, reinforcing the view that no vanadium–imidazole bond is generated as the complex is formed.

The fact that an additional proton can be lost from the vanadium centre of either complex almost certainly means that the products are not five-coordinate. If they were, the proton being lost in the subsequent deprotonation reaction would originate from the ammonium group ($V\text{-}NH_2$-) of the complex since there are no other protons. There is no evidence from this work that the terminal amino functionality is complexed as other than an amino group when either of the products is formed. The $-O^-$ of monoanionic vanadate ($VO_2(OH)_2^-$) might form a hydroxo ligand in the early stages of product formation, possibly by the ammonium changing to amino during the initial stages of complex formation. Following this formalism, an aquo ligand would subsequently be formed by incorporating the hydrogen from the peptide nitrogen into one of the hydroxo ligands as the reaction proceeds, with elimination of water, to form products. Loss of any protons would have been revealed in the pH variation study. The only alternative is that there is proton transfer from the NH_2 group to a hydroxo group to form an aquo ligand. This seems unlikely, but it is possible and might account for the slow formation of these products. The two possibilities are depicted in Scheme 2. (Note that a five-coordinate product would be formed if water was released from **A**.) A reviewer has suggested that the ^{13}C coordination-induced shift of the carbon 5 (~11 ppm) is not large enough to account for the formation of a product such as **B**. This argument has merit since, for **B**, the bonding about nitrogen would, in essence, go from that of a primary ammonium functionality in the free ligand to a secondary amino group in the product. In product **A** the ammonium-type functionality is retained as the product is formed.

Phenylglutamate

Experimental results from a detailed study of the reaction of this dipeptide with vanadate have been reported (17). These results were interpreted to mean that in addition to the expected mononuclear monoligand product, VP, an additional binuclear bisligand product (V_2P) was formed. In view of the complications that can arise from competing interactions and the conclusions drawn from the original work, reevaluation of the published data might provide some useful insights. It has previously been shown that vanadate undergoes a condensation reaction with carboxylates to form a product that is in rapid equilibration with its precursors (18). It is then necessary to analyze the original data in accordance with eq. [5]. When the data were plotted as appropriate for eq. [5], the intercept was $(3.1 \pm 0.3) \times 10^{-3}\ M^{3/4}$, which corresponds to $(1.1 \pm 0.4) \times 10^{10}\ M^{-3}$ for K_{14}. This intercept can be used in conjunction with the concentrations of tetravanadate to ascertain the concentration of monovanadate for all ligand concentrations

[a]All ^{13}C NMR shifts are for 90 mM total vanadate and 100 mM histidylserine in D_2O solution at the indicated pH except for the ligand spectra where 90 mM KCl was added as an electrolyte to repalce the vanadate in the solution. The shifts quoted are for the numbering system shown in Scheme 1.

[b]Product complexes are identified by their ^{51}V chemical shifts.

[c]No signal was observed for this carbon. The signal is expected to lie under those of the free ligand and the −517 ppm product.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

of the study, an important factor for further analysis of the data.

Examination of the data for the major product of the reaction (−515 ppm, pH 7.6) was carried out according to eq. [4]. For this analysis, the concentration of monovanadate was determined from that of tetravanadate and its formation constant. This allowed the formation of the carboxylate-derived product, described above, which is in rapid equilibration with V_1, to be accounted for. Under these conditions, the downward curvature in the graph that was previously reported from the ligand concentration study was not observed (Fig. 5*A*). This result, therefore, is not consistent with the formation of a binuclear monoligand product, as previously reported from analysis of these data (18). The formation constant obtained from this analysis for VP (−515 ppm), obtained from the ligand concentration study, was $(2.4 \pm 0.2) \times 10^2$ M^{-1} (Fig. 5*A*) and $(2.1 \pm 0.1) \times 10^2$ M^{-1}(Fig. 5*B*) from the vanadate ion concentration study (all data from ref. 15). There is no evidence, in Fig. 5*B*, of upward curvature. Therefore, this second graph also provides no evidence for formation of a monoligand bisvanadate product.

Tyrosylglycine

Reaction of tyrosylglycine with vanadate at pH 7.0 revealed the formation of a single product with a vanadium chemical shift of −513 ppm. A vanadate ester formed at the phenolic hydroxyl group will also have formed (14) but it was not observed at the rather low peptide concentrations of this study, maximum 15 mM. The measured formation constant was 34 ± 3 M^{-1} for pH 7.0. The pH variation study did not reveal the formation of any additional products. It did, however, show that the observed product carried a single negative charge and that this product had a pK_a of about 9. The broad product signal could not be accurately integrated at the high pH values, where the signal was of low intensity. As a consequence the pK_a value was only poorly defined.

The reaction of glycyltyrosine with vanadate was not studied in detail. The spectra that were obtained gave a formation constant of about 70 M^{-1} for the product at pH 7.0. A rather detailed study of this system, carried out at pH 7.2, has been reported (18). The reported data give a value of $(1.1 \pm 0.1) \times 10^2$ M^{-1} for K_1.

No product was observed to form with 60 mM tyrosylglycylglycine. Similarly 60 mM tryptophylglycylglycine did not yield an observable product. However, products were formed with tryptophylglycine, glycyltryptophan, tyrosyltyrosine, and similar ligands. Table 3 lists the compounds studied and the product formation constants.

A study of glycyltyrosine has reported the formation of products that are different from those described above and that are formed after several days of incubation (16). Such products were also observed here but they have not been studied in detail. Because of the long incubation times it is possible that an oxidative reaction occurs to give these products. Vanadate is known to oxidize phenolic materials and any V(IV) produced in the oxidation would quickly recycle to V(V) by air oxidation. This could account for the observed NMR spectra.

Tryptophyltyrosine

Only one product was observed from the reaction of tryptophyltyrosine with vanadate. The product observed gave a ^{51}V NMR signal at −520 ppm. This chemical shift is close to that observed for the products formed with other peptides. As for tyrosylglycine, no product of reaction at the hydroxyl group was observed because of the low concentrations employed in the study. When the experimental results were correlated according to eq. [4], a good linear relationship was observed as is shown in Fig. 6. The product formation constant, K_1, obtained from this graph was $(5.7 \pm 0.3) \times 10^2$ M^{-1}.

A pH variation study was carried out for a total ligand concentration of 9.0 mM. The results provided no evidence for additional products. The linear correlation obtained when the

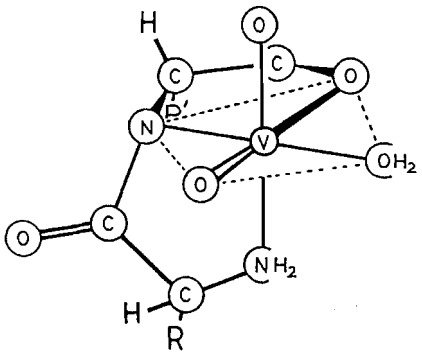
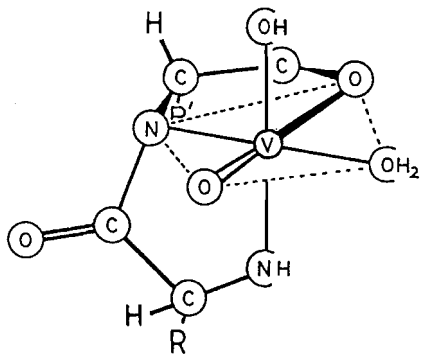
Scheme 2



A



B

reaction was written according to eq. [11] gave a pK_{a2} of 8.5 for the product and a value for K_1' of $(2.1 \pm 0.7) \times 10^2\ M^{-1}$.

[11] $H_2VO_4^- + \text{trptyr} \overset{K_1'}{\rightleftharpoons} VP^-$

K_{a2}' H^+ K_a H^+ K_{a2} H^+

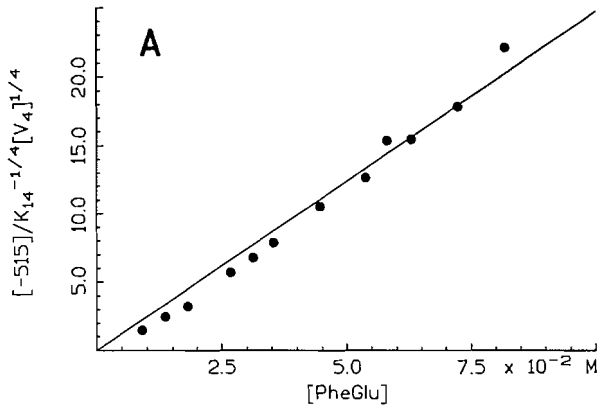
HVO_4^{2-} trptyr^- VP^{2-}

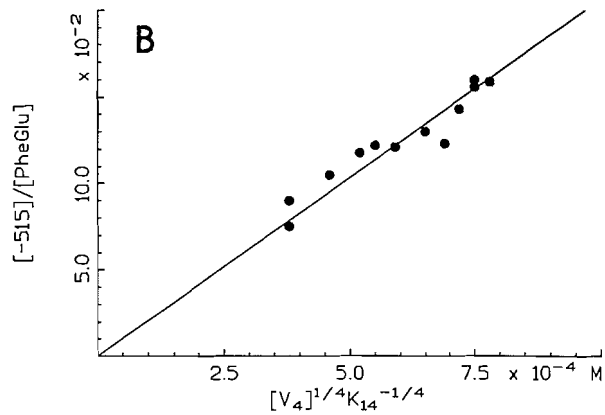
Tryptophyltryptophan

The only observed product of the reaction of tryptophyltryptophan with vanadate gave a −518 ppm NMR signal. A product formation constant of $(1.8 \pm 0.4) \times 10^2\ M^{-1}$ was determined for this ligand. The pH variation study, carried out at 7 mM total ligand, did not reveal the formation of any additional products but gave a value for K_1' of $(2.2 \pm 0.3) \times 10^2\ M^{-1}$ and of 8.1 for the pK_{a2} of the product. This pK_{a2} can be compared with the value of 8.5 obtained for the tryptophyltyrosine product, those in the order of about 7 for the histidine-derived products, and those of about 10 for other dipeptides that have aliphatic side chains (11).

In addition to the preceding two dipeptides, several others with aromatic side chains were studied in a cursory fashion at pH 7.0 and formation constants were estimated by ignoring possible complicating factors such as those already discussed. The results are presented in Table 3.

Fig. 5. The formation of the −515 ppm product of the reaction of phenylglutamate with vanadate is shown. The data for Fig. 5*A* are taken from the ligand concentration study portion of Table 1, ref. 18 while the data for Fig. 5*B* are from the vanadate concentration study section of the same table. The conditions for the experiments were (*A*) total vanadate, 10.0 mM; variable phenylglutamate, 10–90 mM; pH, 7.5; ionic strength, 1.0 M with NaCl; (*B*) total phenylglutamate, 30 mM; variable added vanadate, 3.0–27 mM; pH, 7.5; ionic strength, 1.0 M with NaCl.





Discussion

Product formation, in all the systems studied here, involves tridentate complexation through the peptide nitrogen, the N-terminal nitrogen, and a C-terminal oxygen, as for dipeptides containing nonfunctionalized side chains (9, 11). For the histidine-containing ligands, the formation of the product is quite sensitive to the protonation state of the imidazole ring in free ligand. Presumably this, to a large extent, reflects conformational changes associated with the varying protonation states. ^1H NMR studies of the histidine signals of histidylserine showed that the pK_a values of the imidazolium in the free ligand and in the vanadium complex are not much different from each other. It is expected that this finding also applies to the other histidine-containing ligands of this study (Table 1).

Table 3. Formation constants and ^{51}V chemical shifts for the products of the reaction of a number of dipeptides with vanadate.

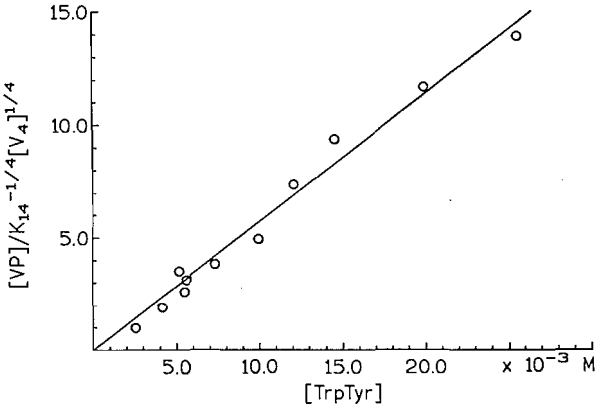
Dipeptide	^{51}V chemical shift (ppm)	K_1 (pH 7.0) (M^{-1})	pK_a
TrpTyr	−520	570 ± 30	8.5 ± 0.3
TrpTrp	−518	180 ± 40	8.1 ± 0.3
TrpPhe[a]	−519	47	
TyrTyr[a]	−519	140	
TyrGly	−511	34 ± 3	
GlyTyr[a,b]	−510	125	
GlyTrp[a]	−510	144	
TrpGly[a]	−511	101	
PheGlu[a,b]	−515	252	
No chelate products were observed under the reaction conditions for 60 mM TyrGlyGly,[c] 80 mM TrpGlyGly			

[a]Values for K_1 were estimated for a small number of spectra obtained at pH 7.0 for each ligand.

[b]The reported value was obtained from the pH 7.2 data in ref. 18 and corrected to pH 7.0.

[c]Reaction at the hydroxyl group of the tyrosine ring was observed, as expected (14).

Fig. 6. A graphical representation of the formation of the −522 ppm product of the reaction of tryptophyltyrosine with vanadate is shown. The graph is consistent with the formation of a monoligand monovanadium product. The conditions of the experiments were as follows: total vanadate, 6.2 mM; total tryptophyltyrosine, variable, 3.0–30 mM; pH, 7.0; ionic strength, 1.0 M with KCl.



The presence of significant electrostatic or hydrogen-bonding interactions between the vanadium centre and the imidazole ring in the product would be expected to have a large effect on the pK_a of the imidazole, compared to that of the free ligand. Since any such effect must be small, it is evident that the pK_a of the imidazole is not the same parameter as the pK_a determined from the pH dependence of the formation constant. They need not be the same because product formation is not necessarily influenced by the charge on a remote group. As previously mentioned, with such dipeptides as glycylglycine, the second pK_a of the product is about 10 (11). There is no apparent reason why this value should drop to near 7 because of the presence of a histidine rather than a glycine. However, other complexes with dipeptides that have an aromatic side chain, tryptophyltryptophan and tryptophyltyrosine, also had reduced pK_a values (Table 3). It seems evident, therefore, that aromatic side chains, including that of histidine, have a significant effect on the stability of vanadate complexes of dipeptides, even though there is no evidence for vanadium – aromatic group bond formation. In the case of histidine, the evidence clearly shows there is no vanadium–imidazole bond formation. A recent X-ray study of a histidine-containing complex also did not show a vanadium – imidazole nitrogen bond (19) although, in other systems, such bond formation does occur as, for example, in a salicylidene – ethyl imidazole complex (20). It is possible that products with imidazole–vanadium bonds also form here but, if they do, they are comparatively disfavoured products.

Dipeptides containing other aromatic side chains such as those of tyrosine or tryptophan do not appear to react much differently with vanadate than do nonfunctionalized peptides. The product formation constants tend to be somewhat larger for the aromatic systems but this may, to a large extent, simply reflect changes in the population density of the various rotomeric isomers of the uncomplexed dipeptides. Clearly, however, electronic influences of the aromatic rings cannot be ignored.

Side chains such as those of glutamate or lysine apparently have little influence on formation of dipeptide–vanadate complexes, although the side-chain carboxylate group of glutamate will react to form an anhydride similar to those formed with acetate and other carboxylic acids (21).

Only seryl and threonyl side chains have been observed to coordinate to vanadate and do so by substituting a terminal carboxylate oxygen of the dipeptide by the oxygen of the hydroxyl group. In the latter case, a proton is released as products are formed (this work, and ref. 11).

With only a few exceptions, in the examples that have been studied, the major products have ^{51}V chemical shifts between −510 and −520 ppm with the frequency shifting to about −500 ppm when a hydroxyl replaces a carboxyl group in the product complex. In this regard, it is interesting to note that vanadate complexes with a number of multidentate ligands related to the peptides of this study had chemical shifts varying from −507 to −521 ppm when the ligand contained a carboxylate group and below 500 ppm for hydroxyl-containing derivatives. A six-coordinate geometry was proposed for these materials (10). A crystalline material prepared from the tetradentate ligand, tris(2-hydroxyethyl)amine, has been characterized by X-ray diffraction studies (22). This material is pentacoordinate but the ^{51}V chemical shift (−483 ppm, ref. 10) is outside the range of chemical shifts observed for the complexes studied here. Overall, for the peptide complexes, the evidence strongly supports a coordination of the form displayed in Scheme 2(**A**) but, for the reasons discussed earlier, a pentacoordinate geometry cannot be unequivocally ruled out.

Abstract: The X-ray crystal and molecular structures of the three benzodiazepine (BZD) receptor ligands are presented and the electronic character of inverse agonist ligands is probed through molecular orbital calculations. Two of the ligands have a 6-benzylamino substituent: 6-benzylamino-β-carboline-3-carboxylic acid methyl ester, **1**, which is a high affinity antagonist with IC_{50} = 10 nM, and 6-benzylamino-β-carboline, **2**, which is a moderate affinity inverse agonist with IC_{50} = 106 nM. The third compound, 3-ethoxy-β-carboline hydrochloride, **3**, displays partial inverse agonist activity with an IC_{50} of 24 nM. Intermolecular interactions, including extensive hydrogen bonding involving both the pyridyl nitrogen atom and the indole N—H as well as π stacking of aromatic rings, are characteristic of β-carbolines and are found in these three structures. In addition, two of these compounds are protonated in the crystalline state, thereby providing a model for interactions in the absence of the 3-carboxylic acid ester function. Electronic calculations show that (1) the partial inverse agonist ligand has the highest charge on the N(2) atom and (2) high affinity β-carbolines possess two neighboring sites that have high electrostatic attraction for a hydrogen atom in an intermolecular interaction. These findings suggest that modifications to the 3-position side chain to enhance the charge on the pyridyl N atom and provide a hydrogen bond acceptor site will facilitate the development of *partial* inverse agonist ligands.

Key words: β-carbolines, benzodiazepine receptor, crystallography, structure–activity relationships.

Résumé : Faisant appel à la diffraction des rayons X, on a déterminé les structures cristallines et moléculaires de trois coordinats récepteurs de benzodiazépine (BDZ) et on a évalué le caractère électronique des coordinats agonistes inverses à l'aide de calculs d'orbitales moléculaires. Deux des coordinats portent un substituant 6-benzylamino, soit l'ester méthylique de l'acide 6-benzylamino-β-carboline-3-carboxylique (**1**), un antagoniste de grande affinité avec IC_{50} = 10 nM, et la 6-benzylamino-β-carbonlin (**2**), un agoniste inverse d'affinité modérée avec IC_{50} = 106 nM. Le troisième composé, le chlorhydrate de la 3-éthoxy-β-carboline (**3**), présente une activité agoniste inverse partielle avec IC_{50} = 24 nM. Les interactions intermoléculaires, comprenant des ponts hydrogènes importants impliquant l'atome d'azote du pyridyle ainsi que le N—H de l'indole de même que l'empilement π des noyaux aromatiques, sont caractéristiques des β-carbolines et on les retrouve dans les trois structures. De plus, deux de ces composés, protonés à l'état cristallin, peuvent servir de modèles pour les interactions en l'absence de la fonction ester de l'acide 3-carboxylique. Les calculs électroniques montrent que (1) le coordinat avec une activité agoniste inverse partielle porte la charge la plus importante sur l'atome N(2) et (2) que les β-carbolines de plus grande affinité possèdent deux sites voisins qui ont une grande attraction électrostatique pour un atome d'hydrogène dans une interaction intermoléculaire. Ces observations suggèrent que des modifications à la chaîne latérale en position 3 augmentent la charge sur l'atome d'azote du pyridyle et qu'elles fournissent un site accepteur de liaisons hydrogènes qui facilite le développement de coordinats possédant une activité agoniste inverse *partielle*.

Mots cles : β-carbolines, récepteur de benzodiazépine, cristallographie, relations structure–activité.

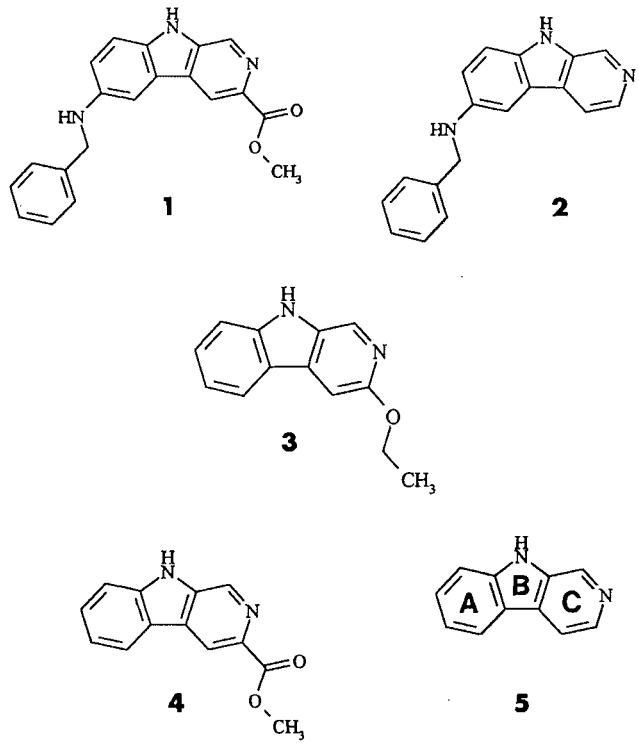
Introduction

The benzodiazepine (BZD) receptor found in brain is part of a ligand-gated ion channel that contains the γ-amino butyric acid (GABA) receptor and the chloride ionophore (1, 2). Ligands for the central nervous system BZD receptor allosterically modulate responses to GABA and mediate anticonvulsant, anxiolytic, hypnotic, and sedative effects (3). Agonist ligands for the receptor elicit these responses, antagonists bind and elicit no response, and inverse agonist ligands elicit opposite responses (convulsant, etc.). In addition to useful properties, the drugs often induce unwanted effects, like amnesia, and tolerance is rapidly developed. Recently the focus has been on the design of ligands that elicit a *partial* response: partial agonists show fewer side effects and partial inverse agonists may be useful as cognition enhancers. Efforts to develop more effective ligands have been advanced by recent progress toward understanding the molecular composition of the receptor complex. The receptor complex has been cloned and functional multisubunit complexes have been expressed; however, the exact stoichiometry of the functional complex in the central nervous system is not known (4). The receptor complex shows extensive heterogeneity, including six forms of the α subunit, three forms of the β subunit, three forms of the γ subunit, and a δ subunit (4). The presence of three types of subunit, α, β, and γ, is required for a functional ion channel controlled by GABA and modulated by BZDs. BZD ligands appear to interact with the α subunit but only behave as modulators of GABA when the γ subunit is also present. Structure–function studies (5–7) on reconstituted channels suggest that different subtypes recognize ligands with different effects, although this information is neither unequivocal or sufficiently broadly tested to be conclusive. Tests on reconstituted complex with a small set of ligands (agonist benzodiazepines and inverse agonist β-carbolines) suggest that the binding sites of agonists and inverse agonists may be in different domains and may be modulated by the specific combination of types of α and γ subunit. Unfortunately, different chemical species (β-carboline inverse agonists and benzodiazepine agonists) were tested, which prevents simple deductions from the evidence; however, these results open the possibility that separate sites for positive and negative efficacy ligands may exist and may require reconceptualization of many of the current models (see ref. 8 for a review) for the BZD binding site.

The structural features that favor binding of a β-carboline at the BZD receptor have been established (9–15). They include a planar, unsaturated ring system, a basic pyridyl N atom, an unobstructed indole N-H group, and at least one additional substituent: either (*a*) a side chain in position 3 that contains a carbonyl oxygen atom or is electron releasing, or (*b*) a hydrophobic group in position 5 or 6, or (*c*) an oxygen-containing side chain in position 4. The binding affinity and specific activity of the β-carbolines seems to be determined by recognition of each of these different types of side chain and a balance among the recognition sites. Many β-carbolines have been synthesized and tested in an effort to develop effective agonist ligands for the BZD receptor. Predicting the balance between the effects of the side chains (*a*)–(*c*), as described above, is challenging. Compound ZK93423, 6-benzyloxy-4-methoxymethyl-β-carboline-3-carboxylic acid ethyl ester, is a potent BZD receptor agonist (IC_{50} = 1.0 nM) (16). When a 6-benzylamino group (17) is added to position 6 of either of the



β-carbolines **4** and **5**, as an isostere for the benzyloxy group, the compounds do not have agonist activity. The addition of the 6-benzylamino to the inverse agonist βCCM (**4**) produces an antagonist, 6-benzylamino-β-carboline-3-carboxylic acid methyl ester, **1**. The same substitution in norharmane, **5**, a compound that has no detectable activity, produces 6-benzylamino-β-carboline, **2**, which is an inverse agonist (17). It appears that substituents in all three positions, (*a*)–(*c*), may be required to achieve agonist activity (18).

In addition to the goal of understanding the components dictating specific activity, a detailed understanding of the features that determine affinity is needed to design partial agonists (19), which are the preferred therapeutic targets because they induce fewer side effects. Thus, exercising precise control over the efficacy of BZD ligands is required. The compounds presented here present some of the issues related to understanding affinity and hence efficacy. The addition of the 6-benzylamino group greatly enhances the affinity of **2** over norharmane (**5**) and may suggest that there is an additional binding site on the receptor, perhaps hydrophobic in nature, which interacts with the benzylamino groups of **1** and **2**. However, compound **1** does not bind more effectively than the related compound βCCM, compound **4**, which has an IC_{50} = 1 nM, even though **1** possesses both the hydrophobic side chain in position 6 and the 3-methyl ester of compound **4**. This difference suggests either that the side chains produce complex electronic effects or that molecular size (in particular, molecular length) is an important criterion for binding. To further investigate the electronic effects of ligands, we studied compound **3**, 3-ethoxy β-carboline, which has an IC_{50} value of 24 nM and an activity profile similar to βCCM and compound **2**, which has an electron-releasing group in position 3. The profiles of the three compounds (**2**, **3**, and **4**) suggest that reasonable affinity and inverse (or partial inverse) agonist activity

[a]The reflections used in the refinement included the observed reflections and those unobserved reflections for which $F_c^2 > 2.5\ \sigma(F_o^2)$.

can be achieved by either an electron-withdrawing or electron-releasing group in the 3-position or by no substituent at the 3-position and a substituent at the 6-position, whereas the presence of both substituents (at 3 and at 6) produces an antagonist of high affinity (**1**).

We report the results of crystal structure determinations of compounds **1**, **2**, and **3**, which establish their preferred intermolecular interactions, along with the results of molecular orbital calculations on the inverse agonists (compounds **2**, **3**, and **4**), which establish the electronic effects of their side chains. This study seeks to provide explanations for the complex structure–activity profile of β-carbolines.

Experimental section

X-ray crystallography

Samples were crystallized in the Wisconsin laboratory from an ethyl acetate – ethanol mixture (**1**), from acetic acid (**2**), and from an ethanol–hydrochloride mixture (**3**) by a slow evaporation. X-ray intensity data were collected at room temperature on an Enraf–Nonius CAD-4F automated diffractometer with Ni-filtered CuK_α radiation (λ = 1.54178 Å) using an ω/2θ scan mode. The cell parameters and orientation matrices were determined by least-squares refinement of the angular positions of 25 reflections with θ-values in the range 41°–67° for **1**, 24°–31° for **2**, and 36°–39° for **3**. During the data collection the intensities of three standard reflections were measured every 2000 s of exposure; they showed no significant variation. All intensities were corrected for Lorentz and polarization effects; absorption corrections were not applied. A summary of crystal data and details of the structure refinements are given in Table 1.

All three structures were solved by direct methods, structures **1** and **2** using MULTAN78 (20*a*) and structure **3** using SHELXS86 (20*b*). Structures 1 and 2 were found to contain two independent β-carboline molecules per asymmetric unit together with several solvent molecules: one molecule of ethyl acetate in **1**, and three acetic acid molecules and one water molecule in **2**. Structure **3** contained one protonated β-carboline and one chloride ion in the asymmetric unit.

All H atoms, except for those of the carboxyl groups in the acetic acid molecules of **2**, were located in difference Fourier syntheses after isotropic refinement. In **2**, subsequent cycles of anisotropic refinement revealed the positions of two of the acetic acid carboxyl H atoms that were hydrogen bonded to the pyridyl nitrogen atoms of the two β-carboline molecules. In molecule **2***a*, the pyridyl N atom was fully protonated. In molecule **2***b*, a ΔF map contained two peaks between the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

pyridyl N atom and one of the acetic acid carboxyl oxygen atoms. One of these peaks was located 1.23 Å from the nitrogen atom, the other 1.28 Å from the oxygen atom. The peaks were of equal height, indicating that the pyridyl N atom of molecule **2***b* is protonated in 50% of the molecules and that the H atom is bonded to the acetic acid molecule in the other half of the molecules. Both H atoms were included in the refinement with fixed coordinates, occupancy factors of 50%, and isotropic thermal parameters equal to 120% of the U_{eq} values of the appropriate N and O atoms. The H atom of the carboxyl group of the third acetic acid molecule (A3) was not located. In contrast to the complex pattern in the crystal structure of compound **2**, in **3** the difference Fourier synthesis indicated that the pyridyl N atom was fully protonated; this difference is probably due to the difference in strength of the acids used in formation of the β-carboline salts.

In structures **1** and **2**, blocked least-squares refinement was performed with the two independent β-carboline molecules in separate blocks and the parameters of the solvent molecules in one (for structure **1**) or two (for structure **2**) blocks. Refinement was done on *F*. In the final cycles of all three structural refinements, the coordinates and anisotropic thermal parameters of all the non-hydrogen atoms and the coordinates and isotropic thermal parameters of most of the H atoms, including all those involved in the hydrogen bonding to β-carboline molecules, were varied. The remaining H atoms were held in fixed positions with U_{iso} equal to the average U_{iso} of the neighboring refined hydrogen atoms.

The reflections used in the refinements included the observed reflections ($I > 2.5\ \sigma(I)$), and those unobserved reflections that had $F_c^2 > 2.5\ \sigma(I)$. Non-hydrogen atom scattering factors and anomalous dispersion corrections were from Cromer and Mann (21) and the H-atom scattering factors from Stewart et al. (22) The isotropic extinction correction used is based on the method of Larsen (23) and Zachariasen (24). All of the calculations except structure solution were done with the XRAY76 system of programs (25) implemented on a Honeywell computer; drawings of the individual β-carboline molecules were prepared with the program ORTEPII (26); the least-squares superpositions of molecules were calculated with the program PROFIT (27) and drawn with the program PLUTO (28).

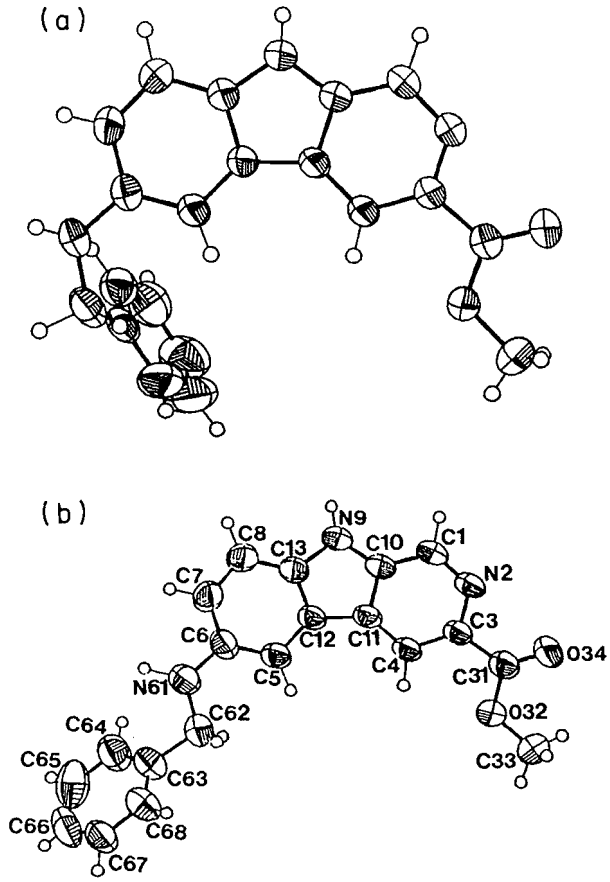
The atomic coordinates and equivalent isotropic thermal parameters for the non-H atoms are given in Table 2. The conformations of the β-carboline molecules and the atom labeling schemes are shown in Figures 1, 2, and 3. The bond distances and bond angles for the non-H atoms are listed in Table 3.[3]

[3] The anisotropic thermal parameters for the non-hydrogen atoms; coordinates, thermal parameters, bond lengths and angles for H atoms and for all atoms of solvent molecules; and the REFCODES of the Cambridge Structural Database search may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

Tables of atomic coordinates, bond lengths and angles, and the REFCODES have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallagraphic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

Fig. 1. Molecular structures and atomic labeling schemes for (*a*) molecule **1***a* and (*b*) molecule **1***b*.



Computational methods

Molecular mechanics calculations were performed using the MM2 force field and extensions to it as provided in the program Macromodel (29) implemented on an IBM RISC/6000 computer. Usage-directed Monte Carlo searching of conformational space was used to examine 3000 conformers with tabulation of those conformers within 50 kJ mol^{-1} of the lowest energy structure.

Ab initio molecular orbital calculations were done by using the GAUSSIAN90 program (30) implemented on an IBM RISC/6000 computer. All calculations were conventional closed-shell molecular orbital calculations wherein equilibrium values of the geometrical parameters were obtained by minimizing the molecular energy. The geometry of each molecular structure was fully optimized using the STO-3G basis set and a stationary point calculation of electronic properties was done with the 3-21G basis set. The 3-21G basis set was used with the SPARTAN program[4] to evaluate the electrostatic potential at attraction energies of -5, -10, -30, -50, and -70 kcal mol^{-1}. Calculations on the 6-benzylamino compounds (**1** and **2**) were done on a model that replaced the phenyl ring with a methyl group and, in all cases, the conformation of the 3-position side chain was restricted to the most common conformation observed in the crystal structure.

Results

In compound **1**, the conformation of the side chain in the 3 position places an oxygen atom in the plane of the β-carboline skeleton and *cis* to the pyridyl nitrogen atom. The coplanar conformation of the ester side chain in **1** allows formation of an extended π system over the side chain and the polycycle; the dihedral angle between the plane of the β-carboline and the plane defined by five side-chain atoms is 8.2(5)° in **1***a* and 5.6(5)° in **1***b*. The torsion angle N(2)-C(3)-C(31)-O(34), which determines the orientation of the carbonyl oxygen atom, is 6.6(5)° and 3.5(4)° in **1***a* and **1***b*, respectively. Although compound **3** does not have a 3-ester substituent, the side chain adopts a conformation that orients one of the lone pairs of electrons on the ether O atom toward N(2), a position similar to the orientation of the lone pairs on the carbonyl oxygen atom of

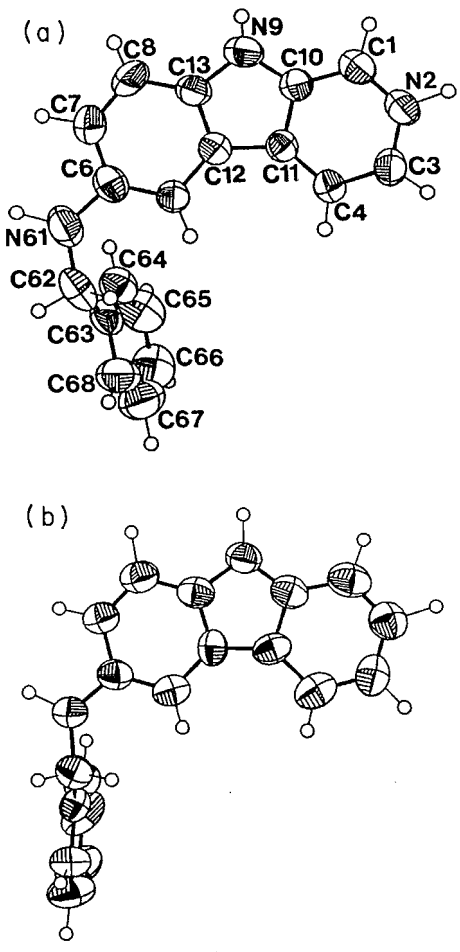

Fig. 3. Molecular structures and atomic labeling schemes for molecule 3.

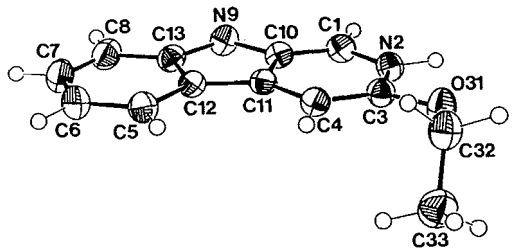

the ester side chain in **1** and related compounds. The ether oxygen atom and the first carbon atom of the ethyl group are in the plane of the polycycle; the torsion angle N(2)-C(3)-O(31)-C(32) is 171.5(2)°.

Compound **1** displays three-center hydrogen bonding, which involves both the ester side chain and the N(2) nitrogen function of the β-carboline. In each unique molecule, the indole N(9)-H donates a hydrogen atom to a neighboring molecule; this H atom is bonded to both the pyridyl N atom and to the carbonyl oxygen atom. The other two structures do not have an ester side chain and, thus, have different hydrogen-bonding patterns (all hydrogen bonds are tabulated in Table 4 and shown for structures **1** and **2** in Figs. 4 and 5). Both compounds **2** and **3** show protonation of the pyridyl nitrogen atom; protonation may be the result of either the acidic crystallization conditions or the greater basicity of the pyridyl nitrogen atom in the absence of the ester side chain. In molecule **2***a*, there is complete transfer of the proton from acetic acid molecule A1 to the pyridyl N atom; this transfer produces delocalization of the π electrons in the carboxyl group of the donor acetic acid molecule so that the two C—O bonds have similar bond lengths, 1.232(7) and 1.240(7) Å. About 50% of the pyridyl N atoms in molecule **2***b* are protonated, so the ob-

served geometry is an average over an ensemble of both protonated and deprotonated states. For **2***b*, the hydrogen-bonded acetic acid molecule (A2) has dissimilar C—O bond lengths of 1.345(7) and 1.225(6) Å. In each structure, the indole N(9)-H group acts as a hydrogen atom donor. In compound **3**, the electron-donating characteristics of the ether side-chain oxygen atom may help to stabilize the proton on N(2); in this structure, the chloride ions link molecules by hydrogen bonding to the protonated N atom and the indole N-H group. In both **1** and **2**, the benzylamino group participates in hydrogen bonding with solvent molecules, as shown in Figs. 4 and 5.

Stacking interactions between the aromatic systems are present in all three of the reported structures. The β-carboline skeletons of all five unique molecules in the three structures are planar; the standard deviations for the least-squares planes of the 13 non-H atoms are in the range 0.012–0.035 Å. In structures **1** and **2**, the π stacking interactions are limited by the out-of-plane conformation of the 6-benzylamino substituent in three of the four unique molecular conformations. Molecules **1***a* form pairs related by a center of symmetry as do molecules **1***b*, to produce a partial overlap of ring A with ring C. The distance between the parallel β-carboline skeletons is 3.459 Å in **1***a* and 3.406 Å in **1***b*. Molecules **2***b* form a close pair related by a center of symmetry; the molecules are 3.371 Å apart with overlap of rings A and B. Extensive overlap of aromatic rings occurs in structure **3** even though the terminus of the side chain is perpendicular to the β-carboline plane; centrosymmetric dimers stack in pairs separated by 3.292 Å.

Compounds **1** and **2** each have a 6-benzylamino substituent; however, as shown in Figs. 1 and 2, molecule **1***a* displays one conformation and molecules **1***b*, **2***a*, and **2***b* display another. In **1***a*, the torsion angle C(6)-N(61)-C(62)-C(63) is 179.8(3)°; the angle ranges in value from −63.4(3)° to −106.0(6)° in the other molecules. To establish the conformational properties of this side chain, the Cambridge Structural Database (31) was searched to identify the crystallographically observed conformations, and molecular mechanics calculations were used to evaluate the energy differences between these conformations. The database search revealed only three fragments with a ben-

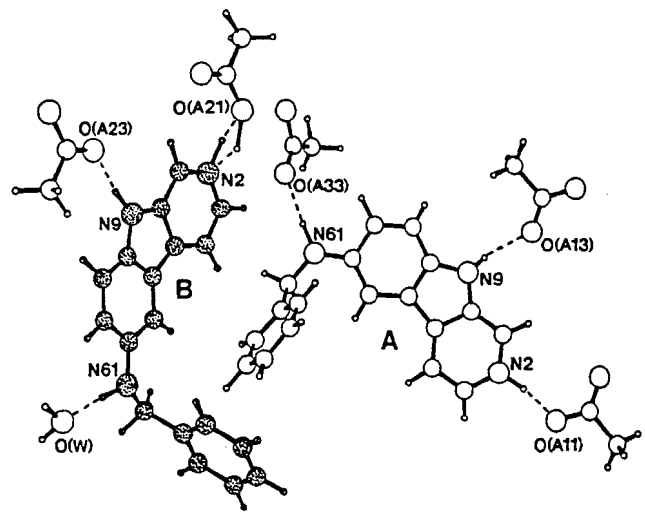
zylamino group attached to a phenyl ring; one of these has the extended conformation observed in **1***a* (with a C_{ph}-N-C-C torsion angle of 178.9°) while the two other have a bent conformation (with C_{ph}-N-C-C angles of −88.5° and −79.2°). A Monte Carlo search of 3000 conformations calculated by molecular mechanics (29) for the benzylaminophenyl fragment produced two highly populated, minimized conformations with torsion angles ±67.7° and 179.5°. The energies of the bent and the extended conformations are the same and the ratio of the populations (2.5:1) favors the bent conformer for statistical reasons due to the symmetry of the fragment (the (+) and (−) torsion angles have the same energy in the calculation). These findings indicate that the distribution of conformers found in the crystal (bent:extended = 5:2) is statistical. The torsion angle C(5)-C(6)-N(61)-C(62) is similar in all four molecular conformations presented here and the three conformations found in the database; this angle is always less than 15°, thereby placing the *p* orbital on the amino nitrogen atom perpendicular to the plane of the phenyl ring (ring A in the β-carbolines) and in position to interact with the aromatic system. In contrast to the benzylamino side chain present in these antagonist and inverse agonist ligands, *agonist* β-carbolines have a 6-benzyloxy side chain. Monte Carlo searching for the low-energy conformations of the benzyloxyphenyl fragment shows a slight difference in energy between the bent and extended conformers with the extended conformer favored by 1 kcal/mol; the distribution of extended to bent conformers is not statistical (1:1) and indicates that the extended conformation is slightly favored.

Fig. 5. The hydrogen-bonding pattern in **2** with hydrogen bonds shown as broken lines. The two unique molecules are labeled A and B and the solvent molecules are labeled A*n* for the *n*th molecule of acetic acid and W for the water molecule. Hydrogen bonds between solvent molecules are not shown but are listed in Table 4. Molecule B is partially protonated in its interaction with acetic acid molecule A2.



A comparison of the geometry found in **1** with that of the carboxylic acid methyl ester, βCCM (compound **4**, ref. 10), shows that the electron-releasing benzylamino group has an influence on the geometry of the β-carboline, with the greatest effect on the two indole C—N bonds that are across the A ring from the benzylamino group. The average C(13)—N(9) bond in **1** is significantly longer (1.395(9) Å), while the average N(9)—C(10) bond is shorter (1.352(4) Å). A similar difference between the two indole C—N bonds is observed in the geometry of **2**. Although the 3-ethoxy side chain is also electron releasing and across the C ring from N(9), the two C—

Table 4. Hydrogen bond geometry. N(9) bonds are nearly the same length in compound **3**: 1.372(2) and 1.378(2) Å, suggesting that the presence of N(2) in the C ring attenuates the effect of the ethoxy group. In the case of an electron-withdrawing group attached to C(3), as present in compound 4, the C—N(9) bonds are almost equal in length: averages over two observations are 1.374(3) and 1.376(6) Å; and, for comparison, these C—N bonds in an unsubstituted β-carboline, norharmane **5** (32), are equal and are 1.371(4) Å.

Comparison of geometries of the pyridine rings (C) shows that the protonation of the atom N(2) in **2** and **3** causes significant changes in the endocyclic bond angles. The C(1)-N(2)-C(3) angle increases from an average of 118.1(1)° for the unprotonated molecules in **1** to an average of 123.1(8)° for the fully protonated molecules **2***a* and **3**. The adjacent angles, C(10)-C(1)-N(2) and N(2)-C(3)-C(4), decrease by approximately 2.5°. Consistent with the partial protonation of atom N(2) in molecule **2***b*, these structural changes are slightly smaller in molecule **2***b* than in the fully protonated structures. These differences, which are due to protonation, are also evident in comparisons between these molecules and the unsubstituted and unprotonated structure, norharmane (32).

The atomic charges on the pyridyl N(2) atom show trends that are related to the electronic character of the side chain on C(3). Structures without a side chain, norharmane and compound **2**, have a charge of −0.648 on N(2). Structures with an electron-withdrawing group, the methyl ester, compound **1**, and βCCM, have smaller charges, of −0.638, on N(2). The highest charge on N(2), −0.686, is calculated for compound **3**, which has an electron-releasing substituent on C(3). The dipole moments of these compounds show an interesting trend. Norharmane has the lowest dipole moment at 3.116 debye and the antagonist, compound **1**, has the highest (5.827 debye). For the three inverse agonists, the trend in the values of the dipole moment follows the IC_{50} values. The lowest affinity compound, **2**, has the lowest dipole moment of 3.749 debye and the highest affinity compound, βCCM, has the highest value of 5.043 debye, with compound **3** falling in between with a dipole moment of 4.156 debye.

Discussion

Intermolecular contacts in crystals serve as models for the molecular interactions that determine recognition of a ligand at a receptor. Extensive crystallographic studies of β-carboline BZD receptor ligands (9, 11–14) have identified three characteristic interactions and proposed that they are important for recognition. The crystal structures of compounds **1**, **2**, and **3** display these interactions.

One interaction is a three-center hydrogen bond in which both the pyridyl nitrogen atom (N(2)) and the carbonyl oxygen atom of the ester side chain act as acceptors. Compounds **1** and **2** differ only in the presence or absence of the ester side chain that allows formation of the three-center hydrogen bond; the difference in the affinity of **1** (IC_{50} = 10 nM) vs. **2** (IC_{50} = 106 nM) suggests the additional interaction of a hydrogen atom with the carbonyl oxygen atom, as well as the pyridyl N atom, is important. As shown in Fig. 4, both unique conformations of compound **1** form this hydrogen bond. The *cis* conformation of the sp^2 hybridized N atom and the carbonyl oxygen atom facilitates formation of this three-center bond; this conformation is found in the crystal structures of most of the ester-containing BZD receptor ligands, regardless of the chemical type or the biological effect of the ligand (9, 11–14). The ethoxy conformation that is observed in crystals of structure **3** could also facilitate a three-center hydrogen bond; the protonation of N(2) represents complete proton transfer to one acceptor and is undoubtedly stabilized by the lone pairs on the ether oxygen atom. This hydrogen-bonding pattern may explain mutation experiments on the BZD binding subunit, α_1,

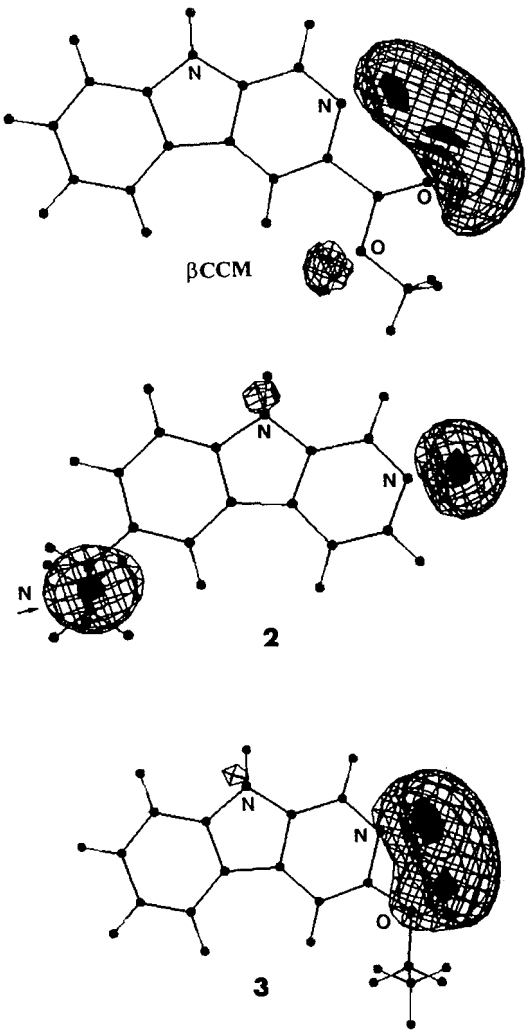
Fig. 6. Maps of the electrostatic potential surface for the three inverse agonist ligands, βCCM, molecule **2,** and molecule **3**. The mesh surface shows the area for an attractive interaction of −50 kcal/mol and the solid surface shows the −70 kcal/mol binding area.



which show that a histidine residue is important for binding agonists and antagonist ligands. Mutant α_1(Arg-101)$\beta_2\gamma_2$ receptors, wherein histidine was replaced with arginine, showed reduced affinity for agonists and the antagonist Ro15-1788 (33). The three-center hydrogen bond with an N-H group imbedded in a five-membered ring, as is observed in β-carboline crystal structures, is a good model for an interaction with histidine and could be formed by the antagonist Ro15-1788 (11); it would be useful if this α_1 mutant was tested against agonist β-carbolines to establish if the His is required for recognition of this type of agonist.

A second intermolecular interaction typical of β-carbolines is the stacking of aromatic rings and coplanar ester side chains. The stacking may model receptor interactions because fully aromatic β-carbolines display high affinity for the BZD receptor, in contrast to their saturated derivatives, which have low affinity for the receptor (9, 14). All of the structures reported here display close stacking of aromatic rings despite the bulk, and out-of-plane conformations, of the side chains in the structures.

The third intermolecular interaction found in inverse agonist β-carbolines is a hydrogen bond donated by the indole N(9)-H group. Methyl substitution at N(9) drastically reduces ligand affinity from IC_{50} = 5 nM for the β-carboline-3-carboxylic acid methyl ester (βCCM) to IC_{50} > 50 000 nM for its 9-methyl derivative (34), thereby suggesting the importance of this hydrogen bond. Even though the hydrogen-bonding patterns are quite different in the three structures reported here, in each case the indole N(9)-H participates in a hydrogen bond (see Table 4), which provides evidence that this group forms a hydrogen bond with the receptor.

The protonated β-carbolines in the structures of **2** and **3** provide a model for the type of interaction with the receptor that could arise for ligands lacking an ester side chain. Theoretical calculations by Loew et al. (35) have shown that protonation is less favored for 3-ester derivatives, by as much as 4.5 kcal/mol for βCCM (**4**) vs. norharmane (**5**). Our calculations of atomic charges, both with semiempirical methods (14) and with *ab initio* methods as reported herein, show that the electronic character of the side chain at position 3 influences the charge on N(2). Compounds **2** and **3** have the highest charge on N(2) and are observed as protonated molecules in the crystal. The absence of an ester side chain in structure **2** increases the basicity of the nitrogen atom and contributes to stabilization of the protonated form (as is true for norharmane in comparison to its methyl ester (36). βCCM and compound **1**, in contrast, have the lowest charges on N(2). A balance between these two extremes is achieved in compound **3** where the electron-releasing group at position 3 produces the largest negative charge at N(2) (see Results) and the protonated form is observed in the crystal.

Proton transfer to the pyridyl N atom and three-centre hydrogen bond formation are possible models for the ligand receptor interaction that can be deduced from the intermolecular interactions observed in the crystals. High charge on N(2) (which may result in proton transfer) seems to be correlated to the desired efficacy, that of *partial* inverse agonist, because compound **3** has reasonable affinity and the highest negative charge on N(2). Binding affinity seems to be better correlated with the presence of an oxygen atom in the 3-position side chain, since the two ester compounds, βCCM and compound **1**, have significantly higher affinity than the related compounds, norharmane and **2**, respectively, which lack a side chain in the 3 position. In addition, compound **3** has an ether side chain and high affinity. Examination of the electrostatic potential surfaces for **2**–**4** for the position of highest attraction for a proton reveals that the three inverse agonists differ in this respect and the difference is due to the side chain, see Fig. 6. The two high-affinity compounds have two positions with >70 kcal attraction energy for a proton; these positions are near N(2) and the O atom in the 3 side chain. Compound **2** has 10-fold lower affinity for the receptor and has only one position of >70 kcal attraction.

The results presented here suggest that a *partial* inverse agonist can be designed by choosing a side chain at position 3, which facilitates the three-center interaction with a proton or hydrogen bond donor and at the same time increases the charge on the N(2) atom. This suggestion for the side chain is supported by the computational results that find the highest charge on N(2) for compound **3** and the presence of two neigh-

For personal use only.

boring sites of attraction for a proton in the high-affinity ligands, and by the crystallographic results, which strongly indicate a particular side chain conformation and a three-center hydrogen bond interaction. These results suggest that the ester side chain common to β-carboline ligands is an unfortunate choice for *partial* efficacy because it serves to reduce the charge on N(2) and, indeed, may shift the preferred position for the hydrogen atom in the intermolecular interaction toward the O atom and away from the N(2) atom. Interestingly, although the ester side chain lowers the charge on N(2), this side chain confers highest affinity on the β-carboline ligands.

The antagonist activity of compound **1** is not explained by these findings. We hypothesize that the molecule is too large to fit into the binding site to the same extent as do the inverse agonists, and thus adopts a different geometry in the critical hydrogen bond interaction. This hypothesis is supported by the fact that β-carboline-3-carboxylic acid *tert*-butyl ester is also an antagonist. It may be that these larger ligands form hydrogen bonds with only the O atom of the side chain due to a restriction in access to the binding site.

In conclusion, the preponderance of crystallographic data on conformations and intermolecular interactions provides a working model for the shape of β-carbolines when bound to a receptor and for the bonds formed. Molecular orbital calculations show that the ligands with desirable effects and high affinity have identifiable electronic properties: desirable effect is found in the ligand with highest charge on N(2) and high affinity is found in the inverse agonist with the highest dipole moment. Taken together, these data suggest that modifications to the 3-position side chain to enhance the charge on the pyridyl N atom and provide an hydrogen bond acceptor site will facilitate the development of *partial* inverse agonist ligands.

Abstract: The crystal structures of hexakis(phenylthio)benzene (HPTB) and its CBr_4 clathrate have been determined by single crystal X-ray diffraction data collected at $T = 18°C$ and refined to final R_w of 0.036 and 0.047, respectively. Pure HPTB is triclinic, space group $P\bar{1}$ (No. 2), with $a = 9.589(2)$ Å, $b = 10.256(1)$ Å, $c = 10.645(2)$ Å, $\alpha = 68.42(1)°$, $\beta = 76.92(2)°$, $\gamma = 65.52(1)°$, and $Z = 1$. The CBr_4 clathrate of HPTB is rhombohedral, space group $R\bar{3}$ (No. 148), with $a = 14.327(4)$ Å, $b = 20.666(8)$ Å, and $Z = 3$. The host–guest mole ratio of HPTB–CBr_4 is 1:2. Neutron powder diffraction was carried out on powders of both compounds in the temperature range $25 K < T < 295 K$. Thermal expansion coefficients were determined for HPTB and HPTB–CBr_4 over this temperature range.

Key words: thermal expansion, crystal structure, clathrate.

Résumé : On a déterminé les structures cristallines de l'hexakis(phénylthio)benzène (HPTB) et de son clathrate CBr_4 à partir de données de diffraction des rayons X par un cristal unique, obtenues à 18°C et affinées jusqu'à des valeurs finales de R_w de 0,036 et de 0,047, respectivement. Le HPTB pur est triclinique, groupe d'espace $P\bar{1}$ (No. 2), avec $a = 9,589(2)$, $b = 10,256(1)$ et $c = 10,645(2)$ Å, $\alpha = 68,42(1)°$, $\beta = 79,92(2)°$ et $\gamma = 65,52(1)°$ et $Z = 1$. Le clathrate CBr_4 du HPTB est rhomboédrique, groupe d'espace $R\bar{3}$ (No. 148), avec $a = 14,327(4)$ et $b = 20,666(8)$ Å et $Z = 3$. Le rapport molaire hôte/invité dans le clathrate est de 1:2. On a effectué une diffraction de neutron par des poudres des deux composés, à des températures allant de 25 K à 295 K. On a déterminé les coefficients d'expansion thermique de HPTB et du HPTB–CBr_4 sur l'ensemble de ces températures.

Mots clés : coefficients d'expansion thermique, structure cristalline, clathrate.

[Traduit par la rédaction]

Introduction

Inclusion compounds are systems in which one type of chemical species (the "guest") is spatially confined in non-rigorously defined cavities distributed within another species (the "host") (1). Clathrates are a subset of inclusion compounds, distinguished either on the basis of the host–guest interaction criteria or by the topology of the host–guest system; the guest molecules in clathrates are held by steric barriers developed within the lattice composed of the host molecules (2, 3). The intermolecular interaction between host and guest molecules in a clathrate is weak in comparison with chemical bonds (4), and the host–guest relationship in clathrates is determined by the steric compatibility of the host lattice voids with the guest molecules. The architecture of clathrates allows studies of the effects of the restricted geometry on the behaviour of individual guest species, their clusters, or even their whole assembly. In addition, the effect of the guest species on the properties of the host structure can be studied. The latter is more formidable since there are not many compounds which yield both a clathrate and a clathrand (i.e., an empty clathrate). This is due to instability of the polymorph of the host lattice, which is isostructural with the clathrate; this structure usually can exist only when buttressed by guest molecules (4).

We have initiated investigations of thermal properties of clathrates to get insight into the aforementioned aspects of molecular behaviour (5–12). Thermal expansion is one of these properties. The driving force for thermal expansivity is brought about by a strain-dependent entropy that creates the elastic response of the solid phase. It is a bulk property that does not have an atomic or molecular counterpart. Thermal expansion reveals the anharmonicity of a crystal lattice and knowledge of it is indispensable in thermodynamic studies for its essential role in analysis of the volume-dependent crystal properties (13).

We report here crystal structures (determined for single crystals) and the thermal expansivity (determined for powders) of systems based on hexakis(phenylthio)benzene, **1**, (HPTB for short). This compound is an archetypal example of one of the first premeditated, engineered clathrates (14, 15). The hexagonal arrangement of six hydrogen-bonded host molecules of clathrates as in hydroquinone or Dianin's systems (1) was the

1

basis for the proposal and realization of the design of HPTB and related systems (15). In HPTB systems the hydrogen-bonded hexamer is replaced by a single host molecule with a permanent consolidated structure (15) (also *vide infra*). The structures of HPTB and its inclusion compounds are of particular interest in light of the proposal that the unusual thermal conductivity observed for clathrate hydrates and Dianin's clathrate is ascribable to resonant scattering of acoustic modes by the localized optic modes brought about by an intrinsic motion of the molecular moieties (7, 11). Examination of the thermal properties of the HPTB system will provide further information on the potential topological and (or) dynamical origin of the unusual thermal behaviour of clathrates.

Experimental procedure

HPTB was prepared by a literature route involving the reaction of C_6Cl_6 with C_6H_5SNa (15). All single crystals prepared here were obtained by slow evaporation: yellow transparent molecular crystals of HPTB were grown from chloroform; yellow (with orange hue) transparent HPTB–CBr_4 crystals were grown from a solution of chloroform with excess CBr_4 (3:1, CBr_4-to-HPTB mole ratio). Powders of HPTB and HPTB–CBr_4 for the neutron powder diffraction were obtained from the same solutions by rapid recrystallization.

Single crystal diffraction data was collected on CAD4/Rigaku AFC5R four-circle diffractometers at room temperature (18 ± 1°C). The crystals were sealed in thin-walled glass capillaries to prevent crystal decomposition caused by possible guest escape during data collection. The intensities were reduced and corrected for Lorentz and polarization effects; empirical absorption corrections were applied (16). Scattering factors for neutral atoms and anomalous dispersion corrections were taken from the literature (17). Positions of the non-hydrogen atoms were obtained from direct methods (18). The H(C) atoms were placed in their geometrically calculated positions (C—H = 1.08 Å) and not refined (U_{iso}(H) = 1.2 B_{eq}(C) of the attached carbon atom). The structure was refined by full-matrix least squares.[2] The function minimized was $\Sigma w(\Delta|F|)$ (17), where w is the weight derived from the counting statistics. The anisotropic temperature factors were defined as exp $[-2\pi(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. Experimental details are given in

[2] Observed and calculated structure factors are available from the corresponding author.

Fig. 1. An ORTEP (30) drawing of an HPTB molecule in pure HPTB.

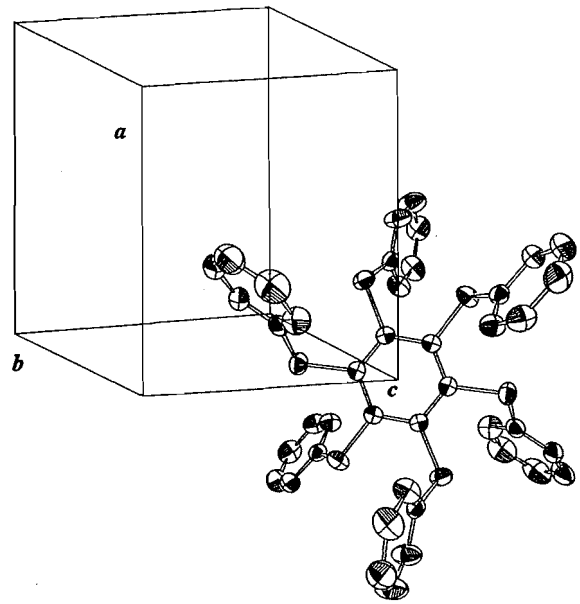

Table 1. The computer programs TEXAN (19) and SHELX (20) were used in the crystallographic investigation.

Thermal expansion measurements were performed by determination of the lattice parameters of powder samples of HPTB and HPTB–CBr_4 within the temperature range 25 K < T < 295 K, using the C2 neutron powder diffractometer in the NRU reactor of AECL Research, Chalk River, Canada. The instrument consists of an 800-wire detector spanning 80° in 2θ, giving 0.1° channel interval. During the measurements the detector was stepped once so that the measured step size for the profile refinements was 0.05°. The samples were loaded into cylindrical vanadium cans with an internal diameter of 4 mm and placed in an open cycle He cryostat. The sample was rotationally centred photographically in the beam before the experiment began. The cryostat was continuously rotated by 90° during the measurement in order to improve the powder averaging in the spectra. The temperature stability was ±1 K during each measurement. The experiment used the reflection from a Si531 monochromator at a take-off angle of approximately 110°. The calibration was performed using a standard Si powder. The wavelength was determined by Rietveld fitting the Si profile and found to be 1.50506(3) Å. The incident collimation used during the experiment was 0.4° and a cooled sapphire filter was used to reduce second-order contamination of the beam. The spectrum was fitted using the GSAS program (21) from 6° to 36°. Three parameters were used to fit the angle-dependent Gaussian line width of the peaks.

Results and discussion

Structure of pure HPTB

The hexakis(phenylthio)benzene molecule is highly symmetrical in the solid state (Fig. 1); phenyl groups are situated alternatively above and below the plane of the central phenyl ring. This compound crystallizes in the space group $P\bar{1}$. The crystallographic axis passes through the C(20)—S(1) bond, so that

[a] $\theta_{min} < \theta < \theta_{max}/n$. The lattice parameters and orientation matrices were obtained by least squares from the setting angles θ of n suitable reflections.

[b] The density was found at T = 22°C by matching the crystal density with aqueous RbI solutions; the density of the clathrate corresponds to 98% of the guest occupancy.

[c] Determined by differential scanning calorimetry.

[d] CAD4, MoKα (graphite monochromator), λ = 0.70926 Å; Rigaku AFC5R, MoKα (graphite monochromator), λ = 0.71069 Å.

[e] $I > 3\sigma(I)$.

half of the molecule is unique and the other half is related by the centre of symmetry. The C—S bond lengths are not unusual, mean 1.768(2) Å. The central and side chain phenyl rings are almost planar. The ability of HPTB to form clathrates stems from the very open molecular topology. The packing coefficient, i.e., the ratio of the van der Waals volume of the molecular content of the unit cell to the volume of the unit cell itself, determined by molecular mechanics (22) is 0.60. Organic molecular crystals typically have packing coefficients in the range 0.65–0.77 (23). Relevant values are presented in Tables 2–4.

Structure of HPTB–CBr_4

The CBr_4 clathrate of HPTB crystallizes in a trigonal crystal system, space group $R\bar{3}(h)$. Its structure is similar to its CCl_4 analogue (15). A cavity, in the zone of the crystallographic c-axis, is formed by eight host HPTB molecules. The guest molecules close the top and the bottom of the cage. The effective

Fig. 2. (*a*) A view of HPTB–CBr_4 showing the placement of the guest and host molecules. The *c*-axis is vertical. For clarity, one HPTB molecule above the plane and one HPTB molecule below the plane are omitted. (*b*) An ORTEP (30) drawing of HPTB and CBr_4 molecules in the clathrate of HPTB.

length of the cavity occupied by two guest species is ca. 18 Å (Fig. 2). The elongated cavity is of the closed cage type. The gaps in the cage wall (determined using van der Waals radii) are smaller than the effective sizes of the guest molecules. The enclathrated guests are oriented such that the axial C—Br bond of CBr_4 molecule is along the 3-fold axis. The geometry of CBr_4 is tetrahedral, the mean Br—C—Br angle is 109.5(12)°. The axial C—Br distance (1.92(2) Å) is not significantly longer than the other C—Br distances (mean 1.904(1) Å). The corrected mean values for C—Br distances and Br—C—Br angles obtained after thermal motion analysis (24) are 1.945(14) Å and 109.5(11)°, respectively.

The anisotropic thermal parameters of the nonhydrogen atoms are ordinary, with the exception of U_{33}[Br(1)] and U_{11} and U_{22}[Br(2)]. The large temperature factors of Br atoms are not unexpected since CBr_4 is a non-bonded guest molecule. The TLS analysis of the thermal motion of the CBr_4 molecule reveals a surprising degree of compliance with the rigid body model, $R(U_{ij})$ = 2.74%, $R_w(U_{ij})$ = 2.58%, rms(U_{ij}) = 0.0020 and rms[esd(U_{ij})] = 0.0014. The mean librational amplitudes about the three principle axes of libration are L_1, 3.9°; L_2, 9.4°, and L_3, 9.4°. The translation motion is essentially isotropic, with mean principal displacement of ~0.24 Å. However, significant screw motion along the S_2 and S_3 directions is also apparent in the screw tensor:

$$\begin{matrix} -0.50 & 0.00 & 0.00 \\ 0.00 & 0.25 & 0.00 \\ 0.00 & 0.00 & 0.25 \end{matrix}$$

The intermolecular Br...Br distance of 3.310(7) Å is shorter

than the shortest intermolecular distance between Br atoms found in the structure of pure CBr_4 (3.78(2) Å) (25) but is comparable to that observed in the CBr_4 clathrate of the seleno analogue of HPTB, hexakis(phenylseleno)benzene (26). The same type of shortening for the Cl...Cl contact with respect to the phase II of pure CCl_4 (27) was also observed in the case of the previously reported structure of the CCl_4 clathrate of HPTB (15). The origin of this effect is not clear.

A crystallographic axis passes through the centre of the central phenyl ring. The sulphur atom is displaced by 0.064 and 0.137 Å from the centres of the phenyl substituent and central phenyl rings, respectively. Yet both the central and the side chain phenyl rings are considered to be satisfactorily planar. The bond lengths and angles are comparable with those of HPTB and its CCl_4 clathrate (15). Relevant values are presented in Tables 5–7.

Thermal expansion of HPTB and HPTB–CBr_4

The results of the room-temperature single crystal X-ray measurement of the CBr_4 clathrate of HPTB at T = 291 K (see Table 1) agree very well with the values extracted from neutron diffraction experiment at T = 295 K: a = 14.328(3) Å, c = 20.663(6) Å, and V = 3674(1) Å^3.

There is satisfactory correspondence for the values obtained for HPTB (see Table 1) at T = 295 K with a = 9.565(9) Å, b = 10.279(7) Å, c = 10.629(10) Å, α = 68.46(6)°, β = 77.09(9)°, γ = 65.81(7)°, and V = 883.0(6) Å^3 as determined by neutron powder diffraction, compared with values (see Table 1) from single crystal X-ray measurements.

Three factors might contribute to slight differences between the X-ray and neutron diffraction results. First, neutrons are scattered by the atomic nuclei, whereas X-rays are scattered by the average electron cloud around the nucleus. Secondly, the compound consists of a significant number of hydrogen atoms, which results in a high background in the neutron diffraction pattern. Third, an intrinsic feature of organic molecular crystals is weak intermolecular interactions, which, with the low symmetry of the HPTB crystal and its open structure, makes the structure susceptible to easy distortion by thermal and mechanical effects. For example, it is known that the structure of powdered samples of the

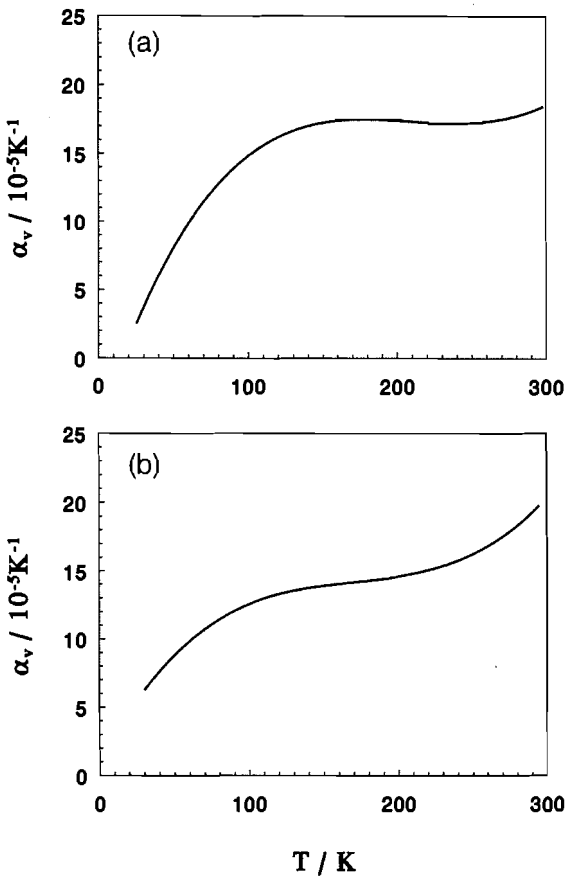
3. The value of the *a*-axis decreases monotonically with decreasing temperature. For the *c*-axis, two regions can be distinguished; above and below ca. 200 K (Fig. 3*b*). Similar behaviour was observed for Dianin's clathrates (9, 10), which have the same space group. The stronger effect of temperature on the *a*-axis than the *c*-axis can be attributed to more accessible space in the cavity in the *a*-direction than in the *c*-direction. Knowledge of the temperature dependence of the unit cell dimensions of HPTB–CBr_4 allows for the determination, through smooth fitting, of the values of the thermal expansion tensor as a function of temperature. Due to the symmetry of the system the tensor for HPTB–CBr_4 has only two non-zero independent components defined as $\alpha_a = a^{-1}da/dT$ and $\alpha_c = c^{-1}dc/dT$, i.e., $\alpha_{11} = \alpha_{22} = \alpha_a$ and $\alpha_{33} = \alpha_c$, respectively (Fig. 4).

In the case of the pure HPTB the largest temperature-dependence in the unit cell dimension is for the *b*-axis. (See Fig. 5 for unit cell dimensions and volume as functions of temperature.) The values of *a* and *c* change only very slowly with temperature. It is difficult to interpret this on the basis of the topological features of the crystal because of the very low symmetry of the structure.

Although both HPTB and HPTB–CBr_4 have anisotropic thermal expansivity neither displays any anomalous behaviour (e.g., negative thermal expansion).

The volume thermal expansivities, i.e. $\alpha_v = V^{-1}dV/dT$, of HPTB and HPTB–CBr_4 are similar in character (Fig. 6) with slightly higher values for pure HPTB. This contrasts with results for clathrate hydrates and Dianin's clathrates, which showed enhanced thermal expansion of the clathrates with respect to the host compound (i.e., ice or the clathrand of Dianin's compound) (9, 10, 28, 29). This was ascribed to the extra pressure exerted by the host molecules on the walls of the cages; molecular dynamics simulations corroborated this view for clathrate hydrates (28). In our opinion the absence of this effect for HPTB and HPTB–CBr_4 stems from differences between their structures and those of the clathrate hydrates and Dianin's clathrates. All three systems conform to the afore-mentioned topological definition of a clathrate compound, i.e., a structure based on lattice lacunae. Yet a subtle,

Fig. 6. (*a*) HPTB volume thermal expansion as a function of temperature, as determined from the least-squares fit to the volume (Fig. 5*d*). (*b*) HPTB–CBr_4 volume thermal expansion as a function of temperature, as determined from the least-squares fit to the volume (Fig. 3*c*).



but most significant, distinction lies in the constitution of these assemblies. Dianin's clathrate and clathrate hydrates form better defined cavities. The clathrate edifice is composed of the host molecules associated through hydrogen bonds, and the steric barriers that limit the volume of the voids are tight; this lets the guest have noticeable impact on the thermal expansion. In contrast, the HPTB clathrates are more open. The guests can be considered as space fillers that are loosely retained in the lattice; although the thermal parameters of CBr_4 are small, the CBr_4 guest molecules can easily be pumped away with destruction of the lattice. This also explains why volatile guests such as CCl_4 and CH_3CCl_3 are easily lost from HPTB (15).

Abstract: The structure and reactivity of the radical cation of (+)-2-carene ((1*S*,6*R*)-3,7,7-trimethyl-*cis*-bicyclo[4.1.0]hept-2-ene (**3**)) have been studied. The radical cation was generated by photoinduced single electron transfer to the first electronically excited singlet state of 1,4-dicyanobenzene in acetonitrile–methanol (3:1). The 1:1:1 (methanol:2-carene:1,4-dicyanobenzene) adducts were formed: *trans*-3-(4-cyanophenyl)-4-(1-methoxy-1-methylethyl)-1-methylcyclohexene (**14**), and *cis*- (**15**) and *trans*-3-(4-cyanophenyl)-6-(1-methoxy-1-methylethyl)-3-methylcyclohexene (**16**) in a combined yield of 80%. The efficiency of the reaction and the yield of products were increased by the addition of biphenyl, serving as a codonor. These photo-NOCAS adducts formally result from cleavage of the three-membered ring of the 2-carene radical cation, at the C1—C7 bond, forming the tertiary carbocation and allylic radical. Reaction of the cation with methanol and coupling of the allylic radical with the 1,4-dicyanobenzene radical anion at the *ipso* position, followed by loss of cyanide ion, completes the sequence. There was no evidence for cleavage of the C1—C6 bond under these conditions; however, when the irradiation was carried out in acetonitrile (no methanol) the (+)-2-carene was partially racemized. Racemization is indicative of C1—C6 bond cleavage. The results of *ab initio* molecular orbital calculations (STO-3G) provide insight into the extent of C1—C7 bond cleavage in the radical cation. The calculated spin and charge distribution, on the 2-carene radical cation global minimum (**3***a*$^{+\cdot}$), is consistent with the observed regiospecificity of adduct formation.

Key words: photoinduced electron transfer, radical ions, molecular orbital calculations, bond cleavage, 2-carene.

Résumé : On a étudié la structure et la réactivité du cation radical du (+)-2-carène ((1*S*,6*R*)-3,7,7-triméthyl-*cis*-bicyclo[4.1.0]hept-2-ène (**3**)). On a généré le cation radical par un transfert photoinduit d'un seul électron vers le premeir état singulet électroniquement excité du 1,4-dicyanobenzène, dans un mélange acétonitrile–méthanol (3 : 1). Il se forme des adduits 1 : 1 : 1 (méthanol : 2-carène : 1,4-dicyanobenzène) : les *trans*- et *cis*-3-(4-cyanophényl)-4-(1-méthoxy-1-méthyléthyl)-1-méthylcyclohexène (**14** et **15**) et le *trans*-3-(4-cyanophényl)-6-(1-méthoxy-1-méthyléthyl)-3-méthylcyclohexène (**16**) avec un rendement combiné de 80%. L'efficacité de la réaction et le rendement sont augmentés par l'addition de biphényle qui agit comme condonneur. Ces adduits photo-NOCAS sont formellement le résultat d'un clivage du cycle à trois chaînons du cation radical du 2-carène, au niveau de la liaison C1—C7, conduisant à la formation du carbocation tertiaire et d'un radical allylique. La réaction du cation avec le méthanol et le couplage du radical allylique avec l'anion radical du 1,4-dicyanobenzène en position *ipso*, suivi de la perte de l'ion cyanure, complète la séquence de réactions. Dans ces conditions, on n'a pas observé de données suggérant un clivage de la liaison C1—C6; toutefois, si l'on effectue l'irradiation dans l'acétonitrile (sans méthanol), le (+)-2-carène se racémise partiellement. La racémisation indique qu'il se produit un clivage en C1—C6. Les résultats de calculs *ab initio* d'orbitales moléculaires (STO-3G) fournissent des indications sur l'importance du clivage de la liaison C1—C7 du cation radical. La distribution de spin et de charge calculées sur le minimum global du cation radical du 2-carène (**3***a*$^{+\cdot}$) est en accord avec la régiosélectivité observée pour la formation des adduits.

Mots clés : transfert photoinduit d'électron, ions radicaux, calculs d'orbitales moléculaires, clivage de la liaison, 2-carène.

Introduction

Interesting results from the study of the reactions of the radical cations of the vinylcyclobutane derivatives, α- and β-pinene (**1** and **2**, reactions [1] and [2] (1*c*, *d*)), have promoted us to extend our examination to the vinylcyclopropane analog, (+)-2-carene ((1*S*,6*R*)-3,7,7-trimethyl-*cis*-bicyclo[4.1.0]hept-2-ene, **3**) (reaction [3]). This naturally occurring chiral terpene has often been used to test reaction mechanisms involving the more common intermediates (3).[3] The radical cation has received less attention (4). Results of this investigation, incorporating (+)-2-carene (**3**) in the photo-NOCAS reaction, are relevant to the broader understanding of the nature of vinyl cyclopropyl, and other substituted cyclopropyl, radical cations (5, 6). Results of a study of the related radical cation of sabinene (**17**) have recently been reported (5*e*).

Results

Irradiation of an acetonitrile–methanol (3:1) solution of 1,4-dicyanobenzene (**4**), biphenyl (**5**), and (+)-2-carene (**3**), at 10°C through a Pyrex filter, with a medium-pressure mercury vapour lamp, leads to formation of the photo-NOCAS adducts (reaction [3]). *trans*-3-(4-Cyanophenyl)-4-(1-methoxy-1-methylethyl)-1-methylcyclohexane (**14**), and *cis*- (**15**) and *trans*-3-(4-cyanophenyl)-6-(1-methoxy-1-methylethyl)-3-methylcyclohexene (**16**) were isolated from the photolysate by dry-column flash (dcfc) and medium-pressure liquid (mplc) chromatography. The combined yield of these 1:1:1 adducts was 80%, based upon 1,4-dicyanobenzene (**4**) consumed.

Adducts **14**, **15**, and **16** are chiral; presumably, the original configuration at C6 (*R*) of (+)-2-carene (**3**) has been maintained. 2-Carene (**3**) recovered from the photolysate showed no loss of optical activity. The addition of the codonor biphenyl (**5**), to the reaction mixture, increased the efficiency and yield of the reaction; however, reaction does occur upon irradiation in the absence of **5**, and the ratio of photo-NOCAS products formed under these conditions was the same.

An acetonitrile solution of 2-carene (**3**), 1,4-dicyanobenzene (**4**), and biphenyl (**5**), without added methanol, was irradiated under similar conditions. No products analogous to the imines **9** and **13**, formed in reactions [1] and [2], were detected (gc/ms, gc/fid); however, the observed optical rotation of the

Biphenyl (5)	1.85	−75.1
1-Methylcyclohexene	1.93	−67.4

[a]Oxidation potentials, estimated as 0.028 V before the peak potential measured at a platinum electrode, relative to the saturated calomel electrode (SCE) using tetraethylammonium perchlorate (0.1 M TEAP) as the electrolyte in acetonitrile (ref. 7).

[b]Based on the Weller equation (ref. 8); $E_{0,0}$ (**4**) = 408.4 kJ mol^{-1}, $E_{1/2}^{red}$ (**4**) = −1.66 V. The Coulombic attraction term was taken to be 5.40 kJ mol^{-1} (ref. 9).

The Weller equation: ΔG_{ET} (kJ mol^{-1}) = 96.48 [$E_{1/2}^{ox}$ (D/D$^{\cdot+}$) − $E_{1/2}^{red}$ (A/A$^{\cdot-}$) − $e/a\varepsilon$] − $E_{0,0}$.

2-carene (**3**) recovered from this photolysate was significantly decreased (reaction [4]).

The oxidation potentials of several compounds of interest, determined by cyclic voltammetry, are summarized in Table 1.

Structure determination

Structural assignments for the new compounds were based primarily on analysis of the ^{1}H and ^{13}C nmr spectra. The overall connectivity was easily established; assigning configuration was more demanding. Details are given in the experimental section. The spectra for the *cis* and *trans* isomers, **15** and **16**, were very similar. In the proton nmr spectrum of the isomer assigned the *cis* configuration (**15**), the signal due to the axial hydrogen (H5) is at lower frequency (0.94 ppm) than the axial hydrogen (H5) (1.58 ppm) of the other isomer (**16**) assigned the *trans* configuration. We attribute this difference to a shielding effect of the aromatic ring that is in the pseudo-axial position of the cyclohexene in the *cis* isomer. Comparison of the ^{13}C nmr spectra of the two isomers provides additional support for this assignment. In the ^{13}C nmr spectrum of **15**, the *cis* isomer, the half-width of the central lines of the quartet corresponding to the carbon of the methyl group at δ 30.31 is relatively narrow (8.2 Hz). This is attributed to relatively small equatorial–equatorial and equatorial–axial $^3J_{C-H}$ couplings. The ^{13}C nmr spectrum of **16**, the *trans* isomer, displays a quartet at δ 26.62 with each line having a half-width of 13.5 Hz. Such a broad signal is indicative of larger axial–axial coupling of the methyl carbon to the axial H4 (at ca. 1.68 ppm) plus other small $^3J_{C-H}$ couplings (10).

Computational details

Ab initio molecular orbital calculations were carried out with the GAUSSIAN 92/DFT series of programmes (11). Open-shell species were treated in the unrestricted Hartree–Fock (UHF) formalism; closed-shell species were treated in the restricted

Table 2. The calculated (*ab initio*) total energies for the neutral 2-carene (**3**), in two conformations, and for several alternative structures of the 2-carene radical cation ($3^{+\cdot}$).

	HF/STO-3G (au)
2-Carene (**3***a*, pseudo-boat conformation)	−383.371 780 (−383.366 190)[a]
2-Carene (**3***b*, pseudo-chair conformation)	−383.372 767 (−383.368 076)[a]
3,7,7-Trimethyl-*trans*-bicyclo[4.1.0]hept-2-ene	−383.303 648
2-Carene radical cation ($3a^{+\cdot}$, pseudo-boat conformation)	−383.175 591

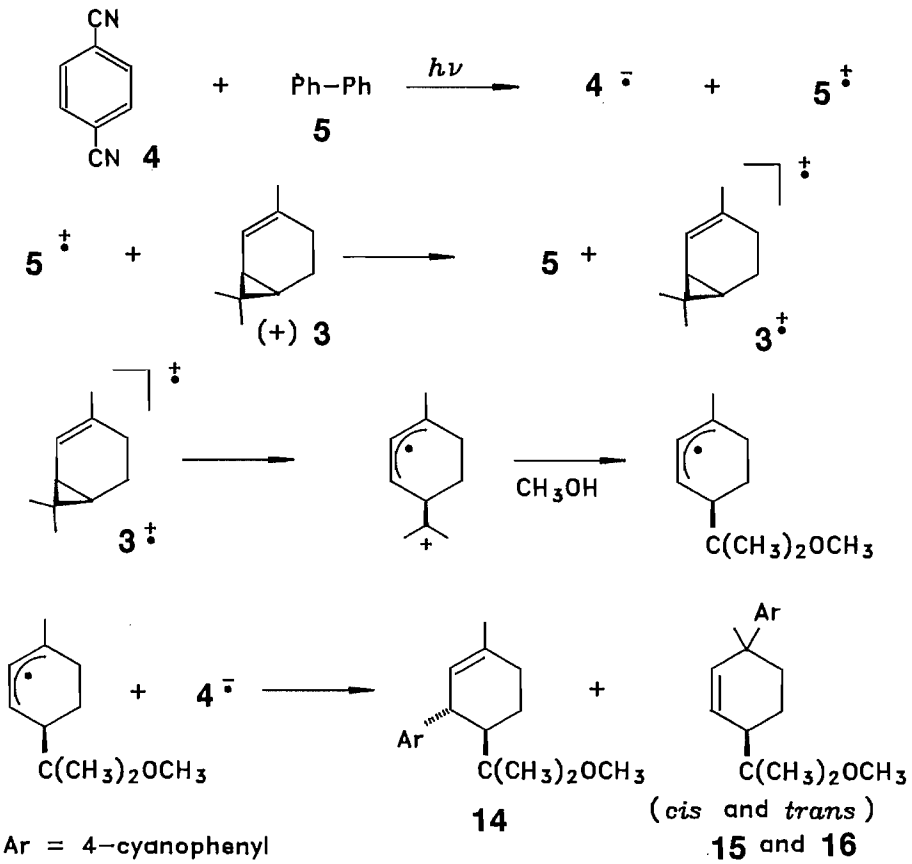
2-Carene radical cation ($3c^{+\cdot}$, ring-cleaved, six-membered)	−383.170 128
2-Carene radical cation ($3d^{+\cdot}$, ring-cleaved, seven-membered)	−383.119 489

[a]Previously reported (STO-3G) (12). The variation in these two numbers can be attributed to differences in conformation involving the methyl groups C8 and C9.

Scheme 1



Hartree–Fock (RHF) formalism. All of the optimized structures were confirmed to be minima by frequency calculations. The charge and spin distributions were calculated by Mulliken population analysis. The calculated (STO-3G) total energies for fully optimized structures are summarized in Table 2.

The calculated total energies for the neutral 2-carene in two conformations, pseudo-boat (**3***a*) and pseudo-chair (**3***b*), indicate a slight preference (2.6 kJ mol^{-1}) for the pseudo-chair conformer. This order is reversed in the radical cations, the pseudo-boat conformer ($3a^{+\cdot}$) is more stable (16 kJ mol^{-1}) than the pseudo-chair conformer ($3b^{+\cdot}$). The distonic, ring-cleaved, six-membered ring radical cation ($3c^{+\cdot}$), formed upon cleavage of the C1—C7 bond, is only 14 kJ mol^{-1} less stable than the global minimum ($3a^{+\cdot}$). The alternative structure, cleavage of the C1—C6 bond ($3d^{+\cdot}$), is significantly (147 kJ mol^{-1}) less stable. These fully optimized structures are shown in Figs. 1–6; charge and spin distribution on the radical cations are summarized in Tables 3–6.

Molecular orbital calculations on 2-carene (3) have been reported previously (12). The differences between the published energies and those reported here can be attributed to variation in conformation of the methyl groups, C8 and C9.

The calculations indicate that the *trans*-fused configurational isomer of the neutral 2-carene (3) is significantly (182 kJ mol^{-1}) less stable than the naturally occurring *cis* isomer.

Discussion

The mechanism proposed for reaction [3] is summarized in Scheme 1.

The oxidation potential of 2-carene (**3**), 1.39 V (vs. sce), is relatively low.[4] Using the Weller equation, we calculate that electron transfer from **3** to the first electronically excited singlet state of 1,4-dicyanobenzene (**4**) is exergonic (−120 kJ mol^{-1}) by an amount sufficient that electron transfer will be diffusion controlled (8). Electron transfer from biphenyl (**5**) (oxidation potential, 1.85 V) to the excited state of **4** is also diffusion controlled (step 1, Scheme 1) (9, 13). Electron transfer from **3** to the radical cation of the codonor ($\mathbf{5}^{+\cdot}$) is exergonic (step 2, Scheme 1). The increase in efficiency of the reaction in the presence of the codonor is attributed to a greater ratio of the rates of radical ion pair cage escape, versus back electron transfer, for the pair ($\mathbf{4}^{-\cdot}$–$\mathbf{5}^{+\cdot}$) relative to the pair ($\mathbf{4}^{-\cdot}$–$\mathbf{3}^{+\cdot}$). This difference is the result of a slower rate of back-electron transfer in the former pair due to a relatively smaller reorganizational energy for $\mathbf{5}^{+\cdot}$ returning to **5** (9, 13).

Analysis of the photoelectron spectra of vinylcyclopropane has provided convincing evidence for a stabilizing conjugative interaction between the π-bond of the alkene and the Walsh "π-type" orbital of cyclopropane in the vinylcyclopropane radical cation (5*c*, *d*). The relatively low ionization potential (8.26 V (4*d*)) and oxidation potential (1.39 V (Table 1)) of 2-carene (**3**) indicate this interaction is also occurring in this radical cation. The molecular orbital calculations lend support to this conclusion. The dihedral angle $C_7C_1C_2C_3$ of the pseudo-boat conformation of the neutral molecule (*3a*) (−62.7°) is favourable for overlap between the π-bond of the alkene linkage C2—C3 and the Walsh "π-type" orbital of the cyclopropane on C1 (Fig. 1). Ionization from the HOMO of this structure gives the global minimum for the radical cation, $3a^{+\cdot}$, which has a long (186.6 pm) C1–C7 bond; the dihedral angle $C_6C_1C_2C_3$ is now almost planar (−0.8°); and bonding at C7 is also almost planar (170°) (Fig. 3).

Carbons C7, C8, and C9 bear 43% of the positive charge density while the spin density is highest (0.837) on C3 (Table 3). Clearly, methanol should (and does) attack this radical cat-

ion at C7, generating the allylic radical. Products resulting from attack of methanol on the original alkene linkage (C2) were not observed. The charge density at C2 is only 7%.

This regioselectivity is predicted from the simple rule: The regioselectivity of radical cation cleavage depends upon the relative oxidation potentials of the fragment radicals; the fragment with the lower oxidation potential will react preferentially as the carbocation (9*b*, 14). The oxidation potential of the *tert*- butyl radical (0.09 V) is significantly lower than that of the relevant allyl radical (ca. 0.15 V) (15).[5]

The difference in energy between the global minimum for the radical cation ($3a^{+\cdot}$) and the distonic ring-cleaved species ($3c^{+\cdot}$) is not significant (14 kJ mol^{-1}). Differences in solvation energy of these two species may in fact reverse this order of stability. It is not clear from the structure of the photo-NOCAS adducts, nor from these *ab initio* calculations, whether methanol attack occurs on the ring-closed ($3a^{+\cdot}$) or ring-cleaved distonic ($3c^{+\cdot}$) radical cation. In reactions [1] and [2], formation of the imines 9 and 13 was attributed to reaction of the ring-cleaved distonic radical cations of α- and β-pinene. This type of product was not observed in reaction [3]; nor was the imine

formed upon irradiation of 2-carene (**3**) in acetonitrile in the absence of added methanol (reaction [4]). The distonic radical cation $3c^{+\cdot}$ has a more localized positive charge; carbons C7, C8, and C9 bear 70% of the positive charge. Therefore $3c^{+\cdot}$ would be expected to be more reactive at C7, less selective toward nucleophilic attack, with consequent reaction with acetonitrile and imine formation. We take this as evidence that the reactive radical cation has the delocalized/stabilized three-membered bridged structure ($3a^{+\cdot}$). Previous studies have provided convincing evidence that some substituted cyclopropane radical cation ring cleavages are nucleophilic assisted (5*e*, 6).

The results of photo-induced CIDNP and mass spectral studies are in complete agreement with these results. The observed CIDNP polarization was consistent with the radical cation of 2-carene (3) having structure $3a^{+\cdot}$ in which spin and charge are delocalized over the olefinic group and the C1—C7 bond (4*a*). The mass spectral behaviour (metastable ion characteristics and collision-induced dissociation) of 2-carene (**3**)

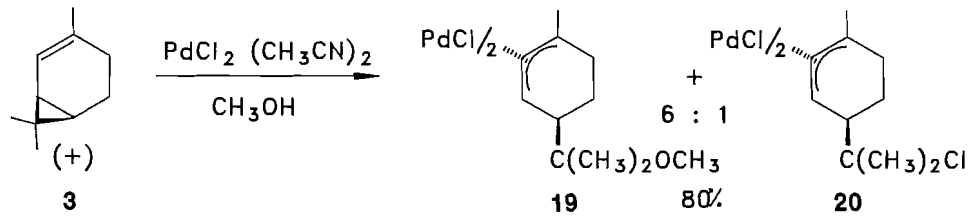
and α-terpinene (**18**) are similar. This observation led to the suggestion that the long-lived molecular ion of 2-carene ($3^{+\cdot}$) cleaves the C1—C7 bond giving a radical cation identical with that of α-terpinene ($18^{+\cdot}$) prior to fragmentation (4*b*, *c*).

When the irradiation was carried out in acetonitrile (without added methanol) the (+) 2-carene (**3**) recovered, after prolonged irradiation, had undergone partial racemization (reaction [4]). It seems reasonable that under these conditions, i.e., no nucleophile, racemization is the result of competitive, less efficient, cleavage of the fused carbon–carbon bond (C1—C6); that is, reversible formation of $3d^{+\cdot}$. We found no evidence of isomerization of 2-carene, i.e., formation of the *trans* isomer. This is not surprising in view of significantly higher calculated total energy of this isomer (Table 2).

An interesting example of this dichotomy, C1—C7 versus C1—C6 bond cleavage depending upon solvent polarity/nucleophilicity, was observed previously (3*l*). The palladium(II)-induced ring opening of 2-carene (**3**), leading to chloro- or oxypalladation, is remarkably solvent dependent. Reaction of **3** with $PdCl_2(MeCN)_2$ in methanol gives a good yield (80%) of the (π-allyl)palladium complexes **19** and **20** resulting from C1—C7 bond cleavage (reaction [5]) (3*l*). When this reaction is carried out in less polar, less nucleophilic, solvent (chloroform) some product resulting from C1—C6 bond cleavage, **21**, is observed (reaction [6]) (3*l*). Furthermore, cleavage of the C1—C6 bond becomes the dominant mode when the solvent is nonpolar (benzene) (3*l*). This reaction is an oxidative addition of the Pd(II); it is perhaps not surprising that factors influencing the reactivity of the radical cation also effect this reaction.

The regio- and stereochemistry of the (next to) last step in the proposed mechanism, coupling of the allylic radical with

Reaction [5] (3l)



Reaction [6] (3l)

the radical anion ($4^{-\cdot}$), deserves comment. Equal amounts of the *cis* and *trans* isomers, **15** and **16**, indicate no steric influence of the remote bulky alkyl substituent; coupling occurs from both the pseudo-axial and pseudo-equatorial positions. When coupling occurs at the carbon adjacent to the alkyl substituent only the less hindered *trans* product (**14**) is formed. The fact that coupling occurs preferentially at the carbon adjacent to the bulky alkyl substituent results from the fact that this is the more reactive, less sterically hindered, *secondary* end of the ambident allylic radical.

We found none of the ethers that could result from reduction of the intermediate allylic radical, followed by protonation. This is consistent with the expected reduction potential of this radical, i.e., more negative than the reduction potential of 1,4-dicyanobenzene (**4**) (−1.66 V).

Experimental

General methods

The ^{1}H and ^{13}C NMR spectra were recorded on a Nicolet 360 NB nmr spectrometer coupled to an Oxford Instruments superconducting magnet and a Nicolet 192 kword data acquisition system, or an EM-360L spectrometer, and are reported in parts per million (ppm) to high frequency from tetramethylsilane (TMS). Elemental analyses were performed by Canadian Microanalytical Services Inc., Delta, B.C. The optical rotations of the starting material and products were determined with a Perkin–Elmer model 141 polarimeter.

The reactions were followed by gas chromatography (gc) using either an HP 5890 gas chromatography, fitted with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33 μm film thickness), coupled to an HP 5970 mass selective detector (ms), or an HP 5890 gas chromatography, fitted with a DB-1701 or DB-225 fused silica WCOT column (30 m × 0.25 mm, 0.25 μm film thickness), with a flame ionization detector (fid), coupled to a HP 3392A integrator. Mass spectra (ms) were recorded on a HP 5970 series mass selective detector and are reported as *m/z* (relative intensity).

Materials

Solvents were fractionally distilled. Acetonitrile (Fisher ACS grade) was distilled successively from sodium hydride and phosphorus pentoxide, and was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h under a nitrogen atmosphere, and fractionally distilled. The 1,4-dicyanobenzene (**4**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Biphenyl (**5**) (Aldrich) was recrystallized from methanol. (+)-2-Carene (**3**) was also obtained from Aldrich Chemical Co. and was used as received.

Cyclic voltammetric measurements

Oxidation potentials were obtained by cyclic voltammetry using an apparatus similar to that previously described (16). The working electrode was a platinum sphere (1 mm diameter), while the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (SCE), which was connected to the solution by a Luggin capillary. The electrolyte was tetraethylammonium perchlorate (TEAP, 0.1 M) and the solvent was acetonitrile. Substrate concentrations were typically 0.005 M. If the anodic wave was not reversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (7).

Formation of photo-NOCAS adducts from methanol, 2-carene (3), and 1,4-dicyanobenzene (4) (reaction [3])

A solution of 2.18 g (16 mmol) (+)-2-carene (**3**), 1.31 g (8.5 mmol) biphenyl (**5**), and 1.03 g (8 mmol) 1,4-dicyanobenzene (**4**) in 160 mL acetonitrile–methanol (3:1) was degassed by nitrogen ebullition for 5 min and irradiated through Pyrex for 140 h. The temperature was maintained at 10°C. The volatile components of the photolysate, including unreacted **3**, were removed by distillation. The nonvolatile residue was treated with 10% ethyl acetate in hexane and unreacted **4** (100 mg) was recovered by filtration. The remaining solution was separated by dcfc, eluting with an ethyl acetate – hexane solvent gradient. Most of the biphenyl (**5**) (91%) was recovered. The photo-NOCAS adducts eluted as a mixture (oil, 1.57 g), which accounts for 80% of the 1,4-dicyanobenzene (**4**) consumed. The photo-NOCAS adducts were separated by repetitive mplc using two different solvent systems, 6% ethyl acetate in toluene and 6% ethyl acetate in hexane. The specific rotation of the starting 2-carene (**3**) was $[\alpha]_D^{20}$ +97.1 (c 1%, $CHCl_3$). A sample isolated from the volatile components of the irradiation mixture, by prep-gc (40% SE-30 on Chromosorb W 60/80), had $[\alpha]_D^{20}$ +97.7 (c 1%, $CHCl_3$).

Thermodynamic characteristics of NADH/NAD$^+$ analogues in acetonitrile: 2-methyl, 4-methyl and 2,4-dimethyl 1-benzyl-dihydronicotinamides and the corresponding pyridinium species

Agnès Anne and Jacques Moiroux

Abstract: Procedures were elaborated for the syntheses of the title compounds. The thermodynamic changes brought about by each methyl substitution were then determined quantitatively. In acetonitrile, the respective one-electron oxidation and one-electron reduction potentials of the NADH and NAD$^+$ analogues were obtained by means of direct and indirect (using ferrocene mediators) cyclic voltammetry. The redox potentials of formal hydride transfers were deduced from the studies of equilibrated reactions occurring between the analogues. The pK_a's of the cation radicals ensued.

Key words: NADH/NAD$^+$ methylated analogues, one-electron transfers, hydride transfer, thermodynamics.

Résumé : On a mis au point des méthodes de synthèse des composés mentionnés dans le titre. On a ensuite déterminé quantitativement les changements thermodynamiques provoqués par chaque substitution par un groupe méthyle. Faisant appel à la voltampérométrie cyclique directe et indirecte (à l'aide de médiateurs ferrocène), on a déterminé les potentiels respectifs de l'oxydation à un électron et de la réduction par un électron des analogues de NADH et NAD$^+$ dans l'acétonitrile. Les potentiels rédox des transferts formels d'hydrure ont été déduits des études sur des réactions équilibrées se produisant entre les analogues. Les pK_a des radicaux cations en découlent.

Mots clés : analogues méthylés de NADH/NAD$^+$, transferts monoélectroniques, transfert d'hydrure, thermodynamique.

[Traduit par la rédaction]

Introduction

Efficient asymmetric reductions of prochiral ketones by NADH analogues, reacting in the absence of enzyme, have been reported using an approach that mimics the selective shielding of one of the diastereotopic C-4 hydrogens of NADH in the enzyme cavity by introducing a methyl substituent at C-4 of a 1,4-dihydronicotinamide (1–4). However, in general, such a modification was accompanied by other changes in the structure. In most cases a second methyl substituent was present at the C-2 position of 1,4-dihydronicotinamide and one or both hydrogens of the amide were substituted by various alkyl groups in order to hinder its free rotation (1, 2, 4).

While the introduction of multiple substituents brings about steric constraints, electronic effects are also involved. Both of these steric and electronic parameters must be taken into account for a careful analysis of the observed changes in reactivity resulting from the substitutions. It is inherent to the electronic effects to affect the reducing strength of the NADH analogue ($\mathbf{A}_i\mathbf{H}$), particularly its overall hydride affinity. For instance, efficient enantioselective hydride transfer can be achieved with a given $\mathbf{A}_i\mathbf{H}$ but only toward highly activated keto or imino substrates due to its poor reducing power (4). In previous studies (5) the redox abilities of a series of $\mathbf{A}_i\mathbf{H}/\mathbf{A}_i^+$ couples, $\mathbf{A}_i^+$ being the corresponding NAD$^+$ analogue, have been characterized by the thermodynamic features of the following [1]–[4] equilibria:

$$[1]\quad \mathbf{A}_i\mathbf{H} \rightleftharpoons \mathbf{A}_i^+ + \underbrace{\mathrm{H}^+ + 2\mathrm{e}}_{\text{or } \mathrm{H}^-} \qquad E^\circ_{i1}$$

$$[2]\quad \mathbf{A}_i\mathbf{H} \rightleftharpoons \mathbf{A}_i\mathbf{H}^{\bullet+} + \mathrm{e} \qquad E^\circ_{i2}$$

$$[3]\quad \mathbf{A}_i\mathbf{H}^{\bullet+} \rightleftharpoons \mathbf{A}_i^\bullet + \mathrm{H}^+ \qquad \mathrm{p}K_{ai3}$$

$$[4]\quad \mathbf{A}_i^\bullet \rightleftharpoons \mathbf{A}_i^+ + \mathrm{e} \qquad E^\circ_{i4}$$

E°_{i1}, the standard potential of the $\mathbf{A}_i\mathbf{H}/\mathbf{A}_i^+$ redox couple, is of straightforward interest for the thermodynamic characterization of the direct hydride transfer. E°_{i2} and E°_{i4} are one-elec-

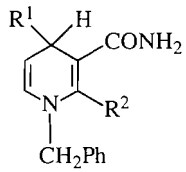
tron standard potentials relevant for overall hydride transfers initiated by electron transfers. In the present paper, all potentials are expressed in mV vs. the aqueous KCl saturated calomel electrode (SCE). pK_{ai3} measures the thermodynamic acidity of the intermediate cation radical. In particular, the behavior of 1-benzyl-1,4-dihydronicotinamide (BNAH = A_4H in the following), the most widely used among the closest analogues of NADH, was thus investigated (*5b*, *d*, *e*).



A_1H R^1 = Me; R^2 = H
A_2H R^1 = H; R^2 = Me
A_3H R^1 = Me; R^2 = Me
A_4H R^1 = H; R^2 = H

As part of a step-by-step study starting with BNAH we undertook to determine quantitatively the thermodynamic changes caused by incremental introductions of methyl substituents first at the C-4 position of the 1,4-dihydronicotinamide ring, second at the C-2 position, third at both the C-2 and C-4 positions, the amido group at C-3 remaining unsubstituted. In the following, the corresponding derivatives are denoted A_1H, A_2H, and A_3H, respectively. The early stages of the procedures previously reported in the literature for the synthesis of A_1H are rather tedious (6). Therefore we developed a more convenient approach followed by the classical route to obtain A_1H. The same classical route was adopted for the preparation of A_2H, a new BNAH derivative. The more elaborate novel compound A_3H was synthesized in a one-step procedure with A_2^+ as the starting material.

Preparation of the A_iH and A_i^+ analogues

Preparation of the A_1^+/A_1H and A_2^+/A_2H couples

We adopted a classical route, i.e., quaternarization of the appropriate nicotinamide, to afford the desired pyridinium A_i^+, followed by dithionite reduction to give the 1,4-dihydronicotinamide A_iH. However, all the reported procedures for the synthesis of the 4-methylnicotinamide **2** needed for the A_1^+/A_1H system involved the drastic and time-consuming preparation of the special intermediate 4-methyl-3-cyanopyridine (6). Therefore, to circumvent this problem, we devised a simple and handy method starting with the commercially available methylnicotinate **1** (Scheme 1). Compound **1** activated by reaction with phenyl chloroformate was converted into its corresponding methyl 4-methylnicotinate according to a very convenient two-step procedure described in the literature (7). The copper-catalyzed regioselective addition of the methyl Grignard reagent to the phenoxycarbonyl salt of **1** followed by aromatization of the crude 4-methyl-1,4-dihydropyridine afforded, at the 0.1 mol scale, the 4-methylated ester in an overall yield of 40%. The desired amide **2** was readily obtained as a pure compound by the action of saturated aqueous ammonia on the crude ester and was then easily alkylated with benzyl bromide in acetonitrile into its pyridinium A_1^+ bromide (*8a*). The reduction of A_1^+ with sodium dithionite has been reported to yield exclusively and quantitatively the 1,4 isomer A_1H (*8b*). Actually, we found that the above mentioned procedure gave a mixture of 1,6 and 1,4 isomers in a ratio of 20 to 80, with a total yield of 40% as reported for slightly different reduction conditions (*8a*). Purification of A_1H by recrystallization was unsuccessful but could be achieved by column chromatography on neutral aluminium oxide.

The commercially available ester methyl 2-methylnicotinate **3** was converted into the 2-methyl nicotinamide **4** (83% yield), followed by alkylation to the pyridinium A_2^+ in a moderate yield (30%). The lower reactivity of **4** compared to that of **2** towards N-benzylation probably results from steric shielding due to the 2-methyl substituent. The dithionite reduction of A_2^+ was carried out at 100°C in a biphasic aqueous alkaline buffer–toluene mixture to give readily, in 20% yield, the desired 1,4 isomer (A_2H) with no apparent formation of the 1,6 isomer.

Preparation of the A_3^+/A_3H system

On the one hand, attempts at ammonolyzing the ethyl 2,4-dimethylnicotinate, a commercially available but sterically hindered ester, failed even at high temperatures and (or) long reaction time, or *via* the use of the ammonia dimethylaluminium-amide reagent (9). On the other hand, the pyridinium A_3^+ once obtained, was tested for reduction with dithionite, and showed poor reactivity with no spectroscopic evidence of formation of a 4-methylated-1,4-dihydropyridine system. Therefore we sought an alternate route that could afford directly the 2,4-dimethyl-1,4-dihydronicotinamide A_3H.

Unhindered alkyl Grignard reagents have been shown to react with N-alkylated pyridinium salts to give predominantly the 1,6- and 1,2-dihydro isomers in a low to moderate yield, and the reaction is apparently of limited interest for preparation of 4-alkylated-1,4-dihydropyridine derivatives. However, we anticipated in light of previous reports that, in the presence of a catalytic amount of cuprous iodide (9), the addition of the methyl Grignard reagent to pyridinium A_2^+, which exhibits a C-2 blocked position (10), would be directed preferentially to the C-4 position (Scheme 2). Low reactivity was observed and some of the starting pyridinium was found unchanged even after long reaction time. Despite this fact, the isolation of the compound of interest, A_3H, was readily achieved by precipitation from the reaction mixture (26% overall yield). No attempt was made at isolation and identification of products other than A_3H.

Scheme 2

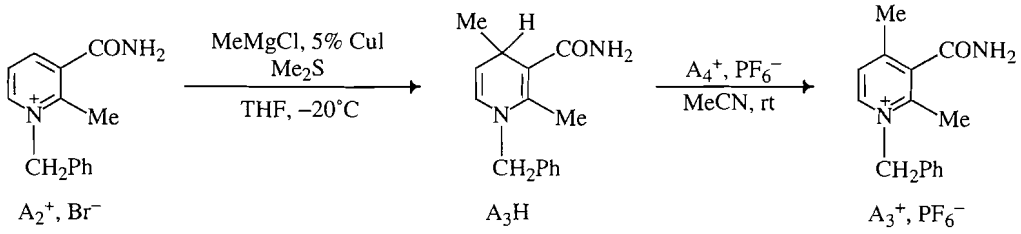

Table 1. Thermodynamic characteristics of the $\mathbf{A}_i\mathbf{H}/\mathbf{A}_i^+$ redox couples. Standard potentials of hydride transfer ($E°_{i1}$), one-electron oxidation of $\mathbf{A}_i\mathbf{H}$ ($E°_{i2}$), one-electron reduction of $\mathbf{A}_i^+$ ($E°_{i4}$), and pK_a of the cation radical $\mathbf{A}_i\mathbf{H}^{\cdot+}$ (pK_{ai3}).[a,b]

$\mathbf{A}_i\mathbf{H}/\mathbf{A}_i^+$	$E°_{i1}$(mV)[c]	$E°_{i2}$(mV)	$E°_{i4}$(mV)	pK_{ai3}
$\mathbf{A}_1\mathbf{H}/\mathbf{A}_1^+$	−22 ± 36	836 ± 8	−1260 ± 25	6.5 ± 1.8
$\mathbf{A}_2\mathbf{H}/\mathbf{A}_2^+$	−43 ± 35	709 ± 8	−1205 ± 25	7.1 ± 1.8
$\mathbf{A}_3\mathbf{H}/\mathbf{A}_3^+$	−59 ± 32	732 ± 8	−1395 ± 25	9.4 ± 1.7
$\mathbf{A}_4\mathbf{H}/\mathbf{A}_4^+$	−22 ± 29[d]	786 ± 8[e]	−1105 ± 10[e]	4.7 ± 1.3

[a]In acetonitrile at 20°C.
[b]All potentials are referred to the SCE.
[c]At pH = 0, anchoring value. The main uncertainty occurs in the case of $\mathbf{A}_4\mathbf{H}/\mathbf{A}_4^+$ (*5a, b*).
[d]From ref. *5b*.
[e]From ref. *5e*.

For the preparation of the pyridinium $\mathbf{A}_3^+$, we utilized the quantitative hydride transfer reaction that occurs from the 2,4-dimethyl dihydronicotinamide $\mathbf{A}_3\mathbf{H}$ to the 4-position of the sterically unhindered pyridinium $\mathbf{A}_4^+$. The reaction was carried out in acetonitrile at room temperature and proceeded cleanly, affording, after column chromatography, the pyridinium $\mathbf{A}_3^+$ in 80% yield.

Determination of the one-electron reduction potentials ($E°_{i4}$) of the $\mathbf{A}_i^+$ cations

Starting at 0 mV toward negative potentials, the cyclic voltammogram of a solution of $\mathbf{A}_i^+$ in acetonitrile, plus 0.1 M supporting electrolyte, exhibits an irreversible cathodic peak whatever the potential scan rate v ($v \leq 400$ V s^{-1}). The features of the voltammogram do not depend on the nature of the electrode material. The cathode may be either a platinum, or gold, or glassy carbon disk. The peak height i_p corresponds to a one-electron transfer. At slow potential scan rate ($v \leq 1$ V s^{-1}), the other peak characteristics, $E_p - E_{p/2} = 39 \pm 2$ mV, $dE_p/d \log v = -20 \pm 2$ mV, ascertain that we are then dealing with a Nernstian heterogeneous electron transfer producing the neutral radical $\mathbf{A}_i^{\cdot}$ (reaction [4]) followed by fast and irreversible dimerization of $\mathbf{A}_i^{\cdot}$ (11), as already observed for $\mathbf{A}_4^+$ and other NAD^+ analogues under the same conditions (*5a, d, e*). E_p is the peak potential, $E_{p/2}$ is the potential at half-peak height. Then, for $v \leq 1$ V s^{-1}, $E_p = E°_{i4} - 57.2 + 19.4 \log(k_{dim}C°_{A_i+}/v)$ (*11a*), k_{dim} being the dimerization rate constant ($-dC_{A_i}/dt = k_{dim}C_{A_i}^2$, with $C_{A_i} = \mathbf{A}_i^{\cdot}$ concentration) and $C°_{A_i+}$ the $\mathbf{A}_i^+$ bulk concentration. The lack of observable reversibility in the cyclic voltammogram for potential scan rates up to 400 V s^{-1} shows that the rate of dimerization of the neutral radical $\mathbf{A}_i^{\cdot}$ is fast indeed. It is probably not very different from that of $\mathbf{A}_4^{\cdot}$ ($k_{dim} = 10^9$ M^{-1} s^{-1}) (*5d*), i.e., the presence of the methyl substituents at positions C-2 and (or) C-4 of the 1,4-dihydronicotinamide ring does not cause any dramatic decrease in the rate of dimerization. Actually the radical–radical coupling may occur at any of the C-2, C-4, or C-6 (unsubstituted) positions and it is probably not slower than that of the neutral radical derived from 10-methylacridinium ($k_{dim} = 10^{7.5}$ M^{-1} s^{-1}) (*5d*). Therefore it seems reasonable to assume that $10^{7.5} \leq k_{dim} \leq 10^9$ M^{-1} s^{-1}. As a result, the measurements of the E_p's, at $v = 0.1$ V s^{-1} and $C°_{Ai+} = 1$ mM, provide the means of calculating the values of the $E°_{i2}$'s reported in Table 1.

Determination of the one-electron oxidation potentials ($E°_{i2}$) of the $\mathbf{A}_i\mathbf{H}$ analogues

Presently, it is well established that the oxidation of $\mathbf{A}_i\mathbf{H}$ proceeds along a DISP 1 mechanism when it is initiated by heterogeneous one-electron abstraction, reaction [2] occurring at the electrode–solution interface in direct electrochemistry (*5a, c, e*). Because the cation radical $\mathbf{A}_i\mathbf{H}^{\cdot+}$ is thermodynamically a strong acid (*5e*), its deprotonation in the presence of base B, reaction [5], is irreversible. Typically, B is a pyridine derivative added in at least 10-fold excess over the $\mathbf{A}_i\mathbf{H}$ concentration. Because the standard potential of the $\mathbf{A}_i\mathbf{H}/\mathbf{A}_i\mathbf{H}^{\cdot+}$ redox couple is much greater than that of the $\mathbf{A}_i^{\cdot}/\mathbf{A}_i^+$ redox couple, the disproportionation reaction, reaction [6], is irreversible. Its driving force is so large that its rate constant is

[2] $\mathbf{A}_i\mathbf{H} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathbf{A}_i\mathbf{H}^{\cdot+} + e \qquad E°_{i2}$

[5] $\mathbf{A}_i\mathbf{H}^{\cdot+} + B \xrightarrow{k_H} \mathbf{A}_i^{\cdot} + BH^+$

[6] $\mathbf{A}_i\mathbf{H}^{\cdot+} + \mathbf{A}i^{\cdot} \xrightarrow{k_6} \mathbf{A}_i\mathbf{H} + \mathbf{A}i^+$

close to the diffusion limit (5*a*,*e*,*c*). With the BNAH analogues, reaction [5] is so fast compared to backward reaction [2] that the determination of $E°_{i2}$ cannot be achieved practically by means of cyclic voltammetry in direct electrochemistry, i.e., when A_iH^+ is generated by the heterogeneous electron transfer of reaction [2] (5*e*). Homogeneous redox catalysis, an indirect electrochemical approach, can be used instead. Cyclic voltammetry is still the excitation and measurement technique. Then the reaction sequence of the catalytic process is as follows:

$$[7] \quad P \rightleftharpoons Q + e \qquad E°_{PQ}$$

$$[8] \quad Q + A_iH \underset{k_{-e}}{\overset{k_{+e}}{\rightleftharpoons}} P + A_iH^{\cdot+}$$

$$[5] \quad A_iH^{\cdot+} + B \xrightarrow{k_H} A_i^{\cdot} + BH^+$$

$$[9] \quad Q + A_i^{\cdot} \xrightarrow{k_9} P + A_i^+$$

The reduced form P of the P/Q mediator couple is introduced in the solution and Q is generated reversibly at the solution–electrode interface. In the presence of the substrate A_iH, the anodic current increases. The value of the ratio $i_p/i_p°$ of the oxidation peak currents in the presence and absence of A_iH, respectively, is a reflection of the kinetics of the reactions following step [7]. The mediators used were selected so that their standard potentials were close enough to the oxidation potential of A_iH to obtain an appreciable increase in current and not too close, so as to avoid overlapping of the catalytic and direct oxidation waves (5*e*, 12). Under these conditions the kinetics of the catalytic process are controlled by the homogeneous, reversible, and uphill electron transfer of reaction [8] and by the irreversible deprotonation of reaction [5]. Two limiting situations can be reached depending on the value of the competition parameter $k_{-e}C°_P/k_HC°_B$ (11*b*, 12*b*, 13), $C°_P$ and $C°_B$ being the respective bulk concentrations of the mediator P and the base B. When it is sufficiently small, the kinetic control is entirely by forward reaction [8]. When it is sufficiently large, the kinetic control passes to reaction [5] with reaction [8] acting as a preequilibrium whose equilibrium constant $K_8 = k_{+e}/k_{-e}$ is given by $RT \ln K_8 = F(E°_{PQ} - E°_{i2})$. The experimental diagnostic criterium ascertaining that the former situation is reached is twofold: $i_p/i_p°$ must be $C°_P$ dependent and $C°_B$ independent. In such circumstances k_{+e} can be derived from the measured $i_P/i°_P$ using appropriate working curves (13*a*, *b*). The most precise results were obtained with P = dimethylferrocene ($E°_{PQ}$ = 317 ± 2 mV) as the mediator for the monoelectronic oxidation of A_1H and P = vinylferrocene ($E°_{PQ}$ = 420 ± 2 mV) for the oxidations of A_2H and A_3H. In each case, measurements were performed successively with pyridine and 3,5-dimethylpyridine as the base B. Identical results were observed. Thus we found 2.9 ± 0.1, 3.3 ± 0.1, 2.9 ± 0.1 for the log k_{+e}'s involved in the experiments carried out with A_1H, A_2H, and A_3H. The value of k_{-e} has been shown to equal the diffusion limit of $10^{9.9}$ M^{-1} s^{-1} provided that $E°_{i2} - E°_{PQ}$ is ca. 400 mV or more (5*c*). Attributing such a value to each of the k_e's needed for the computations of the $E°_{i2}$'s through the use of the set of equations $K_8 = k_{+e}/k_{-e}$ and $RT \ln K_8 = F(E°_{PQ} - E°_{i2})$, we obtained, for the $E°_{i2}$'s, the data reported in Table 1.

These data confirm, a posteriori, the validity of the assumption formulated above concerning the values of the k_{-e}'s.

Determination of the standard potentials ($E°_{i1}$) of hydride transfer of the A_iH/A_i^+ redox couples

The standard potential $E°_{i4}$, determined previously (5*b*), was taken as the anchoring point for the evaluation of the $E°_{i1}$'s (i = 1–3). The experimental determination of a relevant set of equilibrium constants K_{ij} (reaction [10]) was then required since $E°_{i1} = E°_{j1} + 29.61 \log K_{ij}$. To do so we followed the kinetics of reaction [10] starting with A_i^+ and A_jH, until equilibrium. At each time of measurement, the composition of an aliquot of the reaction mixture was analyzed quantitatively by means of UV–visible absorption spectrophotometry after suitable dilution, if necessary.

$$[10] \quad A_i^+ + A_jH \underset{k_{-10}}{\overset{k_{10}}{\rightleftharpoons}} A_iH + A_j^+ \qquad K_{ij} = k_{10}/k_{-10}$$

Then:

$$-\frac{da(1-x)}{dt} = k_{10}a^2(1-x)(n-x) - k_{-10}a^2x^2$$

a and *na* being the respective initial concentrations of A_i^+ and A_jH, and *x* the fraction of A_i^+ transformed at time *t*. That gives:

$$\ln\left(\frac{x_1}{x_2}\frac{x-x_1}{x-x_2}\right) = k_{10}a\frac{K_{ij}-1}{K_{ij}}(x_1 - x_2)t$$

x_1 and x_2 being the solutions of the quadratic equation:

$$\frac{K_{ij}-1}{K_{ij}}x^2 - (n+1)x + n = 0$$

Knowing the experimental *x* vs. *t* data, both k_5 and K_{ij} were adjusted to reach the best linearity for the $\ln([x^2/x^1][(x - x_1)/(x - x_2)])$ vs. *t* plot. The kinetic and thermodynamic data thus obtained are gathered together in Table 2. That $K_{43} = K_{42} \times K_{23}$, within experimental uncertainty, shows the coherence of the data. The ensuing $E°_{i1}$'s, at pH 0, are reported in Table 1. The main uncertainty occurs in the case of A_4H/A_4^+ (5*a*,*b*). The other determinations are made by reference to A_4H/A_4^+ with smaller additional error. Thus, the relative values in the series are known with better accuracy than the absolute values. The same is true for the pK_{ai3}'s calculated below.

The knowledge of $E°_{i1}$, $E°_{i2}$ and $E°_{i4}$ for each derivative enabled us to calculate the pK_{ai3} of the corresponding cation radical since $pK_{ai3} = (2E°_{i1} - (E°_{i2} + E°_{i4}))/58.15$. The values found for the pK_{ai3}'s are given in Table 1.

Discussion

The data gathered in Table 1 show how substitutions at the 2 and (or) 4 positions of the dihydronicotinamide ring affect quantitatively some of the thermodynamic characteristics of the A_iH/A_i^+ redox couple.

As all substituents are electron donating methyl groups, one would expect similar trends in the changes brought about by

Table 2. Determinations of the rate constants (k_5) and equilibrium constants (K_{ij}) of hydride transfers occurring between some $\mathbf{A}_i^+$ and $\mathbf{A}_j\mathbf{H}$.[a]

substitution, i.e., increases in the reducing powers of the $\mathbf{A}_i\mathbf{H}$'s and concomitant decreases in the oxidizing powers of the $\mathbf{A}_i^+$'s with increasing degree of substitution. Accordingly, the standard potentials $E°_{i4}$ show that the oxidizing power of $\mathbf{A}_i^+$ is decreased upon replacing H by CH_3 at C-2 (by 100 mV when there is no CH_3 at C-4, by 135 mV when there is a CH_3 at C-4) and at C-4 (by 155 mV when there is no CH_3 at C-2, by 190 mV when there is a CH_3 at C-2). The introduction of a second methyl group suggests some synergistic effect. However, its apparent magnitude (35 mV) is within experimental uncertainty. Thus a CH_3 at C-2 or C-4 contributes to a greater extent to the stabilization of $\mathbf{A}_i^+$ than to the stabilization of $\mathbf{A}_i^{\cdot}$. This can be explained by stabilization through C—H hyperconjugation (electron donation), the $\sigma_{C-H} \rightarrow \pi$ overlap being larger for $\mathbf{A}_i^+$ than for $\mathbf{A}_i^{\cdot}$.

The standard potentials $E°_{i2}$ show clearly that the reducing power of $\mathbf{A}_i\mathbf{H}$ is increased by introducing a CH_3 at C-2 (by 77 mV when there is no CH_3 at C-4, by 54 mV when there is a CH_3 at C-4). Thus a CH_3 at C-2 stabilizes $\mathbf{A}_i\mathbf{H}^{\cdot+}$ more than it stabilizes $\mathbf{A}_i\mathbf{H}$. This can be explained once more by a difference in $\sigma_{C-H} \rightarrow \pi$ overlaps (C—H hyperconjugation). On the other hand, the introduction of a CH_3 at C-4 decreases the reducing power of $\mathbf{A}_i\mathbf{H}$ by 50 mV when there is no CH_3 at C-2 and the effect is somewhat smaller (27 mV) when there is a CH_3 at C-2 stabilizing $\mathbf{A}_i\mathbf{H}^{\cdot+}$. $\mathbf{A}_i\mathbf{H}$ and $\mathbf{A}_i\mathbf{H}^{\cdot+}$ are not planar and the substituent at C-4 (out of plane) should prefer the pseudo axial orientation to avoid eclipsing the $CONH_2$ group. One possible explanation for the decrease of reducing power by a substituent at C-4 is that $\mathbf{A}_i\mathbf{H}^{\cdot+}$ would be stabilized, again more so than $\mathbf{A}_i\mathbf{H}$, by C_{4-H} hyperconjugation involving the hydrogen in the pseudo-axial orientation in the unsubstituted derivative, whereas such $\sigma_{C4-H} \rightarrow \pi$ overlap would be negligible in the C-4 substituted derivative because the H at C-4 is then in a pseudo-equatorial orientation.

For the standard potential for hydride transfer ($E°_{i1}$), steric effects have an influence on a substituent at C-4, but not at C-2, because steric compression is introduced in going from the nonplanar $\mathbf{A}_i\mathbf{H}$ to the planar $\mathbf{A}_i^+$. This steric compression effect more or less offsets the stabilization of $\mathbf{A}_i^+$ by electron donation (hyperconjugation): $E°_{11} = E°_{41}$ (no substituent at C-2); $E°_{21} > E°_{31}$ by 16 mV (CH_3 at C-2). It would be interesting to compare $E°_{11}$ with $E°_{i1}$ for a *tert*-butyl substituent at C-4, unfortunately we have not been able to determine the latter (12*b*, 14).

Concerning pK_{ai3}, the introduction of a CH_3 at C-2 makes $\mathbf{A}_i\mathbf{H}^{\cdot+}$ less acidic by 2.4–2.9 pK_a units suggesting that a CH_3 at C-2 should stabilize $\mathbf{A}_i\mathbf{H}^{\cdot+}$ more than it stabilizes $\mathbf{A}_i^{\cdot}$. Although not stabilized by C-4 substitution (see above), $\mathbf{A}_i\mathbf{H}^{\cdot+}$ also becomes less acidic by 1.8–2.3 pK_a units when a CH_3 is present at C-4. Within the framework of the tentative explanations put forward in the present discussion it would then require that, in going from the nonplanar $\mathbf{A}_i\mathbf{H}^{\cdot+}$ to the planar $\mathbf{A}_i^{\cdot}$, the contribution of the steric compression would prevail over the electronic effects.

Experimental section

All chemicals were Aldrich Chemical Co. commercial products except methyl 2-methylnicotinate, which was from Lancaster Synthesis Ltd. They were of the highest purity available and used as received. Spectroscopic and electrochemical instruments were the same as previously described (5, 12, 14).

Compounds cited without reference are under current study in our laboratory and were prepared according to well-described procedures (5*b*). Spectral data are given only for compounds that were not previously described or were isolated as impure samples.

Elaboration of the A_1^+/A_1H system

4-Methylnicotinamide **2**

The nicotinamide **2** was prepared from methylnicotinate **1** following a three-step procedure (see Scheme 1). A mixture of **1** (12.1 g, 88 mmol), cuprous iodide (762 mg, 3.8 mmol), and methyl sulfide (17.6 mL) was treated with phenyl chloroformate (10.4 mL, 80 mmol) in 200 mL of THF at −20°C (Dry Ice – CCl_4) followed by addition of a 3 M solution of methyl magnesium chloride (90 mmol) in 30 mL of THF. Details of the reaction and work-up of the solution were similar to those reported in the literature (7). The crude methyl 1-phenacyl-4-methyl-1,4-dihydronicotinate was aromatized with sulfur (3 g, 171 mmol) in refluxing decalin (110 mL, 3 h). Work-up of the solution was analogous to that described in ref. 7. The isolated crude methyl 4-methylnicotinate (5.1 g), obtained as a brown oil, was reacted with concentrated aqueous ammonia (20 mL, 4 days) in a classical manner (15). The pale blond crystals that appeared were collected, washed with acetone, then ether, and dried at 70°C to give 1.9 g of pure 4-methylnicotinamide **2** (overall yield, based on starting **1** and including the second crop, 26%): mp 165°C (lit. (6*b*) mp 147°C), (6*c*) 167°C); ^{1}H NMR (DMSO-d_6) δ (ppm): 8.51 (s, 1 H), 8.40 (d, 1 H, J = 5.0 Hz), 7.88 and 7.47 (2 × bs, 2 × 1H), 7.19 (d, 1H, J = 5.0 Hz), 2.39 (s, 3H). Anal. calcd. (%) for $C_7H_8N_2O$: C 61.75, H 5.92, N 20.57; found: C 62.09, H 6.02, N 20.63. A second crop of **2** (1.2 g) of sufficient purity for the preparation of A_1^+ was obtained as follows: after concentration of the filtrate under vacuum, the residue was taken up in warm MeOH (30–40°C), and acetone was added until solid began to appear. After a while in the refrigerator, the precipitate was collected and recrystallized from a 30% methanol – acetone mixture to afford **2** (mp 164–165°C).

1-Benzyl-4-methyl-3-carbamoylpyridinium A_1^+ *chloride*

The general procedure and relative quantities of reactants were as described previously (8*a*). Typically 1.26 g (70% yield) of the pyridinium A_1^+ chloride (mp 206–209°C) was obtained starting from 1.2 g of **2**. Anal. calcd. (%) for $C_{14}H_{15}ClN_2O$: C 64.00, H 5.75, N 10.68; found: C 63.98, H 5.60, N 10.68.

1-Benzyl-4-methyl-1,4-dihydronicotinamide A_1H

A_1^+ chloride (454 mg, 1.73 mmol) was dissolved in 50 mL of 1 M aqueous sodium hydrogen carbonate and mixed with 80 mL of chloroform under vigorous stirring. The mixture was cooled to 0°C and carbon dioxide was passed through the solution for 10 min. Subsequently, sodium dithionite (2.41 g, 13.8 mmol) was added in small quantities during 30 min. The reaction was run for 20 h at room temperature and the chloroform layer was then separated from the water layer. The organic phase was washed three times with water, dried over sodium sulfate, and concentrated under vacuum. The resulting yellow residue (150 mg, 40% yield) was shown by ^{1}H NMR analysis in $CDCl_3$ to contain the 1,4- and 1,6-dihydronicotinamide isomers in a typical ratio of 80:20. Such a ratio was measured by means of the ^{1}H NMR signals of the methyl protons, respectively found in the 1,4 and 1,6 isomers at δ 1.14 (d, J = 6.5 Hz) and δ 1.98 ppm (d, J = 1.48 Hz) (8). An identical ratio was obtained following either the procedure claimed by the authors to afford only the desired A_1H (8b), or the procedure of ref. 8a. Purification of the residue by recrystallization from aqueous methanol as proposed was unsuccessful. Therefore, a collection of residues isolated from a number of reductions was subjected to preparative LC on a column of neutral aluminium oxide (active neutral, 70–230 mesh, Merck) with ethyl acetate – ethanol (10:1.6) as the eluent. 1-Benzyl-4-methyl-1,4-dihydronicotinamide A_1H was obtained as a yellow solid (overall yield, 15%), contaminated, as judged by ^{1}H NMR, by less than 1% of the undesired 1,6 isomer: mp 119°C (lit. (8*a*) mp 117°C); UV–vis, λ_{max} (nm) (ϵ_{max} (M^{-1} cm^{-1})) in MeCN: 334 (5750). Anal. calcd. (%) for $C_{14}H_{16}N_2O$: C 73.66, H 7.06, N 12.27; found: C 73.43, H 7.02, N 12.43. The 1,6 isomer, 1-benzyl-4-methyl-1,6-dihydronicotinamide, was prepared by borohydride reduction of A_1^+ in a classical manner. The purity of the product was confirmed by ^{1}H NMR. Its melting point (mp 145°C) was identical to that given in ref. 8*a*, while it could not be compared to the quite dubious value of 113°C reported later (8*b*).

Elaboration of the A_2^+/A_2H system

2-Methylnicotinamide **4**

Methyl 2-methylnicotinate **3** (25 g, 0.165 mol) was reacted with concentrated aqueous ammonia (42 mL, 5 days) in the same way as **2**. The white crystals that appeared were filtered, washed with ether, and dried at 70°C to afford 18.6 g (83% yield) of pure 2-methylnicotinamide **4**: mp 161°C; ^{1}H NMR ($CDCl_3$) δ (ppm): 8.57 (dd, 1H, J = 4.9 Hz, J = 1.8 Hz), 7.75 (dd, 1H, J = 7.7 Hz, J = 1.8 Hz), 6.45 (dd, 1H, J = 7.7Hz, J = 4.9 Hz), 5.84 (bs, 2H), 2.73 (s, 3H). Anal. calcd. (%) for $C_7H_8N_2O$: C 61.75, H 5.92, N 20.57; found: C 61.95, H 5.87, N 20.46.

1-Benzyl-2-methyl-3-carbamoylpyridinium A_2^+ *bromide*

In a flask equipped with a $CaCl_2$-protected reflux condenser, a solution of **4** (4.8 g, 35 mmol) and benzyl bromide (18 mL, 4.4-fold excess) in dimethylformamide (100 mL) was heated under reflux at 100°C with vigorous stirring for 24 h. After concentration under vacuum to ca. one half of the initial volume, the resulting white solid was filtered off and washed with acetone. Recrystallization from 60% methanol – ether gave 3.2 g (30% yield) of 1-benzyl-2-methyl-3-carbamoylpyridinium A_2^+ bromide: mp 215°C; UV–vis, λ_{max} (nm) (ϵ_{max} (M^{-1} cm^{-1})) in MeCN: 272 (4570); ^{1}H NMR (DMSO-d_6) δ (ppm): 9.22 (dd, 1H, J = 6.0 Hz, $J_{6,4}$ = 1.3 Hz), 8.62 (dd, 1H, J = 5.9 Hz, J = 1.4 Hz), 8.36 (bs, 1H), 8.14 (app m, 2H), 7.5–7.25 (m, 5H), 5.99 (s, 2H), 2.75 (s, 3H). Anal. calcd. (%) for $C_{14}H_{15}BrN_2O$: C 54.74, H 4.92, N 9.12; found: C 54.80, H 4.87, N 9.06.

1-Benzyl-2-methyl-1,4-dihydronicotinamide A_2H

To a degassed biphasic solution of toluene (6 mL) and water (6.6 mL) containing sodium dithionite (1.2 g, 6.9 mmol) and sodium carbonate (0.71 g, 67 mmol) (16), was added a degassed solution of the pyridinium A_2^+ bromide (334 mg,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

1.09 mmol) in water (1.5 mL). The orange color that appeared instantaneously upon mixing turned pale yellow. The mixture was vigorously stirred for 15 min at 100°C under nitrogen. Upon cooling, a pale yellow precipitate formed in the organic phase; the fluffy solid was filtered off, washed with water, and recrystallized from aqueous methanol to afford pure 1-benzyl-2-methyl-1,4-dihydronicotinamide **A_2H** (70% yield): mp 146°C; UV–vis, λ_{max} (nm) (ϵ_{max} (M^{-1} cm^{-1})) in MeCN: 340 (4700); ^1H NMR ($CDCl_3$) δ (ppm): 7.40–7.20 (m, 5H), 5.80 (dt, 1H, J = 7.9 Hz, J = 1.5 Hz), 5.23 (bs, 2H), 4.72 (dd, 1H, J = 7.6 Hz, J = 3.7 Hz), 4.48 (s, 2H), 3.21 (m, 2H), 2.25 (d, 3H, J = 0.78 Hz). Anal. calcd. (%) for $C_{14}H_{16}N_2O$: C 73.66, H 7.06, N 12.27; found: C 73.39, H 7.09, N 12.02.

Elaboration of the A_3^+/A_3H system

1-Benzyl-2,4-dimethyl-1,4-dihydronicotinamide A_3H

A stirred suspension of A_2^+ bromide (2.5 g, 8.1 mmol) in 24 mL of dry THF containing cuprous iodide (81 mg, 0.4 mmol) and methyl sulfide (2 mL, 30 mmol) was cooled to −20°C (Dry Ice – CCl_4) under nitrogen. A 3 M solution of methyl magnesium chloride in 3.8 mL (11.4 mmol) of THF was added dropwise over 20 min. The yellow mixture was stirred at −20°C for 10 min and then at room temperature for 1 h. Quenching of the reddish solution with 5% aqueous sodium hydrogen carbonate (60 mL) precipitated the magnesium salts as a paste, leaving a clear solution that was separated. Addition of ether (20 mL) under stirring afforded a white precipitate in the ether phase, which was filtered off and washed copiously with water. Recrystallization from MeOH–H_2O afforded a pure sample of **A_3H** (0.48 g, 26% yield): mp 182°C; UV–vis, λ_{max} (nm) (ϵ_{max} (M^{-1} cm^{-1})) in MeCN: 322 (3930); ^1H NMR ($CDCl_3$) δ (ppm): 7.40–7.15 (m, 5H), 5.87 (d, 1H, J = 7.6 Hz), 5.38 (bs, 2H), 4.74 (dd, 1H, J = 7.6 Hz, J = 5.1 Hz), 4.57 (AB q, 2H, J_{AB} = 17 Hz), 3.27 (m, 1H), 2.15 (s, 3H), 1.12 (d, 3H, J = 6.5 Hz). Anal. calcd. (%) for $C_{15}H_{18}N_2O$: C 74.35, H 7.49, N 11.56; found: C 74.26, H 7.47, N 11.46.

1-Benzyl-2,4-dimethyl-3-carbamoylpyridinium A_3^+ hexafluorophosphate

A_3H (106 mg, 0.44 mmol) was placed in a 50 mL flask with 30 mL of MeCN and nitrogen gas was bubbled through the solution. Then 1-benzyl-3-carbamoylpyridinium A_4^+ hexafluorophosphate (150 mg, 0.42 mmol) was added to the solution with stirring and the flask was sealed immediately with a serum cap. The mixture was allowed to react for 16 h at room temperature in the dark under a nitrogen atmosphere. The solvent was evaporated, leaving a residue that was shown by ^1H NMR analysis to contain equal amounts of the dihydronicotinamide **A_4H** and the pyridinium A_3^+ (95% yield). The crude mixture was column chromatographed on neutral alumina: the dihydronicotinamide was first eluted with a mixture of $CHCl_3$–MeOH (80:20) and the 1-benzyl-2,4-dimethyl-3-carbamoylpyridinium A_3^+ hexafluorophosphate was then eluted with methanol and isolated as a white solid (75% yield): mp 146°C; UV–vis, λ_{max} (nm) (ϵ_{max} (M^{-1} cm^{-1})) in MeCN: 270 (5050); ^1H NMR (CD_3CN) δ (ppm): 8.47 (d, 1H, J = 6.6 Hz), 7.76 (d, 1H, J = 6.6 Hz), 7.5–7.25 (m, 5H), 6.72 (bs, 2H), 5.66 (s, 2H), 2.65 (s, 3H) 2.57 (s, 3H). Anal. calcd. (%) for $C_{15}H_{17}N_2OPF_6$: C 46.64, H 4.44, N 7.25; found: C 46.82, H 4.48, N 7.20.

The three pyridinium A_1^+, A_4^+ chloride, and A_2^+ bromide salts were converted into their corresponding hexafluorophosphate salts for experiments that required concentrations higher than ca. 3 mM in MeCN. They were obtained as follows: approximately 2 mmol of the starting pyridinium salt was dissolved in 10–20 mL H_2O, depending on its solubility. To each of these solutions, a 4-fold mol excess of NH_4PF_6 (1.08 g) dissolved in 2.5 mL of water was added dropwise. The white products, which separated promptly, were collected and washed with cold water. Yields were between 60 and 90%. A_1^+, PF_6^-: mp 134°C. Anal. calcd. (%) for $C_{14}H_{15}N_2OPF_6$: C 45.19, H 4.06, N 7.53; found: C 45.33, H 4.02, N 7.57. A_2^+, PF_6^-: mp 167°C. Anal. calcd. (%) for $C_{14}H_{15}N_2OPF_6$: C 45.17, H 4.06, N 7.53; found: C 45.30, H 3.96, N 7.39. A_4^+, PF_6^-: mp 139°C. Anal. calcd. (%) for $C_{13}H_{13}N_2OPF_6$: C 43.59, H 3.66, N 7.82; found: C 43.62, H 3.63, N 7.81.

Abstract: Mesitylketene was generated flash photolytically in aqueous solution by the photo-Wolff reaction of 2,4,6-trimethyldiazoacetophenone and also by rearrangement of mesitylynol obtained through photodecarbonylation of mesitylhydroxycyclopropenone, and rates of hydration of this ketene were measured in dilute perchloric acid, sodium perchlorate, and sodium hydroxide solutions as well as in concentrated sodium perchlorate and perchloric acid solutions. In dilute solution only an uncatalyzed reaction and a sodium-hydroxide-catalyzed process were observed, both of which could be attributed to nucleophilic attack, by water and by hydroxide ion, respectively, at the ketene carbonyl carbon atom. In concentrated sodium perchlorate solutions, a mild decrease in reaction rate with increasing salt concentration was observed, as expected on the basis of decreasing water activity and a consequent slowing of the uncatalyzed reaction. A similar mild decrease was found in perchloric acid solutions up to $[HClO_4] \cong 1$ M, but this then gave way to a rate increase that became dominant above $[HClO_4] \cong 2$ M. This appearance of acid catalysis indicates a change in reaction mechanism from nucleophilic attack of water to an electrophilic process involving rate-determining protonation on the β-carbon atom of the ketene group. Analysis of the acid-catalyzed reaction rate by the Cox–Yates method gives the catalytic coefficient $k_{H^+} = 4.7\ M^{-1}\ s^{-1}$. This, when compared with $k_{H^+} = 1.01 \times 10^4\ M^{-1}\ s^{-1}$ for ketene itself, shows that the mesityl group retards acid-catalyzed hydration by a factor of 2200, and consequently the acid-catalyzed reaction of this, and other aromatic ketenes as well, becomes apparent only under strongly acidic conditions.

Key words: mesitylketene, ketene hydration, acid catalysis, Cox–Yates excess acidity correlation.

Résumé : On a généré le mésitylcétène par photolyse éclair en solution aqueuse à l'aide d'une réaction de photo-Wolff de la 2,4,6-triméthyldiazoacétophénone ainsi que par un réarrangement du mésitylynol obtenu par photodécarbonylation de la mésitylhydroxycyclopropénone et on a mesuré ses vitesse d'hydratation en solution diluée d'acide perchlorique, de perchlorate de sodium et d'hydroxyde de sodium ainsi que dans des solutions concentrées de perchlorate de sodium et d'acide perchlorique. En solutions diluées, on n'a observé qu'une réaction qui n'est pas catalysée et un processus catalysé par l'hydroxyde de sodium; les deux peuvent être attribués à une attaque nucléophile, respectivement par l'eau et l'ion hydroxyde, au niveau du carbone du carbonyle du cétène. En solutions concentrées d'acide perchlorique, on a observé une légère diminution de la vitesse de réaction avec une augmentation de la concentration de sel, tel qu'on peut s'y attendre en se basant sur une diminution de l'activité de l'eau accompagnant un ralentissement de la réaction qui n'est pas catalysée. On a aussi observé une légère diminution semblable dans les solutions d'acide perchlorique jusqu'à des concentrations de $HClO_4$ d'environ 1 M; toutefois, au-delà de cette valeur, il y a une augmentation de la vitesse qui devient dominante au-dessus de $[HClO_4] \equiv 2$ M. Cette catalyse acide apparente indique qu'il se produit un changement de mécanisme de réaction qui passe d'une attaque nucléophile de l'eau à un processus électrophile impliquant une protonation du carbone en β du groupe cétène dans l'étape qui détermine la vitesse. Une analyse de la vitesse de réaction acidocatalysée par la méthode de Cox–Yates fournit un coefficient catalytique $k_{H^+} = 4{,}7\ M^{-1}\ s^{-1}$. Cette valeur, comparée à celle observée avec le cétène non substitué ($k_{H^+} = 1{,}01 \times 10^4\ M^{-1}\ s^{-1}$) montre que le groupe mésityle retarde la réaction d'hydratation acidocatalysée par un facteur de 2200 et que la réaction acidocatalysée de ce cétène ainsi que celles d'autres cétènes aromatiques ne deviennent apparentes que dans des conditions fortement acides.

Mots clés : mésitylène, hydratation de cétène, catalyse acide, corrélation d'acidité en excès de Cox–Yates.

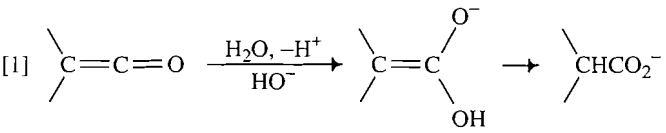
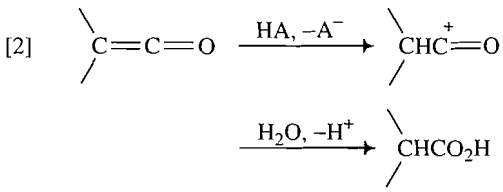
Introduction

The hydration of ketenes in neutral and basic aqueous solution occurs by nucleophilic attack of water or hydroxide ion at the carbonyl carbon atom of the ketene functional group; this is then followed by ketonization of the carboxylic acid enolate ion thus formed, eq. [1] (1).



There is also an acid-catalyzed reaction that takes place by a different mechanism: rate-determining protonation of the β-carbon atom followed by reaction of the ensuing acylium ion with water, eq. [2] (2).

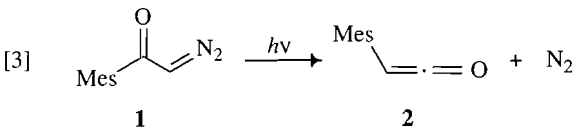


Acid catalysis, however, is generally weak and has until now not been reported for ketenes with aromatic substituents attached directly to the ketene functional group. It is believed that this is so because aromatic substituents stabilize the initial state of the hydration reaction through conjugation with the carbon–carbon double bond of the ketene group; this double bond is destroyed in the rate-determining step of the acid-catalyzed reaction and the stabilization is lost, making the energy difference between initial state and transition state larger, and the reaction consequently slower, than it would otherwise be. In the reaction of ketenes with nucleophiles, on the other hand, the ketene carbon–carbon double bond is retained and conjugative stabilization by aromatic substituents is not lost in the transition state of this process; aromatic substituents, moreover, provide additional transition state stabilization by interaction with the negative charge being generated on the substrate by the nucleophilic attack. Aromatic substituents thus retard acid-catalyzed hydration but accelerate the uncatalyzed nucleophilic attack of water, and this makes a characteristically weak acid catalysis difficult to detect against a strengthened background water reaction.

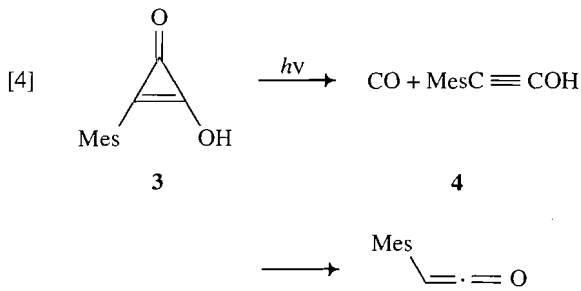
It follows from these considerations that acid catalysis of aromatic ketene hydration might become detectable in concentrated aqueous solutions of strong mineral acids where the superacidity and decreased water activity of such media would slow the water reaction and accelerate the acid-catalyzed process. We have found this to be the case for the hydration of mesitylketene, **2**,[2] in perchloric acid solutions more concentrated than 2 M.

[2] Mesityl = 2,4,6-trimethylphenyl.

Mesitylketene is quite labile, and fast-reaction methods must be used to study its hydration in aqueous solution. We have employed flash photolytic techniques, generating the ketene for the most part by photo-Wolff reaction of 2,4,6-trimethyldiazoacetophenone, **1**, eq. [3] (3). This method, however, could not be used in the more concentrated perchloric acid solutions we employed because of a facile acid-catalyzed



decomposition of the diazo compound, and we consequently supplemented this source of mesitylketene with generation by rearrangement of the corresponding ynol, **4**, produced by photodecarbonylation of mesitylhydroxycyclopropenone, **3**, eq. [4] (4).



Experimental section

Materials

2,4,6-Trimethyldiazoacetophenone (**1**) was prepared by diazo transfer from methanesulfonyl azide to 2,4,6-trimethylacetophenone activated as the formyl derivative (5); the melting point and infrared spectrum of the product were consistent with those reported in the literature (6). Mesitylhydroxycyclopropenone (**3**) was a sample that had been prepared before (4) by Friedel–Crafts reaction of mesitylene with tetrachlorocyclopropene followed by hydrolysis of the trichloride product (7). All other materials were best available commercial grades.

Kinetics

Rates of hydration of mesitylketene were determined spectrophotometrically by monitoring the decrease in ketene absorbance at λ = 260 nm. The ketene was generated flash photolytically using a conventional flash system that has already been described (8). The temperature of the reaction mixtures was controlled at 25.0 ± 0.05°C. All of the kinetic data conformed well to the first-order rate law, and observed first-order rate constants were obtained by nonlinear least-squares fitting of an exponential function.

Results

Rates of hydration of mesitylketene were measured in dilute aqueous solutions of sodium perchlorate using both H_2O

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

and D_2O as the solvent and a fixed sodium perchlorate concentration of 0.10 M. The data are summarized in Table S1.[3] Fourteen separate determinations in H_2O gave $k = 135 \pm 1$ s^{-1} as the average value for that solvent, and ten determinations in D_2O gave the average $k = 90 \pm 2$ s^{-1}. These results provide the solvent isotope effect $k_{H_2O}/k_{D_2O} = 1.50 \pm 0.04$.[4]

Rates of hydration of mesitylketene were also measured in dilute perchloric acid and sodium hydroxide solutions. The acid or base concentrations were varied, from 0.005 to 0.1 M for the perchloric acid solutions and from 0.002 to 0.01 M for sodium hydroxide, but the ionic strength was kept constant at 0.10 M by adding $NaClO_4$ as required. Six to twelve replicate measurements were made at each concentration. The data are summarized in Tables S2 and S3.[3]

Observed first-order rate constants showed no systematic variation with $[HClO_4]$ over the concentration range employed for these dilute solutions. Linear least-squares analysis gave an expression, $k/s^{-1} = (137 \pm 1) + (0.93 \pm 25.1)$ $[HClO_4]$, whose slope was undetermined and whose intercept agrees well with the value obtained in sodium perchlorate solutions, $k/s^{-1} = (135 \pm 1)$. Observed rate constants determined in sodium hydroxide solutions, on the other hand, increased regularly with increasing [NaOH], and least-squares analysis gave the relationship $k/s^{-1} = (133 \pm 27) + (1.01 \pm 0.04) \times 10^5$ [NaOH]; the intercept of this expresson also agrees well with the result obtained in sodium perchlorate solutions.

In addition to these studies performed in dilute solutions at a fixed ionic strength of 0.10 M, rate measurements of mesitylketene hydration were also made in concentrated aqueous sodium perchlorate and perchloric acid solutions. One series of determinations was performed in sodium perchlorate solutions over the concentration range $[NaClO_4] = 0.4$–4 M and another in perchloric acid solutions over the concentration range $[HClO_4] = 0.1$–4 M; in both series the solutions contained no additional electrolyte and the ionic strength was consequently equal to $[NaClO_4]$ or $[HClO_4]$. The data are summarized in Tables S4 and S5,[3] and are displayed in Fig. 1; the various relationships between rate and concentration shown by these data are discussed below.

Discussion

The present results demonstrate that the hydration of mesitylketene occurs by "uncatalyzed" and hydroxide-ion-catalyzed routes but does not show acid catalysis in dilute aqueous solution. This behavior is characteristic of aromatic ketenes. The hydration of phenylketene, for example, also takes place by uncatalyzed and hydroxide-ion-catalyzed routes and is not acid catalyzed (*2a*); the solvent isotope effects on the uncatalyzed reactions of these two substrates, moreover, are also quite similar: $k_{H_2O}/k_{D_2O} = 1.50$ for mesitylketene and 1.44 for phenylketene (*2a*).

The two ketenes do differ in reactivity, but that is in keeping with the expected reaction mechanism of eq. [1]. In this mechanism the substrate is taking on negative charge, and

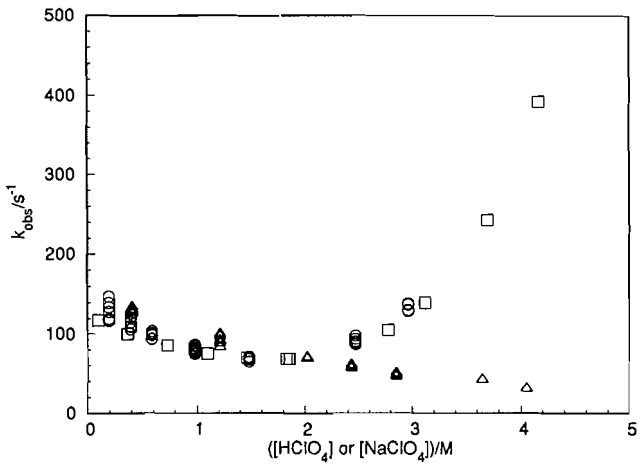
[4] Uncertainties cited are standard deviations of mean values.

Fig. 1. Relationship between rates of hydration of mesitylketene and electrolyte concentration in aqueous $HClO_4$ and $NaClO_4$ solutions at 25°C; (○) $HClO_4$, ketene generated from diazo precursor; (□) $HClO_4$, ynol precursor; (Δ) $NaClO_4$, diazo precursor.



electron-donating substituents such as the methyls in the mesityl group should hinder this process and lower the reaction rate. The data summarized in Table 1 show retardations of 35-fold for the uncatalyzed reaction and 12-fold for the hydroxide-ion catalyzed process. The smaller retardation for the hydroxide-ion-catalyzed reaction is consistent with the greater reactivity and consequent expected lower selectivity of that process.

As Fig. 1 illustrates, the hydration of mesitylketene does show acid catalysis in concentrated aqueous perchloric acid solutions. The rate of reaction first decreases with increasing acid concentration, but a similar retardation also occurs in concentrated sodium perchlorate solutions, and it may be reasonably attributed to a decrease in water activity and a consequent slowing of the uncatalyzed reaction. The rate retardation in sodium perchlorate solutions continues over the entire concentration range investigated, but in perchloric acid solutions it begins to diminish at $[HClO_4] \cong 1$ M and then gives way to a rate acceleration that becomes clearly dominant above $[HClO_4] \cong 2$ M.

The rate retardation in sodium perchlorate solutions can be expressed as a linear relationship between $\log(k_{obs})$ and electrolyte concentration over the entire range examined, as can also the retardation in perchloric acid solutions up to $[HClO_4] = 1.1$ M. Figure 2 demonstrates these relationships; it also shows a steeper dependence upon concentration for the perchloric acid solutions than for the sodium perchlorate solutions, which is consistent with the expected stronger hydration of the H^+ ion than of the Na^+ ion and the consequent lower amount of "free" water in perchloric acid than in sodium perchlorate solutions of the same molar concentration.

The persistence of the linear relationship between $\log(k_{obs})$ and $[NaClO_4]$ up to a concentration of 4 M suggests that the rate retardation in perchloric acid solutions might be similarily related to $[HClO_4]$ up to 4 M as well, and this then pro-

[c]Extrapolated from concentrated acid solutions to an "infinitely dilute" standard state.

vides a means of subtracting out the retardation from observed rate constants measured in perchloric acid solutions in the region of clear acid catalysis, [$HClO_4$] = 2–4 M. When this is done, rate constants for acid catalysis are obtained that increase more rapidly than in direct proportion to [$HClO_4$]. But this is commonly the case for reactions proceeding by rate-determining proton transfer to carbon, such as the present process, and the situation is usually handled by using an acidity function to correlate the data. The Cox–Yates X_0 function (9) appears to be the best scale available for this purpose (10), and the correlating function that applies to the present situation is given in eq. [5] (11). Figure 3 shows that the data conform well to this relationship; least-squares analysis gives the result $\log(k/[H^+]) = (0.669 \pm 0.040) + 1.16 \pm 0.05\ X_0$, which provides the hydronium-ion catalytic coefficient $k_{H^+} = 4.67 \pm 0.43\ M^{-1}\ s^{-1}$.

$$[5] \quad \log (k/[H^+]) = \log (k_{H^+}) + mX_0$$

Comparison of this result with $k_{H^+} = 1.01 \times 10^4\ M^{-1}\ s^{-1}$ for ketene itself (2*b*) gives a mesityl group rate retardation of 2200-fold, which corresponds to a substituent effect of $\delta\Delta G^{\neq} = 4.6$ kcal mol^{-1}. This is not unlike rate-retarding phenyl-group substituent effects found for other reactions that proceed by rate-determining proton transfer to carbon, e.g., $\delta\Delta G^{\neq} = 3.4$ and 4.1 kcal mol^{-1} for the hydrolysis of *cis*- and *trans*-β-methoxystyrene (12) and $\delta\Delta G^{\neq} = 3.1$ and 3.6 kcal mol^{-1} for the ketonization of the *cis* and *trans* enols of phenylacetaldehyde (13).

Theoretical evidence for P—S and P—N $p\pi$—$p\pi$ bonding within the heterocyclopentadienyl framework

Martin T. MacLennan and Katherine Valenta Darvesh

Abstract: SCF and Møller–Plesset calculations have been carried out for systems containing P—S and P—N $p\pi$—$p\pi$ bonds: namely, the 1,3,2-dithiaphospholium cation, the 1,3,2-diazaphospholium cation, and the 1,3,2-azathiaphospholium cation. The computed geometries are reported, along with Mulliken atomic charges and selected vibrational frequencies. ΔH^0 values for heterolytic P—H bond dissociation and for isodesmic bond separation reactions provide information on the energetics and stabilization of the P—S and P—N $p\pi$—$p\pi$ bonds.

Key words: SCF and MP2 calculations, third period $p\pi$—$p\pi$ bonding, bond separation reactions.

Résumé : On a effectué des calculs de champ autocohérent et de Møller–Plesset sur des systèmes contenant des liaisons $p\pi$—$p\pi$ P—S et P—N, soit les cations 1,3,2-dithiaphospholium, 1,3,2-diazaphospholium et 1,3,2-azathiaphospholium. On rapporte les géométries calculées ainsi que les charges atomiques de Mulliken et des fréquences vibrationnelles choisies. Les valeurs des ΔH^0 pour la dissociation de la liaison P—H et pour les réactions de séparation isodesmique de la liaison fournissent de l'information sur les énergies et la stabilisation des liaisons $p\pi$—$p\pi$ P—S et P—N.

Mots clés : calculs SCF et MP2, liaison $p\pi$—$p\pi$ de la troisième période, réactions de séparation de liaison.

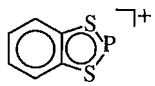
Introduction

There has been renewed interest over the past decade in the ability of third-period elements to form $p\pi$—$p\pi$ bonds (for example, refs. 1, 2). The supposed nonexistence of such compounds has been explained by insufficient overlap, and by the relative weakness of the π bond as compared to the σ bond (Schmidt et al., ref. 1 and references therein). Recently, $p\pi$—$p\pi$ bonding has been experimentally achieved between the group 15 elements and sulfur (2–5). This bonding has been facilitated by the adoption of a template containing a $(4n + 2)$ number of π electrons, namely, the heteroindenyl framework, with heteroatoms replacing C at the 1, 2, and 3 positions. An example is shown:



namely, the 1,3,2-benzodithiaphospholium cation. Experimental evidence suggesting $p\pi$—$p\pi$ bonding came from planarity as noted in the crystal structure, and from the bond lengths (4). For example, in the above cation, the mean sulfur—phosphorus bond length was found to be 2.016 Å, which is considerably shorter than the single P—S bond length of 2.122 Å found in $(PhS)_3P$ (6). Preliminary theoretical studies confirmed the Hückel nature of the compounds (2). While experimental results can be interpreted in terms of $p\pi$—$p\pi$ bonding, experiment cannot show definitively that it occurs. The present work represents a closer theoretical look at these heteroaromatic systems, with a view to explore further the role of $p\pi$—$p\pi$ bonding.

The phenomenon of $p\pi$—$p\pi$ bonding involving third period elements is under active study. It has been reviewed by numerous authors (7–9). In his review of compounds of group 14 and 15 elements involving $p\pi$—$p\pi$ multiple bonding, Norman describes how steric protection can be an effective experimental technique to stabilise the bond (9). In this approach, sterically bulky substituents are bonded to the heteroatom. The chemistry of diphosphenes has been extensively reviewed by Weber (7). On the computational side, Schmidt et al. have established a theoretical table of A=B π bond strengths for C, N, O, Si, P, and S (1). The ability of silicon and other group 4 elements to participate in aromatic bonding has been investigated theoretically (10, 11). Substantial delocalization was found to exist in these structures although there is a drop in "aromaticity" (delocalization energy) between carbon and silicon, when comparing benzene with silabenzene. Theoretical work directly related to this study has been carried out on the carbon heterocycles. A ZDO study of thiazolium and dithiolium reported atomic charge densities (12). A survey of theoretical work on sulfur heterocycles has been carried out (13). These references report many instances where double bonding involving elements of the third period or greater can occur.

Our model has been restricted to the

framework for computational simplicity. Our objective is to quantify the extent of the $p\pi$—$p\pi$ bonding as much as possible, using current *ab initio* computational techniques.

We initially outline the computational methods used. This is followed by a presentation of the theoretically obtained geometries, molecular orbitals, and charge distributions. A section on the relevant vibrational frequencies follows. Finally, thermochemical cycle results are analyzed.

Computational methods

All calculations were performed using GAUSSIAN 90 (14) on a Stellar GS 2500 system. Geometries were fully optimized at the SCF level using the 6-31G* basis set (15, 16), starting with 3-21G optimized structures. SCF force field calculations were carried out, using analytical energy second derivatives. Single point MP2 calculations (17, 18) were also performed at the SCF optimized geometries of the phosphorus systems in order to carry out the thermochemical analysis. These are referred to as MP2/6-31G*//6-31G* calculations.

Results and discussion

A. Geometries

The cationic systems studied were all based on the following framework:

For simplicity, the following shorthand will be used, consistent with previous experimental work on related compounds

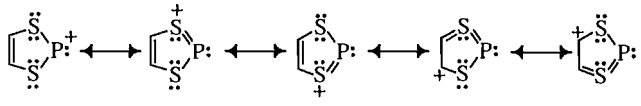
	X	Y	Z	Name	Reference[a]
1[S_2P]	S	P	S	1,3,2-Dithiaphospholium cation	4
1[N_2P]	NH	P	NH	1,3,2-Diazaphospholium cation	19
1[NSP]	NH	P	S	1,3,2-Azathiaphospholium cation	2
1[NSC]	NH	CH	S	1,3-Thiazolium cation	20
1[S_2C]	S	CH	S	1,3-Dithiolium cation	21

[a]Experimental references refer to the benzo-substituted cation.

Neutral systems required for the thermochemical cycles were based on the following framework:

	X	Y	Z	Reference
2[S_2P]	S	PH	S	2
2[N_2P]	NH	PH	NH	22
2[NSP]	NH	PH	S	2

A table of geometrical data is shown (Table 1). A glance at the theoretical P—S distance (2.015 Å) in 1[S_2P] confirms that it is shorter than the P—S single bond length of 2.122 Å found in $(PhS)_3P$ (6). However, it is somewhat longer than the P=S bond length in HPS calculated by Schmidt et al. of 1.903 Å obtained at the 3-21G* level (1). 1[S_2P] can be thought of as a 6π resonance hybrid, using similar structures as for 1,3-dithiolium (23, 24).



A **B** **C** **D** **E**

These structures can certainly account for the shortness of the sulfur–phosphorus bond. The sulfur–carbon distance in 1[S_2P] is also intermediate between an experimentally determined single bond (1.819 Å) and a double bond (1.611 Å) (25). The carbon—carbon bond length of 1.336 Å is more of a pure double bond (typically 1.34 Å). This tends to suggest that the structures **D** and **E** have little weight. The P—N and N—C bond distances in 1[N_2P] and 1[NSP] also appear to show partial double bond character.

The bond distances of the carbon heterocycles 1[S_2C] and 1[NSC] serve to confirm the similar behaviour of the phosphorus compounds. C4—S distances are similar for carbon and phosphorus heterocycles. The C2—S and C2—N distances display considerable evidence of π character due to their similarity with $H_2C{=}S$ (1.611 Å) and $H_2C{=}NH$ (1.273 Å), respectively. For comparison purposes, experimental data on related compounds are included in Table 1. Good agreement is observed between theory and experiment. The only major difference is in the C—C bond, which is longer in the substituted compounds, since it is part of a benzene ring. Apart from that, the maximum deviation from experiment is the S—P bond in 1[NSP], which is 2.0337 Å experimentally for the benzo-derivative, giving a deviation of 0.018 Å. This could be due to the absence of electron correlation, which typically lengthens the bonds.

All systems are planar. This has been verified by force field calculations performed at the optimized geometries, which do not reveal imaginary frequencies.

B. Orbitals and charges

The π energy levels and orbitals for the 5 cationic systems are shown in Fig. 1. A better understanding of the bonding comes from the π orbitals shown. The partial double bond character

[f]The derivative parent phosphine, 5-methyl-2-phenyl-1,3,2-benzodithiaphosphole, ref. 4.

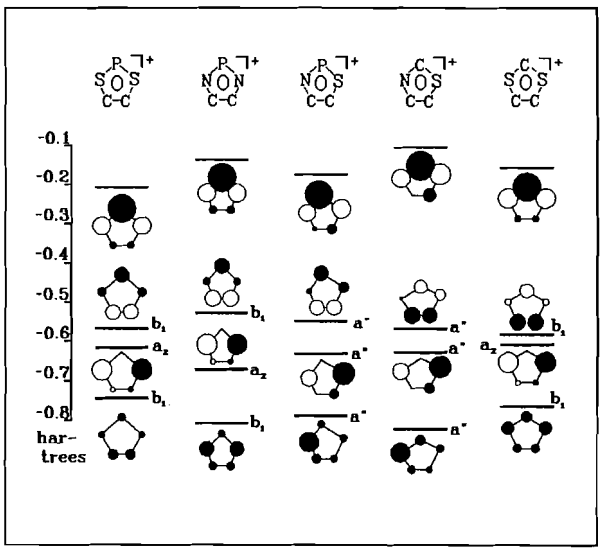
observed in the structures is seen in the orbitals, which bear a strong resemblance to the cyclopentadienyl anion (11). The π-LUMO is located primarily at the 2 position (P or CH), consistent with studies of the benzo-derivatives at the STO-3G level (2). Nucleophilic attack would be expected to occur at the 2 position.

The atomic charges for the cations are given in Table 2. These were obtained via Mulliken population analysis. While the charge partitioning scheme can be argued to be somewhat arbitrary (ref. 26, p. 28), it is expected that some qualitative insight may stem from these results. As Mulliken charges for ions are especially unrealistic, the values for the neutral species calculated are included in the table. The charges relative to the neutral species serve as a guide to the location of the positive charge.

For 1[S_2P] the positive charge is borne by the phosphorus (0.49) and by the two sulfurs (0.28 each). This is confirmed by comparison with 2[S_2P]. In contrast, the 1[S_2C] carbon at the 2 position bears a summed charge of −0.13, and sulfur carries the only positive charge. In 1[NSP] and 1[N_2P], phosphorus bears a positive charge but nitrogen, unlike the sulfur in 1[S_2P] and 1[NSP], is negative, consistent with the higher electronegativity of nitrogen.

The Mulliken overlap population matrix was used to compare the extent of π-overlap between atoms. Results are reported in Table 3. The absolute numbers have little meaning. However, for 1[S_2P] it is immediately obvious there is significant sulfur—phosphorus $p\pi$—$p\pi$ bonding. If the C4—C5 π bond order is placed at 1, then the P—S π bond order appears

Fig. 1. Molecular orbital energy levels for π orbitals.



to be 0.5 and the C—S π bond order is just 0.2. It appears, once again, that structures **D** and **E** of the resonance hybrid have little weight for all five systems studied. The P—N π bond in 1[N_2P] appears to be comparable in strength to the P—S π bond in 1[S_2P], and the results for the mixed species 1[NSP] show that the P—S and P—N π bonds have essentially equal bond orders.

C. Vibrational frequencies

Results for selected computed molecular vibrational frequencies are reported in Table 4. The labels for the vibrations were obtained by sketching the normal mode output of the frequency calculations. It is interesting to note the 1[S_2P] P—S symmetric and asymmetric stretching frequencies. Their values are intermediate to the P—S and P=S frequencies computed by Schmidt et al. (522 and 791 cm^{-1}, respectively) (1). Burford has reported peaks at 525 and 665 cm^{-1} and proposed that they were due to the S—P—S moiety. Our findings are consistent with that view. The P—N stretching frequencies in 1[N_2P] are also intermediate to computed P—N and P=N frequencies (1). The C—S and C—N frequencies in 1[S_2P] and in 1[N_2P], respectively, lie between their respective single and double bond frequencies, but the values fall closer to single bond frequencies. For example, the computed C—S and C=S frequencies reported by Schmidt et al. are 778 and 1196 cm^{-1}, respectively (1).

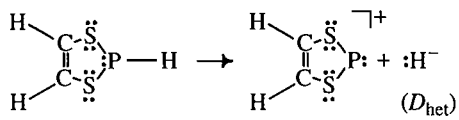
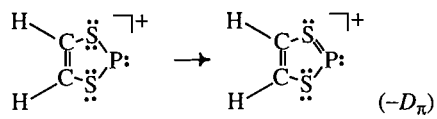
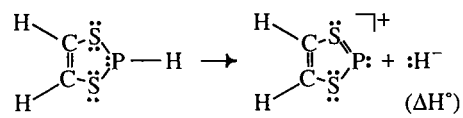
D. Thermochemical cycles

A measure of the energy involved in $p\pi$—$p\pi$ bonding would be the most useful contribution of our study, since geometries and frequencies represent extensions of the benzo-substituted experimental results. We have devised an isogyric reaction (i.e., the number of electron pairs is conserved) to evaluate the π bond strength. The reaction resembles the dehydrogenation cycle of Schmidt et al. (1).

The scheme is drawn for 1[S_2P] as an example:







$$2[S_2P] \longrightarrow 1[S_2P] + H^-$$

The heat of the reaction ΔH^0 can be calculated via our *ab initio* methods, and then the heterolytic bond dissociation energy can be estimated. This gives a direct measure of the π bond strength:

$$D_\pi = D_{het} - \Delta H^0$$

We estimated the heterolytic bond dissociation energy to be 330.4 kcal/mol. This estimate came from MP2 calculations for the species in the following process:

$$PH_3 \longrightarrow PH_2^+ + H^-$$

These values were corrected for zero point vibrational effects.

Table 6. D_π results.[a]

	Corrected[b] MP2 ΔH^0
[S_2P]	90.7
[NSP]	109.2
[N_2P]	128.4

[a]All values in kcal/mol.
[b]Corrected for zero-point vibrational effects using SCF/6-31G* zero point energies, scaled by 0.89 (27).

Tables 5 and 6 report energies and D_π values. Note that the D_π results amount to 90.7, 109.2, and 128.4 kcal/mol for reactions leading to 1[S_2P], 1[NSP], and 1[N_2P], respectively. These numbers are extremely large when compared with the recommended values of 40 and 44 kcal/mol for the P═S and P═N π bond strengths of Schmidt et al. (1). A possible explanation is the fact that the hydride ion is unbound at the MP2 level with the basis set used. However, it should be noted that by applying the formula $D_\pi = D_{het} - \Delta H^0$, the energy of the hydride is subtracted out anyway. It is proposed that the aromaticity of the cationic species accounts at least in part for the extra stabilization. The contribution of the aromaticity to the stabilization was explored by looking at isodesmic bond separation reactions of the type used by Baldridge and Gordon in their study of the aromaticity of metal-substituted benzene and cyclopentadiene (10). The type of reaction shown is only one of the types used by theoreticians in their attempts to quantify aromaticity. Baldridge and Gordon outline several other types (10). In the present work, the bond separation reaction for 1[S_2P] is the following:

Table 7. Total energies for bond separation reactions.[a,b]

[a]All energies in hartrees, E_h.
[b]Energies of some species reported in Table 5.
[c]Zero-point vibrational energy computed at the SCF/6-31G* level.

$$1[S_2P] + PH_3 + 2CH_4 + 3SH_2 \rightarrow SH_3^+ + 2CH_3—SH + S═PH + CH_2═CH_2 + HS—PH_2$$

This reaction satisfies the isodesmic criterion in that the number of bonds of each formal type is conserved. An extra sulfur-containing species was included on both sides to be the bearer of the positive charge on the product side. The energetics of the bond separation reactions are presented in Tables 7 and 8. Note that the ΔH^0 shown suggests that 1[S_2P] is more aromatic than benzene, whose equivalent bond separation reaction

$$C_6H_6 + 6CH_4 \rightarrow 3H_3C—CH_3 + 3H_2C═CH_2$$

has a ΔH^0 of 61 kcal/mol at the SCF/3-21G* level (10). The more appropriate companion to our species is the cyclopentadienyl anion. The ΔE for the bond separation reaction of the cyclopentadienyl anion is 87 kcal/mol, computed at the SCF/3-21G level (11). Our MP2 values are very similar to this result. Comparing ΔH^0 values for 1[S_2P] and 1[N_2P], delocalization stabilization is less for 1[S_2P], in accord with the observation that a larger heteroatom tends to decrease the stabilization (10).

Conclusion

Bond lengths, molecular orbitals, and vibrational frequencies all indicate the presence of $p\pi$—$p\pi$ bonding to the phosphorus in 1[S_2P], 1[N_2P], and 1[NSP]. The D_π values suggest that sta-

For personal use only.

bilization comes from the aromaticity of the species. Bond separation values for ΔH^0 confirm this. The D_π results and the bond separation ΔH^0 values follow the same trends, with their respective maxima at 1[N_2P]. the large ΔH^0 values found in the bond separation reactions highlight the role of delocalization in the viability of these species.

Abstract: A quantitative structure–activity relationship study was performed for a number of aroylhydrazine compounds with respect to their biological activity against spruce budworm. It was found that the biological activity can be modulated by substituents on the aromatic rings. Substituents with high π value and small L value lead to increase in biological activity. Molecular mechanics calculations were used to explain how the active compounds may mimic the strong-binding Y region of ecdysone.

Key words: spruce budworm, ecdysone, agonist, hydrazines, quantitative structure–activity relationship.

