For personal use only.

from **2***f*) and $SOCl_2$ by modification of the literature procedure (15). The products were prepared immediately before further use since they decomposed slowly and could not be purified by distillation or chromatography. They were, however, found to be formed as spectroscopically pure materials (single signal in the ^{31}P NMR spectra), and were identified by ^{1}H NMR spectroscopy.

3a (87%): δ_P: 43.3; δ_H: 1.41 (6H, t, J_{HH} 7.3), 2.10 (3H, d, J_{HP} 17.5), 3.21 (4H, m), 3.41 (2H, m), 4.67 (2H, m).

3b (86%): δ_P: 49.7; δ_H: 1.27 (3H, dt, J_{HP} 25.4, J_{HH} 7.7), 1.40 (6H, t, J_{HH} 7.3), 2.25 (2H, dq, J_{HP} 17.2, J_{HH} 7.6), 3.21 (4H, m), 3.41 (4H, m), 4.66 (2H, m).

Product studies

Decomposition of substrates **2** was followed in DMSO-d_6 by ^{1}H NMR spectroscopy and the products (alkyl alkylphosphonate ion and *N,N,N′,N′*-tetraalkylpiperazinium ion) were easily identified by comparison with literature data (1). In the fragmentation of substrates **3**, followed in $CDCl_3$, the piperazinium ion was absent, and diethyl 2-chloroethylamine formed was identified by its characteristic ^{1}H NMR spectrum, and by the addition of the authentic material.

N,N,N′,N′-*Tetramethylpiperazinium ion*: δ_H (DMSO-d_6): 3.37 (12H, s), 3.95 (8H, s).

N,N,N′,N′-*Tetraethylpiperazinium ion*: δ_H (DMSO-d_6): 1.21 (12H, t, J_{HH} 7.1), 3.01 (8H, q, J_{HH} 7.1), 3.82 (8H, br s).

Diethyl (2-chloroethyl)amine: δ_H ($CDCl_3$): 1.34 (6H, t, J_{HH} 7.2), 3.10 (4H, q, J_{HH} 7.3), 3.28 (2H, t, J_{HH} 6.9), 3.91 (2H, t, J_{HH} 6.9).

Kinetic measurements

A sample of the substrate (30 mg) was dissolved in the appropriate solvent (0.5 mL) in an NMR tube, and the tube was sealed and incubated in a thermoregulated water bath. The ^{1}H NMR spectrum of the solution was recorded periodically, and the reaction progress was determined from the integrated areas of selected signals for the substrate and (or) the product. Good first-order linear plots were obtained (r^2 = 0.996).

Stability of diethyl (2-chloroethyl)amine in solution

Samples of diethyl (2-chloroethyl)ammonium chloride (0.101 g, 0.59 mmol) were dissolved in $CDCl_3$ and in CD_3CN (2 mL each), and anhydrous K_2CO_3 (0.082 g, 0.59 mmol) was added to each solution. The mixtures were stirred at room temperature, and the ^{1}H NMR spectra of the solutions were periodically recorded. The spectrum of the $CDCl_3$ solution was identical to that of the pure free base (*vide supra*), and did not change over the period of 6 days. The spectrum of the CD_3CN solution was initially identical to that obtained in $CDCl_3$ (with a small change in the chemical shift values), but after 1 day a signal at δ_H 2.20 (ring protons in 1,1-diethylaziridinium ion) started to appear. The signal increased in intensity, together with new signals appearing in the range of δ_H 1.2–3.4; 4 days later the aziridinium signal, after passing through a maximum, had disappeared, and the spectrum showed only a large number of signals in the range of δ_H values 1.2–3.4.

Molecular mechanics calculations on the complexes between analogues of Hoechst 33258 and d(CGCGAATTCGCG)$_2$: influence of bulky group substitution on base pair preference of DNA minor groove binders

Ding-Kwo Chang, Shu-Fang Cheng, and Ting-Lin Chien

Abstract: Molecular mechanics calculations were performed on the three structures of the complexes formed by the derivatives of Hoechst 33258 and dodecameric DNA duplex d(CGCGAATTCGCG)$_2$. Formation and docking energies of these complexes were compared. It was found that the CG site that is 3′ to the central AATT region can be tolerated by the drugs. This is probably due to the presence of the bulky piperazine ring and, more pronouncedly, by alkylated analogues of the drug that prefer the wider minor groove formed by the GC base pair region of B-DNA. The argument of bulkiness of the piperazine moiety as the origin of enhancement of GC affinity is supported by detailed structural analysis of the intermolecular interface and widening of the DNA minor groove at the binding site. Implications of the results are discussed.

Key words: minor groove binder, docking energy, sequence specificity.

Résumé : On a effectué des calculs de mécanique moléculaire sur les trois structures des complexes qui se forment à partir des dérivés du Hoechst 33258 et du duplexe dodécamérique de l'ADN, d(CGCGAATTCGCG)$_2$. On a comparé les énergies de formation et de jonction de ces complexes. On a trouvé que le site CG, qui se trouve à 3′ de la région centrale AATT, peut être toléré par les drogues et que cette propriété est probablement due à la présence du volumineux noyau pipérazine et, d'une façon plus prononcée, par les analogues alkylés de la drogue qui préfèrent la rainure mineure plus large qui est formée par la région B-ADN de la paire des bases GC. L'argument de la grosseur de la portion pipérazine comme origine du rehaussement de l'affinité GC est en accord avec l'étude structurale détaillée de l'interface intermoléculaire et de l'élargissement de la rainure mineure de l'ADN au niveau du site de liaison. On discute des implications de ces résultats.

Mots clés : liaison de la rainure mineure, énergie de jonction, spécificité de la séquence.

Introduction

DNA molecules are targets for many anti-viral, anti-bacterial, and anti-cancer antibiotics (1, 2). DNA may be irreversibly modified as in strand cleavage (3) and interstrand cross-linking (4). Alternatively, DNA may interact reversibly with the drugs through intercalation (5), groove binding (6), or charge–charge interaction (7). One of the central issues in the design of DNA-interacting drugs is sequence specificity of DNA by the drugs. In this aspect, groove binders appear to be of advantage since one can extend the number of base pairs spanned by the groove binder, as desired, in a systematic way, to increase the degree of differentiation by increasing the number of base pair sequences for recognition. In the B-DNA structure the minor groove is deep and narrow; a deep electronegative potential well (8) exists that is well suited to a positively charged ligand whose size closely fits the minor groove. This is the case for netropsin and distamycin, which are known to bind strongly to the minor groove of the B-DNA double-stranded helix in the A,T-rich region, which is notably narrower than the GC-rich region (9). Computational study has shown that both van der Waals (vdW) and electrostatic forces, including hydrogen bonding, contribute comparably to the binding stability (enthalpy) of netropsin complexed to B-DNA oligomers containing the AATT sequence (10).

Attempts were made to switch the sequence specificity from AT to GC by replacing pyrrole with an imidazole ring in netropsin analogues. This approach is based on avoiding steric clash between the hydrogen atom on the pyrrole ring and the amino group of guanine and replacing it with a hydrogen bond between the imidazole nitrogen atom and the guanine amino group. Although these "lexitropsins" (11, 12) exhibited a substantial increase in GC recognition, no clear rejection of the

AT base pair was observed and in a number of cases AT-rich sequences were still preferred.

Hoechst 33258 is a synthetic compound that shows anthelmintic (13) and topoisomerase-inhibiting (14) activities. Several studies have shown that the drug binds preferentially to the AT-rich region of double-stranded DNA with a minimum of four consecutive AT base pairs (6). It was found that there were two different modes of the Hoechst 33258 binding to DNA, with binding affinity differing by two orders of magnitude. X-ray crystallographical studies on the complex of Hoechst 33258:d(CGCGAATTCGCG)$_2$ showed the central AATT as binding site (15) at low temperature (16) while ATTC emerged as a possible binding site at room temperature (17). The ATTC mode was also reported for Hoechst 33258 binding to a DNA dodecamer containing central ATAT (18). The AATT binding site is consistent with footprinting (19) and NMR (20) results. The one base shift from GC of the AATT binding site to ATTC was rationalized by the bulky piperazine ring (which fits better the wider groove at the GC pair) and the hydrogen-bond-acceptor N atom connecting the ring to the benzimidazole group (which forms a hydrogen bond with the amino proton of guanine N2). The bulky group could be used as a potential discriminator against the AT base pair, in addition to a hydrogen-bond acceptor such as the nitrogen atom in the imidazole ring that favors the GC base pair.

Energy computation in association with molecular modeling has been increasingly employed to gain insight into the mechanism of the interaction between biopolymers and ligands (21). In particular, it affords an analysis of intermolecular energy by contributions from vdW, hydrogen bonding, and electrostatic terms. In the following, the results of an energetics computation of Hoechst 33258: d(CGCGAATTCGCG)$_2$ complexes using structures deduced from an X-ray diffraction experiment are reported. For the ATTC mode, only the conformation in which the piperazine ring points toward the groove was considered, as the other orientation, in which the ring points away from the minor groove, would yield a smaller docking energy. In addition, to evaluate the steric interference of the piperazine ring on the stability of drug binding to the AATT site, the piperazine ring was rotated approximately 90 degrees with respect to the orientation derived from X-ray diffraction data mentioned previously (17). To explore the effect of the bulky piperazine ring on GC base pair recognition, methyl and ethyl groups were used to substitute the hydrogen atoms on two carbon atoms *ortho* to the bridge nitrogen on the piperazine ring. The comparison sheds some light on the nature of the minor-groove binding mode of the drugs to DNA and may contribute to the rational design of ligands that recognize the desired DNA sequence.

Methods

The coordinates of the complex were taken from data deposited by Pjura et al. in the protein data bank (17) for the reference structure of computation. The initial structures with AATT and two ATTC binding modes (see below) were obtained by docking the drug at appropriate locations and orientations onto the oligonucleotide, whose coordinates were taken from the same crystal structure. For the initial structures used in minimization, docking of drugs onto the oligonucleotide was tried until the van der Waals energy dropped to a negative value, typically -60 kcal mol^{-1}. Attempts were made to use different docked complex structures in each of the three binding modes to examine the effect of varying the starting structures. To minimize the end effect, six atoms at the two ends of the oligonucleotide were fixed in space: C2, C4, C6 of cytosine[1] and C4, C6, C8 of guanine[12]. The Discover program from Biosym Technologies Inc. (San Diego, California, U.S.A) and the AMBER (22) force field were used to compute the energy and to minimize the structure using 15 000 steps of the steepest descent method followed by 500 steps of the conjugate gradient method. In all computations the complex systems were minimized until the root-mean-square (RMS) gradient was 0.15 kcal mol^{-1} Å^{-1} or less. A distance-dependent dielectric constant (i.e., ϵ is numerically equal to the interactomic distance in Å) was employed in the computation. Twenty-one sodium ions were added to neutralize the complex system. These counterions were placed at least 4.5 Å from the two nearest phosphorus atoms. Polarization was not taken into account in considering intermolecular interaction energy as its contribution is relatively small and effectively the same for complexes in the present study. The energy of the system can be expressed as follows.

$$E = E_{\text{bond}} + E_{\text{theta}} + E_{\text{phi}} + E_{\text{imp}} + E_{\text{elect}} + E_{\text{hb}} + E_{\text{vdW}}$$

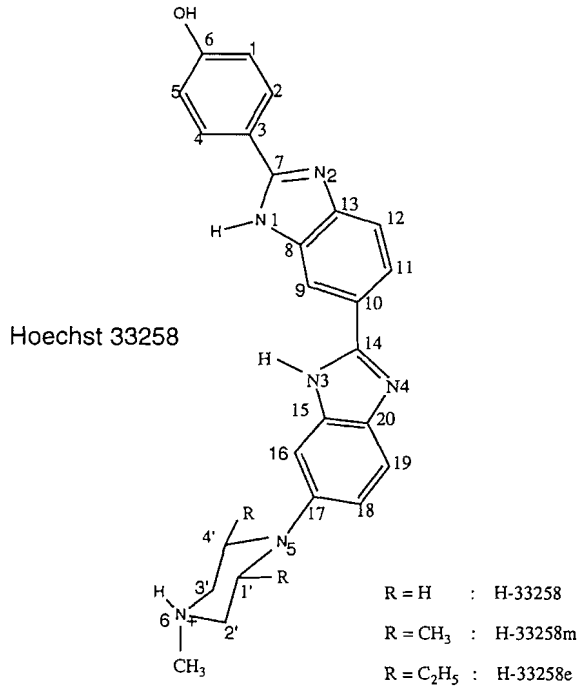
where E_{bond}, E_{theta}, E_{phi}, E_{imp}, E_{elec}, E_{hb}, and E_{vdW} represent the energies of the chemical bond, angle, dihedral angle, improper angle, Coulombic electrostatic, hydrogen bond (H-bond), and van der Waals (vdW) interactions, respectively; 6–12 Leonard–Jones and 10–12 potential functions were used for vdW and hydrogen bond energies, respectively. The final calculated energies were not dependent on the initial docking positions, indicating that a structure corresponding to the local energy minimum is obtained using appropriately docked initial structures for minimization.

In the evaluation of components of intermolecular interaction energy, only vdW and electrostatic terms are reported. Intermolecular docking energy was calculated using the docking module of the Biosym program. Hydrogen bond energy is included in the electrostatic energy. Only enthalpy is considered; entropy is neglected because it requires a more accurate model of the solvent molecules to take account of the hydrophobic effect as water molecules are expelled from the minor groove into the surrounding bulk solvent upon complex formation. Furthermore, only the relative binding energy is relevant in the present study.

Results

The schematic structures of Hoechst 33258 as well as its derivatives and some of the atomic numbering schemes are presented in Fig. 1. Figures 2(*a*), 2(*b*), and 2(*c*) show the starting structures of Hoechst 33258 complexed to d(CGCGAATTCGCG)$_2$ at the AATT site and two piperazine orientations at the ATTC site, respectively. Table 1 shows the intermolecular interaction energy for the three binding modes of Hoechst 33258 and its methyl and ethyl derivatives complexed to the oligomeric helical duplex. Some of the representative intermolecular distances are summarized in Table 2. Detailed stereo views of these three complexes after energy minimization are presented in Fig. 3. Figure 4 indicates the width of the

Fig. 1. Schematic structure of Hoechst 33258, its derivatives, and the atomic numbering scheme.



minor groove as measured from the shortest distance between O4′ and O4′ and P and P on the two opposite strands.

It is also found that the effect of varying the starting complex structures on the final structures and energies is minimal. The conclusions drawn are independent of the starting structures.

Discussion

The results of the computation on the AATT-b mode, in which the orientation of the piperazine moiety is parallel to the floor of the minor groove, are not shown. This is because, after energy minimization, the orientation of drug reverted to the AATT-a mode. For the methyl and ethyl analogues, the phenomenon is more pronounced, presumably due to the bulkiness of the drugs that reduced the binding affinity and stability of the complexes. From Table 1, it can be seen that both vdW and electrostatic components are smaller for the two ATTC binding modes for Hoechst 33258. The difference is significantly smaller for the methyl and ethyl analogues.

The effect of bulky group substitution on the intermolecular distance can be inferred from Table 2 for some representative atom pairs. Since substitution on the piperazine group occurs at one end of the drug analogues, the effect is expected to be more visible at the minor groove of the region T8–C9 and G16–A17 where the piperazine is attached to the oligonucleotide. Thus the distances between C4′ of the drug and N3 of A17 (or N2 of G16) and between C4′ of the drug and O2 of T8 (or O2 of C9) are smaller for H-33258 than for its methylated or ethylated derivatives in the AATT-a mode (or both ATTC modes). This can be visualized from the stereo diagrams of Fig. 3. In the AATT mode, the penetration of both substituted derivatives into the minor groove is not as deep as Hoechst 33258 in the piperazine portion of the drug while the difference is not as significant in the other part of the drug. In both ATTC modes, the effect of methyl and ethyl substitution is not as pronounced as in the AATT mode, which presumably is the result of the larger width of the minor groove at the GC base pair. Figures 4 indicate that the width of the minor groove at

Fig. 2. Starting structures of Hoechst 33258 complexed to d(CGCGAATTCGCG)$_2$ in AATT-a mode (*a*), ATTC-a mode (*b*), and ATTC-b mode (*c*), respectively. The piperazine rings of the drugs are perpendicular and parallel to the floor of the DNA minor groove for modes a and b, respectively.

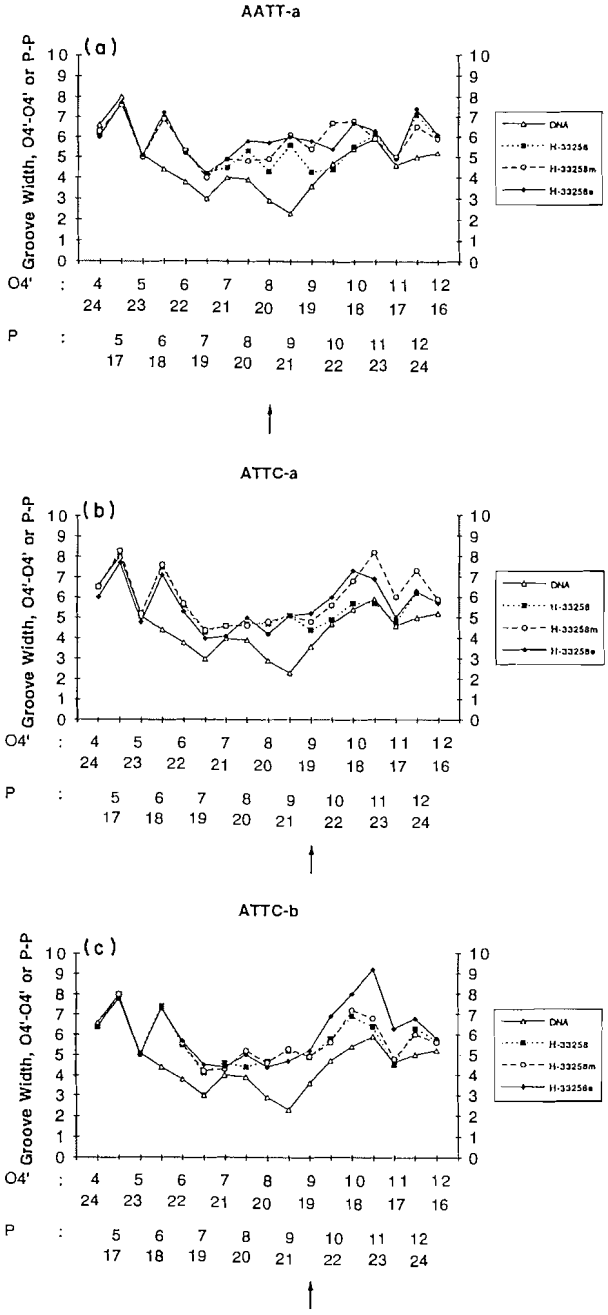
Fig. 4. Minor groove width of AATT-a (*a*), ATTC-a (*b*), and ATTC-b (*c*) as measured by the shortest distances between O4′ and O4′ less 2.8 Å and between P and P less 5.8 Å on the two opposite strands. The numbers of oxygen and phosphorus are shown along the horizontal axis. The C1–G24 end of the helix is on the left, and the G12–C13 end is on the right. Arrows indicate the position on the backbone of the DNA duplex where methyl or ethyl substitution occurs. The structure of the oligonucleotide double helix alone was obtained utilizing water molecules to solvate the molecule and neutralizing counterions; a dielectric constant of unity was used in this particular calculation.



the binding site is substantially increased by the insertion of drug into the groove and the extent of widening is larger for complexes containing methyl or ethyl substituents. Clearly, the latter effect is the result of the substituted piperazine ring. The effect is also manifested in the distance between the drugs and atoms of DNA at the floor of minor groove. For example, the distance of G16 N2 to C4′ of Hoechst 33258 is considerably shorter than that of G16 N2 to C4′ of methyl- or ethyl-Hoechst 33258, in particular in the ATTC-a mode. It is noteworthy in examining the components of docking energy for the complexes in Table 2, that both components are reduced in the case of the methylated or ethylated drug, a phenomenon that correlates with an increase in the distance between the drug and DNA.

Comparison of the distortion energy of DNA and drug upon complex formation reveals that deformation of the drugs is substantially smaller than that of DNA for the three drug complexes in the three different binding modes. In view of the large variation of DNA distortion energy, it is perhaps more reliable to use only the docking energy in evaluating the affinity of drug to DNA. From the docking energy shown in Table 1, it is clear that the difference among the three binding modes is insignificant for methyl or ethyl analogues. This can be rationalized by the deeper electronegative potential well for the minor groove of the A,T-rich stretch of B-DNA, so that electrostatic energy is larger for the AATT site. In the case of methylated and ethylated Hoechst 33258, the difference in the electrostatic term is by and large offset by the vdW term. Notably, due to the bulkiness of the piperazine group the drug does not penetrate as deeply into the groove for the complex in which the piperazine ring is parallel to the floor of the minor groove (cf. ATTC-a and ATTC-b in Table 1). Consequently, both vdW and electrostatic terms are smaller. The difference is significant as the bifurcate hydrogen bond between each of the peptidyl hydrogens of netropsin and N3 of adenine or O2 of thymine amount to 3 kcal mol^{-1}.[2] The effect of introducing methyl or ethyl groups into the piperazine ring of the drug can also be observed in Figs. 4, where the width of the minor groove of the DNA duplex was measured. The widening of the minor groove at the point of substitution is evident. From the energetic and geometric consequences presented here, it is clear that introduction of a bulky moiety into the minor groove binder can be used to reduce AATT specificity while ATTC specificity is enhanced. It may be possible to combine the present approach, taking advantage of local differences in geometry of the minor groove, with the substitution of an aromatic or aliphatic heterocyclic group such as imidazole replacing the pyrrole ring to switch recognition from AT to GC. It is also clear that the potential hydrogen bond between the piperazine nitrogen and the guanine amino hydrogen does not play a dominant role in shifting the binding site to GC since the electrostatic energy is smaller for a complex in the ATTC binding mode than in the AATT mode and the decrease in the vdW term of interaction energy is greater in the AATT than in the ATTC mode when a methyl or ethyl group is introduced into the piperazine ring. Table 1 also shows that the complexes of methylated and ethylated drugs are more stable in the ATTC-b mode than in the ATTC-a mode.

According to computational (21 and footnote 2), spectroscopic (23), and thermodynamic (24) data on several systems involving minor groove interaction, the binding energy for the GC-rich region as binding site is invariably smaller than for

[2] D.-K. Chang and T.-L. Chien, unpublished results.

[b]The values are relative to the reference AATT-a.

the AT-rich region. For example, netropsin has a higher binding affinity than the analogues, which are shown to be less AT specific (24). This is probably due to the deep electronegative potential for the narrow B-DNA minor groove formed by the AT cluster and to the fact that the amino group in the guanine base reduces the electrostatic potential of the minor groove. The design of a DNA sequence-specific minor-groove binding drug is made more complicated by the fact that DNA is not rigid, i.e., it possesses a local degree of freedom so that a small adjustment in atomic position is easily achieved to facilitate ligand binding (25). Thus, it was noted that the difference in the vdW term is small for netropsin binding to the AATT site relative to the GGCC site.[2] This can be explained by the observation that there is a small change in propeller twist for the guanine amino group to avoid steric clash with the hydrogen atom of the pyrrole ring of netropsin (25). The replacement of pyrrole by imidazole ring, so that the extra nitrogen can form a favorable hydrogen bond with the guanine amino group to enhance GC preference, is partially offset by the shallower electrostatic potential in the minor groove of the GC base pair. In the present study, bulky groups were used to render one portion of the drug more favorable to the GC site or less AT-preferable. The basis for this change is the fact that the GC base pair provides a wider minor groove, which better accommodates the bulkier substituent groups so that penetration of the drug containing bulky substituents is deeper, as shown in Table 1. Our results also demonstrate the correlation between vdW and electrostatic interaction energies. The bulky groups can be introduced into molecular chains consisting of charged groups, aromatic rings, and peptidyl linkers, as well as hydrocarbon spacers. The importance of length of the latter has been reported by Greenidge et al. (26).

Conclusion

Using the molecular mechanics method, the energy of various structures of Hoechst 33258 complexed with d(CGCGAATTCGCG)$_2$ was computed and compared. It was found that the bulky piperazine ring reduced AT specificity considerably owing to steric hindrance of substituted derivatives by the narrow minor groove in the AT-rich region of B-DNA. While Hoechst 33258 exhibits some tolerance for the GC base pair, docking energy for the methyl and ethyl analogues is essentially the same for the three binding modes studied in the present study. Van der Waals interaction can thus be utilized to aid in the design of sequence recognition of minor groove binders for B-DNA. The importance of the vdW term in determining AT/GC preference lies, apparently, more in the exclu-

Abstract: The photochemistry in methanol of the esters **12***a–d* has been studied in order to determine the importance of internal return of both ion pair and radical pair intermediates. The efficiency of internal return, determined by monitoring ^{18}O exchange between the alcohol and carbonyl oxygens, was shown to be substituent dependent, varying from approximately 10% for the 4,7-dimethoxy substrate to nearly 50% for the 4-cyano case. The corresponding ground state solvolysis reactions gave about 10% internal return and, within experimental error, were substituent independent. Internal return was also examined by racemization of the chiral center in **12***a* and **12***d*. In summary, these combined results reveal that internal return probably occurs mainly through a contact (not solvent-separated) radical pair. More important, internal return has little effect on previously calculated electron transfer rate constants for converting the radical pair to the ion pair. Therefore, the previously reported Marcus' correlations are valid.

Key words: photochemistry of benzylic esters, internal return, photosolvolysis, electron transfer, radical pairs.

Résumé : Afin d'évaluer l'importance du retour interne de la paire d'ions et de la paire de radicaux intermédiaires, on a étudié la photochimie des esters **12***a–d* dans le méthanol. On a montré que l'efficacité du retour interne, tel que déterminé par une évaluation de l'échange du ^{18}O entre les oxygènes de l'alcool et du carbonyle, dépend de la nature du substituant et qu'il varie d'approximativement 10% pour le substrat 4,7-diméthoxylé à pratiquement 50% dans le cas du dérivé 4-cyano. Les réactions de solvolyse à l'état fondamental conduisent à environ 10% de retour interne et, dans les limites des erreurs expérimentales, elles ne dépendent pas de la nature des substituants. On a aussi étudié le retour interne par un examen de la racémisation du centre chiral des composés **12***a* et **12***d*. En résumé, les résultats combinés révèlent que le retour interne se produit principalement par le biais d'une paire de radicaux en contact (non séparés par le solvant). Il est très important de noter que le retour interne ne provoque que de faibles effets sur les constantes de vitesse de transfert d'électron calculées antérieurement pour la conversion de la paire de radicaux en paire d'ions. On peut en conclure que les corrélations rapportées antérieurement par Marcus sont valides.

Mots clés : photochimie, esters benzyliques, retour interne, photosolvolyse, transfert d'électron, paires de radicaux.

Introduction

Recently, we reported detailed (1–3) studies on the photochemistry in methanol of arylmethyl esters, **1**, of aliphatic carboxylic acids. The observed products and the resulting mechanism are shown in Scheme 1. The major products from these reactions are arylmethyl ethers, **2**, along with the corresponding carboxylic acid, **3**, resulting from photosolvolysis, and coupling products, **4**, **5**, and **6**, resulting from loss of CO_2.

The products **2** and **3** are clearly derived from the ion pair whereas the products **4**, **5**, and **6** are derived from the radical pair. Product yields as a function of the variation of Ar (substituent effects (1, 3), and phenyl (3) versus 1-naphthyl (1)) and R (CH_3, 1°, 2°, 3°, benzyl) (2, 3) are rationalized by a pathway dominated by homolytic cleavage of the acyl oxygen – arylmethyl carbon bond in the excited singlet state ($k_R^S \gg k_I^S$ in Scheme 1). This excited state process is followed by ground state competition between electron transfer (k_{ET}) that converts the radical pair to the ion pair, decarboxylation (k_{CO_2}) of the acyloxy radical, and diffusional escape (k_D) of the radical pair from the solvent cage. Values of k_{ET} range from $\sim 10^7$ s^{-1} to 6×10^{10} s^{-1} and were shown (1, 3) to follow Marcus' theory in both the normal and inverted regions. Values of k_{CO_2} range from $\sim 10^9$ s^{-1} for $R = CH_3$ up to 11×10^9 s^{-1} for $R = C(CH_3)_3$.

A concern during the development of this mechanistic scheme was the possibility that internal return could be an important pathway. There are two possible internal return pathways: internal return to the ground state of the ester by collapse of the radical pair with rate constant k_{IR}^R in Scheme 1 and the corresponding internal return of the ion pair, k_{IR}^I.

Qualitatively, examination of Scheme 1 reveals two very different possibilities. In the first case, $k_R^S \gg k_I^S$; i.e., only

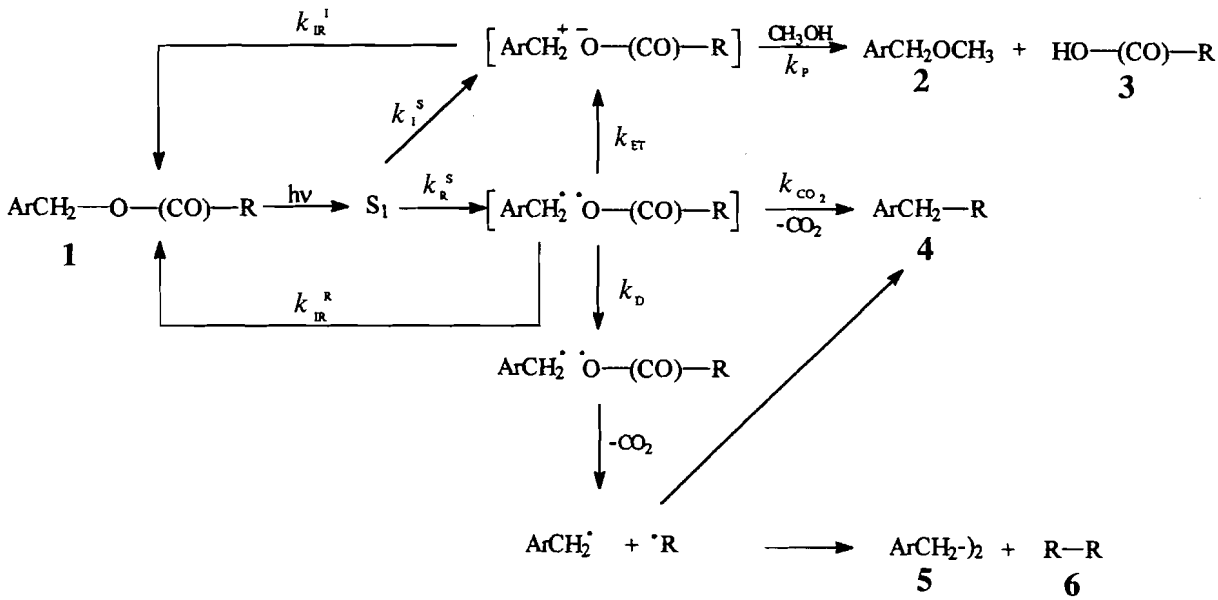
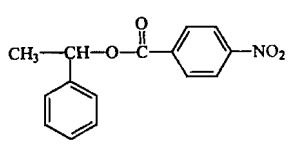
Scheme 1. General mechanism for the photoreactivity of arylmethyl esters in methanol.



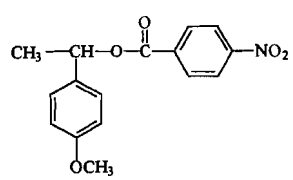
homolytic cleavage of the excited singlet state occurs. Therefore, internal return of the radical pair only decreases the efficiency of product formation and does not alter the partitioning of the radical pair to products. Product yield ratios will still be a reliable measure of k_{ET}, k_{CO_2}, and k_D. On the other hand, internal return of the ion pair will selectively reduce the yield of the ether **2**. Therefore, the value of k_{ET}, determined from that yield, will be lower than the correct value. If the efficiency of this internal return is substituent dependent then the previously reported variation of k_{ET} as a function of substituents is also in error. The correlation with Marcus' theory might then also be incorrect.

The second possibility, from Scheme 1, is that k_R^S and k_I^S are competitive, i.e., both homolytic and heterolytic cleavage of the excited singlet state occur. In this case, either radical pair or ion pair internal return will alter the product distribution. The mechanistic scheme and kinetic analysis are now quite complicated and obtaining reliable values of k_{ET} and k_{CO_2} will be difficult. These kinetic possibilities will be quantified in more detail later in the Discussion section of this paper.

Internal return is a well-established process in ground state solvolysis reactions and has been studied for a number of benzylic benzoates (4). For instance, solvolysis of **7** in 70:30 (v:v) acetone:water at 60°C revealed, by ^{18}O equilibrium between alkyl and carbonyl oxygens, that the rate of internal return is



7



8

76% that of the rate of solvolysis but that racemization is negligible. In contrast, for the more reactive 4-methoxy substrate, **8**, the rate of internal return is 57% that of solvolysis but, in this case, 70% of the internal return results in racemization. These effects are also solvent dependent. In 90:10 (v:v) acetone:water, a solvent of lower ionizing power, the rate of internal return for **8** is now 2.5 times as fast as solvolysis but only 45% of the internal return results in racemization. Detailed trapping studies by azide ion led to the conclusion that, for both substrates, internal return is from the contact ion pair and not the solvent-separated ion pair. Clearly, from these results, the extent of molecular motion in the contact ion pair is dependent on both solvent ionizing power and the stability of the benzylic cation.

Four papers on internal return for excited state benzylic cleavage reactions of esters have also been published and these will be briefly summarized.

Photolysis (5, 6) of **9** in 50% (v/v) methanol:water to 75% conversion resulted in recovered **9** that was 64% equilibrated by ^{18}O scrambling but with no loss of optical activity. In trifluoroethanol, photolysis to 85% conversion gave 100% equilibration and 19% racemization. The authors concluded that the ^{18}O scrambling in methanol is probably by a concerted migration of the benzylic cation from the alcohol oxygen to the carbonyl oxygen so that racemization is prevented. In trifluoroethanol, some ^{18}O equilibration is by an ion pair intermediate that also allows racemization. The radical pair was not invoked as an intermediate since the decarboxylation rate constant of the acyloxy radical at $\sim 10^9$ s^{-1} was stated to be too large to allow internal return.

As reported by Givens et al. (7, 8), photolysis of **10** in dioxane to 50% conversion resulted in recovered ester that was 35% equilibrated by ^{18}O labelling. No racemization was observed. In this non-nucleophilic solvent, no photosolvolysis is possible and only hydrocarbon dimers analogous to **4**, **5**, and **6** are formed. Clearly only radical pair intermediates are important in this case. In the same paper, photolysis of **11** in methanol to 53% conversion was reported to give neither ^{18}O equilibration nor *trans* to *cis* isomerization. In contrast, the product, 1,2-diphenylcyclopropane, was formed as a mixture of *trans* and *cis* isomers. No photosolvolysis products were detected so radical pair intermediates were the only ones considered. Based on these results, Givens et al. also proposed that ^{18}O equilibration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12

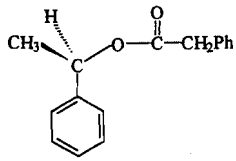
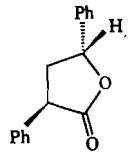
9



10

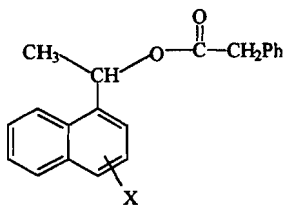


11

occurs by a concerted migration that prevents stereochemical isomerization. For **11**, the concerted migration is geometrically impossible so that even ^{18}O equilibration stops.

To simplify the discussion that follows, no distinction will be made between a "concerted" (5, 7, 8) pathway for ^{18}O exchange and a pathway involving a contact radical pair, which would presumably also allow exchange but not have enough rotational freedom to allow racemization. An experimental distinction between these two mechanistic pathways is probably not currently possible.

On the basis of these results, which are fragmentary but, nevertheless, do show that internal return is competitive with reaction, a systematic study of internal return in photochemical reactions of benzylic esters as a function of substituents seemed necessary.



12*a*, X=H
12*b*, X=4-OCH_3
12*c*, X=4,7-Di-OCH_3
12*d*, X=4-CN

We report here results for the photochemistry in methanol of four esters, **12*a–d***. These were chosen to allow a simultaneous study of both ^{18}O equilibration and racemization. As with our previous studies (1, 3), the substituents were chosen so that that the incipient 1-naphthylethyl radicals span a range of oxidation potentials that includes both the normal and inverted regions of the Marcus' correlation for the electron transfer rates that convert the radical pair to the ion pair. For comparison, ground state solvolysis results for **12b** and **12c** are also reported.

Results

Syntheses of esters 12*a–d*

Four substituted 1-(1-naphthyl)ethyl phenylacetates, **12*a–d***, were synthesized from the corresponding alcohols. The alcohols were prepared by reaction of the aldehydes with either methyllithium or methyl magnesium iodide. Details are given in the experimental section. The 4,7-dimethoxy alcohol is quite unstable and difficult to isolate and purify. By ^1H NMR, the major products of its decomposition are probably two diastereomeric dimers, $ArCH(CH_3)—O—CH(CH_3)Ar$, although no molecular ion corresponding to these dimers was detected by mass spectrometry. Fragmentation to the arylethyl cation, the observed base peak, is presumably too facile. The dimer assignment was made on the basis of the absence of an OH stretch in the IR spectrum and the similarity between the NMR spectra of these mixtures and the alcohol itself.

Syntheses of ^{18}O enriched esters 12*a–d*

The preparation of the labelled esters followed the same procedure as above except that the precursor aldehydes were first equilibrated in ~10% ^{18}O water (Aldrich) – dioxane. The total amount of ^{18}O incorporated is shown in Table 1 as the 0% conversion values. These were calculated using a computer program[2] that corrects the experimentally measured M, M + 1, and M + 2 peak intensities in the mass spectrum for the natural abundance of all isotopes of the molecular formula. The synthetic procedure should specifically enrich the alkyl oxygen of the ester with ^{18}O. Some initial experiments were attempted to see if this premise could be confirmed by mass spectrometry. The unsubstituted ester ($M^{+\cdot}$ = 290) has a fragment ion at m/z = 172 ($C_{12}H_{12}O$) corresponding to the alcohol of the ester and containing only the oxygen where the excess ^{18}O was expected. However, the ^{18}O content of this oxygen was only about 50% of the total. As demonstrated below, this ^{18}O equilibration is occurring in the mass spectrometer after formation of the radical cation. A detailed study of the fragmentations–rearrangements occurring in the mass spectra of these esters is in progress.[3]

Because of this difficulty, the esters were reduced with $LiAlH_4$ to substituted 1-(1-naphthyl)ethanols and 2-phenylethanol. Each alcohol now contains only one oxygen of the ester, the former the alcohol oxygen and the latter the carbonyl oxygen. The ^{18}O content of these alcohols was then measured, without prior separation, by GC–MS using selected ion monitoring of the M, M + 1, and M + 2 peaks for each. For each sample, two injections were made and five mass spectra were taken across the GC peak. These values, given again as 0% conversion, are in Table 1 for both the alkyl oxygen, the carbonyl oxygen, and the sum of the two. This independently determined sum agrees very well with the value for the ester before hydride reduction and confirms that the synthetic esters are selectively ^{18}O enriched at the alcohol oxygen.

Syntheses of optically active esters 12*a* and 12*d*

These optically active esters were prepared from the corresponding alcohols as before. The alcohols were prepared by reduction of 1-acetonaphthones with (+)-DIP-chloride. By analogy with literature results (9) for 2-acetonaphthone, acetophenone, and 4-cyanoacetophenone, these reductions should give the *R* enantiomer with high enantiomeric excess (96–98%). Initially, we attempted to determine the enantiomeric excess of the alcohols by ^1H NMR using the chiral shift reagent, $Eu(hfc)_3$. This worked well for the unsubstituted case, which gave good resolution of the methyl signal and some of the aromatic hydrogens. The enantiomeric excess was greater than 98% since signals for the other enantiomer could be easily

detected after addition of only 4% of the racemic alcohol to the enantiomerically enriched material. Unfortunately, samples of the alcohol obtained after hydride reduction of the optically active ester gave very broadened ^1H NMR signals and poor resolution of the protons of the individual enantiomers. The 4-cyano alcohol also gave unresolved signals in the ^1H NMR.

Because of these difficulties, optical activities were used to measure photochemical racemization. Values for the esters, at 0% conversion, are given in Table 2.

Photolyses of esters 12*a–d* in methanol

The esters were photolyzed in nitrogen-purged methanol using a Pyrex-filtered 200 W medium-pressure Hanovia mercury lamp. For preparative runs the irradiations were continued until more than 90% of the starting material (as determined by HPLC) was consumed. The photoproducts were then separated and their structures determined by spec-

[d]These values were determined by the areas of the peaks on the HPLC trace assuming equal instrument response for each by UV absorbance at 280 nm.

troscopic methods using ^1H and ^{13}C NMR and GC–MS. As shown in eq. [1],

[1] $$\underset{\mathbf{12}a\text{–}d}{ArCH(CH_3)—O—(CO)CH_2Ph} \xrightarrow[CH_3OH]{h\nu} \underset{\mathbf{13}a\text{–}d}{ArCH(CH_3)OCH_3} + \underset{\mathbf{14}a\text{–}d}{ArCH(CH_3)CH_2PH} + \underset{\mathbf{15}c}{[ArCH(CH_3)]_2}$$

the major products are the ether **13** and the in-cage coupling product **14**. For the 4,7-dimethoxy ester, a significant yield of the out-of-cage dimer **15** was also obtained. For quantitative runs, the esters were only irradiated to about 50% conversion and the yields of the products then obtained by calibrated HPLC. Values for these yields are given in Table 3.

Photolyses of alcohol oxygen ^{18}O-enriched esters

In these experiments, the esters were photolyzed to between 43 and 88% conversion. After evaporation of the methanol, the reaction mixture, dissolved in dichloromethane, was extracted with 5% aqueous NaOH to remove phenylacetic acid, and the neutral reaction mixture containing photoproducts and unreacted ester was then reduced in ether with $LiAlH_4$. The resulting alcohols were then analyzed by GC–MS for ^{18}O content. The values are given in Table 1. For the 4,7-dimethoxy ester, **12c**, the reduction product, 1-(4,7-dimethoxy-1-naphthyl)ethanol, did not have an observable molecular ion by GC–MS. The signal at highest mass corresponded to loss of water and, therefore, also to loss of the ^{18}O. Because of this facile fragmentation, the ^{18}O content of this alcohol could not be determined and the values reported are assumed to be the difference between the total ^{18}O and that measured for the ^{18}O content of the carbonyl oxygen.

The definition of ^{18}O exchange in Table 1 requires some explanation. Since this process of ^{18}O exchange is a two-site exchange, -O- to -CO-, it can be treated in the same way as a racemization process between two enantiomers. This method of reporting the results for ^{18}O exchange is recommended in order to avoid the ambiguities in interpreting some of the values in the literature. Even before photolysis, there is some ^{18}O isotope in the -CO- oxygen from natural abundance and, consequently, the sample does not have an ^{18}O excess of 100% in the alcohol oxygen. In the enantiomeric case, the sum of the two forms is always 100% but in these ^{18}O exchange experiments most of the ester molecules are not isotopically enriched and have two ^{16}O isotopes. The sum of the two ^{18}O sites is therefore much less than 100%. "^{18}O excess" in the alcohol oxygen site in Table 1 is therefore reported as the difference between the two sites over the sum. If there is internal return, this value will decrease asymptotically, with percent conversion, toward 0%. "^{18}O exchange" in Table 1 is the measure of this equilibration. Thus, it is evaluated by the difference between ^{18}O excess at a given percent conversion divided by the original ^{18}O excess at 0% conversion. This value will increase asymptotically towards 100%. The data are summarized in Table 4 as the ratio of ^{18}O exchange to % conversion.

Ground state solvolyses of esters 12 in methanol

These experiments were used to assess the importance of internal return in ground state solvolysis reactions where only ion pair intermediates are possible. The ester was dissolved in methanol and left to react at room temperature until the ester was 50% consumed. Work-up, $LiAlH_4$ reduction, and GC–MS analysis as described above gave the results shown in Table 5 and summarized, along with those for photochemical ^{18}O exchange, in Table 4. Only the esters, **12***b* and **12***c*, with electron-donating groups reacted rapidly enough for these experiments to be possible. The unsubstituted compound, **12***a*, had not measurably reacted even on heating in methanol in a sealed tube for 7 days at 125°C.

Photolyses of optically active esters, 12*a* and 12*d*, in methanol

The same procedure for photolysis as described above was used. The esters were re-isolated by column chromatography and the optical activity determined by polarimetry. The values are given in Table 2.

Discussion

Product yields

The products from the photolysis in methanol of the esters, **12**, (eq. [1] and Table 3) will be discussed first. If the general mechanism for the photolysis of arylmethyl esters (Scheme 1) is correct, then the rate constant of a reaction pathway, either k_{ET} or k_{CO_2}, can be obtained from the ratio of products, eq. [2], where k_{ET}^0 is the electron transfer rate constant calculated with the assumption of no internal return, i.e., that both k_{IR}^I and k_{IR}^R are negligibly small.

[2] [Yield of ether **13**]/[Yield of **14** + **15**] = $[P_I]/[P_R]$

$$= k_{ET}^0/(k_{CO_2} + k_D)$$

The coupled product and the dimer are obtained from the decarboxylation pathway and the ether is obtained from the ion pair intermediate after the electron transfer from 1-(1-naphthyl)ethyl radical to phenylacetyloxy radical. The rate constant (4.6×10^9 s^{-1}) of decarboxylation for the phenylacetyloxy radical, from the previous work of Hilborn and Pincock (2), can be used as a "radical clock" to calculate k_{ET} from the product yields. The ratio of product yields and the calculated rate constants of electron transfer from eq. [2] are shown in Table 3. There is very good agreement between the values of k_{ET} obtained from the esters examined here and the previously reported values for the 1-naphthylmethyl esters (1). The rate of electron transfer is slow for the electron-withdrawing cyano group, passes through a maximum for the unsubstituted case, and then decreases again for the strongly electron-donating 4,7-dimethoxy case. This observation reinforces our previous conclusion that these rate constants for electron transfer follow Marcus' theory in both the normal and the inverted regions.

However, as mentioned in the Introduction, the general mechanism in Scheme 1 includes a pathway for internal return from the intermediate ion pair and (or) radical pair. If internal return processes are important and also vary significantly as a function of the substituents on the aromatic ring, then the calculated values of k_{ET} reported here and previously would be incorrect.

Internal return in the photolyses of 1-(1-naphthyl)ethyl esters by ^{18}O exchange

In each case, the labelled ester, in two separate runs, was photolysed to different percent conversions. As described in the Results, the unreacted ester was then reduced with lithium aluminum hydride and the ^{18}O content of the resulting alcohols determined by GC–MS (Tables 1 and 4). The results from these analyses clearly indicate that internal return is dependent on the substituents on the naphthalene ring, electron-withdrawing substituents increasing the efficiency of exchange. The ratio of ^{18}O exchange to % conversion varies from a low of 0.13 for the 4,7-dimethoxy substituted ester to a high of 0.95 for the 4-cyano one.

There are two possible pathways for this ^{18}O exchange in the photolysis. According to Scheme 1, the internal return can occur from the radical pair (k_{IR}^R) and (or) the ion pair intermediate (k_{IR}^I). Results from ground state solvolysis reactions can be used to assess the importance of ion pair internal return.

Internal return in the ground state solvolyses of 1-(1-naphthyl)ethyl esters by ^{18}O exchange

Because the ground state solvolysis mechanism includes only the ion pair intermediate, a comparison of the results for the ground state solvolysis with those for the photolysis was instructive. The assumption used in this analysis is that the ion pairs generated in the thermal and photochemical reactions would have comparable efficiencies of internal return. The

only compounds examined for solvolysis in the ground state were 1-(4-methoxy-1-naphthyl)ethyl phenylacetate, **12***b*, and 1-(4,7-dimethoxy-1-naphthyl)ethyl phenylacetate, **12***c*. For 1-(1-naphthyl)ethyl phenylacetate, **12***a*, thermal solvolysis was tried but the rate of solvolysis was too slow. This observation can be easily explained by an estimate of the time required for solvolysis of the unsubstituted compound compared to that for the 4-methoxy case. A Hammett value of ρ^+ of greater than -5 for the S_N1 solvolysis of benzyl tosylates with electron-donating substituents (10) along with a σ^+ value of -0.78 for the 4-methoxy substituent (11) give a calculated difference in reactivity between the unsubstituted and the 4-methoxy ester of approximately four orders of magnitude. In the methanol solvolysis of the 4-methoxy ester, the time for ~50% conversion was 8 days; the time for the unsubstituted one would be approximately 80 000 days.

The same procedure and work-up as for the photolysis was carried out for the solvolysis reactions in the ground state. The results for **12***b* and **12***c* are shown in Table 5 and are also included in Table 4 as the ratio of ^{18}O exchange to % conversion.

In contrast to the results for the photolysis reactions, the ^{18}O exchange in the ground state solvolysis is, within experimental error, substituent independent, at least for the limited range of compounds studied. When the results from the photolysis and the solvolysis in the ground state are compared, internal return is seen to be mostly from the ion pair intermediate for 1-(4,7-dimethoxy-1-naphthyl)ethyl phenylacetate, **12***c*. In both the excited state and the ground state reactions, internal return is a minor pathway. In contrast, for 1-(4-methoxy-1-naphthyl)ethyl phenylacetate, **12***a*, the efficiency of internal return from the ion pair in the ground state is only about 50% of the total internal return in the excited state reaction. The other 50% of internal return in the photolysis is, therefore, probably by internal return from the radical pair or by the concerted migration. These results can perhaps be extended to the other esters, **12***c* and **12***d*. If internal return for the ion pair is relatively substituent independent, then the larger amounts of internal return observed in the photochemical reactions for the other cases do not reflect internal return in the ion pair. As mentioned in the Introduction, only internal return from the ion pair intermediate will change the calculated values of k_{ET}. Other pathways for internal return only decrease the quantum yield of product formation.

Internal return by racemization

Internal return by racemization was only studied for the 4-cyano and the unsubstituted esters, **12***a* and **12***d*. The results are shown in Table 2. For the 4-methoxy and 4,7-dimethoxy substrates, **12***b* and **12***c*, respectively, internal return by ^{18}O exchange has already been shown to be inefficient. Because the molecular motions required for internal return by ^{18}O exchange are always less than those required for racemization, the former process is always more efficient than the latter. Therefore, racemization results for **12***b* and **12***c* are unnecessary.

The results show that photolyses of the chiral esters to about 50% conversion result in recovered ester with about 20% racemization for the 4-cyano case, **12***d*, and between 5 and 10% for the unsubstituted case, **12***a*. For these same compounds, at the same percent conversion, ^{18}O exchange can be estimated at about 50% and 30%, respectively. These results imply that the intermediate(s) leading to internal return are not completely solvent separated since the racemization is less efficient than the ^{18}O exchange. The contact radical pair or the concerted process are the most likely possibilities.

Kinetic analysis of the effect of internal return on the determination of k_{ET} values

The quantitative effect of internal return on the calculated value of k_{ET} can be determined by a kinetic analysis using the steady state approximation for the ion pair and radical pair intermediates. Scheme 1 shows the possible pathways for the kinetic analysis. Equations [3] and [4] represent the rate of product formation from the intermediate ion pair and radical pair, respectively. The integrated ratio of these two equations gives the ratio of the two products from the two intermediates, $[P_I]/[P_R]$. Application of the steady state approximation for both the ion pair and the radical pair leads to eq. [5] where $\Sigma k = (k_D + k_{CO_2} + k_{ET} + k_{IR}{}^R)$ represents all the possible processes of the radical pair.

$$[3] \quad dP_I/dt = k_P[IP]$$

$$[4] \quad dP_R/dt = (k_{CO_2} + k_D)[RP]$$

$$[5] \quad [P_I]/[P_R] = \{k_{ET}/\Sigma k + k_I{}^S/k_R{}^S\}\{k_P/(k_P + k_{IR}{}^I)\}/\{k_{CO_2} + k_D)/\Sigma k\}$$

The three terms in braces in eq. [5] can be easily visualized. The first term in the numerator represents the sum of the efficiencies for formation of the ion pair from both the radical pair ($k_{ET}/\Sigma k$) and the excited singlet state ($k_I{}^S/k_R{}^S$), respectively. The second term in the numerator corrects for the possibility of internal return for that ion pair. The denominator ($\{(k_{CO_2} + k_D)/\Sigma k\}$) represents the efficiency of the radical pair proceeding to products. Simplification of this equation shows its generality.

First, if the excited singlet state only reacts to give the radical pair by homolytic cleavage because $k_R{}^S \gg k_I{}^S$ and if there is no internal return from the ion pair because $k_P \gg k_{IR}{}^I$, then eq. [5] becomes eq. [2]. Second, if internal return is occuring so that k_P and $k_{IR}{}^I$ are competitive, then eq. [6] results.

$$[6] \quad [P_I]/[P_R] = \{k_{ET}/(k_{CO_2} + k_D)\}\{k_P/(k_P + k_{IR}{}^I)\}$$

These two equations can be used to assess the effect that internal return from the ion pair has on the calculated k_{ET} values. Dividing eq. [6] by eq. [2] and rearranging gives eq. [7].

$$[7] \quad k_{ET} = k_{ET}{}^0(1 + k_{IR}{}^I/k_P)$$

The calculated k_{ET} values can now be directly related to the efficiency of internal return: ^{18}O exchange/% conversion = $k_{IR}{}^I/k_P = 0.1$, $k_{ET} = 1.1k_{ET}{}^0$; $k_{IR}{}^I/k_P = 1.0$, $k_{ET} = 2k_{ET}{}^0$; $k_{IR}{}^I/k_P = 10$, $k_{ET} = 11k_{ET}{}^0$.

From the results reported above, the highest efficiency of internal return occurs for the 4-cyano ester, **12***d*, with the ratio of ^{18}O exchange to % conversion of 0.95. Therefore, the maximum deviation possible for the previously calculated k_{ET} values from the correct ones is a factor of two. Moreover, the ground state solvolyses results suggest that most of the internal return is not from the ion pair. Therefore, the difference is probably much less than this maximum possible factor of two.

Finally, the Marcus' plots we reported previously (1, 3) are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

plots of log k_{ET} versus the oxidation potential of the arylmethyl radical. The rate constants span two powers of 10. On this logarithmic scale, a difference of a factor of two, the maximum possible error for a calculated rate of electron transfer, would not significantly alter the observed correlations.

Experimental

General procedures

^1H and ^{13}C NMR spectra were obtained on an AC 250 F NMR spectrometer. Chloroform-*d* ($CDCl_3$) containing tetramethylsilane (TMS) as an internal standard was used as the solvent. Chemical shifts are reported in parts per million (ppm). Multiplicities are abbreviated as follows: s = singlet, d = doublet, dd = doublet of doublets, t = triplet, q = quartet, and m = multiplet. Infrared spectra were obtained on a Nicolet 205 FTIR spectrometer and frequencies are reported in wavenumbers (cm^{-1}). GC–MS analyses were done on a Hewlett Packard 5890 A GC 5970 with a mass selective detector. The column used was a 25 m × 0.2 mm 5% phenylmethyl silicone on fused silica with a film thickness of 0.25 μm. The carrier gas was helium. The temperature program used was 45°C (2.6 min), 45–250°C (10.25 min), and 250°C (17.15 min). Masses are reported in units of mass over charge (m/z). Intensities are reported as a percent of the base peak intensity. The molecular ion is indicated by $M^{+\cdot}$. HPLC analyses were obtained with a Waters 6000 solvent delivery system and a Waters U6K injector under isocratic conditions with a flow rate of 2 mL/min using a Brownlee Lab Spheri-10 10 μm reverse-phase column (25 × 0.46 cm) with a Waters Model 450 variable wavelength detector. UV detection for monitoring the reactions was at 280 nm. Silica gel on polyester plates from Sigma were used for thin-layer chromatography (TLC). Silica gel 60 Å (70–230 mesh), purchased from the Aldrich Chemical Co., was used for column chromatography. Mass spectra were done by Dr. J. H. Kim, Dalhousie University, on a CEC 21–104 mass spectrometer run at 70 eV using a glass direct introduction probe and a source temperature of 110–120°C. Optical activities of chiral compounds were measured using a Perkin–Elmer 141 polarimeter at 589 nm (the sodium D line) at the National Research Council Laboratory, Halifax, Nova Scotia. Combustion analyses were carried out by Canadian Microanalytical Service Ltd., Delta, B.C., Canada.

The following compounds were purchased from the Aldrich Chemical Company: 1-acetonaphthone, 1-methoxynaphthalene, methyl iodide, methyllithium, phenylacetyl chloride, 10% $H_2{}^{18}O$, (+)-Dip-chloride, $Eu(hfc)_3$, and $AlCl_3$. The preparation of the substituted 1-naphthaldehydes has been described previously (1).

Syntheses of the 1-(1-naphthyl)ethanols

The alcohols required for the corresponding esters were synthesized by the following methods.

1-(1-Naphthyl)ethanol

To a suspension of magnesium metal (7.68 mmol, 20% excess) in anhydrous ether (3 mL) was added dropwise methyl iodide (7.68 mmol, 20% excess) in ether (3 mL). Then 1-naphthaldehyde (6.40 mmol) in ether (5 mL) was added and the reaction mixture stirred for 3 h at room temperature under nitrogen. Saturated aqueous ammonium chloride (25 mL) was then added and the mixture was extracted with ether (2 × 25 mL) and dried with anhydrous magnesium sulfate. Column chromatography, using silica gel and a mixed eluent of ethyl acetate and hexane (10:90), gave a colourless oil (0.94 g, 85% yield); ^1H NMR ($CDCl_3$) δ: 8.14–8.10 (m, 1H), 7.90–7.86 (m, 1H), 7.78 (d, 1H, J = 8.1 Hz), 7.68 (d, 1H, J = 7.0 Hz), 7.56–7.45 (m, 3H), 5.68 (q, 1H, J = 6.6 Hz), 1.96 (s, 1H, exchangeable), 1.68 (d, 3H, J = 6.6 Hz); ^{13}C NMR ($CDCl_3$) δ: 141.5(C), 133.8 (C), 130.3 (C), 128.9 (CH), 127.9 (CH), 126.0 (CH), 125.6 (CH), 125.6 (CH), 123.2 (CH), 122.1 (CH), 67.0 (CH-O), 24.4 (CH_3).

(R)-(+)-1-(1-Naphthyl)ethanol

(*R*)-(+)-1-(1-Naphthyl)ethanol was prepared using the method of Singh (12). In a 3-necked flask, (+)-*B*-chlorodiisopinocampheylborane ((+)-DIP-chloride) (10.8 mmol, 10% excess) was dissolved in tetrahydrofuran (10 mL). Then, 1-acetonaphthone (9.87 mmol) in tetrahydrofuran (5 mL) was added dropwise and the solution was stirred at 0°C for 5 h under nitrogen. After another 5 h at room temperature, the solvent was removed under reduced pressure to give a brown oil. α-Pinene, liberated during the reaction, was collected in a cold trap by a vacuum pumping (~0.3 Torr, 15 h (1 Torr = 133.3 Pa)). The residue was dissolved in ether (50 mL) and diethanolamine (21.7 mmol) was added. The mixture was stirred for 2 h, filtered, and the solid washed with pentane (2 × 20 mL). The combined filtrate was concentrated to give the crude product. Column chromatography on silica gel gave a colourless oil (7.68 mol, 78% yield) with over 96% enantiomeric excess. The ^1H NMR of the purified alcohol was identical to that of racemic 1-(1-naphthyl)ethanol. The enantiomeric excess was determined by ^1H NMR analyses using the chiral shift reagent ($Eu(hfc)_3$).

1-(4-Methoxy-1-naphthyl)ethanol

In a 3-necked flask, 4-methoxy-1-naphthaldehyde (2.69 mmol) was stirred in tetrahydrofuran (5 mL) under nitrogen. Methyllithium (3.50 mmol, 30% excess) was added dropwise. The reaction mixture was then stirred at room temperature for 5 h. After adding 5% sodium bicarbonate (25 mL), the mixture was extracted with ether (2 × 25 mL). The organic layer was then washed with water (2 × 25 mL) and dried over anhydrous magnesium sulfate. The crude alcohol was a yellowish oil (2.13 mmol, 79.2% yield): ^1H NMR ($CDCl_3$) δ: 8.31–8.21 (m, 1H), 7.98–7.90 (m, 1H), 7.49–7.36 (m, 3H), 6.65 (d, 1H, J = 7.9 Hz), 5.42 (q, 1H, J = 6.6 Hz), 3.89 (s, 3H), 2.97 (s, 1H, exchangeable), 1.58 (d, 3H, J = 6.6 Hz); ^{13}C NMR ($CDCl_3$) δ: 155.0 (C), 132.0 (C), 131.7 (C), 126.2 (CH), 126.0 (C), 124.9 (CH), 124.1 (CH), 123.7 (CH), 122.6 (CH), 103.4 (CH), 71.7 (CH-O), 55.5 (OCH_3), 24.1 (CH_3).

1-(4,7-Dimethoxy-1-naphthyl)ethanol

This compound was prepared from the aldehyde using the same procedure as described previously for 1-(4-methoxy-1-naphthyl)ethanol. The resulting alcohol was a yellowish oil that could not be purified using column chromatography due to its instability on silica gel; IR (neat): 3400 (O-H), 2960, 2940, 2805, 1625, 1591, 1455, 1430, 1223, 1094, 1034 (C-O), 815 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 8.18 (d, 1H, J = 9.9 Hz), 7.39 (d, 1H, J = 9.9 Hz), 7.36 (s, 1H), 7.08 (dd, 1H, J = 9.6 Hz, 3.0 Hz), 6.55 (d, 1H, J = 9.0 Hz), 5.38 (q, 1H, J = 6.6 Hz), 3.89 (s,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

3H), 3.83 (s, 3H), 2.47 (s, 1H, exchangeable), 1.56 (d, 3H, $J = 6.6$ Hz).

1-(4-Cyano-1-naphthyl)ethanol
This compound was prepared from 4-cyano-1-naphthaldehyde using the same method as that for 1-(1-naphthyl)ethanol (92% yield). The alcohol was chromatographed using a mixed solvent of ethyl acetate and hexane (25:75) as an eluent to give pale yellow crystals: mp 109–110°C; ^{1}H NMR ($CDCl_3$) δ: 8.19 (m, 1H), 8.08 (m, 1H), 7.85 (d, 1H, $J = 7.6$ Hz), 7.75 (d, 1H, 7.6 Hz), 7.68–7.57 (m, 2H), 5.67 (q, 1H, $J = 6.0$ Hz), 2.52 (s, 1H, exchangeable), 1.63 (d, 1H, $J = 6.6$ Hz); ^{13}C NMR ($CDCl_3$) δ: 147.9 (C), 132.6 (C), 132.6 (CH), 129.7 (C), 128.1 (CH), 127.6 (CH), 126.0 (CH), 123.7 (CH), 121.2 (CH), 118.0 (CN), 109.5 (*C*-CN), 66.7 (C-OH), 24.8 (CH_3).

4-Cyano-1-acetonaphthone
Following the method of Jacobs *et al.* (13), acylation of 1-bromonaphthalene using acetyl chloride and aluminum chloride in carbon disulfide gave 4-bromo-1-acetonaphthone (75% yield). The bromide was converted to the nitrile (85% yield) according to the method of Friedman and Shechter (14) using CuCN in dimethyl formamide. Vacuum distillation of the crude ketone gave a yellow solid: bp 150°C at 0.3 Torr (lit.(14) bp 165–175°C at 2–4 Torr); ^{1}H NMR ($CDCl_3$) δ: 8.75–8.64 (m, 1H), 8.27–8.20 (m, 1H), 7.68 (dd, 2H, $J = 21.0$ Hz, 8.8 Hz), 7.60–7.54 (m, 2H), 2.67 (s, 3H).

(R)-(+)-1-(4-Cyano-1-naphthyl)ethanol
The same procedure as described previously for the preparation of (*R*)-(+)-1-(1-naphthyl)ethanol was used for the preparation of (*R*)-(+)-1-(4-cyano-1-naphthyl)ethanol. The ^{1}H NMR of the purified alcohol (65% yield) was identical to that found for 1-(4-cyano-1-naphthyl)ethanol.

General method for the preparation of esters 12*a–d*
To a solution of the corresponding alcohol (7.4 mmol) in benzene (20 mL) was added a solution of phenylacetyl chloride (8.2 mmol, 10% excess) and pyridine (1 mL) in benzene (10 mL). The solution was stirred at room temperature overnight. Water (20 mL) was added to this solution, then the separated organic layer was washed with 10% hydrochloric acid, 5% sodium hydroxide, and water. The organic layer was dried with anhydrous magnesium sulfate and the solvent was evaporated under reduced pressure to give the crude esters. The esters were chromatographed on silica gel with a mixed solvent of ethyl acetate and hexane as an eluent.

1-(1-Naphthyl)ethyl phenylacetate, ***12a***: Colourless oil; IR(neat): 3140–2950 (C-H), 1737 (C=O), 1257, 1237, 1158, 1069, 799 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 8.29–8.25 (m, 1H), 8.05–8.01 (m, 1H), 7.97 (d, 1H, $J = 8.1$ Hz), 7.75 (d, 1H, $J = 7.0$ Hz), 7.71–7.58 (m, 3H), 7.54–7.46 (m, 5H), 6.94 (q, 1H, $J = 6.5$ Hz), 3.89 (s, 2H), 1.90 (d, 3H, $J = 6.5$ Hz); ^{13}C NMR ($CDCl_3$) δ: 170.9 (C=O), 137.4 (C), 134.1 (C), 133.9 (C), 130.3 (C), 129.4 (CH), 129.0 (CH), 128.7 (CH), 128.5 (CH), 127.2 (CH), 126.4 (CH), 125.7 (CH), 125.4 (CH), 123.3 (CH), 123.3 (CH), 70.1 (CH-O), 41.8 (CH_2Ph), 21.8 (CH_3); MS: 290 (M^+, 29), 156 (13), 155(100), 154 (15), 153 (25), 152 (10), 91 (20). Preparative photolyses
For each photolysis, 300–400 mg of the ester was dissolved in 420 mL of sodium-distilled methanol. The solution, in an immersion well, was purged with nitrogen for 15 min before and during the irradiation. A Pyrex-filtered 200 W medium-pressure Hanovia mercury lamp was used as the light source. The progress of the reaction was monitored by HPLC using a mixed solvent of methanol and doubly distilled water (90:10). Irradiation was stopped when more than 90% of the ester was consumed. The solution was then concentrated under reduced pressure to ~10 mL, and water (20 mL) was added. The aqueous solution was extracted with dichloromethane (3×25 mL). The dichloromethane layer was washed with 5% sodium hydroxide (2 × 25 mL) and evaporated under reduced pressure

to give the photoproduct mixture. The aqueous alkaline layer was acidified with concentrated hydrochloric acid and extracted with dichloromethane (2 × 25 mL). Evaporation of the solvent gave phenylacetic acid.

Characterization of the photoproducts

The photoproducts were isolated by column chromatography and identified by ^1H and ^{13}C NMR and GC–MS.

1-(1-Naphthyl)ethyl methyl ethers, ***13***

X = H, ***13a***: ^1H NMR ($CDCl_3$) δ: 8.25–8.20 (m, 1H), 7.94–7.88 (m, 1H), 7.82 (d, 1H, J = 8.1 Hz), 7.58 (d, 1H, J = 10.7 Hz), 7.63–7.49 (m, 3H), 5.10 (q, 1H, J = 6.6 Hz), 3.36 (s, 3H), 1.66 (d, 3H, J = 6.4 Hz); ^{13}C NMR ($CDCl_3$) δ: 139.1 (C), 134.0 (C), 130.9 (C), 129.0 (CH), 127.9 (CH), 126.1 (CH), 125.9 (CH), 125.6 (CH), 125.5 (CH), 123.4 (CH); GC–MS, R_t = 11.0 min, 186 ($M^{+\cdot}$, 15), 172 (12), 171 (100), 156 (12), 155 (28), 153 (15), 152 (12), 128 (47), 127 (29), 63 (10).

Quantitative photolyses

The procedure for the quantitative photolysis was the same as that for the preparative photolysis. However, less than 50% of the starting material was converted into the products. The amount of the esters used for these analyses was 100–200 mg. A standard solution of each photoproduct was prepared using products that were previously isolated from the preparative photolysis. The photolysis samples and standards were analyzed by HPLC and the areas under the peaks of the photolysis samples were compared with those of the standards.

Method of ^{18}O isotope exchange

As an ^{18}O isotope source, ~10% ^{18}O-enriched water (Aldrich) was used. The following procedure is for the preparation of labelled 4-methoxy-1-naphthaldehyde.

In a 3-necked flask, the aldehyde (8.06 mmol) was dissolved in dioxane (10 mL), which had been purified by passing through a neutral alumina column. ^{18}O-labelled water (1.0 g, 55 mmol) was then added. The progress of ^{18}O isotope incorporation was monitored by GC–MS. The solvent was then evaporated under reduced pressure and dichloromethane (20 mL) was added. This solution was dried over anhydrous magnesium sulfate. The ^{18}O-labelled aldehyde was then purified (6.72 mmol, 83.3% yield) by chromatography on silica gel.

Preparation of ^{18}O-labelled esters

The ^{18}O-labelled aldehydes were used to prepare the esters by the same procedure as for the unlabelled esters.

Photolyses of ^{18}O-labelled esters and analytical determination of ^{18}O exchange

The ^{18}O exchange between the alcohol oxygen and the carbonyl oxygens of the esters was determined by analyzing the amount of ^{18}O incorporated in each oxygen. The labelled esters were photolyzed until ~50% of the starting material was converted into photoproducts. The same work-up procedure as that for preparative photolysis was done to obtain the photoproduct mixture. This mixture, containing the unreacted ester, was dissolved in anhydrous diethyl ether (10 mL) and excess lithium aluminum hydride was added. The mixture was then stirred at room temperature for 2 h. Saturated aqueous ether was then added dropwise to destroy any unreacted lithium aluminum hydride. The mixture was then filtered to remove the precipitate of lithium and aluminum hydroxides. The ether filtrate was washed with water and dried over anhydrous magnesium sulfate.

The ether layer was analyzed by GC–MS. The retention times of the two alcohols, substituted 1-(1-naphthyl)ethanol and 2-phenylethanol, were obtained using the standard GC–MS method. More accurate values of peak intensities were then obtained using "Selected Ion Monitoring (SIM)." The peaks corresponding to the two alcohols were analyzed and the amount of ^{18}O isotope was determined by the intensities of the ($M^{+\cdot}$, M + 1, M + 2) ions, taking five scans across the chromatographic peak. The numbers obtained from the GC–MS results were corrected to those reported here using a program that corrects for the natural abundance of all isotopes of the molecular formula.

Photolyses of optically active esters and determination of optical activities of the unreacted esters

Optically active ester (200–300 mg) was dissolved in 420 mL of sodium-distilled methanol and photolyzed until ~50% of starting material was consumed. The solution was concentrated and the carboxylic acid produced was separated by using simple extraction with 5% sodium hydroxide. The unreacted ester was isolated using column chromatography. The optical activity of these samples was measured using a Perkin–Elmer 141 polarimeter at 589 nm at room temperature. The average value from three readings is reported in Table 2.

Abstract: Excess molar volumes and excess viscosities, at 298.15 K, of the ternary mixtures (2-butanol + 1-chlorobutane + 1-butylamine) and (2-methyl-2-propanol + 1-chlorobutane + 1-butylamine) and of the binary mixtures (2-butanol + 1-butylamine), (2-methyl-2-propanol + 1-butylamine), and (1-chlorobutane + 1-butylamine) have been measured. The ternary excess properties were fitted to the polynomial equation of Cibulka. The experimental results were also compared with those predicted by the empirical equations of Redlich–Kister, Tsao–Smith, Kohler, and Colinet.

Key words: binary and ternary mixtures, excess properties, 2-butanol, 2-methyl-2-propanol, 1-chlorobutane, 1-butylamine.

Résumé : Opérant à 298,15 K, on a mesuré les volumes molaires en excès et les viscosités en excès des mélanges ternaires (butan-2-ol + 1-chlorobutane + 1-butylamine) et (2-méthylpropan-2-ol + 1-chlorobutane + 1-butylamine) et des mélanges binaires (butan-2-ol + 1-butylamine), (2-méthylpropan-2-ol + 1-butylamine) et (1-chlorobutane + 1-butylamine). On a ajusté les propriétés ternaires en excès à l'aide de l'équation binaire de Cibulka. On a aussi comparé les résultats expérimentaux à ceux prédits par les équations empiriques de Redlich–Kister, Tsao–Smith, Kohler et Colinet.

Mots clés : mélanges binaires et ternaires, propriétés en excès, butan-2-ol, 2-méthylbutan-2-ol, 1-chlorobutane, 1-butylamine.

[Traduit par la rédaction]

Introduction

In previous papers we reported the determination of some excess thermodynamic properties of several binary mixtures containing either isomers of butanol or a haloalkane (1–7). In this work, in addition to the binary mixtures, the V^E and η^E of ternary mixtures have been measured at the temperature 298.15 K in order to study the interactions between the OH, NH_2, and Cl groups.

Experimental section

Materials

The liquids used, 2-butanol (better than 99.5 mol%), 2-methyl-2-propanol (better than 99.5 mol%), 1-chlorobutane (better than 99.0 mol%), and 1-butylamine (better than 99.0 mol%), were obtained from Aldrich. The purity of the chemicals was checked not only by comparing the measured densities and viscosities with those reported in the literature but also by gas chromatography using a semicapillary methyl silicone column (o.d. 530 μm) and a flame-ionization detector. Analysis showed that the major peak area exceeds 99.8%. No further purification was considered necessary. The butanols were dried over activated molecular sieve, type 0.3 nm from Merck. Table 1 shows the experimental values of density and viscosity for the pure components at 298.15 K compared with those found in the literature.

Methods

Densities, ρ, of the pure components and the binary and ternary mixtures were determined with an Anton Paar DMA-58 vibrating tube densimeter, calibrated with deionized doubly distilled water and dry air. The uncertainty for the density measurements was $\pm 1 \times 10^{-5}$ g cm^{-3}.

Viscosities, η, of the pure components and the binary and ternary mixtures were determined by using an Ubbelhode

viscosimeter with a Schott-Geräte automatic measuring unit model AVS-440, for which the accuracy of the flow time measurement is ±0.01 s. Details of calibrations and procedures can be found in an earlier paper (3).

The compositions (mole fraction) of binary and ternary blends were determined directly by using a Mettler H20T balance. The uncertainty of the weighing was ±0.01 mg.

Results and discussion

The experimental results for the excess molar volumes and the excess viscosities of the binary mixtures (2-butanol + 1-butylamine), (2-methyl-2-propanol + 1-butylamine), and (1-chlorobutane + 1-butylamine) were fitted to a Redlich–Kister-type equation:

$$[1]\quad Y^E(x_i, x_j)/(\text{cm}^3\ \text{mol}^{-1}) = x_i x_j \sum_{p=0}^{p} A_p (x_i - x_j)^p$$

where $Y^E = V^E$ or η^E, x_i denotes the mole fraction of component i of an i,j mixture with $x_j = 1 - x_i$, and A_p are adjustable parameters by the unweighted least-squares method. In previous papers we determined the V^E and η^E of (alkanol + 1-chlorobutane) mixtures (5, 6). The coefficients A_p and the standard deviations are given in Table 2.

The excess molar volume and excess viscosity data for the binary mixtures are plotted in Figs. 1 and 2.

The excess molar volumes and excess viscosities for the ternary mixtures were fitted to the polynomial equation proposed by Cibulka (10):

$$[2]\quad Y^E_{123} = Y^E_{12} + Y^E_{13} + Y^E_{23} + x_1x_2x_3(B_1 + B_2x_1 + B_3x_2)$$

where Y^E_{ij} is the contribution to the excess property for the binary system i,j given by eq. [1]. The B_i parameters were calculated by the least-squares method. Table 3 presents the values of the B_i coefficients of eq. [2] and the corresponding standard deviations, σ, for the ternary systems. Curves of constant V^E_{123} and η^E_{123} for the ternary systems have been plotted in Figs. 3 and 4.

Also V^E and η^E for the ternary systems have been calculated using the empirical equations proposed by Redlich–Kister, Tsao–Smith, Kohler, and Colinet, which take only the binary contributions into account.

Redlich and Kister (11) proposed an expression to determine any excess property of a ternary mixture:

$$[3]\quad Y^E_{123} = x_1x_2\sum_{\nu=0}^{r}(Av)_{12}(x_1 - x_2)^\nu + x_1x_3\sum_{\nu=0}^{r}(Av)_{13}(x_1 - x_3)^\nu + x_2x_3\sum_{\nu=0}^{r}(Av)_{23}(x_2 - x_3)^\nu$$

where x_i is the mole fraction of component i, and $(Av)_{ij}$ are adjustable coefficients for the binary mixture i,j obtained by the least-squares method.

Tsao and Smith (12) proposed an equation for predicting the excess properties of a ternary mixture:

$$[4]\quad Y^E_{123} = x_2(1 - x_1)^{-1}Y^E_{12} + x_3(1 - x_1)^{-1}Y^E_{13} + (1 - x_1)Y^E_{23}$$

Fig. 1. Excess molar volumes V^E of binary mixtures at 298.15 K; 2-butanol + 1-butylamine (△), 2-methyl-2-propanol + 1-butylamine (□), and 1-chlorobutane + 1-butylamine (▲).

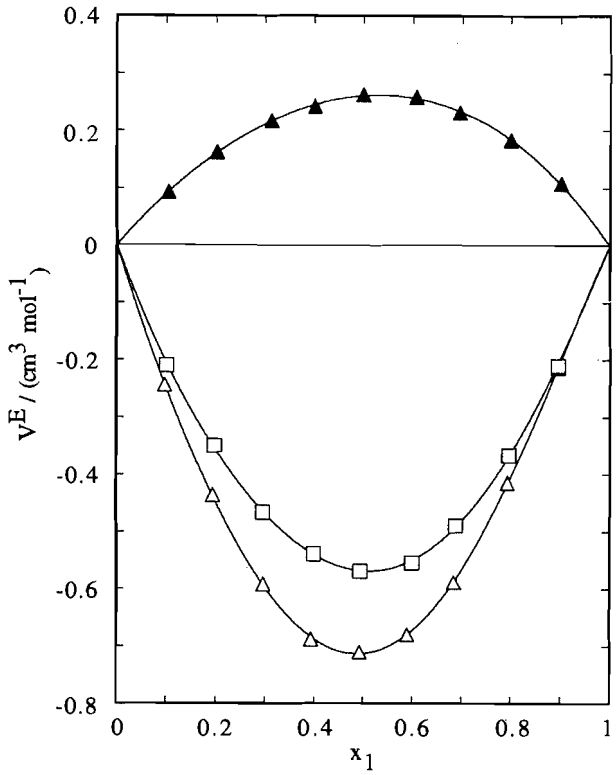

Fig. 2. Excess viscosities η^E of binary mixtures at 298.15 K; 2-butanol + 1-butylamine (△), 2-methyl-2-propanol + 1-butylamine (□), and 1-chlorobutane + 1-butylamine (▲).

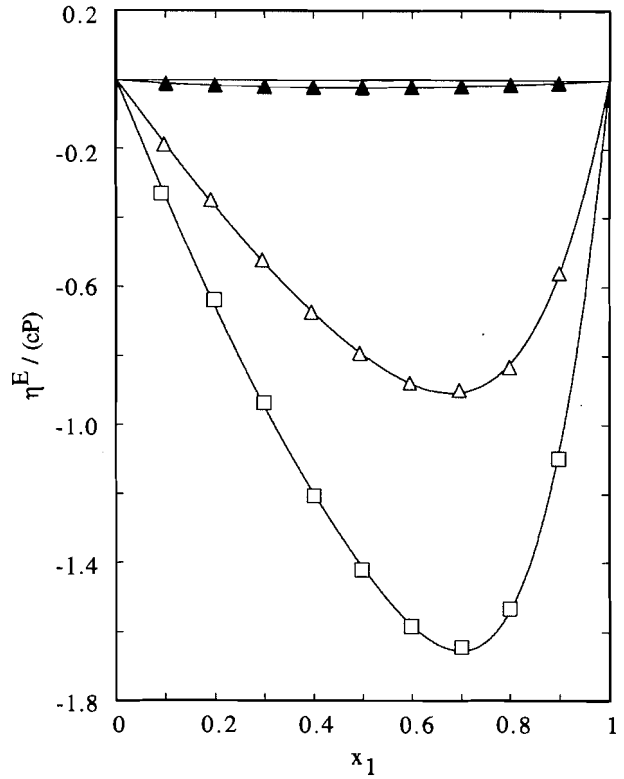

in which x_i is the mole fraction of component i, and Y_{ij}^E refers to the excess properties for the binary mixtures at compositions (x_i^0, x_j^0) such that $x_i^0 = x_1$ for the 1,2 and 1,3 binary systems and $x_j^0 = x_2/(x_2 + x_3)$ for the 2,3 binary system.

Kohler (13) proposed an equation for the excess properties of mixing of a ternary solution:

$$[5] \quad Y_{123}^E = (x_1 + x_2)^2 Y_{12}^E + (x_1 + x_3)^2 Y_{13}^E + (x_2 + x_3)^2 Y_{23}^E$$

in which x_i is the mole fraction of component i, and Y_{ij}^E refers to the excess property of the binary mixtures at a composition (x_i^0, x_j^0) such that $x_i^0 = 1 - x_j^0 = x_i/(x_i + x_j)$.

Coliner (14) established a slightly more complex relationship for expressing the thermodynamic excess properties of multicomponent systems:

$$[6a] \quad Y_{1,2\ldots n}^E = 0.5 \sum_{i=1}^{n-1} \sum_{j>1}^{n} x_i (1 - x_j)^{-1} (Y_{ij}^E)_{xj}$$

in which x_i is the mole fraction of component i, and Y_{ij}^E are calculated from the binary data at constant mole fraction x_j. This equation, although perfectly symmetrical, requires the addition of the thermodynamic properties at six different binary compositions for a ternary solution. In this way the following equation is obtained:

$$[6b] \quad Y_{123}^E = 0.5 \left[\frac{x_2}{1 - x_1} Y_{12}^E(x_1, 1 - x_1) + \frac{x_1}{1 - x_2} Y_{12}^E(1 - x_2, x_2) + \frac{x_3}{1 - x_1} Y_{13}^E(x_1, 1 - x_1) + \frac{x_1}{1 - x_3} Y_{13}^E(1 - x_3, x_3) + \frac{x_3}{1 - x_2} Y_{23}^E(x_2, 1 - x_2) + \frac{x_2}{1 - x_3} Y_{23}^E(1 - x_3, x_3) \right]$$

Table 4 presents the values of standard deviations, σ, of eqs. [3], [4], [5] and [6*b*] for the ternary systems.

The results of V^E for binary mixtures (2-butanol + 1-butylamine) and (2-methyl-2-propanol + 1-butylamine) are negative over the entire composition range, whereas for the system (1-chlorobutane + 1-butylamine) the V^E are positive over the entire composition range. The experimental ternary excess volumes are negative over the whole composition range except for mixtures with a high mole fraction of chlorinated compound for which V_{123}^E shows positive values. The diagrams showing the excess properties for the ternary systems (Figs. 3*a*, 3*b* and 4*a*, 4*b*) have the same shape, although the more negative values appear for the ternary system with 2-methyl-2-propanol.

In view of the results included in Tables 3 and 4 it can be observed that only the V^E obtained by applying the Cibulka equation fit the experimental values. The equations of Redlich–Kister (11), Tsao–Smith (12), Kohler (13), and Colinet (14) (which take only binary contributions into ac-

count) predict V^E values that are quite different from the experimental ones for the ternary mixtures (2-butanol + 1-chlorobutane + 1-butylamine) and (2-methyl-2-propanol + 1-chlorobutane + 1-butylamine); consequently the existence of strong interactions between OH–Cl–NH_2 groups in the ternary systems under study could be deduced. On the other hand, both the Cibulka equation and that of Tsao–Smith lead to good agreement with experimental values of η^E, as can be seen in Tables 3 and 4. These results tally with those reported by M.J. Souza et al. (15).

Knowing that V^E is the result of a sum of several effects, chemical, structural, and physical, these values would represent the breaking of the associated species formed through hydrogen bonds (namely, cyclic and noncyclic multimers in alkanols and noncyclic trimers in the amine (16)), and the subsequent formation of bonds of the same type between OH and NH_2 groups, processes that will yield a greater packing of molecules and therefore a negative excess volume for the mixture (alkanol + 1-butylamine). On the contrary, if a nonassociated compound (such as a chlorinated derivative) is added to the alkanols or the amine, the forceful association of these compounds is broken in such a way that an increase in disorder takes place, making the excess volume values positive. This same argument can be applicable to the V^E of ternary mixtures. Thus, the smaller the ratio of the chlorinated derivative, the more negative V^E will be, and in the reverse manner, an increase in the amount of 1-chlorobutane will be accompanied by a destruction of hydrogen bonds and a rise in excess volume that will become positive in the zone corresponding to a high mole fraction of chlorinated compound and low mole fractions for the other two components. On the other hand, the V^E values obtained for the ternary system with 2-butanol (secondary alkanol) are more negative than those obtained with 2-methyl-2-propanol (tertiary alkanol). This can be justified by means of structural effects. In fact, the ratio of cyclic multimers is larger in 2-methyl-2-propanol than in 2-butanol (17). Moreover, according to electrical information (18), the conversion from linear multimers to cyclic structures (with lower dipole moments) is more extensive for 2-methyl-2-propanol than for the other isomers of butanol. This could explain the volumetric behaviour of mixtures containing 2-methyl-2-propanol, assuming that linear structures occupy a smaller volume than the cyclic ones. Thus, the highest V^E values are expected for those systems in which 2-methyl-2-propanol is included.

The η^E obtained for the binary systems (alkanol + 1-butylamine) and (1-chlorobutane + 1-butylamine) are negative over the whole composition range; these results agree with those provided by Ramanjaneyulu et al. (19) for mixtures of (1-butylamine + cyclic hydrocarbons). The η^E obtained for the ternary systems studied are negative throughout, as well.

A negative excess viscosity indicates a greater facility to flow for the real mixture with respect to the ideal behaviour. This occurs when interactions between the molecules are stronger for the pure compounds than for their mixtures. In our case, the experimental results would suggest that interaction between different functional groups is weaker than that existing between identical groups (OH–OH and NH_2–NH_2). η^E is very close to zero for the mixture (1-chlorobutane + 1-butylamine). This would be caused by the interactions Cl–NH_2 (20), which would compensate for the breaking of hydrogen bonds in the amine. A remarkable asymmetrical distribution can be observed in the ternary mixtures. This distribution could be explained by the character of 1-chlorobutane as a breaker of structures, namely, of the hydrogen bonds of alcoholic and aminic components. The more negative η^E shown by 2-methyl-2-propanol might be a consequence of the greater facility for breaking of its multimers compared to that of mixtures containing 2-butanol.

Cyclometallation of bis(diphenylphosphino)methane ligands on a binuclear ruthenium(0) carbonyl complex

Hameed A. Mirza, Jagadese J. Vittal, and Richard J. Puddephatt

Abstract: The first example of simple orthometallation of a bis(diphenylphosphino)methane ligand at a binuclear centre is reported. Both dppm ligands of the binuclear ruthenium(0) complex $[Ru_2(CO)_5(\mu\text{-dppm})_2]$, **1**, are orthometallated when the complex is heated in benzene solution to yield the unusual complex $[Ru_2(CO)_4(Ph_2PCH_2PPhC_6H_4)_2]$, **2**. The structure of **2** was determined crystallographically (monoclinic, $P2_1/n$, a = 21.349(4), b = 12.209(5), c = 22.457(5) Å, β = 104.34(2)°, Z = 4, R, R_w = 0.0658, 0.0561) and the unusual cyclometallated complex was also characterized spectroscopically. The cyclometallation occurs in such a way that each ligand gives rise to two fused five-membered rings, RuRuPCP and RuRuPCC, fused at the Ru—Ru and Ru—P bonds.

Key words: ruthenium, bis(diphenylphosphino)methane, metallation.

Résumé : On rapporte le préparation du premier exemple d'une orthométallation simple d'un coordinat bis(diphénylphosphino)méthane à un centre binucléaire. Il se produit une orthométallation des deux coordinats dppm du complexe binucléaire du ruthénium(0) $[Ru_2(CO)_5(\mu\text{-dppm})_2]$, **1**, lorsqu'on chauffe le complexe en solution dans le benzène et il y a formation du complexe inhabituel $[Ru_2(CO)_4(Ph_2PCH_2PPhC_6H_4)_2]$, **2**. On a en déterminé la structure par diffraction des rayons X (monoclinique, $P2_1/n$, a = 21,349(4), b = 12,209(5) et c = 22,457(5) Å, β = 104,34(2)°, Z = 4, R = 0,0658 et R_w = 0,0561) et on a aussi caractérisé le complexe inhabituel cyclométallé par spectroscopie. La cyclométallation se produit d'une telle façon que chaque coordinate donne lieu à deux cycles condensés à cinq chaînons, RuRuPCP et RuRuPCC, condensés au niveau des liaisons Ru—Ru et Ru—P.

Mots clés : ruthénium, bis(diphénylphosphino)méthane, métallation.

[Traduit par la rédaction]

Introduction

Diphosphine ligands such as bis(diphenylphosphino)methane, dppm, are well known to stabilize and maintain the integrity of the metallic frameworks in binuclear or cluster complexes during chemical transformations (1). However, under forcing conditions, these ligands can be involved in C—P and (or) C—H bond cleavage reactions, thus forming phosphido (1, 2) and cyclometallated (3–5) complexes, respectively. Phosphido complexes may be formed by cleavage of either P—CH_2 or P—Ph bonds and cyclometallated complexes by activation of a C—H bond of either the CH_2 group or a phenyl group of a dppm ligand (1–5). Cyclometallation by activation of an *ortho* C—H bond of a phenyl substituent of a phenylphosphorus group constitutes an important example of orthometallation, a reaction that is very useful in metal–carbon bond-forming reactions with applications in both organometallic and organic synthesis (6). There are many examples of orthometallation of monodentate tertiary phosphine ligands such as PPh_3 (6, 7), but a much smaller number with diphosphine ligands (3–5, 8).

Because orthometallation of an arylphosphine at a mononuclear centre generates a strained four-membered MPCC ring, **A**, the reactions may be less favourable than in binuclear or cluster complexes where the stable five-membered rings, **B**, are found, for example, in the products of orthometallation of triphenylphosphine on binuclear rhodium complexes (6, 7). An excellent example of a reaction in which rearrangement of a mononuclear to binuclear complex occurs is found in the thermolysis of the mononuclear platinum complex [Pt(OH)(Me)(dppe)], dppe = $Ph_2PCH_2CH_2PPh_2$, to give the binuclear complex $[Pt_2(Ph_2PCH_2CH_2PPhC_6H_4)_2]$, containing the favourable five-membered MMPCC ring in **C** (8). Similar reactions with dppm are not known. There appears to be only one example of simple orthometallation of a dppm ligand, which occurs in the thermolysis of $[Os_3(CO)_{10}(dppm)]$ to give $[Os_3(CO)_8(\mu\text{-H})(Ph_2PCH_2PPhC_6H_4)]$ containing the functional group **D** (3). It is likely that similar reactions occur in other cluster complexes of dppm but the metal hydride formed combines with a phenyl substituent to eliminate benzene and so yield orthometallated phosphido ligands (4). For example, thermolysis of $[Ru_3(CO)_{10}(dppm)]$ gives binuclear and trinuclear complexes containing the functional groups **E** and **F**,

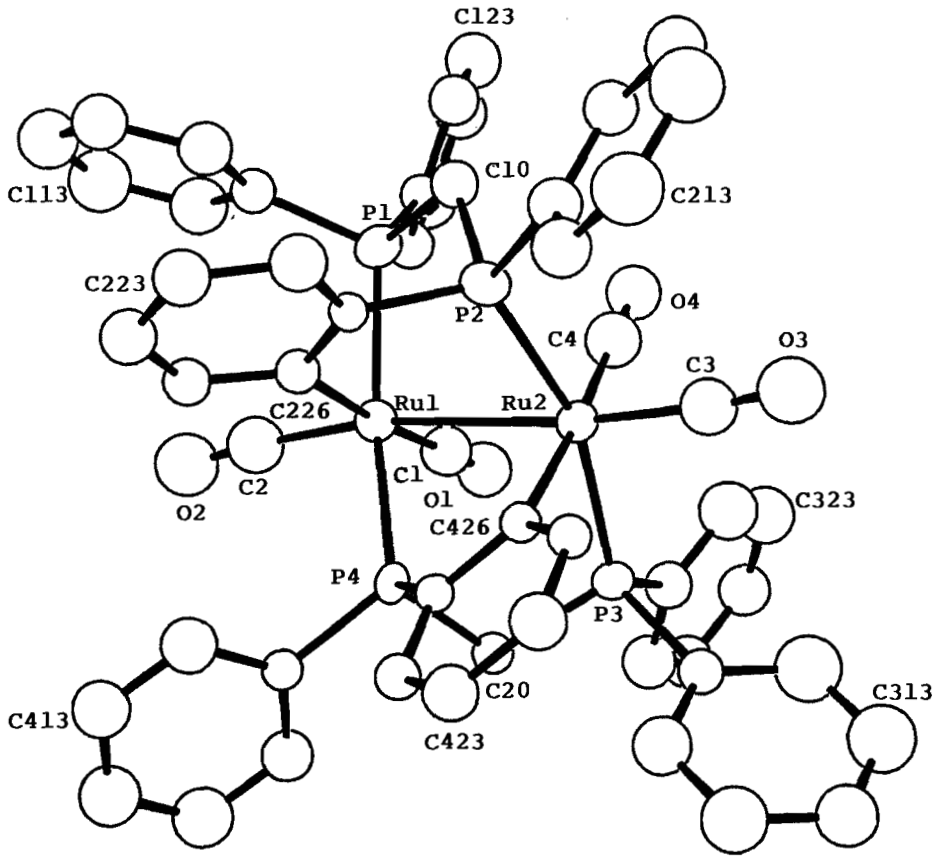
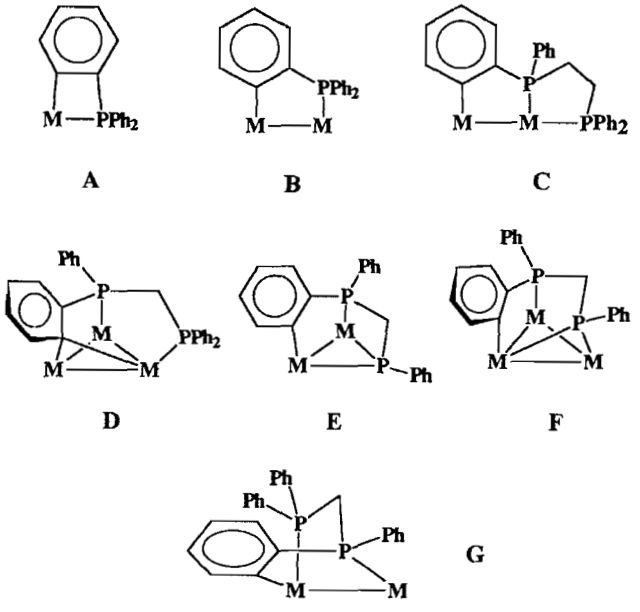
Fig. 1. A view of the structure of complex **2**. H-atoms are not shown.



respectively (4). Although a very large number of binuclear dppm complexes have been studied, there appear to be no reported examples of simple orthometallation reactions at a binuclear centre (1–4). Instead, P—CH_2, P—Ph, or P_2CH—H bond activation reactions occur either alone in or in combination with orthometallation (1–4).



This article reports the first example of simple orthometallation of a dppm ($Ph_2PCH_2PPh_2$) ligand at a binuclear centre to give the functional grouping **G**. In fact, both dppm ligands of the binuclear ruthenium(0) complex $[Ru_2(CO)_5(\mu\text{-dppm})_2]$, **1**, are orthometallated. The functional group **G** has recently been reported in two tetraruthenium clusters prepared, in each case as a component of a very complex mixture of products, by reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with the alkyne $MeO_2CC{\equiv}CCO_2Me$ and with benzyl bromide (6).

Results

Synthesis of the cyclometallated complex

When a solution of $[Ru_2(CO)_5(\mu\text{-dppm})_2]$, **1**, was heated under reflux in benzene under a nitrogen atmosphere for a period of 3 days, a dark orange-brown solution was obtained, from which the yellow crystalline product $[Ru_2(CO)_4(Ph_2PCH_2PPhC_6H_4)_2]$, **2**, was isolated in 45% yield. A possible reaction stoichiometry is shown in eq. [1], although it is not possible to identify the gaseous products under the experimental conditions used.

[1] $[Ru_2(CO)_5(dppm)_2]$

$$\rightarrow [Ru_2(CO)_4(Ph_2PCH_2PPhC_6H_4)_2] + CO + H_2$$

The same product is obtained when the reaction is carried out in the presence of one molar equivalent of $PhC{\equiv}CPh$ but the reaction is then appreciably faster, being complete in 20 h

in refluxing benzene. The role of the PhC≡CPh in this reaction is not clear; it does not appear to act as a hydrogen acceptor since analysis of the reaction mixture does not indicate the presence of stilbene among the products. The alkyne was added in an attempt to trap possible intermediates but no alkyne incorporation into the diruthenium unit was detected.

The structure of complex 2

The complex **2** was characterized by an X-ray structure determination. A view of the molecular structure is given in Fig. 1. Crystal data, selected positional parameters, and bond distances and angles are in Tables 1–3.

Each ruthenium centre has approximately octahedral stereochemistry, with bonds to two *cis* carbonyl ligands, two *trans* phosphine donors, the neighbouring ruthenium atom, and the orthometallated phenyl substituent of a diphosphine ligand. The Ru—Ru distance at 2.933(2) Å is within the bonding range (9) and is slightly longer than in the parent complex $[Ru_2(CO)_4(\mu\text{-}CO)(\mu\text{-}dppm)_2]$, **1**, which has Ru—Ru = 2.903(2) Å (10), while significantly shorter than in $[Ru_2(CO)_4(\mu\text{-}C_2H_2CO)(\mu\text{-}dppm)_2]$ with Ru—Ru = 2.988(1) Å (10). As expected for octahedral coordination, the atoms Ru(1)C(1)C(2)C(226)Ru(2) and Ru(2)C(3)C(4)C(426)Ru(1) are each approximately coplanar with only the carbonyl carbon atoms *trans* to the metal–metal bond lying more than 0.1 Å from the corresponding least-squares plane (C(2) by 0.32(2) and C(3) by 0.24(2) Å). The dihedral angle between the above two planes is 50.7(6)°, which clearly indicates a very significant twist. This large twist is clearly necessary to allow the orthometallated phenyl group on P(2) to bind to Ru(1), thus giving

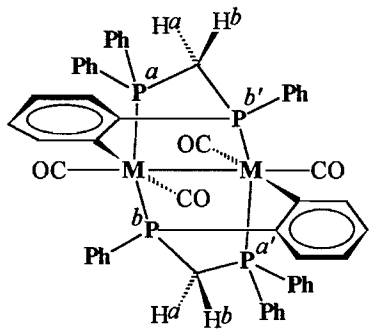
rise to two pairs of five-membered rings with the Ru(1)Ru(2) and Ru(2)P(2) bonds common to both, but it does appear to cause strain in the molecule. For example, the angle P(2)Ru(2)Ru(1) = 73.9(1)° and P(2)Ru(2)P(3) = 161.2(2)° are significantly distorted from the ideal octahedral angles. An alternative structure would have the orthometallated phenyl substituent on P(2) bind to Ru(2) but that would give a four-membered RuPCC ring, which would presumably be even more strained. It is interesting to note that both orthometallated phenyl rings are on the same side of the Ru2P4 plane; the molecules therefore have approximate C_2 symmetry and are chiral.



2

Spectroscopic properties of 2

The spectroscopic data for **2** are fully consistent with the crystallographically determined structure. The infrared spectrum contains four bands due to ν(CO) in the region 1989–1912 cm^{-1}, typical for terminal carbonyl groups.

The ^{31}P NMR spectrum in CD_2Cl_2 solution, shown in Fig. 2, exhibits an AA′BB′ pattern, as expected for structure **2**. Note that the nonequivalent phosphorus atoms P^a and P^b are mutually *trans* on the same ruthenium centre and so the coupling $^2J(P^aP^b)$ is expected to be large. Since the molecule **2** contains no plane of symmetry, the dppm methylene protons are expected to be nonequivalent. However, only one resonance, which appeared as an unsymmetrical multiplet at δ = 4.47, was observed (Fig. 2). This is attributed to accidental degeneracy of the chemical shifts of H^a and H^b.

The FAB mass spectrum of **2** contains an envelope of peaks centred at the expected molecular ion peak at *m/z* = 1082 and similar peaks due to the loss of one, two, three, and four carbonyl groups at *m/z* = 1054, 1026, 998, and 968, respectively.

Discussion

The formation of the bis(cyclometallated) complex **2** in good yield by thermolysis of complex **1** is remarkable. In previous studies, thermolysis of binuclear dppm complexes has led to P—C bond cleavage, either alone or along with cyclometallation (2). There are a few precedents in cluster chemistry for cyclometallation of a coordinated dppm ligand (3, 6) but most such reactions also lead to P—C bond cleavage (4). There is obviously a competition between these possible reactions and the formation of **2** represents the first high-yield example of

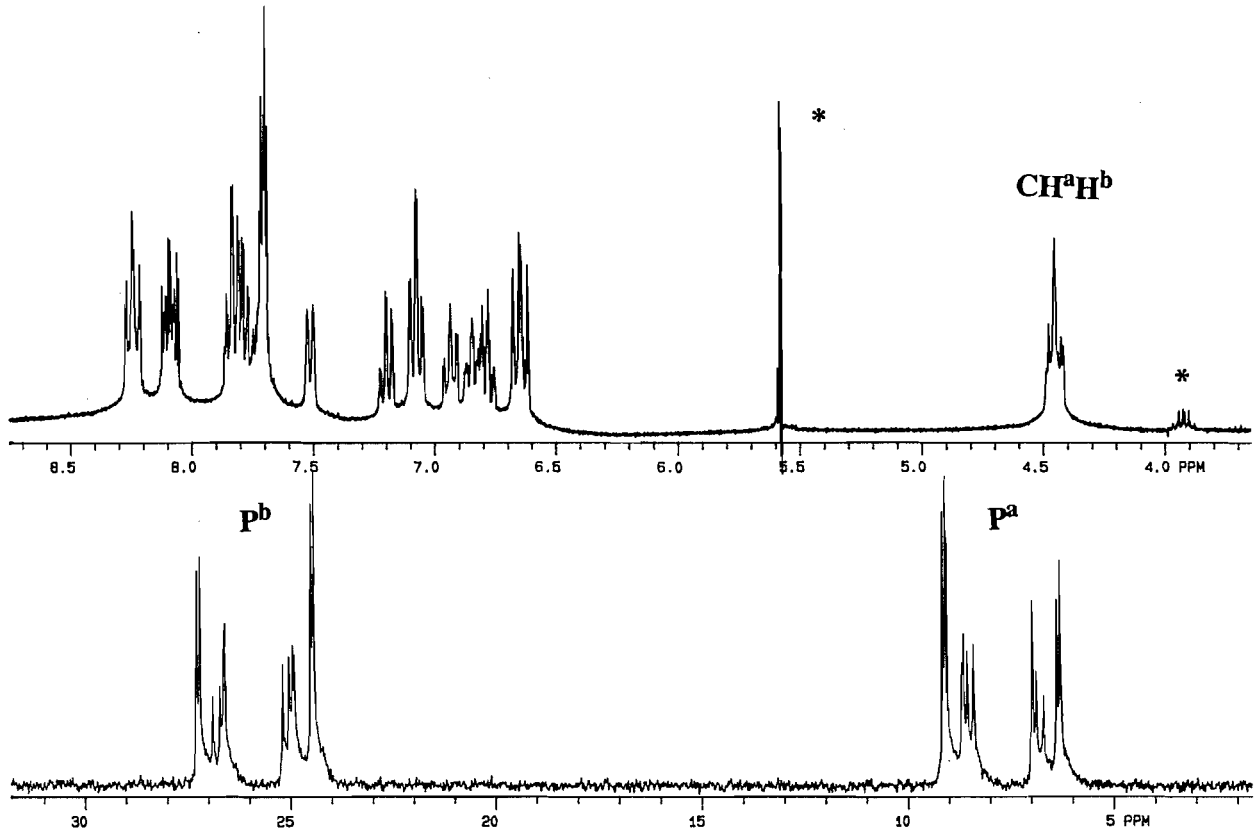
Fig. 2. The ^1H (300 MHz, above) and ^{31}P (121.5 MHz, below) nmr spectra of complex **2**. The peak at δ 5.6 in the ^1H nmr spectrum is due to $CHDCl_2$ and that at δ 3.9 is due to an impurity.



selective orthometallation in competition with P—C bond cleavage (6).

Experimental

Synthesis of $[Ru_2(CO)_4\{Ph_2PCH_2PPh(C_6H_4)\}_2]$, 2

A mixture of $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ (0.34 g, 0.31 mmol) (10) and PhC≡CPh (0.06 g, 0.34 mmol) was heated under reflux in C_6H_6 (30 mL) for 20 h. The colour of the solution initially changed to deep green, then after 6 h of reflux it became dark orange-brown. The solvent was removed under vacuum, the orange solid product was redissolved in CH_2Cl_2 (4–5 mL), and the solution was layered with EtOH (15 mL). Large yellow crystals of the product **2** formed slowly over a period of 4 weeks. They were separated by filtration, washed with EtOH (5 mL), and dried under vacuum. Yield 45%; mp 220°C (dec.). Anal. (sample isolated from benzene solution) calcd. for $C_{54}H_{42}O_4P_4Ru_2 \cdot 0.5C_6H_6$: C 61.07, H 4.02; found: C 61.27, H 4.25%. IR (Nujol), ν(CO): 1991(vs), 1969(vs), 1933(vs), 1915(vs) cm^{-1}; NMR (CD_2Cl_2), ^1H, δ: 4.47 (m, 4H, CH_2P_2), 6.6–8.4 (m, 38H, Ph and C_6H_4); ^{31}P, δ: 7.7 (m, P^a), 25.9 (m, P^b), assignments of P^a and P^b are arbitrary. Solution gives approximate couplings $^2J(P^aP^b) = 280$ Hz, $^2J(P^aP^{b'}) = 75$ Hz. When the solvent was removed from the initial green solution, the NMR indicated the presence of the complexes **1** and **2** and minor amounts of unidentified compounds; the source of the green colour is therefore unknown.

X-ray structure determination

Pale yellow crystals of $\mathbf{2} \cdot 2C_2H_4Br_2$ were grown from a mixture of $C_2H_4Br_2$, C_2H_5OH, and paraffin oil. Many attempts to grow crystals from other solvent mixtures gave crystals that decayed very rapidly; the use of a high-boiling solvent to reduce problems due to solvent loss from crystals appears necessary and explains the very unusual solvent medium. Crystals decayed rapidly on exposure to air so a suitable crystal for diffraction experiments was cut to a size of 0.27 × 0.24 × 0.15 mm, wedged inside a Lindeman capillary tube along with mother liquor, and the tube was flame sealed at both ends. Photo and automatic indexing routines, followed by least-squares fits of 21 reflections ($22.1° \leq 2\theta \leq 28.5°$) gave cell constants and an orientation matrix (11). The Niggli matrix suggested a monoclinic system having symmetry 2/*m* and this was confirmed from an inspection of equivalent reflections. Intensity data were recorded in ω–2θ scan mode at variable scan speeds (1.03–4.12), chosen to optimize counting statistics within a maximum time per dataum of 60 s. Background measurements were made by extending the scan by 25% on each side. Three standard reflections (200, −103, −10−3) were monitored every 120 min of X-ray exposure time and orientation checks were done for every 300 reflections measured. In total, 8697 reflections were collected in the 2θ range 0°–45° ($-23 \leq h \leq 23$, $-1 \leq k \leq 13$, $-1 \leq l \leq 24$). The crystal did not decay significantly during data collection but diffracted poorly when $2\theta > 40°$. The data were processed using the NRCVAX crystal structure programs (12) running on a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

SUN 3/80 workstation. An empirical absorption correction was applied to the data based upon the ψ scans of four reflections with θ ranging from 3.2 to 14.7 (μ = 7.87 cm^{-1}). The maximum and minimum correction factors were 0.984 and 0.755, respectively. The space group was determined to be $P2_1/n$ from the systematic absences (13) and the correctness of the choice of the space group was confirmed by successful solution and refinement of the structure. The equivalent reflections were averaged (R_{int} = 0.026) leaving 7393 unique reflections, of which only 2489 had $I \geq 2.5\sigma(I)$ due to the weakly diffracting nature of the crystal. The structure was solved using the SHELXS-86 program (14) and subsequent difference Fourier techniques. The final full-matrix least-squares refinements on F were done using the SHELX-76 software (15). Scattering factors for neutral non-hydrogen atoms were taken from the International Tables (13). The phenyl rings were treated as regular hexagons (with C—C distance of 1.395 Å) except for those bonded to Ru atoms. The hydrogen atoms of the dppm ligands and the dibromoethane molecules were placed in the calculated positions (C—H = 0.95 Å) and they were included in the least-squares cycles for the purpose of structure factor calculations only. A common thermal parameter was assigned to all the hydrogen atoms and refined in the least-squares cycles. The thermal parameters of Ru, P, and Br atoms were refined anisotropically. In the final difference Fourier synthesis the electron density fluctuated in the range of 0.86 to -1.0 e $Å^{-3}$; of these, the top two peaks were associated with the Br(3) atom at distances of 1.52 and 0.32 Å. The maximum shift/esd in the final cycle was -0.004. The secondary extinction coefficient was refined to $49(23) \times 10^{-6}$. The crystal data are given in Table 1. More complete positional and thermal parameters, anisotropic thermal parameters, calculated hydrogen atom coordinates, selected weighted least-squares planes, and selected torsion angles have been deposited as supplementary material.[2]

Abstract: Treatment of $[Ni_2(\mu\text{-}Br)_2(\eta^3\text{-}C_3H_5)_2]$ with $Na_2[nido\text{-}7,9\text{-}C_2B_{10}H_{12}]$ in THF (tetrahydrofuran) affords the anionic species $[Ni(\eta^3\text{-}C_3H_5)(\eta^6\text{-}7,9\text{-}C_2B_{10}H_{12})]^-$, which was isolated as its $[NEt_4]^+$ salt **8***a*. A similar reaction between $Na_2[nido\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10}]$ and $[Ni_2(\mu\text{-}Br)_2(\eta^3\text{-}C_3H_5)_2]$ in thf gives the anionic species $[Ni(\eta^3\text{-}C_3H_5)(\eta^6\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10})]^-$ isolated as $[N(PPh_3)_2]^+$ (**8***b*) and $[NEt_4]^+$ (**8***c*) salts, respectively. The molecular structure of **8***b* has been established by X-ray diffraction. Crystals are monoclinic, space group $P2_1/c$ (No. 14) with $a = 14.685(3)$ Å, $b = 18.346(2)$ Å, $c = 16.319(1)$ Å, $\beta = 99.93(1)°$, and $Z = 4$. The nickel atom is ligated by the *nido*-7,9-Me_2-7,9-$C_2B_{10}H_{10}$ cage in an η^6 manner, as well as by the allyl group, with the latter adopting an η^3-bonding mode (Ni—C = 2.023(5), 1.939(8), and 1.988(5) Å). The palladium analog **8***d* was similarly prepared from $Na_2[nido\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10}]$ and $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}C_3H_5)_2]$, followed by addition of $[NEt_4]Cl\cdot H_2O$, but in contrast with the nickel species this product was unstable, especially its solutions in air.

Key words: nickel, palladium, allyl complex, carborane.

Résumé : La réaction du $[Ni_2(\mu\text{-}Br)_2(\eta^3\text{-}C_3H_5)_2]$ avec du $Na_2[nido\text{-}7,9\text{-}C_2B_{10}H_{12}]$ dans le tétrahydrofurane (THF) fournit l'espèce anionique $[Ni(\eta^3\text{-}C_3H_5)(\eta^6\text{-}7,9\text{-}C_2B_{10}H_{12})]^-$ qui a été isolée sous la forme de sel de $[NEt_4]^+$ (**8***a*). Une réaction similaire du $[Ni_2(\mu\text{-}Br)_2(\eta^3\text{-}C_3H_5)_2]$ avec du $Na_2[nido\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10}]$ dans le THF fournit l'espèce anionique $[Ni(\eta^3\text{-}C_3H_5)(\eta^6\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10})]^-$ qui a été isolée sous la forme des sels de $[N(PPh_3)_2]^+$ (**8***b*) et de $[NEt_4]^+$ (**8***c*). On a déterminé la structure moléculaire du composé **8***b* par diffraction des rayons X. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$ (No. 14), avec a = 14,685(3), b = 18,346(2) et c = 16,319(1) Å, β = 99,93(1)° et Z = 4. L'atome de nickel et le groupe allyle sont liés à la cage du *nido*-7,9-Me_2-7,9-$C_2B_{10}H_{10}$ d'une façon η^6, alors que le dernier adopte un mode de liaison η^3 (Ni—C = 2,023(5), 1,939(8) et 1,988(5) Å). On a préparé l'analogue du palladium (**8***d*) d'une façon semblable par réaction du $Na_2[nido\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10}]$ et du $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}C_3H_5)_2]$ suivie d'une addition de $[NEt_4]Cl\cdot H_2O$; toutefois, par opposition au comportement des espèces du nickel, celle-ci est instable, particulièrement lorsque ses solutions sont mises en présence d'air.

Mots clés : nickel, palladium, complexe allyle, carborane.

[Traduit par la rédaction]

Introduction

We have recently synthesized the salts $[X][M(\eta^3\text{-}C_3H_5)(\eta^5\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_9)]$ (M = Ni, Pd, or Pt, X = NEt_4^+ or $N(PPh_3)_2^+$) (**1**). Protonation ($HBF_4\cdot Et_2O$) of these products releases propylene, and if CO or CNBu^t are present the complexes $[M(L)_2(\eta^5\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_9)]$ (**2**, L = CO or CNBu^t) are formed, respectively (1).[2] The allyl(carborane)-molybdenum and -tungsten complexes $[X][M(CO)_2(\eta^3\text{-}C_3H_5)(\eta^5\text{-}7,8\text{-}R_2\text{-}7,8\text{-}C_2B_9H_9)]$ (**3**, M = Mo or W, R = Me or H, X = NEt_4 or $N(PPh_3)_2$) undergo similar protonation reactions in the presence of donor ligands, yielding a variety of neutral species such as $[M(CO)_2(L)_2(\eta^5\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_9)]$ (**4**, M = Mo or W, L = CO or PPh_3), $[Mo(CO)(\eta^2\text{-}MeC{\equiv}CMe)_2(\eta^5\text{-}7,8\text{-}Me_2\text{-}$

[2] In the compounds discussed in this paper [*nido*-7,8-R_2-7,8-$C_2B_9H_9]^{2-}$ and [*nido*-7,9-R_2-7,9-$C_2B_{10}H_{10}]^{2-}$ dianions form *closo*-1,2-dicarba-3- and *closo*-1,6-dicarba-4 metallacarborane structures. Use of this numbering scheme results in a cumbersome and confusing nomenclature for the complexes. As in earlier papers we treat the cages as *nido*-11 and *nido*-12 vertex ligands with numbering as for an icosahedron or a docosahedron, respectively, from which one vertex has been removed.

7,8-$C_2B_9H_9$)] (**5**), and [Mo(CO)(η^2-$Me_3SiC{\equiv}CH$){η^2,η^5-7,8-Me_2-10-[C(H)=C(H)$SiMe_3$]-7,8-$C_2B_9H_8$}] (**6**) (2). In all these compounds the metal atoms are ligated in a pentahapto manner by the open pentagonal CCBBB face of a *nido*-icosahedral C_2B_9 cage, a bonding mode for this group to transition metals first identified by Hawthorne and co-workers (3*a*).

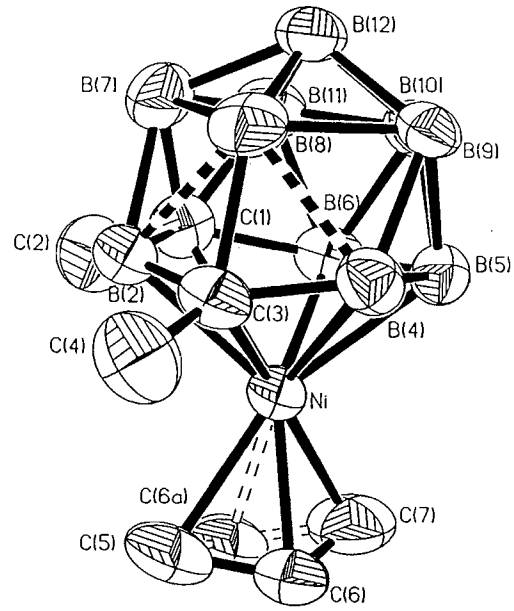
Like [*nido*-7,8-R_2-7,8-$C_2B_9H_9$]$^{2-}$ (R = H or Me), the dianions [*nido*-7,9-R_2-7,9-$C_2B_{10}H_{10}$]$^{2-}$ also coordinate to transition metal centers but in a hexahapto manner (3*b*, 4). This led us to prepare and study the complexes [$N(PPh_3)_2$][$M(CO)_2$(η^3-C_3H_5)(η^6-7,9-Me_2-7,9-$C_2B_{10}H_{10}$)] (**7**, M = Mo or W) (5), which are akin to **3**. The close connection between the salts **3** and **7** suggested that a similar relationship might exist between the anions of the salts **1** and a new series of complex anions of formulation [M(η^3-C_3H_5)(η^6-7,9-R_2-7,9-$C_2B_{10}H_{10}$)]$^-$ (M = Ni, Pd, or Pt; R = Me or H), thus prompting the work described in this paper.

Results and discussion

Treatment of [Ni_2(μ-Br)$_2$(η^3-C_3H_5)$_2$] in THF (tetrahydrofuran) with a solution of Na_2[*nido*-7,9-$C_2B_{10}H_{12}$] in the same solvent gave orange crystals of [NEt_4][Ni(η^3-C_3H_5)(η^6-7,9-$C_2B_{10}H_{12}$)] (**8***a*), after addition of [NEt_4]Cl and column chromatography of the mixture on alumina. A similar procedure employing Na_2[*nido*-7,9-Me_2-7,9-$C_2B_{10}H_{10}$] and [Ni_2(μ-Br)$_2$(η^3-C_3H_5)$_2$], with addition of [$N(PPh_3)_2$]Cl or [NEt_4]Cl yielded, respectively, the salts [X][Ni(η^3-C_3H_5)(η^6-7,9-Me_2-7,9-$C_2B_{10}H_{10}$)] (X = [$N(PPh_3)_2$]$^+$ (**8***b*) and [NEt_4]$^+$ (**8***c*)). The palladium compound [NEt_4][Pd(η^3-C_3H_5)(η^6-7,9-Me_2-7,9-$C_2B_{10}H_{10}$)] (**8***d*) was obtained from the reaction between [Pd_2(μ-Cl)$_2$(η^3-C_3H_5)$_2$] and Na_2[*nido*-7,9-Me_2-7,9-$C_2B_{10}H_{10}$] followed by addition of [NEt_4]Cl. The ^{1}H, ^{13}C{^{1}H}, and ^{11}B{^{1}H} NMR data for these products are listed in Table 1 but discussion is deferred until the results of an X-ray diffraction study on **8***b* are described.

Fig. 1. Molecular structure of the anion of [$N(PPh_3)_2$]-[Ni(η^3-C_3H_5)(η^6-7,9-Me_2-7,9-$C_2H_{10}H_{10}$)] (**8***b*), showing the crystallographic labeling scheme. Thermal ellipsoids are shown at 50% probability level.



The structure of the anion of **8***b* is shown in Fig. 1 and selected internuclear distances and bond angles are listed in Table 2. The nickel atom is ligated by the allyl group and a *nido*-$C_2B_{10}H_{10}Me_2$ cage. The allyl ligand is coordinated to the nickel atom in the usual trihapto manner, but the central methine carbon atom is disordered occupying, respectively, the C(6) and the C(6*a*) positions 50% of the time. The C(5)—C(6,6*a*) distance (avg. 1.317 Å) is slightly shorter than the C(6,6*a*)—C(7) distance (1.355 Å). The nickel is also coordinated to the *nido*-C_2B_{10} cage in a hexahapto manner. Since the *closo*-4,1,6-NiC_2B_{10} skeleton of **8***b* has 13 vertices, distortions occur within this framework which are not found in 12 vertex systems with *closo*-3,1,2-MC_2B_9 icosahedral structures. Thus the CBCBBB face ligating the nickel atom is distinctly non-planar, as in other complexes containing a MC_2B_{10} cage system (5–8). The non-planarity of the CBCBBB ring in **8***b* results in differences in the contact distances between the metal and cage atoms: Ni—C(1) 2.319(4), Ni—B(2) 2.170(5), Ni—C(3) 2.016(4), Ni—B(4) 2.206(5), Ni—B(5) 2.119(5), Ni—B(6) 2.115(5) Å. The C(3) carbon atom is the cage vertex with the lowest connectivity and has the shortest contact distance to the metal atom. The C(3) atom also displays relatively short distances to B(2) (1.548(6) Å) and B(4) (1.520(7) Å). The B(8) boron atom is the highest

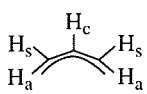
[a]Measured in CD_2Cl_2 at ambient temperatures, unless otherwise stated. Chemical shifts (δ) in ppm, coupling constants (*J*) in Hz. Abbreviations used: s = singlet, d = doublet, m = multiplet, q = quartet, t = triplet, tt = triplet of triplets, vt = virtual triplet, br = broad.

[b]H_a, H_c, and H_s refer to the protons:



[c]Proton resonances for terminal B-H groups occur as broad unresolved peaks in the range δ ca. −2 to +3.

[d]Hydrogen-1 decoupled. Chemical shifts are positive to high frequency of $SiMe_4$.

[e]Hydrogen-1 decoupled. Chemical shifts are positive to high frequency of $BF_3{\cdot}Et_2O$ (external). Signals ascribed to more than one boron nucleus may result from overlapping peaks, and do not necessarily indicate symmetry equivalence.

[f]Measured in acetone-d_6.

[g]Signals ascribed to the cage carbons were not observed in this spectrum, see text.

connectivity vertex with the longest separations represented in Fig. 1 by dashed lines involving B(2) (2.084(8) Å) and B(4) (1.947(7) Å). This results in two essentially quadrilateral faces about C(3). The bond distances and angles within the carborane cage in **8***b* are similar to those found in other compounds with MC_2B_{10} (M = Ti, Mo, W, Co, Ir, or Pd) cages which have been structurally characterized by X-ray diffraction (5–8). As far as we are aware **8***b* is the first such species containing a nickel atom to be synthesized and structurally characterized.

The NMR data (Table 1) for the complexes **8**, measured at ambient temperatures, indicate the occurrence of dynamic behavior, a common feature for compounds containing a MC_2B_{10} cage framework (3*b*, 4, 5). As established for **8***b* and many related 4,1,6-MC_2B_{10} species in the solid state, the CBCBBB face of the cage ligating the metal atom is non-planar, consequently the CMe vertices are in different environments lying on either side of a mean plane through the four boron atoms in this face. Nevertheless, in the ^{1}H NMR spectra of the complexes **8** the cage CMe vertices give rise to one resonance (e.g., **8***b*, δ 1.98) rather than two, and in the $^{13}C\{^{1}H\}$ spectra only two peaks are observed (e.g., **8***b*, δ 75.0 (*C*Me) and 32.2 (*CMe*)) rather than four. As discussed elsewhere (3*b*, 4), the fluxionality results from the CMe fragments changing their relationship with respect to the metal center via a pathway involving a twofold diamond–square–diamond polytopal rearrangement of the cage. The time-averaged structure has a plane of symmetry, and via this intermediate the cage CMe groups are able to flip synchronously from one side of the mean plane through the four boron atoms to the other.

The ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra of the complexes **8** display diagnostic resonances for the allyl ligands similar to those observed in the corresponding spectra of the species **1** and **7**. Thus in the ^{1}H NMR spectrum of **8***c* three signals occur at δ 1.97 (d, 2H, J_{H-H} = 12 Hz), 3.14 (d, 2H, J_{H-H} = 6 Hz), and 4.89 (tt, 1H, J_{H-H} = 6 and 12 Hz). The doublet signals may be assigned to the protons in the methylene groups of the allyl ligand, while the triplet-of-triplets is due to the methine proton. In the ^{1}H NMR spectrum of **1***a*, with a C_2B_9Ni rather than a $C_2B_{10}Ni$ cage, the corresponding resonances are seen at δ 2.22 (d, 2H, J_{H-H} = 12 Hz), 2.71 (d, 2H, J_{H-H} = 6 Hz), and 4.74 (tt, 1H, J_{H-H} = 6 and 12 Hz) (1*a*). In the $^{13}C\{^{1}H\}$ NMR spectrum of **8***c* resonances for the allyl ligand are at δ 101.1 for the CH nucleus and at δ 56.7 for the CH_2 moieties to be com-

pared with signals for these groups in the spectrum of **1***a* at δ 93.7 and 52.0, respectively.

The palladium complex **8***d* proved to be unstable and microanalytical data were not obtained. Solutions of the compound at room temperature rapidly decomposed to black material presumably palladium metal. However, below ca. −30°C decomposition is slowed. Despite these difficulties the ^1H and $^{13}C\{^1H\}$ NMR spectra were measured and the data obtained (Table 1) are in complete accord with the formulation proposed. As mentioned earlier, protonation of the salts **1** in the presence of substrate molecules affords a variety of products (1) and it was hoped that similar behavior would be shown by the species **8**. Disappointingly this proved not to be so. Treatment of **8***d* with $HBF_4{\cdot}Et_2O$ at −78°C led to the formation of a black intractable solid assumed to be palladium metal. Similar protonation reactions of **8***b* in the presence of CO, $CNBu^t$, PPh_3, $P(OMe)_3$, $Ph_2PCH_2CH_2PPh_2$, $[Co_2(CO)_8]$, cycloocta-1,4-diene, and bicyclo-2,2,2-heptadiene all failed to yield stable products.

Experimental

All solvents were dried over appropriate drying agents before use. Light petroleum refers to that fraction of bp 40–60°C. Chromatography columns ca. 15 cm long and 3 cm in diameter were packed with alumina (Brockmann activity II). All experiments were carried out under nitrogen using Schlenk tube techniques. Spectroscopic equipment used has been described previously (2*a*). The compounds $[Ni_2(\mu\text{-}Br)_2(\eta^3\text{-}C_3H_5)_2]$ (9) and $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}C_3H_5)_2]$ (10) were prepared as previously described.

Synthesis of the allyl(carborane) nickel and palladium complexes $[X][M(\eta^3\text{-}C_3H_5)(\eta^6\text{-}7,9\text{-}R_2\text{-}7,9\text{-}C_2B_{10}H_{10})]$ (M = Ni, R = H or Me, X = NEt_4 or $N(PPh_3)_2$; M = Pd, R = Me, X = NEt_4).

The preparation of complex **8***b* illustrates the general procedure followed. A THF (20 cm^3) solution of 1,2-Me_2-1,2-$C_2B_{10}H_{10}$ (0.50 g, 2.9 mmol) was treated with Na cuttings (ca. 1.0 g, 43.5 mmol) and a trace amount of naphthalene, and the mixture was stirred at room temperature for 2 h. The solution containing $Na_2[nido\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10}]$ so formed (3*b*) was then slowly syringed in to a solution of freshly prepared $[Ni_2(\mu\text{-}Br)_2(\eta^3\text{-}C_3H_5)_2]$ (0.54 g, 1.5 mmol) in THF (10 cm^3) held at −50°C. After stirring the mixture for 1 h, it was warmed to 0°C and stirring was continued for a further 15 h. Solid $[N(PPh_3)_2]Cl$ (1.72 g, 3.0 mmol) was then added and the mixture warmed slowly to room temperature. Volatile materials were removed in vacuo, the residue was extracted with CH_2Cl_2 (15 cm^3) and the extracts were filtered through a Celite pad (ca. 5 cm thick). The volume of the solvent was then reduced in vacuo to ca. 5 cm^3, and the solution chromatographed, eluting with CH_2Cl_2/light petroleum (2:1). An orange eluate was collected from which the solvent was removed in vacuo to give $[N(PPh_3)_2][Ni(\eta^3\text{-}C_3H_5)(\eta^6\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10})]$ (**8***b*) (1.55 g) as an orange powder (64% yield). Analytically pure orange crystals of **8***b* may be obtained by crystallization from CH_2Cl_2/Et_2O/light petroleum (1:1:1). Anal. calcd. for $C_{43}H_{51}B_{10}NNiP_2$: C 63.7, H 6.3, N 1.7; found: C 64.3, H 6.6, N 1.8.

The $[NEt_4]^+$ salt **8***c* was obtained in a similar manner, employing $[NEt_4]Cl{\cdot}H_2O$ in place of $[N(PPh_3)_2]Cl$ (60% yield). Anal. calcd. for $C_{15}H_{41}B_{10}NNi$: C 44.8, H 10.3, N 3.5; found: C 45.3, H 10.8, N 4.2.

Similarly, the complex $[NEt_4][Ni(\eta^3\text{-}C_3H_5)(\eta^5\text{-}7,9\text{-}C_2B_{10}H_{12})]$ (**8***a*) (0.61 g, 54% yield) may be obtained from the reaction of $Na_2[nido\text{-}7,9\text{-}C_2B_{10}H_{12}]$ with a half-molar amount of $[Ni_2(\mu\text{-}Br)_2(\eta^3\text{-}C_3H_5)_2]$ (0.54 g, 1.5 mmol) in THF at −50°C, followed by addition of $[NEt_4]Cl{\cdot}H_2O$. Anal. calcd. for $C_{13}H_{37}B_{10}NNi$: C 41.7, H 10.0, N 3.7; found: C 42.2, H 10.5, N 4.4.

Following a similar procedure, $Na_2[nido\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10}]$ was treated with a half-molar amount of $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}C_3H_5)_2]$ (0.55 g, 1.50 mmol) to afford $[NEt_4][Pd(\eta^3\text{-}C_3H_5)(\eta^6\text{-}7,9\text{-}Me_2\text{-}7,9\text{-}C_2B_{10}H_{10})]$ (**8***d*) (0.45 g, 34% yield) as a bright yellow solid. Compound **8***d* may be crystallized from

Residual density (max., min.)/e Å^{-3}	0.36, −0.29

CH_2Cl_2/Et_2O (1:1) but satisfactory microanalytical data were not obtained.

Crystal structure determination and refinement

A clear red single crystal (0.21 × 0.36 × 0.49 mm) of **8***b* was selected for X-ray diffraction analysis on the basis of its optical homogeneity. A conoscopic examination confirmed the biaxial (birefringent) nature and quality of the crystal. Data were collected on an automated diffractometer (*h*: 0 to 14, *k*: 0 to 17, *l*: −15 to 15). A variation of less than 1.3% in the monitored standard reflections (every 2 h of collection time) verified the electronic reliability and crystal stability. All intensity data were corrected for Lorentz and polarization effects after which an empirical absorption correction, based on high-angle ψ scans (minimum, maximum transmission factors = 0.6679, 0.9989), was performed. After elimination of the check reflections and averaging redundant data (R_{int}), 4031 independent reflections remained, of which 3387 were used in the solution. Examination of the resultant data revealed the conditions: *h*0*l*, $l = 2n$ and 0*k*0, $k = 2n$ which are consistent with the space group $P2_1/c$ (No. 14). Crystal data, experimental and statistical summaries, and pertinent refinement parameters are presented in Table 3.

Crystallographic analysis (direct methods) of the data, using the SHELXTL-PC package of programs (11), disclosed the positions of the PNP atoms of the cation and the Ni atom. Subsequent refinement and difference Fourier analysis revealed the location of the remaining non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic thermal parameters. Boron hydrogen atoms were located by difference Fou-

[a]Refined at one-half occupancy.

rier, and the carbon hydrogen atoms were included at geometrically calculated positions (C—H, 0.96 Å). The hydrogen atoms were allowed to ride on their parent carbon or boron atoms with fixed isotropic thermal parameters (U_{iso} = 0.08 and 0.06 Å^2, respectively). The methine carbon atom (C(6) and C(6a)) of the allyl group was disordered and was refined at one-half occupancy for each carbon position. Hydrogen atoms bonded to C(5) and C(7) were also disordered and were placed in calculated positions according to the appropriate adjacent disordered carbon atoms and refined at one-half occupancy. The final cycle of block full-matrix least-squares refinement which included a secondary extinction correction ($g = 1.0(6) \times 10^{-4}$ e^{-2}) yielded final residual indices and a respectable "goodness-of-fit" value. The quantity minimized was $\Sigma w(|F_o| - |F_c|)^2$ and the weighting function was $w = [\sigma^2(F) + 0.0023F^2]^{-1}$. The final electron-density difference synthesis displayed only random fluctuations. Atomic scattering and associated anomalous dispersion correction factors were taken from the usual source (12). Final atoms positional parameters are presented in Table 4. Anisotropic thermal parameters, hydrogen atom parameters, and a complete set of bond lengths and angles are available as supplementary data.[3]

A study of a variety of *O,O*-alkylene dithiophosphate derivatives of triphenyl- and diphenylgermane. Crystal structures of $Ph_3Ge[S_2POCMe_2CMe_2O]$, $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$

John E. Drake, Anil G. Mislankar, Raju Ratnani, and Jincai Yang

Abstract: The *O,O*-alkylene dithiophosphate derivatives of triphenyl- and diphenylgermane, $Ph_3Ge[S_2POCMe_2CMe_2O]$, $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, $Ph_3Ge[S_2POCH_2CEt_2CH_2O]$, $Ph_2Ge[S_2POCMe_2CMe_2O]_2$, $Ph_2Ge[S_2POCH_2CMe_2CH_2O]_2$, and $Ph_2Ge[S_2POCH_2CEt_2CH_2O]_2$, have been prepared and characterized by infrared, Raman, and ^1H, ^{13}C, and ^{31}P NMR spectroscopy, mass spectrometry, and, in three cases, X-ray crystallography. $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, crystallizes as monoclinic in the space group $P2_1/a$ (No. 14) with the cell parameters $a = 12.868(5)$ Å, $b = 11.354(4)$ Å, $c = 17.207(4)$ Å, $\beta = 95.42(2)°$, $V = 2502(1)$ Å^3, $Z = 4$, $R = 0.0640$, and $R_w = 0.0585$. $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, crystallizes as orthorhombic in the space group *Pbca* (No. 61) with the cell parameters $a = 23.007(4)$ Å, $b = 16.840(4)$ Å, $c = 12.068(3)$ Å, $V = 4657(3)$ Å^3, $Z = 8$, $R = 0.0502$, and $R_w = 0.0329$. $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**, crystallizes as monoclinic in the space group *C2/c* (No. 15) with the cell parameters $a = 35.48(2)$ Å, $b = 9.275(5)$ Å, $c = 20.78(1)$ Å, $\beta = 120.93(3)°$ $V = 5866(5)$ Å^3, $Z = 8$, $R = 0.0674$, and $R_w = 0.0562$. As with their methylgermanium analogues, the environment about germanium is essentially that of a distorted tetrahedron, with the terminal sulfur atoms oriented towards germanium rather than away from it, in contrast with analogous noncyclic dithiophosphatogermanes. The substituents on the atoms in both the five- and six-membered rings maintain their nonequivalence in solution, in contrast with tin analogues.

Key words: structure, germanium, diphenyl, triphenyl, cyclic dithiophosphates

Résumé : On a préparé les dérivés. *O,O*-alkylène diphosphates des triphényl- et tétraphénylgermanes, $Ph_3Ge[S_2POCMe_2CMe_2O]$, $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, $Ph_3Ge[S_2POCH_2CEt_2CH_2O]$, $Ph_2Ge[S_2POCMe_2CMe_2O]_2$, $Ph_2Ge[S_2POCH_2CMe_2CH_2O]_2$ et $Ph_2Ge[S_2POCH_2CEt_2CH_2O]_2$ et on les a caractérisé par spectroscopies infrarouge, Raman et RMN du ^1H, du ^{13}C et du ^{31}P, par spectrométrie de masse et, dans trois cas, par diffraction des rayons X. Le composé $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, cristallise dans le groupe monoclinique $P2_1/a$ (No. 14) avec $a = 12,868(5)$, $b = 11,354(4)$ et $c = 17,207(4)$ Å, $\beta = 95,42(2)°$, $V = 2502(1)$ Å, $Z = 4$, $R = 0,0640$, and $R_w = 0,0585$. Le composé $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, cristallise dans le groupe orthorhombique *Pbca* (No. 61) avec $a = 23,007(4)$, $b = 16,840(4)$ et $c = 12,068(3)$ Å,

$V = 4657(3)$ Å^3, $Z = 8$, $R = 0{,}0502$, and $R_w = 0{,}0329$. Le composé $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**, cristallise dans le groupe monoclinique *C2/c* (No. 15) avec $a = 35{,}48(2)$ Å, $b = 9{,}275(5)$ et $c = 20{,}78(1)$ Å, $\beta = 120{,}93(3)°$, $V = 5866(5)$ Å^3, $Z = 8$, $R = 0{,}0674$ et $R_w = 0{,}0562$. Comme dans le cas de leurs analogues méthylgermanium, l'environnement autour du germanium est essentiellement celui d'un tétraèdre déformé dans lequel les atomes de soufre terminaux sont orientés vers le germanium plutôt que dans le sens inverse; ceci fait contraste avec les analogues non cycliques dithiophosphatogermanes. Les substituants sur les atomes des cycles à cinq ainsi qu'à six chaînons maintiennent leur non équivalence en solution, en opposition avec la situation observée avec leurs analogues de l'étain.

Mots clés : structure, germanium, diphényl, triphényl, dithiophosphates cycliques.

Introduction

We have demonstrated that *O,O*-dialkyldithiophosphate derivatives of germanium are monodentate with the nonbonding sulfur atom oriented away from germanium (1, 2), the distance of 5.253 (1) Å in $Ph_3Ge[S_2P(OMe)_2]$ being typical (1). This structure is also typical of xanthate derivatives of germanium (3–5). Recently, we reported the synthesis and characterization of a number of cyclic dithiophosphate derivatives of methylgermanes (6) whose NMR spectra showed unusual features that suggested that the solid state structures were maintained in solution, in contrast to what had been observed in general (7–17) and for tin and tellurium analogues in particular (14, 17). Unfortunately, we were only successful in obtaining a crystal structure for one derivative, $Me_2Ge[S_2POCMe_2CMe_2O]_2$, and so had no evidence of the solid state structures of derivatives containing only one dithiophosphate group. Ironically, we have been able to ob-tain the X-ray structures of all three triphenyl(dithiophosphato)germanes, $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**, but have not been able to get data of sufficient quality to fully solve the structures of any of the diphenylgermanium analogues, **4**–**6**. In all three structures, the second sulfur atom of the dithiophosphate group is oriented toward germanium, rather than away from it as was found for the noncyclic dithiophosphates. However, the Ge--S secondary interactions are much weaker than in tin analogues such as $Ph_2Sn[S_2P(Oi\text{-}Pr)_2]_2$, where the dithiophosphate groups are fully bidentate (18), and are also apparently weaker than those in $Ph_3Sn[S_2POCMe_2CMe_2O]$, even though the dithiophosphate group therein is also anisobidentate (16).

Experimental

Materials

Chlorotriphenyl- and dichlorodiphenylgermane were obtained from Alfa and were used as supplied. Sodium and ammonium salts of *O,O*-alkylene dithiophosphates were prepared in the manner described in the literature and their purity was checked by ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy (19). Benzene, toluene, carbon disulfide, and *n*-hexane were dried and distilled prior to use. All the reactions were carried out in air- and moisture-free conditions to prevent the formation of germanium oxides.

Synthesis of triphenylgermane derivatives of alkylene dithiophosphates

$Ph_3Ge[S_2POCMe_2CMe_2O]$, 1

Typically, the sodium salt of *O,O*-2,3-dimethylbutylene dithiophosphate, $Na[S_2POCMe_2CMe_2O]$ (0.111 g, 0.48 mmol), Ph_3GeCl (0.138 g, 0.40 mmol), and benzene (8 mL) were placed in a reaction vessel attached to a vacuum line and degassed at −196°C. Dry nitrogen was introduced and the mixture was allowed to warm up to ambient temperature and then refluxed for 7 h. The reaction mixture was filtered to separate NaCl and any unreacted salt, after which the solvent was evaporated off in vacuo to yield a pale yellow viscous liquid, which was dissolved in toluene and layered with *n*-hexane. Crystals formed in a matter of days in the refrigerator to give $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**; pale yellow solid, mp 99–101°C, yield 53%. Peaks corresponding to ^{74}Ge in a typical germanium cluster are seen at *m/z* (relative intensity): 515 ($(M-H)^+$, 1%), 438 ($(M-PhH)^+$, 20%), and 304 ($(M-HS_2POCMe_2CMe_2O)^+$, 100%) with a peak clearly not part of a germanium cluster at 212 ($(H_2S_2POCMe_2CMe_2O)^+$, 15%).

$Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, 2, and

$Ph_3Ge[S_2POCH_2CEt_2CH_2O]$, 3

Similarly, using the salts $Na[S_2POCH_2CMe_2CH_2O]$ or $Na[S_2POCH_2CEt_2CH_2O]$ in slight excess to ensure complete substitution of chlorine, the following were prepared: $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**; white solid, mp 145–147°C, yield 50%. Anal. calcd. for $C_{23}H_{25}O_4P_2S_4Ge$: C 55.12, H, 5.05; found: C 54.90, H 5.00. Peaks corresponding to ^{74}Ge in a typical germanium cluster are seen at *m/z* (relative intensity): 501 ($(M-H)^+$, 2%), 424 ($(M-PhH)^+$, 8%), and 304 ($(M-HS_2POCH_2CMe_2CH_2O)^+$, 100%) with a peak clearly not part of a germanium cluster at 199 ($(H_2S_2POCH_2CMe_2CH_2O)^+$, 15%). $Ph_3Ge[S_2POCH_2CEt_2CH_2O]$, **3**; white solid; mp 38–40°C, yield 54%. Peaks corresponding to ^{74}Ge in a typical germanium cluster are seen at *m/z* (relative intensity): 529 ($(M-H)^+$, 2%), 452 ($(M-PhH)^+$, 30%), and 304 ($(M-HS_2POCH_2CEt_2CH_2O)^+$,

For personal use only.

100%) with a peak clearly not part of a germanium cluster at 227 ($(H_2S_2POCH_2CMe_2CH_2O)^+$, 30%). In the case of **3**, crystals of X-ray quality were obtained on recrystallization from benzene to yield $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$.

Synthesis of diphenylgermane derivatives of alkylene dithiophosphates

$Ph_2Ge[S_2POCMe_2CMe_2O]_2$, 4

Typically, $Na[S_2POCMe_2CMe_2O]$ (0.509 g, 2.18 mmol), Ph_2GeCl_2 (0.240 g, 0.68 mmol), and benzene (10 mL) were placed in a Schlenk flask and degassed for *ca.* 30 min at −196°C. The mixture was allowed to gradually warm up to ambient temperature and then stirred for 7 h. The reaction mixture was filtered to separate NaCl and any unreacted salt, after which the solvent was evaporated off in vacuo to yield a white solid of the desired product, $Ph_2Ge[S_2POCMe_2\ CMe_2O]_2$, **4**; mp 174–175°C, yield 65 %. Anal. calcd. for $C_{24}H_{34}O_4P_2S_4Ge$: C 44.44, H 5.28; found: C 43.04, H 5.35. A peak corresponding to ^{74}Ge in a typical germanium cluster that dominates the spectrum is seen at *m/z* (relative intensity): 438 ($(M-HS_2POCMe_2CMe_2O)^+$, 100%).

$Ph_2Ge[S_2POCH_2CMe_2CH_2O]_2$, 5, and
$Ph_2Ge[S_2POCH_2CEt_2CH_2O]_2$, 6

Similarly, using the salts $NaS_2POCH_2CMe_2CH_2O$ or $NaS_2POCH_2CEt_2CH_2O$ in slight excess to ensure complete substitution of chlorine, were prepared: $Ph_2Ge[S_2POCH_2CMe_2CH_2O]_2$, **5**; white solid, mp 68–69°C, yield 62%. A peak corresponding to ^{74}Ge in a typical germanium cluster that dominates the spectrum is seen at *m/z* (relative intensity): 424 ($(M-HS_2POCH_2CMe_2CH_2O)^+$, 100%). $Ph_2Ge[S_2POCH_2CEt_2CH_2O]_2$, **6**; viscous liquid, yield 65%. A peak corresponding to ^{74}Ge in a typical germanium cluster that dominates the spectrum is seen at *m/z* (relative intensity): 452 ($(M-HS_2POCH_2CEt_2CH_2O)^+$, 100%). Unfortunately, despite extensive efforts to grow X-ray quality crystals, none were obtained for compounds **4–6**.

Physical measurements

All solvents were distilled prior to use. The elemental analyses were performed at Guelph Chemical Laboratories, Guelph, Ontario. The infrared spectra were recorded on a Nicolet 5DX FT spectrometer as KBr pellets. The ^1H and ^{13}C NMR spectra were recorded on a Bruker 300 FT NMR spectrometer in $CDCl_3$ solutions using Me_4Si as internal standard. The ^{31}P NMR spectra were recorded on a Bruker 200 FT NMR spectrometer in $CDCl_3$ using H_3PO_4 as external standard. The mass spectra were recorded by LSIMS on a Kratos Profile mass spectrometer. The melting points were determined on a Fisher–Johns apparatus.

X-ray crystallographic analysis

Block-like crystals of $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**, were sealed in thin-walled glass capillaries and mounted on a Rigaku AFC6S diffractometer, with graphite-monochromated Mo Kα radiation.

Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections in the range $8 < 2\theta < 29°$, corresponded to monoclinic (for **1** and **3**) and orthorhombic (for **5**) cells whose dimensions are given in Table 1. The systematic absences (*h0l*, $h = 2n + 1$; *0k0*, $k = 2n + 1$) for **1**, (*0kl*, $k = 2n + 1$; *h0l*, $l = 2n + 1$; *hk0*, $h = 2n + 1$) for **2**, and (*hkl*, $h + k = 2n + 1$; *h0l*, $l = 2n + 1$) for **3** are observed. Based on packing considerations, statistical analyses of intensity distributions, and the successful solution and refinement of the structure, the space group was determined to be $P2_1/a$ (No. 14), *Pbca* (No. 61), and *C2/c* (No. 15) for **1, 2,** and **3**, respectively.

The data were collected at a temperature of 23 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 50.0° for **1** and **2**, and 45.0° for **3**. The ω scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.25°, 0.29°, and 0.28° for **1**, **2**, and **3**, respectively, with a takeoff angle of 6.0°. Scans of (1.42 + 0.30 tan θ)° for **1**, (1.00 + 0.30 tan θ)° for **2**, (1.37 + 0.30 tan θ)° for **3** were made at a speed of 16.0°/min (in ω). The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of two rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The diameter of the incident beam collimator was 0.5 mm, and the crystal-to-detector distance was 285.0 mm.

Of the 4894 (for **1**), 4626 (for **2**), or 4443 (for **3**) reflections that were collected, 4673 (for **1**), 4626 (for **2**), or 4111 (for **3**) were unique ($R_{int} = 0.097, 0.192, 0.202$) for **1**, **2**, and **3**, respectively. The intensities of three representative reflections that were measured after every 150 reflections remained constant throughout data collection, indicating crystal and electronic stability (no decay correction was applied).

The linear absorption coefficient for Mo Kα is 14.7 (for **1**), 15.5 (for **2**), and 12.4 cm^{-1} (for **3**). An empirical absorption correction, based on azimuthal scans of several reflections, was applied that resulted in transmission factors ranging from 0.82 to 1.00 (for **1**), 0.56 to 1.00 (for **2**), and 0.84 to 1.00 (for **3**). The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods (for structure solution methods, see ref. 20). The non-hydrogen atoms other than oxygen and carbon atoms were refined anisotropically and the hydrogen atoms were included in their idealized positions with C—H set at 0.95 Å and with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. The final cycle of full-matrix least-squares refinement[3] was based on 2130 (for **1**), 1532 (for **2**), and 1176 (for **3**) observed reflections ($I > 3.00\sigma(I)$), and 136 (for **1**), 145 (for **2**), and 151 (for **3**) variable parameters, and converged

[3] Least-squares function minimized: $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2(F_o^2), \sigma^2(F_o^2) = [S^2(C + R^2B) + pF_o^2)^2]/(Lp)^2$, S = scan rate, c = total integrated peak count, R = ratio of scan time to background counting time, Lp = Lorentz-polarization factor, and $p = p$ factor.

Table 1. Summary of crystal data, intensity collection, and structural refinement for $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**.

Atom associated with residual density	C(9)	C(15)	C(26)

(largest parameter shift was 0.001 times its esd) with unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||\Sigma|F_o| = 0.0640$ (for **1**), 0.0502 (for **2**), and 0.0674(for **3**) and $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)]^{1/2} = 0.0585$ (for **1**), 0.0329 (for **2**), and 0.0562 (for **3**).

The standard deviations of an observation of unit weight[4] were 2.44, 1.70, and 2.12 for **1, 2**, and **3**, respectively . The weighting scheme was based on counting statistics and included a factor ($p = 0.004$, 0.001, and 0.007 for **1, 2**, and **3**, respectively) to downweight the intense reflections. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, sin θ/λ, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.72 and −0.55 (for **1**), 0.65 and −0.34 (for **2**), and 0.43 and −0.39 e/Å^3 (for **3**).

Neutral-atom scattering factors were taken from Cromer and Waber (21). Anomalous dispersion effects were included in F_c (22); the values for $\Delta f'$ and $\Delta f''$ were those of Cromer (23). All calculations were performed using the TEXSAN (24) crystallographic software package.

The final atomic coordinates and equivalent isotropic thermal parameters for the non-hydrogen atoms are given in Tables 2, 3, and 4, important distances and bond angles in Tables 5 and 6, respectively, and ORTEP diagrams in Figs. 1, 2, and 3. Tables of final thermal parameters of non-hydrogen atoms, final fractional coordinates and thermal parameters of hydrogen atoms, and anisotropic thermal parameters have been deposited.[5]

Results and discussion

Several *O,O*-alkylene dithiophosphate derivatives of triphenyl- and diphenylgermane were prepared in 55–65% yields by the reaction of a slight excess of the sodium or ammonium salt of the appropriate *O,O*-alkylene dithiophosphoric acid with

[4] Standard deviation of an observation of unit weight: $[\Sigma w(|F_o| - |F_c|)^2]/(N_o - N_v)^{1/2}$, where N_o = number of observations and N_v = number of variables.

chlorotriphenyl- or dichlorodiphenylgermane in benzene in accord with the equations below.

[1] $Ph_3GeCl + MS_2POGO \rightarrow Ph_3Ge[S_2POGO] + MCl$

[2] $Ph_2GeCl_2 + 2MS_2POGO \rightarrow Ph_2Ge[S_2POGO]_2 + 2MCl$

(M = Na or NH_4;G = $-CMe_2CMe_2-$, $-CH_2CMe_2CH_2-$, or $-CH_2CEt_2CH_2-$)

The reactions with dichlorodiphenylgermane took place readily at room temperature under standard Schlenk-tube conditions to yield the $Ph_2Ge[S_2POGO]_2$ derivatives $Ph_2Ge[S_2POCMe_2CMe_2O]_2$, **4**, $Ph_2Ge[S_2POCH_2CMe_2CH_2O]_2$, **5**, and $Ph_2Ge[S_2POCH_2CEt_2CH_2O]_2$, **6**. By contrast, the starting materials showed little or no sign of reaction under the same conditions with chlorotriphenylgermane. However, when these reactants were refluxed for several hours in benzene, similar yields of the $Ph_3Ge[S_2POGO]$ derivatives $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]$, **3**, were obtained.

All of the compounds **1–6** are stable on exposure to atmospheric oxygen and moisture and in common organic solvents such as benzene, *n*-hexane, toluene, carbon disulfide, and chloroform, the latter being used as the preferred solvent for NMR spectroscopic studies. Samples of **1-6** are stable over a long period, particularly when kept refrigerated, as can be confirmed by the fact that NMR spectra recorded after several months show no changes from the spectra recorded initially. The ^1H NMR spectra confirm that they are 99% pure relative to any hydrogen-containing impurities.

Extensive attempts were made to grow X-ray quality crystals using a variety of solvents or solvent mixtures for **1–6**, but unfortunately crystals of acceptable quality were only obtained for the three triphenyl derivatives, $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**.

The crystal structure of $Ph_3Ge[S_2POCMe_2CMe_2O]$, 1

Triphenyl(*O,O*-2,3-dimethylbutylene dithiophosphato)ger-

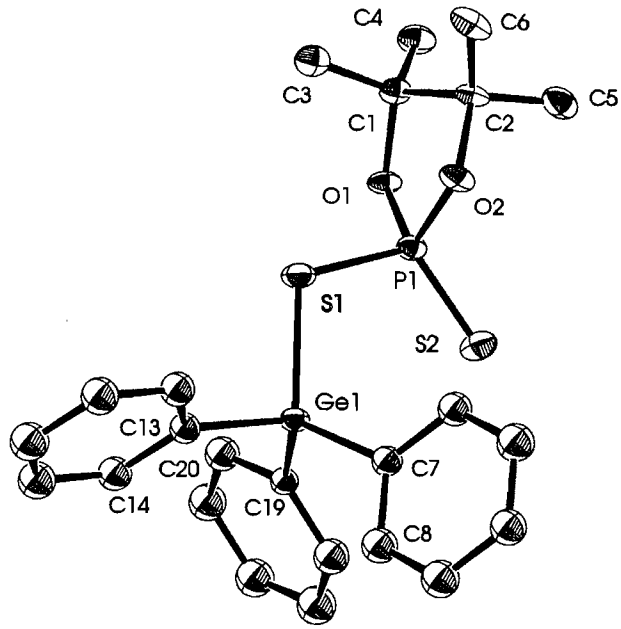
mane, **1**, crystallizes in the space group $P2_1/a$ and its ORTEP diagram (Fig. 1) illustrates that the immediate environment about germanium is that of a distorted tetrahedron. The C-Ge-C angles range from 107.7(3)° to 115.3(3)° and the S-Ge-C angles from 99.4(2)° to 112.8(2)° so that, although the former have an average value larger, 111(4)°, and the latter an average value smaller, 108(7)°, than the all-tetrahedral angle, the difference is within statistical error. This is similar to the situation reported for $Ph_3Sn[S_2POCMe_2CMe_2O]$ where the C-Sn-C angles ranged from 105.7(4) to 118.9(3)° and those of S-Sn-C from 99.8(3) to 111.5(3)° (16). However, it is in contrast to the situation in $Me_2Ge[S_2POCMe_2CMe_2O]_2$ where the C-Ge-C angle is 121.6(5)° and the average of the S-Ge-C angles is 110.2(5)° (6) but not very different from the situation in the noncyclic germanium analogue, $Ph_3Ge[S_2P(OMe)_2]$, where the C-Ge-C angles ranged from 110.6(2) to 114.4(2)° and those of S-Ge-C from 98.7(1)° to 111.9(1)° (1), or in its tin analogue, $Ph_3Sn[S_2P(OEt)_2]$, which has been described as a

Fig. 1. ORTEP plot of the molecule $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**. The atoms are drawn with 25% probability ellipsoids. Hydrogen atoms are omitted for clarity.



unique, monodentate dithiophosphate derivative (25), in which the C-Sn-C angles ranged from 110.8(1)° to 113.1(1)° and those of S-Sn-C from 100.09(9)° to 114.47(9)°. The smallest S-Ge-C angle in $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, involves the carbon atom on the side of the tetrahedron furthest from the dithiophosphate group where there is least steric hindrance, as was observed for $Ph_3Ge[S_2P(OMe)_2]$.

The average Ge—C bond length in **1** of 1.946(10) Å is very similar to that in $Ph_3Ge[S_2P(OMe_2]$ and slightly longer than that in $Me_2Ge[S_2POCMe_2CMe_2O]_2$ where it is 1.915(7) Å (6). The difference is probably associated with the fact that in the latter case there are two dithiophosphate groups rather than one and that methyl groups are present rather than phenyl. Thus the Ge—C bond in $Ph_2Ge[S_2P(OMe)_2]_2$ is shorter, 1.931(2) Å, than in the triphenyl analogue and, in related dithiocarbamates, the methyl derivatives have shorter Ge—C bonds than the phenyl as is demonstrated by those in $Me_2Ge[S_2CNMe_2]_2$, 1.921(7) and 1.910(6) Å, and $Ph_2Ge[S_2CNEt_2]_2$, 1.928(3) Å (26, 27). Ironically, in the methyl series, $Me_3Ge[S_2POGO]$ and $Me_2Ge[S_2POGO]_2$, we were only able to get X-ray quality crystals for $Me_2Ge[S_2POCMe_2CMe_2O]_2$ (1), whereas for the phenyl analogues we solved three structures but all are triphenyl derivatives. The Ge—S bond length of 2.255(3) Å in **1** is similar to those in $Ph_2Ge[S_2P(OMe)_2]_2$, 2.255(4) Å, but shorter than that in $Ph_3Ge[S_2P(OMe)_2]$, 2.285(1) Å, or the average value in $Me_2Ge[S_2POCMe_2CMe_2O]_2$, 2.272(5) Å. The Ge--S distances to the second sulfur atom are very different for the cyclic and noncyclic dithiophosphates, as will be discussed later.

The P—S(Ge) bonds in $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, are only slightly longer, 2.068(3) Å, than the P=S bonds,

1.908(4) Å, and essentially the same as in $Me_2Ge[S_2POCMe_2CMe_2O]_2$. These relatively small differences are typical of all metal dithiophosphates, irrespective of their mode of bonding, and are similar to those reported for $Ph_3Sn[S_2POCMe_2CMe_2O]$ (16) and for the diligands, $[OCMe_2CMe_2OP(S)S]_2$ (28) and $[(i\text{-}PrO)_2P(S)S]_2$ (29). In view of this insensitivity to changes in environment, it is not surprising that the distortion around phosphorus from all tetrahedral angles is similar to that found in $Ph_3Ge[S_2P(OMe)_2]$. The orientation in the five-membered ring system is such that two of the carbon methyl atoms are at an average distance of 3.26(2) Å from the phosphorus atom and the other two are at 3.805(7) Å. A view down the C—C bond of the ring shows that the four methyl groups attached to them are in the staggered configuration expected for the more stable arrangement with the pair at 3.26(2) Å pointing above and below the approximate plane of the distorted ring in an arrangement essentially identical to that observed in $Me_2Ge[S_2POCMe_2CMe_2O]_2$ (6) and $Me_2Te[S_2POCMe_2CMe_2O]_2$ (17).

The crystal structures of $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, 2, and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, 3

$Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, crystallizes in the space group *Pbca* and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**, in *C2/c*, and the orientations chosen for their ORTEP diagrams (Figs. 2 and 3) illustrate that, as with **1**, the immediate environment about germanium is that of a distorted tetrahedron. The C-Ge-C angles range from 107.6(2)° to 113.7(3)° for **2** and from 109.4(6)° to 112.7(6)° for **3** to give very similar average values of 111(3)° and 112(2)°, respectively. The S-Ge-C angles range from 100.6(2)° to 111.9(2)° for **2** and 98.2(5)° to 112.1(4)° for **3** with essentially the same average values of 108(7)° and 107(8)°. Thus, as with **1**, the average value of the C-Ge-C angle is larger than the all-tetrahedral angle and that of the S-Ge-C angle is smaller, but the differences are within statistical error. Also, as with **1**, the smallest S-Ge-C angle in **2** and **3** involves the carbon atom on the side of the tetrahedron furthest from the dithiophosphate group where there is least steric hindrance.

The average Ge—C bond lengths in **2** and **3** of 1.960(6) and 1.94 (2) Å, respectively, are similar to that in **1** of 1.946(10) Å. The Ge—S bond lengths of 2.262(3) and 2.254(6) Å in **2** and **3**, respectively, are similar to that in **1** and those in $Ph_2Ge[S_2P(OMe)_2]_2$, but shorter than that in $Ph_3Ge[S_2P(OMe)_2]$, or the average value in $Me_2Ge[S_2POCMe_2CMe_2O]_2$. It has been noted that the Ge—S bond length of 2.272(5) Å in $Me_2Ge[S_2POCMe_2CMe_2O]_2$ is similar to those in $Ph_2Ge[S_2CNEt_2]_2$ and $Me_2Ge[S_2CNMe_2]_2$, where the dithiocarbamate groups are assumed to be anisobidentate, but longer

than those in $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$, 2.252(3) Å (3), and $Ph_2Ge[S_2P(OMe)_2]_2$, 2.255(4), where the xanthate and noncyclic dithiophosphate ligands are undoubtedly monodentate, because the Ge--S distances to the terminal sulfur atom are 4.754(1) Å in $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$, 5.38(2) Å in $Ph_2Ge[S_2P(OMe)_2]_2$, and 5.253(1) Å in $Ph_3Ge[S_2P(OMe)_2]$. The longer Ge—S bonds in $Me_2Ge[S_2POCMe_2CMe_2O]_2$ and $Ph_2Ge[S_2CNEt_2]_2$ were thus apparently related to the orientation of the second sulfur atom toward, rather than away from, germanium, with Ge--S distances of 3.183(1) Å in $Ph_2Ge[S_2CNEt_2]_2$ and 3.49(3) Å in $Me_2Ge[S_2POCMe_2CMe_2O]_2$. A Ge--S distance of 3.183 (1) Å is considerably shorter than the sum of the van der Waals radii of germanium and sulfur of 3.75 Å (30), whereas one of 3.49(3) Å is relatively long and corresponds to a Pauling partial bond order (17) of only about 0.05. Thus, while the claim of anisobidentate behaviour for the dithiocarbamates appears to be valid, there is some doubt in the case of the cyclic dithiophosphate. For **1, 2**, and **3**, the Ge—S bonds appear to be relatively short and of the same order of magnitude as the clearly monodentate, noncyclic dithiophosphates, but, by contrast, the second sulfur atom is oriented toward, rather than away from, germanium. The Ge--S distances of 3.590(3), 3.889(3), and 4.082(8) Å, respectively, for **1, 2**, and **3,** are considerably less than those in the noncyclic derivatives, but they approach or exceed the sum of the van der Waals radii, and the Pauling partial bond orders are only 0.03, 0.02, and 0.01, for **1, 2**, and **3**, respectively. Thus, in contrast to **1**, where the orientation of the second sulfur atom toward germanium in preference to either of the two oxygen atoms is clear even though the interaction is very weak, for **2** and **3**, with the six-membered ring dithiophosphate, the orientation becomes less defined as the Ge--O distances decrease. This is also demonstrated by the S-Ge-S bite angle, which is 65.59(2)° in **1** but which decreases considerably to 60.27(8)° and 56.4(2)°, respectively, in **2** and **3**.

In the related tin compounds, $Me_2Sn[S_2POCMe_2CMe_2O]_2$ (15) and $Ph_3Sn[S_2POCMe_2CMe_2O]$ (16), the aniso Sn--S distances are shorter, ranging from 3.130(1) to 3.411(3) Å, respectively, in the dimethyl and triphenyl compound, and because of the larger covalent radius of tin these distances correspond to Pauling partial bond orders ranging from 0.19 to 0.10. The S-Sn-S bite angles of 70.68(3)° and 66.8(8)° are consistent with stronger anisobidentate bonding in the dimethyl derivative. By contrast, in the noncyclic dithiophosphate tin derivative, $Ph_2Sn[S_2P(Oi\text{-}Pr)_2]_2$, the dithiophosphate

Fig. 2. ORTEP plot of the molecule $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**. The atoms are drawn with 25% probability ellipsoids. Hydrogen atoms are omitted for clarity.

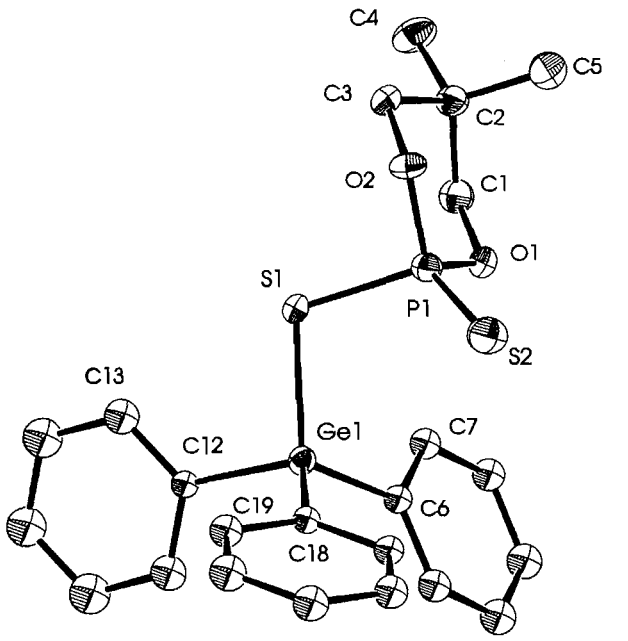

Fig. 3. ORTEP plot of the molecule $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**. The atoms are drawn with 25% probability ellipsoids. Hydrogen atoms are omitted for clarity.

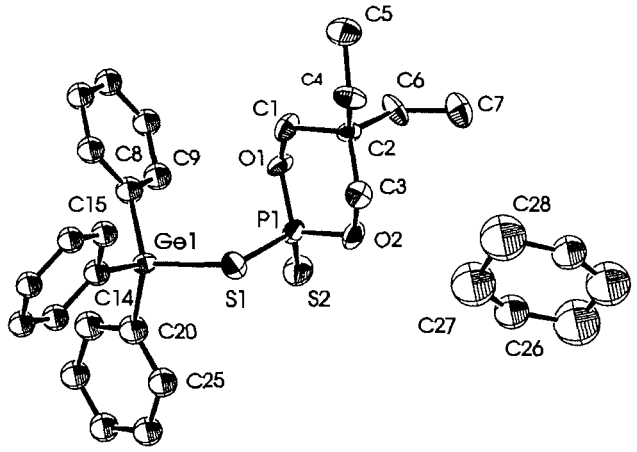

groups are fully bidentate with all four Sn—S bonds covering the range 2.678(1)–2.689(1) Å, with an average partial bond order of 0.55, and with a bite angle of 76.03(3)° (18). Thus, although noncyclic dithiophosphate derivatives of tin are generally bidentate and those of germanium are monodentate, the cyclic dithiophosphates of tin appear to be anisobidentate and those of germanium either weakly anisobidentate or essentially monodentate but still oriented approximately in a similar fashion to the tin analogues.

As with $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, the P—S(Ge) bonds in **2** and **3** are slightly longer, 2.084(4) and 2.09(1) Å for **2** and **3**, respectively, than the P═S bonds, 1.901(4) and 1.912 (7) Å for **2** and **3**, respectively, and, as mentioned earlier, essentially the same as in other related cyclic dithiophosphate derivatives. Thus, again it is not surprising that the distortion around phosphorus from all tetrahedral angles is also similar.

Fig. 4. ORTEP plot of a part of the molecule $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, emphasizing the chair conformation of the six-membered ring. The atoms are drawn with 25% probability ellipsoids. Hydrogen atoms on the carbon atoms in the ring are included. The carbon atoms of the phenyl ring, except those attached to germanium, are omitted for clarity.

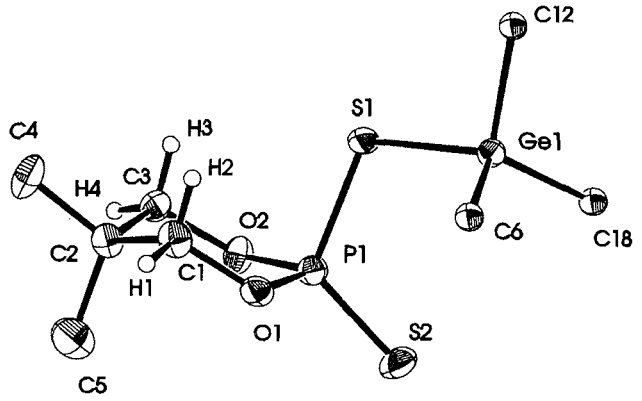

Fig. 5. ORTEP plot of part of the molecule $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**, emphasizing the chair conformation of the six-membered ring. The atoms are drawn with 25% probability ellipsoids. Hydrogen atoms on the carbon atoms in the ring are included. The carbon atoms of the phenyl ring, except those attached to germanium, and those of the benzene ring are omitted for clarity.

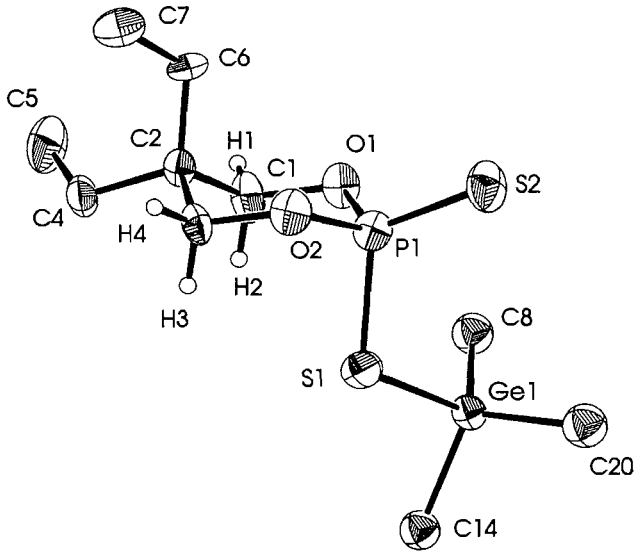

The carbon atoms of the phenyl rings, with the exception of the ones attached to germanium, are omitted from the ORTEP diagrams of $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2**, and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**, in Figs. 4 and 5, respectively, as is the benzene ring in the lattice in the latter case. As a result the figures clearly show that the six-membered ring system is in the chair configuration with one pair of hydrogen atoms being closer to phosphorus, at an average distance of 2.87 Å in **2** and 2.84 Å in **3** for H(2) and H(3), than the second pair at 3.41 Å in **2** and 3.42 Å for in **3** for H(1) and H(4). The methyl

groups attached to the center carbon atom in the ring are also in unique positions relative to their distances to phosphorus, C(4) in **2** and **3** being at 4.47(1) and 4.45(2) Å, respectively, and C(5) in **2** and C(6) in **3** at 3.67(1) and 3.68(2) Å, respectively.

Infrared and Raman spectra

The assignments of the vibrational spectra of **1** and **4** are given in Table 7 and those of **2, 3, 5**, and **6** in Table 8 because characteristic features of the five- and six-membered ring dithiophosphates are sufficiently different that a collation in one table appeared to be confusing rather than helpful. For all six molecules, distinctive features are observed that are characteristic of a monosubstituted benzene ring and are relatively insensitive to the nature of the substituent (31). In general, for Ph_3GeX and Ph_2GeX_2 species, no specific assignments to Ge—C stretching vibrations are possible (32) but six prominent peaks in the infrared spectra are excellent fingerprints for phenyl groups attached to germanium that in decreasing order of intensity are consistently seen at approximately 737 and 696 cm^{-1}, 460 and 335 cm^{-1}, and 1434 and 1090 cm^{-1}. The relative intensities are consistent and increase as the number of phenyl groups attached to germanium increase. In the Raman effect there is only one very intense feature at approximately 1000 cm^{-1}, which is very weak in the infrared spectrum. Thus a distinct change in relative intensities of these peaks associated with the phenyl groups is indicative of an overlapping feature arising from vibrations within the dithiophosphate groups. The infrared spectra of **1–6**, particularly in the region around 1000 cm^{-1}, also contain distinctive strong bands that are similar, but not identical, to those of the starting salts. These are summarized in the tables and assigned to the motion that is probably contributing most to the fundamental, even though the modes are undoubtedly extensively mixed. The similarity of these characteristic features within the dithiophosphate groups is not surprising in view of the similarity in the structure of $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$ and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]$ and in the similarity of the arrangement of the dithiophosphate groups in $Ph_3Ge[S_2POCMe_2CMe_2O]$ and $Me_2Ge[S_2POCMe_2CMe_2O]_2$ (6). The assignments of the Ge–S stretching vibrations in **1–6** are consistent with the dithiophosphate groups being bonded in similar fashion in all six derivatives.

Nuclear magnetic resonance spectra

The ^1H NMR spectra data for compounds **1–6** are presented in Table 9. The splitting patterns and relative intensities of peaks are consistent with the solid state structures being maintained in solution. The peaks attributable to C_6H_5-Ge are clustered to essentially give identical patterns for all six compounds with the chemical shifts being within the range 7.70–7.38 ppm for the triphenyl derivatives, **1–3**, and 7.91–7.40 ppm for the diphenyl compounds **4–6**. The observation of two peaks in the ^1H NMR spectrum of $Ph_3Ge[S_2POCMe_2CMe_2O]$, **1**, at 1.40 and 1.45 ppm, indicates that the four methyl groups in the dithiophosphate are in two different environments. This is in agreement with the structure of **1**, in which the carbon atoms of one pair of methyl groups are at an average distance of

3.26(2) Å from phosphorus and at an average distance of 3.81(2) Å for the second pair. Two peaks are also observed in the ^1H NMR spectrum of $Ph_2Ge[S_2POCMe_2CMe_2O]_2$, **4**, at 1.34 and 1.38 ppm with the appropriate increase in intensity relative to the peaks arising from the phenyl groups. Thus each of the dithiophosphate groups in **4** is maintaining a similar configuration in solution to each other and it is reasonable to assume that the orientation is the same as in the solid state structure of **1**. This is in agreement with the observations for the corresponding methylgermanium derivatives (6) but the maintenance of the nonequivalence in solution is surprising because there have been no reports of such splitting in the ^1H NMR spectra of any other derivatives containing similar cyclic dithiophosphates (7–14). Even the closely related tin compound, $Ph_2Sn[S_2POCMe_2CMe_2O]_2$, displays only one peak in this region at 1.0 ppm (14). Thus the apparent uniqueness of the maintenance of the nonequivalence that we found in the case of $Me_3Ge[S_2POCMe_2CMe_2O]$ and $Me_2Ge[S_2POCMe_2CMe_2O]_2$ (6) is also a feature for these phenyl analogues.

The ^1H NMR spectra of compounds **2, 3, 5**, and **6** all display the same complex pattern arising from the nonequivalence of the hydrogen atoms of the CH_2 groups in the six-membered ring, which is apparent from the X-ray structures of $Ph_3Ge[S_2POCH_2CMe_2CH_2O]$, **2** and $Ph_3Ge[S_2POCH_2CEt_2CH_2O]\cdot C_6H_6$, **3**, as displayed in the ORTEP diagrams in Figs. 4 and 5. The feature is displayed in Fig. 6 for compound **2**, as a representative example. The four CH_2 protons give two sets of multiplets that are as expected for an ABX system, and which appear as two sets of approximate 1:1:1:1 quartets, centered at 4.12 and 3.64 ppm. The multiplet at 4.12 ppm can be analyzed as arising from geminal spin–spin coupling with a value for $J(H_aH_b)$ of 10.8 Hz, with further splitting as a result of coupling with phosphorus to give a value for $J(PH_a)$ of 5.6 Hz. The second multiplet at 3.64 ppm is apparently more clearly split into two doublets because the coupling to phosphorus is much larger with the value of the $J(PH_b)$ coupling constant being 25.0 Hz. The appearance of these two multiplets in the spectra of **3, 5**, and **6** is essentially the same because the values of the chemical shifts and coupling constants are virtually identical in all four compounds, as can be seen from Table 9. Thus the two protons on carbon are nonequivalent, as was observed for the two methyl groups substituted in the corresponding positions in the five-membered rings in **1** and **4**, and the values of the spin–spin coupling constants with phosphorus are different. It is reasonable to assume, by analogy with cyclohexane, that protons H_a (i.e., H(1), H(4)) and H_b (i.e., H(2), H(3)) in Figs. 4 and 5 occupy axial and equatorial positions, respectively, in a chair, rather than boat (6), configuration that is maintained in solution. The values for $J(PH)$ differ because the distance from P to the H_a positions is much larger than that to the H_b positions. Figure 6

[c]Coupling constants in Hz shown in square brackets [ ].

[d]Peaks attributable to the corresponding salts are seen in the ^{1}H NMR spectra of $Na[S_2POCMe_2CMe_2O]$ at 1.46 (12 H, s); of $Na[S_2POCH_2CMe_2CH_2O]$ at 4.03 (4 H, d [15.2]) and 1.05 (6 H, s); and of $NH_4[S_2POCH_2CEt_2CH_2O]$ at 4.13 (4 H, d [15.4]), 1.44 (4 H, q [7.6]), and 0.88 (6 H, t [7.6]).

[e]Both $J(H_aH_b)$ and $J(PH_a)$ coupling are observed.

[f]Both $J(H_aH_b)$ and $J(PH_b)$ coupling are observed.

also demonstrates the absence of any unidentified peaks due to hydrogen-containing impurities. The ^{31}P NMR spectra of **2**, **3**, **5**, and **6** all show a single peak unless recorded without hydrogen decoupling when a triplet of triplets is observed. The larger triplet has a coupling constant of 25.0 Hz, as expected for coupling of phosphorus with the two equatorial protons, and the triplet is further split into a triplet from coupling of the phosphorus with the two axial protons with a value of 5.6 Hz for this coupling constant. These observations are essentially identical to those in $Me_3Ge[S_2POCH_2CMe_2CH_2O]$, $Me_3Ge[S_2POCH_2CEt_2CH_2O]$, $Me_2Ge[S_2POCH_2CMe_2CH_2O]_2$, and $Me_2Ge[S_2POCH_2CEt_2CH_2O]_2$ (6) so that, although we were unable to obtain crystal structures for these methyl derivatives, it is reasonable to assume the conformation of the dithiophosphate groups is the same for them. It is worth noting that a typical value for J(PH) in the starting salts and related cyclic dithiophosphate derivatives that do not show the two separate couplings falls between those of these $J(PH_a)$ and $J(PH_b)$ values (8, 9, 12–14), the values for $Me_2Te[S_2POCH_2CMe_2CH_2O]_2$ and $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$ of 15.6 and 15.8 Hz, respectively, being typical (17).

The $^{13}C\{H\}$ NMR spectral data for compounds **1–6** are presented in Table 10. The peaks attributable to C_6H_5-Ge show the same pattern for all six compounds in terms of relative intensities and do not differ to any large degree from compound to compound. All of the other peaks can be readily assigned to the various carbon atoms of the cyclic dithiophosphate groups at positions virtually identical to those found for the corresponding trimethylgermanium and dimethylgermanium analogues and close to, but not identical to, those of the corresponding salts and acids. However, again in contrast to the features in the salts, acids, or other metal derivatives where the observation of single peaks indicates identical or averaged positions, duplicate peaks are observed for compounds **1–6** for all of the atoms attached to the rings. In general, the values of the coupling constants, $J(PCC)$ and $J(PCCC)$, which are included in Table 10, are typical of such groups in a variety of

For personal use only.

environments, as is the fact that these couplings are not observed in a consistent manner (8, 9, 12, 14, 17).

The $^{31}P\{H\}$ NMR spectra, which are presented in Table 9 along with the ^{1}H NMR data, show a single peak in all compounds **1–6**, consistent with both dithiophosphate groups in **4–6** being in identical environments. It has been proposed that the difference in the phosphorus chemical shift between a derivative and that of the free acid, ΔP, is an accurate indicator of the mode of binding (33). Thus, downfield shifts in the range ΔP = 8–15 ppm are associated with bidentate ligands, and negligible shifts or even upfield shifts are associated with monodentate linkages. In compounds **1–6** the values of ΔP range from 4.3 ppm downfield in **1** to 2.4 ppm upfield in **3**, and therefore are consistent with monodentate ligands. In other words, the shifts are consistent with the structures in solution apparently remaining the same as the solid state structures of **1–3**, where the ligand is monodentate or weakly anisobidentate because the second sulfur atom is oriented toward rather than away from germanium but at a sufficiently large distance to imply, at best, a weak interaction. The shifts are smaller than those observed for the methyl germanium analogues and considerably smaller than those observed for analogous dimethyltellurium derivatives where ΔP ranged from 11 to 16 ppm downfield (17). Although the dithiophosphate groups had similar orientations in $Me_2Te[S_2POCH_2CMe_2CH_2O]_2$ and $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$, the "nonbonding" Te--S secondary interactions were such as to indicate relatively strong anisobidentate linkages and it was assumed these took on bidentate behaviour in solution by rapid exchange. The similarities in the ^{1}H, ^{13}C, and ^{31}P NMR spectra of **1–6** suggest that the weak anisobidenticity found in the solid state structures of **1–3** is maintained in solution for all six compounds. By contrast, in the tin and tellurium analogues, the dithiophosphate groups undergo exchange in solution to bring about equivalence for all atoms in the groups, presumably by interchanging the bonded and aniso-bonded sulfur positions, which is consistent with the general tendency for dithio ligands to be bidentate when attached to tin and tellurium (34, 35). Germanium is apparently unique in terms of size, affinity to sulfur, or both, so that exchange does not occur and as a result the nonequivalence is maintained in solution.

Acknowledgement

We thank the Natural Sciences and Engineering Research Council of Canada and Imperial Oil Canada for financial support. One of us (J.E.D.) expresses his sincere thanks to the members of the Department of Chemistry of the University of Otago where he spent a short but very productive leave, with particular thanks to Professor Jim Simpson without whose help this paper would not have appeared. One of us (R.R.) thanks Dayanand College, Ajmer, India, for a leave of absence.

Abstract: The reaction of $Ru(CO)_4(C_2H_4)$ or $Ru(CO)_5$ with 1,5-$Ph_4P_2N_4S_2$ in CH_2Cl_2–hexane at 23°C produces the dimer $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$ (**4**) in 54% and 11% yields, respectively. The treatment of **4** with methyl triflate (1:1 molar ratio) in dichloromethane yields the mono(N-methylated) derivative $[Ru_2(CO)_4(Ph_4P_2N_4S_2)(Ph_4P_2N_4S_2Me)][CF_3SO_3]$ (**5**) or, in a 1:2 molar ratio, the dimethylated derivative $[Ru(CO)_2(Ph_4P_2N_4S_2Me)]_2[CF_3SO_3]_2$, which exists as a ca. equal mixture of two symmetrical isomers on the basis of ^1H and ^{31}P NMR, and IR spectra. The reaction of **4** with two equivalents of Me_3NO in the presence of acetonitrile generates $[Ru(CO)(CH_3CN)(Ph_4P_2N_4S_2)]_2$, which is also formed as a mixture of isomers in a ratio of ca. 2:1 on the basis of ^1H and ^{31}P NMR, and IR spectra. The X-ray structure of **4**·CH_2Cl_2 shows that the $P_2N_4S_2$ ring is bonded to one ruthenium through two (geminal) nitrogen atoms and the remote sulfur atom while the second sulfur atom acts as a bridge to the other ruthenium. The crystals of **4**·CH_2Cl_2 are triclinic, space group $P\bar{1}$ with a = 12.901(1) Å, b = 13.072(1) Å, c = 10.123(1) Å, α = 100.88(1)°, β = 98.90(1)°, γ = 67.50(1)°, V = 1542.4(3) Å^3, and Z = 2. The final R and R_w values were 0.040 and 0.027, respectively. The X-ray structure of **5** reveals that N-methylation does not significantly perturb the bonding between the heterocyclic ligand and ruthenium. The crystals of **5** are triclinic, space group $P\bar{1}$ with a = 12.912(6) Å, b = 13.435(7) Å, c = 9.948(3) Å, α = 105.04(3)°, β = 102.85(3)°, γ = 70.74(4)°, V = 1555(1) Å^3, and Z = 2. The final R and R_w values were 0.063 and 0.071, respectively.

Key words: ruthenium, tetradentate ligand, $P_2N_4S_2$ ring.

Résumé : La réaction du $Ru(CO)_4(C_2H_4)$ ou du $Ru(CO)_5$ avec le 1,5-$Ph_4P_2N_4S_2$, dans le CH_2Cl_2–hexane, à 23°C, fournit le $[Ru(CO)_2Ph_4P_2N_4S_2]_2$ (**4**) avec des rendements respectifs de 54 et de 11%. Le traitement du composé **4** par le triflate de méthyle (rapport molaire de 1 : 1), dans le dichlorométhane, fournit le dérivé mono(*N*-méthylé) $[Ru(CO)_2(Ph_4P_2N_4S_2)(Ph_4P_2N_4S_2Me)][CF_3SO_3]$ (**5**) ou, dans un rapport molaire de 1 : 26, le dérivé diméthylé $[Ru(CO)_2(Ph_4P_2N_4S_2Me)_2][CF_3SO_3]$ qui, sur la base des spectres RMN du ^1H et du ^{31}P et des spectres IR, existe sous la forme d'un mélange approximativement molaire de deux isomères symétriques. La réaction du composé **4** avec deux équivalents de CH_3NO, en présence d'acétonitrile, fournit du $[Ru(CO)(CH_3CN)(Ph_4P_2N_4S_2)]_2$ qui se forme aussi comme un mélange d'isomères dans un rapport approximatif de 2 : 1, sur la base des spectres RMN du ^1H et du ^{31}P et des spectres IR. La structure déterminée par diffraction des rayons X du composé **4**·CH_2Cl_2 montre que le cycle $P_2N_4S_2$ est lié à un ruthénium par le biais de deux atomes d'azote géminaux et de l'atome de soufre éloigné alors que le deuxième atome de soufre agit comme pont pour l'autre ruthénium. Les cristaux de composé **4**·CH_2Cl_2 sont tricliniques, groupe d'espace $P\bar{1}$ avec a = 12,901(1), b = 13,072(1) et c = 10.123(1) Å, α = 100.88(1)°, β = 98.90(1)° et γ = 67.50(1)°, V = 1542.4(3) Å^3 et Z = 2. Les valeurs finales de R et R_w sont respectivement de 0,040 et 0,027. La structure du composé **5**, telle que déterminée par diffraction des rayons X, montre que la *N*-méthylation ne perturbe pas d'une façon significative la liaison entre le coordinat hétérocyclique et le ruthénium. Les cristaux du composé **5** sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 12.912(6), b = 13.435(7) et c = 9.948(3) Å, α = 105.04(3)°, β = 102.85(3)° et γ = 70.74(4)°, V = 1555(1) Å^3 et Z = 2. Les valeurs finales de R et R_w sont respectivement de 0,063 et 0,071.

Mots clés : ruthénium, ligand tétradentate, cycle $P_2N_4S_2$.

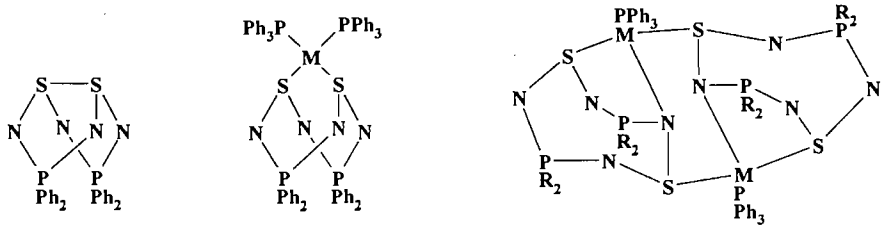
Introduction

Weak, cross-ring S—S bonds are a common feature of π-electron-rich S—N heterocycles (1). These transannular linkages are the result of intramolecular π*(NSN)–π*(NSN) interactions, which have S—S σ-bonding character (2). The most intriguing example of this unusual functionality is provided by S_4N_4. However, the reactions of this inorganic heterocycle with metal carbonyls produce insoluble complexes that are difficult to characterize, e.g., $(S_5N_5)Mo(CO)$ (3), $(S_4N_4)Fe(CO)$ (4), and $S_4N_4Co_2(CO)_2$ (4, 5). With zerovalent complexes of the platinum group metals, S_4N_4 fragments to give complexes containing MSNSN rings (M = Pt, Pd, Ni) (6–8). By contrast, the integrity of the $P_2N_4S_2$ ring is retained in oxidative-addition reactions of **1** (or its tetraalkyl derivatives) with Pt(0) and Pd(0) complexes. The metal–ligand bonding in the η^2-S,S′ complexes **2** so formed involves primarily back donation from the metal to the σ*(S—S) orbital (LUMO) of **1** with a smaller contribution provided by donation from the σ(S—S) orbital (HOMO) of **1** to the metal (*9a*). The coordinatively saturated P(V) "spectator" nuclei in **1** serve as an informative NMR probe of fluxional behavior in metal complexes such as the centrosymmetric dimers **3** formed upon loss of PPh_3 from **2** (*9b*, 10).

The structures of **2, 3**, and η^1-N complexes of **1** with Pt(II) (11) indicate that the $P_2N_4S_2$ ring readily adapts its bonding mode to suit the electronic requirements of the metal centre. To further test this proposition, and in view of the paucity of information about complexes of S–N ligands with metals of the iron triad (12, 13), we have investigated the reactions of **1** with Ru(0) and Fe(0) complexes. In a preliminary communication we described the preparation and brief details of the structure of the unusual ruthenium dimer $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$ (**4**) (14). In this article we report investigations of both the ligand and metal-centered reactivities of 4. In addition to a discussion of the effect of metal coordination on the structural parameters of the $P_2N_4S_2$ ligand, the spectroscopic characterization and structure of the mono(N-methylated) derivative $[Ru_2(CO)_4(Ph_4P_2N_4S_2)(Ph_4P_2N_4S_2Me)][CF_3SO_3]$ are depicted. The NMR characterization of the dimethylated derivative $[Ru(CO)_2(Ph_4P_2N_4S_2Me)]_2[CF_3SO_3]_2$ and $[Ru(CO)(MeCN)(Ph_4P_2N_4S_2)]_2$, both of which are formed as a mixture of isomers, is also described.



1 **2** (M = Pt, Pd) **3** (M = Pt, Pd)

Experimental

All manipulations were conducted under an atmosphere of prepurified nitrogen or argon by using vacuum line techniques. Diethyl ether, toluene, and hexanes were dried and freshly distilled from sodium benzophenone ketyl while dichloromethane was dried and distilled over CaH_2. Oxygen was removed from the solvents via three freeze–thaw–pump cycles under argon. Anhydrous trimethylamine N-oxide was prepared by subliming $Me_3NO{\cdot}2H_2O$ at 70°C under reduced pressure (ca. 0.1 Torr (1 Torr = 133.3 Pa)). The compound $Ru(CO)_4(C_2H_4)$ was prepared by a modified literature method[3] and 1,5-$Ph_4P_2N_4S_2$ was synthesized as previously described (16). Methyl triflate, trimethylamine oxide dihydrate, and triruthenium dodecacarbonyl (all from Aldrich) were used as received. Ethylene (Matheson Gas) was used directly from the cylinder. Elemental analyses were performed by the microanalytical services within the chemistry departments of the University of Calgary and the University of Alberta.

Infrared spectra were recorded in dichloromethane (0.1 mm thick NaCl solution cells) on a Nicolet MX1 FTIR spectrometer. ^{31}P NMR spectra were recorded at either 161.98 MHz by using a Bruker AM-400 spectrometer in dichloromethane with an external D_2O lock signal or at 81.0 MHz in deuterated dichloromethane by using a Bruker AM-200 spectrometer. ^1H and ^{13}C NMR spectra were recorded in CD_2Cl_2 solution either at 300.1 and 75.5 MHz, respectively, on a Bruker AM-300 instrument or at 200.1 and 50.3 MHz, respectively, on the Bruker AM-200 instrument. ^{31}P chemical shifts are given in ppm relative to 85% H_3PO_4 while ^1H and ^{13}C chemical shifts (ppm) are reported relative to $Si(CH_3)_4$. Fast atom bombardment (FAB) mass spectra were obtained on a Kratos MS9 spectrometer in a cleland matrix. The ^{31}P NMR data for compounds **4–7** are gathered in Table 1. All other data relating to the characterization of these new compounds are provided below with the synthetic procedures.

Preparation of $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$, 4

A colorless solution of $Ru(CO)_4(CH_2{=}CH_2)$ (0.148 g, 0.61 mmol) in deoxygenated hexane (30 mL) was transferred by cannula, over 15 min, to a stirred colorless solution of 1,5-$Ph_4P_2N_4S_2$ (0.299 g, 0.61 mmol) in dichloromethane (80 mL) under a nitrogen atmosphere at 23°C. Stirring was continued for 16 h at room temperature, during which time a yellow solution was formed. The solvent was removed under vacuum to give a yellow-brown product, which was washed with diethyl ether (2 × 10 mL) and vacuum dried for 2 h. Slow diffusion of hexane (10 mL) into a dichloromethane solution (10 mL) of the

[2] This complex may be a mixture of products since nitrosylation yields $(NO)_2CoSSNS$ (5).

[3] Hydrocarbon solutions of $Ru(CO)_4(C_2H_4)$ were prepared by a slight modification of the published procedure (see refs. 15*a* and 15*b*) involving external photolysis ($\lambda \geq 370$ nm) of $Ru_3(CO)_{12}$ under 2 atm (1 atm = 101.3 kPa) of ethylene (J. Takats and K. Hofmann. Private communication).

7*a*	63.2(d)	60.0(d)	60.0(d)	63.2(d)	5
7*b*	62.4(s)	60.4(s)	60.4(s)	62.4(s)	

[a]See Scheme 1 for structural drawings of **4**, **5**, **6***a*/*b*, **7***a*/*b*.

[b]In CH_2Cl_2 at 23°C.

[c]The assignments of spin labels for inequivalent P atoms in **5** are shown in Scheme 1. The assignments of the ^{31}P NMR resonances for **7***a* and **7***b* are arbitrary. All four resonances in isomers **6***a* and **7***a* exhibit 5 Hz coupling.

[d]Chemical shifts are quoted in ppm relative to 85% H_3PO_4. Abbreviations used: (s) singlet; (d) doublet; (dd) doublet of doublets.

[e]In Hz.

product afforded bright yellow crystals of **4** (0.213 g, 0.164 mmol, 53%). IR (CH_2Cl_2 solution, cm^{-1}): 2040(s), 1986(s). ^1H NMR (23°C, 200 MHz, CD_2Cl_2): 7.15–7.80 (m, C_6H_5). ^{13}C NMR (23°C, 75.5 MHz, CD_2Cl_2): 127.82–135.19 (m, C_6H_5), 193.69 (s, *C*O). FAB MS (^{102}Ru, *m/z* (%)): 1297 (92, $M + H^+$), 1269 (36, $M - CO + H^+$), 1241 (44, $M - 2CO + H^+$), 1213 (34, $M - 3CO + H^+$), 1185 ($M - 4CO + H^+$). Anal. calcd. for $C_{52}H_{40}N_8O_4P_4Ru_2S_4$: C 48.21, H 3.11, N 8.65, S 9.90, found: C 48.09, H 3.25, N 8.53, S 9.79.

Preparation of $[Ru_2(CO)_4(Ph_4P_2N_4S_2)(Ph_4P_2N_4S_2Me)][SO_3CF_3]$, 5

Methyl trifluoromethanesulfonate (10 μL, 0.092 mmol) in dichloromethane (20 mL) was added dropwise by cannula, over 30 min, to a rapidly stirred yellow-orange solution of $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$ (0.119 g, 0.092 mmol) in dichloromethane (25 mL) at 23°C. During the addition, the solution gradually changed color from yellow-orange to yellow. After the addition, the yellow mixture was stirred for 1 h and then the solvent volume was reduced to ca. 5 mL under vacuum. Diethyl ether (20 mL) was carefully layered on top of the concentrated orange solution and the resulting bilayer was placed in the freezer (−18°C). Yellow crystals of **5**·CH_2Cl_2 (0.098 g, 0.063 mmol) were obtained after 12 h at −18°C. Yield: 69%. IR (CH_2Cl_2 solution, cm^{-1}): 2069(s), 2052(s), 2013(s), 1996(s,br). ^1H NMR (23°C, 200 MHz, CD_2Cl_2): 6.93–7.90 (m, 40H, C_6H_5), 3.45 (d, ^3J(PH) = 9 Hz, 3H, NCH_3). ^{13}C NMR (23°C, 50.3 MHz, CD_2Cl_2): 136.38–128.16 (m, C_6H_5), 38.80 (d, ^2J(PC) = 6 Hz, NCH_3). Anal. calcd. for $C_{55}H_{45}Cl_2N_8O_7F_3P_4S_5Ru_2$: C 42.78, H 2.94, N 7.26, found: C 42.93, H 2.50, N 6.85.

Preparation of $[Ru(CO)_2(Ph_4P_2N_4S_2Me)]_2[SO_3CF_3]_2$, 6

A colorless solution of methyl trifluoromethanesulfonate (8.3 μL, 0.073 mmol) in dichloromethane (20 mL) was added dropwise by cannula over 10 min to a rapidly stirred yellow solution of $[Ru_2(CO)_4(Ph_4P_2N_4S_2)(Ph_4P_2N_4S_2Me)][SO_3CF_3]$ (0.107 g, 0.073 mmol) in dichloromethane (15 mL) at 23°C. The resulting yellow mixture was stirred for 1 h and then th e solvent was removed under vacuum. Recrystallization of the yellow residue from a 1:1 mixture of dichloromethane – diethyl ether (10 mL) at 23°C afforded yellow crystals of $[Ru(CO)_2$-$(Ph_4P_2N_4S_2Me)]_2[CF_3SO_3]_2$ (**6**) (0.111 g, 0.068 mmol, 93%). IR (cm^{-1}, CH_2Cl_2 solution): 2072(s), 2025(s). The ^1H and ^{31}P NMR spectra (see Table 1) indicate that the product **6** is a ca. 1:1 mixture of isomers. ^1H NMR (23°C, 200.1 MHz, 23°): 7.04–7.76 (m, 40H, C_6H_5), 3.49 (d, ^3J(PH) = 9 Hz, 3H, NCH_3), 3.45 (d, ^3J(PH) = 9 Hz, 3H, NCH_3). Anal. calcd. for $C_{56}H_{46}N_8O_{10}F_6P_4S_6Ru_2$: C 41.43, H 2.86, N 6.90; found: C 41.40, H 2.56, N 6.92.

The isomeric mixture **6** was also obtained in yields of 70–90% by the reaction of $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$ with two molar equivalents of methyl trifluoromethanesulfonate in dichloromethane at 23°C.

Preparation of $[Ru(CO)(NCMe)(Ph_4P_2N_4S_2)]_2$, 7

A colorless solution of sublimed Me_3NO (0.023 g, 0.308 mmol) in dichloromethane (30 mL) was added dropwise over 30 min by cannula to a rapidly stirred yellow-orange solution of $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$ (0.200 g, 0.154 mmol) and a large excess of acetonitrile (3.93 g, 96 mmol) in dichloromethane (20 mL) at 23°C. The resulting yellow mixture was stirred for 1 h and the solvent was removed under vacuum. The yellow residue was dissolved in 2 mL of dichloromethane and then 2 mL of diethyl ether were carefully added to this solution by syringe. Yellow crystals of $[Ru(CO)(NCMe)(Ph_4P_2N_4S_2)]_2$·$\frac{1}{2}CH_2Cl_2$ (**7**) (0.120 g, 0.088 mmol, 57%) formed after 5 days at room temperature. IR (cm^{-1}, CH_2Cl_2 solution): 1953(s, br). The ^1H and ^{31}P NMR spectra (see Table 1) indicate that the product **7** is a ca. 2:1 mixture of isomers. ^1H NMR (23°C, 200.1 MHz, CD_2Cl_2): 7.10–8.01 (m, C_6H_5), 5.32 (s, CH_2Cl_2), 1.75 (s, $NCCH_3$), 1.67 (s, $NCCH_3$). The integrated area of the resonance at 1.75 was ca. twice that of the resonance at 1.67. Anal. calcd. for $C_{54.5}H_{47}O_2N_{10}P_4Ru_2ClS_4$: C 47.99, H 3.47, N 10.27; found: C 47.75, H 3.75, N 9.76.

X-ray analyses

Yellow crystals of **4** and **5** suitable for study by X-ray diffraction were grown by the slow diffusion of diethyl ether into

dichloromethane solutions of the complexes. Crystal data, details of the data collection, and structure refinements for **4** and **5** are summarized in Table 2. Accurate cell dimensions and crystal orientation matrices were determined on a Rigaku AFC6S diffractometer by a least-squares fit of the setting angles of 25 reflections. Data were corrected for Lorentz, polarization, and empirical absorption effects (17).

The structures of **4** and **5** were solved by the heavy-atom method. Refinement of the structures was by full-matrix least-squares calculations, initially with isotropic and finally with anisotropic temperature factors for the non-hydrogen atoms. The phenyl groups were allowed to refine as regular hexagons; one of the phenyl groups in **5** was found to be disordered over two sites with unequal site occupancy factors that were allowed to refine. The structure of **5** contains half an anion of CF_3SO_3, which lies close to a special position and is disordered with fluorine atoms distributed over four sites. A molecule of cocrystallized dichloromethane was located in the unit cell of **4**. The structure for **4** refined to $R = 0.040$; $R_w = 0.027$ while **5** converged to $R = 0.063$; $R_w = 0.071$. Scattering factors were those of Cromer and Waber (18) and Stewart, Davidson, and Simpson (19) and allowance was made for anomalous dispersion (20). Fractional atomic coordinates and isotropic temperature factors for **4** and **5** are given in Tables 3 and 4. Sup-plementary experimental details, hydrogen atom parameters, anisotropic thermal parameters, and complete tables of bond lengths, bond angles, and torsion angles have been deposited.[4]

Results and discussion

Synthesis of $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$, 4

As part of a study of the displacement of an η^2-alkene by the bidentate (η^2-S,S′) ligand **1** (9) we chose $Ru(CO)_4(C_2H_4)$,[3] which contains an exceptionally labile C_2H_4 ligand, as a source of ruthenium(0). The addition of a hexane solution of $Ru(CO)_4(C_2H_4)$ (pressurized with ca. 2 atm of ethylene) to a solution of **1** in dichloromethane produced a yellow solid that, on the basis of elemental analyses and the FAB mass spectrum, was identified as the dimer $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$. The yield was 53%. Thus the ring system **1** has replaced both the ethylene ligand and two CO groups (eq. [1]). Compound **4** can be obtained in much lower yield from the reaction of **1** with $Ru(CO)_5$ under similar conditions. Surprisingly, however, the tetraalkyl derivatives of **1** do not add oxidatively to $Ru(CO)_4(C_2H_4)$ even at 70°C in toluene.

$$[1]\quad Ru(CO)_4(C_2H_4) + Ph_4P_2N_4S_2 \xrightarrow[-2CO]{-C_2H_4} \tfrac{1}{2}[Ru(CO)_2(Ph_4P_2N_4S_2)]_2 \qquad \mathbf{4}$$

$B_{eq} = \frac{8}{3}\pi^2(U_{11}(aa^*)^2 + U_{22}(bb^*)^2 + U_{33}(cc^*)^2 + 2U_{12}aa^*bb^* \cos\gamma + 2U_{13}aa^*cc^* \cos\beta + 2U_{23}bb^*cc^* \cos\alpha)$

The mode of attachment of the inorganic heterocycle to the metal center in **4** is of interest. The ^{31}P NMR spectrum of **4** in CH_2Cl_2 exhibits a singlet at 63.9 ppm implying that the $P_2N_4S_2$ ring is coordinated symmetrically to ruthenium and that the S–S cross-ring interaction has been cleaved (*9b*). The IR spectrum of **4** in CH_2Cl_2 shows only two bands in the carbonyl region at 2040 and 1986 cm^{-1} (cf. ν(CO) 2048 and 1978 cm^{-1} for RuI_2(*trans*-bis-piperidine)(*cis*-dicarbonyl)) (21), suggesting that **4** contains two equivalent *cis*-$Ru(CO)_2$ units related by a centre of symmetry. An X-ray structure determination of **4** (vide infra) showed it to consist of a centrosymmetric dimer in which each $P_2N_4S_2$ ring is η^3-N,N′,S bonded to one ruthenium and bridged through the other sulfur atom (μ,η^1-S′) to the second ruthenium atom (see Scheme 1).

In an attempt to determine if coordination complexes of iron with the $P_2N_4S_2$ ring resemble those of ruthenium, the reaction of **1** in THF at 23°C with $Fe(CO)_5$ in the presence of Me_3NO was investigated. This reaction produced a complex mixture of phosphorus-containing products (δ ^{31}P in the range 10–35 ppm) in addition to a singlet at 66 ppm, which may correspond to the iron analogue of **4**. It was not possible to isolate a pure sample of this product.

X-Ray structure of $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$, 4

The coordination geometry of the $P_2N_4S_2$ ring in **4** was estab-

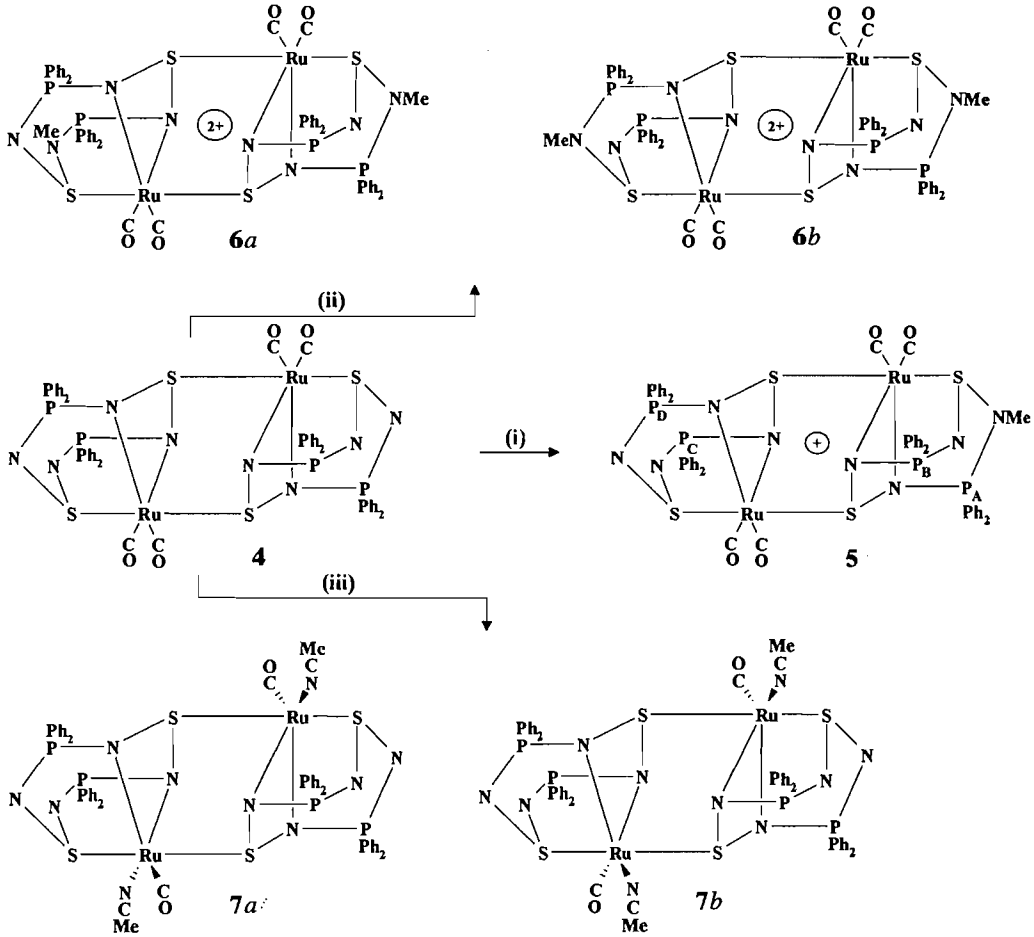
Scheme 1. Formation of $[Ru_2(CO)_4(Ph_4P_2N_4S_2Me)(Ph_4P_2N_4S_2)]^+$ and the *cis* and *trans* isomers of $[Ru(CO)_2(Ph_4P_2N_4S_2Me)]_2^{2+}$ and $[Ru(CO)(NCMe)(Ph_4P_2N_4S_2)]_2$, (*i*) $MeSO_3CF_3$, (*ii*) $2MeSO_3CF_3$, (*iii*) $2Me_3NO/CH_3CN$. The cationic species **5**, **6***a*, and **6***b* are isolated as $SO_3CF_3^-$ salts.



lished by an X-ray structural investigation of $4 \cdot CH_2Cl_2$. An ORTEP drawing of **4** with the atomic numbering scheme is illustrated in Fig. 1 and selected bond lengths and bond angles are summarized in Table 5. The complex **4** is a centrosymmetric dimer in which the $P_2N_4S_2$ ring adopts a tetradentate bonding mode in which it is attached to one ruthenium through two (geminal) nitrogens and the remote sulfur and serves as a bridge via the second sulfur atom to the other ruthenium. It is of particular interest to note that precisely the same bonding mode, i.e., η^3-S,N,N′-μ,η^1-S′, was invoked to explain the fluxional behavior of the dimeric Pt and Pd complexes of the type **3** (10).

