The biosynthesis of antibiotic F-244 in *Fusarium* sp. ATCC 20788: origin of the carbon, hydrogen, and oxygen atoms

Endang Saepudin and Paul Harrison

Abstract: Biosynthetic incorporation experiments were performed with carbon-13 labelled precursors including sodium [1-^{13}C]-, [2-^{13}C], and [1,2-$^{13}C_2$]-acetate as well as [*methyl*-^{13}C]methionine into antibiotic F-244 (**1**) in growing cultures of *Fusarium* sp. ATCC 20788. After conversion to the methyl ester **2**, analysis by NMR showed that the carbon skeleton of **1** derives from seven intact acetate units; the remaining four carbons are from methionine. Hence, the pathway is similar to that reported for **1** in *Scopulariopsis*. The biogenesis of the hydrogen atoms in **1** was also investigated. Incorporation of sodium [1-^{13}C,$^{18}O_2$]acetate gives **2**, which exhibits ^{18}O-induced isotope shifts at C-1 and C-3. The labelling pattern is consistent with formation of the β-lactone ring by nucleophilic attack of a C-3 hydroxyl group in the nascent polyketide precursor onto the C-1 carbonyl.

Key words: biosynthesis, polyketide, F-244, β-lactone, *Fusarium*.

Résumé : On a effectué des expériences d'incorporation biosynthétiques de précurseurs marqués au carbone-13, y compris des [1^{13}C]-, [2-^{13}C]- et [1,2-$^{13}C_2$]-acétates de sodium ainsi que de la [*méthyl*-^{13}C]méthionine, dans l'antibiotique F-244 (**1**) en effectuant des cultures du *Fusarium* sp. ATCC 20788. Après sa conversion en ester méthylique **2**, un analyse par RMN montre que le squelette carboné du produit **1** dérive de sept unités acétates intactes; les quatre autres unités proviennent de la méthionine. Le chemin réactionnel est donc semblable à celui rapporté pour la synthèse de **1** dans le *Scopulariopsis*. On a aussi examiné la biogenèse des atomes d'hydrogène du composé **1**. L'incorporation du [1-^{13}C, $^{18}O_2$]acétate de sodium fournit du composé **2** qui présente des déplacements isotopiques induits par le ^{18}O pour les C-1 et C-3. Le patron de marquage est en accord avec la formation d'un cycle β-lactone par une attaque nucléophile du groupe hydroxyle en C-3 du précurseur polycétide naissant sur le groupe carbonyle en C-1.

Mots clés : biosynthèse, polycétide, F-244, β-lactone, *Fusarium*.

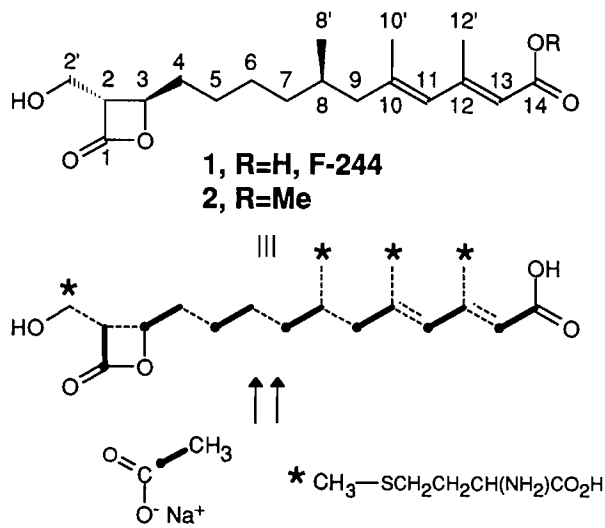
[Traduit par la rédaction]

Introduction

The β-lactone antibiotic **1** (Fig. 1) was first obtained from *Cephalosporium* sp. ACC 1233 as 1233A (1), and later from *Fusarium* species as L-659,699 (2) and from *Scopulariopsis* species as F-244 (2*a*, 3). Interest in this compound stems from its potent inhibitory effect on the growth of microorganisms (3*a*) as well as plants (4); both in vitro (2, 3*b*, 5) and in vivo (2*b*, 3*b*, 5*b*, 6) experiments have shown the compound to be a specific and potent inhibitor of 3-hydroxy-3-methylglutaryl-CoA synthase. A variety of analogues have been investigated (7), and several elegant syntheses have been reported (8).

Recently, Omura and co-workers investigated the biosynthesis of 1233A in *Scopulariopsis* sp. F-244 (9). The results of incorporation experiments with sodium [1-^{13}C]-, [2-^{13}C]-, and [1,2-$^{13}C_2$]-acetate as well as [*methyl*-^{13}C]methionine showed

Fig. 1. Structure (1) and biosynthetic labelling pattern (9) for F-244 (**1**).



that **1** is a typical heptaketide derived from "head-to-tail" coupling of seven acetate units; the remaining four carbons were efficiently labelled by methionine (Fig. 1). Our interest in

polyketide biosynthesis (10) has prompted a study of the biosynthesis of F-244 in *Fusarium* species. Herein we report that there is a similar biosynthetic origin for the carbon atoms of **1** in both microorganisms. Further, we describe the results of labelling experiments designed to elucidate the origin of the hydrogen and oxygen atoms of F-244.

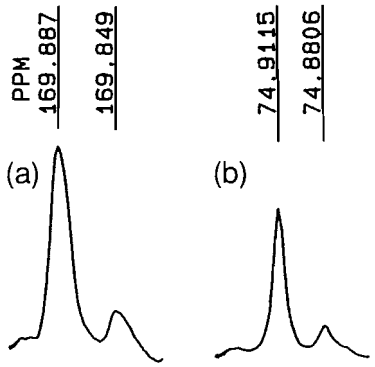
Results

Fusarium sp. ATCC 20788 was grown in a liquid culture medium that was a modification of that reported in the patent literature (11). Extraction and chromatography gave crude F-244, which was treated with diazomethane and further purified to give methyl ester **2** (1*b*). Extensive multidimensional NMR analysis of **2** afforded unambiguous assignments for all of the carbon atoms (Table 1). The results show that the chemical shifts for the carbon-13 resonances in **2** match closely the shifts in **1** that were reported by Omura and co-workers (9), as well as the results of Mori and co-workers (12), with the exception of the expected difference in chemical shift of C-14 due to methylation.

Addition of sodium [1-^{13}C]acetate (**3***a*) to the growing *Fusarium* cultures under the literature conditions (11) gave **2** with very low incorporations. After some experimentation, it was found that reduction of the corn content of the medium enabled incorporations of ca. 5% to be obtained, without diminishing the yield of F-244. The extent of labelling at each position was determined by comparing peak heights for the labelled and unlabelled **2**, after each peak height was standardized relative to the height of the signal from the ester methyl group. For **3***a*, label was only observed at C-1, C-3, C-5, C-7, C-9, C-11, and C-13, while sodium [2-^{13}C]acetate (**3***b*) gave **2**, which was labelled at the complementary positions C-2, C-4, C-6, C-8, C-10, C-12, and C-14 (Table 1). Incorporation of sodium [1,2-$^{13}C_2$]acetate (**3***c*) gave **2**, which exhibited all of the expected one-bond $^{13}C–^{13}C$ couplings, while addition of L-[*methyl*-^{13}C]methionine (**4***a*) to the cultures gave large incorporations at the remaining four carbon atoms, C-2′, C-8′, C-10′, and C-12′.

Incorporation experiments using sodium [1-^{13}C,$^{2}H_3$]acetate (**3***d*) gave **2** that was enriched with carbon-13 at each of the sites that had been labelled by **3***a*; however, none of the signals exhibited a β-deuterium isotope shift (10; for a detailed discussion of these aspects, see ref. 13), nor was any deuterium detected by ^{2}H NMR. In contrast, addition of [*methyl*-^{13}C,$^{2}H_3$]methionine (**4***b*) to the cultures gave F-244, the deuterium NMR spectrum of which exhibited three doublets corresponding in chemical shift to the three methyl groups of F-

Fig. 2. Expansions of signals due to (a) C-1; and (b) C-3 in the carbon-13 NMR spectrum of **2** derived from incorporation of sodium [1-^{13}C,$^{18}O_2$]acetate; the isotopically shifted signals are apparent.



244, as well as signals at shifts equivalent to those for the two diastereotopic protons, H-2′α and H-2′β.

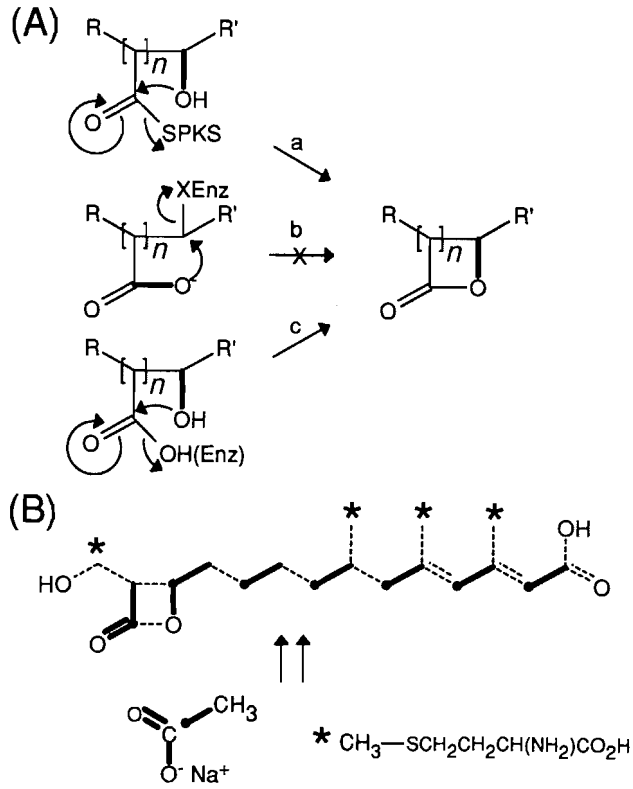
Addition of sodium [1-^{13}C,$^{18}O_2$]acetate (**3***e*) to cultures of the *Fusarium* species gave **2**; the ^{13}C NMR spectrum exhibited enrichments at all of the positions derived from C-1 of acetate. High-resolution carbon-13 NMR showed that, although some molecules of the sample were enriched at C-1 and C-3 with carbon-13 that did not carry ^{18}O substitution, other molecules exhibited isotopically shifted signals (10, 13, 14) induced by the presence of oxygen-18 at both these sites (Fig. 2). At C-1, a single isotopically shifted signal was observed; the magnitude of the shift (Δδ 0.037 ppm) is consistent with that expected for a C=O double bond (i.e., ^{18}O=^{13}C-^{16}O) (15). There was no apparent signal due to the presence of carbon-13 at C-1 attached to either oxygen-18 within the ring (i.e., ^{16}O=^{13}C-^{18}O), or to two oxygen-18 atoms (i.e., ^{18}O=^{13}C-^{18}O). At C-3, a single isotopically shifted signal was observed (Δδ 0.031 ppm). No detectable induced isotope shift was observed at either C-14 or C-2′.

Discussion

Our investigation of F-244 biosynthesis in *Fusarium* sp. ATCC 20788 first required that the origin of the carbon atoms be firmly established, since the results of Omura's study in *Scopulariopsis* (9) cannot be taken *de facto* to apply to the current organism. The results from the carbon-13 labelled acetates **3***a–c* clearly establish that F-244 is derived in *Fusarium* sp ATCC 20788 from "head-to-tail" coupling of seven intact acetate units in a sequence typical of the polyketide secondary metabolites (Fig. 1). Further, the arrangement of units is identical to that observed in *Scopulariopsis*, indicating strong similarities in the biosynthesis of **1** in the two organisms. The carbons of the methyl groups of F-244, as well as C-2′, derive from methionine in both organisms, rather than through incorporation of propionate into the growing polyketide chain. These results enable prediction of the di- and oligo-ketides that are expected to be nascent intermediates in the growth of the carbon chain on the polyketide synthase. Incorporation experiments with advanced intermediates corresponding to the growing chain are currently in progress.

With the biogenesis of the carbon atoms established, the biosynthetic origin of the hydrogen atoms of F-244 was next investigated. The fact that incorporation of carbon-13, but not deuterium, was observed when sodium [1-^{13}C,$^{2}H_3$]acetate (**3***d*)

Fig. 3. Possible mechanisms for in vivo lactone formation.



was administered to the cells strongly suggests that "washout" of deuterium occurred during the biosynthetic process, as is common in polyketide biosynthetic studies (13). Deuterium was retained from methionine, however, as expected; all of the deuterium at each site was coupled to carbon-13, demonstrating intact incorporation of the ^{13}C—^{2}H bonds. This observation is consistent with Omura's (9) description of incorporation of tritium from L-[^{3}H]methionine into F-244.

We next embarked on experiments to determine the biosynthetic source of the oxygen atoms of **1**, using the oxygen-18 induced isotope shift method developed by Vederas and Nakashima (13, 14), in order to address questions about the mechanism of formation of the β-lactone moiety. Although this technique has been used, inter alia, to demonstrate that a variety of five-membered or larger lactone rings are formed with retention of the alkyl carbon–oxygen bond (10, 13) (Fig. 3*A*, pathways a or c but not b), there are no reported applications to the biosynthesis of β-lactones. Due to the ring strain inherent in the latter, it was unclear whether ring formation could occur on the polyketide synthase (path a), or whether a separate enzyme was required to effect the lactonization in F-244.

The results of incorporation of **3***e* show partial exchange of oxygen-16 for oxygen-18 at C-1 and C-3 of F-244 during the biosynthesis, a process that is not uncommon in polyketide biosynthesis (13). However, the observation of a small but significant isotopically shifted signal at C-3 indicates that the C-3—O single bond remains intact throughout the biosynthetic process from acetate (Fig. 3*b*). The magnitude of the shift (0.031 ppm) is large compared to many C—O single bonds (15), perhaps as a result of the ring strain inherent in the β-lactone moiety. Similarly, the C-1=O double bond is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

derived intact from acetate. Failure to observe isotope shifts at C-14 or C-2′ is consistent with the oxygen atoms at these sites being derived from oxygen gas in a late-stage oxidation, as would be predicted (10).

The results are consistent with formation of the β-lactone ring by attack of the hydroxyl group at C-3 of the nascent polyketide onto C-1 (Fig. 3*a*, path a or c), but not with nucleophilic attack by a C-1 carboxylate onto C-3 (path b). Perhaps the most likely pathway (a) involves the formation of the β-lactone ring by direct displacement of the acyl intermediate while still attached to the polyketide synthase (PKS), thereby releasing the cyclized product. In contrast to paths b and c, path a does not require a unique β-lactone cyclizing enzyme.

Conclusion

The biosynthesis of F-244 in *Fusarium* sp. ATCC 20788 proceeds by the normal polyketide pathway, with seven acetate units condensing in a "head-to-tail" fashion. A labelling experiment with sodium [1-^{13}C,$^{18}O_2$]acetate shows that the β-lactone ring is formed with retention of the C-3—O bond, suggesting nucleophilic attack of a hydroxyl group at C-3 of the putative precursor, probably still attached to the polyketide synthase, onto an activated carboxylic acid derivative at C-1. Further aspects of the biosynthetic pathway to **1** will be described in due course.

Experimental

General

Fusarium sp. ATCC 20788 was obtained from American Type Culture Collection. Corn meal and tomato paste were Primo brand. Water was from a Barnstead Nano-pure purification system. Isotopically labelled precursors were purchased from MSD Isotopes. Flash column chromatography was performed according to the method of Still et al. (16) on Merck Type 60 silica gel, 230–420 mesh. Carbon-13 NMR spectra were recorded on a Bruker AM-500 NMR spectrometer.

Growth of *Fusarium* sp. ATCC 20788

Cultures of *Fusarium* sp. ATCC 20788 were grown in petri dishes at 26°C for 5 days on potato dextrose agar (200 g potato, 20 g agar, and 20 g dextrose in 1 L water). The resulting spores were transferred in sterile water to liquid growth medium (0.5 g corn meal, 4 g tomato paste, 1 g oat flour, 1 g dextrose, and 100 mL water in a 500-mL Erlenmeyer flask), which had been sterilized at 121°C for 20 min. The flask was incubated in a rotary shaker – incubator at 28°C and 212 rpm for 3 days. Aliquots (3 mL) of the resulting culture were used to inoculate 24 500-mL Erlenmeyer flasks containing production medium, which was composed of corn meal (4 g), trace element solution (25 mL of 0.1 g/L $MgSO_4 \cdot 7H_2O$ plus 0.1 g/L sodium tartrate plus 0.01 g/L $FeSO_4 \cdot 7H_2O$ plus 0.01 g/L $ZnSO_4 \cdot 7H_2O$), and water (175 mL). The flasks were incubated in the rotary shaker – incubator at 25°C and 212 rpm for 10 days.

Addition of labelled precursors

Labelled precursors (total 1 g per 24 flasks) were added as sterilized solutions in water (25 mL) by injection into the production medium over the period from 3 to 9 days after inoculation.

Extraction of F-244 (1), and isolation of methyl ester 2

The cultures were centrifuged. The supernatant was saturated with NaCl, and extracted with CH_2Cl_2 (4 × 400 mL). The pellet was stirred with MeOH:EtOAc (5:95, 300-mL portions until clear) and the extracts combined with those from the supernatant. The extracts were concentrated on the rotary evaporator to give 3.5 g crude material. Flash chromatography (EtOAc:hexane:AcOH, 30–70:70–30:0.5, stepped by 10% increments) gave fractions containing F-244 (**1**), which were combined and concentrated. To the residue was added diazomethane (slight excess, precautions as normal for diazomethane); excess diazomethane was removed by purging with nitrogen, and the resulting solution concentrated. Flash column chromatography (EtOAc:hexane, 30–70:70–30, stepped by 10% increments) afforded fractions containing virtually pure **2**, which were combined. Repetition of the chromatographic separation gave pure **2** (50 mg).

Abstract: The complex $[Au_2(\mu\text{-dppm})(C{\equiv}Ct\text{-Bu})_2]$, **1**, dppm = $Ph_2PCH_2PPh_2$, is formed by reaction of [AuC≡C*t*-Bu] with dppm. Compound **1**, as an acetone solvate, crystallizes in the monoclinic space group $P2_1/c$ with cell dimensions $a = 14.047(1)$, $b = 16.124(1)$, $c = 17.140(3)$ Å, $\beta = 103.17(2)°$ and four formula units per cell. The crystal and molecular structures of this salt were solved by X-ray diffraction techniques using 2634 counter data with $I > 2\sigma(I)$. Refinement of 278 variables by full-matrix least squares converged at an agreement factor $R = 0.023$. Thermolysis of complex **1** in refluxing toluene led to intermolecular elimination of *t*-BuC≡CH, by combination of a *t*-BuC≡C ligand of one molecule of **1** with a proton from the CH_2P_2 group of a second, and formation of the stable tetragold(I) complex $[Au_4(\mu_3\text{-}Ph_2PCHPPh_2)(\mu\text{-dppm})(C{\equiv}Ct\text{-Bu})_3]$, **2**, which was characterized by its spectroscopic properties.

Key words: acetylide complexes, gold complexes, X-ray crystallography, nmr spectroscopy, bis(diphenylphosphino)methane.

Résumé : La réaction du [AuC≡C*t*Bu] avec le dppm (dppm = $Ph_2PCH_2PPh_2$) fournit le complexe $[Au_2(\mu\text{-dppm})(C{\equiv}Ct\text{Bu})_2]$, **1**. Les cristaux du composé **1**, sous la forme de solvate d'acétone, sont monocliniques, groupe d'espace $P2_1/c$, avec $a = 14{,}047(1)$, $b = 16{,}124(1)$ et $c = 17{,}140(3)$ Å, $\beta = 103{,}17(2)°$ et quatre unités de formule par motif. On a résolu les structures cristallines et moléculaires de ce sel par des techniques de diffraction des rayons X utilisant 2634 données avec $I > 2\sigma(I)$. L'affinement de 278 par la méthode des moindres carrés a conduit à une convergence avec $R = 0{,}023$. La thermolyse du complexe **1** dans le toluène au reflux conduit à une élimination intermoléculaire du *t*-BuC≡CH par la combinaison d'un coordinat *t*-BuC≡C d'une molécule de **1** avec un proton provenant d'un groupe CH_2P_2 d'une seconde et la formation d'un complexe stable tétraor(I) $[Au_4(\mu_3\text{-}Ph_2PCHPPH_2)(\mu\text{-dppm})(C{=}Ct\text{Bu})_3]$, **2**, qui a été caractérisé par ses propriétés spectroscopies.

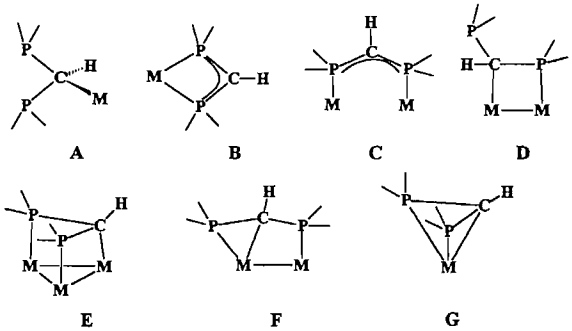
Introduction

The ligands $R_2PCH_2PR_2$ (R = alkyl, aryl, alkoxy, or aryloxy) are often used as bridging ligands and have played an important role in the development of the organometallic chemistry of bimetallic and cluster complexes (1). These ligands can be deprotonated to give the $[R_2PCHPR_2]^-$ or even the $[R_2PCPR_2]^{-2}$ ligand, which can then coordinate to metal centres in several different ways. Thus the $[R_2PCHPR_2]^{-2}$ ligand can act as a monodentate C-donor, **A** (2), a bidentate chelate P, P donor, **B** (3–5); a bidentate bridging ligand with P,P or P,C donors, **C** or **D** (6–8), or as a tridentate P,C,P donor, **E** (9, 10), **F** (11), or **G** (12). The deprotonation of the methylene group of the diphosphine usually occurs in the presence of a base (7) or on pyrolysis of a cluster complex (9, 10). In other cases, the groups attached to the metal centre are basic enough to deprotonate the diphosphine and an example from gold chemistry is shown in reaction [1] (10–14).



It was shown earlier that the ligand $(MeO)_2\text{-}PCH_2P(OMe)_2$ is easily deprotonated in its complexes with AuC≡C*t*-Bu by intra- or intermolecular elimination of *t*-BuC≡CH, ultimately giving, on decomposition in chloroform solution, the remarkable cage complex $[Au_8Cl_2\{\mu_3\text{-}(MeO)_2PCHP(OMe)_2\}_2\{\mu\text{-}(MeO)_2PCP(OMe)_2\}_2]$ (15). It

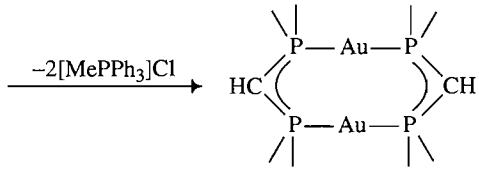
[1] 2 $AuCl(CH_2PPh_3)$ + 2 dppm



was concluded that the easy deprotonation of the dmopm ligand was aided by the electronegative substituents on phosphorus, which increase the acidity of the CH_2P_2 protons. As a result, the simple binuclear gold(I) acetylide derivative $[Au_2(C{\equiv}Ct\text{-}Bu)_2\{\mu\text{-}(MeO)_2PCH_2P(OMe)_2\}]$ was thermally unstable and could not be crystallized (15). In order to investigate further the nature of binuclear alkynylgold(I) complexes and to study the primary steps in the proposed alkyne elimination reactions, it was decided to study the analogous reactions with $Ph_2PCH_2PPh_2$ (dppm) in place of the $(MeO)_2PCH_2P(OMe)_2$ (dmopm) ligand. It was reasoned that the less electronegative phenyl substituents on the dppm ligand would lead to lower acidity of the methylene protons and hence slower alkyne elimination. The results of this study are reported below.

Experimental

Synthesis of $[Au_2(\mu\text{-dppm})_2(C{\equiv}Ct\text{-}Bu)_2]$, 1

To a suspension of [AuC≡C*t*-Bu] (16) (0.650 g, 2.33 mmol) in acetone (10 mL) was added a solution of dppm (0.453 g, 1.18 mmol) in acetone (10 mL). The yellow suspension dissolved, giving a reddish-yellow solution. After 1 h stirring, the solution was concentrated and layered with *n*-pentane. After 3 h a white crystalline solid precipitated, which was filtered, washed with cold acetone and dried under vacuum. Yield: 77%. Anal. calcd. for $C_{37}H_{40}Au_2P_2$: C 47.2, H 4.3; found: C 47.0, H 4.6. ^{1}H nmr ($CDCl_3$): δ = 2.09 [s, 18H, *t*-Bu]; 4.35 [t, ^2J(PH) = 10 Hz, 2H, P_2CH_2]; 8.0–8.6 [m, 20H, Ph]. ^{31}P nmr ($CDCl_3$) δ = 26.7 (s, dppm). Solvated single crystals of a quality suitable for diffraction experiments were grown by diffusing pentane into an acetone solution at 5°C.

Synthesis of $[Au_4(\mu_3\text{-}Ph_2PCHPPh_2)(\mu\text{-dppm})(C{\equiv}Ct\text{-}Bu)_3]$, 2

A solution of $[Au_2(\mu\text{-dppm})(C{\equiv}Ct\text{-}Bu)_2]$, **1**, (0.100 g, 0.11 mmol) in toluene (10 mL) was heated under reflux under an atmosphere of N_2 for 24 h. The initially colourless solution turned yellow. The solvent was removed under vacuum and the yellow residue was dissolved in acetone and layered with pentane. The pale yellow crystals of the product which separated were filtered, washed with pentane, and dried under vacuum. Yield: 55%. Anal. calcd. for $C_{68}H_{70}Au_4P_4$: C 45.4, 3.9; found: C 45.7, H 4.0. ^{1}H nmr ($CDCl_3$): δ = 1.22, 1.26, 1.41 [s, each 9H, *t*-Bu]; 3.30 [t, 2H, $^2J(PH^a)$ = 11 Hz, P_2CH^a]; 4.48 [dt, 1H, $^2J(P^cH^b)$ = 12.5 Hz, $^2J(P^bH^b)$ = 7 Hz, P_2CH^bAu]; 6.75–8.60 [m, 40H, Ph]. ^{31}P nmr ($CDCl_3$): δ = 28.9 [d, $^2J(P^aP^b)$ = 73 Hz, 1P, P^a]; 32.9 [dt, $^2J(P^aP^b)$ = 73 Hz, $^3J(P^bP^c)$ = 15 Hz, 1P, P^b]; 31.2 [d, $^3J(P^bP^c)$ = 15 Hz, 2P, P^c].

X-ray crystallography

Crystals of $[Au_2(\mu\text{-dppm})\{C{\equiv}C{-}CMe_3\}_2].0.5(CH_3)_2CO$ are colourless, transparent prisms. Precession and Weissenberg photographs established the space group (17) and preliminary cell dimensions. The crystal density was measured by the neutral buoyancy method in a mixture of pentane and 1,2-dibromoethane. Data collection of two symmetry equivalents was carried out on an Enraf-Nonius CAD4F diffractometer (28) in ω–2θ scan mode at variable scan speeds within a maximum time per datum of 60 s. Background estimates were made at 25% scan extensions on each side. Standard reflections were monitored every 180 min of X-ray exposure time. Lorentz, polarization, and background corrections were applied using the Enraf-Nonius S.D.P. programs (19) running on a P.D.P. 11/23+ computer. A Gaussian absorption correction (20) was applied to the 7108 data, which were then averaged to yield 3 560 unique data for structure solution and refinement. *R* factors (on F^2) for averaging all data were 0.061 and 0.024 before and after the correction, respectively. Crystal and experimental data are summarized in Table 1.

The structure was solved from Patterson and difference Fourier syntheses, and preliminary refinement was by full-matrix least-squares techniques on *F* (19). In the final cycles, SHELXL93 was used (21). The Au, P, and non-ring C atoms were assigned anisotropic thermal parameters. The phenyl ring carbon atoms were restrained to C_2 geometry with C—C = 1.392 Å and allotted isotropic thermal parameters. All hydrogen atoms were located successfully by difference Fourier methods, placed in calculated positions (C—H = 0.95 Å), and included in the structure factor calculations. The acetone solvate was disordered over a centre of symmetry (Wyckoff b), but refined satisfactorily. A secondary extinction correction was applied to the data. An analysis of variance suggested that the weighting scheme was appropriate. Refinement on F^2 converged at agreement factors R_1 = 0.0427 and R_2 = 0.0632 for 278 variables and 3393 data.

Selected experimental details of the X-ray determination are given in Table 1. Final positional parameters are given in Table 2, while anisotropic thermal parameters, hydrogen atom parameters, and structure amplitudes are available as supplementary material.[1]

Results and discussion

Synthesis and spectroscopic characterization of $[Au_2(\mu\text{-dppm})(C{\equiv}Ct\text{-}Bu)_2]$, 1

Complex **1** was synthesized by reaction of [AuC≡C*t*-Bu], which is probably a tetramer, with the ligand dppm in a 2:1 molar ratio (reaction [2]).

[2] 2 AuC*Ct*-Bu + dppm

[a] $R_1 = \Sigma\{||F_o| - |F_c||\}/\Sigma|F_o|$; $R_2 = [\{\Sigma w(|F_o^2| - |F_c^2|)^2\}/\Sigma w(F_o^2)^2]^{0.5}$.

The product $[Au_2(\mu\text{-dppm})(C{\equiv}Ct\text{-}Bu)_2]$ is a colourless, air-stable solid, which was initially characterized by its ^1H and ^{31}P nmr spectra and by elemental analysis. The ^1H nmr spectrum of **1** contained a triplet resonance at δ = 4.35, with $^2J(PH)$ = 10 Hz, due to the methylene protons of the dppm ligand, and the ^{31}P nmr spectrum contained a singlet at δ = 26.7. These data suggest a symmetrical structure for **1**, which was confirmed by X-ray crystallography.

Crystal and molecular structure of complex 1

The crystal structure consists of well-separated complex and acetone solvent molecules. The closest dimer:solvent approach is H(28B)...H(34) at $(-x, 1 - y, -z)$ 2.82, and the shortest dimer:dimer distance is H(33)...H(18A) at $(x - 1, \frac{1}{2} - y, z - 1)$ 2.57 Å.

Selected interatomic distances and angles are given in Table 3; the remainder have been deposited as Table S3. Molecule **1** contains two gold(I) centres bridged by a dppm ligand. Each Au(I) centre is approximately linearly coordinated to a phosphorus atom and a *t*-butyl acetylide group. The molecule is U-shaped, with the two Au—C≡C*t*-Bu units aligned in close proximity with an intramolecular Au...Au distance of 3.331(1) Å. The isoelectronic complexes

[a]Carbon atoms in phenyl residues are numbered C(*rp*), where *p* is the position, ranging from 1 to 6, and *r* is the residue number.

[b]$U_{eq} = \frac{1}{3}\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* \boldsymbol{a}_i \cdot \boldsymbol{a}_j$.

the complex where PP = $(Ph_2P)_2CH_2$, which possesses crystallographic 2-fold symmetry, Au...Au is 3.351 Å and for PP = *cis*-$Ph_2PCHCHPPh_2$ it is 3.05 Å (22, 23). The *cis*-geometry observed leads to some steric repulsion between the *t*-BuC≡C— groups in that the angles P(1)—Au(1)—C(1) = 169.0(3)° and P(2)—Au(2)—C(7) = 176.6(3)° are distorted from the ideal value of 180° (24). Short Au..Au contacts in otherwise linear gold(I) complexes are common and, although longer than conventional bonds, are believed to result from a weak relativistic bonding force (22–30). The methylene carbon atom of the diphosphine ligand is situated above the $Au_2P_2C_2$ plane. Two of the four phenyl rings of, the dppm ligand lie perpendicular to, and two in the plane of the dimer, Fig. 1. Phenyl ring 2 (i.e., atoms C(21) to C(26) inclusive) is situated roughly parallel to, and about 3.5 Å from phenyl ring 3. The angles at the acetylenic carbon atoms C(1), C(2), C(4), and C(5) range from 173.1(8)° to 177.5(10)° as expected. The Au—C distances are 2.005(9) and 1.990(10) Å, values which are slightly longer than those seen in other complexes containing Au—C(acetylenic) bonds (24) (1.935(19) Å in [C_3H_7-NH_2Au—C≡CPh] (25) and 1.993 Å in [Ph_3PAu—C≡C-(C_6F_5)] (26)). The Au—P distances are indistinguishable with a mean of 2.267(2) Å which is normal for gold–phosphine complexes (16, 24).

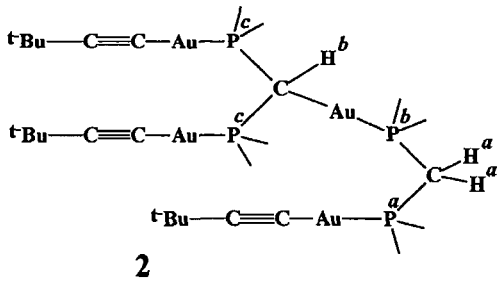
Synthesis and characterization of [$Au_4(\mu_3$-$Ph_2PCHPPh_2)$-(μ-dppm)(C≡C*t*-Bu)$_3$], 2

When a solution of **1** in toluene was heated under reflux, a yellow solution was obtained, from which the pale yellow product [$Au_4(\mu_3$-$Ph_2PCHPPh_2)$(μ-dppm)(C≡C*t*-Bu)$_3$], **2**, was precipitated by adding *n*-pentane (reaction [3]).

[3] $2[Au_2(\mu\text{-dppm})(CCt\text{-Bu})_2]$

$$\xrightarrow{-t\text{-BuCCH}} [Au_4(\mu\text{-dppm})(\mu_3\text{-}Ph_2PCHPPh_2)(CCt\text{-Bu})_3]$$

Single crystals of the product **2** suitable for an X-ray structure determination could not be obtained but the structure of **2** could be determined with confidence by elemental analysis, and from the informative ^{1}H and ^{31}P nmr spectra. The nmr labelling scheme is shown in structure **2**.



2

The ^{31}P nmr spectrum of **2** contained three resonances, all in the region expected for bridging dppm-type ligands (Fig. 2). The signal due to P^a appeared as a doublet centered at δ = 28.9 with $^2J(P^aP^b)$ = 73 Hz. The resonance due to P^b (δ = 32.9) appeared as a doublet of triplets due to coupling to both P^a [$^2J(P^aP^b)$ = 73 Hz] and the two equivalent phosphorus atoms, P^c [$^3J(P^bP^c)$ = 15 Hz]. The signal due to P^c (δ = 32.2) appeared as a doublet with $^3J(P^bP^c)$ = 15 Hz and this peak was twice as intense as those due to P^a and P^b. The ^{1}H nmr spectrum of **2** contained a triplet resonance at δ = 3.30, with ^2J(PH) = 11 Hz, for the P_2CH^a2 protons of the dppm ligand and a resonance at δ = 4.48 due to the P_2CH^b proton of the $Ph_2PCHPPh_2$ ligand. The latter resonance appeared as a doublet of triplets due to the couplings $^3J(P^bH^b)$ = 7 Hz and

[a]Symmetry transformations used to generate equivalent atoms: #1 $-x + 1, -y + 1, -z + 1$.

$^2J(P^cP^b)$ = 15 Hz, respectively. Three well-resolved singlet resonances of equal intensity due to the three non-equivalent *t*-BuC≡C groups appeared at δ = 1.22, 1.26, and 1.44. Structure **2** should give two such resonances in a 2:1 ratio, and the resonances at δ = 1.22 and 1.26 may represent the "equivalent" *t*-Bu groups. Thus, the ^1H and ^{31}P nmr spectral data and analytical data together support the proposed structure **2**.

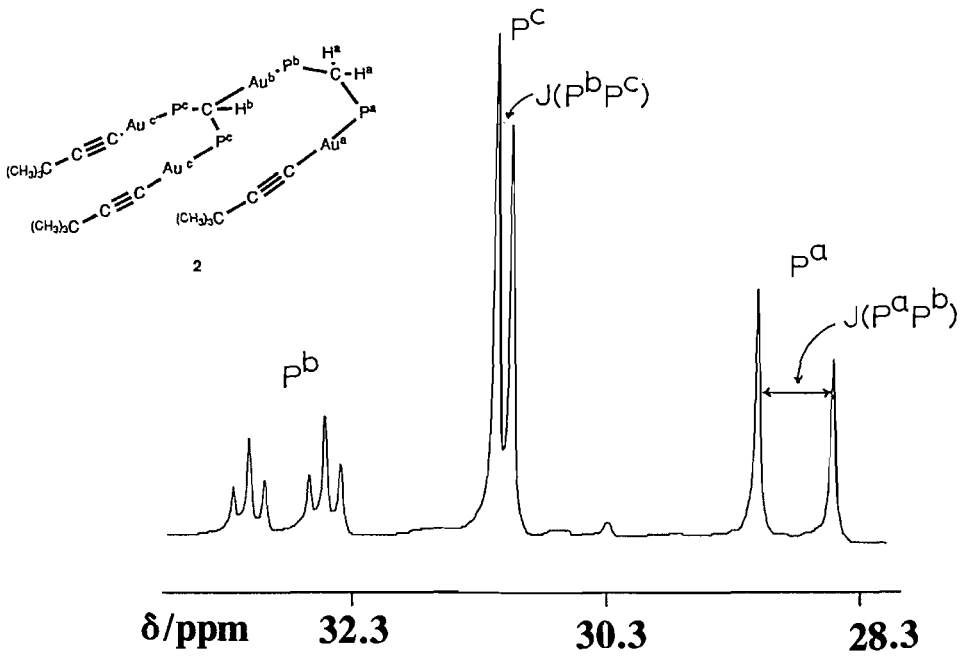
Complex **2** is a novel tetranuclear organogold(I) complex. Each gold(I) centre has the usual linear stereochemistry and each has AuPC coordination. Three of the gold(I) atoms form their Au—C bonds with alkynyl ligands while the fourth binds to the methine carbon of the $Ph_2PCHPPh_2$ ligand. It follows that the formation of **2** from two molar equivalents of **1** occurs by intermolecular elimination of *t*-BuC≡CH. This is likely to be analogous to the first step in the more extensive alkyne elimination reactions leading to formation of the cage complex $[Au_8Cl_2\{\mu_3\text{-}(MeO)_2PCHP(OMe)_2\}_2\{\mu_4\text{-}(MeO)_2PCP(OMe)_2\}_2]$ from $[Au_2(C{\equiv}Ct\text{-}Bu)_2\{\mu\text{-}(MeO)_2PCH_2P(OMe)_2\}]$ (15).

Conclusions

The formation of the U-shaped complex $[Au_2(\mu\text{-}dppm)(C{\equiv}Ct\text{-}Bu)_2]$, **1**, is a simple reaction but the structure strongly suggests the presence of a weak intramolecular Au..Au bond. Thus the structure contains a relatively short Au..Au distance and the "eclipsed" conformation clearly leads to steric interactions between the *t*-butyl substituents. It is interesting that the analogous reaction of [AuC≡CPh] with dppm does not yield the expected complex $[Au_2(\mu\text{-}dppm)(C{\equiv}CPh)_2]$, analogous to **1**, but instead gives the ionic $[Au_3(\mu\text{-}dppm)_2(CCPh)_2][Au(C{\equiv}CPh)_2]$, which also contains short Au..Au distances (27) while the ligand $i\text{-}Pr_2PC_6H_4\text{-}C_6H_4Pi\text{-}Pr_2$ does react with [AuC≡CPh] to give the simple complex $[Au_2(\mu\text{-}i\text{-}Pr_2PC_6H_4C_6H_4Pi\text{-}Pr_2)(C{\equiv}CPh)_2]$ (28). Clearly the preferred product depends on both the nature of the bidentate ligand and the group R in the precursor [AuC≡CR].

The conditions required for formation of **2** from **1** indicate that replacement of the more electronegative substituents R = MeO by less electronegative substituents R = Ph in the ligands $R_2PCH_2PR_2$ does indeed lead to reduced acidity of the P_2CH_2 protons in the alkynylgold(I) complexes. Firstly, the complex $[Au_2(C{\equiv}Ct\text{-}Bu)_2\{\mu\text{-}R_2PCH_2PR_2\}]$ is much more stable towards elimination of *t*-BuC≡CH when R = Ph than when R = MeO, and so complex **1** is sufficiently stable to permit the

Fig. 2. The ^{31}P nmr spectrum (121.5 MHz) of complex **2**.



2

easy growth of single crystals for X-ray structure determination. Secondly, the alkyne elimination requires forcing conditions when R = Ph and, even in refluxing toluene, only one *t*-BuC≡CH elimination step occurs whereas, when R = MeO, further eliminations occur (15).

Complexation of glucose by α- and β-cyclodextrins

Warren Hirsch, Tamas Muller, Richard Pizer, and P.J. Ricatto

Abstract: The concentration of glucose in aqueous solutions was monitored, using a blood glucose meter, as small weighed cyclodextrin portions were added. Equilibrium constants for the formation of inclusion complexes were calculated. A binding constant determined by this method has been verified by a technique involving competition of the guest with methyl orange indicator dye. ΔH^0 values for the reactions were estimated using calorimetry. These values along with ΔG^0 provided estimates of the standard entropies. The values calculated compare favorably with those from a previously determined empirical equation. The possibility of hydrogen bond formation is suggested by the large negative enthalpies as well as by molecular mechanics calculations.

Key words: α-, β-cyclodextrin, glucose, binding constants.

Résumé : Utilisant un glucomètre pour le sang, on a mesuré la concentration du glucose dans des solutions aqueuses alors qu'on y ajoutait des portions mesurées de cyclodextrine. On a calculé les constantes d'équilibre pour la formation de complexes d'inclusion. Faisant appel à une technique impliquant une compétition de l'hôte pour l'indicateur coloré méthylorange, on a vérifié une constante de fixation déterminée par cette méthode. On a évalué les ΔH^0 des ces réactions en utilisant la calorimétrie. Ces valeurs utilisées de concert avec des ΔG^0 ont fourni des évaluations des entropies standard. Les valeurs calculées se comparent avantageusement avec celles obtenues sur la base d'une équation empirique déterminée antérieurement. La possibilité de formation de liaison hydrogène est suggérée par les fortes enthalpies négatives ainsi que par des calculs de mécanique moléculaire.

Mots clés : α-, β-cyclodextrine, glucose, constantes de fixation.

Introduction

Cyclohexaamylose and cycloheptaamylose, also known as α- and β-cyclodextrin, respectively, have been the subject of much intensive research (1, 2). The above cyclodextrins are structured roughly in "doughnut" shapes that are composed of six or seven glucose units. Seen from the side, the molecules are probably better described as "lampshade" shaped since the top and bottom openings are unequal. An important reason for the interest in cyclodextrins is their ability to form inclusion complexes with molecules and anions in aqueous solution (1–4). These complexes serve as a model for the study of enzymes (5), and are also being proposed for increased drug bioavailability (6) and for the removal of harmful substances from the body (7).

The relatively large interior of cyclodextrins allows suitably sized molecules or anions to get trapped within the cavity, with conformational changes perhaps aiding the process (3, 4, 8). Possible binding forces within these inclusion complexes may involve hydrophobic, van der Waals, hydrogen bonding, or dipole interactions (1, 2, 9).

In the present work the complexation of the simple sugar, D-glucose, by α- and β-cyclodextrin has been studied in aqueous solutions. There is an apparent scarcity of data on the inclusion of this type of guest. Free glucose concentrations were monitored at different initial concentrations of cyclodextrin and glucose using a blood glucose meter that had been calibrated for aqueous solutions, and association constants were calculated.

Experimental section

To measure glucose concentrations in aqueous solutions, a Glucometer3 blood glucose meter and Glucofilm test strips were obtained. These are products of Miles Laboratories Inc. These items are ordinarily used to monitor glucose concentrations in whole blood. The test strip is a firm plastic strip with a reagent test pad for determining the concentration of glucose in whole blood. The test strips are specific to glucose and their reaction is based on the glucose oxidase method using dry reagent technology. The reaction utilizes the enzymes glucose oxidase and peroxidase. The glucose oxidase catalyzes the oxidation of glucose in blood in the presence of oxygen in the atmosphere, producing gluconic acid and hydrogen peroxide. In the presence of the peroxidase, the hydrogen peroxide oxidizes tetramethylbenzidine (in the reduced form), turning the test pad blue with an intensity proportional to the glucose concentration. The glucose meter then evaluates the color change using spectrophotometry, providing a digital output of glucose concentration in units of mg/dL. The test provides a quantita-

tive measurement of glucose in whole blood from 20 to 500 mg/dL (1.1–27.7 mmol/L).[2]

Anhydrous reagent grade D-glucose, obtained from Aldrich Inc., was used without further purification. Five standard glucose solutions were prepared. The concentrations used were in the range 1–5 mmol/L. It was determined that ambient temperature changes did not affect the glucose meter reading. The pH of the solutions was adjusted to 7.4 by addition of a few drops of dilute aqueous reagent grade NaOH in order to simulate blood pH. Although cyclodextrins are known to include OH^- ions, there is no significant reduction in free cyclodextrin concentrations at such low OH^- levels (9). To account for other differences between whole blood and the aqueous glucose solutions (ionic strength, viscosity, etc.) a linear calibration plot was prepared for the instrument. Using the calibration plot, the free glucose concentrations in unknown solutions could be determined from reading the glucose meter.

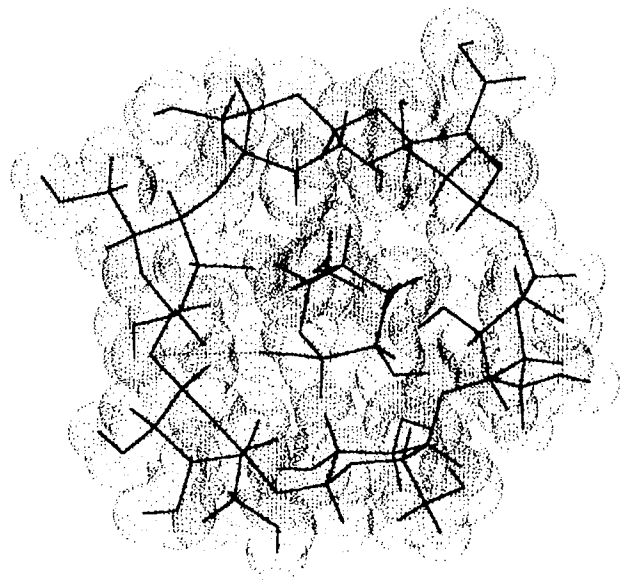
The α- and β-cyclodextrin, obtained from Aldrich Inc., were used as received. Information on the water content was obtained from the manufacturer in order to correct solution concentrations. As a control, it was determined that the Glucofilm test strips do not react with α- or β-cyclodextrin.

Cyclohexaamylose or cycloheptaamylose was added to standard glucose solutions in weighed portions as free glucose concentrations were monitored with the glucose meter. The free glucose concentrations became progressively lower with increasing additions. At least three strips were used for each cyclodextrin addition to ensure reproducibility. All measurements were performed at 25 ± 2°C. From the measured data, association constants were calculated for each set of initial concentrations of the reactants.

As a test of the preceding technique, an independent method of determining the association constants of α-cyclodextrin was employed. It is well known that α-cyclodextrin has the ability to complex and decolorize the red, acidic form of methyl orange (3). The addition of colorless competing guests to the decolorized solution will tend to release free indicator species, and hence to restore the color. In the present work, the competition at pH 1.5 was monitored by visible spectrophotometry at 515 nm with the temperature equal to 25 ± 2°C. The complete details of the method used, including the mathematical treatment of the data, may be found elsewhere (7). The association constant calculated for the α-cyclodextrin–glucose system obtained from the indicator competition method compared favorably with that obtained from the glucose meter method.

[2] Literature from Miles Inc.

Fig. 1. α-Cyclodextrin–glucose complex.



Benchtop calorimetry measurements involved the measurement of the solution enthalpies of glucose in water, cyclodextrin in water, and both of the preceding solids in water together using a calorimetric thermometer accurate to 0.01°C. In the last case, excess glucose was used to ensure complete reaction. At least three separate trials were performed in the determination of each enthalpy. The enthalpy of formation of the cyclodextrin–glucose complex could then be calculated.

Results

The inclusion of the glucose guest in the cyclodextrin cavity may be represented as follows:

[1] $Cy + G \rightleftarrows CyG$

with $K_{CyG} = [CyG]/[Cy]\,[G]$.

Also, we have the mass conservation expressions:

[2] $F_G = [G] + [CyG]$

[3] $F_{Cy} = [Cy] + [CyG]$

where F_G and F_{Cy} represent the total molar concentrations of guest and cyclodextrin species, respectively. Since F_G and F_{Cy} are known and [G] can be determined from the glucose

meter, the concentrations of all species can be found, and the formation constant K_{CyG} can be calculated.

Association constants for inclusion of glucose by cyclohexaamylose and cycloheptaamylose at a temperature of 25 ± 2°C are listed in Table 1 along with the value obtained for the cyclohexaamylose using the indicator competition method at the same temperature.

Discussion

The model equations in the results section assume a 1:1 molecular ratio of glucose to cyclodextrin in each complex. This assumption seems warranted, considering the constancy of the calculated equilibrium constants between the runs, which employed different values for F_{Cy} and F_G. The association constants of α-cyclodextrin obtained by the glucose meter and methyl orange method were in good agreement within experimental error, confirming the accuracy of the glucose meter technique. The binding constants for α- and β-cyclodextrin were indistinguishable within experimental error. Apparently, the "tightness-of-fit" effect is not very important in complexation of glucose by these cyclodextrins.

Molecular mechanics calculations were performed utilizing the graphical interface program HyperChem to set up MM^+ calculations. MM^+ is an "all-atom" force field method that is an extension (providing additional force constants) of the MM2 method of Allinger (10). The calculations further support the 1:1 reaction stoichiometry. Figures 1 and 2 show the fit of glucose within the α- and β-cyclodextrin cavities.