Résumé : On a effectué une étude de la relation quantitative structure–activité d'un certain nombre de composés aroylhydrazines par rapport à leur activité biologique contre tordeuse d'épinette. On a trouvé que l'activité peut être modulée par les substituants attachés au noyaux aromatiques. Les substituants avec des valeurs élevées de π et des valeurs de L faibles augmentent l'activité biologique. On a utilisé des calculs de mécanique moléculaire pour expliquer comment les composés actifs peuvent mimer la région Y de forte liaison de l'ecdysone.

Mots clés : tordeuse d'épinette, ecdysone, agoniste, hydrazines, relation quantitative structure–activité.

Introduction

The spruce budworm (*Choristoneura fumiferana*) is an insect pest that inflicts severe damage to the spruce-fir forest in North America (1). This insect poses a threat to over 150 million acres of susceptible forest in the Eastern United States and Canada, threatening the wood supply from large areas of forest in eastern Canada. The spruce budworm can be found from Virginia to Newfoundland and west across Canada throughout the boreal forest region. Efforts to control the spruce budworm up to now have relied on the spraying of chemical insecticides such as the organophosphate Fenitrothion or the microbial insecticide *Bacillus thuringiensis* (Bt) (2). The widespread use of synthetic broad-spectrum chemical pesticides is a matter of public concern. Furthermore, insect resistance to Bt in the laboratory has recently been reported (3). There is therefore a need to search for alternative, environmentally acceptable, approaches for forest protection against spruce budworm.

We recently reported that azadirachtin (**1**), in the form of an emulsion, is an effective growth regulator and antifeedant for spruce budworm (4). Because of the structural complexity of **1**, structure–activity relationship studies based on **1** will be a considerable challenge (5). The compound specionin (**2**), isolated from the leaves of *Catalpa speciosa* Warder (Bignoniaceae), was reported to deter feeding by spruce budworm at about 50–100 ppm concentration (6). While a number of syntheses of specionin have been reported (7, 8), its biological activity remains to be confirmed (8). Another approach to control of insects is based on the critical role of ecdysone (**3**) in their molting and development (9). In 1988, Wing et al. reported the effect of a non-steroidal ecdysone agonist, 1,2-dibenzoyl-1-*tert*-butylhydrazine (**4**, RH-5849), which mimics the action of 20-hydroxyecdysone (10). The hydrazine **4** was found to be extraordinary potent at promoting molting in larvae of the tobacco hornworm (*Manduca sexta*). We have since reported the X-ray structure of **4** and its effect against spruce budworm (LD_{50} = 0.31 μg) (11). Because of the relative simplicity of its chemical structure and its potency, we have undertaken a structure–activity relationship study of analogues of **4** with respect to their effect on spruce budworm.

Experimental

General

Melting points (mp) were determined on a Gallenkamp block and were uncorrected. Proton nuclear magnetic resonance (^{1}H NMR) spectra were taken on Varian-200, XL-300, and XL-500 instruments. The data are reported in parts per million (ppm) relative to the TMS reference line with the multiplicity

(s, singlet; d, doublet; t, triplet; q, quartet, m, multiplet; b, broad), coupling constants in hertz and the number of protons also given. Carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra were recorded on Varian XL-300 and XL-200 instruments. Mass spectra (MS) were recorded using ammonia chemical ionization (CI) on a Hewlett–Packard 5890A mass spectrometer, or on a Kratos 25 mass spectrometer operating at an ionization potential of 70 eV (EI) and are reported as *m/z* relative intensity %). Exact Mass (HRMS) values were determined on the Kratos instrument. Molecular mechanics calculations were performed with PCMODEL from Serena Software.

Synthesis

Compounds **5** and **7** were obtained commercially from Aldrich. All the hydrazine compounds were synthesized following the general procedure. Compound **4** was reported previously (10). For compounds **8**, **9**, **10**, and **11**, the corresponding chloroformates were used instead of the acid chlorides. Compound **6** was prepared by treating thiobenzoic acid with an equivalent amount of potassium hexacyanoferrate (III) in aqueous sodium hydroxide solution.

1,2,-Dibenzoyl disulfide ***6***: mp 129–129.5°C; ^1H NMR ($CDCl_3$): 7.63 (m); ^{13}C NMR ($CDCl_3$): 128.1, 128.9, 134.3, 186.0; MS (CI): 275 (5.9), 152 (25), 138 (54), 122 (32), 104 (100); HRMS calcd. for $C_{14}H_{10}O_2S_2$: 274.0122; found: 274.0104.

General procedures for tert-butyl aroyl hydrazines

The appropriate acid chloride (8 mmol) was added dropwise to a cooled (0°C) solution of *tert*-butylhydrazine hydrochloride (4 mmol) in aqueous sodium hydroxide (12 mmol) solution. A white precipitate was formed in 30 min. The mixture was filtered after 2 h. The product was recrystallized from ethanol–water (1:1) to give the desired compound in good yield, generally in the range of 60–90%.

Bioassay methods

1. Type 1 bioassays

Diet preparation: Standard McMorran diet (12) was lyophilized and powdered to pass through a 40-mesh screen (425 μm openings). This powdered diet was diluted with cellulose powder (Alphacel) in a proportion of 1 part of diet to 1.5 parts of Alphacel to give 40% McMorran diet. At this concentration of nutrients, the dry weight of the amount eaten by 6th instar larvae approximates the dry weight of host-tree foliage normally consumed (13). Diet containing the desired concentration of the test compound was prepared by treating the powdered 40% McMorran diet with a solution of the compound in methylene chloride and then completely removing the solvent at 30°C in a rotary evaporator. A total of 18 g of the residual powder was hydrated to 75% water content with 54 mL of 0.6% aqueous potassium sorbate solution and mixed into a paste. This potassium sorbate retards the growth of fungus (14). The amount of test compound added to the powdered diet was such as to give a concentration of 10, 50, or 100 ppm in the hydrated diet. Control diets were prepared in a similar way, but with only solvent.

Experimental procedure: Each 72 g of diet paste was divided into 50 aliquots and loaded into fibrin cups. One cup of diet plus one recently moulted, unfed, 6th instar larva was placed in a petri dish (35 × 10 mm). A bioassay consisted of 50 replicates (25 males, 25 females) per concentration per compound. Larvae were reared at 21°C, 17-h photoperiod, and examined daily. The bioassay was terminated when all larvae had either died or pupated. Mortality was recorded. The dishes were examined visually and the amount of diet eaten, relative to the solvent-only control, was estimated. A reduction of about >33% in the amount eaten was obvious. When this occurred, the frass was dried (60°C) and weighed. Frass weight is an accurate measure of the amount of food eaten. (4) Up to 6 bioassays (300 larvae) could be run at one time as a group. Compound **4** was included in seven of these groups as a treatment reference.

2. Type 2 bioassays

The 40% McMorran diet powder was prepared as for the type 1 bioassays and then made into wafers of ca. 1 cm diameter and 1 mm thick and weighing ca. 20 mg (15). These diet wafers were treated with the test compound in methylene chloride solvent and the solvent evaporated in a fume hood. Using this method, the amount of compound in each wafer could be controlled. The wafers were hydrated and fed to recently-moulted unfed 6th instar larvae as in type 1 bioassays. When a larva had eaten all its treated wafer (i.e., ingested the full dose of the test compound), usually within 24 h, it was given non-treated 40% McMorran paste. Solvent-only wafers were used as controls. Mortality was recorded as the failure of a larva to moult to a pupa. This bioassay was used to determine the LD_{50} of 10 compounds, using the SAS probit procedure (16). Two series of dosages were used, 0.025, 0.05, 0.10, 0.15, 0.20 micrograms per larva and 0.2, 0.4, 0.5, 0.6, 0.8 micrograms per larva. These dosages gave concentrations that ranged between ca. 0.3–10 ppm in the hydrated wafers. Each dosage per compound was replicated with 40 larvae (20 males, 20 females).

Results

Type 1 bioassays were conducted with 28 compounds including **4**. At 10 ppm, compound **4** invariably resulted in 100% larval mortality and very high feeding reduction; i.e., in three bioassays when feeding reduction was measured, values of 93.4, 94.0 and 94.4% were obtained. Of the other 27 compounds, **15** and **31** resulted in 22 and 54% larval mortality, respectively, and 43 and 44% feeding reduction, respectively (Table 1). Compounds **17**, **18**, **19**, **23**, **28**, **29**, and **30**, were as active as **4** (Table 1). Compound **27** gave 100% mortality at 10 ppm but feeding reduction was not measured. The other 16 compounds (**5–14**, **16**, **20–22**, **25–26**) were inactive, in that larval mortality never exceeded 6% and there was no obvious effect on amount of diet consumed at 10 ppm concentration for

Table 1. Compounds showing biological activity against 6th instar spruce budworm larvae when incorporated into artificial diet at 10 ppm of the wet weight (Type 1 bioassay).

Compound	Mortality, %	Feeding reduction, %
15	22	43
17	100	95
18	100	94
19	100	93
23	100	90
27	100	Not recorded
28	100	92
29	100	94
30	100	93
31	54	44

5, **12**, **13**, **16**, **20**, **21**, **22**, **25**, **26**; at 50 ppm concentration for **8**, **9**, **10**, **11**, **14**; and at 100 ppm concentration for **6** and **7**.

The LD_{50} values for 10 compounds are given in Table 2 and ranged from 0.120 micrograms (μg) for **24** and 0.311 (μg) for **4**, to an estimated 1.003 μg for **19**. The low LD_{50} values for **4**, **17**, **18**, **23**, **27**, **28**, **29**, and **30** were to be expected from the Type 1 bioassays as the average amount of compound ingested was <0.5 micrograms per larva and resulted in 100% mortality. For **19**, mortality was influenced by the rate of its ingestion rather than the total amount ingested. At concentration of 2–4 ppm, the larvae ingested more compound and suffered lower mortality than when they fed on diets containing 6–10 ppm. The LD_{50} value of 1.003 μg for **19** refers to a diet concentration of 3 ppm; at 10 ppm the LD_{50} value is <0.5 μg. Note that the values for **17**, **18**, and **19** were estimated from the probit analysis as they were outside the range of the concentrations tested, i.e., 0.2–0.8 micrograms per larva. The LD_{50} values for **20**, **21**, **22**, **25**, **26**, and **31** were not determined as they showed no, or attenuated, biological activity at 10 ppm concentration.

Discussion

Preliminary studies

We examined first the effects of the changes of gross structure on the biological activity. Compounds **5–31** were compared with **4** using a feeding bioassay (Type 1 bioassay). All the compounds were tested using sixth instar larvae. The newly moulted sixth instar larvae were maintained on artificial diet containing 10 ppm (wet weight) of the test compound, with untreated diet as the control. At pupation, when feeding inhibition exceeded 33%, the frass was dried (60°C) and weighed, the weights indicating the amount of diet consumed.

Compounds **5** and **6** were designed to probe the effect of replacing the hydrazine linkage by another functionality. It is

immediately clear that replacement of the hydrazine by a planar *E*-alkene (**5**), or a nonplanar 90° S—S linkage (**6**) led to loss of biological activity. Replacement of the *tert*-butyl group on the hydrazine by a hydrogen gave an inactive compound **7**, suggesting that the bulky *tert*-butyl group is critical to the activity. This is in agreement with observations of Hsu who found that the hydrazine class of compounds is active against Lepidopteran larvae as long as the *tert*-butyl group is present (17). An increase or decrease in the bulkiness of the substituent replacing the *tert*-butyl group led to diminishing activity. The next set of compounds, **8–11**, was designed to probe the effect of replacing the amide function with a carbamate function. It is clear that such modification leads to loss of activity. Exchanging the phenyl rings in **4** with cyclohexyl (**12**) or benzyl (**13**) groups also lead to inactive compounds. Loss of activity was also observed when the phenyl rings were replaced by furanyl (**14**) moieties and attenuated activity was observed for the naphthyl (**15**) analogue. Substitution in the phenyl ring can also cause significant change in biological activity. For example, a *p*-hexanoxy (**16**) or a *p*-methoxy (**20**) substituent in the phenyl ring gave inactive compounds at 10 ppm concentration. On the other hand, the *m*-methoxy compound **19** is active. We undertook therefore a quantitative structure–activity relationship (QSAR) study of derivatives of active prototype **4** according to the method of Hansch et al. (18).

Quantitative structure–activity relationship (QSAR) study

Compounds **17–31**, in which the phenyl rings of the parent compound **4** were substituted at the *meta* or the *para* positions, were compared. Most of these compounds were found to be active in either Type 1 (feeding) or Type 2 (LD_{50}) bioassays. The LD_{50} values of the active compounds were determined using sixth instar larvae by a dosage response study of their mortality and are summarized in Table 2.

For a series of structurally closely related compounds, such as the present series in which only the substituents in the phenyl rings are changed, the correlation between the chemical structures and their biological activities could be governed by a number of factors. The first factor is the probability of a compound reaching the site of action within a given time interval. Hansch suggested that this was related to the partition coefficient (*P*) of the compound between an aqueous phase and an organic phase. For substituted aromatic compounds, Hansch has developed a comparative substituent constant π, which is a free-energy-related constant and is a measure of the free energy change resulting from moving a derivative from one phase to another. In Table 2, the π values were the ones derived from the partition coefficients of substituted phenoxyacetic acids between water and octanol in which

$$\pi = \log (P_x/P_H)$$

for a substituent X replacing hydrogen (H). Since it is expected that a molecule outside a cell will have to make many partitions between "aqueous" phases and a variety of different "organic" phases to reach the site of action inside the cell, the optimum probability would not necessarily be a simple function of π but, to a first approximation, of π and π^2 (or even higher order). Another influence of a substituent on the properties of an aromatic system is measured by the Hammett σ constant. The σ constants have been well established and are also listed in Table 2. Some attempts have been made to develop parameters to take into account the steric effect of a substituent. Verloop et al. have selected five dimensions for each substituent and developed a computer program using van der Waals radii, standard bond angles and lengths, and "reasonable" conformations to define the space requirements of a substituents (20). The five dimensions are labelled *L*, *B*1, *B*2, *B*3, and *B*4. The length parameter, *L*, is defined as the length of the substituent along the axis of the bond between the first atom of the substituents and the parent molecule. The four width parameters *B*1–*B*4, are determined by the distance at their maximum point perpendicular to this attachment bond axis and each other. *B*1 is the smallest and *B*4 the largest width. In effect, these parameters define a box around the substituent. Since most of the substituents in Table 2 are spherical, only the *L* parameters are used for the QSAR study. Based on the data compiled in Table 2, multiple linear regression analysis (20) was used to generate the coefficients in eq. [1] Table 3). The physical parameters of the substituents are the independent variables of the regression and the biological activity is the dependent variable. As one can see, the regression analysis gave good correlation coefficient (*R*) or R^2 and low standard deviation (*s*). This is not unexpected in a multivariate analysis. To find out which of the parameters are important to the biological activity, 14 ([2]–[15], Table 3) were generated based on different combinations of the parameters. Equations [6], [13], and [15] all have high *R* square and low *s* values. Removing the σ parameter (eq. [[15]) and the π^2 parameter (eq. [13]) led to eq. [6] with the correlation coefficient still quite significant (R^2 = 0.931).

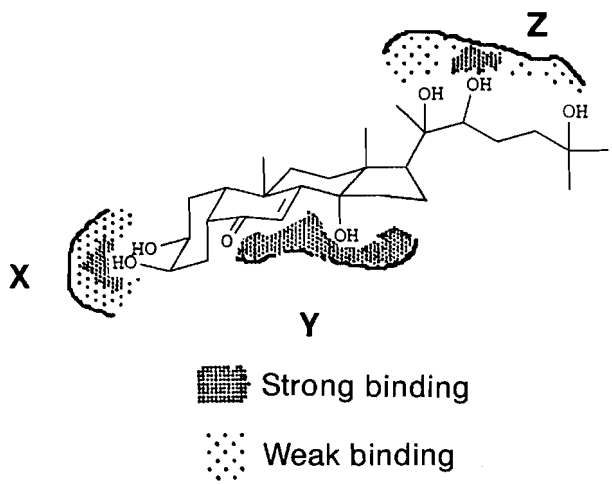
However, removing the π parameter (eqs. [10], [11], and [14]) or the L parameter (eqs. [8], [9], [10], and [12]) greatly lowers the correlation coefficient. The results of the Hansch analysis suggest therefore that the biological activity correlates mainly with π value (lipophilic character) and L value (steric effect). Furthermore, in eq. [6], the π parameter has a negative coefficient, which means that as π value increases, activity increases. Similarly, a positive coefficient for L indicates that as the substituent increases in size, the activity decreases. This may account for the inactivity of compounds **16** and **31**. The inactivity of compounds **20**, **21**, and **22** is then due to the negative π values of these substituents. Finally, compounds **25** and **26** are inactive, possibly because of a combination of low π and high L values.

Molecular mechanics calculations

We previously reported (11) the crystal structure of compound **4**. There are two molecules (labelled A and B) in the asymmetric unit. In terms of the crystal structure, two features are of importance. The first is that while the two amide functions adopt the expected planar structure, the amide bearing the N-H has the *s-cis* conformation, whereas the amide bearing the N-*tert*-butyl group has the *s-trans* conformation. Clearly, the steric bulk of the *tert*-butyl group causes the phenyl group to be directed away. The second important feature is that the N—N bond adopts a *gauche* conformation with a dihedral angle (ϕ) of –71.8° in molecule A and –58.1° in B. The *gauche* conformation is the expected conformation for hydrazine compounds.

Since it has been suggested that the biological activity of **4** is due to its mimicry of ecdysone, we have performed calculations to fit the crystal structure of **4** on a minimized model of ecdysone using MMX. There have been a number of structure–activity relationship studies on ecdysone and its derivatives (21). Most of the studies conclude that there are three important regions, X, Y and Z, of ecdysone involved in binding interactions with the receptor (Fig. 1). The A ring fits into a pocket at the receptor site and important binding interactions take place on the β face (the X region). Particularly strong

Fig. 1. The three binding regions of ecdysone (**3**): X, Y, and Z.



binding occurs at the Y region encompassing the 6-keto-7-ene and the 14-α-OH group in the α face. The Z region is the side chain with specific binding for the 22-OH group but less defined interaction in the other part of the side chain. Because of the difficulty of performing minimization on the side chain of ecdysone, we have performed the calculation on the model **32** (Fig. 2). Our proposal is that atoms 1, 2, 3, 4, and 5 of **4** may mimic atoms 1′, 2′, 3′, 4′ and 5′ of **32**, the strongly binding Y region of ecdysone. The energy-minimized structure of **32** was first obtained using MMX bond angles and bond length data. Certain atoms of the crystal structure of **4** (using A) were then superimposed on the minimized model **32** using the 'compare' function of the program. In the first calculation (Fig. 2), only atoms 1, 2, 3, and 5 were fitted to the corresponding atoms in **32**. It is clear that the relative average deviation of atoms in the best fit was relatively high. In the next three calculations, the *tert*-butyl carbon 4 was included. This lowered the value of average deviation of the atoms significantly. These results suggest that compound **4** can indeed mimic the strongly binding Y region of ecdysone, and that the

tert-butyl group is important in fixing the conformation of **4** into the best fit in the binding region. In such a fit, the aromatic rings in **4** replace rings A and D of ecdysone. Large substituents (high *L* value) on the aromatic ring presumably interfere with the binding and thus lower the biological activity.

Conclusions

Our QSAR studies show that the biological activity of the hydrazine class of compounds can be modulated by substituents on the aromatic rings. Substituents with high π value and small *L* value lead to increase in biological activity. Molecular mechanics calculations using MMX indicate that the *tert*-butyl group is critical in locking the hydrazine **4** into an energy minimum conformation that can best fit into the strong binding Y region of ecdysone.

Abstract: Series of isomeric monohaloalkanoic acids may be prepared from γ- or δ-alkanoic lactones by reaction with hydrogen halides. For example, γ-nonanolactone in 48% hydrogen bromide under reflux affords a 1:1.5:1.7:2.2:2.4 mixture of 4-, 5-, 6-, 7-, and 8-bromononanoic acids. In an examination of possible ways whereby such products are formed, it has been found that the use of 48% *deuterium* bromide leads to the introduction of up to 14 atoms of the isotope per bromoacid. According to ^{1}H, ^{2}H, and ^{13}C nuclear magnetic resonance observations, however, the major components of the isomer mixture contain 8–10 atoms of deuterium confined mainly to carbons 4–8, i.e., close to full deuteration of each of the carbons. This indicates that a prominent mechanism governing the formation of the bromoacid mixture involves repeated elimination and addition of HBr (^{2}HBr) along a strictly limited segment of the carbon chain. Initiated at the C-4 bridge of the lactone and characterized, hypothetically, by a succession of carbocation intermediates, the halogenation reactions appear to include a repetitive migration of transient alkene functions from C-4 through C-8, and an accompanying series of "zipperlike" hydride (deuteride) shifts in the inverse direction.

Key words: deuterohaloalkanoic acids, carbocation rearrangements.

Résumé : On a préparé une série d'acides monohaloalcanoïques à partir d'acides alcanoïques γ- ou δ-lactones, par réaction avec des halogénures d'acide. Par exemple, la γ-nonalactone soumise à un reflux dans de l'acide bromhydrique à 48% fournit un mélange 1 : 1,5 : 1,7 : 2,2 : 2,4 des acides 4-, 5-, 6-, 7- ou 8-bromononanoïques. Dans une évaluation des diverses voies permettant la formation de ces produits, on a trouvé que l'utilisation de DBr à 48% conduit à l'introduction d'un maximum de 14 atomes de l'isotope par molécule d'acide bromhydrique. Toutefois, en se basant sur les spectres RMN du ^{1}H, ^{2}H et ^{13}C, les composants majeurs du mélange d'isomère contiennent de 8 à 10 atomes de deutérium confinés principalement aux carbones 4–8, c'est-à-dire une deutération pratiquement complète de chacun de ces carbones. Ce résultat indique que le mécanisme prédominant dans la formation du mélange des acides bromés implique des éliminations et additions successives de HBr (^{2}HBr) sur une section strictement limitée de la chaîne carbonée. Initiées au pont C-4 de la lactone et caractérisées d'une façon hypothétique par une succession d'intermédiaires carbocationiques, les réactions d'halogénation semblent inclure un migration répétée des fonctions alcènes transitoires de C-4 à C-8 et une série de transferts d'hydrure (deutérure) comme une «fermeture éclair» en direction inverse.

Mots clés : acides deutérohaloalcanoïques, transpositions carbocationiques.

[Traduit par la rédaction]

Introduction

The motive for this report was an unexpected result obtained (1) on reexamining the classical Kiliani reduction of sugar lactones by hydriodic acid. It was found that the reaction of 57% hydriodic acid with aldono-1,4-lactones having from 5 to 8 carbon atoms gave not only the corresponding γ-alkanolactones anticipated, but also a variety of monoiodoalkanoic acids, which had not been reported earlier. These acids were probably secondary products formed from the alkanolactones in the reaction mixture, because when the pure C_5 to C_8 alkanolactones themselves were reacted with hydriodic acid, the same acids were produced. As well, higher homologs of the monoiodoacids were obtained (2) with lactones in which the chain lengths ranged through C_{18}. Then, by using 48% hydrobromic acid and 37% hydrochloric acid, in place of the hydriodic acid, analogous groups of monobromo and monochloro acids, respectively, were prepared (2).

In effect, our initial interest in the reducing properties of hydriodic acid on sugars and derivatives has been expanded to include unexpectedly complex reactions of aliphatic lactones with hydrogen halides.

An unusual feature of these latter reactions is the fact that the lactones having from 6 to 12 carbon atoms yield mixtures of monohalo acids in which each position, from C-4 to the penultimate carbon atom, is halogenated (1, 2). For example, in equilibrated reactions of ~4 h with 48% hydrobromic acid, γ-hexanolactone affords a 1:3.2 mixture of 4- and 5-bromohexanoic acids, whereas the C_{12} homolog gives a mixture of 4-, 5-, 6-, 7-, 8-, 9-, 10-, and 11-bromododecanoic acids in a ratio of 1:1.4:1.7:1.5:1.9:1.9:2.6:2.2. By contrast, the C_{14} and C_{16} lactones are restricted to the formation of only the 4- and

5-monobromo acids, in a ratio of 1:0.1, and the C_{18} lactone undergoes ring opening with virtually no accompanying isomerization, to give 4-bromooctadecanoic acid. Analogous results have been obtained in parallel reactions with 57% hydriodic acid (1, 2).

Overall, these reactions offer a previously unrecognized route to a large number of monohalo-*n*-alkanoic acids, very few of which have been described elsewhere, although their synthetic usefulness will be qualified by the ease with which individual components of the mixtures can be isolated. Of course, there is also a potential for converting the acids into equally novel hydroxy, amino, etc., alkanoic acids, and for the preparation of other series of new compounds from appropriate branched-alkyl and alicyclic lactones.

The fact that so many positional isomers can be created during these reactions, regiospecifically for sites between the lactone bridge and an often-remote penultimate carbon atom, and yet strongly dependent upon chain length, appears to have little precedence in aliphatic chemistry. As a supplement to our earlier comments on these relatively unique observations (1, 2), we offer here some new proposals as to how characteristics of this kind arise.

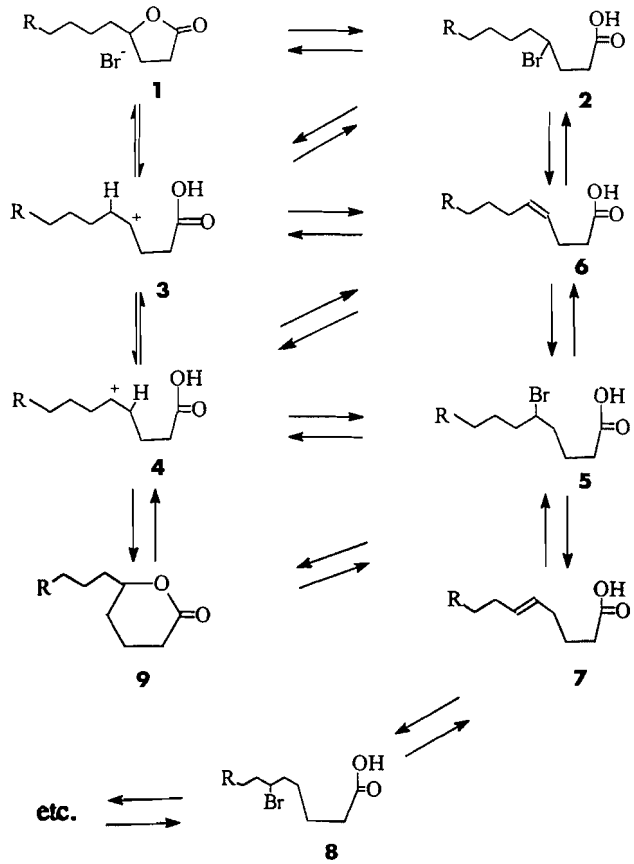
Results and discussion

Formation of positional isomers of bromononanoic acid in hydrobromic and deuterobromic acid

In each instance, the 4-bromo isomer likely arises through a nucleophilic displacement accompanied by opening of the γ-lactone ring (**1** → **2**). The introduction of halogen at higher positions requires other routes, and we assume that these involve carbocation intermediates. For example, if the formation of a C-4 carbocation (**3**) were to be followed by a transfer of the charge to C-5 via a 1,2-hydride shift (**3** → **4**) and also to higher positions by a succession of 1,2-shifts (or, perhaps, 1,3-, 1,4-, etc. shifts) then the 5-bromoacid (**5**), 6-bromo isomer, etc. would appear in admixture. Alternatively, a thermal loss of HBr from **2**, to give a 4-alkenoic acid (**6**), and then hydrobromination (**6** → **4** → **5**), could also afford the 5-bromoacid (as well as **2**) and, by an analogous sequence of steps, a 5-alkenoic acid (**7**) and a 6-bromoalkanoic acid (**8**). That is, one pathway entails the stepwise migration of positive charge from C-4 to, in most instances, the penultimate carbon, whereas the other amounts to a progression of alkene rearrangements along the same segment of the carboxylic acid chain.

Another way in which bromine may be introduced at several different positions is suggested by the fact (1, 2) that γ and δ-*n*-alkanolactones are converted by HBr (or HI) into equivalent mixtures of isomeric haloacids (e.g., γ- and δ-undecanolactones; see Table 3, ref. 1). Rearrangement of a γ-lactone (**1**) into a δ-lactone (**9**) via intermediates **3** and **4** would give a 5-bromoacid (**5**), and larger-ring lactones, assumed to be generated fleetingly at the elevated temperature of these reactions, also would be rapidly converted into correspondingly higher-numbered halogenated acids. In this context, it is worth noting that the presence of a few percent of δ-lactone among the reaction products of its γ-analog is implied by the observation of appropriate, minor, ^{13}CO signals (e.g., at δ 176 in Fig. 5; see later).

Evidence presented here shows that the addition of HBr to a succession of alkene intermediates (e.g., **6** → **5**, **7** → **8**, etc.) is a prominent event in the formation of the bromoalkanoic



acids. It was obtained by examining the reaction of deuterobromic acid with γ-nonanolactone (**1**, R = CH_3), as a representative of the series. Earlier, we reported (2) that this C_9 lactone, in 48% HBr under reflux for 4 h, gave an equilibrium mixture of 4-, 5-, -6-, 7-, and 8-bromononanoic acids in a ratio of 1:1.5:1.7:2.2:2.4, based on the integrated signals of the Br-substituted carbons. If, in the present study, the latter were to be deuterated, their integrals might be unreliable. Consequently, signals of the carboxyl ^{13}C nuclei (see Fig. 1A) were selected instead, as in our examination (2) of iodoalkanoic acid mixtures for which the methinyl ^{13}C peaks were found unsuitable. Based on evidence (2) that the chemical shifts of the ^{13}CO signals increase in sequence with the position of the bromine atom, the values represented by Fig. 1B amount to a ratio of 1:1.5:1.8:2.6:2.7, i.e., in good agreement with that estimated for the methinyl carbons.

In contrast to the group of signals shown in Fig. 1B, the corresponding spectral region (see Fig. 1C) for the products of a 4 h reaction between γ-nonanolactone and ^{2}HBr shows that the deuterated reagent failed to bring about equilibration of the bromoacid mixture. Rather, the 4-bromo isomer was major, and although the 5-, 6-, 7-, and 8-isomers were present, their proportions decreased relative to the 4-isomer in the ratio of 1:0.74:0.66:0.50:0.54. It is worth noting, for comparative purposes, that the 4-bromoacid was preponderant also (see Fig. 1A) in HBr at only 1 h. By prolonging the reaction time with ^{2}HBr to 18 h, the composition of the product mixture (see Fig. 1D) became 1:1.1:1.4:2.6:3.3, a value similar to that already given for equilibration in hydrobromic acid. However, less of the lactone survived the reaction in the deuterated medium, as

Fig. 1. The carboxyl ^{13}C nmr signals (at 67.8 MHz) of mixtures of monobromononanoic acids formed in reactions of γ-nonanolactone with 48% hydrobromic acid under reflux (A) for 1 h and (B) for 4 h, and with 47% deuterobromic acid under reflux (C) for 4 h and (D) for 18 h. The numbered signals are those assigned to the individual isomers in which a bromine atom is attached to, for example, carbon-4 (4) or carbon-8 (8); signal L is due to the C=O group of the lactone. (The δ scale for C and D is arbitrarily expanded (× 2.7) relative to that for A and B.)

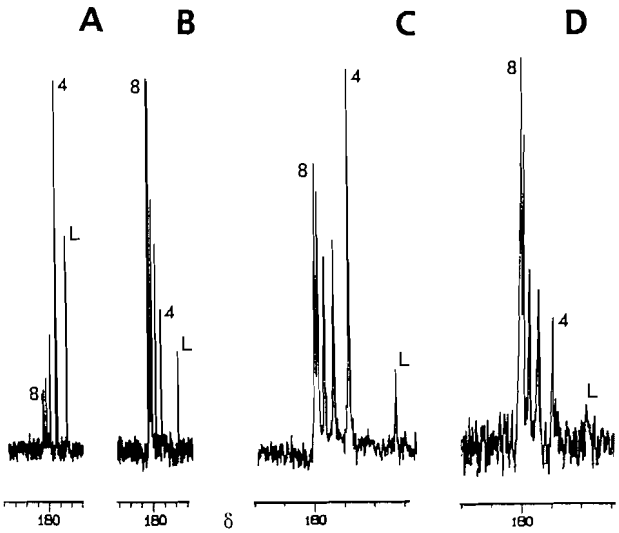

Fig. 2. High-mass regions of the chemically induced (CI) mass spectrum (NH_3 induction) of the mixture of deuterated monobromononanoic acids formed in the reaction of γ-nonanolactone with 47% deuterobromic acid under reflux for 18 h. Inset, above: corresponding response in the molecular ion region for the mixture of acids produced from the lactone in 48% hydrobromic acid.

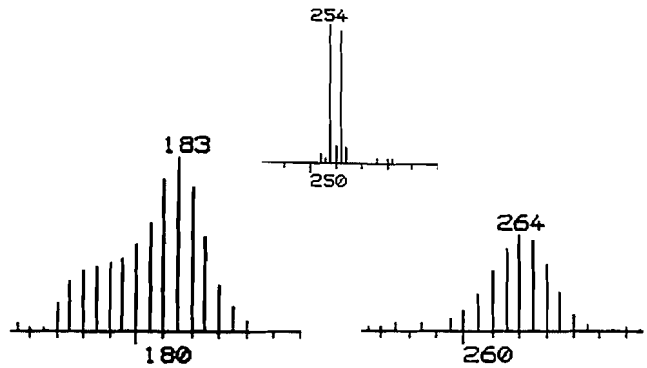

seen from a relatively far weaker ^{13}CO signal at δ 177.6 in Fig. 1D than in Fig. 1B. In the latter, the signal accounts for about 8% of the total carbonyl content (as compared with a lactone content of 12% based on ^1H integrals). By also considering the low relative intensities for lactone peaks ^1H-4 (Fig. 3A) and ^2H-4 (Fig. 3B) at δ 4.47, it is clear that the deuterated 18 h reaction mixture contained only a few percent of γ-nonanolactone.

Consistent with the slower rate of reaction in ^2HBr, and an attendant kinetic isotope effect, is the fact that the products proved to be highly deuterated. As seen from the molecular ion region of the mass spectrum of the 18 h reaction product (Fig. 2; using NH_3 as the chemical ionization reagent), the major MNH_4 ions of *m/z* 263–265 correspond to a combination of species containing ^{79}Br and 9–11 atoms of ^2H, and ^{81}Br and 7–9 atoms of ^2H. (Representing the MNH_4 ions of the nondeuterated bromononanoic acids are the inset peaks of Fig. 2 at *m/z* 254 and 256.) Slightly higher or lower levels of deuteration are represented by the lesser peaks that range from *m/z* 259 to 268. As expected, a similar distribution of peaks is found among fragments of lower mass, such as represented by the cluster about *m/z* 183 arising from the loss of bromine. The "tailing" of this group of peaks is likely due to thermal losses of hydrogen and deuterium from some of the ions.

Distribution of deuterium within the bromoacids

Information about the distribution of isotope within the individual deuterobromoacids in the mixture was obtained by ^1H and ^2H nmr spectroscopy. Major ^1H signals were found for only the H-2,2′, H-3,3′, and CH_3 protons (Fig. 3A). The latter were accounted for by three components: a tall singlet (δ 1.66), produced by the strongly deshielded CH_3 group adjacent to deuterated C-8 of the 8-bromo isomer (in place of a doublet in the spectrum of the nondeuterated compound (see Fig. 3C); a mixture of signals (δ 0.98) attributable to CH_3 groups deshielded slightly by a Br atom on C-7, and showing the effects of partial deuteration nearby; and a cluster of peaks (δ 0.85) due to the CH_3 groups of the other bromoacids. The corresponding resonances for the unlabelled product mixture are to be found in Fig. 3C.

A number of minor signals in Fig. 3A were identified with the aid of a RELAY pulse sequence. These included a group of peaks centered at δ 4.0 due to (proceeding upfield) H-8, -4, -5, -6, and -7, of the individual bromoacids, and a multiplet at δ 2.6 due to H-2,2′ of the 4-bromoacid. A small proportion of undeuterated γ-nonanolactone accounts for a weak multiplet at γ 4.45. The origin of the complex signal at δ 1.3 is the group of methylenic protons that, in the absence of the isotope (see Fig. 3C), produce a far stronger response in this region, as well as methylenic protons of residual lactone.

Complementary to the ^1H data was the ^2H nmr spectrum (see Fig. 3B). For example, the high relative intensity of the group of ^2H peaks around δ 4.0, when compared with that of the corresponding, minor, peaks in Fig. 3A, shows that the halogen-bearing carbons were almost fully deuterated. Similarly, it is evident that the majority of the isotope had been introduced at positions other than C-2, C-3, and CH_3: according to the integrated ^2H spectrum, the latter three locations accounted for only about 15% of the overall deuteration process. In view of the mass spectral evidence that the major molecular species among the monobromononanoic acids contain 8–10 ^2H atoms, most of the methylenic carbons in positions 4 to 8 must have been *doubly* deuterated. As almost full deuteration had taken place at methinyl C-8 of the 8-bromoacid, we assume that isomer would have been full deuterated as well as C-4 to C-8, inclusive, for a total of nine ^2H atoms (as in **10**). Therefore, constituting about one-third of the mixed product, it could substantially account for the major parent ions *m/z* 263 (^{79}Br) and *m/z* 265 (^{81}Br). Similarly for the 7-bromo isomer, which

Modes of deuterium incorporation

These findings raise the possibility that, although there is a constraint under which bromine atoms are introduced sequentially from C-4 towards C-8 and become most heavily populated at that position, there operates simultaneously a stepwise introduction of ^2HBr in the opposite direction. Ultimately, therefore, all protons between C-4 and C-8 could be removed through the elimination of HBr (e.g., **5** → **6**), as equilibration of the mixture of bromoalkanoic acids takes place.

Another possibility may be considered by contrasting the present deuteration pattern with one that occurs (3) during an acid-catalysed (deuterosulfuric acid) conversion of oleic acid into γ-octadecanolactone. In that reaction, most of the isotope incorporated becomes distributed relatively uniformly over the chain segment from C-7 to C-17, presumably through a succession of rearrangements of the alkene group, followed by deuteration at each new site created. However, the methylenic carbons were mainly (if not all) *mono*deuterated. Although the

Table 1. ^{13}C chemical shifts for the monobromononanoic acids produced in the reaction between γ-nonanolactone and HBr.

Carbon no.	Position of bromine atom					Nonanoic acid

therefore, all protons between C-4 and C-8 could be removed through the elimination of HBr (e.g., **5** → **6**), as equilibration of the mixture of bromoalkanoic acids takes place.

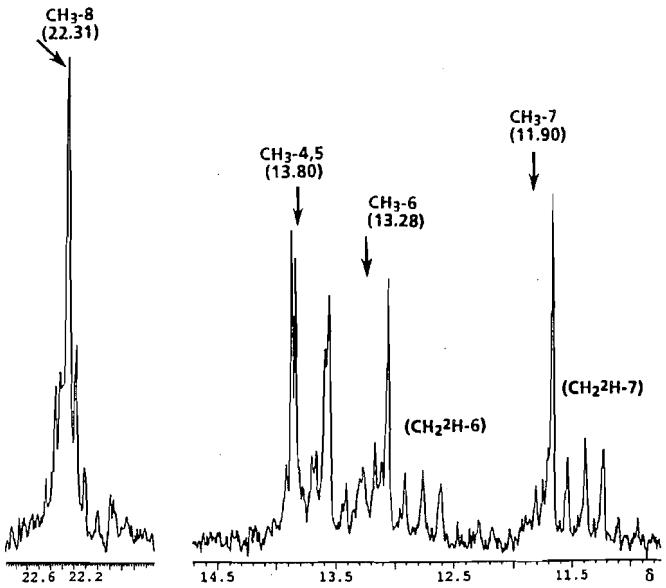
Another possibility may be considered by contrasting the present deuteration pattern with one that occurs (3) during an acid-catalysed (deuterosulfuric acid) conversion of oleic acid into γ-octadecanolactone. In that reaction, most of the isotope incorporated becomes distributed relatively uniformly over the chain segment from C-7 to C-17, presumably through a succession of rearrangements of the alkene group, followed by deuteration at each new site created. However, the methylenic carbons were mainly (if not all) *mono*deuterated. Although the C_{18} alkene intermediates envisaged are analogous to such hypothetical alkenoic acids as **6** and **7**, they can appear only when the reaction sequence proceeds towards the methyl terminus (C-18), and not be recreated by a reversal of the process. We have surmised (3) that when protonation (deuteration) occurs along the carbon chain between C-7 and C-17, the positive charge generated is transferred by a succession of 1,2-hydride shifts analogous to **4** → **3** (a "zipperlike" mechanism) to reach C-4, where the overall reaction is terminated by closure of the γ-octadecanolactone ring. Hence, *double* deuteration of methylenic carbons did not take place. In the present instance, if a "zipper" were to transfer charge between, e.g., C-8 and C-4 and lead to re-formation of γ-nonanolactone, a repetition of the bromination sequence (**1** → **2** → **3**, etc.) should occur. That is, this could serve to introduce a *second* ^2H atom on carbons 4–8, as an alternative, or in addition, to a reversal of the alkene rearrangement sequence.

Although 1,2-hydride shifts in succession would appear to help accommodate the chemical changes observed, a migration of hydrogen atoms within the carbonium ions also might take place over greater distances, i.e., by means of 1,3-, 1,4-, etc. shifts. This type of alternative was proposed to account for small proportions (<1%) of 1,3-, 1,4-, etc. diols formed in the solvolysis of 1-octene oxide (4). Nevertheless, such shifts are likely to be rare in acyclic systems (5), because of the proximity requirement for orbital overlap, in contrast to their prominence in alicyclic systems that offer suitable geometry (e.g., see ref. 6).

The fact that the deuteration process, as well as the halogenation reaction, is largely contained within the confines of the C-4 to C-8 segment of the nonanoic acid chain (and, for halogenation, between C-4 and the penultimate carbon of other alkanoic acid moieties) is taken as further evidence that a carbocation-, rather than a radical-mediated type of mechanism is involved here. That the methyl group is relatively inert conforms analogously, to behaviour expected on the basis of Saytzeff's rule. Also noteworthy is the fact that both the C-2 and C-3 methylenic groups exhibited so little involvement in the reactions. This is in contrast to free radical halogenation (7) in which C-3 can be far more readily substituted than C-2, or to enol-mediated reactions (see, e.g., ref. 8) in which C-2 but not C-3 is halogenated. If, in the present instance, C-2 is strongly deactivated because of its proximity to an electronic contribution from the carboxyl group, then a substantially smaller influence on the halogenation of C-3 would be expected. Yet, only under limited circumstances, in reactions of C_4 lactones, has the formation of a 3-haloalkanoic acid been observed (1). Hence, 3-iodobutyric acid was produced from D-erythronic-1,4-lactone or γ-butyrolactone with 57% HI under reflux, although probably in both instances via 2-butenoic acid as an intermediate. It also was obtained under the same conditions from β-butyrolactone as the direct product of ring-opening displacement. However, when provision was made for a halogen atom on C-3 to undergo rearrangement along a more extended carbon chain, as with β-valerolactone, then the initial substitution product, i.e., 3-iodopentanoic acid, was detected only as an intermediate during its transformation into 4-iodopentanoic acid.

Similarly, evidence of an unexpectedly limited participation of the C-3 methylenic group in these reactions is found in its low level of deuteration, which is approximately equal to that of C-2. That is, assuming carbonium ion **3** to be a valid intermediate, the probability that **6** is formed by a loss of one H-5 is no greater than that a loss of one H-3 would give the

Fig. 4. The 125 MHz ^{13}C nmr spectral region of the methyl groups of the deuterated monobromononanoic acids represented by Figs. 3A and 3B. The numbers refer to the positions of the bromine atom on individual isomers in the mixture, and the arrows indicate the chemical shift positions for the methyl groups of the nondeuterated compounds.



corresponding Δ^3 alkenoic acid. Deuterium could then be introduced on C-3 as readily as on C-5 whereas, in fact, only the latter becomes heavily labelled.

Conceivably, the carboxyl group also exerts a substantial effect on C-4 and beyond in the reactions of higher members of the γ- (and δ-) lactone series, because halogenation is not restricted to the initial location of the lactone bridge. Rather, the introduction of halogen atoms (bromine, chlorine, iodine) seems to be oriented away from the carboxyl terminus, as each position from C-4 (true also for δ-lactone (1, 2)) to the penultimate carbon becomes substituted. The outcome, overall, is the formation of a mixture of the maximally allowed number of isomeric haloalkanoic acids at equilibrium, commensurate (1, 2) with an overall increase in entropy.

^{13}C nuclear magnetic resonance spectra of the monobromononanoic acids

In accord with the foregoing information, by far the strongest signals in the ^{13}C nmr spectrum were those of the nondeuterated C-2, C-3, and CH_3 groups. Signals of the latter exhibited some noteworthy features due to isotope shifts and ^{13}C–^2H coupling. According to data determined for the unlabelled compounds (Table 1) the $^{13}CH_3$ peaks of the 4- and 5-bromo isomers overlap at δ 13.8, whereas those of the 6-, 7-, and 8-isomers resonate at δ 13.2, δ 11.9, and δ 22.3, respectively (see Fig. 4). Some of the corresponding signals of the deuterated bromoacids (Fig. 4) are found to have undergone upfield shifts of about 0.25 ppm, as expected for β-deuterium-isotope shifts by two deuterons (see, e.g., ref. 7). It is possible that the pair of signals centered at δ 13.85 is attributable to the CH_3 groups of those species of the 4- and 5-bromides containing intact penultimate CH_2 groups, and that the pair centered at δ 13.60 represent $CH_3C^2H_2$ structures. Alternatively, the downfield peaks could be due to a CH_3CH_2 structure in most of the 4-bromo molecules (as in **12**), and the upfield pair to a $CH_3C^2H_2$ structure in most molecules of the 5-isomer. Analogously, as the peaks of the 6- and 7-isomers are located ~0.25 ppm upfield, they also represent molecules terminated by a $CH_3C^2H_2$ grouping. As noted earlier, however, the ^1H nmr spectrum (Fig. 3A) suggests that a minor proportion of the 7-bromide molecules contain one or two protons on C-8; no corresponding ^{13}C signal is detected in Fig. 4. Also unaccounted for is the fact that the chemical shift of the $^{13}CH_3$ group in the 8-bromo isomer is found to be unaltered by the presence of the neighboring methinyl deuteron on C-8 (for a similar observation, see ref. 9).

Two triplets ($J \sim 20$ Hz) centered at δ 12.85 and δ 11.40, respectively (Fig. 4), indicate that at least a portion of the deuterium contained in methyl groups (Fig. 3B) is accounted for as $CH_2{}^2H$ in the 6- and 7-bromo isomers. As this is in accord with an α-isotope effect of a single deuteron, causing these triplets to be located 0.23–0.24 ppm upfield, the molecules represented could contain a methyl-terminal grouping of $CH_2{}^2HC^2H_2$, and at least 10 atoms of deuterium, as in **13** and **14**.

The methyl signal assignments were arrived at as part of a fuller analysis of the ^{13}C spectrum of the mixture of bromononanoic acids than made earlier (2). Presented in Table 1, the overall data are based mainly on the following considerations: (*a*) signals of the individual isomers were selected according to their integrated intensities, i.e., the strongest were taken to be those of the 8-isomer, decreasing through 7-, etc., to the weakest as those of the 4-bromide; (*b*) the chemical shifts of C-2 to C-9 were calculated for each isomer relative to the ^{13}C parameters for *n*-nonanoic acid, by assuming that the substituent effects introduced by a bromine atom (10, 11) are (in ppm): α, +28; β, +10; and γ, −3. In most instances, the agreement between the calculated and found ^{13}C chemical shifts was within ±2 ppm.

A final comment (in response to questions raised by one of the referees) is concerned with how suitable nmr spectra may be for the analysis of product composition carried out here, and this applies equally to all of the earlier analyses (1, 2). That is, the samples examined were "crude" residues, extracted from reaction mixtures that had been subjected, ostensibly, to drastic conditions. Although one might have anticipated evidence of substantial degradation and (or) by-product formation, in fact such possibilities are found to occur to an insignificant extent. This is seen from the ^{13}C nmr spectrum of the nondeuterated product described here (see Fig. 5). It shows that virtually all signals of meaningful size may be accounted for by the mixture of the lactone remaining and the five monobromo acids (the latter being identified individually through the assignments proposed in Table 1). This evidence for the absence of other than trace proportions of contaminants is representative of the results obtained consistently throughout the lactone series (1, 2) Accordingly, we conclude that the ^{13}C spectra are sufficiently free of interference as to give reliable product composition data.

Experimental

Nuclear magnetic resonance spectra were recorded with a Varian Unity 500 spectrometer operating at 500 MHz for ^1H,

Fig. 5. The 125 MHz ^{13}C nmr spectrum of the mixture of monobromononanoic acids formed in the reaction of γ-nonanolactone with 48% hydrobromic acid under reflux for 18 h (solvent, C^2HCl_3). The carbonyl signals in the region of δ 180 are analogous to those exhibited in Fig. 1B, the signal at δ 81.1 is that of C-4 of the lactone remaining, whereas the group of five between δ 60.0 and 51.5 are the $H^{13}CBr$ resonances of the 7-, 6-, 5-, 4-, and 8-bromo derivatives, respectively. Table 1 gives parameters for methylenic and methyl carbons of the individual bromo-acids, and the corresponding signals are displayed on an expanded scale in the partial spectrum (inset).

76.7 MHz for ^2H, and 125.7 MHz for ^{13}C, and (or) a Jeol CPF-270 spectrometer operating at 270 MHz for ^1H and 67.8 MHz for ^{13}C. The solvent was $CDCl_3$, and chemical shifts are given with respect to TMS. Mass spectra were recorded with a double-focusing Kratos MS25RFA mass spectrometer. Chemical ionization mass spectra were obtained with ammonia as the ionization reagent. Hydrobromic acid (48%) and deuterobromic acid (47%, >99.0% ^2H), as well as γ-nonanolactone, were obtained from Aldrich Chemical Co.

Estimation of product ratio

The ^{13}C nmr spectra were used to estimate ratios of the isomeric haloacids produced, based on the relative intensities of the resonances of the individual carbonyl carbons. These data were obtained at 67.8 MHz with a pulse angle of 40°, pulse delay of 0.80 s, and acquisition time of 1.0 s (no allowance was made for possible variations in nOe values among the ^{13}CO nuclei). Individual peak assignments were based on analyses of data obtained earlier (2) and known additivity relationships (e.g., see refs. 10, 11).

Reaction of γ-nonanolactone with HBr

A solution of the lactone (0.33 g, 2.11 mM) in HBr (48%, 5 mL) was heated under reflux for 4 h, and then cooled to room temperature. Saturated aqueous NaCl (5 mL) was added, followed by dichloromethane (50 mL). The organic layer was separated, washed with NaCl solution (2 × 5 mL), dried over anhydrous $MgSO_4$, and concentrated. A light brown oil was obtained, 0.53 g (93%), that according to ^1H and ^{13}C nmr spectra (see Figs. 3C and 1B, and Table 1) consisted of a mixture of five monobromononanoic acids, together with 8–12% of the lactone. Other preparations of these products were made with reflux periods of 1 h and 18 h, respectively (see, e.g., Fig. 1A for ^{13}C data).

Reaction of γ-nonanolactone with ^2HBr

A solution of the lactone (0.16 g, 1.0 mM) in ^2HBr (47%) was heated under reflux for 18 h, followed by work-up as above. A light brown oil was obtained, 0.25 g (~100% yield), that according to ^2H and ^{13}C nmr spectra (see Figs. 3B and 1D) and mass spectra (see Fig. 2) consisted of a mixture of five deuterated monobromononanoic acids, together with <5% of the lactone. Another preparation of these products was made with a reflux period of 4 h (see Fig. 1C for ^{13}C data).

Dicyclohexylethyleneglycol, -diethyleneglycol, -triethyleneglycol, and related monosubstituted cyclohexanes. Conformational analysis using low-temperature ^{13}C and ^{1}H NMR spectroscopy

G.W. Buchanan, A. Moghimi, V.M. Reynolds, and K. Bourque

Abstract: Two conformations of each of the title molecules have been detected by 100 MHz ^{13}C NMR at 210 K. For the dicyclohexyl systems, the conformations are related via a single ring inversion. In each case the equatorial–axial conformer is 4.7 ± 0.4 kJ/mol less stable than the diequatorially substituted form in CD_2Cl_2 solution. For monosubstituted models, the conformational free energy ($-\Delta G°$) values of the -O-CH_2-CH_2-OCH_3, -OCH_2-CH_2-O-CH_2-CH_3, and -O-CH_2-CH_2-O-CH-$(CH_3)_2$ groups have been determined to be 5.4, 6.1, and 6.1 ± 0.2 kJ/mol, respectively. In methanol, the latter equilibria are slightly more biased towards the axially substituted conformers.

Key words: substituted ethylene glycols, conformational equilibria.

Résumé : On a détecté les deux conformations de chacune des molécules mentionnées dans le titre par RMN du ^{13}C, à 100 MHz, à 210 K. Pour les systèmes dicyclohexyles, les conformations sont reliées par le biais d'une seule inversion de cycle. Dans chaque cas, en solution dans le CD_2Cl_2, le conformère équatorial–axial est 4,7 ± 0,4 kJ/mol moins stable que le diéquatorial. Pour les modèles monosubstitués, on a déterminé que les valeurs des énergies libres conformationnelles ($-\Delta G°$) des groupes -O-CH_2-CH_2-O-CH_3, -O-CH_2-CH_2-O-CH_2-CH_3 et -O-CH_2-CH_2-O-$CH(CH_3)_2$ sont respectivement de 5,4, 6,1 et 6,1 ± 0,2 kJ/mol. Dans le méthanol, les derniers équilibres sont légèrement plus biaisés en faveur des conformères substitués d'une façon axiale.

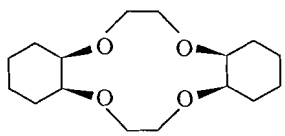
Mots clés : éthylèneglycols substitués, équilibres conformationnelles.

[Traduit par la rédaction]

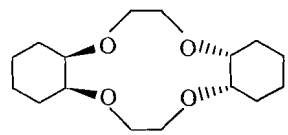
Introduction

Conformational equilibria in *cis-syn-cis*- and *cis-anti-cis*-dicyclohexano-12-crown-4-ethers (**1** and **2** below) as well as their 18-crown-6 and 24-crown-8 analogs are amenable to examination via ^{13}C NMR spectroscopy at low temperature (1–4). Generally, the detected processes are cyclohexane ring inversions, and conformational free energy differences ($-\Delta G°$) are small (i.e., <1.5 kJ/mol) due to the *cis*-1,2-disposition of the oxygenated substituents.

The dicyclohexanoethyleneglycol system **3** is a structural constituent of **1** and **2**, while the diethylene and triethyleneglycol congeners **4** and **5** are constituents of the 18-crown-6 and 24-crown-8 moieties, respectively. As such, it is of interest to determine if **3**, **4**, and **5** possess any conformational equilibria detectable by NMR at low temperature.



1



2

Results and discussion

The 100.6 MHz ^{13}C NMR spectrum of **3** at 300 K in CD_2Cl_2 is shown in Fig. 1*a*. The observation of five resonances is consistent with a situation in which all conformational interconversions are rapid on the NMR time scale. Assignments for the cyclohexyl carbons are straightforward and follow from the well-established effects of equatorial OR groups on ^{13}C chemical shifts (2). As the temperature is lowered, resonances for all carbons except C1′ show extensive broadening and finally separate into doublets of relative intensity of ca. 30:1 at 210 K as depicted in Fig. 1*b*. These integrated intensity measure-

ments were made under conditions in which T_1 differences should be minimal, namely with 30° pulses and 5 s delays between pulses. All ^{13}C chemical shift data are summarized in Table 1.

Two possibilities exist for conformational interconversion in **3**, the first being single cyclohexane ring inversion (process I) below, or the second, a less likely double inversion as shown in process II. In the absence of peak overlap, if process I occurred, the minor conformer would be expected to exhibit 10 lines, whereas if process I is present, the symmetrical minor conformer would show only 5 ^{13}C signals.

From Fig. 1*b*, it appears that only four additional lines are evident at 210 K. Hence one is faced with two possible interpretations of the spectral findings. The first is that the minor conformer must be the symmetrical **3aa** form, since only four additional resonances are detected at low temperature. The second possibility is that the minor conformer is **3ea**, with the cyclohexyl ^{13}C resonances for the equatorially substituted ring having essentially the same chemical shifts as those of the favoured conformer **3ee**.

If process II was operative, it would suggest that there must be an unusual interaction between the two terminal cyclohexane rings that either destabilizes the expected minor conformer **3ea** or stabilizes the **3aa** conformation. Such an interaction would clearly decrease as the length of the interconnecting chain increases. Hence, for the diethyleneglycol derivative **4** and the triethyleneglycol derivative **5** one would expect to observe less of the **aa** conformers. In fact, however, the low-temperature ^{13}C intensities for the major and minor conformers of **4** and **5** are essentially identical to those for **3**, indicating that the two cyclohexane rings invert independently of each other and no such unusual stabilization of the **aa** forms is present. Hence we must conclude that the minor conformations in **3**, **4**, and **5** are the **ea** forms in accord with fundamental conformational theory.

With respect to the actual value of the conformational equi-

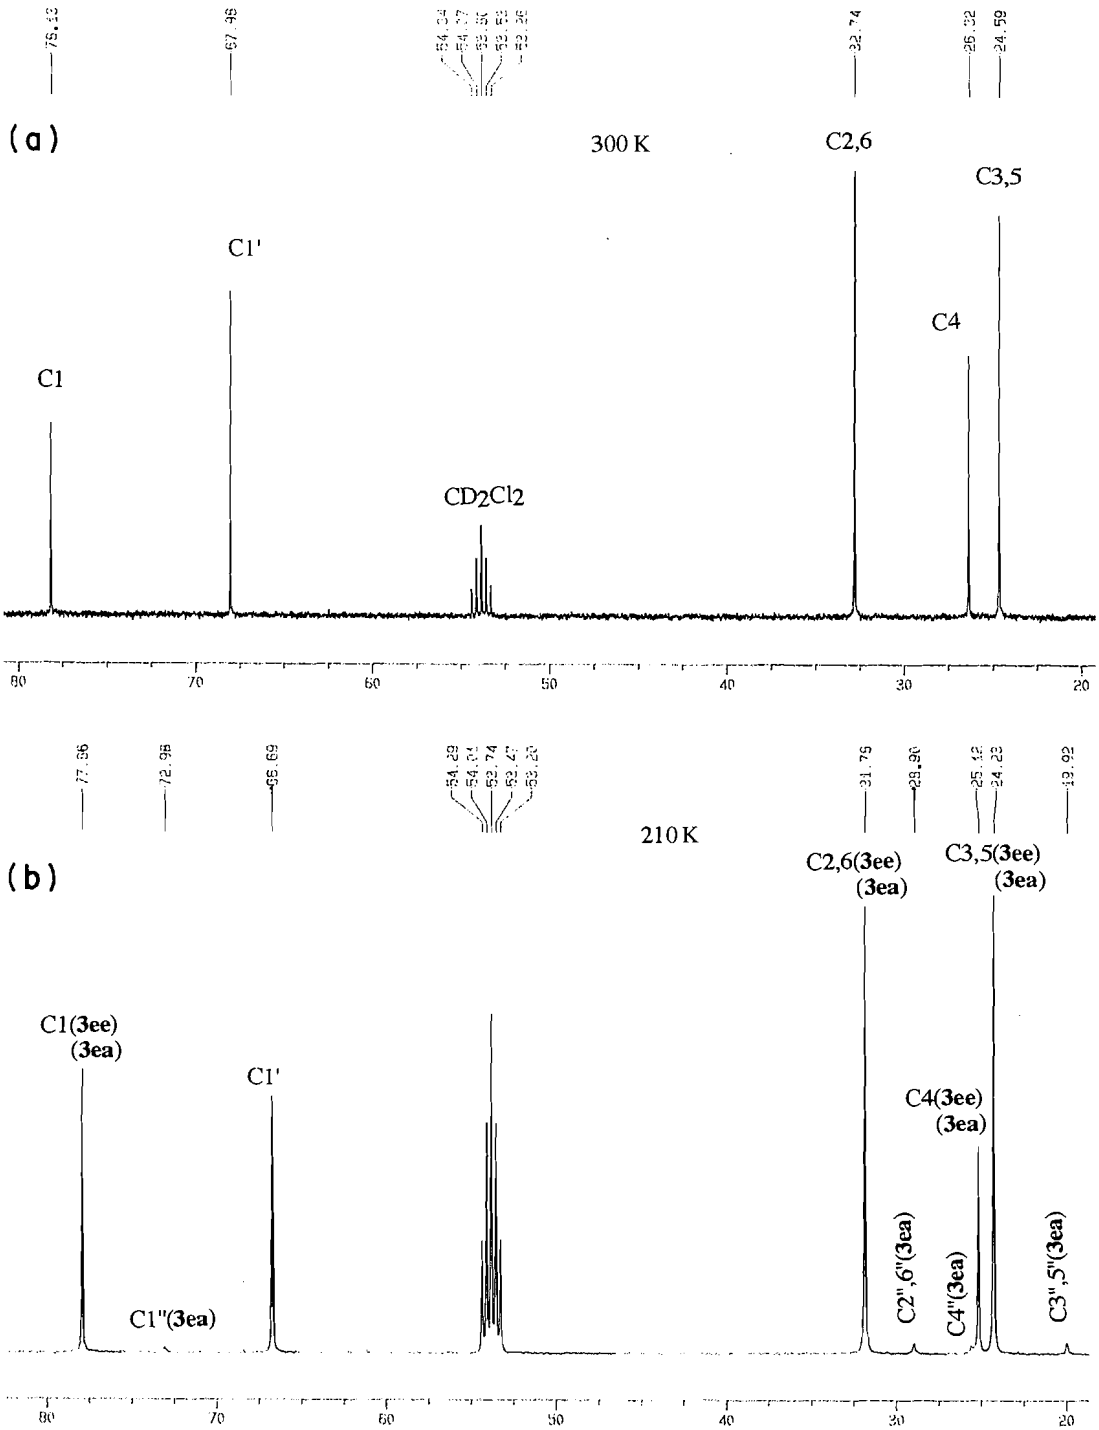
Fig. 1. (*a*) 100.6 MHz ^{13}C NMR spectrum of **3** at 300 K. (*b*) 100.6 MHz ^{13}C NMR spectrum of **3** at 210 K. C1″ etc. denotes resonance for the C1 site of the axially substituted ring of the **ea** conformer.



librium constants K, there are two potentially troublesome aspects of employing ^{13}C NMR for quantitative determination. First of all, variable spin lattice relaxation times (T_1) between corresponding carbons of the two conformers could influence the reliability of the results. The potential nonequivalence of the ^1H–^{13}C nuclear Overhauser enhancements (nOe) may also be a factor. Normally, one can circumvent the latter problem by recording spectra under nOe-suppressed conditions using gated decoupling methods. In the present work, however, the intensities of the resonances corresponding to the minor conformers are so low that these cannot be detected in a reasonable time period at low temperature using nOe-suppressed methods.

Hence it is desirable to measure the K values by ^1H NMR if possible, since ^1H T_1's are relatively short and there is no nOe enhancement. In the case of **3**, this was attempted. It was

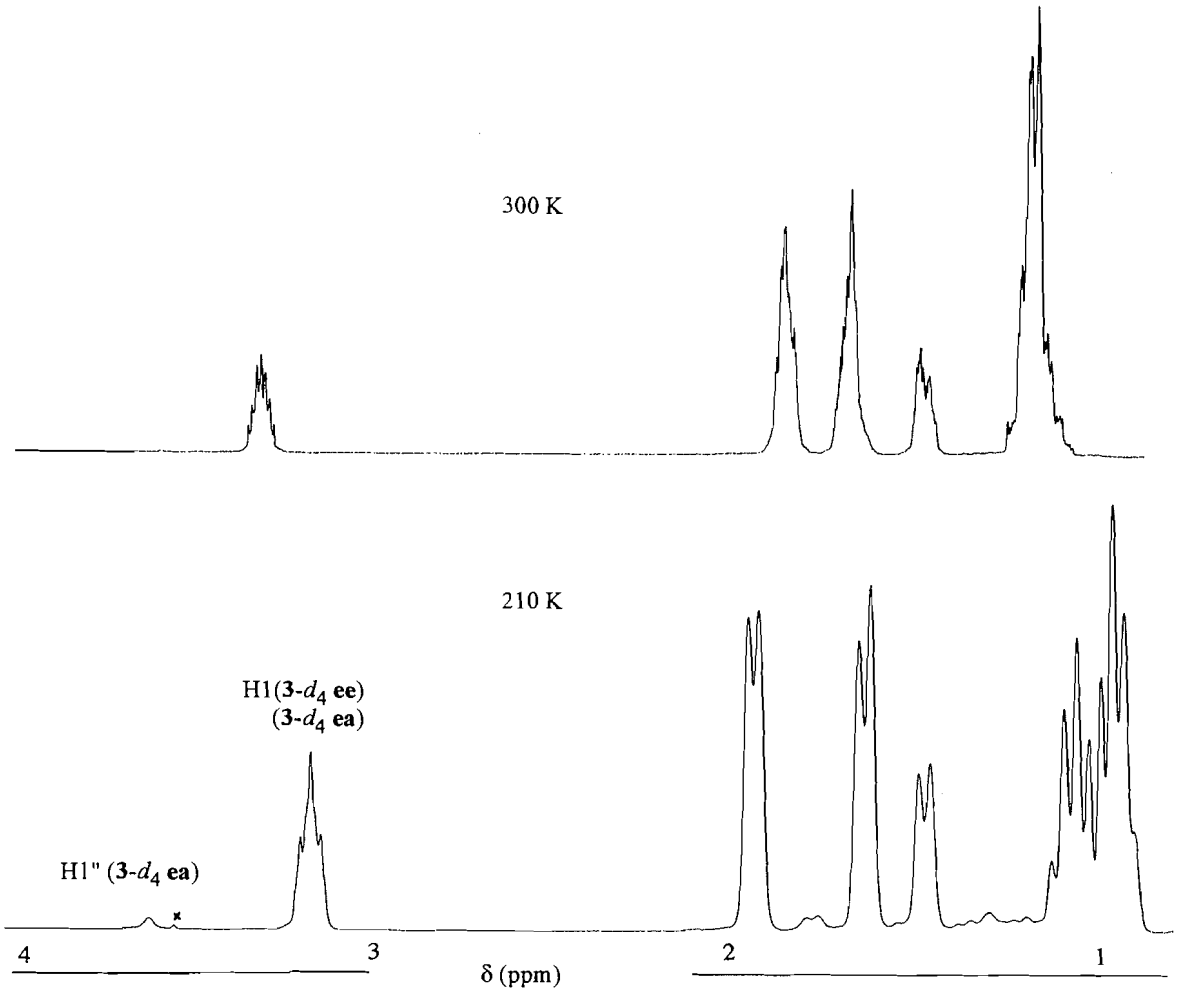
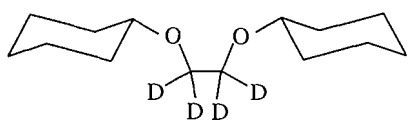
Fig. 2. 400.1 MHz ^{1}H NMR spectra of **3**-d_4 at 300 K and 210 K.



found, however, that the methine proton signal of the minor conformer overlapped with that of the protons at position 1′ at low temperature. Hence synthesis of the d_4 derivative of **3**, depicted below, was undertaken.



3-d_4

Results on this material (Fig. 2) yield relative intensities for the H1 proton resonances in the two conformations that are identical to those obtained by the ^{13}C NMR method, within error limits. Conformation **3ee**, with the axial methine protons, is favoured. The axial H1 proton is 0.42 ppm more shielded than its equatorial counterpart in the axially substituted ring of the minor conformer **3ea**. The enhanced vicinal coupling for the axial proton is evident from the overall line width of the more shielded signal.

Regarding the numerical value of the conformational equilibrium constant K, one must take into account the fact that the major conformation **3ee** is symmetrical, while **3ea**, the minor one, is not. Hence, although the relative peak intensities at 210 K are ca. 30, the actual value of the equilibrium constant will be essentially one half that. Using a value of 15 for this equilibrium constant at a temperature of 210 K, and employing the equation $-\Delta G^\circ = RT \ln K$, one obtains a value of 4.7 $\mp$ 0.4 kJ/mol for the free energy difference between **3ee** and **3ea**. The uncertainty of 0.4 kJ/mol is obtained from the standard deviation in the K values for 10 determinations. Within error limits, the same values are found for **4** and **5**.

The conformational interchanges in the mono-, di-, and triethyleneglycol portions of **3**, **4**, and **5**, respectively, have substantially lower barriers to interconversion than the cyclohexane ring reversals, and hence individual *gauche* and *trans* glycol conformers remain averaged on the NMR time scale at these temperatures. A recent theoretical study of preferred conformers in substituted ethyleneglycols indicates a slight preference for the *trans* conformation about the central O-C-C-O bond (5).

These $-\Delta G^\circ$ values are substantially larger than that of the $-OCH_3$ group, where a value of 3.1 kJ/mol has been determined, in CF_2Cl_2 at 180 K (6). No such data, however, have been reported for $-O-CH_2-CH_2-OR$ functionalities bonded to cyclohexane. Based on the present results for **3–5**, however, we anticipate $-\Delta G^\circ$ values for $-O-CH_2-CH_2-OR$ groups, measured in the same solvent as **3–5** (i.e., CD_2Cl_2) to be in excess of 4.7 kJ/mol, since there will be no symmetry differences

[a]0.1 M in CD_2Cl_2 unless otherwise indicated.
[b]At 300 K.
[c]At 210 K.
[d]0.1 M in CD_3OD.
[e]0.1 M in CS_2.
[f]Assignments may be interchanged.

between conformers of the monosubstituted cyclohexyl systems and hence no significant entropy differences between major and minor conformers. To examine such equilibria, we have undertaken the study of materials **6**, **7**, and **8** depicted below, initially in CD_2Cl_2, but subsequently also in CH_3OD. For **7**, one ^{13}C NMR measurement in CS_2 was also carried out for comparison.

^{13}C chemical shifts for **6–8** are presented in Table 2. Distinction between the resonances for C1′ and C3′ of **7** was made on the basis of COSY and HETCOR experiments. Due to peak overlap at low temperature, ^1H NMR cannot be employed to determine the conformational equilibrium constants in these materials. The integrated intensities for the cyclohexyl carbons of the individual conformers at 210 K can be used, however, for this purpose. In CD_2Cl_2 the K values for **6**, **7**, and **8** are 22.6 ∓ 2.4, 33.5 ∓ 3.8, and 32.6 ∓ 2.1, respectively. These translate into $-\Delta G°$ values of 5.4 ∓ 0.2, 6.1 ∓ 0.2, and 6.1 ∓ 0.2 kJ/mol for **6**, **7**, and **8**, respectively.

Hence it is clear that the -O-CH_2-CH_2-OR groups of **6**, **7**, and **8** are all substantially larger than the -O-CH_3 function, and that **7** and **8** possess essentially equal populations of their respective axial conformers.

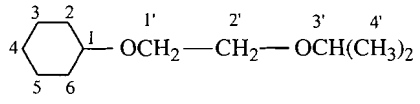
7



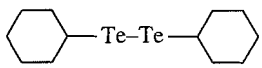
8

These findings also support the interpretation of a single ring inversion as the observed process in **3–5**. Since either of the cyclohexane rings of **3–5** can invert to form the **ea** conformer, this means that the **ea** conformers have an additional entropy of mixing of R ln 2. At 210 K, this translates into a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

$T\Delta S$ term of 1.2 kJ/mol. This, combined with the $-\Delta G°$ value of 4.7 kJ/mol observed for each of **3–5** in CD_2Cl_2 solution, leads to the prediction of $-\Delta G°$ values of 5.9 kJ/mol for an $-OCH_2-CH_2-OR$ moiety, in reasonable agreement with the results obtained for **6–8**.

There appear to be rather few examples in the literature where equilibria of this type involving two cyclohexyl rings have been examined. One recent case (7), however, involves the ditelluride shown below, in which evidence is presented for a single ring inversion, and the $-\Delta G°$ value is ca. 4.2 kJ/mol in $CDCl_3$ solution.



There are significant solvent influences on the conformational preferences of **6–8**. In 0.1 M methanol-*d*, the $-\Delta G°$ values decrease to 4.1, 4.2, and 4.5 ± 0.2 kJ/mol for **6**, **7**, and **8**, respectively, while in CS_2, the value for **7** is 4.6 ± 0.2 kJ/mol. For polar substituents capable of hydrogen bonding with the solvent, one would expect that methanol would lead to an increase in the preference for the equatorial conformer, in contrast to what is observed in these cases. The situation for **6–8** is made more complicated, however, by the presence of the relatively long substituent chain of atoms with two oxygen donor sites for hydrogen bonding.

(i) Spectra

^{13}C NMR spectra with ^1H noise decoupling were recorded at 100.6 MHz using a Bruker AMX-400 instrument. Samples were 0.1 M in CD_2CI_2 contained in 5 mm o.d. tubes. A 30° (4 μs) observe pulse was used routinely, with a 5 s delay period between the pulses. Sweep widths were typically 10 kHz with 16K data points. A line broadening of 3 Hz was introduced during processing. Spectra normally represent 4000 accumulations.

The ^1H spectra were recorded at 400.1 MHz using the same instrument. Normal sweep widths were 4 kHz. Pulse widths were 5 μs (45°) with 1 s pulse interval and 32K data points.

(ii) Materials

Dicyclohexanoethyleneglycol (1,2-dicyclohexoxyethane), **3**, was prepared by hydrogenation of the commercially available 1,2-diphenoxyethane (Aldrich Chemical Company). To 40 mL of absolute ethanol containing 100 mg rhodium-on-alumina catalyst, was added 1,2-diphenoxyethane (2.0 g, 9.3 mmol). Hydrogenation was carried out using an American Instrument Co. 50 000 psi maximum high-pressure apparatus at a pressure of 600 psi (1 psi = 6.9 kPa) and a temperature of 40°C for 20 h. The catalyst was removed by filtration to yield 2.0 g (95%) of **3**, bp 90–91°C at 0.3 Torr (1 Torr = 133.3 Pa) pressure, $n_D^{20} = 1.4699$. Anal. calcd. for $C_{14}H_{26}O_2$: C 74.28, H 11.58; found: C 74.48; H 11.49.

The d_4 derivative of **3** was synthesized starting with the commercially available ethyleneglycol-d_4 (C/D/N isotopes Inc). This was subsequently converted to its ditosylate, via reaction with tosyl chloride in anhydrous pyridine at −5°C. The ditosylate was recrystallized from ethanol to a mp of 124–126°C.

Synthesis of 1,2-diphenoxy-d_4-ethane was accomplished using the following method. Phenol (2.2 g, 20 mmol) was dissolved in 200 mL of anhydrous acetonitrile. To this solution was added 10.0 g of powdered anhydrous potassium carbonate and the solution was stirred vigorously. Subsequently, ethyleneglycol-d_4-ditosylate (2.2 g, 5.8 mmol) dissolved in a minimum volume of acetonitrile was added dropwise with stirring and the mixture was refluxed for 10 days. Following dilution with 0.1 M NaOH (300 mL), the mixture was extracted with CH_2Cl_2 (3 × 100 mL) and the organic layers dried over magnesium sulfate. Solvent removal afforded a white solid, which was recrystallized from ethanol to yield 1,2-diphenoxy-d_4-ethane (1.5 g, 97%), mp 97–98°C.

Hydrogenation to yield **3**-d_4 was carried out as described for the nondeuterated case.

Dicyclohexanodiethyleneglycol (1,5-dicyclohexoxy-3-oxapentane), **4**, was prepared via catalytic hydrogenation of 1,5-diphenoxy-3-oxapentane. The latter material was prepared as follows. A 200 mL round-bottom flask was charged with phenol (3.76 g, 0.04 mol), anhydrous THF (100 mL), and a 57% suspension of sodium hydride (0.84 g, 0.02 mol). This mixture was stirred for 15 min at room temperature. Subsequently, 1,5-dichloro-3-oxapentane (Aldrich Chemical Co.) (1.43 g, 0.01 mol) was added with stirring and the mixture was refluxed for 3 days. Upon cooling, the mixture was filtered and the solvent removed by evaporation at reduced pressure. The residue was dissolved in 100 mL of CH_2Cl_2 and treated with 5% NaOH (3 × 50 mL). The yellowish crude product was purified by column chromatography on silica gel (grade 60, 230–400 mesh) using CH_2Cl_2 as eluent, to yield 2.06 g (80% yield) of 1,5-diphenoxy-3-oxapentane, mp 65–66°C (lit. (8) mp 66°C).

For the hydrogenation, 1,5-diphenoxy-3-oxapentane (1.29 g, 5.0 mmol) was dissolved in 40 mL of methanol. Acetic acid (0.5 mL) and rhodium-on-alumina catalyst (0.3 g) were added to the solution and hydrogenation was performed at 40°C using a pressure of 600 psi for 8 h. Following filtration, the solvent was removed at reduced pressure and the crude product was dissolved in 100 mL of CH_2Cl_2 and washed with saturated NaCl (2 × 10 mL) and water (20 mL). After drying over sodium sulfate and solvent removal, the resultant oil was purified by column chromatography to yield 1.2 g (88%) of 1,5-dicyclohexoxy-3-oxapentane **4**. Anal. calcd. for $C_{16}H_{30}O_3$: C 71.07, H 11.18; found: C 70.39, H 10.87.

1,8-Dicyclohexoxy-3,6-dioxaoctane, **5**, was prepared by hydrogenation of the diphenyl precursor. The latter molecule, 1,8-diphenoxy-3,6-dioxaoctane, was prepared as follows. Phenol (4.0 g, 0.04 mol) was dissolved in 250 mL of anhydrous acetonitrile and powdered potassium carbonate (8.0 g) was added. Subsequently, 1,2-bis(2-chloroethoxy)ethane (Aldrich) (2.7 g, 0.015 mol) dissolved in 50 mL of anhydrous acetonitrile was added dropwise with stirring and the reaction mixture was refluxed for 12 days. Following dilution with 0.1 M NaOH (400 mL), the organic product was extracted with CH_2Cl_2 (3 × 150 mL) and dried over magnesium sulfate. The brown oil resulting from solvent removal was purified by flash chromatography using a 1:1 mixture of ethyl acetate and dichloromethane to give a white solid. Recrystallization from ethanol afforded 1,8-diphenoxy-3,6-dioxaoctane, mp 42–43°C, in 87% yield.

Hydrogenation was carried out by methods analogous to those used for **3** and **4** to give **5** in 90% yield. Purification was accomplished via bulb-to-bulb distillation at an oven temper-

ature of 150°C and 0.3 Torr pressure to yield **5** as a colourless oil, $n_D^{20} = 1.4693$. Anal. calcd. for $C_{18}H_{34}O_4$: C 68.75, H 10.89; found: C 68.56, H 11.01.

Compound **6** was prepared according to the following procedure. Phenol (5.0 g, 0.053 mol) was dissolved in 200 mL of anhydrous acetonitrile. Powdered potassium carbonate (10.0 g, 0.072 mol) was added and the solution was stirred for 15 min. To this was added 2-bromoethyl methyl ether (5.0 g, 0.036 mol) dropwise with stirring and the mixture was refluxed with stirring for 2 days. After cooling, the mixture was filtered and the solvent removed in vacuo. The crude product was vacuum distilled to give 1.4 g (26%) of 1-methyl-4-phenylethylene glycol. Hydrogenation to **6** was carried out via methods analogous to those for **3**, **4**, and **5**. After vacuum distillation the yield of **6** was 90%. This material, $n_D^{20} = 1.4423$, was characterized by high-resolution mass spectrometry, *m/z*: 158.13128 for $C_9H_{18}O_2$.

The precursor to **7**, namely, 1-ethyl-4-phenylethylene glycol, was prepared as described above for the 1-methyl analog, with the exception that 2-bromoethylethyl ether was employed. Catalytic hydrogenation to **7** was accomplished in 95% yield, giving **7**, $n_D^{20} = 1.4738$, high-resolution ms, *m/z*: 172.14357 for $C_{10}H_{20}O_2$.

The precursor to **8**, namely, 1-isopropyl-4-phenyl ethylene glycol, was synthesized via the following method. NaH (2.4 g, 0.1 mol) was added slowly to reagent grade isopropanol (150 mL) and the mixture was stirred for 10 min. To this stirred mixture was added β-bromophenetole (10.0 g, 0.05 mol) and the mixture was refluxed for 2 days. The mixture was diluted with 500 mL of distilled water and extracted with CH_2Cl_2 (3 × 100 mL). The organic extracts were dried over magnesium sulfate and the solvent was removed in vacuo. The crude product was subsequently hydrogenated via methods analogous to those used for **6** and **7** to yield crude **8**. Following column chromatography on silica gel using 1:10 ether:hexane as solvent, pure **8**, $n_D^{20} = 1.4495$, was obtained in 70% overall yield. Anal. calcd. for $C_{11}H_{22}O_2$: C 70.92, H 11.90; found: C 71.02, H 11.65.

Abstract: Six Cu(II) dimers, $[\{Cu(dien)\}_2(\mu\text{-dicyd})][CF_3SO_3]_2$ (**1**), $[\{Cu(dien)\}_2(\mu\text{-Me}_2\text{dicyd})][CF_3SO_3]_2$ (**2**), $[\{Cu(dien)\}_2(\mu\text{-Cl}_2\text{dicyd})][CF_3SO_3]_2$ (**3**), $[\{Cu(L)\}_2(\mu\text{-dicyd})]$ (**4**), $[\{Cu(L)\}_2(\mu\text{-Me}_2\text{dicyd})]$ (**5**), and $[\{Cu(L)\}_2(\mu\text{-Cl}_2\text{dicyd})]$ (**6**), where dicyd^{2-}, Me$_2$dicyd^{2-} and Cl$_2$dicyd^{2-} are unsubstituted, 2,5-dimethyl- and 2,5-dichloro-1,4-dicyanamidobenzene dianions, respectively, dien is diethylenetriamine, and L^- = 1,3-bis(2-pyridylimino)isoindolinato, have been synthesized and characterized by elemental analysis, IR, UV–vis, and EPR spectroscopy, and magnetic studies. Temperature-dependent magnetic susceptibility measurements of the complexes **1**–**6** from 5 to 300 K are reported. The data for **2**, **3**, **5**, and **6** have been fitted to a dimer model with a modified Bleaney–Bowers expression which derived antiferromagnetic exchange constants $-J$ = 10.6, 4.5, 5.2, and 3.0 cm^{-1}, respectively (where the Hamiltonian is of the form $\mathcal{H} = -2J\boldsymbol{S}_a\cdot\boldsymbol{S}_b$). For **4**, an approach to a maximum in χ_m with decreasing temperature gave an estimated $-J < 3.5$ cm^{-1}. Only complex **1** showed Curie–Weiss behavior. This is far weaker antiferromagnetic exchange compared to that observed for dinuclear Ru(III) complexes incorporating the dicyd^{2-} bridging ligands (J. Am. Chem Soc. **114**, 5130 (1992)) and is attributed to a symmetry and energy mismatch between Cu(II) σ^* magnetic orbitals and the π_{nb} molecular orbitals of the bridging ligand which are important for superexchange.

Key words: superexchange, copper dimer, dicyanamidobenzene.

Résumé : On a préparé six dimères du Cu(II), $[\{Cu(dien)\}_2(\mu\text{-dicyd})][CF_3SO_3]_2$ (**1**), $[\{Cu(dien)\}_2(\mu\text{-Me}_2\text{dicyd})][CF_3SO_3]_2$ (**2**), $[\{Cu(dien)\}_2(\mu\text{-Cl}_2\text{dicyd})][CF_3SO_3]_2$ (**3**), $[\{Cu(L)\}_2(\mu\text{-dicyd})]$ (**4**), $[\{Cu(L)\}_2(\mu\text{-Me}_2\text{dicyd})]$ (**5**), et $[\{Cu(L)\}_2(\mu\text{Cl}_2\text{dicyd})]$ (**6**) (dans lesquels dicyd^{2-}, Me$_2$dicyd^{2-} et Cl$_2$dicyd^{2-} sont respectivement les dianions non substitué, 2,5-diméthyl- et 2,5-dichloro-1,4-dicyanamidobenzènes, dien est la diéthylènetriamine et L^- = 1,3-bis(2-pyridylimino)isoindolinato) et on les a caractérisés par analyse élémentaire, spectroscopies IR, UV-visible et RPE ainsi que par des études magnétiques. Opérant à des températures variant de 5 à 300 K, on a mesuré la susceptibilité magnétique des six complexes (**1** à **6**); elle varie avec la température. On a ajusté les données des composés **2**, **3**, **5** et **6** pour un modèle dimère avec une expression de Bleaney–Bowers modifiée et on en a extrait leurs constantes respectives d'échange antiferromagnétique $-J$ = 10,6, 4,5, 5,2, et 3,0 cm^{-1} (dans lesquelles l'Hamiltonien est de la forme $\mathcal{H} = -2J\boldsymbol{S}_a\cdot\boldsymbol{S}_b$). Pour le composé **4**, une approche d'un maximum dans le valeur de χ_m avec une diminution de la température conduit à une valeur de $J < 3{,}5$ cm^{-1}. Le complexe **1** est le seul à présenter un comportement Curie–Weiss. Ceci correspond à un échange antiferromagnétique beaucoup plus faible que celui observé avec les complexes dinucléaires du Ru(III) contenant des coordinats dicyd^{2-} agissant comme ponts (J. Am. Chem. Soc. **114**, 5130 (1992)) et ce comportement est attribué à une symétrie et à une mauvaise adaptation entre les orbitales magnétiques σ^* du Cu(II) et les orbitales moléculaires π_{nb} du coordinat assurant le pont qui sont importantes pour le superéchange.

Mots clés : superéchange, dimère du cuivre, dicyanamidobenzène.

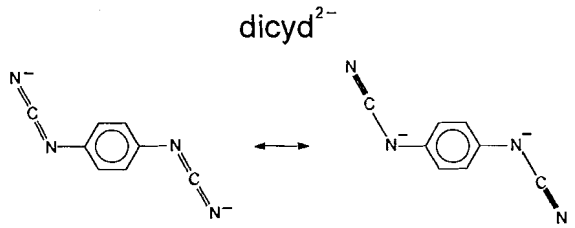
Introduction

The purposeful synthesis of novel magnetic or electronic solid state materials composed in part of metal ions requires a fundamental understanding of electron exchange processes at the molecular level. When the metal ions are not in direct contact, coupling is most effectively achieved by the superexchange mechanism in which the molecular orbitals of a bridging ligand provide a pathway for metal–metal interaction (1). Optimization of superexchange requires that metal orbitals be of the correct symmetry and energy to overlap strongly with a continuous and common molecular orbital of the bridging ligand (2).

We are exploring the coordination chemistry of the cyanamide anion group and in particular the properties of dinuclear complexes which incorporate the bridging ligand 1,4-dicyanamidebenzene dianion dicyd^{2-} and its substituted derivatives.



The dicyd^{2-} ligand has proven itself to be a remarkably effective medium for antiferromagnetic superexchange coupling in $[\{(NH_3)_5Ru\}_2(\mu\text{-dicyd})]^{4+}$ complexes despite the fact that the Ru(III) ions are separated by approximately 13 Å (3). Magnetic exchange coupling constants $-J$ for the complexes ranged from 96 to $\geq$ 400 cm^{-1} (where $\mathcal{H} = -2JS_a \cdot S_b$) and were suggested to arise from a continuous and energetically favorable π interaction between the magnetic πd orbitals of the Ru(III) ions and the π HOMO of the dicyd^{2-} ligand. The magnetic properties of these complexes have recently been shown to be solvent dependent (4). In strong donor solvents, antiferromagnetic exchange is dramatically weakened because of a donor–acceptor interaction between the solvent lone pairs and the hydrogens of the ammine ligands bound to Ru(III). This weakens the interaction of the Ru(III) ions with the cyanamide moieties of the bridging ligand which effectively decouples the Ru(III) ions from the superexchange pathway. In addition, the mixed-valence complexes also showed a similar solvent dependence of metal–metal coupling (4, 5).

In this study, Cu(II) dinuclear complexes have been prepared in which the Cu(II) ions are bridged by 1,4-dicyanamidobenzene dianion derivatives. A comparison between the temperature-dependent magnetic susceptibility of these complexes and their Ru(III) analogues explores the effect of the nature of the metal magnetic orbitals on the magnitude of antiferromagnetic superexchange via the dicyd^{2-} bridging ligand.

Experimental

Physical measurements

Ultraviolet–visible absorption spectra were taken on a Cary 5 spectrophotometer. The IR spectra of samples in KBr discs were obtained with a Perkin-Elmer 1600 series FTIR spectrophotometer. Temperature-dependent magnetic susceptibility measurements were performed on a Quantum Design S.Q.U.I.D. magnetometer from 5 to 300 K in a 1.0 T field. C,H, and N elemental analyses were performed by Canadian Microanalytical Services Ltd. The %Cu was determined by atomic absorption spectroscopy with a Perkin-Elmer 600 spectrophotometer. The reported average %Cu and standard deviation are the result of three determinations. The experimental setup used to perform the cyclic voltammetry experiments has already been described (6). The ferricenium/ferrocene couple with E^0 = 400 mV vs. NHE (7) was used as an internal calibrator. EPR spectra were recorded with a Bruker ESP 300 X-band spectrometer at 295 and 77 K.

Materials

All chemicals and solvents were reagent grade or better. $Cu(CF_3SO_3)_2 \cdot nH_2O$, was prepared by digesting copper metal turnings in triflic acid (Aldrich). The protonated ligand 1,4-bis(pyridylimino)isoindoline (LH) (8), the complexes Cu(L)X (X = Br$^-$ and $CF_3SO_3^-$) (9), and $[Cu(dien)(NO_3)][NO_3]$ (10) were prepared by literature methods. The syntheses of the 1,4-dicyanamidebenzene derivatives (dicydH$_2$), their tetraphenylarsonium salts ($[AsPh_4]_2$[dicyd]) (3, 11), 2,3-dichlorophenylcyanamide (2,3-Cl$_2$pcydH), and its thallium salt [T1][2,3-Cl$_2$pcyd] (12), have already been described.

Cu(II) dimer syntheses

*Preparation of $[\{Cu(dien)\}_2(\mu\text{-dicyd})][CF_3SO_3]_2$, **1***

To a solution of $Cu(CF_3SO_3)_2$ (1.15 g) and dicydH$_2$ (0.19 g) in 2-methoxyethanol was added, under an argon atmosphere, the ligand dien (0.23 g) and triethylamine (1 mL). After stirring for 4 h, the volume of the green solution was reduced to 20 mL. The concentrated reaction solution was then filtered and the filtrate placed in a freezer (–16°C) overnight, precipitating the brown microcrystalline product. The crude product was recrystallized by slow evaporation of a solution of the complex in methanol. Yield: 0.50 g (27%). Anal. calcd. for $C_{18}H_{30}N_{10}O_6F_6S_2Cu_2$: C 27.44, H 3.81, N 17.77, Cu 16.17; found: C 27.53, H 3.77, N 17.74, Cu 16.01 ± 0.22.

*Preparation of $[\{Cu(dien)\}_2(\mu\text{-}Me_2dicyd)][CF_3SO_3]_2$, **2***

The same procedure as above was followed with $Cu(CF_3SO_3)_2$ (1.04 g) and Me$_2$dicydH$_2$ (0.20 g). The crude product was recrystallized in 2-methoxyethanol by slow evaporation. Yield: 0.52 g (29%). Anal. calcd. for $C_{20}H_{34}N_{10}O_6F_6S_2Cu_2$: C 29.45, H 4.17, N 17.17, Cu, 15.58; found: C 29.38, H 3.99, H 3.99, N 16.80, Cu 15.53 ± 0.11.

*Preparation of $[\{Cu(dien)\}_2(\mu\text{-}Cl_2dicyd)][CF_3SO_3]_2$, **3***

Under an argon atmosphere $Cu(CF_3SO_3)_2$ (1.0 g) and $[AsPh_4]_2$[Cl$_2$dicyd] (1.06 g) were dissolved in acetone (100 mL). The ligand dien (0.23 g) was then added. Almost immediately, the pale green product began to precipitate from solution. After 1 h, the product was filtered off, and recrystallized from methanol by slow evaporation. Yield: 0.44 g (24%). Anal. calcd. for $C_{18}H_{28}N_{10}O_6F_6S_2Cu_2$: C 25.23, H 3.25, N 16.38, Cu 14.84; found: C 25.33, H 3.33, N 15.99, Cu 14.66 ± 0.15.

*Preparation of $[\{Cu(L)\}_2(\mu\text{-}Cl_2dicyd)]$, **6***

Degassed 1-methyl-2-pyrrolidinone (100 mL) was transferred under argon to a reaction flask containing Cu(L)(CF_3SO_3) (0.62 g) and Cl$_2$dicydH$_2$ (0.14 g). Triethylamine (0.73 g) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

then added and the solution allowed to stir for 4 h. The now green solution was filtered and the product forced out of the filtrate by the addition of water (150 mL). The resultant green precipitate was collected by filtration and washed with copious quantities of water, acetone, and finally ether. The crude product was recrystallized twice from hot 1,2-dichlorobenzene and dried in vacuo at 110°C. Yield: 0.26 g (45%). Anal. calcd. for $C_{44}H_{26}N_{14}Cl_2Cu_2$: C 55.70, H 2.76, N 20.67, Cu 13.38, found: C 55.06, H 2.78, N 20.29, Cu 13.27 ± 0.10.

Preparation of [{Cu(L)}$_2$(μ-Me$_2$dicyd)]·(1/6)(1,2-dichlorobenzene), 5

This complex was prepared in a similar manner to the Cl_2dicyd analogue except that Cu(L)Br(1.0 g) was used instead of Cu(L)(CF_3SO_3). Yield: 0.55 g (56%). Anal. calcd for $C_{47}H_{32.6}H_{14}Cl_{0.3}Cu_2$: C 60.56, H 3.50, N 21.03, Cl 1.27, Cu 13.62; found: C 59.19, H 3.43, N 21.04, Cl 1.00, Cu 13.55 ± 0.18.

Preparation of [{Cu(L)}$_2$(μ-dicyd)]·(1/6)(1,2-dichlorobenzene), 4

This complex was prepared in a similar manner to the Cl_2dicyd analogue. Yield: 0.41 g (42%). Anal. calcd. for $C_{45}H_{28.6}N_{14}Cl_{0.3}Cu_2$: C 59.76, H 3.17, N 21.69, Cu 14.05; found: C 58.50, H 3.26, N 21.95, Cu 14.31 ± 0.12.

Recrystallization of the above two complexes from 1,2-dichlorobenzene resulted in a persistent solvent impurity despite drying in a vacuum at 110°C.

Mononuclear complex syntheses

Preparation of [{Cu(dien)(2,3-Cl$_2$pcyd)][NO$_3$], 7

[Cu(dien)(NO_3)][NO_3] (0.50 g) and [Tl][2,3-Cl_2pcyd] (0.67 g) were placed in methanol and the mixture refluxed for 5 h. The blue–green reaction mixture was cooled overnight at −15°C then filtered. The filtrate was then concentrated to 30 mL and the product forced out of solution by the addition of ether. Recrystallization from 1:1 methanol/ether at −15°C, gave blue–green needles. Yield: 0.43 g (60%). Anal. calcd. for $C_{11}H_{16}N_6O_3Cl_2Cu$: C 31.87, H 3.86, N 20.26; found: C 31.75, H 3.78, N 19.88.

Preparation of [{Cu(L)(2,3-Cl$_2$pcyd)], 8

[Cu(L)(CF_3SO_3)] (0.50 g) and [Tl][2,3-Cl_2pcyd)] (0.44 g) were placed in 2-methoxyethanol and the mixture refluxed for 2 h. The hot deep green–yellow solution was filtered and the filtrate reduced to 20 mL. Cooling the solution precipitated the crude yellow product. Recrystallization by ether diffusion into 1,2-dichloroethane solution gave pale yellow needles. Yield: 0.32 g (52%). Anal. calcd. for $C_{25}H_{15}N_7Cl_2Cu$: C 54.80, H 2.74, N 17.90; found: C 54.25, H 2.73, N 17.71.

Results

Synthesis

The Cu(dien) dication complexes **1**, **2**, and **3** were prepared from the reaction of the respective 1,4-dicyanamidobenzene dianion ligand with dien and Cu(CF_3-CO_3)$_2$ in 2-methoxyethanol or acetone. These compounds have moderate solubility in polar solvents and various attempts to grow X-ray quality crystals gave microcrystalline powders.

[d]In dichloroethane.

The neutral complexes **4**, **5**, and **6** were prepared by reacting a solution of Cu(L)X, (where X = CF_3SO_3 or Br), in 1-methyl-2-pyrrolidinone with 1,4-dicyanamidebenzene. In the presence of triethylamine, the coordinated dicydH_2 ligand deprotonates and this results in the precipitation of the neutral dinuclear complex. Recrystallization of these complexes gave only powders. The elemental analyses of all the complexes are consistent with their proposed stoichiometry while evidence that dicyd^{2-} is coordinated and bridges two Cu(II) ions can be found through an examination of the copper complexes' visible electronic absorption and IR spectroscopies, electrochemistry, and magnetochemistry. There are numerous crystal structures which show that a phenylcyanamide ligand coordinates to a metal ion by its nitrile nitrogen (3, 13, 14).

Electronic and infrared spectroscopy

Visible electronic absorption data and their assignments for the dinuclear copper complexes have been compiled in Table 1 and a spectrum of the complex [{Cu(dien)}$_2$(μ-dicyd)]$^{2+}$ in methanol is shown in Fig. 1. The two bands seen at wavelengths less than 400 nm are associated with the dicyd^{2-} ligand. There are two main bands in the visible spectra of the

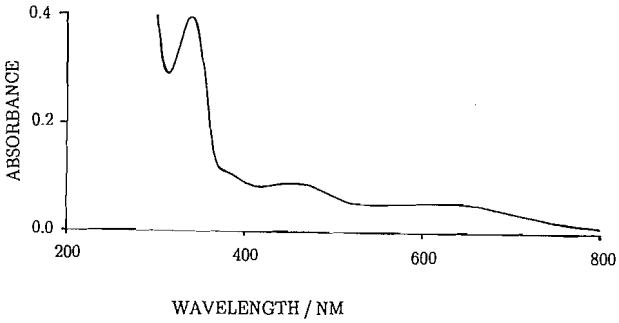
Fig. 1. Visible absorption spectrum of $[\{Cu(dien)\}_2(\mu\text{-}Cl_2\text{-dicyd})][CF_3SO_3]_2$, 3, 2.27×10^{-4} M in methanol.



copper dien complexes. The high-energy band has been assigned to a $\pi \rightarrow \sigma^*$ LMCT transition of the Cu(II)-cyanamide chromophore while the lower energy band has the assignment metal-centered *d–d* transition, in analogy to the similar visible spectra of $[Cu(2,2'\text{-bipyridine})_2(\text{phenylcyanamide})]^+$ complexes (13). For the copper 1,3-bis-(pyridylimino)isoindolinato complexes, an intense ligand $\pi \rightarrow \pi^*$ transition obscures the LMCT transition arising from the Cu(II)-cyanamide chromophore so that only the low-energy *d–d* band can be resolved. Predictably the energy of the *d–d* band shifts to lower energies as the π donor properties of the $dicyd^{2-}$ bridging ligand increases (13). In addition, the higher energy of the *d–d* band in the Cu(dien) complexes compared to Cu(L) complexes likely reflects a greater compression to a more planar geometry in the Cu(dien) complexes (15).

The IR spectra of the tetraphenylarsonium salts of $dicyd^{2-}$, Me_2dicyd^{2-}, and Cl_2dicyd^{2-} show a strong single band assigned to ν(NCN) at 2089, 2093, and 2100 cm^{-1}, respectively (11). Upon coordination to Cu(II), ν(NCN) shifts to higher energies (Table 1) in a manner which seems largely dependent on the charge of the complex. Crystallographic and IR studies have shown that inequivalent cyanamide groups result in multiple ν(NCN) bands (3, 13). The observation of only one sharp ν(NCN) band in the IR spectra of the dinuclear copper complexes leads to the conclusion that both cyanamide groups of a respective bridging ligand are in equivalent coordination environments.

Cyclic voltammetry

Electrochemical data of the free $dicyd^{2-}$ ligands and copper complexes are given in Table 2. Representative cyclic voltammograms of the complexes **2** and **5** are shown in Figs. 2 and 3, respectively. The free $dicyd^{2-}$ ligands are easily oxidized,

$$dicyd^{2-} \overset{-e^-}{\rightleftharpoons} dicyd^{-} \overset{-e^-}{\rightleftharpoons} dicyd^{0}$$

and show two redox couples whose potential depends largely on the nature of the substituents on the phenyl ring (16). The $dicyd^{0/-}$ couples for the three derivatives show good reversibility in both 2-methoxyethanol and dichloroethane, having equivalent anodic and cathodic currents and peak-to-peak separations of 60 mV independent of scan rate (50 to 500 mV/s). On the other hand, the $dicyd^{-/2-}$ couples show evidence of irreversibility with peak-to-peak separations >100 mV.

The cyclic voltammograms of the dinuclear copper complexes (Figs. 2 and 3) were complicated by the complete irreversibility of the Cu(II/I) couple and the increased irreversibility of the $dicyd^{-/2-}$ couple when coordinated to two Cu(II) ions. The Cu(L) complexes **4**, **5**, and **6** were the best behaved showing well-defined ligand and copper waves (Fig. 3). A cyclic voltammogram of the precursor complex, $Cu(L)(CF_3SO_3)$ in dichloroethane showed only the Cu(II/I) cathodic wave at –0.82 V vs. NHE in the range of +0.8 V to –1.0 V. The complexes **4**, **5**, and **6** each showed a similar irreversible Cu(II/I) couple at approximately –0.7 V vs. NHE. The $dicyd^{0/-}$ couple for these copper complexes showed little change in potential compared to the corresponding free ligand couple; however, the $dicyd^{-/2-}$ couple was shifted anodically by approximately 300 mV and indicates the preference of Cu(II) ions for the dianion bridging ligand. This was further supported by our failed attempts to observe spectroelectro-

chemically the one electron oxidation product of the dinuclear copper complexes due to its rapid decomposition upon formation. The cyclic voltammograms of the Cu(dien) complexes **1** and **3** are represented by the voltammogram of **2** in Fig. 2. Only the Dicyd$^{0/-}$ couple is well defined while the dicyd$^{-/2-}$ and Cu(II/I) waves are so broadened that an exact determination of peak potential is difficult.

Magnetic susceptibility

Magnetic susceptibility measurements were made over the temperature range 5–300 K. For the complexes **2**, **3**, **4**, **5**, and **6** the variations in χ_m with temperature are consistent with weak intramolecular antiferromagnetic exchange and the data were fitted with a Bleaney–Bowers expression (17)

$$[1] \quad \chi_m = (2Ng^2\beta^2/3kT)[1 + (1/3)\exp(-2J/kT)]^{-1} + \text{TIP}$$

where g is the powder average g value, J is the antiferromagnetic exchange constant, and TIP is a correction for any temperature-independent or Van Vleck paramagnetism which is usually present in Cu(II) systems. These fitting parameters have been placed in Table 3. Figure 4 shows the data and fitting for the most strongly coupled complex, [{Cu(dien)}$_2$(μ-Me$_2$dicyd)][CF$_3$SO$_3$]$_2$ **2**. For complex **4**, the approach to a maximum in χ_m was insufficient to permit a successful analysis and so only an upper limit ($-J < 3.5$ cm^{-1}) is given. Complex **1** was the only system to show Curie–Weiss behavior in the temperature range covered.

Two of the complexes reported in Table 3 possess anomalously large χ_{TIP} values, namely, those for complexes **3** and **6**, for which susceptibilities on the order of 10^{-2} emu mol^{-1} are found. Typically, for Cu(II) complexes in distorted 6-fold or 5-fold coordination, χ_{TIP} values range up to 10^{-4} emu mol^{-1} per Cu(II) ion so values for a dimeric species could attain the values found for complexes **2**, **4**, and **5**. Possible explanations for **3** and **6** might include the presence of an impurity phase which contributes a high χ_{TIP} or that the values are intrinsic to the materials in question and arise by some unusual mechanism. Evidence against the impurity option comes from an analysis of the "high temperature" data, 60–300 K, using just a Curie–Weiss plus χ_{TIP} function for the fitting. The results for complexes **3** and **6**, respectively, are $C = 0.476$ emu K mol^{-1}, $\theta = -8.1$ K, $\chi_{TIP} = 6.8 \times 10^{-3}$ emu mol^{-1} and $C = 0.438$ emu K mol^{-1}, $\theta = -10.6$ K, $\chi_{TIP} = 1.54 \times 10^{-2}$ emu mol^{-1}. The values of the Curie constants are quite consistent with the ESR g-factor data for both compounds, $g_{av} = 3.26\ C^{1/2}$ giving $g_{av} = 2.10$–2.20. One would not expect such close agreement with the presence of a significant impurity concentration which would introduce a large error into the sample mass used to derive C from the data.

One must then consider the possibility that the observed values are intrinsic. There is no simple explanation for this. Factors which might contribute to a large χ_{TIP} include a highly distorted, low-symmetry Cu(II) site which could lead to small energy denominators in the second-order Van Vleck terms. There is evidence from the optical spectral results of such a low-symmetry environment. It is worth noting that both complexes **3** and **6** contain the same bridging ligand, the Cl$_2$dicyd^{2-}.

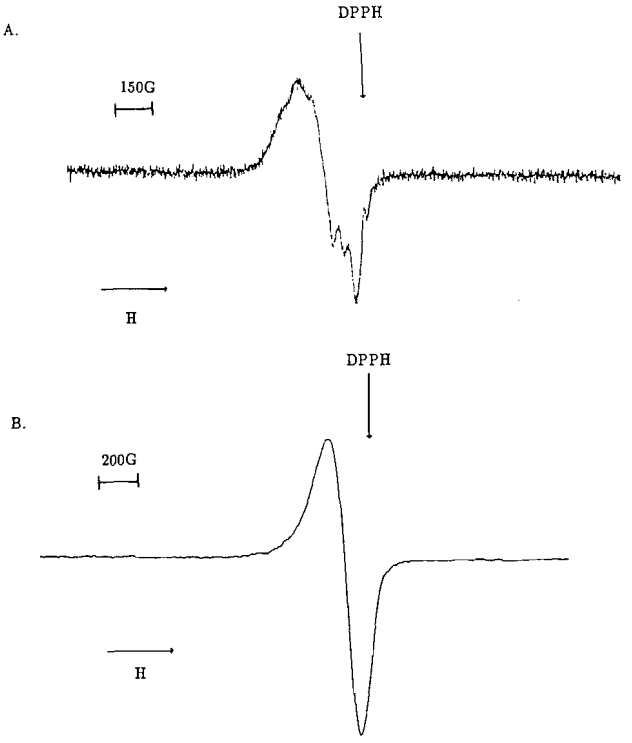
two main features corresponding to the triplet $\Delta M_s = \pm 1$ transitions associated with an axial **g** tensor.[2] Estimates of the g values at 77 K are given in Table 4. For complex **1**, no resonance was observed at 295 or 77 K. The room temperature and 77 K EPR spectra of the complexes **1**, **2**, and **3** in degassed DMF solution are very similar and representative spectra of $[\{Cu(dien)\}_2(\mu\text{-}Cl_2dicyd)]^{2+}$, **3**, are given in Fig. 5 and the data compiled in Table 4. In the presence of oxygen, these complexes decomposed in DMF solutions forming radical anion $dicyd^{-\cdot}$ and gave monomer Cu(II) EPR spectra. Complex **3** showed the greatest resistance to oxidation but even under rigorously oxygen-free conditions, a weak radical anion $dicyd^{-\cdot}$ absorption can still be seen in Fig. 5A in approximately the same position as DPPH. Seven copper hyperfine lines are expected for an exchange-coupled Cu(II) dimer. Five are clearly observed in Fig. 5A with the other two lost because of the poor resolution of spectrum. The estimated average copper hyperfine splitting $A_{av} = 41.7 \times 10^{-4}\ cm^{-1}$ is approximately one-half that of the monomer complex, $[Cu(dien)(2,3\text{-}Cl_2pcyd)][CF_3SO_3]$, **8**, for which $A_{av} = 80.6 \times 10^{-4}\ cm^{-1}$, as expected for an exchange-coupled system (17, 19). Similar results are seen in the solution EPR spectra of delocalized Cu(II)–Cu(I) mixed-valence dimers.[3] The A_{av} for complexes **1** and **2** (Table 4) are somewhat larger and this may be due to significant decomposition of the complex as evidence by the magnitude of the radical anion $dicyd^{-\cdot}$ absorption in these spectra. At 77 K (Fig. 5*B*), the copper hyperfine is lost and only a single broad resonance is observed. Only a weak radical $dicyd^{-\cdot}$ resonance was observed for the complexes **4**, **5**, and **6** in DMF at 295 at 77 K.

Other solvents were tried in an attempt to improve the resolution of the exchange-coupled spectra of complexes **1**, **2** and **3**. Dimethyl sulfoxide gave the same results as DMF solutions; however, acetonitrile and methanol:ethanol solutions gave spectra that were characteristic of monomer Cu(II) complexes. Complex decomposition could explain the monomer Cu(II) EPR spectra but the cyclic voltammetry in 2-methoxyethanol is consistent with an intact Cu(II) dimer. We speculate that solvent perturbations are decoupling Cu(II) ions in much the same manner as that observed for Ru(III) ions in $[\{(NH)_5Ru\}_2(\mu\text{-}Me_2dicyd)]^{4+}$ (4).

[3] It is possible that the partially unresolved seven-line spectrum in Fig. 5 is due to some radical charge delocalization over both copper centers, independent of any antiferromagnetic coupling as occurs in Cu(II,I) mixed-valence complexes (20). However, the observation of solid state antiferromagnetic coupling and the improved resolution of the seven-line spectrum and decreased radical $dicyd^{-\cdot}$ signal with exclusion of oxygen would seem to make this possibility unlikely for the complexes of this study.

Fig. 5. DMF solution EPR spectra of $[\{Cu(dien)\}_2(\mu\text{-}Cl_2dicyd)][CF_3SO_3]_2$ at (*a*) 295 K and (*b*) 77 K.



Discussion

Comparison of Cu(II) and Ru(III) dimers

It is clear from this study of the magnetic properties of Cu(II) dimers that considerable attenuation of antiferromagnetic superexchange (reduction of $-J$ by a factor of at least 40 for the Cu(II) dimers) has occurred relative to their pentaammineruthenium(III) analogues, $[\{(NH)_5Ru\}_2(\mu\text{-dicyd})]^{4+}$ (3). The application of theory gives a qualitative understanding of the origin of this difference. From perturbation theory (21, 22),

$$[2] \quad 2J = K - 2H_{ab}^2/J_{aa}\text{-}J_{ab}$$

where the ferromagnetic term K is the energy required to pair electron spins, H_{ab} is the electron exchange integral, and the difference between Coulomb repulsion integrals J_{aa} and J_{ab} represents the energy required to place both spins on the same atom. The ferromagnetic term K is expected to be small (3) and will probably not differ significantly between Ru(III) and Cu(II) dimers. The difference in energy between Coulomb

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

repulsion integrals J_{aa} and J_{ab} can be estimated from the difference in Ru(III/II) or Cu(II/I) PES orbital binding energies. In this way, $J_{aa} - J_{ab}$ was estimated to be 2.6 eV for the dinuclear Ru(III) complexes (3) and 1.7 eV for the dinuclear Cu(II) complexes (23). It therefore seems clear that the major contributor to the relative difference between Ru(III) and Cu(II) antiferromagnetic exchange is the magnitude of the electron exchange integral H_{ab}.

The magnitude of H_{ab} is governed by the interaction of the metal magnetic orbitals with the superexchange pathway provided by the dicyd^{2-} bridging ligand. The relative symmetry and energy of the metal orbitals compared to those of the bridging ligand therefore become determining factors. For the Ru(III) dimers, the non-bonding HOMO and SHOMO of dicyd^{2-} are of π symmetry and both can mediate antiferromagnetic superexchange between Ru(III) πd magnetic orbitals (3). For the Cu(II) dimers, the EPR powder spectra (Table 4) and the energy of the solution *d–d* band (Table 1) are consistent with a tetragonally distorted coordination sphere and a Cu(II) $d_{x^2-y^2}$ magnetic orbital of σ^* symmetry. It is only the low symmetry of the Cu(II) coordination sphere which allows for partial mixing of σ and π symmetry orbitals and results in the observation of a formally forbidden $\pi \rightarrow \sigma^*$ LMCT band (Fig. 1, Table 1) and antiferromagnetic superexchange (Figs. 4 and 5) via the π_{nb} orbitals of dicyd^{2-} in the Cu(II) dimers. Nevertheless, this mixing of σ and π orbitals is far from optimal and must decrease H_{ab} in eq [2].

The energy separation (ΔE) between Cu(II) magnetic orbitals and the π_{nb} orbitals of dicyd^{2-} should be small to maximize H_{ab}. A measure of this difference in energy is given by

$$[3] \quad \Delta E = E_{op} - \chi$$

where E_{op} is the energy of the $\pi \rightarrow \sigma^*$ LMCT band maximum and χ is a correction to compensate for the change in inner and outer coordination sphere configurations resulting from a transition into an excited vibrational level. An estimate of $\chi = 1.24$ eV was derived from the intervalence transition energy observed for $Cu^{II}Cu^{I}L(ClO_4)$, where L is a macrocyclic ligand, in acetone solution (24). Thus, for complex **2**, ΔE is calculated to be 1.48 eV. This is considerably greater than the value of 0.48 eV calculated (3) for the Ru(III) analogue $[\{(NH)_5Ru\}_2(\mu\text{-}Me_2Dicyd)]^{4+}$ and can be expected to result in far less mixing of Cu(II) *d* orbitals with the π_{nb} orbitals of the dicyd^{2-} bridging ligand. This may well be the dominant factor that explains the attenuation of antiferromagnetic superexchange in the Cu(II) dimers.

Cu(II) dimer antiferromagnetic exchange constants

No clear trend in *J* is observed in Table 3 except that the complexes incorporating Me_2dicyd^{2-} appear to have the largest antiferromagnetic *J*. Ru(III) dimers show the same dependence (3) and this is probably due to the small ΔE between metal orbitals and π molecular orbitals of Me_2dicyd^{2-}. The solid state magnetic measurements showed that only complex **1** followed Curie–Weiss behavior (Table 3). This seems inconsistent with the solution EPR study which for **1** gave an exchange-coupled spectrum (Table 4). A possible explanation is that crystal packing forces may distort the Cu(II) coordination spheres of **1** sufficiently to decouple the Cu(II) ions from superexchange via dicyd^{2-}.

Summary

A comparison between Ru(III) and Cu(II) dimers emphasizes the importance of the nature of the metal–cyanamide interaction to long-range superexchange via the dicyd^{2-} bridging ligand. For the Cu(II) dimers, a mismatch in symmetry and energy between its σ^* magnetic orbitals and the π_{nb} orbitals of dicyd^{2-} significantly attenuates antiferromagnetic superexchange when compared to their Ru(III) analogues. This study compliments the recent observation that outersphere perturbations of the Ru(III)–cyanamide bond in $[\{(NH_3)_5Ru\}_2(\mu\text{-}Me_2dicyd)]^{4+}$ can "tune" the magnitude of antiferromagnetic superexchange (4).

For personal use only.

Résumé : Cette étude a pour objectif une analyse conformationnelle d'unités moléculaires telles que le diphényl éther (DPE) et la diphényl cétone (DPC) constitutives du squelette de polymères tels que PEK, PEEK et le PEEKK, par des calculs semi empiriques en CNDO/2. Deux types de modélisations ont été réalisés : une première série de calculs a été effectuée sans prendre en compte les interactions électroniques et de zones d'impénétrabilité de van der Waals et une deuxième en considérant ces diverses interactions. La conformation d'énergie minimale absolue pour le diphényl éther correspond à la position définie par les angles de torsion $(\theta_1,\theta_2) = (30°,150°)$ avec et sans interaction, et à la position $(\theta_1,\theta_2) = (90°,90°)$ pour la diphényl cétone sans prendre en compte les interactions. Dans les régions sous vitreuses et à contrainte stérique égale au sein d'une chaîne de PEK, PEEK ou PEEKK, on peut stipuler que l'unité moléculaire DPE sera sensiblement plus facilement mise en mouvement que l'unité DPC.

Mots clés : analyse conformationnelle, diphényl éther, diphényl cétone, CNDO/2, barrières de rotation.

Abstract: Diphenyl ether (DPE) and diphenyl ketone (DPK) are the molecular constituents of polymers such as PEK, poly(ether–ketone); PEEK, poly(ether–ether–ketone), and PEEKK, poly(ether–ether–ketone–ketone). A conformational analysis of DPE and DPK is examined by means of semiempirical calculations using CNDO/2 (Complete Neglect of Differential Overlap). The modelization is first run disregarding electronic interactions and steric effects, then introducing them in the calculations. We found that the absolute minimum energy conformer has torsional angles $(\theta_1,\theta_2) = (30°,150°)$ for the DPE (with and without interactions) and $(\theta_1,\theta_2) = (90°,90°)$ for the DPK (without interactions). Considering the polymer chains of PEK, PEEK, and PEEKK, the motion of DPE is expected to be easier than that of DPK in regions of local motions and for equivalent steric effects.

Key words: conformational analysis, diphenyl ether, diphenyl ketone, CNDO/2, rotational barriers.

Introduction

Cette recherche est sous-tendue par une motivation essentielle : l'analyse structurale d'unités moléculaires telles que le diphényl éther (DPE) et la diphényl cétone (DPC), qui constituent le squelette d'unités monomères de divers polymères aromatiques à chaînes linéaires tels que le PEK poly(ether ketone), le PEEK poly(ether ether ketone) et le PEEKK poly(ether ether ketone ketone) (figure 1) employés comme matrices thermoplastiques des matériaux composites technologiquement de pointe.

Depuis plus d'un demi siècle, les études structurales du DPE et de la DPC ont fait l'objet d'un nombre considérable de publications. Plusieurs géométries spatiales ont été envisagées, étudiées et analysées par diverses méthodes théoriques et expérimentales.

Nous jugeons inutile de rappeler, depuis l'origine, tous les travaux publiés sur les différentes approches du problème. Cependant, nous pouvons signaler que les auteurs admettaient, jusque dans les années 1980, quatre modèles principaux

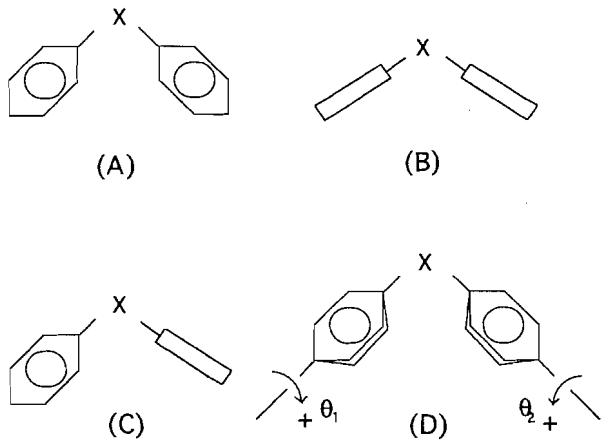
Fig. 2. Les différents modèles conformationnels envisagés pour les unités moléculaires Ph-X-Ph.



A, B, C et D (figure 2) pour représenter de façon simple les unités moléculaires envisagées dans le titre. Les angles de torsion des deux noyaux aromatiques sont désignés par (θ_1,θ_2) et les noyaux aromatiques par (ϕ_1,ϕ_2).

Pour le premier modèle A $(\theta_1,\theta_2) = (0°,0°)$ (1) à structure rigide, la molécules est entièrement plane présentant une contrainte stérique maximale entre les deux hydrogènes 2 et 2′ situés en position *ortho* par rapport à l'atome (ou au groupe d'atomes) X. Cette forme A est stériquement impossible à la température ambiante.

En ce qui concerne le modèle B $(\theta_1,\theta_2) = (90°,90°)$ (2) à structure rigide, les plans des deux noyaux benzéniques sont perpendiculaires au plan formé par CXC. Dans cette structure, la gêne stérique est réduite entre les quatre hydrogènes 2, 2′, 6 et 6′ situés en *ortho* par rapport à X.

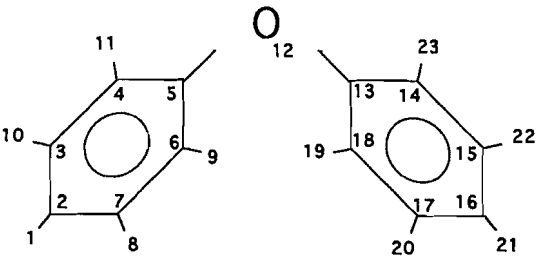
Pour le modèle C $(\theta_1,\theta_2) = (0°,90°)$ (3) également à structure rigide appelé «structure de Morino», l'un des phényles se trouve dans le plan CXC et l'autre est perpendiculaire à ce plan.

La quatrième conformation D (4–13), plus attrayante, est un modèle dans lequel chacun des deux noyaux benzéniques peut pivoter d'un angle variable par rapport au plan défini par CXC. Cette structure mobile peut, selon le sens de rotation des phényles, adopter successivement les géométries des trois modèles A, B et C.

À partir des années 60 (4, 5), les résultats de ces approches, à quelques exceptions, indiquent une nette préférence pour une conformation stable hélicoïdale de type D : l'un des deux noyaux a subit une rotation positive et l'autre négative par rapport au plan CXC. La valeur absolue de ces angles (θ_1,θ_2) de torsion est, selon les auteurs, située dans une plage angulaire allant de 25° à 50° suivant la nature de X. Le fait le plus marquant qui ressort de ces publications est le manque d'homogénéité dans les conclusions qui en ont été tirées.

Tout récemment, certaines approches en mécanique quantique et moléculaire ont été révisées et affinées (14–18 et références citées). Si une relative cohérence apparaît maintenant dans les conclusions, il faut signaler que les divers auteurs se bornent toujours à n'envisager que certains mouvements bien particuliers des noyaux benzéniques, dans chaque cas : DPE et DPC.

Fig. 3. Directions des axes et sens de rotation des noyaux aromatiques.



Nous nous proposons donc d'effectuer, à partir du modèle D, l'étude systématique des diverses conformations possibles que sont susceptibles d'adopter, sous certaines conditions, les deux unités moléculaires DPE et DPC, sachant que les modèles A, B et C peuvent être des géométries issues de la mobilité moléculaire de la structure D.

Moyens utilisés et mode opératoire pour la mise en oeuvre des calculs

Notre étude repose essentiellement sur des calculs de mécanique quantique CNDO/2 (19), CNDO/2 avec interactions et ab initio (méthodologie d'Hartree–Fock) dans la base minimum STO-3G. La numérotation des atomes présentée sur la figure 3 est celle que nous avons utilisée pour effectuer nos calculs.

En ce qui concerne la méthode CNDO/2 avec interactions, nous avons utilisé un artefact géométrique (figure 4) qui nous permet de modéliser la couronne électronique du noyau aromatique. Pour cela, nous avons modifié la position de l'hydrogène H_{19} afin que la distance C_{13}—H_{19} soit au maximum de 1.80 Å permettant ainsi de simuler la demi épaisseur (zone d'impénétrabilité de van der Waals) de cette couronne. Si nous tenons compte de la zone d'impénétrabilité de van der Waals de la couronne électronique des noyaux benzéniques, il existe des contraintes stériques et électrostatiques entre une couronne et l'hydrogène aromatique situé en vis-à-vis et parfois entre deux couronnes.

L'ensemble des calculs ont été réalisés à partir d'une station de travail numérique (VT 420) connectée à un VAX 6000-410.

Par ailleurs, signalons que dans des conditions normales, les valeurs des distances interatomiques et celles des angles de valence utilisées par divers auteurs pour les unités moléculaires DPE et DPC sont souvent disparates. Par exemple, pour le diphényl éther, les distances interatomiques d(C—O) s'échelonnent de 1.28 Å (11) à 1.42 Å (12) et les angles de valence COC varient de 115° (13) à 126° (12). En ce qui concerne la diphényl cétone, les distances d(C—C(O)) vont de 1.42 Å (12) à 1.54 Å (10) et les angles de valences CC(O)C se situent entre 120° (10) et 126° (12).

Afin d'éviter de choisir les unes ou les autres valeurs, nous avons effectué nos propres calculs par optimisation à partir de la conformation D avec une méthode ab initio dans la base STO-3G. Les principaux résultats obtenus par cette méthode pour les distances interatomiques sont d(C—X) : 1.40 Å lorsque X = O et 1.42 Å pour X = CO, et pour l'angle de valence CXC on trouve 117° quel que soit X. Ces valeurs sont utilisées pour effectuer nos calculs en CNDO/2 et CNDO/2 avec interactions.

Fig. 4. Simulation de la couronne électronique.

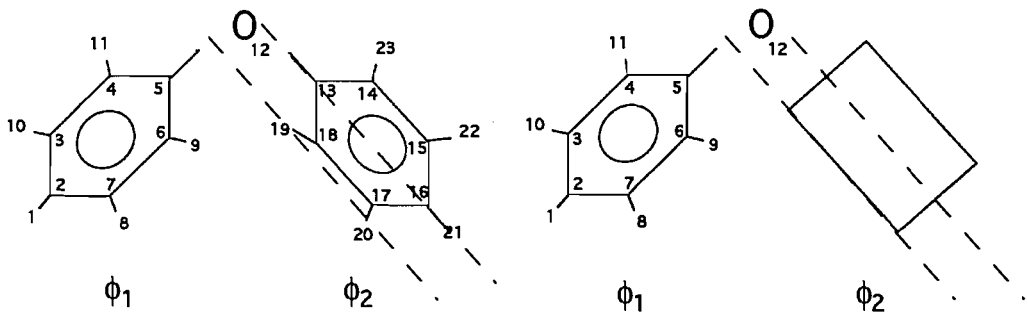


Tableau 1. Paramètres structuraux utilisés dans les calculs en CNDO/2.

Distances interatomiques en angstrom		Angles de valence en degré		
(C—C) aromatique	1,39	(C-C-C)aromatique		120
C—H	1,08	(H-C-C)aromatique		120
C=O	1,23	C-C(O)-C	C-C-C	117
C—C(O)	1,42		O=C-C	121,5
C—O	1,40	C-O-C		117

Pour plus de clarté, nous présentons dans le tableau 1 toutes les distances interatomiques et tous les angles de valence utiles pour effectuer les calculs des unités moléculaires DPE et DPC.

Malgré les nombreuses études, dont ont fait l'objet ces géométries moléculaires, des incohérences demeurent dans la littérature en ce qui concerne la direction des axes autour desquels la giration des phényles se produit et le sens de rotation de ces noyaux benzéniques. Un autre problème essentiel demeure : les noyaux benzéniques pivotent-ils simultanément dans le même sens ou en sens contraire, ou tournent-ils alternativement? En effet, un phényle peut être fixe pendant que l'autre tourne ou inversement.

Pour mener à bien les calculs, nous indiquons les conventions (figure 2 et figure 3) que nous avons utilisées concernant le sens de rotation des noyaux aromatiques ainsi que la direction des axes autour desquels ils pivotent : rotation positive pour les deux phényles ϕ_1 et ϕ_2 lorsqu'ils tournent dans le sens des aiguilles d'une montre avec pour direction des axes respectivement celle de $C_2C_5O_{12}$ et $O_{12}C_{13}C_{16}$.

Pour connaître l'énergie totale de chaque conformation, en prenant en compte toutes les rotations possibles des unités moléculaires, nous avons effectué un nombre important de modélisations. Elles ont été conduites en imprimant une rotation par pas de 10° au phényle ϕ_1, et pour chaque pas, on a fait subir au noyau ϕ_2 une rotation complète de 360° autour de son axe.

Résultats et discussions

Les molécules de DPE et DPC étant symétriques, les tableaux contenant les variations de θ_1 et θ_2 de 0° à 360° peuvent être réduits à un quart en ne présentant les variations des angles de torsion que de 0° à 180°.

Nous devons signaler que les résultats obtenus pour les géométries d'énergie minimale de la DPE et la DPC sont respectivement, selon nos conventions de signe, de : (θ_1,θ_2) = (30°,150°) et (θ_1,θ_2) = (90°,90°). Les conformations d'énergie minimale pour la DPE et la DPC sont d'après Chen et al. (17) celles dont les angles de torsion sont respectivement (θ_1,θ_2) = (30°,30°) et (θ_1,θ_2) = (90°,90°). Nous précisons que notre conformation pour le DPE est parfaitement identique à celle de Chen mais définie selon nos conventions par (θ_1,θ_2) = (30°,−30°) ou (θ_1,θ_2) = 30°,150°). Néanmoins, les barrières d'énergie maximum de rotation qu'ils proposent (61 kcal/mol pour le DPE et 67 kcal/mol pour la DPC) sont nettement inférieures à nos valeurs (419 kcal/mol pour le DPE et 369 kcal/mol pour la DPC). Cependant, nos angles de torsion totaux $(|\theta_1| + |\theta_2|)$ sont assimilables à ceux proposés par Kendrick (18) : 77° pour le DPE et 52.4° pour la DPC, ces valeurs étant déterminées par des calculs ab initio.

Le diphényl éther (DPE)

Le tableau 2 présente la carte des énergies relatives pour toutes les conformations possibles du diphényl éther. La conformation d'énergie minimale «absolue» correspond à la structure D_1 la plus stable avec (θ_1,θ_2) = (30°,150°). Les positions équivalentes sont décalées de 180°.

À partir du tableau 2, nous pouvons proposer et suivre les différents types de mouvements que peuvent subir les phényles à partir d'une position de départ quelconque. En effet, les noyaux aromatiques peuvent effectuer des rotations simultanées ou alternées.

1. Rotations simultanées

Lorsque les deux noyaux subissent une rotation simultanée à partir de positions quelconques, deux types de mouvements sont possibles : (*i*) soit les deux phényles ϕ_1 et ϕ_2 tournent en sens inverse (rotation en engrenage) : rotations simultanées positives (ou négatives) selon nos conventions; (*ii*) soit ils tournent dans le même sens (rotation corrélée) : rotations simultanées, l'une positive l'autre négative selon nos conventions.

Pour imprimer une rotation inversée à ϕ_1 et ϕ_2, les angles de torsion respectifs, θ_1 et θ_2, sont simultanément incrémentés positivement (ou négativement) par pas de 10°, à partir de n'importe quelle position de départ. Pour suivre ce mouvement sur le tableau 2, il faut se déplacer sur une droite de pente

négative (avec θ_1 en ordonnées et θ_2 en abscisses). Cette mobilité moléculaire est reconnue par divers auteurs (10) comme étant la plus logique et la plus facile.

Une droite particulière de ce type est la diagonale de pente négative (θ_1,θ_2) dont les bornes extrêmes sont (0°,0°) et (180°,180°). Nous avons représenté dans ce cas à partir du tableau 2, la courbe d'énergie relative «E_{rel} (kcal/mol) sans interaction» en fonction des variations des angles de torsion (figure 5).

Nous constatons sur cette courbe, la présence d'un minimum «relatif» d'énergie situé à (θ_1,θ_2) = (90°,90°).

Dans le programme CNDO/2 classique que l'on utilise, les interactions électrostatiques (de couronne électronique) et surtout les zones d'impénétrabilité de van der Waals du noyau aromatique (la demi épaisseur du phényle est en moyenne de 1,80 Å) (20, 21) ne sont prises que très partiellement en compte. Nous avons donc réalisé de nouvelles modélisations à l'aide d'un programme CNDO/2 avec interactions.

Nous pouvons à nouveau proposer comme droite particulière la diagonale (θ_1,θ_2) dont les bornes extrêmes sont (0°,0°) et (180°,180°). Nous représentons (figure 5) à partir du tableau 3 la courbe d'énergie relative «E_{rel} (kcal/mol) avec interactions» en fonction des variations des angles de torsion. Afin de faciliter la comparaison des cas sans et avec interactions, nous avons superposé les deux courbes précédentes sur ce même graphe.

Nous pouvons constater sur la courbe d'énergie «E_{rel} (kcal/mol) avec interactions» l'absence de minima d'énergie relative ainsi qu'une augmentation de la hauteur des barrières énergétiques dans certaines plages angulaires.

Dans le cas où, selon nos conventions, les deux phényles tournent dans le même sens il faut, pour effectuer ces mouvements, incrémenter simultanément θ_1 positivement et θ_2 négativement (ou inversement), à partir de n'importe quelle conformation initiale. Pour visualiser cette mobilité moléculaire, il faut se déplacer sur une droite de pente positive. Nous pouvons proposer comme droite particulière (tableau 2), la diagonale (θ_1,θ_2) bornée par (0°,180°) et (180°,0°) sur laquelle on observe deux minima «absolus» d'énergie situés respectivement à (θ_1,θ_2) = (30°,150°) et (150°,30°). Son profil d'énergie relative peut être tracé à partir de ce tableau «E_{rel} (kcal/mol) sans interaction» en fonction des variations des angles de torsion (figure 6).

Si nous voulons prendre en compte les différentes interactions (tableau 3), la même diagonale possède les mêmes minima «absolus» d'énergie que dans le cas précédent avec un profil énergétique différent représenté par la figure 6 : «E_{rel} (kcal/mol) avec interactions» en fonction des variations des angles de torsion.

2. Rotations alternées

Lorsque les phényles ne subissent pas de rotation simultanée, l'un des noyaux peut se situer dans une position fixe quelconque pendant que l'autre décrit 360° autour de son axe.

Deux types de cheminements sont possibles : (*i*) soit ϕ_1 est bloqué et ϕ_2 subit une rotation de 360°; (*ii*) soit ϕ_1 décrit une rotation de 360° et ϕ_2 est bloqué.

Pour le premier, le mouvement est représenté sur le tableau 2 par une horizontale énergétique, alors que pour le second, le mouvement est défini par une verticale. Nous devons faire remarquer que ces mobilités moléculaires sont énergétiquement identiques lorsque la molécule est symétrique (noyaux non diversement substitués).

Pour exploiter de manière plus approfondie les résultats du tableau 2, nous pouvons envisager certains mouvements moléculaires particuliers à partir de probabilités conformationnelles stables :

Hypothèse 1 : cas de molécules de diphényl éther isolées : À basse température, et en supposant l'angle de valence COC

Fig. 5. Variation de l'énergie relative en fonction de l'angle de torsion θ_1 suivant la diagonale (θ_1,θ_2) allant de (0°,0°) à (180°,180°) pour le DPE avec CNDO/2 et CNDO/2 avec interactions.

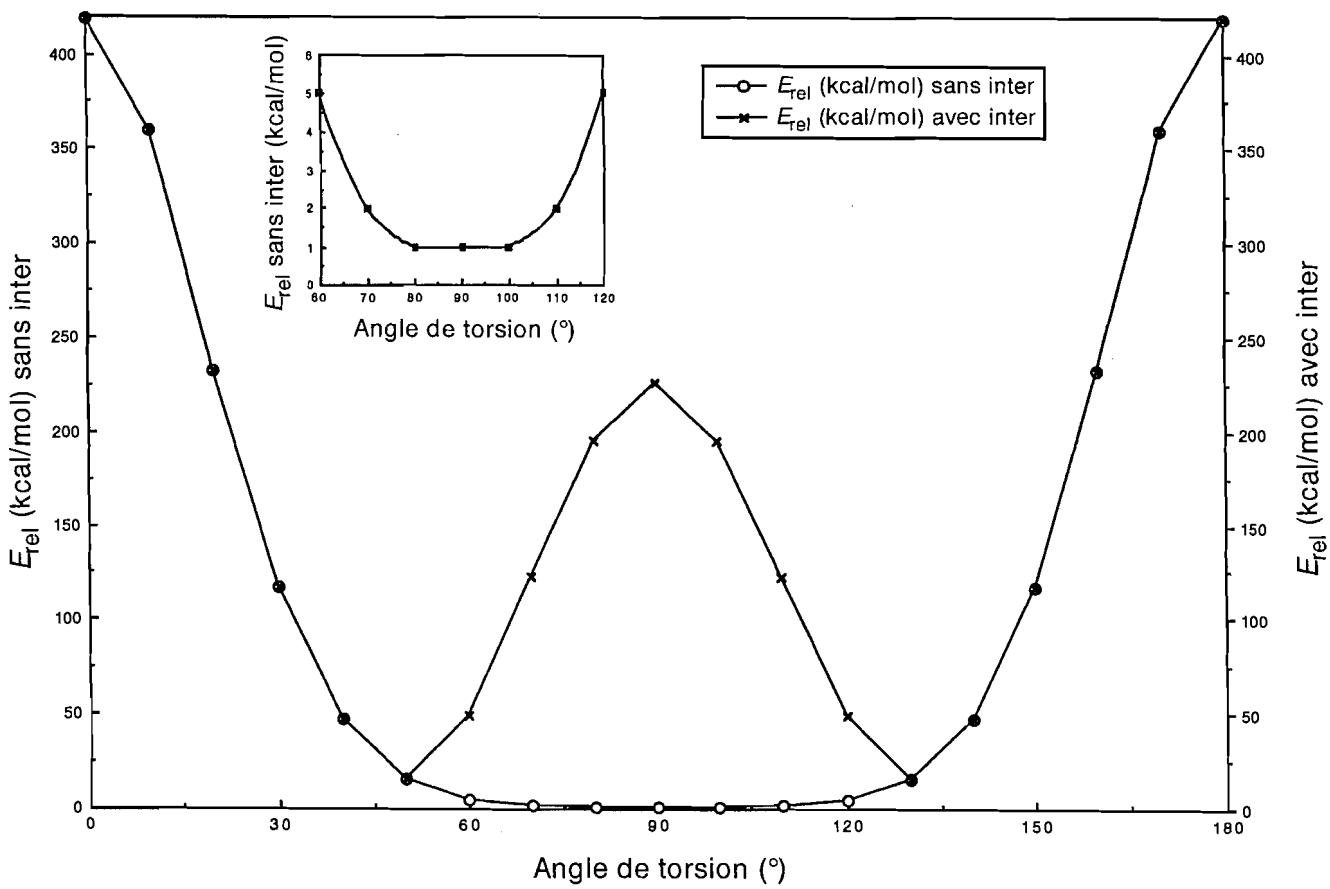

Fig. 6. Variation de l'énergie relative en fonction de l'angle de torsion θ_1, suivant la diagonale (θ_1,θ_2) allant de (0°,180°) à (180°,0°) pour le DPE avec CNDO/2 et CNDO/2 avec interactions.

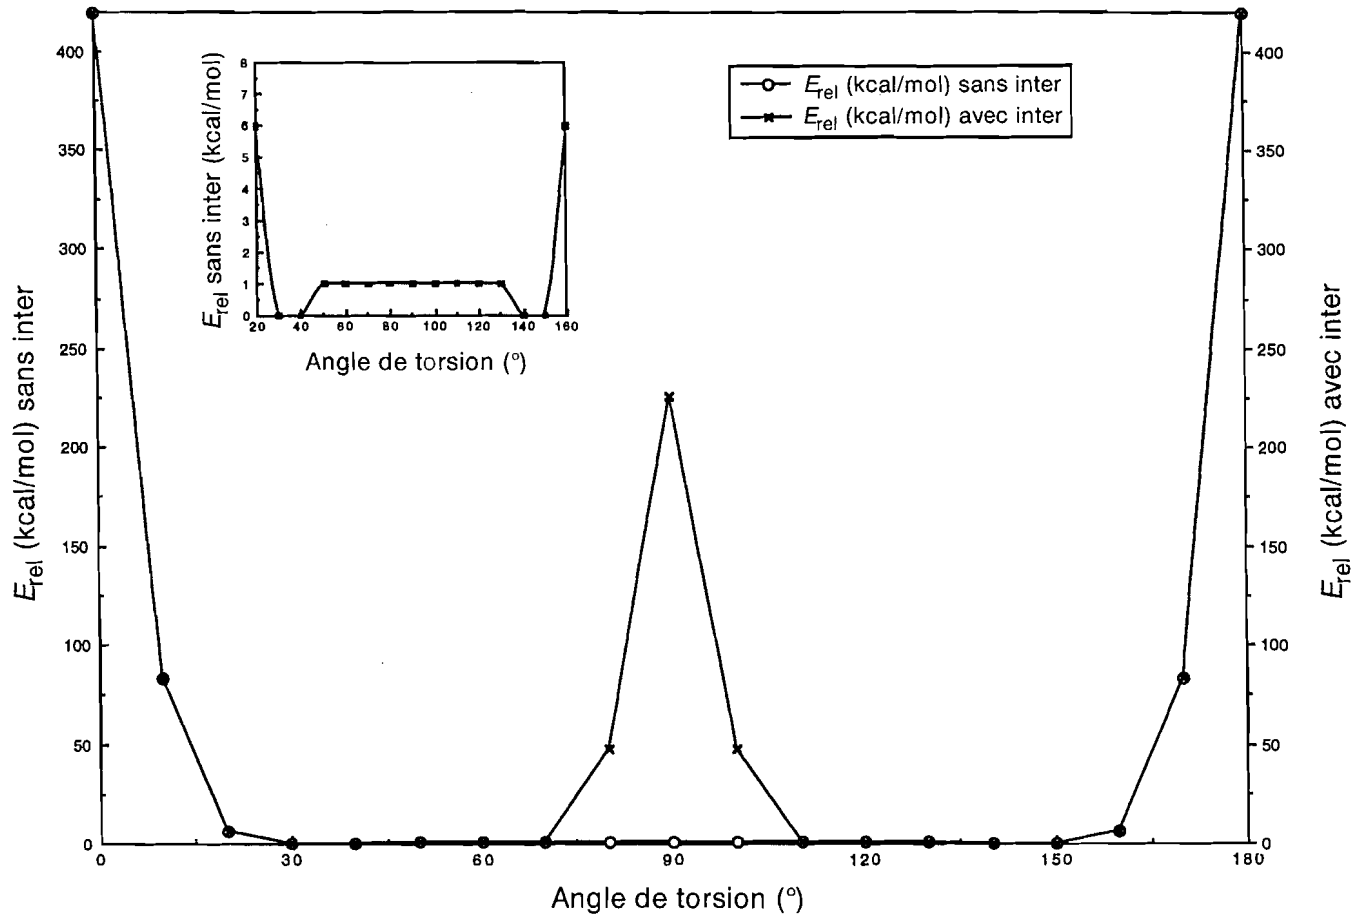

constant au cours du mouvement, la probabilité est maximale pour que cette molécule soit dans la conformation hélicoïdale D_1 la plus stable (30°,150°). Nous sommes en mesure d'étudier tous les mouvements possibles, dans les quatre directions citées précédemment, à partir de cette position en considérant une barrière d'énergie maximale de 14 kcal/mol qui est la valeur approximative du saut énergétique rendant compte de la relaxation sous vitreuse d'un polymère du type PEEK (nous avons choisit cette valeur moyenne à partir de celles proposées par Chen et al. (17) qui indiquent 21 kcal/mol obtenus en spectrométrie mécanique et 10 kcal/mol mesurées en spectrométrie diélectrique). Ces valeurs sont le reflet d'un mouvement local restreint à une ou deux unités moléculaires.

Dans le cas où l'on ne prend pas en compte les interactions, à partir de la structure stable D_1, (θ_1,θ_2) = (30°,150°), la mobilité conrotatoire (les phényles ϕ_1 et ϕ_2 pivotent dans le même sens) suit une droite de pente positive. Le mouvement se limite à un balancement des noyaux compris entre (θ_1,θ_2) = (20°,160°) et (160°,20°). Le coût énergétique ne dépasse pas 6 kcal/mol.

À partir de la géométrie stable D_1, la mobilité disrotatoire (les noyaux ϕ_1 et ϕ_2 pivotent en sens inverse) suit une droite de pente négative. Les rotations simultanées des deux noyaux aromatiques sont définies par les segments de droites (θ_1,θ_2) dont les bornes sont respectivement (0°,120°) et (60°,180°) puis (60°,0°) et (180°,120°). La plage angulaire de torsion de chaque noyau est totale (soit 360°) et le coût énergétique est proche de 1 kcal/mol.

La conformation stable D_1 peut aussi évaluer en suivant l'horizontale (θ_1 est fixé à 30° alors que θ_2 varie). Le balancement angulaire de ϕ_2 est compris entre 60° et 170° pour θ_2. L'énergie nécessaire est encore proche de 6 kcal/mol.

D_1 peut enfin évoluer suivant la verticale (θ_1 variant alors que θ_2 est fixé à 150° (ou −30°)). Le mouvement se réduit aussi à une oscillation de ϕ_1 avec θ_1 compris entre 10° et 120°. L'énergie mise en jeu est au maximum de 6 kcal/mol.

Cependant, si l'on envisage la possibilité d'une pulsation de la molécule animée par une élévation modérée de température (ouverture progressive, mais limitée, de l'angle de valence COC au cours du mouvement) l'amplitude des balancements des noyaux est susceptible d'augmenter tout au plus de la valeur d'un pas de 10° pour θ_1 et θ_2. En effet, au delà l'énergie à mettre en œuvre serait trop importante pour compter ce mouvement dans la zone de la relaxation sous vitreuse d'un polymère.

Lorsque l'on prend en compte les diverses interactions (tableau 3), la conformation la plus stable est toujours D_1 : (θ_1,θ_2) = (30°,150°).

À partir de ce tableau, nous pouvons décrire les différents mouvements possibles de cette conformation D_1 dans les quatre directions définies précédemment :

1. Suivant la droite de pente négative : le cheminement

géométrique possible a lieu suivant les segments de droite $(\theta_1,\theta_2) = (0°,120°)$, $(60°,180°)$ puis $(60°,0°)$, $(180°,120°)$ tout comme précédemment pour le cas où la zone d'impénétrabilité n'était pas prise en compte. Cependant, dans cette nouvelle approche, la différence vient du coût énergétique; il faut maintenant 3 kcal/mol au lieu de 1 kcal/mol.

2. Suivant la droite de pente positive : le mouvement possible est un battement des noyaux ϕ_1 et ϕ_2 avec (θ_1,θ_2) décrivant de $(20°,160°)$ à $(70°,110°)$. Nous pouvons remarquer que celui-ci est très largement réduit par rapport au cas où l'on ne prenait pas en compte les interactions électrostatiques et les zones d'impénétrabilité de van der Waals.

3. Suivant l'horizontale avec $\theta_1 = 30°$: le mouvement possible est un balancement du phényle ϕ_2 avec θ_2 s'étendant de 140° à 170°. À nouveau, l'amplitude angulaire de l'oscillation est réduite par rapport au cas où l'on ne tenait pas compte des interactions.

4. Suivant la verticale avec $\theta_2 = 150°$: le mouvement se réduit à une rotation du phényle ϕ_1 avec θ_1 allant de 10° à 40°. Dans ce cas également, la plage angulaire est réduite.

Hypothèse 2 : cas d'agrégats de molécules de diphényl éther : Nous considérons tout d'abord le cas sans interaction. Ici, les molécules sont susceptibles de présenter un grand nombre de géométries originelles. En effet, en plus des conformations indiquées précédemment, il n'est pas vérifié que les géométries des molécules associées soient rigoureusement les mêmes que celles des molécules isolées et des minima «relatifs» peuvent être observés pour des conformations sensiblement différentes. Dans un agrégat, les molécules subissent certainement les influences de leurs voisines.

En particulier, il est impossible d'exclure au départ, par exemple, des molécules de géométrie de type C : $(\theta_1,\theta_2) = (0°,90°)$. Cette conformation est susceptible d'évoluer dans les quatre directions, si elle le peut, en adoptant diverses géométries. La principale évolution est définie par les segments de droite de pente négative dont les bornes sont $(0°,90°)$, $(90°,180°)$ et $(90°,0°)$, $(180°,90°)$. Le coût énergétique pour décrire ce parcours est, en effet, inférieur à 1 kcal/mol. Dans ce cas, bien que la molécule ne passe par aucune conformation d'énergie minimale «absolue», nous pouvons constater qu'il s'agit de la seule mobilité moléculaire qui ne nécessite pas d'énergie sachant que la déformation structurale existait au départ.

Nous pouvons penser que d'une manière générale, la molécule va plutôt choisir des chemins nécessitant des barrières d'énergie moindre plutôt que décrire une diagonale passant par des minima «absolus» qui obligent la molécule à franchir des barrières d'énergie très importante. Donc, il n'est pas inconcevable d'envisager que la conformation la plus stable D_1, $(\theta_1,\theta_2) = (30°,150°)$ se modifie continuellement en suivant un cheminement en ligne brisée. En effet, la mobilité moléculaire peut suivre un parcours d'énergie faible et modifier son cheminement à l'abord d'un obstacle énergétique. Les divers changements de direction permettent à la molécule de suivre un parcours sinueux ne nécessitant aucun saut énergétique. Nous pouvons systématiquement appliquer ce principe à partir d'une structure conformationnelle quelconque.

Nous remarquons que si nous nous situons dans les «vallées» du tableau 3, c'est à dire, pour des valeurs d'énergie de 0 à 1 kcal/mol, ce sont les mouvements de type engrenage (suivant les droites de pente négative) qui nécessitent un moindre coût énergétique.

Nous constatons d'une façon générale que lorsque nous prenons en compte certaines interactions, le nombre de géométries possibles est fortement réduit ainsi que l'amplitude des battements des noyaux. En conclusion, les mouvements de la molécule sont beaucoup plus restreints et sûrement plus proches de la réalité.

Pour une représentation plus claire des barrières énergétiques, nous avons tracé une courbe 3D en fonction des deux angles de torsion θ_1 et θ_2 ainsi que de l'énergie relative de la molécule en kcal/mol, respectivement, dans le cas sans et avec interactions (figures 7 et 8).

La diphényl cétone (DPC)

Nous suivons exactement le même processus de calculs que pour le diphényl éther, en débutant par des modélisations ne prenant pas en compte les diverses interactions.

Il existe de même quatre types de mouvements possibles suivant les directions envisagées précédemment.

Nous avons représenté (figure 9) d'après le tableau 4, la variation de l'énergie relative en fonction des angles de torsion suivant la diagonale (θ_1,θ_2) de pente négative allant de $(0°,0°)$ à $(180°,180°)$ par «E_{rel} (kcal/mol) sans interaction».

Nous constatons sur cette courbe la présence d'un minimum «absolu» d'énergie situé à $(90°,90°)$.

Nous avons effectué une nouvelle modélisation en tenant compte des différentes interactions électroniques et de zones d'impénétrabilité de van der Waals.

Il est possible de proposer aussi comme droite particulière la diagonale (θ_1,θ_2) dont les bornes extrêmes sont $(0°,0°)$ et $(180°,180°)$. À partir du tableau 5, nous représentons la courbe d'énergie relative dont le profil est donné sur la figure 9 : «E_{rel} (kcal/mol) avec interactions» en fonction des angles de torsion.

Nous constatons dans ce cas, la disparition du minimum «absolu» d'énergie relative préalablement situé à $(90°,90°)$. En effet, lorsque les zones d'impénétrabilité de van der Waals sont prises en compte, cette position devient un maximum d'énergie. Nous pouvons remarquer également une augmentation importante des hauteurs des barrières énergétiques dans certaines plages angulaires, lorsque l'on considère les divers types d'interactions.

Nous avons également représenté à partir du tableau 4 (sans prendre en compte les interactions) la variation de l'énergie relative (figure 10) en fonction des angles de torsion suivant la diagonale (θ_1,θ_2) de pente positive allant de $(0°,180°)$ à $(180°,0°)$ par «E_{rel} (kcal/mol) sans interaction». Nous constatons sur cette courbe, la présence d'un minimum «absolu» d'énergie situé aussi à $(\theta_1,\theta_2) = (90°,90°)$.

Dans le cas où nous prenons en compte les interactions, nous pouvons considérer sur le tableau 5 la même diagonale (θ_1,θ_2) dont les bornes extrêmes sont $(180°,0°)$ et $(0°,180°)$. Nous pouvons représenter la courbe d'énergie dont le profil est donné par la figure 10 : «E_{rel} (kcal/mol) avec interactions» en fonction des variations des angles de torsion.

Sur cette courbe, nous constatons la disparition du minimum «absolu» d'énergie préalablement situé à $(\theta_1,\theta_2) = (90°,90°)$, ainsi qu'une forte augmentation de la hauteur des barrières énergétiques dans certaines plages angulaires. Néanmoins, il existe un minimum d'énergie correspondant à la géométrie $(70°,110°)$.

Fig. 7. Représentation tridimensionnelle des énergies relatives du DPE calculées avec CNDO/2.

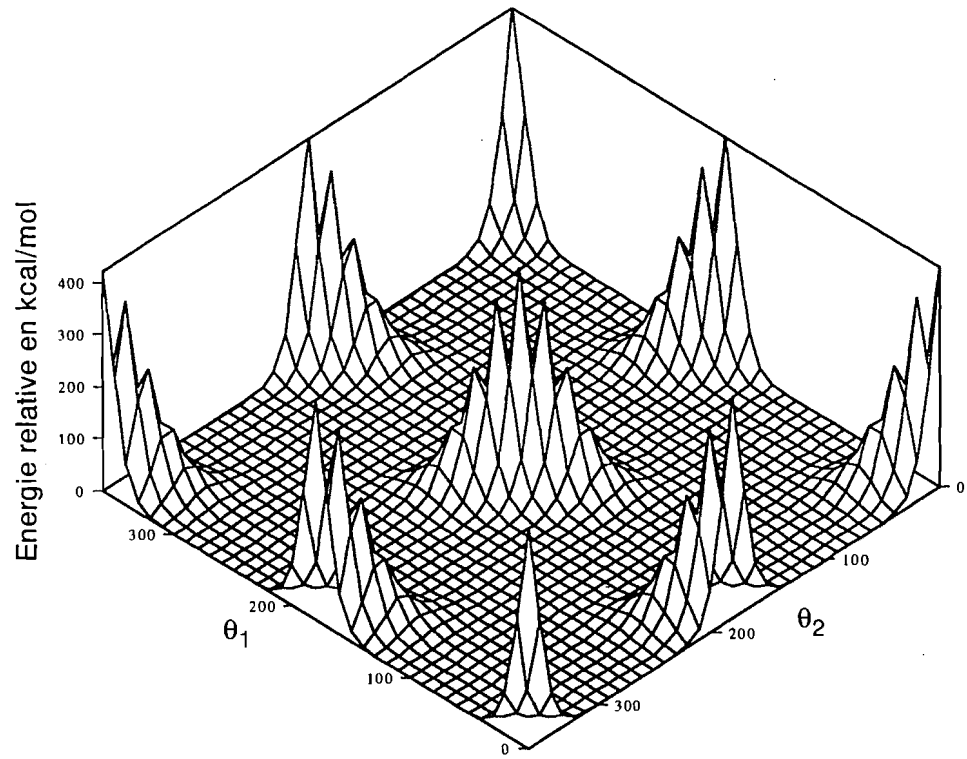

Fig. 8. Représentation tridimensionnelle des énergies relatives du DPE calculées avec CNDO/2 avec interactions.

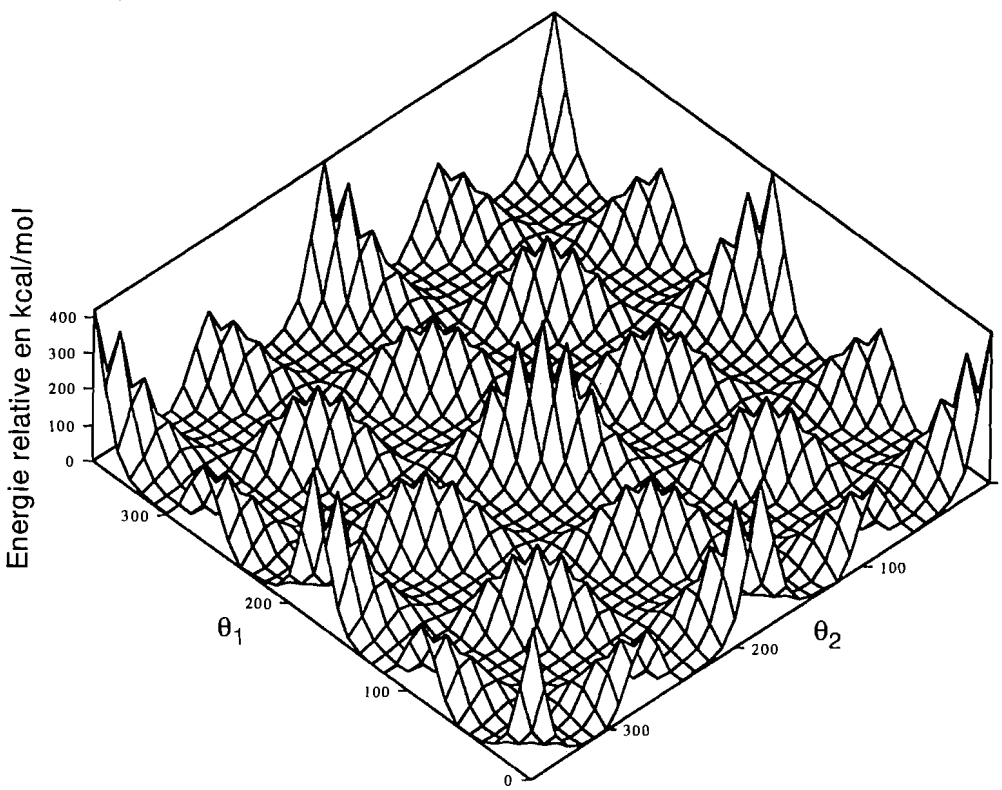

Comme dans le cas du diphényl éther, nous pouvons faire les hypothèses à environnements différents, c'est à dire, d'une molécule isolée et d'un agrégat de molécules.

À basse température, la probabilité pour que la molécule isolée se trouve dans la conformation la plus stable, type B (90°,90°), est maximale. Nous pouvons alors décrire les différents types de mouvements possibles à partir de cette position dans les quatre axes choisis.

Sans considérer les interactions, d'après le tableau 4, suivant la droite de pente négative : le mouvement possible pos-

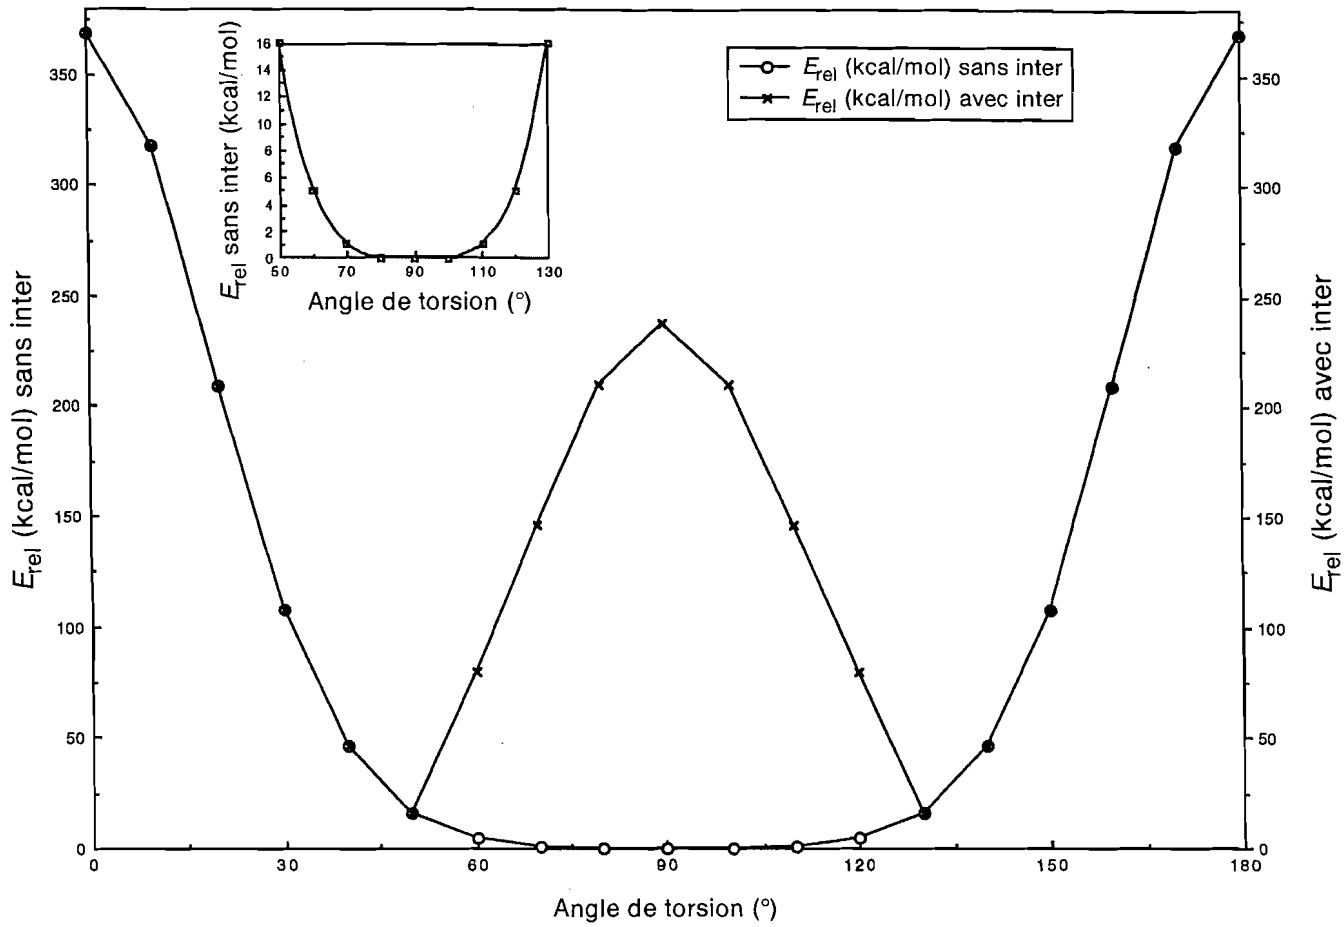
sède une plage angulaire allant de (60°,60°) à (120°,120°). Nous pouvons remarquer que l'amplitude du battement dans ce cas est nettement moins importante que celle que possédait le diphényl éther sans interaction.

1. Suivant la droite de pente positive : le mouvement est réduit à un balancement entre les positions (20°,160°) et (160°,20°). Nous constatons également dans ce cas, que l'amplitude est moindre par rapport à celle observée pour le diphényl éther sans interaction. Le coût énergétique est ici de 12 kcal/mol alors qu'il ne dépassait pas les 6 kcal/mol pour le diphényl éther pour une plage angulaire identique.

2. Suivant l'horizontale : la DPC peut décrire entièrement la droite (θ_1,θ_2) allant de (90°,0°) à (90°,180°); ce mouvement nécessite une énergie maximum de 5 kcal/mol. Dans le cas du

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Fig. 9. Variation de l'énergie relative en fonction de l'angle de torsion θ_1 suivant la diagonale (θ_1,θ_2) allant de (0°,0°) à (180°,180°) pour la DPC avec CNDO/2 et CNDO/2 avec interactions.



diphényl éther, le cheminement suivant l'horizontale nécessitait un coût énergétique de 1 kcal/mol.

3. Suivant la verticale : la DPC peut décrire entièrement la droite, avec une énergie de 5 kcal/mol (identique au cheminement horizontal car la molécule est symétrique). Le diphényl éther avait décrit lui aussi complètement la droite (θ_1,θ_2) allant de (0°,90°) à (180°,90°) pour un apport énergétique de 1 kcal/mol seulement.

Dans le cas d'un agrégat de molécules, nous pouvons considérer des mouvements suivant d'autres droites nécessitant un coût énergétique moindre ou équivalent même si la molécule ne passe pas par des positions d'énergie minimale absolue.

En ce qui concerne les segments de droites de pente négative, nous pouvons envisager les diagonales (0°,70°); (0°,80°); (0°,90°) et les diagonales équivalentes : réciproquement (0°,110°); (0°,100°); (0°,90°) pour une barrière de rotation de 5 kcal/mol.

En comparant le tableau 4 (la DPC sans interaction) et le tableau 5 (la DPC avec interactions), nous pouvons remarquer que lorsque les diverses interactions sont prises en compte : (i) aucun mouvement complet n'est probable suivant une horizontale ou une verticale. Seuls des mouvements ayant une plage angulaire réduite sont possibles. (ii) De même, aucun mouvement complet n'est envisageable suivant une droite de pente positive. La molécule ne peut effectuer que des oscillations avec des battements angulaires faibles. (iii) La description d'un mouvement suivant une droite de pente négative n'est possible que suivant deux droites distinctes alors que lorsque les interactions ne sont pas prises en compte, on peut envisager près d'une dizaine de droites. (iv) Il existe une augmentation de la hauteur des barrières énergétiques pour certaines plages angulaires.

Il nous a paru intéressant d'analyser par comparaison les différents résultats obtenus sur les diverses modélisations du DPE et de la DPC en prenant en compte les diverses interactions : à partir du tableau 3 et du tableau 5, nous pouvons constater que :

1. Suivant les horizontales et les verticales, les mouvements des deux molécules ne sont probables que pour des amplitudes angulaires très faibles.

2. Suivant les droites de pente positive, les balancements de la diphényl cétone sont plus réduits que ceux observés pour le diphényl éther.

3. Pour le diphényl éther, un mouvement peut être observé suivant trois droites de pente négative alors que pour la diphényl cétone, un tel mouvement ne peut être considéré que suivant deux droites.

Conclusion

En ce qui concerne les modélisations moléculaires du diphényl éther et de la diphényl cétone, sans tenir compte des inter-

actions électroniques et des zones d'impénétrabilité de van der Waals, un grand nombre de mouvements est envisageable mais la mobilité de la DPC est plus contrainte que celle du DPE.

Lorsque ces modélisations sont reconduites en prenant en compte les différentes interactions possibles, le nombre de mouvements probables de la DPC et du DPE est très fortement réduit ainsi que les plages angulaires. La diphényl cétone est toujours plus difficilement mobile que le diphényl éther.

Si l'on se trouve dans un liquide pur, on est en mesure de penser que la plupart des molécules ont des difficultés à se mettre en mouvement et que les mobilités, si elles existent, sont certainement dispersées.

Cependant, on peut penser qu'une molécule isolée suivra, en partant de sa conformation la plus stable, le chemin le plus favorable énergétiquement dans l'une des quatre directions possibles. Elle devra modifier sa structure conformationnelle à l'approche d'une barrière énergétique et suivra ainsi un cheminement sinueux énergétiquement faible. En conclusion, dans les zones sous vitreuses et à contrainte stérique égale au sein d'une chaîne de PEK, PEEK ou PEEKK, on peut stipuler que l'unité moléculaire DPE sera sensiblement plus facilement mise en mouvement que l'unité DPC.

Remerciements

Nous tenons à remercier l'ITODYS (Institut de Topologie et de Dynamique des Systèmes) pour nous avoir permis d'accéder à certains programmes de mécanique quantique et moléculaire.

Some physicochemical characteristics of molten salts derived from trimethylsulfonium bromide

M. Ma and K.E. Johnson

Abstract: Ambient temperature melts were derived from trimethylsulfonium bromide (TMSuBr) and $AlBr_3$, $AlCl_3$, or HBr. The aluminum halide melts have low-wavelength UV cutoffs and single-band ^1H NMR spectra. In the TMSuBr–HBr system, the formation of HBr_2^- and likely existence of $H_2Br_3^-$ are indicated by ^1H NMR and IR spectra. Conductivity and viscosity data indicate stronger $TMSu^+$–anion interactions than those between substituted imidazolium and halide anions. A Grotthus mechanism may operate for conduction in TMSuBr:HBr melts.

Key words: ambiant temperature melts, trimethylsulfonium–anion itneractions, Grotthus mechanism.

Résumé : À la température ambiante, des mélanges de bromure de triméthylsulfonium (TMSuBr) et de $AlBr_3$, $AlCl_3$ ou HBr existent à l'état fondu. Les mélanges fondus d'halogénures d'aluminium absorbent complètement à de basses longueurs d'onde dans l'UV alors que leurs spectres RMN du ^1H ne présentent qu'une bande. Dans le système TMSuBr–HBR, les spectres IR et de RMN du ^1H indiquent qu'il y a formation de HBr_2^- et possiblement de $H_2Br_3^-$. Les données de conductivité et de viscosité indiquent que les interactions $TMSu^+$–anion sont plus fortes que celles entre les imidazolium substitués et les anions halogénures. Dans les sels fondus de TMSuBr:HBr, il est possible qu'un mécanisme de Grotthus soit en opération.

Mots clés : mélanges fondus à la température ambiante, interactions triméthylsulfonium–anion, mécanisme de Grotthus.

[Traduit par la rédaction]

Introduction

Although a variety of organic salts can be mixed with the appropriate aluminum halide to produce haloaluminate melts that are liquid at or below ambient temperature, most work in the field has involved two systems: $AlCl_3$:1-butylpyridinium chloride ($AlCl_3$:BPC) (1) and $AlCl_3$:1-ethyl-3-methyl-*1H*-imidazolium chloride ($AlCl_3$:ImCl) (2). Liquids are obtained for $AlCl_3$ mole fractions ranging from 0.37 to 0.67 for the former and from 0.33 to 0.67 for the latter. Potentiometry suggests (3, 4) that acid–base properties of these melts are governed by tetrachloroaluminate dissociation with $K_{eq} \cong 10^{-17}$ at 40°C. Some formation of $Al_3Cl_{10}^-$ may be important at high (>64 mol%) $AlCl_3$ mole fractions (5, 6). The anion–cation interactions that take place in ambient temperature melts have been studied by NMR spectroscopy (7–9). In basic melts the organic cations interact strongly with halide ions, apparently through hydrogen bond formation; in particular, all three Im^+ ring protons interact (10–13) with Cl^-. In acidic melts (excess $AlCl_3$ over Cl^-) little interaction seems to occur (7–9).

Both $AlCl_3$:BPC and $AlCl_3$:ImCl melts do provide wide acidity ranges and electrochemical windows but take considerable time and work to obtain pure. In this context Jones and Blomgren (14) found that a 2:1 $AlCl_3$:trimethylsulfonium chloride (TMSuCl) mixture remained liquid to −50°C and had useful electrochemical stability and electrical conductivity. However, TMSuCl is difficult to prepare and the system was not exploited. TMSuBr, on the other hand, is commercially available and should (like TMSuCl) provide a haloaluminate melt with a high-energy UV cutoff (no unsaturation!) and simple solvent NMR (one methyl signal). We therefore evaluated the $AlBr_3$:TMSuBr and $AlCl_3$:TMSuBr solvent systems.

Furthermore, we followed up recently (15) on the discovery (16) that $ImHCl_2$ is also liquid at ambient temperatures and usable as a proton source in $AlCl_3$:ImCl melts by studying the HCl:ImCl system over the HCl mole fraction range of 0.31 to 0.67 (15). It transpires that the controlling equilibrium in this system is

$$[1] \quad H_2Cl_3^- + Cl^- \Leftrightarrow 2HCl_2^-$$

with $K_{eq} \cong 218$ at 297 K (15, 17). It was appropriate, therefore, to examine the TMSuBr:HBr system in a search for the formation of HBr_2^- and $H_2Br_3^-$ in particular: evidence for the formation of $X(HX)_n^-$ where X = Cl, Br dates from 1909 (18) and extensive discussions of HX_2^- and HXY^- species (19) and systems with strong hydrogen bonding (20) are available.

Experimental

Materials and melt preparation

Trimethylsulfonium bromide (TMSuBr, Eastman, 99%) was twice recrystallized from anhydrous ethanol (Aldrich) and dried *in vacuo* at ~40°C for 3 days. Anhydrous hydrogen bromide was used as received from Matheson. Anhydrous hydrogen chloride, prepared from concentrated sulfuric and hydrochloric acids (Fisher ACS), was kept free of moisture with a gas trap at −78°C, two sulfuric acid wash bottles, and a magnesium perchlorate column. 1-Ethyl-3-methyl-*1H*-imidazolium chloride was provided by J.L.E. Campbell (15). Anhydrous aluminum chloride (Fluka, >99%) was purified by vacuum sublimation at ~210°C through a fine-porosity Pyrex frit. About 1% by weight of NaCl (BDH, ACS) and a piece of Al wire (Aldrich, 99.999%) were added prior to the sublimation to form a molten $NaAlCl_4$ layer to extract ionic impurities. Two or three sublimations produced colorless $AlCl_3$ crystals, which were ground and sealed in glass ampoules awaiting use. Anhydrous aluminum bromide (Fluka, >98%) was vacuum sublimed (× 3) at ~130°C. The purified crystals were colorless.

$AlCl_3$:ImCl (2:1), $AlCl_3$:TMSuBr (2:1), and $AlBr_3$:TMSuBr (2:1) acidic melts were prepared by adding the aluminum halide slowly to the second salt with continuous stirring. The three melts were colorless, pale yellow turning yellow in days, and colorless turning pale yellow in days, respectively. Reactions with TMSuBr were much less exothermic than that with ImCl.

$TMSuHBr_2$ was prepared at room temperature by passing HBr through a needle (26 or 22 G) over weighed amounts of TMSuBr crystals in a 10 mL serum bottle or in a 30 mL Barnes dropping bottle fitted with a septum. The speed of the reaction depended on the HBr pressure, being very slow at 1 atm (101.3 kPa). Consequently, melts of composition $TMSuBr(HBr)_n$ ($1.00 < n < 1.15$) were prepared by applying HBr at a little higher than 1 atm for several minutes and then pumping HBr out of the melts until the required mole ratio, as indicated by gravimetry, was achieved. Melts with $1.15 < n_{HBr} < 1.40$ were prepared directly. All melts were pale yellow. They were transferred to the drybox ready for physical measurements. For melts with $n_{HBr} > 1.25$, the HBr partial pressures above them were quite high so that the melts had to be transferred to appropriate measuring bottles through cannulation using a cannula of Teflon tubing and a syringe. For NMR measurements only, melts with $n_{HBr} > 1.40$ were prepared in situ in NMR tubes with rubber septa secured by Parafilm, and n values were determined gravimetrically. Small needles (26 G) were required to eliminate leaks.

Physical measurements

Densities of $AlCl_3$:TMSuBr and $AlBr_3$:TMSuBr melts were measured at 25°C with either 5 mL or 10 mL volumetric flasks that had been calibrated with distilled water at 25 ± 0.2°C. Densities of $TMSuBr(HBr)_n$ ($1.00 < n < 1.40$) were measured at 25°C using 2.5 mL dilatometric tubes calibrated with distilled water. A reference mark was etched midway up the 2.5 mm bore stem. Once melts were loaded to the mark they were capped with septa to minimize HBr loss.