In the preliminary communication the distorted octahedral geometry about Ru in **4** was discussed, but the implications of the structural parameters of the heterocyclic ligand were not addressed. The S—N bond lengths involving the three-coordinate nitrogen atoms N(1) and N(4) are 1.705(4) and 1.704(4) Å, respectively, while those containing the two coordinate nitrogens N(2) and N(3) are 1.656(4) and 1.670(4) Å, respectively (cf. *d*(S—N) = 1.584(2) and 1.596(3) Å in **1**) (22). There is also a pronounced inequality in the P—N bond distances for the two- and three-coordinate nitrogens. The former are significantly shorter (1.593(4) and 1.605(4) Å) than the latter (1.648(4) and 1.661(4) Å). These trends in the S—N and P—N bond lengths suggest that the $P_2N_4S_2$ ligand in **4** can be represented approximately by the valence bond structure shown in Fig. 2, i.e., reaction (a) involves an oxidative addition of **1** to the ruthenium(0) complex. We note that the dianion $Ph_4P_2N_4S_2^{2-}$ has been prepared recently as dilithium, disodium, or dipotassium derivatives by the reduction of **1** with Superhydride M[Et_3BH] (M = Li (23), Na, K[5]), but the structures of these alkali metal derivatives are unknown.

Methylation of $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$

The inorganic heterocycle **1** is readily N-methylated by methyl triflate with the retention of the cross-ring S—S bond (24). N,N′-Dimethylated dications $Ph_4P_2N_4S_2Me_2^{2+}$ can also be generated and exist in solution as a mixture of a symmetrical and an unsymmetrical isomer on the basis of ^{31}P NMR spectra (24). To determine the effect of coordination to a metal centre on the electrophilic methylation of the $P_2N_4S_2$ ring we have investigated the reaction of **4** with methyl triflate. The reaction of **4** with one molar equivalent of $MeSO_3CF_3$ proceeds smoothly at 23°C in dichloromethane to give $[Ru_2(CO)_4$-$(Ph_4P_2N_4S_2Me)(Ph_4P_2N_4S_2)][CF_3SO_3]$. The occurrence of mono-N-methylation was readily established by

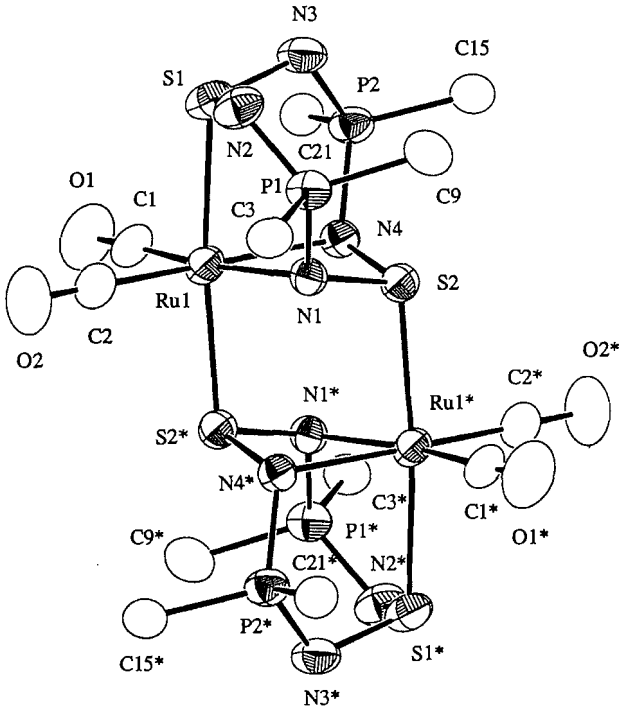
Fig. 1. ORTEP diagram (50% probability ellipsoids) for $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$, 4. For clarity, only the α-carbon atoms of phenyl groups attached to phosphorus are shown. Starred atoms are related to the unstarred atoms by the symmetry operation: $-x+1, -y, -z+2$.



the integrated intensities of the ^1H NMR resonances and the fact that the ^{31}P NMR spectrum exhibits four equally intense resonances (see Fig. 3*a*) suggests that methylation is regiospecific. The X-ray structure of **5**, described below, showed that it is one of the two-coordinate nitrogen atoms in **4** that is methylated. As indicated in Table 1, the ^{31}P NMR chemical shifts of three of the phosphorus atoms in **5** are in the narrow range 63–65 ppm, cf. δ ^{31}P = 64.0 ppm for **4**. The fourth resonance is shifted downfield to 69.3 ppm and is therefore assigned to the phosphorus attached to the methylated nitrogen atom. In addition to the four-bond intraring ^{31}P–^{31}P couplings of ca. 6 Hz for the $Ph_4P_2N_4S_2Me^+$ and ca. 3 Hz for the $Ph_4P_2N_4S_2$ ring in **5** (cf. $^4J(^{31}P–^{31}P)$ = 21 Hz in $[Pt(PPh_3)_2(Ph_4P_2N_4S_2Me)][CF_3SO_3]$) (11), a five-bond coupling of ca. 8 Hz between phosphorus atoms of separate $P_2N_4S_2$ rings is observed.

The complete loss of symmetry upon methylation is also apparent in the IR spectrum of **5**, which shows four distinct carbonyl bands between 1996 and 2069 cm^{-1}. The average value of 2033 cm^{-1} is slightly higher than the average value of 2013 cm^{-1} observed for ν(CO) in **4** consistent with some positive charge delocalization onto the ruthenium atoms.

The treatment of **5** with methyl triflate or of **4** with two molar equivalents of methyl triflate in dichloromethane at 23°C produces the dimethylated derivative $[Ru(CO)_2(Ph_4P_2N_4S_2Me)]_2[CF_3SO_3]$ (**6**). The ^1H NMR spectrum of **6** shows two resonances with approximately equal intensities for N-CH_3 groups while the ^{31}P NMR spectrum (see Fig. 3*b*) consists of a pair of singlets and a pair of mutually coupled doublets (J ~ 5 Hz) with about the same intensity. On the basis of these NMR data, we conclude that **6** consists of an approximately equal mixture of two structural isomers, **6***a* and **6***b*, which are

depicted in Scheme 1.[6] In both these isomers methylation occurs at dicoordinate nitrogen atoms of separate $P_2N_4S_2$ rings so that the two methyl groups are related either by a centre inversion (**6***a*) or a C_2 axis (**6***b*) giving rise to two pairs of equivalent phosphorus atoms and equivalent methyl groups for each isomer. By comparison with the ^{31}P NMR chemical shifts for **5**, the resonances at 70.1 and 69.3 ppm for **6***a*/*b* are assigned to the phosphorus atoms closest to the sites of methylation while the resonances at 64.6 and 65.8 ppm are attributed to the other two equivalent phosphorus atoms for each isomer (see Table 1). In one of these isomers the two resonances appear as mutually coupled doublets. However, it is not possible on the basis of the magnitude of the coupling constant (J = 5 Hz) to distinguish between a four-bond and a five-bond coupling between inequivalent phosphorus nuclei as the source of these doublets since the J values for **5** are of a similar size for these two interactions.

X-ray structure of $[Ru_2(CO)_4(Ph_4P_2N_4S_2Me)(Ph_4P_2N_4S_2)][CF_3SO_3]$, 5

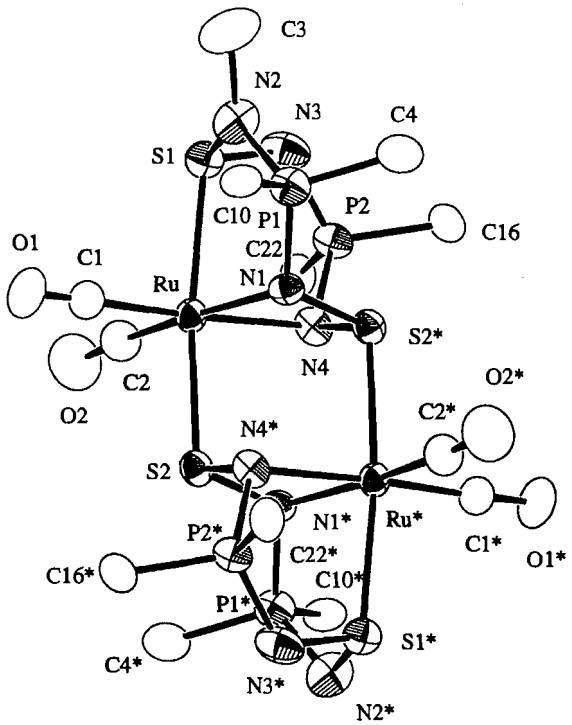
The structure of **5** was confirmed by X-ray crystallography and an ORTEP drawing of the $[Ru_2(CO)_4(Ph_4P_2N_4S_2Me)(Ph_4P_2N_4S_2)]^+$ cation is shown in Fig. 4. Selected bond lengths and bond angles are summarized in Table 5. The structure of **5** contains an inversion disorder that places methyl groups with half occupancy at N(2) and N(2)*. This disorder problem, unfortunately, precludes any detailed structural comparisons between **4** and **5**. Nevertheless, the X-ray structure of **5** clearly shows that methylation occurs at a two-coordinate nitrogen atom and that it does not alter the bonding mode between the $P_2N_4S_2$ ring and ruthenium.

Metal-centered reactivity of $[Ru(CO)(NCMe)(Ph_4P_2N_4S_2)]_2$

We have also investigated reactions at the metal center in **4**. The treatment of **4** with PR_3 (R = Me, Ph) in toluene at reflux does not cleave the dimeric structure or result in replacement of CO groups. However, the reaction of **4** with two molar equivalents of trimethylamine-*N*-oxide in the presence of an excess of acetonitrile gives $[Ru(CO)(NCMe)(Ph_4P_2N_4S_2)]_2$ (**7**) as a yellow crystalline solid that, on the basis of ^1H and ^{31}P NMR data, exists as a mixture of isomers in the approximate ratio 2:1. The ^1H NMR spectrum of **7** exhibits two resonances for CH_3CN ligands at 1.75 and 1.67 ppm while the ^{31}P NMR spectrum (see Table 1) consists of a pair of singlets and two mutually coupled doublets. The IR spectrum of **7** contains just one carbonyl band at 1953 cm^{-1} indicative of a symmetrical dimer with one CO group and one acetonitrile ligand on each ruthenium. The shift of ca. 60 cm^{-1} to lower energy compared to the average value of ν(CO) for **4** is attributed to increased back donation from the metal to the

[6] The possibility that dimethylation occurs at the pair of two-coordinate nitrogen atoms of the *same* $P_2N_4S_2$ ring is considered unlikely since it would involve electrophilic attack at a site with a positive charge.

Fig. 4. ORTEP diagram (50% probability ellipsoids) for $[Ru_2(CO)_4(Ph_4P_2N_4S_2Me)(Ph_4P_2N_4S_2)][CF_3SO_3]$, **5**. For clarity, only the α-carbon atoms of phenyl groups attached to phosphorus are shown. Starred atoms are related to the unstarred atoms by the symmetry operation: $-x, -y, -z$.



remaining CO ligand as a result of the replacement of one CO by an electron-releasing CH_3CN ligand. The proposed structures of the two isomers *7a* and *7b* are illustrated in Scheme 1. They are distinguished by the relative orientation of the MeCN (or CO) ligands. In *7a* they are related by a centre of inversion and in *7b* by a C_2 axis giving rise to two pairs of equivalent phosphorus atoms for each isomer. A variable temperature ^{31}P NMR study showed that *7a* and *7b* do not interconvert in toluene solution up to 100°C.

Conclusions

The neutral ligand $Ph_4P_2N_4S_2$ undergoes oxidative addition to ruthenium(0) complexes without fragmentation to give a centrosymmetric dimer $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$ in which the $P_2N_4S_2$ ring adopts an unprecedented tetradentate (η^3-N,N′,S-μ,η^1-S′) bonding mode. The electrophilic monomethylation of $[Ru(CO)_2(Ph_4P_2N_4S_2)]_2$ occurs regiospecifically at a two-coordinate nitrogen atom without disturbing the metal–heterocycle bonding mode and dimethylated derivatives are produced as an approximately equal mixture of structural isomers. The sulfur-bridged structure is stable towards triorganophosphines, but one CO ligand on each ruthenium can be substituted by CH_3CN. The facile generation of an acetonitrile complex provides a potentially useful starting point for future studies of the metal-centered reactivity of these complexes.

Abstract: $[Cp^*Ir(C_2H_4)(N_2Ar)][BF_4]$ (**1** $\mathbf{BF_4}$; Ar = *p*-$N_2C_6H_4OMe$) has been synthesized by reacting $[ArN_2][BF_4]$ with $Cp^*Ir(C_2H_4)_2$ at low temperature. An initial electrophilic attack of the incoming diazonium ion at iridium, followed by expulsion of C_2H_4, is postulated to account for the mild reaction conditions that are in sharp contrast to the usual inertness of the bis(ethylene) compound toward ligand substitution. The IR and nitrogen NMR data for **1** $\mathbf{BF_4}$ and its $^{15}N_\alpha$ derivative unambiguously establish that the ArN_2 ligand has the singly bent geometry in this complex in solution. The X-ray crystal structure confirms this for the solid state, and establishes that the plane of the aryldiazenido ligand is approximately perpendicular to the plane defined by the Ir atom and the centers of mass of the Cp* and ethylene ligands. An extended Hückel molecular orbital analysis of the singly bent aryldiazenido ligand has been carried out and satisfactorily accounts for the observed orientation of the ArN_2 ligand. An analysis of the variable-temperature ^1H and ^{13}C NMR of **1** $\mathbf{BF_4}$ indicates that *both* restricted rotation of the C_2H_4 ligand and a conformational isomerization of the aryldiazenido ligand are occurring, and $\Delta G^{\neq}_{270}$ for the ethylene rotation barrier is estimated at $\leq 51.5 \pm 0.4$ kJ mol^{-1}. This is lower than the barrier of $\Delta G^{\neq}_{353} = 68.7 \pm 0.2$ kJ mol^{-1} determined previously for the analogous nitrosyl complex $[Cp^*Ir(C_2H_4)(NO)][BF_4]$ (**2** $\mathbf{BF_4}$) and it is suggested that in these half-sandwich complexes both NO and ArN_2 function as single-faced π-acceptors, and in these circumstances ArN_2 is the better π-acceptor. The ethylene in **1** $\mathbf{BF_4}$ is readily displaced by PPh_3 to give $[Cp^*Ir(PPh_3)(N_2Ar)][BF_4]$ (**3** $\mathbf{BF_4}$). This reacts with $NaBH_4$ to yield $Cp^*IrH(PPh_3)(N_2Ar)$ (**4**) in which the ArN_2 ligand has switched to the doubly bent geometry, on the basis of the $^{15}N_\alpha$ NMR chemical shift data. Attempts to synthesize the corresponding chloro analogue **5** resulted in only the chloride salt of the singly bent ArN_2 cation **3**. For example, reaction of **3** $\mathbf{BF_4}$ with HCl yields the aryldiazene complex $[Cp^*IrCl(PPh_3)(NHNAr)][BF_4]$ (**6**), but deprotonation of this with Et_3N yields **3 Cl**, not **5**. Compound **1** $\mathbf{BF_4}$ crystallized in the space group $P2_1/n$ with $a = 8.5780(10)$ Å, $b = 20.5310(23)$ Å, $c = 12.0310(15)$ Å, $\beta = 93.500(10)°$, and $Z = 4$. The structure was refined to $R_f = 0.0281$ on the basis of 2611 observed reflections with $I_o \geq 2.5\sigma(I_o)$ in the range $2\theta = 0$–$50°$ (Mo-K_α).

Key words: iridium, cyclopentadienyl, aryldiazenido, nitrosyl, ethylene.

Résumé : On a synthétisé le $[Cp^*Ir(C_2H_4)(N_2Ar)][BF_4]$ (**1** $\mathbf{BF_4}$; Ar = *p*-$N_2C_6H_4OMe$) en faisant réagir du $[ArN_2][BF_4]$ avec du $Cp^*Ir(C_2H_4)_2$, à basse température. Pour expliquer les conditions réactionnelles douces qui sont en opposition flagrante avec le manque habituel de réactivité du composé bis(éthylène) vis-à-vis les substitutions du coordinat, on suppose qu'il se produit une attaque initiale de l'ion diazonium au niveau de l'iridium, suivie d'une expulsion du C_2H_4. Les données de l'IR et de la RMN de l'azote pour le composé **1** $\mathbf{BF_4}$ et son dérivé $^{15}N_\alpha$ établissent sans ambiguïté que, en solution, le coordinat ArN_2 de ce complexe possède une géométrie avec un seul repli. La structure cristalline par diffraction des rayons X le confirme à l'état solide et établit que le plan du coordinat aryldiazénido est approximativement perpendiculaire au plan défini par l'atome d'Ir et les centres de masse du Cp* et des coordinats éthylène. Faisant appel à la méthode des orbitales

Received October 28, 1994.
This paper is dedicated to Professor William A.G. Graham on the occasion of his 65th birthday.

moléculaires de Hückel, on a effectué une analyse en profondeur du coordinat aryldiazénido avec un seul repli et elle explique d'une façon satisfaisante l'orientation observée du coordinat ArN_2. Une analyse du composé **1** $\mathbf{BF_4}$ par RMN du ^1H et du ^{13}C à basse température indique qu'il se produit une rotation restreinte du coordinat C_2H_4 en même temps qu'une isomérisation conformationnelle du coordinat aryldiazénido; le $\Delta G^{\neq}_{270}$ pour la barrière à la rotation de l'éthylène est évaluée à $\leq$51,5 $\pm$ 0,4 kJ mol^{-1}. Cette valeur est plus faible que la barrière de $\Delta G^{\neq}_{353}$ 68,7 $\pm$ 0,2 kJ mol^{-1} déterminée antérieurement pour la complexe nitrosyle analogue $[Cp^*Ir(C_2H_4)(NO)][BF_4]$ (**2** $\mathbf{BF_4}$) et on suggère que, dans ces complexes à demi-sandwich, le NO ainsi que le ArN_2 fonctionnent tous les deux comme des accepteurs π à face unique et que, dans ces circonstances, le ArN_2 est un meilleur accepteur π. On peut facilement remplacer l'éthylène du **1** $\mathbf{BF_4}$ par du PPh_3 pour obtenir du $[Cp^*Ir(PPh_3)(N_2Ar)][BF_4]$ (**3** $\mathbf{BF_4}$). Ce dernier réagit avec le $NaBH_4$ pour conduire au $Cp^*IrH(PPh_3)(N_2Ar)$ (**4**) dans lequel, sur la base des données de déplacements chimiques en RMN du $^{15}N_\alpha$, le coordinat ArN_2 est déplacé vers une géométrie à double repli. Des essais de synthèse de l'analogue chloro correspondant **5** n'ont conduit qu'au chlorure du cation ArN_2 à simple repli, **3**. Par exemple, la réaction du composé **3** $\mathbf{BF_4}$ avec du HCl fournit le complexe aryldiazène $[Cp^*IrCl(PPh_3)(NHNAr)][BF_4]$ (**6**), mais la déprotonation de ce composé avec du Et_3N conduit au composé **3 Cl**, et non pas au composé **5**. Le composé **1** $\mathbf{BF_4}$ cristallise dans le groupe d'espace $P2_1/n$ avec a = 8,5780(10), b = 20,5310(23) et c = 12,0310(15) Å, β = 93,500(10)° et Z = 4. On a affiné la structure jusqu'à une valeur de R_f = 0,0281 sur la base de 2611 réflexions observées avec $I_o \geq 2{,}5\sigma(I_o)$ pour 2θ = 0–50° (Mo-K_α).

Mots clés : iridium, aryldiazénido, cyclopentadiényle, nitrosyle, éthylène.

[Traduit par la rédaction]

Introduction

Since the synthesis of $CpMo(CO)_2(N_2Ph)$, the first stable aryldiazenido (ArN_2) complex, in 1964 (1), synthetic, structural, and chemical studies of transition metal aryldiazenido complexes have appeared regularly in the literature (2–4). Historically, this development coincided with renewed interest in transition metal nitrosyl chemistry. There is an evident valence electronic similarity between ArN_2 and NO that is expressed in the structural similarity in the bonding modes of terminally coordinated nitrosyl and aryldiazenido ligands. These are characterized by linear and bent M-N-O, and singly bent and doubly bent M-N-N-Ar structural skeletons, portrayed by the valence structures shown in Scheme 1.

Nitrosyl complexes are numerous (5), and for the majority no exact aryldiazenido analogues are known. Nevertheless, there do exist many pairs of analogous nitrosyl and aryldiazenido complexes, and in several cases these have been used to compare the properties of NO and ArN_2 ligands in similar environments. Of particular interest have been the relative π-accepting abilities. In some studies it has been concluded that NO is a better π-acceptor, whereas in others the reverse has been suggested (6–14).

In this paper, we compare results on a new pair of analogous ArN_2 and NO complexes, namely, the half-sandwich iridium ethylene complexes $[Cp^*Ir(C_2H_4)(p\text{-}N_2C_6H_4OMe)]^+$ (**1**) and $[Cp^*Ir(C_2H_4)(NO)]^+$ (**2**) (where Cp^* = η^5-C_5Me_5). The nitrosyl complex has been described in detail in a previous paper (15), and both compounds were included in an earlier preliminary communication (16). Here we provide full details of the aryldiazenido complex **1** and a triphenylphosphine derivative **3**. We draw attention to three important aspects of **1**. One is the orientation of the plane of the aryldiazenido ligand with respect to the plane of symmetry of the $Cp^*Ir(C_2H_4)$ fragment, for which a theoretical interpretation on the basis of extended Hückel molecular orbital (EHMO) calculations is given. The second is that the aryldiazenido ligand is stereochemically nonrigid, the aryl group undergoing a rapid conformational isomerization by either a rotation or inversion process that interconverts the enantiomers of the cation **1** at room temperature. The third is the relative size of the barriers to rotation of the ethylene ligand in **1** and **2**. These barriers are interpreted to reflect the relative π-acceptor abilities of the aryldiazenido and nitrosyl ligands toward the $Cp^*Ir(C_2H_4)$ fragment.

Experimental section

General

All solvents were dried and purified by standard methods and were freshly distilled under nitrogen immediately before use. All reactions and manipulations were carried out in a standard Schlenk apparatus. Infrared spectra were measured for solutions in CaF_2 cells by using a Bomem Michelson 120 FTIR instrument. Some of the routine ^1H NMR spectra were recorded at 100 MHz by using a Varian 100-SY spectrometer. Dynamic ^1H NMR, and $^{13}C\{^1H\}$, ^{14}N, and ^{15}N NMR spectra were obtained by M.M. Tracey on a Bruker AMX 400 instrument at operating frequencies of 400.1, 100.6, 28.9, and 40.5 MHz, respectively. Chemical shifts are reported in ppm, downfield positive, relative to tetramethylsilane (TMS) for ^1H and $^{13}C\{^1H\}$ spectra, and relative to $MeNO_2$ for ^{14}N and ^{15}N spectra, respectively. Coupling constants are reported in Hz.

The temperatures of the samples used in the dynamic NMR studies were obtained from the temperature controller of the AMX 400 spectrometer and are accurate to ±1 K. The free energy of activation at the coalescence temperature was calculated from the following equation (17),

$$[1] \quad \Delta G^{\neq} = -RT_c \ln \frac{\pi \Delta \nu h}{\sqrt{2}\, kT_c}$$

$$= aT_c[9.972 + \log (T_c/\Delta\nu)]$$

where $\Delta\nu$ is the chemical shift difference of the coalescing resonances in the absence of exchange, T_c is the coalescence temperature, and R, h, and k have their normal thermodynamic significance. The reduced parameter $a = 1.914 \times 10^{-2}$ kJ mol^{-1} K^{-1}.

Mass spectra were obtained by G. Owen on a Hewlett–Packard model 5985 GC–MS spectrometer equipped with a fast atom bombardment (FAB) probe (xenon source, Phrasor Scientific, Inc., accessory), and utilized samples dispersed or dissolved in sulfolane or *m*-nitrobenzyl alcohol (NOBA). Chemical ionization mass spectra (CIMS) utilized isobutane. The pattern of the envelope of the fragment ions was matched with that simulated by computer for the species in question. The masses are quoted for ^{193}Ir and ^{37}Cl isotopes. Microanalyses were performed by M.-K. Yang of the Microanalytical Laboratory of Simon Fraser University.

Bis(ethylene)pentamethylcyclopentadienyl iridium was synthesized according to the published method (18). *para*-Methoxybenzenediazonium tetrafluoroborate was prepared from *p*-anisidine (Aldrich) and sodium nitrite, and purified by recrystallization from acetone and diethyl ether. The diazonium salt labelled with ^{15}N at the unsubstituted nitrogen (N_α) was prepared by using $Na^{15}NO_2$ (95% ^{15}N, MSD Isotopes).

Computations were performed by using the extended Hückel method. Literature values of H_{ii} were used for nitrogen, carbon, and hydrogen atoms and the off-diagonal elements H_{ij} were evaluated with the weighted H_{ij} formula (19). The bond distances used for NO^+ and HN_2^+ were the same values used in prior calculations (20). The geometric parameters used for the free PhN_2^+ ion were those taken from an X-ray structure determination (21). The NN and NC bond distances used for the bent PhN_2^+ group were averaged from ca. 40 X-ray structurally characterized, singly bent, aryldiazenido complexes in the literature (3).

Preparation of [Cp*Ir(C_2H_4)(*p*-$N_2C_6H_4OMe$)][BF_4] (**1** BF_4) and **1**-$^{15}N_\alpha$ BF_4

$Cp^*Ir(C_2H_4)_2$ (100 mg, 0.26 mmol) was dissolved in acetone (5 mL) in a 100 mL Schlenk tube equipped with a magnetic stir bar. The solution was cooled for 15 min at −78°C, with at least 2/3 the length of the Schlenk tube immersed in the bath. Then [(*p*-$N_2C_6H_4OMe$)][BF_4] or [*p*-$^{15}NNC_6H_4OMe$][BF_4] (18 mg, 0.26 mmol) in acetone (5 mL) was slowly added dropwise by pipet in such a way that the drops of the diazonium salt solution first touched the upper part of the cold Schlenk tube and then slowly flowed down the wall into the reaction mixture. If the diazonium salt solution was added directly to the reaction mixture without allowing it to cool in this way, the result generally was an impure oily product. The reaction mixture was continuously stirred during addition of the diazonium salt solution and then for an additional hour at −78°C. The colour of the reaction solution changed from colourless to yellow, then to orange-red. The reaction was monitored for the disappearance of the ν(NN) IR band at 2253 cm^{-1} for the free diazonium ion. When the reaction was complete, hexane was added slowly until no more solid precipitated. The supernatant solution was removed and the remaining brown solid washed twice with ca. 20 mL of hexane, affording the analytically pure product **1** BF_4 or **1**-$^{15}N_\alpha$ BF_4 almost quantitatively. Recrystallization of the product from acetone–hexane at −10°C gave dark red crystals in greater than 90% yield. More product could be recovered as fine crystals by evaporation of the supernatant solution; mp 150–155°C. IR, ν(NN): 1710 cm^{-1} (KBr), 1724 cm^{-1} (EtOH); $\nu(^{15}NN)$: 1675 cm^{-1} (KBr). ^1H NMR (400 MHz, $CDCl_3$), δ: 2.25 (s, 15H, C_5Me_5), 3.25 (br s, 4H, C_2H_4), 3.91 (s, 3H, OMe), 7.23 (q, 4H, C_6H_4). $^{13}C\{^1H\}$ NMR ($CDCl_3$), δ: 9.61 ($C_5\mathit{Me}_5$), 49.32 (C_2H_4), 56.01 (OMe), 100.89 (C_5Me_5), 111.77, 117.08, 125.21, and 164.09 (C_6H_4). ^{14}N NMR ($MeNO_2$-d_3), δ: −107.0 (br s, N_β), −2.9 (br s, N_α). ^{15}N NMR for **1**-$^{15}N_\alpha$ BF_4 (acetone-d_6), δ: −2.26 (s, N_α). FABMS, *m/z*: 491 (M^+), 463 ($M^+ - C_2H_4$), 433 ($M^+ - C_2H_4 - OMe$), 405 ($M^+ - C_2H_4 - N_2 - OMe$), 354 ($M^+ - N_2C_6H_4OMe - 2H$). Anal. calcd.: C 39.52, H 4.54, N 4.85; found: C 39.11, H 4.53, N 4.84.

X-ray crystal structure determination of [Cp*Ir(C_2H_4)(*p*-$N_2C_6H_4OMe$)][BF_4] (**1** BF_4)

Crystals suitable for X-ray structure analysis were obtained by recrystallization of **1** BF_4 from acetone and diethyl ether at −10°C. After examination by microscopy with polarized light, a large brown single crystal was slowly ground to a sphere and mounted in a capillary tube, the diameter of which was sufficiently close to that of the crystal to keep the crystal motionless. The crystal was then well centered in the X-ray beam of an Enraf–Nonius CAD-4F diffractometer equipped with graphite-monochromatized MoKα radiation. Selected crystallographic and experimental parameters are given in Table 1.

Intensity data were collected at −40 ± 1°C. Three intensity standards were measured every 1.5 h of acquisition time, and showed no significant change in intensity during the data collection. A final unit cell was determined by least-squares procedures from the setting angles of 25 well-centered reflections (with $18° \leq 2\theta \leq 44°$) chosen from a random variety of points in reciprocal space. A monoclinic unit cell was first assumed

[a]Alternative setting of $P2_1/c$ (x, y, z; $-x$, $-y$, $-z$; $\frac{1}{2}+x$, $\frac{1}{2}-y$, $\frac{1}{2}+z$; $\frac{1}{2}-x$, $\frac{1}{2}+y$, $\frac{1}{2}-z$).
[b]$R_f = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ for observed data.
[c]$R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ for observed data.

and then proven by investigation of selected symmetry-related reflections from the intensity data file. Lorentz, polarization, and spherical absorption corrections (22, 23) were applied and the intensity data converted into the corresponding structure factor amplitudes and their esd's.

The structure was solved by Patterson and conventional Fourier methods and refined by using full-matrix least-squares procedures. Anisotropic thermal parameters for Ir, F, and O atoms and the C atoms in the methyl groups and ethylene ligand, and isotropic thermal parameters for other atoms, were included in the final refinement. The refinement was considered complete when the maximum shift/esd was <0.01. The positions of hydrogen atoms were generated with d(C—H) = 0.95 Å. A total of 54 atoms and 183 variables against 2611 observations were involved in the final refinement. The quantity minimized by the least-squares program was $\Sigma w(|F_o| - |F_c|)^2$, where w is the unit weight. Inspection of average $\Sigma w\Delta^2$ ordered in the ranges of sin θ/λ, $|F_o|$, and the values of individual indices was near constant. The largest feature in the final difference Fourier map had an electron density 1.2 e^{-1} Å^{-3} and was located 0.9 Å from the Ir atom. Positional parameters and thermal parameters of non-hydrogen atoms are listed in Table 2.[2]

[2] Tables 5 (hydrogen atom coordinates) and 6 (anisotropic thermal parameters) for **1 BF_4** (2 pages) have been deposited. Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Table 5 has also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[a]Values marked with an asterisk are $B_{eq} = (8\pi^2/3)\,\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* a_i a_j$.

The computing programs used for data reduction and structure solution and refinement were from the NRC VAX crystal structure system (24). The analytical forms of the scattering factors for neutral atoms (including anomalous scattering) were used in the calculations of structure factors (25). All computations were carried out on an in-house Micro VAX-II computer.

Preparation of $[Cp^*Ir(PPh_3)(p\text{-}N_2C_6H_4OMe)][BF_4]$ (3 BF_4) and 3-$^{15}N_\alpha$ BF_4

To an ethanol solution (10 mL) containing equimolar quantities of $Cp^*Ir(C_2H_4)_2$ (30 mg, 0.078 mmol) and PPh_3 (21 mg, 0.080 mmol) was added $[p\text{-}N_2C_6H_4OMe][BF_4]$ or $[p\text{-}^{15}NNC_6H_4OMe][BF_4]$ (17 mg, 0.077 mmol). Following the addition of the diazonium salt, the colourless solution immediately changed to orange-red. The reaction was monitored for the disappearance of ν(NN) at 2253 cm^{-1} for the free diazonium ion. After the solution was stirred for 1 h, the solution was taken to dryness which gave compound **3 BF_4** or **3-$^{15}N_\alpha$ BF_4** quantitatively as an orange-red oil. IR, ν(NN), 1701 cm^{-1} (ethanol), 1710 cm^{-1} (CH_2Cl_2); ν(^{15}NN): 1676 cm^{-1} (ethanol). ^{1}H NMR (100 MHz, acetone-d_6), δ: 2.12 (d, 15H, $J_{P\text{-}Me}$ = 2, Cp*), 3.85 (s, 3H, OMe), 7.06 (q, 4H, AA′BB′ pattern, C_6H_4), 7.20–7.90 (m, 15H, Ph); δ($CDCl_3$): 1.97 (d, 15H, $J_{P\text{-}Me}$ = 2, Cp*), 3.87 (s, 3H, OMe), 6.98 (d, 4H, $J_{H\text{-}H}$ = 1, C_6H_4), 7.40–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

7.52 (m, 15H, Ph). ^{15}N NMR for **3**-$^{15}N_\alpha$ (acetone-d_6), δ: 33.23 (d, $^{15}N\alpha$, $J_{P-^{15}N\alpha} = 7$). FABMS (NOBA, xenon), *m/z*: 725 (M^+), 590 ($M^+ - N_2C_6H_4OMe$). Anal. calcd.: C 51.79, H 4.60, N 3.45; found: C 52.18, H 4.81, N 3.62.

Complex **3** BF_4 or **3**-$^{15}N_\alpha$ BF_4 can also be made quantitatively from the reaction of freshly synthesized **1** BF_4 or **1**-$^{15}N_\alpha$ BF_4 in ethanol solution with solid PPh_3 at room temperature.

Preparation of Cp*IrH(PPh_3)(*p*-$N_2C_6H_4OMe$) (4) and 4-$^{15}N_\alpha$

An excess of $NaBH_4$ (7 mg, 0.2 mmol) was added to an acetone solution (5 mL) of **3** BF_4 or **3**-$^{15}N_\alpha$ BF_4 (42 mg, 0.052 mmol), and the mixture was stirred for 1 h at −10°C. The colour changed from orange-red to peach-red. The solvent was removed by vacuum, excess hexanes (15 mL) were added to the residue, and the mixture was stirred vigorously for 15 min. The peach-red solution was filtered through Celite to remove the insoluble salts ($NaBF_4$ and $NaBH_4$) and then pumped to dryness to give a rose-purple oily product **4** or **4**-$^{15}N_\alpha$ in 89% yield. IR, ν(Ir-H): 2133 br cm^{-1}(hexanes). ^{1}H NMR (100 MHz, acetone-d_6), δ: −15.9 (d, 1H, $J_{P-H} = 33.5$, Ir-H), 1.51 (dd, 15H, $J_{P-H} = 1.8$, $J_{H-H} = 0.7$, Cp*), 3.57 (s, 3H, OMe), 6.58 (d, 4H, $J = 1.7$, C_6H_4), 7.10–7.60 (m, 15H, Ph). ^{15}N NMR for **4**-$^{15}N_\alpha$ (acetone-d_6), δ: 271.89 (s, $^{15}N_\alpha$). CIMS, *m/z*: 590 ([Cp*Ir(PPh_3)]$^+$), 464 ([Cp*Ir(H)($N_2C_6H_4OMe$)]$^+$). Anal. calcd.: C 57.92, H 5.28, N 3.86, found: C 58.12, H 5.43, N 3.89.

Preparation of [Cp*IrCl(PPh_3)(*p*-$NHNC_6H_4OMe$)][BF_4] (6 BF_4) and 6-$^{15}N_\alpha$ BF_4

Method 1

A solution of freshly synthesized **3** BF_4 or **3**-$^{15}N_\alpha$ BF_4 (42 mg, 0.052 mmol) in ethanol (5 mL) was slowly purged by gaseous HCl for 5 min at room temperature with the flask immersed in a cold water bath at ~10°C to absorb the heat released from the solvation of the HCl. The color changed from orange-red to dark green. After stirring for another 5 min the volatiles were pumped off, leaving a dark yellow solid residue. This was then redissolved in a minimum amount of acetone, and an excess of diethyl ether was added slowly with vigorous stirring until no further solid precipitated. The yellow supernatant solution was removed and the remaining yellow solid was washed twice with 20 mL portions of diethyl ether. This gave **6** BF_4·**0.5**Et_2O or **6**-$^{15}N_\alpha$ BF_4·**0.5**Et_2O as a fine yellow powder in 92% yield. IR, ν(NN): 1483 cm^{-1}, ν(^{15}NN): 1460 cm^{-1} (KBr). ^{1}H NMR (100 MHz, acetone-d_6), δ: 1.54 (d, 15H, J_{P-H} = 2.2, Cp*), 3.93 (s, 3H, OMe), 7.05 and 7.40 (d, 4H, AA′BB′ pattern, C_6H_4), 7.52 and 7.58 (s, 15H, Ph), 13.73 (d, 1H, $J_{^{15}N-H}$ = 70); ^{1}H NMR ($CDCl_3$), δ: 1.52 (d, 15H, $J_{P-H} = 2.2$, Cp*), 3.92 (s, 3H, OMe), 6.92 and 7.19 (d, 4H, AA′BB′ pattern, C_6H_4), 7.45 and 7.50 (s, 15H, Ph), 13.01 (d, 1H, $J_{^{15}N-H} = 69$). ^{15}N NMR for **6**-$^{15}N_\alpha$ BF_4 (acetone-d_6), δ: −64.24 (d, $J_{^{15}N-H}$ = 70). FABMS (NOBA, xenon), *m/z*: 761 (M^+), 625 (M^+ − $NHNC_6H_4OMe$), 589 ($M^+ - N_2C_6H_4OMe - Cl$), 511 (M^+ − $NHNC_6H_4OMe - Cl - Ph$). Anal. calcd. for **6** BF_4·**0.5**Et_2O: C 50.20, H 4.89, N 3.16, found: C 50.21, H 4.83, N 3.09.

Method 2

Freshly synthesized **4** or **4**-$^{15}N_\alpha$ (22 mg, 0.031 mmol) in dry CCl_4 (3 mL) was stirred vigorously in the dark at −10°C. After 20 min, under the same conditions, the solvent was pumped off, resulting in a red solid product. This was redissolved in the minimum amount of acetone to give a red solution to which was slowly added 2 drops of HBF_4 – diethyl ether solution, resulting in an immediate brownish precipitate. The supernatant solution was then removed and the remaining dark yellow solid was pumped overnight. ^{1}H NMR spectroscopy of this solid indicated that **6** BF_4 or **6**-$^{15}N_\alpha$ BF_4 was the major product, but was contaminated with variable amounts of Cp*Ir(PPh_3)Cl_2, identified as follows: ^{1}H NMR (100 MHz, acetone-d_6), δ: 1.34 (d, 15H, $J_{P-H} = 2$, Cp*) and 7.35–7.75 (m, 15H, Ph) (18).

Attempts to observe Cp*IrCl(PPh_3)(*p*-$N_2C_6H_4OMe$) (5)

*(a) By deprotonation of [Cp*IrCl(PPh_3)(p-$NHNC_6H_4OMe$)][BF_4] (6 BF_4)*

To a yellow solution of **6** BF_4 (44 mg, 0.052 mmol) in acetone (5 mL) was added 2 drops of NEt_3. The colour immediately changed to red. Diethyl ether (ca. 2 mL) was added carefully to precipitate pale gray $NHEt_3$·BF_4. After filtering, the filtrate was concentrated to 2 mL under vacuum and excess diethyl ether was added slowly until no further solid precipitated. The supernatant was removed and the remaining solid was washed twice with diethyl ether to yield the product as an orange powder. IR and ^{1}H NMR of this solid indicated that it was a mixture of Cp*Ir(PPh_3)Cl_2 (<5% based on the ^{1}H NMR integration) and a major species that had identical IR and ^{1}H NMR features to compound **3** BF_4: (IR, ν(NN): 1711 cm^{-1} (CH_2Cl_2), 1699 cm^{-1} (KBr); ^{1}H NMR (acetone-d_6), δ: 2.12 (d, 15H, $J_{P-H} = 2$, Cp*), 3.85 (s, 3H, OMe), 7.06 (q, 4H, AA′BB′ pattern, C_6H_4), 7.20–7.90 (m, 15H, Ph). Consequently, this major species is assigned as [Cp*Ir(PPh_3)(*p*-$N_2C_6H_4OMe$)]Cl (**3 Cl**).

(b) By exchange of hydride ligand in 4

Freshly synthesized **4** (22 mg, 0.031 mmol) in dry CCl_4 (3 mL) was stirred in the dark at −10°C for 20 min; a longer reaction time resulted in the formation of Cp*Ir(PPh_3)Cl_2 as a major product after the next procedure. The solvent was pumped off to give a red powder. The IR spectrum of this red solid in the range 2300–1600 cm^{-1} showed only a band at 1711 cm^{-1} (in CH_2Cl_2), or at 1717 cm^{-1} (in CCl_4). The ^{1}H NMR spectra of this solid in either $CDCl_3$ or acetone-d_6 clearly showed the expected resonances in the region due to the protons of the Cp* group, OMe group, and the aromatic groups. However, no reproducible resonance patterns could be obtained. Using the ^{15}N-enriched sample **4**-$^{15}N_\alpha$ as the starting material, ^{1}H NMR spectra of the solid in acetone-d_6 showed, in addition to those resonances due to the Cp*, OMe, and the aromatic groups, a weak doublet at δ 13.71 with a coupling constant of 70 Hz assignable to NH, which showed variable intensity for different samples. The ^{15}N NMR spectrum (by using **4**-$^{15}N_\alpha$) in acetone-d_6 showed, however, no signal due to either free or coordinated $ArN^{15}N^+$, but a singlet at −73 ppm assigned to free ^{15}NN. Microanalysis gave 2.77% nitrogen content in this red solid, which was lower than the calculated 3.68% of nitrogen for Cp*Ir(PPh_3)(Cl)(*p*-$N_2C_6H_4OMe$). Attempts to further purify this material failed due to its facile decomposition to give Cp*Ir(PPh_3)Cl_2 as the main isolated

product. However, protonation of this mixture in solution by HBF_4 – diethyl ether always yielded the compounds $[Cp^*Ir(PPh_3)Cl(p\text{-}NHNC_6H_4OMe)][BF_4]$ (**6** $\mathbf{BF_4}$) and $Cp^*Ir(PPh_3)Cl_2$ as the major products. The relative ratio of these two products produced by the protonation was strongly dependent upon how long the hydrido–chloro exchange reaction had proceeded and the time taken in manipulations in an effort to purify them.

Results

Synthesis and characterization of $[Cp^*Ir(C_2H_4)(p\text{-}N_2C_6H_4OMe)][BF_4]$ (1 $\mathbf{BF_4}$)

The careful, slow addition of a solution of *para*-methoxybenzenediazonium tetrafluoroborate in acetone to a solution of $Cp^*Ir(C_2H_4)_2$ in acetone at −78°C produces the corresponding monoethylene aryldiazenido complex **1** $\mathbf{BF_4}$ in good yield (typically better than 90% after recrystallization). As the reaction proceeds, the mixture first changes from colourless to a transient yellow, and then to orange-red. The final dark-red crystals of **1** $\mathbf{BF_4}$ can be isolated by recrystallization from acetone–hexanes at −10°C. The reaction conditions are rather critical; we have found that a fast addition of the diazonium salt solution to the $Cp^*Ir(C_2H_4)_2$ solution, or a rise in the reaction temperature, often leads to a dark-red reaction mixture. Upon addition of hexanes to this, only a red oily material precipitates. Recrystallization of this red oil from acetone–hexanes at −10°C gave only a low yield of crystals of **1** $\mathbf{BF_4}$, and these were invariably covered with the oily material. Repeating the recrystallization to attempt to obtain crystals free of contamination always resulted instead in more of the red oil. The IR spectrum of a thin film of this on a KBr disc showed (in the range 1600–2300 cm^{-1}) only the absorption at 1710 cm^{-1} due to **1** $\mathbf{BF_4}$. However, the ^1H NMR spectrum in acetone-d_6 showed resonances for **1** $\mathbf{BF_4}$ plus several other small, broad, and featureless signals at δ ca. 1.2–1.8.

Compound **1** $\mathbf{BF_4}$ is very soluble in most common polar solvents, such as acetone, $CHCl_3$, CH_2Cl_2, $MeNO_2$, and MeCN, but is insoluble in nonpolar solvents such as hexanes and diethyl ether. It is stable to air in the solid state; after exposure of the crystals to air at ambient temperature for days, no change in the IR spectrum was observed. However, in solution it has only limited stability. In nonhalogenated solvents it slowly changes from orange-yellow to orange-red over several days, but in halogenated solvents it decomposes rapidly.

1 $\mathbf{BF_4}$ has been characterized by analysis and spectroscopy. Signals due to the parent ion $[Cp^*Ir(C_2H_4)(N_2C_6H_4OMe)]^+$ and the fragments formed by loss of the C_2H_4 ligand and the aryldiazenido ligand are observable in the FABMS spectrum. The IR spectrum displays the expected absorptions for the organic and BF_4 groups and a single absorption at 1724 cm^{-1} (EtOH) that falls within the range generally associated with ν(NN) for a terminally coordinated singly bent aryldiazenido ligand (3). The assignment was confirmed by an isotopic shift of 35 cm^{-1} to lower wavenumber in the $^{15}N_\alpha$-enriched sample. The ^1H NMR spectrum shows all the expected resonances. The aryl group protons occur as a typical AA′BB′ pattern in the aromatic region and singlets at δ 3.91 and 2.25 are assigned to the methyl protons of the OMe and Cp* groups. A broad singlet at δ 3.25 (integral 4H) is assigned to four equivalent protons in the C_2H_4 ligand. The broadness of this peak suggests that the ethylene protons are involved in a dynamic process. Therefore, variable-temperature ^1H and $^{13}C\{H\}$ spectra were obtained and these are reported below. The $^{13}C\{^1H\}$ NMR spectrum of **1** $\mathbf{BF_4}$ is consistent with its ^1H NMR spectrum. At room temperature only a single resonance was observed for C_2H_4, indicating equivalent ethylene carbons. Two broad peaks at δ −2.9 and −107.0 in the ^{14}N NMR spectrum clearly indicate the presence of a singly bent aryldiazenido ligand (3, 26). The downfield signal is assigned to the metal-bound nitrogen (N_α), and this has been confirmed by the ^{15}N NMR of **1**-$^{15}\mathbf{N_\alpha}$ $\mathbf{BF_4}$.

Crystal structure of 1 $\mathbf{BF_4}$

The crystal structure of **1** $\mathbf{BF_4}$ consists of an assembly of an equal number of *R* and *S* enantiomers of the discrete cation $[Cp^*Ir(C_2H_4)(p\text{-}N_2C_6H_4OMe)]^+$ and the anions $[BF_4]^-$ related in the centrosymmetric space group $P2_1/n$. The asymmetric unit is an ion-pair. There are no abnormally short contacts in the crystal.[3] The cation has a half-sandwich structure, and a perspective view together with the numbering scheme is shown in Fig. 1, and important bond lengths and angles are in Table 3.

The Cp* ligand is bonded to the iridium in a typical η^5-coordination mode. The similar bond lengths from the five carbon atoms in the Cp* ring to iridium, from 2.204(8) through 2.238(7) Å, indicate a regular C_{5v} symmetry for the Cp*Ir moiety. Thus, the two different ligands, C_2H_4 and $[p\text{-}N_2C_6H_4OMe]^+$, constituting the "piano stool legs" for this compound, appear to have no measurable differential influence on the coordination geometry of the Cp* ligand.

The ethylene ligand is coordinated in a symmetrical η^2 fashion with Ir—C(10) = 2.190(8) Å and Ir—C(20) = 2.172(9) Å, and is oriented with the C—C bond parallel to the Cp* plane and bisected by the plane defined by Ir, N_α, and the centroid of the Cp* ring. Furthermore, compared to the typical uncoordinated ethylene C═C distance of 1.335(5) Å, the C(10)—C(20) distance of 1.387(16) Å of the ethylene ligand in **1** indicates this bond has been significantly lengthened as a result of coordination. The aryldiazenido ligand clearly has a singly bent geometry, with the Ir-N(1)-N(2) skeleton close to linear and the N(1)-N(2)-C(1) angle about 120°. These values and other related parameters for the aryldiazenido ligand are comparable to those found for $[IrCl(N_2Ph)(PPh_3)_2][BF_4]$ (3), the only other iridium singly bent aryldiazenido complex characterized by X-ray diffraction (Table 4).

The aryldiazenido ligand is essentially planar, which indicates significant π-conjugation throughout the NN, methoxyl, and phenyl ring framework. However, the most striking feature of the aryldiazenido ligand is the orientation of its molecular plane with respect to the rest of the complex. Rather than it being coincident with the local (vertical) plane through Ir and the centroids of the Cp* and ethylene ligands, it is instead approximately perpendicular to it, as indicated by the C-N_β-Ir-Cp*(centroid) torsion angle of 88.4°. A view of the cation **1** down the N(2)-N(1)-Ir axis vividly illustrates this stereochemical arrangement (Fig. 2).

[3] The shortest contacts involve pairs of *p*-methoxyphenyl rings with C—C contacts of approximately 3.65 A across an inversion centre at (1/2, 0, 1/2).

Geometry and electronic structure of the singly bent aryldiazenido ligand

In an effort to provide a theoretical basis for the observed orientation of the aryldiazenido ligand in the cation **1** the frontier orbitals for the fragments $Cp^*Ir(C_2H_4)$ and PhN_2^+ have been considered. As we will describe in the Discussion, overlap of the appropriate orbitals of these fragments does indeed account satisfactorily for the observed orientation.

There do not appear to be any previously published EHMO calculations for either the free or coordinated PhN_2^+ ion, although EHMO calculations for the free HN_2^+ ion and its complexes as well as for complexes with the MeN_2 ligand have been reported previously (20, 27). However, conclusions derived from these calculations are unlikely to be entirely valid for the *aryl*diazonium ion or the *aryl*diazenido ligand because the lack of cylindrical symmetry in the former, and the effect of π-conjugation of the NN group with the planar phenyl group in both instances, are ignored. The significance of π-conjugation for PhN_2^+ can be determined by a comparison of the calculated relative energies of the valence orbitals of the free ions NO^+, HN_2^+, and PhN_2^+ (Fig. 3). The highest occupied molecular orbital (HOMO) for NO^+ or linear HN_2^+ is a σ-type orbital, but for the free

[a]Reference 3.

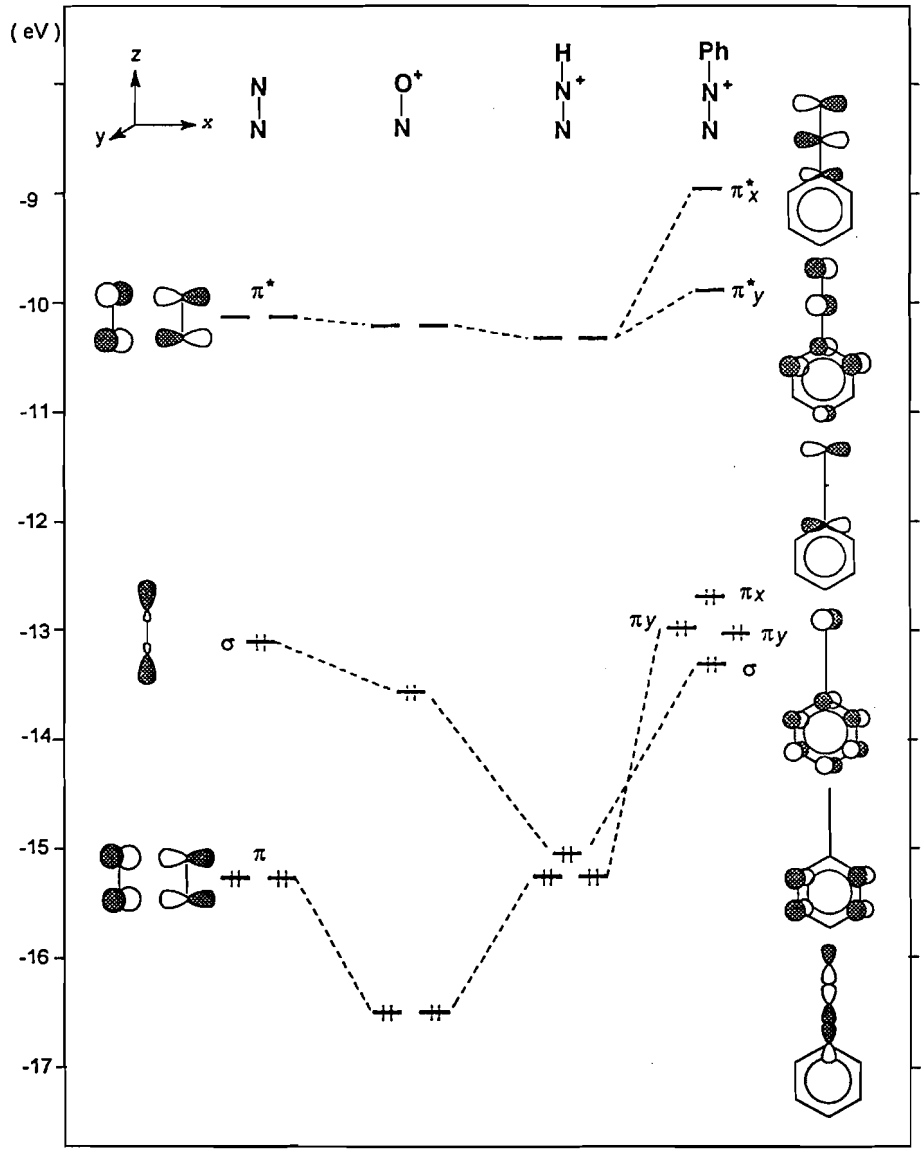
"linear" PhN_2^+ ion it is a nonbonding orbital of π character. In fact, the filled σ orbital of PhN_2^+ is buried beneath three filled π-type orbitals, one with b_1 symmetry and other two with b_2 symmetry in this C_{2v} system. Interestingly, all these three π orbitals have nonbonding character with respect to the N-N-C linkage and they are energetically located rather higher than the corresponding π orbitals in NO^+ and HN_2^+. Another distinguishing feature is that for NO^+ and HN_2^+ the lowest unoccupied molecular orbitals (LUMO's) are two degenerate π antibonding orbitals, but for PhN_2^+, the corresponding π-type orbitals are nondegenerate (π_x^* and π_y^*); the π_y^* orbital, which is conjugated with the π system of the phenyl ring, lies low, and π_x^*, which is perpendicular to it, lies high. Clearly, the main underlying cause of the differences between the frontier orbitals for NO^+ and HN_2^+ and those of PhN_2^+ is the conjugation of the π-system of the *aryl* group with one directional set of π orbitals of the N_2 group in PhN_2^+ (the orbitals π_y and π_y^* in Fig. 3). Furthermore, energetically the "linear" PhN_2^+ ion seems to be neither a better σ-donor nor a better π-acceptor ligand than NO^+.

However, the linear phenyldiazonium ion is not really what we are interested in, when it comes to considering the frontier orbitals for an aryldiazonium ion acting as a *ligand.* This is because the structure of the cation **1** is typical of the class of "singly bent" aryldiazenido complexes (**Ib**, Scheme 1) in that the ligand is invariably found to be bent, not linear, at N_β with an angle typically near 120° (3). Furthermore, in **1** it is bent in a direction that makes N_α, N_β, and the aryl ring coplanar. Clearly, to use the fragment molecular orbital (FMO) method for singly bent aryldiazenido complexes, the MO's of this *bent* aryldiazenido ligand fragment, rather than the linear one, are needed. Moreover, the singly bent aryldiazenido ligand has NN and NC bond lengths that are different from free ArN_2^+. The effect that this bending at N_β, and lengthening of the NN and NC distances, has on the π, π^*, and σ orbitals is shown sequentially in the middle and right-hand side of Fig. 4 (where the bending is assumed to be in the *xz* plane).

As a result of bending at N_β, the local symmetry of PhN_2^+ drops from C_{2v} to C_s. Consequently, the σ- and π_x-type of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

Fig. 3. The frontier orbitals of NN, NO^+, HNN^+, and $PhNN^+$.



orbitals (π_x and π_x*), which were orthogonal in C_{2v}, are now in principle able to interact with each other. The filled σ and π orbitals are very close to one another in energy in the free PhN_2^+ ion, so a strong mixing of this σ orbital and the π_x orbital would be expected. The resulting higher energy orbital $2a'$ produced by this mixing is an orbital of considerable σ character, and is now the HOMO in the bent PhN_2^+ ion. This contrasts directly with the linear PhN_2^+ ion where the HOMO is a π_y orbital. Interestingly, this $2a'$ orbital is located in the plane and points in a direction slightly *trans* to the phenyl group. The mixing also produces a lower energy orbital, the σ orbital $1a'$, which is primarily bonding between N_β and the ipso C atom. Another notable feature is that the bending decreases the energy of the π_x* orbital dramatically, and indeed this becomes the LUMO $3a'$ in bent PhN_2^+, and is a π-acceptor orbital. Thus, **7** is the formal valence structure for the singly bent PhN_2^+ ligand, and the shape and arrangement of the HOMO **8** and LUMO **9** are together shown in simplified fashion in **10**, and resemble those for a vinylidene ligand **11**, especially inasmuch as the acceptor orbital on the terminal N or C atom is a *p* orbital that lies *in the molecular plane.*

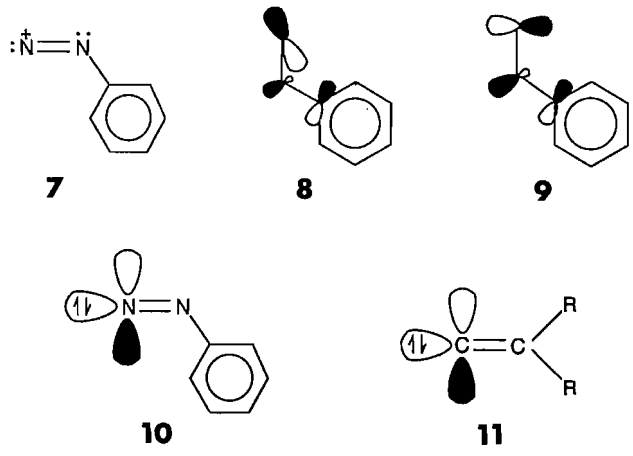


Fig. 4. Effect of NNC bending on the frontier orbitals of $PhNN^+$.

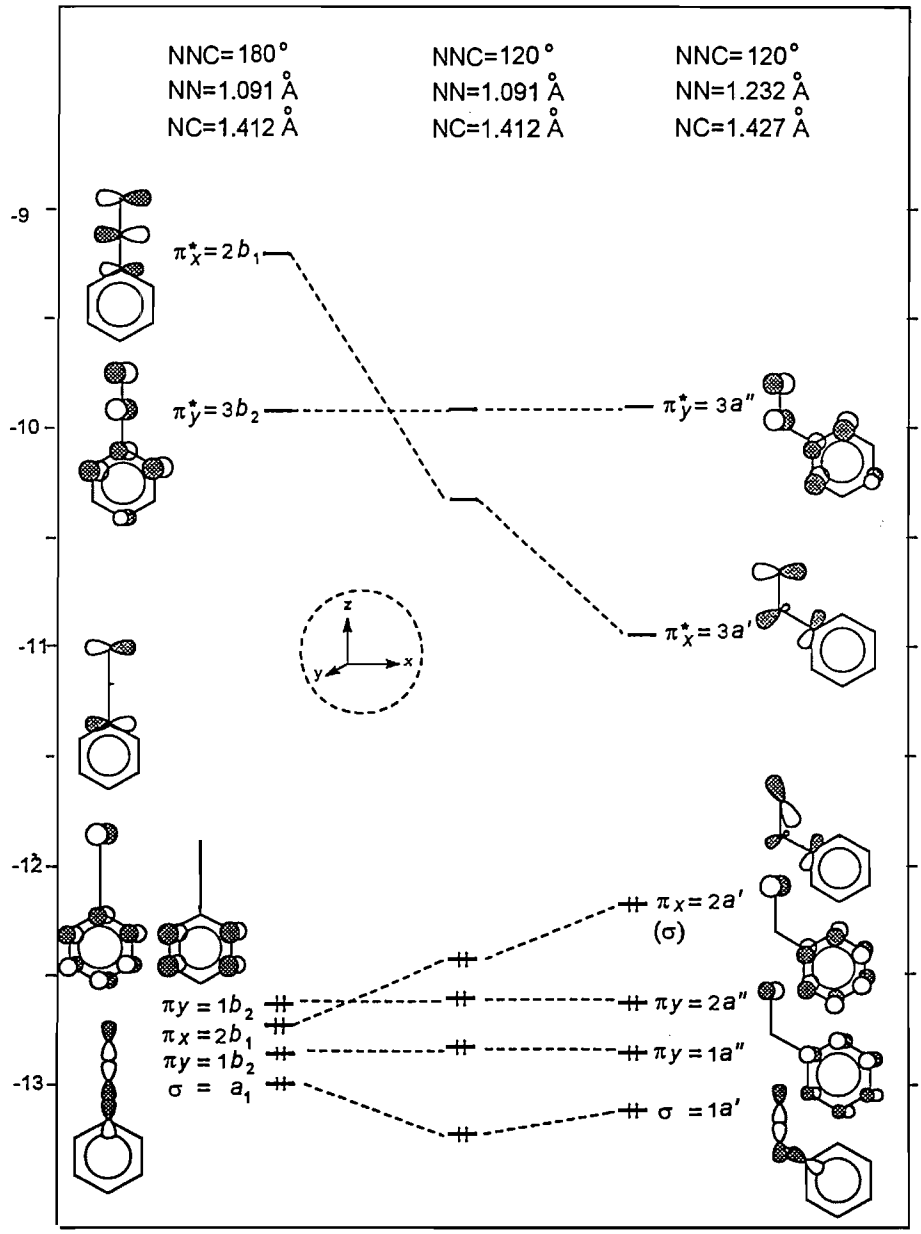

The driving force behind this large energy change of the π_x^* orbital comes mainly from a lessening of the antibonding π interaction between N_α and N_β, and between N_β and the ipso C atom, as a result of the bending at N_β and the longer NN and NC internuclear distances assigned to the bent PhN_2^+ fragment compared with the linear ion. However, the bending and the lengthening have less influence on the energies of the π_y orbitals. This is largely because of the predominantly nonbonding N-N-C character of these π orbitals. Because these occupied $1a''$ and $2a''$ orbitals are of quite high energy, it will be expected that the singly bent PhN_2 ligand will have significant π-basicity, but only in this plane (yz) perpendicular to the molecular plane. Conversely, because the counterpart antibonding orbital π_y^* ($3a'$) is much higher in energy than the LUMO (π_x^*; $3a'$), the bent PhN_2 ligand will be a poor π-acceptor *in this plane yz*. So, as a summary, the bending and bond lengthening have made PhN_2^+ a better σ-donor and a better π-acceptor (but only using the *in-plane* π_x^* orbital), while also possessing some π-donor capacity *perpendicular* to the molecular plane.

From the above analysis, and considering the fact that the d_π orbitals of a transition metal are generally lower in energy than the π^* orbitals of the PhN_2^+ ligand, it is clear that a complex possessing a *linear aryl*diazenido ligand is highly disfavored. This is not only because of the stronger σ-donating ability of the singly bent aryldiazenido ligand, but more importantly because the back-bonding between filled metal d_π orbitals and the empty π^* orbitals is much less favorable for the linear PhN_2^+ ligand than for the singly bent PhN_2^+ ligand. This is clearly consistent with the experimental result that there is not one single structurally characterized example in which the aryldiazenido ligand adopts a linear N-N-Ar arrangement (3).

Dynamic NMR spectroscopic study of [Cp*Ir(C_2H_4)(*p*-$N_2C_6H_4OMe$)][BF_4] (**1** BF_4)

The ambient-temperature ^1H NMR spectrum of **1** BF_4 displays a broad singlet at δ 3.25 for the four protons of the ethylene ligand. This indicates that at this temperature a time-averaged signal results. A series of ^1H NMR spectra were measured in acetone-d_6 solution from 22°C to −63°C (Fig. 5(*a*)). As the solution is cooled, the singlet at δ 3.68 broadens, and at the coalescence temperature of −20°C it is very broad and asymmetric. With further decrease in temperature this broad signal retains its asymmetric envelope, but gradually resolves into a complicated multiplet that is sharp at −63°C and unchanged below this temperature. The limiting spectrum and a computer simulation of the ABCD system are shown in Fig. 5(*b*).

A series of variable-temperature $^{13}C\{^1H\}$ NMR spectra in acetone-d_6 were also measured for **1** BF_4. At 21°C, a single broad peak near δ 50 indicates two equivalent ethylene carbons. As the solution is cooled, this signal first collapses into the baseline at 0°C, and then re-emerges as two equal intensity broad peaks. These sharpen on further cooling, and at −64°C the low-limit spectrum with resonances at δ 48.02 and 50.73 is obtained, and this spectrum is unchanged down to −84°C.

Singly and doubly bent aryldiazenido complexes and diazene complexes containing the Cp*Ir(PPh_3) core

Treatment of **1** BF_4 with an equimolar amount of PPh_3 in ethanol at room temperature afforded quantitatively the corresponding triphenylphosphine aryldiazenido complex, [Cp*Ir(PPh_3)(*p*-$N_2C_6H_4OMe$)][BF_4], **3** BF_4.

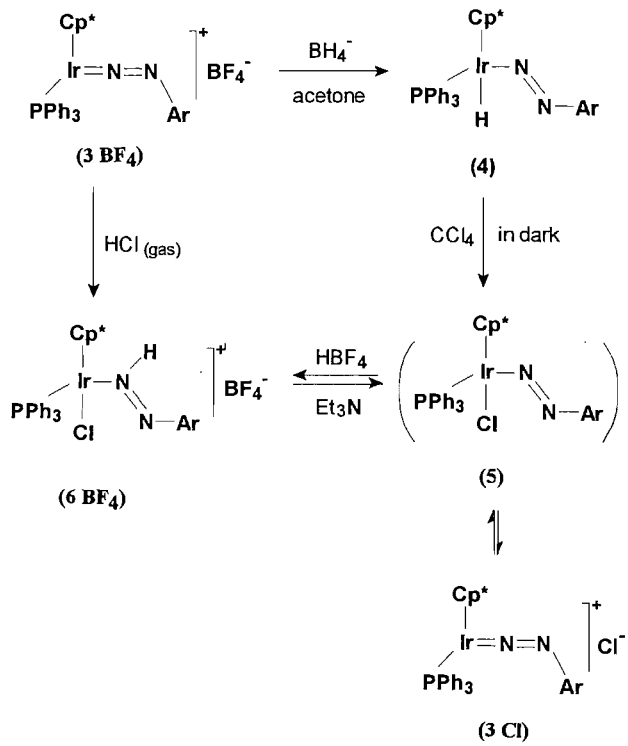
[2] [Cp*Ir(C_2H_4)(*p*-$N_2C_6H_4OMe$)]$^+$ (**1**) $\xrightarrow{PPh_3}$ [Cp*Ir(PPh_3)(*p*-$N_2C_6H_4OMe$)]$^+$ (**3**) + C_2H_4

Alternatively, a direct reaction of Cp*Ir(C_2H_4)$_2$, in situ, with equimolar amounts of PPh_3 and [*p*-$N_2C_6H_4OMe$][BF_4] also gave **3** BF_4 quantitatively. In both cases it was isolated as an oil that is stable under a nitrogen atmosphere either pure or as solutions in nonhalogenated solvents. It decomposes slowly in halogenated solvents, e.g., $CDCl_3$.

Compound **3** BF_4 has been fully characterized by spectroscopic methods and elemental analysis. The ν(NN) absorption at 1710 cm^{-1} observed in EtOH is lower than that of its ethylene precursor **1** BF_4, which has ν(NN) at 1724 cm^{-1} in the same solvent. This is consistent with the general view that the C_2H_4 ligand is a better π-acid than the PPh_3 ligand. In the ^{15}N and $^{31}P\{^1H\}$ NMR spectra of **3**-$^{15}N_\alpha$ BF_4, ^{15}N–P coupling results in each case in a doublet with $J_{P-^{15}N}$ = 7 Hz. The reaction of compound **3** BF_4 with BH_4^- in acetone at −10°C gives a good yield of the neutral hydrido complex Cp*IrH(PPh_3)(*p*-$N_2C_6H_4OMe$) **4**, which forms peach-red solutions in acetone or hexane and is a beautiful rose-purple colour in the solvent-free state. The formula and spectroscopic properties of **4** indicate that the aryldiazenido ligand is now doubly bent and a $1e^-$ donor (Scheme 2).

A broad IR band at 2133 cm^{-1} that was observed in both **4** and **4**-$^{15}N_\alpha$ is assigned to ν(Ir–H). However, no IR band due to ν(NN) of the doubly bent aryldiazenido ligand could be assigned, even with the aid of the ^{15}N-enriched sample. The proton NMR spectrum in acetone-d_6 showed, in addition to the resonances for the aromatic and the methoxy protons, a sharp doublet at δ −15.9 with $^2J_{P-H}$ = 33.5 Hz integrating for 1H assigned to the hydride, and a well-resolved doublet of doublets (δ 1.51 with J_{P-Me} = 1.8 Hz and J_{H-Me} = 0.7 Hz) in the Cp* methyl region integrating for 15 H.

Scheme 2.

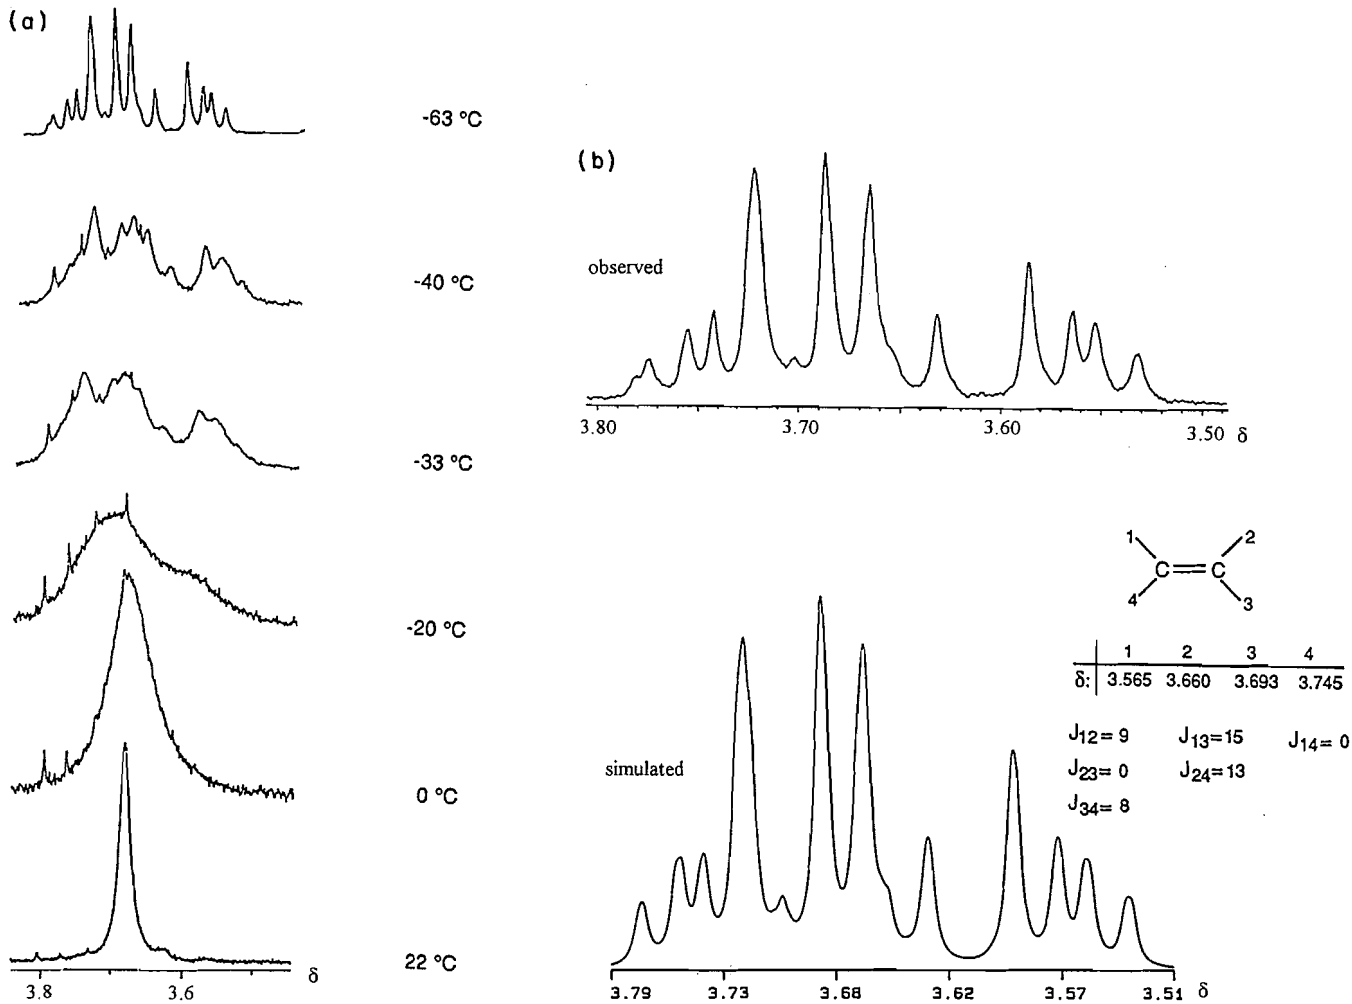


Evidence for a doubly bent aryldiazenido ligand in **4** is unambiguously provided by the ^{15}N NMR spectrum of **4**-$^{15}N_\alpha$. The only resonance is a singlet at δ 271.9, assigned to $^{15}N_\alpha$. This falls within the typical chemical shift range for N_α of a doubly bent aryldiazenido ligand (δ: 200–350 ppm) (3) and can be compared with the values for the corresponding singly bent aryldiazenido ligand in **1**-$^{15}N_\alpha$ and **3**-$^{15}N_\alpha$ (δ −2.26 and 33.2, respectively). No ^{15}N coupling to the hydride or to phosphorus could be observed in the ^1H or ^{15}N NMR spectrum of **4**-$^{15}N_\alpha$.

The aryldiazene complex [Cp*IrCl(PPh_3)(*p*-$NHNC_6H_4OMe$)][BF_4] (**6** BF_4) can be conveniently prepared in high yield from the reaction of **3** BF_4, with HCl gas in ethanol. In the IR spectrum the lower ν(NN) at 1483 cm^{-1} (ν(^{15}NN) 1460 cm^{-1}) is consistent with the presence of a diazene ligand. This has been further substantiated by the ^1H and ^{15}N NMR spectra for **6**-$^{15}N_\alpha$ BF_4. A characteristic doublet (δ 13.73 with $J_{H-^{15}N}$ = 70 Hz in acetone-d_6) observed in the ^1H NMR spectrum, together with a high-field doublet (δ −64.24 with $J_{^{15}N-H}$ = 70 Hz in acetone-d_6) observed in the ^{15}N NMR spectrum, indicates the presence of an aryldiazene ligand. Both the chemical shift and the coupling constant are consistent with analogous data previously established for the η^1-aryldiazene ligand in mononuclear complexes (28–30).

Deprotonation of **6** BF_4 by using triethylamine did not yield the expected compound Cp*IrCl(PPh_3)(*p*-$N_2C_6H_4OMe$) (**5**),

Fig. 5. (*a*) Variable-temperature ^{1}H NMR spectra for the ethylene protons of **1** BF_4. (*b*) Observed and simulated ABCD spectrum at −63°C.



the chloro analogue of the hydride **4**. Instead it produced a mixture of a major product and $Cp^*Ir(PPh_3)Cl_2$ (**31**) (<5%). The major product exhibited IR and ^{1}H NMR spectra identical to **3** BF_4 (except, of course, for BF_4 absorptions), and therefore it is considered that this compound contains the same cation **3**, i.e., $[Cp^*Ir(PPh_3)(p\text{-}N_2C_6H_4OMe)]^+$, but is the chloride salt $[Cp^*Ir(PPh_3)(p\text{-}N_2C_6H_4OMe)]Cl$ (**3 Cl**). In particular, the ν(NN) value of 1711 cm^{-1} in CH_2Cl_2 undoubtedly indicates a singly bent, and not a doubly bent aryldiazenido ligand as required for **3 Cl** but not for **5**. Interestingly, reprotonation of this compound with HBF_4–Et_2O resulted in reformation of the diazene complex $[Cp^*IrCl(PPh_3)(p\text{-}NHNC_6H_4OMe)][BF_4]$ (**6** BF_4) in which the Cl group is again coordinated.

An attempt to obtain $Cp^*IrCl(PPh_3)(p\text{-}N_2C_6H_4OMe)$ (**5**) from hydride **4** by a direct hydrido–chloro exchange reaction using excess CCl_4 also was not successful. The salt $[Cp^*Ir(PPh_3)(p\text{-}N_2C_6H_4OMe)]Cl$ (**3 Cl**), was again produced, as indicated by ν(NN) values (1711 cm^{-1} in CH_2Cl_2 and 1717 cm^{-1} in CCl_4) as well as ^{1}H NMR, together with variable amounts of $Cp^*Ir(PPh_3)Cl_2$. A small amount of $[Cp^*IrCl(PPh_3)(p\text{-}NHNC_6H_4OMe)]Cl$ (**6 Cl**) is also believed to be produced, because a characteristic ^{15}N–H doublet proton signal was invariably observed when using ^{15}N-labelled **4**, although the intensity of this signal varied from preparation to preparation. In situ protonation of the products of this exchange by using HBF_4–OEt_2 always resulted in the production of the aryldiazene complex $[Cp^*IrCl(PPh_3)(p\text{-}NHNC_6H_4OMe)][BF_4]$ (**6** BF_4) and $Cp^*Ir(PPh_3)Cl_2$ as the main products.

Discussion

Mechanism of formation of $[Cp^*Ir(C_2H_4)(p\text{-}N_2C_6H_4OMe)][BF_4]$ (1 BF_4)

The monoethylene aryldiazenido compound **1** BF_4 is readily obtained by the substitution of an ethylene ligand in $Cp^*Ir(C_2H_4)_2$ by the *p*-methoxybenzenediazonium ion at low temperature. $Cp^*Ir(C_2H_4)_2$ appears to be the most inert to substitution among the series of compounds $Cp'ML_2$, (Cp′ = Cp or Cp*; M = Co, Rh, or Ir; L = CO or C_2H_4). Except for the recently reported synthesis of **2** by us (15), direct thermal substitution of an ethylene ligand in $Cp^*Ir(C_2H_4)_2$ to form $Cp^*IrL(C_2H_4)$ is difficult and has rarely been previously reported in the literature (32–35). Attempts by us to obtain $Cp^*IrL(C_2H_4)$ (L = CO or PPh_3) by stirring a hexane solution of $Cp^*Ir(C_2H_4)_2$ saturated with CO gas, or by refluxing $Cp^*Ir(C_2H_4)_2$ with PPh_3 in ethanol for days, were unsuccessful. Obviously, its inertness toward nucleophilic ligand substitution reactions reflects the highly electron-rich metal centre

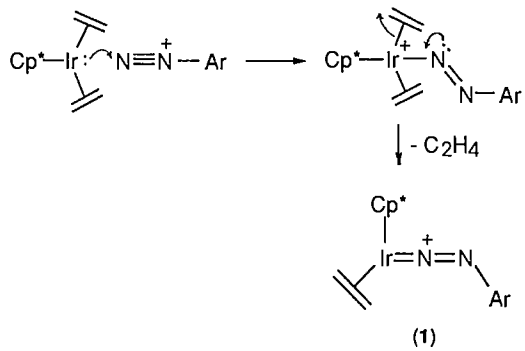
of $Cp^*Ir(C_2H_4)_2$. On the other hand, the observed facile substitution of ethylene by ArN_2^+ or NO^+ indicates that a different mechanism is likely to be involved in these reactions. A mechanism involving an initial *electrophilic* attack by the NO^+ group at the electron-rich metal centre was suggested previously (15), and we postulate a similar mechanism for the reaction with ArN_2^+ (Scheme 3). In this mechanism, the ArN_2^+ ion formally acts as a Lewis acid and an intermediate with a doubly bent aryldiazenido ligand is formed. This intermediate then loses one of the ethylene ligands to give the final singly bent aryldiazenido complex **1**.

Scheme 3.



(1)

The singly bent aryldiazenido ligand as a single-faced π-acid and π-base

The valence orbital picture presented in the results section revealed two important electronic features of the singly bent aryldiazenido ligand. First, the HOMO $2a'$ is located at a rather high energy level (ca. −12.4 eV), actually higher than the valence orbital ionization energy of the nitrogen $2p$ orbital (−13.4 eV) used in the calculations. This reflects the antibonding character of this orbital with respect to the NNC skeleton. Thus when we compare the relative energies of the HOMO for singly bent PhN_2^+ at −12.4 eV (Fig. 4) and that of NO^+ at −13.5 eV (Fig. 3), PhN_2^+ should be a better σ-donor. Secondly, the large energy separation of the two π-accepting orbitals π_x^* ($3a'$) and π_y^* ($3a''$) and the relatively high energy of the occupied π_y orbitals $1a''$ and $2a''$ of the singly bent PhN_2^+ ligand indicate the π-bonding ability of this ligand to be highly anisotropic. In the xz plane (which is the ligand plane) it should behave as a strong π-acceptor, whereas in the perpendicular plane yz it should act as a reasonably strong π-donor. The bent PhN_2 ligand may be described as a "single-faced" π-acceptor, and a "single-faced" π-base.

Clearly, because of this anisotropic character, the singly bent aryldiazenido ligand is significantly different from the linear nitrosyl ligand for which the π-system is degenerate. Thus, although as the free ions these ligands are essentially valence isoelectronic and both coordinate through the nitrogen atom, it is misleading to consider them as analogous ligands. Their local symmetry and frontier orbitals are quite different, and they are not isolobal. This distinction must be carefully considered in any attempts to compare the relative π-accepting abilities of these ligands, and such attempts must take into account the symmetry and availability of suitable π-donor orbitals on the metal.

Orientation adopted by the aryldiazenido ligand in the structure of the cation 1

As described in the results section, the aryldiazenido ligand is oriented unsymmetrically. The NN group is coplanar with the aryl plane, but this local molecular plane is approximately parallel with the ethylene C—C axis and perpendicular to the vertical plane defined by the iridium atom and the centroids of the Cp* and ethylene ligands. Because of this, the cation has no molecular symmetry, and is therefore chiral. So, there are equal numbers of *R* and *S* enantiomers in the centrosymmetric crystal structure. These differ only by the direction, to the left or right of the vertical plane, in which the aryldiazenido ligand is bent. Why is this structure adopted, rather than the symmetrical one derived by rotating the aryldiazenido ligand plane through 90° so it is coincident with the vertical plane? An explanation can be found by examining the frontier orbitals of the aryldiazenido ligand and matching them with those for the $Cp^*Ir(C_2H_4)$ fragment.

On the basis of structure determinations on members of the family of cobalt group bis(ethylene) complexes, in $Cp^*Ir(C_2H_4)_2$ the ethylene ligand C—C axes lie parallel and the plane of these four carbon atoms is parallel to the plane of the Cp* ligand. The dominant orbital interaction responsible is the overlap of the filled iridium d_{yz} orbital with the empty ethylene π* orbitals. When one of the ethylenes is substituted by the singly bent aryldiazenido ligand to give **1**, the empty $3a'$ π-acceptor orbital, the LUMO **9**, will preferentially align in the same manner as the ethylene orbital it has replaced, as shown in **12**. This leads directly to the observed orientation of the aryldiazenido ligand, and both ligands are competing for electron density in the iridium d_π orbital.

The stronger π-accepting property of the ArN_2 ligand should reduce the degree of π back-bonding to the ethylene ligand in **1**, leading to both a lower barrier to rotation of the ethylene (see below) and an increased susceptibility to substitution by an incoming donor ligand compared with the parent bis(ethylene) complex. In agreement, the ethylene ligand in **1** was found to be easily and quantitatively substituted by triphenylphosphine at room temperature to give **3**. In fact, **3** $\mathbf{BF_4}$ is most conveniently synthesized by reacting the bis(ethylene) complex directly with a mixture of equimolar amounts of the diazonium salt and PPh_3 at room temperature. Presumably **1** is consumed by reaction with PPh_3 as quickly as it is formed as a result of the greater lability of the ethylene ligand. (Note that good yields in the synthesis of **1** itself could not be obtained at room temperature.)

Stereochemical nonrigidity of the singly bent aryldiazenido ligand in 1

The ABCD pattern for the four protons, and two equal intensity carbon signals, observed for the ethylene ligand in the ^1H and $^{13}C\{^1H\}$ NMR spectra of **1** $\mathbf{BF_4}$ at low temperatures ($\leq$ −64°C) also require an unsymmetrical frozen structure for the cation in solution. It seems reasonable to suggest that this structure is probably the same as that adopted in the solid state, and predicted to be the stable structure on the above orbital overlap grounds. The variable-temperature ^1H and $^{13}C\{^1H\}$ NMR spectra clearly show that a fluxional process is occurring, and at the high-temperature limit all of the ethylene protons are equivalent on the NMR time scale, as also are the ethylene carbons. Fluxional behavior of coordinated ethylene in half-sandwich complexes of this kind has been well docu-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

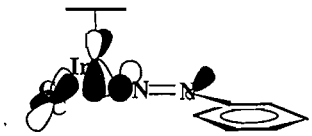
mented to result from hindered rotation about the axis relating the metal to the midpoint of the double bond of the ethylene (18, 36–39). However, for a rapidly rotating ethylene ligand to give a single proton absorption, the cation **1** must at least have mirror symmetry on the NMR time scale. For this to occur, assuming that the frozen-out structure in solution is similar to the solid state structure, the singly bent aryldiazenido ligand must also be involved in a fluxional process, which is related by this mirror symmetry. Therefore, we conclude that at the high-temperature limit both a rotation of the ethylene and a conformational "flipping" of the aryldiazenido ligand (which interconverts the enantiomers) are occurring simultaneously.

If the ethylene rotation were slower than the NMR time scale while the flipping of the aryldiazenido ligand is rapid, then, relative to the ethylene in its equilibrium position, the fragment $Cp^*Ir(N_2Ar)$ would have a time-averaged plane of symmetry and, therefore, the ethylene protons should give a symmetric AA′BB′ pattern, or at least a broad symmetrical envelope of this pattern, at and below the decoalescence temperature. This is not observed. On the other hand, if flipping of the diazenido ligand is slowed first, while rotation of the ethylene is still fast, then the $Cp^*Ir(N_2Ar)$ fragment possesses no element of symmetry so the four protons of the fast-rotating ethylene ligand would again result in an AA′BB′ pattern.

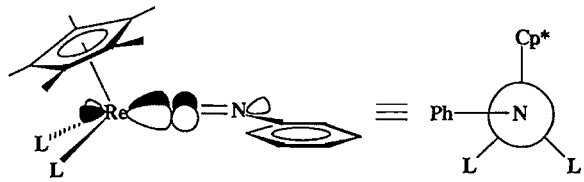
Even at, and below, the coalescence temperature the broad pattern has an unsymmetrical envelope resembling the low-temperature ABCD envelope, and at no temperature is a symmetrical AA′BB′ type of envelope ever evident. Therefore it seems that the two fluxional processes, rotation of the ethylene and flipping of the aryldiazenido ligand, must slow at comparable rates as the temperature is lowered.

It would be of considerable interest to evaluate the barriers for ethylene rotation and aryldiazenido ligand rearrangement in **1**. From the variable-temperature ^1H or ^{13}C NMR spectra it is possible, in principle, to calculate an activation energy; this will correspond to the activation energy for a process that is a combination of the ethylene and ArN_2 ligand rearrangements if they are mechanistically coupled, or to the activation energy for the process with the higher barrier if they are independent. Either way, it provides at least an upper limit of the barrier for each of the ligand rearrangements. The four-spin ABCD pattern for the ethylene protons in the low-limit ^1H NMR spectrum makes such a calculation not trivial. In the case of the ^{13}C NMR spectrum, either rotation of the ethylene or flipping of the ArN_2 ligand *alone* would result in the observed temperature dependence, as also of course would a combination of both processes. The activation barrier at the coalescence temperature is readily calculated from this spectrum to be $\Delta G^{\neq} = 51.5 \pm 0.4$ kJ at $T_c = 270$ K, and while we cannot assign this unambiguously to the barrier for either ethylene rotation or aryldiazenido ligand flipping, we do know from the proton NMR data discussed above that this value must represent an *upper limit* for each of these processes.

The conformational isomerization or flipping of the aryldiazenido ligand can be envisaged to occur either by rotation about the Ir-N-N axis or by an sp^2 inversion of the lone pair on N_β (i.e., a bent–linear–bent change in the geometry of the NNC skeleton). These two mechanisms are illustrated in Scheme 4. To support the case for flipping of the aryldiazenido ligand in **1**, we sought to find an example in which the nonrigidity of the aryldiazenido ligand alone might be observed



12



13

directly by NMR, without the complications attending the simultaneously rotating ethylene ligand. As it transpired, such a system had already been synthesized in our laboratory, namely the half-sandwich complex $[Cp^*Re(PMe_3)_2(p\text{-}N_2C_6H_4OMe)][BF_4]$. Subsequently, investigation of the low-temperature $^{31}P\{^1H\}$ NMR spectrum of this complex resulted in two equal intensity resonances that we ascribed to the aryldiazenido ligand, again adopting an unsymmetrical orientation **13** (which is indeed the orientation observed in the X-ray structure of the carbonyl analogue $[Cp^*Re(CO)(PMe_3)(p\text{-}N_2C_6H_4OMe)][BF_4]$), thus making the two PMe_3 ligands (L) inequivalent. Once again, this orientation maximizes the overlap of the π-acceptor orbital **9** with, in this case, the HOMO of the rhenium fragment as illustrated in **13**. At room temperature a time-averaged single $^{31}P\{^1H\}$ resonance occurs, attributable to the fast conformational isomerization of the ArN_2^+ ligand interconverting the enantiomers. The activation barrier $\Delta G^{\neq}$ obtained from the temperature dependence of the spectrum was 37.0 ± 0.6 kJ mol^{-1} at 190 K; the barriers for several related rhenium aryldiazenido complexes were also measured (40).

A comparison of the ethylene rotation barriers of complexes 1 and 2

From the above discussion $\Delta G^{\neq}$ for ethylene rotation in **1** must be no more than 51.5 ± 0.4 kJ mol^{-1} at 270 K. This value is at least 17 kJ lower than the barrier for the nitrosyl compound **2** for which a value of 68.7 ± 0.2 kJ mol^{-1} at 353 K was obtained (15). The crystal structures of **1** and **2** show no close contacts to the ethylene ligand in either case. Consequently, steric influences, if there are any, are expected to be similar for both complexes, so the different rotation barriers of the ethylene ligand in **1** and **2** are likely to directly reflect differences in the binding of the ethylene ligand to the fragments $Cp^*Ir(NO)^+$ and $Cp^*Ir(N_2Ar)^+$ in the ground and activated states. According to the Dewar–Chatt–Duncanson scheme (41, 42), binding of ethylene to a transition metal atom consists of a σ-bond, formed by overlap of the filled π orbital of the olefin with a metal orbital of the same symmetry, and a π-bond, arising from overlap of the vacant π* orbital of the ethylene with a filled d_π orbital of the metal. The σ component is not of interest here, since it is invariant upon rotation of the ethylene ligand about the metal–ethylene bond axis. However,

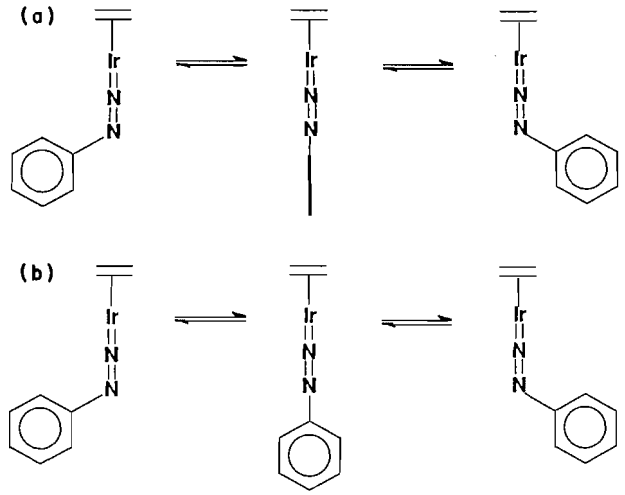
Scheme 4. Possible mechanisms for the conformational isomerization of the ArN_2 ligand: (*a*) rotation about IrNN axis; (*b*) sp^2 inversion at N_β.



the relative strength of the π-bonding component for **1** and **2** will greatly influence the rotation barrier.

As indicated previously, in the ground state, the primary π interaction for the ArN_2 complex **1** is as illustrated in **12**, and analogously for the NO complex **2**. In effect, there exists a competition for the electrons in the metal d_π orbital between the ethylene and the ancillary ligand, NO or ArN_2. The stronger the π-acidity of this ligand situated "*trans*" to the ethylene, the more electron density will be pulled toward to this ligand from the metal centre and the less electron density will be available for the back-bonding to the ethylene. Consequently, there will be a smaller π component of the metal–ethylene bond and a higher ground state energy. In the activated state for ethylene rotation, the ethylene is rotated by 90° and its π-system is now orthogonal to that of the metal d_π HOMO and lies in its nodal plane so that the π-bond is effectively broken. To a first approximation, therefore, the barrier to ethylene rotation should be lowest for the complex with the ancillary ligand that has the greatest demand for the electrons in the iridium d_π HOMO. The observed barrier is lowest for the aryldiazenido complex **1**; in order words, the π-acidity of the singly bent aryldiazenido ligand in **1** seems to be stronger than that of the linear nitrosyl ligand in **2** for this pair of complexes. Further, in both cases the barrier is very much lower than that for $Cp^*Ir(C_2H_4)_2$ itself, for which there is no coalescence of the C_2H_4 proton resonances up to 110°C, indicating that the ethylene rotation barrier in this compound is in excess of 80 kJ mol^{-1} (15, 18). This can be attributed to the fact that in $Cp^*Ir(C_2H_4)_2$ only a weak π-acid ligand C_2H_4 occupies the position "*trans*" to the ethylene in question, so the π-bond is stronger and the ground state is significantly stabilized compared with those of either **1** or **2**.

The relative π-acidity of linear nitrosyl and singly bent aryldiazenido ligands

To seek an explanation for the evidently greater π-acidity of ArN_2 over NO in these particular two complexes **1** and **2** it is worth returning to the results of the EHMO calculations. It has been pointed out earlier in the Discussion that there is a fundamental difference between the singly bent ArN_2 ligand and the linear NO ligand in regard to their intrinsic π-bonding capabilities. The ArN_2 ligand is a π-acceptor only in the molecular plane and is a π-base in the perpendicular plane. It can be described as having "single-faced" π-accepting and π-donating ability. By virtue of its degenerate π-system, the linear NO ligand, by way of contrast, possesses isotropic or cyclindrical π back-bonding ability. Therefore any attempted comparison of the relative π-acidities displayed by these two ligands has to be undertaken with care. In situations where the metal can provide mutually perpendicular d_π orbitals of identical or relatively similar energies, back-bonding to the NO ligand will probably be more effective than to the singly bent ArN_2 ligand simply because the latter can only accept effectively by using the LUMO situated in its molecular plane. In other words, the NO group can back-bond in both planes, whereas the single-faced ArN_2 ligand can only do so in one plane. In fact, in the other plane it acts as a weak π-donor.

But now consider a situation in which the metal is restricted to π-bonding in only one plane. This might arise if the metal has only a single filled d_π orbital or has a low-symmetry environment that removes the degeneracy of the d_π orbitals and leaves only one *d*-orbital effective in back-bonding. Under such circumstances the NO group is also reduced to effectively π-bonding in only one preferred plane (i.e., it is forced to be single-faced), and now its π-accepting ability, compared with that of ArN_2, can be assessed by considering the calculated relative energies of the relevant π-acceptor orbitals in each case. These are shown in Figs. 3 and 4. For the NO ligand the energy of the π* orbital is −10.5 eV while for the singly bent PhN_2 ligand the energy of the 3*a*′ orbital is somewhat lower, −11.0 eV. Thus when both NO and ArN_2 are acting as single-faced π-acceptors it is entirely possible, and indeed likely, that the aryldiazenido ligand could function as the better π-acceptor.

This, we think, is exactly the situation that pertains to complexes **1** and **2**, where the ArN_2 *and NO* ligands are essentially limited to π-bonding with only one iridium d_π orbital, d_{yz}, and thus *both* are forced to function as single-faced π-acceptors with the result that ArN_2 is the better π-acceptor of the two.

Properties and reactions of $Cp^*Ir(PPh_3)(p\text{-}N_2C_6H_4OMe)][BF_4]$ (3 BF_4)

The reactions of the ethylene aryldiazenido complex **1** are complicated by the presence of several sites of possible attack, as was demonstrated previously for the nitrosyl **2** (15). These include the metal, the ethylene ligand, and the ArN_2 group. Some of these reactions have been reported briefly elsewhere. When the ethylene is replaced by PPh_3 to give **3**, many reactions can be better controlled. Most interestingly, preliminary results reported here indicate this to be a rare system in which to observe both singly bent (3*e*-donor) and doubly bent (1*e*-donor) aryldiazenido ligands in readily accessible and stable complexes and to study their interconversion.

The replacement of the ethylene in **1** by PPh_3 to give **3** results in a lowering of ν(NN) of the ArN_2 ligand. PPh_3 is considered to be a better σ-donor than ethylene as a result of its higher lying HOMO and should on this account weaken the Ir—N_α σ-bond and strengthen the N—N bond. This is contrary to the observed trend in ν(NN). Considering now the π interaction, PPh_3 is generally considered to be a poorer π-acceptor than C_2H_4, so there should be more electron density

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

at the metal center available for back-bonding to the antibonding π^* orbitals of the ArN_2 ligand in the phosphine complex **3** than in **1**, and this satisfactorily accounts for the lower ν(NN) value of **3**. The lower field ^{15}N NMR chemical shift for N_α in **3** compared to **1** also indicates greater anisotropy of the π electron density at the N_α position in **3**, which is also consistent with the view that greater π electron density is back-bonded to the ArN_2 ligand from the metal center in **3**.

The reaction of **3** $\mathbf{BF_4}$ with borohydride results in the delivery of a hydrido ligand at the metal and a corresponding rearrangement of the aryldiazenido ligand from a singly bent 3*e* donor to a doubly bent 1*e* donor to give **4**. This type of complex, in which a hydrido ligand coexists with a doubly bent aryldiazenido ligand, is not common. The only other examples of which we are aware are those reported by Haymore and Ibers (43). These are the complexes $MH(CO)_2(PPh_3)_2(N_2Ph)$ (M = Os, Ru), and they were prepared by a very different method, the deprotonation of the corresponding aryldiazene complexes $[MH(CO)_2(PPh_3)_2(NHNPh)]^+$. Haymore and Ibers were unsuccessful in an attempt to obtain these compounds through a reaction of the corresponding five-coordinated singly bent aryldiazenido compounds $[M(CO)_2(PPh_3)_2(N_2Ph)]^+$ with BH_4^-, apparently because the reducing conditions destroyed the aryldiazenido ligand. Therefore, it is significant that we have been able to achieve a similar reaction in high yield in the present system. In another situation we found that borohydride reacts with the singly bent aryldiazenido complex $[CpRe(CO)_2(N_2Ar)]^+$ to give the aryldiazene complex $CpRe(CO)_2(NHNAr)$ (44). The mechanism of this reaction has not been established, so it is not known whether attack may first occur at the metal to give a similar hydrido complex with a doubly bent aryldiazenido ligand, followed by proton migration to N_α. In this context, the observation of a related aryldiazene complex such as **6** in this study becomes important.

Complex **4** is relatively stable either in the solvent-free state or in halogen-free solvents, and so it has been fully characterized. Although no X-ray structure is available, the formulation of this complex is well supported by the spectroscopic data. The hydrido ligand is observed in the ^1H NMR in the expected region and is coupled to the phosphorus of the PPh_3 with an appropriate coupling constant. The best evidence for proposing a doubly bent aryldiazenido ligand is the ^{15}N NMR spectrum of $^{15}N_\alpha$-labeled **4**. The only resonance observed is a singlet at δ 271.9, which must be assigned to N_α, and this falls appropriately within the range established for N_α in other doubly bent aryldiazenido complexes that have been measured, ca. δ 200–350 (3). This large upfield shift has been attributed to the presence of a lone pair of electrons on N_α in the doubly bent structure. A general trend in deshielding of N_α is observed along the series of complexes from **1** (δ −2.26) through **3** (δ 33.2) to **4**. No observable ^{15}N coupling to either the hydride or the phosphorus was evident for **4**. The absence of $^{15}N_\alpha$–H coupling was also noted by Haymore and Ibers for their complexes (43). However, ^{31}P–^{15}N coupling was observed in the ^{15}N NMR spectrum of the singly bent aryldiazenido cation **3**-$^{15}N_\alpha$, so it appears that this coupling is very sensitive to the geometry of the ArN_2 ligand and perhaps the relative disposition of it and the PPh_3 and hydrido ligands.

This simple transformation of the singly bent aryldiazenido ligand to a doubly bent one to incorporate an additional ligand at the metal has, to our knowledge, rarely been observed before (43). However, there are several established examples in which such a transformation effectively occurs, but is accompanied by protonation of the doubly bent aryldiazenido ligand thus formed so that an aryldiazene complex is the actual product. In some cases this can then be deprotonated to give the doubly bent aryldiazenido complex (43). The reaction of **3** with HCl provides a further example of aryldiazene formation in this way, resulting in **6**. However, an attempt to deprotonate this complex by using Et_3N did not yield **5**, the chloro analog of the hydrido complex **6**, but was accompanied by dissociation of the chloride and reversion of the aryldiazenido ligand to the singly bent form, resulting in reformation of the cation **3** as the chloride salt. This serves to underline how sensitive to the nature of the added ligand is the doubly bent – singly bent interrelationship. We shall show in a subsequent article how this relationship can be controlled by the use of added ligands with appropriate σ- or π-donor or -acceptor properties.

Conclusion

In this paper we have presented and discussed in detail several important features of the new half-sandwich iridium ethylene aryldiazenido complex $[Cp^*Ir(C_2H_4)(N_2Ar)]^+$ (**1**), including the orientation of the aryldiazenido ligand, the mechanism of synthesis, the fluxional behavior of the ethylene and aryldiazenido ligands, and the π-accepting ability of the latter relative to nitrosyl in this type of complex. Complex **1** does, by virtue of the substitutional lability of the ethylene ligand, provide a convenient entry to other members of this hitherto unstudied class of half-sandwich iridium aryldiazenido complexes, and we have reported preliminary studies of the PPh_3 derivative, including the transformation of the 3*e*-donor, singly bent aryldiazenido ligand into the 1*e*-donor, doubly bent form. In subsequent papers on this system we shall detail further examples of this substitution chemistry, and the structural variety of the aryldiazenido complexes so obtained.

Synthesis and structure of titanium diolate complexes derived from $CpTiCl_3$

Yujin Huang and Douglas W. Stephan

Abstract: The compounds $[Cl_2CpTi]_2(OCH_2CH_2CH_2O)$ **1**, $[Cl_2CpTi]_2(OCH_2CMe_2CH_2O)$ **2**, and $[Cl_2CpTi]_2$-$(OCHMeCH_2CHMeO)$ **3** were prepared from the reactions of $CpTiCl_3$ and the bis-trimethylsilyl ethers of the diols. Alternatively, these species could be made from the reactions of the diol, imidazole, and $CpTiCl_3$ employing the appropriate stoichiometry. In the presence of excess diol, loss of CpH is observed. In the case of 1,3-propanediol the species $[TiCl(HOCH_2CH_2CH_2O)(OCH_2CH_2CH_2O)]_2$ **4** was isolated. Recrystallization of **4** from THF led to the isolation of $[TiCl_2(OCH_2CH_2CH_2O)(THF)]_{2.5}$, albeit in very low yield. This chemistry is described and the implications are considered. Compounds **1**, **3**, **4**, and **5** were characterized crystallographically; the parameters are summarized as follows: **1**: *C2/c* (No. 15), $a = 12.587(2)$ Å, $b = 9.632(2)$ Å, $c = 15.824(3)$ Å, $\beta = 107.88(1)°$, $V = 1811.3(5)$ Å^3, $Z = 4$; **3**: *C2/c* (No. 15), $a = 12.855(2)$ Å, $b = 10.772(2)$ Å, $c = 15.665(2)$ Å, $\beta = 109.26(1)°$, $V = 2047.7(5)$ Å^3, $Z = 4$; **4**: $P2_1/n$ (No. 14), $a = 8.911(3)$ Å, $b = 7.821(2)$ Å, $c = 13.986(2)$ Å, $\beta = 102.56(2)°$, $V = 951.3(3)$ Å^3, $Z = 2$; **5**: $P2_1/n$ (No. 14), $a = 8.693(3)$ Å, $b = 9.286(2)$ Å, $c = 13.411(2)$ Å, $\beta = 101.18(2)°$, $V = 1062.1(4)$ Å^3, $Z = 2$.

Key words: titanium alkoxides, structure, synthesis.

Résumé : On a préparé les composés $[Cl_2CpTi]_2(OCH_2CH_2CH_2O)$ (**1**), $[Cl_2CpTi]_2(OCH_2CMe_2CH_2O)$ (**2**) et $[Cl_2CpTi]_2(OCHMeCH_2CHMeO)$ (**3**) par réaction du $CpTiCl_3$ avec les bis-triméthylsilyloxydes des diols. On peut aussi les préparer par les réactions des diols, de l'imidazole et du $CpTiCl_3$ en utilisant la stoechiométrie appropriée. En présence d'un excès de diol, on observe une perte de CpH. Dans le cas du propane-1,3-diol, on a isolé le $[TiCl(HOCH_2CH_2CH_2O)(OCH_2CH_2CH_2O)]_2$ (**4**). La recristallisation du composé **4** dans du THF permet d'isoler le $[TiCl_2(OCH_2CH_2CH_2O)(THF)]_2$ (**5**) avec un très faible rendement. On décrit la chimie et on en considère les implications. On a caractérisé les composés **1**, **3**, **4** et **5** par cristallographie; on peut résumer les paramètres comme suit : **1** : *C2/c* (No.15), $a = 12{,}587(2)$ Å, $b = 9{,}632(2)$ Å, $c = 15{,}824(3)$ Å, $\beta = 107{,}88(1)°$, $V = 1811{,}3(5)$ Å^3, $Z = 4$; **3** : *C2/c* (No.15), $a = 12{,}855(2)$ Å, $b = 10{,}772(2)$ Å, $c = 15{,}665(2)$ Å, $\beta = 109{,}26(1)°$, $V = 2047{,}7(5)$ Å^3, $Z = 4$; **4** : $P2_1/n$ (No.14), $a = 8{,}911(3)$ Å, $b = 7.821(2)$ Å, $c = 13{,}986(2)$ Å, $\beta = 102{,}56(2)°$, $V = 951{,}3(3)$ Å^3, $Z = 2$; **5** : $P2_1/n$ (No.14), $a = 8{,}693(3)$ Å, $b = 9{,}286(2)$ Å, $c = 13{,}411(2)$ Å, $\beta = 101{,}18(2)°$, $V = 1062{,}1(4)$ Å^3, $Z = 2$.

Introduction

As part of our ongoing study of the chemistry of chalcogenide derivatives of the early metals we have described macrocyclic alkoxide and thiolate complex of Zr and Ti metallocenes (1). More recently, we focused attention on chalcogenide derivatives of monocyclopentadienyl-titanium(IV). We previously described the Lewis acidity of CpTi-thiolate derivatives such as $CpTi(SCH_2CH_2CH_2S)Cl$ and $CpTi(SCH_2CH_2)_2S)Cl$ (2). Further complex anions of the form $[CpTi(SCH_2CH_2CH_2S)_2]^-$ were shown to be precursors to heterobimetallic complexes and polymers (3) while radical reaction mechanisms were shown to be operative in reactions affording Ti—S bonds (4). More recently, we have shown that related thiolate complexes can mediate the stoichiometric synthesis of organo-sulfur compounds (5). In initiating extensions of this chemistry to oxygen-containing systems, we examined reactions aimed at the syntheses of simple alkoxide derivatives of CpTi(IV). In this paper, we describe the syntheses and structures of dimeric products in which diolates link two $CpTiCl_2$ fragments. In the presence of excess diol, loss of cyclopentadienyl rings is observed, affording dimeric titanium alkoxide complexes. These products have also been structurally characterized and the implications of this chemistry are considered.

Received September 27, 1994.

This paper is dedicated to Professor William A.G. Graham on the occasion of his 65th birthday.

Experimental section

General data

All preparations were done under an atmosphere of dry, O_2-free N_2 employing either Schlenk line techniques or a Vacuum Atmospheres Inert atmosphere glove box equipped with a catalyst column and an atmosphere circulation system. Solvents were reagent grade, distilled from the appropriate drying agents

under N_2 and degassed by the freeze–thaw method at least three times prior to use. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on Bruker AC-300 spectrometers operating at 300 and 75 MHz, respectively. Trace amounts of protonated solvents were used as references and chemical shifts are reported relative to $SiMe_4$. Assignments of the ^1H and ^{13}C NMR resonances and determination of coupling constant values were based on a series of homonuclear decoupling experiments. Combustion analyses were performed by Galbraith Laboratories Inc., Knoxville, Tenn., and Schwarzkopf Laboratories, Woodside, N.Y. $CpTiCl_3$ was purchased from the Strem Chemical Co.

Synthesis of $[Cl_2CpTi]_2(OCH_2CH_2CH_2O)$ 1, $[Cl_2CpTi]_2(OCH_2CMe_2CH_2O)$ 2, and $[Cl_2CpTi]_2(OCHMeCH_2CHMeO)$, 3

These compounds were prepared in similar manners, thus only one preparation is described for each method. (*i*) A mixture of $CpTiCl_3$ (660 mg, 3.0 mmol) and $Me_3SiOCH_2CH_2CH_2OSiMe_3$ (333 mg, 1.50 mmol) in 15 mL THF was stirred for 36 h. The solvent was removed in vacuo, and the residue was washed with 2 × 5 mL pentane and dried. (Yield 90%.) The yellow crystals of **1** were obtained from recrystallization in CH_2Cl_2. (*ii*) Imidazole was added to a stirred 3 mL THF solution of $CpTiCl_3$ (110 mg, 0.5 mmol) and $HOCH_2CH_2CH_2OH$ (45 mg, 0.6 mmol). (34 mg, 0.5 mmol). The reaction mixture was stirred for 1 h, and white solid was formed. The mixture was filtered and solid was washed with 2 × 2 mL THF. The solutions were combined, and solvent was removed in vacuo. After washing with 2 × 2 mL pentane, **1** was obtained in 75% yield. **1**: ^1H NMR ($CDCl_3$, 25°C) δ: 1.97 (q, 2H, $J_{(H-H)}$ = 5.7 Hz), 4.87 (t, 4H, $J_{(H-H)}$ = 5.7 Hz), 6.77 (s, 10H). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25°C) δ: 35.81, 90.19, 120.06. Anal. calcd. for $C_{13}H_{16}Cl_2O_2Ti_2$: C 42.09, H 4.35; found: C 41.89, H 4.13.

2: Reaction time for method (*i*): 72 h. Recrystallized from THF–pentane. Yield: 65%; ^1H NMR ($CDCl_3$, 25°C) δ: 0.94 (s, 6H), 4.55 (s, 4H), 6.76 (s, 10H). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25°C) δ: 21.13, 43.05, 89.37, 120.08. Anal. calcd. for $C_{15}H_{20}Cl_2O_2Ti_2$: C 45.16, H: 5.05; found: C 45.00, H 4.95.

3: Yield: 72%; ^1H NMR ($CDCl_3$, 25°C) δ: 1.40 (d, 6H, $|J_{(H-H)}|$ = 6.6 Hz), 1.70 (d, t, 1H, $|J_{(H-H)}|$ = 7.5 Hz, $|J_{(H-H)}|$ = 5.1 Hz), 1.90 (d, t, 1H, $|J_{(H-H)}|$ = 7.5 Hz, $|J_{(H-H)}|$ = 6.6 Hz), 5.28 (m, 2H), 6.77 (s, 10H). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25°C) δ: 24.19, 48.97, 87.30, 119.68. Anal. calcd. for $C_{15}H_{20}Cl_2O_2Ti_2$: C 45.16, H 5.05; found: C 44.88, H 4.80.

Synthesis of $[TiCl(HOCH_2CH_2CH_2O)(OCH_2CH_2CH_2O)]_2$ 4 and isolation of $[TiCl_2(OCH_2CH_2CH_2O)(THF)]_2$ 5

Imidazole (968 mg, 1 mmol) was added to a stirred 3 mL THF solution of $CpTiCl_3$ (110 mg, 0.5 mmol) and $HOCH_2CH_2CH_2OH$ (45 mg, 0.6 mmol). The reaction was stirred overnight. The compounds **1** and **4** were obtained in 31 and 30% yield (by ^1H NMR). Yellow crystals of **2** were obtained by crystallization from CH_2Cl_2 while subsequent addition of pentane to the mother liquor afforded **4**. Recrystallization of **4** from THF–hexane afforded 4 and a very low yield (less than 1%) of **5**. **4**: ^1H NMR ($CDCl_3$, 25°C) δ: 1.95 (m, 4H), 2.15 (m, 4H), 4.06(m, 2H), 4.17 (m, 2H), 4.24 (m, 2H), 4.32 (m, 4H), 4.45 (m, 4H), 4.60 (br, 2H). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25°C) δ: 31.57, 35.84, 63.90, 69.77, 74.34, 74.93. Anal. calcd. for $C_{12}H_{26}Cl_2O_8Ti_2$: C 31.00, H 5.64; found: C 30.84, H 5.34.

X-ray data collection and reduction

X-ray quality crystals were obtained directly from the preparations as described above. The crystals were manipulated and mounted in capillaries in a glove box, thus maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a Rigaku AFC6 diffractometer equipped with graphite-monochromatized Mo Kα radiation. The initial orientation matrices were obtained from 20 machine-centered reflections selected by an automated peak search routine. These data were used to determine the crystal systems. Automated Laue system check routines around each axis were consistent with the crystal systems reported in Table 1. Ultimately, 25 reflections ($20° < 2\theta < 25°$) were used to obtain the final lattice parameters and the orientation matrices. Machine parameters, crystal data, and data collection parameters are summarized in Table 1. The observed extinctions were consistent with the space groups given in Table 1. The data sets were collected in four shells ($4.5° < 2\theta < 50.0°$) and three standard reflections were recorded every 197 reflections. The intensities of the standards showed no statistically significant change over the duration of the data collection. The data were processed using the TEXSAN crystal solution package operating on a VAX workstation 3520 or employing the TEXSAN package operating on an SGI mainframe computer with remote X-terminals. The reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. Empirical absorption corrections were applied to the data sets based on ψ-scan data.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (6, 7). The Ti atom positions were determined using either the SHELX-86 or MITHRIL direct methods routines. In each case, the remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on F, minimizing the function $\omega(|F_o| - |F_c|)^2$ where the weight ω is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of refinement all Ti, Cl, O, and C atoms were refined anisotropically and, with the exception of C8 in **3**, were assigned anisotropic thermal parameters. Hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded, assuming a C—H bond length of 0.95 Å. In the case of **4** the proton associated with O4 and Cl1 was located in the difference. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. In all cases the hydrogen atom contributions were calculated, but not refined. The following data have been deposited as supplementary material: positional parameters, thermal parameters, selected bond distances and angles, hydrogen atom parameters, and values of 10 F_o and 10 F_c.[2] The final values of R and R_w are given in Table 1. The maximum Δ/σ on any of the parame-

[2] Tables of crystallographic data, positional, thermal, and hydrogen atom parameters, and selected bond distances and angles (19 pages) have been deposited. ters in the final cycles of the refinement are also given in Table 1. The residual electron densities were of no chemical significance. Positional parameters and selected bond distances and angles are reported in Tables 2 and 3.

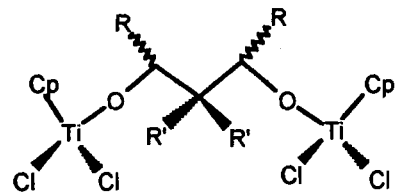
Results

Synthesis

The reaction of two equivalents of $CpTiCl_3$ with $Me_3SiOCH_2CH_2CH_2OSiMe_3$ proceeds slowly over a 3 day period to yield Me_3SiCl and the Ti product **1**. ^1H NMR data for **1** showed resonances at 6.77, 4.87, and 1.97 attributable to the cyclopentadienyl and methylene protons, respectively. $^{13}C\{^1H\}$ NMR data, as well as the integration of the ^1H NMR spectrum, were consistent with the formulation of **1** as $[Cl_2CpTi]_2(OCH_2CH_2CH_2O)$. This formulation was subsequently confirmed by a crystallographic study (*vide infra*). Alternatively, **1** is also formed via the reaction of $CpTiCl_3$ with the diol in the presence of imidazole. Separation from the imidazoleHCl is readily achieved via filtration and extraction of **1** into a small volume of THF, while subsequent recrystallization from CH_2Cl_2 afforded **1** in a crystalline form. Employing analogous procedures and the appropriate diols or disilyl ethers, the compounds $[Cl_2CpTi]_2(OCH_2CMe_2CH_2O)$ **2** and $[Cl_2CpTi]_2$(*rac*-$OCHMeCH_2CHMeO$) **3** were also prepared.



1, R = R' = H; 2, R = H, R' = Me; 3, R = Me, R' = H

In the case of **3** this formulation was also confirmed crystallographically (*vide infra*). In a recent report we demonstrated that substitution reactions involving $CpTiCl_3$, thiol, and imidazole proceed through a radical mechanism involving a Ti(III)–imidazole complex intermediate (4). The formation of **1–3** from the diol–imidazole reactions may also proceed through this intermediate. Similar dimeric products are known to be formed from Ti(III) precursors (eq. [1]) as described by Caulton and co-workers (8, 9) as well as Coutts et al. (10).

[1] $2/n\,[CpTiCl_2]_n + 2R_2CO \longrightarrow CpTiCl_2(OCR_2CR_2O)TiCpCl_2$

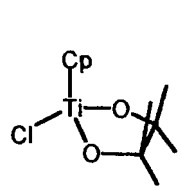
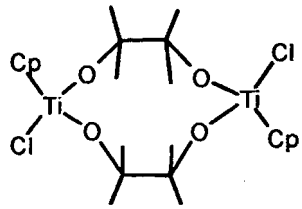
Reactions performed with a 1:1 ratio of Ti and propanediol were expected to yield either monometallic chelate or macrocyclic dimeric complexes analogous to the pinacolate complexes, $CpTiCl(OCMe_2CMe_2O)$ **7** and $[CpTiCl(OCMe_2CMe_2O)]_2$ **8**, reported by Caulton and co-workers (11). Certainly, in the case of the related reactions of diols with Cp_2ZrCl_2 in the presence of base, dimeric macrocyclic products are derived (1). In the present case, monitoring of the reactions by ^1H NMR spectroscopy revealed resonances attributable to **1** and to a second CpTi derivative that exhibited a resonance at 6.24 ppm, suggesting the formation of macrocyclic species similar to **7**. However, this latter species could not be isolated as it appears to be unstable, degrading to several products. ^1H NMR data suggested the liberation of free CpH. This was confirmed via GC–MS of the reaction mixture.



7



8

Upon removal of the solvent and recrystallization of the residue from CH_2Cl_2–pentane, the product **4** was isolated in crystalline form. ^1H NMR data and subsequent X-ray diffraction data were consistent with the formulation of **4** as $[TiCl(HOCH_2CH_2CH_2O)(OCH_2CH_2CH_2O)]_2$ (*vide infra*). When compound **4** was recrystallized from THF–hexane, a small amount (less than 1%) of a second species was also obtained. The isolation of only a few crystals of **5** precluded characterization by spectroscopic methods, although X-ray methods permitted the identification of **5** as $[TiCl_2(OCH_2CH_2CH_2O)(THF)]_2$ (*vide infra*).

Structural studies

Crystallographic studies of **1** and **3** confirmed both the formulation and the similarity of the structures (Figs. 1, 2). In both cases, crystallographically imposed twofold symmetry relates the two halves of the molecule and dictates an orientation in which the cyclopentadienyl rings on symmetry-related Ti atoms are approximately orthogonal. In the case of **3**, this imposed symmetry also dictates identical configurations for the two chiral carbons of the diolate ligand. As the space group is centrosymmetric, the X-ray data confirm the co-crystallization of the *R,R* and *S,S* diastereomers. In addition, the methyl groups occupy equatorial positions relative to the six-membered chelate ring. This orientation minimizes steric interactions between the cyclopentadienyl ring and the methyl group. The Ti—O distances in **1** and **3** are 1.733(6) and 1.750(4) Å, respectively (Table 3). While the latter distance is identical to that found in **6**, these are significantly shorter than the Ti—O distance seen in $Cp_2TiCl(OEt)$ (1.855(2) Å) (8). This is consistent with the greater Lewis acidity of the Ti center upon replacement of a cyclopentadienyl ligand with chloride. The slightly longer Ti—O bond length observed in **3** compared to that in **1** is consistent with the greater steric demands of the 2,4-pentanediolate ligand. The Ti-O-C angles of 158.7(6)° and 158.1(4)° in **1** and **3**, respectively, compare with an angle

Fig. 1. ORTEP drawing of **1**, 30% thermal ellipsoids are shown, hydrogen atoms are omitted for clarity.

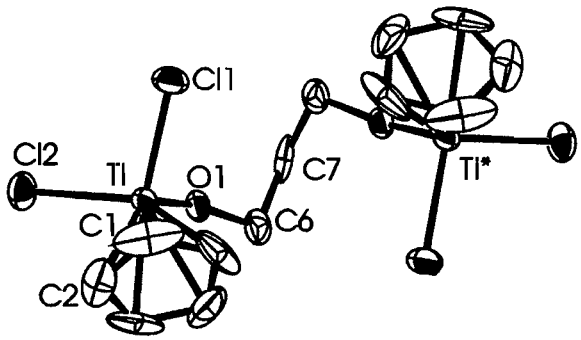

Fig. 2. ORTEP drawing of **3**, 30% thermal ellipsoids are shown, hydrogen atoms are omitted for clarity.

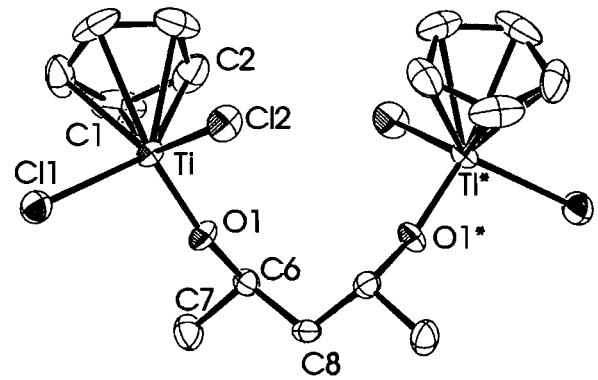

of 166.2(2)° found in **6**. The short Ti—O distances and the obtuse Ti-O-C angles observed in Ti-alkoxide derivatives have been rationalized in term of strong Ti—O π-bonding. Ti—Cl distances range from 2.267(3) to 2.276(2) Å in **1** and **3**, similar to those found in other CpTi(IV)-chloride derivatives.

The structure of **4** was confirmed by an X-ray crystallographic study (Fig. 3). These data show that the compound is a dimeric species in which alkoxide oxygen atoms from each of two diolate ligands bridge the metal centers. The nonbridging end of each diolate ligand occupies the position *trans* to a bridging alkoxide oxygen atom. One more diol ligand chelates to each of the Ti centers. One of the oxygen atoms of these chelates is protonated yielding propanol-olate ligands. The alkoxide ends of these ligands also adopt a position *trans* to a bridging alkoxide oxygen while the alcoholic end occupies an axial position *trans* to a chloride atom. The Ti centers are thus best described as pseudo-octahedral, sharing the edge containing the bridging oxygen atoms. Bite angles for the diol chelates are typical for six-membered rings (89.4(2)°, 83.7(2)°). The Ti—O distances clearly reflect three different oxygen coordination modes. As expected, the bridging alkoxide T—O bond lengths are significantly longer (2.014(3), 2.037(3) Å) than the terminal Ti—O distances (1.795(4) Å, 1.798(4) Å). These terminal and bridging Ti-O distances certainly fall in the range of those seen in related Ti-alkoxide derivatives, among them $Ti_2(DIPT)_3(ONBn_2)_2$, $Ti_3(DIPT)_3(OiPr)_2Br_4$, and $[Ti(DIPT)(OiPr)Br]_4$ (12). The coordinated alcohol moiety results in a Ti—O4 distance that is longer again (2.169(4) Å), consistent with the presence of the proton. The Ti—Cl distance of 2.384(2) Å in **4** is longer than the Ti—Cl distances seen in either **1** or **3**. As the Cl in **4** is axial to the O_4 equatorial plane, π-donation from oxygen to Ti reduces similar π-donation from Cl and thus accounts for the longer Ti—Cl bond. In addition, lengthening of the Ti—Cl bond may be attributed to hydrogen bonding between the alcoholic proton and the Cl (H...Cl 2.06 Å).

The crystallographic characterization of **5** (Fig. 4) revealed a structure similar to that seen for **4**. Two Ti centers are bridged by two alkoxide oxygen atoms while the second oxygen of these diolate ligands binds to the respective Ti atoms in positions *trans* to the bridging oxygens. The pseudo-octahedral coordination spheres of the Ti centers are completed by two *cis* chloride atoms and a molecule of THF. The terminal Ti—O distance in **5** (1.759(5) Å) is slightly shorter than that

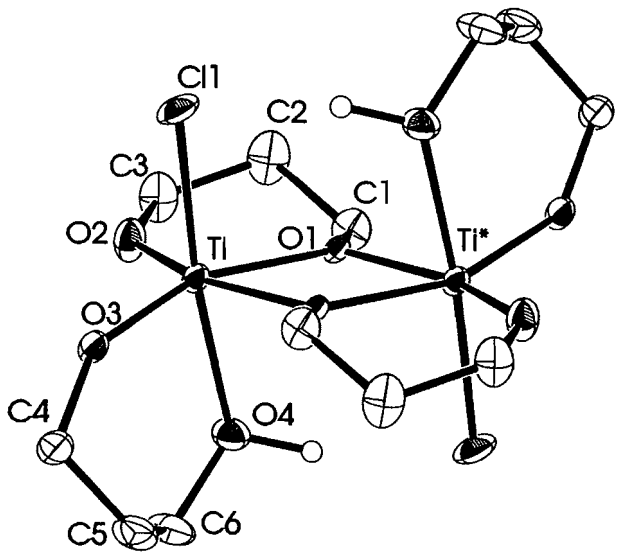
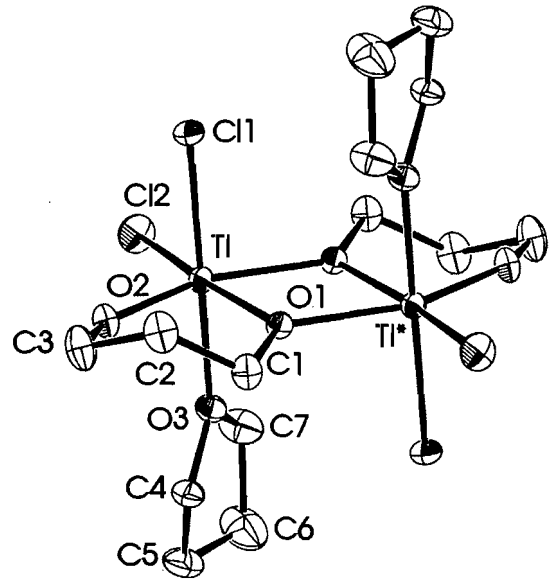
Fig. 3. ORTEP drawing of **4**, 30% thermal ellipsoids are shown, hydrogen atoms are omitted for clarity.



seen in **4** due to the presence of additional oxygen donors in **4** that diminish the Lewis acidity of the Ti center. This is also reflected in the shorter Ti—Cl distances in **5** (2.325(2), 2.330(2) Å). The Ti—O distance for the coordinated THF is 2.133(5) Å, which is slightly shorter than the Ti—O distance seen for the coordinated alcohol of **4**. This is as expected based on basicity trends.

The Ti_2O_2 cores of both **4** and **5** are planar. In the case of **4**, the Ti—O distances are similar, while in **5** the bridging Ti—O distances of 1.990(5) and 2.066(5) Å indicate a distinct asymmetry in the bridge. The Ti...Ti distances of 3.302(2) and 3.275(3) Å in **4** and **5**, respectively, compare with the Ti..Ti distance of 3.348(3) Å found in $[Ti(OiPr)_2(PhCH_2NHCO_2$-

Fig. 4. ORTEP drawing of **5**, 30% thermal ellipsoids are shown, hydrogen atoms are omitted for clarity.



$CHCHO(CONHCH_2Ph)]_2$ (13). The Ti-O-Ti′ and O-Ti-O′ angles in **4** (109.2(2)°, 70.8(2)°) are similar to those seen in **5** (107.7(2)°, 72.3(2)°).These perturbations in the core angles are consistent with the fluctuations in the bridging Ti—O distances and are attributed to the differing acidities of the Ti centers.

Discussion

Caulton and co-workers (8, 9, 11) have studied the formation of **6** from the reaction of **7** and $CpTiCl_3$ and suggest that destabilizing steric interactions between the methyl substituents of the pinacolate and the cyclopentadienyl ring are the driving force for the reaction. Similarly, we suggest that a mononuclear diolate species **9** (Scheme 1) is formed initially in the present reactions and that ligand redistribution reactions in the presence of $CpTiCl_3$ yield the products **1–3**. Such redistributions may be favored by the stabilizing influence of Ti–O p-bonding. Such interactions are maximized via the formation of the bimetallic products since chelation to a single Ti atom restricts the Ti-O-C angle and thus the degree of π-donation. We further suggest that coordination of excess diol affords the intermediate **10** (Scheme 1). The π-donor ability of the oxygen atoms competes with the cyclopentadienyl ring for metal *d*-orbitals and thus facilitates the loss of CpH and the formation of **4**. Although no direct evidence has been obtained for the proposed intermediates, the known species **7** and the established ability of Ti three-legged piano stool complexes to bind additional donor ligands are consistent with these propositions (2).

Ligand redistribution reactions also account for the formation of **5** upon recrystallization of **4** from THF. However, the isolation of only a very few crystals of **5** suggests an equilibrium between **4**, **5**, and other as yet uncharacterized Ti species, in which **4** is the dominant species in solution. A fuller understanding of this solution behaviour and of titanium alkoxide complexes in general requires further study.

Abstract: Solid state ternary and quaternary metal nitrides containing a transition metal and one or two very electropositive metals such as alkali and (or) alkaline earth metals exhibit a number of structures containing low-coordinate transition metals in the transition metal – nitrogen subnetwork. Transition metal – nitrogen double and even triple bonds are found in these structures involving $d\pi \rightarrow p\pi$ bonding from a filled transition metal *d* orbital to an otherwise empty nitrogen *p* orbital. Such multiply bonded nitrogen atoms function as strong field ligands in contrast to amido ligands such as $(Me_3Si)_2N^-$, which generally function as weak field ligands in transition metal chemistry. The transition metal environment in these ternary nitrides can be modelled by "banana bonds" from the polyhedron using the atomic orbitals required for both the σ- and π-bonding to the nitride ligands, e.g., the trigonal prism for the trigonal planar derivatives $M^{III}N_3^{6-}$ (M = V, Cr, Mn, Fe) with three M=N double bonds as well as $Fe^{II}N_2^{4-}$ in $Li_4Fe^{II}N_2$ with two Fe≡N triple bonds and the planar square for the discrete linear $Co^{I}N_2^{5-}$ in $LiSr_2CoN_2$. Reasonable electron counts are also obtained for the anionic metal–nitrogen networks in Ca_2FeN_2, $Sr_2LiFe_2N_3$, $Ba_2LiFe_2N_3$, Li_3FeN_2, CaNiN, $Li_3Sr_3Ni_4N_4$, BaNiN, and $Ba_8Ni_6N_7$.

Key words: chemical bonding, topology, nitrides, transition metals.

Résumé : Les nitrures métalliques ternaires et quaternaires à l'état solide contenant un métal de transition et un ou deux métaux très électropositifs, comme les métaux alcalins et (ou) alcalino-terreux, présentent un certain nombre de structures comportant des métaux de transition de basse coordination dans le sous-réseau azote – métal de transition. On a trouvé des liaisons doubles, et même triples, entre l'azote et le métal de transition dans ces structures impliquant une liaison $d\pi \rightarrow p\pi$ formée à partir d'une orbitale *d* remplie du métal de transition et une orbitale *p* par ailleurs vide de l'azote. De tels atomes d'azote à liaisons multiples agissent comme des coordinats à champ fort par opposition aux coordinats amido, tel que $(Me_3Si)_2N^-$, qui agissent généralement comme des coordinats de champ faible dans la chimie des métaux de transition. On peut faire un modèle de l'environnement du métal de transition de ces nitrures ternaires à l'aide de «liaisons bananes» à partir du polyèdre, en utilisant les orbitales atomiques requises pour les liaisons à la fois σ et π des coordinats nitrures, c'est-à-dire le prisme trigonal des dérivés plans trigonaux $M^{III}N_3^{6-}$ (M = V, Cr, Mn et Fe) avec des trois liaisons M=N ainsi que $Fe^{II}N_2^{4-}$ du $Li_4Fe^{II}N_2$ comportant deux Fe≡N et le plan carré du $Co^{I}N_2^{5-}$ du $LiSr_2CoN_2$. On peut aussi faire un compte raisonnable des électrons des réseaux anioniques métal–azote du Ca_2FeN_2, $Sr_2LiFe_2N_3$, $Ba_2LiFe_2N_3$, Li_3FeN_2, CaNiN, $Li_3Sr_3Ni_4N_4$, BaNiN et $Ba_8Ni_6N_7$.

Mots clés : liaisons chimiques, topologie, nitrures, métaux de transition.

Introduction

A significant development in solid state inorganic chemistry during the past decade has been the discovery of a number of ternary and quaternary transition metal nitrides containing a low-coordinate transition metal and one or two very electropositive metals such as alkali and (or) alkaline earth metals (1). The nitrogen atoms in these metal nitrides function as relatively strong field π-acceptor terminal or bridging ligands leading to apparent multiple transition metal – nitrogen bonding as well as to low transition metal coordination numbers and spin states in the transition metal – nitrogen subnetwork. Interesting structures in recently characterized ternary transition metal nitrides include the discrete trigonal planar MN_3^{6-} ions (M = V, Cr, Mn, Fe) (2) as well as infinite $[NiN_{2/2}^{2-}]_\infty$ chains in AeNiN (Ae = Ca, Ba) (3).

In previous papers the author has discussed the chemical bonding topology in transition metal polyphosphides (4),

superconducting transition metal borides and silicides (5), and superconducting alloys (5). This paper extends these methods to solid state ternary and quaternary transition metal nitrides with particular emphasis on compounds exhibiting unusual structural features. Hughbanks and co-workers have also studied some of the ternary transition metal nitrides using various computational methods including both extended Hückel (2) and *ab initio* (3) methods. The topology-based ideas outlined in this paper serve to relate the structures of the solid state ternary transition metal nitrides to molecular species exhibiting analogous metal electronic configurations and coordination environments.

Background

The ternary and quaternary transition metal nitrides of interest in this work (Table 1) contain an electropositive metal (most commonly an alkaline earth metal), the transition metal, and nitrogen. Complete ionization of the electropositive metal to the typical stable cation, e.g., Ae^{2+} in the case of the bivalent alkaline earth metals (Ae), leads to an anionic transition metal – nitrogen subnetwork, which can consist of either discrete ions, such as MN_3^{6-} in Ae_3MN_3, or infinite polymers, such as the $[NiN_{2/2}^{2-}]_\infty$ chains in AeNiN. The environments of the transition metal and nitrogen atoms in these anionic transition metal – nitrogen subnetworks can now be considered.

A. The metal environment

The atomic orbitals of the transition metals in the metal nitrides are used not only for the usual σ-bonding but also for π-bonding to the nitride nitrogen atoms as noted above. However, the π-bonding in metal nitrides can alternatively be represented by equivalent bent σ-bonds or "banana" bonds (Fig. 1) using hybrid metal orbitals from the same set of metal atomic orbitals required for the total σ + π bonding similar to methods used by Messmer (6) for other transition metal compounds. These methods, which are based on generalized valence bond theory, have been supported by computational studies using the generalized valence bond (GVB) method (7–11). Use of the "bent bond" model for the transition metal – nitrogen bonds in the metal nitrides allows the strong π-bonding in metal nitrides to be included in the transition metal coordination polyhedra without the explicit need to separate σ- and π-bonding. This is similar to considering the boron atoms in diborane as using four sp^3 hybrids for the bonds to hydrogen in the bent bond equivalent of the conventional σ+π C=C double bond of ethylene (Fig. 1) (12).

The bent bond model is particularly informative in the case of the trigonal planar derivatives MN_3^{6-} (M = V, Cr, Mn, Fe), which become trigonal prisms if bent bonding is used to describe both the σ- and π-bonding (Fig. 2). The trigonal planar MN_3^{6-} can be considered to use $sp^2(x,y)$ hybridization with no node through the N_3 plane for the σ-bonding and $pd^2(z,xz,yz)$ hybridization for the π-bonding. However, the sum of these six atomic orbitals, namely $sp^3d^2(xz,yz)$, is exactly the set of six atomic orbitals required for trigonal prismatic six-coordination rather than the more familiar set of six atomic orbitals, namely $sp^3d^2(z^2, x^2 - y^2)$, required for octahedral six-coordination. Treatment of MN_3^{6-} as a trigonal prismatic complex in this manner allows the simple angular overlap model (13, 14) to be used to estimate the *d* orbital splittings for such purposes as predicting magnetic properties and Jahn–Teller distortions (2). Similarly, the bent bond model of linear $Co^{I}N_2^{5-}$ considers it as a square planar complex (Fig. 2) with the d^8 metal electronic configuration so common in square planar complexes of transition metals such as M^{I} (M = Co, Rh, Ir), Ni^{II} (M = Ni, Pd, Pt), Au^{III}, etc. The linear $Co^{I}N_2^{5-}$ can be considered to use $sp(x)$ hybridization for the σ-bonding and $pd(y, x^2 - y^2)$ hybridization for the π-bonding.

The electron counting of the central transition metal atom in ternary metal nitrides is of interest. The accessible *spd* valence orbital manifold of most transition metals consists of nine orbitals (sp^3d^5) and has spherical (isotropic) geometry extending equally in all three dimensions, where the geometry of an orbital manifold relates to contours of $\Sigma\psi^2$ over all orbitals in the manifold. Filling this accessible spherical *spd* manifold with electrons from either the central metal atom or its surrounding ligands results in the familiar 18-electron configuration of the next rare gas (15). This is the favored electron count for a transition metal bonding in all three dimensions, such as metals with tetrahedral, octahedral, or trigonal prismatic coordination.

A specific feature of the chemical bonding in some systems containing the late transition and early post-transition metals observed by Nyholm (16) as early as 1961 is the shifting of one or two of the outer *p* orbitals to such high energies that they no longer participate in the chemical bonding and the accessible *spd* valence orbital manifold is no longer spherical (isotropic). If one *p* orbital is so shifted to become antibonding, then the accessible *spd* orbital manifold contains only eight orbitals (sp^2d^5) and has the geometry of a torus or doughnut (Fig. 3). The "missing" *p* orbital is responsible for the hole in the doughnut. This toroidal sp^2d^5 manifold can bond only in the two dimensions of the plane of the ring of the torus. Filling this sp^2d^5 manifold of eight orbitals with electrons leads to the 16-electron configuration found in square planar complexes of the d^8 transition metals such as Co(I), Rh(I), Ir(I), Ni(II), Pd(II), Pt(II), and Au(III). The locations of the four ligands in these square planar complexes can be considered to be points on the surface of the torus corresponding to the sp^2d^5 manifold. The toroidal sp^2d^5 manifold can also lead to trigonal planar and pentagonal planar coordination for three- and five-coordinate complexes, respectively. The *x*, *y*, and *z* axes for a toroidal sp^2d^5 manifold are conventionally chosen so that the missing *p* orbital is the p_z orbital.

In some structures containing the late transition and post-transition metals, two of the outer *p* orbitals are raised to antibonding energy levels. This leaves only one *p* orbital in the accessible *spd* orbital manifold, which now contains seven orbitals (spd^5) and has cylindrical geometry extending in one axial dimension much further than in the remaining two dimensions (Fig. 3). Filling this seven-orbital spd^5 manifold with electrons leads to the 14-electron configuration found in two-coordinate linear complexes of d^{10} metals such as Ni(0), Pt(0), Cu(I), Ag(I), Au(I), Hg(II), and Tl(III).

B. The nitrogen environment

Examples of tetrahedral sp^3-hybridized, planar sp^2-hybridized, or linear *sp*-hybridized nitrogen atoms are found in the ternary transition metal nitrides (Fig. 4). A tetrahedral sp^3-hybridized nitrogen uses all of its valence orbitals for σ-bonding and thus is incapable of forming metal–nitrogen multiple

Fig. 1. Equivalent σ + π and "bent" bond models for the multiple metal–nitrogen bonding in metal nitrides and their comparison with standard models for ethylene and diborane. For convenience the σ-bonds drawn in Figs. 1, 2, and 5 include only those parts of the atomic orbitals in which the signs of the wave function are the same, rather than the complete orbital.

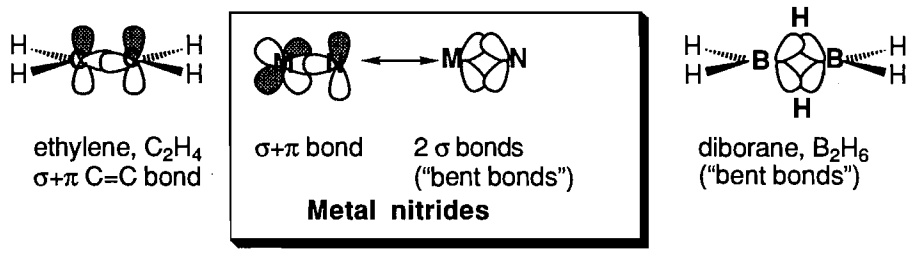

Fig. 2. The relationship of trigonal prismatic "bent bonds" to the metal–nitrogen multiple bonding in $M^{III}N_3^{3-}$ (M = V, Cr, Mn, Fe) and square planar "bent bonds" to the metal–nitrogen multiple bonding in $Co^{I}N_2^{5-}$.

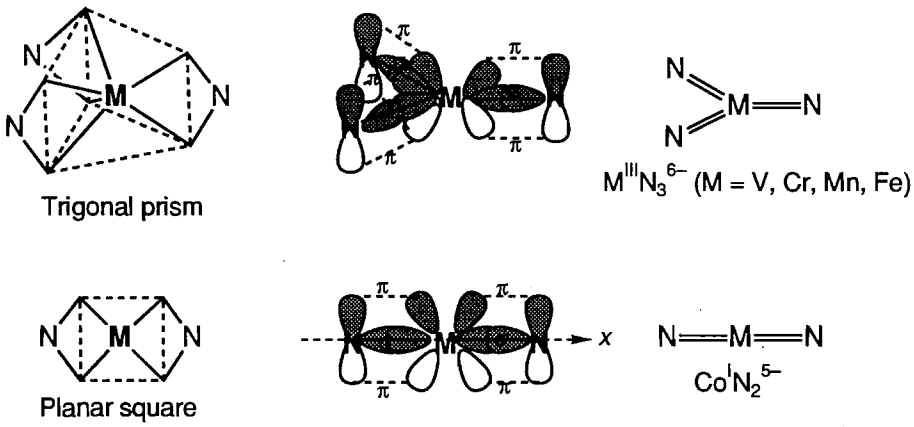


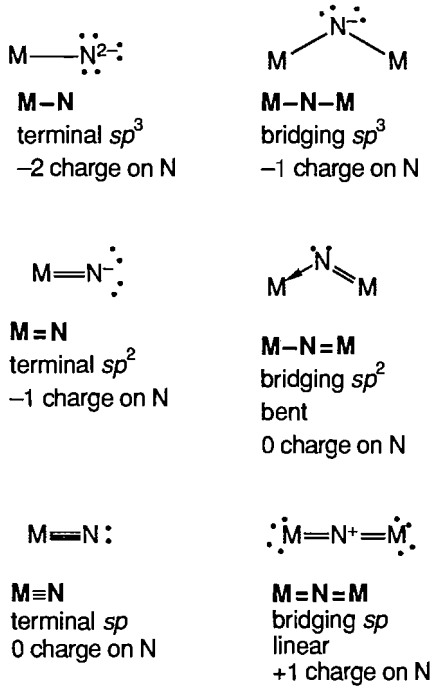
bonds. For this reason tetrahedral sp^3-hybridized nitrogen atoms are not generally favorable in low-coordinate transition metal nitrides in which metal–nitrogen multiple bonding plays a major role. In addition, a neutral terminal sp^3 nitrogen atom singly bonded to a transition metal has three lone pairs and a relatively high –2 formal charge (Fig. 4), also an unfavorable feature, so that this type of sp^3 nitrogen atom is not found in any of the metal nitrides discussed in this paper. A bridging tetrahedral sp^3 nitrogen atom forming single bonds with two transition metals retains two lone pairs and has a –1 formal

Fig. 3. Toroidal sp^2d^5 and cylindrical spd^5 manifolds showing square planar coordination for the toroidal manifold.

Toroidal sp^2d^5 manifold (Square Planar)

Cylindrical spd^5 manifold (Linear)

Fig. 4. The types of nitrogen atoms in the transition metal–nitrogen subnetworks of metal nitrides. Note that all of these types of nitrogen atoms have the favored electron octet.



charge (Fig. 4). The polymeric anion $[Fe^{III}N_{4/2}^{3-}]_\infty$ found in Li_3FeN_2 is the only species discussed in this paper that has a bridging sp^3 nitrogen atom; this is also the only species discussed in this paper in which the transition metal is bonded to *four* nitrogen atoms rather than only two or three nitrogen atoms. A *neutral* bridging sp^3 nitrogen atom is a formal donor of zero electrons to one of the metals and a single electron donor to the other metal.

The nitrogen atoms in the ternary transition metal nitrides in which the transition metal is bonded to only two or three nitrogen atoms may either be considered as planar sp^2-hybridized or linear *sp*-hybridized, with the former situation being more common. The empty *p* orbital in an sp^2-hybridized nitrogen participates in $d\pi \rightarrow p\pi$ back bonding with a transition metal *d* orbital of suitable symmetry so that such a nitrogen atom can complete its octet by forming a transition metal M=N double bond (Fig. 5). A terminal sp^2 nitrogen atom forming one such double bond ($\sigma + \pi$) to a transition metal has two lone pairs and a formal –1 charge (Fig. 4). The σ component of the double bond formed by such a terminal sp^2 nitrogen atom considered formally as a neutral ligand makes it a net one-electron

Fig. 5. The atomic orbitals forming the σ-bonding and π-bonding (i.e., $d\pi \rightarrow p\pi$) components of the transition metal–nitrogen multiple bond in metal nitrides and related compounds.

donor to the transition metal. A bridging (μ_2) sp^2 nitrogen atom forms a double bond ($\sigma + \pi$) with one of the transition metals and a single bond (σ only) with the other transition metal leaving only one lone pair and leading to formal neutrality (Fig. 4). A *neutral* μ_2-bridging nitrogen atom thus acts as a formal one-electron donor to the transition metal to which it is doubly bonded and a formal two-electron donor to the other transition metal to which it is formally only singly bonded. Such planar nitrogen atoms (sp^2 hybridized) can be considered as halogen atoms for which the favored octet is attained by accepting two electrons from a metal *d* orbital of π symmetry into the empty *p* orbital perpendicular to the plane. The $d\pi$–$p\pi$ bond does not affect the electron count because both electrons originate from the metal.

A linear nitrogen atom (*sp* hybridized) with two empty orthogonal *p* orbitals can also be either terminal or bridging (Fig. 4). Two electron pairs from filled transition metal *d* orbitals of suitable symmetry overlap with these empty nitrogen *p* orbitals to form the π components of metal – nitrogen multiple bonds. Terminal *sp*-hybridized nitrogen atoms form M≡N triple bonds whereas bridging (μ_2) *sp*-hybridized nitrogen atoms form M=N double bonds in both directions leading to an M=N=M structural unit similar to CO_2 or allene ($H_2C{=}C{=}CH_2$). Note that the formal charge on an *sp*-hybridized nitrogen atom is +1 higher than the formal charge on a similar type of sp^2-hybridized nitrogen atom. For this reason *sp* nitrogen atoms are likely to form weaker, and thus longer, bonds to transition metals than do sp^2 nitrogen atoms. This may explain why the Fe≡N distance in the linear ion FeN_2^{4-}, which is best formulated with Fe≡N triple bonds, is longer (1.86 Å) than the Co=N distance (1.81 Å) in the likewise linear ion CoN_2^{5-}, which is best formulated with Co=N double bonds. Note also that for the purpose of calculating the metal electron configuration in metal nitride structures a *neutral* doubly bonded terminal nitrogen atom serves as a one-electron donor and a *neutral* triply bonded terminal nitrogen atom serves as a three-electron donor.

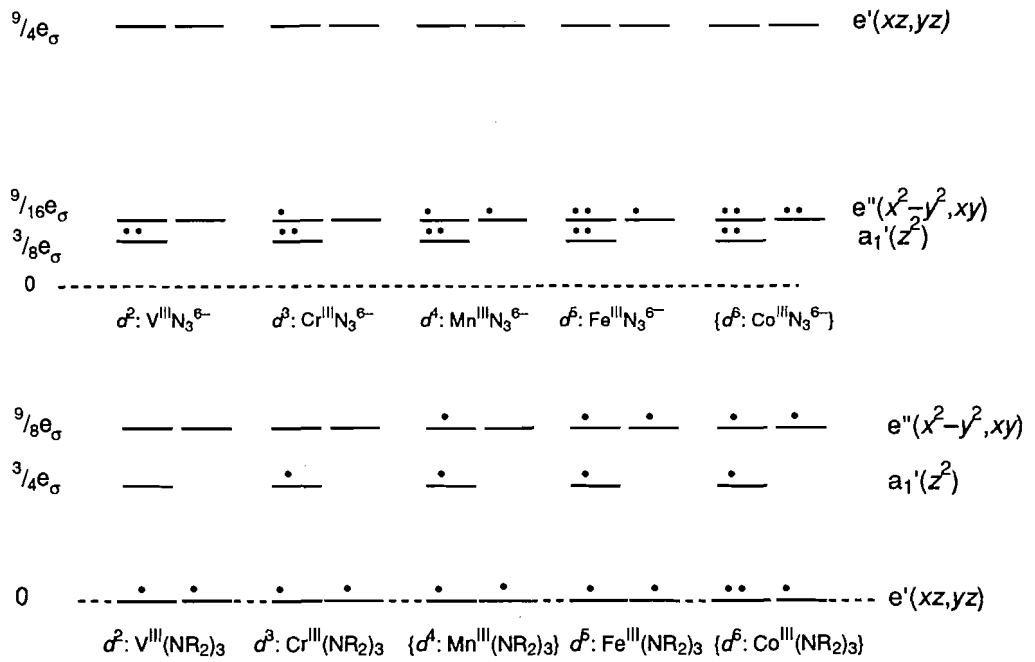
Ternary metal nitrides containing isolated mononuclear anions

A. Tetrahedral MN_4^{n-} derivatives

A variety of ternary metal nitrides with isolated tetrahedral MN_4^{n-} anions are known. These include $Li_7M^VN_4$ (M = V (17), Nb (17), Ta (17), Mn (18)), $Li_6M^{VI}N_4$ (M = Mo, W) (19), and $Ba_3M^{VI}N_4$ (M = Mo, W) (20) that contain the tetrahedral $M^VN_4^{7-}$ and $M^{VI}N_4^{6-}$ anions, which are isoelectronic and isostructural with the corresponding well-known tetraoxometallates $M^VO_4^{3-}$ and $M^{VI}O_4^{2-}$. These tetrahedral tetranitridometallates present no new interesting questions of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

Fig. 6. The *d*-orbital splittings and electron occupancies for the MN_3^{6-} derivatives.



structure and bonding not found in the corresponding tetraoxometallates and thus will not be discussed further in this paper.

B. Trigonal planar MN_3^{6-} derivatives

The trigonal planar anions $M^{III}N_3^{6-}$ (M = V, Cr, Mn, Fe) are found in the compounds Ca_3VN_3 (21), Ca_3CrN_3 (22), Ca_3MnN_3 (23), Sr_3MnN_3 (24), Ba_3MnN_3 (24), Ba_3FeN_3 (25), and Ca_6FeN_5 (= $[NCa_3^{3+}]_2[FeN_3]^{6-}$) (26). The metal–nitrogen π-bonding in these anions is so strong that they can be treated as trigonal prismatic complexes as discussed above (see Fig. 2). Figure 6 shows the *d*-orbital splittings and electron occupancies in these complexes as obtained using the simple angular overlap model with the bond angles 45° above and below the σ_h symmetry plane of the trigonal prism. The general pattern of *d*-orbital splittings is the same as those arising from the extended Hückel calculations of Yee and Hughbanks (2) except for the reversal of the e′ and e″ *d* orbitals.

The orbital splittings and electron occupancies indicated in Fig. 6 suggest the following points:

VN_3^{6-}: This is predicted to be diamagnetic in accord with experimental observations on Ca_3VN_3 (21).

CrN_3^{6-}: Trigonal prismatic Cr(III) has only one unpaired electron in contrast to three unpaired electrons for the much more common octahedral Cr(III). In this connection the magnetic moment of Ca_3CrN_3 was found (22) to be 1.86 μ_B, which is close to the spin only value of $\sqrt{3}$ = 1.73 μ_B for one unpaired electron. In addition, the single electron in the e″ orbital suggests the possibility of a Jahn–Teller distortion from D_{3h} to C_{2v} symmetry (2) consistent with the observed (14) N—Cr—N bond angles in Ca_3CrN_3 of 112.6°, 112.6°, and 134.9° rather than the ideal 120° for D_{3h} symmetry.

MnN_3^{6-}: The half-filled e″ level suggests the absence of Jahn–Teller distortion and two unpaired electrons in MnN_3^{6-}. Ideal D_{3h} symmetry with N—Mn—N angles of 120° is found (24) in Sr_3MnN_3 and Ba_3MnN_3 but not in Ca_3MnN_3 with N—Mn—N angles (23) of 114.7°, 114.7°, and 130.6°.

FeN_3^{6-}: The single hole in the e″ level suggests the possibility of a Jahn–Teller distortion, which is not found experimentally in either Ba_3FeN_3 (25) or $[Ca_3N]_2[FeN_3]$ (26). Information on the magnetic properties of any of the FeN_3^{6-} derivatives does not seem to be available.

CoN_3^{6-}: Ternary metal nitrides containing the CoN_3^{6-} ion have not yet been prepared. The CoN_3^{6-} ion is predicted to be diamagnetic with ideal D_{3h} symmetry and should be favored because of the closed-shell d^6 configuration of the cobalt leading to the favored 18-electron rare gas configuration by the following electron-counting scheme:

Neutral Co atom:	9 electrons
3 Neutral nitrogen ligands: 3 × 1 =	3 electrons
–6 Charge on anion:	6 electrons
Total electronic configuration of cobalt:	*18 electrons*

However, the synthesis of CoN_3^{6-} derivatives may be complicated by the reducing conditions of the high-temperature reactions used to prepare ternary metal nitrides so that Co(I) derivatives, such as $LiSr_2CoN_2$, are formed instead of Co(III) derivatives.

These properties of the trinitridometallates, $M^{III}N_3^{6-}$, relate to the nitride anion, N^{3-}, functioning as a strong field ligand. Exhaustive silylation of the $M^{III}N_3^{6-}$ anions with Me_3SiCl can *formally* lead to the known trigonal planar $[(Me_3Si)_2N]_3M^{III}$ according to the following equation[2]:

[2] In practice, the $[(Me_3Si)_2N]_3M$ derivatives are not prepared by this method but instead by reactions of $(Me_3Si)_2NM$ (M = Li, Na) with transition metal halides.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

Table 2. Metal–nitrogen bond lengths in analogous $[(Me_3Si)_2N]_3M^{III}$ and MN_3^{6-} derivatives

	M = V	M = Cr	M = Fe
M—N length in $[(Me_3Si)_2N]_3M^{III}$, Å	1.910(5)	1.903(6)	1.917(4)
M=N length in $M^{III}N_3^{6-}$, Å	1.81–1.83	1.766(7)	1.770(15)

[1] $MN_3^{6-} + 6\,Me_3SiCl \rightarrow [(Me_3Si)_2N]_3M + 6\,Cl^-$

The $(Me_3Si)_2N^-$ ligands in these $[(Me_3Si)_2N]_3M^{III}$ derivatives (27) function as weak-field ligands forming essentially M—N single bonds in contrast to the N^{3-} ligands in MN_3^{6-} derivatives, which form essentially M=N double bonds. This difference in bond order can be demonstrated by consistently longer metal–nitrogen bond lengths in $[(Me_3Si)_2N]_3M^{III}$ than in the corresponding $M^{III}N_3^{6-}$ derivative (Table 2). The low-field nature of the $(Me_3Si)_2N^-$ ligand leading to high spin complexes is supported by the observed magnetic moments (27) of 3.72 and 5.94 μ_B for the Cr(III) and Fe(III) derivatives, respectively, corresponding to three and five unpaired electrons, respectively.

C. Linear MN_2^{n-} derivatives

1. CoN_2^{5-}

The cobalt–nitrogen bonds in the linear $Co^IN_2^{5-}$ ion (28) in $LiSr_2CoN_2$ can be regarded as Co=N double bonds. Using the bent bond model, the cobalt atom can either be considered as tetrahedral, using sp^3 hybrid orbitals if the two Co—N π-bonds are perpendicular as in allene, or square planar, using $sp^2d(x^2-y^2)$ hybrid orbitals if the two Co—N π-bonds are collinear. The cobalt atom has the typical 16- electron configuration for a square planar d^8 atom determined as follows:

Neutral cobalt atom:	9 electrons
2 Nitrogen ligands: 2 × 1 =	2 electrons
−5 Charge on ion:	5 electrons
Total cobalt valence electrons:	*16 electrons*

This electron counting suggests that the π-bonds from the central cobalt atom to the two nitrogen atoms in $Co^IN_2^{5-}$ are collinear rather than perpendicular, in accord with square planar cobalt hybridization.

(2) FeN_2^{4-}

The linear $Fe^{II}N_2^{4-}$ ion in Li_4FeN_2 (29) and Sr_2FeN_2 (30) has two fewer electrons than the linear $Co^IN_2^{5-}$ ion in $LiSr_2CoN_2$ discussed above. This difference in apparent electron count can be rationalized by considering the iron–nitrogen bonds in $Fe^{II}N_2^{4-}$ to be Fe≡N triple bonds. A *neutral* triply bonded nitrogen atom, (Fig. 4) can be considered to be a three-electron donor in contrast to a neutral doubly bonded nitrogen atom, which, as noted above, functions as a one-electron donor. Using the bent bond model (Fig. 7) the iron coordination can be considered to be trigonal prismatic. The iron atom in FeN_2^{4-} then has the favored 18-electron noble gas configuration by the following electron-counting scheme:

Neutral iron atom:	8 electrons
2 Neutral triply bonded N atoms: 2 × 3 =	6 electrons
−4 Charge on anion:	4 electrons
Total iron valence electrons:	*18 electrons*

The iron–nitrogen triple bonds in FeN_2^{4-} have the same components ($\sigma + 2\perp\pi$) and use the same metal orbitals as the iron–ring triple bonds in ferrocene.

Polynuclear nitridoferrates

A number of polynuclear nitridoferrates (for a brief summary of the types of nitridoferrates see ref. 31) are known in which pairs of iron atoms within bonding distance (typically ~2.4 Å) are bridged by nitride nitrogen atoms. These include the dinuclear (30) $[Fe^{II}_2(\mu\text{-}N)_2N_2]^{8-}$ in Ca_2FeN_2, polymeric (32) $\{[Fe^{II}_2(\mu\text{-}N)_2(\mu\text{-}N)_{2/2}]^{5-}\}_\infty$ in $Sr_2LiFe_2N_3$ and $Ba_2LiFe_2N_3$, and polymeric (33) $[Fe^{III}N_{4/2}^{3-}]_\infty$ in Li_3FeN_2. The iron(II) derivatives (Fig. 8) exhibit distorted trigonal planar FeN_3 coordination whereas the iron(III) derivative (Fig. 9) exhibits tetrahedral FeN_4 coordination. The μ_2-bridging nitride nitrogens, if considered as neutral ligands, can be considered as donors of one electron to one iron atom and two electrons to the second iron atom for a total of three electrons. The direction of the formal one-electron donation from neutral nitrogen to an iron atom is indicated in Fig. 8 by a double bond with the second component of the double bond representing Fe→N $d\pi \rightarrow p\pi^*$ back-donation, which does not affect the formal electron count as noted above. The direction of the formal two-electron donation from neutral nitrogen to an iron atom is indicated in Fig. 8 by an arrow corresponding to donation of a nitrogen lone pair.

A. Iron(II) derivatives (Fig. 8)

The iron atoms in both types of iron(II) derivatives, namely the dinuclear (30) $[Fe^{II}_2(\mu\text{-}N)_2N_2]^{8-}$ anion in Ca_2FeN_2 and the polymeric (32) $\{[Fe^{II}_2(\mu\text{-}N)_2(\mu\text{-}N)_{2/2}]^{5-}\}_\infty$ anion in $Sr_2LiFe_2N_3$ and $Ba_2LiFe_2N_3$, can be considered to have the favored 18-electron configuration if iron–iron bonding is considered. Such iron–iron bonding can be interpreted to be double bonding within an Fe_2N_2 quadrilateral in accord with the short intraquadrilateral iron–iron distances of ~2.4 Å and single bonding between Fe_2N_2 quadrilaterals in the polymeric $\{[Fe^{II}_2(\mu\text{-}N)_2(\mu\text{-}N)_{2/2}]^{5-}\}_\infty$ in accord with the longer interquadrilateral iron–iron distances of 2.6 Å (Fig. 8). The polymeric $\{[Fe^{II}_2(\mu\text{-}N)_2(\mu\text{-}N)_{2/2}]^{5-}\}_\infty$ thus contains infinite chains of alternating single and double iron–iron bonds and might be expected to exhibit one-dimensional conductivity despite the 18-electron configuration of the iron atoms. The magnetic properties of the iron(II) nitride derivatives have not yet been reported.

Fig. 7. The relationship of trigonal prismatic bent bonds to the metal–nitrogen triple bonding in $Fe^{II}N_2^{4-}$.

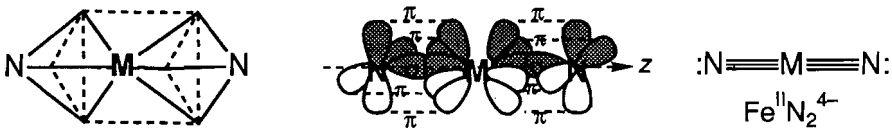

Fig. 8. A schematic representation of the structures of the nitridoferrates(II) showing the distorted trigonal FeN_3 coordination, the distribution of the nitrogen valence electrons, and the iron-iron bonding. The iron–iron distances are labeled in Å.

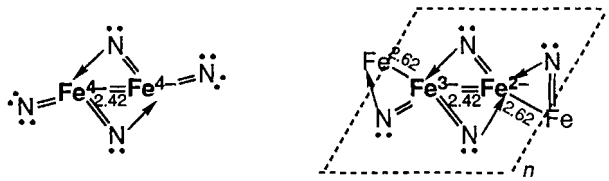

Fig. 9. A portion of the chain of iron atoms in the $[Fe^{III}N_{4/2}]^{3-}$ anion of Li_3FeN_2 showing the tetrahedral FeN_4 unit and two Fe=Fe double bonds from each iron atom. The iron–iron distances are labeled in Å.

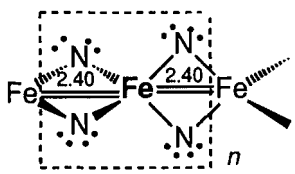

The following electron-counting scheme gives all of the iron atoms in the dinuclear $[Fe^{II}_2(\mu\text{-}N)_2N_2]^{8-}$ anion in Ca_2FeN_2 the normally favored 18-electron configuration:

Neutral iron atom:	8 electrons
Bridging nitride ligand: $^2/_2 \times 3 =$	3 electrons
Terminal nitride ligand: $1 \times 1 =$	1 electrons
–4 Charge on anion per iron atom:	4 electrons
Fe=Fe double bond:	2 electrons
Total iron valence electrons:	*18 electrons*

In this model, each iron atom can be regarded as forming four σ-bonds in an $FeN_3(Fe)$ unit with $sp^2(x,y)d(x^2-y^2)$ distorted square planar hybridization leaving a $p(z)$ orbital for the π component of the Fe=Fe double bond. A pair of d orbitals, $d^2(xz, yz)$ also remains to form the indicated π components of the Fe=N double bonds to the nitride ligands.

A similar-electron counting scheme can be used for the polynuclear (32) $[Fe^{II}_2(\mu\text{-}N)_2(\mu\text{-}N)_{2/2}]^{5-}$ anion in $Sr_2LiFe_2N_3$ and $Ba_2LiFe_2N_3$ as follows (labeling the iron atoms as in Fig. 8):

	"Left" Fe	"Right" Fe
Neutral iron atom:	8 electrons	8 electrons
Intraunit bridging N ligands: $^2/_2 \times 3 =$	3 electrons	3 electrons
Intraunit bridging N ligands:	1 electrons	2 electrons
Negative charge:	3 electrons	2 electrons
Intraquadrilateral Fe=Fe double bond:	2 electrons	2 electrons
Interquadrilateral Fe—Fe single bond:	1 electron	1 electron
Total iron valence electrons:	*18 electrons*	*18 electrons*

In this model each iron atom can be regarded as forming five approximately coplanar σ-bonds in an $FeN_3(Fe_2)$ unit with $sp^2(x,y)d^2(x^2-y^2, xy)$ distorted pentagonal planar hybridization leaving a $p(z)$ orbital for the π component of the Fe=Fe double bond. A pair of d orbitals, $d^2(xz, yz)$, also remains to form the indicated π components of the Fe=N double bonds to the nitride ligands.

B. The iron(III) derivative Li_3FeN_2

The structure of Li_3FeN_2 has been shown to contain infinite chains of $[Fe^{III}N_{4/2}^{3-}]_\infty$ tetrahedra with each iron atom within a short bonding distance to the two adjacent iron atoms in the chain (Fig. 9) (33). The iron–iron bond distances of 2.40 Å are similar to those found in the iron(II) derivatives (30, 32) $[Fe^{II}_2(\mu\text{-}N)_2N_2]^{8-}$ and $\{[Fe^{II}_2(\mu\text{-}N)_2(\mu\text{-}N)_{2/2}]^{5-}\}_\infty$ suggestive of iron-iron double bonds to the two adjacent iron atoms. The magnetic moment of Li_3FeN_2 is 1.71 μ_B, suggesting a single unpaired electron corresponding to low-spin iron(III). The iron atoms in the $[Fe^{III}N_{4/2}^{3-}]_\infty$ anion have 17-electron configurations by the following electron-counting scheme, considering the iron–iron bonds as Fe=Fe double bonds:

Neutral iron atom:	8 electrons
Bridging nitride ligand: $^4/_2 \times 1 =$	2 electrons
Two Fe=Fe double bond: $2 \times 2 =$	4 electrons
–3 Charge per iron atom:	3 electrons
Total iron valence electrons	*17 electrons*

This 17-electron configuration in $[Fe^{III}N_{4/2}^{3-}]_\infty$ is reasonable for a low-spin iron(III) complex (e.g., $Fe^{III}(CN)_6^{3-}$). In addition, note the following about this formulation of $[Fe^{III}N_{4/2}^{3-}]_\infty$ in Li_3FeN_2:

1. This is the only ternary transition metal nitride discussed in detail in this paper in which the nitride nitrogens are formu-

lated with tetrahedral sp^3 hybridization with two lone pairs and no multiple bonding rather than with either planar sp^2 hybridization, one lone pair and one π-bond, or linear sp hybridization, no lone pairs and two π-bonds (Fig. 4). However, $[Fe^{III}N_{4/2}^{3-}]_\infty$ in Li_3FeN_2 is also the only species discussed in this paper in which each transition metal is bonded to four nitrogen atoms rather than to only two or three nitrogen atoms. The metal atoms in tetrahedral MN_4 units are much less susceptible to forming additional π-bonds to the nitrogen atoms than the metal atoms in either trigonal MN_3 units or linear MN_2 units so that tetrahedral MN_4 units are more likely to contain sp^3 tetrahedral nitrogens with no π-bonding capability than are sp^2 planar nitrogens or sp linear nitrogens with π-bonding capabilities. Note also that the Fe—N bond lengths of 1.96 Å in Li_3FeN_2 are the longest M—N bond lengths in any of the ternary metal nitrides discussed in this paper (Table 1) in accord with the absence of Fe—N π-bonding in Li_3FeN_2.

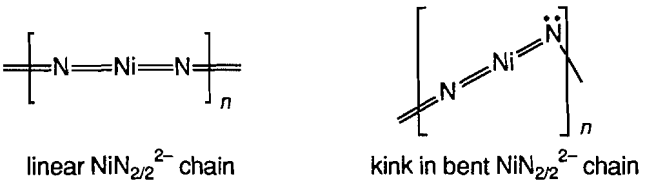
2. In this model, each iron atom can be regarded as forming six σ-bonds with $sp^3d^2(z^2,xy)$ octahedral hybridization in an $FeN_4(Fe_2)$ unit, leaving a pair of d orbitals, $d^2(xz,yz)$, for the indicated π components of the Fe═Fe double bonds. The total set of eight orbitals involved in the $6\sigma + 2\pi$ bonds, namely $sp^3d^4(z^2,xy,xz,yz)$, corresponds to a D_{2d} dodecahedron (bisdisphenoid) in which one of the interlocking disphenoids (distorted tetrahedra) is the FeN_4 iron–nitrogen bond network and the other disphenoid is the $Fe(═Fe)_2$ iron–iron double bond network using the bent bond model.

Infinite chains in nitridonickelates

A number of ternary nickel nitrides are known that are constructed from infinite $[Ni^{I}N_{2/2}^{2-}]_\infty$ chains containing formally nickel(I). Such chains are of two types (Fig. 10): (*a*) linear $[Ni^{I}N_{2/2}^{2-}]_\infty$ chains, such as those found in CaNiN (34) and $Li_3Sr_3Ni_4N_4$ (35), in which all of the Ni—N—Ni angles are close to 180°; (*b*) bent $[Ni^{I}N_{2/2}^{2-}]_\infty$ chains, such as those found in BaNiN (36) and $Ba_8Ni_6N_7$ (37), in which every third nitrogen atom has a kink of about 90°, leading to helical structures. In the compounds with linear $[Ni^{I}N_{2/2}^{2-}]_\infty$ chains all of the Ni...Ni distances are too long for metal–metal bonding (e.g., 3.58 Å in CaNiN) whereas in the compounds with kinked $[Ni^{I}N_{2/2}^{2-}]_\infty$ chains some of the Ni—Ni distances are close enough for bonding, e.g., 2.42 Å for BaNiN and 2.57 Å for $Ba_8Ni_6N_7$. In $Ba_8Ni_6N_7$ the nickel atoms are of three different types present in equal quantities: Ni(1) forms one bond with Ni(3) of length 2.57 Å whereas Ni(2) is not within bonding distance of any other nickel atom.

Simple electron counting in these nitridonickelates is consistent with these observations. Each nickel atom forms linear N═Ni═N units that, by using the bent bond approach outlined above, can be based on either square planar hybridization as in the discrete $Co^{I}N_2^{5-}$ ion discussed above or tetrahedral hybridization. Either type of hybridization might appear to be reasonable since the observed nickel(I) formal oxidation state in $[Ni^{I}N_{2/2}^{2-}]_\infty$ is intermediate between nickel(0), which forms tetrahedral complexes such as $Ni(CO)_4$, and nickel(II), which most often forms square planar complexes. If the $[Ni^{I}N_{2/2}^{2-}]_\infty$ chain is linear, then all five valence electrons of each nitrogen atom are bonded to nickel atoms so that a neutral nitrogen atom of this type can be regarded as a donor of two electrons to one nickel atom and three electrons to the other nickel atom,

Fig. 10. Linear and bent $[Ni^{I}N_{2/2}^{2-}]_\infty$ chains in ternary nickel nitrides.



linear $NiN_{2/2}^{2-}$ chain kink in bent $NiN_{2/2}^{2-}$ chain

i.e., a *neutral* $N_{2/2}$ unit of this type is a five-electron donor. This leads to the following electron-counting scheme for a $Ni^{I}N_{2/2}^{2-}$ unit in a *linear* $[Ni^{I}N_{2/2}^{2-}]_\infty$ chain:

Neutral nickel atom:	10 electrons
$^2/_2$ Linear bridging nitrogen atoms: $^2/_2 \times 5 =$	5 electrons
−2 Charge:	2 electrons
Total nickel valence electrons	*17 electrons*

The 17 valence electrons observed for this formal Ni(I) derivative are intermediate between the 18 valence electrons found in tetrahedral Ni(0) and the 16 valence electrons found in square planar Ni(II).

A similar electron-counting scheme can be derived for an $Ni^{I}N_{2/2}^{2-}$ unit in which one of the two nitrogen atoms has a Ni—N—Ni bond angle of ~90° rather than ~180° (i.e., the "kink" nitrogen atom). The "kink" nitrogen atom has a lone pair and thus can use only three of its five valence electrons for bonding to nickel, similar to the bridging nitrogen atoms in the binuclear and polynuclear ternary iron nitrides discussed above. This leads to the following electron-counting scheme for a $Ni^{I}N_{2/2}^{2-}$ unit located at a kink in the chain:

Neutral nickel atom:	10 electrons
$^1/_2$ Linear nitrogen atom: $^1/_2 \times 5 =$	$2^1/_2$ electrons
$^1/_2$ Kink nitrogen atom: $^1/_2 \times 3 =$	$1^1/_2$ electrons
−2 Charge:	2 electrons
Total nickel valence electrons:	*17 electrons*

Thus a nickel atom at a kink in a bent $[Ni^{I}N_{2/2}^{2-}]_\infty$ chain has an effective 16-electron configuration typical for a square planar nickel atom, so that the kink has the effect of averaging out 15- and 17-electron configurations of the two Ni(I) atoms flanking the kink, to give each of these nickel atoms effectively the favored 16-electron configuration for a square planar nickel atom. The Ni—Ni bonded distance between these nickel atoms then represents the typical bonding interaction between pairs of square planar 16-electron metal atoms. This electron-counting scheme for BaNiN is consistent with the observed 1.73 μ_B magnetic moment for each *trimeric* Ni_3N_3 unit in BaNiN, in which one-third of the nitrogen atoms are kink nitrogen atoms so that two of the three nickel atoms are effectively diamagnetic, leaving one unpaired spin for the Ni(I) atom in each Ni_3N_3 unit not bonded to a kink nitrogen atom.

Effect of a hydrophobic amino acid at position ($i - 1$) on the stability of β-turns in hydrophilic pentapeptides as studied by NMR and molecular mechanics

Xiaohong Liu, Serafin Fraga, Albin Otter, Paul G. Scott, and George Kotovych

Abstract: A detailed NMR study of the peptide NAc-FDEKA-NH_2 in aqueous and in CD_3OH/H_2O solutions as well as the *N*-acetylpentapeptide amides YDEKA, VDEKA, GDEKA, and the protected tetrapeptide NAc-DEKA-NH_2 in methanolic solutions indicates the importance of the first amino acid (at $i - 1$) on stabilizing the type I β-turn. The data illustrate the hydrophobic stabilization of this turn, which is present in FDEKA, YDEKA, and VDEKA. For GDEKA and DEKA, the NMR data indicate that this turn is not present. Molecular mechanics calculations support this conclusion and indicate that for FDEKA and GDEKA the type I β-turn is distorted in both the vacuum and the solvated structures. For the solvated structures, the $C_\alpha(i)$–$C_\alpha(i + 3)$ distance is 4.87 Å for FDEKA and 6.00 Å for GDEKA, which are to be compared with the value of 4.64 Å for an ideal type I β-turn, i.e., the distortion is far greater in GDEKA than in FDEKA. The calculations can be interpreted to indicate the presence of two major conformations in solution.

Key words: β-turns, FDEKA, pentapeptide.

Résumé : Une étude détaillée par RMN du peptide NAc-FDEKA-NH_2 en solution aqueuse et en solution dans le CD_3OH/H_2O et des *N*-acétylpentapeptide amides YDEKA, VDEKA, GDEKA et du tétrapeptide protégé en solution dans le méthanol met en évidence l'importance du premier acide aminé (à $i - 1$) dans la stabilisation de l'hélice du type I-β. Les données illustrent la stabilisation hydrophobique de cette hélice qui est présente dans les peptides FDEKA, YDEKA et VDEKA. Les donnéees de la RMN relatives aux peptides GDEKA et DEKA ne révèlent pas la présence de cette hélice. Cette conclusion est confirmée par les calculs de mécanique moléculaire qui révèlent que cette hélice de type I-β est déformée dans les structures sous vide et dans les structures solvatées des peptides FDEKA et GDEKA. Dans le cas des structures solvatées, la distance $C_\alpha(i)$–$C_\alpha(i + 3)$ est de 4,87 Å pour le peptide FDEKA et de 6,00 Å pour le peptide GDEKA. Ces données comparées à la valeur de 4,64 Å pour une hélice idéale de type I-β montrent que la distorsion est nettement plus accentuée dans le peptide GDEKA que dans le FDEKA. On peut interpréter ces calculs comme étant une indication de la présence de deux conformations principales en solution.

Mots clés : hélices du type β, FDEKA, pentapeptide.

[Traduit par la rédaction]

Introduction

In the process of studying the α-1 chain N-telopeptide of type II collagen with sequence pEMAGGFDEKAGGAQLGVMQ-NH_2 using two-dimensional NMR techniques, a fused βγ-turn between F^6 and A^{10} was observed (1). This turn was stabilized by three hydrogen bonds and a salt bridge between the side-chain end groups of E^8 and K^9. The first five amino acids were extended with a much higher degree of conformational freedom whereas the two Gly residues following the βγ-turn were found to be highly flexible, leaving the spatial position of the second half of the molecule relative to the fused βγ-turn undefined. In view of our continuing interest in the role of salt bridges and hydrogen bonding in the stabilization of β-turns (2), we decided to further investigate the nature of this fused βγ-turn by carrying out a detailed NMR study of NAc-Phe-Asp-Glu-Lys-Ala-NH_2 (NAc-FDEKA-NH_2) in aqueous and in CD_3OH/H_2O (60/40 v/v %) solutions. In addition, the objective was to study the effect of varying the first amino acid ($i - 1$) on the nature of this βγ-turn. Consequently, the protected pentapeptides YDEKA, VDEKA, and GDEKA were synthesized and studied, as well as the protected tetrapeptide

DEKA. This study is especially important because of the current ongoing interest in the factors favoring formation and stabilization of secondary structures at an early stage in the folding process, as discussed in recent reviews (3, 4).

There has been much interest in the folding of short linear peptides. A pentapeptide Tyr-Pro-Gly-Asp-Val has been shown, by using NMR data (5), to form a high population (about 50%) of type II β-turn in water at 278 K. The four residues involved in the turn begin with Tyr, and proline is at the $i + 1$ position of the β-turn. Nanosecond time scale folding dynamics of this pentapeptide in water were also carried out (6) over a period of 2 ns, and the calculations are in partial agreement with the experimental data. Some transient conformations were predicted that were not necessarily the same as the ensemble-averaged, equilibrium structures observed in the experiments. We have studied side-chain salt-bridge stabilization of type I β-turns by analyzing the NOE data of the following 13 hydrophilic protected tetrapeptides: DEKS, NEKS, EEKS, DDKS, DQKS, NQKS, DERS, NERS, EERS, DDRS, NDRS, DQRS, and DKES (2). In addition, based on the statistical predictions of Wilmot and Thornton (7), the peptides NPDM, NSDM, and NDDS were also studied. The results indicated that only DEKS, DERS, and NEKS exhibited a type I β-turn. These results could be reconciled by classifying β-turns into two classes, namely, those that are intrinsically stable because of local steric interactions and hydrogen bonding, and those that depend on long-range interactions (2). Molecular mechanics calculations by Thornton and Fraga on DEKS (8) and DERS (9) confirmed that the type I β-turn is stabilized by a salt bridge between the side chains of E and K and E and R, respectively.

The present study on the protected pentapeptides focuses on hydrophobic stabilization of β-turns arising from the amino acid at the $(i - 1)$ position of the turn. Molecular mechanics calculations are applied in conjunction with the nuclear Overhauser effect data to further study the factors that stabilize this β-turn.

Materials and methods

Materials and sample preparation

The pentapeptides FDEKA, YDEKA, GDEKA, and the tetrapeptide DEKA were synthesized as the *N*-acetyl amides. They were synthesized on an LKB Biolynx 4175 solid-phase peptide synthesizer using 9-fluorenyl-methoxycarbonyl/amino acid derivatives (Pharmacia (Canada) Ltd., Baie d'Urfe, Quebec). Protected VDEKA was from the Alberta Peptide Institute, University of Alberta. All peptides were purified by reversed-phase high-performance liquid chromatography on a Vydac TP218 column (The Separations Group, Hesperia, California). The peptides were judged to be pure on the basis of amino acid analysis and the NMR spectra.

The NMR samples were prepared by dissolving the solid peptide in 280 μL of deionized H_2O. The pH was then adjusted by adding small aliquots of diluted NaOH or HCl, followed by adding the rest of the solvent, namely 420 μL of CD_3OH (from Merck, Sharpe and Dohme) to make the solvent a 60/40 (v/v) CD_3OH/H_2O mixture. Before the NMR experiments, the samples were degassed by bubbling with argon. In addition, FDEKA was studied in 85% H_2O, 15% D_2O solutions at both pH 3.4 and 5.5. For FDEKA the CD_3OH/H_2O solutions were also prepared at both of these pH values. The other peptides, namely YDEKA, VDEKA, GDEKA, and DEKA, were prepared at pH values between 5.1 and 5.7 and were studied in 60/40 CD_3OH/H_2O solutions. The sample concentrations ranged from 5 to 7 mM. The exact concentrations and pH values are presented in Table 1.

NMR spectroscopy

All NMR experiments were carried out on the Varian UNITY 500 spectrometer using a proton-selective 5 mm probe or a triple resonance probe capable of pulsed field gradients. The 90° pulse length was checked at the beginning of every NMR session and the temperature was always controlled to ±0.1°C. For data collection and processing, VNMR software (versions 3.1 and 3.2) was used on SUN Sparc 4/330 and Sparc 4/470 workstations, respectively. Two-dimensional (2D) spectra were acquired nonspinning whereas for one-dimensional experiments the spinner was turned on. For the mixed solvent studies, all chemical shifts were measured relative to the undeuterated fraction of the methyl group of CD_3OH at 3.30 ppm. For FDEKA in H_2O solutions, the chemical shifts are reported in ppm relative to the H_2O signal at 4.80 ppm.

The temperature coefficients for the NH proton chemical shifts were determined from one-dimensional spectra. For example, in the case of GDEKA, experiments were carried out at five temperatures (0, 5, 10, 15, 20°C). All the NH shifts exhibit a linear dependence on temperature. In the case of YDEKA, six temperatures were recorded and analyzed. For FDEKA, shifts were measured at three temperatures as the data were in agreement with the YDEKA data, as expected.

The two-dimensional NMR experiments (10) were carried out in the hypercomplex, phase-sensitive mode (States–Haberkorn–Ruben method) (11) following procedures described previously (1). The decoupler and transmitter offsets were always set equal, a sweep width of 5000 Hz was used in both dimensions, and typically 4K data points in t_2 and 300 or 512 experiments were acquired in t_1. The HOHAHA (TOCSY) experiments (12) were carried out using the basic pulse sequence proposed by Bax and Davis (13) using a 70 ms MLEV-17 spin-lock. The nuclear Overhauser enhancement spectroscopy (NOESY) (14, 15) was carried out with the 90°–t_1–90°–mix–90°–FID pulse sequence with typical mixing times being 400 ms. Solvent suppression was achieved by presaturation during a 1.5 s relaxation delay. For TOCSY and NOESY experiments, the compensation for the first-point distortion caused by analog filters (16) was achieved by reducing the first point of each FID and each $t1$-interferogram by empirically determined values. For data processing, a Gaussian weighting function or a shifted (90°) sine-bell was used in both dimensions.

Molecular mechanics calculations

The calculations for the pentapeptides FDEKA and GDEKA were performed on an IBM RISC System/6000 Powerstation, using the software package maPSI[2]. (Complete details of the main component of this package are given in the work of Coghlan and Fraga (17) and additional information

[a]Chemical shifts are reported in ppm relative to the H_2O signal at 4.80 ppm in aqueous solution and to the methyl group of CD_3OH at 3.30 ppm in CD_3OH/H_2O solution. Coupling constants are measured in hertz. The temperature coefficients of the amide protons are listed in ppb/°C.

[b]The data were recorded in H_2O (15 v% D_2O) at a concentration of 5 mM and the temperature was 10.0 ± 0.1°C.

[c]Pairs of geminal protons x (x = β, γ, δ, ε) are not assigned stereospecifically. When two distinct lines were observed, the larger chemical shift was arbitrarily assigned to x and the smaller to x′.

[d]The data were recorded in CD_3OH/H_2O (60/40 v%) at a concentration of 5 mM and the temperature was 10.0 ± 0.1°C.

[e]The data were recorded in CD_3OH/H_2O (60/40 v%) at a concentration of 6 mM. The pH was 5.1 and the temperature 0.0 ± 0.1°C.

[f]Coupling constants were measured at 5°C from a one-dimensional spectrum.

[g]The data were recorded in CD_3OH/H_2O (60/40 v%) at a concentration of 5 mM. The pH was 5.5 and the temperature 0.0 ± 0.1°C.

[h]The data were recorded in CD_3OH/H_2O (60/40 v%) at a concentration of 5 mM. The pH was 5.7 and the temperature 0.0 ± 0.1°C.

[i]The data were recorded in CD_3OH/H_2O (60/40 v%) at a concentration of 7 mM. The pH was 5.6 and the temperature 0.0 ± 0.1°C.

on its use for the study of the solvation of peptidic chains may be found in the more recent work mentioned above (8, 9).)

The peptides were constructed from the crystallographic structures (with the angles ϕ, χ_1, and ψ rezeroed according to the IUPAC convention) of the corresponding amino acids, with the dihedral angle constraint that the pair EK would form a β-I turn in DEKA. All the remaining dihedral angles were optimized during the construction process. After the construction was completed, the N and C termini of the peptidic chains were protected with the groups H_3C-COO- and -HN-CH_3, respectively, in order to simulate the experimental conditions. To simulate the conditions at neutral pH, the residues D, E, and K were used in charged form (i.e., with ionized carboxyl groups in the side chains of D and E and with a protonated amino group in the side chain of K).

The peptidic chains obtained above were then fully optimized, under a minimum energy criterion, by variation of all the dihedral angles ϕ, ψ, and χ_1 until convergence (to $\pm 2°$) was obtained for all those angles.

Next, a solvation process was performed, using the optimized peptidic chains. This process was carried out as follows. Twenty points, on a sphere centered at the geometric center of the peptidic chain and with an appropriate radius, are chosen as starting points for the approach of the water molecules to the peptide, in an attempt to eliminate any directional bias. A water molecule is placed at the first of these positions and the interaction energy, and its gradient, between the water molecule and the peptide are calculated. The water molecule is then allowed to move a controlled distance along the path of steepest descent. This step-by-step approach of the water towards the peptide is continued until a minimum energy is reached, that is, until a stable molecular association peptide–water has been formed. The process is repeated for all the remaining starting points, thus obtaining the interaction energies of the corresponding molecular associations. The most stable of those associations is selected and a water molecule, with the relative position as in that association, is added to the peptidic chain: that is, the three atoms of the water molecule are incorporated into the list of atoms of the peptide, as part of the side chain of the residue to which the water molecule is closest in that molecular association. The complete procedure is now repeated with a second water molecule, interacting now with the peptidic chain that already contains the first water molecule. At the end of this step, the second water molecule is also incorporated into the peptidic chain. The calculation is continued until the desired number of water molecules have been added to the peptide.

In the present calculation seven water molecules were added, on the basis that the peptide consists of five residues and the two protecting groups, and therefore each component was given the chance of being solvated. With the approach adopted here, a larger number of water molecules would, in all probability, not change appreciably the present results because the freedom of the chain for conformational changes would be highly restricted.

This procedure represents a model by which one attempts to simulate the solvation of the peptide, the rationale being that the water molecules added may be considered to represent the first solvation shell, closely attached to the residues. Variations of this procedure have been used, with success, in the study of the environmental effects on the conformation of peptides in solution (8, 9). In this regard it should be mentioned that the calculations, in the present as well as in previous work, have been performed for the molecules in vacuum, without any consideration of dielectric constant.

Finally, the solvated structures thus prepared are then reoptimized, to the same convergence limit ($\pm 2°$).

Results

NMR spectroscopy

The resonance assignments of all five peptides are based on TOCSY experiments and sequential NOEs of the type $H_\alpha(i)$–NH(i + 1) and NH(i)–NH(i + 1) (18). The coupling constants NH–H_α were accurately measured in the one-dimensional spectra. The assigned resonances are presented in Table 1 together with the coupling constants and the temperature dependence of the NH proton shifts. The NH/NH section of the NOESY spectrum is depicted in Fig. 1 for FDEKA in 60% CD_3OH/40% H_2O solution. The fingerprint region (H_α/NH) of the same experiment is shown in Fig. 2. The chemical shift data for FDEKA in H_2O solutions at both pH values, as well as for the CD_3OH/H_2O solutions, are presented in Fig. 3. Finally, the amino acid sequences of the five peptides together with the observed sequential and medium-range NOEs are presented in Fig. 4. The thickness of the lines indicates qualitatively the relative magnitudes of the NOEs. For FDEKA, volumes of cross peaks were calculated relative to the ββ′ NOE for F as 1000 and then the NOEs were classified as strong (~200), medium (≤100), weak (≤50), and very weak (≤20). The data for FDEKA are presented in Table 2. For GDEKA, there is no internal standard for the integrals, hence only relative magnitudes are presented in Fig. 4.

Molecular mechanics

The results of the calculations produce three structures for each peptide: the β-I conformation, the structure optimized in vacuum, and the conformation stabilized by solvation. For the peptidic structures alone, the order of stability is vacuum structure more stable than solvated structure, which is, in turn, more stable than the β-I structure. Figure 5 presents the theoretical structures predicted for the solvated peptides.

These structures were then analyzed and the corresponding results are as follows.

(a) Dihedral angles

The dihedral angles, ϕ and ψ, for the residues E and K are summarized in Table 3, where it can be observed that the β-I turn has been distorted in both the vacuum and the solvated structures. To establish the magnitude of the distortion, use may be made of the criterion proposed by Rose et al. (19), in terms of the distance $C_\alpha(i)$–$C_\alpha(i + 3)$. For the solvated structures, as an example, those distances are 4.87 Å for FDEKA, and 6.00 Å for GDEKA, to be compared with the value 4.64 A for an ideal β-I turn (19); that is, the distortion (in the solvated structures) is far greater in GDEKA than in FDEKA.

(b) Hydrogen bonds and salt bridges

The results for salt bridges (i.e., strong Coulombic interactions) confirm the results above. The distances (again in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

solvated structures) between the side-chain carboxylic carbon of residue E and the side-chain amino nitrogen of residue K are 5.58 Å in FDEKA and 8.83 Å in GDEKA. That is, there is a much stronger salt bridge in FDEKA than in GDEKA. It should be mentioned that the solvated structure of GDEKA seems to have been stabilized by a salt bridge between the side-chain carboxylic carbon of residue D and the side-chain amine nitrogen of residue K, which are at a distance of 4.94 Å.

The distances between the oxygen of the carboxyl group of residue D and the hydrogen of the amido group of residue A are 5.18 and 3.54 Å, for the vacuum and solvated structures of FDEKA, and 5.81 and 3.89 Å, for the vacuum and solvated structures of GDEKA, respectively. These results, although indicating the absence of a proper H-bond, show a difference between FDEKA and GDEKA, which correlates with the NH temperature-dependent chemical shifts of residues A in both molecules (see Table 1, *d* and *g*).

(c) $d_{NN}(i, i + 1)$ *NOE connectivities*

Because of the dependence of the NOE on the inverse sixth power of the internuclear distance, the NOE connectivities between the amide hydrogens of consecutive residues have been *approximated* in the modeling using eq. [1] (20)

$$[1] \quad d_{NN}(i, i+1) = 10^3 (1.75/R_{i,i+1})^6$$

where $R_{i,i+1}$ denotes the separation between the amide hydrogens of residues i and $i + 1$ and the reference is 1.75 Å for the geminal proton internuclear distance. The corresponding values are presented in Table 2, for the three structures under consideration as well as for a weighted average. The weights used for the evaluation of the averages (3, 63, and 34% for FDEKA and 2, 62, and 36% for GDEKA) have been obtained by a Boltzmann distribution at 298 K. The values are identical for the β-I structures, as they should be, except for the d_{NN} (1,2) connectivity, due to the dependence on the sequence for the optimization of that part of the chain.

Discussion

The NMR data (Fig. 4) on NAc-FDEKA-NH_2 indicate that the fused βγ-turn, observed previously in the 19-amino acid type II N-telopeptide (1), is not present in the pentapeptide, showing the importance of long-range interactions in stabilizing this βγ-turn (2). All five peptides under study (Fig. 4) exhibit strong sequential NOEs, namely ($H_\alpha(i)$–NH), and weaker sequential NH(i)–NH NOEs. In addition, the NOE data for FDEKA, YDEKA, and VDEKA (Fig. 4, Tables 1d–1*f*) indicate that two medium-range NOEs ($H_\alpha(i)$–NH(i + 2)) are observed for these three pentapeptides in CD_3OH/H_2O solutions at pH values above 5.1 where the side chains are ionized. As well, the observation of very small temperature coefficients for the NH proton of A in these three peptides (2.3, 2.1, and 2.6 ppb/°C), respectively, indicates the presence of a hydrogen bond, namely NH(A). . . O═C (D). Consequently, at least three criteria have been met that indicate the high propensity of these peptides to form a type I β-turn in solution (4), namely, (*i*) the NH(i)–NH NOE connectivity between residues 2 and 3 and 3 and 4 of this turn, which are stronger than the NOE from residue 1 to residue 2; (*ii*) the presence of the $H_\alpha(i)$–NH(i + 2) NOE; and (*iii*) the small NH temperature coefficient. The turn involves residues DEKA. In addition, the results indicate that for FDEKA, which was also studied at low pH in CD_3OH/H_2O solutions, a low-field shift of 0.41 ppm is observed for the NH proton of E on increasing the pH from 3.4 to 5.5 (Fig. 3 and Tables 1*c* and 1*d*). This lends further support to the presence of secondary structure for FDEKA in this mixed solvent at high pH. In the case of H_2O solutions (Tables 1*a* and 1*b*, Fig. 3), this shift was only 0.24 ppm and there was no indication of secondary structure in solution at high pH even though there was a lower temperature-dependent coefficient of residue A and a smaller NH–H_α coupling constant of residue E than for the low pH solution.

Fig. 1. The NH/NH region of a 500 MHz phase-sensitive NOESY experiment of NAc-FDEKA-NH_2 in CD_3OH/H_2O (60/40), pH 5.5, 0°C. The mixing time was 400 ms.

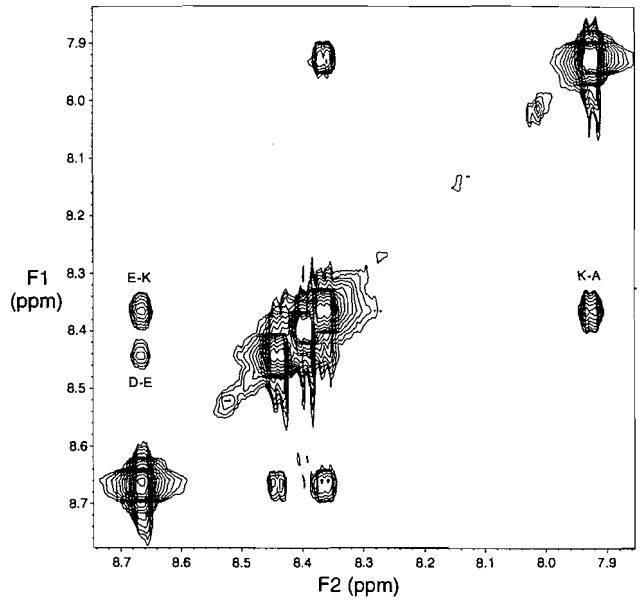

Fig. 2. The H_α/NH region of the same experiment as outlined in Fig. 1. Cross peaks resulting from α(i)–NH(i + 2) interactions are shown in boxes.

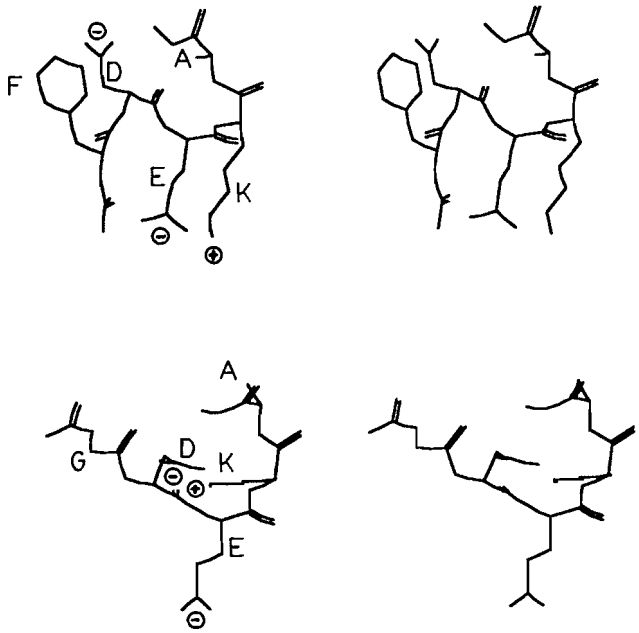
Fig. 5. Stereoscopic representations (showing only the heavy atoms) of the solvated structures of FDEKA and GDEKA. The symbols ⊕ and ⊖ mark the charged atoms, involved in salt bridges, of the side chains of the residues K and D and E, respectively. The stereo figure was obtained using the program "HyperChem" by inputting the dihedral angles from the modeling as described in the text.



The measured NMR parameters for these short linear peptides are averaged (4, 5) over all conformations present, and this precludes a numerically precise interpretation of the data for FDEKA, YDEKA, and VDEKA. However, a comparison may be made with the data observed for GDEKA and DEKA, where the hydrophobic amino acid at position $(i - 1)$ of the turn was replaced by G in the former peptide or removed completely in the latter peptide. The intensities for the $H_\alpha(i)$–NH$(i + 2)$ NOEs are significantly reduced. The NH temperature coefficient of residue A increases to 4.1 ppb/°C for GDEKA and 3.3 ppb/°C for DEKA, indicating the absence of the hydrogen bond in these two peptides. The conclusion is that these two peptides have at the most only a very weak propensity for forming a type I β-turn.

In view of these experimental data, we tried to understand the role of the hydrophobic $(i - 1)$ amino acid on β-turn formation. This was accomplished by means of the molecular mechanics calculations, which definitely indicate the presence of two predominant conformations in solution. A similar approach was used in the study of β-turn formation in YQNPDGSQA (21).

Comparison of the theoretical and experimental values for the d_{NN} connectivities is very difficult. The experimental results correspond to a measurement for a collection of molecules, in a thermal environment, over a given time interval. As a consequence of the interactions with the environment, those molecules will undergo structural changes, with the result that the experimental results cannot be ascribed to a specific conformation, unless (a) very stable structural motif(s) is/are present. The most appropriate tools for a theoretical study (22) of this problem are the Monte Carlo and Molecular Dynamics techniques, whereby the theoretical description is obtained from the complete history of the simulation, that is, with consideration of all the conformations that have been generated during the simulation. Even so, difficulties in the interpretation of the experimental results may still persist (6).

In the present case, though being aware of those difficulties, the interpretation is attempted in terms of two extreme structures (the β-I conformation and the conformation optimized in vacuum) and an intermediate structure, optimized in the presence of water. It is encouraging that the weighted results (Table 2 and Figs. 4 and 5) are in satisfactory agreement with the experimental observations, with very similar results for both FDEKA and GDEKA. On the basis of this comparison one could say that the experimental results may be described in terms of just two conformations: a somewhat extended conformation (~65%) and a distorted β-I conformation (~35%). One should add that the present results are in line with expectations from previous work, with (8, 9) or without (23) consideration of the solvent.

Synthesis of heptamethylindenyl rhodium(III) complexes: molecular structures of $[(\eta^5\text{-}C_9Me_7)RhCl(\mu\text{-}Cl)]_2$ and $[(\eta^5\text{-}C_9Me_7)Rh(PMe_2Ph)Cl_2]$

Ashok K. Kakkar, Graham Stringer, Nicholas J. Taylor, and Todd B. Marder

Abstract: The synthesis of a series of permethylindenyl (Ind*) rhodium(III) complexes, $[(\eta^5\text{-}C_9Me_7)RhCl(\mu\text{-}Cl)]_2$, $[(\eta^5\text{-}C_9Me_7)RhLCl_2]$ (L = PMe_3, PMe_2Ph, PPh_3), and $[(\eta^5\text{-}C_9Me_7)Rh(PMe_3)_2Cl]^+Cl^-$, is reported. The structure of $[(\eta^5\text{-}C_9Me_7)RhCl(\mu\text{-}Cl)]_2$ (**4**) was determined, confirming the dimeric nature of the compound. Ruby red crystals of **4** are monoclinic, space group *C*2/*c*, with four molecules per unit cell of dimensions a = 18.598(5), b = 10.520(3), c = 17.376(3) Å and β = 115.10(2)°. The indenyl rings exhibit minimal distortion from perfect η^5 coordination to the Rh centres. A single crystal X-ray structure determination of $[(\eta^5\text{-}C_9Me_7)Rh(PMe_2Ph)Cl_2]$ (**6**) indicates a more distorted η^5-coordination of the indenyl ligand, with the auxiliary ligand having the greatest *trans* influence, namely, the PMe_2Ph group, being *trans* to the indenyl ring junction C—C bond. Yellow prismatic crystals of **6** are orthorhombic, space group $P2_12_12_1$, with four molecules per unit cell of dimensions a = 8.819(1), b = 15.303(3), c = 17.296(3) Å.

Key words: rhodium, indenyl, permethylindenyl, heptamethylindenyl, phosphine complex, X-ray structure.

Résumé : On a effectué la synthèse d'une série de complexes perméthylindényl(Ind*) rhodium(III), $[(\eta^5\text{-}C_9Me_7)RhCl(\mu\text{-}Cl)]_2$, $[(\eta^5\text{-}C_9Me_7)RhLCl_2]$ (L = PMe_3, PMe_2Ph et PPh_3), et $[(\eta^5\text{-}C_9Me_7)Rh(PMe_3)_2Cl]^+Cl^-$. On a déterminé la structure du composé $[(\eta^5\text{-}C_9Me_7)RhCl(\mu\text{-}Cl)]_2$ (**4**) et confirmé la nature dimère du composé. Les cristaux rubis du composé **4** sont monocliniques, groupe d'espace *C*2/*c*, avec quatre molécules par motif de dimensions a = 18,598(5), b = 10,520(3) et c = 17,376(3) Å et β = 115,10(2)°. Les cycles indényles présentent une distorsion minimale par rapport à une coordination η^5 parfaite avec les centres Rh. Une détermination de structure du $[(\eta^5\text{-}C_9Me_7)Rh(PMe_2Ph)Cl_2]$ (**6**) indique, dans ce cas, qu'il existe une coordination η^5 plus déformée du coordinat indényle avec le coordinat auxiliaire ayant la plus grande influence *trans*, le groupe PMe_2Ph se trouvant *trans* par rapport à la liaison C—C de la jonction avec le cycle indényle. Les cristaux jaunes, prismatiques, du composé **6** sont orthorhombiques, groupe d'espace $P2_12_12_1$, avec quatre molécules par motif de dimensions a = 8,819(1), b = 15,303(3) et c = 17,296(3) Å.

Mots clés : rhodium, indényle, perméthylindényle, heptaméthylindényl, complexe de phosphine, structure par diffraction des rayons X.

Introduction

The strongly electron-donating pentamethylcyclopentadienyl ligand ($[\eta^5\text{-}C_5Me_5]^-$, Cp*) has received considerable attention in organometallic chemistry, and many useful reagents have been prepared via mono-Cp* halide, Cp^*MX_n, precursors.[3] In contrast, there are few reports (3–10) of metal complexes containing the heptamethylindenyl ligand ($[\eta^5\text{-}C_9Me_7]^-$, Ind*). This may, in part, be due to the lack of experimental details for the synthesis of the ligand in the original communication (3). We recently reported detailed preparative procedures for the synthesis of heptamethylindene, Ind*H, on both the 10 g (9) and 90 g (8) scales. Ind*H is reported to have a pK_a of 27.4 in DMSO compared with values of 20.1 for indene, 26.1 for Cp*H, and 18.0 for cyclopentadiene (11). Thus, Ind* should have donor properties similar to, or even stronger than Cp*, while maintaining the unusually high stoichiometric reactivity (12–14) and catalytic activity (15–17) associated with indenyl metal complexes. For example, kinetic studies (5, 10) on the

substitution of CO by PR_3 in a series of indenyl ring substituted $[(\eta^5\text{-}C_9H_{7-n}Me_n)Rh(CO)_2]$ complexes indicate that the second-order rate constant for $[(\eta^5\text{-}C_9Me_7)Rh(CO)_2]$ (**1**) is ca. 150 × smaller than that for $[(\eta^5\text{-}C_9H_7)Rh(CO)_2]$ (**2**) but ca. 10^7 larger than that for $[(\eta^5\text{-Cp*})Rh(CO)_2]$ (**3**). The values of ν_{CO} for complexes **1** and **3** are similar, and the average nonbonding *d*-orbital ionization energy (18) for **1** (7.93 eV) is slightly lower than that for **3** (8.12 eV). Interestingly, in the case of the sandwich complexes $[(\eta^5\text{-L})_2M]$ (L = Cp*, Ind*; M = Fe, Cr, Co) PES and electrochemical studies (8) show that the Ind* ligand is a stronger donor than Cp* for M = Fe and Cr, but for M = Co, the first ionization energy was higher for the Ind* compound. It is also worth noting that X-ray crystallographic studies on $[(\eta^5\text{-L})_2Fe]$ (L = Ind, Ind*) (7), and $[(\eta^5\text{-L})Rh(\eta^4\text{-1,5-COD})]$ (L = Ind, Ind*) (*6b*) showed no significant changes in the structural parameters describing metal – indenyl ring bonding upon permethylation.