Gelb et al. (11) determined the standard enthalpies and entropies for the complexation of 28 different guests with α-cyclodextrin, by utilizing the temperature dependencies of the formation constants. For these guests, which were quite diverse in nature (anions, aliphatics, aromatic carboxylic acids, and other small organic molecules such as alcohols), the following empirical relationship was determined from a linear least- squares plot of ΔH^0 vs. ΔS^0:

$$[4] \quad \Delta H^0 = (410 \pm 15)\,\Delta S^0 - (1.2 \pm 0.2) \times 10^3$$

where the units for ΔH^0 are kcal mol^{-1} and those of ΔS^0 are cal mol^{-1} K^{-1}. However, there are relatively few data dealing with sugar molecules as guests in cyclodextrin inclusion complexes (12, 13).[3] Assuming that eq. [4] holds true for glucose and can be used to estimate the thermodynamic values for β-cylclodextrin complexes as well as those for α, since

$$[5] \quad \Delta G^0 = -RT \ln K = \Delta H^0 - T\Delta S^0$$

one can calculate the standard enthalpies and entropies using the equilibrium constants obtained by the glucose meter method and eqs. [4] and [5]. These data are listed in Table 1.

[3] Both refs. 12 and 13 report the binding of ribose to β-cyclodextrin, but with different equilibrium constants. Reference 12 reports that cyclohexanol binds strongly to β-cyclodextrin and, in fact, the reported binding constant and our value for the the glucose binding constant are quite similar. Reference 12 also reports little binding of glucose by β-cyclodextrin, a result that is not consistent with our findings.

To confirm the accuracies of the above thermodynamic data, some experiments in benchtop solution calorimetry were performed to estimate the enthalpies of formation of the cyclodextrin–glucose complexes. The results are listed in Table 1. The enthalpies obtained by this method compare favorably with those obtained from eq. [4]. The large negative ΔH^0 in conjunction with little or no tightness-of-fit effect suggests that the intermolecular forces are strong and short range. Therefore, one suspects that hydrogen bonds augment the dipole forces postulated by Gelb et al. (11). These researchers explain the fact that their standard entropy changes are consistently quite negative by conformational changes in the ring. This idea has also been advanced by others (8), and probably occurs with the glucose guest. In fact, the molecular mechanics calculations utilizing the program HYPERCHEM in the MM^+ mode creates models that show hydrogen bonds binding the glucose guests. Intramolecular hydrogen bonds causing conformational changes in the case of the β-cyclodextrin ring are also indicated (Figs. 1 and 2).

Investigation of the effect of ring size on the product distribution for the Schiff base reaction of 2-acetylcycloalkanones with diamino alkanes

Raul G. Enriquez, Juan M. Fernandez-G., Ismael Leon, William F. Reynolds, Ji-Ping Yang, and Margaret Yu

Abstract: The Schiff base condensation reaction of 1,2-diaminoethane with a series of 2-acetylcycloalkanones (from cyclopentanone to cyclooctanone) has been investigated and the products characterized by two-dimensional nuclear magnetic resonance. The site of attack of the amino groups, i.e., ring ketone or acetyl ketone, is determined primarily by ring size. 2-Acetylcyclohexanone yields two products in ca. 9:1 ratio, the major product where the two amino groups attack at the ring ketones of two different cyclohexanone molecules, and the minor product where one amino group attacks one ring carbonyl of one cyclohexanone while the second amino group attacks the acetyl group of another. 2-Acetylcyclopentanone yields all three possible products with the major product involving attack at the acetyl groups of two different cyclopentanones. The corresponding reactions for 2-acetylcycloheptanone and 2-acetylcyclooctanone each give a single product corresponding to attack at the acetyl groups of two different cycloalkanones. Similar product distributions are observed for the reactions of the different 2-acetylcycloalkanones with 1,4-diaminobutane.

Key words: Schiff base reactions, diketones, 2D NMR.

Résumé : On a étudié la réaction de condensation conduisant à des bases de Schiff et impliquant le 1,2-diaminoéthane et une série de 2-acétylcycloalcanones (allant de la cyclopentanone à la cyclooctanone) et on a caractérisé les produits par la résonance magnétique nucléaire bidimensionnelle. Le site d'attaque des groupes, à savoir la cétone cyclique ou le groupe acétyle, est principalement déterminé par la grandeur du cycle. La 2-acétylcyclohexanone fournit deux produits, dans un rapport de 9 : 1; le produit principal correspond à un attaque des deux groupes amino sur les cétones cycliques de deux cyclohexanones différentes alors que le produit mineur correspond à l'attaque d'un groupe amino sur le groupe carbonyle d'une cyclohexanone alors que l'autre groupe amino attaque le groupe acétyle d'une autre molécule. L'acétylcyclopentanone fournit les trois produits possibles; le produit majeur est celui qui implique une attaque des groupes acétyles de deux cyclopentanones différentes. Les réactions correspondantes avec la 2-acétylcycloheptanone et la 2-acétylcyclooctanone ne fournissent chacune qu'un seul produit correspondant à l'attaque des groupes acétyles de deux cycloalcanones différentes. On a observé des distributions semblables de produits pour les réactions de diverses 2-acétylcycloalcanones avec le 1,4-diaminobutane.

Introduction

In 1973, Moss and Robinson reported the results of a series of reactions involving the Schiff base condensation of either 2-acetylcyclopentanone or 2-acetylcyclohexanone with one of 1,2-diaminoethane, 1,3-diaminopropane, or 1,4-diaminobutane (1). In all cases they concluded that the product had structure **1** = CH_3), i.e., the result of attack at the side-chain ketone.

This is consistent with other studies, which indicated that polyamines condense very readily at the acetyl group in diketones and triketones (2). Similar products were reported for the corresponding diones with R = CH_2CH_3. However, for the diones with R = $CH(CH_3)_2$, it was concluded that the products had structure **2**. The switch from **1** to **2** for R = $CH(CH_3)_2$ was attributed to greater steric hindrance of the side-chain ketone in that case (1). The main evidence for the proposed structures was provided by mass spectral fragmentation patterns.

Very recently, we repeated the reaction of 2-acetylcyclohexanone with 1,2-diaminoethane in order to synthesize tetradentate chelate ligands for transition metal complexes (3).

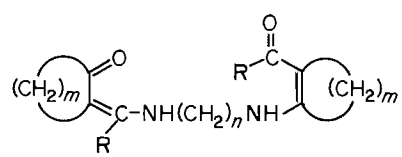
1 2

An X-ray crystal structure determination and a two-dimensional solution nmr investigation of the free ligand and a crystal structure determination of its complex with Cu(II) provided unambiguous evidence that the ligand structure had **2** rather than the previously reported structure **1** (3). Consequently, we decided to carry out a systematic investigation of the reactions of a series of 2-acetylcycloalkanones (with $n = 3$, 4, 5, and 6) with 1,2-diaminoethane in order to determine the structures of the condensation products and the factors determining the preference for structure **1** or **2**. Results of this investigation are reported below. They demonstrate that ring size is the single most important factor in determining the site of attack. Similar product distributions are obtained when 1,2-diaminoethane is replaced by 1,4-diaminobutane, indicating that the length of the bridging group does not affect the course of the reaction.

Results and discussion

We initially repeated the reaction of 2-acetylcyclohexanone with 1,2-diaminoethane and redetermined the ^1H and ^{13}C spectra of the resultant product. Close inspection of these spectra indicated the presence of a second, minor component with peaks ca. 10% as intense as those of the major component. The spectra of the major component were identical to those previously reported. However, while a number of the ^{13}C peaks of the minor component were very similar to those in the major component, some of the peaks had very different chemical shifts. Most noteworthy was the presence of a methyl signal at δ 14.2 (with a corresponding ^1H singlet at δ 1.92) compared to a methyl signal at δ 27.6 ($\delta_H = 2.08$) in the major component. Consequently, a series of two-dimensional spectra (COSY (4), HETCOR (5), and FLOCK (6)) were carried out to obtain further structural information. The FLOCK spectrum was particularly informative since the CH_3 singlet for the major component (δ 2.0) showed cross peaks with carbons at δ 195 and δ 101 (as expected for structure **2**) while the CH_3 singlet at δ 1.92 showed cross peaks with carbons at δ 161 and δ 101, i.e., more consistent with structure **1**. However, in view of the relatively large number of minor component peaks, we suspected that the actual structure of this component was the asymmetric structure **3**.



3

To confirm this, the reaction mixture was separated by high-performance liquid chromatography (hplc). A series of 2D experiments (COSY, NOESY (7), HMQC (8), and HMBC (9)) on the separated components allowed us to both confirm that the major component had structure **2** and that the minor component had structure **3** and to fully assign the ^1H and ^{13}C spectra of the two compounds. HMQC and HMBC were used in place of HETCOR and FLOCK because of the limited amount of some of the pure isomers that was available. These data are reported in Table 1.

The corresponding reaction of 2-acetylcyclopentanone with 1,2-diaminoethane proved to be even more complex, since the ^1H and ^{13}C spectra indicated the presence of at least three products. In this case the ^{13}C spectra showed a strong methyl peak at δ 15.65, and three weaker methyl peaks (of roughly equal intensity) at δ 15.61, δ 27.90, and δ 27.94. This suggested the presence of all three possible products **1**, **2**, and **3** with the relative amounts being 70% **1**, 20% **3**, and 10% **2**, i.e., **1** was the favored product in this case. Once again, chromatographic separation into the three components, followed by a series of 2D nmr experiments identical to those listed in the previous paragraph, allowed unambiguous confirmation of the proposed structures and full ^1H and ^{13}C spectral assignments. NOESY cross peaks between methyl (H-7 or H-7′) protons and H-3 or H-3′ protons were particularly helpful in distinguishing C-3 from C-5. Assignments are given in Table 2.

By contrast, the reactions of 2-acetylcycloheptanone and 2-acetylcyclooctanone with 1,2-diaminoethane each gave only one product. In each case this product had structure **1**, as confirmed by 2D nmr. Spectral assignments for the two compounds are listed in Table 3.

Comparison of the results of the reactions of different 2-acetylcycloalkanones with 1,2-diaminoethane clearly demonstrates that the site of Schiff base condensation is primarily determined by ring size. The six-membered ring shows a moderately strong preference for structure **2**, the five-membered ring has a slightly weaker preference for structure **1**, while the seven- and eight-membered rings both show a strong preference for structure **1**. While the relative stabilities of **1** and **2** for the different ring size undoubtedly reflect some complex blend of steric and electronic interactions, this could be regarded as another example of the Dieckmann–Kon rule (10, 11), i.e., the tendency of six-membered rings to prefer endocyclic double bonds rather than exocyclic double bonds (12). Recent work has shown that this tendency is particularly strong for six-membered rings when it involves a choice between an endocyclic double bond (as in **2**) and two adjacent exocyclic double bonds (as in **1**) (13). Structure **1** can also exist as the OH tautomer with an endocyclic double bond (3). However, selective decoupling of the NH protons for the minor product (**3**) of this reaction of 2-acetylcyclohexanone showed that each NH proton was coupled to a CH_2 group, ruling out the OH tautomer for either end of this unsymmetric molecule. Thus, while six-membered ring compounds may prefer to avoid exocyclic double bonds, the preference for the

NH tautomer over the OH tautomer must have an even greater effect in this case.

Our previous investigation showed that mass spectral fragmentation patterns do not provide a reliable criterion for structure elucidation in this family of compounds (3). The ^{13}C chemical shift of the methyl group does appear to provide an unambiguous criterion, due to the large chemical shift differences in the two forms (δ 14–16 for **1**, δ 27–28 for **2**). In cases

where both structures are formed, the NH chemical shift also appears to be consistently larger for **1** than for **2**. However, the variation of this chemical shift with ring size is even greater, presumably reflecting the variation of intramolecular hydrogen bond strength with ring size. It appears that this hydrogen bond is considerably weaker in the five-membered ring compounds than in the other cases, as well as in structure **2** relative to **1**. From these data, it does not appear that the strength of the

intramolecular hydrogen bond is a major factor in determining the preference for **2** over **1** in the case of the 2-acetylcyclohexanone reactions.

To determine whether the length of the -HN-$(CH_2)_n$-NH- bridge had any effect on the preferred site of attack, the series of reactions were repeated using 1,4-diaminobutane in place

of 1,2-diaminoethane. In each reaction, the product distribution was essentially the same as observed for the diaminoethane reactions. Thus the length of the bridging group appears to have little effect on the site of attack in the Schiff base reaction. Product mixtures were again separated chromatographically, with ^{1}H and ^{13}C spectral assignments for the different compounds listed in Tables 4–6.

One unexpected bonus from this investigation is that it has provided a series of tetradentate ligands, which have subtle differences in structure. An investigation is planned to determine how these differences affect the structures and stabilities of four-coordinate transition metal complexes involving these ligands.

Experimental

Melting points were determined in a Fisher–Johns melting point apparatus and are uncorrected; infrared spectra (KBr disks) were recorded on a Perkin–Elmer model 203-B spectrometer; mass spectra were obtained using a Hewlett–Packard instrument model 5985, at 70 eV ionizing potential, nmr spectra on a Varian XL-400 or Unity-500 spectrometer. Initial experiments on isomeric mixtures used ca. 30 mg of sample in $CDCl_3$. Experiments on individual isomers used 2–10 mg of sample in $CDCl_3$. Toluene, 2-acetylcyclopentanone, 2-acetylcyclohexanone, cyclooctylamine, cycloheptylamine, morpholine, acetyl chloride, 1,4-dioxane, 1,2-diaminoethane, and 1,4 diaminobutane were from Aldrich and were used without further purification. 2-Acetylcycloheptanone and 2-acetylcyclooctanone were obtained by the method described by Stork et al. (14).

General synthetic procedure

To a stirred solution of 10 mmol of the β-diketone in toluene (300 mL) was added a solution of 5 mmol of 1,4-diaminobutane or 1,2-diaminoethane in absolute ethanol (10 mL). The solution was heated under reflux with a Dean–Stark trap. The solvent collected for the first time in the column of the trap was discarded and then the mixture was refluxed for 3.5 h. Afterwards, the remaining solvent was distilled off, yielding an oily product. This was separated by chromatography on a silica gel column using a 95:5 mixture of methylene chloride and methanol. The crude product purity was then checked by nmr. If only a single product was noted, the crude product was recrystallized from dichloromethane. In cases where two or more products were observed, hplc was used to further separate and purify the mixture of products.

High-performance liquid chromatography purification

The hplc purification was carried out on a 250 × 10 mm column of Maxsil C_{18} using as eluent a 70:30 CH_3OH:H_2O mixture in isocratic mode, 2 mL/min flux at 30°C. A uv detector set at 280 nm was used. After a sufficient amount of each component was detected, the samples were evaporated under vacuum and used directly for spectroscopic measurements.

Product characterization

The structure of the major product (**2**) of the reaction of 2-acetylcyclohexanone with 1,2-diaminoethane has previously been characterized by X-ray crystallography and 2-dimensional nmr (3).

No analytical data were obtained for individual isomers owing to the limited availability of purified samples. However, all individual products were characterized by the combination of one- and two-dimensional nmr experiments described in the text. High-resolution mass spectrometry was also used to confirm the empirical formulae for the different isomeric mixtures: cyclopentanone/diaminoethane product, calcd. ($C_{16}H_{24}N_2O_2$): 276.1838; found: 276.1830; cyclopentanone/diaminobutane product, calcd. ($C_{18}H_{28}N_2O_2$): 304.2152; found: 304.2150; cyclohexanone/diamonoethane product, calcd. ($C_{18}H_{28}N_2O_2$): 304.2152; found: 304.2144; cyclohexanone/diaminobutane product, calcd. ($C_{20}H_{32}N_2O_2$): 332.2466; found: 332.2449: cycloheptanone/diaminoethane product, calcd. ($C_{20}H_{32}N_2O_2$): 332.2466; found: 332.2457; cycloheptanone/diaminobutane product, calcd. ($C_{22}H_{36}N_2O_2$): 360.2779; found: 360.2776; cyclooctanone/diaminoethane product, calcd. ($C_{22}H_{36}N_2O_2$): 360.2779; found: 360.2780; cyclooctanone/diaminobutane product, calcd. ($C_{24}H_{40}N_2O_2$): 388.3092; found: 388.3082. Mass spectral fragmentation patterns were obtained for some of the individual isomers but, as noted previously (3), these were extremely complex and of little value for structure elucidation.

Étude théorique de la complexation des cations Pb^{2+} et Hg^{2+} par le D-talose

Marc Palma et Yves Louis Pascal

Résumé : Le comportement des conformères du D-talopyranose et du D-talofuranose en présence des cations Pb^{2+} et Hg^{2+} a été simulé, en phase gazeuse et en présence de quelques molécules d'eau, par la méthode AM1. L'analyse conformationnelle du D-talose libre a été réalisée par une méthode de Monte Carlo (logiciel BATCHMIN). Des minima de plus basse énergie ont été identifiés et les différentes orientations des groupements hydroxyle donnés. L'équilibre de distribution des anomères en phase gazeuse est différent de celui obtenu expérimentalement en solution aqueuse. Ce phénomène peut s'expliquer par la prépondérance des liaisons hydrogène intramoléculaires dans le cas de la molécule isolée et des liaisons hydrogène intermoléculaires en milieu aqueux. En présence du cation, l'analyse a été faite par la méthode AM1 pour chacune des conformations du ligand pur. En phase gazeuse, les prédictions d'Angyal ne sont pas respectées. L'énergie la plus basse est représentée par une forme flexible de l'anomère β du talopyranose et certains complexes sont tetra ou pentacoordinés. Pour les furanoses, l'anomère α qui possède sur le cycle, une séquence de trois OH consécutifs en positions *cis-cis-cis*, est le moins stable. Les complexes des carbohydrates en solution aqueuse avec les cations métalliques sont nombreux avec Pb^{2+} alors qu'on n'en connait pas avec Hg^{2+}. Les calculs montrent que, pour les espèces isolées, ce serait l'inverse qui devrait se produire. La moins grande stabilité dans l'eau des complexes mercuriques par rapport à ceux du plomb pourrait s'interpréter par : (1) un effet entropique d'hydratation plus défavorable; (2) une différence d'entropie de translation moins favorable. Une réponse plus complète ne peut être fournie que par l'étude dynamique du système dans l'eau par une méthode de Monte Carlo.

Mots clés : complexation des cations divalents, conformères du D-talopyranose et D-talofuranose.

Abstract: Molecular modeling of interactions between D-talopyranose and D-talofuranose conformers and Pb^{2+} and Hg^{2+} cations was done in the gaseous state using the AM1 method, both with "naked" species and with some water molecules added. A complete conformational analysis of the free D-talose molecule was carried out using a Monte Carlo method (BATCHMIN program). Lower minima were identified, and the different orientations of the hydroxyl groups given. The calculated equilibrium distribution of anomers in the gaseous phase differs from that obtained experimentally in aqueous solution. This could be related to the predominance of intramolecular hydrogen bonding for the isolated molecule and intermolecular hydrogen bonding in aqueous media. In the presence of a cation, the analysis was carried out using the AM1 method for every conformation of the ligand. In the gaseous phase, Angyal's predictions are not respected. The lowest energy is represented by a flexible β-pyranosic form and some complexes are tetra or pentacoordinated. For the furanosic species, the αF forms bearing a *cis-cis-cis* sequence of hydroxyl groups are the less stable. Amongst the complexes of carbohydrates with metal cations in aqueous solutions, Pb^{2+} forms complexes and Hg^{2+} does not. The calculations show that, for the isolated complexes, the reverse should be true. The lesser stability in water of Hg^{2+} complexes with respect to Pb^{2+} could be interpreted in terms of (1) a more unfavourable entropic hydration effect; (2) a less favourable difference of translational entropy. A complete answer requires the dynamical study of the system in water by a Monte Carlo method.

Key words: complexes with divalent cations, D-talopyranose and D-talofuranose conformers.

Introduction

En solution aqueuse certaines conformations d'hexoses paraissent favorables à la complexation des cations divalents (1–6). Des mesures de spectroscopie RMN (7–10) et les travaux d'Angyal en particulier, ont montré que le cation doit être, dans ce cas, lié à trois atomes d'oxygène de groupes hydroxyle consécutifs du cycle situés en positions *ax-eq-ax* pour les formes pyranosiques, et en positions *cis-cis-cis* pour les formes furanosiques. Dans cet article, nous avons essayé de voir si des méthodes de modélisation moléculaire, largement utilisées dans le domaine des carbohydrates (11), permettaient de retrouver et d'expliquer ce mode de complexation dans le cas des conformations les plus stables, et s'il n'existe pas d'autres types de liaisons possibles. Une analyse conformationnelle a été d'abord effectuée sur le ligand seul, puis sur un modèle simulant le cation et le ligand isolés dans le vide. Nous avons examiné ensuite, sur une forme particulière, comment varient la géométrie du système et la nature des liaisons, quand une ou plusieurs molécules du solvant sont ajoutées au voisinage du site d'interaction. Enfin, nous avons

essayé de montrer pourquoi la complexation par les hexoses de certains cations divalents, comme Hg^{2+} par exemple, n'a jamais été observée (7).

Parmi les isomères du glucose, le D-talose nous a paru intéressant, car la forme chaise $^4C_1$ de l'α-D-talopyranose possède sur le cycle une séquence de trois OH consécutifs en positions *ax-eq-ax* (fig. 1*a*) et devrait, de ce fait, complexer les cations (1). Au contraire, la forme chaise opposée $^1C_4$, ne possédant pas cette séquence, ne devrait pas donner de complexation significative. Le β-D-talopyranose réalise la séquence dans ses deux formes chaises. Quant aux formes furanosiques, seul le β-D-talofuranose possède à l'intérieur du cycle trois OH consécutifs en positions *cis-cis-cis* (fig. 1*b*). Une étude expérimentale en solution aqueuse effectuée au laboratoire, a montré que ce ligand complexait le cation Ca^{2+} (7). Le choix des cations a été imposé par les paramètres disponibles des logiciels de calcul utilisés. De ce fait, nous avons choisi Pb^{2+} qui apparait expérimentalement très complexé, et Hg^{2+} qui ne l'est pas (7).

Méthodes d'analyse conformationnelle

Afin de permettre la comparaison de propriétés entre les différents isomères, nous avons utilisé une numérotation commune dérivée de la forme ouverte du talose, avec les numéros 1–6 pour les atomes de carbone de la chaîne principale et les liaisons C_1—O_7, C_2—O_8, C_3—O_9, C_4—O_{10}, C_5—O_{11} et C_6—O_{12}.

La description des conformations des cycles pyranosiques et furanosiques est donnée par les paramètres de gauchissement de Cremer et Pople (12) qui permettent d'expliciter les distances z_j des sommets d'un cycle par rapport au plan moyen défini par $\Sigma z_j = 0$. Pour un cycle à cinq côtés, ces écarts sont reliés aux paramètres q (écart maximum des z_j) et φ (angle de phase) par la formule

$$z_j = (2/5)^{1/2} q \cos [\varphi + 4\pi(j - 1)/5]$$

φ vaut respectivement 36 et 36p + 18 degrés (p étant un nombre entier quel conque) pour les conformations enveloppes et croisées. Pour un cycle à six côtés, ces écarts dépendent de trois paramètres par la formule

$$z_j = 3^{-1/2} q(\sin \theta \cos [\varphi + 4\pi(j - 1)/3] + (-1)^{j-1} 6^{-1/2} \cos \theta)$$

q est l'écart maximum des sommets au plan moyen, θ prend les valeurs 0° et 180° pour les formes chaises, et 90° pour les formes flexibles, et l'angle de phase φ vaut respectivement $2p \times 30$ et $(2p + 1) \times 30$ degrés pour les conformations bateau et croisées.

Il faut en plus décrire l'orientation de la chaîne exocyclique et celle des différents groupes OH. Pour les anomères du talopyranose, on peut repérer en projection de Newman la position de C_6—O_{12} par rapport aux liaisons C_5—O_{11}, C_5—C_4 et C_5—H en utilisant les notations habituelles G pour une disposition gauche et T pour trans; mais comme il doit y avoir deux dispositions gauches et une trans, il suffit de considérer seulement deux dièdres, ceux de C_6—O_{12} avec C_5—O_{11} et avec C_5—C_4 (13). Comme certaines conformations apparaissent un peu distordues par rapport aux formes décalées, nous avons utilisé la notation G pour un dièdre compris (en valeur absolue) entre 30° et 80°, T entre 150° et 180°, P entre 80° et 150° et C entre 0° et 30°. De la même façon, nous avons décrit ensuite les positions des liaisons O—H avec les notations précédentes (mais en minuscules g, t, p, c) par les dièdres classés dans l'ordre suivant : H-O_{12}-C_6-C_5, H-O_{12}-C_6-H, H-O_7-C_1-O_{11}, H-O_7-C_1-C_2, H-O_8-C_2-C_1, H-O_8-C_2-C_3, H-O_9-C_3-C_2, H-O_9-C_3-C_4, H-O_{10}-C_4-C_3, H-O_{10}-C_4-C_5.

Pour les anomères du talofuranose, les orientations dans la chaîne -CHOH-CH_2OH ont été décrites dans l'ordre par les dièdres O_{11}-C_5-C_4-O_{10}, O_{11}-C_5-C_4-C_3, C_6-C_5-C_4-O_{10}, C_6-C_5-C_4-C_3, O_{12}-C_6-C_5-O_{11}, O_{12}-C_6-C_5-C_4 (symboles majuscules). Pour les OH ont été utilisés les dièdres H-O_{12}-C_6-C_5, H-O_{12}-C_6-H, H-O_{11}-C_5-C_4, H-O_{11}-C_5-C_6, H-O_7-C_1-O_{10}, H-O_7-C_1-C_2, H-O_8-C_2-C_1, H-O_8-C_2-C_3, H-O_9-C_3-C_2, H-O_9-C_3-C_4 (symboles minuscules).

Une première exploration de la surface d'énergie potentielle de la molécule d'hexose a été effectuée par la méthode MM2,[2] par rotation simultanée autour de deux dièdres endocycliques dans le cas du cycle pyranosique ou d'un seul dans le cas du cycle furanosique. Pour les formes α et β du D-talopyranose (notées respectivement αP et βP) nous avons optimisé les géométries en faisant varier l'angle dièdre 3-4-5-11 du cycle par pas de cinq degrés, de 0° à 60° et, pour chacune de ses valeurs, avec le même incrément et les mêmes limites, l'angle dièdre 11-1-2-3. Les courbes de niveau correspondantes ont permis de localiser correctement les minima. Pour chacune des deux formes du D-talofuranose, nous avons fait varier le dièdre 1-2-3-4 de −45° à +45° de 5 en 5 degrés.

Les conformations finales que l'on obtient correspondent à des minima locaux de la surface d'energie potentielle, pouvant servir de géométries initiales pour des calculs ultérieurs, mais pas forcément au minimum global en ce qui concerne l'orientation des substituants, en particulier des groupes OH. Elles dépendent en fait de la conformation initiale. Comme le nombre de degrés de liberté pour les molécules que nous avons étudiées est trop grand pour réaliser une analyse conformationnelle systématique, nous avons utilisé un échantillonnage de Monte Carlo sur 10 000 configurations générées chaque fois en partant de la moins fréquente et dans une fenêtre d'énergie stérique de 3 kcal mol^{-1}, au moyen du programme BATCHMIN de MACROMODEL (14) avec le champ de force MM2, les liaisons hydrogène étant simulées par des fonctions de Lennard–Jones 10–12. Qu'on parte d'une conformation initiale pyranosique $^1C_4$ ou $^4C_1$, cette méthode conduit uniquement à des conformations $^4C_1$ et à des conformations flexibles (bateaux et croisées) si on n'impose pas de contraintes sur les variations des dièdres endocycliques. Afin d'obtenir les conformations $^1C_4$, il a fallu imposer des variations des dièdres endocycliques limitées à ±55° à partir de αP^1C_4 et de βP^1C_4. Il en résulte 239 conformations αP^4C_1 (6,96–9,97 kcal mol^{-1}, 169,6° ≤ θ ≤ 176,3°) et 349 conformations βP^4C_1 (5,56–8,53 kcal mol^{-1}, 172,9° ≤ θ ≤ 179,5°, 46 flexibles αP(flex) (10,95–13,88 kcal mol^{-1}, 87,3° ≤ θ ≤ 92,4°), 79 chaises véritablement αP^1C_4 (11,81–13,94 kcal mol^{-1}, 2,8° ≤ θ ≤ 11,7°), 53 flexibles βP(flex) (10,82–13,81 kcal mol^{-1}, 88,4° ≤ θ ≤ 95,4°) et 25 chaises βP^1C_4 (13,00–13,83 kcal mol^{-1}, 4,7° ≤ θ ≤ 12,9°).

Les conformations furanosiques sont encore plus nombreuses à cause de la flexibilité du cycle et des possibilités d'orientation des hydroxyles et de la chaîne latérale -CHOH-CH_2OH et les écarts à la planéité (décrits par le paramètre q de Cremer) assez homogène : 807 conformations αF (10,53–13,53 kcal mol^{-1}, $0{,}308 \leq q \leq 0{,}390$) et 1051 βF (10,45–13,45 kcal mol^{-1}, $0{,}306 \leq q \leq 0{,}410$).

En phase gazeuse, la méthode de Monte Carlo, avec le champs de force MM2, prévoit donc un ordre de stabilité $\beta P^4C_1 > \alpha P^4C_1$ avec des traces des autres configurations.

Les conformations stables ainsi trouvées ont été réoptimisées complètement par la méthode AM1 (15). Beaucoup ont fusionné et d'autres sont sorties de la fenêtre de 3 kcal mol^{-1} (enthalpie de formation) relative à la plus basse dans chaque série. On a ainsi obtenu 15 conformations αP^4C_1 (ΔH_f compris entre −305,76 et −302,62 kcal mol^{-1}, $163{,}2° \leq \theta \leq 178{,}5°$); 16 conformations βP^4C_1 (−304,93 – −301,79 kcal mol^{-1}, $170{,}8° \leq \theta \leq 179{,}4°$); 12 conformations flexibles αP(flex) (−304,23 – −300,24 kcal mol^{-1}, $87{,}7° \leq \theta \leq 97{,}6°$) et 8 chaises αP^1C_4 (−301,58–300,06 kcal mol^{-1}, $4{,}7° \leq \theta \leq 20{,}6°$); 14 conformations flexibles βP(flex), (−304,21 – −301,11 kcal mol^{-1}, $87{,}0° \leq \theta \leq 97{,}5°$) et 11 chaises (−303,87 – −301,09 kcal mol^{-1}, $0{,}7° \leq \theta \leq 19{,}69°$); 13 conformations αF (−306,19 – −303,03 kcal mol^{-1}, $0{,}097 \leq q \leq 0{,}166$) et 20 βF (−304,76 – −301,53 kcal mol^{-1}, $0{,}092 \leq q \leq 0{,}286$). Les cycles furanosiques apparaissent légèrement plus applatis qu'avec le programme BATCHMIN (qui traite moins bien les liaisons hydrogène). Ensuite nous avons mis les conformères les plus stables en présence des cations et nous avons cherché pour chaque configuration de l'ose le complexe d'énergie la plus basse. Enfin, pour une des formes αP^4C_1 les plus stables, nous avons ajouté, une par une, six molécules d'eau près du site d'interaction cation–talose.

Resultats

Stéréisomères du D-talose

Les caractéristiques géométriques des formes cycliques les plus stables du D-talose (en phase gazeuse) sont consignées dans les tableaux 1*a*–1*c*. Les conformations semblent stabilisées chacune par un grand nombre d'interactions du type liaison hydrogène comme l'indiquent les distances entre atomes H et O de groupes hydroxyles voisins inférieures à la somme des rayons de van der Waals atomiques, mais avec des géométries défavorables en ce qui concerne les angles O—H...O. Les chélations les plus typiques (avec la distance H...O ≤ 2,5 Å et l'angle O—H...O > 110°) sont données dans les tableaux 2*a*–2*c*. Il n'apparait pas de relation nette entre le nombre de ces chélations typiques et les stabilités relatives des différents conformères.

Les populations de Boltzmann globales calculées (en phase gazeuse) pour les différentes structures cycliques du D-talose obtenues par la méthode AM1 sont respectivement de 16,69%, 1,13%, 0,03%, pour αPC_1 αP (flex), αP^1C_4; 6,02%, 1,44%, 0,85% pour βP^4C_1, βP (flex), βP^1C_4; 66,83% et 7,01% pour αF et βF. La précision des calculs ne permet pas le calcul exact des populations conformationnelles, mais permet de prévoir correctement qu'il y a mélange des stéréoisomères, avec des populations du même ordre de grandeur; les effets de solvant et les différences d'entropie liées aux rotations des groupes OH dans les positions axiales et équatoriales et aux flexibilités des cycles, n'ont pas été pris en compte pour les calculs des équilibres conformationnels.

L'anomère αP se présente majoritairement sous une forme chaise stable $^4C_1$ et de façon minoritaire sous des formes flexibles bateau et croisée; la forme chaise $^1C_4$ parait négligeable. De même l'anomère βP est surtout représenté par la chaise $^4C_1$ et quelques formes croisées et chaise $^1C_4$. Les formes flexibles sont plus gauchies que les chaises (valeurs plus élevées du paramètre q de Cremer). αF se présente comme un mélange de formes croisées et enveloppes assez aplaties, et βF plutôt comme un ensemble de formes enveloppes aussi plates. Les dessins correspondants aux conformères les plus stables de chaque série sont représentés sur les figures 1*a* et 1*b*.

Complexes cation–D-talose

L'étude a été réalisée avec les cations Pb^{2+} et Hg^{2+} (de numéro 25), sur l'ensemble des diastéréoisomères du D-talose décrits dans les tableaux 1*a*–1*c*. Pour chaque série, nous n'avons décrit dans les tableaux 3 et 4 que les complexes des cations dans une fenêtre énergétique de 3 kcal mol^{-1} au-dessus du plus stable. Pour les série $^1C_4$, les cations ont parfois induit la transformation de la chaise en forme flexible : les complexes correspondants ont alors été comptabilisés avec ceux de la même structure.

Cas de Pb^{2+}

Afin de déterminer le site privilégié de fixation de Pb^{2+} par exemple sur l'α-D-talopyranose (αP^4C_1), nous avons effectué différentes optimisations par AM1 en faisant varier la distance d entre Pb^{2+} et O_8 de 2 à 3,6 Å par incréments de 0,2 Å. Le tracé des courbes ΔH_f^0 et des indices de liaison Pb—O_8, Pb—O_9 et Pb—O_{10} en fonction de d, montrent que la distance optimale est obtenue pour $d \approx 2{,}3$ Å, ce qui correspond bien à la distance Pb—O observée dans les complexes cristallins de Pb(II) (16). À partir d'un complexe tricoordiné, nous avons ensuite fait varier une des autres distances Pb—O (ne correspondant pas à une liaison) par pas de 0,5 Å jusqu'à une distance de 2,3 Å afin de chercher d'autres types de coordination conduisant à des complexes stables. Nous avons opéré de même pour les autres isomères du talopyranose et du talofuranose décrits dans les tableaux 1*a*–1*c*. Les résultats obtenus figurent dans le tableau 3. Les complexes les plus stables sont visualisés dans les figures 2*a* et 2*b*. La considération des distances interatomiques Pb—O_i ainsi que des indices de liaison et l'examen des figures 2 montrent que Pb^{2+} se fixe toujours sur trois atomes d'oxygène, sauf pour les conformations les plus stables de αF pour lesquelles Pb^{2+} est tétetracoordiné. Les interactions de type liaison hydrogène sont très peu nombreuses et sont données dans le tableau 4. Pour les complexes stables, il en reste en général une seule, plus forte que celle signalée dans la forme correspondante de l'ose, parfois accompagnée d'une autre plus faible.

Pour les talopyranoses : il existe une séquence *ax-eq-ax* de trois groupes hydroxyle du cycle consécutifs pour αP^4C_1, βP^4C_1 et βP^1C_4. Effectivement, les coordinations avec le cation utilisent ces orientations pour les plus stables, mais pas uniquement (voir $\beta P^4C_1Pb^{2+}$). Pour αP^1C_4 (qui correspond aussi au complexe le moins stable), cette séquence n'existe pas et l'hydroxyle du groupe -CH_2OH est impliqué ainsi que deux hydroxyles du cycle. En ce qui concerne les formes flex-

[a]Dispositions de la chaîne exocyclique et des groupes OH décrites dans l'ordre pour C_6-O_{12} (dièdres O_{12}-C_6-C_5-O_{11}, O_{12}-C_6-C_5-C_4) (lettres majuscules), H-O_{12} (H-O_{12}-C_6-C_5, H-O_{12}-C_6-H), H-O_7 (H-O_7-C_1-O_{11}, H-O_7-C_1-C_2), H-O_8 (H-O_8-C_2-C_1, H-O_8-C_2-C_3), H-O_9 (H-O_9-C_3-C_2, H-O_9-C_3-C_4) et H-O_{10} (H-O_{10}-C_4-C_3, H-O_{10}-C_4-C_5).

[b]Les pourcentages ont été calculés selon une distribution de Boltzmann des populations en phase gazeuse de tous les isomères, en utilisant les ΔH_f^0, sans tenir compte des effets entropiques.

ibles, les coordinations peuvent aussi utiliser O_{18} comme le montre la figure 2*a*.

Pour les talofuranoses : la forme βF est la seule à posséder sur le cycle trois OH consécutifs en positions *cis-cis-cis*, et le cation est lié à ces trois groupes (tableau 3). Pourtant les complexes correspondants sont beaucoup moins stables que ceux de αF qui n'a pas cette séquence favorable et pour laquelle le cation est lié à l'oxygène de l'hétérocycle, à un hydroxyle du cycle et à un hydroxyle (voire deux pour αFPb 1 et 2) du groupe -CHOH-CH_2OH exocyclique (figure 2*b*).

Cas de Hg^{2+}

Les différentes formes de complexes figurant dans le tableau 3 ont été recaluculées par AM1, en remplaçant Pb par Hg. Nous avons cherché par la méthode décrite plus haut d'autres types de coordination plus stables. Les résultats obtenus sont consignés dans le tableau 5. On peut observer une coordination différente de celle des complexes du plomb. Elle est égale à 4 (voire 5) pour les formes les plus stables, et 3 pour les moins stables. Les liaisons hydrogène intramoléculaires peu nombreuses sont données tableau 6. Pour les talopyranoses : les prédictions d'Angyal concernant la séquence *ax-eq-ax* ne sont pas vérifiées pour αP^4C_1 et βP^4C_1. La configuration la plus stable est la forme flexible βP (flex) Hg^{2+} qui est pentacoordinée.

Mêmes conclusions pour les talofuranoses où la forme βF est encore de très loin la moins stable donc inexistante vis-à-vis de αF qui est tétracoordinée.

Addition de molécules d'eau sur le complexe

Afin d'avoir des renseignements sur les phénomènes primaires de solvatation en milieu aqueux, nous avons ajouté une à une jusqu'à six molécules d'eau sur un complexe de αP^4C_1

[a]Les orientations dans la chaîne CHOH-CH_2OH ont été décrites dans l'ordre par les dièdres O_{11}-C_5-C_4-O_{10}, O_{11}-C_5-C_4-C_3, C_6-C_5-C_4-O_{10}, C_6-C_5-C_4-C_3, O_{12}-C_6-C_5-O_{11}, O_{12}-C_6-C_5-C_4 (lettres majuscules) et celles des OH par les dièdres H-O_{12}-C_6-C_5, H-O_{12}-C_6-H, H-O_{11}-C_5-C_4, H-O_{11}-C_5-C_6, H-O_7-C_1-O_{10}, H-O_7-C_1-C_2, H-O_8-C_2-C_1, H-O_8-C_2-C_3, H-O_9-C_3-C_2, H-O_9-C_3-C_4 (lettres minuscules).

[b]Même légende que pour le tableau 1*a*.

tion aqueuse, les résultats de la RMN donnent : αP = 29%, βP = 20%, αF = 20% et βF = 11% (17). Cette différence est vraisemblablement due à la prédominance des liaisons hydrogène intramoléculaires dans le cas du ligand isolé, et aux liaisons hydrogène intermoléculaires en milieu aqueux. On peut également observer que dans le cas des pyranosiques, les formes αP^4C_1 sont avantagées par rapport aux βP^4C_1, alors que les formes βP^1C_4 sont avantagées par rapport aux αP^1C_4. De même pour les furanosiques, les formes α sont prévues plus stables que les formes β. Ce résultat est en accord avec l'effet anomère (11, 12) qui stabilise en phase gazeuse la conformation pour laquelle le OH anomère est axial. Les orientations privilégiées des groupements exocycliques par rapport aux liaisons C_5—O_{11} et C_5—O_4 pour les formes pyranosiques sont dans l'ordre GG et GT; pour les furanosiques, par rapport aux liaisons C_5—O_{10} et C_5—O_4 : GG, GT, GP et GG, GT, GG. Il n'y a pas de règle générale pour les positions des liaisons OH du cycle.

Complexes cations–D-talose

Dans le cas des formes pyranosiques de plus basse énergie, l'orientation de la chaîne exocyclique est en général inchangée par rapport au ligand isolé. L'orientation GG reste prédominante à l'exception de $\beta P^1C_4Pb^{2+}$ orienté PG. Les orientations des OH du cycle quant à elles sont en général modifiées car les liaisons hydrogène intramoléculaires deviennent négligeables devant la forte liaison de coordination avec le cation. À l'inverse, les formes furanosiques ne conservent pas l'orientation de la chaîne exocyclique plus longue donc plus apte à se déformer pour participer à la liaison de coordination. On peut

[a]Chélation O_a—H...O_b : *r* = distance H...O_b en Å; θ = angle (O—H...O) en degrés.

remarquer pour les formes αF, qui sont les plus stables, que deux sites de coordination sont constitués par les atomes d'oxygène 11 et 12 de la chaîne exocyclique, portant ainsi la coordination totale à 4. Cette dernière est plus stable que la coordination 3 sur les sites hydroxyles consécutifs du cycle en position *cis-cis-cis*.

Un résultat important de cette étude est que, en milieu isolé, l'association du D-talose avec Hg^{2+} est beaucoup plus forte que celle avec Pb^{2+}. On peut constater en effet que dans les complexes isolés le mercure est plus fortement lié aux atomes d'oxygène du ligand que le plomb, aussi bien en ce qui concerne les énergies de liaison que le nombre de coordinations : tétracoordinances nombreuses, voire pentacoordinance avec Hg; coordinance 3 et une seule conformation de plus basse énergie tétracoordinée avec Pb. Calculons, par exemple, dans le cas des formes αP^4C_1 de plus basse énergie, les enthalpies des réactions de complexation suivantes :

[2] $\alpha P + Hg^{2+} = (\alpha PHg)^{2+}$

Les valeurs des enthalpies de formation des différents réactifs sont données dans les tableaux ou dans la littérature en ce qui concerne les cations (17). Avec $\Delta H_f(Pb^{2+}) = 514$ kcal mol^{-1} et $\Delta H_f(Hg^{2+}) = 668$ kcal mol^{-1}, on trouve $\Delta H_1 = -70{,}2$ kcal mol^{-1} et $\Delta H_2 = -185{,}9$ kcal mol^{-1}. La différence de l'ordre de 115 kcal mol^{-1} est tellement grande que la contribution entropique à la stabilité des complexes, négligée dans ce calcul, ne semble pas être en mesure d'inverser le phénomène, tout du moins à basse température. Les calculs effectués sur les autres formes donnent des résultats du même ordre de grandeur, étant donné la différence importante d'enthalpies de formation des cations.

En milieu aqueux on a pu mettre en évidence de nombreux complexes hexoses–Pb^{2+}, mais jamais de complexes hexoses–Hg^{2+} (7). Notre étude montre qu'en phase gazeuse c'est l'inverse qui devrait se produire. On sait que dans les associations hexoses–cations, la constante d'association est controlée par les modifications de l'hydratation des espèces, lorsque les molécules d'eau solvatant le cation sont remplacées par les groupes hydroxyle des formes complexées de l'hexose (5). Dans cette optique, il est préférable d'examiner les résultats du système lié à quelques molécules d'eau.

Systèmes (complexes, *n* H_2O)

On note un processus d'hydratation nettement différent pour chacun des deux complexes. L'addition jusqu'à deux molécules d'eau sur l'ion Pb^{2+} ne modifie pas son mode de liaison tricoordiné avec le ligand. Cependant, au bout de la troisième addition, on observe la rupture d'une liaison avec le ligand. Si on poursuit encore l'addition, trois molécules d'eau restent liées au plomb et les nouvelles s'éloignent du site pour former des liaisons hydrogène avec des atomes du ligand situés à proximité ou des molécules d'eau déja liées. Ce résultat montre que, dans ce cas, le mode de liaison serait plus conforme aux conclusions de Reeves (19) qui énonce que la formation d'un tel complexe requiert la présence de deux groupements hydroxyle proches : un équatorial et un axial (ou deux équatoriaux) sur deux atomes de carbone adjacents au cycle.

En ce qui concerne αPHg, les quatre liaisons initiales avec le ligand restent inchangées jusqu'à la troisième addition ou la coordinance baisse à trois et les molécules d'eau sont toutes liées au mercure. À partir de la quatrième addition, et au dela, il en accepte quatre. Ceci indique là encore, un mode de liaison plus intense pour le complexe mercurique, comme le confirment des liaisons métal–oxygène plus courtes et des indices de liaison plus grands que pour les complexes du plomb.

Nous avons effectué le calcul AM1 concernant le système formé par le ligand αP^4C_1 et six molécules d'eau; l'enthalpie de formation correspondante est $\Delta H_f^0 = -709{,}81$ kcal mol^{-1}. Si on calcule les enthalpies de complexation des réactions suivantes :

[3] $(\alpha P, 6H_2O) + Pb^{2+} = (\alpha PPb, 6H_2O)^{2+}$

[4] $(\alpha P, 6H_2O) + Hg^{2+} = (\alpha PHg, 6H_2O)^{2+}$

la difference $\Delta H_4 - \Delta H_3 = 144$ kcal mol^{-1}. Cela veut dire que dans le système à six molécules d'eau, la complexation est encore plus favorable pour le mercure que pour le plomb. Des mesures effectuées au laboratoire sur des complexes hexoses–Ca^{2+} ont montré que les constantes d'association, qui sont faibles lorsque le phénomène de complexation existe, résultent d'une large compensation entre une enthalpie favorable et une entropie défavorable due essentiellement à l'hydratation. On pourrait expliquer l'inversion du phénomène en milieu aqueux par un effet entropique d'hydratation beaucoup plus défavorable pour αPHg que pour αPPb. La corrélation entre les enthalpies et entropies d'association mise en évidence expérimentalement (5) nous suggère que l'effet enthalpique, beaucoup plus favorable pour le mercure, entrainerait un effet promoteur sur les molécules d'eau de la couche de première hydratation. Cela augmenterait la structure globale du solvant par effets coopératifs, et en conséquence l'effet entropique de solvatation défavorable à l'association. On peut remarquer un comportement semblable si l'on considère les grandeurs thermodynamiques d'association du cation Ca^{2+} avec respectivement le D(+)talose, le D(−) ribose, et le D(+) allose. Les données expérimentales (5) sont pour les réactions d'association en solution aqueuse à dilution infinie et à 298,15 K :

	ΔH^θ (kJ Mol^{-1})	$T\Delta S^\theta$ (kJ mol^{-1})	ΔG^θ (kJ mol^{-1})
D(+) talose	−18,6	−17,7	−0,9
D(−) ribose	−16,6	−14,9	−1,7
D(+) allose	−15,9	−13,0	−2,9

ce qui montre que pour un cation divalent donné, plus l'effet enthalpique est favorable, plus l'effet entropique est défavorable. De plus en milieu aqueux le processus de complexation peut être envisagé en deux étapes :

(1) une deshydratation partielle du cation

$$Pb(H_2O)_6^{2+} \rightarrow Pb(H_2O)_3^{2+} + 3\ H_2O$$

$$Hg(H_2O)_6^{2+} \rightarrow Hg(H_2O)_4^{2+} + 2\ H_2O$$

(2) complexation par le ligand

$$\alpha P + Pb(H_2O)_3^{2+} \rightarrow [\alpha PPb(H_2O)_3]^{2+}$$

$$\alpha P + Hg(H_2O)_4^{2+} \rightarrow [\alpha PHg(H_2O)_4]^{2+}$$

ce qui donne le bilan

[5] $Pb(H_2O)_6^{2+} + \alpha P \rightarrow [\alpha PPb(H_2O)_3]^{2+} + 3\ H_2O$

[6] $Hg(H_2O)_6^{2+} + \alpha P \rightarrow [\alpha PHg(H_2O)_4]^{2+} + 2\ H_2O$

Les équations [5] et [6] mettent en évidence une autre contribution entropique beaucoup moins favorable pour les complexes du mercure (passage de 2 espèces libres à 3 au lieu de 2 à 4 pour ceux du plomb).

Dans le cas général, cette addition de molécules d'eau sur le site de complexation ne permet pas d'apporter de conclusions définitives quant à l'hydratation du ligand ou du complexe car le modèle ignore l'environnement dynamique du solvant, sa structure et l'effet entropique global exact. Aussi, dans un article ultérieur, nous présenterons une exploration plus systéma-

tique de l'espace des phases en examinant les différentes formes étudées ici en simulant également l'environnement aqueux par la dynamique moléculaire ou la méthode de Monte Carlo. Ces méthodes, qui présentent l'inconvénient de ne pas bien prendre en compte les effets stéréoelectroniques et les liaisons hydrogène, permettent malgré tout une meilleure simulation des espèces en solution. Un calcul de l'enthalpie libre d'hydratation permettrait de confirmer notre hypothèse et répondre à d'autres questions très importantes. Pourquoi, par exemple, les formes βFPb^{2+} dont les enthalpies de formation sont beaucoup plus élevées que celles des αFPb^{2+} sont les seules à avoir été mises en évidence par la RMN (8, 9)?

Méthodes de calcul

Le programme MM2 $(85)^2$ a permis l'exploration initiale de la surface d'énergie potentielle. L'option AM1 (15) implantée dans le programme MOPAC[3] a été utilisée. Toutes les géométries ont été complètement optimisées par les procédures BFGS suivie de EF. L'indice de liaison entre deux atomes A et B est celui donné par MOPAC[3] et défini par

$$P_{AB} = \sum_{\lambda}^{\epsilon A} \sum_{\sigma}^{\epsilon A} \sigma P_{\lambda\sigma}{}^2 \quad \text{avec} \quad P_{\lambda\sigma} = 2 \sum_{i}^{OCC} C_{i\lambda} C_{i\sigma}$$

où $C_{i\lambda}$ est le coefficient LCAO pour l'orbitale atomique dans l'orbitale moléculaire occupée Φ_i. À cause de la somme des carrés des $P_{\lambda\sigma}$, des contributions antiliantes (négatives) entre atomes sont remplacées par des valeurs positives, ce qui peut augmenter des indices de liaison apparents. Des données complémentaires (coordonnées, orbitales moléculaires, grandeurs thermodynamiques) sont disponibles auprès des auteurs.