Viscosities of melts were measured using Cannon–Fenske viscometers (sizes 50, 100, 150, and 300) that had been calibrated with aqueous glycerol (Fisher ACS) solutions (21, 22). A paraffin oil bath with a submerged heater and an Omega 871 digital thermometer were used in temperature control. Viscometers were calibrated by an overlapping technique: distilled water was the primary standard (sizes 50 and 100), 50% aqueous glycerol (sizes 50, 100, and 150) and 85% aqueous glycerol (sizes 150 and 300) the secondary standards. The densities of 50% and 85% glycerol were measured with a 10 mL dilatometer and their viscosities agreed with Sheely's (21) table. Before each measurement the viscometer loaded with melt was immersed in the bath for 10 min; the melt was then drawn (or forced) up by vacuum (or pressure) to 5–10 mm above the upper mark. A minimum flow time of 120 s was required. To minimize HBr loss from TMSuBr(HBr) melts, the ends of the viscometer were capped with rubber septa and connected with Teflon tubing to equalize pressures.

Conductances of $AlBr_3$:TMSuBr and $AlCl_3$:TmSuBr were measured with an Orion model 160 conductivity meter with an Orion 016010 conductance cell that has four glassy carbon electrodes and a temperature sensor. The conductances were frequency independent and the cell constant was 0.609 cm^{-1} (confirmed with 0.1 demal aqueous KCl). Melts were contained in a small glass cylinder and two O-rings were mounted between the cell and the cylinder to get an airtight seal. Conductances of $TMSuBr(HBr)_n$ melts were measured with a YSI model 31 conductivity bridge (Yellow Springs) at 1 kHz. This cell was made by attaching two Pt electrodes on opposite sides of a glass block attached to a glass tube bearing the separated leads; the tube in turn was placed in a melt container drawn from a 50 mL buret fragment, and tube and container were sealed by a nut with Teflon and silicone rubber bushings. The cell was calibrated at 25 ± 0.2°C with 0.1 demal aqueous KCl (23) and the cell constant was 2.26 cm^{-1} ± 1%. The container was immersed in an oil bath such that the melt surface was 3 cm below the oil surface.

Melting points were determined visually by immersing an NMR tube filled with melt in a well-stirred water bath and monitoring the temperature with a digital thermometer. No sharp phase change was observed for these melts, so melting points were taken as the temperatures at which most melt in the NMR tube was melted in a short period (about 10 min).

All of the melts supercooled and, to have an idea of how low the temperature of their supercooling states could go, freezing points were also determined visually with the same NMR tube immersed either in an ice–water bath or in a Dewar bottle filled with acetone and cooled with Dry Ice. Freezing points were less reproducible than melting points and could vary up to 5°C. Therefore, these freezing and melting points can only be taken as a practical guide.

^1H *NMR* spectra were obtained with a Bruker AC-200 NMR spectrometer. 3-(Trimethylsilyl)-1-propanesulfonic acid, sodium salt (Thompson–Packard) dissolved in dimethyl sulfoxide-d_6 was sealed into melting point capillaries and then inserted into 5 mm NMR tubes as an external standard (at 0.49 ppm vs. TMS in $CDCl_3$). NMR tubes were filled with melt in the drybox, capped, and sealed with Parafilm before transfer to the spectrometer.

UV–visible spectra were measured with a Hewlett–Packard model 8452A diode array spectrophotometer.

Infrared spectra of $TMSuBr(HBr)_n$ were recorded with a Perkin–Elmer model 1600 FT-IR spectrophotometer. One or two drops of melt were sandwiched between the two films cut off from a polyethylene sampling bag that, in turn, was placed

V_M is an average molar volume.

between two KBr windows: the film thickness was adjusted by gently pressing the upper window (17).

Cyclic voltammograms were obtained with a BAS model 100A electrochemical analyzer (Bioanalytical Systems) and recorded with a Hewlett–Packard 7475A plotter. A glassy carbon disk (0.071 cm^2) served as working electrode, a coiled Al wire (Aldrich, 99.999%) as counter electrode, and an Al wire, immersed in the 2:1 AlX_3:TMSuBr melt in a compartment separated by a fine porosity glass frit, served as reference electrode.

Elemental analyses were performed on a Perkin–Elmer model 2400 CHN analyzer.

Weighing and material transfers involving AlX_3, TMSuBr, and their mixtures were performed in a drybox under a purified nitrogen atmosphere. Stored materials in the drybox were capped, sealed with Parafilm, and wrapped with Al foil.

Results and discussion

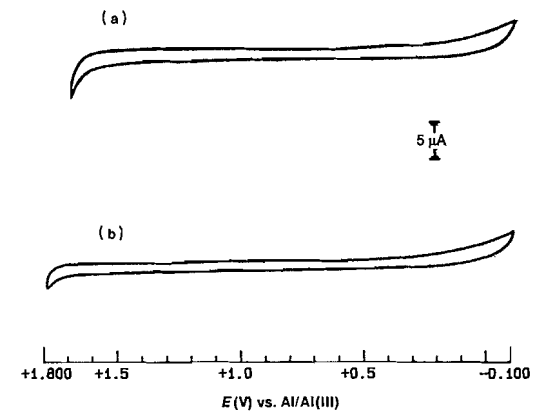
Recrystallized and dried TMSuBr gave satisfactory C and H analyses and, moreover, showed little deterioration after exposure to the laboratory atmosphere (purified salt: C = 22.71%, H = 5.74%, H/C = 3.01; exposed salt: C = 23.19%, H = 5.87%, H/C = 3.02; theoretical: C = 22.94%, H= 5.77%, H/C = 3.00). The reactions of TMSuBr with aluminum halides are much less exothermic than those of ImCl. These two factors favor the preparation and use of TMSuBr derivatives over those of ImCl.

$AlCl_3$:TMSuBr and $AlBr_3$:TMSuBr are liquid at ambient temperature only for AlX_3:TMSuBr mole ratios close to 2:1. They show a range >40°C between freezing and melting temperatures. For the HBr:TMSuBr systems, liquids are found for HBr:TMSuBr ratios >1.00 and the melting and freezing temperatures differ by ~20°C.

Density (ρ), viscosity (η), and conductance (κ) data for the melts studied are compared with literature values for other ambient temperature melts in Table 1. The specific conductance (κ, mS cm^{-1}) of 2:1 $AlBr_3$:TMSuBr showed a linear dependence on temperature (t, °C) over the range 25–60°C, viz.

[2] $\kappa = 0.303 + 0.0455t$ (corr. coeff. 0.9998)

Fig. 1. Cyclic voltammograms of (*a*) 2:1 $AlBr_3$:TMSuBr and (*b*) 2:1 $AlCl_3$:TMSuBr melts at a glassy carbon electrode at 24°C. Scan rate = 100 mV/s.



Melts derived from trimethylsulfonium and aluminum halides were the least conducting and most viscous among those listed, suggesting a stronger cation–anion interaction than in the other acidic chloroaluminates. The n:1 HBr:TMSuBr melts possess viscosities similar to that of 2:1 $AlCl_3$:ImCl but conductances up to 4 times greater. Within the n:1 HBr:TMSuBr system the viscosity variation is more extreme (notice that by $n > 1.24$ we have the most fluid of the systems quoted). Comparing 2:1 $AlBr_3$:TMSuBr and 1:1 HBr:TMSuBr we see that a change from $Al_2Br_7^-$ to HBr_2^- brings about a 7-fold viscosity decrease but a 24-fold conductance increase. This viscosity change may be ascribed to ion size but the conductance change suggests that a Grotthus mechanism of Br^- exchange may be facilitating conduction in a manner similar to that suggested for molten polyiodides by Stegemann et al. (28).

[3] $[Br–H–Br]^- + HBr \Leftrightarrow Br–H + [Br–H–Br]^-$

The electrochemical windows for 2:1 TMSuBr:$AlCl_3$ and TMSuBr:$AlBr_3$ melts are 1.9 and 1.8 V, respectively ($Al_2Br_7^-$ is easier to oxidize than $Al_2Br_6Cl^-$) (Fig. 1). The UV–visible

Fig. 2. UV–visible spectra of (*a*) 2:1 $AlCl_3$:TMSuBr, (*b*) 2:1 $AlBr_3$:TMSuBr, and (*c*) 2:1 $AlCl_3$:ImCl with 0.1 cm quartz cell at 23°C (air reference).

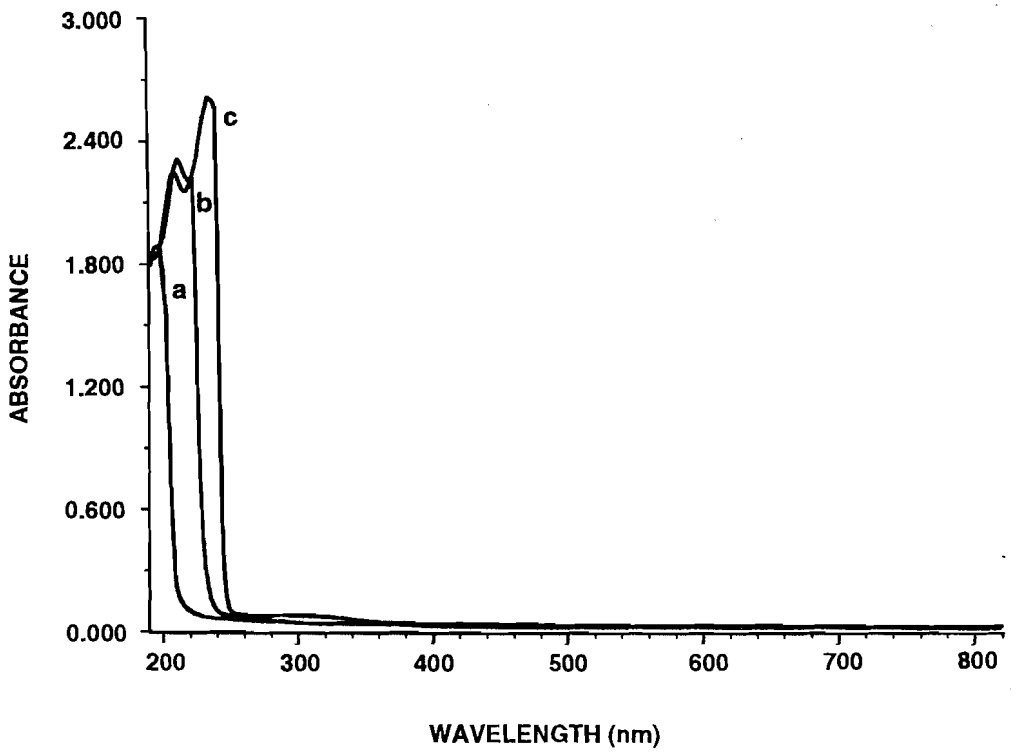

Fig. 3. ^1H NMR spectra of (*a*) 2.0:1 (*b*) 1.4:1, and (*c*) 1.0:1 HBr:TMSuBr melts at 24°C.

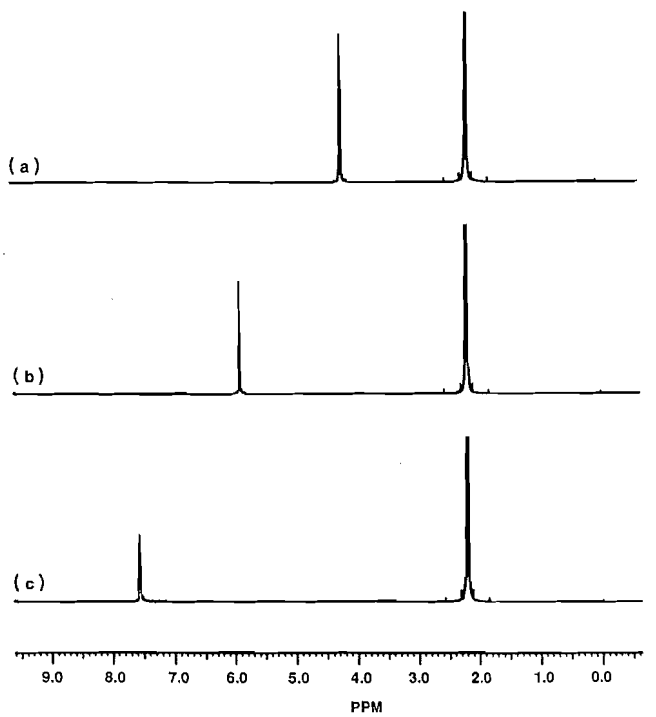
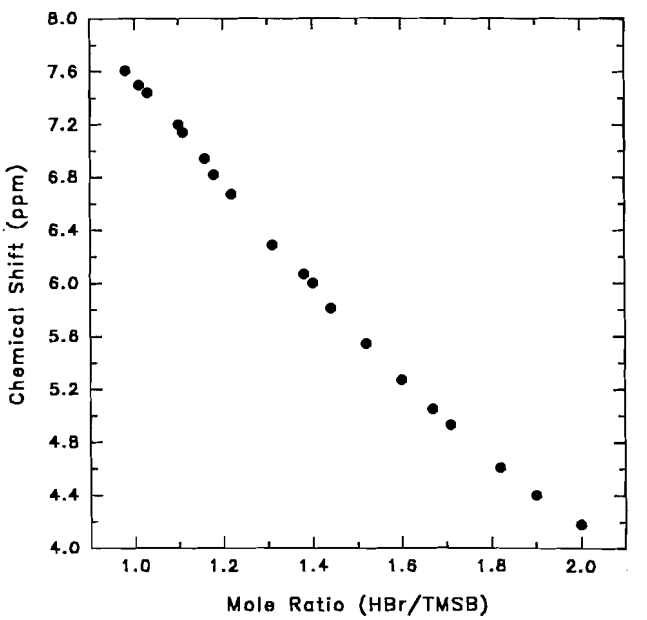


spectra of 2:1 $AlCl_3$:ImCl, $AlBr_3$:TMSuBr and $AlCl_3$:TMSuBr, obtained with a 1 mm cell show UV cutoffs (absorbance = 1) of 242, 228, and 210 nm, respectively (Fig. 2). Thus, bands such as the B band of benzene (λ_{max} = 256 nm) should be completely viewable in the 2:1 AlX_3:TMSuBr (where X is Cl or Br) melts (30).

Fig. 4. ^1H chemical shift vs. HBr:TMSuBr ratio in melts.



The ^1H NMR spectra of 2:1 AlX_3:TMSuBr melts show the simple $TMSu^+$ methyl proton band. This means that a greater scope for studying ^1H-containing solutes exists in TMSuBr-based melts than in $AlCl_3$:ImCl systems (five distinct solvent bands). Typical ^1H NMR spectra of HBr:TMSuBr melts (Fig. 3) consist of a larger singlet at ~2.18 ppm, attributable to the methyl protons of $TMSu^+$ and a singlet at lower field arising

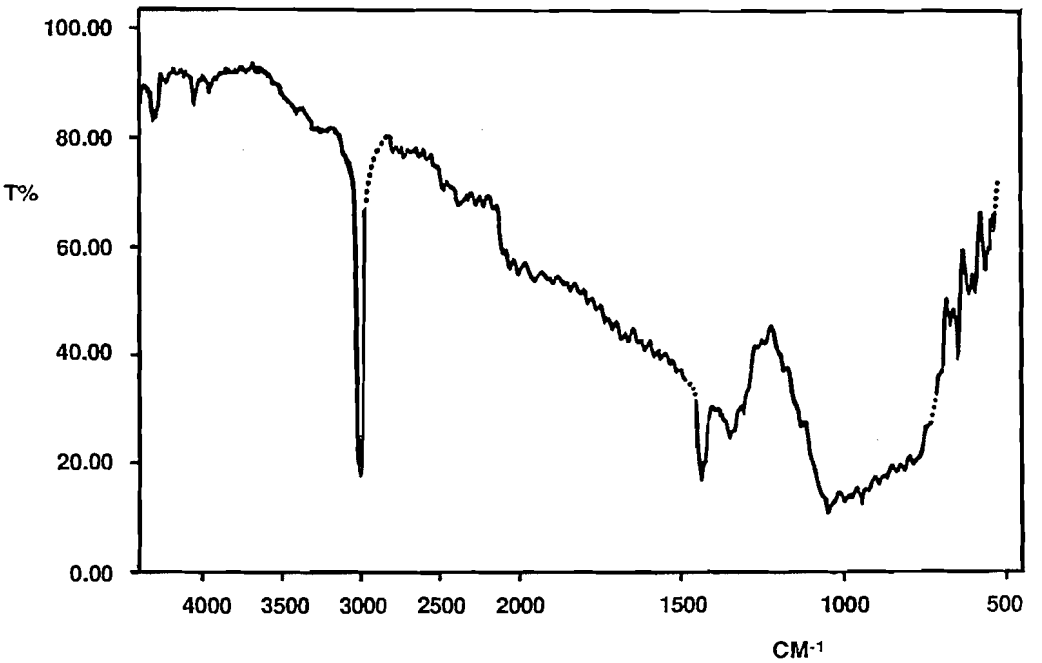
Fig. 5. IR spectrum of 1:1 HBr:TMSuBr melt at 23°C.



from the added HBr. Since the ^1H signal in $CHCl_2CHCl_2$ occurs at −2.73 ppm vs. TMS for HBr and at 10.2 ppm for HBr_2^- (29) we conclude that the HBr_2^- formation reaction is not complete in the 1:1 mixture with a shift of 8.1 ppm vs. TMS (or 7.60 ppm vs. the external standard). This situation is not found in ImCl:HCl melts (15, 16). As the HBr:TMSuBr mole ratio is increased, the $TMSu^+$ signal is unchanged but the lower field signal intensifies and shifts upfield, reaching 4.18 ppm at a ratio of 2:1 (Fig. 4). This type of behavior *is* observed for HCl:ImCl melts and is readily explained in terms of $H_2Cl_3^-$ formation (15). We suggest that the $H_2Br_3^-$ formation reaction may be occurring at higher HBr concentrations in the HBr:TMSuBr system.

Figure 5 depicts the IR spectrum of 1:1 HBr:TMSuBr. The sharp bands at 3000 and 1435 cm^{-1} can be assigned to the methyl C–H stretching and bending vibrations (14) while the broad bands at 1350 cm^{-1} and 780–1050 cm^{-1} can be assigned by comparison with the spectrum of tetrabutylammonium hydrogen dibromide to ν_2, the degenerate bending mode, and combinations of ν_3 and ν_1, the antisymmetric and symmetric stretching modes, of HBr_2^- (31, 32). The broad absorption between 1500 and 2200 cm^{-1} and the weak band at 2500 cm^{-1} are not found for $(R_4N)(HBr_2)$ (31) or TMSuCl (14) and therefore, must be due to HBr or $H_2Br_3^-$. Comparison with spectral data for $H_2Cl_3^-$ (17), which has a broad absorption centred about 2000 cm^{-1}, and HBr gas (33) with absorption at 2650 cm^{-1} leads to the assignment of the 1500–2200 cm^{-1} band(s) to $H_2Br_3^-$ and the weak 2500 cm^{-1} band to HBr.

The overall implication of the NMR and IR data is that stepwise $Br(HBr)_n^-$ formation proceeds less readily than stepwise $Cl(HCl)_n^-$ formation. Thus, ostensibly stoichiometric TMSuHBr$_2$ contains detectable quantities of $H_2Br_3^-$ and HBr while HBr_2^- and $H_2Br_3^-$ require significant HBr pressure for their formation and endurance. In ImCl:HCl systems, by contrast, HCl is *not* found in solution over the composition range studied (17, 34).

In conclusion, TMSuBr readily forms salts with aluminum halides that are liquid at ambient temperature in the more Lewis acidic composition range and, although somewhat viscous, are promising solvents in terms of their spectroscopic and electrochemical windows. Intuitively, one would wonder about the photostability of bromide melts. Reaction of TMSuBr with HBr can produce HBr_2^- and $H_2Br_3^-$ ions, but less readily than ImCl + HCl yield the chloride species. TMSuHBr$_2$ could be used as an HBr source, but it likely includes Br^-, H_2Br_3, and free HBr as well as HBr_2^-.

Ouverture sélective d'époxydes styréniques substitués à l'aide d'azoture de lithium en présence de β-cyclodextrine

Alain Guy, Joël Doussot, Agnès Dallamaggiore et Robert Garreau

Résumé : L'ouverture régio et énantiosélective d'époxydes styréniques substitués racémiques par l'azoture de lithium en présence de β-cyclodextrine est décrite. Le contrôle de la régiosélectivité de la réaction dépend du caractère hydrophobe du substrat qui impose un degré de pénétration plus ou moins important à l'intérieur de la cavité et favorise l'ouverture en β. L'énantiosélectivité observée au cours de la réaction de dédoublement cinétique de l'époxyde racémique est due pour sa part aux interactions non covalentes entre la partie supérieure de la cyclodextrine et la fonction époxyde.

Mots clés : β-cyclodextrine, complexes d'inclusion, contrôle de la régio et stéréosélectivité, chimie en milieu aqueux.

Abstract: Regio- and enantioselective opening of substituted styrenic epoxides by lithium azide in presence of β-cyclodextrin is described. The regioselectivity of the reaction is related to the hydrophobicity of the substrate, which governs its penetration inside the cavity of the cyclodextrin and is favorable to the β opening of the epoxide. The enantioselectivity observed during the kinetic resolution of the racemic epoxide is mainly dependent on the non-covalent interactions between the upper rim of the cyclodextrin and the epoxide.

Key words: β-cyclodextrin, inclusion complexes, regio- and stereocontrol, chemistry in aqueous medium.

Introduction

La synthèse de β-aminophényléthanols chiraux est un domaine de recherche extrêmement actif en pharmacochimie compte tenu des différences d'activités remarquables observées pour les différents stéréoisomères (1). Parmi les méthodes d'accès à ces β-aminoalcools l'ouverture des époxydes par les réactifs azotés est une méthode avantageuse sur le plan industriel car elle permet d'intégrer dans le produit attendu la majorité des atomes présents dans les différents partenaires de la réaction. Comparée à l'ouverture des époxydes aliphatiques celle des époxydes styréniques pose toutefois un problème de régiosélectivité car une attaque nucléophile se fera sur le carbone benzylique qui est le plus électrophile pour conduire au produit d'ouverture α (2). Seules quelques exceptions permettent d'inverser la régiosélectivité en faveur de l'isomère β (3). L'utilisation des phénomèmes d'association intermoléculaires pour contrôler la sélectivité des réactions est particulièrement étudiée ces dernières années (4). Depuis les travaux de Breslow et Campbell (5) l'utilisation de cyclodextrines comme «microréacteurs» dans le contrôle de la régiosélectivité a été souvent étudiée dans des réactions aussi diverses que l'halogénation, la carboxylation, la formylation, la dihalométhylation et l'allylation de composés aromatiques (6). Dans un article récent nous avons montré que l'ouverture de l'oxyde de styrène dans la β-cyclodextrine (β CD) conduit majoritairement au régioisomère β, contrairement à l'ouverture observée dans l'eau en l'absence de cyclodextrine (7).

Résultats et discussion

Ouverture régiosélective en β d'époxydes styréniques substitués

Dans ce présent travail nous avons étudié l'influence de la substitution en *para* du noyau aromatique sur la régiosélectivité de l'attaque nucléophile au niveau du carbone homobenzylique. De nombreux auteurs ont montré que l'interaction entre la cavité hydrophobe de la cyclodextrine et le substrat aromatique dépend fortement de la nature de la substitution du noyau aromatique. Dans une étude récente Sanemasa et al. ont montré dans le cas de la β-cyclodextrine que l'association des différents halogénobenzènes suivait l'ordre : I > Br > Cl > H > F (8) qui correspond bien à la variation du caractère hydrophobe du noyau aromatique; cette même séquence se répète pour les *p*-dihalogénobenzènes (9). Notre présente étude a été effectuée sur une série d'époxydes substitués en *para* par des halogènes ou par des groupements alkyles. Tous ces époxydes **1***b–g* ont été obtenus à partir des benzaldéhydes correspondants selon la méthode de Corey et Chaykowsky (10). Leur ouverture a été réalisée par l'azoture de lithium en milieu aqueux soit en absence ou soit en présence de deux équivalents de β-cyclodextrine (figure 1). L'influence de la cyclodextrine s'exerce de deux façons et ceci quelle que soit la nature du substituant (tableau 1). Tout d'abord la régiosélec-

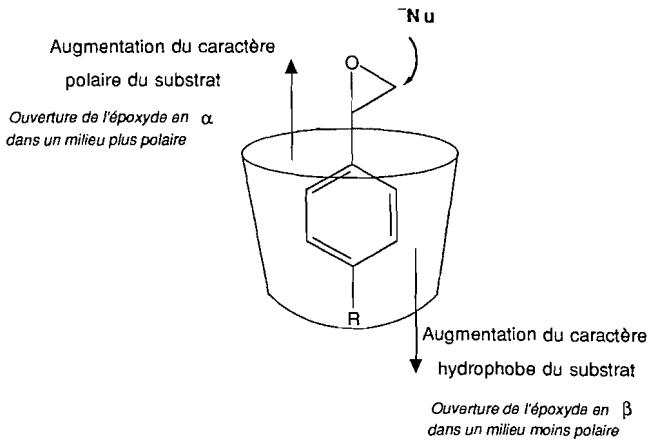
tivité de l'attaque est inversée par rapport à une réaction sans cyclodextrine. L'ouverture des époxydes par LiN_3 en milieu aqueux fournit les 2-aryl-2-azidoéthanols **2***b–g* avec des régiosélectivités $\alpha > 95\%$ tandis qu'une réaction effectuée sur l'époxyde inclus dans la cyclodextrine inverse la régiosélectivité en conduisant par exemple dans le cas du *p*-bromophényloxirane **1***d* au 2-azido-1-(4-bromo-phényl)-éthanol **3***d* avec une régiosélectivité β de 90%. Aucun effet catalytique n'est observé au cours de cette réaction qui est plus rapide en l'absence de β-cyclodextrine. Cette augmentation des temps de réaction semble due à des problèmes d'insolubilité des complexes en milieu aqueux liés à la nature des époxydes de départ. En présence de β-cyclodextrine l'ouverture peut se produire soit à l'extérieur de celle-ci et conduire uniquement au régioisomère α ou soit à l'intérieur en privilégiant cette fois une ouverture en β. Le principal facteur responsable de ce renversement de régiosélectivité semble être le degré d'enfoncement du noyau aromatique à l'intérieur de la cyclodextrine qui conduit à une ouverture en β grâce à un effet microscopique de solvant inhérent au caractère hydrophobe de la cavité. Lorsque le substrat est inclus moins profondément dans cette cavité, l'attaque de l'époxyde se déroule d'une part dans un environnement bien plus polaire et d'autre part est soumise à une assistance électrophile des hydroxyles secondaires ce qui est favorable à une ouverture en α (figure 2). Ce phénomème s'observe d'une façon concordante en comparant l'évolution parallèle de la régiosélectivité de l'attaque en β des oxiranes substitués par les halogènes aux valeurs des contantes d'associations décrites par Sanemasa pour une substitution identique du noyau aromatique.

Dédoublement cinétique au cours de l'ouverture des époxydes

L'étude de l'induction asymétrique obtenue au cours de l'ouverture nucléophile des époxydes conforte l'hypothèse avancée pour expliquer les variations observées sur la régiosélectivité. Il est connu que l'induction asymétrique résultant de la présence des cyclodextrines est due à une participation préférentielle des hydroxyles secondaires de la partie supérieure plutôt qu'à celle des hydroxyles primaires de la partie inférieure (11). Dans le cas de l'ouverture des époxydes la participation de ces hydroxyles secondaires à une catalyse électrophile est fort probable, compte tenu du mécanisme d'ouverture. Le modèle proposé pour rendre compte de la régiosélectivité observée, pour lequel les époxydes présentant le caractère hydrophobe le plus faible se rapprochent de la partie supérieure de la cyclodextrine, est en accord avec la variation de l'énantiosélectivité obtenue : l'excès énantiomérique (e.e.) atteint 66% en énantiomère de configuration *R* pour l'isomère *para*-fluoré β **3***b* et seulement 30% pour le composé *para*-bromé **3***d* (tableau 1). Des phénomènes de dynamique moléculaire difficile à mettre en évidence jouent aussi probablement un rôle déterminant au cours du contrôle de la sélectivité des réactions. L'inclusion d'un substrat dans la cyclodextrine est un phénomène d'échange rapide et l'examen de l'influence de la température montre que l'abaissement de celle-ci produit un effet important sur l'excès énantiométrique comme le montre les résultats obtenus à partir des époxydes **1***d* et **2***g* qui présentent le caractère hydrophobe le plus important et sont donc à priori les moins rapides à s'échanger. L'encombrement stérique du substituant et donc du noyau aromatique qui va de pair avec l'augmentation du caractère hydrophobe défavorise ces phénomèmes d'échange et permet ainsi une amélioration du contrôle de la régiosélectivité.

Fig. 2. Influence de la substitution sur la sélectivité de l'ouverture dans la β CD.



Conclusion

Nous avons montré qu'en présence de β CD l'ouverture en milieu aqueux par l'azoture de lithium d'époxydes styréniques *para*-substitués se fait préférentiellement en position β. Cette régiosélectivité de la réaction dépend du caractère hydrophobe du substrat car il est responsable du degré de pénétration plus ou moins important à l'intérieur de la cavité de la β CD où s'effectue l'ouverture en β.

Le dédoublement cinétique observé au cours de l'ouverture de ces époxydes racémiques est dû pour sa part aux interactions non covalentes entre la partie supérieure de la β et la fonction époxyde ce qui explique que les e.e. les plus élevés sont obtenus cette fois avec les substrats les moins hydrophobes.

Partie expérimentale

Les points de fusion déterminés à l'aide d'un appareil Büchi «méthode Dr Tottoli» ne sont pas corrigés. Les spectres d'absorption ir ont été obtenus avec un spectrophotomètre Philips PU 7916, les produits étants déposés sur des pastilles de KBr. Les spectres de rmn ont été obtenus avec un spectromètre Bruker AC 200 (200 MHz pour le proton et 50 MHz pour le ^{13}C), les échantillons étant dissous dans $CDCl_3$. Les analyses de chromatographie liquide haute performance (CLHP) ont été effectuées à l'aide d'un appareil Waters 590, associé à un détecteur UV Varian de type Vari-chrom. Les basses températures ont été maintenues grâce à un cryostat Fryka-kältetechnik KP 250 avec agitateur magnétique monobloc incorporé. Les microanalyses ont été assurées par les laboratoires Wolff (92583 Clichy Cedex, France).

Ouverture des époxydes 1 par LiN_3 en présence de β CD
Mode opératoire : Une suspension de β CD (le nombre de moles est indiqué dans le tableau 1) et d'époxyde **1** (1 mmol) dans 10 mL d'eau est vigoureusement agitée 2 h à la température ambiante avant d'être refroidie à l'aide d'un cryostat. L'azoture de lithium (1,5 mmol) est alors ajouté en une seule fois. L'évolution de la réaction est suivie par analyse CLHP dans les conditions suivantes : colonne Hypersil Si 60 (granulométrie 5 μm, longueur 15 cm, diamètre 4,6 mm), détecteur UV : $\lambda = 260$ nm, phase éluante : heptane/acétate d'éthyle 90/10, débit 1 mL min^{-1}. La réaction est interrompue en versant la suspension sur un mélange de 50 mL de DMSO et 30 mL d'eau glacée. Les produits sont extraits à l'éther (3 fois 20 mL). Les phases organiques regroupées sont lavées avec une solution saturée de chlorure de sodium, séchées sur sulfate de magnésium et évaporées pour donner un brut qui est chromatographié sur colonne de silice à l'aide du mélange éluant heptane/acétate d'éthyle 70/30. L'e.e. du composé **3** est déterminé après dérivation avec l'acide (*S*)-(−)-α-méthoxy-α-(trifluorométhyl)-phénylacétique (12), ceux de **1** et **2** par analyse CLHP sur une colonne Chiralpack AD de Daicel. Le tableau 1 regroupe les différents résultats.

Abstract: The carbon chemical shift tensors of the carbonyl and thiocarbonyl groups of acetamide, thioacetamide, thioacetanilide, 4′-methoxyacetanilide, and 4′-methoxythioacetanilide have been experimentally determined using dipolar – chemical shift solid-state ^{13}C NMR spectroscopy. The magnitudes of the three principal components of the carbon chemical shift tensors are found to exhibit marked variations between the carbonyl and thiocarbonyl functionalities. However, in contrast to the conclusions of an earlier comparative investigation involving benzophenone and thiobenzophenone, the orientations of the principal axis systems of these chemical shift tensors are found to be similar. These experimental results represent the first complete characterizations of the carbon chemical shift tensor in organic thiocarbonyls. The results of our ab initio GIAO and LORG calculations of carbon chemical shielding tensors in formaldehyde, thioformaldehyde, formamide, and thioformamide as well as in acetamide and thioacetamide are in qualitative agreement with experiment. The findings of the present investigation provide conclusive evidence that the well-known isotropic deshielding of the carbon nucleus in the C=S group relative to C=O is primarily attributable to the decreased energy associated with the $\sigma \leftrightarrow \pi^*$ excitation within the thiocarbonyl fragment. This result is in contrast with the conventional interpretation that the deshielding originates from a red shift in the C=S HOMO–LUMO $n \rightarrow \pi^*$ transition.

Key words: chemical shift tensors, solid-state ^{13}C NMR, carbonyls, thiocarbonyls, ab initio calculations.

Résumé : Utilisant les déplacements chimiques dipolaires de la spectroscopie RMN du ^{13}C à l'état solide, on a déterminé expérimentalement les tenseurs des déplacements chimiques du carbone des groupes carbonyle et thiocarbonyle des acétamide, thioacétamide, thioacétanilide, 4′-méthoxyacétanilide et 4′-méthoxythioacétanilide. On a trouvé que les amplitudes des trois principales composantes des tenseurs des déplacements chimiques du carbone présentent des variations importantes entre les fonctions carbonyles et thiocarbonyles. Toutefois, en opposition avec les conclusions tirées à partir d'une étude comparative antérieure impliquant la benzophénone et la thiobenzophénone, on a trouvé que les orientations des principaux axes de référence de ces tenseurs des désplacements chimiques sont semblables. Ces résultats expérimentaux représentent les premières caractérisations complètes du tenseur du déplacement chimique des thiocarbonyles organiques. Les résultats de nos calculs ab initio GIAO et LORG des tenseurs d'écran chimique du carbone dans les formaldéhyde, thioformaldéhyde, formamide, thioformamide ainsi qu'acétamide et thioacétamide sont en accord qualitatif avec les résultats expérimentaux. Les observations faites dans le présent travail fournissent des bases concluantes qui permettent d'attribuer le déblindage bien connu du noyau du carbone dans le groupe C=S par rapport au C=O à une diminution de l'énergie associée à une excitation $\sigma \leftrightarrow \pi^*$ dans le fragment thiocarbonyle. Ce résultat est en opposition avec l'interprétation conventionnelle qui attribue le déblindage à une déplacement vers le rouge de la transition $n \rightarrow \pi^*$ HO–BV du C=S.

Mots clés : tenseurs des déplacements chimiques, RMN du ^{13}C à l'état solide, carbonyles, thiocarbonyles, calculs ab initio.

[Traduit par la rédaction]

Introduction

The carbonyl carbon chemical shift (CS) tensor has been well characterized with a vast amount of experimental data available for numerous organic and organometallic carbonyls (1). Unfortunately, a comparatively small amount of data exists for thiocarbonyl carbon CS tensors. In fact, to the best of our knowledge, there are only five reports pertaining to the CS tensors of compounds containing C=S (2). Furthermore, only one of these studies involved an organic thiocarbonyl compound (2*b*). In that study, the thiocarbonyl carbon CS tensor of thiobenzophenone was compared with the carbonyl carbon CS tensor in benzophenone using solid-state ^{13}C NMR spectroscopy of powdered samples. Although large differences in the magnitudes of the three principal components of the carbon CS tensors were observed, information concerning the orien-

tation of these tensors in the molecular frame, which would aid in understanding the observed variations, was unavailable from such powder studies. In an earlier ^{13}C single-crystal NMR investigation of benzophenone (3), it was concluded that the least shielded component lies perpendicular to the carbonyl bond and in the C-C(O)-C plane while the component of intermediate shielding lies parallel with the carbonyl bond. The most shielded direction was associated with the normal to the aforementioned plane. Qualitatively, such an orientation is invariably observed for the carbonyl fragment (4, 5). Consequently, based on the observed differences in the magnitudes of the three principal components of the carbon CS tensors in benzophenone and thiobenzophenone as well as simple electronic structure arguments, it was proposed that the two in-plane principal components exchange orientation in thiobenzophenone with respect to benzophenone. The most shielded direction was predicted to lie perpendicular to the C-C(S)-C plane.

The primary objective of this study was to perform a complete investigation of the carbonyl and, for the first time, thiocarbonyl carbon CS tensors of some simple amides and thioamides using dipolar – chemical shift solid-state ^{13}C NMR spectroscopy (6). This has been performed with two main goals in mind. First, to experimentally characterize the orientation of the thiocarbonyl carbon CS tensor principal axis system (PAS) in thioamides and to compare the results with that in the amides. Secondly, such information then permits a concrete analysis of the origin of the well-known large deshieldings observed for the isotropic carbon CS in the C=S group relative to the C=O fragment. Such deshieldings were previously observed in both solution (7) and the earlier solid-state NMR studies (2) and have also been theoretically calculated (8). The solid-state NMR results have been augmented with ab initio GIAO and LORG carbon chemical shielding tensor calculations involving several small carbonyl- and thiocarbonyl-containing molecules.

Theoretical background

Nuclear magnetic shielding is an orientation-dependent interaction that can be described by a second-rank Cartesian tensor (9–11). The chemical shielding tensor can be quantified by three principal components and three angles that specify the orientation of the tensor principal axis system (PAS). The PAS is a reference frame in which the tensor is diagonal. The NMR spectrum of an isolated spin-½ nucleus in a static powder sample consists of a particular pattern known as a powder pattern (12). The powder pattern is observed because all possible orientations of the molecule are present in the applied magnetic field. In practice, one measures chemical shifts in NMR spectra. The three principal components of the CS tensor (the diagonal elements in the PAS), δ_{11}, δ_{22}, and δ_{33}, are directly available from the powder pattern line shape. The isotropic CS, δ_{iso}, observed in high-resolution NMR studies, is the average of the three principal components. The span of the CS tensor, Ω, is defined as $\delta_{11} - \delta_{33}$ and provides a measure of the anisotropic or orientation-dependent nature of the chemical shielding interaction (13). Another informative parameter is the skew, κ, which is given by $3(\delta_{22} - \delta_{iso})/\Omega$ (13).

As mentioned, the three principal components of the CS tensor are readily available from the powder pattern line shape. However, to determine the orientation of the principal components of the CS tensor in the molecular reference frame requires further experimentation. One technique of relevance to the present work involves introducing a second spin (X) in the vicinity of the $I = ½$ nucleus (A) such that the two spins are dipolar coupled (6). Such a spin system can be described as an isolated spin-pair (AX). The powder pattern for nucleus A will then consist of $2S + 1$ sub-spectra, where S is the spin of nucleus X. The magnitude of the dipolar splittings observed at the positions of each of the three principal components of the CS tensor for nucleus A depends upon the relative orientation of the A spin CS tensor and the AX dipolar interaction. Since the orientation of the dipolar interaction is fixed in the molecular reference frame with the unique axis directed along the internuclear vector, information on the orientation of the A spin CS tensor in the molecule can be obtained from the dipolar splittings. The magnitudes of the dipolar splittings, $\Delta\nu_{ii}$, at each of the three principal components of the CS tensor are given by (12, 14)

$$[1] \quad \Delta\nu_{11} = R_{eff}(1 - 3\sin^2\beta\cos^2\alpha)$$

$$[2] \quad \Delta\nu_{22} = R_{eff}(1 - 3\sin^2\beta\sin^2\alpha)$$

$$[3] \quad \Delta\nu_{33} = R_{eff}(1 - 3\cos^2\beta)$$

where α and β are the polar angles defining the relative orientations of the dipolar and CS tensors (Fig. 1) and

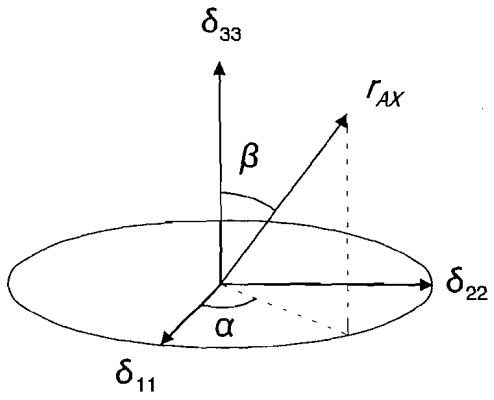
$$[4] \quad R_{eff} = R_{AX} - \frac{\Delta J}{3}$$

$$[5] \quad R_{AX} = \frac{\mu_0}{4\pi}\frac{\gamma_A\gamma_X}{r_{AX}^3}\frac{\hbar}{2\pi}$$

In the above equations, R_{eff} is the effective dipolar coupling constant, R_{AX} is the direct dipolar coupling constant, and ΔJ is the anisotropy in the AX indirect spin–spin (J) coupling. R_{AX} can be calculated provided the AX internuclear separation, r_{AX}, is available (cf. eq. [5]). Note that eqs. [1]–[3] are only strictly valid in the "high-field" limit such that the magnitude of the CS interaction is much greater than the AX dipolar interaction. Under conditions where this requirement is not satisfied and depending upon the relative orientations of these two interactions, asymmetric dipolar splittings may result (14, 15) (cf. Fig. 2 vide infra). Also, since the J coupling involving carbon and nitrogen has previously been found to be small (16), the anisotropy in the J couplings is anticipated to be negligibly small and has not been considered in the present investigation (i.e., $R_{eff} = R_{AX}$).

It is important to indicate that although chemical *shifts*, δ, are measured from NMR spectra, this quantity actually refers to a difference in chemical *shielding*, σ, between the nucleus of interest in a given molecule and in some standard reference compound. Absolute chemical shieldings are reported relative to the bare nucleus (σ = 0 ppm). Consequently, to compare experimental chemical shifts with the theoretical calculations of chemical shielding, the absolute chemical shielding of the nucleus in the reference compound must be known. The refer-

Fig. 1. The orientation of the dipolar vector, r_{AX}, with respect to the chemical shift tensor is defined by the polar angles, α and β.



ence compound used in ^{13}C NMR spectroscopy is tetramethylsilane in which the absolute carbon chemical shielding is 186.0 ppm (17). The convention used for designating the three principal components of the CS tensor is $\delta_{11} \geq \delta_{22} \geq \delta_{33}$ where δ_{11} and δ_{33} are the least shielded and most shielded components, respectively (i.e., $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$).

Experimental

Preparation of amides

The 10% labelled acetamide-^{13}C(CO) was prepared by adding a mixture of 250 mg (3 mmol) of acetyl chloride-^{13}C(CO) and 2.25 g (29 mmol) of acetyl chloride to 10 g (86 mmol) of concentrated aqueous ammonia at −4°C (18). The solvent was then allowed to evaporate and the acetamide was separated from the ammonium chloride by dissolving the acetamide in hot ethyl acetate, filtering the hot mixture, and allowing it to cool. The 10% labelled acetamide-^{13}C(CO) was collected by filtration after the ethyl acetate had cooled to room temperature.

Acetanilide-^{15}N,^{13}C(CO) and 4′-methoxyacetanilide-^{13}C-(CO) were prepared according to the procedure outlined in ref. 19 with the exception that *p*-anisidine was used in the synthesis of the latter compound.

Preparation of thioamides

The amides above were converted to the corresponding thioamides using Lawesson's reagent (LR) (20). The 10% labelled thioacetamide-^{13}C(CS) was prepared by addition of 1.1 g (2.7 mmol) of LR to 0.32 g (5.4 mmol) of 10% labelled acetamide-^{13}C(CO) in THF which was predried over calcium hydride. The solvent was allowed to evaporate under a stream of nitrogen gas (thioacetamide appeared to decompose under reduced pressure) and the mixture was separated on a silica gel column (12:1 dichloromethane:diethyl ether). Thioacetanilide-^{15}N,^{13}C(CS) and 4′-methoxythioacetanilide-^{13}C(CS) were prepared in an analogous fashion except that the solvent was evaporated under vacuum.

Solid-state NMR spectroscopy

The ^{13}C solid-state NMR spectra were acquired at 50.3 MHz on a Bruker MSL-200 spectrometer (B_0 = 4.7 T) and at 100.6 MHz on a Bruker AMX-400 spectrometer (B_0 = 9.4 T). For the MSL, samples were packed into 7 mm o.d. zirconium oxide rotors. For the AMX, 4 mm o.d. zirconium oxide rotors were used. Cross polarization (CP) under the Hartmann–Hahn matching condition (21) was used to increase the sensitivity of the spectra with typical CP contact times between 5 and 6 ms. Proton 90° pulse widths of 3.5 μs at 4.7 T and 5.7 μs at 9.4 T were employed. High-power ^1H decoupling was used during the acquisition of all spectra. The recycle delay time used for 4′-methoxyacetanilide-^{13}C(CO) and 4′-methoxythioacetanilide-^{13}C(CS) was 10 s. Typical recycle delay times of 30–60 s were used for the remaining compounds. Carbon chemical shifts were referenced to tetramethylsilane by setting the high-frequency carbon signal of adamantane to 38.56 ppm (CH_2).

Calculations

Calculations of the carbonyl or thiocarbonyl carbon chemical shielding tensors of formaldehyde, thioformaldehyde, formamide, thioformamide, and thioacetamide were carried out on an IBM RS6000/580 workstation using a direct version of the TEXAS 90 ab initio program package (22), which implements the GIAO (**G**auge-**I**ncluding **A**tomic **O**rbitals) method (23). A Dunning TZP basis set augmented with 2 sets of polarization functions on all atoms was employed. The geometries of formamide and thioformamide used in these calculations were optimized using GAUSSIAN 92 (24) and a 6-311G** basis set. Experimental geometries were used for the remaining molecules (25). The carbonyl or thiocarbonyl carbon chemical shielding tensors of acetamide and thioacetamide have also been calculated using a Silicon Graphics Indigo^2 XL workstation employing the Localized Orbital/Local Origin (LORG) method (26, 27) and a 6-311 + G(3*d*, 2*p*) basis set. The prerequisite SCF wave functions for the LORG calculations were generated using GAUSSIAN 92 (24).

Calculations of ^{13}C NMR powder pattern line shapes were performed on a 486 personal computer with a FORTRAN-77 program that incorporates the POWDER routine (28). The approach employed here for analyzing the ^{13}C solid-state NMR spectra has been to first use the dipolar-splitting-ratio technique (14) to obtain initial guesses for the polar angles α and β. Consequently, this set of solutions was reduced by considering characteristic values for the carbonyl carbon–nitrogen dipolar coupling in amides (15, 19) and thioamides in conjunction with local symmetry considerations. The corresponding values for α, β, and R_{eff} were then optimized by maximizing the agreement between the experimental and calculated dipolar – chemical shift NMR spectra. To emphasize this agreement in the regions of the shoulders and discontinuities of the powder patterns, these comparisons were performed by examining both the first and second derivatives of the static powder pattern line shapes (29).

Results and discussion

(a) Characterization of the carbon CS tensors

(i) Results for 4′-methoxyacetanilide-^{13}C(CO) and 4′-methoxythioacetanilide-^{13}C(CS)

The experimental ^{13}C NMR spectra obtained for a static powder sample of 4′-methoxyacetanilide at external magnetic field strengths of 4.7 and 9.4 T are presented in Fig. 2. Also shown are the calculated spectra that have been found to best fit the experimental data. The calculated spectra were obtained using

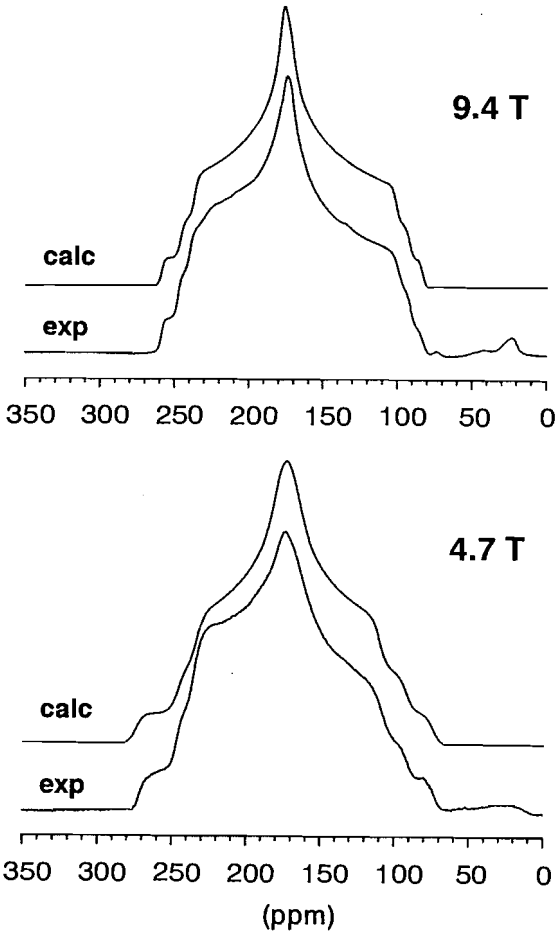
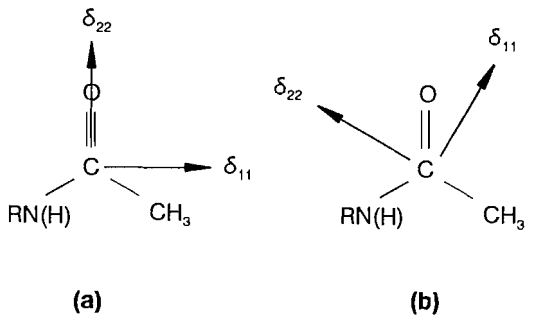
Fig. 2. Experimental and calculated ^{13}C NMR spectra for a static powder sample of 4′-methoxyacetanilide-^{13}C(CO) at external magnetic field strengths of 4.7 and 9.4 T, as indicated. The parameters used to calculate the powder patterns are summarized in Table 1.



the following parameters (see Table 1): $\delta_{11} = 246 \pm 2$ ppm, $\delta_{22} = 177 \pm 2$ ppm, $\delta_{33} = 92 \pm 2$ pm, $\alpha = 29 \pm 3°$, $\beta = 90 \pm 2°$, $R_{eff} = 895 \pm 40$ Hz. The spectral simulations are in very good agreement with the experimental spectra at both external magnetic field strengths employed in this study. It is worth noting that the spectra obtained at the two magnetic field strengths exhibit significant differences from one another. In particular, notice the large asymmetry observed in the dipolar splittings for the δ_{11} region of the spectrum at 4.7 T. At 9.4 T, this asymmetry is significantly attenuated and is qualitatively due to the increased magnitude of the carbon CS tensor with respect to the ^{13}C–^{14}N dipolar interaction at the larger external field strength (14, 15). Also, as expected, the carbonyl carbon CS tensor of 4′-methoxyacetanilide is the same, within experimental error, as that obtained earlier for acetanilide (cf. Table 1) (19). Finally, given the fact that the dipolar interaction is axially symmetric about the dipolar vector axis and considering the local mirror plane defined by the O=C—N fragment, values of $\alpha = 29°$ and $\beta = 90°$ are consistent with two possible orientations of the CS tensor PAS in the molecular reference frame (cf. Fig. 3). Assuming the molecular geometry within the amide plane of 4′-methoxyacetanilide to be the same as that in acetanilide (30), these correspond to orientations of the

Fig. 3. The two possible orientations of the carbonyl carbon CS tensor PAS for 4′-methoxyacetanilide consistent with the results of the analysis of the dipolar – chemical shift NMR spectra. For orientation (*b*), δ_{11} makes an angle of approximately 30° with respect to the C=O bond axis. The most shielded direction is perpendicular to the plane of the page for both orientations.



PAS such that (*a*) the two in-plane components, δ_{11} and δ_{22}, lie approximately perpendicular and parallel to the C=O bond axis, respectively, or (*b*) these components lie at angles of approximately 30° and 60°, respectively, with respect to this axis. As already mentioned, it is well established that the former of these two orientations is invariably observed for the carbonyl fragment (4, 5).

In Fig. 4, ^{13}C NMR spectra obtained at 9.4 T for static powder samples of 4′-methoxythioacetanilide (upper) and 4′-methoxyacetanilide (lower) are displayed on the same chemical shift scale for ease of comparison. Immediately apparent are the marked variations present in the magnitudes of each of the three CS tensor principal components; both the least shielded and intermediately shielded components are significantly more deshielded in the thioamide species while the most shielded component is notably more shielded. These variations lead to an overall increase of approximately 125 ppm in the span of the thioamide CS tensor. However, despite these significant differences, the magnitudes of the dipolar splittings, $\Delta\nu_{ii}$, exhibit striking similarities, which immediately suggests analogous orientations of the carbon CS tensor PAS in these two compounds. It should be emphasized that the possibility of an exchange in orientation of the two in-plane CS tensor components, as speculated for the benzophenone/thiobenzophenone system (2*b*), is readily rejected based on the relative magnitudes of the dipolar splittings, $\Delta\nu_{11}$ and $\Delta\nu_{22}$, extracted from the dipolar – chemical shift powder pattern observed for the thioamide. Such an exchange would result in larger dipolar splittings in the δ_{22} region of the powder pattern compared with the δ_{11} region, contrary to the experimentally observed result. The parameters used to calculate the ^{13}C NMR powder spectra of 4′-methoxythioacetanilide at both applied fields employed in this study are summarized in Table 1. The fact that $\beta = 90°$ indicates that the most shielded component, δ_{33}, lies normal to the S=C—N mirror plane. Although there exists a twofold ambiguity in defining the directions of the two in-plane tensor components, if one considers the symmetry of the electronic framework of the thiocarbonyl fragment as well as the results of ab initio MO carbon chemical shielding tensor calculations for several simple thioamides (vide infra), only the solution for which the intermediately shielded component is directed close to the C=S bond direction is reasonable.

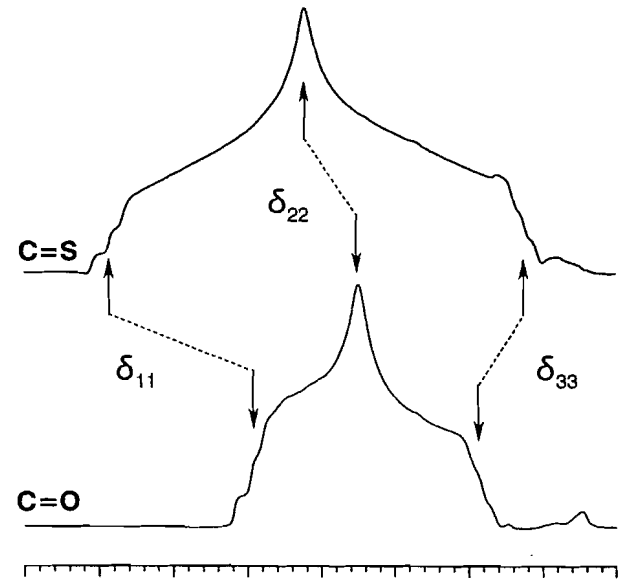
[a]The errors associated with the data obtained in the present investigation are as follows: δ_{ii} ±2 ppm, α ±3°, β ±2°, and R ±40 Hz unless otherwise indicated in the text.

[b]Obtained from CP/MAS solid-state NMR spectra.

[c]From ref. 19.

[d]From ref. 2. Note that the chemical shifts reported in this study were with respect to liquid CS_2. These chemical shifts have been converted to the TMS scale using an isotropic shift for CS_2 of 192.8 ppm with respect to TMS.

Fig. 4. Experimental ^{13}C NMR spectra obtained at 9.4 T for static powder samples of 4′-methoxyacetanilide-^{13}C(CO) (lower) and 4′-methoxythioacetanilide-^{13}C(CS) (upper). Features apparent in the experimental spectra in the region 10–80 ppm are due to carbon-13 nuclei present in natural abundance.



(ii) Results for thioacetanilide-^{15}N,^{13}C(CS)

Carbon-13 NMR spectra for static powder samples of thioacetanilide-^{15}N,^{13}C(CS) have been obtained and analyzed at external magnetic field strengths of 4.7 and 9.4 T, the results of which are summarized in Table 1. These findings can be compared with those of an earlier investigation involving acetanilide-^{15}N,^{13}C(CO) (cf. Table 1) (19). As anticipated, the three principal components of the carbon CS tensor show trends analogous to those observed for the methoxy-substituted species, with the least shielded component displaying the largest sensitivity to sulfur substitution. Analysis of the ^{15}N–^{13}C dipolar splittings observed for thioacetanilide-^{15}N,^{13}C(CS) indicates a similar orientation of the CS tensor PAS to that observed in acetanilide-^{15}N,^{13}C(CO) (19). Despite the aforementioned ambiguity inherent in assigning this orientation to the molecular reference frame, it is quite clear for reasons previously outlined that the CS tensor PAS is oriented such that the most shielded direction is normal to the S=C—N plane while δ_{22} lies within this plane near the thiocarbonyl bond axis. Unfortunately, the absence of structural data for this system precludes a more quantitative analysis of this tensor orientation in the molecular reference frame.

Upon examination of the isotropic region of the ^{13}C CP/MAS spectrum of thioacetanilide-^{15}N,^{13}C(CS) obtained at 4.7 T, a rather peculiar line shape was observed (cf. Fig. 5*a*). The spectrum suggests the presence of at least two crystallographically nonequivalent molecules in the unit cell of thioacetanilide. This conclusion has been verified by a preliminary X-ray structural analysis (T.S. Cameron, unpublished results); unfortunately, the exact number of distinct sites could not be defined due to the poor diffracting characteristics of the thioacetanilide crystals. Also apparent from the spectrum in Fig. 5*a* is the fact that the low-frequency peak has an integrated area approximately three times that of the high-frequency peak, suggesting the presence of unresolved peaks. A ^{13}C CP/MAS spectrum was also obtained at 9.4 T and is displayed in Fig. 5*b*. Clearly, the spectrum obtained at the higher field suggests that there actually exist four crystallographically nonequivalent molecules in the unit cell. We wish to emphasize, however, that given the small range of isotropic chemical shifts observed, 204.1–201.9 ppm, differences in the individual principal components of the carbon CS tensors for the unique sites are expected to be negligibly small and hence have not been considered in analyzing the NMR spectra obtained for a static powder sample of thioacetanilide-^{15}N,^{13}C(CS).

(iii) Results for acetamide and thioacetamide

The results of the analysis of the ^{13}C NMR spectra obtained

for static powder samples of 10% labelled acetamide-^{13}C(CO) and thioacetamide-^{13}C(CS) at 4.7 and 9.4 T are summarized in Table 1. As for the previous two amide/thioamide pairs investigated here, each of the three CS tensor components shows a significant sensitivity to sulfur substitution with both δ_{11} and δ_{22} more deshielded and δ_{33} more shielded in the thiocarbonyl fragment. As well, the least shielded component once again shows the greatest sensitivity, shifting some 87 ppm to higher frequency in the thioamide. The orientations of the carbon CS tensor PAS in these two compounds are qualitatively analogous in that the intermediately shielded component lies near the carbonyl or thiocarbonyl bond and the most shielded direction is normal to the amide/thioamide plane. Once again, a switch in orientation of the two in-plane components, δ_{11} and δ_{22}, would contradict the results of the present investigation. Based on an O=C—N bond angle of 122.3° in acetamide, obtained from an earlier low-temperature neutron diffraction study (31), δ_{22} is calculated to lie 6° off the carbonyl bond axis but on the opposite side compared with the other amides and thioamides considered here. A low-temperature neutron diffraction study has also been carried out for thioacetamide, indicating two crystallographically nonequivalent molecules in the unit cell (25*b*).[2] The two distinct molecules were found to possess slightly different geometries about the thiocarbonyl carbon atom, with one environment planar and the other slightly pyramidal (25*b*). CP/MAS carbon NMR spectra obtained for thioacetamide presumably reflect the presence of these distinct sites; instead of observing a simple asymmetric doublet (32) as for the majority of the amides investigated here, additional fine structure was evident. However, it should be noted that no evidence for these independent sites was apparent in the NMR spectra obtained for static powder samples of thioacetamide. Using the S=C—N bond angle observed for the planar site, 122.7°, yields the result that the intermediately shielded component lies 3° off the C=S bond axis but on the opposite side as in acetamide. The results for the orientations of the carbon CS tensor PAS in these two compounds are illustrated in Fig. 6. It should be mentioned that the errors in the orientation of the CS tensor PAS in thioacetamide are somewhat larger than in the remaining compounds investigated here due to an extensive overlap of the low-frequency end of the thiocarbonyl powder pattern with the methyl region of the spectrum arising from naturally abundant ^{13}C nuclei (1.1% natural abundance).

It is interesting to examine the changes observed in the three principal components of the CS tensors upon comparing the acetamides to the acetanilides. Although the spans of these CS tensors do not exhibit dramatic variations, significant increases are evident in the skew of the acetamide tensors; this is predominantly attributable to sizeable deshieldings of the intermediately shielded component in the acetamides relative to the corresponding acetanilides. Although the complex task of definitively tracing the origins of such deshieldings is not directly feasible, it is worth mentioning that intermolecular influences on the carbon CS tensors will undoubtedly show a

[2] Note that the unit cell of thioacetamide contains two crystallographically nonequivalent molecules in the unit cell. The geometry of the molecule possessing a S=C—N mirror plane was employed in the carbon chemical shielding calculation for thioacetamide.

Fig. 5. CP/MAS ^{13}C NMR spectra of thioacetanilide-^{15}N,^{13}C(CS) obtained at 50.3 MHz (*a*) and 100.6 MHz (*b*). The MAS frequencies employed were 2707 and 5500 Hz for (*a*) and (*b*), respectively.

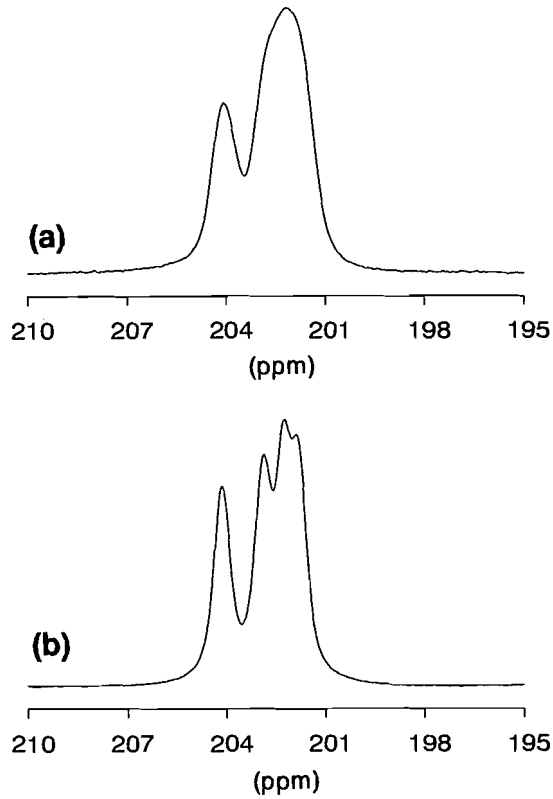

Fig. 6. Experimental results for the orientation of the carbon CS tensor PAS in acetamide (*a*) and thioacetamide (*b*). The angle between δ_{22} and the carbonyl/thiocarbonyl bond axis is 6° and 3° for acetamide and thioacetamide, respectively. The most shielded direction is perpendicular to the plane of the page for both compounds.

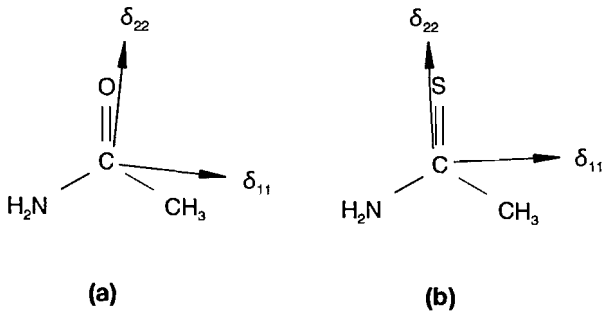

wide variation between the primary and secondary amides/thioamides. For example, in both acetamide and thioacetamide, the group 16 atom is involved in two asymmetric hydrogen bonds with neighbouring molecules (25*b*, 31), unlike the case for acetanilide where a single intermolecular hydrogen bond exists (30). Previous experimental and theoretical work has suggested the component of the carbonyl carbon CS tensor most sensitive to hydrogen bonding to be the component lying nearest the carbonyl bond axis, the intermediately shielded component, δ_{22} (19, 33). This component has been observed to become more deshielded with increasing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

hydrogen bond strength. Consequently, differences in the hydrogen bonding networks may partially account for the observed deshielding of δ_{22} in acetamide relative to the acetanilides. Despite the fact that N-H·····S=C hydrogen bonds are expected to be weaker than N-H·····O=C bonding, the fact that thioacetamide and the thioacetanilides also display this trend is consistent with this argument and provides further support for our conclusion that the intermediately shielded component lies nearest the thiocarbonyl bond axis.

(b) Carbon chemical shielding tensor calculations

The results of the ab initio MO carbon chemical shielding tensor calculations using the GIAO method for formaldehyde, thioformaldehyde, formamide, thioformamide, as well as acetamide and thioacetamide are presented in Table 2. Examination of the magnitudes of the carbon chemical shielding tensor components for each of the three pairs of molecules indicates analogous trends to those observed experimentally, although the calculated shielding differences are somewhat larger than observed. In each case both the least shielded and intermediately shielded components are calculated to be more deshielded in the thiocarbonyl compounds while the most shielded components are predicted to be more shielded in these species. The fact that σ_{11} displays the greatest sensitivity to sulfur substitution in each case is also in agreement with the experimental findings. More importantly for the purposes of the present investigation, for each of the six molecules theoretically examined, the orientation of the carbon chemical shielding tensor PAS is calculated such that σ_{33} is oriented normal to the O=C—N or S=C—N plane and σ_{22} lies within this plane parallel to or nearest the carbonyl/thiocarbonyl bond axis. These results provide further conclusive evidence that the orientations of the carbon CS tensor PAS within the carbonyl and thiocarbonyl fragments are qualitatively the same and that the two in-plane components, σ_{11} and σ_{22}, do not switch orientation within these groups.

In Table 3, the results of the carbon chemical shielding tensor calculations for acetamide and thioacetamide have been converted to chemical shift values in order to facilitate a direct comparison between the experimental and theoretical results. The calculations are reasonably successful in predicting the orientations of the tensors as well as in reproducing the magnitudes of the δ_{22} and δ_{33} components. However, the agreement in the least shielded components is much less satisfactory, particularly in thioacetamide. It is interesting that the calculated isotropic chemical shift in acetamide is the same as the experimental value despite the deviations in the tensor components. This result emphasizes the significance of including the tensor principal components and not just the isotropic value when reporting the results of shielding tensor computations. Finally, improving the agreement between the experimental and theoretical results could undoubtedly be achieved by incorporating the effects of intermolecular interactions into the calculations. Furthermore, electron correlation has previously been found to be significant for the carbon shielding within the carbonyl fragment (34). In light of the nature of the electronic structure of thiocarbonyls relative to carbonyls, this argument is anticipated to also hold true for the C=S group.

(c) Discussion

According to the theory of Ramsey (35), the small induced magnetic fields that are the basis of the chemical shielding interaction originate from two distinct modes of induced electronic motion in the presence of an external magnetic field. These motions give rise to the diamagnetic and paramagnetic contributions to the total chemical shielding experienced by a nucleus. The diamagnetic shielding contribution is positive and yields an increase in shielding. Qualitatively, diamagnetic shielding is dominated by the core electrons of an atom. Consequently, it shows little variation with the orientation of a molecule in an external magnetic field and, for a given nucleus, is relatively insensitive to the nature of the molecular system under investigation. On the other hand, the paramagnetic shielding interaction, which is generally negative and gives rise to decreased shieldings, is highly orientation dependent with the magnitude of paramagnetic shielding in a particular direction being sensitive to induced electronic currents in a plane perpendicular to this direction (36). Qualitatively, such

electronic motion can be envisioned as arising from perturbations to the ground-state electronic structure of a molecule due to the presence of an external magnetic field. More specifically, the external field induces a mixing of certain excited electronic states with the ground state of a molecule provided that the mixed states are related via a rotation of electronic charge (i.e., the mixing is driven by the orbital angular momentum of the relevant electronic states). For further information, the reader is referred to an early article by Jameson and Gutowsky, which provides a "multiplication table" showing the effects of the orbital angular momentum operators on the various *p* atomic orbitals (37). Consequently, the paramagnetic shielding contribution to the total chemical shielding tensor is intricately related to both the local symmetry and structure of the electronic framework of a molecule in the vicinity of the shielded nucleus. It is precisely the nature of these relationships that gives rise to the anisotropic behaviour of paramagnetic shielding as well as its dominance in dictating the range of chemical shifts observed within a particular molecular fragment. Therefore, to understand the orientation dependence of the carbon CS within the carbonyl and thiocarbonyl groups as well as the observed differences between these groups, it is most important to consider variations within the paramagnetic shielding term. Crucial to the following discussions is the fact that paramagnetic shielding is not only sensitive to the molecular wave functions for the relevant mixed electronic states but is also weighted by the inverse energy separation between these states and the ground state (i.e., $\sigma_p \propto 1/\Delta E$). As well, the contributions of the relevant electrons to the paramagnetic shielding term are further weighted according to the inverse cube of their separation from the shielded nucleus (35).

As indicated, the orientation of the carbon CS tensor PAS within the carbonyl fragment is well established (4, 5). In agreement with the experimental results obtained here, the most shielded direction is invariably found to lie normal to the plane comprising the carbonyl group. Therefore, symmetry dictates that the paramagnetic shielding in this direction must originate from high-energy $\sigma \leftrightarrow \sigma^*$ excitations. The least shielded component, δ_{11}, lies within the aforementioned plane and approximately perpendicular to the carbonyl bond axis and is thus influenced by $\sigma \leftrightarrow \pi^*$ as well as $\pi \leftrightarrow \sigma^*$ transitions. Finally, the intermediately shielded component, δ_{22}, also consistently lies within this plane but approximately collinear with the carbonyl bond axis. Based on symmetry considerations, $n \leftrightarrow \pi^*$ excitations contribute to the paramagnetic shielding in this direction. Furthermore, $\sigma \leftrightarrow \pi^*$ and $\pi \leftrightarrow \sigma^*$ transitions involving the C-C and C-N σ-bonds can also influence the paramagnetic shielding along the C=O bond axis. Before discussing the results obtained for the thioamides, it is important to mention that, in general, a rationalization of a tensor orientation based exclusively upon energy differences between the contributing excited states is not justifiable; the orientation of the carbonyl carbon CS tensor illustrates this point. Clearly, based solely on energy considerations, one would anticipate the least shielded direction (δ_{11}) to be along the CO bond as the $n \leftrightarrow \pi^*$ excitation is the HOMO–LUMO transition within the carbonyl fragment. The fact that the CO bond axis corresponds to the intermediately shielded direction must primarily be a manifestation of the distance dependence of the paramagnetic shielding term. More specifically, the lone pair MO involved in the $n \leftrightarrow \pi^*$ transition is essentially localized on the oxygen atom. Consequently, although favoured based on energy considerations, this influence is undoubtedly offset by an attenuation of the paramagnetic shielding along the carbonyl bond axis due to the r^{-3} dependence, resulting in this axis being the intermediately shielded direction.

The fact that both the experimental and theoretical results indicate analogous orientations of the carbon CS tensor PAS within the carbonyl and thiocarbonyl groups immediately indicates that the thiocarbonyl tensor orientation can be understood using electronic transition symmetry arguments as for the carbonyl fragment. An interesting finding of the present investigation is that both of the in-plane CS tensor components, δ_{11} and δ_{22}, are more deshielded in the thioamides than in the amides. Although the origin(s) of this deshielding cannot be traced with certainty from these results, it is worth emphasizing that both δ_{11} and δ_{22} are sensitive to the relative accessibility of the π^* MO given that the in-plane paramagnetic shielding is controlled by out-of-plane excitations. Consequently, the anticipated stabilization of the π-antibonding MO within the thioamides relative to the amides (2*e*) must contribute, at least in part, to the observed in-plane deshielding. The result that the in-plane CS tensor component sensitive to the HOMO–LUMO $n \leftrightarrow \pi^*$ transition, δ_{22}, exhibits an apparent smaller sensitivity to sulfur substitution than that of the in-plane perpendicular component, δ_{11}, is not readily rationalized based exclusively on energy considerations. Once again, the distance dependence of the paramagnetic shielding term must, at least in part, be responsible for this result. Clearly, the fact that the in-plane perpendicular component is influenced by transitions involving MOs that possess a relatively large amount of carbon-2*p* AO character must also contribute to the relative sensitivities of the two in-plane CS tensor components. Finally, it is interesting that the component perpendicular to the amide/thioamide plane is more shielded in the thioamides than in the amides. However, given the multitude of plausible factors that could be influencing this trend, a definitive explanation unfortunately remains elusive.

In an effort to gain further information concerning the origins of the observed CS within the amides and thioamides, ab initio LORG carbon chemical shielding tensor calculations have been performed for acetamide and thioacetamide. Although both the GIAO and LORG approaches employ distributed gauge origins in order to attenuate the well-known gauge dependence of chemical shielding calculations, the latter method has the advantage that these origins are incorporated within localized MOs of the molecule under investigation. Consequently, the chemical shielding tensor within this formalism is constructed as a series of localized bond contributions, which facilitates a physical understanding of the computed tensors. The calculated LORG tensor components of acetamide and thioacetamide are provided in Table 4 and are found to be very similar to the results of the GIAO calculations (cf. Table 2). The calculated σ_{ii} have also been decomposed in Table 4 according to the contributions of the relevant valence MOs. The results predict that the least shielded components in these species are indeed dominated by the carbonyl/thiocarbonyl σ and π MOs (i.e., $\sigma \leftrightarrow \pi^*$ and $\pi \leftrightarrow \sigma^*$) and that the major contributor to the deshielding of δ_{11} in the thioamides relative to the amides involves the C-S σ-bond. As well, the major contributions to the paramagnetic

[b]The results for the orientation of the chemical shielding tensor PAS in acetamide are analogous to the GIAO results (cf. Table 2). The angle ϕ is calculated to be +4°.

[c]The results for the orientation of the chemical shielding tensor PAS in thioacetamide are analogous to the GIAO results (cf. Table 2). The angle ϕ is calculated to be +8°.

shielding along the carbonyl/thiocarbonyl bond axis are associated with the C-C and C-N σ-bonds whereas the lone pair (l.p.) MOs of oxygen and sulfur make a shielding contribution in this direction. It should be mentioned that similar findings were previously reported by Schindler and Kutzelnigg from an IGLO calculation on formaldehyde (38). However, it is interesting that the lone pair MOs are predicted to make the largest contribution to the decreased shielding observed for δ_{22} in thioacetamide relative to acetamide. Finally, the calculations indicate that both the C-S and C-C σ-bonds are the primary sources of the shielding observed normal to the thioamide plane in thioacetamide relative to acetamide.

In light of the experimental findings for the thioamide CS tensors obtained here, the common interpretation of the decreased isotropic chemical shielding in the thiocarbonyl group relative to the carbonyl group in terms of decreased $n \rightarrow \pi^*$ energies (see, for example, ref. 39) must be revoked; it appears a decrease in energy of $\sigma \rightarrow \pi^*$ transitions is the predominant cause of this deshielding. This result is illustrative of the dangers inherent in the familiar practice of deriving relationships between HOMO–LUMO excitation energies and *isotropic* chemical shifts and emphasizes the sensitivity of paramagnetic shielding to factors other than energy differences. Clearly, regardless of the strength of HOMO–LUMO excitation energy and isotropic CS correlations, projecting such findings to rationalize isotropic chemical shift differences is completely unsubstantiated in the absence of information concerning trends in the individual CS tensor components as well as the orientation of these components in the molecular frame.

In closing, some comments concerning the results of the benzophenone/thiobenzophenone investigation (2*b*) are in order. The three principal components of the carbonyl/thiocarbonyl carbon CS tensors measured for these compounds are provided in Table 1. The tensor components show analogous trends to those observed within the amides and thioamides investigated here. It appears that the conclusion of this paper that the two in-plane tensor components exchange orientation was based on the assumption that the CS tensor components lying along the C=O and C=S bonds should be inversely proportional to the $n \rightarrow \pi^*$ excitation energies within these compounds (26 800 cm^{-1} in benzophenone and 16 400 cm^{-1} for thiobenzophenone) (2*b*). Since δ_{22} was known to lie along the C=O bond in benzophenone (3), such a correlation is most closely observed with δ_{11} oriented along the C=S bond in thiobenzophenone. However, based on the results of the present investigation and the discussion in the preceding paragraph, such an assumption is clearly not valid.

Conclusions

The orientations of the carbonyl/thiocarbonyl carbon CS tensors within a series of amides and thioamides have been experimentally characterized using ^{13}C dipolar – chemical shift NMR and are found to be analogous. These findings are supported by the results of ab initio GIAO and LORG carbon chemical shielding tensor calculations. The results of this investigation identify the least shielded component, δ_{11}, to be primarily responsible for the deshielding of the isotropic chemical shift observed within the thiocarbonyl group relative to the carbonyl group. The fact that this component lies approximately perpendicular to the C=S bond and is governed by $\sigma \leftrightarrow \pi^*$ as well as $\pi \leftrightarrow \sigma^*$ excitations dispels the popular belief that this deshielding originates from energy shifts associated with the HOMO–LUMO $n \leftrightarrow \pi^*$ transition. Finally, the present study provides some insight into the complexity of the paramagnetic shielding term and its sensitivity to a multitude of structural factors and, furthermore, exemplifies the need to exercise extreme caution in correlating trends in chemical shifts with any one of these parameters.

Reaction of methylphthalimidoketene with benzylidene- and cinnamylidene-anilines: structure and configuration of the products

Arya K. Mukerjee, Gangadhar J. Sanjayan, and Krishnan Ravikumar

Abstract: Methylphthalimidoketene reacts with cinnamylideneanilines to give tetrahydrooxazin-6-ones exclusively, whereas with benzylideneaniline it also forms β-lactam. Configurations are based on X-ray studies.

Key words: β-lactam, tetrahydro-1,3-oxazin-5-ones, ketene–imine reactions, cycloaddition of methylphthalimidoketene, 3-phthaloylamino-3-methylazetidin-2-one.

Résumé : Le méthylphtalimidocétène réagit avec les cinnamylidèneanilines pour conduire exclusivement aux tétrahydrooxazin-6-ones alors que, avec la benzylidène aniline, il forme aussi une β-lactone. Les configurations sont basées sur des études par diffraction des rayons X.

Mots clés : β-lactames, tétrahydro-1,3-oxazin-5-ones, réactions cétène–imine, cycloaddition du méthylphtalimidocétène, 3-phtaloylamino-3-méthylazétidin-2-one.

[Traduit par la rédaction]

β-Lactams **3**, generally known as azetidin-2-ones, have emerged as important synthons (1, 2), and interest in 3-aminoazetidin-2-ones (3) continues unabated. The first useful synthesis of **3** ($Ar^1 = Ar^2 = Ph$; $R^1 = H_2N$; $R^2 = H$) was achieved by the triethylamine-mediated reaction of phthaloylglycyl chloride (**1***a*) with benzylideneaniline (**2***a*) followed by hydrazinolysis of the resultant 3-phthaloylamino compound **3***a* (4). The similar annulation of **1***a* with cinnamylidene-4-anisidine (**2***b*) afforded (*Z*)-azetidin-2-one **3***b* (5). In continuation of our studies (6) on dehydropeptides carrying a 3-aminoazetidin-2-one ring, we investigated the reaction of phthaloylalaninyl chloride (**1***b*) (for a preliminary report see ref. 7) with imines **2***a, b, c*, with a view to incorporating an alaninyl moiety in the target azetidin-2-ones; the outcome of this attempt is presented in this article.

Results were found to be dependent on the type of reactants and on the reaction conditions. For instance, addition of **1***b* to a solution of benzylideneaniline (**2***a*) containing triethylamine led to the formation of (±)(*E*)-1,4-diphenyl-3-methyl-3-phthaloylaminoazetidin-2-one (**3***c*) and (±)-3,4-diphenyl-5-methyl-5-phthaloylamino-2-(1-phthaloylaminoethylidene)tetrahydro-1,3-oxazin-6-one (**4***a*). Yields of **4***a* improved considerably on increasing the amounts of **1***b* and triethylamine. On the other hand, addition of triethylamine to an equimolar mixture of **1***b* and **2***a* in methylene chloride furnished only azetidin-2-one **3***c*. The triethylamine-mediated reaction of **1***b*, unlike that of **1***a*, with cinnamylideneanilines **2***b, c* gave the corresponding 4-styryl-tetrahydro-1,3-oxazin-6-ones **4***b*, **4***c* exclusively, the formation of **3***d* not being discernible.

The reaction affording oxazinones **4***a, b, c* could be best explained by the intermediacy of ketene **5**. On the other hand, azetidin-2-ones **3***a–c* could be obtained by the cyclodehydrohalogenation of the iminium salt **8**, besides following the ketene route (Scheme 1). It should be mentioned that 2:1 addition in the ketene–imine reaction was reported only in a limited number of cases (8–10), but the precise structural requirements for the reactants have not been established.

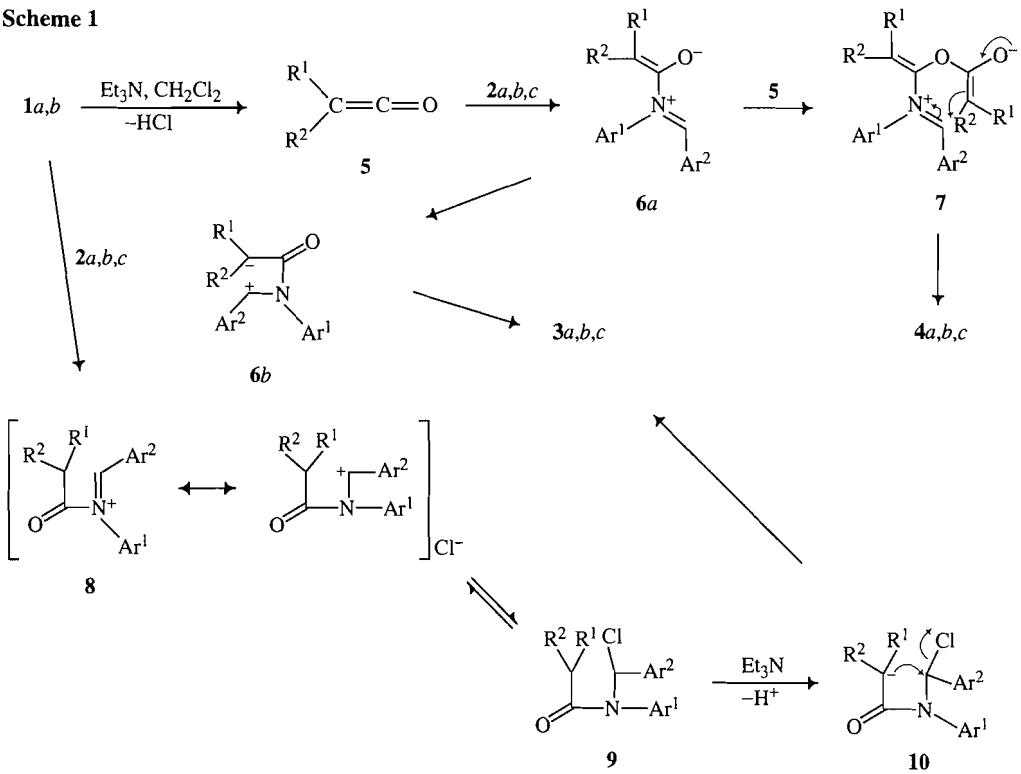
Scheme 1



Products were characterized by spectral data and elemental analyses, and their stereochemistry was based on ^{1}H NMR spectra. Also, the configurations of **3***c* and **4***a* were confirmed by X-ray studies. Oxazinones **4***a, b, c* afforded (±)-3-(*N*-aryl, *N*-phthaloylalaninyl)amino-3-aryl-2-methyl-2-phthaloylaminopropionic acids **11***a, b, c* on saponification (Scheme 2). The acid derivative **11***a* underwent cyclization to **4***a* when treated with tosyl chloride in the presence of triethylamine.

The present finding indicates the possibility of synthesizing tetrahydrooxazinones and (or) azetidin-2-ones starting from *N,N*-diprotected alanine. The compounds reported herein are potentially important as intermediates in the synthesis of peptides and other amino acid related products.

Experimental

Melting points were determined by a Toshniwal melting point apparatus. IR spectra were recorded on a Perkin–Elmer 783 spectrophotometer and ^{1}H NMR spectra, using TMS as an internal reference, were recorded on a JEOL FX 90Q instrument. Mass spectra were recorded on a VG Micromass

Reaction of (±)phthaloylalaninyl chloride (1*b*) with benzylideneaniline (2*a*): formation of 3*c* and 4*a* (7)

Method A

To a cold solution of **2***a* (1.81 g, 0.01 mol) and triethylamine (1.31 g; 1.8 mL; 0.013 mol) in dry methylene chloride (20 mL) was slowly added a solution of **1***b* (2.37 g; 0.01 mol) in dry methylene chloride (20 mL). The reaction mixture was stored overnight at room temperature, concentrated to dryness under vacuum, and the pasty residue obtained was repeatedly washed with cold ethanol, filtered, and recrystallized from ethyl acetate – chloroform (1:1) to give pure **3***c*; yield, 1.72 g (45%); mp 263°C; ν_{max} (Nujol): 1780 (CO, phthalimide), 1750 (CO, β-lactam), 1710 (CO, phthalimide) cm^{-1}; δ ($CDCl_3$): 1.60 (s, 3H, CH_3), 5.45 (s, 1H, C4-H), 7.10–7.90 (m, 14H, ArH) ppm. Anal. calcd. for $C_{24}H_{18}N_2O_3$: C 75.39, H 4.71, N 7.32%; found: C 75.25, H 4.58, N 7.44%.

The ethanolic filtrate and washings were combined and concentrated to dryness under reduced pressure and the residue was triturated with cold ethanol to give yellow crystals of **4***a*. The crude product was recrystallized from chloroform–benzene (1:1); yield, 0.8 g (14%); mp 164°C; ν_{max} (Nujol): 1780 (CO, phthalimide), 1730 (CO, oxazinone), 1680 (C=C) cm^{-1}; δ ($CDCl_3$): 1.52 (s, 3H, C5-CH_3), 2.1 (s, 3H, $CH_3C{=}C$), 6.90–7.90 (m, 19H, C4-H and ArH) ppm. Anal. calcd. for $C_{35}H_{25}N_3O_6$: C 72.04, H 4.28, N 7.20%; found: C 72.02, H 4.36, N 7.46%.

The X-ray data for compounds **3***c* and **4***a* have been deposited as supplementary data.[2]

Method B

This method was similar to Method A with the difference that **1***b*, **2***a*, and triethylamine were taken in the mole ratio 2:1:2.6. Yields of **3***c* and **4***a* were 20 and 46%, respectively.

Method C

To an equimolar mixture of **1**b and **2**a in methylene chloride (30 mL/g of **1**b), cooled in an ice-bath, a solution of triethylamine (1.3 mol/mol of **1**b) in methylene chloride (10 mL/mol of the base) was slowly added. On completion of the reaction, it was worked up as before. In this method azetidin-2-one **3**c was the only product; yield, 62%.

Reaction of (±)phthaloylalaninyl chloride (1*b*) with cinnamylideneanilines 2*b*, *c*. Formation of tetrahydrooxazinones 4*b*, *c*

General procedure

This was the same as outlined in Method B. The crude products were recrystallized from chloroform–ethanol (1:1) to give yellow crystals.

Compound **4**b: Yield, 86%, mp 257°C; ν_{max} (KBr): 1793 (CO, phthalimide), 1716 (CO, oxazinone), 1678 (C=C) cm^{-1}; δ ($CDCl_3$): 1.70 (s, 3H, C5-CH_3), 1.95 (s, 3H, $CH_3C{=}C$), 3.25 (s, 3H, OCH_3), 5.75 (d, 1H, J = 6.50 Hz, C4-H), 6.10–7.70 (m,

19H, C*H*=C*H*Ph and ArH) ppm. M^+ = 639; Anal. calcd. for $C_{38}H_{29}N_3O_7 \cdot 1.5\ H_2O$: C 68.46, H 4.80, N 6.30%; found: C 68.54, H 4.52, N 6.26%.

Compound **4**c: Yield, 90%; mp 268°C; ν_{max} (KBr): 1795 (CO, phthalimide), 1718 (CO, oxazinone), 1674 (C=C) cm^{-1}; δ ($CDCl_3$): 1.76 (s, 3H, C5-CH_3), 2.08 (s, 3H, CH_3C=C), 6.04 (d, 1H, J = 7.5 Hz, C4-H), 6.36–7.80 (m, 20H, C*H*=C*H*Ph and ArH) ppm. M^+ = 609; Anal. calcd. for $C_{35}H_{25}N_3O_3 \cdot H_2O$: 70.81, H 4.62, N 6.69%; found: C 70.70, H 4.99, N 6.39%.

Hydrolysis of tetrahydrooxazinones 4*a*, *b*, *c*. Formation of acids 11*a*, *b*, *c*

General procedure

To a solution of potassium hydroxide (1.2 mol) in 95% ethanol (20 mL/g of **4**) was added **4** (1.0 mol); a brown colour developed that soon disappeared. The reaction mixture was stirred for 10 min in an ice bath. The solvent was removed under reduced pressure, and the pasty substance obtained was dissolved in the minimum amount of water and filtered. The filtrate was acidified with concentrated HCl with cooling, to give a solid that was collected, washed with water, and recrystallized from aqueous ethanol.

Compound **11**a: Yield, 85%; mp 135–137°C; ν_{max} (KBr): 3420, 3200 (OH), 1714 (CO, acid) cm^{-1}; δ ($CDCl_3$): 1.10 (d, 3H, J = 8.0 Hz, C*H*$_3$-CH), 1.70 (s, 3H, CH_3CCOOH), 6.30–7.90 (m, 21H, one exchangeable with D_2O, CH_3CH, Ar^1CH, OH, and ArH) ppm. Anal. calcd. for $C_{35}H_{27}N_3O_7 \cdot 0.5\ H_2O$: C 68.85, H 4.59, N 6.88%; found: C 68.49, H 4.86, N 6.72%.

Compound **11**b: Yield, 84%; mp 150–151°C; ν_{max} (KBr): 3414, 3227 (OH), 1722 (CO, acid), 1639 (CO, amide), 1618 (C=C) cm^{-1}; δ ($CDCl_3$): 1.15 (d, 3H, J = 9.0 Hz, C*H*$_3$CH), 1.75 (s, 3H, CH_3CCOOH), 3.75 (s, 3H, OCH_3), 6.35–8.20 (m, 22H, CH_3CH, C*H*=C*H*, OH, and ArH) ppm. Due to precipitation, the D_2O exchange could not be recorded. Anal. calcd. for $C_{38}H_{31}N_3O_8 \cdot 2\ H_2O$: C 65.80, H 5.05, N 6.06%; found: C 65.42, H 5.0, N 5.66%.

Compound **11**c: Yield, 80%; mp 140–142°C; ν_{max} (KBr): 3481, 3220 (OH), 1722 (CO, acid), 1649 (CO, amide), 1639 (C=C) cm^{-1}; δ ($CDCl_3$): 1.15 (br, d, 3H, C*H*$_3$CH), 1.73 (s, CH_3CCOOH), 6.40–7.70 (m, 23H, CH_3CH, C*H*=C*H*, OH, and ArH) ppm. Due to precipitation, the D_2O exchange could not be recorded. Anal. calcd. for $C_{37}H_{29}N_3O_7$: C 70.81, H 4.62, N 6.69%; found: C 70.55, H 4.75, N 6.59%.

Cyclocondensation of 11*a*. Formation of 4*a*

To a stirred solution of the carboxylic acid (**11***a*, 0.2 g; 0.00033 mol) and triethylamine (0.073 g; 0.1 mL; 0.0072 mol) in dry methylene chloride (10 mL) was added tosyl chloride (0.06 g; 0.00033 mol) at 5–10°C; stirring was continued for 10 min, when an intense colour developed. The reaction mixture was concentrated to dryness and treated with benzene (10 mL); the precipitated triethylamine hydrochloride was filtered and washed with benzene (10 mL). The filtrate and washings were combined and heated under reflux for 30 min. The solvent was removed under reduced pressure and compound **4***a* was separated by preparative TLC (silica gel/ethyl acetate). It was recrystallized from chloroform–benzene (1:1); yield, 0.05 g (26%); mp 264°C. It was identical with the product described above.

1994 Polanyi Award Lecture Concept of active electrons in chemistry[1]

Sigeru Huzinaga

Abstract: The notion of division between active and dormant electrons has been well received and widely used in the chemists' way of thinking. The core–valence separation in atoms is the best-known example. This paper describes a theoretical and computational method called the model potential method, which deals only with active electrons in molecular and solid state calculations. The method is capable of reaching computational accuracy of testing the validity of the separation of active and dormant electrons in individual cases.

Key words: separability of electrons, model potential method, valence orbitals, relativistic effects.

Résumé : La notion de division entre les électrons actifs et dormants est bien accueillie et largement utilisée dans la façon de penser des chimistes. L'exemple le plus connu est la séparation de la valence centrale des atomes. Ce travail décrit une méthode de calculs théoriques, appelée méthode du potentiel modèle, qui ne traite que des électrons actifs dans les calculs moléculaires et de l'état solide. La méthode peut atteindre une précision permettant, dans des cas individuels, de vérifier la validité de la séparation des électrons actifs et dormants.

Mots clés : séparabilité des électrons, méthode du potentiel modèle, orbitales de valence, effets relativistiques.

[Traduit par la rédaction]

1. Introduction

The idea of dividing electrons in atoms into valence electrons and core electrons has been popular among chemists and physicists. The very existence of the periodic table attests to the validity of the notion that the valence electrons determine most of the chemical properties of atoms and molecules and the core electrons are inactive and dormant, just shielding the nuclei and providing an effective potential for the valence electrons.

At the same time, however, we are also intrigued and fascinated by remarkable differences in the chemistry and the physics among atoms with the same number of valence electrons, for instance, among C, Si, and Ge. Is this simply because the effective potentials are different for the valence electrons of the individual atoms? Or, something else is involved?

It would certainly be a worthwhile enterprise to mold the idea of the valence–core separation into a computational scheme in such a way that the validity and the limitations of valence–core language could be tested in precise numerical fashion. Then our interpretative power would be solidified and enhanced in organizing and categorizing a wide variety of chemical and physical observations. At the same time, of course, we expect to be able to economize the computational cost by reducing the number of electrons to be treated explicitly, if so justified.

Since the early days of quantum mechanics, many theoretical formulations have been advanced in which only valence electrons are treated explicitly. "This is not an easy task, although formally one may write the essential equations rather trivially," as Krauss and Stevens (1) stated in their comprehensive review article on the subject. Once Van Vleck and Sherman (2) called the difficulty "the nightmare of the inner core." One of the purposes of the present paper is to address the question: why has this been no easy task?

My own effort to develop a sound theoretical framework for the valence–core separation was first reported in 1971 (3). On the basis of the theoretical framework, the first paper of our model potential method was presented in 1974 (4). Since then, various extensions and improvements have been made. A formal description of the mathematical structure of the method, including some new developments, was published in 1991 (5). In the present paper some cardinal points of what we call the model potential method are explained in a less formal way so that the method may have some appeal to a wider readership than just to specialists in the field.

First of all, we must remind ourselves that electrons are *not* distinguishable: we can not put a tag on an individual electron. All we can do is to rely on the concept of the electron

orbital to divide electrons into a certain set of groups. Secondly, we should be aware of the fact that the core–valence separation is an approximate concept. It follows then that the wavefunction we are dealing with will be an approximate one.

The total wavefunction including both the core and the valence electrons may be written as

$$\Phi = A_{SL}(\Phi_{core}\Phi_{valence})$$

[1] $$\Phi_{core} \equiv \Phi_{core}(1, 2, \ldots, n_c)$$

$$\Phi_{valence} \equiv \Phi_{valence}(n_c + 1, \ldots, n_c + n_v)$$

Φ_{core} and $\Phi_{valence}$ are assumed to be already antisymmetrized according to the Pauli principle. The Slater-type antisymmetrizer A_{SL} takes care of permutations between the core electrons and the valence electrons.

Our mandate is to build a theoretical method to obtain $\Phi_{valence}$ in eq. [1] without explicitly including Φ_{core} in the wavefunction. It means that the antisymmetrizer A_{SL} that ensures the Pauli exclusion between the core and the valence electrons is no longer available. Therefore, we have somehow to incorporate the effect of the Pauli principle into the theory without treating the core electrons explicitly. This is the gist of the matter and the source of Van Vleck's nightmare. The effect may be incorporated into either (*a*) the valence wavefunction $\Phi_{valence}$ in the form of orthogonality constraints, or (*b*) a modified form of the Hamiltonian for the valence electrons.

In general, the exact wavefunction cannot be factored in the form of eq. [1] but a class of approximate wavefunctions may be, as discussed by McWeeny (6). The simplest and most useful example is the Hartree–Fock (HF) wavefunction. At this level, Höjer and Chung (7) laid a firm theoretical foundation for our model potential method.[3] Applying their discussion to a simple example of a closed-shell atom, Be, we shall describe the essential features of the method.

The concept of core and valence electrons is but an example of the general idea of separating physically and (or) chemically active electrons from those inactive and dormant in molecular systems. Lone-pair electrons, π and σ electrons of conjugated hydrocarbons, frontier electrons, and functional groups in organic compounds are other examples. The solid state also presents a variety of phenomena that are supposed to be understood in terms of localized active electrons.

The separation of active and dormant electrons in chemical and physical systems is a wide subject and has been studied by many authors in recent years. This review article is far from comprehensive. Even within our model potential method, there have been numerous contributions from many friends and colleagues. I shall acknowledge them at the end of the paper.

2. Hartree–Fock method for valence electrons in the frozen core approximation

The all-electron HF wavefunction for Be $[1s^2 2s^2, {}^1S]$ is

[2] $$\Phi(1, 2, 3, 4) = A_{SL}[\varphi_{1s}(1)\alpha(1)\varphi_{1s}(2)\beta(2)\varphi_{2s} \times (3)\alpha(3)\varphi_{2s}(4)\beta(4)]$$

[3] The term "model potential" may not have been a good choice. See ref. 8.

The total Hamiltonian in atomic units is

[3] $$\hat{H} = \sum_{i=1}^{4} \hat{h}(i) + \sum_{i>j} \frac{1}{r_{ij}}, \qquad \hat{h}(i) = -\frac{1}{2}\Delta_i - \frac{Z}{r_i}$$

The total energy

$$E = \langle\Phi|\hat{H}|\Phi\rangle \equiv E[\varphi_{1s}, \varphi_{2s}]$$

may be regarded as a functional of φ_{1s} and φ_{2s}. Applying the variational principle to E under the orthonormal constraints for φ_{1s} and φ_{2s},

[4] $$\langle\varphi_{1s}|\varphi_{1s}\rangle = \langle\varphi_{2s}|\varphi_{2s}\rangle = 1, \ \langle\varphi_{1s}|\varphi_{2s}\rangle = \langle\varphi_{2s}|\varphi_{1s}\rangle = 0$$

we obtain the HF equations for the determination of φ_{1s} and φ_{2s},

$$\hat{F}|\varphi_{ns}\rangle = \varepsilon_{ns}|\varphi_{ns}\rangle, \qquad n = 1, 2$$

[5] $$\hat{F} = -\frac{1}{2}\Delta - \frac{Z}{r} + (2\hat{J}_{1s} - \hat{K}_{1s}) + (2\hat{J}_{2s} - \hat{K}_{2s})$$

where

[6] $$\hat{J}_{ns}f(r) = \int \frac{\varphi_{ns}(r')\varphi_{ns}(r')}{|r - r'|}\,dr' \cdot f(r)$$

[7] $$\hat{K}_{ns}f(r) = \int \frac{\varphi_{ns}(r')f(r')}{|r - r'|}\,dr' \cdot \varphi_{ns}(r)$$

$f(r)$ being an arbitrary spatial function. Because the core orbital φ_{1s} and the valence orbital φ_{2s} are eigenfunctions of the same Fock operator $\hat{F}$, they are mutually orthogonal.

Suppose we have solved the HF equations for Be and have obtained the solutions φ_{1s}, ε_{1s}, and φ_{2s}, ε_{2s}. Now, we start all over again with eqs. [2] and [3], but this time φ_{1s} is given and fixed (frozen) and only φ_{2s} is subjected to variation under the constraints,

[8] $$\langle\varphi_{1s}|\varphi_{2s}\rangle = \langle\varphi_{2s}|\varphi_{1s}\rangle = 0, \qquad \langle\varphi_{2s}|\varphi_{2s}\rangle = 1$$

The HF equation for φ_{2s} will be found to be

[9] $$\hat{F}'|\varphi_{2s}\rangle = \varepsilon_{2s}|\varphi_{2s}\rangle$$

[10] $$\hat{F}' = -\frac{1}{2}\Delta - \frac{Z}{r} + (2\hat{J}_{1s} - \hat{K}_{1s}) + (2\hat{J}_{2s} - \hat{K}_{2s}) - 2\varepsilon_{1s}|\varphi_{1s}\rangle\langle\varphi_{1s}|$$

Now, we deal with only the two valence electrons in Be. The wavefunction is

[11] $$\Phi(1,2) = A_{SL}[\varphi_{2s}(1)\alpha(1)\varphi_{2s}(2)\beta(2)]$$

We introduce a modified Hamiltonian (compare with eq. [3]),

[12] $$\hat{H}' = \hat{h}'_1 + \hat{h}'_2 + \frac{1}{r_{12}}$$

[13] $$\hat{h}'_i = -\frac{1}{2}\Delta_i - \frac{Z}{r_i} + (2\hat{J}_{1s} - \hat{K}_{1s}) - 2\varepsilon_{1s}|\varphi_{1s}\rangle\langle\varphi_{1s}|$$

The operators $(2\hat{J}_{1s} - \hat{K}_{1s})$ and $-2\varepsilon_{1s}|\varphi_{1s}\rangle\langle\varphi_{1s}|$ are to be

constructed with the frozen core orbital φ_{1s} and the orbital energy ε_{1s}.

If we derive a new HF equation from $\Phi(1,2)$ and $\hat{H}'$ with the normalization constraint $\langle\varphi_{2s}|\varphi_{2s}\rangle = 1$ but *without* the orthogonality constraint $\langle\varphi_{1s}|\varphi_{2s}\rangle = \langle\varphi_{2s}|\varphi_{1s}\rangle = 0$, we arrive at the same Fock operator in eqs. [9] and [10].

Let us recapitulate what we have achieved so far. We introduce a modified total Hamiltonian [12] for the two valence electrons in Be using the knowledge of $\{\varphi_{1s}, \varepsilon_{1s}\}$. We write the wavefunction as

$$\Phi(1,2) = A_{SL}[\varphi_v(1)\alpha(1)\varphi_v(2)\beta(2)]$$

and work out the HF equation for φ_v *without* paying any attention to the orthogonality of φ_v to the frozen core orbital φ_{1s}. Then we obtain the HF equation for φ_v as

$$[14] \qquad \hat{F}'|\varphi_v\rangle = \varepsilon_v|\varphi_v\rangle$$

where $\hat{F}'$ is identical with $\hat{F}'$ in eq. [10].

To go on toward our model potential method, let us examine the modified one-electron Hamiltonian [13] more carefully. The term $2\hat{J}_{1s}$ represents a Coulombic potential due to the charge cloud $|\varphi_{1s}|^2$ as seen in eq. [6]. Once φ_{1s} is given, $2\hat{J}_{1s}$ can be integrated to be a spherically symmetric local potential function,

$$[15] \qquad 2\hat{J}_{1s} = 2\int \frac{|\varphi_{1s}(r')|^2}{|r-r'|}\,dr' \equiv V_{Coul}(r)$$

The term $\hat{K}_{1s}$ is a quantum mechanical exchange operator and, being a genuine integral operator, it may be replaced *only approximately* by a local function of r. This is one of the pivotal points around which our model potential method have evolved. The last term in eq. [13],

$$[16] \qquad -2\varepsilon_{1s}|\varphi_{1s}\rangle\langle\varphi_{1s}|$$

is to prevent the valence orbital φ_v from collapsing onto the $1s$ core region. It may also be regarded as an energy shift operator in the HF equation [9]. From eqs. [5] and [10],

$$[17] \qquad \hat{F}' = \hat{F} - 2\varepsilon_{1s}|\varphi_{1s}\rangle\langle\varphi_{1s}|$$

Therefore,

$$[18] \qquad \hat{F}'|\varphi_{1s}\rangle = (\varepsilon_{1s} - 2\varepsilon_{1s})|\varphi_{1s}\rangle = -\varepsilon_{1s}|\varphi_{1s}\rangle$$

$$[19] \qquad \hat{F}'|\varphi_{2s}\rangle = \varepsilon_{2s}|\varphi_{2s}\rangle$$

Hence the energy level of the lowest eigenfunction φ_{1s} of the original HF equation [5] is shifted upward by the amount $2|\varepsilon_{1s}|$ by the operator [16], and $\{\varphi_{2s}, \varepsilon_{2s}\}$ becomes the lowest eigensolution of the modified HF equation [14].

The only difference between the energy level spectrum of eq. [14] and that of eq. [5] is the position of the energy level of the eigenfunction φ_{1s}. All other eigensolutions are unchanged in the transition from eq. [5] to eq. [14]. It is also to be noted that all the nodal structures of eigenfunctions of eq. [5] are perfectly preserved in eq. [14].

3. Hartree–Fock method for valence electrons in the model potential approximation

First let us generalize the one-electron Hamiltonian [13] to the case of Z_c core electrons:

$$[20] \qquad \begin{aligned}\hat{h}' &= -\frac{1}{2}\Delta - \frac{Z}{r} + \sum_c (2\hat{J}_c - \hat{K}_c) - \sum_c 2\varepsilon_c|\varphi_c\rangle\langle\varphi_c| \\ &= -\frac{1}{2}\Delta - \frac{(Z-Z_c)}{r} + \hat{V}_{core} + \hat{\sigma}\end{aligned}$$

where

$$[21] \qquad \hat{V}_{core} = \hat{V}_{Coul} + \hat{V}_{exch}$$

$$[22] \qquad \hat{V}_{Coul} = -\frac{Z_c}{r} + 2\sum_c \hat{J}_c$$

$$[23] \qquad \hat{V}_{exch} = -\sum_c \hat{K}_c$$

$$[24] \qquad \hat{\sigma} = -\sum_c 2\varepsilon_c|\varphi_c\rangle\langle\varphi_c|$$

It is assumed that the core orbitals and the orbital energies $\{\varphi_c, \varepsilon_c\}$ have been obtained from the all-electron HF calculation, which has also produced the valence orbitals and the orbital energies $\{\varphi_v, \varepsilon_v\}$.

The Hamiltonian $\hat{h}'$ in eq. [20] is certainly a one-electron operator but the evaluation of the expectation values involves computation of so-called two-electron energy integrals because of $\hat{J}_c$ and $\hat{K}_c$ in $\hat{V}_{core}$, This is *not* a welcome feature because we are actually interested in economizing the molecular calculation by dealing only with valence electrons from the constituent atoms. It is desirable to replace $\hat{V}_{core}$ with something more economical computationally. How to approximate and replace $\hat{V}_{core}$ is the central issue of the model potential method. A challenge here is the non-local character of the exchange operators $\{\hat{K}_c\}$.

Another important point in the development of the model potential method is the inclusion of relativistic effects. We have been motivated to develop the valence-electron-only method because the all-electron molecular calculation of systems that contain heavy atoms is often very expensive. Relativistic effects are significant in the core region of heavy atoms and they often influence the chemistry and phsics of the valence electrons. We should also notice that there is a distinct advantage in dealing with the relativistic effect at the level of the valence electron approximation. It is because valence electrons are still essentially non-relativistic even under the spilled-out influence of relativistic core electrons.

There are several types that have been developed within our model potential method. Before proceeding to describe them, however, we would like to equip ourselves with the rudimental knowledge of the relativistic treatment of electrons in the Cowan–Griffin–Wood–Boring theory and also with a mathematical tool that has turned out to be convenient for handling both exchange operators and relativistic operators.

3.1 Spectral representation of operators

Suppose that $\hat{\Omega}$ is an operator in quantum mechanics and Φ and Ψ are two wavefunctions. We shall consider the following integral,

$$[25] \qquad I = \langle \Phi | \hat{\Omega} | \Psi \rangle$$

If we expand Φ and Ψ by a complete orthonormal basis function set $\{\psi_i\}$,

$$[26] \qquad \langle \Phi | = \sum_i \langle \Phi | \psi_i \rangle \langle \psi_i |$$

$$[27] \qquad | \Psi \rangle = \sum_i | \psi_j \rangle \langle \psi_j | \Psi \rangle$$

then

$$[28] \qquad I = \sum_i \sum_j \langle \Phi | \psi_i \rangle \langle \psi_i | \hat{\Omega} | \psi_j \rangle \langle \psi_j | \Psi \rangle = \langle \Phi | \hat{P} \hat{\Omega} \hat{P} | \Psi \rangle$$

where

$$[29] \qquad \hat{P} = \sum_i | \psi_i \rangle \langle \psi_i |$$

is a projection operator: $\hat{P}^2 = \hat{P}$. Comparing eqs. [25] and [28], we call

$$[30] \qquad \hat{P} \hat{\Omega} \hat{P} = \sum_i \sum_j | \psi_i \rangle \langle \psi_i | \hat{\Omega} | \psi_j \rangle \langle \psi_j |$$

a spectral representation of an operator $\hat{\Omega}$. If $\hat{P}\hat{\Omega}\hat{P}$ has some computational advantage over the original operator $\hat{\Omega}$, the representation becomes a useful mathematical tool. This is the case in the model potential approach to handle $\hat{V}_{\text{core}}$ in eq. [21].

If the integrals $\{\langle \psi_i | \hat{\Omega} | \psi_j \rangle\}$ happen to be negligibly small outside a certain finite range of $\{i\}$, a finite expansion approximation becomes acceptable. Expecting such situations, we shall use a finite basis function set $\{\chi_p\}$ to represent a certain class of operators. In the Roothaan–Hartree–Fock equations such finite *non-orthogonal* basis function sets are used to represent the Hartree–Fock integro-differential equations.

For the present purpose, we limit ourselves to the case where $\hat{\Omega}$ is the one-electron operator and Φ, Ψ, $\{\psi_i\}$, and $\{\chi_p\}$ are all one-electron functions. We also assume that $\{\chi_p\}$ is an n-membered finite non-orthogonal basis function set with a real symmetric overlap matrix,

$$[31] \qquad S_{pq} = \langle \chi_p | \chi_q \rangle = S_{qp}, \qquad p, q = 1, 2, \ldots, n$$

Then, from $\{\chi_p\}$ we can construct a finite orthonormal basis function set $\{\psi_i\}$,

$$[32] \qquad \psi_i = \sum_p \chi_p (S^{-1/2})_{pi}, \qquad i = 1, 2, \ldots, n$$

Let us assume that the integral I in eq. [28] may be computed quite accurately by the finite set $\{\psi_i\}$. Then, in terms of $\{\chi_p\}$,

$$[33] \qquad \hat{P} = \sum_{pq} | \chi_p \rangle (S^{-1})_{pq} \langle \chi_q |$$

and

$$[34] \qquad \begin{aligned} \hat{P} \hat{\Omega} \hat{P} &= \sum_{pq} \sum_{rs} | \chi_p \rangle (S^{-1})_{pq} \langle \chi_q | \hat{\Omega} | \chi_r \rangle (S^{-1})_{rs} \langle \chi_s | \\ &= \sum_{pq} | \chi_p \rangle (S^{-1} \hat{\Omega} S^{-1})_{pq} \langle \chi_q | \end{aligned}$$

Here, it is to be noted that the representation is approximate,

$$\hat{\Omega} \sim \hat{P} \hat{\Omega} \hat{P}$$

3.2 Cowan–Griffin and Wood–Boring formalisms for atoms

There is no counterpart in relativistic quantum mechanics for the many-electron system corresponding to the non-relativistic many-electron Schrödinger equation. We start with the Dirac equations (9) for one electron in a central potential field $V(r)$,

$$[35] \qquad F_k = \left(\frac{\alpha}{2}\right) \frac{1}{1 + (\alpha^2/4)(\varepsilon_k - V)} \left(\frac{\mathrm{d}}{\mathrm{d}r} + \frac{k}{r}\right) G_k$$

$$[36] \qquad G_k = \frac{-2}{\alpha(\varepsilon_k - V)} \left(\frac{\mathrm{d}}{\mathrm{d}r} - \frac{k}{r}\right) F_k$$

where ε_k is the eigenvalue (less the rest energy of the electron) and the quantum number k is related to l and j according to

$$[37] \qquad \begin{aligned} k &= 1 && \text{for } j = l - \tfrac{1}{2} \\ k &= -(l+1) && \text{for } j = l - \tfrac{1}{2} \end{aligned}$$

The Rydberg atomic units are used. $G_k(r)$ is called the large-component and $F_k(r)$ the small-component radial function. Substituting F_k from eq. [35] into eq. [36], we have

$$[38] \qquad \left[-\frac{\mathrm{d}^2}{\mathrm{d}r^2} + \frac{k(k+1)}{r^2} + V(r) + H_{\text{MV}} + H_{\text{D}} + H_{\text{SO}}\right] G_k = \varepsilon_k G_k$$

where

$$[39] \qquad H_{\text{MV}} = -\frac{\alpha^2}{4}(\varepsilon_k - V)^2$$

$$[40] \qquad H_{\text{D}} = -\frac{\alpha^2}{4} B_k \frac{\mathrm{d}V}{\mathrm{d}r} \left(\frac{\mathrm{d}}{\mathrm{d}r} - \frac{1}{r}\right)$$

$$[41] \qquad H_{\text{SO}} = -\frac{\alpha^2}{4} B_k \left(\frac{k+1}{r}\right) \frac{\mathrm{d}V}{\mathrm{d}r}$$

$$[42] \qquad B_k = \left[1 + \frac{\alpha^2}{4}(\varepsilon_k - V)\right]^{-1}$$

H_{MV} is called the mass-velocity term, H_{D} the Darwin term, H_{SO} the spin-orbit interaction term. α is the fine-structure constant. This is essentially the Wood–Boring equation (10).

For a single electron in a central potential field $V(r)$, eq. [38] is still exact. If we solve eq. [38] accurately for G_k, then F_k can be obtained from eq. [40], and they constitute the accurate solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Now we take several steps to transform eq. [38] to a modified form of the Hartree–Fock equations for a many-electron atom. First, we disregard the small component F_k. Second, the spin-orbit term H_{SO} is dropped. Consequently, l can be used instead of k in the equation, because $k(k+1) = l(l+1)$ for both $k = l$ and $k = -(l+1)$. Third, we replace $V(r)$ with the standard potential energy operator in the Fock operator,

$$[43] \qquad V(r) \rightarrow \hat{V} = -\frac{2Z}{r} + \sum_i (a_i \hat{J}_i - b_i \hat{K}_i)$$

The first term is the nuclear attraction (in Rydberg units) and $\hat{J}_i$ and $\hat{K}_i$ are defined with the occupied orbitals $\{G_{nl}\}$. Note that the principal quantum number n is supplied. The constants $\{a_i, b_i\}$ specify the electronic state of the atoms. $\hat{V}$ in eq. [43] is a non-local operator because of the exchange operators $\{\hat{K}_i\}$, and it is not convenient to use in H_{MV} and H_D. Therefore we introduce a local potential approximation of $\hat{V}$,

$$\hat{V} \rightarrow V_{nl}(r)$$

The local potential depends on the quantum numbers of the operand orbital G_{nl}. The resulting equations are

$$[44] \qquad \left[-\frac{d^2}{dr^2} + \frac{l(l+1)}{r^2} + \hat{V} + H_{MV} + H_D \right] G_{nl} = \varepsilon_{nl} G_{nl}$$

where

$$[45] \qquad H_{MV} = -\frac{\alpha^2}{4} (\varepsilon_{nl} - V_{nl}(r))^2$$

$$[46] \qquad H_D = -\frac{\alpha^2}{4} B_{nl} \frac{dV_{nl}(r)}{dr} \left(\frac{d}{dr} - \frac{1}{r} \right)$$

$$[47] \qquad B_{nl} = \left[1 + \frac{\alpha^2}{4} (\varepsilon_{nl} - V_{nl}(r)) \right]^{-1}$$

If we also replace $\hat{V}$ in eq. [44] with the local potential approximation $V_{nl}(r)$, and further replace the differential operator H_D with the local potential

$$[48] \qquad V_{D,nl}(r) = -\frac{\alpha^2}{4} B_{nl} \frac{dV_{nl}}{dr} \left(\frac{1}{G_{nl}} \frac{dG_{nl}}{dr} - \frac{1}{r} \right)$$

we have the Cowan–Griffin equation. The equation is discussed in detal by Cowan and Griffin (11) and by Wood and Boring (10). The solutions $\{G_{nl}\}$ are numerically given at mesh points of the numerical integration of the equation and so are $\{V_{nl}(r)\}$.

We shall now describe four versions of our model potential method. The classification is just for the clarity of describing various developments that have happened over the past 20 years within the method, and as such there is no hierarchic implication.

3.2.1 Version 0

This is little more than a historical record. In the originally proposed form of the method (4), the whole $\hat{V}_{core}$ in eq. [21] is expressed as a local spherical function of r in the form,

$$[49] \qquad \hat{V}_{core} \approx V_{mp}(r) = \frac{1}{r} \left[\sum_I A_I \exp(-\alpha_I r^2) \right]$$

This is the origin of the term "model potential," which probably has survived too long in view of many later developments in the method. The model potential (mp) parameters $\{A_I, \alpha_I\}$ were optimized through a series of atomic HF calculations for the valence electrons using the one-electron Hamiltonian [20] in such a way that the orbital energies and the radial orbital functions $\{\varepsilon_v^{mp}, R_v^{mp}\}$ will be as close as possible to those of the reference all-electron calculation, $\{\varepsilon_v^{ref}, R_v^{ref}\}$. At this stage, the process of optimization was not automated. The model potentials determined in this way were used in several molecular calculations with moderate success. The implementation of the model potential method into a molecular program was originally made by Gropen and we have profited immensely from the work since then.

3.2.2 Version 1

This is a result of the joint work of many people. In this version $\hat{V}_{core}$ is given the form,

$$[50] \qquad \hat{V}_{core} \approx V_{mp}(r) = \frac{1}{r} \left[\sum_I A_I \exp(-\alpha_I r^2) + \sum_J B_J r \exp(-\beta_J r^2) \right]$$

The parameters $\{A_I, \alpha_I; B_J, \beta_J\}$ are optimized through a series of atomic HF calculations by minimizing the following quantity,

$$[51] \qquad \Delta = \sum_v \omega_v |\varepsilon_v^{ref} - \varepsilon_v^{mp}| + \sum_v \sum_k W_v \times [r_k R_v^{ref}(r_k) - r_k R_v^{mp}(r_k)]^2$$

where ε_v and $R_v(r)$ are the orbital energy and the radial function of the v-th valence orbital, and ω_v and W_v are appropriately chosen weight factors. Values of $rR(r)$ are computed at properly chosen discrete points $\{r_k\}$. Minimization of Δ as the function of $\{A_I, \alpha_I; B_J, \beta_J\}$ is computationally automated. This improvement was made by Sakai (12) and proved to be a substantial step toward the extensive preparation of the parameters in the method.

This fitting procedure between $\{\varepsilon_v^{ref}, R_v^{ref}\}$ and $\{\varepsilon_v^{mp}, R_v^{mp}\}$ may be used conveniently to incorporate the relativistic effects at the level of Cowan–Griffin approximation into the model potential method, which was implemented by Klobukowski. As explained in eqs. [44] through [48], we may solve the Cowan–Griffin equations as the reference. $(G_{nl}(r) \rightarrow R_{nl}(r))$. Then we obtain $\{\varepsilon_v^{ref}, \varphi_v^{ref}\}$ as well as $\{\varepsilon_c, \varphi_c\}$, and they then are used in Δ of eq. [51] for the determination of $\{A_I, \alpha_I; B_J, \beta_J\}$, and also for the shift operator $\hat{\sigma}$ in eq. [24].

Actually, the shift operator $\hat{\sigma}$ is also parametrized as

$$[52] \qquad \hat{\sigma}' = -\sum f_c \varepsilon_c |\varphi_c\rangle\langle\varphi_c|$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

In this version, $f_c = 2$ is the chosen value for the majority of atoms, which is referred to as the hard-core value. For some heavy atoms, the soft-core value of $f_c \cong 1.0$ is chosen for better agreement between results of the model potential calculation and those of the reference all-electron calculation for molecules. The reduction of the value of f_c from the theoretical (hard-core) value ($f_c = 2$) is to compensate for the inadequacy of small basis sets adopted in molecular calculations for economic reasons. There are two types of Version 1. One is the non-relativistic (NR) version and another is the quasi-relativistic (QR) version based on the Cowan–Griffin approximation. This version of the model potential method has been extensively developed by Sakai, Klobukowski, Miyoshi, and others (12), and implemented in a couple of major molecular programs. In principle, the implementation of the model potential method is not difficult because changes are required only in the form of the one-electron Hamiltonian.

3.2.3 Version 2

Andzelm et al. (13) initiated the use of the technique of spectral representation of operators in our model potential method. First, the technique was applied only to the tail part of the exchange operator $\hat{V}_{\text{exch}}$ in eq. [23] but now is applied to the whole $\hat{V}_{\text{exch}}$. The present version has been extensively developed, mainly by Seijo and Barandiarán et al. (14), and called the ab initio model potential (AIMP) method.

In the AIMP method, $\hat{V}_{\text{Coul}}$ in eq. [22] is expressed as

$$[53] \qquad \hat{V}_{\text{Coul}} \cong V_{\text{Coul,mp}}(r) = \frac{1}{r}\sum_k A_k \exp(-\alpha_k r^2)$$

where the parameters $\{A_k, \alpha_k\}$ are determined through least-squares fitting to the $\hat{V}_{\text{Coul}}$ calculated with eq. [22] using the frozen core orbitals $\{\varphi_c\}$ and tabulated numerically. Choice of the number of terms in the expansion [53] is a matter of computational convenience. Otherwise $\{A_k, \alpha_k\}$ are completely determined, once $\{\varphi_c\}$ are given. They are *not* adjustable parameters of the method.

The exchange operator $\hat{V}_{\text{exch}}$ is now expressed in the spectral representation by using an appropriate projection operator $\hat{P}$ as given in eq. [33],

$$[54] \qquad \hat{V}_{\text{exch}} \rightarrow \hat{P}\hat{V}_{\text{exch}}\hat{P}$$

To include the quasi-relativistic (QR) effects at the level of the Cowan–Griffin approximation, we use the following one-electron Hamiltonian in place of $\hat{h}'$ in eq. [20],

$$[55] \qquad \hat{h}'_{\text{qr}} = -\frac{1}{2}\Delta - \frac{(Z - Z_c)}{r} + \hat{V}_{\text{core,qr}} + \hat{\sigma}$$

where

$$[56] \qquad \hat{V}_{\text{core,qr}} = \hat{V}_{\text{Coul}} + \hat{V}_{\text{exch}} + \hat{V}_{\text{MV}} + \hat{V}_{\text{D}}$$

At this point, we need to be more explicit about the quantum number specification of the expansion basis functions in eq. [33],

$$\{|\chi_p\rangle\} \rightarrow \{|alm\rangle\}$$

And now,

$$[57] \qquad \hat{P} = \sum_{a,b}\sum_{l}\sum_{m=-l}^{+l} |alm\rangle (S^{-1})_{l,ab} \langle blm|$$

$$(S)_{l,ab} = \langle alm|blm\rangle$$

The operators, $H_{\text{MV}} + H_{\text{D}}$, in eq. [44] depend on nl. Assuming that the valence shell contains only one valence orbital for each symmetry l ($l = s, p, d, \ldots$), we use the following form for $\hat{V}_{\text{MV}} + \hat{V}_{\text{D}}$ in eq. [56],

$$[58] \qquad \hat{V}_{\text{MV}} + \hat{V}_{\text{D}} = \hat{P}\left[\sum_{l\in v} \hat{O}_l (H_{\text{MV},l} + H_{\text{D},l})\hat{O}_l\right]\hat{P}$$

where

$$[59] \qquad \hat{O}_l = \sum_{m=-l}^{+l} |lm\rangle\langle lm|$$

Seijo and Barandiarán call the above formalism the CG-AIMP approximation. They also discuss the approximation based on the Wood–Boring equation [38], including the effect of the spin-orbit interaction.[4] This is called the WB-AIMP approximation.

3.2.4 Version 3

This version has been developed mainly by Katsuki (15). Here the Coulomb potential $\hat{V}_{\text{Coul}}$ is also expressed in the spectral representation,

$$[60] \qquad \hat{V}_{\text{Coul}} \rightarrow \hat{P}\hat{V}_{\text{Coul}}\hat{P}$$

Thus the least-squares fitting in eq. [53] is eliminated. In this method, therefore, once the judicious choice of the expansion basis function set is made, there will be no other parameters in the method.

For atoms where the frozen core electron charge distribution is spherically symmetric, the analytic expression [53] for $\hat{V}_{\text{Coul}}$ would probably be more convenient and accurate than the spectral representation. There are, however, cases where the dormant frozen core may be nonspherical. Often the chemical properties of a functional group are supposed to be governed by a few electrons. For example, the donor characteristics of ammonia may be understood in terms of its lone pair electrons and the rest of the molecule may be regarded as a nonspherical frozen core region. Another example is the planer ethylene as a system of two active electrons (π electrons) and the dormant σ-skeleton core. In such cases it is cumbersome to generalize the analytical expansion [53] to a nonspherical spatial function and it seems more expedient to use the spectral representation technique (15). This strategy has been adopted in Version 3, and applied to a couple of cases. The results of the preliminary applications are encouraging.

The handling of the relativistic effects is very similar to that of the CG-AIMP method, differing only in the technical detail.

4. The nodal structure of valence orbitals

There are various approximate methods in which only the valence electrons are treated explicitly. There is one distinct feature in our model potential method that separates the method from the rest of valence-electron-only methods.

In our method, the nodal structure of valence orbitals in atoms is preserved. The degree of the preservation depends on the flexibility of the basis set to expand the valence orbitals in the Roothaan–Hartree–Fock approximation. If the set is flexible enough, the nodal structure will be reproduced perfectly. This should be obvious from the discussion of the energy shift operator in Sect. 2.

It has been often debated whether or not the valence orbitals in the valence-electron-only method should keep the inner nodal structure existing in the corresponding all-electron method. It is known that reduction of the size of basis set is far more effective in reducing the cost of computation than reduction of the number of electrons to be treated explicitly. Therefore, it is argued that only by smoothing out the inner nodes of the valence orbitals will a substantial saving of the computational cost be achieved. On the other hand, our method enjoys a theoretical transparency that the use of the same basis set employed in the all-electron calculation will reproduce exactly the same valence orbitals and the same orbital energies, granted, at the expense of economy.

We shall discuss some other aspects of the issue by using the hydrogen atom as a simple example. The Schrödinger equation (in atomic units) is

$$[62]\qquad \hat{H}|\varphi_n\rangle = E_n|\varphi_n\rangle, \qquad n = 1, 2, \ldots$$

$$\hat{H} = -\frac{1}{2}\Delta - \frac{1}{r}$$

$$\varphi_1 \equiv \varphi_{1s} = (4\pi)^{-1/2}R_{1s}(r), \qquad E = -1/2$$

$$[63]\qquad \varphi_2 \equiv \varphi_{2s} = (4\pi)^{-1/2}R_{2s}(r), \qquad E_2 = -1/8$$

$$R_{1s}(r) = 2\exp(-r)$$

$$R_{2s}(r) = 2^{-1/2}\left(1 - \frac{r}{2}\right)\exp\left(-\frac{r}{2}\right)$$

We define an energy shift operator to shift the position of the $1s$ energy level,

$$[64]\qquad \hat{\sigma} = \Delta E|\varphi_1\rangle\langle\varphi_1|$$

and add it to the original Hamiltonian [63],

$$[65]\qquad \hat{H} \rightarrow \hat{H}' = \hat{H} + \hat{\sigma} = \hat{H} + \Delta E|\varphi_1\rangle\langle\varphi_1|$$

Then we have

$$\hat{H}'|\varphi_1\rangle = (E_1 + \Delta E)|\varphi_1\rangle$$

$$\hat{H}'|\varphi_2\rangle = E_2|\varphi_2\rangle$$

Note here that $\langle\varphi_1|\varphi_2\rangle = 0$. If we choose $\Delta E = -2E_1 = 1.0$, as in eq. [16],

$$\hat{H}'|\varphi_1\rangle = (+1/2)|\varphi_1\rangle$$

$$\hat{H}'|\varphi_2\rangle = (-1/8)|\varphi_2\rangle$$

Thus, with $\hat{H}'$, the *exact* $2s$ orbital φ_2 is obtained as the *lowest* s eigensolution of the equation,

$$[66]\qquad \hat{H}'|\varphi\rangle = E|\varphi\rangle$$

because the originally lowest energy level of φ_1 is shifted to the position far above the E_2 level, as a matter of fact, in the positive energy continuum. This is an example of unwelcome intruder eigensolutions in the higher region of the energy spectrum of a modified one-electron equation such as eq. [66]. A very similar situation is expected to rise in our modified HF equation [14] or in its generalization. In the Roothaan–Hartree–Fock approximation, these intruder orbitals will be embedded in the so-called virtual orbital space and they should never accommodate electrons in them in the configuration calculation or in the perturbation calculation.

To return to the problem of the nodal structure of valence orbitals, we shall further use the case of the hydrogen atom. This time we choose the amount of the energy shift ΔE as $\Delta E = (E_2 - E_1)$,

$$[67]\qquad \hat{H}' = -\frac{1}{2}\Delta - \frac{1}{r} + (E_2 - E_1)|\varphi_1\rangle\langle\varphi_1|$$

In the eigenvalue spectrum of the above Hamiltonian, the $1s$ level is brought up to the position of the $2s$ level and now they are degenerate. Therefore, any linear combination of φ_1 and φ_2,

$$[68]\qquad \psi = c_1\varphi_1 + c_2\varphi_2$$

also belongs to the eigenvalue E_2:

$$[69]\qquad \left[-\frac{1}{2}\Delta - \frac{1}{r} + (E_2 - E_1)|\varphi_1\rangle\langle\varphi_1|\right]|\psi\rangle = E_2|\psi\rangle$$

From the explicit forms of φ_1 and φ_2 given before, it is seen that we can make the function ψ *nodeless* by choosing c_1 and c_2 properly. The effect of the shift operator on ψ may be formally expressed in the form of a local potential $U(r)$,

$$(E_2 - E_1)|\varphi_1\rangle\langle\varphi_1|\psi\rangle = U(r)|\psi\rangle$$

or

$$[70]\qquad U(r) = \frac{c_1(E_2 - E_1)\varphi_1}{\psi} = \frac{c_1(E_2 - E_1)\varphi_1}{c_1\varphi_1 + c_2\varphi_2}$$

As long as ψ has no zeros except at $r = \infty$ and 0, $U(r)$ can be obtained from eq. [70] for arbitrary values of c_1 and c_2. It is important to note, however, that the energy eigenvalues and eigenfunctions other than E_2 and ψ will be arbitrarily disturbed. A more general approach to obtain $U(r)$ would be to solve the following equation in terms of $U(r)$ with the appropriately chosen nodeless function ψ,

$$[71]\qquad \left[-\frac{1}{2}\Delta - \frac{1}{r} + U(r)\right]|\psi\rangle = E_2|\psi\rangle$$

$$[72]\qquad U(r) = E_2\frac{\left(-\frac{1}{2}\Delta - \frac{1}{r}\right)\psi}{\psi}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

This is the essence of the method used by Kahn et al. (16). With the special choice of the form of ψ as a linear combination of φ_1 and φ_2, eq. [72] takes the same form as eq. [70]. However, the choice is not limited to this form and can be made such that the outer portion of ψ resembles as closely as possible that of the original φ_2. Here again, however, other eigensolutions will be disturbed, because the influence of $U(r)$ is not selective as that of the shift operator.

5. The molecular Hamiltonian

The basic idea is that the active electrons in a molecule consist of valence electrons of the constituent atoms and the molecular core is the sum of the spherical atomic cores. As indicated in the Introduction and especially in the discussion of Version 3, the definition of the active and dormant electrons can be much wider. The following form of the molecular Hamiltonian is general enough to accommodate wider definitions of the active and dormant electrons in molecular and solid state systems.

All the Hamiltonian in the present chapter are the Schrödinger Hamiltonian (in atomic units). Quasi-relativistic effects are included in the form of the effective operators at this level.

The total Hamiltonian for the atom is

$$[73] \quad \hat{H}_{\mathrm{mp}} = \sum_{i=1}^{n} \hat{h}_{\mathrm{mp}}(i) + \sum_{i>j} \frac{1}{r_{ij}}$$

$$[74] \quad \hat{h}_{\mathrm{mp}}(i) = -\frac{1}{2}\Delta_i - \frac{(Z - Z_c)}{r_i} + \hat{V}_{\mathrm{mp}}(i) + \hat{\sigma}(i)$$

The total Hamiltonian for the molecule is

$$[75] \quad \hat{H}_{\mathrm{mp}} = \sum_{i=1}^{n} \hat{h}_{\mathrm{mp}}(i) + \sum_{i>j} \frac{1}{r_{ij}} + \sum_{I>J} \frac{(Z_I - Z_{I,c})(Z_J - Z_{J,c})}{R_{IJ}}$$

$$[76] \quad \hat{h}_{\mathrm{mp}}(i) = -\frac{1}{2}\Delta_i + \sum_{I=1}^{N} \left[-\frac{(Z_I - Z_{I,c})}{r_{Ii}} + \hat{V}_{I,\mathrm{mp}}(i) + \hat{\sigma}(i) \right]$$

In the above molecular total Hamiltonian, it is assumed that the nuclear charge Z_I of the I-th atom is perfectly shielded by the $Z_{I,c}$ core electrons. If the molecular core is not defined as the sum of the spherical atomic cores, it is necessary to use some other appropriate formulas (5).

The operator $\hat{V}_{\mathrm{mp}}$ is the model potential approximation of the core operator $\hat{V}_{\mathrm{core}}$ in eq. [21] in the non-relativistic approximation or $\hat{V}_{\mathrm{core,qr}}$ in eq. [56] in the quasi-relativistic approximation:

$$[77] \quad (\mathrm{NR}): \quad \hat{V}_{\mathrm{core}} = \hat{V}_{\mathrm{Coul}} + \hat{V}_{\mathrm{exch}}$$

$$[78] \quad (\mathrm{QR}): \quad \hat{V}_{\mathrm{core,qr}} = \hat{V}_{\mathrm{Coul}} + \hat{V}_{\mathrm{exch}} + \hat{V}_{\mathrm{MV}} + \hat{V}_{\mathrm{D}}$$

The following is a summary of the explicit expressions for $\hat{V}_{\mathrm{mp}}$ in the three versions.

5.1 Version 1

$$[79] \quad (\mathrm{NR}): \quad \hat{V}_{\mathrm{mp}} = \frac{1}{r}\left[\sum_I A_I \exp(-\alpha_I r^2) + \sum_J B_J r \exp(-\beta_J r^2) \right]$$

(QR): same as above

$$[80] \quad \hat{\sigma} = -\sum f_c \varepsilon_c |\varphi_c\rangle\langle\varphi_c|$$

5.2 Version 2

$$[81] \quad (\mathrm{NR}): \quad \hat{V}_{\mathrm{mp}} = \sum_k A_k \frac{\exp(-\alpha_k r^2)}{r} + \hat{P}\hat{V}_{\mathrm{exch}}\hat{P}$$

$$[82] \quad (\mathrm{QR}): \quad \hat{V}_{\mathrm{mp}} = \sum_k A_k \frac{\exp(-\alpha_k r^2)}{r} + \hat{P}\hat{V}_{\mathrm{exch}}\hat{P} + \hat{V}_{\mathrm{MV}} + \hat{V}_{\mathrm{D}}$$

Note here that the relativistic operators $\hat{V}_{\mathrm{MV}}$ and $\hat{V}_{\mathrm{D}}$ are already processed by the projection operators as shown in eq. [58].

$$[83] \quad \hat{\sigma} = -\sum 2\varepsilon_c |\varphi_c\rangle\langle\varphi_c|$$

5.3 Version 3

$$[84] \quad (\mathrm{NR}): \quad \hat{V}_{\mathrm{mp}} = \hat{P}(\hat{V}_{\mathrm{Coul}} + \hat{V}_{\mathrm{exch}})\hat{P}$$

$$[85] \quad (\mathrm{QR}): \quad \hat{V}_{\mathrm{mp}} = \hat{P}(\hat{V}_{\mathrm{Coul}} + \hat{V}_{\mathrm{exch}})\hat{P} + \hat{V}_{\mathrm{MV}} + \hat{V}_{\mathrm{D}}$$
$$\hat{\sigma} = -\sum 2\varepsilon_c |\varphi_c\rangle\langle\varphi_c|$$

Note that this version may conveniently be applied to the case where the core region is nonspherical (15).

6. Applications

Various versions of the model potential method have been applied to many molecular systems. Through these applications, the atomic parameters $\{A_I, \alpha_I; B_J, \beta_J\}$ and f_c in Version 1 have been determined for a majority of atoms in the periodic table, and along with them adequate Gaussian basis sets for the Roothaan expansion of the valence orbitals have been established. A very gratifying feature of Version 1 is that the quasi-relativistic effects are incorporated into $\{A_I, \alpha_I; B_J, \beta_J\}$ and hence the QR calculation is no more expensive than the corresponding NR calculation. To choose the basis set, a near-Hartree–Fock all-electron calculation is used as the reference. We believe that a good valence-electron-only calculation with a fairly large basis set is better than an all-electron calculation with a small basis set.

In Version 2, the AIMP method of Seijo and Barandiarán, the non-relativistic Hamiltonian is completely specified by the knowledge of the frozen core orbitals and the orbital energies. If the basis set for $\hat{P}$ is judiciously chosen and the expansion basis set for the valence orbitals is the same as that of the reference all-electron Hartree–Fock calculation, the result of the calculation should be the same as that of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

the all-electron Hartree–Fock calculation in the frozen core approximation with the assumption that the core electrons completely shield the nuclear charges. This is true also with Version 3. This is a unique feature not found in any other available effective core methods with nodeless valence orbitals.

It is known that reduction of the size of basis set is much more effective than reduction of the number of electrons explicitly treated when it comes to economizing the computational cost. Our model potential method requires expansion basis sets flexible enough to produce proper inner nodes of the valence orbitals. Therefore one may not expect a very drastic cut in the computational cost. The saving seems to be in the range from 90 to 40% of the cost of the all-electron calculation. However, there are cases where the all-electron calculation is next to impossible. For example, the quasi-relativistic all-electron molecular calculation would be extremely difficult, if not impossible, but our model potential method can be used with confidence and at a reasonable cost. Other such examples may be found in the solid state and in surface phenomena where some sort of localization of electrons must already be assumed in the "all-electron" treatment. Our model potential method is inherently well equipped to handle such localizations.

The following is a very cursory and uneven review of the applications of the model potential method, primarily because I have made only a nominal contribution there. It excludes the works in which the reference all-electron results are used for comparison, through which the dependability of the method is tested and confirmed.

6.1 Version 1

A number of molecular clusters including Pd_4 Pt_4, Pd_4H, and Pt_4H were studied at both the NR and QR level of approximation. The electron affinity of various hexafluoride molecules MF_6 (M = Cr, Mo, W, Au) were studied by the Hartree–Fock calculation and also by the post-Hartree–Fock calculation at the level of singly and doubly excited CI (SDCI) (17). The effects of relativity and the electron correlation were carefully assessed.

This version of the model potential method has been applied actively to the study of various surface phenomena including the study of the CO molecule coadsorbed with *K* on metallic Cu and Ag surfaces. The actual sizes to which the model potential method was applied are $Cu_{12}K_2CO$ and $Ag_{12}K_2CO$ (18).

Inclusion of the electron correlation effect has also been practiced with considerable success in this version. To cite one example, multireference singly and doubly excited CI (MRSDCI) calculations were performed on the NaI molecule (19).

6.2 Version 2

This version, the AIMP method of Seijo and Barandiarán, was applied to study the equilibrium geometry of alkaline earth dihalides MX_2 (M = Mg, Ca, Sr, Ba: X = F, Cl, Br, I) (20), the hydrides XH_2, XH_4 (X = Si, Ge, Sn, Pb), and also the oxides XO (X = Ge, Sn, Pb). These are mostly without the reference all-electron calculation and emphasis was placed on the comparison between the NR-AIMP and the QR-AIMP to gauge the relativistic effect.

Barandiarán and Seijo (21, 22) developed an interesting variation of their AIMP method called the ab initio environment model potential (AIEMP) method. Similar developments have been made also in Version 1 and Version 3. Since the development clearly indicates the applicability of the model potential method to a wider class of phenomena, we shall describe the essential point of the AIEMP method as an illustration.

The method applies to the crystalline system with an impurity as formed by a cluster, that is, a group of nuclei and active electrons that are responsible for the local properties of the crystal associated with the impurity, and groups of nuclei and dormant electrons that are essentially unperturbed and act as the environment for the cluster. Then, we may adopt the following wavefunction as an approximation to describe the crystalline system:

$$[86] \qquad \Phi = A_{SL}(\Phi_{clus}\Phi_{env})$$

which is an obvious variation of Φ in eq. [1]. Φ_{clus} may be a closed-shell, an open-shell, or even a multiconfiguration wavefunction. Φ_{env} may be a product of atomic wavefunctions representing the ions $e, f, \ldots, s$ located on lattice sites outside of the cluster,

$$[87] \qquad \Phi_{env} = \Phi_e\Phi_f \cdots \Phi_s$$

Suppose that $\{\varphi_{clus}\}$ are the orbitals in Φ_{clus}, $\{\varphi_e\}$ in Φ_e, $\{\varphi_f\}$ in Φ_f, and so on. The orthogonalities among these orbital sets are imposed,

$$\{\varphi_{clus}\}\perp\{\varphi_e\}, \qquad \{\varphi_{clus}\}\perp\{\varphi_f\}, \qquad \{\varphi_e\}\perp\{\varphi_f\}, \text{ etc.}$$

Therefore, the trade-mark projection operator in the model potential method for the ion *e*,

$$[88] \qquad \hat{o}_e = -\sum_k 2\varepsilon_{e,k}|\varphi_{e,k}\rangle\langle\varphi_{e,k}|$$

contains all the occupied orbitals of the ion *e*, $\{\varphi_e\}$.

The AIEMP method has been applied to (*a*) the $CuCl_6^{5-}$ cluster embedded in an NaCl lattice (21), (*b*) the $(CrF_8)^{q-}$ lattice ($q = 7$ for the Cr^+ defect and $q = 5$ for the Cr^{3+} defect) in fluorite (23), (*c*) the CrF_6^{3-} cluster in the K_2NaGaF_6 lattice (24), and (*d*) the $(CuO_6)^{10-}$ and $(AgO_6)^{10-}$ clusters in the MgO, CaO, and SrO family of hosts (25).

6.3 Version 3

In 1985 Katsuki already entertained the idea of the environment potential (26). Therefore it is only natural for him to adopt the technique of spectral representation to treat a nonspherical environment, that is, active electrons interacting with a nonspherical core region of dormant electrons. So far, the method has been applied to the interaction between three ammonia molecules (26), and also to the molecules CH_3COOH, CH_3CH_2COOH, and $CH_3CH_2CH_2COOH$, where the functional group COOH is treated as a system with 6 frozen electrons and then progressively with 10, 12, and 18 frozen electrons (27).

7. Concluding remarks

We posed two questions in the Introduction. First, to account

for the differences among atoms with the same number of valence electrons, the carefully crafted effective Hamiltonian is required, and it has been shown that it can be done in our model potential method. Second, do we still have Van Vleck's nightmare? Perhaps no for the atomic inner core, but still yes for the general problem of the localization of electrons in quantum mechanics (28). One manifestation of the problem in our model potential method is the intruder orbitals in virtual orbital space as mentioned in Sect. 4. Care should be taken in performing the CI or the perturbational calculation with our model potential method (29).

The method has been developed to a satisfactory level of sophistication and accuracy. There is, however, one aspect of the method to be supplemented in the near future. In the nonrelativistic formulation, knowledge of the frozen, dormant electrons is sufficient for constructing the effective Hamiltonian for the active electrons. However, in the relativistic formulation based on the Cowan–Griffin–Wood–Boring approximation, knowledge of the valence electrons is also necessary in the reference atomic calculation. This necessity will be removed if we develop the model potential version of the Fock–Dirac relativistic method.

Acknowledgments

I would like to express my sincere gratitude to all of my friends and colleagues who have contributed to the development of the present work. The order of acknowledging their names is more or less chronological: D. McWilliams, A.A. Cantu, V. Bonifacic, O. Gropen, U. Wahlgren, G. Höjer, J. Chung, S. Katsuki, M. Klobukowski, J. Andzelm, E. Radzio, Y. Sakai, H. Tatewaki, L. Seijo, Z. Barandiarán, and E. Miyoshi.

The heterogeneity of two Canadian kraft lignins

R.W. Thring and S.L. Griffin

Abstract: Two kraft lignins, one precipitated with carbon dioxide and the other with sulphuric acid, have been fractionated into three distinct fractions by sequential extraction using organic solvents of increasing hydrogen-bonding capacity. The lignins and fractions were comparatively characterized in terms of yield, methoxyl group content, molecular weight distribution, and ^{13}C NMR spectroscopy. For a given lignin, the fractions showed differences in yield, composition, and chemical structure. A significant portion (21%) of the carbon dioxide precipitated kraft lignin is composed of ethyl acetate soluble material of low molecular weight. This fraction, which is richer in guaiacyl moieties than the other fractions, is virtually absent in the sulphuric acid precipitated kraft lignin. The occurrence of "tails" in the high molecular weight fraction, especially from the carbon dioxide precipitated kraft lignin, suggests the presence of material of very high molecular weight. Data from ^{13}C NMR spectroscopy does little to elucidate the nature or origin of the material causing these tails.

Key words: kraft lignins, heterogeneity, fractionation, characterization.

Résumé : On a précipité deux lignines kraft, l'une par du dioxyde de carbone et l'autre par de l'acide sulfurique, et, utilisant des solvants organiques de capacité croissante à former des liaisons hydrogènes, on les a séparées en fractions distinctes par des extractions séquentielles. On a effectué une caractérisation comparative des lignines et des fractions en fonction des rendements, des contenus en groupes méthoxyles, des distributions des poids moléculaires et de la spectroscopie RMN du ^{13}C. Pour une lignine donnée, les fractions présentent des différences dans les rendements, les compositions et la structure chimique. Une fraction importante (21%) de la lignine kraft obtenue par précipitation avec du dioxyde de carbone est formée de matériel de bas poids moléculaire, soluble dans l'acétate d'éthyle. Cette fraction, qui est plus riche en portions guaïacyles que les autres fractions, est pratiquement absente de la lignine kraft obtenue par précipitation à l'acide sulfurique. La présence de traînées dans la fraction de poids moléculaire élevé, en particulier celle de la lignine kraft obtenue par précipitation avec du dioxyde de carbone, suggère la présence de matériel de poids moléculaire très élevé. Les données de la RMN du ^{13}C n'apportent que peu de lumière sur la nature ou l'origine du produit provoquant ces traînées.

Mots clés : lignines kraft, hétérogénéité, fractionnement, caractérisation.

Introduction

The economic viability of any pulping process would be greatly improved if a high-value application were developed for lignin, the major by-product from such facilities. It is therefore of considerable interest to elucidate the composition, structure, and properties of commercially produced lignins if one or more high-value applications are to be developed from these materials.

The importance of heterogeneity of lignins and their subsequent performance has been demonstrated in the past (1). Chemical heterogeneity affects the chemical reactivities in modification reactions as well as the accessibility of the lignins to solvents. As a consequence, the former will dictate the performance properties of these modified technical lignins. It is therefore imperative that a better understanding of the heterogeneity of lignin and the methodology to eliminate the deleterious components be attained so as to achieve a major improvement of lignins as chemical raw materials.

A number of investigations have been conducted into the elucidation of the physical and chemical structural heterogeneity of lignin by fractionation. As early as 1962, Wada et al. (2) fractionated this lignin from kraft waste liquor into 10 fractions by acid precipitation, by varying the pH of the solution with sodium carbonate, carbon dioxide, and hydrochloric acid. Lin and Detroit (1) studied the heterogeneity of lignin by fractionating sulphite and kraft lignins into five and six fractions, respectively, using ultrafiltration.

More recently, Kringstad et al. (3) used gel permeation chromatography to fractionate a pine kraft lignin. The method, based upon the initial production of silylated lignin derivatives followed by gel permeation chromatography as eluent, was deemed convenient and rapid by the authors. However, small quantities of samples, typically less than 1 g, were obtained by this technique. Hatakeyama et al. (4) fractionated kraft lignin by successive precipitation with water from a dioxane solution. Recently, increasing interest has been shown in the use of

organic solvents in lignin fractionation (5, 6). This may be due to the fact that bulk (kg) quantities of lignin can be fractionated rather effectively by sequential extraction with organic solvents of increasing hydrogen-bonding capability. This approach is based on the work of Schuerch (7), who discovered that the solvation power of a solvent for lignin was a function of both the cohesive energy density and hydrogen-bonding capacity of the solvent. In other words, organic solvents of weak or moderate hydrogen-bonding capacity will solubilize low molecular weight fragments of lignins.

The present paper describes the fractionation of two Canadian kraft lignins by successive extraction with organic solvents of increasing hydrogen-bonding capacity. The starting lignins and their fractions are compared in terms of their yield, molecular weight distribution, functional group analysis, and ^{13}C NMR spectroscopy.

Experimental

Materials

Both kraft lignins were donated by the research group of Professor P. Watkinson (University of British Columbia), involved in conducting research on the use of lignin as a lime kiln fuel (8). One kraft lignin was isolated from a mostly spruce wood furnish at Irving Pulp and Paper Company (New Brunswick, Canada). This lignin was precipitated from strong black liquor using pure carbon dioxide and recovered on a 200 mesh belt filter with some water washing. Since the acid used for precipitation was carbon dioxide, this lignin will be designated as CPKL (carbon dioxide precipitated kraft lignin). The other kraft lignin was extracted from a wood furnish of 45% lodgepole pine, 50% spruce, and 5% Douglas fir at Canfor's Intercontinental Mill in Prince George (British Columbia, Canada). It was acid precipitated from strong (~50% solids) oxidized black liquor using 9.5 N sulphuric acid. This lignin will be designated at SPKL (sulphuric acid precipitated kraft lignin).

Ethyl acetate (ACS Reagent Grade) was purchased from Mallinckrodt Inc., Paris, Kentucky, U.S.A. Methanol (ACS Reagent Grade) was obtained from Anachemia, Montreal, Canada. Hildebrand solubility parameters (σ/MPa$^{1/2}$) for these solvents are 18.6 and 29.6, respectively. Ethyl acetate has a moderate hydrogen-bonding capacity but that of methanol is strong.

Analytical methods

Methoxy group determination

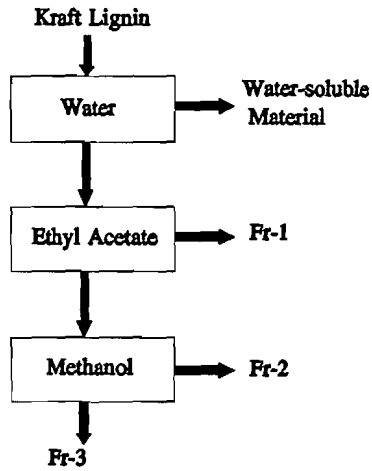
The methoxyl content was quantified using the TAPPI method T209-WD-79 (9).

Fractionation scheme

Each lignin was subjected to the fractionation sequence depicted in Fig. 1. Fractionation was carried out at room temperature using an ultrasonic water bath to facilitate both the penetration of the solvent into the lignin residue and dissolution of the soluble portion of the lignin.

The method may be described as follows. Approximately 50 g (dry basis) of lignin and 200 mL of ethyl acetate were added to a 500 mL extraction flask. The contents were then agitated by ultrasound for 10 min. After allowing the mixture to stand so that any suspended particles could settle out, the supernatant was decanted into a 1 L volumetric flask. The same procedure was repeated three to four times, after which it was considered that most of the solvent-soluble lignin was dissolved and separated from the lignin residue (i.e., the supernatant was very light coloured after the last extraction). The ethyl acetate insolubles were dried for 15 min using a rotary evaporator under reduced pressure.

Fig. 1. Scheme for the fractionation of kraft lignins.



Methanol was then used in the sequence. In this case, removal of the soluble material was deemed complete after three extractions. The remaining residue in the extraction flask, after evaporation of the remaining methanol, constituted the third fraction.

The combined extracts for each of the first two fractions were evaporated under reduced pressure and the residue was dried to constant weight within 100 mg. To ensure complete removal of the solvent, all three residues were kept in a desiccator under vacuum for 2 days. Each fraction was then stored in bottles under a nitrogen blanket in the dark until further use.

All fractions from both kraft lignins were free-running powders and light brown in colour.

The fractionation method described above was rather time consuming but very reproducible, with a high degree of recovery of the solvents.

High-pressure solvent elution chromatography (HPSEC)

A Waters liquid chromatograph connected to an on-line computer via a Waters Maxima NEC 80486 data system was used. Three stainless steel columns in series (3 cm length; 7.5 mm i.d.), packed with ultrastyragel columns (Polymer Laboratories, U.K.) of pore size 10^4, 500, and 100 Å, and a UV detector set at 277 nm were used. A single-piston reciprocating pump maintained a constant flow rate through the system. Operating conditions were as follows: eluent, degassed THF (purged with N_2); temperature, 25°C; injection volume, 100 μL; flow rate, 1 mL/min.

A relative calibration curve was obtained using monodisperse polystyrene standards (Polymer Laboratories). A third-order polynomial of the form $y = ax^3 + bx^2 + cx + d$ best describes the relation between the log of the actual molecular weights of polystyrene standards (y) and their retention times (x). The following coefficients were calculated: $a = 0.0021$, b

Table 1. Fractionation yields and methoxyl group content of kraft lignins and fractions.

	CPKL		SPKL	
Fraction	Yield[a] (%)	Methoxy content (%)	Yield[a] (%)	Methoxy content (%)
1	21	14.1	5	12.0
2	33	15.4	48	14.8
3	46	19.4	47	13.2
Original lignin	100	13.0	100	12.5

[a]Yields were determined on 50 g samples; losses, calculated by difference, amounted to less than 1% (initial sample) for both lignins.

= 0.0283, $c = -1.279$, $d = 20.64$. These gave a fit with a correlation coefficient of 0.99. The size exclusion volume (V_0) for the column system was 6.4.

^{13}C NMR

Both kraft lignins and their fractions were acetylated and analyzed using a Brüker 400 WD spectrometer. Samples were prepared by dissolving ca. 800 mg of lignin in 2 g of DMSO-d_6 at room temperature and placing the solution in 10 mm i.d. glass tubes. In some cases, particularly for the high molecular weight samples, a little heating (~40°C) was required to completely dissolve the acetylated lignin. The instrument was set in proton inverse-gated decoupled mode, with a scan delay of 2 s. All samples were run at a temperature of 50°C.

Results and discussion

Yields

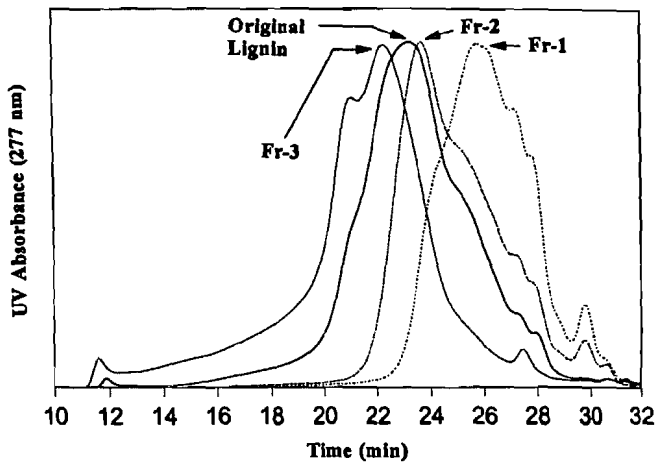
The objective was to determine whether there were significant differences in the fractional yields from each kraft lignin, as a function of the type of lignin. The method of fractionation is based on a previous study on the selective fractionation of a glycol lignin (10). It was found that at the conditions employed, ethyl acetate preferentially solubilized the low molecular weight portion of lignin. Methanol, on the other hand, extracted both low and medium molecular weight material. From Table 1, it is seen that both kraft lignins are heterogeneous in terms of fractional yields. The extraction procedure solubilized an identical quantity of 54% from each lignin. However, Fr-1 represents 21% of CPKL but only 5% is solubilized from SPKL. In both lignins, the methanol solubles are high but are more significant in SPKL (48 versus 33%, respectively).

Thus, both lignins contain comparable quantities of insoluble material not solubilized by the solvent extraction procedure utilized here. However, the CPKL is composed of almost 75% more ethyl acetate solubles but 31% less methanol solubles than the SPKL.

Methoxy content

Analytical determinations of the content of methoxyl groups were carried out for both lignins and their fractions. As shown in the second column of Table 1, the content of methoxyl groups is highest at 19.4% in Fr-3 for CPKL, and, for SPKL, it is highest in Fr-2 (14.8%). This suggests that these fractions

Fig. 2. HPSEC chromatograms of acetylated SPKL lignin and its fractions (calibration based on polystyrene standards).



are the richest in structures consisting of syringyl units. On the other hand, the low molecular weight material, Fr-1, has the lowest methoxyl group content in both lignins, indicative of the high guaiacyl character in this fraction. It should, however, be noted that Fr-1 is almost completely absent in SPKL. Also, it is interesting to observe that both starting kraft lignins have methoxyl group contents of 13%. Clearly, the extraction procedure is more selective in fractionating CPKL than SPKL according to methoxyl group functionality.

HPSEC

As seen in Figs. 2 and 3, both kraft lignins yield three fractions of increasing molecular weight when subjected to sequential solvent extraction. A number of important observations can be made about the chromatograms of the two lignins and corresponding fractions. Both starting lignins exhibit similar distribution patterns, with large peaks whose maxima correspond to about 4500 g/mol (polystyrene weight equivalent). Therefore, this suggests that both lignins contain significant amounts of medium and high molecular weight material. The chromatograms of Fr-1 for both lignins are well separated from the medium and high molecular weight fractions. In both lignins, Fr-3 exhibits a tail of very high molecular weight material. This is much more pronounced for Fr-3 from CPKL. The origin or nature of the material causing this tail is not known at this time. It should be noted that this tail is not present in the chromatograms of the starting lignins. Mörck et al. (5, 11) also observed a tail in HPSEC chromatograms of acetylated softwood kraft lignins. The existence of a tail in a chromatogram will strongly affect the value of M_w, the weight-average molecular weight.

The weight- and number-average molecular weight (relative values of polystyrene) and polydispersity are all shown in Table 2. M_w and M_n values of the CPKL lignin and its fractions are discernibly higher than those of SPKL and its corresponding fractions. However, CPKL lignin contains a higher proportion of low molecular weight material than SPKL as demonstrated by the higher content of ethyl acetate soluble material in the former lignin. A steady increase can be seen in both molecular weight and polydispersity from Fr-1 to Fr-3 in both lignins, suggesting that Fr-1 from either lignin is composed of structures of essentially similar low molecular

weight. The high polydispersity of Fr-3 from both lignins is a reflection of the presence of a mixture of medium and high molecular weight structures. As seen in Fig. 2 and 3, the occurrence of "tails" in the chromatograms of Fr-3 is indicative of very high molecular weight material, which will strongly dictate the calculated M_w and M_n and, therefore, the polydispersity of this fraction.

^{13}C NMR

The spectra of both kraft lignins and their corresponding fractions are shown in Figs. 4 and 5. Assignments of important signals can be found in previous reports (5, 6, 12). The carboxylic signal at 172 ppm is barely perceptible in both starting lignins but is more significant in the fractions, particularly in Fr-1 and Fr-2 for SPKL. Signals at 170 and 168 ppm are attributed to aliphatic and phenolic hydroxyl groups, respectively. A coarse estimate of the relative abundance of these groups is possible in routine NMR analysis from the intensities of the signals because of the similarity in spin-lattice relaxation times of the various acetyl carbonyl carbon atoms (13). As seen in both lignins and fractions, the intensity of the signal of phenolic hydroxyl groups is higher, suggesting that there are more phenolic than aliphatic hydroxyl groups in all cases. This is to be expected since it is known that hydrolysis of lignin during alkaline pulping increases the phenolic hydroxyl groups in lignin (14). From all the spectra it is not obvious whether the aliphatic hydroxyl groups are primary or secondary. Broad peaks can be observed in some of the spectra, particularly in the aromatic region. Since each sample was run overnight, it is probable that some of them, especially the high molecular weight fractions (Fr-3) from each lignin, were not completely dissolved in DMSO-d_6. However, all the lignin samples should be soluble in this solvent since each was acetylated for 2 days in a 50/50 mixture of acetic anhydride and pyridine at room temperature. It is possible, however, that Fr-3 is composed of material whose molecular weight is just too high to be rendered soluble. The decrease in intensity of the signal at 149 ppm (guaiacyl) and the corresponding increase in intensity of the signal at 152 ppm (syringyl) from Fr-1 to Fr-3 suggests the trend form guaiacyl to syringyl moieties with increasing fraction number. The aromatic region (103–148 ppm) is difficult to interpret due to the presence of broad signals, especially in the high molecular weight fractions from both kraft lignins. Thus, no further interpretation of the signals in this region will be attempted in the present study. The almost complete absence of signals in the 85–64 ppm region (aliphatic carbons) in the starting lignins and fractions is indicative of extensive cleavage of interunit linkages (-C-C- and -C-O-C-) as well as those of the side chains of lignin during kraft pulping.

The intensity of signals in the 34–14 ppm region (methine, methylene, and methyl carbons) in the spectra of both kraft lignins reveals the presence of saturated hydrocarbon structures. These signals arise from the formation of new bonds due to condensation reactions. As suggested by Gierer et al. (15), these reactions involve intermediate coniferyl alcohol structures generated after initial cleavage of phenolic β-aryl ether bonds, and may introduce conjugated double bonds as well as saturated hydrocarbon structures to the side chains in lignin. Thus, the nature of the spectra in both lignins and corresponding fractions indicates that these saturated hydrocarbon structures are roughly the same in each set of fractions, except for Fr-1 in both series. In Fr-1 from both lignins, the distribution of the signals in the aliphatic region strongly suggests the dominance of structures containing saturated hydrocarbon side chains. Therefore it can be concluded that CPKL contains a significant amount (21%) of low molecular weight material composed of saturated aliphatic residues. As seen previously, this Fr-1 is virtually absent in SPKL.

Conclusions

Fractionation of both kraft lignins according to solubility is feasible and yields fractions of increasing molecular weight. Fractions of low molecular weight have narrow molecular weight distributions, while the high molecular weight fractions have broad distributions. For the same solvent, the magnitude of the difference between the yields in each lignin decreases with increasing molecular weight. The molecular weight distribution patterns show that the solvent sequence used is more selective for fractionating carbon dioxide precipitated lignin than sulphuric acid precipitated lignin. The low molecular weight fractions (Fr-1) from both lignins are composed of material of essentially the same molecular weight, as reflected by their low polydispersity. Low molecular weight material (EtAc soluble) is virtually absent in the sulphuric acid precipitated kraft lignin, whereas the carbon dioxide precipitated kraft lignin is composed of 21 wt% of this fraction. Also,

Fig. 4. ^{13}C NMR spectra of acetylated SPKL lignin and its fractions: solvent, DMSO-d_6.

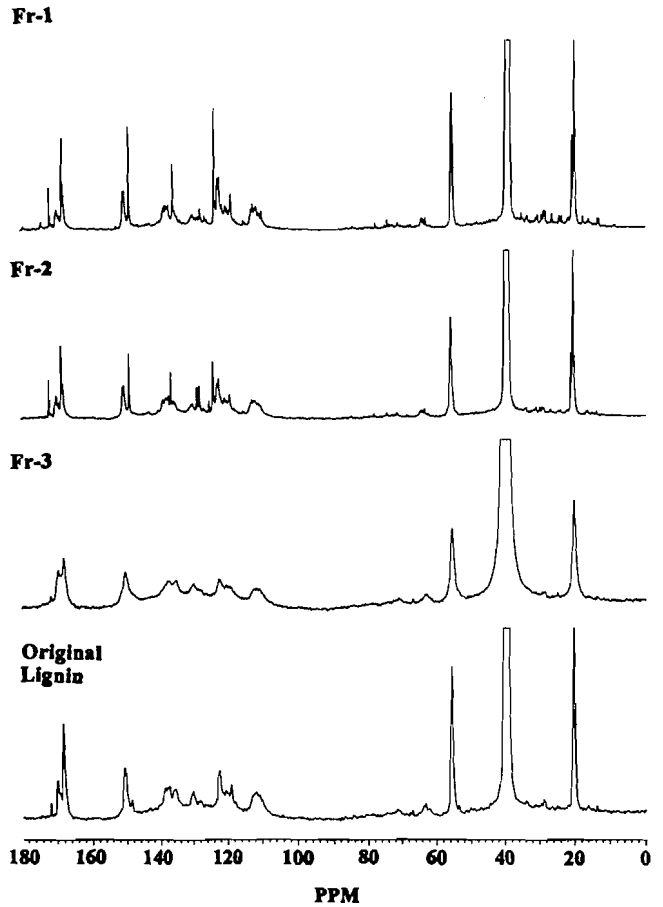

Fig. 5. ^{13}C NMR spectra of acetylated CPKL lignin and its fractions: solvent, DMSO-d_6.

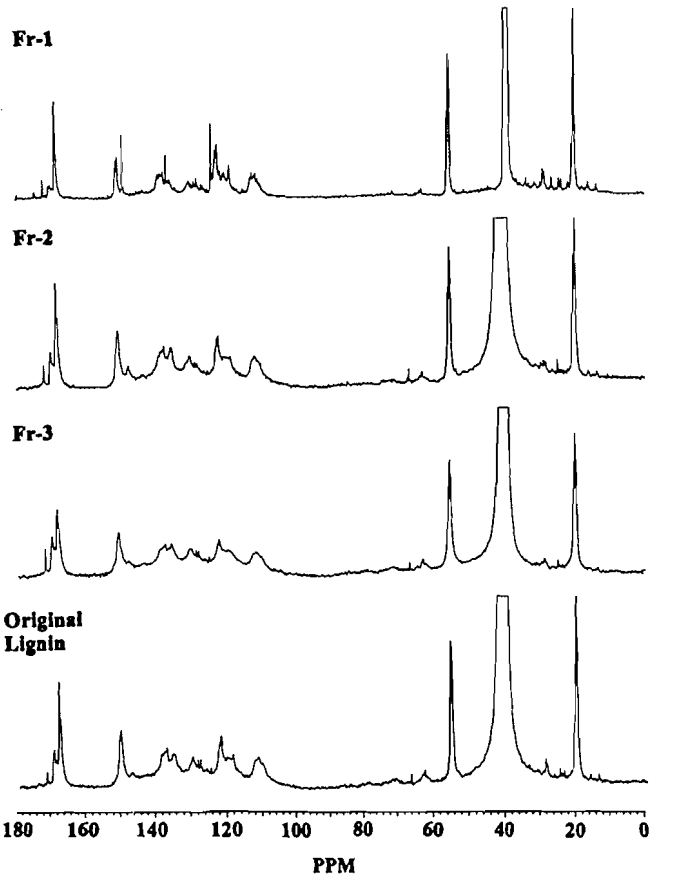

characterization of both lignins and their fractions by methoxyl group determination and ^{13}C NMR spectroscopy confirms the chemical differences existing not only between the lignins, but particularly between Fr-1 and the other fractions. For both lignins, the data indicates the low molecular weight fraction (Fr-1) is richest in guaiacyl moieties, whilst Fr-3 has the highest syringyl character. The low molecular weight fraction is essentially composed of residues containing saturated aliphatic side-chain structures that were selectively extracted from the kraft lignins. The results demonstrate the inhomogeneity of both lignins. More importantly, the data suggest that a little less than 50% of either lignin may be inaccessible to solubilization by many common solvents or to modification reactions.

Therefore, the two technical lignins examined in this study exhibit significant heterogeneity with respect to both molecular dispersity and structural variation.

Acknowledgements

We would like to thank Professor P. Watkinson of the University of British Columbia for supplying samples of both kraft lignins. Useful discussions on kraft lignin recovery with V. Uloth, Senior Research Engineer of the Pulp and Paper Research Institute of Canada, were deeply appreciated. Also, we would like to express our sincere gratitude to the Natural Sciences and Engineering Research Council of Canada for financial support.

Preparation and properties of rhodium(I) and iridium(I) diolefin complexes of heterodifunctional phosphorus–imine chelating ligands and a related iminophosphine. ^{103}Rh NMR parameters of the rhodium complexes obtained via indirect two-dimensional ^{31}P, ^{103}Rh{^{1}H} NMR spectroscopy

David J. Law, Glen Bigam, and Ronald G. Cavell

Abstract: Treatment of $[M(cod)Cl]_2$ (M = Rh, Ir) with iminophosphoranophosphine ligands of the type $Ph_2PQP(Ph_2)$=$NSiMe_3$ (Q = CH_2, CH_2CH_2, 1,2-C_6H_4) afforded the new metallacycles $[(cod)\overline{MPPh_2QPPh_2N}]$ through elimination of Me_3SiCl, ultimately "anchoring" the ligand to the metal through a metal–nitrogen σ bond. The phosphine functionality completes the chelate. Cationic complexes of the type $[M(cod)L_2]^+PF_6^-$ (M = Rh or Ir; L_2 = Ph_2PQPPh_2NR where Q = CH_2, $CH(CH_3)$, 1,2-C_6H_4, and R = *p*-C_6F_4CN, $C_6H_2F(NO_2)_2$, and $C_6H_3(NO_2)_2$ or L = Ph_2PN=C(H)Ph) were readily prepared by treating $[M(cod)Cl]_2$ with L_2 and KPF_6. The detection and chemical shift determination of the insensitive ^{103}Rh nucleus was easily accomplished via ^{31}P detected indirect two-dimensional ^{31}P, ^{103}Rh{^{1}H} NMR spectroscopy. The ^{103}Rh, ^{1}H, and ^{31}P NMR data are discussed.

Key words: rhodium, iridium, phosphoranimine, iminophosphine, Rh NMR.

Résumé : La traitement des $[M(cod)Cl]_2$ (M = Rh, Ir) avec des coordinats iminophosphoranophosphines du type $Ph_2PQP(Ph_2)$=$NSiMe_3$ (Q = CH_2, CH_2CH_2, 1,4-C_6H_4) conduit à de nouveaux métallacycles $[(cod)\overline{MPPh_2QPPh_2N}]$ par une élimination de Me_3SiCl qui « ancre » éventuellement le coordinat au métal par le biais d'une liaison σ métal–azote. Le chélate est complété par la fonctionnalité de la phosphine. On peut facilement préparer les complexes cationiques du type $[M(cod)L_2]^+PF_6^-$ (M = Rh ou Ir; L_2 = Ph_2PQPPh_2NR dans lesquels Q = CH_2, $CH(CH_3)$, 1,2-C_6H_4 et R = *p*-C_6F_4CN, $C_6H_2F(NO_2)_2$ et $C_6H_3(NO_2)_2$ ou L = Ph_2PN=C(H)Ph) en faisant réagir du $[M(cod)Cl]_2$ avec du L_2 et du KPF_6. On peut facilement détecter et déterminer le déplacement chimique du noyau ^{103}Rh insensible en faisant appel à la spectroscopie RMN bidimensionnelle ^{31}P, ^{103}Rh{^{1}H} qui permet de détecter le ^{31}P d'une façon indirecte. On discute des données RMN du ^{103}Rh, du ^{1}H et du ^{31}P.

Introduction

Previous work from our laboratories described the synthesis of novel rhodium(I) (**11**) (1, 2) and iridium(I) (**26**) (2) metallacycles $[(cod)\overline{M\text{-}N{=}P(Ph)_2CH_2P(Ph)_2}]$ utilizing the heterobifunctional iminophosphoranophosphine ligand $Ph_2PCH_2P(Ph)_2$=$NSiMe_3$. Elimination of Me_3SiCl during reaction of this ligand with 1,5-cyclooctadiene rhodium(I) or iridium(I) chloride dimers formed rhodium– or iridium–nitrogen σ bonds and produced a strongly bonded phosphine chelate. There are only a few examples of related P–N chelates in which the nitrogen forms a σ bond with rhodium (3–8). In our laboratories we recently developed an extensive series of heterobifunctional iminophosphoranophosphines with firmly attached substituents on the nitrogen (such as fluoroaromatics

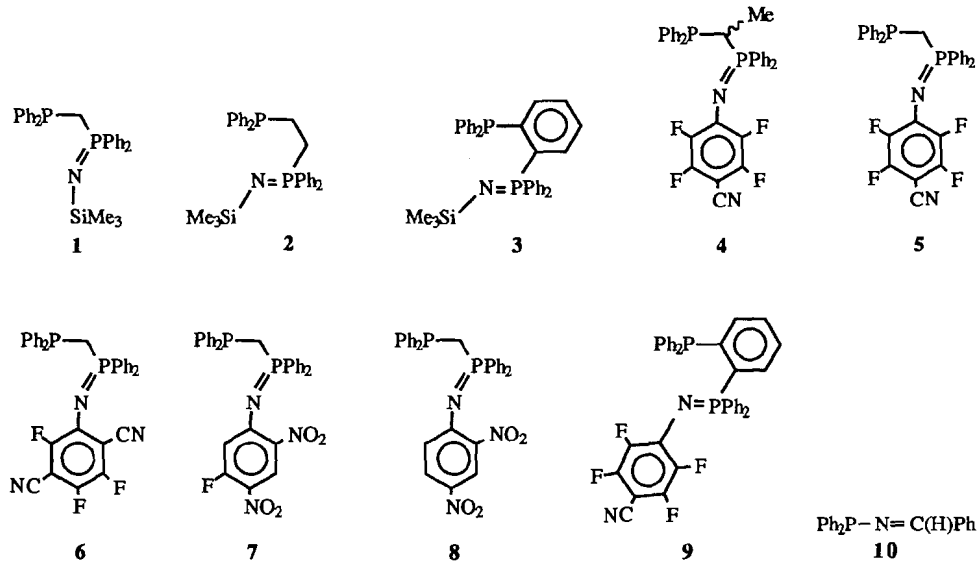
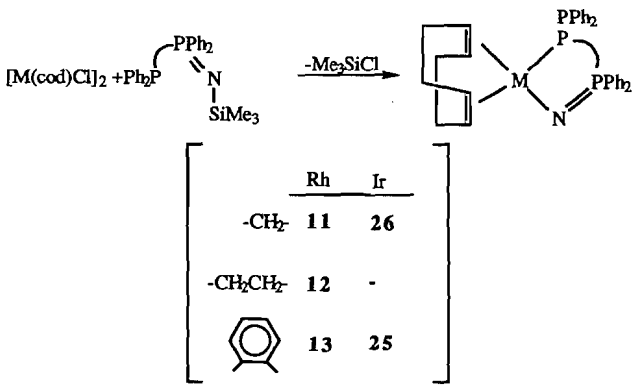
Scheme 1



Scheme 2



obtained from Me_3SiF elimination from activated fluoroaromatics (1, 2, 9–11)) and these ligands were found to be strong bidentate chelators. Each ligand is similar in that it possesses one hard (N) and one soft (P) donor site but the structure, basicity, and "bite" differences conferred by the backbone variety produce complexes of differing conformation and properties. To investigate the chemistry of these ligands we have now examined a series of complexes in which several examples of our heterobifunctional ligands are coordinated to rhodium(I) and iridium(I) centers. The analogous Rh(I) and Ir(I) metallacycles formed by elimination of Me_3SiCl from the parent iminophosphoranophosphine(1, 2) are also included in the comparison.