As part of our continuing study of indenyl complexes, we have begun to examine the synthesis of Ind* complexes that can serve as basic starting materials for subsequent organometallic chemistry. We report herein the synthesis and structure of $[(\eta^5\text{-Ind*})RhCl(\mu\text{-Cl})]_2$ and its reactions with monodentate phosphine ligands.

Results and discussion

Preparation of $[(\eta^5\text{-}C_9Me_7)RhCl(\mu\text{-Cl})]_2$ (4)

Complex **4** was prepared (Scheme 1) by adaptation of the procedure outlined (*2d*, *e*) for the synthesis of $[Cp^*RhCl(\mu\text{-Cl})]_2$ (2). Heptamethylindene and $RhCl_3 \cdot xH_2O$ were heated in refluxing methanol for 24–48 h. Evaporation of the solvent and extraction into toluene gave the dark red compound **4**, which was characterized by elemental analysis, NMR spectroscopy, and by single crystal X-ray diffraction. The solid state structure of **4** is shown in Fig. 1. A summary of the crystallographic data and parameters for data collection is presented in Table 1, and selected bond distances and angles are given in Table 2, together with those reported for $[Cp^*RhCl(\mu\text{-Cl})]_2$ (*2h*). The final atomic coordinates for **4** are given in Table 3. The molecular structure of **4** indicates that the molecule exists as a dimer in the solid state, sitting on a centre of inversion, with two bridging chloride ligands, comparable to $[Cp^*RhCl(\mu\text{-Cl})]_2$. There are, however, differences in the lengths of the metal–chloride bonds in the two compounds. In $[Cp^*RhCl(\mu\text{-Cl})]_2$, the Rh—Cl distances are 2.465(1), 2.452(1), and 2.397(1) Å for the two bridging and one terminal chloride, respectively, whereas the comparable distances for **4** are 2.394(1), 2.499(1), and 2.381(1) Å, respectively. Thus, there is considerably more asymmetry in the bridging system of the Ind* compound. These bond lengths result in nonbonding Rh..Rh′ distances of 3.1791(6) Å for $[Cp^*RhCl(\mu\text{-Cl})]_2$ and 3.612(1) Å for **4**. The yields of **4** were somewhat variable. Occasionally, the preparation of **4** yielded a toluene—insoluble orange-brown solid. It was found, however, that this material reacts with phosphines to yield the same products as does **4.**

Reaction of $[(\eta^5\text{-}C_9Me_7)RhCl(\mu\text{-Cl})]_2$ (4) with phosphines: preparation of $[(\eta^5\text{-}C_9Me_7)RhLCl_2]$ (L = PMe_3 (5), PMe_2Ph (6), PPh_3 (7)

As is the case for the Cp* analogue (1, 2), the bridging Rh—Cl bonds in complex **4** are easily cleaved by tertiary phosphines (Scheme 1) to form monomeric $[\eta^5\text{-Ind*})Rh(PR_3)Cl_2]$ complexes in quantitative yields. These complexes were characterized by elemental analysis, ^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ NMR spectroscopy for **5–7**, and by a single crystal X-ray structure determination for **6**. The solid state structure of **6** is shown in Fig. 2. A summary of the crystallographic data and parameters for data collection are presented in Table 1, and final atomic coordinates and selected bond lengths and angles for **6** are given in Tables 4 and 5.

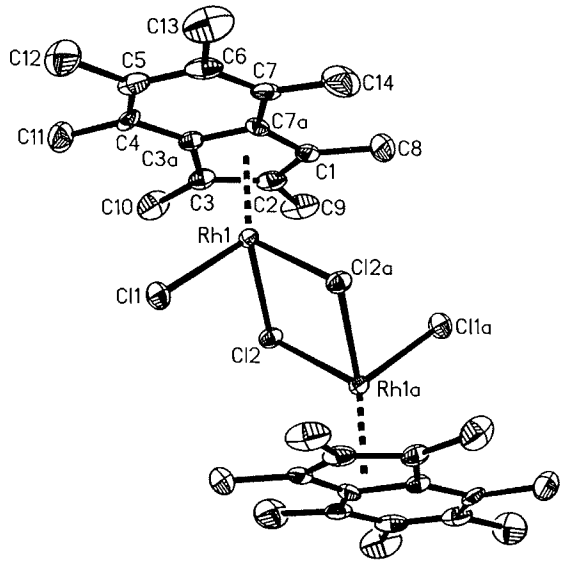

Fig. 1. The ORTEP diagram of the molecular structure of **4**. Hydrogen atoms have been omitted for clarity.

It is well documented (6, 7, 19–23) that all [(η-indenyl)ML_n] complexes show some degree of slip–fold distortion from η^5 *towards* η^3 coordination in the ground state. Structural characterization of many indenyl complexes indicates that the metal to carbon distances M—C_1, M—C_2, M—C_3 are shorter than those to the bridgehead carbons (M—C_{3a}, M—C_{7a}). The degree of distortion in the solid state in these complexes has been discussed (6, 7, 19, 21) in terms of three parameters: (*i*) slip parameter (Δ), which we define as the difference in the average metal to carbon distances of $C_{3a,7a}$ and $C_{1,3}$ ($\Delta = d\{(M\text{—}C_{3a,7a}) - (M\text{—}C_{1,3})\}$); (*ii*) hinge angle (HA), which is the angle between normals to the least-squares planes defined by [C_1, C_2, C_3] and [C_1, C_3, C_{3a}, C_{7a}]; and (iii) fold angle (FA), which is the angle between normals to least-square planes defined by [C_1, C_2, C_3] and [C_{3a}, C_4, C_5, C_6, C_7, C_{7a}]. The values for these parameters range (*6b*, 7, 21) from 0.030 Å (Δ), 2.5° (HA), 4.4° (FA) for "true" η^5 complexes to 0.8 Å (Δ), 28° (FA) for "true" η^3 complexes, with intermediate values of 0.11 – 0.42 Å (Δ), 7–14° (HA), 6–13° (FA) observed for "distorted" complexes in which there is clearly some degree of bonding of the metal to $C_{3a,7a}$. Other geometric parameters have also been used (20, 22) to describe the distortions in indenyl and carboranyl complexes. The critical feature is the soft potential surface for distortions of the indenyl ring system that involve folding of the rings and changes in C—C bond lengths.

The values for the slip–fold parameters for **4** are Δ = 0.087(5) Å; FA = 5.0°, HA = 4.6°. These values imply that

there is very little distortion in this complex. In contrast, the values for the slip–fold parameters for **6** are Δ = 0.154(3) Å; FA = 8.8°, HA = 7.2°, which indicates a distorted η^5 coordination of rhodium to the indenyl ring. Hence, the distortions observed in the d^8-$[(\eta\text{-}C_9H_7)RhL_2]$ complexes also persist for the d^6-$[(\eta\text{-}C_9R_7)RhL_2L']$ systems. Similar findings were reported for d^6-$[(\eta\text{-}C_9H_7)Ir\{P(C_6H_5)_3\}(H)][BF_4]$ for which Δ = 0.185(8) Å (20).

It has been shown (20, 22) that the indenyl ligand exhibits a conformational (i.e., rotational) preference in $[(\eta^5\text{-}C_9R_7)\text{-}ML_2L']$ complexes. The arrangement about the metal centre is such that the ligand with the greatest *trans* influence prefers a position *trans* to the ring junction carbons. For example, in $[(\eta\text{-}C_9H_7)Ir\{P(C_6H_5)_3\}_2(H)][BF_4]$ the hydride ligand, which has a greater *trans* influence than $[P(C_6H_5)_3]$, is *trans* to the C_{3a-7a} bond in the solid state (20). A similar arrangement of ligands is observed in a number of other complexes, including a series of $[(\eta^5\text{-}C_9H_7)Co(\eta^5\text{-}R_2C_2B_9H_9)]$ complexes (22), in which a *cisoid* arrangement of indenyl and carboranyl ligands is preferred. The consequence of having a ligand with a greater *trans* influence *trans* to C_{3a}—C_{7a} is a reduction in the bonding between the metal and $C_{3a,7a}$, which is reflected in increased M—C distances to $C_{3a,7a}$. A more detailed examination of the structure shown in Fig. 2 indicates that the $PPhMe_2$ ligand (which has a higher *trans* influence than chloride) is *trans* to the six-membered ring.

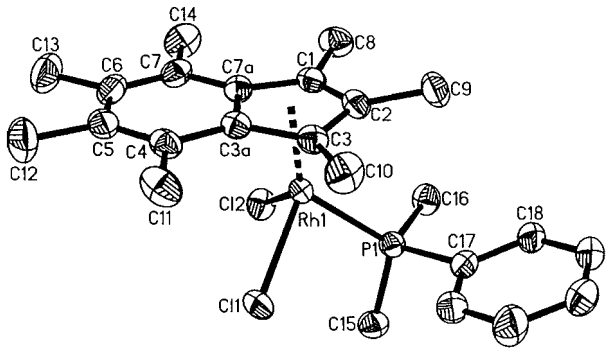
[a]Equivalent isotropic U defined as one third of the trace of the orthogonalized U_{ij} tensor.

Fig. 2. The ORTEP diagram of the molecular structure of **6.** Hydrogen atoms have been omitted for clarity.



The ring C—C distances in **4** and **6** are shown in Fig. 3. It is clear that the average C_4—C_5, C_6—C_7 distances (1.375(7) Å) is shorter than the C_5—C_6 distance (1.442(7) Å) in **4** by 0.067 Å. The difference between these two distances is less in **6**, at 0.041 Å (1.387(5) Å and 1.428(5) Å for average (C_4—C_5, C_6—C_7) and C_5—C_6 distance, respectively), than in **4**. From these data it can be inferred that there is a more localized diene-like structure for the six-membered ring in **4** than in **6.** This trend is consistent with the slip–fold parameters described above, and comparable to the trends observed in η^5 and η^3 bis(indenyl) metal complexes (7).

Formation of $[(\eta^5\text{-}C_9Me_7)Rh(PMe_3)_2Cl][Cl^-]$ (8)

Treatment of **4** with 4 equivalents of PMe_3 results in the initial formation of an orange solution from which **8** precipitated in a quantitative yield. It was characterized by ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$, NMR spectroscopy, and by elemental analysis,

[a] Equivalent isotropic U defined as one third of the trace of the orthogonalized U_{ij} tensor.

which indicate that **8** should be formulated as $[(\eta^5\text{-}C_9Me_7)Rh(PMe_3)_2Cl][Cl^-]$. The $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectra showed obvious disparities from those for **5–7**. The chemical shift of the phosphines in **8** is downfield by ~18 ppm from that in **5–7**. Carbons 1, 2, 3, 3a, and 7a also exhibit a downfield shift in the ^{13}C NMR spectrum of **8**. The value of J_{Rh-P} in **8** is 7 Hz smaller than in **5**, presumably reflecting the opposing effects of better donor ligands *vs.* increasing positive charge at rhodium, with the latter being more important.

Conclusion

In conclusion, we have prepared and structurally characterized heptamethylindenyl ($[C_9Me_7^-]$, Ind*) analogues of $[Cp^*RhCl(\mu\text{-}Cl)]_2$ and $[Cp^*Rh(PR_3)Cl_2]$. These complexes are important starting materials in light of the enhanced reactivity of indenyl metal complexes compared with their Cp counterparts.

Experimental section

General procedures

All reactions were carried out under a nitrogen atmosphere in a glove box, except for the synthesis of **4**, which employed

For personal use only.

standard Schlenk techniques. THF was dried and distilled from Na–benzophenone, and all deuterated solvents were freeze–pump–thaw degassed and distilled on a vacuum line. $RhCl_3 \cdot 3H_2O$ was obtained from Johnson Matthey Ltd., and the phosphine ligands were obtained from Strem Chemicals and used as received. Heptamethylindene was prepared according to the published procedure (8*a*, 9). ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded on Bruker AC200 or AM250 spectrometers. ^1H and chemical shifts are reported in ppm relative to external TMS and referenced to $CDCl_3$ residual proton and carbon resonances, respectively; coupling constants are in Hz. Multiplicities are reported as (br) broad, (s) singlet, (d) doublet, (t) triplet, and (m) multiplet. chemical shifts are reported relative to the external standard H_3PO_4.

Preparation of $[(\eta^5\text{-}C_9Me_7)RhCl(\mu\text{-}Cl)]_2$ (4)

A mixture of heptamethylindene (C_9Me_7H, 260 mg, 1.2 mmol) and $RhCl_3 \cdot 3H_2O$ (250 mg, 0.95 mmol) in methanol (15 mL) and water (0.5 mL) was refluxed for 48 h. After removing the volatiles *in vacuo*, the dark red solid was washed with hexane (to remove excess heptamethylindene), and then extracted into toluene. On cooling to –40°C, compound **4** (276 mg, 67% yield) was obtained as a dark red solid. A single, dark ruby, polyhedral crystal suitable for X-ray diffraction was grown by slow evaporation of a $CHCl_3$ solution, which also produced analytically pure material. ^1H NMR ($CDCl_3$, 250 MHz), δ: 1.56 (s, 6H, CH_3), 1.95 (s, 12H, CH_3), 2.04 (s, 12H, CH_3), 2.52 (s, 12H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 63 MHz), δ: 10.2, 13.3, 17.7, 18.4 (s, CH_3), 81.0 (br d, $C_{1,3}$), 95.1 (d, $J_{Rh-C} = 7$ Hz, C_2), 102.5 (d, $J_{Rh-C} = 9$ Hz, $C_{3a,7a}$), 130.4, 143.5 (s, C_{4-7}). Anal. calcd. for $C_{32}H_{42}Rh_2Cl_4$: C 49.64, H 5.47; found: C 49.78, H 5.53.

Preparation of $[(\eta^5\text{-}C_9Me_7)Rh(PMe_3)Cl_2]$ (5)

Compound **4** (32 mg, 0.04 mmol) was reacted with PMe_3 (9 μL, 0.08 mmol) in THF (10 mL) for 24 h. The solvent was removed *in vacuo* and the solid obtained was recrystallized from a THF–hexane mixture at –40°C. Complex **6** (38 mg, 99% yield) was obtained as an orange solid. $^{31}P\{^1H\}$NMR ($CDCl_3$, 81 MHz), δ: 26.7 (d, $J_{Rh-P} = 145$ Hz). ^1H NMR ($CDCl_3$, 200 MHz), δ: 1.58 (d, $J_{P-H} = 12.5$ Hz, 9H, PMe_3), 1.92 (s, 9H, CH_3), 2.16 (s, 6H, CH_3), 2.53 (s, 6H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 50 MHz), δ: 10.2 (s, 1 CH_3), 13.3 (s, 2 CH_3), 15.4 (d, $J_{P-C} = 37$ Hz, PMe_3), 17.5 (br s, 4 CH_3), 82.1 (d, $J_{Rh-C} = 8$ Hz, $C_{1,3}$), 105.3 (s, C_2), 111.2 (d, $J_{Rh-C} = 3$ Hz, $C_{3a,7a}$), 130.2, 140.1 (s, C_{4-7}). Anal. calcd. for $C_{19}H_{30}RhCl_2P$: C 49.27, H 6.53; found: C 49.37, H 6.89.

Preparation of $[(\eta^5\text{-}C_9Me_7)Rh(PMe_2Ph)Cl_2]$ (6)

Compound **4** (35 mg, 0.05 mmol) was reacted with $PPhMe_2$ (13 μL, 0.09 mmol) in THF (10 mL) for 24 h. Following work-up as for **5**, complex **6** (47 mg, 99% yield) was obtained as an orange solid. A single, pale yellow, prismatic crystal suitable for X-ray diffraction was grown by slow evaporation of a THF solution under N_2 in a glove box. Recrystallization of the material from CH_2Cl_2–Et_2O results in the incorporation of CH_2Cl_2 into the complex. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 81 MHz); δ 28.6 (d, $J_{Rh-P} = 149$ Hz). ^1H NMR ($CDCl_3$, 200 MHz), δ: 1.32 (dd, $J_{P-H} = 5.4$ Hz, $J_{Rh-H} = 1.7$ Hz, 3H, CH_3), 1.72 (s, 6H, CH_3), 1.88 (dd, $J_{P-H} = 13$ Hz, $J_{Rh-H} = 0.8$ Hz, 6H, PPhMe_2), 2.21 (d, $J_{P-H} = 2$ Hz, 6H, CH_3), 2.56 (s, 6H, CH_3), 7.46 (m, 3H, P$PhMe_2$), 7.95 (m, 2H, P$PhMe_2$). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 50 MHz), δ: 8.7 (s, 1 CH_3), 13.0 (s, 2 CH_3), 14.4 (d, $J_{P-C} = 39$ Hz, PPhMe_2), 17.5 (br s, 4 CH_3), 82.4 (d, $J = 8$ Hz, $C_{1,3}$), 104.6 (s, C_2), 111.0 (s, $C_{3a,7a}$), 128.2 (d, $J_{P-C} = 10$ Hz, P$PhMe_2$), 131.0 (d, $J_{P-C} = 10$ Hz, P$PhMe_2$), 131.2 (s, P$PhMe_2$), 133.7 (s, P$PhMe_2$), 130.2, 140.4 (s, C_{4-7}). Anal. calcd. for $\{C_{24}H_{32}RhCl_2P\}_4CH_2Cl_2$: C 53.29, H 5.99; found: C 53.34, H 6.10.

Preparation of $[(\eta^5\text{-}C_9Me_7)Rh(PPh_3)Cl_2]$ (7)

Compound **4** (35 mg, 0.05 mmol) was reacted with PPh_3 (24 mg, 0.09 mmol) in THF (10 mL) for 24 h. Following work-up as for **5**, complex **7** (58 mg, 99% yield) was obtained as an orange solid. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 81 MHz), δ: 40.7 (d, $J_{Rh-P} = 157$ Hz). ^1H NMR ($CDCl_3$, 200 MHz), δ: 1.24(dd, $J_{P-H} = 4.6$ Hz, $J_{Rh-H} = 1.4$ Hz, 3H, CH_3), 1.60(s, 6H, CH_3), 2.17 (t, $J_{P-H} = J_{Rh-H} = 1.4$ Hz, 6H, CH_3), 2.56 (s, 6H, CH_3), 7.25 (br s, 9H, P(C_6H_5)$_3$), 7.69 (m, 6H, P(C_6H_5)$_3$). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 50 MHz), δ: 9.22 (s, 1 CH_3), 13.0 (s, 2 CH_3), 17.8 (s, 2 CH_3), 18.0 (s, 2 CH_3), 84.7 (d, $J = 8$ Hz, $C_{1,3}$), 105.6 (d, $J = 7$ Hz, C_2), 109.8 (s, $C_{3a,7a}$), 127.8 (v br s, P(C_6H_5)$_3$), 134.8 (d, $J_{P-C} = 9$ Hz, P(C_6H_5)$_3$), 130.8, 141.4 (s, C_{4-7}). Anal. calcd. for $C_{34}H_{36}RhCl_2P$: C 62.88, H 5.59; found: C 62.89, H 5.49.

Preparation of $[(\eta^5\text{-}C_9Me_7)Rh(PMe_3)_2Cl]^+[Cl^-]$ (8)

Compound **4** (35 mg, 0.05 mmol) was reacted with PMe_3 (21 μL, 0.2 mmol) in THF (10 mL) for 48 h. The resulting precipitate was collected by filtration and dried *in vacuo*. Complex **8** (49 mg, 99% yield) was obtained as a yellow solid. $^{31}P\{^1H\}$ NMR $CDCl_3$, 81 MHz), δ: 8.7 (d, $J_{Rh-P} = 138$ Hz). ^1H NMR ($CDCl_3$, 200 MHz), δ: 1.58 (t, $J = 5.7$ Hz, 18H, PMe_3), 2.10 (t, $J_{P-H} = 2$ Hz, 9H, CH_3), 2.12 (s, 6H, CH_3), 2.49 (s, 6H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 50 MHz), δ: 11.1 (s, 1 CH_3), 13.9 (s, 2 CH_3), 16.3 (m, 2 PMe_3), 17.2 (s, 4 CH_3), 88.9 (s, $C_{1,3}$), 113.4 (s, C_2), 116.4 (s, $C_{3a,7a}$), 129.2, 141.4 (s, C_{4-7}). Anal. calcd. for $C_{22}H_{39}RhCl_2P_2$: C 49.00, H 7.29; found: C 49.12, H 7.40.

A summary of the crystal data for compounds **4** and **6** is given in Table 1. The data were collected on a Nicolet–Siemens R3m/V diffractometer equipped with graphite-monochromated Mo Kα radiation and a Nicolet LT2 low-temperature device. Accurate unit-cell parameters were derived from 25 general reflections well distributed in reciprocal space. Background measurements were made at the beginning and end of each scan for a total time equal to half the scan time. Crystal stability was monitored by measuring two standard reflections every 100 data; only statistical fluctuations (±2%) were observed. Data were corrected for Lorentz and polarization effects and absorption (for **4**, face indexed analytical, transmission factors 0.8558–0.9186; for **6**, ψ-scan, semi-empirical). The structures were solved by Patterson and Fourier techniques, and refined by full-matrix least-squares methods using Siemens SHELXTL PLUS software (24), the function minimized being $\Sigma w(|F_o|-|F_c|)^2$. Difference Fourier synthesis provided the location of all hydrogen atoms, which were included in the refinement with isotropic thermal parameters. A total of 194 and 382 parameters were refined for **4** and **6**, respectively, with data:parameter ratios of 10.9:1 and 9.3:1. During the final cycles of refinement, a weighting scheme of the form $w^{-1} = \sigma^2(F)$ was included. Refinement of the inverse enantiomorph of **6** gave significantly higher R values, $R = 2.55$, $R_w = 2.79\%$. Scattering factors used, including the anom-

Fig. 3. The C—C bond lengths (Å) in Ind* rings of **4** and **6**.

alous dispersion corrections for rhodium, were taken from the International Tables, Vol. 4 (25). Details of the crystal structure determination including complete tables of coordinates, bond distances and angles, and anisotropic thermal parameters have been deposited.[4]

Abstract: Calculations based on density functional theory have been carried out on the reaction between Cl_2Ti^+–ethyl (**1**) and ethylene. In this study **1** was taken as a model for the cationic metallocenes of group-4 elements, which have been developed by Kaminsky and Brintzinger as efficient catalysts for the polymerization of olefins. The ground state structure of **1** has a β-agostic conformation in which a single C_β—H bond is directed towards the metal center. It was assumed that this conformation also serves as a model for the resting state of the growing chain attached to the cationic group-4 metallocenes between insertions. Two paths were considered for the reaction between **1** and ethylene. The first (**2**) has ethylene approaching the agostic C_β—H bond, whereas ethylene in the second approach (**3**) attacks the Ti—C_α link from the side opposite to the C_β—H bond. The front-side attack (**2**) results in a transfer of hydrogen from the β-carbon of ethyl to ethylene and represents a chain-terminating step with an activation energy of 5.3 kcal/mol. It was not possible to locate a path leading to olefin insertion from the front-side attack (**2**). The back-side attack (**3**) resulted readily in insertion with an activation energy of 3.9 kcal/mol. The study made use of full transition state optimization as well as a tracing of the reaction paths by the intrinsic reaction coordinate (IRC) method of Fukui. Previous investigations have all assumed that olefin insertion takes place via a front-side approach (**2**) based on the known stereochemistry of α-olefin polymerization. The present study suggests that insertion takes place by a back-side approach (**3**), and this suggestion is discussed in connection with the known stereochemistry of olefin polymerization.

Key words: Ziegler–Natta, olefin polymerization, density functional.

Résumé : On a effectué des calculs basés sur la théorie de la densité fonctionnelle sur la réaction du Cl_2Ti^+–éthyl (**1**) et l'éthylène. Dans cette étude, on a utilisé le composé **1** comme modèle pour les métallocènes cationiques des éléments du groupe 4 qui ont été développées par Kaminsky et Brintzinger comme des catalyseurs efficaces pour la polymérisation des oléfines. La strucutre de l'état fondamental du composé **1** possède une conformation agostique-β dans laquelle la liaison simple C_β—H est dirigée vers le centre métallique. On a fait l'hypothèse que cette conformation sert aussi de modèle pour l'état au repos de la chaîne qui croît attachée au niveau des métallocènes cationiques du groupe 4 entre les insertions. On a considéré deux voies réactionnelles pour la réaction du composé **1** et l'éthylène. Dans la première (**2**), l'éthylène approche de la liaison C_β—H alors que dans la deuxième approche (**3**), l'éthylène attaque la liaison Ti—C_α à partir de la face opposée à la liaison C_β—H. L'attaque frontale (**2**) provoque un transfert d'hydrogène du carbone β du groupe éthyle de l'éthylène et elle correspond à une étape de terminaison de chaîne avec une énergie d'activation de 5,3 kcal/mol. Il n'a pas été possible de localiser une voie qui pourrait conduire à une insertion de l'oléfine par une attaque frontale (**2**). L'attaque par le côté (**3**) conduit facilement à une insertion avec une énergie d'activation de 3,9 kcal/mol. L'étude a utilisé une optimisation complète de l'état de transition ainsi qu'un tracé des voies réactionnelles par la méthode de la coordonnée réactionnelle intrinsèque de Fukui. En se basant sur la stéréochimie

bien connue de la polymérisation des α-oléfines, les études antérieures avaient toujours fait l'hypothèse que l'insertion se fait par une approche frontale (**2**). La présente étude suggère que l'insertion se produit par une approche par l'arrière (**3**) et on discute de cette suggestion en liaison avec la stéréochimie bien connue de la polymérisation des oléfines.

[Traduit par la rédaction]

1. Introduction

Metallocene-based systems (**1**) for olefin polymerization have started and will likely continue over the next several years to replace conventional Ziegler–Natta catalyst systems. Metallocene-based products, both conventional and new polymers, are appearing on the market more and more frequently. Metallocene plastics have several unique and desirable properties. Uniformity of the active site in these systems leads to greater uniformity of the polymer microstructure and molecular weight distribution. Additionally, comonomer incorporation with metallocene catalysts is generally uniform throughout the spectrum of molecular weights. Of particular promise have been the cationic metallocenes of group-4 elements first developed by Kaminsky and Brintzinger (1a) as well as by others (1). The cationic catalysts are often generated from neutral dichloro metallocenes of group-4 elements by reaction with a cocatalyst such as methylaluminoxane (MAO) according to eq. [1].

[1]

The polymer is formed in subsequent reactions between olefin and the cationic alkyl species according to eq. [2].

[2] 
Also, part of the "metallocene revolution" are the half-sandwich constrained geometry catalysts (CGC) as exemplified in recent patent claims of Dow and Exxon (2b,c).

The Cossee–Arlman mechanism (3) is the most widely accepted mechanism for both Ziegler–Natta olefin polymerization and olefin polymerization by Kaminsky-type catalysts. The Cossee–Arlman polymerization mechanism for metallocenes is given in eq. [3].

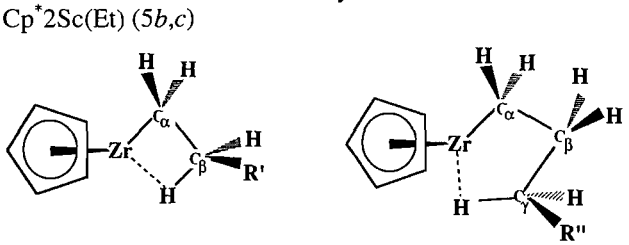
[3] 
1a Active complex — **1b** π-Complex — **1c** Transition state — **1d** γ-Agostic alkyl product

The active species **1a** possesses a vacant coordination site, and for the group-4 transition metal (Ti, Zr, Hf) catalysts this is the alkylated cationic metallocene. The first step of the process involves the complexation of olefin to form a π complex **1b**. In the second step, the olefin inserts into the metal–carbon bond through a four-membered cyclic transition state, **1c**. The newly formed species, **1d**, possesses a vacant coordination site where the M—C bond was formerly located in **1a**.

The Cossee–Arlman mechanism, although well accepted and understood in a conceptual sense, is not fully understood in a mechanistic sense. For example, the exact nature of the active species and the role of the cocatalyst and (or) counterion is a subject of debate. The current belief is (4) that the active species is a cationic complex such as $[Cp_2ZrR^+]$. Jordan and co-workers (5*a*) detected that the benzyl species, $[Cp_2Zr(CH_2Ph)]^+$, catalyzes ethylene polymerization. The role of the cocatalyst, usually MAO, is even less understood. It is thought that the cocatalyst may act only to generate the active species and remove impurities from the system. On the other hand, it may play a more fundamental role such as assisting in the insertion of each monomer unit or reactivating dormant sites.

Molecular modeling has been used extensively in studies of the steps involved in olefin polymerization. Molecular mechanics simulations have so far focused on the stereoregularity of polyolefins by analyzing the steric repulsion at the assumed transition state, **1c**, for the olefin insertion step in the Cossee mechanism (6, 7). A number of *ab initio* (8), semi-empirical (9), and density functional theory (10) (DFT) methods have been employed in studies of the electronic factors of importance in the Cosse mechanism. The active catalytic species in the electronic studies were assumed to be unsaturated cations, L_2MR^+, where M is a group-4 transition metal and the growing chain R is represented by CH_3, whereas L_2 varies from Cl_2, bis-cyclopentadienyl (Cp), to bridged bis-Cp's. The possible influence of the solvent and the counterion (cocatalyst) was ignored in those calculations.

One of the recurring problems encountered in modeling of the insertion process is associated with a lack of structural information about the active species **1a** of eq. [3]. Thus, little is known about the coordination geometry of the growing chain attached to the L_2M fragment in its resting state between insertions. Calculations on L_2MR^+ systems in which R is either ethyl or propyl have revealed that the most stable structure has a β-agostic conformation, **2a**, in which a single C_β—H bond is directed towards the metal center. Of somewhat higher energy is the γ-agostic species, **2b**. It is the objective of this investigation to look at **2a** as a possible resting state for **1a** with R′ representing the growing chain. A β-agostic conformation has been established by Bercaw and co-workers for $Cp^*2Sc(Et)$ (5*b*,*c*)



2a **2b**

With **2a** as a model for the resting state of **1a**, one might envision two insertion paths for an approaching olefin. The

For personal use only.

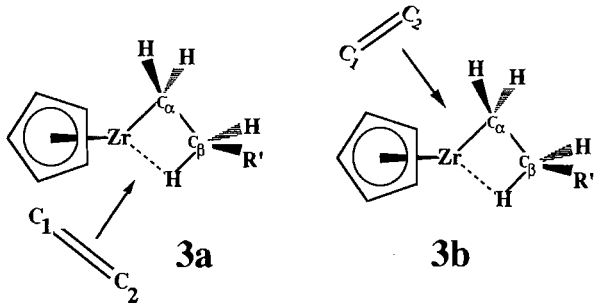
first, **3a**, involves an approach of olefin towards the Zr—H agostic bond. It will be refered to as the front attack. The second, **3b**, has olefin attacking the Zr—C_α bond, and will be referred to as the back-side attack. We shall investigate both paths in detail.



The study will be based on density functional theory (DFT) with the ML_2 moiety modeled by $ZrCl_2^+$ and R' represented by hydrogen. These simplifications allow us to carry out transition state optimizations for the two steps shown in **3a** and **3b**, and to follow the reaction paths by the intrinsic reaction coordinate method of Fukui (11). The IRC method traces the steepest decend paths connecting the transition state with reactants and products. The findings will be compared to the known stereochemistry of the insertion reaction in eq. [3] as well as some of the mechanisms postulated for chain termination of the polymerization process. Many of these issues could not be dealt with in previous quantum mechanical calculations (8–10) on olefin polymerization since the growing chain was modeled with a methyl group where β- and γ-agostic interactions are absent.

2. Computational details

The reported density functional calculations were all carried out by utilizing the program system ADF, developed by Baerends et al. (12, 13) and vectorized by Ravenek (14). The numerical integration procedure applied for the calculations was that of te Velde and co-workers (15). The geometry optimization procedure was based on the method developed by Versluis and Ziegler (16). The electronic configurations of the molecular systems were described by an uncontracted triple-ζ STO basis set (17) for the 3*s*,3*p*,3*d*, 4*s*, and 4*p* valence shells of titanium. Double-ζ STO basis sets (17) were used for carbon (2*s*, 2*p*), hydrogen (1*s*), and chlorine (3*s*, 3*p*). A single 3*d* polarization function was employed for carbon and chlorine whereas a 2*p* function was added to hydrogen. The $1s^22s^22p^6$ configuration on titanium, the $1s^2$ configuration on carbon, as well as the $1s^22s^2$ configuration on chlorine were assigned to the core and treated by the frozen-core approximation (12). A set of auxiliary (18) *s*, *p*, *d*, *f*, and *g* STO functions, centered on all nuclei, was used to fit the molecular density and to present Coulomb and exchange potentials accurately in each SCF cycle. Energy differences were calculated by augmenting the local exchange–correlation energy expression due to Vosko et al. (19) with Becke's nonlocal exchange corrections (20) and Perdew's nonlocal correlation correction (21). The nonlocal corrections were added as a perturbation, NL/P, based on a density obtained from a local calculation. Geometries were optimized without including nonlocal corrections. The application of approximate density functional theory to organometallic chemistry has been reviewed recently (22).

Some of the reactions described in this investigation were studied by the intrinsic reaction coordinate (IRC) method of Fukui (11) in which the transition state is connected to reactant(s) and product(s) by a steepest descend path. The paths can be written as **X**(*s*), where **X** is a nuclear configuration on the path, and |*s*| is the length of the paths from the transition state. Negative values of *s* indicate the direction towards reactant(s), and positive values of *s* the direction towards the product(s). The algorithm used to trace the IRC path was developed by Gonzalez and Schlegel (23). The implementation of the algorithm into the ADF program was carried out by Deng and Ziegler (24). The transition state search was based on the algorithm due to Banerjee et al. (25*a*) in the implementation by Baker (25*b*) and the adaptation for ADF by Fan and Ziegler (25*c*). We expect that the Cl_2Ti^+ fragment is electronically a good model for Cp_2Ti^+. On the other hand, the steric bulk of a Cp ring is not well represented by a chlorine atom.

3. Results and discussion

We shall in the following consider the β-agostic conformation of **2a** as a possible model for the resting state of the polymer attached to the metallocene between insertions. Conformation **2a** can be attacked by an olefin from either the front side, **3a**, or the back side, **3b**, and both approaches will be considered. The species **2a** is in this study represented by $Cl_2Ti^+–C_2H_5$, where the Cp rings have been replaced by chlorine ligands and R' by hydrogen. The β-agostic conformation of $Cl_2Ti^+–C_2H_5$ was optimized without any constraints, and the converged geometry shown in **4a** is virtually of C_s symmetry with a planar Ti-C_α-C_β-$H_{\bar{A}}$ frame. The interaction between the β-hydrogen of the ethyl group and the titanium metal center is visible from the elongated H—C_β bond of 1.16 Å and the Ti—H_β distance of 2.02 Å. The titanium center is tetrahedrally coordinated in **4a** if the β-hydrogen is considered as a normal ligand.

The Ti-C_α-C_β-H_i frame of **4a** can readily move in a plane perpendicular to the Cl_2Ti coordination plane with the normal vector ***x***, **4a**. In fact, another β-agostic structure was found at a C_α-Ti-X angle of 104°, **4b**. The β-agostic interaction in **4b** is even stronger than that in **4a**, which possesses a C_α-Ti-X angle of 33.5°. This is apparent from a longer C—H bond of 1.17 Å and a shorter Ti—H distance of 1.93 Å in **4b** compared to 1.16 and 2.02 Å, respectively, in **4a**. The ClTiCl angle is expanded from 113.8° in **4a** to 125.4° in **4b** due to the deformation from the tetrahedral configuration of the metal center. In terms of energy, **4a** is more stable than **4b** by 1.3 kcal/mol at the LN/P level of theory, most likely due to the distortion of **4b** from a tetrahedral geometry. A calculation of the energy profile leading from **4a** to **4b** reveals a gradual increase in energy. The facile movement of the Ti-C_α-C_β-H frame might provide some flexibility as the incoming olefin approach from the front side,**4a**, and in particular the back side, **4b**.

A detailed description of the two olefin approaches, **3a** and **3b**, is illustrated in Schemes 1 and 2, respectively. For the front-side attack, **3a**, the initial step is the formation of a π-complex, Scheme 1. After the π-complex is formed the process can follow either of the routes A or B. Route A is in accordance with the Cossee mechanism, i.e., olefin insertion is achieved via a four-centered transition state. Route B involves

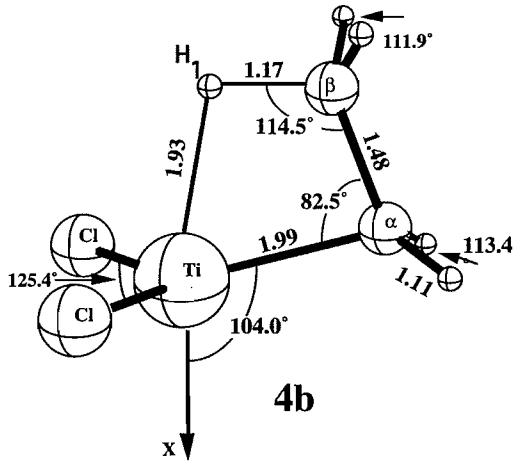
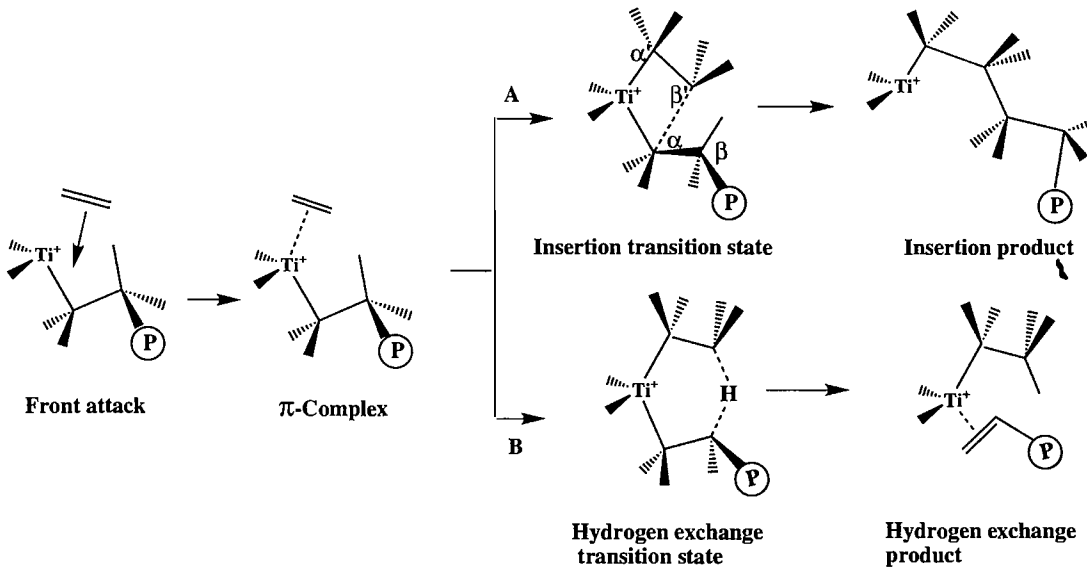
4a

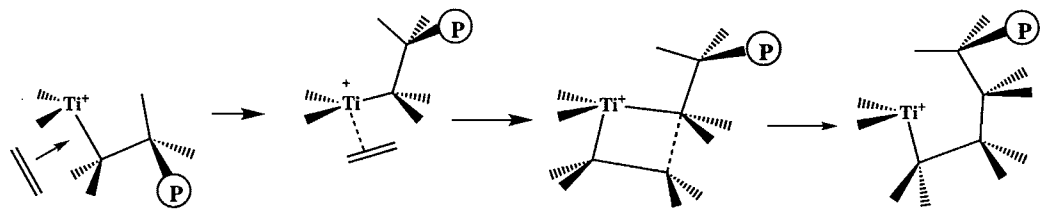


4b

Scheme 1.



Scheme 2.



a transfer of the β-hydrogen from the polymer chain to olefin. The process in B can be considered as an olefin-aided chain-termination reaction. The back-side attack, **3b**, is also initiated by the formation of a π-complex, Scheme 2. After that the process proceeds with insertion.

The π-complexes in Schemes 1 and 2 were fully optimized without symmetry constraints. The converged geometries are both virtually of C_s symmetry, with the ethylene carbons and the Ti-C_α-C_β-H frame coplanar. The optimized structures along with most of the parameters are given as **5a** for the π-complex in Scheme 1, and as **5b** for the corresponding complex in Scheme 2.

The ethyl framework in the olefin complex **5a** is very similar to that of **4a**, except that the C_α-Ti-X angle in **5a** is reduced by 10.4° to 23.1°. Thus the Ti-C_α-C_β-H frame has moved to accommodate the approaching olefin. The β-agostic interaction in **5a** is retained as indicated by a Ti—H distance of 1.94 Å and a C—H bond of 1.19 Å. The ethylene is only loosely bonded to the titanium center with TiM-C distances of 2.34 and 2.50 Å, respectively. The C—C bond length in ethylene is

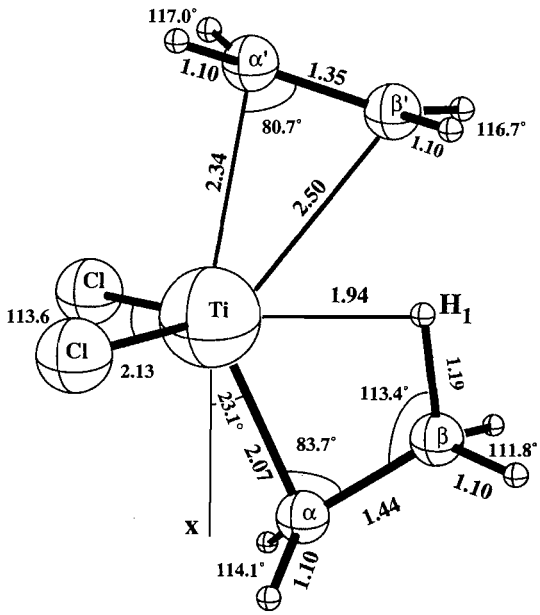
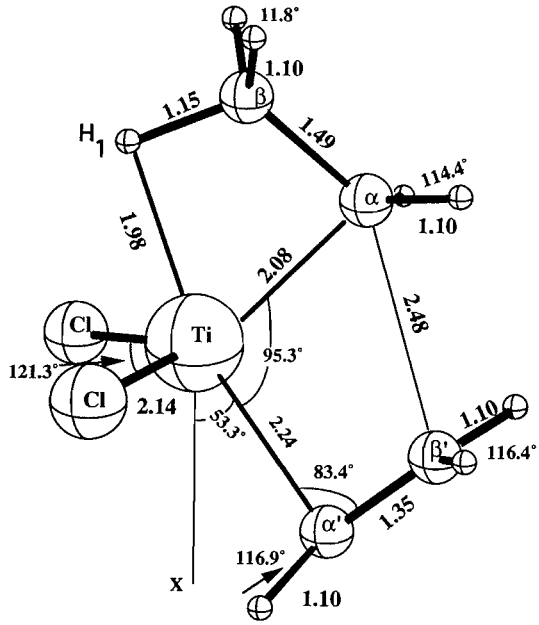
For personal use only.



5a



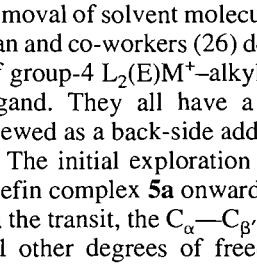
5b

1.35 Å, which is close to the calculated double bond of 1.33 Å for free ethylene.

The π-complex **5b** from the back-side approach of Scheme 2 can be considered as an olefin adduct of **4b**. The ethyl group in **5b** has moved by increasing the C_α-Ti-X angle from 104° in **4b** to 146.6° in **5b**. This is again done to accommodate the incoming olefin. The back donation of electrons from titanium to ethylene is, as expected, weak, judging from the C—C distance of ethylene which is 0.02 Å longer than for free C_2H_4.

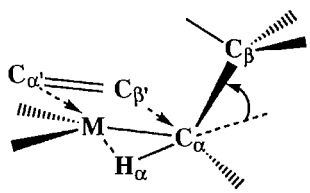
The energies of **5a** and **5b** were found to be essentially the same, with **5a** being only 0.5 kcal/mol more stable than **5b**. The coordination of ethylene to **4a**, yielding **5a**, is exothermic by 25.4 kcal/mol. Correspondingly, the coordination of ethylene to **4b**, yielding **5b**, is exothermic by 27.2 kcal/mol. We did not find any barrier for the formation of the π-complex. In solution the formation of the π-complex will require the removal of solvent molecules that will introduce a barrier. Jordan and co-workers (26) determined the structure for a number of group-4 $L_2(E)M^+$–alkyl complexes, **5c**, where E is a donor ligand. They all have a β-agostic interaction and can be viewed as a back-side adduct between **5b** and E.

The initial exploration of the paths in Scheme 1 from the olefin complex **5a** onward were carried out by a linear transit. In the transit, the C_α—$C_{\beta'}$ distance was reduced in steps while all other degrees of freedom were optimized without constraints. The transit gave rise to an energy maximum , and the structure corresponding to the highest energy was used as a starting point in a regular transition state search (25) . The full transition state optimization resulted in the converged structure shown as **6a**. The structure has C_{2v} symmetry and appears from inspection to represent the transition state for the hydrogen exchange reaction of path B in Scheme 1.



M = Zr,Hf; E = PR_3,$C_4H_{10}O$

5c



5d

The calculated vibrational spectrum of **6a** revealed a single imaginary frequency of 562i cm^{-1}, thus confirming that this structure represents a transition state. The normal mode related to the imaginary frequency is of b_2 symmetry and corresponds to, respectively, a shortening and an elongation of the two symmetrical H_1—C_β bonds. Thus, the b_2 mode has the characteristics of a reaction coordinate representing the hydride exchange process of path B in Scheme 1. To further verify that **6a** is indeed a transition state of Scheme 1B, we studied the intrinsic reaction coordinate (IRC) path (11, 24) from **6a**. The IRC starts from **6a** in the two directions along the b_2 reaction mode and continues by steepest descend in the energy towards reactants and products. The IRC paths can be written (11) as $\boldsymbol{X}(s)$ where $|s|$ is the length of the path from the transition state, Section 2. A step length of Δs = 0.02 Å was used in the descent. The IRC calculation revealed that **6a** is connected to two symmetrical π-complexes with the structures **5a**, thus confirming that **6a** is the transition state for the hydrogen exchange reaction. In the path from **5a** to **6a** the C_β—H_1 bond is gradually broken while another $C_{\beta'}MH_1$ bond is formed. The change in the two key reaction coordinates along the IRC is shown in Fig. 1. It is clear from this figure that the bond breaking and bond formation take place abruptly in a region close to the transition state, **6a**. The path from **5a** to **6a** gives further rise to a number of alternate increases and decreases in the length of bonds that become equivalent in the transition state **6b**. The IRC calculation revealed that all of these alternate geometrical changes take place gradually along the path. The transition state **6a** is best viewed as an adduct between Cl_2Ti—H and two equivalent olefins.

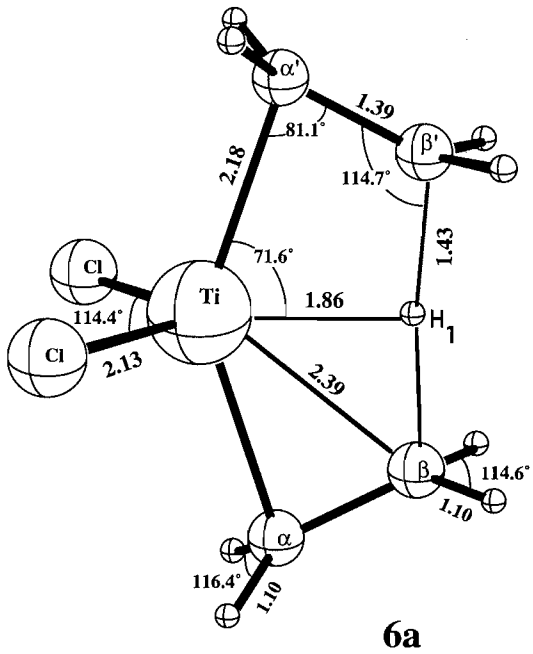

Fig. 1. Change in the $R(C_\beta—H_1)$ and $R(C_{\beta'}MH_1)$ distances along the IRC of the hydrogen exchange process.

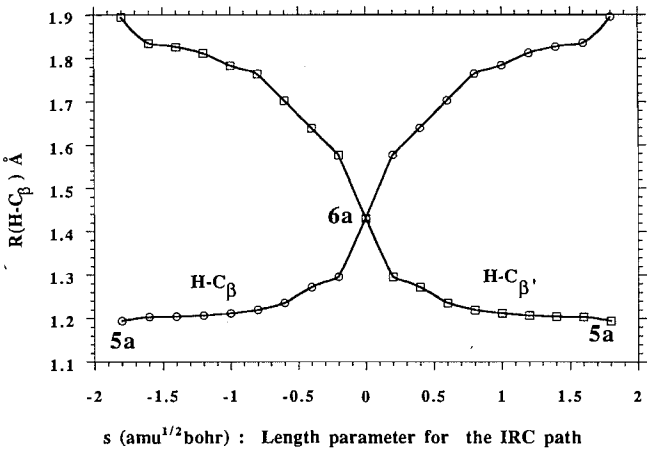

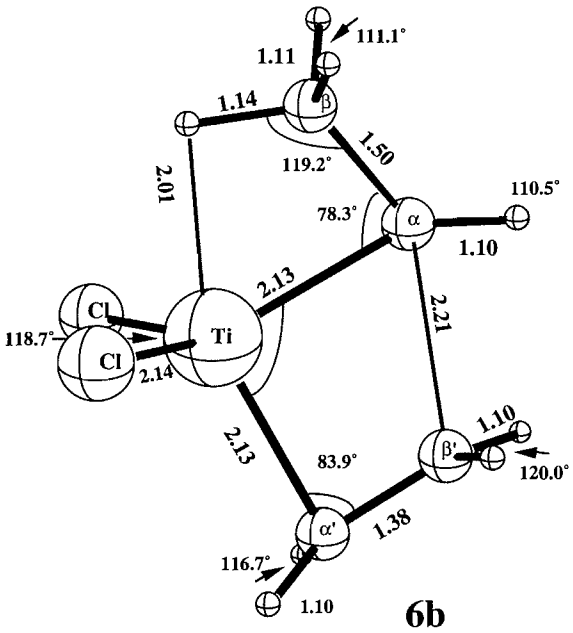

Fig. 2. Energy profile for the hydrogen exchange process along the IRC.

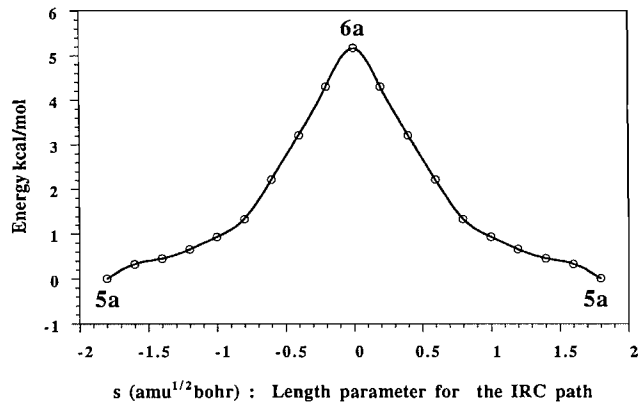


The energy profile for the hydrogen exchange reaction along the IRC path is shown in Fig. 2. The barrier was calculated to be 5.3 kcal/mol at the NL/P level of theory, and it is clear from Fig. 2 that the rise in energy takes place close to the transition state, **6b**, where the stretch in the $C_\beta—H_1$ bond becomes pronounced, Fig. 1.

The linear transit leading from **5a** to the hydrogen exchange transition state **6a** had the Ti-C_α-C_β-H_1 frame coplanar with the incoming ethylene. It is perhaps not surprising that such a coplanar front-side attack will result in hydrogen exchange since the $C_{\beta'}$ atom on ethylene will come into close contact with H_1 before it can interact with C_α on the ethyl group as required for an insertion reaction.

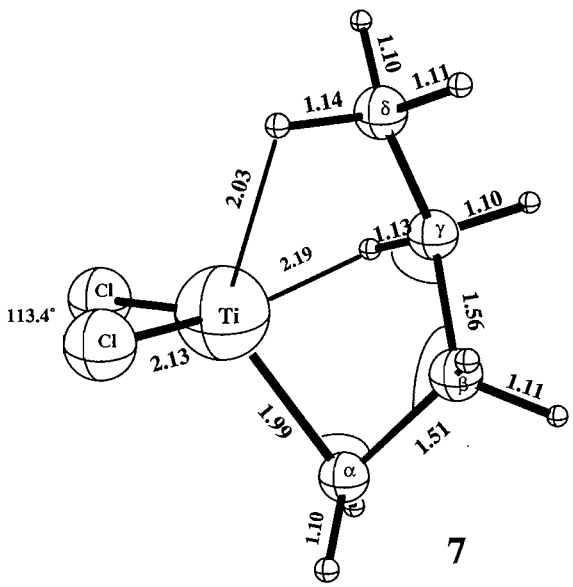
We have attempted several transits in which the C_β atom of the ethyl group was moved out of the C_s plane in **5a** by a rotation around the Ti—C_α axis to ensure a free passage of the $C_{\beta'}$ ethylene atom towards C_α on the ethyl group, **5d**. The rotations were carried out prior to or in concert with the ethylene approach. All of these transits failed to locate a transition state for the insertion along A of Scheme 1. Instead the transits led to hydrogen exchange or high-energy adducts between ethylene and Cl_2Ti^+–C_2H_5, **5d**. The adducts with the C_β atom out of the C_s plane had energies in excess of 15 kcal/mol compared to **5a,** and none of them represented an insertion transition state. We must thus conclude that insertion from a front-side attack along path A in Scheme 1 is highly unlikely or at least unable to compete with hydrogen exchange. Our conclusions will later be reconciled with the available experimental data on the stereochemistry of olefin polymerization catalyzed by cationic metallocenes of group-4 transition metals.

We shall now turn to a discussion of the alternative backside attack of Scheme 2 as a possible route for olefin insertion. A linear transit search for the transition state along the path in Scheme 2 led to a structure that has a planar C_s symmetry. However, a vibrational analysis of this species revealed three normal modes with imaginary frequencies. The symmetric mode with ν = 105 cm^{-1} corresponded to the ethylene insertion, the other two asymmetric modes of 442i cm^{-1} and 198i cm^{-1} were out-of-plane bendings.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

A distortion along the two asymmetric modes resulted in the true transition state **6b**. This species has one single imaginary frequency of ν = 103i cm^{-1} representing the reaction mode, whereas all other modes have real frequencies. The ethylene carbon atom $C_{\beta'}$ is out of the $C_{\alpha'}TiC_{\alpha}$ plane by 17.4° and the ethyl carbon atom C_{β} is out of the $C_{\alpha}TiC_{\alpha'}$ plane by 10.7°. The out-of-plane deformation of the carbon backbone reduces the steric interaction between the otherwise eclipsed hydrogens. The energy difference between **6b** and the C_s structure is 4.8 kcal/mol at the NL/P level of theory. A previous *ab initio* Hartree–Fock (HF) calculation (8*c*) on the $Cl_2TiCH_3^+ + C_2H_4$ insertion process finds a difference of 0.6 kcal/mol between the planar and asymmetric transition states. The out-of-plane deformation is likely more favorable in the planar ethyl insertion with three CH_2 groups eclipsed compared to the planar methyl insertion with only two eclipsed CH_2 groups.

Structure **6b** must be characterized as an early transition state. The Ti-C_α bond about to be broken is only 0.03 Å longer in **6b** than in the π-complex **5b**, and 0.14 Å longer than in the parent ethyl complex, **4b**. At the same time the emerging C_α–$C_{\beta'}$ σ-bond with a distance of 2.21 Å is still far in excess of a single C—C bond length, and has only decreased by 0.26 Å compared to the ethylene adduct **5b**. The β-hydrogen H_1 on ethyl retains its stabilizing interaction with titanium throughout the path from **5b** to **6b**. At the transition state **6b** the C_β—H_1 bond is stretched to 1.14 Å and the Ti—H_1 distance is 2.01 Å. The continuous agostic stabilization from the interaction between the metal center and the C_β—H_1 bond is a distinct feature of the back-side approach. It is in contrast to the front-side attack, **5d**, where the agostic bond between the metal center and the C_β-H_1 linkage has to be broken before the insertion can take place. It is postulated (9*f*) that an α-agostic interaction, **5d**, in this case aids the stability of the transition state.



7

A full IRC path calculation from **6b** revealed that this structure is connected by steepest descend to the π-complex, **5b**, as well as the butyl product **7**. Thus, **6b** represents the transition state for the insertion process of Scheme 2. The energy profile obtained by following the IRC from **6b** is shown in Fig. 3. The insertion reaction is exothermic with a reaction enthalpy of 6.1 kcal/mol at the NL/P level of theory. The corresponding activation barrier is determined as 3.9 kcal/mol, Fig. 3. The butyl complex **7** is the kinetic product for the insertion process in Scheme 2. It has a single hydrogen on both the γ and δ carbon interacting with the metal center. The kinetic product **7** might well rearrange to a β-agostic conformation such as **2a**.

Fig. 3. Energy profile for the insertion process **5b** → **6b** → **7** along the IRC.

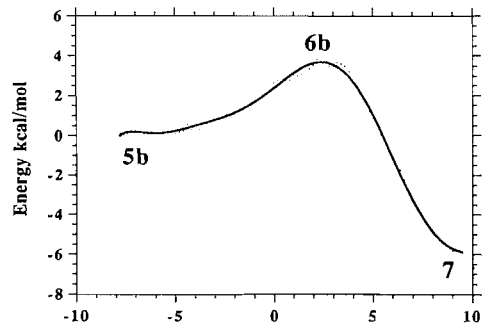


Fig. 4. Change in the $R(C_\alpha—C_{\beta'})$, $R(Ti—C_\alpha)$, and $R(Ti—C_{\alpha'})$ distances for the insertion process **5b** → **6b** → **7** along the IRC.

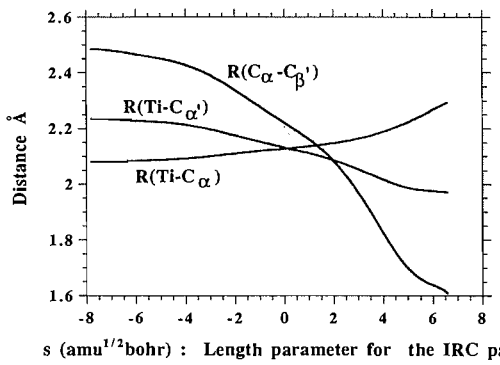

The insertion process of Scheme 2 gives rise to the formation of two bonds, C_α—$C_{\beta'}$ and Ti—$C_{\alpha'}$, whereas the Ti—$C_{\alpha'}$ linkage is broken. Figure 4 displays the change in the length of the three key bonds along the IRC. The graph underlines again that **6b** at $s = 0$ is an early transition state. It is also interesting to note that the two Ti—C bonds are about equidistant at the transition state. The three bonds are further seen to vary linearly in a wide region, $|s| < 4$, around **6b**. The C_α—$C_{\beta'}$ distance has often been used as a reaction coordinate in studies on the insertion process. Figure 4 suggests that this is a reasonable choice given the linear variation of C_α—$C_{\beta'}$ over a long range of the IRC.

4. Concluding remarks

We have carried out DFT-based calculations on the reaction between Cl_2Ti^+–ethyl and ethylene. The Cl_2Ti^+–ethyl species was considered as a model for the cationic group-4 metallocenes used in olefin polymerization (1). The Cl_2Ti^+–ethyl model had a ground state structure, **4a**, with a β-agostic conformation in which a single C_β—H bond is directed towards the metal center, and this conformation was also assumed to represent the resting state of the growing chain attached to the cationic group-4 metallocenes between insertions.

Olefin can approach **4a** in two ways. The first, Scheme 1, leads to an attack on the agostic C_β—H bond whereas the second, Scheme 2, results in an attack of the Ti—C_α link from the side opposite to the C_β—H bond. The present set of calculations found that the front-side attack in Scheme 1 leads to hydrogen exchange, Scheme 1(B), rather than ethylene insertion, Scheme 1(A). On the other hand, the back-side attack of Scheme 2 readily allows for the ethylene insertion.

The isotactic polymerization of propylene has been interpretated in terms of a front-side attack as shown in eq. [4].

[4] 
In the front-side attack the chain swings to the side of the incoming olefin following each insertion. Further, propylene will have its methyl group alternating between "up" and "down" in response to the steric demand of the L_2M^+ fragment of C_2 symmetry. However, the isotactic polymerization of propylene by the same L_2M^+ system can also be explained from a back-side approach as illustrated in eq. [5].

[5] 
Now the chain remains on one side and propylene is always approaching with the methyl group in the same position.

The syndiotactic propylene polymerization is also readily explained by the front-side approach as shown in eq. [6].

[6] 
Again, the chain swings to the side of the incoming olefin following each insertion. However, now the methyl group is always in the same (down) position, resulting in a syndiotactic chain growth.

In the corresponding back-side attack of eq. [7], the chain remains on one side and propylene is always approaching with the

[7] 
methyl group in the same position if its position is dictated by the steric requirement of the L_2M^+ fragment. Thus, the back-side attack would seemingly not produce the observed syndiotactic chain but instead result in a isotactic polymer.

It might seem that our notion about a preference for back-side insertion leads to predictions, eq. [7], in contradiction with experimental observation. However, it is also possible that the orientation of the methyl group on the incoming propylene is dictated by the chain *rather than* the L_2M^+ fragment. If the former is correct, back-side attack in eq. [7] would lead to syndiotactic polymers. We intend to explore this possibility by a combined DFT and molecular mechanics study in which the steric bulk of the ancillary ligands on the metal as well as the growing chain are taken into account.[2] We intend further to explore the front-side insertion, step A of Scheme 1, in more detail, although it seems that a possible transition state should be of high energy.

This study has also pointed to a facile pathway for chain termination via hydrogen exchange, path B of Scheme 1. Chain terminations have traditionally been associated with β-hydrogen abstraction. However, previous calculations from this group (10b) have shown that β-hydrogen abstraction is a high-energy process requiring more than 100 kJ/mol. We intend to explore further the viability of hydrogen exchange as a chain-terminating mechanism in olefin polymerization. Hydrogen exchange has recently been studied by Brintzinger and co-workers (27).

Enantioselective hydrosilation of ketones in the presence of an *S,S*-[1,2-bis(tetrahydroindenyl)ethane]-titanium catalyst

Shixuan Xin and John F. Harrod

Abstract: *S,S*-[1,2-Bis(tetrahydroindenyl)ethane]titanium-based catalysts were used, in conjunction with either diphenyl- or methylphenylsilane, to effect the catalytic hydrosilation of a wide variety of dialkyl ketones. The highest enantioselectivity was observed with *c*-pentylethylketone (70%) and the selectivity was found to be very sensitive to the steric qualities of the alkyl groups, e.g., iPr-Me (15%), iPr-Et (65%), iPr-*n*Pr (60%). Inclusion of a coordinating heteroatom in the alkyl group of the ketone substrate, or carrying out the reaction in a coordinating solvent such as THF, had no significant effect on the rate or selectivity of the reaction.

Key words: hydrosilation, enantioselective catalysis, ketones, *ansa*-metallocenes.

Résumé : On a utilisé des catalyseurs élaborés à partir du *S,S*-[1,2-bis(tétrahydroindényl)éthane]titane, en combinaison avec soit du diphényl- soit du méthylphénylsilane, pour effectuer l'hydrosilation catalytique d'un grand nombre de dialkylcétones. La plus grande énantiosélectivité a été observée avec la *c*-pentyléthylcétone (70%) et on a trouvé que la sélectivité est très sensible aux qualités stériques des groupes alkyles, par exemple, iPr-Me (15%), iPr-Et (65%), iPr-*n*Pr (60%). Si l'on introduit dans le substrat cétonique un hétéroatome pouvant créer une coordination ou si l'on effectue la réaction dans un solvant coordinant comme le THF, on n'observe aucun effet sur la vitesse ou la sélectivité de la réaction.

Mots clés : hydrosilation, catalyse énantiosélective, cétones, métallocènes-*ansa*.

[Traduit par la rédaction]

Introduction

We report here the results of a study of the hydrosilation of a number of prochiral ketones in the presence of a catalyst prepared by reacting *S*-[1,2-bis(tetrahydroindenyl)ethane]titanium(IV) precursors with MeLi, in the presence of organosilane. This study has focused particularly on the reaction of *dialkyl* ketones, for which previously reported asymmetric hydrosilations have only shown very poor enantioselectivities (1, 2). The reaction of primary and secondary organosilanes with simple ketones does not proceed at a measurable rate under ambient conditions in the absence of catalysts.

The susceptibility of hydrosilation to catalysis by coordination complexes has led to extensive study of this class of reaction as a route to chiral products (1). A number of highly enantioselective, chiral, late transition metal complexes have been reported to catalyze hydrosilation of olefinic and carbonyl-containing substrates (3 (reviews for asymmetric hydrosilation), 4). The emergence of chiral early transition metal *ansa*-metallocenes as a class of highly stereospecific catalysts for olefin polymerization has drawn attention to such compounds as potential agents for asymmetric synthesis, both in stoichiometric and catalytic contexts. Group 4 metallocenes have been reported to show activity for hydrosilation of both olefins (5) and ketones (6). A cursory study of the hydrosilation of octan-2-one and acetophenone by triethoxysilane in the presence of several chiral *ansa*-titanocenes gave very discouraging results with respect to enantioselectivity (7). A second report referred to the catalysis of ketone hydrosilation with a catalyst similar to that used in the present work, but no results were described (8).

In the present work we describe results obtained with *S*-[1,2-bis(tetrahydroindenyl)ethane]titanium(IV) catalysts. The catalysts were generated *in situ* by reaction of methyllithium with either the binaphtholate, **1**, or the dichloride, **2**, of S-[1,2-bis(tetrahydroindenyl)ethane]titanium(IV) (9). Although small differences in e/e (enantiomeric excess) were found between the two catalysts, the experiments with **2** confirm that the origin of enantioselectivity is the metal chirality and not the chirality of the ligand. Most the experiments were carried out with **1**, since the preparation and purification of resolved **2** requires several more synthetic steps than **1**.

Results and discussion

The results of a number of hydrosilations of prochiral ketones

Received October 17, 1994.

This paper is dedicated to Professor William A.G. Graham on the occasion of his 65th birthday.

by methylphenyl and diphenylsilanes, summarized in Table 1, lead to the following conclusions: (*i*) significant enantioselectivity can be observed for hydrosilation of simple dialkyl ketones with this catalyst, provided the substrate has appropriate steric encumbrance; (*ii*) the catalyst compares favorably with the best phosphine or rhodium catalysts for hydrosilation of dialkyl ketones (10), and much better than previously reported for *ansa*-titanocene catalysts (2, 7); (*iii*) with the present catalyst system, rates become very slow under conditions that give the highest selectivities; (*iv*) the presence of coordinating heteroatoms in the ketone do not inhibit the reaction, but do degrade the enantioselectivity; (*v*) a coordinating solvent (THF) has only a minor influence on enantioselectivity and rate.

To simplify the synthetic requirements of this project, most reactions were carried out with the binaphtholate, **1**, as catalyst precursor. Since it was necessary to establish that the observed enantioselectivity was not due to the influence of the naphtholate ligand, a limited number of test reactions were also carried out with the resolved dichloride, **2**. Although in general the trends in rate and selectivity for the two catalyst precursors were the same, in some cases dramatic differences were observed (e.g., entries 2 and 12). We do not presently have any information that would allow an explanation of this observation. The near quantitative recovery of lithium binaphtholate from the catalyst generation reaction makes any explanation based on the influence of residual binaphtholate implausible. However, since there is no evidence from other studies that significant racemization of the catalyst occurs under the conditions used to generate it in these reactions, it does seem likely that the explanation lies in a difference in the products of the reactions of MeLi with the two precursors.

In addition to the broad conclusions mentioned above, there are other interesting details in these results. In particular, it is evident that the enantioselectivity outcome becomes quite sensitive to small changes in the steric properties of the substrate at the limits of significant catalytic activity. For example, the change from methyl-isopropyl to ethyl-isopropyl ketone causes a dramatic increase in %e/e (entries 5 and 6), as does the change from ethyl-cyclohexyl to ethyl-cyclopentyl (entries 12 and 13). Although we do not have a simple explanation for these particular effects, it is quite clear that the topological constraints in the bisectorial plane of the ligand–metal centre are quite delicate and, if properly accessed, can give significant enantioselection. It may also be concluded that opportunities for fine tuning these constraints exist and could lead to even greater selectivity.

The absence of a significant effect of coordinating solvent, or coordinating atoms on the substrate, clearly shows that the reaction mechanism does not require a free coordination site on the catalyst. It had been hoped that the inclusion of weakly chelating atoms in the substrate would give a more rigid transition state and lead to higher enantioselectivity. The results show that this is clearly not the case.

An important, but puzzling, feature of the results is the reversal of absolute configuration of the product in some cases, with only seemingly minor structural modification in the substrate (entries 3 and 4, 5 and 6, and 11 and 13). With the exception of entry 10, it is the rule that methyl ketones give the *S*(+) products, while those ketones with both alkyl groups larger than methyl give *R*(−). This suggests the existence of two different enantioselective reaction channels. One, favoured by a large steric bias in the ketone, gives rise to *S*(+) stereochemistry, and a second, favoured by large total steric demand, gives rise to *R*(−) stereochemistry. The simultaneous operation of these two channels could be responsible for degradation of the enantioselectivity. The fact that relatively small changes in substrate topology can cause a dramatic switch from one channel to the other suggests that small changes in catalyst topology could well reinforce the effect and give more selectivity.

Rational modification of the catalyst topology is presently precluded by our ignorance of the mechanism(s) of these reactions. The mechanism(s) most probably involves a combination of insertions and σ-bond metatheses of the type:

[1] $\text{Ti-H} + \text{O=CRR}' \longrightarrow \text{Ti-O-CHRR}'$

[2] $\text{Ti-SiR}''_3 + \text{O=CRR}' \longrightarrow \text{Ti-CRR}'(\text{OSiR}''_3)$

[3] $\text{Ti-O-CHRR}' + \text{H-SiR}''_3 \longrightarrow \text{Ti-H} + \text{R}''_3\text{Si-O-CHRR}'$

[4] $\text{Ti-CRR}'(\text{OSiR}''_3) + \text{H-SiR}''_3 \longrightarrow \text{Ti-SiR}''_3 + \text{RR}'\text{HC-O-SiR}''_3$

A third possibility involves activation of a Si—H bond in a silyl ligand towards addition across the C=O bond.

[5] $\text{Ti-SiR}''_2\text{H} + \text{O=CRR}' \longrightarrow \text{Ti-SiR}''_2\text{O-CRR}'\text{H}$

[6] $\text{Ti-SiR}''_2\text{O-CRR}'\text{H} + \text{SiR}''_2\text{H}_2 \longrightarrow \text{Ti-SiR}''_2\text{H} + \text{HSiR}''_2\text{O-CRR}'\text{H}$

Such a mechanism has recently been observed in a rhodium-catalyzed reaction (11). The relatively large distance of the chiral carbon atom from the metal centre in the transition state for such a mechanism would not be expected to lead to strong enantioselection.

At the moment, it is still not clear whether the true catalyst involves Ti(III), or Ti(IV). We recently isolated the Ti(III) hydride dimer, *rac*-{[1,2-bis(tetrahydroindenyl)ethane]titanium(III)H}$_2$, **3**, in high yield from the reaction of *rac*-**2** with MeLi and PhMeSiH_2 (12). However, it cannot be excluded that the isolation of **3** is due to the fact that it is the least soluble species in the reaction mixture, since there is considerable evidence that titanocene(III) species disproportionate into titanocene(II) and titanocene(IV). Further, although less likely than eqs. [1]–[6], the possibility of a cycling between Ti(IV) and Ti(II) by concerted addition of H-Ti(IV)-Si to ketone to generate Ti(II), followed by oxidative addition of Si-H to Ti(II) to regenerate H-Ti(IV)-Si, cannot be excluded.

A final complication is suggested by some preliminary rate studies. The reaction rates are found to be second order in titanium concentration, a fact that can only be explained on the assumption that the rate-determining step involves either a bimetallic complex, or the reaction of two monometallic titanium complexes. In addition, preliminary results suggest there is a very slight decline in enantioselectivity with increasing catalyst concentration (e.g., for the reaction of entry 13 in the table, the e/e was found to drop from 69.0±1.0% to 65.4±1.0% on changing the catalyst concentration from 0.024 to 0.060 M). If this effect is real, then there must be two different pathways, with different dependencies on catalyst concentration. The pathway that is second order in catalyst is both the dominant pathway and the less enantioselective. To produce the observed

result, the second pathway, probably first order in catalyst, must have a much higher enantioselectivity.

We are continuing to explore the chemistry of this system, and undertaking a careful kinetic study, in order to resolve these questions. If the mechanism and nature of the two stereoselective channels can be identified, the prospect for the design of more reactive, and more enantioselective, catalysts of this type would be greatly improved.

Experimental

The catalyst precursors, **1** and **2**, were prepared and resolved by methods described in the literature (9). Silanes were prepared by $LiAlH_4$ reduction of the corresponding chlorosilanes, which were purchased fom Hüls America Inc. When unavailable from commercial suppliers, ketones were prepared by oxidation of the corresponding carbinols using standard organic reactions (13).

A typical hydrosilation reaction is as follows (all reactions carried out under inert atmosphere): the catalyst precursor (0.05 mmol) was disolved in 1 mL dry THF (or diethyl ether) in a light-shielded Schlenk tube, and 0.14 mmol MeLi (1.4 M solution in diethyl ether) was added. The mixture was stirred under dry argon until the reaction was complete by ^1H NMR (1 h in THF, or 12 h in ether). Either phenylmethyl- or diphenylsilane (5.0 mmol) was added and the mixture was stirred for 30 min to generate the active catalyst. Ketone (5.0 mmol) was then added and the reaction was followed to completion by ^1H NMR and (or) GLC. The mixture was then diluted with 10 mL of dry ether and cooled to −78°C. A PhMgBr solution in ether (6 mmol) was added dropwise via syringe over 10 min to cleave the alkoxysilane. The reaction was followed to completion by TLC (hexanes–THF) and warmed to 0°C. Cold HCl (5 mL; 2 N) was added to quench the reaction. The organic phase was separated and the aqueous phase was extracted with ether (2 × 5 mL). The combined organic phase was dried over anhydrous sodium sulphate and solvent was carefully removed. The oily residue was distilled under reduced pressure to yield the secondary alcohol with a small amount of silane contamination. The alcohol was then converted to the *R*-(+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid ester by standard procedures (14). The esterification reaction was run using a small excess of the acid chloride (10–15%), and to completion to avoid kinetic resolution effects. The e/e was calculated by integration of both ^1H ($CDCl_3$, 500 MHz) and ^{19}F ($CDCl_3$, 470.48 MHz) NMR spectra.

Abstract: The vinyl-bridged cationic complex, $[(\mu\text{-}CHCH_2)Os_2(CO)_8][BF_4]$ (**3**), is obtained readily and in excellent yield either *via* hydride abstraction from octacarbonyl diosmacyclobutane, $(\mu\text{-}\eta^1,\eta^1\text{-}CH_2CH_2)Os_2(CO)_8$ (**1**), or via protonation of octacarbonyl diosmacyclobutene, $(\mu\text{-}\eta^1,\eta^1\text{-}CHCH)Os_2(CO)_8$ (**2**). It is argued that the ^1H and ^{13}C NMR data of complex **3** are consistent with the traditional view of bonding in μ-alkenyl complexes, involving substantial σ,π donation. The solid state X-ray structure of the complex lends support for this formulation. Complex **3** crystallizes in the orthorhombic space group, $P2_12_12_1$, with a = 12.128(2) Å, b = 14.151(3) Å, c = 9.248(3) Å, V = 1587 Å^3, and Z = 4. The final R and R_w values are 0.032 and 0.038, respectively.

Key words: μ-vinyl, diosmacycles, X-ray structure.

Résumé : On obtient facilement et avec un excellent rendement le complexe cationique comportant un pont vinyle, $[(\mu\text{-}CHCH_2)Os_2(CO)_8][BF_4]$ (**3**), soit par l'enlèvement d'un hydrure du diosmacyclobutane octacarbonyle, $(\mu\text{-}\eta^1,\eta^1\text{-}CH_2CH_2)Os_2(CO)_8$ (**1**), soit par une protonation du diosmacyclobutène octacarbonyle, $(\mu\text{-}\eta^1,\eta^1\text{-}CHCH)Os_2(CO)_8$ (**2**). On insiste sur le fait que les données de la RMN du ^1H et du ^{13}C du complexe **3** sont en accord avec le point de vue traditionnel relatif aux liaisons des complexes μ-alcényles, impliquant un don σ,π important. La structure du complexe à l'état solide, telle que déterminée aux rayons X, supporte ce point de vue. Le complexe **3** cristallise dans le groupe d'espace orthorhombique $P2_12_12_1$, avec a = 12,128(2), b = 14,151(3) et c = 9,248(3) Å, V = 1587 Å^3 et Z = 4. Les valeurs finales de R et R_w sont respectivement 0,032 et 0,038.

Mots clés : μ-vinyle, cycles diosmiques, structure aux rayons X.

Introduction

The classical method for providing support for proposed mechanisms of homogeneous and heterogeneous catalytic processes and for surface reactions is the synthesis of "model compounds" of the purported intermediates or proposed surface species (1). A prerequisite for the successful isolation and characterization of targeted model compounds is their robustness. Consequently, third-row transition metals, with strong M—L bonds (2), are particularly well suited and have been used extensively for such purposes.

In the annals of the iron triad organometallic chemistry, osmium occupies a unique place (3). Pioneering work by Professor Graham has been instrumental in identifying some of the unique characteristics, with the synthesis of the singly bridged $Os_2(CO)_9$ (4*a*) and the formation of metal chain structures with no bridging ligands, $H_2Os_3(CO)_{12}$ (4*b*) and $ClOs_3(CO)_{12}SnCl_3$ (4*c*). Thus, in hindsight, it may not be totally unexpected that it was osmium which proved to be the first transition metal capable of supporting simple dimetallacyclobutane-type structures, $(\mu\text{-}\eta^1,\eta^1\text{-}CH_2CH_2)Os_2(CO)_8$ (**1**) and substituted derivatives (5), and to provide entry to an extensive series of $M(CO)_4(\eta^2\text{-alkyne})$ complexes of surprising reactivity (6), including facile condensation reactions leading to dimetallacyclobutene, $(\mu\text{-}\eta^1,\eta^1\text{-}CHCH)Os_2(CO)_8$ (**2**), and dimetallacyclopentenone-type products.

Diosmacycles **1** and **2** are attractive candidates as models for the early stages of chemisorption of ethylene and acetylene on metal surfaces (7). Indeed, **1** has been shown to be an excellent model for di-σ-bonded ethylene chemisorbed on Pt(111) at low temperatures (8), while the ready displacement of ethylene from **1** by olefins (9) and alkynes (10) mimics the desorption step, prior to chemical transformation, from surfaces. Once adsorbed, surface ethylene is known to undergo a complex series of transformations (11), the first step being formation of μ-vinyl species. Here we report that complex **1** is capable of supporting chemical transformations; hydride

abstraction leads to $(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)Os_2(CO)_8^+$ (**3**), a species also available via protonation of the diosmacyclobutene complex **2**.

Experimental

All manipulations were carried out under an atmosphere of prepurified nitrogen or argon using standard Schlenk technique in conjunction with a double vacuum manifold. Solvents were distilled from appropriate drying agents under nitrogen prior to use (CH_2Cl_2 from P_4O_{10}, hexane from potassium metal, and pentane from CaH_2). Acetone, reagent grade, was dried over molecular sieves. $Ph_3C^+BF_4^-$ (Aldrich) was recrystallized from CH_2Cl_2–hexane, and $HBF_4{\cdot}OEt_2$ (Aldrich) was used as received. The diosmacyclic compounds were prepared by literature methods, $(\mu\text{-}\eta^1,\eta^1\text{-}CH_2CH_2)Os_2(CO)_8$ (**1**) (10*b*) and $(\mu\text{-}\eta^1,\eta^1\text{-}CHCH)Os_2(CO)_8$ (**2**) (6).

Infrared spectra were recorded in CH_3NO_2 solution (0.1 mm path length KBr and CaF_2 cells) on a Nicolet MX-1 FTIR spectrometer. ^1H and ^{13}C NMR spectra were collected on a Bruker WP-400 spectrometer. Elemental analyses were performed by the microanalytical services of the Department of Chemistry, University of Alberta.

Preparation of $[(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)Os_2(CO)_8][BF_4]$ (3)

Method A: hydride abstraction from $(\mu\text{-}\eta^1,\eta^1\text{-}CH_2CH_2)Os_2(CO)_8$ (1)

A solution of 0.316 g (0.500 mmol) of **1** in 125 mL of CH_2Cl_2 was cooled to −78°C under nitrogen and 0.182 g (0.550 mmol) of $Ph_3C^+BF_4^-$ was added as a solid to the stirred solution. After warming to room temperature CH_2Cl_2 was removed in vacuo. The residue was extracted with acetone and filtered. Hexanes were added to the filtrate, resulting in a white precipitate. The precipitate was collected, washed with a small amount of CH_2Cl_2, and recrystallized by pentane diffusion into a solution of acetone. This gave **3** (0.330 g, 92%) as off-white crystals that decompose at 220°C. IR (cm^{-1}, CH_3NO_2) ν_{CO}: 2166 w, 2132 s, 2081 vs, 2070 sh, 2045 s. ^1H NMR (δ, CD_3NO_2): 8.56 (dd, J = 9 and 15 Hz, 1H), 5.86 (d, J = 9 Hz, 1H), 3.88 (d, J = 15 Hz, 1H). ^{13}C NMR (δ, CD_3NO_2): 176.3, 172.6, 171.2, 171.1, 170.6, 168.4, 165.7, 164.4, (*CO*); 134.9 (*CH*); 64.8 (CH_2). Anal. calcd. for $C_{10}H_3BF_4O_8Os_2$: C 16.72, H 0.42; found: C 16.64, H 0.42.

Method B: protonation of $(\mu\text{-}\eta^1,\eta^1\text{-}CHCH)Os_2(CO)_8$ (2)

A solution of 0.041 g (0.065 mmol) of **2** was dissolved in 10 mL of CH_2Cl_2 under argon and cooled to −78°C. To this solution was added 8.0 μL (0.065 mmol) of $HBF_4{\cdot}Et_2O$ via syringe. The solution was allowed to warm to room temperature. Solvent was removed in vacuo and the residue recrystallized from acetone–pentane to give off-white crystals of **3** (0.035 g, 75%).

Hydride addition to $[(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)Os_2(CO)_8][BF_4]$ (3)

A solution of 0.053 g (0.074 mmol) of **3** in 20 mL of acetone under argon was treated with 0.003 g (0.079 mmol) of $NaBH_4$ at room temperature. After stirring the reaction mixture for 70 min a sample aliquot showed that no **3** remained in solution. Solvent was removed in vacuo and the resulting residue was extracted with the minimum amount of pentane. Cooling the solution gave **1** (0.015 g, 32%) as evidenced by IR and ^1H NMR spectroscopy. It should be noted that in a separate experiment **1** itself was found to react with $NaBH_4$ under the conditions of this procedure, accounting in part for the low isolated yield in the hydride addition reaction.

X-ray crystal structure analysis

A white, needle-shaped, crystal of **3** was mounted in a nonspecific orientation on an Enraf–Nonius CAD4 automated diffractometer. Accurate cell parameters and crystal orientation matrices were obtained from least-squares refinement of the setting angles of 22 reflections in the range $9 < 2\theta < 23°$.[3] Crystal data, details of the data collection, and structure refinements are summarized in Table 1.

The intensity data were collected at room temperature. Two standard reflections were measured every 60 min to check on crystal and electronic stability over the course of data collection; no significant changes were observed. The data were corrected for Lorentz, polarization, and background effects. Absorption effects were corrected also using an empirical correction based on the absorption surface method of Walker and Stuart (12). The maximum and minimum correction coefficients applied to F_o were 1.2221 and 0.6351, respectively.

The structure was solved using the direct method program MULTAN,[4] which gave the positional parameters for the Os atoms. The remaining non-hydrogen atoms were located by the usual combination of least-squares refinement and difference Fourier synthesis.[5] Refinement of atomic parameters was carried out by using full-matrix least-squares technique on F_o, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$. The neutral atomic scattering factors were calculated from the analytical expression for the scattering factor curves (14*a*). The f' and f'' components of anomalous dispersion (14*b*) were included in the calculations for all non-hydrogen atoms. Two of the three H atoms were located in a difference Fourier map and their contributions were included as fixed atoms with fixed isotropic thermal parameters. In the final cycle, all non-hydrogen atoms were refined anisotropically; the final agreement factors were R = 0.032 and R_w = 0.038. The largest shift in any parameter was 0.04 times its estimated standard deviation. The highest peak in the final difference Fourier map was 2.6(3) e Å^{-3} and was located between the two Os atoms. Final atomic positional and equivalent isotropic thermal parameters are given in Table 2, selected bond distances and angles are listed in Table 3. Supplementary X-ray analysis details, anisotropic thermal parameters, derived hydrogen

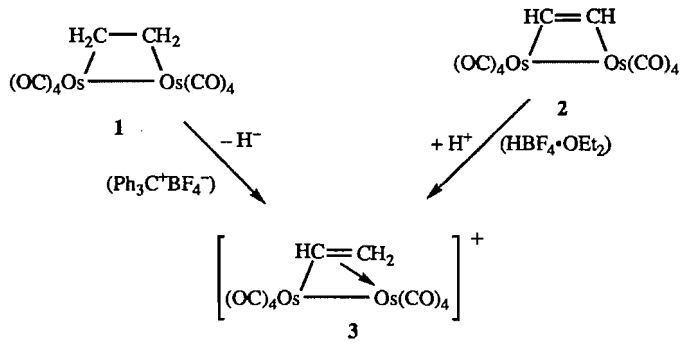
atom parameters, and complete tables of bond lengths, bond angles, and torsional angles have been deposited.[6]

Results and discussion

Syntheses

Hydride abstraction from octacarbonyl diosmacyclobutane (**1**) or proton addition to octacarbonyl diosmacyclobutene (**2**) proceed readily and give the cationic μ-vinyl complex, $[(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)Os_2(CO)_8][BF_4]$ (**3**) as an off-white air-stable solid in excellent yield (Scheme 1). There are numerous methods available for the preparation of bimetallic μ-alkenyl com-

Scheme 1.



plexes related to **3**. These include insertion of a metal into vinylic C—S (15) or C–halogen (16) bond, protonation of alkyne-bridged bimetallic complexes (17) and dimetallacyclopentenones (18), rearrangement of μ-alkylidyne complexes and their reactions with alkenes (19), β-hydride abstraction from μ-alkylidene complexes (20), and addition of alkynes to transition metal carbonyl hydrides (21). Thus, although the protonation route to **3** is precedented, conversion of **1** is the first documented example of an α-hydride abstraction from a saturated dimetallacyclic species toward μ-alkenyl com-

[a]*Indicates an atom refined anisotropically.

The equivalent isotropic thermal parameter is given by: $U = 1/3\ (U_{11} + U_{22} + U_{33} + 2U_{23} \cos\alpha + 2U_{13} \cos\beta + 2U_{12} \cos\gamma)$.

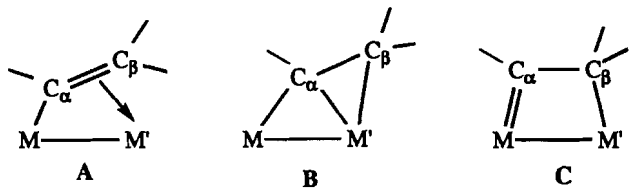
plexes. The reaction finds analogy in the elegant work of Gladysz and co-workers (22) whereby terminal rhenium-alkylidene complexes $[Re{=}CHR']^+$ (where Re is the $(C_5R_5)Re(NO)L$ fragment, R = H, Me) were generated via α-hydride abstraction from rhenium-bonded hydrocarbyl ligands. No doubt, the strength of the metal–carbon σ-bond, in both instances, is responsible in no small part for the successful outcome of these transformations.

Spectroscopic features and μ-vinyl bonding

Infrared monitoring of the reactions indicated clean conversion to complex **3**. The shift to higher frequencies of the terminal carbonyl-stretching bands compared to the parent complexes (ranges in **1** and **2** are 2122–1967 and 2129–1970 cm^{-1}, respectively) is consistent with the formation of a cationic complex and, consequently, the more electron-deficient nature of the osmium centers in complex **3**.

The ^1H NMR spectrum displays three resonances at 8.56 (dd, J = 9 and 15 Hz), 5.86 (d, J = 9 Hz), and 3.88 (d, J = 15 Hz). The coupling pattern is typical of that observed previously in μ-vinyl complexes, for instance $(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)(\mu\text{-}SR)Fe_2(CO)_6$ (15) and $[(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)(\mu\text{-}CO)M_2(C_5H_5)_2(CO)_2]^+$ (M = Fe, **4Fe**; Ru, **4Ru**) (18), with *J*(*trans*) > *J* (*cis*) > *J* (*geminal*), the latter small coupling being unobserved in the present case. On this basis the signal at 8.56 ppm is assigned to the vinylic C*H* proton and the other two signals to the methylenic hydrogens *cis* and *trans* to it, respectively. The ^{13}C NMR spectrum shows two signals for the μ-vinyl group at 134.9 and 64.8 ppm, attributable to the vinylic *C*H, and methylenic *C*H_2 carbons, respectively. In addition, there are eight well-resolved terminal carbonyl signals. Corroborating the IR observation, the range of the carbonyl signals, 176.3–164.4 ppm, is at higher field than those of the diosmacyclic parents (**1**, 180.7–169.7 ppm; **2**, 178.4–169.2 ppm). The observation of eight distinct carbonyl signals clearly shows that the molecule is static at room temperature and, since the ^{13}C NMR spectrum is invariant to 90°C, it remains so up to this temperature. Although vinyl group oscillation between two metal centers is well known (23) and renders numerous μ-alkenyl complexes fluxional, the energetics of the process are both substituent (18, 19*a*) and metal dependent (18). In particular, Knox and co-workers have shown that for complexes **4** the onset of vinyl oscillation for the iron complex is around 50°C, whereas the analagous ruthenium complex is static at this temperature (18). Following this trend, the lack of fluxionality of complex **3** is not that surprising.

The bonding in μ-alkenyl complexes has been described in terms of contributions from three VB (valence bond) structures. The early σ,π description **A** (24) has lately been taken over by the dimetallabicyclobutane description (**B**) both on the



basis of NMR data (18, 19) and structural parameters (25). Indeed the typically low-field ^1H and ^{13}C NMR positions of the $C_\alpha H$ unit argue for substantial μ-carbene character (26). Very convincing examples are provided by the complexes $[(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)(\mu\text{-}CO)M_2(C_5H_5)_2(CO)_2]^+$ (M = Fe, **4Fe**; Ru, **4Ru**) prepared by Knox and co-workers (18). The ^1H and ^{13}C chemical shifts are 12.57, 11.22 and 185.8, 163.6 ppm, respectively, and are similar to those of the μ-carbene complex $[(\mu\text{-}C(H)Me)(\mu\text{-}CO)Fe_2(C_5H_5)_2(CO)_2]$ (27): 11.60 ppm μ-C*H*-(Me) and 172.9 ppm, μ-*C*H(Me). Chisholm and co-workers (28) have argued for contribution from VB structure **C** in $(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)(\mu\text{-}CH_2NMe)W_2Cl_3(NMe_2)_2(PMe_2Ph)_2$, mostly on the basis of metrical parameters (vide infra), but the pronounced low-field position of the $C_\alpha H$ proton (14.75 ppm) and the high-field shift of one of the methylenic protons (1.75 ppm) were also taken as evidence for this.

Compared to these data, the observed ^1H and ^{13}C chemical shifts of the $C_\alpha H$ unit in complex **3** are at higher field (8.56 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

134.9 ppm, respectively) and argue for *less* μ-carbene character and consequently more substantial contribution from the σ,π-vinyl-type bonding, a return to the former traditional description. Thus, it appears that reduced back bonding from the electron-deficient $Os(CO)_4^+$ fragment to the bridging vinyl moiety is sufficient to favor form **A** over **B**; form **C** appears not to make significant contribution to the bonding.

It is interesting that the change in bonding is reflected in the chemical behavior of **3**. Normally cationic μ-alkenyl complexes undergo nucleophilic attack, including hydride addition, at the β carbon to generate μ-alkylidene complexes (18, 19*a*, 20*b*, 27). Hydride attack of **3** is dominated by addition to the α-carbon and regeneration of the parent octacarbonyl diosmacyclobutane **1**. It is not immediately obvious why the σ,π-vinyl bonding should lead to preferential C_α attack, especially in view of the existence of $[(\mu\text{-}C(H)Me)Os_2(CO)_8]$ (5*a*), the expected product of C_β attack. Nevertheless, it is interesting to note that whereas hydride addition to **4Fe** proceeds exclusively at the C_β carbon, the ruthenium congener also undergoes minor C_α attack as evidenced by the low-yield formation of the terminal ethylene complex, $[(\mu\text{-}CO)_2Ru_2(C_5H_5)_2(CO)(C_2H_4)]$ (18). Thus, both the chemical and fluxional behavior of complex **3** follow and complete the observed triad trend of Knox on compounds **4Fe** and **4Ru**.

Molecular structure of 3

To obtain precise metrical parameters and to possibly provide quantitative support for the tendency toward σ,π-vinyl bonding, the solid state structure of **3** was determined by single-crystal X-ray analysis. Two views of the cation, with labeling scheme, are shown in Fig. 1, selected bond distances and angles are listed in Table 3.

The figure shows the now classical orientation and bonding of a bridging vinyl unit, σ-bonded to one osmium (Os2) and π-bonded via the double bond to the other osmium (Os1), which carries the formal positive charge. The μ-vinyl moiety is skewed with respect to the Os—Os bond and the two $Os(CO)_4$ fragments are rotated away from eclipsed conformation by an average of 22°. Puckering of the four-membered diosmacyclobutane ring and concomitant twisting of the $Os(CO)_4$ fragments were also observed in complex **1** (8*a*) and its substituted derivatives (5*b*, 9*c*); the respective average values are 27° and 20°. An Os—Os single bond and four carbonyl ligands on each osmium complete the 18-electron requirements of the metals. The Os1—Os2 distance, 2.8569(5) Å, is typical of an Os—Os single bond and compares favorably to 2.845(1) Å, the vinyl-bridged Os—Os bond in $[(\mu\text{-}CHCH_2)(\mu\text{-}H)Os_3(CO)_{12}]$ (29).

As discussed in the previous section, the bonding of the (μ-vinyl)MM′ fragment has been described mainly in terms of two limiting VB canonical structures, σ,π donation (**A**), and localized dimetallabicyclobutane extremes (**B**). Of course, in molecular orbital (MO) parlance there is a continuum between the extremes, akin to the Dewar–Chatt–Duncanson description of metal–olefin bonding. Nevertheless, a measure of the relative importance of the different VB forms obtains on the basis of the metrical parameters. Thus, near-symmetric metal–C_α distances are consistent with form **B** and the μ-carbenoid character of the C_α carbon. It is on this basis that previous iron triad μ-vinyl complexes were assigned this form, in accord with their NMR chemical shift values (vide supra). The

Fig. 1. Two perspective views of the μ-vinyl cation $[(\mu\text{-}\eta^1\text{-}\eta^2\text{-}CHCH_2)Os_2(CO)_8]^+$ showing the atom numbering scheme. Probability ellipsoids are shown at 50% level for non-hydrogen atoms; the latter are drawn as spheres of arbitrary radius.

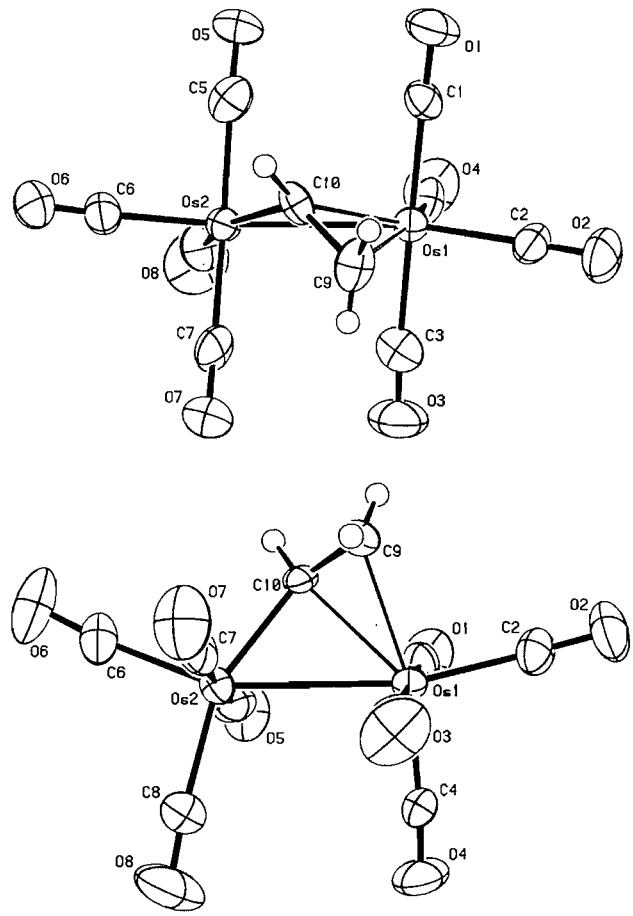


Table 3. Selected bond distances (A) and angles (deg) for $[(\mu\text{-}\eta^1,\eta^2\text{-}CHCH_2)Os_2(CO)_8][BF_4]$ (**3**).

Bond distances

				Os1	Os2	C6	157.2(4)

[a]Numbers in parentheses are estimated standard deviations in the least significant digit.

M,M′—C_α distances in $[(\mu\text{-}CHCH_2)(\mu\text{-}CO)Fe_2(C_5H_5)_2(CO)_2]^+$ (**4Fe**) (25) and $[(\mu\text{-}CHCH_2)(\mu\text{-}H)Os_3(CO)_{10}]$ (29) are 1.980(8) Å for both, and 2.107(3) and 2.273(3) Å, respec-

tively. The nonbridging M′—C_β distance is uniformly longer (2.21(2) Å and 2.362(3) Å), respectively. Clearly, **4Fe** conforms more closely to form **B**. An interesting exception is Chisholm's (μ-$CHCH_2$)(μ-CH_2NMe_2)$W_2Cl_3(NMe)_2(PMe_2Ph)_2$ complex (28) where the difference between M—C_α and M′—C_α distances is pronounced, 2.04(1) versus 2.32(1) Å, with the former the much shorter bond. In addition the M′—C_β distance 2.25(1) Å is shorter than the M′—C_α bond length. The distribution of the metal–carbon distances led to the suggestion of significant contribution from "terminal" metal carbene-type bonding (**C**) in this complex. The relevant M,M′—C_α and M′—C_β distances in complex **3** are Os2—C10 2.061(9) Å, Os1—C10 2.300(10) Å, and Os1—C9 2.340(10) Å, respectively. Although the M—C_α length is short, the other parameters are not in accord with contribution from VB descriptions **C**. If anything, it appears that the σ,π-vinyl structure (**A**) make a more significant contribution to the bonding in **3** than in the related cationic iron complex **4Fe**. The NMR features of the complex also implied this situation. The C—C distance of the coordinated vinyl ligand, C9—C10 is 1.41(2) Å. The lengthening from the free C=C double bond value, 1.34 Å, is expected upon metal coordination. The length of the bond is similar to that found in other μ-vinyl complexes (1.40(2) Å in **4Fe** and 1.42(2) Å in the abovementioned tungsten complex), but shorter than the C—C distance of coordinated ethylene in $Os(CO)_4(\eta^2\text{-}C_2H_4)$ (1.488(24) Å), which has been described as an osmacyclopropane (30). In short, the structural features support significant contribution from VB description **A** to the bonding in complex **3**.

Conclusion

The diosmacyclic complexes **1** and **2** are easily converted to the μ-vinyl cation **3**. The ease of transformations, the stability of the species, and the different behavior of **3** toward hydride addition compared to related iron and ruthenium complexes all are in line with the unique place osmium occupies in the iron triad transition metals.

Acknowledgments

Financial support from The Natural Sciences and Engineering Research Council of Canada and the University of Alberta is gratefully acknowledged. J.T. wishes to thank Bill Graham for "showing the way." Good example generates faithful following, and osmium has also served the author very well for the past several years.

Bidentate and terdentate (P-N-S) complexes of a new thioether azine phosphine *Z,E*-$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4) with molybdenum, tungsten, or platinum

Sarath D. Perera, Mustaffa Shamsuddin, and Bernard L. Shaw

Abstract: Treatment of *Z*-$PPh_2CH_2C(Bu^t)$=NNH_2 with 4-methylphenylthiomethyl methyl ketone gave the thioether azine phosphine *Z,E*-$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4) **1**, which with H_2O_2 gave the corresponding phosphine oxide **2**. Treatment of **1** with [$Mo(CO)_3(\eta^6$-cht)] or [$W(CO)_3(NCEt)_3$] gave the yellow tricarbonyl complexes *fac*-[$M(CO)_3${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4}] **3a** (Mo) or **3b** (W), respectively. Treatment of **1** with [$Mo(CO)_4$(nbd)] gave the pale yellow tetracarbonylmolbdenum(0) complex [$Mo(CO)_4${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}] **4**, in which the ligand **1** is bidentate through P and N. Oxidation of either **3a** or **4** with 1 equivalent of bromine gave the orange neutral seven-coordinate dicarbonylmolybdenum(II) complex [$MoBr_2(CO)_2${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}] **5**, whereas the tungsten complex **3b** with 1 equivalent of bromine gave the seven-coordinate tricarbonyltungsten(II) cation [$WBr(CO)_3${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}]$^+$ isolated as the PF_6 salt **6**. Treatment of **1** with [$PtCl_2(NCMe)_2$]gave the yellow dichloroplatinum(II) complex [$PtCl_2${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}] **7**, in which **1** is bidentate through P and N. When **7** was treated with NH_4PF_6 in methanol it gave the terdentate salt [PtCl{$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}]PF_6 **8a**. Deprotonation of **7** with NEt_3–NaOH gave the orange neutral chloroplatinum(II) complex [PtCl{PPh_2-$CH_2C(Bu^t)$=N-NC(Me)=CHS(C_6H_4Me-4)}] **9**, containing a terdentate ene-hydrazone phosphine ligand. This neutral complex **9** was reprotonated using HBF_4 to give the BF_4 salt **8b**. Treatment of the phosphine **1** with [$PtMe_2$(cod)] gave the white dimethylplatinum(II) complex [$PtMe_2${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)CH_2-$S(C_6H_4Me$-4)}] **10**, containing the bidentate azine ligand. Treatment of **10** with MeI gave the white platinum(IV) iodide salt *fac*-[$PtMe_3${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}]I **11a** in which the azine is terdentate. When **11a** was treated with NH_4PF_6 in MeOH the PF_6 salt **11b** was obtained. Treatment of **10** with picric acid gave the yellow methylplatinum(II) picrate salt [PtMe{$PPh_2CH_2C(Bu^t)$=N-N=C(Me)CH_2-$S(C_6H_4Me$-4)}][$OC_6H_2(NO_2)_3$-2,4,6] **12** and methane. Infrared, ^{31}P–[^1H], ^1H, and some ^{13}C–[^1H] NMR data are given.

Key words: azine phosphine, thioether, metal-carbonyls, platinum.

Résumé : La réaction de la *Z*-PPh_2CH_2C(*tert*-But)=NNH_2 avec la (4-méthylphénylthiométhyl)méthylcétone conduit au thioéther de la phosphine d'azine *Z,E*-PPh_2CH_2C(*tert*-Bu)=N-N=C(Me)$CH_2S(C_6H_4Me$-4), **1**, qui, par réaction avec du H_2O_2, fournit l'oxyde de phosphine correspondant, **2**. Le traitement du composé **1** avec du [$Mo(CO)_3(\eta^6$-cht)] ou [$W(CO)_3(NCEt)_3$] fournit des complexes tricarbonyles jaunes *fac*-[$M(CO)_3${PPh_2CH_2C-(*tert*-Bu)=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}], respectivement **3a** (M = Mo) et **3b** (M = W). Le traitement du composé **1** avec du [$Mo(CO)_4$(nbd)] fournit le complexe jaune pâle tétracarbonylmolybdène(0) [$Mo(CO)_4$-{PPh_2CH_2C(*tert*-Bu)=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}], **4**, dans lequel le coordinat **1** est bidentate par les atomes de P et ce N. L'oxydation soit de **3a** ou de **4** avec un équivalent de brome donne un complexe orange, neutre, heptacoordiné dicarbonylmolybdène(II) [$MoBr_2(CO)_2${PPh_2CH_2C(*tert*-Bu)=N-N=C-(Me)$CH_2S(C_6H_4Me$-4)}], **5**, alors que le complexe de tungstène, **3b**, sous l'action d'un équivalent de brome fournit le cation heptacoordiné tricarbonyltungstène(II), [$WBr(CO)_3${PPh_2CH_2C(*tert*-Bu)=N-N=C-(Me)$CH_2S(C_6H_4Me$-4)}]$^+$, isolé sous la forme de son sel de PF_6, **6**. Le traitement du composé **1** par du [$PtCl_2(NCMe)_2$] donne le complexe jaune de dichloroplatine(II), [$PtCl_2${PPh_2CH_2C(*tert*-Bu)=N-

N=C(Me)$CH_2S(C_6H_4Me$-4)}], **7**, dans lequel **1** est bidentate par le biais des atomes de P et de N. Lorsqu'on traite le composé **7** avec du NH_4PF_6 dans le méthanol, il fournit le sel tridentate [PtCl{PPh_2CH_2C(*tert*-Bu)=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}]PF_6, **8a**. La déprotonation du composé **7** à l'aide de NEt_3–NaOH fournit un complexe orange neutre de chloroplatine(II), [PtCl{PPh_2CH_2C(*tert*-Bu)=N-NC(Me)=CHS$(C_6H_4Me$-4)}], **9**, qui contient un coordinat phosphine ène-hydrazone tridentate. On a reprotoné ce complexe neutre **9** à l'aide de HBF_4 pour obtenir le sel de BF_4, **8b**. Le traitement de la phosphine **1** avec du [$PtMe_2$(cod)] fournit le complexe blanc de diméthylplatine(I), [$PtMe_2${PPh_2CH_2C(*tert*-Bu)=N-N=C(Me)-$CH_2S(C_6H_4Me$-4)}], **10**, qui contient un coordinat azine bidentate. Le traitement du composé **10** par du MeI fournit un sel blanc d'iodure de platine(IV), *fac*-$PtMe_3${PPh_2CH_2C(*tert*-Bu)=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}]I, **11a**, dans lequel l'azine est tridentate. Quand on traite le composé **11a** avec du NH_4PF_6 dans le MeOH, il y a formation du sel de PF_6, **11b**. Le traitement du composé **10** avec de l'acide picrique fournit le picrate jaune de méthylplatine(II), [PtMe{PPh_2CH_2C(*tert*-Bu)=N-N=C(Me)$CH_2S(C_6H_4Me$-4)}][$OC_6H_2(NO_2)_3$-2,4,6], **12**, et du méthane. On rapporte les données IR et de RMN du $^{31}P-\{^1H\}$ et du ^1H et quelques données de $^{13}C-\{^1H\}$.

Mots clés : phosphine d'azine, thioéther, métal-carbonyles, platine.

[Traduit par la rédaction]

Introduction

In a previous paper (1) we described the preparation of a new chelating (P-N) ligand *Z*-$PPh_2CH_2C(Bu^t)$=NNH_2 from the phosphino dimethylhydrazone *Z*-$PPh_2CH_2C(Bu^t)$=$NNMe_2$ using a hydrazine exchange reaction. *Z*-$PPh_2CH_2C(Bu^t)$=NNH_2 condenses with aldehydes and ketones {QC(=O)R} to give mixed-azine monophosphines of type *Z,E*-$PPh_2CH_2C(Bu^t)$=N-N=C(Q)R (1–10), where Q = H or Me and R is sterically more demanding than Q. We have studied the coordination chemistry of these azine phosphines, in particular, the promotion of agostic C—H interaction (3) or aryl fluoride coordination (4) with ruthenium(II), and cyclometallation with Ir(I) (5, 6), W(0) (7), and Pt(II) (8). We have also reported the synthesis of an azine diphosphine *Z,Z*-$PPh_2CH_2C(Bu^t)$=N-N=$C(Bu^t)$-CH_2PPh_2 (11), and the ability of it, or its corresponding *E,Z* isomer, to coordinate to group 6 metal carbonyls (11), and also to platinum and palladium (12, 13), either as a bidentate (P-P) or as a terdentate (P-N-P) ligand. We incorporated the thioether functionality into our azine–phosphine system, in order to investigate the coordination chemistry of a potential terdentate (P-N-S) ligand. In this paper we describe the synthesis of a new thioether azine phosphine *Z,E*-$PPh_2CH_2C(Bu^t)$=N-N=C(Me)CH_2-$S(C_6H_4Me$-4) **1** and its complexes with transition metals such as molybdenum, tungsten, or platinum. There are several reports (14–21) on bidentate (P-S) ligands, viz. $Ph_2P(CH_2)_nSR$ (*n* = 1–3, R = H, Me, Et, or Ph) (16–18, 20); *o*-$Ph_2PC_6R_4SMe$ (R = H or F) (14, 15); $PhP(o\text{-}C_6R_4SMe)_2$ (R = H or F) (14, 19); $P(o\text{-}C_6H_4SMe)_3$ (19); and Ph_2PCH_2P(=S)Ph_2 (21); etc. Tertiary phosphine ligands containing both nitrogen and sulfur donor atoms are rare (22, 23); potential terdentate phosphine ligands $PPh_2CH_2CH(NMe_2)(CH_2)_nSMe$ (*n* = 2, 3), derived from α-amino acids, formed bidentate palladium(II) complexes [$PdCl_2${$PPh_2CH_2CH(NMe_2)(CH_2)_nSMe$}], in which sulfur was not coordinated to palladium (23). Very recently, Faller et al. (24) reported the synthesis of the analogous phosphinite ligands $PPh_2OCH_2CH(NMe_2)(CH_2)_nSMe$ (*n* = 1, 2) and their terdentate (P-N-S) complexes of type *fac*-[$M(CO)_3${PPh_2-$OCH_2CH(NMe_2)(CH_2)_nSMe$}] (M = Mo or W).

Results and discussion

Complexes of 1 with molybdenum and tungsten

The phosphino hydrazone *Z*-$PPh_2CH_2C(Bu^t)$=NNH_2 (1) condensed rapidly with 4-methylphenylthiomethyl methyl ketone in ethanol to give the crystalline thioether azine phosphine *Z,E*-$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4) **1** in 84% yield. The various reactions of the thioether azine phosphine **1** are summarized in Schemes 1 and 2. Elemental analytical and some mass spectral and carbon-13 NMR data are in the Experimental, IR and phosphorus-31 NMR data are in Table 1, and proton NMR data in Table 2. Carbon-13 spectra were assigned using Attached Proton Tests (APT) and by comparison with published data (2, 7, 11–13). Some satellites due to platinum-195 coupling were not identified because of their low intensities or broadness. The $^{31}P-\{^1H\}$ NMR spectrum of the phosphine **1** in $CDCl_3$ was a singlet at −11.1 ppm. The proton NMR spectrum showed a doublet at 3.22 ppm with ^2J(PH) = 4.2 Hz and singlet at 3.28 ppm for the CH_2P and CH_2S protons, respectively. The azine phosphine **1** was treated with an excess of H_2O_2 to give the corresponding phosphine oxide **2** as a white solid in 88% yield. The phosphine oxide **2** showed a phosphorus-31 resonance at 24.4 ppm and, in the proton NMR spectrum, the CH_2P(=O) protons showed a large coupling to P(V), ^2J(PH) = 15.0 Hz.

We first investigated the coordinating ability of the thioether azine phosphine **1** as a terdentate ligand with Mo(0) and W(0) (Scheme 1). Treatment of **1** with [$Mo(CO)_3(\eta^6$-cht)] (25) (cht = cyclohepta-1,3,5-triene) in benzene solution displaced cyclohepta-1,3,5-triene to give the tricarbonylmolybdenum(0) complex **3a** as yellow needles in 85% yield. The infrared spectrum of this complex showed two strong bands for ν(C≡O) at 1930 and 1810 cm^{-1}, close to literature values observed for zerovalent molybdenum tricarbonyls (26–28). The $^{13}C-\{^1H\}$ NMR spectrum of **3a** showed three doublet resonances for the C≡O ligands in a 1:1:1 ratio. The resonances with small ^2J(PC) values of 8.1 and 10.2 Hz were assigned to the carbonyl carbons *cis* to phosphorus and the resonance with a large ^2J(PC) value of 42.4 Hz was assigned to the carbonyl carbon *trans* to phosphorus (7, 10, 11, 29). Hence, this tricarbonylmolybdenum(0) complex has a *fac* geometry. The observed low δ_C value of 24.9 ppm for the methylene carbon is consistent with the values obtained for methylene carbons in six-membered chelate rings (2, 7, 12, 29). In the proton NMR spectrum, the CH_2P protons were nonequivalent with ^2J(HH) 12.9 and ^2J(PH) 9.0 Hz whereas the CH_2S protons gave a broad peak centred at 3.97 ppm. Interestingly, the *Me*C=N proton resonance appeared as a doublet with a five-bond cou-

pling to phosphorus, ^5J(PH) 2.7 Hz. The mass spectrum gave an intensity profile at *m/z* 642 (for molybdenum-98) for the parent molecular ion and profiles due to successive loss of one, two, and three carbonyl ligands (see experimental section). The corresponding tricarbonyltungsten(0) complex **3b** was prepared in 94% yield by treating **1** with one equivalent of $[W(CO)_3(NCEt)_3]$ (30) in benzene. Details of the preparation and characterizing data are in the experimental section and in Tables 1 and 2.

We anticipated that the azine phosphine **1** could also act as a bidentate ligand through *P* and *N*═CMe nitrogen, giving a six-membered chelate ring, as with other azine phosphine ligands (1–4, 29). To investigate this we treated **1** with $[Mo(CO)_4(nbd)]$ (31) (nbd = norbornadiene) and obtained the hoped-for tetracarbonylmolybdenum(0) complex **4**, which showed a phosphorus-31 chemical shift of 52.0 ppm. The IR bands for ν(C≡O) at 2020, 1900, and 1845 cm^{-1} are similar to other values reported for zerovalent molybdenum tetracarbonyls (1, 11, 29). The mass spectrum gave an intensity profile at *m/z* 670 (for molybdenum-98) for the parent molecular ion and profiles due to successive loss of one, two, three, and four carbonyl ligands. The $^{13}C-\{^1H\}$ NMR data indicated the presence of four carbonyl ligands and a six-membered chelate ring. In the proton NMR spectrum, the resonances due to the CH_2P and CH_2S protons were broad at room temperature (20°C). At −40°C, the $^1H-\{^{31}P\}$ NMR spectrum showed two AB patterns, one at 2.36 and 3.34 ppm with ^2J(HH) 12.5 Hz for the CH_2P protons and the other at 3.81 and 4.37 ppm with ^2J(HH) 12.9 Hz for the CH_2S protons. Probably by −40°C the flexible six-membered chelate ring ceases to be fluxional and the CH_2P methylene hydrogens become pseudo-axial and pseudo-equatorial. Alternatively, at −40°C steric interaction might prevent movement of the CH_2S-*p*-tolyl group past the C≡O ligand in the P-Mo-N plane. In either case the CH_2P hydrogens would be nonequivalent as would the CH_2S hydrogens, which would be diastereotopic. We have observed a similar behaviour for the CH_2P hydrogens in $[W(CO)_4\{PPh_2CH_2C(Bu^t)$═N-N═$CH(C_6H_4F\text{-}2)\}]$, which shows broad resonances at 20°C but an AB pattern at low temperatures (−60°C) (7).

We (1, 11, 32, 33) and many others (34–36) have shown that molybdenum(0) or tungsten(0) carbonyl – tertiary phosphine complexes can be oxidized by halogens to give molybdenum(II) or tungsten(II) species. Treatment of **3a** or **4** in CH_2Cl_2 at 0°C with 1 equivalent of bromine in CCl_4 gave the expected neutral seven-coordinate (37–39) dicarbonylmolybdenum(II) complex **5** as an orange solid in 78% yield. The $^{31}P-\{^1H\}$ NMR spectrum showed a singlet at 52.5 ppm. The IR spectrum showed two strong bands for ν(C≡O) at 1970 and 1860 cm^{-1} that were in good agreement with the values (1975 and 1875 cm^{-1}) observed for the neutral seven-coordinate dicarbonylmolybdenum(II) dibromide $[MoBr_2(CO)_2\{PPh_2CH_2C(Bu^t)$═N-N═$C(Bu^t)CH_2PPh_2\}]$, containing a terdentate (P-N-P) ligand (11). Treatment of the corresponding tricarbonyltungsten(0) complex **3b** with 1 equivalent of bromine followed by NH_4PF_6 in methanol gave the seven-coordinate tricarbonyltungsten(II) salt **6** as yellow microcrystals in 82% yield. As expected, it showed three IR bands at 2040, 1965, and 1940 cm^{-1} for ν(C≡O) (11).

Complexes of 1 with platinum

We also studied the ability of the thioether azine phosphine **1** to act as either bidentate (P-N) or terdentate (P-N-S) ligand with platinum (Scheme 2). Treatment of the phosphine **1** with $[PtCl_2(NCMe)_2]$ (12) gave the bidentate dichloroplatinum(II) complex **7**, containing a six-membered chelate ring. The observed δ_P value of 25.4 ppm with platinum-195 satellites ^1J(PtP) = 4085 Hz, and two IR bands at 340 and 290 cm^{-1} due to ν(Pt–Cl) were indicative of a *cis*-$PtCl_2$ arrangement (2, 40). In the proton NMR spectrum, the resonances due to the CH_2P and CH_2S protons were broad at room temperature, as

[a]Measured at 99.55 MHz in $CDCl_3$, δ values to high frequency of TMS, *J* values in Hz.
[b]$^4J(H–CH_3)$.
[c]Recorded at −40°C.
[d]In CD_2Cl_2.
[e]^4J(PtH).
[f]In C_6D_6.
[g]Recorded at 400 MHz.

observed for the bidentate complex **4** containing a six-membered chelate ring. At −40°C, the $^1H–\{^{31}P\}$ NMR spectrum showed two AB patterns centred at 2.57 and 4.47 ppm for the CH_2P and CH_2S groups, respectively. When this complex was treated with NH_4PF_6 in methanol it yielded the terdentate (P-N-S) complex **8a**, which showed a singlet phosphorus-31 resonance at 43.3 ppm with platinum-195 satellites, ^1J(PtP) = 3664 Hz. The smaller ^1J(PtP) value of 3664 Hz agreed with the other values observed for platinum(II) – tertiary phosphine complexes with phosphorus *trans* to sulfur donors (21, 41). The CH_2S protons were inequivalent (^2J(HH) = 17.3 Hz) and coupled to phosphorus (^4J(PH) ~ 4.5 Hz). The $^{13}C–\{^1H\}$ NMR data were in agreement with the proposed structure. We expected that methylene protons on a carbon adjacent to a C=N bond and to a sulfur group would be activated and could be removed by a base (2, 12). Treatment of the terdentate salt **8a** or the bidentate complex **7** with Et_3N–NaOH gave the hoped-for chloroplatinum(II) complex **9** as an orange solid. This neutral complex **9** showed a phosphorus-31 resonance at 23.3 ppm with a ^1J(PtP) value of 3776 Hz, consistent with a phosphorus atom *trans* to a sulfur donor (21, 41). In the proton NMR spectrum, the =C*H*S proton appeared as a doublet at 4.27 ppm with satellites, ^4J(PH) = 5.9 and ^3J(PtH) = 27.4 Hz, whilst the carbon-13 resonance for the =*C*HS carbon absorbed at 72.5 ppm with ^3J(PC) = 2.1 Hz (12). This neutral terdentate complex **9** was readily reprotonated with an excess of HBF_4 to give the BF_4 salt **8b**, which showed similar NMR properties to **8a**. The cation of **8a** and **8b** showed nonequivalent CH_2S hydrogens but apparently equivalent CH_2P protons; we suggest that the CH_2P hydrogens have accidentally the same chemical shift.

Treatment of the phosphine **1** with $[PtMe_2(cod)]$ (12) (cod = cycloocta-1,5-diene) at ca. 20°C in benzene gave the bidentate dimethylplatinum(II) complex **10**, which has a δ_P value of 36.9 ppm with ^1J(PtP) = 2156 Hz. This small value of ^1J(PtP) value is consistent with phosphorus *trans* to a methyl group (2, 8, 12, 40). The proton NMR spectrum showed two doublets with platinum-195 satellites for the two methyl groups on platinum; the signal at 1.41 ppm with ^2J(PtH) = 70.8 Hz is assigned to the protons of the methyl group *trans* to phosphorus (2, 12, 40) and the other, at 1.50 ppm with ^2J(PtH) = 87.4 Hz, is assigned to the protons of the methyl group *trans* to nitrogen (2, 8, 12, 40). The *Me*C=N proton resonance appeared as a doublet at 1.62 ppm with satellites due to coupling to platinum-195, ^5J(PH) 2.0 and ^4J(PtH) 4.8 Hz. At ca. 25°C the CH_2P and CH_2S protons each give AB patterns in the $^1H–\{^1P\}$ NMR spectrum; possibly steric interaction prevents the CH_2S-*p*-tolyl group from being able to pass a Pt-methyl, or the fluxionality of the six-membered chelate ring has effectively ceased at this temperature; either effect would render both sets of methylene hydrogens nonequivalent, as with compound **4** above. Square planar dichloropalladium or dimethylplatinum compounds of type $[MX_2\{PPh_2CH_2C(Bu^t)=N-N=CHPh\}]$ (M = Pd, X = Cl; M = Pt, X = Me) at 25°C also show CH_2P protons as an AB pattern in the $^1H–\{^{31}P\}$ NMR spectrum, with ^2J(HH) = 13.0 (Pd) or 12.6 (Pt) Hz, respectively (2).

Treatment of the dimethylplatinum(II) complex **10** with MeI gave the *fac*-trimethylplatinum(IV) iodide salt **11a**, with a specific molar conductivity (Λ_m) of 0.134 Ω^{-1} mol^{-1} cm^2 in acetone solution at 20°C, typical for a bi-univalent electrolyte (42). Treatment of **11a** with NH_4PF_6 in methanol gave the corresponding PF_6 salt **11b**. The low ^1J(PtP) values of 1252 and 1241 Hz are similar to other values reported for platinum(IV) – tertiary phosphine complexes (2, 8, 12, 13). In the $^{13}C–\{^1H\}$ NMR spectrum of **11b** the Pt*Me* carbon *trans* to phosphorus appeared as a doublet with a large ^2J(PC) value of 114.8 Hz whilst the methyl carbons *cis* to phosphorus gave two singlets, indicating a *fac*-$PtMe_3$ arrangement. The proton resonance at 0.78(d) ppm with ^3J(PH) 7.4 and ^2J(PtH) 55.7 Hz was assigned to the Pt*Me* group *trans* to phosphorus (2, 12, 13) whilst the two doublets at 0.97 ppm, with ^3J(PH) 6.6 and ^2J(PtH) 69.3 Hz, and 1.13 ppm, with ^3J(PH) 7.1 and ^2J(PtH) 69.8 Hz, were assigned to the two Pt*Me* groups *trans* to nitro-

gen (2, 12, 43, 44) or sulfur (45, 46). Protonation of the dimethylplatinum(II) complex **10** with 1 equivalent of picric acid [$HOC_6H_2(NO_2)_3$-2,4,6] gave the methylplatinum(II) picrate salt **12** and methane. The $^{31}P-\{^1H\}$ NMR spectrum showed a singlet at 43.9 ppm with platinum-195 satellites $^1J(PtP)$ = 4214 Hz. The $^1J(PtP)$ value of 4214 Hz is slightly higher than most other values (2800–4100 Hz) (18, 21, 41, 47–53) observed for tertiary phosphine ligands *trans* to sulfur donors, probably due to the presence of the *cis*-methyl group. The presence of a *cis*-alkyl ligand is known to increase $^1J(PtP)$ relative to, say, a halogen ligand (10, 13, 41, 54, 55). In the proton NMR spectrum, the CH_2S protons were coupled to phosphorus ($^4J(PH)$ = 4.9 Hz), indicative of the coordination of sulfur to platinum. Presumably in **12** there is rapid inversion at sulfur on the NMR time scale, causing equivalence of the two sets of CH_2 protons; rapid inversion of sulfur coordinated to platinum is well established (19).

Experimental

All the reactions were carried out in an inert atmosphere of dry nitrogen or dry argon. *tert*-Butyl diphenylphosphinomethyl ketone hydrazone *Z*-$PPh_2CH_2C(Bu^t)$=NNH_2 was prepared as reported in a previous paper (1). 4-Methylphenylthiomethyl methyl ketone was purchased from Maybridge Chemical Co. Ltd. Infrared spectra were recorded using a Perkin–Elmer model 457 grating spectrometer. NMR spectra were recorded using a JEOL FX-90Q spectrometer (operating frequencies for ^1H and ^{31}P of 89.5 and 36.2 MHz, respectively), a JEOL FX-100 spectrometer (operating frequencies for ^1H and ^{31}P of 99.5 and 40.25 MHz, respectively), a Bruker ARX-250 spectrometer (operating frequencies for ^1H, and ^{13}C of 250.13 and 62.9 MHz, respectively), or a Bruker AM-400 spectrometer (operating frequencies for ^1H, ^{31}P, and ^{13}C of 400.13, 161.9, and 100.6 MHz, respectively); ^1H and ^{13}C chemical shifts are relative to tetramethylsilane and ^{31}P shifts are relative to 85% phosphoric acid, coupling constants are in Hz. Electron impact (EI) and fast atom bombardment (FAB) mass spectra were recorded using a VG Autospec with 8 kV acceleration. For metal complexes *m/z* values are quoted for ^{98}Mo, ^{184}W, and ^{195}Pt.

Z,E-{$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4) 1

Methylphenylthiomethyl methyl ketone (6.0 cm^3, 6.0 g, 33.3 mmol) was added to a warm solution of *Z*-$PPh_2CH_2C(Bu^t)$=NNH_2 (8.0 g, 26.8 mmol) in ethanol (25 cm^3). The reaction mixture was left to stand at ca. 20°C for 20 h after which it was cooled to −30°C overnight. The required product **1** precipitated out as pale yellow needles. These were filtered off and washed with cold ethanol. Yield 10.5 g, 84%. $^{13}C-\{^1H\}$ NMR (100.6 MHz, $CDCl_3$) δ_C: 169.4 (1C, d, *J*(PC) 5.3, *C*=N), 159.1 (1C, d, *J*(PC) 1.7, *C*=N), 41.6 (1C, s, CH_2S), 39.4 (1C, d, ^3J(PC) 4.3, CMe_3), 28.6 (3C, d, ^4J(PC) 1.5, CMe_3), 28.5 (1C, d, ^1J(PC) 11.0, CH_2P), 20.9 (1C, s, C_6H_4Me-4), and 16.2 (1C, d, ^6J(PC) 3.2, *Me*C=N). *m/z* (EI): 461 (M + 1), 403 (M – Bu^t), and 337 (M-SC_6H_4Me). Anal. calcd. for $C_{28}H_{33}N_2PS$: C 73.0, H 7.2, N 6.1; found: C 72.9, H 7.2, N, 6.1%.

Z,E-Ph_2P(=O)$CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6H_4Me$-4) 2

An excess of hydrogen peroxide (0.2 cm^3, 30% w/v) was added to a solution of the azine phosphine **1** (100 mg, 0.22 mmol) in acetone (4.0 cm^3) at 0°C. The pale yellow solution was left to stand at ca. 20°C for 0.5 h. On the addition of water (2.0 cm^3), the required product **2** precipitated as a white solid. This was filtered off, washed with water, and dried in vacuo over P_2O_5. Yield 92 mg, 88%. *m/z* (EI): 476 (M^+) and 353 (M − SC_6H_4Me). Anal. calcd. for $C_{28}H_{33}N_2OPS$: C 70.6; H, 7.0; N, 5.9; found: C 70.4, H 6.9, N 5.8%.

***fac*-[$Mo(CO)_3${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)CH_2S-(C_6H_4Me-4)}] 3a**

A solution of [$Mo(CO)_3(\eta^6$-cht)] (59 mg, 0.22 mmol) and the azine phosphine **1** (100 mg, 0.22 mmol) in benzene (2.0 cm^3) was put aside for 0.5 h. The required product **3a** precipitated out as yellow needles. These were filtered off, washed with cold methanol, and dried in vacuo. Yield 120 mg, 85%. $^{13}C-\{^1H\}$ NMR (100.6 MHz, CD_2Cl_2) δ_C: 228.1 (1C, d, ^2J(PC) 8.1, C≡O *cis* to P), 224.6 (1C, d, ^2J(PC) 10.2, C≡O *cis* to P), 210.9 (1C, d, ^2J(PC) 42.4, C≡O *trans* to P), 171.3 (1C, s, *C*=N), 162.7 (1C, d, *J*(PC) 4.8, *C*=N), 50.4 (1C, s, CH_2S), 39.4 (1C, d, ^3J(PC) 2.0, CMe_3), 27.6 (3C, s, CMe_3), 24.9 (1C, d, ^1J(PC) 6.4, CH_2P), 21.1 (1C, s, C_6H_4Me-4), and 18.9 (1C, s, *Me*C=N). *m/z* (EI): 642 (M^+), 614 (M-CO), 586 (M − 2CO), and 558 (M − 3CO). Anal. calcd. for $C_{31}H_{33}MoN_2O_3PS$: C 58.1, H 5.2, N 4.4; found: C 57.9, H 5.1, N 4.4%.

***fac*-[$W(CO)_3${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)CH_2S-(C_6H_4Me-4)}] 3b**

A mixture of [$W(CO)_3(NCEt)_3$] (95 mg, 0.22 mmol) and the azine phosphine **1** (100 mg, 0.22 mmol) in benzene (2.0 cm^3) was warmed until a clear yellow solution was obtained. The mixture was then cooled to give the required product as yellow microcrystals. These were filtered, washed with cold methanol, and dried. Yield 150 mg, 94%. *m/z* (EI) 672(M − 2CO) and 644(M − 3CO). Anal. calcd. for $C_{31}H_{33}N_2O_3PSW$: C 51.1, H 4.6, N 3.9; found: C 51.0, H 4.4, N 3.9%.

[$Mo(CO)_4${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)CH_2S-(C_6H_4Me-4)}] 4

A solution of [$Mo(CO)_4$(nbd)] (98 mg, 0.33 mmol) and the azine phosphine **1** (150 mg, 0.33 mmol) in benzene (3.0 cm^3) was put aside at ca. 20°C for 2 h. The reaction mixture was then filtered through Celite and evaporated to dryness. The required product **4** was obtained as a pale yellow solid by recrystallizing the resultant residue from dichloromethane–methanol. Yield 190 mg, 86%. $^{13}C-\{^1H\}$ NMR (100.6 MHz, $CDCl_3$) δ_C: 220.0 (1C, d, ^2J(PC) 6.9, C≡O *cis* to P), 214.7 (1C, d, ^2J(PC) 35.4, C≡O *trans* to P), 208.2 (2C, br, C≡O), 169.5 (1C, s, *C*=N), 167.2 (1C, d, *J*(PC) 4.0, *C*=N), 45.7 (1C, s, CH_2S), 38.9 (1C, d, ^3J(PC) 1.7, CMe_3), 27.4 (3C, s, CMe_3), 25.6 (1C, d, ^1J(PC) 6.5, CH_2P), 21.1 (1C, s, C_6H_4Me-4), and 19.3 (1C, s, *Me*C=N). *m/z* (FAB): 670 (M^+), 642(M − CO), 614 (M − 2CO), 586(M − 3CO), and 558(M − 4CO). Anal. calcd. for $C_{32}H_{33}MoN_2O_4PS{\cdot}0.1\ CH_2Cl_2$: C 56.9, H 4.9, N 4.1; found: C 56.8, H 4.8, N 4.2%.

[$Mo(CO)_2Br_2${$PPh_2CH_2C(Bu^t)$=N-N=C(Me)$CH_2S(C_6$-H_4Me-4)}] 5

(i) From 4

A solution of Br_2 in carbon tetrachloride (0.16 cm^3, 0.751 M,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

0.12 mmol) was added to a solution of the tetracarbonyl complex **4** (80 mg, 0.12 mmol) in dichloromethane (3.0 cm^3) cooled to 0°C. When the effervescence had subsided, the reaction mixture was filtered and evaporated to low volume. The required product **5** precipitated out as orange microcrystals after trituration with methanol. These were filtered off, washed with cold methanol, and dried. Yield 90 mg, 78%.

(ii) From ***3a***

The complex **5** was isolated in 97% yield after treating **3a** with 1 mole equivalent of Br_2 in a similar fashion to that described in method (i).

$[W(CO)_3Br\{PPh_2CH_2C(Bu^t)$=N-N=$C(Me)CH_2S$-$(C_6H_4Me$-4)$\}][PF_6]$ 6

A solution of Br_2 in carbon tetrachloride (0.14 cm^3, 0.751 M, 0.11 mmol) was added to a solution of **3b** (80 mg, 0.11 mmol) in dichloromethane (2.0 cm^3) cooled to 0°C. After the effervescence had subsided, the reaction mixture was filtered and evaporated to dryness. The residue was redissolved in minimum amount of methanol to which a saturated solution of ammonium hexafluorophosphate(V) in methanol (1.0 cm^3) was added. The required product precipitated out as yellow microcrystals. Yield 83.0 mg, 82%.

$\{PtCl_2\{PPh_2CH_2C(Bu^t)$=N-N=$C(Me)CH_2S(C_6H_4Me$-4)$\}]$ 7

$[PtCl_2(NCMe)_2]$ (0.76 g, 2.17 mmol) was added to a solution of the azine phosphine **1** (1.0 g, 2.17 mmol) in dichloromethane (10.0 cm^3). The pale yellow reaction mixture was allowed to stand at ca. 20°C for 0.5 h, after which it was filtered and evaporated to low volume. The dichloroplatinum complex **7** precipitated out as yellow solids after trituration with *n*-hexane. Yield 1.31 g, 83%. Anal. calcd. for $C_{28}H_{33}Cl_2N_2PSPt{\cdot}0.12CH_2Cl_2$: C 45.8, H 4.55, N 3.8, Cl 10.8; found: C 45.5, H 4.3, N 4.0, Cl 10.85%.

$[PtCl\{PPh_2CH_2C(Bu^t)$=N-N=$C(Me)CH_2S(C_6H_4Me$-4$\})PF_6]$ 8a

A suspension of the dichloroplatinum complex **7** (100 mg, 0.14 mmol) in methanol (4.0 cm^3) was heated to reflux for 0.5 h, upon which the starting material had dissolved to give a clear yellow solution. The reaction mixture was then allowed to cool to ca. 20°C, filtered, and the filtrate evaporated. The residue was redissolved in a minimum amount of methanol (10.0 cm^3) to which a saturated solution of ammonium hexafluorophosphate(V) in methanol (1.0 cm^3) was added. The required complex precipitated out as pale yellow microcrystals. Yield 84.0 mg, 73%. $^{13}C-\{^1H\}$ NMR (62.9 MHz, CD_2Cl_2) δ_C: 185.8 (1C, s, *C*=N), 176.2 (1C, s, *C*=N), 50.1 (1C, s,CH_2S), 41.2 (1C, s, CMe_3), 26.9 (3C, s, CMe_3), 21.3 (1C, s, C_6H_4Me-4), 21.2 (1C, s, *Me*C=N), and 20.7 (1C, d, ^1J(PC) 32, CH_2P). *m/z* (FAB): 691(M − PF_6) and 655(M − PF_6 − HCl). Anal. calcd. for $C_{28}H_{33}ClF_6N_2P_2SPt$: C 40.2, H 4.0, Cl 4.25 N 3.35; found: C 40.25, H 4.0, Cl 4.45, N 3.3%.

$[PtCl\{PPh_2CH_2C(Bu^t)$=N-N=$C(Me)CH_2S(C_6H_4Me$-4$)\}BF_6]$ 8b

Tetrafluoroboric acid (2 drops) was added to an orange solution of the chloroplatinum complex **9** (70 mg, 0.10 mmol) in dichloromethane (2.0 cm^3). The resulting yellow solution was then filtered and the filtrate evaporated to low volume. The required product precipitated out as a cream solid after trituration with *n*-hexane. Yield 70 mg, 89%. *m/z* (FAB): 691(M − BF_4) and 655(M − BF_4 − HCl).

$[PtCl\{PPh_2CH_2C(Bu^t)$=N-NC(Me)=CHS$(C_6H_4Me$-4$)\}]$ 9

An excess of triethylamine (0.2 cm^3) was added to a stirred solution of the dichloroplatinum complex **7** (0.3 g, 0.41 mmol) in dichloromethane (5.0 cm^3). After 0.5 h, a 10% sodium hydroxide solution (2.0 cm^3) was added to the dark orange solution. The organic layer was separated, dried over anhydrous magnesium sulphate, and then evaporated to low volume. The required product was obtained as orange microcrystals after trituration of the residue with methanol. Yield 0.2 g, 70%. $^{13}C-\{^1H\}$ NMR (100.6 MHz, $CDCl_3$) δ_C: 174.7 (1C, s, Bu^t*C*=N), 143.8 (1C, s, Me*C*-N), 72.5 (1C, d, ^3J(PC) 2.1, =*C*HS), 40.3 (1C, d, ^3J(PC) 3.7, *C*Me_3), 28.0 (3C, s, CMe_3), 21.2 (1C, s, C_6H_4Me-4), 19.9 (1C, s, *Me*C-N), and 14.9 (1C, d, ^1J(PC) 36.3, CH_2P). *m/z* (FAB): 691(M^+). Anal. calcd. for $C_{28}H_{32}ClN_2PSPt$: C 48.7, H 4.7, Cl 5.1, N 4.1; found: C 49.0, H, 4.7, Cl 5.4, N 4.1%.

$[PtMe_2\{PPh_2CH_2C(Bu^t)$=N-N=$C(Me)CH_2S(C_6H_4Me-4)\}]$ 10

$[PtMe_2(cod)]$ (144 mg, 0.43 mmol) was added to a solution of the azine phosphine **1** (200 mg, 0.43 mmol) in benzene (3.0 cm^3). The reaction mixture was allowed to stand at ca. 20°C for 4 h, after which it was filtered and evaporated to low volume. The dimethylplatinum complex **10** precipitated out as a white solid after trituration with ethanol. This was filtered off and washed with cold ethanol. Yield 190 mg, 64%. $^{13}C-\{^1H\}$ NMR (62.9 MHz, C_6D_6) δ_C: 170.9 (1C, s, *C*=N), 163.9 (1C, d, *J*(PC) 3.8, *C*=N), 42.4 (1C, s, CH_2S), 39.6 (1C, s, CMe_3), 28.1 (3C, s, CMe_3), 24.8 (1C, d, ^1J(PC) 16.3, CH_2P), 21.2 (1C, s, C_6H_4Me-4) 19.0 (1C, s, *Me*C=N), 10.2 (1C, d, ^2J(PC) 113.4, Pt*Me trans* to P), and −20.6 (1C, d, ^2J(PC) 3.8, Pt*Me trans* to N). *m/z* (FAB): 670 (M − CH_4) and 654 (M − $2CH_4$). Anal. calcd. for $C_{30}H_{39}N_2PPtS$: C 52.55, H 5.75, N 4.1; found: C 52.3, H 5.7, N 3.95%.

***fac*-$[PtMe_3\{PPh_2CH_2C(Bu^t)$=N-N=$C(Me)CH_2S$-$(C_6H_4Me-4)\}]$ 11a**

An excess of iodomethane (0.5 cm^3) was added to a solution of the dimethylplatinum complex **10** (60 mg, 0.09 mmol) in benzene (1.5 cm^3). The required product precipitated out as a white microcrystalline solid. Yield 70 mg, 97%. Λ_m (acetone): 0.134 Ω^{-1} mol^{-1} cm^2. *m/z* (FAB): 700 (M − HI), 670 (M − HI − $2CH_3$). On the use of diamond as a pressure calibrant for near-infrared FT–Raman microspectroscopy at high pressures

Ross D. Markwell and Ian S. Butler

Abstract: The pressure-induced shift of the Raman-active t_{2g} phonon mode of the diamond windows in a commercial diamond-anvil cell, located at 1332.5 cm^{-1} at ambient pressure, can be used as an in situ calibrant for near-IR FT–Raman microspectroscopy at high pressures. The measured pressures are considered to be accurate to within ±2 kbar throughout the 4–45 kbar range for which the associated pressure (P, kbar) vs. wavenumber (ν, cm^{-1}) relationship is $P = 6.66\nu - 1335.9$.

Key words: FT–Raman spectroscopy, diamond, high pressures.

Résumé : Le déplacement induit par la pression du mode phonon t_{2g}, actif dans le Raman, des fenêtres de diamant d'une cellule commerciale à enclume de diamant situées à 1332,5 cm^{-1} à la pression ambiante, peut être utilisé comme calibrant in situ pour la microspectroscopie FT–Raman dans le proche IR, à des pressions élevées. On considère que les pressions mesurées sont précises à ±2 kbar sur toute la plage allant de 4 à 45 kbar pour laquelle la relation associée pression (P, kbar vs. nombre d'onde (ν, cm^{-1}) est $P = 6{,}66\nu - 1335{,}9$.

Mots clés : spectroscopie FT–Raman, diamant, pressions élevées.

[Traduit par la rédaction]

Introduction

Diamond-anvil cells for spectroscopic measurements at high pressures are readily available commercially. The majority of these cells are rated for pressures up to ~100 kbar (1 bar = 100 kPa) and can be used for a variety of different applications including infrared, Raman, and UV–visible spectroscopy (1). For many years, there has been considerable interest in determining the effects of high external pressures on the structures and properties of organic, inorganic (1), and even organometallic molecular crystals (for example, see ref. 2). This interest has increased dramatically of late following two remarkable discoveries: (*a*) the room temperature conversion of Buckminsterfullerene (C_{60}) into diamond (3) and (*b*) the possibility of using pressure-tuning vibrational spectroscopy in human cancer diagnosis (4). In the summer of 1991, the National Science Foundation in the United States emphasized the importance of future high-pressure research by launching a special initiative to develop new high-pressure techniques and discover new high-pressure materials (5).

In a conventional high-pressure Raman experiment, employing visible laser excitation, the pressure sensitivity of the R_1 fluorescence band of a tiny ruby chip is used as the internal pressure calibrant (6). Pressure-tuning FT–micro-Raman measurements involving near-IR Nd^{3+}:YAG laser excitation have recently also been successfully undertaken for $Cr(CO)_4$(bipy) (bipy = 2,2′-dipyridyl) (7) and elemental sulfur (8). Unfortunately, the ruby R_1 fluorescence band was too far removed from the 1064.1 nm excitation wavelength to be accessible by the spectrometers and so no direct internal pressure calibration method was available for these studies. It would have been possible to use the standard ruby calibration procedure but this would have necessitated physical removal of the diamond-anvil cell from the FT–Raman spectrometer and subsequent alignment on a visible Raman instrument so that the pressure could be calibrated in the usual way. In fact, in the study of $Cr(CO)_4$(bipy) (7), another pressure calibration method, which is based on the pressure sensitivity of the IR-active e' N–O stretching mode of the NO_3^- ion, was used (9). This N–O stretching mode is a well-known standard for presure-tuning IR measurements. However, for these pressure-tuning near-IR FT–micro-Raman experiments, it was still necessary to have two separate instruments for the pressure calibration and spectroscopic measurements.

Another serious drawback to the new pressure-tuning FT–Raman microspectroscopic technique is the high sample loading required for all but the strongest Raman scatterers if sufficient signal-to-noise ratios are to be achieved within a reasonable time. This drawback limits the number of pressure calibrants that can be used in such experiments. Ideally, the sample cavity of the diamond-anvil cell should be packed only with sample and an external pressure calibration method should be used. With this objective in mind, we decided to investigate the possibility of using the 1332.5 cm^{-1} Raman-active t_{2g} phonon band of the diamond windows in a diamond-

anvil cell as an in situ pressure calibrant. The results of this investigation are presented in this paper.

Experimental

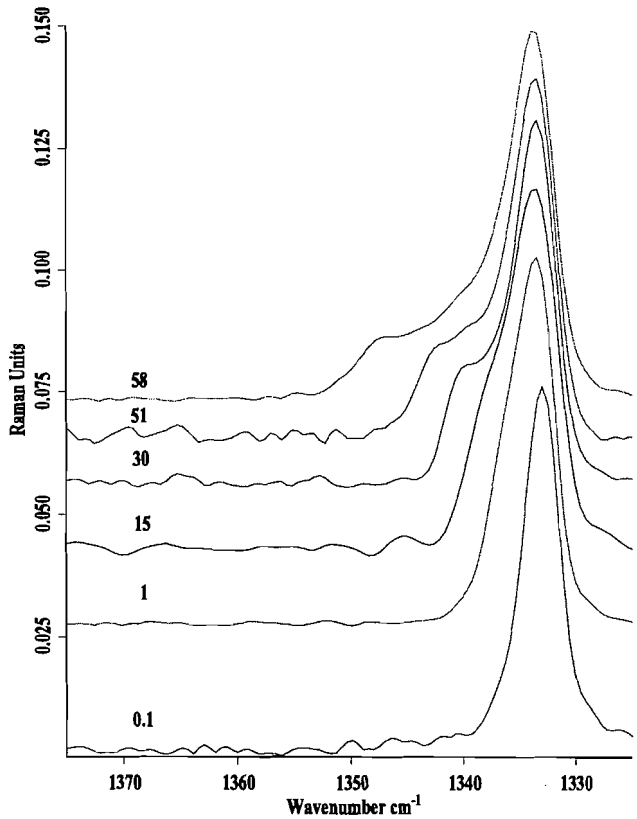
A diamond-anvil cell rated to withstand ~100 kbar pressure was purchased from High Pressure Diamond Optics, Tucson, Arizona, U.S.A. The parallel faces of the two type-II diamonds in the cell were separated by a 12 mm × 12 mm × 240 μm stainless-steel gasket that had been punctured in the center (300 μm diameter round hole). A small crystal chip of $NaNO_3$ (1%) in an NaBr matrix was loaded into the hole with the aid of an optical microscopic. The variation of the position of the NO_3^- calibrant IR peak (1401.3 cm^{-1} at ambient pressure) was measured on a Bruker IFS-48 FT-IR spectrometer coupled to a Bruker A-590 IR microscope equipped with a liquid-N_2-cooled mercury – cadmium telluride detector. Periodic checks were made for pressure gradients within the cell by measuring the spectrum at several points within the gasket hole (a spatial resolution of <10 μm is attainable with this apparatus). No such variation was detected across the sample at the 0.5 cm^{-1} resolution employed. FT–Raman spectra (2.5 cm^{-1} resolution) were recorded on a Bruker IFS-88 FT-IR/FRA-105 Raman module fitted with a Ge proprietary detector and coupled via two 1.0 m photooptic cables to a Nikon Optiphot-II optical microscope equipped with a Nikon 20X super-long-range objective. Near-IR laser radiation (Nd^{3+}:YAG, 1064.1 nm) was directed onto the sample through the objective and collected along the same optical pathway in a 180° backscattering mode. The two faces of the top diamond and the sample were clearly observable with the optical microscope of the Raman instrument and measurements were taken with the objective focused at the internal diamond–sample interface. Pressures in the 1–60 kbar range were applied mechanically to the sample and the measured positions (ν) of the diamond peak (vide infra) were correlated against the pressure (P) determined from the IR calibration procedure.

Results and discussion

The diamond windows in a typical high-pressure spectroscopic anvil cell are extremely strong Raman scatterers and often, because of signal-to-noise considerations, the intense, sharp, triply degenerate (t_{2g}) diamond phonon mode at 1332.5 cm^{-1} is filtered out from the spectra with a holographic notch filter. Under uniaxial pressure, as in the case of the two fixed diamonds in a diamond-anvil cell, the t_{2g} peak loses its degeneracy and splits into a higher energy singlet and a lower energy (unresolved) doublet (10). Raman microspectra of the internal diamond–sample interface in the diamond-anvil cell at different external pressures have shown that there is a linear relationship between the position of the t_{2g} phonon peak and pressure up to ~200 kbar (11). Similar behaviour has been noted for other types of diamond anvils (12) and diamond fragments (13), although the actual mathematical relationships do differ somewhat. It occurred to us that FT-Raman microspectroscopy at the internal diamond–sample interface in a diamond-anvil cell might lead to a suitable in situ calibration method for high-pressure measurements.

The behaviour of the t_{2g} diamond phonon peak up to 60 kbar is quite complicated (Fig. 1). This pressure region was defined

Fig. 1. Effect of increasing pressure (kbar) on the Raman-active diamond t_{2g} phonon band.



by only a single point in the previous work (11). Although some depth resolution is provided by the optical microscope, particularly after use of the aperturing system in the Bruker Raman attachment, there are always some contributions to the spectrum from regions of the diamond other than the point of focus. The spectra at elevated pressures do not represent a continuum from the unshifted peak of the front diamond surface to the spectra of the interface under high pressure. Hence, there appear to be discrete pressure domains within the diamond anvils, each of which behaves as if it were at a single pressure. The domain at the internal diamond–sample interface is that associated with the pressure experienced by the sample. The higher energy singlet of the t_{2g} diamond phonon peak was the most affected by pressure and this peak is considered to reflect the pressure at the internal diamond–sample interface. Depth profiling studies have supported this assumption.[2] Moreover, since this peak is a singlet (10), it was selected as the calibration peak for the FT–micro-Raman measurements.

Location of the precise position of the singlet within the t_{2g} band envelope proved to be the major difficulty with this calibration procedure. Ideally, a calibration should be executed quickly and unambiguously. Several different approaches were tried in order to overcome this problem. Initially, attempts were made to subtract the spectral contributions due to the lower pressure regions from that of the interfacial spectrum. This procedure afforded a moderately reliable calibra-

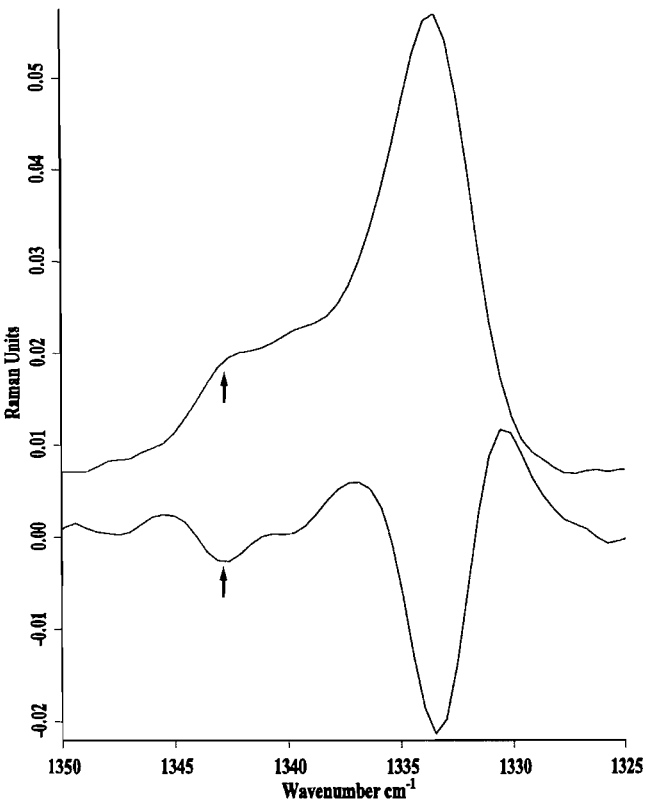
For personal use only.

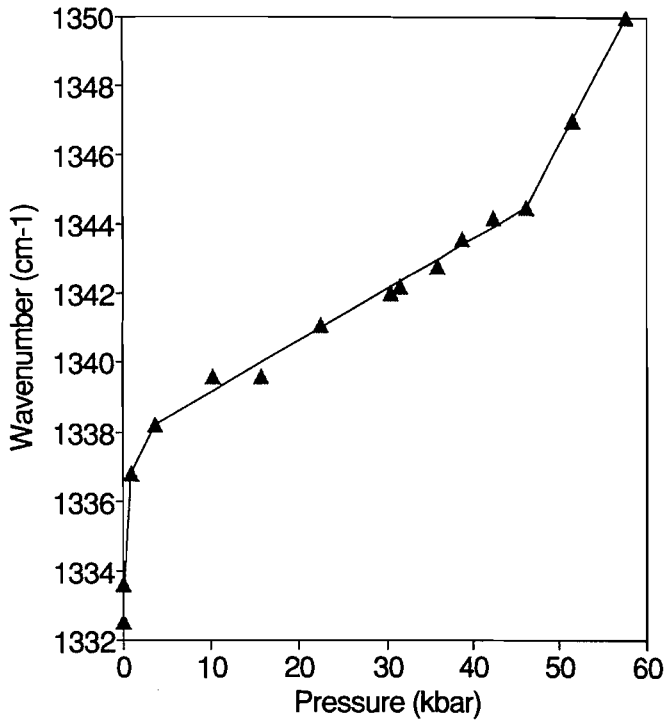
Fig. 2. Location of the half-height position of the most shifted component of the Raman-active diamond t_{2g} phonon band at 51 kbar. The minimum of the second derivative (lower spectrum) is chosen as a reflection of the top of the most shifted component (arrow). This frequency is traced to the original spectrum (upper spectrum; offset from 0.05 Raman units for clarity) and the band intensity is divided by 2 to determine the half-height intensity. The point on the band envelope where the half-height intensity intercepts the upper spectrum is the value used in the P vs. ν plot shown in Fig. 3.



tion, but it suffered from the need for considerable subjective judgement in selecting the band components to be subtracted. Next, a least-squares band-fitting program (Jandel Peakfit 3.11B) was applied to the t_{2g} band envelope at each pressure. This method proved to be the least satisfactory. Quite apart from the time required to acquire and process the spectral data, the loss of degeneracy on application of pressure and the variation of pressure regimes throughout the extent of the anvil precluded precise determination of the number of peaks necessary to fit the data. This approach also required greater signal-to-noise ratios than did the other methods, thus rendering data collection even more time consuming. The most satisfactory calibration procedure, in terms of speed and reproducibility, was to locate the position of the calibration peak from the second derivative spectrum at each pressure.

In using this method it had to be assumed that the width at half height was reasonably constant. The band envelope was essentially free from overlap with neighbouring bands and the good linearity of the wavenumber vs. pressure plot (Fig. 2) demonstrates that the half heights were indeed reasonably constant. In the 4–60 kbar range, this calibration procedure proved to be both precise and much more reliable than were the other methods. Below 4 kbar, the micro-Raman spectra were domi-

Fig. 3. Pressure dependence of the half-height position of the most shifted band of the diamond t_{2g} envelope up to ~60 kbar.



nated by the 1332.5 cm^{-1} peak due to the front face of the diamond window of the anvil. In this pressure range, the 1332.5 cm^{-1} band had to be subtracted first, before processing the data further. This procedure yielded a somewhat less satisfactory calibration, but was only necessary for a limited spectral region.

The diamond phonon peak is reasonably pressure sensitive ($d\nu/dP$ = 0.15 cm^{-1} $kbar^{-1}$) in the 4–60 kbar range and the response is linear up to 45 kbar (Fig. 2). There is a break at 45 kbar and an increase in pressure sensitivity ($d\nu/dP$ = 0.48 cm^{-1} $kbar^{-1}$) from 45 to 60 kbar. Such behaviour would normally indicate a solid-state pressure-induced phase change. However, there was no evidence at all of such a phase change in the earlier studies of diamond fragments under hydrostatic pressure (13) or in diamond anvils (12). The application of pressure in the present case is uniaxial rather than cubic and the data scatter in the previous diamond-anvil experiment (12) appears greater in this region than at higher pressures. The break may also reflect a change in the intensity of the major peak of the spectra. In our work, the behaviour of diamond with respect to pressure was both repoducible and reversible with no evidence of hysteresis.[2] The pressure dependence up to 4 kbar was also linear ($d\nu/dP$ = 0.40 cm^{-1} $kbar^{-1}$) with the phonon peak shifting from 1333.5 to 1334.9 cm^{-1} in this inital applied pressure range. The accuracy of the pressure calibrations in the 4–60 kbar range is estimated to be ±2 kbar.

Despite the need for raw data treatment, our new in situ pressure calibration procedure should find wide applicability in pressure-tuning FT–Raman measurements. However, since the size and shape of the pressure regimes within the anvils may vary from diamond to diamond and may also depend on the cutting process, some caution must be exercised in using the procedure initially. It is probably advisable to calibrate

each diamond anvil individually at the outset. Focusing of the near-IR laser beam directly onto the internal diamond–sample interface is absolutely crucial. For any applications requiring a more detailed pressure analysis, it may be possible to use a more sophisticated peak-fitting routine and (or) principle component analysis to obtain more precise peak positions. The most important benefits of this in situ calibration procedure for pressure-tuning FT–Raman measurements is that a second spectrometer is not required (as is the case for the ruby R_1 fluorescence and IR calibration methods) and the maximum available sample space in the diamond-anvil cell can be used for those materials under investigation.

Preparations for 1,4,7,11,14,17-hexathiacycloeicosane, 1,4,7-trithiecan-9-ol, 1,11-dioxa-4,8,14,18-tetrathiacycloeicosane, 1-oxa-4,8-dithiacyclodecane, and some complexes of iron, cobalt, nickel, and palladium

C. Robert Lucas, Shuang Liu, and John N. Bridson

Abstract: Preparations are reported for the title ligands (L1–L4, respectively) and for $[Co(L1)][ClO_4]_2$, $[Ni(L1)][ClO_4]_2$, $[\{Pd(\eta^3\text{-}C_3H_5)\}_2(L1)][ClO_4]_2$, $[Co(L2)_2][ClO_4]_2$, $[Ni(L2)_2][ClO_4]_2$, $[Co(L3)][ClO_4]_2$, and $[Ni(L3)_2][ClO_4]_2$. Clarification of earlier reports of L2 and some of its complexes has been achieved by X-ray crystallographic characterization. Crystal data for orthorhombic $[Ni(L1)][ClO_4]_2$: space group $Pna2_1$ (No. 33); $a = 13.270(4)$, $b = 16.564(4)$, $c = 11.348(4)$ Å; $Z = 4$; $R = 0.047$, $R_w = 0.040$ for 1474 reflections. For monoclinic $[Ni(L2)_2][ClO_4]_2$: space group $P2_1/c$ (No. 14); $a = 7.617(3)$, $b = 18.034(3)$, $c = 9.098(2)$ Å, $\beta = 91.58(2)°$; $Z = 2$; $R = 0.046$, $R_w = 0.039$ for 1487 reflections. For tetragonal $[Co(L3)][ClO_4]_2$: space group $I\bar{4}2m$ (No. 121); $a = 13.840(5)$, $c = 14.902(4)$ Å; $Z = 4$; $R = 0.054$, $R_w = 0.058$ for 974 reflections. The new complexes and previously reported $[Fe(L1)][ClO_4]_2$ have been examined by cyclic voltammetry, NMR, ESR, electronic spectroscopy, and magnetic susceptibility measurements. The influence of L2's extra-cyclic hydroxyl, of changes in M—S lengths, and of O for S substitution on structural, magnetic, redox, and spectroscopic properties has been studied.

Key words: X-ray structures, electrochemistry, magnetic phenomena.

Résumé : On rapporte les préparations des coordinats mentionnés dans le titre (L1–L4, respectivement) et des complexes $[Co(L1)][ClO_4]_2$, $[Ni(L1)][ClO_4]_2$, $[\{Pd(\eta^3\text{-}C_3H_5)\}_2(L1)][ClO_4]_2$, $[Co(L2)_2][ClO_4]_2$, $[Ni(L2)_2][ClO_4]_2$, $[Co(L3)][ClO_4]_2$ et $[Ni(L3)_2][ClO_4]_2$. Faisant appel à la diffraction des rayons X, on a obtenu des clarifications de données publiées antérieurement sur le L2 et quelques-uns de ses complexes. Les données cristallographiques pour le $[Ni(L1)][ClO_4]_2$ orthorhombique : groupe d'espace $Pna2_1$ (No. 33), avec $a = 13,270(4)$, $b = 16,564(4)$ et $c = 11,348(4)$ Å, $Z = 4$, $R = 0,047$ et $R_w = 0,040$ pour 1474 réflexions. Pour le $[Ni(L2)_2][ClO_4]_2$ monoclinique : groupe d'espace $P2_1/c$ (No. 14), avec $a = 7,617(3)$, $b = 18,034(3)$ et $c = 9,098(2)$ Å, $\beta = 91,58°$, $Z = 2$, $R = 0,046$ et $R_w = 0,039$ pour 1487 réflexions. Pour le $[Co(L3)][ClO_4]_2$ tétragonal : groupe d'espace $I\bar{4}2m$ (No. 121), avec $a = 13,840(5)$ et $c = 14,902(4)$ Å, $Z = 4$, $R = 0,054$ et $R_w = 0,058$ pour 974 réflexions. On a étudié les nouveaux complexes ainsi que le $[Fe(L1)][ClO_4]_2$ préparé antérieurement par voltampérométrie cyclique, RMN, RPE, spectroscopie électronique et mesures de susceptibilité magnétique. On a étudié l'influence du groupe hydroxyle extracyclique du coordinat L2, des changements dans les longueurs M—S et de la substitution d'un O pour un S sur les propriétés structurales, magnétiques, redox et spectroscopiques.

Mots clés : structures aux rayons X, électrochimie, phénomènes magnétiques.

Introduction

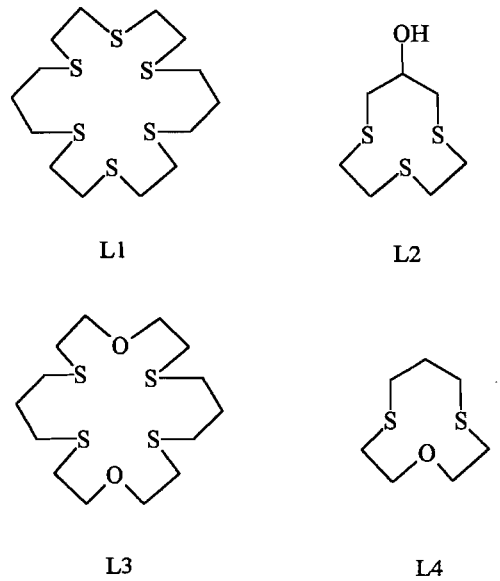
Crown thioethers have been the subject of considerable research interest for at least 10 years and, in contrast to crown ethers, they bind preferentially but not exclusively to transition metals (1–5). Compared to crown ethers, the sulfur analogues have been shown to exhibit markedly different conformational preferences (5) and to produce complexes with unusual properties (7–10). For example, they stabilize less common oxidation states such as Pd(III), Au(II), or Rh(II) (9, 11, 12), unusual coordination geometries (13, 14), and they have a large nephelauxetic effect (15, 16) that leads to low-spin complexes in coordination geometries or with specific metal ions where low-spin cases are rarely encountered. Likewise, rapid electron exchange kinetics have been measured for these complexes and have been attributed to the unique structural and electronic features of the ligands (17–19).

Many important future applications of chemistry in areas such as materials science, catalysis, communications, and data storage devices will require the ability to adjust properties of existing substances (20). For example, achievement of a liquid crystal mesophase when a metal is added to an otherwise inactive organic molecule (21) and combination of the electrochemical capabilities of an organic system with the photoluminescence of a metal species through coordination can produce an electro-photoswitch device (22). For development of such applications, structure–function relationships at the molecular level and appreciation of the relationship between molecular structure and bulk properties are of importance (23). As part of our continuing interest in the influence of ligand structure on properties of thioether–metal complexes (24–29) we now report property effects caused by introduction of an extra-cyclic functional group, replacement of thioether donors by *trans*-ethers, and increased carbon chain length between donor sites of a macrocyclic ligand. The ligands used in this study are shown in Fig. 1.

Experimental

Commercially available reagents were obtained from the Aldrich Chemical Co. Inc. or from Morton Thiokol Alfa Products Inc. and were used without further purification. Those used for cyclic voltammetry measurements were spectroscopic grade. $[Fe(L1)][ClO_4]_2$ was prepared by the published method (30). Spectroscopic data were obtained by using the following instruments: IR, Mattson Polaris FT; UV–VIS, Cary model 17; ESR, Bruker ESP-300 X-band spectrometer operating at ~9.5 GHz; NMR, General Electric 300-NB. Solution "glasses" for ESR measurements were prepared by plunging sealed capillaries containing $\sim 10^{-4}$ mol/L solutions into liquid nitrogen. Magnetic susceptibility data were obtained at room temperature by the Faraday method. Electrochemical measurements were carried out under a nitrogen atmosphere at room temperature by using a Cypress Systems, Inc., CS-1087 computer-controlled potentiostat. Solution concentrations were 10^{-3} mol/L in complex and 0.1 mol/L in supporting electrolyte (tetraethylammonium perchlorate). Voltammograms were recorded in acetonitrile by using a glassy carbon working electrode that was prepolished with 0.3 μm Al_2O_3, a platinum counter electrode, and an aqueous saturated calomel reference electrode checked periodically relative to a 1.0×10^{-3} mol/L solution of ferrocene in acetonitrile containing 0.1 mol/L tetraethylammonium perchlorate for which the ferrocene/ferrocenium reduction potential was 400 mV. The reference electrode was separated from the bulk of the solution by a porous Vycor tube. Junction potential corrections were not used. Voltages reported versus the normal hydrogen electrode were obtained by adding 244 mV to the potential measured versus SCE. Analyses were performed by Canadian Microanalytical Service Ltd.

Fig. 1. Ligand structures.



Ligands

(a) 1,4,7,11,14,17-Hexathiacycloeicosane (ligand L1)

The macrocycle was prepared by a modification of the reported method (31). Sodium metal (2.3 g, 0.10 mol) was dissolved in commercial absolute ethanol (600 mL) under a dry nitrogen atmosphere. 2-Mercaptoethyl sulfide (7.7 g, 0.0499 mol) was added cautiously to the solution and the mixture was heated to reflux for 10 min. A solution of 1,3-dibromopropane (10.1 g, 5.08 mL, 0.0500 mol) in commercial absolute ethanol (150 mL) was added dropwise to the refluxing mixture over 3 h. After addition was complete, refluxing was continued for a further hour. Volatiles were removed on a rotary evaporator and the residue was dissolved in $CHCl_3$. This solution was washed with water several times and dried over $CaCl_2$. The dried solution was treated with activated charcoal and, after filtration to remove the charcoal, it was concentrated to 60 mL. To the hot solution was added hot commercial absolute ethanol (75 mL) with vigorous stirring. The solution was filtered while hot and the filtrate was stored at −20°C overnight. The colourless crystals were separated, washed with a little acetone, and dried in air. Yield: 5.8 g (40%); mp 122–124°C. NMR spectrum ($CDCl_3$, ppm from TMS internal standard), ^1H: 2.80 (m, 16H), 2.70 (m, 8H), 1.91 (m, 4H); ^{13}C (proton decoupled): 32.45, 32.25, 30.72, 29.63. Mass spectrum: parent ion, calcd. for $[C_{14}H_{28}S_6]^+$, *m/z*: 388.05138; found, *m/z*: 388.0525.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

(b) 1,4,7-Trithiecan-9-ol (ligand L2)

This macrocycle was prepared in a manner similar to that used to obtain ligand L1 except that 1,3-dichloro-2-propanol (6.45 g, 4.77 mL, 0.0500 mol) was used instead of 1,3-dibromopropane. Yield 4.3 g (41%); mp 87–89°C. NMR spectrum ($CDCl_3$, ppm from TMS internal standard), ^{1}H: 3.87 (m, 1H), 2.07 (br, s, 1H), 2.80 (m, 12H); ^{13}C (proton decoupled): 67.38 ($(CH_2)_2CHOH$), 32.07 ($(CH_2)_2CHOH$), 31.50 ($SCH_2CH_2SCH_2CH_2S$), 31.33 ($SCH_2CH_2SCH_2CH_2S$). Mass spectrum: parent ion, calcd. for $[C_7H_{14}OS_3]^+$, *m/z*: 210 not found; calcd. for $[C_7H_{14}S_3]^+$, *m/z*: 194; found, *m/z*: 194.

(c) 1-Oxa-4,8-dithiacyclodecane (ligand L4)

This preparation was similar to that for L1 except that 2-mercaptoethyl ether was used in place of 2-mercaptoethyl sulfide and that the product was a viscous oil. The oil was chromatographed on silica by using $CHCl_3$ as eluant and the first band was collected. After removal of the solvent under vacuum, the product remained as a clear colourless oil. Yield 1.8 g (20%). NMR spectrum ($CDCl_3$, ppm from TMS internal standard), ^{1}H: 3.75 (m, 4H), 2.93 (m, 4H), 2.74 (m, 4H), 1.96 (quintet, 2H, J = 6.6 Hz); ^{13}C (proton decoupled): 71.45, 32.87, 30.33, 29.94. Mass spectrum: parent iron, calcd. for $[C_7H_{14}OS_2]^+$, *m/z*: 178; found: *m/z*: 178.

(d) 1,11-Dioxa-4,8,14,18-tetrathiacycloeicosane (ligand L3)

Continued elution of the column described in (*c*) eventually removed a second viscous oil. Yield 2.9 g (32%). NMR spectrum ($CDCl_3$, ppm from TMS internal standard), ^{1}H: 3.68 (t, 8H, J = 6.2 Hz), 2.75 (m, 8H), 2.73 (m, 8H), 1.90 (quintet, 4H, J = 7.2 Hz); ^{13}C (proton decoupled): 71.22, 31.68, 31.40, 29.75. Mass spectrum: parent ion, calcd. for $[C_{14}H_{28}O_2S_4]^+$, *m/z*: 356; found, *m/z*: 356.

Complexes

Note: Perchlorate salts are often treacherously explosive (32) and although we have been unable to cause these compounds to detonate from shock or heat we recommend suitable precautions be taken whenever perchlorates are handled.

(a) [Co(L1)][ClO$_4$]$_2$

A solution of L1 (78 mg, 0.20 mmol) in $CHCl_3$ (10 mL) was added to a solution of $Co(ClO_4)_2 \cdot 6H_2O$ (73 mg, 0.20 mmol) in acetonitrile (10 mL). A violet precipitate appeared immediately and was separated by filtration, washed with acetone, and recrystallized from nitromethane by vapour diffusion of diethyl ether to give deep purple crystals. Yield 90 mg (68%). UV–vis (CH_3CN): λ_{max} in nm (ϵ in mol^{-1} L cm^{-1}); 750 (20), 517 (120), 370 (2600). μ_{eff} (22°C) = 1.75 BM. Anal. calcd. for $C_{14}H_{28}Cl_2CoO_8S_6$: C 25.99, H 4.37, S 29.76, Co 9.12; found: C 26.04, H 4.37, S 29.91, Co 9.08.

(b) [Ni(L1)][ClO$_4$]$_2$

Nickel perchlorate hexahydrate (73 mg, 0.20 mmol) was dissolved in nitromethane (15 mL) and a solution of L1 (78 mg, 0.20 mmol) in $CHCl_3$ (8 mL) was added. The solution was filtered and allowed to evaporate slowly until violet crystals formed that were separated by filtration, washed with acetone, and briefly air-dried. These crystals develop a powdery surface upon standing that gives them a purple rather than violet appearance. The nature of this change is associated with the uptake of water and only the violet crystals are suitable for X-ray crystallographic study. Recrystallization from nitromethane by diethyl ether vapour diffusion affords purified violet crystals. Yield 95 mg (74%). UV–vis (CH_3NO_2) (violet crystals): λ_{max} in nm (ϵ in mol^{-1} L cm^{-1}); 775 (30), 530 (50). μ_{eff} (22°C) = 2.83 BM (violet crystals). Anal. calcd. for $C_{14}H_{28}Cl_2NiO_8S_6 \cdot H_2O$ (purple crystals): C 25.31, H 4.55, S 28.96, Ni 8.83; found: C 25.24, H 4.40, S 26.60, Ni 8.14.

(c) [{Pd(η^3-C$_3$H$_5$)}$_2$(L1)][ClO$_4$]$_2$

Solutions of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (74 mg, 0.20 mmol) in acetone (10 mL) and $AgClO_4$ (83 mg, 0.40 mmol) in acetone (10 mL) were mixed and stirred for 10 min. The mixture was filtered and to the filtrate was added a solution of L1 (78 mg, 0.20 mmol) in $CHCl_3$ (10 mL). The solvent was allowed to evaporate slowly and eventually yellow-orange crystals were deposited. Yield 140 mg (79%). NMR spectrum (CD_3CN, ppm from TMS internal standard), ^{1}H: 5.81 (m, 2H), 4.07 (d, 4H, allyl-*syn*, $^3J_{H-H}$ = 6.6 Hz), 3.22 (d, 4H, allyl-*anti*, $^3J_{H-H}$ = 12.0 Hz), 3.15 (m, 6H), 3.00 (m, 10H), 2.88 (m, 4H), 2.45 (m, 4H), 2.30 (m, 2H), 1.55 (m, 2H); ^{13}C (proton decoupled): 109.52 (η^3-CH_2CHCH_2), 65.40 (η^3-CH_2CHCH_2), 37.84, 33.52, 29.50, 27.20. Anal. calcd. for $C_{20}H_{38}Cl_2O_8Pd_2$: C 27.22, H 4.34; found: C 27.30, H 4.45.

(d) [Co(L2)$_2$][ClO$_4$]$_2$·CH$_3$CN

Solutions of $Co(ClO_4)_2 \cdot 6H_2O$ (70 mg, 0.19 mmol) in acetonitrile (5 mL) and L2 (80 mg, 0.38 mmol) in CH_2Cl_2 (5 mL) were mixed and there was an immediate colour change from pink to red. Upon addition of diethyl ether (10 mL) a red precipitate formed that was separated and redissolved in hot acetonitrile (5 mL). Upon cooling and slow evaporation of the solvent, red crystals were deposited that were separated, washed with acetone and then dichloromethane, and dried in air. Yield 89 mg (69%). UV–vis (CH_3CN): λ_{max} in nm (ϵ in mol^{-1} L cm^{-1}); 830 (20), 490 (100), 340 (1000). μ_{eff} (21°C) = 2.71 BM. Anal. calcd. for $C_{16}H_{31}Cl_2CoNO_{10}S_6$: C 26.70, H 4.34, Co 8.19; found: C 26.24, H 4.28, Co 8.90.

(e) [Ni(L2)$_2$][ClO$_4$]$_2$

Preparation of this compound is the same as that for $[Co(L2)_2][ClO_4]_2 \cdot CH_3CN$ in (*e*) except that the final washing of the purple crystalline product was with diethyl ether. Yield 120 mg (93%). UV–vis (CH_3NO_2): λ_{max} in nm (ϵ in mol^{-1} L cm^{-1}); 782 (12), 520 (40). μ_{eff} (20°C) = 2.93 BM. Anal. calcd. for $C_{14}H_{28}Cl_2NiO_{10}S_6$: C 24.79, H 4.16, Ni 8.65; found: C 26.24, H 4.28, Ni 6.51.

(f) [Co(L3)][ClO$_4$]$_2$

To a solution of $Co(ClO_4)_2 \cdot 6H_2O$ (0.18 g, 0.49 mmol) in methanol–nitromethane (3 mL:20 mL) was added a solution of L3 (0.20 g, 0.56 mmol) in nitromethane (5 mL), causing a colour change to red. After filtration, the solution was allowed to evaporate slowly until deep violet needles formed that were collected and washed with small amounts of dichloromethane, nitromethane, and then acetone, and dried in air. Yield 0.22 g (73%). UV–vis (CH_3NO_2): λ_{max} in nm (ϵ in mol^{-1} L cm^{-1}); 780 (25), 540 (100), 370 (500). μ_{eff} (22°C) = 4.37 BM. Anal. calcd. for $C_{14}H_{28}Cl_2CoO_{10}S_4$. C 27.37, H 4.59, S 20.87, Co 9.59; found: C 27.66, H 4.62, S 19.12, Co 8.78.

(g) [Ni(L3)][ClO$_4$]$_2$

Preparation of [Ni(L3)][ClO$_4$]$_2$ is similar to that for [Co(L3)][ClO$_4$]$_2$ except that the greenish-blue crystalline product was washed with dichloromethane, acetone, and then diethyl ether. Yield 0.20 g (68%). UV–vis (CH_3CN): λ_{max} in nm (ϵ in mol^{-1} L cm^{-1}); 982 (5.9), 596 (4.9), 369 (sh), 328 (40). μ_{eff} (22°C) = 2.98 BM. Anal. calcd. for $C_{14}H_{28}Cl_2NiO_{10}S_4$: C 27.38, H 4.59, S 20.88, Ni 9.56; found: C 27.29, H 4.59, S 18.89, Ni 9.06.

X-ray

A summary of crystallographic data for [Ni(L1)][ClO$_4$]$_2$, [Ni(L2)$_2$][ClO$_4$]$_2$, and [Co(L3)][ClO$_4$]$_2$ is given in Table 1. X-ray diffraction data were collected by using a Rigaku AFC6S diffractometer. All measurements were made with graphite-monochromated Mo Kα radiation and a 2 kW sealed tube generator. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement of the setting angles of 22 ([Ni(L1)][ClO$_4$]$_2$), 23 ([Ni(L2)$_2$][ClO$_4$]$_2$), or 24 ([Co(L3)][ClO$_4$]$_2$) carefully centred reflections in the range $20.50° < 2\theta < 25.01°$ ([Ni(L1)][ClO$_4$]$_2$), $22.59° < 2\theta < 25.55°$ ([Ni(L2)][ClO$_4$]$_2$), or $30.14° < 2\theta < 37.63°$ ([Co(L3)][ClO$_4$]$_2$) corresponded to an orthorhombic ([Ni(L1)][ClO$_4$]$_2$), a monoclinic ([Ni(L2)$_2$][ClO$_4$]$_2$), or a tetragonal ([Co(L3)][ClO$_4$]$_2$) cell with dimensions as shown in Table 1. The space groups were determined by systematic absences, a statistical analysis of intensity distribution, packing considerations, and the successful solution and refinement of the structures. Of the 2525 ([Ni(L1)][ClO$_4$]$_2$), 2460 ([Ni(L2)$_2$][ClO$_4$]$_2$), or 1437 ([Co-(L3)][ClO$_4$]$_2$) reflections collected, 2515 ([Ni(L1)][ClO$_4$]$_2$), 2285 ([Ni(L2)$_2$][ClO$_4$]$_2$), or 1437 ([Co(L3)][ClO$_4$]$_2$) were unique. The intensities of three representative reflections, measured after every 150 reflections, remained constant for [Ni(L1)][ClO$_4$]$_2$ and [Ni(L2)][ClO$_4$]$_2$ throughout data collection, which indicates crystal and electronic stability. For [Co(L3)][ClO$_4$]$_2$, the intensities of the representative reflections declined by 5.10% and a linear correction factor was applied to account for this phenomenon. The linear absorption coefficient for Mo Kα is 15.2 cm^{-1} ([Ni(L1)][ClO$_4$]$_2$) and [Ni(L2)$_2$][ClO$_4$]$_2$) or 11.2 cm^{-1} ([Co(L3)][ClO$_4$]$_2$). Azimuthal scans of several reflections for [Ni(L1)][ClO$_4$]$_2$ indicated no need for an absorption correction. An empirical absorption correction, based on azimuthal scans of several reflections, was applied for [Ni(L2)$_2$][ClO$_4$]$_2$ and [Co(L3)][ClO$_4$]$_2$, and resulted in transmission factors ranging from 0.88 to 1.00 and 0.87 to 1.00, respectively. The data were corrected for Lorentz and polarization effects. The structures were solved by direct methods (33, 34). Non-hydrogen atoms were all refined anisotropically for [Ni(L1)][ClO$_4$]$_2$ but for [Ni(L2)$_2$][ClO$_4$]$_2$ and [Co(L3)][ClO$_4$]$_2$ some (O(1A), O(1B), C(1A), C(1B), C(2A), C(2B) for [Ni(L2)$_2$][ClO$_4$]$_2$ or O(2), O(2A), O(3), O(3A), O(4), O(4A), O(5), O(5A), O(6), O(7), O(8) for ([Co-(L3)][ClO$_4$]$_2$) were refined isotropically. The final cycle of full-matrix least-squares refinement[3] was based on 1474 ([Ni(L1)][ClO$_4$]$_2$), 1487 ([Ni(L2)$_2$][ClO$_4$]$_2$), or 974 ([Co-(L3)][ClO$_4$]$_2$) observed reflections ($I > 2.00\sigma(I)$) and 279 ([Ni-(L1)][ClO$_4$]$_2$), 149 ([Ni(L2)$_2$][ClO$_4$]$_2$), or 56 ([Co(L3)]-[ClO$_4$]$_2$) variables, and converged with unweighted and weighted agreement factors ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)]^{1/2}$) equal to 0.047 and 0.040 ([Ni(L1)][ClO$_4$]$_2$), 0.046 and 0.039 ([Ni(L2)$_2$][ClO$_4$]$_2$), or 0.054 and 0.058 ([Co(L3)][ClO$_4$]$_2$), respectively. The weighting scheme was based on counting statistics. Neutral atom scattering factors were from the usual source (35). All calculations were performed by using the TEXSAN (36) crystallographic software of Molecular Structure Corporation. A description of the experimental procedure, positional parameters, anisotropic thermal parameters, and a full listing of bond lengths and bond angles are available as supplementary data.[4]

Results and discussion

(a) Ligands

Ligand L1 has been reported previously (31, 37). Our preparation of this substance is similar to the relatively less complicated synthesis described in the earlier of these two reports but involves a slower addition of the final reagent and a more dilute reaction mixture. This raises the yield from 30 to 40% and gives a product with a slightly higher melting point.

Ligand L2 has also been reported previously (38) but was prepared by a different (cesium template) method. The yield from that procedure was somewhat lower than reported herein and the physical characteristics of that product differ significantly from ours. Furthermore, the nickel and cobalt complexes described (38) as having been prepared from that substance have different physical and spectroscopic properties from those of the complexes prepared from our material. Since such ligand preparations tend to give mixtures of "small" (10-membered) and "large" (20-membered) rings (for example L3 and L4) that are difficult to distinguish even by NMR, it is possible that one is the "small" and one the "large" ring. Since our L2 has been used to produce in high yield a crystalline derivative, [Ni(L2)$_2$][ClO$_4$]$_2$, from which an X-ray structure has been obtained that indicates presence of two 10-membered rings (see Fig. 3), we believe the preparations and physical characteristics reported herein for L2 and its complexes are correct.

Synthesis of L3 was described previously by a different method (39). During our preparation of L3, chromatographic purification led to separation of the related "small" ring, $C_7H_{14}OS_2$, in lower yield. The IR and NMR spectroscopic characteristics of this substance are nearly identical to those of the "large" ring, $C_{14}H_{28}O_2S_4$, L3 (See Experimental). The two may, however, be distinguished by their mass spectra, which have appropriate molecular ion peaks, and by their chromatographic retention times, which for the "large" ring is much greater.

[3] Function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$; $\sigma^2(F_o^2) = [S^2(C + R^2B) + (pF_o^2)^2]/Lp^2$ and S = scan rate; C = total integrated peak count; R = ratio of scan time to background counting time; B = total background count; Lp = Lorentz-polarization factor.

[4] A complete set of data can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

The experimental procedure and tables of atomic parameters, bond lengths, and bond angles have also been deposited with the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K. Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

(b) Structures

The X-ray structure of $[Ni(L1)]^{2+}$ (Fig. 2) reveals a relatively rare example of an optically active octahedral thioether complex in which the two six-membered chelate rings have *gauche* placement with respect to each other when the octahedron is viewed down the appropriate pseudo-trigonal axis. Normally, such systems adopt a *meso* configuration with the two six-membered chelate rings *anti* as is found in $[Pd(10S3)_2][ClO_4]_2$ (10S3 = 1,4,7-trithiacyclodecane) (40) or the related $[Ni(10N3)_2]^{2+}$ (41) or $[Co(10N3)_2]^{3+}$ (42).

A previous report by Setzer, Grant, and co-workers (39) of a system with similar *gauche* placement of six-membered chelate rings involved $[Fe(10S3)_2][ClO_4]_2$ in which the ligand system is two 10-membered rings instead of one 20-membered ring as for our L1. In their compound, the unit cell contains only one enantiomer whereas in ours there are four cations per unit cell, two of which are the *d* form and two of which are the *l* form so that the sample overall is racemic. Coordination of L1 to produce *gauche* placement of its six-membered chelate rings by use of meridional looping is in contrast to that found for 18S6 (18S6 = 1,4,7,10,13,16-hexathiacyclooctadecane) in $[Ni(18S6)]^{2+}$ in which all loops are facial but is similar to that for 24S6 in $[Ni(24S6)]^{2+}$ (24S6 = 1,5,9,13,17,21-hexathiacyclotetracosane) (43). In $[Ni(L1)]^{2+}$ (L1 = 20S6), there are two meridional loops involving the six-membered chelate rings whereas in $[Ni(18S6)]^{2+}$, which has only five-membered chelate rings, coordination is always facial. In $[Ni(24S6)]^{2+}$, which has all six-membered chelate rings, there are two meridional loops and all others are facial as in our cation. These preferences can be related to ligand dihedral angles that are in turn influenced by intramolecular nonbonding interactions (6). In $[Ni(L1)]^{2+}$,

four of the 12 C—S bonds have *anti* placements of their adjacent atoms whereas in $[Ni(18S6)]^{2+}$ all 12 C—S bonds have *gauche* placements and in $[Ni(24S6)]^{2+}$ there are six of 12 C—S bonds with *anti* placements in order to minimize intramolecular repulsions.

The coordination sphere bond lengths and angles in $[Ni(L1)]^{2+}$ (Table 2) indicate nearly regular octahedral coordination. The Ni—S lengths range from 2.376(4) to 2.413(4) Å, which is comparable to the ranges found for $[Ni(9S3)_2]^{2+}$ (2.375(3)–2.400(5) Å) (9S3 = 1,4,7-trithiacyclononane) (44), $[Ni(18S6)]^{2+}$ (2.377(1)–2.397(1) Å), or $[Ni(24S6)]^{2+}$ (2.413(1)–2.443(1) Å) (43) and shorter, presumably due to compression by the cyclic nature of the ligand, than the average (2.43 Å) (1) for octahedral monodentate thioether complexes. Bond angles in the coordination sphere of $[Ni(L1)]^{2+}$ range from 84.8(1)° to 95.4(1)°, which is again comparable to ranges found for $[Ni(9S3)_2]^{2+}$ (88.04(5)°–91.96(5)°), $[Ni(18S6)]^{2+}$ (88.5(1)°–91.3(1)°), and $[Ni(24S6)]^{2+}$ (82.3(4)°–93.9(3)°) with the greatest deviations from ideal values associated with the six-membered chelate rings.

For $[Ni(L2)_2][ClO_4]_2$ (Fig. 3), the Ni—S lengths and coordination sphere bond angles (Table 4) range from 2.374(2) to 2.419(2) Å and from 84.06(6)° to 95.94(6)°, respectively, both of which are very similar to ranges found for $[Ni(L1)]^{2+}$ and for $[Ni(keto\text{-}10S3)_2]^{2+}$ (keto-10S3 = 1,4,7-trithiacyclodecane-9-one) (2.381(3)–2.424(3) Å) (38). As in $[Ni(L1)]^{2+}$, the greatest deviation from ideal angles for $[Ni(L2)]^{2+}$ is associated with the six-membered chelate rings. In $[Ni(L2)_2]^{2+}$ as in $[Ni(keto\text{-}10S3)_2]^{2+}$, the two six-membered chelate rings are *anti* with respect to each other, giving the usual *meso* isomers instead of being *gauche* as in $[Ni(L1)]^{2+}$ and resulting in *d–l* enantiomeric pairs in the unit cell. There is disorder of the L2 ligand rings involving C(1), C(2), O(1), and their associated hydrogens that places the hydroxyl hydrogens pointing into the ring or out of the ring. Occupancy of the two forms (Table 5) in the crystal is close to 50% of each.

For $[Co(L3)][ClO_4]_2$ (Fig. 4), the Co—S lengths are 2.444(2) Å, the Co—O lengths are 2.098(6) Å, and the coordination sphere bond angles range from 80.43(5)° to 99.57(5)° (Table 6). The Co—S bonds are somewhat longer than those

and the Co—O distance (2.098(6) Å) is comparable to those in pentagonal bipyramidal $[Co(15O5)(H_2O)_2]Cl_2 \cdot H_2O$ (15O5 = 1,4,7,10,13-pentaoxacyclopentadecane) (46) of 2.076(4) (axial H_2O), 2.166(2), 2.213(2), and 2.172(2) Å. The S-Co-S angles in $[Co(L3)]^{2+}$ of the five-membered (86.7(1)°) and six-membered (96.5(1)°) chelate rings are slightly smaller and slightly larger, respectively, than their counterparts in $[Co(10S3)_2]^{2+}$ of 88.0(1)° or 91.5(1)° (five-membered) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

94.4(1)° (six-membered). Unlike $[Ni(L1)][ClO_4]_2$, the six-membered chelate rings of $[Co(L3)][ClO_4]_2$ are *anti* with respect to each other but again there are two meridional loops of ligand. The conformations for the 16 C-C-E-C or E-C-C-E (E = O or S) units in these ligands are all *gauche* except for two pairs of *anti* in each, but the location of the *anti* units differs in the two ligands. In L1, they occur about the sulfur that separates the six-membered and the five-membered chelate rings whereas in L3 they occur about the oxygen atoms, which correspond to separators between adjacent five-membered rings. The changed arrangement of the six-membered rings undoubtedly reflects the different intramolecular nonbonded interactions in the S_4O_2 ligand (L3) compared to those in the S_6 ligand (L1) (6).

(c) Magnetic moments

Since early reports of low-spin cobalt(II) (8, 47), it has become increasingly clear from spectroscopic and magnetic data that, especially when cyclic polythioethers are involved, the ability of these ligands to reduce inter-electronic repulsions (see Sect. (*d*)) is adequate to give low-spin complexes as a general rule. A question remains, however, as to how far these ligands take their complexed metals beyond the spin-crossover point. For $[Fe(L1)][ClO_4]_2$, magnetic susceptibility measurements indicate a diamagnetic sample consistent with a low-spin d^6 system (30). Likewise, for $[Co(L1)][ClO_4]_2$, μ_{eff} (22°C) = 1.75 BM indicates a low-spin d^7 system similar in its coordination sphere and magnetic properties to that of $[Co(18S6)]^{2+}$ (8) or $[Co(10S3)_2]^{2+}$ (45). The effective magnetic moment of $[Co(L2)][ClO_4]_2$ at 21°C, on the other hand, is 2.71 BM, which is appropriate for neither low-spin nor high-spin cobalt(II). The electronic spectrum of this complex is subtly different from other species with superficially similar S_6 coordination spheres and can be interpreted to indicate a tetragonal elongation of the coordination sphere (Sect. (*d*)). If this interpretation is correct, it would not be unreasonable to expect that the elongation decreases the ability of the axial thioethers to engage in reduction of spin-pairing energy and, as a consequence, the magnitudes of the ligand field splitting and spin-pairing energies become more nearly equal. This could lead to a spin-crossover situation such as that recently described for Co(II) species with S_2N_3 coordination spheres (48). In the case of $[Co(L2)_2]^{2+}$, application of eq. [1] (48) (in which n_{hs} is the mole fraction of the sample that is high spin, μ_{hs} is 4.8 BM, and μ_{ls} is 1.9 BM) suggests there is approximately 19% of the sample in the high-spin state at 21°C.

$$[1] \qquad n_{hs} = \frac{\mu_{exptl}^2 - \mu_{ls}^2}{\mu_{hs}^2 - \mu_{ls}^2}$$

Further variable-temperature magnetic susceptibility studies of this and related systems are in progress and it is interesting to note that extra-cyclic substituents such as an OH group can be used to "tune" the magnetic properties of this system compared to low-spin $[Co(10S3)_2]^{2+}$ (38). It is also significant that if the axial thioethers in $[Co(L1)]^{2+}$ or $[Co(L2)_2]^{2+}$ are replaced as in $[Co(L3)]^{2+}$ (Fig. 4) by oxygen atoms, which have even less ability to decrease spin-pairing energy, the trend in magnetic moments is continued with the result that the high-spin state is dominant in $[Co(L3)]^{2+}$ at room temperature (μ_{eff} = 4.37 BM at 22°C).

The effective magnetic moments of 2.83 ($[Ni(L1)][ClO_4]_2$), 2.93 ($[Ni(L2)_2][ClO_4]_2$), and 2.98 BM ($[Ni(L3)][ClO_4]_2$) are consistent with the two unpaired electrons expected for octahedral Ni(II) species.

(d) Electronic spectra

As indicated by its magnetic susceptibility, $[Fe(L1)]^{2+}$ is low spin. Low-spin iron(II) in octahedral symmetry is expected to exhibit two spin-allowed *d–d* transitions (49) and both are observed for $[Fe(L1)]^{2+}$. Ligand field parameters (Table 8) are in reasonable agreement with those reported previously for $[Fe(9S3)_2]^{2+}$ (50) and $[Fe(L1)][ClO_4]_2$ (30) and indicate an even greater ligand field for iron than for nickel as well as a greater nephelauxetic effect (vide infra).

Low-spin cobalt(II) would be expected to exhibit Jahn–Teller distortion and among known hexa-thioether Co(II) coordination spheres both tetragonal elongations (47) and compressions (44) have been observed. Electronic spectra of both compressed and elongated species are similar except for their lowest energy band, which represents the $^2A_{1g} \rightarrow {}^2aT_{2g}$ transition and corresponds to Δ_0 (45). For elongated species, this band appears at longer wavelengths (e.g., $[Co(2,5,8\text{-trithianonane})_2]^{2+}$, λ = 950 nm (47)) and as a result the complexes are often brown or red whereas compressed species have bands at shorter wavelengths (e.g., $[Co(9S3)_2]^{2+}$, λ = 750 nm (44, 45)) and are violet or purple. The spectrum of violet $[Co(L1)][ClO_4]_2$ (see Experimental), with its lowest energy band at 750 nm, is more like spectra of compressed hexa-thioether cobalt(II) complexes and it therefore seems likely that it reflects a Jahn–Teller compressed coordination sphere. For red $[Co(L2)_2]^{2+}$, the lowest energy band occurs at 830 nm and suggests a Jahn–Teller elongated coordination sphere. In that respect, this complex is a contrast to $[Co(9S3)_2]^{2+}$, which might be expected to be very similar but which has been shown to have tetragonal compression, is more violet in colour, and has its longest wavelength band at 750 nm (44, 45). For violet $[Co(L3)][ClO_4]_2$, the lowest energy band that was detected is at 780 nm but this is likely not the lowest energy band overall since magnetic studies (vide supra) have shown this compound to be high spin.

The electronic spectra (see Experimental) of violet $[Ni(L1)][ClO_4]_2$ and of purple $[Ni(L2)_2][ClO_4]_2$ in nitromethane are similar to spectra of other nickel species with pseudo-octahedral thioether coordination spheres (43). Of the three *d–d* bands expected, only the first two are observed, while the highest energy band is obscured by a charge transfer band that extends from about 400 nm into the ultraviolet as is usual for such compounds (16, 43). The Racah parameter, *B*, the nephelauxetic ratio, β, and the ligand field parameter, Δ_0, for the compounds reported in this study are given in Table 8 together with those of some related compounds for comparison. The Δ_0 values for $[Ni(L1)][ClO_4]_2$ of 12 900 cm^{-1} and for $[Ni(L2)_2][ClO_4]_2$ of 12 800 cm^{-1} are similar to values found for most six-coordinate thioether systems (Table 8) and slightly larger than those for six-coordinate N-donor species. The *B* values for $[Ni(L1)][ClO_4]_2$ of 670 cm^{-1} and for $[Ni(L2)_2][ClO_4]_2$ of 720 cm^{-1} give nephelauxetic ratios, β = 0.65 ($[Ni(L1)][ClO_4]_2$) and 0.69 ($[Ni(L2)_2][ClO_4]_2$), which are similar to those found for other six-coordinate thioether systems (Table 8) but smaller than for six-coordinate N-donor species. Together these indicate a slightly larger ligand field

[a]Fe: $A_{1g} \rightarrow T_{1g} = \Delta_0 - C$, $A_{1g} \rightarrow T_{2g} = \Delta_0 + 16B - C$, (assume $C = 4B$) (50). Co: (low spin) lowest energy band ($^2A_{1g} \rightarrow {}^2aT_{1g}$) = Δ_0 (45). Ni: lowest energy band ($^3A_{2g} \rightarrow {}^3T_{2g}$) = Δ_0 (45).

[b]Fe: (see *a*). Ni: $B = (2\nu_1^2 + \nu_2^2 - 3\nu_1\nu_2)/(15\nu_2 - 27\nu_1)$ (16).

[c]$\beta = B_{complex}/B_{free\ ion}$; $B_{free\ ion}$(Fe) = 1058, (Ni) = 1038 cm^{-1} (16, 38).

[d]Co: (high spin).

[e]ttn = 2,5,8-trithianonane.

strength and a much larger nephelauxetic effect for the thioethers than for the N-donors. The increased nephelauxetic effect has been noted before and is attributed to π-bonding capabilities of thioether sulfur (10, 16, 51, 52). For greenish-blue $[Ni(L3)][ClO_4]_2$, the effect of changing two thioethers into a pair of *trans*-ether donors as in the L1 or L2 complexes is visually apparent as a change in colour of the complex from purple to greenish-blue. The value of Δ_0 in the L3 complex is decreased to 10 180 cm^{-1} compared to the L1- and L2-containing species, and B has risen sharply to 1017 cm^{-1}, giving β = 0.98. These changes represent quite remarkable decreases in both ligand field strength and nephelauxetic effect. They parallel, however, the changes in ligand field strength observed for Co(II) with the same series of ligands. For Co(II), the magnetic properties show a trend from low spin through spin crossover to high spin through the series, consistent with a steady decrease in ligand field.

(e) Electrochemistry

Cyclic voltammetry of L1, L2, or L3 in CH_3NO_2 reveals irreversible oxidation of the free ligands at potentials $\geq$ +1.45 V vs. NHE. These processes are somewhat solvent dependent and become quasi-reversible in CH_3CN at $E_{1/2} \sim$ +1.56 V vs. NHE. Similar behaviour has been reported recently for 2,5,8-trithia[9]-*o*-benzenophane and was observed previously for other thioethers (53). The ligands show no tendency for reduction in the potential range over which the complexes have been examined.

For $[\{Pd(\eta^3\text{-}C_3H_5)\}_2(L1)][ClO_4]_2$ in acetonitrile, there is no electrochemical activity within the potential range over which the ligand is electrochemically silent. Cyclic voltammetry of $[Co(L1)][ClO_4]_2$, however, in either acetonitrile or nitromethane shows two reversible one-electron transfers at +0.570 V vs. NHE (ΔE_p = 80 mV at scan rates between 50 and 200 mV/s) and −0.355 V vs. NHE (ΔE_p = 90 mV at scan rates between 50 and 200 mV/s). The former is a Co(II)/Co(III) process whereas the latter is Co(II)/Co(I). There is a close comparison between this behaviour and that of $[Co(10S3)_2]^{2+}$ or $[Co(9S3)_2]^{2+}$ under similar conditions (45). The former exhibits reversible waves at +0.41 and −0.45 V vs. NHE whereas the latter has irreversible waves at +0.42 and −0.48 V vs. NHE. Thus, the presence of only one ligand ring compared to two in the coordination sphere or a change in the length of the carbon chain between donor sites has had only a small effect. These changes have resulted in a slight shift towards positive potentials but the general character of these redox processes appears otherwise unaffected. Comparison with the published data for $[Co(18S6)]^{2+}$ (47) is difficult. A dependence of the form of the cyclic voltammetric waves on the identity of the anion has been observed for some thioether complexes (16, 25) and this is also the case for $[Co(L1)]^{2+}$. Since the anion used in the reported study of $[Co(18S6)]^{2+}$ is not the same as in our current study and the reported potentials and wave forms for $[Co(18S6)]^{2+}$ are radically different from those for $[Co(L1)]^{2+}$, this precludes comparison in any meaningful way. For $[Co(L2)_2]^{2+}$, there are two reversible waves in acetonitrile at −0.28 and +0.65 V vs. NHE. Since redox potential is related to the relative size of the stability constants for the reduced and oxidized forms of the couple, the more positive potential values for both waves of the L2 complex compared to its 10S3 analog suggest that introduction of the OH group on the ligand ring to form L2 from 10S3 has resulted in poorer stabilization of Co(III) in the Co(III)/Co(II) and Co(II) in the Co(II)/Co(I) couples of the L2 complex. In other words, extra-cyclic groups may be used to "tune" the redox potentials of these complexes. We previously observed a similar effect in certain Cu(II) complexes (25). For $[Co(L3)][ClO_4]_2$ in nitromethane, there is no response between −0.7 and +0.7 V vs. NHE (and the compound decomposes in CH_3CN). Thus, metal-centred redox does not occur at potentials comparable to those found for other cobalt complexes in this study. This suggests that the electronic environment of cobalt in this complex is significantly different from that of the cobalt atoms in either the L1 or the L2 species, which is consistent with the findings of the magnetic and electronic spectroscopic studies discussed above.

For $[Ni(L1)][ClO_4]_2$ in CH_3CN, there is a quasi-reversible reduction at −351 mV vs. NHE (ΔE_p = 110 mV at scan rates of 50–300 mV/s) and an irreversible oxidation at +1.204 V vs. NHE as well as the ligand-centred process at 1.56 V. The behaviour of $[Ni(L2)_2][ClO_4]_2$ in nitromethane is similar to that of the L1 complex, which is perhaps not too surprising since their spectral characteristics and coordination spheres are similar. These processes are all strongly solvent dependent, becoming completely irreversible in CH_3NO_2 at potentials of −500 mV, +1.54 V, and +1.68 V vs. NHE. The $Ni^{2+/+}$ process at −351 mV vs. NHE may be compared with related processes for $[Ni(9S3)_2]^{2+}$ (quasi-reversible, $E_{1/2}$ = −710 mV vs. NHE) (54) and $[Ni(10S3)_2]^{2+}$ (quasi-reversible, $E_{1/2}$ = −550 mV vs. NHE) (45). Clearly, ligand structure has pronounced influence on the potential of the redox processes but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

the exact details responsible are not yet completely clear. Chain length between coordination sites is by itself not sufficient to explain the effects as was shown in a study of $[Ni(pttd)]^{2+}$ (pttd = 1,12-bis(2-pyridyl)-2,5,8,11-tetrathiadecane) and $[Ni(pttu)]^{2+}$ (pttu = 1,13-bis(2-pyridyl)-2,5,9,12-tetrathiaundecane), which have identical electrochemical characteristics but different chain lengths (16).

That the electronic situation of the Ni atom in $[Ni(L3)]^{2+}$ is quite different from the situations of the Ni atoms in the L1 and L2 complexes is apparent from electronic spectroscopy, as discussed above. This is reflected in the cyclic voltammetry of $[Ni(L3)][ClO_4]_2$, which bears no resemblance to the response of the other two nickel complexes. The ligand is electrochemically silent between −0.80 and +0.94 V vs. NHE. Scans of the complex carried out between −0.5 and +0.9 V vs. NHE also show no response but if the initial potential is set at less than −0.5 V or a scan into that region precedes a scan to +0.9 V, a wave at +0.47 V vs. NHE appears. Under this condition, there is a reduction wave at −0.80 V accompanied by a minor return wave at −0.51 V vs. NHE as well as the major wave at +0.47 V. Thus, metal-centred oxidation is not a favourable process, while reduction is electrochemically irreversible and probably accompanied by substantial structural rearrangement. No attempts have been made to isolate Ni(I) species from this reaction.

(f) NMR and ESR

The proton-decoupled ^{13}C NMR spectrum of $[Fe(L1)][ClO_4]_2$ shows seven lines while the ^1H spectrum is complex (30) but we have found it to be invariant with temperature up to 70°C at least. These observations indicate, as suggested by Grant et al. (30), that the ligand has adopted a conformation leading to the *meso* isomer rather than the enantiomeric forms either singly or in a racemic mixture, both of which would lead to more than seven lines in the spectrum. Furthermore, the behaviour of the ^1H spectrum with temperature suggests the structure is rigid and non-fluxional up to 70°C at least. Thus, in $[Ni(L1)]^{2+}$ and $[Fe(L1)]^{2+}$ two different conformers of the ligand are seen, one of which produces a *d–l* pair of enantiomers and one of which produces the *meso* isomer. It may be, since Fe—S lengths are often shorter than Ni—S in comparable MS_6 coordination spheres (avg. 2.395 Å in $[Ni(10S3)_2]^{2+}$ (45); avg. 2.262 in $[Fe(10S3)_2]^{2+}$ (38)), that increased steric crowding in $[Fe(L1)]^{2+}$ compared to $[Ni(L1)]^{2+}$ causes intramolecular interactions in the ligand that are minimized in the complex in its *meso* form.

The proton-decoupled ^{13}C NMR spectrum of $[\{Pd(\eta^3\text{-}C_3H_5)\}_2(L1)][ClO_4]_2$ consists of six lines (see Experimental), two of which are readily assigned to the central and equivalent terminal carbons of the equivalent η^3-allyl groups. The remaining four lines are due to L1 and show that there are only four distinct carbon environments in the coordinated ring. This suggests that the two (η^3-allyl)Pd fragments are bound symmetrically to the macrocycle and each is bound to three sulfurs separated only by two-carbon bridges. The three-carbon bridges then serve to separate the (η^3-allyl)PdS_3 units. Alternatively, it is possible in view of the behaviour of related (η^3-allyl)Pd thioether complexes (24, 26) that the dinuclear cation could be exhibiting binding site fluxionality involving all six sulfurs that is already rapid at room temperature. Attempts to investigate the latter possibility by variable-temperature NMR studies below room temperature did not provide a definitive answer due to solubility difficulties.