Remerciements

Les calculs ont été effectués sur l'ordinateur Vax 6410 du centre de calcul de l'Université Blaise Pascal, les stations de travail DEC α400 et α300 du Département de Chimie.

Nous remercions Monsieur le Professeur J.P. Morel pour les discussions fructueuses que nous avons eues avec lui.

For personal use only.

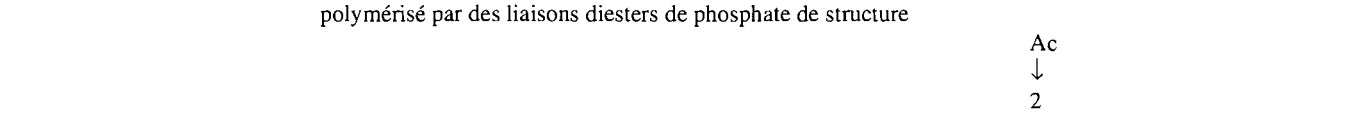
Abstract: The specific capsular antigen of *Streptococcus pneumoniae* serotype 35B was shown by a combination of 2D NMR methods and mass spectrometric and classical carbohydrate chemical techniques to be a high molecular weight polymer containing D-galactose, D-glucose, 2-acetamido-2-deoxy-D-galactose, and ribitol (2:1:1:1). The pentasaccharide repeating unit is polymerized through phosphate diester linkages to give the structure,

Seventy percent of the β-D-Gal_f residues glycosidically linked to the ribitol units carry an *O*-acetyl substituent.

Key words: *Streptococcus pneumoniae*, capsular antigen, polysaccharide structure.

Résumé : Faisant appel à des méthodes de RMN bidimensionnelles, de spectrométrie de masse et de techniques chimiques classiques de hydrates de carbone, on a montré que l'antigène capsulaire spécifique du *Streptococcus pneumoniae*, sérotype 35B, est un polymère de masse moléculaire élevée contenant du D-galactose, du D-glucose, du 2-acétamido-2-désoxy-D-galactose et du ribitol (2 : 1 : 1 : 1). Le motif pentasaccharidique est polymérisé par des liaisons diesters de phosphate de structure



Soixante-dix pour cent des résidus β-D-Gal_f, qui ont un lien glycosidique avec des unités de ribitol, portent un substituant *O*-acétyle.

Mots clés : *Streptococcus pneumoniae*, antigène capsulaire, structure du polysaccharide.

[Traduit par la rédaction]

Introduction

Streptococcus pneumoniae persists as a cause of pneumonia, meningitis, and otitis media despite the availability of antibiotic therapy and capsular polysaccharide vaccines. The composition of the current 23-valent polysaccharide vaccine is based on the serotypes responsible for approximately 90% of infections in the U.S.A. (1). However, the serology of disease isolates varies over time and with the geographical area. Studies on Asian populations have shown that a large proportion of pneumococcal types found in Asia, such as 15A, 23A, 24F, 27, and 34, are not present in the pneumococcal vaccines; furthermore, isolates consisting of the serogroup 35 have been identified in Japan, Taiwan, and China (2). Thus, it may be necessary to develop supplementary vaccines to include some additional types of pneumococcal polysaccharide antigens for use in Asian countries.

Within the group 35 of *S. pneumoniae* four serotypes (35F, 35A, 35B, and 35C) have been recognized and, by the use of factor sera, seven factors (20b, 29b, 34b, 35a, 35b, 35c, and 42a) have been determined (3) although the structural basis for the factors is as yet unknown. *Streptococcus pneumoniae* serotype 35B shows a strong heterologous cross-reaction with antiserum raised against serotype 29 (3). To demonstrate the molecular basis for this observed serological cross-reactivity

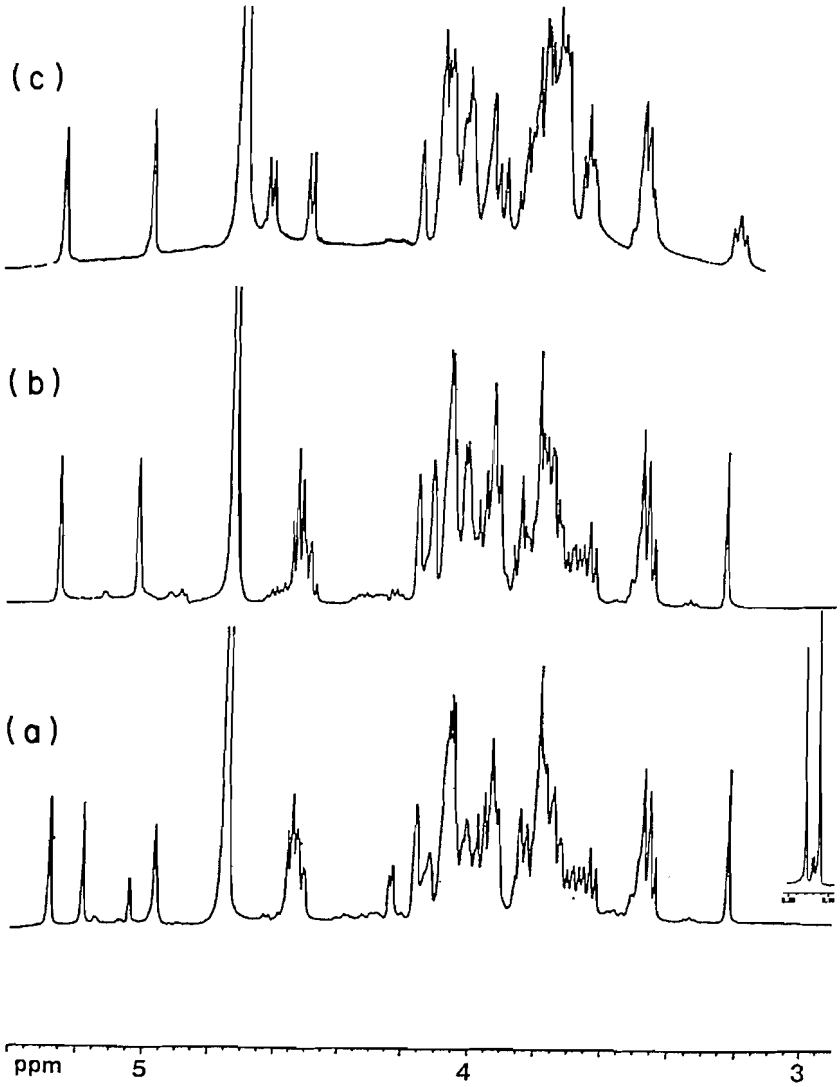
Fig. 1. The ^{1}H NMR spectra (2.90–5.40 ppm) of the *S. pneumoniae* serotype 35B native capsular polysaccharide (*a*), *O*-deacetylated capsular polysaccharide (*b*), the pentasaccharide repeating unit **1** (*c*). Insert in Fig. 1*a*: the high-field region 2.00–2.25 ppm showing the singlets for the methyl protons of the *N*- (2.05 ppm) and the *O*-acetyl (2.15 ppm) substituents.



we now report the results of the structural analysis of serotype 35B capsular polysaccharide.

Results and discussion

Type-specific polysaccharide was isolated from the spent growth medium of *S. pneumoniae* serotype 35B cells. The polysaccharide eluted as the void volume fraction on a Sephadex G-50 gel filtration system, indicating it to be a high molecular weight polymer. This material was further purified by DEAE–Sephacel ion-exchange chromatography where it eluted as a homogeneous fraction in a sodium chloride gradient. The polysaccharide obtained was homogeneous across the fraction for neutral glycoses, aminodeoxyglycoses, and phosphate and had $[\alpha]_D$ −34.7 (*c* 0.7, water). Anal. found: C 35.0, H 6.3, N 1.4, ash 7.9%. The phosphate content was determined colorimetrically to be 8.0%.

Complete acid hydrolysis of the 35B polysaccharide and GLC–MS of the derived alditol acetates gave D-Gal, D-Glc, D-GalN, and ribitol in the molar ratios 1.8:1.0:0.4:0.4. A fifth product was tentatively identified as anhydroribitol on the basis of the GLC–EI-MS spectrum. The absolute configurations of the residues were established by GLC of their trimethylsilylated *R*-(+)-methylbenzylamine derivatives (4).

The low-field region of the ^{1}H NMR spectrum of the native polysaccharide contained four signals at 5.28, 5.18, 5.04, and 4.97 ppm (relative intensities, 1.0:0.7:0.3:0.7) (Fig. 1*a*, Table 1). *O*-Deacylation of the native polysaccharide resulted in the disappearance of the signals at 5.18 and 4.97 ppm (Fig. 1*b*, Table 1) and an increase in the relative intensity of the signal at 5.04 ppm to 1.0. The region of the spectrum between 4.50 and 4.60 ppm contained three doublets at 4.55 ($J_{1,2}$ 7.8 Hz), 4.54 ($J_{1,2}$ 7.8 Hz), and 4.52 ($J_{4,5} \leq 1.0$, $^3J_{H,P}$ 8.0 Hz), and the high-field region contained two singlets at 2.05 and 2.15

umn I) showed the polysaccharide contained *O*-3 substituted D-Glc_p, *O*-6 substituted D-Gal_f, and ribitol residues substituted at *O*-1. The absence of D-Gal_pN residues suggested that these residues were substituted by phosphate.

The structure of the polysaccharide antigen was determined from analysis of the fully assigned ^1H and ^{13}C NMR spectra of the native and *O*-deacetylated polysaccharides and derived oligosaccharides. These assignments were accomplished via a combination of homo- and heteronuclear chemical shift correlation techniques. The COSY spectrum of the *O*-deacetylated polysaccharide contained resonances for four anomeric protons, which were labelled **a**, **b**, **c**, **d** in order of decreasing chemical shift. The resonances corresponding to the β-D-Glc_p residue (**d**) were well resolved and the corresponding subspectrum was readily identified on the basis of the observed proton coupling constants (Table 1). The relatively deshielded values of H-3**d** (3.64 ppm) and C-3**d** (82.9 ppm) compared with those of published data (5) indicated the β-D-Glc_p residue to be substituted at the *O*-3 position. Direct correlation of the resonance for H-2**c** (3.97 ppm) to the corresponding C-2**c** (53.0 ppm) resonance permitted **c** to be identified as the D-Gal_pN residue characterized by chemical analysis. The low-field position (73.5 ppm) and the heteronuclear coupling ($^2J_{C,P}$ 5.9 Hz) observed for the resonance of C-4**c** indicated substitution by phosphate of the D-Gal_pNAc residue at this position.

Identification of the subspectra corresponding to the two β-D-Gal_f residues **a** and **b** was more difficult in part, due to strong coupling between H-3**a** and H-4**a** that precluded measurement of the vicinal coupling constants for residue **a**. The assignment of the ^1H resonances of residues **a**, **b**, and **e** was achieved partially via the corresponding ^{13}C resonances in the

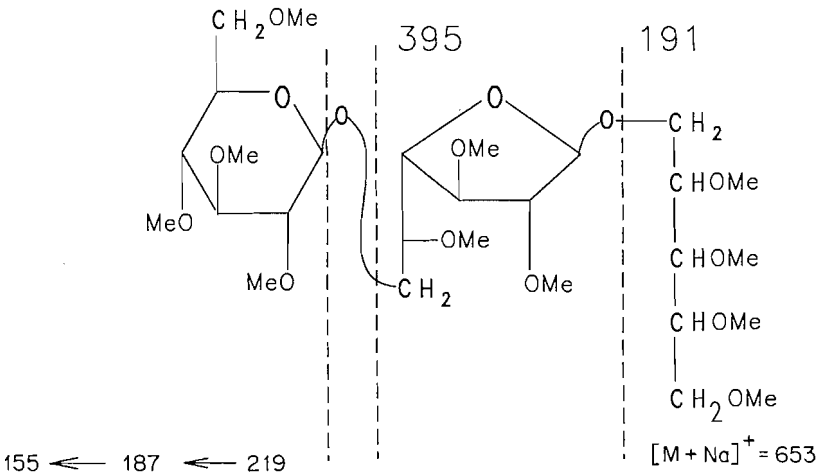
^{1}H–^{13}C chemical shift correlation spectrum with reference to published data (5, 6). Comparison of the chemical shifts for H-2**b** (4.13 ppm) and C-2**b** (81.5 ppm) of the *O*-deacetylated polysaccharide with those for H-2**b** (4.97 ppm) and C-2**b** (83.4 ppm) of the native polysaccharide indicated C-2 to be the site of *O*-acetyl substitution. The downfield shift of the resonances for C-1**e** (68.1 ppm) and C-5**e** (67.5 ppm) in comparison to those of unsubstituted ribitol (C-1 and C-5, 61.8 ppm) suggested that the ribitol residue is linked through both C-1 and C-5 positions. Since only a single phosphate group was indicated by ^{31}P NMR spectroscopy (1.41 ppm) it is probable, from the evidence presented so far, that the repeating unit contains the phosphate diester fragment,

→1)-ribitol-(5→PO$_4$→4)-β-D-Gal$_p$NAc-(1→

Depolymerization of the O-polysaccharide

The polysaccharide was heated in 1 M NaOH containing a trace amount of NaBH$_4$ and subsequently treated with alkaline phosphatase to remove residual phosphate. Fractionation of the sample on a Bio-gel P2 column gave a pentasaccharide **1** (K_{av} 0.38) (Scheme 1), which had $[\alpha]_D$ −42.6 (*c* 2.3, water) and which showed a single discrete spot (R_f 0.09) on analysis

Fig. 3. Fragment ions obtained on GLC–CI-MS analysis of oligosaccharide **3**.



by TLC. FAB-MS of underivatized **1**, in the negative ion mode, gave a $[M - H]^-$ ion at *m/z* 799 and diagnostic fragment ions at *m/z* 637 and 475 (see Fig. 2). Methylation analysis of **1** gave 2,3,4,5-tetra-*O*-methylribitol, 2,4,6-tri-*O*-methylglucitol, 2,3,5-tri-*O*-methylgalactitol, and 2-deoxy-3,4,6-tri-*O*-methy-2-(*N*-methylamino)-galactitol (Table 3, column II).

The ^1H NMR of spectrum of **1** contained four signals in the region for anomeric protons at 5.28 ($J_{1,2}$ 1.6 Hz), 5.01 ($J_{1,2}$ 1.6 Hz), 4.66 ($J_{1,2}$ 8.5 Hz), and 4.51 ppm ($J_{1,2}$ 7.8 Hz) (Fig. 1*c*). A DEPT experiment showed four resonances for anomeric carbons at 108.9, 108.0, 103.3, and 100.9 ppm and five signals for CH_2 at 72.1, 71.9, 69.0, 63.2, 61.6, and 61.0 ppm. The ^1H and ^{13}C NMR spectra were fully assigned using COSY and ^1H–^{13}C chemical shift correlated spectroscopy (Tables 1 and 2). The resonances for H-4**c** (3.94 ppm), C-4**c** (68.4 ppm) and H-5**e**/5′**e** (3.78/3.64 ppm) and C-5**e** (63.2 ppm) were shifted upfield in comparison to those of the native and *O*-deacetylated polysaccharides (Tables 1 and 2) confirming substitution at these positions in these polymers. The sequence of the residues in **1** was determined from a three-bond {HMBC} ^1H–^{13}C chemical shift correlation experiment. The resonances for C-1**a** (108.9 ppm) and C-1**b** (108.0 ppm) showed cross-peaks at H-3**d** (3.63 ppm) and H-1**e**/1′**e** (3.84/3.73 ppm), respectively. The resonance for C-1**c** (100.9 ppm) showed cross-peaks at H-6**a** (3.74 ppm) and H-6′**a** (4.08 ppm), and that of C-1**d** at H-6**b** (3.74 ppm) and H-6′**b** (4.04 ppm). In addition, C-1**c** showed a strong cross-peak at H-2**c** (3.18 ppm), and C-1**d** at H-2**d**/4**d** (3.44 ppm).

Taken together these results allow the structure of **1** to be assigned as,

$$\begin{array}{l} \quad\quad\quad\

35B (7, 8). It differs in the replacement of the β-D-Glc_p residue in the 35B polysaccharide by a β-D-Gal_p residue and also in the lack of *O*-acetyl substituents (8).

$$[\rightarrow 4)\text{-}\beta\text{-D-}Gal_pNAc\text{-}(1\rightarrow 6)\text{-}\beta\text{-D-}Gal_f\text{-}(1\rightarrow 3)\text{-}\beta\text{-D-}Gal_p\text{-}(1\rightarrow 6)\text{-}\beta\text{-D-}Gal_f\text{-}(1\rightarrow 1)\text{-ribitol-}(5\rightarrow PO_4\rightarrow]_n$$

The serological cross-reactivity between *S. pneumoniae* serotypes 35B and 29 is probably related to a structure contained in the common tetrasaccharide component that includes the phosphate diester linkage. The ribitol unit of the *S. pneumoniae* serotype 29 capsular polymer was assigned the D configuration on biosynthetic grounds (7). The absolute stereochemistry of the ribitol residue in the 35B polymer will be determined using the methodology developed by Beynon and Richards (9) for the assignment of the configuration of the glycerol residue in polymers joined by →1)-glycerol-(3→phosphodiester linkages.

Experimental

Isolation of the capsular polysaccharide

Serotype 35B capsular polymer was isolated by ethanol precipitation (50–55% final concentration) from the growth media followed by digestion with DNase, RNase, and trypsin and subsequent fractional precipitation with 2-propanol and serological probing (10) of the fractions. The polysaccharide eluted in the void volume fraction on a Sephadex G-50 column and was further purified by ion exchange chromatography on DEAE–Sephacel as described previously (11).

Analytical methods

Quantitative colorimetric methods used were (*i*) phenol–sulphuric for neutral glycoses (12), (*ii*) the method of Chen et al. for phosphate (13), and (*iii*) the modified Elson-Morgan for aminoglycoses (14).

Analytical GLC–MS was done with a Hewlett–Packard 5985B system and an OV-17 fused silica column (Quadrex Corp.) using an ionization potential of 70 eV (EI) or with ammonia as the reagent gas (CI). The following programs were employed: A (for alditol acetates), 180°C for 2 min, then 4°C/min to 240°C; B (for partially methylated alditol acetates and trimethylsilylated R-(+)-methylbenzylamine derivatives), 180°C for 2 min then 2°C/min to 240°C; C (for methylated oligosaccharides), 210°C for 1 min, then 10°C/min to 290°C.

For analysis of constituent sugars, samples (1 mg) of polysaccharide were hydrolyzed with 4 M trifluoroacetic acid for 1 h at 125°C, and the excess acid was removed by evaporation under a stream of nitrogen gas. Glycoses were determined by GLC–MS of their derived alditol acetates (15).

Methylations were carried out using the method of Ciucanu and Kerek (16). Briefly, to samples (1–2 mg), dissolved in dry DMSO was added powdered NaOH (20–30 mg), followed by iodomethane (0.2 mL), and the mixture stirred for 10 min (15). The products were isolated by partition between dichloromethane and water and the methylated oligosaccharides were analyzed directly by FAB-MS and (or) GLC–CI- and GLC–EI-MS. The methylated products were subsequently hydrolyzed as above, and the methylated glycoses converted to their alditol acetates and analyzed by GLC–EI-MS.

FAB-MS analyses were carried out in the positive and negative ion mode using a JEOL AX505-H mass spectrometer. An accelerating voltage of 3 kV and a mass resolution of 1500 were employed. A Xe atom beam of 5 kV was used to sputter and ionize the sample.

TLC was performed on silica gel (Merck) with 6:3:1 (v/v) *n*-propanol – concentrated NH_3 – water.

NMR spectroscopy

All measurements were made on solutions in D_2O, at 27°C, using a Bruker AMX-500 spectrometer.

Proton spectra, recorded at 500 MHz, were obtained using a spectral width of 1.8 kHz and a 90° pulse. Chemical shifts are expressed relative to internal acetone (δ_H, 2.225 ppm).

Broad-band decoupled ^{13}C NMR spectra were obtained at 125 MHz with a spectral width of 33 KHz and a 90° pulse employing WALTZ decoupling (17). DEPT spectra (18) were obtained with broadband decoupling, a 135° pulse, and a 3.3-ms delay between pulses. Chemical shifts are expressed relative to internal acetone (δ_C, 31.07 ppm).

Phosphorus-31 spectra were recorded at 202 MHz by employing a 90° pulse and a spectral width of 10 KHz. Chemical shifts are referenced to that of an external sample of aqueous 25% phosphoric acid (δ_P 0.0 ppm).

Two dimensional homonuclear chemical shift correlated (COSY) experiments were carried out as previously described (19). The heteronuclear ^{13}C–^1H chemical shift correlations were measured in the ^1H-detected mode via multiple quantum coherence ($^1H\{^{13}C\}$HMQC) with a Bruker 5-mm inverse broadband probe using reverse electronics as previously described (20). The 2D heteronuclear multiple bond correlated ^1H–$^{13}C(^1H\{^{13}C\}$HMBC) experiment on **1** was carried out using the pulse sequence described by Bax and Summer (21).

Depolymerization of the O-polysaccharide

Polysaccharide (30 mg), in 1 M NaOH (6 mL) containing a trace amount of $NaBH_4$, was heated at 100°C for 4 h. The cooled solution was neutralized with glacial CH_3COOH and concentrated via rotary evaporation under reduced pressure. The product was fractionated on a column of Bio-gel P2 and the glycose-positive fractions were pooled and lyophilized. The product (9 mg), dissolved in 0.05 M ammonium carbonate buffer, was mixed with alkaline phosphatase (0.4 mg, Sigma Chemical Co.) dissolved in the same buffer (0.3 mL) and the pH of the solution was adjusted to 10. The mixture was left to react at 37°C for 30 h and was subsequently fractionated on a column of Bio-Gel P2 to give pentasaccharide **1** (K_{av} 0.38).

Polysaccharide (40 mg) was treated with 48% HF at 0°C for 8 h. The reaction was quenched with a mixture of dichloromethane, Dry Ice, and calcium carbonate. Following low-speed centrifugation to remove insoluble material the product was fractionated by Bio-gel P2 chromatography to give oligosaccharides **2** (K_{av} 0.75) and **3** (K_{av} 0.67).

Acknowledgments

We thank Mr. F. Cooper for the expert GLC–MS and FAB analyses.

Oxygen transfer reactions. 3. The oxidation of sulfides by sodium perruthenate

Donald G. Lee and Huifa Gai

Abstract: The transfer of oxygen from transition metal oxidants to sulfur ($MO_4^- + R_2S \rightarrow MO_3^- + R_2SO$) has been studied using the oxidation of alkylthio or arylthioacetic acids ($RSCH_2CO_2H$) by perruthenate as models. These reactions exhibit a first-order dependence on the concentrations of both the oxidant and the reductant, and are directly proportional to the basicity of the medium. The Hammet ρ value is negative ($\rho = -0.66$), a better correlation being obtained when σ, rather than σ^+, substituent constants are used. The entropies of activation for the reactions are large and negative, indicating that the transition state is highly structured. A reaction mechanism involving an activating expansion of the ruthenium coordination shell through incorporation of a hydroxide ion is proposed. Oxygen transfer is then initiated by reaction of a nonbonding pair of sulfur electrons with either a vacant ruthenium *d*-orbital or a Ru=O π*-orbital.

Key words: perruthenate, sulfides, oxygen transfer, oxidation.

Résumé : Utilisant l'oxydation des acides alkylthio- et arylthioacétiques ($RSCH_2CO_2H$) par le perruthénate comme modèles, on a étudié le transfert d'oxygène des métaux de transition oxydants au soufre ($MO_4^- + R_2S \rightarrow MO_3^- + R_2SO$). Ces réactions présentent une corrélation du premier ordre avec les concentrations à la fois de l'oxydant et du réducteur et leurs vitesses sont directement proportionnelles avec la basicité du milieu. La valeur ρ de Hammett est négative ($\rho = -0{,}66$) et on obtient une meilleure corrélation lorsqu'on utilise des constantes de substituants σ plutôt que σ^+. Les entropies d'activation des réactions sont importantes et négatives; ceci indique que l'état de transition est fortement structuré. On propose un mécanisme de réaction impliquant une expansion activante de la couche de coordination du ruthénium par l'incorporation d'un ion hydroxyde. Le transfert d'oxygène est souvent initié par une réaction d'une paire non liée d'électrons du soufre avec soit une orbitale *d* du ruthénium, soit une orbitale π* du Ru=O.

Mots clés : perruthénate, sulfures, transfert d'oxygène, oxydation.

[Traduit par la rédaction]

Introduction

Oxygen transfers, a subset of a larger group of reactions generally referred to as oxidations, are necessary steps in the synthesis of a number of commercially important organic compounds (1) as well as being involved in certain essential biochemical processes (2). A better understanding of these reactions could, consequently, have implications for both commerce and health.

Although biochemical oxygen transfer agents are usually porphyrin-complexed metals such as those found in hemoglobin (3, 4), while the oxidants used in organic syntheses are often high-valent transition metal oxides, oxyanions (5), or complexes (6), all contain metal-oxo functional groups that are believed to be essential participants in transfer reactions; i.e., $L_nMO + R_2S \rightarrow L_nM + R_2SO$. Metals most widely used for these purposes are titanium (7, 8), vanadium (9), chromium (10), manganese (11), iron (12), molybdenum (13), ruthenium (14), and osmium (15). Most prominent among the latter are ruthenium oxo compounds that can exist as RuO_4 (14), RuO_4^- (16–21), RuO_4^{2-} (21–23), RuO_2 (24), or as complexes in oxidation states 2 (25), 3 (26), 4 (26–29), 5 (26, 28, 30), and 6 (26, 27, 28, 31, 32).

In this paper we wish to describe results that have been obtained from a study of one oxygen transfer reaction: the conversion of alkyl and arylthioacetates ($RSCH_2CO_2^-$) into the corresponding sulfoxides by treatment with perruthenate ion in aqueous base (eq. [1]). The reaction has been monitored using stopped-flow spectrophotometry to determine the rate law as well as substituent and temperature effects.

$$\text{[1]}\quad ArSCH_2CO_2^- + 2RuO_4^- + 2OH^- \longrightarrow ArSOCH_2CO_2^- + 2RuO_4^{2-} + H_2O$$

Experimental section

Materials

All reagents were of analytical grade. Water was purified by double distillation, the second time from alkaline permanganate.

Substituted acetic acids ($RSCH_2CO_2H$) were used as substrates to ensure good solubility in aqueous alkaline solutions. (Methylthio)acetic acid was obtained commercially (Fluka) in analytically pure form and used without further purification. (Phenylthio)acetic acid was also obtained commercially (Fluka) and recrystallized from carbon tetrachloride before

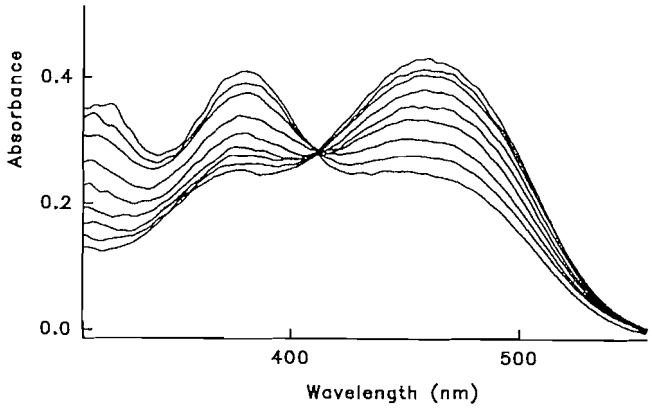
Fig. 1. Sequential scans obtained during the oxidation of (phenylthio)acetic acid (0.01 M) by perruthenate (2×10^{-4} M) in 0.3 M NaOH, at 0.2 s intervals.



use, mp 63.0–63.5°C (lit. (33) mp 63.5°C). Substituted (phenylthio)acetic acids were synthesized by reaction of substituted thiophenols with bromoacetic acid as previously described (34).

Sodium perruthenate solutions were prepared by distillation of ruthenium tetroxide on a stream of nitrogen into 0.3 M NaOH at 0°C (21). After standing at 5°C overnight, the solutions exhibited an absorption spectrum identical to that previously reported for sodium perruthenate (35).

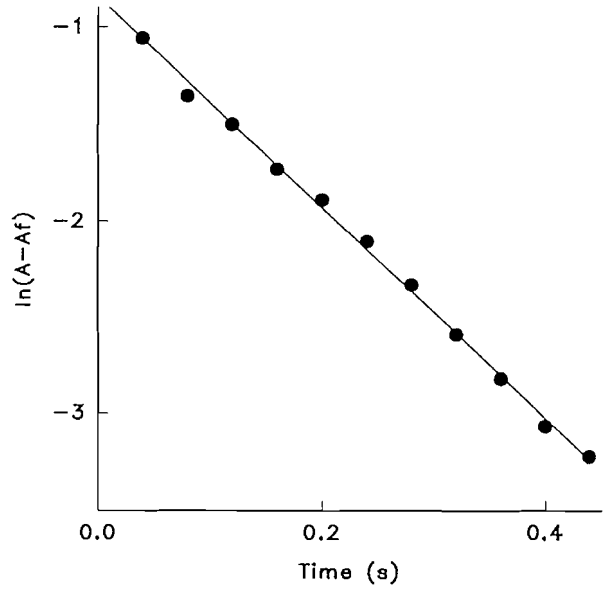
Kinetic method

The rates of reaction were measured using a Tracor Northern TN-1710A diode array stopped-flow spectrophotometer. Stock solutions of 0.010 M reductant and approximately 6×10^{-4} M perruthenate were placed in thermostated syringes and, after 30 min, equal amounts were forced through the mixing chamber and into the cuvette where the absorbance was monitored from 300 nm to 600 nm as in Fig. 1, the final spectrum being due to ruthenate(VI) (35). Good pseudo-first-order plots were obtained (Fig. 2) using absorbance data at 385 nm (ϵ = 2275).

Products

The products obtained from the oxidation of (phenylthio)acetic acid were identified, from an analysis of the proton NMR spectrum, as the corresponding sulfoxide and sulfone. Potassium perruthenate (1.00 g, 4.9 mmol) was added slowly with stirring (over a 10 min period) to a solution of (phenylthio)acetic acid (0.80 g, 4.8 mmol) in 60 mL of 0.5 M NaOH and, after stirring for an additional 30 min, the solution was filtered. The filtrate was acidified with concentrated HCl and extracted with 5×50 mL CH_2Cl_2. Evaporation of the solvent gave a residue (0.83 g) that was soluble in $CDCl_3$. The proton NMR spectrum of this product exhibited a singlet at 5.3 ppm (solvent, 8.3%), a singlet at 11.1 ppm (1 H, carboxylic acid), and a multiplet at 7.1–7.9 ppm (5 H, aromatic). The region from 3.6 to 4.1 ppm contained three distinct peaks, a singlet at 4.1 ppm, a pair of doublets at 3.7–4.0 ppm, and another singlet at 3.6 ppm. These three peaks were attributed (by comparison with authentic spectra) to the methylene hydrogens at the sulfone, the sulfoxide, and the sulfide, respectively. From the integrals it was then possible to calculate approximate yields of 44% sulfoxide, 36% sulfone, and 11% starting material. When this experiment was repeated using less potassium perruthenate (0.50 g, 2.5 mmol) the yields were 23% sulfoxide, 7% sulfone, and 38% starting material.

Fig. 2. Typical pseudo-first-order rate plot for the oxidation of (methylthio)acetic acid (5.0×10^{-3} M) by perruthenate (3.3×10^{-4} M) in 0.3 M NaOH. Slope = -5.46 s^{-1}. $r = 0.999$.



These results suggest that the sulfone is likely formed from the oxidation of the sulfoxide. Under kinetic conditions, where the reductant is held in substantial excess of the oxidant, it is reasonable to assume that very little sulfone would be formed and that the reaction stoichiometry would be given by eq. [1].

Results

The isosbestic point observed at 415 nm (Fig. 1) indicates that no long-lived intermediates are formed during the reaction. Linearity of plots of $\ln(A - A_f)$ vs. time (Fig. 2) indicate that the reaction is first order with respect to perruthenate while plots of log k_1 vs. log[substrate] as in Fig. 3 confirm that the reaction is also first order in reductant. In addition, the reaction exhibited a first-order dependence on the basicity of the solution as indicated in Fig. 4. The rate law for the reaction is therefore given by eq. 2.

[2] $\text{Rate} = -\text{d}[RuO_4^-]/\text{d}t = k_3[RuO_4^-][\text{Reductant}]a_{OH^-}$

Rate constants under various conditions have been collected in Table 1.

Analysis of the rate constants obtained for the oxidation of (arylthio)acetic acids indicated a good correlation ($r = 0.98$) with Hammett σ values (Fig. 5). A less acceptable correlation ($r = 0.88$) was observed when σ^+ values were used.

The activation parameters for the reaction, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, were determined under conditions of constant basicity. The resulting Eyring plot (36) gives $\Delta H^{\ddagger}$ = 2.7 kcal/mol and $\Delta S^{\ddagger} = -49$ eu for the oxidation of (phenylthio)acetic in 0.3 M NaOH (Fig. 6). A similar plot for the oxidation of (methylthio)acetic acid, also linear (r = 0.993), gave $\Delta H^{\ddagger}$ = 2.8 kcal/mol and $\Delta S^{\ddagger} = -35$ eu in 0.4 M NaOH.

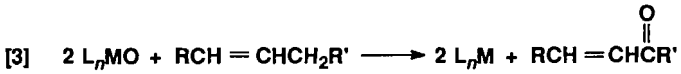
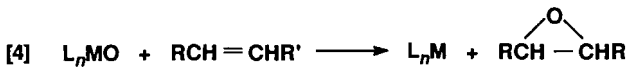
Discussion

Oxygen transfers from metal-oxo's to sulfur (16), phosphorus (32), or nitrogen (37), atoms occur without accompanying bond cleavage in the organic substrate (e.g., $L_nMO + R_2S \rightarrow L_nM + R_2SO$), thereby providing an opportunity to study the mechanisms free from complications encountered with reactions such as allylic oxidations (38) or epoxidations (39) (eqs. [3] and [4]), which require C—H or C—C bond cleavage as well as oxygen transfer.

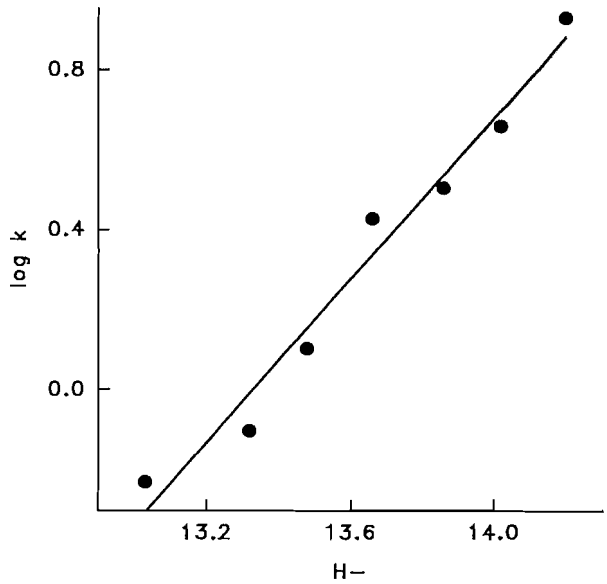




Despite the superficial simplicity of oxygen transfers to atoms such as sulfur or phosphorus, there is currently no definitive general mechanism for these processes. Various possibilities considered in the literature include: (*i*) a reaction initiated by a single electron transfer (40), (*ii*) a one-step oxygen transfer (41), (*iii*) a mechanism initiated by ligand formation using a nonbonding pair of sulfur electrons and an empty *d*-orbital of the metal (34), and (*iv*) a reaction initiated by the interaction of nonbonding sulfur electrons with the π^* orbital of the M=O bond (13). It is therefore of interest to determine which of these four possible mechanisms are most consistent with the results described above.

A negative Hammett ρ value ($\rho = -0.66$, Fig. 5) is consistent with the development of an electron-deficient sulfur in the transition state as required for a single electron transfer mechanism (eq. [5]). However, a reaction resulting in the formation of a radical cation ($ArS\overset{+}{R}$) would be expected to correlate better with σ^+ values than with σ values, as observed for this reaction. The very unfavorable activation entropy $\Delta S^{\neq} =$ −49 eu) is also consistent with a more highly organized transition state than would be expected for a single electron transfer (42).

Fig. 4. Plot illustrating the effect of basicity on the magnitude of the pseudo-first-order rate constants for the oxidation of (phenylthio)acetic acid (1.0×10^{-2} M) by perruthenate (3.4×10^{-4} M). Slope = 1.02, $r = 0.986$. H_- values reported by Rochester (47) were used.



The second possibility, an attack of oxygen by sulfur (eq. [6]) satisfactorily accounts for several features of the reaction including the negative Hammett ρ value and the unfavorable entropy of activation. Such a reaction, however, requires a nucleophilic attack by sulfur on an electron-rich oxygen. On the basis of electrostatic considerations, a nucleophilic attack is more likely to occur at the metal, resulting in the formation of sulfide ligand on ruthenium (eq. [7]).

The observation that the second-order rate constants are directly proportional to the basicity of the solution (Fig. 4) sug-

Table 1. Rate constants for the oxidation of (phenylthio)acetic acid and (methylthio)acetic acid by perruthenate.

Reductant (conc.)	$[RuO_4^-]$ (M)	$[OH^-]$ (M)	k_1 (s^{-1})[a]	k_2 (M^{-1} s^{-1})[b]
(Phenylthio)acetic acid (0.0100 M)	3.3×10^{-4}	0.300	1.26	126
(Phenylthio)acetic acid (0.0250 M)	3.3×10^{-4}	0.300	3.21	128
(Phenylthio)acetic acid (0.0100 M)	3.4×10^{-4}	0.700	3.19	319
(Phenylthio)acetic acid (0.0100 M)	3.4×10^{-4}	1.50	8.44	844
(Methylthio)acetic acid (0.00500 M)	3.4×10^{-4}	0.300	5.28	1.06×10^3
(Methylthio)acetic acid (0.00500 M)	3.4×10^{-4}	1.50	31.0	6.19×10^3

[a]Pseudo-first-order rate constant obtained at 25.0 ± 0.1°C. Each constant is the average of three or more experiments with a standard deviation of ±5% or less.
[b]$k_2 = k_1/[\text{reductant}]$.

gests that the rate-limiting step is preceded by an equilibrium involving the reaction of one of the reactants with a hydroxide ion. A similar observation for the oxidation of alcohols by permanganate (43) has been understood in terms of a proton transfer resulting in the formation of an alkoxide ion (eq. [8]) that would be more easily oxidized than the unionized alcohol. However, deprotonation of (phenylthio)acetate (eq. [9]) would result in the formation of a carbanion with considerable double-bond character between carbon and sulfur (eq. [10]) (44). Oxidation would then be expected to give cleavage products (eq. [11]) rather than sulfoxides and sulfones as observed.

[8] $ROH + OH^- \rightleftharpoons RO^- + H_2O$

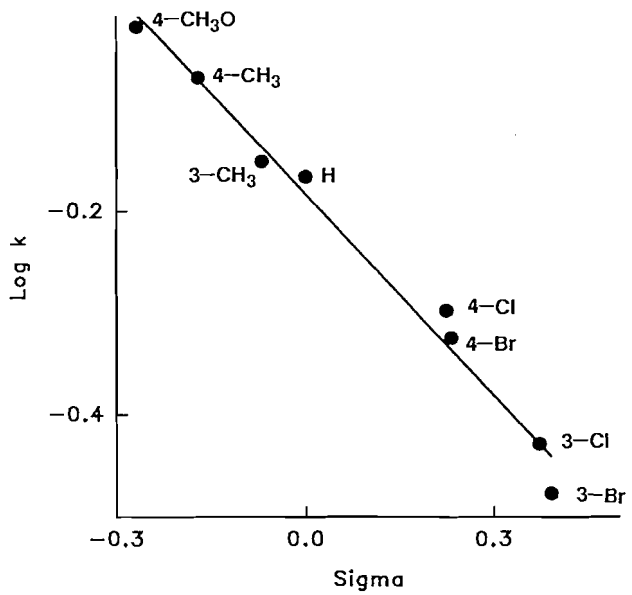
[9] $ArSCH_2CO_2^- + OH^- \overset{K}{\rightleftharpoons} ArS\dot{C}HCO_2^- + H_2O$

[10] $ArS-\dot{C}HCO_2^- \longleftrightarrow Ar\dot{S}=CHCO_2^-$

[11] $Ar\dot{S}=CHCO_2^- \xrightarrow[k'_2]{RuO_4^-} ArSO_3^- + OCHCO_2^-$

Furthermore, because the pK_a values for sulfides are so large (estimated by Bordwell (45) to be about 40–45 in DMSO), the concentrations of carbanions in these solutions would be too small to permit the reaction to proceed at a measureable rate; i.e., it can be shown that the required magnitude of the rate constant for eq. [11], k'_2, would need to be greater than those for diffusion-controlled reactions. The observed rate constant, k_{obs}, for a reaction sequence consisting of the equilibrium in eq. [9] followed by reaction [11] would be $k_{obs} = K_a k'_2[OH^-]/K_w$. Therefore, the required value for the rate constant, k'_2, of reaction [11] would be $k'_2 = k_{obs}K_w/K_a[OH^-] = (1.06 \times 10^3\ M^{-1}\ s^{-1} \times 10^{-14}\ M^2)/(10^{-40}\ M \times 0.3\ M) = 3.5 \times 10^{29}\ M^{-1}\ s^{-1}$. Since this value is about 20 orders of magnitude greater than the second-order rate constants for diffusion-controlled reactions (46), it can be concluded that the carbanion is not an intermediate in this reaction.

Fig. 5. Hammett plot for the oxidation of substituted (phenylthio)-acetic acids by perruthenate in 0.30 M NaOH. Slope = −0.66. r = 0.992. T = 25°C.



Alternatively, reaction of hydroxide with the oxidant would increase the coordination number of ruthenium from four to five (or six if a molecule of solvent is also incorporated) as in eq. [12]. Replacement of the solvent with a molecule of reduc-

[12] 
tant would initiate a reaction that could lead to formation of sulfoxide as indicated in Scheme 1. The intermediate, **3**, in this scheme is structurally similar to the one proposed by Dovleto-

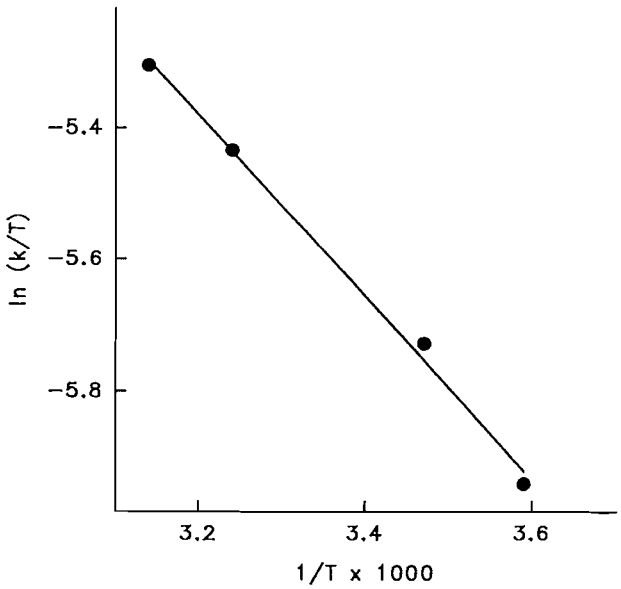
Fig. 6. Eyring plot for the oxidation of (phenylthio)acetic acid (0.010 M) by perruthenate (3.5×10^{-4} M) in 0.30 M NaOH. Slope = -1.38×10^3 K. Intercept = −0.957. $r = 0.998$.

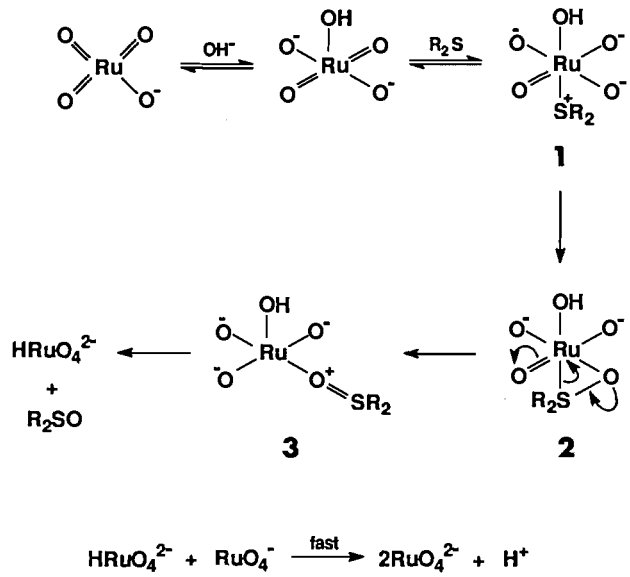


glou and Meyer (32) for the oxidation of phosphines by dioxo complexes of ruthenium(VI).

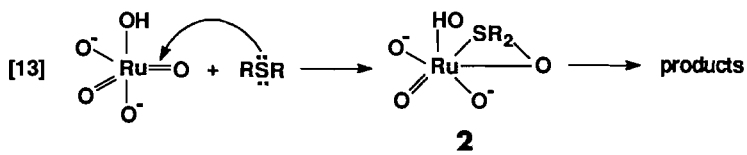
Activation of the oxidant in this way (by expansion of its coordination shell with incorporation of a basic ligand) is reminiscent of osmium tetroxide oxidations in which it is known that the presence of pyridine (48) or other basic ligands (49) greatly accelerates the rate of reaction.

A negative Hammet ρ value (ρ = −0.66, Fig. 5) is also consistent with the development of an electron-deficient transition state (which would likely resemble **2** and be located somewhere along the reaction coordinate between **1** and **3** in Scheme 1). The highly organized transition state in this scheme is also consistent with the large negative entropy of activation noted above.

Scheme 1. A possible mechanism for the transfer of oxygen from perruthenate to a sulfide.



Holm (13) has proposed that the oxidation of triphenylphosphine by molybdenum(VI) is initiated by an interaction of the nonbonding electrons with the π* orbital of the metal–oxo bond. Such a mechanism (eq. [13]) for the reaction of sulfides



with perruthenate would result in the formation of an intermediate identical to **2** in Scheme 1 and it is therefore impossible, on the basis of the evidence currently available, to distinguish between these two possibilities.

Conclusion

The data obtained from a study of the kinetics of the oxidation of sulfides by perruthenate in basic aqueous solutions are consistent with a mechanism in which oxygen transfer is preceded by an activating expansion of the ruthenium coordination shell through incorporation of an hydroxide ion. Reaction of a nonbonding pair of sulfur electrons with either a vacant ruthenium *d*-orbital or with the Ru=O π*-orbital then initiates oxygen transfer as depicted in Scheme 1. Such a mechanism is consistent with the observed base catalysis, the negative Hammett ρ value, and the unfavorable entropy of activation. Other possible mechanisms such as a single electron transfer or an attack by sulfur on oxygen accommodate the data less well.

Dehydrobromination of 1,1-diaryl-1,2-dibromoalkanes catalyzed by iron and iron bromides. An ion-pair-mediated reaction?

Angela R. Suárez, Alejandra G. Suárez, Sandra E. Martín, and María R. Mazzieri

Abstract: The participation of ion-paired Lewis acid/Lewis base in the dehydrohalogenations of 1,2-dibromo-1,1-diarylalkanes catalyzed by Fe^0 and by Fe(II) and Fe(III) bromides was investigated. The reactivities of the catalyst employed were correlated with their chemical *hardness*. The influence of *para* substituents on the phenyl rings of the substrates and the results obtained in Lewis-acid-catalyzed and thermal dehydrobromination of the same compounds were compared. The experimental results could not be explained in terms of a Lewis-acid-catalyzed dehydrobromination.

Key words: dehydrohalogenation, bromoalkanes, Lewis acid catalysts, ion-pair mechanism.

Résumé : On a étudié la participation d'acide de Lewis/base de Lewis en paires d'ions dans les déshydrohalogénations des 1,2-dibromo-1,1-diarylalcanes, catalysées par le Fe^0 et les bromures de Fe(II) et Fe(III). On a établi une corrélation entre les réactivités des catalyseurs utilisés et leur dureté chimique. On a comparé l'influence des substituants en *para* sur les noyaux phényles des substrats et les résultats obtenus lors de réactions catalysées par des acides de Lewis et ceux obtenus avec les mêmes composés lors de réactions de déshydrobromation. On ne peut pas expliquer les résultats expérimentaux en fonction d'une déshydrobromation catalysée par un acide de Lewis.

Mots clés : déshydrobromation, bromoalkanes, catalyseurs d'acide de Lewis, mécanisme des paires d'ions.

[Traduit par la rédaction]

Introduction

1,2-Dibromo-1,1-diphenylethane, **1***a*, yields 2-bromo-1,1-diphenylethene, **2***a*, in the presence of catalytic amounts of some transition and transition-like metals and their bromides. Solutions of **1***a* in nonpolar solvents were heated in contact with the solid catalysts (1, 2). The reaction is represented by eq. [1].

[1] $$\underset{\mathbf{1}a}{(C_6H_5)_2\text{-}CBr - CH_2Br} + MBr_n \rightarrow \underset{\mathbf{2}a}{(C_6H_5)_2C{=}CHBr} + Hbr$$

M = Al, Fe, and Ru; n = 0–3.

We report here the results of research into the possible participation of an ion-pair-initiated mechanism in these reactions, as had been proposed for metal-ion-catalyzed dehydrohalogenation of haloalkanes in the gas phase (3–6).

The mechanism of elimination reactions from gaseous substrates over solid polar catalysts has been studied by Noller et al. (3, 4). Dehydrochlorination of chloroalkanes with lithium and sodium halides has been interpreted on the basis of the Lewis acidity of the cations and coordination chemistry concepts. An E1 or an E1-like mechanism was proposed for these reactions (3). On this account, it is quite reasonable to expect that a similar ion-pair-mediated mechanism may be involved in hydrogen bromide elimination from **1***a* catalyzed by alkali metal halides.

Comparison of the results obtained with alkali metal catalysts and those of dehydrobrominations carried out with transition metal catalysts could provide decisive evidence on the mechanism operative in the latter reactions. With this purpose, dehydrobromination of **1***a* in carbon tetrachloride solution was carried out with solid NaBr and LiCl as catalysts.