Mononuclear cationic rhodium and iridium diene–diphosphine complexes have been extensively studied since the report by Schrock and Osborn (12) that treatment of dimeric diene complexes of rhodium(I) or iridium(I), $[M(diene)Cl]_2$ (M = Rh or Ir) with a phosphine ligand L and a non-coordinating counterion X^- ($X = BF_4^-$, ClO_4^-, PF_6^-), gave cationic four-coordinate complexes of the type $[M(diene)(L)_2]^+X^-$. Complexes of this type have been made with monodentate chelating and chiral phosphines and, in many cases, these complexes have been found to be effective catalyst precursors for homogeneous hydrogenation at ambient temperature and pressure (13–16). Pyridyl phosphines have also been widely used as chelating and bridging ligands for a variety of transition metals including rhodium (17–20). Also widely known are rhodium complexes derived from chelating phosphine–amine bidentate ligands (21–35). There are, however, only a few examples of rhodium complexes containing chelating ligands with both a phosphine and an imine donor site (36–39). There are no examples of cationic rhodium(I) or iridium(I) complexes of phosphoranimine-phosphine heterodifunctional ligands such as those described herein, although the work of Imhoff et al. (40–43) provides several examples of cationic complexes containing doubly oxidized iminophosphorane ligands acting as bidentate ligands to Ir and Rh through the nitrogen atoms or through one nitrogen and one carbon atom.

Although ^{103}Rh NMR spectra have been obtained by various techniques for some time now, as described in two major reviews (44, 45), the method of obtaining rhodium chemical shifts via indirect 2D techniques has only recently been described and only a few examples of an indirect ^{31}P, $^{103}Rh\{^1H\}$ NMR spectrum have been reported (46–48).

Results and discussion

Rhodium and iridium cyclometallaphosphoran-iminatophosphines

We have previously shown (1) that the presence of a reactive Me_3Si—N bond in a ligand such as **1** (Scheme 1) presents the possibility of σ-bond formation by reaction with a metal halide *via* elimination of trimethylsilylhalide to form **11** and **26** (Scheme 2). This is further demonstrated in the present work by ligands **2** (2) and **3** (11), which reacted in a similar manner with $[Rh(cod)Cl]_2$ or $[Ir(cod)Cl]_2$ with elimination of Me_3SiCl to give metallacycles **12**, **13**, and **25** in good yields (Scheme 2). It is interesting to note that the reaction with the ligand **3** containing a 1,2-substituted benzene backbone required extensive refluxing in dichloromethane to obtain the complexes **13** and **25**, whereas reactions with ligands **1** and **2** were facile at room temperature. This pattern of reactivity is related to the mechanism of Me_3SiCl elimination, which probably requires the imine nitrogen of the ligand to act as a

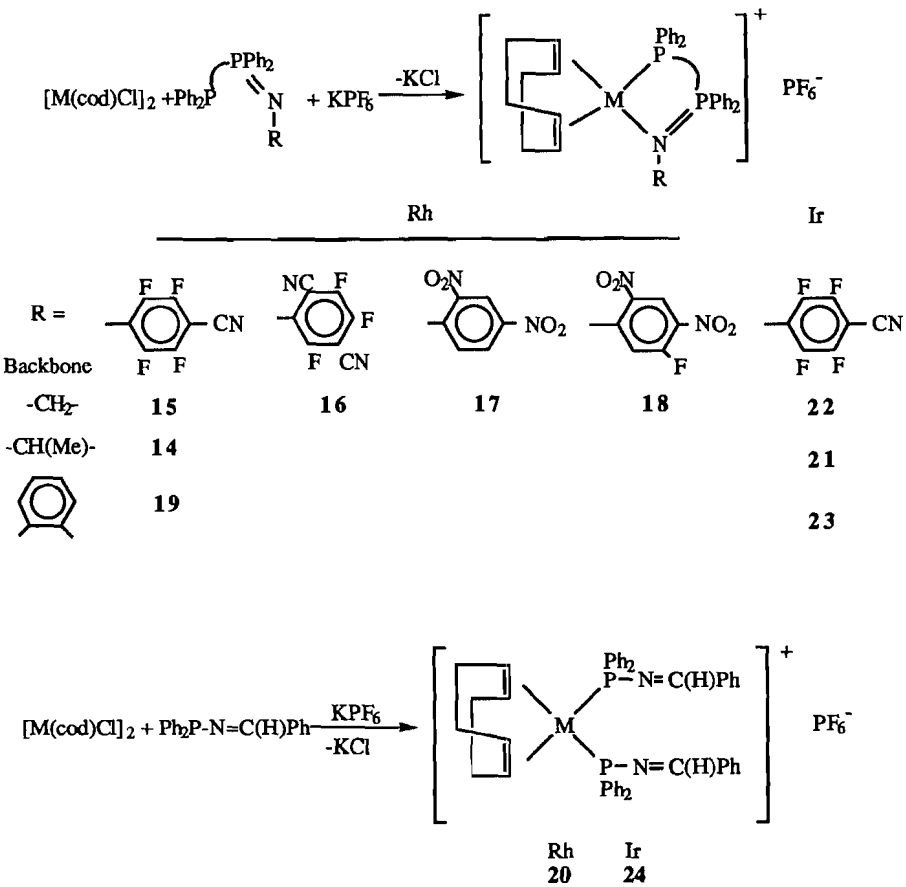
Scheme 3



nucleophile on a metal center. The electron-withdrawing or delocalization effects of the aromatic ligand backbone in **3** reduce the nucleophilicity of the imine nitrogen, which is reflected in lower reactivity for M—Cl bond substitution. The compounds are red-orange microcrystalline solids, soluble in most common organic solvents. Contrary to our preliminary observations (1, 2), these types of compound are now known to decompose slowly in air over relatively long periods of time. Little visual indication of the reaction with air is observed; for example there is almost no visible color change. When the complexes are stored under argon there is no evidence for decomposition, indicating that the complexes are thermally and structurally stable.

The rhodium complexes **12** and **13** exhibit sharp doublets of doublets in their phosphorus-31 NMR spectra, with $^{1}J_{P^{III}Rh}$ and $^{2}J_{P^{V}Rh}$ couplings of the order of 155 and 4 Hz, respectively (Tables 1 and 2). The large coupling to Rh is diagnostic of the formation of a direct Rh—P bond, and the smaller Rh–P coupling and the preservation of $^{2}J_{PP}$ is indicative of the maintenance of the backbone structure. The observed $^{2}J_{P^{V}Rh}$ coupling was smaller than would have been predicted from previous observations for complexes derived from the analogous $Ph_2AsCH_2CH_2P(Ph_2)$=$NSiMe_3$ ligand (2) but the values compare directly to those observed for the complexes of phosphoramine–phosphine ligands, complexes **16**, **17**, and **18**. The spectrum of the iridium complex **25** exhibits two sharp doublets demonstrating the presence of coupled P(III) and P(V) nuclei in the backbone in accord with our formulation.

Trends in the $J_{P^{III}P^{V}}$ coupling constants can be discerned in all the values reported for phosphoraniminephosphine and phosphoraniminatophosphine complexes (Tables 1 and 2). Interestingly, comparison of the $J_{P^{III}P^{V}}$ coupling values for the "free" ligands with the J_{PP} values in complexed ligands indicated that only the ligands containing a 1,2-benzene backbone (**3** and **9**) show an increase in $^{3}J_{P^{III}P^{V}}$ values upon coordination when forming compounds **13**, **19**, **23**, and **25**. Each of the ligands **4**–**8** with a single carbon backbone shows a typical decrease in $^{2}J_{PP}$ of about 20 Hz upon coordination regardless of the substituent on the imine nitrogen. An exception is the chelation of rhodium(I) by ligand **1** to form complex **11** wherein the decrease in $^{2}J_{P^{III}P^{V}}$ is 13 Hz. The ethane backbone ligand **2** shows a larger decrease of 34 Hz in $^{3}J_{P^{III}P^{V}}$ upon the formation of the analogous Rh—N σ-bonded complex **12**. The behavior noted for the 1,2-benzene backbone ligands might be due to the restricted flexibility of this backbone and the strong possibility of some electron delocalization within the metallacycle supported by the aromatic ring.

Rhodium and iridium diolefin cyclometallaphosphoraniminephosphines

Rhodium and iridium chloride 1,5-cyclooctadiene (cod) dimers, $[Rh(cod)Cl]_2$ and $[Ir(cod)Cl]_2$, react cleanly with the ligands **4**–**10** (Scheme 1) in the presence of potassium hexafluorophosphate to give new cationic cyclometallaphosphoraniminephosphine hexafluorophosphate salts **14**–**20** (Rh) and **21**–**24** (Ir) in good yields (Scheme 3). These are the first

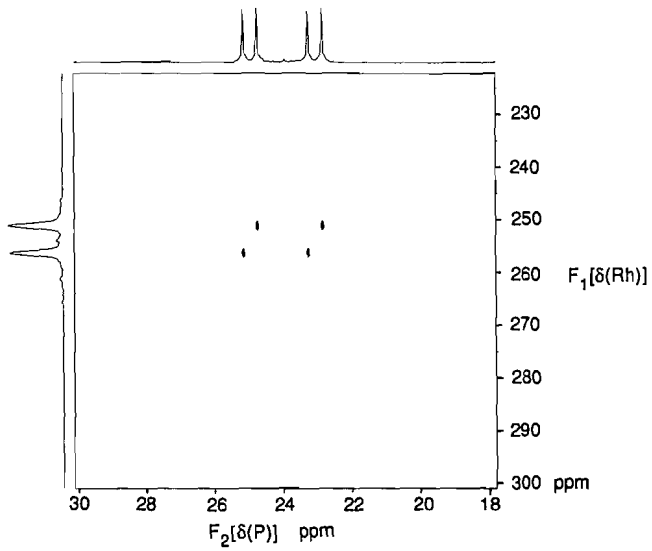
examples of phosphoraniminophosphine ligands in P–N chelates with cationic rhodium(I) and iridium(I) centers. The compounds are microcrystalline solids that are stable over several days in air, monomeric in solution, and only sparingly soluble in common organic solvents. Dichloromethane gives optimum solubility. It was noted that small amounts of decomposition occurred in air after several months, although the compounds appeared to be indefinitely stable under an argon atmosphere.

The phosphorus-31 NMR spectra of the rhodium complexes **14–19** (Tables 1 and 2) exhibit two sharp doublets of doublets readily attributable to the P(III) phosphine and P(V) phosphoranimine moieties, respectively. The P(III) signals show typically large $^1J_{RhP}$ coupling constant values in the order of 152–154 Hz, confirming the binding of P^{III} to Rh, and the P(V) signals occasionally showed small resolved $^2J_{RhP}$ coupling of 3.6–4.9 Hz (complexes **16**, **17**, **18**), again confirming the assigned structure. The spectra of the iridium complexes **21-23** also show the two sharp doublets that are due to the phosphorus(III) and phosphorus(V) centers coupled to each other. The spectra of the rhodium and iridium complexes of the diphenylphosphino–benzylimine ligand **10**, complexes **20** and **24**, showed one signal, with **20** also exhibiting the doublet typical of $^1J_{RhP}$ of 158.8 Hz. All the above compounds showed resonances for the PF_6^- counterion in their ^{31}P NMR spectra with the typical shift value of −144.3 ppm and $^1J_{PF}$ of 711 Hz.

For some years, coordination shifts have been of interest as a means of deducing the nature of metal–ligand interactions in metal–phosphine complexes, particularly where there is a chelate-ring contribution (49). The ^{31}P NMR chemical shifts of the free ligands **1-10** are presented in Table 3 along with observed

Fig. 1. Two-dimensional ^{103}Rh, ^{31}P NMR spectrum of **17** obtained by reverse 2D ^{31}P, $^{103}Rh\{^1H\}$ spectroscopy. $F_1[\delta(Rh)]$ is plotted vertically and $F_2[\delta(P)]$ horizontally. The coupling shown by $F_1[\delta(Rh)]$ is $^2J_{PP}$.



coordination shifts Δ for the present set of complexes. The rhodium and iridium phosphoraniminephosphine complexes **14–18**, **21**, and **22** follow similar patterns of Δ values, whereas the 1,2-benzene backbone phosphoraniminephosphine complexes **19** and **23** show significantly deviant Δ values, which we attribute to the formation of a six-membered metallocycle capable of extensive electron delocalization.

The coordination shifts ΔP^V of the P(V) moiety for complexes **11**, **12**, **13**, **25**, and **26** do not support an extension of our previous interpretation (1, 2). The previously reported (1, 2) complexes **11** and **26** showed marked deshielding of the phosphoraniminato phosphorus (ΔP^V = 52.3 and 62.3 ppm, respectively), which was attributed to the presence of an M—N σ bond. A similar effect was noted for the six-membered cyclometallaphosphoraniminatoarsines

$[(cod)\overline{M\text{-}N{=}P(Ph_2)CH_2CH_2AsPh_2}]$

(ΔP^V; M = Rh, 55.45, M = Ir, 62.2 ppm) (2) and this parallel

10	+49.6		**20**	22.0		**24**	9.8	

suggested that the effect was due to the formation of the M—N σ bond and was also relatively independent of ring size. The ring-size effect, however, seems to be obscured by the simultaneous introduction of As as the coordinating trivalent center. Metallacycles in which the backbone length is increased (e.g., **2** and **3**) whilst maintaining phosphorus coordination show a marked decrease in the P^V coordination shift to 31.4 and 27.5 ppm, respectively, for **2** and **3**, implying a pronounced reduction in this coordination shift with increasing ring size. The Ir metallacycle with the 1,2-phenyl backbone ligand (**25**) also shows a much smaller P^V coordination shift (24.9 ppm). All of the complexes formed from substituted imine and P^{III} donors in the present limited series show very similar coordination shifts and thus no correlation with substituent or backbone is discernable. The reason for the large shifts in certain of the metallacycles is not fully resolved at this time. It does appear, however, that large ΔP^V values in these and other analogous complexes is not a consistent diagnostic of an M—N σ-bond formation as previously suggested (1, 2).

The ^1H NMR resonances of the cod olefinic protons are of interest as they reflect the heterodifunctionality of the ligands by their *trans*-influence and hence their relative shielding or deshielding effect on the coordinated olefin. The complexes **12–23** in general exhibit two distinct ^1H NMR resonances for the cod olefinic proton signals, a high-field set δ 2.9–4.3 ppm and a low-field set δ 4.1–5.9 ppm. Related cationic rhodium complexes (43) show that the cod olefin ^1H signals *trans* to the σ-bound N of phosphoranimine ligands occur in the range δ 2.9–3.8 ppm. Thus the *trans* influence of the phosphoranimine moiety appears to have a shielding effect on the *trans* related olefin signals. With this as a basis, we can assign the high-field olefin resonances of **12–23** to the cod moiety *trans* to phosphorus and the low-field resonances to those *trans* to nitrogen. These qualitative observations also indicate that there is little difference in the *trans* influence of nitrogen-coordinated phosphoranimine to a nitrogen σ-bonded phosphoranimine ligand in these complexes.

Rhodium-103 NMR measurements

The rhodium-103 NMR chemical shifts, reported relative to $\Xi(^{103}Rh) = 3.16$ MHz,[2] for the reported rhodium imine and iminato complexes are given in Table 1. The rhodium-103 chemical shift of the well-known rhodium complex $[(cod)Rh(PPh_3)_2]^+PF_6^-$ is also included for comparison. The ^{103}Rh chemical shift is readily obtained from knowledge of the J_{Rh-P} coupling constant, obtained from the ^{31}P NMR spectrum and by application of recently developed indirect two-dimensional NMR techniques (46–48). An example of a typical spectrum obtained by this technique is given in Fig. 1. The chemical shifts of the majority of the chelated complexes fall in the range of +152.38–+264.48 ppm with the only exceptions being the 1,2-benzene backbone phosphoraniminephosphine complex, **19**, which exhibits a starkly contrasting shift of +504.71. From previously reported ^{103}Rh NMR data (45–48, 51) it is clear that large ranges of chemical shift can be expected. Compared to similar diphosphine complexes such as $[Rh(nbd)dppe]^+ClO_4^-$, $\delta(^{103}Rh) = -390$ ppm, the shifts for the present series of complexes are significantly downfield by the order of 600 ppm. Also of interest are the apparent ΔR contributions within the present series of compounds, which behave oppositely to previously reported systems wherein an upfield shift of $\delta(^{103}Rh)$ is associated with expansion of the ring from five to six members. For example, **11**, containing a five-membered ring, lies to lower field of the six-membered ring systems **12** and **13**; **14-18**, also five-membered ring systems, lie downfield of the analog, **19**, which contains a six-membered ring. It is predictable that strong σ donation by the imine nitrogen to rhodium will make a significant increase in the ligand field splitting of these related compounds and may account for the different NMR behavior exhibited by these complexes relative to the homofunctional bis(phosphine) complexes. However, previous observations have suggested that large upfield shifts for $\delta(^{103}Rh)$ are seen with increasingly strong σ-donor ligands, and not downfield shifts as occur in the present cases. It is, however, unclear how the coordination sphere about rhodium affects the ^{103}Rh chemical shift, but we suggest that chelate ring size and ligand basicity play an important role. It is clear

[2] The Rh NMR shifts are given relative to the absolute frequency standard of 3.16 MHz in the field where TMS protons resonate at 100 MHz (50).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

that more ^{103}Rh NMR data for different types of compounds must be correlated before the factors influencing ^{103}Rh chemical shifts can be extracted and understood.

Experimental section

All experimental manipulations were performed under an atmosphere of dry argon. Solvents were dried and distilled prior to use. $[Rh(cod)Cl]_2$ and $[Ir(cod)Cl]_2$ were prepared by standard procedures (52). The ligands **1–10** were prepared as described elsewhere (1, 2, 9–11).

^{1}H and ^{31}P NMR spectra were obtained on a Bruker WH400 instrument (operating at 400.13 and 161.97 MHz, respectively) using $SiMe_4$ and 85% H_3PO_4 as external standards. In all spectroscopic studies CD_2Cl_2 was used as both solvent and internal lock. Positive shifts lie downfield of the standard in all cases.

Inverse 2D ^{31}P and ^{103}Rh{^{1}H} NMR spectra were obtained on a Bruker WH-200 spectrometer using a 10 mm ^{1}H/^{31}P/^{2}H/^{103}Rh probe, built in our own laboratories, a second PTS 160 synthesizer (ϕ90), BSV-3 heteronuclear decoupler with broadband 1-65 MHz pulse amplifier for ^{103}Rh excitation, and a BVT 1000 temperature controller (±0.5°C). Samples were dissolved in 0.7 cm^3 of CD_2Cl_2 in 5 mm tubes. Pulse lengths were $\tau_{90}(^{31}P) = 15.5$ μs, $\tau_{90}(^{103}Rh) = 87$ μs.

[1] $90°(^{31}P)–1/2\ J(PRh)–90°(Rh)–t_1/2–180°(P)–t_1/2–90°(Rh)–AQ(^{31}P)$

The pulse sequence employed (eq. [1]) uses no 180°(Rh) pulses thus mitigating resonance offset effects caused by the long τ_{90}(Rh) and the large chemical shift range of this nucleus.

The value of J(PRh) and the ^{31}P window were first obtained from a routine ^{31}P{^{1}H} NMR spectrum. A guess of the ^{103}Rh frequency (approximately 6.124 MHz) was then made and a 2D survey spectrum (^{103}Rh sweep width = 50 000 Hz) taken, using an acquisition time of 1 s ($16t_1$ increments).

This process was repeated until the sweep width could be narrowed to 500 Hz. At this stage a complete 2D spectrum can be obtained with high resolution on both axes. After zero filling, the 256 × 1K matrix was transformed and the projections plotted. The F_2 projection is the ^{31}P spectrum with P–Rh coupling. The F_1 projection is the ^{103}Rh spectrum with P–P coupling, a consequence of the chosen pulse sequence. The accuracy of the $\delta(^{103}Rh)$ obtained is ±0.3 ppm.

Synthesis of [Rh(cod)(ligand)]$^+$PF$_6^-$ complexes. General method

The ligand (0.8 mmol) was added to a mixture of $[Rh(cod)Cl]_2$ (0.2 g, 0.4 mmol) and KPF_6 (0.2 g, 1.0 mmol) in dichloromethane (30 cm^3) and water (20 cm^3). The mixture was stirred vigorously at room temperature for up to 2 h. The dichloromethane layer was then removed and washed with water to remove excess KPF_6. The dichloromethane layer was decanted once more and the volume reduced to about 5 cm^3 under reduced pressure. Addition of hexane to the solution precipitated the complexes as microcrystalline orange-brown powders, which were filtered and dried *in vacuo*.

$[Ir(cod)(ligand)]^+PF_6^-$ complexes were obtained by an identical method to the above using $[Ir(cod)Cl]_2$ as the metal source.

*(i) [Rh(cod)(Ph$_2$PCH(Me)P(Ph)$_2$=NC$_6$F$_4$CN)]$^+$ PF$_6^-$ (**14**)*

Treatment with $(Ph_2PCH(Me)P(Ph_2)=NC_6F_4CN)$ (11) (0.46 g, 0.8 mmol) gave **14** as a fine orange microcrystalline powder (0.690 g, 93%); mp 168–180°C (dec.) ^{1}H NMR (CD_2Cl_2) δ: 7.1–8.3 (m, 20H, phenyl), 5.3 (m br, 1H, cod olefinic), 4.4 (m br, 1H, cod olefinic), 3.9 (ddq, 1H, $^3J_{HH}$ 7.2, $^2J_{P^VH}$ 12.2, $^2J_{P^{III}H}$ 22.2 Hz), 3.3 (m. br, 2H, cod olefinic), 1.7–2.7 (m, 8H, cod alkyl), 1.35 (ddd, 3H, $^3J_{HH}$ 7.2, $^3J_{P^VH}$ 10.4, $^3J_{P^{III}H}$ 18.0 Hz). ^{31}P NMR (CD_2Cl_2) δ: 53.4 (d, 1P^V, $^2J_{PP}$ 41.8 Hz), 31.92 (dd, 1P^{III} $^2J_{PP}$, 41.8, $^1J_{PRh}$ 152.7 Hz), −144.3 (PF_6^-) (sept, 1P, $^1J_{PF}$ 710.8 Hz). MS (FAB): (100%) 796.4, [M]$^+$. Anal. calcd. for $C_{41}H_{34}F_{10}N_2PRh$: C 52.3, H 3.8, N 3.0; found: C 51.7, H 3.9, N 2.8%.

The complexes **15–24** were obtained similarly.

*(ii) [Rh(cod)(Ph$_2$PCH$_2$P(Ph$_2$)=NC$_6$F$_4$CN]$^+$ PF$_6^-$ (**15**)*

Treatment with $Ph_2PCH_2P(Ph_2)=NC_6F_4CN$ (2) (0.46 g, 0.8 mmol) gave **15** as a fine orange powder (0.606 g, 81.5%); mp 156–160°C (dec.). ^{1}H NMR (CD_2Cl_2) δ: 7.6 (m, 20H, phenyl), 3.5 (d, 2H, $^1J_{PH}$ 9.25 Hz), 3.3 (s br, 4H, olefinic), 2.2 (m, 8H, cod). ^{31}P NMR (CD_2Cl_2) δ: 51.3 (d, 1P^V, $^2J_{PP}$ 33 Hz), 24.2 (dd, 1P^{III}, $^2J_{PP}$ 33, $^1J_{PRh}$ 153.7 Hz), −144.3 (PF_6^-) (sept, 1P, $^1J_{PF}$ 710.9 Hz). MS (FAB): (100%) 783 [M]$^+$. Anal. calcd. for $C_{40}H_{34}F_{10}N_2P_3Rh{\cdot}CH_2Cl_2$: C 48.5, H 3.5, N 2.8; found: C 48.6, H 3.5, N 2.8%.

*(iii) [Rh(cod)(Ph$_2$PCH$_2$P(Ph$_2$)=NC$_6$F$_3$(CN)$_2$]$^+$ PF$_6^-$ (**16**)*

Treatment with $Ph_2PCH_2P(Ph_2)=NC_6F_3(CN)_2$ (9) (0.46 g, 0.8 mmol) gave **16** as an orange-brown microcrystalline powder (0.427 g, 57%); mp 214°C (dec.). ^{1}H NMR (CD_2Cl_2) δ: 7.1–8.0 (m, 20H, phenyl), 5.3 (m, 2H, cod olefinic), 4.3 (m, 2H, cod olefinic), 3.7 (m, 2H, PCH_2P), 1.9–2.8 (m, 8H, cod alkyl). ^{31}P NMR (CD_2Cl_2) δ: 51.6 (dd, 1P^V, $^2J_{PP}$ 33, $^2J_{PRh}$ 4.5 Hz), 22.9 (dd, 1P^{III}, $^2J_{PP}$ 33, $^1J_{PRh}$ 153.7 Hz), −144.3 (PF_6^-) (sept, 1P, $^1J_{PF}$ 711.1 Hz). MS (FAB): (49%) 790.2 [M]$^+$. Anal. calcd. for $C_{41}H_{34}F_9N_3P_3Rh$: C 49.5, H 3.5, N 4.1; found: C 49.8, H 3.3, N 4.3%.

*(iv) [Rh(cod)(Ph$_2$PCH$_2$P(Ph$_2$)=NC$_6$H$_2$F(NO$_2$)$_2$)]$^+$ PF$_6^-$ (**17**)*

Treatment with $Ph_2PCH_2P(Ph_2)=NC_6H_2F(NO_2)_2$ (9) (0.46 g, 0.8 mmol) gave **17** as an orange-red microcrystalline powder (0.517 g, 67%); mp 180°C (dec.). ^{1}H NMR (CD_2Cl_2) δ: 8.5 (dd, 1H, $^4J_{HF}$ 7.5, $^5J_{HP}$ 1.4 Hz), 7.1–8.0 (m, 20H, phenyl), 6.8 (dd, 1H, $^3J_{HF}$ 11.0, $^3J_{HP}$ 2.0 Hz), 5.5 (m, 1H, cod olefinic), 4.2 (m, 1H, cod olefinic), 3.7 (m, 2H, PCH_2P), 3.4 (m, 1H, cod olefinic), 3.2 (m, 1H, cod olefinic) 1.8–2.9 (m, 8H, cod alkyl). ^{31}P NMR (CD_2Cl_2) δ: 51.0 (dd, 1P^V, $^2J_{PP}$ 32.1, $^2J_{PRh}$ 3.6 Hz), 23.0 (dd, 1P, $^2J_{PP}$ 32.1, $^1J_{PRh}$ 152.9 Hz), −144.3 (PF_6^-) (sept, 1P, $^1J_{PF}$ 712.2 Hz). MS (FAB): (13.6%) 794 [M]$^+$. Anal. calcd. for $C_{39}H_{36}F_7N_3O_4P_3Rh{\cdot}CH_2Cl_2$: C 46.8; H 3.7; N 4.1; found: C 45.3, H 3.8, N 4.0%.

Isolation and structures of the uprolides. I. Thirteen new cytotoxic cembranolides from the Caribbean gorgonian *Eunicea mammosa*[1]

Abimael D. Rodríguez, Ivette C. Piña, Javier J. Soto, Dalila R. Rojas, and Charles L. Barnes

Abstract: Thirteen new cembranolide diterpenoids, uprolides **3–15**, have been isolated from the Caribbean gorgonian *Eunicea mammosa* collected off the West coast of Puerto Rico. Several known metabolites, such as eupalmerin acetate (**1**) and eupalmerin (**2**), were also isolated from the same organism. The structures of the new compounds, which also showed modest in vitro cytotoxic activity, were assigned on the basis of extensive nuclear magnetic resonance analysis, chemical correlation studies, and by comparison with analogous spectral data from known cembranolide diterpenoids. One structure (**3**) was confirmed by X-ray diffraction analysis.

Key words: uprolides, *Eunicea mammosa*, cytotoxicity, Caribbean, gorgonian.

Résumé : On a insolé 13 nouveaux diterpénoïdes de la famille du cembranolide, les uprolides **3–15**, à partir d'*Eunicea mammosa* gorgone des Caraïbes récoltés près de la côte ouest de Porto Rico. À partir des mêmes organismes, on a aussi isolé plusieurs métabolites connus, comme l'acétate d'eupalmérine (**1**) et l'eupalmérine (**2**). Les structures des nouveaux composés, qui présentent aussi une faible activité cytotoxique in vitro, ont été attribuées en se basant sur des analyses poussées de RMN, sur des études de corrélation chimique et par comparaison avec des données spectrales analogues obtenues à partir de diterpénoïdes cembranolides connus. La structure **3** a été confirmée par diffraction des rayons X.

Mots clés : uprolides, *Eunicea mammosa*, cytotoxicité, Caraïbes, gorgonidé.

[Traduit par la rédaction]

Introduction

Although many secondary metabolites isolated from coelenterates have been reported to possess very exciting pharmacological properties, the number of research articles describing new natural products from gorgonians and soft corals appears to be declining. However, despite their paucity, new structures continue to emerge. Invariably, diterpenes continue to represent the major group of compounds isolated from both soft corals and gorgonians (1). The success of gorgonians against predation and against overgrowth by competing organisms may be at least in part due to the secretion of defense substances (2). These substances include diterpenoids related to cembrene, a diterpene with a 14-membered ring. Specimens of *Eunicea mammosa* and *Eunicea succinea*, two common Caribbean gorgonian species, have yielded throughout the last three decades many highly functionalized biologically active cembranolides depending upon their geographical origin (3–20). Recent investigations of the cytotoxic constituents of the Caribbean gorgonian octocoral *E. mammosa* in this laboratory have resulted in the isolation of eight new cembranoid diterpenes that were identified by interpretation of spectral data and chemical interconversions (21–24). Continuing to examine *E. mammosa* extracts from Puerto Rico, we have now isolated and report here on 13 new cembranolide diterpenes, which can be considered as the first examples of naturally occurring cembranolides isolated from a Caribbean gorgonian depicting unsaturation at position C-6 or C-8. The new cembranolide diterpenoids, named collectively as the uprolides,[6] were identified by spectroscopic methods and chemical interconversions, and one structure has been confirmed by X-ray diffraction analysis. These metabolites, which showed moder-

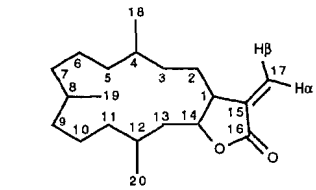
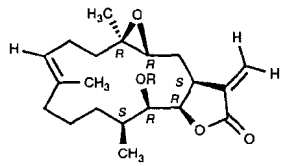
ate cytotoxic action against several animal and human tumor cell lines, could be envisioned as functionalized structural congeners of eupalmerin acetate (**1**) and eupalmerin (**2**), two well-known γ-cembranolides isolated earlier from specimens of the gorgonian collected near Puerto Rican waters (21–24). The specimens of *E. mammosa* were collected off the West coast of Puerto Rico near Mona Island and were frozen after collection and then freeze-dried prior to extraction with 1:1 MeOH–EtOAc. From the hexane and $CHCl_3$ extracts, diterpenes **3–15** were isolated by conventional chromatographic procedures (see Experimental).

Results and discussion

The composition $C_{22}H_{32}O_6$ for the new terpenoid uprolide-A acetate (**3**) derives from high-resolution fabms and ^{13}C nmr



γ-CEMBRANOLIDE SKELETON



1 R = Ac
2 R = H

4

data. The latter, obtained in $CDCl_3$, revealed 22 resonances for 4 CH_3, 6 CH_2, 7 CH, and 5 C. Three of the seven methine carbons were sp^3 at a heteroatom, two were sp^3 not connected to a heteroatom, and two were olefinic. One of the methylene carbons was sp^2 and two of the quaternary carbon atoms were those of ester C=O functionalities. This suggests a tricyclic diterpene all three cycles of which are accounted for by an epoxidized cembranolide, as in the case of eupalmerin acetate (**1**). Uprolide-A acetate (**3**) shows an ultraviolet absorption maximum at 212 nm (ε 25 300) suggesting the existence of an α-methylene-γ-butyrolactone ring. The infrared spectrum inferred the presence of a hydroxyl (3550 cm^{-1}), a conjugated carbonyl (1766 cm^{-1}), and isolated ester (1733 cm^{-1}) moieties. The ^1H nmr spectrum (300 MHz; $CDCl_3$) shows the signals of four olefinic protons (δ 6.10 (1H, d, J = 3.3 Hz), 5.45 (1H, d, J = 15.6 Hz), 5.39 (1H, m), and 5.29 (1H, d, J = 3.3 Hz)), the presence of three 3H singlets at δ 1.89, 1.35, and 1.27 indicating an acetate ester group and methyl groups in an *E*-trisubstituted epoxide and tertiary carbinol, respectively, while a 3H doublet at δ 0.85 (J = 6.9 Hz) indicated a methyl group bonded to a tertiary carbon atom. In addition, the ^1H nmr spectrum shows three separate methine protons on carbon atoms bearing oxygen at δ 5.11 (1H, d, J = 10.2 Hz), 4.80 (1H, d, J = 8.1 Hz), and 2.93 (1H, dd, J = 3.6, 10.2 Hz). The proton networks were determined by H–H COSY and decoupling difference spectra, and the connectivity of each network through the quaternary carbons was deduced by INEPT and NOESY spectra, which led to the structure **3** for uprolide-A acetate. The *E* configuration of the Δ^6 olefin was suspected from the high-field chemical shift value (δ 73.7) of the allylic C-8 resonance line (25), the presence of a strong sharp infrared band at 968 cm^{-1}, the absence of nOe between the ethylenic protons H-6 and H-7, and the coupling constant observed for the partially overlapped doublet centered at δ 5.45 (J = 15.6 Hz) ascribed to H-7. The relative configurations at C-1, C-3, C-4, C-12, C-13, and C-14, all common stereochemistry elements present in eupalmerin acetate (**1**), were established from the ^1H and ^{13}C nmr data, H–H COSY, NOESY, and the similarity of the J values involving protons at these sites to those observed for **1** (22). At this point the only major structural feature that remained to be determined was the stereochemical orientation of the C-8 methyl substituent. Although there were a few intense nOe responses to the Me-19 protons in the NOESY spectrum of **3**, none gave reliable information about the stereochemical identity at C-8. Fortunately, compound **3** could be crystallized in a form suitable for X-ray diffraction analysis, which established the relative configuration at C-8 and confirmed the rest of our structural assignments (Fig. 1). Since the absolute configuration of eupalmerin acetate (**1**) has been established (11) and compounds **1** and **3** have identical relative configuration at all common chiral centers, we can safely assume that they also have the same absolute configuration. Since the C-1,3,4,12,13,14 constellation has been correlated by X-ray diffraction analysis with the remaining chiral center at C-8, the absolute stereochemistry at that center must be *S*.

The high-resolution ei mass spectrum of compound **4**, obtained as a uv-active colorless oil, gave major ions at *m/z* 374.20624 for $C_{22}H_{30}O_5$ and *m/z* 332.19765 for $C_{20}H_{28}O_4$, which reflect fragmentations of $[M - H_2O]^+$ and $[M - AcOH]^+$, respectively, from the actual molecular composition of $C_{22}H_{32}O_6$. This homogeneous compound also showed a hydroxyl absorption at 3552 cm^{-1} and two ester carbonyl absorptions at 1770 and 1740 cm^{-1} in its infrared spectrum. The ^1H and ^{13}C nmr spectra of compound **4** showed a striking similarity to those of uprolide-A acetate (**3**) (see Tables 1 and 4). These similarities, together with the fact that **3** and **4** possess identical molecular formulae, suggested a close structural relationship between these compounds. A detailed comparison of their ^1H and ^{13}C nmr spectra revealed that the few differences observed were in fact consistent with a change in relative stereochemical orientation of the Me-19 group at C-8. The change at C-8 from *S* in **3** to *R* in **4** was clearly indicated by the ^{13}C nmr chemical shift difference of the Me-19 groups (δ 25.6 in **3** vs. 30.1 in **4**) and the signal at δ 18.9 associated with the nearby C-10 methylene in **3**, which appears shifted upfield to 17.1 ppm in **4**. The ^1H and ^{13}C nmr data for **4**, along with the analysis of J values, H–H COSY, NOESY, and a heteronuclear chemical shift correlation with broad-band decoupling (CSCMBB) experiment showed that all common stereochemistry elements remaining were un-changed. Compound **4** was therefore named 8-epi-uprolide-A acetate.

Compound **5**, which was named uprolide-B, was isolated as a uv-active (λ_{max} 212 nm) oily substance that analyzed for $C_{20}H_{30}O_5$ by combined high-resolution fabms and ^{13}C nmr methods. The compound showed ir spectral characteristics consistent with the presence of an epoxide ring (1268 and 822 cm^{-1}) and of an ester carbonyl functionality (1755 cm^{-1}). A very intense broad absorption near 3405 cm^{-1} suggested the presence of more than one hydroxyl functionality. The ^1H nmr

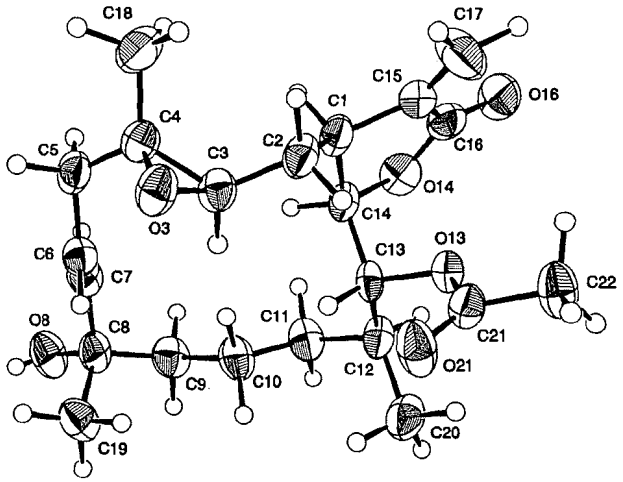
[a]Assignments were aided by H–H COSY, H–C COSY, spin splitting patterns, and comparison of *J* values.

Fig. 1. 3D structure for uprolide-A acetate (**3**) obtained by X-ray diffraction analysis with atomic labeling. Small circles represent hydrogen atoms.



spectrum of uprolide-B (Table 1) showed two sharp 1H doublets at δ 5.98 (*J* = 3.1 Hz) and 5.43 (*J* = 3.1 Hz), suggesting the presence of a γ-lactone conjugated to an exomethylene group, and two multiplets at δ 5.56 (1H, d, *J* = 15.9 Hz) and 5.33 (1H, ddd, *J* = 4.8, 9.6, 15.9 Hz), due, respectively, to a 1,2-disubstituted olefin. Moreover, two doublets centered near δ 4.80 (1H, *J* = 8.2 Hz) and 3.65 (1H, *J* = 10.2 Hz), and one doublet of doublets at δ 3.00 (1H, *J* = 3.0 and 10.8 Hz), could be attributed to methine protons on carbon atoms bearing oxygen (H-14, H-13, and H-3, respectively). The two 3H singlets at δ 1.39 and 1.27 have been ascribed to the methyl groups placed, respectively, at C-8 and C-4, while the doublet at δ 1.03 (*J* = 6.9 Hz), integrating as 3H, is ascribable to the methyl group attached to C-12. The ^{13}C nmr spectrum of uprolide-B exhibited 20 signals separated by APT into 4 quaternary carbons (C-4, C-8, C-15, and C-16), 7 CH groups (C-1, C-3, C-6, C-7, C-12, C-13, and C-14), 6 methylenes (C-2, C-5, C-9, C-10, C-11, and C-17), and 3 Me groups (C-18, C-19, and C-20), 1 ester carbonyl (δ 172.8 (s)), 5 oxygenated carbons (δ 86.2 (s), 79.6 (d), 72.5 (d), 62.8 (s), and 59.1 (d)), and 4 olefinic (δ 140.8 (s), 139.6 (d), 127.5 (d), and 117.0 (t)) carbons. By use of a H–H correlation COSY experiment the chain of coupling between protons H-12 through H-14 and H-1 through H-3, including the terminal methylene protons H-17αβ, could be established. Comparison of the ^{1}H and ^{13}C nmr spectra of uprolide-B (**5**) and eupalmerin (**2**) (23) revealed that these compounds share many common structural features and that all common stereochemistry elements (C-1, C-3, C-4, C-12, C-13, and C-14) remain unchanged. Likewise, comparison of the nmr spectra of uprolides **3** and **5** (including COSY and NOESY) also revealed many common structural features (i.e., same relative configuration at C-8), which suggested that the major differences between these compounds were associated mainly with the stereochemical orientation of the Δ^6 olefin. In the spectrum of uprolide-A acetate (**3**) the olefinic protons H-6 and H-7 nearly

[a]Assignments were aided by H–H COSY, H–C COSY, spin splitting patterns, and comparison of *J* values.

overlap at δ 5.42, whereas the spectrum of uprolide-B (**5**) contains an olefinic signal at δ 5.33 (1H, ddd, $J = 4.8, 9.6, 15.9$ Hz) for H-6 and another at δ 5.56 (1H, d, $J = 15.9$ Hz) ascribable to H-7. Although the large coupling constant (15.9 Hz) observed in **5** for the Δ^6 olefinic protons suggests a *trans* configuration, the strong downfield shift experienced by the C-8 resonance (δ 86.2 in **5** vs. 73.7 in **3**) clearly indicates a change in stereochemical orientation about the ethylenic double bond. *trans* Ethylenic coupling constants (12–24 Hz) are always larger than *cis* ethylenic coupling constants (3–18 Hz) in any vinyl compound or for a pair of 1,2-disubstituted ethylenes (26). However, the literature contains a large amount of scattered data for coupling in olefinic systems that show that the two ranges often overlap (27). Because bond order or bond length, valence angles, and hybridization of the olefinic carbon atoms may also constitute factors determining the magnitude of the olefinic coupling constant, it is unlikely that, at the present state of knowledge, the magnitude of *J* in structure **5** (and that of its acetylated derivatives **6** and **7**), could be directly applied to the solution of their structures. The almost identical coupling constant values of $J_{6,7} \cong 15.7$ Hz observed for **3** and **5** clearly show that the assignment of *trans* and *cis* stereochemistry at Δ^6 in this series is not a simple task and that one must carefully examine other evidence available before the correct geometry can be established. On the other hand, the *E* and *Z* geometry of the Δ^6 double bonds in **3** and **5**, respectively, is clearly shown by the ^{13}C nmr chemical shift difference of the Me-19 groups (δ 25.6 vs. 19.3), the C-8 carbons (δ 73.7 vs. 86.2), and the signal at δ 42.2 associated with the C-9 methylene in **3**, which appears shifted upfield to 38.4 in **5**. Thus an empirical relationship appears to exist between the C-19 methyl, the C-8, and the nearby C-9 methylene carbon chemical shifts with the *E-Z* configuration of the Δ^6 olefin in the uprolide series. The *Z* geometry of the ethylenic double bond in **5** was also supported by a strong nOe between the olefinic protons H-6 and H-7 (absent in **3**) and the absence of a strong band near 968 cm^{-1} in the infrared spectrum that is present in **3**. The present analysis confirms the structure proposed for uprolide-B, including all the stereochemical assignments.

The low-resolution fab mass spectrum and the ^{1}H and ^{13}C nmr data of **6** were consistent with the molecular formula $C_{22}H_{32}O_6$. The infrared band at 3380 cm^{-1} suggested the presence of a hydroxyl group and two strong bands at 1764 and 1740 cm^{-1} could be assigned to ester carbonyl groups. The uv spectrum indicated the presence of the same chromophore observed in all the previous compounds: λ_{max} = 214 nm (ε 9825). Comparison of the ^{1}H and ^{13}C nmr spectra of **6** with those of uprolide-B (**5**) revealed only a few differences, all of which were consistent with the replacement of the hydroxyl group at C-13 in **5** with an acetoxy group in **6**. For instance, in the ^{1}H nmr spectrum of uprolide-B the H-13 proton resonates at δ 3.65 (1H, d, $J = 10.2$ Hz), whereas the spectrum of **6** contained the H-13 signal at δ 5.13 (1H, d, $J = 10.5$ Hz), Also, the presence in the nmr spectra of an acetate signal (δ 1.90 (3H, s);

169.9 (s) or 169.6 (s)) also supported structure **6** for uprolide-B acetate. These spectral features suggested a close similarity between **6** and uprolide-B (**5**).

The ^{1}H nmr spectrum of **7** was almost identical with that of uprolide-B acetate (**6**), with the exception that it contained an extra acetate signal at δ 1.96 (3H, s) and that the signal for Me-19 had shifted from δ 1.35 in **6** to δ 1.50 in compound **7**. The high-resolution ei mass spectrum showed its highest ion peak at *m/z* 392.22073 for $C_{22}H_{32}O_6$, which reflects the loss of one molecule of ketene from the actual molecular composition of $C_{24}H_{34}O_7$, followed by major ions at *m/z* 374.20849 for $C_{22}H_{30}O_5$, *m/z* 332.19698 for $C_{20}H_{28}O_4$, and *m/z* 314.18701 for $C_{20}H_{26}O_3$. The latter ion peaks reflect fragmentations of $[M - AcOH]^+$, $[M - AcOH - C_2H_2O]^+$, and $[M - 2AcOH]^+$, respectively. The ^{13}C nmr spectrum in $CDCl_3$, which also showed a striking resemblance to that of uprolide-B acetate (**6**), exhibited signals for 24 carbon atoms suggesting a diterpene diacetate: 3 were carbonyls (δ 170.0, 169.8, and 169.6) and 5 were methyl carbons (δ 22.4, 20.9, 20.8, 18.3, and 15.9). These spectral features suggested that **7**, named uprolide-B diacetate, had a close similarity to both uprolide-B (**5**) and uprolide-B acetate (**6**). That the stereochemistry at the Δ^6 double bond and chiral center C-8 was identical for the uprolides **5**, **6**, and **7** could be shown by the similarity of the ^{13}C nmr chemical shift values involving these sites (see Table 4).

The ir, uv, high-resolution fabms, and the ^{1}H and ^{13}C nmr data of **8**, **9**, and **10** clearly indicated that they too belonged to the uprolide-B diterpene class. These metabolites exhibited nmr spectra that were virtually superimposable on those of uprolides **5**, **6**, and **7**, respectively, except that the ^{13}C nmr signals for the Me-19 group consistently showed a downfield shift to 24–25 ppm that argued for the net inversion of their stereochemical orientation at C-8. The near identical upfield shift to

[a]Multiplicities were obtained by an Attached Proton Test (APT) experiment. Assignments were made on the basis of heteronuclear chemical shift correlation methods, carbon atom multiplicities, and chemical shift values. The δ values are in parts per million and are referenced to $CDCl_3$ (77.0 ppm).

[b]Values with identical superscripts in each column may be interchanged.

19–20 ppm experienced by the Me-19 group in uprolides **5**, **6**, and **7** is in line with the opposite stereochemistry at C-8 shown for these compounds. Moreover, the 8*R* configuration depicted in **8**, **9**, and **10** is also consistent with the ^{13}C nmr chemical shift values in $CDCl_3$ solution observed for C-10 (16–17 ppm) that consistently appear shifted downfield to 18–19 ppm in uprolides **5**, **6**, and **7**. These trends, which were observed consistently in those cembranolides belonging to the uprolide-A series (i.e., **3** and **4**), where the Δ^6 olefin has the *E* configuration, may constitute an invaluable method for the assignment of relative stereochemistry at C-8 in the uprolide diterpene series. Interestingly, *Z*-olefins **8–10**, in addition to having ^{13}C nmr chemical shift values for C-8 in the expected range (82–84 ppm; see Table 5), have the usual J_{cis} values (11–12 Hz). This observation suggests that the relative stereochemistry of the substituents at C-8 in the uprolide B series may in fact constitute yet another factor in determining the large coupling constant observed for the *Z*-olefinic protons in uprolides **5–7**. The present analysis confirms the structure proposed for 8-epi-uprolide-B (**8**), 8-epi-uprolide-B acetate (**9**), and 8-epi-uprolide-B diacetate (**10**), including their complete stereochemical assignments. The rigorous assignments of the ^1H and ^{13}C nmr spectra of uprolides **8**, **9**, and **10** (Tables 2 and 5) were established by application of several 2D-nmr techniques that included H–H COSY, CSCMBB, and NOESY experiments.

Uprolide-C (**11**) had the molecular formula $C_{20}H_{30}O_5$, *m/z* 357.22510, $[M + Li]^+$, and showed a uv absorption at λ_{max} 212 nm (ε 9800) and infrared absorptions at ν 3433, 1740, 1643, and 1274 cm^{-1}, typical for an alcohol, a γ-lactone, an olefin, and one epoxy group. The ^{13}C nmr spectrum (Table 5) exhibited 20 signals divided by APT into 4 quaternary carbons, 6 methine carbons, 8 methylenes, and 2 methyl groups. The ^1H nmr spectrum (Table 2) contained a proton signal at δ 2.82 (dd, J = 4.8, 9.0 Hz), which could be assigned to an α-epoxy proton, and showed additional signals at δ 6.12 (1H, d, J = 3.3 Hz) and 5.38 (1H, d, J = 3.3 Hz) due to a pair of terminal methylene protons. In addition, the spectrum of uprolide-C showed signals at δ 5.05 (1H, br s) and 5.03 (1H, br s) due to a second pair of terminal methylene protons, some key signals at δ 4.71 (1H, d, J = 8.1 Hz), 4.36 (1H, br t, J = 3.9 Hz), and 3.69 (1H, br d, J = 8.4 Hz), and two methyl signals: one a singlet at δ 1.32 (3H) and one a doublet at δ 1.03 (3H, J = 6.6 Hz). Comparison of the ^1H and ^{13}C nmr spectra of **11** with those of **5** and **8** suggested for **11** the same substituted cembranolide ring as in compounds **5** and **8** and, in addition, suggested that the usual Δ^6 olefin in the latter compounds had now shifted to an exocyclic position and that the C-8 hydroxyl group is now located at C-7 in uprolide-C (**11**). The COSY experiment established the following correlations: H-20 to H-12; H-12 to H-11 and H-13; H-13 to H-14; H-14 to H-1; H-1 to H-2αβ and H-17αβ; H-2αβ to H-3; H-5αβ to H-6αβ; H-6αβ to H-7; and H-7 to H-19αβ. These connec-

[a]Multiplicities were obtained by an Attached Proton Test (APT) experiment. Assignments were made on the basis of heteronuclear chemical shift correlation methods, carbon atom multiplicities, and chemical shift values. The δ values are in parts per million and are referenced to $CDCl_3$ (77.0 ppm).

[b]Values with identical superscripts in each column may be interchanged.

[c]Due to poor solubility this sample was run in a mixture of $CDCl_3/CD_3OD$.

tions established the C-11 to C-3 (including C-17) and C-5 to C-7 (including C-19) segments of the molecule, leaving unconnected the C-3 to C-5 and C-7 to C-9 bonds in a manner consistent with the proposed structure for uprolide-C. The relative stereochemistry shown at C-7 is based on the ^{13}C nmr chemical shift difference of the C-7 carbon (δ 85.9), which appears shifted upfield to 70–73 ppm when the C-7 hydroxyl group is in the β configuration (28–30). Moreover, because uprolide-C is sparingly soluble in $CHCl_3$, we argue that the two hydroxyl groups of diol **11** must be oriented in opposite directions with respect to the cembrane skeleton (i.e., *trans*). Examination of a Dreiding model of uprolide-C (**11**) reveals that when the two hydroxyl groups lie on opposite faces of the cembrane ring, **11** can adopt a stable conformation allowing favorable hydrogen-bonding interactions between them that could reduce its solubility in $CHCl_3$. Interestingly, an attempt to acetylate uprolide-C with pyridine – acetic anhydride at 25°C did not produce the expected diacetate (i.e., **13**). Instead, diol **11** was found to be unstable under these conditions, yielding exclusively uprolide-A acetate (**3**).

The structure of uprolide-C acetate (**12**) could readily be assigned by comparison of its ^1H and ^{13}C nmr data with those of uprolide-C (**11**). The multiplicities of all ^1H nmr resonances in these two compounds were nearly identical as were the chemical shifts, except for one acetate methyl signal in the

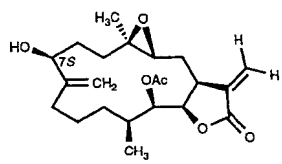
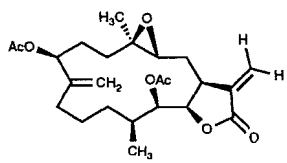
13 R = Ac



14



15

spectrum of **12** and a downfield shift for H-13 consistent with replacing the C-13 hydroxyl group of **11** with an acetoxy group in **12**. Compound **12**, which was readily soluble in $CHCl_3$, can be assigned the same stereochemical orientation at C-7 as found for uprolide-C since, as in **11**, the C-7 nmr resonance appears more downfield (δ 89.8) than those found in the next set of compounds (i.e., **14** and **15**) (28–30). These data, combined with the ir, uv, ms, and 2D-nmr spectra, support the structure assigned to uprolide-C acetate (**12**).

The ^1H nmr spectrum of uprolide-C diacetate (**13**) was vir-

tually superimposable on that of **12** except that it contained one more acetate methyl signal at δ 2.04 (3H, s). The strong upfield shift experienced by C-7 and the downfield shift observed for H-7 in the ^{13}C and ^{1}H nmr spectra, respectively, confirmed that the new acetate group is at position 7. Structure **13** was thus inferred, and this was adequately substantiated by results of ir, uv, high-resolution fabms, H–H COSY, CSCMBB, and NOESY experiments that provided ^{1}H and ^{13}C nmr resonance assignments and skeletal connectivity evidence.

The high-resolution fabms established a molecular formula of $C_{22}H_{32}O_6$ for cembranolide **14**, indicating that it was an isomer of uprolide-C acetate (**12**). Like **12**, compound **14** showed ir absorptions (3493, 1775, and 1741 cm^{-1}) that indicated the presence of a hydroxyl and diester functionalities. Comparison of the ^{1}H and ^{13}C nmr spectra of **14** with those of uprolide-C acetate (**12**) confirmed the structural similarity of these compounds and revealed the presence of one structural feature unique to **14**. The identity and location of the substituents around the cembranolide ring system as well as the unsaturation profile were assumed to be intact in **14** on the basis of similar ir, ms, uv, and 1D- and 2D-nmr data (compare signals of related H's and C's in Tables 3 and 6). The major differences observed, however, were associated with a change in **14** in its relative configuration at C-7. A broad signal at δ 4.25 (1H, br s), assigned to an allylic β-hydroxyl proton (H-7), was correlated in the ^{13}C nmr spectrum to a carbon resonance at δ 73.3 (C-7). Thus, the stereochemistry at C-7 in **14** is based on the chemical shift difference of the C-7 carbon resonance, which appears shifted downfield to δ 89.8 in **12** (28–30). These data suggested that 7-epi-uprolide-C acetate (**14**) contained an allylic β-hydroxyl group at C-7.

Although no molecular ion peak was detected in the high-resolution ei mass spectrum of 7-epi-uprolide-C diacetate (**15**), analysis of the major ion peaks and ^{13}C nmr data revealed the actual molecular composition to be $C_{24}H_{34}O_7$. Therefore, **15** was shown to be an isomer of uprolide-C diacetate (**13**). The high-resolution mass spectrum exhibited $[M - C_2H_2O]^+$, $[M - AcOH]^+$, $[M - AcOH - C_2H_2O]^+$, and $[M - 2AcOH]^+$ peaks at *m/z* 392.21976, 374.21395, 332.19826, and 314.18851, respectively, under a variety of conditions. H–H COSY experiments, and comparison of overall ^{1}H and ^{13}C nmr data revealed similarities between **13** and **15**, and showed that the same partial structures are also present in this compound. However, there were several significant differences in the spectral data that indicated that **15** was the C-7 epimer of uprolide-C diacetate (**13**). Thus, the stereochemistry at position 7 in **15** is based on the chemical shift difference of the C-7 carbon (δ 73.1), which appears shifted downfield to δ 78.1 in epimer **13**. Also, the structure of compound **15** was correlated chemically with that of **14** upon acetylation of the latter with a mixture of pyridine – acetic anhydride for 12 h at 25°C. The acetylation of **14** to give 7-epi-uprolide-C diacetate (**15**) proceeded normally without rearrangement to either **3**, **4**, **6**, or **9**.

Like most structural congeners of eupalmerin acetate (**1**), the uprolides also showed modest cytotoxic activity (in vitro testing). The inhibitory activities of the uprolides A–C against several human tumor cell lines are depicted in Table 7.

Conclusions

Conclusions regarding the spectral analyses of the uprolides were strongly supported by the simultaneous isolation, from the same source, of 13 closely related compounds. The structure of model compound uprolide-A acetate (**3**) was determined by spectral and crystallographic methods. The nmr and other spectral data for the other uprolides were highly analogous with comparable data from **3**. Moreover, an empirical relationship appears to exist in the uprolide-A and -B series between the ^{13}C nmr chemical shift values of C-19, C-8, C-9, and C-10 with the *E-Z* configuration of the Δ^6 olefin. Also, there seems to be an empirical relationship between the ^{13}C nmr chemical shift values of C-19 and C-10 and the relative configuration at C-8. The relative configuration at C-8 in the uprolide-B series could also be a factor in determining the magnitude of the Δ^6 olefinic coupling constant. These efforts provide a partial data base that can be employed in the structure elucidation of new cembranolide analogues.

Experimental

Collection and extraction of *E. mammosa*

The Caribbean gorgonian *E. mammosa* was collected by hand in November 1992 from Mona Island, Puerto Rico, using SCUBA at 15–20 m. The gorgonian was freeze-dried upon arrival and kept frozen until extraction. The dried animal (1.30 kg) was blended with MeOH:EtOAc (1:1) (3 × 2 L) and after filtration the crude extract was evaporated under vacuum to yield a residue (162.25 g) that was partitioned between hexane and H_2O and then between $CHCl_3$ and H_2O. The hexane extract was concentrated in vacuo to yield 94.45 g of a dark-green oily residue. This residue was dissolved in 1 L of toluene and, after filtration through a mixture of sand and Celite, the resulting filtrate was concentrated in vacuo. The residue obtained (49.78 g) was fractionated by size exclusion chromatography on a Bio-Beads SX-2 column using toluene as eluent. The combined terpenoid-rich fractions (tlc-guided) were concentrated to a yellow-orange oil (39.02 g) that was chromatographed over a silica gel column (850 g) with 10% EtOAc in hexane. The less polar fractions consisted of a complex mixture of unidentified sesquiterpenes, sterols, and fatty acid derivatives (17.2 g) and the following known cembranolide diterpenes: eupalmerin acetate (**1**) (2.00 g), eupalmerin (**2**) (2.33 g), pseudoplexauric acid methyl ester (0.47 g), euniolide (6.02 g), (−)-eunicenone (0.65 g), 14-deoxycrassin (1.03 g), eupalmerone (1.12 g), and the known cembranoid diterpene (7*E*, 11*E*)-(1*S*, 3*R*, 4*R*)-3,4; 15,17-diepoxycembra-7,11-diene (0.83 g) (21–24, 31). The more polar portion of the lipids was fractionated roughly into fractions A through O on the basis of the tlc analyses. Repeated column chromatography of fraction O (3.40 g) on silica gel (100 g) with 10% EtOAc in hexane gave four fractions. Purification of fraction II (287 mg) by hplc (Zorbax C-8 ODS silica gel with 35% H_2O in MeOH) afforded 13.1 mg of 8-epi-uprolide-B acetate (**9**). Fraction III (1.38 g) was purified by hplc (Partisil 10 silica gel using 10% isopropanol in hexane) to give pure uprolide-B acetate (**6**) (9.1 mg) and uprolide-C acetate (**12**) (15.9 mg). Fraction IV (1.04 g) was purified by reversed-phase column chromatography with ODS silica gel using a 80:20 mixture of MeOH–H_2O to give pure 8-epi-uprolide-B (**8**) (11.3 mg), followed by a mixture that, after subsequent separation by hplc (Partisil 10 silica gel with 15% isopropanol in hexane), afforded uprolide-B (**5**) (53.7 mg) and uprolide-C (**11**) (33.3 mg).

After filtration and concentration, the $CHCl_3$ extract yielded 39.16 g of a dark-orange oily residue. This residue was dissolved in toluene and then was fractionated by size exclusion chromatography on a Bio-Beads SX-2 column using toluene as eluent. The combined terpenoid-rich fraction (36.06 g) was chromatographed over a silica gel column (850 g) with 20% EtOAc in hexane and separated into seven major fractions on the basis of tlc analyses. Repeated column chromatography of fraction 7 (2.86 g) on silica gel (100 g) with 40% EtOAc in hexane gave fractions I through IX. Fraction III (340 mg) was subsequently purified by hplc (Zorbax C-8 ODS silica gel with MeOH–H_2O (55:45)) to give pure uprolide-B diacetate (**7**) (23 mg), 8-epi-uprolide-B diacetate (**10**) (24 mg), uprolide-C diacetate (**13**) (35 mg), and a fraction that was subsequently purified by hplc (Partisil 10 silica gel with 10% isopropanol in hexane) to yield pure 7-epi-uprolide-C diacetate (**15**) (34 mg) and eupalmerin (**2**) (23 mg). Fraction VII (270 mg) was purified by hplc (Partisil 10 silica gel with 13% isopropanol in hexane), yielding 36 mg of 8-epi-uprolide-A acetate (**4**). Fraction V (208 mg) was also purified by hplc (Zorbax C-8 ODS silica gel with MeOH–H_2O (60:40)), yielding some more 8-epi-uprolide-B acetate (**9**) (11 mg). Fraction IX (575 mg) was chromatographed by hplc (Partisil 10 silica gel with 25% isopropanol in hexane) to give pure uprolide-A acetate (**3**) (110 mg) and 7-epi-uprolide-C acetate (**14**) (55 mg).

Uprolide-A acetate (3): White crystalline solid: mp 210.0–211.0°C; $[\alpha]_D^{25}$ +29.23 (*c* 4.63, $CHCl_3$); ir (neat): 3550, 2970, 2954, 2918, 2889, 1766, 1733, 1385, 1253, 1116, 982, 968, 939 cm^{-1}; uv λ_{max} (MeOH): 212 nm (ε 25 300); ^1H nmr (300 MHz, $CDCl_3$) see Table 1; ^{13}C nmr (75 MHz, $CDCl_3$) see Table 4; hrfabms *m/z* $[M + H]^+$ (rel. %): 393.22750 (100%) ($C_{22}H_{33}O_6$ requires 393.22779).

8-Epi-uprolide-A acetate (4): Colorless oil; $[\alpha]_D^{25}$ +12.03 (*c* 9.12, $CHCl_3$); ir (neat): 3552, 2984, 2911, 2888, 1770, 1740, 1456, 1370, 1261, 1228, 1099, 1028, 981, 968 cm^{-1}; uv λ_{max} (MeOH): 208 nm (ε 23 400); ^1H nmr (300 MHz, $CDCl_3$) see Table 1; ^{13}C nmr (75 MHz, $CDCl_3$) see Table 4; hreims *m/z* $[M - H_2O]^+$ (rel. %): 374.20620 (0.25%) ($C_{22}H_{30}O_5$ requires 374.20940), 332(1.2), 309(1.3), 271(1.4), 249(4.0), 196(5.8), 111(34.9), 81(13.6).

Uprolide-C diacetate (13): Colorless semisolid: $[\alpha]_D^{25}$ +7.22 (*c* 7.1, $CHCl_3$); ir (neat): 2962, 2928, 2873, 1771, 1738, 1372, 1260, 1239, 1095, 1023, 920, 863, 800 cm^{-1}; uv λ_{max} ($CHCl_3$): 244 nm (ϵ 200); ^1H nmr (300 MHz, $CDCl_3$) see Table 3; ^{13}C nmr (75 MHz, $CDCl_3$) see Table 6; hrfabms *m/z* $[M + H]^+$ (rel. %): 435.23790 (100%) ($C_{24}H_{35}O_7$ requires 435.23835).

7-Epi-uprolide-C acetate (14): Colorless oil: $[\alpha]_D^{25}$ +19.02 (*c* 5.1, $CHCl_3$); ir (neat): 3493, 2945, 2871, 1775, 1741, 1372, 1259, 1233, 1096, 1030, 754 cm^{-1}; uv λ_{max} (MeOH): 212 nm (ϵ 9800); ^1H nmr (300 MHz, $CDCl_3$) see Table 3; ^{13}C nmr (75 MHz, $CDCl_3$) see Table 6; hrfabms *m/z* $[M + Na]^+$ (rel. %): 415.20810 (100%) ($C_{22}H_{32}O_6Na$ requires 415.20973).

7-Epi-uprolide-C diacetate (15): Colorless semisolid: $[\alpha]_D^{25}$ +17.51 (*c* 8.3, $CHCl_3$); ir (neat): 2979, 2950, 2875, 1779, 1742, 1372, 1237, 1101, 1029 cm^{-1}; uv λ_{max} (MeOH): 208 nm (ϵ 10 500); ^1H nmr (300 MHz, $CDCl_3$) see Table 3; ^{13}C nmr (75 MHz, $CDCl_3$) see Table 6; hreims *m/z* $[M - C_2H_2O]^+$ (rel. %): 392.21976 (5.1%) ($C_{22}H_{32}O_6$ requires 392.21996), 374(9.5), 332(11.5), 314(14.2), 286(5.7), 179(22.5), 159(28.2), 93(98.0), 55(100).

Acetylation of uprolide-C (11)

A solution of uprolide-C (5 mg, 0.014 mmol) in a mixture of acetic anhydride (2.0 mL) and pyridine (1.0 mL) was stirred at 25°C for 14 h. Excess reagents were removed by rotaevaporation and, after concentration and storage in vacuo, we obtained 8 mg of a homogeneous compound whose retention time (by tlc) and nmr spectra (^1H and ^{13}C) conclusively identified it as uprolide-A acetate (**3**).

Acetylation of 7-epi-uprolide-C acetate (14)

A solution of 7-epi-uprolide-C acetate (12 mg, 0.031 mmol) in a mixture of acetic anhydride (3.0 mL) and pyridine (1.0 mL) was stirred at 25°C for 12 h. Excess reagents were removed by rotaevaporation and the residue obtained was chromatographed over a short column of silica gel (80:20 hexane–EtOAc). After concentration in vacuo 13 mg of pure 7-epi-uprolide-C diacetate (**15**) were obtained.

X-ray diffraction study of uprolide-A acetate (3)[7]

X-ray diffraction data were collected on an Enraf–Nonius CAD4 diffractometer using CuKα radiation (λ = 1.540 56 Å). The structure was solved by direct methods and completed by successive Fourier calculations. The structure was refined by full-matrix least-squares methods, with anisotropic thermal parameters for all non-H atoms. Following initial refinement, H atoms were located from a difference Fourier map. HO8 was refined with a fixed isotropic thermal parameter and all remaining H atoms were included in the final model at calculated positions, riding on the connected atoms. All calculations were performed with the NRCVAX program package (32). Details of the X-ray experiment, crystal data, data collection, reduction, and refinement are given in Table 8 and the atomic parameters are given in Table 9.

Taxus canadensis taxanes: structures and stereochemistry[1]

Lolita O. Zamir, Maria E. Nedea, Zhen-Hua Zhou, Sophie Bélair, Gaétan Caron, Françoise Sauriol, Emile Jacqmain, France I. Jean, François-X. Garneau, and Orval Mamer

Abstract: The structures and stereochemistry of 14 taxanes isolated from *Taxus canadensis* have been rigorously established by high-resolution NMR techniques and mass spectrometry. *Taxus canadensis* is the only yew that accumulates 9-dihydro-13-acetylbaccatin III (also called 7,9-deacetylbaccatin VI) as the most abundant taxane. Five 9-dihydrotaxanes derived from the Canadian yew are novel natural products not reported in the needles of other species of yew (**8–11**, **14**, Fig. 1).

Key words: *Taxus canadensis*, Taxaceae, taxanes, 9-dihydro-13-acetylbaccatin III, taxol.

Résumé : Les structures et la stéréochimie de 14 taxanes isolés du *Taxus canadensis* ont été rigoureusement prouvées à l'aide d'expériences à haute résolution de RMN et SM. *Taxus canadensis* est le seul if accumulant la 9-dihydro-13-acétylbaccatine III (aussi appelée 7,9-désacétylbaccatine VI) comme taxane majoritaire. Cinq 9-dihydrotaxanes dérivés de l'if du Canada sont des nouveaux produits naturels qui n'ont pas été découverts dans les aiguilles d'autres ifs (**8–11**, **14**, Fig. 1).

Mots clés : *Taxus canadensis*, Taxaceae, taxanes, 9-dihydro-13-acétylbaccatine III, taxol.

Introduction

Taxol (**1**, Fig. 1), the anticancer drug of the 1990s[3] was originally extracted from the bark of the Pacific yew, *Taxus brevifolia* (2). Two elegant total syntheses of taxol were recently reported (3, 4). Another very important drug, taxotere (which seems to be more active than taxol) (5), was derived by semi-synthesis: the natural product 10-deacetyl baccatin III (which is abundant in *Taxus baccata* (6, 7) and is very similar to the diterpenoid core of taxol) was chemically coupled at C-13 with a synthetic side chain. There are many reported syntheses of the side chain of taxol (8) and various derivatives are being made and tested.

In this publication we have focused on the Canadian yew, which differs from other yews not only in its physical appearance (it is a ramping small evergreen bush very common in Quebec), but also in its composition. *Taxus canadensis* does produce taxol, cephalomannine, and 10-deacetylbaccatin III (**1**, **4**, **5**, Fig. 1), which are common to all yews, as demonstrated by a major work of the National Cancer Institute research group (9). On the other hand, in a preliminary communication (1), we have shown that *T. canadensis* accumulates a taxane that differs from the diterpenoid core of taxol by a hydroxyl group at C-9, instead of a ketone: 9-dihydro-13-acetylbaccatin III (**7**, Fig. 1). This metabolite, which was reported in trace amounts in the bark of *Taxus chinensis* (10), is at least three to five times more abundant than taxol in the needles of *T. canadensis*. The structure that we proposed for this 9-dihydrotaxane, on the basis of NMR and MS data (**7**, Fig. 1), was subsequently confirmed by X-ray (11). This was an interesting finding, since the successful attachment of the taxol side chain by the Abbott group (12) led to in vivo anticancer activity. Further investigations in our laboratory with *T. canadensis* needles enabled us to rigorously characterize 14 taxanes. Five of these taxanes are new natural products that have not been reported in the needles of other yews (**8**, **9**, **10**, **11**, **14**, Fig. 1).

[3] Taxol was recently approved in the U.S. and Canada for treatment of ovarian cancers.

Results and Discussion

Isolation and purification of taxanes

The discovery of a major taxane, 9-dihydro-13-acetylbaccatin III (**7**, Fig. 1), encouraged us to devise a method whereby this compound and taxol eluted in the same chromatographic fraction and could be easily separated. The choice of solvents and chromatographic techniques enabled us to obtain 9-dihydro-13-acetylbaccatin III at an R_t of 27.34 min, whereas taxol is obtained at R_t = 33.3 min on HPLC. Several steps of reverse-phase HPLC were usually needed to obtain highly pure tax-

anes. Purity of these taxanes was assessed by the formation of symmetrical peaks under three different gradient systems.

Taxanes isolated from *Taxus canadensis*

The structural characterizations of the taxanes were proven by high-field NMR techniques. High-resolution mass spectrometry confirmed the empirical formulas. Known taxanes were compared to the literature and spiked with standards for which we gratefully acknowledge the assistance of Ms Nancita Lomez and Dr. Kathleen H. Groover (National Cancer Institute, Maryland, U.S.A.). *Taxus canadensis* differs from other species of taxus by the presence of large amounts of the taxane

9-dihydro-13-acetylbaccatin III (**7**, Fig. 1). We have therefore chosen to use the nature of the oxygenation at C-9 as the classification criteria.

A. 9-Keto-taxanes

We found taxol (**1**, Fig. 1), cephalomannine (**4**, Fig. 1), and 10-deacetylbaccatin III (**5**, Fig. 1) in *T. canadensis* needles.[4] We identified 10-deacetyltaxol (**2**, Fig. 1), 7-epitaxol (**3**, Fig. 1), and 7-epi-10-deacetylbaccatin III (**6**, Fig. 1) for the first time in the needles of the Canadian yew. These metabolites are known natural products isolated in other taxus species (13). The high-resolution 2D NMR analyses for 7-epitaxol and 7-epi-10-deacetylbaccatin III (**3** and **6**, Fig. 1) are shown in Tables 1 and 2.

B. 9-Dihydrotaxanes (7–14 Fig. 1)

Taxus canadensis is the only species accumulating 9-dihydro-13-acetylbaccatin III (**7**, Fig. 1) in its needles in quantities 3–5 times that of taxol. Structures **7** and **14** were identified subsequently as minor metabolites in the bark of *Taxus chinensis* (10) but were never found in yew needles. The taxane **12** was described in a Chinese publication (14) and compound **13** was also found in *Austrotaxus spicata* (15). The derivatives **8–11** have not been found in other taxus species. We can subdivide this group of 9-dihydrotaxanes into those with an oxetane ring (**7–11**, Fig. 1) and those with a pre-oxetane ring (double bond or C-4 epoxide such as **12–14** (Fig. 1). The initial characterization (1) of the abundant taxane (**7**, Fig. 1) involved 300 MHz NMR analysis and high-resolution mass spectrometry. The structure was confirmed by X-ray analysis (11). The 500 MHz NMR analyses of the new natural products are shown in Tables 3–7. The data for metabolite **7** are included for comparison. Compound **8** is very similar to the major metabolite **7**, the only difference being a substituent at C-2: an acetate replaces the benzoate. Compound **9** has a benzoyl at C-2 and a hydroxyl group on the acetyl at C-10 but otherwise is completely acetylated. Compounds **10** and **11** are stereoisomers differing in the stereochemistry at C-7. These compounds are the least acetylated, having three hydroxyl groups at C-7, C-9, C-10, a benzoyl at C-2, and an acetyl at C-13. The natural co-occurrence of these dihydrotaxanes (**7–11**, Fig. 1) suggests a biosynthetic order of acetylation, the first hydroxyl to be esterified being C-13 (and (or) C-4), followed by the one at C-2, then the other at C-10. The additional 9-dihydrotaxanes shown in Fig. 1 isolated for the first time in *T. canadensis* (1) have pre-oxetane structures on ring C. In compound **12**, ring

[4] We isolated a taxane that we characterized as 1-acetyl-10-deacetylbaccatin III (same structure as **5**, Fig. 1, but with OAc at C-1). The 500 MHz NMR and high-resolution mass spectral data were in agreement with the structure proposed. Unfortunately, we were only able to isolate this compound once!

A is altered, with a cyclization containing a hydroxylated methyl (C-16 or C-17) on the double bond, assisted by an oxygenase.

High-resolution NMR analyses of *T. canadensis* taxanes

The detailed ^1H and ^{13}C assignments of all the metabolites reported for the first time in *T. canadensis* are shown in Tables 1–7. The 500 MHz NMR analyses utilized for all the new taxanes will be illustrated on the metabolite **14**, isolated for the first time in *T. canadensis*.

The proton NMR shifts and the COSY spectrum (16) allowed us to assign most of the protons. However, it was not possible to distinguish H-5 from H-7, H-10 from H-13, and H9/H10 coupled together could have reverse assignments. The four methyl groups could be identified by their couplings. The *gem*-dimethyl (Me-16 and Me-17) could be recognized by a small correlation in the COSY spectra. The methyl at position 19 (Me-19) showed a long-range coupling with H-3, and Me-18 with H-13/H-10. Three of the four acetyls of compound **14** could be easily located by the extra deshielding (~0.8–1 ppm) to the geminal proton (-C*H*-OAc) by comparison to an -OH (-C*H*-OH). These positions are H-2, H-10, and H-13. The position of the fourth acetyl was not immediately apparent.

The carbon-13 NMR assignments of the protonated carbons were established using the HMQC technique (*H*eteronuclear *M*ultiple *Q*uantum *C*oherence) (17) (Table 4). The carbon shifts that could not be determined were the quaternary carbons (C-1, C-4, C-8, C-11, C-12, C-15) and C-5, C-7, C-9, C-10, and C-13. Indeed, the signals of the attached protons (H-5/H-7; H-9/H-10; H-10/H-13) either overlap or are not assigned with certainty.

The additional heteronuclear correlation experiment HMBC (*H*etero *M*ultiple *B*ound *C*orrelation) (18) was therefore crucial for unambiguous assignment of all the carbons. The two-dimensional ^1H–^{13}C correlations for the four methyls are shown in Fig. 2*a*. The protons Me-16 and Me-17 are both correlated to C-15, C-11, and C-1. The protons Me-19 show coupling to C-8, C-9, C-7, and C-3 while methyl-18 correlates to C-13, C-11, and C-12. The HMBC experiment has also enabled us to corroborate the presence of the acetyls at C-10, C-13, and C-2. Indeed, in Fig. 2*b* we note that H-2, H-10, and H-13 are coupled to carbonyl groups. Surprisingly, we also note the most shielded proton (compared to H-13, H-10, H-2, H-9, H-7): a triplet at 4.2 ppm is correlated also to a carbonyl ester carbon (170 ppm). This triplet is also correlated to C-20, C-4, and C-3, confirming that it is indeed H-5. The higher chemical shift observed for H-5 on the acetylated C-5 position can be rationalized by the presence of an α-epoxide. The H-2 proton (Fig. 2*b*) also shows connectivities to six other carbons describing the total environment of that proton. These are C-1, C-14, C-15, C-3, C-4, and C-8 (the quaternary carbons that have not been assigned in HMQC are underlined). Among these quaternary carbons, C-15 and C-1 are assigned by analyzing the correlations of Me-16 and -17, which are coupled to

these two carbons, while the C-8 quaternary carbon is unambiguously identified from the Me-19 trace that is coupled to it (Fig. 2*a*). The H-9 proton, coupled to only one olefinic carbon (C-11), is also associated with C-10, C-7, C-8, and C-19, which describes the environment of this proton and confirms its assignment (Fig. 2*b*). The doublet of doublets located at 4.25 ppm is correlated to C-19 ($^3J_{C-H}$). This correlation allows us to definitely assign this proton as H-7. H-7 is also coupled to C-6 and C-5 (Fig. 2*b*). The connectivities in HMBC that enabled us to position the four acetates are shown in Fig. 2*c*.

The stereochemistry of the substituents, as well as the stereospecific assignment of Me-16 and Me-17, have been established using the NOESY experiment (NOE-2D) (19). In taxanes, despite their relative small size, the NOE cross peaks

Table 5. Comparison between ^{13}C chemical shifts for **10** and **11**. Most chemical shifts are similar (within 0.2 ppm) except for the ones shown in this table.

^{13}C	10	11	Difference (11-10)
C-3	45.83	46.67	Δ=0.8
C-6	36.91	38.16	Δ=1.2
C-7	72.26	74.27	Δ=2.0
C-9	79.77	78.06	Δ=1.7

are relatively strong. In these experiments, the NOE interactions are phased in an opposite fashion to the diagonal (negative phase), whereas the cross peaks originating from chemical exchange (OHs) are phased in a positive fashion. For the hydroxy protons we observe strong chemical exchange peaks (negative phase) and small NOE positive signals. In the NOESY tables (Tables 6, 7), only small positive NOEs (marked with an asterisk) are reported for these groups. Figure 3*a* illustrates the most informative NOEs, which rigorously establish the stereochemistry of ring A in compound **14**: we see that Me-16 points towards ring A and we can observe an NOE between Me-16, H-13 and 14A. Figures 3*b* and 3*c* show the most informative NOEs, which prove the stereochemistry of ring B from the β-side (Fig. 3*b*), and the α-side (Fig. 3*c*) of metabolite **14**. From Fig. 3*b*, we can conclude that Me-17, Me-19, H-2, and H-9 are on the β-side of the molecule **14**. On the other hand, in Fig. 3*c*, H-10, H-7, H-3, and Me-18 are on the α-side of compound **14**. The H-20A on the epoxide ring exhibits a small medium NOE with H-14B (α-orientation). The presence of this NOE suggests that the epoxide is β. For H-5, the vicinal coupling constants with its neighboring H-6 protons are small (J = 3 Hz), indicating a pseudo-equatorial orientation. The NOEs observed for H-5 are not very informative, since this proton interacts only with the vicinal H-6 protons and with H-20B. By molecular modelling we can identify two possible conformations for ring C shown in Figs. 3*d* and 3*e*. The twist-boat conformation of ring C (Fig. 3*d*) is characterized by a β-oxirane and an α-H-5. This configuration explains the observed coupling constants, as well as the NOEs (Fig. 3*d*). Indeed, the H-7 exhibits a large diaxial coupling with H-6A (ϕ = 174°) and a smaller coupling with H-6B (ϕ = 67°). The H-5 has two small couplings with H-6A (ϕ = 156°) and H-6B (ϕ = 37°). The H-5 and H-20B are close in space (≈2, 4 Å), explaining the strong NOE observed between these protons. Figure 3*e* represents a different possible conformation for ring C, which can also explain all the vicinal couplings and the NOEs observed. Indeed, in this chair conformation, the axial H-7 proton exhibits large diaxial coupling with H-6A and smaller axial-equatorial coupling with H-6B. The equatorial H-5 proton would show small couplings with the vicinal H-6A/H-6B. This configuration can also explain the observed NOEs and coupling constants. We can therefore conclude that the stereochemistry of H-5 could not be determined. On the other hand, the β-oxirane seems to be suggested by the data.

*Stereoisomers **10** and **11***

The stereoisomers **10** and **11** were first isolated in a 60:40 ratio. They were then separated and purified. The assignments are shown in Tables 3 and 4. The ^1H NMR of both compounds are very similar. The ^{13}C chemical shifts for both compounds appear at similar shifts (within 0.2 ppm), except for the car-

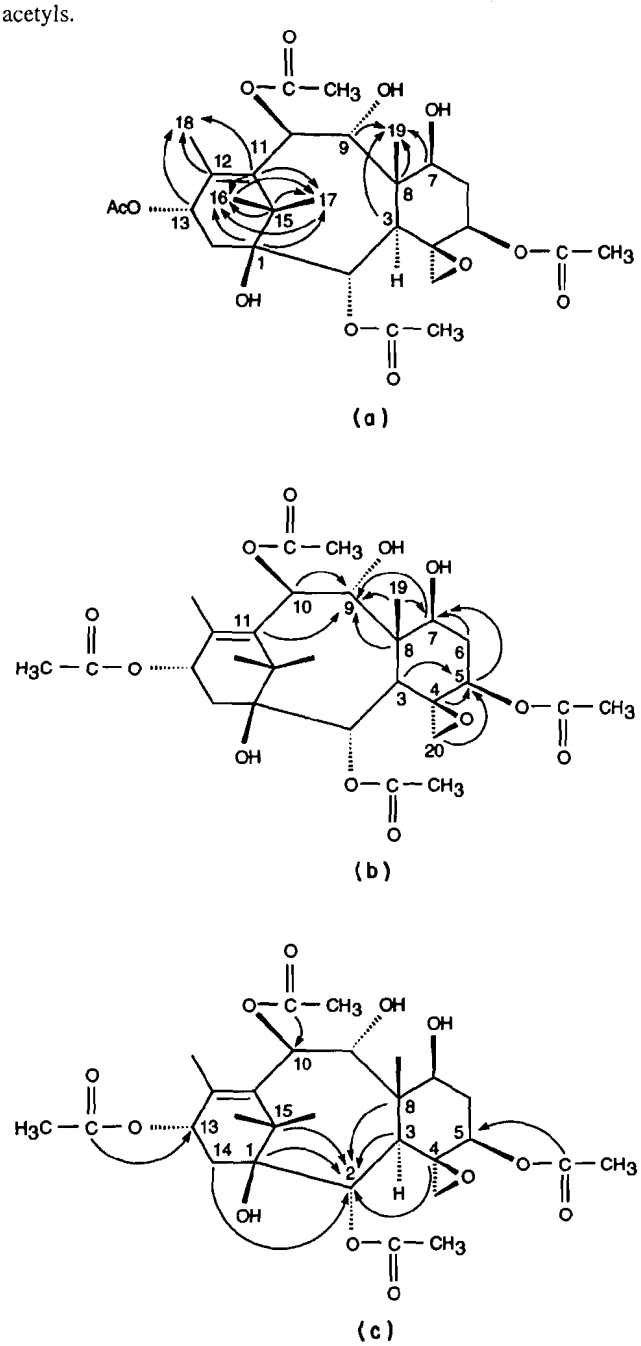
Fig. 2. Two-dimensional ^{1}H–^{13}C correlations obtained for metabolite **14**. Arrows indicate carbon–hydrogen connectivities. Arrow head indicates location of proton. Figure 2*a* shows the ^{1}H–^{13}C correlations for the four methyls. Figure 2*b* shows the ^{1}H–^{13}C connectivities that confirm the assignment of H-9. Figure 2*c* shows the ^{1}H–^{13}C correlations that led to the positioning of the four acetyls.



bons C-3, C-6, C-7, and C-9 (Table 5). The carbons showing these shifts are part of ring C (or close to ring C). In addition, the largest difference is at C-7, suggesting that they differ in the stereochemistry of C-7. Due to the similar NOEs we cannot conclusively determine in which stereoisomer the OH at C-7 is β and in which one it is α.

Mass spectra of *T. canadensis* taxanes

In the experimental section, the low-resolution and high-resolution mass spectra of taxanes are reported. The assignments of the different ions are also given. The results confirm our NMR data.

Experimental

High-performance liquid chromatography

Analytical high-performance liquid chromatography (HPLC) was carried out on a Perkin–Elmer instrument with an isocratic and binary LC pump model 250 coupled to a Waters 990 photodiode array detector, a NEC APC IV computer for data processing, and a Waters 990 plotter. HPLC was performed with two ODS-2 reversed phase columns (Whatman) connected in series (4.6 × 500 mm), at a flow rate of 1 mL/min. Sample injections were done manually using a 1.0 mL loop on a Waters UK6 injector. Separation was achieved with a linear gradient beginning with 75% water – 25% acetonitrile and increasing over 50 min to 100% acetonitrile. Semi-preparative HPLC was performed with two ODS-2 MAG-9 semi-preparative columns (Whatman) connected in series (9.4 × 500 mm), at a flow rate of 3 mL/min. The gradient program was the same, but it lasted either 70 min or 120 min. All ultraviolet detectors were set at 227 nm. All samples were filtered (0.45 μm) before injection. Water and acetonitrile were HPLC grade. The purity of all isolated products was checked by analytical HPLC. Semi-preparative HPLC was performed on a Waters Delta Prep 3000 instrument coupled to a Lambda-Max model 481 variable wavelength detector (Waters) and a Perkin–Elmer 024 recorder.

Nuclear magnetic resonance methodology

All the NMR spectra were obtained at room temperature on a UNITY-500 spectrometer operating at 499.843 MHz for proton and at 125.697 MHz for carbon-13. The NMR spectra were obtained on 1–2 mg samples dissolved in 0.3–0.4 mL of deuterated chloroform ($CDCl_3$). The solvent was used as an internal reference (77.0 ppm for ^{13}C and 7.25 ppm for ^{1}H). For the proton spectra, 8–64 transients were recorded with an 8000 Hz spectral window, 45° pulse, 30K data points, and 1.0 s acquisition time. The carbon-13 NMR spectra were obtained with a spectral window of 30 007.5 Hz, using a 40° pulse, and 50 000–70 000 transients were acquired. In cases were the concentration was too weak to obtain a good spectrum, the shifts were extracted from the HMQC experiment. The NOESY experiment (hypercomplex phase mode) was obtained using a mixing time of 0.3 s and a relaxation delay of 1 s. The acquisition was repeated for 16–32 transients, and 256 complex increments were acquired. The data were processed using a Gaussian apodization function. The final data matrix have 2K by 1K points (zero filling was used only in the evolution domain). For all the studies with taxol derivatives, when the diagonal signals are phased positive, the cross peaks resulting from dipolar relaxation (NOE) are phased negative, while the cross peaks originating from chemical exchange (OH) have positive phasing.

The HMQC experiment with a preceding BIRD nulling period was used with hypercomplex phased mode. The recycling delay was set to 1 s, while the nulling period (following the bird pulse) was set to 0.3 s. The acquisition was repeated 8–16 times and 256 fids were acquired. During acquisition of the proton spectra, C-13 broadband waltz decoupling was

Table 6. NOESY observed on the diastereoisomers **10** and **11**. In these experiments, the NOE cross peaks have a reverse phase (positive) relative to the diagonal (negative), whereas the chemical exchange cross peaks (hydroxy groups) are phased like the diagonal peaks. For the hydroxy protons we observed strong chemical exchange peaks (negative phase) and small NOE positive signal. In the table below, only the small positive NOEs are reported for these groups (*).

applied. The data were processed with a Gaussian function with zero filling in the evolution domain (^{13}C). The final matrix size was 2K by 1K. The spectral window in the carbon domain was 120–140 ppm, while it was about 7–8 ppm in the proton domain. The HMBC experiment was acquired using similar conditions, but without the null period and without ^{13}C decoupling during acquisition. The τ delay to emphasize long-range coupling was set to 100 ms. Also, the carbon window was set larger to accommodate carbonyl carbons (180–200 ppm) in the carbon domain. The HMBC data were processed using a shifted Gaussian function and were displayed and plotted in an absolute value mode.

Mass spectrometry

Low-resolution xenon fast atom bombardment mass spectra were obtained in glycerol, except as noted, with a VG ZAB-HS instrument operated under the following conditions: resolution, 2000; atom energy, 8 kV at 1 mA beam current; scan range 1200–200 Da at 10 s/decade. The samples were dissolved in 0.2 μL of dimethyl sulfoxide in the stage before addition of 0.5 μL of glycerol. The 10 spectra obtained for each sample were averaged to reduce statistical variations.

High-resolution measurements were made similarly in glycerol–DMSO, at a resolving power of 12 000. The ions of interest were manually peak-matched against glycerol cluster

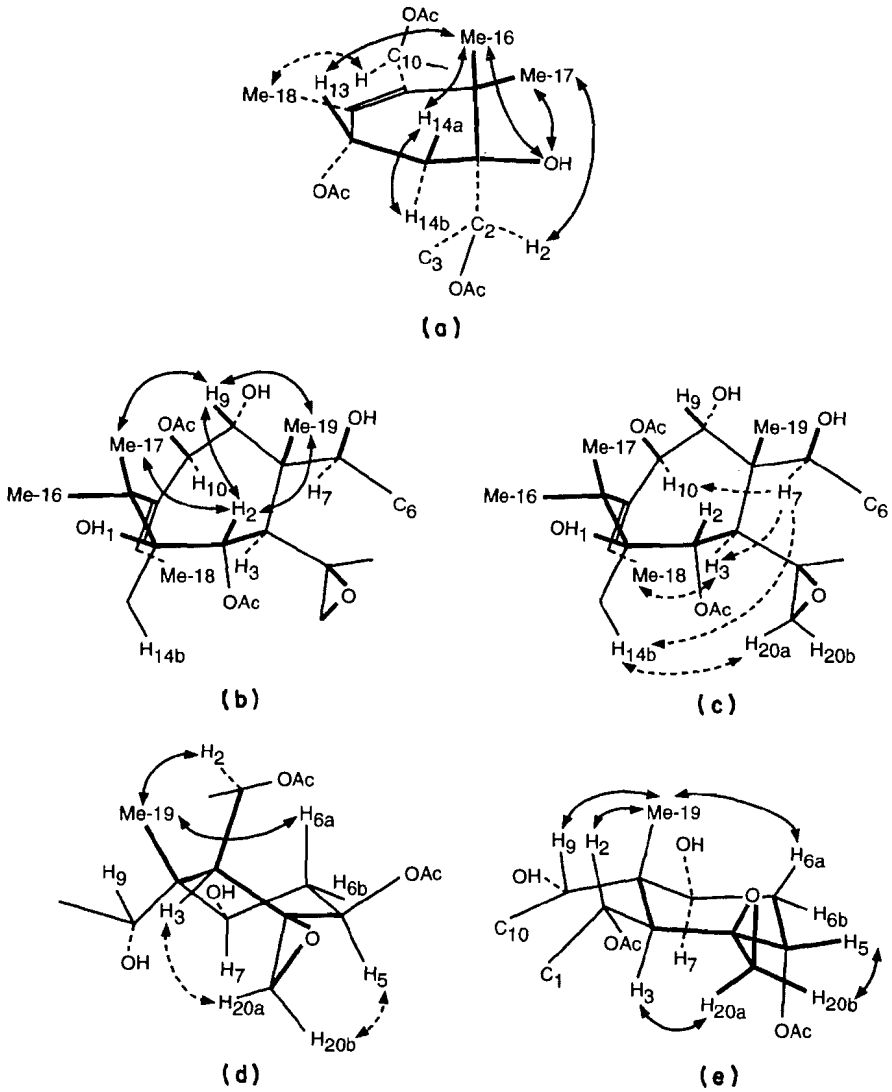
Fig. 3. (*a*) NOESY correlations about ring A of **14**; (*b*), (*c*) NOESY correlations establishing stereochemistry of ring B (β-face b, α-face c); (*d*), (*e*) Plausible conformations for ring C and NOESY correlations.



ions of known compositions, closest to the ions being measured.

IR spectroscopy

IR spectra were recorded using a Bruker IFS-48 FTIR spectrophotometer.

Circular dichroism

CD spectra were recorded using a Jasco J-500C spectropolarimeter with a 1.0 cm wide cuvette.

Plant material

Stems and needles of *Taxus canadensis* were collected at two different sites in Quebec. The material was stored at 4°C. When needed, they were dried at room temperature and ground in a blender for extraction.

Extraction, isolation, and purification of taxanes

Dried powdered needles and small branches of *T. canadensis* (480 g) were extracted twice with CH_3OH–CH_2Cl_2 (1:1, v/v, 4.8 L) during 24 h, at room temperature. The combined extracts were filtered and concentrated in vacuum to a dark brown residue. The residue was suspended in water and extracted with hexane to eliminate lipids. The aqueous layer was extracted with CH_2Cl_2 (3 × 300 mL) and the combined extracts were dried, filtered, and evaporated, giving a syrupy residue (18 g). The resulting extract was coated on Celite 545 and fractioned by flash chromatography on a silica gel column (150 g, 5 × 30 cm). The mixture was eluted with CH_2Cl_2–$CH_3COOC_2H_5$ (85:15) and then with a 5% step gradient starting with hexane–acetone (65:35) and ending with 100% acetone. Fractions eluted with hexane–acetone (65:35) contained taxol **1**, 7-epitaxol **3**, cephalomannine **4**, 9-dihydro-13-acetylbaccatin III **7**, 10-hydroxyacetylbaccatin VI **9**, 5-decinnamate taxagifine **12**, 2-deacetyl-5-decinnamoyl taxinine J **13**, and 1β-hydroxy-7,9-deacetylbaccatin I **14**. Further elution of the mixture with hexane–acetone (60:40) afforded mainly 10-deacetylbaccatin III **5**, and small amounts of 10-deacetyl taxol

2, 10-deacetylbaccatin V **6**, 7,9-deacetylbaccatin IV **8**, and 7,9,10-deacetylbaccatin VI **10** and **11**. For each peak, acetonitrile was removed by evaporation under vacuum and the remaining aqueous solution was lyophilized to yield white amorphous solids. The different taxanes were purified by repetitive HPLC runs, using gradient and isocratic conditions. The very pure taxanes were analyzed by high-resolution NMR and mass spectrometry.

9-Keto-taxanes (1–6, Fig. 1)

The 9-keto-taxanes were purified by repetitive HPLC runs. The preliminary purifications of compounds **1–6** involved semi-preparative HPLC with a gradient over 70 min of CH_3CN:H_2O (25:75) to 100% CH_3CN. The retention times under those conditions are the following: compound **1**, R_t = 36.2 min; **2** (same gradient but over 100 min), R_t = 44.5 min; **3**, R_t = 39.1 min; **4**, R_t = 34.5 min; **5** (same gradient but over 120 min), R_t = 24.2 min; **6** (same gradient but over 120 min), R_t = 34.5 min. These compounds were further purified by analytical HPLC with the same gradient, but over 50 min. The retention times and the overall yields of the pure taxanes are as follows: **1**, R_t = 33.29 min (0.016%); **2**, R_t = 29.15 min (0.0008%); **3**, R_t = 36.75 min (0.0013%); **4**, R_t = 32.43 min (0.002%); **5**, R_t = 19.68 min (0.015%); **6**, R_t = 25.15 min (0.0006%).

The NMR of **1–6** were identical to literature values (13). In addition, their structures were confirmed by high-resolution mass spectrometry: **1** (taxol) MH^+: 854.33850; $C_{47}H_{52}NO_{14}$ requires 854.33878; **2** (10-deacetyltaxol) MH^+: 812.32791; $C_{45}H_{50}NO_{13}$ requires 812.32821; **3** (7-epitaxol) MH^+: 854.33850; $C_{47}H_{52}NO_{14}$ requires 854.33878; **4** (cephalomannine) MH^+: 832.35435; $C_{45}H_{54}NO_{14}$ requires 832.35443; **5** (10-deacetylbaccatin III) MH^+: 545.23871: $C_{29}H_{37}O_{10}$ requires 545.23867; **6** (10-deacetylbaccatin V) M + H^+ − $2H_2O$: 509.21758; $C_{29}H_{33}NO_8$ requires 509.21754; MH^+ − H_2O − HOAc: 449.19620; $C_{27}H_{29}NO_6$ requires 449.19641.

9-Dihydrotaxanes (7 – 14)

The purifications for all these taxanes involved (*i*) a semi-preparative HPLC with a gradient of acetonitrile (25–100%) in water over times specified for individual taxane followed when necessary by an isocratic run and (*ii*) analytical HPLC. The 500 MHz ^1H and ^{13}C NMR analyses and NOESY experiments for these 9-dihydrotaxanes are reported in Tables 3–7. The chemical structures of these metabolites were confirmed by mass spectrometry and low- and high-resolution data.

9-Dihydrotaxane **7**: IR (film) ν_{max}: 1743, 1714, 1371, 1245, 1179, 1111, 1053, 1018, 970 cm^{-1}; UV λ_{max} (CH_3OH): 228 nm (ϵ = 19 200); $[\alpha]_D^{22}$ −24.1 (c = 1.01, $CHCl_3$); [Θ] from CD (CH_3OH): +18.9 deg M^{-1} cm^{-1} at λ_{max} 252 nm and −8.6 deg M^{-1} cm^{-1} at λ_{min} 293 nm; MH^+: 631.27567; $C_{33}H_{43}O_{12}$ requires 631.27545. The retention time of **7** in semi-preparative HPLC with a gradient over 70 min, R_t: 39.10 min; analytical HPLC R_t: 27.34 min. The overall yield of **7** is 0.04%. Acetylation of metabolite **7** led to baccatin VI (9). The acetylation procedure is the following: 1 mg of **7** in dry pyridine (60 μL) was mixed with 90 μL acetic anhydride and stirred at room temperature overnight. Following removal of the pyridine, the acetylated product was purified by semi-preparative HPLC. Analyses of the NMRs of **7** and its acetylated derivative (1) established that metabolite **7** has hydroxyls at C-7 and C-9. In addition, the mass spectral data (low and high resolution) confirmed the structure of acetylated metabolite **7**: *m/z*: 715 (49.7%) MH^+: 715.29679; $C_{37}H_{47}O_{14}$ requires 715.29658); 697 (38.0%) ($MH^+ - H_2O$; 655 (90.8%) (MH^+ − AcOH); 637 (24.8%) (655−H_2O or 697−AcOH); 595 (60.7%) (655−AcOH); 535 (40.8%) (595 – AcOH).

9-Dihydrotaxane **8**: IR (film) ν_{max}: 1733, 1436, 1370, 1234, 1043, 1053, 1018, cm^{-1}; UV λ_{max} (CH_3OH): 217 nm (ϵ = 7400); $[\alpha]_D^{22}$ +24.05 (c = 1.83, $CHCl_3$); [Θ] from CD (CH_3OH): +32.9 deg M^{-1} cm^{-1} at ν_{max} 245 nm; *m/z*: 569 (35.9%) MH^+: 569.25989; $C_{28}H_{41}O_{12}$ requires 569.25980); 551 (29.6%) ($MH^+ - H_2O$); 509 (100%) (MH^+−AcOH), 491 (38.1%) (509−H_2O); 449 (37.3%) (509−AcOH); 431 (15.1%) (491−AcOH or 449 – H_2O). The retention time of **8** in semi-preparative HPLC with a gradient over 120 min, R_t = 20.5 min; isocratic CH_3CN:H_2O (26:74), R_t = 27.9 min; analytical HPLC R_t: 18.9 min. The overall yield of **8** was 0.0006%.

9-Dihydrotaxane **9**: IR (film) ν_{max}: 1734, 1374, 1245, 1099, 1052, 1027, 983, 803, cm^{-1}; UV λ_{max} (CH_3OH): 229 nm (ϵ = 13 653); [Θ] from CD (CH_3OH): 94.2 deg M^{-1} cm^{-1} at λ_{max} 290 nm; *m/z*: 753 (15.1%) (M + Na^+: 753.27357; $C_{37}H_{46}O_{15}Na$ requires 753.27344); 731 (5.7%) (MH^+); 713 (3.1%) ($MH^+ - H_2O$). The retention time of **9** in semi-preparative HPLC with a gradient over 70 min, R_t = 37 min; analytical HPLC isocratic CH_3CN:H_2O (42:58), R_t = 47.9 min. The overall yield of **9** is 0.0006%.

*9-Dihydrotaxanes **10** and **11***: UV λ_{max} (CH_3OH): 228 nm (ϵ = 12 600). The high-resolution NMR data of the two stereoisomers corresponding to **10** and **11** are shown in Tables 3–6. The stereochemistry of C-7 in both stereoisomers **10** and **11** could not be rigorously proven by NOESY experiments. The low- and high-resolution mass spectral data were identical for both. The Exact Mass for each compound was 589.26471: $C_{31}H_{41}O_{11}$ requires 589.26488. Both metabolites form a sodium adduct found *m/z* 611 and peaks corresponding to $MH^+ - H_2O$ at *m/z* 571. The retention time of **10** in semi-preparative HPLC with a gradient over 120 min, R_t = 30.3 min; isocratic CH_3CN:H_2O (28:72), R_t = 54.5 min. The retention time of **11** in semi-preparative HPLC with a gradient over 70 min, R_t = 25.5 min. In analytical HPLC isocratic compounds **10** and **11**, R_t = 23.85 min. The overall yield of **10** is 0.002% and of **11** is 0.0008%.

The detailed NMR analyses of **12** and **13** are shown in Tables 3 and 4. Since **12** and **13** are not new natural products, their structures were confirmed by rigorous NMR analyses, comparison with the literature, and low-resolution mass spectrometry. Metabolite **12** showed a weak (M+ H^+) peak at *m/z* 567 (7.2%), a prominent M+ H^+ − H_2O peak at *m/z* 549 (92.6%), and a sodium adduct at *m/z* 589 (M + Na^+); other peaks were at *m/z* 489 (549 – AcOH) (67.0%); 531 (549−H_2O) (6.1%); 429 (489 – AcOH) (29.5%); 507 (M+ H^+−AcOH) (18.7%); 467 (507 – AcOH) (25.8%). Metabolite **13** showed a sodium adduct at *m/z* 559 (14%) and a prominent peak at *m/z* 477 (M+ H^+ – AcOH) (68.7%) and at *m/z* 459 (477 – H_2O) (33.7%). The retention time of both **12** and **13** in semi-preparative HPLC with a gradient over 70 min is R_t = 25.5

min. They were separated in analytical HPLC: R_t of **12**: 23.55, and of **13**: 25.48 min. The overall yield of **12** and of **13** is 0.004%.

9-Dihydrotaxane ***14***: IR (film) ν_{max} : 1734, 1436, 1371, 1239, 1022, 979, 962 cm^{-1}; UV λ_{max} (CH_3OH): 220 nm (ϵ = 7500); $[\alpha]_D^{22}$ +65.84 (c = 0.571, $CHCl_3$); [Θ] from CD (CH_3OH): +57.2 deg M^{-1} cm^{-1} at λ_{max} 286 nm; MH^+: 569.25989; $C_{28}H_{41}O_{12}$ requires 569.25980. The fragmentation pattern shows the following peaks: *m/z*: 569 ($M + H^+$) (11.1%); 591 ($M + Na^+$) (12.5%); 551 ($MH^+ - H_2O$) (12.1%); 509 (569 − AcOH) (21.1%); 491 (551 − AcOH) (26.5%); 449 (569 − 2AcOH) (12.6%); 431 (551 − 2AcOH) (11.9%); 389 (MH^+ − 3AcOH) (24.7%); 371 ($MH^+ - H_2O$ − 3AcOH) (10.5%). The retention time of **14** in semi-preparative HPLC with a gradient over 70 min, R_t: 22.5 min; analytical HPLC, R_t: 21.05. The overall yield of **14** is 0.004%.

The reactions of $O(^3P)$ with acetonitrile and propionitrile

Suzanne Budge and John M. Roscoe

Abstract: The reactions of $O(^3P)$ with acetonitrile and propionitrile have been studied kinetically in the gas phase as a function of temperature and nitrile concentration. The rate constants obtained experimentally for the consumption of $O(^3P)$ in these reactions, in the units L mol^{-1} s^{-1}, obey the following relations: O + acetonitrile: $\ln k = 20.98 \pm 0.23 - 2100 \pm 200/T$; and O + propionitrile: $\ln k = 21.01 \pm 0.19 - 1900 \pm 200/T$. Mechanisms are discussed in which the reaction is initiated by hydrogen atom abstraction and in which initiation is by addition of $O(^3P)$ to the nitrile, followed by decomposition of the addition complex. The kinetic and analytical results are best explained by the mechanism in which the reactions are initiated by RCN + O → R + OCN. In the case of the reaction with acetonitrile, the absolute rate constant is smaller than the experimental value by a factor of 7 ± 20%, independent of temperature, as a result of secondary reactions.

Key words: kinetics, reactions of $O(^3P)$ with nitriles.

Résumé : On a réalisé une étude cinétique des réactions du $O(^3P)$ dans l'acétonitrile et le propionitrile en phase gazeuse, en fonction de la température et de la concentration en nitrile. Les constantes de vitesse obtenues expérimentalement pour la consommation du $O(^3P)$ dans ces réactions, exprimées en L mol^{-1} s^{-1}, obéissent aux relations suivantes : O + acétonitrile : $\ln k = 20{,}98 \pm 0{,}23 - 2100 \pm 200/T$; et O + propionitrile : $\ln k = 21{,}01 \pm 0{,}19 - 1900 \pm 200/T$. On discute des mécanismes dans lesquels la réaction est initiée soit par l'enlèvement d'un atome d'hydrogène soit par l'addition du $O(^3P)$ sur le nitrile, suivie par une décomposition du complexe d'addition. La meilleure façon d'expliquer les résultats est de faire appel au mécanisme dans lequel les réactions sont initées par : RCN + O → R + OCN. Dans le cas de la réaction avec l'acétonitrile, des réactions secondaires font que la constante absolue de vitesse est plus faible que la valeur expérimentale par un facteur de 7 ± 20%.

Mots clés : cinétique, réactions du $O(^3P)$ dans les nitriles.

Introduction

Reactions of polar organic compounds with atomic oxygen tend to have unusually small preexponential factors when compared with the corresponding reactions of saturated hydrocarbons (e.g., refs. 1–8). While it is usually accepted that the reactions of $O(^3P)$ with polar organic compounds proceed by hydrogen abstraction, the small preexponential factors have been attributed to the electrophilic nature of $O(^3P)$ (2). It has been postulated that the initial attack is between the oxygen atom and an electron-rich site on the substrate molecule. The resulting collision complex can then either decompose back to reactants or proceed to products via hydrogen atom abstraction. The qualitative picture is that a large proportion of the collision complexes simply decompose to reactants because of unfavourable geometry for chemical reaction, leading to an unusually small preexponential factor.

The effect described above has been observed for organic compounds containing oxygen at the electron-rich site. However, it seemed desirable to study reactions in which an addition complex between $O(^3P)$ and the organic reactant might be able to yield a characteristic decomposition product, permitting detection of a reaction channel other than hydrogen abstraction. The nitriles seemed to represent such a system since one might expect a relatively stable addition complex to form between $O(^3P)$ and the C≡N bond. The resulting complex might then decompose to products containing the CN functional group. It is also possible that hydrogen abstraction from the alkyl group might occur. This would lead to a second channel in which one might expect the initial production of OH followed by its reaction with the excess organic reagent to give water. Analysis of the reaction products for water and for compounds containing the CN group would then allow separation of the reaction into two identifiable channels and the relative importance of these channels could be evaluated as a function of the nature of the aliphatic group.

Examination of the literature reveals only a single study of reactions of $O(^3P)$ with nitriles (9). In that work, the reactions of CH_3CN and CF_3CN with $O(^3P)$ were studied. Rate constants were measured from the loss of $O(^3P)$ in the presence of a large excess of the nitrile using flash photolysis. Four temperatures were used, in the range 383–500 K, at pressures of 100–300 Torr (1 Torr = 133.3 Pa) Evidence from mass spectrometric measurements was consistent with the formation of HCN and H_2CO or NO. The measurement of a very small deuterium isotope effect, which increased in magnitude with

increasing temperature, was taken to suggest that the dominant reaction channel did not involve hydrogen abstraction but that at higher temperatures hydrogen abstraction might become more important. We report here the results of kinetic experiments over the temperature range 320–578 K in which the reactions of $O(^3P)$ with acetonitrile and propionitrile were studied to provide information on the nature of the available reaction channels in these systems.

Experimental

The experimental methods used have been outlined in earlier publications from this laboratory (1, 3, 7, 8). The main features will be described here. The reactions were studied in a conventional flow system at a pressure of approximately 1 Torr and linear flow velocities in the cylindrical reaction vessel ranged from 700 to 1100 cm s^{-1}. The substrate entered the reactor through a movable inlet and the $O(^3P)$ concentration was monitored at a fixed point at the downstream end of the reaction vessel. The reaction vessel was heated electrically and the temperature was measured by a calibrated iron–constantan thermocouple located in the tip of the movable inlet. This arrangement also made it possible to verify uniformity of temperature along the axis of the reaction vessel. At the highest temperatures used, the temperature variation was no more than ±2°C over the part of the reaction vessel used for the kinetic measurements and this variation became smaller as the temperature was lowered.

Oxygen atoms were made by titrating $N(^4S)$ atoms, formed in a microwave-powered discharge through N_2, with NO. This procedure avoids interference from O_2, which has been found to alter the mechanism of some reactions of $O(^3P)$ (1). The concentration of $O(^3P)$ was controlled and kept small in the kinetics experiments by passing only a small part of the total N_2 flow through the discharge. The balance of the N_2 was diverted through a bypass around the discharge and mixed with the discharge products upstream from the NO inlet. This arrangement made it possible to attain as much as a 5000-fold excess of the organic reagent to minimize the effects of secondary reactions of $O(^3P)$ with free radical intermediates such as OH. It also provided a suitable range of concentrations of the organic reagent for the kinetic analysis. The concentration of $O(^3P)$ was monitored by observing the NO_2 chemiluminescence produced by addition of a small (a few percent) excess of NO beyond the titration end point. The initial concentration of $O(^3P)$ was obtained from the flow rate of NO at the titration end point in the absence of the organic reagent. The rate constants obtained in this way were independent of the amount of excess NO.

Acetonitrile (Fisher, certified, ACS), propionitrile (Aldrich, 99%), and acetone (Anachemia, toxigraphic, distilled glass) were dried and thoroughly degassed before use and showed no impurities detectable by gas chromatography. A few kinetic experiments were done periodically with acetone, which has been well characterized kinetically under conditions such as those used in this work (2, 8), to verify that the entire apparatus was functioning reliably. Gas chromatographic analysis was done on an 8 ft column packed with Porapak Q, using a thermal conductivity detector because of the need to determine HCN and water. Reaction products were collected for chromatographic analysis by pumping approximately 1% of the gas stream leaving the reaction vessel through the glass sample loop of the gas chromatograph. The sample loop was cooled in liquid nitrogen and, after the sample had been collected for a measured period of time, the loop was isolated, warmed rapidly to room temperature, and its contents injected onto the column. The transfer time between the reaction vessel and the sample loop was long enough to ensure virtually complete consumption of all free radical and atomic species before the sample was collected for analysis.

Two procedures were used to calibrate the gas chromatograph. In the first method, measured flow rates of the analytes were added to the gas stream flowing through the reactor in the absence of $O(^3P)$ and $N(^4S)$. The condensable material was collected in the sample loop in the same manner as described above and was injected into the gas chromatograph for analysis. In the second method, an aliquot of a calibration mixture of known composition was injected into the gas chromatograph for analysis. The mixture contained a known amount of acetonitrile, which was used as an internal standard. This was possible since the experiments with atomic oxygen always had a sufficient excess of acetonitrile that only a negligible amount was consumed by reaction. The results obtained with these methods agreed within the experimental uncertainty of the chromatographic measurements. The latter method was preferred because of its greater convenience and speed in that no trapping in the sample loop was required.

The method of calculating first-order rate constants was altered slightly from that used in our earlier work by using the Guggenheim first-order analysis (10) rather than simply fitting the data to a single exponential decay. This has the advantage of automatically correcting the light intensities for small amounts of stray light, which can be troublesome to measure and can lead to relatively large errors in the NO_2 chemiluminescence measurements at the longer reaction times. Briefly, this analysis requires that the data be divided into two sets containing an equal number of points. Pairs of points in the two sets are separated by a constant time interval. If the atom signals corresponding to the two sets are S_1 and S_2, and the signal decays as a single exponential, it may be shown that

$$\ln(S_1 - S_2) = -kt_1 + \ln[S_0(1 - \exp(-k\Delta t)]$$

Since the signal at "zero time", S_0, and the separation of points in the two data sets, Δt, are both constants, a plot of $\ln(S_1 - S_2)$ against t_1, the time for the set 1 data points, will be linear with slope equal to $-k$, the negative of the first-order rate constant. Some typical Guggenheim plots are found in Fig. 1. These plots typically had linear correlation coefficients of better than 99% and the first-order rate constants calculated from them had standard deviations of less than 5%.

As in some of our earlier work (8, 9), the organic reactants were found to adsorb strongly on the surface of the reaction vessel and desorbed very slowly. The effects of possible heterogeneous reactions of $O(^3P)$ were avoided as in the earlier work by measuring first-order rate constants of $O(^3P)$ removal with several large excesses of the organic reagent. The first-order rate constants were then plotted against the concentration of the organic reagent, giving good straight lines of the form

$$k_{obs} = k_0 + k_R[\text{nitrile}]$$

The intercept presumably reflects the composite of all constant first-order loss routes for $O(^3P)$ and the slope represents

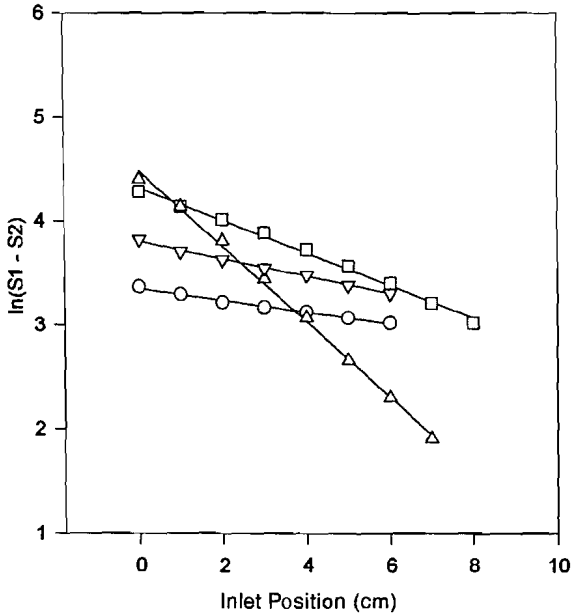
Fig. 1. Guggenheim plots for first-order rate constants. (○) CH_3CN, 386 K, [O] = 1.91×10^{-8} mol L^{-1}, [CH_3CN] = 4.58×10^{-6} mol L^{-1}; (△) CH_3CN, 521 K, [O] = 6.56×10^{-9} mol L^{-1}, [CH_3CN] = 3.26×10^{-6} mol L^{-1}; (□) C_2H_5CN, 577 K, [O] = 6.70×10^{-9} mol L^{-1}, [C_2H_5CN] = 1.83×10^{-6} mol L^{-1}; (▽) C_2H_5CN, 354 K, [O] = 1.34×10^{-8} mol L^{-1}, [C_2H_5CN] = 3.98×10^{-6} mol L^{-1}



the second-order rate constant for homogeneous loss of $O(^3P)$. Interpretation of the intercepts is difficult, at best, since detailed analysis of the behaviour of a flow system operated in our configuration requires consideration of heterogeneous effects both upstream and downstream from the movable reactant inlet. Such analysis shows that the intercepts of plots such as those in Fig. 2 will be positive if heterogeneous atom loss is greater in the reaction zone than upstream from the reactant inlet, and negative if the reverse is true. Since the region upstream from the reaction zone contains both the surface of the movable reactant inlet and the reactor surface, it has a larger *S/V* than the reaction zone. Consequently, a negative intercept would be expected even for uniform wall conditions along the entire length of the reaction vessel. Some typical plots are found in Fig. 2. The linearity of these plots was not as good as that of the Guggenheim plots, partly because of the limited number of data points that could be obtained. However, in all cases the linear correlation coefficients were greater than 90% and in most cases greater than 98%. The slopes of the plots had standard deviations of less than 10%.

Results

The kinetic data for acetonitrile and propionitrile are summarized in Table 1 and Fig. 3. In both systems, good Arrhenius behaviour was observed within the scatter of the data. Also shown in Fig. 3 for comparison are the results of the flash photolysis experiments of Bonanno et al. (9) for acetonitrile. All three activation energies are within their combined standard deviations, while our Arrhenius preexponential factors are significantly larger than those obtained by Bonanno et al. As discussed later, this is likely to be due to a stoichiometric factor resulting from secondary reactions in our experiments that

may not have been applicable under the conditions used by Bonanno et al.

The observation of effectively equal activation energies for the reactions of $O(^3P)$ with acetonitrile and propionitrile differs significantly from the behaviour found for the reactions of $O(^3P)$ with alcohols (1, 7) and with ketones (2, 8) in which lengthening and branching of the aliphatic chain significantly reduced the activation energy of the reaction. This lends support to the suggestion by Bonanno et al. that the main channel in the reaction of $O(^3P)$ with acetonitrile is addition to the CN group. On the other hand, the activation energies are comparable to or slightly larger than those for the reactions of $O(^3P)$ with alcohols and ketones while the preexponential factors are comparable to those for the reactions of $O(^3P)$ with ketones (1–8). If the reactions of $O(^3P)$ with nitriles were to proceed by addition, the activation energies would be expected to be much smaller and perhaps negative. If addition is the mode of attack, it seems that the addition complex must undergo a rearrangement requiring a significant activation energy before it decomposes to products.

The two possibilities for the initial mode of attack of $O(^3P)$ on acetonitrile, abstraction and addition, lead to the mechanisms outlined in Table 2. The addition mechanism is based on the reactions suggested by Bonanno et al., initiated by reaction [1*a*], with the inclusion of some additional secondary reactions such as reaction [4] that might be involved. The addition mechanism is invoked by setting A_{1b} equal to zero and A_{1a} equal to 4.38×10^8. The abstraction mechanism is initiated by reaction [1*b*] and is invoked by setting A_{1a} equal to zero and A_{1b} equal to 4.38×10^8. Otherwise, it differs from the addition mechanism only in the absence of reaction [11] for which the necessary OCN intermediate is no longer formed. It will be noted that only one loss route for the OCN radical is included. Hydrogen abstraction from CH_3CN by this radical has been omitted because the available kinetic data (17) for such reactions of OCN suggest that the rate constant would be

too small to enable it to compete effectively with reaction [11]. Addition of OCN to CH_3CN has also been omitted for the same reason. Also given in these tables are the kinetic parameters for the reactions that have been reported in the literature. In only two cases are direct measurements of these parameters not available and in both cases reasonable estimates can be made.

It should be possible to test these mechanisms by product analysis. The most obvious difference between them is the production of NO in only the addition mechanism. However, the two mechanisms also differ in their sources of OH and HCN and should lead to different relative yields of HCN and H_2O. We must rely largely on analytical data for the yields of these latter products since we were unable to analyse reliably for NO. This results from its incomplete trapping at liquid nitrogen temperature. Moreover, the necessity to use a thermal conductivity detector for H_2O and HCN resulted in comparatively poor sensitivity for H_2CO. While formaldehyde was well resolved from the other possible reaction products in chromatograms of standard mixtures, the detection sensitivity was too poor to detect it in the yields that would have been produced under our reaction conditions.

Yields of reaction products were measured with [nitrile]/$[O(^3P)]$ ratios in the range 5–30. These ratios are some 10–100

Table 2. Summary of the reaction mechanism for $O + CH_3CN$.

Reaction	*A*-factor ($L\ mol^{-1}\ s^{-1}$)	Activation energy ($kJ\ mol^{-1}$)	Reference

times smaller than those used in the kinetic measurements, but this was necessary in order to produce large enough quantities of reaction products for analysis in a reasonable length of time. Both H_2O and HCN were found in the products of the reaction of atomic oxygen with acetonitrile and the results are summarized in Table 3. The yields of HCN were generally more reproducible than those of H_2O. The yields of H_2O were roughly five times as large as the yields of HCN and this ratio showed no systematic variation with temperature and [nitrile]/[$O(^3P)$] ratio within the scatter of the data. The yields of HCN amounted to some 5–15% of the oxygen atom consumption, increasing somewhat with increasing temperature. The yields of water ranged from about 30% of the oxygen atom consumption at 304 K to about 50% at 552 K. In all these measurements, strong adsorption of acetronitrile was evident, as easily measurable peaks were obtained for acetonitrile in chromatograms of material collected in the traps a considerable time after the acetonitrile flow had been turned off. To minimize the effects of adsorbed acetonitrile on the chromatographic analysis, a blank was run as the first measurement each day before the actonitrile had been turned on. Product yields were then measured for systematically increasing flow rates of acetonitrile. The observation of yields of water that were larger than those of HCN was unexpected in view of the failure of Bonanno et al. to find a primary deuterium kinetic isotope effect. On the surface, the implication of the significant water yields could be that the reaction was initiated to a significant degree by hydrogen abstraction and that the OH formed in this way was producing the water found in the product analysis. On the other hand, the reaction of OH with acetonitrile has been studied (13) and is evidently too slow to be able to produce the amount of water found in our experiments.

Theoretical product yields were calculated for comparison with the measured yields by numerical integration of the set of differential equations for the system of reactions summarized in Table 2, using the kinetic parameters given in that table. The calculations used the LSODE subroutine for stiff systems of differential equations, included in a computer program that we have used in other work (18). Both the abstraction- and addition-initiated mechanisms predicted yields of water that were roughly two orders of magnitude smaller than the measured values. The yields of HCN were predicted to be some five to ten times the measured yields. The calculated yields of HCN could be made comparable to the experimentally measured yields if the rate constant for the reaction

[3] $O + CH_2CN \rightarrow CH_2O + CN$

was decreased by factor of 10 from the estimate given in Table 2. However, the yield of water was unaffected. The only reaction that had a significant impact on the yield of water was

[6] $OH + CH_3CN \rightarrow H_2O + CH_2CN$

but the rate parameters for this reaction were measured by direct experiment (13) and the increase in the rate constant for this reaction that would be required to make the water yield agree with our experiments was far greater than would be permitted by reasonable uncertainty limits for the directly measured kinetic parameters. Finally, the rates of consumption of atomic oxygen calculated from either the addition or the abstraction mechanism were very much greater than those measured in our experiments. It seemed clear that the extent of secondary reactions consuming $O(^3P)$ was seriously overestimated by the mechanism outlined in Table 2.

A plausible solution to the difficulties outlined above was suggested by the strong adsorption of acetonitrile on the walls of the reaction vessel, referred to earlier. If one estimates the number of collisions of OH radicals, present in concentrations of the magnitude predicted by the kinetic model, with the walls of our reaction vessel during the time period used for collecting the products for chromatographic analysis, the measured yields of water would be obtained if many of these collisions led to heterogeneous production of water. This seems reasonable since the CN group is likely to be closest to the glass surface so that the CH_3 groups would be exposed to the OH radicals striking the surface. When a heterogeneous first-order reaction of OH with CH_3CN adsorbed on the walls of the reactor, producing water, is inserted in the model, with a rate constant estimated from the collision frequency with the walls of the reaction vessel, the calculated yields of water and HCN predicted by the addition mechanism were brought into good

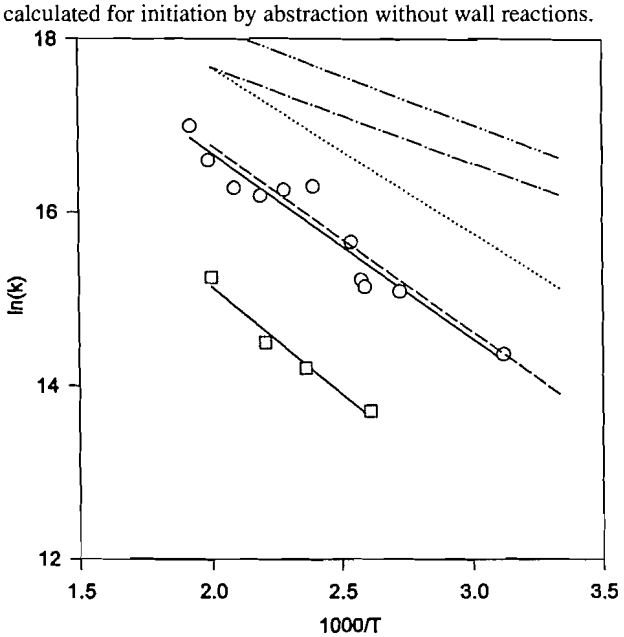
Fig. 4. Comparison of kinetic data for CH_3CN obtained experimentally and with the four potential reaction mechanisms. (○) Experimental data, this work; (□) experiments of ref. 9; (----) calculated for initiation by addition with wall reactions; (·····) calculated for initiation by addition without wall reactions; (-·-·) calculated for initiation by abstraction with wall reactions; (-···-) calculated for initiation by abstraction without wall reactions.



agreement with the measured yields. The quality of the agreement with experiment did not change as the rate constant for the heterogeneous reaction was substantially reduced. As few as 0.5% of the collisions of OH with the walls were required to provide acceptable agreement with the experimental results. The abstraction mechanism still did not provide good agreement with the experimental yields. Inclusion to a comparable extent of the analogous heterogeneous reactions of the other reaction intermediates such as H and CH_2CN had no discernable effect on the calculated yields of HCN or H_2O. The extent of agreement with the measured yields of HCN the H_2O is indicated in Table 3. The fundamental significance of these results is somewhat limited because of the intrinsic variability of surface conditions in such experiments. Indeed, variations in surface conditions are likely to be responsible for much of the scatter in the product analysis. The main value of these results is in confirming that heterogeneous reactions are a plausible explanation of the behaviour observed experimentally.

Perhaps the most convincing evidence in support of the mechanism initiated by reaction [1*a*], addition of $O(^3P)$ to CH_3CN, is found in the data summarized in Fig. 4. These data, both experimental and calculated from the mechanism, are based on the rate of loss of $O(^3P)$ at much larger [nitrile]/$[O(^3P)]$ ratios than those used to measure the product yields. In that figure are presented (*i*) the experimental kinetic data from ref. 9, (*ii*) our experimental kinetic data, and the rate constants calculated from the rates of $O(^3P)$ consumption calculated theoretically from the models for (*iii*) abstraction without wall reactions, (*iv*) abstraction with wall reactions, (*v*) addition without wall reactions, and (*vi*) addition with wall reactions. It is clear that the only model that provides agreement with our experimental data is the model initiated by reaction [1*a*], the addition channel. In that case, use of the kinetic parameters reported by Bonanno et al. (9) leads to virtually exact agreement with our kinetic measurements over the entire temperature range covered by our experiments. On that basis, we estimate that a stoichiometric factor of (1/7) ± 20% should be applied to our experimental rate constants, since these are approximately seven times as large as those calculated from the Arrhenius temperature dependence of ref. 9.

The results obtained for the reaction of $O(^3P)$ with propionitrile were similar to those for acetonitrile. The yield of HCN was again some 5–15% of the consumption of atomic oxygen. The yields of water were somewhat larger, up to an amount approximately equivalent to the consumption of atomic oxygen. However, very few kinetic data are available for the relevant secondary reactions so it is not clear to what extent heterogeneous reactions are responsible for the increased water yields. Nevertheless, the similarity of the kinetic behav-

iour of the reactions of atomic oxygen with acetonitrile and propionitrile suggests that both reactions occur by similar mechanisms involving initiation by addition of $O(^3P)$ to the CN bond, followed by decomposition of the addition complex to give intermediates that lead to the final products.

Synthesis of 5-substituted pyrrole-2-carboxaldehydes. Part I. Generation of formal 5-lithiopyrrole-2-carboxaldehyde equivalents by bromine–lithium exchange of 2-bromo-6-(diisopropylamino)-1-azafulvene derivatives[1]

Sylvie L. Berthiaume, Brian L. Bray, Petr Hess, Yanzhou Liu, Michael L. Maddox, Joseph M. Muchowski, and Markus E. Scheller

Abstract: The first known lithiated 1-azafulvene derivatives, e.g., **8** and **13***a*, were generated by a low-temperature bromine–lithium exchange procedure with *tert*-butyllithium. These lithio species show substantial stability at ≤–90°C because, at these temperatures, the sterically demanding 6-diisopropylamino moiety, unlike the dimethylamino group, completely inhibits nucleophilic addition to C-6. At higher temperatures, the addition of *tert*-butyllithium to C-6 is significant and it can become the dominant process. The lithio species **8** is a useful formal equivalent of 5-lithiopyrrole-2-carboxaldehyde since, on reaction with electrophilic reagents and subsequent hydrolysis, a wide variety of regiochemically pure 5-substituted pyrrole-2-carboxaldehydes is formed. The 6-dialkylamino-1-azafulvenes described herein exist predominantly or exclusively as the *syn* conformer in solution at room temperature. This conformational preference is confirmed by a significance NOE effect between H-4 and H-6 in the parent diisopropylamino compound **3***f*. The origin of the *syn* conformational preference stems from a substantial contribution of the charge-separated form **16** to the ground state structure of these compounds, a phenomenon that is strongly supported by variable temperature NMR measurements on 2-bromo-6-diisopropylamino-1-azafulvene (**3***c*).

Key words: 2-bromo-6-diisopropylamino-1-azafulvenes, stereochemistry, lithiation, pyrrole-2-carboxaldehydes.

Résumé : On a préparé les premiers dérivés 1-azafulvène lithiés connus, **8** et **13***a*, par une méthode d'échange du brome et du lithium, à basse température, utilisant du *tert*-butyllithium. Ces espèces lithiées présentent une stabilité importante à des températures ≤ –90°C parce que, à ces températures, la portion 6-diisopropylamino, qui possède une demande stérique importante par rapport à celle du groupe diméthylamino, inhibe complètement l'addition nucléophile en C-6. À des températures plus élevées, l'addition du *tert*-butyllithium en C-6 devient importante et, dans quelques cas, elle peut devenir prédominante. L'espèce lithiée **8** est un équivalent formel utile du 5-lithiopyrrole-2-carboxaldéhyde puisque, par réaction avec des réactifs électrophiles et hydrolyse subséquente, il y a formation d'une grande variété de pyrrole-2-carboxaldéhydes substitués en position 5 régiochimiquement purs. En solution, à la température ambiante, les 6-dialkylamino-1-azafulvènes décrits dans le présent travail existent exclusivement ou d'une façon prédominante comme conformères *syn*. Cette préférence conformationnelle est confirmée par un EON important entre les H-4 et H-6 du composé parent diisopropylamino **3***f*. La préférence conformationnelle *syn* provient d'une contribution

Introduction

Substituted pyrrole-2-carboxaldehydes are synthetic intermediates of much importance (1–5). The most generally useful synthesis of these compounds is by the Vilsmeier–Haack formylation of the appropriate 2-substituted pyrrole (6). This process is, however, associated with the inconvenience of requiring the separate preparation of each 2-substituted pyrrole, and has the limitation that a deactivating substituent (at C-2) gives rise to a mixture in which the 4-formylated compound (kinetic product) is a significant or even the major component (1, 4, 6). We have devised two complementary routes to 5-substituted pyrrole-2-carboxaldehydes based on the generation of 5-lithiopyrrole-2-carboxaldehyde equivalents of a nature such that there is no need for pyrrole N-protection.[6] One of these involves the lithiation of the easily prepared 6-(dimethylamino)-1-azafulvene dimer and its 3-bromo derivative (8). The other concerns the bromine–lithium exchange of the stable monomeric 2-bromo-6-(diisopropylamino)-1-azafulvenes. Herein are found the full details of the latter process as well as information on the synthesis and some of the properties of such azafulvenes (for preliminary communications, see ref. (9)).

The first 2-halo-6-(dialkylamino)-1-azafulvenes were prepared by von Dobeneck and co-workers (10) by reaction of 3,4-dialkyl-3-pyrrolin-2-ones with the Vilsmeier–Haack reagents derived from DMF and $POCl_3$ or $POBr_3$ followed by basification under mild conditions. Such compounds have also been obtained by the sodium hydride deprotonation of the di- and tribromination products of the ternary iminium perchlorates derived from pyrrole-2-carboxaldehyde (11). von Dobeneck and co-workers (10) showed that these azafulvenes were particularly susceptible to nucleophilic addition at C-6, undergoing a variety of addition elimination reactions[7] including hydrolysis to the corresponding aldehydes. We recognized that if this proclivity for nucleophilic addition could be reduced, halogen–lithium exchange at C-2 would produce a lithiated 1-azafulvene functionally equivalent to a 5-lithiopyrrole-2-carboxaldehyde derivative.

Results and discussion

Synthesis of the azafulvenes

2-Bromo-6-dimethylamino-1-azafulvene (**3***a*, Scheme 1) was the first azafulvene unsubstituted at C-3,4 that we prepared. This compound was obtained by deprotonation (10, 11) of the iminium salt **2***a* with aqueous sodium hydrogen carbonate. When prepared by this route, compound **3***a* was always contaminated with a small amount of the 2-chloro compound **3***b*, which stemmed from the hydrogen chloride induced bromine–chlorine exchange during the formation of **2***a* by the Vilsmeier–Haack reaction on 2-bromopyrrole (**1***a*).[8] The halogen exchange problem was solved (13) by conversion of the iminium salts **2***d,e* into the covalent Strecker-type nitriles (**4**), which underwent highly regioselective bromination at C-5 at –70°C with *N*-bromosuccinimide. These bromo compounds (**5**) were converted into the 2-bromoazafulvenes **3***c* and the 6-methyl compound **3***e* by sequential treatment with aqueous hydrochloric acid and sodium hydroxide, a process that proceeds via the iminium salts **2** (not isolated).

The azafulvenes **3***c* and **3***d* could also be generated, in modest yields, by heating the carboxaldehydes **6***a* and **6***c* with excess diisopropylamine. This condensation was expected based on the observation of Kira et al. (14) that 4- and 5-nitropyrrole-2-carboxaldehydes were converted into the corresponding stable azafulvenes with unhindered secondary amines in ethanol at room temperature.

As expected (see below), the brominated 6-diisopropylamino-1-azafulvenes **3***c* and **3***d* showed pronounced resistance to nucleophilic attack at C-6. Thus, complete hydrolysis of **3***c* to the carboxaldehyde **6***a* with excess sodium hydroxide (6 equiv.) in aqueous methanol at room temperature required 5 h (13)[9] whereas the 6-dimethylamino compound **3***a* already reacted at 0°C. The significant stability of **3***c* suggested that the parent compound itself ought to be isolable. Indeed, deprotonation of the iminium salt **2***e* with triethylamine at room temperature efficiently generated **3***f*, which, though sensitive to hydrolysis, is indefinitely stable in the absence of water and, in contrast to the 6-dimethylamino congener, shows no tendency whatsoever to dimerize (15).

Bromine–lithium exchange of the bromoazafulvenes

Reaction of 2-bromo-6-dimethylamino-1-azafulvene (**3***a*) with 2 equivalents of *tert*-butyllithium in THF at –78°C and subsequent quenching of the reaction mixture with water or other electrophilic reagents gave variable amounts of the highly unstable amine **7***a* (Scheme 2). In no case were products derived from the 2-lithiated azafulvene observed. In contrast, bromine–lithium exchange of the 6-diisopropylamine compound **3***c* under the same conditions, followed by reaction

[6] The generation of C-lithiopyrroles by halogen–lithium exchange of N-unsubstituted halogenopyrroles has been accomplished at least twice (7). In contrast, 2-bromo-1*H*-pyrrole is not C-lithiated even with excess *t*-BuLi in THF. J.M. Muchowski and R. Naef. Unpublished data.

[7] For a review on the synthesis and properties of this general class of compounds see ref. 12.

[8] The extent of this exchange, which must occur by protonation of **2***a* at C-4, is dependent on the length of time that this salt remains in contact with the reaction medium. Thus hydrolysis to the aldehyde immediately upon consumption of **1***a* gave a 95:5 mixture of aldehydes **6***a* and **6***b* whereas hydrolysis after 24 h gave a 1:1 mixture of **6***a* and **6***b*.

[9] It was previously erroneously reported (13) that the hydrolysis of **3***a* (compound **5***a* in ref. 13) required 5 h at room temperature. The hydrolysis conditions given are actually those for the conversion of **3***c* to the aldehyde **6***a* (i.e., **5***b* to **6***a* in ref. 13, p. 1307).

with methyl iodide and aqueous sodium acetate hydrolysis in the same pot, gave 5-methylpyrrole-2-carboxaldehyde (**10***a*) in 61% yield after column chromatography (Expt. 3, Table 1). Obviously, the bulky nitrogen substituents had significantly suppressed nucleophilic addition to C-6, permitting the generation of the 2-lithioazafulvene **8** (Scheme 2). The lithio species thus generated was reacted with a series of electrophilic reagents, giving rise to the corresponding 5-substituted pyrrole-2-carboxaldehydes **10** (Scheme 1), in most cases in modest yields (Table 1). It was noted that the product mixture from each of these reactions contained significant amounts of an unstable substance determined to be the alcohol **11**, the hydrolysis product of **7***b*. These results demonstrated that addition of *tert*-butyllithium to **3***c* was still occurring at –78°C. When the bromine–lithium exchange was conducted at –105°C, compound **11** was only a minor component (<10%) of the reaction mixture, and the protonolysis–hydrolysis product, pyrrole-2-carboxaldehyde (**6***d*), was isolated in 90% yield (Expt. 2). It is absolutely necessary that the THF used in all of these lithium–bromine exchange reactions be freshly distilled from sodium benzophenone ketyl to remove any inhibitor of peroxide formation and (or) peroxides themselves. If this is not done, neither the exchange nor the addition process takes place (e.g., with undistilled 99.9% THF containing butylated hydroxytoluene). This is consistent with both processes occurring by a mechanism involving electron transfer.) In contrast, at –10°C, addition product **11** was obtained in 97% yield (Expt. 1). The lithioazafulvene **8**, when generated at –105°C, reacted with a broad spectrum of electrophilic reagents, producing the expected 5-substituted pyrrole-2-carboxaldehydes **10**, usually in considerably better yields than when the lithiation was effected at –78°C (Table 1). *n*-Butyl iodide and triisopropylsilyl chloride both gave the anticipated products but only when HMPA (2 equiv.) was used. Benzaldehyde and cyclohexanone also reacted in the expected sense, but because the primary products are quite unstable, they were reduced in the

same pot to the 2,5-disubstituted pyrroles **12***a* and **12***b* with sodium borohydride in boiling 2-propanol (16). It should be noted that –105°C is probably an unnecessarily low temperature for the efficient formation of the lithioazafulvene **8**, since a –90°C reaction with DMF gave rise to pyrrole-2,5-dicarboxaldehyde in over 60% yield (Expt. 12).

The primary product in the reaction of **8** with electrophilic reagents is the azafulvene **9**, the presence of which is readily established by ^1H NMR spectroscopy. The susceptibility of these compounds to hydrolysis varies greatly. For example, with aqueous sodium acetate in a two-phase system (reflux) the hydrolysis of the 2-methyl compound **9***a* is complete in 15 h (Expt. 3) whereas the 2-methylthio compound **9***d* requires 5 days (Expt. 7). The hydrolyses are considerably faster in homogeneous solution, e.g., the conversion of the 2-butyl compound **9***b* to **10***b* is complete in 2 h at room temperature in aqueous methanolic sodium acetate (Expt. 5).

It was of interest to examine 2,3-dibromo-6-isopropylamino-1-azafulvene (**3***d*) as a progenitor of 3,4-disubstituted pyrrole-2-carboxaldehydes. To be synthetically valuable this would require a highly selective exchange of one of the bromine atoms in **3***d* for lithium. Indeed, lithiation of this compound with a *tert*-butyllithium at –105°C followed by quenching with water and hydrolysis, gave a >65:1 mixture of the aldehydes **6***a* and **6***e*. When the lithiation was effected at –78°C, this ratio decreased to ca. 20:1. Lithiation of **3***d* at –105°C, followed by aging the solution of **13***a*,*b* at –78°C and then sequentially quenching with methyl iodide and hydrolysis, gave an 18:1 mixture of the methylated aldehydes **14***a* and **14***b* (Scheme 3) from which pure 3-methyl-5-bromopyrrole-2-carboxaldehyde (**14***a*) could be obtained by crystallization. Elimination of the hydrolysis step permitted the isolation of the azafulvene **13***c* in about 60% yield. Alternatively, if the mixture of azafulvenes **13***c* and **13***d*, generated as described above, was sequentially lithiated, reacted with DMF, and hydrolyzed, 3-methylpyrrole-2,5-dicarboxaldehyde (**15**) could be isolated from the product mixture by column chromatography in about 30% yield (unoptimized). Thus, the dibromoazafulvene **3***d* would appear to have potential utility as a 4,5-dilithiopyrrole-2-carboxaldehyde equivalent although it is clear that optimization of the second lithiation would be necessary to make the process more synthetically attractive.

To date, our efforts to extend the scope of the 2-lithiated-1-azafulvene process to the synthesis of 5-substituted 2-acylpyrroles in general have met with failure. Firstly, reaction of 2-bromo-6-methyl-6-diisopropylamino-1-azafulvene (**3***e*, Scheme 1) with *tert*-butyllithium at –105°C, followed by quenching with methyl iodide and hydrolysis, gave a complex

mixture that contained little, if any, 5-methyl-2-acetylpyrrole (**6***f*). Small amounts of 5-bromo-2-acetylpyrrole (**6***g*) and the corresponding N-methyl derivative, that is, the hydrolysis and N^1-methylation–hydrolysis products, respectively, of **3***e*, were the only pure compounds isolated from the mixture. Secondly, the generation of the 6-phenyl analog of **3***e* could not be achieved because the Vilsmeier–Haack reaction of pyrrole with the iminium salt derived from *N,N*-diisopropylbenzamide and oxalyl chloride did not produce the required product.

Some properties of 6-dialkylamino-1-azafulvenes

The stable monomeric 6-dialkylamino-1-azafulvenes comprise two types. The most widely studied class consists of those congeners that are push–pull stabilized (10, 11, 13, 14) and contain one to three electron-attracting substituents at C-2,4. Compounds **3***a–e* are examples of this type. The second type, which so far consists of a single member (**3***f*), owes its stability as a monomer entirely to the presence of the sterically demanding N-6 substituents. In the absence of push–pull stabilization, the size of these substituents is crucial since azafulvenes with less bulky N-6 substituents spontaneously dimerize at room temperature (15). These monomers can, however, be generated in situ at low temperature where they have an appreciable half-life, by deprotonation of the corresponding iminium salts (19).

The 6-dialkylamino-1-azafulvenes obviously are basic, but only weakly so. For example, the pK_a of **2***c*, the conjugate acid of **3***c*, was found to be ~6.7 in 50% aqueous methanol. The pK_a of **2***e* could not be measured under these conditions because of its facile conversion into pyrrole-2-carboxaldehyde (**6***d*). These azafulvenes undergo [6 + 2] cycloaddition reactions at N-1 and C-6 with a variety of dipolarophiles (11, 20) and also are alkylated at N-1 with methyl iodide (11, 21).

Perhaps one of the more notable properties of these azafulvenes is that in solution they exist predominantly, if not exclusively, as one conformer,[10] and in this conformer the dialkylamino group is *syn* to the azafulvene nitrogen atom. This conformation was unequivocally established for compound **3***f* by NMR spectroscopic methods. Thus, the methine protons of the two isopropyl groups are found at δ 3.83 and 6.61 (Fig. 1*a*). The low-field absorption indubitably corresponds to the methine hydrogen of the isopropyl group that is proximal to the azafulvene nitrogen atom by which it is

[10] Most of the azafulvenes described herein contain a minor amount (10–20%) of another component the NMR spectrum of which is consistent with that expected for the *anti* conformer (see also ref. 11). There is no doubt that we are dealing with conformers since the ratio of the two species is solvent dependent. For example, **3***c* is an 85:15 *syn–anti* mixture in $CDCl_3$ and $C_2D_2Cl_4$ but exists as the pure *syn* species in DMSO-d_6, C_6D_6, and C_7D_8. Furthermore, saturation of either of the singlets corresponding to H-6 of the *syn* and *anti* conformers of **3***c* (δ 7.09 and 7.79) results in a strong diminution of the intensity of the other, indicating that the two species are exchanging at room temperature.

Scheme 3

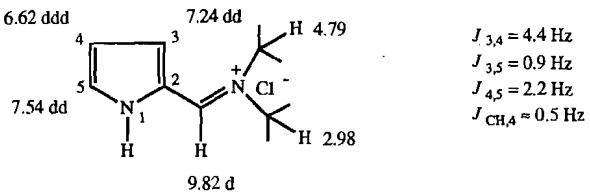
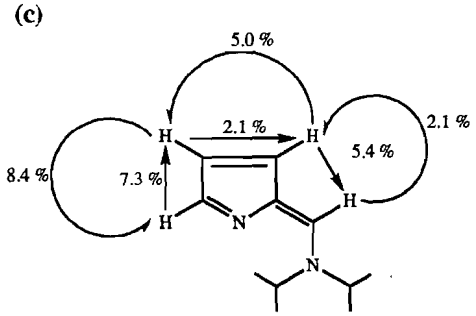
(b)



(c)



strongly deshielded. This deshielding is considerably greater than that found in **2***e*, the iminium salt precursor of **3***f* (Fig. 1*b*). In addition to the large chemical shift difference of the isopropyl methine hydrogens, H-6 is long-range coupled to H-1 by 1.1 Hz. (The connectivity in **3***f* was established by COSY and decoupling experiments.) This long-range coupling is analogous to that observed for most pyrrole-2-carboxaldehydes (22) for which the *syn* conformer predominates at room temperature. In contrast, in the iminium salt **2***e* the proton of the iminium carbon is weakly coupled to H-4, indicative of the *anti* conformation (23). Also noteworthy in the ^{1}H NMR spectrum of **3***f* is the small value of $J_{2,3}$ (0.8 Hz) as compared to $J_{4,5}$ (2.2 Hz) in the iminium salt **2***e*. This coupling constant is nearly identical to that reported (0.86 Hz) for $J_{2,3}$ in 6,6-diphenyl-1-azafulvene by Hafner and Pfeiffer (24). The most definitive evidence for the *syn* conformer in **3***f* is derived from NOE difference measurements, which show a 2–5% NOE between H-4 and H-6 (Fig. 1C)! The NOE difference measurements also confirmed the connectivity sequence of the hydrogens bonded to the sp^2 carbon as established by the COSY and decoupling experiments.

What is the reason for the preponderance of the *syn* conformer in 6-dialkylamino-1-azafulvenes? We suggest that the charge-separated form **16** (Scheme 4) must make a substantial contribution to the ground state structure of these compounds and the consequent electrostatic attraction between the two nitrogen atoms causes the *syn* form to be favored. Variable temperature NMR experiments on the 2-bromo compound **3***c* support this contention. Compound **3***c* exists as an 85:15 mixture of *syn* and *anti* conformers in dideuterated 1,1,2,2-tetrachloroethane (also in $CDCl_3$) as indicated by major and minor absorptions for H-6 at δ 7.02 and 7.79. The isopropyl methine hydrogens for the *syn* conformer are found at δ 3.82 and 6.37 and at δ 3.82 and 4.62 for the *anti* conformer. The doublets for the isopropyl methyl groups of the *anti* conformer are obscured by those for the *syn* conformer centered at δ 1.33. On warming, the isopropyl doublets coalesced to a clean doublet at about 353 K, but the absorptions for H-6 had only broad-

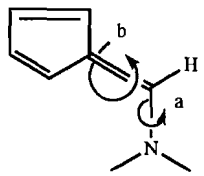
3*c*



17

ened. These latter absorptions had broadened further but were still showing no signs of coalescing at 383 K at which temperature the HD salt of **3***c* formed by dehydrohalogenation of the solvent. Although coalescence of the signals for H-6 could not be achieved (*syn* conformer exclusively in DMSO-d_6 or toluene d_8) it is clear that the higher and lower energy dynamic processes in **3***c* correspond to rotation around bonds "b" and "a" (Scheme 4) analogous to that found in 6-dimethylaminofulvene (**17**, Scheme 4; see ref. 25). Although the rotational barrier about the isopropyl groups is clearly the lower energy process, the existence of this barrier is still consistent with a substantial contribution of the charge-separated form **16** to the ground state structure of **3***c*. In contrast, the 6-methyl analog **3***e* of **3***c* shows a singlet at δ 2.71 for the 6-methyl group, a single doublet for the four isopropyl methyls, and a very broad (δ 4.2–5.4) absorption for the two isopropyl methine hydrogens. This indicates that the coalesence temperature for rotation about the C-6—N bond is at or near ambient temperature and that the charge-separated form contributes much less to the ground state structure in this case.

Conclusions

2-Bromo-6-diisopropylamino-1-azafulvene (**3***c*) undergoes bromine–lithium exchange with *tert*-butyllithium at ≤90°C, and the lithium species **8** obtained thereby on reaction with electrophilic reagents and subsequent hydrolysis provides a wide variety of 5-substituted pyrrole-2-carboxaldehydes.

6-Dialkylamino-1-azafulvenes exist predominantly or exclusively in the *syn* conformer in solution at room temperature. This conformer is favored over the *anti* conformer because the charge-separated form **16** contributes substantially to the ground state structure of these molecules. These phenomena are supported by both ambient and variable temperature NMR experiments.

Experimental section

The melting points were determined in a Mel-Temp II melting point apparatus and are not corrected. The infrared spectra were measured with a Nicolet 5 PC FT infrared spectrophotometer. The ^{1}H NMR spectra were measured with a Bruker WM 300 or a Bruker AM 500 NMR spectrometer in $CDCl_3$ (unless specified otherwise) and are expressed as parts per million (δ) from internal tetramethylsilane. When exchangeable protons were present, the data are given for D_2O exchanged spectra. Those NMR spectra not found in the experimental section can be obtained from the Depository of Unpublished Data.[11] The low-resolution mass spectra were obtained with a MAT CH-7 or a MAT 1125 mass spectrometer while the high-resolution mass spectrum was measured on a Finnigan MAT 311A mass spectrometer.

The terms "worked up in the usual manner" or "the usual work-up" signify that the extract was dried over anhydrous magnesium or sodium sulfate and evaporated in vacuo.

N,N-Diisopropyl 2-bromopyrrole-5-formiminium chloride (2*c*)

To a solution of pure 2-bromo-6-diisopropylamino-1-azafulvene (**3***c*) (0.50 g, 1.94 mmol) in ether (25 mL) at 0°C, prepared by one of the methods described below, was added a freshly prepared 0.23 M solution of HCl gas in ether (8.5 mL, 1.96 mmol). The precipitated solid was collected by filtration and dried in vacuo (0.50 g, 88% yield). It was analytically pure and had mp 200–201°C; pK_a (1:1 MeOH–H_2O) = 6.67 ± 0.08; IR (KBr): 3440, 1634 cm^{-1}; NMR (300) δ: 1.53 (d, 6H, J = 6.66 Hz, NCH*Me*$_2$), 1.60 (d, 6H, J = 6.71 Hz, NCH*Me*$_2$), 4.18 (sept, 1H, J = 6.71 Hz, NC*H*Me$_2$), 4.74 (sept, 1H, J = 6.66 Hz, NC*H*Me$_2$), 6.57 (d, 1H, $J_{3,4}$ = 4.44 Hz, H-3), 7.20 (d, 1H, $J_{3,4}$ = 4.44 Hz, H-4), 9.76 (s, 1H, CH=N). Anal. calcd. for $C_{11}H_{18}BrClN_2$: C 44.99, H 6.17, N 9.54, found: C 44.96, H 6.15, N 9.51.

2-Bromo-6-dimethylamino-1-azafulvene (3*a*) by deprotonation of the iminium salt 2*a*

Oxalyl chloride (2.1 mL, 3.06 g, 24.1 mmol) was carefully added dropwise at room temperature (vigorous exotherm) to a stirred solution of dry DMF (1.57 mL, 1.48 g, 20.3 mmol) in dry dichloromethane (40 mL). After 25 min at room temperature, the solvent was evaporated in vacuo with protection from moisture and the very hygroscopic white solid was dried in vacuo for 20 min. A solution of 2-bromopyrrole (1*a*) (prepared from 20 mmol of pyrrole (26)) in dry dichloromethane (20 mL) was slowly added to the above solid at 0°C. When the addition was complete, the solution was left to reach room temperature and 25 min thereafter 0.5 M $NaHCO_3$ solution was added. The organic phase was separated, combined with a dichloromethane extract of the aqueous phase, and the extract was washed sequentially with 10% aqueous NaOH, 0.5 M $NaHCO_3$, and saturated NaCl solutions. After the usual work-up the crude product was crystallized from hexane–ethyl acetate to give 3*a* as a solid (3.25 g, 81%) with mp 101–103°C; IR (CCl_4): 1640 cm^{-1}; NMR (300) δ: 3.30 (s, 3H, NMe), 3.75 (s, 3H, NMe), 6.32 (d, 1H, J = 3.8 Hz, H-3), 6.90 (d, 1H, J = 3.8 Hz, H-4), 6.98 (s, H-6). The NMR spectrum also showed absorptions for the *anti* conformer (17%) at δ 6.42 (d), 7.04

[11] These spectra can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada ON K1A 0S2.

For personal use only.

(d), 7.68 (s) and for the chloro compound **3***b* (8%) at δ 6.15 (d), 6.96 (s). Anal. calcd. for 0.92 $C_7H_9BrN_2$·0.08 $C_7H_9ClN_2$: C 42.76, H 4.61, N 14.25; found: C 42.58, 42.38; H 4.63, 4.58; N 13.92, 14.08.

2-Bromo-6-diisopropylamino-1-azafulvene (3*c*) from the bromoaldehyde 6*a* and diisopropylamine

A solution of the aldehyde **6***a* (18) (7.28 g, 41.8 mmol) and diisopropylamine (15.2 mL, 11.7 g, 116 mmol) in ethanol (150 mL) was heated at reflux temperature for 20 h. The solution was evaporated to dryness in vacuo and the residue was dissolved in ether and extracted with ice-cold 1 M HCl solution. The usual work-up of the ether phase gave recovered **6***a* (2.40 g). The ice-cold acidic phase was made alkaline with ice-cold 10% aqueous NaOH solution and the product was extracted into ether. The usual work-up gave the azafulvene **3***c* as a solid (5.64 g, 52% yield; 78% based on recovered **6***a*), mp 108–112°C. Recrystallization of this material from hexane–ether gave pure **3***c*, mp 110.5–112°C, identical in all respects to a specimen synthesized via the brominated Strecker-type nitrile **5***a* (13).

2,3-Dibromo-6-diisopropylamino-1-azafulvene (3*d*) from the dibromoaldehyde 6*c* and diisopropylamine

A solution of the dibromo aldehyde **6***a* (18) (2.00 g, 7.9 mmol) in diisopropylamine (100 mL) containing suspended 4A molecular sieves (large excess) was heated at reflux temperature for 38 h. The mixture was cooled to room temperature, filtered, and the filtrate was evaporated in vacuo. The residue was worked up as described for **3***c* except that 0.5 M HCl was used. This procedure gave the starting material (0.29 g) and crude **3***d* (2.3 g, mp 131–133°C). One crystallization from pentane–ether gave the pure compound (2.00 g, 75% yield), mp 135–137°C; IR ($CHCl_3$): 1618 cm^{-1}; NMR (500) δ: 1.32 (d, 6H, J = 6.7 Hz, NCH*Me*$_2$), 1.36 (d, 6H, J = 6.7 Hz, NCH*Me*$_2$), 3.85 (sept, 1H, J = 6.7 Hz, N*CH*Me$_2$), 6.33 (sept, 1H, J = 6.7 Hz, N*CH*Me$_2$), 6.72 (s, 1H, H-3), 7.00 (s, 1H, H-6). The NMR spectrum also showed peaks for the *anti* conformer (20%) at 1.36 (d), 1.38 (d), 3.87 (sept), 4.56 (sept), 7.08 (s), and 7.72 (s). Anal. calcd. for $C_{11}H_{15}Br_2N_2$: C 39.43, H 4.51, N 8.36; found: C 39.28, H 4.78, N 8.27.

2-Bromo-6-methyl-6-diisopropylamino-1-azafulvene (3*e*) via Strecker-type nitrile 5*b*. Hydrolysis of 3*e* to 5-bromo-2-acetylpyrrole 6*g*

Phosphorus oxychloride (5.9 g, 38.5 mmol) and dry *N,N*-diisopropylacetamide (5.0 g, 35 mmol) were combined and the solution was left at room temperature for 6 h by which time the contents of the flask had solidified. A solution of pyrrole (2.3 g, 35 mmol) in dry dichloromethane (50 mL) was added and the resulting solution was left at room temperature for 10 h. The solvent was removed in vacuo to give the crude Vilsmeier–Haack product in quantitative yield. This salt (**2***d*) was dissolved in dry MeCN (250 mL) and solid NaCN (25 g, 500 mmol) was added. The resulting mixture was stirred at room temperature for 8 h and about 75% of the solvent was removed in vacuo. The slurry so obtained poured into water (250 mL) and the product was extracted into ether. The extract was washed with saturated NaCl solution and then dried over anhydrous potassium carbonate. The ether solution of **4***b* was decolorized with activated charcoal, filtered, and evaporated in vacuo to give a solid (4.5 g) that was crystallized from hexane–ethyl acetate to give pure **4***b* (2.3 g, 34% yield), mp 86–88°C; IR (KBr): 3337, 2217 cm^{-1}; NMR (300) δ: 1.16 (d, 6H, J = 6.9 Hz, NCH*Me*$_2$), 1.28 (d, 6H, J = 6.9 Hz, NCH*Me*$_2$), 1.86 (s, 3H, 6-Me), 3.20 (sept, 2H, J = 6.9 Hz, N*CH*Me$_2$), 6.13 (t, 1H, H-4), 6.32 (dd, 1H, $J_{3,4}$ = 3.5 Hz, $J_{3,5}$ = 1.5 Hz, H-3), 6.75 (dd, 1H, $J_{3,5}$ = 1.5 Hz, $J_{4,5}$ = 2.8 Hz, H-5). Anal. calcd. for $C_{13}H_{21}N_3$: C 71.19, H 9.65, N 19.16, found: C 71.20, H 9.63, N 19.30.

N-Bromosuccinimide (0.203 g, 1.14 mmol) was added to a stirred solution of **4***b* (0.250 g, 1.14 mmol) in dry THF (25 mL) at –78°C. The solution was stirred at –78°C for 3 h, left to reach room temperature, and then evaporated in vacuo. The residue (**5***b*) was dissolved in MeOH (10 mL), 10 wt.% NaOH (3 mL) was added, and the solution was left at room temperature for 10 min and poured into water. This solution was brought to pH 2 with 1 M HCl and then the reaction mixture was worked up as described for the synthesis of **3***c* to give the azafulvene **3***e* as an oil (0.210 g, 68% yield) that solidified on standing. This compound is chromatographically unstable and could not be recrystallized. It had a purity of ca.95% by NMR spectroscopy; the only contaminant was 5-bromo-2-acetylpyrrole (**6***g*). This sample of **3***e* was used as such for the bromine–lithium exchange experiment; NMR (300) δ: 1.44 (d, 12 H, J = 6.9 Hz, NCH*Me*$_2$), 2.71 (s, 3H, 6-Me), 4.2–5.4 (v br, 2H, N*CH*Me$_2$), 6.32 (d, 1H, J = 3.9 Hz, H-3), 7.02 (d, 1H, J = 3.9 Hz, H-4); MS (EI) *m/z*: 272 (8), 270 (8), 229 (35), 227 (38), 189 (61), 187 (63), 174 (87), 172 (100), 146 (21), 144 (22), 86 (42), 44 (73). The identity of this material was further established by hydrolysis to **6***g*.

A sample of the azafulvene **3***e* (0.110 g, 0.41 mmol) was passed through a column of Act II neutral alumina using hexane – ethyl acetate (2:1) as the eluting solvent. Compound **6***g*, a solid (0.070 g, 92% yield, mp 100–101°C), was obtained that on recrystallization from hexane–ethyl acetate had mp 105–106°C; IR (KBr): 3432, 3345, 1646 cm^{-1}; NMR (300) δ: 2.40 (s, 3H, COMe), 6.24 (d, 1H, J = 3.9 Hz, H-4), 6.81 (d, 1H, J = 3.9 Hz, H-3). Anal. calcd. for C_6H_6BrNO: C 38.32, H 3.21, N 7.44; found: C 38.40, H 3.20, N 7.43.

6-Diisopropylamino-1-azafulvene 3*f* by deprotonation of the iminium salt 2*e*

Triethylamine (1.49 g, 14.7 mmol) was added to a solution of the iminium salt **2***e* (13) (2.10 g, 9.80 mmol) in dichloromethane (50 mL) at room temperature. After 10 min the solution was washed with saturated NaCl solution, dried over anhydrous potassium carbonate, and then the solvent was removed in vacuo. The oil thus obtained (1.37 g, 78% yield) crystallized on standing. One crystallization of this material from hexane–ether gave analytically pure **3***f* (1.05 g, 60% yield), mp 63–65°C; IR (KBr): 1615 cm^{-1}. For the NMR spectrum in $CDCl_3$ see Fig. 1*a*; for other solvents see supplementary data.[11] Anal. calcd. for $C_{11}H_{18}N_2$: C 74.11, H 10.17, N 15.71; found: C 74.21, H 10.45, N 16.01.

Generation of 2-lithio-6-diisopropylamino-1-azafulvene (8) and reaction electrophilic reagents

(a) Formation of 8 in THF solution

A solution of 1.7 M *tert*-butyllithium in pentane (2.4 mL, 4.08 mmol) was added dropwise to a stirred solution of **3***c* (0.499 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

1.94 mmol) in dry THF (30 mL, freshly distilled from sodium benzophenone ketyl) cooled to –105°C under an inert atmosphere at a rate such that the internal temperature did not exceed –100°C. The solution thus obtained was stirred at –105°C for 15 min; then the electrophilic reagent (1.2–3 equiv.) was added and the reaction temperature was raised to –78°C where it was maintained for 15 min. The temperature was then left to rise to 0°C and the reaction mixture was worked up by one of the methods described below.

(b) Formation of ***8*** *in THF solution containing HMPA*

A solution of **8** in THF prepared at –105°C as described above was warmed to –78°C and after 15 min HMPA (2 equiv.) dissolved in dry THF (1.5 mL/mmol HMPA) was added. After a further 15 min at –78°C the electrophilic reagent was added. The remainder of the procedure was identical to that described above.

Conversion of the 2-substituted-6-diisopropylamino-1-azafulvenes (9) to 5-substituted pyrrole-2-carboxaldehydes 10 or 5-alkyl-2-methylpyrroles (12)

(a) Procedure A

A solution of sodium acetate (5 equiv.) in water (1 mL/mmol) was added to the azafulvene solution prepared as in (a) above and the mixture was heated at reflux temperature for the time period indicated in Table 1. The mixture was poured into water and extracted with ether. The ether extract was washed with saturated NaCl solution and then worked up in the usual manner. The crude product was then purified by column chromatography (see Table 1) and then, if appropriate, the product was recrystallized from a suitable solvent system (Table 1).

Alternatively, for compounds **10***b* and **10***g* the aqueous sodium acetate solution was first brought to pH 2 with 1 M HCl (to remove small amounts of unhydrolyzed azafulvene) and then the usual work-up was followed.

(b) Procedure B

The azafulvene solution obtained as in (*a*) or (*b*) above was concentrated in vacuo. The residue was dissolved in methanol (5 mL/mmol azafulvene) and a solution of sodium acetate (5 equiv.) in water (0.5 mL/mmol) was added. The mixture was stirred at room temperature for the time period indicated in Table 1 and then it was poured into saturated NaCl solution. The remainder of the work-up followed that described in procedure A.

(c) Procedure C

To the THF solution of the azafulvene obtained as in (a) above was added 2-propanol (50 mL/mmol azafulvene) and sodium borohydride (2–3 parts by weight) and the solution was treated at reflux temperature for 15 h. The reaction mixture was poured into saturated aqueous ammonium chloride solution and extracted with ether. The remainder of the work-up was the same as that described in procedure A. The crude product was purified by column chromatography on silica gel using hexane – ethyl acetate (40:1) to elute the 5-alkyl-2-methylpyrrole derivatives.

*5-*n*-Butylpyrrole-2-carboxaldehyde (**10**b):* IR (neat): 3260, 1645 cm^{-1}; NMR (300) δ: 0.93 (t, 3H, J = 7.3 Hz, Me), 1.38 (sext, 2H, ΣJ = 7.5 Hz, Me$CH_2$$CH_2$$CH_2$), 1.65 (m, 2H, Me$CH_2$$CH_2$$CH_2$), 2.69 (t, 2H, J = 7.7 Hz, Me$CH_2$$CH_2$$CH_2$), 6.08 (d, 1H, J = 3.8 Hz, H-4), 6.91 (d, 1H, J = 3.8 Hz, H-3), 9.34 (s, 1H, CHO). Monolithiation of 2,3-dibromo-6-diisopropylamino-1-azafulvene (3*d*) and reaction with methyl iodide

*(a) Synthesis of 2-bromo-3-methyl-6-diisopropylamino-1-azafulvene (**13**c)*

tert-Butyllithium in pentane (5.0 mL of a 1.4 M solution; 7.0 mmol) was added to a stirred solution of **3***d* (1.12 g, 3.34 mmol) in dry THF (75 mL) maintained at –105°C in an inert atmosphere. The solution was stirred for 15 min at –105°C, warmed to –78°C, stirred 15 min at this temperature, and then methyl iodide (0.62 mL, 1.42 g, 10.0 mmol) was added. The cooling bath was removed and after 1 h the solution was poured into ice-cold 0.1 M HCl. The aqueous phase was washed with ether and then made alkaline with ice-cold 10 wt.% NaOH solution. The product was extracted into ether, the extract was washed with saturated NaCl solution and dried over anhydrous potassium carbonate, and the solvent was removed in vacuo. The residue was subjected to column chromatographic separation on Act II neutral alumina using hexane – ethyl acetate (4:1) to elute the azafulvene **13***c* as a solid. Crystallization of this material from hexane gave pure **13***c* (0.575 g, 63.5%), mp 84–86°C. IR (KBr): 1618 cm^{-1}. The NMR spectrum ($CDCl_3$) indicates that the azafulvene is a 7:3 mixture of *syn* and *anti* conformers; δ (syn): 1.29 (d, J = 6.7 Hz, Me_2CH), 1.33 (d, J = 6.7 Hz, Me_2CH), 2.06 (s, 3-Me), 3.78

(sept, J = 6.7 Hz, Me_2CH), 6.32 (sept, J = 6.7 Hz, Me_2CH), 6.67 (s, H-4), 6.87 (s, H-6); δ (*anti*): 2.11 (s, 3-Me), 4.58 (sept, Me_2CH), 6.82 (s, H-4), 7.63 (s, H-6). Anal. calcd. for $C_{12}H_{19}BrN_2$: C 53.14, H 7.06, N 10.33; found: C 53.33, H 7.19, N 10.01.

*(b) Synthesis of 5-bromo-4-methylpyrrole-2-carboxaldehyde (**14***a*)*

A solution of the azafulvene **13***c* was prepared as in (a) above and the THF was removed in vacuo. The residue (from a 2.40 mmol reaction) was dissolved in methanol (20 mL) and 20 wt.% aqueous NaOH (8 mL) and the solution was left at room temperature for 60 h. The reaction mixture was poured into saturated NaCl solution and the solution was made acidic (pH 2) with 1 M HCl. The products were extracted into dichloromethane and after the usual work-up the solid mixture of **14***a* and **14***b* was purified by column chromatography on Act II neutral alumina using hexane – ethyl acetate (3:1) to coelute the 18:1 **14***a*:**14***b* mixture as a solid (0.385 g, 85% yield) from which **14***a* was obtained pure by crystallization from hexane – ethyl acetate, mp 124–125°C. NMR (300) δ: 2.07 (d, 3H, J = 0.6 Hz, 4-Me), 6.78 (q, 1H, J = 0.6 Hz, H-3), 9.30 (s, 1H, CHO). Anal. calcd. for C_6H_6BrNO: C 38.32, H 3.21, N 7.45; found: C 38.41, H 3.19, N 7.49.

Sequential lithiation of 3*d* and synthesis of 3-methylpyrrole-2,5-dicarboxaldehyde 15

The azafulvene **3***d* (0.645 g, 1.93 mmol) was lithiated as described in (*a*) above. Methyl iodide (0.13 mL, 0.296 g, 2.09 mmol) was added to the THF–pentane solution (40 mL THF) at –78°C. After 10 min, the solution was warmed to 0°C and after 30 min it was cooled back down to –105°C. A 1.7 M solution of *tert*-butyllithium in pentane (2.49 mL, 4.23 mmol) was added to the stirred solution. After 10 min the solution was warmed to –78°C and 20 min later a solution of DMF (0.30 mL, 0.283 g, 3.87 mmol) in dry THF (1 mL) was added. After 10 min the cooling bath was removed and after a further 45 min water (0.5 mL) was added and the solution was concentrated in vacuo. The residue was dissolved in methanol (20 mL) and 10 wt.% sodium hydroxide (8 mL) and after 30 min at room temperature the reaction mixture was poured into a mixture of ice and 1 M HCl. The products were extracted into dichloromethane, the extract was washed with saturated NaCl solution, and after the usual work-up the residue was subjected to flash column chromatographic separation on silica gel using hexane – ethyl acetate (3:1) to elute the crystalline (0.075 g, 28% yield) dialdehyde **13***c*. **13***c* had mp 80–81°C after crystallization from ether–hexane; IR (KBr): 3426, 1682, 1661 cm^{-1}; NMR (300) δ: 2.43 (s, 3H, 3-Me), 6.79 (s, 1H, H-4), 9.71 (s, 1H, CHO), 9.90 (s, 1H, CHO); MS (EI) *m/z*: 137 (M^+, 100), 136 (44), 108 (17), 80 (22), 53 (28). This substance contained 0.075 H_2O as determined by integration of the NMR signal for water at δ 1.78. Anal. calcd. for $C_7H_7NO_2 \cdot 0.075\ H_2O$: C 60.73, H 5.15, N 10.12; found: C 60.73, H 5.16, N 10.12.

Synthesis and characterization of various unsubstituted and mono-N-substituted tetraazamacrocycles

I. Meunier, A.K. Mishra, B. Hanquet, P. Cocolios, and R. Guilard

Abstract: Syntheses of tetraazamacrocycles have been carried out by using *p*-toluenesulfonyl chloride as protective group. The [14(ane) N4] and [15(ane) N4] were also obtained by the template synthesis. Mono-N-functionalization of tetraazamacrocycles was accomplished by reaction of a fivefold excess of the free macrocycles with 1 equivalent of a suitable alkylating or arylating reagent. The key point of the synthesis lies in the use of an excess of the macrocycle over the substituting reactants to reduce the formation of polysubstituted derivatives, and in the easy separation of the excess of unreacted macrocycle. All the products were characterized on the basis of spectral studies (^{1}H and ^{13}C NMR, including 2D NMR and NOE difference studies) and mass spectrometry.

Key words: tetraazamacrocycles, improved synthesis, protective group, N-tosylation, template synthesis, NOE difference spectroscopy.

Résumé : La synthèse de tétraazamacrocycles a été réalisée en utilisant le chlorure de *p*-toluène sulfonyle comme réactif de protection. Les [14(ane) N4] et [15(ane) N4] ont également été préparés par la voie «template». La monofonctionnalisation sur l'un des atomes d'azote des tétraazamacrocycles a été effectuée en faisant réagir un excès (5 fois) de macrocycle avec 1 équivalent du ligand alkylant ou arylant adapté. Le point crucial de la synthèse réside dans l'utilisation de l'excès de macrocycle par rapport au réactif de substitution afin de réduire la formation de dérivés polysubstitués, ainsi que dans la facilité de séparation de l'excès de macrocycle inchangé qui peut être recyclé. L'ensemble des produits a été caractérisé par des études spectroscopiques (RMN ^{1}H et ^{13}C à une et deux dimensions, étude par différence d'effet Overhauser) et par spectrométrie de masse.

Mots clés : tétraazamacrocycles, amélioration de synthèse, groupe protecteur, N-tosylation, synthèse «template», spectroscopie de différence d'effet Overhauser.

[Traduit par la rédaction]

Introduction

The interest in polyazamacrocycles, compared to simple aliphatic linear polyamines, conjugated aromatic ligands, or porphyrins, as ligands for metal ions has considerably increased during the past decade. Attention has been particularly drawn to the structure and the properties of metal complexes useful in therapy or those able to coordinate reversibly or activate small molecules. Our interest is mostly oriented towards cobalt and iron metal complexes, which can be good models for metal–dioxygen binding.

The polyazamacrocycles show some advantages over the other ligands in their ability to form stable complexes, their good behavior towards oxidation, and their solubility in aqueous media without any addition of hydrophilic groups. However, simple and cheap syntheses, applicable to industrial processes, are not described in the literature.