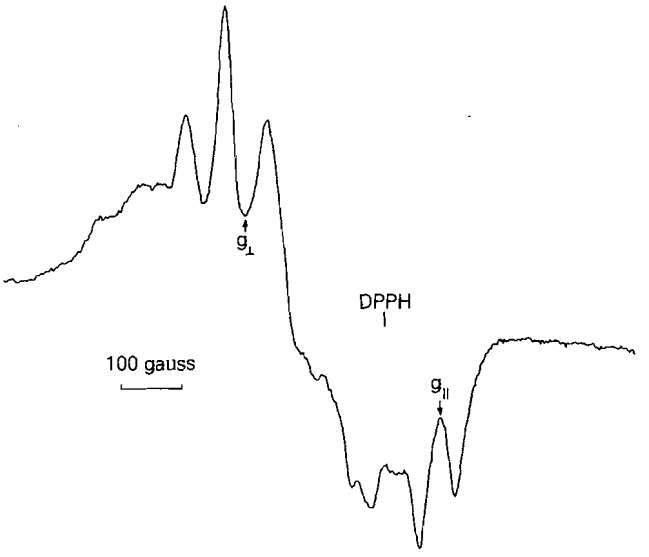

Fig. 5. ESR spectrum at 77 K and 9.60 GHz of $[Co(L2)_2][ClO_4]_2$ in CH_3NO_2 "glass".

The ESR spectrum of a polycrystalline sample of $[Co(L1)][ClO_4]_2$ is invariant with temperature between 77 and 295 K and consists of a single featureless line at $g = 2.13$ with a peak-to-peak width of 292 G. The absence of hyperfine splitting due to ^{59}Co ($I = 7/2$) can be attributed to weak intermolecular exchange interactions found in the crystalline material (47). In CH_3NO_2 solution at room temperature, however, an 8-line isotropic signal ($g_{iso} = 2.106$, $A_{iso} = 38$ G) is detected, confirming the low-spin character of the complex since high-spin species are not expected to exhibit a signal at room temperature (47). At 77 K, the spectrum of a "glass" in CH_3NO_2 is poorly resolved, showing only three distinctly visible lines on the high-field and three more on the low-field branches of the signal. The splitting on these lines is 63 G but no further structural information was extracted from the spectrum.

For $[Co(L2)_2][ClO_4]_2$, the spectrum at 77 K of a CH_3NO_2 "glass" is more clearly resolved (Fig. 5) and resembles that of tetragonally elongated $[Co(10S3)_2]^{2+}$ ($g_\perp = 2.138$ ($A_\perp = 80$ G) and $g_\parallel = 2.067$ ($A_\parallel = 60$ G) (45). Analysis of the spectrum for $[Co(L2)_2]^{2+}$ yields $g_\perp = 2.148$ ($A_\perp = 70$ G) and $g_\parallel = 1.951$ ($A_\parallel = 60$ G) consistent with the tetragonal elongation of the coordination sphere indicated by other physical measurements (see Results and discussion, Sects. (*c*) and (*d*)).

For $[Co(L3)][ClO_4]_2$, no signal is detected in the solid state at room temperature or at 77 K, consistent with the room temperature magnetic moment, $\mu_{eff} = 4.37$ BM, indicating a high-spin complex (47).

Conclusions

Improved preparations for three ligands (L1–L3) have been reported as well as a synthesis for the new ligand L4. Ligand L1 (20S6) differs by only two -CH_2- groups from previously reported 18S6 and comparisons of L1 complexes with published data from 18S6 complexes reveals that the extra -CH_2-

groups have little influence on the properties of the complexes but alter the way in which the ligand loops itself about the central metal. It appears that the choice of meridional or facial looping may be controlled by intramolecular interactions since it is variable with L1 adopting one conformation in $[Ni(L1)]^{2+}$ and another in $[Fe(L1)]^{2+}$, the latter of which is expected to have shorter M—S bonds and therefore greater steric crowding in its coordination sphere. Futhermore, changing to an S_4O_2 donor set in L3 and hence altering the intraligand interactions produces a slightly different looping of the ligand and *anti* placement of the six-membered chelate rings. Confusion in the literature concerning the preparation and properties of L2 and some of its complexes has been corrected and a new macrocyclic ligand (L4) with an S_2O donor set has been prepared. Its separation from the related "large" ring, L3, which is usually also formed in the same reaction, and distinguishing features of L3 and L4 have been described. The use of electronic spectroscopy to distinguish between tetragonally elongated and compressed low-spin Co(II) octahedra has been illustrated and the use of an extra-cyclic functional group and partial substitution of O for S donors to adjust the ligand field, nephelauxetic effect, and hence other dependent properties such as redox potential and magnetic phenomena has been demonstrated.

Abstract: Treatment of orange solutions of Cp*M(NO)(η^2-CH_2Ph)Cl (M = Mo or W) with an equimolar amount of solid $AgBF_4$ in MeCN affords the salts [Cp*M(NO)(η^2-CH_2Ph)(NCMe)]BF_4 as analytically pure crystals in good yields. Both orange complexes have been subjected to single-crystal X-ray crystallographic analyses in order to establish their molecular geometries and their intramolecular metrical parameters. Both salts consist of discrete organometallic cations and tetrahedral BF_4^- anions, the intramolecular dimensions of the two cationic complexes being essentially the same and resembling those found for related Cp*M(NO)-containing compounds. The isolated [Cp*M(NO)(η^2-CH_2Ph)(NCMe)]$^+$ cations are quite electrophilic, being able to abstract Cl^- from a NaCl IR cell to revert to their chloro precursors. However, treatment of the [Cp*W(NO)(η^2-CH_2Ph)(NCMe)]BF_4 salt with various unsaturated substrates (e.g., diphenylacetylene, 2,3-dimethyl-1,3-butadiene, carbon monoxide, and acetone) in $CDCl_3$ results in no detectable chemical reaction. Lewis bases weaker than Cl^- evidently cannot displace the acetonitrile ligand from the coordination sphere of the metal or induce the benzyl ligand to diminish its hapticity. Such a diminution does occur for the CH_2Ph ligand when the MeCN group in the cationic complexes is replaced by a carboxylate anion to produce neutral Cp'M(NO)(η^1-CH_2Ph)(η^2-O_2CR) complexes. The latter complexes are obtainable by treatment of Cp*M(NO)(η^2-CH_2Ph)Cl with AgO_2CR (R = CH(Et)(Ph)) in CH_2Cl_2 and have been fully characterized by conventional spectroscopic methods.

Key words: organomolybdenum, organotungsten, benzyl, cations.

Résumé : Le traitement des solutions de Cp*M(NO)(η^2-CH_2Ph)Cl (M = Mo ou W) avec une quantité équimolaire de $AgBF_4$ solide dans le MeCN fournit les sels [Cp*M(NO)(η^2-CH_2Ph)(NCMe)]BF_4, sous la forme de cristaux analytiquement purs, avec de bons rendements. Dans le but de déterminer leurs géométries moléculaires et leurs paramètres métriques intramoléculaires, on a soumis les deux complexes oranges à des analyses par diffraction des rayons X par des cristaux uniques. Les deux sels sont formés de cations organométalliques et d'anions BF_4^- individuels; les dimensions intramoléculaires des deux complexes cationiques sont essentiellement les mêmes et elles ressemblent à celles que l'on retrouve dans des composés apparentés contenant du Cp*M(NO). Les cations [Cp*M(NO)(η^2-CH_2Ph)(NCMe)]$^+$ isolés sont assez électrophiles; ils sont capables d'enlever les Cl^- d'une cellule IR en NaCl pour redonner leurs précurseurs chloro. Toutefois, le traitement du sel [Cp*W(NO)(η^2-CH_2Ph)(NCMe)]BF_4 avec divers substrats insaturés (par exemple, le diphénylacétylène, le 2,3-diméthylbuta-1,3-diène, le monoxyde de carbone ou l'acétone) dans du $CDCl_3$ ne conduit pas à des réactions chimiques détectables. Les bases de Lewis plus faibles que le Cl^- ne peuvent évidemment pas déplacer le coordinat acétonitrile de la sphère de coordination du métal ou induire le coordinat benzyle à diminuer son hapticité. Une telle diminution se produit pour le coordinat CH_2Ph lorsque le groupe MeCN des complexes cationiques est remplacé par un anion carboxylate pour conduire à des complexes neutres Cp*M(NO)(η^1-CH_2Ph)(η^2-O_2CR). On peut obtenir ces derniers complexes par le traitement des

[Traduit par la rédaction]

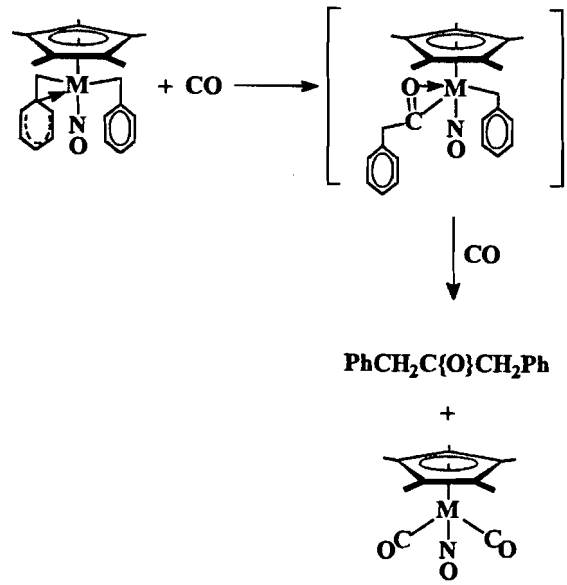
Introduction

The chemistry of coordinatively and (or) electronically unsaturated metal centres continues to be a prime focus of transition-metal organometallic chemistry (1, 2). Our recent efforts in this area have centred principally on the characteristic stoichiometric chemistry of hydrocarbon ligands attached to the 14-valence-electron fragments, $Cp'M(NO)$ (M = Mo, W; Cp′ = $Cp(\eta^5\text{-}C_5H_5)$, $Cp^*(\eta^5\text{-}C_5Me_5)$). In particular, we have expended considerable effort in developing the chemistry of the symmetric 16-electron complexes, $Cp'M(NO)R_2$ (R = alkyl, aryl) (3). Subsequently, we developed methodology to synthesize the asymmetric 16-electron analogues, Cp*M-(NO)(R)R′, (4, 5) and were thus afforded the opportunity to study the comparative reactivity of two different hydrocarbyl ligands attached to the same metal centre (6). In general, the preparation of these hydrocarbyl complexes is non-trivial and presents significant synthetic challenges primarily because of their electronic unsaturation. It was during this work that we discovered the utility of the benzyl group as a hydrocarbyl ligand capable of stabilizing electronically unsaturated metal centres (7). The stabilization arises from the fact that the CH_2Ph ligand can function either as a one- or a three-electron donor to the metal centre when coordinated in an η^1- or an η^2-fashion, respectively, as shown below.

This dual hapticity of the benzyl ligand can, on occasion, permit the metal centre to attain some degree of electronic saturation and consequently diminished reactivity. For instance, the bis(benzyl) complexes, $Cp'M(NO)(CH_2Ph)_2$, are stereochemically nonrigid in solutions and possess the instantaneous 18-valence-electron molecular structures $Cp'M(NO)$-$(\eta^2\text{-}CH_2Ph)(\eta^1\text{-}CH_2Ph)$ that render them less reactive towards air and water than their 16-electron bis(alkyl) analogues, $Cp'M(NO)R_2$ (7*b*). Nevertheless, they can be induced to react just like the bis(alkyl) complexes (8), see eq. [1]. In other words, the stabilization provided by the unique benzyl ligand in these neutral complexes is not so great as to prohibit further reactivity.

It therefore became of interest to us to determine whether benzyl ligands could be utilized similarly to stabilize reactive cationic organometallic complexes, some of which have recently attracted considerable attention as potent Lewis acids (9). In this paper we present the results of our studies in this regard to date. Specifically, we report the extension of our earlier work to encompass the related cationic complexes $[Cp^*M(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$. The benzyl ligands in the organometallic cations have the potential to change their coordination modes from η^2 to η^1 (cf. eq.[1]), thereby opening a vacant coordination site and recducing the formal valence-

[1]



electron configuration at the metal from 18 to 16. During this work we have also demonstrated that just such a hapticity change occurs for the CH_2Ph ligand when the MeCN group in the cationic complexes is replaced by a carboxylate anion to produce neutral $Cp'M(NO)(\eta^1\text{-}CH_2Ph)(\eta^2\text{-}O_2CR)$ complexes.

Experimental

All reactions and subsequent manipulations involving organometallic reagents were performed under anaerobic and anhydrous conditions in an atmosphere of purified dinitrogen or argon. Conventional glovebox and vacuum-line Schlenk techniques were utilized throughout (10). General procedures routinely employed in these laboratories have been described in detail previously (11). $Cp'M(NO)(\eta^2\text{-}CH_2Ph)Cl$ reactants were prepared by the published procedures (7*c*). Infrared and elemental analyses data for all new complexes isolated during this work are collected in Table 1, and their ^1H and ^{13}C NMR data are presented in Table 2.

Preparation of $[Cp^*M(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$

The Mo and W complexes were prepared in a similar manner, and the preparation of the W complex is described below as a representative example.

An orange solution of $Cp^*W(NO)(\eta^2\text{-}CH_2Ph)Cl$ (1.4 g, 3.0 mmol) in MeCN (45 mL) was prepared, and its IR spectrum was recorded (AgCl cell, ν_{NO} = 1548 cm^{-1}). Solid $AgBF_4$ (0.58 g, 3.0 mmol) was added to the stirred solution, whereupon the reaction mixture immediately lightened in colour and a flocculent white precipitate formed. The reaction mixture was stirred for 8 h at ambient temperatures to ensure that the reaction was complete, and it was then filtered through a Celite plug (5 × 2 cm) supported on a medium-porosity glass frit. An IR spec-

trum of the light orange filtrate in an AgCl cell revealed a ν_{NO} band at 1642 cm^{-1}. The volume of the filtrate was reduced in vacuo to ~8 mL, and Et_2O (30 mL) was then added. The resulting solution was stored at −30°C overnight. The orange crystals that deposited were isolated by removing the supernatant solution via cannula and were then washed with Et_2O (15 mL) to obtain analytically pure $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ (1.2 g, 69% yield).

$[Cp^*Mo(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ was prepared in a similar manner and was isolated in 80% yield as an orange crystalline solid. Crystals of both complexes suitable for X-ray crystallographic analyses were selected from the samples prepared as described above.

Treatment of $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ with diphenylacetylene, 2,3-dimethyl-1,3-butadiene, and acetone

Typically, $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ (50 mg) was mixed in a small vial with approximately 1 equivalent of each reagent. Approximately 600 mg of $CDCl_3$ were added to the vial, and the final solution was transferred to an NMR tube fitted with a Kontes Rotoflow top. ^1H NMR spectra were recorded immediately, and also after warming of the tubes and their contents at 55°C for 3 days. Only signals characteristics of $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ and unreacted reagent were present in all spectra recorded.

Treatment of $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ with carbon monoxide.

Approximately 50 mg of $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ was dissolved in $CDCl_3$ (600 mg) in an NMR tube fitted with a Kontes Rotoflow top. The solution was frozen, and the tube was evacuated before being refilled with CO to a pressure of approximately 2 atm (1 atm = 101.3 kPa). The tube was warmed to room temperature, and the ^1H NMR spectrum of its contents only exhibited signals attributable to the organometallic reactant. The spectrum did not change upon warming the sample to 55°C for 3 days.

Preparation of $Cp'M(NO)(\eta^1\text{-}CH_2Ph)(\eta^2\text{-}O_2CR)$ (R = CH(Et)(Ph))

The three complexes $CpMo(NO)(CH_2Ph)(O_2CR)$, $Cp^*Mo(NO)(CH_2Ph)(O_2CR)$, and $Cp^*W(NO)(CH_2Ph)(O_2CR)$ were prepared in a similar manner. The preparation of the $Cp^*Mo(NO)(CH_2Ph)(O_2CR)$ species is given as a representative example.

To a Schlenk tube containing $Cp^*Mo(NO)(\eta^2\text{-}CH_2Ph)Cl$ (0.41 g, 1.1 mmol) and silver 2-phenylbutyrate (0.29 g, 1.1 mmol) immersed in a water bath at 10°C was added CH_2Cl_2 (40 mL) by syringe. The cooling bath was removed, and the reaction mixture was stirred for 3 h at ambient temperatures. During the course of the reaction, the initial red solution became lighter in colour and a white solid precipitated. The final reaction mixture was filtered through a Celite plug (4 × 2 cm) supported on a medium-porosity frit, and the light orange filtrate was taken in vacuo to a glassy foam. This foam was triturated with hexanes (15 mL) to obtain an orange powder. Toluence was added dropwise to the hexanes suspension of the orange powder until all the solid had dissolved. The saturated solution was placed in a refrigerator (5°C) overnight to induce crystallization fo the desired product. The solid that crystallized from the toluence – hexanes solution was isolated by removing the mother liquor by cannulation and washing the remaining solid with hexanes (10 mL). These operations afforded $Cp^*Mo(NO)(\eta^1\text{-}CH_2Ph)(\eta^2\text{-}O_2CR)$ as large red-orange crystals (0.23 g, 41% yield).

The ^1H NMR spectrum of the product indicated the presence of two diastereomeric pairs of enantiomers (*R,S/S,R* and *R,R/S,S*) in a ~1:1.5 ratio as determined by integration of the proton signals for the Me group of the carboxylate ligands. The supernatant mother liquor was placed in a freezer (−10°C) to induce the crystallization of more product. In this manner an additional 0.21 g (38% yield) of product were obtained (1:1.4 ratio of diastereomeric pairs).

On a similar reaction scale $Cp^*W(NO)(\eta^1\text{-}CH_2Ph)(\eta^2\text{-}O_2CR)$ was isolated as red-orange blocks in two crystallizations (0.26 g, 39% yield, 1:1.4 diastereomeric pair ratio; 0.19 g, 29% yield, 1:1.5 diastereomeric pair ratio) and $CpMo(NO)(\eta^1\text{-}CH_2Ph)(\eta^2\text{-}O_2CR)$ was isolated as orange needles (0.14 g, 29% yield, 1:1 ratio of diastereomeric pairs; second crop crystallized at −25°C: 0.21 g, 42% yield, 1:1.1 ratio of diastereomeric pairs).

X-ray crystallographic analyses of $[Cp^*M(NO)(NCMe)(\eta^2\text{-}CH_2Ph)]BF_4$ (M = Mo, W)

Suitable crystals of the complexes, obtained as described in the preceding paragraphs, were mounted in thin-walled glass capillaries under N_2 and transferrerd to an Enraf–Norius CAD4-F diffractometer (graphite monochromatized Mo*K*α radiation, $\lambda(\alpha_1)$ = 0.70930, $\lambda(\alpha_2)$ = 0.71359 Å). Unit-cell parameters were obtained by least-squares analysis of 2 sin θ/λ values for 25 reflections with θ = 17.6°–20.1° and 21.9°–23.4° for the Mo

[a]Probe temperatures 150°C. No attempts were made to obtain mass spectra of the cationic species.
[b]The *m/z* values are for the highest intensity peak of the calculated isotopic cluster.
[c]Multiplicities of carbon resonances were determined by a gated decoupled pulse sequence.
[d]Spectra recorded in CD_3NO_2.
[e]Spectra recorded in $CDCl_3$.
[f]Spectra contain signals for an equal amount of both diastereomeric pairs of enantiomers.
[g]Intensities of Cp proton signals are lower than expected due to long T_1 values.
[h]Assignment by analogy to the free acid: C_{ipso} = δ 138.38 in $CDCl_3$.
[i]Indistinguishable overlapping signals for both diastereomeric pairs of enantiomers.
[j]Minor diastereomeric pair of enantiomers.
[k]Major diastereomeric pair of enantiomers.
[l]These proton signals were located by resolving them from obscuring resonances of the Cp* rings by use of the HOM2DJ pulse program supplied with the Varian XL-300 NMR spectrometer for homonuclear 2-dimensional *J*-resolved ^{1}H NMR spectroscopy (for example, see ref. 24). The standard parameters supplied for acquisition and processing were used.

and W compounds, respectively. Three standard reflections for the Mo compound showed no significant variation, but those for the W compound had an average decay of 17%, and the data were scaled accordingly. Lorentz, polarization, and absorption corrections were applied (12, 13).[2] The crystallographic data and experimental details are summarized in Table 3.

The Mo and W positions in the isomorphous structures were determined from the Patterson functions, and the full structures were then derived by conventional electron-density methods, and refined full-matrix least-squares methods on *F*, minimizing $\Sigma w(F_o\text{-}F_c)^2$, where $w = 1/\sigma^2(F)$. The F atoms of the BF_4^- anion in the Mo compound were each disordered over two sites (50% occupancies); in the W compound, the F atoms were placed in single sites, but large anisotropic thermal parameters indicate possible disorder. Final cycles were carried out with anisotropic thermal parameters for all heavier atoms, except the disordered F atoms (isotropic); benzyl H atoms were refined, and methyl H atoms were fixed in calculated sites based on difference-map peaks. Final values of $R = 0.050$, 0.038 and $R_w = 0.069$, 0.049 were obtained for the Mo and W complexes, respectively. The largest final difference-map peaks are about 1 e Å^{-3} for the Mo compound (about 1.5 Å from the B atom, suggesting incomplete modeling of the disorder), and 1.7 e Å^{-3} for the W compound (near the W atom).

Scattering factors were from ref. 14. Final positional and isotropic thermal parameters (U_{eq} = 1/3 × trace of diagonalized *U*) are listed in Table 4, and selected interatomic distances and angles are collected in Table 5. Anisotropic thermal parameters, hydrogen parameters, bond lengths and angles, and packing diagrams are provided as supplementary material.[3]

Results and discussion

Preparation and physical properties of the [Cp*M(NO)(η^2-CH_2Ph)(NCMe)]BF_4 salts

These orange organomolybdenum and organotungsten salts are preparable in good yields by chloride abstraction from their alkyl chloride precursors in acetonitrile. The progress of the reactions may be easily monitored by IR spectroscopy, the diminution of the ν_{NO} bands characteristic of the starting

[2] The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least squares, and ORFFE, function and errors, by W.R. Busing, K.O. Martin, and H.A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEPII, illustrations, by C.K. Johnson.

[3] Supplementary material mentioned in the text may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom parameters, bond lengths, and bond angles as well as the packing diagrams have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

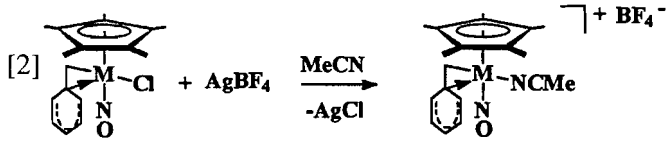
materials (W, 1584 cm^{-1}; Mo, 1610 cm^{-1}) being accompanied by the growth of new ν_{NO} bands at higher energy (W, 1622 cm^{-1}; Mo, 1647 cm^{-1}) for the cationic products.



Unlike the related cationic complexes $[Cp^*W(NO)(CH_2CMe_3)(NCMe)_2]BF_4$ (5) and $[Cp^*W(NO)(CH_2SiMe_3)(NCMe)_2]BF_4$ (15), the benzyl-containing cations require only one stabilizing MeCN molecule in the coordination spheres of the metals. This feature reflects the unique ability of the benzyl ligand in its η^2-coordination mode to provide three electrons to the metal centres. Nevertheless, the isolated $[Cp^*M(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]^+$ cations are quite electrophilic, being able to abstract Cl^- from a NaCl IR cell. This process can be detected simply by leaving acetonitrile solutions of the complexes as their BF_4^- salts in NaCl cells and monitoring the progress of the chloride abstraction by IR spectroscopy. This monitoring reveals the complete loss of the ν_{NO} bands for the cationic complexes and the return of the ν_{NO} bands of the starting benzyl chloro species in a matter of minutes at ambient temperatures. The use of AgCl plates in the solution cell allows IR monitoring of reactions [2] without the occurrence of halide abstraction from the cell material.

In preliminary studies we have also established that treatment of the $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(MeCN)]BF_4$ salt with various unsaturated substrates (e.g., diphenylacetylene, 2,3-dimethyl-1,3-butadiene, carbon monoxide, and acetone) in $CDCl_3$ results in no detectable chemical reaction. Thus, Lewis bases weaker than Cl^- evidently cannot displace the acetonitrile ligand from the coordination sphere of the metal or induce the benzyl ligand to diminish its hapticity. Our current efforts are thus directed at generating these cations in weakly coordinating solvents such as CH_2Cl_2 and utilizing them in situ.

Solid-state molecular structures of the $[Cp^*M(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ complexes

Solid-state X-ray crystallographic analyses of the cationic molybdenum and tungsten complexes have been performed in order to establish the exact natures of the metal–benzyl linkages present and to compare them with those extant in related neutral benzyl complexes (7). The two complexes are essentially isostructural, and a stereoview of the $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$ complex is presented in Fig. 1. Both salts

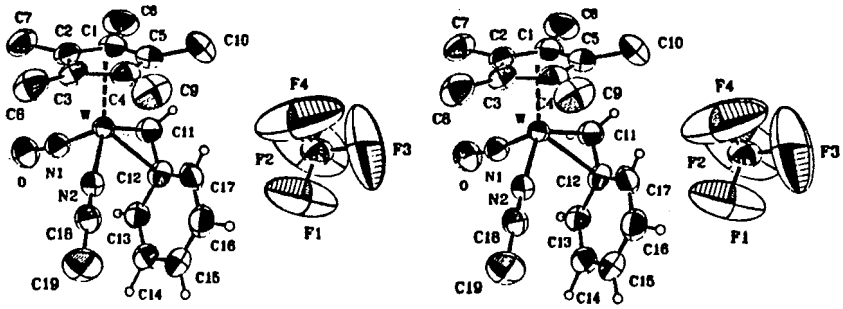
Fig. 1. Stereoview of the solid-state molecular structure of $[Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(NCMe)]BF_4$. The molybdenum analogue is isostructural.



consist of discrete cations and tetrahedral BF_4^- anions, the intramolecular dimensions of the two cationic complexes being essentially the same and resembling those found for related Cp*M(NO)-containing compounds (16). All the metal–ligand bond distances are virtually identical for both congeners (Table 5), an expected feature since the covalent radii of Mo and W are very similar. The Mo and W complexes also contain essentially isostructural M-C_1-C_{ipso} moieties, with similar metal–$C_{methylene}$ (Mo, 2.182 (6) Å; W, 2.175 (8) Å) and metal–C_{ipso} (Mo, 2.389(5) Å; W, 2.383(7) Å) bond lengths.

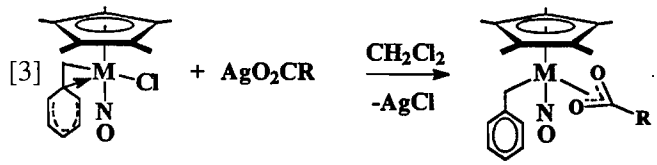
M—N—O	171.2(4)	173.1(6)
M—N—CMe	175.6(5)	176.7(6)

Interestingly, the bonding in the cationic complexes appears to be slightly different than that extant in the neutral η^2-benzyl complexes. One specific difference to be noted between the neutral and cationic benzyl complexes is in the bond lengths within the aromatic ring. In the neutral complexes, Cp*M(NO)(η^2-CH_2Ph)X (X = Cl, CH_2SiMe_3), the C—C bond lengths within the benzyl ring are indicative of the existence of delocalized π-electron density within the aromatic ring. Conversely, as shown in Scheme 1, alternation of longer and shorter C—C bonds around the phenyl ring in the cations suggests that the π-electrons are slightly more localized in these species. The localization of electron density that occurs in the cationic species is similar to that previously reported for the $CpMo(CO)_2$(η^3-*p*-xylyl) complex (17), though the differences in C—C bond lengths are much more pronounced in the *p*-xylyl complex (Scheme 1). With the existence of these differences, the benzyl ligands in the cationic complexes are intermediate between η^2 and η^3 in character. This conclusion is substantiated by the fact that the smallest metal–C_{ortho} separations for both of the cationic complexes (Mo—C_{ortho} = 2.83 Å, W—C_{ortho} = 2.86 Å) are still much larger than those expected for a normal M—C single-bond length (~2.4 Å)

(18) but less than the 3.004 Å found in authentic metal-η^2-benzyl linkages (Scheme 1).

Preparation and physical properties of the Cp′M(NO)-(CH_2Ph)(O_2CR) complexes (R = CH(Et)(Ph))

In contrast to the halide abstraction effected with a silver salt containing the weakly coordinating BF_4^- anion (eq. [2]), the reactions of the benzyl chloro complexes with a racemic mixture of a chiral silver carboxylate produce neutral carboxylate complexes (eq. [3]) as a mixture of two diastereomeric pairs of enantiomers (*R,S/S,R* and *R,R/S,S*).



R = CH(Et)(Ph)

It is interesting to note that coordination of the three-electron-donor carboxylate anions causes the benzyl ligands to change their coordination modes from η^2 to η^1. The physical properties of the carboxylate complexes (Tables 1 and 2) are consistent with their possessing the molecular structures shown in eq. [3]. They are thermally stable in solutions, no change in the ^1H NMR spectra of $CDCl_3$ solutions of these complexes being evident after storage at room temperatures for several days. As solids, the complexes can also be transferred and weighed in air with no noticeable decomposition occurring. The slight solubility of the complexes in aliphatic solvents, as well as their ready solubility in aromatic solvents, are features consistent with the formulation of their possessing covalently bonded carboxylate ligands. Finally, the highest *m/z* features in the low-resolution mass spectra of all three complexes may be assigned to the monomeric $[Cp'M(NO)(CH_2Ph)(O_2CR)]^+$ mass ions.

The inherent asymmetry of $Cp'M(NO)(\eta^2\text{-}CH_2Ph)Cl$ and related complexes could make them potentially very useful reagents or catalysts for organic synthesis. However, to realize this synthetic potential, the compounds must be made enantiomerically pure. The reaction of the benzyl chloro complexes with chiral silver carboxylate reagents discussed in the preceding paragraph is one possible means of resolving the racemic mixtures of the starting materials. The utility of the diastereomeric $Cp'M(NO)(\eta^1\text{-}CH_2Ph)(\eta^2\text{-}O_2CR)$ complexes for this purpose is the subject of ongoing research, the initial results of which indicate that resolution of the Cp* complexes may be more easily achieved than that of the Cp complexes. Silver carboxylates are the reagents of choice since optically active carboxylic acids can be readily obtained, either commercially or by established resolution procedures (19), and silver carboxylates are easily prepared from these acids (20).

In summary, this work has afforded new types of benzyl nitrosyl complexes, which demonstrate that even though a dihapto benzyl ligand exerts a more pronounced stabilizing effect at a cationic metal centre than at a neutral one, the electronic stabilization is not so great that its hapticity cannot be reduced from η^2 to η^1 under appropriate experimental conditions. Our studies with these interesting molecules are continuing.

Synthesis and structural characterization of an ether-bridged cobalta-bis(dicarbollide): a model for Venus flytrap cluster reagents

David E. Harwell, Juliet Nabakka, Carolyn B. Knobler, and M. Frederick Hawthorne

Abstract: The synthesis of bis-(1-carboranylmethyl) ether was first published in 1963; however, its subsequent complexation with a transition metal was never reported. We now report the complexation of cobalt and the corresponding X-ray structure for the triphenylmethylphosphonium salt of the cobalta-bis(carboranylmethyl) ether. The cobalt complex crystallized in the monoclinic space group $C2/c$ with $a = 21.729(6)$ Å, $b = 9.845(2)$ Å, $c = 35.565(9)$ Å, $\beta = 105.363(9)°$, $V = 7336$ Å^3, and $Z = 8$. Data were collected using CuKα radiation, to a maximum $2\theta = 115°$, giving 4123 unique reflections, and the structure was solved by heavy atom methods. The final discrepancy index was $R = 0.093$, $Rw = 0.100$ for 1919 independent reflections with $I > 3\sigma(I)$. This metala-bis(carboranylalkyl) ether is the first in a new class of Venus flytrap compounds (VFC), containing an ether linkage, to be synthesized as model compounds for the development of reagents suitable for use in the radioimmunodetection and radioimmunotherapy of cancer.

Key words: cobalt, radioimmunodetection, radioimmunotherapy, Venus flytrap.

Résumé : La première synthèse du bis(1-carboranylméthyl)éther a été publié en 1963; toutefois, sa complexation subséquente avec un métal de transition n'a pas encore été rapportée. Dans ce travail, on a réalisé sa complexation avec le cobalt et on rapporte les résultats d'études de diffraction des rayons X sur le sel triphénylméthylphosphonium du cobalta-bis(carboranylméthyl)éther. Les cristaux du complexe de cobalt sont monocliniques, groupe d'espace $C2/c$, avec $a = 21,729(6)$, $b = 9,845(2)$ et $c = 35,565(9)$ Å, $\beta = 105,363(9)°$, $V = 7336$ Å^3 et $Z = 8$. On a obtenu les données (4123 réflexions uniques) en utilisant le rayonnement CuKα, jusqu'à un maximum de $2\theta = 115°$, et on résolu la structure à l'aide de la méthode aux atomes lourds. Les valeurs finales de R et R_w sont respectivement de 0,093 et 0,100 pour 1919 réflexions indépendantes avec $I > 3\sigma(I)$. Ce métala-bis(carboranylalkyl) éther est le premier d'une nouvelle classe de composés dionée gobe mouches, contenant une liaison éther, à être synthétisé comme composé modèle pour le développement de réactifs pouvant être utilisés dans la radioimmunothérapie du cancer.

Mots clés : cobalt, radioimmunodétection, radioimmunothérapie, dionée gobe mouche.

[Traduit par la rédaction]

Introduction

Functionalized Venus flytrap clusters (VFC) have been shown to be useful for binding radiotransition metals to tumor-associated monoclonal antibodies, thus providing conjugates that are clinically useful for radioimmunodiagnosis and radioimmunotherapy (1, 2). Until now the preparation of these compounds has involved tedious reaction schemes culminating in numerous protection and deprotection steps, each step with limited yields. In the past the carboranyl units of the VFC have been linked with alkylene or arylene groups and were derived by direct attachment of the linking group with either the carbon or the boron atoms of the cage (3, 4). This synthetic route has been both challenging and arduous.

Grafstein et al. first reported the synthesis of bis-(1-carboranylmethyl) ether **1** in 1963 (5), and no corresponding metallacarborane derivatives have been previously reported. Compound **1** is easily prepared in high yields, and we subsequently degraded the ether-bridged **1** to the corresponding dianionic species **2**. The salts of **2** are very soluble in tetrahydrofuran and thermally stable, and they may be handled in air for extended periods of time (6, 7).

Results and discussion

Base degradation of **1** with potassium hydroxide in ethanol yielded the corresponding dianionic species **2** in a 67% yield

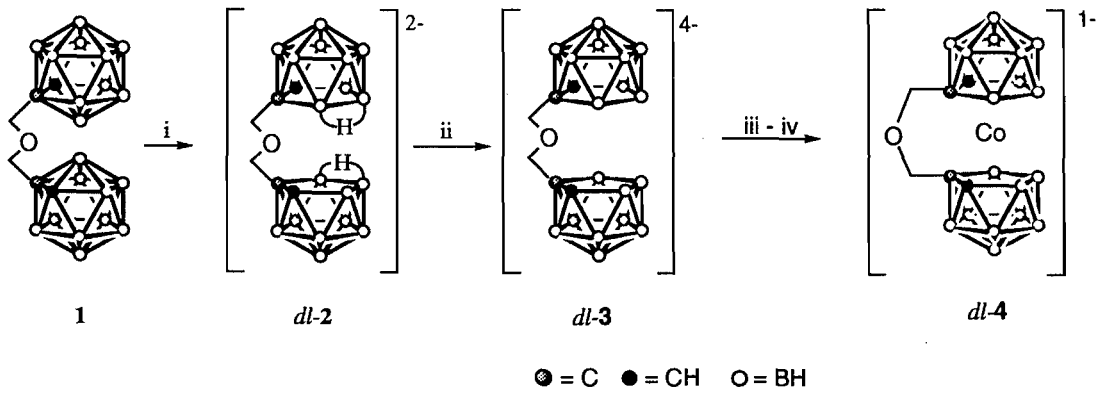
Scheme 1. i. (*a*) KOH, EtOH (*b*) Bu_4NBr; ii. NaH/THF; iii. $CoCl_2$; iv. PPh_3MeBr. A similar scheme for the *meso* isomer also exists.



(see Scheme 1). The ^1H NMR spectrum of compound **2** exhibited two sets of peaks for the α-methylene unit of the ether bridge, presumably due to the presence of both *dl* and *meso* isomers. One isomer exhibited a doublet of doublets due to the enantiotopic nature of the α-methylene protons, while the other isomer exhibited only a singlet, indicating the magnetic equivalence of its α-methylene protons. Attempts to separate the isomers by chromatographic methods were unsuccessful and, therefore, resonances due to a specific isomer could not be definitively assigned. The ^{11}B and ^{13}C NMR spectra of **2** were as expected and no spectral differences between the isomers were observed. Treatment of **2** with excess NaH in THF afforded the desired bridged dicarbollide anion **3**. Filtration followed by the addition of anhydrous cobaltous chloride resulted in the cobaltacarborane **4**, which was isolated in 65% yield. *dl* and *meso* isomers are possible, and evidence for both is seen in the ^1H NMR spectra. However, the crystal that was separated from the mixture for X-ray diffraction study contained only the *dl* isomers. The ^{11}B NMR spectrum of **4** exhibited a group of peaks in a 1:1:3:1:1:1:1 ratio consistent with a *commo*-carborane.

Previous studies involving alkylene bridges have indicated an optimal bridge length of four methylene units for metal complexation (3); however, the bite-size of the 2-oxapropylene-bridged VFC, with only three atoms in the linking group, seems to have no such limitation. This is conceivably due to increased flexibility in the linking group afforded by the oxygen in the ether linkage. There is no interaction between the oxygen atom in the bridge and the cobalt atom, as is apparent in the X-ray crystal structure (see Fig. 1). The oxygen does not attain the optimal conformation required for proper molecular overlap and is observed to be 3.14 Å from the cobalt atom, precluding any bonding interaction.

We predict that coordination between the oxygen center and the metal atom will occur in VFC ethers that contain longer bridging units containing more methylene units, thereby enabling the oxygen to obtain such an optimal geometry. Indirect evidence supporting this type of coordination was observed in the case of $[7,7'\text{-}\mu\text{-}TosN(CH_2CH_2\text{-})_2(7,8\text{-}C_2B_9H_{10})_2]^{2-}$. The ligand, which contains a bridging nitrogen, formed complexes with cobalt in higher yields than its corresponding alkylene-linked counterpart. It is suspected that the interaction of the lone pair of electrons on the bridge nitrogen of the ligand provided a favorable chelation effect (3).

The molecular structure of **4** is presented in Fig. 1. Instrument parameters, crystal data, and data collection parameters are summarized in Table 1, while Table 2 lists individual atomic coordinates and their respective thermal parameters. Selected interatomic distances and angles are given in Table 3. Tables containing observed and calculated structure factors, hydrogen atom parameters, and torsion angles have been deposited.[2] The cobalt atom is bound in the η^5-fashion to the five-membered face of each of the two dicarbollide ligands. The distance of the cobalt atom to each mean plane of the dicarbollide cage faces is 1.49 Å, comparable to other cobaltacarboranes (8). Each of the bonding faces of the dicarbollide moieties is planar to within 0.04(1) Å. The two faces are staggered rather than eclipsed. The angle between the normals of these two faces is 6.4°.

The two icosohedra that share the cobalt atom as a common apex in **4** are further linked by a $\text{-}CH_2OCH_2\text{-}$ bridge that spans from C(1) to C(1′). The oxygen atom in the bridge is 3.14 Å away from the cobalt atom, precluding it from any chelation interaction.

A one-electron reduction consistent with Co(III/II) at −1.27 V vs. Ag/AgCl was observed for compound **4**. A plot of $v^{1/2}$ vs. i is linear, indicating electrochemical reversibility for the process.

Experimental

General considerations

Bis-(1-carboranylmethyl) ether was prepared according to literature methods (5, 9). Standard glovebox, Schlenk, and vacuum line techniques were employed for all manipulations of air- and moisture-sensitive compounds.

Reaction solvents were reagent grade and were distilled from appropriate drying agents under nitrogen prior to use. Tetrahydrofuran and toluene were distilled from sodium ben-

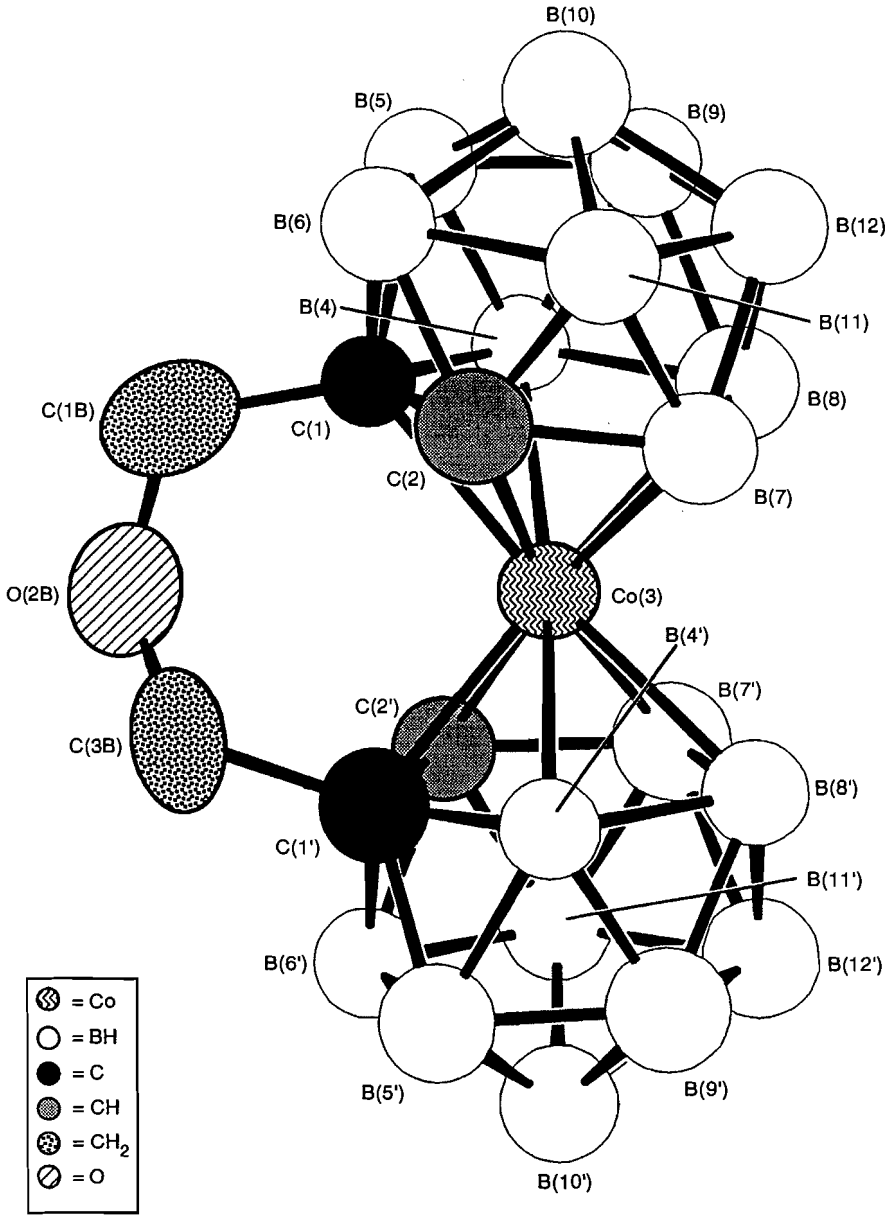
Fig. 1. ORTEP representation of *dl*-**4**, showing the numbering scheme. All hydrogens were removed for clarity. Ellipsoids were drawn at the 0.50 probability level.



zophenone ketyl; ethyl sulfide was distilled from lithium aluminum hydride. Deuterated solvents were obtained from Cambridge Isotope Laboratories Inc., Knoxville, Tenn. Sodium hydride (Aldrich) was used as received. Cobalt chloride (Cerac) was obtained in argon-filled vessels and was used without further purification. Bis-(1-carboranylmethyl) ether **1** was prepared according to literature methods (5, 9).

Physical measurements

Proton (^{1}H NMR) spectra were obtained on a Brucker AF 200 instrument at 200.133 MHz. Carbon (^{13}C NMR) spectra were obtained on a Brucker AM 400 instrument at 100.625 MHz. Boron (^{11}B NMR) spectra were obtained at 160.46 MHz on a Brucker AM 500 spectrometer. Chemical shifts for ^{1}H and ^{13}C NMR spectra were referenced to $SiMe_4$ (0.00 ppm) and measured with respect to residual protons in deuterated solvents. Chemical shift values for ^{11}B spectra were referenced relative to external $BF_3{\cdot}OEt_2$ (0.00 ppm). Resonances observed upfield of the reference compounds were obtained as Nujol mulls and were recorded on a Nicolet 205 FT-IR instrument. Negative FAB mass spectra were obtained from the UCR Mass Spectrometry Facility at University of California, Riverside. Cyclic voltammetry was performed with a CV-27 cyclic voltammograph from Bioanalytical Systems Inc. All electrochemical measurements were carried out at room temperature under a nitrogen atmosphere with CH_3CN solutions of the complex in 0.1 M Et_4NPF_6 as a supporting electrolyte. Potentials are referenced to a Ag/AgCl electrode. A glassy carbon electrode and a platinum wire were used as the working electrode and the auxiliary electrode, respectively.

Preparation of mixture containing [7,7′-μ-1,3-CH_2OCH_2-(7,8-$C_2B_9H_{11}$)$_2$][(C_4H_9)$_4$N]$_2$ and related isomers (2)

To a solution of potassium hydroxide (1.71g, 30.3 mmol) in ethanol (100 mL) was added **1** (1.01g, 3.03 mmol). The solution was heated at reflux overnight and cooled. Dry Ice was added to the solution until no more precipitate was formed. The potassium carbonate was separated by filtration and washed with ethanol (3 × 50 mL). The filtrates were combined and added to a solution of tetrabutylammonium bromide. The solids were filtered out, dried, and recrystallized from hot water to give **2** in 67% yield (1.94 g, 2.04 mmol), mp >245°C. IR (Nujol, cm^{-1}): 2959 (s), 2926 (s), 2854 (s), 2522 (w), 1460 (m), 1377 (m). ^{1}H NMR ($CDCl_3$): 3.52 (dd, 3.2H, α-CH_2 *dl* or *meso*), 3.44 (s, 0.8H, α-CH_2 *dl* or *meso*), 3.19 (m, 16H, NC-H), 1.94 (s, 2H, Cb C-H), 1.62 (m, 16H, NCC-H), 1.42 (m, 16H, NCCC-H) 0.97 (t, 24H, NCCCC-H). ^{13}C NMR (*d*-acetone): 38.4, 59.4, 24.4, 20.3, 13.8. ^{11}B NMR (acetone): −9.3 (d, 2B), −13.9 (d, 1B), −15.6 (d, 1B), −17.3 (d, 2B), −22.0 (d, 1B), −32.4 (d, 1B), −36.5 (d, 1B).

Preparation of mixture containing [1,1′-μ-1,3-CH_2OCH_2-((3)-1,2-$C_2B_9H_{10}$)$_2$Co][(C_6H_5)$_3$$PCH_3$] and related isomers (4)

To a solution of **2** (1.62 g, 2.04 mmol) in THF (100 mL) was added NaH (0.360 g, 15.0 mmol). The reaction mixture was stirred at reflux overnight and then cooled. The solution was filtered through a glass frit. To the solution was added anhydrous cobaltous chloride (0.265 g, 2.04 mmol). The solution gradually changed from blue to brown over a 12 h period. The solution was refluxed overnight, cooled, and filtered to remove cobalt metal and KCl. After removal of the solvent in vacuo, the residue was dissolved in hot water. The resulting aqueous solution was filtered, and the orange solution was added to an aqueous solution of methyltriphenylphosphonium bromide (1.11 g, 3.12 mmol). The aqueous solution was extracted with methylene chloride, dried over magnesium sulfate, and chromatographed (SiO_2) with methylene chloride without separation of isomers; only the *dl*-isomers were observed. The product was crystallized from a CCl_4–pentane solution to give orange platelets of **4** in 65% yield (853 mg, 1.33 mmol), mp 218°C. IR (Nujol, cm^{-1}): 2953 (s), 2924 (s), 2852 (s), 2553 (w), 1459 (m), 1377 (w), 1114 (w). ^{1}H NMR ($CDCl_3$): 7.70 (m, 15H, Ph), 4.02 (m, 4H, α-CH_2), 3.80 (s, 2H, Cb C-H), 2.89 (d, 3H, J_{PH} = 13.0, PCH_3). ^{13}C NMR ($CDCl_3$): 135.5, 133.0, 130.7, 118.4, 73.8, 10.5. ^{11}B NMR (acetone): 5.3 (d, 1B), 1.1 (d, 1B), −5.8 (d, 3B), −7.7 (d, 1B), −15.2 (d, 1B), −16.6 (d, 1B), −18.1 (d, 1B). High-resolution negative-ion mass spectroscopy calculated mass for $C_6H_{24}{}^{10}B_6{}^{11}B_{12}OCo$ *m/e*: 363.30; observed *m/e*: 363.30.

Collection and reduction of X-ray data for *dl*-4·1/2 CCl_4

An orange crystal, obtained from a CCl_4–pentane solution, was mounted on a fiber and placed on a Syntex $P\bar{1}$ diffractometer modified by Professor C.E. Strouse of this department. Unit cell parameters were determined from a least-squares fit of 27 accurately centered reflections (17.1 < 2θ < 40.2°).

These dimensions and other parameters, including conditions of data collection, are summarized in Table 1. Data were collected on a Syntex $P\bar{1}$ diffractometer modified by Professor C.E. Strouse of this department, at 25°C in the θ–2θ scan mode. Three intense reflections (4 0 2, 2 0 −8, 1 1 −6) were monitored every 97 reflections to check stability. Intensities of these reflections did not decay during the course of the experiment (99.1 h). Of the 4123 unique reflections measured, 1919 were considered to be observed ($I > 3\sigma(I)$) and were used in the subsequent structure analysis. Data were corrected for Lorentz and polarization effects and for secondary extinction and absorption. Programs used in this work include locally modified versions of the following programs: CARESS (Broach, Coppens, Becker, and Blessing), peak profile analysis, Lorentz and polarization corrections; ORFLS (Busing, Martin, and Levy), structure factor calculation and full-matrix least-squares refinement; ABSCOR, absorption correction based on psiscans; SHELX76 (Sheldrick), a crystal structure package; SHELX86 (Sheldrick), a crystal structure solution package; and ORTEP (Johnson).

Solution and refinement of the structure of 4·1/2 CCl_4

Atoms were located by the use of heavy atom methods. All calculations were performed on a VAX 3100 computer in the J.D. McCullough X-ray Crystallography Laboratory. Cl, Co, O, P, and methylene C atoms were refined with anisotropic parameters. All other nonhydrogen atoms were refined with isotropic parameters. Phenyl carbon atoms were included as members of rigid C_6H_5 groups, C—C = 1.395 Å, angles 120°. All phenyl, methyl, and methylene H were included in calculated positions, C—H = 1.0 Å. H on the carborane ligand were included in located positions. H atoms were assigned isotropic displacement values based approximately on the value for the attached atom. Scattering factors for H were obtained from Stewart et al.(10) and for other atoms were taken from The International Tables for X-ray Crystallography (11). The largest peak on a final difference electron density map was 0.23 e $Å^{-3}$. Final position and thermal parameters for nonhydrogen atoms are given in Table 2. The crystal contains 1/2 molecule of CCl_4 per anion. The CCl_4 is located near a 2-fold axis at x = 0, z = 1/4 and is disordered.

Conclusions

The complex **4** described in this report represents the first in a series of ether-bridged and carbon-linked metallacarboranes to be used as model compounds in the development of radiotransition-metal carriers for the antibody-mediated γ-imaging and β-therapy of tumors (1, 2). We are currently in the process of characterizing other metal (Cu, Ni) complexes of **2**. Results of these studies will be published at a later date. We are also developing other ether-linked VFCs that can be readily functionalized and conjugated with monoclonal antibodies.

Novel binuclear doubly vinyl-bridged iridium complexes formed by olefinic C—H activation

Helmut Werner, Justin Wolf, Angelika Nessel, Arno Fries, Bernd Stempfle, and Oliver Nürnberg

Abstract: Treatment of $[C_5H_5IrX_2]_n$ (**2**: X = Cl; **3**: X = Br) with $CH_2{=}CHtBu$ in the presence of Na_2CO_3–iPrOH gives, besides the bis(olefin) complex $[C_5H_5Ir(CH_2{=}CHtBu)_2]$ (**4**), the doubly vinyl-bridged iridium(II) compound $\{[C_5H_5Ir(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHtBu)]_2\}$ (**5**). The related binuclear complex $\{[CH_2(C_5H_4)_2][Ir_2(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHtBu)_2]\}$ (**9**) was obtained from $\{[CH_2(C_5H_4)_2][IrBr_2]_2\}_n$ (**8**) and $CH_2{=}CHtBu$–Na_2CO_3 in ethanol and characterized by an X-ray structure analysis (monoclinic, *C2/c* (No. 15), $a = 20.050(8)$, $b = 8.843(1)$, $c = 24.25(1)$ Å, $\beta = 99.53(2)°$, $V = 4241$ Å^3, $Z = 8$, $R = 0.032$, $R_w = 0.041$). Protonation of both **5** and **9** with $HBF_4{\cdot}OEt_2$ yields the BF_4 salts of the unsymmetrical hydridometal cations **10** and **11** in which the vinyl bridges are still intact. The reaction of the binuclear bis(cyclooctene)metal compounds $\{[CH_2(C_5H_4)_2][Rh(C_8H_{14})_2]_2\}$ (**14**) and $\{[CH_2(C_5H_4)_2][Rh(C_8H_{14})_2][Ir(C_8H_{14})_2]\}$ (**17**) with bromine yields almost quantitatively the polymeric (or oligomeric) dibromo derivatives **16** and **18**, which could, however, not be converted to vinyl-bridged complexes by treatment with $CH_2{=}CHtBu$–Na_2CO_3–ROH.

Key words: iridium complexes, C-H activation, bridging vinyl ligands, cationic hydridometal complexes, heterometallic complex.

Résumé : Le traitement du $[C_5H_5IrX_2]_n$ (**2** : X = Cl; **3** : X = Br) avec du $CH_2{=}CHtBu$ en présence de Na_2CO_3–iPrOH conduit, en plus du complexe bis(oléfinique) $[C_5H_5Ir(CH_2{=}CHtBu)_2]$ (**4**), le composé de l'iridium à double pont vinyle $\{[C_5H_5Ir(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHtBu)]_2\}$ (**5**). On a obtenu le complexe binucléaire apparenté $\{[CH_2(C_5H_4)_2][Ir_2(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHtBu)_2]\}$ (**9**) par réaction du $\{[CH_2(C_5H_4)_2][IrBr_2]_2\}_n$ (**8**) avec du $CH_2{=}CHtBu$–Na_2CO_3 dans l'éthanol et on l'a caractérisé par diffraction des rayons X (monoclinique, groupe d'espace *C2/c* (No. 15), avec $a = 20{,}050(8)$, $b = 8{,}843(1)$, et $c = 24{,}25(1)$ Å, $\beta = 99{,}53(2)°$, $V = 4241$ Å^3, $Z = 8$, $R = 0{,}032$, et $R_w = 0{,}041$). La protonation des composés **5** et **9** par du $HBF_4{\cdot}OEt_2$ conduit aux sels de BF_4 des cations hydridométalliques non symétriques **10** et **11** dans lesquels les ponts vinyles sont encore intacts. La réaction du brome avec les composés binucléaires bis(cyclooctène)métal $\{[CH_2(C_5H_4)_2][Rh(C_8H_{14})_2]_2\}$ (**14**) et $\{[CH_2(C_5H_4)_2][Rh(C_8H_{14})_2][Ir(C_8H_{14})_2]\}$ (**17**) fournit presque quantitativement les dérivés dibromés polymériques (ou oligomériques) **16** et **18** que l'on ne peut malheureusement pas transformé en complexes avec pont vinylique par traitement avec du $CH_2{=}CHtBu$–Na_2CO_3–ROH.

Mots clés : complexes d'iridium, activation du C-H, ponts coordinats vinyliques, complexes cationiques hydridométalliques, complexes hétérométalliques.

[Traduit par la rédaction]

Introduction

In the general context of transition-metal-mediated C-H activation, there has been recent interest in the formation of vinyl-metal complexes from olefinic substrates (1). Bergman and Stoutland originally reported in 1985 (2) that the 16-electron fragment $[(C_5Me_5)Ir(PMe_3)]$, which is generated either on photolysis of $[(C_5Me_5)IrH_2(PMe_3)]$ or thermolysis of $[(C_5Me_5)IrH(C_6H_{11})(PMe_3)]$, reacts with ethene to afford not only the expected olefin derivative $[(C_5Me_5)Ir(C_2H_4)(PMe_3)]$ but also the hydrido(vinyl) complex $[(C_5Me_5)IrH(CH{=}CH_2)(PMe_3)]$. The latter, on heating to ca. 180°C, rearranges to give the thermodynamically more stable isomer $[(C_5Me_5)Ir(C_2H_4)(PMe_3)]$. A clear case in which the stability order $[L_nM(C_2H_4)] > [L_nMH(CH{=}CH_2)]$ is reversed was observed by Graham et al. (3) who found that the iridium compound $[(\eta^2\text{-}HBPf_3)Ir(CO)(C_2H_4)]$ (where $HBPf_3^-$ is the tris(3-(trifluoromethyl)-5-methylpyrazol-1-yl)borato anion) reacts in cyclohexane at 100°C to yield almost quantitatively the isomeric hydrido(vinyl)metal complex. The important role of the formally "innocent" ligands L for the conversion of $M(C_2H_4)$ to $MH(CH{=}CH_2)$ units has also become evident from work in our laboratory on the rearrangement of *trans*-$[IrCl(C_2H_4)$-

Received November 25, 1994.

This paper is dedicated to Professor William A.G. Graham, a pioneer in modern organometallic chemistry and an old friend, on the occasion of his 65th birthday.

$(PR_3)_2]$ to $[IrHCl(CH{=}CH_2)(PR_3)_2]$ where the equilibrium between the two isomers is strongly influenced by the nature of the coordinated phosphine (4).

The aim of the present work was to find out whether dihalogenoiridium(III) compounds such as $[C_5H_5IrX_2]_n$ (X = Cl, Br), on treatment with $CH_2{=}CHR$ in the presence of Na_2CO_3–ROH, would afford olefin (possibly hydrido(vinyl)) complexes or, by base-induced fragmentation of the alcohol, would give carbonyl(hydrido)metal derivatives. It was previously shown (5) that $[(mes)OsCl_2]_n$ (mes = 1,3,5-$C_6H_3Me_3$) reacts with ethene and Na_2CO_3–EtOH to form $[(mes)Os(C_2H_4)_2]$ whereas, if C_2H_4 is replaced by $CH_2{=}CHtBu$, the carbonyl(hydrido)methyl complex $[(mes)OsH(CH_3)(CO)]$ is isolated (6). It should furthermore be noted that $[(C_5Me_5)IrCl_2]_2$ behaves similarly to $[(mes)OsCl_2]_n$ and, on treatment with C_2H_4 and Na_2CO_3–EtOH, yields the bis(ethene) derivative $[(C_5Me_5)Ir(C_2H_4)_2]$ (7).

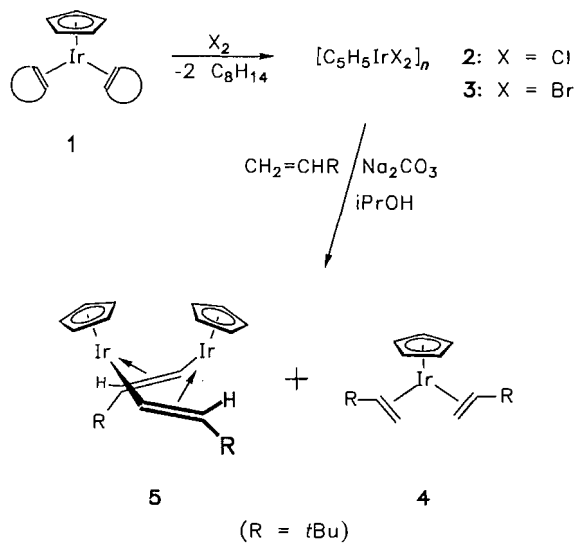
In this paper we describe our investigations on the reactivity of dibromo and dichloro iridium, rhodium, and mixed iridium–rhodium compounds toward $CH_2{=}CHtBu$ and Na_2CO_3–ROH, and in particular the structure and properties of some novel binuclear doubly vinyl-bridged iridium species. Some preliminary results of this work have already been communicated (8).

Results and discussion

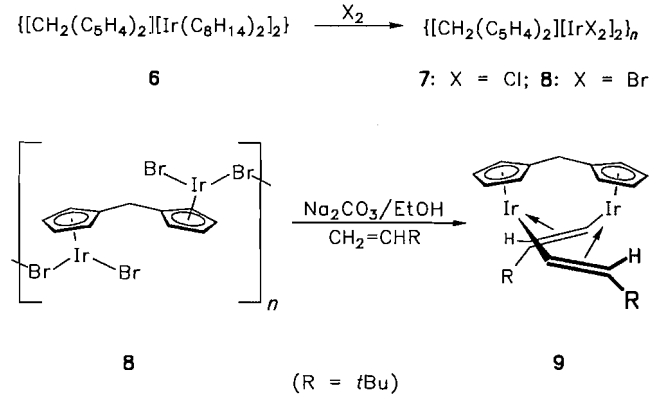
In contrast to the behaviour of $[(mes)OsCl_2]_n$ (6), the reaction of $[C_5H_5IrX_2]_n$ (**2**, **3**) with 3,3-dimethyl-1-butene and Na_2CO_3–EtOH does not give a carbonyl(hydrido) complex but leads to a mixture of products in which, besides $[C_5H_5Ir(CH_2{=}CHtBu)_2]$ (**4**), a small amount of the binuclear compound **5** is also present. We note that we observe only one of the two possible isomers of **4**, for which we assume the configuration shown in Scheme 1. Using 2-propanol instead of ethanol, complex **5** (a yellow moderately air-stable solid) is isolated in 30% yield. The proposed structure of **5** is supported by the ^1H as well as the ^{13}C NMR data (for details see experimental section), which unequivocally show the presence of a β-C-substituted vinylic ligand.

A clean reaction occurs between the dibromoiridium(III) species **8** (9) and $CH_2{=}CHtBu$ in the presence of Na_2CO_3–EtOH. Compound **8** as well as the corresponding dichlorometal derivative **7** were prepared from the bis(cyclooctene) complex **6** and bromine or chlorine in hexane–dichloromethane (9:1), respectively. Both compounds **7** and **8** are red air-stable solids and, since they are virtually insoluble in common organic solvents, we assume that they are polymeric (or at least oligomeric) in nature. A structural proposal for **8** is shown in Scheme 2. The reaction of **8** to **9** proceeds in ethanol at 75°C and gives the binuclear product in ca. 60% yield. In contrast to the bis(olefin) complex **6**, the ^1H NMR spectrum of **9** displays four (instead of two) multiplets for the C_5H_4 protons in the intensity ratio of 1:1:1:1, which indicates that there is no plane of symmetry in the molecule passing through the carbon atom of the CH_2 bridging unit and the midpoints of the two five-membered rings. The two doublets of the vinylic protons of **9** appear at δ 9.02 and 2.77 and thus at similar positions as found for **5**. The ^{13}C NMR spectrum of **9** shows, in addition to the signals of the cyclopentadienyl and *tert*-butyl carbon atoms, two resonances at δ 98.7 and 69.6 that according to

Scheme 1.



Scheme 2.



COSY measurements are assigned to the sp^2 C atoms of the vinyl ligands. It should be mentioned that these signals are observed at considerably higher field than in $[C_5H_5IrH(CH{=}CH_2)(C_2H_4)]$ (10), $[C_5H_5IrH(CH{=}CH_2)(CO)]$ (11), and $[(C_5Me_5)IrX(CH{=}CH_2)(PMe_3)]$ (X = H, Br) (2*c*), probably due to the bridging position of the CH=CHR units.

The results of the X-ray structural analysis of compound **9** are shown in Fig. 1. Each vinylic group is coordinated to one metal atom via a σ-bond and to the other via a π-bond and thus behaves as an unsymmetrical bridging ligand. A similar arrangement was found in the binuclear ruthenium complex $\{[C_5H_5(CO)Ru]_2(\mu\text{-}H)(\mu\text{-}CH{=}CHMe)\}$ (12) and the related dirhodium species $\{[(C_9H_6Me)Rh]_2(\mu\text{-}CH{=}CH_2)(\mu\text{-}CMe{=}CHMe)\}$ (13), the latter of which was prepared from $[(C_9H_6Me)Rh(C_2H_4)_2]$ and but-2-yne.

The most noteworthy structural feature of **9** is the Ir—Ir distance of 2.5495(5) Å, which is significantly shorter than an Ir—Ir single bond (2.70–2.75 Å) (14). Although for electronic reasons (both iridium centers are formally in the oxidation state II) such a single bond would be expected, the observed distance is comparable (in fact almost identical) to that of an Ir—Ir double bond (2.55 Å) (15). We assume that the short metal–metal bond length is caused by the strain exerted by the bis(cyclopentadienyl)methane ligand on the rest of the molecule. This strain is reflected in the size of the angle C(17)-

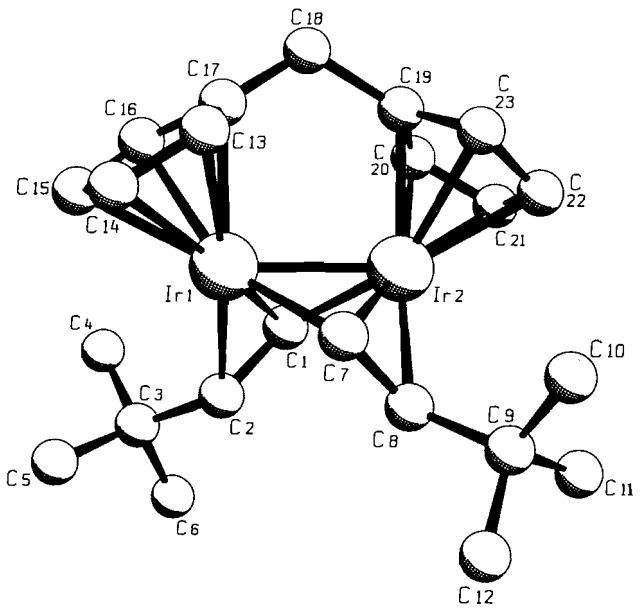
Fig. 1. Molecular structure (SCHAKAL drawing) of compound **9**.



C(18)-C(19) (119.1(9)°), which is about 10° wider than the tetrahedral angle. In the less strained binuclear rhodium complex $\{[CH_2(C_5H_4)_2]Rh_2(CO)_2(\mu\text{-}CO)\}$ (16) and in the analogous mixed-metal Co–Rh compound $\{[CH_2\text{-}(C_5H_4)_2][Rh(CO)][Co(CO)](\mu\text{-}CO)\}$ (17), which in addition to the $[CH_2\text{-}(C_5H_4)_2]^{2-}$ unit contain only one bridging CO ligand, the angle C-CH_2-C is 112.3(4)° and 110.8(3)°, respectively.

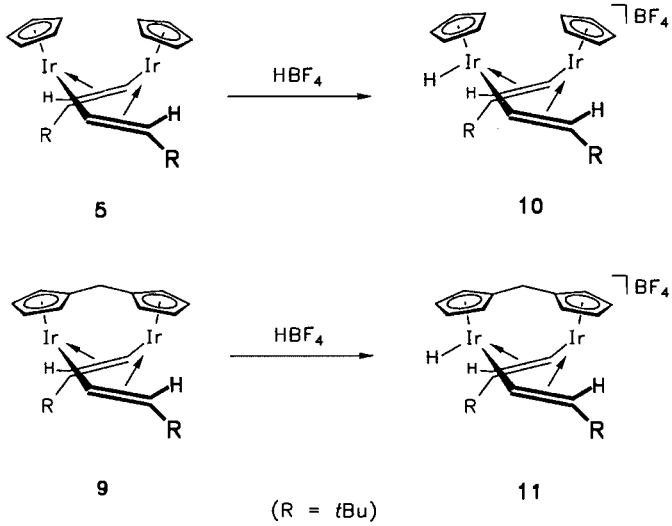
While the distances Ir(1)—C(7) and Ir(2)—C(1) (see Table 1) representing the Ir—C σ-bonds correlate quite well with that of the Ir—C(vinyl) bond of $[(C_5Me_5)IrH(CH{=}CH_2)(PMe_3)]$ (2.054(4) Å) (*2c*) and $[IrH(CH{=}CH_2)(acac)(PiPr_3)_2]$ (2.02(1) Å) (18), the bond lengths C(1)—C(2) and C(7)—C(8) are considerably longer than the vinyl C—C distance of the mononuclear iridium compounds. This elongation is certainly due to the π-coordination of the vinylic units. We note that there is an unsymmetrical interaction between the C—C π-bonds and the metal centers, which leads to differences in the Ir—C distances of about 0.12 and 0.07 Å, respectively. A similar effect was observed in vinyl-bridged binuclear ruthenium (12) and trinuclear osmium complexes (19) in which the bond lengths M—C_α are also significantly shorter than M—C_β.

Although the apparent bond strain in the Ir(μ-η^1,η^2-CH=CH*t*Bu)Ir units gives rise to the assumption that the vinyl bridges can be opened by nucleophilic substrates, all attempts to coordinate CO or CNR to one or both of the iridium centers failed. After a solution of **9** in toluene is warmed to 90°C in either a CO atmosphere or the presence of CN*t*Bu, the starting material is recovered almost quantitatively. The inert behaviour of the binuclear iridium complex is remarkable insofar as the related rhodium compound $\{[(C_9H_7)Rh]_2(\mu\text{-}CH{=}CH_2)(\mu\text{-}CMe{=}CHMe)\}$ readily reacts with CO by bridge cleavage to give $[(C_9H_7)Rh(CO)_2]$ and $CH_2{=}CHC(=O)CMe{=}CHMe$ (13).

However, both of the binuclear species **5** and **9** can be protonated by $HBF_4{\cdot}OEt_2$ to form cationic hydridometal derivatives in which the bridging units are still intact. The complexes **10** and **11** (see Scheme 3), which are yellow to orange air-sensitive solids, are isolated in 70–75% yield. For both compounds, correct elemental analyses have been obtained. The ^{1}H NMR spectra of **10** and **11** display, besides the hydride signal at high field, *two* resonances for each of the C*H*= and the =C*H*tBu vinylic protons as well as two resonances for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

Scheme 3.



C_5H_5 and four resonances for the C_5H_4 ring protons, which is in agreement with the unsymmetrical structure of the cationic species. Accordingly, also in the ^{13}C NMR spectra of **10** and **11** two signals for each of the *C*H═ and ═*C*H*t*Bu carbons and two signals for the C_5H_5 and *ipso*-*C*(C_5H_4) carbon atoms appear.

With the hope that doubly vinyl-bridged dirhodium and iridium–rhodium compounds analogous in structure to **9** can be obtained via the same route as the diiridium complex, the corresponding dibromometal derivatives were prepared. As outlined in Scheme 4, the crucial initial step is the synthesis of the mono- and binuclear bis(cyclooctene)rhodium compounds **14** and **15**, which are obtained in moderate (**14**) to good (**15**) yield from $[RhCl(C_8H_{14})_2]_2$ and $[C_5H_5CH_2C_5H_4]Na$ (**13**). We note that the formation of *both* mono- and binuclear species containing $[C_5H_5CH_2C_5H_4]^-$ and $[CH_2(C_5H_4)_2]^{2-}$ as ligands from **13** is not unique and has already been observed in the reactions of *trans*-$[RhCl(PhC{\equiv}CPh)(PiPr_3)_2]$ and $[IrCl(C_8H_{14})_2]_2$ with $[C_5H_5CH_2C_5H_4]Na$ (20). The two bis(cyclooctene)rhodium complexes **14** and **15** can be separated by chromatographic techniques and have been characterized both by elemental analysis and NMR spectroscopy.

The synthesis of the mixed-metal compound **17** (Scheme 5) is based on the metalation of the precursor **15** with *n*BuLi at low temperature in hexane followed by treatment of the lithium derivative with $[IrCl(C_8H_{14})_2]_2$ in THF. After chromatographic work-up, the rhodium–iridium complex **17** was isolated in 57% yield. The solid material is thermally remarkably stable and only moderately air-sensitive. In contrast to **14**, in which both C_5H_4 moieties are coordinated to rhodium, an unambiguous assignment of the ring carbon resonances in the ^{13}C NMR spectrum is possible for **17** because those signals which belong to the C_5H_4Rh unit are split into a doublet due to Rh—C coupling.

The reactions of **14** and **17** with bromine proceed almost instantaneously and lead quantitatively to the formation of the dibromometal complexes **16** and **18**. Both are red air-stable solids that, like compound **8**, are insoluble in all common organic solvents. We therefore conclude that they are polymeric in nature, containing bromo bridges between the metal centers. In contrast to **8**, neither **16** nor **18** react with 3,3-dimethylbut-1-ene in the presence of Na_2CO_3–EtOH to give binuclear vinyl-bridged species, and as well, the expected products could not be obtained by using 2-propanol instead of ethanol and NaOH instead of Na_2CO_3 (for comparison, see ref. 21).

Concluding remarks

To the best of our knowledge, compound **9** is the first example of a binuclear iridium complex in which the two iridium centers in the oxidation state II are bridged by three organo groups and in which no terminal ligands such as CO, PR_3, CH_3, or Cl are present. Particularly noteworthy in the synthesis of **9** are the mild conditions for the activation of an olefinic C—H bond in $CH_2{=}CHtBu$ with Na_2CO_3–EtOH, which leads to the formation of a metal-bonded vinylic group. A similar conversion of an olefin $CH_2{=}CHR$ (R = iPr, Ph) to a vinyl ligand CH═CHR in a mononuclear rhenium complex with *t*BuOK as base has recently been described by Peng and Gladysz (22); in that case the positive charge at the metal center presumably supports the cleavage of the C—H bond.

The second remarkable feature of this work is the ease of the protonation that occurs on treatment of **5** and **9** with $HBF_4{\cdot}OEt_2$. The doubly vinyl-bridged compounds thus behave as "metal bases" (23), which is unexpected since no strong donor ligands such as PMe_3 or C_5Me_5 are coordinated to the metal centers. The behaviour of **5** and **9** toward acids is similar to that of the doubly phosphido-bridged complexes $\{[(C_5R_5)M(\mu\text{-}PMe_2)]_2\}$ (M = Co, R = H; M = Rh, R = CH_3) (24) in which the metal is also in the oxidation state II and which equally undergo electrophilic addition reactions without cleavage of the M—M bond.

Experimental

All experiments were carried out under an atmosphere of argon by using standard Schlenk tube techniques. The starting materials $[C_5H_5Ir(C_8H_{14})_2]$ **1** (25), $\{[CH_2(C_5H_4)_2][Ir(C_8H_{14})_2]_2\}$ **6** (9), $\{[CH_2(C_5H_4)_2][IrBr_2]_2\}_n$ **8** (9), $[RhCl(C_8H_{14})_2]_2$ **12** (26), $[C_5H_5CH_2C_5H_4]Na$ **13** (17), and $[IrCl(C_8H_{14})_2]_2$ (27) were prepared as described previously. IR spectra were recorded on a Perkin–Elmer 1420 infrared spectrometer and NMR spectra on a Varian EM 360 L, a Jeol FX 90Q, and Bruker AC 200 and WM 400 instruments. Melting points (dec. temp.) were determined by DTA.

Preparation of $[C_5H_5IrCl_2]_n$ *2*

A solution of **1** (146 mg, 0.31 mmol) in 15 mL of hexane was treated, under continuous stirring, dropwise with a saturated solution of Cl_2 in dichloromethane until the formation of a flocky orange-red precipitate was completed. The solvent was removed, and the precipitate was repeatedly washed with hexane and dried in vacuo. Yield: 83 mg (83%); mp 116°C (dec.). Anal. calcd. for $C_5H_5Cl_2Ir$: C 18.30, H 1.54; found: C 18.63, H 1.64. Due to the low solubility of the orange-red air-stable solid, no reliable NMR spectra could be obtained.

Preparation of $[C_5H_5IrBr_2]_n$ 3

The procedure was analogous to that described for **2**, using **1** and a solution of Br_2 in hexane as starting materials. A dark-red air-stable solid (insoluble in most common organic sol-

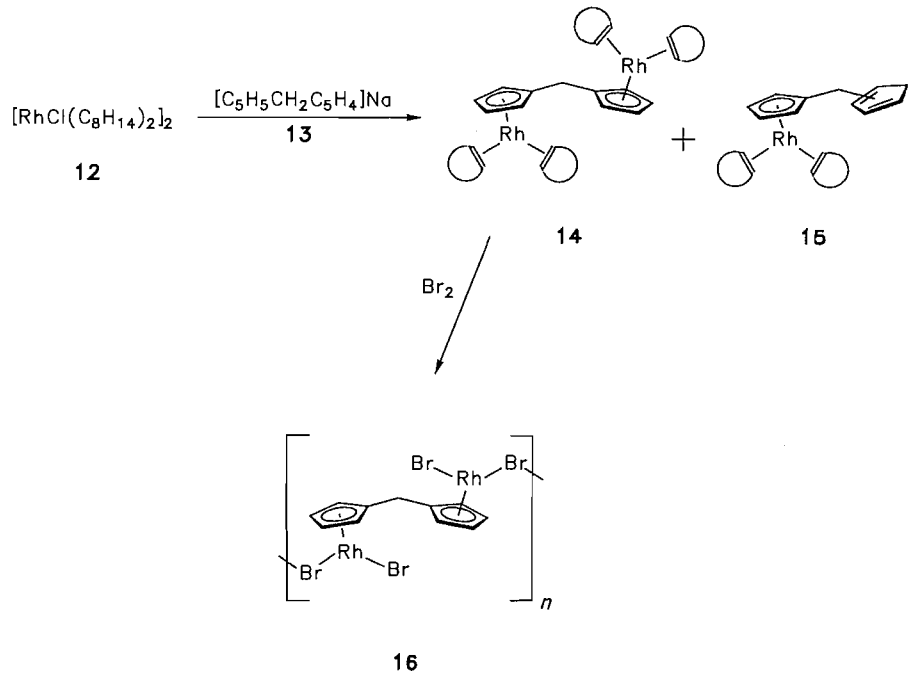
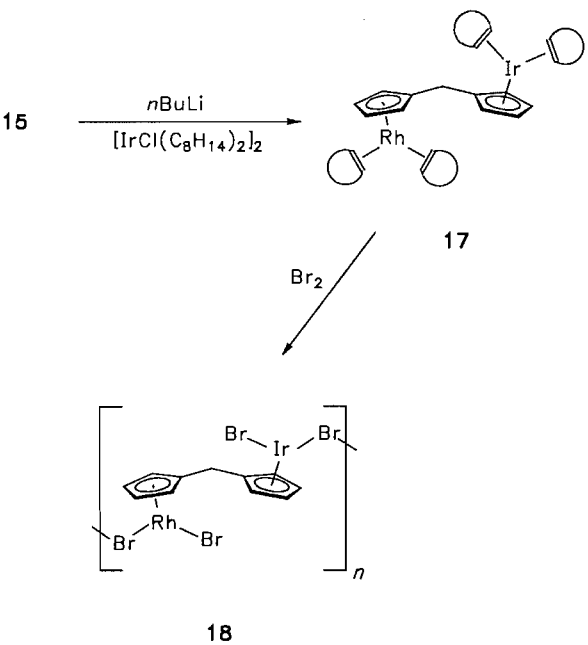


Scheme 5.



vents) was obtained in about 90% yield. Anal. calcd. for $C_5H_5Br_2Ir$: C 14.40, H 1.21; found: C 14.28, H 1.17.

Preparation of $[C_5H_5Ir(CH_2{=}CHtBu)_2]$ 4 and $\{[C_5H_5Ir(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHtBu)]_2\}$ 5

A suspension of **3** (121 mg, 0.15 mmol for $n = 1$) in 10 mL of 2-propanol was treated with $CH_2{=}CHtBu$ (0.4 mL, 3.17 mmol) and excess Na_2CO_3 (ca. 500 mg) and stirred for 3 h at 75°C. After the reaction mixture was cooled to room temperature, the solvent was removed, the residue was extracted with 25 mL of pentane, and the extract was brought to dryness in vacuo. The red-brown oily residue was dissolved in 4 mL of hexane, and the solution was chromatographed on Al_2O_3 (neutral, activity grade V, length of column 20 cm). With hexane, first an orange and then a yellow fraction was eluted. The orange fraction was evaporated in vacuo and the oily residue characterized as **4** by ^1H NMR spectroscopy (see below). The solvent of the yellow fraction was also removed and the residue recrystallized from pentane. After storing at −78°C, yellow moderately air-stable crystals precipitated that were filtered, washed twice with small amounts of pentane (−20°C), and dried. Yield: 30 mg (30%); mp 154°C dec. ^1H NMR (90 MHz, C_6D_6), δ: 8.71 (d, J(HH) = 9.6 Hz, $CH{=}CHtBu$), 5.03 (s, C_5H_5), 2.42 (d, J(HH) = 9.6 Hz, $=CHtBu$), 1.04 (s, CCH_3); ^{13}C NMR (22.5 MHz, C_6D_6), δ: 97.2 (s, $CH{=}CHtBu$), 78.8 (s, C_5H_5), 69.3 (s, $=CHtBu$), 35.2 (s, CCH_3), 31.2 (s, CCH_3). Anal. calcd. for $C_{22}H_{32}Ir_2$: C 38.81, H 4.74; found: C 38.99, H 4.74. ^1H NMR of **4** (60 MHz, C_6D_6), δ: = 4.98 (s, C_5H_5), 2.67 (d J(HH) = 10.6 Hz, H(*cis*) of $CH_2{=}$), 1.56 (d, J(HH) = 8.3 Hz, H(*trans*) of $CH_2{=}$), 0.97 (s, CCH_3), 0.34 (dd, J(HH) = 10.6 and 8.3 Hz, $=CHtBu$).

Preparation of $\{[CH_2(C_5H_4)_2][IrCl_2]_2\}_n$ 7

A solution of **6** (123 mg, 0.13 mmol) in 10 mL of hexane–dichloromethane (9:1) was treated, under continuous stirring, dropwise with a saturated solution of Cl_2 in dichloromethane as described for **2**. An orange-red air-stable solid was obtained. Yield: 73 mg (86%); mp 113°C (dec.). Anal. calcd. for $C_{11}H_{10}Cl_4Ir_2$: C 19.77, H 1.51; found: C 19.89, H 1.68. Due to the low solubility of the compound, no reliable NMR spectra could be obtained.

Preparation of $\{[CH_2(C_5H_4)_2][Ir_2(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHtBu)_2]\}$ 9

The procedure was analogous to that described for **5**, using **8** (97 mg, 0.12 mmol for $n = 1$), $CH_2{=}CHtBu$ (0.4 mL, 3.17

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

mmol), and Na_2CO_3 (ca. 500 mg) as starting materials and ethanol as solvent. The residue was extracted twice with hexane (10 mL each) and after the solvent was removed a red crystalline solid was obtained. Yield: 49 mg (59%); mp 159°C (dec.). ^{1}H NMR (90 MHz, $CDCl_3$), δ: 9.02 (d, *J*(HH) = 9.8 Hz, C*H*=CH*t*Bu), 5.65, 5.04, 4.10, 3.91 (all m, C_5H_4), 3.90 (m, CH_2), 2.77 (d, *J*(HH) = 9.8 Hz, =C*H*tBu), 1.08 (s, CCH_3); ^{13}C NMR (22.5 MHz, $CDCl_3$), δ: 98.75 (s, *C*H=CH*t*Bu), 95.86 and 95.23 (both s, *ipso*-C of C_5H_4), 85.8, 82.9, 78.85, 77.0 (all s, C_5H_4), 69.7 (s, =*C*H*t*Bu), 34.5 (s, *C*CH_3), 31.4 (s, C*C*H_3), 28.1 (s, *C*H_2). Anal. calcd. for $C_{23}H_{32}Ir_2$: C 39.87, H 4.66; found: C 40.02, H 4.86.

Preparation of $[(C_5H_5)_2Ir_2H(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHtBu)_2]BF_4$ 10

A solution of **5** (132 mg, 0.19 mmol) in 5 mL of ether was treated at −78°C with a 54% solution of HBF_4 (26 μL, 0.19 mmol) in ether. While the solution was slowly warmed up to room temperature, a yellow air-sensitive solid precipitated. The solvent was removed, and the precipitate was washed twice with ether (5 mL each) and dried in vacuo. Yield: 106 mg (71%). ^{1}H NMR (400 MHz, CD_3NO_2), δ: 11.02 (d, *J*(HH) = 10.9 Hz, C*H*=CH*t*Bu), 10.67 (d, *J*(HH) = 10.5 Hz, C*H*=CH*t*Bu), 5.99 and 5.92 (both s, C_5H_5), 4.43 (d, *J*(HH) = 10.9 Hz, =C*H*tBu), 3.95 (d, *J*(HH) = 10.5 Hz, =C*H*tBu), 1.11 (s, CCH_3), -21.57 (s, Ir*H*); ^{13}C NMR (100.6 MHz, CD_3NO_2), δ: 103.76 and 102.86 (both s, *C*H=CH*t*Bu), 95.03 and 90.79 (both s, C_5H_5), 85.39 and 84.23 (both s, =*C*H*t*Bu), 39.75 (s, *C*CH_3), 30.12 (s, C*C*H_3). Anal. calcd. for $C_{22}H_{33}BF_4Ir_2$: C 34.37, H 4.33; found: C 35.07, H 4.63.

Preparation of $\{[CH_2(C_5H_4)_2][Ir_2H(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHtBu)_2]\}BF_4$ 11

The procedure was analogous to that described for **10**, using **9** (84 mg, 0.12 mmol) and a 54% solution of HBF_4 (16 μL, 0.12 mmol) in ether as starting material. An orange-yellow air-sensitive solid was obtained. Yield: 71 mg (75%); mp 95°C (dec.). ^{1}H NMR (400 MHz, CD_3NO_2), δ: 9.80 (d, *J*(HH) = 10.3 Hz, C*H*=CH*t*Bu), 9.71 (d, *J*(HH) = 11.5 Hz, C*H*=CH*t*Bu), 6.28, 5.80, 5.52, 5.24 (all m, C_5H_4), 4.41 (s, CH_2), 3.37 (d, *J*(HH) = 11.5 Hz, =C*H*tBu), 3.34 (d, *J*(HH) = 10.3 Hz, =C*H*tBu), 0.96 and 0.90 (both s, CCH_3), -16.74 (s, Ir*H*); ^{13}C NMR (100.6 MHz, CD_3NO_2), δ: 110.29 and 108.43 (both s, *C*H=CH*t*Bu), 103.17 and 100.02 (both s, *ipso*-C of C_5H_4), 94.72, 92.57, 85.35, 84.36 (all s, C-2 to C-5 of C_5H_4), 81.90 and 79.95 (both s, =*C*H*t*Bu), 37.47 and 35.23 (both s, *C*CH_3), 30.98 and 30.18 (both s, C*C*H_3), 26.58 (s, *C*H_2). Anal. calcd. for $C_{23}H_{33}BF_4Ir_2$: C 35.38, H 4.26; found: C 35.11, H 4.20.

Preparation of $\{[CH_2(C_5H_4)_2][Rh(C_8H_{14})_2]_2\}$ 14 and $[(C_5H_5CH_2C_5H_4)Rh(C_8H_{14})_2]$ 15

A suspension of **13** (109 mg, 0.66 mmol) in 15 mL of THF was treated at −78°C, under continuous stirring, with a solution of **12** (251 mg, 0.35 mmol) in 10 mL of THF. After the solution was warmed to room temperature, it was stirred for 2 h, then the solvent was removed and the residue was extracted three times with hexane (5 mL each). The combined extracts were concentrated in vacuo to ca. 1 mL and the solution was chromatographed on Al_2O_3 (neutral, activity grade III, length of column 10 cm). With hexane, two yellow fractions were eluted that were brought to dryness in vacuo. From the first fraction, a golden-yellow oil that consisted of the mononuclear complex **15** was isolated. Yield: 174 mg (57%). The second fraction gave a yellow, moderately air-sensitive solid that corresponds to **14**. Yield: 61 mg (24%).

Data for **14**: ^{1}H NMR (200 MHz, C_6D_6), δ: 4.97 (m, H-2 and H-5 of C_5H_4), 4.51 (m, H-3 and H-4 of C_5H_4), 3.49 (s, *C*H_2 of bridge), 2.34 (m, =C*H* of C_8H_{14}), 1.60 and 1.31 (both m, *C*H_2 of C_8H_{14}). Anal. calcd for $C_{43}H_{66}Rh_2$: C 65.47, H 8.43; found: C 65.75, H 8.77.

Data for **15**: ^{1}H NMR (200 MHz, $CDCl_3$), δ: 6.56, 6.40, 6.35, 6.24, 6.14, 5.99 (all m, C*H* of C_5H_5), 4.92 and 4.41 (both vt, *J* = 4.0 Hz, C_5H_4), 3.50 and 3.43 (both m, CH_2 of bridge), 2.85 (m, CH_2 of C_5H_5), 2.30 (m, =C*H* of C_8H_{14}), 1.58 and 1.28 (both m, CH_2 of C_8H_{14}); ^{13}C NMR (50.3 MHz, $CDCl_3$), δ: 148.3 and 146.3 (both s, *ipso*-C of C_5H_5), 135.5, 134.4, 133.1, 128.3, 127.6 (all s, sp^2 C of C_5H_5), 108.3 and 107.4 (both d, *J*(RhC) = 4.0 Hz, *ipso*-C of C_5H_4Rh), 91.00 and 90.05 (both d, *J*(RhC) = 3.7 Hz, C-2 and C-5 of C_5H_4Rh), 88.2 (m, C-3 and C-4 of C_5H_4Rh), 65.1 and 64.2 (both m, =*C*H of C_8H_{14}), 43.6 and 41.9 (both s, *C*H_2 of C_5H_5), 33.4, 33.0, 27.0 (all s, *C*H_2 of C_8H_{14}), 27.05 and 25.3 (both s, *C*H_2 of bridge). Anal. calcd for $C_{27}H_{39}Rh$: C 69.52, H 8.43; found: 70.07, H 8.71.

Preparation of $\{[CH_2(C_5H_4)_2][RhBr_2]_2\}_n$ 16

A solution of **14** (155 mg, 0.20 mmol) in 10 mL of hexane–dichloromethane (9:1) was treated, under continuous stirring, dropwise with a 10% solution of Br_2 in CH_2Cl_2 until the formation of a flocky red precipitate was completed. The work-up procedure was the same as that described for **2**. A red air-stable solid was obtained. Yield: 119 mg (91%); mp 88°C (dec.) Anal. calcd. for $C_{11}H_{10}Br_4Rh_2$: C 19.79, H 1.51; found: C 20.44, H 1.54. Due to the low solubility of the compound, no reliable NMR spectra could be obtained.

Preparation of $\{[CH_2(C_5H_4)_2][Rh(C_8H_{14})_2][Ir(C_8H_{14})_2]\}$ 17

A solution of **15** (173 mg, 0.37 mmol) in 15 mL of hexane was treated, at −78°C, dropwise with a 1.6 M solution (0.23 mL, 0.37 mmol) of *n*BuLi in hexane. After the reaction mixture was warmed to room temperature, it was stirred for 1 h, and then the solvent was removed. The residue was washed twice with hexane and dissolved in 10 mL of THF. The solution was cooled to −78°C and treated with a solution of $[IrCl(C_8H_{14})_2]_2$ (170 mg, 0.19 mmol) in 10 mL of THF. After warming to room temperature, the solution was stirred for 2 h at 25°C and for 1 h at 50°C. It was then brought to room temperature and the solvent was removed. The residue was extracted three times with toluene (5 mL each), the combined extracts were concentrated to ca. 3 mL in vacuo, and the solution was chromatographed on Al_2O_3 (neutral, activity grade V, length of column 15 cm). With ether–hexane (1:5), a yellow fraction was eluted from which a yellow air-stable solid was isolated after removal of the solvent. Yield: 185 mg (57%); mp 203°C (dec.). ^{1}H NMR (400 MHz, C_6D_6), δ: 5.02 (m, H-2 and H-5 of C_5H_4), 4.57 (m, H-3 and H-4 of C_5H_4), 3.63 (s, *C*H_2 of bridge), 2.35 (m, =C*H* of C_8H_{14}), 1.77 and 1.51 (both m, *C*H_2 of C_8H_{14}); ^{13}C NMR (100.6 MHz, C_6D_6), δ: 108.38 (d, *J*(RhC) = 4.1 Hz, *ipso*-C of C_5H_4Rh), 102.69 (s, *ipso*-C of C_5H_4Ir), 91.31 (d, *J*(RhC) = 3.0 Hz, C-2 and C-5 of C_5H_4Rh), 90.69 (s, C-2 and C-5 of C_5H_4Ir), 86.87 (d, *J*(RhC) = 3.7 Hz, C-3 and C-4 of C_5H_4Rh), 86.52 (s, C-3 and C-4 of

C_5H_4Ir), 64.57 and 64.37 (both m, =*C*H of $C_8H_{14}Rh$), 46.20 and 46.12 (both s, =*C*H of $C_8H_{14}Ir$), 33.83, 33.61, 32.86, 26.89, 26.80 (all s, *C*H_2 of C_8H_{14}), 26.50 (s, *C*H_2 of bridge). Anal. calcd. for $C_{43}H_{66}IrRh$: C 58.54, H 7.54; found: C 59.15, H 7.63.

Preparation of $\{[CH_2(C_5H_4)_2][RhBr_2][IrBr_2]\}_n$ 18

The procedure was analogous to that described for **16**, using **17** (141 mg, 0.16 mmol) and a solution of Br_2 in dichloromethane as starting materials. A red air-stable solid was obtained. Yield: 116 mg (96%); mp 114°C (dec.). Anal. calcd. for $C_{11}H_{10}Br_4IrRh$: C 17.45, H 1.33; found: C 17.71, H 1.68. Due to the low solubility of the compound, no reliable NMR spectra could be obtained.

X-ray crystal structure determination of 9

Single crystals were grown from benzene and a crystal of dimensions 0.40×0.35×0.15 mm^3 was used for analysis. Crystal data: monoclinic space group *C*2/*c* (No. 15), $a = 20.050(8)$ Å, $b = 8.843(1)$ Å, $c = 24.25(1)$ Å, $\beta = 99.53(2)°$, $V = 4241$ $Å^3$, $Z = 8$, $d_{calcd} = 2.18$ g cm^{-3}, $d_{exp} = 2.16$ g cm^{-3}. Enraf–Nonius CAD4 diffractometer, Mo-K_α radiation (0.70930 Å), graphite monochromator, zirconium filter (factor 16.55), $T = 293$ K, ω/Θ scan, max. $2\Theta = 40°$; 4458 reflections were measured (only $h + k = 2n$), 4140 independent, 1742 were regarded as being observed ($F_o > 3\sigma(F_o)$); intensity data were corrected for Lorentz and polarization effects, and an empirical absorption correction ($\mu = 62.5$ cm^{-1}, ψ scan method, min. transmission 34%) was applied. The structure was solved by Direct methods (SHELXS86); atomic coordinates (see Table 2) and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least squares (266 parameters, program packet Enraf–Nonius SDP); hydrogen atoms were calculated for ideal geometry (distance C—H 0.95 Å) and varied according to the riding method. $R = 0.032$, $R_w = 0.041$; reflex/parameter ratio 6.6; residual electron density +0.96/-1.17 $Å^{-3}$. Complete crystallographic data have been deposited as supplementary material.[2]

Alkyne transformations at RhMn centres. Facile conversion between parallel and perpendicular alkyne binding modes and conversions to vinyl groups

Li-Sheng Wang and Martin Cowie

Abstract: The heterobinuclear complex $[RhMn(CO)_4(dppm)_2]$ (**1**) (dppm = $Ph_2PCH_2PPh_2$) reacts with alkynes (RC≡CR; R = CO_2Me (DMAD), CF_3 (HFB)) to yield the alkyne-bridged products $[RhMn(CO)_4(\mu\text{-}RC_2R)(dppm)_2]$ (**3***a*, **3***b*), in which the alkyne binds parallel to the metals. These species lose one carbonyl to yield two isomers in which the bridging alkyne group is either parallel or perpendicular to the Rh–Mn vector (**4** or **5**). Unusually facile interconversion between these two alkyne binding modes occurs. Protonation of the different alkyne-bridged species appears to occur at the metals with subsequent transfer to the alkyne ligand, yielding a series of vinyl complexes. These vinyl complexes are also obtained from the reaction of the hydride-bridged complex $[RhMn(CO)_4(\mu\text{-}H)(dppm)_2][BF_4]$ (**2**) with alkynes. A related vinyl species $[RhMn((CH_3)C{=}CH_2)(CO)_4(dppm)_2][BF_4]$ (**9***a*) is obtained in the reaction of **2** with allene. Also obtained in the allene reaction is the isomeric η^1-allyl complex $[RhMn(\eta^1\text{-}CH_2C(H){=}CH_2)(CO)_4(dppm)_2][BF_4]$ (**9***b*), which converts to **9***a* upon refluxing. The methyl analogues $[RhMnCH_3(CO)_4(dppm)_2][X]$ (X = SO_3CF_3, I) have been characterized and their structural formulations offer support for those of the vinyl species.

Key words: heterobinuclear, alkyne complexes, vinyl complexes.

Résumé : Le complexe hétérobinucléaire $[RhMn(CO)_4(dppm)_2]$ (**1**) (dppm = $Ph_2PCH_2PPh_2$) réagit avec les alcynes (RC≡CR; R = CO_2Me (DMAD), CF_3 (HFB)) pour conduire à des produits avec des ponts alcynes $[RhMn(CO)_4(\mu\text{-}RC_2R)(dppm)_2]$ (**3***a*, **3***b*), dans lesquels l'alcyne se lie d'une façon parallèle avec les métaux. Ces espèces perdent un carbonyle pour donner deux isomères dans lesquels le groupe alcyne agissant comme pont est soit parallèle soit perpendiculaire au vecteur Rh–Mn (**4** or **5**). Il se produit une interconversion inhabituellement facile entre ces deux modes de liaison des alcynes. La protonation de diverses espèces avec ponts alcynes semble se produire au niveau des métaux avec un transfert subséquent vers le coordinat alcyne qui fournit une série de complexes vinyliques. On peut aussi obtenir ces complexes vinyliques par réaction du complexe avec un pont hydrure $[RhMn(CO)_4(\mu\text{-}H)(dppm)_2][BF_4]$ (**2**) avec les alcynes. On obtient une espèce vinylique apparentée $[RhMn((CH_3)C{=}CH_2)(CO)_4(dppm)_2][BF_4]$ (**9***a*) par réaction du composé **2** avec l'allène. Lors de cette réaction, on obtient aussi le complexe η^1-allylique isomère $[RhMn(\eta^1\text{-}CH_2C(H){=}CH_2)(CO)_4(dppm)_2][BF_4]$ (**9***b*), qui se transforme en **9***a* par chauffage au reflux. On a aussi caractérisé les analogues méthylés $[RhMnCH_3(CO)_4(dppm)_2][X]$ (X = SO_3CF_3, I) et leurs formulations structurales offrent un support pour celles des espèces vinyliques.

Mots clés : hétérobinucléaire, complexes alcynes, complexes vinyliques.

Introduction

The coordination and activation of alkynes at two metal centres and subsequent transformations involving these substrates have attracted considerable attention (see, for example, ref. 1). Our recent interest in such chemistry has been aimed at elucidating the alkyne coordination modes in binuclear systems (2–6) with interest in determining the influence of the different binding modes on the subsequent chemistry. Two types of alkyne transformations, occurring at bimetallic cores, that we have recently been studying involve the conversions to vinyl (7–9) and vinylidene (10–12) ligands. Vinyl complexes can be prepared by the insertion of alkynes into metal–hydrogen bonds — a fundamental process in organometallic chemistry (13), or alternately by protonation of preformed alkyne complexes, or of the tautomeric vinylidene analogues (14).

Our interest in vinyl complexes stems from recent reports in which surface-bound vinyl groups, rather than alkyls, have

been implicated as key species in Fischer–Tropsch synthesis (15). These ideas have been based on the ease of migratory insertions involving vinyl and bridging methylene groups, which occur more readily than for the alkyl analogues (*15b*, 16). The ease of these migratory insertions also suggests applications for vinyl complexes in organic synthesis (17, 18).

In this paper we report alkyne chemistry at adjacent Rh and Mn centres, on the assumption that the tendency of one of these centres (Mn) to maintain a coordinately saturated configuration might lead to subtle differences from analogous species based on dirhodium, diiridium, or rhodium/iridium. In addition, we also report transformations to vinyl complexes based on the conversion of both alkynes and allene.

Experimental section

General procedures

Purified argon and carbon monoxide were obtained from Linde and hydrogen sulfide from Matheson. The 99% carbon-13-enriched carbon monoxide was purchased from Isotec Inc. All gases were used as received. Diethyl ether, hexane, and tetrahydrofuran were dried over Na-benzophenone ketyl, and methylene chloride was dried over P_2O_5. All solvents were distilled under argon before use. The perdeuterated methylene chloride was dried over molecular sieves and deoxygenated by repeated freeze–pump–thaw cycles. The compounds, dimethyl acetylenedicarboxylate (DMAD), tetrafluoroboric acid–diethyl (and dimethyl) etherate, triflic acid, trifluoroacetic acid, and methyl triflate were used as received from Aldrich. Hexafluoro-2-butyne (HFB) was received from PCR Inc., hydrated rhodium trichloride from Johnson Matthey, and $Mn_2(CO)_{10}$ from Strem Chemicals Inc. Compounds $[RhMn(CO)_4(dppm)_2]$ (**1**) (19) and $[RhMn(CO)_4(\mu\text{-}H)(dppm)_2][BF_4]$ (**2**) (20) were prepared by the reported procedures. Reactions were routinely carried out under Schlenk conditions.

All routine NMR experiments were conducted on a Bruker AM-400 spectrometer, whereas the $^{13}C\{^1H\}$ NMR experiments were run on a Bruker AM-200 spectrometer. For all NMR experiments CD_2Cl_2 (except ^2H experiments for which CH_2Cl_2 was used) was used as solvent. IR spectra were recorded on either a Nicolet 7199 Fourier transform interferometer or a Perkin–Elmer 883 spectrophotometer as solids (Nujol mull or CH_2Cl_2 cast) or CH_2Cl_2 solutions. Elemental analyses were performed by the microanalytical service within the department. The spectral data for all compounds are given in Tables 1 and 2. All compounds were moderately air sensitive in solution so were routinely handled under dinitrogen or argon.

Preparation of compounds

*(a) [RhMn(CO)$_3$(μ-DMAD)(μ-CO)(dppm)$_2$] (**3a**).*
To a CH_2Cl_2 solution of $[RhMn(CO)_4(dppm)_2]$ (**1**) (50 mg, 48 μmol in 10 mL under CO) was added 15 μL of DMAD (122 μmol), resulting in an immediate color change from yellow to red. After stirring for 1 h the solvent was reduced to ca. 1 mL by a rapid flow of CO; at that time a red crystalline solid precipitated from solution. The solid was separated from the mother liquor by filtration and was washed with 1 mL of CH_2Cl_2. A red crystalline solid was obtained in 70% yield and was stored under CO. Anal. calcd. for $RhMnP_4O_8C_{60}H_{50}\cdot CH_2Cl_2$: C 57.88, H 4.14, Cl 5.60; found: C 57.79, H 4.16, Cl, 5.66.

*(b) [RhMn(CO)$_3$(μ-HFB)(μ-CO)(dppm)$_2$] (**3b**)*
A CH_2Cl_2 solution of compounds **4***b* and **5***b* (100 mg in 10 mL) was put under CO (10 psi; 1 psi = 6.9 kPa)). The solution was cooled to −78°C and stirred for 1 h. The color of the solution changed to orange from green and an orange solid precipitated out of the solution. Hexane (50 mL) was added to precipitate the solid and the supernatant was removed by canula. The solid was dried by the rapid flow of CO and the solid was stored under CO. The solid was unstable in air toward the loss of CO; therefore the elemental analysis was not attempted.

*(c) [RhMn(CO)$_3$(μ-DMAD)(dppm)$_2$] (**4a**)*
To a THF solution of $[RhMn(CO)_4(dppm)_2]$ (**1**) (50 mg, 48 μmol in 10 mL) was added 8 μL of DMAD (65 μmol). Refluxing for 1 h yielded a black-purple solution. Recrystallization from CH_2Cl_2–hexane gave a black solid in 80% yield. Anal. calcd. for $RhMnP_4O_7C_{49}H_{50}\cdot 0.6\ CH_2Cl_2$: C 59.49, H 4.29, Cl 3.50; found: C 59.15, H 3.76, Cl 3.51. A CH_2Cl_2 solution containing **4***a* could be obtained by dissolving the solid at −78°C.

*(d) [RhMn(CO)$_3$(μ-HFB)(dppm)$_2$] (**4b**)*
Compound **1** (200 mg) was placed in a Schlenk tube (100 mL) and put under vacuum. The tube was filled with hexafluoro-2-butyne and 20 mL of CH_2Cl_2 was added. The solution was stirred for 24 h. Removal of the solvent in vacuo and recrystallization from CH_2Cl_2 (10 mL of Et_2O and 40 mL of hexane) gave a green crystalline solid (80%). Anal. calcd. for $RhMnP_4F_6O_3C_{57}H_{44}$: C 58.36, H 3.75; found: C 57.92, H 3.83. A CH_2Cl_2 solution of **4***b* could be obtained by dissolving the solid at temperatures below 0°C.

*(e) [RhMn(CO)$_3$(μ-η^2:η^2-DMAD)(dppm)$_2$] (**5a**)*
The crystalline solid of compound **4***a* was dissolved in CD_2Cl_2 (5 mg in 0.5 mL) at room temperature. The ^{31}P and ^1H NMR showed the formation of the mixture of compound **5***a* and compound **4***a* in a ratio of about 0.2:1.

*(f) [RhMn(CO)$_3$(μ-η^2:η^2-HFB)(dppm)$_2$] (**5b**)*
The crystalline solid of compound **4***b* was dissolved in CD_2Cl_2 (5 mg in 0.5 mL) at room temperature. After 1 h the ^{31}P and ^1H NMR showed the formation of the mixture of compound **5***b* and compound **4***b* in a ratio of about 0.7:1.

*(g) [RhMn(H)(CO)$_4$(μ-DMAD)(dppm)$_2$][BF$_4$] (**6a**)*
To a CD_2Cl_2 solution of compound **3***a* (3 mg, 2.5 μmol in 0.5 mL, in an NMR tube) at −78°C was added 1 μL of $HBF_4\cdot Et_2O$ (4.8 μmol). The compound was characterized by NMR at −80°C.

*(h) [RhMn(H)(CO)$_4$(μ-HFB)(dppm)$_2$][BF$_4$] (**6b**)*
To a CD_2Cl_2 solution of compound **3***b* (3 mg, 2.5 μmol in 0.5 mL, dissolved at −78°C under 10 psi of CO in an NMR tube) was added 2 μL of $HBF_4\cdot Me_2O$ (16 μmol). The compound was characterized by NMR at −40°C.

*(j) [RhMn(C(COOMe)=CH(COOMe))(CO)$_2$(μ-CO)$_2$(dppm)$_2$][BF$_4$] (**7a**·BF$_4$)*

Method (i): To a CH_2Cl_2 solution of compound **3** (50 mg, 42

mental analysis of the BF_4^- salt was not obtained; that of the $SO_3CF_3^-$ salt (**7a**·SO_3CF_3) is given below.

*(k) [RhMn(C(COOMe)=CH(COOMe))(CO)$_2$(μ-CO)$_2$(dppm)$_2$][SO_3CF_3] (**7a**·SO_3CF_3)*

To a CH_2Cl_2 solution of compound **3** (50 mg, 42 μmol in 10 mL) was added 3.8 μL of CF_3SO_3H (42 μmol), resulting in an immediate color change from red to yellow. After 1 h the solvent was removed and the residue was recrystallized from THF–Et_2O. A yellow solid was obtained in 87% yield. Anal. calcd. for $RhMnSP_4F_3O_{11}C_{61}H_{51}$: C 55.05, H 3.86; found: C 55.48, H 4.54.

*(l) [RhMn(C(CF$_3$)=CH(CF$_3$))(CO)$_2$(μ-CO)$_2$(dppm)$_2$][BF$_4$] (**7b**·BF$_4$)*

To a CH_2Cl_2 solution of compound **3***b* (50 mg, 42 μmol in 10 mL under 10 psi of CO at −78°C) was added 6 μL of $HBF_4{\cdot}Me_2O$ (49 μmol). After stirring for 0.5 h the solution was warmed to room temperature and was stirred for another 0.5 h. The solvent was removed and the residue was recrystallized from CH_2Cl_2–Et_2O. A yellow solid was obtained in 82% yield. Anal. calcd. for $RhMnP_4F_{10}O_4BC_{58}H_{45}$, 0.4 CH_2Cl_2: C 53.01, H 3.46; found: 52.92, H 4.51. The amount of CH_2Cl_2 was established from the ^1H NMR spectrum in d_8-THF.

*(m) [RhMn(CO)$_3$(μ-C(COOMe)=CH(COOMe))(dppm)$_2$][BF$_4$] (**8a**·BF$_4$)*

To a CD_2Cl_2 solution of isomers **4***a* and **5***a* (5 mg, 4 μmol in 0.5 mL in an NMR tube) was added 2 μL of HBF_4Me_2O (16 μmol) at −78°C. The solution turned grey from black. The compound was characterized by NMR experiments at −80°C.

*(n) [RhMn(CO)$_3$(μ-C(COOMe)=CH(COOMe))(dppm)$_2$][CO_2CF_3] (**8a**·CO_2CF_3)*

To a CD_2Cl_2 solution of isomers **4***a* and **5***a* (5 mg, 4 μmol in 0.5 mL in an NMR tube) was added 10 μL of CF_3CO_2H (130 μmol) at −78°C. The solution turned grey from black. The compound was characterized by NMR experiments at −80°C.

*(o) [RhMn(C(Me)=CH$_2$)(CO)$_2$(μ-CO)$_2$(dppm)$_2$][SO_3CF_3] (**9a**)*

Allene (10 mL, ca. 400 μmol) was syringed to a THF solution of $[RhMn(CO)_4(\mu\text{-H})(dppm)_2][SO_3CF_3]$ (**2**) (50 mg, 42 μmol in 10 mL). The solution was refluxed for 6 h and cooled to ambient temperature, resulting in the precipitation of a yellow solid. The supernatant was removed by syringe and the solid was washed with Et_2O. A yellow solid was obtained (yield 64%). Anal. calcd. for $RhMnC_{58}H_{49}O_7F_3P_4S$: C 56.68, H 3.99; found: C 56.39, H 3.99.

*(p) Compound **9** and [RhMn(CH$_2$CH=CH$_2$)(CO)$_2$(μ-CO)$_2$(dppm)$_2$][SO_3CF_3] (**9b**)*

A Schlenk tube containing 50 mg of compound **2** was filled with allene at ca. 1 atm (1 atm = 101.3 kPa) and 5 mL of CH_2Cl_2 was added. The solution was stirred for 4 d. Removal of the solvent and recrystallization from CH_2Cl_2–Et_2O gave a yellow solid (76% yield). NMR characterization showed it to be an approximate 1:1 mix of **9***a* and the η^1-allyl product **9***b*. Refluxing a mixture of **9***a* and **9***b* in THF for 3 h resulted in the transformation of **9***b* to **9***a*.

*(q) [RhMnMe(CO)$_2$(μ-CO)$_2$(dppm)$_2$][SO_3CF_3] (**10b**)*

To a CH_2Cl_2 solution of $[RhMn(CO)_4(dppm)_2]$ (**1**) (100 mg, 96 μmol in 10 mL) was added 15 μL of $CF_3SO_3CH_3$ (133 μmol) and the mixture was stirred for 18 h. Removal of the solvent and recrystallization from CH_2Cl_2–Et_2O gave a yellow compound in 70% yield. Anal. calcd. for $RhMnSP_4F_3O_7C_{56}H_{47}$: C 55.91, H 3.91; found: C 55.58, H 3.80.

*(r) [RhMnMe(CO)$_2$(μ-CO)$_2$(dppm)$_2$] [I] (**10b**)*

To a CH_2Cl_2 solution of $[RhMn(CO)_4(dppm)_2]$ (**1**) (50 mg, 48 μmol in 10 mL) was added 50 μL of CH_3I (80 μmol). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

solution was stirred for 18 h. Removal of the solvent and recrystallization from CH_2Cl_2–Et_2O gave a yellow compound in 82% yield.

(s) [RhMn(C(O)Me)(CO)$_4$(dppm)$_2$][SO$_3$CF$_3$] (11)
A CH_2Cl_2 solution of [RhMnMe(CO)$_2$(μ-CO)$_2$(dppm)$_2$]-[SO_3CF_3] (**10***a*) (100 mg, 83 μmol in 5 mL) was put under CO (10 psi) and was stirred for 5 weeks. Removal of the solvent and recrystallization from THF–Et_2O gave a yellow solid in 76% yield. Anal. calcd. for $RhMnSP_4F_3O_8C_{57}H_{47}$: C 55.61, H 3.82; found: C 56.25, H 3.95.

(t) [RhMn(CO)$_3$(μ-H)(μ-HFB)(dppm)$_2$][BF$_4$] (12) and [RhMn(CO)$_3$(μ-H)(μ-η^2:η^2-HFB)(dppm)$_2$][BF$_4$] (13a)
[RhMn(CO)$_3$(μ-HFB)(dppm)$_2$] (**4***b*, 5 mg, 4 μmol) was dissolved in 0.5 mL of CD_2Cl_2 at −78°C to which 2 μL of HBF_4·Me_2O (16 μmol) was added. These compounds were formed in ratio of *ca* 0.5:1, respectively, at 0°C and were characterized by NMR experiments.

(u) [RhMn(CO)$_3$(μ-H)(μ-η^2:η^2-HFB)(dppm)$_2$][CO$_2$CF$_3$] (13b)
[RhMn(CO)$_3$(μ-HFB)(dppm)$_2$] (**4***b*, 5 mg, 4 μmol) was dissolved in 0.5 mL of CD_2Cl_2 at −78°C; 25 μL of CF_3CO_2H (16 μmol) was then added. The compound was characterized by NMR experiments at 0°C.

Kinetics for the transformation of 4*b* to 5*b*
The green solid of isomer **4***b* was dissolved in CD_2Cl_2 at −78°C (5 mg in 0.5 mL) in an NMR tube (at this temperature no isomerization occurs) and the temperature of the NMR probe was set to the appropriate running temperature (20, 25, 30, or 35°C (corrected)). A beaker of water was prepared at the same temperature as the probe and the NMR tube was placed in this beaker for 1 min. The use of the bath ensured that the sample warmed to running temperature as soon as possible. The sample was placed into the NMR probe and the ^{19}F NMR spectra were obtained at regular intervals (6 min), starting from the time the sample was immersed into the warm water.

The transformation of **4***b* to **5***b* is a first-order system coming to equilibrium (21), and can be represented as:

$$[1] \quad A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B$$

in which A and B represent **4***b* and **5***b*, respectively. From this, the expression:

$$[2] \quad -\ln \frac{[B]_e - [B]}{[B]_e - [B]_o} = (k_1 + k_{-1})t$$

can be obtained, where $[B]_o$, [B], and $[B]_e$ are the concentrations of **5***b* at $t = 0$, $t = t$, and $t = \infty$, respectively. Assuming $[B]_o = 0$, eq. [2] simplifies to:

$$[3] \quad -\ln\left(1 - \frac{[B]}{[B]_e}\right) = (k_1 + k_{-1})t$$

The units of concentration used were mole fractions, and $[B]_e$ was obtained after the sample had sat at room temperature for 1 day, and then at the desired temperature for 1.0 h. Plots of $-\ln(1-[B]/[B]_e)$ against t give the slope $k_1 + k_{-1}$. The ratio k_1/k_{-1} equals $[B]_e/(1-[B]_e)$. From $k_1 + k_{-1}$ and k_1/k_{-1} values of k_1 and k_{-1} can be calculated and are given in Table 3. Values of $\Delta H°*$ and $\Delta S°*$ were derived by the application of the transition state theory eq. [4].

Table 3. Forward and reverse rate constants for the reversible conversion of **4***b* to **5***b*.

	Rate constant	
Temperature (°C)	k_1(min^{-1}) × 10^3	k_{-1}(min^{-1}) × 10^3
20	6.63	9.17

30	26.5	37.3
35	48.2	68.8

$$[4] \quad \ln(k/T) = -\Delta H°*/RT + (23.76 + \Delta S°*/R)$$

Results and discussion

(a) Alkyne species
The reaction of [RhMn(CO)$_4$(dppm)$_2$] (**1**) with dimethyl acetylenedicarboxylate (DMAD) under CO yields the DMAD-bridged product [RhMn(CO)$_4$(μ-DMAD)(dppm)$_2$] (**3***a*), as was observed in the isoelectronic compounds, [RhRe(CO)$_4$(μ-DMAD)(dppm)$_2$] (22), and [RhOs(CO)$_4$(μ-DMAD)(dppm)$_2$]$^+$ (4), and spectral characterization of **3***a* proceeded much as reported for these analogues. Although coordination of the alkyne perpendicular to the Rh–Mn axis was considered in **3***a*, it was ruled out on the basis of the ^1H NMR spectrum. This spectrum showed two separate resonances for the DMAD methyl groups, which are in different environments by virtue of their proximity to either Rh or Mn; a perpendicular arrangement would have only one methyl signal. The $^{13}C\{^1H\}$ NMR spectrum of **3***a* shows a resonance for the terminal carbonyl on Rh at δ 193.8 ($^1J_{Rh-C}$ = 57 Hz), two for the terminal carbonyls on Mn (δ 221.8, 223.5), and one corresponding to a semibridging carbonyl at δ 248.7, showing a weak interaction with Rh($^1J_{Rh-C}$ = 10 Hz). This semibridging interaction is substantiated by the low carbonyl stretch at 1727 cm^{-1} in the IR spectrum. The similarities in the spectroscopic parameters for **3***a* (see Table 1) to those of the Rh/Re and Rh/Os analogues lead to the formulation shown in Scheme 1 (note that in the schemes the dppm groups above and below the plane of the drawing are usually omitted for clarity).

If the reaction of **1** with DMAD is carried out in the absence of CO, a mixture of **3***a* and two new species **4***a* and **5***a* is obtained. Refluxing this mixture in THF yields **4***a* and **5***a* and recrystallization yields only **4***a*, as a black solid. A solution containing only **4***a* can be prepared by dissolving the black solid in CH_2Cl_2 at −78°C. Upon gradually increasing the solution temperature to −40°C compound **5***a* begins to appear, as shown by the $^{31}P\{^1H\}$ NMR spectra. At temperatures between 0° and 20°C an equilibrium mixture of **4***a* and **5***a* is present in an approximate 85:15 molar ratio. Both new

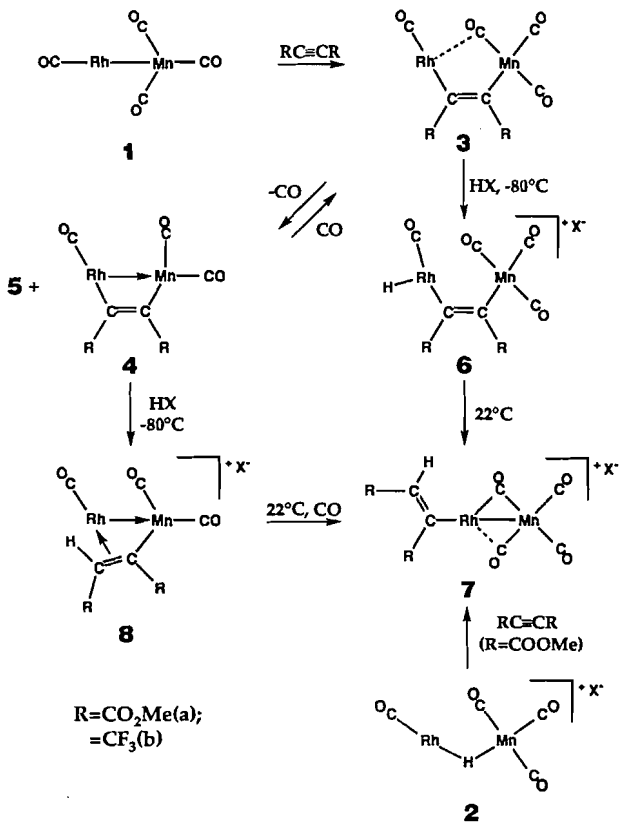
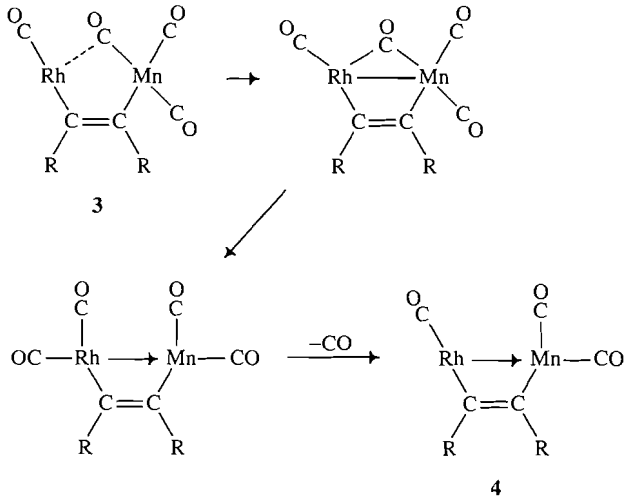
Scheme 1.

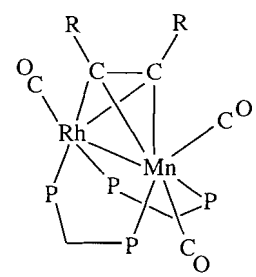


products are isomers of formulation $[RhMn(CO)_3(\mu\text{-}DMAD)(dppm)_2]$, resulting from carbonyl loss from **3***a*. The major isomer (**4***a*) has the structure shown in Scheme 1, and is the species expected based on previous work with the related Rh/Re and Rh/Os systems; in particular the Rh/Os analogue $[RhOs(CO)_3(\mu\text{-}DMAD)(dppm)_2]^+$ was previously characterized by an X-ray structure determination (4). The $^{13}C\{^1H\}$ NMR spectrum of **4***a* shows one carbonyl ligand on Rh and two on Mn, in addition to two singlets for the DMAD-carbonyl groups at δ 175.0 and 168.0, and two signals for the methyl groups at δ 50.3 and 50.1. Only one acetylenic carbon resonance was observed at δ 140.9 as a triplet of triplets, displaying coupling to both sets of ^{31}P nuclei; the other acetylenic resonance was not observed and appears to be obscured by phenyl resonances (non isotopically enriched DMAD was used so the signals due to DMAD are of low intensity). The ^1H NMR spectrum also displays two signals for the DMAD methyl groups consistent with a parallel DMAD coordination in which the two ends of the alkyne are inequivalent by virtue of their proximity to either Rh or Mn. A dative Rh → Mn bond is proposed to give Mn an 18-electron configuration, as was previously suggested for the Rh/Os analogue, in which the metal–metal interaction was supported by the X-ray study. Carbonyl loss from **3** probably occurs by transfer of the semibridging carbonyl to Rh, followed by CO loss from this metal. Concomitant with the transformation of this carbonyl from semibridging, to symmetrically bridging, to terminal on Rh, is a change in the metal–metal bonding, from no bond in **3**, to a conventional Rh—Mn bond in the symmetrically CO-bridged intermediate, to a Rh → Mn dative bond in the last species, as shown below. This shift of electron density from



Rh to Mn accompanies the movement of the carbonyl's donor pair from Mn to Rh, and demonstrates how the adjacent metal (Rh) can assist in the labilization of a ligand from normally inert, 18e center (Mn).

The minor isomer **5***a* is proposed to have a perpendicular alkyne binding mode, shown below, as has been previously observed within the Co triad for $[Rh_2(CO)_2(\mu\text{-}\eta^2\text{-}PhC_2Ph)(dppm)_2]$ (23), $[Ir_2(CO)_2(\mu\text{-}\eta^2\text{-}DMAD)(dppm)_2]$ (6), a series of related dicobalt complexes (24–30), as well as other dirhodium (31, 32) and diiridium (33) systems. This proposed structure is based on the spectral data. The $^{31}P\{^1H\}$ NMR spectrum shows an AA′BB′X spin system in which the



5*a* (R = CO_2Me); **5***b* (R = CF_3)

Mn-bound phosphorus nuclei resonate at δ 98.9; this is 47 ppm downfield from the related signal in **4***a* in which a *trans* arrangement of phosphines is proposed. The resonance for the Rh-bound phosphorus nuclei is also somewhat downfield from that observed in **4***a*. Both Mn-bound carbonyls display unusually high coupling (48 and 38 Hz) to the Mn-bound phosphorus nuclei, compared to values between 10 and 20 Hz when a *trans* diphosphine arrangement is involved, suggesting a geometry in which the CO and phosphines are at an angle other than 90°. Also, unexpectedly, the Rh-bound CO displays weak coupling to the Mn-bound phosphorus nuclei, presumably through the Rh—Mn bond. Only one signal is observed in the $^{13}C\{^1H\}$ NMR spectrum corresponding to the two equivalent DMAD carbonyls (δ 176.0) and another for the two methyl groups. In addition the ^1H NMR spectrum also shows only one resonance for both methyl groups. These data support the perpendicular orientation of the alkyne, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

would result in both ends of the alkyne being chemically equivalent.

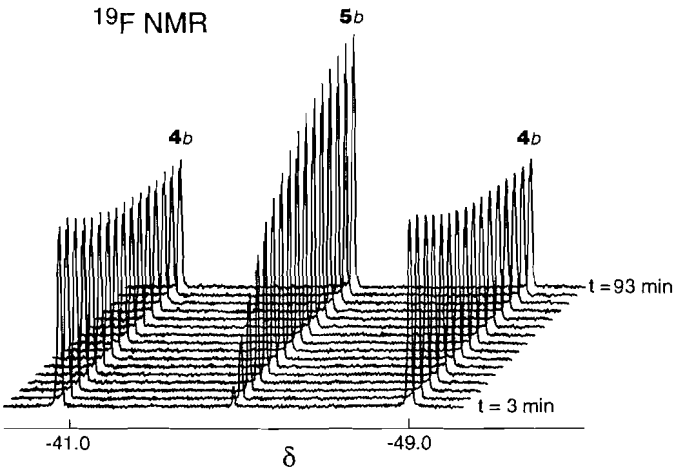
Although the perpendicular coordination mode of the alkyne and the concomitant *cis*-diphosphine arrangement seem clear, the resulting geometry at Mn, regarding the positions of the carbonyls, is still ambiguous.

All routes to **4***a* and **5***a* invariably yield these species in a constant ratio in solution, suggesting an equilibrium between the two. This has been confirmed by spin-saturation transfer experiments at 60°C in which saturation of the signal for the Mn-bound phosphorus nuclei of one isomer results in a substantial intensity decrease (>60%) for the corresponding signal of the other isomer. Although reversible conversion of one alkyne-bridged mode to the other has been reported upon ligand gain or loss (34, 35), we know of only one other study in which such a reversible transformation in alkyne bonding modes occurs with no change in the number of ligands; this conversion from a dimetallacyclobutene structure to the perpendicular binding mode for $[Cp^*(CO)_2Re]_2(\mu\text{-DMAD})$ was induced upon photolysis and was reversed upon heating.[2] However, the facility of this reversible change in alkyne binding mode (**4***a* $\rightleftharpoons$ **5***a*) is unprecedented. A facile interconversion between alkyne bonding modes has been proposed to explain the ease of ligand addition to the coordinatively saturated complex $[Cp_2Rh_2(\mu\text{-CO})(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)]$, but the other rotamer was not observed (1*k*). At ambient temperature spin-saturation transfer between **4***a* and **5***a* was not observed because at this temperature the exchange rate is too slow.

The reaction of **1** with hexafluoro-2-butyne (HFB) leads to a series of HFB-bridged complexes **3***b*, **4***b*, and **5***b*, exactly analogous to the DMAD-bridged compounds discussed, and are again shown in Scheme 1 (R = CF_3). These products show very similar spectroscopic properties to their DMAD analogues. The major difference lies in the relative proportions of isomers **4** and **5**. Whereas isomer **5***a*, having the perpendicular alkyne bridge, was the minor isomer for DMAD, both isomers **4***b* and **5***b* are present in comparable amounts with HFB. The ^{19}F NMR spectra (see Table 2) conveniently differentiate between the parallel and perpendicular alkyne binding modes, with the parallel isomer **4***b* showing two multiplet resonances for the inequivalent CF_3 groups while **5***b* displays only one multiplet resonance for the chemically equivalent CF_3 groups. Carrying out ^{19}F NMR experiments on **4***b* with selective and broad-band ^{31}P-decoupling shows that the fluorine resonance at δ −40.8 couples to only the Mn-bound phosphorus atoms so is assigned to the CF_3 group adjacent to Mn, whereas the signal at δ −49.0 surprisingly couples to all phosphorus nuclei. In addition, the two CF_3 groups display a mutual coupling of 13 Hz, typical of a *cis* arrangement. The single ^{19}F resonance in **5***b* collapses to a singlet upon decoupling the Rh-bound phosphorus nuclei, but shows no apparent coupling to the Mn-bound ends of the diphosphines, suggesting a stronger binding to Rh. Although the coordinatively unsaturated **4***b* immediately reverts to **3***b* at −40°C under CO, **5***b* remains unreacted at this temperature, consistent with the coordinatively saturated formulation for this species. The electronic effect of substituting DMAD by the better π-accepting HFB group (36) shows up in the greater lability of the fourth carbonyl in **3***b*. Therefore the tetracarbonyl species $[RhMn(CO)_4(\mu\text{-HFB})(dppm)_2]$ (**3***b*) is only observed under CO at −40°C; otherwise the tricarbonyl isomers are the only species observed. In none of the alkyne-bridged species described was a C≡C stretch visible in the IR spectra.

[2] C.P. Casey and R.S. Carino, personal communication.

Fig. 1. ^{19}F NMR spectra (at 376.5 MHz) at 20°C showing the conversion of compound **4***b* to **5***b* over a 90 min period; the spectra were acquired at 6 min intervals.



The isomerization of **4***b* to **5***b* is less facile than for the DMAD analogue; whereas conversion of **4***a* to **5***a* was observed at −40°C, that for **4***b* to **5***b* did not occur appreciably until temperatures near 0°C. Even at 60°C, exchange between **4***b* and **5***b* was too slow to be detected by spin-saturation transfer experiments. However, over the temperature range between 20 and 35°C this conversion can be conveniently monitored by ^{19}F NMR. Figure 1 shows the changes in ^{19}F NMR spectra that occur as **4***b* slowly converts to **5***b* at 20°C. For this first-order system coming to equilibrium the forward and reverse rate constants (k_1 and k_{-1}) can be obtained (21), and from the transition-state theory (T = 20, 25, 30, 35°C), values for ΔH^* and ΔS^* for the forward (23.3 kcal mol^{-1}, 2.9 cal K^{-1} mol^{-1}) and reverse (23.6 kcal mol^{-1}, 4.7 cal K^{-1} mol^{-1}) reactions can be obtained. Although the corresponding kinetic study was not carried out for the conversion between the DMAD analogues **4***a* and **5***a*, the more facile conversion at lower temperatures indicates a lower barrier to rotation. This presumably reflects the stronger binding of HFB by virtue of its better π-accepting ability.

(b) Vinyl species

Addition of protic acids to **3***a* at −80°C results in protonation at Rh to yield $[RhMnH(CO)_4(\mu\text{-DMAD})(dppm)_2][X]$ (X = BF_4 (**6***a*)). The hydride resonance at δ −14.3 in the ^1H NMR spectrum displays coupling to Rh of 38 Hz and to the phosphorus nuclei on Rh, confirming its terminal coordination to this metal. All other spectroscopic data (see Table 1), including the observation of two resonances for the DMAD methyl protons, support the structure shown. The observed protonation at only one metal is in contrast to the protonation of the metal–metal bond in the related compound $[Rh_2(CO)_2(\mu\text{-DMAD})(dmpm)_2]$ (dmpm = $Me_2PCH_2PMe_2$) to give a hydride-bridged species (8).

Upon warming, compound **6***a* transforms to the vinyl complex **7***a*. $^{13}C\{^1H\}$ NMR spectra for the BF_4^- salt show four separate carbonyl resonances. The low-field signal, at δ 243.4,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

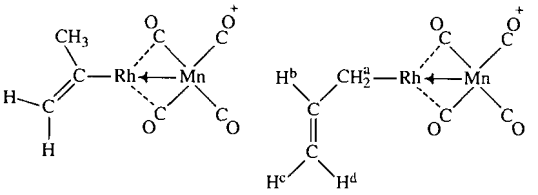
displays coupling of 29 Hz to Rh and 8 Hz to the Mn-bound phosphines, so is formulated as a bridging carbonyl. The resonance at δ 235.6 displays coupling to Rh and to the Mn-bound phosphines, both of 14 Hz, so is formulated as semibridging, whereas the remaining two carbonyls are terminally bound to Mn, as shown in Scheme 1. It appears that the weaker interaction of the semibridging carbonyl with Rh results from repulsion of this group by a methoxycarbonyl substituent of the terminal vinyl group, with the conventionally bridged carbonyl adjacent to the hydrogen on the β-carbon. Such a proposal presumes that there is no facile rotation about the Rh–vinyl bond. The vinylic proton of **7***a* (X = BF_4 or SO_3CF_3) is observed at ca. δ 4.4 and displays coupling of 2 Hz to Rh, suggesting that the vinyl group is bound to Rh. In any case, with no other ligand bound terminally to Rh, the vinyl group must be terminally bound to this metal. The IR spectra of **7***a* show two terminal-carbonyl stretches, two corresponding to bridged carbonyls, between 1809 and 1854 cm^{-1}, and a strong band due to the ester carbonyl groups and a weak stretch at ca. 1585 due to the C=C bond of the vinyl moiety.

Protonation of the HFB-bridged species **3***b* again parallels that involving the DMAD-bridged analogue, yielding the hydrido intermediate **6***b* at low temperature, which rearranges to the vinyl species **7***b* at ambient temperature. In **7***a* (R = CO_2Me) our spectroscopic data could not differentiate between a *cis* or *trans* arrangement of CO_2Me groups about the vinylic C=C bond, so we assumed a cis arrangement, as normally observed in such migratory insertions (37–41). Having CF_3 substituents we are now able to establish a cis arrangement based on ^{19}F–^{19}F coupling constants. In **7***b* this coupling ($^5J_{F-F}$ = 12 Hz) is typical of a cis arrangement (42-45), and compares well to the values of 17, 13, and 18 Hz observed in **3***b*, **4***b*, and **6***b*, respectively.

Compound **7***a* can also be prepared by the reaction of the hydride-bridged species, $[RhMn(CO)_4(\mu\text{-}H)(dppm)_2][BF_4]$ (**2**) with DMAD, via migratory insertion.

A very similar vinyl product, $[RhMn(C(Me)=CH_2)(CO)_2(\mu\text{-}CO)_2(dppm)_2][SO_3CF_3]$ (**9***a*), containing an isopropenyl group, that is terminally bound to Rh, can be prepared by the insertion of allene ($H_2C=C=CH_2$) into the metal-hydride bond of the above hydride-bridged complex in refluxing THF. A similar transformation was previously observed in a closely related Rh/Os complex and this isopropenyl product was structurally characterized by an X-ray study (46). Compound **9***a* shows four carbonyl resonances in the $^{13}C\{^1H\}$ NMR with two at low field corresponding to bridging groups, displaying 20 Hz coupling to Rh and 11 Hz coupling to the phosphorus nuclei on Mn. On the basis of this coupling pattern and the magnitude of the Rh coupling, these carbonyls are assigned as semibridging. The assignment of two bridging and two terminal carbonyls is also supported by the IR data. In the ^1H NMR spectrum, two separate resonances are observed for the inequivalent vinyl protons of **9***a* and a singlet for the three methyl protons.

Surprisingly, if the reaction of **2** with allene is carried out at room temperature for several days **9***a* is obtained together with another species (**9***b*) in approximately equal proportions. This new species can be shown to be the isomer $[RhMn(CH_2CH=CH_2)(CO)_2(\mu\text{-}CO)_2(dppm)_2][SO_3CF_3]$ containing an η^1-allyl group. The $^{13}P\{^1H\}$ NMR resonances of **9***a* and **9***b* are quite similar, and although the $^{13}C\{^1H\}$ NMR spectrum of **9***b* has only two carbonyl resonances, corresponding to two equivalent semibridging and two equivalent terminal carbonyls, the chemical shifts and coupling constants are similar to those for **9***a*. However, the ^1H NMR spectra of the two isomers are quite distinct, showing four different resonances for the allyl group. The resonance at δ 2.73, corresponding to the two methylene protons adjacent to Rh, shows 8 Hz coupling to the Rh-bound phosphorus nuclei as well as 6 Hz coupling to H^b on the adjacent carbon. The slight broadening of this resonance obscures the expected 2 Hz coupling of these protons to Rh (see, for example, compound **10**). The three olefinic protons resonate at δ 5.30, 3.70, and 2.63, with the low-field signal appearing as a shoulder on the solvent peak (the poor solubility of **9***b* in $CHCl_3$ or THF precluded the use of these solvents). Protons H^b and H^d were shown to be mutually *trans*, based on the 17 Hz coupling between them, and this value can be compared with the 10 Hz coupling between H^b and H^c that is consistent with a *cis* arrangement. Other than the hydrocarbyl ligands, the only substantial difference between **7** and **9** is that, for the latter, two carbonyls are semibridging, instead of one being bridging and the other semibridging. Refluxing a mixture of **9***a* and **9***b* in THF results in the disappearance of **9***b* with a corresponding increase in the concentration of the thermodynamic product **9***a*.



9*a* **9***b*

The formation of both **9***a* and **9***b* from allene and the hydride-bridged compound **2** is presumed to proceed via an allene-hydride intermediate, with allene coordinated at Rh (although this intermediate was not observed). These results support the earlier proposals (47–50) of allene-hydride intermediates being involved in the isomerization of isopropenyl to η^3-allyl groups. In our system this conversion is reversed, with the isopropenyl species being thermodynamically favoured. The stability of the allyl group over the isopropenyl in the previous studies is presumably due to the η^3-binding mode of the former. We assume that this mode is not favoured in our system owing to steric repulsions that would result, involving the dppm phenyl groups above and below the equatorial plane of the metals. That being the case, we propose that when only the η^1-binding mode of an allyl is considered, the isopropenyl isomer is favoured, owing to a stronger metal–carbon bond involving the sp^2 carbon rather than the sp^3 carbon of the η^1-allyl group. In another report involving interconversion between an η^1-allyl and a vinyl group, the vinyl group was again favoured (51).

The prototype in this series, having an organic group (CH_3) σ-bound to Rh, can be prepared either by the addition of methyl triflate to **1**, yielding $[RhMn(CH_3)(CO)_2(\mu\text{-}CO)_2(dppm)_2][SO_3CF_3]$ (**10***a*), or by the addition of MeI to **1** to give the analogous iodide salt, $[RhMn(CH_3)(CO)_2(\mu\text{-}CO)_2(dppm)_2][I]$ (**10***b*). All spectroscopic data (Table 1) support a structure like those proposed for **7** and **9**, with the methyl group terminally bound to Rh, exactly as observed in the Rh/Re analogue, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

was characterized by an X-ray structure determination (52). The $^{31}P\{^1H\}$ NMR and $^{13}C\{^1H\}$ NMR spectra of **10** are very closely comparable to those of **9***b*, and the ^1H NMR spectrum of **10** shows the expected triplet of doublets for the methyl resonance, displaying 11 Hz coupling to the two Rh-bound phosphorus nuclei and 2 Hz coupling to Rh. This terminal binding of a methyl group to Rh has now been observed in a number of related mixed-metal binuclear systems (9, 52–54), and all display closely comparable spectroscopic parameters, adding further support for our formulation for the closely related isopropenyl (**9***a*) and η^1-allyl (**9***b*) products.

Reaction of **10***a* with CO results in a migratory insertion to give the acyl species $[RhMn(C(O)CH_3)(CO)_2(\mu\text{-}CO)_2(dppm)_2][SO_3CF_3]$ (**11**). The ^1H NMR signal for the methyl group appears as a singlet at δ 1.04 when ^{12}CO is used or as a doublet ($^2J_{CH}$ = 5 Hz) when ^{13}CO is used. In the $^{13}C\{^1H\}$ NMR the acyl carbon appears as a low-field doublet with 28 Hz coupling to Rh. Migratory insertion has resulted in a subtle change in the bridging carbonyls such that one shows stronger coupling to Rh (20 Hz) than the other (10 Hz), suggesting a strong and a weak semibridging interaction. Substitution of the methyl by the poorer donor acyl group means that there is less need for π back donation from Rh. However, it is not clear why the bridging interactions should be asymmetric rather than two identical but weaker semibridging interactions. There appears to be no compelling steric argument, as for the related vinyl species.

The alkyne-bridged tricarbonyl species **4***a* can also be protonated but, in this case, even at −80°C no metal hydride is observed. Instead an unstable species, $[RhMn(CO)_3(\mu\text{-}C(CO_2Me)=C(H)CO_2Me)(dppm)_2][X]$ (**8***a*), containing what is proposed to be a bridging vinyl moiety, is obtained. Unfortunately the presence of paramagnetic impurities, resulting from decomposition of **8***a*, has led to broad resonances and the signal due to the vinylic hydrogen was not observed in the ^1H NMR spectrum. Upon warming, compound **7***a* was obtained (as the tetrafluoroborate salt), together with several unidentified products, some of which are presumably the source of the extra carbonyl needed in the transformation of **8***a* to **7***a*. Whether **8***a* has the structure shown in Scheme 1, or the related structure in which the vinyl moiety is σ-bound to Rh and π-bound to Mn, could not be determined. The interaction of the vinyl π-bond with either Rh or Mn is required to give the metals a 16e or 18e configuration, respectively. An analogous vinyl binding mode was previously proposed in related dirhodium (1*k*, 8, 55) and dimanganese (56) complexes. Compound **8** readily transforms to **7** upon addition of CO.

Although protonation of the species **5***a* having the perpendicularly bound DMAD group could not be followed because of its very low abundance, the protonation of both isomers **4***b* and **5***b*, having parallel and perpendicular HFB groups, respectively, was possible since both are present in comparable amounts. Starting with **4***b*, the addition of $HBF_4\cdot Me_2O$ at −78°C does not result in a reaction until temperatures near 0°C are reached, at which point substantial amounts of **5***b* appear. At 0°C and higher, two hydride-bridged products **12** and **13** are obtained, corresponding to protonation of the Rh—Mn bonds in **4***b* and **5***b*, respectively, as shown in Scheme 2. Compounds **12** and **13** are isomers of $[RhMn(CO)_3(\mu\text{-}H)(\mu\text{-}HFB)(dppm)_2][X]$ having either a parallel (**12**) or perpendicular (**13**) alkyne orientation, as in the respective precursors. The more abundant isomer **13** is assumed to have a perpendicular alkyne orientation based on the similarity of its spectral parameters with those of **5***b*. In particular, **13** shows only one resonance for the CF_3 groups, whereas two resonances are observed in **12** owing to the chemical inequivalence of the two ends of the alkyne. The appropriate selective and broad-band decoupling experiments show that the hydrides in both **12** and **13** couple to Rh($^1J_{RhH}\simeq 15$Hz) and to all four phosphorus nuclei, confirming their bridging assignments. Although both isomers **12** and **13** (as BF_4^- salts) are obtained upon protonation with $HBF_4\cdot Me_2O$, only **13** [$CF_3CO_2^-$] is obtained if trifluoroacetic acid is used. It is not clear what the function of the non-innocent $CF_3CO_2^-$ anion is in this case.

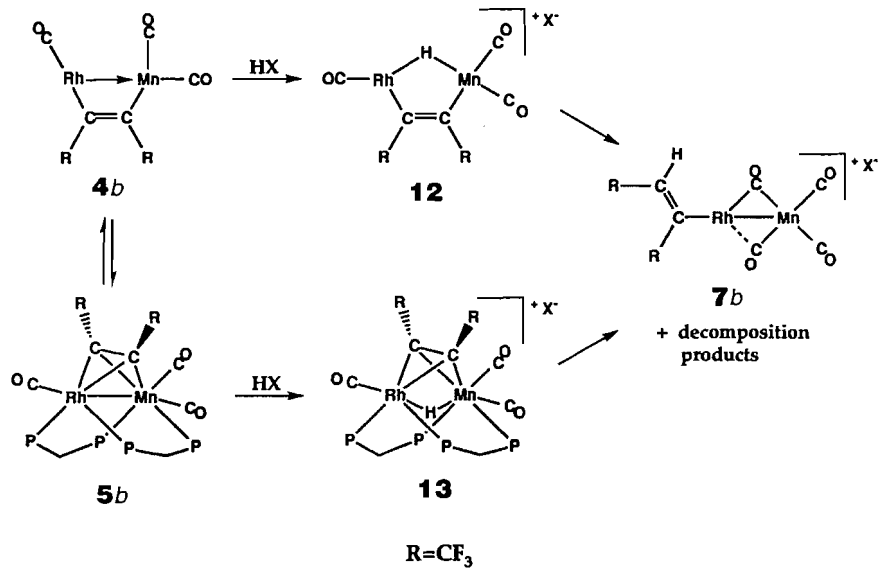
After several hours at ambient temperature both **12** and **13** transform to the vinyl complex **7***b*, together with unidentified species that are presumably the source of the additional carbonyl needed in the transformation of the tricarbonyl precursors to the tetracarbonyl product.

Summary and conclusions

The product resulting from the reaction of either of the activated alkynes, DMAD or HFB, with $[RhMn(CO)_4(dppm)_2]$ is hardly unusual, having the alkyne coordinated parallel to the metal–metal bond, as is frequently observed in dppm-bridged species (1*c*, 2–5, 57). However, the facile loss of CO that occurs from the coordinatively saturated Mn centre is unusual in that it demonstrates two interesting ways in which saturation can be maintained at this centre by virtue of the close proximity of Rh. In one isomer carbonyl loss is accompanied by formation of a dative Rh → Mn bond in which Rh utilizes its filled d_{z^2} orbital for donation to Mn, whereas in the second, rotation of the alkyne to a perpendicular orientation occurs with formation of a conventional metal–metal bond. In this transformation the 2-electron-donor alkyne becomes a 4-electron donor. This system is unique in demonstrating reversible interconversion of the two alkyne bonding modes, which occurs with unprecedented ease; we know of no other system in which both isomers are in equilibrium and are observed simultaneously.

Protonation of all alkyne-bridged products at ambient temperature yields a series of vinyl complexes while at low temperatures observation of metal-hydride intermediates is possible. In the alkyne-bridged complexes without a Rh—Mn bond, protonation appears to occur at Rh, followed by transfer to the alkyne. However, in the Rh—Mn bonded species protonation at the metal–metal bond occurs. Although in this latter case the hydride and alkyne groups are on opposite faces of the dimer, appearing not to be well placed for subsequent migratory insertion, movement of the hydride between the metals to the opposite face of the complex has been shown to be facile (8), so the observed structure appears to present no appreciable barrier to vinyl formation. These vinyl complexes also result from the reaction of the alkyne with the hydride-bridged complex $[RhMn(CO)_4(\mu\text{-}H)(dppm)_2][X]$. This hy-dride species also reacts with allene to give two isomers of $[RhMn(C_3H_5)(CO)_4(dppm)_2][X]$ having either a methyl vinyl (isopropenyl) or an η^1-allyl group σ-bound to Rh; the first results from transfer of the hydride ligand to a terminal carbon of allene while the second is a result of H-transfer to the central carbon. The vinyl species is

Scheme 2.



thermodynamically favoured, presumably because of the stronger Rh—C σ-bond involving an sp^2 carbon rather than an sp^3 carbon. This observation of both tautomeric forms resulting from the reaction of allene with a metal hydride is unusual and presents strong support for the involvement of an allene-hydride intermediate in the interconversion between allyl and vinyl complexes.

Electrocatalytic activity of a graphite electrode coated with hexadecachlorophthalocyanatoiron(II) toward sulfide oxidation, and its possible application in electroanalysis

Jiujun Zhang, A.B.P. Lever, and W.J. Pietro

Abstract: A graphite electrode coated with hexadecachlorophthalocyanatoiron(II), $Fe^{II}[Cl_{16}Pc(2-)]$, serves as an electrocatalyst for the oxidation of sulfide ion in basic solutions (pH range: 8–14). The surface electrochemical responses of this catalyst and corresponding electrocatalytic activity are discussed. The sulfide ion concentration dependences of the peak current in cyclic voltammograms are examined to show the possible application of this catalyst-coated electrode in amperometric sulfide sensors.

Key words: phthalocyanine, modified graphite electrode, sulfide oxidation, electroanalysis, electrocatalysis.

Résumé : On peut utiliser une électrode de graphite recouverte d'hexadécachlorophtalocyanatofer(II), $Fe^{II}[Cl_{16}Pc(2-)]$, comme électrocatalyseur pour l'oxydation de l'ion sulfure, en solutions basiques (pH allant de 8 à 14). On discute des réponses électrochimique de surface de ce catalyseur et de l'activité électrocatalytique correspondante. Dans le but de démontrer l'application possible de cette électrode recouverte de catalyseur comme senseur ampérométrique des sulfures, on a examiné les relations qui existent entre la concentration de l'ion sulfure et le courant de pic des voltampérogrammes cycliques.

Mots clés : phtalocyanine, électrode de graphite modifiée, oxydation du sulfure, électroanalyse, électrocatalyse.

Introduction

Perhalogenated metallophthalocyanines have been reported to be effective catalysts for the reduction of dioxygen (1, 2). Most recently, we discovered that one of the perhalogenated metallophthalocyanines, hexadecachlorophthalocyanatoiron(II) (abbreviated as $Fe^{II}[Cl_{16}Pc(2-)]$), when it is coated on a graphite electrode (labelled as $Fe^{II}[Cl_{16}Pc(2-)]/C$ in this paper), displays very high activity toward the oxidation of sulfide ion in basic solutions.

The electrocatalytic oxidation of sulfide ion on graphite electrodes modified by metallophthalocyanines such as CoPc and FePc (3), CoTmtppa (Co(II)-N,N′,N″,N‴-tetramethyltetra-3,4-pyridinoporphyrazine) (4),[2] CoTapc (Co(II)-tetraaminophthalocyanine) (5), and CuAc (Cu(II)-alizarin complexone) (6) have been studied extensively. However, of the metallophthalocyanines that we have tested (almost 20 metallophthalocyanines containing Co(II), Fe(II), Mn(II), Ru(II), Cr(II), Cu(II), or Rh(II), and with various substituents), $Fe^{II}[Cl_{16}Pc(2-)]$ proves to form the most stable surface species with very high catalytic activity for sulfide oxidation. As a continuing examination of surface electrocatalysis and its application in electrochemical sensors (1, 4–7), this paper reports the electrocatalytic behaviour of $Fe^{II}[Cl_{16}Pc(2-)]$ toward the oxidation of sulfide ion.

Generally, electrodes used to oxidize sulfide ion are fouled (poisoned) by the elemental sulfur that is then deposited thereon. While deposition also occurs on this electrode, the elemental sulfur can be stripped off by reduction back to sulfide ion and thereby regenerates an electrode that behaves like the pristine electrode.

Received November 30, 1994.

This paper is dedicated to Professor William A.G. Graham on the occasion of his 65th birthday.

Experimental section

Chemicals and solutions

Hexadecachlorophthalocyanatoiron(II) was synthesized, purified, and characterized according to the methods described in ref. 1. Sodium sulfide ($Na_2S{\cdot}9H_2O$, BDH Chemicals) was reagent-grade and used without further purification, as were other reagent grade chemicals. The pH (8–14) of the solution was controlled with 0.01 M $NaH_2PO_4/Na_2HPO_4/NaOH$ buffers, which were added to 0.1 M $NaClO_4$ supporting electro-

For personal use only.

lyte. Solutions were deaerated by bubbling with pure argon gas (99.99%). Test solutions of sodium sulfide were prepared from 0.1 M Na_2S stock solution prepared before each experiment, by addition to a previously deaerated supporting electrolyte solution to a desired concentration. Water was purified by double distillation with $KMNO_4$, followed by passage through the Barnstead organic removal cartridge and two Barnstead mixed-resin Ultrapure cartridges.

Electrode preparation

Basal pyrolytic graphite (BPG) electrodes (Union Carbide) were sealed to stainless steel shafts with heat shrinkable polyolefin tubing. The electrodes, mounted with basal planes of the graphite exposed, were polished using 0.5 μm alumina powders, sonicated for 5 min in water, and rinsed with acetone and water before each experiment. The electrode area, 0.17 cm^2, was calibrated using a solution of 1 mM $[Fe(CN)_6]^{3-}$.

The electrode surface was modified by soaking a clean polished electrode in a DMF solution containing 1 mM $Fe^{II}[Cl_{16}Pc(2-)]$ for 15 min; the electrode was then washed and transferred to the test solution to record cyclic voltammetry.

Electrochemical measurements

Cyclic voltammetry was performed using the Pine Instruments RDE3 potentiostat and an X–Y recorder. A conventional three-compartment electrochemical cell with an SCE reference and a Pt counter electrode was used for the electrochemical studies.

Results and discussion

A. Surface electrochemical responses of a graphite electrode coated with $Fe^{II}[Cl_{16}Pc(2-)]$

Cyclic voltammograms (Fig. 1) of a graphite electrode coated with 1.3×10^{-9} mol cm^{-2} of $Fe^{II}[Cl_{16}Pc(2-)]$, recorded in a 0.1 M NaOH + 0.1 M $NaClO_4$ solution, show three redox couples, labelled (I′/I), (II′/II), and (III′/III) to more negative potentials, respectively. Because there is no $Fe^{II}[Cl_{16}Pc(2-)]$ in the test solution, all three waves are attributed to surface responses, which was confirmed by the linear relationships between the peak current and potential scan rate shown by the insert in Fig. 1. These data using basal-plane pyrolytic graphite are of somewhat better quality than those previously described using highly oriented pyrolytic graphite (1), and hence merit further comment. Waves (I′/I), (II′/II) and (III′/III) are the redox processes of couples $Fe^{III}[Cl_{16}Pc(2-)]^+$ /$Fe^{II}[Cl_{16}Pc(2-)]$, $Fe^{II}[Cl_{16}Pc(2-)]$/$Fe^{I}[Cl_{16}Pc(2-)]^-$, and $Fe^{I}[Cl_{16}Pc(2-)]^-$/$Fe^{I}[Cl_{16}Pc(3-)]^{2-}$, respectively, as confirmed in a previous study (1).

The waves for $Fe^{III}[Cl_{16}Pc(2-)]^+$/$Fe^{II}[Cl_{16}Pc(2-)]$ and $Fe^{II}[Cl_{16}Pc(2-)]$/$Fe^{I}[Cl_{16}Pc(2-)]^-$, which are the responses of the metal centre, exhibit much smaller peak currents and area than the wave for the $Fe^{I}[Cl_{16}Pc(2-)]^-$ /$Fe^{I}[Cl_{16}Pc(3-)]^{2-}$ couple, which is a ligand reduction process. This phenomenon was observed in previous studies for a series of metallophthalocyanines (1, 2, 4, 8–10 and footnote 2).

For a one-electron Nernstian response from the reactant confined to the electrode surface, the peak-to-peak potential separation should be zero, and the half-bandwidth should be about 90.6 mV (11). The response of wave (I′/I) (in Fig. 1) with a zero peak-to-peak potential separation and a half-bandwidth of 91 mV is consistent with Nernstian behaviour. However, the responses of wave (II′/II), with a 30 mV peak-to-peak separation and half-bandwidth of 140 mV, and wave (III′/III), with a peak-to-peak separation of 190 mV (scan rate: 100 mV s^{-1}) and half-bandwidths of 55 mV (cathodic) and 120 mV (anodic), deviate from Nernstian behaviour.

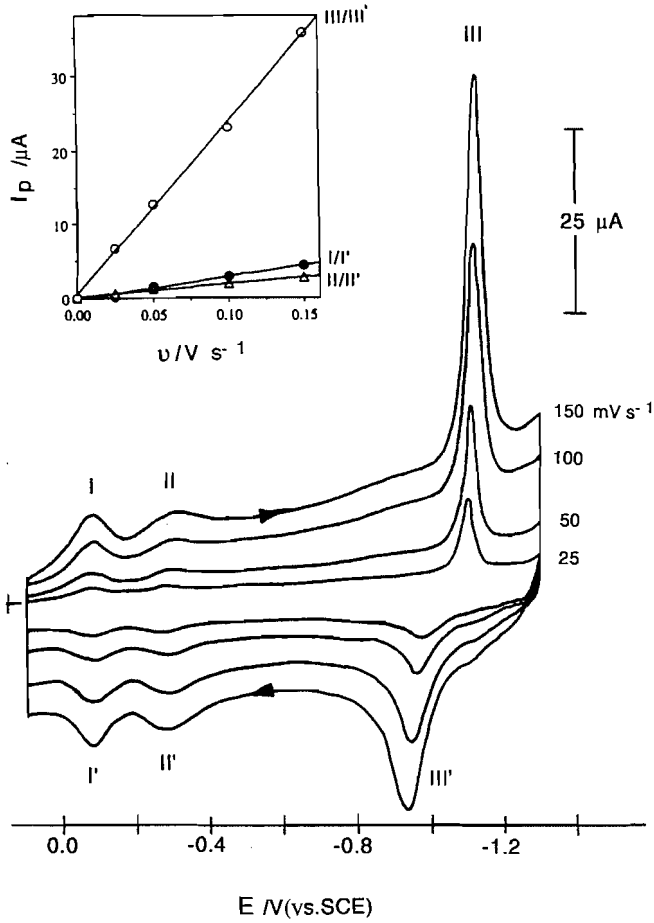

Fig. 1. Cyclic voltammetry of $Fe^{II}[Cl_{16}Pc(2-)]$ (1.3×10^{-9} mol cm^{-2}) coated on a BPG electrode. The freshly polished electrode was first soaked in 1×10^{-3} M $Fe^{II}[Cl_{16}Pc(2-)]$ DMF solution for 15 min, washed, and transferred to pure supporting electrolyte (0.1 M NaOH + 0.1 M $NaClO_4$, pH 13) to record the voltammograms. Equlibrium scan. Potential scan rates as marked in the figure. Insert: Potential scan rate dependence of the average peak current of waves (I′/I), (II′/II), and (III′/III).

By measuring the charge under waves (I′/I) we arrive at a surface concentration of approximately 1.5×10^{-10} mol cm^{-2} (assuming a one-electron process), which corresponds roughly to a monolayer. This suggests that even though the coating is much thicker than a monolayer, only the $Fe^{II}[Cl_{16}Pc(2-)]$ in direct contact with the surface is electrochemically active insofar as the iron centres are concerned.

The charge under wave III is some 10 times greater, suggesting that for this ligand process the entire layer of $Fe^{II}[Cl_{16}Pc(2-)]$ is involved. This is likely interpreted in terms of electronic interactions between adjacent Pc units in the stacked aggregated layer on the electrode surface (1, 2), resulting in rapid electron exchange and hence allowing the entire layer to be oxidized or reduced at the ligand site. Evidently this is not so facile for the metal-centred redox processes. The

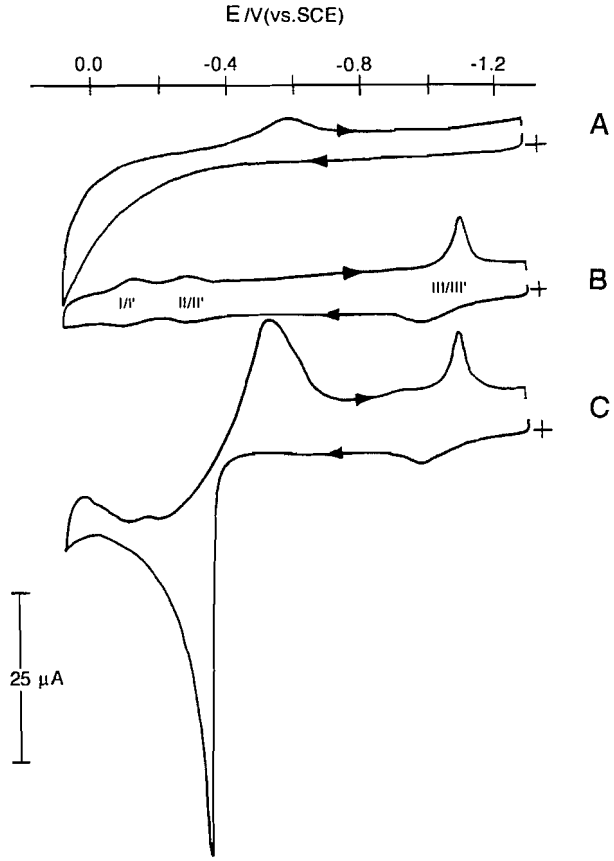
Fig. 2. Cyclic voltammograms for the oxidation of sulfide ion on a BPG electrode: (*A*) a bare electrode in a solution containing 1×10^{-3} M Na_2S; (*B*) a BPG electrode coated by 1.3×10^{-9} mol cm^{-2} of $Fe^{II}[Cl_{16}Pc(2-)]$ in pure supporting electrolyte; and (*C*) a BPG electrode coated by 1.4×10^{-9} mol cm^{-2} of $Fe^{II}[Cl_{16}Pc(2)]$ in the presence of 1×10^{-3} M Na_2S. The supporting electrolyte was 0.1 M $NaClO_4$ + 0.1 M NaOH. First scan. Potential scan rate: 20 mV s^{-1}.

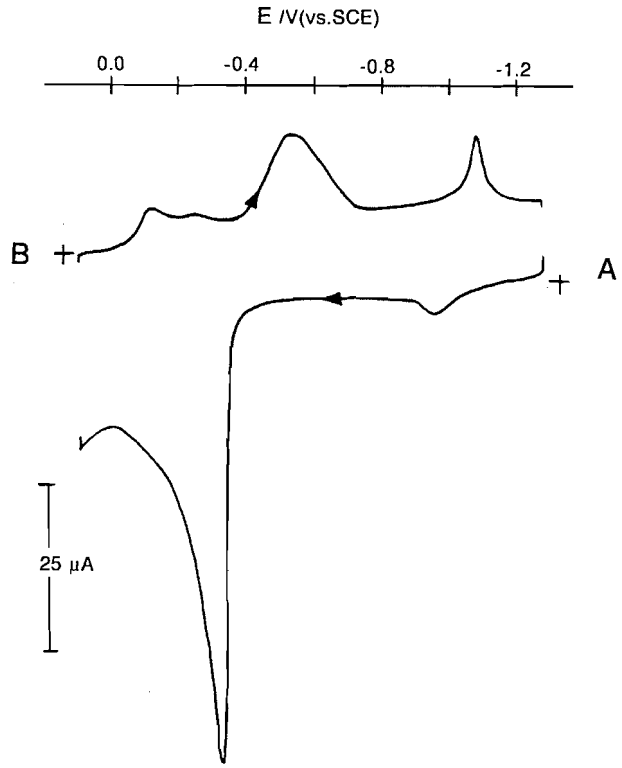


pH dependencies of these waves (average of the anodic and cathodic components) are similar to those previously described (1), i.e., waves (I′/I) and (III′/III) show dependencies of −87 and −68 mV/pH respectively, while waves (II′/II) are essentially pH independent, in agreement with previous literature expectation (10). However, we note that wave III has a potential that becomes pH independent (at −1.12 V) beyond pH 12.0; its oxidation component, wave III′, apparently remains pH dependent in this regime. For further discussion of the pH dependences, see refs. 1 and 2.

B. Electrocatalytic activity of $Fe^{II}[Cl_{16}Pc(2-)]$/C toward the oxidation of sulfide ion

A $Fe^{II}[Cl_{16}Pc(2-)]$ coated graphite electrode displays very strong catalytic activity toward the oxidation of sulfide ion in a basic solution (Fig. 2). On a bare electrode (Fig. 2*A*), in the presence of sulfide ion, the oxidation current that starts at about −0.2 V spreads over a wide potential range. This process corresponds to oxidation from S^{2-} to S^0, which then deposits on the electrode surface (see ref. 6 for more detail). The reduction of the deposited S^0 occurs at about −0.57 V (see reverse wave in Fig. 2*A*). However, when $Fe^{II}[Cl_{16}Pc(2-)]$ is coated on the same electrode, a significant catalytic current for

Fig. 3. Linear sweep voltammetry of a BPG electrode on which 1.2×10^{-9} mol cm^{-2} of $Fe^{II}[Cl_{16}Pc(2-)]$ was coated. (*A*) In 1.2×10^{-3} M Na_2S, potential scanning from −1.3 to 0.1 V; (*B*) the electrode in (*A*) was transferred to a pure supporting electrolyte solution, potential scanning from 0.1 to −1.3 V. The supporting electrolyte was 0.1 M $NaClO_4$ + 0.1 M NaOH. Potential scan rate: 20 mV s^{-1}.



sulfide oxidation starting from −0.4 V can be observed (Fig. 2*C*). The steep rise in oxidation current, maximum at −0.33 V (20 mV s^{-1}), reflects a high catalytic rate. The catalytic oxidation commences near the potential of wave (II′/II) (Fig. 2*B*), which strongly suggests that $Fe^{II}[Cl_{16}Pc(2-)]$ (i.e., in oxidation state (II)) is the active catalyst (see below). A reverse wave near −0.55 V (Fig. 2*C*) indicates that the product of sulfide oxidation can be reduced when the potential is scanned back to the negative range. Since the reduction current rapidly descends to zero current, following (more negative than) the peak, this reverse wave is a surface process, proven by the experiment shown in Fig. 3.

In Fig. 3, linear sweep voltammetry was recorded on a $Fe^{II}[Cl_{16}Pc(2-)]$ coated electrode in a 1.2 mM Na_2S solution from a potential ranging from −1.3 to 0.1 V (Fig. 3*A*). The electrode was then taken out of the sulfide-containing solution, washed, and transferred to a solution containing only supporting electrolyte to record the current–potential curve from 0.1 to −1.3 V (Fig. 3*B*). In curve 3*B*, a surface stripping wave near −0.53 V can be observed. In our previous study of a Cu^{II}–Alizarin complexone coated electrode, a similar stripping wave is assigned to the reduction of electrodeposited S^0 to S^{2-} by a two-electron transfer process (6). The three other peaks near −0.1, −0.27, and −1.1 V in curve 3*B* are the waves I, II, and III, respectively.

To estimate roughly how many electrons are involved in the catalytic oxidation of sulfide ion in Fig. 2*C*, a set of cyclic vol-

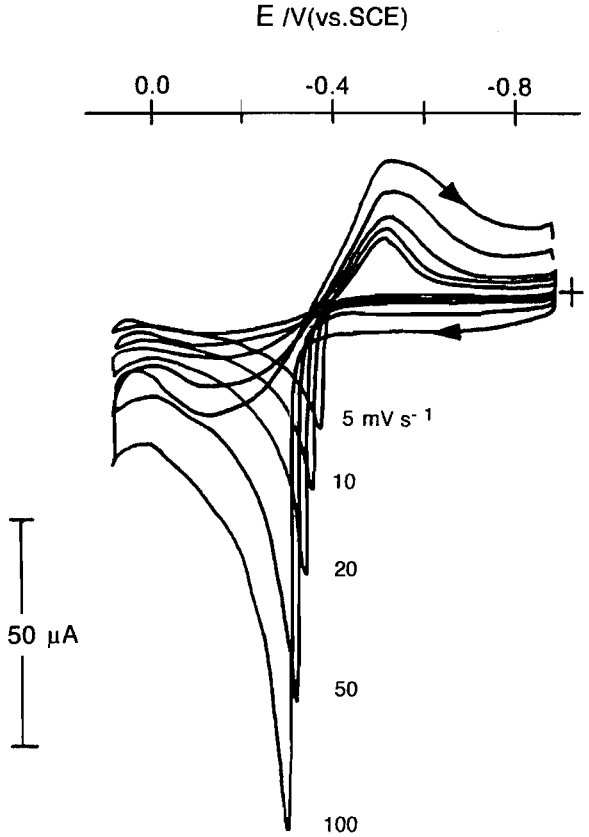
Fig. 4. Cyclic voltammograms of a BPG electrode coated by 1.2×10^{-9} mol cm^{-2} of $Fe^{II}[Cl_{16}Pc(2-)]$ in 1×10^{-3} M Na_2S + 0.1 M $NaClO_4$ + 0.1 M NaOH solution. Potential scan rates as marked in the figure.



tammograms was obtained at various potential scan rates (Fig. 4). Assuming that the catalytic oxidation is a totally diffusion-controlled process, a combination between the relationships for E_p vs. log v, and I_p vs. $v^{1/2}$ (where E_p is the peak potential of oxidation current, I_p is the peak current, and v is the potential scan rate) allows one to estimate the number of electrons involved in the corresponding process (7). Figure 5 shows these experimental relationships. The linear relationships indicate that the model described by eqs. [1] and [2] fits the electrocatalytic process for sulfide oxidation.

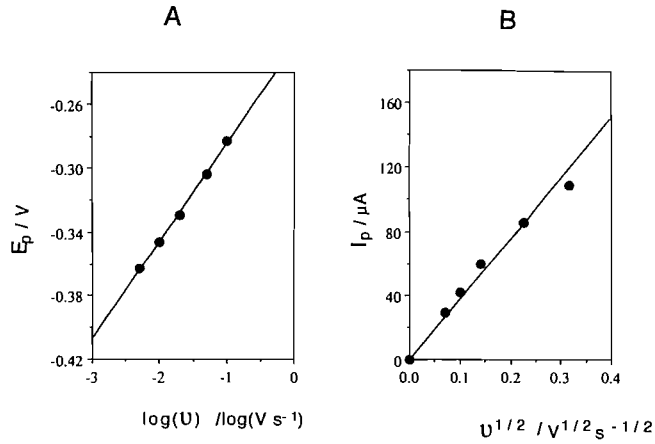
$$[1] \quad E_p = K + (0.03/\alpha n_\alpha) \log v$$

$$[2] \quad I_p = 2.99 \times 10^5 n (\alpha n_\alpha)^{1/2} A C_0 D_0^{1/2} v^{1/2}$$

From the slope of the line in Fig. 5*A*, a value of $\alpha n_\alpha = 0.49$ can be calculated. The slope from Fig. 5*B* can be combined with this value of αn_α, and the assumed value of D_0 (1.7×10^{-5} cm^2 s^{-1}, which is the diffusion coefficient of sulfide ion in the form of HS^-) to obtain the value of the electron number, $n = 2.2$. As expected, we observed a two-electron process of the electrocatalytic oxidation of sulfide ion.

The area under the oxidation wave (Fig. 3*A*) corresponds to 3.3×10^{-9} moles of sulfide ion. The stripping wave near -0.53 V in Fig. 3*B*, which is a reduction of S^0 back to S^{2-} by a two-electron transfer, corresponds to 5.8×10^{-10} moles, which is only 17.5% of the total quantity of sulfide ion involved in the

Fig. 5. (*A*) Peak potential in cyclic voltammograms (Fig. 4) as a function of logarithm of potential scan rate; (*B*) magnitude of the peak current in cyclic voltammograms (Fig. 4) as a function of square root of potential scan rate.



catalytic oxidation. The remaining 82.5% of oxidized sulfide ion is probably in the form of soluble S_x^{2-} in the basic solution, and is not electrochemically detected. The solubility of elemental sulfur in sulfide ion solution will increase with increasing concentration of sulfide; thus at very low concentrations of sulfide ion, a greater proportion of the elemental sulfur remains deposited on the electrode, as indicated by a larger ratio of the stripping current to the oxidation current (data not shown). We must also suppose that, as the potential is scanned through the sulfide oxidation wave, some elemental sulfur is being deposited on the electrode and may partially inhibit the depolarization of the incoming sulfide ion. Thus the current maximum at -0.33 V (20 mV s^{-1}) is probably slightly underestimated.

C. A suggested mechanism for electrocatalytic oxidation of sulfide ion on a $Fe^{II}[Cl_{16}Pc(2-)]$/ C electrode

The electrochemical oxidation of sulfide ion to elemental sulfur has been studied very extensively in the literature (6, 12–22); here we will only deal with the involvement of the surface coating of $Fe^{II}[Cl_{16}Pc(2-)]$ and other aspects will not be explored.

As indicated in Figs. 2*B* and 2*C*, in which the catalytic oxidation commences near the potential of wave (II′/II), the $Fe^{II}[Cl_{16}Pc(2-)]$ species is believed to be the active catalyst that is confined to the electrode surface to undergo the inner-sphere mechanism for sulfide oxidation.

In this inner-sphere mechanism, the first step is formation of a sulfide adduct:

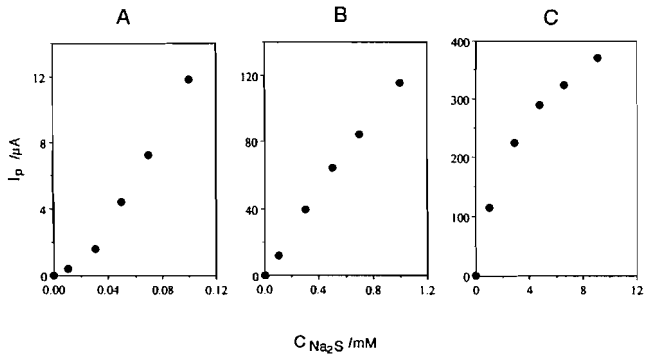
$$[3] \quad Fe^{II}[Cl_{16}Pc(2-)] + HS^- \longleftrightarrow HS^-\text{-}Fe^{II}[Cl_{16}Pc(2-)]$$

followed by electron transfer from bound HS^- to electrode through the catalyst to form, under oxidative polarization by the electrode, the final product:

$$[4] \quad HS^-\text{-}Fe^{II}[Cl_{16}Pc(2-)] + OH^- \longrightarrow Fe^{II}[Cl_{16}Pc(2-)] + S^0 \text{ (and (or) } S_x^{2-}) + H_2O + 2e^-$$

Since the product is the regenerated Fe^{II} species, the process

Fig. 6. Sulfide concentration dependences of peak current in cyclic voltammograms recorded on a BPG electrode on which 9.1×10^{-10} mol cm^{-2} of $Fe^{II}[Cl_{16}Pc(2-)]$ was coated, in three concentration ranges: (*A*) $0–10^{-4}$ M; (*B*) $0–10^{-3}$ M; and (*C*) $0–10^{-2}$ M. The supporting electrolyte was 0.1 M NaOH + 0.1 M $NaClO_4$, pH 13. Potential scan rate: 100 mV s^{-1}.



is electrocatalytic. A more detailed assessment of the mechanism would require much more detailed experimental data, which have not yet been obtained.

D. Sulfide concentration dependence of peak current in cyclic voltammograms, and its possible application in sulfide analysis

The dependence of peak current on sulfide ion concentration ($10^{-5}–10^{-2}$ M) in cyclic voltammetric studies recorded at a $Fe^{II}[Cl_{16}Pc(2-)]$/C electrode in basic solution is shown in Fig. 6. Cyclic voltammograms in a solution containing a low sulfide concentration, for example, down to 1×10^{-5} M (not shown here) (0.32 ppm), still show measurable catalytic currents near −0.4 V, indicating that a very low concentration of sulfide could be determined by measuring the peak current. Although the relationship between sulfide ion concentration and peak current, shown in Fig. 6, is not perfectly linear, probably due to the poison effects discussed above, it is reproducible and suitable, after calibration of an electrode, for the purpose of analysis.

The sensitivity for determining sulfide ion using cyclic voltammetry is limited to 1×10^{-5} M (0.32 ppm). The measurable concentration range in aqueous solutions is 1×10^{-5} to 1×10^{-2} M.

D.1 Surface concentration of catalyst

The effect of surface concentration on the electrocatalytic peak current in the cyclic voltammograms was examined briefly in a solution (pH 13) containing 1×10^{-3} M sulfide ion. Below a surface concentration of 0.8×10^{-9} mol cm^{-2} (ca. 5 layers), the peak current is almost proportional to the surface concentration of the catalyst. However, with thicker layers, when the surface concentration exceeds 1.0×10^{-9} mol cm^{-2}, saturation in the peak current can be observed (data not shown). This observation may conflict with our earlier analysis that only the monolayer in contact with the electrode is active insofar as couple (I′/I) is concerned. Possibly the sulfide ions can mediate the redox process occurring at subsequent layers.

D.2 Poisoning of the surface catalyst and recovery therefrom

The S^0 layer deposited upon oxidation (reaction [4]) actually poisons the catalytic activity of the $Fe^{II}[Cl_{16}Pc(2-)]$ surface if the S^0 is not removed. Experiments with a rotating BPG disk electrode coated with $Fe^{II}[Cl_{16}Pc(2-)]$ in a sulfide-containing solution gave very ill-featured current-potential curves. A peaklike diffusion current rather than a plateau was observed, indicating deactivation of the catalyst. However, the catalytic activity of $Fe^{II}[Cl_{16}Pc(2-)]$/C can be recovered if the deposited sulfur layer is stripped at −0.5 V, after which the full catalytic current is retained both in the cyclic voltammogram and current–potential curves using a rotating disk electrode.

Because the coating of sulfur poisons the rotating disk electrode, a more quantative analysis of the kinetics of this electrocatalytic oxidation of sulfide ion was not pursued.

D.3 Long-term stability

The continued cycling of an electrode in a sulfur-containing solution leads to voltammograms that are superimposable over many hours. Coated electrodes that are removed from solution, dried, and stored for several days can then be returned to the same sulfur-containing solution to regenerate an almost identical voltammogram. Longer term studies of stored electrodes are in progress.

D.4 Interference tests

In interference tests, common species such as F^-, Cl^-, Br^-, $[CO_3]^{2-}/[HCO_3]^-$, $[SO_4]^{2-}$, $[SO_3]^{2-}$, $[NO_3]^-$, $[NO_2]^-$, NH_3, H_2O_2, and O_2 show no effect on the catalytic current for sulfide oxidation in pH 13 solution. Common metal ions, which are precipitated in such a basic solution, show no interference with sulfide measurements. However, species such as I^-, SCN^-, and CN^- interfere with the measurements due to strong coordination to the Fe(II) centre in the catalyst blocking the active centre for adduct formation.

Conclusion

A catalyst that is electrocatalytically active toward the oxidation of sulfide ion, $Fe^{II}[Cl_{16}Pc(2-)]$, can be easily coated onto a graphite electrode surface by dipping a freshly polished electrode into a DMF solution of this catalyst.

The active species, $Fe^{II}[Cl_{16}Pc(2-)]$, catalyzes the sulfide ion oxidation in a basic solution through a two-electron transfer process from S^{2-} to S^0, which is then partially deposited on the electrode surface, deactivating the catalyst. However, the active catalyst $Fe^{II}[Cl_{16}Pc(2-)]$/C can easily be recovered, quantitatively, by stripping off the S^0 deposition layer at −0.5 V.

The high stability of $Fe^{II}[Cl_{16}Pc(2-)]$/C and the high reproducibility of catalytic oxidation current in cyclic voltammograms make it feasible to employ this modified electrode for sulfide electroanalysis in basic solutions.

Extensions of the applicability of the MMX molecular modelling system to determination of barriers to rotation of π-bonded ligands

Joel Polowin, Robert Poe, and Michael C. Baird

Abstract: The commercially available molecular mechanics package PCMODEL, which has been shown to be very useful for determining conformational energy profiles for rotation of σ-bonded ligands, cannot be utilized to determine barriers to rotation of π-bonded ligands because of limitations in the way the π-bonding interactions are defined. This paper describes a partially successful modification of the dihedral driver of PCMODEL that makes possible reasonable calculations of the conformational energy profiles for rotation of the π-bonded arene ligands in the compounds $(\eta^6\text{-arene})Cr(CO)_2(PPh_3)$ (arene = C_6H_6, C_6Me_6) and of the π-bonded ethylene ligands in $[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$ and $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}CH_2{=}CH_2)]^+$. The steric barriers to ethylene rotation in the latter two complexes were found to be small relative to the electronic barriers to ligand rotation.

Key words : molecular mechanics, olefin rotation, conformational energy profile.

Résumé : Le programme de mécanique moléculaire PCMODEL disponible commercialement est très utile pour déterminer les profiles d'énergie conformationnelle des rotations autour des coordinats avec des liaisons σ; toutefois, à cause de ses limitations dans la façon dont les interactions dans les liaisons π y sont définies, on ne peut l'utiliser pour déterminer les barrières à la rotation des coordinats avec des liaisons π. Ce travail décrit un modification conducteur dièdre de PCMODEL qui permet, avec des succès partiels, de faire des calculs raisonnables des profiles d'énergie conformationnelle pour la rotation des coordinats arènes avec des liaisons π dans les composés $(\eta^6\text{-arène})Cr(CO)_2(PPh_3)$ (arène = C_6H_6 et C_6Me_6) et les coordinats éthylène avec des liaisons π dans $[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$ et $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}CH_2{=}CH_2)]^+$. On a trouvé que les barrières stériques à la rotation de l'éthylène dans les deux derniers complexes est faible par rapport aux barrières électroniques à la rotation du coordinat.

Mots clés : mécanismes moléculaires, rotation d'oléfine, profile d'énergie conformationnelle.

Introduction

Bill Graham joined the Department of Chemistry at the University of Alberta in 1962, and very quickly began making significant contributions to the rapidly developing field of organotransition metal chemistry.[2] One of the earlier contributions by the Graham group, in 1967, involved recognition of possibly the first example of conformational isomerism in an organometallic compound. Compounds of the type $\eta^5\text{-}C_5H_5Fe(CO)_2X$ normally exhibit two bands of comparable intensity in the carbonyl stretching region of the IR, the symmetric and the asymmetric carbonyl stretching modes. In contrast, the solution IR spectra of the compound $\eta^5\text{-}C_5H_5Fe(CO)_2SiMeCl_2$ exhibited doubling of the carbonyl stretching bands, an observation interpreted in terms of population of two rotamers, **A** and **B** (1*a*).

As only a single cyclopentadienyl resonance was observed in the ^1H NMR spectrum, it was concluded that interconversion between **A** and **B** via rotation about the Fe—Si bond is rapid on the NMR time scale.

Since 1967, numerous examples of rotational isomerism in organometallic compounds have been deduced on the basis of IR spectroscopy (1*b–f*), and information concerning the conformational energy profiles has in many cases become avail-

[2] Bill Graham made a very significant impact on the development of organometallic chemistry in Canada in particular. During the early 1960s, inorganic chemical research in Canadian universities was carried out almost completely by "imports" from the United Kingdom and, as the first native-born Canadian organometallic chemist to gain an international reputation for his research, Bill served as a much appreciated role model for the many younger Canadians who were beginning their careers at that time.

A B

able through variable temperature (VT) NMR spectroscopy (1*e*, 2) and, more recently, via molecular mechanics (MM) calculations (1*e*, 2). We (1*e*, 2*d*), utilizing MMX,[3] and others (2*a*–*c*) have demonstrated that the latter approach has considerable merit. Calculated conformational energy profiles for ligand rotation, for instance, in a variety of flexible organometallic compounds are in very good agreement with relevant experimentally derived information.

Our use of MMX has been limited, however, to determination of barriers to rotation of σ-bonded ligands, which are satisfactorily treated using a normal MM2-based force field (4) (see below). In contrast, while π-ligands are coordinated to metal atoms via otherwise "normal" bonds, MMX does not define force constants for either dihedral angles or bond angles associated with coordination. The dihedral-driver function of PCMODEL requires that the dihedral angle being driven be in the list of dihedral angles used by the program's minimization routines. One of the consequences of this is that one part of a structure cannot be rotated with respect to the rest of the structure unless that part is attached to the main structure with a normal bond. This connection is necessary to create the dihedral angle for the list, and thus calculations of barriers to rotation of π-bonded ligands have heretofore not been possible.

A bonding connection between two atoms is described inside PCMODEL with an integer value that specifies the bond order, i.e., 1, 2, or 3 for single, double, or triple bonding, respectively. Coordination of a π atom to a metal is handled by PCMODEL in much the same way as is a regular bond, the information being stored in the same data array, and the integer 9 being used to describe the bond type. When PCMODEL creates its lists of bond angles and torsional angles for a given molecule, it checks for bonds of type 9 and atoms of type-80 (transition-metal atoms). Bond angles with type 80 atoms at their centres and torsional angles involving bonds of type 9 are excluded from the lists.[4] It is therefore impossible to utilize the dihedral driver to rotate a π-coordinated group with respect to the rest of the structure: none of the dihedral angles between the two parts of the structure are included in the list, since the connections between the parts are made only with type-9 "bonds." This paper describes an algorithm that allows conformational energy profiles to be computed for rotation of simple π-bonded ligands.

Computational methodology

PCMODEL was modified to allow a π-coordinated group to be rotated by defining a new atom type, a dummy atom of atom type number 79. This number is close to the transition-metal type 80, since that type also is treated differently than the other types in many relevant parts of the program; making the two special cases numerically close was found to be advantageous. Similarly, a new bonding type was defined, type 8, for the connections between a dummy atom and its attachments. Again, the numerical similarity between this and the other special case, type 9, expedited modifications.

Bonding type 8 is used for all connections to dummy atoms and only for that purpose. Except when a dummy atom is attached to fewer than two atoms, its location is defined as the centroid of its attachments, i.e., at the arithmetic mean of their (*x*, *y*, *z*) coordinates. A dummy atom is never moved directly by the program, but any time any of its attachments are moved, the position of the dummy is recalculated.

Atom type 79 was defined as having a covalent radius of 0 and a hardness parameter of 0, and the program was otherwise modified so that all bonded and nonbonded interactions between a dummy atom and other atoms are ignored. The routine that makes the lists of bond angles was changed to ignore any angle that included a dummy atom, thus avoiding the usual requirement of PCMODEL that parameters be defined for all of these interactions. The dummy atoms are not in the standard parameter set, and it is desirable not to require a PCMODEL user to use an external parameter file any time a dummy atom is to be used.

The routine that makes the list of torsional angles was changed so that a bond of type 8 would, like a coordination "bond" of type 9, not count as part of a three- or four-membered ring; these small rings are treated specially in the MMX force field. This routine was otherwise not modified, so that regular torsional angles with dummy atoms *would* be included in the list.

When PCMODEL finds a torsional angle for which it does not have appropriate parameters, it uses a default torsional force constant of 0. The routine that checks atom types to try to use generalized parameters, when specific parameters cannot be found, was modified to ensure that any torsional angle that includes a dummy atom would be identified as matching none of the general parameter sets. All torsional angles that include dummy atoms therefore make no contribution to the potential energy of the system, except if one of those angles is used by the dihedral driver. The dihedral-driver function specifies different (and very large) torsional force constants for the specific angle being driven, replacing the usual values.

Thus the dihedral driver now works normally on torsional angles that include dummy atoms, although all other energy functions involving bonding ignore the dummy atoms. Other energy functions, such as charge interactions, were also changed to ignore the dummy atoms, the single exception being the distance-fixing function, which allows the creation of a new bonding-type interaction with user-specified k_s (force constant) and l_0 (bond length) parameters between any pair of atoms regardless of whether or not they are actually con-

[3] Available as PCMODEL from Serena Software, Bloomington, Ind. See ref. 1*e*, 2*d*, and 3. MMX is an extension of the well-known MM2 molecular modelling program (4).

[4] It is possible to specify parameters for a bond angle about a metal atom in an external parameter file, just as for any other kind of bond angle, but this has no effect since the angle itself is ignored by the software. The angle in the model will still be controlled only by steric effects.

nected; this is now allowed to work with dummy atoms. It was felt that this could be very useful since, for example, a dummy atom could be set as the centroid of an arene ring and the distance between that centroid and a coordinated metal could be fixed. This would allow the user some control over the distance between the ring and the metal atom without constraining their relative positions and orientations as much as would fixing distances between the metal atom and several of the ring atoms. For space-filling pictures, dummy atoms are drawn as if they have covalent radii of 0.2 Å ; thus they are visible in figures as small spheres amidst the real atoms.

In summary, the properties of a dummy atom as they were defined for this work are as follows. The only potential energy interactions that a dummy atom can have with other atoms are if the user specifies a fixed distance between the dummy and another atom, or if the dummy is one of the defining atoms of a torsional angle that is being operated on by the dihedral driver. A dummy atom has a radius of 0, but is drawn as a small sphere in space-filling pictures. Its location is fixed if it is attached to one atom or not attached at all, and otherwise is defined as the centroid of its attachments.

A limitation of this approach arises from the fact that the algorithm of the energy minimizer assumes that each atom can be moved independently. For each atom in the structure, it determines the gradient of the potential as the sum of the contributions from all of the interactions in which that atom is involved. It then moves the atom a short distance in the direction that it predicts will most rapidly decrease the potential energy of the system. However, the dummy atoms violate the assumption of independent motion because they move whenever one of their attachments moves. If the dummy atom is involved in a fixed-distance or dihedral-driver interaction, its motion changes the potential energy of the system in a way that is not predicted by the usual minimizer. It was expected that this would tend to result in slow minimizations, since the atoms would be moved in directions that lead less directly to the minimum energy configuration. However, tests of the modified program, forcing the rotation of coordinated benzene and ethylene groups in several complexes, indicated that the minimization process was at worst only slightly less efficient with dummy atoms in a dihedral-driver calculation than otherwise.

Results and discussion

We utilized the dihedral driver of PCMODEL to compute the conformational energy profiles for rotation of the arene ligands in the arene complexes (η^6-arene)$Cr(CO)_2(PPh_3)$ (arene = C_6H_6, C_6Me_6), and for ethylene rotation in the olefin complexes $[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$ and $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}CH_2{=}CH_2)]^+$.

(η^6-Arene)$Cr(CO)_2(PPh_3)$

As noted previously (*2d*), Hunter, Schlögl, and co-workers (*2e,f*) observed no decoalescence of the resonances of the coordinated arenes in variable temperature ^{13}C NMR spectra of the compounds (η^6-C_5H_5)$Cr(CO)_2(PPh_3)$ (**1**) and (η^6-C_6Me_6)$Cr(CO)_2(PPh_3)$ (**2**). Minimum energy structures from previous work on these compounds (*2d*), with PCMODEL's aromatic-type carbon atoms and Cr—L distances fixed to the crystal values of (η^6-C_6Et_6)$Cr(CO)_2(PPh_3)$, were modified for both molecules by attaching dummy atoms to each of the arene atoms and the Cr. This placed the dummy atoms of both on the lines between the centroids of the rings alone and the Cr atoms (to be precise, at one seventh of the distances along those lines). The dihedral driver was then used to rotate each ring, using torsional angles defined by one of the ring atoms, the dummy, the Cr, and the P atom.

The calculated barrier to the rotation of the C_6H_6 in **1** was found to be 0.8 kcal/mol regardless of the direction of rotation. The conformational energy profile for arene rotation exhibited, as anticipated, a definite periodicity with minima (and maxima) appearing every 60°. The barrier thus appears to be due to interactions of the benzene hydrogen atoms with the nearest *ortho* hydrogen atoms of the phosphine phenyl rings nearest the benzene, although the origin of such subtle effects is difficult to ascertain with certainty.

In contrast, the barrier to rotation of the C_6Me_6 in **2** was found to depend on the direction of rotation, being 1.9 kcal/mol for (−) rotation, in which the C_6Me_6 slides past the Ph rings in a glancing, face-on manner, and and 3.7 kcal/mol for (+) rotation, which results in edge-on interactions in which the methyl groups collide with the edges of the phenyl rings. Somewhat similar observations were made previously for PPh_3 rotation in **1** and **2** (*2d*). The conformational energy profile again exhibits sixfold maxima and minima, and again the barrier appears to be a result of interactions of the arene methyl groups with the nearby phenyl *ortho* hydrogens.

Unfortunately, no specific experimental results are available for direct comparison. Although Hunter, Schlögl, and coworkers (*2e,f*) reported the lowest temperature used in their study as 158 K, decoalescence was not observed and it was impossible to estimate upper limits to the barriers. However, Gryff-Keller *et al.* (*5a*) found by VT-NMR spectroscopy that the barrier to C_6H_6 rotation in (η^6-C_6H_6)$Cr(CO)_3$ in solution must be less than 0.55 kcal/mol, and Delise *et al.* (*5b*) found that the barrier to C_6H_6 rotation in crystalline (η^6-C_6H_6)$Cr(CO)_3$ is 4.2 ± 0.1 kcal/mol, very close to the barrier to benzene rotation in solid benzene.

Since the MMX force field describes systems that do not interact with their environments, the barriers calculated with PCMODEL are expected to be quite similar to those that would be measured for chemical systems in the gas phase, and reasonably similar to those in solution in a nonpolar solvent. Because of interactions of the arene ring with the phenyl rings in **1**, the barrier to C_6H_6 rotation in this molecule should be slightly greater than that for its rotation in (η^6-C_6H_6)$Cr(CO)_3$, and thus the 0.8 kcal/mol barrier calculated for **1** is in excellent agreement with the experimental results (*5a*).

We find that rotation of the arene rings does not cause the PPh_3 to rotate in the way that the rotation of PPh_3 apparently causes the C_6Me_6 to rotate in **2** (*2d*). Since the phenyl groups are splayed away from the phosphorus atom, they are necessarily forced close to the arene (i.e., within the van der Waals space of the rotating arene ring) in a periodic fashion when the PPh_3 is forced to rotate with the dihedral driver. In contrast, when the arene is forced to rotate, it need not approach a staggered pair of phenyl rings to a significant extent. The effect is rather like a pair of gears, one of which (the PPh_3) is missing most of its teeth. When the latter is made to rotate, the remaining teeth will engage the gear that is whole (the arene) and cause it to rotate, but rotating the whole gear can have little effect on the partial gear.

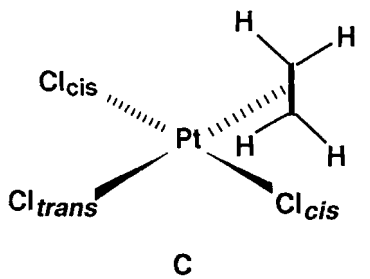
$[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$ (3)

Attempts to build square planar complexes utilizing regular PCMODEL procedures have been found generally to fail because structure optimization routines, which minimize the steric interactions between ligands, invariably result in a tetrahedral structure. Use of two lone-pair "atoms" in the mutually *trans* axial positions[5] was ineffective, presumably because the lone pairs were too small, but use of two hydrogen atoms as "placeholders" in the axial sites[6] did prove effective.

The standard graphical interface of PCMODEL was used to create the model of $[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$, with the added hydrogen atoms. Initially the ethylene carbon atoms were marked as sp^2-type carbon atoms, but attempted minimizations during dihedral runs failed because of a problem in the π-matrix diagonalization routines.[7] Aromatic-type carbon atoms were therefore used for all further calculations on **3**. The ethylene was coordinated to the platinum with the standard function, the complex was flagged as "square planar," and the metal was designated as uncharged. (The program documentation actually recommends not using charges and, in any case, previous work had indicated that a charge on the metal atom would not significantly affect the results.) All parameters used were the program default values. A dummy atom, the location of which was defined as the centroid of the two ethylene carbon atoms and the platinum atom, was added, and the structure was minimized.



C

As anticipated, the overall structure of the complex was well reproduced, with the C=C axis of the coordinated ethylene being perpendicular to the $PtCl_3$ plane, as in **C**, the Cl_{cis}-Pt-(C_2H_4 centroid)-C torsional angle being 89.8°. The calculated Pt—Cl_{cis} and Pt—Cl_{trans} bond lengths were both found to be 226 pm, in reasonable agreement with neutron diffraction data (230.2, 234.0 pm, respectively) (6), although the subtle electronic weakening of the Pt—Cl_{trans} bond was not, of course, reproduced. The Pt—C distances were calculated to be 268 pm, in poor agreement with the neutron diffraction data (212.8, 213.5 pm), while the Cl_{cis}-Pt-Cl_{trans} and Cl_{cis}-Pt-Cl_{cis} bond angles were found to be 93.9° and 172.2°, respectively, in satisfactory agreement with neutron diffraction data (90.05, 90.43° and 177.65°, respectively).

To obtain the conformational energy profile for ethylene rotation, the olefin was forced to rotate with respect to the $PtCl_3$ plane using the dihedral driver of PCMODEL and working on a C-dummy atom-Pt-Cl_{cis} torsional angle θ. The range of rotation was 1.5 rotations (540°), and the resulting replicated configurations at the beginning and at the end of the run were essentially identical. The resulting conformational energy profile is shown in Fig. 1.

As can be seen, global minima occur at $\theta = \pm 90°$, i.e., the perfectly staggered structure, as expected. Quite unanticipated, however, is the finding that the global maximum occurs not at $\theta = 0°$, where the C=C axis eclipses the $PtCl_3$ plane, but at about $\theta = \pm 35°$, where pairs of hydrogen atoms eclipse the $PtCl_3$ plane. There is actually a local minimum (lying about 0.4 kcal/mol below the global maximum energy) at $\theta = 0°$, apparently corresponding to positions where the pairs of geminal hydrogen atoms straddle the chlorine atoms.[8]

The steric barrier to ethylene rotation in $[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$ is calculated to be 2.2 kcal/mol using the optimized structural parameters discussed above, while a similar calculation, using fixed, shorter, platinum–ligand bond lengths approximating those reported in the neutron diffraction study (6) gave a somewhat higher barrier of 5.4 kcal/mol. While no experimental data are available for comparison, the free energy of activation for ethylene rotation in the very similar compound $PtCl_2(\eta^2\text{-}CH_2{=}CH_2)$(acac) (acac = acetylacetonate anion) has been found to be 12.5 ± 0.6 kcal/mol (8).[9] This compares well with a theoretical electronic barrier to ethylene rotation of ~15 kcal/mol (9), and it appears that the steric barrier deduced here is small relative to the electronic barrier to ethylene rotation.

$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}CH_2{=}CH_2)]^+$ (4)

Gladysz and co-workers (10*a*) used VT-NMR spectroscopy to measure the barrier to the rotation of ethylene in **4**, finding $\Delta G^{\ddagger} = 16.4$ kcal/mol. To carry out the calculations, the structure was built with PCMODEL (bonds being allowed to assume their natural lengths since no crystal structure data were available), and optimized in the usual way (1*e*, 2*d*). No charge was specified for the metal. Only one of the two metal-chiral forms was tested, that with the *S* configuration, but both the *M* and *P* chiralities of PPh_3 (2*d*) were assessed with the C_2H_4 being driven in both directions. Any simulation involving the opposite metal chirality would have been mirror-symmetric with one of the cases that was studied.

A dummy atom was added to the structure, attached to both ethylene C atoms and to the Re. Rotation of the ethylene was then forced, with the dihedral driver operating on a torsional

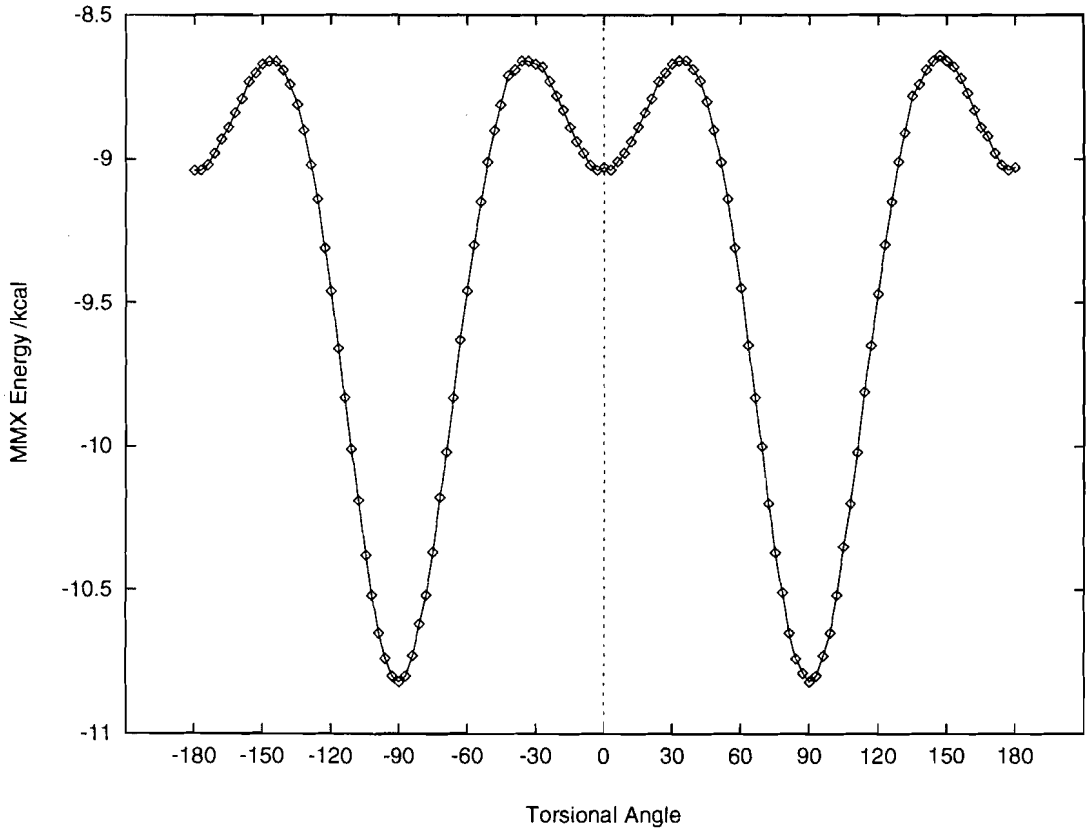
[7] A software bug cause the V_2 force constant applied to the planar ethylene system to sometimes be recalculated as a negative number. As a result, the system would do a half-twist as the two ends of the ethylene suddenly tried to become mutually perpendicular. This problem did not occur when the ethylene atoms were of the aromatic type, since the π calculations were then omitted.

[8] The calculated H—Cl_{cis} distances vary between a maximum of ~307 pm at $\theta = 0, \pm 90°$ and a minimum of ~282 pm at $\theta = \pm 50, 135°$, compared with 297 pm, the sum of the van der Waals radii (7). The calculated C—Cl_{cis} distances vary between a minimum of ~313 pm at $\theta = 0°$ and a maximum of ~340 pm at $\theta = 90°$, compared with 345 pm, the sum of the van der Waals radii (7). While the definitions of van der Waals radii for the hydrogen atoms and for the sp^2-hybridized carbon atoms along the π bond are questionable, it seems clear that H—Cl_{cis} and the C—Cl_{cis} steric interactions are minimal at the global energy minima, and that both contribute at and near the global energy maxima.

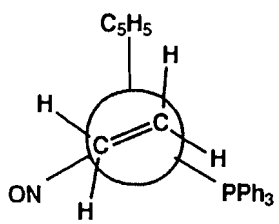
[9] The value given was estimated on the basis of an observed coalescence temperature.

Fig. 1. Conformational energy profile for ethylene rotation in $[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$.



angle defined by one of the ethylene C atoms, the dummy, the Re, and the P atom. Thus dihedral angles of 0° and 180° had the ethylene double bond eclipsing the Re—P bond. The ethylene carbon atoms were marked as aromatic-type carbon atoms, as with $[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$.

The barriers to the C_2H_4 rotation in **4** were determined as functions of the rotational direction and the phosphine chirality, and energy minima were found for dihedral angles of 110° and −70°, in which the C=C bond lies approximately perpendicular to the Re—P bond, essentially eclipsing the Re—NO bond as in **D**. In all cases, the barriers were found to be ~4.0



D

kcal/mol, much lower than the experimentally determined value of $\Delta G^{\ddagger}$ for ligand rotation (10). It seems quite unlikely that the explanation lies in a significant difference in entropy between the bottoms and tops of the C_2H_4 rotational barriers for these systems, an argument that has been used to rationalize differences in calculated values of $\Delta H^{\ddagger}$ and experimental values of $\Delta G^{\ddagger}$ for other systems (11).

The most likely reason for the difference is that the orientation of the ethylene ligand is affected strongly by electronic effects, which PCMODEL cannot account for, and indeed, extended Hückel calculations suggest that the most stable orientation of the ethylene group in this complex has the C=C double bond eclipsing the Re—P bond (10*b*). Thus as with the $[PtCl_3(\eta^2\text{-}CH_2{=}CH_2)]^-$ ion, discussed above, it seems likely that the experimentally determined barrier to ethylene rotation reflects dominant electronic rather than steric factors.

Attempts to extend this investigation to complexes of substituted olefins such as $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}$*cis*- and *trans*-CHMe=CHMe)]$^+$ (**5**, **6**) (11) failed because of deficiencies in this extension of the functioning of the dihedral driver of PCMODEL. As currently applied, the minimizer halts when, after moving each atom in a direction that should give a lower energy, the total energy of the system increases; this indicates to the minimizer that it has found a minimum energy configuration. However, with a dummy atom included in the definition of a dihedral-driver angle or a fixed-distance atom pair, the computed optimal atom movements may not be truly optimal. This is because, as noted above, movements of dummy atoms resulting from their attachments being moved are not taken into account by the minimizer. As a result, the minimizer is on occasion not merely inefficient; it sometimes stops altogether when the minimization is far from complete because moving the dummy atom makes the energy of the system increase. This happens most often when something like a dihedral-driver series is being performed, because here the torsional angle is being used to push the system past potential barriers. The tendency of the system to oppose forced motion to higher potential energies has the dihedral-driver dummy

For personal use only.

atom moving in directions that lead to much higher total energies, especially because the force constant applied to the dihedral-driver angle is very large.

This problem is most serious when the barrier to the rotation of the ligand is large. With the rotations of the π-coordinated ligands in compounds **1–4**, the barriers are sufficiently small that the minimizer works well. With the more sterically congested **5** and **6**, however, the barriers are sufficiently large that the minimizer often failed. The torsional angle would be changed, the atoms would be moved, the energy would increase immediately, the minimizer would halt, and the torsional angle would be incremented again. Instead of finding the optimal structure for each torsional angle, the coordinated 2-butene ligands kept rotating to increasingly strained configurations until the strain was unrealistically high. This behaviour often occurred after a reasonably anticipated rotational barrier maximum had actually been passed, yielding generally inconsistent results. Attempts to solve the problem failed.

Summary

A useful methodology for utilizing MMX to calculate small steric barriers to rotation of π-bonded ligands has been developed, the barriers calculated for η^6-arene rotation in two chromium(0) complexes being in reasonable agreement with experimentally determined barriers. The finding that calculated steric barriers to η^2-ethylene rotation in two quite different types of olefin complexes are apparently significantly less than the corresponding electronic barriers does not negate the methodology, as comparisons of steric and electronic barriers are generally useful, as is determination of sterically preferred structures.

Routes to dicationic ruthenium(II) nitrile complexes containing chelating diphosphine ligands: X-ray analyses of $Ru(dppb)(MeCN)_4^{2+}2PF_6^-$ (dppb = $Ph_2P(CH_2)_4PPh_2$) and *trans*-$RuCl_2(MeCN)_4$

Deryn E. Fogg, Steven J. Rettig, and Brian R. James

Abstract: Routes to the $Ru(PP)(RCN)_4^{2+}$ $2PF_6^-$ complexes (PP = $Ph_2P(CH_2)_4PPh_2$, dppb; R = Me, Ph) from the Ru(II) precursors $Ru_2Cl_4(PP)_2$ and $RuCl_2(PP)(PPh_3)$ have been established. The X-ray crystal structure of the dppb-MeCN derivative (**3**) is described, and the steric effect of the diphosphine ligand is examined by comparison with the crystal structure of *trans*-$RuCl_2(MeCN)_4$ (**5**), which is also presented. Crystals of **3** are triclinic, a = 13.845(3), b = 14.419(2), c = 12.984(3) Å, α = 108.75(2)°, β = 116.40(1)°, γ = 68.58(1)°, and Z = 2, space group $P\bar{1}$; and those of **5** are orthorhombic, a = 13.058(2), b = 11.790(2), c = 8.562(1) Å, and Z = 4, space group *Pbca*. The structures were solved by the Patterson method and refined by full-matrix least-squares procedures to R = 0.039 and 0.024 (R_w = 0.046 and 0.028) for 9973 and 1131 reflections with $I \geq 3\sigma(I)$, respectively. Crystallographic and infrared data suggest that the nitrile ligands function solely as σ-donors in these ruthenium(II) complexes.