We previously reported evidence of a cationic mechanism in the dehydrohalogenation of 1,1-diaryl-1,2-dihaloalkanes catalyzed by silica gel (7). The same types of compounds were employed in the present work to evaluated the effect of *para* substituents in the phenyl rings on hydrogen bromide elimination catalyzed by powdered Fe^0, anhydrous Fe(III) bromide, and silica gel. Thermal dehydrobrominations of the same compounds were performed for comparison. The substrates employed in this study were 1,1-diphenyl-1,2-dibromoethane, **1***a*; 1,1-bis(4-chlorophenyl)-1,2-dibromoethane, **1***b*; 1,1-bis(4-methylphenyl)-1,2-dibromoethane, **1***c*; 1,1-diphenyl-1,2-dibromopropane, **1***d*; 1,1-bis(4-chlorophenyl)-1,2-dibromopro-

pane, **1***e*; and 1,1-bis(4-methylphenyl)-1,2-dibromopropane, **1***f*.

Results

The results obtained from the dehydrobromination of **1***a* in carbon tetrachloride solutions of different iron-containing catalysts, i.e., Fe^0, Fe(II) bromide, and Fe(III) bromide, at 76°C and at 50°C, are listed in Tables 1 and 2.

The reaction mixtures were evaluated by ^1H NMR spectra. The ^1H NMR spectra of the mixtures of uncompleted reactions showed a deficit of nonaromatic protons, that is, the sum of the molar fraction of methylenic protons from substrate **1***a* and vinylic proton from product **2***a* was lower than 1. Normal proton integration resulted at the end of the reactions and only **2***a* was detected by ^1H NMR. In previous reports, the "undetected" protons in the NMR spectra measured at room temperature were tentatively assigned to the dynamically interchanged protons of organometallic intermediates (1, 2).

The reactions carried out at 50°C, Table 2, secondary products appeared at the end of the reactions. They were identified as 1,1,4,4-tetraphenylbutadiene, **3**, and 1-bromomethyl-1,2,2-triphenylindane, **4**, as described in the experimental section. The total **3** + **4** molar fraction amounted to as much as 5% of the reaction mixture. These products were performed with any of the three iron catalysts. Despite careful searching in the ^1H

[a]Average of at least eight reactions.
[b]Average of at least five reactions.
[c]Average of three reactions. N.C. = thermal reactions performed without catalyst.

NMR spectra of the reactions carried out at 76°C and in earlier samples of reactions at 50°C, the signals corresponding to **3** and **4** could not be detected. To explore a possible origin for these compounds, 2-bromo-1,1-diphenylethane, **2***a*, was refluxed at 50°C for 4 h with 10 mol% of Fe(III) bromide but the signals corresponding to **3** and **4** were absent in the ^1H NMR spectra of the reaction mixtures. According to these results, **3** and **4** were probably formed by reaction of **2***a* with some unidentified reaction intermediate.

At the end of the reactions, the remaining solids arising from the catalysts were analyzed by UV–visible spectroscopy. The results demonstrated that whichever initial catalyst was employed, these solids consisted of Fe(III) bromide (8), indicating that Fe^0 and Fe(II) had been oxidized to Fe(III) by reaction with the hydrogen bromide eliminated from **1***a*.

Results with alkali metal salts are shown in Table 3. The substrate **1***a* dehydrobrominated to **2***a* with NaBr and LiCl in a substrate:catalyst ratio of 1:1. With a 10:1 ratio, a small catalytic effect was detected with LiCl whereas reactions with NaBr behaved similarly to those performed without catalyst.

To investigate the influence of the substituents placed in the phenyl rings on the presumed development of a positive charge in the benzylic carbon, reactions of 1,1-bis(4-chlorophenyl)-1,2-dibromoethane, **1***b*, and 1,1-bis(4-methylphenyl)-1,2-dibromoethane, **1***c*, with Fe^0 and Fe(III) bromide were also studied at 76°C. By comparing the results summarized in Tables 1 and 4, it is evident that **1***b* dehydrobrominations were slower than those of **1***a*. In turn, dehydrohalogenation of **1***c* was very similar either in the presence or in the absence of catalysts.

Dehydrobrominations of **1***d–f* catalyzed by anhydrous Fe(II) bromide showed the same tendency. The *para*-chloro derivative, **1***e*, and the *para*-methyl derivative, **1***f*, were both less reactive than the unsubstituted compound, **1***d*. The order of reactivity was **1***d* > **1***f* ⩾ **1***e*. Conversely, in reactions accomplished by heating solutions of **1***d–f* without catalyst and in silica-gel-catalyzed reactions, the order of reactivity was **1***f* > **1***d* ⩾ **1***e*. These results are listed in Table 5.

Discussion

Considering the chemical *hardness* of both alkali cations, Li^+ and Na^+, and the high ionic degree of their halides, it is expected that active Lewis acid sites should remain on the solid surface of the alkali halides used in this work. Noller and Kladnig proposed that every cation of the surface may be an active Lewis Acid site (3).

The easily polarizable bromine atom in the benzylic position of **1***a* could react at those sites to form an ion pair. Allison and co-workers also suggested the development of a positive charge during halogen atom elimination from alkyl halides in gas-phase reactions catalyzed by bare alkali ions. This initial ion–dipole interaction should be followed by hydrogen halide elimination and formation of a π-complex between the alkali metal and the olefinic product (5, 6).

As shown in Table 3, solid alkali metal halides catalyzed the dehydrobromination of **1***a* to **2***a* when a substrate:catalyst ratio of 1:1 was employed. The reactions carried out with NaBr in a substrate:catalyst ratio of 10:1 behaved similarly to the thermal decomposition of **1***a*, whereas a small catalytic effect was noticed with a 10:1 substrate:LiCl ratio.

A similar ion–dipole complex has been considered as the most probable intermediate in gas-phase reactions of naked transition M^+ metal ions with several alkyl derivatives (5, 6, 9). This Lewis-acid-induced charge-separation mechanism is similar to that proposed by Yoon and Kochi for reactions of halocyclohexanes with anhydrous Fe(III) halides in nonpolar solvents (8).

If this mechanism were operative in the catalytic dehydrobromination reported in this work (Tables 1, 2, and 4) and in previous reports (1, 2), the reactions represented in Scheme 1 should take place:

Scheme 1

$$\underset{\text{RCBrH}}{\overset{|}{\text{Ar}_2\text{C}}} - \text{Br} + \text{MBr}_n \rightarrow \underset{\text{RCBrrH}}{\overset{|}{\text{Ar}_2\text{C}^+}}\ \text{MBr}_{n+1}^-$$

1*a* **5**

$$\mathbf{5} \rightarrow \mathbf{2}a + \text{HBr} + \text{MBr}_n$$

Species **5** in Scheme 1 represents the ion pair formed by the benzylic carbocation and a tetrabromometalate anion. The most likely reaction for the ion pair **5** under our experimental conditions is the abstraction of the β-hydrogen as a proton by the anion to form product **2***a*. Formation of **5** induced by Lewis acid/Lewis base interaction should be the rate-controlling step in an E1-like mechanism.

We have listed below, I, the order of reactivity of the metal catalysts employed in this study and in work previously reported (1, 2). In II are reproduced the chemical hardness values of metal ions and neutral metals given by Pearson (10):

I: $FeBr_3 = FeBr_2 = Fe^0 > RuBr_3 > Ru^0 = AlBr_3 > Al^0 \gg LiCl > NaBr$

II: $Al^{3+} > Li^+ Na+ \gg Fe^{3+} > Ru^{3+} > Fe^{2+} \gg Fe^0 > Ru^0 > Al^0$

Evidently, there is no correlation between the order of activity and the Lewis acidity of the catalyst used in our work.

The second series of experiments carried out, to investigate the possible involvement of a Lewis-acid-induced charge-separation mechanism, were those with *para*-phenyl-substituted substrates. Fe(III) bromide was used as catalyst in these reactions because Fe(III) is a hard Lewis acid (10) that should facilitate the formation of the benzylic carbocations in ion pairs like **5**, as shown in Scheme 1. For comparison, reactions catalyzed by Fe^0, a soft Lewis acid (10), and reactions without catalyst were also carried out.

The 4-chlorine substituent in **1***b* and **1***e* and the 4-methyl substituent in **1***c* and **1***f* must produce an opposite effect on the formation of a benzylic carbocation according to the Hammett σ^+ values (11). The results listed in Table 4 demonstrate that both compounds, **1***b* and **1***c*, were less reactive than **1***a*. Moreover, thermal reactions of **1***c*, carried out without catalyst, showed a similar behaviour to reactions observed in the presence of Fe^0 and Fe(III) bromide. It is evident that the contribution of the transition-metal-catalyzed dehydrobromination of **1***c* was negligible. These results do not support the formation of a benzylic carbocation intermediate induced by Lewis acids.

The results of dehydrobromination of compounds **1***d–f* with Fe(III) bromide (Table 5) provide clearer data. In reactions with Fe(III) bromide, the 4-methyl derivative, **1***f*, and the 4-chloro derivative, **1***e*, were both less reactive than the unsubstituted substrate, **1***d*. On the other hand, the activating effect of the 4-methyl group in **1***f* was opposite to the effect of the 4-chlorine atom in **1***e* in the thermal as well as in silica-gel-catalyzed HBr eliminations. This latter behaviour could be explained by a carbenium ion mechanism (7).

Conclusion

Comparison of the activity and Lewis acidity of the catalysts, and the effect of substituents placed on the phenyl rings of the substrates, strongly suggests that, with the exception of the alkali halides, an ion-pair-mediated mechanism cannot be the main route to dehydrobromination of 1,1-diaryl-1,2-dibromoalkanes catalyzed by the metals and metal halides used in our work.

The previously reported spectroscopic evidence indicates that some organometallic intermediates are more probably involved in these reactions (1, 2).

Experimental section

The ^{1}H NMR spectra were obtained using a T-60 Varian spectrometer with TMS as internal standard and CCl_4 as solvent, or a Bruker 200 FT spectrometer with CCl_4 as solvent and a capillary tube containing acetone-d_6 fixed into the NMR tube for locking purposes and as standard references. Electron absorption spectra were recorded in a Shimadzu 260 spectrophotometer. Mass spectra were measured on a Finnigan 3300 spectrometer. IR spectroscopy was carried out using a Nicolet 5 SXC FT-IR spectrometer. Reactions were carried out in a Lauda Ultra-Thermostat provided with an electronic relay, temperature accuracy ±1°C. Melting points were reported without correction.

Materials

Solvents were purified by the usual procedures (12). Carbon tetrachloride used as solvent in the reactions was further dried and maintained over 4A molecular sieves. Fe^0 (Merck, 2–7 μm particle diameter) was washed with ether and vacuum dried before use. Metal halides were the following: anhydrous Fe(II) and Fe(III) bromides supplied by Strem Chemicals Co, NaBr AR from Mallinckrodt, and LiCl was Carlo Erba RP. Silica gel employed as catalyst was Kieselgel 60 from Merck, activated at 110°C for 1 h before use.

Carbon tetrachloride and dichloromethane were Merck Uvasol and bromine was Merck P.A., less than 1×10^{-4}% in heavy metals. Silica gel for column chromatography was Kieselgel Merck 60, and for flash chromatography a Kieselgel Merck 60 H was employed. In both cases they were activated for 1 h at 110°C.

Diphenylethane (Fluka) was flash chromatographed on silica gel with *n*-hexane before use. The 1,1-bis(4-chlorophenyl)-ethane, 1,1-bis(4-methylphenyl)ethane, 1,1-diphenylpropene, 1,1-bis(4-chlorophenyl)propene, 1,1-bis(4-methylphenyl)propene, and 1,1-diphenylethanol were synthesized, purified, and identified by known methods.

The 1,2-dibromides were prepared by addition of a CCl_4 solution of bromine to a solution of the olefins in the same solvent at temperatures from −12°C to −30°C. The dibromides: 1,2-dibromo-1,1-diphenylethane (**1***a*), 1,1-bis(4-chlorophenyl)-1,2-dibromoethane (**1***b*), 1,2-dibromo-1,1-diphenylpropane (**1***d*), and 1,1-bis(4-chlorophenyl)-1,2-dibromopropane (**1***e*) were isolated and purified by different procedures. Physical constants agree with those reported in the literature.

Unstable dibromides 1,1-bis(4-methylphenyl)-1,2-dibromoethane (**1***c*) and 1,1-bis(4-methyl)-1,2-dibromopropane (**1***f*) were not isolated. Addition of the bromine solution to the olefine was checked by ^{1}H NMR and UV spectroscopy. Once the bromine addition was complete, the solutions were used without isolation of these reagents.

General procedure for dehydrobromination reactions

The reaction equipment consisted of a Pyrex tube attached to a condenser and with a water trap on the top. The equipment was dried at 120°C before use and allowed to reach room temperature in a desiccator. The presence of air was not avoided, but the reaction tube was covered with aluminum foil since dibromides of **1** are light sensitive. Because the anhydrous catalysts are decomposed by moisture, they were placed in a preweighed reaction tube in a glovebag under dry atmosphere. The closed tube was weighed again and then a solution of the substrate in carbon tetrachloride was added to the solid. The substrate:catalyst ratio was 10:1 with the exception of some reactions with alkali halides as catalysts that were carried out with a 1:1 substrate:catalyst ratio. The total amount of dibromide employed was about 1 mmol in 2 mL of solvent. The reaction tube with the reagents was then immersed in a bath at the desired temperature. The reaction mixtures were filtered at the appropriate times and checked by ^{1}H NMR.

Yields obtained with the transition metal catalysts were seldom duplicated exactly in the same reaction time. For this reason, two series of six simultaneous reactions were carried out. We considered that a result was valid if at least 8 out of 12 values gave product yields with differences lower than 6% of the total dehydrobromination yield. Yields with higher differences were not taken into account in calculating the reported average values. As thermal reactions and those catalyzed by

alkali halides rendered reproducible results, they were carried out in triplicate.

Electron absorption spectra of the remnant solid arising from the iron catalysts Fe^0, and Fe(II) and Fe(III) bromides were carried out in dichloromethane solutions. The recorded spectra corresponded to that of Fe(III) bromide (8).

Dehydrobrominations of 1a with iron catalysts at 50°C
In reactions of **1***a* catalyzed by Fe^0, and Fe(II) and Fe(III) bromides at 50°C, after 240 min signals appeared in the ^1H NMR spectra that did not correspond to either **1***a* or **2***a*. These signals were identical in reactions with the three iron catalysts. In the ^1H NMR spectra of reactions carried out at 76°C and in earlier examples of reactions at 50°C, these signals were not detected. For this reason, the lack of nonaromatic protons in reactions performed at 50°C was not reported after 240 min of reaction, and the molar fraction of **2***a* was variable.

A number of reaction mixtures were collected and their components isolated by column chromatography on silica gel with *n*-hexane:benzene 80:20 as eluents. After several chromatographic separations two compounds were isolated and their ^1H NMR spectra corresponded to the unknown compounds detected in the reaction mixtures. They were identified as 1,1,4,4-tetraphenylbutadiene, **3**, and an indane derivative, **4**.

1,1,4,4-Tetraphenylbutadiene, 3: Recrystallized from *n*-hexane, mp 192.5–193°C (lit. (13) mp 204–205°C (acetone–ethanol). The ^1H NMR, electron absorption, IR, and mass spectra agree with literature data. Mass spectra overlapped with those of the NBS Library.

1-Bromomethyl-1,2,2-triphenylindane, 4: Recrystallized from *n*-hexane, mp 145–147°C. IR (KBr): typical bands of aliphatic methylene groups, phenyl rings and C–Br stretching bands were observed. UV (*n*-heptane): bands corresponding to transitions of the phenyl rings were observed. ^1H NMR (CCl_4): 3.48–3.61 (dd, 2H, AB system), 3.87 (s, 2H), 7.01–7.39 (m, 19H) ppm. MS (20 eV) *m/z*(%): 442(1), 440(2), 438(1), 358(43), 345(37), 253(96), 255(100), 203(53), 167(55), 91(23).

From the proton NMR and mass spectra and by comparison with the results of Patai et al. (14), we propose the structure **4** for this compound.

Dehydrobrominations catalyzed by silica gel
The experimental arrangement was as described in the General Procedure and was as previously reported (7). Solutions containing 1 mmol of the substrates **1***d–f* were refluxed in contact with 20 mg of silica gel. At the appropriate time, the colourless reaction mixtures were filtered and the silica gel was washed with CCl_4. The filtrate and the washings were combined to evaluate the composition of the reaction mixtures by ^1H NMR, rendering very reproducible yields.

Abstract: The four-coordinate anion $Cu^{I}(dpym)_2^-$ (Hdpym = 3,3′,5,5′-tetramethyl-4,4′-dicarboethoxydipyrromethene) can be prepared in solution in acetone either by electrochemical reduction of the known tetrahedral complex $Cu^{II}(dpym)_2^0$ ($E^0 = -290$ mV vs. SCE) or by the quantitative reaction of 2Hdpym with $Cu(CH_3CN)_4^+$ in the absence of O_2. The latter reaction does not go to completion in solvents that bind relatively strongly to Cu^I or that are poor proton acceptors. Ligand exchange between $Cu^{I}(dpym)_2^-$ and excess Hdpym in acetone is "fast" in the ^1H NMR timeframe, with $k_1 = 1.4 \times 10^7$ L mol^{-1} s^{-1} at 298 K (first order in each reactant), $\Delta H_1^{\ddagger} = 3.4 \pm 0.6$ kJ mol^{-1}, and $\Delta S_1^{\ddagger} = -97 \pm 3$ J K^{-1} mol^{-1}. In the absence of excess Hdpym, dissociation of $Cu^{I}(dpym)_2^-$ in acetone remains negligible. Homogeneous electron exchange between $Cu^{I}(dpym)_2^-$ and $Cu^{II}(dpym)_2^0$ in acetone falls in the "slow" ^1H NMR timeframe, with $k_{ex} = 5.9 \times 10^3$ L mol^{-1} s^{-1}, $\Delta H_{ex}^{\ddagger} = 48.5 \pm 3.0$ kJ mol^{-1}, and $\Delta S_{ex}^{\ddagger} = -10 \pm 10$ J K^{-1} mol^{-1}, at ionic strength $I \approx 0.007$ mol L^{-1} and 298 K, while for the same self-exchange on a Pt electrode the heterogeneous rate constant $k_{el} = 0.16 \pm 0.04$ cm s^{-1} at $I \approx 0.1$ mol L^{-1} and 298 K, according to AC voltammetry. These values of k_{ex} and k_{el} are of the order expected for $Cu^{II/I}$ couples in which no significant change in coordination number or geometry accompanies electron transfer.

Key words: Electron transfer, copper complexes, ligand substitution kinetics, dynamic NMR.

Résumés : On peut préparer l'anion tétracoordiné $Cu^{I}(dpym)_2^-$ (Hdpym = 3,3′,5,5′-tétraméthyl-4,4′-dicarboéthoxydipyrrométhène) en solution dans l'acétone soit par une réduction électrochimique du complexe tétraédrique $Cu^{II}(dpym)^0$ ($E^0 = -290$ mV vs. SCE) ou par la réaction quantitative de 2Hdpym avec le $Cu(CH_3CN)_4^+$ en l'absence de O_2. La dernière réaction n'est pas complète dans des solvants qui se lient relativement fortement au Cu^I ou qui sont de pauvres accepteurs de proton. L'échange de coordinat entre le $Cu^{I}(dpym)_2^-$ et un excès de Hdpym dans l'acétone est rapide par rapport à la RMN du ^1H; $k_1 = 1{,}4 \times 10^7$ L mol^{-1} s^{-1} à 298 K (premier ordre par rapport à chaque réactif), $\Delta H_1^{\ddagger} = 3{,}4 \pm 0{,}6$ kJ mol^{-1} et $\Delta S_1^{\ddagger} = -97 \pm 3$ J K^{-1} mol^{-1}. En l'absence d'un excès de Hdpym, la dissociation du $Cu^{I}(dpym)_2^-$ dans l'acétone est négligeable. L'échange homogène d'électron entre le $Cu^{II}(dpym)^0$ dans l'acétone est lent à l'échelle de temps de la RMN du ^1H; $k_{éch} = 5{,}9 \times 10^3$ L mol^{-1} s^{-1}, $\Delta H_{éch}^{\ddagger} = 48{,}5 \pm 3{,}0$ kJ mol^{-1} et $\Delta S_{éch}^{\ddagger} = -10 \pm 10$ J K^{-1} mol^{-1}, à une force ionique d'environ 0,007 mol L^{-1} et à 298 K alors que, d'après la voltampérométrie CA, pour le même autoéchange sur une électrode de platine, $k_{él} = 0{,}16 \pm 0{,}04$ cm^{-1}, à une force ionique d'environ 0,1 mol L^{-1} et 298 K. Ces valeurs de $k_{éch}$ et $k_{él}$ sont de l'ordre de grandeur attendu pour les couples $Cu^{II/I}$ dans lesquels il ne se produit pas de changement significatif dans le nombre de coordination ou dans la géométrie qui accompagne le transfert d'électron.

Mots clés : transfert d'électron, complexes du cuivre, cinétique de substitution des coordinats, RMN dynamique.

[Traduit par le rédaction]

Introduction

According to the Vallee–Williams principle (1), the rates of outer-sphere electron transfer processes involving copper(II/I) couples will tend to be rather slow if the normally preferred coordination geometries (tetrahedral four-coordination for copper(I), tetragonal six- or five-coordination for copper(II)) prevail, as the extensive ligand rearrangement accompanying oxidation state change would then make a large Franck–Condon contribution to the free energy of activation $\Delta G^{\ddagger}$ (2). Thus, electron transfer in the $Cu(aq)^{2+/+}$ couple is extremely slow, with a self-exchange rate constant $k_{ex} \approx 5 \times 10^{-7}$ L mol^{-1} s^{-1} at 25°C in the absence of catalysis (e.g., by Cl^-) (3). Consequently, as Rorabacher and co-workers (4, 5) have shown, application of the Marcus cross relation to estimate $Cu^{II/I}$ self-exchange rate constants may give different results in oxidation and reduction modes, if conformational changes are rate limiting — the redox cycle follows a "square scheme"

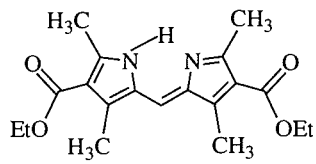
in which the intermediate involved in the oxidation of Cu^I is different from that produced in the reduction of Cu^{II}.

If, however, the coordination environments of the Cu^I and Cu^{II} partners are constrained to be similar, the intermediates of the square scheme become virtually identical, the Marcus cross relationship (2) should be valid, and the $Cu^{II/I}$ self-exchange should be fast. In synthetic $Cu^{II/I}$ couples, this is most readily achieved when five-coordination is enforced in both the Cu^I and Cu^{II} partners ($k_{ex} > 10^4$ L mol^{-1} s^{-1}) (6). The efficacy of Cu-based biological redox reagents may be understood on this basis — except that in the case of the type I or "blue" copper proteins (azurins, plastocyanins, stellacyanins, etc.) the Cu centres are constrained to a *four*-coordinate, distorted tetrahedral environment, regardless of oxidation state, and their $Cu^{II/I}$ self-exchange in aqueous solution is fast ($k_{ex} \approx 10^5$–10^6 L mol^{-1} s^{-1}) unless strong electrostatic effects operate (7).

Synthetic couples in which the Cu^{II} as well as the Cu^I is known to be constrained to an approximately tetrahedral environment are few (8–13), and not all lend themselves to kinetic studies. For the couple $Cu(dmp)_2^{2+/+}$ (dmp = 2,9-dimethyl-1,10-phenanthroline), molecular models show that the methyl groups block the phenanthroline ligands from becoming coplanar when the Cu^I complex, which is known to be tetrahedral in its solid salts, is oxidized to Cu^{II}. It may therefore be *presumed* that the environment of Cu^{II} in $Cu(dmp)_2^{2+}$ is quasi-tetrahedral, although there is a possibility that one or both of the dmp complexes are five-coordinate (through acquisition of a solvent ligand) in solution (14). In any event, we found by direct NMR measurements that electron self-exchange in $Cu(dmp)_2^{2+/+}$ is indeed quite fast, with rate constant k_{ex} in triflate media at 25°C = 2.0×10^5, 4.9×10^3, and 3.1×10^3 kg mol^{-1} s^{-1} in D_2O, CD_3CN, and $(CD_3)_2CO$ at ionic strength $I \approx$ 0.002, 0.1, and 0.1 mol kg^{-1}, respectively (14). In contrast, Knapp et al. (11) found that electron exchange in the near-tetrahedral $CuL_2^{2+/+}$, where L = 2,2′-bis(2-imidazolyl)biphenyl, was surprisingly slow ($k_{ex} < 10^2$ L mol^{-1} s^{-1} in acetonitrile, −20 to +20°C). Furthermore, Lappin and Peacock (9) estimated k_{ex} for the self-exchange of aqueous 12-tungstocuprate(II/I), in which the Cu atom occupies a tetrahedral site, to be only 2.6 L mol^{-1} s^{-1} at 298 K — this result, however, came from application of the Marcus cross-relation (2) to the oxidation of $CuW_{12}O_{40}^{7-}$ by $Fe(CN)_6^{3-}$ rather than from direct measurement. Thus, there is a need for further kinetic data, particularly direct rate measurements, to assist in establishing the norm for $Cu^{II/I}$ exchanges.

In the present study, we have examined electron transfer kinetics in the $Cu^{II/I}(dpym)_2^{0/-}$ couple (Hdpym = 3,3′,5,5′-tetramethyl-4,4′-dicarboethoxydipyrromethene) in which the



= Hdpym

coordination of Cu in $Cu(dpym)_2^0$ ("bis(dipyrromethene)copper(II)") is known from X-ray crystallography to be close to tetrahedral (8), at least in the solid state, again presumably because of the steric effects from the methyl groups. The Cu^{II} complex is interesting in that the ligands provide a porphyrin-like environment, but with tetrahedral rather than square-planar disposition of the N donor atoms about Cu. There are, however, special experimental difficulties — e.g., the uncharged $Cu^{II}(dpym)_2^0$ has very low solubility in polar solvents, its reduced form $Cu^{I}(dpym)_2^-$ has not hitherto been characterized, traces of oxidants must be excluded, and the rate of ligand exchange in the Cu^I complex can be fast on the redox timescale. Ligand exchange was found not to be competitive with electron transfer in the $Cu(dmp)_2^{2+/+}$ study reported previously (14), but Frei and Geier (15) have shown that ligand substitution in tetrahedral bis(diimine) complexes of Cu^I is generally rapid, and therefore we also examined the kinetics of the $Cu(dpym)_2^-$/Hdpym exchange in acetone.

Experimental

Preparation of Hdpym, $Cu(dpym)_2$, and $Zn(dpym)_2$

The deep red hydrochloride salt $[H_2dpym]Cl$ of the free ligand and the dark green bis(dipyrromethene)copper(II) were made by the method of Mellor and Lockwood (16), and gave good microanalyses for C, H, and N. The UV/visible spectrum of $[H_2dpym]Cl$ in acetonitrile showed a maximum at 467 nm (molar absorbance $\epsilon = 9780$ L mol^{-1} cm^{-1}) with shoulders near 440 and 410 nm, and the proton NMR spectrum in $CDCl_3$ is given in Table 1. The HCl-free ligand Hdpym was obtained by

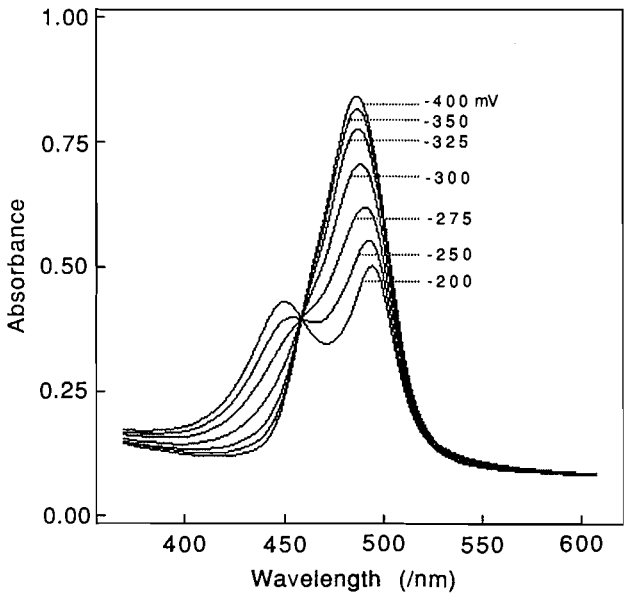
Fig. 1. Potential-resolved spectra of $Cu^{II}(dpym)_2^0$ (0.360 mmol L^{-1}) acetone containing 0.1 mol L^{-1} $[TBA]BF_4$ at 21°C. The spectra at −200 mV and −400 mV correspond to unreduced and completely reduced $Cu^{II}(dpym)_2^0$, respectively.



shaking a solution of $[H_2dpym]Cl$ (0.1 g) in dichloromethane (75 mL) with saturated aqueous $NaHCO_3$ (15 mL) for 1 min, drying the separated organic layer with anhydrous Na_2SO_4, evaporating off the solvent, and recrystallizing the bright orange solid twice from ethanol. Anal. calcd. for $C_{19}H_{24}O_4N_2$: C 66.26, H 7.02, N 8.13; found: C 66.18, H 7.04, N 8.00. The UV/visible spectrum in acetone showed a single absorbance maximum at 447 nm ($\epsilon = 6.28 \times 10^4$ L mol^{-1} cm^{-1}), while the fluorescence spectrum (with excitation at 447 nm) showed an emission maximum at 500 nm. The solubility of Hdpym in acetone at 25°C was determined spectrophotometrically to be 5.81×10^{-3} mol L^{-1}. The proton NMR spectrum in $CDCl_3$ is given in Table 1.

The UV/vis spectrum of $Cu(dpym)_2^0$ in ethanol (absorbance maxima at 496, 453, 263, and 225 nm, $\epsilon/10^4$ L mol^{-1} cm^{-1} = 10.6, 8.67, 2.93 and 5.57, respectively) agreed with that reported by Fergusson and Ramsay (17), and was the same in acetone (Fig. 1), acetonitrile, and CH_2Cl_2. The fluorescence spectrum in acetone showed maximum emission at 743 nm with excitation at 496 nm, and at 680 nm when excitation was at 453 nm.The solubility of $Cu(dpym)_2^0$ in acetone at 25°C was determined spectrophotometrically to be 3.60×10^{-4} mol L^{-1}. Its proton NMR spectrum in $CDCl_3$ is given in Table 1, along with that of $Zn(dpym)_2^0$ (17) which was prepared for comparison purposes in the same manner as $Cu(dpym)_2^0$. The major peaks of the ^1H NMR spectrum of $Cu(dpym)_2^0$ at 200 and 400 MHz were broadened by the paramagnetism of the copper(II) centre, but were readily identifiable after 16 transients. The resonance of the single methene proton on each ligand was greatly broadened resonance by virtue of the proximity of that proton to the Cu^{II} centre and weak because of its low relative abundance, but, with a saturated $Cu(dpym)_2^0$ solution in $CDCl_3$ at 0°C in a 10 mm sample tube, a broad singlet could be distinguished in a 400 MHz spectrum at 9.07 ppm after 10 000 transients.

Synthesis of the bis(dipyrromethene)copper(I) anion

Attempts to isolate pure, crystalline salts of $Cu^I(dpym)_2^-$ were unsuccessful, and this anion was characterized in solution following its preparation by alternative routes — reduction of $Cu^{II}(dpym)_2^0$ in solution:

[1] $Cu^{II}(dpym)_2^0 + e^- \rightarrow Cu^I(dpym)_2^-$

and displacement of acetonitrile in $(CH_3CN)_4Cu^+$ by Hdpym:

[2] $(CH_3CN)_4Cu^+ + 2Hdpym \rightarrow Cu^I(dpym)_2^- + 2H^+ + 4CH_3CN$

Solutions of $Cu^I(dpym)_2^-$ were found to oxidize to $Cu^{II}(dpym)_2^0$ over about an hour when exposed to the air, so all synthetic procedures were carried out in Schlenk glassware under dry N_2 or Ar.

In attempts to make $Cu^I(dpym)_2^-$ by direct reaction of a source of $dpym^-$ with $(CH_3CN)_4Cu^+$, chloride-free reagents (specifically, Hdpym rather than $[H_2dpym]Cl$) were necessary to prevent precipitation of CuCl, and solvents with a relatively strong affinity for Cu^I such as acetonitrile or dimethylsulfoxide were avoided as they gave mixtures of 1:1 and 2:1 dpym:Cu complexes, even with Hdpym in large excess. Since H^+ is formally produced in reaction [2], poor proton acceptor solvents such as alkanes, dichloromethane, chloroform, CCl_4, or nitromethane gave only reprecipitated starting materials. Methanol and ethanol caused slow oxidation of the $Cu(dpym)_2^-$ ion to $Cu(dpym)_2^0$. Although $Cu(dpym)_2^-$ appeared to form by reaction [2] in *N,N*-dimethylformamide and in propylene carbonate and seemed stable in these solvents over 24 h or longer, these high-boiling solvents were unsuited to the vacuum-line techniques described below. The only sufficiently volatile solvent that could be found that dissolved enough of the reagents required for this study without competing effectively with Hdpym for Cu^I or causing oxidation was acetone. For these experiments, acetone (BDH Assured) was dried over 4A molecular sieves, redistilled, and degassed by freeze–pump–thaw cycles at ca. 10 Pa before use; cyclic voltammetry with 0.1 mol L^{-1} tetrabutylammonium (TBA) perchlorate gave a clean sweep over the stability range of the solvent, −0.6 to +1.3 V vs. a saturated calomel electrode. It was established that, in acetone, dissociation of $Cu(dpym)_2^-$ was negligible, so that a 2:1 stoichiometric mixture of Hdpym and $[(CH_3CN)_4Cu]BF_4$ gave the desired $Cu(dpym)_2^-$ quantitatively. However, in order to remove all CH_3CN (from $(CH_3CN)_4Cu^+$) that might conceivably compete with Hdpym for Cu^I, a powdery product (presumably $H_2Cu^I(dpym)_2BF_4$) was first isolated by vacuum evaporation of the acetone and any remaining CH_3CN, then redissolved in acetone when required.

Tetra(acetonitrile)copper(I) tetrafluoroborate was made from Cu_2O (Fisher Certified) by the method of Kubas (18) and stored under dry nitrogen in the refrigerator. The Cu content was checked by standard methods (19). There were no absorbance bands in the visible spectrum , 350–700 nm, and the proton NMR spectrum showed a single methyl resonance at 2.22 ppm. Typically, stoichiometric amounts of $[(CH_3CN)_4Cu]BF_4$ (0.0234 mmol) and Hdpym (0.0467 mmol) were mixed in a 10 mm tube on a vacuum line and purged several times with argon before pumping at 7 Pa for 15 min to remove O_2, after which acetone (ca. 3 mL), purified as above, was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

condensed onto the solids at low pressure with liquid N_2. The mixture was then kept at 25–30°C for about 10 min, so that the bright orange solids dissolved completely and reacted to form a brown solution. The solution was then frozen in liquid N_2 and the acetone was pumped away; the residue was warmed to about 30°C and pumped at 7 Pa for at least 15 min to remove any residual acetonitrile. The resulting powder was stable in air for up to one week, but was customarily stored under dry nitrogen and dissolved in purified acetone as required. Proton NMR of solutions in acetone-d_6 prepared in this way showed no trace of either residual CH_3CN or uncomplexed Hdpym; the observed resonances (Table 1) were as would be expected for $Cu(dpym)_2^-$ (cf. the isoelectronic $Zn^{II}(dpym)_2^0$). The UV/visible spectrum showed a single absorbance maximum at 488 nm (ϵ not accurately calculable), and excitation at 488 nm produced fluorescence with a sharp maximum at 732 nm.

The anionic nature of the brown complex was verified by electrophoresis of an acetone solution of ca. 10 μmol L^{-1} $Cu(dpym)_2^-$ and 0.1 mol L^{-1} $[TBA]BF_4$ through glass wool at 1.0 V; a single brown band migrated into the anode compartment, and the UV/visible spectrum of this band showed the single characteristic absorption maximum at 488 nm. The anionic character of the brown solute was further demonstrated by its absorption from acetone solution on dehydrated Dowex 1-X4 anion exchange resin (Cl^- form) and subsequent elution with 0.1 mol L^{-1} [TBA]Cl, although the UV/visible spectrum of the eluate did not match that of the original solution accurately, presumably because of dissolution of the resin by acetone or partial complexing of the Cu complex by chloride. The brown solute was not retained on the cation exchange resin Dowex 50W-X4 in a similar experiment. Neither $Cu^{II}(dpym)_2$ nor Hdpym were retained by Dowex 1-X4 or 50W-X4 under these conditions. FAB-MS of the powder in a nitrobenzylamine matrix gave a strong cluster of peaks centred at m/e = 749 as well as lighter fragments, as expected for $Cu(dpym)_2^-$. Thus, the brown solute was unquestionably $Cu(dpym)_2^-$, but attempts to precipitate it as a pure salt for structural analysis with Na^+, K^+, R_4N^+ (R = methyl, ethyl, and butyl), and tetraphenylarsonium cations were unsuccessful.

Attempts to make $Cu(dpym)_2^-$ in various solvents by chemical reduction of $Cu^{II}(dpym)_2^0$ with amalgamated Zn (which gave $Zn^{II}(dpym)_2^0$), hydroxylamine hydrochloride, hydrazine, dithionite, dithionate, thiosulfate, and sodium amalgam were unsuccessful. With $Cu(dpym)_2^0$ in acetone, potassium superoxide gave the characteristic 488 nm band of $Cu(dpym)_2^-$, but the reaction was not quantitative, and excess KO_2 destroyed the product. Electrochemical reduction methods, described below, were used to generate $Cu(dpym)_2^-$ in dilute solution, and to obtain definitive UV/visible spectra of it.

Electrochemistry and spectroelectrochemistry

Electrochemical measurements employed either acetone or dichloromethane containing 0.1 mol L^{-1} $[TBA]BF_4$ as supporting electrolyte. Dichloromethane was distilled from CaH_2. Spectroscopic grade acetone (BDH Assured) was dried over 4A molecular sieves and then fractionally distilled immediately before use. $[TBA]BF_4$ was recrystallized from isopropanol/water and dried in vacuo at 80°C. All solutions were purged with argon to remove O_2. Potential control in all experiments was accomplished with a HiTek model DT2101 potentiostat operating in conjunction with a HiTek model PPR1 waveform generator.

Cyclic voltammetry was carried out with a 125 μm diameter Pt disk working electrode positioned ca. 2 mm from the tip of a Luggin capillary. A home built aqueous saturated calomel electrode (SCE) was used as reference electrode, and a Pt wire helix served as counter electrode.

Thin-layer reflectance spectroelectrochemistry employed a 7 mm diameter Pt disk polished to a mirror finish, and a SCE as reference electrode. The details of the cell design, the rapid scanning spectrometer, and the experimental procedures have been published previously (20, 21).

The diffusion coefficient of $Cu(dpym)_2$ in acetone was determined by chronoamperometry. The cell employed a 7 mm diameter Pt disk working electrode fitted into a Teflon cell body. The electrode area was calibrated by chronoamperometry of $K_4Fe(CN)_6$ in 1 mol L^{-1} aqueous KCl, using the known (22) diffusion coefficient for $Fe(CN)_6^{4-}$. A Pt wire wound into a helix served as a counter electrode. For convenience, and to avoid contamination of nonaqueous solvents by the aqueous SCE, the cell was fitted with a silver wire quasi-reference electrode sealed into heat-shrink Teflon, with the exposed tip positioned ca. 1 mm from the edge of the Pt disk working electrode.

AC voltammetric measurements were used to determine the heterogeneous electron transfer rate constant of $Cu(dpym)_2^{0/-}$ in acetone. Phase angle data as a function of frequency (25–135 Hz) were measured at the experimentally observed half wave potential of the complex with a PAR model 124A lock-in amplifier. Phase angles were corrected for the influence of background current and uncompensated resistance, measured in the absence of Faradaic species, according to the procedures outlined by Smith (23). AC measurements were carried out in the same cell as was employed for chronoamperometric measurements.

NMR measurements

Proton NMR spectra were obtained on a Bruker AM-400 (9.4 T) spectrometer fitted with a N_2-flow temperature regulator.

For NMR studies of the rate of ligand exchange of $Cu(dpym)_2^-$ with Hdpym, an accurately weighed quantity of a stock acetone solution of Hdpym was evaporated to dryness on a vacuum line in a 5 mm NMR tube with a collar specially constructed for this purpose, so depositing 2.6–10.6 μmol of Hdpym. Freshly-dissolved $[(CH_3CN)_4Cu]BF_4$ (1.1–2.7 μmol) was introduced in acetone, whereupon the Hdpym dissolved to give a brown solution containing $Cu(dpym)_2^-$. The contents of the tube were then quickly frozen in liquid N_2, the tube was reattached to the vacuum line, and the tube was allowed to warm slowly while the solvent was pumped off at ca. 1 Pa (with care to avoid bumping of the evaporating solvent). The deposited solid was pumped for at least 15 min at 30°C and 1 Pa to remove all traces of acetonitrile, then a weighed amount of degassed acetone-d_6 that had been dried over 4A molecular sieves was distilled on to the solid, and the tube was sealed with a small flame. The NMR spectrum of the thawed solution in the vicinity of the methene resonance at chemical shift $\delta \approx$ 8.0 ppm was then recorded at descending temperatures from 300 to 230 K. At each temperature, 15 min were allowed for thermal equilibration, then the magnetic field was reshimmed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Measurements below 230 K were rejected because of precipitation of the reactants and high solvent viscosity. The temperature readout was calibrated against the chemical shift difference of the methylhydroxyl protons of a methanol sample.

For NMR line-broadening measurements of the rate of electron transfer between $Cu(dpym)_2^0$ and $Cu(dpym)_2^-$ in acetone-d_6, a mixture of solid Hdpym and $[(CH_3CN)_4Cu]BF_4$ in 2:1 (±1.0%) molar ratio was prepared by the acetone evaporation technique outlined above — no excess of $[(CH_3CN)_4Cu]BF_4$ could be tolerated, as this was found to reduce $Cu(dpym)_2^0$, while excess Hdpym could cause line broadening through ligand exchange. The requisite amount of $Cu(dpym)_2^0$ was then added in acetone solution, and the solvent was evaporated as above. A weighed quantity of acetone-d_6 was then distilled on to the residue in a 10 mm NMR tube using the vacuum line. The amount of $Cu(dpym)_2^0$ was limited by its low solubility in acetone (vide supra). The linewidth of the methene proton line of $Cu^I(dpym)_2^-$ at 8.15 ppm was measured with careful exclusion of air. The temperature display was calibrated with neat methanol.

Results

Identity and characteristics of the reduced species

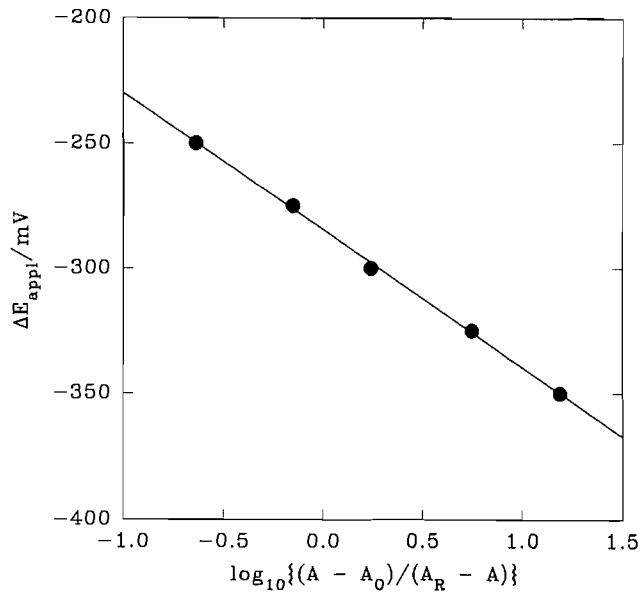
The cyclic voltammograms of 3.6×10^{-4} mol L^{-1} $Cu(dpym)_2^0$ in acetone and dichloromethane were fully reversible (peak-to-peak separation 60 mV at sweep rate 100 mV s^{-1}), implying that species formed by its electrochemical reduction did not undergo ligand loss (despite the high dilution) on the 10 s timescale of the CV experiments, and that the ligand was not irreversibly altered in the process. These facts suggest rapid electron transfer to and from the Cu centre, and, since it is shown below that the reduced compound is the same as the *labile* product of reaction [2], the reaction observed was [1] and the product $Cu^I(dpym)_2^-$ is very stable *thermodynamically* with respect to ligand loss. The half-wave potentials, which may be equated approximately to the electrode potential E^0, were −290 and −380 mV vs. SCE in acetone and dichloromethane, respectively, with 0.1 mol L^{-1} $[TBA]BF_4$ as the supporting electrolyte.

The reversibility and single-step nature of the reduction were confirmed by the potential-resolved spectra in Fig 1, in which there is a clean isosbestic point at 460 nm. Furthermore, a plot (Fig. 2) of $\log\{(A - A_O)/(A_R - A)\}$ vs. the applied potential ΔE_{appl},

$$[3] \quad \Delta E_{appl} = E^0 - (RT/nF) \ln \{(A - A_O)/(A_R - A)\}$$

where A is the absorbance of the solution at ΔE_{appl} and A_O and A_R are the absorbances initially and after complete reduction, respectively, gave an intercept E^0 = −285 mV vs. SCE (cf. −290 from the CV half-wave potential) and a slope $-0.0548 = -2.303RT/nF$, corresponding to a transfer of $n = 1.0_8$ electron. The limiting spectrum (at −400 mV in Fig. 1) as reduction in acetone progresses has an absorbance maximum at 488 ± 1 nm with $\epsilon = 1.44 \times 10^5$ L mol^{-1} cm^{-1}, and is identical in shape and position to that of the product of reaction [2]; it may be taken to be characteristic of $Cu^I(dpym)_2^-$. Spectroelectrochemical reduction of $Cu^{II}(dpym)_2^0$ in CH_2Cl_2 gave the same absorbance band, with maximum at 489 ± 1 nm, $\epsilon = 1.48 \times 10^5$ L mol^{-1} cm^{-1}; since the spectrum of $Cu^{II}(dpym)_2^0$ is also

Fig. 2. Nernst plot (equation [3]) for the spectroelectrochemical reduction of $Cu^{II}(dpym)_2^0$ in acetone. Conditions as in Fig. 1.



independent of solvent, this implies that neither $Cu^{II}(dpym)_2^0$ nor $Cu^I(dpym)_2^-$ has coordinated solvent in acetone or dichloromethane, and that both exist as four-coordinate, quasi-tetrahedral species in these solvents.

The proton NMR spectrum of the acetonitrile-free product of reaction [2] (Table 1) confirms that it is a dpym complex, different from the others listed but more closely resembling the isoelectronic $Zn^{II}(dpym)_2^0$ than its paramagnetic precursor $Cu^{II}(dpym)_2^0$, except that the minor splitting of the signal of the methyl group *cis* to the ring N atoms in $Zn^{II}(dpym)_2^0$ (suggesting a distorted tetrahedral coordination geometry) is absent. This confirms the identity of $Cu^I(dpym)_2^-$. The absence of Hdpym features from the proton NMR spectrum of solutions of $Cu^I(dpym)_2^-$ in acetone at concentrations of the order of 10^{-4} mol L^{-1} showed that $Cu^I(dpym)_2^-$ is less than 1% dissociated under those conditions. The methene resonance showed marked sensitivity to its chemical environment, and was broadened to the limit of detectability in the paramagnetic $Cu^{II}(dpym)_2^0$.

Kinetics of the exchange of dpym between bis(dipyrromethene)copper(I) and Hdpym in acetone

The methene proton spectrum of mixtures of $Cu^I(dpym)_2^-$ and Hdpym in acetone-d_6 consisted of a single peak that narrowed with increasing temperature or concentrations, indicating that chemical exchange of $dpym^-$ between Cu^I and H^+ sites was occurring on the "fast exchange" NMR timescale. Thus, the first-order rate constants k_A and k_B for the exchange of ligand on species A ($Cu(dpym)_2^-$, mole fraction p_A of total dpym pool) and B (Hdpym, mol fraction p_B of total dpym), respectively were related to the corresponding methene proton linewidths w_A and w_B by the expressions

$$[4] \quad k_A = 4\pi p_A p_B^2 (\delta\nu)^2 \{W - (p_A w_A + p_B w_B)\}^{-1}$$

$$[5] \quad k_B = 4\pi p_A^2 p_B (\delta\nu)^2 \{W - (p_A w_A + p_B w_B)\}^{-1}$$

in which $\delta\nu$ is the difference in chemical shift between the

[a] $[H^+] = 2[Cu^I(dpym)_2^-]$, $[BF_4^-] = [Cu^I(dpym)_2^-]$.
[b] Calculated on basis that the exchange rate is first order with respect to both $Cu^I(dpym)_2^-$ and Hdpym.

methene singlets of A and B in separate solutions at the same temperature T, and W is the linewidth of the coalesced methene proton peak in the exchanging mixture (24). Since there are two methene protons in A but only one in B, the rate R of ligand exchange between A and B is then given by

$$[6] \quad R = 2k_A[A] = k_B[B] = 2k_1[A]^a[B]^b$$

where k_1 is the rate constant for the exchange reaction of order a in [A] and b in [B] (25). Details of the experimental conditions, chemical shifts δ and linewidths W of the coalesced line, and exchange rate data are given in Table 2. Over the temperature range of these experiments (300–230 K), δν increased monotonically from 328.5 to 336.0 Hz, w_A from 1.65 to 4.18 Hz, and w_B from 1.34 to 1.54 Hz, with most of the increases taking place at the lowest temperatures.

The ligand exchange rate data in Table 2 are presented as rate constants k_1 with the assumption that the exchange is first order with respect to each of $Cu(dpym)_2^-$ and Hdpym (i.e., $a = b = 1$ in eq. [6]). The useful ranges of Hdpym and $Cu(dpym)_2^-$ concentrations were limited on the one hand by the need to have enough solute to give accurately measurable spectra, and on the other by the narrowing of the linewidth with increasing concentrations when working at the fast exchange limit of the NMR linewidth technique. Given the rather large uncertainties arising from these limitations, it will be seen that k_1 is effectively constant at a given temperature. Thus, the foregoing assumption is vindicated, and k_1 can be identified with the process:

$$[7] \quad Cu(dpym)_2^- + Hdpym^* \rightarrow Cu(dpym)(dpym^*)^- + Hdpym$$

The k_1 values of Table 2 show only a slight temperature dependence which is obscured by the considerable scatter, but they may be summarized by the Eyring activation parameters $\Delta H_1^{\ddagger} = 3.4 \pm 0.6$ kJ mol^{-1} and $\Delta S_1^{\ddagger} = -97 \pm 3$ J K^{-1} mol^{-1}, corresponding to $k_1 = 1.4 \times 10^7$ L mol^{-1} s^{-1} at 298 K.