These polyazamacrocycles have been shown generally to produce strong ligand field, but they cannot always completely wrap up the majority of transition metal ions. To obtain more insight into their ability to coordinate such ions, it is interesting either to modify the ring size or to append coordinating groups to the periphery of the macrocycle. These groups may coordinate the central metal (see **A** below) and thus increase the ligating ability of the macrocycle towards axially coordinated small molecules, preventing further reaction of the complex. For example, compounds having a pendant pyridine (**B**) or carboxylic (**C**) group as a side chain could be suitable ligands for such purposes:

Several synthetic procedures (1) have already been described in the literature for the synthesis of different sizes of both free and N-monofunctionalized tetraazamacrocycles. Among them, the family of N-monofunctionalized tetraazamacrocyclic [14 (ane) N4] compounds has been well studied (2–9) and their corresponding transition metal complexes have been synthesized (10–18) and characterized. However, these starting tetraazamacrocycles were not obtained with high yields (8% overall yield for cyclam) and

their spectroscopic properties have not been fully investigated.

To increase the yields of free ligands and to get access to new N-substituted macrocycles, we report here an *improved* synthesis of 1,4,7,10-tetraazacyclododecane (or cyclen) **1***a*, 1,4,8,11-tetraazacyclotetradecane (or cyclam) **2***a*, and 1,5,9,13-tetraazacyclohexadecane **3***a* based on the so-called "template synthesis" and by use of tosyl protective groups. Among the synthesized ligands the following are reported here *for the first time*: 1,4,7,10-tetraazacyclododecanes **1***b*–**1***d*, 1,4,8,11-tetraazacyclotetradecanes **2***d*–**2***f*, and 1,5,9,13-tetraazacyclohexadecanes **3***b*–**3***c*.

[14 (ane) N4]

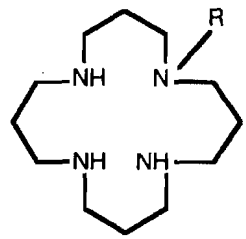
2*a*, R = H
2*b*, R = CH_2-CO_2H
2*c*, R = $(CH_2)_2$-CO_2H
2*d*, R = CH_2-*m*Py
2*e*, R = CH_2-*o*Py
2*f*, R = $(CH_2)_2$-*o*Py

In this paper we also report ^1H and ^{13}H NMR data for the above ligands with particular emphasis on the three pyridine derivatives **2***d*, **2***e*, and **2***f*.

Results

(a) Synthesis of unsubstituted tetraazamacrocycles

Cyclam, or 1,4,8,11-tetraazacyclotetradecane **2***a*, was synthesized using the kinetic template effect (2). In this approach, the geometric arrangement of macrocycles within the coordination sphere of a metal ion provides constraints that control the final product obtained by reaction of precursors with the metal



[16 (ane) N4]

3*a*, R = H
3*b*, R = CH_2-CO_2H
3*c*, R = $(CH_2)_2$-CO_2H

ion. Instead of the reported reduction of the diimine with hydrogen under pressure (20% yield) or with $NaBH_4$ (40% yield) (3), reduction with Raney alloy in sodium hydroxide solution (19) increased the yield of **2***a* after demetallation with NaCN, up to 67% (see Scheme 1).

This scheme is a very simple one-pot synthesis. Large quantities of cyclam (about 50 g) may be isolated in a 2-day work-up procedure. The final product is obtained in an acid-free form and can be used easily in the complexation step. However, to avoid the use of large quantities of cyanide ions during the demetallation process, we investigated another synthesis approach.

The tosyl approach includes the protection of the four nitrogen atoms in order to prevent the formation of polymerization products. Cyclen or 1,4,7,11-tetraazacyclododecane (20–22) **1***a*, 1,4,8,11-tetraazacyclotetradecane **2***a*, and 1,5,9,13-tetraazacyclohexadecane (23) **3***a*, have been synthesized according to Scheme 2, using tosyl moieties (24–28). This condensation step in performed in DMF giving a tetratosylated derivative, which is further cleaved at 100°C in concentrated sulfuric acid.

The tosyl approach, although it has some advantages for industrial application, includes a challenging step, i.e., the cleavage of the tosyl groups, and requires careful crystallization of the free macrocycle.

(b) Synthesis of mono-N-substituted tetraazamacrocycles

Carboxylic acid side chain

The unequivocal synthesis of mono-N-functionalized derivatives involves several synthetic steps including the protection (29–31) of some nitrogen atoms. These procedures can be convenient methods of synthesis but are not general, especially when a functional group is present on the side chain.

The substitution can also be done by condensation of the alkylating reagent with the free macrocycle. The tetraazamac-

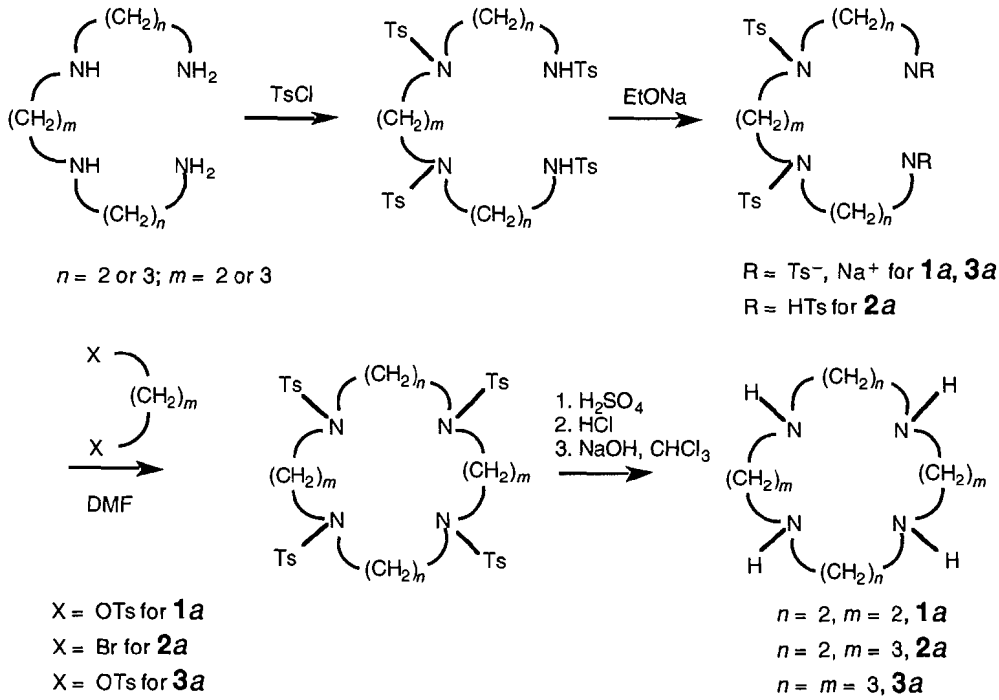
Scheme 2. Synthesis of free tetraazamacrocycles by condensation of tosylated precursors.



rocycles bearing a carboxylic group are obtained in high yields by reaction of a fivefold excess of the macrocycle and 1 equivalent of halogen-substituted alkyl carboxylic acid in ethanol with LiOH as base. In the presence of a large excess of macrocycle, the *mono-N*-alkylated derivative is the major product of the reaction, together with unreacted derivative recovered (about 90–95% of pure macrocycle) at the end of the synthesis. After refluxing the mixture, extraction, and protonation with concentrated HCl, the tetramines **1***b*, **1***c*, **3***b*, and **3***c* are obtained in good yields (56–78%) as new macrocycles.

Pyridinic side chain

The macrocycles bearing a pyridyl group as a side chain on one of the nitrogen atoms have been synthesized by reaction of a fivefold excess of the free macrocycle and 1 equivalent of the chloromethyl or chloroethylpyridine in DMF at 110°C while stirring for few hours (32). After cooling the reaction mixture at 10°C, the excess of unreacted macrocycle is recovered (about 90–95% of the pure macrocycle after partial removal of DMF). Mono-N-substituted derivatives (**1***d*, **2***d*, **2***e*, **2***f*) are obtained as chlorhydrates with yields in the range of 40–80%.

(c) NMR analysis

All the products were characterized on the basis of their spectral data, which are summarized in the experimental section. Three of them (**2***d*, **2***e*, and **2***f*) have been studied in detail by one- and two-dimensional ^1H and ^{13}C NMR spectroscopy (NOE difference and homo and heteronuclear correlation spectra). All the spectra of the final products were recorded in acidic D_2O in order to protonate the four nitrogen atoms. The ^1H and ^{13}C NMR spectral data of these derivatives are given in Table 1 with numbering used in the text.

Knowledge of the spectroscopic data of the free bases in solution is essential to study the further complexation reaction and the axial ligand coordination reactions as well as to determine the pK_a values of the ligands. However, because the peak assignments and the spectral interpretation were not possible on the basis of one-dimensional ^1H and ^{13}C NMR spectroscopy, NOE difference and homo and heteronuclear correlation spectroscopy of compounds **2***d*, **2***e*, and **2***f* were performed.

Study of the N-(2-pyridylmethyl), 2e, and N-(3-pyridylmethyl), 2d, derivatives

On the basis of the one-dimensional ^1H NMR spectrum of the *N*-(2-pyridylmethyl) cyclam **2***e* (not reproduced) it is easy to assign the methylene protons of the pyridinic chain. The ^1H–^1H correlation (COSY) spectrum (see Fig. 1) only concerns the aliphatic region: the two and three methylene moieties are clearly identified. The final attribution is given by the NOE difference experiments. The spectrum obtained after presaturation of peak K (see Fig. 2, spectrum *b*) is compared to the normal 1D spectrum (spectrum *a*). The observed enhancements are given on the formula. Other NOE experiments led to complete information.

The NOE data are summarized in Table 2 where we differentiate the presaturated peak and the signals showing an Overhauser effect. These results allow to assign all the protons of the macrocycle (see Table 1).

The proton-decoupled ^{13}C-1D spectrum only permits us to assign the peak at position 15 due to its important deshielding. The other signals and, more specifically, the cyclic methylene protons give signals between 20 and 53 ppm. Thus it appears necessary to record the ^{13}C–^1H heteronuclear correlation spectrum to totally assign the ^{13}C spectrum.

Coupling of each carbon–proton system appears as a correlation spot. It has to be noted that only short couplings ($^1J_{C-H}$) are observed and quaternary carbon atoms do not give rise to any correlation. Each carbon atom in the aliphatic region is coupled to two isochronous protons, leading to only one correlation spot. The assignments of each carbon atom are given in Table 1.

A similar study has been performed for compound **2***d*. The ^1H and ^{13}C NMR parameters are listed in Table 1.

Study of the N-(2-pyridylethyl) cyclam, 2f

In acidic D_2O solution compound **2***f* exhibits (see Fig. 3, spectrum *a*) a very crowded region (18 protons) between 3.2 and 3.5 ppm. To solve the problem of the chemical shift assignments, a *J*-resolved spectrum has been recorded. On the *F*2 projection (see Fig. 3, spectrum *c*) the different methylenic protons are well separated, making it possible to explain the COSY spectrum (not reproduced). Most of the resonances were attributed on the basis of the previous studies. Different NOE difference experiments were performed, giving the enhancements shown in Table 3.

The simulated spectrum obtained from the chemical shifts and the coupling constants (see Fig. 3, spectrum *b*) is in good accordance with the experimental spectrum.

Comparisons between the pyridinic derivatives 2d, 2e, and 2f

The proton NMR spectra of the three pyridinic derivatives are very similar. By comparison with the cyclam, the methylene protons α to the N-substituted atom show a slight upfield shift (up to 0.3 ppm). All the other protons are deshielded by 0.1–0.3 ppm. The most important feature to be pointed out is the wrap-up of the ethyl-pyridinic arm in compound **2f**, promising a coordination ability.

The carbon-13 chemical shifts are all upfield-shifted except for C14 (α to the nitrogen atom). The largest shift variations (about 10 ppm) are observed for C9 and C10, indicating a significant overlap of the appending group.

Conclusion

Two different syntheses, namely, the template effect or the use of tosyl derivatives of the free bases, for the preparation of cyclen, cyclam, and 1,5,9,11-tetraazacyclohexadecane have been improved in order to produce these compounds on a large scale. New mono-N-substituted macrocycles have been synthesized in high yields. The most promising target molecules in the cyclam series, for complexation by cobalt and reactivity of the complexes with dioxygen, have been fully characterized by using a combination of several NMR techniques.

This study also demonstrates the ability of pendant arms to overlap the cavity of the macrocycle and the possible use of such monosubstituted derivatives to lead to pentacoordinating ligands exhibiting hydrophobic pockets. These ligands may thus be suitable to mimic molecules of biological relevance.

Experimental part

Elemental analyses were obtained from the Service Central d'Analyse du C.N.R.S.

The NMR spectra were recorded on a Bruker WM400 NMR spectrometer operating at 400.13 MHz for ^1H and at 100.64 MHz for ^{13}C. The samples were prepared as acidic D_2O (or $CDCl_3$) solutions containing TMSP (or TMS) as internal reference. The chemical shifts (δ) are given in parts per million (ppm) and the coupling constants (*J*) in hertz (Hz). The multiplicities (m) are noted s: singlet, d: doublet, t: triplet, quint: quintet. Proton spectra were recorded using a 4 kHz spectra width and 32K data points, giving a final resolution of 0.2 Hz (for ^{13}C: 16 kHz, 32K, 1 Hz). The 1D and 2D spectra were recorded using the standard Bruker library programs. Homonuclear COSY consisted of a 256 × 2K data matrix (16 scans, 5 s saturation time for residual water suppression), giving a 3 Hz final resolution in both dimensions. For heteronuclear COSY a 128 × 4K matrix was acquired (128 scans, 1.5 s recovery time). The *F*1 and *F*2 resolutions were, respectively, 8 and 7 Hz. NOE difference spectra were recorded with 3 s of relaxation time and 2 s of presaturation time using two control frequencies.

The mass spectra were performed on the Kratos Concept IS

Table 1. ^{1}H and ^{13}C NMR data of the *N*-(3-pyridylmethyl) cyclam **2***d*, the *N*-(2-pyridylmethyl) cyclam **2***e*, and the *N*-(2-pyridylethyl) cyclam **2***f*.

at CSMUB (Centre de Spectroscopie Moléculaire de l'Université de Bourgogne) using DCI or EI mode. Peak positions are given in *m/z* and relative abundance as a percentage.

1,4,7,10-Tetraazacyclododecane (cyclen), 1*a*

The compound **1***a* is obtained in four steps, according to the following procedure.

Step 1: 1,4,7,10-tetratosyl-1,4,7,10-tetraazadecane

To a stirred solution of triethylenetetramine (14.6 g; 0.1 mol) and sodium hydroxide (16 g; 0.4 mol) in water (108 mL), *p*-toluenesulfonyl chloride (76.2 g; 0.4 mol) in 400 mL of ether is added dropwise. The mixture is left at room temperature under stirring for 1 h. The white precipitate is filtered off and washed in hot methanol (60 g; yield 78.6%).

For personal use only.

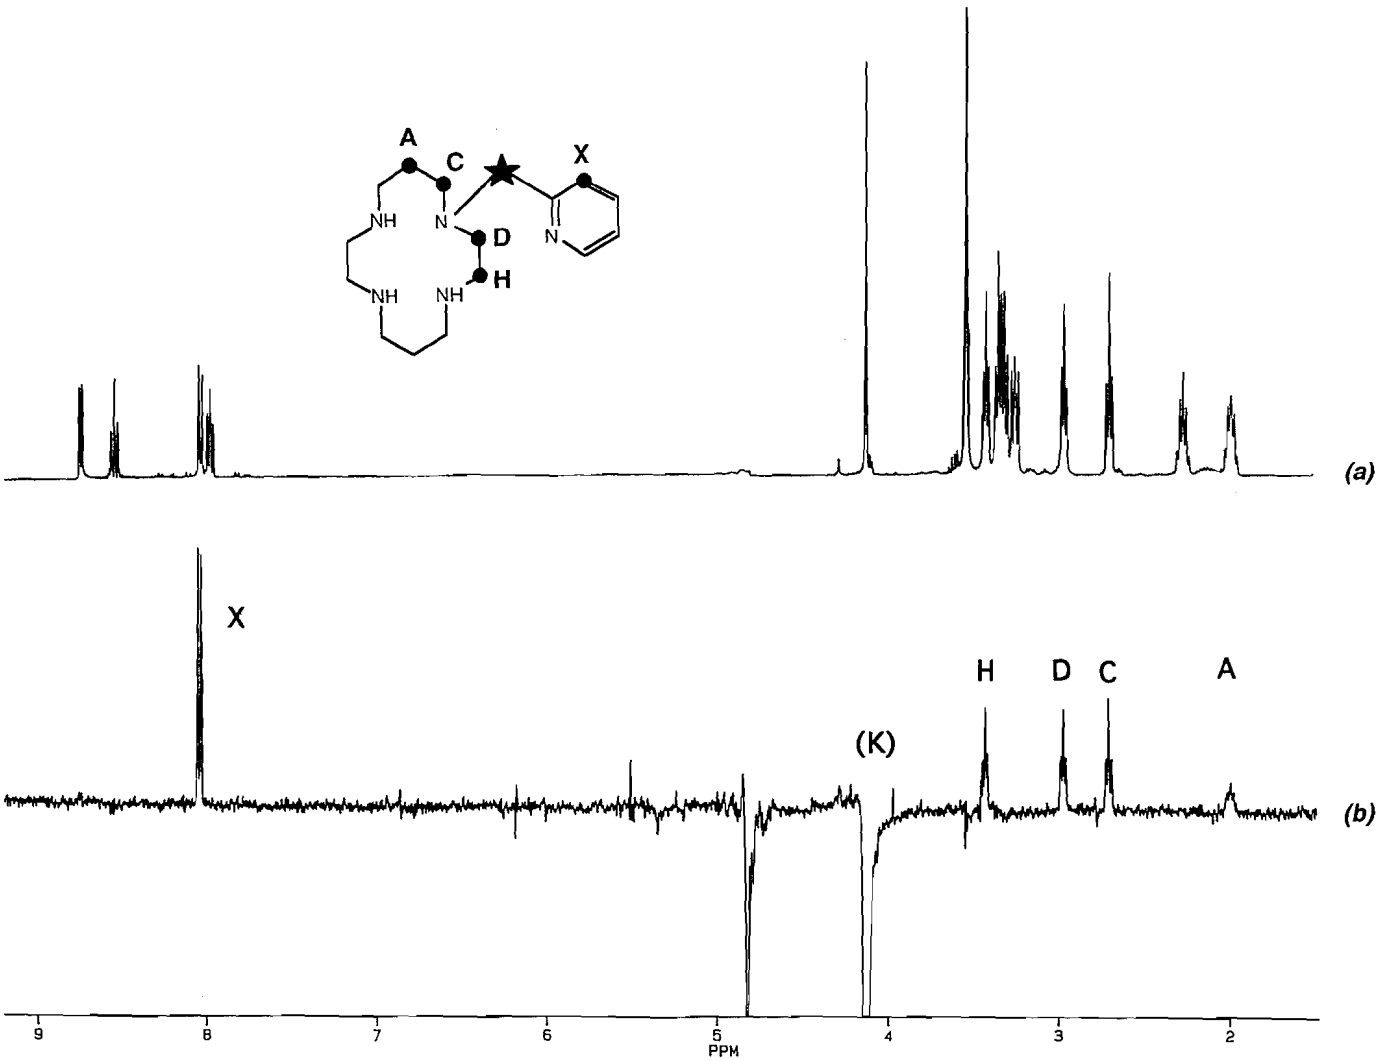
Fig. 2. (*a*) Normal proton spectrum and (*b*) NOE difference spectrum of the *N*-2(2-pyridylmethyl) derivative **2***a* in D_2O at pH 1.74.



Step 2: disodium salt of 1,4,7,10-tetratosyl-1,4,7,10-tetraazadecane

A suspension of 10 g of 1,4,7,10-tetratosyl-1,4,7,10-tetraazadecane in boiling ethanol (50 mL) is reacted with 2 equivalents of sodium ethoxide. After dissolution, the mixture is refluxed for 30 min after which time the desired product precipitates. The product is filtered and dried under vacuum (yield 100%).

Step 3: 1,4,7,10-tetratosyl-1,4,7,10-tetraazacyclododecane

To a heated mixture (110–120°C) of the sodium salt of 1,4,7,10-tetratosyl-1,4,7,10-tetraazadecane (0.021 mol) in 200 mL of DMF is added, over a period of 2 h, a solution of ditosylated ethylene glycol (14.3 g; 0.038 mol) in 200 mL of DMF. The reaction mixture is maintained at 110°C with stirring. After 24 h, the solvent is evaporated to one tenth of the original volume. The resulting mixture is poured over cold water (800 mL). The white solid that precipitates is filtered and dried at 30–40°C under vacuum (12.2 g; yield 74%).

Step 4: 1,4,7,10-tetraazacyclododecane (cyclen, 1a)

Tetratosylated cyclen (12.0 g; 0.015 mol) is treated in 96% sulfuric acid (50 mL) at 110°C for 72 h. The resulting brown solution is brought to 5°C and 175 mL of ethanol, followed by 148 mL of ether, are slowly added. The brown precipitate is filtered, washed with ethanol and ether, and dried under vacuum for 6 h. It is then dissolved in 150 mL of water and the pH is brought to 12 by addition of 2 M NaOH. The resulting solution is then extracted with chloroform (6 × 130 mL). The organic phase is dried over $MgSO_4$, filtered, and evaporated to yield a white solid. Recrystallization from THF affords cyclen (mp 110–112°C; 1.4 g; yield 54%). ^1H NMR δ ($CDCl_3$): 2.12 (s, 4H, NH), 2.67 (s, 16H, CH_2). ^{13}C NMR δ ($CDCl_3$): 46 (CH_2). MS *m/z* (EI): 173 [M + 1] (100%). Anal. calcd. for $C_8H_{20}N_4$: C 57.78, H 11.70, N 32.52; found: C 57.55, H 11.4, N 32.9.

1,4,8,11-tetraazacyclotetradecane (cyclam), 2*a*, (template synthesis)

1,5,8,12-Tetraazadodecane (15 g; 0.086 mol) obtained as described in the literature is placed in 348 mL of distilled water and nickel chloride hexahydrate (20.4 g; 0.086 mol) is added. The resulting violet solution is cooled at 6°C, and 14.4 mL of 40% aqueous glyoxal solution is added dropwise. The reaction mixture is kept at room temperature under stir-

ring for 12 h. A 2 M NaOH solution (384 mL) is added quickly, followed by fractional addition of Raney alloy (19.2 g). The stirring is maintained for 2 h. The solution is then filtered over Celite to remove the Raney alloy. Sodium cyanide (28.8 g) is added to the resulting brown solution, which is refluxed for 2 h. The remaining solid is filtered off and the filtrate is extracted with chloroform (8 × 100 mL). Extracts are combined and dried over $MgSO_4$, then filtered and the solvent evaporated. The crude product is crystallized from THF and dried under vacuum (mp 187–188°C; 11.5 g,

1,4,8,11-Tetraazacyclotetradecane (cyclam), 2*a*, (tosyl coupling)

Step 1: 1,5,8,12-tetratosyl-1,5,8,12-tetraazadodecane
To a stirred solution of 1,5,8,12-tetraazadodecane (6.9 g; 0.043 mol) and sodium hydroxide (6.8 g; 0.17 mol) in water (54 mL), *p*-toluenesulfonyl chloride (32.4 g; 0.17 mol) in 420 mL of ether is added dropwise. The mixture is kept at room temperature under stirring for 1 h. The tetratosyl tetramine is isolated as an oily phase separated by decantation. After drying, a white semi-solid is obtained (25 g; yield 74.6%).

Step 2: 1,4,8,11-tetratosyl-1,4,8,11-tetraazacyclotetradecane
To a heated mixture (110–120°C) and anhydrous potassium carbonate (20 g; 0.144 mol) in 1000 mL of DMF, is added dropwise (1 drop every 10 s) a solution of 1,5,8,12-tetratosyl-1,5,8,12-tetraazadodecane (11.65 g; 0.015 mol) and 1,3-dibromopropane (3.03 g; 0.015 mol) mixed in 270 mL of DMF. The reaction mixture is maintained under stirring at 110°C. After 8 h, the reaction mixture is brought to room temperature and the salt present is eliminated by filtration. After concentration to one tenth of the filtrate, the resulting mixture is poured over cold water (1000 mL). The white solid that precipitates is dried at 30–40°C under vacuum (9.6 g; yield 78.3%).

Step 3: 1,4,8,11-tetraazacyclotetradecane, 2a
The tetratosylated derivative (8 g; 0.098 mol) is treated with 96% sulfuric acid (33 mL) at 110°C for 50 h. The resulting brown solution is brought to 5°C and 125 mL of ethanol, followed by 120 mL of ether, are slowly added. The brown precipitate is filtered, washed with ethanol and ether, and dried under vacuum for 6 h. It is then dissolved in 150 mL of water and the pH is brought to 12 by addition of 2 M NaOH. The resulting solution is then extracted with chloroform (6 × 130 mL). The organic phase is dried over $MgSO_4$, filtered, and evaporated to yield a white solid that is recrystallized from THF, giving 0.7 g of free cyclam (yield 35%).

1,5,9,13-Tetraazacyclohexadecane, 3*a*

The compound **3***a* is obtained in a four-step procedure, described as follows.

Step 1: 1,5,9,13-tetratosyl-1,5,9,13-tetraazatridecane
To a stirred solution of tripropylenetetramine (18.8 g; 0.1 mol) and sodium hydroxide (16 g; 0.4 mol) in water (108 mL), *p*-toluenesulfonyl chloride (76.2 g; 0.4 mol) in 400 mL of ether is added dropwise. The mixture is kept at room temperature under stirring. The white precipitate is filtered and washed by hot methanol (62.5 g; yield 77.6%).

Step 2: disodium salt of 1,5,9,13-tetratosyl-1,5,9,13-tetraazatridecane
A suspension of 16 g of 1,5,9,13-tetratosyl-1,5,9,13-tetraazatridecane in boiling ethanol (70 mL) is reacted with 2 equivalents of sodium ethoxide. After dissolution the mixture is refluxed for 30 min after which time the desired product precipitates. It is filtered and dried under vacuum (yield 100%).

Step 3: 1,5,9,13-tetratosyl-1,5,9,13-tetraazacyclohexadecane
To a heated mixture (110–120°C) of the sodium salt of the 1,5,9,13-tetratosyl-1,5,9,13-tetraazatridecane (16.9 g; 0.02 mol) in 200 mL of DMF is added, over a period of 2 h, a solution of *O*,*O*′-ditosyl-1,3-propanediol (11.5 g; 0.03 mol) in 200 mL of DMF. The reaction mixture is maintained under stirring at 110°C. After 24 h, the solvent is evaporated to one tenth of the original volume. The resulting mixture is poured over cold water (800 mL). The white solid that precipitates is filtered and dried at 30–40°C under vacuum (yield 63%).

Step 4: 1,5,9,13-tetraazacyclohexadecane, 3a
The tetratosylated derivative (0.015 mol) is treated in 96% sulfuric acid (50 mL) at 110°C for 72 h. The resulting brown solution is brought to 5°C and 175 mL of ethanol, followed by 148 mL of ether, are slowly added. The brown precipitate is filtered, washed with ethanol and ether, and dried under vacuum for 6 h. It is then dissolved in 150 mL of water and the pH is brought to 12 by addition of sodium hydroxide (2 mol/L).

1-(2-Acetic acid)-1,4,7,10-tetraazacyclododecane, 1*b*

Cyclen (10 g; 0.058 mol) is dissolved in 150 mL of ethanol and 30 mL of cold water (5°C) containing 0.84 g (0.02 mol) of lithium hydroxide. After complete dissolution a mixture of bromoacetic acid (1.53 g; 0.011 mol) in 80 mL of water is added slowly. The reaction mixture is then refluxed for 6 h after which time the solvent is evaporated. The product is taken up in water and the pH adjusted to 12.5 by addition of a NaOH solution. The solution is extracted several times with chloroform to remove the excess of cyclen. The aqueous phase is concentrated and cooled to 0°C. Cold ethanol (100 mL) is added and the solution kept at 5°C for 3 h. The precipitate is filtered off and the filtrate is treated with 37% HCl at 220°C. The turbid solution obtained is kept at 5°C for 4 h. During this period a white solid separates out and is filtered, washed with ethanol and acetone, and dried under vacuum to give 3.1 g of the 1-(2-acetic acid)-1,4,7,10-tetraazacyclododecane in its protonated form (yield 74%). ^{1}H NMR d (D_2O): 3.44, 3.64, 3.71, 3.79 (t, 16H, NH-*CH_2*), 3.90 (s, 2H, *CH_2*-CO_2H). ^{13}C NMR d (D_2O): 44.66, 45.55, 45.81, 51.83, 56.04, 177.25. MS *m/z* (EI): 58 [(CH_2CO_2H) 2 H]$^+$ (9.7%), 212 [M 2 H_2O]$^+$ (21%), 231 [M + H]$^+$ (5.3%). Anal. calcd. for $C_{10}H_{22}N_4O_2 \cdot 4HCl \cdot 2H_2O$: C 29.14, H 7.34, N 13.59, Cl 34.40; found: C 28.9, H 7.0, N 13.4, Cl 31.55.

1-(2-Carboxyethyl)-1,4,7,10-tetraazacyclododecane, 1*c*

The *N*-(2-carboxyethyl)-1,4,7,10-tetraazacyclododecane is synthesized following the same method as previously described using 1.68 g of bromopropionic acid (0.011 mol) and 10 g (0.058 mol) of cyclen (yield 72%). ^{1}H NMR d (D_2O): 3.20, 3.09, 3.28 (t, 12H), 3.40–3.70 (m, 8H). ^{13}C NMR d (D_2O): 33.0, 45.2, 45.79, 47.25, 47.34, 51.89, 179.11. MS *m/z* (EI): 73 [$(CH_2)_2CO_2H$)]$^+$ (74%), 173 [M 2 [$(CH_2)_2CO_2H$] + 2H] (12.5%), 245 [M + H]$^+$ (3.2%).

1-(2-Acetic acid)-1,4,8,11-tetraazacyclotetradecane, 2*b*

Compound **2*b*** is obtained in the same way as **1*b***, starting from cyclam (20.0 g; 0.1 mol), lithium hydroxide (1.68 g; 0.04 mol), and 2-bromoacetic acid (2.78 g; 0.02 mol) in 77% yield. ^{1}H NMR d (D_2O): 1.93 (quint, 2H, CH_2-*CH_2*-CH_2), 2.03 (quint, 2H, CH_2-*CH_2*-CH_2), 2.86 (t, 2H), 2.93 (t, 2H), 3.13 (t, 2H), 3.19 (t, 4H), 3.25 (t, 2H), 3.27 (t, 2H), 3.34 (t, 2H), 3.47 (s, 2H, *CH_2*-CO_2H). ^{13}C NMR d (D_2O): 22.97, 23.61, 42.17, 43.41, 44.23, 45.30, 45.56, 46.09, 52.14, 54.31, 56.98, 175.89. Anal. calcd. for $C_{12}H_{26}O_2N_4 \cdot 3HCl \cdot 2H_2O$: C 35.70, H 8.24, N 13.88, Cl 26.34; found: C 35.1, H 8.2, N 13.4, Cl 25.2.

3-(1,4,8,11-Tetraazacyclotetradec-1-yl) propionic acid, 2*c*

Following the same procedure as above, compound **2*c*** is obtained from cyclam (20 g; 0.1 mol) and 3-iodopropionic acid (3.98 g; 0.02 mol) in 65% yield. ^{1}H NMR d (D_2O): 2.09 (quint, 2H, CH_2-*CH_2*-CH_2), 2.13 (quint, 2H, CH_2-*CH_2*-CH_2), 2.83 (t, 2H), 3.23 (t, 2H), 3.31 (t, 4H), 3.33 (t, 4H), 3.42 (t, 2H), 3.46–3.57 (m, 6H). ^{13}C NMR d (D_2O): 20.97, 21.44, 31.57, 40.23, 40.37, 40.56, 43.74, 43.86, 44.32, 48.08, 50.10, 53.13, 176.57. Anal. calcd. for $C_{13}H_{28}O_2N_4 \cdot 4HCl \cdot 2H_2O$: C 34.37, H 7.99, O 14.09, N 12.33, Cl 31.22; found: C 34.3, H 8.1, O 15.1, N 13, Cl 32.0.

2-(1,5,9,13-Tetraazacyclohexadec-1-yl) acetic acid, 3*b*

Compound **3*b*** is synthesized following the same method as previously described for **1*b*** using bromoacetic acid and 1,5,9,13-tetraazacyclohexadecane (yield 62%). ^{1}H NMR d: 2.05 (2q, 4H, CH_2-*CH_2*-CH_2), 2.10 (2q, 4H, CH_2-*CH_2*-CH_2), 3.32 (m, 12H, N-*CH_2*-CH_2), 3.45 (t, 4H, N-*CH_2*-CH_2), 3.90 (s, 2H, *CH_2*-CO_2H). ^{13}C NMR d: 20.61, 21.18, 42.75, 43.02, 43.57, 51.56, 58.47, 170.81. Anal. calcd. for $C_{14}H_{30}O_2N_4 \cdot 5HCl \cdot 3H_2O$: C 32.17, H 7.91, N 10.72, Cl 33.91; found: C 32.8, H 8.1, N 10.1, Cl 32.7.

1-(2-Carboxyethyl)-1,5,9,13-tetraazacyclohexadecane, 3*c*

N-(2-Carboxyethyl)-1,5,9,13-tetraazacyclohexadecane is synthesized following the same method as previously described for **1*b*** using bromopropionic acid and 1,5,9,13-tetraazacyclohexadecane (yield 68%). ^{1}H NMR d: 2.06 (q 4H, CH_2-*CH_2*-CH_2), 2.10 (q, 4H, CH_2-*CH_2*-CH_2), 2.86 (t, 2H, N-*CH_2*-CH_2-CO_2H), 3.32 (t, 12H, N-*CH_2*-CH_2), 3.45 (t, 4H, N-*CH_2*-CH_2), 3.54 (t, 2H, *CH_2*-CO_2H). ^{13}C NMR: 20.18, 21.05, 31.58, 42.59, 42.93, 43.51, 50.30, 53.54, 176.35.

1-(2-Pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane, 2*e*

Cyclam (5.0 g; 0.025 mol) is dissolved in 125 mL of DMF at 110–120°C and 2-chloromethylpyridine-hydrochloride (0.82 g; 0.005 mol) in 5 mL of DMF is slowly added. The stirring is maintained at this temperature for 2 h, after which time the reaction mixture is left for 12 h at 5°C. The precipitate is filtered off to remove excess of cyclam and the filtrate is concentrated by evaporation. The obtained oily product is taken up in 20 mL of water and the pH is adjusted to 11.5 by addition of NaOH. The solution is extracted with chloroform and the organic phase is dried over $MgSO_4$, filtered, and evaporated. The orange oily product is treated with ether to precipitate the remaining cyclam, which is then eliminated by filtration. The filtrate is evaporated and the residue (1.2 g) is taken up in 10 mL of ethanol, 37% HCl is added at 220°C, and the mixture is left for 12 h. The white solid is filtered, washed with ether, and dried under vacuum (yield 74%). MS *m/z* (EI): 93[CH_2(*o*-Py) + H]$^+$ (100%), 199[M 2 [CH_2(*o*-Py)]]$^+$ (88.4%), 292[M + H]$^+$ (52.7%). Anal. calcd. for $C_{16}H_{29}N_5 \cdot 4HCl \cdot 5H_2O$: C 36.44, H 8.22, N 13.28, Cl 26.89; found: C 36.3, H 8.0, N 13.0, Cl 27.1.

1-(3-Pyridylmethyl)-1,4,7,10-tetraazacyclododecane, 1*d*

N-(3-Pyridylmethyl)-1,4,7,10-tetraazacyclododecane is prepared following the same method as described for the preparation of *N*-(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane (yield 60%). ^{1}H NMR d (D_2O): 2.93 (t, 4H, *CH_2*-CH_2), 3.00 (t, 4H, *CH_2*-CH_2), 3.22 (t, 4H, *CH_2*-CH_2), 3.31 (t, 4H, *CH_2*-CH_2), 4.13 (s, 2H, *CH_2*-*m*-Py), 8.11 (t, 1H, *m*-Py), 8.66 (d, 1H, *m*-Py), 8.88 (s, 1H, *m*-Py). ^{13}C NMR d ($CDCl_3$): 46.12, 46.73, 48.08, 52.05, 57.55, 124.03, 134.93, 137.15, 149.21, 150.88. MS *m/z* (EI): 93 [CH_2 (*o*-Py) + H]$^+$ (100%), 171 [M 2 [CH_2(*o*-Py)]$^+$ (19.7%), 264 [M + H]$^+$ (51.4%). Anal. calcd. for

$C_{14}H_{25}N_5$: C 63.84, H 9.57, N 26.59; found: C 63.7, H 9.6, N 26.0.

1-(3-Pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane, 2*d*

N-(3-Pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane is prepared as described above using 3-chloromethyl pyridine and 1,4,8,11-tetraazacyclotetradecane (yield 80%). MS *m/z* (EI): 94 $[CH_2(m\text{-Py}) + 2H]^+$ (100%), 199 $[M\ 2\ [CH_2(m\text{-Py})]]^+$ (1.5%), 292 $[M + H]^+$ (19.8%). Anal. calcd. for $C_{16}H_{29}N_5 \cdot 4.8HCl \cdot 2.2H_2O$: C 37.95, H 7.55, N 13.84, Cl 33.68, found: C 37.6, H 7.2, N 13.1, Cl 33.5.

1-(2(-2-Pyridyl)ethyl)-1,4,8,11-tetraazacyclotetradecane, 2*f*

N-(2(-2-Pyridyl)ethyl)-1,4,8,11-tetraazacyclotetradecane is prepared as described above by using 5 g (0.025 mol) of cyclam and 0.89 g (0.005 mol) of 2-(2-chloroethyl) pyridine in DMF (yield 40%). MS *m/z* (EI): 106 $[(CH_2)_2(o\text{-Py})]^+$ (83.7%), 201 $[M\ 2\ [(CH_2)_2(o\text{-Py}) + 2H]^+$ (17%), 306 $[M + H]^+$ (18.4%). Anal. calcd. for $C_{17}H_{31}N_5 \cdot 5HCl \cdot 3H_2O$: C 37.65, H 7.55, N 12.92, Cl 32.78; found: C 37.8, H 8.3, N 12.9, Cl 33.0.

Abstract: The model potential, in which the Coulomb and exchange core operators are converted to the matrix elements by use of the spectral representation technique, should be equivalent to the frozen-core operator, if the basis set of the spectral representation is complete. Its fidelity to the frozen-core operator is examined in this paper through a thorough study of basis set convergence in both the spectral space and the atomic orbital space, along with comparison with the Sakai–Huzinaga and the Huzinaga–Seijo–Barandiaran–Klobukowski model potentials. The RHF molecular calculations on N_2, P_2, As_2, Sb_2, PN, and AsN show that the present model potential can approximate, with reliable accuracy, the results obtained from the frozen-core calculations.

Key words: model potential, spectral representation, molecular orbital calculation, electronic structure.

Résumé : Le potentiel modèle, dans lequel les opérateurs centraux de Coulomb et d'échange sont transformés en éléments matriciels par le biais de la représentation spectrale, devrait être équivalent à l'opérateur central fixe si l'ensemble de base de la représentation spectrale est complet. Dans ce travail, on examine sa fidélité par rapport à l'opérateur central fixe par le biais d'une étude de la convergence de l'ensemble de base dans l'espace spectral ainsi que dans l'espace de l'orbitale atomique et aussi par une comparaison avec le potentiel du modèle de Sakai–Huzinaga et avec le potentiel du modèle de Huzinaga–Seijo–Barandiaran–Klobukowski. Des calculs moléculaires RHF sur les N_2, P_2, As_2, Sb_2, PN et AsN montrent que le potentiel modèle proposé peut fournir une approximation fiable et précise des résultats obtenus à l'aide de calculs effectués par la méthode de l'opérateur central fixe.

Mots clés : potentiel modèle, représentation spectrale, calculs d'orbitales moléculaires, structure électronique.

Introduction

A number of valence-electron methods, known as pseudopotential, effective potential, or model potential, have recently been proposed (1, 2). Their main purpose is to make feasible calculations that would be prohibitively expensive if done at the all-electron level, without loss of accuracy. Among these, the model potential method first introduced by Bonifacic and Huzinaga (3), improved by Sakai and Huzinaga (4) (mp1), and reformulated, based on an ab initio philosophy, by Huzinaga, Seijo, Barandiaran, and Klobukowski (5) (mp2) makes use of valence orbitals showing the correct nodal structure. The model potential discussed in this paper is derived from the Huzinaga model potential (3). In the present model (6–8), the mathematical technique of spectral representation (5, 9) is used to replace not only the exchange (5, 10) but also the Coulomb interaction between the core electrons and the valence electrons with a model potential V_{mp3}. As a result, the present model potential (mp3), which is the third version of the Huzinaga model potential (3), invokes no adjustable and (or) fitting parameters. Therefore, once the core orbitals of the constituent atoms are obtained and basis sets for the spectral representation are chosen, the model potentials in the spectral representation form can be prepared without parameters. Thus, anyone can obtain a model potential suitable to particular requirements, such as a model potential for an atom in a neutral state, or a model potential for an atom in an ionic state embedded in a crystal, etc., if and only if the orbitals to be frozen have already been obtained.

The quality of the model potential should be evaluated by its fidelity to the frozen-core operator. The closer a model potential approximates frozen-core results, the more useful it is. In this paper we examine the fidelity of the present model potential to the frozen-core operator by a thorough study of basis set convergence in both the spectral space and the atomic orbital space, along with comparison with mp1 and mp2.

Method

According to the Hartree–Fock approximation, the eigenfunction is expressed in terms of molecular orbitals ψ_i which satisfy the Hartree–Fock equation

$$[1] \qquad F\psi_i = \epsilon_i\psi_i$$

with the Fock operator F (in the case of a closed-shell electron configuration)

$$[2] \qquad F = -\frac{1}{2}\Delta - \sum_A \frac{Z_A}{r_A} + \sum_j (2J_j - K_j)$$

where

$$[3] \qquad J_j f(1) = \int d\nu_2 \psi_j^*(2)\psi_j(2)\frac{1}{r_{12}} f(1)$$

$$[4] \qquad K_j f(1) = \int d\nu_2 \psi_j^*(2) f(2)\frac{1}{r_{12}} \psi_j(1)$$

Under the frozen-core approximation, the Fock operator [2] may be rewritten as follows by introducing a complete set $\{\chi\}$, which is not necessarily an orthogonal set

$$[5] \qquad F = -\frac{1}{2}\Delta - \sum_A \frac{Z_A - Z_A^c}{r_A} + \sum_j^{val}(2J_j - K_j) + \sum_A V_{mp3}^A$$

where

$$[6] \qquad V_{mp3}^A = \Omega^A\left[-\frac{Z_A^c}{r_A} + \sum_j^{core}(2J_j^A - K_j^A)\right]\Omega^A + P^A$$

$$[7] \qquad \Omega^A = \sum_{ab}|\chi_a^A\rangle(S^A)_{ab}^{-1}\langle\chi_b^A|$$

$$[8] \qquad S_{ab}^A = \langle\chi_a^A|\chi_b^A\rangle$$

$$[9] \qquad P^A = -\sum_j^{core} 2\epsilon_j^A|\phi_j^A\rangle\langle\phi_j^A|$$

and Z_A, Z_A^c, ϵ_j^A, ϕ_j^A represent the atomic number, the number of core electrons, the core-orbital energies, and core orbitals belonging to the atom A, respectively. The projection operator P^A is added in eq. [6] to guarantee the Fock equation [1] being solved in the functional space excluding the core-function space. The operator.

$$[10] \qquad \Omega O\Omega = \Sigma_{abcd}|\chi_a\rangle(S^{-1})_{ab}\langle\chi_b|O|\chi_c\rangle(S^{-1})_{cd}\langle\chi_d|$$

is called the spectral representation of operator O. V_{mp3}^A (eq. [6]) may be called the model potential in spectral representation form. We designate it the mp3 model potential, because it is the third version of the Huzinaga model potential. The energy of the valence electrons E_v in this case is calculated as

$$[11] \qquad E_v = \sum_j^{val}\left\{\epsilon_j + \langle\psi_j|-\frac{1}{2}\Delta - \sum_A\left(\frac{Z_A - Z_A^c}{r_A} + V_{mp3}^A\right)|\psi_j\rangle\right\} + \sum_{AB}\frac{(Z_A - Z_A^c)(Z_B - Z_B^c)}{R_{AB}}$$

Fidelity of the model potential in the spectral representation

The procedure to obtain the model potential by spectral representation is straightforward; this property is one of the merits the mp3 has over the other model potentials. However, the most important property that a model potential should have is fidelity to the frozen-core operator; the valence-electron method with the model potential should faithfully approximate the results obtained from the frozen-core calculation. Equation [5] could produce the same results as those obtained by the frozen-core approximation, if a complete set $\{\chi\}$ were used. However, $\{\chi\}$ is always an incomplete set. Therefore, we evaluated the fidelity of the mp3 by using limited basis sets.

We calculated the spectroscopic constants of N_2, P_2, and As_2 using common valence-orbital basis sets in the frozen-core calculations and in the mp3 calculations using several $\{\chi\}$, and compared the results obtained from these two calculations. The results are presented in Tables 1*a* through 1*c*. The results obtained from the all-electron calculations are also listed in Tables 1*a*–1*c*. A comparison of the results confirms that the frozen-core approximation is valid.

We used two valence-orbital basis functions for nitrogen (Table 1*a*). The first one was the well-tempered Gaussian-type orbital (wtgto) of Huzinaga et al. composed of (14*s*9*p*) primitive Gaussian-type orbitals (pgto) and contracted as (10,10,1111/51111) according to their suggestion (11). The second one was the (10*s*7*p*) pgto set taken from Huzinaga's book (12) and contracted as (7111/4111). The results obtained by the mp3 method agree very well with the values obtained from the frozen-core calculation and the all-electron calculation. Because the frozen-core orbital of nitrogen is the only 1*s* orbital localized tightly around the nucleus, the results listed in Table 1*a* are very similar each other.

We used two valence-orbital basis sets for phosphorus (Table 1*b*): the wtgto composed of (14*s*9*p*) pgto and contracted as (13,13,13,111/88111) according to the suggestion of Huzinaga et al. (11) and the basis set of (11*s*8*p*) pgto contracted as (53111/5111) (12). The equilibrium bond distances R and the stretching frequencies ν obtained by the mp3 agree well with the frozen-core and all-electron results. The dissociation energies obtained by the mp3 method, however, deviate slightly from the values obtained from the frozen-core and the all-electron calculations. If we use a larger wtgto (13) as the spectral representation basis function, we get better results, as seen in the fourth and the eighth rows of Table 1*b*.

The following should be noted here. The all-electron calculation predicts that the P_2 molecule is unbounded by 0.60 or 0.66 eV and addition of the *d* polarization function is required (5, 11). However, we do not perform here the molecular calculation using the basis set augmented with the *d* polarization function, because the purpose of this paper is to examine the fidelity of the mp3 and not to obtain the realistic dissociation energy.

As the wtgto for arsenic (Table 1*c*) was too large to perform the all-electron calculation, we used only one basis function: (11*s*8*p*3*d*) pgto contracted as (43211/4211/3) (12), and four basis sets for the spectral representation: (11*s*8*p*3*d*) (12), (20*s*14*p*9*d*) (13), (26*s*20*p*14*d*) (14), and (30*s*23*p*17*d*) (15). The values of R and ν are slightly dependent on the basis sets for the spectral representation, but the value of D is severely

dependent on them. We will discuss this point in more detail in the last section. Table 1*c* indicates that a better basis set for the spectral representation can produce better results.

Our results indicate that if we use the proper basis functions for spectral representation, the mp3 can approximate, with a high degree of fidelity, the results obtained from frozen-core calculations.

Reduction of sizes of basis sets and comparison with other model potentials

We used the same basis sets for the mp3 calculations, the frozen-core calculations, and the all-electron calculations, because we wished to examine the fidelity of the mp3 to the

For personal use only.

frozen-core operator. The reason the model potential methods are widely used is that they have made it feasible at reasonable expense to calculate the electronic structures of large molecules. The most important single factor for economizing molecular calculations is the reduction in the sizes of the valence-orbital basis sets. We attempt to determine if the sizes of the valence-orbital basis sets used in the mp3 can be reduced without degrading the quality of the results, comparing the results with those obtained from the frozen-core calculation and those by the other two model potentials mp1 and mp2.

There are three generations of the Huzinaga model potential family including the present model potential mp3. They are designated in this paper as mp1, mp2, and mp3, respectively. The model potential mp1 has the following form:

$$[12] \quad V_{\mathrm{mp1}} = -\frac{Z - Z^{\mathrm{c}}}{r}\sum_{\mathrm{I}} A_{\mathrm{I}} r^{\nu_{\mathrm{I}}} \exp(-\varsigma_{\mathrm{I}} r) - \sum_i^{\mathrm{core}} F_i \epsilon_i |\phi_i\rangle\langle\phi_i|$$

where Z, Z^{c}, ϵ_i, and $|\phi_i\rangle$ represent the atomic number, the number of core electrons, the core-orbital energies, and the core orbitals, respectively, and ν_{I} is allowed to take values 0 and 1. The factors F_i are usually taken to be equal to 2. The model potential parameters, A_{I} and ς_{I}, are adjustable parameters and determined from minimization of the differences between the reference valence-orbital shapes and energies and those generated from the model potential eigenvalue problem with these parameters (4). The basis sets for the valence orbitals obtained by the mp1 are rather small and economical.

The local core Coulomb operator $V_{\mathrm{mp2}}^{\mathrm{core}}$ of the model potential mp2 (5)

$$[13] \quad V_{\mathrm{mp2}} = V_{\mathrm{mp2}}^{\mathrm{core}} + V_{\mathrm{mp2}}^{\mathrm{exch}} - \sum_i^{\mathrm{core}} 2\epsilon_i |\phi_i\rangle\langle\phi_i|$$

is well tailored to the following model function

$$[14] \quad V_{\mathrm{mp2}}^{\mathrm{core}} = \sum_{\mathrm{I}} A_{\mathrm{I}} r^{\mathrm{vI}} \left[\frac{\exp(-\zeta_I r^2)}{r}\right]$$

where the parameters A_{I} and ζ_I are determined through least-squares fitting to the core Coulomb potential calculated with use of core orbitals obtained from the all-electron calculation. The spectral representation (cf. eq. [10]) is used for the nonlocal exchange potential $V_{\mathrm{mp2}}^{\mathrm{exch}}$. Once the atomic model potential V_{mp2} is obtained, the valence basis set is optimized by minimization of the valence self-consistent-field energy using the standard all-electron calculation.

The present model potential mp3 is defined by eq. [6]. If the fitting for the Coulomb potential $V_{\mathrm{mp2}}^{\mathrm{Coul}}$ of the mp2 is perfect and the spectral-representation basis sets $\{\chi\}$ for the exchange potential $V_{\mathrm{mp2}}^{\mathrm{exch}}$ of the mp2 and for the model potential $V_{\mathrm{mp3}}^{\mathrm{A}}$ of the mp3 are complete, then the mp2 and mp3 have the same effect on the valence orbitals. Therefore, the valence-orbital basis sets obtained by the mp2 may be suitable basis sets for the mp3 calculations. We used the valence-orbital basis sets obtained by the mp2 for the present calculations.

Tables 2*a*, 2*b*, 2*c*, and 2*d* present the results obtained from the calculations using the mp3 with the valence basis sets obtained by the mp2 (5) for N_2, P_2, As_2, and Sb_2, respectively. The results obtained from the frozen-core calculations and the calculations using the mp2 and mp1 are also included in Tables 2*a* through 2*d* for comparison.

Comparison of the results obtained by the mp2 and mp1 methods with those obtained by the frozen-core calculations suggest that the fitting of the Coulomb potential $V_{\mathrm{mp2}}^{\mathrm{Coul}}$ of the mp2 is excellent and that the mp1 can produce remarkable results in spite of the smaller and more economical sizes of the valence-orbital basis sets. (The mp1 for antimony (Table 2*d*) includes the quasi-relativistic effects, and the results in the last row are, therefore, a little different from the other values, which were obtained without relativistic effects.) From the numerical values listed in Tables 2*a* through 2*d*, we see that if we use the better basis sets for the spectral representation $\{\chi\}$ we get better results, and that the results obtained by the mp3 methods are comparable with those obtained by the mp2 and the mp1 methods, which have already been recognized as reliable model potentials in the quantum chemistry community.

To test the balance of different cores, we tried calculations on PN and AsN and listed the results in Tables 2*e* and 2*f*. The agreement between the results obtained by mp3 and by the frozen-core method is excellent.

Discussion and conclusions

We have seen in the preceding sections that the equilibrium bond distances and the stretching frequencies (i.e., the curvature and minimum of the potential curve) are slightly dependent on the basis sets for the spectral representation $\{\chi\}$, but the dissociation energies are dependent on $\{\chi\}$. We will elucidate this basis set dependence in more detail by using As_2 as a typical example. The results obtained by using the same basis set for the valence and core orbitals and several different basis sets $\{\chi\}$ for the spectral representation are tabulated in Table 3. In the first row of the table, the results obtained by the frozen-core calculation are listed once more for comparison. The dissociation energy obtained using the (26*s*20*p*14*d*) wtgto of Huzinaga and Klobukowski (14) deviates from the frozen-core value as shown in the second row. The even-tempered gto basis function (etgto) of Clementi et al. (15) shows good dissociation energy as listed in the third row. While the results obtained by using the hybrid basis function between the *sp* orbitals of the etgto (30*s*23*p*) and the *d* orbital of the wtgto (14*d*) (listed in the fourth row) is almost the same as the values listed in the second row, the dissociation energy obtained with the hybrid basis function between the *sp* orbitals of the wtgto (26*s*20*p*) and the *d* orbital of the etgto (17*d*) (listed in the fifth row) is very close to the value obtained by the frozen-core calculation. To reinforce the wtgto, we augmented its *d* orbital with three more exponents: 6602.447, 2902.7472, and 0.10425203, which are used in the *sp* orbitals of the wtgto. The dissociation energy obtained by the use of this augmented basis set (26*s*20*p*17*d*) is very good. The results listed in the last row of Table 3 are obtained with the wtgto augmented to the *d*-orbital pgto with one exponent of the value 0.10425203. Therefore, the wtgto (26*s*20*p*14*d*) becomes a good basis set for the spectral representation, if its *d*-orbital pgto is augmented with one exponent of the value 0.10425203. It should be noted that the present study may be used to determine whether the basis sets are complete. It should also be noted

Basis functions, for valence orbitals: As (711/5111) N (41/311); for core orbitals: As (20*s*14*p*9*d*) N (14*s*9*p*); for spectral representations: As (30*s*23*p*17*d*) N (14*s*9*p*).

that the total atomic energies of the arsenic atom calculated with the use of the original wtgto (26*s*20*p*14*d*) and the two augmented basis sets (26*s*20*p*17*d*) and (26*s*20*p*15*d*) are the same to within 12 digits. Therefore it may be said that the wtgto (26*s*20*p*14*d*) works quite well as the atomic basis set.

We conclude that the mp3 model potential is a reliable one and stable in the sense that the better basis set for spectral representation produces results closer to the frozen-core results. As far as the curvature and minimal point of the potential energy are concerned, the same basis set as the all-electron valence orbital may be enough for spectral representation. However, if reliable values of the molecular valence electron energy relative to the atomic valence electron energies are desired, the wtgto or the etgto should be used.

We would like to emphasize that the procedure for obtaining the mp3 model potential is straightforward, and anyone who has the Hartree–Fock program for the one- and two-electron integral calculations can obtain it. Once the mp3 model potential is obtained and stored in the computer file, it can be economically incorporated in the molecular orbital calculations, because the necessary calculations are the overlap integrals between the basis functions of the valence orbitals and those of the spectral representation. As the calculation needed

Abstract: We studied the relatively complex polar systems 6-substituted-1,4-dioxospiro[4.5]decanes and 7-substituted-1,5-dioxospiro[5.5]undecanes with substituents X = CH_3, F, Cl, CN, OH, OCH_3, and NO_2. Solvent effects on the equilibrium have been analysed by means of a Self-Consistent-Reaction-Field model and the PM3 method. Complete geometry optimizations have been carried out for all the structures in the gas phase and in solution. For some substituents, a set of rotamers have been separately optimized. The discussion of the results is focussed on the effects arising from structural aspects and from steric and electrostatic interactions on the axial/equatorial relative stability. The role played by multipole moment is considered. In general, good agreement with available experimental data and with previous theoretical studies has been obtained. Though the use of semiempirical methods and simple solvent models prevents us from reaching definitive conclusions, this approach seems to be very useful in predicting the main role of solute–solvent interactions in conformational equilibria of complex systems for which ab initio calculations cannot be performed.

Key words: conformational equilibria, spiro decanes and undecanes, cavity model, SCRF, solvent effect, PM3 calculations.

Résumé : On a étudié les systèmes polaires relativement complexes des 1,4-dioxospiro[4.5]décanes substitués en position 6 et des 1,5-dioxospiro[5.5]undécanes substitués en 7 portant chacun des substituants X = CH_3, F, Cl, CN, OH, OCH_3, et NO_2. On a analysé les effets de solvants sur les équilibre en se basant sur le modèle d'un champ réactionnel autocohérent et par la méthode PM3. On a effectué une optimisation complète de la géométrie de toutes les structures en phase gazeuse et en solution. Pour quelques-uns des substituants, on a aussi optimisé un ensemble de rotamères séparément. La discussion des résultats est orientée vers les effets provoqués par des aspects structuraux et des interactions stériques et électrostatiques sur les stabilités relatives axiales/équatoriales. On a considéré le rôle joué par le moment dipolaire. D'une façon générale, on a obtenu de bons accords entre les données expérimentales disponibles et les résultats de calculs théoriques antérieure. Même si l'utilisation de méthodes semiempiriques et de modèles simples pour les solvants nous empêchent de donner des conclusions définitives, il semble que cette approche soit utile pour prédire le rôle principal des interactions soluté–solvant dans les équilibres conformationnels de systèmes complexes pour lesquels il n'est pas possible d'effectuer des calculs ab initio.

Mots clés : équilibre conformationnel, spiro décanes et undécanes, modèle de cavité, SCRF, effet de solvant, calculs PM3.

Introduction

Experimental data on conformational equilibria are quite useful in improving the understanding of intramolecular interactions and ultimately in allowing prediction of the most stable structure of complex systems (1–7). Conformational equilibria of 1,1,2 trisubstituted cyclohexanes have been studied (6) and the experimental ΔG values give direct information on the most stable conformations. In particular, 1-(OR), 1-(OR′), 2-(R″) derivatives have atracted much attention because they are suitable for investigating different interactions. Zefirov and co-workers (3, 4) showed that 2-substituted propylene ketals usually prefer the axial orientation but this preference decreases as the polarity of the solvent increases. Ethylene ketals behave in almost the opposite direction except for OH and OCH_3 derivatives. Some experimental results are given in Table 1. Wolff et al. studied similar compounds experimen-

tally and compared their results with molecular mechanic calculations (7). Other molecular mechanics results are available for these compounds (5).

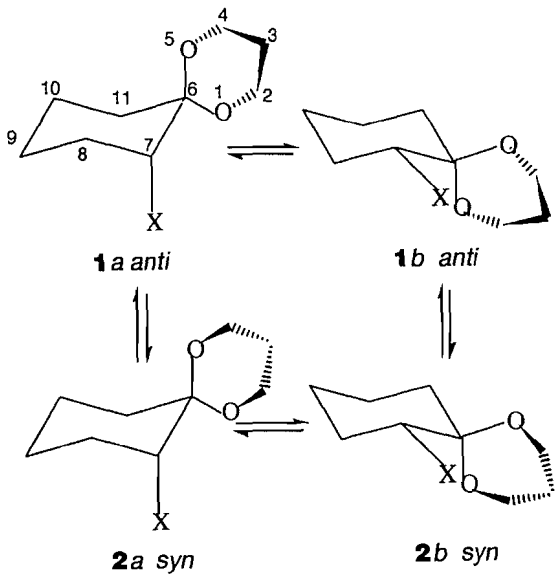
Molecular mechanics has been widely used and represents an interesting approach to dealing with conformational problems in large systems (5, 7). Its main limitation is due to the rather poor description of electronic effects, in particular in those cases in which there are lone pairs. On the other hand, ab initio computations are too expensive for large molecules, which are in general the most interesting ones for the experimentalists. Hence, semiempirical methods appear as an intermediate approach. Though quantitative molecular properties are not always obtained with these methods, their trend in a chemical family, or their modification through an external perturbation, is, in general, correctly reproduced. Moreover, a common problem to tackle in conformational equilibrium analysis is the effect of electrostatic solute–solvent interactions. The possibility offered by continuum models to include this perturbation in the solute's Hamiltonian has allowed quantum chemistry to study chemical processes in solution. In previous papers (8), we used a self-consistent reaction field (SCRF) model to study solvent effects on some conformational problems.

In the present work, we extend the methodology to the case of 2-substituted cyclohexanone ethylene and propylene ketal derivatives. The substituents considered are F, Cl, CN, CH_3, OH, OCH_3, and NO_2.

Methodology

We used the PM3 method (9) and the MOPAC (10) and GEOMOS (11) program packages. We carried out the solvated molecule computations using a continuum model of the solvent that has previously been described (12, 13) and implemented in GEOMOS. The electrostatic and the induction energies are assumed to be responsible for the main variations of the ΔG of the conformational equilibrium in solution and are the only terms considered here. Other terms such as the dispersion term or the cavitation term might be important in the conformational equilibria but these terms remain almost constant in the different conformations of this work. An ellipsoidal cavity shape has been employed. Full geometry optimizations have been carried out.

Fig. 1. *syn* and *anti* orientations of 2-substituted cyclohexanone propylene ketal derivatives. X = F, Cl, CN, CH_3, OH, NO_2, OCH_3.



Results

Structures

Combining the two chair forms of cyclohexane and the two chair forms of dioxane, four different conformers, represented in Fig. 1, are obtained.

Conformations of the cyclohexane and puckered dioxolane rings are represented in Fig. 2. For *anti* conformers **1***a* and **1***b*, the dioxolane fragment is positioned away from the substituent whereas for *syn* conformers **2***a* and **2***b* it is extended towards the substituent.

We scanned the rotation around the C5—O1 and C5—O4 bonds at 5° intervals from 95° to 140°. The most stable form of dioxolane ring was then used as the starting geometry for substituted molecules (it corresponds to about 15°–20° deviation from planarity).

We fully optimized the geometries and calculated the energies of the four most probable conformers in Figs. 1 and 2 for

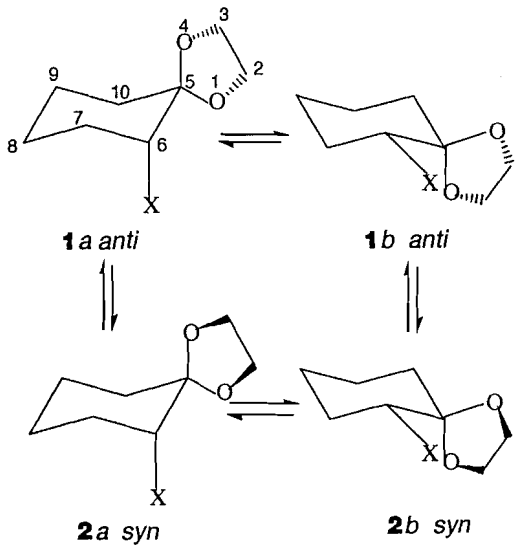

Fig. 3. Illustration of the exocyclic angles of cyclohexane, α and β.

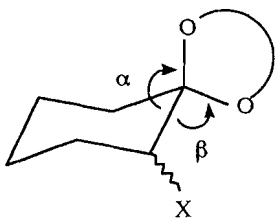

each substituent. Minima were further checked by force calculations.

Angles around the quaternary carbon are those that are subjected to change with varying conformation (*syn* vs. *anti* and axial vs. equatorial). The *syn* vs. *anti* conformations are manifestations of the dihedral angles in the ketal ring and are accompanied by alterations of the exocyclic angles of cyclohexane, α and β, in Fig. 3.

The general trend observed is such that the α and β angles are larger for equatorial conformations than are their analogues for axial conformations and they are also larger for *syn* conformations that are their analogues for *anti* conformations. Comparison of α to β in axial and equatorial conformations indicates a slightly twisted ketal ring for equatorial conformations. In addition, for the OH, OCH_3, and NO_2 substituents, we also computed the potential energy corresponding to the rotation around the bond between the cyclohexane ring and the first atom of the substituent, since several rotamers having close energies may exist. The results are given for the rotamer of lowest energy (unless otherwise indicated). Complete data for potential energy surfaces are available from the authors upon request.

Careful analysis of geometrical parameters for the optimized structures shows thay they are, in general, not much affected by the solvent.

Relative energies

We present the computed total and relative energies and the corresponding dipole moments for the gas phase in Tables 2 and 3. Total axial-conformer percentages, computed using a Boltzmann distribution for the four conformers, are also summarized. Table 2 shows that for propylene ketals, F, CN, NO_2, and OH prefer the equatorial orientation but Cl, CH_3, and OCH_3 prefer the axial orientation in the gas phase. In contrast, all ethylene ketal derivatives except OCH_3 prefer the equatorial orientation.

Solvent effects on conformational equilibria have been evaluated in a nonpolar solvent (CCl_4, ε = 2.24) and a polar solvent (CD_3CN, ε = 37.50) where ε represents the dielectric constant of the solvent. The results for the solvation energies and the relative energies in solution are given in Tables 4 and 5.

The common trend for all the propylene ketals studied (except for the methyl derivative, which is not quite sensitive to the medium) is that as the dielectric constant of the medium increases, the computed axial percentage decreases. This is in agreement with the experimental data in Table 1. The total % axial trends for ethylene ketal derivatives (Table 5) are also in

parallel with experimental data in Table 1 except for the OH derivative. For ethylene ketal derivatives, calculations for F-, Cl-, CN-, and OH-substituted molecules show that the amount of axial orientation increases with increase in polarity of the solvent. On the other hand, CH_3, OCH_3, and NO_2 derivatives show a trend in the opposite direction.

Discussion

Gas phase

Propylene ketals

On the basis of steric effects only, one could expect the axial conformation to be the most stable since the dioxane moiety and the substituent are closer when the latter occupies the equatorial position. The dependence of preference for the axial or the equatorial position on the nature of the substituent indicates that other important factors have to be considered. Our results (Table 2) show that at the PM3 level the equatorial *anti* conformation, **1***b*, is preferred for the F, CN, OH, and NO_2 derivatives whereas the axial conformation, *anti* or *syn*, is preferred by the CH_3 and OCH_3 and by the Cl derivatives, respectively.

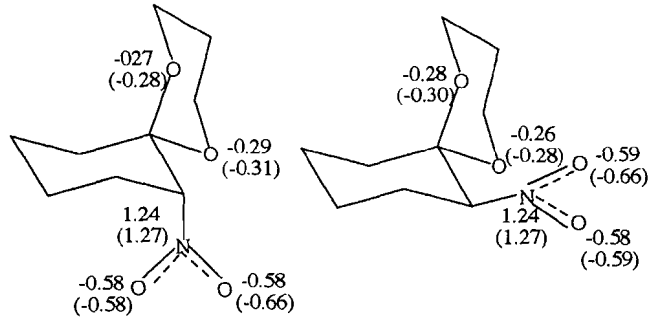
[a]The CN derivative has been calculated in $CDCl_3$ (ε = 4.81).

Fig. 4. Net atomic charges in 2-nitro cyclohexanone propylene ketal in the gas phase and in acetonitrile (values in parentheses).



Electrostatic interactions between the substituent and the oxygens of the dioxane moiety may be responsible for the equatorial preference of CN, and NO_2 (Fig. 4). The fluorine derivative is observed to behave in the opposite direction to that of the other halogen derivative as it usually is in equilibration with other fluorocyclohexane derivatives. Interpretations

[a]The CN derivative has been calculated in $CDCl_3$ (ε = 4.81).

based on the small size of fluorine and (or) lone-pair interactions (14) have been given. Finally, for the hydroxyl substituent, the equatorial preference may be explained through weak hydrogen bond interactions since in the equatorial conformation the optimized geometry shows that the hydrogen atom of the hydroxyl is pointing towards one of the oxygens in the dioxane ring with an O—H distance of 2.48 Å.

In general, for the propylene ketal derivatives considered, *anti* conformations are more favorable than *syn* conformations. The preference for the axial or equatorial conformations to be *anti* depends basically on the balance between steric effects and the electrostatic repulsive forces between the dipole moments situated at the dioxane ring and CX bond. This is illustrated for the **1***b* and **2***b* propylene ketal conformers in Fig. 5. The dipoles are more or less parallel in the *anti* conformation, leading to a destabilizing electrostatic interaction. From the results in Table 2 one may conclude that steric effects are the main factors in determining the *syn* or *anti* conformation for the equatorial conformers since, in all cases, **1***b* is substantially more stable than **2***b*. However, for the axial

smaller μ

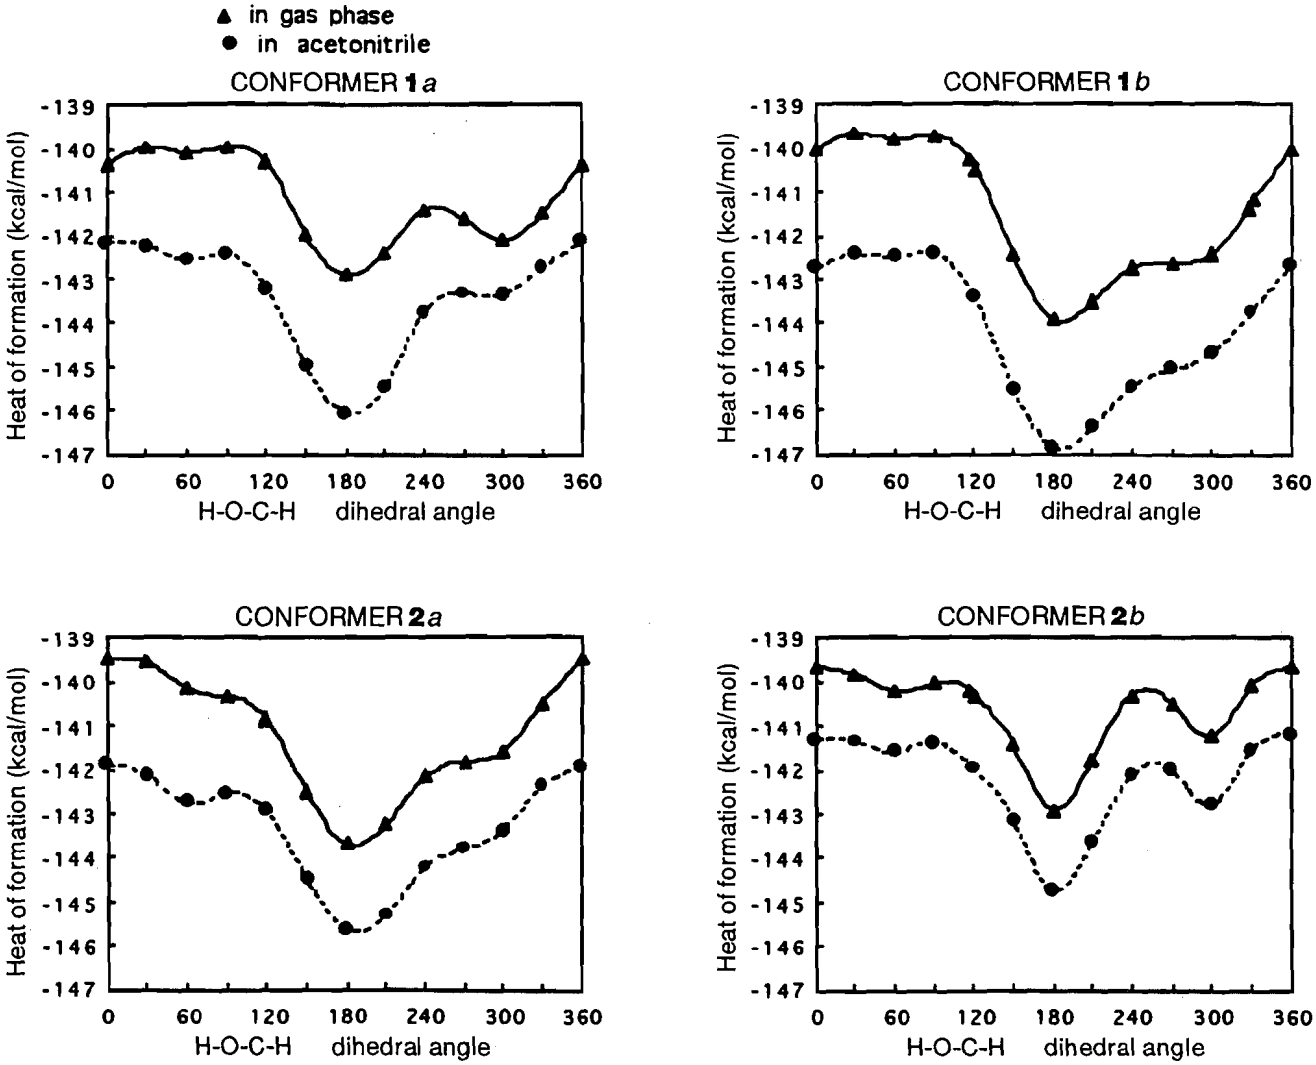
conformers, where the steric interactions between the substituent and the dioxane ring are less important, electrostatic effects play a role that is probably at the origin of the larger stability of **2***a* with respect to **1***a*, predicted for the OH and OCH_3 derivatives.

In a similar way, energy change through rotation of the substituent may be interpreted in general as due to steric and electronic interactions between the substituent and the dioxane ring. For NO_2, we found that there is only one minimum for a geometry in which the H-C-N plane and the NO_2 group are nearly coplanar and only one maximum at an O-N-C-H dihedral angle of 90°. The barrier to rotation varies from 2 kcal/mol (for **1***b* and **2***b*) to 4.2 kcal/mol (for **1***a*). In the case of OH, the computed potential energy is represented in Fig. 6. The absolute minimum is also a coplanar structure in which the H-C-O-H angle is close to 180°. The energy barriers are 3.5 kcal/mol (**1***a* and **2***b*) and 4.5 kcal/mol (**1***b* and **2***a*). Local minima have been also found for angles close to 300° and 60° for all four conformations. The energy differences between the rotamers are not very large (about 1.5 kcal/mol). Finally, for OCH_3, we found two rotamers for each conformation at H-C-O-C angles 174° and −16°, 180° and −5°, 174° and −21°, and 150° and 9° for **1***a*, **2***a*, **1***b*, and **2***b*, respectively. The absolute minima correspond to H-C-O-C ~180° in the case of **1***a*, **2***a*, and **1***b* and 9° in the case of **2***b*. Here, the energy differences between rotamers are smaller than the results for the OH derivative.

Ethylene ketals

When the substituent is in the axial position, **2***a-syn* is generally the preferred conformer except for the Cl derivative (Table 3). Similarly, when the substituent is in the equatorial position, conformer **2***b-syn* is generally preferred except for CN and NO_2. The fact that in most of them **2***a* and **2***b* exhibit smaller dipole moments than **1***a* and **1***b* indicates, contrary to the propylene ketals, the predominance of electrostatic forces between the dipole moments situated at the dioxolane ring and the C—X bond over the steric interactions shown in Fig. 5. For CN and NO_2 derivatives, electrostatic forces between the substituents and the oxygens of the dioxalane fragment dominate because these equatorial substituents interact with negatively charged ring oxygens (Fig. 4). In addition, the dipole moment of **2***b* is smaller than that of **1***b*, which is a favorable situation in terms of electrostatic interactions in the gas phase. Therefore, all the other ethylene ketals except CN and NO_2 prefer **2***b* over **1***b*. The rotamer studies for the poten-

Fig. 6. Potential scans of four conformers from PM3 calculations of 2-hydroxy propylene ketal.



tial curve of the NO_2 derivative show features similar to its propylene ketal analogue: only one minimum around 180° and one maximum around 90°, the dihedral angles showing a flat surface near the minimum. The potential curves of OH and OCH_3 showed a very similar rotational profile to that of the propylene ketals. The absolute minima of these molecules appear around the 180° dihedral angle for **1***a*, **2***a*, **1***b*, and **2***b* except for OCH_3 **1***b* and **2***b*, which are 169° and 166°, respectively.

Finally, when we compare the propylene and ethylene ketal systems, the most striking difference is that, in general, conformer **2***b* is destabilized in propylene ketals whereas it is the most favorable conformer in ethylene ketals and, usually, the least polar conformer in both systems. This indicates the predominance of electronic interactions over steric ones in ethylene ketals since in **2***b* there are also unfavorable X—H repulsions as shown in Fig. 5 for propylene ketals. In this system, such repulsions are not very effective because the five-membered dioxolane ring is more flattened than the six-membered dioxane ring that allows hydrogens to stay further away from the substituent. These repulsions are dominant in propylene ketals. This interpretation is confirmed by potential scans around the C—OMe bond of methoxy derivatives where the rotational barrier for **2***b* at a dihedral angle of 240° is about 9 kcal in propylene ketal but only 6 kcal in ethylene ketal. A common feature of both systems is the stability of conformer **1***b*-*anti* over the others for the CN and NO_2 derivatives despite the fact that this preference is contrary to the behavior of other derivatives in ethylene ketals.

Solution

The generally most stable *anti* structures for propylene ketals, **1***a* and **1***b*, have the highest solvation energy for the equatorial conformer **1***b* (Table 4). Only for the OH and OCH_3 derivative is the solvation energy of **1***a* in acetonitrile greater than that for **1***b*. In the gas phase, the *syn* structure is preferred in the axial conformation for these molecules. In polar solvents, however, the *anti* structure is expected to be more stable.

The electrostatic solvation energy is in general larger for the most polar conformations although there are some exceptions that are due to the fact that multipole contributions are substantial in many cases. The molecules considered may be

divided into three categories according to the effect that the solvent has on their relative conformational energies.

The first group corresponds to those systems in which the substituent X has a dipole moment contribution parallel to the CX bond (F, Cl, CN, NO_2). In that case, *anti* equatorial conformations **1***b* have always the largest total dipole moment since the CX dipole adds to the dioxane ring dipole. The solvent stabilizes these conformations to a larger extent so that in a medium polar solvent, such as acetonitrile, they become the most stable.

The OH- and OCH_3-substituted molecules represent another group of derivatives. Here, the situation is different since the oxygen lone pairs of the substituent contribute to the CX dipole moment so that its direction is not parallel to the CX bond. Besides, they may have several stable rotamers with close energies, the stability of which may be substantially modified through the effect of the environment. The total dipole moment is obviously quite dependent on the rotation angle. However, the rotamer study in acetonitrile showed that the location of the minima does not change upon rotation around C—X in these molecules. The dipole moment values of the most stable rotamer for the **1***a* and **1***b* conformers are close and larger than those for the **2***a* and **2***b* conformers (Table 2). Therefore, the solvation energies of **1***a* and **1***b* are also larger than those for the other conformations.

Finally, the CH_3 derivative may be considered. Since in this case the CX dipole is small, the total molecular dipole moment does not change much (Table 2) with conformation and the solvent effect on the conformational equilibrium is small.

For the ethylene ketals, the molecules can be categorized in two groups. The first group consists of F, Cl, CN, and OH derivatives. In these molecules, the content of axially oriented molecules starts to increase as the solvent polarity increases in our calculations. This tendency to axial orientation is expected on the basis of solute–solvent electrostatic interactions since **1***a* and **2***a* conformers, having larger dipole moments than **1***b* and **2***b* conformers, are stabilized more in polar solvents than an equatorially oriented substituent. Note in Table 5 that **1***b*, whose dipole moment is close to those of **1***a* and **2***a*, is more stable than **2***b* in acetonitrile for F and Cl derivatives. The CH_3-, NO_2-, and OCH_3-substituted ethylene ketals fall in the second category. In these molecules, the tendency to equatorial position increases as the dielectric constant of the solvent increases. As expected, for CH_3 the magnitude of the tendency is small. As pointed out above, comparison with available experimental data shows that the predicted solvent effects are in general correct, except for the OH derivative. Though it is difficult to elucidate the origin of this disagreement without performing more accurate computations one can imagine that specific interactions can play a role in this case and should stabilize the axial conformation in solvents like acetonitrile.

Conclusion

Semiempirical PM3 calculations on conformational equilibria of 2-substituted cyclohexanone ketal derivatives showed that these conformational equilibria are strongly solvent dependent. Without exception, in all of the propylene ketal derivatives studied, the polar solvent stabilizes the equatorial substituent. Therefore, preference to equatorial orientation increases as the polarity of solvent increases. We showed that the equatorial orientation that would be stabilized by the polar solvent should be **1***b* due to its large dipole moment. For ethylene ketal derivatives, calculations of F-, Cl-, CN-, and OH-substituted molecules showed that the content of the axial orientation increases with increase in the polarity of the solvent. On the other hand, CH_3, OCH_3, and NO_2 derivatives show a trend in the opposite direction. The predicted solvent effects are in fairly good agreement with available experimental data except in 2-hydroxy cyclohexanone ethylene ketal for which specific interactions with the solvent are probably important. Hence, the SCRF-PM3 method appears to be a suitable approach to analysing conformational equilibria in solutions of polar molecules of large size.

Density Functional calculations for some hydrogen-bonded systems. Influence of a dielectric surrounding

Y. Jeanvoine, F. Bohr, and M.F. Ruiz-López

Abstract: We present Density Functional calculations for hydrogen-bonded systems with small, medium, and large association energies, in a vacuum and in a dielectric environment. The results are in reasonably good agreement with accurate ab initio results and available experimental data. They confirm that DFT is very promising for modeling liquid state properties.

Key words: hydrogen bond, Density Functional, cooperative effect, liquid state.

Résumé : Une série de systèmes liés par des liaisons hydrogène plus ou moins fortes a été étudiée à l'aide des calculs de type «Fonctionnelle de la densité» en phase gazeuse et dans un environnement diélectrique. Les résultats sont en bon accord avec ceux obtenus par des calculs ab initio poussés et avec les données expérimentales disponibles. Ils confirment que la théorie de la fonctionnelle de la densité est très prometteuse pour l'étude des propriétés de l'état liquide.

Mots clés : liaison hydrogène, fonctionnelle de la densité, effet coopératif, état liquide.

1. Introduction

Among the most interesting approaches to studying the liquid state and chemical processes in solution, mixed Molecular Mechanics – Density Functional Theory (DFT) methods are very promising (1). Formally, DFT can be easily coupled with liquid simulations although the aptness of current DFT exchange-correlation potentials to correctly describe intermolecular interactions remains to be tested. The Gordon–Kim method (2) or other approximate related approaches (3, 4) can be envisaged, although a rigorous treatment requires solving the Kohn–Sham equations (5) for a supermolecule or cluster. Hydrogen-bonded systems are particularly important and some work has already been reported, for instance, for water (6*a*, 6*b*) and ammonia (6*c*) dimers.

With the aim of studying a larger interaction energy range, we have considered here slightly bonded complexes, such as $(H_2S)_2$ and $(HCl)_2$, as well as systems in which proton transfer is partially carried out, such as $FH\cdots NH_3$. The intermediate dimers $(HF)_2$ and $(HCN)_2$ have been also studied.

Since cooperative interactions in the liquid state are important, we have also investigated the influence of a dielectric surrounding on the water–dimer structure. This system has been chosen because of the large number of studies that have been devoted to liquid properties of water. In particular, recent ab initio results have shown that the properties of the water dimer in liquid water are substantially modified through electrostatic interactions (7).

2. Computations

Computations were carried out using the deMon program (8). Atomic orbital basis sets are (8) (41/1) for H, (7111/411/1) for C, N, O, and F, (7321/621/1) for Cl, and (7321/621/1) for S. Auxiliary basis sets used for density integrals are H(4;4), C(4,4;4,4), N(4,4;4,4), O(4,4;4,4), F(4,4;4,4), Cl(5,4;5,4), and S(5,4;5,4) (8).[3] The total energy is computed using numerical integration for the exchange-correlation contribution on a FINE grid (8), as proposed and described in ref. 6*a*. Results using the VWN local potential (9*a*) and the gradient-corrected BP potential (9*b*) are compared.[4] Gradient corrections are included self-consistently.

To evaluate the effect of a dielectric surrounding on the properties of hydrogen-bonded complexes, we used the SCRF approach (10), which has recently been implemented (10*a*) in deMon. In this method, the solute is assumed to be placed into a cavity created in a infinite dielectric and polarizable continuum. The charge distribution of the solute polarizes the continuum, which in turn creates an electric field inside the cavity. The total electrostatic free energy change corresponding to the electrostatic solvation process is given by the expression

$$[1] \qquad \Delta F = -1/2\, E_{int}$$

[3] For details on basis sets, see program deMon (7), ref. 6*a*, and Sim et al. (8).

[4] BP potential refers to Becke's correction for exchange combined with Perdew's correlation correction. PP potential refers to Perdew's correction for both exchange and correlation.

where E_{int} is the interaction energy, which in our approach is written:

$$[2] \qquad E_{int} = \sum_{\substack{l=0,\infty \\ m=-l,+l}} \sum_{\substack{l'=0,\infty \\ m'=-l',+l'}} f^{lm,l'm'} \langle M^{lm} \rangle \langle M^{l'm'} \rangle$$

The quantities M^{lm} are the components of the spherical multipole moments of the solute molecule. The factors $f^{lm,l'm'}$ depend only on the dielectric permittivity of the continuum and on the cavity shape, and are computed from the continuity conditions at the cavity surface boundary. Analytical expressions are obtained for constant cavity surfaces such as the sphere or the ellipsoid but they may be computed numerically for any cavity shape (10*b*, *c*). The reaction field polarizes the electronic distribution of the solute. To account for this polarization, the Kohn–Sham equations are solved iteratively by minimizing the intrinsic energy of the solute plus the free energy of solvation.

In this work, we employed an ellipsoidal cavity shape that appears to be a good approximation for the systems studied and allows geometry optimization with analytical algorithms (10*d*). The volume is constrained to be equal to the average molecular volume in the liquid, which can be evaluated from the volume limited by the van der Waals surface. The axes of the cavity are related to the axes of inertia of a solid of uniform density limited by the van der Waals surface. More details on cavity definition can be found in previous papers (7, 10).

3. Results and discussion

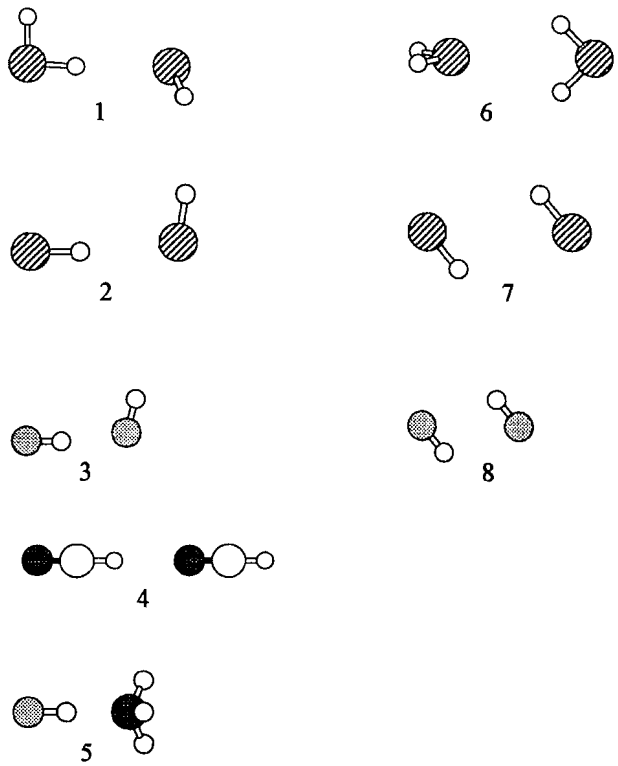
In Table 1, we have summarized the results for the series of hydrogen-bonded complexes considered. Available experimental and ab initio results are also included. To compare the theoretical binding energies to the experimental data, the values gathered in Table 1 do not include zero-point energy (ZPE) contributions. Part of the difference between theory and experiment can then be associated with the way the experimental data have been corrected for ZPE, although this effect is expected to be small. Besides, our theoretical calculations have not been corrected to account for BSSE so that our association energies are probably overestimated. However, on the basis of previous works, BSSE corrections are not expected to be very large. For instance, Frisch et al. (15) evaluated BSSE for the water dimer using the counterpoise method. Obviously, the correction depends on the basis set used but for a medium size basis set, such as the 6-31 + G**, it is of the order of 0.14 kcal mol^{-1} at the RHF level and 0.04 kcal mol^{-1} at the MP2 level. DFT computations for the water dimer by Sim et al. (6*a*) predicted a counterpoise correction of 0.4 kcal mol^{-1} using basis set and exchange-correlation potentials close to those used here. Hence, in our results, the same order of magnitude is expected.

A scheme representation of the optimized structures is given in Fig. 1 (structures 1–5).

The distances d_{AB} and d_{AH}, and the angle θ, i.e., the HAB angle for the A—H···B complexes, are given in Table 1. Other geometrical parameters can be obtained from the authors but it must be pointed out that, in all cases, the symmetry of the most stable conformation predicted by our computations (at the VWN or BP levels) is in agreement with that obtained with the best ab initio calculations reported to date (see the figure).

As previously shown (6*a*), the local density approach (here

Fig. 1. Structures obtained at the BP level for energy minima (left) and saddle points (right) of some hydrogen bonded systems. 1: $(H_2S)_2$; 2: $(HCl)_2$; 3: $(HFl)_2$; 4: $(HCN)_2$; 5: $FH\cdots NH_3$; 6: bifurcated $(H_2S)_2$; 7: cyclic $(HCl)_2$; 8: cyclic $(HFl)_2$.



the VWN results) substantially overestimates the association energy through hydrogen-bond interaction. The dimer formation energy is too large, especially for $(HCl)_2$ where the VWN is twice the experimental value. Gradient-corrected computations (BP) lead to substantially better agreement with ab initio results and experimental data. The agreement is very good for $(HF)_2$ and $(HCl)_2$ and appears to be fairly good for $FH\cdots NH_3$ and $(HCN)_2$ (note that, in the latter, correlation energy was not included in the ab initio calculation so that the BP result is probably more reliable). In the case of $(H_2S)_2$, the BP association energy is in better agreement with experiment than the ab initio result, probably because of the relatively simple basis set used in the latter calculation.

The local density approach predicts too short intermolecular distances in all cases. On the other hand, the AH bonds are lengthened too much through hydrogen-bond formation, as compared to ab initio predictions. It appears that proton transfer is substantially overestimated, as shown also by the charge transfer values. Note, however, that values of Δq cannot be compared directly to ab initio data since the former are obtained using Mulliken Population Analysis while the latter are computed through Natural Population Analysis. Geometrical parameters obtained at the BP level are again in much better agreement with ab initio and experimental values.

Therefore, in DFT studies of hydrogen-bonded complexes, density gradient corrections in the exchange-correlation potentials must be included in order to get reliable results. It is important to point out that BP gives reasonably good results even for weakly bonded complexes, such as $(HCl)_2$ or $(H_2S)_2$. We have not carried out a systematic study with other

exchange-correlation functionals but we recomputed the $(HF)_2$, $(HCN)_2$, and $FH\cdots NH_3$ complexes using the PP functional (9*a*). d_{AB} distances very close to BP results are obtained but larger association energies are predicted, as has also been pointed out in the water dimer study (6*a*).

Some other systems have been considered. A bifurcated structure of $(H_2S)_2$ (structure 6 in Fig. 1) has been optimized. The energy of this structure is 0.88 kcal mol^{-1} higher than the global minimum in Table 1. This compares well with the semiempirical value of 1.2 kcal mol^{-1} obtained in previous work (21). Vibrational frequency computations predict, however, that this is not a local minimum but a saddle point. Experimental data in the gas phase cannot clearly determine whether the trans-linear water dimer-like structure or the bifurcated one is the most stable (22). We have also considered a cyclic $(HX)_2$ structure with C_{2h} symmetry for X = Cl, F (structures 7 and 8 in the figure), which is in fact a transition structure for the exchange of the donor and acceptor molecules in the noncyclic dimers. We predict these structures to lie 1.36 kcal mol^{-1} (for F) and 0.69 kcal mol^{-1} (for Cl) over the most stable ones in Table 1. These values are in very good agreement with MP2/6-31+G**//6-31+G** results (13), which led to 1.28 kcal mol^{-1} and 0.53 kcal mol^{-1}, respectively.

Table 2. Computed properties for the water molecule and water dimer in liquid water: ab initio vs. Density Functional (BP) calculations. Atom numbering in the water dimer is the following: $H_1O_1H_2 \cdots O_2H_3H_4$. Geometry in Å and degrees, dipole moment in Debye, association and solvation energies in kcal mol^{-1}. Bond orders are computed as proposed by Mayer (23). Cavity volumes employed in this work are 36.98 $Å^3$ for water and 73.73 $Å^3$ for the water dimer.

[a]MP2/6-311G++(2*d*, 2*p*) calculations (7).

To investigate hydrogen-bond formation in the liquid phase, we considered the water dimer immersed in a polarizable dielectric continuum. The SCRF model described above was employed to evaluate the electrostatic medium effect on the dimer structure. We chose this system because of its physical importance and the availability of ab initio results (7). The latter have shown that cooperative interactions with the surroundings tend to enhance the hydrogen-bond strength and the study of this fundamental property is suitable for testing DFT calculations in liquid-phase chemical problems.

Comparison between BP and MP2 calculations for the water monomer and the water dimer is made in Table 2. Note that MP2 results are those reported in ref. 7 and refer to MP2/6-311G++(2*d*, 2*p*) computations. Since the DFT basis set is less extended, comparison must be made with some caution. For instance, in a vacuum, the O—H bond lengths predicted by the BP calculations are larger (by about 0.02 Å) than the MP2 results whereas the O—O distance in the water dimer is substantially shorter (by 0.036 Å). Nevertheless, our DFT results for the water molecule and water dimer are close to other DFT values reported in the literature (6). They are also comparable to ab initio calculations with smaller basis sets. Thus, MP2/6-31++G* predicts an O—H bond length of 0.971 Å for the water monomer and an O—O bond length of 2.895 Å in the water dimer (see ref. 15 for a detailed analysis of the basis set dependence of the water molecule and water dimer structures).

Qualitatively, the solvent effects predicted by the MP2 and BP computations are in good agreement. The absolute values are substantially different for some properties, but this is due in part to the fact that the description of the hydrogen bond in a vacuum presents some discrepancies, as already described (*6a*). For instance, the intermolecular O_2H_2 bond order is rather large in DFT calculations.

When the water molecule is placed in a dielectric medium, the O—H bonds are lengthened (by 0.003 Å at the MP2 or BP levels) and weakened and the molecule is substantially polarized. The solvation energy is slightly larger in BP calculations. It is interesting to compare these perturbations on the water molecule with those produced by the formation of an isolated water dimer. In this case, the O—H length of the donating bond is substantially increased (by 0.007 Å at the MP2 and 0.012 Å at the BP level) whereas the other O—H bond lengths change slightly. The perturbation due to specific interactions is larger than the electrostatic effect, which is probably due to neglect of charge-transfer interactions in the continuum model.

Let us now consider the electrostatic effect on the water dimer. Going from the gas phase to the liquid, the hydrogen bond is strengthened. This is illustrated by the decrease of the O_1H_2 bond order and the increase of the O_2H_2 bond order (for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

atom numbering, see Table 2). In spite of that, the O_1—O_2 bond length increases when electrostatic interactions with the medium are considered. The increase is especially large in the BP computations. Due to the flatness of the potential energy surface, the electrostatic effect on the intermolecular parameters is quite sensitive to the computational scheme (7) and the large differences obtained between MP2 and BP calculations are not surprising. Note that, for the same reason, the intermolecular parameters may depend on the cavity shape although the ellipsoidal cavities used here fit the molecular shape well and are, in any case, almost equivalent in the MP2 and BP computations.

The implicit hydrogen bonds of the external hydrogen atoms with other molecules in the liquid (see O_1H_1, $O_2H_{3,4}$ bond lengths and bond orders) are strengthened. The increase in charge transfer through the effect of the bulk liquid is noticeable. Moreover, the absolute value of the association energy is greater in the liquid. It must be pointed out that, in the liquid, the association energies represent the difference between the free energy of solvation of the dimer and the monomers and, strictly speaking, they are not true association energies. The internal energy may be estimated as proposed in ref. 7. This would lead to a still larger stabilization of the hydrogen bond in the dielectric medium.

From these results, one sees that DFT calculations predict a cooperative effect between long-range electrostatic interactions and hydrogen-bond formation, which is in reasonably good agreement with the ab initio results. However, as pointed out above, specific interactions in water are only qualitatively reproduced by the continuum model and a more sophisticated liquid model should be employed to obtain accurate properties in water solution. This can be done by means of various approaches. The simplest one would consist of the study of a cluster of water molecules immersed in a continuum. However, the number of energy minima increases with the number of water molecules and a statistical treatment may be necessary. On the other hand, Monte Carlo or molecular dynamics simulations of a quantum system in a classic liquid can now be carried out with several mixed DFT/MM potentials (1). These techniques represent a substantial improvement in the modeling of molecular liquids but they remain expensive and we do not envisage employing them here.

4. Conclusions

In this paper, several hydrogen-bonded systems with quite different association energies have been studied at the DFT level with non-local exchange-correlation corrections to the total energy. The effect of a dielectric continuum on the structure of the water dimer has been examined and cooperative interactions have been discussed. The results agree fairly well with previous ab initio calculations and experimental measurements. Though it is not easy from these preliminary results to give definitive conclusions on the performance of approximate DFT methods in investigating the liquid state, in particular when hydrogen bonds are present, the approach appears to be very promising.

Abstract: Elemental selenium dissolves in sulfite solution to form selenosulfate ion: $Se + SO_3^{2-} = SeSO_3^{2-}$. The formation constants for this equilibrium at temperatures from 0 to 35°C are reported for the first time. The isomeric thioselenate anion, $SSeO_3^{2-}$, is not, however, produced by the reaction of sulfur with selenite nor is the selenoselenate ion, $Se_2O_3^{2-}$, formed from selenium and selenite. Selenotrithionate is formed rapidly from the reaction of selenous acid with sulfite and hydrogen sulfite according to: $HSeO_3^- + 3\ HSO_3^- = Se(SO_3)_2^{2-} + SO_4^{2-} + 2\ H_2O$. Two isomers of the selenotrithionate ion are observed by Se-77 NMR and Raman spectroscopy, one with O-bonded Se, $Se(OSO_2)_2^{2-}$, and the other with S-bonded Se, $Se(SO_3)_2^{2-}$. Both isomers are formed in reactions with hydrogen sulfite but only the O-bonded isomer is formed in sulfite solutions at ambient temperatures. The Raman and Se-77 NMR spectra of the various sulfur–selenium anions formed are given and the parallel with the reactions of selenous acid and thiols is discussed.

Key words: selenium, sulfite, selenosulfate, selenotrithionate, Se-77 NMR, Raman spectroscopy, equilibria, aqueous solutions.

Résumé : Le sélénium élémentaire se dissout dans une solution de sulfite pour former l'ion sélénosulfate : $Se + SO_3^{2-} = SeSO_3^{2-}$. On a déterminé pour la première fois les constantes de formation pour cet équilibre, à des températures allant de 0 à 35°C. Toutefois, l'ion isomère thiosélénate, $SSeO_3^{2-}$, n'est pas produit par la réaction du soufre avec le sélénite; l'ion sélénosélénate, $Se_2O_3^{2-}$, ne se forme pas non plus à partir du sélénium et du sélénite. Le sélénotrithionate se forme rapidement par la réaction de l'acide séléneux avec le sulfite et le sulfite d'hydrogène, suivant l'équation : $HSeO_3^- + 3\ HSO_3^- = Se(SO_3)_2^{2-} + SO_4^{2-} + 2\ H_2O$. On a observé deux isomères de l'ion sélénotrithionate par RMN du ^{77}Se et par spectroscopie Raman; l'un comporte un O lié au Se, $Se(OSO_2)_2^{2-}$, et l'autre comporte un S lié au Se, $Se(SO_3)_2^{2-}$. Les deux isomères se forment au cours de réactions avec le sulfite d'hydrogène; toutefois, à la température ambiante, en solutions dans le sulfite, il ne se forme que l'isomère comportant une liaison O. On rapporte les spectres RMN du ^{77}Se des divers anions soufre–sélénium obtenus et on discute du parallèle qui existe avec les réactions de l'acide séléneux et des thiols.

Mots clés : sélénium, sulfite, sélénosulfate, sélénotrithionate, RMN du ^{77}Se, spectroscopie Raman, équilibre, solutions aqueuses.

Introduction

Our knowledge of the chemistry of the oxosulfur anions that exist is well developed and for the common oxidation states parallel selenium species are known (1). The stepwise substitution of sulfur by selenium in polyoxosulfur anions has been little studied. For thiosulfate, for instance, two isomers are possible. Early work showed that elemental selenium could be taken up by sulfite, indicating that selenosulfate, $SeSO_3^{2-}$ (2), was stable, but the formation of thioselenate, $SSeO_3^{2-}$, from sulfur and selenite, has been controversial (3–5). Substitution of sulfur by selenium in the trithionate ion gives two possible isomers. In the selenotrithionate anion, $SeS_2O_6^{2-}$, selenium lies in the central position of a three-chalcogen chain (6). The second isomer has not been observed. In the selenium disulfur dichlorides, however, both isomers, ClSeSSCl and ClSSeSCl, are known (7). Other species related to selenotrithionate but with more Se atoms, $Se_nS_2O_6^{2-}(n = 2,3,4)$, have been detected by electrophoretic methods (8) but no isomers amongst these species have been observed. The synthesis of potassium diselenotetrathionate by the oxidation of selenosulfate has been reported (9, 10). Probably the most easily prepared selenopolythionate is selenopentathionate, $SeS_4O_6^{2-}$ (11). The crystal structure of the barium salt shows selenium in the central position of a five-chalcogen chain (12).

None of these selenothionates have been characterized by Raman and Se-77 NMR spectroscopy and, for this reason, it was of interest to use these methods to study the formation and structural nature of the simpler species, selenosulfate and selenotrithionate. The formation of selenotrithionate from selenous acid and sulfite may parallel the formation of bis(thio)selenides according to (13)

[1] $SeO_2 + 4\,RSH = RSSeSR + RSSR$

and, in view of our understanding of the mechanism of this reaction for alkyl thiols (14) and 2-mercaptoethanol (15), extension of this work to sulfite was of interest.

Experimental section

Materials

Sulfur (BDH;>99%) and freshly ground vitreous selenium (BDH;>99.5%) were used directly. Selenium dioxide (Aldrich) was analyzed before use by potentiometric titration with standard NaOH. Sodium (Sigma) and potassium metabisulfite (BDH) were used directly. These salts showed no evidence of any oxidation to sulfate. Sulfite salts, on the other hand, were often contaminated with sulfate. Sodium sulfite (BDH), which was free flowing, contained no sulfate but sodium sulfite from other suppliers contained varying amounts of sulfate. The contamination was associated with clumping of the salt, probably as a result of bottling while still moist. Wet sulfites are subject to air oxidation. None of the potassium sulfite from various suppliers was free of sulfate and it was found preferable to make up potassium sulfite solutions by neutralization of potassium metabisulfite with potassium hydroxide in oxygen-free water. The criterion of purity for the sulfites was the absence of the 453 cm^{-1} band of sulfate in the Raman spectrum. The strong sulfate band at 980 cm^{-1} is a poor measure of the presence of sulfate since it is coincident with a strong sulfite band. Ammonium sulfate (BDH), sodium thiosulfate (BDH), barium chloride dihydrate (BDH), and sulfur dioxide (Air Products) were used directly. Distilled water, purged of oxygen by passage of nitrogen, was used throughout.

Preparations

Potassium trithionate was prepared by standard methods (16). Saturated sulfur dioxide solution (10.64 g/100 mL = 1.6 M (17)) was prepared by passing sulfur dioxide through water at 20°C via a sintered inlet for 1 h. Potassium selenosulfate was prepared by dissolving 24 g of analyzed K_2SO_3 (82.4%) and 5.9 g $BaCl_2 2H_2O$ in 10 mL water, removing the $BaSO_4$ by filtration, and then saturating with Se (3.1 g) over 2 h at ca 60°C, filtering through a glass fibre filter paper to remove any excess Se, and leaving standing at 0°C, protected from oxygen, overnight. The colourless solution produces white crystals, which analyze as $K_2SeSO_3 \cdot 3.5H_2O$ (obsd. %Se: 26.4; calcd. %Se: 26.3). Care must be taken that no residual Se is present since this acts as seed crystal for the decomposition to sulfite (reverse of reaction [2]). The product was stable if stored dry in the dark at ambient temperatures. The salt has kinetic stability when dissolved in water but does produce elemental selenium on standing. Immediate precipitation of selenium normally occurs upon addition of hydrochloric acid but with good mixing a 1.29 M solution of selenosulfate did not produce elemental selenium until the acid concentration reached 0.29 M at ambient temperature. Potassium selenotrithionate was prepared by exploiting the stoichiometry of the sulfite/selenium dioxide reaction discussed below. A solution of 4.44 g of selenium dioxide was prepared in 10 mL of water and another solution of 8.89 g potassium metabisulfite ($K_2S_2O_5$) and 6.32 g potassium sulfite was made up in 85 mL of water with mild heating. The solutions were cooled and mixed with efficient stirring. A barium chloride solution (9.8 g $BaCl_2 \cdot 2H_2O$ in 20.0 mL of water) was then added to precipitate sulfate and the solution was filtered. The yellow coloured supernatant was left to cool at 0°C and produced pale yellow crystals. Both the crystals and the yellow supernatant produced red selenium over a period of hours even when protected from light and stored at −10°C. The crystals analyzed as $K_2SeS_2O_6$ (obsd. %Se: 23.5; calcd. %Se: 24.9 %) and gave an X-ray powder diffraction pattern consistent with the unit cell dimensions reported earlier (6).

Methods

Selenium analysis was done by gravimetry (18). Formation constants for selenosulfate were determined by saturation of the sulfite solution with a known mass of selenium over a 2 h period. This time period was shown to be sufficient for complete saturation. The remaining selenium was filtered and weighed and the amount of selenium dissolved was determined by difference. Temperature control was within ±0.2°C.

Raman spectra were measured with a Jobin–Yvon Ramanor HG.2S monochromator in conjunction with a PAR/Hamamatsu photon-counting system. The spectra were excited with the krypton ion line at 15 454 cm^{-1}. Quantitative spectra were measured at ambient temperature (23°C) and normalized against 1.0 M perchloric acid for which the 910 cm^{-1} band was taken to have an intensity of 6.45 cm^2 (19). The spectra were taken at fixed slit width (1600 μm), which gave a resolution of 5–7 cm^{-1}. The molar scattering intensity for the 1150 cm^{-1} band of SO_2 was determined from the spectrum of a solution saturated with SO_2 at 20°C (1.6 M (17)) ($I^{1150}(SO_2) = 5.5 \pm 0.2$ cm^2 M^{-1}). The molar scattering intensity for the 980 cm^{-1} band of the sulfate ion was determined for 0.5, 1, and 2 M $(NH_4)_2SO_4$ solutions and found to be 6.7 ± 0.4 cm^2 M^{-1}. Deconvolution of overlapped peaks was done assuming Lorentzian line shapes.

Se-77 NMR spectra were determined using a Bruker AMX 500 spectrometer operating at 95.47 MHz. A 30° tip angle was used with 0.3 s acquisition time and no pulse delay. Probe temperature was 21°C. Samples were contained in 10 mm o.d. precision NMR tubes. Chemical shifts were determined by sample replacement and using saturated selenous acid as the standard (20). All chemical shifts are given on the dimethylselenide scale ($\delta(Me_2Se) = \delta(H_2SeO_3) + 1300$ ppm (20)).

Results and discussion

Selenosulfate formation constant

Sulfite and selenosulfate are in equilibrium according to

[2] $SO_3^{2-}(aq) + Se(s) \overset{K}{=} SeSO_3^{2-}$

The values of K at various temperatures are given in Table 1. Our result at 20°C, $K = 0.43 \pm 0.01$, lies in the range of values previously reported for ambient temperature (21), $K = 0.33 - 1.0$. The results given in Table 1 show that the solubility of selenium in sulfite solution increases with temperature, as reported previously (22). A plot of ln K against $1/T$ for the data in Table 1 gives $\Delta H = 18.1 \pm 0.6$ kJ mol^{-1}. This value, the standard free energy change calculated from the equilibrium constant at 25°C, and the entropy change from the Gibbs–

[b]Recalculated from data in ref. 24

Helmholtz equation are listed in Table 2 along with comparable data for $HOC_2H_4SSe^-$ and thiosulfate formation. The thiosulfate formation constant at 25°C, calculated from $\Delta G°$, is 14.2, significantly greater than that for selenosulfate. The enthalpies of chalcogenosulfate formation for sulfur and selenium are comparable and the difference in formation constant is largely determined by the more favourable entropy change for the thiosulfate. The enthalpy of formation of the SeS bond in $SeSC_2H_4OH^-(aq)$ is less favourable than that in the selenosulfate, which parallels the greater bond strength of the S(VI)–selenium linkage compared to that of the S(II)–selenium linkage. The more favourable entropy change for $SeSC_2H_4OH^-$ compared to $SeSO_3^{2-}$ is a result of decreased solvation effects in the mononegative ion compared to the dinegative ion as well as the less symmetric nature of the selenomercaptide.

No evidence for the formation of selenoselenate, $SeSeO_3^{2-}$, by the reaction of SeO_3^{2-} with Se in water was found by gravimetry.

Spectroscopy

The Se-77 NMR spectrum of a 1.0 M sodium sulfite solution saturated with elemental selenium gives a single resonance at 646.3 ppm with a half-height linewidth of 6.3 Hz (Table 3), which is assigned to the selenosulfate ion. The Raman spectrum of this solution is given in Fig. 1 (Trace A) along with spectra of a 1.0 M sodium sulfite (Trace B) and solid potassium selenosulfate (Trace C). In addition to strong bands due to sulfite ion at 480, 620, and 965 cm^{-1}, trace A shows bands at 310, 530, 645, 995, and 1120 cm^{-1}. These bands parallel those observed for solid K_2SeSO_3 (Trace C) and are assigned to the $SeSO_3^{2-}$ ion. From the normalized molar peak intensity of the sulfite band at 965 cm^{-1} in Trace B ($I^{968}(SO_3^{2-}) = 4.4\ cm^2\ M^{-1}$) and the normalized peak intensity measured of the deconvoluted envelope at 965 cm^{-1} in the selenosulfate solution (Trace A), the sulfite concentration is found to be 0.66 M and K for equilibrium [2] is estimated to be 0.52, in reasonable agree-

ment with that determined from gravimetry at ambient temperature. The frequencies of the normal modes of the selenosulfate ion in solid and solution are listed along with those of some symmetry-related ions in Table 4. Except for the selenium–sulfur stretching mode, the frequencies of the $SeSO_3^{2-}$ and $S_2O_3^{2-}$ are very similar. Judging from the frequency of the δ(BrSO) mode in the $BrSO_3^-$ ion, the related deformation for selenosulfate ion is masked by the strong band at 310 cm^{-1}.

Selenoselenate and thioselenate

Elemental selenium undergoes no reaction in 1.0 M Na_2SeO_3 as demonstrated by gravimetry, Se-77 NMR, and Raman spectroscopy, which confirms Rathke's observations (2). The reported solubility and evidence for the formation of $Se_2O_3^{2-}$ (4) may be accounted for by the disproportionation of selenium in basic solution according to the reaction (26),

[3] $$(2n + 1)\ Se + 6\ OH^- = 2\ Se_n^{2-} + SeO_3^{2-} + 3\ H_2O$$

Similarly, no evidence was found for the formation of thioselenate, $SSeO_3^{2-}$, from sulfur and hydrogen selenite or selenite. The Raman spectrum of a 1.0 M $NaHSeO_3$ solution containing sulfur, which was heated at 110°C in an ampoule for 72 h, showed only bands due to hydrogen selenite ion (810 and 370 cm^{-1}). Heating for longer periods of time (7 days) produced bands corresponding to the formation of $S_2O_3^{2-}$ (450 and 1000 cm^{-1}) and SO_4^{2-} (980 cm^{-1}). With even longer heating the thiosulfate peaks disappeared and only sulfate was observed. These changes were accompanied by precipitation of red Se on the surface of the sulfur and the solution remained colourless, which indicates that hydrogen selenite oxidizes sulfur and disproportionation of sulfur at the pH of a 1.0 M sodium hydrogen selenite solution (pH 5) does not occur. Similarly sulfur does not dissolve in 1.0 M Na_2SeO_3 over a period of days at ambient temperature. It has been claimed that thioselenate formation is optimal after 30 min reflux of a selenite–sulfur solution (4, 5). We found no change in the Raman spectrum after such treatment. After heating for 1 day at 115°C in a sealed ampoule only traces of elemental selenium were observed and the Raman spectrum showed only bands for selenite ion. After 9 days heating selenite was still present but the characteristic sulfate band at 980 cm^{-1} was apparent and elemental selenium was present. In earlier preparative work on thioselenate salts (4, 5) excess hydroxide was used and the results may be accounted for by the disproportionation of sulfur in basic solution to give thiosulfate and polysulfides (27).

[4] $$(2n + 2)\ S + 6\ OH^- = S_2O_3^{2-} + 2\ S_n^{2-} + 3\ H_2O$$

In this earlier work no protective measures against air oxidation were taken and this may also account for some of the results.

Reaction of selenite and sulfite

The addition of sulfur dioxide to a strongly acidic solution of selenite immediately produces a yellow solution that rapidly precipitates elemental selenium. This is the basis of the gravimetric analysis for selenite (18). The addition of hydrogen sulfite to selenite produces an immediate yellow coloration but selenium precipitation does not take place for several hours. With sulfite, the selenite solution is initially colourless, turns yellow over a period of hours, and does not yield selenium for several days. Paper electrophoresis studies of the sulfite–selenite solutions have shown that a range of selenopolythionates are formed (8). The Raman spectrum of a solution 0.91 M in $Na_2S_2O_5$ and 0.46 M in SeO_2 (4:1 S(IV)/Se(IV)), which was prepared at –10°C and the spectrum recorded immediately, is given in Fig. 2. No peaks due to HSO_3^- or $S_2O_5^{2-}$ (28) or selenite species (29) are observed. The characteristic strong peaks due to SO_2 and SO_4^{2-} appear at 1151 and 980 cm^{-1}, respectively. Using the molar scattering intensities for SO_2(5.5±0.3 $cm^2\ M^{-1}$) and SO_4^{2-}(6.7±0.4 $cm^2\ M^{-1}$) and the normalized intensities for these bands in this spectrum, the concentrations both of SO_2 and SO_4^{2-} may be estimated to be 0.5 M. This is consistent with the reaction

[5] $$4\ HSO_3^- + H_2SeO_3 = Se(SO_3)_2^{2-} + SO_2 + SO_4^{2-} + 3\ H_2O$$

At 3:1 S(IV)/Se(IV) stoichiometry, no peak corresponding to SO_2 formation is observed and addition of an amount of barium chloride equimolar to H_2SeO_3 caused the 980 cm^{-1} peak to disappear, confirming the stoichiometry of reaction [5]. This 3:1 S(IV)/Se(IV) stoichiometry was proposed earlier to account for the rapid and exothermic reaction of hydrogen sulfite and hydrogen selenite (30) and the appearance of sulfate in the electrophoresis of such solutions (8). The Se-77 NMR spectrum of a 0.91 M $Na_2S_2O_5$ and 0.46 M SeO_2 solution, listed in Table 3, gives two strong signals at 1191.7(1.0) and 881.2(0.9) ppm and a very weak signal at 958.9(0.1) ppm (intensities in parentheses). These three signals must arise from isomers of the selenotrithionate ion, $O_3SSeSO_3^{2-}$,

$O_2SOSeSO_3^{2-}$, and $O_2SOSeOSO_2^{2-}$. In general, the more electronegative the group attached, the less shielded the Se-77 signal (31), and the three signals may be assigned to -OSeO-, -OSeS-, and -SSeS- species in order of decreasing shift. The signal for the -SSeS- species at 881.2 ppm lies some 200 ppm above the normal range for the -SSeS- group in RSSeSR compounds (600–700 ppm)(32) but the high value is expected since the attached sulfur atoms (S(VI)) are the most electronegative bound to Se(II), studied until now. There are no examples of NMR shifts for Se(II) bound to two oxygens. Selenenic acids and their esters represent the closest models and the Se-77 NMR shift range for these is 1053–1269 ppm (33), which brackets the signal observed at 1191.7 ppm. The weak signal at 958.9 ppm is intermediate between the two strong signals for -OSeO- and -SSeS-, as expected for a -OSeS- group.

No evidence for the formation of higher selenopolythionates, which were observed by paper electrophoresis (8), was found in the NMR or Raman spectra. The chromatographic work was done with more dilute solutions (c(Se(IV)) = 0.10 M) than our work (c(Se(IV)) = 0.46 M) and the duration of the experiments was over weeks compared to hours. These differences in conditions as well as the presence of buffer in the chromatographic work could account for the observation of other selenopolythionates in the earlier work (8).

Selenotrithionates are difficult to prepare and decompose to give a red selenium coloration even when stored dry and protected from light. Preparation from selenium acetylacetonate (34) has been used but involves the preparation of the Se(II) starting material. Other methods (10, 35) result in the precipitation of large amounts of elemental selenium and are unreliable, no doubt due to kinetic factors. We have found that dropwise addition of a solution of potassium hydrogen sulfite and potassium sulfite in 2:1 mole ratio to one of selenous acid in 3:1 S(IV)/Se(IV) mole ratio at 0°C produces no elemental selenium, and addition of the stoichiometric amount of barium chloride, to precipitate the sulfate produced, gives a solution from which potassium selenotrithionate is readily crystallized. The Raman spectrum of this product and that of crystalline potassium trithionate are given in Fig. 3. Except for the pair of bands at 276 and 293 cm^{-1} in the spectrum of the selenium anion and the pair at 423 and 437 cm^{-1} in that of the trithionate anion, the spectra are very similar. The crystal structures of potassium trithionate (36) and selenotrithionate (6) show the anions to possess -SSS- and -SSeS- chains. This indicates that these pairs of bands in each case are associated with modes involving the central trichalcogen chain and represent the symmetric and asymmetric -SSeS- (-SSS-) stretching modes. In each case the bands lie slightly below those for the comparable seleno-(SeS-) and thio-sulfate (SS-) stretching modes given in Table 4, further strengthening this assignment. The

bands for each compound and those for their aqueous solutions are listed in Table 5. The Raman spectrum of the aqueous solution of the selenotrithionate anion made up from disulfite and selenium dioxide at room temperature is complicated by the presence of both the S- and O- bonded isomers. However, a preliminary assignment based upon the frequencies of similar modes in other sulfur oxoanions (37) may be made for the $S(SO_3)_2^{2-}$ and $Se(SO_3)_2^{2-}$ anions and this is given in Table 5. The Raman spectrum for the aqueous solution of the $Se(SO_3)_2^{2-}$ given Fig. 2 shows predominantly bands due to the O-bonded isomer but solutions made up at room temperature also exhibit bands due to the S-bonded isomer. The bands listed for an aqueous solution of selenotrithionate ion in Table 5 arise from both isomers and the assignment is more tentative in this case. It is noteworthy that all of the Raman bands observed, for which accurate intensity measurements can be made, are polarized. This suggests that for the trithionate ion, and very likely for the S-bonded selenotrithionate ion also, the symmetry adopted in solution is C_1 ($\Gamma = 21A$), for which all of the modes are polarized, and not the other possible symmetries, C_{2v} ($\Gamma = 7A_1 + 4A_2 + 6B_1 + 4B_2$), C_s ($\Gamma = 13A' + 8A''$), or C_2 ($\Gamma = 11A + 10B$), for which a smaller proportion of the modes is totally symmetric.

It was not possible to record the spectrum of the S-bonded isomer alone. Solutions made up from $K_2Se(SO_3)_2$ continually produced elemental selenium, even after filtration, which interfered with measurement of the Raman spectrum. The difference in the Raman spectra of the O- and S-bonded selenotrithionate ions is clearer for less acidic solutions where reactants may be mixed at room temperature and conversion to the S-bonded ion is slower. The Raman spectra of 0.375 M selenotrithionate solutions made up from sodium sulfite, sodium disulfite, and selenium dioxide in 1:1:1 mole ratio are given in Fig. 4. The spectrum in trace A was taken immediately upon mixing, when the solution was colourless, and that in Trace B after 6 days at room temperature, when the solution had become yellow but no sign of Se^0 was observed. The two spectra are presented under the same conditions of normalization and the band intensities are, therefore, directly comparable as shown by the identical scattering intensities for the 980 cm^{-1} band of the sulfate ion in the two traces. A small peak at 450 cm^{-1}, due to the E deformation mode of sulfate ion (ν_2), is also observed in the spectra. On standing over several days the SO stretch at 1044 cm^{-1} has fallen in intensity and a new peak at 1030 cm^{-1} has appeared, the peaks at 653, 320, and 236 cm^{-1} have decreased while that at 285 cm^{-1} has grown stronger. A peak at 285 cm^{-1} arises from the SeS modes of the S-bonded anion, which forms with time at the expense of the O-bonded isomer. The new peak at 1030 cm^{-1} must also arise from the S-bonded species while the peak at 655 cm^{-1}, which lies in the region expected for SeO single bond stretching (620 cm^{-1} for H_2SeO_3 and 600 cm^{-1} for $HSeO_3^-$ ion (37)), falls in intensity as expected for a band belonging to the O-bonded isomer.

Various stoichiometric ratios of Na_2SO_3 to SeO_2 were studied by Se-77 NMR (Table 3) and Raman (Fig. 5) spectros-

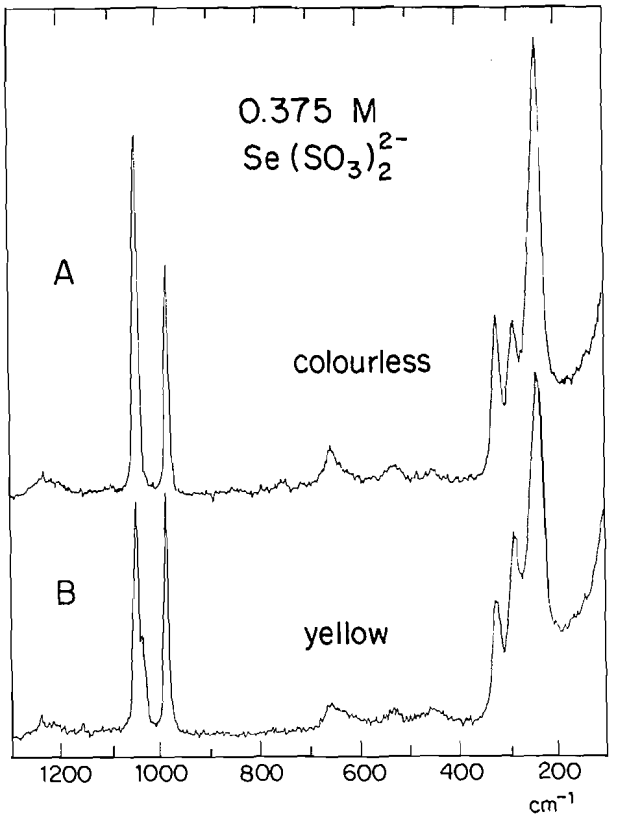
Fig. 4. Raman spectra of 0.375 M solutions of selenotrithionate ion made up from a 1:1:1 stoichiometric ratio of Na_2SO_3, $Na_2S_2O_5$, and SeO_2. Trace A is the spectrum taken immediately after preparation of the solution and Trace B, after 6 days.



copy. A solution of 0.80 M Na_2SO_3 and 0.80 M SeO_2, mixed at 5°C and run immediately, gave an Se-77 NMR spectrum that consisted of two signals, at 1315.2 ppm from $HSeO_3^-$ (20), and 1191.2 ppm from O-bonded selenotrithionate, with intensity ratio 2 to 1, respectively. The same solution, made up at ambient temperature, showed that a small trace of S-bonded selenotrithionate was formed (Table 3). The Raman spectrum, which is given in Fig. 5, shows a normalized peak intensity for sulfate ion corresponding to a concentration of 0.26 M. No characteristic peak for the HSO_3^- ion at 1030 cm^{-1} (28) is observed although $HSeO_3^-$ is present as shown by the peak at 860 cm^{-1} (37). These observations are consistent with the formation of the O-bonded selenotrithionate according to the reaction:

$$[6] \quad HSeO_3^- + HSO_3^- = 1/3\ Se(OSO_2)_2^{2-} + 1/3\ SO_4^{2-} + 2/3\ HSeO_3^- + 2/3\ H_2O$$

Heating of this solution for 5 min at 80°C produced a trace amount of S-bonded selenotrithionate, shown by the NMR signal at 880.6 ppm, and heating over a period of 0.5 h at 100°C resulted in signals at 1190.9, 962.5, and 880.5 ppm due to the three selenotrithionate isomers, in addition to the $HSeO_3^-$ signal at 1303.4 ppm. Some red Se was present in this solution. The Se-77 NMR chemical shifts, for solutions with larger sulfite to selenium dioxide stoichiometric ratios are also given in Table 3. This increase in stoichiometric ratio gives generally more basic solutions and this is reflected in the selenite chemical shifts which decrease as the ratio increases, as expected ($\delta(HSeO_3^-)$ = 1313.9 ppm; δ (SeO_3^{2-}) = 1272.6 ppm (20)). As the ratio increases, the amount of O-bonded isomer sele-

Fig. 5. Raman spectra of solutions of Na_2SO_3 and SeO_2. Trace A: 0.80 M Na_2SO_3 and 0.80 M SeO_2, Trace B: 1.60 M Na_2SO_3 and 0.80 M SeO_2, Trace C: 1.71 M Na_2SO_3 and 0.57 M SeO_2, Trace D: 1.82 M Na_2SO_3 and 0.46 M SeO_2.

For personal use only.

notrithionate increases but selenite is always present in excess of that expected if the reaction were complete. Selenotrithionate to selenite concentration ratios of 1:2, 2:1, and 1:0 are expected for sulfite to selenous acid stoichiometric ratios of 1:1 (reaction [6]), 2:1, and 4:1 but the observed concentration ratios are 1:2, 0.9:1, and 1.25:1, indicating that selenotrithionate formation is less complete in more basic solutions. Similar conclusions may be drawn from the Raman spectra for these stoichiometries shown in Fig. 5. All of these spectra show the 980 cm^{-1} band for the sulfate ion as well as the characteristic bands for the selenotrithionate. As the stoichiometric ratio of sulfite to selenium dioxide increases, the sulfite peak at 970 cm^{-1} grows in relative strength and, because of the increasing basicity of the solutions, hydrogen selenite (860 cm^{-1}(37)) concentration decreases while selenite (810 cm^{-1}(37)) concentration increases. In addition, the peak at 655 cm^{-1} is present in all spectra, indicating the presence of the O-bonded selenotrithionate ion. The apparent slight increase in relative intensity of the 285 cm^{-1} band is due to the strong shoulder from sulfite ion, which lies on the broad low-frequency wing of the exciting line and extends from 320 to 110 cm^{-1} (Fig. 1, trace B). Inasmuch as the NMR spectra do not show the presence of the S-bonded selenotrithionate ion, this peak must also arise in part from the O-bonded isomer. No sulfite ion is present in the solution with 1:1 stoichiometry (Trace A, Fig. 5; $c_{Se} = 0.80$ M) and quantitative Raman spectroscopy gives a sulfate concentration of 0.25 M, which supports the stoichiometry for reaction [6]. As in the case of the NMR experiments, however, the Raman spectra show that as the solutions become more basic as a result of increasing sulfite concentration, the formation of selenotrithionate is less complete. For instance, at 2:1 sulfite to selenous acid stoichiometry (Trace B, Fig. 5; $c_{Se} = 0.80$ M) deconvolution of the sulfate and sulfite peaks near 980 cm^{-1} permits calculation of the normalized peak intensities for these anions and calculation of a sulfate concentration of 0.32 M, which is less than the 0.53 M, calculated for this stoichiometry, assuming the reaction goes to completion. It should be noted that the Raman spectrum of the solution with 4:1 sulfite to selenous acid stoichiometry (Trace D, Fig. 5; $c_{Se} = 0.46$ M) exhibits a peak at 1097 cm^{-1} due to dithionate ion (37). This suggests that selenotrithionate decomposes in the presence of excess sulfite in a similar way to that observed for bis(thio)selenides in the presence of a stoichiometric excess of thiolate (15, 38).

[7] $Se(OSO_2)_2^{2-} + SO_3^{2-} = S_2O_6^{2-} + SeSO_3^{2-}$

Further work will be necessary to confirm this.

Conclusions

In a parallel reaction to that of sulfur and sulfite to produce thiosulfate, elemental selenium dissolves in sulfite solution to produce selenosulfate. The isomer, thioselenate, is not, however, produced by reaction of sulfur and selenite. Generally for isomers such as these, the stable compound is the one in which the most electronegative elements are in terminal positions and the most electropositive share their valence electrons with the terminal ligands. However, selenosulfate is exceptional, since the least metallic element, sulfur, is central and the most metallic is terminal. Certainly this stereochemistry is contrary to that expected from Pauling's scale of electronegativity, where sulfur is more electronegative than selenium (S:2.58, Se:2.55 (39)) but it should be noted that others have found the electronegativities of S and Se to be reversed (Sanderson scale; S:2.66, Se:2.76; Allred–Rochow; S:2.44, Se:2.48 (39)). On the other hand, Se(VI) is more strongly oxidizing than S(VI) and selenosulfate is expected to be more stable than thioselenate on this basis.

Hydrogen sulfite reacts with selenous acid quantitatively, according to 3:1 SO_3^{2-}/H_2SeO_3 stoichiometry, to give selenotrithionate. The O-bonded isomer is formed first and this converts slowly to the S-bonded isomer. The mechanism is probably parallel to that established for the reaction of thiolates and selenous acid (13–15) but for thiolates 4:1 stoichiometry is observed.

[8] $RSH + H_2SeO_3 = RSSeO_2H + H_2O$

[9] $RSH + RSSeO_2H \longrightarrow (RS)_2SeO + H_2O$

[10] $(RS)_2SeO \longrightarrow RSSeOSR$

[11] $RSH + RSSeOSR \longrightarrow (RS)_2Se + RSOH$

[12] $RSH + RSOH \longrightarrow RSSR + H_2O$

The fourth mole of thiolate is consumed in reaction with sulfenate which is displaced when the selenium dithiolate is formed. In the case of sulfite, when selenotrithionate is formed the displaced group is sulfate ion and a fourth mole of sulfite is not used. The reaction then requires 3:1 and not 4:1 stoichiometry. Drawing from the proposed mechanism for the thiolate reaction with selenous acid (14, 15), the mechanism would be

[13] $HSO_3^- + H_2SeO_3 = HSeSO_5^- + H_2O$

[14] $HSeSO_5^- + HSO_3^- \longrightarrow OSe(OSO_2)_2^{2-} + H_2O$

[15] $OSe(OSO_2)_2^{2-} + HSO_3^- \longrightarrow Se(OSO_2)_2^{2-} + H^+ + SO_4^{2-}$

[16] $Se(OSO_2)_2^{2-} \longrightarrow Se(SO_3)_2^{2-}$

We observed no spectroscopic evidence for the Se(IV) products of steps [13] and [14] and conclude that reactions [13],[14], and [15] are rapid on the time scale of solution preparation and reaction [16] is slow. Step [15] requires, in addition to nucleophilic attack on Se(IV) by hydrogen sulfite, the transfer of oxygen from Se to S, which is different from the analogous step for thiolates where oxygen insertion into the SeS bond occurs.

Several examples of sulfite ion binding, through either oxygen or sulfur to a Lewis acid centre (Co^{3+}(40); H^+(28*a*); SO_2(41)), are known. In this work we have observed for the first time linkage isomerism in binding to Se(II). Although the selenotrithionates are undergoing slow decomposition, it is clear that the O-bonded isomer, $Se(OSO_2)_2^{2-}$, is favoured in basic solution and is the first species formed. Isomerization may take place intramolecularly, parallel to the isomerization of nitrito Co(III) complexes (42), but the evidence suggests that conversion to the S-bonded isomer is promoted by acid conditions. Further work, particularly kinetic studies,

will be necessary to complete our understanding of these reductions.

Calorimetric investigations of aqueous amino acid and dipeptide systems from 288.15 to 328.15 K

Andrew W. Hakin, Michelle M. Duke, Lori L. Groft, Jocelyn L. Marty, and Matthew L. Rushfeldt

Abstract: Densities and heat capacities have been measured for aqueous solutions of L-asparagine, L-glutamine, glycylglycine, glycyl-L-valine, glycyl-L-asparagine, and glycyl-DL-leucine at 288.15, 298.15, 313.15, and 328.15 K. These data have been used to calculate apparent molar volumes, $V_{2,\phi}$, and apparent molar heat capacities, $C_{p,2,\phi}$, which in turn have been used to obtain standard state volumes, $\overline{V}^0_2$, and heat capacities, $\overline{C}^0_{p,2}$. The semi-empirical modelling procedures of Helgeson, Kirkham, and Flowers have been used to subdivide the calculated standard state volume and heat capacity data into solvation and nonsolvation contributions. The nonsolvation components of the standard state properties are used in group additivity analyses. These analyses yield structural contributions to standard state volumes and heat capacities for the $CH(NH_2)CO_2H$, CH_2, OH, COOH, CH, $CONH_2$, and CONH groups. The temperature dependences of these contributions are discussed. Some comments are reported concerning the practicality of using the thermodynamic properties of aqueous amino acid and peptide systems as the basis for modelling standard state thermodynamic properties of aqueous protein systems.

Key words: heat capacities, densities, volumes, amino acids, peptides, group additivity.

Résumé : On a mesuré les densités et les capacités calorifiques de solutions aqueuses de L-asparagine, L-glutamine, L-glycylgycine, glycyl-L-valine, glycyl-L-asparagine et glycyl-DL-leucine à 288,15, 298,15, 313,15 et 328,15 K. On a utilisé ces données pour calculer les volumes molaires apparents, $V_{2,\phi}$, ainsi que les capacités calorifiques molaires apparents, $C_{p,2,\phi}$, qui ont été à leur tour utilisés pour obtenir les volumes et les capacités calorifiques dans les états standard, $\overline{V}^0_2$ et $\overline{C}^0_{p,2}$. On a utilisé les méthodes de modélisations semi-empiriques de Helgeson, Kirkham et Flowers pour subdiviser les données calculées pour le volume et capacité calorifique dans l'état standard en contributions de solvatation et de non solvatation. On a utilisé les composantes de non solvatation des propriétés de l'état standard dans des analyses d'additivité de groupe. Ces analyses fournissent des contributions structurales aux volumes et aux capacités calorifiques standard des groupes $CH(NH_2)CO_2H$, CH_2, OH, COOH, CH, $CONH_2$ et CONH. On discute des variations de ces contributions avec la température. On rapporte quelques commentaires relatifs au caractère pratique de l'utilisation des propriétés thermodynamiques des systèmes aqueux d'acides aminés et de peptides pour la modélisation des propriétés thermodynamiques standard des systèmes aqueux de protéines.

Mots clés : capacités calorifiques, densités, volumes, acides aminés, peptides, additivité de groupes.

[Traduit par la rédaction]

Introduction

The investigation of the thermodynamic properties of aqueous amino acid and simple aqueous peptide systems continues to attract our attention (1–3), and that of several other authors (4–6). Most recently, we proposed a group additivity scheme that may be used to estimate standard state volumes and heat capacities for aqueous amino acid systems in the temperature range 288.15–328.15 K at ambient pressure (3). One aim of this research is to assess the feasibility of using amino acid systems as potential building blocks for estimating the properties of aqueous protein systems at elevated temperatures and pressures. There are many uses for such data, but one area that is currently of great interest is the investigation of microbial life forms that can exist at temperatures in excess of 100°C and at elevated pressures. These organisms are very important commercially. For example, thermophilic *Pyrococcus furiosus* is used to obtain thermostable DNA polymerases, which are utilized in the technique of DNA amplification (7).

One problem associated with using amino acids in additivity-type schemes is the inherent charge associated with such systems in solution, the zwitterionic form of the amino acid species almost invariably being the major component in nonbuffered aqueous systems. Our analyses overcome this prob-

lem by utilizing a semi-empirical modeling procedure proposed by Helgeson, Kirkham, and Flowers (HKF) (8) to access only the structural components of the standard state properties of interest. It is these calculated structural contributions to standard state properties that are used as input into our group additivity analyses.

To advance our previous additivity analyses (3) from simple amino acid systems to peptide systems necessitates that we obtain group contributions to standard state volumes and heat capacities for the peptide group, CONH. The current paper addresses this problem by utilizing standard state volume and heat capacity data for aqueous solutions of the amino acids L-asparagine L-glutamine, and the dipeptides glycylglycine (glygly), glycyl-L-valine (glyval), glycyl-L-asparagine (glyasn), and glycyl-DL-leucine (glyleu). These data have been used to obtain peptide group contributions to the structural components of standard state volumes and heat capacities over the temperature range 288.15–328.15 K at ambient pressure. The predictive powers of our analyses are investigated by comparing literature values for standard state volumes and heat capacities for several N-terminal glycyl dipeptide systems (9) at 298.15 K with those that can be estimated from our additivity analyses.

Experimental

L-Asparagine (99+%), L-glutamine (99+%), and glygly (99.5 +%) were obtained from Sigma Chemicals Limited whilst glyval, glyasn, and glyleu were obtained from ICN Biochemicals Inc. All compounds were purified by repeated recrystallization from water + ethanol. The purified chemicals were dried and stored over phosphorus pentoxide in a vacuum oven set at 50°C. Characterization of these systems was performed using a Brüker 250 MHz NMR instrument in which D_2O was used as an internal standard. The recorded NMR spectra were in excellent agreement with those reported in the literature (10).

All solutions used in our investigations were prepared by weight on the molality concentration scale using bi-distilled, degassed water. The unbuffered solutions were stored in sealable 125 mL Nalgene bottles.

The densities of our solutions were measured relative to water with a Sodev O2D vibrating tube, flow densitometer (11). This instrument has a thermal stability of ±0.001°C and routinely measures densities with part per million precision. Volumetric heat capacities were measured relative to water using a Picker flow microcalorimeter (12). Small residual heat leaks in our calorimeter were corrected for by a calorimetric heat loss correction factor, or f factor (13). This factor was evaluated as $f = 0.997 \pm 0.003$ at 298.15 K using standard solutions of sodium chloride in water. For our calorimetric system f is assumed to be a constant that is independent of temperature.

Details of the densitometer, the flow microcalorimeter, and procedures used in their calibration have been described previously (1, 2, 14).

Results and discussion

Experimentally determined data, namely, relative densities $(\rho-\rho_1^0)$ and heat capacity ratios $[c_p\rho/(c_{p,1}^0\rho_1^0) - 1]$, for L-glutamine, L-asparagine, glygly, glyval, glyasn, and glyleu are reported in Tables 1–6. These tables also contain apparent molar volumes and heat capacities that were calculated from the experimental data using eqs. [1] and [2], respectively.

$$[1] \qquad V_{2,\phi} = \left[\frac{M}{\rho}\right] - \left[\frac{\rho-\rho_1^0}{m\rho\rho_1^0}\right]$$

$$[2] \qquad C_{p,2,\phi} = Mc_p + \frac{(c_p - c_{p,1}^0)}{m}$$

In these equations M represents the molar mass of the solute, m is the molality of the solution, c_p and $c_{p,1}^0$ are the specific heat capacities of the solution and of pure water, and ρ and ρ_1^0 are the densities of the solution and of pure water. The densities and heat capacities of pure water, used in our calculations, are those reported by Kell (15, 16). Standard state volumes and heat capacities for the six systems investigated were calculated at each temperature by fitting equations of the general form described by eq. [3] to our calculated apparent molar volume and apparent molar heat capacity data. Weighted linear regression analyses were utilized.

$$[3] \qquad Y_{2,\phi} = Y_{2,\phi}^0 + S_Y m$$

In eq. [3] Y represents the extensive thermodynamic property of interest, $Y_{2,\phi}^0$ is the value of $Y_{2,\phi}$ at infinite dilution (i.e., the standard state property $\overline{Y}_2^0$), and S_Y is the experimental slope. The weights used in these calculations were calculated as the reciprocals of the squares of the uncertainties in the apparent molar volumes and heat capacities (1, 17). Calculated uncertainties are contained in parentheses in Tables 1–6. Calculated standard state volumes and heat capacities are reported, and compared to available literature data (5, 9, 18–26),[3] in Table 7.

The temperature dependences of apparent molar volumes of aqueous solutions of L-glutamine and L-asparagine have been previously investigated by Kharakoz (20). Good agreement is shown between the two sets of data for the L-glutamine system; however, agreement is not so good for the L-asparagine system. The values reported in ref. 20 for this system appear to be consistently lower than ours. In trying to explain this apparent discrepancy, we note that Kharakoz reports averaged apparent molar volumes obtained at concentrations of 3 mg mL^{-1} (approximately 0.023 mol kg^{-1}). This concentration does not strictly apply to infinitely dilute solutions.

The reported standard state volume at 298.15 K for glygly is in very good agreement with the results reported by Mishra and Ahluwalia (19) and Jolicoeur and Boileau (18); however, the result reported by Cabani and co-workers (23) appears to be too high. Our standard state data for this system are in very good agreement with the averaged apparent molar volumes reported as a function of temperature in a recent paper by Chalikian et al. (5).

The standard state volume data at 288.15 K, reported in Table 7 for glyleu, glyval, and glyasn, are in good agreement with data obtained by Hedwig.[3] Hedwig has also obtained standard state volume data at 298.15, 303.15, and 308.15 K for glyval and at 303.15 and 308.15 K for glyasn.[3] These data closely follow the temperature dependence trends we observe in our own standard state volume data.

[3] Also, G.R. Hedwig, personal communication.

[a]Estimated uncertainties for $V_{2,\phi}$ and $C_{p,2,\phi}$ appear in parentheses.

Literature data for the standard state heat capacities of the systems investigated in this paper are limited to 298.15 K. For glygly, our value of 102.6 ± 0.9 J K^{-1} mol^{-1} is in good agreement with the value of 100.8 ± 0.3 J K^{-1} mol^{-1} reported by Reading and Hedwig (9) and the value of 99.3 ± 1.0 J K^{-1} mol^{-1} reported by Bhat and Ahluwalia (26). For L-glutamine, our standard state heat capacity at 298.15 K is in apparent disagreement with the value obtained, using a Picker flow microcalorimeter, reported by Jolicoeur et al. (25). We have repeated this experiment several times with new samples of L-glutamine and remain unable to explain this discrepancy. Our value of 123.9 J K^{-1} mol^{-1} for L-asparagine agrees well with the value reported by Jolicoeur et al. (25) and would appear to confirm that the earlier value reported by Huffman and Bersook (22) is too high. There is reasonable agreement between the standard state heat capacities for glyleu and glyval reported by Bhat and Alhuwalia (26) and those reported in Table 7. The standard state heat capacity for glyasn at 298.15 K (188.1 J K^{-1} mol^{-1}) reported by Reading and Hedwig (9) is in excellent agreement with our reported value of 189.8 J K^{-1} mol^{-1}.

Table 4. Relative densities, $(\rho - \rho_1^0)$, apparent molar volumes, $V_{2,\phi}$, heat capacity ratios, $[c_p^0\rho/(c_{p,1}\rho_1^0) - 1]$, and apparent molar heat capacities, $C_{p,2,\phi}$, of aqueous solutions of glycyl-L-valine at 288.15, 298.15, 313.15, and 328.15 K.[a]

m (mol kg^{-1})	$(\rho - \rho_1^0)$ (g cm^{-3})	$V_{2,\phi}$ (cm^3 mol^{-1})	$10^3\left(\frac{c_p\rho}{c_{p,1}^0\rho_1^0} - 1\right)$	$C_{p,2,\phi}$ (J K^{-1} mol^{-1})

chemical properties of aqueous amino acid systems that we are constructing (1–3). This data base provides the framework on which we have constructed group additivity analyses that allow for the estimation of standard state volume and heat capacity data for aqueous amino acid and peptide systems in the temperature range 288.15–328.15 K. More specifically, the data reported in this paper allow for the calculation of the temperature dependences of peptide group contributions to structural components of standard state volumes and heat capacities.

Group contribution schemes, which may provide a means of modelling the thermodynamic properties of aqueous protein systems, have been previously investigated by several authors (27, 28). However, these authors do not usually consider using thermodynamic data for amino acids as the bases of their analyses, the major problem discouraging them from this route being the inherent charge of the zwitterionic species in aqueous solution. We avoided this obstacle by subdividing our standard state volume and heat capacity data into solvation and structural contributions. We subsequently used only the structural contributions in our group analyses schemes. This subdivision of the extensive thermodynamic standard state properties is represented by eq. [4];

$$[4] \qquad \overline{Y}_2^0 = \overline{Y}_s^0 + \overline{Y}_e^0$$

where subscripts s and e define the structural and solvation contributions to the standard state property, respectively. The solvation contributions of the standard state properties may be calculated using reported effective Born coefficients and parameters calculated using the temperature and pressure

dependences of the dielectric constant of the solvent (3, 29). Effective Born coefficients, for the dipeptide systems used in our analyses, were calculated from estimated standard state entropies using the relationship described in ref. 29. Standard state entropies for the dipeptides were estimated using a group additivity type scheme. This method of analysis is based upon the HKF semi-empirical modelling procedures (8, 29, 30), and we reported details of our calculations in previous publications (1–3).

The format of our additivity analyses may be represented by the general equation

$$[5] \qquad \overline{Y}^0_s = \sum_i n_i \overline{Y}^0_i$$

where n_i represents the number of times each structural group appears in a given molecule and $\overline{Y}^0_i$ represents the extensive thermodynamic group contribution to the structural component of the standard state property of interest. Our analyses yield estimates of the contributions made by the $CHNH_2COOH$, OH, COOH, CH_2, CH, $CONH_2$, and CONH groups. Equation [5] may therefore be written in the form:

$$[6] \qquad \overline{Y}^0_s = n_{CH(NH_2)COOH}\overline{Y}^0_{CH(NH_2)COOH} + n_{CH_2}\overline{Y}^0_{CH_2} + n_{OH}\overline{Y}^0_{OH} + n_{COOH}\overline{Y}^0_{COOH} + n_{CH}\overline{Y}^0_{CH} + n_{CONH_2}\overline{Y}^0_{CONH_2} + n_{CONH}\overline{Y}^0_{CONH}$$

In addition, contributions from H atoms and methyl groups may be obtained by the use of two simplifying assumptions (31–33), eqs. [7] and [8].

$$[7] \qquad \overline{Y}^0_{CH_3} = 1.5\ \overline{Y}^0_{CH_2}$$

$$[8] \qquad \overline{Y}^0_H = 0.5\ \overline{Y}^0_{CH_2}$$

Estimates of structural contributions, $\overline{Y}^0_i$, were obtained from eq. [6] using conventional multiple regression fitting procedures. Calculated group contributions to structural standard state volumes and heat capacities are contained in Table 8 together with their calculated standard errors. Experimental standard state properties are compared to our group analyses calculated values in Table 9. In general, standard state volumes appear to be slightly better represented than standard state heat capacities by our group additivity approach. An explanation for this behaviour is explored in a discussion of our calculated structural group contributions.

The addition of the six systems investigated in this paper to our input data base for the group additivity analyses significantly adds to the numbers of degrees of freedom of the analyses. Accordingly, we have been able to expand the number of structural groups for which we solve at any one time and hence overcome some of the structural approximations we were forced to make in our previous analyses (3).

The current additivity analyses do not significantly alter previously reported (3) trends in the temperature dependences of the structural components of standard state volumes and heat capacities for the $CH(NH_2)CO_2H$, CH_2, OH, and COOH groups. It is interesting to note, however, that our analyses predict that the apolar CH and CH_2 (hence CH_3 and H) group contributions dominate the magnitude of standard state heat capacities. By comparison, the contributions made by polar groups to standard state heat capacities are small.

Table 8. Calculated group contributions of structural components of standard state volumes and heat capacities at 288.15, 298.15, 313.15, and 328.15 K.

In brief, the group contributions to structural components of standard state heat capacities of apolar species are seen to decrease with increasing temperature whilst the group contributions of polar species increase with increasing temperature. These trends are indicative of the respective hydrophobic or hydrophilic character of the species under discussion.

The temperature dependences of group contributions to structural components of standard state volumes yield less definitive conclusions. The differences between group contributions reported in this paper and those we reported previously (3) are not unexpected given the manner in which we have expanded our additivity analyses to look at an increased number of functional groups. Trends in group contributions for the $CH(NH_2)CO_2H$, OH, and COOH groups follow the expected behavior of polar groups, i.e., increases in the vol-

ume contributions with increasing temperature. However, the CH_2 group exhibits a very small increase in its standard state volume contribution as a function of temperature that would appear to be in conflict with the apolar nature of the species.

Structural group contributions of the CH group to standard state volumes are predicted to be virtually temperature independent, and in this respect follow the trends shown by the CH_2 group. Contributions to the standard state heat capacities by CH generally decrease with increasing temperature as one would expect of an apolar group. Our $\overline{C}^0_{p\mathrm{CH}}$ value of 62.9 J K^{-1} mol^{-1} at 298.15 K is in good agreement with the value of 65 J K^{-1} mol^{-1} reported in ref. 27. By comparison, the value of 23 J K^{-1} mol^{-1}, obtained from an analysis of standard state heat capacities of compounds of the type H-$(CH_2)_n$-X by Nichols, Skold, Spink, Suurskuusk, and Wadsö (28), would appear to be low.

Increases in structural contributions to standard state volumes and heat capacities of the $CONH_2$ group as a function of

temperature follow the expected trends of a polar group. Mishra and Ahluwalia (19) report $\overline{V}^0_{CONH_2} = 38.9$ cm^3 mol^{-1} at 298.15 K using an additivity analysis based on compounds of the general form $CH_3(CH_2)_nCONH_2$. This value is much higher than our predicted value of 25.10 cm^3 mol^{-1}.

Our group additivity analysis of heat capacity data indicates that structural components to standard state heat capacities for the peptide group increase with increasing temperature. This behavior chimes well with the known hydrophilic character of the group. Several authors have reported CONH group contributions for standard state heat capacities at 298.15 K and ambient pressure and there appears to be considerable disagreement regarding a recommended value. Nichols, Skold, Spink, Suurskuusk, and Wadsö (28) report a value of -61 J K^{-1} mol^{-1} calculated from heat capacity data for simple amide systems. Cabani et al. (34) give an approximate value of 0 J K^{-1} mol^{-1} calculated from heat capacity data for cyclo mono- and dipeptide systems, and a value of 2 J K^{-1} mol^{-1} may be calculated from the homopeptide heat capacity data reported by Makhatadze and Privalov (35). In a recent investigation, Hedwig, Reading, and Lilley (27) report values, depending upon which form of additivity scheme was utilized, of -7.5 and -13 J K^{-1} mol^{-1}. Our calculated value of -23.0 ± 8.5 J K^{-1} mol^{-1} falls between these reported values.

Structural contributions to standard state volumes of the peptide group, calculated from our data base of standard state volume data, are predicted to increase with increasing temperature. As noted for the heat capacities of the peptide group, this behavior is indicative of hydrophilic character. There are already several estimations in the literature of the standard state volume contribution of the peptide group at 298.15 K. Mishra and Ahluwalia (19) report values of 20.5 ± 0.3, 19.3, 35.8, and 16 ± 1 cm^3 mol^{-1} from the analyses of standard state volume data for *N*-acetylamino acids, alkyl ureas, alkyl amides, and amino acids and dipeptides, respectively. Accepting that the methylene group contribution to standard state volumes is approximately 16 cm^3 mol^{-1} at 298.15 K, then a value of $\overline{V}^0_{CONH} = 22$ cm^3 mol^{-1} may be obtained from Jolicoeur and Boileau's (18) value for $\overline{V}^0_{CH_2CONH}$, which is calculated from standard state volume data for low molecular weight peptide systems. Our value of $\overline{V}^0_{CONH} = 15.48 \pm 0.36$ cm^3 mol^{-1} agrees very well with the amino acid dipeptide-derived value reported in ref. 19.

In comparing our group standard state data to those obtained by other authors, we remind the reader that our group contributions represent only structural contributions. Our analyses do not provide for the calculation of group solvation contributions to standard state volumes and heat capacities.

We conclude from our survey of available group additivity data that any values of group contributions to standard state volumes and heat capacities are extremely sensitive to the data set used as input to an additivity scheme. In addition, although the HKF analysis we have used in this paper goes some way towards accounting for the solvation characteristics of the investigated amino acids and peptides, it may well be that this contribution is underestimated in the low temperature and pressure region that we have studied. The charging of these species is known to have a large effect on standard state heat capacities.

The predictive powers of our group additivity analyses can be partially demonstrated by using the group contributions contained in Table 8 to calculate standard state volumes and heat capacities for several aqueous dipeptide systems for which literature data are available at 298.15 K (9). Solvation contributions to the standard state properties were calculated in the manner described earlier. The results of these calculations are contained in Table 10.

The agreement between the literature and our calculated standard state properties is promising, especially for standard state volumes, given that at best the results of group additivity analyses should be viewed as approximations.

There are several areas that require further examination before it would be feasible to apply simple additivity schemes, of the type described in this paper, to the calculation of standard state properties for aqueous protein systems. It is clear from our work that additivity schemes are often unable to differentiate between structural isomers. For example, the calculated structural components to standard state volumes and heat capacities of L-leucine and L-isoleucine are identical. In effect, the difference in structure between these two amino acids has been averaged out by our additivity analyses. A previous investigation (27) indicated a problem when using an additivity approach to obtain standard state volumes for dipeptide systems in which one switches the amino acid residue at the N-terminus, e.g., glycylalanine and alanylglycine. Simple group additivity analyses cannot distinguish between these two structures and it is likely that one should expand any analyses to account for the way in which a given molecule orients itself in the solvent. The correlations between side-chain group contributions to standard state heat capacities and solvent-accessible surface area of amino acid side chains reported by Jolicoeur et al. (25) would appear to support this expectation.

We recently began to investigate the orientations of dipeptide molecules, of the type described above, in water using the commercial modeling software package Hyperchem. It is hoped that these investigations will lead to a greater understanding of the dynamics of aqueous peptide systems. This in turn should lead us to enhanced additivity analyses and closer to our goal of estimating key thermodynamic properties for aqueous protein systems.

Evidence for reversible dissociative adsorption in the reaction of molecular chlorine with gallium arsenide

Kin-Chung Wong and Elmer A. Ogryzlo

Abstract: The reaction of molecular chlorine with the (100) face of a gallium arsenide crystal has been studied at pressures of Cl_2 between 0.10 and 9.0 Torr and in the temperature range from 90 to 110°C. In contrast to an earlier report, the etch rate was found to be half order with respect to Cl_2. The similarity of these results to those obtained for the reaction of molecular chlorine and bromine with silicon points to a mechanism in which the gaseous halogen molecule is first physisorbed on the semiconductor surface and then dissociates into chemisorbed atoms. The data indicate that both steps occur reversibly at higher pressures, where the composite half-order rate constant can be represented by the Arrhenius equation:

$k_{1/2} = 10^{13.6\pm2.6}$ μm min^{-1} Torr$^{-1/2}$ $e^{-(100\pm19\text{ kJ mol}^{-1}/RT)}$

At low pressures the first-order rate constant is given by the equation:

$k_1 = 10^{10.4\pm2.3}$ μm min^{-1} Torr^{-1} $e^{-(76\pm16\text{ kJ mol}^{-1}/RT)}$

Key words: etching, gallium arsenide, molecular chlorine, kinetics.

Résumé : On a étudié la réaction du chlore moléculaire avec la face (100) d'un cristal d'arséniure de gallium à des pressions de chlore allant de 0,10 à 9,0 Torr et à des températures allant de 90 à 110°C. En opposition avec un rapport antérieur, on a trouvé que la vitesse de gravage est d'ordre une demie par rapport au chlore. La similarité de ces résultats avec ceux obtenus lors de la réaction du chlore et du brome moléculaires avec le silicium suggère un mécanisme dans lequel la molécule d'halogène gazeux subit dans un premier temps une adsorption physique sur la surface du semiconducteur et qu'elle se dissocie par la suite en atomes chimisorbés. Les données indiquent que, à des pressions plus élevées, les deux étapes se produisent d'une façon réversible alors que la constante de vitesse composée d'ordre une demie peut être représentée par l'équation d'Arrhenius :

$k_{1/2} = 10^{13.6\pm2.6}$ μm min^{-1} Torr$^{-1/2}$ $e^{-(100\pm19\text{ kJ mol}^{-1}/RT)}$

À de faibles pressions, la constante de vitesse du premier ordre est donnée par l'équation suivante :

$k_1 = 10^{10.4\pm2.3}$ μm min^{-1} Torr^{-1} $e^{-(76\pm16\text{ kJ mol}^{-1}/RT)}$

Mots clés : gravage, arséniure de gallium, chlore moléculaire.

[Traduit par la rédaction]

Introduction

Etching of gallium arsenide (GaAs) by halogen atoms and molecules is commonly used in the fabrication of microelectronic circuits based on this semicondutor. However, the mechanisms of these reactions and the rate constants for the elementary steps in the processes remain largely poorly characterized. In 1988 Ha et al. (1) reported a kinetics study of the etching of GaAs by molecular chlorine in which they found that the etch rate was not a linear function of the chlorine pressure. From the form of the pressure dependence that they observed, they concluded that the etch rate reached a plateau at high pressures because of the "saturation" of sites for reaction on the surface. Such an interpretation of the nonlinear kinetics was reinforced by similar earlier observations and interpretations in the reactions of Br_2 (2) and Cl_2 (3) with silicon. However, more recently it has been shown that neither of these latter reactions reaches a plateau at high pressures, and that at high pressures they both simply remain half order with respect to the partial pressure of the molecular halogen (4, 5). Furthermore, the reaction of GaAs with Br_2 (6), I_2 (7), and ICl (8) have all been found to be consistent with half-order kinetics. We therefore decided to reinvestigate the GaAs–Cl_2 reaction to see if any systematic errors occurred in the earlier work that prevented this reaction from being recognized as half order.

Experimental

Single crystal GaAs (100) chips were cut from a 7.5 cm diameter and 0.5 mm thick wafer supplied by Crystar (nee Johnson Matthey, nee Cominco). They were patterned with silicon nitride stripes, which were 20 μm wide and 20 μm apart, aligned either along the $\langle 0\bar{1}\bar{1}\rangle$ or the $\langle 01\bar{1}\rangle$. direction. Chips were generally rectangular and had a surface area of about 0.04 cm^2.

Matheson High Purity chlorine with a quoted purity of 99.99% was used without further purification. The Cl_2 was passed over the GaAs samples at a flow rate that was at least 5000 times that consumed by reaction. This avoided any dilution of reactant stream by the gaseous products and also prevented the formation of any reactant concentration gradient above the GaAs surface. A rotary vacuum pump was used to back a liquid-nitrogen-cooled trap, which functioned as a cryogenic pump for the Cl_2. A control valve located upstream from the reactor (the flow controller) was used to change the pressure over the substrate by increasing the flow rate of chlorine into the system. A second control valve (the exhaust throttle) located between the reactor and the cryostatic pump could be used to change the evacuation speed. In the present study, the pressure was regulated only by adjusting the flow controller setting. This ensured that the residence time of the gas over the etching sample was relatively constant at all pressures. This is in contrast to the manner in which the pressure was changed in the earlier work (1). In that study, the pressure was changed by adjusting the throttle valve. This meant that the total gas flow through the system was not changed and therefore the residence time of the gas over the sample increased with increasing pressure. Under these circumstances, the reaction became increasingly diffusion controlled at high pressures because the products were not swept away as quickly as they might be if the pressure were increased by increasing the total gas flow rather than by throttling the flow. It is quite probable that the small but significant differences between the data obtained in this work and the earlier study can be attributed to this simple difference in flow control techniques.

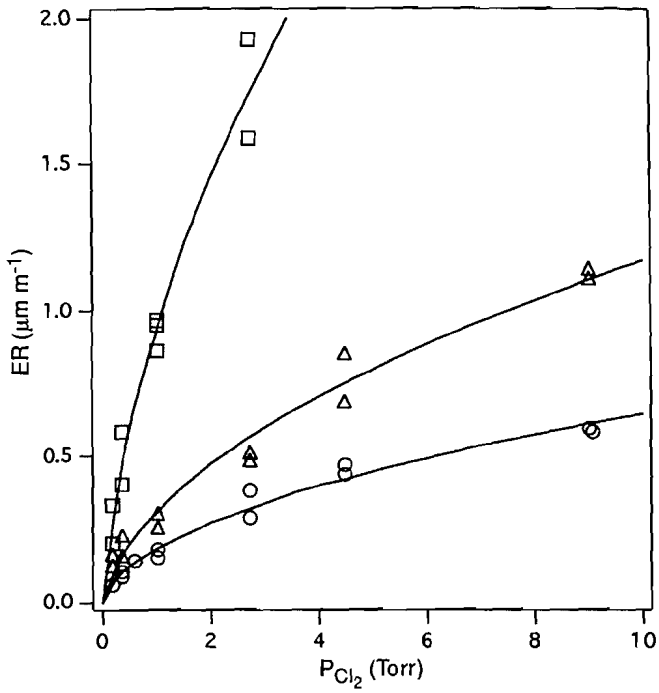
Before the etching experiment, the GaAs sample was immersed in 38% concentrated hydrochloric acid for 30 s to remove any native oxide layer on the surface and then it was mounted with a glass spring on a thermally oxidized silicon block that acted as a heat sink. The temperature of the GaAs chip was measured with a thermocouple embedded in the silicon block and the pressure of $Cl_{2(g)}$ was measured with an MKS baratron pressure gauge.

Etch rates were measured in situ by laser interferometry (1, 3). Temperatures and pressures were chosen so that the etch rates were between 0.05 and 2.0 μm min^{-1} because these were most easily measured by our monitoring method.

Results and discussion

The reaction of Cl_2 with GaAs(100) was studied at 90, 100, and 110°C to determine the activation energy and the order of the reaction with respect to Cl_2. The pressure dependence of the etch rate (ER) is shown in Fig. 1. It can be seen that although the relationship is not linear, the etch rate continues to increase as the pressure of the Cl_2 increases and no obvious saturation of the reaction rate is observed in this pressure range.

Fig. 1. The GaAs(100) etch rate as a function of the pressure of Cl_2 at 90 (○), 100 (△), and 110°C (□).



To determine the order of the reaction with respect to Cl_2 pressure, ln (ER) was plotted against ln (P_{Cl_2}). For the data shown in Fig. 1, straight lines with slopes between 0.5 and 0.7 were obtained, suggesting a half-order dependence on the Cl_2 pressure over the entire pressure range for which data were obtained. A plot of etch rate against $\sqrt{P_{Cl_2}}$ is presented in Fig. 2. As in the silicon etching experiments (4, 5), the "least-squares" lines through these points have small negative y-intercepts and the magnitudes of these intercepts show a systematic increase with increasing temperature.

Such behavior is consistent with the "reversible dissociative adsorption" mechanism proposed earlier (4, 5). In this mechanism, the Cl_2 molecule first dissociatively adsorbs on the GaAs surface to form two chemisorbed chlorine atoms ($Cl_{(ads)}$) as represented by eqs. [1,-1]. In the second step (eq. [2]), this $Cl_{(ads)}$ species reacts with the surface to form reaction products or some intermediates that yield such products in a subsequent non-rate-controlling process.

$$[1,-1] \quad Cl_{2(g)} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} 2Cl_{(ads)}$$

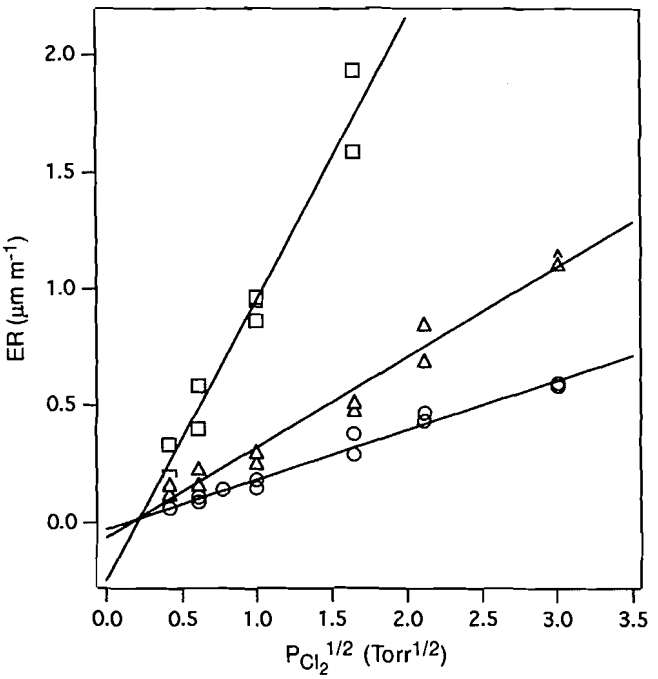
$$[2] \quad Cl_{(ads)} + GaAs \xrightarrow{k_2} \text{product}$$

The rate law for such a reaction mechanism was derived previously (4). Once a steady state is established, the rate law takes the form:

$$[3] \quad ER = \frac{k_2^2}{4k_{-1}}\sqrt{1 + \frac{16k_1k_{-1}}{k_2^2}P_{Cl_2}} - \frac{k_2^2}{4k_{-1}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Fig. 2. A plot of the etch rate versus $\sqrt{P_{Cl_2}}$ at 90 (○), 100 (△), and 110°C (□).



At low pressure, eq. [3] reduces to

$$[4] \qquad \mathrm{ER} = 2k_1 P_{Cl_2}$$

i.e., reaction [1] is rate controlling and so the etch rate exhibits a first-order dependence on P_{Cl_2}. On the other hand, at high pressures, eq. [3] reduces to

$$[5] \qquad \mathrm{ER} = k_2\sqrt{\frac{k_1}{k_{-1}}}\sqrt{P_{Cl_2}} - \frac{k_2^2}{4k_{-1}}$$

i.e., the reaction approaches half-order kinetics with respect to Cl_2 because reaction [2] now becomes rate controlling and an equilibrium concentration of $Cl_{(ads)}$ is maintained by reactions [1,-1]. We will refer to $(k_2\sqrt{k_1/k_{-1}})$ as the "composite half-order rate constant" and abbreviate it as $k_{1/2}$.

According to eq. [5], in the high-pressure regime, the plot of ER versus $\sqrt{P_{Cl_2}}$ will result in a straight line with a negative y-intercept. This is consistent with the data shown in Fig. 2 where the slopes and intercepts are equal to $(k_2\sqrt{k_1/k_{-1}})$ and $(-k_2^2/4k_{-1})$, respectively, and the first-order rate constant k_1 can subsequently be determined from the relationship:

$$[6] \qquad k_1 = \frac{-\text{slope}^2}{4 \times y\text{-intercept}}$$

The rate constants calculated in this way are presented in Table 1. Assuming that both k_1 and $k_{1/2}$ exhibit an Arrhenius temperature dependence, i.e.,

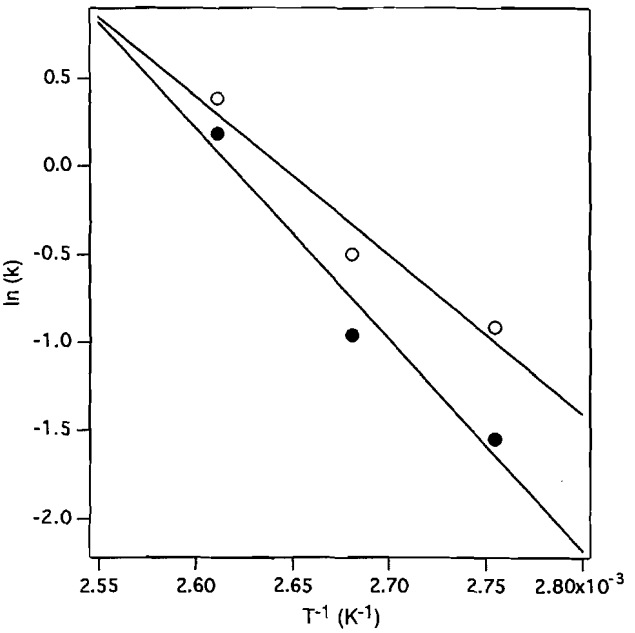
$$k = Ae^{-E_a/RT}$$

where A is a temperature-independent pre-exponential factor, E_a is the activation energy, R is the gas constant, and T is the temperature in Kelvin; E_a and A for k_1 and $k_{1/2}$ can be determined by plotting ln (k) versus $1/T$. Such plots are shown in Fig. 3, and the following expressions for k_1 and $k_{1/2}$ are obtained:

Table 1. Experimental values of the first- and the half-order rate constants.

Temperature (°C)	k_1 (μm min^{-1} Torr^{-1})	$k_{1/2}$ (μm min^{-1} Torr$^{-1/2}$)
90	0.40 ± 0.23	0.21 ± 0.01
100	0.60 ± 0.41	0.39 ± 0.02
110	1.47 ± 0.75	1.20 ± 0.09

Fig. 3. An Arrhenius plot for k_1 (open circle) and $k_2\sqrt{k_1/k_{-1}}$ (closed circle).



$$[7] \qquad k_1 = 10^{10.4\pm2.3}\,\mu\mathrm{m\ min^{-1}\ Torr^{-1}}\ e^{-(76\pm16\ \mathrm{kJ\ mol^{-1}}/RT)}$$

$$[8] \qquad k_{1/2} = 10^{13.6\pm2.6}\,\mu\mathrm{m\ min^{-1}\ Torr^{-1/2}}\ e^{-(100\pm19\ \mathrm{kJ\ mol^{-1}}/RT)}$$

The activation energy for k_1 (i.e., for the dissociative adsorption) is 76 kJ mol^{-1}. This is 166.6 kJ mol^{-1} below the bond dissociative energy of Cl_2. Although it represents a large reduction in the dissociation energy, the value is not unreasonable. The potential energy curve for the reaction is shown schematically in Fig. 4. The dissociative adsorption of $Cl_{2(g)}$ on the GaAs surface to form 2 $Cl_{(ads)}$ is represented by movement over the first energy barrier of 76 kJ mol^{-1} on the left-hand side of the diagram. Although $Cl_{(ads)}$ must lie below the first transition state, its position in the figure is undetermined and it is therefore represented by a dotted line on the diagram. This $Cl_{(ads)}$ species then reacts to yield reaction products through a second transition state. Though the

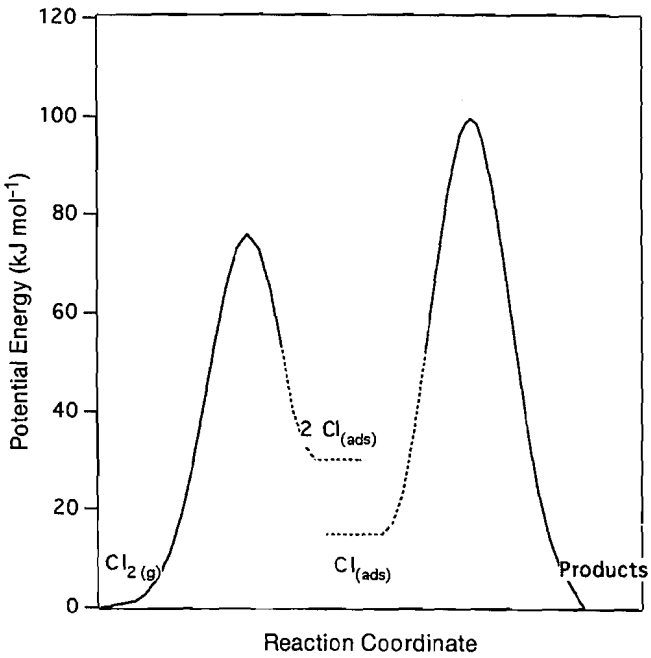
Fig. 4. Potential energy curve for the rate-determining steps in the etching of gallium arsenide by molecular chlorine gas.



activation energy for the second step is also undetermined, the energy of the second transition state relative to the initial reactants is 100 kJ mol^{-1}.

As in the case of the reaction of silicon with halogen molecules, the pre-exponential factor in eq. [7] is several orders of magnitude larger than the collision frequency. The collision frequency for Cl_2 molecules on a surface under our experimental condition is 2.17×10^{24} collision m^{-2} s^{-1} $Torr^{-1}$, which, expressed in the same units as the etch rate, equals 6000 μm min^{-1} $Torr^{-1}$. However, the experimental pre-exponential factor is $10^{10.4}$, i.e., 2.5×10^{10} μm min^{-1}, which is more than 6 orders of magnitude larger than the collision frequency. Such "large" pre-exponential factors have also been observed in silicon etching by Br_2 and Cl_2 (3, 4). They have been rationalized by proposing the occurrence of a reversible physisorption step (with a zero or very small activation energy) prior to the dissociative chemisorption. The experimental rate constant (k_1) then represents a composite rate constant that can have a pre-exponential factor not directly related to the Cl_2 collision frequency. Such a reaction sequence is illustrated in eq. [9],

$$[9] \qquad Cl_{2(g)} \rightleftharpoons Cl_{2(ads)} \rightleftharpoons 2Cl_{(ads)}$$

Although the above mechanism can provide a rationalization of the observed half-order kinetics, alternative mechanisms have been considered (4). In these mechanisms, the Cl_2 molecule is thermally dissociated into gas phase Cl atoms either through collisions with other molecules in the gas phase or by collisions with the walls of the reaction vessel. Provided the gas phase atom concentration is in equilibrium with molecular chlorine, this mechanism is equally capable of explaining the change from first- to half-order kinetics. However, using thermodynamic data for this equilibrium at 100°C (9), the degree of dissociation of Cl_2 is found to be only 1.48×10^{-11}%. Under a Cl_2 partial pressure of 2.0 Torr, the number of Cl_2 molecules flowing past the sample is 4.69×10^{19} molecule s^{-1}, and so, if an equilibrium concentration of atoms is formed, there will be 1.39×10^7 Cl atom passing over the GaAs per second. Assuming that all the Cl atoms react with GaAs with zero activation energy, the predicated etch rate would be 9.41×10^{-9} μm min^{-1}. This is only 2.35×10^{-6}% of the observed etch rate (0.40 μm min^{-1}). The above analysis shows that the thermal dissociation of Cl_2 in the gas phase is insufficient to explain the observed kinetics, even if we disregard the need for the occurrence of a back reaction, and the unlikelihood that the dissociation can be made to occur rapidly enough in the short heated region immediately before the gas strikes the GaAs surface.