Key words: ruthenium, nitriles, diphosphine ligands.

Résumé : On a déterminé les routes d'accès aux complexes $Ru(PP)(RCN)_4^{2+}$ $2PF_6^-$ (PP = $Ph_2P(CH_2)_4PPh_2$, dppb; R = Me, Ph) à partir des précurseurs du Ru(II) $Ru_2Cl_4(PP)_2$ et $RuCl_2(PP)(PPh_3)$. On décrit la structure cristalline déterminée par diffractions des rayons X du dérivé dppb-MeCN (**3**) et on a examiné l'effet stérique du coordinat diphosphine par comparaison avec la structure cristalline du *trans*-$RuCl_2(MeCN)_4$ (**5**) qui est aussi présentée. Les cristaux du composé **3** sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 13,845(3), b = 14,419(2) et c = 12,984(3) Å, α = 108,75(2)°, β = 116,40(1)°, γ = 68,58(1)° et Z = 2, alors que ceux du composé **5** sont orthorhombiques, groupe d'espace *Pbca*, avec a = 13,058(2), b = 11,790(2) et c = 8,562(1) Å, et Z = 4. On a résolu les structures par la méthode de Patterson et on les a affinées par la méthode des moindes carrés (matrice complète) jusqu'à des valeurs de R = 0,039 et 0,024 (R_w = 0,046 et 0,028) pour respectivement 9973 et 1131 réflexions avec $I \geq 3\sigma(I)$. Les données cristallographiques et d'infrarouge suggèrent que les coordinats nitrile ne fonctionnent que comme des donneurs σ dans ces complexes ruthénium(II).

Mots clés : ruthénium, nitriles, coordinats diphosphine.

Introduction

Ruthenium(II) complexes with chelating diphosphine ligands have been the focus of considerable recent attention, in large part because of their demonstrated utility in asymmetric hydrogenation of a wide range of substrates (1). To identify the structural features associated with high catalytic and enantioselective ability (2), we have undertaken the preparation of a range of such complexes, in most of which the coordination sphere contains potentially labile nitrile (3) or arene (3, 4) ligands. The monocationic complexes $RuCl(PP)(RCN)_3^+PF_6^-$ (**1**) were of particular interest because of their reported lability regarding loss of nitrile (5, 6), a useful property for a catalyst precursor. Work from this laboratory had originally reported on the PP = dppb, R = Me, *mer* and *fac* species (5), while Shao et al. (6) reported on the PP = binap, R = Ph species during the course of the present studies (binap = 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl); $^{31}P\{^1H\}$ NMR data in solution revealed an "extra" resonance that was assigned to a coordinatively unsaturated species **2**, governed by the equilibrium shown in eq. [1]

Received October 12, 1994.

This paper is dedicated to Professor William A.G. Graham on the occasion of his 65th birthday.

[1] $RuCl(PP)(RCN)_3^+ \rightleftharpoons RuCl(PP)(RCN)_2^+ + RCN$
1 **2**

We now report that the "extra" ^{31}P signal, in the case of the dppb system, results from the presence of Ru(dppb)-$(MeCN)_4^{2+}$, which is isolated and structurally characterized as the PF_6 salt **3**; the benzonitrile analogue (**4**) is also isolated, and structural details of **3** are compared with those determined also for *trans*-$RuCl_2(MeCN)_4$ (**5**), a previously known complex (7, 8). It should be noted that the AB quartet assigned to a species of type **2** in the binap work (6) is not due to $Ru(binap)(PhCN)_4^{2+}$ (see below); a ^{31}P singlet is expected for the latter complex (9).

Experimental

Manipulations were carried out under an argon atmosphere using standard Schlenk techniques. Solvents were dried and distilled under nitrogen. Acetonitrile and benzonitrile were obtained from BDH, distilled from CaH_2, and stored under Ar. NH_4PF_6 was used as received from Aldrich. $RuCl_2$-$(dppb)(PPh_3)$ (10), $Ru_2Cl_4(dppb)_2$ (10), and $RuCl_2(C_6H_6)$-(MeCN) (4) were prepared according to published procedures. NMR spectra were recorded at room temperature (r.t.) on a Varian XL300 spectrometer, using the residual proton of the solvent (^1H) or PPh_3 (^{31}P: $CDCl_3$, −5.46 ppm; CD_2Cl_2, −5.64 ppm with respect to 85% external H_3PO_4) as internal standards (s = singlet, sept = septet, m = multiplet). IR spectra (Nujol mulls, KBr plates) were recorded on a Bomem Michelson 100 FT-IR spectrometer (w = weak, m = medium). Elemental analyses were performed by Mr. Peter Borda of this department.

Preparation of $Ru(dppb)(MeCN)_4^{2+}$ $2PF_6^-$, 3

Method a

A mixture of $Ru_2Cl_4(dppb)_2$ (76.1 mg, 0.0635 mmol) and NH_4PF_6 (41.4 mg, 0.254 mmol) in MeCN (5 mL) was stirred for 3 h at r.t. The pale yellow solution was stripped of solvent, the residue redissolved in CH_2Cl_2, and the suspension filtered through Celite. Concentration of the filtrate to ~1 mL and addition of Et_2O precipitated a white crystalline product, which was washed with Et_2O and dried under vacuum (107 mg, 86%). Colourless prisms of **3** were grown from MeCN–Et_2O.

Method b

Addition of MeCN (10 mL) to a mixture of green $RuCl_2(dppb)(PPh_3)$ (140 mg, 0.163 mmol) and NH_4PF_6 (53.4 mg, 0.328 mmol) gave a cloudy yellow solution, which was stirred for 30 min. The solvent was then removed, the residue taken up in CH_2Cl_2, and the mixture filtered through Celite. Concentration of the filtrate and addition of Et_2O gave the product (133 mg, 83%). IR: 2291, 2320 cm^{-1} (w). ^1H NMR (CD_2Cl_2): 7.2–8.0 (m, 20H, Ph), 2.63–2.73 (m, 4H, CH_2), 2.30 (s, 6H, Me), 2.14 (s, 6H, Me), 1.66–1.80 (m, 4H, CH_2). $^{31}P\{^1H\}$ NMR ($CDCl_3$): 39.2 (s), −144.5 (sept, J = 713 Hz, PF_6). $^{31}P\{^1H\}$ (CD_2Cl_2): 38.8 (s), −144.6 (sept, J = 708 Hz). Anal. calcd. for $C_{36}H_{40}F_{12}N_4P_4Ru$: C 44.05, H 4.11, N 5.71; found: C 43.99, H 4.12, N 5.77%.

Preparation of $Ru(dppb)(PhCN)_4^{2+}$ $2PF_6^-$, 4

A solution of $RuCl_2(dppb)(PPh_3)$ (47.4 mg, 0.055 mmol) and NH_4PF_6 (35.7 mg, 0.219 mmol) in a mixture of PhCN (3 mL) and acetone (10 mL) was stirred at r.t. for 24 h, then stripped of solvent. The residue was taken up in CH_2Cl_2 and the mixture filtered through Celite. Concentration of the filtrate and addition of Et_2O gave the product as a white precipitate (42 mg, 63%). IR: ν(C≡N) 2245 cm^{-1} (w). ^1H NMR ($CDCl_3$): 7.3–7.7 (m, 40H, Ph), 2.8–3.0 (m, 4H, CH_2), 1.8–2.0 (m, 4H, CH_2), 1.54 (s, 2H, H_2O). $^{31}P\{^1H\}$ NMR ($CDCl_3$): 37.3 (s), −144.2 (sept, J = 713 Hz, PF_6). Anal. calcd. for $C_{56}H_{48}F_{12}N_4P_4Ru \cdot H_2O$: C 53.89, H 4.04, N 4.49; found: C 54.08, H 4.00, N 4.36%.

Preparation of *trans*-$RuCl_2(MeCN)_4$, 5

The complex was prepared by a reported method (7). IR: ν(C≡N) 2278 cm^{-1} (m). ^1H NMR ($CDCl_3$): 2.51 (s, 12 H, Me), 1.55 (s, 1 H, H_2O). Anal. calcd. for $C_8H_{12}N_4Cl_2Ru \cdot 0.5\ H_2O$: C 27.84, H 3.79, N 16.23, Cl 20.54; Found: C 27.87, H 3.62, N 16.24, Cl 20.75%. Brown prisms of **5** (nonhydrated) suitable for X-ray analysis were serendipitously formed by leaving $RuCl_2(C_6H_6)(MeCN)$ (32 mg, 0.11 mmol) in MeCN–C_6D_6 (~10:1, total volume 0.6 mL) over two weeks at room temperature.

X-ray crystallographic analyses of 3 and 5

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares refinement of the setting angles for 25 reflections with 2θ = 39.0°–43.0° for **3** and 47.9°–51.8° for **5**. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random fluctuations. The data were processed,[2] corrected for Lorentz and polarization effects, and absorption (empirical, based on azimuthal scans for three reflections).

The structures were solved by conventional heavy atom methods, the coordinates of the heavy atoms being determined from the Patterson function, and those of the remaining non-hydrogen atoms from subsequent Fourier syntheses. The structure analysis of **3** was initiated in the centrosymmetric space group $P\bar{1}$ the basis of the E-statistics and the Patterson function. This choice was confirmed by the subsequent successful solution and refinement of the structure. Complex **5** lies on a crystallographic centre of symmetry. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, B_H = 1.2 $B_{\text{bonded atom}}$). Corrections for secondary extinction were not necessary. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for X-Ray Crystallography (11).

The final atomic coordinates and equivalent isotropic thermal parameters for the non-hydrogen atoms of **3** and **5** are given in Table 2. Selected bond lengths and angles for **3** are given in Table 3; bond lengths and angles for **5** are given in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, complete listing of lengths and angles for **3**, torsion angles, intermolecular contacts, and least-squares planes

are included as supplementary material (Tables S1–S8).[3] Measured and calculated structure factor amplitudes are available from the authors.

Results and discussion

The complex $RuCl(dppb)(MeCN)_3^+PF_6^-$ (**1a**) was synthesized earlier in this laboratory (5) by abstraction of halide from the triply chloro-bridged species $Ru_2Cl_4(dppb)_2$(acetone) (10) using two equivalents of $AgPF_6$. The $^{31}P\{^1H\}$ NMR spectrum in CD_2Cl_2 revealed a principal singlet at δ 41.2 (consistent with *fac*-**1a**), the high-field septet of PF_6^-, and a low-intensity singlet at δ 38.7 (~5% integrated intensity) that was attributed to the five-coordinate species $RuCl(dppb)(MeCN)_2^+$ (**2a**) (5). More detailed studies on the chemistry of **1a** (3) reveal that the less intense singlet is due to the presence of the chlorine-free dication $Ru(dppb)(MeCN)_4^{2+}$ (**3**). A $^{31}P\{^1H\}$ singlet is expected for each of the complexes *fac*-**1a**, **2a**, or **3**, but ^1H NMR data readily distinguish the species. Complex **3**, characterized by X-ray crystallography (see below), shows two methyl singlets in a 1:1 ratio, each integrating 6:20 against the phenyl protons; the singlets correspond to the two acetonitriles *trans* to the P atoms, and to the two mutually *trans* acetonitriles. The associated $^{31}P\{^1H\}$ singlet of **3** corresponds to that incorrectly assigned to **2a** (5).

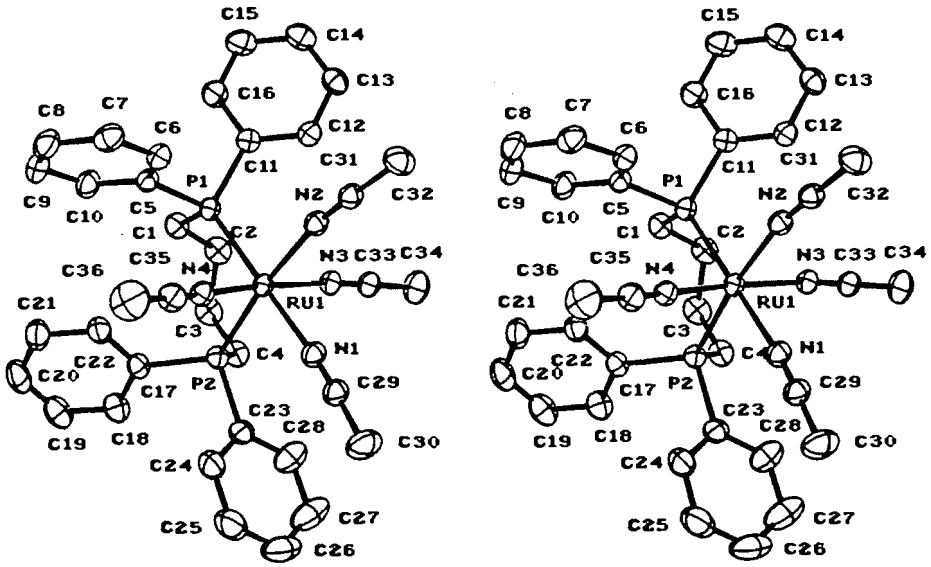
Bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, UK

Fig. 1. Stereoview of the $Ru(dppb)(MeCN)_4^{2+}$ cation in **3**; 33% probability thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity.



Complex **3** and its PhCN analogue **4** are accessible in quantitative yield by abstraction of halide from $Ru_2Cl_4(dppb)_2$ or $RuCl_2(dppb)(PPh_3)$ in acetonitrile or benzonitrile–acetone solvent, respectively. Treatment with NH_4^+ effects complete removal of chloride via monocationic intermediate **1** (PP = dppb, R = Me or Ph), the reaction being driven by the insolubility of ionic NH_4Cl in MeCN or PhCN–acetone. The mixed phosphine precursors $RuCl_2(PP)(PPh_3)$ are much less air-sensitive than the dimeric $Ru_2Cl_4(PP)_2$ precursors, and in solution they dissociate the monodentate PPh_3. Preliminary results suggest that the corresponding binap-acetonitrile complex is likewise accessible from $RuCl_2(binap)(PPh_3)$, but treatment of this with excess NH_4PF_6 in PhCN yields only a monocation of type **1** (3), removal of the second chloride ligand appears to require use of the stronger halide-abstracting agent Ag^+, perhaps because of an unfavourable steric interaction between the bulky, rigid binap ligand and a coordinated PhCN. Isolation of $Ru(binap)(MeCN)_4^{2+}$ $2BF_4^-$ following treatment of $Ru(binap)(OCOMe)_2$ with aqueous HBF_4 in MeCN was reported by Takaya and co-workers (9) during the course of our work. Analogous complexes with monodentate phosphine and phosphite ligands were obtained by Ashworth and Singleton from the dicationic precursor $Ru(COD)(MeCN)_4^{2+}$ $2PF_6^-$ (12) (COD = 1,5-cyclooctadiene). Rather surprisingly, $AgPF_6$ was apparently required for synthesis of the dication; treatment of polymeric $[RuCl_2(COD)]_x$ with NH_4PF_6 in refluxing MeCN was reported to yield only $RuCl(COD)(MeCN)_3^+PF_6^-$, though whether NH_4PF_6 was used in excess is unclear (12). A practical consequence of facile abstraction of halide from species of type **1** by NH_4^+ is the formation of small amounts of the dication during attempts to synthesize solely **1** from "$RuCl_2$" species (3); such facile abstraction also accounts for the original observation of **3** as a by-product, and led to the incorrect formulation of equilibrium [1] (5). The nitrile chemistry of these systems is in fact intricate, and involves not only species of types **1** and **3** (3), but also $RuCl_2(PP)(RCN)_2$, $Ru_2Cl_4(PP)_2(RCN)$, and $Ru_2Cl_3(PP)_2(RCN)_2^+X^-$ (X = Cl, PF_6) (3). In situ formation of the last-mentioned species (PP = binap, R = Ph, X = Cl) has been shown (3) to be responsible for the AB pattern attributed by Shao et al. to a complex of type **2** (6). A detailed discussion of the complexes accessible, and the pathways relating them, will be reported separately.

Complex **4** gave good elemental analysis for a monohydrate, and the ^1H NMR data were consistent with such a formulation. *trans*-$RuCl_2(MeCN)_4$ (**5**) was made by a reported procedure involving catalyzed H_2-reduction of $RuCl_3 \cdot 3H_2O$ in MeCN (7); our elemental analysis and ^1H NMR data were consistent with a hemi-hydrate formulation, although the crystals used for the X-ray analysis were non-hydrated. These were obtained by a reaction involving displacement of coordinated benzene of $RuCl_2(C_6H_6)(MeCN)$ by MeCN.

The crystal structure of **3** is shown in Fig. 1. Crystallographic analysis of **5**, prepared in the course of related work (4), offers some insight into the structural constraints imposed by the diphosphine ligand in **3**, and an ORTEP representation of **5** is shown in Fig. 2.

The cation within **3** is monomeric, containing chelated dppb in *cis* sites and four N-bound MeCN ligands. Associated with the Ru cation are two essentially octahedral PF_6 counterions (not illustrated); one of the anions has P—F bond lengths in the range 1.566–1.591 Å, while for the other anion the lengths are in the range 1.486–1.564 Å, but the differences likely result from thermal libration; note the significant differences in the thermal parameters of the two anions (Table 2). Within the internuclear distances, there are just two F...H bond lengths <2.5 Å, a criterion that may be used for the existence of a hydrogen bond (13): F(5)—H(12) = 2.39 Å and F(6)—H(35) = 2.36 Å, implying weak hydrogen bonding to a phenyl-H and to a methyl-H of MeCN. Weak H..F interactions involving toluene ring atoms were observed in our earlier work on the $RuCl(\eta^6\text{-toluene})(dppb)^+$ cation (5).

The $Ru(dppb)(MeCN)_4^{2+}$ cation consists of a slightly distorted octahedron, in which the bond angles between the nitrile ligands both in the P-Ru-P plane and projecting above

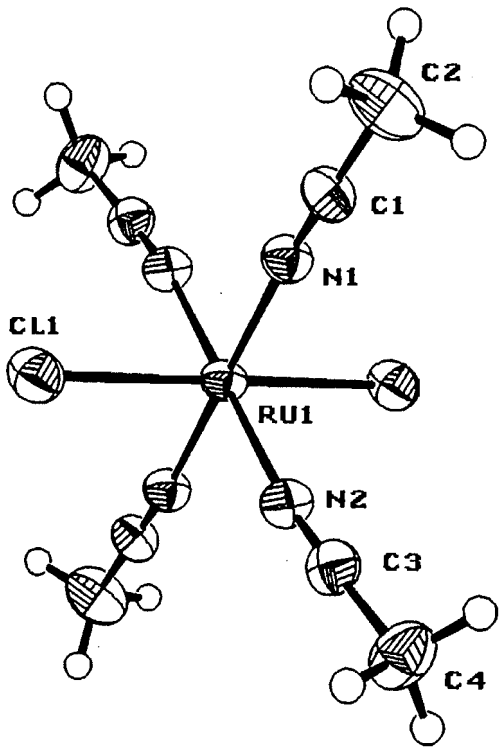
Fig. 2. Perspective view of *trans*-$RuCl_2(MeCN)_4$, **5**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.



and below it are compressed slightly. Distortions of the coordination sphere in **3** result primarily from intramolecular steric repulsion between the diphosphine ligand and two of the nitrile ligands (the contacts N(1)···C(23) = 3.010 Å, N(4)···C(6) = 3.055 Å, and C(35)···C(6) = 3.199 Å are all at or below the sum of van der Waals radii) as well as the inherent steric constraints of the dppb ligand, and secondarily from the formation of a weak C—H···F hydrogen bond between the nitrile ligand containing N(3) and one of the anions (C(34)—H(35)···F(6), H···F = 2.63 Å, C···F = 3.302 Å, C—H···F = 160°). These factors are responsible for the small but significant deviation from linearity of N(3)-Ru-N(4) angle (171°) relating the mutually *trans* nitrile ligands. The corresponding angle in the related complex $Ru(MeCN)_6^{2+}$ **6**, which is free of the steric constraints imposed by the diphosphine ligand, is 178° (14). All *trans* angles in **5** are exactly linear as a consequence of the crystallographic C_i symmetry. Since the P-Ru-P angle in **3** is obtuse (94°, see Table 3), the opposite N-Ru-N angle is expected to be acute but the actual value of 83° suggests some additional compression arising from the above-mentioned steric factors. The deviation of the *cis* N-Ru-N angles in **5** (86° and 94°, see Table 4) from 90° can only result from intermolecular steric interactions. The Ru-N-C angles in **3** (170°–172°) are similar to those in **5** (172°–173°) while those in both **6** and $Ru(C_6H_6)(MeCN)_3^{2+}$ **7** (15) average 176°. Since the Ru-N-C angles involving the sterically hindered nitrile ligands (those containing N(1) and N(4)) assume the intermediate values (Table 3), it is most likely that the nonlinearity of these angles results from packing forces in both **3** and **5**. The nitrile N-C-C angles in **3**, **5**, and **6** are all ca. 178°.

The high symmetry implied by the appearance of only two methylene multiplets in the ^1H NMR spectrum of **3** (presumably one for the central two CH_2 groups and one for the two P-CH_2 groups) suggests that the two halves of the carbon backbone are related by a twofold axis. Although in the solid state the P-C-C bond angles at C(1) and C(4) differ by nearly 5° (with values of ~114° and 119°, respectively), and the C-C-C angles at C(2) and C(3) by 3° (114° and 117°), flexing of the diphosphine unit in solution must render these differences insignificant. In the solid state structure, the seven-membered chelate ring has an irregular chair conformation and the four phosphine phenyl rings are planar, the geometry of the Ru(dppb) moiety being essentially the same as those within $RuCl(\eta^6$-toluene)$(dppb)^+$ (5) and (DMSO)(dppb)Ru(μ-$Cl)_3$RuCl(dppb), where DMSO is S-bonded dimethyl sulphoxide (10). Based on ^1H NMR data for various $Ph_2P(CH_2)_nPPh_2$ ligands (16), the multiplets at δ ~2.7 and ~1.7 are assigned to the CH_2-P and CH_2-CH_2 protons, respectively.

While the average Ru—N bond distance for the mutually *trans* nitriles in **3** (2.03 Å) is closely comparable to the average values in **5**, **6**, and **7** (2.03, 2.03, and 2.06 Å, respectively), the remaining pair of nitriles exhibits a slight lengthening of these bonds (average 2.12 Å), owing to the strong *trans* influence exerted by the phosphine. Even the shorter Ru—N bonds, however, are slightly longer than ~2.0 Å, the sum of the estimated single covalent radii (17), implying little Ru(II)→N, $d\pi$-$p\pi$ backbonding. Where such backbonding is significant, shorter Ru—N bonds are observed, as, for example, in Ru(II)-N_2 complexes: although the accuracy of crystallographic data for dinitrogen complexes is sometimes low, the more reliable Ru—N bond lengths of 1.822(13) Å (18) and 1.894(9) Å (19) in Ru-porphyrin and -bis(ethylenediamine) species, respectively, are significantly shorter than those in the Ru(II)-nitriles. The C—N bond lengths in the four nitrile complexes range from 1.12 to 1.14 Å, being slightly *shorter* than the value of 1.157 Å calculated for MeCN in the gas phase (20), as commonly observed in both transition metal (21) and main group (22) complexes of nitriles. Shortening of the C—N bond is perhaps evidence against any π-backbonding component to the ligand–metal interaction, as are the positive infrared coordination shifts of ν(C≡N) for N-bonded nitrile complexes generally (21) and for complexes **3**–**5**; see Experimental; cf. values of 2254 and 2231 cm^{-1} for free MeCN and PhCN, respectively. The corresponding data for complexes **6** and **7** are not reported. (Of the two IR bands observed generally in the 2270–2320 cm^{-1} region, the lower energy one is ν(C≡N), while the higher energy one is a combination of ν(C—C) and $\delta(CH_3)$ (21)). Also, while any backbonding from the metal might be expected to be greatest for **5**, in which the metal centre is neutral rather than dicationic, the C—N bond lengths are actually shortest in this complex, although the differences are hardly significant. Thus despite the strong π-donor capacity of low-spin Ru(II) (23), there is no definitive evidence to suggest that the nitrile ligands function as π-acceptors in these Ru(II) species. This view contrasts with that of Ludi and Merbach and co-workers (15, 24, 25) who describe MeCN as a typical π-acceptor that permits strong backbonding from the electron-rich Ru^{2+} ion. In the papers reporting the crystal structures of **6** and **7** (14, 15), the shortening in the Ru—N and C—N bond lengths, which is difficult to reconcile with the π-backbonding model, is not discussed. A smaller downfield ^1H NMR shift of the η^6-C_6H_6 singlet for

$Ru(C_6H_6)(MeCN)_3^{2+}$ (**7**) versus the corresponding tris(aquo) complex was also attributed to π-backbonding to the nitrile (24), but this effect could equally well result from the weaker σ-donor ability of MeCN relative to H_2O. Lower substitutional lability and much higher oxidation potentials of some Ru(II)-nitrile complexes relative to aquo species are certainly, however, readily interpreted in terms of the π-backbonding from Ru(II) to MeCN (24, 25). Clearly, more detailed solution studies on crystallographically characterized Ru(II)-nitrile complexes are needed to unravel the subtleties of the backbonding problem, particularly the effect of the nature and number of ancillary ligands. Coordination shifts of the $\nu(C{\equiv}N)$ of MeCN and PhCN to lower wavenumbers have been observed, for example, within the $Ru(NH_3)_5(RCN)^{2+}$ and related complexes, but this is comparatively rare (particularly for MeCN species), and is usually associated with an enhanced π-donor ability of the metal fragment (26, 27).

Elucidation of the structures of the hydridothiolato complexes $WH(SC_6H_2Pr^i_3\text{-}2,4,6)_3(L)(PMe_2Ph)$, L = PMe_2Ph or pyridine, by NMR and X-ray techniques

Timothy E. Burrow, Alan J. Lough, Robert H. Morris, and Raymond L. Richards

Abstract: Measurement of the T_1 values of the ^{31}P nuclei in the unusual capped trigonal bipyramidal complexes $WH(tipt)_3(PMe_2Ph)_2$ (**1**, tipt = $SC_6H_2Pr^i_3$-2,4,6) and $W(^2H)(tipt)_3(PMe_2Ph)_2$ allows the determination of the phosphorus–hydride distance of 2.2 ± 0.2 Å and the P-W-H angle of about 62 ± 7°. An approximate location of the hydride on an S_2P face is proposed on the basis of steric interactions. The crystal structure of $WH(tipt)_3\text{-}(NC_5H_5)(PMe_2Ph)$ (**2**) is reported; the WS_3NP core consists of a distorted trigonal bipyramidal system with the phosphine and pyridine ligands axial and the thiolate ligands equatorial. The hydride ligand was not located by X-ray diffraction but can be positioned on an open S_2P face at an angle P-W-H of about 65°. The small P-W-H angle results in large $^2J(H,P)$ couplings for **1** and **2**. The ^1H NMR spectrum of complex **2** is assigned by use of NOE and homodecoupling NMR methods. This complex has the same crowded structure in solution as in the crystalline state. The pyridine ligand, which is sandwiched between two tipt aryl groups, is hindered from rotating around the W—N bond.

Key words: molybdenum, tungsten, thiolate, hydride, NMR, NOE.

Résumé : Des mesures des valeurs T_1 des noyaux ^{31}P dans des complexes bipyramidaux trigonaux inhabituels $WH(tipt)_3(PMe_2Ph)_2$ (**1**, tipt = $SC_6H_2Pr^i_3$-2,4,6) et $W(^2H)(tipt)_3(PMe_2Ph)_2$ permettent de déterminer que la distance phosphore–hydrure est égale à 2,2 ± 0,2 Å et que l'angle P-W-H est d'environ 62 ± 7°. En se basant sur les interactions stériques, on propose une location approximative de l'hydrure sur la face S_2P. On a déterminé la structure cristalline du $WH(tipt)_3(NC_5H_5)(PMe_2Ph)$ (**2**); le noyau WS_3NP est un système bipyramidal trigonal déformé dans lequel les coordinats phosphine et pyridine sont axiaux et les coordinats thiolates sont équatoriaux. On n'a pas pu déterminer la position du coordinat hydrure par diffraction des rayons X; on peut toutefois le fixer sur une face ouverte du S_2P, avec un angle P-W-H d'environ 65°. Le petit angle P-W-H conduit à des couplages $^2J(H,P)$ élevés pour les composés **1** et **2**. On a attribué les bandes du spectre RMN du ^1H complexe **2** en faisant appel aux méthodes de l'effet Overhauser nucléaire et de l'homodécouplage RMN. En solution, ce complexe possède la même structure encombrée qu'à l'état solide. Le coordinat pyridine est pris en sandwich entre deux groupes aryles tipt; sa rotation autour de la liaison W–N est empêchée.

Mots clés : molybdène, tungstène, thiolate, hydrure, RMN, EON.

[Traduit par la rédaction]

Introduction

We are studying molybdenum and tungsten complexes that contain hydride and thiolate donor ligands (1, 2) because of their possible relevance to nitrogenase (3, 4) and to the hydrodesulfurization reaction (5, 6).

A difficulty in this work is ascertaining the location of a hydride ligand in such a transition metal compound. In single crystal X-ray diffraction studies, the low electron density of the hydride ligand, next to a heavy metal, makes its location and refinement difficult or impossible. Neutron diffraction analysis gives the most accurate results since it relies on the scattering from the nucleus rather than the electron cloud and the scattering factor for hydrogen is substantial. Unfortunately, there are only a few, heavily used, single crystal neutron diffractometers in the world.

Since the relaxation of a nucleus is dependant on its environment, it can be used to probe the molecular structure of a

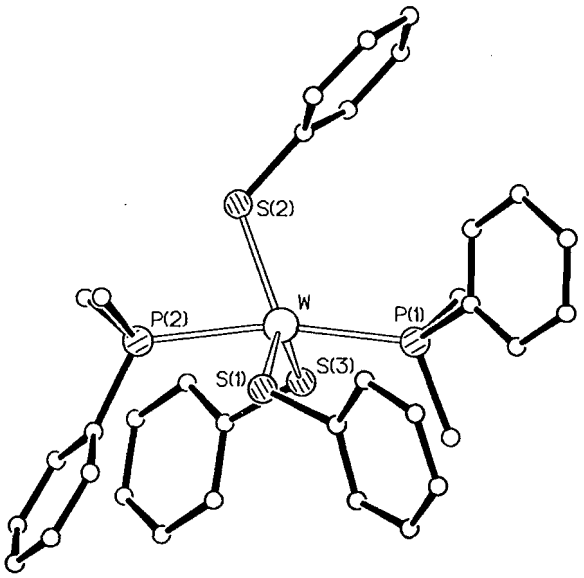
Fig. 1. Molecular structure of **1** as determined by single crystal X-ray diffraction; reproduced by permission from ref. 1. The isopropyl groups on the tipt ligands have been omitted for clarity.



compound. Here we report the use of NOE and T_1 measurements to probe the location of the hydride ligand in $WH(tipt)_3(PMe_2Ph)_2$ (**1**) and $WH(tipt)_3(NC_5H_5)(PMe_2Ph)$ (**2**). The synthesis and crystal structure of **1** have been reported but the hydride ligand was not located (1). Its WS_3P_2 core geometry is distorted trigonal bipyramidal with the thiolate ligands arranged equatorially and the phosphine ligands axial, Fig. 1. The hydride ligand was not located even after repeating the data collection at low temperature. Complex **2** is prepared by substitution of a PMe_2Ph ligand by pyridine in **1** (2). The molecular structure of the molybdenum analogue of **2** has been described recently, but again the hydride position was not certain (7).

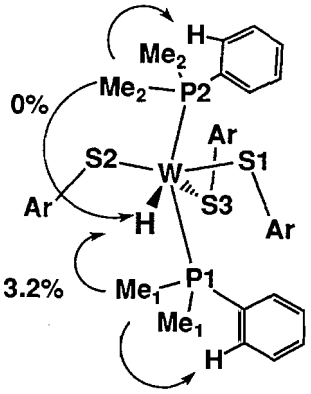
Results and discussion

NMR studies of $WH(tipt)_3(PMe_2Ph)_2$

As reported previously (1), the ^{31}P NMR spectrum of **1** has two doublet resonances at −125.2 and −150.5 ppm versus $P(OMe)_3$. These are assigned to atoms P1 and P2, which correspond to P(1) and P(2) of the X-ray-determined structure (Fig. 1) as described below. The coupling $^2J(P1,P2)$ is 100.7 Hz and there are tungsten satellites as reported previously (1). The hydride ligand gives a doublet of doublets resonance in the ^1H NMR spectrum with $^2J(H,P1)$ and $^2J(H,P2)$ of 105 and 8 Hz, respectively; there are also tungsten satellites. These assignments were originally in the reverse order because it was assumed that P2, being pseudo-*trans* to the hydride, would cause the large coupling of 105 Hz; however, we now know that P1, *cis* to the hydride, is associated with this coupling (see below).

The ^1H NMR spectrum also has two doublets belonging to the methyl groups, Me_1, attached to P1, and Me_2 attached to P2, each with a coupling of approximately 8 Hz. The ^1H–^{31}P heteronuclear-correlated two-dimensional NMR spectrum of **1** showed that P1 is coupled to the ^1H nuclei, which resonate at 1.63 ppm (Me_1), and P2 is coupled to the PMe_2Ph resonance at

Fig. 2. Summary of NOE studies of **1**.



1.69 ppm (Me_2). Low-power irradiation of Me_1 resulted in a 3.2% nuclear Overhauser effect enhancement of the W*H* resonance but irradiation of Me_2 resulted in no enhancement of W*H* (Fig. 2). Thus the hydride ligand is in close proximity to P1. This implies that the hydride ligand has the large *cisoid* coupling of 105 Hz to P1. As Fig. 2 indicates, there are also NOE contacts between neighbouring methyl and *ortho*-phenyl protons in the phosphine ligands.

The hydride location was further refined by calculating the P1–H distance from the difference in relaxation rates of P1 in $W(^1H)(tipt)_3(PMe_2Ph)_2$ and $W(^2H)(tipt)_3(PMe_2Ph)_2$ under identical conditions. The spin-lattice relaxation times of P1, $T_1(P1)$, for the two complexes in toluene-d_8 at −57°C are 0.44 and 0.50 s, respectively, while the $T_1(P2)$ values are identical (Table 1). Since a proton, with its large gyromagnetic ratio, is much more efficient at relaxing nearby nuclei through dipole–dipole relaxation than is a deuteron, the difference in relaxation rates (1/0.44 − 1/0.50) can be used to calculate the H—P internuclear distance. The standard equation for dipole–dipole relaxation, which relates T_1 and distance between dipolar nuclei to the sixth power (8), can be used to calculate the ^1H—^{31}P distance once the correlation time of the molecule, τ_c, is determined. The correlation time was estimated, using the Geirer–Wirtz model of the Stokes–Einstein–Debye equation:

$$[1] \qquad \tau_c = f\frac{V\eta}{kT}$$

where f is the microviscosity factor, V is the volume of the solute, and η is the viscosity of the solute. The volume, V, was calculated from the volume of the unit cell of the crystalline complex, dividing by the number of molecules in the unit cell and correcting for a molecule of benzene in the unit cell. The viscosity of the solvent, η, at 216 K was extrapolated from the values at other temperatures (9). The value for f was estimated as 0.3 from the ratio of solute to solvent volume (Table II in ref. 10). A maximum value of 1.0 was used as an upper limit on τ_c. The internuclear distance was calculated to be between 2.0 and 2.4 Å. Despite the uncertainty in the correlation time, the error in distance (±0.2 Å) becomes acceptably small because the sixth root is taken in calculating the distance.

The best location for the hydride ligand is postulated on the basis of maximizing the distance of the hydride ligand from the sulfur atoms. This was done by using the atomic coordi-

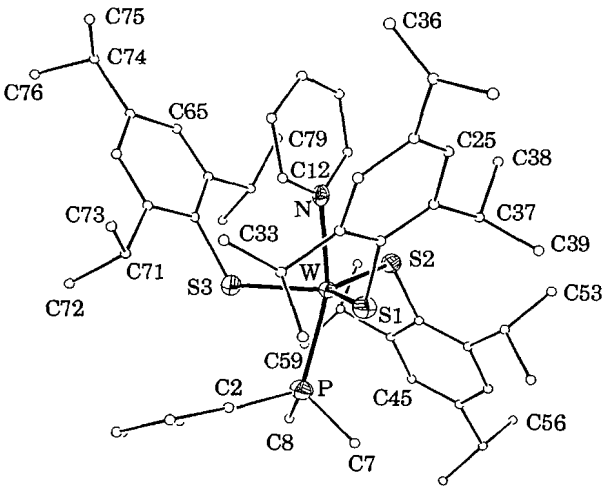
nates from the X-ray crystal structure determination (Fig. 1) and rotating the WH vector around the WP1 vector, keeping a constant distance, d(W—H), of 1.7 Å and a distance from P1 of 2.0 Å. Positions with short distances to carbon or hydrogen atoms were rejected. The best location puts the hydride ligand in the middle of the P1S1S2 face, where S1 and S2 have the aryl groups oriented in the same direction (Fig. 2). These two thiolate ligands define the largest S-W-S angle of 124.7(1)°. This location is similar to that refined for the hydride ligand in the X-ray structure of $WH(SeC_6H_3Pr^i_2\text{-}2,6)_3(PMe_2Ph)_2$ (11).

It is of interest that the approximate H-W-P1 angle is 62 ± 7° (from d(W—H) = 1.70 ± 0.02, d(W—P) = 2.418(3), d(P—H) = 2.2 ± 0.2 Å) and this results in a ^2J(H,P) coupling of 105 Hz while the H-W-P2 angle of approximately 125 ± 5° gives a coupling of only 8 Hz. The complex $MoH(tipt)_3(PMe_2Ph)_2$ must have similar properties because it is virtually isostructural with complex **1** and has a large ^2J(H,P) value of 98 Hz. This could be a general phenomenon for W(IV) and Mo(IV) complexes since the complex $MoH(tp)_2(tipt)(PEtPh_2)$ (tp = NC_5H_4S-2) also has a small H-Mo-P angle of 65 ± 1° and a large ^2J(H,P) coupling of 104 Hz (7). The small size of the ^2J(H,P2) coupling can be explained by considering that 90° H-M-P angles usually give medium-sized negative couplings while 180° angles give large positive couplings. The H-W-P2 angle is between these values so that the coupling may be near to zero. The P1-W-P2 angle is 166.4° and this results in a coupling, ^2J(P,P), of 100.7 Hz.

Structural study of $WH(tipt)_3(NC_5H_5)(PMe_2Ph)$

The molecular structure of $WH(tipt)_3(NC_5H_5)(PMe_2Ph)$ (**2**) is shown in Fig. 3. Atomic coordinates and selected bond distances and angles are given in Tables 2 and 3, respectively. The structure of **2** is very similar to that of $MoH(tipt)_3(NC_5H_5)(PMe_2Ph)$ (Table 3) although the two complexes crystallized in different space groups with the latter containing a crystallographically imposed mirror plane of symmetry (7).

Fig. 3. Molecular structure of **2** as determined by single crystal X-ray diffraction.



The hydride was not located in the present study nor in the study of the molybdenum complex. The molecule contains a distorted trigonal bipyramidal arrangement of ligands other than the hydride. The thiolate ligands are arranged equatorially to minimize steric repulsion with two arene rings oriented up and the other, down. This arrangement for the bulky thiolate ligands is very common (12). The pyridine ligand is sandwiched between the two "up" aryl rings. The NS_3 grouping defines a fairly regular trigonal pyramid with the N atom at the apex. The P atom does not cap this pyramid symmetrically to form the trigonal bipyramid, but instead has a longer distance to S2 (4.04 Å) than to S1 (3.16) or S3 (3.02 Å); the corresponding angles follow this trend with S2-W-P 116.5(1)°, S1-W-P 84.2(1)°, and S3-W-P 79.2(1)°. It is possible that the hydride is located on the PS1S2 face, which is more open than the PS1S3 face and much more open than the other faces; this would also explain the wide S2-W-P angle. However, the positioning of the hydride on the PS1S3 face, at an angle P-W-H of about 65° is more consistent with the solution NMR data (see below); also the S1-W-S3 angle of 127.8(1)° is the largest of the three S-W-S angles. This is the face proposed to accommodate the hydride in the $MoH(tipt)_3(py)(PMe_2Ph)$ (7).

The MS distances for the complexes $MH(tipt)_3(PMe_2Ph)_2$ and $MH(tipt)_3(py)(PMe_2Ph)$, M = Mo, W, are given in Table 4. The Mo and W analogues are almost isostructural. The covalent radii of tungsten and molybdenum are very similar: 1.38 and 1.37 Å, respectively (13). The Mo—S distances in 31 arene thiolate complexes listed in the Cambridge Structural Database average to a value of 2.408 Å, with a σ of 0.056 (14). There is not a statistically significant number of tungsten thiolate complexes. Therefore the Mo—S and W—S distances in these thiolate hydride complexes are at the short end of this M—S range.

The arene thiolate ligands have both σ and π donor capabilities. The π donation can act to stabilize electron-deficient metal centres. Because of the π bonding, a distortion in the MSR angle is expected; a σ bond would be expected to form the tetrahedral angle of 109°, whereas a π bond would favour a 180° angle. The bond angles observed here are in the range 112–125° and are a compromise of the electronic and steric factors.

NMR studies of $WH(tipt)_3(py)(PMe_2Ph)$

The hydride resonance of **2** at room temperature is a doublet with tungsten satellites at 9.55 ppm while the proton-coupled ^{31}P NMR spectrum is a doublet with the same large coupling, $^2J(H,P)$, of 102 Hz. This coupling suggests that the hydride is near to the phosphorus atom in **2**, by analogy to the NMR properties of **1**. Indeed, NOE experiments confirm this (see below). This is one piece of evidence that the complex has the same structure in solution as in the solid state; further evidence is presented below.

The proton resonances of **2** at room temperature in the 0–10 ppm region were assigned by use of selective decoupling experiments and NOE and two-dimensional NOESY ^1H experiments. The results are summarized in Table 5 and the labelling of the groups is shown in Fig. 4. Integrations of the peaks are also consistent with the assignments of Table 5. Only the resonance for the *para* proton of the pyridine ligand is observed at room temperature at 500 MHz; the other pyridine peaks are too broad to observe at this temperature. The isopropyl methine region (2.5–4 ppm) shows a pattern of five septets of integration ratio 2:2:2:1:2, which can be explained by the three equatorially arranged triisopropyl benzene thiolate ligands in a "two up – one down" configuration with a mirror plane cutting through the N, P, W, H, and S2 atoms (1, 15). The assignment of the chemical shifts of the *para* isopropyl groups I and III (Table 5) is supported by the ^1H NMR spectrum of the complex $WH(SeC_6H_3Pr^i_2\text{-}2,6)_3(py)(PMe_2Ph)$ (11) which does not have *para* isopropyl groups: the methine region is identical to that of **2** except for the lack of the two septets of groups I and III at 2.96 and 2.66 ppm. One would expect 10 doublets arising from the magnetic inequivalence of the two methyl groups in each isopropyl group of **2**. There are only eight doublets observed (Table 5) because the methyl groups on the (*para*) isopropyl groups I and III are in similar magnetic environments and thus give rise to one doublet each instead of the expected two doublets each. The two doublet resonances for the *para* isopropyl groups are distinctly sharper (smaller line width, greater spin–spin relaxation or T_2) than the other six doublets due to the slower relaxation rates resulting from fewer neighbouring dipolar nuclei in close proximity. The 2D NOESY spectrum was used to establish the assignments of the aromatic ring protons for the tipt and phosphine groups. It is interesting to note that the aryl groups attached to S3 and S1 (Fig. 4) cannot rotate. The aromatic *meta* proton between isopropyl groups IV and III and the one between groups V and III are inequivalent (resonating as doublets at 6.58 and 6.80 ppm, respectively) and couple to each other with $^4J(H,H)$ of 1.7 Hz. Cross peaks in this spectrum rep-

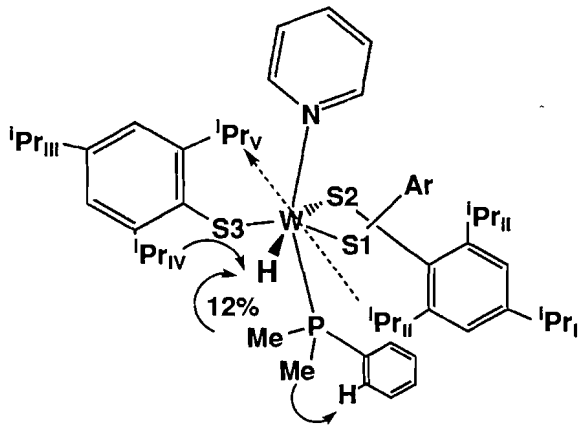
resenting close contacts between the tipt aromatic protons and certain isopropyl groups allowed the assignment of the individual isopropyl methine and methyl resonances. An intergroup contact between the methine protons of isopropyl groups V and II (dotted line in Fig. 4) was another indication that the structure in solution is very similar to the structure in the crystal. The distance between methine hydrogen H57 (on the isopropyl group II of Fig. 4 containing the label C59 in Fig.

Fig. 4. Labelling of the groups of **2**, and important NOE contacts.



3, which is behind the tungsten atom) and methine hydrogen H77 (on the group V of Fig. 4 with the label C79 in Fig. 3 behind the pyridine ring) is short at 2.58 Å. There is a corresponding set of methine hydrogens related to H57 and H77 on the other groups II and V by the pseudo mirror plane; these are

[a]Only observed below 5°C in toluene-d_8 by use of a 500 MHz spectrometer.

H51 and H37, which are separated by 2.30 Å in the crystal. These are the shortest distances between pairs of methine protons. The NOESY spectrum also revealed that the hydride and phosphine methyls are in close proximity, as did the NOED spectra as described below.

The NOESY spectrum did not show the expected cross peak between the *para* and *meta* protons on the pyridine ligand; in fact no *meta* or *para* peaks are visible at room temperature, 500 MHz. The explanation for this became apparent when the variable temperature ^1H spectrum was recorded (shown, in part, in Fig. 5). At −60°C the doublet of the hydride of **2** appears centred at 9.25 ppm and broadens somewhat. It is not known why the hydride resonances shift with temperature. In addition, there is a doublet at 9.48 ppm with a small coupling, ^3J(H,H), of 5 Hz that is assigned to one *ortho* proton of the pyridine ligand. The other *ortho* proton doublet is centred at 6.41 ppm while the *meta* protons are pseudo triplets at 6.36 and 5.41 ppm (Table 5). When the sample is warmed to 5°C these pyridine peaks broaden because of exchange due to pyridine rotation. In a 200 MHz spectrum of **2** at 20°C in C_6D_6, a very broad peak is observed at 5.9 ppm that corresponds to the coalesced lineshape of the *meta* proton resonances. From this information an approximate free-energy barrier to rotation of 14 kcal/mol can be calculated.

Proton NOED spectra of **2** in C_6D_6 at 25°C (Fig. 6) and the knowledge of the proton assignments were used to locate the hydride ligand. Irradiating the methyl resonances of the phosphine at 2.09 ppm, Fig. 6(*d*), caused a 12% enhancement in the hydride resonances as well as an enhancement of the *ortho* phenyl protons of the phosphine at 7.76 ppm. Irradiating the hydride doublet, Fig. 6(*a*), caused a 1% enhancement in the phosphine methyl doublet as well as increases in intensity of the *ortho* phenyl protons of the phosphine, the methine proton of isopropyl group IV at 3.20 ppm, and possibly the methine hydrogens of groups II and V at 3.98 and 3.68 ppm, respectively, as well as the methyl hydrogens of groups II and IV at 1.52, 1.44, and 1.19 ppm. This indicates that the hydride and the phosphine ligand are in close proximity and that the isopropyl groups are positioned predominantly as in the X-ray structure. The observation that irradiating the hydride causes a small enhancement in the phosphine methyl groups (Fig. 6(*a*)) is most likely explained by the fact that relaxation of the hydride is not purely by a dipole–dipole mechanism, see below (16).

The results of irradiation of the tipt aryl resonances at 6.80 (Fig. 6(*b*)) and 6.56 (Fig. 6(*c*)) are consistent with the assignments in Table 5. In (*b*) the peak irradiated consists of the aryl protons of the two "up" tipts (with Pr^iIII and Pr^iIV). This causes enhancement of the methine resonances at 3.20 (Pr^iIV) and 2.66 (Pr^iIII) ppm with the latter showing the greater increase (4%); methyl resonances for groups IV and III are also excited. Irradiation at 6.58 ppm (Fig. 6 (*c*)) excites tipt aryl protons next to groups III and V. The negative enhancement of the *para* pyridine resonance at 6.22 might be due to an error in centering the excitation frequency.

Relaxation measurements on $WH(tipt)_3(py)(PMe_2Ph)$

Unexpectedly the T_1 values of the hydride doublet in the ^1H NMR spectrum of 2 are different; see Tables 6, 7. The lower

[b]In C_6D_6.

frequency peak has a T_1 of 0.72 ± 0.03 s while the other is 0.62 ± 0.02 s at 25°C, 9.4 T. This suggests that another relaxation mechanism than dipole–dipole is important. The minimum T_1 was found to occur between 209 and 220 K at 7.0 T for both resonances.

Könisberger and Sterk (17) state that if there are cross-correlation spectral densities in an AX spin system consisting of two weakly scalar coupled spin 1/2 nuclei with dipole–dipole relaxation, then the two components of each doublet would have different relaxation rates.

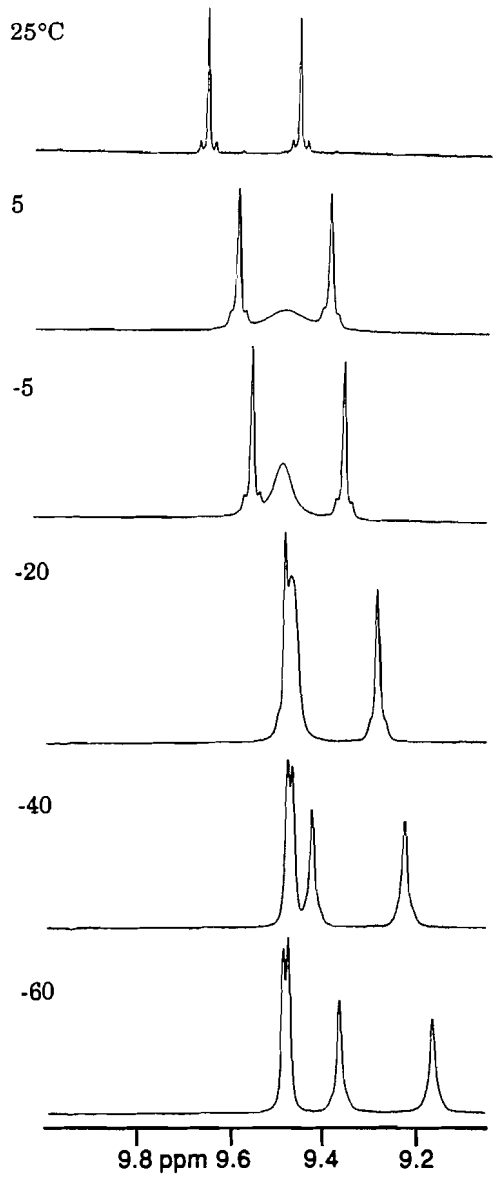
The relationship between the T_1 and the spectrometer field was measured, Fig. 7. If the dipole–dipole mechanism were predominant, in the extreme narrowing conditions ($\omega_0\tau_c << 1$), the T_1 should be independent of the field used. If chemical shift anisotropy is predominant, the T_1 should be related to the inverse of the square of the field strength. In the case where the minimum T_1 is near 25°C, the T_1 would also depend upon the inverse of the square of the field. The observed relationship is linear at low field, then levelling off at the higher field. Since the measured minimum T_1 is near −30°C at 7 T, this indicates that chemical shift anisotropy (csa) is the cause of this levelling. Since the contributions of csa and dipolar relaxation are not additive in this case, the effects are difficult to separate.

Conclusions

The measurement of the contribution of the hydride to the relaxation rate of a neighbouring phosphorus in complex **1** allows the $^1H—^{31}P$ distance to be estimated as 2.2 ± 0.2 Å. This allows an unambiguous positioning of the hydride on the S1,S2,P1 face of the distorted trigonal bipyramid of the WS_3P_2 core (Fig. 2). This is the position suggested for the analogous molybdenum complex on the basis of crystallographic considerations (1) and found in the low-temperature single crystal X-ray structure determination of $WH(SeC_6H_3Pr^i2\text{-}2,6)_3(PMe_2\text{-}Ph)_2$ (11).

The geometry suggested for complex **2** is a trigonal bipyramidal WS_3PN core with a hydride capping a triangular S_2P face. NMR studies suggest that the structure in solution is very

Fig. 5. The variable temperature, 500 MHz, ^1H NMR spectra of **2** in toluene-d_8 in the region containing the hydride resonance.



similar to the one determined in the single crystal by X-ray diffraction. Changes in the variable temperature ^1H NMR spectra are explained in terms of restricted rotation of the pyridine ligand, which is observed in the crystal to be sandwiched between two tipt aryl groups. The relaxation rate of the hydride in **2** is determined by contributions from dipolar nuclei and from chemical shift anisotropy of the W—H bond.

A general feature of complexes **1** and **2**, their molybdenum analogues (1, 2), and the complex $MoH(tp)_2(tipt)(PEtPh_2)$ (7) is the large ^2J(H,P) coupling associated with a small P-M-H angle of about 62 ± 7°. The phosphorus–hydride distance is short (≈2 Å) and so ^2J(H,P) might have a through-space component.

Experimental

General

The syntheses of **1** and **2** have been reported previously (1, 2).

NMR samples were prepared under N_2 in 5 mm or 10 mm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

Fig. 6. ^{1}H NOED spectra at 400 MHz of **2** in C_6D_6 at 25°C irradiated at (*a*) the hydride doublet at 9.55 ppm, (*b*) the tipt aryl proton resonance at 6.80 ppm, (*c*) the tipt aryl proton resonance at 6.56 ppm, and (*d*) the phosphine methyl doublet at 2.06 ppm. The singlet at 7.1 ppm in each spectrum is due to the C_6D_6.

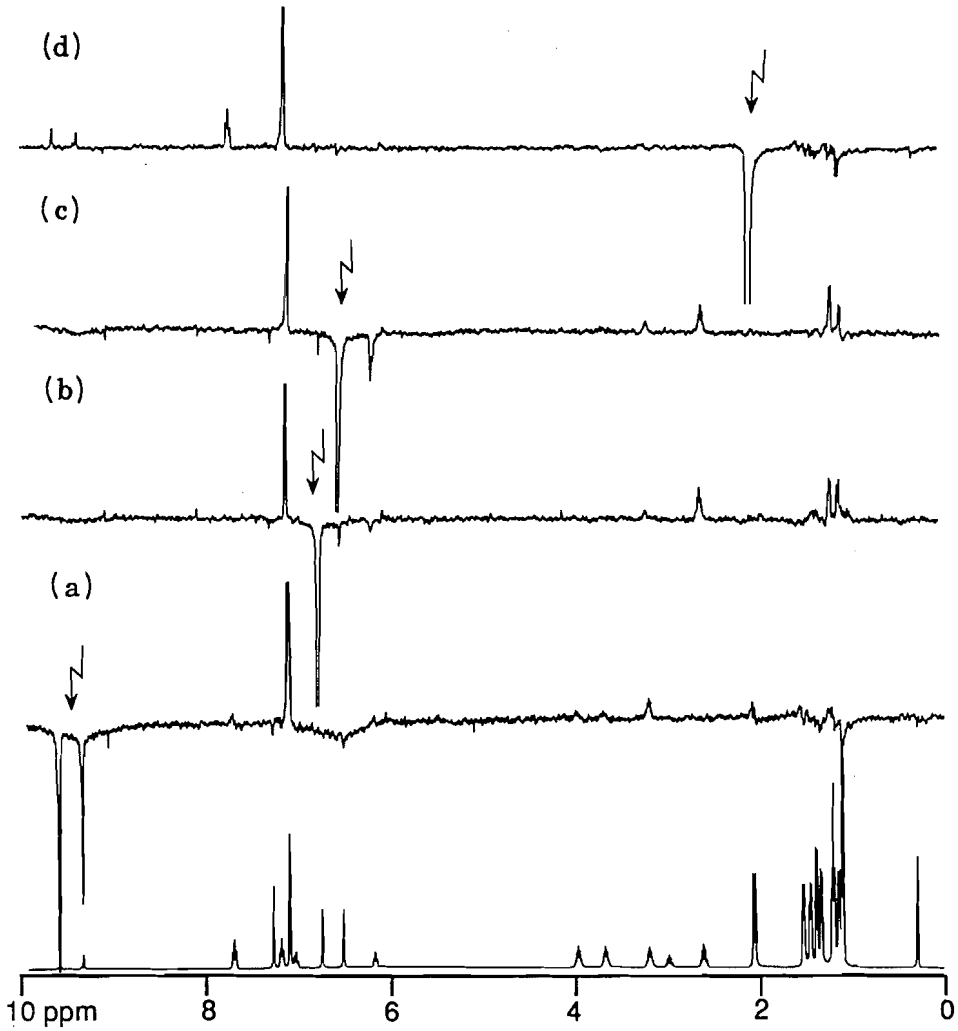


Fig. 7. Plot of T_1 values versus spectrometer field strength for **2** in C_6D_6.

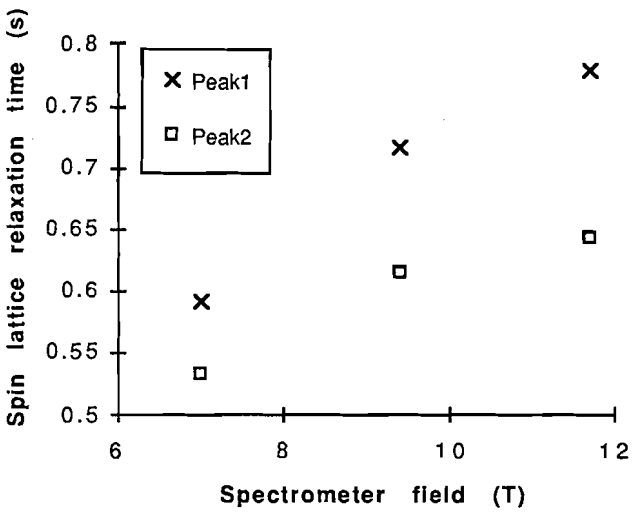

NMR tubes. The spectra were acquired on either a Varian Unity 500 11.8 T machine, a Varian Unity 400 9.4 T machine, a Varian XL-400 9.4 T machine, a Varian Gemini 300 7.0 T machine, a Varian XL-200 4.7 T machine, or a Varian Gemini 200 4.7 T machine. Chemical shifts for ^{31}P were measured internally relative to 1% (v/v) $P(OMe)_3$ in C_6D_6 sealed in coaxial capillaries. ^{31}P NMR are reported as decoupled to ^{1}H unless otherwise indicated. The uncoupled spectra are reported along with significant hydride–phosphorus couplings. ^{1}H chemical shifts are referenced to partially deuterated solvent peaks and are adjusted to the scale of tetramethylsilane (TMS). Deuterated benzene (Cambridge Isotope Laboratories) is the solvent used for proton NMR unless otherwise indicated.

Nuclear Overhauser difference NMR spectroscopy of ***1***

(a) Proton NMR: Data collection was done on a Varian XL-400 using the standard pulse sequence NOEDIF. The sweep width was 5998.8 Hz, the transmitter offset was 800 Hz, $D1$ = 12 s, $D2$ = 50 ms.

Two experiments were conducted. For the first one, $F1$ and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

$F3$ were −1209.5 Hz (corresponding to one half of the doublet of the PMe_2Ph at 1.65 ppm), $F2$ and $F4$ were −1217.3 Hz (corresponding to the other half of the doublet of the PMe_2Ph at 1.65 ppm), OFFRES was 3500 Hz (a blank area of the spectrum downfield). For the second one: $F1$ and $F3$ were −1233.2 Hz (corresponding to one half of the doublet of the PMe_2Ph at 1.70 ppm), $F2$ and $F4$ were −1241.9 Hz (corresponding to the other half of the doublet of the PMe_2Ph at 1.70 ppm), OFFRES was 3500 Hz (a blank area of the spectrum downfield). The irradiation resulted in an asymmetric pattern in the doublet irradiated because only one half of the doublet could be irradiated at one time and so relaxation could occur between the two energy levels.

(b) Phosphorus-31 NMR: Approximately 50 mg of sample was dissolved in about 1 mL of C_6D_6 under N_2 gas.

Data were collected on a Varian XL-400 spectrometer with standard pulse sequences. The hydride resonances were irradiated with low power and a ^{31}P spectrum was acquired. The phosphorus resonances both showed enhancement, the peak at $\delta = -125$ ppm showed 20% enhancement while the peak at −150 ppm showed 15% enhancement.

Heteroscalar correlated two-dimensional NMR spectroscopy of ***1***

The sample (approx. 50 mg) was dissolved in approximately 1 mL C_6D_6 under Ar gas.

Data were collected on a Varian XL-400 using the standard HETCOR pulse sequence assuming a coupling of 11 Hz. Proton NMR was done with a sweep width of 609.3 Hz and transmitter offset of −1400 Hz. Twelve transients were collected, each of 2048 points with 4096 zero points. Phosphorus-31 data collection had a sweep width of 5503.6 Hz with a transmitter offset of −100 Hz.

Measurement of the T_1 values of the phosphorus atoms of ***1***

The T_1 values were measured by use of a Varian Gemini 300 and the standard pulse sequence on a sample of **1** at −57°C in toluene-d_8. The delay was 12 s between pulses and variable delays between the 180° pulse and the 90° observe pulse were 5.45×10^{-3}, 1.65×10^{-2}, 4.94×10^{-2}, 0.148, 0.444, 1.333, 4.000, 12.000 s. Two samples, one of $WH(tipt)_3(PMe_2Ph)_2$ and the other $W^2H(tipt)_3(PMe_2Ph)_2$ (approx. 70% deuterated), were used. The T_1 values for the phosphorus resonances in the partially deuterated sample were used since the resonances for the nondeuterated and deuterated forms could both be measured. The T_1 of the deuterated form (W^2H) was 0.503 ± 0.014 s while the T_1 of the protide form was 0.446 ± 0.011 s.

Crystallization and NMR properties of $WH(tipt)_3(py)(PMe_2Ph)$ (***2***)

The green powder, ca. 100 mg, was dissolved in a minimum amount of hot toluene and then layered with methanol. The mixture was left for 2 weeks at −30°C, producing green crystals. ^1H NMR: (see Table 5). $^{31}P\{^1H\}$ NMR: −118.6 (s; d, $^1J_{PW}$ = 172.3 Hz), $^{31}P\{^1H$ coupled$\}$ NMR: −118.6 (d, $^2J_{PH}$ = 100 Hz; dd, $^2J_{PH}$ = 100 Hz, $^1J_{PW}$ = 172.3 Hz).

Nuclear Overhauser difference NMR spectroscopy of ***2***

The data were collected on a Varian XL-400 using standard pulse sequences. About 50 mg of sample was dissolved in approximately 0.5 mL of C_6D_6.

Homonuclear decoupling NMR spectroscopy of ***2***

The sample, approximately 30 mg, was dissolved in about 1 mL of C_6D_6. Data were acquired on a Varian Gemini-200 with decoupler hardware. The five spectra were recorded with homonuclear decoupler offsets (DO) at −536.4 Hz (2.61 ppm), −461.0 Hz (2.99 ppm), −418.5 Hz (3.20 ppm), −322.5 Hz (3.68 ppm), and −263.2 Hz (3.98 ppm). For all cases the decoupler low power (DLP) was 1800 and DHP was 1.0. The sweep width was 3000.3 Hz for all spectra, with NP of 16 000, PW of 10 ms, and 64 transients were collected.

NOESY NMR spectroscopy of ***2***

Approximately 20 mg of **2** was dissolved in 0.5 mL of toluene-d_8. The sample was run on a 500 MHz (11.8 T) Varian Unity-500 using the standard Varian NOESY pulse sequence. The mixing time was 600 ms.

Single crystal X-ray structure data for $[WH(tipt)_3(py)(PMe_2Ph)]$

Crystal data: $C_{58}H_{86}NPS_3W$, M = 1108.3, orthorhombic, space group $P2_12_12_1$ (no. 19), a = 15.954(5), b = 17.410(3), c = 20.322(4) Å, U = 5644(2) Å^3, Z = 4, D_c = 1.304 g cm^{-3}, T = 150 K, $F(000)$ = 2312, μ(Mo-Kα) = 22.6 cm^{-1}, λ(Mo-Kα) = 0.71069 Å, R = 0.040 for 4205 reflections with $I > 2.5\sigma(I)$.

Data collection: The dark-green crystal had dimensions 0.25 × 0.20 × 0.35 mm. Intensity data were collected on an Enraf–Nonius CAD-4 diffractometer using graphite monochromated Mo-Kα radiation. The ω–2θ scan technique was applied with variable scan speeds. Intensities of three standard reflections measured every 2 h showed less than 1% decay. An empirical absorption correction (18) was applied to the data (max. and min. corrections 1.112 and 0.906).

Structure solution: The coordinates of the W atom were determined from a Patterson map and the positions of the other non-hydrogen atoms were located from successive Fourier and difference Fourier maps. All non-hydrogen atoms were refined with anisotropic thermal parameters by block-diagonal least squares to minimize $\Sigma\omega(F_o - F_c)^2$, where $\omega = (\sigma(F)^2 + 0.005\,F_o^2)^{-1}$. Hydrogen atoms were positioned on geometric grounds (C—H 0.95 Å, U(H) = U(C) + 0.01 Å^2).

All calculations were carried out on an Apollo DN10000 computer using NRCVAX (19), SHELX-76 (20), and SHELXS-86 (21).

Tables: Final atomic coordinates and selected bond distances and angles are listed in Tables 2 and 3, respectively. Complete lists of atomic parameters, thermal parameters, crystal structure information, and bond distances and angles have been deposited as Tables S1–S4.[2]

Abstract: Ruthenium(II) complexes of the thiacyclophane ligands 2,5,8-trithia[9]-*o*-cyclophane (TT[9]OC) and 5-oxa-2,8-dithia[9]-*o*-cyclophane (ODT[9]OC) were synthesized by ligand displacement reactions employing $RuCl_2(DMSO)_4$, $RuCl_2(PPh_3)_3$, and $RuHCl(PPh_3)_3$ as starting materials. X-ray crystal structures of two of these complexes, $RuCl_2(DMSO)(TT[9]OC)$ and $RuCl_2(PPh_3)(ODT[9]OC)$, demonstrate how TT[9]OC and ODT[9]OC bind to Ru(II). $RuCl_2(DMSO)(TT[9]OC)$ crystallized as the DMSO solvate in the orthorhombic space group *Pbca* with $a = 19.590(5)$, $b = 16.849(4)$, $c = 13.149(4)$ Å, $V = 4340(3)$ Å^3, and $Z = 8$. The structure refined to $R = 5.27\%$ and $R_w = 6.27\%$ for 2472 reflections with $F_o^2 > 3\sigma(F_o^2)$. $RuCl_2(PPh_3)$-(ODT[9]OC) crystallized as a $ClCH_2CH_2Cl$ solvate in the monoclinic space group $P2_1/c$ with $a = 7.912(1)$, $b = 22.419(5)$, $c = 18.794(3)$ Å, $\beta = 101.12(1)°$, $V = 3271.2(9)$ Å^3, and $Z = 4$. The structure refined to $R = 4.96\%$ and $R_w = 5.14\%$ for 1800 reflections with $F_o^2 > 3\sigma(F_o^2)$. Both compounds are octahedral with the thiacyclophane ligand bound through three donor atoms in a *facial* coordination mode, *cis* chlorine atoms, and the unique ancillary ligand, DMSO or PPh_3, bound *trans* to the central S or O donor of the macrocycle. The X-ray structures support ^{1}H NMR spectral evidence which shows that the ligands are bound in an "*endo*" mode for L = DMSO and in an "*exo*" mode when L = PPh_3. The reaction of $RuHCl(PPh_3)_3$ with TT[9]OC yields the ruthenium hydride complex $RuHCl(PPh_3)_2(TT[9]OC)$. ^{1}H and ^{31}P NMR spectroscopy are consistent with an octahedral species for which the macrocycle occupies only two coordination sites acting as a bidentate η^2-chelating ligand.

Key words: thioether, macrocycle, hydride, crystal structure.

Résumé : On a synthétisé les complexes du ruthénium contenant des coordinats thiacyclophanes (2,5,8-trithia[9]-*o*-cyclophane, TT[9]OC, et 5-oxa-2,8-dithia[9]-*o*-cyclophane, ODT[9]OC, en soumettant les $RuCl_2(DMSO)_4$, $RuCl_2(PPh_3)_3$ et $RuHCl(PPh_3)_3$ à des réactions de déplacement de coordinats. Les structures cristallines (déterminées par diffraction des rayons X) de deux de ces complexes, $RuCl_2(DMSO)(TT[9]OC)$ et $RuCl_2(PPh_3)(ODT[9]OC)$, démontrent la façon dont le TT[9]OC et le ODT[9]OC se lient au Ru(II). Le $RuCl_2(DMSO)(TT[9]OC)$ cristallise sous une forme solvatée par du DMSO; les cristaux sont orthorhombiques, groupe d'espace *Pbca*, avec $a = 19,590(5)$, $b = 16,849(4)$ et $c = 13,149(4)$ Å, $V = 4340(3)$ Å^3 et $Z = 8$. On a affiné la structure jusqu'à des valeurs de R et R_w de 5,27 et 6,27% respectivement pour 2472 réflexions avec $F_o^2 > 3\sigma(F_o^2)$. Le $RuCl_2(PPh_3)(ODT[9]OC)$ cristallise sous une forme solvatée par du $ClCH_2CH_2Cl$; les cristaux sont monocliniques, groupe d'espace $P2_1/c$, avec $a = 7,912(1)$, $b = 22,419(5)$ et $c = 18,794(3)$ Å, $\beta = 101,12(1)°$, $V = 3271,2(9)$ Å^3 et $Z = 4$. On a affiné la structure jusqu'à des valeurs de R et R_w de 4,96 et 5,14% respectivement pour 1800 réflexions avec $F_o^2 > 3\sigma(F_o^2)$. Les deux composés sont octaédriques avec le coordinat thiacyclophane lié par trois atomes donneurs dans un mode de coordination *facial*; l'atome de chlore est *cis* et le coordinat ancillaire unique, DMSO ou PPh_3, est lié d'une façon *trans* à l'atome donneur central, O ou S, du macrocycle.

Les données de la diffraction des rayons X sont en accord avec celles de la RMN du ^1H qui montrent que les coordinats sont liés dans un mode *endo* pour L = DMSO et dans un mode *exo* lorsque L = PPh_3. La réaction du $RuHCl(PPh_3)_3$ avec le TT[9]OC fournit l'hydrure complexe du ruthénium, $RuHCl(PPh_3)_2$(TT[9]OC). Les données de la spectroscopie RMN du ^1H et du ^{31}P sont en accord avec l'existence d'une espèce octaédrique dans laquelle le macrocycle occuperait seulement deux sites de coordination et agirait comme un coordinat η^2-chélatant bidentate.

Mots clés : thioéther, macrocycle, hydrure, structure cristalline.

Introduction

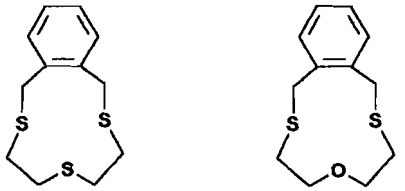
Until recently, most crown thioether complexes were synthesized for investigations into oxidation state stability and electrochemical properties (1–3). However, investigations by Schröder and co-workers (4), Hill and co-workers (5), and our group (6) have shown that crown thioether complexes of Ru, Rh, and Ir that contain organic ligands such as olefins, σ-vinyl, and thiocarbonyl groups can be prepared. In this regard, Hill (5) showed that the reaction of $[Ru(CH{=}CHR)Cl(CO)(PPh_3)_2]$ with 9S3 (1,4,7-trithiacyclononane) gives $[Ru(CH{=}CHR)(CO)(PPh_3)(9S3)]Cl$ in quantitative yield (*5a*) and Bennett et al. (7) have shown that intramolecular deprotonation, ring opening, and subsequent C—C bond formation occurs when $[Ru(\eta^6\text{-}C_6Me_6)(9S3)][PF_6]_2$ reacts with KO^{t}Bu to yield $[Ru(SCH{=}CH_2)(\eta^6\text{-}C_6Me_5CH_2CH_2CH_2SCH_2CH_2S)]$. This base-induced bond cleavage was found to be irreversible (reprotonation did not occur) and the study suggested that this may limit the extent to which crown thioethers can be attached to electron-rich transition metal centres, and the reaction chemistry they promote or undergo. Ru(II) crown thioether complexes have also been utilized in the modelling of the active sites of the oxidoreductases (8, 9). The influence of the thioether ligand appears to be important in these models, in that there is a tendency to stabilize unusual structures, oxidation states, and species containing NO and N_2H_4.

The thiacyclophane ligands 2,5,8-trithia[9]-*o*-cyclophane (TT[9]OC) and 5-oxa-2,8-dithia[9]-*o*-cyclophane (ODT[9]-OC) also have the potential to bind metal centres as tridentate capping ligands, similar to 9S3, tripodal phosphine, pyrazolylborate, η^5-cyclopentadienyl, or η^6-arene ligands (10–12). In this paper, we describe synthetic routes to the complexes $RuCl_2(X)(L)$ (X = DMSO, PPh_3 and L = TT[9]OC, ODT[9]OC), as well as the hydride complex $RuHCl(PPh_3)_2$(TT[9]OC). NMR spectroscopic characterization of these species is presented along with the X-ray crystal structures of $RuCl_2$(DMSO)(TT[9]OC) and $RuCl_2(PPh_3)$-(ODT[9]OC).

Experimental section

$RuCl_2(PPh_3)_3$ (13), $RuHCl(PPh_3)_3$ (14), TT[9]OC (15), ODT[9]OC (6), and $RuCl_2(DMSO)_4$ (16) were prepared by literature methods. All deuterated solvents were purchased from Aldrich and used as received. All reactions were carried out under an atmosphere of N_2 using standard Schlenk techniques, and all solvents were dried and degassed prior to use. ^1H NMR spectra were recorded at 300.1 MHz on a Bruker AC300 spectrometer locked to the deuterated solvent. $^{31}P\{^1H\}$ NMR spectra were recorded at 81.0 MHz on a Bruker AC200 spectrometer with an external H_3PO_4 reference. Infrared spectra were recorded on a Nicolet 5DX FTIR spectrometer. Elemental analyses were performed by Canadian Microanalytical Services, Delta, British Columbia.

Scheme 1.



Synthesis of $RuCl_2$(DMSO)(TT[9]OC)

To a yellow solution of $RuCl_2(DMSO)_4$ (330 mg, 0.68 mmol) in $CHCl_3$ (10 mL) was added a colourless solution of TT[9]OC (175 mg, 0.68 mmol) in $CHCl_3$ (5 mL). The clear yellow solution was refluxed for 2 h, producing an orange solution. The solvent was removed and the resulting solid was washed with diethyl ether (2 × 5 mL). The product was recrystallized from DMSO, yielding orange crystals of the complex as the DMSO solvate. Yield 302 mg, 76%. ^1H NMR of the initial reaction product showed the presence of two isomers with an A:B ratio of 1:4. ^1H NMR ($CDCl_3$), isomer A, δ: 7.26–7.16 (m, 4H, aromatic), 4.61 (d, 2H, benzylic, J = 14.1 Hz), 3.81 (d, 2H, benzylic, J = 14.1 Hz), 3.53 (s, 3H, SCH_3), 3.45 (s, 3H, SCH_3), 2.81–2.58 (m, 4H, SCH_2), 2.17–1.68 (m, 4H, SCH_2). Isomer B, δ 7.26–7.16 (m, 4H, aromatic), 4.89 (d, 1H, benzylic, J = 14.0 Hz), 4.78 (d, 1H, benzylic, J = 13.7 Hz), 3.92 (d, 1H, benzylic, J = 14.0 Hz), 3.86 (d, 1H, benzylic, J = 13.7 Hz), 3.38 (s, 3H, SCH_3), 3.29 (s, 3H, SCH_3), 2.81–2.58 (m, 4H, SCH_2), 2.17–1.68 (m, 4H, SCH_2). Anal. calcd. for $C_{16}H_{28}Cl_2O_2RuS_5$: C 32.86, H 4.84; found: C 33.19, H 4.98.

Synthesis of $RuCl_2$(DMSO)(ODT[9]OC)

To a yellow solution of $RuCl_2(DMSO)_4$ (243 mg, 0.52 mmol) in $CHCl_3$ (10 mL) was added a colourless solution of ODT[9]OC (121 mg, 0.52 mmol) in $CHCl_3$ (5 mL). The clear yellow solution was refluxed for 2 h, producing a yellow-orange solution. The solvent was removed and the resulting solid washed with diethyl ether (2 × 5 mL). Yield 219 mg, 89%. ^1H NMR of the initial reaction product showed the presence of two isomers with an A:B ratio of 1:1. ^1H NMR ($CDCl_3$), isomer A, δ: 7.31–7.16 (m, 4H, aromatic), 4.82 (d, 2H, benzylic, J = 14.2 Hz), 4.32–4.19 (m, 4H, OCH_2), 3.85 (d, 2H, benzylic, J = 14.2 Hz), 3.49 (s, 3H, SCH_3), 3.38 (s, 3H, SCH_3), 2.98–2.05 (m, 4H, SCH_2). Isomer B, δ: 7.31–7.16 (m, 4H, aromatic), 4.57 (d, 1H, benzylic, J = 13.9 Hz), 4.56 (d, 1H, benzylic, J = 13.5 Hz), 4.32–4.19 (m, 4H, OCH_2), 4.06 (d, 1H, benzylic, J = 13.9 Hz), 3.85 (d, 1H, benzylic, J =

13.5 Hz), 3.44 (s, 3H, SCH_3), 3.37 (s, 3H, SCH_3), 2.98–2.05 (m, 4H, SCH_2). Anal. calcd. for $C_{14}H_{22}Cl_2O_2RuS_3$: C 34.28, H 4.53; found: C 34.09, H 4.44.

Synthesis of $RuCl_2(PPh_3)$(TT[9]OC)

To a brown solution of $RuCl_2(PPh_3)_3$ (1.00 g, 1.04 mmol) in CH_2Cl_2 (30 mL) was added a solution of TT[9]OC (267 mg, 1.04 mmol) in CH_2Cl_2 (10 mL). The brown solution was stirred for 12 h, becoming orange. Solvent was removed in vacuo, and the orange oil washed with diethyl ether (4 × 10 mL) to remove excess PPh_3. The product was dried under vacuum, and recrystallized by cooling a concentrated CH_2Cl_2 solution to −20°C for 24 h. Yield 583 mg, 81%. ^1H NMR showed the presence of two isomers with an A:B ratio of 1:1. ^1H NMR ($CDCl_3$), isomer A, δ: 8.09 (m, 3H, PPh_3), 7.91 (m, 3H, PPh_3), 7.66 (m, 3H, PPh_3), 7.44–6.96 (m, 10H, PPh_3, TT[9]OC), 3.30 (d, 2H, benzylic, J = 14.2 Hz), 2.87 (d, 2H, benzylic, J = 14.2 Hz), 3.02–2.49 (m, 4H, SCH_2), 1.97–1.23 (m, 4H, SCH_2). Isomer B, δ: 8.09 (m, 3H, PPh_3), 7.91 (m, 3H, PPh_3), 7.66 (m, 3H, PPh_3), 7.44–6.96 (m, 10H, PPh_3, TT[9]OC), 5.34 (d, 1H, benzylic, J = 14.1 Hz), 5.20 (d, 1H, benzylic, J = 13.1 Hz), 3.88 (d, 1H, benzylic, J = 14.1 Hz, J = 8.0 Hz), 3.74 (d, 1H, benzylic, J = 13.1 Hz), 3.02–2.49 (m, 4H, SCH_2), 1.97–1.23 (m, 4H, SCH_2). $^{31}P\{^1H\}$ NMR (CH_2Cl_2), isomer A, δ: 36.61 (s, PPh_3). Isomer B, δ: 32.06 (s, PPh_3). Anal. calcd. for $C_{30}H_{31}Cl_2PRuS_3$: C 52.16, H 4.53; found: C 51.89, H 4.40.

Synthesis of $RuCl_2(PPh_3)$(ODT[9]OC)

Method 1

To a brown solution of $RuCl_2(PPh_3)_3$ (1.00 g, 1.04 mmol) in CH_2Cl_2 (50 mL) was added a solution of ODT[9]OC (250 mg, 1.04 mmol) in CH_2Cl_2 (10 mL). The mixture was stirred for 3 days, during which time the solution turned orange and an orange precipitate formed. Solvent was removed in vacuo, and the orange residue was washed with toluene (3 × 15 mL) and dried under vacuum. The product was recrystallized by cooling a CH_2Cl_2 solution to −20°C for 24 h. Yield 547 mg, 78%. ^1H NMR ($CDCl_3$), isomer A, δ: 8.09 (m, 9H, PPh_3), 7.74–7.01 (m, 10H, PPh_3 ODT[9]OC), 4.45 (m, 4H, OCH_2), 3.34 (d, 2H, benzylic, J = 13.9 Hz), 2.96 (d, 2H, benzylic, J = 13.9 Hz), 2.92 (m, 2H, SCH_2), 2.80 (m, 4H, SCH_2), 2.51 (m, 2H, SCH_2). $^{31}P\{^1H\}$ NMR (CH_2Cl_2), δ: 56.21 (s, PPh_3). Anal. calcd. for $C_{30}H_{31}Cl_2OPRuS_2$: C 53.40, H 4.64; found: C 53.22, H 4.43.

Method 2

$RuCl_2(PPh_3)_3$ (1.00 g, 1.04 mmol) and ODT[9]OC (250 mg, 1.04 mmol) were stirred together in toluene (50 mL) for 2 days, forming a yellow slurry. The mixture was filtered in air on a Buchner funnel, and washed with toluene (2 × 10 mL). The crude product was then recrystallized by cooling a CH_2Cl_2 solution to −20°C. Yield 510 mg, 73%. ^1H NMR showed the presence of two isomers with an A:B ratio of 1:1. Data for isomer A is given above. ^1H NMR ($CDCl_3$), isomer B, δ: 7.76–7.11 (m, 19H, aromatic), 5.02 (d, 1H, benzylic, J = 13.8 Hz), 4.71 (d, 1H, benzylic, J = 13.2 Hz), 4.28 (m, 4H, OCH_2), 4.00 (d, 1H, benzylic, J = 13.8 Hz), 3.94 (d, 1H, benzylic, J = 13.2 Hz), 2.83 (m, 4H, SCH_2). $^{31}P\{^1H\}$ NMR (CH_2Cl_2), δ: 41.73 (s, PPh_3).

Synthesis of $RuHCl(PPh_3)_2$(TT[9]OC)

$RuHCl(PPh_3)_3$ (200 mg, 0.216 mmol) was suspended in benzene (10 mL) under N_2, and a solution of TT[9]OC (56 mg, 0.216 mmol) in benzene (10 mL) was added via syringe. The $RuHCl(PPh_3)_3$ dissolved, the solution became brown, and an off-white precipitate formed after 15 min. After stirring for 2 h, the solid was filtered on a Schlenk filter, washed with benzene (2 × 3 mL), and dried in vacuo. Yield of pale yellow microcrystals: 85 mg, 43%. IR: ν(Ru–H) 1939 cm^{-1}. ^1H NMR (acetone-d_6), δ: 7.83 (m, 4H, TT[9]OC aromatic), 7.61–7.14 (m, 30H, PPh_3), 4.00 (s, 2H, benzylic), 3.96 (d, 1H, benzylic, J = 13.2 Hz), 3.85 (d, 1H, benzylic, J = 13.2 Hz), 3.24 (m, 2H, SCH_2), 3.02 (m, 2H, SCH_2), 2.88 (m, 2H, SCH_2), −0.01 (td, 1H, SCH_2), −0.39 (td, 1H, SCH_2), −11.69 (dd, 1H, Ru-H, J_{P-H} = 20.2 Hz). $^{31}P\{^1H\}$ NMR (acetone), δ: 53.84 (d, PPh_3, J_{P-P} = 32.7 Hz), 50.37 (d, PPh_3). Anal. calcd. for $C_{48}H_{47}ClP_2RuS_3$: C 62.76, H 5.17; found: C 62.13, H 5.05.

General X-ray crystallography

Diffraction experiments were performed on a four-circle Rigaku AFC6S diffractometer with graphite monochromatized Mo Kα radiation. The unit cell constants and orientation matrices for data collection were obtained from 20 centred reflections (15° < 2θ < 35°). Instrument parameters, crystal data, and data collection parameters are summarized in Table 1. The intensities of three standard reflections were recorded every 150 reflections and showed no statistically significant changes over the duration of the data collections. The intensity data were collected using the ω–2θ scan technique, in four shells (2θ < 30,° 40,° 45,° and 50°). Empirical absorption coefficients were calculated and absorption corrections applied to the data. The data were processed using the TEXSAN software package running on an SGI Challenge XL computer system.[2] Refinements were carried out by using full-matrix least-squares techniques on F by minimizing the function $\Sigma w(|F_o| - |F_o|)^2$, where $w = 1/\sigma^2(F_o)$ and F_o and F_c are the observed and calculated structure factors. Atomic scattering factors (17) and anomalous dispersion terms (18, 19) were taken from the usual sources. Fixed H-atom contributions were included with C—H distances of 0.95 Å and thermal parameters 1.2 times the isotropic thermal parameters of the bonded C atoms. No H atoms were refined, but all values were updated as refinement continued.

X-ray structure determination of $RuCl_2$(DMSO)(TT[9]OC)

Orange crystals of $RuCl_2$(DMSO)(TT[9]OC) suitable for X-ray diffraction were grown by vapour diffusion of diethyl ether into a DMSO solution of the complex. A statistical analysis of intensity distributions and a determination of systematic absences were consistent with the space group *Pbca*. This was confirmed by a successful structure refinement. A total of 4282 reflections were collected and 2472 reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. The position of the ruthenium atom was determined using direct methods and the *E*-map with highest figure of merit. The remaining non-hydrogen atoms were located from successive difference Fourier calculations. In the final cycles of refinement, the ruthenium, chlo-

rine, sulphur, oxygen, and carbon atoms of the complex were assigned anisotropic thermal parameters while the atoms of the DMSO solvent molecule were refined with isotropic thermal parameters. During refinement it became apparent that the DMSO solvent molecule was severely disordered. Repeated Fourier analyses produced a single central sulphur atom with three other major peaks in a triangular arrangement about the centre. Any attempt to model this as overlapping DMSO molecules with separate sulphurs, with or without threefold disorder about the three remaining atoms, resulted in a single central sulphur atom with a relatively large thermal parameter. Since there is no question the molecule of solvation is DMSO and since variations in the disorder model had insignificant effects on the geometric parameters for the complex, the solvent molecule was modelled as a single entity with a flattened geometry and a large thermal parameter for the S-atom. This resulted in $R = 5.27\%$ and $R_w = 6.27\%$ at convergence. A goodness-of-fit calculation resulted in a value of 3.21, and a final difference Fourier map calculation showed a maximum residual of 1.2 e/Å^3 associated with the solvent molecule, S(5). Atomic positional parameters and selected bonding parameters are summarized in Tables 2 and 3. Thermal parameters, hydrogen atom parameters, and a listing of $10|F_o|$ vs. $10|F_c|$ are deposited as supplementary material in Tables S-1, S-2, and S-5.[3]

X-ray structure determination of $RuCl_2(PPh_3)(ODT[9]OC)$

Orange crystals of $RuCl_2(PPh_3)(ODT[9]OC)$ suitable for X-ray diffraction were grown by cooling a dichloroethane solution of the complex to −20°C for 3 days. A statistical analysis of intensity distributions and determination of systematic absences were consistent with the space group $P2_1/c$. This was confirmed by a successful structure refinement. A total of 3459 reflections were collected and 1800 reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. Intensities of the standard reflections showed significant decay (18.4%) above $2\theta = 40°$ due to loss of solvent from the crystal lattice; therefore a linear decay correction was applied to the data. The position of the ruthenium atom was determined using direct methods and the E-map with highest figure of merit, and the remaining non-hydrogen atoms were located from successive Fourier calculations. In the final cycles of refinement, the ruthenium, sulphur, oxygen, phosphorous, and chlorine atoms were assigned anisotropic thermal parameters and the carbons isotropic thermal parameters, resulting in $R = 4.96\%$ and $R_w = 5.14\%$. A goodness-of-fit calculation resulted in a value of 1.92, and a final difference Fourier map calculation showed a maximum residual of 0.4 e/Å^3 associated with the solvent molecule, Cl(3). Atomic positional parameters and selected bonding parameters are summarized in Tables 4 and 5. Thermal parameters, hydrogen atom parameters, and a listing of $10|F_o|$ vs. $10|F_c|$ are deposited as supplementary material in Tables S-3, S-4, and S-6.[3]

[3] Supplementary Tables S-1–S-6 may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of nonessential bonding parameters and hydrogen atom parameters have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[a]Atoms of the noncoordinated DMSO solvent molecule. See the text for a description of the disorder.

Results and discussion

The ligands TT[9]OC and ODT[9]OC easily displace three molecules of DMSO from $RuCl_2(DMSO)_4$ to produce the octahedral complexes $RuCl_2$(DMSO)(TT[9]OC) and $RuCl_2$(DMSO)(ODT[9]OC) in which the thiacyclophane ligand occupies three coordination sites in a *facial* arrangement. ^{1}H NMR spectra of the initial products indicate that two isomers exist in $CDCl_3$ solution with A:B ratios of 1:4 and 1:1 for $RuCl_2$(DMSO)(TT[9]OC) and $RuCl_2$(DMSO)-(ODT[9]OC), respectively. These isomers exist because there are two possible positions for the unique DMSO ligand: *trans* to the benzylic S-atoms or *trans* to the central donor (S or O) of the thiacyclophane. The two isomers are easily distinguished by their NMR spectra since isomer A contains a mirror plane and is therefore symmetrical while isomer B is asymmetric and the number of resonances observed is doubled.

Recrystallization of $RuCl_2$(DMSO)(TT[9]OC) from DMSO over a 2 week period yields crystals of isomer A as the DMSO adduct and the X-ray structure was determined. The unit cell contains eight molecules of $RuCl_2$(DMSO)(TT[9]OC) and eight molecules of DMSO. A perspective ORTEP drawing of the complex is shown in Fig. 1. $RuCl_2$(DMSO)(TT[9]OC) is six-coordinate with a slightly distorted octahedral geometry at the Ru(II) centre; Cl(1)-Ru-S(3) 174.0(1),° Cl(2)-Ru-S(1) 170.5(1)°, and S(2)-Ru-S(4) 176.8(1)°. TT[9]OC is coordinated *facially*, with Ru—S(benzylic) distances of Ru—S(1) 2.300(3) Å and Ru—S(3) 2.292(3) Å and a Ru—S(2) distance of 2.351(3) Å. The seven-membered chelate ring spans an angle of S(1)-Ru-S(3) 104.1(1)° and the angles at Ru for the five-membered chelate rings are S(1)-Ru-S(2) 88.1(1)° and S(2)-Ru-S(3) 87.6(1)°. The DMSO ligand is sulphur-bound *trans* to the central S(2) atom with a Ru—S(4) distance of

2.279(4) Å. The two chlorine atoms occupy the two remaining coordination sites: Ru—Cl(1) 2.459(3) Å and Ru—Cl(2) 2.453(4) Å. The Ru—S(benzylic) bond distances are slightly shorter than published Ru—S distances, which range from 2.377 Å for $[Ru(9S3)_2][BPh_4]_2$ (20) to 2.356 Å for $RuCl_2(PPh_3)(9S3)$ (5*c*). This is probably due to the increased flexibility of TT[9]OC compared to 9S3. All other bond distances and angles compare well to those reported. Attempts to isolate a single isomer of $RuCl_2$(DMSO)(ODT[9]OC) by recrystallization from DMSO failed to produce suitable quality crystals.

Both TT[9]OC and ODT[9]OC react slowly with $RuCl_2(PPh_3)_3$ at room temperature, displacing two PPh_3 ligands to yield the coordinatively saturated complexes $RuCl_2(PPh_3)$(TT[9]OC) and $RuCl_2(PPh_3)$(ODT[9]OC). These complexes are soluble in chlorinated solvents, likely due to hydrogen bonding that occurs between the chlorinated solvent, the chloride ligands, and the macrocycle ethylene protons, as observed for the complex $RuCl_2(PPh_3)(9S3)$ (5*b*). They are not, however, soluble in other polar organic solvents such as acetone or acetonitrile, but are soluble in DMSO. Analogous to the complexes with DMSO ligands, those with PPh_3 can exist in two isomeric forms depending on the arrangement of ligands and it was possible to achieve limited control over which isomer was produced by varying the reaction conditions.

$RuCl_2(PPh_3)$(TT[9]OC) was prepared by stirring a CH_2Cl_2 solution of $RuCl_2(PPh_3)_3$ with TT[9]OC for 24 h. This resulted in a moderate, 70%, yield of orange microcrystalline solid after recrystallization from CH_2Cl_2. The ^1H NMR spec-

Scheme 3.

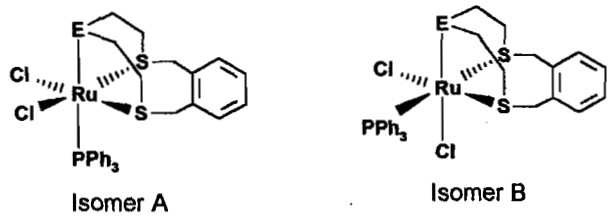

Fig. 1. ORTEP drawing of $RuCl_2(DMSO)(TT[9]OC)$ showing the atom-numbering scheme. Thermal ellipsoids of 30% probability are shown.

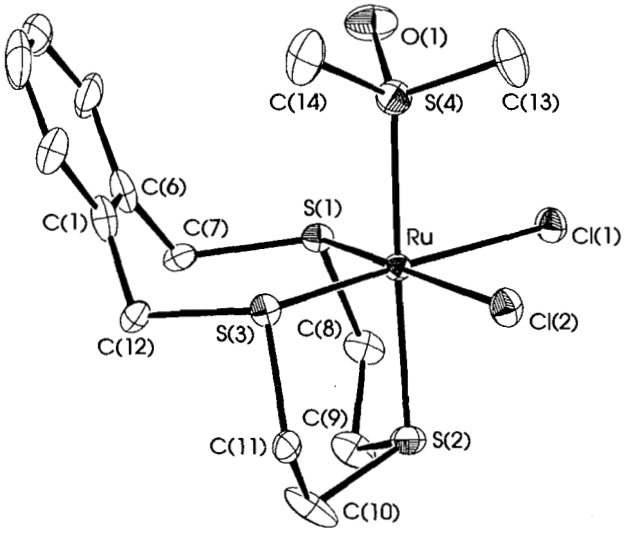
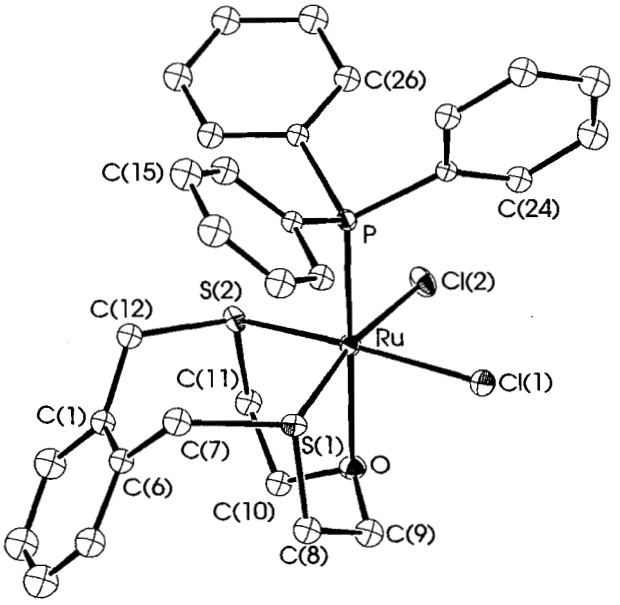


trum showed evidence for both isomers A and B. The $^{31}P\{^1H\}$ NMR spectrum of the mixture shows two resonances at δ 36.61 and 32.06 ppm. Since the PPh_3 ligand is *trans* to sulphur in both isomers, it is not expected that these resonances would be significantly different.

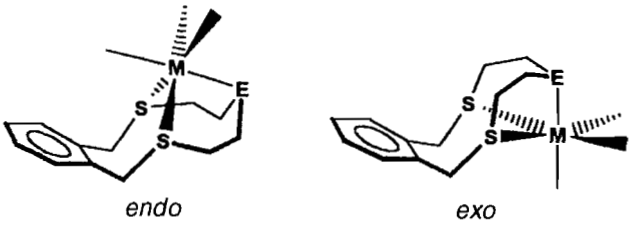
$RuCl_2(PPh_3)(ODT[9]OC)$ is an air-stable, yellow solid obtained in moderate yield by cooling a concentrated CH_2Cl_2 solution of the complex. The ^1H NMR spectrum of $RuCl_2(PPh_3)(ODT[9]OC)$ indicates that only one product is formed when the complex is prepared in CH_2Cl_2. The $^{31}P\{^1H\}$ NMR spectrum of $RuCl_2(PPh_3)(ODT[9]OC)$ shows one resonance at δ 56.21 ppm; the downfield shift compared to $RuCl_2(PPh_3)(TT[9]OC)$ indicates that PPh_3 is *trans* to the oxygen donor of the crown thioether, and this was verified to be isomer A by an X-ray diffraction study (vide infra). The synthesis of $RuCl_2(PPh_3)(ODT[9]OC)$ from toluene results in the formation of two isomers: A in which PPh_3 is *trans* to oxygen, and B, in which PPh_3 is *trans* to sulphur. The ^1H NMR spectrum shows two clearly resolved sets of benzylic resonances for the two isomers and the $^{31}P\{^1H\}$ NMR spectrum shows a second peak at δ 41.73 ppm for isomer B. The mixture of products entirely isomerizes to isomer A after being stirred in chlorinated solvent for 12 h.

Recrystallization of $RuCl_2(PPh_3)(ODT[9]OC)$ from CH_2Cl_2 gave X-ray quality crystals of the complex but these lost solvent in a few hours. Subsequent recrystallization from $Cl(CH_2)_2Cl$ yielded similar crystals and since these lost solvent much more slowly it was possible to obtain an X-ray crystal structure. The unit cell contains four molecules of

Fig. 2. ORTEP drawing of $RuCl_2(PPh_3)(ODT[9]OC)$ showing the atom-numbering scheme. Thermal ellipsoids of 30% probability are shown.



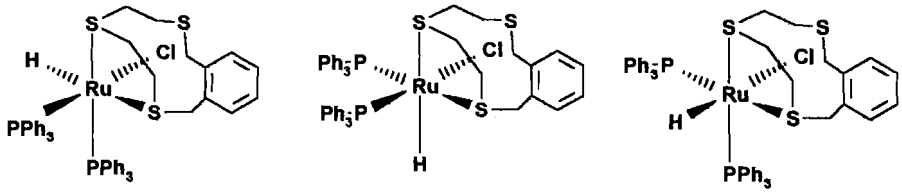
Scheme 4.



$RuCl_2(PPh_3)(ODT[9]OC)$, isomer A, and four molecules of $Cl(CH_2)_2Cl$. A perspective ORTEP drawing of $RuCl_2(PPh_3)(ODT[9]OC)$ is shown in Fig. 2. $RuCl_2(PPh_3)(ODT[9]OC)$ is six-coordinate with a slightly distorted octahedral geometry at the Ru(II) centre; Cl(1)-Ru-S(2) 170.2(1),° Cl(2)-Ru-S(1) 169.7(1)°, and S(2)-Ru-S(4) 179.5(3)°. ODT[9]OC is coordinated *facially*, with Ru—S(benzylic) distances of Ru—S(1) 2.310(4) Å and Ru—S(2) 2.289(3) Å and a Ru—O distance of 2.234(8) Å. The seven-membered chelate ring spans an angle of S(1)-Ru-S(3) of 102.5(1)°, and the angles at Ru for the five-membered chelate rings are S(1)-Ru-O 81.8(2)° and S(2)-Ru-O 83.9(3).° The PPh_3 ligand is *trans* to the central O-donor atom with a Ru—P distance of 2.256(4) Å. The two chlorine atoms occupy the two remaining coordination sites: Ru—Cl(1) 2.429(3) Å and Ru—Cl(2) 2.430(4) Å. As noted previously for $RuCl_2(DMSO)(TT[9]OC)$, the Ru—S(benzylic) bond distances are slightly shorter than published Ru—S distances; however, all other bond distances and angles compare well to those reported.

It is interesting to compare the structures of $RuCl_2(DMSO)(TT[9]OC)$ and $RuCl_2(PPh_3)(ODT[9]OC)$. Not surprisingly, there are some minor, and to some extent predictable, differences in bonding parameters, attributable to the change from a sulphur to an oxygen donor and the difference between DMSO and PPh_3 as an ancillary ligand. However, there is also a gross structural difference between the bonding

Scheme 5.



mode for TT[9]OC in $RuCl_2$(DMSO)(TT[9]OC) and ODT[9]OC in $RuCl_2(PPh_3)$(ODT[9]OC).

In every other X-ray structure determined for a complex of the ligand TT[9]OC or ODT[9]OC, the ligand is coordinated in an "*endo*" fashion as observed herein for $RuCl_2$(DMSO)-(TT[9]OC) (6, 21, 22). The structure of $RuCl_2(PPh_3)$-(ODT[9]OC) provides the first example of an "*exo*" coordination mode for this type of ligand. In the more common *endo* mode, the *o*-phenylene moiety is *syn* with respect to the neutral ancillary ligand while in the *exo* mode the *o*-phenylene moiety is *anti* with respect to the neutral ancillary ligand. This can be quantified as a difference in the dihedral angles between the plane defined by the benzylic S atoms, the Ru atom, and the Cl atoms and the plane defined by C(1), C(6), C(7), and C(12) of the thiacyclophane ligand. These dihedral angles are 142.3° and 112.9° for $RuCl_2$(DMSO)(TT[9]OC) and $RuCl_2(PPh_3)$-(ODT[9]OC), respectively. This can be rationalized on steric grounds as the aromatic ring of ODT[9]OC in $RuCl_2(PPh_3)$-(ODT[9]OC) appears to be bent downward away from the PPh_3 group in order to minimize interactions between the two ligands. The benzylic CH_2 groups are then oriented toward the face of one of the aromatic rings of the PPh_3 ligand and this explains the upfield shift of the benzylic protons in the ^1H NMR spectrum, the result of shielding by the phenyl rings of the phosphine ligand. It can also be inferred from ^1H NMR shifts that, in isomer B of this complex, ODT[9]OC is in an *endo* conformation as found previously for Rh(I) and Ir(I) complexes of this ligand.

The A:B isomer distribution formed upon preparation of complexes of the type $RuCl_2(X)(L)$ depends on the nature of X, L, and the conditions used. It appears that the more symmetrical isomer A is the thermodynamic product and can be generated exclusively in various solutions over periods of time varying from a few hours to a few weeks. NMR spectroscopic and X-ray structural evidence provided herein verifies the nature of the bonding and ligand conformation for this isomer.

$RuHCl(PPh_3)_2$(TT[9]OC) was prepared by displacing PPh_3 from $RuHCl(PPh_3)_3$. The product precipitates from a toluene solution as pale yellow microcrystals in 40% yield. Synthesis of $RuHCl(PPh_3)_2$(TT[9]OC) at reduced temperature or under an atmosphere of H_2 does not improve yields. $RuHCl(PPh_3)_2$-(TT[9]OC) is soluble in acetone and chlorinated solvents, and slowly decomposes in the latter. The presence of two sets of benzylic resonances, a pair of doublets at δ 3.96 and 3.85 ppm, and a singlet at δ 4.00 ppm, indicates that the thiacyclophane is bound via an asymmetric η^2-mode to Ru(II), through S(1) and S(2) with S(3) unbound. Two triplets of doublets at approximately δ 0 ppm are due to the ethylene protons of TT[9]OC, which are shielded by the PPh_3 phenyl rings. The ruthenium hydride is observed at δ −11.69 ppm, coupled to two phosphorus atoms, resulting in two doublets with coupling constants of approximately 20 Hz. The $^{31}P\{^1H\}$ NMR spectrum of this complex indicates that two PPh_3 ligands are present, and the P–P coupling of 32.7 Hz is in the range for *cis* phosphorus atoms (23). Thus, spectroscopic characterization indicates that this species contains (*i*) an asymmetrically coordinated thiacyclophane ligand, (*ii*) two PPh_3 ligands with a *cis* orientation, (*iii*) a hydride ligand positioned *cis* to the two phosphines, and (*iv*) a chloride ligand. There are three isomers that could account for these observations although only one is actually present. No solution data are available for unambiguous assignment of structure but it is likely that $RuHCl(PPh_3)$(TT[9]OC) is isomer C since (*i*) the hydride is *trans* to chloride in $RuHCl(PPh_3)_3$, (*ii*) the hydride resonance for RuHCl-(PPh_3)(TT[9]OC) is shifted less than 1 ppm from that found for $RuHCl(PPh_3)_3$, and (*iii*) the PPh_3 resonances are relatively close as would be expected if they are both *trans* to a sulphur atom. Present efforts are focused on obtaining suitable crystals for an X-ray diffraction study to verify this structural assignment.

Heating $RuHCl(PPh_3)_2$(TT[9]OC) in an attempt to displace PPh_3 and form $RuHCl(PPh_3)$(TT[9]OC), in which all three sulphur donors coordinate to the metal centre, was not successful. $RuHCl(PPh_3)_3$ does not react with ODT[9]OC. Since ODT[9]OC requires an S, O chelate, it is presumed the ether O atom is too poor a donor to displace PPh_3. The facile reaction of $RuCl_2(PPh_3)_3$ with crown thioethers or other ligands that substitute for PPh_3 is related to the fact that one PPh_3 ligand is quite labile and in solution $RuCl_2(PPh_3)_3$ readily dissociates to $RuCl_2(PPh_3)_2$. The fact that $RuHCl(PPh_3)_3$ does not undergo a similar facile dissociation of PPh_3 to form $RuHCl(PPh_3)_2$ (24) is consistent with our inability to generate $RuHCl(PPh_3)$-(TT[9]OC) from $RuHCl(PPh_3)_2$(TT[9]OC).

Reaction of $Cp_2(CH_3)Ta{=}CH_2$ with $Ru_3(CO)_{12}$: deoxygenative coupling of carbon monoxide and methylene units to give a heteronuclear cluster-bound 4-cumulene ligand

Grant Proulx, Frederick J. Hollander, and Robert G. Bergman

Abstract: The mechanisms of reactions that deoxygenate carbon monoxide (CO) and convert it into longer-chain hydrocarbons are not well understood. A reaction is reported between an early metal methylidene complex and a late transition metal carbonyl species that results in CO deoxygenation along with coupling of the CO carbon to methylidene groups and other CO carbons. The Schrock tantalum-methylene complex (η^5-C_5H_5)Ta(=CH_2)(CH_3) reacts with the trinuclear metal carbonyl species $Ru_3(CO)_{12}$ to yield the cluster complex $Cp_2(CH_3)Ta(\mu\text{-}O)Ru_3(C_4H_4)(CO)_9$. This material contains a 4-cumulene ligand that bridges the three late-metal centers. Also formed in this reaction is the unstable free tantalum oxo species, (η^5-C_5H_5)Ta(=O)(CH_3). A crystal structure of the $TaRu_3$ cluster is reported along with a proposed mechanism for this unusual carbon–carbon bond-forming reaction.

Key words: deoxygenation, carbon monoxide, alkylidene, coupling, cluster.

Résumé : Les mécanismes des réactions qui permettent de désoxygéner le monoxyde de carbone (CO) pour le transformer en chaînes plus longues d'hydrocarbures ne sont pas bien comprises. On rapporte l'observation d'une réaction impliquant un complexe d'un méthylidène d'un métal du début du tableau avec une espèce carbonylée d'un métal de transition qui provoque une désoxygénation du CO avec le couplage du carbone du CO avec les groupes méthylènes et avec les carbones d'autres CO. Le complexe tantale-méthylène de Schrock (η^5-C_5H_5)Ta(=CH_2)(CH_3) réagit avec l'espèce métal-carbonyl trinucléaire $Ru_3(CO)_{12}$ pour fournir l'agrégat complexe $Cp_2(CH_3)Ta(\mu\text{-}O)Ru_3(C_4H_4)(CO)_9$. Ce matériel comporte un coordinat 4-cumulène qui sert de pont aux trois atomes des métaux de transition. Dans cette réaction, il se forme aussi l'espèce libre d'oxo tantale, (η^5-C_5H_5)Ta(=O)(CH_3). On a déterminé la structure cristalline de l'agrégat $TaRu_3$ et on propose un mécanisme pour cette réaction inhabituelle qui crée des liaisons carbone–carbone.

Mots clés : désoxygénation, monoxyde de carbone, alkylidène, couplage, agrégat.

[Traduit par la rédaction]

The reduction of carbon monoxide and its incorporation into longer-chain hydrocarbons is one of the most intensely studied fields in organotransition metal chemistry. One of the reasons for this is that carbon monoxide offers a potentially inexpensive route to a wide array of useful synthetic fuels and materials (1). A number of homogeneous systems have been found that reduce CO in the presence of H_2 and convert it to methanol (2). Equally interesting are deoxygenation–oligomerization processes, such as the Fischer–Tropsch reaction, that convert CO into longer-chain hydrocarbons by replacement of oxygen with hydrogen and new carbon–carbon bonds (3–5).

One route to understanding such processes is the identification and study of reactions in homogeneous solution that deoxygenate and oligomerize CO. A few homogeneous solution reactions are known in which CO molecules are coupled (6–9) or cleaved (10, 11), but more extensive homogeneous C—C bond-forming processes with this ligand are still rare. We recently reported the stoichiometric reduction and coupling of metal-bound CO in the reactions between Schrock's tantalum alkylidene complex $Cp_2Ta(CH_2)(CH_3)$ (12) (**1**; Cp = η^5-C_5H_5) and various metal carbonyl complexes such as $Co_2(CO)_8$, $Re_2(CO)_{10}$ and $RRe(CO)_5$ (R = alkyl or aryl) (13, 14). In certain steps of the deoxygenation processes, we provided evidence that these reactions proceed through an unstable vinylidene intermediate, which can be trapped in a variety of ways. We have now found that a similar

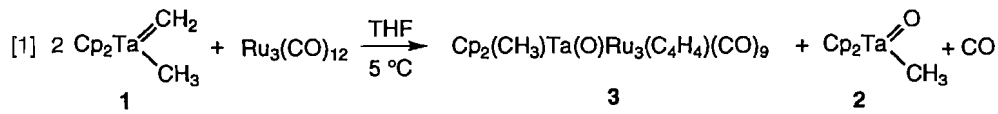
reaction between the methylidene complex **1** and a larger cluster, $Ru_3(CO)_{12}$, is capable of deoxygenating several molecules of CO en route to an isolable $TaRu_3$ complex that contains a novel C_4H_4 ligand bridging three metal centers. We report herein the X-ray structure of this novel complex and propose a mechanism for the transformation.

Treatment of a THF slurry of ruthenium dodecacarbonyl ($Ru_3(CO)_{12}$) with two equivalents of the tantalum alkylidene complex $Cp_2Ta(CH_2)(CH_3)$ (**1**) at temperatures greater than 5°C results in the formation of one equivalent of the previously characterized oxo complex, $Cp_2Ta(=O)(CH_3)$ (14) (**2**), and a $TaRu_3$-containing cluster complex, **3** (eq. [1]).[2] Monitoring this reaction by NMR demonstrated that this species was formed in 57% yield (based on ^1H NMR). Recrystallization provided analytically pure **3** as yellow crystals in 32% yield.



The mass spectrum of **3** showed a parent ion at $[M^+] = 950.8$ *m/z*, and the fragmentation pattern was consistent with a general structural formula of $Cp_2(CH_3)Ta(O)(Ru_3(C_4H_4)(CO)_9$.[3] A C_6D_6 solution of **3** shows a methyl singlet at 0.35 ppm, a singlet for each of two inequivalent cyclopentadienyl groups at 5.10 and 5.17 ppm, and signals for four inequivalent methylene protons. One set of methylene doublets appearing at δ 4.39 and 4.26 ppm are coupled to each other with $^2J_{HH} = 2.6$ Hz while a second set of doublets at δ 2.00 and 1.51 ppm have a coupling constant $^2J_{HH} = 1.3$ Hz. The ^{13}C NMR spectrum with DEPT analysis showed (in addition to the carbonyl resonances) the presence of two methylene carbons and two quaternary carbons and characteristic resonances for the $Cp_2(CH_3)Ta(=O)$ bridging oxo species. Our initial assignment of the species as a triruthenium cluster core, to which are bound a $Cp_2(CH_3)Ta=O$ fragment and a 4-cumulene ($H_2C=C=C=CH_2$) ligand, was based on its similarity to allylic species previously observed in the reactions of **1** with the $Co_2(CO)_8$ and $Fe_2(CO)_9$ clusters. However, there was still some structural ambiguity. For this reason, a single crystal X-ray diffraction analysis was undertaken to confirm our initial hypothesis.[4] An ORTEP diagram of the molecule is shown in Fig. 1, and a blowup of the C_4H_4 ligand with selected distances and angles is shown in Fig. 2. In the solid state, the structure consists of two crystallographically related molecules of **3** and one molecule of benzene in the triclinic unit cell. There are no unusually short contacts between clusters or between clusters and the solvate.

Within the cluster, the $Cp_2(CH_3)Ta=O$ moiety bound to one end of the Ru_3 chain appears to simply fill one of the coordination sites left vacant by loss of a CO ligand at the Ru_1 center, a situation that is superficially similar to that observed in the previously reported $Cp_2(CH_3)Ta=O$-Re(C(=CH_2)Ph)-$(CO)_4$ complex (13). However, the Ta=O-Ru bonding in the two complexes appears to be different. In the Ta=O-Re case, the angle between the three atoms is essentially linear (179°), whereas the Ta=O-Ru angle in **3** is 162.8(2)°. We do not know whether this difference is caused by electronic or steric factors.

Each of the three ruthenium atoms has three apparently normal terminal carbonyl ligands attached to it. These do not seem to have the bridging character that was observed in the $TaFe_2$ allylic cluster structure reported previously, which is not surprising considering the general periodic trends in CO bridging between transition metals (15). There are also two apparent Ru—Ru bonds, from Ru_1 to Ru_2 (2.94 Å) and from Ru_2 to Ru_3 (2.77 Å). The Ru-Ru-Ru angle is 91.3°, indicating that there is no third Ru—Ru bond (the Ru_1 to Ru_3 distance is > 4 Å). The longer Ru_1—Ru_2 interaction may or may not correspond to a full single bond. Distances ranging from 2.64 to 3.16 Å have been found in 140 other ruthenium cluster structures that contain a Ru-Ru-Ru fragment (16, 17). Distances at the higher end of this range (> 3.1 Å) are probably too long to be conventional two-electron covalent bonds and most

---

[2] Preparation of $Cp_2(CH_3)Ta(\mu\text{-}O)Ru(C_4H_4)(CO)$ (**3**): A THF (5 mL) solution of $Cp_2Ta(CH_2)(CH_3)$ (76.2 mg, 0.224 mmol) at 0°C was added dropwise to a rapidly stirring slurry of $Ru_3(CO)_{12}$ (138 mg, 0.217 mmol) in THF (12 mL) at 0°C. The slurry turned a deep red/brown and was stirred for a period of 25 min while slowly warming to room temperature. The slurry was then filtered to remove excess starting $Ru_3(CO)_{12}$. The filtrate was then concentrated in vacuo leaving a brown residue. This residue was extracted with C_6H_6 (ca. 20 mL) and filtered through a 1 in. silylated silica gel plug (Kieselgel 60). The yellow filtrate was then concentrated in vacuo to ca. 5 mL, and a benzene–pentane vapor diffusion recrystallization was performed. The yellow crystals of **3** that formed were isolated (34.1 mg) in 32% yield.

Fig. 1. Structure of $Cp_2(CH_3)Ta(\mu\text{-}O)Ru_3(C_4H_4)(CO)_9$ (**3**) showing the atom-labeling scheme.

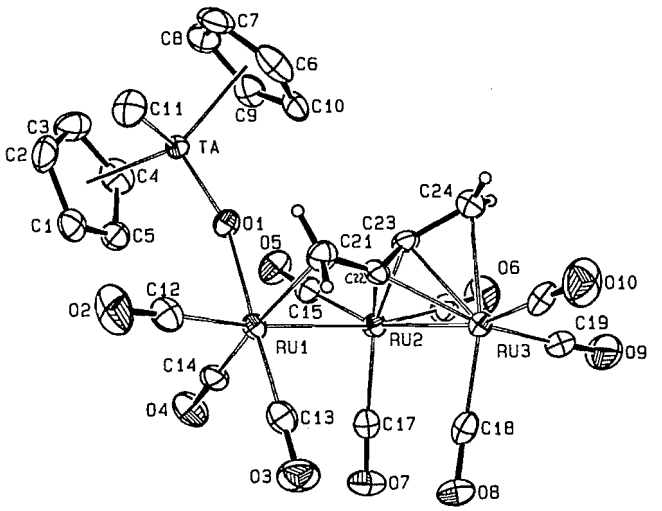

Fig. 2. Expanded view of the $(\mu\text{-}O)Ru(C_4H_4)$ core of **3** showing selected bond distances (Å), bond angles (°) and torsional angles (°) viewed from the Ru_3 plane.

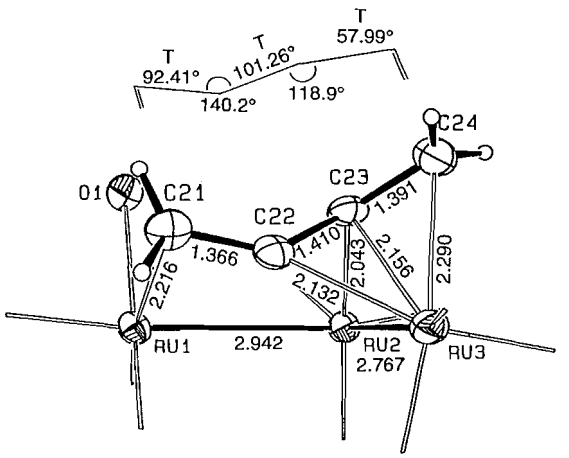

likely represent bridging structures that do not require a large degree of metal–metal interaction. Each Ru center is approximately octahedrally coordinated. The pseudo-octahedron of Ru_1 is tilted about 45° with respect to the pseudo-octahedra of Ru_2 and Ru_3, and the latter are approximately parallel to each other.

There are no apparent systematic differences in the Ru—C distances or Ru—O distances to the carbonyl ligands, so it is unlikely that localized differences in oxidation state are present for the three Ru atoms. The shortest Ru—CO distance (1.853 Å between Ru_1 and C_{13}) is most probably due to the *trans* disposition of this carbonyl to the Ta=O fragment. This is similar to bond lengths observed in previous bridging oxo structures and is not surprising considering the weakly coordinated and weakly electron-accepting oxo species (the Ru_1—O_1 distance is 2.102 Å).

"Above" the Ru_3 plane lies a twisted linear ligand of composition C_4H_4. The hydrogen atoms at each terminus were located and refined. Each carbon atom of the ligand coordinates to at least one Ru atom, and C_{23} bridges the Ru_2—Ru_3 bond. The Ru—C distances vary from 2.04 to 2.29 Å with the longest distance being Ru_3—C_{24}. The C—C distances and angles and C-C-C-C torsion angle are not consistent with any obvious simple organic bonding scheme. The hybridization at C_{21} appears to be essentially sp^2, with a somewhat lengthened C=C double bond, but this atom is also bonded to Ru_1 with a C=C-Ru angle of 82.4° and a C-C-C-Ru torsion angle of 92.4°. The hydrogen atoms are located nearly in the C-C-C plane, with both displaced slightly away from the coordinated Ru.

The bonding at C_{22} and C_{23} is more complex. The C-C-C angle of 140.2° at C_{22} is reasonable for two coordinated *sp*-hybridized carbons, such as those found in complexed alkynes, but the angle at C_{23} (118.9°) is more typical of a relatively undistorted sp^2 carbon. Ru_3 is in the C_{21}-C_{22}-C_{23} plane, but the coordination is more consistent with that of a C=C double bond, with both C_{22} and C_{23} at essentially the same distance from Ru_3 and with the C—C distance lengthened to 1.41 Å. In addition, there is an obvious Ru—C single bond from Ru_2 to C_{23}, but Ru_2 lies out of the plane of C_{21}-C_{22}-C_{23} by 1.81 Å (and out of the C_{22}-C_{23}-C_{24} plane by 1.26 Å).

This is further complicated by a twisting of the C_4 ligand, leading to a C-C-C-C torsion angle of 101.3°. This twist clearly excludes the possibility of an undistorted cumulene structure. Instead, Ru_3 coordinates to three of the carbons in what at first appears to be an allylic-type bonding arrangement with respect to the C_{22}-C_{23}-C_{24} plane. The C_{23}—C_{24} distance of 1.39 Å reflects a typically allylic bond order of approximately 1.5, but the bonding distance to C_{24} is much longer than the distances to C_{22} and C_{23}, making even this interaction highly unsymmetrical. In addition, the hydrogen atom positions on C_{24} are twisted with respect to the C_{21}-C_{22}-C_{23} plane so as to give them more equivalent Ru-C-H angles.

With these unusual positional parameters in mind, a formal bonding scheme is still difficult to formulate. However, a somewhat distorted allylic-type interaction, as shown in Scheme 1, is the simplest formulation of the bonding between C_{22}-C_{23}-C_{24} and the Ru_3 core.[5] With a C_{23}—Ru_2 single bond, the only bonding assignments left are those between C_{21}, C_{22}, and Ru_1. If the 1.366 Å distance between C_{21} and C_{22} is a somewhat lengthened double bond, then one must consider whether there is any significant C_{22}—Ru_1 bonding. This is difficult to say decisively, but we have not found any clear evidence for a Ru—C bonding distance of greater than 2.35 Å. Thus our formulation does not include a bond between these two atoms. Because it seems clear that the sp^2 carbon is in the proper arrangement for it, we postulate a donor coordination from C_{21} to Ru_1.

Complex **3** is the first product that we have been able to isolate from reactions of $Cp_2(CH_3)Ta{=}CH_2$ with a 4*d* metal center as well as the first from reaction with a trimeric metal complex. Although the final product is substantially different from those obtained with other metal carbonyls, the mechanism, at least in its initial stages, may be similar to others in this series. As shown in Scheme 1, we suggest that the reaction is initiated by an overall cycloaddition between the $Ta{=}CH_2$

[5] A referee has cautioned us against attempting to apply simple valence bond theory to clusters. We agree, but the structure in Scheme 1 seems to us a useful way of keeping track of the bonding electrons in this system.

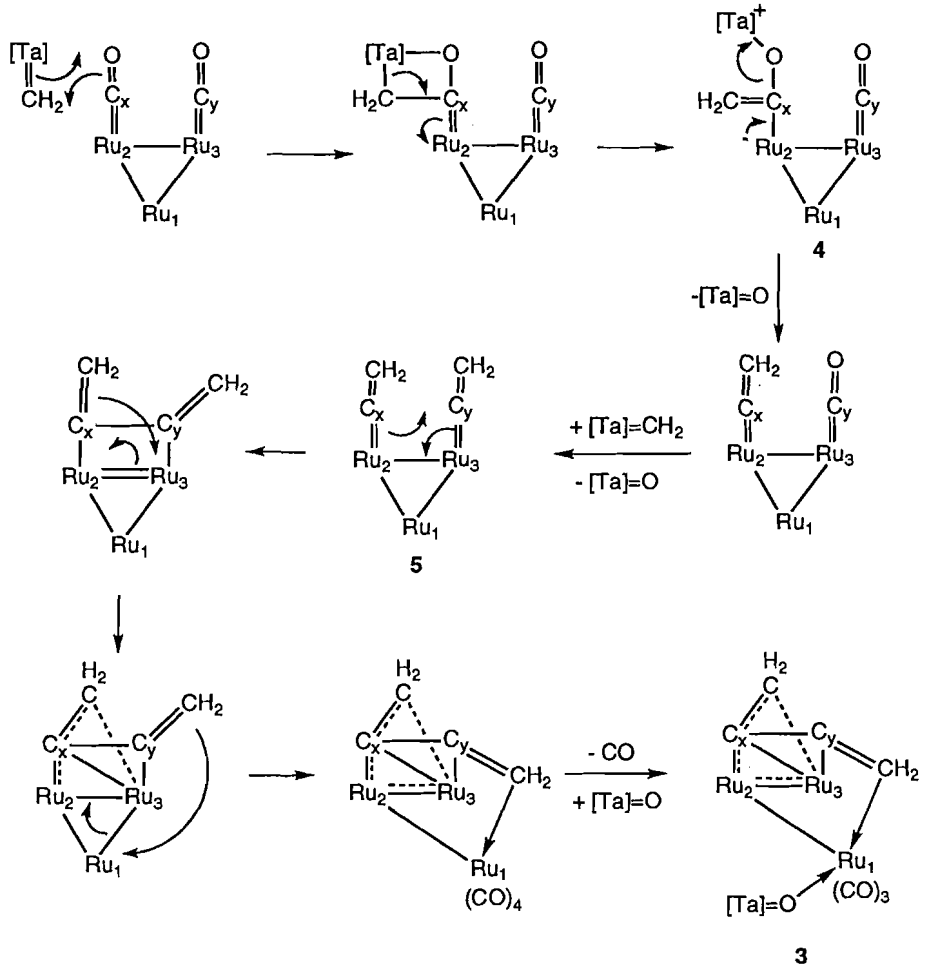
Scheme 1.



groups from two molecules of **1** and two CO ligands at separate Ru centers, probably through the zwitterionic species **4** similar to the one structurally characterized earlier in the reaction of $Cp_2(CH_3)Ta{=}CH_2$ with $C_3F_7Re(CO)_5$, in which the Ta-C bond is broken.[6] Following this step, two molecules of $Cp_2(CH_3)Ta{=}O$ are extruded to give the bis-vinylidene species **5**. Overall [2+2] cycloaddition of the Ru=C bonds then provides the carbon–carbon bond-forming step necessary to reach a C_4H_4 fragment. We propose this complex then rapidly rearranges, as shown in Scheme 1, to give the final product **3**. During the reaction there must also be loss of CO and addition of one of the $Cp_2(CH_3)Ta(=O)$ fragments to the terminal Ru center, but we do not yet know at which point in the overall transformation this occurs.

In conclusion, these observations constitute a new example of a reaction in homogeneous solution, between early and late transition metal complexes, in which CO molecules are deoxygenated and coupled to one another and to CH_2 ligands. The rapid rate of this reaction appears to be a direct result of the interaction of two electronically different metal centers. It is unclear whether transformations exhibiting related types of cleavage and rearrangement on surfaces proceed by mechanisms similar to those in the reactions described here, but the potential analogies are interesting. We are continuing our investigations in hopes of testing the mechanistic hypotheses engendered by this series of reactions.

Dinuclear dihydride complexes of iridium: a study of structure and dynamics

D. Michael Heinekey, David A. Fine, T. Gregory P. Harper, and Suzanne T. Michel

Abstract: Reaction of the neutral dihydride complexes (η-C_5R_5)Ir(L)H_2 (L = P(OPh)$_3$, CO; R = H, Me) with triflic acid (HO_3SCF_3) at ambient temperature or above affords hydrogen and the dimeric hydride bridged species {[(η-C_5R_5)Ir(L)H]$_2$(μ-H)}O_3SCF_3. Deprotonation of the cationic complexes gives the neutral dimers of the form [(η-C_5R_5)Ir(L)H]$_2$. Spectroscopic data are consistent with the presence of only terminal hydride ligands in these complexes. Variable temperature ^{1}H and ^{31}P NMR studies indicate that a rapid dynamic process exchanges the two terminal hydride ligands and that the complexes exist as unequal mixtures of the racemic and meso diastereomers. Synthesis of a lower symmetry derivative, [(η-C_5Me_4Et)Ir(CO)H]$_2$, reveals that a rapid epimerization process occurs that interconverts the two diastereomers. Thermolysis of the carbonyl complex [(η-C_5Me_5)Ir(CO)H]$_2$ affords [(η-C_5Me_5)Ir(CO)]$_2$ and dihydrogen.

Key words: iridium, hydride, bimetallic, dynamics, epimerization.

Résumé : La réaction des complexes neutres dihydrures (η-C_5R_5)Ir(L)H_2(L = P(OPh)$_3$, CO; R = H, Me) avec de l'acide triflique (HO_3SCF_3), à des températures ambiante ou supérieure, fournit les espèces dimériques pontées dihydrures {[η-C_5R_5)Ir(L)H]$_2$(μ-H)}O_3SCF_3. La déprotonation des complexes cationiques fournit les dimères neutres de la forme [(η-C_5R_5)Ir(L)H]$_2$. Pour ces complexes, les données spectroscopiques sont en accord avec la présence uniquement de coordinats hydrures terminaux. Des études de RMN du ^{1}H et du ^{31}P indiquent qu'il existe des processus d'échange dynamiques rapides des deux coordinats hydrures terminaux et que les complexes existent sous la forme de mélanges inégaux de diastéréomères racémiques et méso. La synthèse d'un dérivé de symétrie moindre, [(η-C_5Me_4Et)Ir(CO)H]$_2$, révèle qu'il se produit un processus d'isomérisation rapide qui permet l'interconversion des deux diastéréomères. La thermolyse du complexe [(η-C_5Me_5)Ir(CO)H]$_2$ fournit du [(η-C_5Me_5)Ir(CO)]$_2$ et du dihydrogène.

Mots clés : iridium, hydrure, bimétallique, dynamique, épimérisation.

[Traduit par la rédaction]

Introduction

The reductive elimination of hydrogen from dihydride complexes is a reaction of central importance to organometallic chemistry, and has been studied in great detail in monomeric complexes (1, 2). The corresponding reaction in metal dimers, dinuclear reductive elimination (3–7), has not been conclusively observed and is thought to be unfavorable, based on orbital symmetry considerations (8). The ideal system for studying this problem would be a conformationally flexible metal dimer with a metal–metal single bond and two terminal hydride ligands. Surprisingly, there are relatively few examples of such complexes, since the vast majority of known dinuclear and polynuclear metal hydride complexes contain bridging hydride ligands. The only well-characterized examples of dimers containing only terminal hydride ligands are $H_2Os_2(CO)_8$ (9) and $H_2Os_2(CO)_6(PPh_3)_2$ (10). An iron analog, $H_2Fe_2(CO)_8$, is less well characterized but is thought to have terminal hydride ligands.[2] In all these cases, the putative product of dihydrogen elimination is known to be very unstable.

Attempts to prepare suitable dinuclear complexes have no doubt been hampered by the lack of generally useful synthetic methodology. In this paper, we report the development of a potentially general condensation of monomeric hydride complexes induced by protonation to afford dinuclear complexes in excellent yields. The ultimate products of these procedures are neutral dinuclear iridium dihydride complexes of the form [CpIr(L)H]$_2$(Cp = C_5H_5, L = P(OPh)$_3$; Cp = C_5Me_5 (Cp*), or C_5Me_4Et (Cp′), and L = CO). These complexes have been shown by spectroscopic and structural studies to have terminal hydride ligands. The dimeric complexes in every case have

been shown by variable temperature NMR spectroscopy to exist as rapidly equilibrating mixtures of diastereomers.

Preliminary investigations of the thermal chemistry of $[Cp^*Ir(CO)H]_2$ show that there is a very substantial kinetic barrier to elimination of hydrogen and that formation of $[Cp^*Ir(CO)]_2$ occurs very slowly.

Experimental

General procedures

All manipulations were conducted under argon or nitrogen using standard Schlenk and drybox techniques. Argon and nitrogen were deoxygenated and dried by passage through Chemical Dynamics Corp. R3-11 CuO catalyst followed by Mallinckrodt Aquasorb containing P_2O_5. Air-sensitive compounds were manipulated in an MBraun labmaster 130 glove box equipped with integrated dry train loaded with copper catalyst and molecular sieves. Solvents were purified by distillation from Na–K–benzophenone (except CH_2Cl_2 from P_2O_5) under nitrogen. Deuterated NMR solvents (purchased from Cambridge Isotope Laboratories) were degassed, and stored over the following drying agents: CD_2Cl_2, $CDCl_3$ over CaH_2; C_6D_6, THF-d_8 over Na–K–benzophenone. $CDFCl_2$ was prepared according to the reported procedure (12) and stored over CaH_2. Carbon monoxide-^{13}C was purchased from Cambridge Isotope Laboratories and adsorbed on activated charcoal (coconut, 8–12 mesh, EM Science).

$[Cp'IrCl_2]_2$ (Cp′ = η-C_5Me_4Et) was prepared from $[(COD)IrCl]_2$ (COD = 1,5-cyclooctadiene) according to the method reported (13) for $[Cp^*IrCl_2]_2$. $Cp^*Ir(CO)Cl_2$ was prepared with slight modification to the published procedure (14). $CpIr(P(OPh)_3)H_2$ was prepared in a manner analogous to that previously reported (15) for $CpIr(PMe_3)H_2$. Triflic acid (HO_3SCF_3) and 1,8-bis(dimethylamino)naphthalene (Proton Sponge®) were purchased from Aldrich Chemical Co. and used as received.

^1H NMR spectra were recorded on Bruker AC200, WM250, AF300, or WM500 spectrometers and referenced internally to the residual proton resonance of the deuterated solvent or tetramethylsilane (TMS). ^{13}C NMR spectra were collected on the AC200, AF300, and WM500 spectrometers operating at a frequency of 50.32, 75.46, and 125.76 MHz, respectively, and referenced internally to the solvent. ^{31}P NMR spectra were collected on the AC200 and WM500 spectrometers at frequencies of 81.02 and 202.45 MHz, respectively, and referenced externally to 85% H_3PO_4. Variable temperature ^1H NMR measurements were performed using the Bruker B-VT1000 temperature control module with a copper–constantan thermocouple. Temperature calibration was obtained by measurement of the chemical shift difference between the -CH_3 and -OH peaks of pure methanol using the method of Van Geet (16). Temperature calibration below the freezing point of methanol was achieved with a copper–constantan thermocouple inserted in the NMR probe sample chamber. Line shape analysis of variable temperature ^1H NMR spectra was performed using a modified version of the DYNAMAR program (17).

Infrared spectra were recorded on a Perkin–Elmer model 1600 Fourier transform spectrophotometer (2.0 cm^{-1} resolution). Samples were examined as solutions in sealable 0.1 mm path length NaCl cells or as Nujol mulls.

Electron impact mass spectra were obtained using a Kratos Profile HD3 magnetic sector instrument with a direct insertion probe. Data were collected in nominal mode, which rounds off results to the nearest mass unit.

Elemental analyses were performed by Galbraith Laboratories.

$Cp'Ir(CO)Cl_2$

A vessel fitted with a high-vacuum Teflon stopcock was charged with $[Cp'IrCl_2]_2$ (0.62 g, 0.75 mmol). Methylene chloride (10 mL) was vacuum transferred onto the solid. The red-orange solution was subjected to three freeze–pump–thaw cycles, pressurized with CO (2.1 atm; 1 atm = 101.3 kPa), and allowed to stir overnight. The solution was transferred via filter cannula into cold stirring heptane, causing immediate precipitation of the product. The yellow powder was collected by filtration through a medium glass frit, washed with heptane, and dried in a desiccator. Yield 0.61 g (92%). Recrystallization from CH_2Cl_2–Et_2O afforded yellow-olive green crystals. IR (Nujol): 2034 (s, ν_{CO}) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 2.31 (q, J = 7.6 Hz, 2H), 1.95 (s, 6H), 1.90 (s, 6H), 1.19 (t, J = 7.6 Hz, 3H). Anal. calcd. for $C_{12}H_{17}Cl_2IrO$: C 32.73, H 3.89; found: C 32.34, H 3.95.

$Cp^*Ir(CO)H_2$

Methanol (about 20 mL) was added to a Schlenk flask charged with 0.27 g of $Cp^*Ir(CO)Cl_2$ (0.64 mmol) and 0.43 g of Zn dust (6.6 mmol). Glacial acetic acid (1.0 mL) was added and the mixture was immediately subjected to three freeze–pump–thaw cycles. The solution was allowed to stir overnight under argon. An aqueous solution of NaOH saturated with NaCl (approx. 15 mL, argon sparged) was transferred via cannula to the deep purple-red solution and stirred for 20 min. The mixture was extracted with 4 × 10 mL of pentane. The extracts were transferred via cannula onto oven-dried $MgSO_4$ and left to stir for 1 h. The pale gold-colored liquid was transferred via filter cannula to a sublimation apparatus. The $MgSO_4$ was washed with pentane and this liquid was combined with the previous extracts. The solvent was removed in vacuo leaving a mostly white crystalline residue, with some brown material. The air-sensitive product was isolated by sublimation (35°C, dynamic vacuum) into a liquid N_2 cooled Schlenk flask. Low-melting, pale yellow crystals were recovered and stored under argon at −30°C. Yield: 0.23 ± 0.02 g (ca. 100%). IR (Nujol): 2131 (m, ν_{IrH}), 2013 (m), 1990 (s), 1945 (m) cm^{-1}. ^1H NMR (CD_2Cl_2) δ: 2.22 (s, 15H), −16.48 (s, 2H). ^1H NMR (C_6D_6) δ: 1.87 (t, $^4J_{H-H}$ = 0.8 Hz, Cp^*), −15.76 (m, $^4J_{H-H}$ = 0.8 Hz, Ir-H). $^{13}C\{^1H\}$ NMR ($CDFCl_2$) δ: 98.0 (s, $C_5(CH_3)_5$), 11.1 (s, $C_5(CH_3)_5$). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: 97.1 (s, $C_5(CH_3)_5$), 10.6 (s, $C_5(CH_3)_5$). Anal. calcd. for $C_{11}H_{17}IrO$: C 36.96, H 4.79; found: C 36.60, H 4.70.

$Cp^*Ir(^{13}CO)H_2$

Prepared as above for $Cp^*Ir(CO)H_2$. IR (Nujol): 2131 (m, ν_{IrH}), 1964 (sh), 1942 (s), 1900 (m) cm^{-1}. IR (heptane): 2137 (m, ν_{IrH}), 1970 (m), 1950 (s), 1906 (m) cm^{-1}. ^1H NMR (CD_2Cl_2) δ: 2.22 (q, $^4J_{H-H}$ = 0.7 Hz, $^4J_{C-H}$ = 0.6 Hz, Cp^*), −16.49 (d of m, $^4J_{H-H}$ = 0.7 Hz, $^4J_{C-H}$ = 8.7 Hz, Ir-H). In the $^{13}C\{^1H\}$ NMR (CD_2Cl_2) spectrum of the enriched sample, a singlet resonance for the carbonyl ligand was detected at δ 171.5.

$Cp'Ir(CO)H_2$

Prepared as above for $Cp^*Ir(CO)H_2$. Recovered as an air-sensitive pale yellow oil. ^1H NMR (CD_2Cl_2) δ: 2.46 (q, $J = 7.6$ Hz, 2H), 2.22 (s, 6H), 2.21 (s, 6H), 1.07 (t, $J = 7.6$ Hz, 3H), −16.47 (s, 2H). $^{13}C\{^1H\}$ NMR (CD_2Cl_2) δ: 171.5 (s, CO), 103.9 (s, $C(CH_2CH_3)$), 97.7, 97.6 (s, $C(CH_3)$), 18.8 (s, $C(CH_2CH_3)$), 17.7 (s, $C(CH_2CH_3)$), 11.0, 10.8 (s, $C(CH_3)$).

*$\{[CpIr(P(OPh)_3)H]_2(\mu\text{-}H)\}O_3SCF_3$ (**1**)*

A vessel equipped with a high-vacuum Teflon stopcock was charged with $CpIr(P(OPh)_3)H_2$ (255 mg, 0.448 mmol). Methylene chloride (about 25 mL) was vacuum transferred onto the solid. One-half an equivalent of triflic acid (19.8 μL, 0.224 mmol) was added via syringe. The solution was degassed by three freeze–pump–thaw cycles and kept under vacuum. With the vessel wrapped in foil, the solution was heated to reflux for 15 h in an oil bath at 80°C, during which the solution became deep orange. When the reaction was complete by NMR the solution was transferred via cannula to a Schlenk flask. The solution was concentrated to about 5 mL and heptane (30 mL) added to precipitate the yellow product. The solvent was removed with a filter cannula. The air-stable powder was washed with 2 × 15 mL heptane and dried in vacuo. Yield 262 mg (95%). ^1H NMR (CD_2Cl_2) δ: 7.3–7.2 (m, 30H), 5.01 (d, $J_{P-H} = 2$ Hz, 10H), −18.54 (t, $J_{P-H} = 18.5$ Hz, 3H). ^1H NMR ($CDFCl_2$, 153 K) δ: −17.22 (d, $J = 34$ Hz, Ir-$H_{terminal}$), −19.92 (br t, $J = 19$ Hz, Ir-H_{bridge}). ^{31}P NMR (selective decoupling of aromatic hydrogens, CD_2Cl_2) δ: 79.0 (q, $^2J_{P-H} = 18$ Hz). Anal. calcd. for $C_{47}H_{43}Ir_2O_9P_2SF_3$: C 43.85, H 3.37; found: C 43.96, H 3.23.

*$[CpIr(P(OPh)_3)H]_2$ (**2**)*

The protonated dimer **1** (42 mg, 0.033 mmol) and 1.1 equivalents of lithium diisopropylamide (3.7 mg, 0.034 mmol) were placed in one side of an H-tube reactor. The reactor consisted of two vessels fitted with high-vacuum Teflon stopcocks and joined at a glass frit. THF (20 mL) was vacuum transferred onto the solids. The reactor was wrapped in foil and allowed to stir for 2 h, yielding a clear, bright yellow solution. The solvent was removed in vacuo leaving a pale yellow oil. Heptane was added via vacuum transfer and the solution stirred for 1 h. The solution was filtered through the frit to the other side of the reactor and the heptane removed in vacuo to leave a bright yellow, air-sensitive powder. ^1H NMR (C_6D_6) δ: 7.3–7.0 (m, 30H), 5.00 (d, $J_{P-H} = 2$ Hz, 10H), −16.67 (t, $J_{P-H} = 24$ Hz, 2H). ^1H NMR (THF-d_8) δ: 7.3–7.0 (m, 30H), 4.84 (d, $J_{P-H} = 2$ Hz, 10H), -17.02 (t, $J_{P-H} = 24$ Hz, 2H). $^{31}P\{^1H\}$ NMR (THF-d_8) (300 K) δ: 81.01 (s); (215 K) δ: 86.34 (s), 82.95 (s). Anal. calcd. for $C_{46}H_{42}Ir_2O_6P_2$: C 48.58, H 3.72; found: C 47.92, H 3.82.

*$\{[Cp^*Ir(CO)H]_2(\mu\text{-}H)\}O_3SCF_3$ (**3**)*

A small Schlenk flask was charged with 34 mg of $Cp^*Ir(CO)H_2$ (0.094 mmol). Methylene chloride (2–3 mL) was transferred onto the solids via cannula furnishing a pale yellow solution. With the solution immersed in a CO_2-isopropanol bath, triflic acid (8 μL, 0.09 mmol, 100% stoichiometric excess) was added via syringe. Three freeze–pump–thaw cycles (thaw to −78°C) were performed and the solution stirred for 30 min at −78°C. The flask was then transferred to an ice–NaCl bath and the solution stirred for an additional 30 min, becoming deep yellow. The solvent was removed in vacuo and the yellow-brown residue was washed with three aliquots of cold Et_2O. Residual volatiles were removed under vacuum overnight leaving a light brown, air-sensitive solid. Yield: 26 mg (66%). IR (Nujol): 2111 (w, ν_{Ir-H}), 2020, 1990 (s, ν_{CO}) cm^{-1}. ^1H NMR (CD_2Cl_2) δ: 2.22 (s, 30H), −16.47 (s, 3H). ^1H NMR ($CDFCl_2$, 300 K) δ: 2.23 (s, Cp^*), −16.44 (s, Ir-H); ($CDFCl_2$, 138 K) δ: -15.35 (br s, Ir-$H_{terminal}$), −18.10 (br s, Ir-H_{bridge}). $^{13}C\{^1H\}$ NMR ($CDFCl_2$) δ: 120.1 (q, $J_{C-F} = 317$ Hz, O_3SCF_3), 102.0 (s, C_5Me_5); 10.9 (s, C_5Me_5).

*$\{[Cp^*Ir(^{13}CO)H]_2(\mu\text{-}H)\}O_3SCF_3$ (**3***)*

Prepared using a procedure analogous to that for **3**. ^1H NMR ($CDFCl_2$) δ: 2.23 (s, Cp^*), -16.44 (br s, Ir-H). The linewidth of the hydride resonance is increased by an unresolved coupling to the protons of the Cp^* rings. When a spectrum was collected with homonuclear decoupling of the Cp^* resonance, the hydride resonance was resolved into a triplet ($J_{C-H} = 3.4$ Hz). In the $^{13}C\{^1H\}$ NMR ($CDFCl_2$) a singlet resonance for the carbonyl ligands was observed at δ = 166.9.

*$\{[Cp'Ir(CO)H]_2(\mu\text{-}H)\}O_3SCF_3$ (**5**)*

Prepared as above for **3**. Recovered as yellow-brown oil. ^1H NMR (CD_2Cl_2) δ: 2.48 (q, $J = 7.6$ Hz, 4H), 2.22 (s, 12H), 2.20 (s, 12H), 1.13 (t, $J = 7.6$ Hz, 6H), −16.52 (s, 3H). $^{13}C\{^1H\}$ NMR (CD_2Cl_2) δ: 166.2 (s, CO), 105.7 (s, $C(CH_2CH_3)$), 102.1, 101.4 (s, $C(CH_3)$), 18.7 (s, $C(CH_2CH_3)$), 15.7 (s, $C(CH_2CH_3)$), 10.6, 10.5 (s, $C(CH_3)$).

*$[Cp^*Ir(CO)H]_2$ (**4**)*

Methylene chloride was added via cannula to a Schlenk flask containing 90 mg of **3** (0.10 mmol) and 33 mg of proton sponge (0.15 mmol). The solution was subjected to three freeze–pump–thaw cycles and allowed to stir for 2 h. The solvent was removed under static vacuum leaving a yellow-brown residue. The residue was extracted three times with heptane and the yellow extracts transferred to a clean Schlenk flask via filter cannula. The solution was concentrated in vacuo and storage at −30°C for 16 h afforded yellow crystals. IR (heptane): 2180 (w, ν_{Ir-H}), 1971 (s), 1942 (s) cm^{-1}. ^1H NMR (CD_2Cl_2) δ: 2.13 (s, 30H), −16.30 (s, 2H). ^1H NMR (C_6D_6) δ: 2.04 (s, Cp^*), −15.91 (s, Ir-H). ^1H NMR ($CDFCl_2$, 300 K) δ: −16.2 (s, Ir-H); ($CDFCl_2$, 147 K) δ: −15.89 (s, Ir-H, major species), −19.02 (s, Ir-H, minor species). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 96.82 (s, C_5Me_5), 11.32 (s, C_5Me_5). MS (EI): *m/e* 712 ($[(Cp^*{}^{191}Ir(CO)H)(Cp^*{}^{193}Ir(CO)H)]^+$).

*$[Cp^*Ir(^{13}CO)H]_2$ (**4***)*

Prepared as above for **4**. ^1H NMR ($CDFCl_2$, 300 K) δ: 2.15 (s, Cp^*), −16.22 (br t, $J_{C-H} = 4.5$ Hz, Ir-H). ^1H NMR ($CDFCl_2$, 145 K) δ: −15.89 (d, $J = 7.9$ Hz), −19.04 (t, $J = 6.0$ Hz). $^{13}C\{^1H\}$ NMR (CD_2Cl_2) δ: 176.5 (s, CO), 11.3 (s, C_5Me_5).

*$[Cp'Ir(CO)H]_2$ (**6**)*

Prepared as above for **4**. IR(Nujol): 2202 (w, ν_{Ir-H}), 1968, 1939 (s, ν_{CO}), 1921 (sh) cm^{-1}. ^1H NMR (CD_2Cl_2) δ: 2.46 (q, $J = 7.6$ Hz, 4H), 2.13 (s, 12H), 2.12 (s, 12H), 1.03 (t, $J = 7.6$ Hz, 6H), −16.24 (s, 2H). $^{13}C\{^1H\}$ NMR ($CDFCl_2$) δ: 97.6, 96.8 (s, $C(CH_3)$), 20.0 (s, $C(CH_2CH_3)$), 16.5 (s, $C(CH_2CH_3)$), 11.5, 11.3 (s, $C(CH_3)$). Anal. calcd. for $C_{24}H_{36}Ir_2O_2$: C 38.90, H 4.90; found: C 38.40, H 4.74.

Structure determination for [Cp'Ir(CO)H]$_2$ (6)

A yellow crystal of dimensions 0.25 × 0.30 × 0.35 mm was mounted in a stream of nitrogen gas at 183 K on an Enraf–Nonius CAD-4 diffractometer using MoKα radiation. Systematic absences were consistent with the monoclinic space group *C2/c*. A total of 2084 independent reflections were collected with $2\theta \leq 50°$, of which 1753 with $I > 3\sigma(I)$ were used in the refinement. The structure was solved by direct methods that gave the location of the Ir atoms. The remaining non-hydrogen atoms were located in difference Fourier maps. The hydrogen atoms were placed at calculated positions. The final R factor was 2.98%.

Crystal data tables, bond lengths and angles, anisotropic displacement coefficients, and hydrogen atom coordinates have been deposited as supplementary material.[3]

*Thermolysis of [Cp*Ir(CO)H]$_2$ (4)*

To an NMR tube fitted with a high-vacuum Teflon stopcock was added 5.0 mg of **4** (7.0 μmol). Degassed benzene-d_6 (about 0.5 mL) was vacuum transferred onto the solids. The NMR tube was sealed under vacuum and placed in an oil bath heated to 100°C and shielded from light.

Results

Synthesis

Reaction of CpIr(P(OPh)$_3$)H$_2$ (Cp = η-C$_5$H$_5$) with one-half equivalent of triflic acid in methylene chloride with subsequent heating affords H$_2$ and the dimeric cation {[CpIr(P(OPh)$_3$)H]$_2$(μ-H)}O$_3$SCF$_3$ (**1**) as shown in Scheme 1 for the analogous Cp'-carbonyl (Cp' = η-C$_5$Me$_4$Et) compounds. Complex **1** can also be prepared by reaction of isolated[4] CpIr(P(OPh)$_3$)H$_3^+$ with CpIr(P(OPh)$_3$)H$_2$.

Deprotonation of **1** is readily carried out by treatment with strong bases such as LDA (lithium diisopropylamide) or sodium bis(trimethylsilyl)amide to afford the neutral species [CpIr(P(OPh)$_3$)H]$_2$ (**2**). The dynamics of this dimeric dihydride as revealed by variable temperature NMR spectroscopy proved to be quite complex, as described below.

By a similar procedure, protonation of Cp*Ir(CO)H$_2$ (Cp* = η-C$_5$Me$_5$) with triflic acid affords the dimeric cation {[Cp*Ir(CO)H]$_2$(μ-H)}O$_3$SCF$_3$ (**3**). Complex **3** is readily deprotonated by relatively mild bases such as triethylamine or 1,8-bis(dimethylamino)naphthalene to afford the neutral dimer [Cp*Ir(CO)H]$_2$ (**4**). The structure and dynamic behaviour of **3** and **4** are similar to those exhibited by the triphenylphosphite complexes **1** and **2**, and are detailed below.

Scheme 1.

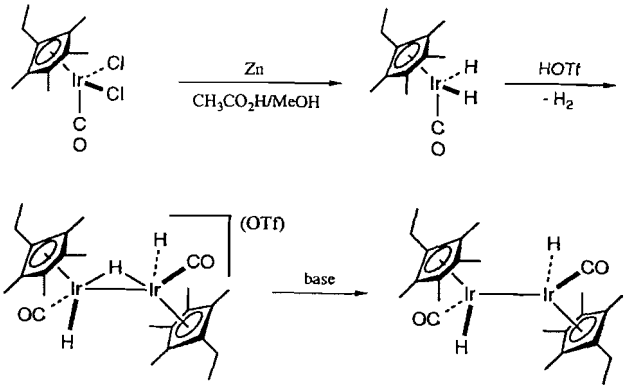

Table 1. Crystallographic data for [Cp'Ir(CO)H]$_2$ (**6**).

$Ir_2C_{24}H_{36}O_2$	fw 740.9
a = 20.262(2) Å	Space group *C2/c*
b = 7.913(2) Å	λ = 0.71073 Å
c = 16.771(3) Å	ρ_{calcd} = 2.077 g/cm^3
β = 117.52(2)°	μ = 112.36 cm^{-1}
V = 2369.7(5) Å^3	Z = 4
$R(F_o)$ = 0.0298	$R_w(F_o)$ = 0.0377

An additional probe of the stereodynamics of these complexes is available in the lower symmetry derivatives prepared with the ethyltetramethylcyclopentadienyl ligand (Cp' = η-C$_5$Me$_4$Et). Thus {[Cp'Ir(CO)H]$_2$(μ-H)}O$_3$SCF$_3$ (**5**) and [Cp'Ir(CO)H]$_2$ (**6**) were prepared from Cp'Ir(CO)H$_2$ by the procedures outlined in Scheme 1.

Structure of [Cp'Ir(CO)H]$_2$ (6)

A summary of the crystallographic data is given in Table 1. An ORTEP diagram is shown in Fig. 1. Atomic coordinates for the non-hydrogen atoms are in Table 2 and selected bond lengths and angles are given in Table 3. The hydride ligands were not located, but a structure with terminal hydride ligands is indicated for **2**, **4**, and **6** based on the observation of terminal Ir–H stretching bands in the infrared spectrum[5] and variable temperature NMR data (see discussion section).

Variable temperature NMR spectroscopy

The ^{1}H NMR spectrum obtained for [CpIr(P(OPh)$_3$)H]$_2$(μ-H)$^+$ in the hydride region at ambient temperature consists of a single triplet resonance with J_{H-P} = 18.5 Hz. At lower temperatures, the signal broadens and ultimately decoalesces to give a doublet resonance at −17.22 ppm (J_{H-P} = 34 Hz) and a poorly resolved triplet at −19.92 ppm (J_{H-P} = 19 Hz) in the intensity ratio 2:1. The limiting spectrum was obtained at 153 K (CDFCl$_2$, 500 MHz). These observations indicate that the ground state structure of **1** has two terminal hydride ligands and one bridging hydride ligand and that a rapid rearrangement process causes site exchange of the terminal and bridging hydride ligands. Lineshape analysis of spectra obtained for

1 in the temperature range 153–210 K gave $\Delta G^{\ddagger}_{298} = 8.8 \pm 0.6$ kcal mol^{-1}, $\Delta H^{\ddagger} = 6.8 \pm 0.2$ kcal mol^{-1}, and $\Delta S^{\ddagger} = -6.8 \pm 1.2$ cal mol^{-1} K^{-1}.

In the case of $[CpIr(P(OPh)_3)H]_2$ (**2**), each metal center is chiral and the complex can in principle exist as a mixture of two diastereomers, which would be expected to give distinct signals in the ^{1}H NMR spectrum. In fact, the ^{1}H NMR spectrum of **2** recorded at ambient temperature (THF-d_8) gives only one resonance in the hydride region at −17.0 ppm (triplet, $J_{H-P} = 24$ Hz) (see Fig. 2). Lowering the observation temperature leads to broadening of this triplet resonance and the appearance of a new, very broad signal at −17.4 ppm. Further cooling causes the new minor resonance to sharpen into a well-resolved triplet ($J_{H-P} = 24$ Hz). At 200 K, the major signal

[a]Cp(1) refers to the centroid of the C_5Me_4Et ring on Ir(1).

sharpens into a well-resolved doublet at −16.8 ppm (J_{H-P} = 47 Hz). Integration of the hydride resonance indicates a ratio of the major doublet resonance to the minor triplet resonance of 4.2:1. A similar temperature dependence was noted in the $^{31}P\{^1H\}$ NMR spectra of **2** recorded at various temperatures in that a major and a minor species were observed. The signals coalesced at 288 K. The activation energy for the interconversion was estimated using the method of Shanan-Atidi and Bar-Eli (18). This analysis gives $\Delta G^{\ddagger}_{288} = 13.5 \pm 0.6$ kcal mol^{-1} for the conversion of the major species to the minor species, and $\Delta G^{\ddagger}_{288} = 12.7 \pm 0.5$ kcal mol^{-1} for the reverse reaction.

A second fluxional process is clearly operational in complex **2** and is manifest by the change in the hydride coupling to the two ^{31}P nuclei. At low temperature, the doublet splitting in the major species is consistent with two localized, terminal hydride ligands (the three-bond H–P coupling appears to be approximately zero). At higher temperatures, a dynamic process occurs that interchanges these two hydride ligands, leading to a triplet pattern in the ^1H NMR spectrum, with half the coupling observed in the low-temperature doublet. The hydride exchange in the minor species appears to be more facile and is not frozen out at 200 K. The spectra of the minor species were not sufficiently well resolved for detailed analysis, but analysis of the hydride lineshape for the major species indicates that $\Delta H^{\ddagger} = 10.2 \pm 0.5$ kcal mol^{-1}, $\Delta S^{\ddagger} = -4.4 \pm 2$ cal mol^{-1} K^{-1}, and $\Delta G^{\ddagger}_{288} = 11.5 \pm 1$ kcal mol^{-1}.

The room temperature ^1H NMR spectrum of $[Cp^*Ir(CO)H]_2(\mu\text{-}H)^+$ (**3**) in $CDFCl_2$ exhibits a single sharp resonance in the hydride region at –16.44 ppm. Even at very low temperatures, a static limit ^1H NMR spectrum could not be obtained. At 138 K in $CDFCl_2$ (500 MHz), two broad resonances were observed at −15.3 and −18.1 ppm. Reliable integrals could not be obtained due to the extreme broadness of the resonances. The intensity of the downfield peak is greater and it is assigned by analogy to the spectrum of **1** to the terminal hydride ligands. The peak at −18.1 ppm is attributed to the bridging hydride ligand.

The room temperature ^1H NMR spectrum ($CDFCl_2$, 500 MHz) of $[Cp^*Ir(CO)H]_2$ (**4**) in the hydride region consists of a single resonance at −16.2 ppm. Lowering the temperature to 263 K gives substantial line broadening. At 229 K, a sharp signal at −16.0 ppm and a weak broad peak at −19.2 ppm were observed. The ratio of the two peaks was determined by integration to be 12.3:1. Continued cooling decreases the peak linewidths and shifts the ratio to 2.2:1 at 168 K. All spectral changes with temperature are fully reversible. A van't Hoff plot of ln K_{eq} versus $1/T$ yields the thermodynamic parameters for the interconversion between the two species: $\Delta H° = 1.98 \pm 0.23$ kcal mol^{-1} and $\Delta S° = 13.3 \pm 1.2$ cal mol^{-1} K^{-1}. The activation energy for the interconversion was estimated from the coalescence temperature as outlined above. At the coalescence temperature (240 K) $\Delta G^{\ddagger} = 11.2 \pm 0.6$ kcal mol^{-1} for the conversion of the major species to the minor species, and $\Delta G^{\ddagger} = 10.0 \pm 0.4$ kcal mol^{-1} for the reverse reaction.

To probe for a dynamic process that would exchange the two terminal hydride ligands in **4**, the complex was prepared with ^{13}C labeling in the carbonyl groups, i.e., $[Cp^*Ir(^{13}CO)H]_2$ (**4***). The ^1H NMR spectrum of **4*** exhibits a poorly resolved triplet hydride resonance (J_{C-H} = 4.5 Hz) at room temperature. At 145 K, two resonances are observed as was the case for **4.** The major resonance at −15.89 ppm is a doublet (J_{C-H} = 7.9 Hz), and the minor resonance at −19.04 ppm is a triplet (J_{C-H} = 6.0 Hz).

The variable temperature ^1H NMR spectrum of $[Cp'Ir(CO)H]_2$ (**6**) in the hydride region is similar to that described above for complex **4**. Interconversion between a major and minor species is frozen out at low temperature. In addition, the major species exhibits four distinct methyl resonances, while the minor species shows only two methyl resonances.

Thermolysis of $[Cp^*Ir(CO)H]_2$ (4)

At room temperature, the neutral dihydride dimer (**4**) is thermally stable with respect to loss of H_2 as a solid or in solution. When a solution of **4** in benzene-d_6 is heated to 100°C, $[Cp^*Ir(CO)]_2$ (^1H NMR: δ 1.57) is produced. The reaction is extremely slow, with only ca. 15% conversion after 2 weeks under these conditions. After the initial period in which only $[Cp^*Ir(CO)]_2$ was formed, the appearance of small amounts of monomeric $Cp^*Ir(CO)H_2$ was noted.

Discussion

Synthesis

Protonation of the neutral metal dihydride complex $CpRh(PiPr_3)H_2$ was reported by Werner and Wolf (19) to generate H_2 and a cationic dimeric species, formulated as $[CpRh(PiPr_3)]_2(\mu\text{-}H)_3^+$. In the case of similar iridium complexes, Gilbert and Bergman reported (20) that protonation of $Cp^*Ir(PMe_3)H_2$ affords the monomeric cation $Cp^*Ir(PMe_3)H_3^+$. Hydrogen loss from this cationic species

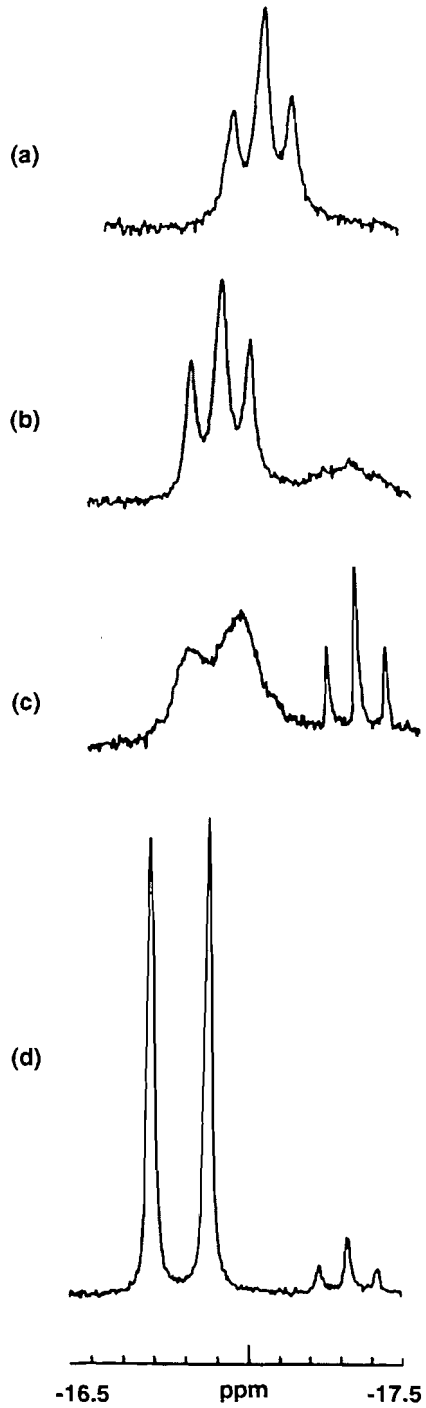
For personal use only.

Fig. 2. Partial ^{1}H NMR (250 MHz) spectra of $[CpIr(P(OPh)_3)H]_2$ (**2**) in THF-d_8: (*a*) 300 K, (*b*) 257 K, (*c*) 238 K, (*d*) 200 K.



does not occur readily. The dimeric iridium species identified as $[Cp^*Ir(PMe_3)H]_2(\mu\text{-}H)^+$ was prepared (20) by reaction of $[Cp^*Ir]_2(\mu\text{-}H)_3^+$ with PMe_3. We find that protonation of monomeric iridium dihydride complexes such as $CpIr(P(OPh)_3)H_2$ cleanly affords dimeric cations. This reaction also works well for $Cp^*Ir(CO)H_2$. The dimer formation reaction depicted in Scheme 1 proceeds via initial protonation of the neutral dihydrides to afford the cationic trihydride complexes. In the case of L = $P(OPh)_3$ (as well as several other phosphines), this complex is isolable and has been previously reported (15). When L = CO, hydrogen loss is facile, and the monomeric trihydride complex has only been observed at very low temperatures.[6] This condensation methodology is very efficient. When the progress of the reaction between $Cp^*Ir(CO)H_2$ and triflic acid is monitored by ^{1}H NMR spectroscopy, the yield of dimer is quantitative. Isolated yields are somewhat diminished by losses during manipulation. The relative facility with which these various $(\eta\text{-}C_5R_5)Ir(L)H_3^+$ compounds lose H_2 and hence undergo the condensation to dimers (i.e., $Cp^*Ir(CO)H_2$ > $CpIr(P(OPh)_3)H_2 \gg Cp^*Ir(PMe_3)H_2$) correlates well with the decreasing electron density at the metal.

Deprotonation of the carbonyl dimers $[Cp^*Ir(CO)H]_2(\mu\text{-}H)^+$ and $[Cp'Ir(CO)H]_2(\mu\text{-}H)^+$ is readily effected by mild bases such as triethylamine or 1,8-bis(dimethylamino)naphthalene (Proton Sponge®). While quantitative pK_a data have not yet been obtained, it is clear that the phosphite complex $[CpIr(P(OPh)_3)H]_2(\mu\text{-}H)^+$ is a much weaker acid than the cationic carbonyl dimers. A stronger base, such as LDA, is required to carry out the deprotonation in this case. This is consistent with lower electron density at the metal centers in the carbonyl-containing complexes.

The same synthetic path was followed in the preparation of ^{13}C labeled derivatives of the Cp* complexes. Reaction of $[Cp^*IrCl_2]_2$ with ^{13}CO gives $Cp^*Ir(^{13}CO)Cl_2$. Subsequent transformations were carried out as detailed above for the unlabelled analogs.

Structure of $[Cp'Ir(CO)H]_2$ (6)

An X-ray structure determination confirmed the dimeric nature of **6** with an Ir—Ir bond length of 2.724 Å and terminal carbonyl ligands. While the hydride ligands could not be definitively located in the structure determination, the infrared spectrum indicates the presence of terminal hydride and terminal carbonyl ligands. The results of investigations of **2**, **4**, and **6** by variable temperature NMR spectroscopy indicate that the ground state structure has terminal hydrides (see below). Intraligand angles in **6** are similar to those observed (21) in closely related monomeric complexes such as $Cp^*Ir(PMe_3)(H)Cy$, in which, for example, the angle between the Cp* centroid and the phosphine is 131°. The comparable angle in **6** between the Cp′ moiety and the carbonyl group is 137°.

There are few structurally characterized examples of unbridged Ir—Ir single bonds in the literature. Examples include a distance of 2.717 Å reported (22) in 1973 for $Ir_2(NO)_4(PPh_3)_2$ and a distance of 2.839 Å reported (23) for the dication $[Cp^*Ir(CO)_2]_2^{2+}$. A closely related complex with bridging carbonyl ligands and a formal Ir—Ir double bond is $[Cp^*Ir(CO)]_2$, which has an Ir—Ir distance of 2.554 Å (24). Structural characterization of $[Cp^*Os(CO)(\mu\text{-}H)]_2$, a very similar dimeric complex of osmium, indicates that the two hydride ligands are bridging the Os═Os double bond, which has a bond length of 2.677 (25). In $[Cp^*Os(CO)(\mu\text{-}H)]_2$, unlike in $[Cp'Ir(CO)H]_2$ (**6**), the metal atoms, the carbonyl carbons, and the ring centroids all form a plane.

The structural results indicate that **6** has crystallized as the racemic diastereomer (*RR/SS* enantiomeric pair). Solution

NMR spectroscopy data discussed below show that there is a rapidly established equilibrium between the racemic and meso forms of **6** from which the racemic form crystallizes.

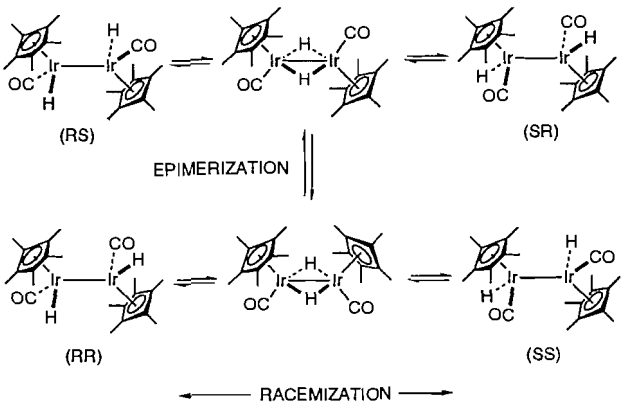
Dynamics

The variable temperature NMR spectroscopy of the trihydride dimers **1**, **3**, and **5** is consistent with the presence of one bridging and two terminal hydride ligands. A rapid dynamic process is operational in these complexes that allows site exchange of the terminal and bridging ligands. In the case of $[CpIr(P(OPh)_3)H]_2(\mu\text{-}H)^+$ (**1**), this process is indicated by the observation of a single triplet resonance (J_{H-P} = 18 Hz) in the hydride region of the ^1H NMR spectrum at room temperature. This observation would also be consistent with a triply bridging structure, as suggested by Werner and Wolf (19) for the related dimeric trihydride complex that results from the reaction of $CpRh(P\textit{i}Pr_3)H_2$ with acid. The observation at low temperature of two distinct hydride resonances in the intensity ratio 2:1 favors the less symmetrical, singly bridged structure. The coupling to ^{31}P is in agreement with this structure, in that the resonance corresponding to one hydride is a triplet, while the more intense signal is a doublet. This same structure was found by Gilbert and Bergman (20) for the closely related trimethylphosphine complex $[Cp^*Ir(PMe_3)H]_2(\mu\text{-}H)^+$. Complex **1** differs from the previously reported PMe_3 complex in having a somewhat lower barrier to the dynamic process that permutes the bridging and terminal hydride ligands. A very similar situation was reported by Werner et al. (26) for the structure of $\{[CH_2(C_5H_4)_2][RhH(P\textit{i}Pr_3)]_2(\mu\text{-}H)\}^+$. In this case, the presence of bridging and terminal hydride ligands was indicated crystallographically, but the bridge–terminal exchange process was too facile to be frozen out by low-temperature NMR spectroscopy.

Qualitatively similar observations were made for $[Cp^*Ir(CO)H]_2(\mu\text{-}H)^+$ (**3**). The structural assignment here is less definitive, since ^{31}P coupling is not available to aid in the differentiation of terminal and bridging hydride ligands. In an attempt to verify that the dynamic behavior of **3** is analogous to that of **1**, we prepared complex **3** with ^{13}C labels in the carbonyl carbon atoms (referred to as **3***). At ambient temperature, the ^1H NMR spectrum for **3*** shows a triplet hydride resonance with J_{H-C} = 3.4 Hz. The expected doublet and triplet H–C couplings in **3*** were not resolvable in the low-temperature spectra.

The structures of complexes **2**, **4**, and **6** are thought to be dihydride dimers with two terminal hydride ligands. This structural hypothesis is based on the observation of terminal Ir–H stretches in the infrared spectra, and on the couplings between the hydride ligands and adjacent spin active nuclei observed in the ^1H NMR spectra. For example, $[CpIr(P(OPh)_3)H]_2$ (**2**) exhibits a triplet signal for the hydride ligands at high temperature, due to coupling to two ^{31}P nuclei. While this observation alone is consistent with the presence of bridging hydrides, variable temperature data show that the hydride resonance (of the major species, see below) simplifies to a doublet at low temperature. This is consistent only with a ground state structure having terminal hydride ligands and a rapid permutation process that causes the hydride ligands to exchange. We propose that this process takes place via an intermediate or transition state with two bridging hydride ligands (see Scheme 2). The observation that the hydride signal of the *minor* species of **2** remains as a triplet in the ^1H NMR down to 200 K is consistent with a ground state structure possessing bridging hydrides (see Fig. 2). We believe, however, that the slight broadening of the triplet resonance at 200 K indicates that the hydrides are indeed terminal and fluxional and that at still lower temperatures the signal would become a doublet.

Scheme 2.



In addition to the dynamic process that causes the permutation of the two hydride ligands, variable temperature NMR (^1H and ^{31}P) observations on complex **2** indicate the presence of two different species. The relative concentrations of these two species vary with temperature, consistent with a rapid reversible equilibrium.

Since both metal centers in dimers such as **2** are chiral, the existence of two diastereomers is possible. The two diastereomers are the racemic form (*RR*/*SS* enantiomeric pair) and the meso structure (*RS* or *SR*). It is proposed that rapid epimerization occurs, causing rapid equilibration of the two diastereomers of **2**. Thermodynamic parameters for the interconversion have been estimated from the lineshapes of the ^1H and ^{31}P NMR spectra. Note that the hydride site exchange process will lead to synchronous inversion of configuration at both Ir centers *without* epimerization.

It should be noted that the suggestion of rapid epimerization of pseudo-octahedral complexes of iridium is somewhat novel. In closely related *monomeric* complexes such as $Cp^*Ir(CO)(H)(\text{-}CH_2CMe_3)$ (27), the diastereotopic methylene protons are distinct in the ^1H NMR spectrum at room temperature, indicating that the metal center is configurationally rigid on the NMR time scale at this temperature. Similar observations have been reported (28) for $Cp^*Ir(PMe_3)(H)(\text{-}CH_2CMe_3)$. The mechanism of the rapid epimerization observed in the dimeric complexes studied here is not clear, but there are obviously large differences in stereochemical nonrigidity between closely related monomeric and dimeric complexes.

Similar observations have been made for $[Cp^*Ir(CO)H]_2$ (**4**). Infrared spectra are only consistent with the presence of terminal carbonyl and terminal hydride ligands. Variable temperature ^1H NMR spectra reveal that two species are present in rapid equilibrium. The incorporation of two ^{13}C labels in the carbonyl groups (designated **4***) allowed the detection of coupling to the hydride ligands. The hydride resonance of **4*** is a poorly resolved triplet ($J_{H-C} \approx$ 4–5 Hz) at room temperature. At lower temperatures, two distinct signals are observed: the major signal is a doublet (J_{H-C} = 7.9 Hz), while the resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

due to the minor species remains a triplet (J_{H-C} = 6.0 Hz) at all accessible temperatures. The overall situation for complex **4** is very similar to that of **2**.

To directly verify the stereochemical nonrigidity of the metal centers in these dimers, complex **6** has been prepared in which the Cp^* ligands of **4** have been replaced by η-C_5Me_4Et (Cp′). This ligand provides a convenient probe for stereochemical nonrigidity at the metal centers in that the diastereotopic methylene protons[7] and the diastereotopic methyl groups will be rendered equivalent by a rapid change (on the NMR timescale) of configuration at the metal center. We find that the variable temperature ^{1}H NMR spectrum of **6** at room temperature exhibits a single hydride resonance and only two resonances for the methyl groups attached to the ring carbons. At lower temperatures, two hydride resonances of unequal intensity are observed, similar to the situation observed in complex **4**. The methyl region of the spectrum also exhibits a major and minor set of resonances. The major species has four distinct methyl resonances, consistent with the freezing out of the configuration at the metal centers. This is in accord with the observation of a doublet resonance for the hydride ligands of the major species at low temperature in the ^{1}H NMR spectrum of complex **4***. The minor species of complex **6** exhibits only two methyl resonances at all accessible temperatures, indicating that the metal centers are not configurationally stable. This is again consistent with the observation of a triplet resonance for the hydride ligands of the minor species at all temperatures in the ^{1}H NMR spectrum of complex **4***.

The presence of rotamers with respect to the Ir—Ir bond is an alternative hypothesis that warrants consideration to explain the observation of two rapidly equilibrating species for **2**, **4**, and **6**. In this scenario, the interconversion of the major to minor species involves simple rotation around the Ir—Ir bond and would not alter the configuration at the metal centers. *However*, hydride migration between Ir atoms within a given rotamer would lead to racemization of those metal centers and hence would also render the diastereotopic groups of **6** equivalent. The observation of decoalescence of the resonances of the diastereotopic ring methyl groups in **6** is thus consistent with this hypothesis. We believe, however, that the rotamer hypothesis is unlikely as it requires that only a single diastereomer be present. This would require that the reactions that lead to formation of all the neutral dimers be completely diastereoselective.

Thermolysis of $[Cp^*Ir(CO)H]_2$ (4)

Complex **4** is thermally robust. Prolonged heating to 100°C affords the known (24) carbonyl-bridged, doubly bonded dimer $[Cp^*Ir(CO)]_2$. The apparent large activation energy barrier to elimination of hydrogen is consistent with that expected for a formally symmetry-forbidden, concerted, 1,2-dinuclear reductive elimination reaction. Further studies to elucidate the mechanism of this novel reaction were complicated by secondary chemistry that begins to be significant after about 30% conversion. Specifically, the formation of $Cp^*Ir(CO)H_2$ was noted,[8] indicative of dimer fragmentation. A similar, very slow thermal reaction of a tungsten dihydride dimer to afford H_2 was recently reported by Tilset et al. (29). In this case, a radical chain mechanism was proposed. The stereochemical nonrigidity of the dimeric iridium complexes noted above suggests that a *cis* hydride geometry suitable for 1,2 hydrogen elimination should be accessible. The product doubly bonded dimer $[Cp^*Ir(CO)]_2$ is extremely thermally robust. These observations are consistent with a high kinetic barrier to reductive elimination imposed by orbital symmetry constraints.

[7] We found the diastereotopic methylene protons to be poor probes of stereochemical nonrigidity due to small chemical shift inequivalence and the presence of complicated coupling (ABX_3 spin system). Hence the diastereotopic methyl groups were used exclusively.

[8] $Cp^*Ir(CO)H_2$ has been previously reported (30).

Conclusions

The protonation of monomeric dihydrides of the form $CpIrLH_2$ (Cp = C_5H_5, L = $P(OPh)_3$; Cp = C_5Me_5 or C_5Me_4Et, L = CO) provides a general and efficient route for the generation of the dinuclear complexes (**1**, **3**, **5**). The resulting cationic trihydride dimers each exhibit a single resonance in the hydride region of the ^{1}H NMR spectrum at ambient temperature. Variable temperature ^{1}H NMR spectroscopy reveals that the ground state structure possesses one bridging and two terminal hydride ligands that rapidly exchange at room temperature.

Deprotonation of **1**, **3**, and **5** affords the neutral dihydride dimers (**2**, **4**, and **6**). Variable temperature ^{1}H NMR, IR, and crystallographic analysis indicate that these compounds have terminal hydride and terminal carbonyl ligands, i.e., unsupported Ir—Ir bonds. Very few examples of this structural type have been reported previously. As in **1**, **3**, and **5**, the hydride ligands rapidly permute between Ir centers at room temperature.

Compounds **2**, **4**, and **6** can each achieve two diastereomeric configurations (*RR/SS* or *RS/SR*) due to the presence of two chiral iridium centers per molecule. Although closely related monomeric complexes are configurationally stable on the NMR time scale, these dimers undergo facile epimerization.

Thermolysis of $[Cp^*Ir(CO)H]_2$ (**4**) leads to slow loss of H_2 to afford the doubly bonded dimer $[Cp^*Ir(CO)]_2$. The mechanism of H_2 elimination has yet to be established.

Acknowledgments

We thank the National Science Foundation for support of this research. Partial support was also provided by the Petroleum Research Foundation, administered by the American Chemical Society. We thank Dr. David Barnhart for the crystallographic analysis and Ms. Amber Hinkle for help with variable temperature NMR work.

Preparation and characterization of a new series of Cr(II) hydroborates

Michel Dionne, Shoukang Hao, and Sandro Gambarotta

Abstract: The synthesis and characterization of a new series of mono-, di-, and trinuclear Cr(II) borohydride compounds is described. The reaction of $CrCl_2$(TMEDA) with two equivalents of $NaBH_4$ afforded the thermally unstable (TMEDA)Cr(BH_4)$_2$ (**1**), which was converted by treatment with pyridine into the octahedral monomeric (Py)$_4$Cr(BH_4)$_2$ (**2**). The reaction proceeds via formation of an intermediate trinuclear complex {[(TMEDA)(Py)Cr(η^2-BH_4)]$_2$[(Py)$_2$Cr(η^2-BH_4)$_2$]}(μ,η^1-BH_4)$_2$ (**3**), which was isolated and characterized by X-ray crystallography. Reaction of **1** and **2** with both CO_2 and RN=C=NR (R = Cy, *i*Pr) afforded hydride insertion and formation of the corresponding diamagnetic lantern-type Cr(II) formate $(HCO_2)_4Cr_2Py_2$ (**4**) and formamidinate compounds [RNC(H)NR]$_2$Cr$_2$(μ-BH)$_4$ (R = Cy (**5***a*), iPr (**5***b*)), respectively, with supershort Cr—Cr quadruple bonds. The structures of **1**, **2**, **3**, and **5***b* were elucidated by X-ray analysis. Crystal data are as follows. **1**: $C_6H_{24}N_2B_2Cr$, monoclinic, *Cc*, a = 8.517(2) Å, b = 15.921(5) Å, c = 9.624(2) Å, β = 115.59(1)°, Z = 4, R = 0.022, R_w = 0.029; **2**: $C_{28}H_{44}N_4B_2O_2Cr$, monoclinic, $P2_1/n$, a = 12.021(1) Å, b = 15.555(1) Å, c = 15.723(1) Å, β = 90.13(2)°, Z = 4, R = 0.074, R_w = 0.086; **3**: $C_{32}H_{76}N_8B_6Cr_3$, monoclinic, $P2_1/n$, a = 8.515(1) Å, b = 14.525(1) Å, c = 18.286(2) Å, β = 91.38(1)°, Z = 2, R = 0.051, R_w = 0.060; **5***b*: $C_{21}H_{49}N_6BCr_2$, monoclinic, *C2/c*, a = 17.000(1) Å, b = 9.033(1) Å, c = 19.160(1) Å, β = 105.579(9)°, Z = 4, R = 0.069, R_w = 0.078.

Key words: divalent chromium, borohydride, Cr—Cr quadruple bond.

Résumé : On décrit la synthèse et la caractérisation d'une série de borohydrures mono-, di- et trinucléaires du Cr(II). La réaction du $CrCl_2$(TMEDA) avec deux équivalents de $NaBH_4$ fournit le (TMEDA)Cr(BH_4)$_2$ (**1**) qui est thermiquement instable et qui, par traitement avec de la pyridine, se transforme en (Py)$_4$Cr(BH_4)$_2$ (**2**). La réaction se produit par le biais de la formation d'un complexe intermédiaire trinucléaire {[(TMEDA)(Py)Cr(η_1-BH_4)]$_2$[(Py)$_2$Cr(η^2-BH_4)$_2$]}(μ,η^1-BH_4)$_2$ (**3**) que l'on a isolé et caractérisé par diffraction des rayons X. Les réactions de composés **1** et **2** avec le CO_2 ou le RN=C=NR (R = Cy ou iPr) conduisent à une insertion d'hydrure et à la formation des composés diamagnétiques correspondants, respectivement le formiate de Cr(II) de type lanterne, $(HCO_2)_4Cr_2Py_2$ (**4**), et les formamidinates, [RNC(H)NR]$_2$Cr$_2$(μ-BH)$_4$ (R = Cy (**5***a*), iPr (**5***b*)), dans lesquels les longueurs des liaisons quadruples Cr—Cr sont extrêmement courtes. On a élucidé les structures des composés **1**, **2**, **3** et **5***b* par diffraction des rayons X. Les données cristallines sont les suivantes: **1**, $C_6H_{24}N_2B_2OCr$, monoclinique, *Cc*, a = 8,517(2), b = 15,921(5) et c = 9,624(2) Å, β = 115,59(1)°, Z = 4, R = 0,022 et R_w = 0,029; **2**, $C_{28}H_{44}N_4B_2O_2Cr$, monoclinique, $P2_1/n$, a = 12,021(1), b = 15,555(1) et c = 15,723(1) Å, β = 90.13(2)°, Z = 4, R = 0,074 et R_w = 0,086; **3**, $C_{32}H_{76}N_8B_6Cr_3$, monoclinique, $P2_1/n$, a = 8,515(1), b = 14,525(1) et c = 18,286(2) Å, β = 91,38(1)°, Z = 2, R = 0,051 et R_w = 0,060; **5***b*, $C_{21}H_{49}N_6BCr_2$, monoclinique, *C2/c*, a = 17,000(1), b = 9,033(1) et c = 19,160(1) Å, β = 105,579(9)°, Z = 4, R = 0,069 et R_w = 0,078.

Mots clés : chrome divalent, borohydrure, liaison quadruple Cr—Cr.

[Traduit par la rédaction]

Introduction

Tetrahydroborate complexes of transition metals are employed not only as versatile precursors for the preparation of transition metal polyhydrides (see, for example, ref. 1) and alkyls (2), but also as important and efficient catalysts for hydrogenation and polymerization reactions (3). For example, tetrahydroborate complexes of group 4, 5, and 6 metals are used in the catalytic hydrorefinement of petroleum sludges and residues to light hydrocarbons and to other useful commodity chemicals freed from asphaltenes, metal impurities, and sulfur (4). In view of these useful applications transition metal, lanthanide and actinide tetrahydroborate complexes have been widely investigated (5–7) and, as a result of the considerable amount of research in this field, only a few transition metal tretrahydroborate complexes remain unexplored. Unfortunately, a large variety of catalytic transformations promoted by these systems has been reported only in the patent literature and therefore knowledge about the chemical behavior of these species remains scarce.

Aside from their importance in industrial processes, tetrahydroborate complexes of transition metals are also popular

Received October 19, 1994.

This paper is dedicated to Professor William A.G. Graham on the occasion of his 65th birthday and in recognition of his accomplishments for the advancement of inorganic chemistry in Canada.

because of their close relation with transition metal hydrides. As a matter of fact, a common method of preparing polyhydride complexes typically consists of the reaction of transition metal tetrahydroborates with a Lewis base or water (5, 6, 8). In addition, although the mechanisms of reactions catalyzed by transition metal hydroborates have not been completely elucidated, there is evidence that in situ generated polyhydride complexes are likely to be the most important intermediates of the catalytic cycles (9).

Given this background, it is surprising that chromium tetrahydroborates are poorly known, and that only a few very stable species such as $CpCr(BH_4)$ (10), $Cr(BH_4)_2THF_2$ (11), $Cr(BH_4)_2py_2$ (11), and $Cr(BH_4)_2en$ (11) have been reported and formulated on the exclusive basis of their spectroscopic and microanalytical data. Only in the case of $Cr(BH_4)H(dmpe)_2$ (7) has a complete structural analysis been reported. This paucity of the literature is in striking contrast with the great potential offered by these compounds for the preparation of rare chromium hydrides (12).

In this paper we describe the preparation and characterization of a novel series of chromium(II) tetrahydroborates together with a preliminary study of their chemical reactivity. One of the *stimuli* to undertake this study was provided by the variety of possible bonding modes displayed by the BH_4^- anion (5). Since Cr(II) complexes generally display a marked preference for square-planar structures with high-spin electronic configurations (see, for example, ref. 13), we were interested in testing the ability of the tetrahydroborate anion to facilitate the assembly of dimers with a lantern-type structure, where the BH_4^- anion would adopt a three-center chelating bridging bonding mode. To achieve this goal we have decided to use a chelating amine such as TMEDA (TMEDA = *N,N,N',N'*-tetramethylethylenediamine) as supporting ligand. This ligand offers sufficient stabilization for the complex, while at the same time may dissociate to enable dimerization reactions. Chelating amines are also desirable because of their ability to remove BH_3 from the BH_4^- anion, which in the present case should lead to the formation of new Cr(II) hydrides.

Experimental section

All operations were performed under inert atmosphere in a dry-box (Vacuum Atmosphere) or using standard Schlenk techniques. $CrCl_2THF_2$ (14) was prepared according to published procedures. $NaBH_4$, CyN=C=NCy, (iPr)N=C=N(iPr), and $Me_3SiN{=}C{=}NMe_3$ (Aldrich) were purchased and used without further purification. NMR spectra were recorded on a Varian Gemini-200 and a Bruker AMX-500 spectrometer by using vacuum-sealed tubes. Solvents for NMR spectroscopy were dried over the appropriate desiccating agent, vacuum-transferred into ampoules, and stored inside a dry-box. Infrared spectra were recorded on a Mattson 9000 FT-IR instrument from Nujol mulls. Samples for magnetic susceptibility measurements were weighed under inert atmosphere and sealed into calibrated tubes. Magnetic measurements were carried out with a Gouy balance (Johnson Matthey) at room temperature. The magnetic moments were calculated according to standard methods (15), and corrections for underlying diamagnetism (16) were applied to data. Combustion analysis data were obtained with a PE 4000 analyzer.

$Cr(BH_4)_2TMEDA$ (1)

A suspension of $CrCl_2THF_2$ (1.78 g, 6.7 mmol) in THF (100 mL) was stirred at room temperature in the presence of an excess of TMEDA (5 mL, 34.5 mmol). The resulting bright-blue suspension was treated with excess $NaBH_4$ (1.06 g, 26.3 mmol). After stirring for 24 h at room temperature, NaCl and the excess $NaBH_4$ were removed by filtering the boiling solution. The deep-blue filtrate was allowed to cool slowly to room temperature, upon which violet crystals of **1** were formed (0.7 g, 3.5 mmol, 52%). IR (Nujol mull, cm^{-1}) ν: 2380(vs, br), 2230(m), 2120(vs, br), 1455(vs, br), 1405(w), 1375(vs, br), 1295(w), 1285(s), 1230(m), 1200(w), 1175(sh), 1155(s), 1120(vs, br), 1100(sh), 1060(m), 1040(m), 1010(s), 1000(sh), 950(s), 800(s), 770(m), 720(w), 590(w), 510(w, br). Anal. calcd. (found) for $C_6H_{24}N_2B_2Cr$: C 36.36(36.29), H 12.12(12.03), N 14.14(14.09). $\mu_{eff} = 4.8\ \mu_B$.

$Cr(BH_4)_2Py_4$ (2)

A suspension of **1** (1.9 g, 9.6 mmol) in THF (30 mL) was treated with pyridine (3 mL, 38 mmol) at room temperature and boiled for a few minutes until a clear green solution was formed. The solution was allowed to cool slowly to room temperature, upon which very air-sensitive red-orange crystals of **2** separated (1.8 g, 7.5 mmol, 78%). Occasionally formed green prisms of $\{[(TMEDA)(Py)Cr(\eta^1\text{-}BH_4)]_2[(Py)_2Cr(\eta^2\text{-}BH_4)_2]\}$ $(\mu,\eta^1\text{-}BH_4)_2$ (**3**) were eliminated by addition of one extra equivalent of pyridine. IR (Nujol mull, cm^{-1}) ν: 2300(vs, br), 2180(s), 2120(s), 2080(s), 1650(w), 1610(s), 1490(s), 1464(sh), 1450(s, br), 1380(m), 1310(w), 1240(w), 1220(s), 1150(m), 1110(sh), 1080–1040(vs, br), 1015(s), 915(m), 770(s), 705(s), 640(s), 600(w), 510(w, br), 440(s). Anal. calcd. (found) for $C_{20}H_{28}N_4B_2Cr{\cdot}2THF$: C 62.01(61.95), H 8.18(8.16), N 10.33(10.26). $\mu_{eff} = 2.83\ \mu_B$.

$Cr_2(CO_2H)_4Py_2$ (4)

A green solution, obtained by dissolving deep-red crystals of **2** (0.7 g, 2.9 mmol) in THF (100 mL), was saturated with CO_2 (room temperature, 1 atm (101.3 kPa)). The original green color turned red in about 20 min. The resulting solution was concentrated in vacuo and allowed to stand at −30°C overnight, upon which red crystals of **4** separated (0.2 g, 0.7 mmol, 48%). IR (Nujol mull, cm^{-1}) ν: 1620–1580(s, br), 1450(vs, br), 1380–1340(vs, br), 1220(m), 1155(w), 1065(w), 1036(m), 1006(w), 880(w), 770(s), 755(sh), 720(w), 700(s), 620(m), 435(s, br), 404(w). Anal. calcd. (found) for $C_{14}H_{14}N_2O_8Cr_2$: C 38.02(37.99), H 3.19(3.22), N 6.33(6.26). $\mu_{eff} = 0.6\ \mu_B$ per Cr_2 unit.

$Cr_2(CyNCHNCy)_3(BH_4)$ (*5a*)

Solid CyN=C=NCy (2.5 g, 12.1 mmol) was added to a blue suspension of **1** (1.2 g, 6.1 mmol) in THF (100 mL) at room temperature and the color turned dark yellow after a few minutes. The volume of the solution was reduced to ca 10 mL and yellow crystals of ***5a***, along with a small amount of white crystals of $TMEDA(BH_3)_2$, precipitated upon standing at −30°C overnight. Analytically pure yellow crystals of ***5a*** were obtained in low yield after several recrystallizations from THF (0.6 g, 0.8 mmol, 26%). IR (Nujol mull, cm^{-1}) ν: 2410(s), 2360(s), 2220(w), 2062(m, br), 1930(m, br), 1840(w, br), 1578(vs), 1450(vs, br), 1375(s), 1362(s), 1342(s), 1326(s), 1300(m), 1285(s), 1252(m), 1185(m), 1160(sh), 1150(s),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

1120(s), 1102(s), 1086(s), 1080(s), 1048(w), 1020(m), 990(m), 962(w), 886(s), 846(m), 804(m), 782(m), 722(m), 508(s), 484(s), 436(s). ^{1}H NMR (C_6D_6, 200 MHz, 25°C, ppm) δ: 8.6 (s, 2H, C-H formamidine), 8.5 (s, 1H, C-H formamidine), 3.5 (m, 4H, C-H cyclohexyl), 2.65 (m, 2H, C-H cyclohexyl), 2.2–0.8 (series of lines, 34H, cyclohexyl and BH_4). Anal. calcd. (found) for $C_{39}H_{73}N_6BCr_2$: C 63.23(63.17), H 9.93(9.86), N 11.34(11.19).

Cr_2[iPr)NC(H)N(iPr)]$_3$(BH_4) (*5b*)

The addition of neat (iPr)N=C=N(iPr) (2.9 mL, 18.5 mmol) to a blue suspension of **1** (1.83 g, 9.2 mmol) in THF (100 mL) at room temperature formed a dark yellow solution. The resulting solution was concentrated to small volume in vacuum and allowed to stand at −30°C overnight, upon which orange crystals of ***5b***, contaminated by a small amount of colorless needles of $(BH_3)_2$TMEDA, precipitated. Analytically pure ***5b*** was obtained in low yield (less than 10%) after several recrystallizations from THF. IR (Nujol mull, cm^{-1}) ν: 2401(s), 2365(s), 2236(w), 2101(m, br), 1966(w, br), 1583(s, br), 1456(s, br), 1409(m), 1375(s), 1360(s), 1301(s), 1175(s), 1122(s), 1101(s), 1056(w), 1025(m), 953(m), 932(w), 853(w), 816(w), 726(w), 668(w), 649(w), 570(w), 524(s), 486(s), 421(s). ^{1}H NMR (C_6D_6, 400 MHz, 25°C, ppm) δ: 8.53 (s, 2H, C-H formamidine), 8.50 (s, 1H, C-H formamidine), 3.77 (hept, J = 6.5 Hz, 4H, C-H isopropyl), 2.97 (hept, J = 6.5 Hz, 2H, C-H isopropyl), 1.32 (m, 4H, BH_4), 1.21 (d, J = 6.5 Hz, 12H, CH_3 isopropyl), 1.03 (d, J = 6.5 Hz, 12H, CH_3 isopropyl), 0.82 (d, J = 6.5 Hz, 12H, CH_3 isopropyl). Anal. calcd. (found) for $C_{21}H_{49}N_6BCr_2$: C 50.40(50.31), H 9.87(9.81), N 16.79(16.71).

Cr_2[(iPr)NC(H)N(iPr)]$_3$(O_2CH) (*6*)

A yellow solution of ***5b*** in d_6-benzene was saturated with CO_2 (1 atm, room temperature) inside an NMR tube. As the intensity of the signals of the starting material decreased, new peaks were observed. After 2 days the reaction was complete and the spectrum was consistent with the formulation Cr_2(iPr)NC(H)N(iPr)]$_3$(O_2CH). ^{1}H NMR (C_6D_6, 500 MHz, 25°C, ppm) δ: 8.86 (s, 1H, CH formate), 8.65 (s, 2H, CH formamidine), 8.61 (s, 1H, CH formamidine), 3.71 (m, 4H, CH isopropyl), 3.15 (m, 2H, CH isopropyl), 1.31 (d, J = 6.2 Hz, 12H, CH_3 isopropyl), 1.05 (d, J = 6.2 Hz, 12H, CH_3 isopropyl), 0.87 (d, J = 6.2 Hz, CH_3 isopropyl).

Cr_2(CyNCHNCy)$_4$ (*7a*)

A suspension of $Cr_2Cl_2THF_2$ (2.23 g, 8.4 mmol) in THF (100 mL) was stirred at room temperature in the presence of an excess of TMEDA (5 mL, 34.5 mmol). An excess of $NaBH_4$ (1.85 g, 48.7 mmol) was added to the resulting bright-blue suspension. After stirring for 24 h at room temperature, a violet solid was formed. The addition of 1,3-dicyclohexyl carbodiimide (5.0 g, 24.3 mmol) at room temperature immediately produced a yellow suspension. After boiling the mixture for a few minutes, the solvent was evaporated in vacuo. The addition of toluene (40 mL) to the resulting residue produced a yellow solution and a white solid, which was removed by filtration. The filtrate was allowed to stand at −30°C overnight, upon which yellow crystals of **7***a* (0.4 g, 0.86 mmol, 10%) separated. IR (Nujol mull, cm^{-1}) ν: 1662(w), 1596(s, br), 1451(s, br), 1376(s), 1360(s), 1348(s), 1326(s), 1294(s), 1257(s), 1238(w), 1203(w), 1178(w), 1150(s), 1125(s), 1103(s), 1084(s), 1071(s), 1049(w), 1018(m), 986(w), 955(m), 917(w), 889(s), 845(m), 798(m), 729(m), 694(w), 600(w), 550(m), 512(s), 487(s), 465(s), 430(s). ^{1}H NMR (C_6D_6, 200 MHz, 25C°) δ: 8.43 (s, 4H, formamidine), 7.08(pseudo quartet, 4H, toluene), 311(pseudo quintet, 8H, cyclohexyl), 2.10(s, 3H, toluene), 2.07(pseudo d, 16H, cyclohexyl), 1.81(pseudo d, 16H, cyclohexyl), 1.63(pseudo d, 8H, cyclohexyl), 1.30(m, 40H, cyclohexyl). Anal. calcd. (found) for $C_{52}H_{92}N_8Cr_2$·toluene: C 69.10(68.99), H 9.83(9.77), N 10.93(10.85).

Cr_2[(iPr)NC(H)N(iPr)]$_4$ (*7b*)

A suspension of $CrCl_2THF_2$ (2.09 g, 7.8 mmol) in THF (100 mL) was stirred at room temperature in the presence of an excess of TMEDA (5 mL, 34.5 mmol). An excess of $NaBH_4$ (1.91 g, 50.3 mmol) was added to the resulting bright-blue suspension. After stirring for 24 h at room temperature, a violet solid was formed. The addition of 1,3-diisopropylcarbodiimide (5.0 mL, 31.7 mmol) to the resulting suspension at room temperature formed a yellow suspension. The solvent was evaporated in vacuo after boiling for a few minutes. The addition of toluene (30 mL) to the resulting yellow solid produced a yellow solution and a white solid, which was removed by filtration. The filtrate was allowed to stand at −30°C overnight, upon which yellow crystals of **7***b* (0.5 g, 1.8 mmol, 20%) separated. IR (Nujol mull, cm^{-1}) ν: 1598(s, br), 1572(sh), 1458(s, br), 1408(m), 1373(s), 1357(s), 1348(s), 1297(s, br), 1180(s), 1161(s), 1120(s), 1101(s), 1025(s), 952(s), 930(w), 911(w), 873(w), 861(w), 816(m), 800(m), 725(w), 649(w), 551(w), 525(m), 484(s), 446(w), 424(s). ^{1}H NMR (C_6D_6, 200 MHz, 25°C, ppm) δ: 8.42 (s, 4H, CH formamidine), 3.53 (hept, J = 6.6 Hz, 8H, CH isopropyl), 1.20 (d, J = 6.6 Hz, 48H, CH_3 isopropyl). Anal. calcd. (found) for $C_{28}H_{60}N_8Cr_2$: C 54.88(54.81), H 9.87(9.85), N 18.28(18.21).

X-ray crystallography

Data were collected at low T in in the range −157 to −160°C using the ω–2θ scan technique, to a maximum 2θ value of 50.0°, for suitable air-sensitive crystals mounted on glass fibers. Cell constants and orientation matrices were obtained from the least-squares refinement of 25 carefully centered high-angle reflections. The intensities of three representative reflections were measured after every 150 reflections to monitor crystal and instrument stability, showing no significant decay. Data were corrected for Lorentz and polarization effects but not for absorption. The structures were solved by either Patterson or direct methods (11). The non-hydrogen atoms were refined anisotropically. Hydrogen atom positions were located in the difference Fourier maps and refined isotropically in the case of favorable observation/parameter ratio. The final cycle of full-matrix least-squares refinement was based on the number of observed reflections with $I > 2.5\sigma(I)$. Neutral atomic scattering factors were taken from Cromer and Waber (17). Anomalous dispersion effects were included in F_{calc}. All calculations were performed using the TEXSAN software package on a Digital VAX station. Details on data collection and structure refinement are reported in Table 1. Selected bond distances and angles are given in Table 2.

factors, torsion angles, bond angles and distances, and hydrogen atom positional parameters associated with complexes **1**, **2**, **3**, and **5***b* have been deposited as supplementary material.[2]

[2] Copies of this material can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of atomic positional parameters, bond angles and distances, and hydrogen atom parameters have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

Results and discussion

The reaction of $CrCl_2(THF)_2$ with $NaBH_4$ in THF at room temperature and in the presence of an excess of TMEDA gave the divalent chromium tetrahydroborate complex $Cr(BH_4)_2$(TMEDA) (**1**) in good yield (Scheme 1). Although the reaction was rather straightforward, the purification was somewhat problematic due to the thermal instability of **1**, which prevented normal extraction techniques from being used for its separation from the excess of $NaBH_4$ and NaCl. Complete decomposition of the complex with formation of black tarry material was observed after refluxing for 1 h in THF. The magnetic moment of **1** (μ_{eff} = 4.87 μ_B at room temperature) was as expected for the d^4 electronic configuration of a Cr(II) ion, according to the formulation indicated by analytical data. The infrared spectrum showed the characteristic absorptions of

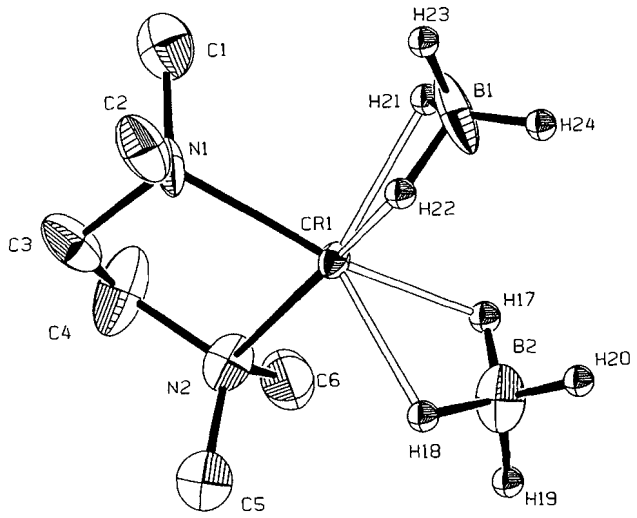

Fig. 2. ORTEP plot of **2**. Thermal ellipsoids are drawn at the 50% probability level.

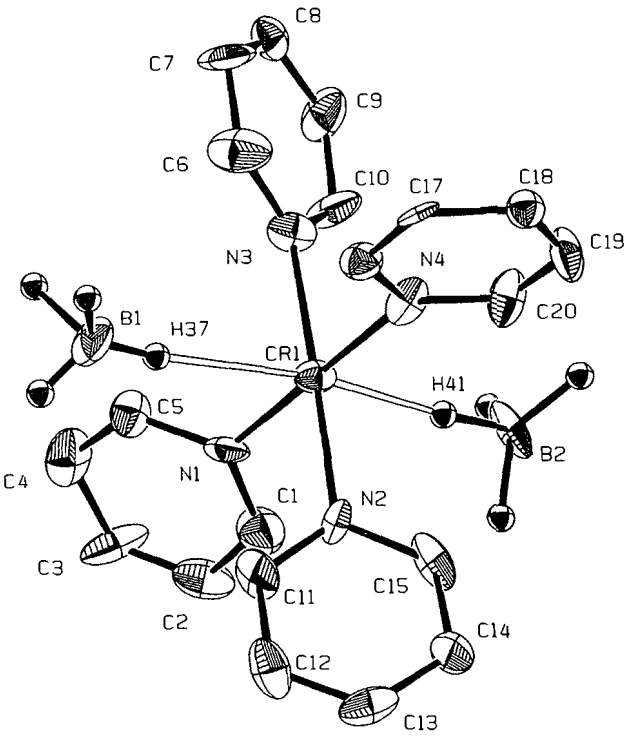

BH_4^- as two very intense and broad resonances at 2380 and 2120 cm^{-1} (terminal boron–hydrogen stretching) and a medium resonance at 2230 cm^{-1} (B–H stretching). These resonances, together with an intense band at 1120 cm^{-1} (BH_2 deformation), are diagnostic of a bidentate bonding mode of the BH_4 group (5). This conclusion is substantiated by the X-ray crystal structure.

Complex **1** is monomeric (Fig. 1) with the chromium atom adopting a distorted pseudo square-planar geometry. The molecular plane centered on chromium is defined by the two nitrogen atoms of TMEDA and the two boron atoms. The coordinated TMEDA shows rather normal bond distances and angles (Cr1—N1 = 2.128(7)Å, Cr—N2 = 2.171(7)Å). As a possible result of the bidentate bonding mode of the BH_4^- groups, the Cr—B distances (Cr1—B1 = 2.44(1)Å, Cr1—B2 = 2.42(1)Å) are rather short compared to those of other Ti and V brohydride complexes (1*d*, *e*, 6). The difference Fourier maps revealed the positions of all the hydrogen atoms. Each of the two BH_4^- tetrahedra points two of the four hydrogen atoms, located above and below the molecular plane, towards the Cr atom (Cr1—H22 = 1.87 Å, Cr1—H17 = 1.93 Å, Cr1—H21 = 2.08 Å, Cr1—H18 = 2.09 Å). The coordination geometry of the boron atom is that of a regular tetrahedron with normal B—H distances (from 0.995 to 1.198 Å) and H-B-H angles. No significant differences were observed between the B—H bond distances of bridging and terminal hydrogens.