Kinetics of electron transfer between bis(dipyrromethene)copper(II) and -(I) in homogeneous solution in acetone

The rate of the self-exchange reaction of $Cu(dpym)_2^{0/-}$ in acetone-d_6 was well within the "slow exchange" region in the NMR timeframe, as shown by the constancy of the methene proton chemical shift of $Cu^I(dpym)_2^-$ at 8.15 ± 0.01 ppm, whether or not Cu^{II} was present, and by the increase in linewidth as the concentration of Cu^{II} increased. The rate constant k_{ex} was given by $\pi(W - W_0)/[Cu^{II}(dpym)_2^0]$, where W and W_0 are the Cu^I methene proton linewidths with and without the addition of $Cu^{II}(dpym)_2^0$, respectively. Because the solubility of $Cu^{II}(dpym)_2^0$ is low, the broadenings were less than 30% at 294 K, but Table 3 shows that the k_{ex} values so obtained were reproducible to about 10% over the accessible range of $Cu^{II}(dpym)_2^0$ concentrations, with an average of $(4.8 \pm 0.3) \times 10^3$ L mol^{-1} s^{-1} at 294.2 K and $I \approx 0.007$ mol L^{-1}. At 320.5 K, linewidths were broadened two- to three-fold by addition of $Cu^{II}(dpym)_2^0$ (Table 3), giving an average $k_{ex} = (2.25 \pm 0.08) \times 10^4$ L mol^{-1} s^{-1} from five measurements. Figure 3 is an Eyring plot for a single solution sample over the temperature range 294.2–320.5 K; the data are summarized by $\Delta H_{ex}^{\ddagger} = 48.5 \pm 3.0$ kJ mol^{-1} and $\Delta S_{ex}^{\ddagger} = -10.0 \pm 9.8$ J K^{-1} mol^{-1}, corresponding to $k_{ex} = 5.9 \times 10^3$ L mol^{-1} s^{-1} at 298 K.

Kinetics of heterogeneous electron transfer between bis(dipyrromethene)copper(II) and -(I) at a Pt electrode in acetone

The heterogeneous rate constant k_{el} for electron exchange in the $Cu(dpym)_2^{0/-}$ couple in acetone at a Pt electrode was determined by AC voltammetry using the relationship

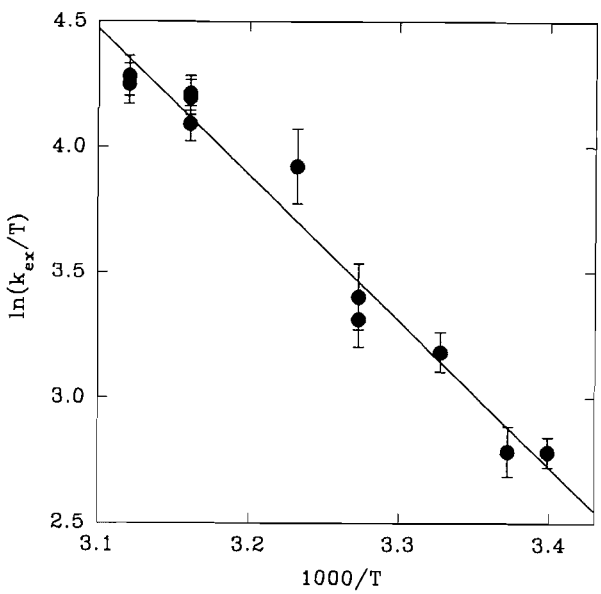
Fig. 3. Eyring plot showing the temperature dependence of the rate constant k_{ex} for electron transfer between $Cu(dpym)_2^0$ (0.256 mmol L^{-1}) and $Cu(dpym)_2^-$ (3.62 mmol L^{-1}) in acetone-d_6.



[8] $k_{el} = (2\pi fD/2)^{1/2}(\cot \phi - 1)^{-1}$

where f is the frequency of the current in Hz, D is the diffusion coefficient of the electroactive species (assumed to be the same for the oxidized and reduced forms), and ϕ is the phase angle (26). The diffusion coefficient for $Cu(dpym)_2^{0/-}$ (1.237×10^{-4} mol L^{-1}) was measured in acetone containing 0.1 mol L^{-1} [TBA]BF_4 using the Cottrell relation (26)

[9] $i_t = nFAC^*D^{1/2}(\pi t)^{-1/2}$

in which i_t is the current measured at time t during reduction of $Cu(dpym)_2^0$, C^* is the concentration of $Cu(dpym)_2^0$ in mol cm^{-3}, F = 96 487 C mol^{-1}, and A is the area of the working electrode in cm^2. Plots of i_t vs. $t^{-1/2}$ were accurately linear, as were those for an aqueous solution of 0.01 mol L^{-1} $K_4Fe(CN)_6$ in aqueous 1.0 mol L^{-1} KCl that was used as a calibrant to eliminate A (22). For $Cu(dpym)_2^0$, D was found to be 3.60×10^{-5} cm^2 s^{-1} in acetone at 25°C. Values of k_{el} obtained at various frequencies f are listed in Table 4. Since the heterogeneous electron transfer rates were near the upper limit accessible by AC voltammetry (i.e., near the time domain in which diffusion from the working electrode becomes rate-determining), the k_{el} values show considerable scatter, but the average value of 0.16 ± 0.04 cm s^{-1} is at least a semi-quantitative measure of the rate constant.

Table 4. Rate constant for heterogeneous electron transfer in $Cu(dpym)_2^{0/-}$ at a Pt surface in acetone at 25°C.[a]

Discussion

We have shown that the species with light absorption maximum at 488 nm ($\epsilon = 1.44 \times 10^5$ L mol^{-1} cm^{-1}) prepared by electrochemical reduction of the known quasi-tetrahedral species $Cu(dpym)_2^0$ in acetone or dichloromethane is the same as that formed by reaction of Cu^I with Hdpym in acetone, that it carries one negative charge, and that its ^{1}H-NMR and mass spectra are consistent with the formulation $Cu(dpym)_2^-$. In acetone — a weak donor solvent — $Cu(dpym)_2^-$ forms quantitatively from Hdpym and Cu^I in a 2:1 molar ratio with no detectable free ligand, and the full reversibility of cyclic vol-

For personal use only.

tammograms of $Cu(dpym)_2^{0/-}$ in acetone or CH_2Cl_2 confirms that ligand loss from $Cu(dpym)_2^-$ is negligible. Since the exchange of $Cu(dpym)_2^-$ with free Hdpym was shown to be fast, this stability of $Cu(dpym)_2^-$ is thermodynamic rather than simply kinetic. Since the UV/visible spectra of neither $Cu(dpym)_2^0$ nor $Cu(dpym)_2^-$ were solvent-dependent, neither species contains coordinated solvent, and therefore both are four-coordinate and quasi-tetrahedral, as $Cu(dpym)_2^0$ is known to be in the solid state (8).

The $Cu(dpym)_2^-$/Hdpym exchange in acetone is fast (k_1^{298} = 1.4×10^7 L mol^{-1} s^{-1}) because of the remarkably low enthalpy of activation (3.4 kJ mol^{-1}). Since the reaction seems to be first order with respect to both $Cu(dpym)_2^-$ and Hdpym, and since the dissociation of $Cu(dpym)_2^-$ is negligible, the simplest mechanism consistent with the very low $\Delta H^{\ddagger}$ is proton transfer from Hdpym to $Cu(dpym)_2^-$ followed by interchange of the newly-formed coordinated Hdpym and free $dpym^-$. An alternative possibility, attack of Hdpym on $Cu(dpym)_2^-$ followed by internal proton transfer and ligand loss, is less likely because steric hindrance would result in a substantial $\Delta H^{\ddagger}$.

Although the rate constants for homogeneous and heterogeneous electron transfer for $Cu(dpym)_2^{0/-}$ in acetone ($k_{ex} = 5.9 \times 10^3$ L mol^{-1} s^{-1} at I $\approx$ 0.007 mol L^{-1} and $k_{el} \approx 0.16$ cm s^{-1} at I = 0.1 mol L^{-1}, respectively, at 25°C) are dimensionally incompatible, they are mutually confirmatory in that they conform well to the $k_{ex} - k_{el}$ correlation demonstrated by Cannon (27) — Cannon's data, however, were for aqueous systems rather than acetone solutions. The value of k_{ex} is close to that found (14) for the $Cu(dmp)_2^{2+/+}$ exchange in the same solvent (3×10^3 kg mol^{-1} s^{-1} at I = 0.1 mol kg^{-1} and 25°C), ignoring possible minor effects of ionic strength. For $Cu(dpym)_2^{0/-}$, $\Delta H_{ex}^{\ddagger}$ is some 20 kJ mol^{-1} higher and $\Delta S_{ex}^{\ddagger}$ about 70 J K mol^{-1} more positive than for $Cu(dmp)_2^{2+/+}$, but these compensate in k_{ex} at near-ambient temperatures. This disparity in activation parameters might be supposed to indicate a difference in electron transfer mechanism, such as some sort of inner-sphere process for $Cu(dpym)_2^{0/-}$ as opposed to outer-sphere for $Cu(dmp)_2^{2+/+}$, and indeed we have shown that $Cu(dpym)_2^-$ is very labile. Under the conditions of our electron transfer rate measurements, however, the rate of ligand exchange on $Cu(dpym)_2^-$ was shown to be negligible, and an outer-sphere mechanism may be assumed for both couples.

The similarity in k_{ex} values for the two copper couples in acetone suggests that k_{ex} for the $Cu(dpym)_2^{0/-}$ exchange in water (which is inaccessible because of the insolubility of $Cu^{II}(dpym)_2^0$) might be about 3×10^5 L mol^{-1} s^{-1} at ca. 300 K, by analogy with $Cu(dmp)_2^{2+/+}$. Rorabacher et al. (28), however, point out that the presence of chloride ion during measurements on the latter aqueous system opens the possibility of a chloride-mediated electron transfer path in that case, so that the extrapolation may not be valid. Indeed, a change of solvent ordinarily has only a minor effect on outer-sphere electron transfer rates (29). Comparison of electron transfer rates in $Cu(dpym)_2^{0/-}$ or $Cu(dmp)_2^{2+/+}$, whatever the solvent, with those of the "blue" copper proteins in water (which are some two orders of magnitude faster) may not be entirely appropriate, since copper in the proteins is in a highly distorted but rigid N_2S_2 environment, whereas in the $dpym^-$ and dmp complexes the environment is N_4 with essentially tetrahedral geometry and some degree of flexibility. As noted elsewhere (30), such flexibility may lower electron transfer rates relative to those of encapsulating ligand systems by increasing the Franck–Condon barrier.

In any event, the $Cu(dpym)_2^{0/-}$ exchange may be considered to be at least moderately fast in the context of copper(II/I) electron transfer reactions, the values of k_{ex} and k_{el} being of the order expected for $Cu^{II/I}$ couples in which no significant change in coordination number or geometry accompanies electron transfer. The relative slowness of self-exchange in the bis(2,2′-bis(2-imidazolyl)-biphenyl)copper(II/I) exchange couple in acetonitrile is evidently an anomaly that reflects some special property of this system, as suggested by Knapp et al. (11). The self-exchange rate constant reported (9) for the aqueous $CuW_{12}O_{40}^{6-/7-}$ couple is also surprisingly low, but it was estimated indirectly from the Marcus cross relationship using a literature value of k_{ex} for the $Fe(CN)_6^{3-/4-}$ couple. Since this latter value depends strongly upon the cation concentration (31), and since the Coulombic work terms would be unusually large in the nominally 7-/3- cross reaction, the k_{ex} value estimated for the $CuW_{12}O_{40}^{6-/7-}$ self-exchange may be substantially in error.

Deprotonation energetics of some nucleosides in water from EMF measurements

Sonali Ganguly and Kiron K. Kundu

Abstract: The deprotonation constants of uridine (K_1 and K_2), thymidine (K_1 and K_2), cytidine (K_1 and K_2), guanosine (K_1, K_2, and K_3), and xanthosine (K_1, K_2, and K_3) have been obtained in water from EMF measurements of Harned-Ehler type cells comprising H_2 and Ag-AgI electrodes at different temperatures. The pK values were substituted in the temperature equation: $pK = AT^{-1} + B + CT$ and A, B, and C were obtained by the method of least squares. Related thermodynamic quantities viz. ΔG^0, $T\Delta S^0$, and ΔH^0 were obtained from coefficients A, B, and C of the respective nucleosides.

Key words: deprotonation energetics, uridine, thymidine, cytidine, guanosine, xanthosine.

Résumé : Faisant appel à des mesures de fém de cellules du type de Harned-Ehler et à des électrodes de Ag-AgI et opérant à diverses températures, on a mesuré les constantes de déprotonation de l'uridine (K_1 et K_2), de la thymidine (K_1 et K_2), de la cytidine (K_1 et K_2), de la guanosine (K_1, K_2 et K_3) et de la xanthosine (K_1, K_2 et K_3) en solution dans l'eau. On a introduit les valeurs des pK dans l'équation: $pK = AT^{-1} + B + CT$ et on a déterminé les valeurs de A, B et C par la méthode des moindres carrés. On a aussi déterminé les valeurs thermodynamiques correspondantes, à savoir le ΔG^0, $T\Delta S^0$ et ΔH^0 à partir des coefficients A, B et C des divers nucléosides.

Mots clés : énergies de déprotonation, uridine, thymidine, cytidine, guanosine, xanthosine.

Introduction

As a continuation of our thermodynamic studies on deprotonation processes of pyrimidine bases and adenine and its derivatives in pure water (1) we now report the same for some nucleosides with a view to identifying the probable sites involved in the deprotonation steps of the various biochemical reactions.

A nucleoside is best defined as a unit composed of a purine or pyrimidine base and a sugar moiety (pentose or deoxypentose). The components are united by a β-glycosidic linkage between the carbon 1′ of the sugar and the nitrogen at position 9 in the purines or at position 1 in the pyrimidines (2) as shown in Fig. 1.

Among numerous publications on nucleoside deprotonation constants (K) in the literature (3*a*) only a few have reported data at zero ionic strength. The notable exceptions which provide data at zero ionic strength and 25°C are those of Izatt et al. (3*b*, 3*d*). However, data between 10^{-4} – 10^{-10} have been obtained mostly by half neutralization point method using glass (H^+) electrodes and aqueous saturated calomel electrodes SCE(w) cells with liquid junctions, while data above 10^{-4} and below 10^{-10} have been obtained by an indirect entropy titration method using calorimetry. In this paper, we report our findings on deprotonation constants of the different acidic sites and the related thermodynamic quantities, viz. ΔG^0, ΔS^0, and ΔH^0 of uridine (urd), thymidine (thd), cytidine (cyd), guanosine (guo), and xanthosine (xao) at zero ionic strength and 25°C by measuring the EMF's of the Harned-Ehler type (4) galvanic cells without liquid junctions, and comprised Pt, H_2 (g, 1 atm) and Ag-AgI electrodes and buffers of different ionic strengths at five equidisant temperatures from 15 to 35°C.

As in our previous papers (1), the Harned-Ehler type cells used for determining the pK's of the nucleosides and related energetics are [A]–[E].

For determining $(pK_1)_{H_2A}$ of urd and thd and $(pK_2)_{H_2A}$ of guo and xao, we used

Experimental

urd (grade U 3750), thd (grade T 9250), cyd (grade C 9505), guo (grade G 6752), and xao (grade X 0750) were obtained from Sigma Chemical Co. and were used as such after drying in a vacuum desiccator at 0–5°C. Purities of all chemicals were checked by UV spectroscopy (5, 6) and were found to be within 98–99%. Triple distilled CO_2-free water was used. Sodium hydroxide (GR), potassium iodide (GR), and hydroiodic acid (GR) were obtained from E. Merck.

Cell solutions of different ionic strengths were prepared by mixing appropriate weighed amounts of biochemicals, NaOH and KI of known molality, and triple distilled water in well stoppered Jena bottles. Appropriate amounts of standard NaOH solutions were used for stepwise neutralization of the acids in order to get the desired concentrations of the corresponding conjugate bases. For the determination of PK_1's of cyd, guo, and xao, HI acid was used instead of the alkali solution. The method of HI distillation was similar to that described earlier (7).

EMF method

The EMF's of the cells were measured using a Leeds and Northrup K_4-potentiometer fitted with a moving coil galvanometer (Cambridge Instrument Co.) as the null point detector. The preparation of Ag-AgI electrodes was described elsewhere (8). General experimental procedures including the preparation of H_2 (Pt) electrodes and the measurements of EMF were similar to those described earlier (7). As indicated in our previous papers (1), Ag-AgI electrodes were introduced after an hour's discharge of hydrogen gas through the cells. The equilibrium was attained in 3–4 h. A constant EMF reading to about ±0.1 mV for 1 h was taken as the criterion of equilibrium. The readings were first taken at 15°C and then successively at higher temperatures at 5°C intervals. The readings at 25°C when back checked after 35°C agreed to within ±0.1 mV.

Results

The measured EMF's of cells corrected to $p_{H_2} = 1$ atm gave the values of E. The emf data (E) of cells [A]–[E] at different temperatures and corresponding molalities of KI, H_2A, NaHA for cell [A], KI, NaHA, Na_2A for cell [B], KI, $H_2A^+I^-$, HA for cell [C], KI, HA, NaA for cell [D], and KI, $H_3A^+I^-$, H_2A for cell [E] for each of the cell solutions are given in Table 1.

Similar to our previous studies (1), the pK_1 and pK_2 values of urd, thd, cyd, guo, and xao and pK_3 of guo and xao were evaluated by using the functions pK_1', pK_2' and pK_3' defined by eqs [1]–[5].

$$pK_1(\text{urd, thd}) \text{ or } pK_2(\text{guo, xao}) = (E - E^0)/k + \log (m_{I^-} m_{H_2A}/m_{HA^-}) + \log (\gamma_{I^-}\gamma_{H_2A}/\gamma_{HA^-})$$

[1] $$pK_1'(\text{urd, thd}) \text{ or } pK_2'(\text{guo, xao}) = (E - E^0)/k + \log [m_3(m_1 + m_{OH^-})/(m_2 - m_{OH^-})] = pK_1(\text{urd, thd}) \text{ or } pK_2(\text{guo, xao}) + f(\mu)$$

[1′] $$\log m_{OH^-} = \log K_w + p_wH \text{ (Bates acidity function)} = -\log a_H \cdot \gamma_{OH^-} = -\log a_H \cdot \gamma_{I^-} = (E - E^0)/k + \log m_{I^-} \text{ (ref. 8).}$$

μ (ionic strength) $= m_2 + m_3$; $k = 2.3026RT/F$; m_{OH^-} stands for the molality of the hydroxyl ions that are formed from the hydrolysis of the conjugate bases where the pK's of the acids are greater than 9–10; K_w is the ionic product of water; m and γ denote the molality and molal activity coefficients of the species involved; E^0 is the standard electrode potential of the Ag-AgI electrodes in water (8); R, the universal gas constant; F, Faraday; T, absolute temperature in Kelvin; and $f(\mu)$ denotes a function of μ which is usually linear (1).

$$pK_2(\text{urd, thd}) \text{ or } pK_3(\text{guo, xao}) = (E - E^0)/k + \log (m_{I^-} m_{HA^-}/m_{A^{2-}}) + \log (\gamma_{I^-}\gamma_{HA^-}/\gamma_{A^{2-}})$$

[2] $$pK_1'(\text{urd, thd}) \text{ or } pK_3'(\text{guo, xao}) = (E - E^0)/k + \log [m_3(m_{1^-} + m_{OH^-})/(m_2 - m_{OH^-})] + 2S_f(\mu d_0)^{1/2} = pK_2(\text{urd, thd}) \text{ or } pK_3(\text{guo, xao}) + f(\mu)$$

where m_{OH^-} is given by eq. [1′], $\mu = m_1 + 3m_2 + m_3 - m_{OH^-}$, S_f (Debye-Hückel constant) $= 1.824 \times 10^6 (\epsilon_w T)^{-3/2}$, ϵ_w = the dielectric constant of water, and d_0 = density of water.

$$pK_1(\text{cyd} = \log (m_{H^+} m_{HA}/m_{H_2A^+}) - \log (\gamma_{H^+}\gamma_{HA}/\gamma_{H_2A^+})$$

[3] $$pK_1'(\text{cyd}) = -\log [m_{H^+}'(m_2 + m_{H^+}')/(m_1 - m_{H^+}')] = pK_1(\text{cyd}) + f(\mu)$$

where

[3′] $$-\log (m_{H^+}') = (E - E^0)/k + \log (m_{I^-}) - 2S_f(\mu d_0)^{1/2} \text{ (ref. 9)}$$

and $\mu = m_1 + m_3 \cdot m_{H^+}'$ denotes the apparent molality of hydrogen ion that results from significant deprotonation of the acid where pK is less than 3–4.

Table 1. EMF values at different temperatures for different cell solutions in pure water for deprotonation constant of urd, thd, cyd, guo, and xao.

$$pK_2(\text{cyd}) = (E - E^0)/k + \log (m_{I^-}m_{HA}/m_{A^-}) + \log (\gamma_{I^-}\gamma_{HA}/\gamma_{A^-})$$

[4] $$pK_2'(\text{cyd}) = (E - E^0)/k + \log [m_3(m_1 + m_{OH^-})/(m_2 - m_{OH^-})] = pK_2(\text{cyd}) + f(\mu)$$

where m_{OH^-} is given by eq. [1′] and $\mu = m_2 + m_3$

$$pK_1(\text{guo, xao}) = -\log (m_{H^+}m_{H_2A}/m_{H_3A^+}) - \log (\gamma_{H^+}\gamma_{H_3A^+})$$

[5] $$pK_1'(\text{guo, xao}) = -\log [m_{H^+}'(m_2 + m_{H^+}')/(m_1 - m_{H^+}')] = pK_1(\text{guo, xao}) + f(\mu)$$

where m_{H^+}' is given by eq. [3′] and $\mu = m_1 + m_3$.

In the above equations the required $E^0_{Ag\text{-}AgI}$ values at different temperatures were taken from the literature (8). The activity coefficients in water involved were obtained approximately from the Brønsted form of Debye–Hückel equation (9):

$$-\log \gamma_i = S_f Z_i^2 (\mu d_0)^{1/2} + b_i \mu.$$

where μ = molal ionic strength of the cell solutions, Z_i = charge of the species involved, S_f = Debye–Hückel constant, and b_i = constant for species i depending on the nature of the solvent and the temperature. Since in all cases pK_i' values were found to be linear with respect to μ, the pK values at different temperatures were obtained from the linear fit of the type $pK_i' = pK_i + b\mu$, where b stands for the algebraic sum of b_i for i species involved in the respective equations. The pK_i values along with the standard deviations are listed in Table 2.

For each acid, pK values at different temperatures were fitted into the Harned-Robinson type expression (10)

[6] $$pK = AT^{-1} + B + CT$$

using the method of least squares. The thermodynamic parameters ΔG^0, ΔS^0, and ΔH^0 accompanying deprotonation of the acids were evaluated using the same relations as described in our previous paper (1*a*). The values of ΔG^0, ΔS^0, and ΔH^0 so obtained and the values of the constants A, B, and C are presented in Table 3. The maximum uncertainties in ΔG^0, ΔS^0, and ΔH^0 as calculated by Please's method (11) are ±0.01 kJ mol^{-1}, ±1 J K^{-1} mol^{-1}, and 0.3 kJ mol^{-1}, respectively.

Discussion

The observed deprotonation constants for urd (K_1 and K_2), thd (K_1 and K_2), cyd (K_1 and K_2), guo (K_1, K_2, and K_3) and xao (K_1, K_2, and K_3) and related energetics at zero ionic strength and 25°C are compared in Table 4 with some literature data. The probable sites of ionization for all compounds studied are discussed below and the equilibria involved in the deprotonation processes are depicted in Schemes 1–5.

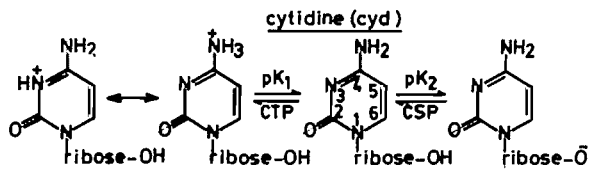
[a]Correlation coefficient for $pK_{1,urd/thd/guo/xao} = pK_{2,urd/thd/guo/xao} = pK_{3,guo/xao} = 1$ at different temperatures.

Scheme 3.



The fairly low magnitude of entropy change accompanying the first step deprotonation of cyd, guo, and xao indicates that the ionization processes involved were charge transfer processes (CTP) and the deprotonation sites were either $-\overset{+}{N}H-$ or $-\overset{+}{N}H_3$. The NMR spectrum of guanosine triphosphate in acidic D_2O (12) and IR studies of guanosine cation (13) confirm N_7 as the protonation site in guo. Based on the structural similarity between guo and xao Izatt et al. suggested N_7H^+ as the deprotonation site in protonated xao. Jardetzky et al.'s NMR data (12, 14) and calorimetric study (3*b*) favored N_3 protonation in cyd. However, as per Zana's ultrasonic studies of proton transfer reaction in the acidic range (15) and similar to cytosine as described in our previous paper (1*a*), the $-\overset{+}{N}H_3$ group can be considered the deprotonation site for protonated cyd.

Shapiro proposed that from UV and IR studies (16) N_1H- was the ionization site for uncharged guo. Similarity between the spectra of 1,7-dimethylxanthine and xao indicates ionization of the neutral xao to occur at the N_3H group. However, ultrasonic studies support the fact that the second step deprotonation of guo and xao are characterised by the formation of $C_6—O^-$ and $C_2—O^-$ groups, respectively (see Schemes 4 and 5).

For first step ionization of urd and thd, second step ionization of cyd, and second and third step ionizations of xao and guo, the accompanying entropy change is negative, indicating that the equilibria involved are charge separation processes (CSP) and the deprotonation sites are those shown in Schemes 1 to 5.

Similar to uracil and thymine (1*a*), in an alkaline solution two ionizations were detected for urd and thd. Ultrasonic studies indicate that pK_1 of urd and thd is characterised by 2-OH groups. The first step ionization of urd from 2-OH group is

also supported by the fact that the resulting anion is stabilized by intramolecular H-bond between 2-O$^-$ and 2′-OH group on the ribose. This is possible as nucleosides primarily exist in *anti* form in aqueous solutions (17).

The third step ionization of guo was demonstrated to occur at the ribose group (3*c*). Similarly the second step ionization of cyd and urd is assigned to the ribose moiety and for thd, to the dexyribose group (3*b*). By analogy with guo and other nucleosides, the third step ionization for xao is also expected to take place at the sugar group.

Interestingly enough, it is observed that the entropy of ionization accompanying the first step deprotonation of thd is less

than that for urd, i.e., $\Delta S^0_{1,thd} < S^0_{1,urd}$. This may be due to two reasons: First, in the thd anion, the water molecules solvate the 2-O^- group unlike the solvation of the urd anion where the 2-O^- forms intramolecular H-bond with the 2′-OH group. Second, in the case of the thd anion the water molecules are structured about the hydrophobic methyl group at 5-positions, causing more solvation for the thd conjugate base than for the urd conjugate base.

The entropy changes accompanying the second step ionization of urd ($\Delta S^0_{2,urd}$) and third step ionization of xao and guo ($\Delta S^0_{3,xao/guo}$) are less than that for the first step ionization of urd and second step ionizations of xao and guo, respectively. As discussed in our previous papers (1, 18, 19), the above observations can be explained by the nature of the equilibria and the accompanying entropy change. If H_2A denotes urd, xao, and guo and the equilibria were $H_2A + H_2O \; ^{\circ}HA^- + H_3O^+$ and $HA^- + H_2O \; ^{\circ}A^{2-} + H_3O^+$,

$$[7] \quad \Delta S_{HA^- — H_2A} = (\bar{S}^0_{H_3O^+} - \bar{S}^0_{H_2O}) + (\bar{S}^0_{HA^-} - \bar{S}^0_{H_2A})$$

and

$$[8] \quad \Delta S^0_{A^{2-} — H_2A} = (\bar{S}^0_{H_3O^+} - \bar{S}^0_{H_2O}) + (\bar{S}^0_{A^{2-}} - \bar{S}^0_{HA^-})$$

Since H_3O^+ carrying a charge must be solvated, resulting in more orderliness, there is a decrease in entropy of H_3O^+ relative to H_2O, i.e. $\bar{S}^0_{H_3O^+} < \bar{S}^0_{H_2O}$. For similar reason $\bar{S}^0_{HA^-} < \bar{S}^0_{H_2A}$ and $\bar{S}^0_{A^{2-}} < \bar{S}^0_{HA^-}$. But as the entropy of hydration of any ion is directly proportional to the square of ionic charge, it is expected that $(\bar{S}^0_{A^{2-}} - \bar{S}^0_{HA^-}) < (\bar{S}^0_{HA^-} - \bar{S}^0_{H_2A})$. In other words, $\Delta S_{A^{2-} — HA^-} < \Delta S^0_{HA — H_2A}$. This explains why $\Delta S^0_{2,urd}$ and $\Delta S^0_{3,xao/guo}$ are less than $\Delta S^0_{1,urd}$ and $\Delta S^0_{2,xao/guo}$, respectively.

Thus in conclusion it can be summarised that the generally good agreement of these precise deprotonation constant data and ionization energetics of the nucleosides obtained from our emf study and the earlier results serves to put the ionization thermodynamics of these important biomolecules on a relatively secure footing. Besides, these data also help to identify the possible sites of ionization in urd, thd, cyd, guo and xao. However, it is worth noting that we did not have data on the free energy of formation (ΔG^0_f) and enthalpy of formation (ΔH^0_f) for the nucleosides. We are therefore limited in our evaluation of energetics of formation in solution [$\Delta X^0_{f,soln}(A^-/HA^-)$] for the corresponding anions which otherwise should have provided a better insight towards the relative solvation behavior.

Completeness profiles of one-electron basis sets

Delano P. Chong

Abstract: The completeness profile is used to provide a visual assessment of the quality of one-electron basis sets. The approach is illustrated by examples of a number of basis sets for the carbon atom. New insight is gained regarding the superiority of spin density calculations using Chipman's basis sets.

Key words: One-electron basis sets.

Résumé : On utilise le profil du caractère complet pour obtenir une évaluation visuelle de la qualité des ensembles de base à un électron. On illustre cet approche par des exemples d'un certain nombre d'ensembles de base pour l'atome de carbone. On obtient une nouvelle compréhension concernant la supériorité des calculs de densité de spin en utilisant les ensembles de base de Chipman.

Mots clés : des ensembles de base à un électron.

Introduction

In *ab initio* quantum chemical computations, the accuracy of variation methods depends on the completeness of both n-electron and one-electron spaces. In post-Hartree–Fock calculations, one is concerned with how well the n-electron space is represented by the truncated treatments. For example, configuration interaction (CI) computations with singly and doubly excited configurations are sometimes compared with full CI. On the other hand, in the independent particle approximation, self-consistent field molecular orbital (SCF-MO) computations with split-valence basis sets are often compared with results using more extensive basis sets. In this work, we are concerned only with the completeness of the one-electron space.

Different properties emphasize different regions of coordinate space of atoms or molecules. Accuracy of calculated *tight* properties, such as $\langle\delta(\mathbf{r})\rangle$ and the electric field gradient tensor at the nucleus (weighting approximately as r^{-3}), depends on the reliability of the wavefunction at or around the nucleus. Consequently, basis functions with high exponents are needed. Energy operators weight the wave function roughly as r^{-2} and r^{-1} and require completeness of basis a little less tight. Dipole moments and diamagnetic susceptibilities go as r and r^2, respectively, emphasizing the importance of correct representation of about the same region of space as normal bonds. Finally, diffuse basis functions are necessary for proper description of polarizabilities, long-range interactions, and weakly bonded complexes.

The quality of one-electron basis functions has received reviews from time to time (1–3). Furthermore, some workers focused their attention on the asymptotic behaviour (4), or concentrated on calculations of chemical shifts (5) and spin densities (6, 7), while others studied momentum space properties (8). Some recent investigations used information theory to examine the quality of one-electron basis sets (9–12). In contrast, the object of this work is to present a simple visual representation of the completeness of atomic orbital basis sets at different regions of space as tested by a scanning orbital (13). We call this the completeness profile of a basis set.

Received July 7, 1994.

Theory

Suppose we are interested in a certain contracted Gaussian-type orbital (GTO) basis set

[1] $\phi_k = \Sigma\, \chi_j C_{jk}$ i.e., $\boldsymbol{\phi} = \boldsymbol{\chi}\mathbf{C}$

where χ_j represent the primitive GTO's. Let us first define a projection operator $\mathcal{P}$ by

[2] $\mathcal{P} = |\boldsymbol{\phi}\rangle\, \langle\boldsymbol{\phi}|\boldsymbol{\phi}\rangle^{-1}\langle\boldsymbol{\phi}|$

From the definition, it is easy to see that

[3] $\mathcal{P}^2 = \mathcal{P} = \mathcal{P}\dagger$

In terms of an orthonormalized basis set

[4] $\psi = \phi\mathbf{T}$, i.e., $\psi_m = \Sigma\phi_k T_{km}$

the projection operator is given by

[5] $\mathcal{P} = \Sigma|\psi_m\rangle\, \langle\psi_m|$

In this work, the transformation matrix $\mathbf{T}$ is chosen to be the popular Löwdin's symmetric orthonormalization matrix $\mathbf{S}^{-1/2}$. Now, we shall examine the completeness of the basis set in representing a normalized GTO $G(\alpha)$, with exponent α, as measured by how close

For personal use only.

[6] $Y(\alpha) = \langle \mathcal{P}G(\alpha)|\mathcal{P}G(\alpha)\rangle = \langle G(\alpha)|\mathcal{P}G(\alpha)\rangle$

comes to unity. Substitution of eq. [5] into [6] gives

[7] $Y(\alpha) = \Sigma\langle G\alpha)|\psi_m\rangle\langle\psi_m|G(\alpha)\rangle$

The quantity $Y(\alpha)$ is nothing more than the sum of squares of the overlap of the test GTO $G(\alpha)$ with the orthonormalized basis $\{\psi\}$. We are free to choose the value of exponent α of the scanning GTO $G(\alpha)$. By the completeness profile, we mean $Y(\alpha)$ plotted against $x = \log \alpha$, as first introduced in our earlier paper (13).

For simplicity, we use $G(\alpha) = 1s(\alpha)$, $2p(\alpha)$, and $3d(\alpha)$ GTO's for $l = 0$, 1, and 2, respectively. If one uses a six-component d-shell, one introduces an extra $3s$ GTO. The effect is almost like adding an extra $1s$ GTO with exponent equal to $(3\ \alpha_d/7)$ (14). In the following calculations, we assume that five-component d-functions are being used.

Although GTO's have been used as the example, one can apply the same procedure to Slater-type orbitals equally well if one so desires.

Calculations

To illustrate our procedure, we have chosen a number of basis sets for the carbon atom. The popular STO-6G, 6-31G*, and 6-311G* basis sets have been well documented (15). The atomic natural orbitals (ANO) denoted by [321], [432], and [543] are due to Almlöf and Taylor (16). New correlation-consistent basis sets cc-pVnZ (n = D, T, Q) from Dunning and co-workers (17–20) are also included, as well as sample internal basis sets in the deMon density functional program (21, 22). Finally, the basis sets specially designed by Chipman (6, 7) for spin-density calculations are also studied. Table 1 summarizes the size of the primitive and contracted GTO sets as well as the contraction schemes.

The actual computation of $Y(\alpha)$ can be performed on a microcomputer. The program is easy to write or can be requested from the author.[2] In this work, we use $\log \alpha$ as the x-values and $Y(\alpha)$ for $l = 0$, 1, and 2 as the y-values. Eighty-one values of $x = \log \alpha$ ranging from -4.0 to $+4.0$ are preselected.

Results and discussion

Energy-optimization of basis sets has a tendency to overemphasize the tight region of space, at the expense of the bonding region. Conversely, higher completeness at high $x = \log \alpha$ tends to lead to a better energy. On the other hand, extension of adequate coverage towards the diffuse region (low x) tends to improve the description of bonding.

The results of our calculations are presented in Figs. 1 to 6, which display the completeness profile of each basis set for $x = -4$ to $+4$.

At first sight, many of the profiles appear rather similar. For example, it seems necessary for all basis sets to be fairly complete around $x = 1$ for carbon. Moreover, the completeness profiles of all split-valence basis sets show a dip about $x = 0.35$ (for carbon), indicating that there is less need for a basis set to be complete around the nodal region of the $2s$ orbital. To compare the completeness profiles in finer details, however, one needs to make a transparency of each completeness profile and to superimpose it on the other figures.

Let us first examine Fig. 1. For the minimal STO-6G basis, there is no d-function and hence no d-space completeness profile. The 6-31G* set extends the coverage of the valence region and 6-311G* improves the completeness over the tight region (high x). Comparison of Figs. 2 and 3 indicates that the completeness profiles of the ANO and cc-pVnZ basis sets are actually very similar in appearance. In Fig. 4, the two different valence double-ζ basis sets internal to the deMon program show almost identical completeness profiles, even though the DZVP3 was constructed from a much larger primitive space.

From these completeness profiles for the *Nl*-spaces, we see that the ANO basis sets appear to be slightly superior in every case for a given N, with two exceptions. For $4s$ and $5s$ contracted GTO, the correlation-consistent basis sets cc-pVTZ and cc-pVQZ seem better. In a recent paper, Schäfer *et al.* (23) proposed a new TZP basis set. For B to Ne, the contraction is from $11s6p$ primitives to $5s3p$ contracted GTO. Since the contracted s-space is larger than valence triple-ζ, the energy from this new basis set should not be directly compared (23) with that from the 6-311G basis. The completeness profiles of this new TZP basis for carbon (not shown) are actually slightly inferior to the $5s$ of cc-pVQZ and the $3p$ of [432] ANO, shown in Figs. 3 and 2, respectively.

In the completeness profiles in Fig. 5 for Chipman's basis sets, designed for spin density calculations, there are two features that stand out most of all. Firstly, $Y(\alpha)$ for s-space is

greater than 0.7 even at $x = 2$, confirming our expectation that tight properties require relatively high completeness in the tight region of coordinate space. The second special feature is the absence of the dip in the region of $0 < x < 1$. This also is not difficult to understand. The main source of many spin densities is spin polarization, largely taken into account by the UHF approach. In UHF calculations, the 2*s* nodes in the MO for α and β electrons occur at different *r* values and therefore higher completeness is needed throughout. From Fig. 5, it is not surprising to find that the smaller EPR521 basis set can give as reliable spin densities as the EPR631 set, chosen by Chipman himself (24) for larger radicals.

Except for Chipman's basis, we have been studying the quality of various general-purpose sets. However, it is well known that diffuse functions are necessary for a faithful description of anions and weak van der Waals complexes, as well as for the accurate computation of polarizabilities, hyperpolarizabilities, and theoretical momentum profiles (TMP) for electron momentum spetroscopy. In Fig. 6, we compare the completeness profiles of three basis sets containing diffuse functions, all starting with a comparable valence triple-ζ basis. In the [432*f*] basis, the set of [432] ANO was augmented by a single set of *d*-type field-induced polarization function (25–27). In the [432] + 111 basis, the set of [432] ANO was augmented by uncontracting the outermost primitive GTO in each type (28). Finally, the aug-cc-pVTZ basis includes one set of optimized diffuse functions of each type (19). Woon and Dunning (19) compared the results of calculated polarizabilities when they augmented the cc-pVnZ basis by several sets of diffuse functions. From Fig. 6, we can see that the completeness profiles are very similar for *d*-type functions. Consequently, we expect the three basis sets to lead to very similar polarizabilities. However, the [432f] basis lacks diffuse *p*-type functions. For anions and TMP, the aug-cc-pVNZ basis sets are therefore recommended.

Although we have selected the carbon atom as an example, other atoms can be studied in the same manner. Except for different numerical *x*-values, we expect the completeness profiles to show very similar qualitative behaviour.

In conclusion, a simple method has been proposed in this paper to provide a visual assessment of the completeness of one-electron basis sets. The quality of the completeness profile in different regions of coordinate space is expected to lead to new insight regarding the design and performance of different basis sets.

New extracellular fatty acids in culture filtrates of *Sporothrix flocculosa* and *S. rugulosa*

Streeti R. Choudhury, James A. Traquair, and William R. Jarvis

Abstract: Two new and rare unsaturated, extracellular fatty acids were identified in the culture filtrates of the biocontrol fungi, *Sporothrix flocculosa* and *S. rugulosa*. 16-Methyl-9*E*-nonadecenoic acid (**1**) and (*Z,Z*)-10,14-eicosadienoic acid (**2**) were characterized on the basis of infrared (IR) and nuclear magnetic resonance spectra (^{13}C and ^{1}N NMR), and gas chromatographic – mass spectrometric data (GC–MS). The structure of compounds **1** and **2** was confirmed by oxidative degradation to the known standards, dimethyl azelate, dimethyl succinate, dimethyl sebacate, and methyl caproate.

Key words: unsaturated fatty acids, fungi.

Résumé : On a identifié les nouveaux et peu abondants acides gras insaturés : les acides 16-méthyl-9*E*-nonadecénoique (**1**) et (*Z,Z*,)-10,14-eicosadiénoique (**2**) dans les filtrats de culture des champignons de biocontrôle, *Sporothrix flocculosa* et *S. rugulosa*, et on les a caractérisés par spectroscopie IR et de RMN du ^{13}C et du ^{1}H et par les données de chromatographie en phase gazeuse couplée à un spectromètre de masse (GC–MS). On a confirmé les structures des composés **1** et **2** par dégradation oxydante de standards connus : l'azélate de diméthyle, le succinate de diméthyle, le sébacate de diméthyle et la caproate de méthyle.

Mots clés : acides gras insaturés, champignons.

[Traduit par la rédaction]

Long-chained, unsaturated fatty acids with 14–24 carbon atoms and one or more double bonds are characteristic of the fungi, particularly the yeast and yeastlike species. The major unsaturated fatty acids associated with the cellular fractions of these fungi are oleic (C18:1) and linoleic (C18:2) acids (1, 2). A few rare and unusual fatty acids in the fungi include methyl-branched fatty acids and hydroxy fatty acids (1). Most studies deal with cellular fatty acids, which are involved in membrane structure and function. For example, linoleic acid is implicated in the structural integrity and activity of mitochondria (3). Linoleic acid has been reported as a morphogenetic factor in the sexual reproduction of the phytopathogens *Ophiostoma ulmi* (4) and *Nectria haematococca* (5). In general, fatty acids are also implicated in the synthesis of other secondary metabolites such as cyclopentanes, polyacetylenes, and polyketide aromatic compounds, which can be potent antibiotics and mycotoxins (1, 3). Four fungitoxic C18:2 hydroxy-unsaturated fatty acids have been identified in the stroma of the endophytic phytopathogen, *Epichloe typhina* (6). Little is known about extracellular fatty acids in the fungi, but acetylated and hydroxy fatty acids have been reported (1).

Recently, we identified a new antimicrobial, methyl-substituted C18:2, extracellular fatty acid in the culture filtrates of the yeastlike, biocontrol fungi, *Sporothrix flocculosa* and *S. rugulosa* (7). In the present report we describe two new and rare extracellular C20 fatty acids that are not antimicrobial.

Results and discussion

The new unsaturated, C20 extracellular fatty acids were identified from filtrates of both *Sporothrix flocculosa* and *S. rugulosa* grown for 28 days on yeast–malt extract broth in static liquid culture. Compound **1** is an oil with molecular formula $C_{20}H_{38}O_2$. An FT-IR spectrum contained absorption bands at 3300 cm^{-1} (-OH stretch) and 1710 cm^{-1} (C=O stretch), indicating the presence of a spectrum -COOH group. The presence of this group was also revealed in the ^{1}H NMR spectrum at 11.65 ppm, while in the ^{13}C NMR spectrum resonances at 34.1 (C-2) and 180.0 ppm (C-1) were expected for attachment of this group to a methylene (8). The mass spectrum of compound **1** shows fragmentation at 293 [M – 17] and 266 [M – 44], which indicates the presence of an acid group at the terminal end in a chain (9). The ^{1}H NMR shows $\delta = 5.30$ ppm (t, 2H, $J = 17.1$ Hz, -CH=), indicating the presence of one double bond. Normally for *E* isomers the *J* values range between 12.0 and 18.0 Hz (10). We note that the coupling constant values thus indicate an *E* isomer, which was supported by ^{13}C NMR. The DEPT ^{13}C NMR showed two peaks at 130.35 and 130.45 ppm, which indicates the presence of a double bond. The position of the double bond was identified by following the technique given by Bus et al. (11), for the ^{13}C values of the neighbouring carbons of the double bonds. The *trans* unsaturations possess higher values in the range 29.5–38.0 ppm, whereas *cis* unsaturations have values of 26.0–28.5. The ^{13}C

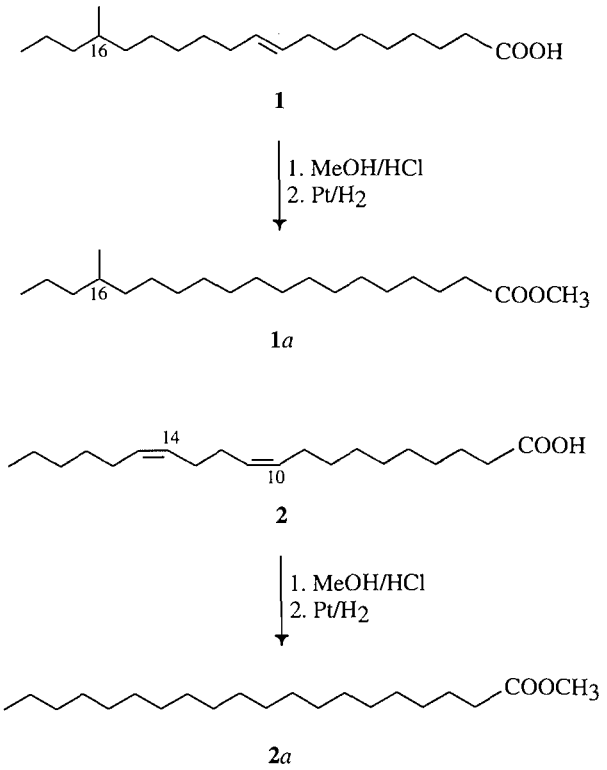
values of compounds **1** are 32.6–32.65 for C-8 and C-11, which implies that the position of the *trans* unsaturation is between C-9 and C-10. This confirms the position of the double bond between C-9 and C-10.

The presence of two methyl groups was revealed by ^{13}C and ^{1}H NMR: one, at 14.5 (C-19), indicating a terminal methyl group that is shielded by methyl branching at the γ-position (^{1}H nmr δ = 0.9 (t, J = 6 Hz, 3H, -CH_3)) and another value at 19.8 (-CH_3 at C-16), indicating methyl branching at C-16 (ref. 8, p. 56). The triplet at 1.15 ppm (J = 6.3 Hz, 3H, -CH_3) is observed in ^{1}H NMR, and a singlet with a downfield shift in APT ^{13}C NMR indicating the presence of branching (12). In general, the APT ^{13}C NMR shows downfield shifts for both the CH_3 and CH, whereas in DEPT both CH_3 and CH give upfield shifts (ref. 10, p. 276). The ^{13}C NMR of the carbon bearing the methyl group shows resonance at 32.2 (C-16), which confirms the position of methyl branching at C-16 (13). The carbons next to the methyl branching show values 36.5 (C-15) and 38.7 (C-17). These values are deshielded by the methyl branching at C-16. The position of methyl branching was further supported by the fragmentation pattern of 16-methyl methylnonadecanoate **1***a*. Two large peaks are observed, one at 282 [M – 44] (50%) and the second at 255 (42%), with a small peak at 269 (5%) that carried the methyl group. The peaks at 251 and 233, observed by the loss of a methanol and a water molecule simultaneously from the fragment $^{+}CH(CH_3)(CH_2)_{14}$-$COOCH_3$, are also characteristic of the branching at C-16 (9).

To confirm the structure of compound **1** its methyl ester was oxidized using the Lemieux–von Rudloff reagent (14). This method was used to indicate the position of the double bond. Esterification of the acid fragments with HCl/MeOH after von Rudloff's oxidation gave two major components: one is 7-methyl methyldecanoate (Mol. Wt. 200). The *m/e* fragmentation pattern has two major peaks at 156 (40%) and 129 (45%) along with a small peak at 143 (7%). The smaller peak is the indication of the carbon bearing the methyl group; the peaks observed at 125 and 107 indicate the simultaneous loss of methanol and water from the fragment $^{+}CH(CH_3)(CH_2)_5$-$COOCH_3$. This confirms the methyl branching at C-7. The second major component is nonanedioic acid dimethyl ester (Mol. Wt. 216). The *m/e* fragmentation pattern shows the base peak at 98 (100%), which indicates the presence of dimethyl ester. This establishes the position of the double bond between C-9 and C-19. The catalytic hydrogenation of the methyl ester of compound **1** with PtO_2 resulted in formation of 16-methyl methylnonadecanoate **1***a*. From all these data it was concluded that this new fatty acid **1** is 16-methyl-9*E*-nonadecenoic acid.

Compound **2** is an oil with molecular formula $C_{20}H_{36}O_2$. An FT-IR spectrum contained broad absorption bands at 3310 cm^{-1} (-OH stretch) and 1710 cm^{-1} (-C=O). The ^{1}H NMR resonances at 11.60 (s, H, -COO*H*) as well as ^{13}C NMR signals at 180.1 (C-1) and 34.1 (C-2) indicate the presence of a -COOH group (8). The terminal acid group was also determined with the help of fragmentation patterns at 291 [M–17] and 264 [M – 44] (9). The ^{1}H NMR resonances at 5.32 (m, 4H, J = 10.2 Hz, -CH=) indicate the presence of two double bonds. Normally for *Z* isomers the range of J values is 6.0–12 Hz, but we have observed that the coupling constant of both the double bonds is 10.2 Hz, which indicates *Z,Z* isomers. The presence of two unsaturations in compound **2** was supported by the DEPT ^{13}C NMR (6), which gave four upfield signals at 129.30, 129.45, 130.22, and 130.35, indicating that double bonds are present between C-10 and C-11 and between C-14 and C-15. Compound **2** was reported previously as a principal component of corn oil, but without stereochemistry (15). The *cis* unsaturation of both the double bonds was confirmed in our study with the help of ^{13}C NMR, which shows a range of values between 27.2 and 27.5 for the neighboring carbons 9, 12, 13, and 16 (11).