It is probably worth noting that, because of the limited pressure and temperature range of our current experiments, our results can be fitted equally well to the "surface site saturation mechanism" originally proposed for this reaction (1). The significance of our experiments lies in the fact that the original data in ref. 1 could not be fitted to the "dissociative absorption mechanism," and hence presented a conundrum because every other etching reaction by diatomic molecules that we have studied could be fitted to this mechanism. The experiments described in this paper simply indicate that the kinetic behavior of this system does indeed resemble that observed for other such etching reactions, and hence this reaction does not necessarily occur by another mechanism.

Conclusions

A reinvestigation of the reaction of Cl_2 with GaAs suggests that the nonlinear dependence of the etch rate on the Cl_2 pressure is probably not due to the occurrence of a plateau in the etch rate at high pressures, but is the result of a change in the order of the reaction from first order to half order as the pressure is increased. The first- and the half-order rate constants were determined and can be represented in the form of the following Arrhenius equations:

$$k_1 = 10^{10.4 \pm 2.3} \text{ μm min}^{-1} \text{ Torr}^{-1} \, e^{-(76 \pm 16 \text{ kJ mol}^{-1}/RT)}$$

$$k_{1/2} = 10^{13.6 \pm 2.6} \text{ μm min}^{-1} \text{ Torr}^{-1/2} \, e^{-(100 \pm 19 \text{ kJ mol}^{-1}/RT)}$$

This behavior can be explained by a reversible dissociative adsorption mechanism in which the gaseous molecules are first physisorbed on the semiconductor surface, then dissociate into chemisorbed atoms, and finally react with the surface to yield gaseous products.

COMMUNICATION

A new synthesis of lactones from tertiary alkenylcarbinols by cobalt-catalyzed photocarbonylation under ambient conditions

Yuan L. Chow, Yu-Jin Huang, and Veljko Dragojlovic

Abstract: In the presence of a Co catalyst, tertiary vinyl-, propenyl-, and allylcarbinols were chelatively cycloadded to carbon monoxide to produce lactones by xanthone-sensitized photoreaction in tetrahydrofuran, under CO at 1 atmosphere and at room temperature. At lower temperatures the isomerization of alkenylcarbinols was suppressed and lactones were obtained with improved selectivity. The photoprocess was facilitated by addition of pyridine or hydrogen and retarded in presence of amines or phosphines. Mechanistic interpretations for the process and the accompanying effects are discussed.

Key words: chelative carbonylation, photocarbonylation, carbonylation of olefins, lactones synthesis from alkenylalcohols.

Résumé : En solution dans le tétrahydrofurane, à la température ambiante, sous 1 atmosphère de CO en présence de catalyseurs de Co, les carbinols tertiaires contenant des chaînes vinyle, propényle et allyle donnent, par une photoréaction sensibilisée par la xanthone, une cycloaddition chélatante conduisant à des lactones. À des températures inférieures, l'isomérisation des alcénylcarbinols est supprimée et les lactones sont obtenues avec une sélectivité accrue. Le photoprocessus est facilité par l'addition de pyridine ou d'hydrogène et il est retardé en présence d'amines ou des phosphines. On discute du mécanisme de ces processus et des effets qui les accompagnent.

Mots clés : carbonylation chélatante, photocarbonylation, carbonylation des oléfines, synthèses de lactones à partir d'alcools alcéniques.

[Traduit par la rédaction]

The carbonylation of olefins catalyzed by transition metal carbonyls is a major homogeneous catalytic reaction of industrial importance and occurs typically either under high temperature (140–170°C) and pressure (100–200 atm; 1 atm = 101.3 kPa) or aided by redox cycles of a noble metal (Pt or Rh) under more moderate conditions (1). We have established that olefins incorporate CO and an alcohol in the presence of cobalt catalysts promoted by ketone sensitization at 1 atmosphere CO and room temperature (2). An application of this mild photocarbonylation to insert CO into the termini of alkenylcarbinols would be facilitated by preferential sizes of ring formation and by the ready availability of starting alkenylcarbinols. The alcohols **1**, **4**, and **7** (Scheme 1) were prepared from appropriate ketones and vinyl-, propenyl-, or allylmagnesium halides according to standard procedures.

A solution of **1** (2 mmol), bisacetylacetonylcobalt(II) [$Co(acac)_2$] (0.1 mmol), pyridine (ca. 0.4 mmol), and xanthone (0.2 mmol) in THF (20 mL) was irradiated in a Pyrex Hanovia-type irradiator equipped with a 450-W medium-pressure mercury lamp (PC 451.050) under slow purging of CO and H_2 (9:1) to give about 95% conversion in 10–15 h. At intervals, the photolysate was withdrawn for GC analysis. At the end of irradiation, water was added to the reaction mixture and products were extracted with ether and chromatographed to afford 76–80% of γ-lactones **2** and small amounts of the γ-lactols **3**. The latter were identified by GC–MS. The presence of either pyridine or hydrogen, but not necessarily both, increased the rate of conversion and the yields were comparable to those obtained with photocarbonylation without pyridine or hydrogen. Also, the presence of hydrogen in the purging gas increased the yield

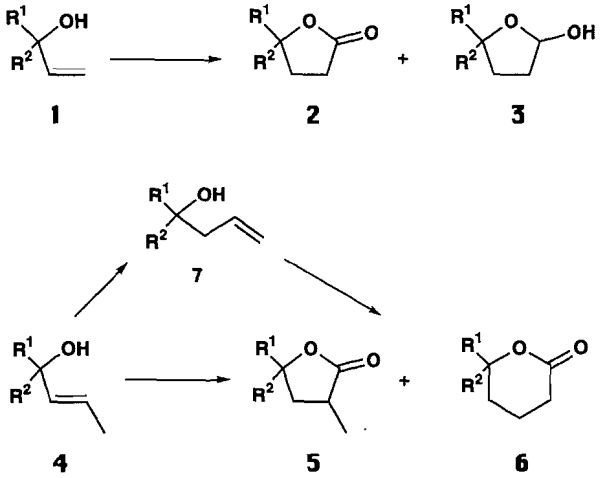
Scheme 1.



of lactols slightly. In contrast, attempted photocarbonylation of 2-propenol and 2-butenol gave a complex mixture arising from disproportionation and other reactions. 1-Phenyl-2-propenol gave propiophenone (74%) and a trace of the expected 4-phenylbutyrolactone (3%).

Photocarbonylation of geminal propenylcarbinols **4** gave not only γ-lactones **5** but also minor amounts of δ-lactones **6** (Table 1). The latter are produced from rearranged olefin **7** as evidenced by other experimental data (vide infra). The effect of temperature on the photocarbonylation of ***4a*** was significant, giving the ratio of lactones ***5a/6a*** as 2/1, 71/29, and 89/11 at 17, 11, and 0–2°C, respectively. The results indicate that the isomerization of **4** to the corresponding allylcarbinols **7** was suppressed at lower temperatures. The migration of a double bond during cobalt-catalyzed carbonylation is known (2, 3). Indeed, in separate experiments conducted under the same conditions, allylcarbinols **7** gave the mixture of lactones **5** and **6** in which the δ-lactones **6** predominated (Table 1). While the presence of pyridine increased the rate and the yields of photocarbonylation, *N,N,N′,N′*-tetramethyl-1,3-propyldiamine, 4,4′-dipyridine, 4-dimethylaminopyridine, or tributylphosphine retarded the rate and decreased the yield. Addition of phosphines also increased yields of the corresponding lactols **3**.[2]

Previous reports have established that the photosensitized reduction of cobalt salts with triplet-excited ketones under CO atmosphere in methanol or THF gives a 16-valence electron species $HCo(CO)_3$ or $Co(CO)_3^-$, which is most likely the species entering into the carbonylation sequence **8–11** (Scheme 2) (4, 5). This cobalt species was also proposed in thermal carbonylation processes, with supporting evidence (6, 7). A catalytic photochemical mechanism is proposed in Scheme 2 as the basis for the discussion, although the sensitization step may be also required in steps other than the excitation of $Co(CO)_4^-$.

Phosphines and amines retard the reaction rate through quenching triplet-excited ketones by electron transfer (8, 9), and 4,4′-bipyridine does the same, most likely by energy transfer mechanisms. These observations confirm that triplet sensitization is required to drive the catalytic cycle. The isomerization of propenylcarbinol **4** to the corresponding allylcarbinol **7** is a thermal process, which can be accounted for by reversible addition and nonspecific elimination of $HCo(CO)_3$ (2, 3). The process accounts for the isomerization of 2-propenol and 2-butenol to the corresponding aldehydes. While the reaction sensitized by triplet ketone is simple and facile, the use of substrates and ligands that interact with excited ketones could pose complications and further modifications may be necessary. However, the photoprocess offers

The 1994 Alcan Award Lecture Density functional theory as a practical tool in studies of organometallic energetics and kinetics. Beating the heavy metal blues with DFT[1]

Tom Ziegler

Abstract: An evaluation is given of approximate density functional theory as a practical tool in studies on organometallic energetics and kinetics. The evaluation covers electronic excitations and ionizations, electron capture, conformational changes, molecular vibrations, and bond energies, as well as reaction profiles.

Key words: density functional theory, energetics, kinetics, organometallic, catalysis.

Résumé : On présente une évaluation de la théorie de la densité fonctionnelle comme un outil pratique dans l'étude des énergétiques et des cinétiques des organométalliques. L'évaluation comprend les excitations et les ionisations électroniques, la capture électronique, les changements conformationnels, les vibrations moléculaires et les énergies de liaison ainsi que les profils réactionnels.

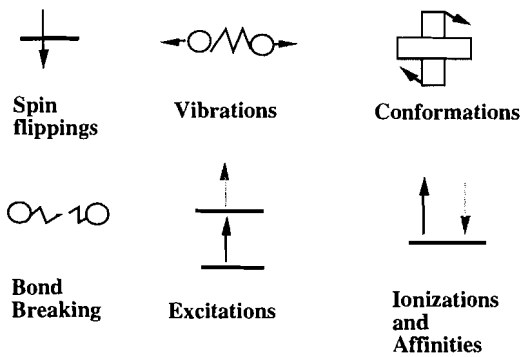
Mots clés : théorie de la densité fonctionnelle, énergétique, cinétique, organométallique, catalyse.

[Traduit par la rédaction]

1. Introduction

Molecular energetics covers a variety of properties, **1**, encompassing electronic excitations and ionizations, electron capture, conformational changes, molecular vibrations, and bond breakings, as well as the flipping of an electronic spin. Most of these properties are important at one time or another in studies involving organometallic thermochemistry and kinetics. It is thus necessary in theoretical studies on organometallic energetics to make use of computational methods that are able to treat all the properties in **1** accurately, or at least on an "equal footing."

Traditionally most theoretical studies have been carried out by *ab initio* Hartree–Fock (HF) methods or post-HF extensions in which electron correlation is included. We shall here discuss an alternative approach based on approximate Density Functional Theory (DFT) (1), which over the past decade has emerged as a tangible and versatile computational method. It has been employed successfully to obtain thermochemical data (2, 3) ; molecular structures (4, 5) ; force fields and frequencies (6); assignments of NMR (7), photoelectron (8), UV (9), and ESR (10) spectra; and transition state structures, as well as activation barriers (11); dipole moments (12); and other one-electron properties. Thus, approximate DFT is now applied to many problems previously covered exclusively by *ab initio* Hartree–Fock (HF) and post-HF methods. The recently acquired popularity of approximate DFT stems in large measure from its computational expedience, which makes it amenable even to large-size molecules. More important, perhaps, is the fact that expectation values derived from approximate DFT in most cases are better in line with experiment than results obtained from HF calculations and standard post-HF methods. This is, in particular, the case for systems involving transition metals. An analysis of why approximate DFT affords more reliable results than HF has recently been published by Cook and Karplus (13*a*) as well as Tschinke and Ziegler (13*b*). A recent analysis of DFT has been given by van Leeuwen (14).



1

We shall in the present account evaluate DFT as a practical tool in studies of organometallic energetics and kinetics.

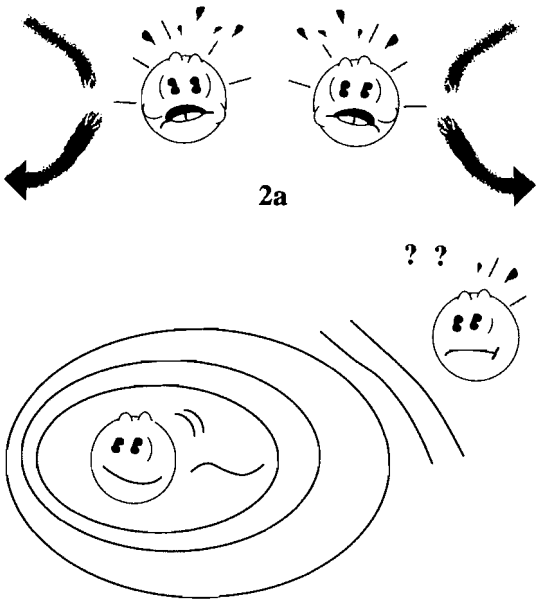
2. General theory and practical implementations

An electron will try to maximize the attraction from the nuclei and minimize the repulsion from the other electrons, **2a**, as it moves around in the molecular framework. This is done by creating an exclusion area or "no-fly zone" around each electron, **2b**, into which no other electron can penetrate. The exclusion zone is referred to as the exchange and correlation hole, and it is the way in which this hole is modeled that distinguishes one electronic theory from another (14, 15).



2a

2b

The first generation of DFT-based methods took their hole from the homogeneous electron gas. The Hartree–Fock–Slater method (HFS) (16) treats only exchange whereas the local density approximation (LDA) (17) takes into account both exchange and correlation. The HFS and LDA schemes are often referred to as the local methods. The second generation of DFT based theories acknowledges the fact that the density in molecules is far from homogeneous by introducing correction terms based on electron density gradients. These theories (LDA/NL) due to Langreth and Mehl (18*a*), Becke (18*b*), and Perdew (18*c*) are referred to as nonlocal. Nonlocal corrections are essential for a quantitative estimate of bond energies (18*e–k*) as well as metal–ligand bond distances (4*b*). They are also of importance for other properties (11*e*, 18*l*). Both LDA and LDA/NL suffer from the fact that they allow an electron to interact with itself to some degree. A number of authors have recently suggested ways in which the "self-interaction" error can be eliminated in a computationally efficient way (18*m*, *n*). These new methods form the vanguard for the third generation of DFT-based schemes.

A practical DFT-based calculation is in many ways similar to a traditional HF treatment in that the final outcome is a set of molecular orbitals. These functions are referred to as Kohn–Sham (KS) orbitals (1*a*) and are often expanded in terms of a basis set as in the traditional linear combination of atomic orbital (LCAO) approach of traditional methods.

In the earliest implementation of DFT applied to molecular problems, Johnson (19) used scattered-plane waves (20) as a basis, and the exchange–correlation energy was that of the LDA method. This SW-Xα method assumed in addition that the Coulomb potential is spherical around each atom, the muffin-tin approximation. This approximation is well suited for solids for which the SW-Xα method originally was developed. However, it is less appropriate in molecules where the potential around each atom might be far from spherical. The SW-Xα method is computationally expedient compared to standard ab initio techniques and has been used with considerable success (9) to elucidate the electronic structure in complexes and clusters of transition metals. However, the use of the muffin-tin approximation precludes accurate calculations of total energies. The method has for this reason not been successful (21) in studies involving molecular structures and bond energies.

The first implementations of self-consistent DFT, without recourse to the muffin-tin approximations, are due to Ellis and Painter (22) (DVM), Baerends et al. (23) (ADF),[3] Sambe and Felton (24), Dunlap et al. (25) (LCGT-LDA), as well as Gunnarson et al. (26) (LCMTO). Other implementations (27–30)[4] and refinements have also appeared more recently.

A unique approach in which the KS-orbitals are found directly without basis sets has lately been taken by Becke (31).[5] This approach, which seems promising, was first applied to diatomic molecules and more recently to polyatomics.

The use of plane waves as basis functions has received renewed interest in connection with the recent pioneering work by Car and Parrinello (CP) (32*a*). These authors were able to study molecular dynamics from first principles by evaluating the required forces "on the go" from DFT calculations. The method is best suited for plane-wave basis sets. Blöchl and co-workers (32*b*) eliminated some of the drawbacks of plane waves by introducing projector-augmented plane waves (CP-LAPW). The CP-LAPW method has great potential in studies of organometallic kinetics.

The various SCF schemes based on DFT are attractive alternatives to conventional *ab initio* methods in studies on large-size molecules since the computational effort increases as n^3 with the number of electrons, n, as opposed to between n^4 and n^7 for post-HF methods of similar accuracy. The scope of density-functional-based methods has further been enhanced to include pseudo-potentials (33) and relativistic effects (34), as well as energy gradients of use in geometry optimization (4, 35) and analytical second derivatives (32*d–g*) with respect to nuclear displacements. The existing program packages, ADF (23), DeMon, DMOL (35*f*),[4] DGAUSS (30*b*), GAUSSIAN/DFT (32*c*), and CADPAC (32*d*), are now nearly as user friendly as their *ab initio* counterparts although much work remains to be done.

3. A validation of approximate density functional theory

Our contribution to the development of practical DFT-based methods has focused on schemes that would enable a full

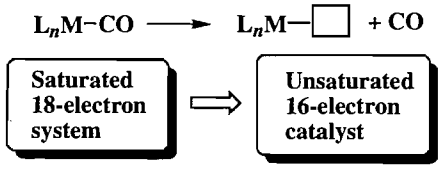
study of an elementary reaction step in organometallic chemistry and homogeneous catalysis. We have as a prerequisite explored how well approximate DFT evaluates the structure and energetics of organometallics, and developed algorithms that would make the calculation of these properties tractable. We shall in the following provide an account of the results obtained from these efforts.

Bond energy calculations

The generation of a coordinatively unsaturated 16-electron reactive species (catalyst) by dissociation of an 18-electron saturated (and unreactive) complex, **3**, is a recurring theme in homogeneous catalysis. Table 1 affords calculated values for such a process involving the first CO dissociation in a number of binary metal carbonyls.



3

It follows from Table 1 that the first generation of DFT methods based on LDA overestimate the M—CO bond energies considerably. The overbinding is typical for LDA (1*c*), and it appeared for a while as if approximate DFT would be of limited use in studies of organometallic thermochemistry.

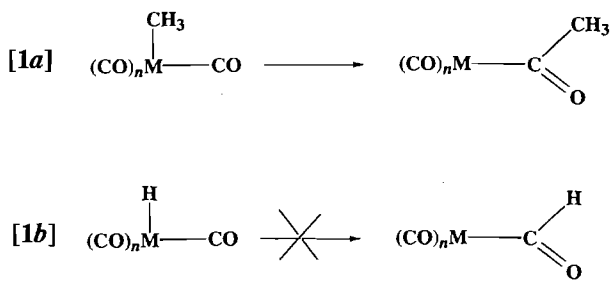
This situation was changed by the development of gradient-based corrections due to Becke (18*b*), Perdew (18*c*), and others. Thus, adding the nonlocal exchange (18*b*) and correlation (18*c*) corrections to the LDA energy expressions, LDA/NL, improves considerably the agreement between theory and experiment. In fact, the agreement is now so good that LDA/NL actually might be useful as a predictive tool, Table 1. This is important since reliable metal–ligand bond energies are difficult to obtain experimentally.

The results in Table 1 include relativistic effects for all three members of the chromium triad although these only are important for the heavier 5*d* congener tungsten. The importance of relativistic effects for the heavier 5*d* element is underlined by including the calculated nonrelativistic W—CO bond energy in parentheses. It follows from the comparison between the two sets of W—CO bond energies that relativity strengthens the W—CO bond to the point where it is stronger than the Mo—CO linkage. Thus relativity is responsible for the V-shaped trend in the M—CO bond energies within the chromium triad with a minimum at the 4*d* element molybdenium. We have found a similar V-shaped trend in the series $M(CO)_5$ (M = Fe, Ru, Os) (18*j*); $M(CO)_4$ (M = Ni, Pd, Pt) (18*j*); $M(PH_3)_2X$ (M = Ni, Pd, Pt; X = O_2, C_2H_2, C_2H_4) (36*a*); $M(PH_3)_4X^+$ (M = Co, Rh, Ir; X = O_2, C_2H_2, C_2H_4) (36*b*); $M(PH_3)_4C_2H_4$ (M = Fe, Ru, Os (36*a*); and $M(CO)_5H_2$ (M = Cr, Ru, Os) (36*c*).

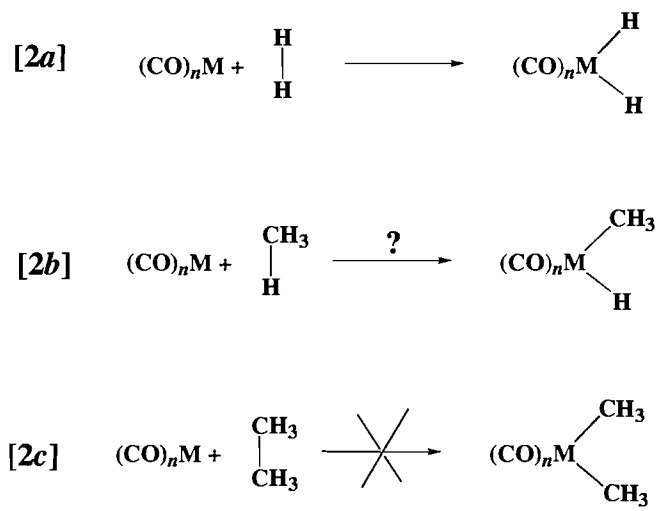
The relativistic stabilization of the M—X bond, where X is a π^* or σ^* acceptor, is a result of a relativistic destabilization of the metal 5*d* orbitals that increases the back-donation to the ligand X. The 5*d* levels are destabilized as relativity contracts the core orbitals and reduces the effective nuclear charge (36*d*,*e*). Our calculations confirmed and rationalized the experimental observation according to which the dissociation of a π-acceptor ligand often is most facile within a homologous series for the 4*d* member of a triad.

The most important steps in a catalytic cycle, after the coordinatively unsaturated 16-electronic species, **3**, has been generated, involve the formation and dissociation of metal–carbon or metal–hydrogen σ-bonds. The relative strength of these bonds is further delicately balanced and this balance has important implications for the type of elementary reaction steps that are possible in homogeneous catalysis.

Thus, CO will readily insert into a M—CH_3 bond, eq. [1*a*], whereas the corresponding insertion into a M—H linkage basically is unknown, eq. [1*b*].



Also, the H_2 molecule is known to add oxidatively to several metal fragments, eq. [2*a*], whereas the corresponding oxidative addition of the H–alkyl bond, eq. [2*b*], is more difficult and the alkyl–alkyl bond addition is virtually unknown, eq. [2*c*].



Oxidative addition and CO insertion are typical for late to middle transition metals and the trends in eqs. [1 and 2] have

[b]Reference 40.

been explained by assuming that the M—H bond is stronger than the M–alkyl bond for these metals.

It is clear that the approximate DFT methods must be able to account for the important differences between M—H and M—CH_3 bond energies in order to be of use in studies of organometallic energetics. Table 2 compares calculated M—R (R = CH_3, H) bond energies with the experimental data available for late to middle transition metals. It follows from Table 2 that LDA/NL is able to reproduce the experimental $(CO)_3Mn—H$, $(CO)_5Mn—CH_3$, and $(CO)_4Co—H$ bond energies well and to predict the Mn—H bond to be stronger than the Mn—CH_3 linkage. Unfortunately, reliable experimental (37–39) bond energies for both M—H and M–alkyl with respect to the same metal are only available for a few systems, which makes a more extensive comparison between experiment and theory (40) impossible.

However, we present in Fig. 1 a systematic theoretical study of M—R (R = H, CH_3) bond energies for late, middle, and early transition metals as well as *f*-block elements. The figure provides in addition the trends in the M—R bond energies within a triad of metals. The study presented in Fig. 1 is based on an older and less accurate second-generation functional (18*e*,*f*, 41*b*) than that used to generate the data in Table 1 (40). Thus, the Mn—R and Co—R bond energies differ slightly from those in Fig. 1. However, the trends should be accurate.

It follows from Fig. 1 that the M—R bond increases in strength as we descend a triad of transition metals. Further, for the late to middle transition metals the M—H bond is stronger than the M—CH_3 linkage. On the other hand, for early transition metals and *f*-block elements the two bonds are quite similar in strength. The trend can be rationalized by observing that the occupied C—H bond orbitals suffer a destabilizing interaction with occupied *d*-orbitals for the electron-rich late to middle transition metals. A similar repulsive interaction is not present in the metal hydrides. On the other hand, for the early transition metals and *f*-block elements the destabilization of the M—CH_3 bond disapears since the *d*-orbitals on the metal center are empty. Thus, the M—H and M—CH_3 bonds become similar in energy.

It seems at the present time that the LDA method augmented with nonlocal exchange and correlation corrections (LDA/NL) represents the most efficient and accurate method for the evaluation of bond energies within the density functional framework. Calculations on metal carbonyls (18*i*,*j*), binuclear metal complexes (40, 41*g*), and alkyl and hydride complexes (18*e*,*h*), as well as complexes containing M—L bonds for a number of different ligands (18*h*), have shown that LDA/NL affords metal–ligand and metal–metal bond energies of nearly chemical accuracy (±5 kcal mol^{-1}).

Molecular structures

The full optimization of molecular structures has been carried out routinely by *ab initio* methods since the algorithm of analytical energy gradients was developed in the early 1970s. *Ab initio* methods at the Hartree–Fock level usually yield satisfactory equilibrium structures for main group molecules (42). More accurate electron-correlation calculations can also be carried out to improve the agreement between theory and experiment as long as the size of the molecule under investigation remains reasonably small. The size of systems that can be handled by such calculations has been constantly increasing for the past two decades due to the fast development of computer technology and improved software.

The reasonable performance of the Hartree–Fock method on main group molecules seems not to be transferable to transition-metal complexes (43). Thus, a discrepancy of 0.1 Å between HF results and experimental findings is not uncommon for metal–ligand and metal–metal bonds. Faegri et al. (44*a*) have pointed out that such discrepancies most likely are due to the inherent shortcomings of the HF method rather than basis set limitations. Thus post-HF methods are essentially necessary in the study of transition metal compounds. It is, however, unlikely that *ab initio* methods beyond the Hartree–Fock level can be applied routinely to larger systems involving transition-metal complexes in the foreseeable future.

Density functional theory (DFT) has been widely applied to the investigations of systems involving transition metal complexes, and it has proven to be a very successful alternative to the computationally more demanding post-HF *ab initio* methods (1). Geometry optimizations by LDA and LDA/NL are now feasible due to the successful implementation of analytical energy gradients (4, 5, 35). The agreement between experimental geometries and structures optimized by DFT is, in general, good (4, 5, 35). For main group molecules, LDA/NL overestimates bond distances by 0.01 Å (35*g*) and angles deviate by 1°. The third-generation functionals by Becke (18*m*) reduce the error in bond distances to 0.005 Å (35*g*).

The superiority of DFT-based methods over the HF scheme is most striking in the prediction of metal–ligand bond lengths, as shown in Table 3. The M—L bond distances optimized by the LDA method are 0.02–0.05 Å shorter than the experimental values for the molecules listed in Table 3. On the other hand, *ab initio* calculations at the HF level yield bond distances that are too long by 0.05–0.2 Å. The only exception is the HF calculation on C_5H_5NiNO, where the the Ni—N bond distance was found to be too short by 0.2 Å, most likely due to the minimal STO-3G basis sets employed in the calculations. It is important to note that the HF method in the case of $Fe(CO)_5$ provides a distorted geometry for $Fe(CO)_5$ with the Fe—C_{ax} bond much longer than the Fe—C_{eq} distance, whereas experiment and LDA find the two Fe—CO distances to be about equal, Table 3.

The LDA method systematically underestimates (4*b*, 45) metal–ligand bond distances, and the same trend (4*b*) is found in connection with calculations based on other first-generation DFT schemes. Fortunately, the deficiencies of the local methods are seen largely to be eliminated by the nonlocal correction to exchange and correlation. Thus, the LDA/NL metal–ligand bond distances (4*b*) in Table 3 are within 0.01 Å of experiment. It is gratifying that the LDA/NL method not only

affords better bond energies, Table 1, but also more accurate geometrical parameters.

Table 4 displays M—CO and C—O distances for the three hexacarbonyls $M(CO)_6$ (M = Cr, Mo, W) determined by various computational methods as well as by X-ray diffraction. We note that LDA/NL improves the LDA M—CO estimates for M = Cr and Mo whereas the W—CO distance calculated by LDA/NL is too long. However, a much better agreement with experiment is obtained for the W—CO distance by including relativistic effects in the LDA/NL+QR scheme, Table 4. Thus, relativity is essential for an accurate estimate of geometries since it might result in metal–ligand bond contractions of 0.10 Å (18*i*–*k*).

Also included are estimates of the M—CO bond distances calculated by the simplest post-HF method, MP2 (44*b*), with

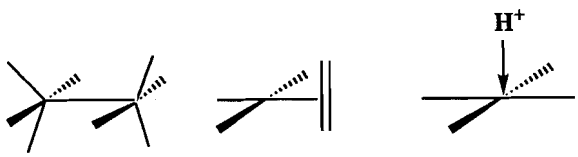
relativistic effects included. We note that the MP2 results are in line with experiment for the 4*d* and 5*d* elements whereas the Cr—CO distance is too short. For 3*d* elements, high-level and rather expensive methods such as the coupled cluster scheme CCSD(T) are required in order to obtain good geometries (44*d*). It should be noted that the CCSD(T) scheme also provides accurate estimates of the M—CO dissociation energies (44*d*).

Energy differences of isomers and conformers.

There have been a number of DFT-based studies on the relative stability of isomers and conformers. These include the relative energies of eclipsed and staggered conformations in $Fe(C_5H_5)_2$ and C_2H_6 (45), as well as a number of binuclear metal complexes (41*g*, 46, 47). Conformational energy differences seem (45) to be well represented even by the first generation of DFT methods such as LDA and HFS. The energetics for different coordination modes of ligands complexed to transition metals have been studied for phosphaalkene (48*a*), F_2 and H_2 (48*b*), alkenes and alkynes (48*c*,d), BH_4^- (48*e*), O_2 (48*d*), X_2, CX_2 (X = O, S, Se, Te) (48*f*,*g*), carbocycles (48*i*), thio- and selenoethers (48*j*,*k*), and carbenes (48*l*–*n*), as well as H (48*h*). A special energy decomposition scheme, the extended transition state method (ETS), has been devised (30,41*d*,48*c*,49) that breaks down the coordination energy of a ligand into steric and electronic factors. The ETS scheme makes it possible to explain interaction energies as well as conformational preference of a ligand in terms of well-established chemical concepts. As examples, the decomposition analysis is able to provide estimates of the respective contributions from the σ π and δ components in binuclear metal complexes (41*g*, 47, 48*j*) with multiple bonds, **4a**; the relative importance of donation and back-donation in transition metal complexes of unsaturated ligands (48, 49) such as olefins, **4b**, or carbonyls; the contributions (48*h*) to the protonation energy, **4c**, from the pure electrostatic interaction between the proton and the metal fragment, as well as the charge rearrangement following the formation of the protonated complex.



4a **4b** **4c**

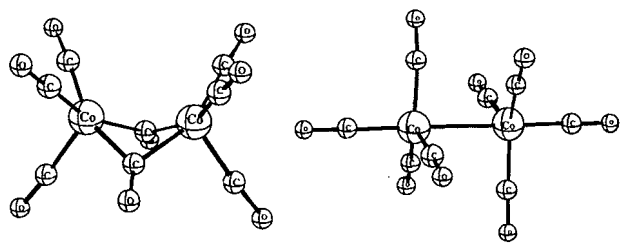
An illustrative example of how ETS is used is given in Table 5 where the first carbonyl dissociation energy (FCDE) of $W(CO)_6$ is decomposed as

[3] $FCDE = E_{steric} + E_{donation} + E_{back\text{-}donation} + E_{prep}$

for both the nonrelativistic (LDA/NL) and relativistic (LDA/NL+QR) case. In eq. [3] E_{steric} represents the steric interaction energy (destabilizing) between CO and $W(CO)_5$ whereas $E_{donation}$ represents the stabilizing CO to $W(CO)_5$ charge donation and $E_{back\text{-}donation}$ the corresponding stabilizing $W(CO)_5$ to CO back-donation. Finally, E_{prep} represents the energy required to distort CO and $W(CO)_5$ to the geometries they have in the combined $W(CO)_6$ complex. The ETS analysis in Table 5 clearly indicates that relativity enhances the back-donation contribution, $E_{back\text{-}donation}$, and decreases the donation energy term, $E_{donation}$. The reason for this was explained previously in the section on bond energy calculations. Further, back-donation is seen to be more important than donation for the W—CO bond strength.

The HF method represents conformational energies of saturated systems, such as rotation barriers in alkanes, quite well. It is not likely that LDA or LDA/NL will afford substantially different results for this type of systems. However, examples are known among transition-metal complexes for which HF- and DFT-based methods differ. Thus, HF (50*a*) finds $HCo(CO)_4$ of C_{2v} symmetry, with hydrogen in an equatorial position, to be more stable than the experimentally observed C_{3v} structure where hydrogen is in the axial position. On the other hand, LDA (50*b*) finds the C_{3v} structure to be the more stable conformation.

A very recent (40) conformational study based on DFT involves $Co_2(CO)_8$ with the two structures **5a** and **5b**. The study finds **5a** with bridging carbonyls to be 22 kJ/mol more stable than **5b** with an unsupported cobalt-cobalt bond. Conformation **5a** is found to be the more stable in the gas phase and the solid state whereas **5b** is prevalent in solution.



5a **5b**

Electronic excitation energies and excited states

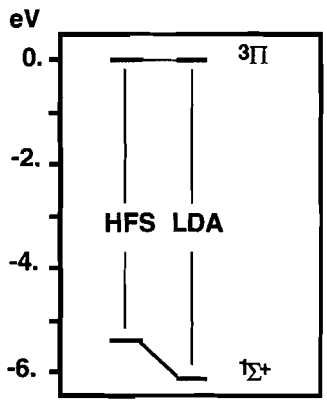
We shall in the following sections discuss calculations on energy differences associated with the processes of (*a*) excitation from one electronic state to another; (*b*) ionization; (*c*) electron attachment. The change in energy ΔE associated with these processes can be written as

Table 6. Excitation energies (eV).

	HFS	LDA	LDA/NL	Expt.
CO ($5\sigma \rightarrow 2\pi$)	5.37	6.12	6.18	6.3
CS ($5\sigma \rightarrow 2\pi$)	2.87	3.42	3.48	3.42
O_2 ($^3\Sigma g \rightarrow {}^1\Delta g$)	1.34	1.04	0.82	0.98

Reference to original data given in ref. 51.

Fig. 2. Comparative estimates of the first excitation energy of the CO molecule from HFS and LDA calculations. The energy of the triplet states is the reference level for the HFS and LDA energies.



$$[4] \quad \Delta E = \Delta E_k + \Delta E_{ne} + \Delta E_{ee} + \Delta E_x + \Delta E_c$$

The first three terms in eq. [4] represent the change in kinetic, electron–nuclear attraction, and electron–electron repulsion energies, respectively, whereas the last two terms represent the change in exchange and correlation energies, respectively.

In our assessment of the HFS, LDA, and LDA/NL methods, we shall consider as our first case the energy ΔE required to promote CO or CS from the $^1\Sigma$ ground state to the first excited triplet state $^3\Pi$. The HFS method differs from LDA in that ΔE_c in eq. [4] is neglected ($\Delta E_c = 0$). The contribution from ΔE_c to ΔE should, however, be positive, as $^1\Sigma$ has one additional pair of electrons with opposite spins compared to $^3\Pi$, and thus[6] $E(^1\Sigma)$ has a larger negative contribution from E_c than $E(^3\Pi)$. Thus, we expect that ΔE from a HFS calculation (51) should be smaller than ΔE calculated by the LDA method, as indicated in Fig. 2. This expectation is borne out by our numerical calculations, Table 6. In fact, for CO and CS the excitation energies calculated by the HFS method are too small compared to experiment, whereas the larger ΔE values due to the LDA method are more in line with experimental excitation energies, Table 6.

Also considered in Table 6 is the energy ΔE required to promote O_2 from its $^3\Sigma_g$ ground state to the first excited state $^1\Delta_g$. For this process, the term ΔE_c in the expression of eq. [4] should be negative, since $^1\Delta_g$, compared to $^3\Sigma_g$, has one additional pair of electrons with opposite spins. Neglecting the contribution to ΔE from ΔE_c, as is done in the HFS method, must now lead to too large an excitation energy, Table 6, whereas LDA in which correlation between electrons of different spins is taken into account provides a smaller value for ΔE (since ΔE_c is negative), more in line with the experimental excitation energy, Table 6. It is finally seen that nonlocal corrections give rise to a small improvement in the calculated excitation energies.

The local DFT scheme (16) has been used extensively to calculate excitation energies, and many of the applications have been reviewed (9). An indication of the high accuracy usually obtained by approximate DFT methods is given in Table 7. This table presents calculation (52*a*) on the three first excited states in tetrahedral d^0 oxo complexes MnO_4^-, CrO_4^{2-}, and VO_4^{3-}. A special method has been developed by Ziegler et al. (52*b*) to resolve multiplets in electronic configurations by DFT.

In particular, the electronic spectrum of MnO_4^- has served as an acid test for new theoretical methods, and post-HF schemes failed for a long time to calculate the excitation energies of MnO_4^- with near quantitative accuracy. It is only recently, nearly 20 years after the DFT results, that post-HF methods have become available (53*b*,*c*) that can deal accurately with the excited states of transition-metal complexes such as MnO_4^-. Buijse and Baerends (54) recently analyzed the error sources in HF calculations on MnO_4^-. A more recent DFT study looked at the electronic spectrum of iron(III) porphines (53*a*).

It has often been stated that DFT applies only to ground state properties. This is not the case, either from a formal (53*d*) or a practical (52*b*) point of view. In fact, the first chemical applications (19) of DFT all dealt with excitation energies of metal complexes. DFT can be used to evaluate molecular properties of excited states in much the same way it treats ground state properties. As an example involving geometries, we display in Fig. 3 the harmonic potential energy surface along the totally symmetric Mn—O stretch in the case of the three first excited states corresponding to the $t_1 \rightarrow 2e$, Fig. 3*a*, $4t_2 \rightarrow 2e$, Fig. 3*b*, and $t_1 \rightarrow 5t_2$, Fig. 3c, transitions. All transitions are from nonbonding oxygen lone pairs (t_1 and $4t_2$) to antibonding metal *d*-orbitals ($2e$ and $5t_2$). We note a substantial elongation of the Mn—O bond from the ground state equilibrium distance, indicated by an arrow, at R(Mn—O) = 1.632 Å. It should be possible to use DFT to calculate excited state properties in much the same way as expectation values for the ground state, and studies on this subject are likely to appear in the near future.

Ionization potentials

Photoelectron spectroscopy (PES) emerged in the early 70s as a new and exciting technique with direct bearing on molecular orbital energies. It is thus not surprising that PES has served as a testing ground for new and increasingly sophisticated theoretical methods including DFT-based schemes. In fact, one of the first successful applications of the HFS method in chemistry involved the assignment of photoelectron spectra. The early work based on the SW-Xα method has been reviewed by Case (9).

We shall now consider the energy ΔE required to remove an electron from a molecule. In the corresponding expression of

[6] We base our rationalization of the trend in ΔE_c on the assumptions that the correlation energy in atoms and molecules is roughly proportional to the number of opposite-spin electron pairs.

eq. [4], the contribution from ΔE_c to ΔE will be positive for the molecules considered here, since the neutral molecule has one additional pair of electrons with opposite spins compared to the ion. As indicated in Fig. 4, we must thus expect HFS ($\Delta E_c = 0$) to provide smaller ionization energies than LDA ($\Delta E_c > 0$).

It follows from Table 8, where we compare the first two ionization energies for a number of molecules calculated by the two methods with experimental values, that HFS provides too small ionization energies, whereas the larger LDA values are more in line with experiment. However, as shown in Table 8,

the correlation correction to the HFS method, while of the right sign, is not large enough to align LDA ionization energies with experiment, leaving some room — and need — for further improvement of the HFS method. This improvement is accomplished by the LDA/NL scheme. The non local corrections are seen to supply a small but significant improvement for all the molecules. A more detailed analysis of how

nonlocal corrections improve on the calculated ionization potentials is given elsewhere (51).

There have been several recent applications of approximate DFT to photoelectron spectroscopy, including some in which relativistic effects have been taken into account (46, 47, 48*g*). In Table 9 we present HFS calculations on the first two ionization potentials for a number of organometallics. The agreement with experiment is in general quite good. An extensive investigation combining the calculation of bond distances and PE spectra involves the binuclear complexes $M_2(O_2CR)_4$ and $M_2Cl_4(PR_3)_4$ (M = Cr, Mo, W) with a quadruple metal–metal bond (47*b*). Their PE spectra, see Fig. 5, reveal three bands (*A*, *B*, *C*) corresponding to an ionization out of the δ, π, and σ, metal–metal bonding orbitals with the *B* band being considerably broader than either *A* or *C*. The assignment of *A*, *B*, and *C* has been controversial. Approximate DFT calculations (47*b*) assign *A*, *B*, and *C* to δ, π, and σ, respectively. The potential energy surfaces in Fig. 5 were, in addition, able to explain the broad feature of *B* in terms of a large change in the the R_{MM} equilibrium distance for the π ion state.

It is to be expected that the more accurate LDA/NL scheme will replace the HFS method in calculation of ionization potentials. It would be interesting to carry out a systematic evaluation of how well LDA/NL is able to calculate ionization potential and PES spectra for transition-metal complexes. However, such a study has not yet been carried out.

Electron affinities

The adiabatic electron affinity (EA_{ad}) of a molecule represents the decrease in energy of the molecular system when a single electron is added. It is, in general, a difficult property to obtain from experimental as well as computational techniques. The most accurate experimental estimates of electron affinities are obtained by laser photo-ionization of negatively charged systems. However, this technique is limited to anions that can be studied in the gas phase. It is still not routine to measure electron affinities accurately, and values obtained by alternative techniques often differ considerably even for relatively simple molecules.

Electron affinities also offer a considerable challenge from the computational point of view. In the first place, one must be able to describe accurately the difference in geometry between the neutral molecule M and the corresponding anion M^-. The computational method must in addition be able to account quantitatively for the difference in electron correlation energy between M and M^-. This difference is in most cases substantial due to the change in the number of electron pairs. Finally, the basis set employed must be flexible enough to describe M as well as M^- with a somewhat more diffuse charge distribution. It is thus not surprising that accurate electron affinities are available only for a very limited number of molecules.

We compare in Table 10 calculated EA_{ad} values with experiment for a number of small well-studied molecules. The comparison includes (55) HFS and LDA, as well as LDA with nonlocal exchange corrections (LDA/NL). Also included are results (56) based on HF, configuration interaction with all single and doubles (RCISD), as well as the equation of motion approach (EOM) (57). Several experimental EA_{ad} values have been published for each of the molecules in Table 10, covering quite a range. The experimental data selected represent what currently are considered to represent the best estimates. Flexible basis sets are crucial in theoretical evaluations of EA_{ad} and all calculations were carried out with extensive basis sets.

It follows from Table 10 that HF and HFS, in which correlation between electrons of different spins is absent, underestimate EA_{ad}. This is understandable as the lack of correlation is more crucial (destabilizing) for the negative ions A^- than for the neutral species. This is because A^- has one more pair of electrons than A. Thus the exclusion of correlation will underestimate the energy gap between A and A^-. The explicit inclusion of electron correlation greatly improves the theoretical

results both in the case of the *ab initio* methods (CISD, EOM) and in the case of the DFT-based LDA scheme. The addition of nonlocal exchange correction to LDA (LDA/NL) is seen to bring the theoretical results further in line with experiment. It seems clear that approximate DFT calculations on EA_{ad} require the inclusion of both electron correlation and nonlocal correction. However, at that level of approximate DFT the calculated results are comparable in quality to *ab initio* values based on extensive configuration interaction (CISD and EOM). Approximate DFT has also been used to calculate atomic electron affinities.

Molecular force fields

The construction of molecular harmonic force fields from experimental data (based on infrared and Raman spectroscopy) has benefited considerably over the past decade from new developments in computational chemistry. Thus, Pulay (58*a*) with his force method, in which force fields and vibrational frequencies are evaluated from a numerical differentiation of analytical energy gradient calculated by *ab initio* methods, has been able to study a number of small molecules. The studies by Pulay have more recently been augmented by investigations in which the second derivatives of the total energy with respect to nuclear displacements were calculated analytically (42).

Calculations of frequencies and force fields on the Hartree–Fock level of theory are now carried out almost routinely (42) although the basis sets employed in calculations on larger size molecules are often somewhat restricted to cut down on the computational cost. The HF frequencies differ considerably from experimental estimates and it is general practice to scale the calculated force constants in order to obtain good agreement with experiment (58*b*). Alternatively, one might improve the fit with experiment by resorting to post-HF calculations. However, frequencies and force-field calculations in which correlated *ab initio* methods have been employed are still restricted to small-size molecules and the evaluation of first, and in particular, second derivatives of the energy by such methods is rather demanding.

The recent implementation of energy derivatives (4, 5, 35) within the DFT framework makes it now manageable (6, 59) to evaluate frequencies from a numerical differentiation of the energy gradients in the spirit of Pulay's force method or directly from analytical second derivatives of the energy with respect to nuclear displacements (32*c–g*). Frequencies have also been calculated by Margl et al. (32*b*) from dynamic Car–Parrinello (32*a*) calculations. It is the general conclusion (6, 32*e,f*, 58*c,f*, 59) that frequencies calculated by LDA/NL and third-generation functionals (18*m*, 59) are of the same quality as post-HF second-order Møller–Plesset results (MP2) for main group molecules.

For transition-metal complexes, DFT seems at the moment to be the only practical scheme by which one can obtain accurate force fields (6*b,d*, 58*e*, 60). Table 11 displays the harmonic frequencies for $Ni(CO)_4$ calculated by several methods and compared to experimental estimates. The HF frequencies (58*d*) evaluated at the experimental geometry for $Ni(CO)_4$ are as usual overestimated, and scaling factors (58*b*) would have

[d]Reference 60.

to be applied in order to reproduce experiment. The LDA and LDA/NL schemes afford a much better fit to experiment, especially in the case of the C—O stretching frequencies, although deviations as large as 60 cm^{-1} still remain.

The remaining deviations could be due to differences between optimized and observed geometries or the inability of LDA and LDA/NL to evaluate force constants accurately. This point has been examined (58*e*) by calculating the LDA frequencies at the experimental geometry with the appropriate correction terms due to non-zero forces (58*g*) included. The results are shown under the heading LDA*. It follows from Table 11 that the LDA* frequencies are in excellent agreement with experiment. Thus, more accurate force-field calculations by DFT methods will depend on the development of functionals that can reproduce geometrical parameters with even higher accuracy than LDA/NL.

A promising related application of DFT is the evaluation of molecular mechanics (MM) force fields for transition-metal complexes. MM force fields are usually developed from experimental data. However, the available empirical imput is too limited in the area of organometallic chemistry for the construction of accurate force fields. Thus, the only alternative seems to be a generation of force constants from quantum mechanical calculations based on DFT.

Table 12 affords a few key force constants from two recent LDA studies on benzene (Bz) (6*c*), the cyclopentadienyl (Cp) anion (6*b*), $Fe(Cp)_2$ (6*b*), LiCp (6*b*), $Cr(Bz)_2$ (60), and $Cr(Bz)(CO)_3$ (60). The table reveals how the force constants for the C—H and, in particular, C—C stretches are changed as Bz and Cp are coordinated to a metal center. Also shown are the variations in the skeletal force constants for the M–ring stretch and M–ring tilt. The calculated force constants are in good agreement with the few experimental estimates, and might form the basis for constructing a MM force field.

Reaction profiles for elementary organic reaction steps

One of the most fundamental tasks of theoretical chemistry is undoubtedly to provide a perspective on reaction mechanisms through a determination of transition state structures and reaction profiles. The application of DFT to reaction profiles involving main group elements was pioneered by Fan and Ziegler (11*a*,*e*), and a number of applications in the field of organic chemistry have since appeared (11*b*–*d*, 61). The experience to date is that LDA/NL affords much better estimates of activation energies than either HF or MP2 (11*b*–*d*). For transition states in which bond making is involved, LDA/NL and MP4 provide energy barriers of similar accuracy (11*b*–*d*), with the LDA/NL estimate being too low and the MP4 barrier too high. The deviations are typically in the range of 1–5 kcal/mol. An example is given in Fig. 6 where the cyclization of butadiene to cyclobutene has been considered by both *ab initio* and DFT techniques (61*c*). There are indications (61*d*) that the third generation of functionals (18*m*) improve the agreement with experiment compared to LDA/NL.

It should also be mentioned that DFT makes it possible to follow a reaction path by the so-called intrinsic reaction coordinate (IRC) method due to Fukui (61*e*). This scheme traces the reaction path by a steepest descend in terms of energy from the transition state towards the product(s) and reactant(s). Deng has pioneered the application of IRC within the DFT framework (11*b*–*d*, 61*c*).

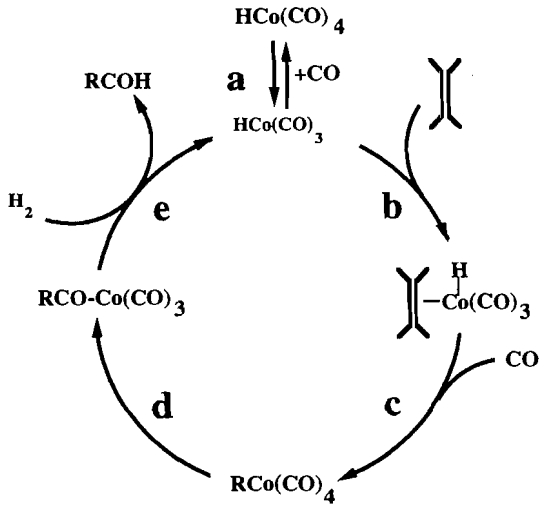
Scheme 1.

Hydroformylation Mechanism



Heck and Breslow, 1962

4. Applications of approximate density functional theory to elementary reaction steps in organometallic chemistry

We have in the previous sections documented that DFT-based methods are able to provide information on bond energies and molecular geometries of reasonable accuracy. We shall in the ensuing section provide a single illustration of how the same methods can be used to trace energy profiles for elementary reaction steps involving organometallic compounds. Reference will, in addition, be given to a number of recent DFT-based studies on organometallic kinetics.

Hydroformylation

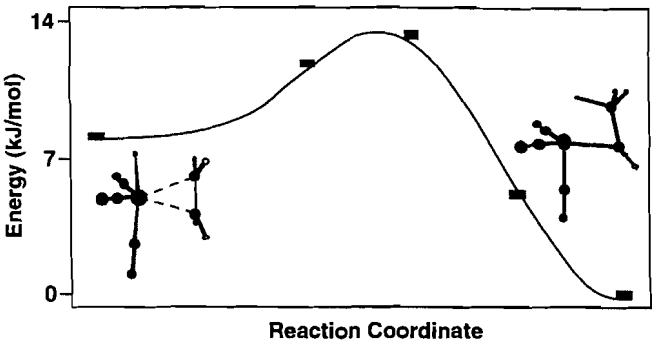
We shall use the hydroformylation process of Scheme 1 to illustrate how DFT is applied in studies of organometallic reaction steps. The hydroformylation process according to the mechanism by Heck and Breslow (62) was the first complete catalytic cycle investigated by a DFT-based method. We shall in the following give a more detailed account of the steps **a** (63*a*), **b** (63*b*), **c**–**d** (64), and **e** (65) of Scheme 1.

Insertion of ethylene into the cobalt–hydrogen bond

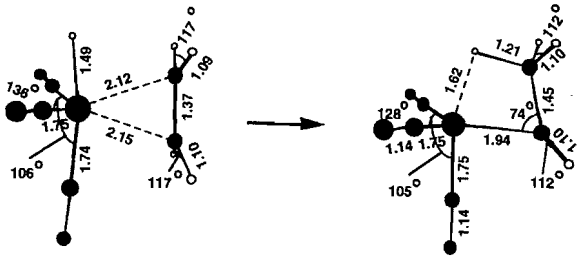
The first step in the catalytic hydroformylation process is the insertion of ethylene into the cobalt–hydrogen bond, **b** of Scheme 1. Experimental findings suggest that the migration of a hydride to a coordinated olefin group is very facile. In fact, the hydride–olefin insertion reaction has, with a few exceptions, rarely been directly observed. As a consequence, metal complexes containing both hydride and olefin are scarce and it has only in a few cases been possible to study the insertion process by experimental techniques.

We have studied (63*b*) the insertion process, **6a** → **6b**. The energy profile for the reaction is given in Fig. 7. We find the reaction to have a very small activation barrier, $\Delta E^{\neq}$, of only 6 kJ/mol and a modest reaction enthalpy of −8 kJ/mol. The

Fig. 7. Energy profile for the step **6a** → **6b**. The energy zero point refers to structure **6b.**



product of the reaction is an ethyl complex, **6b**, with a pronounced agostic interaction between the metal center and hydrogen. The ethyl complex, **6b**, has a short metal–hydrogen distance of 1.62 Å. This distance is only 0.12 Å longer than the Co—H bond distance in the parent complex **6a**. The bond length of the agostic hydrogen with the corresponding carbon atom of the ethyl ligand is, on the other hand, substantially elongated with R(H—C) = 1.21 Å, in comparison to a normal ethyl C—H bond length of 1.11 Å. The C—C bond distance in the ethyl group is 1.45 Å, which is somewhat longer than the corresponding value in the parent structure **6a** (1.37 Å), but it is still substantially shorter than the C—C bond length of an undistorted ethyl group (1.53 Å). Also the bond angle Co-C_{et}-C_{et} is, with 74°, considerably smaller than the expected value of about 109° for a normal ethyl ligand. The optimized molecular parameters of structure **6b** clearly indicate that the π-bond character of the initial ethylene ligand has been retained to a large extent. This is also underlined by the small calculated energy difference of 8 kJ/mol between the parent structure **6a** and complex **6b**. The modest activation barrier found in this study stems from the fact that the hydrogen atom is close to cobalt throughout the migration reaction.



6a **6b**

Migratory insertion of alkyl into the Co—CO bond

The next important elementary reaction step in the hydroformylation cycle, **d** of Scheme 1, is the migratory insertion of an alkyl group into the metal–carbonyl bond.

[5] $RCo(CO)_4 \rightarrow RC(O)Co(CO)_3$

We have modeled this step with R = CH_3. The process in eq. [5] could in principle proceed by an insertion of a CO into the Co—CH_3 bond of **7a**, producing the coordinatively unsaturated complex, **7b**, with the acyl group in an axial position. Alternatively, the methyl group might migrate to a *cis*-carbo-

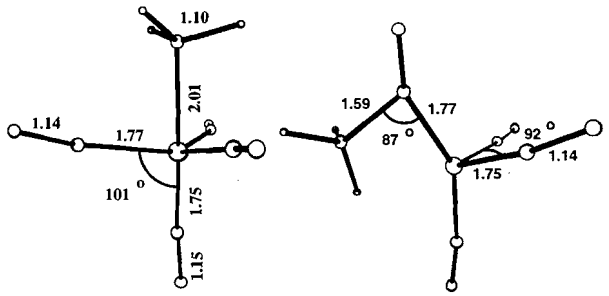
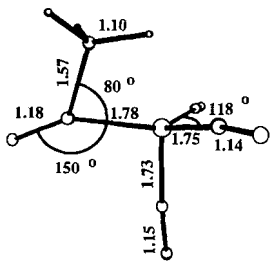
For personal use only.



7a **7b**



7c

nyl, thus affording the complex **7c** with the acyl group in an equatorial position.

We find (64), perhaps not surprisingly, that the energy profile for the CO insertion, **7a** → **7b**, into the Co—CH_3 bond has a prohibitively high activation barrier of 200 kJ/mol, Fig. 8. The CO insertion can, as a consequence, not be a viable mechanism for the process in eq. [5]. The migration of CH_3 to the *cis*-CO ligand, **7a** → **7c**, was on the other hand calculated (64) to have an endothermicity, ΔH, of 71 kJ/mol and a very modest activation barrier, $\Delta E^{\neq}$, of only 9 kJ/mol for the reverse reaction **7c** → **7a**, Fig. 9. Thus the CH_3 migration, **7a** → **7c**, seems to be favored as the mechanism for the process in eq. [5].

The calculated reaction enthalpy and activation barrier for **7a** → **7c** compare well with an earlier study (66) on the CH_3 to CO migration in $CH_3Mn(CO)_5$, where we found ΔH to be 75 kJ/mol and $\Delta E^{\neq}$ 11 kJ/mol. Our findings are also in agreement with a recent kinetic study by Roe (67), who found the rate constant of the methyl back-migration of $CH_3C(O)Co(CO)_3$ to be considerably larger than the rate constant for the corresponding forward reaction. The structures in Fig. 9 illustrate nicely how the methyl group can slide almost parallel along the *cis* C—Co bond onto the *cis* carbonyl carbon, while the remaining $Co(CO)_3$ framework stays almost unchanged. The 10 kJ/mol calculated for $\Delta E^{\neq}$ in the present study is an upper bound to the actual value, and we can thus conclude that the methyl migration, **7a** → **7c**, should proceed with a rather modest activation barrier.

H_2-induced aldehyde elimination

The last step in the catalytic cycle of the hydroformylation process, **e** of Scheme 1, is the reaction of the acyl intermediate with H_2, which results in the formation of the desired aldehyde molecule and the regeneration of the catalyst $HCo(CO)_3$.

There are several possible routes by which the aldehyde product can be formed from the acyl intermediate. Heck and

Fig. 8. Reaction profile for the CO insertion process.

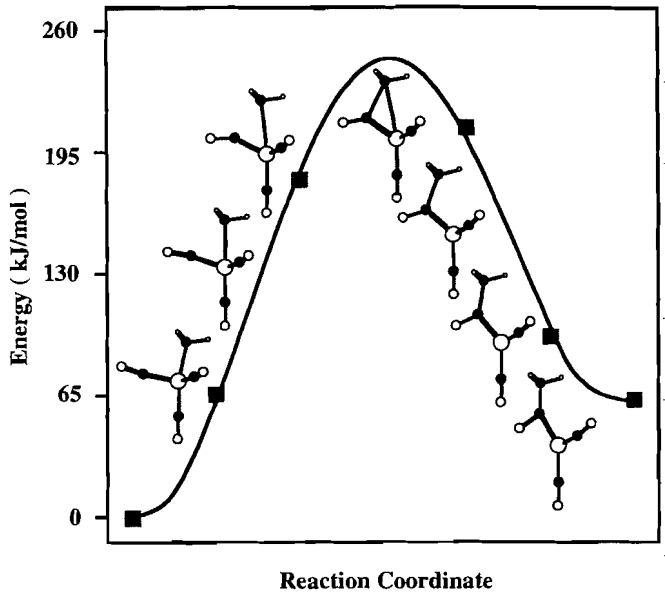


Fig. 9. Reaction profile for the methyl migration process.

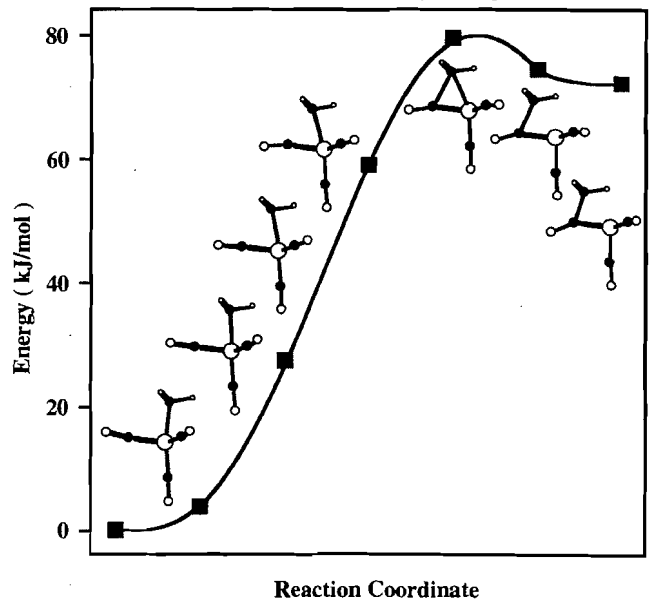


Breslow (62) proposed a mechanism in which the coordinatively unsaturated acyl complex undergoes first an oxidative addition of H_2, affording a dihydro acyl compound, eq. [6], followed by an irreversible reductive elimination of an aldehyde molecule, eq. [7].

[6] $R(O)CCo(CO)_3 + H_2 \rightarrow R(O)CCo(CO)_3(H)_2$

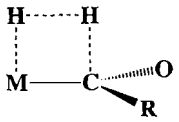
[7] $R(O)CCo(CO)_3(H)_2 \rightarrow RCHO + HCo(CO)_3$

This type of process has been inferred for numerous catalytic and stoichiometric systems; as a consequence these reactions have been studied extensively by experimental as well as theoretical techniques. However, in the case of the cobalt-based hydroformylation process it has not been established

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

that the product formation proceeds in fact via the oxidative addition – reductive elimination mechanism.

For electron-poor systems such as early-transition-metal complexes the hydrogenolysis of the M—C bond proceeds via a mechanism in which an incoming H_2 molecule initially forms an η^2 adduct with the metal complex, followed by the concerted cleavage of the hydrogen bond and the formation of an H—M and H—C bond by way of a four-center intermediary structure such as illustrated by **8**.



8

This reaction mode thus omits the oxidative addition – reductive elimination mechanism. Such a process could also be envisioned for the cobalt system studied here and has been speculated upon by earlier workers (68).

In this section we will concentrate our efforts on the study of those cobalt complexes that can result from an interaction of the acyl intermediates with an incoming H_2 molecule. Furthermore, attention will be given to the oxidative addition process of H_2 to the metal fragment as well as to the hydrogenolysis reaction through a four-center intermediary structure (vide ante).

The two most stable products from the interaction between an acyl complex and H_2 are the dihydrogen complexes **9a** and **9b** with H_2 in the equatorial position. Both represent energy minima on the energy surface and **9b** is about 19 kJ/mol above **9a** in energy.

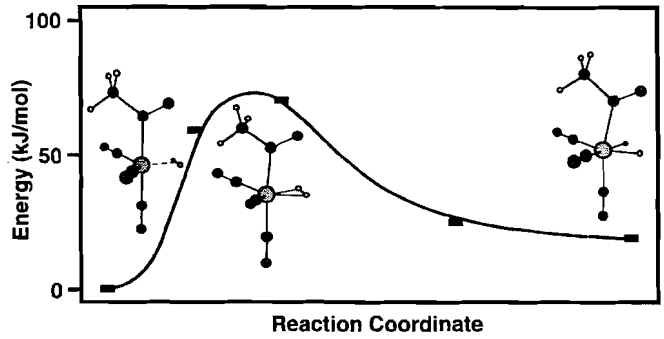
It is suggested in the mechanism by Heck and Breslow (62) that H_2 adds oxidatively to the unsaturated acyl complex to form a dihydride, **9c**. The dihydride complex of configuration **9c** was found to be 25 kJ/mol higher in energy than the η^2 adduct **9a**. Thus the H_2 complex is more stable than the product of the oxidative addition.

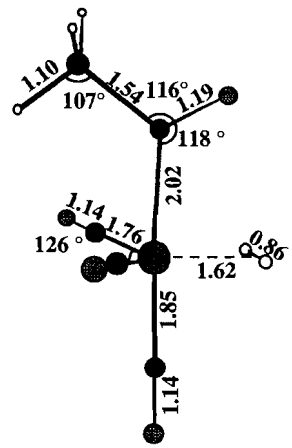
We display in Fig. 10 the energy profile for the oxidative addition reaction **9a** → **9c**. We find an activation energy ΔE^* of 77 kJ/mol. This value is markedly larger than the activation energies determined theoretically for the oxidative addition of H_2 to transition-metal complexes containing phosphine ligands. This can be attributed to the stabilization of the η^2–H_2 adduct by the π-acceptor CO ligands. The energy curve modeled in Fig. 10 ascends steeply during the early stages of the reaction, indicating that the activation energy arises largely from the initial elongation of the H—H bond distance.

The fact that the oxidative addition process, **9a** → **9c**, exhibits a sizable activation barrier led us to consider an alternative mechanism for the last product-forming step, **e** of Scheme 1, in the hydroformylation cycle. The alternative mechanism considers that one hydrogen atom of the η^2–H_2 complex shifts directly towards the acyl group, thereby forming an aldehyde molecule and regenerating the catalyst $HCo(CO)_3$. This type of reaction mechanism, in which a direct oxidative addition of H_2 is avoided, has, to our knowledge, never been investigated theoretically for the cobalt-based hydroformylation process.

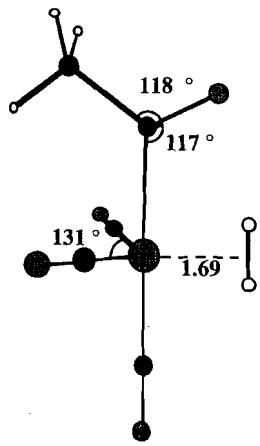
The approximate profile for the reaction **10a** →**10b** → **10c** is given in Fig. 11. The first part of the profile connecting **10a** and **10b** was obtained by changing the internal coordinates of

Fig. 10. Energy profile for the oxidative addition of H_2 according to eq. [6].

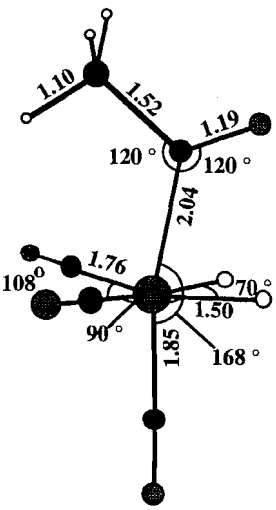




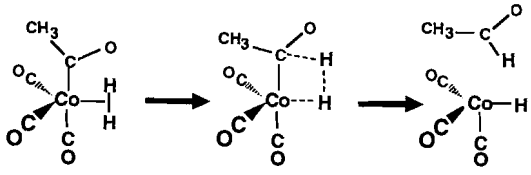
9a



9b

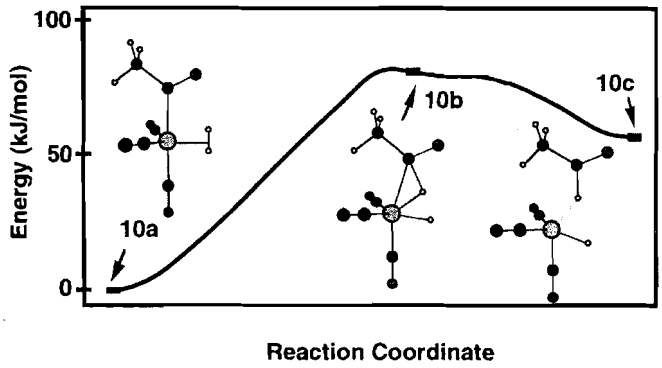


9c



10a **10b** **10c**

Fig. 11. Energy profile for the reaction **10a** → **10b** → **10c**.



10a into those of **10b** in a linear and stepwise fashion. A total of six steps was used in the transit. We find the reaction to proceed with a minimal activation barrier, Fig. 11. The activation energy for the first part, **10a** → **10b**, is therefore essentially equivalent to the reaction enthalpy ΔE for the reaction **10a** → **10b**, which was calculated to be 83 kJ/mol (vide ante). We also traced the energy surface for the reaction **10b** → **10c**. The step **10b** → **10c,** which as already mentioned is exothermic with a reaction enthalpy of $\Delta E = -26$ kJ/mol, is seen to have a negligible activation energy. Finally, the system **10c** is lowered in energy by 69 kJ/mol as the adduct **10c** breaks up into acetaldehyde and $HCo(CO)_3$ in its ground state conformation.

Dissociation of CO from $HCo(CO)_4$ to form the catalyst $HCo(CO)_3$

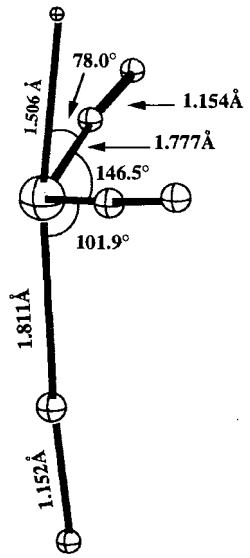
The initial key step, **a** of Scheme 1, in the hydroformylation process is represented by the dissociation of a CO ligand from $HCo(CO)_4$. The dissociation process results in the formation of the catalytically active species $HCo(CO)_3$, eq. [8].

[8] $HCo(CO)_4 \rightarrow HCo(CO)_3 + CO$

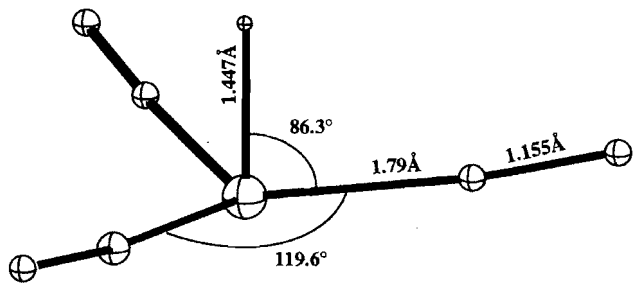
The dissociation is assumed to take place prior to, or in concert with, the complexation of an olefin leading to the olefinic π-complex $HCo(CO)_3(\eta^2$-olefin), step **b** of Scheme 1. The coordinatively unsaturated 16-electron species, $HCo(CO)_3$, has been identified by matrix isolation techniques (69), but its structure is unknown. We have explored (63) possible structures for $HCo(CO)_3$.

The pre-catalyst $HCo(CO)_4$ has a TBP ground state conformation with the hydride in an axial position. Dissociation of either an equatorial or axial CO ligand from $HCo(CO)_4$ will thus give rise to **11a** and **11b**, respectively.

Both **1a** and **1b** constitute in our calculations local minima on the singlet surface of $HCo(CO)_3$. We calculate $HCo(CO)_3$ with the butterfly shape (**11a**) to be 35 kJ/mol lower in energy than the trigonal-shaped $HCo(CO)_3$ species, **11b**. The equatorial ($HCo(CO)_4 \rightarrow$ **11a**) and axial ($HCo(CO)_4 \rightarrow$ **11b**) CO dissociation energies were found to be 169 and 207 kJ/mol, respectively. Some experimental evidence for the existence of $HCo(CO)_3$ in different configurations was given in a recent publication by Sweany (70), who inferred, based on results from the photolysis of $HCo(CO)_4$ in an argon matrix, that $HCo(CO)_3$ forms two isomers consistent with the structures **11a** and **11b**.



11a



11b

Concluding remarks on hydroformylation study

The DFT calculations indicate that the last product-forming step, **e** of Scheme 1, in which aldehyde elimination is induced, has the highest activation energy with $\Delta H^{\neq} \sim 80$–90 kJ/mol. Step **d** was calculated to have a similar activation energy of $\Delta H^{\neq} \sim 70$–80 kJ/mol. The insertion of olefin into the Co—H bond, steps **b–c**, was on the other hand estimated to have a negligible activation energy of $\Delta H^{\neq} \sim 10$–20 kJ/mol. We finally determined that the formation of the active catalyst $HCo(CO)_3$ from $HCo(CO)_4$ by CO dissociation, step **a**, requires 169 kJ/mol.

Other DFT studies on elementary reaction steps

Other studies on organometallic reactions include oxidative addition of H_2 to $Co(CO)_4$ (65) as well as H_2 and CH_4 to CpML (L = CO, PH_3; M = Rh, Ir) (71) and CH_3Cl (72) to Pd, polymerization of organosilanes (73), halogen abstraction by metal carbonyl anions (74), and insertion of aldehydes into the Co—H bond (75).

A large number of studies have been concerned with the role of four-center transition states and intermediates(76*a*,*b*). They include the metathetical ($2\sigma+2\sigma$) exchange reactions between Cp_2MR (M = Lu, Sc; R = H, CH_3) and H_2,

5. Concluding remarks. A personal and historical perspective on the application of density functional in chemistry

Johnson (19) was the first to apply a density-functional-based method to chemical problems, Table 13. In his approach use was made of the muffin-tin approximation with spherical potentials around each atom (20). This approximation precluded calculations of geometries and bond energies. The muffin-tin approximation was eliminated in subsequent approaches put forward by Ellis and Painter (22), Baerends et al. (23), and Sambe and Felton (24). A further step forward was taken when Ziegler and Rauk (30), Dunlap et al. (25), and Jones and co-workers (26) introduced methods that allowed total energies to be calculated accurately within the DFT framework, Table 13.

By 1977 the way had been paved in principle for DFT-based studies of molecular energetic and dynamics, and some promising applications did appear shortly after (25, 26, 30, 48*c*, 41*a*, 41*d*). However, from a theoretical and practical point of view, several hurdles had to be overcome.

From a theoretical point of view, all calculations were based on the first generation of local approximations such as HFS (16) or LDA (17). These methods provided reasonable frequencies and geometries (1*d*) but overestimated bond energies by as much as 100%. The energy problem was overcome by the introduction of nonlocal corrections (LDA/NL) due to Langreth and Mehl (18*a*), Becke (18*b*), and Perdew (18*c*), as well as others. Thus, Becke demonstrated in a number of seminal papers (18*b*, 31*c–e*), in which he combined the nonlocal corrections with his unique NUMOL[5] program, that LDA/NL affords bond energies for main-group molecules of nearly chemical accuracy (±5 kcal/mol). Similar promising results based on LDA/NL were obtained for structures (4*b*) and bond energies (18*j*, 40) of transition-metal complexes.

From a practical point of view, the early implementations (20, 25, 26) in which total energies could be calculated lacked automated features for geometry optimizations. Thus structure determinations were carried out from a laborious and manual tracing of the potential energy surface. This was changed by the introduction of analytical energy gradients (4, 5, 35) that also made it possible to calculate force constants (6, 59). Force constants can now also be calculated directly by analytical second-order energy derivatives (32*c–g*).

DFT is now a well-established method after a bumpy and exhilarating path through the 1970s and 1980s. Many of its previous opponents have become lukewarm practitioners or even staunch supporters, and it has been incorporated into a number of major program packages such as ADF (23, 29*c*), DeMon (30*e*), DMOL (35*f*, 30*d*), DGAUSS (30*b,c*), GAUSSIAN/DFT (32*c*), and CADPAC (32*d*).

Much still has to be done in terms of improving the existing functionals (18*m,n*). Applications to excited states have to be explored (52, 53*d,e*), further and new applications to properties such as NMR shifts (7) and ESR (79) hyperfine tensor are emerging. Other new developments are the first-principle molecular dynamics method by Car and Parrinello (32*a*), which has the potential to introduce temperature into the description of molecular behavior, and the divide and conquer scheme by Yang (80), which allows one to describe large systems, as well as several recent inclusions of solvation effects (81) into the DFT formalism.

All of the new methods are bound to benefit organometallic chemistry to the same degree as the development of DFT over the past decade, and it is this author's expectation that DFT will become as indispensable a research tool in chemistry as any of the major spectroscopic techniques.

Acknowledgment

I would like to thank my inorganic colleagues, Professors T. Chivers and M. Boorman at the University of Calgary, for their support and encouragement. Also a thanks to former students: Dr. L. Versluis, Dr. V. Tschinke, Dr. L. Fan, and E. Folga, as well as present students H. Jacobsen, A. Berces, L. Deng, G. Schreckenbach, and T.K. Woo and research associates Dr. J. Li, Dr. R. Dickson, Dr. J. Lohrenz, and D. Swerhone. Finally a special thanks to Professors A.D. Becke (Queens University) and E.J. Baerends (Free University of Amsterdam) as well as to the Natural Sciences and Engineering Research Council of Canada (NSERC) for support.

Abstract: The photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction of methanol, 2,6-dimethyl-1,6-heptadiene, and 1,4-dicyanobenzene yields three distinct types of 1:1:1 adducts: an acyclic product, 4-(1-methoxymethyl-1,5-dimethyl-5-hexenyl)benzonitrile (**8**, 5%); a *cis–trans* pair of cyclohexanes, 4-(3-methoxymethyl-1,3-dimethylcyclohexyl)benzonitrile (**9** *cis* (12%) and **9** *trans* (11%)); and a *cis–trans* pair of cycloheptanes, 4-(4-methoxy-1,4-dimethylcycloheptyl)benzonitrile (**10** *cis* (12%) and **10** *trans* (10%)). Variation in the concentration of the nucleophile, methanol, and codonor, biphenyl, affects the product ratio and it has been possible to establish the mechanisms for the formation of these products. The acyclic product is formed by a typical photo-NOCAS reaction, that is, addition (*anti*-Markovnikov) across one of the heptadiene double bonds. The cyclohexane products are formed following 1,6-*endo* cyclization of the intermediate β-alkoxy radical. And the cycloheptane products result from 1,7-*endo,endo* cyclization of the initially formed 2,6-dimethyl-1,6-heptadiene radical cation. Comparison of the relative rates of these cyclization processes can be made with those of the next smaller homolog, 2,5-dimethyl-1,5-hexadiene.

Key words: photochemistry, photoinduced electron transfer, radical ions, radicals, cyclization.

Résumé : La réaction de substitution aromatique par combinaison photochimique nucléophile–oléfine (photo-NOCAS) du méthanol avec le 2,6-diméthylhepta-1,6-diène et le 1,4-dicyanobenzène conduit à trois types distincts d'adduits 1 : 1 : 1 : un produit acyclique, le 4-(1-méthoxyméthyl-1,5-diméthylhex-5-ényl)benzonitrile (**8**, 5%); une paire de cyclohexanes *cis–trans*, les 4-(3-méthoxyméthyl-1,3-diméthylcyclohexyl)benzonitriles (**9** *cis* (12%) and **9** *trans* (11%)) et une paire de cycloheptanes *cis–trans* les 4-(4-méthoxy-1,4-diméthylcycloheptyl)benzonitriles (**10** *cis* (12%) and **10** *trans* (10%)). Des variations dans la concentration du nucléophile, du méthanol et du co-donneur, le biphényle, affectent les concentrations relatives des produits et il a été possible d'établir les mécanisme de formation de ces produits. Le produit acyclique se forme par une réaction photo-NOCAS typique, à savoir une addition (*anti*-Markovnikov) sur les doubles liaisons de l'heptadiène. Les produits cyclohexaniques se forment par une cyclisation 1,6-*endo* du radical intermédiaire β-alkoxy. Et les produits du cycloheptane résultent d'une cyclisation 1,7-*endo,endo* du cation radical 2,6-diméthylhepta-1,6-diène qui se forme initialement. On peut faire une comparaison des vitesses relatives de ces divers processus de cyclisation avec celles observées pour l'homologue inférieur immédiat, le 2,5-diméthylhexa-1,5-diène.

Mots clés : transfert électronique photoinduit, ions radicaux, radicaux, cyclisation.

[Traduit par la rédaction]

Introduction

Part 6 of this series on the photo-NOCAS reaction reported the formation of acyclic and cyclic 1:1:1 (methanol, 2,5-dimethyl-1,5-hexadiene (**2**), and 1,4-dicyanobenzene (**1**)) adducts (reactions [1] and [2]) (1*a*). The ratio of acyclic (**3**) to cyclic (**6**) products was dependent upon the concentration of methanol and biphenyl (**5**), serving as a codonor. The mechanism proposed to account for these results is summarized in Scheme 1. This study has now been extended to the next higher homolog, 2,6-dimethyl-1,6-heptadiene (**7**), with these objectives: to increase our understanding of radical cation reaction dynamics, and to further define the scope and synthetic utility of this reaction. We were particularly interested in the possibility of a 1,7-*endo,endo* cyclization of the 2,6-dimethyl-1,6-heptadiene radical cation ($\mathbf{7}^{+\cdot}$); there are few general methods for the synthesis of medium-sized rings.

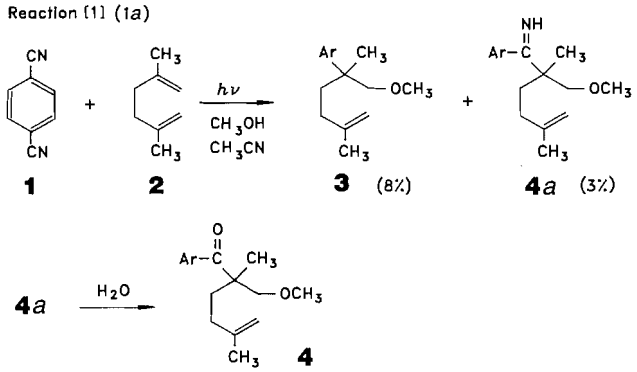
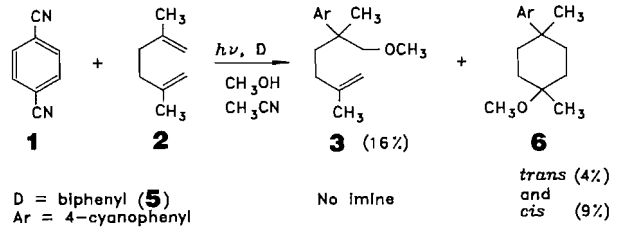
Reaction [1] (1*a*)



Reaction [2] (1*a*)



D = biphenyl (**5**)
Ar = 4-cyanophenyl

No imine

Organic reactions that induce cyclization have attracted considerable attention; the scope and limitations of this process involving the more common intermediates, closed-shell ions and neutral radicals, have been defined. We have Baldwin's "rules" for the cyclization of carbocations and carbanions and we have the generalizations of Beckwith and Ingold for cyclization of radical intermediates (3, 4). Much less is known regarding the cyclization of radical cations and radical anions (5–8). Some cyclizations of radical cations involving the formation of a new oxygen–carbon bond are known (5). Examples of the cyclization of 1,5-hexadienes have been reported (1*a*, 6, 7). Recently, the cyclization of enol silyl ethers into pendant double bonds has been demonstrated (8). There is no reason to doubt that these cyclization reactions of radical ions will be as important as those involving ions and radicals.

Results

A solution of 1,4-dicyanobenzene (**1**) (0.1 M), biphenyl (**5**) (0.1 M), and 2,6-dimethyl-1,6-heptadiene (**7**) (0.1 M), in acetonitrile–methanol (3:1), was irradiated through Pyrex with a medium-pressure mercury vapour lamp (reaction [3]). Progress of the reaction was followed by capillary column gas chromatography with either a flame ionization (gc/fid) or a mass selective (gc/ms) detector. Five products were formed with molar mass corresponding to 1:1:1 (methanol:2,6-dimethyl-1,6-heptadiene:1,4-dicyanobenzene–HCN) adducts. Biphenyl (**5**) was largely recovered. Products were isolated by medium-pressure liquid chromatography (mplc) on silica gel.

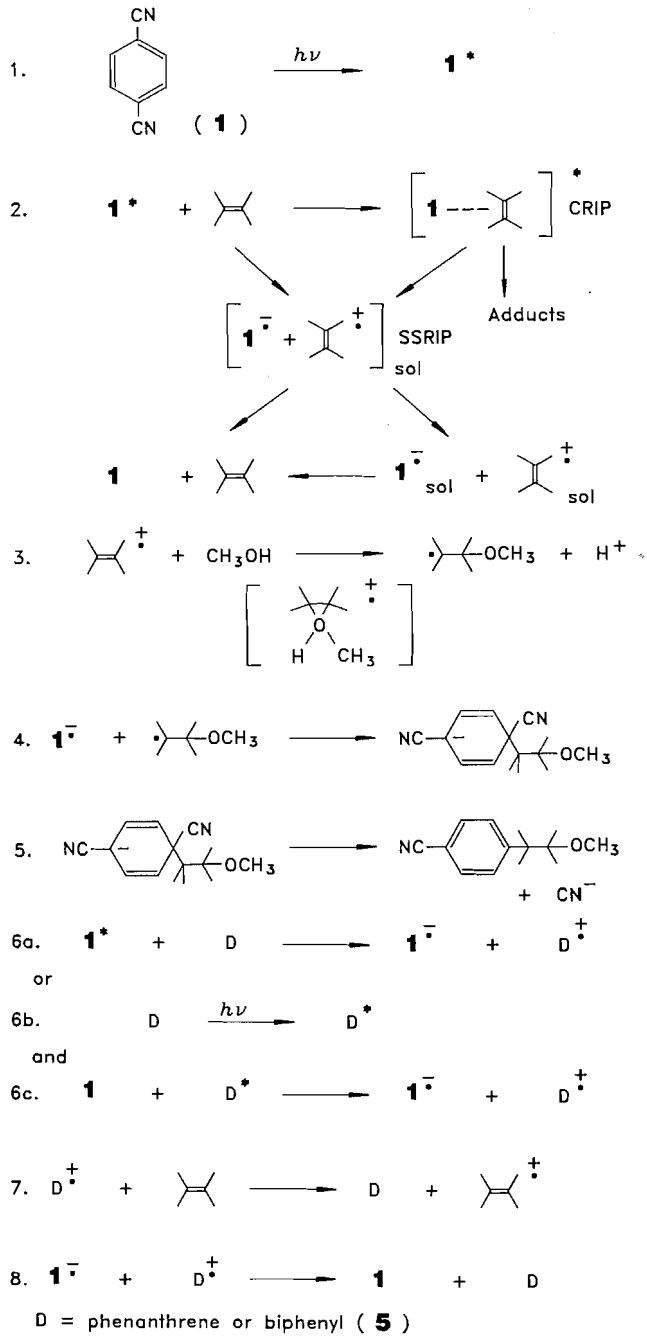
Scheme 1.

Mechanism for formation of photo–NOCAS products.



D = phenanthrene or biphenyl (**5**)

One of the five photo-NOCAS adducts, 4-(1-methoxymethyl-1,5-dimethyl-5-hexenyl)benzonitrile (**8**, (5%)) involves only one of the double bonds of the diene and is therefore analogous to a simple mono-alkene adduct. The other four products involve cyclization of the diene: a *cis–trans* pair of cyclohexanes, 4-(3-methoxymethyl-1,3-dimethylcyclohexyl)-benzonitrile (**9** *cis* (12%) and **9** *trans* (11%)); and a *cis–trans* pair of cycloheptanes, 4-(4-methoxy-1,4-dimethylcycloheptyl)benzonitrile (**10** *cis* (12%) and **10** *trans* (10%)). The combined yield of photo-NOCAS adducts was 50% at ca. 50% conversion.

Structures were established largely on the basis of ^{1}H and ^{13}C nmr spectra. The structures of **9** *cis* and 4-(*cis*-4-methoxy-1,4-dimethylcycloheptyl)benzoic acid (**10a** *cis*), obtained upon mild hydrolysis of **10** *cis*, were determined by X-ray diffraction analysis on single crystals.[3]

The product ratios were dependent upon the concentration of methanol and biphenyl (**5**). Small-scale irradiations were carried out in Pyrex tubes (5 mm) under conditions similar to those used for the preparative scale reaction described above. The concentrations of the reactants, other than methanol, were kept the same as in the preparative scale reaction. The concentration of methanol was varied, 0.50–3.0 M. The ratio of products was determined from the corresponding peak heights in the gas chromatogram (gc/fid, Table 1 and Fig. 1). An increase in methanol concentration caused an increase in the yield of the acyclic (**8**) and cyclohexane products (**9** *cis* and *trans*) relative to the cycloheptanes (**10** *cis* and *trans*).

Similarly, small-scale irradiations were carried out with variation in the concentration of biphenyl (**5**) (0–0.1 M) while the concentrations of the other reactants were maintained the same as in the preparative scale reaction (acetonitrile–methanol (3:1), ca. 6 M methanol). When no biphenyl was present, neither the cyclohexanes (**9** *cis* and *trans*) nor the cycloheptanes (**10** *cis* and *trans*) were produced in detectable (gc/fid) quantities. As the concentration of biphenyl (**5**) was increased, the yield of the cycloheptanes (**10** *cis* and *trans*) increased relative to the other photo-NOCAS products (Table 2 and Fig. 2).

Structural assignments

The connectivity of all of the products was readily established from the infrared, the mass, and the ^{1}H and ^{13}C nmr spectra. Determining the stereochemistry of the cyclohexanes (**9**) and cycloheptanes (**10**) afforded a more formidable challenge and was ultimately achieved by X-ray diffraction analysis on single crystals. The *cis*-cyclohexane product (**9** *cis*) is a crystalline compound and an X-ray analysis established the structure (Fig. 3). The *cis*-cycloheptane product (**10** *cis*), a colourless liquid, was hydrolysed to the crystalline carboxylic acid, 4-(*cis*-4-methoxy-1,4-dimethylcycloheptyl)benzoic acid (**10***a* *cis*) and an X-ray analysis was carried out on this derivative (Fig. 4). The ^{1}H nmr spectra of the nitrile (**10** *cis*) and the carboxylic acid (**10***a* *cis*) are almost identical; the X-ray analysis on the crystalline derivative provides firm evidence for the structure of the initial product (**10** *cis*).

The structure of the acyclic adduct (**8**) was easily established. The ^{1}H nmr spectrum has two weakly coupled signals in the vinyl proton region, similar to those seen in the starting diene (**7**), which integrate for one proton each. Distinctive signals in the aromatic region for the *para*-substituted phenyl ring, a sharp singlet at relatively low field assigned to the methoxy methyl group, and two higher-field singlets for the

For personal use only.

other methyl groups, show that this is a 1:1:1 adduct. The relatively high-frequency AB quartet is evidence for the methylene bearing a methoxy group and a stereogenic quaternary carbon. The remaining three signals in the aliphatic region integrate for two protons each. Of these, the signal at highest frequency, a slightly broadened triplet, is assigned to the allylic methylene (C-4). The other two signals are complex second-order patterns as expected for adjacent methylene groups in an asymmetric environment.

Two-dimensional nmr (COSY) confirms that the triplet splitting of the allylic methylene is the result of coupling to the protons at lowest frequency (bonded to C-3), and that the allylic protons are also weakly coupled to one of the vinyl protons. The C-3 methylene is also coupled to the other methylene, which is not further coupled, and is therefore assigned to C-2, i.e., the methylene adjacent to the quaternary stereogenic carbon.

This assigned structure is consistent with the number, multiplicity, and chemical shift of the signals in the ^{13}C nmr spectrum of **8**.

The *cis* cyclohexane (**9** *cis*) is a crystalline compound and an X-ray diffraction analysis of a single crystal firmly established the structure. The mass spectral fragmentation pattern, and the ^{1}H and the ^{13}C nmr spectra of **9** *trans* are very similar to those of **9** *cis*; clearly, these compounds are diastereomers.

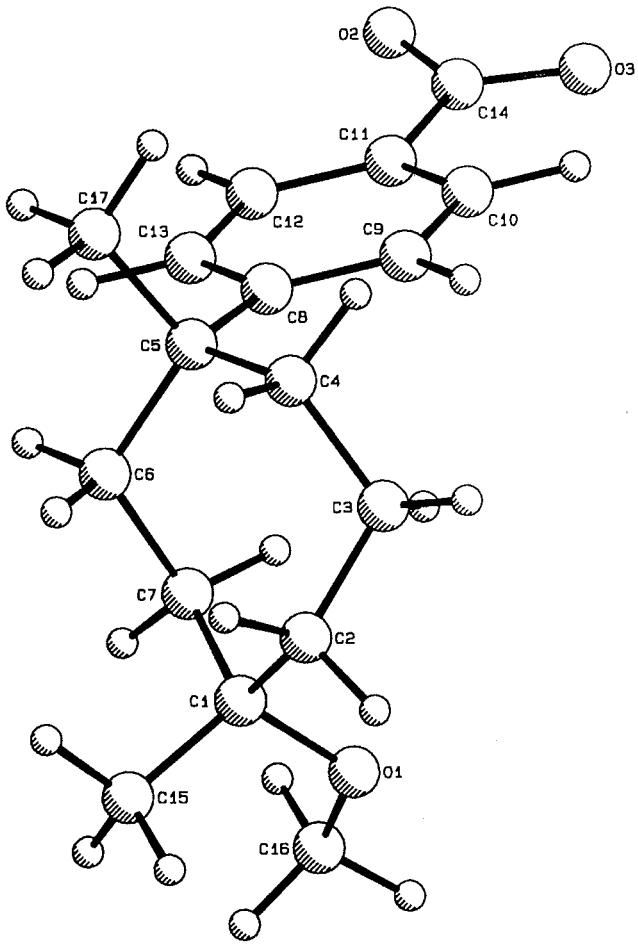
The ^{1}H nmr spectra of both **9** *cis* and *trans* have the expected AA′XX′ pattern in the aromatic region indicative of a *para*-substituted phenyl ring. Both spectra have a low-field (ca. 3 ppm) three-proton singlet consistent with a methoxy methyl group, and two higher-field singlets for the uncoupled methyl groups. There are no signals in the vinyl proton region of the spectrum of either isomer. These observations indicate that both products, **9** *cis* and **9** *trans*, are 1:1:1 adducts of methanol, the diene, and 1,4-dicyanobenzene, which have cyclized in such a way that the aliphatic methyl groups are on quaternary centres. The spectra of both of these compounds have AB quartets for two protons, slightly upfield of the methoxy methyl signals. This is good evidence that the methoxy group is bonded to what was a terminal methylene carbon of a former double bond and that the vicinal olefinic carbon has become quaternary. The upfield shift of this AB quartet of **9** *cis*, relative to that of **9** *trans*, is consistent with the *cis* stereochemistry evident from the X-ray data. This upfield shift indicates that the methoxy-substituted methylene is in the shielding cone of the phenyl ring. A similar upfield shift is seen in the signal due to the methoxy methyl group of **9** *cis*.

The *cis* cyclohexane (**9** *cis*) has ^{1}H nmr spectral evidence for another isolated diastereotopic methylene group (C-2); the sharp doublets (J = 14 Hz) at 2.30 and 1.29 ppm are assigned to the equatorial and axial protons, respectively. The mutual and exclusive coupling of these protons was confirmed by the COSY experiment. The difference in chemical shift between these geminal protons is expected for a conformationally constrained cyclohexane.

Signals were assigned for the other six aliphatic protons, aided by the results of the COSY experiment. The axial proton on the central carbon (C-5) of this group of methylenes would be expected to have three relatively large couplings. Geminal couplings and axial–axial couplings are larger than axial–equatorial and equatorial–equatorial couplings. This expectation assumes that all the large couplings are observable and the coupled protons are not coincident. The two-proton multiplet at 1.44 ppm is the only one that has more than one correlation (COSY). One of these protons must be the axial C-5 proton. The broad doublet (J = 13 Hz) for one proton (2.25 ppm) must be one of the equatorial protons, and the single-proton signal at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Fig. 4. X-ray crystallographic structure of 4-(4-methoxy-1,4-dimethylcycloheptyl)benzoic acid (**10***a cis*).



1.18 ppm must be another axial proton because it has two large and one small couplings. In view of the fact that this signal (1.18 ppm) has only one correlation, which is to the proton assigned to the central axial position (1.44 ppm), the other (geminal) coupling must be to the proton at the same shift position (1.44 ppm). This might represent either of the methylenes C-4 or C-6. The alternate methylene must have proton signals coincident at 1.6 ppm since that signal shows only one correlation, which is to the signal at 1.44 ppm. The broad doublet (2.25 ppm) must be the C-5 equatorial proton. It seems likely that the coincident methylene protons (1.6 ppm) are at C-6. At that position it is possible that only the axial proton is in the aromatic deshielding region and (or) only the equatorial proton is in the shielding cone. These affects could counteract the normal deshielding of equatorial protons relative to axial protons such that these geminal protons have coincident chemical shifts.

The ^{1}H nmr spectrum of the *trans* cyclohexane (**9** *trans*) shows less dispersion of the signals due to the aliphatic protons than does the diastereomer and a complete assignment would be speculative; however, the spectrum does have several features, in addition to those mentioned above, which are consistent with the assigned regio- and stereochemistry. The spectrum has two relatively low-field doublets (2.31 and 2.09 ppm) as does **9** *cis*. One of these doublets is probably due to the equatorial proton on C-2, between the quaternary ring positions, and the other is due to an equatorial proton on the other side of the ring (C-5). Neither doublet is sharp; perhaps some four-bond coupling is operative on the proton on the isolated ring position in this isomer. Both doublets are coupled to protons at higher field (1.6 and 1.3 ppm, respectively) as shown by COSY and C–H heterocorrelation data.

The high-field singlet (0.31 ppm) is evidence for a methyl group in the shielding cone of the aryl ring. This indicates that this molecule is in a conformation where the aryl ring and this shielded methyl group are in a 1,3-diaxial relationship. This conclusion is reasonable, the aryl group is known, from the X-ray diffraction data, to be axial in the *cis* isomer and this conformation has been shown, by molecular mechanics calculations, to be preferred when phenyl and methyl groups are geminal on a cyclohexane ring (9).

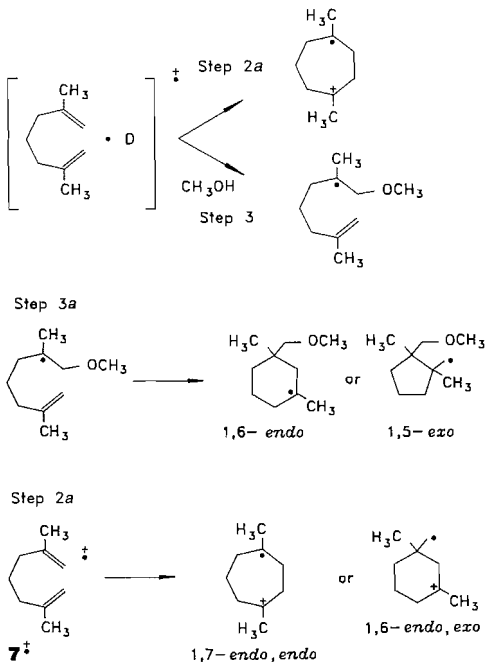
The infrared, the mass, and the ^{1}H and ^{13}C nmr spectra of **10** *cis* and **10** *trans* are very similar; clearly, these two compounds are diastereomers. The ^{1}H nmr spectra of these compounds were not as well dispersed as they were for the isomeric cyclohexanes. The spectra of both show the AA′XX′ pattern in the aromatic proton region for the *para*-substituted phenyl ring. Both spectra have relatively low-field singlets, attributable to the methoxy methyl groups, and both have a pair of singlets for the aliphatic methyl groups. The signals due to the other aliphatic methylene groups were poorly dispersed and further analysis was not feasible. The assigned structures were consistent with the number, the coupling pattern, and the chemical shifts of all of the peaks in the ^{13}C nmr spectra for both isomers (**10** *cis* and **10** *trans*). The distinction between these two isomers rests firmly upon the X-ray analysis of **10***a cis*.

Discussion

These results provide insight into the behaviour of the unusual intermediates involved and further evidence of the potential synthetic utility of the photo-NOCAS reaction. Three different reaction pathways produce the acyclic adduct (**8**), the *cis–trans* pair of cyclohexanes (**9** *cis* and *trans*), and the *cis–trans* pair of cycloheptanes (**10** *cis* and *trans*). The sequence of events that produces the acyclic adduct is analogous to the general mechanism originally proposed for the reaction with mono alkenes (Scheme 1); formation of the cyclic products requires a more complex mechanism.

The acyclic adduct (**8**) is the *anti*-Markovnikov addition product. Step 1 of the proposed mechanism (Scheme 1) involves excitation of the 1,4-dicyanobenzene (**1**) to the first electronically excited singlet state (^1L_b). This state has a long enough lifetime (9.74 ns (10)) to allow rapid bimolecular reaction. The oxidation potential of 2,6-dimethyl-1,6-heptadiene (**7**) is low enough (2.6 V (sce)) to allow exothermic electron transfer; the ΔG_{ET}, calculated from the Weller equation, is -2.8 kJ mol^{-1} (11). This photo-induced single electron transfer occurs within the solvent cage, forming a solvent-separated radical ion pair (SSRIP) (step 2). Reaction of the radical cation $\mathbf{7}^{+\cdot}$ with methanol, within the methanol-solvent cage, leads to formation of the β-alkoxy radical (step 3). Rapid coupling of this radical with the geminate radical anion ($\mathbf{1}^{-\cdot}$) at the *ipso* position (step 4), before solvent separation or cyclization, leads on to the acyclic product (**8**).

As expected, methanol attacks the less hindered carbon of



the alkene radical cation to produce the more heavily substituted (more stable) tertiary radical. The Markovnikov addition product was not detected. This is consistent with the results of the photo-NOCAS reaction involving 2-methylpropene, a similarly substituted mono-alkene (1*d*,*e*). In general, the Markovnikov adduct is a minor product when the olefinic carbons are secondary and tertiary; the reaction is regioselective when the olefinic carbons are primary and tertiary, as in this diene (**7**). The first-formed intermediate is a bridged distonic radical cation (Scheme 1, step 3). Deprotonation of the distonic radical cation, from the oxygen, forms the alternative β-alkoxy radicals, which are not bridged, in a ratio dependent upon relative stability.

The acyclic adduct (**8**) might react further at the remaining double bond; the oxidation potential of **8** is not significantly higher than that of **7**. However, under the conditions used for this reaction (reaction [3]), carried out to ca. 50% conversion, 2:1:2 adducts were not observed (gc/ms).

The efficiency of the reaction is greatly increased upon the addition of biphenyl (**5**). Biphenyl (**5**) serves as a codonor. This increase in efficiency has been attributed to a greater ratio for the rate of separation of the SSRIP [$\mathbf{1}^{-\cdot} - \mathbf{5}^{+\cdot}$] (step 6*a*) divided by the rate of back electron transfer (step 8) for this pair than for the SSRIP [$\mathbf{1}^{-\cdot} - \mathbf{7}^{+\cdot}$] (1). The free, completely solvated, biphenyl radical cation ($\mathbf{5}^{+\cdot}$) then oxidizes the diene to the radical cation $\mathbf{7}^{+\cdot}$ (step 7). Under these conditions, the radical cation $\mathbf{7}^{+\cdot}$ is generated completely separated from the radical anion $\mathbf{1}^{-\cdot}$. Reaction of the radical cation $\mathbf{7}^{+\cdot}$ with methanol leads to the β-alkoxy radical, which now has time to cyclize (step 3*a*).

Formation of the cyclohexanes (**9** *cis* and *trans*) is attributed to a 1,6-*endo* cyclization of the intermediate β-alkoxy radical (step 3*a*). The resulting tertiary radical then couples with the radical anion of 1,4-dicyanobenzene ($\mathbf{1}^{-\cdot}$) (step 4) followed by rearomatization by loss of cyanide ion (step 5) of the general mechanism.

An alternate route to the cyclohexanes would involve 1,6-*endo,exo* cyclization of the radical cation of the diene ($\mathbf{7}^{+\cdot}$) (step 2*a*). The resulting cyclic, distonic radical cation would be expected to have high positive charge density on the tertiary position while the spin density would be largely associated with the primary centre. This follows from the relative stability of the radical and cationic centres; the oxidation potential of a tertiary radical is significantly lower that of a primary radical (12). This intermediate would lead to products in which the methoxy and cyanophenyl groups are interchanged with respect to the observed products.

Cyclization of the intermediate β-methoxy radical (step 3*a*) is expected to proceed 1,6-*endo*, rather than the alternative 1,5-*exo*, based upon Beckwith's work with 5-hexenyl radicals bearing different substitution patterns. For the unsubstituted 5-hexenyl radical the rate ratio, 1,6-*endo*/1,5-*exo* cyclization, is 1:50, in favour of 1,5-*exo* closure. For the 1,1,5-trimethyl-hex-5-enyl radical, 1,6-*endo* cyclization is 100 times faster than 1,5-*exo* cyclization (13). The reversal is observed upon substitution at the 5-position alone; however, cyclization becomes regioselective only when both the 5- and 1-positions are substituted.

There is a slight preference for formation of the *cis* cyclohexane (**9** *cis*) over the *trans* isomer (**9** *trans*). This product ratio must be determined at the time of coupling between the cyclized radical and the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\cdot}$) (step 4). The intermediate methylcyclohexyl radical, in a *pseudo*-chair conformation, is substituted at the 3-position by methyl and methoxy methyl groups. The *A* values for the methyl (1.74) and methoxy methyl (1.72) groups, *in nonpolar solvent*, are essentially identical (14). Molecular mechanics calculations on cyclohexane bearing geminal methyl and methoxy methyl groups indicate a slight (0.13 kJ mol) preference for the axial methoxy methyl conformer.[4] However, in polar hydrogen-bonding solvents the effective size of the methoxy methyl group may be larger. Coupling of the methylcyclohexyl radical with the radical anion ($\mathbf{1}^{-\cdot}$) will take place preferentially on the side leading to equatorial aryl substitution; the axial directing effect of an α-methyl group is not as great as the equatorial directing effect of the axial methyl, or methoxy methyl, group at the 3-position (15). The rates of equatorial attack on the two conformations of the radical should be almost the same. The fact that the *cis* product dominates may indicate that, under these reaction conditions (polar hydrogen-bonding solvent), the conformer with the axial methyl is preferred (slightly) over the axial methoxymethylene in the methylcyclohexyl radical.

The initially formed chair conformer of either diastereomer will convert to an axial aryl conformer; the 1-phenyl-1,3,3-trimethylcyclohexane molecule has a preference (14 kJ mol^{-1}, calculated) for the chair conformer having the axial phenyl group (9). These force field calculations also show that the twist-boat conformer is less stable than the chair conformer, and that the axial phenyl ring is rotated to avoid the axial methyl group. This fits well with the observations of the upfield shift in the ^{1}H nmr signals for the axial methyl group in the *trans* isomer (**9** *trans*) and for the axial methylene of the methoxy methyl group in the *cis* isomer (**9** *cis*).

The cycloheptane products (**10** *cis* and *trans*) are the result

of 1,7-*endo,endo* cyclization of the radical cation of the diene ($7^{+\cdot}$) (step 2*a*). This mode of cyclization is the least hindered of the alternatives and the only option that leaves the reactive centres, both the radical and the carbocation, at tertiary positions. The *cis* and *trans* products, (**10** *cis*) and (**10** *trans*), are formed by steps 3, 4, and 5 of the general mechanism (Scheme 1). Again, there is a slight preference for the formation of the *cis* isomer (**10** *cis*). This stereochemistry is determined at the aromatic substitution step (step 4), as in the case of the cyclohexanes described above, but the analysis of the conformations of the cycloheptyl radical and the diastereofacial selectivity for the radical coupling step are less well established with the cycloheptyl ring system.

The effect of variation in methanol and biphenyl (5) concentration.

The results of variation in the concentration of methanol are shown in Table 1 and Fig. 1; lowering the concentration of methanol results in an increase in the yield of the cycloheptanes (**10** *cis* and *trans*) relative to the cyclohexanes (**9** *cis* and *trans*) and acyclic (**8**) products. Following the initial formation of the solvated diene radical cation ($7^{+\cdot}$) (step 7), 1,7-*endo, endo* cyclization leading ultimately to the cycloheptanes (step 2*a*) is in direct competition with reaction with methanol (step 3) leading to the acyclic and cyclohexane products. The observed variation in product ratio is consistent with this proposed mechanism. These results are similar to those observed with the homolog, 2,5-dimethyl-1,5-hexadiene (**2**) (1*a*). In that case also, lowering the concentration of methanol favoured radical cation cyclization and increased the relative yield of the radical cation cyclized product (**6**) (reaction [2]). No quantitative conclusions regarding the rates of cyclization and attack by methanol can be made in either of these cases. It seems likely that cyclization of the radical cation $7^{+\cdot}$ is reversible. Calculations show the acyclic radical cation of 2,5-dimethyl-1,5-hexadiene ($2^{+\cdot}$) is 10 kJ mol^{-1} more stable than the 1,6-*endo,endo* cyclized distonic radical cation (16). The kinetic expressions are further complicated by the interaction of the radical cations, acyclic and cyclic, with biphenyl (**5**).

The variation in biphenyl (**5**) concentration also has an effect on the product ratio. In addition to the initial role of biphenyl (**5**), generating the radical cation $7^{+\cdot}$ remote from the radical anion $1^{-\cdot}$, further increase in the biphenyl concentration produces relatively more cycloheptanes (Table 2 and Fig. 2). Again, analogous results were observed for the reaction of 2,5-dimethyl-1,5-hexadiene (**2**) (reaction [1]) (1*a*). These results support the hypothesis that there is a complex formed between the radical cation of the diene (or alkene) and biphenyl (**5**). The complexing biphenyl could have a shielding (steric) effect. Furthermore, biphenyl has a lower oxidation potential than the diene and therefore most of the spin and charge density resides on the biphenyl (**5**). The complexed alkene radical cation may be deactivated toward nucleophilic attack for electronic as well as steric reasons. This complex might also facilitate the cyclization process (step 2*a*) by favouring a conformation of the diene that brings the double bonds closer together.

The fact that the electron transfer from the alkene to the biphenyl is, in many cases, endothermic has been cause for previous consideration of the existence of a complex (1, 17). Some support for this hypothesis is the observation of a radical cation complex of benzene and ethylene as well as the observation of dimeric complexes involving aromatic radical cation (18, 19).

Experimental

General information

The ^1H and ^{13}C nmr spectra were recorded on Bruker AC 250F (Quattro Probe) and AMX 400 (wide bore) spectrometers. Spectra are reported in parts per million (ppm) relative to tetramethylsilane. The infrared spectra were produced on a Nicolet 205 Fourier transform infrared spectrometer. The samples were thin liquid films on sodium chloride plates unless otherwise noted. The peaks are reported in wavenumbers (cm^{-1}) calibrated with the absorption of polystyrene at 1601.4 cm^{-1}. The mass spectra were taken with a Hewlett–Packard 5970 series quadrupole mass selective detector. Mass-to-charge ratios are listed with the relative intensities in parentheses. Exact Mass determinations were obtained on a ZAB-E mass spectrometer. Elemental analyses were carried out by Canadian Microanalytical Services Limited, Delta, B.C.

Gas chromatography, for analyses of reaction mixtures, was done on a Hewlett–Packard 5890 chromatograph fitted with a DB-1701 fused silica WCOT column (30 m × 0.25 mm) and a flame ionization detector (gc/fid) or on a Hewlett–Packard 5890 with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm) and a Hewlett–Packard 5970 mass selective detector (gc/ms).

Purification of 2,6-dimethyl-1,6-heptadiene (**7**) and the volatile products, for elemental analysis, by preparative gas chromatography was done on a Varian Aerograph 90-P gas chromatograph (prep-gc). Medium-pressure liquid column chromatography (mplc) was done on thin-layer grade silica gel, without binder (Merck, 60 PF_{254}). The chromatographic columns were 2.5 cm × 1 m and were eluted with a hexanes – ethyl acetate solvent gradient under helium pressure (10 psi; 1 psi = 6.9 kPa). The eluent was monitored by a uv–visible spectrophotometer. The fraction size was 10 mL.

Materials

Acetonitrile (Fisher, ACS grade) was distilled over sodium hydride and then over phosphorus pentoxide. It was then passed through a column of basic alumina, refluxed over calcium hydride in a nitrogen-purged apparatus for 24 h, and distilled. The purified acetonitrile was stored over 3Å molecular sieve. Distilled methanol was also stored over 3Å molecular sieve.

The tetrahydrofuran was dried and purified by refluxing over phosphorus pentoxide, distillation, refluxing over sodium until added benzophenone caused a persistent blue colour (the radical anion), and a final distillation from sodium.

The Zn dust was activated by stirring several minutes in hydrochloric acid (2 M) followed by consecutive washing with water, ethanol, acetone, and diethyl ether, after which it was oven-dried.

Purification of 1,4-dicyanobenzene (**1**) (Aldrich) was accomplished by treatment with activated charcoal (Norite) followed by filtration and recrystallization from ethanol (95%). Biphenyl (**5**) was recrystallized from methanol.

Preparation of 2,6-dimethyl-1,6-heptadiene (7)

2,6-Dimethyl-1,6-heptadiene (**7**) was synthesized by a two-

For personal use only.

step procedure. 2,6-Heptanedione was made by a previously reported method from diketene and formalin in 20% yield (20). The diene (**7**) was made from this diketone in 22% yield by a method using $Zn–CH_2Br_2–TiCl_4$ as described by Lombardo (21).

Diketene (100 g) (Aldrich) was added to formaldehyde (50 g, 37% aqueous solution with 10–15% methanol as stabilizer) and distilled water (240 mL). This mixture was heated and stirred in a round-bottom flask equipped with a condenser. When the temperature reached 50°C the heat was removed and ice-water was occasionally used to keep the temperature from rising much above 50°C. When the exothermic reaction subsided, heat was again applied to keep the mixture warm (50°C) overnight. Sodium chloride (80 g) was added to the reaction mixture, which was stirred for 1 h. The organic product was extracted into benzene. The combined extract was washed with brine, dried over magnesium sulphate (anhydrous), and the solvent was evaporated. The resulting yellow liquid was purified by vacuum distillation on a silvered, vacuum-jacked column (40 cm × 1.5 cm) with a variable-take-off head. The crude mixture gave a clear, colourless product that distilled at 89°C (7 Torr; 1 Torr = 133.3 Pa) and usually crystallized.

Activated zinc metal dust (21 g) and dry tetrahydrofuran (200 mL) were put in an oven-dried flask with dibromomethane (7.0 mL) and cooled to −40°C. Titanium tetrachloride (8.1 mL) was added over about 20 min. The mixture was stirred at 5°C under a nitrogen atmosphere for 3 days. The flask was cooled in an ice-water bath and dichloromethane (35 mL) was added. 2,6-Heptanedione (4.2 g) was added, over 15–20 min, by syringe. The mixture was allowed to come to room temperature. It was stirred occasionally over 4 h. Distilled pentane (210 mL) and a slurry of sodium bicarbonate (105 g) in water (55 mL) were added. After effervescence, the organic layer was poured off and the remainder shaken with more pentane. The combined pentane solution was shaken with a mixture of sodium sulphate (70 g) and sodium bicarbonate (15 g). The solution was filtered and distilled. The distillate was purified by column chromatography using silica (70–230 mesh) with dichloromethane as eluent. The diene **7** was purified by prep-gc (40% SE-30, 100°C) to give a clear, colourless volatile oil (1.7 g). The ^{1}H nmr spectrum was similar to that reported (22).

2,6-Dimethyl-1,6-heptadiene (**7**): ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 4.70 (s, 2H, vinyl), 4.68 (s, 2H, vinyl), 2.01 (t, 4H, $^3J_{3-4}$ = 7.4 Hz, C-3 and C-5), 1.72 (s, 6H, 2 methyls), 1.57 (quintet, 2H, $^3J_{4-3}$ = 7.4 Hz, C-4); ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_{TMS}: 145.94 (tertiary vinyl), 109.85 (primary vinyl), 37.40 (C-3 and C-5), 25.58 (C-4), 22.41 (methyls).

Formation of the methanol, 2,6-dimethyl-1,6-heptadiene (7), 1,4-dicyanobenzene (1) photo-NOCAS adducts 8, 9 *cis* and *trans*, and 10 *cis* and *trans*: reaction [3]

A solution of 1,4-dicyanobenzene (**1**) (0.10 M) and biphenyl (**5**) (0.10 M) in acetonitrile–methanol (3:1 by volume) was purged by nitrogen ebullition for 3 min in Pyrex tubes (2 cm i.d.) and the tubes were sealed with Teflon-lined caps. 2,6-Dimethyl-1,6-heptadiene was then injected into the solution through the cap to make the alkene concentration 0.10 M. Solutions were irradiated with a 1-kW, medium-pressure mercury vapour lamp (Canadian General Electric) in a Pyrex jacket with water cooling. The tubes were arranged around the jacket in a water-bath kept at 10°C. Progress of the reaction was followed by gc/fid. The solvent was removed by distillation at atmospheric pressure. Five 1:1:1 adducts were detected (gc/ms). The photolysate was separated by column chromatography (mplc) using hexanes–ethyl acetate as the solvent system. Of the isolated products: **8**, **9** *trans*, and **10** *cis* and *trans* were colourless oils; **9** *cis* was a solid. The combined yield was 49%. The yield was based on the amount of 1,4-dicyanobenzene (**1**) consumed (44%). The yields of the individual products are based on the integrated peaks in the gas chromatogram (gc/fid) of the photolysate.

4-(1-Methoxymethyl-1,5-dimethyl-5-hexenyl)benzonitrile (**8**): yield: 5%; infrared (Nicolet 205) ν: 3074(w), 2969(s), 2938(s), 2875(s), 2831(m), 2227(s), 1649(w), 1607(m), 1507(w), 1459(m), 1452(m), 1407(w), 1390(w), 1374(w), 1198(w), 1109(s), 888(m), 838(m); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 7.60 (dt, 2H, aryl hydrogens adjacent to nitrile), 7.44 (dt, 2H, aryl hydrogens adjacent to alkyl group), 4.67 (s, 1H, terminal vinyl H), 4.59 (s, 1H, terminal vinyl H), 3.49 (d, 1H, ^2J = 9.0 Hz, H on methoxy-substituted carbon), 3.36 (d, 1H, ^2J = 9.0 Hz, H on methoxy-substituted carbon), 3.29 (s, 3H, methoxy), 1.93 (t, 2H, $^3J_{3-4} = {}^2J$ = 7.3 Hz, allylic methylene C-4), 1.50–1.76 (multiplet, 2H, H's at C-2), 1.61 (s, 3H, allylic Me), 1.35 (s, 3H, methyl on C-1), 1.00–1.33 (multiplet, 2H, H's on C-3); ^{13}C nmr (62.9 MHz, $CDCl_3$, multiplicities by DEPT) δ_{TMS}: 152.04 (s, 4′ aryl C), 145.35 (s, substituted end of double bond), 131.89 (d, 2′ and 6′ aryl C), 127.80 (d, 3′ and 5′ aryl C), 119.15 (s, cyano C), 110.19 (t, unsubstituted end of double bond), 109.63 (s, 1′(cyano-substituted) aryl C), 81.24 (t, methoxy-substituted C), 59.36 (q, methoxy), 42.79 (s, benzylic C-1), 38.55 (t, C-2 methylene), 38.07 (C-4 methylene), 22.58 (q, benzylic methyl) 22.20 (q, allylic methyl), 21.54 (t, C-3 methylene); ms *m/z* (% rel. abund.): 257(6), 169(11), 156(35), 143(11), 142(13), 130(44), 129(12), 116(23), 115(11), 69(13), 55(13), 45(100), 43(10), 41(27). Preparation of 4-(*cis*-4-methoxy-1,4-dimethylcycloheptyl)benzoic acid (10*a cis*)

A small sample of 4-(*cis*-4-methoxy-1,4-dimethylcycloheptyl)benzonitrile (**10** *cis*) (44.5 mg) in aqueous sodium hydroxide (4.0 mL, 10%) was stirred and heated, at the boiling point, until the oily photo-NOCAS product dissolved; the solution turned slightly yellow. This mixture was cooled and extracted with dichloromethane. The aqueous layer was acidified with hydrochloric acid (conc.), and extracted with benzene. Evaporation of the solvent left a colourless viscous oil (35 mg). Ammonia gas was bubbled into a benzene solution of this oil and a solid precipitated. The solvent was evaporated to dryness, the residue was redissolved in benzene, and crystals (**10***a cis*) for X-ray analysis, grew upon cooling.

*4-(*cis-*4-Methoxy-1,4-dimethylcycloheptyl)benzoic acid (**10a** cis)*: mp 117–120°C; infrared (Nicolet 205) ν: 2961(s), 2937(s), 2926(s), 2905(s), 2871(s), 1718(s), 1688(vs), 1610(m), 1417(m), 1284(s), 1248(m), 1122(m), 1070(m); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 8.03 (d, 2H, aryl hydrogens next to carbonyl), 7.47 (d, 2H, aryl hydrogens next to alkyl), 3.12 (s, 3H, methoxy), 2.10–2.35 (m, 2H), 1.86–1.94 (m, 1H), 1.35–1.65 (m, 7H), 1.25 (s, 3H), 1.16 (s, 3H); ^{13}C nmr (62.9 MHz, $CDCl_3$, proton decoupled) δ_{TMS}: 171.56, 157.12, 130.17 (d), 126.48, 126.21 (d), 76.92, 48.66 (q), 41.55 (t), 41.51, 41.16, 33.25, 32.86 (t), 31.44, 25.45, 19.47; mass spectral data by Finnigan 4500 with programmed solids probe (70 eV) *m/z* (% rel. abund.): 276.3(11.4), 261.3(2.8), 215(2.7), 149.1(5.2), 99.1(23.5), 85.1(100); X-ray data: see supplementary material; $C_{17}H_{24}O_3$.[3]

Metal ion – biomolecule interactions. Part 16.[1] C(2)-H isotopic exchange in Co(III)-coordinated imidazoles

Erwin Buncel, Fan Yang, Robert Y. Moir, and Ikenna Onyido

Abstract: Transition-metal-bound imidazoles are suitable models for evaluating the roles of metal ions in biomolecules having the imidazole moiety and similar heterocyclic residues as part of their structure. Such studies provide useful insights into metal–biomolecule interactions in biological systems, especially when the lability of the metal–ligand bond is substantially reduced, such that the identity of the metal–ligand complex is preserved during the course of the reaction under investigation. The present paper reports on a kinetic study of tritium exchange from the C(2) position of the imidazole moiety in the substitution-inert complex cations $[Co(NH_3)_5[2\text{-}^3H]\text{-imidazole}]^{3+}$ (**1**) and $[Co(NH_3)_5\text{-1-methyl-}[2\text{-}^3H]\text{-imidazole}]^{3+}$ (**2**). Rate–pH profiles have been determined in aqueous solution at 60°C. Both substrates are believed to react through rate-determining attack of hydroxide ion (k^{M+} pathway) at C(2)-T. Dissection of the kinetic data reveals an additional pathway for **1** consequent upon deprotonation of its pyrrole-like N-H(T) to yield **3**, which is then attacked by hydroxide at C(2) (k^M pathway). The ratio $k^{M+}/k^M = 10^3$ that is obtained is in accord with the expected reduced reactivity of **3**. Comparison of the present data with those reported for a variety of heterocyclic substrates shows that the order of reactivity, protonated ≫ metal ion coordinated ≫ neutral form of substrates, prevails. The superiority of the proton over metal ions in catalyzing isotopic hydrogen exchange is attributed to its larger ground state acidifying effect coupled with the greater transition state stabilization it affords, relative to metal ions. The exchange reaction of **3** via the k^M pathway is the first example of a reactive anionic species in which the negative charge is located α to the exchanging C-H.

Key words: tritium exchange, cobalt (III)-coordinated imidazoles.

Résumé : Les imidazoles liés à des métaux de transition sont des modèles appropriés pour évaluer les rôles des ions métalliques dans des biomolécules dont une partie de la structure contient de l'imidazole ou des résidus hétérocycliques semblables. De telles études fournissent des données utiles sur les interactions métal–biomolécule des systèmes biologiques, en particulier lorsque la labilité du complexe métal–coordinat est grandement réduite alors que l'identité du complexe métal–coordinat est préservée durant la réaction étudiée. Dans ce travail on rapporte les données obtenues au cours d'une étude cinétique de l'échange du tritium de la position C(2) de la portion imidazole lors de substitutions des cations complexes inertes $[Co(NH_3)_5\{2\text{-}^3H\}\text{-imidazole}]^{3+}$ (**1**) et $[Co(NH_3)_5\text{-1-méthyl-}\{2\text{-}^3H\}\text{-imidazole}]^{3+}$ (**2**). On a déterminé les profils vitesse–pH en solutions aqueuses à 60°C. On croit que les deux substrats réagissent par le biais d'une attaque de la position C(2)-T par l'ion hydroxyde (voie k^{M+}) qui détermine la vitesse de la réaction. La dissection des données cinétiques révèle l'existence d'une autre voie réactionnelle du composé **1** qui suit la déprotonation de son N-H(T), qui ressemble à un pyrrole, en composé **3** qui est alors attaqué par l'hydroxyde en position C(2) (voie k^M). Le rapport $k^{M+}/k^M = 10^3$ qui est obtenu est en accord avec la réactivité réduite attendue pour le composé **3**. Une comparaison des données obtenues ici avec celles rapportées pour une variété de substrats hétérocycliques montre que l'ordre de réactivité, protoné ≫ ion métallique coordiné ≫ forme neutre des substrats, prévaut. On attribue la supériorité du proton sur les ions métalliques dans la catalyse de l'échange des isotopes de l'hydrogène à son effet plus prononcé d'acidification de l'état fondamental couplé à la stabilisation plus grande de l'état qu'il lui fournit par rapport aux ions métalliques. La réaction d'échange du composé **3** par le biais d'une voie k^M est le premier exemple d'une espèce anionique réactive dans laquelle la charge négative est située en alpha de la liaison C-H qui s'échange.

Mots clés : échange du tritium, imidazoles coordinés au cobalt(III).

Introduction

Considerable interest has been devoted to the study of isotopic hydrogen exchange in imidazole and similar five-membered heterocycles and their derivatives (1–4), which are key constituents of many naturally occurring biologically important molecules whose roles are important to life processes (5, 6). As the heteroaromatic component of histidine, imidazole functions to bind metal ions to protons (7). The utility of isotopic hydrogen exchange from the C(2) position of imidazole as a diagnostic tool in biological system has been successfully exploited in the identification of site specificity in the binding of histidine residues of β-lactamase II and superoxide dismutase with metal ions (8).

Studies of metal ion effects on isotopic hydrogen exchange in these ligands and their derivatives, including purines, have been undertaken with the aim of evaluating the role of metal ions in biological systems (9–11). Two approaches are available in these studies. The first consists in the direct introduction of metal ions as their soluble salts into reaction media containing the ligand. A common problem with this method lies in the fact that, in most cases, the metal ions involved, e.g., $CH_3Hg(II)$, Ag(I), Pb(II), Co(II), Zn(II), etc., form *kinetically labile* complexes in solution (12), leading to unknown dissociation equilibria and uncertain stoichiometries, with attendant kinetic complications and ambiguities in evaluating rate data. A new strategy that we have adopted in the present paper involves the synthesis, isolation, and study of the exchange rates of labelled *substitution inert* complexes (12). This approach overcomes the pitfalls pointed out above and is preferred because it ensures that the identity of the reacting species is established under optimized experimental conditions. Both these approaches have been combined in the general Scheme 1. In this scheme the metal-coordinated species can be considered as formed through addition of salts, or alternatively, as in the present work, isotopic exchange is studied on the isolated complexes.

We report herein a kinetic investigation of the detritiation of the *substitution inert* complex cations $[Co(NH_3)_5[2\text{-}^3H]\text{-imidazole}]^{3+}$, **1**, and $[Co(NH_3)_5\text{-1-methyl-}\{2\text{-}^3H\]\text{-imidazole}]^{3+}$, **2**. There is general interest in cobalt (III) complexes of imidazole derivatives because of the role this metal has in vitamin B_{12} and related compounds (13).

A number of studies in the literature compare reactivity towards hydron exchange at C(2) of free and Co(III)-coordinated imidazoles. Thus imidazole undergoes C(2) deuteration at 50°C and pH 10–11 with $t_{1/2}$ = 119 min (2*b*). Coordination to Co(III) as in **1** reduces reactivity of the ligand to the extent that no exchange occurs at 44°C under basic or acidic conditions (14). Similarly, 1-methylimidazole undergoes deuteration in D_2O at the same position with $t_{1/2}$ = 42 min at pH 10–11 and 50°C (2*b*), and $t_{1/2}$ = 99 min and 5 days at pH 8.1 and 5.0, respectively, at 44°C (14). When the imidazole ligand is coordinated to Co(III) as in **4**, deuterium exchange at room temperature and pH 12 occurs with the substantially different $t_{1/2}$ of 16 h (15). These data point to the apparent inhibitory effect of Co(III) coordinated at N(3), relative to the proton, towards C(2)-H exchange in the imidazoles. Similar effects by other metals ions have been reported in our earlier work (9) and by other workers (10, 11) for other imidazole-containing systems.

The present paper reports on the detritiation rates of **1** and **2**

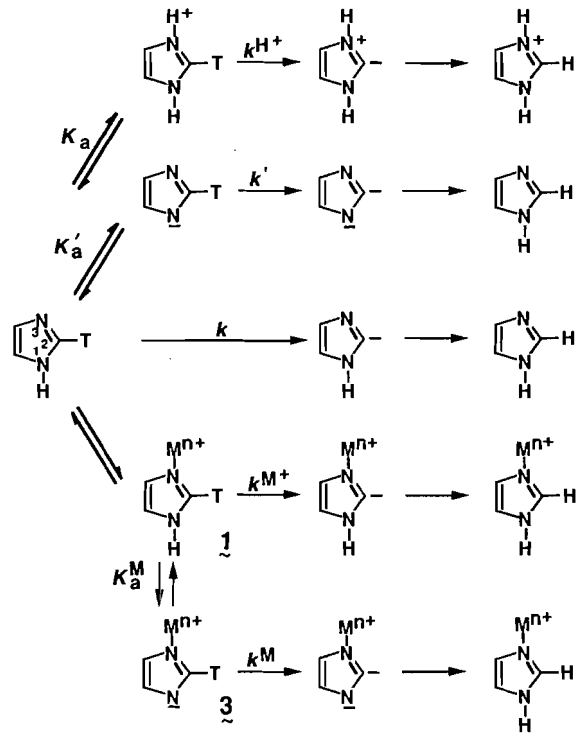
Scheme 1.



under experimental conditions corresponding to work reported in our previous paper (9), thus enabling comparison of reactivity in these systems. As well, the data presented herein provide a firm basis for the comparison of proton activation versus metal ion activation.

Kinetic and thermodynamic rationales for the inferior activating capability of metal ions relative to the proton are discussed in relation to Scheme 1 in which structures **1** and **3** are shown in abbreviated form. Surprisingly, dissection of the rate data for **1** provides kinetic evidence for the exchange of the imidazolide ion, **3**, resulting from N-H deprotonation of **1**.

This is the first reported instance of hydroxide ion attack on an imidazolide ion bearing negative charge adjacent to the exchange site. Comparison with rate data for detritiation of anionic forms of purine derivatives (at N(1) or N(3)) (16*a*) affords an indication of the magnitude of electrostatic influences on reactivity in these systems, noting that in the purines N-H ionization takes place in the ring annelated onto the imidazole ring where C-H exchange occurs, whereas in imidazoles the effect of N-H deprotonation on exchange is expected to be much greater.

Results and discussion

Rate profiles, mechanism, and identity of reacting species

The observed first-order rate constants, k_{obs}, measured for the detritiation of $[Co(NH_3)_5\{2\text{-}^3H\}\text{-imidazole}]^{3+}$ (**1**) and $[Co(NH_3)_5\text{-1-methyl-}\{2\text{-}^3H\}\text{-imidazole}]^{3+}$ (**2**) in aqueous buffer solutions at 60°C are listed in Table 1 and shown graphically in Figs 1 and 2 in the forms of rate–pH profile over the pH range 7.7–10.5 for **1** and a plot of k_{obs} vs. $[OH^-]$ for **2**.

The mechanism of detritiation of imidazole-type compounds as shown in Scheme 1 is believed to involve rate-limiting attack of hydroxide ion on either the N(3)-protonated (k^{H+} pathway) or the neutral forms (k pathway) of the substrate (1*a*, 3, 4, 16). In the former case, the reaction proceeds through an ylide intermediate. Neutral forms of the substrate are by far less reactive than their protonated counterparts, rate constants for the reaction of the latter species being 10^7–10^9 times greater than for the former in purines where data are available. It is reasonable to suppose that rate differences of a similar magnitude also exist in imidazole and related heterocycles. At high pH the pyrrole-type N-H in these substrates can undergo deprotonation and the resulting species may in principle also be reactive (k' pathway). Note that this pathway has been observed in purines where deprotonation occurs in the other ring, at N(1) as in Scheme 2, but not in imidazoles. Rate–pH profiles of various descriptions have been reported and these provide information regarding the identity of reacting species as well as the presence of any derived but unreactive species (16).

The simplest kinetic scenario for isotopic exchange in these heterocycles is presented by model compounds such as 1,3-dimethylimidazolium (2*d*) and 1,3-dimethylbenzimidazolium (16*d*) ions in which N-alkylation at N(1) and N(3) prevents proton transfer processes that occur at the heteroatoms in acidic and basic media. Such compounds obey a simple second-order rate expression, as in the present case for complex **2**. Thus complex **2** obeys eq. [1], as is shown by the linear plot in Fig. 2. The second-order rate constant for hydroxide ion attack on **2** is obtained as the slope of the plot in Fig. 2, $k^{M+} = 1.47 \times 10^{-1}$ m^{-1} s^{-1}, $r = 0.997$, at 60°C.

$$[1] \quad k_{obs} = k^{M+}[OH^-]$$

Comparing **1** and **2**, the only structural difference between the two complexes is in the methylation state at N(1) and any difference in the rate profiles of the two substrates can reasonably be accounted for by consideration of N-H deprotonation in **1**. Scheme 1 provides a composite picture for the reaction of **1** and two mechanisms are discernable. In the first mechanism, termed *Mechanism I*, hydroxide ion attack on **1** is the only significant pathway to generate products; thus $k^M = 0$ and **3** forms a reservoir of unreactive substrate. The relevant rate expression for this mechanism, derived according to standard procedures, is given by eq. [2] in which k^{M+} is the second-order rate constant for hydroxide ion attack on the complex, while K_w (= 9.64×10^{-14}) (17) and K_a^M are the ionization constants for water and N(1)-H of **1**, respectively.

$$[2] \quad k_{obs} = \frac{k^{M+}K_w}{K_a^M + [H^+]}$$

The second mechanism (*Mechanism II*) confers kinetic activity on both substrate forms in solution, hence k^{M+} and k^M have finite values, although it is reasonable to expect that the condition $k^{M+} > k^M$ holds. Equation [3] is the appropriate rate equation for this mechanism, k^M being the second-order rate constant for hydroxide ion attack on **3**, the anionic form of **1**.

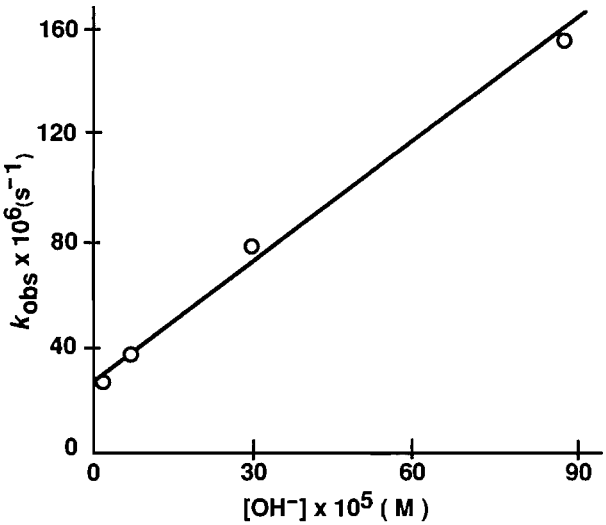
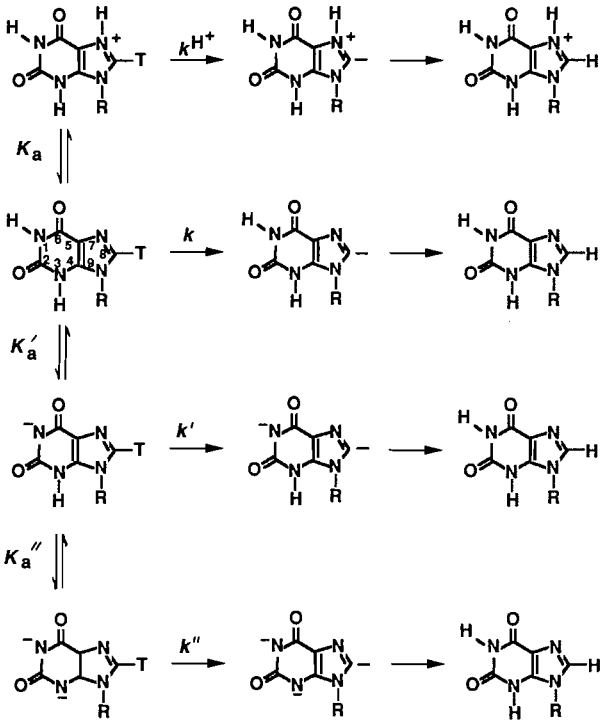
Fig. 2. Plot of k_{obs} vs. $[OH^-]$ according to eq. [1] for the detritiation of $[Co(NH_3)_5$-1-methyl{2-^{3}H}imidazole$]^{3+}$, **2**, in aqueous buffers at 60°C.



Scheme 2.



$$[3]\quad k_{obs} = \frac{k^{M+}K_w + k^M K_a{}^M[OH^-]}{K_a{}^M + [H^+]}$$

In consideration of the two mechanisms, I and II, an important clue lies in the nature of the rate–pH profiles that are predicted by eqs. [2] and [3]. Rate–pH profiles have in the past been found diagnostic of mechanism in isotopic exchange studies of imidazole and purine compounds in the presence of metal ions (16). Thus eq. [2] corresponding to Mechanism I predicts an initial increase in rate at low pH to be followed by a plateau at high pH. On the other hand, for eq. [3], which corresponds to Mechanism II, no pH-independent region is expected, rather a curve with an inflection point is predicted, with an increase in k_{obs} in the high pH region (>10).

Table 2. Rate and equilibrium data obtained by nonlinear least-squares treatment of kinetic data for **1**.

Mechanism	$pK_a{}^{M}$[a,b]	k^{M+} (M^{-1} s^{-1})[a]	k^M (M^{-1} s^{-1})[a]	s.d.[c]
I	8.09	1.10		0.127
II	8.00	1.24	1.21×10^{-3}	0.046

[a]These quantities are defined in the text.
[b]Values are obtained as adjustable constants in the nonlinear least-squares treatment.
[c]Standard deviation from calculated curve.

Kinetic data for **1** in Table 1 have been subjected to nonlinear least-squares treatment for both mechanisms. The results are given in Table 2, along with $pK_a{}^M$ values obtained as adjustable constants by logarithmic fitting. *The superiority of Mechanism II over Mechanism I is clearly evident* from the magnitude of the standard deviation obtained by assuming either mechanism.

Figure 1 shows that the curve calculated according to eq. [3] fits the experimental data well in the sense that an initial sharp rise in rate in the low-pH region is followed by a region of moderate increase in rate, with an inflection point apparent in the curve, and is followed by a more rapid increase in rate at pH > 10. Experimental points could not be obtained at pH ≥ 11 due to instability of **1** in strongly basic solutions. However, it is noted that if one chooses to remove the experimental point at pH 10.5, the fit of the data according to eq. [3] (i.e., nonlinear least-squares treatment) is essentially as good as when the point is incorporated and the resulting curve passes above the omitted point. The increase in rate in the high-pH region on the basis of Mechanism II is readily seen, on inspection of eq. [3], as resulting from the second term in the equation, which accords the contribution from the k^M-containing term to the ionized form of the substrate, **3**. In the present case N(1)-H in **1** is relatively acidic with a calculated $pK_a{}^M$ value at 60°C of 8.00 (the measured value is 10.0 at 25°C (8)). Hence even at the lowest pH studied a significant proportion of the substrate (36%) exists as **3**. At pH 10.5 an overwhelming proportion (99.6%) is in its N(1)-deprotonated form. Thus as long as k^M holds a finite value, an increase in rate in the high-pH region is predicted.

Therefore we have here clear evidence of titrium exchange from an anionic species in which the negative charge is located α to the exchanging position, the first reported instance of such a process. The ratio $k^{M+}/k^M = 10^3$ shows overwhelming preference for the former pathway and indicates the magnitude of the unfavourable electrostatic interaction resulting from approach of hydroxide ion to the exchange site. Hitherto, such information was available only in purines where the negative charge is located *outside* the imidazole ring (vide infra).

In concluding this section it is appropriate to comment on the magnitude of the acidifying effect of Co(III) in this system. First we can compare the pK_a value for N(I)-H ionization in **1** with that in neutral imidazole, for which pK_a values have been given as 10.0 and 14.2, respectively (18, 6*b*). This acidi-

[a]The quantities given in this table are defined in the text; p*K* values are at 25°C while kinetic data are at 85°C, except when stated otherwise.
[b]Value obtained from nonlinear least-squares treatment of kinetic data for **1** at 60°C. (pK_a^M, see Scheme 1).
[c]Kinetic data at 60°C.
[d]Refers to the dissociation of the exocyclic $-NH_2$ or -SH function.
[e]Calculated from kinetic data at 85°C by application of the Perrin equation (see ref. 32).
[f]Calculated from original data.

fying effect can be ascribed to a highly effective charge withdrawal by Co(III), thus stabilizing the deprotonated form. Considering next proton loss at C(2), the stabilizing effect of Co(III) will be greater than for N(1)-H ionization since this effect attenuates with distance (18). The *kinetic acidity* enhancement is expected to be less than thermodynamic acidity enhancement, but one could well expect a 10^3–10^4 enhancement of kinetic acidity in **1** relative to imidazole in C(2)-H abstraction.

Since we have previously found (19), for detritiation of imidazole at C(2), $k = 1.28 \times 10^{-2}$ M^{-1} s^{-1} at 85°C, which can be corrected to 60°C as $k = 1.15 \times 10^{-3}$ M^{-1} s^{-1}, then using E_a = 20.2 kcal/mol (2*d*) and the presently determined value k^{M+} = 1.24 M^{-1} s^{-1} (Table 2), we obtain the rate ratio $k^{M+}/k \approx 1 \times 10^3$. Though N(1)-deprotonated imidazole is unreactive in isotopic exchange (11*a*, 19) (i.e., k' in Scheme 1 not measurable), it is feasible that the acidifying effect of Co(III), as in **3**, has brought this kinetic process into a measurable range, thus accounting for our conclusion that Mechanism II in Scheme 1 is operating, with $k^{M+}/k^{M} \approx 10^3$. Further discussion of the acidifying effect of various metal ions at N(3)/N(7), in imidazoles and purines, is given in a later section.

Proton activation versus metal ion activation

Table 3 summarizes rate and equilibrium data for a number of heterocycles for subsequent discussion. For compounds containing the imidazole moiety, including **1**–**3**, rate constants are as defined in Scheme 1 while K_a and K_a' refer to ionization constants for N(3) and N(2). For purines k' and k'' refer to second-order rate constants for hydroxide ion attack on the N(1) mono-anionic and N(1), N(3) dianionic species while K_a' and K_a'' are the corresponding acid ionization constants and K_a is the ionization constant for N(7), see Scheme 2; other quantities for the purines retain the same significance as for imidazoles.

Previous studies (11, 16, 20) involving purines and related substrates have shown that, where no kinetic complications arise from the existence of zwitterionic forms of the substrate in solution, the conjugate acid of the substrate reacts 10^7–10^9 times faster than the neutral substrate. This can be illustrated

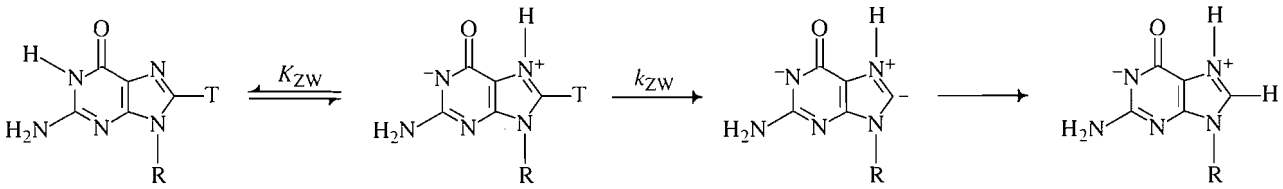
Scheme 3



by considering the ratios k^{H+}/k, the proton-activating factor (16*b*, *c*) obtainable from Table 3 for 9-alkylpurines, adenosine, caffeine, and theobromine (not shown in Table 3). Values of k for the reactions of the neutral forms of imidazole, 1-methylimidazole, and benzimidazole are not available, but it is reasonable to expect k^{H+}/k ratios of similar magnitude. The rest of the substrates in Table 3, including histidine (4*e*) and 1-methylhistidine (9), give rise to zwitterionic forms in solution. It has been shown (9, 21*c*) that for such substrates k is a composite function according to eq. [4], where k_0 is the rate constant

$$[4] \quad k = k_0 + k_{zw}K_{zw}$$

for hydroxide ion attack on the "neutral" molecule, k_{zw} is the rate constant for attack on the zwitterionic form, and K_{zw} is the equilibrium constant for zwitterion formation. Guanosine affords a good example of such substrates and the relationship between k_{zw} and K_{zw} is shown in Scheme 3. This latter group of substrates are not good models for the reaction of neutral forms because k_{zw} is of the same magnitude as k^{H+}, giving rise to exaggerated k values (eq. [4]).

The kinetic superiority of protonated substrates over their neutral counterparts arises from the location of the positive charge at N(3)/N(7) in the protonated forms, a position α to the exchange site. In principle, placement of multiple charges at N(3)/N(7) of imidazoles or purines through coordination with multiply charged metal ions should produce accelerations of greater magnitude than those induced by the proton, such that $k^{M+} > k^{H+}$. Hence k^{H+}/k^{M+} ratios should be less than 1 but, in practice, metal-coordinated substrates have exhibited reactivity far smaller in magnitude than their protonated analogues, reported k^{H+}/k^{M+} values being of the order of 10^2–10^5. The values of this ratio for several heterocycles and different metal ions are listed in Table 4. Combination of the rate data for imidazole and 1-methylimidazole (1) with the present results for **1** and **2** provides estimates of k^{H+}/k^{M+} values of ca. 8×10^2 and 1×10^4 for imidazole and 1-methylimidazole, respectively, after correction for temperature differences in the two studies. This provides a quantitative indication of the kinetic effect of Co(III) relative to the proton in these processes. To date, there has been only one reported case of acceleration of isotopic hydrogen exchange in heterocycles due to coordination by a metal ion, of equal magnitude to or exceeding that induced by protonation (1*b*).

Metal-ion-coordinated species versus neutral species

In Table 4 is evaluated also the activating influence of metal ions, the so-called metal-activating factor (16*b*), expressed as the ratio k^{M+}/k. This quantity has been obtained either directly from rate data reported for the relevant species or as an estimate by taking the ratio $(k^{H+}/k)/(k^{H+}/k^{M+})$. The picture that emerges is one in which metal-coordinated species are 10^3–10^6 times more reactive than the neutral substrates, even though the former are themselves less reactive than the protonated forms. The following hierarchy of reactivity therefore emerges: protonated ≫ metal-ion-coordinated ≫ neutral species.

We have already examined (9) the disparity in behaviour between protonated and metal-coordinated forms of substrates in these systems and concluded that it results from a difference in the magnitude of positive charge located on N(3) or N(7) α to the exchange site, based on a simple electrostatic model proposed by Norris, Buncel, and Taylor some years ago (22). Thus the fractional charge at N(3) of imidazoles (or N(7) of purines and similar substrates) is much higher with the proton or the methyl cation (a good model for the proton on electrostatic grounds) than with metal ions. The C(2)/C(8) proton is substantially acidified through N(3)/N(7) protonation as is evident from the estimated pK_a values listed in Table 5. Deprotonation of C(2)-H/C(8)-H from the conjugate acid of the substrate produces an ylide intermediate that is stabilized by charge delocalization. The transition state for C(2)-H/C(8)-H deprotonation is believed to be product-like (4*b*); hence it will benefit substantially from resonance stabilization of the ylide and this would result in appreciable rate enhancement when compared with the unprotonated substrate. Both of these ground-state and transition-state effects are absent in the neutral molecule. We have here a clear case of thermodynamic and kinetic factors reinforcing each other to produce relatively facile C(2)/C(8) proton transfer in the protonated species.

When the proton is replaced by a metal ion, the positively charged centre is effectively removed from N(3)/N(7) and is located on the metal itself; hence the acidifying effect of the metal is far less than that of the proton. The pK_a values of C(2)-H in Table 5 are in this direction. As well, Rowan et al. (14) reported ^{1}H nmr chemical shift differences (Δδ) of 1 and 0.5 ppm for C(2)-H of imidazole upon protonation and coordination to Co(III), respectively. Also consistent with the above hypothesis is the observed (23) decrease in electron density in coordinated heterocycles induced by the following electrophiles according to the order: H^+ > Co(III) > Rh(III). Furthermore, the pK_a values of −1.7, 7.3, and 1.7 measured for the acid–base equilibrium of eq. [5] for M = H^+, Cu(II), and Co(III), respectively (10, 24), indicate that (*i*) these metal ions are poorer Lewis acids than the proton, and (*ii*) the polarizing power of the proton is by far greater than of the metals. Taken together, it is manifestly clear that C(2)-H/C(8)-H is more acidic in the protonated substrate than in the metal-ion-coordinated form.

$$[5] \quad M(H_2O)_n^{z+} \rightleftharpoons M(H_2O)_{n-1}(OH^-)^{(z-1)+} + H^+$$

[a]Reference 18*b*.
[b]Estimated in ref. 16*d* from kinetic data obtained at 85°C.
[c]Estimated (3*b*) from kinetic data obtained at 30°C.
[d]Estimated from kinetic data obtained in this work at 60°C by assuming that reprotonation of the carbenoid intermediates is diffusion controlled.

Superimposed on the inferior acidifying capability of the metal ion relative to the proton is the loss of resonance stabilization by the carbenoid intermediate derived from the metal-coordinated species. This intermediate is stabilized solely by the inductive effect provided by the metal through M^{n+}—N σ-bond polarization. Conceivably, this effect will be much less than the resonance stabilization afforded the ylide intermediate, with the consequence that the transition state for formation of the metal-coordinated carbenoid species will be less stabilized than the corresponding transition state for ylide formation, leading to rate reduction in the former process. On both thermodynamic and kinetic grounds, therefore, the protonated species is favoured over its metal-ion-coordinated counterpart.

There are indications, however, that π-type metal–ligand back-bonding may be important in these systems (20)[3], though a full discussion of the scope and magnitude of such an effect is not warranted at this stage. Systematic variation of transition metal ions coordinated to N(3)/N(7) to produce a range of *substitution-inert* complexes will aid such discussion. Such experiments are being planned.

Isotopic exchange in anionic species

Anionic forms of imidazole and benzimidazole produced through N(1)-H deprotonation at high pH have not previously been observed to show kinetic activity (11*a*, 16*a*, 19). The same situation is observed with purine itself in which the N(9)-H deprotonated form is unreactive (21*a*). This has been attributed to the proximity of the negative charge on N(1)/N(9) to the exchange site, with the effect that the approaching hydroxide ion experiences unfavourable electrostatic interactions (destabilization of the dianionic intermediate and of the transition state leading up to it). In principle, therefore, development of negative charge at a site remote from the exchanging C(2)-H/C(8)-H should result in less inhibiting electrostatic interactions, with the possibility of observing anionic species with measurable kinetic activity. Purine-type molecules, with ionizable N-H groups at N(1) or N(3), sites that are well removed from the exchanging C(8)-H, meet this requirement.

Jones and co-workers have reported rate constants (k') for exchange reactions of anionic species derived from theobromine (16*a*), paraxanthine (16*a*), 6-mercaptopurine riboside (25), and xanthosine (16*a*) (Table 3). Values of k' obtained, though small (10^{-4}–10^{-3} M^{-1} s^{-1}), are not drastically different from those of k (10^{-3}–10^{-2} M^{-1} s^{-1}), emphasizing the fact that electrostatic interactions become less important with increased distance, as expected. The anionic form of 6-mercaptopurine riboside, in which the negative charge resides on the exocyclic sulfur atom, has reactivity comparable to that of theobromine. Values of k and k' for xanthosine appear to be unusually high and it is interesting to note that this substrate exchanges also in its dianionic form, via the k'' pathway.

Complex **3** with its negative charge located on N(1), α to the exchange site, shows a reactivity that is comparable to that of N(1)-deprotonated theobromine. This reflects a balance between the destabilizing electrostatic effect of the negative charge on N(1) and the evidently larger acidifying/stabilizing effect of Co(III) in **3**. A good model with which to compare the behaviour of **3** would be the anionic form of 3-methylimidazolium ion, for which, however, no data are available.

Reactivity of imidazole/1-methylimidazole versus 1/2

In our previous studies (1*a*, 9) we observed increased reactivity consequent upon methyl or benzo substitution of the imidazole nucleus. These reactivity differences could not be explained on the basis of linear free energy considerations (3*a*, 16) in which the pK_a for N(3) or N(7) protonation in imidazoles or purines would reflect the magnitude of fractional charge on C(2) and thus provide a measure of C(2)-H acidity. Thus, in the pairs imidazole/1-methylimidazole,

[3] E. Buncel and H.A. Joly. Unpublished work.

For personal use only.

benzimidazole1/1-methylbenzimidazole, and histidine/1-methylhistidine, the N-methylated substrate reacts ca. 2–3 times faster than its unmethylated analogue, in spite of their identical pK_a's. We explained (1*a*, 9) this unusual reactivity sequence in terms of frontier and perturbational molecular orbital theory (FMO and PMO theory, respectively), in which N-methylation effects greater stabilization energy difference in the intermediate state than in the reactant state such that $\delta SE^I > \delta SE^R$. Comparing the substrate pair **1/2** with the imidazole/1-methylimidazole pair, it is noted that the reactivity sequence observed in the latter is reversed in the former. Thus, while k_{Me}/k_H is ca. 2 in the imidazole/1-methylimidazole pair, the same ratio is 0.13 in **1/2**. The rate constant k_{Me}/k_H ratio for the imidazole/1-methylimidazole pair actually refers to their protonated forms; hence replacing the proton in that reactant pair with Co(III) in **1/2** has reversed the observed reactivity pattern.

The effect of Co(III) on the magnitude of the k_{Me}/k_H ratios probably reflects the influence of *d*-orbital interactions in the systems involving transition metal ions that are absent when the electrophile coordinated at N(3) is the proton. It is to be noted that the present results can be accommodated by the inductive effect of the N(1)-CH_3 in the transition state, which is destabilizing on the incipient negative charge at C(2). Clearly more work is needed in order to understand more fully the effects of different transition metal ions on k_{Me}/k_H ratios.

Conclusions

The results discussed herein permit us to draw the following conclusions:

1. The effect of N(3) protonation on C(2)-H exchange in imidazoles is far greater than the effect of Co(III) coordination at the same site, as in **1** and **2**, which in turn, is activating for C(2)-H deprotonation relative to the neutral substrates. Thus the order of reactivity is protonated ≫ metal coordinated ≫ neutral forms of the substrate.

2. When the substrate is capable of existing as a zwitterion in solution, the value of the second-order rate constant for reaction of the neutral form, *k*, is exaggerated through contribution from k_{zw}, the kinetic constant for reaction of the zwitterionic form; the latter quantity is of the same magnitude as the rate constant for the proton-catalyzed pathway, k^{H+}.

3. The superiority of protonation over metal-ion coordination in facilitating the exchange process has both thermodynamic and kinetic components. Thus the acidifying effect of the proton and the stabilization of the transition state of reactions in which it is present at N(3)/N(7) are both greater than the corresponding effects of metal ions.

4. Deprotonation of **1** produces **3** in solution, which, in turn, has been found to undergo exchange at C(2), thus furnishing the first reported example of C(2)-H exchange occurring at a position α to N(1) bearing negative charge. Both acidifying and rate-enhancing effects of Co(III) override the destabilizing influence of the negative charge, to produce rates comparable to those in anionic forms of purines where the negative charge is remote from the exchange site.

5. The observed reactivity relationship in which N(1)-CH_3 is rate enhancing relative to N(1)-H is reversed on coordination by Co(III), pointing to the more complex situation represented by replacement of a proton by a transition metal ion in these processes.

Experimental section

Preparation of complexes

$[Co(NH_3)_5imidazole](ClO_4)$ and $[Co(NH_3)_5$-1-methylimidazole$](ClO_4)$ were prepared according to literature procedures (14, 26, 27) and their identities and purity checked by comparing their uv–visible and ^1H nmr spectroscopic characteristics with published data (26–29).

Tritiation of complexes

Tritiated water (20 μL, 1 Ci/mL) was added via a syringe to $[Co(NH_3)_5imidazole](ClO_4)$ (17.4 mg) placed in a heavy-walled glass ampoule. The glass ampoule was stoppered with a rubber septum, its contents frozen in liquid N_2, and the ampoule evacuated. It was then sealed, and suspended in an oil-bath at 75°C for 48 h, following which it was removed and allowed to equilibrate to room temperature. The ampoule was then opened and its contents pipetted into a 25 mL pear-shaped flask to which 1 mL of distilled water was added to exchange labile tritium. The solvent was removed by lyophilization. Aliquots of 1 mL of water were added successively and lyophilized until the activity of the lyophilized water became negligible. A stock solution of **1** was then prepared by dissolving a known amount in 0.8 mL of freshly distilled DMSO in a test tube, which was stoppered and stored in a refrigerator.

The same procedure was adopted for $[Co(NH_3)_5$-1-methylimidazole$](ClO_4)_3$ except that 15 mg of the complex was used and that the tritriation was carried out in an oil bath at 60°C for 30 h.

Hydrogen–deuterium exchange experiments

Preparation of NaOD solutions

Sodium metal, purified by refluxing freshly cut sodium metal for 1.5 h in pure xylene, was dissolved in small portions in 50 mL of D_2O in a dry box previously flushed with dry N_2. The resulting NaOD was standardized with HCl and diluted as appropriate for the deuterium exchange experiments.

2. C(2)-H exchange measurement by nmr

The diamagnetic nature of Co(III) complexes makes it possible to optimize reaction conditions for detritiation experiments by following the rates of deuteriation of the exchangeable proton using ^1H nmr spectroscopy, which was done using a Bruker HX-60 or AC-F200 spectrometer. Typically, a sample of the substrate (ca. 15 mg) was dissolved in D_2O and the pH adjusted to the required value with NaOD in a dry box. An aliquot was then pipetted into an nmr tube and kept at constant temperature. At various intervals, the ^1H nmr spectrum of the sample was recorded with integration of peak areas. The fraction of the exchanging H left at a given time was calculated by reference to a nonexchanging peak, in this case the C(4)-H or C(5)-H, which are unreactive under the experimental conditions. The result was expressed as per cent exchange.

It was found from these ^1H nmr studies that the detritiation experiments could be conveniently carried out within the pH range 7.7–10.5 at a temperature of 60°C. At lower pH the exchange rate was very slow, while the complexes decomposed at higher pH and higher temperatures.

Preparation of buffer solutions

Sodium borate – hydrochloric acid and sodium carbonate – sodium bicarbonate buffers (32) were prepared for the kinetic measurements at the pH range of the study.

Kinetic study of tritium exchange

The rates of detritiation of **1** and **2** were measured by determining changes in radioactivity of the reaction mixtures with time (t_n). The substrate solution (20 μL) was in each case pipetted into 20 mL of buffer solution contained in a 50 mL round-bottom flask. The reaction mixture was equilibrated for no less than 30 min at 60°C and then shaken thoroughly. Aliquots of 1 mL were withdrawn at known times (t_0, ... t_n) using an Eppendorf automatic pipette and transferred to a 50 mL round-bottom flask containing 0.1 g NaCl. The flask was quickly frozen with liquid N_2 and the time recorded. The flask was then attached to a freeze-drying apparatus and water was removed by lyophilization. An aliquot of 0.1 mL of the lyophilized water was pipetted into a scintillation vial containing 4 mL of Beckman HP Ready-solv and assayed for tritium (C_t) on a Beckman LS5801 liquid scintillation counter. All kinetic samples were treated similarly. The infinity count (C_∞) was taken by assaying 0.1 mL of the initial reaction mixture in 4 mL of the liquid scintillator.

The first-order rate constants, k_{obs}, for C(2)–T exchange of **1** and **2** in aqueous buffers were obtained from the slopes of the plots of log ($C_\infty - C_t$) vs. time. All such plots yielded good straight lines for 75% exchange or more.

Calculation of surface tension of salt solutions: effective polarizability of solvated ions

Robert A. Stairs

Abstract: The Onsager–Samaras version of Wagner's theory of surface tension of solutions of 1:1 salts has been modified to include ion-induced dipole terms in the image potential. Effective solvated ionic polarizabilities are used, which are large and negative owing to local dielectric saturation around the ions. The modified theory agrees with the order of magnitude of the variation among various alkali halides (e.g., $\Delta\sigma$ for 0.1 molar aqueous KI is about 70% of the corresponding value for KCl). Polarizabilities were estimated from Hasted's dielectric decrements.

Key words: surface tension, salt solutions, symmetric electrolytes, effective polarizability, theory.

Résumé : On a modifié la version de la théorie de Wagner, elaborée par Onsager et Samaras, de la tension superficielle des solutions des sels 1 : 1, par l'addition à l'expression pour l'énergie potentielle due à l'image d'un terme représentant l'énergie charge/dipolaire. On a employé des polarisabilités effectives qui sont grandes et négatives, à cause de la saturation diélectrique près de l'ion solvaté. La théorie ainsi modifiée est en accord approximatif avec la variation entre divers sels. (Par exemple, l'élévation de la tension superficielle de l'eau dans une solution 0,1 molaire par le IK est de 70% de celle par le CIK.) On a estimé les polarisabilités à partir des décroissements diéléctriques de Hasted.

Motsclés : tension superficielle, solutions de sels, électrolytes symétriques, polarisabilité effective, théorie.

Simple salts, when dissolved in a molecular solvent, raise the surface tension, σ, by small amounts (in contrast with surface-active agents, which may depress the surface tension substantially at very low concentrations). The magnitude of the increase depends upon the charge and size of the ions and on the nature of the solvent.

The functional form of the dependence of $\Delta\sigma$ ($= \sigma - \sigma_0$) on concentration is very uncertain, especially the approach to zero concentration. Most data (1) for aqueous solutions are at concentrations above 0.1 mol L^{-1}. Other properties of strong electrolyte solutions, such as equivalent conductivity and the logarithm of the activity coefficient, which are explained by the Debye–Hückel theory or theories based on it, are represented by equations having a leading term in the square root of c. It would not be surprising if surface tension was similar in this respect:

$$[1] \quad \Delta\sigma = A_0\sqrt{c} + Bc$$

The leading constants, corresponding to A_0, for the other properties depend only on charge type and on εT to a negative power. To see whether this was the case with surface tension also, data for half a dozen alkali halides in five solvents were fitted (2) to equations of the above form, and the values of A_0 were then fitted to an equation of the form:

$$[2] \quad A_0 = a + b/\varepsilon T$$

with $a = -2.4 \times 10^{-6}$ J $m^{-1/2}$ $mol^{-1/2}$ and $b = 1.83 \times 10^7$ J $m^{-1/2}$ $mol^{-1/2}$ K^{-1}. The coefficient of determination (a statistic that is unity for a perfect fit and zero for uncorrelated data) was only 0.64.

Theories

Published theories fall into three groups: (*i*) direct calculations (typified by those of Oka (3) and Ariyama (4)) of the work of separation at a surface originally in the interior of the solution to make two new surfaces; (*ii*) calculations of the depletion ("negative adsorption") of electrolyte in a surface layer, followed by use of the Gibbs adsorption equation (see below); (*iii*) calculations starting from a radial distribution for the ions, and proceeding by statistical-mechanical methods (5, 6). The main theories in the second group are (a) those of Wagner (7) and Onsager and Samaras (8) ("WOS"), modified by later authors (9, 10), and (b) that of Péres Masiá and co-workers (11, 12).

Binary mixtures of nonelectrolytes exhibit surface tensions that are lower than the values calculated with an assumption of additivity on a molar basis, i.e., :

$$[3] \quad \sigma < \sigma_1 x_1 + \sigma_2 x_2$$

where σ represents the surface tension of the solution, σ_i is

the surface tension of pure component **i** and x_i is its mole fraction. The reason for this is that the surface tension, which is the same as the surface free energy, is reduced by an excess of the component with the lower surface free energy appearing in the surface layer. Gibbs showed how to relate the surface excess ("adsorption") of one component to the decrease in the surface tension, through the Gibbs Adsorption Equation (13), a form of which is eq. [4]:

$$[4] \quad d\sigma/d\ln a_2 = -RT\Gamma_2$$

Here σ is as defined above, a_2 is the activity of component **2**, R is the gas constant, T the absolute temperature, and Γ_2 is the surface excess of component **2**. The definition of Γ_2 is somewhat dependent on the placing of an arbitrary plane that marks the geometrical surface (the real surface being actually a somewhat diffuse region). Gibbs showed that for dilute binary solutions it is always possible to place this plane so that the surface excess is equal to the integral of the local excess of component **2** (the solute) from the arbitrary plane into the body of the solution, to infinity, eq. [5]:

$$[5] \quad \Gamma = \int_0^\infty [c(x) - c(\infty)]\,dx$$

where x is the distance from the surface into the solution, and $c(x)$ and $c(\infty)$ are the concentrations at x and ∞ ("bulk").

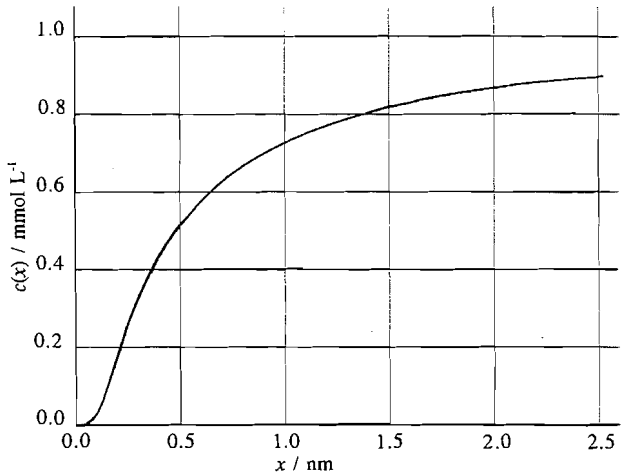
Where the solute is a strong electrolyte, each of the ions interacts with the surface, independently of the others in the limit of extreme dilution. By treating the surface as a plane that divides space into two regions, one the solvent, with electric permittivity ε, and the other the gas or vapour, with a permittivity essentially equal to the permittivity of free space, ε_o, it may be shown (14) that an ion of charge ze will be subject to a repulsive force equal to that which would be exerted by a charge of magnitude $ze(\varepsilon - \varepsilon_0)/(\varepsilon + \varepsilon_0)$ at the place where the image of the ion would be were the surface a mirror, with the permittivity everywhere equal to ε. This results in the ion having an x-dependent contribution to its potential energy, given by eq. [6],

$$[6] \quad W = fe^2/16\pi\varepsilon x$$

where $f = (\varepsilon - \varepsilon_0)/(\varepsilon + \varepsilon_0)$, the ratio of the image charge to the real charge. The extra factor 4 in the denominator arises because, in the integration of the force to obtain the potential energy, one must take account of the motion of the image as the ion is moved.

The dependence of concentration on distance from the surface is then obtained as $c(x) = c(\infty)\exp(-W/kT)$, where k is Boltzmann's constant. WOS show that this leads to Γ's being negative and infinite. At any finite concentration of electrolyte, however, the range of the Coulombic force of repulsion (the "image force") should be limited by the effect of the ionic atmosphere, being attenuated by the Debye–Hückel factor $\exp(-\kappa r)$. The radial coordinate r causes intractable mathematical complications; it was replaced by Wagner by a new coordinate parallel to x, and by Onsager and Samaras by $2x$ (because the distance from the image to the real ion is $2x$). The Debye–Hückel reciprocal length κ is not constant in the region of the solution where the concentration is not uniform. Onsager and Samaras argue that the value corresponding to the bulk concentration may be used without serious error. With these simplifications, they obtain a dependence of concentration on distance from the surface of the form shown in Fig. 1 (redrawn from part of Onsager and Samaras's Fig. 2). The area between the curve and the horizontal line at $c(\infty)$ is the quantity $-\Gamma$. Treatment of the liquid as a continuous dielectric should break down within molecular distances from the geometrical surface. Fortunately this is just the region that is essentially salt free. Integration of the Gibbs equation then gives $\sigma(a)$ or $\sigma(c)$.

Fig. 1. Distribution of an ionic solute near the solution surface. The bulk concentration is 1.000 mmol L^{-1}. The local concentration is plotted as a function of the distance from the surface, x; the quantity $-\Gamma$, which is the depletion (negative adsorption) of the solute, is the area between the curve and the horizontal line at c = 1 mmol L^{-1}. It is equivalent to total exclusion of solute from a surface layer about 0.8 nm thick. (Recalculated after Onsager and Samaras's Fig. 2 (8).)



Pérez Masiá and co-workers (11, 12) begin by calculating the Born solvation energy of the ions, and then the loss of solvation due to truncation of the solvation sphere by the surface. They then proceed to calculate $c(x)$ and $-\Gamma$ essentially as WOS, except that they explicitly calculate the effect of the difference in the solvation of the cation and anion. Any difference in the degree of repulsion from the surface creates an electrical double layer; this gives rise to an additional effect that they calculate through the Lippman–Helmholtz equation:

$$[7] \quad \left(\frac{\partial\sigma}{\partial E}\right)_{T,p,n} = -\left(\frac{\partial Q}{\partial A}\right)_{T,p,n} = -q$$

where E is the surface potential, and q is the surface charge density, defined by the middle term. The subscripts indicate that the derivatives are at constant temperature, pressure and composition. This additional effect (which would lead to a decrease in surface tension) is small when the ions have equal and opposite charges. It was neglected by WOS, and is neglected in **this work**.

All of these theories predict concentration dependence that is either linear for strong electrolytes or slightly concave towards the concentration axis. The curvature arises from two sources: (*a*) at higher concentrations from ion pairing (e.g.,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

Oka (*3b*): he includes a factor α for the degree of dissociation) or from the activity coefficient (e.g., WOS) and (*b*) at low concentrations from a term proportional to $-c\ln(c)$ (WOS and successors). Nichols and Pratt (15) show that in their application of the WOS approach to interfacial tension between two liquids the leading term may have the form either $-c\ln(c)$ or $c^{1/2}$, depending on the difference in the degree of repulsion from the surface between the anion and the cation, especially if the salt shows some solubility in both liquids. Unfortunately the effect is so small that these two forms of dependence on c are experimentally indistinguishable.

In reviewing these various theories from the point of view of an engineer seeking smoothed or estimated values, Horvath (16) concludes that for lower concentrations (below about 0.1 mol L^{-1}), WOS best represents the data. (He prefers Schmutzer (5), Buff–Stillinger (6), or Molyneux (17) at higher concentrations, although their derivations are also for very dilute solutions.) The chief problem seems to be that WOS underestimate the effect of ionic size. Onsager and Samaras themselves also say that they slightly underestimate the magnitude of the main effect (8).

Calculations

Onsager and Samaras, in calculating the "image" force, treat the ions as having no properties except charge and size, but, without elaborating, they mention the possibility of including polarizability. M.J. Sienko, in about 1953, suggested in conversation[2] that we should explore the addition of polarizability to see whether it might account for ionic size effects more realistically. The calculation seemed too difficult, and, except for a rough order-of-magnitude estimate, we were unable to pursue the problem at that time. The present paper is the belated fruit of Sienko's suggestion.

To allow for the size of the ions, WOS modify the potential energy of the ion by introducing the Debye–Hückel distance of closest approach, a, and arrive at the form (their eq. 19):

$$[8]\quad W(x) = \left(\frac{\exp(\kappa a)}{1+\kappa a}\right)\left(\frac{fz^2e^2}{16\pi\varepsilon x}\right)\exp(-2\kappa x)$$

(where x is the distance from the surface, a and κ are the Debye–Hückel distance of closest approach and ionic-atmosphere parameter, ε is the permittivity, z is the charge number, e is the elementary charge, and we have here restored the omitted f, the ratio of the image to the real charge: $(\varepsilon-\varepsilon_0)/(\varepsilon+\varepsilon_0)$).

We now add a term, the sum of two identical terms, for the potential energy W_μ due to the force (*i*) between the image charge and the induced dipole at the real ion and (*ii*) between the image of the induced dipole and the real charge. To obtain this term, consider the local field, E, which is (in one dimension) the derivative of the potential due to the image:

$$[9]\quad E = \frac{d\phi}{dx} = \frac{d}{dx}(W(x)/ze)$$

The induced dipole moment, μ, is equal to the product of the local field and the polarizability α. The force on the dipole is given by the product of the dipole moment and the derivative of the field:

$$[10]\quad F_\mu = \frac{dE}{dx}\alpha E = \alpha\frac{d^2\phi}{dx^2}\frac{d\phi}{dx}$$

and the potential energy W_μ due to this force is:

$$[11]\quad W_\mu = -\alpha\int\frac{d\phi}{dx}\frac{d^2\phi}{dx^2}dx = -\alpha\int\frac{d\phi}{dx}d\left(\frac{d\phi}{dx}\right) = -\frac{\alpha}{2}\left(\frac{d\phi}{dx}\right)^2$$

(The constant of integration is taken to be zero, the force and the potential energy both being zero at great distance.)

By itself, this term, which is attractive if α is positive, causes the potential energy of an ion at the surface to be large and negative, so the area Γ again becomes infinite and positive. Since the effective polarizability of a solvated ion is always negative, however (see below), the area remains finite and negative. A term representing the (induced) dipole–dipole potential was originally added. Since the range of the corresponding force is short, it serves only to reduce further the concentration very close to the surface, from which the solute is nearly totally excluded by the other forces. Its effect is therefore negligible.

The final form of the potential function is now:

$$[12]\quad W(u) = \frac{\exp(\kappa_0 a c^{1/2})}{1+\kappa_0 a c^{1/2}}F_1(u)c^{1/2} - 2\left\{\frac{\exp(\kappa_0 a c^{1/2})}{1+\kappa_0 a c^{1/2}}\right\}^2 F_2(u)c^2\alpha$$

where $u = 2\kappa x = 2\kappa_0 c^{1/2}x$ (writing κ_0 for $\kappa/c^{1/2}$), and

$$[13]\quad F_1 = \frac{fz^2e^2\kappa_0\exp(-u)}{2\varepsilon u}$$

$$F_2 = \left\{\frac{2\kappa_0(1+u)F_1(u)}{zeu}\right\}^2$$

Then the concentration as a function of distance from the surface:

$$[14]\quad c(u) = c(\infty)\exp\left(\frac{-W(u)}{kT}\right)$$

is used to obtain the adsorption:

$$[15]\quad -\Gamma = \int_0^\infty (c(\infty)-c(u))dx = 2\kappa\int_0^\infty (c(\infty)-c(u))du$$

followed by integration of the Gibbs equation, eq. [4], to obtain $\Delta\sigma(c)$. Corrections for the activity coefficient were made following Onsager and Samaras (8). They state that the effect of the added term linear in ionic strength to the extended Debye–Hückel equation makes little difference. By the use of Davies's approximation (18) to the extended Debye–Hückel equation for aqueous solutions at 25°C:

$$[16]\quad -\log_{10} f_\pm = \frac{z^2}{2}\left(\frac{1}{1+I^{-1/2}} - 0.3I\right)$$

where I is the ionic strength in mol/L, we found that it does indeed make a difference at concentrations above 0.1 mol L^{-1} for 1:1 electrolytes; presumably it is even more important with ions of higher charge.