Following a trend commonly observed in the chemistry of low-valent early transition metals, the coordinated TMEDA of complex **1** was easily replaced by pyridine, forming different products, depending on the amount of pyridine added. For example, the addition of 2 equivalents of pyridine to an intense blue solution of **1** afforded a light-green solution from which thermally robust brown-red crystals of $Cr(Py)_4(BH_4)_2$ (**2**) were obtained in good yield. While the formula was suggested by analytical results, the IR spectrum showed the resonances characteristic of a BH_4 group bonded in a monodentate fashion. The magnetic moment (μ_{eff} = 2.83 μ_B) was also as expected for a d^4 low-spin electronic configuration of Cr(II), possibly indicating an octahedral structure. Although complex **2** can be conveniently recrystallized from THF, the structure in solution is probably very different since the red crystals dissolved to yield deep-green paramagnetic solutions. Unfortunately, attempts to investigate the structure in solution by both NMR and EPR techniques were unsuccessful because the spectra were uninformative.

Complex **2** is monomeric with the chromium atom placed in the center of a regular octahedron defined by the four nitrogen atoms of the four pyridine molecules (Cr1—N1 = 2.104(9) Å, Cr1—N2 = 2.128(9) Å, Cr1—N3 = 2.12(1) Å, Cr1—N4 = 2.156(9) Å, N1-Cr1-N2 = 89.5(4)°, N1-Cr1-N4 = 180.00°) and two BH_4^- groups placed in *trans* positions with respect to each other (Fig. 2). The positions of the hydrogen atoms were

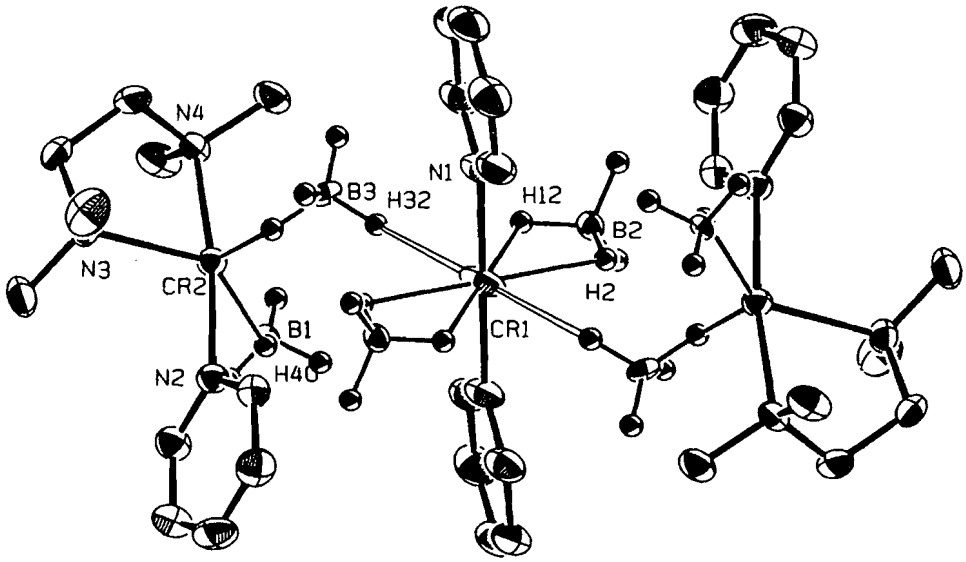
Fig. 3. ORTEP plot of **3**. Thermal ellipsoids are drawn at the 50% probability level.



revealed by the difference Fourier maps. Although the data file was not of sufficient quality to refine the hydrogen atom positions, the H atoms were found at their expected positions, forming normal bond distances and angles. The bonding between chromium and the two hydroborate groups is realized through only one bridging hydrogen per each η^1-BH_4 group. The bridging hydrogen atom was found at a rather long distance from the chromium atom (Cr1—H37 = 2.33 Å, Cr1—H41 = 1.94 Å) but close to the boron atom (B1—H37 = 0.98 Å, B2—H41 = 1.16 Å), forming an almost linear Cr-H-B array (H37-Cr1-H41 = 171.7°). Therefore, the bonding of the BH_4^- groups may be considered somewhere between the ionic and the η^1-covalent. The two H atoms of the two BH_4^- groups used for bridging the metal atom are also aligned with the chromium atom, forming an axis perpendicular to the $Cr(Py)_4$ plane (Cr1-H37-B1 = 173.9°). The η^1-bonding mode of the BH_4^- groups is also substantiated by the much longer Cr—B distances (Cr1—B1 = 3.309(9) Å, Cr1—B2 = 3.253(9) Å) compared to complex **1**.

When the reaction of **1** was carried out with a smaller amount of pyridine, the red crystalline mass of **2** was found to be contaminated by a variable amount of bright green crystals of a new compound, **3**. Repeated attempts to make the reaction selective by modifying the amount of pyridine failed and therefore it was not possible to obtain **3** in analytically pure form. Nevertheless, addition of pyridine to the heterogeneous crystalline mass dissolved the green crystals and improved the yield of the red **2**, which could be then isolated in analytically pure form. This indicated that the green **3** might be just an intermediate during the formation of **2**. The green crystals of **3** were sufficiently large and of adequate quality to undertake an X-ray crystal structure determination.

The most interesting feature of the structure is that the unit cell contains two different types of fragments: two $Cr(BH_4)(Py)TMEDA$ units and a central $Cr(BH_4)_2Py_2$ unit that, differently from **2**, contains only two coordinated pyridine moieties rather than four (Fig. 3). The three fragments are loosely connected by bridging hydrogen interactions. The central $Cr(BH_4)_2Py_2$ unit can be regarded as *trans* square planar with the molecular plane bound by the nitrogen of the two pyridine and the two boron atoms (N1-Cr1-N1a = 180.00°, N1-Cr1-B2 = 90.2(1)°, N1-Cr1-B2a = 89.8(1)°, B2-Cr1-B2a = 180.00°). Even in this case it was possible to locate all the H atom positions, thus revealing the bonding of the BH_4^- groups. As indicated by the short Cr—B distances (Cr1—B2 = 2.426(5) Å), the two BH_4^- groups adopt the η^2-bonding mode. The coordination geometry of the Cr atom in the two identical lateral units is that of a distorted trigonal bipyramid with one nitrogen atom of pyridine and one nitrogen atom of TMEDA placed in the axial positions (N2-Cr2-N4 = 172.8(1)°, N2-Cr2-B1 = 87.4(1)°, N2-Cr2-N3 = 92.01(1)°, N3-Cr2-N4 = 82.6(1)°), and two BH_4^- groups and the second nitrogen atom of TMEDA defining the equatorial plane (N4-Cr2-B1 = 93.2(1)°, N4-Cr2-B3 = 92.8(1)°, N3-Cr2-B1 = 136.7(1)°, N3-Cr2-B3 = 106.6(1)°, B1-Cr-B3 = 116.7(1)°). The two BH_4^- groups are placed at remarkably different distances from the chromium atom (Cr2—B1 = 2.488(4) Å, Cr2—B3 = 2.716(4) Å) in spite of the fact that both are placed in two equivalent equatorial positions, as a result of two different monodentate bonding modes. While the first BH_4^- forms a significantly bent Cr-H-B vector (Cr2-H4-B1 = 110.3°), the second BH_4 forms an almost linear array (Cr2-H34-B3 = 178.1°). In addition, one of the hydrogens of the second BH_4^- group points toward the chromium atom of $Py_2Cr(BH_4)_2$, forming a short nonbonding contact (Cr1—H32 = 3.20 Å). Obviously, it is impossible to decide whether these contacts are artifacts of the crystal packing or are weak hydrogen bonds. In any case, it is unlikely that these contacts are able to preserve the trimeric aggregation in solution. The Cr—N distances (Cr—N1 = 2.098(3) Å, Cr2—N2 = 2.119(3) Å, Cr—N3 = 2.227(3) Å, Cr—N4 = 2.137(3) Å) are comparable to those of the other two complexes reported in this work.

The ability of nitrogen donor ligands such as TMEDA and pyridine to stabilize a monomeric "$Cr(BH_4)_2$" moiety is rather remarkable in view of the fact that "$Cr(BH_4)_2THF_2$" exists only below −20°C and rapidly decomposes at room temperature (11). Complexes **1** and **2**, in addition to possessing significantly different geometries from those of the phosphine derivative $Cr(BH_4)H(dmpe)_2$ (18), are chemically rather inert and do not react with a number of substrates such as CO

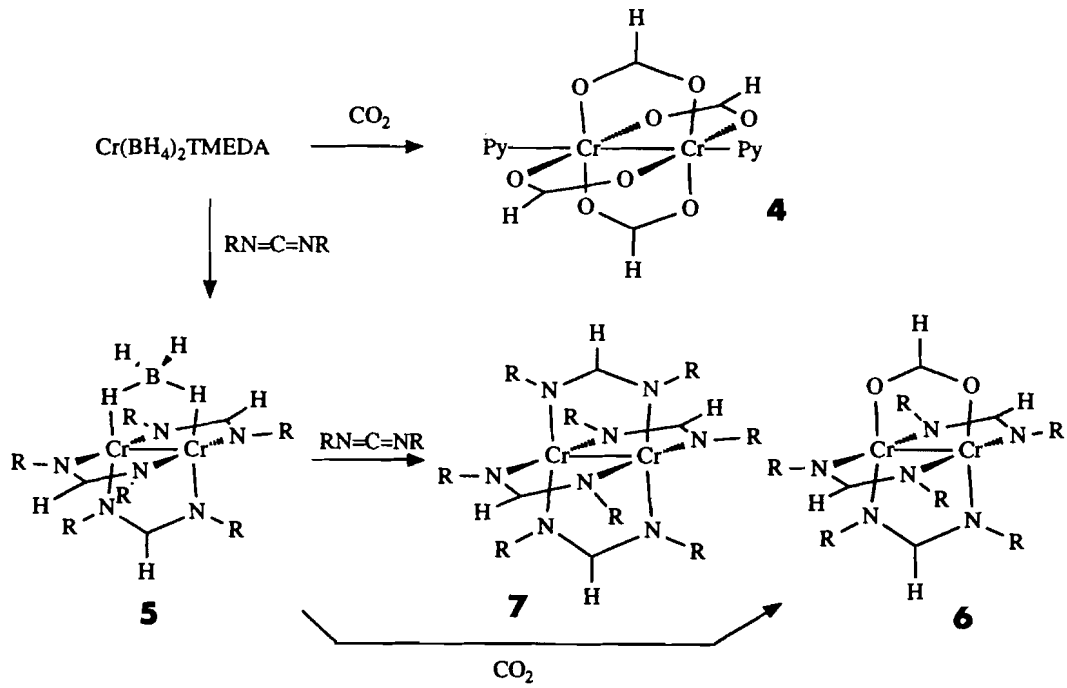
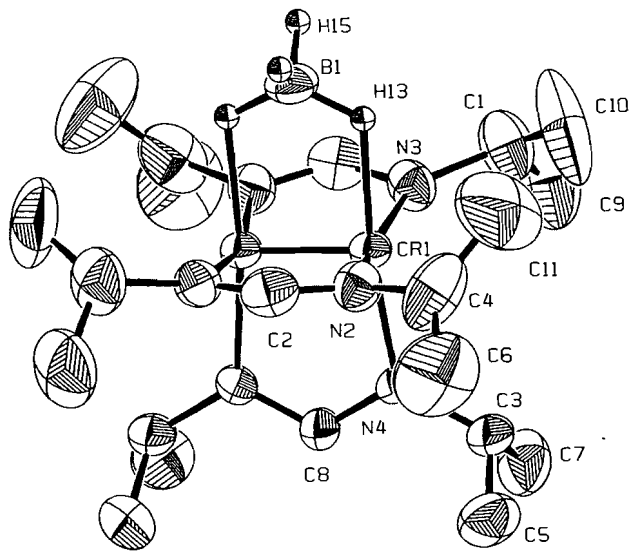
Scheme 2.



(1 atm, room temperature), $H_2C{=}CH_2$ (1 atm, room temperature), ^{t}BuCCH, or $Me_3SiN{=}C{=}NSiMe_3$. However, complex **1** readily reacted with CO_2 in the presence of pyridine at room temperature to form the paramagnetic $Cr_2(CO_2H)_4Py_2$ (**4**) for which a crystal structure was previously reported (19). It also reacted with other cumulenes such as RN=C=NR (R = Cy, iPr), forming a series of diamagnetic chromium dimers $[RNC(H)NR]_3Cr_2(\mu\text{-}BH_4)$ (**5**) and $[RNC(H)NR]_4Cr_2$ (**7**), depending on the stoichiometry employed (Scheme 2). Reaction of **1** with 3 equivalents of 1,3-dicyclohexylcarbodiimide in THF at room temperature yielded a mixture of $[CyNC(H)NCy]_3Cr_2(\mu\text{-}BH)_4$ (**5***a*) and $(BH_3)_2$TMEDA. The separation of the two components was somewhat problematic due to their rather similar solubility properties. However, it was possible to obtain analytically pure samples, albeit in very poor yield, after several recrystallizations from THF. A very similar behavior was observed with 1,3-diisopropylcarbodiimide. However, in this case not only was the purification of the corresponding $Cr_2[iPr)NC(H)N(iPr)]_3(BH_4)$ (**4***b*) more easily achieved through standard extraction techniques, but also the crystallinity was sufficient to allow an X-ray crystal structure determination.

The structure of the complex showed the typical dimeric arrangement (lantern-type) observed in many other formamidine complexes of several transition metals (20) (Fig. 4). The molecule consists of a Cr_2 unit bridged by three formamidinate groups and one borohydride group, with one pair of *trans*-positioned ligands defining a plane perpendicular to the plane bound by the third formamidine, the Cr_2 unit, and the BH_4^- moiety. Each formamidinate ligand adopts the characteristic three-center chelating geometry where each of the two donor atoms of one ligand molecule binds one of the two metal centers, forming a five-membered ring with the Cr_2 unit. The borohydride also adopts the three-center chelating geometry where boron is connected to each of the two chromium atoms via bridging hydrogens. The coordination geometry of the two

Fig. 4. ORTEP plot of **5***b*. Thermal ellipsoids are drawn at the 50% probability level.



chromium atoms is distorted square planar (N2-Cr1-N3 = 163.5(2)°, N2-Cr1-N4 = 94.5(2)°, N3-Cr1-N4 = 95.1(2)°) with the chromium atoms slightly elevated above the plane defined by the three nitrogen atoms and a hydrogen atom of the $\mu\text{-}BH_4^-$ group (Cr1-Cr1-N angles ranging from 95.7(2)° to 96.5(2)°). The Cr—Cr distance (Cr1—Cr1 = 1.844(2) Å) is among the shortest formed in this type of complex and places **5***b* in the family of the supershort quadruply bonded dichromium species (21). The Cr—N bonding distances are normal (Cr1—N2 = 2.018(5) Å, Cr1—N3 = 2.021(5) Å, Cr1—N4 = 2.012(5) Å) and compare well with those of other monomeric and dimeric Cr(II) complexes reported in this work. The angles subtended at the formamidinic carbon by the nitrogen

For personal use only.

donor atoms (N4-C8-N4 = 121.3(8)°, N2-C2-N3 = 121.1(6)°) are similar to those of the dimeric compound $Cr_2(CyNCHNCy)_4$. The structural features of **1**, **2**, **3**, and **5** compare well with those of other η-BH_4 complexes of different transition metals described in the literature (22).

Both **5***a* and **5***b* are diamagnetic at room temperature and showed well-resolved ^1H NMR spectra. The two resonances expected for the two unequivalent formamidine groups (*cis* and *trans* with respect to the BH_4^- group) were observed at the expected positions. The resonance of the BH_4^- group appeared as a broad multiplet centered at 1.32 ppm in the case of **5***b*, while in the case of **5***a* the resonance was hidden by the resonances of the cyclohexyl groups. Magnetic measurements carried out with a Gouy balance at room temperature were also consistent with the diamagnetism inferred by the NMR data. In fact, no significant variation of chemical shift was observed when NMR spectra in d^8-toluene were recorded at −80°C, thus indicating that these compounds do not possess a significant magnetic anisotropy. This is in contrast to the case of $[(tol)NC(H)N(tol)]_4Cr_2$ (23), which has a comparable Cr—Cr distance. Nevertheless, spectra carried out at variable temperatures above 25°C showed that the two C-H formamidinic signals coalesce, while a very significant signal broadening was observed for all the resonances. Since the coalescence can be reversed by lowering the temperature, so far we are unsure whether this phenomenon is generated by conformational motions or by dissociation equilibria to yield monomeric and paramagnetic units. On the other hand, supershort quadruple bonds are well known to be paradoxically weak in dichromium species (20), unlikely to be able to maintain a dinuclear structure in the absence of bridging interactions and to spontaneously dissociate (24). Therefore, we believe that dissociation equilibria are more likely to be responsible for this behavior in solution. The by-product $(BH_3)_2TMEDA$ was often isolated in variable amounts and characterized by an X-ray crystal structure (20). Its formation suggests that more than one process occurred simultaneously during the insertion reactions.

Further reaction of **5** with CO_2, carried out in deuterated benzene solution, showed during an NMR-tube experiment that the intensities of the original peaks were slowly diminished to yield a new spectrum that accounts very well for a $[(iPr)NC(H)N(iPr)]_3Cr_2(O_2CH)$ (**6**) formulation. The reaction was rather slow at 25°C and it was 48 h before the resonances of the unreacted starting material disappeared from the NMR spectrum. Similarly, reaction of **5** with excess carbodiimide gave the corresponding diamagnetic $[RNC(H)NR]_4Cr_2$ (**7**) dimers.

Activated cycloheptenone dienophiles. A versatile approach to 6,7-fused ring targets[1]

Hsing-Jang Liu, Wen-Lung Yeh, and Eric N.C. Browne

Abstract: Several 2-carbalkoxy-2-cyclohepten-1-ones were prepared and their Diels–Alder characteristics examined in order to develop a facile general approach to the synthesis of cycloheptane ring-containing polycyclic natural products. Substitution pattern on the seven-membered ring was found to greatly affect the Diels–Alder behavior. In addition, some extraordinary facial stereoselectivity was observed.

Key words: Diels–Alder reaction, 2-carbalkoxy-2-cyclohepten-1-ones, 6,7-fused ring system.

Résumé : On a préparé plusieurs 2-carbalcoxycyclohept-2-én-1-ones et, dans le but de développer une approche générale facile à la synthèse de produits naturels polycycliques contenant du cycloheptane, on a examiné leur comportement dans les réactions de Diels–Alder. On a trouvé que le patron de substitution sur le cycle à sept chaînons influence grandement le comportement de Diels–Alder. De plus, on a observé de la stéréosélectivité faciale extraordinaire.

Mots clés : réaction Diels–Alder, 2-carbalcoxycyclohept-2-én-1-ones, système de cycles amalgamés en 6,7.

[Traduit par la rédaction]

Introduction

The rapidly increasing number of natural products possessing a 6,7-fused ring system[4] make attractive synthetic targets because of their structural complexity and interesting biological activity. Few successful synthetic approaches have been directed toward these compounds because general synthetic tools for preparation of systems bearing a seven-membered ring are limited in the literature. One approach that has proven to be useful is homologation by carbocyclic ring expansion. Several methods are available[5] and some are particularly effective for making cycloheptanones with incorporation of specific functionalities. However, the ring expansion approach often suffers from needing multiple steps to accomplish the simple homologation. Of the examples given, the diazoacetate method (2*h*) is particularly useful because it completes the conversion in a single step and in generally high yield.

Over the last two decades, extensive efforts have been directed toward improving the Diels–Alder reactivity of cycloalkenones, resulting in development of two general schemes for enhancement of dienophilicity (3). One approach applies Lewis acid catalysis to increase the rate, as well as the regio- and stereoselectivity of the addition. In the other approach, the rates and yields are improved by placing an additional electron-withdrawing group on either the α- or β-carbon of the dienophilic moiety, as predicted by the Alder rule (4). We have reported on an extensive study of Lewis acid catalyzed Diels–Alder reactions of 2-carbalkoxy-activated cycloalkenones (5). As an example of the two activation approaches mentioned above, the closely related 4,4-dimethyl-2-cyclohexenone is a rather poor dienophile and our preliminary study on its Diels–Alder reaction with isoprene and 1,3-butadiene using boron trifluoride etherate or aluminum chloride as a catalyst was unsuccessful (5*c*). Wenkert and co-workers (6) made this reaction synthetically useful by adding the diene to the solution only after allowing complexation between the dienophile and aluminum chloride. We use an α-carbalkoxy-activated system and discovered that the cycloaddition proceeded smoothly with isoprene in the presence of Lewis acid (5*d*).

In continuation of our research in this field and to find a better synthetic approach to 6,7-fused ring polycyclic natural products, we were interested in the Diels–Alder reaction of various 2-carbalkoxy-2-cycloheptenones. In spite of the apparent utility of the approach suggested by the superior Diels–Alder reactivity of simple cycloheptenone, compared to cyclohexenone and cyclopentenone, there are only three examples of Diels–Alder reactions involving cycloheptenones in the literature (Scheme 1) (6, 7). A study of activated derivatives could provide important and exciting new results, which would significantly broaden the usefulness of the approach. We have undertaken a systematic study of the

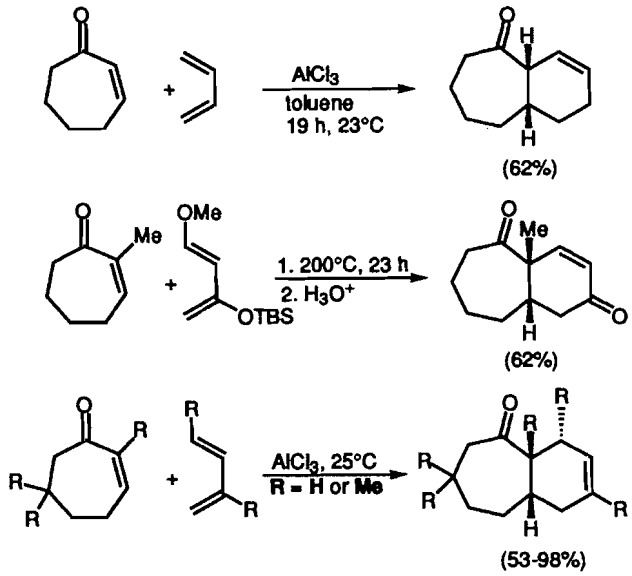
Scheme 1.



Diels–Alder chracteristics of several 2-carbalkoxy-2-cycloheptenones and preliminary results are described in this report.

Results and discussion

A general two-step approach was used for preparation of various 2-carbalkoxy-2-cycloheptenones. Ring expansion of cyclohexanones with ethyl diazoacetate (2*h*) allowed direct incorporation of the desired β-keto ester system with a high degree of regioselectivity. Phenylselenenylation followed by oxidative elimination was used for insertion of the conjugated double bond (8). The results of these preparations are summarized in Table 1. Bicyclo[2.2.2]octan-2-one **18** (9) was synthesized from 1,3-cyclohexadiene and methyl vinyl ketone via the following operations as shown in Scheme 2: (*i*) Diels–Alder addition, (*ii*) catalytic hydrogenation, (*iii*) Baeyer–Villiger oxidation, (*iv*) hydrolysis, and (*v*) oxidation.

These activated dienophiles are more stable than their six-membered ring analogues and can be purified by flash chromatography without apparent decomposition. Although some enolization was observed by ^{1}H NMR, no polymerization was detected. For example, 2-carbethoxy-2-cycloheptenone (**3**) could be easily purified by flash chromatography, in sharp contrast to 2-carbomethoxy-2-cyclohexenone, which was found to decompose rapidly (5*g*). A variety of temperatures and Lewis acids were explored for the Diels–Alder reaction of enone **3** and isoprene to find the most suitable initial conditions. The results are summarized in Table 2. The experimental procedure for zinc chloride catalyzed reactions was slightly different from those using ferric chloride, boron trifluoride etherate, and tin(IV) chloride. The zinc chloride used in the Diels–Alder reactions was dried carefully by a flame before being dissolved in ether. To the resulting zinc chloride solution was then added an ether solution of the dienophile. After stirring for half an hour, allowing the complex formation, a diene was then added. The procedure for the Diels–Alder reactions catalyzed by the other Lewis acids was straightforward. The Lewis acid was simply added to a solution of dienophile and diene. Zinc chloride required a longer reaction time but gave the best yield of adduct **22**, the regiochemistry of which (from

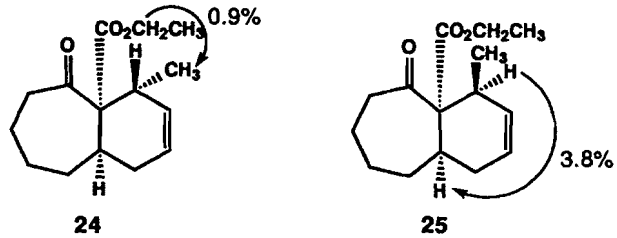
Fig. 1.



the *para*-rule) was confirmed by the ^{1}H decoupling experiments. Irradiation of the vinylic signal at δ 5.34 resulted in change on the broad doublet at δ 2.33 and the quartet of doublets of doublets at δ 2.65 due to the C-11 methylene protons. Conversely, irradiation of the doublet at δ 2.33 resulted in the change of the vinylic signal. Due to the superiority of zinc chloride in this series, it was used as the catalyst in further investigations of the other cycloheptenone dienophiles.

The results obtained for the zinc chloride catalyzed Diels–Alder reactions of enone **3** with isoprene and other dienes are summarized in Table 3. When one equivalent of zinc chloride catalyst was used, the cycloadditions with 2,3-dimethyl-1,3-butadiene and *trans*-piperylene proceeded faster than with isoprene. However, the rates were generally slower than the rates of similar reactions with six-membered ring analogues. The yields were moderate. The amount of zinc chloride was increased from one equivalent to two equivalents in an attempt to accelerate the reaction, but the results were generally less satisfactory.

The Diels–Alder reaction of enone **3** and *trans*-piperylene catalyzed by zinc chloride did not show any stereoselectivity. A separable 1:1 mixture of ester-*endo* adduct **24** and keto-*endo* adduct **25** was produced in 62% combined yield. The ratio was not changed by employing two equivalents of zinc chloride. The stereochemistry of the epimeric adducts **24** and **25** was deduced on the basis of the results of the NOE experiments summarized in Fig. 1.

Zinc chloride catalyzed Diels–Alder reactions of enone **6** proceeded much less efficiently than those of enone **3**. As shown in Table 4, the required reaction times were doubled or tripled, and the yields were moderate to poor. This could be due to steric hindrance of the germinal dimethyl group, interrupting the access of the diene. Ferric chloride, stannic chloride, and aluminum chloride were also examined as catalysts

in the cycloaddition of **6** with isoprene in an attempt to improve the efficiency of the cycloaddition. However, in every case extensive decomposition was observed.

When one equivalent of zinc chloride was used, the reaction of **6** with isoprene took more than 10 days to give only 28% yield of adduct **26**. By increasing the amount of zinc chloride to two equivalents, the reaction rate was greatly accelerated. Only 68 h were required to give an improved yield of 43%. We attempted to further improve the reaction using three equivalents of zinc chloride. The reaction time was reduced to 43 h but the yield was slightly worse. The regiochemical assignment of the adduct follows from the evidence provided by the ^1H decoupling experiment. Upon irradiation of the broad vinylic singlet at δ 5.33, the pair of broad doublets at δ2.91 and 2.14 due to the protons at C-11 sharpened while the signals for the C-8 protons remained intact.

Better results were obtained for 2,3-dimethyl-1,3-butadiene. When one equivalent of zinc chloride was used, the cycloaddition was complete in 69 h to give cycloadduct **27**, with a melting point of 62–63°C, in 52% yield. When two equivalents of zinc chloride were used, the reaction was complete in 46 h and the yield was improved to 61%. In the cycloaddition of *trans*-piperylene to enone **6**, good stereoselectivity was observed using one equivalent of zinc chloride. A 10:1 mixture of stereoisomers **28** and **29** was produced in 30% yield. The less favored keto-*endo* transition state could be caused by the steric effect of the geminal dimethyl group at C-5. By increasing the amount of zinc chloride to two equivalents, the reaction time was shortened to 94 h and the yield was improved to 42%, but stereoselectivity was sacrificed. Figure 2 depicts the results obtained from the NOE experi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12

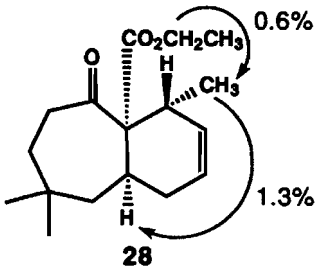
Fig. 2.



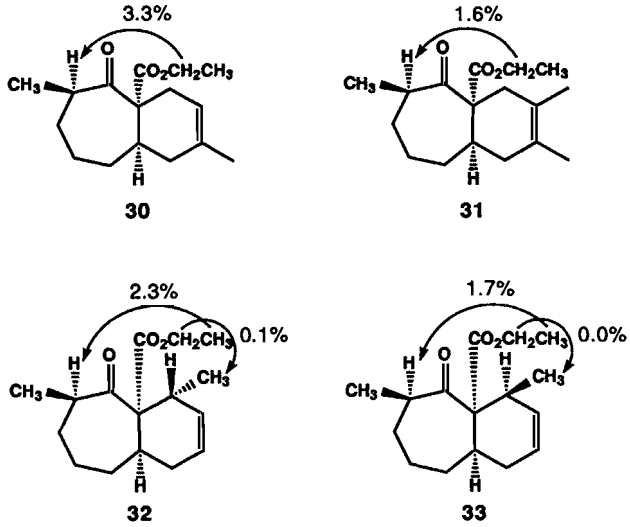
ments carried out on the major isomer **28**. Accordingly, its stereochemistry was determined. The minor isomer **29** could not be isolated in pure form, and its stereochemistry was assigned by inference.

From the cycloadditions of cycloheptenones **3** and **6**, we concluded that two equivalents of zinc chloride typically provided the best results with regard to reaction time and yield. Subsequent reactions with other activated cycloheptenones were carried out using two equivalents of zinc chloride.

Somewhat expectedly, enone **9** was resistant to any Diels–Alder reaction with *trans*-piperylene under zinc chloride catalysis, possibly due to the serious steric hindrance caused by the geminal dimethyl group at C-7. When ferric chloride was used as a catalyst, extensive decomposition occurred.

In the Diels–Alder reactions of enone **13**, some interesting and unexpected phenomena emerged. As shown in Table 5, all the reactions were completed in 1 day and the yields were extraordinarily high. Surprisingly, a high degree of face-selectivity was displayed with preferential addition of the diene from the sterically more hindered methyl side.[6] It appears that the methyl group plays a key role in directing the addition of the diene. The exact cause of this unusual stereoselectivity remains to be determined. Zinc chloride catalyzed Diels–Alder cycloaddition of *trans*-piperylene to enone **13** generated a 1:2 mixture of enones **32** and **33** in a combined yield of 85%. The unusual selectivity favoring keto-*endo* product **33**, in contrast with the previous reactions, and its relation to the inscrutable effect of the C-3 methyl group is unexplained at this time. The stereochemical assignments of adducts **30–33**[7] were again facilitated by the NOE experiments. The results are depicted in Fig. 3.[8]

Fig. 3.



In the additions to **17** complete facial selectivity favoring the addition of the diene from the ethano bridge side, as evident from the NOE experiments on adducts **34–36**[9,10] (Fig. 4), was observed in every case as shown in Table 6. This high selectivity cannot be explained by the steric effect alone. Kobuke and co-workers reported a similar facial stereoselectivity (10). In the Diels–Alder reaction of isodicyclopentadiene and methyl propiolate, the addition occurs completely from the ethano bridge side of isodicyclopentadiene. Two possible explanations are offered. One is a greater steric attraction than steric repulsion by the ethano bridge that stabilizes the *syn* transition state. The other is based on a stereoelectronic effect resulting from a mixing of the unstable σ orbitals of the norbornane skeleton and the π orbitals. This mixing would bias the charge density of the π orbital in space above and below the cyclopentadiene plane and therefore favor the *syn* orientation of an attacking dienophile. However, Gleiter and Paquette (11) later stressed that the σ/π interaction must be carefully evaluated in any rationalization of Diels–Alder stereoselectivity and implies a combined effect with other influences such as van der Waals forces (the first explanation above), induced dipole–dipole interactions, and steric effects. None of these explanations can completely account for the stereoselectivity observed in our case.

Another feature of the reactions of enone **17** is that they proceeded to completion with the shortest reaction time of all the additions examined. The yields were fairly good.

Compared to the facile reactions of **17**, the Diels–Alder reactions of enone **21** were rather sluggish. When the cycloaddition of *trans*-piperylene to enone **21** was performed as usual, using zinc chloride as a catalyst, **21** was still present in large

[6] The possibility that epimerization of the methyl substituent at C-3 in adducts of **13** has occurred is considered highly unlikely. No trace of another product identifiable as a possible C-3 epimer was observed. Examination of Dreiding molecular models indicates that neither of such a pair of epimers should predominate exclusively in an equilibrated mixture and we logically infer that since complete epimerization is not possible and partial epimerization is not detected then no epimerization occurs at C-3 under the applied conditions.

[7] The regiochemistry of adduct **30** was determined by the decoupling experiments. Irradiation of the vinylic signal at δ 5.35 caused simplification of the signals at δ 2.72 and 2.24 (2 × *H*-11) and vice versa.

[8] We believe that the NOE data for **32** and **33** strongly support the assignments as drawn. The enhancement of 0.1% on the C-11 methyl is small but can be contrasted with the enhancement of 0.0% on the isomeric methyl in **33**. This does not, however, constitute absolute proof of the assignments.

[9] The *para* regiochemistry of **34** was confirmed by irradiating the vinylic multiplet at δ 5.52, which simplified the signals at δ 2.57 (H-4).

[10] The bridge stereochemistry of compound **35** is unambiguously defined by the NOE experiment. The NOE evidence strongly supports the assignment of **34** as drawn but the proof is not absolute. The NOE data for compound **36** (5.2% enhancement of the bridge proton) does not prove the stereochemistry and so this structure should not be considered confirmed. We have tentatively drawn it as shown based on analogy with the other two compounds.

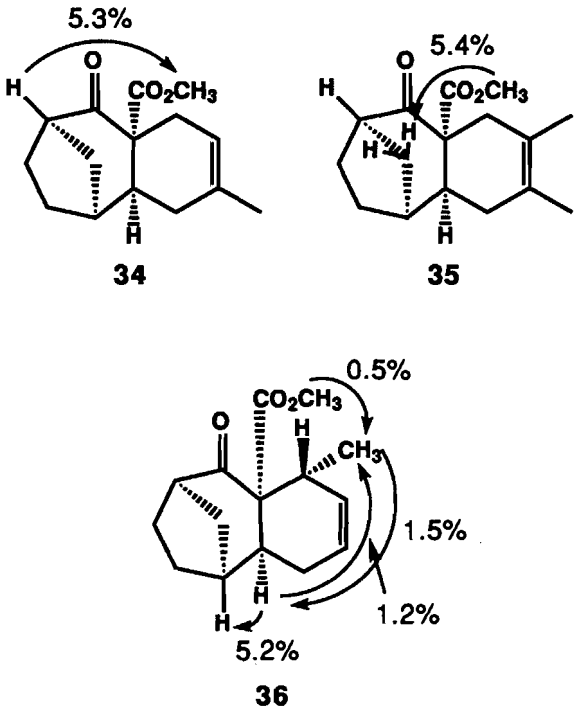

Fig. 5.

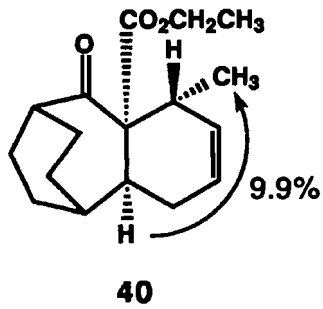

quantity in the reaction medium after prolonged reaction time (272 h), as indicated by TLC analysis. Only by employing ferric chloride as a catalyst did these reactions proceed at reasonable rate and give useful yields of the desired adducts **38**–**40**[11] (Table 7). Complete ester-*endo* selectivity was observed when *trans*-piperylene was added to enone **21** and the cycloadduct **40**, the stereochemistry of which was clearly indicated by the NOE results depicted in Fig. 5, was formed in 45% yield. This selectivity could easily be rationalized by steric hindrance of the ethano bridge in the keto-*endo* transition state.

Conclusion

Lewis acid catalyzed Diels–Alder reaction of 2-carbalkoxy-2-cycloheptenones displayed synthetic promise, interesting

[11] The regiochemistry of **38** was also confirmed by decoupling experiments. When each of the signals at δ 2.38 and 2.55 due to the C-4 methylene protons was irradiated, the broad singlet at δ 5.43 (*H*-5) was sharpened. Conversely, irradiation of the latter signal resulted in simplification of the former signals.

stereoselectivity, and unexpectedly high face-selectivity. In most cases the expected stereoselectivity favoring ester-*endo* adducts was exhibited due to sterically disfavored keto-*endo* transition states. In the one exception with favored keto-*endo* adduct, the cycloaddition with enone **13**, the extra methyl group of the dienophile certainly played an important but unclear role in directing the unusual selectivity. Complete facial stereoselectivity was observed in cycloadditions with enones **13** and **17**. Further study is required to explore the reasons for this unusual phenomenon. The substitution pattern on the seven-membered ring also produced large differences in rates and yields of the reactions. As a general trend in the related skeletal series, a monosubstituted enone having diastereotopic faces reacts the fastest and gives the highest yield, followed by the unsubstituted enone that has enantiotopic faces. The disubstituted enone having enantiotopic faces reacts slowly with poor yields. Accordingly for the rate and yield of the corresponding Diels–Alder reactions, the order of **13** (monosubstituted) > **3** (unsubstituted) > **9** (disubstituted) was observed. Similarly, **17** (with diastereotopic faces) was found to be better as a dienophile than **21** (with enantiotopic face). This study on the Diels–Alder chemistry of 2-carbalkoxy-2-cycloheptenones serves as a good basis for the stereoselective synthesis of various polycyclic natural products containing a six-membered ring fused with a seven-membered one.

Experimental

General

Melting points were recorded on a Köfler hot stage apparatus and are uncorrected. Infrared spectra (IR) were recorded using Nicolet 7-199, Nicolet MX-1, or Perkin–Elmer FTIR spectrometers. High-resolution mass spectra (MS) were obtained using a Kratos AEI MS-50 high-resolution mass spectrometer. Elemental analyses were carried out by the microanalytical laboratory of this department. Proton nuclear magnetic resonance spectra (^{1}H NMR) were recorded using Bruker WH-200 (200 MHz) and Bruker WH-400 (400 MHz) spectrometers. Coupling constants are reported to within ± 0.5 Hz. The following abbreviations were used: s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, br = broad. Carbon-13 nuclear magnetic resonance spectra (^{13}C NMR) were recorded on Bruker WH-200 (50 MHz) and Bruker WH-400 (100 MHz) instruments. Carbon-13 multiplicities were derived from off-resonance or Carr–Purcel–Meiboom–Gill spin echo *J*-modulated experiments (APT or Attached Proton Test). Methylene groups and quaternary carbons appear as signals in-phase with respect to the deuteriochloroform signal while the signals out-of-phase to that of deuteriochloroform are for the methyl and methine groups. Nuclear Overhauser Enhancement (NOE) experiments were determined in the difference mode in which a reference (undecoupled) spectrum was computer-subtracted from the irradiated spectrum after Fourier transformation. Positive enhancements are defined as signals possessing antiphase with respect to the irradiated signal.

Products were purified either by flash chromatography using silica gel 60 (230–400 mesh), distillation using a bulb-to-bulb Kugelrohr apparatus, or by fractional crystallization. All reactions were monitored by analytical thin-layer chromatography (TLC) performed on aluminum-backed plates precoated with silica gel 60 F_{254} as supplied by Merck. The visualization of the chromatograms was performed by dipping in either an ethanol solution of vanillin (5%, w/v) or an aqueous solution of phosphomolybdic acid (3%, w/v). Solvents were removed under reduced pressure on a rotary evaporator. Anhydrous magnesium sulfate was used for drying organic solutions.

General procedure for the ring expansion reactions

Boron trifluoride etherate (15 mmol, 1.5 equiv.) was added to a solution of ketone (10 mmol, 1.0 equiv.) in dry ether (20 mL) at 0°C. A solution of ethyl diazoacetate (15 mmol, 1.5 equiv.) in dry ether (5 mL) was then added over a period of 15 min and the resulting solution was stirred at room temperature under an argon atmosphere. When the reaction completed, it was cooled to 0°C and neutralized with saturated aqueous sodium bicarbonate solution. The resulting mixture was extracted with chloroform (3 × 20 mL). The combined extracts were washed with saturated aqueous sodium chloride solution, dried, and concentrated. Purification by bulb-to-bulb distillation under reduced pressure gave the desired keto ester. Yield and time of each reaction are to be found in Table 1.

Keto esters **2** (12), **5**, **8**, **11**, **12**, **19**, and **20** showed the following spectral data:

2-Carbethoxycycloheptanone (2)

Keto ester **2** was shown by the following spectral data to exist as a mixture of 75% keto form and 25% enol form: IR (CH_2Cl_2, cast): 1742 (C=O, ester), 1707 (C=O, ketone), 1638 (C=O, enol ester) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 12.75 (s, 0.25H, =C(O*H*)-), 4.18 (m, 2H, -COOC*H*$_2$CH$_3$), 3.52 (dd, *J* = 10.5, 4 Hz, 0.75H, -COC*H*(COOEt)-), 2.65–1.40 (7 × m, 10H), 1.30 (t, *J* = 7 Hz, 0.75H, -COOCH$_2$C*H*$_3$), 1.26 (t, *J* = 7 Hz, 2.25H, -COOCH$_2$C*H*$_3$); MS *m/z* (M^+) calcd. for $C_{10}H_{16}O_3$: 184.1100; found: 184.1101.

2-Carbethoxy-5,5-dimethylcycloheptanone (5)

Keto ester **5** was shown by the following spectral data to exist as a mixture of 95% keto form and 5% enol form: IR ($CHCl_3$, cast): 1743 (C=O, ester), 1707 (C=O, ketone), 1640 (C=O, enol ester) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 12.70 (s, 0.05H, =C(O*H*)-), 4.19 (q, *J* = 7 Hz, 1H, -COOC*H*HCH$_3$), 4.17 (q, *J* = 7 Hz, 1H, -COOCH*H*CH$_3$), 3.51 (t, *J* = 7.5 Hz, 0.95H, -COC*H*(COOEt)-), 2.64 (ddd, *J* = 16.5, 10, 5.5 Hz, 0.95H, -C*H*HCO-), 2.45 (ddd, *J* = 16.5, 6.5, 4 Hz, 0.95H, -CH*H*CO-), 2.35 (m, 0.1H), 1.97 (m, 2H), 1.65–1.55 (m, 3H), 1.38 (m, 1H), 1.26 (t, *J* = 7 Hz, 3H, -COOCH$_2$C*H*$_3$), 0.98 (s, 3H, -C*H*$_3$), 0.93 (s, 3H, -C*H*$_3$); MS *m/z* (M^+) calcd. for $C_{12}H_{20}O_3$: 212.1413; found: 212.1413.

2-Carbethoxy-7,7-dimethylcycloheptanone (8)

Keto ester **8** was shown by the following spectral data to exist completely in the keto form: IR ($CHCl_3$, cast): 1748 (C=O, ester), 1708 (C=O, ketone) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.14 (q, *J* = 7 Hz, 2H, -COOC*H*$_2$CH$_3$), 3.86 (dd, *J* = 12, 3 Hz, 1H, -COC*H*(COOEt)-), 2.13 (br d, *J* = 14 Hz, 1H), 1.88 (br d, *J* = 14 Hz, 1H), 1.82–1.50 (m, 4H), 1.39 (br dd, *J* = 12, 12 Hz, 1H), 1.22 (t, *J* = 7 Hz, 3H, -COOCH$_2$C*H*$_3$), 1.18 (s, 3H, -C*H*$_3$), 1.14 (m, 1H), 1.10 (s, 3H, -C*H*$_3$); MS *m/z* (M^+) calcd. for $C_{12}H_{20}O_3$: 212.1413; found: 212.1415. Anal. calcd. for $C_{12}H_{20}O_3$: C 67.89%, H 9.50%; found: C 67.60%, H 9.68%.

*2-Carbethoxy-7-methylcycloheptanone (**11**) and* trans*-2-carbethoxy-3-methylcycloheptanone (**12**)*

Ring expansion of 2-methycyclohexanone gave a 9:1 mixture of regioisomers **11** (existing as a mixture of two stereoisomers in a ratio of 7:2) and **12**. All the isomers were shown to exist completely in the keto form: IR (film): 1743 (C=O, ester), 1709 (C=O, ketone) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 4.15 (m, 2H, -COO*CH*$_2$CH$_3$), 3.67 (dd, *J* = 7.5, 5 Hz, 0.2H, -CO*CH*(COOEt)-), 3.48 (dd, *J* = 12, 4.5 Hz, 0.7H, -CO*CH*(COOEt)-), 3.13 (d, *J* = 10 Hz, 0.1H, -CO*CH*(COOEt)CH(CH$_3$)-), 1.25, 1.23 (2 × t, *J* = 7 Hz, 3H, -COOCH$_2$*CH*$_3$), 1.12 (d, *J* = 6.5 Hz, 2.1H, -*CH*$_3$), 1.11 (d, *J* = 6.5 Hz, 0.6H, -*CH*$_3$), 1.01 (d, *J* = 6.5 Hz, 0.3H, -*CH*$_3$); MS *m/z* (M^+) calcd. for $C_{11}H_{18}O_3$: 198.1256; found: 198.1261. Anal. calcd. for $C_{11}H_{18}O_3$: C 66.64%, H 9.15%; found: C 66.63%, H 9.24%.

*3-Carbethoxybicyclo[3.2.2]nonan-2-one (**19**) and 2-carbethoxybicyclo[3.2.2]nonan-3-one (**20**)*

Ring expansion of bicyclo[2.2.2]octanone gave a 11:4 mixture of regioisomers **19** (keto form:enol form = 5:6) and **20** (keto form:enol form = 1:1): IR ($CHCl_3$, cast): 1744 (C=O, ester), 1704 (C=O, ketone), 1643 (C=O, enol ester), 1610 (-C=C-OH) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 12.72 (s, 0.13H, =C(OH)-), 12.62 (s, 0.4H, =C(O*H*)-), 4.20 (m, 2H, -COO*CH*$_2$CH$_3$), 3.80 (dd, *J* = 12, 8.5 Hz, 0.33H, -CO*CH*(COOEt)-), 3.52 (ddd, *J* = 3, 1, 1 Hz, 0.13H, -CO*CH*(COOEt)-), 1.29 (m, 3H, -COOCH$_2$*CH*$_3$); MS *m/z* (M^+) calcd. for $C_{12}H_{18}O_3$: 210.2156; found: 210.1258. Anal. calcd. for $C_{12}H_{18}O_3$: C 68.56%, H 8.63%; found: C 68.28%, H 8.82%.

(1S,5R*)-3-Carbomethoxybicyclo[3.2.1]octan-2-one (**16**)*

Dimethyl carbonate (4.30 mL, 50.73 mmol) was added to a suspension of sodium hydride (60% dispersion in mineral oil, 1.01 g, 25.37 mmol) in dry tetrahydrofuran (15 mL). The resulting mixture was heated under reflux under an argon atmosphere. A solution of bicyclo[3.2.1]octan-2-one (85%, 1.05 g, 8.455 mmol) in dry tetrahydrofuran (15 mL) was then added. After refluxing for 2.5 h, the solution was cooled, neutralized with 10% acetic acid, and extracted with ether (3 × 30 mL). The combined extracts were washed with saturated aqueous sodium chloride solution, dried, concentrated, and purified by bulb-to-bulb distillation (85°C/1 Torr (= 133.3 Pa)) to give keto ester **16** (1.24 g, 95% yield based on 85% purity of the ketone: keto form:enol form = 2:5) as a colorless oil: IR ($CHCl_3$, cast): 1748 (C=O, ester), 1725 (C=O, ketone), 1655 (C=O, enol ester), 1615 (-C=C-OH) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 11.91 (s, 0.71H, =C(O*H*)-), 3.75 (s, 0.86H, -COO*CH*$_3$), 3.72 (s, 2.14H, -COO*CH*$_3$), 3.47 (dd, *J* = 12, 8 Hz, 0.29H, -CO*CH*(COOCH$_3$)-); MS *m/z* (M^+) calcd. for $C_{10}H_{14}O_3$: 182.0943; found: 182.0949.

Preparation of bicyclo[2.2.2]octanone (18)

A. (1S,4S*,5S*)-5-Acetylbicyclo[2.2.2]oct-2-ene*

To a solution of 1,3-cyclohexadiene (5.02 g, 62.65 mmol) and methyl vinyl ketone (26.1 mL, 313.24 mmol) in dry dichloromethane (40 mL) at 0°C, tin(IV) chloride (7.3 mL, 62.65 mmol) was slowly added. The resulting solution was stirred at 0°C under an argon atmosphere for 1 h. The solution was then neutralized with saturated aqueous sodium bicarbonate solution. The dichloromethane layer was separated and the aqueous layer was extracted with dichloromethane (30 mL). The combined dichloromethane solutions were washed with water, dried, concentrated, and purified by flash chromatography (20% ether in Skelly B) to give the desired adduct (8.0 g, 85% yield) as a colorless oil: IR ($CHCl_3$, cast): 1709 (C=O) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 6.28 (ddd, *J* = 7, 7, 1 Hz, 1H, =C*H*-), 6.10 (ddd, *J* = 7, 7, 0.5 Hz, 1H, =C*H*-), 2.89 (m, 1H), 2.66 (ddd, *J* = 9, 7, 2 Hz, 1H, -C*H*(COCH$_3$)-), 2.60 (m, 1H), 2.10 (s, 3H, C*H*$_3$CO-), 1.65 (m, 2H), 1.60 (m, 1H), 1.49 (m, 1H), 1.32 (m, 1H), 1.25 (m, 1H); MS *m/z* calcd. (M^+) for $C_{10}H_{14}O$: 150.1045; found: 150.1043.

B. 2-Acetylbicyclo[2.2.2]octane

The above enone (7.88 g, 52.46 mmol) was dissolved in ethyl acetate (70 mL), Palladium on carbon (50%, 0.45 g) was added. The mixture was hydrogenated under 20 psi (1 psi = 6.9 kPa) of hydrogen for 5 h using a Parr hydrogenation apparatus. The mixture was then filtered and concentrated to give the title ketone (7.77 g, 97% yield) as a colorless oil: IR (CH_2Cl_2, cast): 1710 (C=O) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 2.63 (ddd, *J* = 10, 6, 2.5 Hz, 1H, -C*H*(COCH$_3$)-), 2.17–1.90 (m, 3H), 2.13 (s, 3H, C*H*$_3$CO-), 1.70–1.35 (m, 9H); MS *m/z* (M^+) calcd. for $C_{10}H_{16}O$: 152.1202; found: 152.1202.

C. Bicyclo[2.2.2]octan-2-ol

To a mixture of the above ketone (4.59 g, 30.15 mmol) and disodium hydrogen phosphate (12.84 g, 90.45 mmol) in dry dichloromethane (50 mL) was added *m*-chloroperoxybenzoic acid (70%, 14.87 g, 60.30 mmol). The resulting solution was stirred at room temperature under an argon atmosphere for 25 h. At the end of this time, the solution was neutralized with saturated sodium bicarbonate solution. The dichloromethane layer was separated and the aqueous layer was extracted with dichloromethane (50 mL). The combined dichloromethane solutions were washed with saturated aqueous sodium sulfite solution, dried, and concentrated. The residue was dissolved in methanol (50 mL). The methanol solution was mixed with 1 N aqueous sodium hydroxide solution (50 mL). After stirring at room temperature for 4.5 h, the solution was acidified with 1 N hydrochloric acid and extracted with dichloromethane (3 × 50 mL). The combined extracts were washed with water, dried, concentrated, and purified by flash chromatography (40–50% ether in Skelly B) to give the alcohol (3.80 g, 100% yield) as a white solid: mp 88–89°C (Skelly B); IR (CH_2Cl_2, cast): 3293 (O-H) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 3.95 (dddd, *J* = 9, 4, 4, 1.5 Hz, 1H, -C*H*(OH)-), 2.01 (dddd, *J* = 14, 9.5, 3, 2.5 Hz, 1H), 1.88 (m, 1H), 1.60 (m, 4H), 1.50–1.30 (m, 7H); MS *m/z* (M^+) calcd. for $C_8H_{14}O$: 126.1045; found: 126.1044.

*D. Bicyclo[2.2.2]octanone (**18**)*

Pyridinium chlorochromate on alumina (0.9 mmol/g, 50.18 g, 45.16 mmol) was added to a solution of the above alcohol (3.80 g, 30.11 mmol) in dry dichloromethane (70 mL) and the resulting mixture was stirred at room temperature under an argon atmosphere for 2 h. The mixture was then filtered through Florisil, concentrated, and purified by flash chromatography (20% ether in Skelly B) to give ketone **18** (2.86 g, 76% yield) as a volatile white solid: IR (CH_2Cl_2, cast): 1727

(C=O) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 2.24 (br s, 3H), 2.15 (m, 1H), 1.80 (m, 4H), 1.73–1.55 (m, 4H); MS *m/z* (M^+) calcd. for $C_8H_{12}O$: 124.0888; found: 124.0889.

General procedure for phenylselenenylation and oxidative elimination reaction

To a solution of phenylselenenyl chloride (12.0 mmol, 3 equiv.) in dry dichloromethane (20 mL) at 0°C, pyridine (12.0 mmol, 3 equiv.) was slowly added. After stirring at 0°C under an argon atmosphere for 15 min, a solution of keto ester (4.0 mmol, 1 equiv.) in dry dichloromethane (10 mL) was then added. The resulting dark red solution was stirred at room temperature under an argon atmosphere. When the reaction was completed, it was cooled to 0°C. Aqueous 30% hydrogen peroxide (1 mL each addition) was then added at intervals of 10 min until the solution turned colorless (ca. 5–10 times). At the end of this time, the mixture was diluted with water. The dichloromethane layer was separated, washed with saturated aqueous sodium bicarbonate solution, 1 N hydrochloric acid, and saturated aqueous sodium sulfite solution, dried, and concentrated. Purification by either flash chromatography or bulb-to-bulb distillation gave the desired carbalkoxy enone. Yield and time of each transformation are to be found in Table 2.

The keto esters **3**, **6**, **9**, **13**, **14**, **17**, and **21** showed the following spectral data:

*2-Carbethoxy-2-cyclohepten-1-one (**3**)*

Keto ester **3** was shown by the following spectral data to exist completely in the keto form: IR ($CHCl_3$, cast): 1725 (C=O, ester), 1694 (C=O, ketone) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 7.36 (t, *J* = 6 Hz, 1H, -*H*C=CCO-), 4.22 (q, *J* = 7 Hz, 2H, -COOC*H*$_2$CH$_3$), 2.68 (t, *J* = 6.5 Hz, 2H, -C*H*$_2$CO-), 2.49(dt, *J* = 6 Hz, 2H, -C*H*$_2$CH=CCO-), 1.92–1.70 (m, 4H), 1.28 (t, *J* = 7 Hz, 3H, -COOCH$_2$C*H*$_3$); MS *m/z* (M^+) calcd. for $C_{10}H_{14}O_3$: 182.0943; found: 182.0944.

*2-Carbethoxy-5,5-dimethyl-2-cyclohepten-1-one (**6**)*

Keto ester **6** was shown by the following spectral data to exist as a mixture of 90% keto form and 10% enol form: IR ($CHCl_3$, cast): 1728 (C=O, ester), 1690 (C=O, ketone), 1634 (C=O, enol ester) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 13.28 (s, 0.1H, =C(O*H*)-), 7.32 (t, *J* = 7.5 Hz, 0.9H, -*H*C=CCO-), 6.04 (d, *J* = 13.5 Hz, 0.1H, -*H*C=CH-), 5.26 (d, *J* = 13.5 Hz, 0.1H, -HC=C*H*-), 4.25 (q, *J* = 7 Hz, 0.2H, -COOC*H*$_2$CH$_3$), 4.24 (q, *J* = 7 Hz, 1.8H, -COOC*H*$_2$CH$_3$), 2.52 (dd, *J* = 2.5, 2.5 Hz, 1H), 2.51 (d, *J* = 12 Hz, 1H), 2.20 (d, *J* = 7 Hz, 2H), 1.64 (dd, *J* = 2.5, 2.5 Hz, 1H), 1.64 (d, *J* = 12 Hz, 1H), 1.29 (t, *J* = 7 Hz, 3H, -COOCH$_2$C*H*$_3$), 1.03 (s, 6H, 2 × -C*H*$_3$); MS *m/z* (M^+) calcd. for $C_{12}H_{18}O_3$: 210.1256; found: 210.1259.

*2-Carbethoxy-7,7-dimethyl-2-cyclohepten-1-one (**9**)*

Phenylselenenylation – oxidative elimination of keto ester **8** did not proceed to completion; 61% of **8** was recovered. Keto ester **9** was shown by the following spectral data to exist completely in the keto form: IR (CH_2Cl_2, cast): 1722 (C=O, ester), 1695 (C=O, ketone); cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 7.16 (t, *J* = 5 Hz, 1H, -*H*C=CCO-), 4.20 (q, *J* = 7 Hz, 2H, -COOC*H*$_2$CH$_3$), 2.42 (ddd, *J* = 6, 6, 6 Hz, 2H, -C*H*$_2$CH=CCO-), 1.71–1.60 (m, 4H), 1.25 (t, *J* = 7 Hz, 3H, -COOCH$_2$C*H*$_3$), 1.18 (s, 6H, 2 × -C*H*$_3$); MS *m/z* (M^+) calcd. for $C_{12}H_{18}O_3$: 210.1256; found: 210.1252.

*2-Carbethoxy-7-methyl-2-cyclohepten-1-one (**13**) and 2-carbethoxy-3-methyl-2-cyclohepten-1-one (**14**)*

Phenylselenenylation – oxidative elimination of the inseparable 9:1 mixture of keto esters **11** and **12** did not proceed to completion; 7% of **12** was recovered. Carbethoxy enones **13** (keto form:enol form = 2:1) and **14** (keto form only) were separated by flash chromatography and obtained in a ratio of 24:1.

General procedure for $ZnCl_2$ catalyzed Diels–Alder reactions

Zinc chloride (1–3 equiv.) was fused in a reaction flask under argon and then dissolved in dry ether (5 mL). A solution of carbalkoxy cycloheptenone (0.3 mmol, 1 equiv.) in dry ether (3 mL) was added. After stirring at room temperature for 30 min, diene (3.0 mmol, 10 equiv.) was added. The resulting mixture was stirred at room temperature until the reaction was complete. Then it was neutralized with saturated aqueous sodium bicarbonate solution. The ether layer was separated and the aqueous layer was extracted with ether (10 mL). The combined ether solutions were washed with saturated aqueous sodium chloride solution, dried, concentrated, and purified by flash chromatography (ether – Skelly B) to give the desired adduct(s). Yields and times of the reactions as well as the

quantities of zinc chloride relative to carbalkoxy cycloheptenone are shown in Tables 3–6.

General procedure for $FeCl_3$, $AlCl_3$, $SnCl_4$, and $BF_3{\cdot}OEt_2$ catalyzed Diels–Alder reactions

To a solution of carbalkoxy cycloheptenone (0.5 mmol, 1 equiv.) in dry ether (10 mL), diene (5.0 mmol, 10 equiv.) was added. Lewis acid (0.5 mmol, 1 equiv.) was then added and the resulting solution was stirred under argon. When the reaction was complete, it was neutralized with saturated aqueous sodium bicarbonate solution. The ether layer was separated and the aqueous layer was extracted with ether (10 mL). The combined ether solutions were washed with saturated sodium chloride solution, dried, concentrated, and purified by flash chromatography (ether – Skelly B) to give the desired adduct(s). Yields, times, and temperatures of the reactions are shown in Tables 2 and 7.

The synthesis of tellurometalates by the reduction of binary telluride melts with potassium in liquid ammonia

For personal use only.

Abstract: The reduction of binary telluride melts with potassium in liquid ammonia in the presence of 18-Crown-6 or 2,2,2-Crypt has been employed to synthesize and precipitate tellurometalates. The method is more rapid than conventional extraction techniques and, since lower temperatures are involved, potentially unstable fragments are conserved. A melt of nominal composition $CdTe_3$ dissolved with K and 18-Crown-6 in liquid NH_3 affords $[K(18\text{-Crown-6})]_4[Cd_4Te_{12}]$ (**1**) after recrystallization from CH_3CN–Et_2O. Compound **1** crystallizes in the triclinic space group $C_i^1-P\bar{1}$ with one formula unit in a cell of dimensions $a = 12.673(1)$ Å, $b = 13.694(3)$ Å, $c = 14.483(3)$ Å, $\alpha = 117.54(2)°$, $\beta = 96.43(1)°$, and $\gamma = 100.00(1)°$ at 113 K. Full anisotropic refinement of the structure on F_o^2 led to a value of $R_1 = 0.026$ for those 6654 reflections having $F_o^2 > 2\sigma(F_o^2)$. The $[Cd_4Te_{12}]^{4-}$ anion of **1**, which may be formulated as $[Cd_4(Te)_2(Te_2)_2(Te_3)_2]^{4-}$, consists of a rectangular array of four Cd^{2+} centers linked by Te^{2-}, Te_2^{2-}, and Te_3^{2-} ligands. As expected from the solid-state structure, the ^{125}Te NMR spectrum of **1** in CD_3CN shows four resonances at −11, −259, −548, and −1682 ppm. A melt of nominal composition $PbTe_2$ was dissolved with K and 2,2,2-Crypt in liquid NH_3 to afford $[K(2,2,2\text{-Crypt})]_2[Pb_2Te_3]\cdot CH_3CN$ (**2**) after recrystallization from CH_3CN. Compound **2** crystallizes in the triclinic space group C_i^1-P1 with one formula unit in a cell of dimensions $a = 11.105(3)$ Å, $b = 11.748(4)$ Å, $c = 11.922(3)$ Å, $\alpha = 118.78(2)°$, $\beta = 96.52(2)°$, and $\gamma = 91.03(3)°$ at 113 K. Full anisotropic refinement of the structure on F_o^2 led to a value of R_1 of 0.074 for those 11 135 reflections having $F_o^2 > 2\sigma(F_o^2)$. The anion of **2** consists of a triangle of Te^{2-} ligands capped above and below the plane by two Pb^{2+} centers to define a trigonal bipyramid. The ^{125}Te NMR spectrum of **2** in CD_3CN shows one resonance at −928 ppm (J_{Pb-Te}: 1090 Hz).

Key words: tellurometalates, liquid ammonia, synthesis, crystal structure.

Résumé : On a utilisé une réduction de tellurures binaires, à l'état fondu, par du potassium dans de l'ammoniac liquide, en présence de l'éther 18-couronne-6 ou de 2,2,2-Crypt, pour synthétiser et pour précipiter des tellurométallates. La méthode est plus rapide que les techniques conventionnelles d'extraction et, puisque les températures impliquées sont moins élevées, on conserve les fragments qui sont potentiellement instables. Un produit fondu de composition nominale $CdTe_3$ dissous avec du K et de l'éther 18-couronne-6 dans du NH_3 liquide conduit, après recristallisation dans du CH_3CN–Et_2O, au composé $[K(\text{éther 18-couronne-6})]_4[Cd_4Te_{12}]$ (**1**). Les cristaux du composé **1** sont tricliniques, groupe d'espace $C_i^1-P\bar{1}$ avec une formule par unité de dimensions $a = 12{,}673(1)$, $b = 13{,}694(3)$ et $c = 14{,}483(3)$ Å, $\alpha = 117{,}54(2)°$, $\beta = 96{,}43(1)°$ et $\gamma = 100{,}00(1)°$, à 113 K. Un affinement anisotropique complet de la structure sur F_o^2 conduit à une valeur de $R_1 = 0{,}026$ pour les 6654 réflexions pour lesquelles $F_o^2 > 2\sigma(F_o^2)$. L'anion $[Cd_4Te_{12}]^{4-}$ du composé **1** peut être représenté par la formule $[Cd_4(Te)_2(Te_2)_2(Te_3)_2]^{4-}$ et consiste d'un arrangement rectangulaire de quatre centres Cd^{2+} liés par des coordinats Te^{2-}, Te_2^{2-} et Te_3^{2-}. Comme on peut s'y attendre sur la base de la structure à l'état solide, le spectre RMN du ^{125}Te du produit **1**, dans le CD_3CN, présente quatre bandes de résonances à −11, −259, −548 et −1682 ppm. Un produit fondu de composition nominale $PbTe_2$ dissous avec du K et du 2,2,2-Crypt dans du NH_3 liquide conduit, après recristallisation dans du CH_3CN, au composé $[K(2,2,2\text{-Crypt})]_2[Pb_2Te_3]\cdot CH_3CN$ (**2**). Les cristaux du composé **2** sont tricliniques, groupe d'espace C_i^1-P1, avec une formule par unité de dimensions $a = 11{,}105(3)$, $b = 11{,}748(4)$ et $c = 11{,}922(3)$ Å, $\alpha = 118{,}78(2)°$, $\beta = 96{,}52(2)°$ et $\gamma = 91{,}03(3)°$, à 113 K. Un affinement anisotropique complet de la structure sur F_o^2 conduit à une valeur de $R_1 = 0{,}074$ pour les 11 135 réflexions pour lesquelles $F_o^2 > 2\sigma(F_o^2)$. L'anion du composé **2** est formé d'un triangle de coordinats Te^{2-} avec des caps, au-dessus et au-dessous du plan, de deux centres Pb^{2+} qui définissent une bipyramide

trigonale. Les spectres RMN du ^{125}Te du composé **2** en solution dans le CD_3CN ne présente qu'une raie de résonance à −928 ppm (J_{Pb-Te} : 1090 Hz).

Mots clés : tellurométallates, ammoniac liquide, synthèse, structure cristalline.

[Traduit par la rédaction]

Introduction

Chalcogenometalates have attracted attention over the past two decades because of their rich chemistry, unusual structures, and their potential role as precursors for technologically important materials (1–3). While most of the studies have centered on the sulfidometalates (4–9), interest in the chemistry of the selenometalates and tellurometalates has developed (10–14).

The number of tellurometalates has increased dramatically in the past few years through the use of synthetic techniques other than that of traditional nonaqueous solution chemistry. These techniques include cathodic dissolution of electrodes composed of metal telluride alloys (15–19), solventothermal sealed-tube reactions (20–29), and the revisiting of the old technique of solvent extraction (30, 31) of metal telluride phases (32–37). Here we report new syntheses and characterization of the previously known tellurometalate anions $[Cd_4Te_{12}]^{4-}$ and $[Pb_2Te_3]^{2-}$. Syntheses were accomplished through the reduction of binary telluride melts in liquid NH_3 in the presence of K and an encapsulating ligand. This method, which has not been previously applied to the synthesis of tellurometalates, is more rapid than conventional solvent extraction techniques and takes place at lower temperatures.

Experimental

Standard Schlenk-line (dry N_2 atmosphere) and glove box (dry Ar atmosphere) techniques were used in the manipulation of the complexes described below. Anhydrous acetonitrile (CH_3CN) and anhydrous diethyl ether (Et_2O) were purchased from the Aldrich Chemical Co., Milwaukee, Wis., distilled under dry N_2 from CaH_2 and Na–benzophenone, respectively, and further purged with dry N_2 before use. Anhydrous NH_3 was purchased from Union Carbide Corp., Linde Div., Hillside, Ill., and used without further purification. Elemental Te (99.999%), Pb (99.999%), and K (99.95%), as well as 18-Crown-6 and 2,2,2-Crypt were purchased from Aldrich Chemical Co., Milwaukee, Wis., elemental Cd (99.999%) was obtained from the Johnson Matthey Co., Ward Hill, Mass. Melts of nominal composition $CdTe_3$ and $PbTe_2$ were prepared by the fusion of stoichiometric amounts of the constituent elements under an inert atmosphere; "$CdTe_3$" is a homogeneous mixture of α-CdTe and Te whereas "$PbTe_2$" is a homogeneous mixture of α-PbTe and Te. These melts were finely ground immediately prior to use. Elemental microanalyses were performed by Oneida Research Services, Whitesboro, N.Y. ^{125}Te NMR data were obtained on samples in DMF/CD_3CN on a Varian Unity + 400 MHz spectrometer equipped with a 10 mm tunable broad-band probe and a deuterium lock. The following conditions were employed: scanning frequency, 126 MHz; delay time, 1 s; pulse width, 14.5 μs; acquisition time, 0.032 s. All ^{125}Te NMR chemical shifts are referenced to the external secondary standard Et_2Te at δ = 380 ppm. The chemical shift scale is based upon Me_2Te at δ = 0.0 ppm.

Syntheses

(a) $[K(18\text{-Crown-6})]_4[Cd_4Te_{12}]$ (1)

18-Crown-6 (528 mg, 2 mmol) and K (80 mg, 2 mmol) were placed in a Schlenk flask. NH_3 (ca. 60 mL) was condensed into the flask at liquid N_2 temperature and the resultant blue solution was stirred for 30 min at −78°C. Finely ground $CdTe_3$ (988 mg, 2 mmol) was then added and the mixture was stirred for 2 d to provide a brown solution. The NH_3 was allowed to evaporate at room temperature and CH_3CN (30 mL) was added to the residual material. The resultant solution was filtered. Et_2O (90 mL) was layered on top of the filtrate to afford, after 5 d, dark red blocks of **1** (yield, 240 mg of crystals, 15.0% based on Cd). Anal. calcd. for $C_{48}H_{96}Cd_4K_4O_{24}Te_{12}$: C 18.05, H 3.03, K 4.90; found: C 18.19, H 2.87, K 4.36. ^{125}Te NMR (DMF/CD_3CN, ppm) δ: −11, −259, −548, −1682 ppm.

(b) $[K(2,2,2\text{-Crypt})]_2[Pb_2Te_3]\cdot CH_3CN$ (2)

2,2,2-Crypt (1506 mg, 4 mmol) and K (160 mg, 4 mmol) were placed in a Schlenk flask. NH_3 (ca. 60 mL) was condensed into the flask at liquid N_2 temperature and the resultant blue solution was stirred for 30 min at −78°C. Finely ground $PbTe_2$ (925 mg, 2 mmol) was then added and the mixture was stirred for 2 d to afford a bright red solution. The NH_3 was allowed to evaporate at room temperature and CH_3CN (30 mL) was added to the residual material. The solution was filtered and the CH_3CN was removed under reduced pressure. The resultant powder was redissolved in CH_3CN (10 mL). The flask was cooled to −20°C to provide, after 3 d, dark red plates of **2** (113 mg of crystals, 6.8% based on Pb). Anal. calcd. for $C_{38}H_{75}K_2N_5O_{12}Pb_2Te_3$: C 27.34, H 4.53, N 4.20, K 4.68; found: C 27.32, H 4.59, N 3.94, K 4.93. ^{125}Te NMR (CD_3CN, ppm) δ: −928 (J_{Pb-Te}: 1090 Hz).

Crystallographic studies

Dark red blocks of **1** or red plates of **2** were placed under degassed Krytox (Dupont) oil and were mounted on glass fibers in a glove bag filled with dry N_2. A fiber with a suitable crystal was transferred to the cold N_2 stream of an Enraf–Nonius CAD4 automatic diffractometer. Intensity data were collected at 113 K with MoKα radiation. The resultant profile data were processed (38) and then were corrected for absorption effects (39). For all structural analyses the SHELXTL–PC graphics programs were employed (40) and the structures were refined on F^2 through the use of the SHELXL–93 least-squares refinement program (41).

(a) $[K(18\text{-Crown-6})]_4[Cd_4Te_{12}]$ (1)

The unit cell of **1** was determined by least-squares refinement of the setting angles of 25 reflections automatically cen-

tered in the range $19 \leq \theta \leq 20°$. Data were collected for all reflections in the range $2° \leq \theta \leq 25°$. The intensities of six standard reflections, which were measured every 3 h, remained constant throughout the data collection. Crystallographic data are listed in Table 1 and additional details are provided in Table SI.[2]

The triclinic cell did not reduce to indicate higher symmetry. Both the agreement among Friedel pairs and intensity statistics favored the centrosymmetric space group $P\bar{1}$ and the structure was successfully solved and refined in that space group. With one formula unit in the cell, the $[Cd_4Te_{12}]^{4-}$ anion has a crystallographically imposed center of symmetry. The positions of the two Cd, six Te, and two independent K atoms were determined from a direct methods solution (40); the positions of the remaining nonhydrogen atoms were found from successive difference electron density maps. Some disorder of a cation was apparent. The model used to describe this disorder involves two separate conformations of five C atoms and two O atoms in the first cation. The first conformation C(4)-O(3)-C(5)-C(6)-O(4)-C(7)-C(8) has atom O(3) bonded to atom K(1). The second conformation C(4A)-O(3A)-C(5A)-C(6A)-O(4A)-C(7A)-C(8A) has atom O(3A) bonded to K(2) in the other cation. The occupancy of each conformation was refined with the sum of the occupancies of the corresponding atoms in the two conformations fixed at 1.0; the occupancies of the two conformations refine to 0.483(7) and 0.517(7). The locations of atoms C(5) and C(6A), although they correspond to different C atoms in the connectivity of the two groups, could not be distinguished from each other and so were fixed to have the same position and thermal parameters. All hydrogen atom positions were placed at calculated positions and were included in the final refinement. For those reflections having $F_o^2 > 2\sigma(F_o^2)$ the final cycle of least-squares refinement converged to a value of R_1 of 0.026 (6654 observations, 470 parameters). Final nonhydrogen atom positions and equivalent isotropic displacement parameters are listed in Table 2, anisotropic thermal displacement parameters are provided in Table SII, and hydrogen atom positions are listed in Table SIII.[2]

(b) $[K(2,2,2\text{-Crypt})]_2[Pb_2Te_3]\cdot CH_3CN$ (2)

The unit cell of **2** was determined by least-squares refinement of the setting angles of 25 reflections automatically centered in the range $20 \leq \theta \leq 22°$. The resultant cell, which was triclinic, did not reduce. Data were collected for all reflections in the range $2 \leq \theta \leq 30.5°$. The intensities of six standard reflections, which were measured every 3 h, remained constant throughout the data collection. Crystallographic data are listed in Table 1 and additional details are provided in Table SIV.[2]

The distribution of intensities strongly favored the absence of a center of symmetry and thus the apparent space group is $P1$. Among known structures of all types of materials this space group is remarkably rare compared with its centrosymmetric counterpart $P\bar{1}$. Consequently, intensity statistics were ignored and an attempt was made to solve the structure in $P\bar{1}$. The resultant direct-methods solution was interesting. It showed Pb atoms at the apices of a Pb_2Te_3 trigonal bipyramid, but the bipyramid had a crystallographically imposed center of symmetry and thus the equatorial plane consisted of six half-Te atoms. In addition, the solution revealed the positions of two K atoms too close to each other to be encapsulated with 2,2,2-Crypt ligands. Such features suggested that removal of the center of symmetry would lead to a chemically sensible

[2] Copies of material on deposit: crystallographic details (Table SI (**1**), Table SIV (**2**)), thermal displacement parameters (Table SII (**1**), Table SV (**2**)), hydrogen atom positions (Table SIII (**1**), Table SVI (**2**)), bond distances and angles (Table SVII (**1**), Table SVIII (**2**)), may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

With the exception of thermal displacement parameters, this material has also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

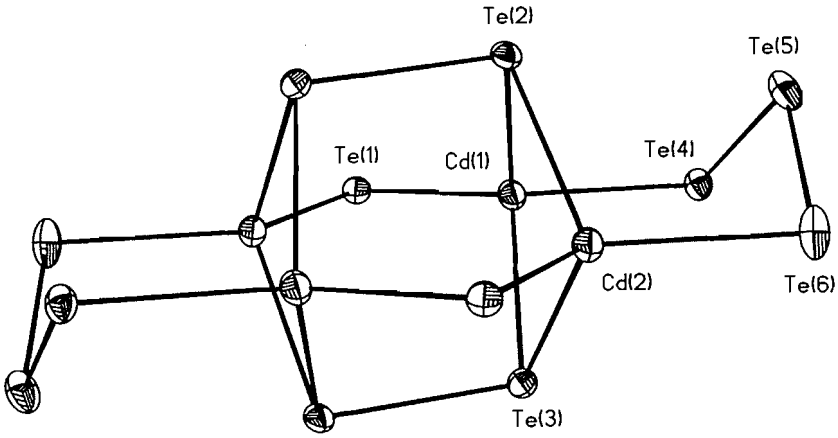
Fig. 1. The $[Cd_4Te_{12}]^{4-}$ anion of **1**. Here and in Fig. 2 the 50% probability ellipsoids are shown.



structure. Subsequently, a solution in the non-centrosymmetric space group $P1$ made chemical sense, and successive refinement of this solution revealed not only the positions of the two independent 2,2,2-Crypt ligands but also of one CH_3CN solvent molecule. At the conclusion of a standard anisotropic refinement on F_o^2 of all nonhydrogen atoms, with inclusion of hydrogen atoms at their calculated positions, the values of the agreement indices were $wR_2 = 0.172$ for 12 926 data and 561 parameters and $R_1 = 0.0823$ for 11 135 observations having $F_o^2 > 2\sigma(F_o^2)$. The Flack parameter of 0.372(7) strongly suggested that, while the absolute structure of the major component was correct, there was twinning to the extent of 0.63:0.37. Refinement of a twin led to values of wR_2 of 0.153 and R_1 of 0.0736 and a twinning parameter of 0.376(6). Final nonhydrogen atom positions and equivalent isotropic displacement parameters are listed in Table 3, anisotropic thermal displacement parameters are provided in Table SV, and hydrogen atom positions are listed in Table SVI.[2]

Discussion

The tellurometalates described above were synthesized by dissolving the appropriate binary telluride melt in liquid NH_3 in the presence of K and either 18-Crown-6 or 2,2,2-Crypt. The use of an alkali metal sequestering agent is essential to prevent reversion of the species formed to insoluble materials during the evaporation of the solvent (31). The binary telluride melts were finely ground prior to addition to the K–NH_3 solution to foster rapid dissolution.

Compound **1** is $[K(18\text{-Crown-6})]_4[Cd_4Te_{12}]$. It was obtained as dark red blocks from the reaction of $CdTe_3$ with K and 18-Crown-6 in liquid NH_3, followed by recrystallization from CH_3CN–Et_2O. $CdTe_3$ is a homogeneous mixture of α-CdTe and Te. The corresponding reaction with α-CdTe did not afford **1**. The anion of **1** was previously crystallized as $[Na(15\text{-Crown-5})]_4[Cd_4Te_{12}]\cdot 8DMF$ through a traditional route involving the reaction of Na_2Te_3 with $Cd(OAc)_2\cdot 2H_2O$ in DMF solution in the presence of 15-Crown-5 (42) and as $[NEt_4]_4[Cd_4Te_{12}]$ through a traditional route involving the reaction of K_2Te_2 with CdI_2 in DMF solution in the presence of NEt_4Br (43). The $[Cd_4Te_{12}]^{4-}$ anion may be formulated as $[Cd_4(Te)_2(Te_2)_2(Te_3)_2]^{4-}$ (Fig. 1). The anion has a crystallographically imposed center of symmetry. It contains a rectangular array of tetrahedrally coordinated Cd atoms (formally, Cd^{2+}). The long sides of the rectangle are symmetrically bridged by two Te^{2-} anions and the short sides are linked by two Te_3^{2-} chains. In addition, the four Cd atoms are bridged above and below the rectangular faces by two Te_2^{2-} units. Selected distances found in the present structure are given in Table 4 and a complete listing is given in Table SVII.[2] The metrical details for the anion are very similar to those reported earlier (42, 43). The distances from the Cd atoms to the bridging Te^{2-} species are 2.721(1) and 2.727(1) Å. The distances from the Cd atoms to the Te atoms of the Te_2^{2-} bridges range from 2.911(1) to 2.940(1) Å and the Te—Te distance is 2.773(1) Å. The distances from the Cd atoms to the Te atoms of the Te_3^{2-} chains are 2.796(1) and 2.805(1) Å and the Te—Te distances are 2.727(1) and 2.733(1) Å. The angles about the Cd

atoms range from 97.97(2)° to 128.01(2)° to provide distorted tetrahedral geometry about the Cd^{2+} centers. The two $[K(18\text{-Crown-6})]^+$ cations are packed perpendicularly to one another. The two cations are sufficiently close to allow for a disorder in which one of the O atoms (O(3A)) of the first cation coordinates to the atom K(2) of the second cation, as discussed above. The K(2)—O(3A) distance of 2.814(11) Å falls in the range of the other K—O bonds found in the cations (Table 4). The cation distances and angles are normal (Table SVII).

The ^{125}Te NMR spectrum of **1** shows four lines. This strongly suggests that the solid-state structure of the anion of **1** is maintained in solution.

Compound **2** is $[K(2,2,2\text{-Crypt})]_2[Pb_2Te_3]\cdot CH_3CN$. It was obtained as dark red plates from the reaction of a melt of nominal composition $PbTe_2$ with K and 2,2,2-Crypt in liquid NH_3, followed by recrystallization from CH_3CN. The unsolvated compound $[K(2,2,2\text{-Crypt})]_2[Pb_2Te_3]$ was previously synthesized from the dissolution of $KPb_{0.65}Te$ in ethylenediamine in the presence of 2,2,2-Crypt (44). The ^{125}Te NMR spectrum of the **1** (one resonance at −928 ppm, J_{Pb-Te} = 1090 Hz) agrees with that found previously (one resonance at −927.1 ppm, J_{Pb-Te} = 1070 Hz) (45).

The structure of the $[Pb_2Te_3]^{2-}$ anion is shown in Fig. 2. It consists of a triangle of Te^{2-} ligands capped above and below the plane by two Pb^{2+} centers to define a trigonal bipyramid. Selected metrical details for the structure of **2** are given in Table 5 and a complete listing is in Table SVIII.[2] The Pb—Te distances range from 2.954(2) to 3.015(1) Å, the Pb—Pb distance is 3.232(1) Å, and the Te-Pb-Te angles range from 92.21(4)° to 94.33(4)°. These may be compared with the Pb—Te distance of 2.943(2) Å, the Pb—Pb distance of 3.248(3) Å, and the Te-Pb-Te angle of 92.46(4)° in $[K(2,2,2\text{-Crypt})]_2[Pb_2Te_3]$ (44) where the anion has crystallographically imposed 32 symmetry. In the present structure the K(2,2,2-Crypt) anions have their expected structures.

The preparation of $[K(18\text{-Crown-6})]_4[Cd_4Te_{12}]$ (**1**) and $[K(2,2,2\text{-Crypt})]_2[Pb_2Te_3]\cdot CH_3CN$ (**2**) through the reduction of binary telluride melts in liquid NH_3 in the presence of K and an encapsulating ligand appears to be the first use of liquid NH_3 for the preparation of tellurometalates, although liquid NH_3 was used previously in the preparation of Zintl phases (31). The method is more rapid than conventional extraction techniques and, since the reaction is carried out at a lower temperature, potentially unstable fragments are conserved. Indeed, with the use of this technique we recently isolated the very unstable $[GaTe_3]^{3-}$ and $[In_3Te_7]^{5-}$ anions (46).

ansa-Metallocene imide niobium compounds

Alexander N. Chernega, Malcolm L.H. Green, and Alehandra G. Suárez

Abstract: The *ansa*-metallocene imide compounds of niobium {Nb[$Me_2C(\eta^5\text{-}C_5H_4)(\sigma\text{-}C_5H_4)$]($\eta^5\text{-}C_5H_5$)(NBu^t)} and {Nb[$Me_2C(\sigma\text{-}C_5H_4)(\eta^3\text{-}C_9H_6)$]($\eta^5\text{-}C_5H_5$)(NBu^t)} have been prepared and their crystal structures have been determined.

Key words: *ansa*, metallocene, niobium, cyclopentadienyl.

Résumé : On a préparé les composés *ansa*-métallocène imides du niobium {Nb[$Me_2C(\eta^5\text{-}C_5H_4)(\sigma\text{-}C_5H_4)$]($\eta^5\text{-}C_5H_5$)(NBu^t)} et {Nb[$Me_2C(\sigma\text{-}C_5H_4)(\eta^3\text{-}C_9H_6)$]($\eta^5\text{-}C_5H_5$)(NBu^t)} et on a déterminé leurs structures cristallines.

Mots clés : *ansa*, métallocène, niobium, cyclopentadiényle.

[Traduit par la rédaction]

There has been a current interest in *ansa*-metallocene complexes due to their application as homogeneous Ziegler-Natta catalysts for the production of isospecific polymers (1). Most *ansa*-metallocene derivatives are known for the Group 4 transition metals (2), for chromium (3), molybdenum and tungsten (4), calcium and barium (5), and samarium and ytterbium (6). Here we describe the synthesis and properties of the first examples of *ansa*-metallocenes of niobium.

Experimental

All manipulations and reactions were carried out under an atmosphere of dinitrogen (<10 ppm oxygen or water) using standard Schlenk-vessel and vacuum-line techniques or in a dry-box. Solvents were predried over activated 5 Å molecular sieves and then distilled under an atmosphere of dinitrogen from potassium (tetrahydrofuran), sodium (toluene), or sodium–potassium alloy (light petroleum (bp 40–60°C) and diethyl ether). Deuterated solvents for NMR samples were stored in ampoules with sodium ([$^2H_8$]-toluene) or dried using calcium hydride ([$^2H_2$]-dichloromethane) and transfered by vacuum distillation.

NMR spectra were recorded on Brüker AM-300 (^{1}H: 300 MHz, ^{13}C: 75.43 MHz) or AC-200 (^{1}H: 200 MHz) NMR spectrometers and referenced internally using residual protio solvent resonances (^{1}H) and solvent resonances (^{13}C) relative to tetramethylsilane (δ = 0 ppm). Low-resolution mass spectra were obtained on an AEI MS 302 mass spectrometer, updated by a data-handling system supplied by Mass Spectroscopy Services Ltd. Elemental analyses were performed by the analytical laboratory in this department.

Received November 25, 1994.

This paper is dedicated to Professor William A.G. Graham on the occasion of his 65th birthday.

Synthesis of {Nb[$Me_2C(\eta^5\text{-}C_5H_4)(\sigma\text{-}C_5H_4)$]($\eta^5\text{-}C_5H_5$)(NBu^t)} 1

A suspension of the *n*-butyllithium-generated anions of [$Me_2C(C_5H_4)_2$](7) (0.32 g, 1.73 mmol) in THF (30 mL) was treated with a solution of [Nb($\eta^5\text{-}C_5H_5$)(NBu^t)Cl_2] (8) (0.40 g, 1.33 mmol) in THF (70 mL) dropwise at room temperature and the mixture was stirred for 12 h, giving an orange-yellow solution. The volatiles were removed under reduced pressure and the residue was extracted with toluene (2 × 50 mL). After filtration, the filtrate was concentrated under reduced pressure and cooled to −80°C. After 24 h yellow crystals separated and these were collected and dried in vacuo. They were recrystallized from toluene as air-sensitive yellow crystals. Yield, 200 mg, 38%. ^{1}H NMR of the 1:1 mixture of diastereomers (the prime indicates the other isomer) (300 MHz, CD_2Cl_2, 180 K): 6.80 (1H, C_5H_4), 6.60 (1H, C_5H_4), 6.47 (1H, C_5H_4), 6.36 (1H, C_5H_4), 6.20 (1H, C_5H_4), 5.94 (5H, C_5H_5), 5.73 (1H, C_5H_4), 5.69 (1H, C_5H_4), 5.59 (1H, C_5H_4), 5.51 (1H, C_5H_4), 5.49 (1H, C_5H_4), 5.24 (5H, C_5H_5), 5.01 (1H, C_5H_4), 4.59 (1H, H10′ or H10), 4.50 (1H, H10 or H10′), 1.55 (3H, Me), 1.50 (3H, Me), 1.45 (3H, Me), 1.39 (3H, Me), 0.99 (9H, Bu^t), 0.61 (9H, Bu^t). ^{13}C–{^{1}H}NMR of the 1:1 mixture of isomers (75.43 MHz, CD_2Cl_2, 180 K): 144.7 (q, C16 or C17), 141.6 (CH, C_5H_4), 140.4 (CH, C_5H_4), 139.6 (q, C17 or C16), 126.7 (CH, C_5H_4), 126.5 (CH, C_5H_4), 121.4 (CH, C_5H_4), 114.4 (C_5H_5), 114.1 (CH, C_5H_4), 113.8 (CH, C_5H_4), 112.9 (C_5H_5), 111.0 (CH, C_5H_4), 109.0 (CH, C_5H_4), 108.4 (CH, C_5H_4), 106.7 (CH, C_5H_4), 105.1 (CH, C_5H_4), 95.6 (CH, C_5H_4), 73.6 (q, C1 or C1′), 73.0 (q, C1′ or C1), 66.1 (C10 or C10′), 62.6 (C10′ or C10), 40.1 (q, C15 or C37), 40.0 (q, C15 or C15′), 37.1 (CH_3), 35.8 (CH_3), 35.0 (Bu^t), 34.3 (Bu^t), 30.2 (CH_3), 29.6 (CH_3). There were no bands assignable to C18 and C18′ and it is assumed they are hidden under the bands assignable to the cyclopentadienyl ligands at 114.3 and 112.9 ppm. Also, the

^{13}C spectrum has one fewer band than expected for the C_5H_4 ligands and we assume that there are two bands which coincide. Mass spectrum: *m/z* 399 $[M]^+$. Anal. calcd.: C 66.2, H 7.0, N 3.5; found: C 64.4, H 7.1, N 3.25%.

Synthesis of {Nb[$Me_2C(\sigma$-$C_5H_4)(\eta^3$-$C_9H_6)$](η^5-C_5H_5)(NBu^t)} 2

A solution of [Nb(η^5-C_5H_5)Cl_2NBu^t] (9) (2.0 g, 6.06 mmol) in THF (200 mL) was treated with the dilithium salt of the 2-cyclopentadienyl,2-indenylpropane (9) (2.0 g, 7.9 mmol) in THF (minimum volume) dropwise (45 min) at room temperature and the mixture was stirred for 12 h. The volatiles were removed under reduced pressure and the residue was extracted with toluene (3 × 50 mL). After filtration the filtrate was concentrated under reduced pressure and cooled to −80°C for 24 h, giving yellow crystals. These were collected, dried in vacuo. and recrystallized from light petroleum (bp 40–60°C) to afford bright yellow crystals. Yield, 0.983 g, 36%. ^1H NMR (200 MHz, CD_2Cl_2, 230 K): 7.80 (1H, d, *J* = 8, H23 or H26), 7.34 (1H, d, *J* = 8, H23 or H26), 7.07 (1H, pseudo t, *J* = 8, H24 or H25), 6.99 (1H, pseudo t, *J* = 8, H24 or H25), 6.70 (1H, d, *J* = 3.2, H19 or H20), 6.62 (1H, br d, *J*(H11H12) 4.7), 6.15 (1H, dd, *J*(H11H12) 4.7, *J*(H12H13) 2.3, H12), 6.08 (1H, d, *J* = 3.2, H19 or H20), 5.54 (1H, pseudo t, *J*(H11H13) 2.3, *J*(H12H13) 1.7, H13), 5.40 (5H, s, H5–9), 4.32 (1H, s, H10), 2.05 (3H, s, Me), 1.80 (3H, s, Me), 0.75 (9H, s, Bu^t). ^{13}C–{^1H}NMR (75.43 MHz, CD_2Cl_2, 250 K): 160.1 (q, C14), 136.0 (q, C18 or 21 or 22), 133.6 (CH, C_5H_4 or C_9H_6), 125.7 (q, C18 or 21 or 22), 124.7 (CH, C_5H_4 or C_9H_6), 123.1 (CH, C_5H_4 or C_9H_6), 122.7 (CH, C_5H_5 or C_9H_6), 122.4 (CH, C_5H_4 or C_9H_6), 121.6 (q, C18 or 21 or 22), 119.8 (CH, C_5H_4 or C_9H_6), 119.5 (CH, C_5H_4 or C_9H_6), 107.1 (C_5H_5), 106.6 (CH, C_5H_4 or C_9H_6), 75.7 (CH, C_5H_4 or C_9H_6), 69.1 (q, C1), 63.9 (C10), 37.6 (q, C15), 32.1 (CH_3), 29.6 (CH_3), 28.4 (Bu^t). Mass spectrum: *m/z* 451 $[M]^+$, 378 $[M - NBu^t]^+$. Anal. calcd.: C 69.5, H 6.7, N 3.1; found: C 70.0, H 6.8, N 3.2%.

Crystal structure determination for compounds 1 and 2

Crystal data, data collection, and processing parameters are given in Table 1. The general procedure was as follows. A crystal was mounted in a Lindemann tube (0.7 mm) under dinitrogen and sealed with a small flame. This was transferred to the goniometer head of an Enraf–Nonius CAD4 diffractometer. Unit-cell parameters were calculated from the setting angles of 24 strong, high-angle, carefully centered reflections. Three reflections were chosen as intensity standards and were measured every 3600 s of X-ray exposure time, and three orientation control reflections were measured every 200 reflections. The data were collected at room temperature using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) and an ω–2θ scan mode (the ratio of the scanning rates ω/θ = 1.2). Neither significant crystal decay nor movement was noted.

All data were corrected for Lorentz and polarization effects and an empirical absorption correction (10) based on azimuthal scan data was applied. Both structures were solved by direct methods. Non-hydrogen atoms were refined with anistropic thermal parameters by full-matrix least-squares procedures. An empirical absorption correction using the DIFABS (11) program was applied after isotropic convergence. For both structures all hydrogen atoms were located in the difference Fourier maps and included in the final refinement with the fixed positional and thermal parameters. A Chebyshev weighting scheme (12) was applied and the data were corrected for the effects of anomalous dispersion. All crystallographic calculations were performed using the CRYSTALS program package (13*a*) on a MicroVAX 3800 computer and neutral atom scattering factors were taken from the usual sources (13*b*). Additional material deposited as supplementary data comprises tables of H-atom coordinates, thermal parameters, and the remaining bond lengths and angles.[2]

(NBu^t)Cl_2] with the dilithium salt of the dianion $[Me_2C(C_5H_4)_2]^{2-}$ in THF gave yellow crystals of {*ansa*-Nb[$Me_2C(\eta^5\text{-}C_5H_4)(\sigma\text{-}C_5H_4)$]($\eta^5\text{-}C_5H_5$) ($NBu^t$)} **1** as a 1:1 mixture of diastereomers in *ca.* 38% yield. Similarly, treatment of [Nb($\eta^5\text{-}C_5H_5$)(NBu^t)Cl_2] with the dilithium salt of the dianion $[Me_2C(C_5H_4)(C_9H_6)]^{2-}$ in THF at room temperature gave yellow crystals of {Nb[$Me_2C(\sigma\text{-}C_5H_4)(\eta^3\text{-}C_9H_6)$]($\eta^5\text{-}C_5H_5$)($NBu^t$)} **2** in ca. 36% yield. The characterizing data show that only a single diastereomer of **2** is formed. Presumably steric forces restrict formation of the other stereoisomer.

The crystal structures of **1** and **2** were determined by X-ray diffraction. The compound **1** has two chiral centres, namely, at the niobium centre, which posseses four different groups arranged in a pseudotetrahedral manner around the metal, and at the the chiral carbon of the σ-cyclopentadienyl group. The compound **1** is monomeric; the asymmetric unit contains both enantiomers **1A** and **1B** as crystallographically independent units. The enantiomers differ only very slightly in their structural parameters. Figure 1*a* shows the molecular structure of one of the two enantiomers (**1A**). Selected bond distances and angles of both molecules are given in Table 2 and the fractional atomic coordinates for all non-hydrogen atoms appear in Table 3. The metal–nitrogen bond lengths are 1.755(3) and 1.758(3) Å and the Nb-N-C(1) bond angles are almost linear: 175.2(3)° and 174.8(3)°. These values are very similar to those of the bis(η-cyclopentadienyl)imide niobium complexes [Nb(σ-C_5H_5)($\eta^5\text{-}C_5H_5$)$_2$(NBu^t)] **3** and [Nb($\eta^5\text{-}C_5H_5$)$_2$-(NBu^t)Cl] **4** in which the Nb—N bond distances and Nb-N-C(1) bond angles are 1.756(3) Å and 176.8(3)° for **3** and 1.789(4); 1.737(6) Å and 173.6(4), 179.4(5)° for **4** (14, 15). These structural data are comparable to the values found for other Nb=NR groups where the neutral NR group acts as a

four-electron donor ligand (16). The (ring centroid)-metal-(ring centroid) angles, 124.0 and 124.8°, are very similar to those of complexes **3** and **4**, as well as the metal–(ring centroid) distances (Nb—$Cp_{cent(1)}$ 2.212, 2.210 Å and Nb—$Cp_{cent(2)}$ 2.223, 2.209 Å). The Nb—C_{ipso} of the σ-cyclopentadienyl ligand are 2.312(3), 2.307(4) Å, which are comparable to the one in compound **3**, 2.330(3)Å (2). The bond angles C(18)-C(15)-C(14) are 105.7(3)° and 104.5(3)°.

The Nb—C bond distances of both substituted η-cyclopentadienyl ligands show that they are not coordinated in an ideal

[a]CEN(1) denotes the centroid of the ring C(5)–C(9).

η^5-fashion to the metal, and a significant ring-slip distortion is apparent.The view of **1** through the Nb-C_5H_5 ring normal-metal vector, shown in Fig. 1*b*, reveals that the metal is displaced in the direction of the ring carbons C(30) and C(31), which are staggered with respect to the Nb—N bond. However, the deviations in the inter-ring carbon distances of the η-cyclopentadienyl ligands are not sufficiently pronounced to support an allyl-ene description of the ring distortion. The C—C distances in the unsubstituted η-C_5H_5 ring are normal. It appears that the formally 20-electron compound **1** shows structural features that are consistent with ring-slip distortions towards an 18-electron bonding mode. The crystals of **2** are composed of discrete mononuclear molecules of {Nb[$Me_2C(\eta^5$-$C_5H_4)(\eta^3$-$C_9H_6)](\eta^5$-$C_5H_5)(NBu^t)$}. The molecular structure is shown in Fig. 2*a* and 2*b*, selected distances and bond angles are given in Table 4, and the fractional atomic coordinates for all non-hydrogen atoms appear in Table 5. The most noticeable differences between **1** and **2** are a consequence of increasing steric repulsion between the bulky substituents in **2** that leads to the decrease of the dihedral angle between the C(5)–C(9) and C(18)–C(22) planes from 131.0° in **1A** and **1B** to 122.8° in **2**. There is also a decrease in the Nb—CEN(1) distance from 2.212 and 2.210 Å in **1A** and **1B** to 2.179 Å in **2**. The ring system C(18)–C(26) of **2** is planar within 0.088 Å; the dihedral angle between planes of the C(18)–C(22) and C(21)–C(26) rings is only 3.5°. The geomet-

rical features of the Nb═N—CBu^t group (Nb═N 1.755(3), 1.758(3) Å in **1** and 1.760(1) Å in **2**, N—C(1) 1.446(5), 1.446(4) Å in **1** and 1.450(2) Å in **2**, Nb-N-C(1) 175.2(3)°, 174.8(3)° in **1** and 169.3(1)° in **2**) are similar to those found for other Nb═NR groups (12, 13) where the neutral NR group acts as a four-electron donor ligand. The Nb—N bond distance is 1.760(1) Å in **2** and is comparable to the values found for the analogous complexes mentioned above, where the neutral NR group also acts as a four-electron donor ligand (16, 17).

The C—C distances in the five-membered ring of the indenyl ligand are as follows: C(18)—C(19) 1.400(2), C(19)—C(20) 1.414(3), C(20)—C(21) 1.438(3), C(21)—C(22) 1.427(2), and C(18)—C(22) 1.462(2) Å. These values show that the deviations in the inter-ring carbon distances are not very pronounced but are comparable with other allyl-ene descriptions of the ring distortion (18). The metal–carbon bond distances of the η^3-C_5 ring of the indenyl ligand are Nb—C(18) 2.539(2), Nb—C(19) 2.421(2), and Nb—C(20) 2.424(2) Å. The bond distance between the metal and the central carbon of the allyl portion is the shortest (see Fig. 2*b*). We note that the metal atoms in η^5-indenyl complexes also have a small slip distortion, usually in the direction of the central carbon of the allyl portion (19). We conclude that the above structural data indicate that complex {Nb(η^5-C_5H_5)[Me_2C(σ-C_5H_4)(η^3-C_9H_6)](NBu^t)} **2** has a formal 18-electron configuration.

The NMR spectra of **1** and **2** are consistent with the solution structures being the same as found in the crystalline state. Thus the ^1H and ^{13}C NMR spectra of {Nb(η^5-C_5H_5)[Me_2C(η^5-C_5H_4)(σ-C_5H_4)] (NBu^t)} **1** show the presence of two compounds in solution 1:1 ratio. The $^{13}C\{^1H\}$ NMR spectrum of **1** shows a large chemical shift difference ($\Delta\delta$ = 39 ppm) between the quaternary and the methyl carbons of the *tert*-butylimide ligand. This large value lies at the high end of the range previously recorded for *tert*-butylimide-metal derivatives (16), indicating a low electron density on the imide nitrogen due to the high degree of N→M π donation (16, 19).

The ^1H and ^{13}C NMR spectra of **1** show broad signals at room temperature, which may be due to the exchange between the η- and σ-cyclopentadienyl ligands of the C_5H_4-CMe_2-C_5H_4 ligand system. A variable temperature NMR study gave only a poorly resolved spectrum at 180 K, the lowest accessible temperature. The presence of two diastereomers increases the complexity of the spectra and for both the ^1H and ^{13}C NMR spectra it was not possible to detect all the proton and carbon signals expected for the diastereomeric mixture.

The ^1H NMR spectra of **2** at room temperature shows some broad signals and poor resolution. This suggests a degree of fluxionality or the presence of the quadrupolar moment of the ^{93}Nb nucleus (spin I = 9/2, natural abundance 100%). At 230 K the spectrum is well resolved and is given with assignment in the experimental section.

The large chemical shift difference ($\Delta\delta$ = 40 ppm) between the quaternary and the methyl carbons of the NBu^t group in the $^{13}C\{^1H\}$ NMR spectrum of **2** indicates a low electron density

on the nitrogen atom (16, 19). This is consistent with the imide ligand acting as four electron donor.

In conclusion, the formally 20-electron compound **1** shows structural features that are consistent with ring-slip distortions towards an 18-electron bonding mode and the compound **2** achieves an 18-electron configuration by virtue of the η^3-bonding of the indenyl group.

Metal complexes of biologically important ligands, LXXVIII.[1] Synthesis of palladium complexes of ferrocenyl-substituted amino acid derivatives

Doris Freiesleben, Kurt Polborn, Christian Robl, Karlheinz Sünkel, and Wolfgang Beck

Abstract: Schiff bases from ferrocene aldehyde and α-amino acidates react with $PdCl_2$ or Na_2PdCl_4 to give N,O-chelate complexes (**2***a–e*, **3**). The related *N*-ferrocenylmethylen-α-amino acid esters give, with $Pd(OAc)_2$, cyclopalladated acetate-bridged complexes (**4***a*,*b*). N,O-chelate complexes (**5–7**) are obtained from Na_2PdCl_4 with *N*-ferrocenylmethyl prolinate and-alaninate as well as with *N*,*N*-dibenzyl glycinate. The ethyl ester of *N*,*N*-dibenzylglycine and $Pd(OAc)_2$ form the cyclopalladated acetate-bridged complex **8**, while the ester of *N*-monobenzylglycine and Na_2PdCl_4 affords *trans*-$PdCl_2(L)_2$ with a monodentate N-coordinated ligand. The structures of **2***a*, **4***a*, **5**, **7**, and **9** were determined by X-ray diffraction.

Key words: ferrocene, amino acids, palladium(II) complexes, crystal structures.

Résumé : Les bases de Schiff obtenues à partir de l'aldéhyde du ferrocène et d'α-amino-acides réagissent avec le $PdCl_2$ et la Na_2PdCl_4 pour donner des complexes N,O-chélatés (**2***a–e*, **3**). Les esters apparentés des acides *N*-ferrocénylméthylène-α-aminés, par réaction avec le $Pd(OAc)_2$, conduisent aux complexes acétates pontés cyclopalladiés, **4***a*,*b*. On obtient les complexes N,O-chélatés **5–7** par réaction du Na_2PdCl_4 avec les prolinate (et alaninate) de *N*-ferrocénylméthyle et avec le glycinate de *N*,*N*-dibenzyle. L'ester éthylique de la *N*,*N*-dibenzylglycine et le $Pd(OAc)_2$ forme le complexe acétate ponté cyclopalladié **8** alors que l'ester de la *N*-monobenzylglycine et le Na_2PdCl_4 fournissent le *trans*-$PdCl_2(L)_2$ avec un coordinat monodentate N-coordiné. On a déterminé les structures des composés **2***a*, **4***a*, **5**, **7** et **9** par diffraction des rayons X.

Mots clés : ferrocène, amino-acides, complexes de palladium(II), structures cristaux.

[Traduit par la rédaction]

Introduction

Palladium compounds have found widespread application in organic synthesis (2). Coordination compounds of the type PdL_4 or PdL_2Cl_2 are used in many catalytic processes, particularly in the field of asymmetric catalysis. Besides "normal" coordination to the donor atoms of the ligands L, very frequently "cyclopalladation," especially orthopalladation, e.g., formation of a Pd—C bond in *ortho* position to the aromatic substituent bearing the coordinating functionality, has been used in stoichiometric organic transformations (3). In an effort to combine "classical" coordination chemistry with organometallic chemistry, bimetallic complexes containing a ferrocene moiety in the ligand backbone have attracted special interest, due to their potential as "redox-switchable" ligands. Many donor atom combinations have been examined, but most of them contain a nitrogen atom. For instance, many palladium complexes of P,N-donor ferrocenes such as $Fe(C_5H_4PR_2)[C_5H_3(CHRNMe_2)(PR_2)]$ have been used as catalysts in stereospecific reactions (4). Ferrocenes with N,O-donor systems have also been examined as ligands for alkali ions or Ag^+, though so far not with palladium (5), but N,S-donor derivatives coordinate to Pd^{2+} and have proven to be quite active catalysts (6). Ferrocenylalkylamines can undergo asymmetric cyclopalladation affording cyclopalladium complexes of high optical purity, which might then be used in further transformations to yield enantiomerically pure new ferrocenyl ligands (7). The formation of cyclopalladated derivatives of ferrocenylimines has also been investigated recently (8).

In the course of our studies on coordination compounds of biologically important ligands we became interested in the possibility of combining the aforementioned aspects of palladium-ferrocene chemistry with the coordination chemistry of amino acids. Ferrocenyl-substituted amino acids have been known for quite awhile (9). Also, Schiff bases from amino acids and their esters and formyl ferrocene have been reported (10) and, after reduction, have been used for the masking of peptide bridges (11). Since these complexes appeared to us as

Received November 30, 1994.

This paper is dedicated to Professor William A.G. Graham on the occasion of his 65th birthday.

potential N,O-donor ligands, we decided to examine their coordination behaviour towards Pd^{2+}.

Results

When ferrocenylmethylidene-substituted imino acid derivatives are generated in situ from glycine, L-alanine, L-valine, L-leucine, or anthranilic acid and formylferrocene (**1**), and are then treated with Na_2PdCl_4, the bis-N,O chelates **2***a–e* containing two ferrocene moieties per palladium ion are obtained (Scheme 1).

When the glycine derivative is treated with $PdCl_2$, the tetrametallic chloro-bridged complex **3** is formed, where only one Schiff base ligand is coordinated as an N,O donor to one Pd(II) moiety.

All complexes show characteristic IR absorptions at ca. 1650 (ν_{as} CO_2), 1620 (C=N), 490 (Pd-N), and 475 (Pd-O) cm^{-1} (in KBr). For further characterization, the crystal structure of **2***a* was determined by X-ray diffraction (vide infra).

However, when the Schiff bases obtained in situ from amino acid *esters* derived from glycine, L-alanine, and **1** were treated with $Pd(OAc)_2$ in the presence of MeOH and KOAc, orthopalladation at the ferrocene ring took place and the tetrametallic acetate-bridged complexes **4***a,b* could be isolated (Scheme 2). The IR spectra (in KBr) of **4***a,b* show the presence of the uncoordinated ester moiety by the CO absorptions at 1730–1740 cm^{-1} and the coordination of the imine nitrogen by the C=N absorptions at 1620–1640 cm^{-1} and Pd-N bands at ca. 500 cm^{-1}. For further characterization, the crystal structure of **4***a* was determined by X-ray diffraction (vide infra).

Scheme 2.

	R	R'
4*a*	H	C_2H_5
4*b*	CH_3	CH_3

Treatment of **1** with alanine in the presence of $MgCl_2$–NaOAc–MeOH or with proline in MeOH and consecutive reduction of the intermediate Schiff bases with $NaBH_4$ (11) gives *N*-ferrocenylmethylamino acidates that afford, with Na_2PdCl_4 **5**, a trimetallic structural analogue of **2** and a tetrametallic complex **6**, a structural analogue of **3** (Scheme 3).

The coordination of the carboxylate can be seen from the IR spectra (in KBr), where $\nu_{as}(CO_2)$ absorbs at 1641 (**5**) and 1655 (**6**) cm^{-1}. This was also confirmed by a X-ray structure determination of **5** (vide infra).

To summarize the results reported so far, basically two types of coordination can be observed with *N*-ferrocenylmethylidene-substituted amino acid derivatives: (*a*) N,O chelation (compounds **2**, **3**, **5**, **6**); (*b*) orthopalladation with C,N coordination (compounds **4**.)

Additionally, there is a slight variation insofar as the Pd^{2+} ions might or might not be bridged by acetate or chloride ions.

Quite interestingly, a similar coordination behaviour could be observed with *N*-benzyl derivatives of glycine or its ethyl ester. Orthopalladation of benzylamine and its *N*-monosubstituted derivatives has been reported only recently (12), while the orthopalladated α-methylated benzylamines have already found application in the resolution of chiral amines and phosphines (13). With α-phenylethylamine, formation of a $PdCl_2$ complex with two monodentate amines was also observed (13*b*). *N*-benzylglycine derivatives have been used for the extraction of metals (14).

N,*N*-Dibenzylglycine and Na_2PdCl_4, in the presence of NaOAc, yield the bis-N,O chelate **7**. Its ethyl ester reacts with palladium acetate under orthopalladation, forming a bimetallic acetate-bridged complex **8**. Finally, when *O*-ethyl-*N*-benzylglycinate is treated with Na_2PdCl_4 in the presence of NaOAc, a *trans*-$PdCl_2$ complex **9** with two monodentate *N*-coordinating amino acidates can be isolated (Scheme 4). The IR spectrum of **7** shows the coordinated CO_2 group at 1640 cm^{-1}, while the coordinated ester groups in **8** are observed at 1730 cm^{-1} and the uncoordinated ester functions in **9** at 1735 cm^{-1} (in KBr). To get more information about structural details, X-ray structure determinations of **7** and **9** were performed (vide infra).

Crystal structure determinations

The molecular structures of the complexes **2***a*, **4***a*, **5**, **7**, and **9** were examined by X-ray diffraction. Representative views of the compounds can be seen in Figs. 1–5, experimental details of the structure determinations in Table 1, and atomic coordinates together with isotropic temperature parameters in Tables 2–6.[4] Since we are, in this context, only interested in the coordination sphere of the palladium ions, geometrical parameters of the ligand backbones will not be discussed here.

First of all, we want to look at the N,O-chelate complexes **2***a*, **5**, and **7**. All of them are bis-chelates, and all of them have *trans-N,N*/*trans-O,O* geometries. In **2***a* and **7**, this molecular symmetry is combined with a crystallographic symmetry, imposed by the Pd ions residing on an inversion centre. Consequently, complex **2***a*, derived from the chiral

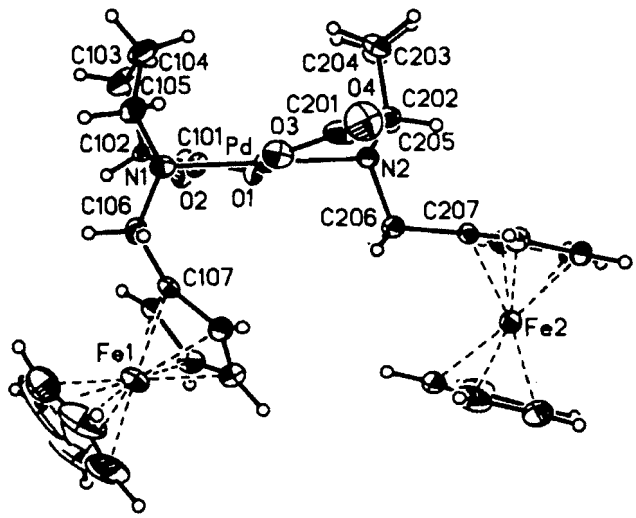
Angles (°): O1-Pd-N1 84.7(2), O1-Pd-N2 96.4(2), N2-Pd-O3 83.9(2), O3-Pd-N1 95.1(2), Pd-O1-C101 114.9(5), Pd-O3-C201 113.1(6), Pd-N1-C102 105.6(4), Pd-N2-C202 102.9(5).



their coordination to palladium, with the *S* configuration at the α-C atom of proline, *R* configuration at the coordinating N atoms is induced for geometric reasons, and thus the only diastereomer found in the crystal is the $S_C R_N S_{C'} R_{N'}$ form,

which has also been observed with other prolinate complexes.[5]

The coordination geometries around the Pd atom are essentially planar for **2***a* and **7** for crystallographic reasons, but also in **5** the sum of angles around Pd is 360.1° and Pd is thus in a planar environment as well. The best plane through the five atoms of the chelate rings in **2***a* (mean deviation 0.09 Å) includes an angle of 7° with the coordination plane; in **5**, the five atoms deviate 0.10 Å (Pd, O1, N1, etc.) and 0.15 Å (Pd, O3, N2, etc.) from their best planes, which include an angle of 21° between each other and angles of 8° and 13°, respectively, with the coordination plane.

The Pd—O distances and Pd—N distances show a slightly stronger coordination of the *imino* ligand compared with the two *amino* ligands. The chelate angles at Pd are very similar. At nitrogen and oxygen, however, the difference between the imino and amino systems becomes more obvious.

The ferrocenyl moieties are on opposite sides of the coordination plane in **2***a* (of course, due to the inversion centre at Pd), while they are on the same side in **5** with, however, two different conformations relative to the C—N bonds. Quite interestingly, one of the ferrocene units (C207–C211) is nearly coplanar with the coordination plane (angle 7°). In **7**, one of the phenyl rings "caps" each side of the coordination plane. However, no indication of any agostic interactions between Pd and the phenyl hydrogens (closest contact 2.87 Å with H9) could be obtained.

[5] With N-unsubstituted prolinates, the equivalent configuration is, of course, $S_C S_N$: see, for example, ref. 15.

[a] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = \{\Sigma[w(|F_o| - |F_c|)^2]/\Sigma[w|F_o|^2]\}^{1/2}$, $w^{-1} = \sigma^2_{|F|} + g|F|^2$.

The molecular structure of an orthopalladated compound was determined as well. Compound **4***a* crystallizes in the centrosymmetric space group $P2_1/n$, but both "halves" of the molecule are crystallographically independent. Since **4***a* is a glycine derivative, there is no element of central chirality, but orthopalladation leads to planar chirality in the ferrocene moiety (7). Thus, with two ferrocene moieties in the molecule of **4***a*, formation of diastereomers should be possible. However, in the crystal both ferrocene subunits show the same configuration and, because of the centrosymmetric space group, their enantiomeric counterparts are also present. The unit cell contains therefore only the $R_{Fc}R_{Fc'}/S_{Fc}S_{Fc'}$ diastereoisomeric pair. Actually, the same selectivity has been observed with an analogous orthopalladated ferrocenylmethylidene complex derived from 2,4,6-trimethylaniline as the amine compound (8*a*). The palladacycles deviate only slightly from planarity (0.03 Å at Pd1 and 0.005 Å at Pd2) and are also nearly coplanar with the cyclopentadienyl rings to which they are attached (3° in both halves). The coordination planes around the Pd^{2+} ions show only 0.03 Å (at Pd1) and 0.04 Å (at Pd2) deviation from planarity, and include angles of 6° and 3° with the corresponding chelate rings and of 35° between each other. This "folding" of the molecule has been observed with several other acetate-bridged dipalladium complexes (and adds another element of chirality to the system), while it is absent in the corresponding chloro-bridged dimers (8, 16). The acetate bridges are not planar. The close contact between the two Pd^{2+} ions is a consequence of the folding, and has been reported for other complexes of this type as well (16). The Pd—N distances lie intermediate between the values found for imino- and aminoacidate systems, presumably due to the different *trans* influence of the acetate ligand compared to a nitrogen ligand. The Pd—C distances (avg. 1.936 Å) are quite short, and consequently, the *trans* Pd—O distances (avg. 2.136 Å) are approximately 0.10 Å longer than the Pd—O bonds *trans* to the imino nitrogen. All these bond parameters are quite similar to the values reported for $Pd_2[4\text{-}OCH_3C_6H_4N{=}C(COPh)Ph]_2(OAc)_2$ (16) and $[Pd\{cpFeC_5H_3C(H){=}N\text{-}2,4,6\text{-}Me_3C_6H_2\}OAc]_2$ (8*a*). The C=N bond of the imino group (avg. 1.278 Å) is slightly elongated when compared with the situation in **2***a*, but still shorter than the literature values for the two above-mentioned complexes.

Finally, the structure of a compound with a unidentate amino acid derivative, **9**, was also determined. Here again, the Pd^{2+} ion resides on a crystallographic inversion centre. Consequently, the chiral nitrogen atom has the *R* configuration in one half of the molecule and the *S* configuration in the other. The $R_NR_{N'}$ or $S_NS_{N'}$ diastereomers are absent in the crystal.

The Pd—N bond length compares well with the values found in the two other compounds with a sp^3 nitrogen.

NMR Spectra

The ligands described in this paper usually display quite complicated patterns in their ^{1}H NMR spectra, due to overlapping resonances of the ferrocene part with the amino acid part. Generally, protons of substituted ferrocenes appear at $4 < \delta < 5$ ppm with multiplicities strongly dependent on the kind of substituent present. With a chiral substituent, the α as well as the β protons become diastereotopic, thus generating ABCD spin systems. Also, the resonance of the α-proton of the amino acid residue is expected in the same region of the NMR spectrum. The other protons of the amino acid usually absorb between 0.8 and 2.2 ppm, with only alanine having a really characteristic doublet absorption due to the methyl group. Finally, the proton of an imino function is expected around 8 ppm as a singlet (8) that is well separated from the other proton resonances except for the aromatic amino acidates.

It is quite clear, therefore, that unambiguous *complete* assignments of NMR spectra are either very difficult or even impossible, particularly when the formation of isomeric species has to be considered as well (vide infra). Any discussion of the species present in solution depends on the observation of well-separated signals for the imino protons in the ^{1}H NMR spectra.

Discussion

As was already mentioned, the interaction of Pd^{2+} with N-functionalized amino acid derivatives leads to formation of three different types of products. With amino acid anions, the exclusive formation of N,O chelates is observed. With amino acid esters and Na_2PdCl_4 only monodentate coordination via the nitrogen occurs, while the use of $Pd(OAc)_2$ leads to ortho-palladation. This ease of formation of cyclometallated products with $Pd(OAc)_2$ has been reported before (12*a*).

In many of the complexes presented in this paper the forma-

[a]The equivalent isotropic U_{eq} is calculated as one third of the trace of the orthogonal U_{ij} tensors.

tion of isomers is possible. These isomers might arise either from the generation of new stereogenic centers on complexation, e.g., planar chirality induced by orthopalladation, *cis/trans* isomers at the palladium ion, or *cis/trans-* isomerism around the imino functionalities.

Thus, with restricted rotation around the C=N bond, and with two such imino functions in the molecule in compounds **2** and **3**, three isomers *Z/Z*, *Z/E*, and *E/E* might be expected. For steric reasons, however, the *E/E* isomer should be strongly favoured, since it shows the least interaction between the ferrocenyl moiety and the chelate ring. This is also observed in the solid state structure of **2***a*. The ^{1}H NMR spectra of **2***a,b,d* show only one singlet for the imino protons, at δ 7.9, indicating also only one species present in solution. (It should be noted that the crystal structure determination of **2***a* indicated at least partial racemization of the amino acid. This in turn opens up the possibility of diastereoisomer formation (*R/R*, *R/S*), which should give rise to two independent NMR signal sets, which are not, however, observed.)

For the cyclopalladated compounds **4**, without any asymmetric induction by the attached amino acidate, both α positions in the substituted ferrocene ring could have been

attacked by Pd; thus an enantiomeric pair of the palladacycle should be generated. With two such palladacycles in a molecule, diastereomers $R_{Fc}R_{Fc'}$ and $R_{Fc}S_{Fc'}$ together with their enantiomers should be formed. With an additional centre of chirality as in **4***b*, three diastereomers: $R_{Fc}R_{Fc'}S_CS_{C'}$, $R_{Fc}S_{Fc'}S_CS_{C'}$, and $S_{Fc}S_{Fc'}S_CS_{C'}$ become possible, which should give rise to three independent (plus one equally intensive) sets of signals. The formation of at least two of these isomers (one symmetrical and one unsymmetrical) can be deduced from the ^1H NMR spectrum of **4***b*, the third isomer either being formed to a lesser extent, or its signals accidentally hidden by the other isomers.

In the corresponding *N*-dibenzylglycine derivative **8** the element of planar chirality is missing. However, the nitrogen atoms become stereogenic centres by coordination, and thus the formation of two diastereomers $R_NR_{N'}$ and $R_NS_{N'}$ together with their enantiomers should be possible. A similar argument holds for the *trans* $PdCl_2$ complex **9**. In both cases, however, the overlap of the methylene protons on one side and the phenyl protons on the other, which are all diastereotopic due to the inherent chirality, does not allow an unambiguous statement about the number of isomers formed. Due to solubility problems, the ^{13}C NMR spectra are of too poor quality to make any decisions. However, since there seems to be no source of asymmetric induction, we assume that both diastereomers are formed.

Experimental

All reactions were performed using standard Schlenk technique, under nitrogen, with N_2-saturated dry solvents. All reagents were commercially available and were used without further purification. For the NMR spectra a Jeol-GSX 270 instrument was used, for IR spectra Perkin–Elmer 841 and Nicolet 520 spectrometers. The X-ray analyses were performed on a Enraf–Nonius CAD 4 (**2***a*–**4**), Syntex R3 (**5**), and Siemens R3m/V (**7**, **9**). The programs used to solve and refine the structures were included in the Siemens–Nicolet SHELXTL-plus program package on a Microvax II computer.

Elemental analyses together with selected IR data and yields are presented in Table 7.

Bis-(*N*-ferrocenylidene-aminoacidate)-palladium(II) 2*a*–*e*

General procedure

The amino acid (1.0 mmol), dissolved in 2 mL MeOH, is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12

treated with a 0.5 M solution of NaOMe in MeOH until no solids or cloudiness remain. This solution is treated with 1.0 mmol formyl ferrocene (214 mg) and a small quantity of Al_2O_3. After stirring for 1 h at room temperature, the suspension is filtered and the residue washed with MeOH. The combined liquids are concentrated in vacuo to about 2 mL and then treated with 0.5 mmol Na_2PdCl_4 (147 mg). After 15 h of stirring at room temperature, the red precipitate (for **2***e* the addition of water is necessary to obtain a precipitate) is isolated and washed three times with 2 mL MeOH. Recrystallization from $CHCl_3$–hexane yields red crystals.

For the synthesis of **3**, instead of 0.5 mmol Na_2PdCl_4, 1.0 mmol $PdCl_2$ (177 mg) is added to the solution of the Schiff base.

Selected ^{1}H NMR data (270 MHz): **2***a*: 7.9s (CH=N), 4.4–4.7m, 1.8d; **2***b*: 7.9s (CH=N), 4.3m, 4.7m, 2.3m, 1.34d, 1.26d; **2***d*: 7.9s (CH=N), 4.7m, 4.4s, 4.2m; **3**: 7.9s (CH=N), 4.7m, 4.4m, 4.2m. ^{13}C NMR data (69 MHz; in $CDCl_3$): δ (*C*HN): 168.1 (for **2***a*,*c*), 169.3 (for **2***e*, **3**); δ (*C*O): 182.8 (**2***a*), 180.1 (**2***c*), 179.7 (**2***e*, **3**).

Bis(μ-acetato)-bis(*N*-ferrocenylidene-*O*-alkylamino-acidate)-dipalladium (II) 4*a*,*b*

General procedure

A solution of 1.0 mmol formylferrocene, 3 mmol Na_2CO_3 (300 mg), and 1.0 mmol *O*-ethyl- or methylamino acid hydrochloride in EtOH is refluxed for 2 h. After centrifugation the precipitate is discarded, and the solution is evaporated in vacuo to yield a dark red oil. This is dissolved in 4 mL MeOH, treated with 1.0 mmol KOAc (100 mg) and 1.0 mmol $Pd(OAc)_2$ (226 mg), and stirred for 15 h. After filtration through a Hyflo Super Cel filter aid (to remove the Pd powder also generated in the reaction) the solution is concentrated in vacuo to leave again a red oil. Several recrystallizations from CH_2Cl_2–hexane yield **4** in pure form as red crystals. ^{1}H NMR ($CDCl_3$): **4***a*: 7.4s (CH=N), 4.2–4.5m, 3.9d, 3.3q, 2.1s, 1.3t; 4b: 7.8–8.2″m″ (CH=N), 3.4–4.8m, 0.9–2.2m.

Bis(*N*-ferrocenylmethylprolinate)-palladium(II) 5

Formylferrocene 1.0 mmol, (214 mg) and 1.0 mmol L-proline (115 mg) are dissolved in 3 mL MeOH and stirred for 30 min at room temperature. The now violet solution is chilled to −78°C and treated with 5 mmol $NaBH_4$ (189 mg). While continuously stirring, the mixture is brought back to room temperature, when the solvent is stripped off in vacuo. Twenty minutes after addition of a small amount of water, 1.0 mmol NBu_4Br (322 mg) is added, and the suspension extracted with CH_2Cl_2. The organic phase is separated, dried with Na_2SO_4, filtered, and freed from solvent in vacuo. A brownish yellow powder is left. A mixture of 55 mg of this powder and 0.05 mmol Na_2PdCl_4 (15 mg) is stirred for 30 min in 1 mL of a 1:1 water–methanol mixture. Evaporation of the MeOH precipitates the product, which can be isolated by filtration and recrystallized from CH_2Cl_2 to yield yellow crystals of **5**. ^{1}H NMR ($CDCl_3$): 4.2–4.4m, 4.1s, 3.7m, 3.3m, 2.9m.

Di-μ-dichloro-*N*-ferrocenylmethylalaninate)-dipalladium(II) 6

Formylferrocene (0.3 mmol, 64 mg), dissolved in 1 mL MeOH, is treated with 0.95 mmol $MgCl_2$ (90 mg), 0.3 mmol L-alanine (27 mg), and 0.3 mmol NaOAc (25 mg). After stirring for 6 h at room temperature, the reaction mixture is chilled to −78°C and 1.5 mmol $NaBH_4$ (57 mg) is added. Over 15 h the suspension is brought back to ambient temperature. Then 1 mL 2 M HCl is added, with stirring for 20 min, to hydrolyze unreacted $NaBH_4$, after which the pH of the solution is brought to 8 by addition of 2 M NaOH. After the addition of 0.15 mmol Na_2PdCl_4 (44 mg) and stirring for 30 min, **6** can be isolated as a yellow powder.

Bis(*N*,*N*-dibenzylglycinate)-palladium(II) 7

Na_2PdCl_4 (1.0 mmol), dissolved in 8 mL MeOH, is treated with 2.0 mmol *N*,*N*-dibenzylglycine (510 mg) with stirring for 2 h. Filtration and washing with EtOH and Et_2O leaves **7** as a red powder that can be recrystallized from CH_2Cl_2–hexane. ^{1}H NMR ($CDCl_3$): 7.4–7.6m, 3.8–4.2m, 3.44s.

Bis(*N*-benzyl-*O*-ethylglycinate)-dichloro-palladium (II) 9

9 can be obtained similarly from 1.0 mmol Na_2PdCl_4, 2.0 mmol *N*-benzyl-*O*-ethylglycinate, and 2.0 mmol NaOAc. ^{1}H NMR ($CDCl_3$): 7.4–7.6m, 3.8–4.2m, 3.4m, 1.2m.

Compound 8

$Pd(OAc)_2$ (1.0 mmol, 224 mg), *N*,*N*-dibenzyl-*O*-ethylglycinate (2.0 mmol; 570 mg), and NaOAc (2.0 mmol; 164 mg) in 8 mL MeOH are stirred for 20 h at room temperature. Filtration through the filter aid removes the precipitated palladium. The solution is evaporated in vacuo, the residue taken up in CH_2Cl_2, and the solution added to Et_2O. The precipitate is discarded, and the solution chromatographed on silica gel-60 (Merck). The first yellow band, containing the product, is collected. Concentration of the solution in vacuo, followed by careful addition of hexane, yields **8** in the form of light yellow crystals. ^{1}H NMR ($CDCl_3$): 6.7–8.3m, 3.2–4.4m, 2.1s, 1.2m.

Abstract: The preparation of a mixed donor ligand consisting of an enolate and neutral phosphine is described and its coordination chemistry with nickel reported. The phosphino ketones R_2PCH_2COPh (R = Cy or Pr^i) are prepared by the reaction of the corresponding secondary phosphines with bromoacetophenone to form the corresponding phosphonium salts $[R_2P(H)CH_2COPh]^+Br^-$ (R = Cy or Pr^i); subsequent deprotonation leads to the neutral ketones. The enolates are formed by addition of $NaN(SiMe_3)_2$ to the neutral ketone. The crystal structure of the sodium enolate having isopropyl substituents at phosphorus displays a tetrameric structure in the solid state and there is an interaction of the phosphorus donor with the sodium anion: Na—P, 2.852(2) Å. The preparation of a series of nickel complexes was achieved by addition of the sodium enolate to the appropriate Ni(II) starting material. The structures of the nickel derivatives are reported. The catalytic behaviour of one of these complexes in the polymerization and oligomerization of ethylene is briefly described. Crystals of $\{Na[Pr^i_2PC(H)=C(O)Ph]\}_4$, **2***b*, are tetragonal, $a = b = 20.790(2)$ Å, $c = 13.539(7)$ Å, $Z = 4$, space group $I4_1/a_1$; those of $[Cy_2PC(H)=C(O)Ph](PPh_3)NiPh$, **3***a*, are triclinic, $a = 10.742(2)$ Å, $b = 19.811(3)$ Å, $c = 10.621(2)$ Å, $\alpha = 101.88(1)°$, $\beta = 119.24(1)°$, $\gamma = 91.08(1)°$, $Z = 2$, space group $P\bar{1}$; and those of $[Pr^i2PC(H)=C(O)Ph](PPh_3)NiPh$, **3***b*, are triclinic, $a = 10.219(1)$ Å, $b = 17.432(3)$ Å, $c = 9.788(1)$ Å, $\alpha = 101.18(1)°$, $\beta = 100.19(1)°$, $\gamma = 85.32(1)°$, $Z = 2$, space group $P\bar{1}$. The structures were solved by direct (**2***b*) and Patterson (**3***a* and **3***b*) methods and were refined by full-matrix least-squares procedures to $R = 0.045$, 0.044, and 0.032 ($R_w = 0.038$, 0.041, and 0.030) for 965, 4483, and 5085 reflections with $I \geq 3\sigma(I)$ respectively.

Key words: nickel, sodium enolate, homogeneous catalyst, oligomerization.

Résumé : On décrit la préparation d'un coordinat donneur mixte, formé d'un énolate et d'une phosphine neutre, et on rapporte sa chimie de coordination avec le nickel. On a prépare les phosphinocétones, R_2PCH_2COPh (R = Cy or Pr^i) par réaction des phosphines secondaires correspondantes avec la bromoacétophénone conduisant aux sels de phosphonium correspondants $[R_2P(H)CH_2COPh]^+Br^-$ (R = Cy or Pr^i) dont la dépronation conduit aux cétones neutres. On forme les énolates par addition de $NaN(SiMe_3)_2$ à la cétone neutre. La structure cristalline de l'énolate de sodium portant des substituants isopropyles sur le phosphore présente une structure trimère à l'état solide et il existe une interaction entre le phosphore donneur et l'anion sodium: Na—P, 2,852(2)Å. On a réalisé la préparation d'une série de complexes de nickel en procédant à l'addition de l'énolate de sodium sur le produit de départ approprié de Ni(II). On a déterminé les structures cristallines des dérivés du nickel. On décrit brièvement le comportement catalytique de l'un de ces complexes dans la polymérisation et l'oligomérisation de l'éthylène. Les cristaux du $\{Na[Pr^i_2PC(H)=C(O)Ph]\}_4$, **2***b*, sont tétragonaux, groupe d'espace $I4_1/a$, avec $a = b = 20,790(2)$ Å, et $c = 13,539(7)$ Å, $Z = 4$; ceux du $[Cy_2PC(H)=C(O)Ph](PPh_3)NiPh$, **3***a*, sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 10,742(2)$, $b = 19,811(3)$ et $c = 10,621(2)$ Å, $\alpha = 101,88(1)°$, $\beta = 119,24(1)°$, et $\gamma = 91,08(1)°$ et $Z = 2$ et ceux du $[Pr^i2PC(H)=C(O)Ph](PPh_3)NiPh$, **3***b*, sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 10,219(1)$, $b = 17,432(3)$ et $c = 9,788(1)$ Å, $\alpha = 101,18(1)°$, $\beta = 100,19(1)°$, $\gamma = 85,32(1)°$ et $Z = 2$. On a résolu les structures par des méthodes directes (**2***b*) et de Patterson (**3***a* et **3***b*) et on les a affinées par les

[Traduit par la rédaction]

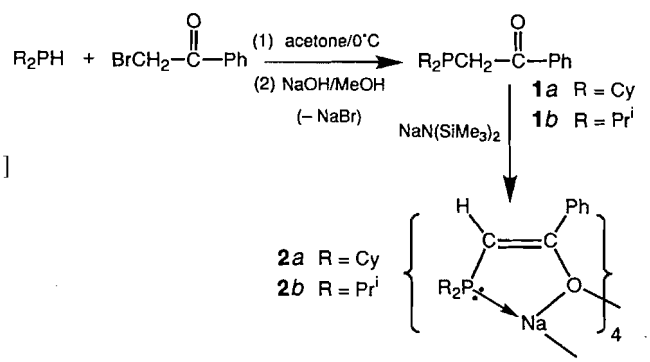
Introduction

The discovery that certain nickel(II) complexes incorporating mixed P,O donor ligands were effective catalyst precursors for ethylene oligomerization reactions in the so-called Shell-Higher-Olefin-Process (SHOP) (1–7) has sparked a number of groups to devise new ancillary ligands that can be utilized (8–14). The original preparation (1) involved reaction of a keto-phosphorus ylid of the type $Ph_3P{=}CHCOPh$ with $Ni(COD)_2$ and PPh_3 to produce, after phenyl transfer, the complex $Ni(Ph)PPh_3[Ph_2PCH{=}C(O)Ph]$. The reaction is not general since phosphorus ylids that contain two electron-rich alkyl substituents, such as $Pr^i_2PhP{=}CHCOPh$, do not transfer a phenyl to $Ni(COD)_2$ even at elevated temperatures.[3] In an effort to extend the preparation of potential SHOP catalyst precursors, the use of β-phosphinoenolates (9, 15–17) in concert with a nickel(II) starting material seemed promising since, in principle, this should allow incorporation of a variety of substituents at the phosphorus end of the mixed-donor chelate.

In this report we outline the synthesis of a mixed P,O donor ligand that has bulky electron-rich substituents attached at phosphorus. The structure of the sodium enolate of this ligand is also described along with its coordination chemistry with nickel. We also include some preliminary experiments on the catalytic behavior of these nickel derivatives.

Results and discussion

The ligand was prepared (eq. [1]) by addition of a secondary phosphine, R_2PH (R = Cy or Pr^i), to bromoacetophenone to generate the corresponding phosphonium salt, which was subsequently neutralized with methanolic NaOH to generate the keto-phosphines **1***a*, *b* as either an air- and moisture-sensitive solid (R = Cy) or a liquid (R = Pr^i). The keto-phosphines **1***a*, *b* can also be prepared via reaction of the enolate of acetophenone with the corresponding chlorophosphine, $ClPR_2$ (17). The formation of the sodium enolate derivatives **2***a*, *b* was accomplished by addition of $NaN(SiMe_3)_2$ to an ether solution of the respective keto-phosphine.



[1]

The NMR spectroscopic parameters for the sodium enolates **2***a*, *b* clearly indicate that only one diastereomer is observed in solution; the crystal structure of **2***b*, shown in Fig. 1, indicates that the *Z* enolate is present. Not only is this the expected kinetic enolate isomer (18), but the additional binding by the phosphine to the sodium cation at the enolate oxygen presumably makes this the thermodynamically most-favored isomer as well.

Fig. 1. Above: a schematic picture of the sodium β-phosphino-enolate **2***b* showing one unit of the tetramer and (below) the structure and numbering scheme from the X-ray crystal structure of the tetramer with some of the atoms removed for clarity (only the ipso carbon, C3 of the phenyl group, and the α-carbons, C9 and C12, of the isopropyls are shown). Some selected bond lengths (Å) and bond angles (°): P1—Na1 2.852(2); Na1—O1 2.431(4); Na1—O1′ 2.282(4); Na1—O1″ 2.312(4); O1—C2 1.321(5); C1—C2 1.357(6); C1—P1 1.778(5); C2—C3 1.503(7); Na1-O1-C2 119.1(3); O1-C2-C1 126.1(5); P1-C1-C2 123.6(4); Na1-P1-C1 94.8(2); P1-Na1-O1 72.67(9); Na1-O1-Na1* 84.3(1); Na1-O1-Na″ 90.7(1); Na*-O1-Na″ 87.1(1).

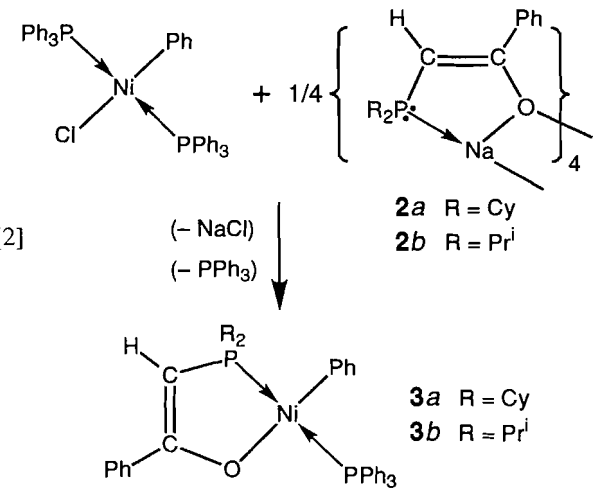
The X-ray crystal structure of **2*b*** (Fig. 1) displays a number of notable features. The tetrameric cubane structure is evident; in addition, the sodium atom is also coordinated by the phosphine moiety. The Na—O bond lengths are unsymmetrical and have the values of 2.282(4), 2.312(4), and 2.431(4) Å. The distance from the sodium to the phosphorus donor is 2.852(2) Å, shorter than that of 2.948(6) Å found (19) in the sodium salt of the bis(diphenylphosphino)benzyl ylid, $Na^+[Ph_2PCHPPh_2\text{-}CHPh]^-$. Other sodium–phosphorus bond lengths known are generally longer than that found in **2*b***, even when the interaction involves anionic phosphide type salts: in $[NaPHCy\cdot pmdeta]_2$, the Na—P bond distances are 2.883(8) and 2.936(7) Å (20), while in $NaPMes(SiFBu^t_2)\cdot 2THF$ the bond length is 2.890(1) Å (21).

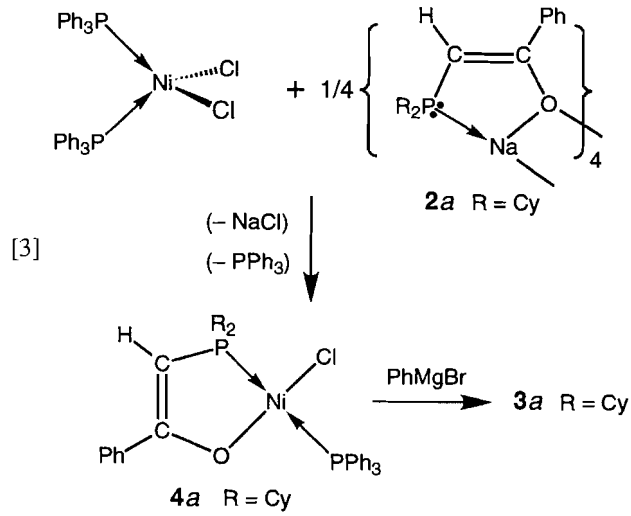
Other than the layered aggregates of simple alkoxide salts, the structural motifs encountered in the solid-state structural analyses of sodium alkoxides and enolates, $\{NaOR\}_n$, range from tetramer ($n = 4$) to hexamer units ($n = 6$) with even non-americ structures ($n = 9$) having been found (22). In these structures, each sodium cation is generally found to be three-coordinate and sitting at the corner of the appropriate geometrical shape. In the presence of Lewis bases, adduct formation results in higher coordination numbers for the sodium and generally the formation of smaller repeating units, typically dimers or trimers although monomers are also known (23, 24). It is clear that the present cubane structure is stable enough, at least in the solid state, to tolerate the weak phosphine binding.

These sodium enolates can be used in metathetical-type reactions to prepare new coordination complexes. For example, addition of the sodium derivatives **2*a*, *b*** to suitable Ni(II) derivatives results in incorporation of the bidentate ligand (eq. [2]).



In solution, complexes **3*a*** and **3*b*** show a *trans* disposition of inequivalent phosphine donors as evidenced by the AX pattern in the $^{31}P\{^1H\}$ NPR spectrum where large $^2J_{PP}$ couplings of 272 and 275 Hz, respectively, are observed. The X-ray crystal structures of both **3*a*** and **3*b*** have been determined and both give virtually identical dimensions; only the diisopropyl derivative **3*b*** is shown in Fig. 2 along with some selected bond lengths and bond angles. The solid-state structure confirms the solution structure in that the phosphorus ligands are indeed *trans* disposed; the geometry around nickel is nearly square planar as expected. In fact, the bond angles and bond distances in both of these complexes are extremely similar to those found in the diphenylphosphino derivative $Ni(Ph)PPh_3[Ph_2PCH{=}C(O)Ph]$ mentioned earlier (1).

The preparation of these complexes can also be achieved by, first, reaction with $NiCl_2(PPh_3)_2$ to generate complex **4*a*** with the P,O ligand attached, then addition of PhMgBr to produce **3*a*** having the necessary nickel carbon bond; this is summarized in eq. [3].



We have also examined the preparation of the corresponding allyl complex $Ni(\eta^3\text{-}C_3H_5)[Cy_2PCH{=}C(O)Ph]$ **5*a***; addition of the sodium enolate **2*a*** to allynickel dimer $[(\eta^3\text{-}C_3H_5)Ni]_2(\mu\text{-}Br)_2$ does produce the corresponding allyl complex **5*a***. However, this is accompanied by considerable amounts of decomposition products, one of which was identified as the bis(P,O)-ligand complex $Ni[Cy_2PCH{=}C(O)Ph]_2$. Subsequent investigations have shown that this reaction is very sensitive to the purity of the starting allylnickel dimer; the use of freshly recrystallized $[(\eta^3\text{-}C_3H_5)Ni]_2(\mu\text{-}Br)_2$ generates the corresponding allyl derivative **5*a*** in virtually quantitative yield.

These new nickel complexes are active in the oligomerization and polymerization of ethylene; for example, a solution of **3*b*** in toluene at 40–70°C under ethylene (2 atm; 1 atm = 101.3 kPa) produced a range of olefins (up to C_{22} as detected by GC–MS) and polyethylene (mp = 103–108°C). It would appear that the presence of an electron-rich phosphine in the bidentate, mixed-donor ligand does not seriously diminish the catalytic activity of these nickel complexes although accurate comparisons have yet to be made.

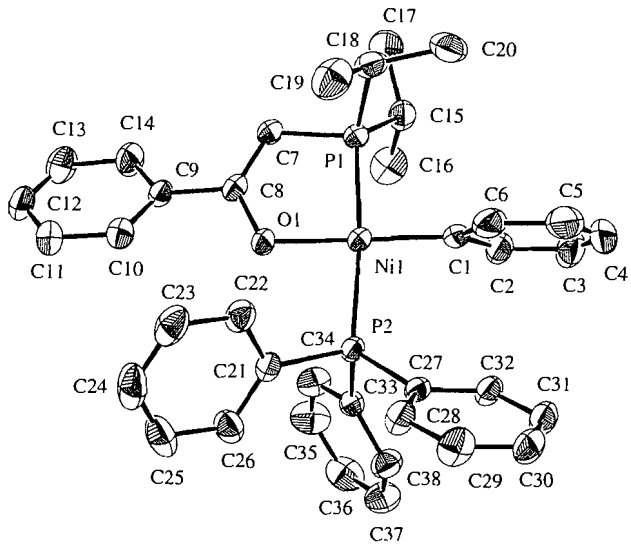
Experimental procedure

All reactions were preformed under purified nitrogen in dry, degassed solvents. NMR spectra are referenced externally to standard values as described previously (25).

$Cy_2PCH_2C(O)Ph$ (1*a*)

A solution of Cy_2PH (4.33 g, 0.0218 mol) in acetone (5 mL) was added dropwise to an acetone (20 mL) solution of $BrCH_2C(O)Ph$ (4.35 g, 0.0219 mol); the reaction is mildly exothermic. After the addition, the volatiles were removed under vacuum to yield an oil that was then dissolved in cold (0°C) MeOH (15 mL), and to it was added slowly one equiv-

Fig. 2. The structure and numbering scheme of the nickel phenyl complex **3***b*. Some selected bond lengths (Å) and bond angles (°): Ni1—P1 2.1756(7); Ni1—C1 1.893(2); Ni1—P2 2.2324(6); Ni1—O1 1.918(1); O1—C8 1.321(2); C7—C8 1.346(3); P1—C7 1.764(2); C8—C9 1.495(3); P1-Ni1-P2 174.62(3); O1-Nil-C1 178.03(9); P1-Ni1-C1 92.25(7); P2-Ni1-C1 93.12(7); P1-Ni1-O1 86.48(5); P2-Ni1-O1 88.16(5); Ni1-O1-C8 118.3(1); O1-C8-C7 122.5(2); P1-C7-C8 113.8(2); Ni1-P1-C7 98.91(7).



alent of NaOH (0.874) in MeOH. The resultant solution was stirred for 10 min and was then pumped to dryness. The residue was extracted with ether (2 × 25 mL), filtered to remove NaBr, dried over Na_2SO_4, then over activated molecular sieves, filtered again, and pumped to dryness. The crude product was recrystallized from pentane at –30°C to give colorless crystals in 66% (4.56 g) yield. ^{1}H NMR (C_6D_6, δ): 7.0–7.2 (m, Ph), 8.1–8.2 (m, Ph), 2.95 (d, $^2J_{PH}$ = 0.65 Hz, CH_2), 1.0–2.0 (m, Cy). ^{31}P{^{1}H} NMR (C_6D_6, δ): 0.65 (s). Anal. calcd. for $C_{20}H_{29}OP$: C 75.92, H 9.24; found: C 76.06, H 9.30.

$Pr^i_2PCH_2C(O)Ph$ (1*b*)

The same procedure as for **1***a* was followed using Pr^i_2PH and $BrCH_2C(O)Ph$ except that, after filtration, the solvent was removed under vacuum and the yellow liquid distilled at 0.001 Torr (1 Torr = 133.3 Pa) (bp 125–130°C) to give the product as a colourless liquid in 51% yield (12.05 g). ^{1}H NMR (C_6D_6, δ): 8.05–8.15 (m, Ph), 7.0–7.2 (m, Ph), 2.89 (d, $^2J_{PH}$ = 0.60 Hz, CH_2), 1.61 (d of hept, $^3J_{HH}$ = 7.05 Hz, $^2J_{PH}$ = 0.59 Hz, PCH^iPr), 1.00 (dd, $^3J_{HH}$ = 7.06 Hz, $^3J_{PH}$ = 3.09 Hz, CH_3), 0.94 (dd, $^3J_{HH}$ = 7.04 Hz, $^3J_{PH}$ = 5.58 Hz, CH_3). ^{31}P{^{1}H} NMR (C_6D_6, δ): 7.21 (s).

{Na[Cy_2PCH=C(O)Ph]}$_4$ (2*a*)

To a cold (–30°C) solution (10 mL) of the dicyclohexylphosphino ketone **1***a* (1.01 g, 3.21 mmol) diethyl ether (10 mL) was added an ethereal solution (10 mL) of $NaN(SiMe_3)_2$ (0.589 g, 3.21 mmol). The solution was allowed to warm to room temperature, stirred for 3 h, and was pumped to dryness to remove the ether and $HN(SiMe_3)_2$. The residue was recrystallized from ether–pentane to give the sodium salt **2***a* as colorless crystals. Yield: 0.90 g (83%). ^{1}H NMR (C_6D_6, δ): 7.6–7.8 (m, Ph), 6.8–7.3 (m, Ph), 4.54 (d, $^2J_{PH}$ = 5.6 Hz, C(O)=C*H*-P), 1.0–2.0 (m, Cy). ^{31}P{^{1}H} NMR (C_6D_6, δ): –26.97 (s). Anal. calcd. for $C_{20}H_{28}OPNa$: C 70.99, H 8.34; found: C 71.14, H 8.29.

{Na[Pr^i_2PCH=C(O)Ph]}$_4$ (2*b*)

Using the same procedure as above on the diisopropylphosphino ketone **1***b*, colourless crystals were obtained after recrystallization from ether–pentane. Yield: 94%. ^{1}H NMR (C_6D_6, δ): 7.65–7.8 (m, Ph), 7.1–7.3 (m, Ph), 4.49 (d, $^2J_{PH}$ = 5.85 Hz, C(O)=C*H*-P), 1.58–1.63 (m, PCH), 0.9–1.25 (m, CH_3). ^{31}P{^{1}H} NMR (C_6D_6, δ): –17.98 (s). Anal. calcd. for $C_{14}H_{20}ONaP$: C 65.11, H 7.80; found: C 64.89, H 7.96.

Ni(Ph)PPh_3[Cy_2PCH=C(O)Ph] (3*a*)

To a toluene solution (50 mL) of *trans*-Ni(PPh_3)$_2$(Ph)Cl (0.966 g, 1.39 mmol) maintained at 0°C was added dropwise a toluene solution (15 mL) of **2***a* (0.47 g, 1.39 mmol). The color of the solution went from yellow-orange to dark orange after several drops of the enolate was added. After the addition, the solution was stirred overnight, filtered, and pumped to dryness; the product was recrystallized from ether–hexanes as dark orange crystalline blocks. Yield: 0.59 g (60%). ^{1}H NMR (C_6D_6, δ): 6.7–7.7 (m, Ph), 4.5 (dd, $^2J_{PH}$ = 1.96 Hz, $^4J_{PH}$ = 0.95 Hz, C(O)=CH-P)), 2.5–1.0 (m, Cy), ^{31}P{^{1}H} NMR (C_6D_6, δ): 35.0 (d, $^2J_{PP}$ = 272.2 Hz), 20.0 (d). Anal. calcd. for $C_{44}H_{48}NiOP_2$: C 74.07, H 6.78; found: C 74.16, H 6.90.

Ni(Ph)PPh_3[Pr^i_2PCH=C(O)Ph] (3*b*)

To a slurry of *trans*-Ni(PPh_3)$_2$(Ph)Cl (0.361 g, 0.5188 mmol) in ether (40 mL) at –78°C was added an ethereal solution of 2*b* (0.134 g, 0.5188 mmol). The mixture was vigorously stirred was warmed up to room temperature after 0.5 h. The orange solution thus formed was stirred for an additional hour and was filtered. The filtrate was pumped to ≈5 mL and hexanes (20 mL) added. Removal of the solvents under vacuum gave orange crystals of 3*b*. Yield: 0.312 g (95%). ^{1}H NMR (C_6D_6, δ): 6.7–7.7 (m, 25 H, Ph), 4.47 (dd, $^2J_{PH}$ = 2.06 Hz, $^4J_{PH}$ = 0.96 Hz, PC*H*=C(O)), 1.84 (dhept, $2J_{PH}$ = 20.62 Hz, $^3J_{HH}$ = 3.48 Hz, PC*H*Me_2), 1.07 (dd, $^3J_{PH}$ = 14.29 Hz, $^3J_{HH}$ = 6.88 Hz, PCHCH_3), 1.01 (dd, $^3J_{PH}$ = 16.10 Hz, $^3J_{HH}$ = 7.08 Hz, PCHCH_3). ^{31}P{H} NMR (THF, D_2O insert, δ): 43.76 (d, $^2J_{PP}$ = 274.66 Hz), 20.76 (d). Anal. calcd. for $C_{38}H_{40}NiOP_2$: C 72.06, H 6.37; found: C 71.80, H 6.27.

Ni(Cl)PPh_3[Cy_2PCH=C(O)Ph] (4*a*)

A solution of 2*a* (0.563 g, 1.664 mmol) in toluene (5 mL) was added dropwise to a slurry of $NiCl_2(PPh_3)_2$ (1.089 g, 1.664 mmol) in toluene (15 mL). The resultant orange solution was stirred for 3 h and was filtered. The filtrate was pumped to dryness and the residue was crystallized from ether–hexanes to give compound 4*a* in 72% yield (0.8 g). ^{31}P{^{1}H} NMR (C_6D_6, δ): 41.09 (d, $^2J_{PP}$ = 325.6 Hz), 9.62 (d). Anal. calcd. for $C_{38}H_{43}ClNiOP_2$: C 67.93, H 6.45; found: C 67.79, H 6.35. Reaction of this compound with PhMgBr in ether gave Ni(Ph)PPh_3[Cy_2PCH=C(O)Ph] (3*a*), identical to that described above.

Ni(η^3-C_3H_5)[Cy_2PCH=C(O)Ph] (5*a*)

The sodium phosphino-enolate 2*a* (0.272 g, 0.8037 mmol) in toluene (10 mL) was added dropwise to a toluene solution (10

Values given for *R*, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

mL) of $[(\eta^3\text{-}C_3H_5)Ni]_2(\mu\text{-}Br)_2$ (0.144 g, 0.4018 mmol). The resultant solution was stirred overnight and was filtered to remove some black solid. The filtrate was pumped to dryness and the residue was redissolved in a minimum amount of ether, then diluted with one-third the volume of hexanes. Orange crystals deposited overnight that were identified as the bis(ligand) complex $Ni[Cy_2PCH{=}C(O)Ph]_2$. To the mother liquor was added more hexanes. Brownish-orange crystals deposited at −30°C with a yield of 0.1 g, 30%. ^1H NMR (C_6D_6, δ): 8.2–8.27 (m, *para* Ph), 7.1–7.3 (m, *ortho/meta* Ph); allyl protons: 4.97 (dddd), 4.55 (d, $^2J_{PH}$ = 1.22 Hz), 4.23 (m), 3.12 (dd, J_{HH} = 4.64 Hz, J_{HH} = 14.4 Hz), 2.32 (m); remaining proton is buried in the Cy multiplets; 1.0–2.1 (m, Cy + one allyl H). $^{31}P\{^1H\}$ NMR (C_6D_6, δ): 42.53 (s). Anal. calcd. for $C_{23}H_{333}OPNi$: C 66.54, H 8.01; found: C 66.88, H 8.07. This reaction proceeds in nearly quantitative yield if pure, recrystallized $[\eta^3\text{–}C_3H_5)Ni]_2(\mu\text{–}Br)_2$ is used.

Reaction of $Ni(Ph)PPh_3[Pr^i_2PCH{=}C(O)Ph]$ (*3b*) with ethylene

Run 1

3*b* (35 mg) was dissolved in toluene (40 mL) in a thick-walled glass bomb (80 mL) that was connected to a three-way valve; the valve was also connected to a vacuum line and an ethylene cylinder. The system outside the glass bomb was pumped, first, to remove air and, then, head space of the bomb was evacuated. After the connection to the vacuum line was closed, the bomb was opened to the ethylene cylinder. The pressure of ethylene was maintained at 2 atm during the reaction. The bomb was placed in an oil bath and the bath temperature was maintained at 40°C. After being stirred for 12 h, the slurry was filtered and the white precipitate was washed with methanol (3 × 20 mL) and dried under vacuum. Yield of polyethylene: 1.24 g. GS–MS analysis of the filtrate found

oligomers: C_{14}–C_{22}. The total amount of the oligomers was 87 mg.

Run 2

3*b* (70 mg) was used. The reaction conditions were similar to those described in Run 1, but the reaction temperature was increased to 70°C. Ten minutes after ethylene (2 atm) was introduced into the bomb, the solution became turbid. After 6 h the reaction mixture was so thick that it was difficult to stir. The reaction was stopped and the mixture was cooled to room temperature. The solid was filtered and was washed with methanol (3 × 50 mL). Yield of polyethylene: 7.05 g.

X-ray crystallographic analyses of $Na[Pr^i_2PC(H)=C(O)Ph]_4$ (2*b*), $Ni(Ph)PPh_3[Cy_2PCH=C(O)Ph]$ (3*a*), and $Ni(Ph)PPh_3[Pr^i_2PCH=C(O)Ph]$ (3*b*)

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 15.6°–28.0° for **2***b*, 24.7°–30.4° for **3***a*, and 38.2°–43.1° for **3***b*. The intensities of three standard reflections, measured every 200 reflections, showed only small random fluctuations for the three data collections. The data were processed (26), corrected for Lorentz and polarization effects, and for absorption (empirical: based on azimuthal scans for three reflections).

The structure of **2***b* was solved by direct methods and those of **3***a* and **3***b* were solved by conventional heavy atom methods. The structure analyses of **3***a* and **3***b* were both initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the *E*-statistics and the appearance of the Patterson functions. These choices were confirmed by the subsequent successful solutions and refinements of the structures. The tetrameric complex **2** has crystallographically imposed S_4 symmetry. The non-hydrogen atoms of all three structures were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in idealized positions (C—H = 0.99 Å for **2** and 0.98 Å for **3***a* and **3***b*, $B_H = 1.2\ B_{\text{bonded atom}}$). A secondary extinction correction (Zachariasen type) was applied for **3***a*, the final value of the extinction coefficient was 5.7 (2) × 10^{-7}. Neutral atom scattering factors and anomalous dispersion corrections for all atoms were taken from the *International tables for X-ray crystallography* (27). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths and angles, hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes are available as supplementary material.[3]

[3] The supplementary material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

With the exception of the tables of anisotropic thermal parameters, torsion angles, and least-squares planes, the supplementary material has also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor tables are no longer being deposited and may be obtained on request from the author.

Reductions by ferrocytochrome c peroxidase: 5. Kinetics of ferricyanide reduction

Eddy Cheung and Ann M. English

Abstract: The kinetics of reduction of ferricyanide by yeast ferrocytochrome c peroxidase (CPP^{II}) were investigated as a function of ionic strength in phosphate buffers at pH 7.0 and 25 ± 1°C. The observed bimolecular rate constant (k_{12}) is 8.4×10^4 M^{-1} s^{-1} in 0.1 M phosphate. The dependence of the reaction rate on ionic strength indicates a change of −9 on the protein at pH 7.0, which is in good agreement with the total charge of −11 estimated for CCP^{II} from its amino acid content. Substituting k_{12} at infinite ionic strength (k_{12}^{∞}) into the Marcus cross relation yields an electron self-exchange rate constant (k_{11}^{∞}) for the Fe^{III}/Fe^{II} couple of CCP of 7.2×10^{-5} M^{-1} s^{-1}. This value is over four orders of magnitude higher than that calculated for the Fe^{IV}/Fe^{III} couple of CCP from literature data for cross-reactions with ferrocyanide at pH 7.0. Possible reasons for the large difference in the two CCP k_{11}^{∞} values are discussed. Literature data also allowed k_{11}^{∞} values for various other heme proteins to be determined from their cross-reactions with ferricyanide. The calculated rate constants vary by eight orders of magnitude, and the variation of k_{11}^{∞} with protein structure suggests that the redox reactivity of ferrous heme proteins towards ferricyanide is dependent on the spin state and coordination of iron, as well as on the accessibility of the heme.

Key words: cytochrome c peroxidase, ferricyanide, Marcus cross relation, electron self-exchange.

Résumé : On a étudié la cinétique de la réduction du ferricyanure par la peroxydase du ferrocytochrome c (CCP^{II}) de la levure en fonction de la force ionique de tampons de phosphate, à un pH de 7,0 et 25 ± 1°C. À 0,1 M de phosphate, la constante de vitesse bimoléculaire observée (k_{12}) est égale à $8,4 \times 10^4$ M^{-1} s^{-1}. La variation de la vitesse de réaction avec la force ionique indique que la protéine porte une charge de −9 à un pH de 7; cette valeur est en bon accord avec la charge totale de −11 évaluée pour la CCP^{II} à partir de son contenu en acide aminé. Lorsqu'on substitue la valeur de k_{12} à force ionique infinie (k_{12}^{∞}) dans l'équation de Marcus, on détermine que la constante de vitesse d'autoéchange d'un électron (k_{11}^{∞}) pour le couple Fe^{III}/Fe^{II} du CCP est égale à $7,2 \times 10^{-5}$ M^{-1} s^{-1}. Cette valeur est quatre ordres de grandeur plus grande que celle calculée pour le couple Fe^{IV}/Fe^{III} du CCP à partir des données rapportées dans la littérature pour les réactions croisées du ferrocyanure, à un pH de 7,0. On discute des raisons qui pourraient expliquer les grandes différences entre les deux valeurs k_{11}^{∞} du CCP. Les valeurs consignées dans la littérature ont permis de déterminer les valeurs de k_{11}^{∞} de diverses réactions croisées du ferricyanure avec d'autres protéines de l'hème. Les constantes de vitesses calculées varient par huit ordres de grandeur et la variation de k_{11}^{∞} avec la structure de la protéine suggère que la réactivité rédox des ions ferreux des protéines de l'hème par rapport à l'ion ferricyanure dépend de l'état de spin et de la coordination du fer ainsi que de l'accessibilité de l'hème.

Mots clés : peroxydase du cytochrome c, ferricyanure, relation croisée de Marcus, autoéchange d'électron.

Introduction

Heme proteins carry out a diversity of functions in nature. In all instances the heme group is known to undergo redox changes. For the simple heme electron transferases, such as cytochromes c and b_5, this involves the $Fe^{II/III}$ couple (1). Heme enzymes, such as cytochrome c oxidase and heme-containing peroxidases, have more complex enzymic cycles that involve Fe^{IV}=O species (2). Hemoglobin and myoglobin (Mb) reversibly bind O_2 in nature when the iron is present in the ferrous state. However, these proteins also undergo biological and nonbiological redox reactions involving the $Fe^{II/III}$ couple (3).

Since the heme group of most heme proteins is protoporphyrin or a derivative of protoporphyrin, the redox reactivity of the heme is largely determined by the nature of the protein matrix. Despite the sensitivity of its electron-transfer reactions to medium effects, the ferri/ferrocyanide redox couple has been used extensively to probe metalloprotein electron-

transfer mechanisms, particularly those of cytochromes and heme peroxidases (4–11). For this reason ferricyanide was chosen as an oxidant in the present study, and the reaction under investigation is the following:

$$[1] \qquad CCP^{II} + Fe(CN)_6^{3-} \underset{}{\overset{k_{12}}{\rightleftharpoons}} CCP^{III} + Fe(CN)_6^{4-}, \qquad \Delta E^o = 0.603\ V$$

where ΔE^o was calculated from the data given in footnote *d*, Table 2. The dependence of the reaction rate on salt concentration was examined in P_i buffers at pH 7.0 and room temperature.

Erman and co-workers (7, 8) have measured ferrocyanide oxidation rates by the Fe^{IV}=O (oxyferryl) heme of compound II (CpdII)[3] of CCP:

$$[2] \qquad CpdII + Fe(CN)_6^{4-} \underset{}{\overset{k_{12}}{\rightleftharpoons}} CCP^{III} + Fe(CN)_6^{3-}, \qquad \Delta E^o = 0.678$$

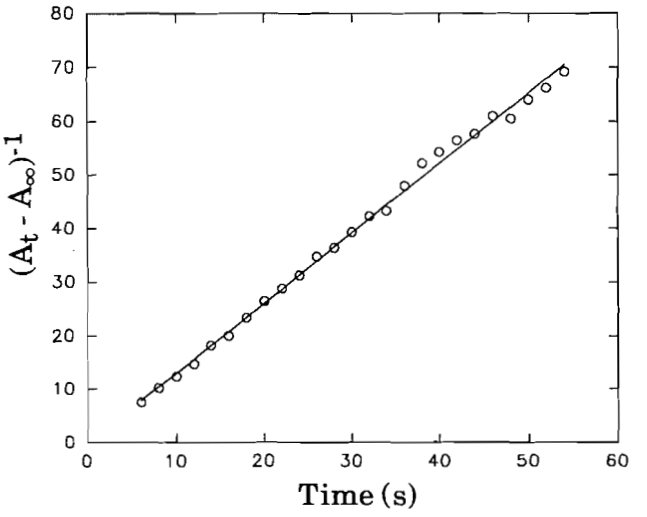
where the value of ΔE^o in this case was calculated from E^o = 1.087 and 0.409 V for CpdII (8) and ferricyanide (footnote *d*, Table 2), respectively. Thus, analysis in terms of the Marcus cross relation of the rate data obtained here for reaction [1] and of the literature data for reaction [2] will permit a comparison of the redox reactivity of the $Fe^{II/III}$ and $Fe^{IV/III}$ couples of CCP with the same redox reagent. This is the first application of the Marcus cross relation to reactions of two redox couples of the *same* metalloprotein with the *same* redox reagent. In addition, rate data from the literature for the reduction of ferricyanide by a number of other ferrous heme proteins are analyzed by Marcus theory with compensation for nonspecific electrostatic effects. The results, including those for CCP^{II}, are interpreted in terms of the different biological functions of the heme proteins.

Experimental

CCP was isolated from bakers' yeast according to the published procedures (12, 13) and its purity index (A_{408}/A_{280}) was 1.3. CCP^{III} concentrations were determined spectrophotometrically using an extinction coefficient of 98 mM^{-1} cm^{-1} at 408 nm (14), and ~ 3 μM CCP^{III} solutions were prepared in 5.0–200 mM sodium phosphate buffers (pH 7.0). Samples were deaerated in 1-cm cuvettes under argon for 30 min and, following the addition of 0.008% acetophenone and 2% isopropyl alcohol (which do not alter the spectral properties or activity of CCP^{III}), UV photoreduction of CCP^{III} to CCP^{II} was performed according to the procedure of Ward and Chang (15). Potassium ferricyanide solutions were prepared by weight using reagent grade material, and aliquots containing *stoichiometric* amounts of oxidant were transferred to the cuvettes by a gas-tight syringe and the solutions were rapidly mixed manually. The disappearance of CCP^{II} was monitored by following the absorbance at 440 nm on a HP 8451A rapid-scan diode-array spectrophotometer at room temperature (25 ± 1°C). A 400-nm UV cutoff filter was used to eliminate UV photoreduction by the polychromatic monitoring beam of the HP 8451A. The bimolecular rate constants were calculated from second-order (equal concentration of reagents) analysis of the rate data.

[3] **Abbreviations:** CCP, cytochrome c peroxidase; CCP^{II}, ferroCCP; CCP^{III}, ferriCCP; CpdI, compound I of CCP, which contains a ferryl (Fe^{IV}=O) heme, and an amino acid radical; CpdII, compound II of CCP, which is formed on the one-electron reduction of CpdI and contains a Fe^{IV}=O heme at pH 7 (17); Mb, myoglobin; P_i, sodium phosphate; *I*, ionic strength.

Fig. 1. Reduction of ~3 μM ferricyanide by equimolar CCP^{II} in 200 mM P_i, pH 7.0, 25 ± 1°C. Fit (solid line) to second-order kinetics (equal concentrations of reactants) over ~15 half-lives or 94% completion of the absorbance changes at 440 nm (circles); A_t and A_∞ are the absorbances at time *t* and after the reaction was completed, respectively.



Results

The absorption maximum of CCP shifts from 408 to 440 nm upon photoreduction, with an isosbestic point at 421 nm. At 440 nm, the molar absorptivities of CCP^{II} and CCP^{III} were found to be 87 and 19 mM^{-1} cm^{-1}, respectively; hence, $\Delta\varepsilon_{440}$ = 68 nM^{-1} cm^{-1}. Figure 1 shows the fit to second-order kinetics over ~15 half-lives of the absorbance decrease at 440 nm when equal concentrations (3 μM) of CCP^{II} and $Fe(CN)_6^{3-}$ were mixed in 200 mM P_i. Excellent fits to second-order kinetics were also obtained for the 1:1 reaction in buffers containing 5.0–100 mM P_i and Table 1 lists the observed rate constants (k_{12}) as a function of P_i concentration. Because of the extreme O_2 sensitivity of CCP^{II}, it was not possible to examine reaction [1] by stopped-flow at Concordia. However, using a stopped-flow apparatus with ~1 ms time resolution in a glove box at the University of Sussex, the oxidation of ~3 μM CCP^{II} was also shown to follow second-order kinetics and to obey the simple rate law $-d[CCP^{II}]/dt = k[CCP^{II}][Fe(CN)_6^{3-}]$ under pseudo-first-order conditions with $Fe(CN)_6^{3-}$ concentrations up to 0.2 mM. Thus, unlike the reduction of ferricytochrome c by CCP^{II} (16), the reduction of $Fe(CN)_6^{3-}$ by the peroxidase is bimolecular under the conditions investigated here.

From the data presented in Table 1 it can be seen that k_{12} increases from 2.1 × 10^4 M^{-1} s^{-1} in 5.0 mM P_i to

Table 1. Observed rate constants (k_{12}) for the reduction of $Fe(CN)_6^{3-}$ by CCP^{II} in phosphate buffers, pH 7.0 at 25 ± 1°C.[a]

$[P_i]$ (mM)	Ionic strength (mM)	k_{12} (M^{-1} s^{-1})
5.0	9.3	2.1×10^4
10.0	19	4.2×10^4
15.0	28	5.1×10^4
25.0	46	6.6×10^4
50.0	93	7.6×10^4
100	186	8.4×10^4
200	372	8.7×10^4

[a]The CCP^{II} and ferricyanide concentrations were ~3 μM in each case.

8.7×10^4 M^{-1} s^{-1} in 200 mM P_i; this is consistent with both reagents being negatively charged at pH 7.0 (pI = 5.26 for CCP (17)). Although the conditions of the experiments do not allow the strict application of Debye–Hückel theory, estimates of the *effective* electrostatic charge on CCP^{II} and the rate at infinite dilution (k_{12}^0) were obtained from the ionic strength dependence of the rate constants (4, 6):

$$[3] \qquad \ln k_{12} = \ln k_{12}^0 + \frac{(2Z_1Z_2 + Z_2^2)\alpha I^{1/2}}{1 + \kappa R_1} - \frac{Z_2^2 \alpha I^{1/2}}{1 + \kappa R_2}$$

where $\alpha = 1.17$ and $\kappa = 0.329I^{1/2}$ $Å^{-1}$ for water at 25°C; Z_1, Z_2 and R_1, R_2 are the charges and radii of CCP^{II} and ferricyanide, respectively; and I = ionic strength. In eq. [3] it was assumed that the radius of the activated complex was equal to R_1 since $R_1 \gg R_2$. Equation [3] is plotted in Fig. 2(*a*) for I = 9.3–372 mM using values[4] of 23.5 and 4.5 Å (19) for R_1 and R_2, respectively. The data are a good fit to eq. [3] over the range of ionic strengths investigated, and extrapolation to $I = 0$ gives $k_{12}^0 = 1.0 \times 10^3$ M^{-1} s^{-1}. Assuming $Z_2 = -3$, the slope of the plot yields $Z_1 = -9$ for CCP^{II}.

The observed rate constant can also be related to the rate constant at infinite ionic strength (k_{12}^∞) by correcting for electrostatic interactions using Marcus-type work terms (6, 20, 21):

$$[4] \qquad \ln k_{12} = \ln k_{12}^\infty - 3.576\left[\frac{\exp(-\kappa R_2)}{1 + \kappa R_1} + \frac{\exp(-\kappa R_1)}{1 + \kappa R_2}\right] \times \frac{Z_1 Z_2}{R_1 + R_2}$$

where κ, R, and Z are as defined above. Figure 2(*b*) shows a plot of eq. [4], which is a reasonable fit to the experimental data over the ionic strength range investigated when the point at I = 9.3 mM is omitted; extrapolation to infinite ionic strength gives $k_{12}^\infty = 1.0 \times 10^5$ M^{-1} s^{-1} and the slope yields $Z_1 = -3$ for CCP^{II}. Use of eq. [4] to analyze the data reported by Jordi and Erman (7) for the oxidation of ferrocyanide by CpdII also gives a low charge (−4) for the protein. Thus, the Marcus theory treatment of electrostatic interactions appears to lead to a uniformly lower charge on CCP than that predicted from sequence data.

[4] Calculated from the molecular weight (M) of 35 350 (17) for CCP using the following equation: $R_1 = 0.717 \times M^{1/3}$ (18).

Fig. 2. Ionic strength (I) dependence of the reduction of ferricyanide by CCP^{II} in P_i buffer, pH 7.0, 25 ± 1°C. (*a*) Plot of $f(k)$ vs. $f(I)$ using eq. [3] in the text, and (*b*) plot of $f'(k)$ vs. $f'(I)$ using eq. [4] in the text, where $f(k), f(I), f'(k), f'(I)$ are defined as follows:

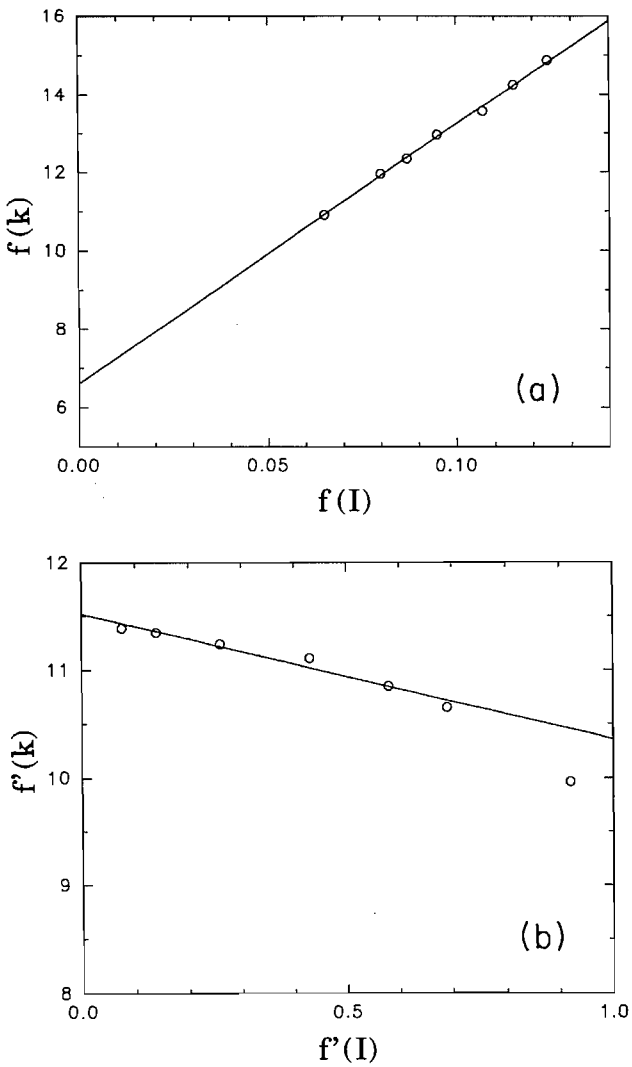
$$f(k) = \ln k_{obs} + \frac{Z^2 \alpha I^{1/2}}{1 + \kappa R^2}$$

$$f(I) = \frac{\alpha I^{1/2}}{1 + \kappa R_1}$$

$$f'(k) = \ln k_{obs}$$

$$f'(I) = \frac{\exp(-\kappa R_2)}{1 + \kappa R_1} + \frac{\exp(-\kappa R_1)}{1 + \kappa R_2}$$

The circles indicate the experimental points and the lines show the fits. In (*b*) the point at $f'(I) > 0.9$ was not included in the analysis.



Discussion

The reduction of ferricyanide by CCP^{II} (eq. [1]) exhibited bimolecular kinetics under the experimental conditions used here (Fig. 1). This is in sharp contrast to the reduction of

Table 2. Fe^{II}/Fe^{III} homonuclear electron self-exchange rate constants at infinite ionic strength (k_{11}^{∞}) for heme proteins from their cross-reactions with $Fe(CN)_6^{3-}$.

[d]Redox potentials for the cross reactions assuming E^o for ferricyanide at 0.1 M ionic strength is 409 mV (Table I in ref. 21), and the following E^o (mV) values for the proteins: CCP^{III}, −194 (32); Mb^{III}, 58.8 (23); cyt c_{552}^{III}, 370 (33); and cyt c^{III}, 262 (34).

[e]Experimental second-order rate constants for the reduction of $Fe(CN)_6^{3-}$ from the following sources: CCP^{II}, Table 1, this work; Mb^{II}, in 0.1 M phosphate, pH 6.0, 19°C (5); cyt c_{552}^{II}, in phosphate buffer, pH 7.0, 23°C (Table II in ref. 33); cyt c^{II} in phosphate buffer, pH 7, $I = 0.10$ M, 25°C (9).

[f,g]k_{12}^{∞} and k_{11}^{∞} are the values corrected to infinite ionic strength for the protein cross-reaction and self-exchange rate constants, respectively. k_{11}^{∞} values were calculated using eq. [5] with $k_{22}^{\infty} = 8.76 \times 10^5$ M^{-1} s^{-1} for $Fe(CN)_6^{3-/4-}$, which was calculated from the reported value of 1.5×10^4 (Table 1 in ref. 21).

horse and yeast ferricytochromes c by CCP^{II}, which followed first-order kinetics in low and high P_i buffers (16, 22). At low P_i, cytochrome c and CCP form a stable complex so intracomplex electron transfer was expected (16). However, the electrostatically stabilized cytochrome c – CCP complex dissociates at high salt, so a conformational change in CCP^{II} was proposed to explain the first-order kinetics observed for the reduction of ferricytochrome c at high salt (16, 22). Since only bimolecular kinetics were observed for the reduction of ferricyanide, the mechanism of CCP^{II} reduction of the large (ferricytochrome c) and small (ferricyanide) oxidants is clearly different.

Analysis using eq. [3] of the ionic strength dependence of reaction [1] yields an effective charge of −9 for CCP^{II}, which is in good agreement with the value of −9.5 for CCP^{III} obtained by pH titration (7), and close to the value of −11 calculated for CCP^{II} from sequence data (17) following the procedure in ref. 21. Thus, the net charge on CCP^{II} appears to determine its reactivity with ferricyanide. This was previously shown to be the case for the reduction of ferricyanide at low ionic strength by cytochrome c_{552}, which carries a charge of −9 at pH 7.0 (4).

The Marcus cross relation has been used extensively to rationalize the reactivity of small inorganic reagents with redox proteins (6, 8, 20, 21). Assuming that the reactions possess similar adiabaticity factors, and that the precursor and successor complexes have similar stabilities, the observed bimolecular electron-transfer rate constant for the cross-reaction (k_{12}) is given by the following equation (6):

$$[5] \qquad k_{12} = (k_{11}k_{22}k_{12}f)^{1/2}$$

where k_{11} and k_{22} are the self-exchange rate constants for each of the reagents, K_{12} the equilibrium constant for the cross-reaction, and f is given by:

$$[6] \qquad \ln f = (\ln K_{12})^2/4 \ln(k_{11}k_{22}/Z^2)]$$

where Z is the collision frequency ($\sim 10^{11}$ M^{-1} s^{-1}). According to eq. [5], the bimolecular rate constant for the cross-reaction can be related to the driving force (K_{12}) for the cross-reaction and the homonuclear electron self-exchange rate constants for each of the reactants. To correct for non-specific electrostatic interactions between the proteins and the inorganic reagent, the electrostatics-corrected rate and equilibrium constants ($k_{12}^{\infty}, k_{22}^{\infty}, K_{12}^{\infty}$) were calculated as described previously (6, 20, 21), and these values were used in eq. [5]. Thus, If k_{22}^{∞} is known for the small reagent, then k_{11}^{∞} for the protein can be obtained from k_{12}^{∞}. Assuming a charge of −11 on CCP^{II}, a value of 2.1×10^5 M^{-1} s^{-1} was calculated for k_{12}^{∞} for the reduction of ferricyanide by CCP^{II}, which is similar to the value of 1.0×10^5 M^{-1} s^{-1} obtained on extrapolation of the experimental k_{12} to $I = \infty$ (eq. [4]). For $Fe(CN)_6^{3-/4-}$, k_{22}^{∞} was calculated to be 8.76×10^5 M^{-1} s^{-1} based on the reported self-exchange rate constant of 1.5×10^4 M^{-1} s^{-1} at $I = 0.1$ M (Table 1 in ref. 6). From these data a value of 7.2×10^{-5} M^{-1} s^{-1} was estimated for the self-exchange rate of CCP^{II} at infinite ionic strength (Table 2).

The value of k_{11}^{∞} gives a quantitative estimate of the electron-transfer reactivity of a protein towards the inorganic reagent used in the cross-reaction. Thus, it would be informative to compare the k_{11}^{∞} values for the Fe^{IV}/Fe^{III} and Fe^{III}/Fe^{II} couples of CCP obtained from their cross-reactions with the ferri/ferrocyanide redox couple. Ferrocyanide will rapidly reduce CpdII to CCP^{III}, and reaction [2] has been studied as a function of both ionic strength and pH (7, 8). Again, the ionic strength dependence of the rate constant is consistent with ferrocyanide seeing the net charge on the protein at pH 7.0 ($Z_1 = -9.5$ (7)). Extrapolation of k_{12} for reaction [2] (1.5×10^3 M^{-1} s^{-1} at pH 7.0 (7)) to infinite ionic strength, assuming charges of −9/−10 on $CpdII/CCP^{III}$, yields $k_{12}^{\infty} = 4.5 \times 10^3$ M^{-1} s^{-1}, and $k_{11}^{\infty} = 1.9 \times 10^{-9}$ M^{-1} s^{-1}. Hence, k_{11}^{∞} for the Fe^{IV}/Fe^{III} couple of CCP is over four orders of magnitude smaller than that for the Fe^{III}/Fe^{II} couple.

A comparison of the crystal structures of CCP^{III} and CpdI[3] revealed only small differences at the heme (24). This suggests that no major conformational changes take place on CpdI formation, and presumably also on CpdII formation.

Hence, the $>10^4$-fold variation in the reactivity of CCP^{II} and CpdII towards the $Fe(CN)_6^{3-/4-}$ couple, as reflected in the k_{11}^{∞} values, may be due to differences in the heme reorganizational energies coupled to electron transfer in CCP^{II} and CpdII. Resonance Raman data indicate that the Fe atom is high spin and 5-coordinate in both CCP^{II} and CCP^{III} (25), whereas the Fe^{IV}=O heme is 6-coordinate, low spin (26). Since cleavage of the Fe^{IV}=O bond occurs on reduction of CpdII, the inner-sphere reorganizational energy for the CpdII/CCP^{III} couple is expected to be greater than that for CCP^{II}/CCP^{III}.

The rate of reduction of CpdII by ferrocyanide increased ~100-fold on lowering the pH from 7.0 to 5.0 (7). Because of a strong pH dependence, Yandell and Yonetani (27) have suggested that proton addition to the oxene ligand in CpdII *precedes* electron transfer from ferrocyanide or other small reducing reagents. Thus, k_{11}^{∞} for CpdII/CCP^{III} derived from its cross-reactions with ferrocyanide may apply to a combined proton and electron transfer. Only a 5-fold increase was observed in the rate of ferricyanide reduction by CCP^{II} over the same pH range (A. English, unpublished results). Such a rate increase could be attributed to more favourable electrostatic interactions at pH 5.0 since CCP has a pI = 5.26 (17), suggesting that proton transfer is not rate determining in the electron-transfer reactions of CCP^{II} at neutral pH. This is consistent with the proposed site of protonation in CpdII being the oxygen atom of the Fe^{IV}=O moiety (26, 27). Therefore, the smaller k_{11}^{∞} for CpdII/CCP^{III} compared to that for CCP^{II}/CCP^{III} may be due to the existence of (partially) rate-limiting proton transfer and Fe^{IV}=O bond cleavage on reduction of CpdII.

To compare the relative reactivities of other ferrous heme proteins and CCP^{II} with the same inorganic reagent, k_{11}^{∞} values calculated from literature rate data on ferricyanide cross-reactions are listed in Table 2 for the Fe^{III}/Fe^{II} couples of CCP, Mb, and cytochromes c and c_{552}. Because of the reported sensitivity of the electron-transfer properties of ferricyanide to the medium (21), second-order rate constants, which were obtained under similar reaction conditions to those in Table 1, were chosen from the literature (footnote *e*, Table 2) to calculate the k_{11}^{∞} values listed in Table 2. The Fe^{II} forms of both deoxy Mb and CCP are 5-coordinate, high spin (28, 25), but Mb binds a water molecule on oxidation to Fe^{III}, giving rise to a 6-coordinate, high spin heme (23) whereas CCP remains 5-coordinate, high spin (25). However, despite the absence of any Fe ligation change, k_{11}^{∞} for CCP is $<10^{-5}$ that of k_{11}^{∞} for Mb. The heme group in Mb is embedded in a cleft near the surface of the molecule and ~18% of the heme is solvent-exposed (29). The heme in CCP is bound between two protein domains ~10 Å from the protein surface and only the propionate side groups of the porphyrin ring are accessible to the external environment (30, 31). Thus, a smaller k_{11}^{∞} is consistent with the reduced accessibility of the heme of CCP. The $>10^3$-fold higher electron-transfer reactivity of the cytochromes c and c_{552} compared to Mb can be largely attributed to the heme remaining 6-coordinate low spin in the Fe^{III}/Fe^{II} states of the cytochromes.

The k_{11}^{∞} values given in Table 2 can also be rationalized in terms of the biological function of the various heme proteins. Cytochromes c and c_{552} are designed to be simple electron transferases; hence, the polypeptide around the heme should promote rapid oxidation and reduction of the heme Fe. The biological function of Mb is to reversibly bind oxygen, which it does only in the ferrous state, so Mb is not expected to be as efficient as the cytochromes at transferring electrons. In fact, the protein matrix serves to reduce the autooxidation rate of oxyMb by several orders of magnitude compared to that in free hemes (35). Finally, as mentioned above, the enzymic cycle of CCP generates the highly oxidizing intermediates, CpdI and CpdII. Clearly, if the oxidizing equivalents of this protein are not to be randomly discharged, the highly reactive Fe^{IV}=O heme has to be well insulated. Nature achieves this by burying the heme ~10 Å below the protein surface and designing the surface of the protein such that its reducing substrate, ferrocytochrome c, recognizes and binds to the surface of CCP prior to electron transfer (17, 31), as confirmed in the recent X-ray structure of the CCP–cytochrome c complex (36). Access of small redox reagents to the heme appears to require diffusion ~10 Å up a channel that leads from the surface of the protein to the δ-*meso* heme edge (37). This should result in a large steric effect consistent with the small k_{11}^{∞} for CCP^{II} in Table 2.

In summary, the relative magnitudes of the protein self-exchange rate constants in Table 2 from the ferricyanide cross-reactions reflect structure–function relationships in this series of heme proteins. Of particular significance is the $>10^4$ difference in the k_{11}^{∞} values for the two redox couples of CCP estimated from the cross-reactions with ferri/ferrocyanide. This, as well as the data in Table 2, underscores the relevance of applying the Marcus cross relation to protein–small molecule data (20, 21).

Abstract: The kinetics have been studied of the substitution reactions of $Ru_3(CO)_{11}L$ and $Ru_3(CO)_{10}L_2$ (L = PCy_3 (Cy = C_6H_{11}), P-*n*-Bu_3, P(*p*-$MeOC_6H_4)_3$, P(*p*-$ClC_6H_4)_3$, $P(OPh)_3$, and etpb ($P(OCH_2)_3CEt$) with $AsPh_3$ or various P-donor nucleophiles, L′, in hexane. The reactions proceed through both [L′]- independent (CO dissociative) and [L′]-dependent (associative) paths. The values of the rate constants, k_1, for the dissociative path for $Ru_3(CO)_{11}L$ can be combined with other published data and are found to fit well to the equation: $\log k_1 = \alpha + \beta_L\delta_L + \gamma_L\theta_L$. ($\beta_L$ and γ_L are constants that define how sensitive the values of $\log k_1$ are to Bodner's electronic parameter, δ_L, and to Tolman's steric parameter, θ_L, respectively.) Values of β_L and γ_L are both positive, increasing electron donicity and increasing size of L both leading to increased rates. The steric effect is more important and accounts for ca. 60% of the decrease in the free energies of activation. The effects, on the fit and on the values of β_L and γ_L, of using different electronic (Bartik's χ values) and steric (Brown's E_R values) parameters are examined and found to be small, and the question of which goodness-of-fit parameters should be used is considered. The kinetic effects of the substituents are only a small (ca. 20%) perturbation on the average free energies of activation, and the steric effect shows that use is made of only a few percent of the available ligand–ligand repulsion energy in accelerating the reactions. The second-order reactions of $M_3(CO)_{11}L$ with Me_3NO (M = Ru or Os) also fit an equation analogous to that given above and the values of β_L and γ_L obtained for these assisted CO displacement reactions are compared with those for the unimolecular, unassisted, CO dissociation. Unassisted reactions of the $Ru_3(CO)_{10}L_2$ clusters show values of β_L and γ_L that are closely similar to those for $Ru_3(CO)_{11}L$, but published data for CO dissociative reactions of some $Ru_3(CO)_9L_3$ clusters lead to much larger positive values of β_L and a large *inverse* steric effect, i.e., rates actually decrease substantially with increasing substituent size after electronic effects are allowed for. This effect is accounted for in terms of the different natures of the $Ru_3(CO)_8L_3$ intermediates.

Key words: metal carbonyls, ruthenium, clusters, kinetics, substituent effects.

Résumé : On a étudié la cinétique des réactions de substitution du $Ru_3(CO)_{11}L$ et $Ru_3(CO)_{10}L_2$ (L = PCy_3 (Cy = C_6H_{11}), P-*n*-Bu_3, P(*p*-$MeOC_6H_4)_3$, P(*p*-$ClC_6H_4)_3$, $P(OPh)_3$, et etpb ($P(OCH_2)_3CEt$) avec le $AsPh_3$ ou divers autres nucléophiles donneurs, L′, dans l'hexane. Les réactions se produisent par des voies qui dépendent (associatives) ou qui ne dépendent pas (dissociative de CO) de la [L′]. On peut combiner les valeurs des constantes de vitesse, k_1, de la voie dissociative du $Ru_3(CO)_{11}L$ avec d'autres données publiées dans la littérature et on a trouvé qu'elles peuvent facilement s'ajuster à l'équation : $\log k_1 = \alpha + \beta_L\delta_L + \gamma_L\theta_L$ (dans laquelle β_L et γ_L sont des constantes qui définissent la sensibilité des valeurs de $\log k_1$ respectivement au paramètre électronique de Bodner, δ_L, et au paramètre stérique de Tolman, θ_L. Les valeurs de β_L and γ_L sont toutes les deux positives; les vitesses de réactions augmentent avec une augmentation du caractère électrodonneur et de la grosseur de L. L'effet stérique est plus important et il est la cause de 60% de la diminution des énergies libres d'activation. On a examiné les effets, tant sur l'ajustement que sur les valeurs de β_L and γ_L, de l'utilisation de paramètres électroniques (valeurs χ de Bartik) et stériques (valeurs E_R de Brown) et on a trouvé qu'ils sont faibles et on a considéré la question de quels paramètres devraient être utilisés pour obtenir un bon ajustement. Les effets cinétiques des substituants ne correspondent qu'à de faibles (environ 20%) perturbations sur les énergies libres moyennes d'activation et l'effet stérique montre que, de l'énergie de répulsion coordinat–coordinat disponible, il n'y a qu'un faible pourcentage qui est utilisé pour accélérer les

réactions. Les réactions du deuxième ordre du $M_3(CO)_{11}L$ avec le Me_3NO (M = Ru ou Os) peuvent aussi être ajustées à l'aide d'une équation analogue à celle donnée plus haut et on a comparé les valeurs de β_L et γ_L obtenues pour ces réactions assistées de déplacement de CO avec celle de la réaction de dissociation unimoléculaire du CO, non assistée. Les valeurs de β_L et γ_L des réactions non assistées des agrégats de $Ru_3(CO)_{10}L_2$ sont très semblables à celles du $Ru_3(CO)_{11}L$; toutefois, les données publiées dans la littérature pour les réactions dissociatives de quelques agrégats de $Ru_3(CO)_9L_3$ conduisent à des valeurs de β_L qui sont beaucoup positives et à un effet stérique *inverse*, c'est-à-dire que, après avoir tenu des effets électroniques, les vitesses diminuent considérablement avec une augmentation de la taille du substituant. On explique cet effet par les natures différentes des intermédiaires $Ru_3(CO)_8L_3$.

Mots clés : carbonyles de métaux, ruthénium, agrégats, cinétique, effets de substituants.

[Traduit par la rédaction]

Introduction

Studies of the effects of P-donor or other substituents on the rates of unimolecular substitution reactions of binary metal carbonyl clusters have appeared in the literature sparingly and sporadically throughout the last 20 years (1–7). A study of the PPh_3-substituted tetrairidium carbonyl clusters represented the first quantitative evidence that such effects did exist (1). Upon increasing n in $Ir_4(CO)_{12-n}(PPh_3)_n$ from 0 to 2 the rate constants for unimolecular substitution increased markedly. More extensive studies by Sonnenberger and Atwood (2) and Darensbourg et al. (3*a*) have been carried out on a relatively wide variety of $Ir_4(CO)_{12-n}L_n$ clusters (n = 1–3, L = As- or P-donor ligands) and the unimolecular rate constants vary substantially with the value of n and the nature of L. The results have been summarized and discussed qualitatively in terms of varying electronic and steric contributions (4). Studies of substituent effects in reactions of Co_4 (3*e*), Rh_4 (5), Ru_3 (6), and Os_3 (7) clusters have been reported but the nature and number of the substituents were not varied sufficiently for clear-cut trends to be apparent.

We have therefore undertaken a systematic study of some $Ru_3(CO)_{11}L$ and $Ru_3(CO)_{10}L_2$ clusters containing quite a wide variety of substituents, and find it possible to quantify the separate electronic and steric effects of the substituents on the rates of unimolecular substitution. The method of data analysis is also found to be useful when applied to published results for the clusters $Ru_3(CO)_9L_3$.

Experimental

The complexes $Ru_3(CO)_{11}L$ (L = $P(C_6H_{11})_3$ (PCy_3), P-*n*-Bu_3, $P(p\text{-}MeOC_6H_4)_3$, $P(OPh)_3$, $P(p\text{-}ClC_6H_4)_3$, and $P(OCH_2)_3CEt$ (etpb)) and $Ru_3(CO)_{10}L_2$ (L = PCy_3, P-*n*-Bu_3, $P(p\text{-}MeOC_6H_4)_3$, $P(OPh)_3$, and etpb) were prepared (8) from $Ru_3(CO)_{12}$ (Strem Chemicals) by published methods (9). These clusters were characterized by comparison of their IR spectra in hexane with those for identical or very similar complexes published elsewhere (9*c*). Their purity was demonstrated by their ^{31}P NMR spectra measured in hexane ($Ru_3(CO)_{11}L$) or dichloromethane ($Ru_3(CO)_{10}L_2$). The IR and ^{31}P NMR spectral data are shown in Table 1 together with the main bands shown in the UV–vis spectra. Etpb, $P(OPh)_3$, $P(OEt)_3$, P-*n*-Bu_3, PPh_3, and $AsPh_3$ were obtained and purified exactly as described previously (10). $P(p\text{-}MeOC_6H_4)_3$ and $P(p\text{-}ClC_6H_4)_3$ (Strem Chemicals) were used as received. THF (tetrahydrofuran) was distilled over sodium benzephenone under nitrogen before use. Other solvents (Aldrich reagent grade) were dried over molecular sieves. Spectra were measured with a Nicolet 10DX FTIR spectrophotometer, a Varian XL-200 NMR spectrometer, and a Cary 2300 UV–vis spectrophotometer.

Kinetic studies

Hexane solutions of $Ru_3(CO)_{11}L$ or $Ru_3(CO)_{10}L_2$ (ca. 1×10^{-4} M) containing the various nucleophiles (0.002–0.500 M) were prepared as previously described (6*d*,11). Particular care was taken to ensure that air was excluded when preparing ligand solutions of air-sensitive nucleophiles. Kinetic studies were carried out by monitoring the UV–vis spectra of pre-thermostated solutions in 10-mm cuvettes placed in the thermostated cell holder of a Cary 2300 spectrophotometer. Slower reactions were followed by repetitive scanning of groups of up to four reacting solutions. Faster reactions were monitored by following absorbance changes using the time-drive mode. Cell temperatures were measured with an iron–constantan thermocouple connected to a digital multimeter. In some cases reactions were followed using IR monitoring techniques (6*d*, 11) and employing standard Schlenk-tube methods. Samples were withdrawn from thermostated solutions of complex (ca. 5×10^{-4} M) and nucleophile (0.01–0.20 M) at timed intervals. The samples were immediately cooled and their spectra measured. Spectroscopic data for the products are shown in Table 2.

Results

Reactions of $Ru_3(CO)_{11}L$ with L′

These reactions were studied kinetically at 40°C, the highest temperature possible without some of the reactions being too fast to measure conveniently. Most reactions proceed via a mixture of unimolecular and bimolecular paths, i.e., with the rate equation $k_{obs} = k_1 + k_2[L']$. A high temperature minimizes the relative contribution of the k_2 paths to the rates.[2] Different entering ligands, L′, were also chosen to minimize the contribution of the k_2 paths and to provide sufficiently pronounced spectroscopic changes. Thus $Ru_3(CO)_{11}(PCy_3)$ and $Ru_3(CO)_{11}(P\text{-}n\text{-}Bu_3)$ are both very susceptible to nucleophilic attack and sensitive to the nature of the incoming nucleophile. $AsPh_3$ was used as the entering ligand in both cases. No [$AsPh_3$] dependence of the rates was observed and convenient increases in absorbance occurred so that good values of k_1 were easily obtained.[3] No complications from further substi-

[2] This is because unimolecular paths almost invariably have higher activation enthalpies than bimolecular ones occurring with the same compounds.

[3] The reaction of $Ru_3(CO)_{11}(PCy_3)$ with $AsPh_3$ leads to little change in the position of the UV–vis band but there is a sufficient increase in intensity for good rate data to be obtained.

[e]IR spectrum: 2044(6), 1970(100), 1941(39) cm^{-1}.
[f]IR spectrum: 2082(19), 2024(77), 2000(100), 1982(sh)(68) cm^{-1}.

tution into the products were observed (see below). The choice of reacting ligand for the substitution reactions of $Ru_3(CO)_{11}L$ (L = etpb, $P(OPh)_3$, and P(*p*-$ClC_6H_4)_3$) was made so as to generate convenient reaction times and suitably large spectroscopic changes. These three clusters were not particularly susceptible to nucleophilic attack and the subsequent reactions undergone by the product clusters, $Ru_3(CO)_{10}LL'$, were much slower than the initial reactions under the conditions used.

The reactions of $Ru_3(CO)_{11}L$ (L = P-*n*-Bu_3 and P(*p*-$MeOC_6H_4)_3$) with $AsPh_3$ and $P(OPh)_3$, respectively, were also monitored by IR techniques. This was done in order to confirm the nature of the products and to see whether any subsequent reaction of the product clusters was likely to affect the A_∞ values obtained for the initial reactions by UV–vis monitoring. The decrease of absorbance of a prominent reactant band (2044 cm^{-1}, for reactions of both clusters) was followed in a region where the products of either the initial or subsequent reactions did not absorb. The reaction of $Ru_3(CO)_{10}$(P(*p*-$MeOC_6H_4)_3$)($P(OPh)_3$) with $P(OPh)_3$ following the initial reaction of $Ru_3(CO)_{11}$(P(*p*-$MeOC_6H_4)_3$) with $P(OPh)_3$ proved to be too rapid to allow accurate values of A_∞ to be obtained when employing UV–vis monitoring but no evidence for significant further reaction of $Ru_3(CO)_{10}$(P-*n*-Bu_3)($AsPh_3$) with $AsPh_3$ was observed. UV–vis monitoring of the reactions of $Ru_3(CO)_{11}$(P-*n*-Bu_3) with $AsPh_3$ was thereby confirmed to be satisfactory in providing good values of A_∞ but all rate measurements for the reactions of $Ru_3(CO)_{11}$(P(*p*-$MeOC_6H_4)_3$) with $P(OPh)_3$ had to be obtained through IR monitoring.

The main UV–vis bands in the spectra of the reaction products are shown in Table 2 together with selected examples of their IR spectra. The intensities of the UV–vis bands were comparable with those of the reactants and there was no spectroscopic evidence for formation of appreciable amounts of mononuclear products. This is as expected since fragmentation of Ru_3 clusters seems to occur only via associative reactions (11, 12) and the small contribution of the k_2[L′] terms to k_{obs} ensures that these are quite unimportant.

The pseudo-first-order rate plots of the reactions of $Ru_3(CO)_{11}L$ with L′ to form $Ru_3(CO)_{10}LL'$ were linear for ca. 80–90% reaction. Values of k_{obs} were found to depend slightly on [L′] except when L′ was $AsPh_3$. An appropriately weighted linear least-squares analysis (7) was applied to the rate constants in order to obtain values for k_1 in the cases where an [L′]-dependent path was observed. When L′ = $AsPh_3$ the values of k_{obs} were simply averaged to give k_1, and the values of k_1 for all these reactions are also given in Table 3. The uncertainties are estimates of standard deviations that are based on a standard error, $\sigma(k_{obs})$, in each individual measurement of k_{obs} that is assumed to be the same for all the reactions. The value of $\sigma(k_{obs})$ was estimated (7) by the method of pooled variances (e.g., ref. 13).

Reactions of $Ru_3(CO)_{10}L_2$ with L′

The reactions of $Ru_3(CO)_{10}L_2$ (L = etpb, $P(OPh)_3$, PCy_3, P-*n*-Bu_3, P(*p*-$MeOC_6H_4)_3$, and P(*p*-$ClC_6H_4)_3$) with L′ were fol-

[a]For reactions of $Ru_3(CO)_{11}L$ with L′. Values of k_1 were obtained by weighted least-squares analysis of $k_{obs} = k_1 + k_2[L']$ with four different values of [L′] or, when there was clearly no dependence on [L′], by averaging the four values of k_{obs}. The uncertainties are based on a standard error of ±7.2% for each measurement of k_{obs} found from the method of pooled variances applied to all 24 measurements.

[b]For reactions of $Ru_3(CO)_{10}L_2$ with L′. Unless otherwise indicated, values of k_1 were obtained as in footnote *a* and the standard error in k_{obs} was ± 6.0%.

[c]Values of k_1 were obtained from weighted least-squares analyses of $k_{obs} = k_1 + k_2[L']$ for L′ = etpb, $P(OEt)_3$, $P(OPh)_3$, P-*n*-Bu_3, PPh_3, $P(p\text{-}MeOC_6H_4)_3$, and PCy_3 (L = PCy_3 or P-*n*-Bu_3), and L′ = $P(p\text{-}MeC_6H_4)_3$ (L = P-*n*-Bu_3). Standard errors for each measurement of k_{obs} were ± 3.5% (L = P-*n*-Bu_3) and ± 4.8% (L = PCy_3).

lowed by UV–vis monitoring. However, for these reactions, the growth of the band due to the product, $Ru_3(CO)_9L_2$ L′, was monitored with time. This method of measurement was chosen because of the larger spectral changes associated with the growth of the product and the well-defined values of A_∞ that could be obtained. The $Ru_3(CO)_{10}(P(p\text{-}ClC_6H_4)_3)_2$ cluster was not isolated but was synthesized in situ from the reaction of $Ru_3(CO)_{11}(P(p\text{-}ClC_6H_4)_3)$ with excess $P(p\text{-}ClC_6H_4)_3$. Once spectroscopic examination showed that the mono-substituted cluster had disappeared, and only the bis-substituted cluster remained, the subsequent reaction of the bis-substituted cluster with additional $P(p\text{-}ClC_6H_4)_3$ was monitored.

The susceptibility to nucleophilic attack is very low for these clusters and unimolecular substitution is the only significant reaction path at low values of [L′]. The substitution reactions were conveniently studied at 25°C. Furthermore, the choice of entering group, L′, depended mainly on obtaining a suitable change in spectrum, the nucleophilicity of L′ not being as important. Since the bimolecular path was negligible or small in these reactions, there was essentially no loss of cluster due to fragmentation (12) and the products of these reactions were virtually 100% $Ru_3(CO)_{10}L_2L'$. Spectroscopic data for these products are given in Table 2.

The pseudo-first-order rate plots for these reactions were linear for ca. 90% reaction. The values of k_1 and $\sigma(k_{obs})$ were obtained as before except for the clusters $Ru_3(CO)_{10}(P\text{-}n\text{-}Bu_3)_2$ and $Ru_3(CO)_{10}(PCy_3)_2$. Reactions of these clusters were studied with a range of ligands of widely different nucleophilicity and at higher [L′] values, to be able to obtain values for k_2 as well as k_1. The values of k_2 will be discussed elsewhere. Weighted averages of the various values of k_1 obtained from the weighted linear least-squares analysis of the dependence of k_{obs} on [L′] are given in Table 3 together with values of k_1 for the other $Ru_3(CO)_{10}L_2$ clusters.

Derivation of electronic and steric profiles

The quantitative empirical characterization of separate electronic and steric effects in associative reactions of metal carbonyls with P-donor and other nucleophiles has been known to be possible for many years (10*a*, 12, 14). Similar characterization of the effects of substituents on the rates of CO dissociative reactions is much less common (15) but is equally possible. Since the rates of reaction are being examined as a function of the natures of various P donors present as substituents, rather than as nucleophiles, the parameters chosen to represent the electronic natures of the ligands should reflect their π-acidity as well as their σ-donor capacity. In principle, the balance between σ-basicity and π-acidity effects for a given ligand should depend on the nature of the metal to which it is attached, the oxidation state of the metal, the nature of other ligands, and whether the metal is bonded to other metal atoms (16), but no generally available parameters that represent such details exist. One is forced, faut de mieux, to accept the χ values of Bartik et al. (17) or the $\delta(^{13}CO)$ parameters of Bodner et al. (18), which are available for a very wide range of P donors and which reflect the σ/π balance of the ligands when present in the standard complex $Ni(CO)_3L$. These parameters are linearly related to each other (19) but the latter, although somewhat less precise,[4] have the advantage that a value is known for L = CO. They have been used successfully in analyzing a substantial number of other kinetic data (15*a*, 21).

A plot of log k_1 vs. δ_L for reactions of $Ru_3(CO)_{11}L$ is shown in Fig. 1 where it is immediately obvious that there is no general linear relationship. Steric effects are clearly important since the reactions are fastest when L = PCy_3 (Tolman cone angle (20),θ_L, = 170°) and slowest when L = CO, etpb, or $P(OEt)_3$ (θ_L = 95°, 101°, and 109°, respectively). However, the ligands $P(OPh)_3$ (θ_L = 128°) and P-*n*-Bu_3 (θ_L = 132°) are almost isosteric, and an initial quantitative measure of the electronic effect can be obtained from the gradient (β_L = 0.19 ppm^{-1}) of the line joining the values of log k_1 for these two ligands. This enables values of log k_1^0 = log k_1 − $\beta_L\delta_L$ to be calculated and a linear steric profile (i.e., a plot of log k_1° vs.