Scheme 1



The lack of branching was confirmed by ^{1}H NMR. A triplet appeared for 3*H* at 0.8 ppm (J = 6.0 Hz) and DEPT ^{13}C NMR: 14.1 ppm (C-20) with an upfield shift indicating the presence of a terminal methyl group in the chain. Oxidation of compound **2** was done by Lemieux–von Rudloff's reagent (14) to establish the position of the double bonds. A mixture of three short-chain dimethyl esters was obtained, one of which was the dimethyl ester of succinic acid. Production of this ester indicates the presence of two -CH_2 groups between the two double bonds in the fatty acid **2**. The second dimethyl ester was decane-1,10-dioic acid dimethyl ester, whose formation located the position of the first double bond at Δ^{10}. The third ester was methyl hexanoate, whose formation indicated the position of a second double bond at Δ^{14}. On the basis of these data, compound **2** is *Z,Z*-10,14-eicosadienoic acid. Upon catalytic hydrogenation using PtO_2, the methyl ester derivative of this acid (2) gave eicosanoic acid methyl ester **2***a*. The ^{1}H NMR showed resonance at 3.6 ppm (s, 3H, -COOCH_3) and ^{13}C NMR signals were at 51.40 (-COOCH_3) and 174.45 (-$COOCH_3$).

Experimental

General experimental procedures

Proton nuclear magnetic resonance (^{1}H NMR) and ^{13}C (APT

and DEPT) spectra were recorded using $CDCl_3$ as solvent on a 200 MHz Varian XL-200 spectrometer with tetramethylsilane (TMS) as internal standard. All chemical shifts were recorded in ppm downfield from TMS. All infrared spectra were recorded on films using a Bruker FT-IR instrument with IBM FT-IR/32 software; intensities of all the bands are stated in cm^{-1}. UV spectra were obtained using $CHCl_3$ as solvent on a Shimadzu UV/VIS-160 spectrophotometer. Gas chromatographic (GC) analysis was carried out on a Varian 3400 GC fitted with a 10 m microbore glass column (0.53 mm diameter, 2.65 μm film thickness SE-30 stationary phase), using nitrogen (20 mL/min) as the carrier gas under temperature-programmed conditions (initial temperature of 140°C, final temperature 250°C, rate 5°C/min) or isothermally (200°C) and a flame ionization detector. For GC–MS analysis, gas chromatography on a Varian 3400 GC coupled with a MS Finnigan MAT-8230 mass spectrometer, with a mass selective detector fitted with a 12 m capillary glass column (0.2 mm internal diameter, 0.33 μm film thickness, cross-linked methyl silicone gum), and helium (ca. 2 mL/min) as a carrier gas were used under temperature-programmed conditions (initial temperature 140°C, final temperature 240°C, rate 5°C/min). Thin-layer chromatography (TLC) was performed on microscope glass plates coated with silica (about 0.1 mm thickness). A mixture of *n*-hexane–chloroform and *n*-hexane – ethyl acetate in various concentrations was used as developer. Preparative TLC was carried out on Kieselgel 60 F_{254} plastic sheets (Merck) coated with silica. Column chromatography was performed on Baker 60–200 mesh silica gel using gradient elution of mixtures of *n*-hexane–chloroform for compound **1** and *n*-hexane – ethyl acetate for compound **2**. Collected fractions were checked by TLC before pooling. Dimethyl succinate, methyl caproate, dimethyl azelate, and dimethyl sebacate acid (Aldrich Chemicals) were used as standards.

Growth of the fungi and extraction of free fatty acids

Voucher cultures are maintained in the Patent Depository at the American Type Culture Collection (ATCC), Rockville, Maryland, as ATCC 64874 (*S. flocculosa*) and ATCC 64875 (*S.rugulosa*). The fungi were grown on yeast–malt–potato–dextrose (0.5:1.0:2.0) broth (7) in 10 250-mL cotton-plugged Erlenmeyer flasks each containing 100 mL of broth. The mycelium from 28-day-old static liquid cultures grown at 23°C in the dark was filtered through a Buchner funnel using Whatman filter paper no. 2 to remove the mat. Remaining spores were removed by millipore filtration (0.22 μm) and then the cell-free filtrate was extracted seven times with $CHCl_3$ in a separatory funnel. The extracts were combined and dried over anhydrous Na_2SO_4 (1.89 g). Further purification was done by column chromatography on silica gel (60–200 mesh) using a procedure similar to that of Privett et al. (16). The two new fatty acids were investigated by preparative TLC using $CHCl_3$–hexane (3:7) as eluting solvent for compound **1** (yield 75 mg, 3.968%) and hexane–EtOAc (1:4) as eluting solvent for compound **2** (yield 82 mg, 4.33%).

*Compound **1** (oil)*: IR ν_{max}: 3300, 1710, 1660, 1410, and 920 cm^{-1}. ^1H NMR: 11.65 (s, 1H, COO*H*), 5.30 (5, 2H, J = 17.1 Hz, C*H*=), 2.3 (t, 2H, J = 6.5 Hz, CH_2COOH), 1.2–1.5 (m, 27H, CH_2), 1.15 (5, 3H, J = 6.3, CH_3, br), and 0.9 (t, 3H, J = 6 Hz, CH_3). ^{13}C NMR: 14.5 (C-19), 19.8 (C-20), 20.8 (C-18), 24.8 (C-3), 26.9 (C-14), 29.2 (C-6), 29.4 (C-5), 29.5 (C-4, 12), 29.6 (C-7), 29.8 (C-13), 32.2 (C-16), 32.60 (C-8), 32.65 (C-11), 34.1 (C-2), 36.5 (C-15), 38.7 (C-17), 130.35 (C-9), 130.45 (C-10), and 180.0 (C-1). (Z,Z)-10,14-Eicosadienoic acid methyl ester
A solution of **2** (30.8 mg, 0.01 mmol) in 10 mL of methanolic HCl was boiled under reflux for 60 min (17). The solvent was removed under reduced pressure and the pure methyl ester was obtained by column chromatography using *n*-hexane and ethyl acetate (1:2) (26.5 mg, 82.8%). IR ν_{max}: 2980, 2820, 1735, 1450, 1154, and 998 cm^{-1}. ^1H NMR: 5.34 (m, J = 10 Hz, 4H), 3.68 (s, 3H), 2.33 (t, J = 6.5 Hz, 2H), 1.3–1.5 (m, 26H), and 0.9 (t, J = 6 Hz, 3H). HRFABMS *m/z* (rel.int.) $\{M\}^+$ 322.2869 ($C_{21}H_{38}O_2$ requires 322.2871). EIMS, *m/z* $\{M\}^+$: 322(5), 307(10), 293(2.4), 291(8), 280(30), 265(27), 263(42), 251(39), 250(57), 249(40), 238(31), 235(23), 225(29), 221(44), 206(47), 197(28), 192(25), 184(15), 179(6), 172(46), 166(16), 157(16), 152(18), 142(28), 138(54), 130(32), 125(20), 115(40), 112(35), 101(74), 97(45), 88(58), 84(60), 74(100), 71(90), 59(85), 57(78), and 43(82).

Methyl eicosanoate **2**a
Compound **2** (32.2 mg, 0.01 mmol) was dissolved in MeOH (10 mL) and added to a catalytic amount of PtO_2 in MeOH and stirred in a stream of hydrogen for 1 h. The suspension was filtered and solvent was removed under reduced pressure to give **2***a* (29.7 mg, 91.1%). IR ν_{max}: 1740 and 1460 cm^{-1}. ^1H NMR: 0.8 (t, J = 6 Hz, 3H, CH_3), 1.2–1.8 (m, 34H, CH_2), 2.3 (t, J = 6.9 Hz, 2H, CH_2COOCH_3), and 3.6 (s, 3H, $COOCH_3$). ^{13}C NMR: 14.1 (C-20), 23.3 (C-19), 29.2–29.8 (C-3–C-17), 32.8 (C-18), 34.2 (C-2), 51.40 (OCH_3), and 174.45 (C-1). HRFABMS *m/z* (rel.int.) $\{M\}^+$ 326.3179 ($C_{21}H_{42}O_2$ requires 326.3184). EIMS, *m/z* $\{M\}^+$: 326(35), 311(20), 283(15), 255(6), 227(12), 198(42), 171(22), 143(8), 115(24), 87(38), 74(100), and 59(66).

Lemieux–von Rudloff oxidation
To establish the position of the double bonds a modified Lemieux–von Rudloff oxidation (14) was performed on the methyl esters. A stock oxidant solution of sodium metaperiodate (2.09 g) and $KMnO_4$ (0.04 g) in water (100 mL) was prepared. This solution (1 mL) together with K_2CO_3 solution (1 mL; 2.5 g/L) was added to the methyl ester (1 mg) in *t*-BuOH (1 mL) in a test tube and the mixture was shaken thoroughly at room temperature for 1 h. At the end of this time, the solution was acidified with one drop of concentrated sulphuric acid, and excess oxidant was destroyed with $NaHSO_3$. The solution was extracted with diethyl ether (3 × 4 mL). The organic layer was dried over sodium sulphate and removed in a stream of nitrogen at room temperature. The products were methylated with 1.2 N HCl/MeOH for GC–MS analysis. The oxidative compounds obtained from compound **1** are nonanedioic acid dimethyl ester (azelaic acid dimethyl ester) and 7-methyl methyldecanoate. Decane-1, 10-dioic acid dimethyl ester (sebacic acid dimethyl ester), succinic acid dimethyl ester, and methyl hexanoate (methyl caproate) are the oxidative products of compound **2**. The spectroscopic data were compared with authentic samples supplied by Aldrich Chemicals. The following MS data were collected for the oxidative compounds.

7-Methyl methyldecanoate: m/e (rel.int %): 200(44), 169(20), 157(30), 156(40), 143(7), 141(72), 129(45), 125(32), 107(22), 115(12), 101(25), 87(35), 74(100), and 59(42).

Dimethylazelate: m/e (rel.int %): 216(54), 185(32), 152(24), 143(55), 124(72), 111(60), 98(100), 92(42), 84(38), 73(40), 64(50), 55(35), and 41(22).

Dimethyl sebacate: m/e (rel.int %): 230(50), 199(34), 166(45), 157(62), 138(55), 124(40), 106(58), 98(100), 92(65), 73(44), 64(33), 55(28), and 41(60).

Dimethyl succinate: m/e (rel.int %): 146(65), 115(32), 98(100), 91(72), 86(54), 83(48), 73(40), 55(35), 63(58), and 60(54).

Methyl caproate: m/e (rel.int %): 130(35), 129(72), 115(45), 101(32), 99(62), 87(54), 74(100), 71(58), and 59(66).

On the purported axial preference in 2-methylthio and 2-methoxycyclohexanones: steric effects versus orbital interactions

Robert R. Fraser and Neil C. Faibish

Abstract: The value for the equilibrium constant representing the ratio of equatorial to axial conformers for 2-methylthio- and 2-methoxycyclohexanone has been measured in five solvents using 500 MHz ^{1}H nuclear magnetic resonance. In cyclohexane solvent, the methylthio group is found to have a large axial preference while that for the methoxy is negligible. For both compounds the equilibrium shows a strong solvent dependence. Comparison of these results with those known for the halo derivatives shows the amount of axial to increase in the order: fluoro, methoxy, chloro, bromo, and methylthio. With the aid of molecular mechanics calculations it is concluded that the order of conformational preference can be attributed to a variation in the van der Waals interaction between the substituent and the carbonyl group in the equatorial conformer.

Key words: α-substituted cyclohexanones, conformation, MMX calculations, steric and dipolar effects.

Résumé : Utilisant la résonance magnétique nucléaire du ^{1}H à 500 MHz et opérant dans cinq solvants, on a mesuré la valeur de la constante d'équilibre représentant le rapport des conformères équatorial et axial des 2-méthylthio- et 2-méthoxycyclohexanones. Dans le cyclohexane comme solvant, on trouve que le groupe méthylthio a une préférence axiale alors que celle du groupe méthoxy est négligeable. Pour les deux composés, l'équilibre dépend fortement du solvant. Une comparaison de ces résultats avec ceux connus pour les dérivés halogénés montre que la quantité de conformère axial augmente dans l'ordre : fluoro, méthoxy, chloro, bromo et méthylthio. En se basant sur des calculs de mécanique moléculaire, on conclut que l'ordre de préférences conformationnelles peut être attribué à une variation de l'interaction de van der Waals entre le substituant et le groupe carbonyle du conformère équatorial.

Mots clés : cyclohexanones α-substituées, conformation, calculs MMX, effets stériques et dipolaires.

[Traduit par la rédaction]

In the course of studies on the effects of α substituents on the rates of nucleophilic addition to a carbonyl group, we have made use of the conformationally fixed biaryl ketone, **1**(R = H), and a number of its derivatives (1). Each derivative consisted of two diastereomers whose relative stabilities varied widely. For the fluoro derivative, **1**(R = F) the equatorial isomer was strongly favored, while for the methylthio derivative, **1**(R = SCH_3) the axial isomer was the dominant component of an equilibrated mixture. To aid our understanding of the relative stabilities of these stereoisomers we sought, for comparison, the pertinent literature data on 2-substituted cyclohexanones. The latter compounds are conformational isomers that interconvert rapidly at room temperature as shown in equilibrium [1].

The conformations of cyclohexanones bearing a halogen substituent at the α carbon have been extensively studied (2). Infrared, dipole moment (3), and ^{1}Hmr (4) measurements all

[1] 
showed the bromo and chloro derivatives to exist mainly in the axial conformation in hydrocarbon solvent, with fluoro having no preference. In solvents of increasing polarity the proportion of equatorial increased, becoming dominant for the chloro and fluoro derivatives in acetonitrile (4). Three main factors, steric, dipole–dipole, and orbital interactions, have been proposed (2) to account for these changes in equilibrium [1] with structure and solvent.

For 2-methoxycyclohexanone the axial conformation seems to have earned a reputation for being dominant (2, 5–7), although there is but one piece of experimental evidence to that effect. Cantacuzene and Tordeux (8), using 60 MHz ^{1}Hmr, found 63% of the axial form in carbon tetrachloride, and 16% in acetonitrile. An earlier report described it as being mainly axial, regardless of solvent, although experimental details were not provided (9). However, considerable evidence from equilibration of diastereoisomers indicates an equatorial preference

in polar solvents (10–12). And, very recently, a thorough study of this compound in deuterochloroform, using five separate nmr parameters for comparative assessment, reported it to be 28 ± 5% axial (13). In the same paper using the same criteria, 2-methylthiocyclohexanone was found to be 85% axial in deuterochloroform (13). Earlier, it has been estimated from infrared measurements (14) to contain 70% axial in carbon tetrachloride. In an independent study, equilibration of the 2-methylthio derivative of 4-*tert*-butylcyclohexanone in methanol was also reported to give 70% axial (15*a*).[2] To clarify the above inconsistencies we have determined the position of equilibrium [1] for both 2-methylthiocyclohexanone **2** and 2-methoxycyclohexanone **3** in five solvents from polar to nonpolar in character. Using 500 MHz ^{1}Hmr, the percent of axial methylthio conformer was found to vary from 94% in cyclohexane to 59% in acetonitrile. For methoxyl the range in percent axial was from 57 to 20. These results, combined with previous literature data on the halogens, offer further insight regarding the factors affecting K_{eq}.

Previous determinations of the conformational equilibrium [1] for cyclohexanones by ^{1}Hmr measurements relied upon either the chemical shift parameter (4) or the spin–spin splitting of the methine proton at C2 (4, 8). The latter method used the magnitude of the half bandwidth relative to that observed in model compounds to assess the proportion of equatorial conformer. When possible, direct measurement of a single coupling constant, (i.e., $J_{5',6}$), which represents a weighted average of the two conformations as in eq. [2], should provide

Table 1. Equilibrium data for **2**.

Solvent	J_{obs} (Hz)	n_a	K	ΔG (kcal/mol)
C_6D_{12}	13.0	0.94	0.064	1.6
CCl_4	12.7	0.91	0.099	1.4
$CDCl_3$	11.2	0.78	0.28	0.7
CD_3COCD_3	9.9	0.67	0.5	0.4
CD_3CN	9.0	0.59	0.71	0.2

a more accurate evaluation of the mole fractions n_e, n_a and their ratio $n_e/n_a = K_{eq}$ (16).

[2] $J_{obs} = n_a J_{aa} + n_e J_{ee}$

The 500 MHz spectrum of **2** in $CDCl_3$ appears in Fig. 1. In the inset the protons are labeled to indicate their *cis* or *trans* (H′) relation to the *S*-methyl group. It is a first-order spectrum in that all nine ring protons are free from overlap with their neighbors.[3] The proton assignments were unambiguously determined by proton COSY and HMQC spectra. The triplet at δ 3.23 represents the methine proton at C2 whose small vicinal splitting clearly indicates its predominantly equatorial orientation. The predominantly axial proton at C6, δ 2.94, is strongly deshielded, in all likelihood by the axial *S*-methyl group (6) at C2. Its appearance as an octet provides values for the geminal coupling constant, $J_{6,6'}$, and the two vicinal couplings, $J_{5,6}$ and $J_{5',6}$. In the above spectrum we find J_{obs} for $J_{5',6} = 11.2$, which with the use of eq. [2] provides a value of 0.78 for n_a and thereby of 0.28 for K_{eq} in equilibrium [1]. In this calculation the values $J_{aa} = 13.7$ and $J_{ee} = 2.2$ were used for the purely diaxial and diequatorial coupling constants, as obtained from the splitting observed for the α protons in the spectrum of 4-*tert*-butylcyclohexanone.[4] These values are consistent with earlier measurements reported for cyclohexanone (17). In this way the values for J_{obs} were determined in five solvents, providing the data in Table 1 for equilibrium [1]. In carbon tetrachloride, 2-methylthiocyclohexanone shows a stronger bias towards the axial isomer than estimated by infrared (14). In deuterochloroform, our result agrees within experimental error with that reported by Basso et al. (13). The conformation changes markedly with increasing solvent polarity, from 94% axial in perdeuterated cyclohexane to 59% axial in the most polar solvent, acetonitrile. This solvent effect is very similar to that observed previously for the halo derivatives (3, 4). What is unique for the thiomethyl group is the magnitude of its axial preference, greater than that for any other heteroatom substituent.

[3] Using the program PCPMR (Serena Software, Box 3076, Bloomington, IN 47402), spectral simulation of the proton absorption in **2** using the observed splittings reproduced the experimental line positions to within 0.1 Hz.

[4] As described in the experimental, values for these two coupling constants were confirmed by simulation. By observing the sensitivity of the simulated spectra to the variations in input parameters we can estimate them to be reliable to within 0.2 Hz. As a result, eq. [2] should provide values for n_a accurate to ±0.02 in the middle of its range and to ±0.04 at either end of the range. ΔG will have consequent error limits of 0.1–0.4 kcal/mol.

Table 2. Equilibrium data for **3**.

Solvent	J_{obs} (Hz)	n_a	K	ΔG (kcal/mol)
C_6D_{12}	6.7	0.57(0.55)[a]	0.75	0.2
CCl_4	7.3	0.51(0.50)	0.96	0.0
$CDCl_3$	10.0	0.22(0.19)	3.5	−0.7
CD_3COCD_3	9.8	0.24	3.2	−0.7
CD_3CN	10.5	0.16	5.3	−1.0

[a]Values in parentheses were determined from $J_{5'6}$.

In assessing the position of the conformational equilibrium for 2-methoxycyclohexanone **3** it was not always possible to use the splittings in the absorption patterns for the protons at C6 due to overlapping shifts. To obtain a consistent set of data we used the splitting between the methine proton at C2 and the *trans* proton at C3 as J_{obs}. For this interaction it was necessary to modify the values for J_{aa} and J_{ee} to include the electronegativity effect of the methoxyl (18). Accordingly, the value for J_{aa} was reduced to 12.0 Hz and that for J_{ee} raised to 2.7 Hz. Application of eq. [2] led to the values appearing in Table 2. These results, in contrast to earlier assertions (2, 5–7, 9), show no axial preference for the methoxy substituent except in the least polar solvent, cyclohexane-d_{12}.

Factors affecting the conformational equilibrium [1]

Previous studies toward the understanding of substituent effects on this equilibrium have considered a variety of factors to explain the results (2). They can be divided into three main categories. The first of these, steric in nature, includes torsional and van der Waals interactions. In simple cyclohexanes, torsional effects are responsible for the increasing stability of the equatorial conformer in the series methyl, ethyl, and isopropyl for which the values of ΔG_{ea} are 1.7, 1.8, and 2.1 (19). However, in cyclohexanones there is an added steric factor, the 2-alkyl ketone effect, which favors the axial isomer. Its contribution to ΔG_{ea} is estimated at 0 for methyl, 1.0 for ethyl, and 1.7 kcal/mol for isopropyl (20). This trend has been explained by a repulsive interaction between the lone pair on the oxygen and the α substituent (a type of $A^{1,3}$ strain (21)). A second factor of importance is the greater repulsive interaction between the two dipoles in the equatorial conformer (22) that is diminished as the dielectric constant of the solvent increases. The third factor, a two-electron attractive orbital interaction involving either σ–π^* or n–π^* donation in the axial conformer, has frequently been cited to explain its unexpected stability. Orbital energies are expected to be more strongly influenced by the latter interaction (23).

To assess the relative importance of these factors, Table 3 presents data for the measurements in carbon tetrachloride and acetonitrile, the two solvents that are common to all present and previous ^{1}Hmr studies. For the sake of completeness, data on the phenoxy, phenylthio, and phenylseleno substituents (15*b*, 15*c*) are included. In carbon tetrachloride solution, the individual substituents exhibit conformational preferences from mainly axial (Br and SMe) to mainly equatorial (F). All show an appreciable increase in the amount of equatorial in acetonitrile. Calculations have shown (3, 4, 24) that the difference in dipole–dipole interactions for the two conformers is

Table 3. Solvent effects on 2-substituted cyclohexanones.

[a]Numbers in parentheses calculated by MMX represent $\Delta\Delta E_T$.

effectively nullified by the change in dielectric constant of the solvent from 2.2 for carbon tetrachloride to 37.5 for acetonitrile. The magnitude of the dipole–dipole interaction energy can be estimated from the change in ΔG_{ea}, the conformational free energy difference, from solvent to solvent. This change, $\Delta\Delta G_{ea}$ appears in the last column. It is quite similar for most substituents and is a qualitative reflection of the group dipole moment of the substituent. Without the influence of dipole–dipole interactions, the data in acetonitrile (see column 2) represent equilibria that should reflect the influence of steric and orbital interactions only. To further probe the nature of these factors we carried out molecular mechanics calculations using the MMX program (25).[5]

Calculation of conformational energy differences using MMX

We have calculated the energies of the axial and equatorial conformers of methylthio-, methoxy-, bromo-, chloro-, and fluorocyclohexanone for media of dielectric constant 2.2 (carbon tetrachloride) and 37.5 (acetonitrile). The results appear in Table 4. In all cases the dipole/charge term[6] substantially favors the axial conformer in carbon tetrachloride, but has a negligible effect in acetonitrile, as was reported previously (3, 4, 24). For three of the substituents the calculated energy differences for ΔE_T are in reasonable agreement with experiment, overestimating ΔE by up to 0.7 kcal/mol. For the methoxyl and fluoro derivatives MMX gives poor results, the discrepancy with experiment averaging 2 kcal/mol. In all likelihood the torsional contributions to ΔE_T are the main source of error. Very recently it was concluded, on the basis of ab initio calculations and supporting infrared data, that the torsional parameters for the CCCO and CCCF fragments originally derived from the *A* values of cyclohexanes for use in MM2 need to be revised (26). What is impressive is the agreement obtained between the value for $\Delta\Delta E_T$ calculated for equilibrium [1] in CCl_4 and CD_3CN and that observed experimentally as $\Delta\Delta G$. This comparison appears in the last column of Table 3.

As previously suggested and confirmed by the above calculations, the percent axial conformer in acetonitrile will be free from the influence of dipole–dipole interactions. As seen in column 2 of Table 3 the amount of axial conformer increases in the order F, OCH_3, Cl, Br, SCH_3. Two aspects of this order require explaining: the large preference of fluorine for the equatorial position and the order of substituent preference. The preference shown by fluorocyclohexanone should be regarded as an intrinsic property of this ketone. There is no reason to anticipate its conformation based on the behavior of cyclohexanes. In more specific terms, we lack the model data from which to estimate the torsional parameter for a CC(O)CF fragment. We can only offer the observation that a stable conformation with bonds having electronegative substituents synperiplanar has precedence in olefins bearing vicinal halogens or methoxyl groups (27).

The increase in axial from 13% for F to 59% for SCH_3 represents a change in ΔG_{ea} of 1.3 kcal/mol. Qualitatively, this increase can be attributed to a change in the nonbonded interaction between the lone pair of electrons of the carbonyl oxygen and the equatorial substituent.[7] A numerical estimate is available from the difference in the van der Waals terms for the two conformers as calculated by MMX. In Table 4 this term changes by 0.9 kcal/mol from attractive, 0.3 for fluorine, to repulsive, 0.6 for the methylthio substituent. Clearly, the experimentally observed variation of 1.3 ± 0.4 kcal/mol can be accounted for entirely by the variation in van der Waals interactions. Consequently, consideration of an n–σ^* orbital interaction appears unnecessary. These conclusions regarding the relative importance of nonbonded interactions can be expected to apply to the derivatives of **1** (1).

Experimental

All spectra were measured using a Bruker AMX500 and an inverse detection probe with homogeneity optimized to give resolution to 0.4 Hz or less. Digital resolution of better than 0.1 Hz was used throughout. The ^1H–^1H COSY and HMQC spectra were obtained using the Bruker software. Deuterochloroform (99.96%) and acetone-d_6 (99.9%) were obtained from Merck, Sharp and Dohme. Acetonitrile (99.5%) was

[5] The MMX program, as part of PCMODEL, is available from Serena Software, Box 3076, Bloomington, IN.

[6] The MMX program calculates the dipole–dipole and other electrostatic interactions using the point-charge distributions obtained from MMPI and bond dipole moments as described in ref. 25.

[7] Evidence in support of such a steric effect has been reported in 2-alkoxycyclohexanones (8), where the percent of axial conformation was found to increase with the size of the alkoxy group.

obtained from Cambridge Isotopes. 2-Methoxycyclohexanone was purchased from Aldrich. 2-Methylthiocyclohexanone was synthesized from cyclohexanone via reaction of its enolate with methyl methanethiolsulfonate (28).

The measured splittings reported as J_{obs} are estimated to be accurate to within 0.2 Hz or better as a consequence of line widths usually being between 0.8 and 1.0 Hz due to unresolved long-range couplings. The spectrum of **2** in $CDCl_3$ was reproduced by spectral simulation using PCPMR (13). Because this program's capacity is limited to eight nuclei, it was necessary to omit the proton at C2 from the calculations. Using input parameters based on the observed line spacings in each multiplet, the eight-line pattern calculated for H6 had line positions that agreed to within 0.1 Hz with those observed. Allowing for the absence of perturbation by H2, other multiplets showed similar agreement.

Fig. 2. A portion of the 500 MHz ^{1}Hmr spectrum for 4-*tert*-butylcyclohexanone in acetone-d_6: (*a*) the absorption for an axial (δ 2.3–2.4) and equatorial (δ 2.2–2.28) protons at C2; (*b*) the spectrum calculated by PCPMR using the parameters given in Table 5.

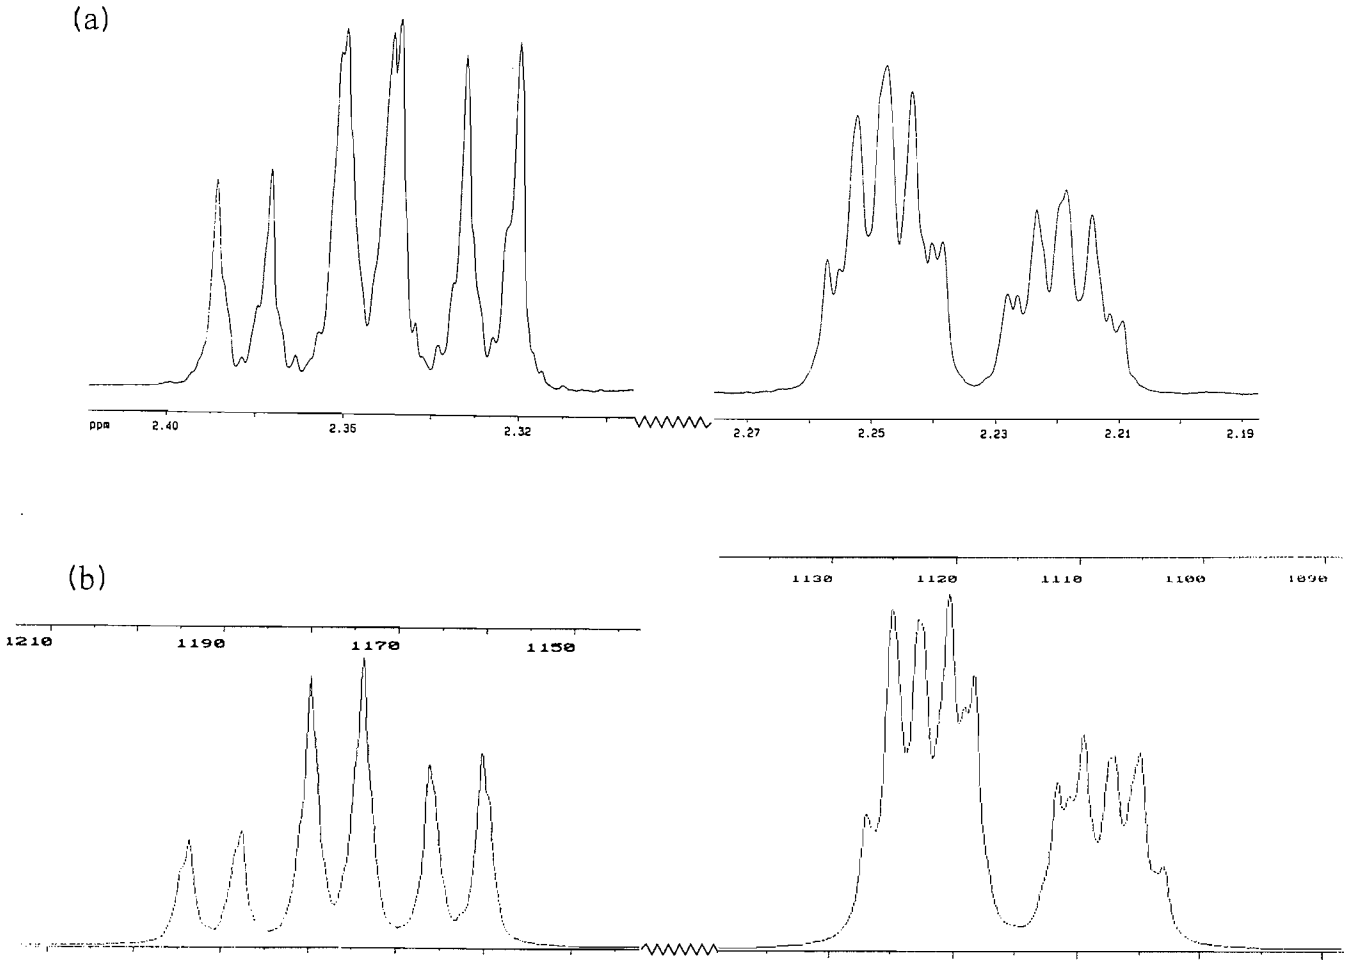

Table 5. Spectral parameters.

(*a*) 2-Methylthiocyclohexanone ($CDCl_3$)

Chemical shifts (Hz from TMS): H2 1615, H3 1030, H3′ 1083, H4 934, H4′ 837, H5 988, H5′ 875, H6 1485, H6′ 1119
Coupling constants (Hz): J_{35} = 1.6, $J_{4'6'}$ = 1.6, $J_{34'}$ = 4.9, J_{34} = 3.5, $J_{3'4'}$ = 3.8, $J_{3'4}$ = 10.1, $J_{33'}$ = −14.1, $J_{4'5'}$ = 3.8, $J_{4'5}$ = 4.9, $J_{45'}$ = 10.1, J_{45} = 3.5, $J_{44'}$ = −13.6, $J_{55'}$ = −13.2, $J_{56'}$ = 4.8, J_{56} = 5.8, $J_{5'6'}$ = 4.6, $J_{5'6}$ = 11.2, $J_{66'}$ = −14.5

(*b*) 4-*tert*-Butylcyclohexanone (acetone-d_6)

Chemical shifts (Hz from TMS): H_{2ax}, H_{6ax} 1176; H_{2eq}, H_{6eq} 1116; H_{3ax}, H_{5ax} 705; H_{3eq}, H_{5eq} 1040
Coupling constants (Hz): $J_{2ax2eq} = J_{6ax6eq}$ = −14.5, $J_{3ax3eq} = J_{5ax5eq}$ = −12.3, $J_{2ax3ax} = J_{5ax6ax}$ = 13.7, $J_{2eq3eq} = J_{5eq6eq}$ = 2.2, $J_{2ax3eq} = J_{5eq6ax}$ = 6.1, $J_{2eq3ax} = J_{5ax6eq}$ = 4.6, $J_{2eq6eq} = J_{3eq5eq}$ = 2, $J_{3eq5ax} = J_{3ax5eq}$ = 1, $J_{2eq6ax} = J_{2ax6eq}$ = 0.8

The spectrum of 4-*tert*-butylcyclohexanone in acetone-d_6 was chosen for determination of J_{aa} and J_{ee} for the protons at C2 and C6 as all ring protons were free from serious overlap in this solvent. The axial proton absorption pattern was reproduced by simulation using PCPMR, with omission of the axial proton at C4. Both proton patterns were difficult to reproduce, being sensitive to the long-range coupling constants, J_{35} and J_{26}, as well as to the vicinal and geminal interactions. A comparison of the experimental and simulated spectra for both α protons appears in Fig. 2. In view of the uncertainty associated with the absence of H4, the observed agreement is acceptable. The parameters used in the two simulations appear in Table 5.

All molecular mechanics calculations were carried out using the MMX program contained in PCMODEL (25). Energy minima were found for both conformational isomers and all three rotamers of the 2-substituent. In one case only, that for the equatorial isomer of **2** in acetonitrile, rotamers with the methyl *trans* to CH_2 and to CO were found to have the same minimum energy. Otherwise, a single rotamer, that with

methyl *trans* to CO, dominated regardless of the value for the dielectric constant.

Abstract: The title compound was synthesized as part of an effort to produce a more effective fungicide to combat Dutch Elm Disease (DED), which is caused by the fungus *Ceratocystis ulmi*. A full X-ray structural analysis of the 1:1 adduct has been carried out and the results are reported along with the Mössbauer data for the compound. The crystals are monoclinic, space group $P2_1/a$ with $a = 19.240(3)$ Å, $b = 9.1463(24)$ Å, $c = 19.3512(24)$ Å, $\beta = 118.874(8)°$, $V = 2982.0(10)$ Å^3, $z = 4$, and $D_{calc} = 1.427$ Mg m^{-3}. The final discrepancy factors are $R_F = 0.056$ and $R_w = 0.058$ for 1915 significant reflections. The QS and IS values in the Mössbauer spectrum of the complex are 3.08 mm s^{-1} and 1.28 mm s^{-1}, respectively. The 2,3-diphenylthiazolidin-4-one behaves as a monodentate ligand and coordinates to the tin through the oxygen atom. The complex exhibits a trigonal bipyramidal configuration with the three phenyl groups in equatorial positions and the chloride and ligand oxygen occupying the apical sites.

Key words: triorganotin, fungicide, Dutch Elm Disease, thiazolidin-4-one.

Résumé : On a synthétisé le composé mentionné dans le titre dans un effort orienté vers la mise au point d'un fongicide plus efficace pour combattre la maladie des ormes qui est causée par le champignon *Ceratocystis ulmi*. Une analyse structurale complète par diffraction des rayons x de l'adduit 1 : 1 a été réalisée et on rapporte les résultats avec des données de Mössbauer du composé. Les cristaux sont monocliniques, groupe d'espace $P2_1/a$ avec $a = 19,240(3)$, $b = 9,1463(24)$ et $c = 19,3512(24)$ Å, $\beta = 118,874(8)°$, $V = 2982,0(10)$ Å^3, $z = 4$ et $D_{calc} = 1,427$ Mg m^{-3}. Les facteurs finaux de convergence sont $R_F = 0,056$ et $R_W = 0,058$ pour 1915 réflexions significatives. Les valeurs QS et IS du spectre de Mössbauer du complexe sont respectivement 3,08 mm s^{-1} et 1,28 mm s^{-1}. La 2,3-diphénylthiazolidin-4-one se comporte comme un coordinat monocoordinant; sa coordination à l'étain se fait par l'atome d'oxygène. Le complexe présente une configuration trigonale bipyramidale avec trois groupes phényles en positions équatoriales alors que le chlore et le coordinat oxygéné occupent des sites apicaux.

Mots cles : triorganoétain, fongicide, maladie des ormes, thiazolidin-4-one.

[Traduit par la rédaction]

Introduction

Organotin compounds have a wide range of biological applications depending on the number and species of the organic substituents present (1–3). The use of triphenyltin compounds as fungicides is well documented (1–6). However, when fungicides are to be used on living vegetation, the phytocidal properties of the compounds must also be taken into account.

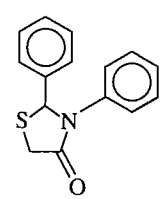
One class of triphenyltins that has been shown to possess a high fungicidal to phytocidal ratio is the triphenyltin chloride adducts (7). The title compound was synthesized as part of an effort to produce a more effective fungicide to combat Dutch Elm Disease (DED), which is caused by the fungus *Ceratocystis ulmi*. Earlier results have indicated that the triphenyltin moiety is effective in the inhibition of this fungus (8, 9). The 2,3-disubstituted thiazolidin-4-ones are compounds with known biological activity (10, 11), and so it was considered likely that an adduct of the two could well show increased fungicidal effects due to synergism. The ligand selected was 2,3-diphenylthiazolidin-4-one, whose structure is shown below:



2,3-diphenylthiazolidin-4-one

While the adduct formed may have biological significance, it also presents an interesting structural problem since the ligand has three possible coordination sites, and no structural studies on complexes of this ligand have previously been reported. A full X-ray structural analysis of the 1:1 adduct has been carried out and the results are reported along with the Mössbauer data for the compound.

Experimental

Materials

Triphenyltin chloride was purchased from the Aldrich Chemical Co. and acetone obtained from Fisher Scientific. Both were used without further purification. The synthesis of 2,3-diphenylthiazolidin-4-one was carried out according to the literature method (10).

Preparation of complex

A solution of 2,3-diphenylthiazolidin-4-one (2.55 g, 10 mmol) in acetone (30 mL) was added dropwise to a solution of triphenyltin chloride (4.06 g, 10 mmol) in acetone (80 mL). The mixture was stirred at room temperature for 30 min and then allowed to stand for an additional 3 h. It was filtered and the filtrate was concentrated on a rotary evaporator, then dried in vacuum to give an oily residue. Scratching the sides of the flask resulted in solidification of the residue. The product was recrystallized from ligroin to yield needle-shaped crystals (5.60 g, 88% yield, mp 88–89°C). Anal. calcd. for $C_{33}H_{28}NOSClSn$: C 61.85, H 4.40, Sn 18.52; found: C 61.88, H 4.22, Sn 18.30.

Mössbauer spectroscopy

The Mössbauer spectra were measured at 80 K on a Ranger Scientific model MS-900 Mössbauer spectrometer in the acceleration mode with a moving source geometry using a liquid nitrogen cryostat (11). The sample was mounted in a Teflon holder. The source was 15 mCi $Ca^{119m}SnO_3$, and the velocity was calibrated at ambient temperature using a composition of $BaSnO_3$ and Sn foil (splitting = 2.52 mm s^{-1}). The resultant spectra were analyzed by a least-square fit to Lorenzian-shaped lines. All isomer shifts were calculated relative to $BaSnO_3$. The quadrupole splitting (QS) and isomer shift (IS) values for the complex are 3.08 ± 0.07 mm s^{-1} and 1.28 ± 0.02 mm s^{-1}, respectively.

X-ray analysis

Space group and cell dimensions

The crystals are monoclinic, space group $P2_1/a$ with a = 19.240(3) Å, b = 9.1463(24) Å, c = 19.3512(24) Å, β = 118.874(8)°, V = 2982.0(10) Å^3, z = 4, and D_{calc} = 1.427 Mg m^{-3}. Crystal dimensions: 0.40 × 0.15 × 0.05 mm. Empirical formula: $C_{33}H_{28}NOSClSn$. FW = 640.79. $F(000)$ = 1301.73, μ = 8.66 mm^{-1}.

Data collection, structure solution, and refinement

Cell dimensions were obtained from 12 reflections with 2θ in the range 60–70°. The intensity data were collected at 293 K on a Rigaku model AFC6S diffractometer run by the TEXRAY (12) diffractometer control program, using the θ/2θ scan mode and $Cu_{K\alpha}$ radiation (λ = 1.54056 Å). A total of 3125 reflections were measured, of which 3003 were unique. Of these, 1915 had $I_{net} > 2.5\sigma(I_{net})$ and R_{int} = 2.7%. The h, k and l ranges were −17 to 16, 0 to 9, and 0 to 19, respectively, and $2\theta_{max}$ was 100°. Absorption corrections were made with the NRC program ABSORB using ψ-scan data (13). The minimum and maximum transmission factors are 0.221 and 0.325. The structure was solved by direct methods, followed by a difference Fourier. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in the calculated positions and not refined. Secondary extinction was refined (14) to 0.83(5). The refined parameter is the average length of a mosaic block in microns. Least-squares refinement was carried out on F. The final least-squares cycle was calculated with 66 atoms and 344 parameters. Weights based on counting-statistics were used. Final residuals are R_F = 0.056, R_W = 0.058 for data with $I_{net} > 2.5\sigma(I_{net})$, R_F = 0.126, R_W = 0.061 for all data. The goodness-of-fit was 2.07. Maximum shift/error was 0.098. In the last difference Fourier map, the top peak was 0.390 e/Å^3, and the deepest hole was −0.490 e/Å. Scattering factors were taken from the literature (15). Structure solution and refinement was performed using the NRCVAX system of crystal structure solving programs (16).

Discussion

Complexes of triphenyltin chloride are almost invariably five-coordinate with equatorial phenyl groups, even with potentially bi- or tridentate ligands (17–22). One spectroscopic tool that has been used for deducing the structural configuration of organotin compounds is Mössbauer spectroscopy. Mössbauer spectroscopy gives rise to two parameters, the isomer shift (IS) and the quadrupole splitting (QS). The isomer shift is related to the *s*-electron density at the tin nucleus, which can provide information as to its oxidation states and the bonding of the tin atom. The quadrupole splitting reflects the symmetry of the electronic environment around the tin nucleus and thus gives information concerning the arrangement of the ligands about the tin atom. Observed QS values in the range of 2.76–3.86 mm s^{-1} have been found for trigonal bipyramidal (TBP) organotin structures with axial ligand groups (1, 23, 24). Values of the parameter ρ, which is the QS/IS ratio, have been used to indicate the coordination number of the tin atom (23, 24). Although borderline ρ values are of questionable value, those falling well within the prescribed ranges can be very significant in structure identification (24). A ρ value of greater than 2.1 is indicative of a coordination number greater than four. The QS and IS values for the synthesized adduct are 3.08 mm s^{-1} and 1.28 mm s^{-1}, respectively. The observed ρ value of 2.41 would indicate that the adduct is greater than four coordinated. The ρ value, along with the observed QS value of 3.08 mm s^{-1}, would indicate that the triphenyltin chloride adduct is TBP with equatorial phenyl groups and the chloride atom and the ligand group occupying the axial positions. The TBP geometry of the molecule, with equatorial phenyl groups, predicted by the Mössbauer spectrum is confirmed by the X-ray structural investigation. An ORTEP (25) plot of the organotin complex is given in Fig. 1. A stereo pair showing the packing arrangement of the molecules in the unit cell is shown in Fig. 2. The final fractional coordinates of non-hydrogen atoms with equivalent isotropic thermal parameters are listed in Table 1, while the bond lengths and bond angles for the complex are presented in Tables 2 and 3, respectively. Fig. 2. The structure of the complex.

carbon–tin angles in the trigonal plane of the complex is 355.7° (116.8° + 119.7° + 119.2°), slightly less than the 358.2° value observed in triphenyltin *N*-salicylidene-6-aminohexanoate (26) and the 358.9° reported for terpyridyl-aquachlorotriphenyltin(IV) (19). This is probably a result of the relatively greater Cl—Sn—C(phenyl) angles observed in the present complex, indicating that the Sn atom is pulled slightly out-of-plane towards the Cl atom. The mean Cl—Sn—C(phenyl) angle for the title compound is 97.0° whereas for terpyridyl-aquachlorotriphenyltin(IV) the corresponding value is 93.6° (19). This increase in the Sn—Cl attraction is reflected in the shorter Sn—Cl bond length (2.45 Å) seen in the title complex, compared to that reported (2.52 Å) for the terpyridyl complex (19). In other respects, the coordination geometries about the tin atoms in these two complexes are very similar. The Sn—C(phenyl) distances are almost the same, showing average values of 2.12 Å for the title complex and 2.13 Å for the terpyridyl complex. The Sn—O bond distance in the title compound is 2.50 Å, within the range expected for a keto–oxygen interaction with tin (27). There are no short intermolecular contacts, and the packing in the unit cell appears to be controlled by the steric requirements of the five phenyl groups, which project in all directions from the complex.

Novel O-C-C-O and C-O-C-C stereochemistry in crown ether analogs. X-ray crystal structure and NMR studies of dibenzo-20-crown-6

G.W. Buchanan, A. Moghimi, and C. Bensimon

Abstract: The X-ray crystal structure of the title material indicates that the molecule possesses a pseudo-centre of inversion. A pair of O-C-C-O bonds have a *trans* conformation in contrast to normal *gauche* stereochemistry for such units in crown ethers. For the C-O-C-C networks, which are normally *transoid* in crown ethers, all four such units involving methylene carbons of the 20-membered ring exhibit unusual geometries. Two units possess *gauche* conformations and the other two have torsion angles near 120°. Solution ^{1}H and ^{13}C NMR spectra have been recorded as a function of temperature and ^{13}C solid state spectra are included.

Key words: crown ether, solid state conformation.

Résumé : La structure cristalline du composé mentionné dans le titre, telle que déterminée par diffraction des rayons X, indique que la molécule possède un pseudo-centre d'inversion. Une paire de liaisons O-C-C-O existe dans une conformation *trans* alors que la stéréochimie normale de telles unités dans des éthers couronnes est *gauche*. Pour les réseaux C-O-C-C qui sont généralement transoïdes dans les éthers couronnes, les quatre unités impliquant les carbones méthyléniques du cycle à 20 chaînons présentent tous des géométries inhabituelles. Deux unités possèdent des conformations *gauche* et les deux autres ont des angles de torsion de 120°. On a déterminé les spectres RMN du ^{1}H du ^{1}H et du ^{13}C en fonction de la température et on a aussi inclus les spectres RMN du ^{13}C à l'état solide.

Mots clés : éther couronne, conformation à l'état solide.

[Traduit par la rédaction]

Introduction

The X-ray crystal structures of many dibenzo crown ethers are now available, including those for the dibenzo-18-crown-6 (1) and dibenzo-24-crown-8 (2) systems illustrated below. The conformations of C-O-C-C units are normally *transoid* in these structures, while O-C-C-O units where the carbons are not part of the aromatic ring adopt *gauche* geometries. The most substantial deviation from the *gauche* O-C-C-O stereochemistry occurs in the 24-crown-8 case where expansions of the torsional angle up to values of ca. 84° are found (2).

As part of our continuing program to examine structures and complexation features of novel crown ether analogs, we have now prepared the dibenzo-20-crown-6 system **1** shown below. Herein we report its X-ray structure as well as solution and solid state NMR spectral features. The solid phase ^{13}C shifts are discussed in terms of earlier ab initio shift calculations for constituent structural units.

Results and discussion

The structure and numbering scheme for dibenzo-20-crown-6, **1**, is depicted in Fig. 1. The ORTEP plot for **1** is shown in Fig. 2, while the ^{13}C CPMAS spectra are depicted in Fig. 3. Table 1 contains bond lengths, Table 2 has bond angles, and torsion angles involving non-H atoms are presented in Table 3. Crystallographic data are listed in Table 4 and atomic parameters in

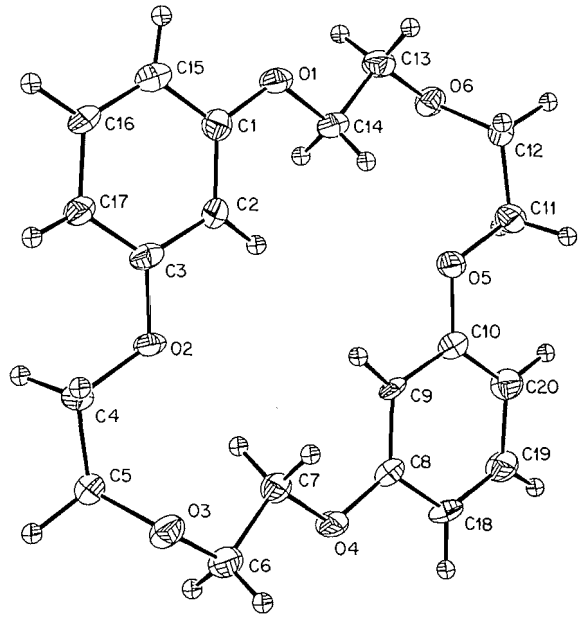
Table 5. In Table 6 are collected the ^{1}H NMR data while ^{13}C NMR chemical shifts are presented in Table 7.

X-ray crystal structure

The structure of **1**, as determined at −100°C, exhibits a pseudo-centre of inversion. Regarding the O-C-C-O networks, *gauche*-type geometries are present in the O2-C4-C5-O3 and O5-C11-C12-O6 units in accord with expectations based on "normal" preferred crown ether conformations (3, 4). In contrast, the torsion angles for the O3-C6-C7-O4 and O6-C13-C14-O1 units are 176.0° and −177.4°, respectively. Examination of molecular models indicates that these *trans* O-C-C-O geometries are adopted by the molecule in order to minimize a potentially repulsive steric interaction between the aromatic

Fig. 2. ORTEP diagram for **1**.