Polarizability

We have not yet discussed the choice of the values for the polarizabilities of the solvated ions. Hasted, Ritson, and Collie (19) have considered this problem and have made (very difficult!) measurements of the effect of dissolved salts on the permittivity of water, in the limit of low frequency, expressing the results in the form:

$$[17] \quad \varepsilon = \varepsilon_s + \delta c$$

The factor δ is called the "dielectric decrement," for the effect of the ions is to strongly orient the solvent molecules in their vicinity, much reducing their freedom to respond to an applied field, and so decreasing ε below the solvent value, ε_s. The measurements were made at concentrations from 0.5 molar upwards and extrapolated to zero concentration. The authors make a somewhat arbitrary division of the observed values between cation and anion, and report for univalent ions: H^+ −17, Li^+ −11, Na^+ −8, K^+ −8, Rb^+ −7, F^- −5, Cl^- −3, I^- −7, and OH^- −13 (all ±0.5) L mol^{-1}. The relative magnitudes accord more or less with expectation, those for the cations diminishing as the radius increases, a trend that seems to be followed also by fluoride and chloride. Iodide seems to be anomalous. That H^+ and OH^- show the largest effects in their respective series is not surprising, considering their unusually large mobilities in water and their special structural relation to that solvent.

To translate the dielectric decrement into effective polarizability, we use the mixing rule for a dilute suspension of spheres of permittivity ε_1 in a medium of permittivity ε_s, eq. [18] (20):

$$[18] \quad \varepsilon = \varepsilon_m + 1.5\phi_2(\varepsilon_1 - \varepsilon_m)$$

(Here ϕ_2 is the volume fraction of the suspended spheres.) Writing the volume fraction ϕ_2 in terms of the molar concentration c, and noting that one mole of a symmetrical electrolyte contains two moles of particles (eq. [19]),

$$[19] \quad \phi_2 = 2Lvc$$

(v is the volume of a sphere and L is Avogadro's constant), we obtain eq. [20]:

$$[20] \quad \varepsilon = \varepsilon_m + 3Lv(\varepsilon_1 - \varepsilon_m)c$$

Bleaney and Bleaney (21) express the polarizability of such a suspended sphere by eq. [21]:

$$[21] \quad \alpha = \frac{3}{4\pi} \frac{\varepsilon_m(\varepsilon_1 - \varepsilon_m)v}{(\varepsilon_1 + 2\varepsilon_m}$$

Eliminating the volume of the spheres between eqs. [20] and [21], we obtain eq. [22]:

$$[22] \quad \varepsilon = \varepsilon_m + 4\pi L \frac{(\varepsilon_1 + \varepsilon_m)}{\varepsilon_m} \alpha c$$

which, by comparison with the Hasted equation (eq. [17]), allows us to write:

$$[23] \quad \bar{\alpha} = \frac{1}{4\pi L} \frac{\varepsilon_m}{(\varepsilon_1 + 2\varepsilon_m)} \bar{\delta} = G\bar{\delta}$$

The bars are added to indicate that the properties δ and α refer to averages of the properties of the two ionic species. The numerical value of the proportionality constant G is 6.52×10^{-26} mol in aqueous solutions at 25°C, taking $\varepsilon_m = 78.304\ \varepsilon_0$ and assuming $\varepsilon_1 = 2\varepsilon_0$, close to the "optical" value. (The Hasted values of δ are in L mol^{-1}, and should be expressed in m^3 mol^{-1} to obtain polarizabilities in m^3. The value for a salt is the average, not the sum, of the ionic values.)

Results and discussion

The calculated values of $\Delta\sigma$ ($= \sigma - \sigma_0$) for concentrations from 0.0004 to 0.100 molar for uni-univalent electrolytes with mean effective ionic polarizabilities from zero to −2.0 nm^3 are listed in Table 1. For $\alpha = 0$ they are in close (though not exact) agreement with those calculated by Onsager and Samaras (8). Figure 2 shows the results of this work plotted as $\Delta\sigma/c$ vs. $\log_{10}c$. The lowest curve is for $\alpha = 0$. A few of Onsager and Samaras's calculated values are shown: their simplest calculation, ignoring the activity coefficient and the size of the ions, as squares, and their full calculation as crosses. The small differences are due to slightly different values of the fundamental constants used, slightly different values (22)[3] for ε and (following Bravina (23) the restoration of the factor $(\varepsilon - \varepsilon_0)/(\varepsilon + \varepsilon_0)$ in the magnitude of the image charge, which WOS omit. The circles represent very careful measurements by Long and Nutting (24) on KCl solutions. As noted above, they are somewhat higher than the calculated values, except at the lowest concentrations, where Long and Nutting suggest that they may not have quite eliminated the Jones and Ray effect (25).[4] The upper curves represent the results of this work with α varied, plotted in the same fashion. Values of $-\alpha$ used were 0.5, 1.0, 1.5, and 2.0 nm^3. (cf. argon: $\alpha = 0.00166$ pm^3.) The value of $-\alpha$ required to reproduce the experimental results for KCl is greater than 2 nm^3. The additional effect, $\sigma(\alpha) - \sigma(0)$ at $c = 0.100$ mol L^{1-} is closely proportional to $(-\alpha)^{1/2}$. The value $-\alpha = 0.36$ nm^3 corresponds to $\delta = -5.5$ L mol^{-1} for KCl (Hasted (20), p. 140).

It appears that the present theory using these effective polarizabilities is able to predict only very approximately the effect of ion size differences on surface tension for 1:1 salts, as represented by the alkali halides. There also remain some puzzles, the chief of which is the behaviour of strong acids. The Hasted dielectric decrement value for HCl is −10 L mol^{-1}, which translates to an effective polarizability of −1.3

[3] For temperatures other than 298 K, quadratically smoothed values were used.

[4] The Jones–Ray effect consists of an apparent depression of the surface tension of salt solutions at very low concentrations, as measured by the method of capillary rise. Langmuir's explanation of the effect as due to the electrical double layer at the glass–solution interface (26) has been generally accepted.

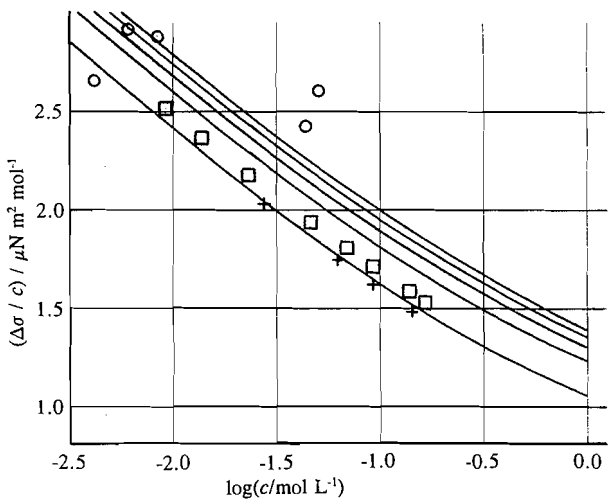
Fig. 2. Surface tension divided by concentration for solutions of 1:1 electrolytes in water at 25°C, plotted against log(c/mol L^{-1}). The curves are calculated (this work) for values of the mean polarizability of the solvated ions (from the lowest curve upwards): α = 0, −0.5, −1.0, −1.5, −2.0 nm^3. The plotted points are (○) experimental (KCl, Long and Nutting (24)); (+) Onsager and Samara's simplest calculation; (□) Onsager and Samara's full calculation (8).



nm^3, and predicts a surface tension increment higher than for any of these salts. Experimental values are much lower, in fact slightly negative (1). Some structural or other special effect arising in the surface from the close relation of the hydronium ion to water must be operating. Among the alkali halides, Hasted's values of δ do not correlate very well with other properties that would be expected to show similar trends with changes in ionic radii (e.g., entropies of solvation, viscosity B coefficients). The value of δ for KI is more negative (−8) than that for KCl (−5), but measured surface tension increments[1i] are nearly 30% smaller.

The effects of variation of temperature, and of independent variation of the temperature, the permittivity, and the ionic charge (symmetric electrolytes only) were explored. The nature of the solvent might be expected to appear, given the electrostatic basis of the calculation, as proportionality to the permittivity to some negative power. Available data (27) do not give this much support. Good data for nonaqueous solvents are hard to find. Part (*a*) of Table 2 lists calculated values of the relative increment of surface tension for 1:1 salts at several concentrations and at several temperatures. Part (*b*) of the same table lists the results of similar calculations, but with the relative permittivity ("dielectric constant," $D = \varepsilon/\varepsilon_0$) fixed at the value appropriate to 298 K. In Part (*c*) the temperature is fixed at 298 K, with the dielectric constant varied from 60 to 100. The last column of Table 2(*b*) lists the values of the slopes of plots of the calculated values as log($\Delta v/c$) vs. log (T). The temperature effect appears to work mainly indirectly, through the temperature dependence of the permittivity, the factor RT in the Gibbs equation and the Boltzmann factor exp(-W/kT) having contrary effects. The slopes in Table 2(*b*) show the near-cancellation of the direct temperature effects. Part (*c*) of Table 2 shows the result of varying the dielectric constant while keeping T constant. The last column, analogous to that in Part (*a*), shows that the effect depends approximately on D^{-1}, in the range explored.

The dependence on charge type is curious. I naïvely expected dependence on the charge as z or z^2, and proportionality to the number of ions of each kind. This would lead to the effects of, e.g., LiCl, $BaCl_2$, and $MgSO_4$ being in the ratios 1:2:2 (if proportional to z) or 1:3:4 (if z^2). In

aqueous solution at concentrations above 1 mol L^{-1} they are actually (28) in the ratios 1:1.8:1.3, which suggest a dependence on $z^{1/2}$, approximately, not obviously predicted by any current theory. The effect of ionic charge calculated here is surprising, in that it is strongly concentration dependent (see Table 3). At 1 mol L^{-1} the ratio of the surface tension increments predicted for 2:2 to 1:1 salts is about 1.9, which may be compared to the experimental value of about 1.3 cited above. At 0.0001 mol L^{-1} the ratio is nearly 5. The reason for this strange behaviour relates to the two influences of z on the results: at the lowest concentrations the repulsive force is of long range and depends on z^2, while at higher concentration the range of the force is limited by the ionic atmosphere, so the thickness of the layer of solution depleted in solute decreases as z increases. Thus the effect of increasing z is to increase $-\Gamma$ at low concentrations, but

ultimately to decrease it at high concentrations. Note the behaviour of $\Delta\sigma/c$ for $z = 2$ and 3 in Table 3.

In conclusion, it should be pointed out that comparison of these and other theoretical calculations of surface tension of electrolyte solutions with experiment is difficult owing to the paucity of data for sufficiently dilute solutions. The present theory and all the other theories cited here were derived using assumptions that are most appropriate at very low concentrations, while the data mostly refer to concentrations much above 0.1 molar. Trustworthy data for nonaqueous systems in any concentration range are especially rare.

Aqueous nonelectrolyte solutions. Part XIII. Ice and hydrate freezing points of aqueous ethylene oxide solutions and the formula of congruent ethylene oxide hydrate

David N. Glew and Norman S. Rath

Abstract: Ice freezing temperatures and hydrate formation temperatures have been measured by the dynamic cooling method for aqueous ethylene oxide (EO) solutions containing from 0 to 95 mol% EO. The ice and the congruent hydrate freezing temperatures exhibited standard errors on a single measurement of 0.004°C and 0.013°C, respectively. The ice–hydrate eutectic temperature was observed at –2.107°C with standard error 0.001°C and composition 1.991 mol% EO with standard error 0.008 mol% EO. The congruent hydrate was found to freeze at 11.083°C with standard error 0.002°C and composition 12.64 mol% EO with standard error 0.02 mol% EO. The formula of the congruent hydrate was EO·6.91H_2O with standard error 0.013 mol water/mol EO. Only a single hydrate was found over the whole composition range down to –26°C: the shoulder of the hydrate freezing curve above 40 mol% EO resulted from the high activity coefficients to dilute water in concentrated EO solutions. Equations and best values for the ice freezing temperatures and the hydrate formation temperatures together with their standard errors were evaluated by the method of least squares.

Key words: clathrate hydrate of ethylene oxide, freezing of water – ethylene oxide, ethylene oxide hydrate.

Résumé : Faisant appel à la méthode de refroidissement dynamique sur des solutions aqueuses d'oxyde d'éthylène (OE) contenant de 0 à 95% d'OE, on a mesuré les températures de congélation de la glace et de formation d'hydrate. Sur une seule mesure, les températures de congélation et de formation congruente d'hydrate ont présentés des erreurs standards qui sont respectivement de 0,004°C et 0,013°C. On a observé la température eutectique glace–hydrate à –2,107°C, avec une erreur standard de 0,001°C; la composition est alors de 1,991 mol% d'OE, avec une arreur standard de 0,008 mol% d'OE. On a trouvé que le point de congélation de l'hydrate congruent est 11,083°C avec une erreur standard de 0,002°C et une composition de 12,64 mol% d'OE, avec une erreur standard de 0,02 mol% d'OE. La formule de l'hydrate congruent est OE·6,91H_2O avec une erreur standard de 0,013 mol d'eau par mol d'OE. On n'a trouvé qu'un seul hydrate sur l'ensemble des compositions, jusqu'à –26,0°C : l'épaulement observé dans la courbe de congélation de l'hydrate, au-dessus de 40% d'OE, est le résultat de coefficients d'activité élevés de l'eau dans des solutions concentrées en OE. On a fait appel à la méthode des moindres carrés pour évaluer les équations, les meilleures valeurs des températures de congélation et de formation d'hydrate ainsi que leurs erreurs standards.

Mots clés : clathrate hydrate d'oxyde d'éthylène, congélation d'eau – oxyde d'éthylène, hydrate d'oxyde d'éthylène.

[Traduit par la rédaction]

Introduction

As a part of earlier studies on aqueous nonelectrolyte solutions and gas hydrates (1–17), the water – ethylene oxide (EO) system was of particular interest to us because the liquids water and EO (*i*) exhibited a complete range of liquid miscibility, and (*ii*) thus provided homogeneous solutions, which on cooling precipitated solid EO hydrate.

Received June 30, 1994.

D.N. Glew[1] **and N.S. Rath.** Exploratory Research Laboratory, Dow Chemical Canada Inc., Sarnia, ON N7T 7M1, Canada

[1] Retired; author to whom correspondence may be addressed at 536 Highbury Park, Sarnia, ON N7V 2J9, Canada. Telephone: (519) 337-3136.

The complete miscibility made it possible to measure directly the volumetric properties (11), the proton magnetic resonance chemical shifts (11), and the enthalpy of mixing (17) for aqueous EO solutions over the whole range of composition: these solution properties showed the variation of the water – hydrogen bond interactions from the extensively and strongly bonded water-rich solutions to the weakly bonded solutions of dilute water in aprotic EO (11, 17).

The complete miscibility also permitted direct measurement of the temperature for hydrate formation from solution over nearly the whole composition range, enabling a direct and accurate determination of the formula for the congruent EO hydrate.

The freezing point curve for EO hydrate had been measured

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

on two earlier occasions (1, 2). In consideration of the lesser purity of the liquid EO and of the equipment used at the earlier time, we decided (*i*) to remeasure the freezing point curve for EO hydrate with improved precision over a wider range of solution composition and temperature, and (*ii*) to measure for the first time the freezing point curve for the EO deuterohydrate.

Work with the deuterium oxide solutions of EO will be reported later.

A comprehensive review of the clathrate hydrates, including much work on the EO hydrate, up to 1973 has been given Davidson (18).

Experimental

Materials

Briefly, all materials were as described earlier (11). EO was selected from the production of Dow Chemical Canada, Limited; analysis for water, aldehydes, and nonvolatiles showed that the total of these impurities was less than 80 parts per million by weight.

Water was triply distilled and had a specific conductivity of less than 4×10^{-7} ohm^{-1} at room temperature, about 25°C.

Apparatus and procedure

The construction, testing, and the method of use of the freezing point cell have already been described (8). The data for the ice freezing points of the water solutions of EO were reported in part, and analysed in a different manner, earlier (11).

The experimental runs, e.g., denoted R125, were numbered consecutively in the order in which they were performed: after measurements with the water solutions were complete, runs were made with the deuterium oxide solutions. The later runs with the higher run numbers were usually found to be slightly more reliable, because of the small improvements of technique that inevitably evolved with increased experience of operation.

For data comparison and later statistical analysis the measurements using the water solutions were divided into three chronological sets: the early runs R106–R462 were defined as Set 1, R463–R584 were Set 2, and the later runs R585–R833 Set 3.

Calibration of thermocouple of freezing point cell

The thermocouple of the freezing point cell was calibrated against a standardized (IPTS-48) platinum resistance thermometer in a thermostat bath at more than 200 temperatures between +15 and –25°C (11). Calibrations were made (*i*) initially, (*ii*) in the middle of, and (*iii*) at the end of the runs with the water solutions, and (*iv*) at the end of the runs with the deuterium oxide solutions. Over this 4-year period the electrical signal of the thermocouple indicated no significant deviation or drift from the initial calibrations. The standard error on a single temperature determination, due only to electrical instrumental effects, (*i*) was 0.0035°C between –6.5 and +6.5°C, (*ii*), was 0.0070°C between –13 and –6.5°C and between 6.5 and 13.0°C, and (*iii*) was 0.014°C between –26 and –13°C and between 13 and 15°C. These estimates give the minimum values for the standard error on any single temperature determination.

The original experimental temperatures were measured on the International Practical Temperature Scale of 1948 (IPTS-48): these measurements were converted to the International Temperature Scale of 1990 (ITS-90), using the approximate differences in Table 4 given by Goldberg and Weir (19). The conversion had a root-mean-squared bias of less than 0.0004°C over the range –25 to +15°C, almost an order of magnitude smaller than our most precise measurements. All temperatures and equations are reported in units of degree Celsius (ITS-90).

Measurement of temperature for freezing of ice

The freezing of ice from water and dilute EO solutions generally exhibited much larger supercoolings (~0.4–0.7°C) than those found for the formation of hydrate (~0.005–0.1°C) from the same solutions. Consequently, the preselected cooling temperature differentials applied to the freezing point cell for freezing ice could not be reduced to less than ~0.4°C, and so the resulting observed temperature for the freezing of ice was invariably biased below its true equilibrium value. Table 1 lists the ice freezing temperatures corrected for bias.

Measurement of temperature for formation of eutectic

Measurement of the eutectic temperature was made directly, both from solutions initially freezing ice and those initially forming hydrate, using a final small cooling differential of ~0.1°C. The 15 eutectic temperatures found in Set 3 are listed in Table 1.

The earlier direct measurements of the eutectic temperature in Set 2 used a larger final cooling differential of ~0.4°C.

Measurement of temperature for formation of hydrate

With the development of the cooling technique of the freezing point cell, the preselected temperature differential applied to the freezing point cell was reduced from 1.7°C, used initially in Set 1, to 0.1°C, used later in Set 3. Consequently, the observed solution supercooling was reduced and the resulting temperature of formation of hydrate was found to be slightly increased, and thus nearer to its true equilibrium value. All temperatures for the formation of hydrate listed in Table 2 were extrapolated from two or more measurements to zero supercooling (8).

After the temperature of hydrate formation had been measured, the result was plotted against solution composition on a large-scale graph so that the continuity and smoothness of the temperature envelope of adjacent measurements could immediately be assessed. Any measurement that showed an obvious large deviation was repeated and replaced by an acceptable replicate measurement or measurements. Obvious deviations usually exhibited a negative bias of the measured temperature below that of the adjacent smooth envelope. This indicated experimentally that the temperature of formation of hydrate listed in Table 2, as determined by our dynamic cooling method, would usually contain an associated negative bias relative to its true equilibrium value. Support for the same negative bias was found in later least-squares regression analyses, where the few observed outliers usually exhibited negative temperature deviations below their model estimates.

Results and discussion

Measurements of freezing of ice

Table 1 lists the corrected temperature for freezing of ice for measurements of aqueous solutions containing between zero and 2.0003 mol% EO. The first column of the table shows the R-number of the run, the second column the solution composition, and the third the corrected temperature for the freezing of

ice from that solution. The 28 calibrations, for freezing ice from pure water, showed a bias of −0.0126°C with an estimated standard error of 0.0042°C for a single freezing point determination. The 35 measurements, for freezing ice from EO solutions, comprised the following: 24 from Set 3+2 with bias −0.0129 and standard error 0.0044°C, and 11 from Set 1+2 with bias −0.0297 and standard error 0.0041°C. The large bias of −0.0297°C for Set 1+2 resulted from the large cooling differential of about 1.7°C initially used for those earlier measurements.

The temperature for freezing of ice, T_{FI}, from aqueous EO is best represented by the three-parameter equation

$$[1]\quad T_{FI} = \underset{(0.0008)}{0.0000} - \underset{(0.0034)}{1.0327}\,C - \underset{(0.00173)}{0.01727}\,C^2$$

whereas T_{FI} is in degree Celsius and C is the solution concentration of EO in mol% EO. Least-squares estimates of the standard error on the parameters are shown in parentheses and the standard error on a single ice freezing point determination was 0.0043°C with 58 degrees of freedom.

Measurement of formation of eutectic

The eutectic temperature −2.107°C, with estimated standard error 0.0006°C, was the mean of the 15+1 measurements of Set 3+2 listed in Table 1, with initial solution compositions between 1.9498 and 3.0039 mol% EO. The standard error for a single eutectic temperature determination was 0.0023°C, which corresponded with the minimum error 0.0035°C from thermocouple calibration.

Thirteen earlier direct measurements of the eutectic temperature in Set 2 had given a mean value −2.134°C, with bias −0.027°C below the best value from Set 3+2, and with a standard error 0.0036°C on a single determination: the larger negative bias resulted from the earlier use in Set 2 of larger final cooling temperature differentials.

The eutectic composition 1.991 mol% EO, with standard

Table 2. (ITS-90) Variation of temperature for formation of hydrate with composition.

error 0.0076 mol% EO, was estimated from the observed eutectic temperature together with the intersections of the curves for the freezing of ice and for the formation of hydrate. The ice–hydrate intersection estimate for the eutectic temperature was −2.130°C, with bias −0.023°C below the best observed value from Set 3+2: this negative bias arose from the combined biases both for the freezing of ice and for the formation of hydrate.

Since it was found experimentally that the direct eutectic temperature measurements of Set 3+2 had minimum bias, the bias of the temperature for formation of hydrate in Set 3 was at least −0.023°C at 1.991 mol% EO. This bias is to be compared with that −0.106°C found for eight replicates of Set 2 relative to Set 3 at 2.0488–2.0603 mol% EO.

Measurement of formation of hydrate

Table 2 lists the measurements of the temperature for formation of EO hydrate from aqueous solutions containing between 1.9565 and 95.0001 mol% EO. The first column of the table

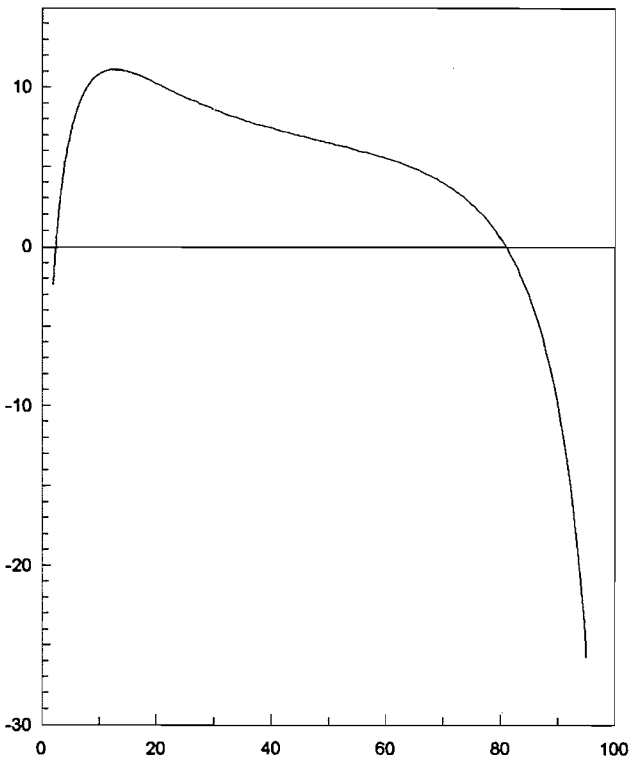
X-axis: Ethylene oxide fraction /mol%.



shows the R-number of the run, the second column the solution composition, and the third the temperature for formation of hydrate from that solution. The precision of the measurements justifies four decimal places for the mol% EO in solution, and three places for the temperature of hydrate formation in °C. Figure 1 provides a line plot of these measurements showing the envelope of the temperature for formation of hydrate with solution composition: this envelope is commonly known as the hydrate "freezing point" curve.

Initial data analyses indicated that our early hydrate measurements up to run R224 in Set 1 were incomplete and of lower reliability so they were excluded from Table 2.

Preliminary and separate regression analyses indicated that the measurements of Set 1 and of Set 2 in the congruent region were of equal precision despite the fact that they were made at times more than 1 year apart. These measurements were subsequently analysed together with those of Set 3 as the single combined Set 1+2+3 and were found to give a proper estimate of error in the congruent region between compositions 8.3993 and 20.5056 mol% EO.

Set 1 contained almost all of the measurements in the EO-rich region with compositions between 20.0308 and 95.0001 mol% EO: a few replicate determinations, made later as a check in Set 3, were found to be in good agreement with those of Set 1. Subsequent regression analyses used the combined measurements as a single Set 1+3.

In the water-rich region, for solutions containing less than 10 mol% EO, comparison of the hydrate measurements of Set 2 with those of Set 3 showed that the earlier measurements of Set 2 became systematically more biased and unreliable as the solution was diluted below 5 mol% EO and as the hydrate formation temperature moved towards the eutectic temperature. As a result the measurements in Set 2 for solutions containing less than 3.6019 mol% EO were evaluated as unreliable and were excluded from Table 2.

The water-rich region was defined by the measurements of only Set 3 between 1.9565 and 3.6012 mol% EO, by the combined measurements of Set 3 and Set 2 between 3.6496 and 10.0005 mol% EO, and by the combined measurements of Set 2 and Set 1 between 10.0006 and 12.5947 mol% EO.

Apparently, in those runs of Set 2 that were rejected, the large impressed cooling jacket temperature differential, of 1.7°C below that of the stirred test solution, for example, was the main cause for the large mean bias –0.106°C of hydrate formation temperature for the eight replicate solutions containing 2.0488–2.0603 mol% EO: the internal variability of these replicates gave an estimated standard error of 0.033°C for a single measurement, indicating their internal precision. The bias of these Set 2 measurements relative to Set 3 was discovered experimentally by checking with repeat measurements in Set 3 using reduced impressed cooling differentials of ~0.1°C. The large observed bias in Set 2 was shown to be clearly related to three factors: (*i*) the large cooling temperature differential applied to the freezing point cell, (*ii*) the large local slope of the hydrate formation temperature envelope, and (*iii*) the large change of solution composition caused by the formation of a relatively small amount of hydrate. The slow rate of energy release, derived from the slow rate of formation of hydrate from these incongruent water-rich solutions (15, 16), was inadequate to balance the large impressed cooling energy loss.

The hydrate measurements of Set 3, in the same water-rich region, still include a negative bias –0.023°C of hydrate formation temperature similar to, but much smaller than, that found for Set 2.

The final measurements included in Table 2 and shown in Fig. 1 exhibited a smooth and continuous envelope for all compositions, without discontinuities of value or of slope: this experimental continuity proved the existence of only one type of EO hydrate over the whole range of solution composition.

The later statistical analyses of the data in Table 2 involved taking a significant number (e.g., 24–112) of adjacent measurements around a predefined solution composition and making a local least-squares regression analysis of the hydrate formation temperature as a polynomial function of the solution composition. The order of the polynomial equations tested ranged from first up to sixth power of composition. This gave consecutive representative equations that (*i*) under-fitted the data, (*ii*) best-fitted the data, and (*iii*) over-fitted the data. The best-fit and over-fit equations gave unbiased estimates of the local standard error of a single temperature measurement for formation of hydrate. The best-fit and over-fit residuals were invariably random and reconfirmed the continuity of the measurements over the whole solution composition range.

Estimates of temperature for formation of hydrate with composition

The eutectic point is listed in the first row of Table 3. Estimates of the EO hydrate formation temperature with composition are listed in Table 3 and were defined by the 34 best-fit regression analyses at the solution compositions shown in column one. Estimates of the temperature for formation of hydrate T_{FH}, its standard error SE T_{FH}, the standard error on a

single hydrate measurement SE T_{obs}, the slope of the T_{FH} envelope and its standard error are listed, respectively, in columns two to six. In column seven the two numbers separated by a dash indicate the number of measurements and the number of parameters used in the best representative polynomial model.

The results for four sets of replicate measurements at the compositions 3.60, 50.0, 80.0, and 94.75 mol% EO are included in Table 3 to provide a comparison of the standard error on a single determination with those estimates from the regressions.

The errors of hydrate measurements were greatest at the lowest temperatures using the most EO-rich (water-dilute) solutions, as seen in the final row of Table 3. Column four shows the progressive decrease of error with the increase both of hydrate formation temperature and of water content of the solution, down to a minimum error at 7.0 mol% EO. Below 7.0 mol% EO the errors of measurement again increase with the decrease both of hydrate temperature and of EO content of the solution. Over the wide range of solution composition 6.0–60.0 mol% EO, the standard error on a single hydrate temperature determination was 0.015°C, and was sensibly constant.

The congruent temperature 11.083°C, with estimated standard error 0.0018°C, was determined from the maximum of the hydrate formation curve representing 112 measurements with solution compositions between 8.3993 and 20.5056 mol% EO. The temperature for formation of hydrate, T_{FH}, was best represented by the five-parameter equation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

$$[2]\quad T_{FH} = \underset{(0.0018)}{11.083} + \underset{(0.0012)}{0.0000D} - \underset{(0.00026)}{0.02919D^2} + \underset{(0.000085)}{0.002739D^3} - \underset{(0.000011)}{0.000137D^4}$$

where T_{FH} is in °C and D = (mol% EO –12.644) = (C–12.644) mol% EO. Least-squares estimates of the standard error on the parameters are shown in parentheses and the standard error on a single hydrate temperature determination was 0.013 °C with 107 degrees of freedom, in excellent agreement with the estimates from the smaller adjacent local regressions.

The congruent composition 12.644 mol% EO, with estimated standard error 0.021 mol% EO, was determined as the composition for zero slope of eq. [2], and the standard error from the error on that slope. The formula found for the congruent EO hydrate was $EO{\cdot}6.91H_2O$ with an estimated standard error 0.013 mol water/mol EO.

The congruent hydrate comprises $6.66EO{\cdot}46H_2O$ per unit cell, with EO molecules occupying mainly the six tetrakaidecahedral sites and filling at least one third of the two dodecahedral sites (8, 9, 10).

These estimates of the congruent hydrate freezing temperature and composition and their standard errors are in general agreement with, and supersede all of our earlier estimates (8, 10, 15, 18).

The slope of the hydrate formation curve in the EO-rich region is negative and passes through a narrow minimum at about 20 mol% EO and through a wide maximum at about 50 mol% EO. The small absolute values of the negative slopes between 14.0 and 60.0 mol% EO reflect (*i*) a high enthalpy change for crystallization of EO hydrate from solution (20), together with (*ii*) positive and high Raoult-law activity coefficients for water in these EO-rich solutions (21, 22).

Comparison with earlier work

A similar numerical evaluation by us of seven hydrate measurements from Maass and Boomer (1) indicated a congruent hydrate freezing at 10.72°C with standard error 0.08°C, consistent with their error estimate 0.20°C on a single determination. This congruent hydrate freezing temperature was significantly lower by –0.36°C (–4.7 their standard errors) than that of our work. The lower hydrate temperatures observed probably resulted from the use of relatively larger cooling jacket energy fluxes in that earlier work (1). The congruent composition found was 13.28 mol% EO with standard error 1.22 mol% EO, which gave a hydrate formula $EO{\cdot}6.53H_2O$ with standard error 0.69 mol water/mol EO. This congruent composition with its large standard error was not significantly different from our present value. The hydrate formula indicated was near to the mean of the formula limits, $EO{\cdot}5H_2O$ and $EO{\cdot}8H_2O$, given by the authors (1). An earlier assessment of these measurements (1) by von Stackelberg and Meuthen (4) had suggested a hydrate formula $EO{\cdot}6.5H_2O$ with an error 0.5 mol water/mol EO.

The EO hydrate temperatures reported by Mazzucchelli and Armenante (2) were significantly higher by 0.88°C (59 standard errors) than those found in our work, and indicated a large standard error of 0.76°C on a single hydrate temperature determination. The paucity of measurements in the congruent region together with their low accuracy precluded any reliable evaluation of the congruent hydrate properties from that work (2).

The ice freezing temperatures given by Mazzucchelli and Armenante (2) were significantly higher by 0.25°C (59 standard errors) than those observed in our work. Their reported eutectic temperature and composition were, respectively, significantly lower by –0.12°C (–53 standard errors) and significantly higher by 0.29 mol% EO (45 standard errors) than those observed in our work.

Synthesis and structural characterization of barium complexes containing the bulky amino-siloxide hybrid ligand $^{-}OSi(^{t}Bu)_2((CH_2)_3NMe_2)$

Pengcheng Shao, David J. Berg, and Gordon W. Bushnell

Abstract: The bulky amino-siloxide hybrid ligand $^{-}OSi(^{t}Bu)_2((CH_2)_3NMe_2)$ allows isolation of dinuclear, hydrocarbon-soluble barium complexes. The structures of two mono(ligand) complexes, $\{Ba[OSi(^{t}Bu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2]\}_2$ (**1**) and $\{Ba[OSi(^{t}Bu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2][THF]\}_2$ (**3**), have been determined by X-ray diffraction (crystal data: **1**, monoclinic, *C*2/*c*, $a = 20.451(4)$ Å, $b = 14.277(3)$ Å, $c = 22.258(5)$ Å, $\beta = 101.14(2)°$, $V = 6376.1(2)$ Å^3, $Z = 4$ (dimers), $R = 0.069$, $R_w = 0.100$; **3**, monoclinic, $P2_1/c$, $a = 11.025(4)$ Å, $b = 22.414(3)$ Å, $c = 13.925(2)$ Å, $\beta = 104.05(2)°$, $V = 3338.0(1)$ Å^3, $Z = 2$ (dimers), $R = 0.090$, $R_w = 0.117$). Complex **1** is stable towards ligand redistribution in d_6-benzene or d_8-toluene, but in d_8-THF both **1** and **3** exist in equilibrium with the ligand redistribution products $Ba[N(SiMe_3)_2]_2[THF]_2$ and $Ba[OSi(^{t}Bu)_2((CH_2)_3NMe_2)]_2$ (**2**). Complex **2** was prepared independently and appears to exist as a monomer–dimer equilibrium in d_6-benzene solution. Complexes **1**–**3** do not sublime when heated under high vacuum (200°C, 10^{-4} Torr).

Key words: siloxide, barium, synthesis, structure, bis(trimethylsilyl)amide.

Résumé : Le coordinat hybride amino-siloxyde volumineux $^{-}OSi(^{t}Bu)_2((CH_2)_3NMe_2)$ permet d'isoler les complexes dinucléaires du baryum solubles dans les hydrocarbures. Faisant appel à la diffraction des rayons X, on a déterminé la structure de deux complexes monocoordinés, $\{Ba[OSi(^{t}Bu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2]\}_2$ (**1**) et $\{Ba[OSi(^{t}Bu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2][THF]\}_2$ (**3**) (données cristallographiques : **1**, monoclinique, *C*2/c, $a = 20{,}451(4)$, $b = 14{,}277(3)$ et $c = 22{,}258(5)$ Å, $\beta = 101{,}14(2)°$, $V = 6376{,}1(2)$ Å^3, $Z = 4$ (dimères), $R = 0{,}069$ et $R_w = 0{,}100$; **3**, monoclinique, $P2_1/c$, $a = 11{,}025(4)$, $b = 22{,}414(3)$ et $c = 13{,}925(2)$ Å, $\beta = 104{,}05(2)°$, $V = 3338{,}0(1)$ Å^3, $Z = 2$ (dimères), $R = 0{,}090$, $R_w = 0{,}117$). Le complexe **1** est stable par rapport à une redistribution des coordinats dans du d_6-benzène ou du d_8-toluène; toutefois, dans du d_8-THF, les composés **1** et **3** subissent tous les deux une redistribution de coordinats conduisant aux produits $Ba[N(SiMe_3)_2]_2[THF]_2$ et $Ba[OSi(^{t}Bu)_2((CH_2)_3NMe_2)]_2$. On a préparé le complexe **2** d'une manière indépendante et, en solution dans le d_6-benzène, il semble exister sous la forme d'un équilibre monomère–dimère. Les complexe **1**–**3** ne se subliment pas lorsqu'on les chauffe sous vide poussé (200°C, 10^{-4} Torr).

Mots clés : siloxyde, baryum, synthèse, structure, bis(triméthylsilyl)amide.

Introduction

The current interest in high T_c mixed metal oxide superconductors (1) has led to intense investigation of metal alkoxides as potential precursors to these materials (2). As a result, the design of soluble alkoxide complexes suitable for the sol–gel process is now possible (3). However, the preparation of high volatility alkoxides for use in the growth of thin-film superconductors remains problematic, particularly for large electropositive metals such as barium. Several approaches to this problem have been investigated, including the use of fluorinated or bulky alkoxides (4). Recently, we reported that the use of a bulky siloxide containing a pendant amine donor (**I**) leads to monomeric yttrium and lanthanide complexes of enhanced solubility and volatility (5). Herrmann et al. have reported a similar strategy using bulky alkoxides incorporating amine or ether donors (6).

I 
In this contribution we report the extension of this approach to barium complexes. The larger size of barium makes it much more difficult to achieve coordinative saturation than for yttrium or the lanthanides (ionic radii in six coordination: Ba^{2+} 1.35, La^{3+} 1.032, and Y^{3+} 0.900 Å) (7). In addition, the 2+ oxidation state limits the number of anionic ligands per barium to two in a neutral complex, so that ligand bulk becomes partic-

ularly important. The combination of ligand bulk and an additional amine donor site should make **I** an attractive ligand for generating barium complexes of low nuclearity.

Experimental section

General procedures

All manipulations were carried out under an argon atmosphere, with the rigorous exclusion of oxygen and water, using standard glovebox (Braun MB150-GII) or Schlenk techniques. Tetrahydrofuran (THF), hexane, and toluene were dried by distillation from sodium benzophenone ketyl under argon immediately prior to use. $Ba[N(SiMe_3)_2]_2[THF]_2$ (8) and $HOSi(^tBu)_2((CH_2)_3NMe_2)$ (5) were prepared according to literature methods.

^{1}H, ^{13}C, and ^{29}Si NMR spectra were recorded on a Bruker WM-250 MHz or a Bruker AMX-360 MHz spectrometer. Spectra were recorded in C_6D_6, C_7D_8, or C_4D_8O solvent, previously distilled from sodium under argon, using 5 mm tubes fitted with a Teflon valve (Brunfeldt). ^{29}Si spectra were recorded using an INEPT pulse sequence. ^{1}H and ^{13}C NMR spectra were referenced to residual solvent resonances while ^{29}Si NMR were referenced to external TMS. NMR data for compounds **1–3** are collected in Tables 1 and 2. Melting points were recorded using a Reichert hot stage and are not corrected. Elemental analyses were performed by Canadian Microanalytical, Delta, B.C.

$\{Ba[OSi(^tBu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2]\}_2$ (1)

A solution of $HOSi(^tBu)_2((CH_2)_3NMe_2)$ (0.514 g, 2.09 mmol) in 25 mL of toluene was added dropwise over 15 min to a stirred solution of $Ba[N(SiMe_3)_2]_2[THF]_2$ (1.259 g, 2.09

$^bR_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w(|F_o|)^2]^{1/2}$.

mmol) in 25 mL of toluene in the glovebox. After an additional 30 min of stirring, the solvent was removed by rotary evaporation and the white powder redissolved in a minimum of hexane. Cooling at −30°C afforded colourless crystals of **1**. Yield: 0.74 g (66%); mp 143–145°C. Anal. calcd. for $C_{38}H_{96}Ba_2N_4O_2Si_6$: C 42.09, H 8.92, N 5.17%; found: C 41.32, H 8.61, N 4.98%.

$Ba[OSi(^tBu)_2((CH_2)_3NMe_2)]_2$ (2)

Compound **2** was prepared using a procedure analogous to that described above for **1** except that a 2:1 ratio of silanol to silylamide was employed. The product **2** was isolated as a colourless oil of extremely high hexane solubility. We were unable to obtain satisfactory elemental data on this compound, presumably because of the presence of trace impurities. The low volatility of this compound did not allow purification by distillation because significant decomposition occurred during heating. Similarly, attempts to obtain mass spectroscopic data for **2** led to extensive fragmentation under chemical ionization conditions and the compound is not compatible with other techniques due to reaction with the common matrix solvents employed. Despite these difficulties, the extremely clean NMR spectra obtained in d_8-THF (see Tables 1, 2, and the discussion section) indicate that **2** is of reasonably high purity and that the impurities that affect the elemental data are minor in nature. Nevertheless, the formulation of **2**, while consistent with the data we were been able to obtain, must remain tentative in the absence of adequate analytical or mass spectroscopic data.

$[Ba[OSi(^tBu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2][THF]]_2$ (3)

Compound **3** was isolated directly from the reaction mother liquors using the same procedure as given for **1** but with hexane rather than toluene as solvent. Yield: 82%; mp. 94–95°C. A satisfactory elemental analysis could not be obtained due to the tendency of **3** to lose THF. Despite prolonged vacuum drying, the analytical data were consistently low in carbon and hydrogen and high in nitrogen, consistent with loss of weakly coordinated THF. A typical analysis is as follows: calcd. for $C_{46}H_{112}Ba_2N_4O_4Si_6$: C 44.97, H 9.19, N 4.56%. found: C 42.86, H 8.36, N 4.65%.

X-ray crystallographic studies

Crystallographic data for **1** and **3** are summarized in Table 3. Crystals of **1** (0.4 × 0.4 × 0.4 mm) and **3** (0.37 × 0.74 × 0.22 mm) were loaded into glass capillaries in the glove box and subsequently flame sealed. The crystals were transferred to a Nonius CAD4F diffractometer equipped with Mo Kα radiation. The unit cell of **1** was refined using 24 reflections in the 2θ range of 17°–35° while that of **3** was refined using 25 reflections in the 2θ range of 21°–36°. Experimental densities were not obtained because of the air sensitivity of both compounds. Three standard reflections, measured periodically during data collection (for **1**: 0,6,0; 12,0,0; 0,0,8 and for **3**: 3,0,0; 0,8,0; 0,0,4), showed no significant decline in intensity during data collection. Intensity measurements were collected over one quarter of the sphere for both **1** and **3**. After the usual data reduction procedures, including an absorption correction according to a measured PSI scan, the structures were solved by direct methods (NRC Solver) (9). The refinements minimized $\Sigma w((|F_o|-|F_c|)^2)$ and proceeded normally using SHELX76 (10). Criteria for inclusion of reflections were $I > 2.5\sigma(I)$ and $I > 4\sigma(I)$ for **1** and **3**, respectively. The weighting scheme was determined by counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$. Convergence was satisfactory for both compounds: max shift/esd = 0.069 for **1**, and 0.045 for **3**. A total of 235

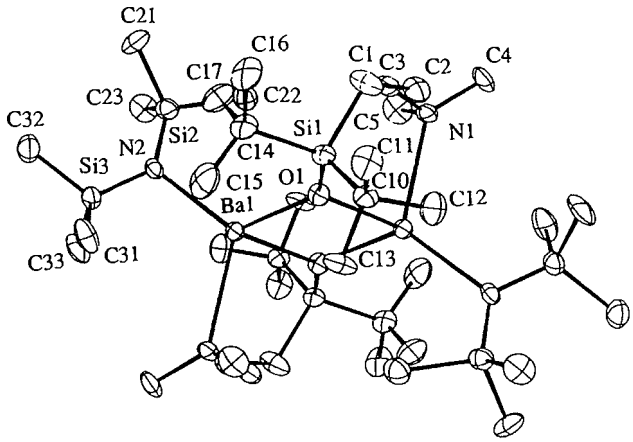
Fig. 1. ORTEP drawing of **1**.



parameters (26 atoms × 9 parameters per atom + scale) were refined for **1**. For **3**, 280 parameters (31 atoms × 9 parameters per atom + scale) were refined in two blocks. No intermolecular contacts shorter than 3.5 Å were observed in either structure. The structural perspective plots were drawn using ORTEP (11). Complete tables of bond distances and angles (Tables S1, S3, S4) and anisotropic temperature parameters Tables S2, S5) have been deposited as supplementary material.[2]

Results and discussion

Reaction of $Ba[N(SiMe_3)_2]_2[THF]_2$ with 1 or 2 equivalents of $HOSi(^tBu)_2((CH_2)_3NMe_2)$ proceeded smoothly in toluene to yield the mono- (**1**) or bis(siloxide) (**2**) complexes (eqs. [1] and [2]). Complex **1** was isolated as a crystalline, solvent-free dimer (*vide infra*) while **2** was obtained as an oil of extremely high hexane solubility.

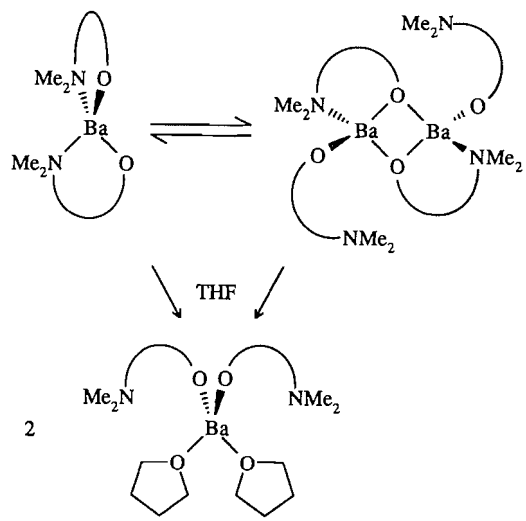
$$[1]\quad 2\,Ba[N(SiMe_3)_2]_2[THF]_2 + 2\,HOSi(^tBu)_2((CH_2)_3NMe_2) \rightarrow \{Ba[OSi(^tBu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2]\}_2 + 2\,HN(SiMe_3)_2 + 4\,THF \qquad (1)$$

$$[2]\quad Ba[N(SiMe_3)_2]_2[THF]_2 + 2\,HOSi(^tBu)_2((CH_2)_3NMe_2) \rightarrow Ba[OSi(^tBu)_2((CH_2)_3NMe_2)]_2 + 2\,HN(SiMe_3)_2 + 2\,THF \qquad (2)$$

An X-ray diffraction study of **1** was carried out in order to shed light on its molecular structure. The structure of **1** is shown in Fig. 1, atomic coordinates are given in Table 4, and selected bond lengths and angles are collected in Table 5. Complex **1** crystallizes as a centrosymmetric dimer containing bridging siloxide ligands. The geometry at barium is distorted tetrahedral with one terminal silylamide and one dimethylamino group completing the coordination sphere. As expected, the bridging Ba—O(siloxide) distances in **1** (2.602(11) and 2.645(12) Å) are considerably longer than the terminal Y—O(siloxide) distances in $Y[OSi(^tBu)_2((CH_2)_3NMe_2)]_3$ (**4**) (5) even after correction for metal ionic radius and coordination number (C.N.) (predicts ca. 2.53 Å) (7).[3] The Ba—N(amine) distance of 2.94(2) Å is significantly shorter than that in **4** (predicts ca. 3.03 Å)[3] suggesting that **1** is less sterically crowded than **4**.

The bis(siloxide) complex **2** gives a single set of ^1H NMR resonances for the $OSi(^tBu)_2((CH_2)_3NMe_2)$ ligands in d_8-THF solution between −80 and +80°C (Table 2). However, in d_6-benzene two sets of resonances are observed in ca. 3:2 ratio at room temperature (Table 1). These observations are consistent with the existence of a monomer–dimer equilibrium in benzene solution and cleavage to a monomeric species in THF (eq. [3]). The variable temperature NMR data do not allow us to determine whether the predominant species at room temperature is the monomer or the dimer because the ratio changes little throughout the accessible temperature range. Furthermore, we cannot be certain whether or not the NMe_2 arms are coordinated or how many THF molecules bind to the monomer in d_8-THF solution. This is because the exchange of free and coordinated Lewis bases is generally rapid for barium compounds and, as a result, fluxional behaviour is usually observed even at −80°C. The structures depicted in eq [3] are reasonable given the apparent tendency of barium to be 4-coordinate in complexes containing the $OSi(^tBu)_2((CH_2)_3NMe_2)$ ligand, as evidenced by the solid state structures of **1** and **3** (discussed below).

[3]



During the preparation of **1**, we noticed that the ^1H NMR spectrum of the crude powder differed from that of the recrystallized product. This was attributed to the presence of residual THF (from $Ba[N(SiMe_3)_2]_2[THF]_2$). Crystals of a THF adduct $\{Ba[OSi(^tBu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2][THF]\}_2$ (**3**) were subsequently isolated directly from the reaction mother liquors. Recrystallization of **3** from hexane afforded pure **1**. The crystal structure of **3** is shown in Fig. 2, while selected distances and angles and atomic coordinates are given in Tables 5 and 6, respectively. The structure of **3** is similar to that of **1** with the important difference that one THF molecule

[a]Coordinates × 10^n where n = 5 for Ba, 4 for Si, O, and N, and 3 for C. Temperature parameters × 10^n where n = 4 for Ba, and 3 for Si, O, N, and C.

[b]U_{eq} = the equivalent isotropic temperature parameter = $1/3\ \Sigma_i\Sigma_j U_{ij} a_i^* a_j^* (a_i \cdot a_j)$. $T = \exp(-8\pi^2 U_{iso} \sin^2\theta/\lambda^2)$.

has displaced the dimethylamino arm from each Ba center (the closest Ba···NMe_2 contact is 6.19 Å between Ba(1) and N(1)). The Ba(1)—O(2) (THF) distance of 2.78(2) Å is significantly shorter than the Ba(1)—N(1)′ (amine) distance of 2.94(2) Å in **1**. Nevertheless, the THF ligands in **3** are readily lost under vacuum, implying that THF is not a significantly better donor than the dimethylamino groups in these complexes. Presumably the tendency for amine dissociation, which was also observed with $Y[OSi(^tBu)_2((CH_2)_3NMe_2)]_3$ (5), could be decreased by using shorter chain lengths so that 5- and 6-membered chelate rings are formed rather than the 7-membered rings formed with **I**.[4]

While this work was in progress Hanusa and co-workers reported the structural characterization of (clox)Ca-$[N(SiMe_3)_2][THF]_3$ (clox = $OCPh_6(CH_6C_6H_4$-Cl-4) (12), which is, to our knowledge, the only other mixed alkoxide-amide complex of a group-2 metal. The Ca—$N(SiMe_3)_2$ distance of 2.353(5) Å is only marginally longer than those found

[4] The choice of chain length was in part dictated by synthetic practicalities (2-chloroethylamines do not form Grignards while 3-chloropropylamines do) but we are currently investigating alternate synthetic routes to the 1- and 2-C chain (5- and 6-membered chelate ring) ligands.

in **1** and **3** (2.630(14) and 2.58(2) Å, respectively) after applying a correction of +0.33 Å to account for differences in metal ionic radius and coordination number.[5] Similarly the Ba(1)—O(2) (THF) distance in **3** (2.78(2) Å) falls within the range of Ca—O(THF) distances observed for (clox)Ca-$[N(SiMe_3)_2][THF]_3$ (2.398(5)–2.460(5) Å) after application of this correction factor.

Complexes **1** and **3** exhibit the same NMR spectra as one another in d_8-THF solution but these spectra differ markedly from those obtained in d_6-benzene. In d_8-THF, the *same two sets* of silylamide and siloxide resonances are observed in the ^1H, ^{13}C, and ^{29}Si NMR spectra of either **1** or **3** (Table 2), indicating that the *same species* is present in solution for both compounds. Close inspection of the ^{29}Si and ^1H NMR chemical shifts also indicated the presence of Ba[N-$(SiMe_3)_2]_2[THF]_2$ and **2** as the minor components (ca. 10%). This was confirmed by the disappearance of signals due to **2** upon addition of a fivefold excess of free Ba[N-$(SiMe_2)_2]_2[THF]_2$ (Fig. 3). Thus, in THF solution, ligand redistribution *is* occurring although the equilibrium lies well on the side of intact **3** (eq. [4]).

In d_6-benzene (or d_8-toluene) **1** and **3** exist as distinct compounds, as is clearly evident from the observation of different NMR spectra. Variable temperature NMR spectra of **3** from −80 to +80°C shows a single set of siloxide resonances that is consistent with either complete dissociation of dimeric **3** into monomers *or* rapid exchange of free and coordinated NMe_2 arms in a dimeric structure similar to that observed in the solid

[5] Based on extrapolated ionic radii of 1.27 and 0.94 Å for Ba^{2+} in 4-coordination and Ca^{2+} in 5-coordination, respectively (ref. 7).

[b]U_{eq} = the equivalent isotropic temperature parameter = $1/3\ \Sigma_i\Sigma_j U_{ij} a_i^* a_j^* (a_i \cdot a_j)$. $T = \exp(-8\pi^2 U_{iso} \sin^2\theta/\lambda^2)$.

state (Fig. 2). We favour the latter explanation because rapid exchange of free and coordinated NMe_2 groups has previously been observed in $Y[OSi(^tBu)_2((CH_2)_3NMe_2)]_3$ (5). Complex **1** also shows a single set of resonances for the siloxide ligand over the same temperature range. This observation is consistent with either a monomeric or dimeric structure but we favour the dimeric structure because the large barium ion is unlikely to prefer 3-coordination in solution when 4-coordination is easily accommodated, without any unusual distortions, in the solid state structure.

Complexes **1** and **3** do not appear to undergo ligand redistribution as readily in benzene or toluene as they do in THF. There is no evidence for the presence of **2** or $Ba[N(SiMe_3)_2]_2$ in solutions of **1** in toluene or benzene throughout the −80 to +80°C range. Trace (<5%) amounts of **2** and $Ba[N(SiMe_3)_2]_2$ are just detectable in the NMR spectra of **3**. The presence of

some ligand redistribution in the case of **3** is probably attributable to the presence of THF in this compound.

It is possible that ligand redistribution occurs more readily in d_8-THF solution because THF is required to stabilize $Ba[N(SiMe_3)_2]_2$ (i.e., to favour the right-hand side of eq. [4]). The solution behaviour of **1** is more reminiscent of $Cp^*CaI(THF)_2$ (13) than $(clox)Ca[N(SiMe_3)_2][THF]_3$ since the former undergoes ligand redistribution in THF while the latter does so in toluene. It appears from these results that the susceptibility to ligand redistribution cannot be predicted reliably from the type of ancillary ligation (e.g., Cp* versus alkoxide) but depends, as might be expected, on the subtle interplay between steric and electronic factors for *all species* involved in the redistribution process (such as those in eq. [4]).

[4] $\{Ba[OSi(^tBu)_2((CH_2)_3NMe_2)][N(SiMe_3)_2][THF]\}_2$
(3)

$$\rightleftharpoons Ba[N(SiMe_3)_2]_2[THF]_2 + Ba[OSi(^tBu)_2((CH_2)_3NMe_2)]_2$$
(2)

While complexes **1**–**3** are soluble in hydrocarbons, they are not volatile at 10^{-4} Torr (1 Torr = 133.3 Pa) and undergo decomposition during prolonged heating at 200°C. Consistent with this observation, none of these complexes gives molecular ions in the mass spectrum (EI or CI). Attempts are currently underway to modify the amino–siloxide ligand described in this work with the goal of achieving increased volatility and greater stability towards ligand redistribution for the mono(ligand) derivatives.

The influence of surfactants on the electrocatalytic hydrogenation of organic compounds in micellar, emulsified, and hydroorganic solutions at Raney nickel electrodes[1]

Philippe Chambrion, Laurence Roger, Jean Lessard, Valérie Béraud, Josée Mailhot, and Marc Thomalla

Abstract: The electrocatalytic hydrogenation (ECH) of limonene (**1**) and carvone (**4**) at a Raney nickel cathode was studied both in hydroorganic medium (methanol–water) and aqueous micellar and emulsified solutions. In methanol–water, the ECH of **1** stopped at *p*-menthene (**2**) and proceeded with low current efficiencies (18–24%). In micellar solutions containing a cationic surfactant (CTAB), the ECH of **1** was more efficient, giving *p*-menthane (**3**) as the main product with current efficiencies up to 30%. The pH of the solution (hydroorganic and micellar) had little influence. With anionic (SDS) and nonionic (Brij 35) surfactants, some *p*-menthane (**3**) was formed but the conversion rate and current efficiency were much lower. The ECH of carvone (**4**) was slightly less efficient in methanol–water than in micellar and emulsified solutions. The saturated alcohols neocarvomenthol (**8**), carvomenthol (**9**), isocarvomenthol (**10**), and neoisocarvomenthol (**11**) were the main products with current efficiencies of 75% (hydroorganic medium) to 90% (micellar solutions). The effect of surfactant concentration and pH on the efficiency and stereochemistry of the ECH of carvone (**4**) was also studied.

Key words: electrocatalytic hydrogenation, limonene, carvone, Raney nickel, micellar medium.

Résumé : L'hydrogénation électrocatalytique (HEC) du limonène (**1**) et de la carvone (**4**) sur cathodes de nickel de Raney a été étudiée et en milieu hydroorganique (méthanol–eau) et en milieu aqueux micellaire et émulsionné. Dans le méthanol–eau, l'HEC de **1** s'arrête au *p*-menthène (**2**) avec de faibles efficacités de courant (18–24%). En milieu micellaire avec un surfactant cationique (CTAB), l'HEC de **1** est plus efficace : formation de *p*-menthane (**3**) comme produit principal avec des efficacités de courant de 30%. Le pH de la solution (hydroorganique et micellaire) a peu d'influence. La formation de *p*-menthane (**3**) est observée aussi avec des surfactants anioniques (SDS) et non-ioniques (Brij 35) mais avec des rendements, taux de conversion et efficacités de courant beaucoup plus faibles. L'HEC de la carvone (**4**) est un peu moins efficace en milieu méthanol–eau qu'en milieu micellaire et émulsionné. Les alcools saturés, néocarvomenthol (**8**), carvomenthol (**9**), isocarvomenthol (**10**) et neoisocarvomenthol (**11**) sont obtenus très majoritairement avec des efficacités de courant allant de 75% (milieu hydroorganique) à 90% (milieu micellaire). On a aussi étudié l'influence de la concentration du surfactant et du pH sur l'efficacité et la stéréochimie de l'HEC de la carvone (**4**).

Mots clés : hydrogénation électrocatalytique, limonène, carvone, nickel de Raney, milieu micellaire.

Introduction

The electrocatalytic hydrogenation (ECH) of unsaturated organic substrates in hydroorganic solutions at a Raney nickel cathode has significant advantages over the chemical catalytic hydrogenation (2): (*i*) the chemisorbed hydrogen is generated in situ at low overpotential (reaction [1]) and its concentration may be controlled by monitoring the current density; (*ii*) the kinetic barrier related to the low hydrogen solubility and its dissociative adsorption is bypassed (3); and, as a consequence, (*iii*) the hydrogenation can be carried out at relatively low pressures and temperatures with few or no side reactions. However, the competing hydrogen evolution reaction (HER) (reactions [2]) can drastically lower the current efficiency of ECH and in the worst cases can even prevent the hydrogenation of the organic compound (reactions [3] – [5]). On highly porous

Raney nickel electrodes and in basic medium (1 M KOH), the HER was shown to occur through a Vomer (eq. [1]) – Herovsky (eq. [2]) mechanism both in aqueous (4) and in aqueous–methanolic (5) solutions. Furthermore, in the presence of an ECH reaction, the Heyrovsky reaction is the rate-limiting step of the HER, which implies that the surface coverage by adsorbed hydrogen increases with the potential (6). The relative rates of hydrogenation (reactions [3]–[5]) and hydrogen evolution (reactions [2]) depend on several parameters among which, for a given electrode, the strength of the bond to be hydrogenated and the local concentration of the organic substrate adsorbed on the catalyst are particularly important (2).

[5] $YH - ZH_{ads} \rightarrow YH - ZH$

Electrochemical reactions can take place in aqueous electrolytes in the presence of surfactants in either heterogeneous (emulsions) or homogeneous (micelles, microemulsions) solutions (7). Micelle formation and especially surfactant adsorption strongly influence the electrochemical processes by changing formal potentials, local reactant concentrations, and (or) activation parameters (7–9) as in the well-known micellar catalysis and inhibition phenomena (10, 11). The substrate–micelle association can lead to chemo- and regioselectivity in thermal and photochemical reactions (10–13). Chemical heterogeneous catalytic hydrogenation of unsaturated organic substrates has been performed in direct and reversed micellar and microemulsified systems with modification of both the activity of the catalyst and the selectivity of the reaction (14–16). Surfactants can also enhance the rate of homogeneous hydrogenation (17) and they have recently been used in asymmetric hydrogenation reactions (18).

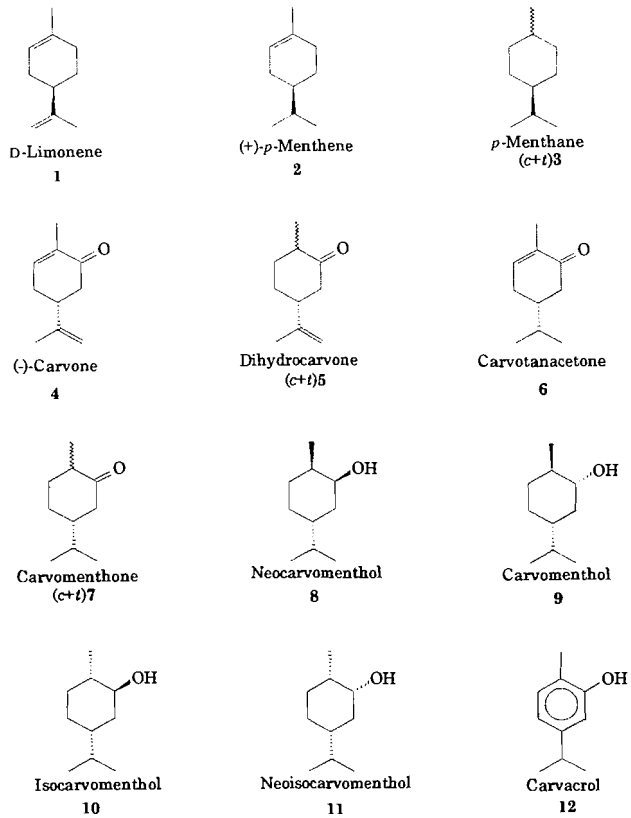
For these reasons, we have studied the influence of cationic (cetyltrimethylammonium salts), anionic (sodium dodecylsulfate), and nonionic (Brij 35) surfactants on the ECH of limonene (**1**), *p*-menthene (**2**), and carvone (**4**) (Fig. 1) in emulsified and micellar solutions and compared the results obtained in these systems with those observed in hydroorganic solutions with limonene (**1**) and carvone (**4**). The chemo-, regio-, and stereoselectivity of ECH was also investigated.

Experimental

Reagents

Commercially available compounds were used as received: D-limonene (98%) from Eastman Kodak, (+)-*p*-menthene (99%) from Fluka, (–)-carvone (98%) and cetyltrimethylammonium bromide (CTAB) (99%) from Jansen Chemica, polyoxyethylene-23-dodecanol (Brij 35) (purum) from Aldrich, sodium dodecylsulfate (SDS) and 25% aqueous solution of cetyltrimethylammonium chloride (purum) from Fluka. Methanol, ethanol, and water were distilled before use.

Fig. 1. Structure of substrates and reactions products.



Electrolyses

The electrochemical apparatus, the cell, the preparation of Raney Ni electrodes, and the electrolysis procedure were previously described (2). Some experiments, especially the ECH of carvone, were performed on a Tacussel PRT-100 potentiostat with a Tacussel IG5-LN integrator in the auxiliary circuit. As previously indicated (2), the percentage of alloy deposited on the cathode was calculated by the relation 100 $m_1/(m_1 + m_2)$ where m_1 and m_2 are, respectively, the mass in grams of alloy and electroplated Ni. This percentage varied between 50 and 65% and the corresponding amount of Raney Ni catalyst (after leaching of the 50/50 Ni–Al alloy) on the 4 × 3 cm^2 cathode varied between 0.6 and 0.9 g. The electrolysis conditions are indicated in the tables (footnotes *a*). In galvanostatic experiments, the cathodic potential changed with the pH (unbuffered conditions). Otherwise it was constant and varied between –0.6 (acidic solutions) and –1.1 V (basic solutions) vs. SCE. These potential values were those used in potentiostatic electrolyses in acidic and basic solutions, respectively. All the electrolyses were carried out at 30°C (temperature higher than that of the Kraft point for the different surfactants).

The catholyte composition is indicated in the tables (footnotes). The aqueous buffers used are described in the Handbook of Chemistry and Physics (19). The pH was measured either with a glass electrode or with Merck non-bleeding pH

[a]Constant current electrolyses (J = 3.3 mA cm^{-2}) at 30°C on 10 mmol of **1** (76 mM solution) and on 3.9 mmol of **2** (30 mM solution), Q = 7 F mol^{-1} (except in entries 6 (8 F mol^{-1}) and 7 (6.5 F mol^{-1}).

[b]Hydroorganic: 0.2 M NaCl, ethanol–water (85:15 v/v) (entry 2: +H_3BO_3 0.2 M); micellar: 5.5 × 10^{-2} M CTAB, 0.2 M NaCl, water; emulsified: 3.6 mmol of **1** (36 mM) in aqueous buffer without surfactant.

[c]Unbuffered solutions (except in entry 5). The first and second figures correspond to the pH at the beginning and at the end of electrolysis, respectively. The initial pH was adjusted with dilute HCl or NaOH solutions (except in entry 7).

[d]Determined by vpc and based on the initial amount of substrate.

indicator strips (see ref. 20 on pH measurements in micellar systems). To favor the proton transfer from the anodic to the cathodic compartment through the cation exchange Nafion-324 (E.I. du Pont de Nemours & Co) membrane, the anolyte consisted of a solution (in the same solvent as the one used for the catholyte) of a mineral acid (H_2SO_4) or HCl) at higher concentrations than those in the catholyte, without any other additive (supporting electrolyte, surfactant, etc.). The concentration of the acid in the anolyte (from 0.1 M to 4 M) was a function of the medium (homogeneous or micellar solutions). The buffering effect of such a device was only partial, as shown by the pH variation during the electrolyses in unbuffered solutions (especially in the presence of surfactants).

Products

For the ECH of limonene (**1**) and *p*-menthene (**2**) in homogeneous solutions, the work-up procedure was the same as that reported in ref. 2. With micellar solutions, the surfactant was removed by filtration on Merck 60 silica gel, then the usual work-up procedure was followed, or the cathodic solution was saturated with NaCl and then continuously extracted by ether. The products were identified by comparison (IR, ^{1}H NMR, mass spectra) with authentic samples (*p*-menthene, see above, *cis* and *trans* paramenthane from Wiley Organics (98% and 99%)). The yields were determined by vapor phase chromatography (vpc) as described in ref. 2, using nonane (99%) (Aldrich) or 2-decyne (Fluka) as internal standard.

In the experiments with carvone (**4**) in hydroorganic solutions, before the usual work-up, methanol was removed from the cathodic solution by distillation at atmospheric pressure. For micellar solutions, the surfactant was removed by filtration on silica gel or continuous with ether (see above). The crude product was separated by flash chromatography on silica gel (0.03–0.075 mm) and preparative vpc, and the products were identified by comparison of their spectral characteristics (IR, ^{1}H and ^{13}C NMR, mass spectra) with those of commercially available authentic samples (dihydrocarvone (**5**) (98%) from Jansen Chemica, carvacrol (**12**) (98%) from Aldrich Chemicals) or with literature data (21–27). Yields were determined by vpc on semi-capillary (15 m, 1 μm) or capillary (30 m, 0.25 μm) polar DBwax columns (J and W) (Varian 3300 chromatograph equipped with thermal conductivity or flame ionization detectors) using pentadecane (99+%, Aldrich) as internal standard. Product distribution (yields and mass balance) during the electrolyses on limonene and carvone was determined by vpc with aliquots (0.5 or 1 mL) extracted with ether after addition of a saturated NaCl solution (1 or 2 mL).

Results and discussion

ECH of limonene (1) and *p*-menthene (2)

In ethanol–water, the ECH of limonene (**1**) stopped at *p*-menthene (**2**) (Table 1, entries 1 and 3), even in the presence of boric acid (entry 2), which is known to increase the ECH efficiency (2). Current efficiencies were low (18–24%), which indicates that competing hydrogen evolution (reaction [2]) was important. In the same conditions, ECH of *p*-menthene (**2**) did not occur (entry 4). The pH of the solution has no influence: the conversion rate, chemical yield, and current efficiency at the end of the electrolysis (entries 1 and 3) and the relative percentages of **1** and **2** during the electrolysis (Fig. 2, curves 1 and 2) were similar in acidic and basic media. However, the variation of these relative percentages with the quantity of electricity depends on the amount of Raney Ni on the cathode: with 60% of Raney Ni alloy on the precursory electrode (see Experimental), the ECH was more efficient (Fig. 2, curves 3 and 4) than with 50% of alloy (curves 1 and 2).

In cationic micelles, namely cetyltrimethylammonium bromide (CTAB, 5.5 × 10^{-2} M), ECH was more efficient than in hydroorganic solutions. Indeed, the ECH of limonene (**1**) gave a mixture of *p*-menthene (**2**) and *p*-menthane (**3**) and the current efficiencies were higher in the micellar solutions (compare entries 6–8 (micellar solution) with entries 1–3 (hydroorganic solution) of Table 1 and curves 3–6 (micellar solution) with curves 1 and 2 (hydroorganic solution) of Fig.

Fig. 2. Variation of the relative percentage of limonene (**1**) and *p*-menthene (**2**) with the charge of the ECH of **1** in hydroorganic solution. Electrolysis conditions: $J = 3.3$ mA cm^{-2}, 30°C, 10 mmol of **1** (76 mM solution), EtOH–H_2O 85:15 (v/v), NaCl 0.2 M. Curves 1 and 2: 50% Raney Ni alloy, ○ pH 4–3.6 and ● pH 13–14. Curves 3 and 4: 60% Raney Ni alloy, pH 10.

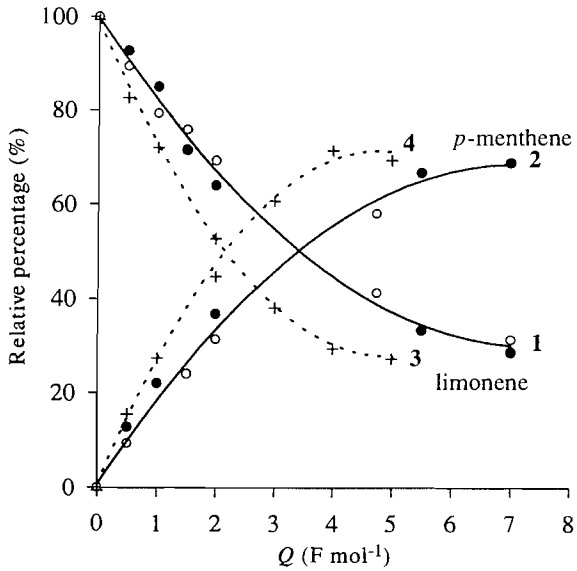

Fig. 3. Variation of the relative percentage of limonene (**1**) and *p*-menthene (**2**) + *p*-menthane (**3**) with the charge during the ECH of **1** in hydroorganic and micellar solutions. Electrolysis conditions: $J = 3.3$ mA cm^{-2}, 30°C, 76 mM solution of **1**. Curves 1 (**1**) and 2 (**2**): hydroorganic solution (EtOH–H_2O 85:15 (v/v), NaCl 0.2 M). Curves 3–6: cationic micellar solution (CTAB 5.5 × 10^{-2} M, NaCl 0.2 M); curves 3 (**1**) and 4 (**2** + **3**): pH 2; curves 5 (**1**) and 6 (**2** + **3**): pH 12.

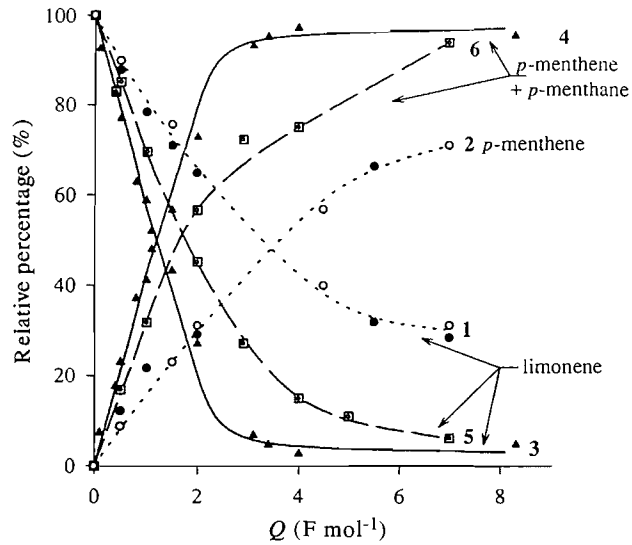

3). The ECH of **1** was more efficient in acidic medium with a 57% yield of **3** and a current efficiency of 30% (entry 6) than in basic medium (25% yield of **3**, 27% current efficiency (entry 8)). In acidic medium, **3** was converted quantitatively to **3** with an 18% current efficiency (entry 9). The percentage of precursory alloy on the precursory electrode was higher in entry 6 (55%) than in entry 8 (51%), so this contributes slightly, as well, to the higher yield of **3** in entry 6.

The higher efficiency of ECH in cationic micelles can result from an increase in the rate of reaction [4] or from a decrease in the rate of reaction [2] or both. Maoka and Enyo (28, 29) previously found that the adsorption of thiourea retarded the Tafel step (reaction [2]) of the HER on a palladium electrode. Moreover, they found that the adsorption of tetrabutylammonium hydroxide accelerated the Tafel step but slowed down the Volmer step (reaction [1]) (28, 29). If CTAB has a similar influence on the HER at Raney nickel electrodes, the amount of chemisorbed hydrogen would be less in micellar solution and both the HER and ECH should be disfavoured. Recently Vittori and co-workers (30) studied the influence of different surfactants (CTAB, SDS, Brij) on the HER on Ni cathodes. Even at the higher concentrations used (1.4–8 mM), the adsorption of surfactants had only a slight effect on the HER (the formal rate constant for the overall process was decreased by a factor of 3 in the presence of surfactant, and variations of the transfer coefficient were small (except with SDS)) (30). Considering the above results from the literature, a decrease in the rate of reaction [2] should play a minor role on the influence of surfactants on ECH. So the increase in the efficiency of ECH in micellar solutions would be due to an increase in the rate of hydrogenation (reaction [4]).

Rate enhancement of bimolecular processes in micellar solutions is mainly a consequence of high reactant concentrations in the micellar volume (pseudophase); solvent effects and changes in activation parameters are often less important (10–13, 31), The same is true for catalytic hydrogenation in direct and reversed micellar and microemulsified systems: the main effects result from an increase in local reactant concentrations on the catalyst (15, 16). Then, in ECH, a similar trend[3] would lead to higher concentrations of adsorbed organic substrate (eq. [3]) in micellar solutions and to an increase of the rate of hydrogenation (reaction [4]).

In an aqueous emulsion, in the absence of surfactant, the ECH of limonene (**1**) did not occur (Table 1, entry 5). That means there was no (or very little) substrate adsorption on the catalyst. The different mechanisms of charge and *mass transfer* for the electrochemical conversion of an organic depolarizer emulsified in an aqueous electrolyte have been described by Wendt and co-workers in several basic papers (32–36). They have shown that wetting of the electrode by the dispersed organic phase (direct contact between organic droplets and the electrode) is not operative, especially when the density of the organic phase is lower than that of the aqueous phase (this is the case for organic liquids like limonene and *p*-menthene). Under such conditions, diffusion of the organic substrate to the electrode (and its subsequent adsorption) is limited by its solubility in the aqueous electrolyte. Owing to the low solubility of limonene (**1**) in water, the amount adsorbed on the cathode was too small to allow its hydrogenation in aqueous emulsions.

In emulsions containing surfactant and in micellar solutions, the efficiency of the ECH of limonene (**1**) (i.e., competition between reactions [2] and [4]) was strongly dependent

[3] In the ECH of carvone (**4**), solvent effects, if they occur at all (see below), are not important.

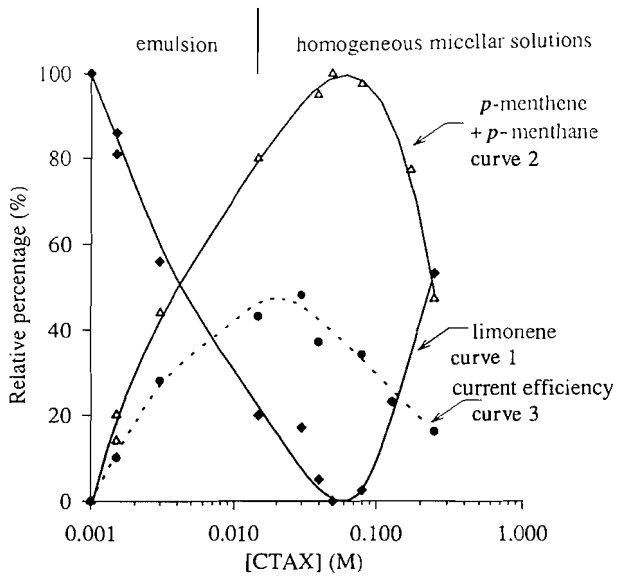
Fig. 4. Variation of the current efficiency (curve 3) and of the relative percentage of limonene (**1**) (curve 1) and *p*-menthene (**2**) + *p*-menthane (**3**) (curve 2) with the concentration of surfactant (logarithmic scale) during the ECH of **1**. Electrolysis conditions: $J = 3.3$ mA cm^{-2} (–0.9 to –1 V vs. SCE), 30°C, pH 10 (buffer), NaCl 0.1 M, 18 mM (emulsions) or 35 mM (homogeneous micelles) solutions of **1**, $Q = 5$ F mol^{-1}.



on the cationic surfactant concentration. The conversion of **1**, the amount of *p*-menthene (**2**) and *p*-menthane (**3**) formed, and the current efficiency first increased with the cetyltrimethylammonium salt concentration, then reached a maximum for surfactant concentrations between 2.5×10^{-2} and 5.5×10^{-2} M, and finally decreased (Fig. 4). In these experiments, the surfactant concentration was always higher than the critical micellar concentration (CMS $\sim 9 \times 10^{-4}$ M).

The presence of a surfactant can enhance the substrate adsorption in two ways: (*i*) by increasing the substrate solubility in the whole bulk; (*ii*) by the formation, on the cathode, of a hydrophobic adsorbed surfactant layer in which the substrate can be incorporated (Figs. 5*a* and 5*b*). In the first way, the solubility of the organic substrate increases with the number (and the size) of micelles, i.e., with the surfactant concentration. At lower concentrations of surfactant, limonene (**1**) remained partially emulsified. At concentrations of CTAX (X = Br or Cl) higher than 2.5×10^{-2} M, **1** was entirely soluble in the micelles and maximum efficiency for the ECH was then obtained. For still higher surfactant concentrations, dilution of **1** in the micellar pseudophase (the whole micelles in the electrolyte bulk) lowered its adsorption on the cathode and therefore did lower the efficiency of hydrogenation (Fig. 4). It must be noticed that the higher efficiency of ECH in micelles compared to hydroorganic solutions does not result from a solubility effect because the amounts of limonene in micellar solutions were lower than those in EtOH–H_2O (see caption of Fig. 4 and footnote *a* of Table 1). The second way to enhance substrate adsorption has been shown to be operative in heterogeneous catalytic hydrogenation of unsaturated fatty acids (16). Surfactant adsorption (especially of the cationic ones) can be important even for low concentrations (below CMC). For instance, ac impedance measurements of double layer capacity of a Ni electrode indicate that there is adsorption of Brij 35 and CTAB at concentrations of 10^{-5} and 10^{-4} M, respectively (30). The importance of the hydrophobic adsorbed CTAX layer on the ECH of limonene (**1**) is shown by the extent of hydrogenation, which is the molar fraction of *p*-menthane (**3**) in the hydrogenated products (mol of **3**/(mol of **2** + mol of **3**). This ratio was the highest (0.8) for the lowest CTAX concentration and decreased as the surfactant concentration increased (Fig. 6). This can be interpreted as a competition between the hydrogenation of **1** to **2** and the hydrogenation of **2** to **3**. As in catalytic hydrogenation over different catalysts (37, 38*a*, 39), the hydrogenation by ECH of the trisubstituted endocylic carbon–carbon double bond (in **1** and in **2**) is more difficult than that of the exocyclic disubstituted one (in **1**). However, the relative rates of ECH of **1** and **2** depend also on the relative amounts of **1** and **2** adsorbed on the catalyst. The CTAX concentration influences the relative amounts of adsorbed **1** and **2** in two ways: in controlling the thickness of adsorbed surfactant layer and in controlling the solubility of the compounds in the bulk solution. Both the thickness of the surfactant layer and the solubility of **1** and **2** increase as the CTAX concentration increases. At the beginning of the electrolysis, the concentration of limonene (**1**) in the bulk solution is high (for an emulsion, this corresponds to saturation). As a result, an increase of surfactant concentration leads to an increase of limonene adsorption but to a decrease of *p*-menthene (**2**) adsorption because the low concentration of **2** in the bulk solution favours its desorption. Moreover, the partition coefficient P between octanol and water is smaller for **2** than for limonene (**1**) (log P(octanol / H_2O) = 4.4 and 4.7, respectively (40)). Thus, for low CTAX concentrations, *p*-menthene (**2**) would desorb slowly and remain on the surface long enough to be hydrogenated to *p*-menthane (**3**) (mol of **3**/(mol of **2** + mol of **3**) closer to 1). As the surfactant concentration and thus the solubility of **2** increases, less remains adsorbed on the electrode long enough to be hydrogenated and the ratio (mol of **3**/(mol of **2** + mol of **3**)) decreases. This is clearly seen from the product distribution in the ECH of **1** at the "optimum" CTAB concentration (Fig. 7): very little *p*-menthane (**3**) was formed at the beginning of the electrolysis; the hydrogenation of **2** became important only after about 70% of **1** had been hydrogenated, which corresponds to a **2**/**1** ratio close to **2** (after a charge corresponding to 2 F mol^{-1}).

Changing the counterion of the cetyltrimethylammonium salt (from Br^- to Cl^-) had little influence on the conversion rate and current efficiency of the ECH of limonene (**1**) and had no influence on the molar fraction of *p*-menthane (**3**) (Table 2). On the other hand, the *nature of the surfactant* did strongly influence the hydrogenation. Changing the surfactant (2% by weight, 10^{-2}–10^{-1} M) from CTAB to SDS or Brij 35 lead to a significant decrease of substrate conversion, lower current efficiencies, and low yields of **3**: compare entries 3 and 4 of Table 3 (respectively, 57 and 67% of recovered **1**, 14 and 11% current efficiency, 8 and 6% yield of **3**) with entry 1 (3% of recovered **1**, 30% current efficiency, 57% yield of **3**). Even at a low cationic surfactant concentration (entry 2, Table 3) that gave a poor conversion rate (19%) and a poor current efficiency (13%), **3** did represent 80% of the hydrogenated products, i.e., a much higher proportion than the 18–19% obtained in the presence of SDS or Brij 35. This is in agreement with numerous literature results (41): cationic surfactants have a

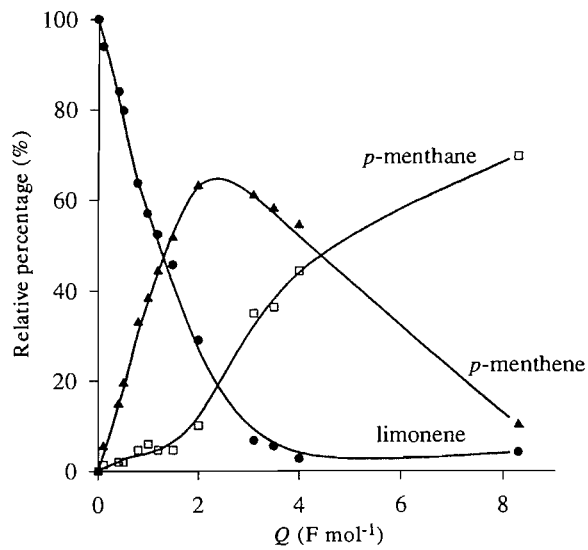
stronger influence than anionic and nonionic surfactants.

Concerning the *stereochemistry* of the ECH of limonene (**1**) (and *p*-menthene (**2**)), the *trans* isomer of *p*-menthane (**3**) was predominant in cationic micellar solutions, the *cis/trans* ratio varying between 0.59 and 0.85 (see Table 3 and Fig. 8). There

Fig. 7. Variation of the relative percentage of limonene (**1**) (●), *p*-menthene (**2**) (▲), and *p*-menthane (**3**) (□) with the charge during the ECH of **1**. Electrolysis conditions: $J = 3.3$ mA cm^{-2}, 30°C, pH 1.7–2.3, CTAB 5.5×10^{-2} M, NaCl 0.2 M, [**1**] = 76 mM.



was a small concentration effect in the case of CTAX, as shown in Fig. 8. The *cis/trans* ratio reached a maximum value (0.85) for a CTAX concentration corresponding to the highest

ECH of (–)-carvone (4)

In methanol–water solutions, the ECH of carvone (**4**) gave *cis* and *trans* dihydrocarvone (**5**), carvomenthone (**7**),[4] and the four diastereoisomeric saturated alcohols **8**–**11** (Fig. 1). Carvotanacetone (**6**) was detected (≤1%) under basic conditions (pH 12) only. Small amounts (2–6%) of carvacrol (**12**) were also observed (Table 4). This aromatic product results from hydrogenation–dehydrogenation and (or) isomerization reactions. No unsaturated alcohol (carveol or dihydrocarveol) was detected by vpc during the electrolyses using authentic samples. Thus the electrohydrogenation of the conjugated carbon–carbon double bond was faster than that of the carbonyl groups, as in the catalytic hydrogenation of carvone (**4**) over Raney nickel (42), and in accordance with the fact that the energy barrier for the hydrogenation of a carbon–carbon double bond on nickel (14.2 kJ mol^{-1}) is lower than the barrier for the hydrogenation of a carbonyl group (44.7 kJ mol^{-1}) (42).

The following points can be drawn from the study of the product distribution during the progress of the electrohydrogenation of carvone (**4**) *in methanol–water* at pH 2 and 12 (Fig. 9). *Firstly*, the fact that the saturated alcohols **8** and **9** were formed at the beginning of the electrolysis (after a charge corresponding to 1 F mol^{-1}, see Figs. 9*a* and 9*b*) shows that the complete electrohydrogenation of **4** is easier than that of limonene (**1**), as a consequence of the presence of the polar carbonyl group. This cannot be due to a classical electroreduction (electronation–protonation (EP)) process since the controlled-potential electrohydrogenations of Table 4 were carried out at a much less negative potential (–0.6 to –1 V vs. SCE) than that required to electronate an α,β-unsaturated car-

bonyl group (e.g., –1.5 V vs. SCE in neutral and alkaline solution) (43). Moreover, the electroreduction (EP) of **4** is known to give coupling products (44) and none were detected in the electrolyses of Table 4. *Secondly*, the fact that (*i*) up to a 70% conversion of **4**, dihydrocarvone (**5**), and carvomenthone (**7**) still represented more than 50% of the hydrogenated products, (*ii*) that the amount of **5** remained higher than that of **7**, and (*iii*) that no carvotanacetone (**6**) was formed indicates that the electrohydrogenation did proceed according to the sequence of Scheme 1. This is in agreement with the results of catalytic hydrogenation in which a carbon–carbon double bond conjugated to a carbonyl is hydrogenated in preference to an isolated double bond (38). *Thirdly*, the pH of the medium had little influence on the conversion rate, the product yields and distribution, and the current efficiency (see Fig. 9 and Table 4, entries 1–5). The small variations observed could be attributed to differences in the percentage of Raney nickel on the electrode (e.g., 54 and 46% of Raney alloy in the precursory electrode in entry 1 (pH 2) and entry 5 (pH 12), respectively) as in the case of limonene (**1**). The absence of carvotanacetone (**6**) is surprising considering the fact that the catalytic hydrogenation of (+)-carvone over Raney Ni under neutral and acidic conditions was reported to give a mixture of ketones where **6** is always the major product (42). Yet **6** was not detected in alkaline solutions (42). This suggests that in the electrohydrogenations, even at pH 2, the pH at the electrode surface might be alkaline as a consequence of continuous production of hydroxide ions (or consumption of protons) (reactions [1]).

Concerning the *stereochemistry* of the electrohydrogenation of **4** *in methanol–water*, the pH had some effect on the relative proportion of isomers with the methyl and isopropyl (or isopropylidene) groups *trans* and isomers with these two substituents *cis*. Indeed, the *trans*-dihydrocarvone (*t*-**5**)/*cis*-dihydrocarvone (*c*-**5**) ratio was 2.2 at pH 2 and 4.4 at pH 12 and the ratio of alcohols **8** + **9** (resulting from the electrohydrogenation of *t*-**5**) over alcohols **10** + 11 (coming from the electrohy-

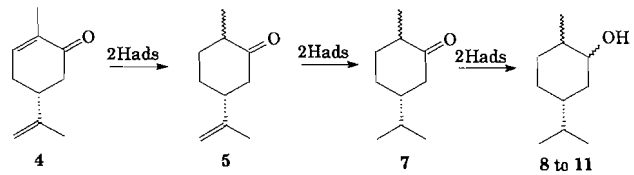
Scheme 1.



drogenation of *c*-**5**) was 1.6 at pH 2 (Table 5, entry 1) and 2.1 at pH 12 (Table 5, entry 5). Both the *t*-**5**/*c*-**5** and the **8** + **9/10** + **11** ratios were constant during the electrolysis. The *trans*/*cis* ratio is thus larger than 1, as in catalytic hydrogenation of **4** over Raney nickel in EtOH–H_2O (94/6) at 20°C and atmospheric pressure, e.g., *t*-**5**/*c*-**5** = 3.5 at pH 4.5, 2.2 at pH 7, 2.5 at pH 11 (42). As previously indicated by Godunova et al. (42), the adsorption of the conjugated double bond of carvone (**4**) on the catalyst would be less hindered for the formation of *trans* **5**. So the *trans* isomer is kinetically favored. It is also the more stable isomer with the two alkyl substituents in the equatorial orientation. The stereochemistry of the reduction of the carbonyl group of *trans* and *cis* dihydrocarvones (*t*-**5** and *c*-**5**) and carvomenthones (*t*-**7** and *c*-**7**) is given by the ratios of alcohol **8**/alcohol **9** and alcohol **10**/alcohol **11**, respectively. These ratios (and the relative proportions of alcohols **8**, **9**, **10**, and **11**) were constant throughout the electrolyses. As shown in Table 5, entries 1–5, the relative proportions of alcohols **10** and **11** did not change significantly with the pH whereas the percentage of the major isomer, alcohol **8**, increased and that of alcohol **9** decreased as the pH was increased. The relative proportions of the four alcohols **8**–**11** at pH **12**, respectively 60, 8, 12, and 20% (entry 5), are close to those obtained in catalytic hydrogenation over Raney nickel at pH 11, respectively 64, 12, 8, and 16% (42). As discussed before by Godunova et al. (42), alcohol **8** predominates over alcohol **9** because the approach of *trans* carvomenthone (*t*-**7**) to the catalyst leading to the formation of neocarvomenthol (**8**) is less hindered than the approach giving the isomeric carvomenthol (**9**). For similar reasons, the hydrogenation of *cis* carvomenthone (*c*-**7**) gives predominantly neoisocarvomenthol (**11**) (42). One explanation for an increase of the **8/9** ratio from 2.1 at pH 2 to 7.5 at pH 12 could be the slow hydrogenation of the enolate at pH 12.[5] Epimerization of alcohol **9** to alcohol **8** (through dehydrogenation–hydrogenation) is very unlikely since **8** with the hydroxy group axial should be less stable than **9** with the hydroxy group equatorial (38*c*).

In aqueous emulsions without any surfactant, the ECH of (–)-carvone (**4**) proceeded with a current efficiency (77%), conversion rate (92%), and yield of ketones (25%) and alcohols (61%) (Table 4, entry 6) similar to those observed in hydroorganic solutions (Table 4, entries 1–5). Under these conditions, limonene (**1**) was not electrohydrogenated (see above) and the greater facility of electrohydrogenation of **4** can be attributed to its higher solubility in water.

In emulsified or micellar solutions containing a cationic surfactant (CTAB), the electrohydrogenation of carvone (**4**) was more efficient than in hydroorganic or emulsified solutions with higher current efficiencies (78–99%) and a greater extent of hydrogenation (61–84% of alcohols) (Table 4, entries 7–10). The effect of surfactant is less pronounced than with limonene (**1**) as a consequence of the more facile hydrogenation of **4**. Moreover, with **4**, the maximum effect was observed at a much lower surfactant concentration (8.2×10^{-5} M, see Table 6, entry 6, and Fig. 10) than with **1** ($\sim 10^{-3}$ M, see Fig. 6). The molar fraction of alcohols (**8** + **9** + **10** + **11**)/(all hydrogenated products)) is a measure of the extent of hydrogenation of **4**. It is clear from Fig. 10 and Table 6 that the largest extent of hydrogenation was obtained with a CTAB concentration (8×10^{-5} M) lower than the CMC ($\sim 9 \times 10^{-4}$ M). *Therefore there were no micelles in the solution and the effect of surfactant on the reaction can only result from the formation of an hydrophobic layer on the cathode* (Fig. 5*a*). The association between the hydrophobic layer of adsorbed CTAB and the organic compounds enhances their adsorption and subsequently favours their hydrogenation. The importance of a hydrophobic layer on the efficiency of ECH reactions has been recently shown by Pintauro and Boutha (45): the ECH of aromatic compounds was achieved using *very high* concentrations (up to 2.5 M) of hydrotopic tetraethylammonium salts that cannot give micelles but only adsorption on the electrode. The variations of the ECH efficiency of **4** with

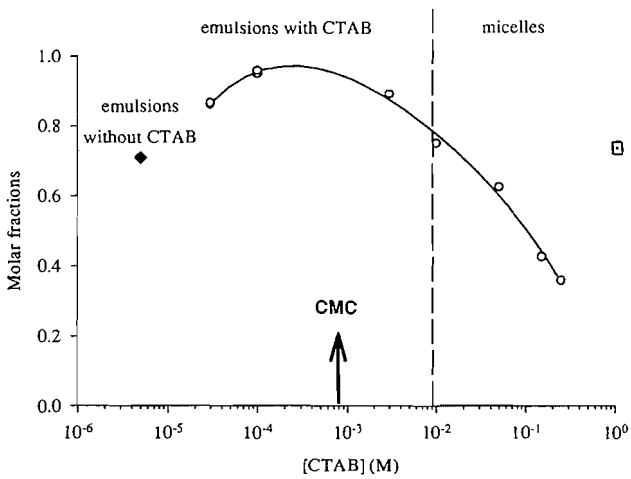
[c]Emulsion.

Fig. 10. Molar fraction of saturated alcohols **8**–**11** (alcohols **8** + **11**/totality of hydrogenated products) in the ECH of carvone (**4**) at different surfactant (CTAB) concentrations. Electrolysis conditions: E = −0.65 ±0.05 V vs. SCE, Q = 6 F mol^{-1}, pH 2, 30°C, 0.1 M NaCl, 15.9 mM solution of **4** (□, hydroorganic solution: CH_3OH–H_2O (50:50 v/v), 31.9 mM solution of **4**).



the CTAB concentration (Fig. 10) can thus be interpreted as follows. At concentrations of CTAB lower than 8×10^{-5} M, the hydrophobic layer is thinner than at the 8×10^{-5} M concentration and therefore the adsorption of **4** was less important and the ECH less efficient (Fig. 10 and Table 6, entries 6 and 7). At concentrations of CTAB higher than the CMC and as the concentration of surfactant increases, the adsorption of **4** on the catalyst was less important than at the CMC and gradually decreased because of the dilution of **4** in the micellar pseudophase (as in the case of limonene (**1**)). This resulted in a lowering of the efficiency (extent of hydrogenation) of the ECH of **4** as measured by the molar fraction of the alcohols **8**–**11** (see Fig. 10 and entries 5 to 1 of Table 6) because of a decrease in the rate of hydrogenation (eqs. [3]–[5]) competing with hydrogen evolution (eq. [2]). At the highest CTAB concentration (0.274 M, entry 1), the extent of hydrogenation was much lower than that in hydroorganic solutions as shown in Fig. 10 (point ⊡ corresponds to the molar fraction in hydroorganic solutions).

The *regiochemistry* of the ECH of carvone (**4**) in micellar solutions[6] differs from that in hydroorganic solutions. As already pointed out, in hydroorganic solutions, carvotanacetone (**6**) was barely detected so the electrohydrogenation proceeded as in Scheme 1: hydrogenation of the conjugated double bond (**4** → dihydrocarvone (**5**)) followed by hydrogenation of the isopropylidene group (**5** → carvomenthone (**7**)), then hydrogenation of the carbonyl group. In micellar solutions, carvotanacetone (**6**) was formed and could be the major unsaturated ketone at the beginning of the electrolysis (see Fig. 11). Thus, the CTAB hydrophobic layer on the electrode must orient the adsorption of carvone (**4**) through the isopropylidene chain so it can be hydrogenated before or at the same time as the conjugated double bond. On the other hand, the adsorption of CTAB has little or no influence on the *stereochemistry* of the ECH of **4**.[7] Indeed, the relative proportions of alcohols **9**–**11** were nearly the same for a similar pH of the solution, in the absence (hydroorganic solution, emulsion) and in the presence of CTAB (emulsified and micellar solution) as can be seen from Table 5.

Contrary to what was observed with limonene (**1**), the association of carvone (**4**) with the hydrophobic layer does not depend on the surfactant. Indeed, as shown in Table 7, the efficiency of the ECH of **4** (yield of alcohols, current efficiency) was the same in emulsions containing a surfactant at concentrations below the CMC whether the surfactant was cationic (CTAB, entry 1), anionic (SDS, entry 2) or nonionic (Brij 35, entry 3). Moreover, the isomeric distribution of alcohols was the same with the three surfactants.

Conclusion

In emulsified and micellar solutions, the presence of hydrophobic layer formed by surfactant adsorption on the cathode surface increases the efficiency and the extent of ECH of unsaturated

[6] It was not possible to take representative samples during the electrolysis of emulsions and therefore to follow the sequence of formation of the products as the electrolysis proceeded.
[7] The relative proportions of the *cis* (*c*-**7**) and *trans* (*t*-**7**) carvomenthones are not taken into account because of the *cis* ↔ *trans* isomerization.

organic compounds. This results from an increase of the local substrate concentration on the catalyst. For each substrate, the maximum effects are obtained at a given surfactant concentration range. With carvone (**4**), quasi-quantitative formation of alcohols was obtained for surfactant concentrations below the CMC whatever the nature of surfactant. On the contrary, with limonene (**1**), the best results were obtained with a cationic surfactant (CTAB) and at concentrations 20 to 50 times the CMC. Nevertheless, even using the best conditions, the hydrogenation of **1** was not complete and mixtures of *p*-menthene (**2**) and *p*-menthane (**3**) were obtained. In methanol–water, the ECH of limonene (**1**) was less efficient than in micellar medium and stopped at *p*-menthene (**2**) with low current efficiencies whatever the pH of the solution, whereas the ECH of carvone (**4**) was slightly less efficient than in micellar and emulsified solutions. Both the ease of hydrogenation of the conjugated double bond of **4** and its higher solubility in water (and in methanol–water) can account for the different behaviour of **4** and **1**. With **1**, micelles are needed to increase its solubility and allow adsorption on the electrode surface. In the case of carvone (**4**), the regiochemistry of ECH, hence the orientation of the adsorption on the electrode surface, was influenced by the presence of a hydrophobic layer of CTAB. With the two substrates and for the three surfactants studied, the surfactant had no noticeable influence on the stereochemistry of ECH.

Experimental and theoretical assessments of the substituent and medium dependence of the internal rotational potentials in benzyl fluoride. 3,5-Difluorobenzyl fluoride and 4-fluorobenzyl fluoride

Ted Schaefer, Robert W. Schurko, Rudy Sebastian, and Frank E. Hruska

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

Abstract: The ^1H, ^{19}F, and ^{13}C {H} nuclear magnetic resonance spectra at 300 K of 4-fluoro- and 3,5-difluorobenzyl fluoride, dissolved in CS_2–C_6D_{12} and acetone-d_6, are fully analyzed. Spin–spin coupling constants over four, five, and six formal bonds are used to derive expectation values of $\sin^2\theta$ and $\sin^2\phi$ and the apparent twofold internal rotational potentials; $\phi(\theta)$ is the angle by which the α C—F (C—H) bond twists out of the ring plane. The conformation of lowest energy has $\phi = 0°$ for the 3,5-difluoro compound in the polar and nonpolar solutions, whereas it has $\phi = 90°$ for the 4-fluoro derivative. The magnitudes of the potentials lie between 2 and 4 kJ/mol, that is, comparable to thermal energies. These data are compared with previous results for the parent compound and its 3,5-dichloro derivative. Geometry-optimized molecular orbital computations, including some correlation-gradient procedures, for benzyl fluoride and the two fluoro derivatives have $\phi = 90°$ for the conformations of highest energy of the free molecules. However, geometry-optimized SCFRF calculations of the solvent perturbations of the potential (dipole terms are insufficient) are in semiquantitative agreement with experiment in the sense that both solvents are predicted to destabilize the conformation with $\phi = 0°$. For example, the predominant twofold component in the computed (6-31G*) potential is 3.4 (free), −0.7 (CS_2), and −3.3 (acetone-d_6) kJ/mol for benzyl fluoride, a negative number indicating $\phi = 90°$ for the stable conformer; the experimental values are −0.8(2) (CS_2) and −2.7(2) (acetone-d_6) kJ/mol. The agreement between experiment and theory is of a similar quality for the fluoro derivatives. The stabilization of the conformer with $\phi = 90°$ for the 4-fluoro derivative is tentatively attributed to hyperconjugative electron acceptance by the α C—F bond, enhanced by the π-electron donor at the *para* position. A number of coupling constants are discussed in terms of the possible mechanisms of their transmission. Future experiments are indicated.

Key words: ^1H, ^{19}F, ^{13}C NMR of 4-fluorobenzyl fluoride and 3,5-difluorobenzyl fluoride; MO calculations and internal rotational potentials in benzyl fluoride, 3,5-difluorobenzyl fluoride, and 4-fluorobenzyl fluoride; solvent effects and experimental and theoretical approaches to internal rotational potentials in 3,5-difluorobenzyl fluoride and 4-fluorobenzyl fluoride.

Résumé : On a déterminé les spectres résonance magnétique nucléaire du ^1H, du ^{19}F et du $^{13}C\{H\}$ des fluorures des 4-fluoro- et 3,5-difluorobenzyles, à 300 K, en solution dans l'acétone-d_6 et dans le mélange CS_2–C_6D_{12} et on a analysé les spectres obtenus. On a utilisé les constantes de couplage spin–spin à travers quatre, cinq et six liaisons formelles pour calculer les valeurs attendues de $\sin^2\theta$ et $\sin^2\phi$ ainsi que les potentiels binaires apparents à la rotation interne; $\phi(\theta)$ est l'angle de déplacement de la liaison C—F (C—H) α par rapport au plan du noyau. Pour la conformation de plus base énergie du composé 3,5-difluoré en solutions dans des solvants polaires et non polaires $\phi = 0°$ alors que, pour le dérivé 4-fluoré, cette valeur est égale à 90°. Les amplitudes des potentiels se situent entre 2 et 4 kJ/mol; cette valeur est comparable à celle des énergies thermiques. On a comparé ces données avec les résultats rapportés antérieurement pour le composé fondamental et son dérivé 3,5-dichloré. Des calculs d'orbitales moléculaires avec optimisation de la géométrie, comprenant quelques méthodes de gradient de corrélation, ont été effectués sur le fluorure de benzyle et ses deux dérivés fluorés; elles conduisent

à des valeurs de $\phi = 90°$ pour les conformations de plus haute énergie des molécules libres. Toutefois, des calculs SCFRF optimisés pour la géométrie des perturbations du potentiel par les solvants (les moments dipolaires sont insuffisants) sont en accord semiquantitatif avec les valeurs expérimentales, c'est-à-dire que les calculs permettent de prédire que les deux solvants déstabilisent la conformation pour laquelle $\phi = 0°$. Par exemple, pour le fluorure de benzyle, la composante binaire prédominante du potentiel calculé (6-31G*) est de 3,4 (libre), −0,7 (CS_2) et −3,3 (acétone-d_6) kJ/mol alors qu'une valeur négative indique que $\phi = 90°$ pour le conformère stable; les valeurs expérimentales sont de −0,8(2) (CS_2) et −2,7(2) (acétone-d_6) kJ/mol. L'accord entre les valeurs expérimentales et calculées est d'une qualité semblable pour les dérivés fluorés. Pour le dérivé 4-fluoré, on attribue la stabilisation du conformère pour lequel $\phi = 90°$ à une par une acceptation d'électron de la liaison C—F α par hyperconjugaison aidée par le donneur-π présent en position *para*. On discute d'un certain nombre de constantes de couplage en fonction de mécanismes possibles pour leur transmission. On indique l'orientation de futures expériences.

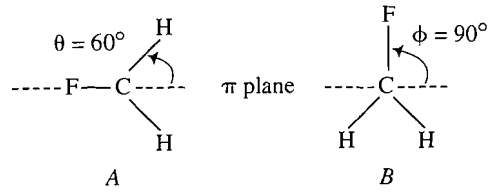
[Traduit par la rédaction]

Introduction

The phase of the internal rotational potential in benzyl fluoride, **1**, small and of the order of thermal energies at ambient temperatures, is determined by the presence or absence of intermolecular forces (1–6). Molecular orbital studies (refs. 1 and 6, and see below) imply that *A* is the conformation near which the potential[2] has a minimum, that the latter is dominated by a twofold term in the angle, ϕ, and, therefore, that *B* is the conformation of highest energy. The twofold term is computed to have a magnitude near 3 kJ/mol so that, at ordinary temperatures, all angles ϕ are significantly represented in an ensemble; a discussion in terms of discrete conformations (the so-called rotational isomeric state model) would be bootless.



A *B*

In solution, long-range nuclear spin–spin coupling constants (1, 7), as well as residual dipolar coupling constants[3] for nematic solutions (2), imply that the phase of the internal potential is shifted by 90°: *B* now lies at the minimum. For example, the apparent twofold barrier is 3.2(2) kJ/mol in the polar CD_3CN solution and sinks to 0.7(2) kJ/mol in the nonpolar C_6D_{12} solution (1). It is therefore plausible that experiment will find *A* to correspond to a potential minimum for the gas phase of benzyl fluoride. Such a definitive experiment has not been done (but see ref. 11); it cannot be done by the use of small spin–spin coupling constants, for obvious reasons.

Not only intermolecular force fields, but also ring substituents, can alter the phase of the internal potential in benzyl fluoride. The long-range coupling constants between ring protons and the protons or ^{19}F nuclei in the side chain show that the conformer analogous to *A* is now most stable for 3,5-dichlorobenzyl fluoride in solvents of various polarities (12). Just as for the parent compound, however, the polar solvents act to favor a phase shift of the potential minimum towards the perpendicular *B*. It seems possible that the proper combination of substituents and solvent will lead to a vanishing internal rotational potential.

This report has two aims. First, the solvent dependence of internal barriers in 3,5-difluorobenzyl fluoride, **2**, and 4-fluorobenzyl fluoride, **3**, is to be determined from a number of long-range coupling constants involving ^1H, ^{13}C, and ^{19}F nuclei. It is anticipated, and confirmed, that **2** behaves similarly to 3,5-dichlorobenzyl fluoride, **4**, *A* being the conformer with a lower energy than that of *B*. By way of contrast, the π-electron donor, fluorine, is predicted (6) to favor the perpendicular conformer, *B*; this prediction is also confirmed.

The second aim is to compute the solvent effect on the internal rotational potential by means of ab initio continuum methods (13–15). In particular, the model of Rivail and co-workers (13) is employed. The model uses an ellipsoidal cavity for the solute molecule and a multipole expansion (up to $l = 6$, $l = 1$ corresponding to the dipole term) for the solute charge density. As computed dipole moments for the various conformers of **2** and **3** demonstrate, for example, truncation at $l = 1$ is unsuitable. Use of the basis 6-31 G*, geometries being optimized, yields qualitative agreement with experiment for **1**–**3**, based on comparisons of expectation values of $\sin^2 \phi$.

Experimental

Compounds **2** and **3** were prepared by fluorination of the corresponding alcohols (Aldrich) with morpholinosulfur trifluoride (morph-DAST) in the standard way (16). Dilute solutions of **2** and **3** in CS_2–C_6D_{12}–C_6F_6–TMS and in acetone-d_6–C_6F_6–

[2] The computed potentials are spectroscopic potentials, not activation energies; the spin–spin coupling constants, discussed below, sample the spectroscopic potential and are determined by its shape over the whole range of ϕ or, equivalently, θ.

[3] A recent investigation (8) of the other benzyl halides finds that an increase in the height of the potential, located at *B*, is caused by more polar liquid crystal solvents. The same conclusion was reached for benzyl chloride on the basis of spin–spin coupling constants for isotropic solvents (9). In the gas phase these heavier halides are also nonplanar, according to low-resolution microwave studies (10). So far, no definitive spectroscopic studies are available for benzyl fluoride as a vapor.

[a]For a 5.0 mol% solution in CS_2 containing also 10 mol% of C_6D_{12}, 0.5 mol% of TMS, and 0.25 mol% of C_6F_6.
[b]For a 5.0 mol% solution in acetone-d_6 containing also 0.5 mol% of TMS and 0.25 mol% of C_6F_6.
[c]In Hz to high frequency of internal TMS at 300.13493 MHz.
[d]In Hz relative to internal C_6F_6 at 282.362 64 MHz, a negative number indicating increased screening.
[e]Except where otherwise noted, the standard deviations in all parameters were $\leq 10^{-3}$ Hz.
[f]The marked solvent dependence of $^nJ(H, F)$ within the phenyl group for a variety of fluorobenzene derivatives is well documented (32–34, 44); more polar solvents increase $^5J(H, F)$ algebraically, that is, a negative $^5J(H, F)$, for example, becomes smaller in magnitude (35, 36).

TMS (see Tables 1 and 2 for details) were filtered into 5 mm o.d. nmr sample tubes, degassed by at least four freeze–pump–thaw cycles, and were then flame-sealed under vacuum, taking care to produce reasonably symmetric tops.

The ^1H, ^{19}F, and proton-decoupled ^{13}C nmr spectra were acquired on a Bruker AM 300 spectrometer at 300 K. Intensive shimming, employing the TMS and C_6F_6 free induction decays, eventually yielded peak widths as low as 0.025 Hz in some instances. For ^1H and ^{19}F spectra, 32 decays, with acquisition times of 41 s, were coadded, followed by zero-filling to twice or four times the original data table. Digital resolution was 0.004 to 0.006 Hz/point. The ^{13}C nmr spectra resulted from the transformation of between 200 and 2500 decays, using acquisition times of 10–12 and digital resolution of 0.01 to 0.02 Hz/point. Resolution enhancements, normally 0.6 GB and −0.1 LB, were also imposed on the final data.

Spectral analyses used the program NUMARIT (17), the latter having been reworked extensively by R. Sebastian.

The ^1H and ^{19}F nmr spectra of **2** and **3** arise from AA′B M_2R_2X and AA′BB′M_2RX spin systems, respectively. Because of perturbations of ^{19}F chemical shifts by ^{13}C nuclei, the spectra arising from ^{13}C-2 and ^{13}C-3 in **2** were analyzed as arising from ABMX spin systems, under conditions of proton decoupling. First-order spectra were obtained for the other ^{13}C nuclei in **2** and for those in **3**.

Molecular orbital computations in **1**–**3** used the program GAUSSIAN 92 (18). Internal rotational potentials were obtained by fixing the angle ϕ in *B* at values of 0°, 30°, 45°, 60°, 75°, and 90° and optimizing the values of the other angles and bond lengths, with the constraint, however, that the phenyl moiety remained planar. Various basis sets[4] were employed in the HF SCF procedures. In addition, correlation-gradient computations, MP2/6-31G* and MP2/6-31G**, were also done for the free molecules. The calculations of solvent perturbations[5] of the internal rotational potentials used the program SCRF PAC (15), utilizing the full multipole expansion, that is, up to $l = 6$. Again, geometries were optimized as for the free molecules, now using the 6-31G* basis set.

[4] Explanations of the various split-valence basis functions, their notation, and references to them, and of the MP2 method of approximating electron correlation, can be found in ref. 19.

[5] A recent comprehensive discussion of methods based on continuous distribution of the solvent is given by Tomasi and Persico (20).

^2J(C-2, F)	22.60	22.52(2)									

[a]For the samples in Table 1.
[b]In Hz at 75.468 92 MHz to high frequency of internal TMS.
[c]Unless otherwise noted, the standard deviations were ≤10^{-2} Hz.
[d]For the CS_2–C_6D_{12} solution; similar numbers occur for the acetone-d_6 solution.
[e]A two-bond isotope shift on fluorine, $^2\Delta(^{13}C/^{12}C)$, relative to $^4\Delta$, gave $^2\Delta - {}^4\Delta$ as 5.951(6) Hz for the CS_2–C_6D_{12}, 6.01(2) Hz for the acetone-d_6, solution, entirely similar to values (39–43) for other aromatics. The C-2 spectra corresponded to the X parts of ABRX spin systems (increased screening of F-3 by C-2).

The SAS nonlinear regression procedure, NLIN (21), gave fits of the internal potentials to functions of the form

$$V(\phi) = \Sigma_n V_n \sin^2 (n\phi/2)$$

where n indicated the foldedness of the contributing term. Expectation values of $\sin^2\phi$ and $\sin^2\theta$ were calculated at 300 K with the software known as MAPLE V (22). INDO MO FPT (23) computations of the conformational dependencies of spin–spin coupling constants utilized the geometries obtained by MP2/6-31G** approaches for **1** and by MP2/6-31G* methods for **2** and **3**. The ensuing numbers were fit to various functions of θ and φ, as desired, with the SAS programs, to confirm previous assessment (7, 24, 25) of their angular dependence.

Results and discussion

Spectral data

Tables 1–4 present the ^{1}H, ^{19}F, and ^{13}C nmr spectral parameters for the 3,5-difluoro, 2, and 4-fluoro, 3, derivatives of benzyl fluoride. An example of a typical ^{1}H nmr spectrum is displayed in Fig. 1, showing the methylene proton spectrum of 3 in acetone-d_6 solution.

Experimental values of $\langle\sin^2\phi\rangle$ and $\langle\sin^2\theta\rangle$

There is little doubt that ^6J(H, CH_2) and ^6J(H, CH_2F) are proportional to $\sin^2\theta$ and $\sin^2\phi$, respectively (1), the proportionality constants between these quantities being the $^6J_{90}$ values, either for θ or φ. These coupling constants arise from σ, π

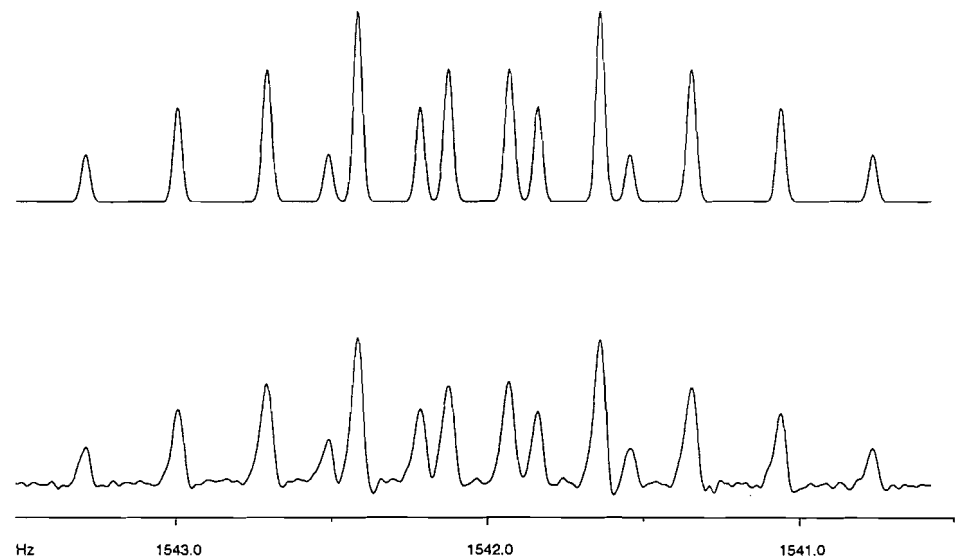
^2J(C-1, F)	18.05(4)	17.41			

[a]For the samples described in Table 1.
[b]In Hz at 75.468 92 MHz to high frequency of internal TMS.
[c]All spectra were analyzed as arising from AMX spin systems; the standard deviations in the parameters were all $\leq 10^{-2}$ Hz, except as noted. The root-mean-square deviations ranged from 0.000 to 0.04 Hz; the latter value occurred for C-1 in the CS_2–C_6D_{12} solution due to a noisy signal.

Fig. 1. Half the ^1H nmr spectrum at 300 MHz and 300 K of the methylene protons of 4-fluorobenzyl fluoride as a 5.0 mol% solution in CS_2–C_6D_{12} is shown. The computed spectrum assumes the spectral parameters in Table 2 and a linewidth of 0.03 Hz. The experimental spectrum displays relatively minor imperfect shimming characteristics, usually more prevalent in this solvent than in acetone-d_6.



electron mechanisms and can be thought of as being proportional to the product of the hyperfine interaction parameter, Q_{CH}^H, with either Q_{CCH}^H or Q_{CCH}^F: the latter two are positive, the former is negative.[6] To a good approximation (see some computed molecular structures below and ref. 12), one may therefore write that $\langle \sin^2\phi \rangle = 1.5 - 2.0 \langle \sin^2\theta \rangle$, angular brackets indicating expectation values. A change in the internal rotational potential, caused by a change in the solvent, entails a change in the expectation values. On the assumption that the $^6J_{90}$ values are solvent-independent, one then has enough equations to establish these values, as well as the expectation values in each solvent. This calculation was done for benzyl fluoride (1) with the results summarized in Table 5. The values of $\langle \sin^2\phi \rangle$ are greater than 0.5 in both solutions (a value of 0.5 corresponds to a vanishing barrier) and hence the minimum in the potential occurs at $\phi = 90°$, defining the perpendicular conformer. The apparent twofold barrier, V_2, derived from a hindered rotor model (26, 27) or from a classical averaging procedure, increases in the more polar solvent.

Turning to the 3,5-dichloro derivative, **4**, the substituents shift the phase of the potential so that its minimum occurs at $\phi = 0°$ (12), but the polar solvent again *tends* to stabilize the perpendicular conformer and therefore *lowers* the height of the potential for the range of solvents used for **4** (12); two examples are given in Table 5. Note that the $^6J_{90}$ values for ^6J(H,

[6] Thus, a spin polarization mechanism ensures that a certain spin state of a proton at the *para* position favors a spin state of the same sign for the electron in the π-type orbital on the *para* carbon atom. By definition, this situation is described by $Q_{CH}^H < 0$.

Table 5. Experimental solvent dependence of the internal rotational potentials in benzyl fluoride and some of its derivatives.

[d]These are values for ^6J(F, CH_2F).
[e]Assumed to be the value for **1** and used to derive $\langle\sin^2\theta\rangle$.
[f]Assuming a purely twofold barrier. A negative sign means that the minimum in the potential occurs in the perpendicular conformer, *B*, for $\phi = 90°$.
[g]The minimum in the potential occurs at $\phi = 0°$.

CH_2) and ^6J(H, CH_2F) differ by only about 1% from those derived for benzyl fluoride. For **4** it was demonstrated (12) that ^4J(H, CH_2) could be treated in the same way as ^6J(H, CH_2) and that $^4J_{90}$ was −1.23(1) Hz. Application of this procedure to the parent compound gives $^4J_{90}$ as 1.28(1) Hz, in reasonable agreement with the magnitude for **4**.

The spectral data for the 3,5-difluoro derivative, **2**, confirm the phase shift in the internal rotational potential found for **4**. Furthermore, the decrease in $\langle\sin^2\phi\rangle$ and the concomitant increase in $\langle\sin^2\theta\rangle$ relative to **4** implies a greater stabilization of the in-plane conformer by the fluorine than by the chlorine substituents. The simplest plausible reason for this result is that the more electronegative fluorine substituents are more effective in their polarization of *ortho* C—H bonds, thereby causing a larger attractive C^--H^+ ··· $^-$F-$^+$C interaction with the C—F bond in the side chain. Again, $^4J_{90}$ for ^4J(H, CH_2) in **2** is −1.22(1) Hz, assuming the behaviour displayed by **4** (Table 5). This result, apparently satisfactory, is important for the 4-fluoro derivative, **3**, where ^{6}plain8J(H, VH_2) and ^6J(H, CH_2F) are not present.

In this connection, an examination and interpretation of ^5J(C-4, F) for benzyl fluoride in a range of solvents (1) concluded that it is also a σ, π parameter and, as such, proportional to $\sin^2\phi$. A $^5J_{90}$ of 5.03(10) Hz was deduced, compatible with the number (4) for a model compound. Use of $\langle\sin^2\phi\rangle$ for **2** and the values of ^5J(C-4, F) in Table 3, yields $^5J_{90}$ as 5.32(15), implying a reasonably minor perturbation by the *meta* fluorine substituents.

A comparison of the $^{4,5,6}J_{50}$ values in Table 5 for **1**, **2**, and **4** suggests that such numbers do not vary by more than a few percent and that they form a reliably consistent set. Hence a subset may well be applicable to 4-fluorobenzyl fluoride, **3**.

For **3** it is sensible to take $^4J_{90}$(H, CH_2) as that for the parent compound; the substituent is relatively remote from the coupling pathway. The values of $\langle\sin^2\phi\rangle$ and $\langle\sin^2\theta\rangle$ that follow from this assumption are found in Table 5. The $^5J_{90}$ (C-4, F) then follows as 5.20(2) Hz, suggesting[7] a minor perturbation of the σ, π parameter by the fluorine atom attached to C-4 (the π electron spin density in the $2p\pi$ orbital at C-4 is not altered appreciably or, if it is, a compensating change occurs at the fluorine atom in the CH_2F group).

Note that the 4-fluoro substituent, a π-electron donor, stabilizes the perpendicular conformer in both solvents relative to the parent compound. The stabilization makes sense if it is accepted that the α-CF bond is a hyperconjugative π-electron acceptor, as previously postulated on the basis of ^{19}F nmr chemical shifts in **1** and some of its *para* derivatives (6). The present results in Table 5 represent the first experimental assessment of the energy involved in such a hyperconjugative interaction. It amounts to 1.0 ± 0.4 kJ/mol for **3** in both CS_2 and acetone-d_6 solution (the errors in the apparent V_2 values in Table 5 are quoted as twice the formal errors). It is apparent that the present methods, based on ^4J(H, CH_2) and ^5J(C-4, F), should allow similar assessments for a range of 4-X-benzyl fluoride derivatives.

Other long-range coupling constants

The many other long-range coupling constants in Tables 1–4 are only partially understood. As an extreme example, consider ^5J(F, CH_2) in **2**; the magnitudes are 0.24 and 0.16 Hz in CS_2 and acetone-d_6 solutions, respectively (Table 1). It is known that, in the 3,5-difluoro derivatives of toluene, ethylbenzene, and isopropylbenzene (29), ^5J(F, CH_2) can be positive or negative, depending on the orientation of the C—H bonds with respect to the benzene plane: it is given by $^5J = 0.08 - 2.43\langle\sin^2\theta\rangle + 1.68\langle\sin^2(\theta/2)\rangle$ and reproduces the magnitudes and signs correctly. If the coefficient of $\langle\sin^2\theta\rangle$ is reduced by a factor of 0.94/1.20, for well-documented reasons (1, 30, 31), then ^5J(F, CH_2) for **2** is predicted to be −0.20 and

[7] Indeed, in 4-fluorotoluene, ^5J(C-4, H) is not very strongly perturbed by the fluorine attached to C-4 (28).

[a]Geometry-optimized at intervals of 15° in ϕ (ϕ = 0 corresponds to the conformer in which the C—F bond of the side chain lies in the benzene plane) with the proviso that the atoms of the benzene moiety remain in a plane.

[b]The energy minimum occurs at ϕ = 18.7°, 0.04 kJ/mol lower than at ϕ = 0°.

[c]The minimum energy corresponds to ϕ = 13.5°, 0.01 kJ/mol lower than at ϕ = 0°.

[d]At ϕ = 24.7°, the energy is 0.14 kJ/mol lower than at ϕ = 0°.

[e]The energy is 0.08 kJ/mol lower at ϕ = 21.1° than at ϕ = 0°.

[f]The total lowest computed energy; the fits to $V(\phi) = \Sigma_n V_n \sin^2 (n\phi/2)$ had standard errors near 0.01 kJ/mol.

−0.13 Hz in CS_2 and acetone-d_6 solutions, respectively. The conclusion is very likely, therefore, that these numbers are, in fact, negative, and are so designated (within parentheses) in Table 1.

Similar sign assessments can be made for some other long-range coupling constants in these tables. Such signs are indicated within parentheses in Tables 1–4. We postpone more discussion, which would not further the aims of the present report, until data are available for a number of other derivatives of the parent compound.

The computed barriers

(a) Free molecules

Table 6 presents the internal rotational potentials for benzyl fluoride, **1**, and its 3,5-difluoro, **2**, and 4-fluoro, **3**, derivatives. All basis sets, including the correlation-gradient calculations, yield a dominent twofold component, V_2, of the potential. Yet, V_4 is significant in magnitude and opposite in sign to V_2. Indeed, the magnitude of V_4 is large enough to cause the minimum energy to occur, not at ϕ = 0° (which is indeed the minimum in the potential for **2**), but between 13° and 25° for **1** and **3**. These minima are predicted by the correlation-gradient computations. However, the barrier to ϕ = 0° is very small, amounting to only as much as 0.14 kJ/mol. The HF computations have the in-plane conformer, *A*, at a definite minimum in the potential. Notice that, qualitatively, the computations agree with the conclusions from the coupling constants measured in solution: the *meta* substituents enhance the stability of *A*, the *para* substituent does the opposite. Quantitatively, the discrepancy between theory for the free molecules and experiment in solution is marked: for **1** and **3** there exist phase shifts of 90° in the potential minima and for **2** the magnitudes of the potentials differ by as much as a factor of two. Prior to the description of the computational results about solvent effects, some information of use to molecular spectroscopists is presented.

Figure 2 displays the MP2/6-31G** geometries of benzyl fluoride for the in-plane and perpendicular conformers. The equilibrium bond lengths and angles appear eminently reasonable and should be useful to microwave spectroscopists, for example, in studies of the internal rotational potential, which, it is stressed, is likely of a magnitude particularly suitable to such a method.

It is also of interest that the bond angles at the formally sp^3 carbon atom in the side chain do not deviate substantially from tetrahedral. In *A*, the HCH angle is 108.4°. For an ideal angle, the twist angle, θ, is 60° for the α-CH bonds. The theoretical angle of 108.4° implies a twist angle between 59.5° and 60°, so that the assumption of ideal angles in computing $\langle\sin^2\theta\rangle$ and $\langle\sin^2\phi\rangle$ is rather good.

Another point of interest concerns the lengthening and shortening, respectively, of the C—F and Csp^2—Csp^3 bonds, as the molecule rotates internally from *A* to *B*. The increase in the C—F bond length is consistent with hyperconjugation in *B* (bond, no-bond resonance structures in valence-bond terminology); hyperconjugation should shorten the Csp^2—Csp^3 bond in *B* relative to *A*, as in the resonance structure, *C*.

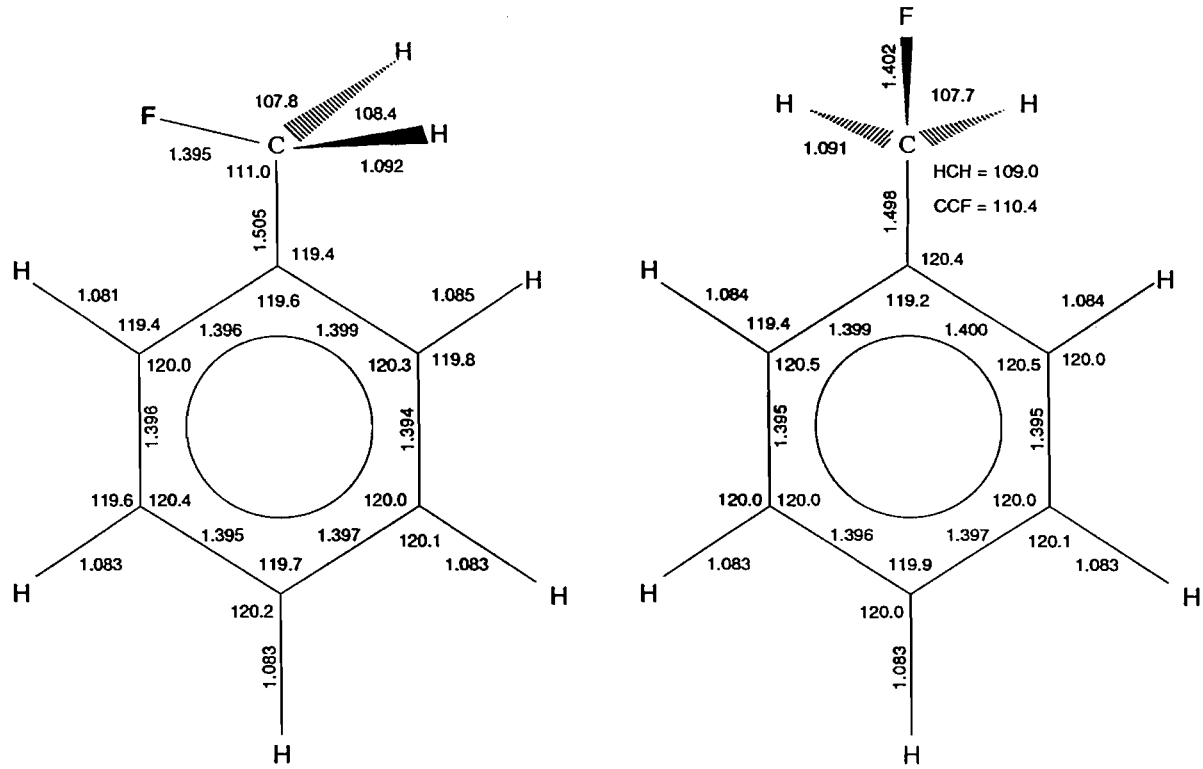
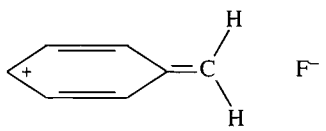
Fig. 2. The MP2/6-31G* geometries are displayed for the in-plane and perpendicular conformers of benzyl fluoride, **1**. The bond lengths and angles are as expected on the basis of available data (1, 37). Note that the fluorine substituent reduces the perturbation by a methyl group of the bond angles in the phenyl group. Thus, at the ipso position, a methyl group reduces the bond angle to 118.1° (38). The tetrahedral geometry at the α carbon atom is not severely altered, important for the arguments used in deriving expectation values of conformational angles (see text).





C

(b) Theoretical internal rotational potentials in solution

The potentials for the free molecule and that dissolved in CS_2 and acetone solutions are presented in Table 7. The dielectric constants of the solutions were taken as 2.6 and 20.3; no doubt these are not exact and may be a source of error in the computations. The basis set, 6-31G*, was used and the geometry was optimized at each value of the conformational angle, ϕ. As can be seen from the total energies appearing in Tables 6 and 7, the solvent is calculated to lower the energy of all conformers of benzyl fluoride and its 3,5-difluoro and 4-fluoro derivatives. Furthermore, qualitatively the computed solvent effects agree with experiment in the sense that while, for the free molecule, the minimum in the potential occurs for *A*, the solvent acts to favor *B*: that is, *B may* not be computed to lie at the minimum in the potential, but for each molecule the in-plane conformer is less stable in solution than in the free state.

Comparison of the theoretical and experimental values of $\langle \sin^2\phi \rangle$ in Table 7 suggests that theory, at this level, overestimates the interaction with the polar solvent and perhaps underestimates it for the less polar solution. Whether this disagreement can be attributed to the basis set or to the model is not clear. Note that the dipole term ($l = 1$) for benzyl fluoride itself can contribute significantly to solvent effects (see computed dipole moments in Table 7) but, within the present model, will have a negligible contribution to the solvent perturbations for the two derivatives.

Figure 3 conflates the theoretical and experimental results for benzyl fluoride. It would be of interest to perform solvent-effect calculations using much larger basis sets and also at the post-Hartree–Fock level of theory. Such computations are not feasible with our present resources.

Nevertheless, we take the present computations as a confirmation of our previous nmr experiments, which yielded *B* as the minimum in the internal rotational potential for benzyl fluoride in six solvents and which, on the basis of an extrapolation of a dielectric function, predicted *A* as the minimum in the potential for the free molecule (1).

Further experiments

It is clear that each benzyl fluoride derivative in a particular solvent will have a unique internal rotational potential. At present, some symmetrical 2,6-disubstituted derivatives are under investigation with a view to establishment of solvent effects on the rather larger internal rotational potentials in such molecules. Perturbations of the long-range coupling constants by polar and nonpolar *ortho* substituents are of interest. As the number of reliable coupling constants involving ^1H, ^{13}C, and ^{19}F nuclei in benzyl fluoride derivatives grows, it may well be that additional conformational markers will be found; another aim is to provide theoreticians with a body of data for

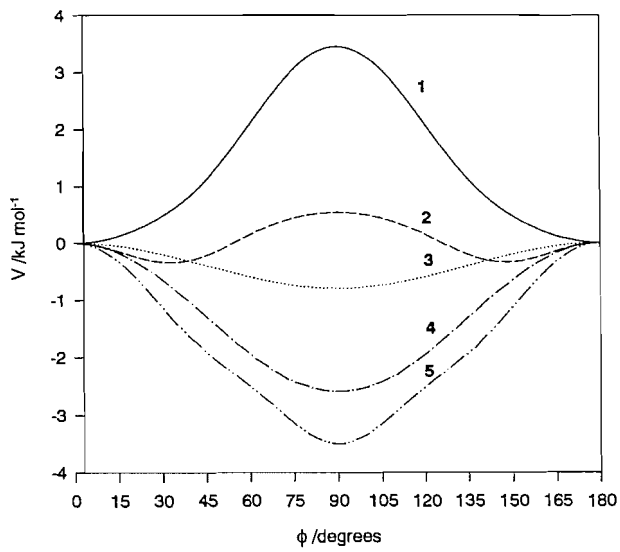
Fig. 3. The theoretical 6-31G* potential for the free benzyl fluoride molecule, curve 1, is compared with those computed for its solution in CS_2, curve 2, and acetone, curve 5, as calculated with the SCRF PAC program (15) in which the solvent is treated as a dielectric continuum. The apparent twofold potentials, derived from coupling constants, are shown for CS_2, curve 3, and acetone, curve 4. Part of the disagreement between theory and experiment, of course, may be basis set dependent. As well, the exact dielectric constants of the solutions are unknown. Table 7 summarizes the computations of the solvent perturbations of the internal rotational potential for benzyl fluoride and its 3,5-difluoro and 4-fluoro derivatives.



one basic system sufficient to stimulate computational progress. After all, if the complete conformational dependence of J, that is, its value at every value of the defining angle, were known, then high-resolution nmr of "small" molecules would become a powerful method for the characterization of their flexibility in solution.

Synthesis of nitropolychlorinated dibenzo-*p*-dioxins (NPCDDs) and their photochemical reaction with nucleophiles[1]

Simona G. Merica and Nigel J. Bunce

Abstract: A series of nitropolychlorodibenzo-*p*-dioxins (NPCDDs) was synthesized by condensation between catechols and 2,6-dinitrohalobenzene derivatives. In the presence of sodium ethoxide in anhydrous ethanol, these underwent photochemical S_N2Ar^* substitutions *meta* to the nitro group in high chemical yield and moderate quantum yield. Both ring-opening and chloride replacement reactions were observed. The reactions involved the triplet excited state of the NPCDD, and showed a linear relationship between Φ^{-1} and $[\text{nucleophile}]^{-1}$. Analogous reactions with KCN in methanol showed similar behaviour, but the products could not be isolated.

Key words: photosubstitution, S_N2Ar^*, dibenzo-*p*-dioxins.

Résumé : On a synthétisé une série de nitropolychlorodibenzo-*p*-dioxines (NPCDD) par condensation de catéchols et de dérivés 2,6-dinitrohalobenzènes. En présence d'éthylate de sodium dans l'éthanol anhydre, ces derniers subissent des réactions de substitutions photochimiques S_N2Ar^* en *méta* du groupe nitro; les rendements chimiques sont élevés et les rendements quantiques sont modérés. On a observé des réactions d'ouverture de cycle ainsi que des réactions de remplacement de l'halogénure. Les réactions impliquent l'état triplet excité du NPCDD et elles présentent une relation linéaire entre Φ^{-1} et $[\text{nucléophile}]^{-1}$. Les réactions analogues avec le KCN dans le méthanol présentent un comportement similaire; toutefois, on n'a pas pu isoler les produits.

Mots clés : photosubstitution, S_N2Ar^*, dibenzo-*p*-dioxines.

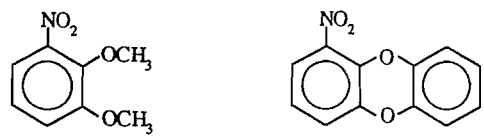
[Traduit par la rédaction]

Introduction

Polychlorinated dibenzo-*p*-dioxins (PCDDs) are well known as environmental contaminants, but their chemistry is relatively unexplored. Concern about PCDDs in the environment stems from the toxicity of the congeners that are fully chlorinated in the 2, 3, 7, and 8 positions (1–3); their toxicity has been shown to correlate with the efficiency of binding to an intracellular protein known as the Ah receptor, which accommodates them on the basis of size, shape, and lipophilicity (4–6).

In a preliminary paper, we showed that the binding ability of certain nitropolychlorinated dibenzo-*p*-dioxins (NPCDDs) to the Ah receptor is rapidly lost upon photolysis in the presence of hydroxide ion (7). Although no product identification was carried out in this preliminary study, the failure to complex with the Ah receptor implied that photochemical reaction with hydroxide ion had changed the molecular size, shape, or lipophilicity of the NPCDDs. In turn, this suggested that the photochemical reaction products might be less toxic than the starting NPCDDs, and that such a photochemical reaction might be useful for destroying the parent PCDDs.

Fig. 1. Structures of 3-nitroveratrole and 1-nitrodibenzo-*p*-dioxin.



A reasonable hypothesis for an efficient photoreaction between NPCDDs and OH^- is nucleophilic substitution (S_N2Ar^*) *meta* to the nitro group, thereby opening the central ring of the dibenzo-*p*-dioxin system and changing the shape and lipophilicity of the molecule. The dibenzo-*p*-dioxin system contains 16 π-electrons, and so the nitro-substituted moiety of an NPCDD was expected to behave like a nitro-substituted veratrole rather than as a delocalized aromatic system (Fig. 1). Nucleophilic aromatic photosubstitutions have been extensively examined for nearly 40 years, with nitrophenyl ethers being among the most thoroughly studied (8–11). Two major reaction mechanisms have been distinguished: the S_N2Ar^* mechanism involving direct formation of a σ-complex by attack of the nucleophile at a ring position *meta* to NO_2; and an electron transfer reaction that is possible when

the "nucleophile" is relatively easily oxidized, and which normally leads to substitution *para* to the nitro group (12–17). In the present work we have explored the feasibility of inducing the S_N2Ar^* reaction between NPCDD congeners and the poorly oxidizable nucleophiles CN^- and EtO^-, with a view to identifying the products and elucidating the reaction mechanisms. Since one of the two ring oxygen atoms of the dibenzo-*p*-dioxin is always *meta* to the nitro group, ring photochemical opening was expected to be facile, with the formation of a dihydroxydiphenyl ether derivative (eq. [1]).

[1] 
Experimental

Fuming nitric acid, fuming sulphuric acid, and most organic chemicals were obtained from Aldrich. Melting points were measured with a Mel-Temp apparatus using open capillaries. Thin-layer chromatography (TLC) was performed using premade glass plates coated with silica gel GF (Merck), containing a 254 nm fluorescence indicator, with a thickness of 0.25 mm. Flash chromatography on 60–120 mesh silica gel (BDH) or 230–400 mesh silica gel (Merck) was used for purifying reaction products. HPLC analyses were performed on a Waters system: Waters 501 HPLC pump, U6K injector, and model 440 absorbance detector (254 nm) and were recorded using a Hewlett Packard model 3390 A integrator. Analytical separations were performed using a Waters μBondapak C_{18} 3.9 mm × 300 mm column. Preparative separations (samples ≤100 mg) were performed on a Whatman Magnum 9 Partisil ODS-3 C_{18} (reversed phase) 9.4 mm × 250 mm column or an Econosphere C_{18}, 10 mm × 250 mm column. All solvents used were HPLC grade and were filtered through 0.45 μm Nylon 66 membranes to remove microparticulates.

^{1}H NMR spectra were recorded on a 200 MHz Varian Gemini spectrometer or on a Varian Unity 400 MHz NMR spectrometer; samples were dissolved in $CDCl_3$ with TMS as an internal standard. Analytical GC–MS was performed on a Hewlett Packard 5890 Series II gas chromatograph equipped with a J&W DB5 capillary column (0.25 mm i.d., 30 m length, 0.25 μm film thickness), with temperature programming, interfaced to a Hewlett Packard 5971 Series mass selective detector. High-resolution GC–MS employed a Kratos 890 double focussing mass spectrometer. FT-IR analyses were performed on a Nicolet model 205 SX/C FT-IR using NaCl cells; UV–visible spectra were obtained using a Perkin–Elmer Lambda 3 UV–visible spectrometer.

Synthesis of nitropolychlorinated dibenzo-*p*-dioxins and precursors

2,6-Dinitrochlorobenzene was prepared by the procedure of Gunstone and Tucker (18) from 2,6-dinitroaniline (3 g, 16 mmol) in glacial acetic acid (33 mL), which was added dropwise to a stirred solution prepared from concentrated H_2SO_4 (14 mL) and sodium nitrite (1.24 g, 18 mmol), keeping the temperature during the addition below 40°C. The diazonium salt was added dropwise to a suspension of CuCl (3.6 g, 36 mmol) in concentrated HCl (33 mL), and the solution was then heated to 80°C for 30 min, diluted with an equal volume of water, and kept at 0°C overnight. After filtration and air drying, the yellow product was crystallized from benzene – petroleum ether, affording 2.21 g (67%) of pure 2,6-dinitrochlorobenzene, mp 86–87°C (lit. (18) mp: 86–88°C), ^{1}H NMR ($CDCl_3$) δ: 8.01 (d, J = 8.1 Hz, 2H), 7.61 (t, J = 8.1 Hz, 1H).

3,4,5-Trichlorofluorobenzene was prepared in 71% yield by the method of Mahiou and Deinzer (19), involving Schiemann decomposition of the diazonium tetrafluoroborate prepared from 3,4,5-trichloroaniline. After purification by flash chromatography, eluting with 20% dichloromethane in hexane, the product had ^{1}H NMR ($CDCl_3$)δ: 7.16 (d, J = 7.8 Hz, 2H). Similarly prepared was *2,3-dichlorofluorobenzene* (90% yield); after flash chromatography, eluting with 2% dichloromethane in hexane, it had ^{1}H NMR ($CDCl_3$)δ: 7.25 (dd, J = 7.1, 5.4 Hz, 1H), 7.18 (ddd, J = 9.2, 6.7, 3.1 Hz, 1H), 7.08 (ddd, J = 8.0, 6.5, 8.5 Hz, 1H).

3,4,5-Trichloro-2,6-dinitrofluorobenzene was prepared by a modification of the procedure reported by Mahiou and Deinzer (19), which gave a very low yield. In a 50-mL round-bottomed flask equipped with a stir bar and a condenser (connected to a drying tube) were placed 3,4,5-trichlorofluorobenzene (1.0 g, 5.0 mmol), fuming nitric acid (3 mL), and fuming sulphuric acid (3 mL) containing 20% of sulphur trioxide. The mixture was refluxed for 24 h and at every 8 h a new portion of fuming nitric acid (3 mL) was added. After cooling, the reaction mixture was poured onto ice, and the precipitate collected by filtration and dissolved in chloroform. The chloroform layer was washed with water and dried over anhydrous magnesium sulphate. The solvent was removed using the rotary evaporator. The solid was recrystallized from 95% ethanol–water and dried under vacuum to give the product in 88% yield (1.27 g). GC–MS *m/z* (relative intensity): 288(78, M^+), 196(100), 161(85), 126(80). *2,3-Dichloro-4,6-dinitrofluorobenzene* was prepared similarly in 74% yield; after purification by flash chromatography, eluting with 50% dichloromethane in hexane, it had ^{1}H NMR ($CDCl_3$) δ: 8.61 (d, J = 7.0 Hz, 1H).

1,4-Dinitrotetrachlorobenzene was prepared from 1,2,3,5-tetrachlorobenzene by the procedure of Berckmans and Holleman (20): yield, 75% after two recrystallizations from 95% ethanol–water; mp 227–228°C (lit. (19, 20) mp 227–228°C); GC–MS *m/z* (relative intensity): 304(74, M^+), 230(15), 214(65), 177(43), 142(81).

4,5-Dichlorocatechol (21, 22): To an ice-cooled solution (maintained under nitrogen) of catechol (37.5 g, 0.325 mol) in anhydrous ether (150 mL) was added, dropwise, with stirring over a period of 180 min, sulphuryl chloride (58 mL, 97 g, 0.72 mol), which was distilled under nitrogen before reaction. The solution was allowed to warm to room temperature and was evaporated under nitrogen to a volume of ca 75 mL. The crystalline precipitate that formed on standing was collected to afford 4,5-dichlorocatechol (29.5 g, 51%); ^{1}H NMR ($CDCl_3$) δ: 6.98 (s, 2H), 5.56 (s, 2H, 2 × O*H*); GC–MS *m/z* (relative intensity): 178(85, M^+), 149(15), 113(10), 97(66), 85(32).

1-Nitrodibenzo-p-*dioxin* (**1**) was prepared by the procedure of Loudon and McCapra (23). In a 50 mL three-necked, round-bottomed flask, equipped with a stir bar, nitrogen inlet, and a reflux condenser (connected to a bubbler), were placed catechol (0.544 g, 4.9 mmol), potassium carbonate (1.365 g,

9.8 mmol), and dried acetone (10 mL). 18-Crown-6 (2.5 g, 9.8 mmol) was added and the mixture was refluxed under nitrogen for 45 min. A solution of 2,6-dinitrochlorobenzene (0.993 g, 4.9 mmol) in dried acetone (10 mL) was then added using a syringe. The reaction mixture was refluxed under nitrogen for an additional 8 h. After cooling, the reaction mixture was poured onto ice, and the yellow precipitate was collected by vacuum filtration and air dried. The product was purified by flash chromatography, eluting with 40% dichloromethane in hexane, affording 1-nitrodibenzo-*p*-dioxin (0.74 g, 66%): mp 126–126.5°C (lit. (23) mp 126°C); IR (CH_2Cl_2): 3058; 1539 and 1358 (NO_2); 1593, 1495, 1477, 1427, 1295, 1262, 1259, 1104, 1070, 1032, 848 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.51 (dd, J = 8.0, 1.8 Hz, 1H), 7.07 (dd, J = 7.2, 1.6 Hz, 1H), 6.96 (m, 4H), 6.87 (m, 1H); GC–MS *m/z* (relative intensity): 229(100, M^+), 183(53), 171(6), 155(7), 127(29).

2-Nitrodibenzo-p-*dioxin* (**2**) was obtained in 83% yield by the condensation of catechol with 2,4-dinitrofluorobenzene, using the procedure described above for the preparation of the 1-isomer: mp 140–141°C; IR (CH_2Cl_2): 3058, 2991; 1533 and 1345 (NO_2); 1506, 1490, 1431, 1421, 1297, 1264, 1125, 1101, 1078, 1030, 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.82 (dd, J = 9.0, 2.8 Hz, 1H), 7.73 (d, J = 2.6 Hz, 1H), 6.96 (m, 4H), 6.86 (m, 1H); GC–MS *m/z* (relative intensity): 229(100, M^+), 183(44), 171(9), 155(3), 127(20).

1,2-Dichloro-3-nitrodibenzo-p-*dioxin* (**3**) was prepared similarly by the base-promoted condensation of catechol (0.414 g, 3.7 mmol) and 2,3-dichloro-4,6-dinitrofluorobenzene (0.95 g, 3.7 mmol) in refluxing acetone in the presence of 18-crown-6 (1.038 g, 7.45 mmol). The product (**3**) was obtained in mixture with 1-chloro-2,4-dinitrodibenzo-*p*-dioxin (**4**). The isomers were separated by silica gel column chromatography, eluting with 40% dichloromethane in hexane. 1,2-Dichloro-3-nitrodibenzo-*p*-dioxin (**3**, 31%) had mp 171–172°C; IR (CCl_4): 2968, 2927; 1561 and 1338 (NO_2); 1541, 1505, 1475, 1453, 1303, 1298, 1261, 1100, 1020, 863, 841 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.40 (s, 1H), 7.00 (m, 3H), 6.84 (m, 1H); MS *m/z* (relative intensity): 297(100, M^+), 251(53), 160(40), 108(12). The by-product 1-chloro-2,4-dinitrodibenzo-*p*-dioxin (**4**, 45%) had ^1H NMR ($CDCl_3$) δ: 7.42 (s, 1H), 7.02 (m, 3H), 6.88 (m, 1H); GC–MS *m/z* (relative intensity): 308(100, M^+), 232(12), 216(54), 183(14), 160(20).

2,3,4,7,8-Pentachloro-1-nitrodibenzo-p-*dioxin* (**5**) was prepared similarly by the condensation of 4,5-dichlorocatechol (0.68 g, 3.8 mmol) and 3,4,5-trichloro-2,6-dinitrofluorobenzene (1.1 g, 3.8 mmol) in the presence of potassium carbonate (1.058 g, 7.6 mmol) and 18-crown-6 (1.0 g, 3.8 mmol) in refluxing acetone. After purification by flash chromatography, eluting with 10% dichloromethane in hexane, the product **5** was obtained in 91% yield; mp 238–239°C; IR (CH_2Cl_2): 3020; 1555 and 1306 (NO_2), 1489, 1471, 1440, 1379, 1359, 1110, 995, 890, 859 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.17 (s, 1H), 7.07 (s, 1H); GC–MS *m/z* (relative intensity): 399(100, M^+), 353(31), 318(8), 262(22).

1,3,4,7,8-Pentachloro-2-nitrodibenzo-p-*dioxin* (**6**) was prepared by the method of Mahiou and Deinzer (19), in which 4,5-dichlorocatechol (0.836 g, 4.67 mmol) and 1,4-dinitrotetrachlorobenzene (1.0935 g, 4.67 mmol) were condensed in refluxing acetone in the presence of potassium carbonate (1.291 g, 9.34 mmol) and 18-crown-6 (1.23 g, 4.67 mmol). The product was obtained in 80% yield after purification by flash chromatography, eluting with 2% dichloromethane in hexane; mp 206–207°C; IR (CCl_4): 2970, 2934; 1570 and 1302 (NO_2); 1480, 1469, 1433, 1362, 1360, 1060, 984, 868, 832 cm^{-1}; ^1H NMR ($CDCl_3$)δ: 7.15 (s, 1H), 7.13 (s, 1H); GC–MS *m/z* (relative intensity): 399(100, M^+), 353(34), 318(16), 262(31).

Preparative irradiations

Preparative scale irradiations were performed in 25 mm × 195 mm Pyrex tubes, using as the light source a Rayonet model RPR photoreactor, equipped with 16 lamps, having maximum emission at 300 nm. Sodium ethoxide solutions were prepared by dissolving the calculated quantity of metallic sodium in anhydrous ethanol.

1-Nitrodibenzo-p-*dioxin/EtO⁻*

A solution of **1** (22.9 mg 1-NDD in 100 mL ethanol, 1.0 mM) was mixed with 0.1 M NaOEt in ethanol (100 mL) and irradiated in four Pyrex tubes for 2 h. After irradiation, a large amount of water (≈200 mL) was added to the reaction mixture and the aqueous solution was then extracted repeatedly with dichloromethane (20 × 10 mL). The organic extract was dried over $MgSO_4$ and the solvent removed under reduced pressure. HPLC showed a large peak due to the product, along with a small peak from the unreacted starting material. After preparative HPLC, eluting with methanol at a flow rate of 4 mL/min, the product (71%) was analyzed by GC–MS and ^1H NMR, which showed that two isomers were present in 4:1 ratio: 2-ethoxy-6-nitro-2′-hydroxydiphenyl ether **7** and 2-ethoxy-3-nitro-2′-hydroxydiphenyl ether **8**. The minor isomer **8** was the product of a thermal reaction, and was isolated pure, as follows. In a 50 mL round-bottomed flask, equipped with a stir bar and a reflux condenser, a solution of 1-NDD (20 mg, 0.087 mmol) in anhydrous ethanol (10 mL) was combined with a solution of 0.5 M NaOEt (10 mL). The reaction mixture was heated to reflux for 1 h, and the product appearance was monitored on HPLC. After the reaction was complete, a large amount of water was added and the aqueous solution was extracted with dichloromethane (20 × 10 mL). The organic extract was then dried ($MgSO_4$), evaporated to dryness, and a portion of the residue was purified by preparative HPLC. Compound **8**: ^1H NMR ($CDCl_3$) δ: 7.55 (dd, J = 7.4, 2.2 Hz, 1H), 7.12 (m, 4H), 6.97 (m, 2H), 4.27 (q, J = 7.0 Hz, 2H, -OCH_2CH$_3$), 1.65 (s, 1H, -O*H*), 1.39 (t, J = 7.0 Hz, 3H, -OCH$_2$CH_3); GC–MS: RT = 15.60 min, *m/z* (relative intensity): 275(53, M^+), 247(5), 229(100), 199(15), 183(9). HRMS calcd. for $C_{14}H_{13}NO_5$: 275.0794; found: 275.0776. By comparing the ^1H NMR and GC–MS spectra of the isomer mixture with those of the thermal isomer, the following data were deduced for isomer **7**: ^1H NMR ($CDCl_3$) δ: 7.45 (dd, J = 8.0, 1.6 Hz, 1H), 7.28 (m, 3H), 6.65 (m, 3H), 3.98 (q, J = 7.0 Hz, 2H, -OCH_2CH$_3$), 3.78 (s, 1H, -O*H*), 1.21 (t, J = 7.0 Hz, 3H, -OCH$_2$CH_3); GC–MS: RT = 16.26 min, *m/z* (relative intensity): 275(100, M^+), 229(2), 199(2), 183(1), 167(15). HRMS calcd. for $C_{14}H_{13}NO_5$: 275.0794; found: 275.0773.

2-Nitrodibenzo-p-*dioxin/EtO⁻*

A similar procedure afforded a mixture of isomers in 73% yield and a 1:1 ratio. A thermal reaction yielded 2-ethoxy-5-nitro-2′-hydroxy-diphenyl ether (**10**): ^1H NMR ($CDCl_3$) δ:

8.05 (dd, J = 9.0, 2.8 Hz, 1H), 7.93 (d, J = 2.4 Hz, 1H), 7.02 (m, 3H), 6.90 (m, 1H), 6.83 (dd, J = 6.2, 2.4 Hz, 1H), 5.92 (s, 1H, -O*H*), 4.17 (q, J = 7.0 Hz, 2H, -OCH_2CH$_3$), 1.42 (t, J = 7.0 Hz, 3H, -OCH$_2$CH_3); GC–MS: RT = 16.94 min, *m/z* (relative intensity): 275(100, M^+), 247(9), 230(59), 200(37), 171(8). HRMS calcd. for $C_{14}H_{13}NO_5$: 275.0794; found: 275.0779. By comparing the ^{1}H NMR and GC–MS spectra of the photochemical isomer mixture with those of the thermal isomer, the following data were deduced for 2-ethoxy-4-nitro-2′-hydroxydiphenyl ether (**9**): ^{1}H NMR ($CDCl_3$) δ: 7.82 (m, 3H), 7.02 (m, 3H), 6.86 (m, 1H), 4.17 (q, J = 7.0 Hz, 2H, -OCH_2CH$_3$), 1.62 (bs, 1H, -O*H*), 1.43 (t, J = 7.0 Hz, 2H, -OCH$_2$CH_3); GC–MS: RT = 16.43 min, *m/z* (relative intensity): 275(100, M^+), 247(13), 230(34), 200(21), 183(3), 171(7). HRMS calcd. for $C_{14}H_{13}NO_5$: 275.0794; found: 275.0778.

1,2-Dichloro-3-nitrodibenzo-p-*dioxin/EtO*$^-$

A solution of **3** (10 mg in 33 mL anhydrous ethanol, 1.0 mM) was mixed with a solution of 0.1 M NaOEt (33.5 mL) and divided between two Pyrex tubes (25 mm × 195 mm) which were irradiated for 90 min. After irradiation, the reaction mixture was extracted as described for **1**. The products were 2,3-dichloro-6-ethoxy-4-nitro-2′-hydroxydiphenyl ether **11** and 3,4-dichloro-2-ethoxy-5-nitro-2′-hydroxydiphenyl ether **12**. Isomer **12** was synthesized by thermal reaction of **3** with NaOEt: ^{1}H NMR ($CDCl_3$) δ: 7.33 (s, 1H), 7.11 (dd, J = 6.8, 2.0 Hz, 1H), 7.03 (m, 1H), 6.91 (m, 2H), 4.26 (q, J = 7.0 Hz, 2H, -OCH_2CH$_3$), 3.12 (bs, 1H, -O*H*), 1.43 (t, J = 7.0 Hz, 3H, -OCH$_2$CH_3); GC–MS: RT = 19.19 min, *m/z* (relative intensity): 347(11, M^+ + 4), 345 (66, M^+ + 2), 343(100, M^+), 315(59), 298(31), 268(32), 251(4), 233(7). HRMS calcd. for $C_{14}H_{11}Cl_2NO_5$: 343.0014; found: 343.0014. Spectral comparison allowed the following data to be deduced for isomer **11**: ^{1}H NMR ($CDCl_3$) δ: 7.38 (s, 1H), 7.03 (m, 2H), 6.91 (m, 2H), 3.99 (q, J = 6.6 Hz, 2H, -OCH_2CH$_3$), 2.40 (bs, 1H, -O*H*), 1.25 (t, J = 6.6 Hz, 3H, -OCH$_2$CH_3); GC–MS: RT = 19.06 min, *m/z* (relative intensity): 347(11, M^+ + 4), 345(66, M^+ + 2), 343(100, M^+), 315(17), 298(13), 268(14), 251(6), 233(7). HRMS calcd. for $C_{14}H_{11}Cl_2NO_5$: 343.0014; found: 343.0010.

2,3,4,7,8-Pentachloro-1-nitrodibenzo-p-*dioxin/EtO*$^-$

A solution of 0.1 M NaOEt (100 mL) was added to a 0.4 mM solution (100 mL) of **5** in anhydrous ethanol and the reaction mixture was irradiated at 300 nm for 1 h. A similar work-up procedure as described previously yielded 2,4,7,8-tetrachloro-3-ethoxy-1-nitrodibenzo-*p*-dioxin **13** (12.0 mg, 0.0293 mmol, 73%): ^{1}H NMR ($CDCl_3$)δ: 7.16 (s, 1H), 6.60 (s, 1H), 4.14 (q, J = 7.0 Hz, 2H, -OCH_2CH$_3$), 1.25 (t, J = 7.0 Hz, 3H, -OCH$_2$CH_3); GC–MS: RT = 22.49 min, *m/z* (relative intensity): 413(24, M^+ + 4), 411(52, M^+ + 2), 409(39, M^+), 381(79), 364(12), 307(10), 271(11). HRMS calcd. for $C_{14}H_7Cl_4NO_5$: 408.9078; found: 408.9065.

1,3,4,7,8-Pentachloro-2-nitrodibenzo-p-*dioxin/EtO*$^-$

A solution of 0.1 M NaOEt (50 mL) was combined with a solution of **6** (8.03 mg in 50 mL anhydrous ethanol, 0.4 mM) and the reaction mixture was irradiated in two Pyrex tubes for 1 h. Work-up by the procedure already described afforded 1,3,7,8-tetrachloro-4-ethoxy-2-nitrodibenzo-*p*-dioxin **14** (7.2 mg, 0.0175 mmol, 86%): ^{1}H NMR ($CDCl_3$)δ: 7.15 (s, 1H), 6.63 (s, 1H), 4.08 (q, J = 7.0 Hz, 2H, -OCH_2CH$_3$), 1.32 (t, J = 7.0 Hz, 3H, -OCH$_2$CH_3); GC–MS: RT = 23.06 min, *m/z* (relative intensity): 413(40, M^+ + 4), 411(79, M^+ + 2), 409(61, M^+), 381(79), 350(9), 335(52), 307(13), 271(22). HRMS calcd. for $C_{14}H_7Cl_4NO_5$: 408.9078; found: 408.9069. A thermal reaction was also performed in which **6** (10 mg, 0.025 mmol) was dissolved in a solution of 0.1 M NaOEt (100 mL) and the reaction mixture was refluxed for 1 h. After reaction, a large amount of water (≈200 mL) was added and then the reaction mixture was extracted with dichloromethane (15 × 10 mL). One major product (compound **15**) with molar mass 457 g/mol (a tetrachlorodiethoxyhydroxynitrodiphenyl ether) was obtained (7.96 mg, 0.0174 mmol, 70%); ^{1}H NMR ($CDCl_3$)δ: 7.13 (s, 1H), 6.78 (s, 1H), 4.11 (q, J = 7.04 Hz, 2H, -OCH_2CH$_3$), 4.01 (q, J = 7.04 Hz, 2H, -OCH_2CH$_3$), 1.65 (bs, 1H, -O*H*), 1.30 (t, J = 7.04 Hz, 3H, -OCH$_2$CH_3), 1.26 (t, J = 7.04 Hz, 3H, -OCH$_2$CH_3); GC–MS: RT = 22.61 min, *m/z* (relative intensity): 459(52, M^+ + 4), 457(100, M^+ + 2), 455(84, M^+), 409(51), 381(28), 351(10), 335(12), 308(19). HRMS calcd. for $C_{16}H_{13}Cl_4NO_6$: 454.9497; found: 454.9475. A tetrachloroethoxynitrodibenzo-*p*-dioxin (molar mass 411 g/mol) was also found to be present in trace amounts in the reaction mixture; it had GC–MS: RT = 23.10 min, *m/z* (relative intensity): 413(40, M^+ + 4), 411(79, M^+ + 2), 409(M^+, 61), 381(78), 350(13), 335(43), 307(9), 271(17).

Kinetic irradiations

Analytical scale irradiations were performed in Pyrex tubes using a "merry-go-round" Rayonet model RPR photoreactor, equipped with 16 lamps, having maximum emission at 300 nm. Because of the low solubility of NPCDDs, the solutions were prepared in the concentration range 0.4–1.0 mM, using methanol (for reactions with KCN) or anhydrous ethanol (for reactions with NaOEt) as solvent. To make sure the solid was completely dissolved, the solution was sonicated for at least 5 min. Solutions of 0.1 M nucleophile (NaOEt, KCN) were also prepared. In 18 mm × 150 mm Pyrex tubes, solutions of substrate (2 mL) were combined with solutions of nucleophile (2 mL) to give the final samples, which were sealed with serum caps and irradiated at the ambient temperature. Four samples were analyzed for each NPCDD congener: deaerated sample, aerated sample, dark sample, and sample without nucleophile. The samples were deaerated by bubbling nitrogen in the solution for 2 min. The samples were irradiated and periodically a 50–100 μL aliquot was removed by means of a syringe for HPLC monitoring of reaction progress. The reaction was monitored for substrate loss and product appearance using the external standard method, using hexachlorobenzene (1×10^{-3} M solution) as the external standard.

Yields

Chemical yields were calculated in terms of substrate reacted, using hexachlorobenzene as an external standard (added after irradiation). Standards for quantitation were prepared from the NPCDD congeners previously synthesized and a separate calibration curve was drawn for each.

Quantum yields were determined using the method of Hatchard and Parker (24), using potassium ferrioxalate as actinometer. The actinometer and the test solution (2 mL, prepared as for the determination of chemical yields) were placed into 5 mm i.d. Pyrex tubes, which were then inserted into 25 mm i.d. Pyrex tubes containing the chemical filter

Table 1. Quantum yields for the disappearance of NPCDDs.

Substrate	Nucleophile (0.1 M)	Solvent	Φ_{313}
1-NDD (**1**)	EtO^-	Ethanol	0.10
	CN^-	Methanol	0.13
2-NDD (**2**)	EtO^-	Ethanol	0.12
	CN^-	Methanol	0.11
1,2,-DCDD-3-NO_2 (**3**)	EtO^-	Ethanol	0.03
	CN^-	Methanol	0.02
1,3,4,7,8-PeCDD-2-NO_2 (**6**)	EtO^-	Ethanol	0.04
	CN^-	Methanol	0.03
2,3,4,7,8-PeCDD-1-NO_2 (**5**)	EtO^-	Ethanol	0.04
	CN^-	Methanol	0.04

solution (25) (0.2 g/L K_2CrO_4–$NiSO_4$, 0.1% NaOH) to isolate radiation at 313 ± 10 nm. These solutions were irradiated in the Rayonet photoreactor, using 300 nm lamps and a "merry-go-round" to ensure equal illumination of all samples. The reaction was monitored for substrate loss by HPLC, using the external standard method. The intensity of the incident radiation near 313 nm was 1.53×10^{-6} mol min^{-1}. The results are presented in Table 1.

Results and discussion

Preparation of NPCDD congeners

Two general methods have been used to prepare NPCDDs: nitration of the parent PCDDs and condensation between a chlorinated catechol and a suitably substituted chlorinated 1,3-dinitrobenzene. Disadvantages of the former method include the extremely low reactivity of the apical (1, 4, 6, and 9) positions compared with the lateral (2, 3, 7, and 8) positions, and lack of regioselectivity when more than one lateral (or apical) position is available. For example, whereas 1,3,6,8-tetrachlorodibenzo-*p*-dioxin (1,3,6,8-TCDD) nitrated smoothly using NH_4NO_3 in trifluoroacetic acid (26), the isomeric 2,3,7,8-TCDD could be nitrated only with reagents such as NO_2BF_4 at elevated temperature (27). The condensation method is more generally applicable, although the possibility of positional isomerism in the products still exists, due to the intervention of a Smiles-like rearrangement at an intermediate stage of the condensation (28), see Scheme 1. In this work, we avoided this complication by using only symmetrical catechol synthons, thereby rendering the Smiles-like rearrangement degenerate. In the presence of base, the conjugate base of the catechol attacks the chlorinated dinitrobenzene *ortho* to both NO_2 groups; the leaving group may be either chloride or, as in the improvement introduced by Mahiou and Deinzer (19), fluoride ion. Attack by the second $-O^-$ of the original catechol leads to cyclization with elimination of one of the NO_2 groups as NO_2^- (although, in the case of the condensation of catechol with 2,3-dichloro-4,6-dinitrofluorobenzene, elimination of Cl^- to give 1-chloro-2,4-dinitrodibenzo-*p*-dioxin **4** competed to a minor extent with elimination of NO_2^- to give 1,2-dichloro-3-nitrodibenzo-*p*-dioxin **3**.

Nucleophilic photosubstitution of NPCDDs

In earlier work on nitrodibenzo-*p*-dioxins, Leoni et al. (29) observed that **2** reacted photochemically with propylamine to give chiefly the isomeric (*N*-propylamino)hydroxynitrodiphenyl ethers **16** and **17** in polar solvents (Scheme 2), while **1** was photochemically inert. In cyclohexane, *N*-(propylamino)-2-nitrophenoxazine, **18**, a minor product in the polar solvent, was the sole product isolated. The quantum yield of the disappearance of 2-NDD gradually fell with the solvent polarity, as did the quantum yield of formation of **16** and **17**, but the quantum yield of formation of product **18** remained practically unchanged. The authors explained this effect by assuming that the interaction of triplet **2** with the amine leads initially to an exciplex, which either dissociates into radical ions affording **16** and **17**, or which forms **18** from the undissociated exciplex. Another possible explanation is that **16** and **17** are S_N2Ar^* products and **18** comes from electron transfer within the exciplex.

NPCDDs absorb with moderate intensity at 300 nm ($\log \epsilon \approx 3$) with shoulders near 360 nm due to the $n\pi^*$ transition centred on the nitro group. We have previously shown that NPCDDs photolyze rapidly at 300 nm in the presence of dilute sodium hydroxide (7). The photolyzates from the NPCDDs failed to bind to the Ah receptor, implying that the photoproducts had changed their shape, presumably by ring opening. An attempt to identify the products was unsuccessful due to their intractability (B. Mahiou, unpublished work). In the present study also, the products obtained using CN^- were intractable, but those from EtO^- were identifiable. Ethoxide was chosen as the nucleophile rather than methoxide because the ^1H NMR pattern of the ethoxy group was more diagnostically useful than that of a singlet methoxy. The semipreparative irradiations were carried out in a Rayonet photoreactor equipped with 300 nm lamps; for the quantum yield determinations, low-pressure mercury lamps were used with a chemical filter (K_2CrO_4–$NiSO_4$, 0.1% NaOH) (25) to isolate radiation near 313 nm.

The photoreactions of **1**, **2**, and **3** with NaOEt all afforded ring-opened products compatible with an S_N2Ar^* reaction. In every case, a competing thermal ring opening also occurred *para* to the nitro group: e.g., Scheme 3. The isomeric ethoxyhydroxydiphenyl ethers obtained in the photochemical reactions could not be separated preparatively, although they were separable by capillary GC, and so it was necessary to deduce the ^1H NMR spectrum of the photoproduct by isolating the thermal product in a separate reaction, and then substracting its spectrum from that of the mixture.

The two pentachlorinated NPCDDs both underwent substi-

tution with loss of chloride, instead of ring opening. 2,3,4,7,8-Pentachloro-1-nitrodibenzo-*p*-dioxin (**5**) yielded, upon irradiation with NaOEt, a tetrachloroethoxynitrodibenzo-*p*-dioxin, which was presumed to be 2,4,7,8-tetrachloro-3-ethoxy-1-nitrodibenzo-*p*-dioxin, **13**, based on the *meta* activation of the nitro group (eq. [2]). Control experiments showed that compound **5** is stable on irradiation in the absence of the nucleophile. A thermal reaction was detected in the dark sample containing NaOEt, which yielded a tetrachlorodiethoxyhydroxynitrodiphenyl ether. The isomeric 1,3,4,7,8-pentachloro-

2-nitrodibenzo-*p*-dioxin (1,3,4,7,8-PeCDD-2-NO_2) **6**, when irradiated in the presence of NaOEt, afforded only one product **14**, which was identified as 1,3,7,8-tetrachloro-4-ethoxy-2-nitrodibenzo-*p*-dioxin, resulting from substitution of chlorine *meta* to the nitro group rather than from ring opening (Scheme 4). Control experiments showed that 1,3,4,7,8-PeCDD-2-NO_2 is stable on irradiation in the absence of EtO^- but a slow reaction was detected in the dark sample containing NaOEt.

$$[ArXNu]^- \xrightarrow{k_4} ArNu + X^-$$

Reaction mechanism

Because of the low solubilities of the NPCDDs, the photoreactions were all carried out under conditions where little of the initial light intensity was absorbed. Under conditions of constant light intensity, such photoreactions are pseudo first order; experimentally, linear relationships were obtained between ln c_0/c_t (c_0: initial concentration of NPCDD; c_t: NPCDD concentration at time t) and time of irradiation, t, see Fig. 2, for example.

Quenching with piperylene showed that the reactive excited state is of triplet multiplicity, consistent with the NPCDDs, like other nitroaromatic compounds, undergoing intersystem crossing to the lowest triplet state with high efficiency following photoexcitation. Plots of Φ_q/Φ_0 vs. [quencher] (Φ_q: quantum yield of reaction in the presence of quencher and Φ_0 in the absence of quencher) were linear for all substrates, over the concentration range 0–0.2 M piperylene, see Fig. 3 for example.

Scheme 5 shows a reaction pathway consistent with the S_N2Ar^* mechanism. The excited triplet ArX* (assumed to be formed with near maximum efficiency) can undergo radiationless decay to the ground state (rate constant k_1) or interact with the nucleophile Nu^- (rate constant k_2) to give a σ-complex

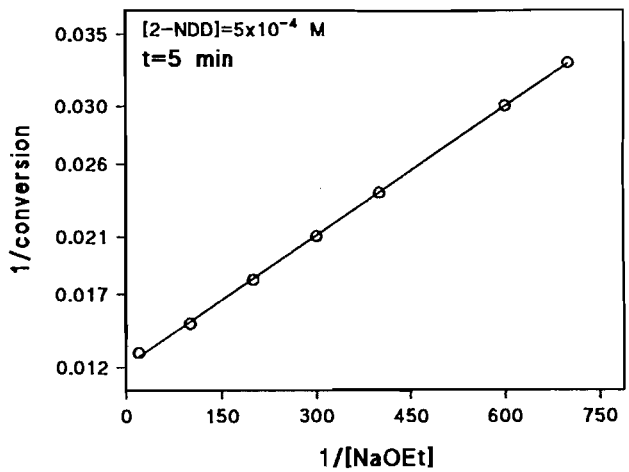
Table 2. Kinetic parameters for the irradiation of NPCDDs at varying concentrations of NaOEt (1/consumed concentration vs. 1/[NaOEt]).

Substrate (starting concentration)	Slope	Intercept ($\times 10^{-3}$ M)	Intercept/slope	Regression coefficient
1-NDD (5×10^{-4} M)	34	2.9	86	0.984
2-NDD (5×10^{-4} M)	5.6	2.7	480	0.994
1,2-DCDD-3-NO_2 (5×10^{-4} M)	3.8	2.5	660	0.979
2,3,4,7,8-PeCDD-1-NO_2 (2×10^{-4} M)	18	11	62	0.983
1,3,4,7,8-PeCDD-2-NO_2 (2×10^{-4} M)	49	16	330	0.991

Fig. 4. Double reciprocal plot: conversion^{-1} vs. (nucleophile concentration)$^{-1}$ for the photoethoxidation of 2-nitrodibenzo-*p*-dioxin.