[4] The values of $\delta(^{13}CO)$ are more precise (18) than Tolman's χ values (20) but less precise than Bartik's (17).

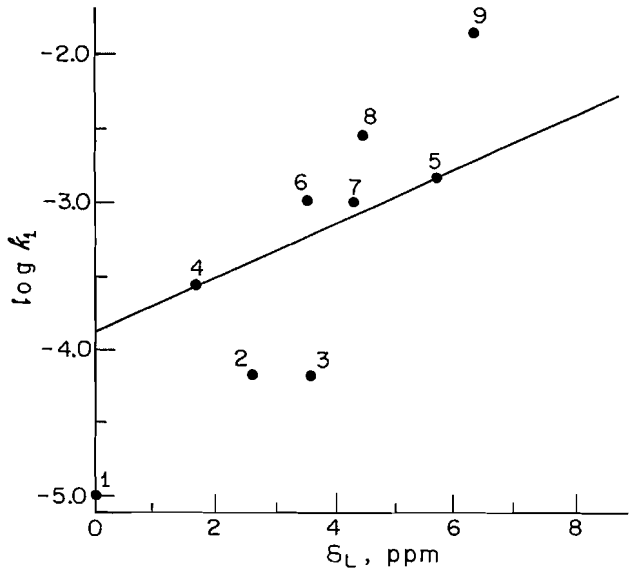

Fig. 2. Dependence of log k_1^0 (= log k_1 − $\beta_L\delta_L$) on the Tolman cone angles, θ_L, of L for the CO dissociative reactions of $Ru_3(CO)_{11}L$ (●, at 40°C) and $Ru_3(CO)_{10}L_2$ (▲, at 25°C). Ligand numbering from Table 4.

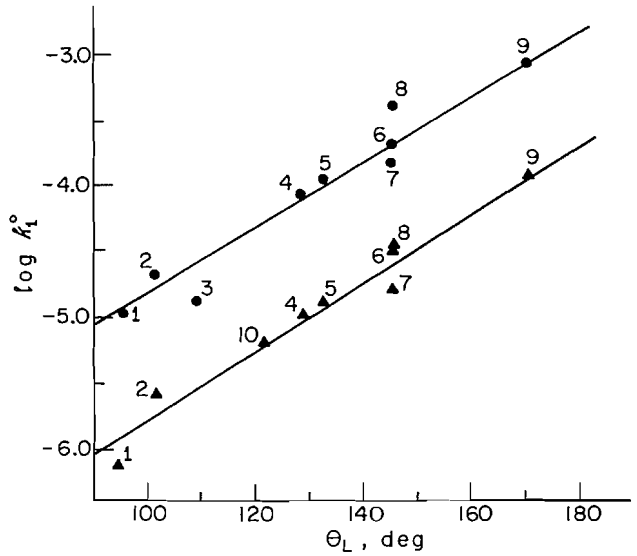

θ_L) is then obtained. This linearity shows that the data should fit eq. [1], and multiple linear regression (22) leads to the values of α, β_L, and γ_L given in Table 5.

$$[1]\quad \log k_1 = \alpha + \beta_L\delta_L + \gamma_L\theta_L$$

When data for only P-donor ligands are included, the value of β_L is not precise but is fully consistent with the initial approximate value obtained above. These parameters allow us to calculate the rate constant for L = CO, i.e., k_1 for loss of CO from $Ru_3(CO)_{12}$, and a value that is 40% higher than the experimentally observed value is obtained, showing that the procedure has quite good predictive value. If the data for L = CO are included in the analysis according to eq. [1] the fit is improved (Table 5). The RMSD is slightly reduced and $100(1 - R^2)$ decreases, the latter being a measure (23) of the extent to which the model, represented by eq. [1] and its parameters, fails to account for the data. The steric profile, obtained by using the best value of β_L, is shown in Fig. 2. An identical procedure was followed in analyzing the data for $Ru_3(CO)_{10}L_2$ and the resulting parameters are also shown in Table 5, the steric profile being shown in Fig. 2.

The use of the electronic parameter χ_L in place of δ_L inevitably leads to different values of α and β_L because of the different units, and the data for L = CO cannot be included because of the unavailability of a χ_L value (17). The value obtained for γ_L, however, is essentially identical with that obtained when δ_L was used, and the fit of the data generally is equally good (Table 5). The use of the steric parameter, E_R (24), instead of θ_L might be thought to be preferable because it is a measure of the repulsion energies between L and the other

ligands in the reference compound $Cr(CO)_5L$. However, the fit to eq. [1] (with θ_L replaced by E_R) is considerably less good, although the value of β_L is unchanged (Table 5).

Discussion

The spectroscopic data in Tables 1 and 2 show that the reactions studied here involve the displacement of CO from $Ru_3(CO)_{11}L$ by L′ to form $Ru_3(CO)_{10}LL'$. No evidence for fragmentation of the clusters (11, 12) was obtained. Displacement of L by L′ in a rate-determining step would have led in two stages to $Ru_3(CO)_{10}L_2'$ as the product, and no evidence for this was observed either.

The reactions governed by the rate constants k_1 can therefore all be assigned to a CO dissociative process (*6d*) because the values of k_1 depend only on the nature of L and are independent of the concentrations and natures of the entering ligands. They proceed cleanly and give rise to precise rate constants. The fits of the data to eq. [1], or analogues that use different electronic or steric parameters, are generally good, the values of $100(1 - R^2)$ being small enough to show that the model represented by that equation and its parameters accounts for almost all the variation in the rates.[5] In particular, there seems to be no need for the "aryl parameter" that has recently (25) been found to contribute significantly to the values of some physicochemical parameters, including rate constants for reactions involving P-donor ligands. The fit is good even though a wide range of ligands is involved, including π-acid phosphites (16) and even CO. Inclusion of data for CO in similar analyses has been successful elsewhere (21).

A closer examination of the goodness-of-fit raises some interesting features. Specifically it is found that the data for L = $P(OEt)_3$ give the least good fit to eq. [1], especially when E_R is used as the steric parameter in which case the value of log $k_1°$ is 0.74 low. This implies that the value of E_R considerably overestimates the steric effect of this ligand in $Ru_3(CO)_{11}L$. The deviations are not due to experimental error because the kinetic data for $Ru_3(CO)_{11}(P(OEt)_3)$ are very extensive and precise (*6d*), and it is not clear why the parameters assigned to $P(OEt)_3$ lead to such a poor fit in this system.

More generally, in analyses such as these it is not sufficient to use values of R or $100(1 - R^2)$ alone as indicators of the goodness-of-fit of the model to the data (23). They need to be supplemented by the standard errors of measurement of log k_1, or the RMSD values (Table 5), which are important as indicators of the predictive merits of the analyses. Moreover, any inadequacy in the parameters describing the ligands should be investigated by measuring, as is possible with the data presented here for instance, the mean deviations, $\Delta\theta$(mean) or ΔE_R(mean), of values of θ_L or E_R from those that would lead to a perfect fit. Although this is to ascribe all the failure of the model to the steric parameters of the ligands, and nothing to the electronic parameters, the results can be informative and some values are included in Table 5. The best analyses lead to $\Delta\theta$(mean) = ± ca. 4° or ΔE_R(mean) = ± ca. 5 kcal mol^{-1}, which are quite comparable in the light of the ranges of θ_L (75°) and E_R (109 kcal mol^{-1}) for the ligands used. Although no uncertainties for E_R have been explicitly given (24), values of θ_L are believed to be good to ± ca. 2° (20) so that a signif-

[5] It must be remembered that it is generally not the *data* that are being tested (since log k values are very precise) but the *model*.

icant proportion of the deviations, and of the uncertainties of the parameters β_L and γ_L, can be ascribed to perfectly acceptable variations in the cone angles appropriate to the ligands in these clusters.

The fact that the data for L = CO fit so well to the trends determined by the P-donor substituents is interesting. The smaller number of CO ligands in the substituted clusters would be expected to require a reduction in the value of log k_1 for $Ru_3(CO)_{12}$ for statistical reasons before it could be fitted to the trends. Any such correction would lead to an increase in the deviation of the data for L = CO from the profiles but the magnitude of the correction is quite uncertain. It could be as much as log 3 if loss of CO in a substituted cluster could occur only from one particular Ru atom. At the other extreme, no correction at all would be required if it is an axial CO that dissociates and if the substituent effect is distributed equally all round the cluster so that six CO ligands are available to dissociate in each of the clusters. This is not unreasonable since axial CO ligands are more weakly bound than equatorial ones (26) and, although the products are equatorially substituted and the entering ligand becomes attached to a previously unsubstituted Ru atom, dissociation of any axial CO ligand could be rate determining. If it occurs from an already substituted Ru atom, the vacant coordination site could be transferred from that Ru atom to another after the rate-determining step (2*b*). The Ru—CO_{ax} bond lengths do not seem to depend appreciably on whether the Ru atom is substituted or not (26). Apart from any possible statistical effects, the fit of the data for L = CO to those for L = P donors must arise in part from the facts that the electronic parameters, δ_L, are actually defined relative to L = CO, and that the cone angles or E_R values are either independent of the chemical natures of the donor atoms or they are taken into account. Nevertheless the data for L = CO in $Ru(CO)_4L$ and $Mn(CO)_4LBr$ do not fit with those for the complexes where L = P donors, the rates being much faster than projected (15*a*). This may be an indication that CO dissociation from a Ru atom to which a P donor is bonded is retarded, compared with dissociation from a non-substituted Ru atom, and that the CO that dissociates from the cluster does come from an unsubstituted Ru atom. In this case some statistical correction would be required as discussed above, and the substituent effects defined by the parameters β_L and γ_L would be due to effects transmitted across the cluster.

The value of β_L for the $Ru_3(CO)_{11}L$ clusters shows that increased electron donicity of the substituents stabilizes the transition states relative to the ground states, presumably by compensating for any electron density lost by the cluster during CO dissociation. The effect is quite small and not very precise. Nevertheless, the fact that the value of β_L is ca. 2 standard deviations above zero suggests that the probability that β_L is zero or negative is only ca. 1 in 20, allowing for the six degrees of freedom involved. Analogous values of β_L for the few mononuclear carbonyls for which data are available vary from $+0.13 \pm 0.06$ ppm^{-1} to -0.11 ± 0.06 ppm^{-1} (15*a*). The value of γ_L is more precise and is positive, as are those for all the mononuclear complexes studied in this way. This would be expected from a release of steric strain as the CO leaves. The magnitude of the steric effect in the $Ru_3(CO)_{11}L$ clusters is similar to that in the mononuclear carbonyl $Ru(CO)_4L$, but smaller than those in octahedral mononuclear complexes.

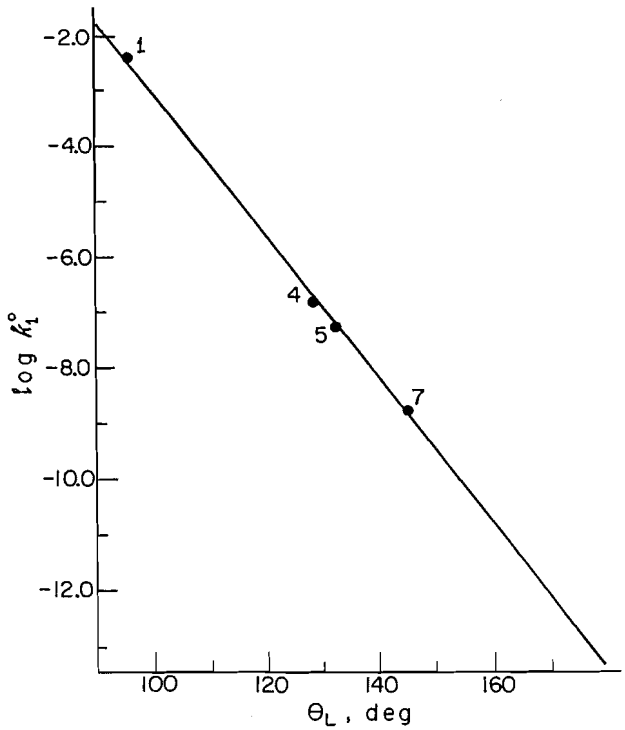
The values of β_L and γ_L for the $Ru_3(CO)_{10}L_2$ clusters are surprisingly similar to those for $Ru_3(CO)_{11}L$, the small difference in the temperatures at which the reactions were studied being unlikely to affect the comparison significantly (14*d*). The second substituent evidently affects the transition states to the same extent as the ground states. The data for the $Ru_3(CO)_{10}$(dppm) cluster fit very well to the trend established by the $Ru_3(CO)_{10}L_2$ clusters. Detailed accounting for these effects is complicated by the structural changes due to the different substituents. A series of 15 Ru—P bond lengths (*d*) in mono- and bis-substituted Ru_3 clusters (26) show that they depend linearly on θ_L according to eq. [2] with a RMSD of ± 1.7 pm and with $100(1 - R^2) = 8.4\%$.

$$[2] \quad d(\text{Ru—P})/\text{pm} = (198.6 \pm 2.9) + (0.264 \pm 0.022)\theta_L$$

In addition to this, the Ru—Ru bonds *cis* to the substituents in the $Ru_3(CO)_{11}L$ clusters show a substantial increase from 282.7 pm (L = etpb) to a more or less constant value of 291 pm when $\theta_L \geq 140°$. Thus the kinetics may well reflect an increase in effective basicity of the P-donor ligands, and an increase in the Ru—P bond strengths, as the CO leaves and the Ru—P bonds can contract. A similar but less regular effect may occur because of Ru—Ru bond shortening. A number of other structural effects accompany substitution into the Ru_3 cluster (26) but these are too subtle to be incorporated into any discussion of the kinetics. Indeed, the relative simplicity of the trends in the kinetic parameters is quite surprising in view of the multiplicity of structural and energetic changes that must be taking place during formation of the transition states, but the fact remains that eq. [1] does give an excellent empirical representation of the data. These show that increasing electron donicity accounts for a decrease in activation free energies of 1.9 ± 0.9 kcal mol^{-1} while steric effects account for a decrease of 2.6 ± 0.4 kcal mol^{-1} in $\Delta G^{\ddagger}$ for the particular selection of substituents involved. The kinetic effects, though clearly noticeable, are relatively small perturbations on the overall values of $\Delta G^{\ddagger}$, which are ca. 24 ± 2 kcal mol^{-1}, and it is interesting to compare the steric effect of ca. 3 kcal mol^{-1} with the 109 kcal mol^{-1} range of E_R values. Evidently, only a very small proportion of the available repulsion energy is actually applied to increasing the rates of reaction. This implies that the steric repulsions in the transition states are only marginally less than those in the ground states, i.e., that the process of Ru—CO bond breaking, on going to the transition states, does not result in much decrease in steric repulsions. This is consistent with the proposal discussed above, that as the CO ligand moves out a P-donor ligand moves in.

A few data are available for CO dissociation from the trisubstituted clusters $Ru_3(CO)_9L_3$ (27) and these also fit well to eq. [1] with parameters as shown in Table 5. The data for L = CO (10*a*) have to be used in the analysis but the qualitative features of the results are not affected by this. The most striking features of the results are the large positive electronic effect ($\beta_L = +0.61$ ppm^{-1}) and the *inverse* steric effect, i.e., the rates of CO dissociation decrease with increasing ligand size as shown in Fig. 3. The magnitude of γ_L is such that there is almost a 10^7 change in rate attributable to a cone angle change of 50°. The activation parameters for these reactions change significantly with L and lie on an isokinetic plot with an isokinetic temperature of ca. 260°C (27). The trends were inter-

Fig. 3. Dependence of log k_1^0 on θ_L for the CO dissociative reactions of $Ru_3(CO)_9L_3$. Numbering from Table 4.



preted in terms of widely differing structures for the $Ru_3(CO)_8L_3$ intermediates, a high $\Delta H^{\neq}$ and positive $\Delta S^{\neq}$ for L = PPh_3 corresponding to a more open, loose form, and the low $\Delta H^{\neq}$ and negative $\Delta S^{\neq}$ for L = P-*n*-Bu_3 to a contracted, tightly bonded cluster. The reasons for this trend were not apparent at the time but it can now be concluded that the rates are strongly accelerated by highly donating ligands, which favour tightly bound $Ru_3(CO)_8L_3$, but are retarded by larger substituents that require more open intermediates.

Finally, it is interesting to compare the parameters in Table 5 for the unassisted dissociation of CO ligands with analogous parameters obtained (28) from published data (29) for CO displacement assisted by Me_3NO. This attacks the CO ligands at the coordinated C atom and removes them as CO_2. These reactions were studied with L = $P(OMe)_3$, $P(OEt)_3$, P-*n*-Bu_3, PPh_3, $AsPh_3$, and $SbPh_3$. Values of the highest frequency C—O stretching bands in $Ru_3(CO)_{11}L$ were available as electronic parameters and a good fit to eq. [1] can be obtained with δ_L replaced by ν_{co} (28). These same parameters can be used in an analysis (28) of corresponding data for $Os_3(CO)_{11}L$ (29). Use of δ_L in place of ν_{co} does not give a good fit unless data for $SbPh_3$ are omitted, and an inspection of the correlation between δ_L and ν_{co} suggests that this is due to an incorrectly high value of δ_L. Parameters obtained are included in Table 5 where it can be seen that the sign of β_L is negative, i.e., opposite to that for spontaneous CO dissociation. This is what would be expected since better electron donors would increase the electron density on the coordinated C atom that is undergoing nucleophilic attack. The Ru_3 cluster appears to allow a more effective transmission of the electronic effect of L than does the Os_3 cluster. Larger ligands still accelerate the reactions (i.e., the value of γ_L is positive) but to a lesser extent than for unassisted dissociation. This suggests that M—CO bond breaking is pronounced enough in the transition state for release of steric strain still to occur, but it is partially offset by the steric repulsion involved in nucleophilic attack by the Me_3NO at the C atom of a CO ligand.

Organic and inorganic templates bearing $CCo_3(CO)_9$ cluster fragments: X-ray crystal structures of $C(CH_2OCOCCl_3)_4$ and of $CH_3C(O)CHC(OH)ML_n$ where $ML_n = CCo_3(CO)_9$ or $(C_6H_5)Cr(CO)_3$

Lisa C.F. Chao, Andreas Decken, James F. Britten, and Michael J. McGlinchey

Abstract: Pentaerythritol and trichloroacetyl chloride react to yield the tetrakis-trichloroacetate ester $C(CH_2\text{-}O_2C\text{-}CCl_3)_4$, **5**, which crystallizes in the triclinic space group $P\bar{1}$ with $a = 9.874(2)$ Å, $b = 11.811(2)$ Å, $c = 12.858(3)$ Å, $\alpha = 114.35(3)°$, $\beta = 95.63(3)°$, $\gamma = 99.11(3)°$, and $V = 1326.5(5)$ Å^3 for $Z = 2$. The molecule adopts a geometry in which the trichloroacetate chains fold to produce a flattened tetrahedron, giving a molecule of approximate D_{2d} symmetry. Treatment of **5** with $Co_2(CO)_8$ gave, as the highest molecular weight product, the tris-cluster complex $C[CH_2\text{-}O_2C\text{-}CCo_3(CO)_9]_3(CH_2\text{-}O_2C\text{-}CCl_3)$, **6**, rather than the tetra-cluster $C[CH_2\text{-}O_2C\text{-}CCo_3(CO)_9]_4$, **7**. A space-filling model of **7**, derived by replacing the CCl_3 groups in **5** by $CCo_3(CO)_9$ moieties, exhibited considerable molecular crowding. Reaction of several 1,1,1-trichloroacetylacetonate salts with $Co_2(CO)_8$ gave the corresponding cluster complexes of Co(II), Co(III), or Al(III). The uncomplexed cluster ligand $CH_3C(O)CHC(OH)CCo_3(CO)_9$, **9**, crystallizes in the orthorhombic space group $Pna2_1$ with $a = 16.226(2)$ Å, $b = 11.6300(10)$ Å, $c = 9.919(2)$ Å, $V = 1871.7(4)$ Å^3 for $Z = 4$. The direction of enolization of **9** has been studied by EHMO calculations. The tendency to enolize is also found in (benzoylacetone)$Cr(CO)_3$, **17**, which crystallizes in the tetragonal space group $P4_32_12$ with $a = 10.0840(10)$ Å, $b = 10.0840(10)$ Å, $c = 25.387(5)$ Å, $V = 2581.5(6)$ Å^3 for $Z = 8$.

Key words: inorganometallic clusters.

Résumé : Le pentaérythritol et le chlorure d'acétyle réagissent pour donner l'ester tétrakis-trichloroacétate correspondant, $C(CH_2\text{-}O(O)CCCl_3)_4$, **5**, qui cristallise dans le groupe d'espace triclinique $P\bar{1}$, avec $a = 9,874(2)$, $b = 11,811(2)$ et $c = 12,858(3)$ Å, $\alpha = 114,35(3)°$, $\beta = 95,63(3)°$ et $\gamma = 99,11(3)°$, $V = 1326,5(5)$ Å^3 et $Z = 2$. La molécule adopte une géométrie dans laquelle les chaînes trichloroacétates se replie de façon à donner un tétraèdre aplati conduisant à une symétrie moléculaire qui approximativement D_{2d}. La réaction du composé **5** avec du $Co_2(CO)_8$ conduit, comme produit de poids moléculaire le plus élevé, à un complexe à trois clusters, $C[CH_2\text{-}O(O)C\text{-}CCo_3(CO)_9]_3(CH_2\text{-}O(O)C\text{-}CCl_3)$, **6**, plutôt qu'au complexe à quatre clusters, $C[CH_2\text{-}O(O)CCCo_3(CO)_9]_4$, **7**. Un modèle spatial du composé **7** obtenu en remplaçant les groupes CCl_3 du produit par des entités $CCo_3(CO)_9$ montre la présence d'un encombrement moléculaire important. La réaction de plusieurs sels 1,1,1-trichloroacétylacétonates avec du $Co_2(CO)_8$ conduit aux complexes avec clusters correspondants du Co(II), Co(III) et Al(III). Le ligand non complexé, $CH_3C(O)CHC(OH)CCo_3(CO)_9$, **9**, cristallise dans le groupe d'espace orthorhombique $Pna2_1$, avec $a = 16,226(2)$, $b = 11,6300(10)$ et $c = 9,919(2)$ Å, $V = 1871,7(4)$ Å^3 et $Z = 4$. On a étudié le sens de l'énolisation du composé **9** à l'aide de calculs d'EHMO. On a aussi déterminé la tendance à l'énolisation de la (benzoylacétone)$Cr(CO)_3$, **17**, qui cristallise dans le groupe d'espace tétragonal $P4_32_12$, avec $a = 10,0840(10)$, $b = 10,0840(10)$ et $c = 25,387(5)$ Å, $V = 2581,5(6)$ Å^3 et $Z = 8$.

Mots clés : clusters inorganométalliques.

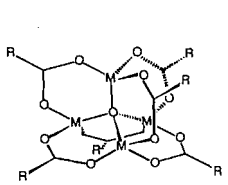
Introduction

While the synthesis of large clusters is not quite the haphazard process it once was (1), there is still a rôle for serendipity. In an attempt to prepare $(OC)_9Co_3CC(O)SiR_3$, Schore and co-workers (2) obtained the 22-cobalt cluster $Co_4O[O_2C\text{-}CCo_3(CO)_9]_6$, **1**, from an unexpected self-assembly process when a mixture of $Co_3(CO)_9CCl$ and $AlCl_3$ in CH_2Cl_2 was poured over cracked ice. This molecule is important, not merely for its picturesque symmetry, but also because it bridges organometallic and coordination chemistry in a potentially controllable fashion. This concept was independently recognized by Fehlner and co-workers, who devised logical synthetic routes to such molecules as **2** through **4** (3–5). The crucial point is the existence of the $[(OC)_9Co_3C\text{-}CO_2]^-$ anion and its use in the preparation of complexes analogous to those containing bridging acetate ligands (6). These reports prompt us to communicate our own results whereby we discuss the use of poly(trichloroacetate) esters as precursors of poly-$(CO)_9Co_3C$ clusters; moreover, routes to nonacarbonyl-tricobalt-carbynyl derivatives of the ubiquitous acetylacetonate ligand are described.

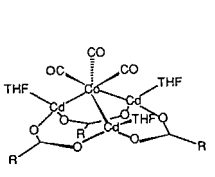
Results and discussion

Clusters derived from organic templates

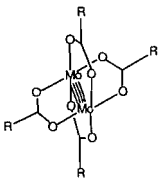
In recent years, the attachment of metal carbonyl fragments to surfaces has been the subject of considerable activity (7). Analogously, one can readily envisage coating a molecule of a selected shape and size with a layer of cluster fragments. Thus, one might choose to build prolate, oblate, spherical, or disk-like molecules. To investigate the viability of such a project, it was decided to attempt the synthesis of an oligo-cluster based upon a tetrahedral precursor. To this end, pentaerythritol, i.e., tetra(hydroxymethyl)methane, was treated with CCl_3-CO-Cl to yield the tetrakis-trichloroacetate ester $C(CH_2\text{-}O_2C\text{-}CCl_3)_4$, **5**. Reaction of **5** with excess $Co_2(CO)_8$ led to a complex mixture of products, several of which were separable on a column by flash chromatographic techniques. The highest molecular weight product corresponded to the tris-cluster complex $C[CH_2\text{-}O_2C\text{-}CCo_3(CO)_9]_3(CH_2\text{-}O_2C\text{-}CCl_3)$, **6**. One is tempted to ascribe the failure to isolate the tetra-cluster $C[CH_2\text{-}O_2C\text{-}CCo_3(CO)_9]_4$, **7**, to problems of steric crowding. To model this 12-cobalt molecule, it was decided first of all to obtain the X-ray crystal structure of the 12-chloro complex **5** and then to use



1: M=Co
2: M=Zn
R=$CCo_3(CO)_9$



3



4

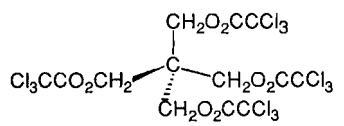
a molecular modelling program to replace the CCl_3 units by $CCo_3(CO)_9$ moieties.

Molecules in which a tetrahedral atom bears four identical bulky groups have been extensively studied by Iroff and Mislow (8*a*). For example, in tetrakis(trimethylsilyl)silane $Si(SiMe_3)_4$, the steric crowding causes each methyl group to mesh tightly with those in the remaining trimethylsilyl groups. $Si(SiMe_3)_4$ does not adopt T_d symmetry; instead, the twisting of the four groups lowers the symmetry to that of the rotational sub-group T, in which the C_3 axes are retained but the mirror planes are lost.

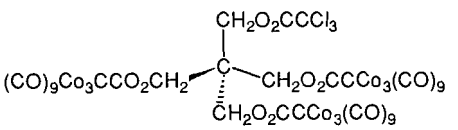
The tetra-ester **5** crystallizes in the triclinic space group $P\bar{1}$ with two molecules per unit cell. As shown in Fig. 1, the molecular structure reveals that the tetrahedral symmetry of **5** is indeed broken, but in a different fashion to that found for $Si(SiMe_3)_4$. The trichloroacetate chains fold to produce a flattened tetrahedron; they are oriented in pairwise fashion to give a molecule of approximate D_{2d} symmetry in which the C_3 axes are lost but two mirror planes and the S_4 axis are retained. The crystallographic collection parameters, atom coordinates, and selected bond length and angle data for **5** are listed in Tables 1 through 3.

Subsequently, using the modelling program ALCHEMY,[2] the four trichloromethyl units in **5** were replaced by $CCo_3(CO)_9$ fragments. These latter groups were constructed by using parameters taken from the X-ray crystal structure of $CH_3CCo_3(CO)_9$ (9). The computer-derived model of the molecule $C[CH_2\text{-}O_2C\text{-}CCo_3(CO)_9]_4$, **7**, constructed as described above and energy minimized so as to avoid unfavorable steric interactions between carbonyl ligands, appears as Fig. 2*a*; a space-filling representation of **7** is shown in Fig. 2*b*. It is apparent that the desired molecule can indeed adopt a viable conformation but it is less certain that the intermediates involved in the conversion of the CCl_3 groups into tricobalt clusters can be accommodated.

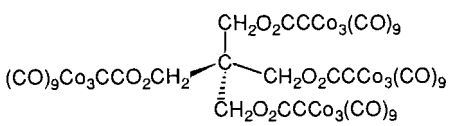
We note that other potential routes to **7** have been investi-



5



6



7

gated. Thus, although the acylium cation $[(OC)_9Co_3C\text{-}C{=}O]^+$ reacts readily with alcohols, phenols, or diols to give mono- or bis-clusters (10), the corresponding reaction with pentaerythritol is thwarted by the very low solubility of the tetra-alcohol in solvents that are themselves unreactive towards the organometallic acylium salt.

[2] ALCHEMY is available from Tripos Associates. St. Louis, Mo.

Cluster analogues of acetylacetonates

The exquisite molecules synthesized by Schore (2) and by Fehlner (3–6) depend for their existence on the stability and ready availability of the tricobalt cluster carboxylic acid $(OC)_9Co_3C\text{-}CO_2H$, which was first reported by Seyferth 20 years ago (11). However, we are unaware of any published route to the corresponding analogues of acetylacetone, i.e., $R^1\text{-}CO\text{-}CH_2\text{-}CO\text{-}R^2$, where one or both R groups are $CCo_3(CO)_9$ moieties rather than methyls. Since $RCCo_3(CO)_9$ clusters are frequently obtainable by treatment of the corresponding $RCCl_3$ precursors with dicobalt octacarbonyl, the obvious first step was to try to use 1,1,1-trichloropentan-2,4-dione (tcacH), **8**, as the cluster precursor. The ligand tcacH is readily preparable by the reaction of trichloroacetonitrile and pentan-2,4-dione with sodium acetate to give $Cl_3CC(NH_2)=CHC(O)CH_3$; subsequent treatment with concentrated HCl yields tcacH, **8**, as a colorless liquid (12, 13). However, the reaction of **8** with $Co_2(CO)_8$ does not yield useful quantities of the desired complex $CH_3\text{-}CO\text{-}CH\text{-}C(OH)\text{-}CCo_3(CO)_9$, **9**. This behavior is reminiscent of Seyferth's report that the presence of hydroxyl functionalities in the trichloromethyl precursor often limits the utility of this approach. For example, $Co_3(CO)_9C\text{-}CH_2OH$ can not be obtained directly from $Co_2(CO)_8$ and CCl_3CH_2OH (14).

From the ^1H and ^{13}C NMR spectra of tcacH, it is evident that the ligand exists in solution primarily as an enol tautomer; indeed, other electron-withdrawing groups are well known to

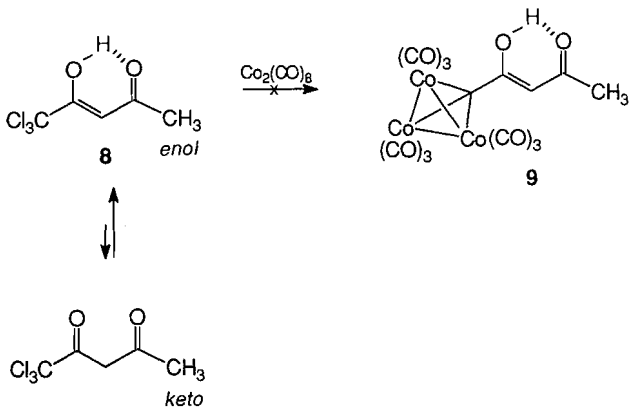

Fig. 2. (*a*) Computer-derived model of $C[CH_2\text{-}O_2C\text{-}CCo_3(CO)_9]_4$, **7**. (*b*) Computer-derived space-filling representation of $C[CH_2\text{-}O_2C\text{-}CCo_3(CO)_9]_4$, **7**.

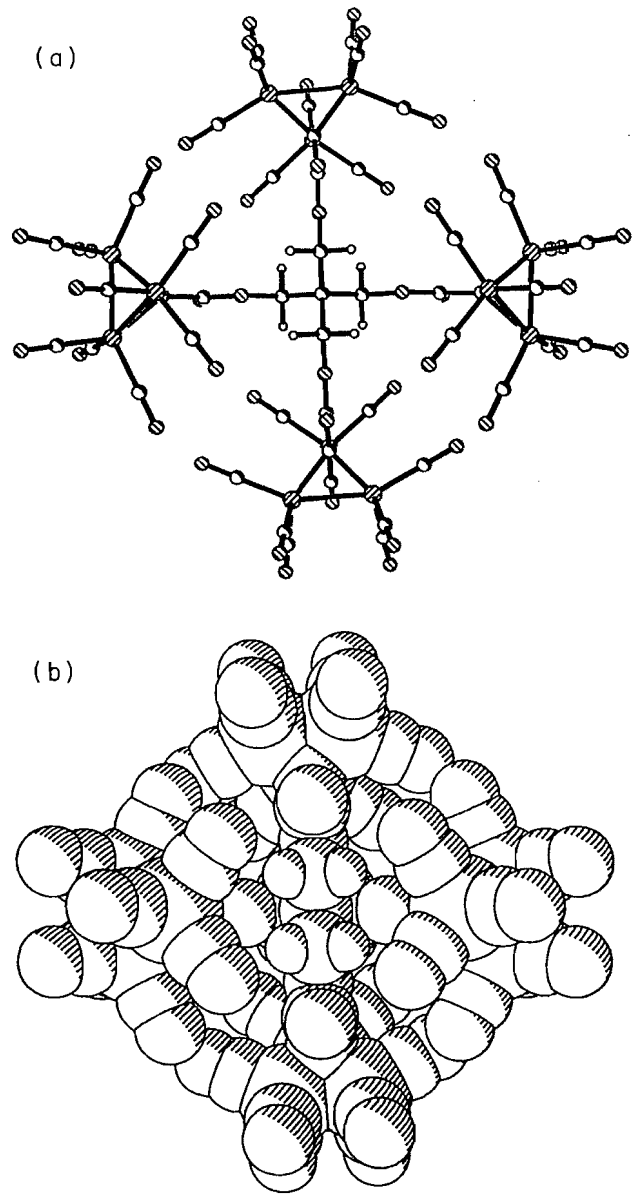

have a marked influence on the keto–enol equilibrium (15). 1,1,1-Trichloroacetylacetone, **8**, has been reported to yield complexes with a variety of di- and trivalent metals such as Cr(III), Mn(II), Fe(III), Co(II), Cu(II), and Al(III) (16). By using this approach to avoid the presence of a hydroxyl group in the ligand, we have shown that prior coordination of $[CCl_3\text{-}CO\text{-}CH\text{-}CO\text{-}CH_3]^-$ to a metal center before treatment with $Co_2(CO)_8$ does indeed lead to cluster formation, albeit in low yield. Typically, $Al(tcac)_3$, **10**, reacts with excess dicobalt octacarbonyl to yield the corresponding cluster-substituted complex **11**. The cluster **11** is conveniently identified by its FAB mass spectrum, which exhibits a [P − 1CO] peak and sequential loss of 23 carbon monoxide fragments. Moreover, one sees loss of a $Co_3(CO)_9C\text{-}C(O)CHC(O)CH_3$ fragment from the molecular ion followed by loss of 10 additional carbonyls.

Interestingly, analogous treatment of $Cu(tcac)_2$, **12**, yields,

after chromatographic separation of the products, the Co(II) and Co(III) complexes **13** and **14**, respectively. Evidently, the central cobalt atoms must derive from $Co_2(CO)_8$; this observation is reminiscent of Schore's synthesis of $Co_4O[O_2C\text{-}CCo_3(CO)_9]_6$, **1**, whereby the Co(II) centers arise from decomposition of the original cobalt cluster. The octahedral systems **11** and **14** derived from trivalent metals yield *mer* and *fac* isomers and, thus far, have not allowed the isolation of single crystals suitable for a diffraction study. However, in an attempt to obtain an X-ray quality crystal of **13**, repeated chromatographic purification yielded black crystals that were subsequently shown to be the parent ligand **9**.

Recrystallization of $CH_3\text{-}CO\text{-}CH\text{-}C(OH)\text{-}CCo_3(CO)_9$, **9**,

from 50/50 CH_2Cl_2/hexane gave parallelepipeds suitable for an X-ray structure determination. The cluster crystallizes in the orthorhombic space group $Pna2_1$ with four molecules in the unit cell. The crystallographic collection parameters are listed in Table 1, and atomic coordinates and selected bond length and angle data for **9** appear in Tables 4 and 5; a view of the molecule appears as Fig. 3.

Each molecule has approximate C_s symmetry with the two oxygens of the acac-type unit oriented to lie over the midpoint of a cobalt–cobalt vector. The tetrahedral Co_3C core exhibits typical bond lengths: Co—Co (2.47 Å), Co—CO (1.81 Å), and Co—C_{cap} (1.90 Å). In the solid state, the molecule exists in the enol form $CH_3C(O)$-CH=C(OH)-$CCo_3(CO)_9$, rather than as the keto tautomer. The hydroxyl moiety is at the cluster end of the five-carbon chain and the OH proton is hydrogen-bonded to the ketonic oxygen neighboring the methyl carbon. This tautomeric structure is evident from the C(2)—C(3), C(2)—O(2), C(3)—C(4), and C(4)—O(4) distances of 1.389(8), 1.320(7),

1.408(8), and 1.262(8) Å, respectively. In this structure, the C—O distances are significantly different; moreover, the enolic hydrogen can be seen in the final difference map.

We are aware of only one other structurally characterized organometallic acac-type derivative: the X-ray crystal structure of the ferrocenyl complex **15** has recently been reported, and the molecule was shown to adopt the tautomeric form in which the site of enolization is remote from the electron-donating ferrocenyl moiety (17). Analogously, in the thiophene derivative **16**, the enol-H is bonded to the oxygen adjacent to the strongly electron-withdrawing CF_3 group (18). Furthermore, it has been reported that the infrared spectrum of (benzoylacetone)$Cr(CO)_3$, **17**, indicates that in solution the enol tautomer predominates (19). From our ^{13}C NMR data, the observed keto–enol ratio in **17** is ≈1:5, but the preferred site of enolization is unknown.

In an attempt to rationalize the favored site of enolization found in the cobalt cluster **9**, molecular orbital calculations at the extended Hückel level were carried out. The crystallographically observed tautomer, in which the enol is adjacent to the cluster, is favored by ≈3.4 kcal/mol relative to the case when the OH is sited at C(4), as in $CH_3\text{-}C(OH)=CH\text{-}C(O)\text{-}CCo_3(CO)_9$. Figure 4 depicts the changes in the HOMO of **9** as the enol-H migrates from O(2) to O(4) and the C(2)—C(3) and C(3)—C(4) distances are modified accordingly. Initially (Fig. 4*a*), there is an in-plane π^* interaction between C(2) and O(2) that is augmented as the migration proceeds (Fig. 4b); that is, the system is somewhat destabilized. However, this rather simplistic approach does not account for the observed tautomer of the ferrocenyl-acac complex **15**, and it may be that a higher level of theory is needed to rationalize the behavior of such systems.

The X-ray crystal structure of (benzoylacetone)$Cr(CO)_3$, 17

It was noted previously (19) that replacement of a methyl group in acacH by an (η^6-phenyl)$Cr(CO)_3$ substituent, as in **17**, leads

predominantly to an enol tautomer of unknown structure. To resolve this dichotomy, an X-ray quality crystalline sample of **17** was prepared and its structure determined. (Benzoylacetone)$Cr(CO)_3$, **17**, crystallizes in the tetragonal space group $P4_32_12$ with eight molecules in the unit cell. The crystallographic collection parameters are listed in Table 1, and atomic coordinates and selected bond length and angle data for **17** appear in Tables 6 and 7; a view of the molecule appears as Fig. 5.

The acac and phenyl rings are essentially coplanar and the $Cr(CO)_3$ tripod adopts an almost staggered orientation with respect to the phenyl carbons. Although the acac portion of the molecule is clearly an enol, and the C(3) carbon is sp^2-hybridized, the C(2)—O(2) and C(4)—O(4) distances, 1.288(4) Å and 1.285(5) Å, are not significantly different. Likewise, the C(2)—C(3) and C(3)—C(4) distances, 1.390(5) Å and 1.392(5) Å, are essentially the same, perhaps indicating that the enolic H is symmetrically bonded to both oxygens. In accord with the X-ray data, the ^{13}C CPMAS spectrum of **17** exhibits peaks only for the enol tautomer.

Conclusions

Preliminary attempts to use organic templates as surfaces on which to deposit $Co_3(CO)_9C$ cluster fragments reveal that,

17

although the general approach of coating the central core with trichloroacetate esters is viable, care must be taken not to place too many bulky clusters in close proximity. It has also been demonstrated that coordination of the 1,1,1-trichloroacetylacetonate ligand to a variety of metal centers facilitates the construction of a range of inorganometallic clusters. The X-ray crystal structure of the parent ligand, CH_3-C(O)-CH=C(OH)-$CCo_3(CO)_9$, **9**, reveals that it exists as the enol tautomer in which the OH substituent is adjacent to the cluster moiety. Likewise, in (benzoylacetone)$Cr(CO)_3$, **17**, the 1,3-dione exists primarily in the enol form.

Experimental section

All reactions were carried out under an atmosphere of dry nitrogen employing conventional benchtop and glovebag techniques. All solvents were dried according to standard procedures before use (20). Silica gel (particle size: 20–45 μm) was employed for flash column chromatography. ^1H and ^{13}C solution NMR spectra were recorded on a Bruker AC-200 spectrometer. ^{13}C CPMAS spectra were recorded on a Bruker MSL 100 instrument. Infrared spectra were recorded on a Perkin–Elmer 283, or a Bio-Rad FTS-40 instrument using NaCl plates. Fast Atom Bombardment (FAB) was performed on a VG analytical ZAB-ZE spectrometer. 3-Nitrobenzyl alcohol was used as the sample matrix and xenon was the bombarding gas (8 keV). Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected.

Preparation of $C[CH_2O_2CCCl_3]_4$, 5

$ClCOCCl_3$ (16.4 mL, 146.8 mmol) was added dropwise over a period of 1.5 h to a solution of $C(CH_2OH)_4$ (5.00 g, 36.7 mmol) and pyridine (17.0 mL, 210.2 mmol) in ether (80 mL) and was then allowed to stir for 6 h. Excess pyridine was added until the mixture was no longer acidic. The mixture was then extracted with 4 × 100 mL of 1.2 N HCl. The ether layer was dried with Na_2SO_4 and removed, leaving a white solid, **5**, which was further washed with petroleum ether (7.03 g, 9.79 mmol, 27%), mp 150–152°C. Recrystallization of **5** from diethyl ether – petroleum ether (50:50) gave X-ray quality crystals. IR (CH_2Cl_2): $\nu_{C=O}$ 1770 (s) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 4.53 (s). ^{13}C NMR ($CDCl_3$) δ: 161.0 (ester carbonyl), 88.9 (CCl_3), 65.3 (CH_2), and 43.6 (tertiary *C*). Mass spectrum (DCI) *m/z* (%): 730 (100) $[M + NH_3]^+$, 677 (7) $[M - Cl]^+$, 551 (51) $[M - O_2CCCl_3]^+$, 390 (12) $[M - 2(O_2CCCl_3)]^+$, 244 (25) $[M - 4(CCl_3)]^+$, and 227 (8) $[M - 3(O_2CCCl_3)]^+$. Peaks quoted are in each case the lowest mass in each envelope and correspond to ^{35}Cl.

Reaction of 5 with $Co_2(CO)_8$

$Co_2(CO)_8$ (1.77 g, 5.12 mmol) and $C[CH_2O_2CCCl_3]_4$ (0.52 g, 0.72 mmol) in 20 mL of THF were heated at 40°C for 3.5 h. After cooling, the mixture was filtered to remove cobalt salts, and the solvent was removed in vacuo. Flash chromatography using 100% CH_2Cl_2 as eluant showed the presence of at least six different products. The first band to elute was $Co_4(CO)_{12}$, a purple-black solid (0.251 g, 0.439 mmol). The second band obtained was $C[CH_2O_2CCCo_3(CO)_9]_3(CH_2O_2CCCl_3)$, **6**, a purple oil (0.099 g, 0.059 mmol, 7%). IR (CH_2Cl_2): ν_{CO} at 2111 (w), 2067 (vs), 2048 (s); $\nu_{C=O}$ at 1607 (m, br) cm^{-1}. Mass spectrum: (*a*) (FAB^+, MCA) *m/z* (%) 1208 (18) $[M - 17CO]^+$, 1180 (18) $[M - 18CO]^+$, 1095 (38) $[M - 21CO]^+$, 1068 (20) $[M - 22CO]^+$, 1039 (42) $[M - 23CO]^+$, 984 (15) $[M - 25CO]^+$, 956 (37) $[M - 26CO]^+$, and 927 (100) $[M - 27CO]^+$. (*b*) (FAB^+) *m/z* (%) 1068 (24) $[M - CCo_3(CO)_9 - CH_2O_2CCCl_3]^+$, 1040 (68) $[M - CCo_3(CO)_9 - CH_2O_2CCCl_3 - CO]^+$, 958 (46) $[M - CCo_3(CO)_9 - CH_2O_2CCCl_3 - 4CO]^+$, 928 (100) $[M - CCo_3(CO)_9 - CH_2O_2CCCl_3 - 5CO]^+$, 844 (38) $[M - CCo_3(CO)_9 - CH_2O_2CCCl_3 - 8CO]^+$, and 760 (79) $[M - CCo_3(CO)_9 - CH_2O_2CCCl_3 - 11CO]^+$. The fourth band, a purple oil (0.033 g, 4.4%), was tentatively assigned as $C[CH_2O_2CCCo_3(CO)_9](CH_2O_2CCCl_3)_3$. IR ($CH_2Cl_2$): ν_{CO} at 2103 (w), 2050 (vs), 2042 (s); $\nu_{C=O}$ at 1606 (w) cm^{-1}. Mass spectrum: (FAB^+, MCA) *m/z* (%): 1036 (7) $[M^+]$; 1007 (27) $[M - CO]^+$; 924 (20) $[M - 4CO]^+$. Peaks quoted are in each case the lowest mass in each envelope and correspond to ^{35}Cl.

Preparation of $Cl_3CC(O)CH_2C(O)CH_3$, 8

According to the procedures of Coenen et al. (12) and of Ringel and Mayer (13), Cl_3CCN (35.0 g, 0.24 mol) and acetylacetone (25.0 g, 0.24 mol) were dissolved in 100 mL MeOH. While stirring, 50 mL of a saturated aqueous solution of sodium acetate was slowly added. The reaction mixture was stirred for 2 h and was then slowly poured into 700 mL of cold H_2O, in which a white precipitate formed immediately. It was subsequently filtered and recrystallized from hexane to give $Cl_3CC(NH_2)$=$CHC(O)CH_3$ (44.25 g, 0.22 mol, 90%). This product was then treated with 78.8 mL of concentrated HCl. Heat was evolved and NH_4Cl and an oil separated out. After cooling the solution 63.0 mL of H_2O was added. The oily layer was then treated with 118 mL of ether, dried with Na_2SO_4, and filtered. Removal of the solvent gave a liquid, which was distilled at reduced pressure (bp_{18} 100–101°C) to yield **8** as a colorless liquid (31.68 g, 0.16 mol, 71%). IR (CH_2Cl_2): $\nu_{C=O}$ at 1595 (vs) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 6.10 (s, 1H, C*H* of enol), 4.05 (s, 2H, CH_2 of keto), 2.29 (s, 3H, CH_3 of keto), and 2.15 (s, 3H, CH_3 of enol). ^{13}C NMR ($CDCl_3$) δ: 186.8, 185.3 (carbonyls), 94.7 (CCl_3), 92.9 (*C*H of enol), 48.9 (CH_2 of keto), 30.1 (CH_3 of keto), and 22.9 (CH_3 of enol). Mass spectrum (EI) *m/z* (%): 202 (18) $Cl_3CC(O)CH_2C(O)CH_3$ $[M]^+$, 187 (5) $[M - CH_3]^+$; 167 (36) $[M - Cl]^+$; 152 (25) $[M - Cl - CH_3]^+$, 139 (100) $[M - Cl - CO]^+$, and 117 (27) $[M - C(O)CH_2C(O)CH_3]^+$. Peaks quoted are in each case the lowest mass in each envelope and correspond to ^{35}Cl.

Preparation of $Al[Cl_3CC(O)CHC(O)CH_3]_3$, 10

Although **10** has been reported previously and characterized by mass spectrometry (16), no synthetic procedure or NMR data are available. **8** (2.00 g, 9.83 mmol) was added to a solution of aluminum isopropoxide (0.669 g, 3.28 mmol) in 6.4 mL of benzene. After the solution was allowed to stand for 2 h, benzene and the 2-propanol produced were removed by using a rotovap to yield a white solid, **10** (1.614 g, 2.54 mmol, 78%). IR (CH_2Cl_2): $\nu_{C=O}$ 1614 (s), $\nu_{C=C}$ 1513 (s) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 6.41 (s, 1H), 6.40 (s, 1H), 6.38 (s, 3H), 6.32 (s, 1H), 2.32 (s, 3H), 2.28 (s, 12H), and 2.23 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: at 201.0, 200.4, 199.9 ($C(O)CCl_3$); 179.3, 178.7, 178.1 ($C(O)CH_3$); 95.1, 94.7, 94.4 (*C*H); and 28.34 (CH_3). Mass spectrum (FAB^+) *m/z* (%): 429 (79) $[M - tcac]^+$, 394 (49) $[M - tcac - Cl]^+$, 359 (24) $[M - tcac - 2Cl]^+$, 347 (28) $[M - tcac - CCl_2]^+$, 312 (25) $[M - tcac - CCl_3]^+$, and 228 (55) $[M - 2(tcac)]^+$. Peaks quoted are in each case the lowest mass in each envelope and correspond to ^{35}Cl and ^{27}Al.

Preparation of $Cu[Cl_3CC(O)CHC(O)CH_3]_2$, 12

Although **12** has been reported previously and characterized by mass spectrometry (16), no synthetic procedure is available. Copper nitrate trihydrate (2.969 g, 12.29 mmol) was dissolved in 27.5 mL of water and to this was added, with mixing, **8** (5.00 g, 24.58 mmol) and sodium acetate (2.015 g, 24.57 mmmol) in 2.75 mL water. A solid precipitated out of solution and was filtered and dried. Recrystallization from methanol yielded a grey-green solid, **12** (3.965 g, 8.46 mmol, 69%), with a melting point of 197–198°C. IR (CH_2Cl_2): $\nu_{C=O}$ 1601 (s), $\nu_{C=C}$ 1507 (s) cm^{-1}. Mass spectrum (FAB^+) shows evidence for dimerization; *m/z* (%): 729 (9) [M - tcac]$^+$, 571 (20) $[M - tcac - CHC(O)CCl_3]^+$, 528 (12) $[M - 2(tcac)]^+$, 465 (51) $[M - 2(tcac) - Cu]^+$, 458 (28) $[M - 2(tcac) - 2Cl]^+$, 416 (100) $[M - 2(tcac)\ Cu - CH_2 - Cl]^+$, 369 (66) $[M - 2(tcac) - CHC(O)CCl_3]^+$, and 348 (31) $[M - 2(tcac) - CCl_3 - Cu]^+$. Peaks quoted are in each case the lowest mass in each envelope and correspond to ^{35}Cl and ^{63}Cu.

Preparation of $Al[Co_3(CO)_9CC(O)CHC(O)CH_3]_3$, 11

10 (1.755 g, 2.77 mmol) and $Co_2(CO)_8$ (5.109 g, 14.94 mmol) in 50 mL of THF were stirred at room temperature for 1.5 h and at 40°C for 1.5 h. The resulting solution was filtered and the solvent removed *in vacuo*. Column chromatography, using as eluant ether/hexanes (1:4), yielded $Co_4(CO)_{12}$ (1.51 g, 2.64 mmol) as the first band and **11**, a brown-black oil, as the second band (0.310 g, 0.19 mmol, 7%). IR (CH_2Cl_2): ν_{CO} at 2108 (w), 2063 (vs), 2045 (s); $\nu_{C=O}$ at 1723 (m), 1601 (w), and 1525 (w) cm^{-1}. ^{13}C NMR ($CDCl_3$) δ: 220.8 ($C(O)CCo_3(CO)_9$), 196.2 (Co-*C*O's), 187.6 ($C(O)CH_3$), 117.4 (*C*H), and 29.7 (CH_3). Mass spectrum (FAB^+) *m/z* (%): 1574 (7) $[M - CO]^+$, 1518 (14) $[M - 3CO]^+$, 1378 (11) $[M - 8CO]^+$, 1294 (11) $[M - 11CO]^+$, 1238 (20) $[M - 13CO]^+$, 1210 (23) $[M - 14CO]^+$, 1182 (30) $[M - 15CO^+]$, 1154 (24) $[M - 16CO]^+$, 1126 (35) $[M - 17CO]^+$, 1077 (30) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3]^+$, 1049 (25) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - CO]$, 1014 (25) $[M - 21CO]^+$, 986 (23) $[M - 22CO]^+$, 958 (42) $[M - 23CO]^+$, 937 (50) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 5CO]$, 909 (68) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 6CO]^+$, 881 (100) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 7CO]^+$, 853 (70) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 8CO]^+$, 825 (60) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 9CO]^+$, and 797 (36) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 10CO]^+$.

Preparation of $Co[Co_3(CO)_9CC(O)CHC(O)CH_3]_2$, 13, and $Co[Co_3(CO)_9CC(O)CHC(O)CH_3]_3$, 14

12 (0.76 g, 1.62 mmol) and $Co_2(CO)_8$ (2.00 g, 5.84 mmol) were dissolved in 30 mL of THF and stirred at room temperature for 1 h and at 40°C for 1 h. This mixture was allowed to cool, and filtration and solvent removal in vacuo yielded a crude solid that was purified by flash chromatography (CH_2Cl_2/hexanes, 1:1). The first band was a brown-black oil, **13** (0.180 g, 0.162 mmol, 10%). IR of **13**, (CH_2Cl_2): ν_{CO} at 2108 (m), 2063 (vs), 2045 (s); $\nu_{C=O}$ at 1722 (vw), and 1599 (w) cm^{-1}. Mass spectrum (FAB^+) of **13**; *m/z* (%): 1109 (20) $Co[Co_3(CO)_9CC(O)CHC(O)CH_3]_2$, $[M]^+$, 1082 (12) $[M - 1CO]^+$, 1024 (73) $[M - 3CO]^+$, 998 (32) $[M - 4CO]^+$, 941 (33) $[M - 6CO]^+$, 913 (100) $[M - 7CO]^+$, 885 (77) $[M - 8CO]^+$, 857 (58) $[M - 9CO]^+$, 829 (85) $[M - 10CO]^+$, and 800 (69) $[M - 11CO]^+$. The second band was a brown-black oil, **14** (0.126 g, 0.077 mmol, 7%). IR of **14**, (CH_2Cl_2): ν_{CO} at 2107 (m), 2063 (vs), 2044 (s); $\nu_{C=O}$ at 1723 (w), 1595 (m), and 1515 (m) cm^{-1}. Mass spectrum (FAB^+) of **14**; *m/z* (%): 1521 (10) $[M - 4CO]^+$, 1353 (33) $[M - 10CO]^+$, 1297 (42) $[M - 12CO]^+$, 1157 (37) $[M - 17CO]^+$, 1129 (43) $[M - 18CO]^+$, 1024 (51) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 3CO]^+$, 997 (72) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 4CO]$, 913 (100) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 7CO]^+$, 885 (76) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 8CO$, 857 (77) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 9CO]$, 829 (96) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3\ 10CO]^+$, and 801 (94) $[M - Co_3(CO)_9CC(O)CHC(O)CH_3 - 11CO]$. Repeated chromatography on **13** led to decomposition and yielded black crystals of **9**. Recrystallization from methylene chloride/ hexane (50:50) gave an X-ray quality sample of **9**.

Preparation of (benzoylacetone)$Cr(CO)_3$, 17

According to the literature procedure (19), (methylbenzoate)chromiumtricarbonyl (1.117 g, 4.104 mmol) and acetone (0.285 g, 4.907 mmol) in ether (20 mL) were treated with NaOEt (0.293 g, 4.309 mmol) over 1 h under N_2 atmosphere. A bright yellow precipitate formed that was filtered and then dissolved in water. Bubbling CO_2(g) resulted in the formation of an orange-red precipitate, which was extracted with ether. The ether layer was dried over Na_2SO_4, filtered, and then removed, yielding a brick-red solid, **17** (0.653 g, 2.190 mmol, 54%), mp 119–121°C [Lit. (19) mp 115–117°C]. IR (CH_2Cl_2): $\nu_{C=O}$ at 1980 (s), and 1909 (s) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 5.99 (d, 2H, *ortho-H*), 5.84 (s, 1H, C*H* of enol), 5.56 (t, 1H, *para-H*), 5.28 (t, 2H, *meta-H*), 3.86 (s, 2H, CH_2 of keto), 2.31 (s, 3H, CH_3 of keto), and 2.15 (s, 3H, CH_3 of enol). ^{13}C NMR (acetone-d_6) δ: 232.6 (Cr-*C*O of enol), 232.1 (Cr-*C*O of keto), 202.3, 192.9 (*C*O of keto), 191.3, 185.3 (*C*O of enol), 97.78 (*ipso-C* of enol), 97.2, 96.1 (*para-C*, *C*H of enol), 94.7, 92.1 (*meta-C*, *ortho-C*), 53.2 (CH_2 of keto), 24.4 (CH_3 of enol). ^{13}C CPMAS; δ: 233.0 (Cr-*C*O of enol), 195.1, 183.0 (*C*O of enol), 97.3, 94.4 (*ipso-C*, *para-C*, *meta-C*, *ortho-C*, and *C*H of enol), and 26.6 (CH_3 of enol). Mass spectrum (DEI) *m/z* (%): 298 (5) $[M]^+$, 242 (8) $[M - 2CO]^+$, 214 (30) $[M - 3CO]^+$, 171 (10) $[M - 3CO - COCH_3]^+$, and 52 (100) $[Cr]^+$.

X-ray crystallography

X-ray crystallographic data for **5** were collected on a Rigaku AFC6R diffractometer with a rotating anode and graphite-monochromated Cu Kα radiation (λ = 1.54178 Å). The X-ray crystallographic data for **9** and **17** were collected on a Siemens P4 diffractometer with a rotating anode and graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The background measurements were obtained by using a stationary crystal and stationary counter at the beginning and end of the scan, each for 25% of the total scan time. The scan type used was θ–2θ. The scan rate was 32.0°/min in ω for **5**, while the scan speed was variable for **9** (1.50–60.00°/min) and for **17** (5.00–60.00°/min) in ω. In **5**, three standard reflections were measured after every 150 reflections. In **9** and **17**, three standard reflections that were measured after every 97 reflections showed no instrument instability and only minor crystal decay. The molecule **5** was solved by using Direct Methods, while for **9** and **17**, the Patterson Method was used. Both of these procedures are contained in the SHELXTL-PLUS program library (22).[3] The method of refinement was full-matrix least squares in each case. Crystal data collection parameters are listed in Table 1. Atom coordinates and selected bond lengths and angles for **5**, **9**, and **17** are collected in Tables 2 through 7.[4]

[3] SHELXTL-PLUS was written by G.M. Sheldrick. Nicolet XRD. Madison, Wis.

[4] Tables of thermal parameters, bond lengths and angles, and positional parameters for hydrogen atoms for molecules **5**, **9**, and **17** are available as supplementary material and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A OS2.

Tables of bond lengths and angles and positional parameters have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

Molecular orbital calculations were performed via the extended Hückel method using weighted H_{ij}'s (21); orbital drawings were obtained by use of the program CACAO (22). Orbital parameters were taken from ref. 23.

Acknowledgements

Financial support from the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged. Mass spectra were obtained courtesy of Dr. Richard Smith of the McMaster Regional Centre for Mass Spectrometry, and solid state NMR data were kindly provided by Brian G. Sayer. We thank Dr. Carlo Mealli, Consiglio Nazionale delle Richerche, Florence, Italy, for the program CACAO.

The syntheses and structures of the phenyl-di-μ-methylene-dirhodium complexes, $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Ph)(Br)]$ and $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Ph)_2]$

Zhi-Qiang Wang, Harry Adams, Neil A. Bailey, Michael L. Turner, and Peter M. Maitlis

Abstract: Reaction of PhMgBr with $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)_2(Br)_2]$ in a halide-specific reaction gave, first, the monophenyl complex **2***a* $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Ph)(Br)]$ and then the diphenyl complex **3** $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Ph)_2]$. X-ray crystal structure determinations showed both molecules to have *trans* structures, $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Ph)(Br)]$ ($a = 10.066(3)$, $b = 11.065(3)$, $c = 14.002(3)$ Å; $\alpha = 85.23(2)°$, $\beta = 70.10(2)°$, $\gamma = 65.22(2)°$; $U = 1328.2(6)$ Å^3; $Z = 2$; space group $P\bar{1}$, final R, 0.0586) and $[\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Ph)_2]$ ($a = 17.102(8)$, $b = 10.396(4)$, $c = 16.134(7)$ Å; $U = 2869(2)$ Å^3; $Z = 4$; space group $Pccn$ (D_{2h}^{10}, No. 56), final $R = 0.0426$).

Key words : X-ray structure determination, pentamethylcyclopentadienyl, di-μ-methylene, rhodium

Résumé : La réaction du PhMgBr avec le $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Br)_2]$, dans une réaction à halogénure spécifique, conduit premièrement au complexe monophénylé **2***a* $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}(Ph)(Br)]$ et ensuite au complexe diphénylé **3** $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}(Ph)_2]$. Des études par diffraction des rayons X ont permis de montrer que les deux molécules possèdent des structures *trans*. Pour le $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}(Ph)(Br)]$, $a = 10{,}066(3)$, $b = 11{,}065(3)$ et $c = 14{,}002(3)$ Å, $\alpha = 85{,}23(2)°$ $\beta = 70{,}10(2)°$ et $\gamma = 65{,}22(2)°$, $U = 1328{,}2(6)$ Å^3, $Z = 2$, groupe d'espace $P\bar{1}$ et valeur finale de $R = 0{,}0586$ alors que pour le $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}(Ph)_2]$, $a = 17{,}102(8)$, $b = 10{,}396(4)$ et $c = 16{,}134(7)$ Å, $U = 2689(2)$ Å^3, $Z = 4$, groupe d'espace $Pccn$ (D_{2h}^{10}, No. 56) et valeur finale de $R = 0{,}0426$.

Mots clés : détermination de structure, diffraction des rayons X, pentaméthylcyclopentadiényle, di-μ-méthylène, rhodium.

[Traduit par la rédaction]

Introduction

We have previously reported extensive explorations of the chemistry of the di-μ-methylene-bis(pentamethylcyclopentadienylrhodium) complexes and have shown that the $\{(\eta^5\text{-}C_5Me_5Rh)(\mu\text{-}CH_2)\}_2$ unit is unexpectedly stable, despite formally containing Rh(IV) metal centres. This has allowed the synthesis of a large number of substituted species such as $[\{(\eta^5\text{-}C_5Me_5Rh)(\mu\text{-}CH_2)\}_2(X)(Y)]$ where X, Y are anionic (e.g., halide or pseudo-halide (1–3), alkyl (4), allyl (5), benzyl (6), vinyl (7), carbonate (8), etc.) or neutral ligands (e.g., MeCN, py, CO (9), etc.). For the neutral ligands, the complexes are of course ionic and bear positive charges.

The introduction of phenyl has, however, proved quite elusive until now, and neither the mono- nor the diphenyl complex had been efficiently obtained by standard routes. For example, reactions of $[\{(\eta^5\text{-}C_5Me_5Rh)(\mu\text{-}CH_2)\}_2Cl_2]$ with phenyllithium in solvents such as toluene, tetrahydrofuran, ether, or hexane were largely unsuccessful, and only a very small amount (<10%) of the diphenyl-dirhodium complex (**3**) was isolated when phenylmagnesium bromide was reacted with $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2Cl_2]$ in toluene. Since the chemistry of such aryl dirhodium systems is potentially of great interest, we persevered and now report the successful preparation of both the monophenyl monobromo complex, **2***a*, and the diphenyl complex, **3**, by an unexpectedly simple variation of the standard method. The key proved to be the use of the dibromo complex $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2Br_2]$, **1**, in place of the dichloro complex $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2Cl_2]$ to react with PhMgBr. Since there is no special reason to expect Br^- to be a better leaving group from $\eta^5\text{-}C_5Me_5Rh$ than

Cl^-, this suggests that the key step in the reaction may well be an electron transfer from the rhodium halide complex to the Grignard, which occurs more easily for bromide than for chloride.

Results and discussion

Reaction of $[\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2Br_2]$ in toluene with 3–4 equivalents of phenylmagnesium bromide (in ether) at low temperatures gave first the bromophenyl complex **2***a*, isolated in 86% yield. If the temperature was allowed to rise to ambient during the latter part of the reaction (the other conditions remaining the same), the diphenyl complex **3** was formed, and was isolated in 45–52% yield. The yield could not be further improved due to the formation of $[\{(C_5Me_5)RhBr_2\}_2]$ (^1H NMR, δ 1.65 C_5Me_5) as by-product.

Since the phenyl dirhodium complexes have been so elusive, we have also determined the X-ray structures of **2***a* and **3** in order to see if they hold a clue to the difficulty of preparing them.

The X-ray determination showed that complex **2***a* had the expected structure (Fig. 1 and Table 1) with methylenes bridging the two rhodiums (Rh(1)—C(1) 2.012(6); Rh(1)—C(2) 2.024(6); Rh(2)—C(1) 2.036(6); Rh(2)—C(2) 2.046(6); Rh(1)—Rh(2) 2.641(1) Å). Both rhodiums are η^5-bonded to C_5Me_5 rings; in addition Rh(1) is bonded to the phenyl (Rh(1)—C(23) 2.031(6) Å) and Rh(2) to bromide (Rh(2)—Br 2.522(1) Å). The two substituents and the two rings are *trans* to each other. Both the geometry and the bond lengths are similar to those found previously in compounds of this type; however, this complex has different substituents on the two rhodiums, and hence a somewhat asymmetric $Rh(\mu\text{-}CH_2)_2Rh$ bridge is present, with the $\mu\text{-}CH_2$ slightly further from the rhodium bearing the bromine (2.036, 2.046(6) Å) than from the rhodium bearing the Ph (2.012, 2.024(6) Å). A related asymmetry is seen in the tetranuclear complex $[\{\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2\}_2(CN)_2]^{2+}$ (3). The structures of the bromo phenyl complexes, $[(C_5Me_5)Rh(PR_3)(Ph)(Br)]$ (PR_3 = PPh_2Me, PMe_3, PPh_3, and PMe_2Ph) show Rh—Br lengths, 2.543(1), 2.533(2), 2.525(3), and 2.524(2) Å, respectively (10); thus the value of 2.522 for Rh—Br for **2***a* comes at the bottom of the

[a]Symmetry transformations used to generate equivalent atoms: $-x + 1, -y, -z + 1$.

range. Similarly, the length of the Rh—C(phenyl) bond in **2***a*, 2.031 Å, is substantially shorter than those in $[(C_5Me_5)Rh(PR_3)(Ph)(Br)]$ with values of 2.065(5), 2.054(9), 2.08(1), and 2.082(6) Å, respectively, for the above series. Part of the reason for the smaller bond lengths must be the smaller size expected for Rh(IV) in **2***a* compared to that for Rh(III) in the mononuclear complexes.

The diphenyl complex **3** was characterized by elemental analysis, ^1H NMR, ^{13}C NMR, and mass spectra, and by an X-ray determination, which showed that the molecule had a *trans*-centrosymmetric structure (Fig. 2 and Table 2) with methylenes bridging the two rhodiums (Rh—CH_2, 2.009(6), 2.038(6) Å). Each rhodium is η^5-bonded to a C_5Me_5 ring and σ-bonded to a phenyl (Rh—C_6H_5 2.038(6) Å).

The Rh—Rh distances are 2.622(1) Å in **3** and 2.641(1) Å in **2***a*. While the differences are small and there are only 10 determined structures so far, these values are towards the shorter end of the range which spans 2.588(2) Å (for $[\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(CH{=}CH_2)_2]$ (7)) and 2.620(1) Å (for $[\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2Me_2]$ (4)) to 2.678 Å (for $[\{(C_5Me_5)Rh)_2(\mu\text{-}CH_2)(\mu\text{-}CHMe)\}Cl_2]$ (2)) and 2.676(3) Å (for $[\{\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2\}_2(CN)_2]^{2+}$ (3)). This suggests that substituents of low electronegativity (e.g., C) lead to shorter and stronger Rh—Rh bonds, while more electronegative substituents such as Cl lead to rather longer and presumably weaker Rh—Rh bonds. Presumably the Cl pulls some electron density out of the Rh—Rh bond. This suggestion finds support from other structural data for **2***a*; thus the Rh—Rh bond length is longer for the bromophenyl than for the diphenyl complex. Further, the angles at the rhodium bearing the phenyl are also slightly larger than those at the rhodium bearing the bromine, e.g., for CH_2-Rh-CH_2 99.6(2) against 98.1(2)°.

For the whole series of 10 structurally characterized dinuclear complexes, the Rh—CH_2 distances are all rather similar (typically 2.01–2.06 Å), within the experimental limits, as are the angles Rh-CH_2-Rh (typically 80°–83°) and CH_2-Rh-CH_2 (typically 96°–99°). The angles X-Rh-CH_2 do vary somewhat,

but are quite close to perpendicular (85°–95°); thus the coordination about the metal atoms with respect to the two CH_2's and the R or X ligand is reasonably thought of as *fac*-octahedral. The Rh—R bond lengths in the three complexes $[\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2R_2]$, R = Me, 2.118 av.(16) Å (4); R = Ph, 2.039(6), and R = CH=CH_2, 2.001(6) Å (7) probably reflect the different hybridizations at the carbon (and hence their different sizes), and differential π-bonding to the metal.

The two phenyl groups and the two η^5-C_5Me_5 rings in complex **3** are *trans* to each other; this arrangement is also retained in solution, as shown by the ^{1}H NMR spectra of the methylenic hydrogens. In addition to synthesizing the phenyl complexes **2***a* and **3**, we have also made the mono-*p*-tolyl and the mono-*p*-fluorophenyl complexes **2***b* and **2***c*, by the same route and in similar yield to that for **2***a*. The ^{1}H NMR spectra in the μ-CH_2 region again indicate that all the complexes have the same, *trans*, structure in solution. It is interesting that there is no indication of any dynamic behaviour (or isomerization to a *cis* isomer) in the NMR spectra of any of the complexes **2***a–c* even in acetone-d_6 down to −40°C. This contrasts with the situation in the related methylchloro complex, $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Me)(Cl)]$, which is static in C_6D_6 but shows isomerization and dynamic behaviour in even slightly more polar solvents (11).

Conclusion

The di-μ-methylene-dirhodium complex $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}(Br)_2]$ undergoes a halide-specific reaction with PhMgBr that gives, first, the monophenyl complex **2***a* $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Ph)(Br)]$ and then the diphenyl complex **3** $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(Ph)_2]$. X-ray crystal structure determinations showed both molecules to have *trans* structures. There are no obvious structural features that suggest why previous attempts to make phenyl complexes of this series failed, but the success of the Grignard reaction here does appear to depend on the exclusive use of bromides.

Experimental

^{1}H NMR and ^{13}C NMR spectra were measured on a Bruker AM-250 spectrometer using the solvent as internal standard, and IR spectra on a Perkin–Elmer 1710 FT spectrometer. Elemental analyses were performed by the Sheffield University Microanalysis Service. FAB-MS spectra were recorded on a Fisons-VG ProSpec 3000 spectrometer.

All reactions were carried out under nitrogen in Schlenk tubes. Solvents were dried and distilled immediately prior to use. Phenylmagnesium bromide, *p*-fluorophenylmagnesium bromide, and *p*-tolylmagnesium bromide were purchased from Aldrich; $[\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2Me_2]$, $[\{(C_5Me_2)Rh(\mu\text{-}CH_2)\}_2Br_2]$, and $[\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2Cl_2]$ were prepared according to published procedures (1–9).

$[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CH_2)\}_2(C_6H_5)Br]$ (2*a*)

Phenylmagnesium bromide in ether (3.0 M; 0.1 mL, 0.3 mmol) was added dropwise over 10 min by syringe to a deep red solution of $[\{(C_5Me_5)Rh(\mu\text{-}CH_2)\}_2Br_2]$ (66.4 mg, 0.1 mmol) in freshly distilled toluene, and was cooled to −40°C. The solution was allowed to warm slowly from −40°C to −10°C over 4 h; it was then quenched with saturated aqueous NH_4Br (100 μL), and filtered. The filtrate was evaporated to dryness, and the resulting brown-red solid was extracted with pentane (3 × 50 mL) and the extract filtered and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

evaporated to afford 53 mg (86%) of analytically pure **2*a*** after recrystallization from hexane. ^{1}H NMR ($CDCl_3$) δ: 1.27 and 1.56 (2 × C_5Me_5), 7.05 (dt, 2H, *o*-Ph), 6.86 (tt, 2H, *m*-Ph), 6.72 (tt, 1H, *p*-Ph); 9.28 (ddd, 2H, *J*(Rh–H) 4.5; *J*(H–H) 2 Hz, μ-CH_2), 10.26 (ddd, 2H, *J*(Rh–H) 5; *J*(H–H) 2Hz, μ-CH_2). ^{13}C NMR δ: 9.3 and 10.2 (2 × C_5Me_5), 103.6 (s) and 101.4 (d, *J* 5 Hz, C_5Me_5), 156.4 (d, *J*(Rh–C) 41 Hz, i-Ph), 138.2 (s, *o*-Ph), 121.9 (s, *m*-Ph), 127.3 (s, *p*-Ph), 178.6 (dd, *J*(Rh–C) 30 Hz, CH_2). Anal. calcd. for $C_{28}H_{39}BrRh_2$: C 50.85, H 5.9, Br 12.1%, MW 661; found: C 50.8, H 5.8, Br 12.05%, MS, FAB$^+$: *m/e* 661 (M^+, 10%).

Crystals of **2*a*** were grown from diethyl ether as red blocks; crystal dimensions 0.80 × 0.40 × 0.30 mm; the crystallographic data are summarized in Table 3. Crystal data for $C_{28}H_{39}BrRh_2$: M = 661.32. Triclinic, a = 10.066(3), b = 11.065(3), c = 14.002(3) Å, α = 85.23(2)°, β = 70.10(2)°, γ = 65.22(2)°, U = 1328.2(6) Å^3, Z = 2, D_c = 1.654 g cm^{-3}, space group $P\bar{1}$ (C_i^1, No. 2), Mo-K_α radiation ($\bar{\lambda}$ = 0.71073 Å), μ(Mo-K_α) = 27.60 cm^{-1}, F(000) = 664. Three-dimensional, room temperature X-ray data were collected in the range 3.5 < 2θ < 45° on a Siemens P4 diffractometer by the ω scan method. The 3239 independent reflections (of 4302 measured) for which $|F|/\sigma(|F|) > 4.0$ were corrected for Lorentz and polarization effects, but not for absorption. The structure was solved by direct methods and refined by full-matrix least squares on F^2. Hydrogen atoms were included in calculated positions and refined in riding mode. Refinement converged at a final R = 0.0586 (wR_2 = 0.1572 for all 4302 unique data, 280 parameters, mean and maximum δ/σ 0.000, 0.000), with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density −2.62 and 1.99 e Å^{-3}. A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.1313*P)^2 + 1.29*P]$ where $P = (F_o^2 + 2*F_c^2)/3$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXL 93 (12) as implemented on the Viglen 486dx computer.

Selected bond lengths and angles, crystallographic parameters, and fractional atomic coordinates are in Tables 1, 3, and 4 respectively; further details, tables of bond lengths and angles, thermal parameters, and atomic coordinates have been deposited as supplementary material.[2]

Table 5. Crystal data and structure refinement for complex **3**, [{(C_5Me_5)Rh(μ-CH_2)}$_2$($Ph)_2$].

Empirical formula	$C_{34}H_{44}Rh_2$
Formula weight	658.51
Temperature	293(2) K
Wavelength	0.71073 Å
Crystal system	Orthorhombic
Space group	*Pccn*
Unit cell dimensions	a = 17.102(8) Å α = 90°
	b = 10.396(4) Å β = 90°
	c = 16.134(7) Å γ = 90°
Volume	2869(2) Å^3
Z	4
Density (calculated)	1.525 Mg m^{-3}
Absorption coefficient	1.171 mm^{-1}
F(000)	1352
Crystal size	0.7 × 0.45 × 0.3 mm
θ range for data collection	2.29 to 22.48°
Index ranges	$-1 \le h \le 18$, $-1 \le k \le 11$, $-1 \le l \le 17$
Reflections collected	2567
Independent reflections	1877 (R_{int} = 0.0244)
Absorption correction	Semi-empirical
Max. and min. transmission	0.355 and 0.294
Refinement method	Full-matrix least squares on F^2
Data/restraints/parameters	1877/0/163
Goodness-of-fit on F^2	1.078
Final R indices [$I > 2\sigma$(I)]	$R1$ = 0.0426, $wR2$ = 0.1178
R indices (all data)	$R1$ = 0.0521, $wR2$ = 0.1235
Largest diff. peak and hole	0.674 and −0.555 e Å^{-3}

0.1 mmol) in freshly distilled toluene (10 mL) cooled to −40°C. The reaction mixture was stirred at this temperature, and was allowed to warm slowly to −10°C over 2 h; it was finally allowed to warm to room temperature, where it was stirred for 6 h. The mixture was then quenched with saturated aqueous NH_4Br (100 μL), filtered, and the filtered solution quickly passed through a short Florisil column, eluting with toluene. Removal of the toluene in vacuo left a red solid, which was extracted with pentane (15 mL); removal of the pentane left 34 mg (52%) of analytically pure [{(C_5Me_5)Rh(μ-CH_2)}$_2$$Ph_2$]. ^{1}H NMR ($CD_2Cl_2$) δ: 1.12 (s, 30H, C_5Me_5), 8.90 (t, μ-CH_2, 4H, J(Rh–H) 1.5 Hz), 7.0 (dt, 4H, J 7 Hz, 1.5 Hz), 6.76 (dt, 4H, J 7 Hz, 1.5 Hz), 6.68 (dt, 2H, J 7 Hz, 1.5 Hz). ^{13}C NMR (CD_2Cl_2) δ: 9.37 (s, C_5Me_5), 102.4 (s, C_5Me_5), 121.7(s), 126.9(s), 139.4 (s), 156.6 (dd, J 43 and 10 Hz), 174.2 (t, CH_2, J(Rh–C) 29 Hz). Anal. calcd. for $C_{34}H_{44}Rh_2$: C 62.0, H 6.7, M 658; found: 61.9, 6.8%, FAB–MS: 658 (M$^+$, 100%).

Deep red oblong crystals of **3** were grown from pentane–methanol, the crystallographic data are summarized in Table 5. Crystal data for $C_{34}H_{44}Rh_2$: M = 658.51; crystal dimensions 0.70 × 0.45 × 0.3 mm. Orthorhombic, a = 17.102(8), b = 10.396(4), c = 16.134(7) Å, U = 2869(2) Å^3, Z = 4, D_c = 1.525 g cm^{-3}, space group *Pccn* (D^{10}_{2h}, No. 56), Mo-K_α radiation ($\bar{\lambda}$ = 0.71073 Å), μ(Mo-Kα) = 1.171 mm^{-1}, F(000) = 1352. Three-dimensional, room temperature X-ray data were collected in the range $3.5 < 2\theta < 45°$ on a Siemens P4 diffractometer by the ω scan method. The 1518 independent reflections (of 2567 measured) for which $|F|/\sigma(|F|) > 4.0$ were corrected for Lorentz and polarization effects, and for absorption by analysis of 10 azimuthal scans (minimum and maximum transmission coefficients 0.294 and 0.355). The structure was solved by direct methods and refined by full-matrix least squares on F^2. Hydrogen atoms were included in

Tin and lead derivatives of a Schiff base – bis(orthoquinone) ligand

Bruce R. McGarvey, Andrzej Ozarowski, Zhigang Tian, and Dennis G. Tuck

Abstract: The condensation of two molecules of 3,5-di-*tert*-butylcatechol (dbc) with ammonia under oxidizing conditions is believed to proceed via a keto-imine radical. Further condensation, and subsequent reaction with tin(II) or lead(II) halides, yields complexes of identical composition, M[dbqdi]$_2$, where dbqdi is 3,5-di-*tert*-butyl-1,2-quinone-1-(2-hydroxy-3,5-di-*tert*-butylphenyl)imine anion; this name is used without prejudice as to the actual structure of the ligand. The two compounds differ in crystallographic and magnetic properties, and ESR measurements show that the tin compound has a triplet ground state. Both involve six-coordination of the metal in a distorted environment; tin is in the +IV state, but lead is +II, and there are corresponding differences in the form of the ligand. For Sn^{IV}(dbqdi)$_2$, the crystal parameters are orthorhombic, space group $C222_1$, a = 19.597(4), b = 24.375(4), c = 23.755(6) Å, Z = 8, and R = 0.073 for 1405 unique reflections. For Pb^{II}(dbqdi)$_2$, monoclinic, space group $P2_1/n$, a = 14.56(1), b = 25.967(9), c = 15.13(1) Å, β = 99.81(7)°, Z = 4, R = 0.065 for 4911 unique reflections. The different complexation behaviour is shown to be a consequence of the redox properties of the two metallic elements.

Key words: tin, lead, ESR, coordination chemistry, electron transfer.

Résumé : On croit généralement que la condensation de deux molécules de 3,5-di-*tert*-butylcatéchol (dbc) avec de l'ammoniac, dans des conditions oxydantes, se produit par le biais d'un radical céto-imine. Une condensation subséquente, avec réaction ultérieure avec des halogénures d'étain(II) ou de plomb(II), fournit des complexes de composition identique, M(dbqdi)$_2$, dans lesquels dbqdi est l'anion 3,5-di-*tert*-butyl-1,2-quinone-1-(2-hydroxy-3,5-di-*tert*-butylphényl)imine; on utilise ce nom sans égard à la structure réelle du coordinat. Les propriétés cristallographiques et magnétiques des deux composés sont différentes et les mesures de RPE indiquent que le dérivé de l'étain possède une état fondamental triplet. Les deux impliquent un niveau de coordination de six pour le métal, avec un environnement déformé; l'étain est dans un état +IV alors que pour le plomb il est de +II et on peut observer des différences correspondantes dans le forme du coordinat. Pour le Sn^{IV}(dbqdi)$_2$, les cristaux sont orthorhombiques, groupe d'espace $C222_1$, avec a = 19,597(4), b = 24,375(4) et c = 23,755(5) Å, Z = 8 et R = 0,073 pour 1405 réflexions uniques. Pour le Pb^{II}(dbqdi)$_2$, les cristaux sont monocliniques, groupe d'espace $P2_1/n$, avec a = 14,56(1), b = 25,967(9) et c = 15,13(1) Å, β = 99,81(7)°, Z = 4 et R = 0,065 pour 4911 réflexions uniques. On montre que le comportement différent de complexation est un conséquence des propriétés redox de deux éléments métalliques.

Mots clés : plomb, étain, RPE, chimie de coordination, transfert d'électron.

[Traduit par la rédaction]

Introduction

The reactions of substituted orthobenzoquinones with main group elements, or the low oxidation state derivatives of such elements, have been the subject of a number of recent papers from this laboratory. In general, the products of these processes are the appropriate catecholate or semiquinone derivatives, which have been characterized by spectroscopic and crystallographic methods. An important feature of these results is that the redox reactions in question have been shown to be one-electron transfer processes (1).

We have now extended this research to an investigation of the structure of the compounds formed when tin or lead in the +II state react with a heavily substituted catechol. Girgis and Balch (2) found that by treating an aqueous ethanol solution of 3,5-di-*tert*-butylcatechol and various divalent metal ions (Mg, Zn, Fe, Ni, Cu, Cd) with concentrated ammonium hydroxide in the presence of air, complexes of the 3,5-di-*tert*-butyl-1,2-quinone-1-(2-hydroxy-3,5-di-*tert*-butylphenyl)imine (dbqdi) anion could be formed. This name is used without prejudice since, in principle and in practice, this ligand may exist in forms varying in charge from +1 to −3, as shown in Scheme 1, and we refer to these as dbqdi-I, etc. in the discussion of our results.

All of these species may contribute in principle in the ligation of this interesting system. Many such complexes of transition metal complexes, with the metal in different oxidation

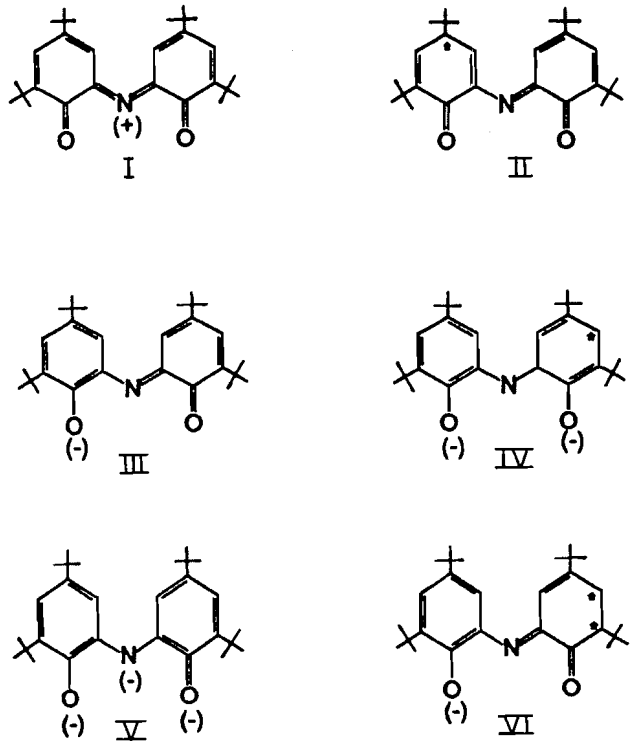
Scheme 1.



states (e.g., M^{2+}, M = Ni, Cu, Zn, Cd; M^{3+}, M = Fe, Co; M^{4+}, M = Ti, Mn) have been prepared and studied by spectroscopic, electrochemical, and X-ray crystallographic methods (2–6), but there has been relatively little work on main group analogues. In addition to the preparative work by Girgis and Balch, Stegmann, Ulmschneider, and Scheffler (7, 8) reported that a series of tin(IV) complexes could be produced from the reaction of 2-amino-4,6-di-*tert*-butylphenoxyl with aryltin(IV) halides, although the structure which they proposed has been questioned (2). One of the interesting outcomes of the present work is that reactions involving tin(II) and lead(II) halides as starting materials give rise to products with differing magnetic and structural characteristics.

Experimental section

General techniques

All the chemicals in this work were reagent grade or better, and were used as supplied. Microanalysis was carried out by Canadian Microanalytical Services Ltd. Infrared spectra in the 400–4000 cm^{-1} region were run as KBr discs on a Nicolet 5DX spectrometer, ^1H and ^{13}C NMR spectra on a Bruker AC-300L spectrometer, the UV–visible spectrum on a Shimadzu spectrometer, and ESR spectra on a Bruker ESP-300 instrument, using methods described previously (9).

Preparative

Reaction with $SnCl_2$

Tin(II) chloride (0.113 g, 0.6 mmol) was suspended in a solution of 3,5-di-*tert*-butylcatechol (0.530 g, 2.41 mmol) in 95% ethanol (50 cm^3). After addition of concentrated aqueous ammonia (5 cm^3), a stream of air was gently bubbled through the mixture, whereupon the solution turned dark blue. After overnight stirring, this solution was filtered and the dark blue solid was collected and washed with 95% ethanol (2 × 5 cm^3). The vacuum-dried product weighed 0.480 g; yield 75%, based on the proposed molecular formula. Anal. calcd. for $C_{56}H_{80}N_2O_4Sn$: C 69.8, H 8.37, N 2.91%; found: C 69.5, H 8.29, N 2.92. Crystals suitable for X-ray crystallographic analysis were obtained by recrystallization of the reaction product from methylene dichloride.

Reaction with PbF_2

(*i*) A suspension of lead difluoride (0.294 g, 1.20 mmol) in a solution of 3,5-di-*tert*-butylcatechol (1.060 g, 4.82 mmol) in 95% ethanol (50 cm^3), was treated with concentrated ammonia solution (5 cm^3), and a stream of air gently bubbled through the mixture. The solution turned dark olive-green at this point and, after about 30 min stirring, a dark black-green solid was detected. After being stirred overnight, the mixture was filtered, and the dark green solid product washed with 95% ethanol (2 × 5 cm^3). The vacuum-dried product weighed 1.010 g; yield 80%, based on the proposed molecular formula. Anal. calcd. for $C_{56}H_{80}N_2O_4Pb$: C 63.9, H 7.66, N 2.66%; found: C 63.9, H 7.57, N 2.70. Recrystallization from chloroform gave crystals suitable for X-ray crystallography.

(*ii*) In a related experiment, 3,5-di-*tert*-butyl-*o*-benzoquinone (0.265 g, 1.21 mmol) and 3,5-di-*tert*-butylcatechol (0.265 g, 1.21 mmol) reacted with lead(II) fluoride (0.147 g, 0.6 mmol). The same procedure as in (*i*) was used, except that the treatment with air was omitted. The vacuum-dried dark green product weighed 0.485 g; yield 72%. The product of this reaction had the same IR and ^1H NMR spectra as in (*i*).

Both compounds are moderately soluble in chloroform, acetone, and dichloromethane, giving dark blue (Sn) or green (Pb) solutions. The lead complex has broad strong absorption at 778, 467, 352, 293 sh, and 232 nm (cf. 793, 736, 430, 365, 300 sh, and 241 nm for the zinc complex (2).

Crystallographic analysis

(*i*) In the study of $SnO_4N_2C_{56}H_{80}$, **1**, a dark blue block crystal on a glass fibre was mounted in a Rigaku AFC6S diffractometer, equipped with graphite monochromated Mo- Kα radiation (λ = 0.71069 Å) and a rotating anode generator. Cell constants, and orientation matrices for data collection, were obtained from least-squares refinements, using 20 carefully centred reflections in the range $12.61 < 2\theta < 19.62°$. Based on the systematic absences *hkl*: $h + k \neq 2n$; 001: $l \neq 2n$, the space group was uniquely identified as $C222_1$ (no. 20), and this was confirmed by subsequent solution and refinement of the structure. Details of the intensity collection are given in Table 1.

The intensities of three representative reflections were measured after every 150 reflections. Over the course of data collection, the standards decreased by −2.1%, and a linear correction factor was applied to the results. Absorption corrections were unnecessary (cf. Table 1), but the values were corrected for Lorentz and polarization effects. The structure was solved by direct methods, and expanded using Fourier techniques. The non-hydrogen atoms were refined isotropically; hydrogen atoms on carbon were included in ideal positions but were not refined. The final cycle of full-matrix least-squares refinement was based on 1405 observed reflections ($I > 3\sigma(I)$) and 253 variable parameters, and the solution converged at

R	0.073	0.065
R'	0.065	0.072
Maximum shift/error in final cycle	0.01	0.08
Maximum, minimum peaks in final difference map (e Å^{-3})	0.70, −0.68	0.96, −1.55

Fig. 1. Structure of Sn(dbqdi)$_2$, showing the numbering system; ORTEP diagram, with atoms shown as 30% probability ellipsoids. Hydrogen atoms have been omitted for clarity.

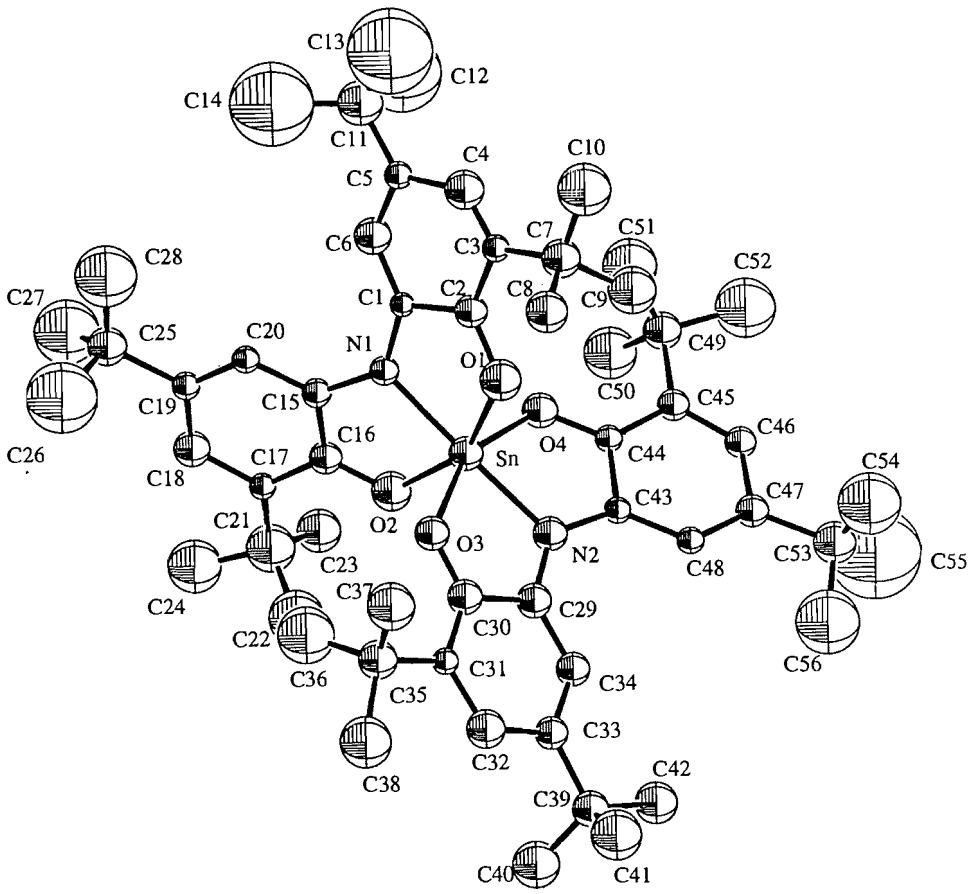

Fig. 2. Structure of $Pb(dbqdi)_2$, showing the numbering system; ORTEP diagram, with atoms shown as 30% probability ellipsoids. Hydrogen atoms have been omitted for clarity.

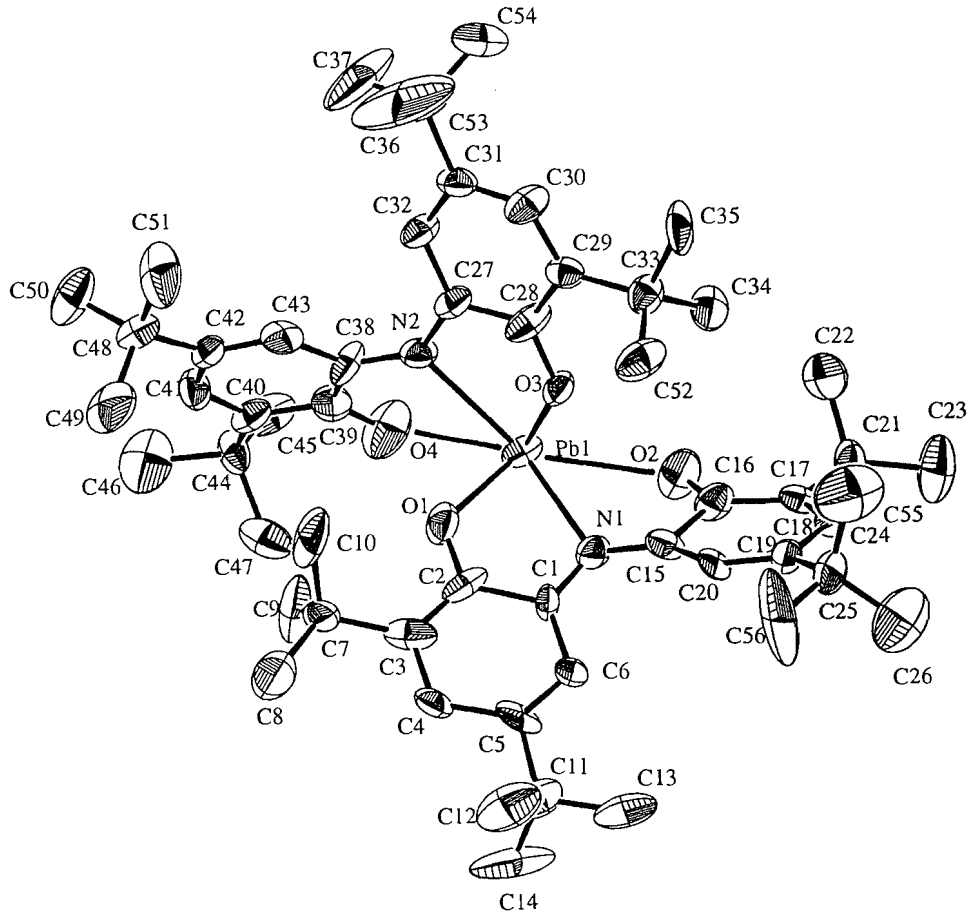

$R = 0.073$ and $R' = 0.065$. A final Fourier difference map calculation showed no peaks of chemical significance; the maximum and minimum peaks corresponded to 0.70 and -0.68 e $Å^{-3}$, respectively.

(*ii*) A dark green block crystal of $PbO_4N_2C_{56}H_{80}$, **2**, was used, with the techniques just described. Cell constants, and an orientation matrix for data collection, were obtained from a least-squares refinement using 25 carefully centred reflections in the range $25.12 < 2\theta < 29.06°$. From the systematic absences $h0l$: $h + l \neq 2n$; $0k0$: $k \neq 2n$, the space group was identified as $P2_1/n$ (no. 14), and this was confirmed by subsequent solution and refinement of the structure. Details of the intensity collection are given in Table 1.

No decay correction was applied, since the intensities of three representative reflections, measured after every 150 reflections, remained constant throughout the data collection, indicating crystal and electronic stability. An empirical absorption correction, using the program DEFABS (10), was applied with transmission factors ranging from 0.92 to 1.01; the data were also corrected for Lorentz and polarization effects. The structure was solved by direct methods. The non-hydrogen atoms were refined anisotropically, except that carbon atoms C(7)–C(13), C(17), C(38), C(41), and C(44)) were refined isotropically; hydrogen atoms on carbon were initially included in ideal positions, and subsequently refined isotropically. After several cycles of refinement, the structure converged to $R = 0.068$ and $R' = 0.083$. A final Fourier difference map calculation showed no peaks of chemical significance; the maximum and minimum peaks corresponded to 1.20 and 1.90 e $Å^3$, respectively.

In both sets of calculations, neutral-atom scattering factors were taken from Cromer and Waber (11). Anomalous dispersion effects were included in the calculations (12); the values for $\Delta f'$ and $\Delta f''$ were those published by Cromer (13). All calculations were performed using the TEXSAN (14) crystallographic software package. The structure of the molecules are shown in Figs. 1 and 2, the positional parameters are in Table 2 and 4, and the important bond distances and angles in Tables 3 and 5.

Tables of hydrogen-atom coordinates and thermal parameters, anisotropic thermal parameters for other atoms, least-squares planes, and structural data for aromatic rings and *tert*-butyl groups for each structure are available as supplementary data.[2]

[2] This supplementary data can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom coordinates and structural data have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Results and discussion

Spectroscopic

The structural differences between the tin and lead derivatives of dbqdi are immediately illustrated by their ESR and NMR spectra. A solution of the tin compound in toluene at room temperature gave a complicated partially resolved ESR spectrum, centred at $g = 2.0016$, and with $A_{Sn} \sim 12$ G (Fig. 3). The spectrum of the frozen solution (Fig. 4) is clearly that of a molecule with a triplet spin state. The zero-field splitting parameters D and E which can be derived from this spectrum are $D = 0.121 \pm 0.005$ cm^{-1} and $E \sim$ O. These is also a sharp line in the centre of the spectrum, of negligible intensity, and we believe that this is due to contamination by some unidentified mono-radical species.

The magnitude of D, which measures the extent of the dipole–dipole interaction between the two spins in the $Sn(dbqdi)_2$ molecule, calls for some discussion. The value is 5–10 times higher than in a series of *cis*-$M(dbbsq)_2$ complexes (15) (M = Mg, Zn, Cd; dbbsq = 3,5-di-*tert*-butyl-1,2-benzosemiquinonate anion), for which D is typically 0.02 cm^{-1}, and $E \sim 0.0005$ cm^{-1}. In the *cis* and *trans* Sn—Sn bonded dimers $(Cl_2(dbbsq)SnSn(dbbsq)Cl_2$, in which the semiquinone ligands are of the order of 5 Å apart, the D values are 0.023 and 0.0065 cm^{-1}, respectively (9). In our previous work (15), the dipole–dipole interactions were calculated using the assumption that each of the two unpaired electrons was delocalized over one aromatic ring of dbbsq, but this approach is not applicable in the present case; even with the unrealistic assumption that the electrons are localized on each of the two nitrogen atoms bonded to tin, we calculate $D = 0.093$ cm^{-1}, which is significantly below the experimental value. This implies that we are dealing with a triplet state in which both unpaired spins are delocalized over both ligands. The EPR spectrum of a dilute liquid solution (Fig. 3) is qualitatively in agreement with this conclusion, although we have not been able to simulate this spectrum. The intensity of the EPR frozen solution spectrum increases with decreasing temperature at rate higher than changes in $1/T$, confirming that the ground state of the molecule is a triplet. We return to this point below. The zero value of E appears to be in agreement with the approximately D_{2d} symmetry of the coordination kernel of the complex, and indi-

Table 4 (*concluded*).

cates that the structure identified in the solid state is retained in the solution phase.

The lead complex is diamagnetic, and ^1H and ^{13}C NMR spectra have been recorded (See Table 6). The ^1H spectrum is in keeping with those of corresponding zinc and cadmium species, of the parent 3,5-di-*tert*-butylcatechol, and of the related *o*-quinone. No spectrum of the free dbqdi ligand is available; paramagnetic species were present in the parent solution from which $Pb(dbqdi)_2$ was isolated (see below) and an NMR spectrum could therefore not be obtained from this source. The most obvious feature of the ^{13}C spectrum of $Pb(dbqdi)_2$ is the presence of four resonances for each type of *tert*-butyl carbon atom, and two for each of the aromatic carbon atoms. The assignments in Table 6 follow from previous work (16), and from the crystallographic results; C^1 is the highest frequency, being attached to an imido nitrogen, and C^6 is bonded to a phenolic oxygen. The asymmetry of the dbqdi ligand in this compound is consequent upon the differing Pb—O bond lengths (see below), and accounts for the four different sets of *tert*-butyl resonances, and the two different aromatic rings. The largest difference in these ^{13}C resonances is at C^1 (9.1 ppm), with smaller values of ca. 5 ppm for C^2, C^4, and C^6, and of ca. 1.5 ppm for C^3 and C^5, which carry the *tert*-butyl groups. This again is in keeping with the differences in the C—N and C—O bonds in the structure.

The infrared spectra are less informative; the most noteworthy features are the absence of both N-H and O-H modes, and of vibrations in ν(C=O) region, for each complex.

Structural

The complex $Sn(dbqdi)_2$, **1**, consists of a six-coordinate tin atom bonded to two identical ligands, with a SnO_4N_2 core which is far from octahedral in symmetry because of the constraints imposed by the ligand geometry. In contrast to the lead derivative, the tin–ligand interaction is essentially symmetrical, with two Sn—O bonds whose lengths (Sn—O(1) = 2.08(2) Å, Sn—O(2) = 2.07(3) Å; Sn—O(3) = 2.05(2) Å, Sn—O(4) = 2.07(2) Å) are identical for both ligands within experimental error. These values are close to those reported for other tin(IV) compounds, as in $Sn(trop)_2Cl_2$ (trop = tropolonate anion) (Sn—O = 2.07(s) (avg.)) (17); $Sn(malt)_2Cl_2$ (malt = 3-hydroxy-2-methyl-4-pyronate anion) (Sn—O = 2.09(1) (avg.)) (17); $[Sn(O_2C_6Cl_4)_3]^{2-}$ (Sn—O = 2.06(1) (avg.) (18); and a series of substituted phenol derivatives (Sn—O = 2.07(1) (avg.)) (19). Similar agreement can be found between *r*(Sn—N) in **1** (2.08(3) Å) and the values

in diperchlorato-tetraphenolporphinatotin(IV), for which *r*(Sn—N) = 2.073 Å (20). Longer bonds have been observed in molecules in which $NHMe_2$ is coordinated to tin phenolates (Sn—N = 2.30 Å (avg.)) (19), or in which the donor is 2-(2-pyridyl)benzimidazole (L); Sn—N for Me_2SnCl_2L = 2.422(2) and 2.447(2) Å, and for $SnBr_4L$ = 2.212(4) and 2.271(4) Å) (21). The average C—O bond length in **1** is 1.32(3) Å, between the characteristic values for C=O in *o*-semiquinones and C—O in catecholates (1). The C—N bond lengths (1.40(4) Å, avg.) and angles (C-N-C = 129(3)°) suggest that there is some double bond character.

The most immediate contrast between the tin and lead compounds lies in the M—O bonds, which are highly unsymmetrical in the latter case, with Pb—O = 2.28(2) and 2.78(2) Å. The shorter of these is similar to that in a macrocyclic Schiff base derivative of lead(II), for which Pb—O = 2.337 Å (avg.) (22); in contrast, Pb—O in the organolead(IV) compound (23) $Ph_3PbOSiPh_3$ is 2.01 Å. The larger Pb—O distance, and the Pb—N value of 2.59(2) Å, are similar to those in a lead(II) tetraimine Schiff base (2.54 and 2.67 Å (avg.), respectively) (24); in crown ether derivatives of $Pb(NO_3)_2$, Pb—O distances range between 2.645 and 3.060 Å (25, 26). In general, these results point to the presence of lead in the +II state, with one weak and one strong Pb—O bond. In keeping with the Pb—O bond distances, we find two different C—O bonds, one averaging 1.31(2) Å and the other 1.27(2), and two C—N bonds at 1.28(2) and 1.38(3) Å.

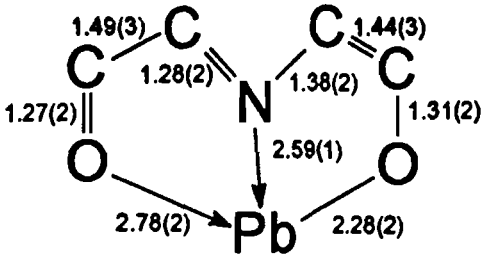
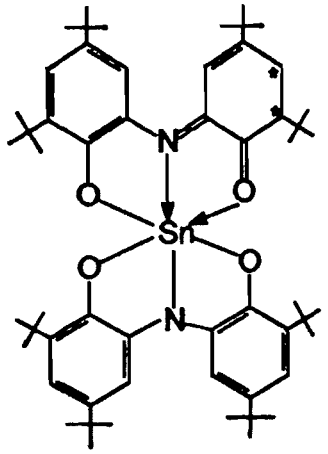
Scheme 2.



Scheme 3.



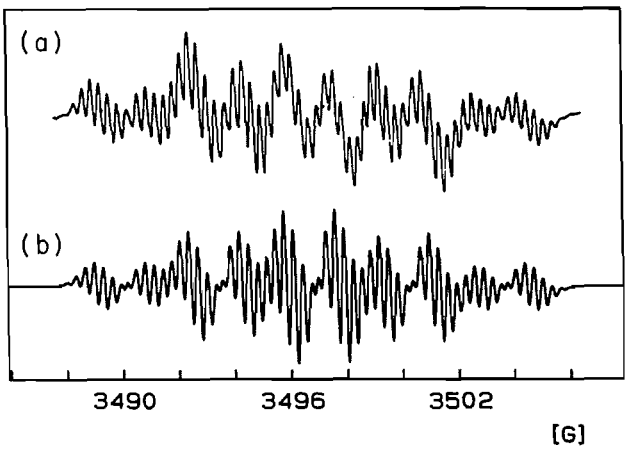
These results, and the spectroscopic data, allow some conclusions about the structure of the ligand in the two complexes. The lead complex is the easier to assign, since the diamagnetism allows only dbqdi-III and V to be considered, and since V would require lead to be in the +VI oxidation state, $Pb^{II}(dbqdi\text{-}III)_2$ is the only reasonable structure. The two Pb—O bond lengths reflect the different oxygen atoms in this form of the ligand, and point to the absence of delocalization, at least within the coordination kernel. Within the limits of the experimental errors, this is borne out by the C—N bond distances as shown in Scheme 2. The C—C bond lengths clearly do not support this idealized structure, but these bonds are part of aromatic rings so that there must be a considerable influence here from delocalization within these rings. This limitation apart, the formulation as a lead(II) complex of dbqdi-III is well founded.

The structure of the tin compound, with its triplet ground state and symmetrical Sn—O bonding, can be understood in terms of a delocalized structure, one localized form of which is shown in Scheme 3. In this formula, the ligands are portrayed as the diradical monoanion V and the anion VI, of charge −3, so that the oxidation state of tin is +IV. The C—N and C—O bonds are both of order 1¼, which is in keeping with the experimental results. A description of the actual molecular orbital scheme that leads to delocalization over the whole molecule has yet to be established.

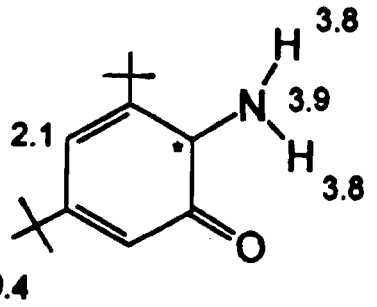
General and preparative

The ligand dbqdi is formed by the condensation of two molecules of dbc with ammonia, followed by deprotonation, oxidation, and electron redistribution. The ESR spectrum of a

Fig. 5. (*a*) ESR spectrum of solution formed during the preparation of $Pb(dbqdi)_2$. (*b*) Simulated spectrum.



Scheme 4.



sample of the solution remaining after the synthesis and collection of the lead complex is shown in Fig. 5(*a*). There is no evidence of splitting due to coupling to a lead atom, and the spectrum can be simulated by assuming that one *tert*-butyl group ($A_H = 0.40$ G), two equivalent hydrogens with $A_H = 3.81$ G, a second hydrogen with $A_H = 2.08$ G, and a nitrogen atom with $A_N = 3.93$ G each contribute to the splitting pattern. This interpretation appears to rule out a molecule with an unpaired electron delocalized over two aromatic rings, or with an unpaired electron on one ring of a structure such as II or IV in Scheme 1, and the spectrum is tentatively assigned as being that of the species shown in Scheme 4, with the identification of the *A* values as shown. The spectrum can be reasonably simulated using these hyperfine coupling constants (Fig. 5(*b*). Further condensation of dbc at the amino site, and deprotonation, could give rise to dbqdi-III, which would be ESR-silent.

The reactions of this species with a metal ion will then depend on the redox properties of this ion. In the case of lead (II), straightforward ligation

$$[1] \quad Pb^{2+} + 2[dbqdi\text{-}III]^- \rightarrow Pb^{II}[dbqdi\text{-}III]_2$$

would give the observed diamagnetic complex in which one Pb—O bond is covalent, and the other weaker interaction is essentially weak donation from the carbonyl oxygen of the ligand. In the case of tin(II), which is a stronger reducing state than lead(II), the initial complex formation would be followed, or accompanied, by reduction of each of the ligands from

dbqdi-III to dbqdi-IV, which contains one more electron, and the subsequent delocalization to give the structure discussed above

[2] $Sn^{2+} + 2[dbqdi\text{-}III]^{-} \rightarrow Sn^{II}[dbqdi\text{-}III]_2$

[3] $\rightarrow Sn^{IV}[dbqdi\text{-}IV]_2$

[4] $\rightarrow Sn^{IV}[dbqdi\text{-}V][dbqdi\text{-}VI]$

The identification of the tin and lead derivatives of dbqdi as involving both metal and ligand in differing oxidation states is confirmed by both ESR and crystallographic evidence.

These results are compatible with earlier work on the complexes of transition metals with the dbqdi ligand, but show some of the characteristic features of main group chemistry in that the differing redox properties of tin and lead are key to understanding both the preparative route and the structural characteristics of these complexes.

Abstract: The binary carbonyl $Os_4(CO)_{15}$, **1**, has been prepared by the addition of $Os(CO)_5$ to $Os_3(CO)_{10}$-(cyclooctene)$_2$ at −15°C. The related clusters $Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$, **2**, and $Os_4(CO)_{14}(CNBu^t)$, **3**, have been synthesized from $Os_4(CO)_{13}(PMe_3)$ and $Os_4(CO)_{15}(CNBu^t)$, respectively. The crystal structures of **1**, **2**, and **3** reveal similar planar metal skeletons with short (2.774 (1) – 2.793 (2) Å) and long (2.978 (2) – 3.019 (2) Å) peripheral Os—Os bonds; the hinge Os—Os bond in **1–3** ranges in length from 2.936 (2) to 2.948 (1) Å. The variable temperature ^{13}C nuclear magnetic resonance spectra of **1** and **3** show that both are highly nonrigid in solution even at −120°C. The mechanism of nonrigidity is believed to be an all-equatorial, merry-go-round carbonyl exchange. The variable temperature ^{13}C nmr spectra of **2** indicate it is rigid on the nmr time scale in solution at −45°C. Carbonyl exchange is, however, observed in the spectrum at −6°C. From the mode of collapse of the signals it is believed that the lowest energy exchange processes in **3** involve axial-equatorial, merry-go-round CO exchanges in the two planes that each contain a short Os—Os bond. Crystallographic data for compound **1**: space group $C2/c$; a = 12.802 (3) Å, b = 10.217 (3) Å, c = 16.380 (5) Å, β = 91.39 (2)°; R = 0.044, 1204 observed reflections. For compound **2**: space group $P2_1/c$; a = 11.106 (7) Å, b = 16.931 (5) Å, c = 16.481 (5) Å, β = 97.71 (5)°; R = 0.051, 2117 observed reflections. For compound **3**: space group $P2_1/n$; a = 11.747 (3) Å, b = 18.009 (5) Å, c = 12.448 (2) Å, β = 92.65 (2)°; R = 0.054, 2131 observed reflections.

Key words: osmium, carbonyl, cluster, nonrigidity.

Résumé : On a préparé le complexe carbonyle binaire $Os_4(CO)_{15}$, **1**, par addition du $Os(CO)_5$ à du $Os_3(CO)_{10}$(cyclooctène)$_2$ à −15°C. On a synthétisé les agrégats apparentes $Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$, **2**, et $Os_4(CO)_{14}(CNBu^t)$, **3**, à partir du $Os_4(CO)_{13}(PMe_3)$ et $Os_4(CO)_{15}(CNBu^t)$ respectivement. Les structures cristallines des composés **1, 2** et **3** révèlent que les squelettes métalliques sont plans et similaires avec des longueurs de liaisons périphériques Os—Os courtes (2,774 (1)–2,793 (2) Å) et longues (2,978 (2)–3,019 (2) Å); la longueur de la liaison charnière Os—Os des composés **1–3** varie de 2,936 (2) à 2,948 (1) Å. Les spectres de résonance magnétique nucléaire du ^{13}C à température variable des composés **1** et **3** montrent que les deux manquent grandement de rigidité, même à −120°C. On croit que ce manque de rigidité provient d'un mécanisme d'échange de carbonyle de type carrousel entièrement èquatorial. Les spectres de rmn du ^{13}C à température variable du composé **2** indiquent qu'il est rigide à l'échelle de temps de la rmn, en solution, à −45°C. On observe toutefois un échange de carbonyle à −6°C. Sur la base du mode de disparition des signaux, on croit que les processus d'échange de basse énergie dans le composé **3** impliquent des échanges de CO de type carrousel axial-équatorial dans les deux plans qui contiennent chacun une liaison Os—Os courte. Les données cristallographiques du composé **1** sont : groupe d'espace $C2/c$, avec a = 12,802 (3), b = 10,217 (3) et c = 16,380 (5) Å, β = 91,39 (2)°, et R = 0,044 pour 1204 réflexions observées. Pour le composé **2** : groupe d'espace $P2_1/c$, avec a = 11,106 (7), b = 16,931 (5) et c = 16,481 (5), β = 97,71 (5)°, et R = 0,051 pour 2117 réflexions observées. Pour le composé **3** : groupe d'espace $P2_1/n$, avec a = 11,747 (3), b = 18,009 (5) et c = 12,448 (2) Å, β = 92.65 (2)°, et R = 0,054 pour 2131 réflexions observées.

Mots clés : osmium, carbonyle, agrégat, manque de rigidité.

Introduction

Osmium forms more neutral binary carbonyl compounds than any other transition metal, with compounds with one to eight metal atoms known. The common carbonyls of osmium, namely, $Os(CO)_5$ and $Os_3(CO)_{12}$, were first prepared by Hieber and Stallmann in 1943 (1). Moss and Graham (2) described the synthesis of $Os_2(CO)_9$ in 1970; binary carbonyls with five, six, seven, and eight osmium atoms were first reported in 1972 by the Johnson and Lewis group (3).

It was not, however, until 1987 that work from this laboratory described the preparation of $Os_4(CO)_{15}$, **1**, the first tetranuclear binary carbonyl of osmium (4). Subsequently, $Os_4(CO)_{16}$ and $Os_4(CO)_{14}$ were prepared from **1** (5). The structure of **1** consists of an unusual planar "kite" Os_4 arrangement with adjacent short and long peripheral metal–metal bonds that we had observed previously in $Os_4(CO)_{14}(PMe_3)$ and rationalized in terms of three-center, two-electron metal–metal bonds (6).

Herein, we describe the details of the synthesis and structure of **1**, along with those of two related clusters, $Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$, **2**, and $Os_4(CO)_{14}(CNBu^t)$, **3**. The remarkable nonrigid properties of clusters **1** – **3** as ascertained by ^{13}C nmr spectroscopy are also described. Some of the results presented here, besides appearing in a preliminary communication (4), have also been quoted as unpublished results in a review (7).

Experimental

Reactions and isolation of products were carried out under a nitrogen atmosphere with the use of standard Schlenk techniques; solvents were thoroughly dried before use. The following compounds were prepared by literature methods: $Os(CO)_5$ (8), $Os_3(CO)_{10}$(cyclooctene)$_2$ (9), $Os_4(CO)_{14}(PMe_3)$ (6), and $Os_4(CO)_{15}(CNBu^t)$ (10). An improved preparation of $Os_4(CO)_{13}(PMe_3)$ (6) is described below. The ^{13}CO-enriched clusters were prepared from ^{13}CO-enriched (~40%) $Os_3(CO)_{12}$ (11).

Infrared spectra were recorded on a Perkin–Elmer 983 spectrometer; the internal calibration of the instrument was periodically checked against the known absorption frequencies of gaseous CO. Nuclear magnetic resonance spectra were recorded on a Bruker WM400 or Bruker SY-100 spectrometer. The ^{13}C nmr spectra were obtained on ^{13}CO-enriched samples in a solvent of $CHFCl_2$–CD_2Cl_2 (~5/1) unless otherwise stated. The nmr line-shape simulation shown in Fig. 5 was carried out with a computer program written by Professor R.E.D. McClung of the University of Alberta. The microanalyses were obtained by M. K. Yang of the Microanalytical Laboratory of Simon Fraser University.

Preparation of $Os_4(CO)_{15}$ (1)

A Schlenk tube was cooled to 0°C and $Os_3(CO)_{10}$(cyclooctene)$_2$ (60 mg, 0.057 mmol) in CH_2Cl_2 (2 mL) was added along with $Os(CO)_5$ (~20 mg, ~0.06 mmol) in hexane (30 mL). The vessel was sealed and stored at −15°C for 4 d during which time dark red crystals of product formed. The mother liquor was removed and the crystals were washed with hexane and dried on the vacuum line. This yielded analytically pure $Os_4(CO)_{15}$ (48 mg, 73%) as dark red, air-stable crystals: mp 185°C (dec.). Infrared (CH_2Cl_2) ν_{CO}: 2086 (s), 2073.5 (m), 2045 (vs), 2023 (m), 2002 (sh), 1939 (m, br) cm^{-1}; ^{13}C nmr (−56°C) δ: 190.6 (4C), 188.9 (4C), 171.7 (7C). Anal. calcd. for $C_{15}O_{15}Os_4$: C 15.26, H 0.0; found: C 15.51, H, 0.0.

Improved preparation of $Os_4(CO)_{13}(PMe_3)$

A Pyrex tube was charged with $Os_4(CO)_{14}(PMe_3)$ (98 mg, 0.080 mmol) and hexane (50 mL). The stirred solution was purged with nitrogen and subjected to ultraviolet irradiation for 2.5 h (there were approximately 3 cm between the edge of the reaction vessel and the water jacket of the 200-W ultraviolet light source). The solution was purged for a further 5 min and then concentrated on the vacuum line and stored at −15°C overnight. The mother liquor was decanted from the crystals of $Os_4(CO)_{13}(PMe_3)$ (82 mg, 86%), which were dried on the vacuum line. The product was pure as determined by infrared spectroscopy (6).

Preparation of $Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$ (2)

To a solution of $Os_4(CO)_{13}(PMe_3)$ (48 mg, 0.040 mmol) in hexane (60 mL) at room temperature, $P(OMe)_3$ was slowly added dropwise until the color of the solution changed from red to dark green. An infrared spectrum of the solution at this stage showed no absorptions due to $Os_4(CO)_{13}(PMe_3)$. The solvent and excess $P(OMe)_3$ were removed on the vacuum line, and the brown residue dissolved in a minimum volume of CH_2Cl_2 and chromatographed on a silica gel column (15 × 2.5 cm). A small amount of an unidentified yellow compound was eluted with hexane and discarded. The desired product was eluted as a red-green band with hexane–dichloromethane (1/1). The product-containing fractions were combined, concentrated on the vacuum line, and stored at −15°C for 4 d. The mother liquor was decanted from the red crystals of $Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$ (49 mg, 92%), which were dried under vacuum: mp 127°C. Infrared (CH_2Cl_2) ν_{CO}: 2102 (m), 2075 (w), 2044 (m), 2036.5 (s), 2024 (vs), 2016 (sh), 1997.5 (m), 1977 (sh), 1970 (m), 1961 (m), 1904.5 (m) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.65 (d, J_{PH} = 12 Hz), 1.83 (d, J_{PH} = 11 Hz); ^{13}C nmr (CH_2Cl_2–CD_2Cl_2, −44°C) δ: 214.8 (2C), 203.7 (2C, d, J_{PC} = 9.0 Hz), 201.6 (2C, d, J_{PC} = 12.3 Hz), 195.4 (1C), 178.0 (1C), 176.4 (1C), 173.3 (1C), 173.1 (1C), 173.0 (2C). Anal. calcd. for $C_{19}H_{18}O_{16}Os_4P_2$: C 17.22, H 1.37; found: C 17.66, H 1.45.

Preparation of $Os_4(CO)_{14}(CNBu^t)$

To a stirred solution of $Os_4(CO)_{15}(CNBu^t)$ (76 mg, 0.050 mmol) in CH_2Cl_2 (30 mL) was added Me_3NO (5 mg, 0.07 mmol) slurried in CH_2Cl_2; the solution changed from amber to dark green during the addition. The course of the reaction was also monitored by the disappearance of the ν_{CN} absorption at 2222 cm^{-1} in the infrared spectrum of the solution. Upon completion of the reaction, the solvent was removed on the vacuum line. The green-brown residue was dissolved in a minimum amount of CH_2Cl_2 and the resulting solution filtered through Celite. Hexane was added to the filtered solution, which was then stored at −15°C for 2 d. The mother liquor was decanted from the product, which was washed with hexane and dried on the vacuum line to afford $Os_4(CO)_{14}(CNBu^t)$ (46 mg, 62%): mp 124°C. Infrared (hexane) ν_{CN}: 2185 (m) cm^{-1}; ν_{CO}: 2110 (m), 2074.5 (s), 2066 (s), 2054.5 (s), 2045 (vs), 2030 (vs), 2015 (vs), 2005 (s), 1944.5 (m), 1933.5 (m) cm^{-1}; ^1H nmr (C_7D_8) δ: 0.96, 0.95 (ratio approximately 1:1). Anal. calcd. for $C_{19}H_9NO_{14}Os_4$: C 18.46, H 0.73, N 1.13; found: C 18.42, H 0.97, N 1.28.

X-ray structure determinations of 1, 2, and 3

The following procedure was employed for each of the three structure determinations. Additional details relating to an individual determination are given after the general procedure. A crystal of suitable size (Table 1) was mounted, in air, on an Enraf–Nonius CAD4F diffractometer. Diffraction data unless otherwise stated were collected at 21 ± 1°C with the use of graphite-monochromated Mo Kα, radiation (λ = 0.710 69 Å). Background measurements were made by extending the scan range by 25% on each side of the scan. Two standard reflections were monitored every hour during data collection, and intensity data were scaled appropriately (in each case the standard reflections varied by less than ±3% during data collection). Lorentz, polarization, and absorption corrections were applied. Accurate cell dimensions were assigned on the basis of 25 carefully centered high-angle (2θ > 25°) reflections that were widely scattered in reciprocal space.

The structures were solved either by direct methods or by inspection of a Patterson map that gave the positions of the osmium atoms. All other non-hydrogen atoms were located from Fourier difference maps alternated with least-squares refinement. Unit weights were employed initially, but weighting schemes based on counting statistics (for **2**) or on an empirical form (for **1** and **3**) were employed in the final refinements. Neutral-atom scattering factors with anomalous dispersion corrections were used (12). The computer programs used were from the NRC Vax 750/780 crystal structure system (13) or the CRYSTALS program suite (14) except that the thermal ellipsoid diagrams were made with the SNOOPI program (15). All programs were run on a MicroVAX II computer. Crystallographic data and details of each data collection are given in Table 1. Tables of thermal parameters for **1**, **2**, and **3**, and hydrogen atom coordinates for **3** have been deposited as supplementary material.[2]

$Os_4(CO)_{15}$

Crystals of **1** could not be obtained by crystallization; suitable crystals were, however, obtained directly from the synthesis when carried out as described above (i.e., at −15°C, solution unstirred). An initial data set was collected at room temperature and the structure solved by direct methods. After all the atoms were placed in the model, evidence was found that indicated the molecule was disordered in the unit cell. To better model the disorder, the data were recollected on the same crystal at −73°C and the latter data set used in subsequent refinement of the structure. The space group was determined to be either *C2/c* or *Cc* by the systematic absences. The final choice of *C2/c* (disordered) over *Cc* (ordered) was based on the refinement: the best ordered model in *Cc* had substantially worse agreement ($R = 0.052$, 120 variables) than the final disordered model in *C2/c* ($R = 0.044$, 108 variables). The asymmetric unit consists of two overlapping half molecules of $Os_4(CO)_{15}$, each of half occupancy. The two fold axis of space group *C2/c* relates the two half molecules such that one of the half molecules is equivalent to the "missing" half of the other molecule. The number of variables was limited by assigning one common isotropic temperature factor to the carbon atoms, another to the oxygen atoms, and one to each type of osmium atoms. Bond length restraints were employed during the initial stages of refinement on all Os—C and Os—O distances.

[2] These tables can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A OS2.

The hydrogen atom coordinates for **3** have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[a]Restraint was applied to this bond length.

These restraints were lifted in the final stages of the refinement. Restraints were also applied to Os—Os distances such that the chemically equivalent bond lengths were refined to their mean values. After convergence of the refinement, an empirical weighting scheme was adopted; the weight for a given reflection was given by $w = [4.35147t_0(X) + 5.6181t_1(X) + 1.65544t_2(X)]^{-1}$, where $X = |F_o|F_{max}^{-1}$ and t_n are polynomial functions of the Chebyshev series (16). Additional details of data collection and refinement are given in Table 1. Atomic positional parameters for one molecule of the disordered pair of **1** are listed in Table 2; bond lengths and selected bond angles are given in Table 3.

$Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$

There was evidence for disorder of the methoxy groups of the trimethyl phosphite ligand, but this was not modelled. (Disorder is a common problem in structures with a trimethyl phosphite ligand (17).) Six weak reflections that had asymmetric backgrounds and also the largest $\langle w(|F_o| - |F_c|)^2 \rangle$ values were excluded from the final cycles of refinement. These reflections were, (−8, 4, 6), (−9, 2, 6), (11, 4, −4), (8, 7, -5), (8, 12, −6), and (8, 3, −6). There were significant peaks (2.0 (3) e Å^{-3}) near the osmium atoms (within 1 Å) in the final electron density difference map; these were likely the result of improperly modelled absorption. No peaks were observed that could be reasonably attributed to the methyl hydrogen atoms and no attempt was made to include them in calculated positions. A weighting scheme based on counting statistics was adopted during the final cycles of refinement ($K = 4 \times 10^{-4}$). Further details of the data collection and structure refinement are given in Table 1. Atomic positional parameters for **2** are presented in Table 4; important bond lengths and angles are contained in Table 5.

$Os_4(CO)_{14}(CNBu^t)$

After anisotropic refinement of the osmium atoms, an electron density difference map revealed a pair of large peaks (~4 e Å^{-3}) around each osmium atom. The peak–osmium–peak angles were approximately 180°, and the peak–peak vectors nearly parallel. Such a pattern is consistent with poorly modelled absorption or crystal twinning. The latter possibility was ruled out because the peak positions were inconsistent with chemically reasonable split osmium atom positions. An empirical absorption correction based on Ψ-scans (18) gave essentially the same agreement as the analytical correction for equivalent isotropic models with a similar pattern of peaks

near the osmium atoms in the Fourier difference map. Because of these difficulties, the data reduction was carried out followed by isotropic refinement and a "pseudo" absorption correction applied by using the method of Walker and Stuart (R = 13% with no correction; R = 7% after application of DIFABS) (19)). After refinement of the model (anisotropic osmium atoms) with this "absorption" correction, the largest peaks in the electron density difference map were still near the osmium atoms, but were less than 2.5 (3) e Å^{-3} and showed a more random pattern. At this point, the methyl hydrogen atoms were included at calculated positions (d(C—H) = 0.96 Å); the positions of these atoms were not refined. The number of variables was limited by refining one common isotropic thermal motion parameter for all carbonyl oxygen atoms, one for all carbonyl carbon atoms, one for the methyl carbon atoms, and one for the hydrogen atoms. An empirical weighting scheme was employed during the final cycles of refinement with the weight, w, given by the expression $w = [26.5710t_0(X) + 40.5720t_1(X) + 24.4554t_2(X) + 8.03540t_3(X)]^{-1}$, where $X = |F_o|F_{max}^{-1}$ and t_n are polynomial functions of the Chebyshev series (16). Additional details of the data collection and structure refinement are given in Table 1; Table 6 lists the atomic positional parameters for the non-hydrogen atoms of **3**, and Table 7 contains the bond lengths and selected angles for **3**.

Results and discussion

$Os_4(CO)_{15}$

Addition of $Os(CO)_5$ to $Os_3(CO)_{10}(COE)_2$ in hexane at −15°C afforded $Os_4(CO)_{15}$ (**1**) in approximately 70% yield (eq. 1.). Attempts to displace acetonitrile from $Os_3(CO)_{11}(CH_3CN)$ with $Os(CO)_5$ were unsuccessful. In contrast,

$$[1]\quad Os_3(CO)_{10}(COE)_2 + Os(CO)_5 \xrightarrow{-15°C} \underset{\mathbf{1}}{Os_4(CO)_{15}}$$

$Os(CO)_4(PMe_3)$ does displace CH_3CN from $Os_3(CO)_{10}(CH_3CN)_2$ to yield $Os_4(CO)_{14}(PMe_3)$ (6). Compound **1** was isolated as dark red, air-stable crystals. Concentrated solutions of **1** in CH_2Cl_2 are red whereas dilute solutions are green. Similar dichroism (20) was observed for $Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$ and $Os_4(CO)_{14}(CNBu^t)$, described below, and for $Os_4(CO)_{14}(PMe_3)$ (6).

The structure of **1** at room temperature was determined by X-ray crystallography. The structure was, however, disordered and the data were recollected at −73°C in order to better model the disorder (Experimental). The latter structure determination is discussed here; it reveals (Fig. 1) an essentially planar metal skeleton: the dihedral angle between the Os(1)Os(2)Os(3) and Os(1)Os(3)Os(4) planes is 179.0°. The Os_4 unit has adjacent short (Os(1)—Os(2) = 2.774 (1), Os(1)—Os(4) = 2.775 (1) Å) and long (Os(2)—Os(3) = Os(3)—Os(4) = 2.998 (1) Å) bonds. Although somewhat long, the diagonal Os(1)—Os(3) bond length at 2.948 (1) Å is more

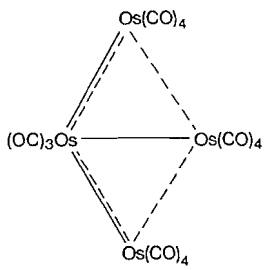
typical of an Os—Os single bond. The average Os—Os bond length in $Os_3(CO)_{12}$ of 2.877 (3) Å is usually taken as representative of the length of an Os—Os single bond in low-nuclearity osmium clusters (21).

As discussed for $Os_4(CO)_{14}(PMe_3)$ (6) these unusual bond lengths may be rationalized in terms of three-center, two-electron metal–metal bonds as shown in Chart 1. In this way, the

Chart 1.



short peripheral metal–metal bonds are assigned a bond order of 1.5 and the long bonds an order of 0.5, and each osmium atom achieves an 18-electron configuration.

Many years ago Pauling proposed a simple equation for cal-

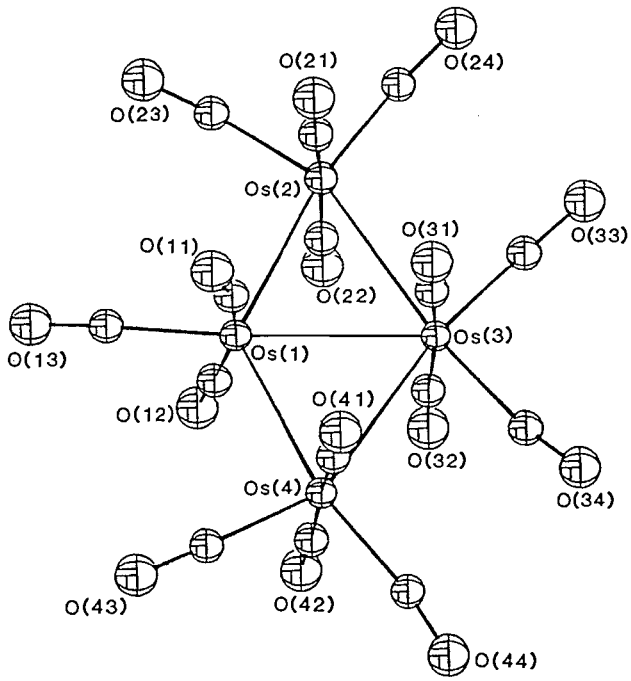
Fig. 1. Molecular structure of $Os_4(CO)_{15}$ (**1**).



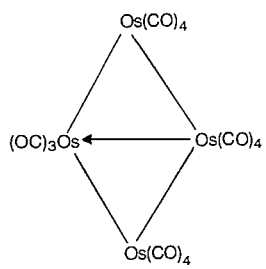
culating the bond order of a bond given its length; this is given in eq. [2] where $d(n)$ is the distance of the bond in question, d_1 is the length of a single bond of the same type, and n is the bond order (22).

$$[2] \quad d(n) = d_1 - 0.60 \log(n)$$

If a value of 2.88 Å is assumed for the length of an Os—Os single bond (the value found in $Os_3(CO)_{12}$), then application of Pauling's relationship to the Os—Os bond lengths of **1** yields a bond order of 1.5 for the short Os—Os bonds and an order of 0.6 for the long Os—Os bonds. These bond orders are therefore consistent with the interpretation shown in Chart 1. The cationic cluster $[Pt_2Au_2(PPh_3)_4(CNC_6H_3Me_2)_4]^{2+}$ has adjacent, long Pt—Au bonds that have been rationalized in terms of partial three-center, two-electron bonds (23).

An alternative electron-counting scheme for **1** is shown in Chart 2. In this scheme each Os—Os bond is considered as a

Chart 2.



single bond but with the added feature than the diagonal (hinge) metal–metal bond is a donor–acceptor (dative) bond. Molecular orbital calculations by Mealli and Proserpio favor this interpretation (24). We have described a number of binuclear, trinuclear, and cluster compounds with unsupported Os—Os dative bonds (5, 6, 10, 25). We (26–28) and others have also proposed that in some osmium clusters donor–acceptor metal–metal bonds are present as part of the cluster framework (29). If the diagonal bond in **1**, and related clusters, is a dative metal–metal bond it is difficult to rationalize the difference in the lengths of the peripheral metal-metal bonds even allowing for the lower coordination about Os(1). Furthermore, in $Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$ (described below), $Os_4(CO)_{14}(PMe_3)$ (6), and $(\eta^5\text{-}C_5Me_5)IrOs_3(CO)_{12}$ (4), the noncarbonyl ligands are not coordinated to the osmium atom that acts as the donor atom in the proposed dative metal–metal bond. In our studies of complexes with dative metal–metal bonds we have observed, not unexpectedly, that where possible the better σ-donor ligand (i.e., the noncarbonyl ligand) is bound to the donor metal–metal atom (5, 25), and in some cases this electronic preference apparently overrides considerable steric repulsions (26, 27).

It is pointed out here that there are some planar tetranuclear clusters of Ru and Os in which there are long metal–metal bonds that are not adjacent (i.e., in $Os_4(\mu\text{-}O_2CCF_3)_2(CO)_{12}$ (30), $Ru_4(\mu\text{-}PPh_2)_2(CO)_{13}$, and $Ru_4(\mu\text{-}PPh_2)_4(CO)_{10}$ (31)).

Osmium–osmium bonds are expected to have low stretching force constants and therefore the bond should be readily deformed. There are, however, innumerable trinuclear osmium clusters with a variety of ligands of varying steric bulk and yet the unbridged Os—Os bonds in these clusters are usually within ±0.05 Å of 2.877 Å, the average Os—Os length in $Os_3(CO)_{12}$. For example, in the extremely crowded molecule $Os_3(CO)_6[P(OMe)_3]_6$ (with threefold symmetry) prepared in this laboratory the Os—Os bond length is 2.927 (1) Å, and it is known that a P-donor ligand causes a lengthening of the Os—Os bond in the *trans* position (32). It is therefore probable that bond lengthening or shortening of more than ~0.05 Å from 2.877 Å can be attributed to electronic rather than steric effects. The exact nature of those electronic effects remains an intriguing problem in metal cluster chemistry.

Planar tetranuclear clusters were, until recently, rare. The butterfly and tetrahedral arrangement are the common geometries observed for tetranuclear clusters (33). The butterfly configuration is the common structure found for 62-electron clusters (**1** is a 62-electron cluster). The butterfly unit (an arachno octahedron) is also the structure most consistent with the polyhedral skeletal electron pair theory (PSEPT) for these clusters. Prior to the initial report of **1**, the only planar tetranuclear clusters without bridging ligands reported were $[Re_4(CO)_{16}]^{2-}$ (34) and $HOs_3Re(CO)_{15}$ (35). The metal–metal bond lengths in these clusters do not show the same variation as those in **1**. The structure of $HOs_3Re(CO)_{15}$ was, however, badly disordered and more recent work on $(Ph_3P)(OC)_3Re(\mu\text{-}H)Os_3(CO)_{11}$ suggests it may contain a long, unbridged Re—Os bond (28).

Planar tetranuclear osmium clusters with bridging ligands include $Os_4(\mu_3\text{-}S)(CO)_{13}$ (36) and $Cl_2SnOs_3(\mu\text{-}CH_2)(CO)_{11}$ (37). It has also been pointed out by Hoffmann[3] (see also ref. 38) that **1** is an isolobal analogue $[C_4H_7]^+$, the structure of which still remains uncertain after many years of study (39).

One of the fascinating properties of metal carbonyl clusters is their stereochemical nonrigidity (40), and the clusters

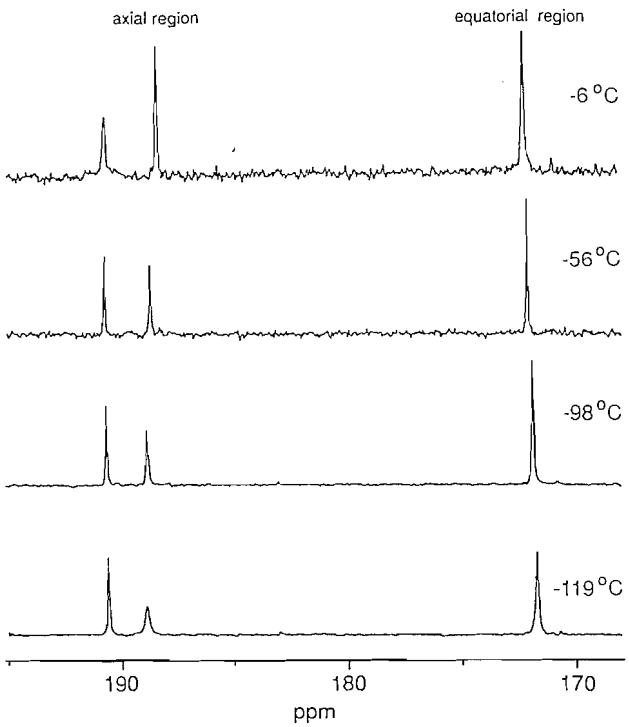
Fig. 2. Variable temperature ^{13}C nmr spectra of **1** (in $CHFCl_2$–CD_2Cl_2 except spectrum at −6°C: CH_2Cl_2–CD_2Cl_2).



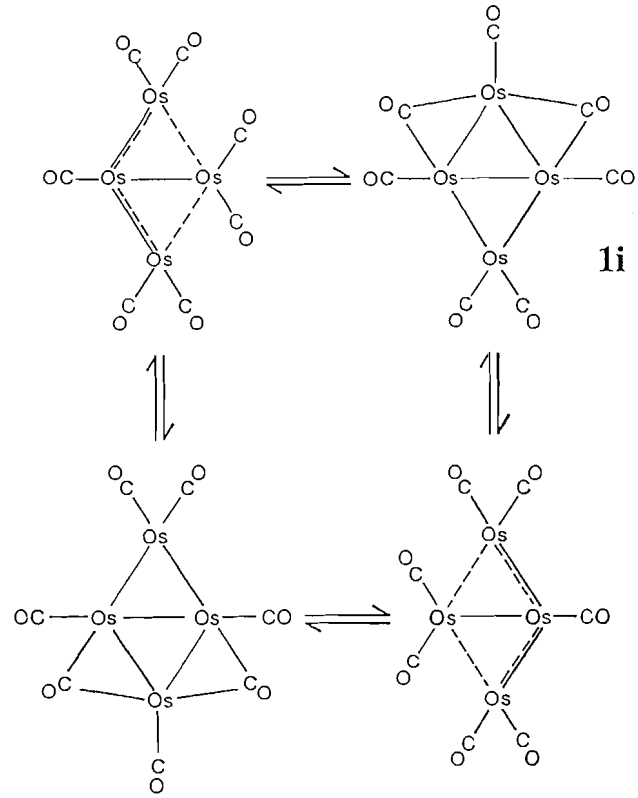
described here are no exception. Variable temperature ^{13}C nmr spectra of **1** (^{13}CO-enriched) in CD_2Cl_2–$CHFCl_2$ below 0°C are shown in Fig. 2. Because of the unusual bonding in the cluster, care must be taken when assigning resonances in a specific region of the spectrum as due to carbonyls of a certain type (i.e., axial or equatorial). For example, some of the carbonyl signals in the ^{13}C nmr spectrum of the related $Os_4(CO)_{14}(PMe_3)$, at −115°C where it is rigid, have unusual chemical shifts (6). However, by analogy to the spectra of most Os_3 clusters (41, 42) and the spectrum of $Os_4(CO)_{14}(PMe_3)$ (6), the two signals (each of intensity 4) downfield of δ 180 are confidently assigned to axial carbonyls whereas the singlet (of intensity 7) to high field of δ 175 is assigned to the equatorial carbonyl ligands.

The spectrum at −56°C is interpreted in terms of **1** with the same structure in solution as found in the solid state, but with rapid all-equatorial, merry-go-round CO-exchange taking place in the molecule; this is shown in Chart 3. This type of CO exchange has rarely been proposed for trinuclear group-8 carbonyl clusters (43). Axial-equatorial, merry-go-round CO exchange appears more common (41, 44, 45). The suggested mechanism for the low-energy carbonyl exchange in **1** is, however, consistent to that proposed for $Os_4(CO)_{14}(PMe_3)$ (6) and for $(OC)_5Cr[Os(CO)_3(PMe_3)]_2$.[4]

The spectrum of **1** at −119°C (Fig. 2) indicates CO exchange is beginning to slow on the nmr time scale: the signals δ 188.9 and 171.7 are significantly broadened relative to that at δ 190.6. This allows the assignment of the signal at δ 188.9 to the axial carbonyls on the hinge atoms that would be inequivalent in **1** if it were rigid, and therefore the signal at δ

[4] H.B. Davis and R.K. Pomeroy. Unpublished results.

Chart 3.



190.6 is attributed to the axial carbonyls on the wingtip metal atoms.

The low activation barrier for the CO exchange in **1** probably indicates that the intermediate with bridging carbonyls (**1i** in Chart 3) is not much higher in energy than the ground state structure of **1**. Note that in **1i** all the Os—Os bonds are considered as two-center, two-electron metal-metal bonds.

In the spectrum at −6°C there is evidence for a further fluxional process since the signal assigned to the axial carbonyls on the wingtip osmium atoms is broadened along with the signal attributed to the equatorial carbonyls. A mechanism that accounts for this observation is a threefold twist mechanism at the wingtip osmium atoms that exchanges an axial and the equatorial carbonyl ligands attached to these osmium atoms. We have proposed this type of rearrangement to account for some of the higher energy, nonrigid processes that occur in the $Os_3(CO)_{12-x}[P(OMe)_3]_x$ (x = 1–5) clusters (41, 46). (An axial-equatorial, merry-go-round CO exchange similar to that proposed for **2**, below, would cause all the signals to broaden simultaneously.)

$Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$

This cluster was prepared in high yield by the addition of $P(OMe)_3$ to $Os_4(CO)_{13}(PMe_3)$ in hexane at room temperature (eq. [3]). Like **1** and $Os_4(CO)_{13}(PMe_3)$, **2** is an air-stable, red

[3] $Os_4(CO)_{14}(PMe_3) + P(OMe)_3 \longrightarrow \underset{\mathbf{2}}{Os_4(CO)_{13}(PMe_3)[P(OMe)_3]}$

solid that is dichroic in solution.

The X-ray crystal structure of **2** shows the geometry given in Fig. 3. As can be seen, the metal skeleton in **2** is essentially

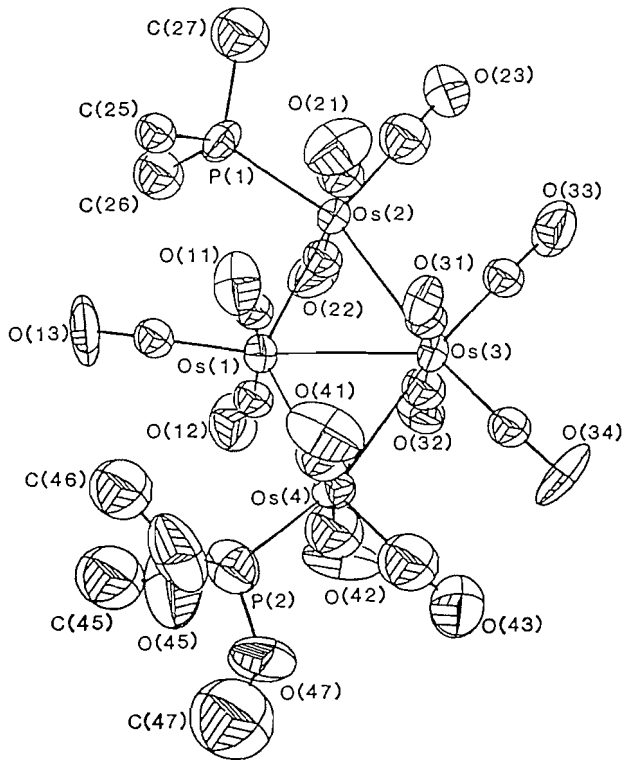
Fig. 3. Molecular structure of $Os_4(CO)_{13}(PMe_3)[P(OMe)_3]$ (**2**).



the same as that in **1**. Furthermore, the Os—Os bond lengths in **2** (and in $Os_4(CO)_{14}(PMe_3)$ and $Os_4(CO)_{14}(CNBu^t)$) are all within 0.021 Å of their counterparts in **1** (Table 8). This suggests that the difference in the length of the long and the short Os—Os bonds in these molecules cannot be attributed to packing forces or the *trans* influences of the peripheral ligands.

As expected, the phosphorus ligands occupy the sterically least encumbered sites in **2**, namely the equatorial sites that are *cis* to the $Os(CO)_3$ unit. Bulky phosphorus ligands invariably occupy equatorial sites in trinuclear metal carbonyl clusters (32, 47, 48). The Os—P distance to the phosphite at 2.22 (1) Å is shorter than that to the phosphine (2.31 (1) Å) and can be attributed to the better π-acceptor properties of the phosphite ligand (49, 50).

Variable temperature ^{13}C nmr spectra of **2** (^{13}CO-enriched) in CH_2Cl_2–CD_2Cl_2 are presented in Fig. 4. It is immediately apparent from the figure that, unlike **1** and $Os_4(CO)_{14}(PMe_3)$, **2** is rigid on the nmr time scale in solution at −45°C. The number of signals in the carbonyl region is that expected from the solid state structure of **2**.

The assignment of the carbonyl resonances shown in Fig. 4 (see also Fig. 3) is as follows. The doublets at δ 203.7 (2C) and 201.6 (2C) are assigned to the axial carbonyls on Os(2) and Os(4), respectively, by virtue of their intensity, chemical shift, and phosphorus coupling compared to those of related trinuclear osmium derivatives (41, 42). The resonances at δ 214.8 (2C) and 195.4 (1C) are assigned to the axial and equatorial carbonyls bound to Os(1), respectively, on the basis of their unusual chemical environment (a similar situation was observed in the spectrum of $Os_4(CO)_{14}(PMe_3)$ (6)). The remaining signal of intensity 2 at δ 173.0 is therefore assigned to the axial carbonyls on Os(3) (also an unusual region for such a resonance). The assignment of the remaining resonances is less straightforward; it is based on the relative chemical shifts expected (from studies on trinuclear Os compound) for signals of the equatorial carbonyls of $Os(CO)_3(L)$ (L = CO, PMe_3, $P(OMe)_3$) units, and the mode of collapse of the signals and the proposed mechanism for the exchange described below.

Table 8. Metal–metal bond lengths in **1**, $Os_4(CO)_{14}(PMe_3)$, **2** and **3**.

	1	$Os_4(CO)_{14}(PMe_3)$[a]	**2**	**3**
Os(1)—Os(2)	2.774 (1)	2.779 (2)	2.783 (3)	2.793 (2)
Os(1)—Os(4)	2.775 (1)	2.784 (2)	2.792 (2)	2.775 (2)
Os(2)—Os(3)	2.998 (1)	3.013 (2)	2.937 (2)	2.985 (2)
Os(3)—Os(4)	2.998 (1)	2.982 (2)	3.019 (2)	2.983 (2)
Os(1)—Os(3)	2.948 (1)	2.935 (2)	2.978 (2)	2.936 (2)

[a]From ref. 6.

The rearrangement to account for the low-temperature carbonyl exchange in **1** and $Os_4(CO)_{14}(PMe_3)$ involves movement of carbonyl ligands from one equatorial site to another; it is therefore not surprising that the carbonyls in **2** are far more rigid. Such a mechanism in **2** would require the migration of one of the phosphorus ligands from a wingtip Os atom to Os(1), and migration of a phosphorus ligand from one metal atom to another is known to be a high-energy process in osmium cluster chemistry (41, 51).

In the ^{13}C nmr spectrum of **2** at −6°C all the carbonyl resonances have broadened and collapsed to the base line except for those resonances assigned to the carbonyl ligands of the (hinge) $Os(CO)_4$ grouping (Fig. 4). This behavior is interpreted in terms of axial-equatorial, merry-go-round carbonyl exchanges about the short peripheral Os—Os bonds. This is shown in Chart 4. The lowest energy carbonyl exchange in $Os_3(CO)_{11}(PEt_3)$ (45) and $Os_3(CO)_{11}[P(OMe)_3]$ (41) has been interpreted as proceeding by a similar mechanism (i.e., in that plane that contains both axial and equatorial carbonyls and is also approximately orthogonal to the Os—P bond). In **2** it is proposed there are two such merry-go-round exchanges, both of which involve the axial and equatorial carbonyls on Os(1).

Careful simulation of the ^{13}C nmr spectrum at −6°C (Fig. 5) shows that the first order rate constants of the two exchange processes are slightly different: 30 ± 3 s^{-1} for the exchange that occurs in the plane that is orthogonal to the PMe_3 ligand, and 25 ± 3 s^{-1} for the exchange in the plane orthogonal to the $P(OMe)_3$ substituent. These rates translate into activation energies of ($\Delta G^{\ddagger}_{267}$) of 13.8 and 13.9 kcal mol^{-1}, respectively. In unpublished results, we have observed that the barrier to the lowest energy CO exchange in $Os_3(CO)_{11}(PMe_3)$ is lower than that in $Os_3(CO)_{11}[P(OMe)_3]$.[5]

Above room temperature the signals assigned to the CO ligands on Os(3) begin to broaden such that at 70°C (toluene–toluene-d_8 solvent) these signals have also disappeared into the base line (Fig. 4). The mechanism of how this takes place is uncertain although a localized carbonyl exchange at Os(3) as the sole mechanism can be ruled out. Given the closeness of the chemical shifts of the carbonyl resonances of the $Os(CO)_4$ grouping, such a mechanism would only cause minor broadening and rapid coalescence to a sharp signal. In other words,

carbonyl exchange is taking place over all four osmium atoms in **2** in solution at 71°C.

$Os_4(CO)_{14}(CNBu^t)$

Dropwise addition of Me_3NO (in CH_2Cl_2) to $Os_4(CO)_{15}(CNBu^t)$ also in CH_2Cl_2 at room temperature caused a color change from amber to dark green. The progress of the reaction (eq. [4]) was monitored by infrared spectroscopy. The product, $Os_4(CO)_{14}(CNBu^t)$ (**3**), was isolated in 62% yield as dark red, air-stable crystals. The X-ray crystal

Fig. 5. Calculated (*a*) and observed (*b*) ^{13}C nmr spectra of **2** at −6°C in CH_2Cl_2–CD_2Cl_2.

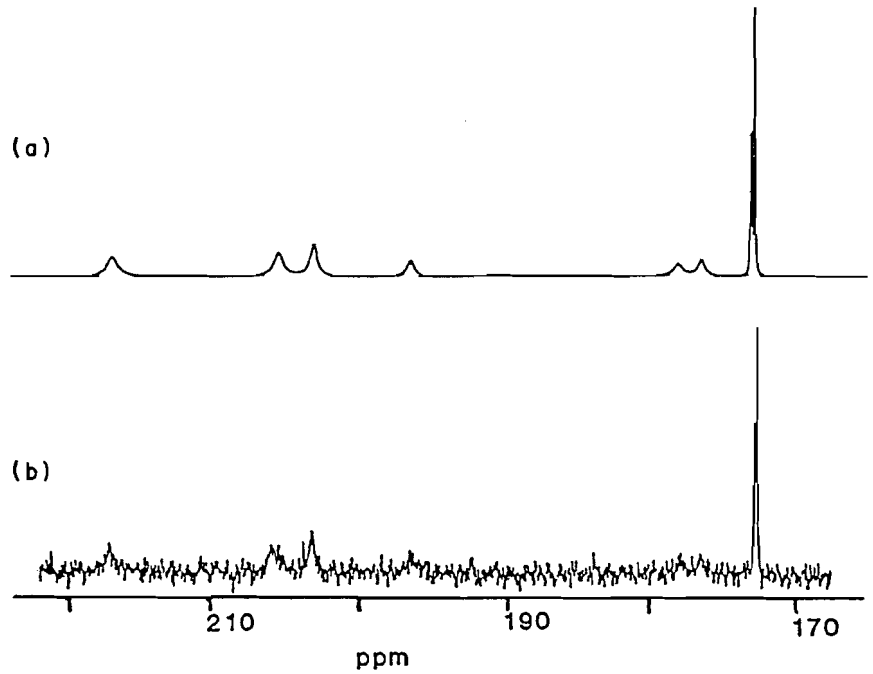

Fig. 6. Molecular structure of $Os_4(CO)_{14}(CNBu^t)$ (**3**).

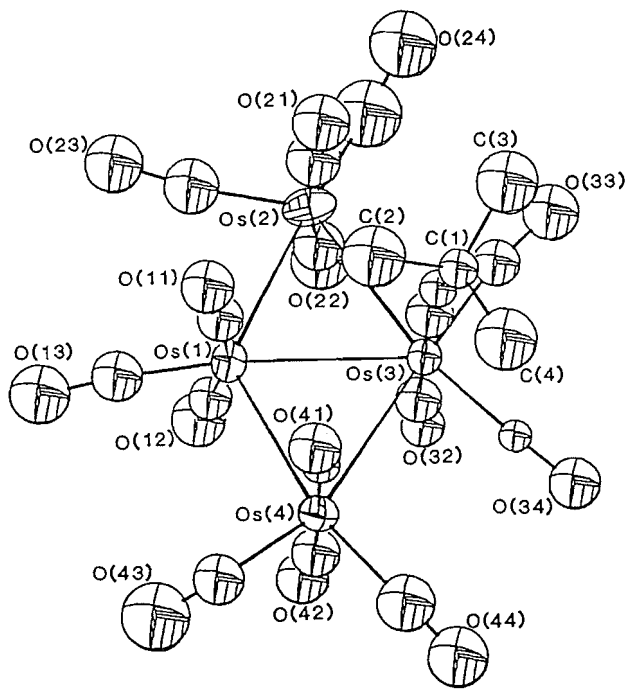

[4] $Os_4(CO)_{15}(CNBu^t) + Me_3NO \xrightarrow[62\%]{25°C} \underset{\mathbf{3}}{Os_4(CO)_{14}(CNBu^t)}$

structure of **3** again reveals (Fig. 6) a planar Os_4 skeleton with long and short peripheral Os—Os bonds (Table 8). Unlike the phosphorus-ligand derivatives of $Os_4(CO)_{15}$ (i.e., $Os_4(CO)_{14}(PMe_3)$ and **2**), the noncarbonyl ligand in **3** occupies an axial site. This was anticipated since in triosmium carbonyl clusters isocyanide ligands occupy axial rather than equatorial sites (48, 52, 53). The axial site that the isocyanide ligand occupies in **3** is, however, at the hinge osmium atom that has four terminal ligands. It might be thought that an axial site on a hinge metal atom may be sterically more hindered than an axial site on a wingtip metal atom since at the former site there are three rather than two repulsive axial-axial interactions between ligands. The Os—Os bonds that involve the Os atom (Os(3)) of the $Os(CO)_3(CNBu^t)$ grouping are, however, all longer than 2.93 Å so that the axial-axial interactions of this grouping may be less than those at the axial sites on the wingtip Os atoms since the latter metal atoms are involved in a short Os—Os bond to the other hinge Os atom (Os(1)).

The site the isocyanide ligand occupies in **3** is the site that would be expected if the Os atom of the $Os(CO)_3(CNBu^t)$ unit is acting as a net electron-donor metal atom, that is, if the electronic structure shown in Chart 2 applies to **3**. We have observed that the noncarbonyl ligand, L, in most clusters of the type $Os_5(CO)_{15}(L)$ occupies a sterically crowded site at the one osmium atom in the cluster that has four ligands coordinated to it. It is believed that this metal atom is a net electron-donor metal atom in these molecules and the better donor ligand, L, coordinated to this metal atom stablilizes the donation (26, 27).

The ^1H nmr spectrum (at an operating frequency of 100 MHz) of **3** in toluene-d_8 at ambient temperature exhibits two signals, at δ 0.95 and 0.96, of almost equal intensity. The signal at δ 0.95 was slightly broader than the other signal. The spectrum was essentially unchanged at an operating frequency of 400 MHz and with the sample at −50°C. This behaviour is interpreted in terms of two isomers present in solution that are tentatively assigned as having the solid-state structure and the isomer with the isocyanide ligand coordinated to the axial site of a wingtip osmium atom. The latter isomer is thought reasonable given that rapid carbonyl exchange in the equatorial plane in **3**, as observed in **1**, would render the remaining axial isomer equivalent to the first on the nmr time scale at room

temperature. Furthermore, migration of a *tert*-butyl isocyanide ligand from one metal atom to another in a triosmium cluster has been observed previously (53). The extra broadness of the resonance at δ 0.95 may be due to quadrupolar broadening by the nitrogen atom.

Variable temperature ^{13}C nmr spectra of **3** (^{13}CO-enriched) are shown in Fig. 7. A completely satisfactory explanation of the spectra is not possible at this time. It is believed that there is rapid exchange of the equatorial carbonyl groups in the two isomers of **3** present in solution at low temperatures so as to give an averaged signal for the equatorial carbonyls of each isomer, in a similar manner to that observed for the parent **1**. The two strong signals observed in the spectrum of **3** at −45°C at δ 174.7 and 174.8 are therefore assigned to the averaged signal due to the equatorial carbonyls of the two isomers (in **1** the corresponding signal occurs at δ 171.1). These two signals of **3** become accidentally degenerate in the spectra at −87°C and −121°C. As in **1**, the axial carbonyls in the isomers of **3** are thought not to undergo rapid exchange. Because of this and the presence of the (axial) isocyanide ligand, each isomer is expected to give rise to a 2:2:1:1:1 pattern for the axial carbonyls (i.e., a total of 10 signals). The weak signals observed in the region δ 189 – 195 are assigned as due to axial carbonyls; they appear in the region expected for such resonances. The weak signal to high field of δ 175 is assigned to an axial carbonyl attached to the osmium atom of one of the isomers that has four terminal ligands; this by analogy to **2** (see above) and $Os_4(CO)_{14}(PMe_3)$ (6). Not all of the signals due to the axial carbonyls were observed, presumably due to their low intensity or to accidental degeneracy with other signals.

Although the evidence is not as strong as for **1** and $Os_4(CO)_{14}(PMe_3)$, we do believe there is rapid all-equatorial, merry-go-round carbonyl exchange in **3**. That the signal attributed to the equatorial carbonyls is slightly broadened in the spectrum at −121°C may indicate the onset of decoalescence which in turn indicates that the barrier to this process is similar to that in **1**.

COMMUNICATION

The controlled synthesis of triosmium chain clusters

Jack Lewis and John R. Moss

Abstract: The reaction of $H_2Os_3(CO)_{12}$ with $ClSnPh_3$ in the presence of diethylamine gives exclusively the pentametallic chain compound 1,3-*ax,ax*-$Ph_3SnOs(CO)_4Os(CO)_4Os(CO)_4SnPh_3$. A similar reaction with $ClAuPPh_3$ gives 1,3-*ax,eq*-$Ph_3PAuOs(CO)_4Os(CO)_4Os(CO)_4AuPPh_3$. The di-tin compound reacts with HCl to give 1,3-*ax,ax*-$Cl_3SnOs(CO)_4Os(CO)_4Os(CO)_4SnCl_3$. These products are obtained in high yield and the reactions are selective.

Keywords: osmium carbonyl chain cluster complex.

Résumé : La réaction du $H_2Os_3(CO)_{12}$ avec le $ClSnPh_3$, en présence de diéthylamine, fournit exclusivement le composé pentamétallique linéaire 1,3-*ax,ax*-$Ph_3SnOs(CO)_4Os(CO)_4Os(CO)_4SnPh_3$. Une réaction du $ClAuPh_3$ fournit le 1,3-*ax,eq*-$Ph_3PAuOs(CO)_4Os(CO)_4Os(CO)_4AuPh_3$. Le composé contenant deux atomes d'étain réagit avec le HCl pour donner le 1,3-*ax,ax*-$Cl_3SnOs(CO)_4Os(CO)_4Os(CO)_4SnCl_3$. Ces produits sont obtenus avec des rendements élevés et les réactions sont sélectives.

Mots clés : agrégats complexes de chaînes d'osmium carbonyle.

[Traduit par la rédaction]

Introduction

Transition metal compounds containing three metals in a chain, with no bridging ligands, are relatively rare. An early example of this type of compound is the dihydride $H_2Os_3(CO)_{12}$ (1, 2). Although this compound has been known for over 25 years, its structure has never been determined due to the lack of suitable single crystals. The structure is, however, believed to be 1,3-*eq,eq*-$H_2Os_3(CO)_{12}$ by comparison with known structures of related compounds $Os_3(CO)_{12}I_2$ (3), $Os_3(CO)_{12}Cl_2$ (4), $Os_3(CO)_{12}Me_2$ (5) and on the basis of spectroscopic results (6). Since $H_2Os_3(CO)_{12}$ can be obtained in good yield from $Os_3(CO)_{12}$, it may be a useful starting material for other chain clusters. Indeed it has recently been used in the controlled assembly of new Os_6 and Os_9 clusters (7).

Previously, it has been shown that the reaction of $SnCl_4$ with $Os_3(CO)_{12}$ leads to the formation, in high yield, of the tetrametallic chain cluster compound $ClOs_3(CO)_{12}SnCl_3$ (8) which is believed to have the 1,3-*ax,eq*-structure. This compound has more recently been shown to react with metal nucleophiles (9, 10) and the structure of $ClOs_3(CO)_{12}SnCl_2[CpW(CO)_3]$ has confirmed that it is a penta-metallic chain with 1,3-*ax,eq*-substitution (viz. *eq*-Cl and *ax*-$SnCl_2R$) at the linear triosmium centre (10). Other important triosmium dodecacarbonyl chain derivatives prepared include 1,3-*ax,ax*-$Cl_3SiOs_3(CO)_{12}SiCl_3$ (11) from $Os_3(CO)_{12}$ and $HSiCl_3$ and 1,3-*eq,eq*-$(CO)_5ReCH_2CH_2Os_3(CO)_{12}CH_2CH_2Re(CO)_5$ from $H_2Os_3(CO)_{12}$ via deprotonation with KH (12). The reaction of $Os_3(CO)_{12}$ with $ClAuPPh_3$ was originally reported to yield $ClOs_3(CO)_{12}AuPPh_3$ (13) but this compound was later found to be $Os_3(CO)_{10}(\mu\text{-}AuPPh_3)(\mu\text{-}Cl)$ with a triangulo structure (14). The reaction of $Os_3(CO)_{12}$ with halogens (15) has been found to be more complex than originally thought and shown to involve initial formation of 1,3-*ax,eq*-$Os_3(CO)_{12}X_2$ which readily isomerizes to 1,3-*eq,eq*-$Os_3(CO)_{12}X_2$ (16).

We sought to find a general route to triosmium chain cluster compounds that would go in high yields under mild conditions and which could contain functional groups that could be elaborated on. Such compounds could be precursors to inorganic polymers where the polymer is held together only by metal–metal bonds.

Results and discussion

Some years ago, Collman et al. showed that the dihydride $H_2Os(CO)_4$ could be used to build up metallic chain oligomers such as *trans*-$[Os(CO)_4(SnPh_3)_2]$ (17). Since $H_2Os_2(CO)_8$ and $H_2Os_3(CO)_{12}$ are other members of the same homologous series as $H_2Os(CO)_4$ (2), we believed that they may undergo similar reactions. Thus, starting with $H_2Os_3(CO)_{12}$, we may be able to build up chain clusters with a linear triosmium backbone.

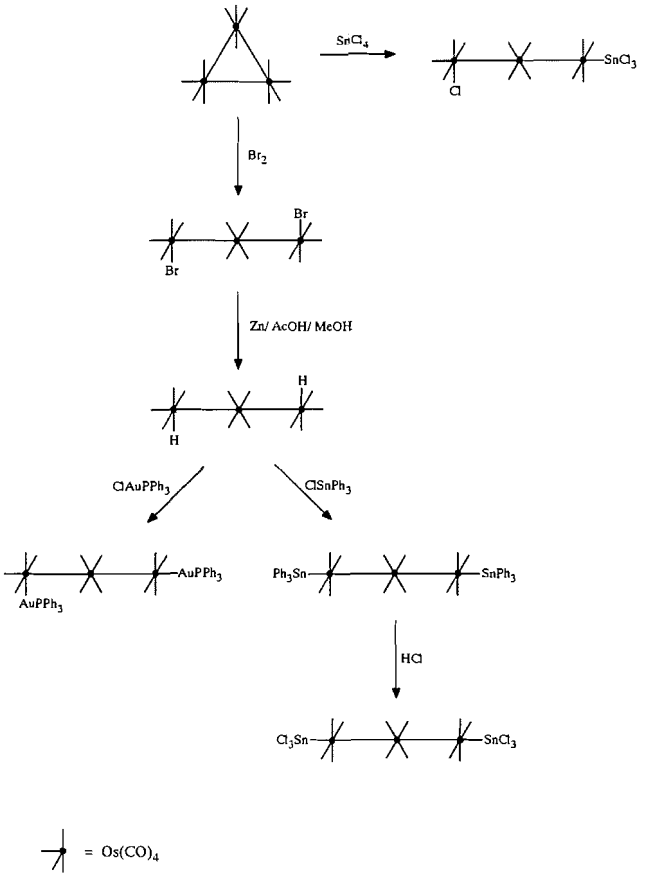
The reaction of $H_2Os_3(CO)_{12}$ with $ClSnPh_3$ in the presence of Et_2NH readily occurred at room temperature to give quantitative conversion to a new compound (as judged by IR). The product was isolated, after recrystallization, as very pale yellow platelets, mp 214–216°C (57% yield). Elemental analysis was consistent with the molecular formula $Os_3(CO)_{12}(SnPh_3)_2$ and this was confirmed by mass spectrometry where a parent ion was seen at *m/e* 1607. Both the IR spectrum: ν(CO) (CH_2Cl_2) 2091 w 2022 vs 1945 wbr cm^{-1} and the ^{13}C NMR spectrum, in the carbonyl region: (CD_2Cl_2) δ 188.2 and δ 184.2 (approximate intensity ratio 1:2) are consistent with this compound being a pentametallic chain with the 1,3-*ax,ax*-structure. Thus, each step of the reaction sequence starting with $Os_3(CO)_{12}$ and ending in $Os_3(CO)_{12}(SnPh_3)_2$ is both highly chemo- and regioselective, in respect to the isolated products (see Scheme 1). The reasons for the compound $Os_3(CO)_{12}(SnPh_3)_2$ adopting the diaxial configuration could be both steric and electronic. We have also investigated similar reactions with other halo-tin derivatives and will report on these later.

This methodology can also be extended to other metal chlorides. Thus reaction of $H_2Os_3(CO)_{12}$ with $ClAuPPh_3$ in the presence of Et_2NH gives, after work-up and recrystallization, beige platelets of a new compound (70% yield), mp 195–198°C. Elemental analysis is consistent with the compound being the pentametallic chain $Ph_3PAuOs(CO)_4Os(CO)_4$-$Os(CO)_4AuPPh_3$. The mass spectrum (negative FAB) shows the highest *m/e* peak at ca. 1339, which may correspond to $[P - AuPPh_3 - CO]^+$. IR shows ν(CO) (CH_2Cl_2): 2117 w, 2096 m, 2044 vs, 1995 w cm^{-1}. The ^{13}C NMR spectrum in the carbonyl region (CD_2Cl_2) shows peaks at δ 190.0, 183.8, 180.4, 180.2, 176.9 (approximate intensity ratios 4:4:1:2:1). This would suggest that the *ax, eq*-isomer has been isolated.

In order to elaborate further on these pentametallic chain complexes, it is necessary to activate the complexes. The mononuclear complex $Os(CO)_4(SnPh_3)_2$ has previously been shown to give $Os(CO)_4(SnBr_3)_2$ on reaction with HBr (17). We investigated the reaction of $Ph_3SnOs_3(CO)_{12}SnPh_3$ with an excess of HCl. The reaction goes quantitatively (by IR) to give colourless needles mp 190–195°C (dec.) (81% yield after recrystallization). The mass spectrum shows the highest *m/e* peak envelope at ca. 1358, which corresponds to the parent ion for $Cl_3SnOs_3(CO)_{12}SnCl_3$. The IR shows ν(CO) (CH_2Cl_2): 2125 w, 2060 vs, 2009 w cm^{-1}, which suggests that the diaxial configuration of the $SnCl_3$ groups has been maintained in this reaction and this is further supported by the ^{13}C NMR spectrum, which shows peaks at δ 192.3 and 185.2 (intensity ratio 1:2) in CD_2Cl_2.

This work shows that it is possible to carry out reactions at a linear triosmium chain that are both highly chemoselective and regioselective. Experiments are underway to build up other chain clusters and to further elaborate the pentametallic chains described herein.

Scheme 1.



Experimental

A solution of $H_2Os_3(CO)_{12}$ (59 mg, 0.065 mmol) in dry nitrogen saturated CH_2Cl_2 (5 mL) was treated with $ClSnPh_3$ (50 mg, 0.13 mmol). An excess of NEt_2H (0.8 mL) was added and the solution stirred for 45 min. The solvent was removed under reduced pressure to give a pale yellow solid. This was recrystallised from CH_2Cl_2/CH_3OH to give very pale yellow plates of $Ph_3SnOs_3(CO)_{12}SnPh_3$ (0.057 g, 57%).

1994 McBryde Medal Award Lecture Investigations of organized monolayer films for biosensor development[1]

Ulrich J. Krull, Michael S. Heimlich, Krishna M.R. Kallury, P.A.E. Piunno, John D. Brennan, R. Stephen Brown, and Dimitrios P. Nikolelis

Abstract: Our interests have focused on the investigation and development of biosensors that use chemically selective membranes to measure the concentration of specific species in complex media. One fundamental idea is that protein, which can bind selectively to a specific organic or biochemical species, can be incorporated into an ordered lipid or surfactant membrane assembly such that selective binding events lead to changes in the structure of the membrane (transduction) that can be measured quantitatively. The primary advantage of this method of detection is that it is applicable to interactions of enzymes, antibodies, receptors, and lectins, and it may be extended to investigations of DNA/RNA hybridization. This detection method therefore provides a sensitive generic strategy for sensor applications. The central problem to be solved is how the alteration of the structure of a membrane that is caused by binding events of protein or genetic material can give rise to an analytical signal. We have been focusing our efforts in the areas of fluorescence spectroscopy and electrochemical methods. The electrochemical methods rely on detection in changes of the permeability of membranes to ions and provide systems with very low background signal, leading to the possibility of detection of single molecular-binding events. Fluorescent systems operate on the basis that a chemically selective membrane containing a fluorescent indicator can provide an analytical signal caused by the change of the structure of the membrane due to the binding events.

Key words: fluorescence, lipid membrane, electrochemistry, receptor, biosensor.

Résumé : Nos travaux sont orientés vers l'étude et le développement de biosenseurs qui utilisent des membranes chimiquement sélectives pour mesurer la concentration d'espèces spécifiques dans des millieux complexes. Une des hypothèses fondamentales suggère que, si une protéine peut se lier sélectivement à une espèce organique ou biochimique spécifique, on peut l'incorporer dans un assemblage ordonné de lipide ou de membrane d'agent de surface; dans de telles conditions, les événements reliés à une liaison spécifique conduisent à des changements dans la structure de la membrane (transduction) que l'on peut mesurer quantitativement. L'avantage primaire de cette méthode de détection est que l'on peut l'appliquer à des interactions d'enzymes, d'anticorps, de récepteurs et de lectines et que l'on peut l'étendre à des études sur l'hybridation de ADN/ARN. Cette méthode de détection fournit alors une stratégie générique sensible pour les applications aux senseurs. Le problème central à être résolu est le suivant : comment l'altération de la structure de la membrane causée par les événements reliés à une liaison de protéine ou de matériel génétique peut-elle donner lieu à un signal analytique? On a orienté nos efforts vers la spectroscopie de fluorescence et les méthodes électrochimiques. Ces dernières sont fondées sur une détection de changements de perméabilité de membranes aux ions et elles conduisent à la possibilité de détection d'événements de liaisons moléculaires uniques. Les systèmes de fluorescence sont basés sur le fait qu'une membrane chimiquement sélective contenant un indicateur fluorescent peut fournir un signal analytique causé par un changement de structure de la membrane dû à des événements de liaison.

Mots clés : fluorescence, membrane lipidique, électrochimie, récepteur, biosenseur.

Fluorescence methods

The use of fluorophores that are embedded within an organized membrane has the advantages that there is no need for labelling of any portion of the selective binding protein, and that direct transduction of the extent of the selective binding interactions is achieved. Analytical assays involving tagged ligands, or complicated separation steps, are unnecessary. The membrane provides an environment in which many proteins can be embedded with retention of a high degree of biological activity. Furthermore, the membrane provides a unique intrinsic amplification since a limited number of selective molecular interactions can lead to a macroscopic spatial alteration of structure (e.g., phase transition) that concurrently influences many fluorophores that are in the membrane. We have an additional advantage to studying membrane systems because we measure fluorescence. Fluorescent probe techniques are very powerful for obtaining structural information about membranes, and we are able to study some of the fundamental physical chemistry of protein–membrane interactions.

Investigation by fluorescence spectroscopy of physically stabilized monolayer membranes requires specialized methods to improve collection of emitted radiation. We have incorporated total internal reflection fluorescence (TIRF) methods using optical fibers, and surface plasmon resonance microscopy and photopyroelectric spectroscopy methods, for investigations of immobilized membrane systems.

1. A fluorescent label for study of membrane perturbation

The quantum yield of a fluorescent molecule can be very dependent on its mobility in any specific chemical environment. It is possible, by incorporation of a fluorescent probe into a membrane, to detect selective binding events that perturb the structure of the membrane and hence alter the fluorescence intensity of the probe molecule. All our experiments have used nitrobenzoxadiazole dipalmitoylphosphatidylethanolamine (NBD-PE) as the fluorescent probe because of the similarity of its chemical structure to that of natural lipid molecules, its facile incorporation into membranes, and its potential for excitation by conventional nitrogen and argon ion lasers (1). At low concentrations (<2 mol%), the probe has little impact on the usual structure of lipid membranes. The probe partitions preferentially into areas of low order and the emission of the probe is sensitive to molecular mobility and self-quenching. While NBD-PE has been used over the last decade as a label of choice for fluorescence microscopy studies of phase structure in monolayer lipid membranes (2), it had been poorly characterized with respect to a quantitative model of emission. Such a model is of significance to interpretation of the mechanism of transduction of binding events by a membrane, and to the establishment of conditions for optimization of the S/N ratio for development of analytical systems and methods.

To investigate self-quenching (3), NBD-PE was incorporated into monolayers and vesicles composed of Egg phosphatidylcholine at concentrations of 0.1–50 mol%. Monolayer samples were dipcast onto glass slides at a pressure of 35 mN m^{-1}. Both the integrated intensity per fluorophore (quantum yield) from the vesicles and monolayers, and the mean fluorescence lifetime from the vesicles, decreased as the concentration of fluorophore in the membranes was increased. At all concentrations studied the decay of NBD-PE fluorescence was fitted to two discrete exponentials, and both lifetime components were observed to change with concentration. The complexity of the fluorescence decay did not permit the use of standard theoretical models such as the Klafter–Blumen or Stern–Volmer equations, which are normally employed to describe changes in fluorescence lifetime with changes in quencher concentration. Instead, a phenomenological approach was used to develop an empirical model of fluorescence self-quenching that could describe the observe alterations in he fluorescence lifetime and intensity. The model was based on a combination of Perrin quenching and Foerster energy transfer, and takes the following steady-state form:

$$\frac{F}{F_0} = \frac{\exp(-\pi R_c^2 C)}{1 + \pi^3 C^3 R_0^6} + \frac{\pi^3 C^3 R_0^6 \exp(-2\pi R_c^2 C)}{1 + \pi^3 C^3 R_0^6}$$

where F_0 and F are the fluorescence intensity in the absence and presence of quencher, respectively, C is the bulk concentration of fluorophore, R_c is the critical distance for trap formation, and R_0 is the Foerster energy transfer distance. The fluorescence data were fit by a model wherein NBD-PE formed non-emissive trap sites with a critical radius of R_c = 1.0 nm (Perrin quenching), with Foerster energy transfer occurring to the trap sites with an R_0 value of 2.55 nm as determined from spectral overlap integrals.

2. Transduction of selective binding events

Selective interactions of proteins located in a membrane can alter the distribution of phase structure, and such alterations can be directly visualized by fluorescence microscopy, and can be further characterized by fluorescence spectroscopy. The protein systems that we chose to study were (*a*) the selective interaction of the acetylcholine receptor with agonist/antagonist, (*b*) acetylcholinesterase with substrate, and (*c*) urease with substrate.

(i) Molecular receptor

Acetylcholine receptor (AChR) was studied because it is one of the best characterized molecular receptors with respect to structure and function in bilayer lipid membranes (BLMs). The physiological activity (electrochemical) of AchR is very sensitive to the composition of the surrounding lipid membrane, and the protein has "binding sites" for various lipids. This indicates that the effects of selective binding processes may be transmitted to the lipid matrix. Vesicles containing unlabelled AchR, NBD-PE, and soybean lecithin were prepared, and were then allowed to interact with the agonist carbamylcholine and the antagonist bungarotoxin. Fluorescence intensity enhancements were observed for both of the selective interactions, and the data were quantitatively analysed to determine the dissociation constant and the sensitivity of the fluorescence detection system (4). The experiments using carbamylcholine indicated a sensitivity of 30% relative fluorescence enhancement per μmole and a detection limit of 300 nM (linearity over only one order of magnitude). The toxin provided greater sensitivity with a detection limit of approximately 10 nM concentration. Wavelength shifts from the fluorophore were not apparent for interactions of either the carbamylcholine or the bungarotoxin, and no identification of

For personal use only.

these species was possible based on fluorescence intensity measurements. This emphasizes a common limitation of many chemical sensors, in that unambiguous identification of binding species may not be possible if only one dimension of analytical information is available (i.e., average intensity). Time-resolved spectrofluorimetry in combination with excitation or emission energy variation provides a much greater quantity of analytical information and can be considered multidimensional in nature. Fluorescence lifetime analyses of NBD-PE in lipid vesicles containing AChR gave biexponential fits. The results of the lifetime analyses before and after enhancement of fluorescence intensity suggest that the pre-exponential factors show promise for discriminating between the agonist and toxin complexes (5). The data could not be used to provide a molecular interpretation of the origin of the two lifetime components. The results of the work with AChR demonstrated that the NBD-PE labelled lipid membranes could serve as a generic host matrix that was capable of transduction of events such as the conformational change of a molecular receptor that occurred on selective complexation with ligands. The mechanism for fluorescence transduction was consistent with a description that considers AChR perturbation of the physical and electrostatic properties of lipid membranes. The increase in fluorescence intensity of over 200%, as was seen in some of the experiments, was likely the result of changes in the self-quenching of the NBO-PE.

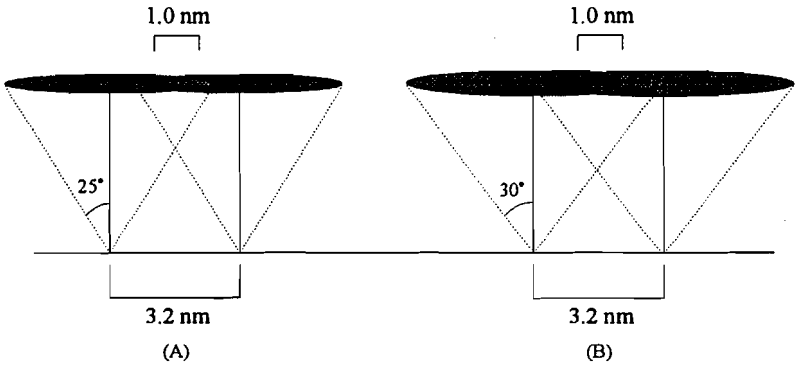
(ii) Enzymes

The enzyme acetylcholinesterase (AChE) was used to investigate the response of a monolayer lipid membrane to selective reactions of a hydrolytic enzyme that was known to be active in both vesicle and monolayer membranes. In this case, the mechanism for inducing reversible structural transitions within lipid membranes was based on a change of surface pH. The enzymatic catalysis of acetylcholine to acetic acid (and choline) provided a high localized hydronium ion activity at the surface of the membranes in which the enzyme was bound. Electrostatic repulsions between acidic functional groups in the headgroup region of the membrane were partly controlled by the dynamic reaction process when acetylcholine was available for the enzymatic reaction to proceed. A ratio of 7:3 DPPC/DPPA (alternatively PC/PA; dipalmitoylphosphatidylcholine and dipalmitoylphosphatidic acid) was chosen as a useful lipid mixture for examining the fluorescence response of monolayers because a significant amount of zwitterionic headgroups such as PC are necessary to promote incorporation of AChE into monolayers and because major structural changes such as phase separations are induced if a significant proportion of negatively charged headgroups such as PA are present in the membrane. AChE was deposited onto lipid monolayers that contained 1 mol% NBD-PE and were prepared at a surface pressure of 25 mN m^{-1} on a Langmuir trough, and a fluorescence microscope was used to investigate phase structure and average intensity (2, 4). The surface pressure was observed to increase to a final value of 32 mN m^{-1}. The small increase in surface pressure of the monolayer on addition of the AChE suggested that the enzyme was not interspersed deeply within the monolayer, but was likely associated with the headgroups at the membrane–water interface. Addition of 1 μmol of acetylcholine (ACh) to the subphase in the imaged region of the monolayer resulted in an increase of fluorescence intensity of about 50% with maximum signal achieved in 20 s. The signal rapidly decayed to the initial value, and the transduction by the lipid monolayers was reversible and reproducible (precision about 6%). As the quantity of ACh added to the subphase was increased the enhancement of fluorescence intensity increased, although saturation was eventually achieved. Control experiments provided no indication of intensity variation and involved the addition of electrolytes, the use of ACh without enzyme, and the use of denatured enzyme. Addition of HCl or NaOH to 7:3 DPPC:DPPA monolayers resulted in transient increases in fluorescence intensity that were similar to those observed for the reaction of AChE with ACh. Hydrochloric acid was added in 5 μmol aliquots to monolayers consisting of either pure DPPC (no enhancement observed), pure DPPA, or various mixtures of the two phospholipids to determine whether the sensitivity of transduction could be enhanced. Monolayers that contained 30 mol% or more of DPPA produced similar enhancements of fluorescence intensity (approx. 50%). Increases of fluorescence intensity did not vary systematically with the proportion of DPPA present in the monolayers, suggesting that the fluorescence signal was dependent on the degree of protonation of the PA headgroups as well as the lateral phase separation and size of domains in the imaged field. Fluorescence spectra were collected from stationary monolayers at pressures ranging from 1 to 45 mN m^{-1}. The wavelength of maximum emission due to the NBD-PE did not shift as the lateral pressure was increased, but the fluorescence intensity decreased during compression of the monolayers. This indicated that changes of fluorescence intensity were likely due to self-quenching of the fluorophore. The relative intensity at a subphase pH of 4 was always greater than at 7.4 (at constant surface area), indicating that the degree of self-quenching was decreased at the lower pH. An increase of surface pressure resulted in changes in the microscopic phase domain structure that were consistent with the growth of more condensed phases and lateral phase separation of DPPC and DPPA. DPPA has a net charge of about 1.3 at pH 7.4, and thus there is a high degree of electrostatic repulsion between headgroups. Reduction of the pH to a value of 4 reduces the anionic surface charge to a value of about 0.5 negative charges per headgroups. This decrease in headgroup–headgroup repulsion would be expected to result in a net decrease of the lateral pressure of the monolayer (at constant molecular area), which is consistent with the decrease in pressure observed in these experiments. A reduction in surface pressure would produce a change in the structure of the monolayer involving an increase in the net proportion of fluid phase, and may also promote phase separation. The higher proportion of fluid phase increases the area into which the NBD-PE may partition, and thus increases the average distance between fluorophore molecules. This leads to a decrease in self-quenching and the observed increase of fluorescence intensity (transient due to dissipation of pH gradient into large volume of subphase).

3. Towards a practical sensing configuration

The development of a portable and rugged sensing device requires that the selective recognition element be directly interfaced to the physical transducer. In the case of transducers based on fluorescent membranes, this entails stabilization of the assembly onto an optically transparent solid support such

Fig. 1. Representation of the relationship between rotational mobility (in terms of angular displacement relative to the normal to the plane of a membrane) of NBD-PE within CIMs and the probability of formation of transient trap sites. (*A*) Ionized membrane with low mobility; (*B*) neutral membrane with higher mobility.



as an optical fiber. Surface stabilization of membranes must provide sufficient ruggedness to permit use over an extended period of time without severe alteration of the response characteristics of the membrane. However, the stabilization method must allow the membrane to retain characteristics of molecular mobility and fluidity that are essential for transduction of selective reactions. Our work has investigated the analytical sensitivity that can be obtained from fluorescent membranes that were stabilized onto quartz surfaces by either the Langmuir–Blodgett (L–B) dipcasting method (6, 7), or by covalent linkage of individual amphiphiles onto a surface (8, 9). Covalent immobilization of a membrane to a solid surface is a desirable alternative to L–B techniques as this methodology has the ability to produce far more stable membranes. Covalently immobilized membranes (CIMs) were prepared from species having chain lengths between 11 and 16 carbons and having a reactive silane group at one terminus and a carboxylic acid or amine functionality at the other terminus. A small amount of (1–3 mol%) of NBD-PE was partitioned into CIMs from an aqueous suspension. The enzymes AChE or urease, which both produce shifts in pH upon reaction with the substrates acetylcholine and urea, respectively, were introduced into the membranes either by adsorption or by covalent linkage directly onto the functional groups of the membranes that coated the quartz surfaces. Addition of substrate to coated wafers and optical fibers placed in aqueous solution resulted in substantial changes of fluorescence intensity from both carboxylic acid and amine functionalized membranes. For examples with adsorbed AChE, the fluorescence intensity from the monolayer could be used to distinguish changes in bulk solution concentration of ACh with a limit of detection of 2 μm ACh. For samples with colvalently immobilized urease a limit of detection of 40 μm of urea was observed. The response times were about 10–20 s for both the AChE and urease systems. An assay of enzyme activity based on fluorescence was developed, and was based on the emission of the pH probe seminaphtharhodafluor-X (10). This probe has two emission maxima, which alter in intensity relative to each other with changes of pH, providing for sensitive detection of pH changes and the use of the concept of rationing to minimize errors due to instrumental drift and photobleaching. The assay was able to measure activity from covalently immobilized enzyme on monolayer membranes (approx. 50% surface coverage by enzyme), with an accuracy of about 10% for surface areas on the order of 1 cm^2. The assay indicated that the sensitivity of the membrane-based transducers degraded tenfold over a period of 7 days when the samples were stored in phosphate buffer at 4°C.

Table 1. Slope of response of fluorescence intensity to change of pH. The pH is shifting from 4.0 to 9.0

Membrane	Slope of response to pH
Carboxylic acid	Positive
Carboxylic acid + urease	Negative
Alkylamine	Negative
Alkylamine + urease	Positive

Model for intensity changes of CIMs

An investigation of the processes responsible for changes in the intensity of NBD-PE emission in CIMs has shown that the signal is not based on direct effects of pH, polarity, surface potential, or surface charge, and that the emission intensity is strongly influenced by changes in local concentration of the fluorophore (3). Alterations in the surface charge of CIMs will change the electrostatic interactions between adjacent amphiphiles, which in turn can result in changes in the degree of rotational mobility of the covalently bound amphiphile molecules and NBD-PE. Increased rotational mobility in terms of angular distortion away from the normal to the plane of a membrane would be expected to result in an increase in the number of statistical trap sites, and therefore increases in self-quenching (Fig. 1). It is thus necessary to consider how the electrostatic interactions between an enzyme (e.g., urease) and membranes may change with pH to affect molecular mobility within a membrane. A summary of such changes and the interpretation of mechanism are presented in Table 1 and Fig. 2, respectively. The carboxylic acid membrane containing urease produced decreases in fluorescence intensity as the pH was increased, indicating that there was an increase in the self-quenching of the NBD-PE. It is likely that an increase in the area swept out by the cone associated with rotational mobility is a result of the protein occupying less surface area due to a reduction in the attractive charge interactions between the protein and the membrane. This situation would occur as a result

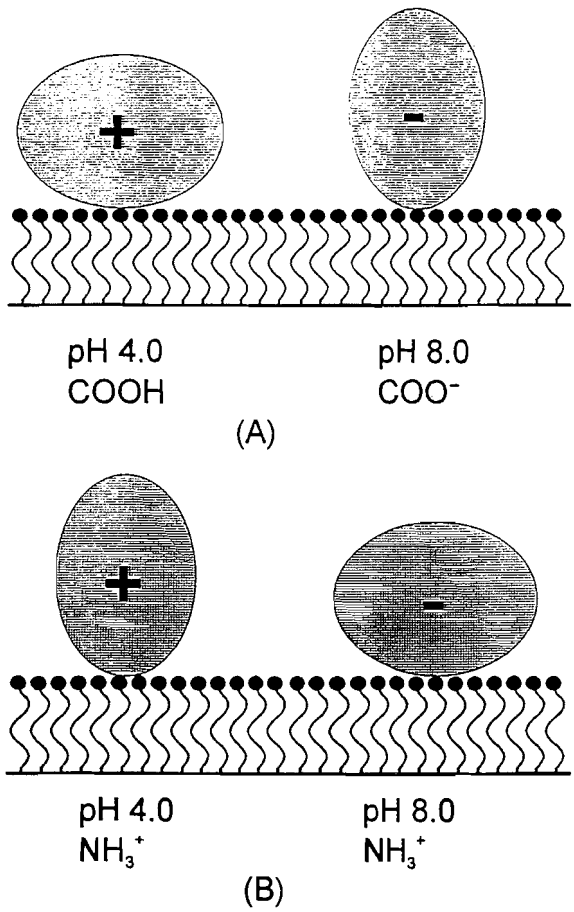
Fig. 2. Changes in electrostatic interactions between urease and headgroups of membranes as a function of pH, and relationship to membrane mobility. (*A*) carboxylic acid membrane with urease (shaded oval); (*B*) alkylamine membrane with urease.



of the net charge of the protein becoming increasingly negative as the pH is raised, owing to urease having a pI of 5.1. At the same time, the carboxylic acid headgroups become negatively charged, thus repelling the protein from the surface of the membrane. The repercussions of this situation are an increase in the mobility of the fluorophores and an increase in fluorophore–fluorophore interactions (more trap sites), providing an increase in self-quenching as the pH is increased. For the alkylamine membrane, the protein again becomes more negatively charged as the pH increases from 5.1 to 9.0, but the membrane amphiphiles are positively charged and become neutral as the pH is raised. It is expected that at low pH (around 4.0) the membrane is highly positively charged while the protein is also positively charged, and thus an electrostatic repulsion should exist between the headgroups and the protein. Under these conditions, the membrane should have some degree of mobility. As the pH is raised to a value of 8.0, the protein becomes neutral and then negatively charged, while the membrane remains essentially completely ionized and positively charged. As the negative charge density of the protein increases, attractive electrostatic interactions between the protein and the membrane increase and the protein therefore interacts with a greater number of headgroups. This would reduce the mobility of the membrane and would cause decrease in the self-quenching and increases in the intensity, as observed during pH titrations.

Electrochemical methods

Natural chemoreception offers a glimpse of a biosensing system that might be replicated in a rudimentary fashion for development of practical devices. Chemoreceptive membranes consist of a bimolecular layer of lipids, which are physically associated with proteins that have molecular recognition properties, i.e., receptors. The ion channel system that is found in biological organisms is associated with rapid, reversible, sensitive, and selective chemical signalling, with unique features such as the amplification and transduction of chemical information into an electrical pulse by switching of channel conductivity.

Theoretical and experimental reports have indicated that disordered states of lipid structure, as encountered during phase transitions, are highly permeable to ions. This is relevant to the process of ion permeation through lipid membranes, as bilayer and monolayer lipid membranes can be composed of mixed phased in coexistence. The interfacial boundary between different phases in a zone of low structural order could provide a highly conductive pathway for ion permeation, ion current being modulated by aspects of molecular density, mobility, and electrostatic charge (i.e., artificial pore).

1. Control of conductivity pathways in membranes

It has been suggested that high intramembrane concentrations of 10-hydroxystearic acid (10-HSA) are responsible for changes in the permeability of gases and ions through membranes of alveolar cells of cystic fibrosis patients. Characterization of the mechanism and control of the magnitude of ion current through membranes by 10-HSA could provide an insight into the preparation of chemically selective membranes (11).

Solvent-free planar BLMs and monolayer films were prepared from a lipid mixture (by mass) containing 34% phosphatidylcholine, 19% dipalmitoylphosphatidylserine (PS), 47% cholesterol (C), and variable amounts of 10- and 12-hydroxystearic acid (0–50%). The structures of monolayer films at the air–water interface of a Langmuir–Blodgett trough were studied by pressure–area (π–A) correlations and by further correlations with microscopic phases separation as revealed by fluorescence microscopy. The ion currents through BLMs were found to increase approximately exponentially with the mole ratio of HSA (corrected for surface charge).

In a simplified view, two models for the transport process in BLMs composed of lipid, cholesterol, and 10- or 12-HSA are possible. The first model considers the hydroxyl moiety at the 10- or 12-position of the acyl chain as a "polar defect" distributed homogeneously throughout the hydrophobic interior or the membrane. The interaction of hydrated K^+ with polar hydroxyl groups would be energetically favourable in the nonpolar interior of the BLM. Therefore, the ions could be transported across the membrane via polar defects in the "hopping" mechanism. The second model considers that the same energetics associated with the first model are applicable, but that the 10- or 12-HSA is heterogeneously distributed in zones of high relative HSA concentration.

Fig. 3. Fluorescence microscopy images (full scale of image 250 μm) showing domain structure of monolayers at different pressures and with different compositions of 10-HSA. Images a, b are of monolayers that contain 12 mol% 10-HSA at average molecular areas of 0.85 and 0.50 nm^2, respectively. Images c, d are of monolayers that contain 35 mol% 10-HSA at average molecular areas of 0.85 and 0.52 nm^2, respectively.

The 10- and 12-HSA have only one acyl chain, whereas the lipids (PC and DPPS) each have two acyl chains per molecule. The lipids also have a glycerol backbone that is not present in the 10- or 12-HSA. Therefore, the average molecular area decreased as the molar proportion of 10- or 12-HSA was increased. The 10- or 12-HSA has a carboxylic acid headgroup that is deprotonated at pH 7.4, indicating that the anionic form was present in the membranes used for these investigations. The negative charge present on the 10- or 12-HSA implies that electrostatic repulsion exist between 10- or 12-HSA and DPPS molecules. Hence, on structural and electrostatic principles, the 10- or 12-HSA represents an impurity in domains otherwise rich in either lipid or cholesterol components. The lowest energy state of the system could be expected to arise if the 10- or 12-HSA initially partitioned into interfacial regions between the lipid and cholesterol phases. Interfacial energetics are known to dominate cholesterol–lipid interactions at the molecular level and it is, therefore, expected that the introduction of 10- or 12-HSA would alter the phase structures in the mixed cholesterol–lipid systems.

Fluorescence microscopy indicated that 10-HSA could significantly alter the shape and distribution of domains, resulting in a substantial increase in the total interfacial area of the domains (Fig. 3). The formation of domains with "crescent" shapes has been previously linked to interfacial processes. The four-component mixture used in these experiments complicates predictions of phase structure and the extent of domain coexistence. The evolution of an inflection point in the π–A curves for a low concentration of 10-HSA could be due to the formation of a miscible eutectic mixture. The large condensation effect caused by relatively small concentrations of 10-HSA further suggests that the material is not homogeneously distributed as a bulk constituent of the monolayer, but that it is located in interfacial regions that then control phase distribution. The inflection point in the π–A isotherms occurs at a constant pressure once the concentration of 10-HSA is above 35 mol%, which suggests that an immiscible mixture is formed, resulting in a distinct phase that is rich in 10-HSA.

The appearance of a distinct phase in a BLM should alter transmembrane ion current in comparison with results obtained for lipid compositions containing less than 35 mol.% 10- or 12-HSA. There is an inflection in the trend of ion current change with HSA content of BLMs near the 35 mol.% HSA composition. The slope of ion current versus 10- or 12-HSA content is much greater for HSA compositions above 35 mol.%, indicating that a new pathway with a lower energy barrier is available for ion permeation. This pathway is likely to be associated with a phase that is rich in 10- or 12-HSA, and could involve dipolar interactions of hydroxyl residues. This cooperativity is consistent with the logarithmic relationship of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

HSA composition and ion current. A further significant feature is that extrapolation of a plot to an HSA composition of zero yields an ion current substantially greater than that actually observed for BLMs that did not contain HSA. This again suggests that the HSA is heterogeneously distributed in the BLMs, in a location that affects ion current in a nonlinear fashion.

2. Critical phenomena at the BLM surface

Molecular switching systems may provide the basis for a new class of chemical sensing devices, which can be envisaged most simply as any chemically selective molecular arrangement that can exist in two or more discrete physical states. Switching between states could be represented as a change in molecular receptor conformation on binding a stimulant. However, the absolute analytical signal (e.g., ion current) associated with single ion channel events encountered in nature is usually very small, limiting the practical utility of such an analytical strategy.

A primary binding event, which locally alters the structure or electrostatic field of a lipid membrane, provides a physical change that can readily be detected by electrochemical or optical methods. Amplification of the analytical signal can be achieved by inducing a greater spatially distributed structural change caused by the selective binding event. Ideally, this concept would converge in a phase transition of the lipid membrane caused by a very limited number of receptor binding events. Such macroscopic state-switching provides opportunities for the sensing of very low concentrations of target species by monitoring the discontinuities in a relatively invariant analytical signal.

Our approach begins with the immobilization of active proteins directly onto a carefully defined lipid mixture at an air–electrolyte interface, followed by a film-casting technique for BLM formation (12). Subsequent experiments have shown that selective chemical reactions can be transduced as time-dependent singular transient ion current signals. The electrochemical event is due to the rapid reorganization of the double layer and physical structure of a BLM, and provides the basis for the construction of switchable biosensors with rapid response times and reversibility.

BLMs prepared from mixtures of a neutral lipid such as Egg phosphatidylcholine (PC) and an ionizable lipid develop an electrical double layer at the membrane–electrolyte interface. Dipalmitoylphosphatidic acid (DPPA) has two accessible ionizations with titration endpoints of about pH 4 and 7–8.5, and mixtures of PC and DPPA are very sensitive to alterations of membrane surface charge. Substantial reorganization of the phase distribution of a membrane based on the extent of DPPA ionization has considerable impact on the magnitude of the ion current and the S/N ratio. We have found electrochemical evidence that there are phase rearrangements in BLMs under certain conditions (13). As the concentration of DPPA in BLMs is increased from 0 to 20% w/w, the residual ion current through BLMs increases linearly (for pH in the range of 7–9). Between 20 and 30% w/w DPPA there is a substantial decrease in ion current that probably occurs because of an alteration of the structure of the membrane. As the content of DPPA in the membrane is increased above 30% w/w, residual ion current is again linearly related to percent composition DPPA but with a smaller slope than for the 0–20% DPPA region. It appears that 25% w/w DPPA represents a critical concentration, below which DPPA self-associates to form DPPA-rich domains, and above which DPPA and PC are distributed relatively homogeneously. Charged lipids such as DPPA can also play an important structural role for the immobilization of biochemical species at BLMs by formation by hydrogen bonds with relevant amino acid side chains of proteins. The formation of hydrogen-bonding networks enhances the immobilization, and connects regions with differing proton or electron density to provide rapid conduction between such regions.

The difficulty of selecting an initial pH to optimize the sensitivity of the response to pH of negatively charged BLMs, and to concurrently optimize the activity of chemically selective proteins, can be overcome by introducing Ca^{2+} to the bulk electrolyte solution (14). Adjustment of the intrinsic sensitivity of BLMs is achieved by selecting the lipid composition to contain concentrations of DPPA greater than 25% w/w and by related adjustments of the pH and calcium ion activity. The interaction of calcium ions with divalent negatively charged lipid (pH about 8) results in a phase separation of PC and DPPA and the formation of conductive zones in BLMs. These zones can be switched on or off by selecting a pH value of the electrolyte solution below or above 7, respectively, in the presence of a limiting Ca^{2+} concentration that depends on the DPPA composition of BLMs.

Generally the ion current magnitude is maximized for more fluid BLMs and minimized surface potential, when the ion current is the result of surface charge alterations.

3. Transduction of enzyme–substrate reactions

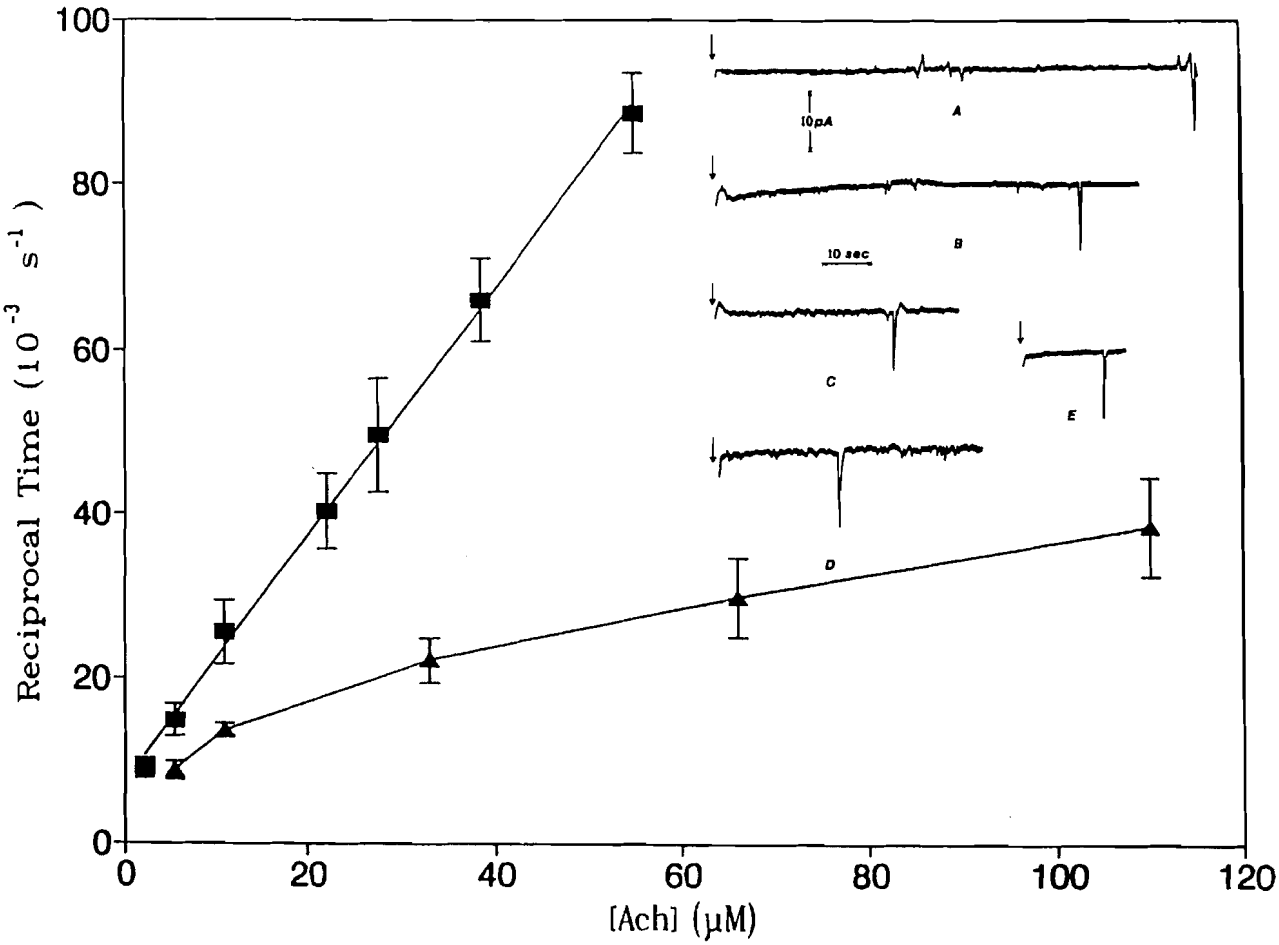
Electrochemical transduction of the pH changes associated with the reaction of acetylcholinesterase with acetylcholine by BLMs consisting of DPPA and PC has recently been reported (15). Acetylcholinesterase was incorporated into the BLMs so that there was a lipid-to-protein ratio of 150:1 (about 2×10^{-4} U). A transient change in current (analytical signal) appeared after a delay time of seconds to minutes (dependent on substrate concentration, Fig. 4) as a singular event after acetylcholine was added to solution. The transient signals for different concentrations of acetylcholine were approximately 10 pA in magnitude (background current 1 pA) and lasted for a period of about 1 s. These signals were due to the acetylcholine–acetylcholinesterase reaction as demonstrated by: control experiments in which acetylcholine or choline was added to the solution compartment in the absence of enzyme, by the use of denatured acetylcholinesterase, and by addition of the acetylcholinesterase inhibitor Neostigmine, which confirmed the reduction of enzyme activity as controlled by the concentration of inhibitor.