H's on C2 and C9. This minimization of inter-ring repulsion is also apparently more important than the maintenance of "normal" (3, 4) *trans* conformations in the C-O-C-C units. For example, the C5-O3-C6-C7 and C12-O6-C13-C14 units have torsion angles of 78.2° and −77.4°, respectively, while C6-O3-C5-C4 and C13-O6-C11-C12 exhibit angles of −127.5° and 126.6°, respectively. Hence all aliphatic C-O-C-C units of **1** have "abnormal" geometries.

With regard to the stereochemistry of the aryl-O-C units, there are two distinctly different types of geometries observed in crystalline **1**. For example, the C14-O1-C1-C15 unit and its pseudo-symmetry related counterpart C7-O4-C8-C18 are *transoid*, with torsion angles of −172.9° and 171.6°, respectively. In contrast, the C4-O2-C3-C17 unit and its counterpart C11-O5-C10-C20 are *cisoid*, with torsion angles of 1.5° and −1.2°, respectively. Such differences in environment between the terminal atoms of these units lead to very large ^{13}C chemical shifts between C15,18 and C17,20 in the solid state, while in solution these carbons exhibit one conformationally averaged resonance (*vide infra*).

Solution NMR spectra

The ^{1}H spectrum of **1** in $CDCl_3$ exhibits the expected A_2XY spin system for the aromatic protons and an AA'BB' type multiplet for the aliphatic hydrogens. Apart from minor temperature-dependent chemical shifts, both the ^{1}H and ^{13}C spectra are independent of temperature between 310 and 200 K, indicating fast conformational interchange on the NMR time scale throughout this temperature range.

First-order spectral analysis yielded the aromatic proton shifts and couplings collected in Table 6 while iterative computer analysis was employed for the aliphatic data. Assignment of the more deshielded half of the AA'BB' multiplet to protons on C4,7,11,14 was made on the basis of the observed nuclear Overhauser enhancement between the resonance centered at 4.150 ppm and the aromatic proton resonances on C2, 9 and C15,17,18,20.

It is of interest to compare the aliphatic vicinal coupling constants for **1**, having two *gauche* and two *trans* O-C-C-O networks, with those determined previously (5) for dibenzo-18-crown-6, which possesses four *gauche* O-C-C-O units. Both materials were examined in $CDCl_3$ solution. From the X-ray data, it is clear in the crystal that there will be two sets of *trans* vicinal protons and two sets of *gauche* vicinal protons in each O-C-C-O unit of **1**. By contrast, in crystalline dibenzo-18-crown-6, there will be one pair of *trans* vicinal protons and three pairs of *gauche* vicinal protons in each O-C-C-O moiety. Assuming that the preferred conformation in the crystal also exists in solution, one would anticipate substantially larger ^3J values for **1** than for dibenzo-18-crown-6. In reality there is a small increase observed. The ^3J values for dibenzo-18-crown-6 are 5.7 and 3.3 Hz (5), while those for **1** are 5.9 and 3.8 Hz. Hence conformational averaging in solution appears to render the vicinal couplings more nearly equal than would be expected based on crystal geometries alone.

With respect to the solution ^{13}C NMR spectrum, the aromatic region can be readily assigned. Quaternary carbons 1, 3, 8, and 10 are the most deshielded, as expected (5) from early data on aromatic ethers. The known shielding effect (6) of *ortho* oxygen atoms is clearly operative here, giving rise to the resonance at 102.9 ppm for C2,9. The resonance at 107.4 is twice the intensity of that at 102.9, consistent with the assignment of the 107.4 peak to C15,17,18,20. The remaining CH resonance at 129.7 arises from C16,19. In the aliphatic region, the more shielded methylene carbon resonance at 67.8 ppm is attributed to C4,7,11,17 based on results of a ^{1}J HETCOR experiment and the known ^{1}H assignments for the methylene protons. This result is also consistent with trends found previously for dibenzo-15-crown-15 (7) and tetrabenzo-30-crown-10 (8) systems.

In the solid phase, the ^{13}C spectral multiplicity will reflect the asymmetric unit in the crystal if no unusual crystal packing effects or nonequivalent molecules in the unit cell are present

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

(9). For **1**, there is a pseudo-centre of inversion, which is apparent from examination of the torsion angle data in Table 3. Hence in the ^{13}C CPMAS spectrum (Fig. 3) one expects to observe 10 unique resonances in the absence of any peak overlap. Of the six anticipated aromatic resonances, all are resolved; however, the four aliphatic resonances appear as a broad singlet centered at 68.5 ppm.

15,18	107.4	111.5
16,19	129.7	131.1
17,20	107.4	101.6

[a] 0.1 M in $CDCl_3$.

The most shielded aromatic singlet at 99.4 ppm is assigned to C2,9 by analogy with the solution spectrum. Most interestingly, the resonance for C15,18,17,20, which is averaged to one line in solution with a chemical shift of 107.4 ppm, becomes a doublet in the solid phase, with components at 111.5 and 101.6 ppm, respectively. Due to the lack of conformational averaging in the solid phase, the resonance for the C15,18 pair is now distinct from the peak arising from C17,20. The more shielded resonance at 101.6 is attributed to the C17,20 pair. Examination of the torsion angles in the X-ray structure shows that both C17 and C20 are involved in essentially coplanar γ-interactions with aliphatic carbons C4 and C11, respectively. The interactions involved here are C4-O2-C3-C17 (θ = 1.5°) and C11-O5-C10-C20 (θ = −1.2°). By contrast, the C15, C18 pair experience nearly *trans*-coplanar γ-interactions with the aliphatic carbons C14 and C7, respectively. The pertinent torsion angles here are 172.9° for the C14-O1-C14-C15 network and 171.6° for the C7-O4-C8-C18 unit. It is well known (10) that *cis*-coplanar γ-interactions lead to substantially shielded terminal carbon resonances relative to the corresponding *trans* situations. Hence we are confident in the assignment of the more shielded line to C17, 20.

The resonance at 131.1 ppm is due to the pseudo-symmetry equivalent C16,19 pair and is within 2 ppm of the solution chemical shift. Finally, the C1,8 and C3,10 sites gives rise to resonances at 159.9 and 161.1 ppm. Subtle differences in the electronic environments at these pairs of carbons in the solid

may be responsible for the small chemical shift difference observed. The most effective conjugative electron release by the oxygen lone pairs into the aromatic ring (and hence more aryl C—O double bond character) is expected when the aliphatic carbon bonded to the oxygen is coplanar with the aromatic ring. Since these interactions are more nearly coplanar for the C3,10 pair than for C1,8 (vide supara), we assign these to the more deshielded resonance at 161.1 ppm to C3,10. The extra smaller absorption at ca. 158 ppm in the normal ^{13}C CPMAS spectrum disappears in the dipolar dephased version and henced is an impurity, since no aromatic CH in **1** would resonate in this region.

Experimental

Materials

Dibenzo-20-crown-6 was prepared according to the following procedure. A 2.0 L round-bottom flask was charged with resorcinol (Aldrich) (11.0 g, 0.1 mol), distilled water (200 mL), and $LiOH{\cdot}H_2O$ (2.1 g, 0.05 mol) and the mixture was stirred for 5 min. To this was added dropwise 1,5-dichloro-3-oxapentane (Aldrich) (7.2 g, 0.05 mol) and the reaction mixture was refluxed for 72 h. After cooling to 40°C, an additional 2.1 g of $LiOH{\cdot}H_2O$ was added, followed by another 7.2 g of the dichloride. Subsequent to dilution with 12 mL of distilled water, the mixture was refluxed for another 72 h. After cooling, the mixture was acidified to pH 2 by addition of dilute sulphuric acid and extracted with CH_2Cl_2 (4 × 15 mL). After washing with 5% NaOH (3 × 150 mL), saturated NaCl (4 × 150 mL), and water, the extracts were dried over anhydrous Na_2SO_4. Following solvent removal, the resultant crude solid was recrystallized from acetone to yield 1.5 g (4%) of dibenzo-20-C-6, mp 165–167°C. No attempt was made to optimize the yield.

Spectra

All solution NMR spectra were recorded using a Bruker AMX-400 spectrometer equipped with a 5 mm inverse probe and an Aspect X32 computer. An Aspect 3000 process controller was employed and all standard microprograms used are in the Bruker Software Library.

For the NOESY experiment, the mixing time used was selected to be consistent with the $1/T_1$ criterion (11), and in the present case it was set to 0.3 s. For the $^1H^{13}C$ HETCOR experiment, the free induction decays were acquired over 1024 data points for each of the 512 values of the evolution time, with a digital resolution of ca. 8 Hz/point in $F2$ and 4 Hz/point in $F2$. The raw data were zero filled in $F1$ prior to transformation using the qsine window function for both $F1$ and $F2$. The proton relaxation delays were set to 1 s. Delays were chosen to emphasize J values of 135–140 Hz.

The solid phase ^{13}C NMR spectra were recorded at 45.3 MHz using a Bruker CXP-180 spectrometer via techniques described previously (12). For the dipolar dephased spectrum, the ^1H decoupler was gated off for a period of 40 μs during the delay before the ^{13}C acquisition.

X-ray crystallographic measurements and structure solution

A summary of the crystallographic data is given in Table 4. Diffraction intensities were collected on a Rigaku diffractometer using MoKα radiation at −110°C. The Ω–2θ scan technique was used to a maximum 2θ value of 49.9°. The space group was determined by systematic absences. Unit cell parameters were obtained from least-squares refinement using the setting angles of 25 reflections in the range $40 < 2\theta < 50$. The data were corrected for Lorentz and polarization effects (13). No absorption correction was made. The structure was solved by direct methods plus Fourier maps and was refined by full-matrix least-squares analysis with weights based on counting statistics. Non-H atoms were refined anisotropically and H atoms isotropically. No crystal decay was noted during data collection. All calculations were performed using the NRC VAX Crystal Structure programs (14). Anisotropic temperature factors are available as supplementary data.[2]

Theoretical and experimental barriers to internal rotation in 2,6-difluorobenzaldehyde and 2,4,6-trifluorobenzaldehyde. Relatively low barriers

Ted Schaefer, Craig S. Takeuchi, Guy M. Bernard, and Frank E. Hruska

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Abstract: The free energies of activation at 110 K for rotation about the exocyclic C—C bonds in 2,6-difluorobenzaldehyde and 2,4,6-trifluorobenzaldehyde, in dimethyl ether solutions, are 18.8 ± 0.5 and 20.0 ± 0.5 kJ mol^{-1}, respectively, as determined from $^{19}F\{^1H\}$ dynamic nuclear magnetic resonance measurements. For the parent compound $\Delta G^{\ddagger}$ is 32.2 kJ mol^{-1} in the same solvent. These free energy barriers, the lowest available for benzaldehyde derivatives, are likely a result of steric and electrostatic repulsions between the C^+—O^- and C^+—F^- bonds. Computations of the spectroscopic barrier in the 2,6-difluoro compound at various levels of molecular orbital theory imply that the barrier is predominantly twofold, with a fourfold component of opposite sign, whose magnitude is about 10% of the twofold component. A correlation-gradient computation, MP2/6-31G*, finds a barrier height of 18.6 kJ mol^{-1} for this compound, lower by 3.0 kJ mol^{-1} than found with the 6-31G* basis and 2.9 kJ mol^{-1} with 6-31G**. Similar computations are compared for the parent compound and the 4-fluoro, 2,4,6-trifluoro, and 3,5-difluoro derivatives. Linear relationships exist between the computed spectroscopic barriers (ΔE values at absolute zero for the free molecules) and the free energy barriers for benzaldehyde and the four fluoro derivatives; the theoretical barriers utilize 6-31G** and correlation-gradient MP2/6-31G* procedures. For the 2,6-difluoro derivative, the computed frequencies of the torsional motions about the exocyclic C—C bond yield spectroscopic twofold barriers. These barriers are much lower than the computed energy differences between the planar and perpendicular conformers, perhaps because the negative fourfold components flatten the potential at its minimum. A rough estimate of the relationship between $\Delta G^{\ddagger}$ and ΔE_0 for the 2,6-difluorobenzaldehyde suggests that the solvent increases the internal barrier by only about 3 kJ mol^{-1}. By way of contrast, the AM1 barriers, scaled by a factor of 1.9 (as previously recommended) range from 17.3 to 22.6 kJ mol^{-1}, the $\Delta G^{\ddagger}$ values from 18.8(5) to 34.4 kJ mol^{-1}, and the MP2/6-31G* (correlation-gradient) barriers span 18.6 to 36.8 kJ mol^{-1} for benzaldehyde and the four fluorine derivatives. It seems likely that the internal barrier in benzaldehyde is considerably larger than that modeled on torsional frequencies.

Key words: Free energies of activation, internal rotational barriers in 2,6-difluoro- and 2,4,6-trifluorobenzaldehyde; molecular orbital computations, internal rotational barriers in 2,6-difluoro- and 2,4,6-trifluorobenzaldehyde; correlation gradient computations on internal barriers in benzaldehyde and four of its fluorine derivatives.

Résumé : En se basant sur des mesures de résonance magnétique nucléaire dynamique du $^{19}F\{^1H\}$, on a établi que les énergies libres d'activation, à 110 K, pour la rotation autour des liaisons exocycliques C—C des 2,6-difluoro- et 2,4,6-trifluorobenzaldéhydes, en solutuions dans le méthoxyméthane, sont respectivement de 18,8 ± 0,5 et 20,0 ± 0,5 kJ mol^{-1}. Pour le composé parent, le $\Delta G^{\ddagger}$ est de 32,2 kJ mol^{-1}, dans le même solvant. Ces barrières d'énergies libres sont les plus basses disponibles pur des dérivés du benzaldéhyde et elles sont probablement le résultat de répulsions stériques et électrostatiques entre les liaisons C^+—O^- et C^+—F^-. Des calculs de barrière spectroscopique pour le composé 2,6-difluoré, à divers niveaux de la théorie des orbitales moléculaires, impliquent que la barrière est principalement binaire, qu'elle comporte une composante quaternaire de signe opposé dont l'amplitude est d'environ 10% de celle de la composante binaire. Un calcul de gradient de corrélation, MP2/6-31G*, a permis d'établir que, pour ce composé, la hauteur de la barrière est de 18,6 kJ mol^{-1}; cette valeur est respectivement 30 et 2,9 kJ mol^{-1} plus basse que celles trouvées avec des base 6-31G* et 6-31G**. On a comparé des calculs semblables pour le composé parent et les dérivés 4-fluoré, 2,4,6-trifluoré et 3,5-difluoré, Il existe des corrélations linéaires entre les barrières spectroscopiques calculées (valeurs de ΔE

au zéro absolu, pour des molécules libres) et les barrières d'énergies libres du benzaldéhyde et les quatre dérivés fluorés; les barrières théoriques ont été obtenues à l'aide de procédures 6-31G** et des gradients de corrélation MP2/6-31G*. Pour le dérivé 2,6-difluoré, les fréquences calculées des mouvements de torsion autour de la liaison exocyclique C—C conduisent à des barrières binaires. Ces barrières sont beaucoup plus faibles que les différences d'énergie calculées entre les conformères plans et perpendiculaires; cette différence est peut-être causée par les composantes quaternaires qui aplatissent le potentiel à son minimum. Une évaluation grossière de la relation entre le $\Delta G^{\ddagger}$ et le ΔE_0 dans le cas du 2,6-difluorobenzaldéhyde suggère que le solvant augemente la barrière interne par environ 3 kJ mol^{-1}. Pour fins de comparaison, les barrières AM1 (ajustées par le facteur de 1,9 recommandé antérieurement) varient de 17,3 à 22,6 kJ mol^{-1} et les valeurs du $\Delta G^{\ddagger}$ varient de 18,8(5) à 34,4 kJ mol^{-1} alors que les barrières MP2/6-31G* (gradient de corrélation) varient de 18,6 à 36,8 kJ mol^{-1} pour le benzaldéhyde et ses quatre dérivés fluorés. Il semble probable que le barrière interne dans le benzaldéhyde soit considérablement plus élevée que celle dérivée du modèle des fréquences de torsion.

Mots clés : énergies d'activation, barrières à la rotation interne dans les 2,6-difluoro- et 2,4,6-trifluorobenzaldéhydes; calculs d'orbitales moléculaires, barrières à la rotation interne dans les 2,6-difluoro- et 2,4,6-trifluorobenzaldéhydes; calculs de gradients de corrélation sur les barrières internes dans le benzaldéhyde et quatre de ses dérivés fluorés.

[Traduit par la rédaction]

Introduction

The experimental and theoretical approaches to the barrier to rotation about the exocyclic Csp^2—Csp^2 bond in benzaldehyde have an interesting history. In the vapor, torsional frequencies assessed by various spectroscopic methods (1–3) imply a predominantly twofold barrier with a magnitude lying between 19 and 23 kJ mol^{-1}. Ab initio molecular orbital computations (4, 5) at the MP2/6-311G**//6-31G* level of approximation give a barrier height of 34.7 kJ mol^{-1}; whether correlation-gradient computations would alter this value substantially is not known. However, another approximation to the effect of electron correlation on the barrier, at the MCSCF level, yields 18–21 kJ mol^{-1} (6). The disagreement between the theoretical values has been discussed (7, 8). More theoretical and experimental work is needed (8).

One criticism (4) of the experimental value of the mainly twofold barrier derived from far-infrared data is that it also contains a positive fourfold component (3), whereas a negative component is found for related molecules (4). This criticism does not apply to the vibronic fluorescence results (2). Another might be that the torsion measurements imply a decrease in the barrier in the presence of a 4-fluoro substituent (9, 10), whereas theory (5) and intuition (the substituent increases the mobile bond order for the Csp^2—Csp^2 linkage) suggest the opposite. Another curious fact concerns the computation of the torsional frequency in benzaldehyde. For example, at the STO-3G level this frequency is computed as 111.1 cm^{-1} and is measured as 110.9 cm^{-1} in the vapor. Accordingly, the magnitudes of V_2, computed and experimental (torsion model), are essentially identical at 19.3 kJ mol^{-1}. The computed energy difference, ΔE_0 between the planar ground state and the perpendicular transition state is, however, 22.9 kJ mol. Similar comparisons hold for another basis set (5).

In solution, the internal barrier of benzaldehyde apparently increases to about 27 kJ mol^{-1} (9), as deduced from torsional frequencies. Dynamic nmr measurements have $\Delta G^{\ddagger}$ as 32.3 kJ mol^{-1} (11) and other nmr data yield $\Delta H^{\ddagger}$ as 30.5 kJ mol^{-1} (12). The apparent increase in the barrier in solution has been attributed (11) to the stabilization by the dielectric continuum of the polar ground state relative to the less polar transition state. Allowance for the zero-point energies of the planar and perpendicular conformers of benzaldehyde, estimated (5) at 1.3–2.0 kJ mol^{-1} (to be here subtracted from the theoretical barrier), yields about 33 kJ mol^{-1} as an approximation[2] to $\Delta H^{\ddagger}$. The rough agreement between the approximate, theoretical $\Delta H^{\ddagger}$ and the experimental $\Delta H^{\ddagger}$ is rather striking. It may be accidental; if not, the solvent effect on the barrier is relatively small. Similar remarks apply to 4-fluorobenzaldehyde and some other *para* derivatives (5).

If the barrier to internal rotation in benzaldehyde is closer to 30 kJ mol^{-1} than to 20 kJ mol^{-1}, it would be then interesting to know how the two kinds of experimental approaches compare to theoretical calculations in assessing rather lower barriers to rotation in appropriate benzaldehyde derivatives. Preliminary molecular orbital computations on 2,6-difluoro- and 2,4,6-trifluorobenzaldehyde implied barrier heights near 20 kJ mol^{-1}. Such a magnitude is perhaps just within the lowest range assessable by DNMR.

Accordingly, $^{19}F\{^1H\}$ experiments were performed on these molecules, with the result that reasonable magnitudes of $\Delta G^{\ddagger}$ became available. We here report on these results and compare them with molecular orbital computations of the barriers, including gradient-optimized post-Hartree–Fock estimates of the internal barrier height. In addition, the computations are compared with experimental results, previously reported (14), for 3,5-difluorobenzaldehyde. These are of interest because the barrier in this molecule is lower than in benzaldehyde, not immediately obvious from chemical intuition, and unlike the barrier in 4-fluorobenzaldehyde, which is higher than in benzaldehyde (according to DNMR but not according to torsional frequencies), as expected from a π-electron-donating *para* substituent.

Results

In dimethyl ether solution at 110 K, $\Delta G^{\ddagger}$ is 20.0 ± 0.5 kJ mol^{-1} for 2,4,6-trifluorobenzaldehyde and is 18.8 ± 0.5 kJ mol^{-1} for 2,6-difluorobenzaldehyde (see Experimental). The latter barrier is the smaller one, as expected from the additional presence of a π donor in the *para* position in the trifluoro derivative.

[2] A discussion of the relationship of a potential barrier to an activation energy is available (13).

Fig. 1. In (*b*) the equilibrium, planar, 6-31G* geometry is shown for 2,6-difluorobenzaldehyde; in (*a*) the correlation-gradient structure using MP2/6-31G* procedures. Although bond angles are different by up to only 0.3°, bond length differences are as large as 0.038 Å, the MP2 values being the larger ones and rather close to expectations (35).

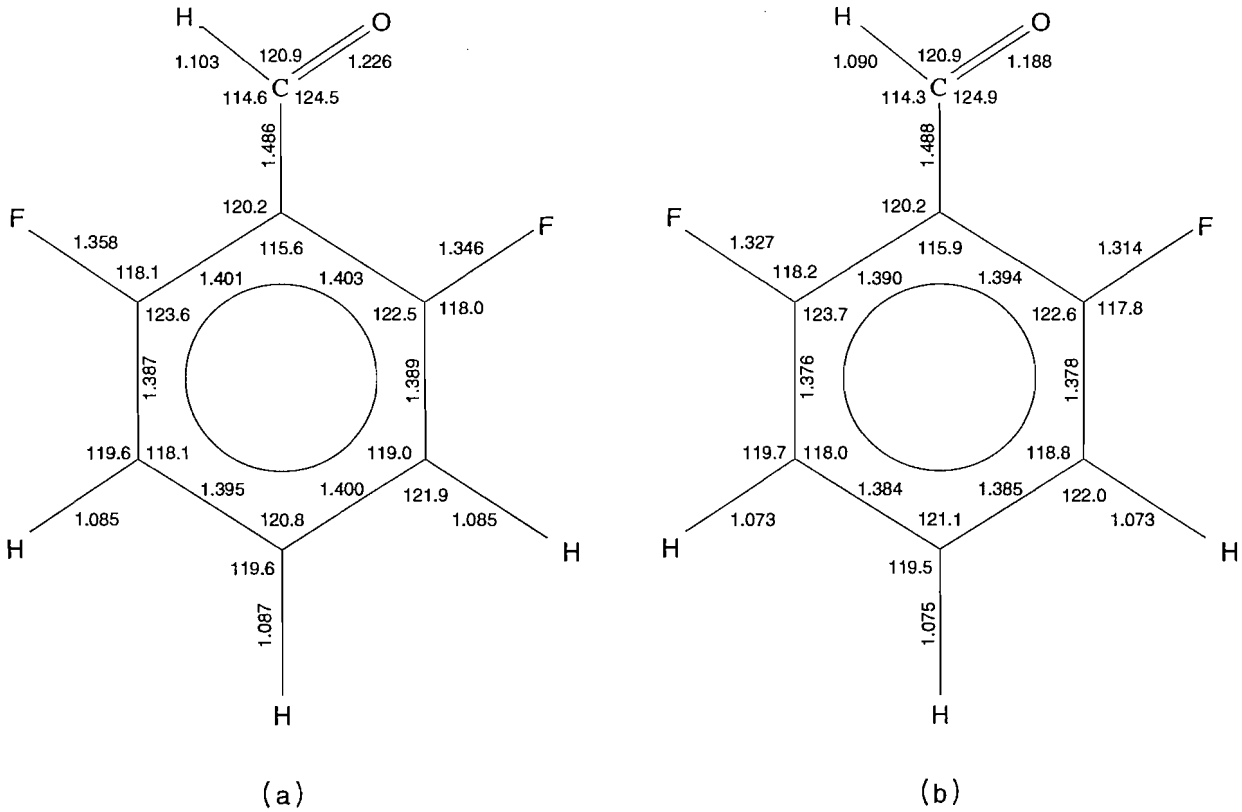

Table 1. Fourier components (in kJ mol^{-1}) of the computed barriers to internal rotation in 2,6-difluorobenzaldehyde.

Method	V_2[a]	V_4	V_6[d]	V_8	Standard error[e]
AM1	9.31	−0.59	−0.11	0.00	<0.01
STO-3G	20.09	−0.73	0.01	0.02	<0.01
3-21G	32.79	−2.02	0.43	−0.10	0.02
6-31G	19.55	−1.81	0.21	−0.06	0.01
6-31G*	21.27[b]	−2.10	0.21	−0.04	<0.01
6-31G**	21.29[c]	−2.03	0.19	−0.05	<0.01

[a]The total energies at 0° (planar) were −534.037 710, −538.152 867, −540.932 613, −541.126 702 and −541.133 864 au for bases STO-3G to 6-31G** in the order given in column 1.

[b]Geometry-optimized (correlation-gradient) MP2 (frozen core) computations of the conformers at 0° and 90° with the basis 6-31G* gave the barrier height, ΔE_0, as 18.56 kJ mol^{-1}; E_0 at 0° was −542.515 134 au.

[c]Computation of the zero-point energies for the planar and perpendicular conformers, as described in the text, gave ΔH_0 as 20.09 kJ mol^{-1}; the zero-point energy of the ground state is higher than that of the transition state by 1.39 kJ mol^{-1}.

[d]The barrier height is given by $V_2 + V_6$.

[e]In the fit to seven values of the relative computed energy, E_0, at 15° intervals in the torsion angle between 0° and 90°.

Table 2. V_2 values for 2,6-difluorobenzaldehyde as obtained[a] from the computed frequencies of torsion about the exocyclic C—C bond.

Method	υ_t(cm^{-1})	I_r(amu Å^2)	F[b]	V_2(kJ mol^{-1})
AM1	52.7	11.57	1.456	5.7
STO-3G	85.4	11.27	1.495	14.6
3-21G	100.5	10.84	1.555	19.4
6-31G	73.4	11.00	1.531	10.5
6-31G*	77.8	10.71	1.573	11.5
6-31G**	78.1	10.73	1.571	11.6

[a]V_2(cm^{-1}) = $\nu_t^2/4F$ where ν_t is given in cm^{-1}, I_r in amu Å^2, and F = 16.852/I_r.

[b]F is obtained from reduced moments of inertia based on the Pitzer formulation (15) and values are calculated with a locally written program using the computed geometries.

Table 1 presents the Fourier components of the computed internal rotational barriers of 2,6-difluorobenzaldehyde for various basis sets. In these computations, done at 15° intervals of the torsion angle, *all* other bond angles and lengths were optimized. An optimization was also performed with the 6-31G** basis in which all bond parameters, including the torsion angle, were allowed to vary. The result was that the torsion angle was zero (planar). Torsional frequencies were computed for the planar conformers, for which the "tight" option was chosen while computing the geometries. The torsional frequencies were used to compute V_2 values for the barriers (see Experimental); these are found in Table 2. Figure 1 presents the planar geometries found for 2,6-difluorobenzal-

Table 3. The AM1, 6-31G**, and correlation-gradient MP2/6-31G* internal barriers and the $\Delta G^{\ddagger}$ values[a] for benzaldehyde and four of its symmetrically substituted fluorine derivatives.

Compound	AM1[b]	6-31G**	MP2/6-31G*	$\Delta G^{\ddagger}$	μ[i]
C_6H_5CHO	11.2(21.3)	37.2[c]	35.4[d]	32.3(6)[f]	3.2[j]
4-F	11.9(22.6)	39.9	36.8	34.4(8)[g]	2.0[k]
3,5-di F	9.1(17.3)	32.8	34.6[e]	28.0(5)[h]	2.0[l]
2,4,6-tri F	9.9(18.8)	23.9	20.1	20.0(5)	~3.0[m]
2,6-di F	9.2(17.5)	21.5	18.6	18.8(5)	~4.2[m]

[a]In kJ mol^{-1}.

[b]Numbers in parentheses are greater by a factor of 1.9 (see text).

[c]The planar conformers have energies, in order down the column, of −343.444 137, −442.293 979, −541.139 250, −639.981 977, and −541.133 864 au.

[d]For these correlation gradient computations, the planar conformers have energies (down the column) of −344.486 360, −443.505 275, −542.521 821, −641.531 898, and −542.515 134 au.

[e]This number is of questionable quality. For the other four compounds the 6-31G* and 6-31G** barriers differ by less than 0.1 kJ mol^{-1} (see Table 1, for example). For 3,5-difluorobenzaldehyde, the 6-31G* barrier is 1.4 kJ mol^{-1} higher than that from the 6-31G** barrier and the correlation-gradient computation is higher yet, by 1.2 kJ mol^{-1} relative to the 6-31G* result.

[f]The mean of three values (16–18).

[g]The mean of two values (11–19).

[i]The dipole moment in units of debye.

[j]From ref. 20.

[k]From ref. 21.

[l]Taken as the dipole moment of 3,5-dichlorobenzaldehyde (22); the dipole moments of the 4-fluoro and 4-chloro derivatives are equal (21, 22).

[m]Estimated from STO-3G and 6-31G calculations as described in the text.

dehyde with the 6-31G** basis and with *geometry-optimized* MP2/6-31G* computations (frozen core). MP2 computations yield bond lengths much nearer the accepted values than does the RHF calculation. Bond angles, however, are less sensitive to correlation effects.

The zero-point energies of the planar and perpendicular forms of this molecule were obtained by scaling the computed frequencies by 0.89; the basis set was 6-31G**. The ΔE_0 value (absolute zero), 21.50 kJ mol^{-1} and identified with $V_2 + V_6$, thereby became a ΔH_0 value of 20.09 kJ mol^{-1}. The ΔE_0 value for the correlation-gradient MP2 computations with the 6-31G* basis was 18.56 kJ mol^{-1}.

AM1, 6-31G**, and correlation-gradient MP2/6-31G* computations of ΔE_0 (spectroscopic barriers) are collected in Table 3 for benzaldehyde and four of its symmetrically fluorinated derivatives. $\Delta G^{\ddagger}$ values and dipole moments are also given for these molecules.

Discussion

The free energy barrier in 2,6-difluorobenzaldehyde

The $\Delta G^{\ddagger}$ of about 19 kJ mol^{-1} for 2,6-difluorobenzaldehyde at 110 K is roughly 13 kJ mol^{-1} lower than that of 32 kJ mol^{-1} at 160 K, also in dimethyl ether, for benzaldehyde (18). It is likely that dipole–dipole repulsion between $C^+{=}O^-$ and *ortho* C^+—F^- bonds accounts[3] for much of the decrease in $\Delta G^{\ddagger}$. In addition, steric repulsion between fluorine and oxygen atoms is also important, the interatomic distance of 2.5 Å being rather smaller than the sum of their van der Waals radii, 2.7$_6$ Å. This suggestion is in line with the observation that in 2,6-dichlorobenzaldehyde the barrier to internal rotation is much lower than in the fluoro analog and leads to a relatively large magnitude (23) of ^6J(H,CHO), an indicator of nonplanarity. Yet the C^+—Cl^- bond dipole is very nearly of the same magnitude as that of a C^+—F^- dipole and the O,Cl and O,F distances in the planar forms are almost exactly the same; the van der Waals radius of chlorine is, however, the larger. Repulsion between the C=O and C—F dipoles is also indicated by the free energy differences between the O-*cis* and O-*trans* conformers of 2-fluorobenzaldehyde (24); they are 7.6 ± 0.3 kJ mol^{-1} in CS_2 solution at 300 K and 4.5 ± 0.2 kJ mol^{-1} in acetone-d_6 solution, favoring the O-*trans* conformer. The two π donors in 2,6-difluorobenzaldehyde will stabilize the planar ground state, by how much is not known, countering the dipolar and steric destabilizations. Note that, to within experimental error, the increase in $\Delta G^{\ddagger}$ of 1.2 ± 1.0 kJ mol^{-1} caused by a 4-fluoro substituent, forming the 2,4,6-trifluoro derivative, is the same as the increase of 2.1 ± 1.4 kJ mol^{-1} in $\Delta G^{\ddagger}$ measured for 4-fluorobenzaldehyde relative to the parent compound.

As to the stabilization of the ground state by the solvent, at least the dipole moments of the planar and perpendicular conformers are needed for a first-order calculation in reaction field theory (25). The dipole moment of 2,6-difluorobenzaldehyde is not known. However, the experimental dipole moment of 2-fluorobenzaldehyde is reasonably well reproduced by the mean of the values calculated with the STO-3G and 6-31G bases (24). For the 2,6-difluoro derivative, the corresponding means is 4.15 D for the planar and 3.78 D for the perpendicular form. The dimethyl ether solution at 110 K is taken to have a dielectric constant of 12 (p. 567 of ref. 25), with the result that the ground state is stabilized by only 1.8 kJ mol^{-1}. A similar number would be calculated for benzaldehyde itself, indicating that a large second-order, quadrupolar, term would be needed to account for the large solvent effect (as indicated by the torsional frequencies) of about 6–8 kJ mol^{-1} on the barrier of this molecule.

Now, if the solvent stabilization of the ground state of the present two benzaldehyde derivatives is also large, as for benzaldehyde, then their internal barriers in the vapor should be some 6 kJ mol^{-1} less than in solution, a supposition to be addressed by the following discussion.

The theoretical barriers for 2,6-difluorobenzaldehyde

The theoretical barrier heights for the 2,6-difluoro compound (Table 1), ignoring the 3-21G result, range from 9.3 kJ mol^{-1} (AM1) to 21.5 kJ mol^{-1} (6-31G**) with the RHF geometry optimizations. An optimized MP2 calculation predicts the energy difference of planar and perpendicular forms as 18.6 kJ

[3] The dipolar repulsion is not sufficient to destroy the planarity of the molecule in its stable form, according to the molecular orbital calculations in the previous section. Also, a substantial deviation from planarity would have been manifested (23) by a measurable ^6J(H-4,CHO), whose magnitude, however, we find to be at <0.03 Hz (unpublished).

mol^{-1}. The barrier heights correspond to predominantly V_2 values; the V_4 components contribute not more than 10% to the barrier shape and not to the height. The V_6 terms do contribute to the height but are very small.

It has been suggested (6, 7) that an AM1 barrier for benzaldehydes should be scaled by a factor of 1.9. In the case it would yield 17.5 kJ mol^{-1}, not far from most of the values in Table 1 and close to the MP2 estimate of 18.6 kJ mol^{-1}. The implication would be (6, 7) that the internal barrier for the free molecule is also reasonably well given by the largest basis sets in Table 1. In the computations on benzaldehyde and some of its *para*-substituted derivatives, various basis sets were used to calculate υ_t, the fundamental torsional frequency about the C—CHO bond. For example, for benzaldehyde the STO-3G basis gave υ_t as 111.11 cm^{-1}, the measured value being 110.9 cm^{-1}. A V_2 then follows (footnote *a* in Table 2) in the manner employed by molecular spectroscopists. The curious result is that the computed V_2, while necessarily in agreement with the experimental value, is rather smaller than the energy difference between planar and perpendicular forms computed with the same basis.

Table 2 presents data bearing out this curious fact also for 2,6-difluorobenzaldehyde. The V_2 values entailed by the computed torsional frequencies are as much as 10 kJ mol^{-1} lower than the computed energy differences. Of course, the negative V_4 components in the theoretical potential curves somewhat alter the slope of the curve near the planar conformer and could account for part of the discrepancies. No experimental value of υ_t is available for the molecule in the vapor or liquid phase. Harrison and Green found 118 and 58 cm^{-1} for vibrations of the proper symmetry for υ_t in gaseous pentafluorobenzaldehyde, but state that there is no certain way of treating either of these modes as a purely torsional motion (26). Treatment of these modes as pure torsions yields V_2 values of 29.6 or 7.5 kJ mol^{-1}; it is suggested (26) that the true barrier lies between these extremes.

Comparison of $\Delta G^{\ddagger}$ and theoretical barriers for 2,6-difluorobenzaldehyde

A $\Delta G^{\ddagger}$ is not a V_2, of course, nor, equivalently, a ΔE_0, the computed energy difference at absolute zero. To obtain a ΔH_0, correction of ΔE_0 for zero-point energies is necessary. The latter were computed with the 6-31G** basis set for 2,6-difluorobenzaldehyde, giving ΔH_0 as 20.09 kJ mol^{-1}, smaller by 1.4 kJ mol^{-1} than ΔE_0; the computed frequencies had been scaled by a factor of 0.89. Now, an approximation to $\Delta H^{\ddagger}$ can be had (13, 27) by allowing for the loss of a vibrational degree of freedom in the transition state. In the presence case, one then has $\Delta H^{\ddagger}$ as ΔH_0–0.5 kJ mol^{-1}, or 19.6 kJ mol^{-1}. $\Delta H^{\ddagger}$ could not be measured by DNMR, obviously, so that an estimate of $T\Delta S^{\ddagger}$ is desirable. Use of eqs. 7.9d of ref. 27, assuming a υ_t of 85 cm^{-1} and that the transition state can be reached in two ways from the planar ground state, yields $\Delta G^{\ddagger}_{110} = \Delta H^{\ddagger} - T\Delta S^{\ddagger} = 19.6 - 0.6$ or 19.0 kJ mol^{-1}. The $\Delta S^{\ddagger}$ of 5.5 J mol^{-1} K^{-1} is rather smaller than the 15 J mol^{-1} K^{-1} obtained for benzaldehyde in dimethyl ether solution by DNMR; the range of temperature in this experiment was only 21°, however, so that a rather large error must be expected (18). Of course, had the MP2 result of 18.6 kJ mol^{-1} for ΔE_0 been used in this path towards $\Delta G^{\ddagger}$, assuming the same magnitudes of corrections, the estimated value of $\Delta G^{\ddagger}_{110}$ would be 16.1 kJ mol^{-1} for the free molecule. An error estimate is hardly reliable, that is, what the errors are in the approximations needed to arrive at $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values from ΔE_0. Nevertheless, if this value of $\Delta G^{\ddagger}_{110}$ is taken as given, then the solvent causes an increase of 2.7 ± 0.5 kJ mol^{-1} in $\Delta G^{\ddagger}$; the dipole term in the reaction field model is estimated above as 1.8 kJ mol^{-1}. In these terms the MP2/6-31G* (a correlation-gradient calculation) value for ΔE_0, and therefore for V_2, of 18.6 kJ mol^{-1} would appear to be reasonably accurate. Such a barrier corresponds to a pure torsional frequency of 98.8 cm^{-1} for a twofold potential. Should a considerably lower frequency be found for a vibrational mode of 2,6-difluorobenzaldehyde in the vapor phase and a higher one in solution (see Table 2), the same situation as for benzaldehyde will arise: a large apparent solvent effect on the internal barrier, as indicated by υ_t, contrasting with a larger barrier calculated by present methods for the free molecule and therefore a closer agreement with (corrected) $\Delta G^{\ddagger}$ values as measured by DNMR in solution. In any event, the present experimental value of $\Delta G^{\ddagger}$ is less than 60% as large as that for benzaldehyde. It will be of interest to see how the various arguments (7, 8) about he proper approach to the computation of carbonyl group rotation will be resolved in the case of the difluoro derivative.

2,4,6-Trifluorobenzaldehyde and 3,5-difluorobenzaldehyde

The computed spectroscopic barriers for the trifluoro derivative are 9.9 kJ mol^{-1} (AM1) and 23.9 kJ mol^{-1} (6-31G**). The increase of 2.4 kJ mol^{-1} (6-31G**) relative to the 2,6-difluoro derivative is qualitatively consistent with the presence of the π-electron donor in the *para* position and with the difference in $\Delta G^{\ddagger}$ values measured for the two compounds. For the 3,5-difluoro compound the AM1 and 6-31G** spectroscopic barriers are 9.1 and 32.8 kJ mol^{-1}, respectively, and the latter is 4.4 kJ mol^{-1} lower than calculated for benzaldehyde (Table 3). The $\Delta G^{\ddagger}$ values also differ by 4.3 ± 1.0 kJ mol^{-1} (14).

Empirical relationship between ΔE_0 and $\Delta G^{\ddagger}$

Whatever the merits of the previous discussion of 2,6-difluorobenzaldehyde, the $\Delta G^{\ddagger}$ values in Table 3 correlate reasonably well with the ΔE_0 (spectroscopic barriers) values obtained from 6-31G** and MP2/6-31G* geometry-optimization procedures.[4] One has ΔE_0 (6-31G**) = 1.14 $\Delta G^{\ddagger}$ + 0.54 (r = 0.999) in units of kJ mol^{-1}. Also, ΔE_0 (MP2/6-31G*) = 1.19 $\Delta G^{\ddagger}$ – 3.8 (r = 0.999) if the numbers for 3,5-difluorobenzaldehyde are omitted (see footnote *e* in Table 3 for the difficulties encountered in the correlation-gradient computations for this compound).

The correlation-gradient MP2/6-316*spectroscopic barriers in Table 3 are 1.8 – 3.8 kJ mol^{-1} lower than those for the 6-31G** basis set (again ignoring the data for 3,5-difluorobenzaldehyde). For benzaldehyde the correlation-gradient procedure yields a barrier that is 0.6 kJ mol^{-1} lower in energy than the corresponding single-point computation (5). Further, a single-point calculation (5), MP2/6-311G*//6-31G*, at 34.7 kJ mol^{-1}, for the barrier is 0.7 kJ mol^{-1} lower than the 35.4 kJ

[4] Such correlations are not peculiar to fluorobenzaldehydes. For benzaldehyde and some 4-X derivatives, X = F, CN, OH, one has (5) that ΔE_0 (6-31G*) = 1.00 $\Delta G^{\ddagger}$ – 5.5 (r = 0.996) in units of kJ mol^{-1}.

mol^{-1} obtained in Table 3 for the geometry optimized MP2/6-31G* procedure. A correlation-gradient MP2 computation with the 6-311G* basis, not at present feasible with our computing resources, might therefore cause a further lowering of about 1 kJ mol^{-1} in the spectroscopic barrier that, however, is then still larger than $\Delta G^{\ddagger}$ and very much larger than the V_2 obtained from spectroscopic work.

The measured and estimated dipole moments in Table 3 imply that first-order solvent perturbations of the $\Delta G^{\ddagger}$ values are rather different fro the various molecules and would in any event not exceed about 2 kJ mol^{-1}. A solvent effect on the barrier, proportional to $\Delta G^{\ddagger}$, consistent with the linear correlation above, would therefore be unexpected. The AM1 barriers in parentheses, recommended (7) as reliable for the free molecules, illustrate, first, the large discrepancy between the various approaches to the barriers for the first three compounds and, second, that the recommendation (7), if correct for these compounds, cannot also be correct for the 2,6-difluoro derivatives.

Conclusion

The present experiments and (or) computations on benzaldehyde and four of its symmetrical fluorine derivatives suggest to us that the internal barrier to rotation in benzaldehyde is modified relatively little by the presence of solvent molecules and that, therefore, the barriers deduced from torsional frequencies are too small (8). In this connection, the comparison of computed barriers with those calculated form the computed torsional frequencies in Table 2 is important. Again, in our opinion the scaled (6) AM1 barriers in Table 3, having a range of only 5 kJ mol^{-1} for the five compounds, are inadequate.

Experimental

DNMR measurements

The $^{19}F\{^1H\}$ spectra of 2,6-difluorobenzaldehyde and 2,4,6-trifluorobenzaldehyde in dimethyl ether solutions at low temperatures were accumulated on Bruker AM 300 and WH 90 nmr spectrometers in a manner described previously for 4-bromo-2,6-difluoro-*N*-methylaniline (28). At 120 K the spectrum of the *para*-fluorine nucleus is a triplet (^4J = 11.0(1) Hz) while at lower temperatures the peaks broaden to essentially obscure the fine structure. At 110 K the *ortho*-fluorine nuclei give rise (84.7 MHz) to an incompletely separated doublet with a spacing of 350 Hz. At lower temperatures the signal disappears due to freezing or precipitation of solute. At 112 K the peaks coalesce to a singlet with a flat top and a width at half height of 550 Hz. The width of the signal from the *para*-fluorine nucleus is 41.0 Hz; this width includes 22 Hz from the $^4J(F_o,F_p)$ of 11 Hz, which also contributes to the line widths of the signal from the *ortho* fluorine nuclei. An analysis of the ^1H and ^{19}F nmr spectra of the compound at 300 K (CS_2/C_6D_{12} solution) showed that the coupling constant for the *ortho*-fluorine nuclei was 2.80 Hz. At coalescence, the width at half height for a simple, uncoupled AX system equals the chemical shift in the absence of exchange. Allowing for an error of 10% in the correct width at coalescence, and therefore in the rate constant, and 2° in T_c, yields $\Delta G^{\ddagger}_{110}$ as 20.0 ± 0.5 kJ mol^{-1} (eq. 7.13c of ref. 27).

Assessment of $\Delta G^{\ddagger}$ for 2,6-difluorobenzaldehyde depended on the reasonable assumption that the peak separation at slow exchange would be the same as for the trifluoro derivative. The coalescence temperature could not be reached in the sense that the sample "froze out" at 107 K. At 110 K the width at half height was 121 ± 2 Hz (84.7 MHz), whereas the reference compound, C_6F_6, had a width of 24 Hz. Measurements of this kind were also made at 120 and 130 K at 84.7 MHz and at 130 and 135 K at 284.3 MHz. Use of eq. 6.2d in ref. 27 and the assumption that the internal shift is 530 Hz for slow exchange gave $\Delta G^{\ddagger}110$ as 18.8 ± kJ mol^{-1}. This number reproduced the measured peak widths reasonably well at the different resonance frequencies and temperatures. For example, at 130 K and 84.7 MHz, $\Delta G^{\ddagger}$ values of 19.3 and 18.3 kJ mol^{-1} imply line widths of 9.3 and 3.7 Hz, respectively; the measured value is 7.7 Hz, corresponding actually to a $\Delta G^{\ddagger}$ of 19.0 kJ mol^{-1}. Again, because an analysis of the ^1H and ^{19}F nmr spectra of a CS_2/C_6D_{12} solution gave ^4J(F,F) as 3.2 Hz, its presence alters the analytical approach very little (compare 530 Hz for the internal shift in the absence of exchange). The coalescence temperature at 300 MHz is calculated as 112 ± 2 K; unfortunately such a temperature could not be reached on the AM 300.

Molecular orbital calculations

The program GAUSSIAN 92 (29) was used in all molecular orbital computations, employing the AM1 (30) parameterization, as well as the STO-3G (31), 3-21G (32), 6-31G (33), 6-31G* (34), and 6-31G** (34) basis sets in the ab initio procedure. The energy of the 2,6-difluorobenzaldehyde molecule was calculated at 15° intervals, between 0° and 90°, of the angle of torsion about the exocyclic C—C bond. During these optimizations *all* other bond angles and lengths were allowed to vary. These computations were performed with normal thresholds, as were the geometry-optimized MP2 computations (frozen core) with the 6-31G* basis. For purposes of computing vibrational frequencies the optimizations were done using the "tight" option, where final forces (hartrees Bohr^{-1} or hartrees radian^{-1}) and displacements (Bohr or radian) were all less than 0.00002.

Abstract: The stepwise synthesis of two new selenium coronands containing an odd number of selenium atoms, starting from the fragments HO-$(CH_2)_3$-Cl, HO-$(CH_2)_3$-Br, HO-$(CH_2)_3$-SeCN, and NCSe-$(CH_2)_3$-SeCN, is described. The key diol containing one selenium atom, 4-selenaheptan-1,7-diol **4**, was obtained in 97% yield from the reaction of 3-bromo-1-propanol **3** and the selonolate anion derived from 3-selenocyanato-1-propanol **2** by sodium metal reduction in liquid ammonia. The ditosylate **5**, obtained from **4**, was then treated with the bisselenolate anion derived from 1,3-bisselenocyanatopropane **6** to give the target selenium coronand, 1,5,9-triselenacyclododecane [12Se3] **7**, in 96% yield. The ditosylate **5** was treated with two equivalents of the selenolate anion derived from **2** to give a second key acyclic diol **8** now containing three selenium atoms. The ditosylate **9**, obtained from **8**, was then treated with the bisselenolate anion derived from **6** to afford the second target coronand, 1,5,9,13,17-pentaselenacycloeicosane [20Se5] **11** in 44% yield.

Key words: selenium coronands, stepwise synthesis, macrocycles, heterocycles.

Résumé : Utilisant des fragments OH-$(CH_2)_3$-Cl, HO-$(CH_2)_3$-Br, HO-$(CH_2)_3$-SeCN et NCSe-$(CH_2)_3$-SeCN, on a réalisé la synthèse par étapes de deux nouveaux coronands du sélénium contenant un nombre impair d'atomes de sélénium. On a obtenu le diol clé contenant un atome de sélénium, le 4-sélénahepta-1,7-diol (**4**), avec un rendement de 97% par la réaction du 3-bromopropan-1-ol (**3**) avec l'anion sélénolate dérivé du 3-sélénocyanatopropan-1-ol (**2**) par réduction avec du sodium métallique dans l'ammoniac liquide. On traite alors le ditosylate **5**, obtenu à partir du composé **4**, avec l'anion bissélénolate dérivé du 1,3-bissélénocyanatopropane **6** pour obtenir le coronand sélénié désiré, le 1,5,9-trisélénacyclododécane [12Se3] (**7**), avec un rendement de 96%. On traite le ditosylate **5** avec deux équivalents de l'anion sélénolate obtenu à partir du composé **2**, pour obtenir le deuxième diol acyclique clé (**8**) qui contient maintenent trois atomes de sélénium. Le ditosylate **9**, obtenu à partir du produit **8**, est alors traité par l'anion bissélénolate dérivé du composé **6** pour fournir le deuxième coronand désiré, le 1,5,9,13,17-pentasélénacycloeicosane [20Se5] (**11**), avec un rendement de 44%.

Mots clés : coronands du sélénium, synthèse par étapes, macrocycles, hétérocycles.