$[ArXNu]^-$, which may then dissociate to ground state reactants (k_3) or afford the substitution products (k_4). Application of the steady-state approximation to Scheme 5 affords eq. 3, consistent with the observed linear relationship between Φ^{-1} and $[Nu]^{-1}$.

$$[3] \quad \Phi^{-1} = (1 + k_3/k_4)(1 + k_1/k_2[Nu^-])$$

The quantum yields for disappearance of the NPCDDs (± 10%) were determined using potassium ferrioxalate actinometry (24) at 313 nm in the presence of 0.1 M nucleophile and are summarized in Table 1. The low quantum yield even at a high concentration of nucleophile means either that the majority of triplets must fail to form σ-complexes, or that the σ-complexes must preferentially revert to reactant rather than proceed to products. The dependence of the reaction quantum yield upon the concentration of nucleophile showed the linear relationship between Φ^{-1} and $[Nu]^{-1}$ characteristic of an S_N2Ar^* reaction. This was seen for all the NPCDDs studied, for both CN^- and EtO^- as the nucleophiles: see Table 2, and Fig. 4. In every case the high value of the parameter intercept/slope $\equiv k_2/k_1$ shows that a high proportion of excited triplets will form σ-complexes whenever [Nu] > 0.01 M and hence that the low overall quantum yield results principally from the inherent tendency of the σ-complex to partition towards reactants rather than products.

The present work had as one objective, to explore whether photochemically induced nucleophilic substitution reactions of NPCDDs might be a technologically viable method for the destruction of PCDDs in an environmental matrix. Such a putative technology might involve nitration of the PCDD followed by photochemical ring opening in the presence of a nucleophile. Our studies show that this idea is not feasible. PCDDs are difficult to nitrate unless they have an open lateral position, yet the congeners of the greatest environmental concern are precisely those that are fully chlorinated in the lateral positions. In addition, nucleophilic ring opening is not universal among the NPCDDs studied; the pentachloro congeners underwent nucleophilic replacement of a *meta* chlorine instead. Finally, the intractability of the products, using a "convenient" nucleophile such as OH^-, means that the nature and toxicity of the products cannot be determined, and so it would be unacceptable to release them into the environment.

In conclusion, the nitrodibenzo-*p*-dioxin congeners studied here behave as typical nitro-substituted ethers such as the 3- and 4-nitroveratroles (8, 17) in their photochemical reaction with the poorly oxidizable nucleophile ethoxide ion. One triplet excited state is involved, and the photochemical kinetics are completely consistent with substitution by the S_N2Ar^* mechanism.

Structural studies of organoboron compounds LXIII.[1] Reaction of ketoximes with aldehydes and diphenylborinic acid, and the crystal and molecular structures of two different types of boron chelates and one of the precursor aldehyde adducts

Wolfgang Kliegel, Ulf Riebe, Steven J. Rettig, and James Trotter

Abstract: The diphenylboron chelates of ketoxime adducts to formaldehyde and trichloroacetaldehyde (chloral) have been synthesized. The reactions were carried out as three-component one-pot reactions, and also as two-step reactions for the ketoxime chloral adducts, which were isolated and characterized before reaction with oxybis(diphenylborane) to form the diphenylboron chelates. One of the intermediate adducts and two of the diphenylboron chelates have been characterized by X-ray crystallographic analysis. Crystals of *O*-(2,2,2-trichloro-1-hydroxyethyl)-2-propanonoxime, **8***d*, are monoclinic, $a = 7.010(2)$, $b = 11.832(3)$, $c = 11.684(2)$ Å, $\beta = 90.48(2)°$, $Z = 4$, space group $P2_1/c$; those of 4-isopropylidene-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, **9***a*, are orthorhombic, $a = 11.098(2)$, $b = 15.364(1)$, $c = 8.715(2)$ Å, $Z = 4$, space group $P2_12_12_1$; and those of 5-trichloromethyl-2-isopropylidene-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, **10***d*, are monoclinic, $a = 9.164(2)$, $b = 15.304(3)$, $c = 13.859(2)$ Å, $\beta = 105.28(1)°$, $Z = 4$, space group $P2_1/n$. The structures were solved by direct methods and refined by full-matrix least-squares procedures to $R = 0.037$, 0.044, and 0.040 ($R_w = 0.041$, 0.016, and 0.042) for 1082, 1256, and 3062 reflections with $I \geq 3\sigma(F^2)$, respectively. The X-ray analyses show that the products from the reaction between acetonoxime, oxybis(diphenylborane), and formaldehyde or trichloroacetaldehyde, respectively, possess different boron chelate structures. With formaldehyde a COBON chelate ring is obtained and with trichloroacetaldehyde a BOCON chelate ring is formed.

Key words: boron chelates, boron compounds, organboron compounds, crystal structures.

Résumé : On a synthétisé les chélates du diphénylbore des adduits de la cétoxime avec le formaldéhyde et le trichloroacétaldéhyde (chloral). On a fait appel à des réactions unipots à trois composants ainsi qu'à des réactions en deux étapes pour les adduits de la cétoxime du chloral qui ont été isolés et caractérisés avant leur réaction avec l'oxybis(diphénylborane) pour former les chélates du diphénylbore. On a caractérisé un des adduits intermédiaires et deux des chélates du diphénylbore par diffraction des rayons X. Les cristaux du *O*-(2,2,2-trichloro-1-hydroxyéthyl)propan-2-onoxime, **8***d*, sont monocliniques, groupe d'espace $P2_1/c$ avec $a = 7{,}010(2)$, $b = 11{,}832(3)$ et $c = 11{,}684(2)$ Å, $\beta = 90{,}48(2)°$ et $Z = 4$; ceux du 4-isopropylidène-2,2-diphényl-1,3-dioxa-4-azonia-2-boratacyclopentane, **9***a*, sont orthorhombiques, groupe d'espace $P2_12_12_1$ avec $a = 11{,}098(2)$, $b = 15{,}364(1)$ et $c = 8{,}715(2)$ Å, et $Z = 4$ et ceux du 5-trichlorométhyl-2-isopropylidène-3,3-diphényl-1,4-dioxa-2-azonia-3-boratacyclopentane, **10***d*, sont monocliniques, groupe d'espace $P2_1/n$ avec $a = 9{,}164(2)$, $b = 15{,}304(3)$ et $c = 13{,}859(2)$ Å, $\beta = 105{,}28(1)°$ et $Z = 4$. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R de 0,037, 0,044 et 0,040 ($R_w = 0{,}041$, 0,016 et 0,042) pour respectivement 1082, 1256 et 3062 réflexions avec $I \geq 3\sigma(F^2)$. Les analyses par rayons X montrent que les produits des réactions entre l'acétonoxime, l'oxybis(diphényl)bore et le formaldéhyde (ou le

trichloroacétaldéhyde) possèdent chacun des structures de chélates du bore différentes. Avec le formaldédyde, on obtient un cycle de chélate COBON alors qu'avec le trichloroacétaldéhyde il se forme un cycle de chélate BOCON.

Mots clés : chélates du bore, composés du bore, composés organobores, structures cristallines.

[Traduit par la rédaction]

Introduction

N-Hydroxydialkylamines form labile adducts with carbonyl compounds that can be trapped as boron chelates (1). Because of the ambident nucleophilic character of the hydroxylamine components the molecular structure of the resulting chelates had to be questioned (2). To provide unambiguous proof, the reaction of *N*-hydroxydimethylamine, **1**, with formaldehyde ($R^1 = R^2 = H$) and a diphenylborinic acid delivering reagent (anhydride or ester) was carried out, as an example. The resulting diphenylboron chelate **4***a* was characterized by an X-ray crystallographic analysis (3).[3] The analogous molecular structure **4***b* resulted when the bulkier carbonyl compound acetone ($R^1 = R^2 = CH_3$) was employed in the chelate-forming reaction (4). These results demonstrate that of the two possible α-hydroxyalkylation intermediates, **2** and **3**, the *N*-oxide **2** is preferred as the bidentate ligand, even if the sterically hindered acetone is applied as the carbonyl component in the chelatization reaction.[4] Likewise ambident, though less basic, nucleophiles are the ketoximes **6**, which can also be α-hydroxyalkylated to give either the *N*-oxides **7**, or the *O,O*-hemiacetal derivatives **8**, as initial adducts. The structure **7** ($R = CCl_3$) has already been ascribed to the crystalline adducts of trichloroacetaldehyde (chloral) to several oximes in a German patent of 1892 (5). Later (1*c*) an analogous formulation **8** (R = H) was suggested for the labile adducts of formaldehyde to acetone- and cyclohexanonoxime, both of which could be trapped as diphenylboron chelates with a postulated BOCON ring structure **10**. This assumption seemed, however, somewhat contradictory considering the analytical results for the diphenylboron chelates **4**, and also those for the similar six-membered boron chelates **12** that are derived from *N*-(β-hydroxyalkyl)oximes (nitrones) **11** (6). Thus, by analogy to the CCOBON ring skeleton of **12**, the five-membered COBON ring structure **9** was most likely that of the diphenylboron chelates of oxime/aldehyde adducts (7).

Because the existing analytical data are unsatisfactory, and not sufficient for structure assignment, we have synthesized the diphenylboron chelates of ketoxime adducts to formaldehyde and trichloroacetaldehyde (chloral). The reactions were carried out as three-component one-pot reactions, and also as two-step reactions for the ketoxime chloral adducts, which were isolated and characterized before reaction with oxybis(diphenylborane) to form the diphenylboron chelates. The elemental analyses, infrared spectra, and ^1H and ^{11}B nmr spectra are consistent with both of the isomeric chelate structures, the COBON ring **9** and the BOCON ring **10**, but offer no means of distinguishing between the two.

Table 1. Selected infrared and nmr data for **8**, **9**, and **10**.

Compound	Infrared (cm^{-1})	^1H nmr (δ, ppm)	^{11}B nmr (δ, ppm)
	(C=N)	(O-CH-O)	
8/10*d*	1653/1671	5.63/5.80	—/9.5
8/10*e*	1659/1688	5.67/5.80	—/8.7
8/10*f*	1647/1651	5.66/5.83	—/9.2
		($N-CH_2-O$)	
9*a*	1676	5.36	12.7
9*b*	1690	5.33	12.7
9*c*	1665	5.40	12.1

	R_2C	R^1
7–10 *a*	Me_2C	H
7–10 *b*	$(CH_2)_4C$	H
7–10 *c*	$(CH_2)_5C$	H
7–10 *d*	Me_2C	CCl_3
7–10 *e*	$(CH_2)_4C$	CCl_3
7–10 *f*	$(CH_2)_5C$	CCl_3

Comparison of the spectral data of the intermediate ketoxime chloral adducts with those of the corresponding diphenylboron chelates shows: (*i*) the disappearance of the hydroxyl group (infrared and ^1H nmr); (*ii*) the characteristic shift of the C=N stretching to higher frequencies in the infrared, indicating the enhanced iminium salt character upon chelate formation (6); and (*iii*) a minor downfield shift of the acetalic methine proton signal (~0.2 ppm), consistent with an increased deshielding of this proton by greater electron withdrawal upon chelation of the Lewis acid diphenylborenium ion (Table 1). Furthermore, the magnetically equivalent methyl groups of the acetone oxime give rise to two signals of distinctly different shift in the diphenylboron chelates of both the formaldehyde and the chloral adducts, showing the incorporation into a rigid ring system that fixes the methyl groups in magnetically inequivalent environments.

For a definitive assignment to the structure **9** or **10** we prepared single crystals of the diphenylboron chelates derived from the acetonoxime adducts of formaldehyde and chloral for X-ray analysis. The isolable acetonoxime-chloral adduct gave high-quality crystals and was also subjected to an X-ray analysis to establish the structure of the initial α-hydroxylation product of the oxime, either **7** or **8**.

[3] Proceeding on the assumption that all boron chelates of this structural type are cyclic *B,N*-betaines with a COBON ring skeleton (**4**), the previously suggested BOCON ring formulation **5** for these chelates (1), based on the α-hydroxyalkylation product **3**, has to be corrected to **4**.

[4] There is no direct proof of the existence of the *N*-oxide forms **2** and **7**, and the rearrangement intermediate **3**. However, (*i*) alkylations at *N*-hydroxydialkylamines generally lead preferably to *N*-oxides, but alkylations at oximes give both *N*-oxides and *O*-alkyls; (*ii*) the 1,2-shift of carbenium ions from N to O in *N*-oxides (e.g., Meisenheimer rearrangement) is well known and should be very easy and fast in an acetal type *N*-oxide; (*iii*) thus 1,2-shift equilibria **2** ⇌ **3** and **7** ⇌ **8** could probably occur as well as the addition/elimination equilibria.

Experimental

O*-(2,2,2-Trichloro-1-hydroxyethyl)-2-propanonoxime, 8*d

Acetonoxime (2.2 g, 30 mmol), chloral hydrate (5.0 g, 30 mmol), and dry Na_2SO_4 (5 g) are refluxed in 40 mL of dichloromethane for 4 h. After filtration and evaporation of the solvent the residue is crystallized from dichloromethane – petroleum ether. Yield: 2.9 g (43%) of colorless crystals; mp 72°C (lit. (5) mp 72°C). Infrared (KBr): 3130 (br, O—H), 1653 (C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS),

δ (ppm): 2.00 (s, 2 CH_3), 5.36 (s, br, O-CH-O), 6.10 (s, br, exchangeable, OH). Anal. calcd. for $C_5H_8Cl_3NO_2$: C 27.24, H 3.66, Cl 48.24, N 6.35; found: C 26.68, H 3.66, Cl 47.44, N 6.13.

Crystals of **8***d*, suitable for an X-ray analysis were obtained by slow crystallization over a period of 5 weeks using the liquid diffusion method (8) with chloroform as solvent and petroleum ether as precipitant at 6–8°C.

O-(2,2,2-Trichloro-1-hydroxyethyl)-cyclopentanonoxime, 8*e*

Cyclopentanonoxime (3.0 g, 30 mmol) is reacted with chloral hydrate (5.0 g, 30 mmol), as described above for **8***d*. Yield: 4.8 g (63%) of colorless crystals; mp 90–91°C (from CH_2Cl_2 – petroleum ether). Infrared (KBr): 3160 (br, O-H), 1659 (C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.67–1.93 (m, C-CH_2-CH_2-C), 2.33–2.70 (m, N=C(CH_2)$_2$), 5.66 (s, O-CH-O), 5.00–7.00 (s, br, exchangeable, OH). Anal. calcd. for $C_7H_{10}Cl_3NO_2$: C 34.11, H 4.09, Cl 43.14, N 5.68; found: C 33.95, H 4.09, Cl 42.92, N 5.50.

O-(2,2,2-Trichloro-1-hydroxyethyl)-cyclohexanonoxime, 8*f*

Cyclohexanonoxime (3.4 g, 30 mmol) is reacted with chloral hydrate (5.0 g, 30 mmol), as described above for **8***d*. Yield: 5.0 g (61%) of colorless crystals; mp 108–109°C (from CH_2Cl_2 – petroleum ether) (lit. (1*c*): mp 107°C). Infrared (KBr): 3160 (br, O-H), 1647 (C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.67 (m_c, C-(CH_2)$_3$-C), 2.27 and 2.57 (m and m, N=C(CH_2)$_2$), 5.63 (s, br, O-CH-O), 6.20 (s, br, exchangeable, OH). Anal. calcd. for $C_8H_{12}Cl_3NO_2$: C 36.88, H 4.64, Cl 40.82, N 5.38; found: C 35.89, H 5.12, Cl 40.84, N 4.78.

4-Isopropylidene-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, 9*a*

Acetonoxime (0.37 g, 5 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and 1 mL of aqueous formaldehyde solution (35%) are dissolved in 5 mL of ethanol (96%). Crystallization commences while the solution is stirred at room temperature. Yield: 1.09 g (82%) of colorless crystals; mp 145–147°C (from ethanol); 144–145°C (from $CHCl_3$ – petroleum ether) (lit. (1*c*) mp 148–149°C). Infrared (KBr): 1676 (C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.80 and 2.25 (s and s, N=C(CH_2)$_2$), 5.36 (s, N-CH_2-O), 7.13–7.60 (m, 10 aromatic H); ^{11}B nmr (64.2 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 12.7 ($w_{1/2}$ = 190 Hz). Mass spectrum (EI, 70 eV, 400°C); *m/z*: 237 (24%, $M^+ - CH_2O$), 222 (100%, $M^+ - CH_2O - CH_3$), 181 (26%, Ph_2BO), 165 (12%, Ph_2B), 133 (6%), 118 (20%, PhBON), 103 (6%), 77 (52%), 57 (38%). Anal. calcd. for $C_{16}H_{18}BNO_2$: C 71.94, H 6.79, B 4.05, N 5.24; found: C 71.88, H 6.74, B 4.04, N 5.20.

The product gives a blue-colored solution upon addition of diphenylcarbazone in ethanol, indicating the presence of the chelated diphenylborenium ion (9). Crystals suitable for X-ray analysis were obtained by very slow crystallization from $CHCl_3$ – petroleum ether using the liquid diffusion method (8).

4-Cyclopentylidene-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, 9*b*

Cyclopentanonoxime (0.50 g, 5 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and 1 mL of aqueous formaldehyde solution (35%) are dissolved in 5 mL of ethanol and heated rapidly to the boiling point. Crystallization commences as the solution is cooled to room temperature. Yield: 1.37 g (93%) of colorless crystals; mp 151–153°C (from ethanol). Infrared (KBr): 1690 (C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.70–2.00 (m, C-$CH_2$$CH_2$-C), 2.17–2.47 and 2.63–2.97 (m and m, N=C(CH_2)$_2$), 5.33 (s, N-CH_2-O), 7.14–7.66 (m, 10 aromatic H); ^{11}B nmr (64.2 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm) = 12.7 ($w_{1/2}$ = 280 Hz). Anal. calcd. for $C_{18}H_{20}BNO_2$: C 73.74, H 6.88, B 3.69, N 4.78; found: C 73.74, H 6.95, B 3.58, N 4.76. **9***b* gives a blue color reaction with diphenylcarbazone as described for **9***a*.

4-Cyclohexylidene-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, 9*c*

Cyclohexanonoxime (0.57 g, 5 mmol) is reacted with oxybis(diphenylborane) (0.87 g, 2.5 mmol) and formaldehyde (1 mL 35% aqueous solution) as described above for **9***a*. Yield: 1.05 g (68%) of colorless crystals; mp 134–136°C (from ethanol) (lit. (1*c*) mp 137–138°C). Infrared (KBr): 1665 (C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.40–1.90 (m, C-(CH_2)$_3$-C), 2.03–2.26 and 2.68–2.93 (m and m, N=C(CH_2)$_2$), 5.40 (s, N-CH_2-O), 7.13–7.65 (m, 10 aromatic H); ^{11}B nmr (64.2 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 12.1 ($w_{1/2}$ = 260 Hz). Mass spectrum (EI, 70 eV, 400°C); *m/z*: 237 (24%, $M^+ - CH_2O$), 222 (100%, $M^+ - CH_2O - CH_3$), 181 (26%, Ph_2BO), 165 (12%, Ph_2B), 133 (6%), 118 (20%, PhBON), 103 (6%), 77 (52%), 57 (38%). Anal. calcd. for $C_{19}H_{22}BNO_2$: C 74.29, H 7.22, B 3.52, N 4.56; found: C 74.26, H 7.21, B 3.54, N 4.54. **9***c* gives a blue color reaction with diphenylcarbazone as described for **9***a*.

5-Trichloromethyl-2-isopropylidene-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, 10*d*

Method A

Acetonoxime (0.37 g, 5 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and chloral hydrate (0.81 g, 5 mmol) are dissolved in 5 mL of ethanol and heated rapidly to the boiling point. The solvent is removed in vacuo, and the residue taken up in chloroform. Crystallization is induced by addition of petroleum ether. Yield: 1.41 g (73%) of colorless crystals; mp 175–179°C (from $CHCl_3$ – petroleum ether).

Method B

8*d* (0.55 g, 2.5 mmol) and oxybis(diphenylborane) (0.44 g, 1.25 mmol) are each dissolved separately in 2.5 mL of ethanol. The solutions are mixed under stirring at room temperature. After 1 h of stirring, the microcrystalline precipitate is filtered off, and recrystallized from ethanol. Yield: 0.39 g (41%); mp 175–177°C (from ethanol). Infrared (KBr): 1671 (C=N) cm^{-1}; the spectra of the materials obtained from methods A and B are identical; ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.90 and 2.31 (s and s, N=C(CH_2)$_2$), 5.80 (s, O-CH-O), 7.23–7.56 (m, 10 aromatic H); ^{11}B nmr (64.2 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 9.5 ($w_{1/2}$ = 300 Hz). Mass spectrum (EI, 70 eV, 110°C), *m/z*: 308/306 (98%/100%, $M^+ - C_6H_5$), 264 (2%, $M^+ - C_6H_5 - (CH_3)_2C$), 222 (5%, $Ph_2BONCCH_3$), 165 (30%, Ph_2B), 105 (15%, PhBOH), 77 (16%), 57 (86%); (DCI, NH_3, pos. mode); *m/z*: 786 (4%, 2 M + NH_4), 401 (100%, M + NH_4), 384 (41%, M + H), 306 (18%,

M − C_6H_5), 238 (44%, $Ph_2BN(OH)C(CH_3)_2$), 199 (22%), 182 (43%, Ph_2BOH), 121 (10%), 91 (12%), 74 (51%), 58 (19%). The experimental isotope pattern of the molecular ion (M + H)$^+$ is in excellent agreement with that calculated for **10***d*. Anal. calcd. for $C_{17}H_{17}BCl_3NO_2$: C 53.11, H 4.46, B 2.81, Cl 27.66, N 3.64; found: C 53.11, H 4.47, B 2.78, Cl 27.62, N 3.61. **10***d* gives a blue color reaction with diphenylcarbazone as described for **9***a*. Crystals suitable for X-ray analysis were obtained by slow crystallization (3 days) from $CHCl_3$ – petroleum ether using the liquid diffusion method (8).

5-Trichloromethyl-2-cyclopentylidene-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, 10*e*

8*e* (0.62 g, 2.5 mmol) and oxybis(diphenylborane) (0.44 g, 1.25 mmol) are reacted as described above for **10***d* (method B). Yield: 0.48 g (47%) of colorless crystals; mp 158–159°C (from ethanol). Infrared (KBr): 1688 (C=N) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.60–2.00 (m, C-CH_2CH_2-C), 2.00–2.70 and 2.70–3.00 (m and m, N=C$(CH_2)_2$), 5.80 (s, O-CH-O), 7.16–7.60 (m, 10 aromatic H); ^{11}B nmr (64.2 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 8.7 ($w_{1/2}$ = 300 Hz). Anal. calcd. for $C_{19}H_{19}BCl_3NO_2$: C 55.59, H 4.66, B 2.63, Cl 25.91, N 3.41; found: C 55.63, H 4.82, B 2.85, Cl 25.31, N 3.27. **10***e* gives a blue color reaction with diphenylcarbazone as described for **9***a*.

5-Trichloromethyl-2-cyclohexylidene-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, 10*f*

Method A

Cyclohexanonoxime (0.37 g, 5 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and chloral hydrate (0.81 g, 5 mmol) are reacted as described for **10***d* (method A). Yield: 1.27 g (60%) of colorless crystals; mp 158–159°C (from $CHCl_3$ – petroleum ether).

Method B

8*f* (1.30 g, 5 mmol) and oxybis(diphenylborane) (0.87 g, 2.5 mmol) are reacted as described above for **10***d* (method B). Yield: 1.45 g (68%); mp 157–158°C (from ethanol). Infrared (KBr): 1651 (C=N) cm^{-1}; the spectra of the materials obtained from methods A and B are identical; ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.20 and 3.10 (m, -$(CH_2)_5$-), 5.83 (s, O-CH-O), 7.20–7.60 (m, 10 aromatic H); ^{11}B nmr (64.2 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 9.2 ($w_{1/2}$ = 280 Hz). Anal. calcd. for $C_{20}H_{21}BCl_3NO_2$: C 56.58, H 4.99, B 2.55, Cl 25.05, N 3.30; found: C 56.86, H 5.05, B 2.80, Cl 24.36, N 3.09. **10***f* gives a blue color reaction with diphenylcarbazone as described for **9***a*.

X-ray crystallographic analyses of 8*d*, 9*a*, and 10*d*

Crystallographic data appear in Table 2. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 27.6°–35.9° for **8***d*, 70.2°–91.0° for **9***a*, and 35.0°–41.7° for **10***d*. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random fluctuations for **8***d* and **9***a*, and decayed linearly by 2.7% for **10***d*. The data were processed,[5] corrected for Lorentz and polarization effects, decay (for **10***d*), and absorption (empirical, based on azimuthal scans for three reflections).

The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an *E*-map or from subsequent difference Fourier syntheses. Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms of **8***d* and **10***d* were refined with isotropic thermal parameters and those of **9***a* were fixed in idealized positions (C—H = 0.98 Å, B_H = 1.2 $B_{\text{bonded atom}}$). Corrections for secondary extinction were applied for **8***d* and **9***a*, the final values of the extinction coefficients being 1.2(3) × 10^{-6} and 7.7(2) × 10^{-6}, respectively. Neutral atom scattering factors for all atoms (10*a*) and anomalous dispersion corrections for the non-hydrogen atoms (10*b*) were taken from the *International tables for X-ray crystallography*. A parallel refinement of the mirror-image structure of **9***a* gave slightly higher residuals, the *R* and R_w factor ratios both being 1.002. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and intra-annular torsion angles appear in Tables 3–6, respectively. Stereoviews of the **8***d*, **9***a*, and **10***d* molecules are shown in Figs. 1–3, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes have been deposited as supplementary material.[6] Measured and calculated structure factor amplitudes are available from the authors.

Results and discussion

The X-ray analyses show that the products from the reaction between acetonoxime **6** (R = Me), oxybis(diphenylborane), and formaldehyde or trichloroacetaldehyde, respectively, possess essentially different boron chelate structures. The diphenylboron chelate of the formaldehyde adduct to acetonoxime has the molecular structure **9***a* (Fig. 2), corresponding to the reaction products of *N*-hydroxydialkylamines with carbonyl compounds and diphenylborinic acid, **4**. The COBON ring skeleton that can also be assigned to the other ketoxime derivatives, **9***b* and *c*, demonstrates that α-hydroxymethylated oximes react in the *N*-oxide (nitrone) form **7** preferentially as bidentate ligands, similar to the *N*-oxide form of α-hydroxyalkylated hydroxylamines, **2**. Thus the five-membered che-

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Mo-K_α (λ = 0.71069 Å) or Cu-K_α (λ = 1.54178 Å) radiation, graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1, up to 8 rescans), $\sigma^2(F^2) = [S^2(C + 4B)]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count) (*no* fudge factors (pI^2) used, which accounts for the slightly high gof values), function minimized $\Sigma w(|F_o|-|F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o|-|F_c|)^2/(m-n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(F^2)$.

Fig. 1. Stereoview of **8***d*; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

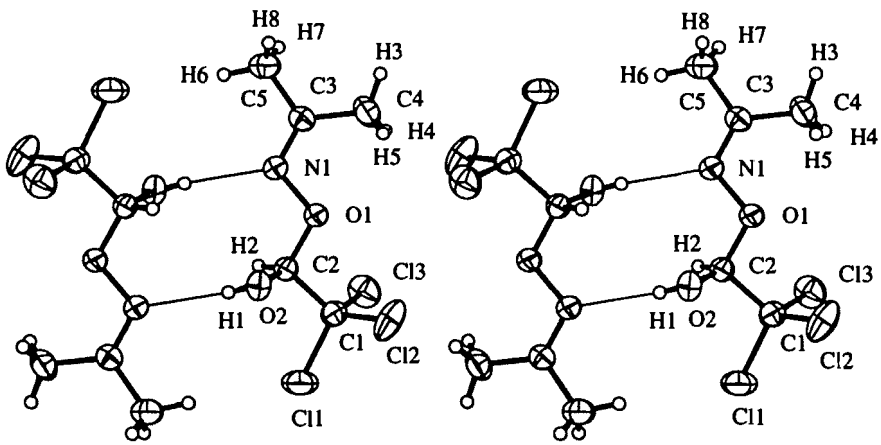

Fig. 2. Stereoview of the **9***a* molecule; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

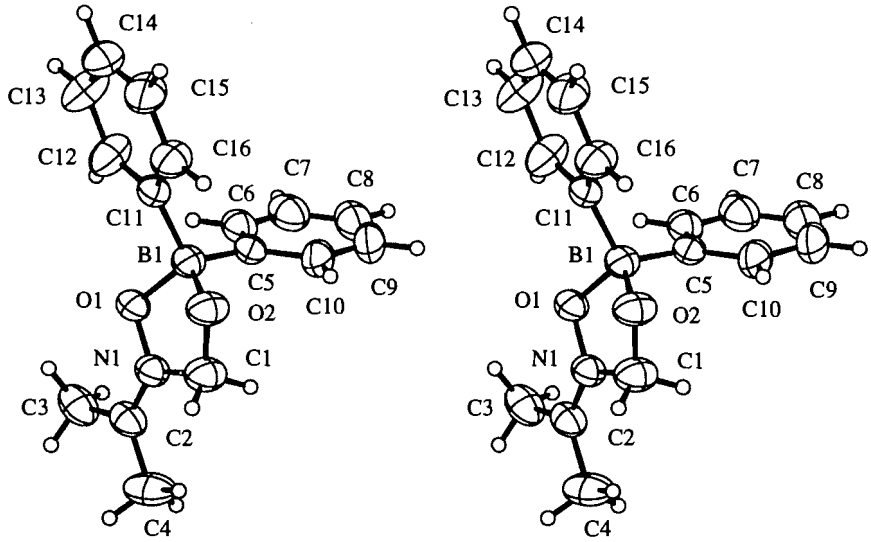

Fig. 3. Stereoview of the **10***d* molecule; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

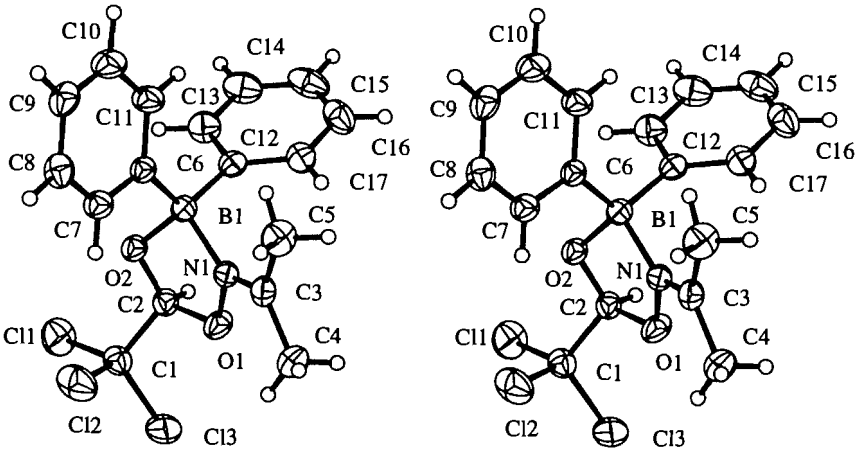

lates **9** are in accord with the six-membered diphenylboron chelates **12**, derived from the *N*-(β-hydroxyalkyl)nitrones **11** (6). As expected (11), the C=N absorption band in the infrared spectra of five-membered COBON species **9** (1665–1690 cm^{-1}) is found at higher frequencies than the analogous six-membered CCOBON ring compounds **12**. The highest frequency of 1690 cm^{-1} is found in the spectrum of **9***b*, the C=N vibration of which is influenced by the ring strain of the two five-membered rings fused at the C=N double bond.

The ^1H nmr signals of the *N,O*-acetalic methylene group in **9** (5.33–5.40 ppm) appear in the same region as the comparable signal of **4***a* (5.25 ppm) (3), as do the ^{11}B nmr signals of **9** (12.1–12.7 ppm) compared to those of **4***a* (11.1 ppm) (3).

No molecular ion signal was detected in the EI mass spectrum of **9***a*. The highest mass fragment, characterized by the (thermolytic?) loss of formaldehyde, corresponds to the monomeric (alkylideniminoxy)-diarylboranes observed in the mass spectra of the BONBON dimers, $(R_2C{=}NOBPh_2)_2$ (12).

In contrast to the O-B-O diphenylboron chelate of *N*-hydroxymethylated acetoxime (**9***a*), the chelate of the acetonoxime chloral adduct has an isomeric BOCON ring structure, **10***d*, formed by O-B-N coordination (Fig. 3). In this case the α-hydroxyalkoximine **8** (and not the α-hydroxyalkylamine *N*-oxide **7**) serves as a bidentate ligand for the chelate formation. Further support for **8** as an intermediate comes from the reaction of the preformed crystalline acetonoxime chloral adduct **8***d* with oxybis(diphenylborane), which gives a boron chelate identical to the product from the three-component reaction.

The X-ray analysis of the acetonoxime chloral adduct confirms the molecular structure **8***d* (Fig. 1), indicating a preferred α-hydroxyalklation at the oxime oxygen atom by the strongly electrophilic trichloroacetaldehyde as the alkylating agent, similar to the favored *O*-acylation of oximes (13). In the crystal, **8***d* does not form an intramolecular hydrogen bond, but is stabilized as a centrosymmetric, twofold O—H···N bonded dimer (Fig. 1).[7]

Interestingly, in a mass spectroscopic experiment employing chemical ionization of **10***d* conducted to verify a molecu-

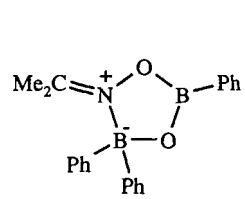
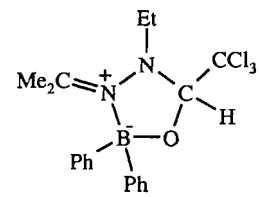
[a] $B_{eq} = (8/3)\pi^2\Sigma\Sigma U_{ij}a_i^*a_j^*(\mathbf{a}_i\cdot\mathbf{a}_j)$

lar mass (not detectable in the EI experiment), a dimer[8] was observed in addition to the molecular ion, although in low relative abundance. This dimer might have the structure "**10**-dimer" which could be formed directly from the 10-membered hydrogen-bridged "**8**-dimer" found in the crystal of **8*d*** by replacement of the ring hydrogen atoms by diphenylboron moieties.

The reaction of chloral hydrate, $Cl_3C\text{-}CH(OH)_2$, with the ketoximes and the subsequent chelatization with diphenylborinic acid is analogous to the reaction of phenylboronic acid, $Ph\text{-}B(OH)_2$, with acetonoxime and diphenylborinic acid, resulting in the BOBON heterocycle **13** (16), which is a boron analog to the BOCON ring type **10**. In both cases a strongly electrophilic alkylation/acylation agent attacks the oxime oxygen atom, followed by the stabilizing chelate formation with diphenylborinic acid using the oxime nitrogen atom as one of the ligands. A nitrogen analog (azalog) of **10** is exemplified by



13

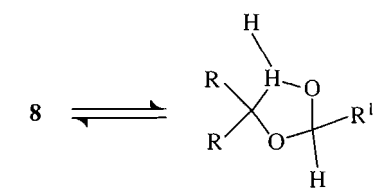


14

the diphenylboron chelate **14**, obtained by the reaction of an acetone hydrazone derivative with chloral and a diphenylborinic acid ester (17). Both structures, of **13** (16) and of **14** (17), were established by X-ray crystallographic analyses, and thus confirm the analogy to **10**.

The five-membered COBON ring of **9*a*** has an envelope conformation with a slightly distorted O(1)-N(1)-C(1)-O(2)

[7] In solution an equilibrium between **8**-dimer and **8** can be supposed. A possible ring tautomer of the open-chain oxime form **8** could not be detected by ^1H nmr spectroscopy in $CDCl_3$ solutions:



This type of 1,4,2-dioxazolidine ring system is found within various molecules reported in the literature, *N*-unsubstituted (14) as well as *N*-substituted (15).

[8] It is not yet clear whether the dimer was produced in the mass spectrometer, or whether it was a contaminant of the sample used for the experiment.

plane (maximum deviation from the mean plane is 0.081(4) Å) with the B(1) atom on the flap, displaced 0.521(4) Å from the ONCO mean plane. The 4-isopropylidene moiety is nearly coplanar with the envelope mean plane (ONCO), the dihedral angle between normals to the mean planes being 4.7°. The C=N bond length (1.279(4) Å) is not significantly different from that reported for acetonoxime (1.29(3) Å) (18), and is close to the value observed for an acetonoximato complex of gadolinium (1.26(2) Å) (19). The N—O bond length of **9***a* (1.358(3) Å) is equal to that of the above-mentioned Gd complex (1.36(2) Å) (19). The C=N and N—O distances both lie within the general ranges reported for oximes (20). The most striking differences between the COBON rings of **9***a* and the related diphenylboron chelate **4***a* (3) involve the N—O bond, which is shorter in **9***a* than in **4***a* by 0.051(6) Å, and the endocyclic C-N-O angle, which is 5.5(5)° wider in **9***a* (C(1)-N(1)-O(1) = 110.5(2)°) than in **4***a* (105.0(4)°). This is to be expected on the basis of the hybridization differences between the ring nitrogen atoms (sp^2 in **9***a* vs. sp^3 in **4***a*). As in **4***a* there is a conspicuous difference between the two O—B bonds in **9***a*. The B(1)—O(1) bond involving the azomethine *N*-oxide oxygen atom is longer by 0.069(6) Å than the B(1)—O(2) bond involving the alcoholate oxygen atom originating from the carbonyl oxygen. This difference in the nucleophilic character of the ligand oxygen atoms is a general phenomenon in compounds containing both *N*-oxide and alcoholate or phenolate groups within the same boron chelate molecule (21). The C(1)—O(2) bond in **9***a* (1.380(4) Å), derived from the inserted

O(2)-B(1)-N(1)-O(1)	27.1(2)

formaldehyde, is, like that in **4***a* (3) and related boron chelates of formaldehyde adducts (22) and the acetone adduct **4***b* (4), shorter than the C—O bonds found in other boron chelates with hydroxyalkyl ligands that have normal C—O single bond distances (21). The B—C(phenyl) bond lengths in **9***a* are in good agreement with those observed in other five- to eight-membered chelates of the type "Ph_2BO_2" (21) and display a typical difference of 0.020(7) Å between the B—C bonds involving the (pseudo)equatorial and the (pseudo)axial phenyl groups, the axial B—C bonds being longer as a rule (21). The mean B—C distance of 1.600 Å is typical for B—C(phenyl) bonds involving tetrahedrally coordinated sp^3-boron atoms in this type of compound. The boron coordination is distorted tetrahedral, with a narrow O-B-O angle of 99.9(3)° within the chelate ring.

The five-membered BOCON ring of **10***d* also has a distorted envelope conformation; the OCON moiety is planar within 0.083(2) Å with B(1) displaced 0.530(2) Å from the OCON mean plane. The 4-isopropylidene grouping (planar to within 0.058(4) Å) is nearly coplanar with the OCON fragment of the chelate ring, the angle between normals to the mean planes being 18.6°. The positioning of the two *B*-phenyl groups above and below the mean BOCON ring plane is not distinctly axial or equatorial, and in this case the two B—C(phenyl) distances are equal within experimental error. The coordinative N(1)—B(1) bond in **10***d* (1.631(3) Å) is significantly shorter than the corresponding N—B bond in the BOBON ring of **13** (1.665(4) Å) (16), indicative of a higher basicity of the oxime nitrogen atom in **10***d* and (or) a decreased Lewis- acidity of the diphenylboryloxy moiety in **13**. In the hydrazone derivative **14** (17) the N—B bond is even shorter (1.603 Å). The difference of about 0.03 Å between the N—B coordinative bonds of **10***d* and **14** reflects the basicity difference between the oxime and hydrazone moieties. A N—B distance similar to that in **10***d* has been reported for the five-membered diphenylboron chelate of 2-hydroxymethylpyridine: 1.642 Å (23), in which the coordinative donor bond involves the (sp^2) pyridine nitrogen atom and forms a ring of the same size as that in **10***d*. The C(2)—O(2) bond in **10***d*, derived from the C=O bond of the inserted chloral, is even shorter (1.357(2) Å) than the comparable C—O bond in the COBON ring of **9***a* (see above). A similar shortening of the C—O single bond of the inserted chloral is observed in compound **14** (17). For crystalline chloral hydrate the C—O bond distances are reported as 1.44 and 1.52 Å (X-ray) (24), and more reliably as 1.386(1) and 1.387(1) Å (neutron data) (25). The C(2)—O(1) bond in **10***d*, originating from the oxime oxygen alkylated by chloral, is 0.093(3) Å longer than the C(2)—O(2) bond derived from the chloral C=O function.

The acetonoxime moieties in both compounds, the COBON chelate **9***a* and the BOCON chelate **10***d*, have nearly equal dimensions except for the N—O bond distance, which is shorter in **9***a* (1.358(3) Å) than in **10***d* (1.401(2) Å). This reflects the main difference between the two ligands involved, the *N*-oxide (nitrone) intermediate **7** introducing the short N—O bond in the case of **9***a*, and the *O*-hydroxyalkylated intermediate **8** inserting the longer N—O bond in the case of **10***d*.

Comparing the intermediate **8***d* with the diphenylboron chelate **10***d*, it can be seen that there is no change in the dimensions of the isopropylidene moiety. The C=N double bond is of nearly equal length in both compounds, as are the C—C bonds and angles. The most notable differences occur at the N(1)-O(1)-C(2) section. The N—O bond of **8***d* (1.423(3) Å) is shortened to 1.401(2) Å in **10***d*, whereas the C—O bond is lengthened from 1.403(4) Å in **8***d* to 1.449(2) Å in **10***d*. In addition, the replacement of the proton at O(2) of the ligand **8***d* by the diphenylborenium ion (Ph_2B^+) to give the chelate **10***d* causes a shortening of the C(2)—O(2) bond from 1.374(4) to 1.357(2) Å. As expected, there are no structural changes in the tetrahedral arrangement of the trichloromethyl substituent going from the ligand to the chelate.

In the crystal, two molecules of **8***d* are linked by O—H···N hydrogen bonds (O(2)—H(1)···N(1)$(1-x, 1-y, 1-z)$, H···N = 2.10(4) Å, O···N = 2.810(4) Å, O—H···N = 172(4)°) to form centrosymmetric dimeric units ("**8**-dimer"). A similar dimeric associate was reported for the benzamidoxime chloral adduct, a stable *O*-hemiacetal with O—H···N hydrogen bonds having O···N = 2.775 Å (26). Molecules of **9***a* are separated by normal van der Waals interactions, the shortest intermolecular distance between non-hydrogen atoms being O(1)···C(1) = 3.367(5) Å. Molecules of **10***d* are linked by weak C—H···O interactions in the solid state (C(4)—H(2)···O(2)$(-1/2 + x, 1/2 - y, -1/2 + z)$, H···O = 2.49(4) Å, C···O = 3.364(4) Å, C—H···O = 158(3)°).

To the best of our knowledge, **8***d* is the first structurally characterized *O*-(α-hydroxyalkyl)oxime in the literature.The compounds **9***a* and **10***d*, described in this work, are the first structurally defined examples of boron chelates of the types **9** and **10**.

Electrocatalytic hydrogenation of conjugated enones on nickel boride, nickel, and Raney nickel electrodes[1]

Behzad Mahdavi, Philippe Chambrion, Julie Binette, Eric Martel, and Jean Lessard

Abstract: The selectivity of the electrocatalytic hydrogenation (ECH) of conjugated enones to the corresponding carbonyl compounds has been investigated in aqueous methanol under constant current at nickel boride, fractal nickel, and Raney nickel electrodes made of pressed powders. The influence of various parameters (water percentage, pH, concentration of substrate, and current density) on the selectivity of the carbon–carbon double bond hydrogenation was studied with cyclohex-2-en-1-one at nickel boride electrodes. Under given electrolysis conditions, fractal nickel electrodes were found to give the highest selectivity. The selectivity of the ECH of a variety of conjugated enones at fractal nickel electrodes was determined under electrolysis conditions that gave the best selectivity with cyclohexenone at nickel boride electrodes.

Key words: electrocatalytic hydrogenation, α,β-unsaturated ketones, selective hydrogenation, nickel based cathodes.

Résumé : Nous avons fait l'étude de la sélectivité de l'hydrogénation électrocatalytique (HEC) d'énones conjuguées en cétones saturées correspondantes dans le methanol–eau à courant constant sur des électrodes de borure de nickel, nickel fractal et nickel de Raney fabriquées par pressage de poudres. L'influence de divers paramètres (le pourcentage d'eau, le pH, la concentration du substrat et la densité du courant) sur la sélectivité a été étudiée avec la cyclohex-2-én-1-one sur électrodes de borure de nickel. Sous des conditions d'électrolyse données, la sélectivité s'est averée la plus élevée avec les électrodes de nickel fractal et celles-ci ont été utilisées pour une étude de la sélectivité de l'HEC de diverses cétones conjugées sous les conditions d'électrolyse ayant donné la meilleure sélectivité dans le cas de la cyclohexénone.

Mots clés : hydrogénation électrocatalytique, cétones α,β-éthyléniques, hydrogénation sélective, cathodes à base de nickel.

Introduction

Electrocatalytic hydrogenation (ECH) of unsaturated organic molecules in aqueous or mixed aqueous-organic media has been carried out since the beginning of the century.[3] The mechanism is described by reactions [1]–[4] where M represents the metallic surface, (H)M chemisorbed hydrogen, and (Y=Z)M the adsorbed organic substrate. The first step is the electroreduction of water (or hydronium ions) with the formation of adsorbed hydrogen on the electrode surface (Volmer reaction [1]), followed by reaction of the adsorbed substrate (Y=Z)M with chemisorbed hydrogen (reaction [3]). There is a competition between hydrogenation (reaction [3]) and the desorption of hydrogen by an electrochemical (Heyrovsky reaction [5]) and (or) chemical (Tafel reaction [6]) pathway. Since, in the ECH of organic substances, the sole processes occurring are hydrogenation and hydrogen evolution (1, 9), the current efficiency is a measure of the competition between the two reactions.

[1] $2H_2O(H_3O^+) + 2e^- + M \rightarrow 2\,(H)M + 2OH^-(H_2O)$

[2] $Y{=}Z + M \rightarrow (Y{=}Z)M$

[3] $(Y{=}Z)M + 2(H)M \rightarrow (YH{-}ZH)M$

[4] $(YH{-}ZH)M \rightarrow YH{-}ZH + M$

[5] $(H)M + H_2O + e^- \rightarrow H_2 + M + OH^-$

[6] $(H)M + (H)M \rightarrow H_2 + M$

This competition depends on a number of factors such as the substrate, the electrode, and reaction conditions (1, 3, 7). The hydrogenation steps (reactions [2], [3], and [4]) are the same

as in catalytic hydrogenation and this was recently shown experimentally by Anantharaman and Pintauro (7) who were able to describe the rate of ECH of glucose to sorbitol from the chemical catalytic hydrogenation rate equation.

ECH presents several advantages over catalytic hydrogenation. *Firstly* ECH uses the very mild conditions (room temperature and atmospheric pressure) normally employed in electrochemical synthesis, mainly because there is no mass transport of poorly soluble molecular hydrogen and because the kinetic barrier for its dissociation is bypassed (1). In fact, the chemisorbed hydrogen is produced in situ, at the surface of the catalyst. Furthermore, its generation can be controlled by adjusting the current density, which makes the reaction easier to handle and may also increase the reaction selectivity (1, 7, 9). Thus, ECH is expected to be more selective than catalytic hydrogenation. *Secondly*, in some cases, the adsorption of poisons can be diminished or even prevented by cathodic polarization of the catalyst (1). When compared to electrohydrogenation by the electronation–protonation (EP) process, ECH has the advantage of requiring less energy. Indeed, the formation of chemisorbed hydrogen by reduction of water on a low hydrogen overvoltage cathode requires a less negative potential than the electronation of most functional groups of organic chemistry (with the exception of the nitro group family). Furthermore, the formation, for instance, of dimerization products in the electrohydrogenation of carbonyl compounds may be avoided since reactive intermediates such as radical anions and radicals are not produced (3, 9). However, an advantage of the EP process is the possibility of controlling the product selectivity by potentiostatic reduction.

This paper reports the results of a study of the ECH of various conjugated enones in aqueous methanol at nickel boride, fractal nickel, and Raney nickel electrodes made of pressed powders. First, we describe the influence of different electrolysis conditions (water percentage, pH, concentration of substrate, and current efficiency) on the selectivity, and of the ECH of cyclohex-2-en-1-one at nickel boride electrodes. Then, we compare fractal nickel and Raney nickel electrodes with nickel boride electrodes under given electrolysis conditions. Finally, the ECH of some conjugated enones was investigated at fractal nickel electrodes under electrolysis conditions giving the best selectivity with cyclohexenone at nickel boride electrodes.

Experimental

The electrolyses were carried out with a 410 potentiostatic controller, 640 digital coulometer, and 2830 digital multimeter (Electrosynthesis Company). A two-compartment glass H-cell (volume of each compartment 25 mL) having a Nafion-324 (E.I. du Pont de Nemours & CO) membrane (1.8 cm^2) as separator was used. The counter electrode was a glassy carbon plate (≈12 cm^2). The substrate was dissolved in a stock solution (25 mL) of sodium chloride (0.1 M) and boric acid (0.1 M) in methanol–water (v/v) by stirring the solution in the cathodic compartment. The anodic compartment was filled with the above stock solution (25 mL). The cathodic compartment was deaerated (N_2). The cathode and the counter electrode were immersed and electrolysis was performed at constant current. The catholyte was stirred magnetically. The apparent pH was measured with a Sargent Welch 6000 pH meter and a Cole Parmer glass electrode that was calibrated in aqueous buffer. Aliquots (0.2 mL) from the catholyte were extracted with ether after the addition of a saturated NaCl solution (1 mL) and were analyzed by vpc. The products were identified by comparison of retention times with those of authentic samples. They were identified also by GC–MS and by IR and ^1H and ^{13}C NMR spectroscopy after extraction with ether and, when needed, thick-layer chromatographic separation (Merck Silica Gel 60 F_{254}, layer tickness: 250 μm). The mass balance was determined by weighing the isolated crude product after extraction and thorough rinsing (CH_3OH, then ether) of the electrode. Some cyclohexanone and cyclohexanol (less than 8% altogether in the worse cases) were lost upon solvent removal. With the other less volatile substrates, the material balance was close to 100% in all cases. There was no organic product in the anolyte after completion of the electrolysis, according to vpc analysis.

P-1 nickel boride (Ni_2B) was obtained as a powder (average particle size of 0.5 μm and specific surface area of 9 $m^2\ g^{-1}$ (5)) by reduction of nickel acetate with $NaBH_4$ in aqueous NaOH (10). The filamentary nickel powder (particle size of 2.2–2.8 μm and specific surface area of 0.68 $m^2\ g^{-1}$) was purchased from Inco (type 255 nickel powder) and consisted of spiky (fractal characteristics) spheres. The Raney nickel alloy (Ni–Al 50:50 w/w) powder (particle size of 45–125 μm) was purchased from BDH. The specific surface area of the spongy Raney nickel (RaNi) particles (average diameter <40 μm) after leaching in aqueous NaOH is of the order of 65 $m^2\ g^{-1}$ (11). The electrodes were obtained by pressing the powders at p = 800 MPa at room temperature. The pressed Raney alloy powder was leached in 10% NaOH for 3 h at 50°C to afford the RaNi electrodes. The geometric area of the electrodes was 2π cm2 considering that both faces of the disc were used.

Results and discussion

Electrocatalytic hydrogenation of cyclohex-2-en-1-one on nickel boride electrodes

The electrocatalytic hydrogenation (ECH) of cyclohex-2-en-1-one to cyclohexanone has been already studied under different experimental conditions on various electrodes: Pd(0) microparticles in poly(pyrrole-viologen) film (6), Raney nickel powder on a nickel plate (9), palladium and platinum deposited on carbon powder (9), and Ni(0) microparticles electrodeposited in Nafion films (12). In all cases, the ECH of cyclohex-2-en-1-one produced cyclohexanone and cyclohexanol as major products. The presence of cyclohex-2-en-1-ol was hardly or not detected in the reaction mixture (9, 12). We studied the influence of the proportion of water, the pH of the solution, the substrate concentration, and the current density on the selectivity of the ECH of the carbon–carbon double bond of cyclohexenone in methanol–water solutions under constant current conditions. The hydrogenated products observed were cyclohexanone and cyclohexanol, as expected. No other product was detected by vpc analysis. The material balance was determined by weighing the reaction product after extraction with ether and solvent removal, and in some cases small amounts (≤8%) of material were lost by evaporation. The selectivity was evaluated by the ratio of the yield of cyclohexanone to the conversion rate. The efficiency of the electrohydrogenation was evaluated from the conversion rate and the

[a]The electrodes were prepared by pressing the Ni_2B powder at p = 800 MPa.

[b]Electrolysis conditions: MeOH–H_2O (v/v); 0.1 M NaCl; 0.1 M H_3BO_3; room temperature; charge passed = 2 moles of electrons per mole of cyclohex-2-en-1-one.

[c]pH_i = pH at the begining of the electrolysis, pH_f = pH at the end. The pH meter was calibrated using buffers in aqueous solutions.

[d]Based on the geometric area.

[e]The conversion rate and yield of products were determined by vpc analysis. The yields are based on converted cyclohex-2-en-1-one (material balance 92–100%).

[f]Selectivity = (yield of cyclohexanone/conversion) × 100.

[g]Range obtained from two different electrolyses.

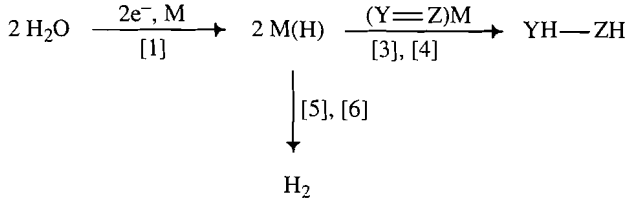
[h]HCl was added at the begining of the electrolysis.

current efficiency. The charge passed corresponded to two moles of electrons per mole of substrate, the charge required for complete hydrogenation of the carbon–carbon double bond of the substrate. The results obtained under the different electrolysis conditions are summarized in Table 1. As shown in entry 1, different pressed nickel boride powder electrodes gave very reproducible results as in the case of the ECH of phenanthrene (5). Changing the proportion of water from 5 to 80% (entries 1–3) had little effect on the selectivity, which varied from 74–80%. The effect on the conversion rate (64–68%) and the current efficiency (71–84%) was also not very important. Kam Cheong et al. (3) likewise observed that the relative proportion of water had little effect on the efficiency of the ECH of cyclohexanone on RaNi electrodes. A methanol–water ratio of 50/50 was chosen because this ratio permits a range of organic substrates and supporting electrolytes to dissolve easily.

As seen from Table 1 by comparing entry 4 (pH 1.7–4.6) with entry 1 (pH 5.3–8.6), the ECH of cyclohexenone was more efficient (higher conversion rate and current efficiency) under the more acidic conditions but the pH of the medium had no effect on the selectivity (74% in both entries).[4] Osa and al. (9) reported that there was no well-defined correlation between the pK_a of the proton source and the efficiency and selectivity of the ECH of cyclohexenone at Raney Ni, Pt/C, and Pd/C electrodes.

The effect of increasing the cyclohexenone concentration from 16 to 48 mM is shown in entries 1, 5, and 6 of Table 1. The efficiency of the process increases upon increasing the concentration of the substrate due to an increase of the hydrogenation step (reaction [4]) (see Scheme 1). A current efficiency of 100% was obtained for a 48 mM solution (entry 6). At this concentration, under the conditions used, all the chemisorbed hydrogens did react with the adsorbed substrate and there was no formation of gaseous hydrogen by the Heyrovsky and (or) Tafel reactions (reactions [5] and [6]). As expected, the cyclohexenone concentration had no effect on the selectivity of the hydrogenation (74–76%).

Scheme 1. Competition between hydrogenation and desorption of hydrogen.



The effect of current density on the efficiency and on the selectivity of the ECH of cyclohex-2-en-1-one is shown in entries 1 and 7–9 of Table 1. The conversion rate increases from 67% (entry 1) to 84% (entry 9) as the current density decreases from 250 to 50 mA dm^{-2} (geometric area), which shows that a decrease of current density favors hydrogenation over hydrogen evolution (Scheme 1). Assuming that the mechanism of the HER in methanol–water at pH 5.3–8.3 on nickel boride electrodes is the same as in aqueous alkaline solutions, that is, a Volmer–Heyrovsky mechanism (reactions [1] and [5]) (14, 15), the competition between hydrogenation and hydrogen evolution (Scheme 1) becomes a competition between a chemical process (reactions [2]–[4]) and an electrochemical process (reaction [5]) (Scheme 1). The increase in

[4] Apparent pH values of 10 or higher during the electrolysis had to be avoided to prevent the formation of 3-methoxycyclohexanone (9, 13).

Table 2. Effect of the electrode material and the charge passed on the ECH of cyclohex-2-en-1-one[a]

[a]Electrolysis conditions: 16 mM solution of cyclohex-2-en-1-one; MeOH–H_2O (50/50, v/v); 0.1 M NaCl; 0.1 M H_3BO_3; pH = 5.3–9.3; room temperature; J = 250 mA dm^{-2}.

[b]The electrodes were prepared by pressing the powder at p = 800 MPa.

[c]See footnote *e* of Table 1.

[d]The values were obtained at a charge of 80 coulombs (2 F mol^{-1}) and 160 coulombs (4 F mol^{-1}).

[e]See footnote *f* of Table 1.

[f]The catalytic hydrogenation was carried out under the same conditions as those of ECH except that no potential was applied to the electrode (open circuit). The values were obtained after periods of time corresponding to the consumption of 2 moles (90 min) and 4 moles (180 min) of electrons per mole of cyclohex-2-en-1-one, respectively, in the ECH experiments.

[g]The electrode used in the catalytic hydrogenation experiment (entry 4) was washed with MeOH–H_2O (50:50, v/v) and used in the ECH experiment of entry 5.

the ECH efficiency upon decreasing the current density would then result from a decrease in the rate of the electrochemical reaction. It is noteworthy that the current efficiency remained the same (83–86%) as the current density was decreased by a factor of five (compare entries 1 and 7–9). In other examples of ECH reported in the literature (1, 2, 16), a decrease of current density was generally associated with an increase of current efficiency and of conversion rate. But in the ECH of cyclohexenone, a decrease in current density is associated with an increase in conversion rate and a decrease in the extent of further hydrogenation of cyclohexanone to cyclohexanol (increase in selectivity). This can be explained by the fact that the chemisorbed hydrogen would be more active at higher current densities (at more negative potentials), which would translate into a faster hydrogenation of the cyclohexanone molecules generated at the surface of the electrode by the hydrogenation of cyclohexenone. At lower current densities, the hydrogenation of cyclohexanone would become slow enough to allow its diffusion to the bulk solution before being hydrogenated. The results of entries 1–9 of Table 1 discussed above allowed us to choose the optimum conditions: MeOH–H_2O = 50/50, pH = 1.7–5.5, J = 50 mA dm^{-2} (geometric area), substrate concentration = 48 mM (see entry 10). Under these conditions, a selectivity of 100% and an efficiency close to 100% were obtained for the formation of cyclohexanone (entry 10). Before the present systematic study, the ECH of cyclohexenone had been studied on various electrodes but under different electrolysis conditions (6, 9, 12). The differences observed in the efficiency and selectivity were attributed solely to the performance of the electrode (catalytic) material (6). A true and meaningful comparison of various electrode materials must be carried out under specific electrolysis conditions.

Table 2 summarizes the results of a study of the effect of the electrode material (nickel boride (Ni_2B), fractal nickel (Ni), and Raney nickel (RaNi)) and the charge passed (80 C (2 F mol^{-1}) and 160 C (4 F mol^{-1}) corresponding to the theoretical charge for hydrogenation to cyclohexanone and to cyclohexanol, respectively) on the ECH of cyclohex-2-en-1-one under electrolysis conditions corresponding to those of entry 1 of Table 1: MeOH–H_2O = 50/50, pH = 5.3–8.6, J = 250 mA dm^{-2} (geometric area), substrate concentration = 16 mM. Both the selectivity and the efficiency were found to depend on the electrocatalyst and the charge. As expected, the current efficiency decreased with the charge for the three types of electrode materials (see entries 1, 2, 3, and 5). Indeed, as the charge increases, the concentration of cyclohexenone decreases, and hydrogen evolution becomes more and more important (Scheme 1) (1, 3) since cyclohexanone is more difficult to hydrogenate than cyclohexenone and cyclohexanol is not reducible. As a result, the current efficiency decreases. The current efficiencies higher than 100% in entries 3 and 5 reflect the fact that chemisorbed hydrogen generated during leaching of the Raney alloy was present on the electrode at the beginning of the electrolysis (1). The results of catalytic hydrogenation of cyclohexenone on a freshly leached RaNi electrode (Table 2, entry 4) show that the amount of chemisorbed hydrogen present after leaching corresponds to more than 0.63 mmole of molecular hydrogen[5] since there was still some chemisorbed hydrogen left, as shown by the current efficiency of 110% after a charge of 2 F mol^{-1} when the same electrode as that used in the catalytic hydrogenation experiment (entry 4) was reused for the ECH experiment of entry 5. There was no active chemisorbed hydrogen present on the Ni_2B and Ni electrodes before the electrolysis: no hydrogenation of cyclohexenone was observed in open circuit experiments. The decrease of selectivity as the charge increases is due to the decrease in concentration of cyclohexenone and the

[5] Similar quantities of active chemisorbed hydrogen were found for RaNi electrodes consisting of RaNi particles embedded in a nickel matrix: 0.48–0.66 mmol when the precursory electrodes contained about 0.7 g of precursory alloy (57–59% of alloy in the nickel matrix) (1).

increase in the amount of cyclohexanone formed; as a result, a point is reached where the rate of hydrogenation of cyclohexanone becomes equal to that of hydrogenation of cyclohexenone. The selectivity was also greatly dependent on the type of catalytic electrode, increasing from 20% (2 F mol^{-1}) and 9% (4 F mol^{-1}) with the RaNi electrodes (entry 3) to 74 and 46%, respectively, with the Ni2B electrodes (entry 1) and to 86 and 78% with the fractal Ni electrodes (entry 2). This is the order of decreasing activity (apparent activity) of these three electrodes for the ECH of phenanthrene in ethylene glycol–water at 80°C, fractal Ni being much less active than the two other electrodes (5).[6] It is reasonable to assume that the order of activity would be the same for the ECH of cyclohexenone in methanol–water at room temperature and the most active RaNi electrodes then gave the lowest selectivity for the hydrogenation of the carbon–carbon double bond, as expected. A RaNi electrode that had been used in an open circuit experiment (the catalytic hydrogenation experiment of entry 4) gave higher selectivities (57% (2 F mol^{-1}) and 34% (4 F mol^{-1}), entry 5) than a freshly prepared RaNi electrode (20 and 9%, respectively, entry 3) for the ECH of cyclohexenone. This results from the deactivation of RaNi in the catalytic hydrogenation experiment and confirms the conclusion reached above by comparing the selectivities of the three electrode materials; that is, the selectivity reflects the activity. In the catalytic hydrogenation experiment in which only the chemisorbed hydrogen produced during the leaching process was used (entry 4), the selectivity was the same after 90 min (48%) and 180 min (50%) since the conversion merely increased (from 73–83%, respectively) over the last 90 min due to a decrease in both the amount of chemisorbed hydrogen and in the substrate concentration. For similar conversion rates, the selectivity obtained with a freshly prepared RaNi electrode was lower in the ECH experiment (20% after 2 F mol^{-1}, entry 3) than in the catalytic hydrogenation experiment (48–50%, entry 4). Thus polarized RaNi (entry 3) would be more active than nonpolarized RaNi (entry 4). As already pointed out, in the ECH reactions, the selectivity decreases as the electrolysis proceeds due to mass transfer phenomena related to changes in the relative concentrations of cyclohexenone and cyclohexanone. The decrease in selectivity in increasing the charge from 2 to 4 F mol^{-1} was the most pronounced with the freshly leached RaNi (most active) electrode (55% decrease, entry 3), was of the same order of magnitude for the deactivated RaNi electrode (38% decrease, entry 5) and the Ni_2B electrode (40% decrease, entry 1), and was by far the smallest for the least active fractal Ni electrode (9% decrease, entry 2). This shows that fractal Ni is the best electrocatalytic material for the selective electrohydrogenation of the carbon–carbon double bond of cyclohexenone.

Electrocatalytic hydrogenation of various conjugated enones at fractal nickel electrodes

The fact that fractal nickel can be used as a catalytic material for the selective ECH of a carbon–carbon double bond conjugated to a keto group is very interesting because it is not an expensive material. The ECH of some conjugated enones has been investigated at fractal Ni electrodes under conditions that gave the highest selectivity with cyclohexenone at Ni_2B electrodes (see Table 1, entry 10). The results are reported in Table 3. Comparison was made both at a given charge of 2 F mol^{-1} (the theorical charge for hydrogenation the α,β carbon–carbon double bond) and at conversion rates of the order of 80–93%.

At a given charge of 2 F mol^{-1}, only the carbon–carbon double bond of the conjugated enones was electrohydrogenated, as shown by selectivities higher than 99% in entries 1, 2, 4, 6, 10, 12, and 14 of Table 3. Then, the efficiency of the ECH process evaluated from the conversion rate and the current efficiency, which both depend on the ratio of the rate of hydrogenation to the rate of hydrogen desorption (Scheme 1), the latter being constant under given conditions, reflects the ease of hydrogenation of the α,β carbon–carbon double bond. From the conversion rates and current efficiencies of entry 1 (93–95%), entry 2 (48–51%), entry 4 (42–43%), and entry 6 (33%), the rate of hydrogenation of the double bond decreases in the order cyclohexenone > isophorone ≥ 2,4,4-trimethylcyclohex-2-en-1-one > verbenone. This can be attributed to an increase in steric interactions, making the adsorption of the substrate on the catalytic surface more difficult (17), and, as a result, the transfer of adsorbed hydrogens to the double bond is also more difficult. The lower efficiency of the ECH of the carbon–carbon double bond of β-ionone (28–36%, entry 10) when compared to *trans*-4-phenylbut-3-en-2-one (23–36%, entry 14) must also be due mainly to larger steric interactions with β-ionone although the adsorption of the phenyl ring of phenylbutenone probably has some influence as well. The slightly less efficient ECH of the double bond of 2,4,4-trimethylcyclohex-2-en-1-one (42–43%, entry 4) when compared to isophorone (48–51%, entry 2) most probably reflects the fact that the *gem*-dimethyl group is closer to the double bond in the former (stronger steric interactions), rather than the effect of the position of the methyl group on the double bond (β and α position in trimethylcyclohexanone and isophorone, respectively). Acetylcyclohexene with a trisubstituted endocyclic double bond is more difficult to hydrogenate (69–73% efficiency, entry 8) than cyclohexenone with a disubstituted double bond (93–95% efficiency), as expected again from steric effects. In the case of carvone (entry 12), there was extensive hydrogenation of the isopropylidene group, as shown by product distribution and yields after 4 F mol^{-1}: 5-isopropyl-2-methylcyclohex-2-ene-1-one (carvotanacetone), 12%; 3-isopropyl-6-methylcyclohexanone (carvomenthone), 55%; 3-isopropylidene-6-methylcyclohexanone (dihydrocarvone), 8%. This corresponds, for the hydrogenation of the conjugated double bond only (2 F mol^{-1}), to a conversion of 65% and a current efficiency of 65%. Thus the efficiency of the hydrogenation of the conjugated double bond of carvone and carvotanacetone is similar to that of acetylcyclohexene (entry 8), as expected from the fact that the conjugated double bond is trisubstituted in both cases. Being equatorial, the isopropylidene group of carvone and the isopropyl group of carvotanacetone have little effect on the adsorption of the molecule and the hydrogenation of the conjugated double bond.

The results of ECH of the enones of Table 3 on fractal nickel electrodes at high substrate conversion (≥80%, see entries 1, 3, 5, 7, 9, 11, 13, and 15) show that high selectivities (96–100%) for the hydrogenation of the conjugated carbon–carbon double bond were obtained in all cases. The lower selectivities

[6] The intrinsic or true activity of the electrode material for the ECH of phenanthrene was found to be the same for RaNi and Ni_2B but lower for fractal Ni (5).

Table 3. ECH of conjugated enones on fractal nickel electrodes[a]

17		4	100	51	75

[a]Electrolysis conditions: 48 mM solution of substrate; MeOH–H_2O (50/50, v/v); 0.1 M NaCl; 0.1 M H_3BO_3; pH = 1.7–5.5; room temperature; fractal nickel pressed powder electrodes (p = 800 MPa); J = 50 mA dm^{-2}.

[b]See footnote *e* of Table 1.

[c]Selectivity = (yield of α,β-dihydroketone/conversion rate) × 100.

[d]Data after a charge corresponding to 4 F mol^{-1} are given because there was extensive hydrogenation of the isopropylidene group (2 F mol^{-1}, 67%).

[e]Selectivity = ((yield of dihydrocarvone + yield of carvomenthone)/(100 – (yield of carvone + yield of carvotanacetone)) × 100.

observed with 2,4,4-trimethylcyclohex-2-ene-1-one (96% at 80% conversion) and β-ionone (98% at 80% conversion) reflect once more the fact the double bond is more hindered relative to the carbonyl group than in the other enones. The ECH of the conjugated double bond was much less selective in *trans*-cinnamaldehyde (entries 16 and 17: selectivities of 56 and 51% for conversion rates of 69 and 100%, respectively) than in *trans*-phenylbutenone (100% selectivity at 87% conversion in entry 15), in agreement with the fact that the carbonyl group of an aldehyde is less hindered and more reactive than that of a ketone. Aldehydes have indeed been shown to be hydrogenated more readily than ketones in both catalytic (18) and electrocatalytic (3) hydrogenations.

Conclusion

We have shown that, in the ECH of cyclohex-2-en-1-one at nickel boride electrodes, the selectivity of the carbon–carbon double bond hydrogenation can be increased to 100% by decreasing the current density, and the efficiency can be increased to 100%, also by both increasing the concentration of the substrate and decreasing the current density. The selectivities were quite low with the more active Raney nickel electrodes. Fractal nickel electrodes were found to give higher selectivities than nickel boride electrodes under given conditions and were shown to be quite useful for the selective ECH of the conjugated carbon–carbon double bond of a variety of enones.

The crystal structure of 2-(4-bromophenyl)-4-(2-fluoroethyl)-5,6-dihydro-4*H*-1,3,4-oxadiazine hydrochloride, an octopaminergic insecticide/miticide

Mark A. Dekeyser, W. Ashley Harrison, Nicholas J. Taylor, and Roger G.H. Downer

Abstract: The crystal structure of 2-(4-bromophenyl)-4-(2-fluoroethyl)-5,6-dihydro-4*H*-1,3,4-oxadiazine hydrochloride, a new octopamine agonist, has been established by Patterson and Fourier methods and refined to a final *R* value of 0.0293 for 2123 absorption-corrected observed data. The crystals are monoclinic, a = 14.336(3), b = 12.649(3), c = 6.989(1) Å, β = 93.48(1)°, and the space group is $P2_1/c$. Its structural similarities with the crystal structure of the invertebrate neurotransmitter, octopamine, are described and support the hypothesis that the pesticidal properties of dihydrooxadiazines are, at least partially, due to perturbation of octopaminergic systems.

Key words: dihydrooxadiazine, octopamine agonist.

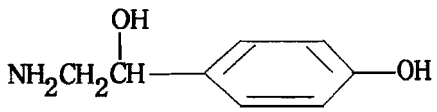
Résumé : Utilisant les méthodes de Patterson et de Fourier, on a déterminé la structure cristalline du chlorhydrate de 2-(4-bromophényl)-4-(2-fluoroéthyl)-5,6-dihydro-4*H*-1,3,4-oxadiazine, une nouvelle octopamine agoniste, et on l'a affinée jusqu'à des valeurs finales de R = 0,0293 pour 2123 absorptions corrigées à partir des données observées. Les cristaux appartiennent au group d'espace monoclinique $P2_1/c$ avec a = 14,336(3), b = 12,649(3), c = 6,989(1) Å, β = 93,48 (1)°. On décrit ses ressemblances structurelles avec la structure cristalline du neurotransmetteur des invertébrés, octopamine, qui confirment l'hypothèse à savoir que les propriétés pesticides des dihydrooxadiazines sont, au moins partiellement, dues à une perturbation du système octopaminergique.

Mots clés : dihydrooxadiazine, octopamine agoniste.

[Traduit par la rédaction]

Introduction

One biorational approach in the development of safer and more selective pesticides is to select targets that are vital and specific to pest species, thereby minimizing toxicity to nontarget organisms (1). In this regard, much attention has been directed at the octopaminergic system as a valid target in the search for novel pesticides (2, 3). Octopamine **1** is one of the most abundant and studied biogenic amines in the insect nervous system (4, 5). Octopamine functions as a neurotransmitter, neurohormone, and neuromodulator, regulating several vital physiological functions in insects and mites, including



1

feeding, locomotion, and reproduction (6, 7). Compounds that stimulate octopaminergic systems in insects and mites have the potential to cause physiological, behavioral, and lethal effects that often are highly compatible with integrated pest management (IPM) systems. The octopamine receptor has been recognized as a useful target since the discovery of the insecticidal and miticidal properties of formamidines, which function as octopamine agonists by stimulating cyclic adenosine monophosphate (cyclic AMP) (8–10). Two formamidines, chlordimeform **2** and amitraz **3**, are commercial pesticides (11). Pesticidal activity has been also associated with the imidazoline (12) and oxazoline (13) classes of octopamine agonists.

Recently, dihydrooxadiazines were identified (14, 15) as novel octopaminergic insecticides. They were shown to be octopamine agonists in the two-spotted spider mite, *Tetranychus urticae* (16), and in the American cockroach,

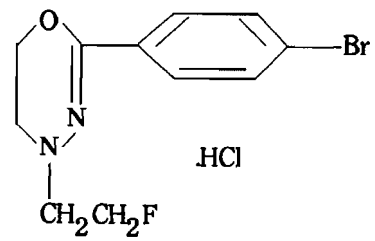
Periplaneta americana (17). 2-(4-Bromophenyl)-4-(2-fluoroethyl)-5,6-dihydro-4*H*-1,3,4-oxadiazine hydrochloride **4** was reported to mimic the action of octopamine in stimulating the production of cyclic AMP (16, 17). Furthermore, the compound was found to be extremely potent at controlling eggs of the two-spotted spider mite, *T. urticae*, and the tobacco budworm, *Helicoverpa virescens* (15).



4

The significant activity reported for **4** is encouraging with regard to its possible use as a new octopamine agonist for control of insect and mite pests. From the chemistry point of view, it is interesting to speculate why **4** should behave as an octopamine agonist when the two compounds, **1** and **4**, do not obviously resemble one another. Through molecular modelling studies, structural similarities between dihydrooxadiazines and octopamine have been shown (14). To validate the molecular modelling studies, we required a precise structure of a highly active dihydrooxadiazine compound. In this study, we determined the crystal structure of **4** and compared this structure to the crystal structure of **1**.

Experimental

(4-Bromophenyl)-4-(2-fluoroethyl)-5,6-dihydro-4*H*-1,3,4-oxadiazine hydrochloride **4** was synthesized according to the procedure of Dekeyser et al. (18). It was recrystallized from methanol to give colorless needles with mp 163°C. A crystal of dimensions 0.08 × 0.16 × 0.72 mm was mounted on a glass fibre. Data were collected at 180 K on a Nicolet LT2 equipped R3m/V diffractometer using Mo $K\alpha$ radiation (λ = 0.71073 Å). Twenty-five reflections (22° < 2θ < 32°) were used in the unit cell refinement. An ω scan data collection (4° < 2θ < 56°) of $hk \pm l$ reflections yielded 3056 unique data of which 2123 with $F_o > 4\sigma(F_o)$ were considered observed and were used in the structure solution and refinement. Two standard reflections, monitored every 100 measurements, exhibited only statistical fluctuations. Background measurements were made at the beginning and end of each scan for a total of half the scan time. Crystal data are as follows:

$C_{11}H_{13}BrClFN_2O$ MW 323.6 g mol^{-1}

Monoclinic, $P2_1/c$ (no. 14), a = 14.336(3), b = 12.649(3), c = 6.989(1) Å, β = 93.48(1)°, V = 1265.1(4) Å^3 (180 K), Z = 4, d_c = 1.699 g cm^{-3}, μ = 34.58 cm^{-1} (face-indexed absorption correction, transmission factors 0.5348–0.7734).

Data reduction, structure solution, and refinement were carried out using Siemens SHELXTL PLUS software on a VAX 3100. The structure was solved by Patterson and Fourier techniques and refined by full-matrix least-squares methods. All hydrogen atoms were located by difference Fourier synthesis but were included in the refinement riding in calculated positions, except H(4), which was fixed in the found location. Hydrogen atom isotopic thermal parameters were refined. The final refinement, on 168 parameters, based on observed wF's, was weighted with $w^{-1} = \sigma^2(F)$ and gave residuals R = 0.0293, wR = 0.0263 with S = 1.32 where $R = \Sigma||F_o| - |F_c||/\Sigma F_o$, $wR = [\Sigma w(|F_o| - |F_c|)^2/\Sigma(wF_o^2)]^{1/2}$, and $S = [\Sigma w(|F_o| - |F_c|)^2/(N_{obs} - N_{var})]^{1/2}$. The largest final cycle shift/error was 0.005 and the most significant features of a final difference map were a hole of −0.40 e/Å^3 and a peak of 0.34 e/Å^3. An extinction correction of the form $F^* = F[1 + 0.002\ X\ F^2/\sin 2\theta]$, X variable, gave X = 0.00012(1).

The X-ray conformations of octopamine **1** and dihydrooxadiazine **4** were superimposed using the HyperChem® Release 4 and ChemPlus™ package[2] running on a 80486 33 MHz IBM-compatible personal computer. Superimpositions were done using the RMS Fit module of ChemPlus to find the best fit for the two structures by overlaying three pairs of atoms in the two structures. The atoms chosen for this fit procedure were the first and fourth carbon atoms in the phenyl rings and the corresponding nitrogen atom of each structure.

Results and discussion

The final atomic coordinates[3] and equivalent isotropic temperature factors for the non-hydrogen atoms are listed in Table 1 and a view of the crystal structure, showing the atom-numbering scheme, is presented in Fig. 1. Bond distances and bond angles are given in Tables 2 and 3, respectively.

The racemic dihydrooxadiazine hydrochloride **4** crystals contained four molecules, two pairs of enantiomers, in the

crystallographic unit cell, which is centrosymmetric. The analysis shows that the dihydrooxadiazine ring adopts a half-chair conformation. Figure 2 illustrates the puckering of the dihydrooxadiazine ring. Atoms C(6), O(1), C(2), N(3), and N(4) define a plane (plane 1), whereas C(5) lies 0.685 Å below this plane. A similar conformation of a dihydrooxadiazine ring was reported for the crystal structure of (*E*)-6-(bromomethylene)-5,6-dihydro-4,4-dimethyl-2-phenyl-4*H*-1,3,4-oxadiazinium bromide (19).

The phenyl ring is planar, with the bromine atom located just above this plane. The phenyl ring and the dihydrooxadiazine ring are almost coplanar. The phenyl ring plane is twisted 12.9° from plane 1 of the dihydrooxadiazine ring. In the study of the above oxadiazinium compound, it was found that the phenyl ring was twisted by 20° (19). This twist angle is also typical of biphenyl compounds without *ortho* substituents (20). The fluoroethyl chain lies extended from and nearly coplanar with the dihydrooxadiazine ring. The fluorine atom lies below plane 1 of the dihydrooxadiazine ring. The hydrogen and chlorine atoms of the salt portion both lie above the dihydrooxadiazine ring.

Fig. 1. Molecular structure of dihydrooxadiazine **4** and its atomic numbering scheme with thermal ellipsoids at the 50% probability level. (Hydrogen atoms are shown with arbitrary size for clarity.)

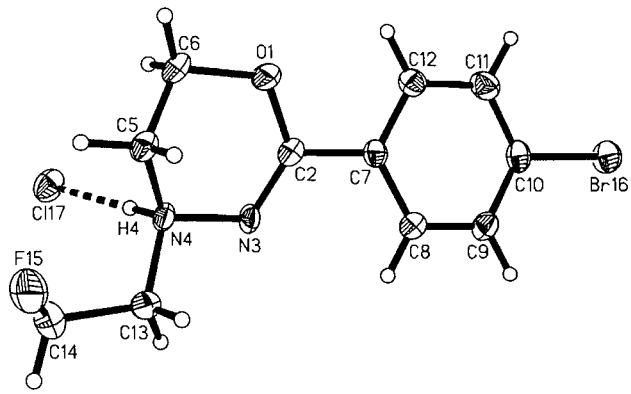

Fig. 2. Half-chair conformation of the dihydrooxadiazine ring.

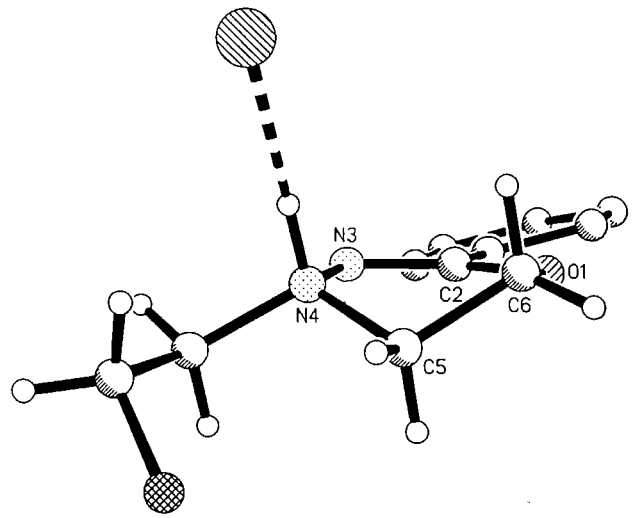

Most of the bond distances (Table 2) are close to accepted values (21–24) with the exception of the hydrogen–chlorine bond, which, at 2.03 Å, is somewhat shorter than the more typical 2.30–2.40 Å. There are no untoward intramolecular contacts, the shortest being F(15) – H(5y) at 2.54 Å. There are also no untoward intermolecular contacts, the shortest being 2.52 Å between H(6y) and the fluorine atom of an adjacent molecule.

In view of the proposed octopamine agonist activity of **4**, it was decided to compare its crystal structure with that of octopamine. In 1977, the crystal structure of octopamine hydrochloride was determined by Paxton and Hamor (25). For comparison purposes, a computer-generated perspective drawing of the final X-ray model of octopamine hydrochloride **1** superimposed on dihydrooxadiazine **4** is shown in Fig. 3. The most obvious difference, apart from the larger size of the dihydrooxadiazine molecule, is the orientation of the phenyl rings. A comparison of the dihedral angles of five corresponding atoms shows that the phenyl ring in **4** is rotated 62.8° from

Table 3. Bond angles (deg) for **4**.

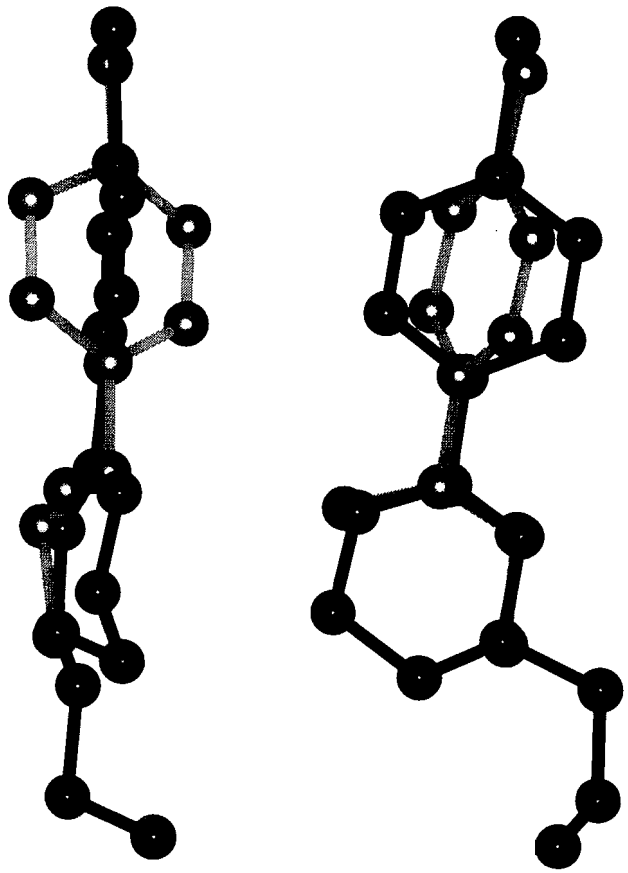
Fig. 3. Superimposed computer-generated structure of octopamine **1** (light) and dihydrooxadiazine **4** (dark). (Hydrogen and chlorine atoms have been omitted for clarity.)



that in **1**. Variations in the dihedral angles of similar compounds have been rationalized in terms of the effects of crystal packing on molecular conformations (20).

Superimposition of **1** and **4** revealed structural and conformational similarities that might account for the agonistic activity of **4**. As shown in Fig. 3, when the amino nitrogen and the first and fourth carbon atoms in the phenyl ring of each molecule are overlaid, C(2)-N(3)-N(4) oxadiazine ring atoms of **4** can occupy space similar to the ethylamino group of octopamine **1**. The RMS deviation of the superimposition of **4** and **1** based on these atoms was 0.1 Å. The two functionalities deemed to be essential to octopaminergic pesticidal action (14), a phenyl ring and a suitably situated amino group, appear to be conserved in **4**. A similar comparison between the octopaminergic pesticide, chlordimeform **2**, and octopamine **1** also resulted in identification of common structural features (26). Therefore, in spite of the extra steric volume, dihydrooxadiazine **4** appears to be structurally and conformationally analogous to octopamine **1**.

In conclusion, we have studied the crystal structure of one pesticidally active example of a new class of conformationally restricted octopamine agonists. We have established the structure of **4** unequivocally by X-ray crystallography and shown that it closely overlays the X-ray structure of octopamine hydrochloride **1**. The conformational constraint and the extra steric volume introduced by the dihydrooxadiazine ring allow the overlay of the presumed essential functionality of octopamine **1** with the dihydrooxadiazine **4**. This evidence supports the proposal that dihydrooxadiazine **4** exerts its insecticidal and miticidal activity through an interaction with octapamine receptors. Our results suggest that certain structural requirements are important for the rational design of octopaminergic pesticides. Further studies to evaluate structure–activity relationships in dihydrooxadiazines are in progress.

Electrochemistry of polyoxometalates immobilized in ion exchange polymer films

Kasem K. Kasem and Franklin A. Schultz

Abstract: The polyoxometalate ions $PMo_{12}O_{40}^{3-}$, $PW_{12}O_{40}^{3-}$, and $SiW_{12}O_{40}^{4-}$ are incorporated in polymeric ruthenium(II)(vinyl)bipyridine (poly-Ru(vbpy)$_3^{2+}$) films from aqueous and dioxane–water electrolytes. Despite their large mass the ions exist as freely diffusing species that compensate for up to 30% of the charge in poly-Ru(vbpy)$_3^{2+}$. An investigation of the effect of environmental conditions on electrochemical behavior reveals that the first two one-electron reduction waves of $SiW_{12}O_{40}^{4-}$ coalesce into a single two-electron reaction and those of $PW_{12}O_{40}^{3-}$ shift significantly in potential upon a change from pure aqueous to 50(v/v)% dioxane/water solvent. The observation is attributed to destabilization of the one-electron reaction products as the solvent is enriched is dioxane. Incorporation of polyoxometalates in protonated poly(vinyl)pyridine and poly-Ru(vbpy)$_3^{2+}$ films from dioxane–water solvent results in differences in electrochemical behavior. Polyoxometalate anions incorporated in poly-Ru(vbpy)$_3^{2+}$ films catalyze the electrochemical reduction of hydrogen ion.

Key words: polyoxometalate, electrochemistry, poly-Ru(vbpy)$_3^{2+}$, electrocatalysis, immobilization.

Résumé : On a incorporé les ions polyoxométallates $PMo_{12}O_{40}^{3-}$, $PW_{12}O_{40}^{3-}$ et $SiW_{12}O_{40}^{4-}$ dans des films polymériques de ruthénium(II)(vinyl)bipyridine (poly-Ru(vbpy)$_3^{3+}$) à partir d'électrolytes en solutions dans l'eau ou dans un mélange eau–dioxane. Malgré leurs masses importantes, les ions existent sous la forme d'espèces qui diffusent librement et ils peuvent compenser électrostatiquement jusqu'à 30% de la charge du poly-Ru(vbpy)$_3^{3+}$. Une étude de l'effet des conditions environnementales sur le comportement électrochimique révèle que le potentiel des deux premières vagues de réduction du $SiW_{12}O_{40}^{4-}$ par un électron est fortement modifié lorsqu'on passe de l'eau pure à un mélange de solvants formé à 50% (v/v) de dioxane/eau. On attribue ces observations à la déstabilisation des produits de réduction par un électron lorsqu'on enrichit le solvant en dioxane. L'incorporation de polyoxométallates dans des films de poly(vinyl)pyridine ou de poly-Ru(vbpy)$_3^{3+}$ protonés à partir de solvants mixtes dioxane–eau provoque des différences dans le comportement électrochimique. Les anions polyoxométallates incorporés dans les films de poly-Ru(vbpy)$_3^{3+}$ catalysent la réduction électrochimique de l'ion hydrogène.

Mots clés : polyoxométallate, électrochimie, poly-Ru(vbpy)$_3^{3+}$, électrocatalyse, immobilisation.

[Traduit par la rédaction]

Introduction

Polyoxometalates are soluble polymeric oxides formed by hydrolysis of the early transition elements (1–4). They have been widely studied as catalysts of thermal (5–7) and photochemical (8–10) reactions and as models for catalytic reactions at metal oxide surfaces (11). Although the electrochemistry of polyoxometalates has been investigated for several decades (12–25), exploitation of their catalytic properties in electrochemical reactions has begun only recently. Polyoxometalates should be excellent electrocatalysts because of their chemical stability and capacity to undergo multielectron charge transfer reactions. Several recent investigations have illustrated the electrocatalytic properties of polyoxometalates and of related metal oxide aggregates (26–31).

One means of enhancing the properties of electrocatalytic reagents is by entrapping them in chemically modified layers on electrode surfaces (32). Although widely used in applications based on its electron transfer properties (33), polymeric tris(4-vinyl-4′-methyl-2,2′-bipyridine)ruthenium(II), poly-Ru(vbpy)$_3^{2+}$, is a useful ion exchange polymer (34) because of its chemical stability, wide electrochemical window, and ability to be used in aqueous and non-aqueous solvents. In this publication we describe incorporation of three heteropolyoxometalate Keggin anions, $PMo_{12}O_{40}^{3-}$, (PMo_{12}), $PW_{12}O_{40}^{3-}$, (PW_{12}), and $SiW_{12}O_{40}^{4-}$ (SiW_{12}) in poly-Ru(vbpy)$_3^{2+}$ films. The present work compares the electrochemistry of these heteropolyanions in poly-Ru(vbpy)$_3^{2+}$ with that observed in homogeneous solution and in other polymeric matrices (28, 35–37) and reports on their ability to electrocatalytically reduce hydrogen ion under such conditions.

Experimental section

Material and methods

The $PMo_{12}O_{40}^{3-}$, $PW_{12}O_{40}^{3-}$, and $SiW_{12}O_{40}^{4-}$ ions were obtained commercially as phosphomolybdic (Aldrich), phosphotungstic (Fluka), and tungstosilicic (Fluka) acid, respectively, and used as received. The monomeric reagent, $Ru(vbpy)_3^{2+}$, was prepared from $RuCl_3$ and 4-vinyl-4′-methyl-2,2′-bipyridine (vbpy) following the procedure of Denisevich et al. (33) and isolated as the hexafluorophosphate salt. The vbpy ligand was prepared by the method of Abruna et al. (38) and characterized by ^{1}H NMR spectroscopy. Poly(4-vinyl) pyridine (PVP) was obtained from Scientific Polymer Products. Films of poly-$Ru(vbpy)_3^{2+}$ were prepared as described in ref. 34 by cycling the potential of a glassy carbon (GC) disk electrode (0.071 cm^2 surface area, Bioanalytical Systems) between −0.9 and −1.9 V vs. Ag/AgCl in an acetonitrile solution containing 1–2 mM $[Ru(vbpy)_3](PF_6)_2$ plus 0.1 M tetra-*n*-butylammonium hexafluorophosphate. Scans were carried out at a sweep rate of 200 mV s^{-1} for a period of ca. 8 min, which resulted in electrodes with surface coverages of (4–9) $\times 10^{-9}$ moles Ru per cm^2. Films of PVP on GC electrodes were prepared and cross-linked with 1,12-dibromododecane as described in ref. 35.

Heteropolyanions were incorporated in the ion polymer films by soaking modified electrodes for 2–24 h in aqueous or 50(v/v)% dioxane/water solutions containing 0.5 M H_2SO_4 and 0.01 M heteropolyacid. The electrodes then were rinsed thoroughly and transferred to reactant-free electrolyte where their electrochemical response was examined. The electrode surface coverage, Γ, of the anions was determined by integrating the area under voltammetric *i–E* curves using equipment and procedures described previously (34). The apparent diffusion coefficient of ions in the film, D_{app}, was determined from the slope of i–$t^{-1/2}$ transients of potential step electrolysis experiments (33). Formal potentials were determined as the average of cathodic and anodic peak potentials in cyclic voltammetry experiments. The number of electrons transferred in each electrode reaction was evaluated from the magnitude of the voltammetric response and, in bulk solution experiments, from the separation between reverse and forward peak potentials. Electrode potentials are reported relative to a Ag/AgCl reference electrode whose potential is −45 mV vs. the saturated calomel electrode.

Results and discussion

Incorporation of heteropolyanions in Poly-$Ru(vbpy)_3^{2+}$

The $PMo_{12}O_{40}^{3-}$, $PW_{12}O_{40}^{3-}$, and $SiW_{12}O_{40}^{4-}$ ions are incorporated in poly-$Ru(vbpy)_3^{2+}$ films by immersing modified electrodes in aqueous or 50(v/v)% dioxane/water solutions of these reagents. Figure 1*A* shows the result of soaking a 4.6×10^{-9} mol cm^{-2} poly-$Ru(vbpy)_3^{2+}$ film for 2 h in a 0.5 M H_2SO_4 dioxane–water solution containing 10 mM $SiW_{12}O_{40}^{4-}$ and then transferring the electrode to reactant-free electrolyte. The waves observed near −0.45 and −0.60 V are due to reduction and reoxidation of $SiW_{12}O_{40}^{4-}$. The small broad feature at −0.05 to −0.2 V is a component of the voltammetric background of poly-$Ru(vbpy)_3^{2+}$-covered GC electrodes. It is observed before and after loading of the polymer films with heteropolyanions. A fraction of the electroactive material initially retained by the film is lost upon repeated voltammetric cycling of the SiW_{12} redox waves, but after a period of several minutes a steady-state concentration of reactant is achieved within the film (Fig. 1*B*). This material exhibits the symmetrical wave shape, small peak potential separation and linear peak current vs. sweep rate response (Fig. 1*C*) that is characteristic of a surface-confined species. The behavior is similar to that exhibited by anionic transition metal complexes confined within poly-$Ru(vbpy)_3^{2+}$ films (34).

Table 1 illustrates the effect of varying the immersion time and conditions on the amount of $SiW_{12}O_{40}^{4-}$ incorporated in the film. The quantity of material incorporated increases with immersion time; at longer times a limiting steady-state coverage is reached. SiW_{12} exhibits the largest limiting coverage of the three heteropolyanions. The value of $G_{Si}/G_{Ru} = 0.156$ corresponds to electrostatic compensation of 30% of the Ru^{2+} charge sites in the film. PMo_{12} and PW_{12} exhibit lower limiting coverages of G_P/G_{Ru} equal to 0.074 (11%) and 0.09 (13%), respectively. At these lower than saturation coverages, the larger incorporation of $SiW_{12}O_{40}^{4-}$ is consistent with greater electrostatic interaction between the Ru^{2+} sites and the tetranegative SiW_{12} ion compared with trinegative PW_{12} and PMo_{12}. The foregoing results demonstrate that high molecular mass polyoxometalate ions can be incorporated in $Ru(vbpy)_3^{2+}$ films. This result is of interest because of the ability of $Ru(vbpy)_3^{2+}$ films to exclude reagents on the basis of molecular size (39). However, the 5.6 Å hydrodynamic radius of the Keggin ions (12) is not much larger than that of transition metal cyanides (e.g., $r = 4.6$ Å for $Fe(CN)_6^{3-}$ (40)), which are readily incorporated in such films, and is significantly smaller than that of reagents such as $Ru(bpy)_3^{2+}$ ($r = 6.9$ Å (41)), which are excluded. Therefore, incorporation of Keggin ions in poly-$Ru(vbpy)_3^{2+}$ is dimensionally feasible.

However, when so incorporated, the polyoxometalates exhibit apparent diffusion coefficients that are 2 to 3 orders of magnitude smaller than their bulk solution values of ca. 10^{-6} cm^2 s^{-1} (Table 1). The magnitude of D_{app} decreases as the

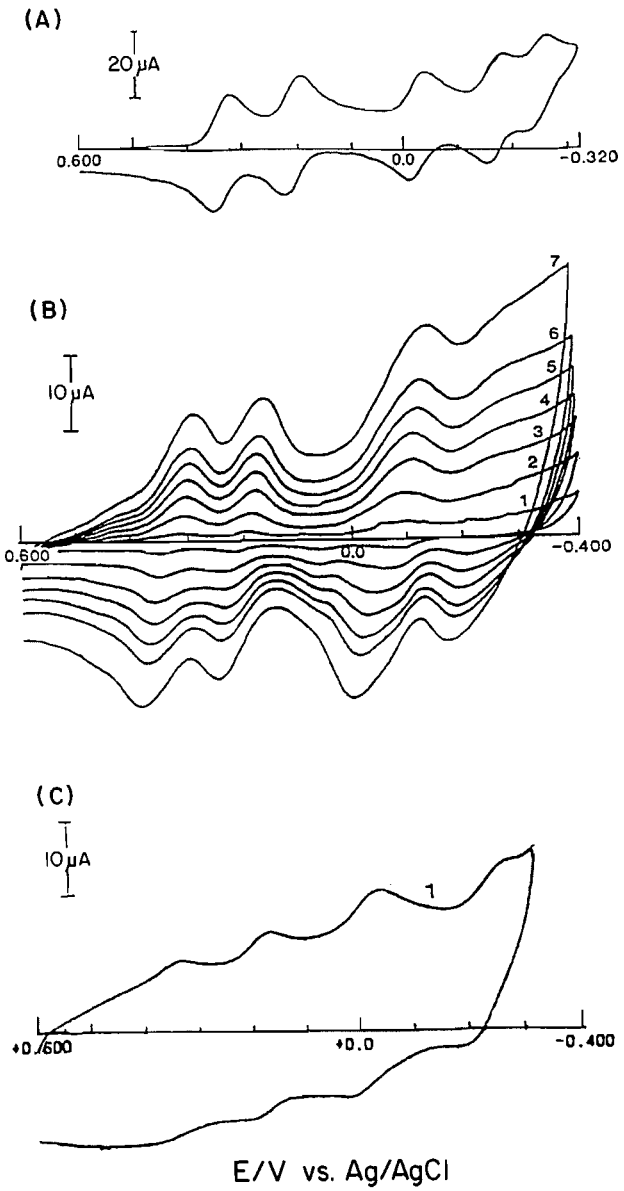
Fig. 2. Cyclic voltammetric traces of $PMo_{12}O_{40}^{3-}$. (*A*) At a bare GC electrode in 50% dioxane/water containing 0.5 M H_2SO_4 (1 mM PM_{12}, sweep rate = 100 mV s^{-1}). (B) After incorporation in poly-Ru(vbpy)$_3^{2+}$from the same electrolyte ($\Gamma_{PMo12} = 4.4 \times 10^{-10}$ mol cm^{-2}, sweep rate = 5, 20, 40, 60, 80, 100, and 150 mV s^{-1} for traces 1–7, respectively). (*C*) After incorporation in PVP from the same electrolyte ($\Gamma_{PMo12} = 1.4 \times 10^{-10}$ mol cm^{-2}, sweep rate = 150 mV s^{-1}).



loading of the film increases. The behavior may be due to single-file diffusion or to electrostatically induced constriction of the film as the concentration of electroactive ion increases. The effect is observed for transition metal anions incorporated in poly-Ru(vbpy)$_3^{2+}$ (34).

Effect of solution and polymer environment on redox properties

The electrochemical response of polyoxometalates is influenced by solvent and other solution variables (8, 22–24). Since changes in electrochemical response may alter potential electrocatalytic ability, we have characterized the extent to which redox potentials and the number of electrons transferred in the first two to three redox waves of PMo_{12}, SiW_{12}, and PW_{12} are altered by changing from aqueous to dioxane–water solvent and by incorporation in different ion-exchange polymer films.

Figure 2 shows the cyclic voltammetric response of $PMo_{12}O_{40}^{3-}$ at a bare GC electrode in dioxane–water solution containing 0.5 M H_2SO_4 and after incorporation in a poly-Ru(vbpy)$_3^{2+}$and PVP films from the same medium. The homogeneous solution response of PMo_{12} agrees with the previously reported behavior of this compound (15, 18–20) and consists of a series of chemically reversible two-electron reductions, which occur at +0.37, +0.25 , −0.02, −0.16, and −0.25 V vs. Ag/AgCl. Figures 2*B* and 2*C* and Table 2 show that some changes in PMo_{12} electrochemistry occur after incorporation in poly-Ru(vbpy)$_3^{2+}$ and PVP. Specifically, the third and fourth reductions merge into a single composite wave that is approximately twice as large as the first two, and the fifth wave becomes broad and poorly defined in poly-Ru(vbpy)$_3^{2+}$ (Fig. 2*B*). On the other hand, Fig. 2*C* shows that, whereas the merging of the third and the fourth reduction waves occurs also in PVP, the fifth wave can be identified at $E^{0'} \approx -0.220$ V. Calculation of the charge involved in the reduction process by integrating the area under the reduction waves indicated that ca. four electrons are involved in the third wave in poly-Ru(vbpy)$_3^{2+}$ and PVP, which is twice the value for the first and the second reduction waves (Fig. 2*B* and *C*). Thus, incorporation of PMo_{12} in either PVP or poly-Ru(vbpy)$_3^{2+}$ results in the merging of the third and the fourth waves into a single four-electron reduction.

Figures 3*A* and 3*B* compare the bulk solution electrochemical behavior of SiW_{12} in dioxane–water and water containing 0.5 M H_2SO_4. The voltammetric trace in Fig. 3*B* shows two one-electron reactions followed by a two-electron transfer, which is typical of the behavior exhibited by this ion in aqueous electrolytes (12, 15, 16, 22, 23). The response differs from that of Fig. 3*A*, where two two-electron transfers are observed in dioxane–water. The electron stoichiometry of these waves is established from the magnitudes of the peak currents and the peak potential separations ($\Delta E_p = 35$–50 mV), which are consistent with electron transfer accompanied by a small amount of uncompensated solution resistance or slow electrode kinetics. Coalescence of two one-electron reductions into a single two-electron step has been observed in nonaqueous solvents (8) and in aqueous media containing high concentrations of hydrogen ion (22). Solvent studies (24) show that E_1^{0-} for $SiW_{12}O_{40}^{4-}$ shifts in the negative direction by several hundred millivolts upon a change from aqueous to non-aqueous solvent. The results are consistent with destabilization of the one-electron reduction product of $SiW_{12}O_{40}^{4-}$ by a change from aqueous to non-aqueous conditions. However, molecular details of the process are unclear at this time.

Realization that the electrochemistry of $SiW_{12}O_{40}^{4-}$ is sensitive to its environment prompted an examination of its reactivity following incorporation in ion polymer films. Figure 3*C* shows the result of incorporating SiW_{12} in poly-Ru(vbpy)$_3^{2+}$ from dioxane–water. The response is similar to that in the homogeneous mixed solvent solution. Incorporation of $SiW_{12}O_{40}^{4-}$ into a PVP film from dioxane–water, however,produces a change in the electrochemical response to one

that is more like that in aqueous medium (Fig. 3*D*). The behavior suggests that the solvent environment accessible to $SiW_{12}O_{40}^{4-}$ in PVP under these conditions more closely approximates an aqueous solution.

Figure 4 and Table 2 illustrate the effects of solvent composition and of polymer film incorporation on electrochemical reduction of $PW_{12}O_{40}^{3-}$. In this case, the change from an aqueous (Fig. 4*B*) to a mixed solvent (Fig. 4*A*) shifts both E_1^{0-} and E_2^{0-} in the negative direction. Since, the one-electron electrode reactions do not combine into a single two-electron transfer, two one-electron and one two-electron waves are observed in dioxane–water. PW_{12} does not exhibit well-defined electrochemistry following incorporation in poly-$Ru(vbpy)_3^{2+}$ (Fig. 4*C*) and PVP (Fig. 4*D*). However, the response is sufficient to determine approximate formal potentials (Table 2), which do not differ significantly from bulk solution values.

The results of the foregoing experiments indicate that changes in solution conditions and polymer environment influence the electrochemical behavior of all three polyoxometalates. The nature of the change depends on the transition metal heteroatom. For the heteropolytungstates, changes occur primarily in the first two one-electron reactions of SiW_{12} and PW_{12}. However, for PMo_{12} the first two waves are relatively unaffected, and changes in response occur in subsequent redox processes.

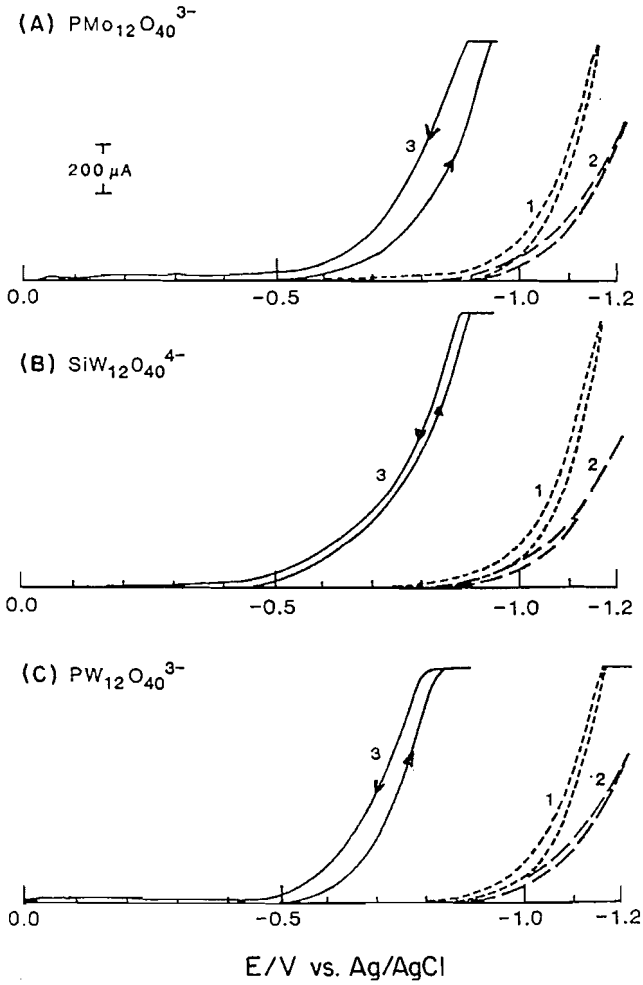
Electrocatalytic reduction of hydrogen ion

In mixed dioxane–water with acidic electrolyte, heteropolyanions incorporated in poly-$Ru(vbpy)_3^{2+}$ show no evidence of catalytic activity towards hydrogen reduction. Thus catalytic studies were performed in aqueous 0.5 M H_2SO_4; $PMo_{12}O_{40}^{3-}$ is not stable indefinitely under these conditions. However, as the electrocatalytic behavior of PMo_{12} is similar to that of PW_{12} and SiW_{12}, we assume that the species produced by reduction of PMo_{12} or its decomposition products are similar to those derived from the other polyoxoanions.

Figure 5 illustrates the electrocatalytic reduction of H^+ in 0.5 M H_2SO_4 initiated by reduction of PMo_{12}, PW_{12}, and SiW_{12} incorporated in poly-$Ru(vbpy)_3^{2+}$. In this experiment the electrode was cycled between 0 and −1.2 V five times over a period of 1.5 before the observed catalytic response was recorded. After this time the characteristic redox waves of the polyoxoanions are no longer observable, indicating that the initial electrode products have undergone subsequent chemical reaction. However, the species produced in these reactions are catalytically active as illustrated by the solid traces in Fig. 5. Furthermore, this response is unchanged by continued scanning at 200 mV s^{-1} for a period of 1.5 h, indicating that the electrocatalysts are stable and that they have prolonged activity.

Figure 5 shows that significant hydrogen ion reduction commences at −0.5 to −0.7 V. At this potential the initial PW_{12} and SiW_{12} reactants are reduced by four electrons and PMo_{12} by ≥ eight electrons. Thus, as observed previously in studies of hydrogen ion reduction at surfaces modified with electrodeposited derivatives of polyoxometalates (27, 42, 43), it appears that several electrons must be added to each polyoxoanion unit to produce a catalytically active species. The composition of the catalytically active substances described in the present work is not known. However, XPS analysis of reduced poly-

Fig. 5. Catalytic reduction of hydrogen ion initiated by reduction of polyoxometalates ions incorporated in poly-$Ru(vbpy)_3^{2+}$ films. Aqueous 0.5 M H_2SO_4, sweep rate = 100 mV s^{-1}. In each panel trace 1 was recorded at a bare GC electrode, trace 2 at GC electrode modified with (3–6) × 10^{-9} mol cm^{-2} poly-$Ru(vbpy)_3^{2+}$ and trace 3 at a poly-$Ru(vbpy)_3^{2+}$-modified electrode containing (*A*) 0.5 × 10^{-10} mol cm^{-2}; (*B*) 2.8 × 10^{-10} mol cm^{-2}; (*C*) 2.7 × 10^{-10} mol cm^{-2} of the indicated polyoxometalate. The indicated current scale is applicable in all three experiments.



tungstate ions[3] indicates the presence of W(VI), -(V), and -(IV) oxidation states. Thus, we believe the observed catalytic activities arise from stable, mixed-valence species of heteropolyanions , whose reduction at potentials more negative than ca. −0.5 V catalyzes the reduction of H^+.

Synthesis and photoisomerization of provitamin D analog with 11β,19-oxide bridge

Rafał R. Siciński

Abstract: Triol diester **1** was converted into the B-ring 5,7-diene **6** representing the first example of the provitamin D analog where the 10β angular methyl group is connected to ring C by a C11/C19 ether linkage. Ultraviolet light irradiation of **6** resulted in the formation of stereoisomeric 9β,10α-compound **8***a*. The structure of the photoproduct was established by analysis of vicinal ^1H–^1H coupling constants and by molecular mechanics.

Key words: 11β,19-oxido steroids, lumisterol analog, 5,7-androstadienes, electrocyclic reactions, photochemistry.

Résumé : On a transformé le diester du triol **1** en un cycle B 5,7-diène **6** représentant le premier exemple d'un analogue de la provitamine D dans lequel le méthyle angulaire 10β est relié au cycle C par un lien éther en C11/C19. L'irradiation ultraviolette du composé **6** conduit à la formation du stéréoisomère 9β,10α **8***a*. On a établi la structure du produit photochimique par l'analyse des constantes de couplage vicinal ^1H–^1H et par la mécanique moléculaire.

Mots clés : 11β,19-oxido stéroides, analogue du lumistérol, 5,7-androstadienes, réactions électrocycliques, photochimie.

Introduction

Vitamin D_3 (cholecalciferol) is formed biogenetically in the skin (1), by irradiation of 7-dehydrocholesterol (provitamin D_3) to previtamin D_3, followed by a thermal isomerization (Fig. 1). An analogous route has commonly been used for the chemical synthesis of vitamin D_3 as well as of its metabolites and analogs (2, 3). Photochemical and thermal conversions of previtamins D have proved to be an interesting area of organic chemistry. It is well established that the cisoid previtamin D triene, that produced by an ultraviolet light-induced opening of the B-ring 5,7-diene, can undergo a photochemical *Z*/*E* isomerization into tachysterol, as well as an electrocyclic ring closure to the starting provitamin D and lumisterol (4, 5). The sequence of these reversible photoisomerizations was determined in 1955 by Velluz et al. (6) for the D_2 series. Previtamin D can also be thermally equilibrated with the thermodynamically more stable vitamin D; higher temperatures (>100°C) cause an irreversible electrocyclization of the previtamin triene system and result in the formation of pyro- and isopyrocalciferols (4).

It was proposed (7) that the kind of products formed in photochemical and thermal processes of previtamin D_3 can be predicted from the corresponding ground-state conformations of the latter. Thus, various reaction pathways were proposed for antarafacial, sigmatropic 1,7-hydrogen shifts occurring in the thermal previtamin–vitamin equilibration. It was postulated (8, 9) that hydrogen migration involves the s-*cis*, s-*cis* (*cZc*) conformation of the previtamin triene moiety (Fig. 2) twisted in a right- or left-handed sense (*P* and *M* chirality); the absence of such a preference was also suggested (10). Studies on the photochemistry of previtamins D led to a conclusion that the most stable, planar s-*trans*, s-*cis* conformation (*tZc*) of the triene is responsible for the formation of tachysterols, whereas right- and left-handed helical *cZc* conformations are precursors of lumisterols and provitamins D, respectively (11). Analogously, it was also suggested that the latter *P* and *M* conformations were involved in the pyrolysis of previtamins D to the respective cyclized compounds, i.e., pyro- and isopyrocalciferols.

Force-field calculations carried out by Dauben and Funhoff (12) on a previtamin D analog showed that interconversion of the two *cZc* forms via the *tZc* conformation seems possible at room temperatures. On the contrary, the calculated rotational barriers (ca. 29 and 34 kcal/mol) of direct interconversion of the *cZc* forms passing through a planar transition state led to the conclusion that such processes are not feasible.

It was, therefore, of interest to synthesize the previtamin D analog with a "frozen" *cZc* geometry and examine its photochemical isomerization. We chose easily accessible compounds possessing the 11β,19-oxide bridge. The ether linkage between C-19 and the C-ring carbon seemed to be a reasonable choice since it was established (13, 14) that an alkoxy

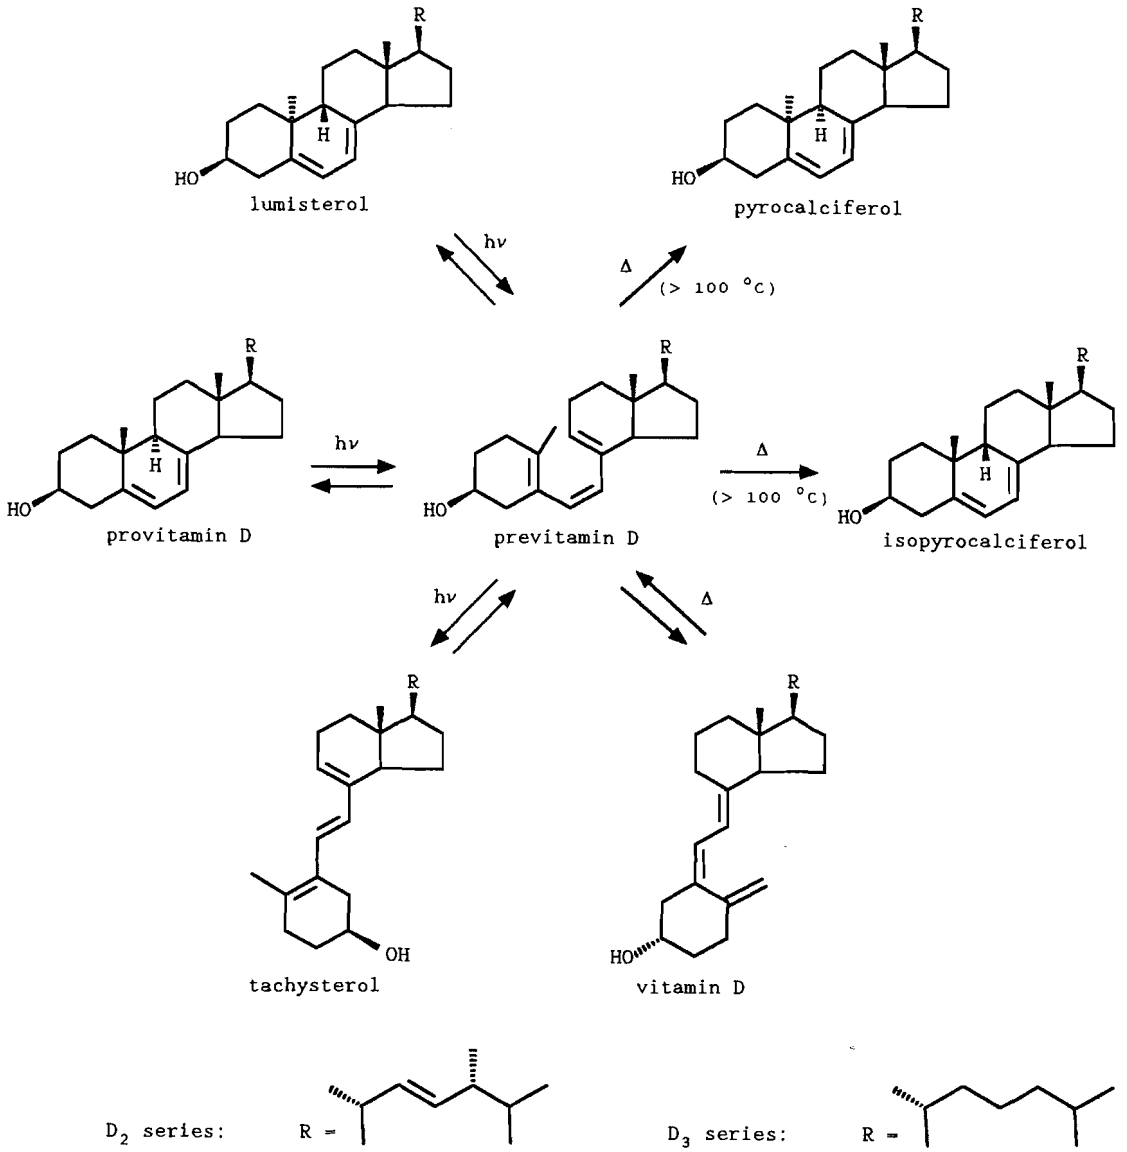
Fig. 1. Scheme of established photochemical and thermal isomerizations within the vitamin D_2 and D_3 series.



substituent at C-19 in the previtamin D molecule does not influence the course of the photochemical opening of the B-ring diene moiety. It is well known that the nature of the side chain in the previtamin D system does not play any significant role in its photochemical and thermal processes. Therefore, in the present work, the triol diester **1** (Fig. 3) was used as a starting material; its synthesis from androstenolone acetate was reported previously (15).

Results

The synthetic sequence involved first a transformation of **1** into diepoxide **3** using the approach described by Kaufman and co-workers (16, 17). Epoxidation of the olefin **1** with *m*-chloroperbenzoic acid in dichloromethane gave a mixture of the α- and β-epoxides **2***a,b* in 74% yield. The products, easily distinguishable by ^{1}H NMR, were separated by column chromatography on silica. Predominant formation of the β-epoxide **2***b* results from an interaction between the peracid molecule and the 19-OH group. Reaction of **2***b* with lead tetraacetate and iodine in boiling cyclohexane afforded, in addition to the expected diepoxy compound **3** (41% yield), a number of minor, unidentified products. The β-epoxide moiety present in the oxidized compound **2***b* plays an important role by (*i*) protecting the double bond (19-hydroxy-5-ene steroids are known to undergo an oxidative fragmentation upon conditions of the lead tetraacetate reaction), (*ii*) increasing the internuclear distances between the C-19 oxy radical and the relevant A-ring δ-carbon atoms, with the result that the corresponding axial hydrogens at C-2 and C-4 are less likely to be abstracted (17). The next synthetic step involved the regeneration of the C(5)—C(6) double bond. Reduction of the diepoxide **3** with tungsten chlorides of low valency (18) gave the expected 5,6-unsaturated compound **4** in high yield (88%).

Another set of experiments was aimed at the introduction of an additional C(7)—C(8) double bond into the olefin **4**. At first, this was accomplished by the traditional method of allylic bromination–dehydrobromination (19). Thus, the reaction of **4** with 1,3-dibromo-5,5-dimethylhydantoin in refluxing benzene–hexane afforded two allylic bromides **5***a* and **5***b*

Fig. 2. Conformers of previtamin D and the corresponding isomers that originate from them (ref. 11).

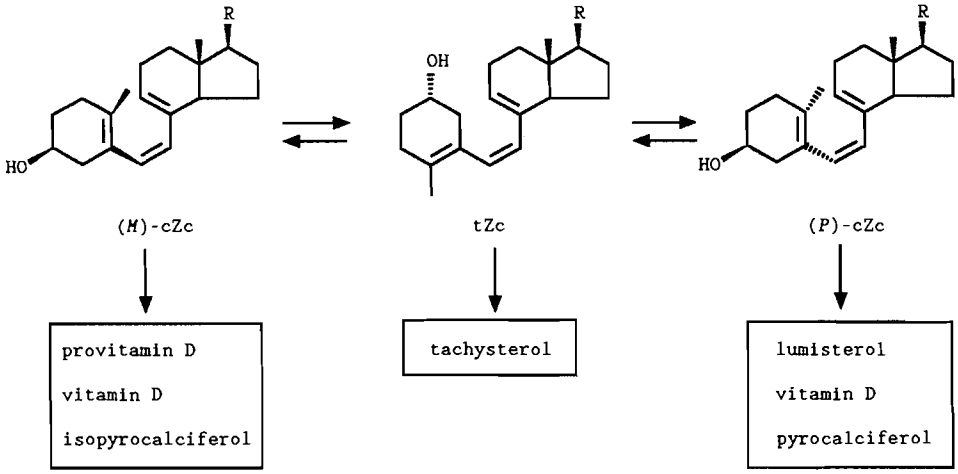


Fig. 3. Chemical structures of starting triol diester **1** and the synthesized compounds.

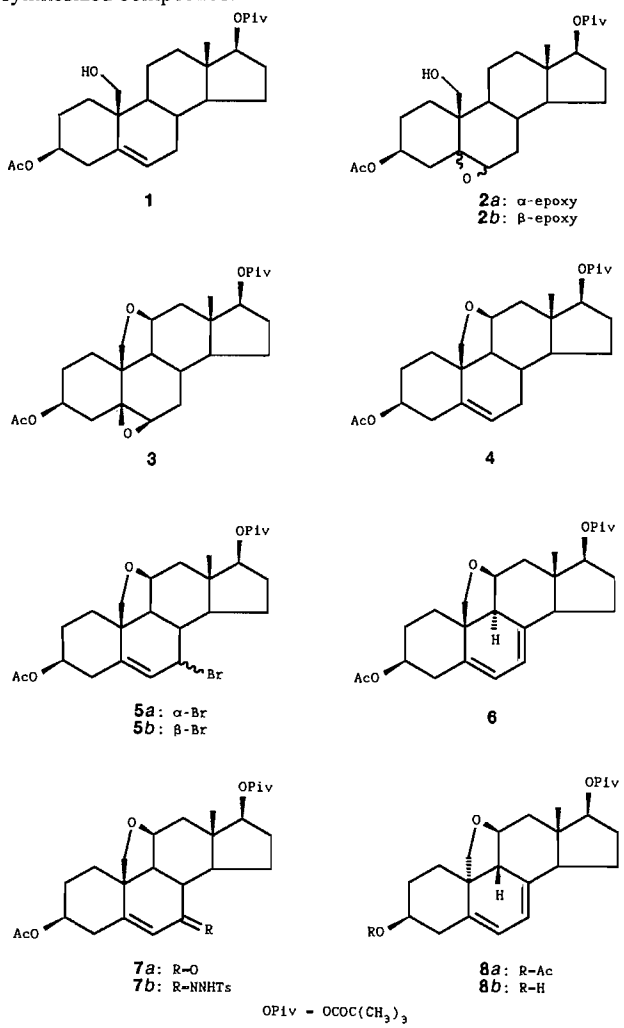

in a 3:1 ratio. Due to the instability of the latter, only the major isomer **5***a* could be obtained in the analytically pure form (62% yield). However, a careful analysis of the ^{1}H NMR spectrum of the crude mixture of bromides **5***a*,*b* allowed assignment of the resonances derived from the minor epimer **5***b*. The large diaxial coupling constant found for its allylic proton at C-7 (δ 4.50, dt, J = 10.0, 1.5 Hz) clearly established the equatorial 7β-orientation of the bromine atom. A comparison of the optical rotation values of the main bromination product ($[\alpha]_D^{24}$ −208.1) and the starting olefin **4** ($[\alpha]_D^{24}$ +10.9) supported the presence of the 7α-bromine substituent in **5***a*; literature data indicate that 7α-substituted-5-ene steroids are considerably more levorotatory than their parent 7-unsubstituted olefins, whereas the 7β-epimers are usually more dextrogyratory (20). The dehydrobromination of **5a** to give the desired 5,7-diene **6** in a good yield turned out to be difficult; this indicates that the 11β,19-oxide bridge affects the process. A treatment of **5***a* with s-collidine or trimethyl phosphite in refluxing xylene, successfully employed in the synthesis of some provitamins D, failed to give the expected elimination product. However, the fluoride ion-promoted dehydrobromination (21) of **5***a* afforded 5,7-diene **6** in an 84% yield; when the crude mixture of bromides **5***a*,*b* was used, the overall yield of the reaction sequence **4** → **5** → **6** amounted to 70%. The UV spectrum of **6** does not differ essentially from those of steroidal 19-unsubstituted- (22) or 19-alkoxy-5,7-dienes (23), the corresponding absorption maxima being shifted (5–6 nm) to smaller wavelengths. Understandably, the multiplet of the homoallylic 11α-H in the ^{1}H NMR spectrum of diene **6** was significantly more deshielded (Δδ 0.22) than an analogous signal in the spectrum of olefin **4**.

The high yield of the bromination–dehydrobromination procedure was somewhat surprising in view of the fact that the synthesis of 19-functionalized provitamins D from 5,6-unsaturated steroids usually employs another pathway, that involving allylic oxidation to 7-oxo compounds and reduction of their tosylhydrazone derivatives (23, 24). It was therefore interesting to examine also the latter alternative route leading to the ring-B diene **6**. However, the first step of the attempted synthesis, i.e., the direct conversion of **4** into the 7-oxo compound **7***a*, failed because the starting olefin was highly deactivated toward allylic oxidation. Using a reactive chromium trioxide–pyridine reagent (25), even under forcing conditions and long reaction times, the oxidation was incomplete and

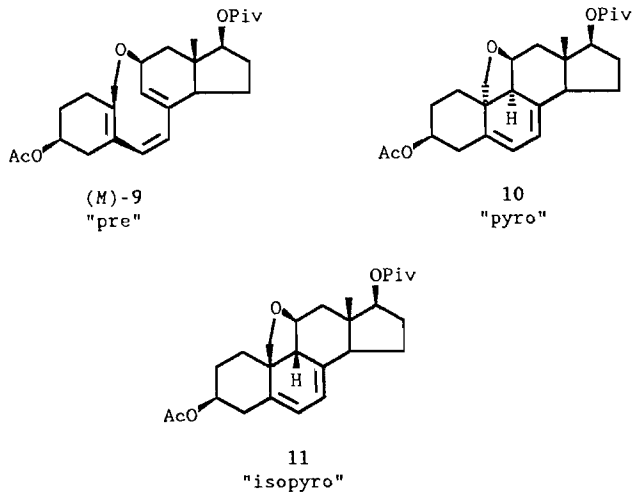
afforded a complex mixture of products. However, the desired α,β-unsaturated ketone **7***a* was efficiently prepared (71% overall yield from **4**) by an oxidation of the allylic bromides **5***a*,*b* with bis(tetrabutylammonium) dichromate in methylene chloride (26). The UV spectrum of the enone **7***a* exhibited a maximum at 238.0 nm (ε 9700) indicating, in comparison with the spectra of other 19-alkoxy enones (23), a weak blue shift (ca. 4 nm) and a decreased ε value. Reaction of the conjugated ketone **7***a* with *p*-toluenesulfonyl hydrazide yielded quantitatively a tosylhydrazone **7***b*. Subsequent modified Bamford–Stevens reaction of **7***b* afforded the ring-B diene **6** in a 67% yield. Thus, the overall yield of **6** synthesized by the path **4** → **5** → **7***a* → **7***b* → **6** was considerably lower (48%) than the previously investigated customary procedure.

Ultraviolet irradiation of **6** was carried out in benzene–ether (1:4) solution at 0°C, and the concomitant reaction was monitored by TLC and analytical HPLC. It was found previously for the 10β-methyl analog and for various nonbridged 19-substituted compounds that 10 min were sufficient to achieve photoequilibrium (14). However, with the diene **6**, even after 20 min of irradiation, more than 60% of the starting material was still present in the reaction mixture. A slow buildup of a more polar product was observed and, in addition, a number of other minor ultraviolet-detectable compounds were formed. It was established that further irradiation did not offer an increasing proportion of the main product but, on the contrary, it resulted in the more complex HPLC profile with no major product present. Unreacted substrate **6** and the slightly impure main photoproduct (ca. 12% yield based on recovered **6**) were isolated from the reaction mixture by column chromatography on silica. Final HPLC purification provided the analytically pure compound. The "lumisterol-like" 5,7-diene 9β,10α-structure has been assigned to this main photoisomer **8***a* and its 3β-hydroxy derivative **8***b*, prepared for a further characterization purpose, on the basis of spectral data and molecular mechanics calculations.

A molecular ion peak at *m*/*z* 428 found in the mass spectrum of **8***a* indicated that the structure is isomeric to that of **6**. The line shape of the UV absorption of **8***a* closely resembles that of lumisterol$_2$ (22*a*), with the corresponding absorption maxima at 267.0 and 275.5 nm; the latter, as in the case of an analogous pair, **6** and ergosterol, are blue-shifted by ca. 6 nm. In the ^{1}H NMR spectrum of the isolated photoproduct **8***a*, the presence of two ring-olefinic signals at δ 5.66 (m) and 5.80 (d, J = 5.4 Hz) supported the $\Delta^{5,7}$-unsaturation whereas the single-proton signals at δ 3.64, 4.05, and 4.34 indicated an intact 11,19-oxide bridge. The latter signal, ascribed to the methine proton at C-11, as well as the multiplet of the methine proton at C-3 were particularly informative because an analysis of their coupling constants was helpful in establishing the configuration at C-9 and C-10. Thus, the signal of the methine 3α-proton at δ 5.07 was deshielded by ca. 0.3 ppm in **8***a* when compared to the analogous signal of the 9α,10β-compound **6**; a similar effect was observed in the case of the corresponding lumisteryl$_2$ acetate – ergosteryl acetate pair (22b). Moreover, the halfwidth of the 3α-H multiplet (8 Hz) in compound **8***a* indicated an equatorial orientation of the proton and, therefore, the *cis* A/B-ring system. The signal of 11α-H, differing considerably from the multiplet patterns of the analogous protons in the spectra of other 11β,19-oxides **3**–**7**, indicated an axial position of the proton concerned; the latter could result from the *cis* B/C-ring junction. To support these conclusions and to get some information on the conformations of the pentacyclic compounds synthesized, molecular mechanics calculations were employed. Molecular modeling was performed using the MM+ molecular mechanics algorithm (an enhanced version of MM2).[2] Force-field calculations were carried out for the starting provitamin analog **6** ("pro"), the 9,10-seco structure **9** (in the *M*-helical conformation), and other cyclized B-ring 5,7-dienes differing in configurations at C-9 and C-10, i.e., structures **8***a*, **10**, and **11** representing lumisterol ("lumi"), pyrocalciferol ("pyro"), and isopyrocalciferol ("isopyro") analogs, respectively (Fig. 4). The estimated values of steric energies and other conformational properties of the isomeric compounds concerned are given in Table 1.

Fig. 4. Previtamin D analog **9** (in the left-handed helical conformation) and ring-B closed compounds of the pyro- and isopyrocalciferol structure.



According to the force-field calculations, the chair conformation of the A ring (with the exception of **9**) and the half-chair conformation of the D ring are energetically favorable for all of the compounds examined. Energy-minimized structures were utilized in order to establish the orientation of 3α-H and to calculate the respective dihedral angles between 11α-H and the vicinal protons at the neighboring carbon atoms C-9 and C-12. These torsional angles were used, in turn, to calculate the expected ^{1}H–^{1}H coupling constants. Analysis of the vicinal coupling constants for compounds **6**, **8***a*, **10**, and **11** was aided by Altona's modified Karplus relationship (27), which takes into account the electronegativities of the substituents. The experimental coupling constants for the methine protons at C-11 (dt, J = 8.0, 10.1 Hz) and C-9 (br d, J = 10 Hz) in the isolated photoproduct **8***a* provide a best match with the calculated values for the "lumi" 9β,10α-structure. Of the remaining isomeric structures only **10** ("pyro"), with the 3α-H in equatorial position, could be considered but the calculated coupling constants of its 11α-proton differ considerably from the experimental values.

[2] The calculations of optimized geometries and strain energies were carried out using the algorithm from the MM+ HyperChem™ (release 4.0) software package (*Autodesk, Inc.*, 1994). MM+ is an all-atom force field based on the MM2 functional form.

Fig. 5. Possible photochemical interconversion of the diene **6** into 9β,10α-diastereoisomer **8***a* (energy-minimized structures; top to bottom: **6**, (*M*)-**9** and **8***a*).

Discussion

Considering previtamin analog **9** as an obvious initial product of the photoinduced ring opening of diene **6**, the subsequent photochemical cyclization of its hexatriene system should occur by a conrotatory process leading to **8***a* or back to **6**, if the requirements of retention of orbital symmetry are met (28). The energy-minimized conformations for **6**, **8***a*, and **9** are represented in Fig. 5. It can be expected that the primary conformation of **9** formed from **6** is that with the 19-CH_2 group above the plane of the C ring; therefore, the following reverse electrocyclization reaction yielding the starting 9α,10β-structure **6** ("pro") should be more feasible than the alternative process providing the "lumi" 9β,10α-isomer **8***a*. The latter would require an interconversion of the highly strained molecule **9** from its left- to right-handed conformation passing through an extremely crowded transition state. Taking into account previous results of our studies (13, 14) on the photochemistry of 19-alkoxy 5,7-dienes, it is reasonable to assume that the photoinduced ring opening of diene **6** can be the preferred photoreaction. The high proportion of unreacted **6** during the irradiation would, consequently, indicate that the photoequilibrium between **6** and energetically unfavorable **9** is shifted to the diene side.

In spite of the fact that the symmetry-allowed photochemical conrotatory electrocyclization of the *M*-triene system in **9**

to the lumisterol analog **8***a* seems unlikely, in view of the geometrical restraints involved, the formation of such a cyclic product observed in the present work leaves open the question of whether the possibility of a direct interconversion between both helical (*M*)- and (*P*)-*cZc* conformers of previtamin D analogs (or their $\pi \rightarrow \pi^*$ excited forms) can be excluded.

Experimental

General procedures

Proton magnetic resonance spectra (^{1}H NMR) were recorded on a Bruker AM-500 spectrometer using $CDCl_3$ as a solvent and Me_4Si (δ 0.00) as an internal standard. Ultraviolet spectra (UV) were taken on a Beckman Acta M VI apparatus (solutions in 96% ethanol). Infrared spectra (IR) of KBr pellets were recorded on a Zeiss UR-20 spectrometer. Mass spectra (MS) were determined with a AMD-604 instrument at 70 eV. High-resolution data (HRMS) were obtained by peak matching. Optical rotations were measured in chloroform using a Perkin–Elmer 241 automatic polarimeter at 24°C.

Thin-layer chromatography (TLC) was carried out on precoated aluminum silica sheets from Merck (R_f values are given for the benzene–ethyl acetate 8:2 solvent system), column chromatography on silica gel Macherey–Nagel (100–200 mesh), and high-pressure liquid chromatography (HPLC) on a Zorbax-Sil 6.2 mm × 25 cm column (R_V values are given for the hexane–ethyl acetate 85:15 solvent system). Melting points were measured on a Köfler type (Boetius) hot stage apparatus and are cited without corrections.

*5α,6-Oxido-5α- and 5β,6-oxido-5β-androstan-3β,17β,19-triol 3-acetate 17-trimethylacetate (***2**a *and* **2**b*)*

Triol diester **1** (15) (10 g, 23.1 mmol) in dichloromethane (100 mL) was treated with 3-chloroperoxybenzoic acid (80–85%, 6.0 g; added in portions). The temperature of the reaction mixture was maintained below 25°C. After addition of all reagent the mixture was allowed to stand at room temperature with occasional shaking. When the reaction reached completion (about 1 h), the aromatic acids were removed by extraction with 5% NaOH, and the organic layer was washed with water and dried (Na_2SO_4). The solvent was evaporated to give a colorless solid residue, which was repeatedly crystallized from acetone to obtain 6.1 g of pure 5β,6-oxide **2***b*. The mother liquor was chromatographed on silica gel column. Elution with benzene–ether (95:5) gave an additional 1.1 g of crystalline **2***b* (total yield 7.2 g, 69%). Further elution with benzene-ether (93:7) afforded an isomeric 5α,6-oxide **2***a*, which was crystallized from acetone–hexane (yield 0.52 g, 5%).

*5β,6:11β,19-Dioxido-5β-androstan-3β,17β,19-triol 3-acetate 17-trimethylacetate (***3***)*

A suspension of lead tetraacetate (39.9 g, 90 mmol; dried over KOH) and calcium carbonate (40 g) in cyclohexane (1100 mL, distilled from P_2O_5) was refluxed with vigorous stirring for 1 h (heating with a 1000 W lamp). Epoxide **2***b* (4.9 g, 11 mmol) was then added and stirring continued while iodine (12.7 g, 50 mmol) was added in portions during 15 min. After the substrate vanished on TLC (about 1 h) the mixture was filtered off and the filtrate was washed with dilute Na_2SO_3, water, dried (Na_2SO_4), and evaporated. The oily residue was chromatographed on a silica gel column. Elution with benzene–ether (95:5) afforded a solid material (2.4 g) that was repeatedly crystallized from acetone–hexane; the first and second crop of crystals gave analytically pure diepoxide **3** (1.2 g). Chromatography of the mother liquor on silica and subsequent crystallization from hexane afforded an additional 0.8 g of **3** (total yield 2.0 g, 41%): mp 186–190°C; $[\alpha]_D^{24}$ +13.1 (*c* 1.0); TLC, R_f 0.47; IR ν_{max}: 1042, 1172, 1249, 1734 cm^{-1}; ^{1}H NMR δ: 0.94 (3H, s, 18-H3), 1.18 (9H, s, CO-*t*Bu), 2.03 (3H, s, OAc), 3.24 (1H, d, *J* = 2.8 Hz, 6α-H), 3.73 (1H, d, *J* = 8.4 Hz, one of 19-H2), 4.06 (1H, br t, *J* = 3.6 Hz, 11α-H), 4.08 (1H, dd, *J* = 8.4, 0.9 Hz, one of 19-H2), 4.58 (1H, dd, *J* = 9.1, 7.9 Hz, 17α-H), 4.79 (1H, m, *w*/2 = 28 Hz, 3α-H). Anal. calcd. for $C_{26}H_{38}O_6$: C 69.93, H 8.58; found: C 69.86, H 8.62.

*11β,19-Oxido-5-androsten-3β,17β,19-triol 3-acetate 17-trimethylacetate (***4***)*

Tungsten (VI) chloride (6.0 g, 15 mmol) in freshly distilled THF (42 mL) was cooled to −62°C and a solution of *n*-BuLi (18 mL, 20% in hexane) was added with stirring. The mixture was allowed to warm up to room temperature within 20 min and a solution of diepoxide **3** (1.1 g, 2.5 mmol) in THF (20 mL) was then added. The reaction mixture was left for 30 min at ambient temperature; the liquid phase was then decanted from a semisolid violet residue, concentrated to a small volume under vacuum, and diluted with chloroform. The semisolid residue was dissolved in 5% KOH (500 mL) and extracted with chloroform. The combined chloroform solutions were washed with water, dried (Na_2SO_4), and evaporated. The crude product was purified on a silica gel column and it was eluted with benzene–ether (96:4). Crystallization from acetone–hexane afforded pure compound **4** (0.93 g, 88%): mp 180–183°C; $[\alpha]_D^{24}$ +10.9° (*c* 0.9); TLC, R_f 0.59; IR ν_{max}: 1039, 1168, 1247, 1665 (w), 1734 cm^{-1}; ^{1}H NMR δ: 0.97 (3H, s, 18-H3), 1.20 (9H, s, CO-*t*Bu), 2.03 (3H, s, OAc), 3.73 (1H, dd, *J* = 8.2, 1.6 Hz, one of 19-H2), 3.96 (1H, d, *J* = 8.2 Hz, one of 19-H2), 4.27 (1H, dt, *J* = 1.8, 3.8 Hz, 11α-H), 4.61 (1H, dd, *J* = 9.3, 7.8 Hz, 17α-H), 4.65 (1H, tt, *J* = 11.4, 4.6 Hz, 3α-H), 5.61 (1H, dt, *J* = 6.3, 1.6 Hz, 6-H). Anal. calcd. for $C_{26}H_{38}O_5$: C 72.53, H 8.90; found: C 72.76, H 8.82.

*7α-Bromo- and 7β-bromo-11β,19-oxido-5-androsten-3β,17β,19-triol 3-acetate 17-trimethylacetate (***5***a and* **5**b*)*

A mixture of olefin **4** (215 mg, 0.5 mmol) and $NaHCO_3$ (200 mg) in benzene-hexane (1:1, 10 mL) was heated under reflux, and the hot solution was treated with 1,3-dibromo-5,5-dimethylhydantoin (86 mg, 0.3 mmol). The mixture was refluxed for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

10 min, and an additional portion of dibromantine (23 mg, 0.08 mmol) was added. The reflux was continued for an additional 10 min until no **4** was detected on TLC. The cooled reaction mixture was filtered and the filtrate dried under reduced pressure. The residue consisted of two main products **5***a* and **5***b* (R_f values 0.62 and 0.51, respectively) in a 3:1 ratio. Analysis of the ^{1}H NMR spectrum of the material allowed us to assign the following resonances (not overlapped by those derived from the prevailing **5***a*; see below) for the minor isomer **5***b*: δ: 1.02 (s, 18-H3), 3.79 (dd, J = 8.2, 1.5 Hz, one of 19-H2), 3.94 (d, J = 8.2 Hz, one of 19-H2), 4.30 (m, $w/2$ = 12 Hz, 11α-H), 4.50 (dt, J = 10.0, 1.5 Hz, 7α-H), 5.81 (m, $w/2$ = 4 Hz, 6-H).

The crude mixture of bromides could be used for subsequent reactions without further purification. For analytical purposes, the predominant epimer **5***a* was obtained in a pure form after column chromatography on silica. Elution with benzene–ether (98:2) afforded a crystalline compound. Recrystallization from acetone–hexane gave **5***a* (158 mg, 62%): mp 194–198°C; $[\alpha]_D^{24}$ −208.1° (*c* 0.9); TLC, R_f 0.62; IR ν_{max}: 1042, 1166, 1255, 1655 (w), 1732 cm^{-1}; ^{1}H NMR δ: 0.99 (3H, s, 18-H3), 1.20 (9H, s, CO-*t*Bu), 2.03 (3H, s, OAc), 3.72 (1H, dd, J = 8.3, 1.4 Hz, one of 19-H2), 3.97 (1H, d, J = 8.3 Hz, one of 19-H2), 4.35 (1H, m, $w/2$ = 11 Hz, 11α-H), 4.56 (1H, m, $w/2$ = 12 Hz, 7β-H), 4.66 (1H, dd, J = 9.0, 7.9 Hz, 17α-H), 4.73 (1H, tt, J = 11.3, 4.7 Hz, 3α-H), 5.87 (1H, dd, J = 5.9, 1.7 Hz, 6-H). Anal. calcd. for $C_{26}H_{37}O_5Br$: C 61.29, H 7.32; found: C 61.26, H 7.52.

11β,19-Oxido-7-oxo-5-androsten-3β,17β,19-triol 3-acetate 17-trimethylacetate (7a)

(*a*) A solution of bromide **5***a* (127 mg, 0.25 mmol) and bis(tetrabutylammonium) dichromate (1.75 g, 2.5 mmol) in dry chloroform (8 mL) was heated under reflux for 4 h. The reaction mixture was cooled and applied to a silica gel column. Elution with benzene–ether (95:5) yielded a yellowish residue that was crystallized from acetone–hexane to give pure enone **7***a* (92 mg, 83%): mp 197–200°C; $[\alpha]_D^{24}$ −3.5 (*c* 0.9); TLC, R_f 0.37; UV (EtOH) λ_{max}: 238.0 nm (ε 9700); IR ν_{max}: 1043, 1169, 1248, 1633 (w), 1694, 1732 cm^{-1}; ^{1}H NMR δ: 0.99 (3H, s, 18-H3), 1.19 (9H, s, CO-*t*Bu), 2.05 (3H, s, OAc), 4.03 (1H, dd, J = 8.6, 1.4 Hz, one of 19-H2), 4.06 (1H, d, J = 8.6 Hz, one of 19-H2), 4.38 (1H, dt, J = 2.0, 3.6 Hz, 11α-H), 4.62 (1H, dd, J = 9.3, 7.5 Hz, 17α-H), 4.75 (1H, tt, J = 11.3, 4.6 Hz, 3α-H), 5.79 (1H, d, J = 1.6 Hz, 6-H). Anal. calcd. for $C_{26}H_{36}O_6$: C 70.24, H 8.16; found: C 70.26, H 8.00.

An analogous reaction of the crude mixture of bromides **5***a* and **5***b* (obtained from the bromination of **4**) afforded also the crystalline enone **7***a* (71% overall yield from **4**).

(*b*) Olefin **4** (69 mg, 0.16 mmol) in dry CH_2Cl_2 (1 mL) was added to a solution of CrO_3–(pyridine)$_2$ complex, prepared from CrO_3 (390 mg, 3.9 mmol) and pyridine (0.63 mL, 7.8 mmol) in CH_2Cl_2 (1 mL), and the mixture was allowed to react for several days at room temperature with constant stirring. TLC control of the reaction indicated that a complex mixture of products was formed with traces of **7***a* only.

11β,19-Oxido-5,7-androstadien-3β,17β,19-triol 3-acetate 17-trimethylacetate (6)

A. Dehydrobromination of the allylic bromides **5**a *and* **5**b: (*a*) Bromide **5**a (41 mg, 0.08 mmol) was dissolved in a solution of tetrabutylammonium fluoride (0.8 mL, 1 M in THF) containing s-collidine (5 μL). The mixture was stirred at room temperature for 2 h. The solution was diluted with ether, washed with water, cold 5% HCl, and saturated $NaHCO_3$, and then dried with Na_2SO_4. Concentration in vacuo yielded a residue that was chromatographed on a silica gel column. The column was eluted with benzene–ether (98:2) yielding pure crystalline diene **6** (29 mg, 84%): mp 169–171°C (from acetone–hexane); $[\alpha]_D^{24}$ +133.5° (c 0.4); HPLC, R_V 31 mL; TLC, R_f 0.57; UV (EtOH) λ_{max}: 257.5 nm (sh, ε 8100), 265.5 (10 800), 276.0 (10 900), 287.0 (5900); IR ($CHCl_3$) ν_{max}: 1037, 1172, 1259, 1620 (w), 1675 (w), 1728 cm^{-1}; ^{1}H NMR δ: 0.76 (3H, s, 18-H3), 1.19 (9H, s, CO-tBu), 2.04 (3H, s, OAc), 3.63 (1H, dd, J = 8.0, 1.3 Hz, one of 19-H2), 3.93 (1H, d, J = 8.0 Hz, one of 19-H2), 4.49 (1H, m, $w/2$ = 12 Hz, 11α-H), 4.70–4.78 (2H, m, 3α- and 17α-H), 5.52 (1H, m, $w/2$ = 10 Hz, 7-H), 5.69 (1H, dd, J = 5.7, 2.4 Hz, 6-H). Anal. calcd. for $C_{26}H_{36}O_5$: C 72.87, H 8.47; found: C 72.96, H 8.51.

The reaction of the crude mixture of bromides **5***a* and **5***b*, obtained from the bromination of **4**, carried out in an analogous manner (except that catalytic amount of Bu_4NBr was added) afforded also the crystalline diene **6** (70% overall yield from **4**). The compound gave a single peak on HPLC and was judged to be 99% pure.

(*b*) A solution of bromide **5***a* (10 mg) in anhydrous *p*-xylene (2 mL) containing s-collidine (70 μL) was heated at reflux for 30 h under nitrogen. TLC of the reaction mixture showed the presence of unreacted **5***a* (more than 50%) and traces of the desired diene **6** accompanied by other by-products.

(*c*) A solution of bromide **5***a* (10 mg) in anhydrous *p*-xylene (3 mL) containing trimethyl phosphite (100 μL) was refluxed for 7 h; only unchanged starting material was shown on TLC.

B. Reduction of the tosylhydrazone 7b: A solution of enone **7***a* (89 mg, 0.2 mmol) and *p*-toluenesulfonyl hydrazide (93 mg, 0.5 mmol) in benzene (2 mL) was heated at 65°C for 10 h. The mixture was cooled, diluted with benzene–ether (1:1, 20 mL), and washed thoroughly with 5% HCl. The organic phase was washed with saturated $NaHCO_3$ and water, dried (Na_2SO_4), and evaporated to dryness under vacuo to yield a solid residue (122 mg) that was sufficiently pure (TLC and NMR) to be used for the next step without any further purification.

Tosylhydrazone **7***b*: TLC, R_f 0.32; IR ν_{max}: 819, 1041, 1172, 1246, 1603 (w), 1641 (w), 1731, 3230 cm^{-1}; ^{1}H NMR δ: 0.96 (3H, s, 18-H3), 1.20 (9H, s, CO-*t*Bu), 2.05 (3H, s, OAc), 2.44 (3H, s, Ar-CH_3), 3.82 (1H, dd, J = 8.5, 1.3 Hz, one of 19-H2), 3.97 (1H, d, J = 8.5 Hz, one of 19-H2), 4.26 (1H, m, $w/2$ = 10 Hz, 11α-H), 4.60 (1H, dd, J = 9.0, 8.0 Hz, 17α-H), 4.65 (1H, tt, J = 11.3, 4.6 Hz, 3α-H), 6.07 (1H, d, J = 1.4 Hz, 6-H), 7.32 (2H, br d, J = 8.3 Hz, Ar-H), 7.52 (1H, m, $w/2$ = 9 Hz, NH), 7.84 (2H, d, J = 8.3 Hz, Ar-H).

Lithium hydride (36 mg, 4.5 mmol) was added to a solution of the crude tosylhydrazone **7***b* (110 mg, 0.18 mmol) in dry toluene (4.5 mL) and the mixture was heated under reflux for 1.5 h. An additional portion of lithium hydride (16 mg, 2 mmol) was added and the reflux was continued for 30 min. Fast filtration of the cooled reaction mixture into ice-cold 2% H_2SO_4, followed by washing of the organic layer with saturated $NaHCO_3$ and water, drying (Na_2SO_4), and concentration under vacuo, yielded a residue that was chromatographed on a silica gel column. Elution with benzene–ether (98:2) afforded a crys-

talline material (62 mg), which after recrystallization from acetone–hexane gave an analytically pure diene **6** (52 mg, 67%).

11β,19-Oxido-9β,10α-androsta-5,7-dien-3β,17β,19-triol 3-acetate 17-trimethylacetate (8a) and 3β-hydroxy derivative 8b

A solution of diene **6** (30 mg) in benzene–ether (1:4, 350 mL) was cooled to 0°C and degassed by an argon purge for 40 min. The mixture was irradiated for 20 min through a water-cooled (0°C) quartz inner well with a 350 W Hanau S 81 lamp. Solvents were evaporated and the residue was chromatographed on a silica gel column. Elution with benzene–ether (98:2) provided the unreacted **6** (19 mg). Further elution with the same solvent gave a complex mixture of compounds. Slightly impure compound **8a** (1.3 mg, 12% based on recovered substrate **6**) was then eluted with benzene–ether (97:3). The identical irradiation experiments and chromatographical separations were repeated twice and all fractions containing **8a** were combined. Subsequent high-pressure liquid chromatography afforded analytically pure diene **8*a*** (2.0 mg): HPLC, R_V 54 mL; TLC, R_f 0.48; UV (EtOH) λ_{max}: 267.0 nm (ϵ 7000), 275.5 (6700), 288.0 (sh, 4200); ^{1}H NMR δ: 0.92 (3H, s, 18-H3), 1.20 (9H, s, CO-tBu), 2.06 (3H, s, OAc), 2.93 (1H, br d, J = 10 Hz, 9β-H), 3.64 (1H, dd, J = 7.9, 2.0 Hz, one of 19-H_2), 4.05 (1H, d, J = 7.9 Hz, one of 19-H_2), 4.34 (1H, dt, J = 8.0, 10.1 Hz, 11α-H), 4.89 (1H, dd, J = 9.0, 7.8 Hz, 17α-H), 5.07 (1H, m, w/2 = 8 Hz, 3α-H), 5.66 (1H, m, w/2 = 11 Hz, 7-H), 5.80 (1H, d, J = 5.4 Hz, 6-H); MS, *m/z* (rel. intensity): 428 (M^+, 13), 368 (14), 366 (27), 57 (100); HRMS calcd. for $C_{26}H_{36}O_5$: 428.2563; found: 428.2559.

Saponification of the diene **8*a*** (1 mg) was carried out in 5% methanolic NaOH (1 mL) at 40°C for 20 min. Conventional work-up afforded the 3-hydroxy derivative **8*b*** (0.9 mg): TLC, R_f 0.28; UV (EtOH) λ_{max}: 267.0 and 276.0 nm ($\epsilon \sim 7000$); ^{1}H NMR δ: 0.92 (3H, s, 18-H3), 1.20 (9H, s, CO-*t*Bu), 2.96 (1H, br d, J = 10 Hz, 9β-H), 3.64 (1H, dd, J = 7.8, 2.0 Hz, one of 19-H2), 4.03 (1H, d, J = 7.8 Hz, one of 19-H2), 4.13 (1H, m, *w*/2 = 12 Hz, 3α-H), 4.34 (1H, dt, J = 8.0, 9.8 Hz, 11α-H), 4.88 (1H, dd, J = 9.0, 7.8 Hz, 17α-H), 5.68 (1H, m, *w*/2 = 11 Hz, 7-H), 5.91 (1H, d, J = 5.4 Hz, 6-H).

Fragmentation of 2-(dialkylamino)ethyl phosphate derivatives. Mechanism change as a function of substituents at phosphorus

Andre Pienaar and Tomasz A. Modro

Abstract: The products and the first-order rate constants for the fragmentation of six phosphonic diesters (**2**) and two phosphonic monester chlorides (**3**), all containing the 2-(dialkylaminoethyl) group as one of the ester functions, have been determined. On the basis of different reaction products, different rates of decomposition, and different activation parameters, a new mechanism for the fragmentation of ester chlorides (**3**) is proposed: fragmentation involving release of the chloride ion and the formation of the 1,1-dialkylaziridinium ion and metaphosphonate as the reactive intermediates.

Key words: fragmentation of phosphates and phosphorochloridates, "metaphosphate" mechanism of phosphates, activation entropy in mechanistic change, 2-(dialkylamino)ethylphosphates.

Résumé : On a déterminé la nature des produits et les constantes de vitesse du premier ordre des fragmentations de six diesters (**2**) et de deux chlorures monoestérifiés (**3**) de l'acide phosphonique qui contenaient tous le groupe 2-(dialkylaminoéthyle) comme l'une des fonctions esters. Sur la base des produits des réactions, des diverses vitesses de décomposition et des paramètres d'activation, on propose un nouveau mécanisme pour la fragmentation des chlorures monoestérifiés **3**: fragmentation impliquant la libération de l'ion chlorure avec formation de l'ion 1,1-dialkylaziridinium et du métaphosphonate comme intermédiaires réactifs.

Mots clés : fragmentation des phosphates et phosphorochloridates, mécanisme «métaphosphate» des phosphates, entropie d'activation dans les changements de mécanisme, 2-(dialkylamino)éthylphosphates.

Alkyl 2-(dialkylamino)ethyl esters of phosphorus acids **1** are interesting substrates because they undergo spontaneous structural changes, often under very mild conditions. Transformations of systems **1** can proceed in two directions (Scheme 1): bimolecular dealkylation leading to a final zwitterionic product (pathway (a)), and (or) the unimolecular fragmentation resulting in the final formation of a piperazinium phosphate salt (pathway (b)). The mechanisms of those reactions are well understood (1–4), and the isomerization to a zwitterionic species found application as a route to phospholipid analogues (5). Convincing kinetic evidence for pathway (b) was given by Benschop et al. (1), who studied the decomposition of two phosphonic derivatives: isopropyl 2-(dimethylamino)ethylmethylphosphonate, Me-P(O)(OPr^i)($OCH_2CH_2NMe_2$), **2a**, and 2-(dimethylamino)ethylmethylphosphonofluoridate, Me-P(O)($OCH_2CH_2NMe_2$)F. Both substrates gave the same *N,N,N′,N′*-tetramethylpiperazinium ion according to first-order kinetics, but the fluoro derivative was found ca. 800 times more reactive than **2***a* ($\log k_{rel} = 2.92$). The difference in the rate was explained by the basicity difference of the leaving groups (methylphosphonofluoridate anion vs. isopropyl methylphosphonate anion). The difference in the acidities of the respective conjugate acids is, however, only $\Delta pK_a = 1.15$, conspicuously low to explain the observed relative rates. For example, the rates of the base-promoted elimination of 1-halo-2-phenylethanes decrease with the decrease of the nucleofugality of a halide ion ($\log (k_I/k_F) = 4.42$) (6), but the acidities of the corresponding acids HX span a range of ΔpK_a of ca. 13. Since the rates faster than predicted from the Bronsted plot of pK_a (leaving group) often indicate change in the reaction mechanism (7), and since we observed earlier (8) that 2-arylethyl phosphorochloridate systems decompose easily via a "metaphosphate" mechanism (9), we decided to reinvestigate the mechanism of the fragmentation of 2-(dialkylamino)ethyl alkylphosphonic derivatives with variable substituents at phosphorus.

Results and discussion

Six alkyl 2-(dialkylamino)ethyl alkylphosphonic diesters **2***a*–**2***f*, and two 2-(dialkylamino)ethyl alkylphosphonochloridates **3***a*, **3***b*, were prepared (Scheme 2), and the products and the rates of their fragmentation were determined. Preparation of substrates **3** proved difficult, and will be discussed in a separate report. Once synthesized, chloridates **3** were found highly

unstable, and had to be used without purification, immediately after their preparation. The rates of the fragmentation of esters **2** were measured under the same conditions as described in the literature for **2***a* (1), that is, in DMSO-d_6 at 60°C. The products were identified by NMR (^{1}H and ^{31}P) spectroscopy, and in all cases were in full agreement with the reaction shown in Scheme 1, pathway (b). Concentration changes were monitored by ^{1}H NMR spectroscopy, in most cases following the increase in intensity of the piperazinium ion signal at $\delta_H = 3.4$. Phosphonochloridates **3** were found to be remarkably stable in DMSO solutions (no change in the ^{1}H NMR spectrum after 56 h at 60°C). The nature of that stabilizing solvent effect is currently being studied in our laboratory, but the fragmentation of substrates **3** could easily be determined in $CDCl_3$ or CD_3CN solutions. For the kinetic studies, the *N,N*-diethylaminoethyl derivatives **3***a* and **3***b* were used, since the *N,N*-dimethylaminoethyl analogues decomposed so quickly that it was not possible to prepare pure samples of the substrates.

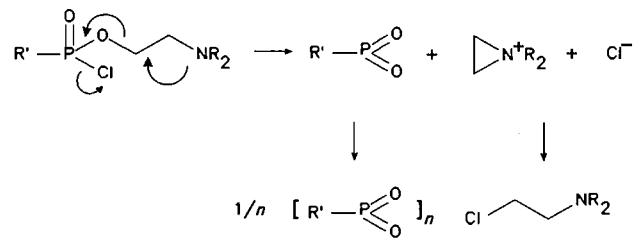
Table 1. Kinetic data on the fragmentation of phosphonic diesters **2** and phosphonochloridates **3** at 60°C.

Substrate	Solvent	$10^7 \times k_1$ (s^{-1})	k_{rel}
2*a*	DMSO-d_6	0.82[a]	1.0
2*b*	DMSO-d_6	1.02	1.2
2*c*	DMSO-d_6	6.83	8.3
	$CDCl_3$	1.03	1.3
	CD_3CN	5.00	6.1
2*d*	DMSO-d_6	2.00	2.4
2*e*	DMSO-d_6	5.17	6.3
2*f*	DMSO-d_6	8.33	10.2
3*a*	$CDCl_3$	31.7	38.7
	CD_3CN	70.0	85.4
3*b*	$CDCl_3$	55.0	67.1

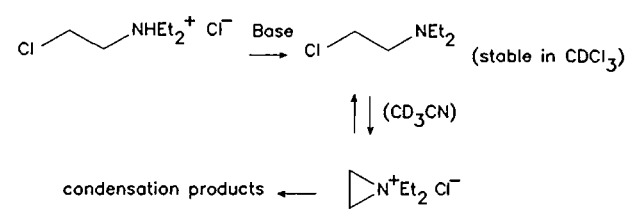
[a]Literature (1) $k_1 = 1.35 \times 10^{-7}$ s^{-1}.

Fragmentations of all substrates followed first-order kinetics, and the rate data are given in Table 1. The diesters **2** react with similar rates, the variations of k_{rel} values not exceeding a factor of 10. Reactivity variations do not seem to follow any particular trend, with perhaps the exception of the case when k(**2***c*) > k(**2***d*) > k(**2***a*), following the expected order of the effect of an alkyl ester group on the acidity of the phosphate group (9). Since the relative acidities of phosphates and phosphonates in DMSO are not known, any correlations with the pK_a values for aqueous solutions have to be, however, treated with caution. We think that small reactivity differences observed for diesters **2** result mostly from the entropic factors, associated with the conformational changes required for the closure of the aziridinium ring in the rate-determinig step of the fragmentation, and we believe that all diesters **2** decompose according to a common mechanism. As for a reaction in which two ions are formed from a neutral substrate in a slow step, the fragmentation is expected to be sensitive to the polar-

Scheme 3.



Scheme 4.



ity of the solvent (10). Table 1 shows that the rate of fragmentation of **2***c* decreases with the decrease in the polarity of the medium.

Phosphonic monoester monochlorides **3** show fragmentation behavior significantly different from that observed for diesters **2**. Although the rates were measured in a less polar solvent than DMSO, the reactions were in all cases much faster, giving (after accounting for a solvent effect) the approximate relative reactivity $k_3/k_2 \geq 50$. The difference in the reactivity itself is not sufficient evidence for a mechanistic change; we have found, however, that the fragmentation of **3** leads to different products that cannot be explained by the mechanism presented in Scheme 1, pathway (b). In both cases the piperazinium ion was absent in the reaction product, and the sole non-phosphorus product observed in $CDCl_3$ was diethyl (2-chloroethyl)amine, unambigously identified by comparison with and addition of the authentic material. The same product was formed in CD_3CN solution, but in that solvent it slowly changed to a mixture of polycondensation products (*vide infra*). As far as the phosphorus-containing products are concerned, the ^{31}P and ^{1}H NMR spectra were also different from those obtained for the diesters: instead of single signals of the corresponding phosphonic monoester monoanion, the spectra showed formation of large number of structurally similar products.

We propose therefore that the fragmentation of substrates **3** follows a different mechanistic pattern, that is, it involves departure of the chloride ion and the release of the aziridinium ion, together with a metaphosphonate species (Scheme 3). In that sense, decomposition of substrates **3** has a close analogy in the previously reported (8) fragmentation of the (2-arylethyl)phosphorochloridates, where the 2-aryl group provided the "internal nucleophile" that aided the cleavage of the phosphate P—O bond, with a simultaneous release of a good leaving group present at phosphorus (Cl^-). The released chloride ion can then compete with the unreacted substrate in the opening of the aziridinium ion, yielding the dialkyl (2-chloroethyl)amine product. We tested the stability of that amine in a given solvent by releasing it from the commercial hydrochloride salt and recording the ^{1}H NMR spectra of the solution as a function of time. In $CDCl_3$ the free amine was found to be perfectly stable, giving rise to the same spectrum as that observed for the fragmentation product of **3**. In CD_3CN the amine was slowly converted into the *N,N*-diethylaziridinium ion (δ_H 2.20), which, after reaching a maximum, slowly gave way to a mixture of products resulting from self-condensation of the aziridinium species (11) (Scheme 4).

The reaction shown in Scheme 3 represents another example of a facile fragmentation of an organophosphorus substrate proceeding with the extrusion of a "metaphosphate" species. Since the transition state for the proposed fragmentation

Table 2. Activation parameters for the unimolecular fragmentation of phosphonic and phosphoric esters.

Substrate (solvent)	$\Delta G^{\ddagger}$ (kJ mol^{-1})	$\Delta H^{\ddagger}$ (kJ mol^{-1})	$\Delta S^{\ddagger}$ (J mol^{-1} K^{-1})
2*c*			
(CD_3CN)	122.4	85.4	−111
3*a*			
(CD_3CN)	117.3	49.3	−204
1*a*[a]			
(EtOH)		86.0	−76
(H_2O)		93.7	−28

involves the cleavage of two bonds, and the formation of two bonds (as opposed to the cleavage of one bond and the formation of one bond in the "classical" mechanism), the activation parameters, and the entropy term in particular, should be significantly different for those two types of fragmentation. In their study on the hydrolysis of alkyl chlorosulfates, Buncel and Millington (12) pointed out that the mechanistic change from the "classical" displacement to the fragmentation of the leaving group to SO_3 and Cl^- should strongly affect the activation entropy. The direction of the change is difficult to predict, as the increased solvation of the species being formed in the transition state should lead to a more negative $\Delta S^{\ddagger}$, while the gain in the degrees of freedom might result in the increase of the entropic term. We have determined activation parameters for one phosphonic diester (**2***c*) and one phosphonochloridate (**3***a*); acetonitrile-d_3 was found to be the best solvent in which the rates could be conveniently measured for both substrates. The results, together with those reported for an analogous fragmentation of the triester, dimethyl 2-(dimethylamino)ethyl phosphate (**1***a*, R = R′ = Me; Y = OMe) (2), and for a similar reaction of diethyl 2-(ethylmercapto)ethyl thionophosphate $(EtO)_2P(S)OCH_2CH_2SEt$, **4** (13), are given in Table 2. It is clear that the behavior of the phosphonochloridate is qualitatively different from that of the other substrates, in full agreement with the hypothesis of a different ("metaphosphate") mechanism of its fragmentation. Although the activation energies obtained for **2***c* and **3***a* are very similar, fragmentation of **3***a* is characterized by a much lower $\Delta H^{\ddagger}$ value, and by a much more negative value of $\Delta S^{\ddagger}$. According to the accepted mechanism for the fragmentation of diesters **2**, and the proposed mechanism for the fragmentation of chlorides **3**, the respective activated complexes can be represented

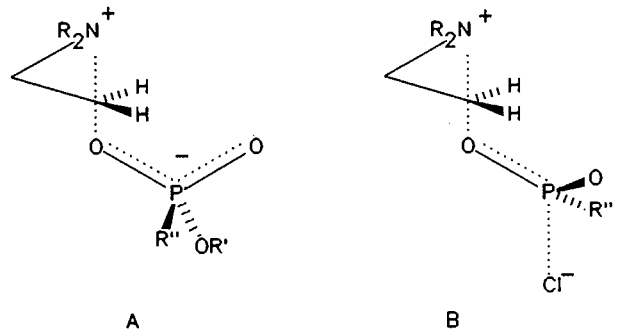
Scheme 5.



A B

by structures A and B, given in Scheme 5. As far as the enthalpy of activation is concerned, the major difference is that, in B, cleavage of a relatively weak bond (P—Cl) is compensated by the formation of a strong (phosphoryl) bond in the incipient metaphosphonate. Our results show that such a difference is reflected by a ca. 40% reduction of the $\Delta H^{\neq}$ value. The enthalpy gain is, however, almost completely counterbalanced by the further, strong decrease in the entropy of activation. As illustrated in Scheme 5, the difference in the $\Delta S^{\neq}$ indicates a much more rigorous geometry of the transition state B, dictated presumably by the stereoelectronic requirements of the whole N···C···O···P···Cl system in which two bonds are being cleaved and two are being formed in a more or less concerted fashion. We previously also obtained highly negative entropies of activation ($\Delta S^{\neq} < -100$ J mol^{-1} K^{-1}) for another type of fragmentation of an organophosphorus substrate, thermal decomposition of dialkyl 2-acyloxyalkyl-phosphonates, which also involves extrusion of a metaphosphate species and requires transfer of the alkyl group from the phosphate function to the carbonyl oxygen (14).

In conclusion, we believe that substrates of the type **3** represent yet another example of the organophosphorus system in which a "metaphosphate" unit is incorporated into the molecular framework, and can be released via a fragmentation under mild conditions.

Experimental section

NMR spectra were recorded on a Bruker AC300 spectrometer at a probe temperature of 30°C. Chemical shift values are given relative to $SiMe_4$ (^{1}H and ^{13}C) or 85% H_3PO_4 (^{31}P). Coupling constants are given in Hz. Chloroform-*d*, acetonitrile-d_3, and DMSO-d_3 (all Uvasol, Merck) were dried over molecular sieves (Merck, 0.4 nm). Kinetic studies were performed in a thermoregulated water bath fitted with a Gallenkamp Thermostirrer. Micro distillations were carried out using a Buchi GKR-50 glass tube oven. Diethyl 2-chloroethylammonium chloride (Aldrich) was dried azeotropically with benzene, kept under high vacuum, and pulverized before use.

2-(Dialkylamino)ethyl alkyl alkylphosphonates **2** were prepared from the corresponding alkyl alkylphosphonochloridates and the corresponding 2-(dialkylamino)ethanol as described in the general procedure below. The details of the preparation of substrates **3** (alkyl alkylphosphonochloridates) will be described elsewhere.[2]

[2] A. Pienaar and T.A. Modro. In preparation.

Preparation of ***2****. General procedure*

A mixture of 2-(dialkylamino)ethanol (5.7 mmol) and triethylamine (6.3 mmol) in ether (2 mL) was added dropwise to a stirred solution of the alkyl alkylphosphonochloridate (5.7 mmol) in ether (10 mL) at −15°C. The precipitate formed was filtered off and dissolved in chloroform (20 mL), anhydrous potassium carbonate (6.6 mmol) was added, and the mixture was stirred overnight. After filtration and evaporation of the solvent, crude **2** was purified by bulb-to-bulb (b-t-b) distillation. The distilled products were spectroscopically pure (single signal in the ^{31}P NMR spectrum) and they were identified by ^{1}H and ^{13}C NMR spectroscopy in $CDCl_3$, as well as by heteronuclear 2D (^{13}C, ^{1}H) NMR spectra (correlating signals are indicated below by matching superscripts at the δ_H and δ_C values).

2a (36%): distilled b-t-b (at 70°C/0.3 Torr; 1 Torr = 133.3 Pa); δ_P: 30.6; δ_H: 1.28^x (6H, d, J_{HH} 6.2), 1.44^y (3H, d, J_{HP} 17.5), 2.24^z (6H, s), 2.54^w (2H, t, J_{HH} 5.9), 4.05^v (2H, m), 4.66^u (1H, m); δ_C: 11.9^y (dq, J_{CP} 144.9, J_{CH} 128.1), 23.9^x (dq, J_{CP} 4.1, J_{CH} 126.7), 45.6^z (q, J_{CH} 133.2), 59.2^w (dt, J_{CP} 6.4, J_{CH} 131.3), 62.8^v (dt, J_{CP} 6.3, J_{CH} 146.1), 70.15^u (dd, J_{CP} 6.3, J_{CH} 146.3).

2b (22%): distilled b-t-b (at 75°C/0.3 Torr); δ_P: 34.8; δ_H: 1.12^x (3H, dt, J_{HP} 20.0, J_{HH} 7.7), 1.29^y (3H, t, J_{HH} 7.0), 1.73^z (2H, dq, J_{HP} 18.3, J_{HH} 7.7), 2.24^w (6H, s), 2.55^v (2H, t, J_{HH} 5.9), 4.07^u (4H, m); δ_C: 6.53^x (dq, J_{CP} 6.4, J_{CH} 129.3), 16.4^y (dq, J_{CP} 6.4, J_{CH} 127.1), 18.8^z (dt, J_{CP} 143.1, J_{CH} 126.7), 45.7^w (q, J_{CH} 133.2), 59.4^v (dt, J_{CP} 6.4, J_{CH} 132.8), 61.6^u (dt, J_{CP} 6.4, J_{CH} 146.6), 63.1^u (dt, J_{CP} 6.4, J_{CH} 146.3).

2c (33%): distilled b-t-b (at 60°C/0.5 Torr); δ_P: 33.1; δ_H: 1.46^x (3H, d, J_{HP} 17.4), 2,24^y (6H, s), 2.54^z (2H, t, J_{HH} 5.7), 3.69^w (3H, d, J_{HP} 11.3), 4.08^v (2H, m); δ_C: 10.5^x (dq, J_{CP} 144.8, J_{CH} 128.4), 45.6^y (q, J_{CH} 133.1), 52.0^z (dq, J_{CP} 6.3, J_{CH} 147.3), 59.3^w (dt, J_{CP} 5.8, J_{CH} 131.7), 63.1^v (dt, J_{CP} 15.5, J_{CH} 147.4).

2d (72%): distilled b-t-b (at 65°C/0.5 Torr); δ_P: 31.7; δ_H: 1.29^x (3H, t, J_{HH} 7.1), 1.46^y (3H, d, J_{HP} 17.6), 2.24^z (6H, s), 2.54^w (2H, t, J_{HH} 5.9), 4.07^v (4H, m); δ_C: 10.8^y (dq, J_{CP} 144.8, J_{CH} 128.4), 15.9^x (dq, J_{CP} 5.7, J_{CH} 126.5), 45.2^z (q, J_{CH} 133.0), 58.9^w (dt, J_{CP} 6.0, J_{CH} 133.7), 61.0^v (dt, J_{CP} 6.0, J_{CH} 147.0), 62.6^v (dt, J_{CP} 6.1, J_{CH} 145.1).

2e (6%): bp 87°C/0.9 Torr; δ_P: 32.8; δ_H: 0.99^x (6H, t, J_{HH} 7.2), 1.44^y (3H, d, J_{HP} 17.5), 2.54^z (4H, q, J_{HH} 7.1), 2.68^w (2H, t, J_{HH} 6.3), 3.68^v (3H, d, J_{HP} 11.1), 4.03^u (2H, m); δ_C: 10.5^y (dq, J_{CP} 144.6, J_{CH} 128.5), 11.6^x (q, J_{CH} 125.4), 47.5^z (t, J_{CH} 132.6), 52.0^v (dq, J_{CP} 6.3, J_{CH} 144.2), 52.8^w (dt, J_{CP} 6.2, J_{CH} 134.6), 63.6^u (dt, J_{CP} 6.4, J_{CH} 147.2).