Similar experiments were done using the urea–urease system, where this second hydrolytic enzyme produced pH changes associated with the evolution of basic reaction products (16). Transient signals observed for the urea–urease system were similar in magnitude and profile, but opposite in direction, to those observed for the acetylcholinesterase-catalyzed hydrolysis of acetylcholine.

Mechanism for transduction based on electrochemical switching

Substantial conductivity differences between BLMs prepared from DPPA/PC have been observed when the membranes

Fig. 4. Calibration of the analytical signal, using in part the data of the insert. Triangles represent data from experiments at pH 5.5 and squares represent pH 8.0. The insert shows results obtained at pH 8.0 (0.1 M KCl, HEPES 10 mM, calcium ion 1 mM) with BLMs consisting of 35% DPPA when 3 μL of AChE (1.0 mg/mL) was codeposited at the air–water interface (before BLM formation). ACh concentrations (μM): (*A*) 2.20, (*B*) 5.50; (*C*) 11.0; (*D*) 22.0; (*E*) 38.5.



were formed at different values of pH, indicating that differences in surface charge density could alter ion permeability. If the transient currents observed for enzyme–substrate reactions were related to a well-defined steady-state BLM structure, then the current, g, would be approximated as:

$$g = A^*(1 + 0.381\sigma)$$

where A^* depends on electrolyte composition and σ is surface charge density. The surface charge density increases rapidly with pH and increases at the pK_a of the titration of DPPA, and conductivity might also be expected to change rapidly here. However, it is unlikely that this is responsible for the transient signals observed in the enzyme experiments. The surface charge density will continue to change past the pK_a as the pH continues to change, and a continuation of the trend of a change of conductivity would be expected (not a transient current response).

The appearance of a transient response has also been observed in some of our fluorescence microscopy studies of DPPA/PC monolayers at an air–water interface, during which a monolayer composed of lipids and acetylcholinesterase was rapidly exposed to a high concentration of acetylcholine. The fluorescence microscopy images indicated the presence of membranes of mixed phase structure. After a brief period of time following addition of acetylcholine (0.5–1 min) the image brightened substantially for a period of up to a few seconds, and then darkened again to a new equilibrium value of intensity. During the fluorescence "flash" there was no distinguishable change of phase structure in the fluorescence images.

The observed transient signals resulted from a change in pH at the membrane surface. However, just how the transient signal arises from a change in pH has yet to be determined. There are two possibilities, and the signal may result from a combination of these: (*i*) the signal results from rearrangements of the ions in the electrical double layer adjacent to the membrane during a rapid change of the extent of ionization of the lipids in the membrane; (*ii*) the transient results from the rearrangements of the structure of the BLM leading to a transient change in permeability of the membrane.

The mechanism of transient signal generation from BLMs prepared from DPPA/PC has been further investigated by continuous variation (titration) of pH in bulk solution to alter the surface charge density due to DPPA at the membrane surface (17).

PC is a zwitterion and thus has no net charge over the pH range of interest herein (pH 5–9). DPPA can be partially or fully ionized based on negative charges that are associated with apparent pK_a values. An electrical double layer would form at the surface of a BLM if it contained negatively charged phospholipid head groups. In a solution of 0.1 M KCl as used in these experiments, the primary layer would consist largely of potassium ions. This is significant since it is cations that are responsible for most of the ion current through these BLMs.

The surface potential of the membrane should change rapidly near the pK_a during a pH titration of the DPPA component of the membrane, and this should result in a rapid rearrangement of the double layer and therefore ion current as more cations move to compensate for the altered negative charge at the membrane. If the observed transient signal is due only to rearrangements of the electrical double layer, then the voltage change at the membrane surface when the signal is observed should correspond to that calculated by use of the Gouy–Chapman–Stern (GSC) model. If the voltage change associated with the total charge movement of an ion current transient is substantially larger than that predicted by GCS theory, then this would suggest that there s a pH-related phenomenon other than rearrangement of the electrical double layer that occurs.

During continuous pH titrations of BLMs prepared from PC/DPPA, large sharp transient signals (>10 mV) occurred at pH values between 8.1 and 7.0 (pH determined from calibration curves). For these experiments the actual pH at the surface of a BLM is lower than that in bulk solution, and can be approximated using a model of smeared uniform surface charge based on the Boltzmann relation. The increase in surface potential for an increase of DPPA content from 15 to 50% w/w would be associated with roughly an order of magnitude increase of H_3O^+ concentration at the membrane surface (for bulk solution pH in the range of 7–8), yet no clear distinction can be seen between the pH ranges at which sharp current transients were observed. The change in pH over the time course of transient signals is less than 0.1 unit, corresponding to a maximum change in potential of 2 mV as predicted by GCS theory. The area of the transient signals generally indicates that a capacitive charging potential would be of substantially larger magnitude than 2 mV. If the surface potential change of a BLM is calculated based on the pH change from the beginning of an experiment, then the magnitude of the capacitive charging phenomenon could be considered equivalent to the change of surface potential for many experiments. However, this is not the case for the largest transients, where the mismatch between theoretical surface potential and charging potential is beyond an order of magnitude. This suggests that rearrangement of the electrical double layer is not the only phenomenon responsible for the large transient signals that were observed. It would appear that during the course of the structural change the membrane becomes more permeable to ions, since the structure is less organized during the structural transition.

4. Transduction of antibody–antigen interactions

Transient ion currents similar in appearance to those associated with hydrolytic enzyme–substrate reactions were observed for an antibody–antigen interaction involving modulation of surface charge by virtue of formation of the complex (18). The thyroxin (T4) – anti-rabbit T4 interaction was chose as the immunological reaction owing to the clinical significance of T4. Recordings of signals obtained at pH 6.0 (without Ca^{2+} in bulk solution) for different concentrations of T4 with BLMs composed of 15% DPPA indicate the appearance of singular transient current signals. An important distinction in comparison to the enzyme–substrate results is that the magnitude of these transient responses is in direct proportion to the logarithm of the antigen concentration in bulk solution. Control experiments demonstrated that these signals were due to selective interactions, and involved application of antigen to BLMs in the absence of antibody, and the use of nonselective protein in the presence of antibody.

Rabbit anti-thyroxin antiserum contains antibodies with pI's between 6.3 and 9.0, whereas the pI of T4 is 5.0. Electrostatic forces are important in the mechanism of the formation of the antibody–antigen complex. The kinetics of the immunological reaction and the electrostatics of this interaction on one side of a BLM would be expected to cause a slow nonlinear double layer reorganization to occur.

The relatively constant delay times for transient current evolution for widely varying concentrations of antigen indicate that the mechanism responsible for the transient is not directly related to the charge associated with varying quantities of antigen at the BLM surface.

Similar singular current transients are not evident for BLMs composed only of PC, which may indicate that the phase structure of membranes is a predominant factor in the immobilization of immunoglobulins in BLMs, as these proteins prefer fluid areas enriched in DPPA. An increase of the pH of bulk solution (e.g., 8.0), which increases the degree of DPPA ionization (but decreases the number of hydrogen bonds between DPPA molecules) and reduces the positive charge of the antibody, results in a decrease of the signal magnitude. The presence of calcium ions in bulk solution reduces signal magnitude and dramatically delays the time for the appearance of the transient signals. BLMs can therefore be designed to provide fast and sensitive transduction of immunological interactions; e.g., detection limit of 1.0 nM of thyroxin (based on the experimental noise level of 0.7 pA) in a period of about 100 s.

5. Direct transduction of insecticides

To eliminate loss of calibration of a sensor due to denaturation of proteins, it is desirable to transduce insecticide composition into a measurable physical signal by means of selective interactions of the "stimulant" (analyze) directly with a membrane, i.e., no use of membrane-embedded receptor (19). The transduction can be designed to result from alterations of the electrostatic fields and (or) phase structure of the lipid membrane. Investigations of the direct interaction of pesticides with membranes are generally limited to absorption and permeability studies using natural cell membranes. Recently such studies have been extended beyond insecticide–acetylcholinesterase interactions to include receptors, and modulation of ion channel activity by insecticides.

Some typical pesticides were chosen for our studies and included Monocrotofos, Carbofuran, Aldicarb, and Methyl-parathion. Monocrotofos and Methyl-parathion are organophosphorus insecticides, Carbofuran is a carbamate derivative, whereas Aldicarb is an aliphatic carbamoyl-oxime. These toxicants are expected to adsorb and partition into the lipid membrane as determined by solubility parameters; the degree

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

of such an interaction depends largely on the chemical structure of the insecticide.

Transient current responses were observed for these experiments only for Monocrotofos and Carbofuran. A transient appeared at a relatively constant time after exposure of the membrane to monocrotofos (3.3 ± 0.3 min, $N = 5$). Similar transient current signals were obtained when using Carbofuran, and the transient signals appeared with a relatively constant delay time that was longer than that for Monocrotofos (4.8 ± 0.5 min, $N = 5$). A constant delay time of current transients was obtained when using a constant concentration (4.48×10^{-6} M) of Carbofuran (4.9 ± 0.4 min, $N = 5$), indicating that the reproducibility of the time of appearance of the signal is on the order of ca. ±9%. The magnitudes of the transient of current increased with an increase in the concentration of insecticide. Further transients of similar size were not observed over periods of 30 min after the large transient signal. The magnitude of the transient signals can be used to quantify the concentrations of Carbofuran and Monocrotofos, as the heights of the transients are linearly related to the concentration of insecticide. Reproducibility of the determination of concentration of both insecticides by use of the height of transients is about ±10%.

The transient signals have a duration of seconds or less and are indicative of alterations of the electrostatic fields of BLMs. These alterations include membrane double layer and hydrogen-bonding-network reorganizations owing to the adsorption of Monocrotofos and Carbofuran onto the membranes. These insectides are hydrophilic, which contributes to adsorption onto membranes. Monocrotofos has a structure similar to that of phosphatidic acid but the methoxy moieties impart some lipophilicity to the molecule. Both phosphatidic acid and Monocrotofos can form a hydrogen-bonding network at the membrane surface by interactions with the oxygen atoms, and alterations of such hydrogen-bonding networks are associated with reorganization of the double layer at one side of the BLM. A rapid reorganization would be observed as a phenomenon such as a transient signal.

The magnitude and sensitivity of the signal for insecticide determination depends on the quantity of DPPA in the BLM structure and the concentration of calcium ions in bulk solution. The signal magnitude is increased when the quantity of the charged lipid in the BLM is increased and (or) in the presence of calcium ions in bulk electrolyte solution. These results suggest that the presence of a phase distribution of the BLM is important for maximizing signal magnitudes.

The detection limit for Monocrotofos and Carbofuran determination measured in these experiments can be set to be three times the standard deviation of the background signal of 0.4 pA. Such a detection limit in our experiments will be 4.5×10^{-8} M and 4.8×10^{-7} M for Monocrotofos and Carbofuran, respectively. These detection limits are similar in magnitude to those obtained by electrochemical methods based on the inhibition of cholinesterases, but Monocrotofos and Carbofuran can be determined much more quickly when using detection based on BLMs.

6. Physical stabilization by surface immobilization of membranes

Development of practical devices must include mechanical stabilization of a lipid membrane onto a solid electrode, where covalent linkages between the support and the lipid/receptor molecules are desirable. To avoid the effects caused by accumulation of ions on one side of a stabilized membrane, the measurements must be made by driving the system with an a.c. voltage and by monitoring admittance with a phase-sensitive amplifier. We have described progress towards a surface-stabilized a.c. admittance modulation lipid-membrane-based biosensor that operates on the basis of control of ion permeation by artificial ion channels (20).

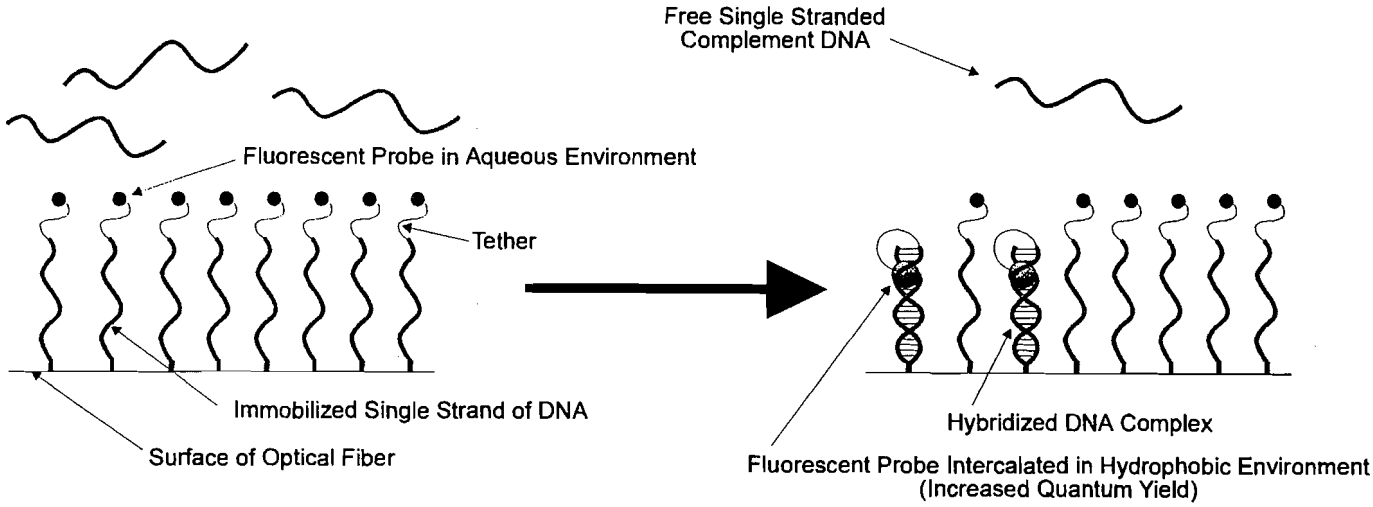
A portable admittance modulation measurement device was constructed, and was designed to measure both the in-phase and out-of-phase signal components for determination of "effective" ion current and membrane capacitance. The sensitivity and detection limit for the a.c. system were tested by studying the interaction of the ionophore valinomycin with planar BLMs. The electrochemical effects were observed as conductance changes of the membrane, with the limit of detection for valinomycin being at the 1 nmol dm^{-3} concentration level.

Metal electrodes were used as supports for covalent attachment of amphiphiles. Platinum electrodes with a surface area of 1 cm^2 were oxidized to provide a high density of surface hydroxyl sites. Immobilization of amphiphiles was carried out by reaction of the hydroxyl sites with silane. Gold electrodes were prepared by vacuum deposition of a 250 nm layer of the metal onto a 30 nm layer of chromium that covered borosilicate glass slides. Surface attachment of amphiphiles to this metal was achieved by sulphur–gold interactions.

A wide variety of amphiphiles differing in hydrocarbon chain length, number of chains (one or two), chain polarity, head group charge, and head group size (e.g., acidic phosphate, carboxylic acid and ester, phosphatidylcholine) were attached to both the platinum and gold surfaces. Two-step attachment procedures, as exemplified by the initial deposition of aminopropyltriethoxysilane (APTES) onto platinum followed by linkage of a 10-carbon phosphatidylcholine through an amide bond to the amino group; of APTES, often provided greater surface coverage than it an equivalent 16-carbon phosphatidylcholine had been deposited directly by the reaction of hydroxyl moieties with silane at the metal surface. Surface coverage for most experiments was in the range 40–85% as determined by X-ray photoelectron spectroscopy, and was dependent on the deposition procedure, the chain length, and the number of chains. The electrochemical results indicated that the best blockage of ion conductivity occurred when the amphiphiles contained long hydrocarbon chains. Species such as trichloro-octadecylsilane and octadecylthiol provided the best blockage, reducing the in-phase signal component by 95% for both types of metal electrode. Analogues of natural lipids such as dimyristoylphosphatidylcholine reduced the in-phase component by values of about 50%. Subsequent incubation of lipid-coated electrodes in solutions containing membrane-soluble species such as cholesterol greatly reduced the magnitude of the in-phase component of the signal to values approaching those found for BLMs. These latter electrodes were tested for response to the presence of valinomycin, and achieved detection limits in the range 10–100 nmol dm^{-3}.

A further series of analytical experiments were carried out to develop electrodes that were sensitive to pH variations, to extend the concept of control of phase domain structure to immobilized membranes. Linear 10-carbon silane and thiol

Fig. 5. Proposed scheme for development of fiber optic sensor to detect DNA hybridization.



carboxylic acids were immobilized onto platinum and gold surfaces, and both systems showed good sensitivity to pH (e.g., a pH change from 7 to 8 caused a conductivity change of 25%). Modification of this system to evaluate a biosensing strategy was then done. In separate experiments, active urease and acetylcholinesterase were adsorbed onto these acidic surfaces, and urease was also covalently immobilized through the acidic functional group. The electrochemical transduction of substrates for both of these enzymes indicated the presence of time-dependent singular transients of current, thereby confirming that stabilizing sensors similar in function to BLMs could be produced. Further work involving improvement of longevity of protein function, and optimization of signal magnitude, is now underway.

New directions

We are continuing to investigate the use of organized membranes for selective chemical transduction and have recently focused attention on the use of immobilized single-stranded DNA on optical fibers for development of an analytical sensor. Fluorescent dyes are incorporated into the DNA fragments as a means of signalling the binding of DNA complement. By this approach, we can use the TIRF method for detecting binding events to "receptor" attached to an optical fiber. The use of DNA and RNA as analytical markers for applications in biotechnology and for detecting pathogenic organisms has become widespread. An important advantage provided by DNA when used as a biorecognition element is that it provides excellent chemical selectivity and outstanding chemical stability with respect to denaturation. The general focus of the research work is to use fluorescence methods to investigate hybridization of DNA (from target organism nucleus) or RNA (from cytoplasm) from sample solutions with organized monolayer membranes of complementary DNA. The specific goals of the work are to determine how the molecular organization of oriented single-stranded DNA at an interface can be controlled to permit rapid hybridization and rapid, complete dissociation of hybridized sequences using thermal and chaotropic methods. As a first step in developing this idea, we have used an automated DNA synthesizer to grow thymidylic acid icosanucleotides (dT_{20}) onto quartz optical fibers. These were then used in a TIRF configuration in a flow-through solution compartment. The covalently immobilized oligomers were able to hybridize with only complementary DNA, as indicated by the use of the fluorescent DNA stain ethidium bromide. Even without optimization, this procedure provided a detection limit of 86 ng mL^{-1} of complementary DNA, and the system could be used reversibly with a response time in the range of 20–30 min (21). We are now developing single-step immobilization schemes for attachment of complete oligomers in high density, and the use of tethered dyes (Fig. 5) so that the sensing systems are effectively internally calibrated and require no external additions of reagents for detection of hybridization.

Further work is focusing on the development of new spectroscopic techniques for investigation of monolayers at solid surfaces. Perhaps the most promising of these is the combination of photopyroelectric spectroscopy with the surface plasmon resonance achieved by the design and use of small metal particles. This approach will provide electric field enhancements at a surface for spectroscopy, and can be used to provide thermal decay pathways so as to maximize heating and therefore the sensitivity of pyroelectric detection (22). We have already demonstrated that such a sensor configuration can readily detect sub-monolayer surface coverage using low-power optical sources, and that chemically selective organized monolayer assemblies can provide substantial advantages in terms of improvements of S/N in comparison to the use of random chemically selective films (23).

1994 Merck Frosst Award Lecture New strategies for the stereoselective synthesis of natural and unnatural products via organometallic reagents and catalysts[1]

Mark Lautens, Yi Ren, Patrick Delanghe, Pauline Chiu, Shihong Ma, and John Colucci

Abstract: Samarium in the presence of diiodomethane selectively cyclopropanates an allenic alcohol to yield a methylenecyclopropane with modest to excellent diastereoselectivity. The effect of substituents at the carbinol carbon and the allenic carbon on the diastereoselectivity was investigated. A palladium catalyst was shown to promote the intramolecular cycloaddition of the methylenecyclopropane with an electron-deficient alkyne to yield a methylenecyclopentane. The reaction was stereospecific with retention of stereochemistry as proven by X-ray diffraction. Nickel catalysts accelerate the hydroalumination of oxabicyclo[3.2.1]alkenes, leading to bicyclic trialkylalanes. Upon treatment with a Lewis acid (diisobutylaluminum chloride), the trialkylalanes fragment to provide cycloheptenols. This reaction, followed by an enantioselective enzyme-catalyzed esterification, was used as a key step in a synthesis of the mevinic acid lactone.

Key words: methylenecyclopropane, palladium, stereocontrol, oxabicyclic, nickel.

Résumé : Le samarium, en présence de diiodométhane, transforme sélectivement un alcool allénique en méthylènecyclopropane avec une diastéréosélectivité allant de modeste à excellent. On a étudié l'effet d'un substituant porté par le carbone carbinolique, et par le carbone allénique, sur la diastéréosélectivité. On montre qu'une catalyse par le palladium favorise la cycloaddition intramoléculaire du méthylènecylopropane, avec un alkyne déficient en électron, pour donner un méthylènecyclopentane. La réaction est stéréospécifique avec rétention de la stéréochimie tel que l'indique la diffraction de rayons X. La catalyse par le nickel accélère l'hydroalumination des oxabicyclo[3.2.1]alcènes conduisant aux trialkylalanes bicycliques. Ces trialkylalanes traités par un acide de Lewis (chlorure de diisobutylaluminium) se fragmentent pour donner des cyclohepténols. On utilise cette réaction suivie d'une estérification catalysée par une enzyme énantiosélective comme étape clé dans une synthèse de la lactone de l'acide mévinique.

Mots clés : méthylènecyclopropane, palladium, stéréocontrôle, oxabicyclique, nickel.

[Traduit par la rédaction]

1. Introduction

New reactions and strategies are important for the stereoselective synthesis of natural and unnatural products having interesting architectures and (or) biological activity. Results are described from two of our programmes, which have as a common theme the use of cyclic molecules as templates for the control of stereochemistry in the efficient construction of natural product skeletons. An efficient method for the synthesis of stereochemically defined methylenecyclopropanes is presented and preliminary data on the stereoselectivity of transition-metal-catalyzed intramolecular cycloaddition reactions are discussed. In the second section, the use of metal catalysts in hydrometalation–fragmentation reactions leading to substituted cycloheptenols is described.

Received January 4, 1995.

This paper is dedicated, with respect, to Professor Michael J. Dignam (1931–1994).

2. Stereochemical relay in cyclopentane formation

The use of methylenecyclopropanes as precursors to methylenecyclopentanes through a nickel- or palladium-catalyzed process has been known since the pioneering studies of Noyori, Odagi, and Takaya, and Binger and Schuchart more than 20 years ago, eq. [1] (1). The field has been reviewed

For personal use only.

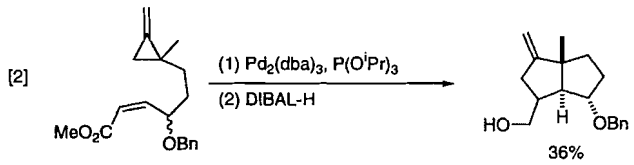
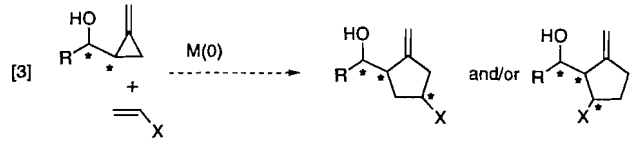
several times and only the most relevant background information is provided (2). This reaction is more complex than it appears since substrate, catalyst, and acceptor each play a role in influencing whether the distal or proximal carbon–carbon bond undergoes initial reaction with the metal. It is informative to compare the results described herein with those obtained from palladium-catalyzed trimethylenemethane (TMM) cycloadditions when attempting to resolve mechanistic issues surrounding these reactions (3).

While the intermolecular methylenecyclopropane reaction has been the most extensively studied, intramolecular versions of the cycloaddition are known. Yamago and Nakamura and Motherwell independently made the first contributions to this area (4). The example reported by Motherwell is particularly interesting since a *trans*-fused [3.3.0] system is formed, eq. [2].



At the outset of these studies it was not known whether transition-metal-promoted cycloaddition reactions of methylenecyclopropanes catalyzed by nickel or palladium were stereospecific and (or) stereoselective and if stereochemical information could be transferred from the pre-existing stereocentres to new stereocentre(s) created in the cyclopentane, eq. [3].



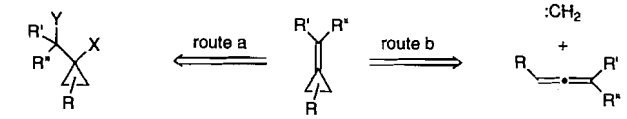
To investigate these questions, an efficient route to diastereomerically and enantiomerically enriched starting materials was essential. Furthermore, a determination of substituent effects within the methylenecyclopropane and the acceptor would define the utility of this reaction and also provide mechanistic information. While data answering all these questions is not yet in hand, progress on several fronts has been achieved.

3. Preparation of starting materials

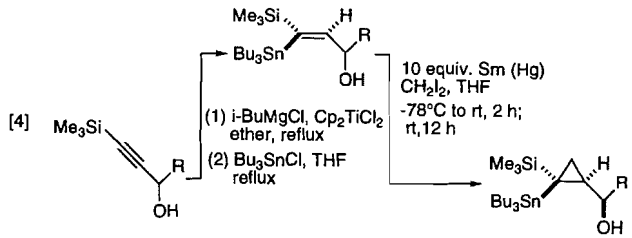
There are many reported routes to methylenecyclopropanes in the literature (5). Unfortunately, many of these approaches are not easily adapted to preparing diastereomerically and enantiomerically pure products that have a hydroxyalkyl group (R = CH(OH)R). Two that appeared to be promising for our needs are illustrated in Scheme 1. The initial plan was to examine route "a" since we had developed access to 1,1-bimetallic compounds by a hydroxyl-directed cyclopropanation of vinyl bimetallic compounds (6).

We found that the Molander cyclopropanation (Sm, CH_2I_2, THF) (7) gave the bimetallic cyclopropanes in 75–92% yield and the diastereoselectivity was in excess of 200:1 as a result of the tributyltin moiety acting as a controlling group, eq. [4].

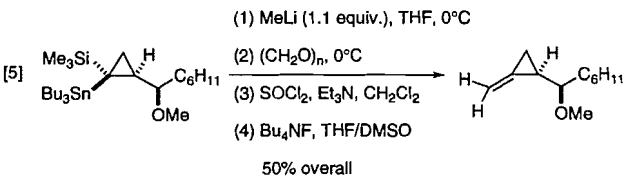
Scheme 1.



X=SiMe₃, Y=OH



The starting 1,1-bimetallic alkenes were readily prepared in 68–85% yield by a modification of the Sato hydrometallation procedure (Cp_2TiCl_2, i-BuMgCl, Et_2O) (8). Following protection of the alcohol as the methyl ether, treatment of the cyclopropyl stannane with MeLi at 0°C gave the lithiocyclopropane, which was trapped with formaldehyde. This product does not readily undergo Peterson elimination except when the alcohol is converted to the chloride, which then reacts with Bu_4NF in THF/DMSO, eq. [5]. The overall yield for this four-step, three-pot procedure typically exceeds 50%.

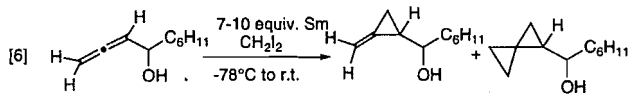


While this reaction sequence was successful, a more direct and efficient route was required. The selective cyclopropanation of an allenic alcohol would represent an ideal approach to the preparation of methylenecyclopropanes. The potential of this approach was first recognized more than 25 years ago by Bertrand and Maurin (9). However, they reported that under Simmons–Smith conditions, mono- and biscyclopropanation occurred and, furthermore, the reaction was not diastereoselective. We reexamined their results using various modifications of the Simmons–Smith reaction (10) and confirmed the lack of selectivity they reported. The best results were obtained when the sodium alkoxide of the allenic alcohol was treated with Et_2Zn–CH_2I_2. Up to 13:1 selectivity toward the olefin proximal to the hydroxy group was observed, but it was necessary to stop the reaction prior to complete consumption of starting material or an erosion in selectivity was noted.

In considering alternatives to Zn-based cyclopropanation, two observations from earlier studies using the Sm-promoted reaction of allylic alcohols suggested it might be more selective. Firstly, the oxygen of an allylic ether was a poor substrate for cyclopropanation, indicating that direction by the free hydroxyl was occurring. Secondly, homoallylic alcohols, react much more slowly than allylic alcohols, implying that the carbenoid cannot reach the more remote olefin. When an allenic alcohol was subjected to the Molander conditions we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

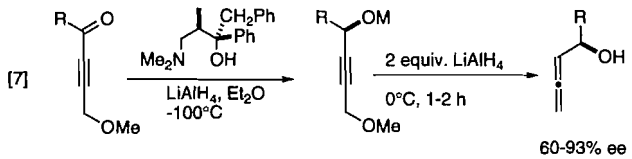
obtained the desired product in 64% yield and the selectivity was >70:1 in favour of monocyclopropanation, eq. [6]. Using



$ClCH_2I$ led to a further improvement in the yield, to 82%, with no loss of selectivity. Furthermore, under these conditions it was not necessary to add $HgCl_2$ to initiate the cyclopropanation.

With this encouraging result in hand, we prepared several more allenic alcohols using routes developed by Landor, Yamamoto, and Brandsma and co-workers, respectively, to study the effect of substitution on the diastereoselectivity (R, R′ = alkyl, H) (11).

A route to enantiomerically enriched allenic alcohols was also developed by combining an enantioselective carbonyl reduction with the Landor allenic alcohol synthesis, eq. [7].



The use of a Chirald®-$LiAlH_4$ complex (12) gave the best overall results since reduction of the ynone to the propargyl alcohol could be followed by the S_N2' delivery of hydride to form the allene moiety without isolation of the intermediate. In practice this approach worked smoothly but additional $LiAlH_4$ was required following the carbonyl reduction step. This was surprising since species containing active hydride remained. We conclude that the Chirald®-$LiAlH_4$ complex is unable to effect the S_N2' reaction.

With the starting materials in hand, a determination of the substituent effects on the diastereoselectivity was undertaken. In the initial experiments with R = Cy, ratios approaching 10:1 were obtained for either CH_2I_2 or $ClCH_2I$. A correlation was observed between the steric size of the R group and the diastereoselectivity, Scheme 2. As we and others had observed previously, *n*-alkyl groups give poor and opposite selectivity (7). Smaller R groups may be capable of adopting the "inside" position, leading to the diastereomeric product. A transition state structure is shown that predicts the stereochemistry of the major diastereomer. Proof of the relative stereochemistry relied on comparison with an authentic sample prepared by an alternative route, vide infra.

The effect of substituents at other positions was also determined, Table 1. The most surprising result was that, whereas changing from R′ = H to R′ = Me had little or no effect on the diastereoselectivity, when R′ = OMe significant improvement in selectivity was observed. Clearly, electronic factors also influence the level of selectivity.

4. Proof of stereochemistry

Three different methods were used to assign the relative stereochemistry of the methylenecyclopropanes. Conversion of a 1,1-bimetallic compound of known stereochemistry to the methylenecyclopropane was used whenever possible, eq. [5].

Scheme 2.

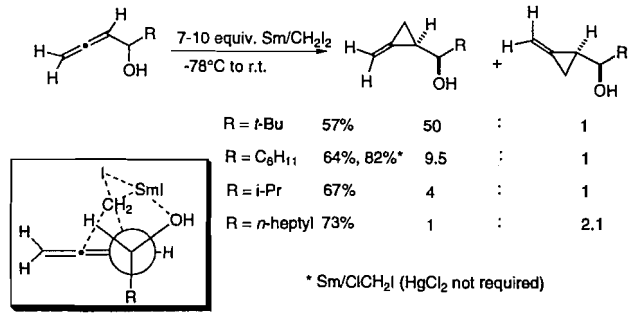


Table 1.

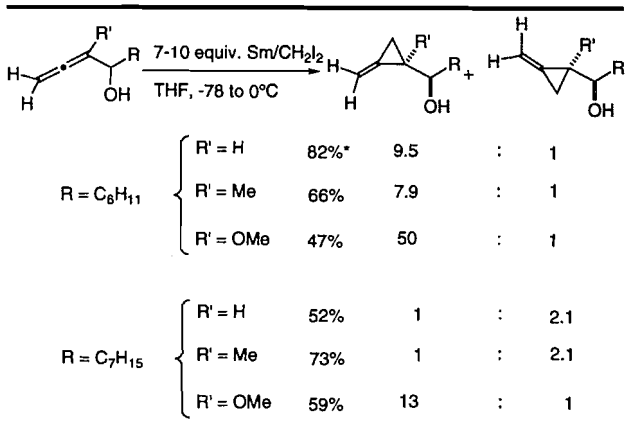

Fig. 1.

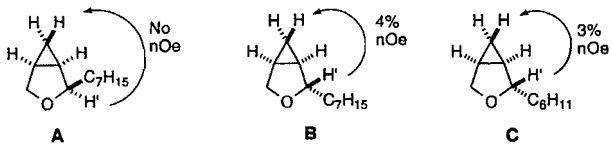
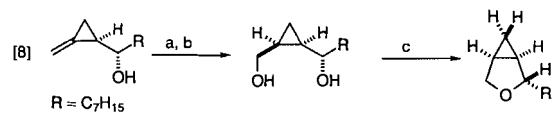


For R = cyclohexyl, R′ = OMe and Me, X-ray diffraction was used.

Nuclear Overhauser enhancements (nOe's) were also used to determine the stereochemistry. Rigid cyclic bicyclo[3.1.0] ethers were prepared by hydroboration, selective tosylation, and in situ cyclization, eq. [8]. Whereas the ether from the



(a) BH_3 (3 equiv.), THF, 0°C. (b) H_2O_2, NaOH, EtOH, 66%. (c) *p*-TsCl (1 equiv.),Pyridine, 0°C, 83%

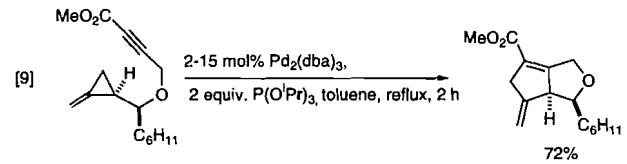
minor diastereomers showed a 3–4% nOe between the *endo* cyclopropyl hydrogen and H′ (**B** and **C**), no nOe was observed for the ether prepared from the major diastereomer **A**, Fig. 1. All these studies confirm that the facial selectivity of the cyclopropanation is identical irrespective of the substituent R′.

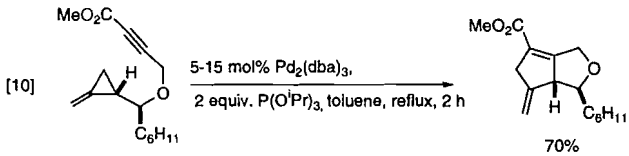
5. Intramolecular cycloadditions of methylenecyclopropanes

It was possible to address the question of stereoselectivity/

specificity in the metal-catalyzed cycloaddition by subjecting each of the diastereomeric methylenecyclopropanes to the reaction conditions and analyzing the stereochemistry of the products. Intramolecular reactions were examined first because they are known to be more efficient with substituted methylenecyclopropanes. Palladium catalysts were used because they consistently give exclusive insertion into the distal bond (1*b*,*c* and 2).

The side chain was introduced by deprotonation of the alcohol with KH–THF in the presence of 18-crown-6, addition of propargyl bromide, deprotonation of the terminal acetylene (*n*-BuLi, THF, 0°C), and addition of $ClCO_2Me$. Treatment of the substrates with $Pd_2(dba)_3$, 2 equivalents of $P(O^iPr)_3$ to Pd in toluene at reflux for 2 h, gave the cycloadducts in 70 and 72% yield, respectively, eqs. [9] and [10]. Examination of the ^1H





and ^{13}C NMR spectra clearly indicated that the products were not identical and that a stereospecific process had occurred (13). An X-ray structure revealed that cycloaddition with retention of configuration at the cyclopropyl stereocentre had taken place (14).

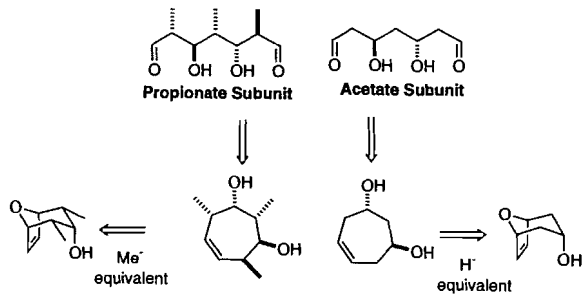
6. Conclusions

We have shown that Sm-promoted cyclopropanation of allenic alcohols is the most efficient route to the synthesis of diastereomerically enriched methylenecyclopropanes. Substitution is tolerated at every position in the allene and significant variation in the diastereoselectivity is observed as a function of steric and electronic factors. Intramolecular palladium-catalyzed cycloaddition onto an electron-deficient alkyne is stereospecific and occurs with retention of configuration. This information can be utilized in the design of natural product syntheses.

7. Stereocontrol via oxabicyclic templates

This program of research seeks to develop chemical reactions that convert a bicyclic molecule to an acyclic molecule with a resulting increase in the stereochemical content of the product. Our objective was to develop a strategy toward aldol-type products via non-carbonyl-based reactions (15). Ideally, the new strategy would avoid the iterative nature of many aldol reaction sequences. The challenges to be met include: access to all possible *syn* and *anti* products, high diastereo- and enantioselectivity, and chemical efficiency as measured by number of synthetic operations and chemical yields. Some of these objectives have been met and studies are ongoing.

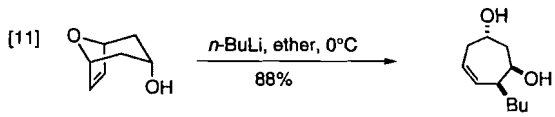
Scheme 3.

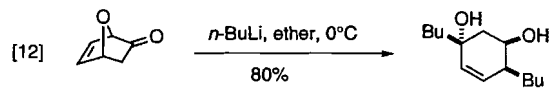


Specifically we were interested in utilizing the stereochemical information contained within oxabicyclic compounds as a route to acyclic molecules bearing acetate and propionate aldol sub-units, Scheme 3. The correct choice of starting material and nucleophile would provide access to a diverse collection of stereochemically useful products.

In a projected synthesis of ionomycin, we anticipated that the C_1–C_{23} section could be assembled from three subunits that would arise from a common starting material. The synthesis of ionomycin has been the subject of considerable interest and two total syntheses have been reported (16). Molecules of this complexity provide an opportunity to develop new strategies and test the state of the art in organic synthesis. Considerable progress toward this objective has been achieved and the methodology that is being utilized in this synthetic effort is presented.

The concept of using nucleophiles to open oxabicyclic starting materials was first reported more than 20 years ago by Caple et al. (17). Reaction of highly strained benzooxabicyclic derivatives with an organolithium and dehydration of the products gave a route to 2-substituted naphthalenes. Concurrent with our studies using cuprates and organolithium reagents with oxabicyclo[3.2.1] substrates was elegant work by Arjona, Fernandez de la Pradilla, Plumet and co-workers on the [2.2.1] series, eqs. [11], [12] (18).





We extended the range of nucleophiles to include ring opening by a hydride source (reductive ring opening). Two sources of hydride were identified: organomagnesium reagents bearing a β-hydride react with oxabicyclic compounds in the presence of excess $MgBr_2$ but the reaction is slow and limited in scope (19*a*); a more general method uses excess DIBAL-H in refluxing hexanes (19*b*). The solvent and temperature were important variables in the latter case since the reducing agent seems to also function as a Lewis acid in assisting the opening. Other nucleophilic reducing agents such as $LiAlH_4$ are much less efficient. The optimized conditions utilized 3–5 equivalents of DIBAL-H in hexanes at reflux for 1–16 h, eq. [13]. While many substrates give good yields of the desired product, a side-product was isolated in which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

reduction of the alkene occurred. Hydroalumination of the ring-opened product seems to be competitive with the initial ring-opening reaction in some cases. A technical problem is that these two products are often difficult to separate by chromatography or distillation.

[13] 
R=H, 8-12 h	83%	13%
R=Bn, 24 h	<10%	75%

A search for a more selective reducing system was initiated and the mildness of transition metal-catalyzed hydrometalations was noted (20). Nickel, palladium, zirconium, and titanium all accelerate the hydroalumination of alkenes and alkynes (20, 21). It was not clear at the outset if the hydroaluminated oxabicyclic compound could be observed or if it would undergo immediate ring opening. In the latter scenario, the product could also undergo hydroalumination, defeating the purpose of using the catalyst. Experiments to answer some of these questions were initiated.

After a survey of catalysts, Ni(0) complexes were found to be the most suitable since the reaction occurred rapidly at −78 to 0°C with 5–14 mol% of catalyst and with only 1.2 equivalents of hydrometalating agent (DIBAL-H), whereas reaction in the absence of catalyst required 5 equivalents of DIBAL-H at elevated temperatures. The trialkylalane was observed rather than the ring-opened product, as proven by deuterium trapping and oxidation studies (22).

Upon warming the trialkylalane to 70°C for 16 h, elimination occurs to provide the desired product in 65% yield accompanied by the oxabicyclic alkane in 34% yield, Scheme 4. The alkane may result from protonation of unreacted alane since elimination is quite difficult under these conditions. It is not possible to determine if epimerization precedes the *anti* elimination or if a *syn* elimination is occurring. We reasoned that addition of a Lewis acid would provide assistance to either of these processes by complexing to the bridging oxygen, thereby improving its leaving-group ability (23). Under optimized conditions, heating a mixture of the hydroaluminated product and DIBAL-Cl to 65°C gave the cycloheptenol in 88% yield.

An example of the dramatic improvement in the efficiency of this process is illustrated in the reaction of an unsubstituted oxabicyclic compound, Table 2. Using 5 equivalents of DIBAL-H in the absence of catalyst, a 1:1 mixture of the cycloheptene and cycloheptane diols was obtained. Addition of nickel avoided the formation of the alkane but the ring opening was inefficient and an equimolar amount of the oxabicyclic alkane was isolated. However, the combination of a nickel catalyst, DIBAL-H, and then a Lewis acid catalyst gave the *meso* cycloheptene diol in 85% yield with only a trace of the oxabicyclic alkane, which was easily separated. This diol was used in a synthesis of the lactone portion of mevinolin as described below (24). A second key step in the synthesis is the differentiation of the enantiotopic hydroxyl groups that was achieved by taking advantage of the high specificity of enzymes in ester formation and hydrolysis (25).

8. Synthesis of the mevinolin lactone

Mevinolin is a potent inhibitor of HMG-CoA reductase and as

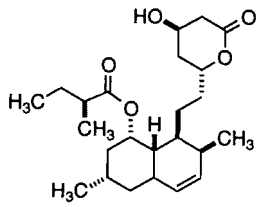
a result has attracted significant attention from the synthetic and biological communities (26). The lactone moiety is essential for biological activity, whereas structural variation in the hexahydronaphthalene moiety is possible.



Mevinolin

As mentioned above, conversion of the *meso* diol to an enantiomerically enriched hydroxyester was achieved using an enzyme, Scheme 5. Transesterification using isopropenyl acetate and Lipase AY-30 gave the hydroxyester in 78% yield and in 95% ee as measured by Chiral GC (27). Alternatively, double acetylation of the *meso* diol furnished a *meso* diacetate, which was selectively hydrolyzed using Lipase PS30 (28). Only one enantiomer was detected under these conditions but the reaction suffered from modest yields (54%). The absolute configuration using either route to the hydroxyester was identical and was predicted based on analysis of the Mosher ester ^1H NMR spectrum at 500 MHz. The signals for H′ appear at 1.91 ppm in the major diastereomer and at 2.01 ppm in the minor diastereomer.

With ready access to the enantiomerically pure hydroxyester,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12

two routes to the mevinic lactone were examined, Scheme 6. Direct ozonolytic cleavage of the olefin gave a dialdehyde, which reacted with the unprotected hydroxy group to form a lactol aldehyde that served to differentiate the two aldehyde groups. Selective reaction of the free aldehyde with a phosphorus ylide gave the olefin as a mixture of isomers (*trans*:*cis* = 2:1). Oxidation of the lactol to the lactone using TPAP/NMO (29) and hydrogenation of the olefin gave an aryl mevinic acid derivative.

Alternatively, protection of the free hydroxyl as a TBDMS ether occurred in 96% yield, Scheme 6, steps e–g. Oxidative cleavage of the double bond to the diacid followed by selective deprotection of the silyl group under acidic conditions resulted in concomitant lactonization to the lactone-acid in 57% yield. It is interesting to note that the enantiomeric product is also potentially available by cleavage of the acetate rather than the silyl moiety following the oxidation step.

9. Conclusions

Oxabicyclic compounds are readily available starting materials and they have been found to undergo novel reductive ring-opening reactions. Transition-metal-promoted hydrometalation–fragmentation using nickel catalysts and an aluminum hydride is superior to our previously reported reductive procedures, providing improved yields and milder reaction conditions. Application of this reaction represented a key step in a synthesis of the mevinic acid lactone.

Summary

Palladium catalysts promote stereospecific reactions of methylenecyclopropanes with alkynes, providing the first information on the fate of a preexisting stereocentre during the insertion and cycloaddition process. The use of a nickel catalyst in the reaction of oxabicyclic compounds opens up the potential of regio- and enantioselective reactions by the addition of phosphine ligands (30). The information obtained in these studies is currently being used in the synthesis of complex natural products.

Tautomérie du 2,5-dimercapto-1,3,4-thiadiazole et synthèse de thiadiazoloacridiniques

Pascale Amiel, Abdallah Mahamoud, Pierre Brouant, Jean Pierre Galy, Jacques Barbe, Janina Karolak-Wojciechowska et Maciej Posel

Résumé : On a préparé des 2(3*H*)-thione-5-alkylthio-1,3,4-thiadiazoles dont l'arylation par différentes 9-chloroacridines a conduit, dans la pyridine servant de solvant et de base, à des 2-thione-(*N*)3-acridinyl-5-alkylthio-1,3,4-thiadiazoles. La structure moléculaire de ces composés a été précisée par spectroscopie de RMN. En outre, on a procédé à l'étude radiocristallographique d'un intermédiaire de synthèse, la 2(3*H*)-thione-5-[2′-(diéthylamino)éthylthio]-1,3,4-thiadiazole. On a ainsi mis en évidence l'existence d'une fonction thione à l'état solide, la RMN l'ayant déjà démontrée à l'état dissous. Par ailleurs, on a préparé les 2-thioacridinyl-5-alkylthio-1,3,4-thiadiazoles à partir du sel de sodium des 2-mercapto-5-alkylthio-1,3,4-thiadiazoles. On a ainsi montré que la tautomérie jouait un rôle déterminant dans la réactivité du substrat de départ.

Mots clés : acridines, thiadiazoles, tautomérie.

Abstract: Some 2(3*H*)-thione-5-alkylthio-1,3,4-thiadiazoles were prepared with a view to arylating these compounds with 9-chloroacridines. Using pyridine as solvent and base, this arylation led to the 2-thione-(*N*)3-acridinyl-5-alkylthio-1,3,4-thiadiazoles. Molecular structures of the latter were determined either by NMR spectroscopy or by referring to X-ray crystallography of the 5-(diethylaminoethylthio)-1,3,4-thiadiazole-2-thione. Thus, with respect to the tautomeric equilibrium of the compound investigated, the thione group was detected either in the solid state or in solution. In contrast, 2-acridinylthio-5-alkylthio-1,3,4-thiadiazoles were prepared by using the sodium salt of 2-mercapto-5-alkylthio-1,3,4-thiadiazoles as starting material.

Key words: acridines, thiadiazoles, tautomerism.

Introduction

On a voulu préparer des produits originaux où se retrouveraient les propriétés trypanocides des acridiniques (1, 2) et des thiadiazoles (3). Ainsi a-t-on cherché à remplacer dans les 9-thioalkylacridines, les groupements alkylés par un reste thiadiazole. On a choisi à cette fin le 2,5-dimercapto-1,3,4-thiadiazole **1**, comme produit de départ, en raison de sa réactivité particulière. En effet, cette molécule peut exister théoriquement sous les trois formes tautomères **1***a*, **1***b* et **1***c* (4–6) données dans la figure 1.

Résultats et discussion

Le but était de préparer des dérivés thioalkylés du thiadiazole **1** afin de les condenser ultérieurement avec des 9-chloroacridines **2** diversement substituées (figure 2).

On a donc d'abord synthétisé les composés monothiosubstitués **3** selon la méthode d'Inoue et al. (7) qui utilise le butanol normal à reflux en milieu alcalin avec un équivalent de réactif par rapport à **1** et, comme base, un équivalent de pyridine. Ce protocole a permis d'obtenir les dérivés **3** avec de bons rendements (environ 90%), car il évite la formation parasite de produits de dithiosubstitution comme il s'en produit par exemple en suivant d'autre conditions expérimentales décrites dans la littérature (8). On a par ailleurs voulu vérifier si la dithioalkylation du produit de départ **1** était possible par la même méthode; on a donc doublé les quantités de réactif et de base. On n'a toujours obtenu que le produit de monothiosubstitution **3**, d'ailleurs avec un rendement moins élevé que dans les conditions précédentes (environ 70%). De même, il n'a été possible de préparer par cette méthode les dérivés dithiosubstitués **4** à partir des dérivés monothiosubstitués **3** (sous forme de base

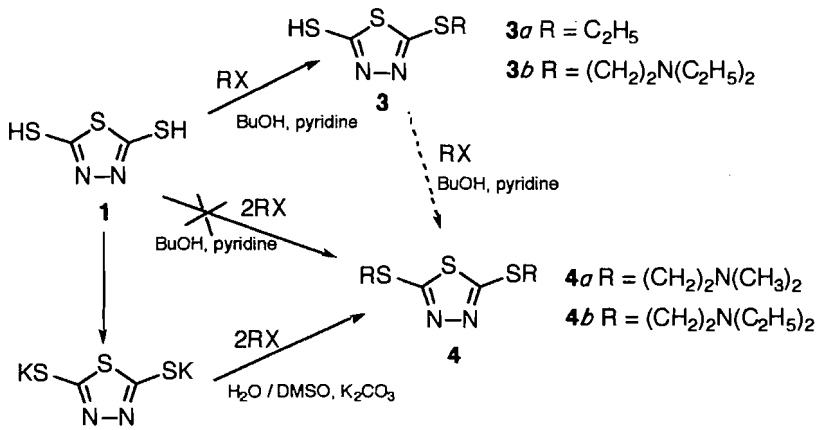
Fig. 3. Monothioalkylation et dithioalkylation du 2,5-dimercapto-1,3,4-thiadiazole.



libre), qu'avec des rendements faibles (<25%). Pour obtenir les composés **4** avec de meilleurs rendements, on a donc dû alkyler le sel dipotassique du 2,5-dimercapto-1,3,4-thiadiazole (Sigma–Aldrich), dans un mélange DMSO–H_2O en présence de K_2CO_3 (9) (figure 3). Les rendements en base libre sont alors ≥ 65%.

Cependant, pour obtenir les dérivés **6** qui sont substitués sur chaque atome de soufre exocyclique par des groupements différents, le protocole décrit est inapplicable parce que les 9-chloroacridines **2** choises comme second agent d'alkylation sont, dans les conditions de l'expérience, hydrolysées en 9-acridinones. Aussi, pour obtenir ainsi les dérivés **5**, a-t-on salifié la fonction thiol libre des composés **3** (tautomérie) au moyen de méthylate de sodium. Les composés **5**, en présence de 9-chloroacridiniques, dans la pyridine et sous atmosphère inerte, ont conduit alors aux dérivés **6** recherchés.

On a pensé pouvoir échapper à la préparation des composés intermédiaires **5**, en alkylant directement les dérivés monothiosubstitués **3** dans des conditions évitant l'hydrolyse des 9-chloroacridines **2**. On a ainsi effectué les synthèses selon le mode opératoire décrit pour préparer les dérivés **6**. Les composés obtenus ont été identifiés par RMN du ^1H et RMN du ^{13}C. Ils se sont avérés être des 2-thione-*N*(3)-acridinyl-5-alkylthio-1,3,4-thiadiazoles **7** (figure 4).

Cette structure est explicable compte-tenu, chez les composés intermédiaires **3**, des résultats de la RMN du carbone 13, de ceux de l'infrarouge et de la radiocristallographie. Des exemples en sont donnés à propos du composé *3b*.

Les spectres réalisés et enregistrés, après pastillage dans le bromure de potassium ou mise en solution dans la pyridine du composé *3b*, montrent une bande vers 1480 cm^{-1} qui doit être attribuée à νC=S (6). L'intensité de cette bande est forte en raison de la probable participation de contributions ioniques du type N^+=C-S^- (10) ou N-C^+-S^- (11). À noter que cette bande n'existe pas dans le spectre de *5b*. En revanche, les bandes situées à 1435–1415 cm^{-1} sont attribuables à νC-S-R (6). Elles sont observées aussi bien chez *3b* que chez *5b*. La bande caractéristique de νSH (2245–2300 cm^{-1}) (12) ne se manifeste pas dans les spectres IR de ces composés.

Toujours pour *3b*, le spectre de RMN du ^{13}C dans le diméthylsulfoxyde hexadeutérié présente un déplacement chimique à 187,96 ppm et un autre à 156,10 ppm. Dans la pyridine-d_5, ces déplacements sont à 189,62 ppm et 157,47 ppm. On peut les attribuer aux carbones C=S et C-SR car les valeurs sont proches de celles antérieurement relevées chez les acridinethiones et les alkylthioacridines (13) : 192,9 ppm (C=S) et 146,15 ppm (C-SR). Ceci démontre donc l'existence en solution d'une forme 2-thione-5-alkylthio au lieu d'une forme 2-mercapto-5-alkylthio. La fonction thione exocyclique existant dans les composés **3** est toujours présente dans les composés **7**. En effet, la RMN du carbone 13, effectuée sur les composés de la série **7**, montre le signal

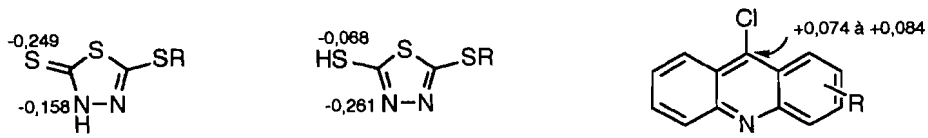
Fig. 5. Valeurs des charges calculées pour les atomes engagés dans les réactions de substitution nucléophile.



caractéristique d'un carbone engagé dans une fonction thione. Celui-ci est situé entre 187 et 190 ppm, selon le solvant utilisé.

Par ailleurs, le calcul des densités de charges faite par la méthode de Gasteiger–Hückel (Logiciel SYBYL, Tripos Assoc.), a conduit aux résultats schématisés sur la figure 5.

La charge présente sur l'azote porteur d'un hydrogène est ici significativement plus favourable à une action avec le carbone (C-9) électrophile des chloroacridiniques que celle portée par le soufre du groupement thiol. Lors de l'attaque de la base (pyridine), il devrait s'ensuivre une délocalisation de la charge négative générée par l'arrachement du proton. Cette charge sera préférentiellement portée par l'azote N(3) puisqu'on a observé que la réaction avait lieu entre cet atome et le C(9) de l'acridinique pour conduire aux molécules **7**. Il devrait s'ensuivre le mécanisme de substitution donné sur la figure 6.

Enfin, la configuration cristalline de **3***b* est rapportée sur la figure 7 : c'est celle d'une 2(3*H*)-thione-5-alkylthio-1,3,4-thiadiazole. La distance C=S correspond à une double liaison. Aucun hydrogène n'a pu être détecté autour de l'atome S(2) mais en revanche, l'hydrogène de l'atome N(3) a été mis en évidence sans ambiguïté.

Les coordonnées atomiques sont données dans le tableau 1 et les paramètres moléculaires les plus significatifs sont donnés dans les Tableau 2 et 3. Il apparaît (figure 8) que l'unité structurale consiste en deux molécules unies par des liaisons hydrogène dont les paramètres sont donnés dans le Tableau 4. L'ion chlore participe à deux liaisons hydrogène quasiment identiques N(3)-H(3)·····Cl^-·····H(6)-N(6)$^+$.

La géométrie du cycle thiadiazole est en accord avec les résultats de la littérature (14). L'atome d'azote protoné (N-6) possède une coordination tétraédrique, la somme des angles entre les substituants autres que H valant 348,5° et l'élévation de l'atome hors du plan valant 0,409(3) Å.

La radiocristallographie confirme donc ici l'existence d'une fonction thione à l'état solide, son existence à l'état dissous ayant déjà été démontrée par la RMN du carbone 13.

Conclusion

D'une part, l'alkylation du 2,5-dimercapto-1,3,4-thiadiazole **1** par un halogénure d'alkyle donne une S-alkylation pour conduire aux composés **3**. Une deuxième alkylation, suivant la première et faite dans les mêmes conditions opératoires ne donne des 2,5-dialkylthio-1,3,4-thiadiazoles qu'avec de faibles rendements. En revanche, une dialkylation en une seule étape sur le sel dipotassique de **1** permet d'augmenter les rendements. Ainsi, on met en évidence le rôle des conditions opératoires dans la réactivité de ce type de molécules qui, de plus, présentent une tautomérie prototropique. Il semble, en particulier, que le butanol favorise la monothiosubstitution.

Fig. 6. Synthèse des *N*-thiadiazoloacridiniques **7** : mécanisme réactionnel.

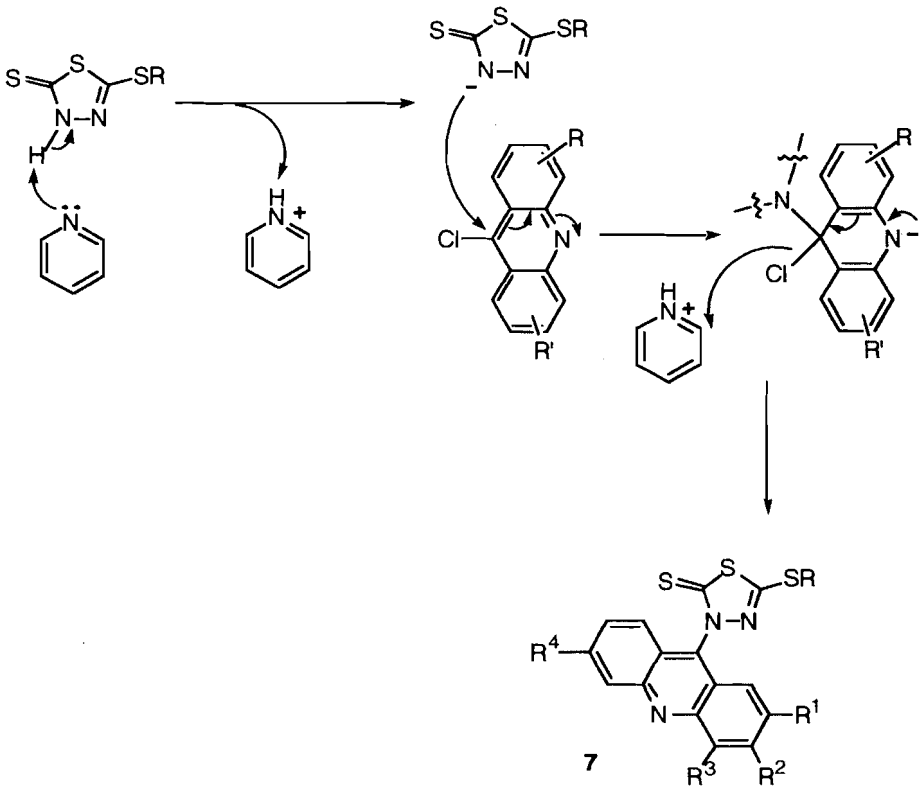

Fig. 7. Géométrie moléculaire et numérotation de **3***b*.

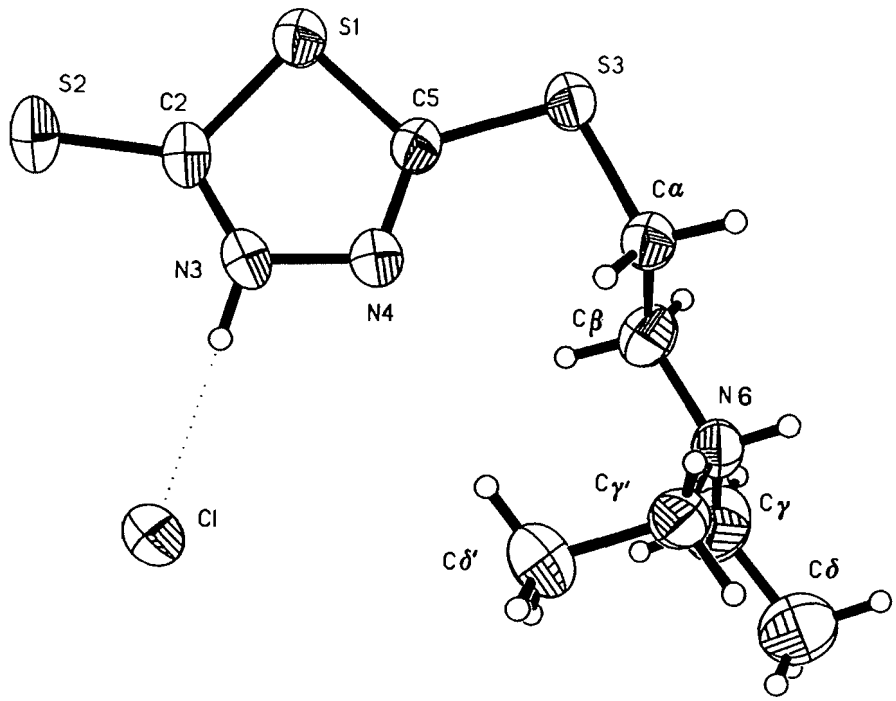

D'autre part, les sels de sodium des 2-mercapto-5-alkylthio-1,3,4-thiadiazole **4** réagissent avec les 9-chloroacridiniques pour donner les 2-acridinylthio-5-alkylthio-1,3,4-thiadiazoles **6** alors que les 2(3*H*)-thione-5-alkylthio-1,3,4-thiadiazoles **3** correspondants donnent avec les mêmes réactifs, des 2-thione-(*N*)3-acridinyl-5-alkylthio-1,3,4-thiadiazoles **7**, par condensation au niveau d'un azote intracyclique. Cette orientation particulière tient à la structure thioalkyl-thione (thioamide) et non mercapto-thioalkyl (imidothiol) des composés intermédiaires dans le milieu réactionnel.

Partie expérimentale

Résonance magnétique nucléaire

La numérotation des atomes est donnée dans la figure 9. Les spectres ont été enregistrés à 20 ± 0,01°C sur un spectromètre Bruker AM 200. Les déplacements chimiques (δ ppm) ont été mesurés par rapport au tétraméthylsilane pris comme référence interne. Les constantes de couplage *J* sont exprimées en hertz.

Spectrophotométrie infrarouge

Les spectres, après pastillage à 1% dans KBr ou dissolution des produits dans la pyridine, ont été enregistrés à température ambiante sur un spectrophotomètre IRFT 57 Biorad.

Synthèses

Les analyses centésimales ont été réalisées dans le Service Commun de Microanalyse (Faculté des Sciences, Campus de St-Jérôme, Marseille) sur un autoanalyseur Technicon CHN.

stamment basique. Le précipité formé est filtré, séché et rapidement repris par trois fois 750 mL d'éther éthylique chauffé à reflux. Les impuretés insolubles sont séparées par filtration et le filtrat éthéré est évaporé à sec. Rdt = 50%; F = 210–212°C (aiguilles oranges); RMN ^{1}H (DMSO-d_6) δ ppm : 6,38 (s, 2H), 6,98 (s, 1H), 7,28 (d, 1H, J = 9,3 Hz), 7,50 (m, 1H), 7,80 (m, 1H), 7,96 (d, 1H, J = 8,6 Hz), 8,41 (d, 1H, J = 9,3 Hz), 8,23 (d, 1H, J = 8,5 Hz); RMN ^{13}C (DMSO-d_6) δ ppm : 102,84 (C4), 117,83 (C11), 121,01 (C14), 122,76 (C2), 124,03 (C8), 124,46 et 124,87 (C1 et C7), 128,10 (C5), 130,19 (C6), 138,91 (C9), 148,68 (C13), 150,10 (C3 et C12). Anal. calc. pour $C_{13}H_9ClN_2$: C 68,27, H 3,93, N 12,25; trouvé : C 68,31; H 3,95; N 12,29%.

Préparation des composés ***3***

On chauffe à reflux sous agitation pendant 30 min, un mélange équimoléculaire de pyridine et de 2,5-dimercapto-1,3,4-thiadiazole dans du butanol normal. On rajoute un léger excès d'agent alkylant (1,2 pour 1). On laisse sous agitation et reflux pendant 1 nuit puis le mélange est placé au réfrigérateur. Le précipité formé est filtré, séché et recristallisé dans l'alcool éthylique absolu.

2-Mercapto-5-éthylthio-1,3,4-thiadiazole ***3***a : Rdt = 81%; F = 124°C (litt. (16, 17) : 125°C) (paillettes beiges brillantes); RMN ^{1}H (DMSO-d_6), δ ppm : 1,30 (t, 3H, J = 7,3 Hz), 3,12 (q, 2H, J = 7,3 Hz). Anal. calc. pour $C_4H_6N_2S_3$: C26,96; H 3,37; N 15,73; trouvé : C 26,98; H 3,35; N 15,68%.

Chlorhydrate du 2-mercapto-5-(2-diéthylaminoéthylthio)-1,3,4-thiadiazole ***3***b : Rdt = 88%; F = 186°C (litt. (7) : non exprimé) (paillettes blanches brillantes); IR (KBr) : 2998–2812, 1465 cm^{-1}; RMN ^{1}H (DMSO-d_6) δ ppm : 1,22 (t, 6H, J = 7,2 Hz), 3,20 (q, 4H, J = 7,2 Hz), 3,40 (m, 2H), 3,60 (m, 2H); RMN ^{13}C (DMSO-d_6) δ ppm : 8,32 (Cδ), 26,56 (Cα), 46,45 (Cγ), 49,53 (Cβ), 156,10 (C5), 187,93 (C2). RMN ^{13}C (pyridine-d_5) δ ppm : 9,19 (Cδ), 27,87 (Cα), 47,08 (Cγ), 50,49 (Cβ), 157,47 (C5), 189,62 (C2). Anal. calc. pour $C_8H_{16}ClN_3S_3$: C 33,62; H 5,60; N 14,71; trouvé : C 33,59; H 5,61; N 14,73%.

Préparation des composés ***4***a *et* ***4***b

On chauffe à 65°C sous agitation pendant 30 min une solution de sel dipotassique de 2,5-dimercapto-1,3,4-thiadazole (5 mmol) et d'agent alkylant (10 mmol) dans un mélange diméthylsulfoxyde–eau (50/50; V/V) en présence de carbonate de potassium (2 équivalents). Après refroidissement, on extrait par le chloroforme. La solution chloroformique est séchée sur sulfate de sodium anhydre, filtrée puis évaporée à sec. L'huile recueillie (base libre) est dissoute dans l'éther. Sous agitation, on rajoute de l'éther acide qui fait précipiter le dichlorhydrate. On le sépare par filtration. On le lave plusieurs fois à l'éther et on le garde 48 h au dessiccateur. La recristallisation des produits ainsi préparés n'est pas nécessaire.

2,5-Bis(diéthylaminoéthylthio)-1,3,4-thiadiazole ***4***a : Base libre : Rdt = 70%; huile jaune pâle. RMN ^{13}C ($CDCl_3$) δ ppm : 10,60 (Cδ et Cδ′), 30,45 (Cα et Cα′), 46,95 (Cγ et Cγ′), 51,25 (Cβ et Cβ′), 165,13 (C2 et C5). Dichlorhydrate : Rdt = 33%; F = 162–164°C (poudre blanche); RMN ^{1}H (D_2O) δ ppm : 1,20 (t, 12H, J = 7,3 Hz), 3,20 (q, 8H, J = 7,3 Hz), 3,50 (m, 8H). Anal. calc. pour $C_{14}H_{30}Cl_2N_4S_3$: C 39,90; H 7,12; N 13,30; trouvé : C 39,94; H 7,07; N 13,32%.

2,5-Bis(diméthylaminoéthylthio)-1,3,4-thiadiazole **4**b : Base libre : Rdt = 65%; huile jaune pâle. Dichlorhydrate : Rdt = 35%; *F* = 218–220°C (poudre blanche); RMN ^{1}H (DMSO-d_6) δ ppm : 2,73 (s, 12H), 3,36 (m, 4H), 3,65 (m, 4H). Anal. calc. pour $C_{10}H_{22}Cl_2N_4S_3$: C 32,87; H 6,02; N 15,34; trouvé : C 32,90; H 6,07; N 15,37%.

Préparation des composés **5**

On dissout 5 mmol de composé **3** sous forme de base dans 20 mL de méthanol anhydre. On rajoute goutte à goutte une quantité stoechiométrique de méthylate de sodium. Après 15 min d'agitation au bain-marie (90°C), on évapore à sec. Le résidu obtenu est trituré dans l'éther de pétrole. On recueille par filtration un précipité qui est séché. La recristallisation des produits ainsi préparés n'est pas nécessaire.

5-Éthylthio-1,3,4-thiadiazole-2-sulfure de sodium **5**a : Rdt = 89%; *F* = 188–190°C (poudre crayeuse blanche); RMN ^{1}H (D_2O) δ ppm : 1,20 (t, 3H, *J* = 7,3 Hz), 2,94 (q, 2H, *J* = 7,3 Hz); RMN ^{13}C (D_2O) δ ppm : 14,51 (Cβ), 29,68 (Cα), 163,79 (C5), 182,22 (C2). Anal. calc. pour $C_4H_5NaN_2S_3$: C 24,00; H 2,50; N 14,00; trouvé : C 24,05; H 2,53; N 14,04%.

5-Diéthylaminoéthylthio-1,3,4-thiadiazole-2-sulfure de sodium **5**b : Rdt = 90%; *F* = 64–66°C (poudre crayeuse blanche); RMN ^{1}H (D_2O) δ ppm : 0,92 (t, 6H, *J* = 7,2 Hz), 2,48 (q, 4H, *J* = 7,2 Hz), 2,72 (t, 2H, *J* = 6,4 Hz), 3,08 (t, 2H, *J* = 6,4 Hz); RMN ^{13}C (D_2O) δ ppm : 10,73 (Cδ), 31,18 (Cα), 46,92 (Cγ), 51,17 (Cβ), 162,62 (C5), 182,73 (C2). Anal. calc. pour $C_8H_{14}NaN_3S_3$: C 35,42; H 5,16; N 15,49; trouvé : C 35,45; H 5,19; N 15,54%.

2-(9′-Acridinylthio)-5-éthylthio-1,3,4-thiadiazole **6**

On chauffe à reflux sous agitation et sous courant d'azote pendant 30 min 200 mg (0,995 mmol) du sel de sodium du 2-mercapto-5-éthylthio-1,3,4-thiadiazole **5***a* dans 20 mL de pyridine anhydre. On ajoute par petites portions 210 mg (0,995 mmol) de 9-chloroacridine **2***a* et on maintient le reflux pendant 3 h. Le précipité obtenu est filtré et lavé à l'eau. Rdt = 71%; *F* = 138–140°C; RMN ^{1}H ($CDCl_3$) δ ppm : 1,33 (t, 3H, *J* = 7,3 Hz), 3,14 (q, 2H, *J* = 7,3 Hz), 7,67 (m, 2H), 7,84 (m, 2H), 8,31 (dd, 2H, *J* = 8,7 Hz), 8,70 (dd, 2H, *J* = 8,7 Hz); RMN ^{13}C ($CDCl_3$) δ ppm : 14,42 (Cβ), 28,53 (Cα), 125,80 (C3′ et C6′), 128, 26 (C2′ et C7′), 130,51 (C1′ et C8′), 130,61 (C4′ et C5′), 135,54 (C9′), 149,21 (C12′ et C13′), 164,08 (C5), 166,96 (C2); C (11′) et C (14′) ne sont pas observables. Anal. calc. pour $C_{17}H_{13}N_3S_3$: C 57,46; H 3,66; N 11,83; trouvé : C 57,49; H 3,68; N 11,87%.

Préparation des composés **7**b, **7**c, **7**e, **7**h, **7**j, **7**m

On porte à reflux sous agitation et sous courant d'azote une solution de composé **3** dans la pyridine anhydre. On ajoute 1/4 d'équivalent d'hydrure de sodium. Au bout de 30 min, on rajoute par petites portions une quantité équimoléculaire d'agent d'alkylant. On maintient le reflux pendant 5 h. Le mélange refroidi est versé dans l'eau. Le précipité formé résultant est filtré, lavé à l'eau et séché avant d'être recristallisé dans un solvant approprié précisé ci-dessous pour chaque composé après le rendement.

*2-Thione-3(*N*)-(2′-nitro)-9′-acridinyl]-5-éthylthio-1,3,4-thiadiazole* **7**b : Rdt = 65% (éther éthylique – chloroforme); *F* = 204–206°C (poudre jaune clair); RMN ^{1}H ($CDCl_3$) δ ppm : 1,45 (t, 3H, *J* = 7,4 Hz), 3,21 (q, 2H, *J* = 7,4 Hz), 7,80 (m, 2H), 8,00 (m, 1H), 8,57 (m, 3H), 8,76 (d, 1H, *J* = 2,2 Hz); RMN ^{13}C ($CDCl_3$) δ ppm : 14,56 (Cβ), 28,34 (Cα), 120,84 (C3′), 121,14 (C14′), 123,25 (C8′), 123,35 (C11′), 123,46 (C5′), 129,25 (C7′), 130,68 (C4′), 132,59 (C1′), 132,75 (C6′), 142,89 (C9′), 146,16 (C13′), 149,70 (C12′), 152,18 (C2′), 159,35 (C5), 188,11 (C2). Préparation des composés 7d *et* 7k
On chauffe 30 min à reflux sous agitation et sous courant d'azote une solution de composé **3** dans la pyridine anhydre. On ajoute alors par petites portions un équivalent d'agent alkylant. On maintient le reflux pendant encore 5 h. Le mélange est ensuite refroidi et versé dans de l'éther éthylique. Il se forme un fin précipité qui est filtré et séché. On le reprend par un minimum d'eau et on alcalinise le milieu. On filtre, on lave à l'eau et on sèche le produit qui est recristallisé dans un solvant approprié précisé ci-dessous pour chaque composé après le rendement.

*2-Thione-3(*N*)-[(3′-amino)-9′-acridinyl]-5-éthylthio-1,3,4-thiadiazole* 7d : Rdt = 18% (éthanol absolu); F = 152–154°C (déc.) (poudre rouge); RMN ^{1}H ($CDCl_3$) δ ppm : 1,38 (t, 3H, J = 7,3 Hz), 3,15 (q, 2H, J = 7,3 Hz), 5,18 (s, 2H), 7,15 (d, 1H, J = 8,8 Hz), 7,35 (s, 1H), 7,40–7,60 (m, 3H), 7,77 (m, 1H), 8,29 (d, 1H, J = 8,8 Hz). Anal. calc. pour $C_{17}H_{14}N_4S_3$: C 55,13; H 3,78; N 15,13; trouvé : C 55,18; H 3,82; N 15,19%.

*2-Thione-3(*N*)-[(3′-amino)-9′-acridinyl]-5-diéthylaminoéthylthio-1,3,4-thiadiazole* 7k : Rdt = 14% (éthanol absolu); F = 138–140°C (déc.) (poudre ocre); RMN ^{1}H ($CDCl_3$) δ ppm : 0,90 (t, 6H, J = 7,1 Hz), 2,46 (q, 4H, J = 7,1 Hz), 2,75 (t, 2H, J = 6,8 Hz), 3,23 (t, 2H, J = 6,8 Hz), 4,38 (s, 2H), 7,10 (dd, 1H, J = 8,7 et 2,1 Hz), 7,35 (d, 1H, J = 2,1 Hz), 7,42–7,58 (m, 3H), 7,72 (m, 1H), 8,16 (d, 1H, J = 8,7 Hz); RMN ^{13}C ($CDCl_3$) δ ppm : 11,76 (Cδ), 32,22 (Cα), 46,83 (Cγ), 50,74 (Cβ), 106,37 (C4′), 117,69 (C11′), 120,48 (C14′), 122,57 (C8′), 122,82 (C2′), 124,11 (C1′), 125,83 (C7′), 129,17 (C5′), 130,51 (C6′), 139,59 (C9′), 148,66 (C13′), 150,26 (C3′), 151,72 (C12′), 158,89 (C5), 187,63 (C2). Anal. calc. pour $C_{21}H_{23}N_5S_3$: C 57,14; H 5,21; N 15,87; trouvé : C 57,09; H 5,23; N 15,93%.

Radiocristallographie
Le composé **3***b* a été recristallisé dans l'éthanol absolu. La détermination de la maille et l'enregistrement des intensités diffractées ont été effectués sur un diffractomètre 4 cercles KM4 (Kuma Diffraction, Wroclaw, Poland) à monochromateur au graphite pour λ (Cu) = 1,541 78 Å. Le groupe spatial et les dimensions de la maille ont été obtenues au moyen d'un ajustement par la méthode des moindres carrés à partir des positions angulaires de 25 réflexions.

On a utilisé la technique de balayage θ–2θ. On a réalisé des contrôles d'intensité toutes les 100 mesures. Les variations d'intensité se sont avérées être non significatives. Les intensités mesurées n'ont pas été corrigées pour l'absorption. On a mesuré 3040 réflexions (2787 réflexions uniques) dont 1950 respectant le critère $F > 4\sigma(F)$. Pour calculer $\sigma(F)$, on a utilisé la formule : $\sigma(F) = \sigma(F^2)/(2F^2)$ pour $F^2 > \sigma(F^2)$ et $\sigma(F) = 0{,}5\sqrt{\sigma(F^2)}$ pour $F^2 < \sigma(F^2)$.

La structure a été déterminée par méthode directe[3] avec $R(E)$ = 0,21. Les atomes d'hydrogène ont tous été localisés sur les cartes de Fourier-différences. Seuls les hydrogènes des atomes d'azote ont été inclus dans les derniers cycles d'affinement qui ont eu lieu en matrice entière tandis que les autres ont été aussi inclus dans les premiers cycles. On a affecté à tous les atomes des coefficients d'agitation thermique anisotrope à l'exception des atomes d'hydrogène pour lesquels on a utilisé un facteur d'agitation thermique isotrope correspondant à 1,5

fois le facteur thermique des atomes porteurs. La fonction à minimiser est $\Sigma w(|F_o| - |F_c|)^2$. Le facteur d'accord R et le facteur d'accord pondéré Rw sont donnés par : $R = \Sigma||F_o| - |F_c||/\Sigma F_o$ et $R_w = \Sigma\sqrt{w}||F_o| - |F_c||/\Sigma\sqrt{w}F_o$. Dans ces expressions $w = 1{,}0/\sigma^2$ (F_o). L'erreur sur une observation de poids unitaire est donnée par : $S = [\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$ avec m = nombre de réflexions utilisées et n = nombre de paramètres affinés.

L'enregistrement des intensités diffractées et les calculs ont été réalisés dans le Département de Cristallographie de l'Université Technologique de Lodz. Les données cristallographiques sont précisées dans le tableau 5.[4]

Évaluation des ruptures de liaison α(C—H) centrale et terminale dans la photolyse du propène gazeux à 184,9 nm

George R. De Maré, Guy J. Collin et Hélène Deslauriers

Résumé : Nous avons repris l'étude de la photochimie du propène gazeux dans la région de l'ultraviolet lointain (λ = 184,9 nm) dans le but explicite d'apprécier les rendements quantiques des réactions de scission des liaisons α(C—H) situées de part et d'autre de la liaison double. Alors que les réactions de rupture des liaisons β(C—H) et α(C—C) sont de loin les réactions les plus importantes et constituent probablement plus de 95% des fragmentations de la molécule photoexcitée, la somme des rendements quantiques des réactions de scission α(C—H) est de l'ordre de 0,03 avec un avantage marqué (4 pour 1, comparé à 1 pour 2 statistiquement) pour la rupture de la liaison C—H centrale : ϕ(H secondaire) = 0,02 ± 0,01 et ϕ(H primaire) = 0,005 ± 0,003. L'énergie de la liaison qui se rompt est donc un facteur déterminant bien que l'énergie photonique soit nettement supérieure à celle nécessaire pour rompre ces liaisons. Les paramètres géométriques, l'énergie totale et les fréquences des modes normaux des radicaux *cis*- et *trans*-propèn-1-yle et propèn-2-yle ont été déterminés en utilisant des méthodes *ab initio* à plusieurs niveaux de théorie (bases STO-3G, 3-21G, 6-31G, 6-31G* et 6-31G**; méthodes UHF, ROHF et GVB). On trouve que le *cis*-propèn-1-yle est plus bas en énergie (0,6–1,0 kJ mol^{-1}) que le *trans*-propèn-1-yle, sauf avec la base minimale STO-3G. Les calculs prédisent que le propèn-2-yle est 14 ± 3 kJ mol^{-1} plus stable que les radicaux *cis*- et *trans*-propèn-1-yle.

Mots clés : propène, réactions unimoléculaires, photochimie, scission α(C—H), radicaux propènyles.

Abstract: The minor, α(C—H) photofragmentation processes in the far-UV photolysis of gaseous propene at λ = 184.9 nm are investigated. At this wavelength the β(C—H) and α(C—C) photofragmentation processes are of major importance, accounting for more than 95% of the primary reaction process. The total quantum yield of the three α(C—H) bond cleavage processes is close to 0.03. However ϕ(H secondary) = 0.02 ± 0.01 and the sum of the two ϕ(H primary) cleavages is 0.005 ± 0.003. Thus ϕ(H secondary)/ϕ(H primary) ≅ 4:1 whereas statistically one expects 1:2. Thus the energy of the bond that is breaking is important, even though the photon energy is much higher than that required to break it. The geometrical parameters, total energies, and fundamental frequencies of the *cis*- and *trans*-propen-1-yl and propen-2-yl radicals have been determined by *ab initio* methods at various levels of theory (STO-3G, 3-21G, 6-31G, 6-31G*, and 6-31G** basis sets; UHF, ROHF, and GVB methods). *cis*-Propen-1-yl is predicted to be 0.6–1.0 kJ mol^{-1} lower in energy than *trans*-propen-1-yl, except with the minimal STO-3G basis set. The optimizations predict that propen-2-yl is more stable than the *cis*- and *trans*-propen-1-yl radicals by 14 ± 3 kJ mol^{-1}.

Key words: propene, unimolecular reactions, photochemistry, α(C—H) cleavage, propenyl radicals.

1. Introduction

Il est bien connu que lors de la photolyse directe du propène (**M**) en phase gazeuse les réactions primaires principalement observées sont les scissions des liaisons β(C—H) et α(C—C) de la molécule photoexcitée (**M****) (1–3). Ces deux réactions produisent respectivement le radical allyle et un atome d'hydrogène d'une part et les radicaux méthyle et vinyle d'autre part :

[1] $\mathbf{M} + h\nu \rightarrow \mathbf{M}^{**}$

[2] $\mathbf{M}^{**} \rightarrow (\overline{CH_2—CH—CH_2})^* + \dot{H}$

[3] $\mathbf{M}^{**} \rightarrow (CH_2{=}\dot{C}H)^* + \dot{C}H_3$

Les espèces radicalaires R* correspondent à des entités ayant une énergie interne suffisante et sont susceptibles de se fragmenter :

[4] $(\overline{CH_2—CH—CH_2})^* \rightarrow CH_2{=}C{=}CH_2 + \dot{H}$

[5] $(CH_2{=}\dot{C}H)^* \rightarrow C_2H_2 + \dot{H}$

Ces deux dernières réactions sont en compétition avec les

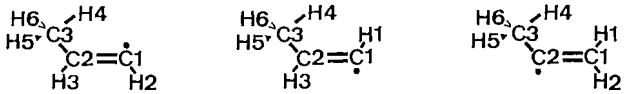
Schéma 1.



1 : *cis*-propèn-1-yle **2** : *trans*-propèn-1-yle **3** : propèn-2-yle

réactions de stabilisation par collision et sont donc observées à basse pression. Les rendements quantiques des processus primaires [2] et [3] à 184,9 nm ont été évalués respectivement à 0,63 et 0,36 ce qui, ajouté à d'autres processus primaires de plus faible importance, conduisait à un rendement quantique total de fragmentation de la molécule photoexcitée égal à 1,07 ± 0,10 (1), laissant ainsi peu de place à d'autres processus de fragmentation ou de désactivation.

Nous avons repris cette étude afin d'évaluer spécifiquement les rendements quantiques des réactions de fragmentation de type α(C—H) :

[6] $\mathbf{M}^{**} \rightarrow (CH_3—CH{=}\dot{C}H)^* + \dot{H}$

où les radicaux $(CH_3—CH{=}\dot{C}H)^*$ peuvent avoir la geométrie *cis* (**1**) ou *trans* (**2**)) (voir le Schéma 1 ci-dessus) et

[7] $\mathbf{M}^{**} \rightarrow (CH_3—\dot{C}{=}CH_2)^*(\mathbf{3}) + \dot{H}$

Les réactions déjà identifiés dans la photolyse de **M** indiquent la présence de radicaux libres thermalisés (incapables de se fragmenter dans toutes les conditions utilisées) et excités (capables de se fragmenter éventuellement à basse pression) (1). On a déjà établi que l'on pouvait considérer les rendements des radicaux allyles (ϕ = 0,62 ± 0,05) et méthyles (ϕ = 0,36 ± 0,03) ainsi que celui des atomes d'hydrogène (ϕ = 0,63 ± 0,05) indépendants de la pression totale entre 0 et 120 Torr (0 et 16 000 N m^{-2}). Les atomes d'hydrogène s'additionnent rapidement sur la double liaison de **M** en formant des radicaux isopropyles (4, 5) :

[8] $\dot{H} + \mathbf{M} \rightarrow CH_3—\dot{C}H—CH_3$

Il s'ensuit que les principales réactions secondaires sont les combinaisons (réactions [9]–[14]) et dismutations des radicaux.

[9] $2CH_3—\dot{C}H—CH_3 \rightarrow$ 2,3-diméthylbutane

[10] $2\overline{CH_2—CH—CH_2} \rightarrow$ hexa-1,5-diène

[11] $2\dot{C}H_3 \rightarrow$ éthane

[12] $CH_3—\dot{C}H—CH_3 + \overline{CH_2—CH—CH_2} \rightarrow$ 4-méthylpent-1-ène

[13] $CH_3—\dot{C}H—CH_3 + \dot{C}H_3 \rightarrow$ isobutane

[14] $\overline{CH_2—CH—CH_2} + \dot{C}H_3 \rightarrow$ but-1-ène

Nous négligerons les réactions de dismutation car les réactions mettant en jeu au moins un radical insaturé comptent en général moins de 10% de dismutation par rapport à la combinaison (5, 6). Pour la même raison on a également négligé les réactions d'addition de l'atome d'hydrogène sur le carbone centrale de **M** produisant ainsi quelques radicaux propyles primaires (4). Il faut enfin ajouter à ce tableau les réactions des radicaux vinyles thermalisés également répertoriés et mesurés dans ce système : $\phi(CH_2{=}\dot{C}H) = 0,10$ (1).

Dans la photolyse directe des but-2-ènes à λ = 184,9 nm, il a été démontré que des radicaux C_3H_5 (structure **1** et (ou) **2**) sont formés par scission d'une liaison α(C—C), réaction en compétition avec la rupture d'une liaison β(C—H) (7).[2] On aurait pu s'attendre à ce que les rapports des rendements des ruptures α(C—C)/β(C—H) soient, sinon identiques, au moins très voisins l'un de l'autre, pour les photolyses directes des isomères géométriques du but-2-ène. En fait ces rapports sont assez différents : α(C—C)/β(C—H) = 0,95 et 1,34 pour le *cis*- et le *trans*-but-2-ène, respectivement (7). Nous avons donc entrepris, en parallèle à l'étude expérimentale de la photolyse de **M**, une étude théorique des chemins réactionnels conduisant aux radicaux **1**, **2** et **3** (8).

2. Méthode

2.1 Expérimentale

Le produit **M** (Matheson, Canada) utilisé est de très haute pureté : l'analyse par chromatographie en phase gazeuse montre seulement la présence de traces de propane (160 ppm), de but-1-ène + isobutène + buta-1,3-diène (25 ± 3 ppm) et de butane normal (12 ± 3 ppm). L'hexafluorure de soufre (Merck, Sharp et Dohme, Canada) à un pureté nominale de 99,99%. Il a été utilisé tel que reçu.

Les photolyses ont été réalisées dans un appareil sans trace de mercure avec une lampe au mercure «basse pression», de telle sorte que seule la raie de résonance située à 184,9 nm est active. Les analyses chromatographiques ont été réalisées sur trois colonnes remplies (Ucon, Durapak et squalane) qui ont été décrites précédemment (1). L'actinométrie a été réalisée par comparaison en photolysant de l'éthylène dans les mêmes conditions (9). Les temps d'irradiation utilisés, combinés avec l'intensité de la lampe, ont produit un taux de transformation de **M** situé entre 0,1 et 4% dépendant de la pression. On n'a pas observé de variations significatives des rendements quantiques avec la variation du taux de conversion.

2.2 Théorique

Les optimisations de géométrie *ab initio* ont été effectués avec le programme MONSTERGAUSS (10) sur le Cray Y-MP2E/116 au Centre de Calcul «Université Libre de Bruxelles/Vrije Universiteit Brussel» en utilisant les bases classiques STO-3G (11), 3-21G (12), 6-31G (13), 6-31G* (14) et 6-31G** (14). Les minima d'énergie ont été localisés avec la technique OC (optimally conditioned variable-metric gradient minimization technique (15)).

Les méthodes UHF (Unrestricted Hartree–Fock (16)), ROHF (Restricted Open-Shell Hartree–Fock (17)) et GVB (Generalized Valence Bond (18)) ont été utilisées. Dans les calculs GVB(X) la valeur de X donne le nombre d'orbitales de valence, doublement occupées, qui sont couplées chacune à l'orbitale virtuelle correspondante dans le concept de «perfect pairing» (18).

Les fréquences des modes normaux de vibration ont été calculées avec le programme GAUSSIAN 90 (19) aux niveaux

2. Pour une discussion plus détaillée du rapport des scissions des liaisons α(C—C) et β(C—H) voir réf. 7*b*.

3. Résultats et discussion

3.1 Partie expérimentale

Les résultats de quelques photolyses de **M** gazeux à 184,9 nm sont présentés dans le tableau 1. Pour les exigences de cette étude, les produits sont limités à ceux formés par la combinaison des radicaux **1**, **2** et **3** avec d'autres radicaux. (Aux taux de transformation utilisés dans cette étude les quantités des produits issues des réactions de combinaison des radicaux **1**, **2** et **3** entre eux sont trop faibles pour être mesurées.)

Les radicaux issus des fragmentations α(C—H) vont réagir avec l'ensemble des radicaux libres présents. Comme les constantes de vitesses des réactions de type radical hydrocarboné + radical hydrocarboné sont toutes similaires quel que soit le couple de radicaux hydrocarbonés mis en cause (mariage par spin antiparallèle), on admet seulement que l'importance de ces réactions est statistiquement lié aux concentrations radicalaires, négligeant l'effet de masse (20) ou tout autre facteur stérique (5, 20). Ainsi les réactions [15]–[22],

[15] **1** ou **2** + $CH_3—\dot{C}H—CH_3 \rightarrow$ *cis*- et *trans*-4-méthylpent-2-ène

[16] **1** ou **2** + $\overline{CH_2—CH—CH_2} \rightarrow$ hexa-1,4-diène

[17] **1** ou **2** + $\dot{C}H_3 \rightarrow$ *cis*- et *trans*-but-2-ène

[18] **1** ou **2** + $CH_2{=}\dot{C}H \rightarrow$ *cis*- et *trans*-penta-1,3-diène

et

[19] **3** + $CH_3—\dot{C}H—CH_3 \rightarrow$ 2,3-diméthylbut-1-ène

[20] **3** + $\overline{CH_2—CH—CH_2} \rightarrow$ 2-méthylpenta-1,4-diène

[21] **3** + $\dot{C}H_3 \rightarrow$ isobutène

[22] **3** + $CH_2{=}\dot{C}H \rightarrow$ isoprène

dovient être prises en considération. La recherche des produits de combinaison formés dans ces réactions et la mesure quantitative de leur rendement devraient permettre d'évaluer les rendements quantiques des réactions primaires [6] et [7] dans la mesure où il n'y a pas d'isomérisation des radicaux par transfert d'atome d'hydrogène.

En première approximation, les rendements quantiques des six premiers produits apparaissant au tableau 1 sont dans l'ordre d'importance des rendements quantiques des radicaux isopropyles, allyles, méthyles et vinyles observés précédemment dans la photolyse de **M** à 184,9 nm (1). Il en est de même pour les rendements quantiques des quatre derniers produits. Cependant il y a quelques différences qu'il faut discuter : étant donné que les quantités des radicaux méthyles et vinyles formées devraient être les mêmes (réaction [3]), les rendements des but-2-ènes (réaction [17]) devraient être voisins de ceux des penta-1,3-diènes (réaction [18]) et les rendements de l'isobutène (réaction [12]) proches de ceux de l'isoprène (réaction [22]). (Les rendements quantiques du *cis*-but-2-ène avec l'addition de SF_6 nous semblent erratiques : l'augmentation observée pour l'ajout de 51 Torr de SF_6 à 1,7 Torr de **M** n'est pas confirmée à plus hautre pression (tableau 1).) Mais il apparaît que les rendements en but-2-ènes sont moins élevés que ceux des penta-1,3-diènes (déficit de radicaux méthyles par rapport aux radicaux vinyles) et les rendements de l'isobutène plus élevés que ceux de l'isoprène (excès de radicaux méthyles par rapport aux radicaux vinyles). Cette dernière observation est en accord avec le fait que l'on sait qu'une

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

portion des radicaux vinyles excités se fragmente, donnant de l'acétylène (réaction [5], ϕ = 0,08 (1)). Les rendements des penta-1,3-diènes semblent donc trop élevés.

En tenant compte de toutes les produits mesurés et provenant de réactions impliquant les radicaux vinyles et méthyles, on trouve que le rendement en radicaux vinyles thermalisés est voisin de 0,10 et celui en radicaux méthyles de 0,36 (ce travail et réf. 1). Il y a donc un déficit en rendement des radicaux vinyles de 0,18. Notons que la réaction de fragmentation moléculaire suivante

[23] $\mathbf{M}^{**} \rightarrow CH_4 + HC{\equiv}HC$

bien que favorisée énergétiquement (6), ne peut expliquer le déficit car elle donnerait du méthane et de l'acetylène en quantités égales.

Il se peut qu'une partie des radicaux vinyles vibrationellement et (ou) électroniquement excités réagit directement avec **M** dans une réaction exceptionelle de condensation :

[24] $(CH_2{=}\dot{C}H)^* + \mathbf{M} \rightarrow (CH_3{-}\dot{C}H{-}CH_2{-}CH{=}CH_2)^*$

Suivie de l'élimination d'un atom d'hydrogène, cette condensation expliquerait l'apparent excès des penta-1,3-diènes.

Un des rapporteurs nous a demandé pourquoi on ne tenait pas compte des éventuelles réactions de condensation des autres radicaux avec **M**. Il est généralement admis que l'addition d'un radical thermalisé sur une liaison multiple à la température ambiante est très lente (énergie d'activation non-nulle et faible facteur pré-exponentiel (21)). De plus, à basse pression, l'exothermicité de cette addition est suffisante pour provoquer la décomposition du complexe (radical + oléfine) avant qu'une collision avec un troisième corps ne le stabilise.

Tenant compte de tous les produits issus des radicaux vinyles avec les radicaux **1**, **2** et **3**, sauf pour les penta-1,3-diènes et l'isoprène, l'estimation des rendements des produits issus des radicaux C_3H_5 vinyliques conduit aux valeurs suivantes : $\phi(\mathbf{3}) = 0{,}02 \pm 0{,}01$ et $\phi(\mathbf{1} + \mathbf{2}) = 0{,}005 \pm 0{,}003$. Il apparaît ainsi que la rupture de la liaison centrale ϕ(C—H) est favorisée d'un facteur 4 par rapport à la somme des ruptures des liaisons α(C—H) terminales alors que statistiquement on s'attendrait à un facteur un demi. L'énergie de dissociation de la liaison α(C—H) secondaire est légèrement inférieure à celle d'une liaison α(C—H) primaire (voir par exemple réf. 22). Il semble que l'énergie de dissociation de la liaison C—H qui se rompt (vide infra) joue un rôle déterminant bien que l'énergie fournie par le photon soit nettement supérieure à l'énergie necessaire pour rompre ces liaisons.

3.2 Calculs *ab initio*

Les géométries optimisées, les moments dipolaires et les énergies des radicaux **1**, **2** et **3**, obtenus avec les différentes méthodes de calcul *ab initio*, sont rassemblés dans les tableau 2–4, respectivement. Comme dans le cas de **M** (23), la structure la plus basse en énergie de chaque radical est de symétrie C_S avec un atome d'hydrogène du groupe méthyle situé dans le plan et au dessus de la double liaison (angles dièdres H4C3C2C1 optimisés $\equiv$ 0,00°) (8). Les résultats des calculs ne sont pas donnés ici mais notons que les structures C_S avec l'atome d'hydrogène du groupe méthyle dans le plan et dirigé vers l'extérieur sont des états de transition (maxima d'énergie) pour la rotation du groupe méthyle.

Les longueurs de liaisons obtenues avec la méthode GVB sont généralement plus grandes que celles obtenues avec la même base et les méthodes UHF et ROHF. Une exception remarquable est la liaison C1=C2 pour laquelle les valeurs optimisées UHF/STO-3G sont les plus grandes pour chaque radical. Ceci est une conséquence de la contamination de spin (influence des états électroniques supérieurs) qui est importante dans ces calculs.

Les moments dipolaires sont donnés dans les tableaux à titre indicatif. Pour les molécules les moments dipolaires obtenus avec la base STO-3G sont généralement trop petits (~50%). Enfin, les moments dipolaires obtenus avec les bases étendues se rapprochent des valeurs expérimentales mais peuvent être soit trop petits, soit trop grands (24).

3.2.1 Radicaux 1 et 2

Sauf pour les calculs avec la base minimale STO-3G, l'énergie relative du radical **1** est plus basse d'environ 1 kJ mol^{-1} que celle du radical **2**. Cette différence est vraiment minime et les enthalpies de formation des deux radicaux doivent être très proches l'une de l'autre. (Il faut encore tenir compte d'une éventuelle différence dans les «Zero Point Energies» (ZPE) (sommes des énergies vibrationnelles à 0 K; ZPE = 0,5 $\Sigma(\omega_e)$, vide infra).) Nos résultats indiquent que la difference des rapports des rendements des ruptures α(C—C) et β(C—H) obtenus dans les photolyses directes du *cis*- et du *trans*-but-2-ène à λ = 184,9 nm (α(C—C)/β(C—H) = 0,95 et 1,34, respectivement (7)) ne peut pas être expliquée par une différence dans les énergies ou enthalpies de formation des radicaux.

Que le groupe méthyle soit du même côté ou du côté opposé à l'atome d'hydrogène sur le centre radicalaire C1 ne semble pas avoir une influence majeure sur les paramêtres géometriques pour lesquelles C1 est impliqués : ainsi les valeurs de C1=C2 dans les deux radicaux, les longueurs des liaisons H2Ċ1 et H1Ċ1 et les valeurs des angles H2Ċ1C2 et H1Ċ1C2 sont similaires à chaque niveaux théorique (voir tableaux 2 et 3). Tous les calculs prédisent un élargissement de chacun des deux angles (de 10° $\pm$ 2°) par comparaison avec les angles correspondants de **M**. Ceci semble être un phénomène général : un élargissement d'environ 8° des angles HĊC concernant les centres radicalaires des radicaux *trans*-(s-*trans*)-, *trans*-(s-*cis*)-, *cis*-(s-*trans*)- et *cis*-(s-*cis*)-2-vinylcycloprop-1-yle, par comparaison avec les angles correspondant du vinylcyclopropane, est aussi prédit par les calculs *ab initio* (25). Néanmoins, notons ici que l'augmentation des angles CĊC étaient seulement d'environ 1,5° par comparaison avec les angles correspondants des rotamères du vinylcyclopropane (25). Dans ce cas les petites différences sont sans doute dues à la rigidité du cycle à trois.

Quant à la barrière à la rotation autour de la liaison double (processus **1** $\leftrightarrow$ **2**), elle serait d'environ 60 kJ mol^{-1} d'après des calculs UHF/STO-3G. Dans la photolyse de **M** à 184,9 nm, l'énergie résiduelle dans les radicaux après rupture de la liaison C—H est donc suffisante pour permettre l'isomérisation.

3.2.2 Radical 3

Pour ce radical, vu la similarité des résultats aux différents niveaux de théorie pour **1** et **2**, nous avons limités les optimisations à celles avec les bases STO-3G et 6-31G* (voir tableaux 4 et 5). L'élargissement de l'angle C1Ċ2C3 par rapport aux structures de **1**, **2** et **M** est remarquable et ressemble fort à

[a]Relative au radical **1** (voir tableau 2).

ceux observés pour les angles H2Ċ1C2 et H1Ċ1C2 dans **1** et **2**, respectivement. Ceci confirme que les petits changements dans les valeurs des angles CĊC (~1,5°) dans les radicaux 2-vinylcycloprop-1-yles (25) sont un reflet de la contrainte de géometrie du cycle.

La liaison vinylique secondaire H3Ċ2 est moins forte que les liaisons vinyliques primaires. L'énergie de **3** relative à celle de **1** est donc située dans une fourchette de 12 à 17 kJ mol^{-1} plus basse (voir tableau 4).

Les résultats des photolyses de **M** indiquent un excès de

radicaux **3** par rapport aux facteur statistique. Cela pourrait être expliqué par un effet énergétique : dans la mercurisensibilisation du propane à 253,7 nm, le rapport de formation des radicaux isopropyles/*n*-propyle ≃ 9 tandis que le rapport statistique des liaisons (C—H secondaires)/(C—H primaires) = 1/3 (26–28). D'autres possibilités d'explication existent, par exemple une isomérisation de **1** ou **2** vers **3** par un transfert de l'atome d'hydrogène de C2 à C1 (il y a une barrière non-négligeable à ce genre de transfert en général).[3] Notons aussi que des expériences de mercurisensibilisation à 253,7 nm d'isotopomères du propane, deutériés spécifiquement, ont démontré qu'aucune isomérisation des radicaux *n*-propyles ↔

isopropyles ne pouvait être détectée (26). Bien que les réactions d'échanges,

[24] **1** ou **2** + **M** → **M** + **III**

puissent aussi être source d'un excédent de **3**, la réaction

[25] *n*-propyle + propane → propane + isopropyle

a été exclue dans les mercurisensibilisations du propane à 253,7 nm (26, 27). L'extension de ces résultats aux photolyses du propane ou de **M** à 184,9 nm doit être cautionée (*i*) par la plus grande énergie disponible à courte longueur d'onde et (*ii*) par la différence des états électroniques impliqués dans les processus primaires.

3.2.3 Fréquences des modes normaux

Les fréquences des modes normaux, les ZPE et les constantes de rotation des trois radicaux ont été déterminés aux niveaux UHF/6-31G*//UHF/6-31G* et ROHF/6-31G*//ROHF/6-31G* (tableau 5). Ces résultats doivent être considérées avec les géométries UHF/6-31G* et ROHF/6-31G* correspondantes (tableaux 2–4).

En général, les fréquences fondamentales déterminées par les méthodes *ab initio* utilisées dans ce travail sont surestimées de 10 à 20%. Néanmoins nous pensons qu'elles peuvent être utilisées directement pour des calculs RRKM pourvu que les fréquences pour la molécule parente soient obtenues avec la même méthode.

Les différences d'enthalpie de formation des radicaux à 0 K ($\Delta(\Delta H_f^0)$) sont obtenues en ajoutant les différences des ZPE aux énergies relatives rapportées aux tableaux 3 et 4. Les ZPE calculées pour **2** sont 0,4 kJ mol^{-1} plus élevées que celles pour **1** et donc la valeur $\Delta(\Delta H_f^0(\mathbf{2}) - \Delta H_f^0(\mathbf{1})) \simeq 1{,}1$ kJ mol^{-1}. Cette différence est trop petite pour changer les conclusions décrites ci-dessus. Notons aussi que les ZPE de **3** sont presque identiques à celles de **1**.

4. Conclusions

Dans la photochimie du propène gazeux à λ 184,9 nm, la somme des rendements quantiques des réactions de scission des liaisons α(C—H) situées de part et d'autre de la liaison double est de l'ordre de 0,03. Il y a un avantage marqué (4 pour 1, comparé à 1 pour 2 statistiquement) pour la rupture de la liaison C—H centrale: $\phi(\mathbf{3}) = 0{,}02 \pm 0{,}01$ et $\phi(\mathbf{1} + \mathbf{2}) = 0{,}005 \pm 0{,}003$. L'énergie de la liaison qui se rompte est donc importante, comme cela à déjà été observé pour la photosensibilisation du propane par le mercure triplet à 253,7 nm (26–28).

On trouve que le radical **1** est plus bas en énergie (0,6–1,1 kJ mol^{-1}) que le radical **2**, sauf avec la base minimale STO-3G. Les calculs UHF/6-31G*//UHF/6-31G* et ROHF/6-31G*//ROHF/6-31G* conduisent aux différences $\Delta(\Delta H_f^0(\mathbf{2}) - \Delta H_f^0(\mathbf{1})) = 1{,}1$ et 1,2 kJ mol^{-1} et aussi à $\Delta H_f^0(\mathbf{3}) - \Delta H_f^0(\mathbf{1}) = -13{,}4$ (UHF) et $-14{,}2$ (ROHF) kJ mol^{-1}, respectivement. Les enthalpies de formation de **1** et **2** à 0 K sont donc très voisines et on n'y trouve pas une explication pour la différence dans le rapport des scissions α(C—C)/β(C—H) dans la photolyse directe des *cis*- et *trans*-but-2-ènes à 184,9 nm (7).

5. Remerciements

Nous remercions la Division des Affaires Scientifiques et de l'Environnement de l'O.T.A.N. pour son soutien financier (CRG.920599). G.J.C. tiens à exprimer sa reconnaissance au Conseil de Recherche en Sciences Naturelles et en Génie (Canada) qui a financé une partie de cette étude. Nous remercions également MM. Earl Evleth (U. Pierre et Marie Curie, Paris) et Jean Olbregts (U. Libre de Bruxelles) pour les nombreuses discussions fructueuses au sujet de ce travail.

Excess properties for cyclohexanone + butanols at 298.15 K

Roque Riggio, Hector E. Martinez, Norma Z. de Salas, Miriam D. de Toigo, and Juan F. Ramos

Abstract: Densities, viscosities, and refractive indexes of the binary systems cyclohexanone + *n*-butanol, + *sec*-butanol, and + 2-methyl-1-propanol have been measured at 298.15 K and atmospheric pressure, over the whole composition range. The excess values of molar volume, viscosity, Gibbs free energy of activation of viscous flow, and internal pressure were calculated from experimental measurements. Based on the variations of the excess functions with composition, conclusions about the molecular interactions in these kinds of mixtures were obtained.

Key words: excess properties, binary mixtures, butanols, cyclohexanone.

Résumé : Opérant à 298,15 K et à la pression ambiante, on a mesuré les viscosités et les indices de réfraction des systèmes binaires cyclohexanone + *n*-butanol, + *sec*-butanol et + 2-méthylpropan-1-ol, sur l'ensemble des compositions. Utilisant les données expérimentales, on a calculé les valeurs en excès du volume molaire, de la viscosité, de l'énergie libre d'activation de Gibbs de l'écoulement visqueux et de la pression interne. Sur la base des variations des fonctions d'excès avec la composition, on a tiré des conclusions concernant les interactions moléculaires de ces divers mélanges.

Mots clés : propriétés en excès, mélanges binaires, butanols, cyclohexanone.

Introduction

In previous works we studied several binary liquid solutions of alcohols with different kinds of ketones (1–4). In this contribution we report the following excess properties: molar volumes (V^E), viscosity (η^E), molar free energy of activation of viscous flow (G^{*E}), and internal pressures (Pi^E), for the mixtures: cyclohexanone (CH) + *n*-butanol (B_1), + *sec*-butanol (B_2), and + 2-methyl-1-propanol (B_3), which were calculated from the density, viscosity, and refractive index measured.

Experimental

Materials

Components were supplied by Merk-Darmstadt (A.R. grade). All species were dried with anhydrous K_2CO_3 and fractionally distilled under a flow of nitrogen. The middle fractions were stored over 3 A molecular sieve and cyclohexanone over 4 A molecular sieve.

All solutions were prepared by weight using an H11 Mettler balance and were stored in air-tight stoppered bottles.

Density

Densities (ρ) were determined with an Anton Paar DMA46 density meter with a built-in thermostat. The accuracy was estimated to be ± 0.1 kg m^{-3}.

Viscosity

Viscosities (η) were measured with a Cannon–Fenske viscosimeter, which was calibrated with doubly distilled water and benzene. The accuracy was estimated to be $\pm 0.5\%$.

Refractive index

Refractive indexes (n_D) of pure components as well as mixtures (sodium D line) were measured with a Jena dipping refractometer with an accuracy of ± 0.00002. For the viscosity and refractive index a thermostatic water bath, whose temperature was controlled to ± 0.01°C, was used.

Results

We report in Table 1 the experimental physical properties of the pure liquids along with some literature values for comparison purposes. Densities, viscosities, and refractive indexes of the binary mixtures are reported in Table 2.

The excess functions of the binary systems can be represented by a Redlich–Kister-type equation:

$$[1] \qquad X^E = x_i x_j \sum_{k=0}^{n} a_k (2x_i - 1)^k$$

where X^E represents any of the following properties: V^E, η^E, G^{*E}, Pi^E; x_i and x_j are the mole fractions of components i and j, respectively, and a_k denotes the polynomial coefficients. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error of the estimate with n:

$$[2] \qquad \sigma = \left[\sum (X^E_{obs} - X^E_{cal})^2 / n_{obs} - n)\right]^{1/2}$$

where n_{obs} is the number of measurements.

The excess functions were calculated with the following equations, previously used by several authors (5–8):

$$[3] \qquad V^E = V - (x_1 V_1 + x_2 V_2)$$

$$[4] \qquad \eta^E = \eta - (x_1 \eta_1 + x_2 \eta_2)$$

$$[5] \qquad G^{*E} = RT[\ln \eta V - (x_1 \ln \eta_1 V_1 + x_2 \ln \eta_2 V_2)]$$

$$[6] \qquad Pi^E = \frac{2^{1/6}RT}{2^{1/6}V - dN^{1/3}V^{2/3}} - \left[x_1 \frac{2^{1/6}RT}{2^{1/6}V_1 - d_1 N^{1/3} V_1^{2/3}} + x_2 \frac{2^{1/6}RT}{2^{1/6}V_2 - d_2 N^{1/3} V_2^{2/3}}\right]$$

where V and η are the molar volumes and the viscosities of the mixtures; V_1, V_2, η_1 and η_2 are the molar volumes and viscosities of the pure components, respectively.

The excess internal pressures (Pi^E) of the liquid mixture were obtained (9) by the equation:

$$[7] \qquad Pi^E = Pi - (x_1 Pi_1 + x_2 Pi_2)$$

where Pi, Pi_1, and Pi_2 are the internal pressures of the mixtures and the pure components, respectively, which can be obtained from the Buchler–Hirschfelder–Curtis equation of state (10):

$$[8] \qquad Pi = \frac{2^{1/6}RT}{2^{1/6}V - dN^{1/3}V^{1/3}}$$

N is Avogadro's number and d the molecular diameter of the mixture or the pure components, calculated by the following relation (11):

$$[9] \qquad d = 2\left[\frac{n_D^2 - 1}{n_D^2 + 2} V \frac{3}{4\pi N}\right]^{1/3}$$

n_D are the refractive indexes of the mixtures or the pure components.

Table 3 shows the values of the coefficients a_k for the excess functions of the binary systems and their standard deviation, which were calculated by the method of least squares.

Discussion

When mixing an alcohol, highly associated in the pure state (12–14), with a different polar solvent, certain phenomena

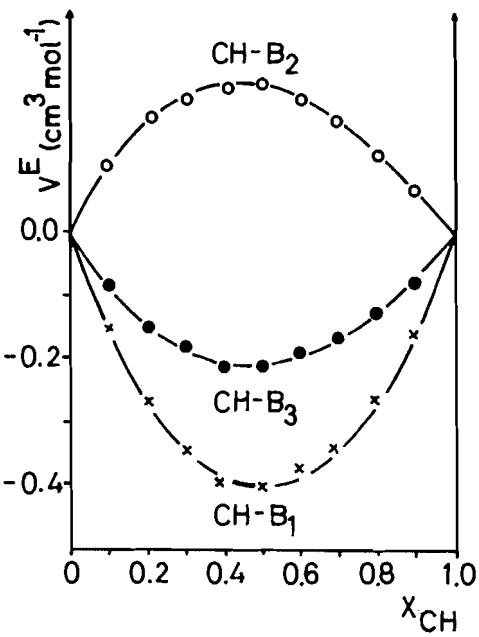

Fig. 2. Excess viscosities of the systems at 298.15 K.

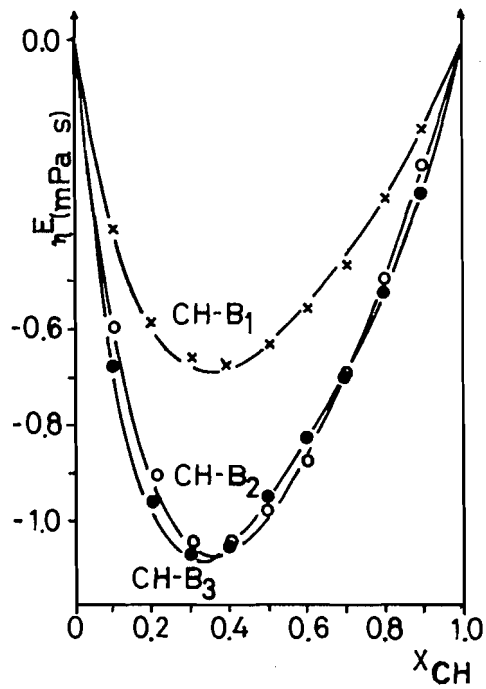

occur. Firstly, a breaking of the alcohol's associations due to hydrogen bonding takes place. Secondly, specific interactions appear in the mixtures (15). For the systems studied in this work, we justify these effects through analyses of the following excess properties: molar volume, viscosity, free energy of viscous flow, and internal pressure.

From the isothermal curves at 298.15 K in Fig. 1, excess molar volumes are plotted against composition. It can be seen that the isothermal curve at 298.15 K is positive for the CH + B_2 system, while for the CH + B_1 and CH + B_3 systems these are negative over the whole composition range. From these observations we can conclude that in all cases the alcohol's structure is broken when the mixture is formed. In the mixture containing secondary butanol (B_2) there exists a slight possibility of geometric ordering due to the OH position. Meanwhile, for the CH + B_1 system and to a lesser extent for the CH + B_3 system, both containing primary alcohols, we believe that a compensating effect produces a negative contribution to the V^E values (16, 17). The observed behaviour differences between the B_1 and B_3 mixtures and the B_2 mixture can be attributed to the higher steric freedom of the primary alcohols to form intermolecular association complexes through hydrogen bonds between the alcohol's OH and the enol form to the ketone (18). For the B_3 mixture the lower V^E negative values are probably due to the steric effect of the α-methyl group and the small keto–enol–OH associates formed.

In Fig. 2, it is observed that all mixtures present negative excess viscosity values, whose decreasing order is the following:

$$CH + B_1 \approx CH + B_3 < CH + B_2$$

Fig. 3. Molar excess free energies of viscous flow activation of the systems at 298.15 K.

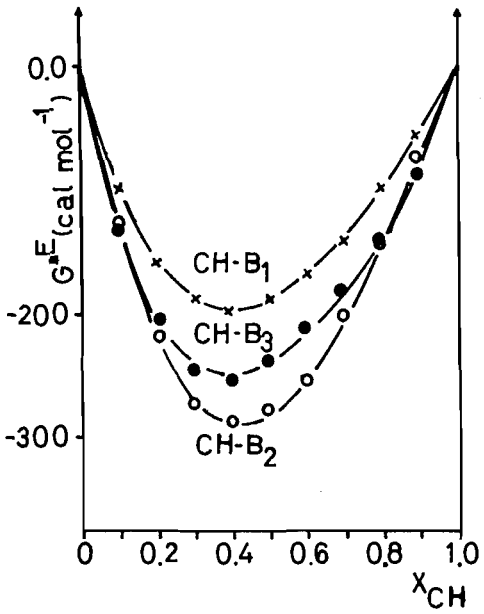

Fig. 4. Excess internal pressures of the systems at 298.15 K.

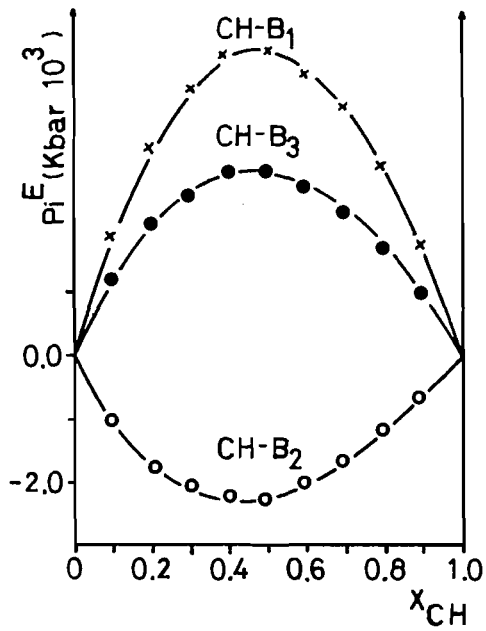

According to the above order, which is in complete agreement with the conclusions reached for the V^E behaviour, negative deviations occur when dispersion forces are preponderant (19).

Figure 3 shows the dependence of the calculated G^{*E} values upon composition. Increasing negative deviations with composition can be observed according to the following order:

$$CH + B_2 < CH + B_3 < CH + B_1$$

It is known that the strength of molecular interactions increases as G^{*E} decreases. In particular, for the above systems the interactions decrease according to the given order, which is in full accord with our previous conclusions.

On the other hand, Fig. 4 shows excess internal pressure versus composition. We can observe negative Pi^E deviations for the CH + B_2 system; meanwhile, for the CH + B_1 and CH + B_3 mixtures the opposite behaviour is present. The tendency towards negative values indicates qualitatively that the repulsion forces have a predominant effect. For those mixtures showing positive deviations the attraction forces are greater than those of repulsion. We know that cyclohexanone is present in high concentration as the enol form (20), and so it could be expected that the addition of B_1 and B_2 to cyclohexanone would cause, in these systems, keto–enol interactions. Thus our results may be in good agreement with those expected through predictions reported in the literature.

Methine bases in the benzothiazole, benzoselenazole, and quinoline series, and geometry and conformational preferences of their acyl derivatives

Ajay K. Gupta, Ali Ben-Mahmud, Lisa J. Kamphuis, Jennifer L. Mueller, Suzie S. Rigby, Martin S. Gibson, Mary Frances Richardson, Linda Humeniuk, and Stanley Walker

Abstract: Dimeric structures **2***a–c* are confirmed for the "methine bases" obtained from 2-methylbenzothiazolium and -selenazolium salts and aqueous sodium hydroxide, whereas monomeric structures **3** are confirmed for methine bases similarly derived from 2-methylquinolinium salts. The latter monomers dimerize slowly on standing. Monomeric methine bases **6–9**, too hindered to dimerize, are described. 2-Acetonylidene-2,3-dihydro-3-methylbenzothiazole **10***a* and related compounds are assigned (*Z*) configurations on the basis of NOE difference spectra. Molecular mechanics calculations predict a slightly higher steric energy for the observed *s-cis* conformer of **10***a* than for the *s-trans*, indicating a stabilizing S···O interaction in the *s* conformer that need only be a few kJ mol^{-1} in magnitude. For the quinolines **13***a* and *b*, the (*E*) configuration/*s-cis* conformation is favoured. The dielectric absorption method provides a rotational energy barrier of approximately 60 kJ mol^{-1} for acetyl group relaxation in **10***a*. Oxygen–sulfur exchange is observed in the conversion of **10***a* to **12***a* by thioacetic acid.

Key words: conformation, configuration, heterocyclic compounds, S···O interaction.

Résumé : On confirme les structures dimères **2***a–2c* pour les «bases méthines» obtenues par réaction des sels de 2-méthylbenzo-thiazolium et sélénazolium avec l'hydroxyde de sodium aqueux; par ailleurs, on confirme la structure monomère **3** pour les bases méthines obtenues de la même manière à partir des sels de 2-méthylquinolinium. Laissés au repos, ces derniers monomères se dimérisent lentement. On décrit aussi les bases méthines **6–9** qui sont trop encombrées pour se dimériser. En se basant sur les différences dans les spectres d'eOn, on a attribué les configurations (*Z*) au 2-acétonylidène-2,3-dihydro-3-méthylbenzothiazole (**10***a*) et aux composés apparentés. Des calculs de mécanique moléculaire permettent de prédire que l'énergie stérique du conformère *s-cis* observé du composé **10***a* est légèrement supérieure à celle du composé *s-trans*; ces résultats indiquent que, dans le conformère *s-cis*, il existe une interaction S···O stabilisante dont l'amplitude ne doit pas dépasser quelques kJ mol^{-1}. Pour les quinoléines **13***a* et **13***b*, la configuration (*E*) avec conformation *s-cis* est favorisée. La méthode d'absorption diélectrique permet de déterminer que la barrière à l'énergie rotationnelle pour la relaxation du groupe acétyle du composé **10***a* est d'environ 60 kJ mol^{-1}. On a observé de l'échange oxygène–soufre lors de la conversion du composé **10***a* en **12***a* par de l'acide thioacétique.

Mots clés : conformation, configuration, composés hétérocycliques, interaction S···O.

[Traduit par la rédaction]

Introduction

Traditionally, treatment of quaternary salts derived from heteroaromatic bases such as 2-methylbenzothiazole or 2-methylquinoline with aqueous sodium or potassium hydroxide has been thought to give methine bases, e.g., **1**. However, the product from 2,3-dimethylbenzothiazolium perchlorate (1) was shown to be dimeric (2) and, subsequently, to possess the structure **2***a* (3); our experience in the 1,3,4-thiadiazole series has been similar (4). Formation of **2***a* under these conditions is thought to occur by addition of **1** to C2 of the antecedent quaternary cation (3). To avoid coexistence of these two species, Owen (5) used a modified base treatment of the quaternary *p*-toluenesulfonate to prepare the monomeric methine base **1** and its selenium analogue. Similar ambiguities have arisen in the quinoline series with, e.g., the product described as **3***a* being reported both as a buff and as a red solid (6, 7). We have reexamined a number of the earlier reports and confirmed the product formulations as monomeric (**1** or **3**) or as dimeric (**2**, **4**, or **5**). We have also prepared the monomeric methine bases (**6–9**); steric constraints make approach to dimeric structures improbable in these cases.

Acyl derivatives of these methine bases, e.g. **10** and **11**, and the related thioacyl compounds **12** have attracted some attention over the years. Thus **10***a* and *b* have been prepared from 2-methylthiobenzothiazolium salts (8) and from other sources (9, 10), and in each case the same geometrical isomer has been isolated. We have encountered a similar situation in the 1,3,4-thiadiazole series, and established the (*Z*) configuration for the products with a weak hypervalent or "non-bonded" S···O interaction stabilizing the *s-cis* (*cisoid*) confirmation (4, 11). We now present evidence that again it is the (*Z*) isomers that are produced, stabilized by a S or Se···O interaction in the *s-cis* conformation (cf. ref. 12), and we provide an estimate of the internal barrier to rotation of the acetyl group in **10***a* around the acetyl – methine carbon bond. We append some observations on the related compounds **13***a* and *b* for which the (*E*) configuration/*s-cis* conformation has been proposed (13); this conformation may be stabilized by weak O···H—C3 bonding (14).

Experimental section

The following instruments were used: a Bruker AC200 spectrometer for ^{1}H NMR spectra (200 MHz; $SiMe_4$ as internal standard) and ^{13}C NMR spectra (50 MHz; solvent as internal standard); Varian Gemini 200 and Varian XL 200 spectrometers for NOE and NOE difference spectra, and a JEOL 270 spectrometer for ^{1}H–^{1}H COSY spectra; an AEI MS30 double beam mass spectrometer interfaced to a Kratos DS 55 data system and Kratos Concept 1S double focussing mass spectrometer for mass spectra (*m/z* values are quoted for the most abundant isotopic species; *m*-nitrobenzyl alcohol was used as matrix for FAB spectra). Melting points are uncorrected.

2-Methylbenzothiazole, 2-methylbenzoselenazole, and 2- and 4-methylquinolines were commercial materials, while 1-methyl-3,4-dihydroisoquinoline, 2,3-cyclopentanoquinoline, and 1,2,3,4-tetrahydroacridine were prepared by literature methods (15, 16). Quaternary salts were prepared by refluxing the base with iodomethane, iodoethane, or 3-bromopropene

(allyl bromide) as appropriate. Parenthetically, 9-methylphenanthridine (17) and allyl bromide reacted slowly to give 9-methylphenanthridinium bromide.

Molecular mechanics calculations were performed as described previously (11) with Chem3D Plus, which implements Allinger's MM2 force field (18).

Dimeric methine bases: benzothiazole and benzoselenazole series

Compounds were prepared from the respective quaternary salts by reported method (1, 7, 19); spectroscopic data were as follows.

2*a*, mp 176–177°C (lit. (3) mp 178°C): the ^{1}H NMR spectrum corresponded with that reported (3); ^{1}H NMR ($CDCl_3$) δ: 1.67 (s, 3H, CH_3), 2.61 (s, 3H, CH_3), 3.24 (s, 3H, CH_3), 4.45 (s, 1H, methine CH), and 6.33–7.15 (m, 8H, arom H).

2*b*, mp 125–127°C (lit. (7) mp 126–128°C): ^{1}H NMR ($CDCl_3$) δ: 1.18 (t, 3H, CH_3), 1.27 (t, 3H, CH_3), 1.78 (s, 3H, CH_3), 3.18 (q, 2H, CH_2), 3.76 (q, 2H, CH_2), 4.55 (s, 1H, methine CH), and 6.34–7.24 (m, 8H, arom H); EI mass spectrum *m/z*: 177 (M^+, monomer, 62) and 149 (100%); FAB mass spectrum *m/z*: 354 (M^+, 5), 353 (7), and 178 (monomer + H^+, 100%).

2*c*, mp 147–149°C (lit. (19) mp 157–158°C): ^{1}H NMR ($CDCl_3$) δ: 1.88 (s, 3H, CH_3), 2.62 (s, 3H, CH_3), 3.27 (s, 3H, CH_3), 4.81 (s, 1H, methine CH), and 6.38–7.28 (m, 8H, arom H); ^{13}C NMR ($CDCl_3$) δ: 29.2, 29.7, and 32.3 (methyl carbons), 92.1 (methine carbon), 109.0, 110.2, 119.6, 120.0, 124.4, 125.5, 125.9, and 126.1 (arom. HC carbons), 121.0, 123.0, 143.8, 147.6, and 148.1 (quaternary carbons); EI mass spectrum *m/z*: 211 (M^+, monomer, 100%); FAB mass spectrum *m/z*: 422 (M^+, 35), 421 (63), and 212 (monomer + H^+, 100%).

3-Allyl-2,3-dihydro-2-methylenebenzothiazole together with its dimer (isolated by immediate extraction (cf. ref. 6) with deuteriochloroform), light brown oil that reddened on standing; ^{13}C NMR ($CDCl_3$) δ: 32.1 (CH_3, dimer), 81.0 (methine carbon, monomer), and 87.9 (methine carbon, dimer). The alternative procedure (cf. ref. 7) gave a glassy buff solid that turned red and gummy on drying in a vacuum desiccator; ^{13}C NMR ($CDCl_3$) δ: 22.2 (CH_3) and 170.0 (CO) ppm; EI mass spectrum *m/z*: 207 (M^+, $C_{11}H_{13}NOS$, 100), 165 (51), and 136 (86%).

Methine bases; quinoline, isoquinoline, and condensed quinoline series

Compounds were prepared from the respective quaternary salts and isolated by each of two general literature procedures (6; 7 and 16). For **3***a*, the earlier isolation procedure (6) gave the monomeric species, whereas the later procedure (7) gave **3***a* contaminated with **4***a*. Spectroscopic data were as follows.

3*a*, mp 70–71°C (lit. (6) mp 71–72°C); ^{1}H NMR ($CDCl_3$) δ: 3.09 (s, 3H, CH_3), 3.59 (s, 1H of methine CH_2), 3.71 (s, 1H of methine CH_2), 6.30 (d, 1H, olefinic H), 6.41 (d, 1H, olefinic H), and 6.68–7.43 (m, 4H, arom H); ^{13}C NMR ($CDCl_3$) δ: 32.8 (CH_3), 80.2 (methine carbon), 110.9 (C3), 119.0 (C4), 126.1, 126.6, 127.2, and 129.2 (arom. carbons), 122.4, 143.4, and 148.4 (quaternary carbons); EI mass spectrum *m/z*: 157 (M^+, 100%). The brick-red solid obtained on standing showed the following additional signals in the ^{13}C NMR spectrum ($CDCl_3$) δ: 30.9, 33.4, and 34.8 (CH_3), 52.4 (HC), 100.2, 104.5, 111.2, 111.4, 118.4, 120.4, 121.1, 122.0, 125.8, 126.9, 128.8, and 129.3 (arom. and vinyl HC carbons), 135.7, 136.2, 137.6, 137.7, 142.2, and 142.4 (quaternary carbons); EI mass spectrum *m/z*: 314 (M^+ of dimer, ca. 1.5%) and 157 (M^+, 100%).

3*b*, mp 76–78°C (dec.) (lit. (7) mp 79°C (dec.)); ^{1}H NMR ($CDCl_3$) δ: 1.18 (t, 3H, CH_3), 3.66 (q with two s superimposed, 4H, NCH_2 and methine CH_2), 6.30 (d, 1H, olefinic H), 6.41 (d, 1H, olefinic H), and 6.60–7.33 (m, 4H, arom. H); ^{13}C NMR ($CDCl_3$) δ: 10.0 (CH_3), 40.2 (NCH_2), 79.2 (methine carbon), 110.6 (C3), 118.9 (C4), 126.1, 127.0, 127.3, and 129.4 (arom. carbons), 122.6, 141.4, and 144.8 (quaternary carbons); FAB mass spectrum *m/z*: 172 (M + H^+, 100%). For the brick-red solid obtained on standing: FAB mass spectrum *m/z*: 343 (dimer + H^+, 4), 342 (dimer M^+, 7), 341 (dimer − H^+, 21), and 172 (monomer + H^+, 100%).

3*c* (cf. ref. 7), yellow solid, mp 80–81°C (dec., after blackening from 65°C), which darkened and finally became purple on standing; ^{13}C NMR ($CDCl_3$) δ: 40.1 (CH_2), 80.8 (methine carbon), 111.5, 119.3, 126.0, 126.9, 127.0, 129.2, and 130.6 (arom. and vinyl HC carbons), 116.7 (CH_2), 122.5, 142.0, and 145.5 (quaternary carbons).

5, mp 64°C (dec.); ^{13}C NMR ($CDCl_3$) δ: 35.7, 37.7, and 38.8 (methyl carbons), 57.8 (HC), 100.4 (methine carbon), 105.9, 110.3, 110.8, 113.3, 116.1, 116.8, 121.9, 122.4, 123.0, 123.3, 123.5, 128.5, and 133.8 (arom. and vinyl HC carbons), 129.1, 139.9, and 144.1 (quaternary carbons); EI mass spectrum *m/z*: 313 (M − H^+, ca. 1%), 312 (3), 158 (monomer M + H^+, 95), 157 (monomer M^+, 82), and 144 (100%).

6, oil: ^{1}H NMR ($CDCl_3$) δ: 2.86 (s, 3H, NCH_3), 2.91 (t, 2H, CH_2), 3.15 (t, 2H, CH_2), 3.86 (s, 1H, methine CH), 4.61 (s, 1H, methine CH), and 7.08–7.72 (m, 4H, arom. H); ^{13}C NMR ($CDCl_3$) δ: 40.6 (CH_3), 30.2 and 50.0 (2 × CH_2), 79.0 (methine carbon), 124.5, 126.1, 127.4 and 128.3 (arom. HC carbons), 131.8, 134.4, and 148.5 (quaternary carbons).

7, mp 179°C (dec.) (lit. (16) mp 170°C (dec.)); ^{1}H NMR ($CDCl_3$) δ: 2.35–2.64 (m, 4H, 2 × CH_2), 2.99 (s, 3H, CH_3), 4.30 (s, 1H, methine CH), 6.05 (s, 1H, CH), and 6.53–7.23 (m, 4H, arom. H); ^{13}C NMR ($CDCl_3$) δ: 27.8 and 28.0 (2 × CH_2), 32.8 (CH_3), 94.5 (methine carbon), 109.4, 115.3, 119.0, 125.9, and 127.3 (arom. and vinyl HC carbons), 124.6, 141.3, 144.4,

and 146.2 (quaternary carbons); EI mass spectrum *m/z*: 183 (M^+, 71) and 182 (100%).

8 (16), mp 184–185°C (dec.); ^{1}H NMR ($CDCl_3$) δ: 1.65–1.74 (m, 2H, CH_2), 2.30–2.48 (m, 4H, 2 × CH_2), 3.02 (s, 3H, CH_3), 4.44 (s, 1H, methine CH), 6.18 (s, 1H, CH), and 6.68–7.72 (m, 4H, arom. H); ^{13}C NMR ($CDCl_3$) δ: 21.6, 25.4, and 31.3 (3 × CH_2), 32.6 (CH_3), 93.5 (methine carbon), 110.3, 118.2, 121.0, 126.1, and 128.0 (arom. and vinyl HC carbons), 122.8, 132.9, 139.6, and 142.2 (quaternary carbons); EI mass spectrum *m/z*: 197 (M^+, 97) and 196 (100%).

For **9**, the quaternary salt (1.08 g, 3.2 mmol) was dissolved in DMSO (6.2 mL) prior to treatment with 1 M NaOH solution. The orange methine base **9** (0.42 g, 63%), mp 78°C (dec.), was isolated by extraction with $CDCl_3$; ^{1}H NMR ($CDCl_3$) δ: 3.25 (s, 3H, CH_3), 4.17 (s, 1H, methine CH), 4.72 (s, 1H, methine CH), and 6.83–7.91 (m, 8H, arom. H); ^{13}C NMR ($CDCl_3$) δ: 34.9 (CH_3), 82.7 (methine carbon), 112.6, 119.1, 122.0, 122.9, 124.5, 127.6, 128.6, and 129.2 (arom. HC carbons), 120.4, 129.7, 130.3, 141.5, and 145.9 (quaternary carbons); EI mass spectrum *m/z*: 207 (M^+, 100%). Exact Mass calcd. for $C_{15}H_{13}N$ 207.1049; found: 207.1064.

2-Acetonylidene-2,3-dihydro-3-methylbenzothiazole 10*a*

A mixture of 2,3-dimethylbenzothiazolium iodide (4.0 g, 14 mmol), Ac_2O (2.9 g, 28 mmol), NEt_3 (2.9 g, 29 mmol), and MeCN (15 mL) was heated under reflux for 2 h. The mixture was concentrated in vacuo and then poured into water. The crude product was collected and chromatographed on silica ($CHCl_3$–EtOAc as eluant). **10*a*** (1.5 g, 53%) crystallized from aqueous EtOH as needles, mp 158–159°C (lit. (9) mp 160–161°C); ^{1}H NMR ($CDCl_3$) δ: 2.23 (s, 3H, CH_3), 3.52 (s, 3H, CH_3), 5.84 (s, 1H, methine CH), and 7.09–7.57 (m, 4H, arom. H); ^{13}C NMR ($CDCl_3$) δ: 29.0 (CH_3), 32.3 (CH_3), 90.1 (methine carbon), 109.6, 122.1, 122.5, and 126.0 (aromatic HC carbons), 126.9, 139.7, 160.5, and 191.1 (quaternary carbons): EI mass spectrum *m/z*: 205 (M^+, 56) and 190 (100%).

2-Acetophenonylidene-2,3-dihydro-3-methylbenzothiazole 10*b*

A mixture of 2,3-dimethylbenzothiazolium iodide (1.0 g, 3.4 mmol), benzoic anhydride (0.8 g, 3.5 mmol), NEt_3 (1.0 g, 10 mmol), and MeCN (10 mL) was heated under reflux for 4 h. The oily crude product was extracted with EtOAc. Chromatography (silica; EtOAc) and crystallization from EtOH gave **10*b*** (0.7 g, 76%) as needles, mp 175–177°C (lit. (10) mp 179.5–180°C); ^{1}H NMR ($CDCl_3$) δ: 3.63 (s, 3H, CH_3), 6.52 (s, 1H, methine H), 7.12–7.65 (m, 7H, arom. H), and 8.00 (dd, 2H, arom. H); ^{13}C NMR ($CDCl_3$) δ: 32.3 (CH_3), 86.9 (methine carbon), 109.7, 122.1, 122.6, 126.3, 127.0, 128.1, and 130.6 (arom. HC carbons), 126.8, 139.4, 139.8, 162.0, and 184.2 (quaternary carbons); EI mass spectrum *m/z*: 267 (M^+, 14), 190 (10), 164 (39), and 105 (100%).

2-Acetonylidene-2,3-dihydro-3-ethylbenzothiazole 10*c*

Prepared similarly to **10*b*** (16 mmol scale; 1 h reflux), **10*c*** (0.3 g, 84%) had mp 106–108°C (lit. (9) mp 111–113°C); ^{1}H NMR ($CDCl_3$) δ: 1.40 (t, 3H, CH_3), 2.27 (s, 3H, CH_3), 4.13 (q, 2H, CH_2), 5.95 (s, 1H, methine H), and 7.00–7.80 (m, 4H, arom. H); EI mass spectrum *m/z*: 219 (M^+, 100), 204 (95), and 176 (58%).

2-Acetonylidene-2,3-dihydro-3-methylbenzoselenazole 11*a*

A mixture of 2,3-dimethylbenzoselenazolium iodide (1.0 g, 3.0 mmol), Ac_2O (0.32 g, 3.1 mmol), NEt_3 (0.29 g, 2.9 mmol), and MeCN (10 mL) was heated under reflux for 1.5 h. Isolation as for **10*a*** gave **11*a*** (0.3 g, 40%) as yellow needles, mp 163–165°C (lit. (20) mp 165°C); ^{1}H NMR ($CDCl_3$) δ: 2.24 (s, 3H, CH_3), 3.56 (s, 3H, CH_3), 6.15 (s, 1H, methine H), and 7.10–7.66 (m, 4H, arom. H); EI mass spectrum *m/z*: 253 (M^+, 69) and 238 (100%).

2-Acetophenonylidene-2,3-dihydro-3-methylbenzoselenazole 11*b*

(*a*) A mixture of 2,3-dimethylbenzoselenazolium iodide (1.0 g, 3.0 mmol), benzoic anhydride (0.6 g, 2.7 mmol), NEt_3 (0.29 g, 2.9 mmol), and MeCN (20 mL) was heated under reflux for 2 h. Chromatography (silica; EtOAc–CH_2Cl_2) and crystallization from EtOH gave **11*b*** (0.6 g, 65%) as shiny yellow plates, mp 137–139°C (lit. (21) mp 140–140.5°C); ^{1}H NMR ($CDCl_3$) δ: 3.68 (s, 3H, CH_3), 6.84 (s, 1H, methine H), 7.13–7.75 (m, 7H, arom. H), and 8.10 (dd, 2H, arom. H); EI mass spectrum *m/z*: 315 (M^+, 5), 238 (4), 212 (7), 122 (12), and 105 (100%).

(*b*) A mixture of **2*c*** (100 mg, 0.24 mmol), benzoic anhydride (110 mg, 0.49 mmol), NEt_3 (50 mg, 0.50 mmol), and $CHCl_3$ (10 mL) was heated under reflux for 1 h. Isolation as above gave **11*b*** (60 mg, 40%), mp 137–139°C, identical with the foregoing sample.

2,3-Dihydro-3-methyl-2-thioacetonylidenebenzothiazole 12*a*

A mixture of **10*a*** (500 mg, 2.44 mmol) and thioacetic acid (5 mL) was heated under reflux for 4 h. Evaporation in vacuo and trituration with EtOAc gave **12*a*** as an orange solid (350 mg, 61%) that crystallized from EtOH as orange needles, mp 187–189°C; ^{1}H NMR ($CDCl_3$) δ: 2.74 (s, 3H, CH_3), 3.68 (s, 3H, CH_3), 6.96 (s, 1H, methine H), and 7.12–7.75 (m, 4H, arom. H); EI mass spectrum *m/z*: 221 (M^+, 84), 206 (22), and 188 (100%). Exact Mass calcd. for $C_{11}H_{11}NS_2$: 221.0333; found: 221.0344.

2,3-Dihydro-3-methyl-2-thioacetophenylidenebenzothiazole 12*b*

(*a*) A mixture of 2,3-dimethylbenzothiazolium iodide (1.0 g, 3.4 mmol), carboxymethyl dithiobenzoate (0.72 g, 3.4 mmol), NEt_3 (0.36 g, 3.6 mmol), and MeCN (20 mL) was heated under reflux for 2 h. Evaporation in vacuo, chromatography (silica; $CHCl_3$), and crystallization from EtOH gave **12*b*** (0.3 g, 29%) as orange-red needles, mp 168–170°C; ^{1}H NMR ($CDCl_3$) δ: 3.84 (s, 3H, CH_3) and 7.12–7.83 (m, 10H, methine H and arom. H); EI mass spectrum *m/z*: 283 (M^+, 97), 250 (100), 221 (53), and 188 (59%). Exact Mass calcd. for $C_{16}H_{13}NS_2$: 283.0489; found: 283.0486.

(*b*) A mixture of **10*b*** (100 mg, 0.37 mmol) and thioacetic acid (3 mL) was heated under reflux for 8 h and the mixture was then concentrated in vacuo. Chromatography (silica; benzene–EtOAc) and crystallization from EtOH gave **12*b*** (60 mg, 57%), mp 166–168°C, identical with the foregoing sample.

Reaction of 2*c* with phenyl isothiocyanate

A mixture of **2*c*** (50 mg, 0.12 mmol), phenyl isothiocyanate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.90.12.36 on 09/08/12
For personal use only.

(20 mg, 0.15 mmol), and $CHCl_3$ (5 mL) was heated under reflux for 2 h, and the red solution was then concentrated in vacuo. Preparative TLC (silica; $CHCl_3$) and crystallization from EtOH gave the adduct **12***c* (40 mg, 78% based on phenyl isothiocyanate) as tiny yellow crystals, mp 158–160°C; ^1H NMR ($CDCl_3$) δ: 3.48 (s, 3H, CH_3), 6.58 (s, 1H, methine H), 7.12–7.68 (m, 9H, arom. H), and 8.05 (s, 1H, NH, exchangeable with D_2O); EI mass spectrum *m/z*: 346 (M^+, 100), 313 (43), and 254 (58%). Exact Mass calcd. for $C_{16}H_{14}N_2SSe$: 346.0043 (for ^{80}Se); found: 346.0027.

Results and discussion

Syntheses and characterization

Treatment of 2,3-dimethylbenzothiazolium, 3-ethyl-2-methylbenzothiazolium, and 2,3-dimethylbenzoselenazolium iodides with aqueous sodium hydroxide as originally described gave **2***a*, **2***b*, and **2***c*, respectively; these structures follow from consideration of NMR and mass spectra. 3-Allyl-2-methylbenzothiazolium bromide gave predominantly a mixture of monomeric and dimeric species (if isolated by solvent extraction) or the ring-opened amide (if isolated by filtration and desiccation) depending on the length of time in contact with water (cf. ref. 22). Similar treatment of 1,2-dimethylquinolinium iodide gave the monomeric methine base **3***a* as primary product (isolated by extraction as a buff solid (6); extraction with deuteriochloroform is useful as an aid for obtaining NMR spectra). This compound shows the methine carbon signal upfield at ca. 80 ppm and the signal due to the methine protons at ca. 3.6 ppm in its ^{13}C and ^1H NMR spectra, respectively. If, however, the product is isolated from this preparation by filtration and drying in a desiccator (7), a brick-red solid is obtained that is a mixture of monomeric and dimeric species. The ^{13}C NMR spectrum of the red solid contains 22 signals in addition to those due to **3***a* and points to the presence of **4***a*, a conclusion supported by the mass spectrum. The monomer **3***a* described above also reddens on keeping, with concomitant formation of **4***a*. The case of 1-ethyl-2-methylquinolinium salts (7) was reexamined by Metzger et al. (23) who reported obtaining mixtures of **3***b* and **4***b*. We were able to isolate **3***b* as a buff solid that reddened on keeping (7), due to the formation of **4***b*. We noted similar behaviour with 1-allyl-2-methylquinolinium bromide.

Treatment of 1,4-dimethylquinolinium iodide with aqueous sodium hydroxide solution gave a red solid that was identified as the dimeric species **5**; this turned into a purple-blue dye on exposure to air. Monomeric methine bases **6–9** were obtained from the corresponding quaternary iodides by treatment with aqueous sodium hydroxide. For these compounds, there is considerable hindrance to dimer formation and indeed no signs of dimers were detected. We conclude that a kinetically controllable procedure (cf. ref. 5) should be used to prepare monomeric methine bases from quaternary salts if a tendency to dimer formation is expected; otherwise, the aqueous base or tertiary base/acetonitrile procedures should suffice.

We turn now to the acyl and thiocyl derivatives of the methine bases in the benzothiazole and benzoselenazole series. We have used acylation of the appropriate methine base, generated in situ from the quaternary salt and triethylamine in acetonitrile, by a carboxylic chloride or anhydride to prepare **10***a–c*, and **11***a* and *b*. We also prepared **11***b* by benzolation of **2***c* (24). The Vongerichten–Rotta procedure was used to prepare **13***a* and **13***b* (13). Thioacyl derivatives have previously been made by reacting the foregoing acyl derivatives with phosphorus pentasulfide, but we have found that thioacetic acid is more convenient for the preparation of **12***a*. We had already used this reagent in the 1,3,4-thiadiazole series, where thioacetic acid had appeared to behave (unusually) as a thioacetylating agent (25). Success in the present work suggests that it plays the role of an oxygen–sulfur exchange reagent. **12***b* was prepared by thiobenzoylation of **1**, generated in situ, and **12***c* by reaction of **2***c* with phenyl isothiocyanate.

Molecular configuration

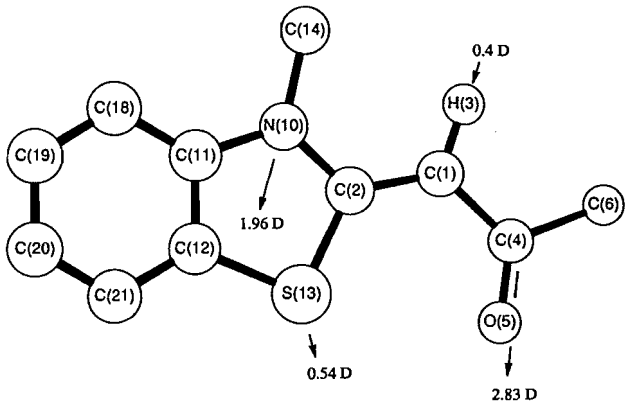
In the 1,3,4-thiadiazole series, we used N-aryl substitution (4) and X-ray crystallography (11) to determine the geometries of the acyl and thioacyl derivatives of the methine bases. In the present work, we use nuclear Overhauser effect (NOE) studies for this purpose, but first we note that the ^1H NMR spectra of representative compounds (**10***a*, **11***b*, **12***a* and *b*) in $CDCl_3$ are unchanged by running at 183 K.

First examined was **10***b* for which we deduce (*Z*) geometry. Thus, irradiation of the olefinic proton of a 0.2 M solution of **10***b* in $CDCl_3$ at δ 6.53 led to a +16.2% enhancement of the NCH_3 signal at δ 3.63. However, irradiation of the NCH_3 signal resulted in a −62.6% enhancement of the olefinic proton. This large negative enhancement was unexpected for a small molecule like **10***b*. Negative NOE's are frequently observed for macromolecules (26) that exhibit prolonged molecular motional correlation times τ_c (27). Williamson and Williams (28) have shown that negative NOE's can be observed when, by use of a viscous solvent such as Voltalef 10S (a polmer of chlorotrifluoroethylene), tumbling of the solute can be slowed down, i.e., τ_c can be prolonged. They used the observed negative NOE's to deduce the solution conformation of the antibiotic echinomycin.

A NOE difference spectrum of **10***b* (ca. 0.1 M) in $CDCl_3$ was then run. Irradiation of the NCH_3 signal at δ 3.63 led to a −24.4% enhancement of the olefinic proton at δ 6.53, a +12.5% enhancement of the aromatic proton *ortho* to the NCH_3 at δ 7.15, and a +5.3% enhancement of the aromatic protons *ortho* to the carbonyl group at δ 8.00. These enhancements were measured by normalization of the intensity of the saturated NCH_3 signal in the difference spectrum as a reference, and integrating the enhanced peaks relative to this scale. The assignment of the doublet of doublets at δ 8.00 to the aromatic protons *ortho* to the carbonyl group was further confirmed by reference to the ^1H–^1H COSY spectrum of **10***b*. The involvement of aromatic protons *ortho* to the carbonyl group in the dipolar relaxation clearly indicates molecular aggregations at high solute concentrations (29) and also helps to explain the observed large negative NOE's. In further support of molecular aggregation, irradiation of the NCH_3 protons of a 0.02 M solution of **10***b* in $CDCl_3$ led to a +7.2% enhancement of the olefinic proton.

NOE studies were used to establish the configurations of two further compounds. In the case of **10***a*, irradiation of the NCH_3 signal at δ 3.52 of a 0.2 M solution in $CDCl_3$ gave a +11% enhancement of the olefinic proton at δ 5.84, providing evidence for (*Z*) geometry. Similarly, (*Z*) geometry was established for **11***b*; irradiation of the NCH_3 signal at δ 3.68 of a 0.2

Fig. 1. The structure of **10***a* (compiled from data in ref. 30).



M solution in $CDCl_3$ gave a +24.1% enhancement of the olefinic proton at δ 6.84, while irradiation of the olefinic proton gave a +9.5% enhancement of the NCH_3 signal.

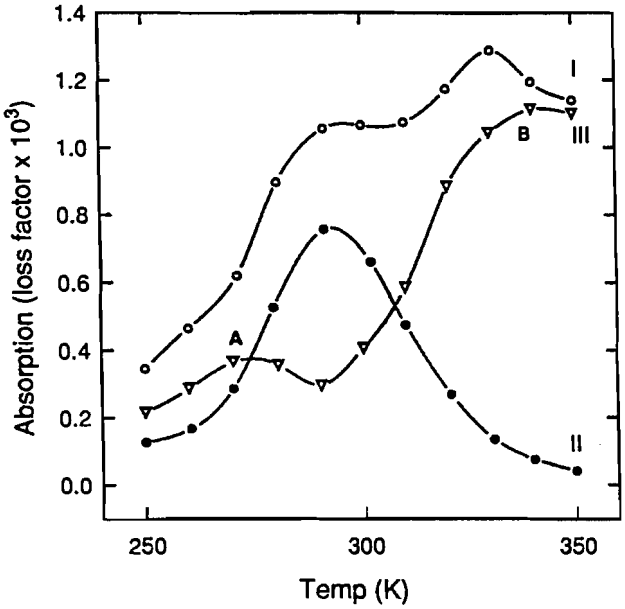
Molecular structure and molecular mechanics; structures 10*a* and 13*a*

The compounds **10** show a number of similarities with analogous 1,3,4-thiadiazoles reported previously. The IR carbonyl absorptions for **10***a* and *c* appear at 1604 and 1614 cm^{-1} respectively, and corresponding absorptions for a series of 2-acylidene-3-(1-cycloalkenyl)-2,3-dihydrobenzothiazoles all lie in the range 1600–1620 cm^{-1} (30). Trapani et al. (30) have reported an X-ray structure determination on one of their compounds, establishing (*Z*) geometry; we compute the S···O interatomic distance in that compound as 2.615 Å, well within the range found for corresponding 1,3,4-thiadiazoles, and indicative of a similar S···O interaction. From the coordinates given in that paper (30), we construct the model shown in Fig. 1 for compound **10***a*. The important points to note at this stage are the S···O interatomic distance (2.616 Å), the pseudo-torsion angle S(13)-N(10)-C(4)-O(5) of 1.4°, and the C(2)—C(1) and C(1)—C(4) bond orders of 1.761 and 1.374 respectively.

Using molecular mechanics, we compute the following steric energies for the (*Z*) isomer of **10***a*: *s-cis* conformer, 43.6 kJ mol^{-1}; *s-trans* (*transoid*) conformer, 38.5 kJ mol^{-1}. Corresponding energies for the (*E*) isomer are *s-cis* conformer, 52.7 kJ mol^{-1}; *s-trans* conformer, 66.4 kJ mol^{-1}. As in the thiadiazole series, the two (*Z*) conformers have lower energies than the two (*E*) conformers, and the overwhelming predominance of the (*Z*) isomer in the *s-cis* conformation in spite of a lower steric energy for the *s-trans* is an additional argument for a stabilizing S···O interaction.

For **13***a*, the argument for the (*E*) isomer existing as the *s-cis* conformer is based on the observed chemical shift for H3 in the ^1H NMR spectrum at δ 9.15, downfield due to deshielding by the proximate C=O group (13); for **13***b*, we note the corresponding signal at δ 8.89. The ^1H NMR spectrum of **13***a* in $CDCl_3$ is unchanged by running at 183 K; further, irradiation of the methine proton at δ ɔ.ϑ2 leads to a +27% enhancement of the NCH_3 signal at δ 3.62. This provides additional support for the (*E*)-*s-cis* assignment. As above, we compute the following steric energies for the (*E*) isomer: *s-cis* conformer, 49.6 kJ mol^{-1}; *s-trans* conformer, 51.0 kJ mol^{-1}. Corresponding energies for the (*Z*) isomer are *s-cis* conformer, 59.7 kJ mol^{-1}; *s-trans* conformer, 69.6 kJ mol^{-1}. The two (*E*) isomers have lower energies than the two (*Z*) isomers, and the dominant (*E*) isomer in the *s-cis* conformation may be further stabilized by weak hydrogen bonding (O···H—C3), which is not explicitly considered in the molecular mechanics calculation (14).

Fig. 2. Plot of the loss factor vs. temperature (K) at 5.02 kHz for **10***a* at a concentration of 5 wt.% solution in a polypropylene matrix (curve I). Curve II is a similar plot for pure polypropylene while curve III emerges from the subtraction of curve II from curve I at each of the experimental temperatures.



Intramolecular reorientation in 10*a*

The dielectric absorption of **10***a* has been studied with a view to determining whether the acetyl group reorients and, if so, to determine its energy barrier. The dielectric absorption method employing inert matrices (31) has, in the past 20 years, proved a most effective technique of detecting intramolecular motion and evaluating the corresponding energy barrier, and several studies have been made on acetyl group relaxation in a variety of aromatic molecules.

10*a* was dispersed in a polypropylene matrix and the dielectric absorption of its compressed disc measured at 11 temperatures at each of the following frequencies: 1010, 2020, 5020, and 10 200 Hz. This was repeated for a pure polypropylene disc, and its absorption at each temperature for a given frequency was subtracted from that of the solute-containing matrix. The results at 5020 Hz are presented in Fig. 2 where curve I gives the absorption of the solute-containing matrix, curve II that of the polypropylene, and III that for the solute itself. In case III, two absorption peaks emerge; the lower temperature peak at 276 K is designated A and the higher temperature peak, B.

The dielectric absorption technique and methods of evaluation of the results have been described previously (31–36).

It is now required to identify which of the two peaks is the intramolecular process. Molecular reorientation would account for one peak while, in view of previous studies on a wide variety of aromatic ketones, the relaxation of the acetyl

group is the most likely candidate for the other. Identification as to which peak corresponds with each of these processes is facilitated by making (rough) estimates of the dipole moment components responsible for each of the two processes. If μ_1 and μ_2 are the dipole moment components for the molecular and intramolecular processes, then the square of their values govern the intensities of each of these processes. For the present, we shall assume that the intramolecular process is acetyl group relaxation about the C(1)—C(4) bond (Fig. 1).

Published bond moment data (37, 38), shown in Fig. 1, were used in rough estimations of μ_1 and μ_2, and the inclination of the acetyl group moment to the C(2)-S(13)-C(12) group moment for the (*Z*) isomer was estimated as 25°. These estimations yielded $\mu_1 \sim 5.7$ D and $\mu_2 \sim 2.28$ D. Thus it is apparent that the intensity of the molecular relaxation process would be appreciably greater than that for the acetyl; hence the latter process is allocated to peak A and the higher temperature one to the molecular process (peak B). A temperature maximum (T_m) of about 340 K appears reasonable for the molecular process when compared with molecules such as biphenyl-4-carboxaldehyde and 9*H*-fluorene-2-carboxaldehyde, which have their molecular relaxation processes around this temperature (39) and are of a similar size.

We shall concern ourselves solely with the intramolecular process peak A. From the T_m values of 270 K, 275 K, 276 K, and 280 K at the corresponding frequencies (really frequency maximum (f_m) values) of 1010, 2020, 5020, and 10 200 Hz and the Arrhenius equation (40):

$$\log_{10} f_m = -E_A/2.303RT + A$$

where E_A is the Arrhenius energy of activation of the intramolecular process and, in our case, $T = T_m$ and A is a constant. A plot of $\log f_m$ vs. $1/T_m$ is made in Fig. 3. The f_m values may be regarded as accurate, but an error line corresponding to ±2 K was placed on the values of $1/T_m$ since partial overlap of the molecular and the intramolecular processes places some uncertainty on the determined T_m values. From the slope of the line, E_A was found to be 63 kJ mol^{-1} and its error could be greater than the normal ±10% for our dielectric procedure (32).

From the equation (39, 40):

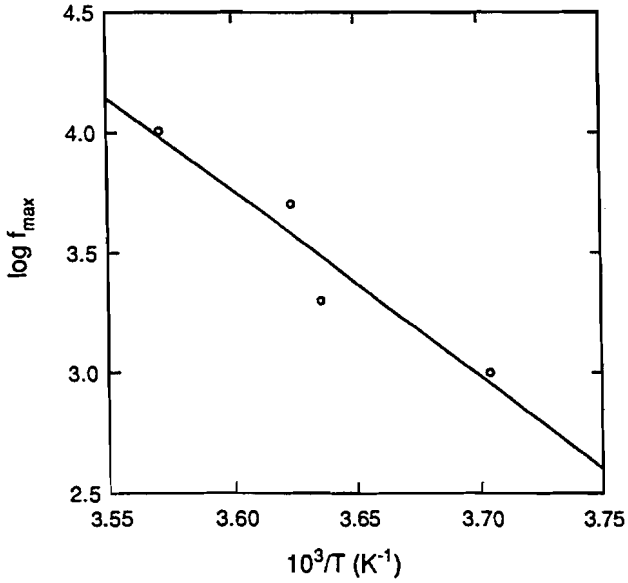
$$E_A = \Delta H_E + RT$$

ΔH_E, the Eyring enthalpy of activation for the intramolecular process, is found to be 61 kJ mol^{-1}, that is, of the order of 60 kJ mol^{-1}.

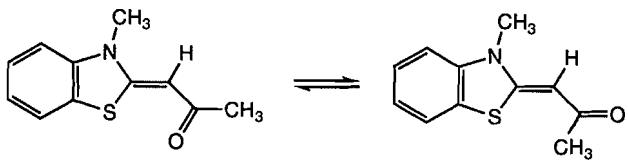
The temperature region of absorption of this intramolecular process is fairly similar to that for acetyl group relaxation in *N*-acetylimidazole (41), which absorbs around 270 K for the frequencies employed. It is interesting to note, though, that the molecular relaxation process for this much smaller molecule occurs in the 120–160 K range, about 200 K lower than that of **10***a*.

For **10***a*, the reorientation of the acetyl group between its equilibrium positions corresponds with an asymmetrical free energy diagram in which ΔG_{E_1} and ΔG_{E_2} are the free energies of activation corresponding to the switch from the conformer of lower energy (*s-cis*) to that of the higher (*s-trans*) and to the switch from that from the higher (*s-trans*) to that of the lower

Fig. 3. Plot of $\log f_{max}$ vs. $10^3/T$ (K^{-1}) for **10***a* in a polypropylene matrix. The data correspond with process A in curve III, Fig. 2.



(*s-cis*), respectively, and $\Delta G°$ is the difference in free energy between the *s-cis* and *s-trans* conformers ($\Delta G_{E_1} - \Delta G_{E_2}$). The dielectric absorption method yields a free energy of activation value corresponding to the switch from the conformer with the higher energy (*s-trans*) to that of the lower (*s-cis*) (ΔG_{E_2}), and our determined ΔH_E value is for this reorientation (34*a*). The ΔH_E value for the alternative reorientation is expected to be larger since ΔS_E values are normally small for acetyl group relaxation.



(*Z*)-s-*cis* (*Z*)-s-*trans*

The ΔH_E value of about 60 kJ mol^{-1} is to be compared with (*a*) those of 30 kJ mol^{-1} for acetyl group relaxation in acetophenone (32) and 4-acetylbiphenyl (32), which could be regarded as a typical value for simple aromatic ketones with no special conjugation effects, and (*b*) the acetyl group in *N*-acetylimidazole (41) with a value of 50 kJ mol^{-1} as a result of enhanced conjugation. Table 1 bears this out where the energy barriers for group reorientation are very similar for benzaldehyde, acetophenone, biphenyl-4-carboxaldehyde, and 4-acetylbiphenyl while appreciable increases are observed in the molecules that exhibit enhanced conjugation.

Thus, the ΔH_E value of about 60 kJ mol^{-1} for our intramolecular process is consistent with group reorientation in the more highly conjugated aldehyde and acetyl aromatic compounds, and, consequently, we assign the process to acetyl group reorientation.

We conclude that the magnitude of this ΔH_E value for acetyl group reorientation in **10***a* indicates enhanced conjugation of the keto group with the conjugated system over that in, say, acetophenone and 4-acetylbiphenyl. The value of ΔH_E for the

Table 1. ΔH_E values for group relaxation in selected carbonyl compounds.

alternative reorientation, *s-cis* to *s-trans* conformer, will be larger than 60 kJ mol^{-1} because of the combination of (*a*) enhanced conjugation and (*b*) the stabilizing interaction between the S and O atoms. The latter interaction is perhaps comparable in its effect to that of a weak hydrogen bond (cf. ref. 11).

This behaviour is also predicted from the theoretical analysis (42) of **10***a* and the related molecule 2-acetonylidene-1,2-dihydro-1-methylquinoline. In the planar configurations (*Z* and *E*, respectively), the nominally double bonds of the acetonylidene side chain and adjacent ring are longer while the single bonds are shorter and exhibit some π character. The distinction between bond types returns when the acetyl group is rotated perpendicular to the ring plane. The calculations, performed at the HF/3-21G* level, predict a stabilization due to this extended conjugation. The barrier to internal rotation is found to be asymmetric, since the *s-cis* conformation allows for a further stabilizing interaction between S and O in **10***a*, and between (C3)H and O in the quinoline. This nonbonded or "closed shell" interaction is found to be a significant factor in the barrier to internal rotation, providing an additional lowering of energy for the *s-cis* conformation in each case. While the level of calculation is fairly good, given the size of these molecules, it cannot be expected to give a truly accurate prediction of barrier heights. Nevertheless, the qualitative picture is considered to be a reliable representation of the factors contributing to the stability of the preferred conformations.

Acknowledgments

We thank Dr. F. Souriel (Department of Chemistry, McGill University, Montreal, Québec) for providing NOE difference spectra, and Professor K.M. Gough (Brock University) for her interest in conducting the theoretical study (42) relevant to this work. We are grateful to the Natural Sciences and Engineering Council of Canada for financial support.

Ab initio interpretation of conformer stabilization through S···O and C—H···O bonding in the acetyl derivatives of two representative heterocyclic methine bases

Kathleen M. Gough and Janice Millington

Abstract: *Ab initio* calculations (STO-3G and 3-21G* basis sets) have been performed on **2** and **3** to determine the most favorable structure and to provide an estimate of the barrier to internal rotation of the acyl group. The *Z* configuration is preferred in **2**, the *E* configuration in **3**, with calculated barriers to internal rotation of 79.9 and 68.7 kJ/mol, respectively, at the 3-21G* level. The wave functions from the 3-21G* calculations are analyzed with the theory of atoms in molecules. The identification of bond critical points characteristic of a closed shell interaction establishes the existence of a weak bond between S···O in **2** and between H···O in **3**, for the preferred configurations. The energy required to break this bond as well as the loss of extended conjugation throughout the hetero ring and its side chain are responsible for the asymmetry in the barrier. These findings provide a theoretical explanation for experimental observations on this class of molecules in which one conformer is preferred to any other and only one crystal structure is identified.

Key words: nonbonded sulfur–oxygen interaction, closed shell interaction, hydrogen bonding, 3-21G* basis set, theory of atoms in molecules.

Résumé : On a effectué des calculs *ab initio* (ensembles de base STO-3G et 3-21G*) sur les composés **2** et **3** dans le but de déterminer leur structure la plus favorable et d'obtenir une évaluation de la barrière à la rotation interne du groupe acyle. Les conformations préférées sont la *Z* pour le composé **2** et la conformation *E* pour le composé **3**; au niveau 3-21G*, les barrières calculées à la rotation interne sont respectivement de 79,9 et de 68,7 kJ mol^{-1}. On a analysé les fonctions d'onde obtenues par les calculs au niveau 3-21G* à l'aide de la théorie des atomes dans les molécules. L'identification de points critiques dans les liaisons, caractéristiques d'une interaction à couche fermée, permet d'établir que, dans les configurations préférées, il existe une liaison faible entre S···O dans le composé **2** et H···O dans le composé **3**. Ces résultats fournissent une explication théorique des observations expérimentales sur cette classe de molécules dans lesquelles un conformère est préféré à tous les autres et avec lesquelles on n'identifie qu'une seule structure cristalline.

Mots clés : interaction non liée soufre–oxygène, interaction à couche fermée, liaison hydrogène, ensemble de base 3-21G*, théorie des atomes dans les molécules.

[Traduit par la rédaction]

Introduction

The concept of the chemical bond is subject to a wide range of interpretations, as required by the interactions to which this term can be applied. The criteria that are accepted as defining the existence of a bond between two atoms are similarly varied. Problems arise when the nature of the interaction is far from the typical covalent behavior, as is the case for hydrogen bonding and for the so-called "hypervalent" interactions between formally nonbonded heavy atoms (1–6). While it may be more difficult to establish the existence of such weak bonds in some systems, it is nonetheless clear that such interactions do exist, and can be of vital importance in determining the stability of particular conformers and of particular crystal structures, as well as determining preferred reaction pathways.

In a recent study (1) of acyl derivatives of methine bases such as 2-acetonylidene-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazole, **1**, it was proposed that some bicyclic character existed in the form of a partial hypervalent bond between S and O.

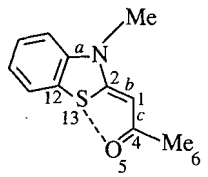
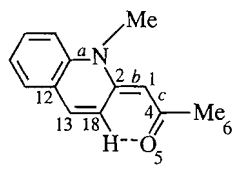
This conclusion was based on the observation that only one of the two possible geometrical isomers could be isolated. In addition, crystal structures showed that the S···O distance was on the order of that expected for "hypervalent" interaction. Theoretical investigations (2, 3) into the possible existence of some type of nonbonded interaction between S and O in smaller molecules with the same structural fragment have drawn the same conclusion. The evidence presented consists of calculated interatomic distances from optimized geometries, energy changes, and Mulliken population analysis. In one paper (3), a bond order was estimated from the exchange part of the second-order density matrix, according to the definition of Mayer. While this evidence is compelling, it seemed reasonable to presume that an analysis of the topological distribution of the charge density could provide further insight into the nature of the interaction. Such an analysis would also be useful for the examination of the changes in energy, molecular structure, and bonding during internal rotation and in a comparison of the *E* and *Z* configurations.

Accordingly, we present here the results of an *ab initio* study of two representative molecules: 2-acetonylidene-2,3-dihydro-3-methylbenzothiazole (**2**) and 2-acetonylidene-1,2-dihydro-1-methylquinoline (**3**).



2 (*Z* configuration)



3 (*E* configuration)

In **2**, the *Z* configuration allows the S···O interaction to occur in the *s-cis* conformation, as shown; in **3**, this interaction is replaced by a possible H···O bond in the *E* configuration. In the calculations and discussion which follow, both the geometries pictured above are referred to as 0° torsion, where rotation occurs about the bond labelled *c* in the figures above. Some of the atoms are numbered for later reference and in accordance with the preceding paper. Optimized geometries were obtained with both the STO-3G and 3-21G* bases for both the 0° and 180° rotamers, and for several points along the path of internal rotation of the acetyl group, between these two extremes. The wavefunctions from the 3-21G* calculations were obtained for each geometry and analyzed with the theory of atoms in molecules (7). This topological analysis of the charge density enables one to examine the charge density between atoms, to determine whether a bond truly exists, and to examine the nature of such bonds. We have also investigated the degree of single/double bond character in the ring bonds during internal rotation and the existence of a ring-like structure. Crystal studies (1, 11) indicate that the molecules are planar; thus for the majority of the analyses, a planar constraint was imposed. Fully unconstrained calculations were performed for the 0°, 90° and 180° conformers and are compared to the constrained planar calculations.

Computational method

The starting geometries for the calculations on **2** were taken from the crystal data for a related molecule (8), in which the N-methyl group is replaced by a cyclohexenyl ring and the acyl methyl by a propyl group. Replacement by methyl groups accelerated the computations and made the topological analysis more tractable, without loss of those aspects which most strongly influenced the geometry about the nonbonded region of interest. No crystal data were available for the quinoline molecule, therefore the starting geometry was adapted from that of the thiazole.

For each molecule, the Gaussian90 molecular orbital program (9) was used to obtain the optimized geometry for the given basis set, with the following constraints. The majority of the calculations were performed with all heavy atoms coplanar, with the exception of the portion undergoing internal rotation. This choice was made because the crystal data on related compounds indicate a stable planar geometry. The internal rotation was modeled by fixing the torsional angle made between the acyl group and the defined heavy atom plane, and allowing all other parameters to relax. In the 1,3,4-thiadiazole cases, crystal data (1, 11) indicated that there might be a slight residual twist of about 1.7° of the acyl group relative to the plane; therefore several points were taken in this region. The twist angle in the benzothiazole case is 1.4° and again several points were taken in this region. The *ab initio* calculations model the gas phase behavior, where the nonplanarity may be more pronounced. Unconstrained geometry optimizations were performed for the 0°, 90°, 120°, and 180° rotamers to compare the barrier estimates and provide an upper limit to the degree of nonplanarity that might be expected.

The wave function from the optimized geometry for each rotamer was obtained with PSIG90 (10) and the topology of the charge density at selected critical points was calculated with SADDLE (10). Both programs are part of the AIMPAC suite (10), used for the analysis of atoms in molecules according to the theory developed by Bader. Bond orders can be estimated from a correlation between parameters at the bond critical points and those for bonds with well-defined bond orders. We therefore obtained these parameters for methane, ethane, ethylene, acetylene, and benzene with the 3-21G* basis for comparison with **2** and **3**.

Results and discussion

Magnitude and shape of the barriers

(a) constrained planar

The change in energy during internal rotation of the acetyl group is illustrated in Figs. 1 and 2 for the thiazole, **2**, and the quinoline, **3**, respectively. When the rest of the molecule is contrained to be planar, the 3-21G* calculated barrier to internal rotation is 75.9 kJ/mol in **2**, and only slightly lower, at 68.7 kJ/mol, in **3**. The barriers to internal rotation calculated with the STO-3G basis were 33.4 and 34.7 kJ/mol, respectively. Underestimation of the barrier is typical of these minimal basis set calculations and the 3-21G* results are to be preferred. The values are in quite good agreement with those estimated from the dielectric absorption method (11).

(b) unconstrained

The barriers drop to 74.5 and 61.8 kJ/mol, respectively, when the planarity constraint is removed. The greatest change in dihedral angle occurs in the vicinity of the N atom, at which a pyrimidal geometry would be anticipated. The dihedral angles between bonds labelled *a* and *b* (above) are:

Fig. 1. Plot of total molecular energy of thiazole **2**, during internal rotation, calculated with 3-21G* basis set.

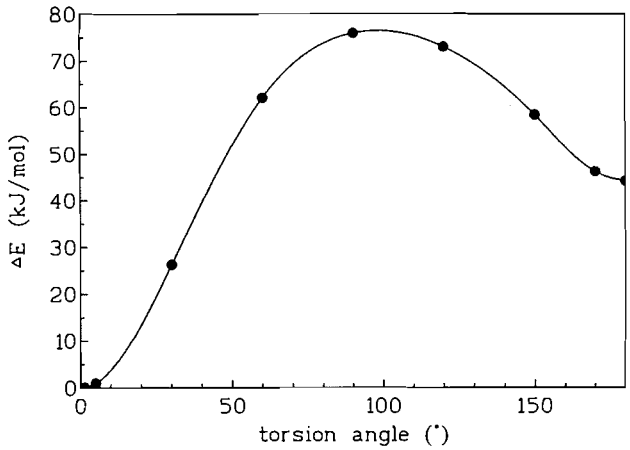


Fig. 2. Plot of total molecular energy of quinoline **3**, during internal rotation, calculated with 3-21G* basis set.

	0°	90°	180°
Thiazole(**2**)	183.9	188.8	186.0
Quinoline(**3**)	191.8	195.6	196.0

The most significant change is that the maximum in the barrier for the quinoline now occurs at 90° instead of at 120° as it appears in Fig. 2. The entire side chain remains more nearly coplanar with the S in the Z configuration (**2**) or the CH in the *E* configuration (**3**). The aromatic ring remains essentially planar throughout. This lack of tendency towards nonplanarity, combined with the crystal data, justifies our decision to examine the planar structures in more detail.

These calculated barriers are both fairly large; however, they are not inconsistent with the data estimated from the dielectric absorption method for similar compounds (11, 12). The latter estimates refer to an enthalpy difference between the 180° and 90° rotamers; however, they should provide a lower limit to the total barrier. For molecule **2**, it is suggested that the considerable height of the barrier is due to the extended conjugation between the acetonyl moiety and the ring. In both molecules, the preferred geometry is the 0° torsion. The barrier to internal rotation is significant, and its origin is of interest.

Table 1. Bond critical point parameters from standard molecules for comparison with **2** and **3**, calculated with 3-21G* basis (bond length in Å, ε and ρ (r_c) in atomic units).

					Bond order	
Molecule	Bond	Bond length	ε	ρ(r_c)	True	Est.
Ethane	C—C	1.5425	0.0	0.2178	1.0	.99
Benzene	C═C	1.3846	0.1435	0.3007	1.6	1.60
Ethene	C═C	1.3149	0.2316	0.3392	2.0	2.01
Ethyne	C≡C	1.1875	0.0	0.4077	3.0	2.88
Methane	C—H					
Ethane	C—H	1.0842	0.0110	0.2607		
Benzene	C—H	1.0721	0.0028	0.2715		
Ethene	C—H	1.0736	0.0076	0.2681		
Ethyne	C—H	1.0506	0.0	0.2777		

Clearly the hypervalent interaction should be of importance, along with loss of extended conjugation. We next use the theory of atoms in molecules to analyze the wavefunctions from the 3-21G* calculations in order to examine these factors in a more quantitative manner.

AIM properties

The theory of atoms in molecules has been presented in detail in the literature (7) and only points essential to the discussion are reviewed here. The principal properties of interest are the charge density, $\rho(\boldsymbol{r})$, the gradient ($\nabla\rho(r)$), the curvature ($\nabla^2\rho(\boldsymbol{r})$), and the ellipticity of the charge distribution (ε) at bond critical points. Within a molecule, maxima in the charge density appear at each nucleus. This density decreases as one moves away from a nucleus, then increases again as another nucleus is approached. The surface of an atom in a molecule is defined by the union of the points about the nucleus at which the charge density reaches a local minimum, that is, by the surface for which there is zero flux in the charge density. For exterior atoms, the outer surface falls away to zero at infinity, but, for practical purposes, it has been defined as the surface for which the charge density falls to 0.001 au.

A bond may be described as a *shared interaction*, where the degree of interaction may range from pure covalent to pure ionic and may include the weakly bonded interactions of interest in this study (7, 13–15). When a covalent bond forms, there is a lowering of the potential energy due to the increase in charge density between the two nuclei. If two atoms are bonded, there will be a line joining the atoms along which the charge density is maximum in the plane orthogonal to the bond path. The charge density along this line will fall to a minimum where the interatomic surface crosses the bond path, at the *bond critical point.* The three values associated with the curvature of the charge density at the bond critical point, $\nabla^2\rho(\boldsymbol{r}_c)$, are referred to as the eigenvalues of the Hessian of ρ at $\boldsymbol{r}_c$, or as λ_1, λ_2, and λ_3. The lone positive value, associated with the curvature along the bond path, is assigned to λ_3. The distribution of the charge density about a bond is frequently found to be non-uniform, as measured by the *ellipticity*, $\varepsilon = [(\lambda_1/\lambda_2) - 1]$. For the 3-21G* basis, the ellipticity varies from 0 in the C—C bond of ethane to 0.23 in ethyne (Table 1). The charge density at the bond critical point has been used to

obtain an estimate of the bond order in a molecule. Both parameters offer a measure of the amount of π character in a bond. A correlation between bond lengths and $\rho(r_c)$ parameters for C—C and S—S bonds has been observed in a number of studies (16). Such points exist even for very weakly interacting atoms, such as those joined by a hydrogen bond. Finally, when a molecule contains a ring, a *ring critical point* is found to exist in the charge density. At such a point, two of the three eigenvalues of the Hessian are positive and the plane of the ring represents a maximum in the charge density for any line or plane cutting through it.

Origin of the barrier

(a) Hypervalent/H-bond interactions

The structural and topological changes in the charge density accompanying rotation are listed in Tables 2–5. The parameters of interest are the bond lengths, the charge density and ellipticity at the bond critical points or ring critical points, and the estimated bond order. Tables 2 and 3 provide details of the changing interaction between the nonbonded atoms (S···O in **2** and H···O in **3**) during internal rotation. Tables 4 and 5 highlight the extended conjugation between the side chain and the ring atoms.

According to studies on weak atomic interactions (14, 15), the type of bonding found here between the S···O and H···O would be classified as a closed-shell interaction (Tables 2 and 3). The value of ρ_c is typically an order of magnitude smaller than that for a covalent bond. The curvature of the charge is still positive along the bond path, and negative in directions orthogonal to the path; however, $|\lambda_3| > |\lambda_2| \approx |\lambda_1|$. In both molecules, the bond is fairly strong, comparable to that of the hydrogen bond in the water dimer, as opposed to that found in weak van der Waals complexes between Ne or Ar and HF (7). In previous studies of closed shell interactions, the relative depletion of charge between the two atoms resulted in only a slight lowering of the potential energy and a correspondingly weak bond. The atoms were typically found to have opposite net charges and the stability of the arrangement was based mainly on the ionic-like attraction. In the present system, it appears that the interaction may also be mainly ionic, as in that of a typical hydrogen bond. The structures **2** and **3** are both too large to be analyzed fully with the AIMPAC suite. A much more detailed study of the Laplacian of the charge density, possibly on a smaller model compound, would be required if one wished to investigate the location of valence shell charge concentrations, which are the quantum mechanical counterpart of the lone pairs in VSEPR theory, and thereby ascertain the role of the sulfur *d* orbitals. The admittedly crude estimates provided by a Mulliken population analysis give charges of −0.63 (oxygen), +0.57 (sulfur) in **2** and −0.63 (oxygen), +0.34 (hydrogen) in **3**.

In both **2** and **3**, the formation of the closed-shell interaction is accompanied by the apearance of ring critical points that exhibit characteristics analogous to those of the weak bond critical points. During internal rotation, the closed-shell interaction breaks somewhere between the 30° and 60° postions. Interestingly, the weak ring critical point reforms when the methyl group is rotated to within 30° of the S or H, i.e., the 150° position, and continues on to the 180° position. The energy lowering associated with such a point is small but, since the geometry stabilization investigated here is a combination of weak factors, it is worth noting.

(b) Extended conjugation

The charge density (ρ_c) at the bond critical points of standard molecules has been obtained for this basis set (Table 1) in order to allow a bond order to be calculated from the expression (13):

$$[1] \quad n = \exp\{A(\rho - B)\}$$

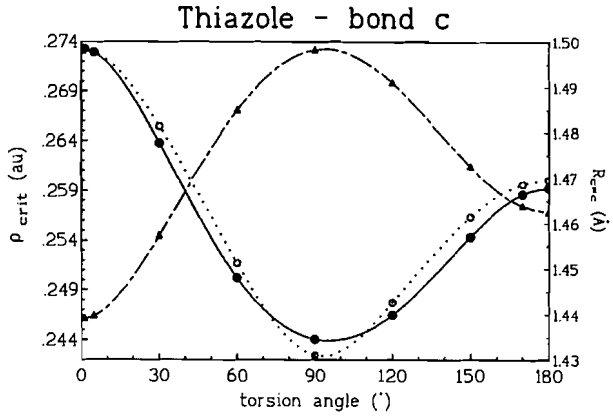
Fig. 3. Changes in charge density (ρ: –●–), bond length ($R_{C=C}$: --▲--), and bond ellipticity (ε: ···○···) for bonds labelled *b* and *c* in the structure of thiazole **2**. Values for ρ appear on the left axis; for $R_{C=C}$ on the right axis. Values for ellipticity range from a maximum of 0.317 au to a minimum of 0.268 au for bond *b* and 0.138 au to 0.041 au for bond *c*.



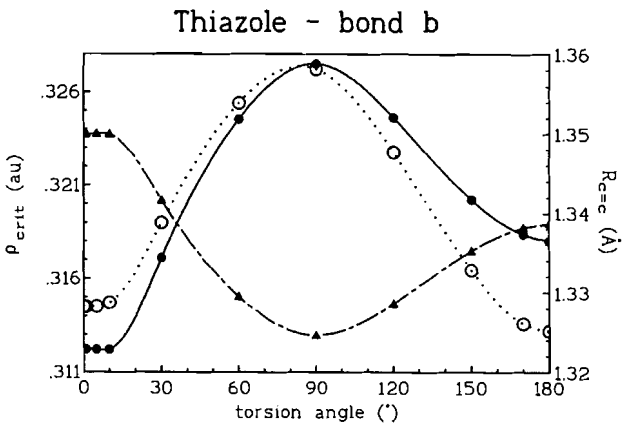


Fig. 4. Changes in charge density (ρ: –●–), bond length ($R_{C=O}$: --▲--) and bond ellipticity (ε: ···○···) for the carbonyl bonds in thiazole **2** and quinoline **3**. Values for ρ appear on the left axis; for $R_{C=O}$ on the right axis. Values for ellipticity range from a maximum of 0.053 au to a minimum of 0.021 au in the thiazole and 0.052 au to 0.024 au in the quinoline.

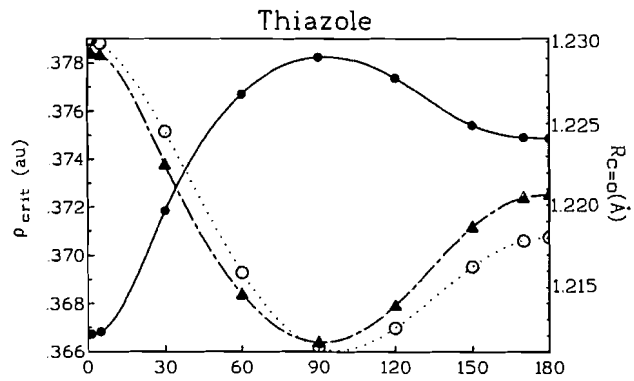

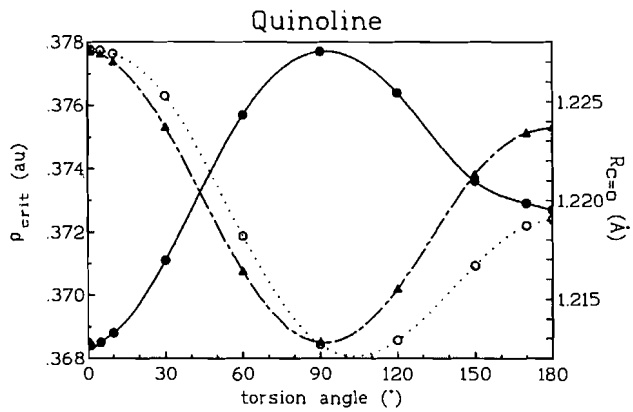

For the present study, the values of the fitted parameters are $A = 5.83$ and $B = 0.220$. The estimated bond orders for **2** and **3** are included in Tables 4 and 5. The 0° and 180° planar structures of both molecules exhibit a strong conjugative interaction. The bonds depicted as double decrease in length while the charge density about the bond becomes more elliptical, as the acyl group is rotated up out of the plane. At the same time, those designated as single become longer, and the charge density less elliptical. Typical behavior is illustrated in Fig. 3 for the bonds labelled *b* and *c* in the thiazole. As the rotation proceeds, the bond *b*, which is depicted as double, becomes shorter. The ellipticity increases, indicating an increase in the π character of the bond. The charge density at the bond critical point also increases, corresponding to the increased strength of the bond. The behavior of these properties is exactly the opposite for the bond labelled *c*, which becomes longer and weaker, while the ellipticity decreases. This nicely illustrates the loss of conjugation that occurs during the rotation. The instability of the system rises steadily as the rotation proceeds and continues to increase even after the closed-shell interaction disappears (>30°). The only obvious cause of instability is the continuing decrease in extended conjugation. The ellipticity at the bond critical point is another measure of the degree of π character in a bond. Comparison of the ellipticities of the standard bonds in Table 1 with those in Tables 4 and 5 show that the extended π bonding and the changes that occur during internal rotation are also manifested in this parameter. These data serve to further illustrate the changes in conjugation that occur during the internal rotation. A similar situation is observed for the internal rotation in the quinoline. If one assumes that the asymmetry in the barrier to internal rotation arises solely from the closed-shell interaction in the *s-cis* conformations, and that extended conjugation contributes the same amount of stability to the molecules in either the *E* or *Z* configuration, then the energy plots in Figs. 1 and 2 indicate that the closed-shell interaction is the more important, providing 45–50 kJ/mol stabilization, while the extended conjugation provides an additional 20–30 kJ/mol.

The behavior of the carbonyl bond during internal rotation is illustrated in Fig. 4, for both molecules. We note that the bond is shortest when the rotation angle is 90° and the conjugation is minimized. The bond is also less elliptical, in contrast to the C=C bond, *b*. We interpret this as indicative of the true

nature of a nonconjugated carbonyl double bond, in which the "lone pair" electrons on the oxygen actually are sharing in the bonding and the bond is more cylindrical. When the conjugation is at a maximum (0°or 180°), the increased ellipticity reflects the preference for the formation of a distinct π bond that can interact with the π bonds elsewhere along the chain. For both the C=O and C=C bonds, the conjugation results in a longer, weaker bond.

The terminal aromatic ring is altered only marginally during internal rotation, even in the 90° rotamer, and does not appear to contribute to the preference of one isomer over another. Even in the structures for which the aromatic ring is constrained to be coplanar with the hetero ring and side chain, there is almost no interaction between the two portions. However, since its presence presumably adds to the rigidity of the hetero ring, it is considered to be an essential part of the system. The bond lengths (**2**: 1.3836±0.004 and **3**: 1.388±0.009 Å) are quite similar to those in benzene. Bond orders estimated frm ρ_c and eq. [1] also indicate that the ring is essentially aromatic. This does not change during internal rotation of the acyl group.

It is interesting to compare our results with recent studies on the nature of the hydrogen bond (17, 18), which have produced the concept of the resonance-assisted hydrogen bond (rahb) in cases of homonuclear hydrogen bond formation. The latter applies to bonds of the type (O···H—O), where the oxygen atoms are part of a π conjugated fragment, such as in the enol form of a β-diketone. The authors note that extensive correlation of crystallographic data supports the notion that homonuclear hydrogen bonds are inherently different from hetero hydrogen bonds. The two cases studied in the present work fall into the latter class yet, because of their molecular structure, extended conjugation and hydrogen bonding are found to be working together to produce the most stable conformer.

From the present study, the observed stability of the 0° rotamer in **2** and **3** appears to arise from a combination of factors:

(*a*) there is a strong nonbonded interaction between the S···O and the H···O, as evidenced by the existence of a bond critical point between these atom pairs, which provides 45–50 kJ/mol stabilization energy;

(*b*) the nonbonded interaction creates a weak ring-like structure, with a ring critical point shared by the ring atoms, disappearing for a torsion >30°;

(*c*) extended conjugation contributes a further 20–30 kJ/mol to the stability of the planar configurations;

(*d*) the tendency for the molecule to pucker in the vicinity of the N atom is counterbalanced by the extended conjugation for the 0° rotamer;

(*e*) while the adjacent aromatic ring may be imparting an increased rigidity to the system, it does not participate in the electronic changes that occur during rotation.

In related experiments on a similar molecule (11), the barrier height between the 90° and 180° regions (Figs. 1 and 2) has been estimated by measuring relaxation times after promotion to the less stable configuration. This lower barrier provides an estimate of the hyperconjugation energy, and is similar to that calculated here. Finally, we note the usefulness of *ab initio* calculations in the elucidation of this problem. In particular, the charge density at the bond critical point and the bond ellipticity, obtained in the analysis of the wavefunction, should be considered in similar situations.

Ionic conductivity in the water-rich region of aqueous 2-butoxyethanol

Yoshikata Koga, Virginia J. Loo, and Kataryna T. Puhacz

Abstract: Ionic conductivities of HCl, KOH, and KCl were measured in aqueous solutions of 2-butoxyethanol (BE) at 25°C. The quantity, $\Lambda_j' = \sigma/x_j$, which is almost proportional to the molar conductivity, was extrapolated to the infinite dilution $x_j \rightarrow 0$. σ is the conductivity and x_j is the mole fraction of j(= HCl, KOH, or KCl). The plots of ${}^0\Lambda_j'$, the value of Λ_j' extrapolated to infinite dilution, against x_{BE} showed a change in slope at x_{BE} = 0.0175. The previous work from this laboratory indicated that the mixing scheme changes qualitatively at the same locus, x_{BE} = 0.0175. By mixing scheme we simply mean the way in which BE and H_2O molecules mix with each other. Assuming additivity in ${}^0\Lambda_j'$ in terms of constituent ions, those values for H^+OH^- were calculated. Plots of ${}^0\Lambda_{H^+OH^-}'$ thus calculated as a function of x_{BE} in the water-rich region, $0 < x_{BE} < 0.0175$, suggest that the hydrogen bond probability decreases in the bulk of solution, as x_{BE} increases.

Key words: aqueous 2-butoxyethanol, ionic conductivities, mixing schemes, hydrogen bond network.

Résumé : On a mesuré les conductivités ioniques du HCl, du KOH et du KCl dans des solutions aqueuses de 2-butoxyéthanol (BE) à 25°C. On a extrapolé, à dilution infinie $x_j \rightarrow 0$, la quantité $\Lambda_j' = \sigma/x_j$, qui est presque proportionnelle à la conductivité molaire. σ représente la conductivité et x_j représente la fraction molaire de j(= HCl, KOH ou KCl). Les courbes de ${}^0\Lambda_j'$, la valeur extrapolée de Λ_j' à dilution infinie, en fonction de x_{BE} montrent un changement de pente à x_{BE} = 0,0175. Les travaux antérieurs réalisés dans ce laboratoire indiquent que les schémas de mélange changent qualitativement au même point, x_{BE} = 0.0175. Par schéma de mélange nous entendons simplement la manière dont les molécules de BE et d'eau se mélangent les unes aux autres. En admettant l'additivité dans ${}^0\Lambda_j'$, en termes d'ions constitutifs, on a calculé l'additivité des ions H^+OH^-. Les courbes de ${}^0\Lambda_{H^+OH^-}'$ ainsi calculées en fonction de x_{BE} dans la région riche en eau $0 < x_{BE} < 0{,}0175$, suggèrent que la liaison hydrogène décroit probablement dans la masse de la solution lorsque x_{BE} augmente.

Mots clés : 2-butoxyéthanol aqueux, conductivités ioniques, schémas de mélange, réseau de la liaison hydrogène.

Introduction

The mobilities of H^+ and OH^- in ice are higher by an order of magnitude than those in liquid H_2O, which are in turn considerably higher than those of other univalent ions in aqueous solutions. This is explained by the mechanism whereby H^+ and its hole (OH^-) hop cooperatively along two potential minima between two oxygen atoms in the hydrogen bond network of H_2O (1, 2). The hopping may be understood to occur as quantum mechanical tunneling (2), or via the "coherent dissipative structure." A quantum mechanical correlation exists between H^+ and H's of the surrounding H_2O molecules (3, 4). This causes H^+ or its hole (OH^-) to delocalize along the hydrogen bond network of H_2O.

The hydrogen bond network is complete in ice, while a portion of the hydrogen bonds are broken in liquid H_2O. It has been pointed out (5), however, that at moderate temperatures the hydrogen bond network of liquid H_2O is "percolated." If the diamond structure is topologically correct in liquid H_2O in terms of hydrogen bond connectivity, the bond percolation threshold will be 0.39 of the probability of intact hydrogen bonds (6). An estimate (5) indicates that hydrogen bond probability decreases as temperature increases and reaches 0.39 at about 80°C. Below this temperature, the hydrogen bond network is connected throughout the entire bulk, i.e., percolated. The high H^+ conduction in liquid water must be realized through the percolated hydrogen bond network. Thus the conductivities of H^+ or OH^- may serve as an indicator of whether or not the hydrogen bond network exists, or whether the hydrogen bond probability increases or decreases in aqueous solutions of non-electrolytes.

We have made extensive thermodynamic studies on aqueous 2-butoxyethanol (BE) (7–18). It became evident that the mixing scheme changes qualitatively at x_{BE} = 0.0175 at 25°C, as the mole fraction of BE, x_{BE}, increases. In region I, $0 < x_{BE} < 0.0175$, the partial molar enthalpy (15, 17, 18), entropy (16), and volume (12, 13) data indicate that the hydrogen bond network of H_2O is progressively enhanced as x_{BE} increases. At x_{BE} = 0.0175, however, the solution can no longer accommo-

date an additional BE in the same manner, and a different mixing scheme sets in. In region II, $0.0175 < x_{BE} < 0.5$, the solution consists of two kinds of clusters, rich in BE and in H_2O, respectively. These clusters are precursory to the phase separation with LCST at $x_{BE} = 0.06$ and 49.4°C (19), or to the nucleation of a solid solution below −3.7°C (8). That is, under appropriate conditions, they grow to macroscopic droplets or solid nuclei. At $x_{BE} \approx 0.06$, for example, when the temperature increases from below towards 49.4°C, the intensity of light scattering increases sharply (19, 20). When the temperature is lowered towards −3.7°C, the forward X-ray scattering intensity increases dramatically (7).

The purpose of the present work is to determine ionic conductivities of HCl, KOH, and KCl at infinite dilution in aqueous solutions of BE. Firstly, we wish to examine whether ionic conductivity behaves differently in regions I and II. Secondly, the conductivities of H^+ and OH^- calculated from those of the above three electrolytes may provide information about the effect of BE on the hydrogen bond network of H_2O. We note that the presence of an electrolyte dopant may affect the nature of BE–H_2O mixtures even at infinite dilution. It turns out, however, that the conductivities at infinite dilution show different behaviour in regions I and II, as shown below. A dopant apparently did not alter the existence of the two mixing schemes in BE–H_2O, at least at infinite dilution. Therefore, we tentatively assume that the mixing schemes in the binary BE–H_2O system remain the same in the ternary system (HCl, KOH, or KCl)–BE–H_2O, at infinite dilution.

Experimental

2-Butoxyethanol from Aldrich (99+%, spectroscopic grade) was used without further purification. H_2O was freshly distilled before use. A 0.1 M standard NaOH from Fisher Scientific was used to determine the concentration of a 1 M stock solution of HCl, and in turn that of KOH. KCl from Fisher Scientific (Certified ACS) was dried at 150°C overnight.

Ionic conductivities, σ, were determined by an AC bridge (YSI-35) at 60 Hz. A cell (YSI-3403) with blackened platinum electrodes was used. The nominal cell constant, k, was 1 cm^{-1}. The conductivity of the sample, σ, is calculated as

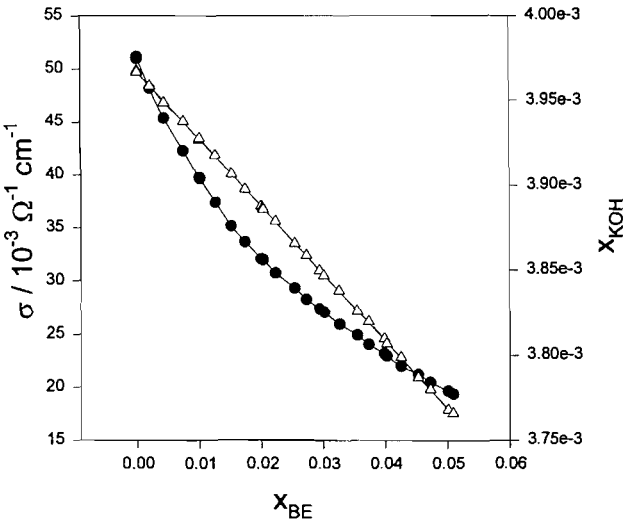
$$[1] \quad \sigma = k/R$$

where R is the resistance measured by the bridge. The cell constant, k, was calibrated using the literature value of the molar conductivity of aqueous KCl at infinite dilution (21).

Aqueous solutions containing BE in the range $0 < x_{BE} < 0.04$ and the ionic dopants (HCl, KOH, or KCl) in the range $0.0005 < x_j < 0.09$, or $0.01 < C_j < 0.5$ M (j = HCl, KOH, or KCl), were prepared by weighing. Since the three-component system (HCl, KOH, KCl)–BE–H_2O, is expected to show complicated volumetric behaviour and such data are not available, we mostly use mole fractions as concentration variables. Thus, instead of molar conductivity, $\Lambda_j = 1000\,\sigma/C_j$, we use the quotient, $\Lambda_j' = \sigma/x_j$, as the quantity almost proportional to Λ_j, particularly so at the infinite dilution.

The temperature of the bath in which conductivity measurements were made was controlled within ±0.05°C. The temperature for the KCl–BE–H_2O series was 25.0°C, while that for HCl–BE–H_2O was 24.5°C and for KOH–BE–H_2O 24.6°C.

Fig. 1. Plots of measured values of σ and x_{KOH} in KOH–BE–H_2O against x_{BE}: ●, σ; △, x_{KOH}.



Small temperature corrections were made to the data at infinite dilution for the latter two series, using the temperature dependence for aqueous HCl and KOH (21).

Results and discussion

For pure H_2O ($x_{BE} = 0$), the molar conductivity, Λ_j, changed linearly with $\sqrt{C_j}$, as expected (21). Extrapolation to $C_j = 0$ was made to obtain Λ°_{KCl}, the value used to calibrate the cell constant (k = 1.023 cm^{-1}). The values of Λ°_{HCl} and Λ°_{KOH} were corrected for the respective temperature variation, using literature values of the temperature coefficients (21). The resulting values of Λ°_{HCl} and Λ°_{KOH} agree within 0.1% with those in ref. 21, as shown in the last two columns of Table 1. Figure 1 shows the plots of σ and x_{KOH} against x_{BE} for a series of KOH–BE–H_2O solutions starting with 0.220 M KOH solution. Small amounts of BE were added successively by weighing. Similar graphs for each starting value of C_{KOH} were obtained. From each graph, the values of σ and x_{KOH} were read off a smooth curve at fixed values of x_{BE}. For a given fixed value of x_{BE}, values of $\Lambda'_{KOH} = \sigma/x_{KOH}$ were plotted against $\sqrt{x_{KOH}}$. Extrapolation was then made to infinite dilution, $x_{KOH} \rightarrow 0$ to obtain ${}^0\Lambda'_{KOH}$ as a function of x_{BE}. The results of ${}^0\Lambda'_j$ (j = HCl, KOH, or KCl) thus obtained are listed in Table 2, after temperature corrections, assuming that the temperature coefficients are the same as that at $x_{BE} = 0$. They are plotted in Fig. 2. The uncertainty in ${}^0\Lambda'_j$ is estimated to be ±0.2 Ω^{-1} cm^{-1}, about the size of symbols in the figure. Assuming additivity in ${}^0\Lambda'_j$, the values of ${}^0\Lambda'_{H^+OH^-}$ were calculated as

$$[2] \quad {}^0\Lambda'_{H^+OH^-} = {}^0\Lambda'_{HCl} + {}^0\Lambda'_{KOH} - {}^0\Lambda'_{KCl}$$

and are listed in Table 2 and plotted in Fig. 2.

As is evident from the figure, the dependence of ${}^0\Lambda'_j$ on x_{BE} shows different behaviour in regions I and II. This suggests that the mechanisms of ionic conduction are different in each region due, no doubt, to differences in the mixing scheme. Thus, the presence of dopant ions at infinite dilution evidently

did not alter the existence of different mixing schemes I and II. This may in turn provide some assurance that the behaviour of the ionic conductivity at infinite dilution may properly reflect the hydrogen bonding nature of each mixing scheme.

Another feature to be noted in Fig. 2 is that ${}^0\Lambda'_{H^+OH^-}$ decreases sharply as x_{BE} increases. This suggests that the hydrogen bond probability actually *decreases*, as x_{BE} increases, if the ionic conduction of H^+ and OH^- occurs via the hydrogen bond network. In our earlier work, the dependence of the excess partial molar enthalpy (15, 17, 18), entropy (16), and volume (12, 13) on x_{BE} suggested the enhancement of the hydrogen bond network of H_2O in the vicinity of solute BE. It was therefore hinted that, as x_{BE} increases, the hydrogen bond probability increases progressively to the boundary at x_{BE} = 0.0175 at 25°C, at which the hydrogen bond network was thought to be complete. According to Fig. 2, therefore, this view is not correct. Rather, the hydrogen bond probability actually decreases, at least locally, as x_{BE} increases.

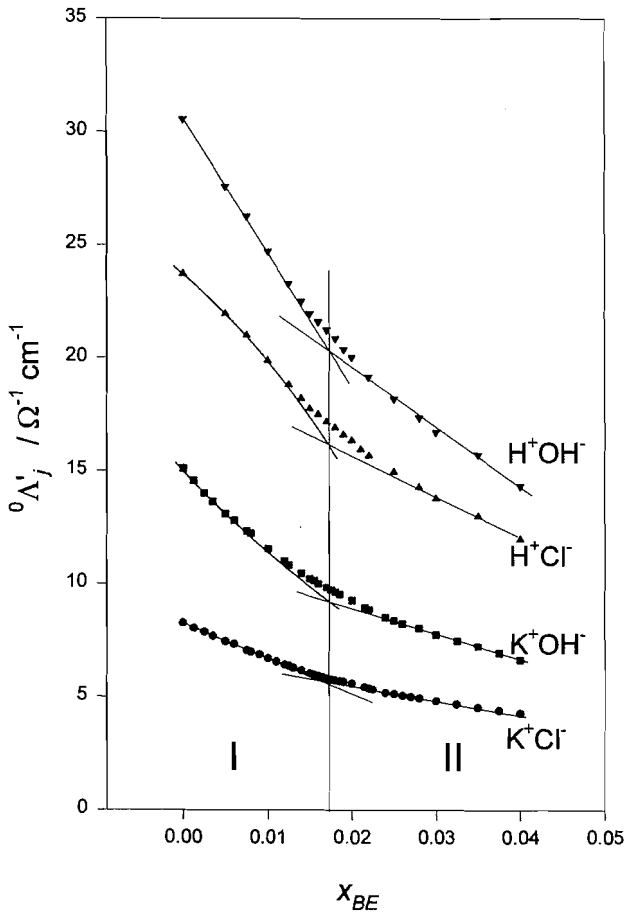
Fig. 2. Plots of ${}^0\Lambda_j$ against x_{BE}, for j = HCl, KOH, KCl, and H^+OH^-.



We tentatively suggest that the hydrogen bonds become stronger in the vicinity of solute BE, while the hydrogen bond probability of bulk H_2O away from BE is reduced. Noteworthy in this connection is the recent suggestion based on the results of high-resolution inelastic neutron scattering that there are two kinds of hydrogen bond with the strength ratio of 2:1 in ice Ih (22). If such possibility also exists in liquid water, the hydrogen bonds are strengthened in the vicinity of BE, which in turn weakens those of bulk water away from BE. In this view, as x_{BE} increases, the hydrogen bond probability away from BE gradually decreases to the percolation threshold, 0.39, whereupon the percolation is broken and the system consists of two kinds of regions, rich in either BE or H_2O, precursory to phase separation at higher temperatures.

A close inspection of the boundary separating mixing schemes I and II also gives some support to the latter revised view. The boundary starts at about 85°C at $x_{BE} = 0$ and ends at the incongruent melting point of an addition compound (x_{BE} = 0.0260) (8). That is, the boundary slants towards lower values of x_{BE} as the temperature increases. If the hydrogen bond were to be brought to completion at the boundary, then the boundary should slant to higher values of x_{BE} as the temperature increases, since at higher temperatures the hydrogen bond probability is lower in pure H_2O, and hence more BE molecules are needed to bring the hydrogen bond probability to unity. If, on the other hand, the hydrogen bond probability is reduced to the percolation threshold, 0.39, at the boundary, fewer BE molecules would be sufficient to bring it down to 0.39 at higher temperatures, consistent with the observed manner in which the boundary slants. Furthermore, the boundary connects smoothly to the percolation threshold of pure H_2O about 85°C.

Clearly, more spectroscopic work, inelastic neutron scattering, in particular, is needed to further elucidate the nature of this transition in the mixing scheme.