[Traduit par la rédaction]

Introduction

There have been relatively few reports of the synthesis of selenium coronands. To the best of our knowledge, prior to our report of the serendipitous discovery of the simple selenium coronands in 1988 (1, 2), the only macrocyclic seleno ethers reported were the cyclic oligomers of selenaformaldehyde (3), diselenacyclophanes (4), and a selenium porphyrin derivative (5). Since our initial disclosure, we have reported the one-step syntheses of other prototype selenium coronands (6) and there have been reported syntheses of other macrocyclic diselena ethers (7), selenium porphyrin derivatives (8), tetraselena-3,4-benzocyclooctadecane, (9) mixed selena oxa macrocyclic ethers (9–12), and a tetraselenacyclohexadecine bis-naphthalene derivative (13).

It is also surprising, given the current interest in chalcogen macrocycles as models for metalloenzymes and metalloproteins and in the structure and bonding of metal–chalcogen macrocyclic complexes (see, for example, ref. 14), that there have not been more reports of the metal-ion complexes of these compounds. To date, we have reported the electron transfer reaction of the first metal-ion complex of a selenium coronand, the Cu(II) complex of 1,5,9,13-tetraselenacyclohexadecane (16Se4) (15), and Kelly et al. (16) have reported

Received August 17, 1994.

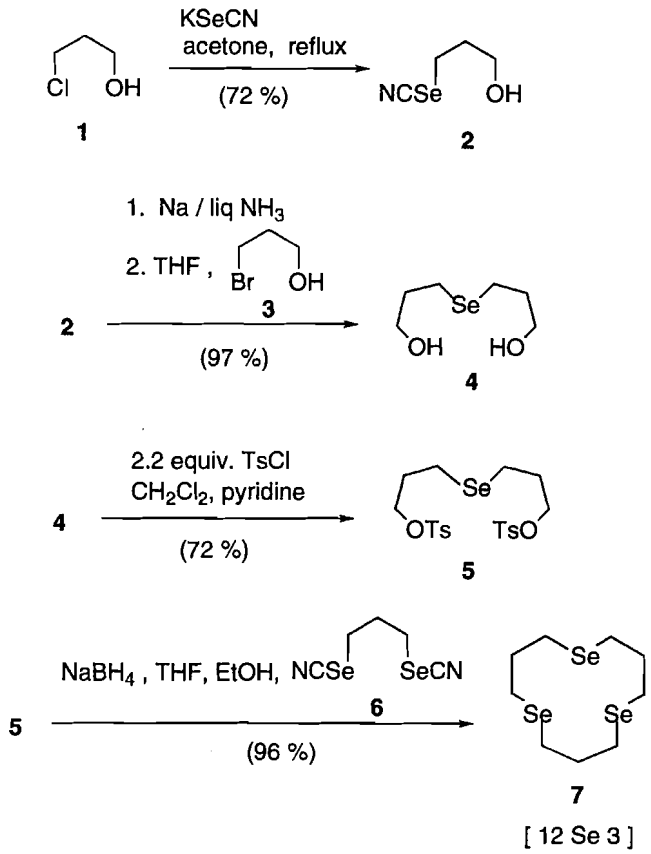
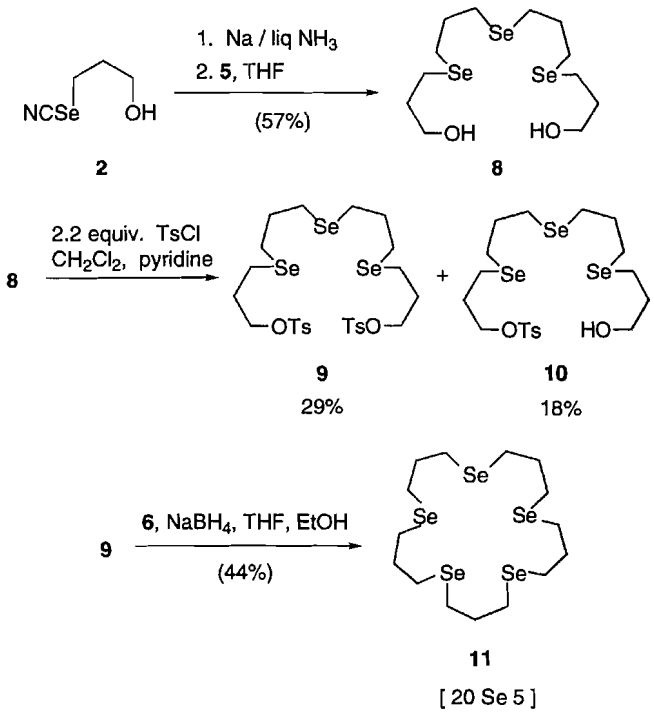
Scheme 1



Scheme 2



the synthesis of a Rh(III) complex of 16Se4. We have also reported the study of the adducts of 16Se4 with Cu(I) triflate and Hg(II) cyanide (17) and communicated our results on Cu(I), Cu(II), and Pd(II) complexes of the prototype selenium coronands (18). Three other reports of transition metal-ion complexation by macrocyclic selena ethers have also appeared (7, 9, 12).

The reported one-step synthesis of selenium coronands (1, 2, 6) is ideally suited to the synthesis of macrocycles containing an even number of constituent selenium atoms. To expand the repertoire of available selenium coronands and in the interest of developing more efficient synthetic routes, we chose to examine the stepwise synthesis of selenium coronands. We report herein the stepwise synthesis of two new selenium coronands containing an odd number of selenium atoms starting from the fragments HO-$(CH_2)_3$-Cl, HO-$(CH_2)_3$-Br, HO-$(CH_2)_3$-SeCN, and NCSe-$(CH_2)_3$-SeCN.

Results and discussion

3-Chloro-1-propanol **1** was converted to the key unit, 3-selenocyanato-1-propanol **2**, in 72% yield by treatment with potassium selenocyanate in refluxing acetone (Scheme 1). Reductive cleavage of the Se—CN bond in **2** with sodium in liquid ammonia then gave the selenolate anion, which was reacted with 3-bromo-1-propanol **3** to give 4-selenaheptan-1,7-diol **4** in 97% yield. Functionalization of the diol as the bis-*p*-toluenesulfonate gave **5** in 72% yield. Treatment of this unit with sodium propane-1,3-bisselenolate, derived from the borohydride reduction of propane-1,3-bisselenocyanate **6** (19), then afforded the target selenium coronand, 1,5,9-triselenacyclododecane [12Se3] **7** in 96% yield. The optimum conditions for the latter reaction consisted of the simultaneous addition of the ditosylate **5** and the bisselenocyanate **6** to a suspension of sodium borohydride in ethanol and THF over a period of 20 h.

The synthesis of the higher homologue containing five selenium atoms was executed in an analogous manner with common building units. Thus, treatment of the ditosylate **5** with 2 equivalents of the selenolate anion derived from 3-selenocyanato-1-propanol **2** afforded the acyclic derivative **8** containing three selenium atoms in 57% yield (Scheme 2). Tosylation of compound **8** proceeded in modest yield to give a mixture of the desired ditosylate **9** and the monotosylate **10**. Cyclization with sodium propane-1,3-bisselenocyanate, as described above for the case of **7**, then afforded the target coronand, 1,5,9,13,17-pentaselenacycloeicosane [20Se5] **11**, in 44% yield.

The syntheses described above represent the first examples of stepwise syntheses of selenium coronands from simple units and of selenium coronands containing an odd number of selenium atoms. The compounds will serve as new candidates for study of the metal-ion complexation behaviour of selenium coronands and their electron-transfer chemistry.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. ^{1}H NMR, ^{13}C NMR, and ^{77}Se NMR spectra were recorded on a Bruker AMX-400 NMR spectrometer at 400.13, 100.6, and 76.3 MHz, for proton, carbon, and selenium, respectively. All spectra were recorded in deuterochloroform and chemical shifts are given in ppm downfield from TMS. Chemical shifts and coupling constants were obtained from a first-order analysis of the spectra. For

For personal use only.

the ^{77}Se NMR spectra, chemical shifts are given in ppm downfield from Me_2Se. Chemical ionization mass spectra were measured on a Hewlett–Packard HP-5985 mass spectrometer with isobutane as the reacting gas.

Analytical thin-layer chromatography (TLC) was performed on aluminum plates precoated with Merck silica gel 60F-254 as the adsorbent. The developed plates were air-dried, exposed to UV light and (or) sprayed with 5% sulfuric acid in ethanol, and heated at 150°C. Compounds were purified by flash chromatography on Kieselgel 60 (230–400 mesh).

Solvents were distilled before use and were dried, as necessary, by literature procedures. Solvents were evaporated under reduced pressure and below 40°C. Reactions performed under nitrogen were effected by means of standard Schlenk-tube techniques.

Microanalyses were performed by M.K. Yang of the Microanalytical Laboratory of Simon Fraser University.

3-Selenocyanato-1-propanol (2)

To a solution of 3-chloro-1-propanol (19.7 g, 0.208 mol) in spectral grade acetone (150 mL) was added potassium selenocyanate (30.0 g, 0.208 mol). The reaction mixture was refluxed overnight, filtered, and evaporated in vacuo to give a light yellow oil. Purification by silica gel flash chromatography (hexane:ethyl acetate (1:1)) gave **2** (24.5 g, 72%); ^1H NMR δ : 2.11 (2H, p, $CH_2(OH)CH_2CH_2SeCN$), 2.17 (1H, br s, $CH_2(OH)CH_2CH_2SeCN$), 3.20 (2H, t, $CH_2(OH)CH_2CH_2SeCN$), 3.77 (2H, t, $CH_2(OH)CH_2CH_2SeCN$); ^{13}C NMR δ : 26.4 ($CH_2(OH)CH_2CH_2SeCN$), 32.4 ($CH_2(OH)CH_2CH_2SeCN$), 60.4 ($CH_2(OH)CH_2CH_2SeCN$), 102.9 ($CH_2(OH)CH_2CH_2SeCN$). The compound was used in the next step without further characterization.

4-Selenaheptan-1,7-diol (4)

To 3-selenocyanato-1-propanol **2** (3.60 g, 21.95 mmol) in liquid ammonia (100 mL) and dry THF (40 mL) was added Na metal in small pieces until a colorless homogeneous solution was obtained. A solution of 3-bromo-1-propanol **3** (3.05 g, 21.95 mmol) in dry THF (30 mL + 3 × 5 mL rinse) was added dropwise. The ammonia was allowed to escape and the reaction mixture was diluted with water (250 mL) and extracted with methylene chloride (3 × 100 mL). The combined organic extracts were washed with water (100 mL), dried ($MgSO_4$), and evaporated in vacuo to yield a light yellow oil. Purification by silica gel chromatography (hexane:ethyl acetate (1:1)) gave **4** (4.1 g, 97%); ^1H NMR δ : 1.90 (4H, p, J = 6.2 Hz, $SeCH_2CH_2CH_2OH$), 2.65 (6H, t, J = 7.2 Hz, $SeCH_2CH_2CH_2OH$), 3.70 (4H, t, J = 6.1 Hz, $SeCH_2CH_2CH_2OH$); ^{13}C NMR δ : 20.2 ($SeCH_2CH_2CH_2OH$, J_{Se-C} = 55 Hz), 32.9 ($SeCH_2CH_2CH_2OH$), 61.8 ($SeCH_2CH_2CH_2OH$); CI MS, *m/e*: 198 (M^+ + 1 isotopic cluster). Anal. calcd. for $C_6H_{14}O_2Se$: C 36.56, H 7.16; found: C 36.38, H 7.21.

4-Selenaheptan-1,7-di-*p*-toluenesulfonate (5)

To a solution of **4** (6.21 g, 31.5 mmol) in CH_2Cl_2 (200 mL) and pyridine (17 mL, 220 mmol) was added dropwise a solution of *p*-toluenesulfonyl chloride (13.22 g, 69.3 mmol) in CH_2Cl_2 (50 mL). The reaction mixture was stirred at room temperature overnight, diluted to 300 mL with CH_2Cl_2, and washed with 10% HCl (3 × 200 mL), saturated $NaHCO_3$ (3 × 200 mL), water (300 mL), and brine (300 mL), dried ($MgSO_4$), and evaporated in vacuo to give a light yellow oil. Purification by silica gel flash chromatography (hexane:ethyl acetate (3:1)) gave **5** (11.50 g, 72%); ^1H NMR δ: 1.83–2.00 (4H, m, $SeCH_2CH_2CH_2OTs$), 2.44 (6H, s, Me), 2.49 (4H, t, J = 8.0 Hz, $SeCH_2CH_2CH_2OTs$), 4.07 (4H, t, J = 7.0 Hz, $SeCH_2CH_2CH_2OTs$), 7.33 (4H, d, J = 7.7 Hz, Ar), 7.77 (4H, d, J = 7.7 Hz, Ar); ^{13}C NMR δ: 18.9 ($SeCH_2CH_2CH_2OTs$), 21.3 (Me), 29.4 ($SeCH_2CH_2CH_2OTs$), 69.5 ($SeCH_2CH_2CH_2OTs$), 127.6 (C4′), 129.7 (C3′, C5′), 132.7 (C2′, C6′), 144.7 (C1′); CI MS, *m/e*: 506 (M^+ + 1 isotopic cluster). Anal. calcd. for $C_{20}H_{26}O_6S_2Se$: C 47.52, H 5.18; found: C 47.28, H 5.06.

1,5,9-Triselenacyclododecane (7)

To a suspension of $NaBH_4$ (0.15 g) in THF (100 mL) and EtOH (5 mL) was added simultaneously, via two separate dropping funnels, propane-1,3-bisselenocyanate **6** (19) (0.125 g; 0.5 mmol) and **5** (0.25 g; 0.5 mmol) each in THF:EtOH (80:20; 20 mL). The addition time was 20 h. The reaction mixture was filtered and evaporated in vacuo to give white crystals. These crystals were further purified by flash chromatography (hexane:ethyl acetate (3:1)) and recrystallized from hexane:ethyl acetate (3:1) to give long white needles **7** (0.175 g, 96%), mp 94–95.5°C; ^1H NMR δ: 2.01 (6H, p, J = 7.0 Hz, $SeCH_2CH_2CH_2Se$), 2.72 (12H, t, J = 7.0 Hz, $SeCH_2CH_2CH_2Se$); ^{13}C NMR δ: 22.5 ($SeCH_2CH_2CH_2Se$, J_{Se-C} = 31.4 Hz), 29.6 ($SeCH_2CH_2CH_2Se$); ^{77}Se NMR (76.3 MHz, $CDCl_3$) δ: 130; CI MS, *m/e*: 365 (M^++1 isotopic cluster). Anal. calcd. for $C_9H_{18}Se_3$: C 29.77, H 4.99; found: C 29.56, H 4.85.

4,8,12-Triselenapentadecan-1,15-diol (8)

To 3-selenocyanato-1-propanol **2** (325 mg, 1.98 mmol) in liquid ammonia (30 mL) was added Na metal in small pieces until a colorless homogeneous solution was obtained. Under a dry nitrogen environment, distilled THF (23 mL) was added to the reaction flask to dissolve the reduced selenium species. The liquid ammonia was removed under high vacuum until approximately 10 mL of THF solvent remained. Compound **5** (500 mg, 0.99 mmol) was dissolved in dry THF (2.5 mL) and then added dropwise to the oxygen-free system. The reaction mixture was stirred at room temperature overnight. The reaction mixure was then dissolved in distilled water (100 mL). The water layer was extracted with dichloromethane (3 × 45 mL). The CH_2Cl_2 layer was then washed once with distilled water (40 mL), dried over anhydrous $MgSO_4$, filtered, and evaporated in vacuo to yield a yellow oil. The yellow oil was further purified by flash chromatography (hexane:ethyl acetate (1:1)) to give **8** (248 mg, 57%); ^1H NMR δ: 1.84–1.96 (4H, m, $SeCH_2CH_2CH_2Se$), 1.96–2.05 (6H, m, $SeCH_2CH_2CH_2OH$), 2.59–2.69 (12H, m, $SeCH_2CH_2CH_2Se$, $SeCH_2CH_2CH_2OH$), 3.72 (4H, br t, J = 6.1 Hz, $SeCH_2CH_2CH_2OH$); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 20.3 ($SeCH_2CH_2CH_2Se$), 23.7 ($SeCHCH_2CH_2OH$, J_{Se-C} = 31.4 Hz), 31.1 ($SeCH_2CH_2CH_2Se$), 33.0 ($SeCH_2CH_2CH_2OH$), 62.3 ($SeCH_2CH_2CH_2OH$); CI MS, *m/e*: 440 (M^+ + 1 isotopic cluster). Anal. calcd. for $C_{12}H_{26}O_2Se_3$: C 32.82, H 5.96; found: C 33.20, H 6.08.

4,8,12-Triselenapentadecane-1,15-di-*p*-toluenesulfonate (9) and 4,8,12-triselena-1-pentadecanol-15-*p*-toluenesulfonate (10)

To a solution of **8** (0.370 g, 0.842 mmol) in CH_2Cl_2 (15 mL)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

was added dropwise a solution of p-toluenesulfonyl chloride (0.353 g, 1.85 mmol) in pyridine (0.47 mL, 5.89 mmol). The reaction mixture was stirred at room temperature for 17 h. The reaction mixture was diluted with CH_2Cl_2 (100 mL) and then washed with distilled water (3 × 40 mL), 10% HCl (3 × 40 mL), saturated $NaHCO_3$ (2 × 40 mL), and water (2 × 40 mL), dried (anhydrous $MgSO_4$), and evaporated in vacuo to give a light yellow oil. Purification by silica gel flash chromatography (hexane:ethyl acetate (3:1)) gave **9** (0.182 g, 0.244 mmol, 29%); R_f 0.27 in hexane:ethyl acetate (3:1), and **10** (0.090 g, 0.152 mmol, 18%); R_f 0.09 in hexane:ethyl acetate (3:1).

9. ^{1}H NMR δ: 1.85–2.00 (8H, m, $SeCH_2CH_2CH_2Se$, $SeCH_2CH_2CH_2OTs$), 2.44 (6H, s, Me), 2.50–2.70 (12H, m, $SeCH_2CH_2CH_2Se$, $SeCH_2CH_2CH_2$-OTs), 3.47 (4H, t, J = 6.0 Hz, $SeCH_2CH_2CH_2OTs$), 7.34 (4H, d, J = 8.1 Hz, Ar), 7.78 (4H, d, J = 8.1 Hz, Ar); ^{13}C NMR δ: 19.1 ($SeCH_2CH_2CH_2Se$), 21.6 ($SeCH_2CH_2CH_2OTs$), 23.6 ($SeCH_2CH_2CH_2Se$), 23.7 (Me), 29.8 ($SeCH_2CH_2CH_2Se$), 31.0 ($SeCH_2CH_2CH_2OTs$), 69.6 ($SeCH_2CH_2CH_2OTs$), 127.9 (C4′), 129.9 (C3′, C5′), 133.1 (C2′, C6′), 144.8 (C1′). 10. ^{1}H NMR δ: 1.85–2.00 (8H, m, $SeCH_2CH_2CH_2Se$, $SeCH_2CH_2CH_2OTs$), 2.44 (3H, s, Me), 2.50–2.70 (13H, m, $SeCH_2CH_2CH_2Se$, $SeCH_2CH_2$-CH_2OTs, $SeCH_2CH_2CH_2OH$), 3.47 (2H, t, J = 6.1 Hz, $SeCH_2CH_2CH_2OTs$), 3.72 (2H, t, J = 6.1 Hz, $SeCH_2CH_2CH_2OH$), 7.34 (2H, d, J = 8.0 Hz, Ar), 7.77 (2H, d, J = 8.3 Hz, Ar); ^{13}C NMR δ: 19.1 ($SeCH_2CH_2CH_2Se$), 20.3 ($SeCH_2CH_2CH_2Se$), 20.6 ($SeCH_2CH_2CH_2OH$), 21.6 ($SeCH_2CH_2CH_2OTs$), 23.6 ($SeCH_2CH_2CH_2Se$), 23.7 (Me), 29.8 ($SeCH_2CH_2CH_2Se$), 30.6 ($SeCH_2CH_2CH_2Se$), 31.0 ($SeCH_2CH_2CH_2$-OTs), 33.0 ($SeCH_2CH_2CH_2OH$), 62.4 ($SeCH_2$-CH_2CH_2OH), 69.6 ($SeCH_2CH_2CH_2OTs$), 127.9 (C4′), 129.9 (C3′, C5′), 133.1 (C2′, C6′), 144.8 (C_1′). Anal calcd. for $C_{19}H_{32}O_4SSe_3$: C 38.46, H 5.44; found: C 38.73, H 5.43.

1,5,9,13,17-Pentaselenacycloeicosane(11)

To a suspension of $NaBH_4$ (0.2 g) in THF:EtOH (80:20, 300 mL) was added, simultaneously in two separate dropping funnels, propane-1,3-bisselenocyanate **6** (19) (0.21 g, 0.83 mmol) and **9** (0.62 g, 0.83 mmol), each in THF:EtOH (80:20, 10 mL). The addition time was 20 h. The reaction mixture was filtered and evaporated in vacuo to give white crystals. Flash chromatography of the crude product with hexane:ethyl acetate (20:1) gave **11** (0.22 g, 44%) as white needles, mp 41–42°C; ^{1}H NMR δ: 2.03 (10H, p, J = 7.2 Hz, $SeCH_2CH_2$-CH_2Se), 2.69 (20H, t, J = 7.2 Hz, $SeCH_2CH_2CH_2Se$); ^{13}C NMR δ: 23.7 ($SeCH_2$-CH_2CH_2Se, $J_{^{13}C-Se}$ = 31 Hz), 31.3 ($SeCH_2CH_2CH_2Se$); ^{77}Se NMR δ: 152; CI MS, *m/e*: 606 (M^+ + 1 isotopic cluster). Anal. calcd. for $C_{15}H_{30}Se_5$: C 29.77, H 5.00; found: C 29.90, H 4.87.

Étude par radiolyse pulsée des propriétés spectrales et cinétiques de l'électron solvaté dans l'hexane-1,2,6-triol liquide

J.-P. Jay-Gerin, J. Chevrel, C. Ferradini, E. Ray, M.H. Klapper et M. Faraggi

Résumé : Le spectre d'absorption optique de l'électron solvaté (e_s^-) dans l'hexane-1,2,6-triol liquide a été mesuré par radiolyse pulsée nanoseconde à différentes températures (10–40°C) afin d'examiner l'influence de valeurs élevées de la viscosité du solvant sur les propriétés spectrales et cinétiques de e_s^-. En utilisant un accélérateur linéaire (durée de l'impulsion : 50 ns et dose par impulsion : 2,4–2,75 Gy), on observe un spectre dont le maximum d'absorption se situe à $\lambda_{max} = 560$ nm. La variation de cette longueur d'onde en fonction de la température, si elle existe dans la zone considérée, est inférieure aux erreurs expérimentales. À 20°C et 150 ns après le début de l'impulsion, le produit $G\epsilon_{max}$ du rendement en e_s^- et du coefficient d'extinction molaire à λ_{max} est égal à $2{,}55 \times 10^4$ molécule/(M cm 100 eV). Nous avons été amenés à comparer les résultats précédemment décrits avec ceux obtenus à l'aide d'un Febetron (durée de l'impulsion : 4 ns et dose par impulsion : 215 Gy). Cette comparaison nous a permis d'étendre les mesures vers les temps courts et d'évaluer l'influence des variations de la dose par impulsion. Dans le cas des expériences effectuées avec l'accélérateur linéaire, les absorbances décroissent en fonction du temps en suivant à toutes les longueurs d'onde une loi du premier ordre. Les courbes cinétiques obtenues avec le Febetron traduisent initialement une compétition en faveur d'une loi du second ordre. Celle-ci est remplacée, pour des temps plus longs, par une loi du premier ordre (ou du pseudo-premier ordre) dont la constante de vitesse (en s^{-1}) est comparable à celle déterminée à l'aide de l'accélérateur linéaire. Cette loi en fonction de la température implique, dans les deux cas, une énergie d'activation de ~45 kJ mol^{-1}. L'allure des spectres obtenus à l'aide de l'accélérateur linéaire et du Febetron diffère pour les doses par implusion étudiées, les différences observées croissant en fonction tu temps. Ces variations pourraient être attribuées au processus de second ordre mis en évidence uniquement dans le cas des forts débits de dose. Par ailleurs, le ralentissement de la vitesse de solvatation de l'électron dû à la viscosité ne semble pas être suffisamment important pour être décelable dans nos conditions expérimentales.

Mots clés : hexane-1,2,6-triol liquide, radiolyse pulsée, accélérateur linéaire et Febetron, électron solvaté, spectre d'absorption optique, propriétés cinétiques, viscosité du solvant, effets de dose et de température.

Abstract: The optical absorption spectrum of the solvated electron (e_s^-) in liquid hexane-1,2,6-triol has been measured by nanosecond pulse radiolysis at different temperatures (10–40°C) to investigate the influence of high solvent viscosity values on the spectral and kinetic properties of e_s^-. The wavelength at the absorption maximum, λ_{max}, is equal to 560 nm, and its variation with temperature, if it exists in the considered zone, is less than the experimental error. At 20°C and 150 ns, the value of the product $G\epsilon_{max}$ of the yield of e_s^- and the molar extinction coefficient at λ_{max} is 2.55×10^4 molecule/(M cm 100 eV). In the context of this work, we have compared results obtained with both a linear accelerator and a Febetron, a comparison that has allowed us to evaluate the influence of variations of the dose per pulse and to extend measurements to short times. In the case of experiments performed with the linear accelerator, e_s^- is found to decay at all wavelengths by a first-order reaction (or by a pseudo-first-order reaction) with an activation energy of ~45 kJ mol^{-1}. By contrast, kinetic curves obtained with the Febetron seem to show a competition in which a second-order law is followed at short

times. The fact that the shape of the spectra seems to vary as a function of the dose per pulse indicates the possible intervention of another species whose formation is favored by the use of high radiation doses. In other respects, the kinetics of electron solvation does not seem to be controlled by the viscosity of the solvent in our experimental conditions.

Key words: liquid hexane-1,2,6-triol, pulse radiolysis, linear accelerator and Febetron, solvated electron, optical absorption spectrum, kinetic properties, solvent viscosity, dose and temperature effects.

Introduction

De nombreux travaux de radiolyse, tant théoriques qu'expérimentaux, concernant le processus de solvatation de l'électron dans les liquides polaires, ont été développés (pour des revues d'ensemble récentes, voir, par exemple, réfs. 1–5). Le rôle de la viscosité (η) du solvant dans ce processus a été particulièrement étudié dans le cas des alcools liquides (voir, par exemple, réfs. 6 et 7). L'influence de valeurs élevées de η sur les propriétés spectrales et cinétiques des électrons en excès dans le milieu reste toutefois mal connue. On pourrait en effet envisager que le processus de solvatation soit ralenti et qu'il soit alors possible d'étudier celui-ci à l'échelle de la nanoseconde comme dans le cas des alcools liquides à basse température (8). Nous avons, dans ce but, caractérisé le spectre d'absorption de l'électron solvaté (e_s^-) dans l'hexane-1,2,6-triol ($HOCH_2$-$(CH_2)_3CH(OH)CH_2OH$), solvant de constante diélectrique statique $\epsilon_s = 29$ dont la viscosité est très élevée (2490 cP à 20°C) (9). Cette valeur de η à 20°C est plus de 500 fois supérieure à celles des alcools, plus de 20 fois à celles des diols et environ 2 fois celle du propane-1,2,3-triol (glycérol), donc supérieure à celles de tous les solvants déjà étudiés à ce point de vue à cette température (voir réf. 9).

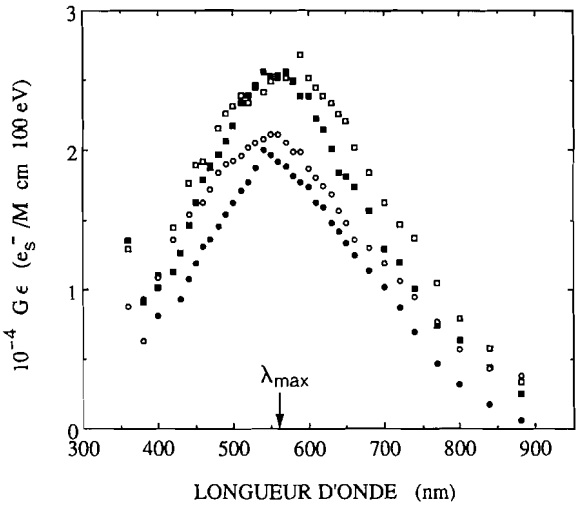
Dans ce travail, nous nous sommes attachés à caractériser à différentes températures le spectre d'absorption de l'électron dans ce solvant et son évolution. Nous avons été amenés, dans ce cadre, à comparer les résultats obtenus à l'aide de deux accélérateurs. Le premier est un accélérateur linéaire pour lequel la dose par impulsion est comprise entre 2,4 et 2,75 Gy, la première mesure se situant 150 ns après le début de l'impulsion. Le second est un Febetron dont la dose moyenne par impulsion est de 215 Gy, la première mesure étant effectuée 4 ns après le début de l'impulsion. Cette comparaison nous a permis d'une part d'évaluer l'influence des variations de la dose par impulsion et d'autre part d'étendre les mesures vers les temps courts.

Matériel et méthodes

L'accélérateur linéaire utilisé (Varian V-7715A) est celui de l'Ohio State University à Columbus (10). Les électrons avaient une énergie de 4 MeV, la durée de l'impulsion était de 50 ns et la dose par impulsion était comprise entre 2,4 et 2,75 Gy. Le trajet optique était de 6 cm. La dosimétrie était effectuée par irradiation d'une solution aérée de KSCN 0,01 M et mesure à 480 nm du radical dithiocyanate $(SCN)_2^{\cdot -}$ en prenant pour le produit $G\epsilon[(SCN)_2^{\cdot -}]$ la valeur $2{,}1 \times 10^4$ molécule/(M cm 100 eV) (11).

Le Febetron 708 du Laboratoire de chimie-physique de l'Université Paris V (12) fournissait des impulsions d'électrons, de durée 4 ns à mi-hauteur et d'énergie 800 keV. Le trajet optique était égal à 1 cm. La dosimétrie était effectuée par microcalorimétrie. L'électron hydraté a été utilisé pour l'étalonnage de celle-ci en prenant à 400 nm un coefficient d'extinction molaire de 2000 M^{-1} cm^{-1} et un rendement à 20 ns de 3,2

Fig. 1. Spectres d'absorption de l'électron solvaté (e_s^-) dans l'hexane-1,2,6-triol pur, aéré, irradié à 10°C (□), 20°C (■), 30°C (○) et 40°C (●) à l'aide de l'accélérateur linéaire. Les absorbances ont été mesurées 150 ns après le début de l'impulsion. Durée de l'impulsion : 50 ns; dose par impulsion (en Gy) : 2,75 à 10°C, 2,65 à 20°C, 2,4 à 30°C et 2,5 à 40°C (l'influence de la densité électronique du solvant a été prise en compte); trajet optique : 6 cm. $\lambda_{max} = 560$ nm est la longueur d'onde correspondant au maximum des spectres observés. G est le nombre d'électrons solvatés présents à un instant donné pour 100 eV d'énergie absorbée et $\epsilon(e_s^-)$ est le coefficient d'extinction molaire exprimé en M^{-1} cm^{-1}. Rappelons que le produit $G\epsilon(e_s^-)$ est égal à $AN_{Av} \times 100/(ld \times \text{dose})$, où A est l'absorbance, N_{Av} est le nombre d'Avogadro, l est le trajet optique en cm, d est la densité en g L^{-1}, et où la dose est exprimée en eV g^{-1}.



molécule/100 eV. L'influence de la densité électronique du solvant sur la valeur de la dose a été prise en compte. Les valeurs de l'absorbance ont été normalisées à une dose de $1{,}34 \times 10^{18}$ eV par gramme et par impulsion (215 Gy), les doses réelles par impulsion ne différant que peu de cette dose moyenne.

L'hexane-1,2,6-triol utilisé dans ce travail était, en ce qui concerne les expériences menées avec le Febetron, un produit Prolabo d'«usage courant», de pureté garantie à 97%, tandis que les expériences utilisant l'accélérateur linéaire portaient sur un produit Aldrich, de pureté 98%. Les deux produits étaient employés sans purification ultérieure ni dégazage préalable.

Résultats expérimentaux

La figure 1 donne les spectres de e_s^- obtenus à l'aide de l'accélérateur linéaire pour l'hexane-1,2,6-triol pur, aéré, irradié à 10, 20, 30 et 40°C, avec des doses respectivement de 2,75, 2,65, 2,4 et 2,5 Gy par impulsion. Les valeurs indiquées

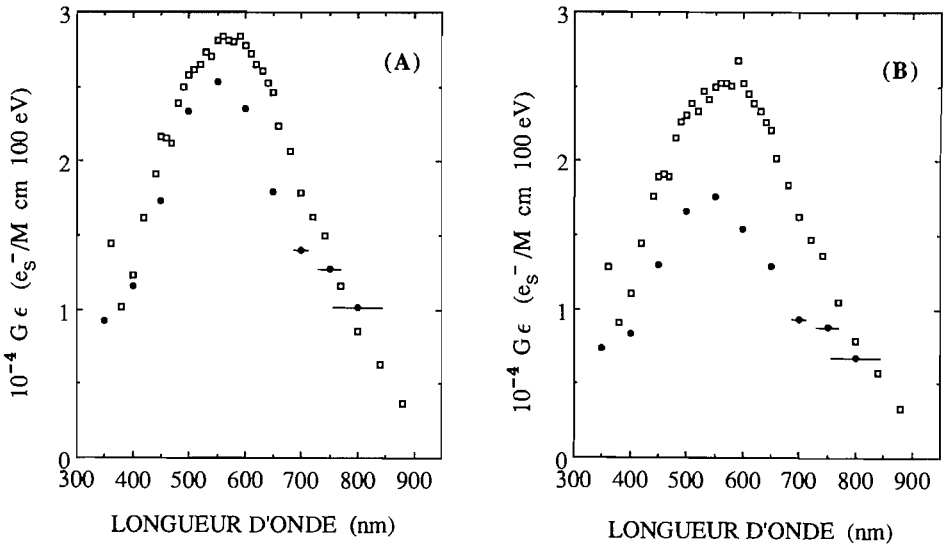
For personal use only.

Fig. 2. Comparaison des spectres d'absorption de l'électron solvaté dans l'hexane-1,2,6-triol pur, aéré, irradié à 10°C à l'aide de l'accélérateur linéaire avec une dose de 2,75 Gy par impulsion (□) et à (10,5 ± 0,5)°C à l'aide du Febetron avec une dose moyenne de 215 Gy par impulsion (●). (*A*) Dans le cas de l'accélérateur linéaire, les absorbances sont obtenues à 25 ns par extrapolation des courbes cinétiques. Dans le cas du Febetron, les absorbances ont été mesurées immédiatement après l'impulsion d'électrons dont la durée est de 4 ns à mi-hauteur. (*B*) Comparaison des spectres à 150 ns. Les barres d'incertitude indiquent, dans le cas du Febetron, les largeurs de bande spectrale associées aux largeurs de fente correspondantes du monochromateur utilisé.



pour le produit $G\epsilon(e_s^-)$ sont celles obtenues à 150 ns après le début de l'impulsion. G dénote ici le nombre d'électrons solvatés présents par 100 eV d'énergie absorbée et $\epsilon(e_s^-)$ est le coefficient d'extinction molaire en unités M^{-1} cm^{-1}.

Les figures 2*A* et *B* montrent les comparaisons des spectres obtenus dans le cas de l'accélérateur linéaire à 25 ns, par extrapolation des courbes cinétiques, et à 150 ns, avec ceux obtenus à l'aide du Febetron dans les conditions déjà décrites, pour la température de 10°C. Les figures 3*A* et *B* montrent les mêmes comparaisons, mais à 20°C. Dans le cas du Febetron, la mesure des absorbances est effectuée à la fin de l'impulsion dont la durée est 4 ns à mi-hauteur, et les températures considérées sont respectivement de 10,5 (± 0,5)°C et 19 (± 1)°C. Dans ce cas également, l'addition d'un capteur d'électrons, le phénol en concentration 1 M, inhibe totalement l'absorbance à toutes les longueurs d'onde.

Les résultats obtenus avec l'accélérateur linéaire à 20°C nous permettent de déduire la longueur d'onde λ_{max} (ou l'énergie $E_{A_{max}}$(eV) = 1240/λ_{max}(nm)) correspondant au maximum des spectres observés et la largeur à mi-hauteur de ceux-ci : λ_{max} = 560 nm ($E_{A_{max}}$ = 2,21 eV) et $W_{1/2} \sim$ 1,25 eV. $W_{1/2}$ peut être divisé en une partie $W_b \sim$ 0,75 eV du côté haute énergie de $E_{A_{max}}$ et une partie $W_r \sim$ 0,50 eV du côté basse énergie. La variation de ces valeurs en fonction de la température, si elle existe dans la zone 10–40°C, est inférieure aux erreurs expérimentales.

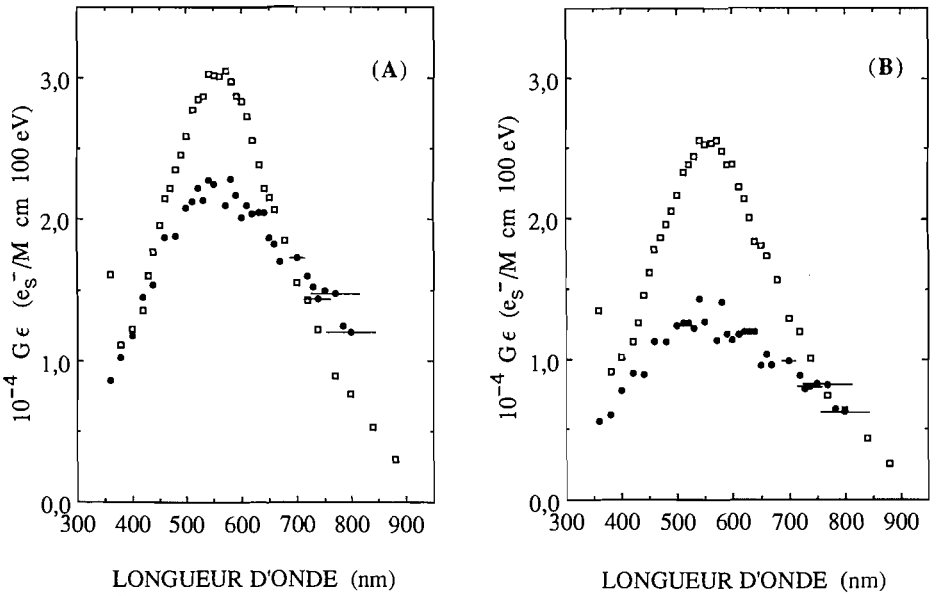
Dans le cas des expériences effectuées avec l'accélérateur linéaire, les absorbances décroissent en fonction du temps en suivant à toutes les longueurs d'onde une loi exponentielle. Leur représentation semi-logarithmique est une droite dont la pente est fonction de la température. On obtient les valeurs suivantes (moyennes effectuées, à chaque température, sur environ 40 longueurs d'onde entre 400 et 700 nm) pour la constante de vitesse apparente du premier ordre (k) ainsi déterminée :

Température (°C)	Viscosité (réfs. 9 et 13) (cP)	k (10^6 s^{-1})
10	6154	0,88 ± 0,04
20	2490	1,5 ± 0,1
30	1011	5,1 ± 0,3
40	484	6,7 ± 0,3

Les courbes cinétiques obtenues avec le Febetron, donc à grandes doses et à temps courts, semblent traduire une compétition. La figure 4 donne, dans ce cas, en fonction du temps, la variation du logarithme de l'absorbance à 550 nm, et celle de son inverse pour les deux températures étudiées, à savoir, 10,5 et 19°C. On voit que, initialement, une loi du second ordre semble suivie. Elle est remplacée vers 300 ns à 19°C et vers 450 ns à 10,5°C par une loi du premier ordre dont la constante de vitesse apparente est comparable à celle observée dans le cas de l'accélérateur linéaire pour les deux mêmes températures et le même intervalle de temps. Une évolution similaire est obtenue aux autres longueurs d'onde.

L'ensemble des déterminations des constantes de vitesse du premier ordre a été reporté figure 5 sous forme d'un diagramme d'Arrhenius, ln(k) versus 1/T, où T est la température absolue. La pente de la droite représentative, obtenue à l'aide d'un ajustement direct sur les données brutes par une méthode de moindres carrés non-linéaire, conduit à une énergie d'activation de 45 (± 19) kJ mol^{-1}, la valeur entre parenthèses donnant l'intervalle de confiance à 95%.

Fig. 3. Comparaison des spectres d'absorption de l'électron solvaté dans l'hexane-1,2,6-triol pur, aéré, irradié à 20°C à l'aide de l'accélérateur linéaire avec une dose de 2,65 Gy par impulsion (□) et à (19 ± 1)°C à l'aide du Febetron avec une dose moyenne de 215 Gy par impulsion (●). (*A*) et (*B*) correspondent aux mêmes conditions expérimentales que celles des figures 2*A* et *B*. Les barres d'incertitude indiquent, dans le cas du Febetron, les largeurs de bande spectrale associées aux largeurs de fente correspondantes du monochromateur utilisé.



Discussion

Les spectres de e_s^- de la figure 1 ressemblent à ceux trouvés par d'autres auteurs (14–17) pour le glycérol et à ceux décrits pour les diols (18). On note qu'entre 10 et 40°C, dans la limite de la précision des mesures, leur forme n'est sensiblement pas affectée par la température. Pourtant la viscosité du solvant, dans cette gamme de température, varie de manière importante, passant de 6154 cP à 10°C à 484 cP à 40°C (13).

Comme le montre la figure 1, au maximum du spectre de e_s^-, correspondant à la température de 20°C (560 nm) et à un temps de 150 ns, $G\epsilon_{max}$ est égal à $2{,}55 \times 10^4$ molécule/(M cm 100 eV), valeur comparable à celles trouvées dans le glycérol (16, 17) ou dans les diols (18) à la température ambiante.

On peut tenter de calculer séparément chacune des deux grandeurs G et ϵ_{max} d'une manière approximative. En effet, il a été proposé (3, 19) la relation empirique suivante reliant ϵ_{max} à l'énergie $E_{A_{max}}$ correspondant au maximum du spectre de e_s^-:

$$\epsilon_{max} = \epsilon^0_{max} \exp(-\alpha E_{A_{max}})$$

avec $\epsilon^0_{max} = 5{,}54\ (\pm\ 0{,}89) \times 10^4\ M^{-1}\ cm^{-1}$ et $\alpha = 0{,}82\ (\pm\ 0{,}11)\ eV^{-1}$ (les valeurs entre parenthèses donnent les limites de confiance à 95% des paramètres). L'application de cette relation à l'hexane-1,2,6-triol ($E_{A_{max}} = 2{,}21$ eV) donne $\epsilon_{max} = 9015\ (\pm\ 3645)\ M^{-1}\ cm^{-1}$, ce qui conduit, en utilisant la valeur proposée ci-dessus pour le produit $G\epsilon_{max}$, à un rendement en e_s^-, immédiatement après l'impulsion (150 ns), égal à 2,7 (± 1,2) molécule/100 eV. Cette valeur est compatible avec celle du rendement en ions libres (G_{fi}), à $\sim 10^{-6}$ s, qui peut être estimée égale à 1,6 molécule/100 eV pour l'hexane-1,2,6-triol, à partir de la relation empirique (20)

Fig. 4. Comparaison des courbes cinétiques obtenues avec le Febetron à 550 nm, et à 10,5°C (+) et 19°C (×). La durée de l'impulsion d'électrons est de 4 ns à mi-hauteur. Les absorbances (*A*) sont normalisées à la dose moyenne de 215 Gy par impulsion. La figure donne en fonction du temps (en ns) la variation du logarithme de l'absorbance ln(*A*) et celle de son inverse 1/*A* pour les deux températures étudiées. Les droites en trait plein montrent une estimation des parts respectives en fonction du temps des deux lois d'évolution (voir texte).

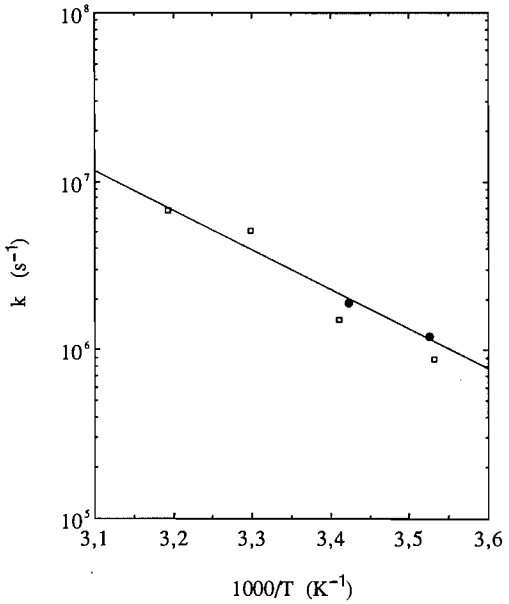
Fig. 5. Diagramme d'Arrhenius (en représentation semi-logarithmique) montrant la variation de k en fonction de $10^3/T$, où k est la constante de vitesse du premier ordre (en s^{-1}) de la disparition de e_s^- dans l'hexane-1,2,6-triol et T est la température absolue (en K). Les valeurs de k déterminées à 10, 20, 30 et 40°C (□) à l'aide de l'accélérateur linéaire sont indiquées dans le texte. Celles obtenues à l'aide du Febetron sont : $k = (1,9 \pm 0,2) \times 10^6$ s^{-1} à 19°C et $k = (1,2 \pm 0,1) \times 10^6$ s^{-1} à 10,5°C (●). La droite en trait plein passant par les points expérimentaux a été déterminée en utilisant un ajustement direct sur les données brutes par une méthode de moindres carrés non-linéaire. La pente de celle-ci, égale à $-E_a/R$, où E_a est l'énergie d'activation et R est la constante des gaz parfaits, conduit à $E_a = 45$ (± 19) kJ mol^{-1}, la valeur entre parenthèses correspondant aux limites de confiance à 95%. Le facteur pré-exponentiel s'élève à $2,2 \times 10^{14}$ s^{-1}.



$$G_{fi} = G_{fi}^{\infty} \exp(-a/\epsilon_s)$$

où $G_{fi}^{\infty} = 3,7$ molécule/100 eV, $a = 25$ et $\epsilon_s = 29$ est la constante diélectrique statique du solvant (9). Elle est, de plus, du même ordre de grandeur que celle (2,27 molécule/100 eV) estimée à 10 ns pour le glycérol pur désaéré à 32°C en supposant $\epsilon_{max} = 12\,000$ M^{-1} cm^{-1} (16).

La largeur $W_r \sim 0,50$ eV des spectres de e_s^- dans l'hexane-1,2,6-triol du côté rouge de $E_{A_{max}}$ est très voisine de celles observées pour le glycérol (0,50 eV) (17) et pour les diols (0,54 ± 0,4 eV) (18). Le rapport $W_r/E_{A_{max}} \sim 0,23$ se compare également bien à ceux trouvés dans le glycérol (0,22 eV) (17) et dans les diols (0,23 ± 0,01 eV) (18). Le rapport W_b/W_r, qui donne une mesure de l'asymétrie des spectres, s'élève à ~1,5 pour l'hexane-1,2,6-triol; il est sensiblement inférieur à ceux trouvés pour le glycérol (1,8) (17) et pour les diols (1,6–2,1) (18).

Le fait de trouver, quelque soit le débit de dose, des valeurs similaires pour la constante de vitesse et l'énergie d'activation semble indiquer que la décroissance du premier ordre observée pour e_s^- correspond toujours à la même réaction. Il pourrait s'agir de la réaction de l'électron solvaté avec l'oxygène dissous qui conduit à une réaction du pseudo-premier ordre. Malheureusement, cette hypothèse n'a pas pu être vérifiée, la viscosité du solvant rendant très difficile sa désaération.

Pour expliquer la différence entre les spectres obtenus avec l'accélérateur linéaire et le Febetron (figs. 2 et 3), on peut se demander quelle est la nature de l'espèce (ou des espèces) transitoire(s) modifiant les spectres obtenus avec le Febetron. Comme cette espèce n'est pas formée dans le cas de l'accélérateur linéaire, sa production peut être favorisée par l'utilisation des hautes doses. Il est possible qu'elle apparaisse lors du processus de deuxième ordre survenant au début de l'évolution et impliquant l'électron solvaté (voir fig. 4). Ce processus pourrait être attribué à la réaction de celui-ci avec un des ions positifs présents. Ce serait les produits de cette réaction qui perturberaient le spectre.

Des expériences complémentaires seraient nécessaires pour obtenir une meilleure compréhension du comportement de l'électron en excès dans les milieux de grande viscosité. Il faudrait en particulier faire varier les paramètres dose et température dans de plus larges domaines.

Les présentes expériences semblent toutefois montrer que la viscosité est un paramètre moins important qu'on ne pouvait le penser *a priori* puisque nous n'avons pas observé de ralentissement de la vitesse de solvatation de l'électron dans nos conditions expérimentales.

Remerciements

Les auteurs remercient le Dr Bernard Hickel pour de fructueuses discussions. Cette étude a bénéficié de l'aide financière du Programme de subventions à la recherche coopérative de l'OTAN (subvention n° 91/0996) et du Programme de coopération franco-québécoise en recherche médicale. L'un de nous (J.-P. J.-G.) tient également à exprimer ses remerciements au Programme d'échanges INSERM–FRSQ en recherche en santé, ainsi qu'au Conseil de recherches médicales du Canada.

Photoinduced addition of dioxygen molecules in the unsaturated sites of the $Pd_3(dppm)_3CO^{2+}$ catalyst

Pierre D. Harvey, Marielle Crozet, and Khin T. Aye

Abstract: The photoinduced addition of O_2 onto the unsaturated cluster $Pd_3(dppm)_3CO^{2+}$ (as a $CF_3CO_2^-$ salt) in acetonitrile is reported. The final product $Pd_3(dppm)_3(O_2)_2^{2+}$ ($\nu(O_2)$ = 838 and 866 cm^{-1}) is formed in a multistep fashion in which two photochemical intermediates are observed (presumably $Pd_3(dppm)_3(O_2)(CO)^{2+}$ and $Pd_3(dppm)_3(O_2)^{2+}$). No X-ray structure could be obtained, but numerous spectroscopic findings demonstrate that O_2 binds the Pd_3 center as a peroxo-O_2, and acts as a two-electron donor that triply bridges the metal atoms (forming a 44-electron cluster). The very small excited state lifetimes (between 25 and 35 ± 10 ps) obtained by picosecond flash photolysis indicate that the primary photoreaction is unimolecular, and demonstrate that the first photochemically added O_2 molecule must be preassembled in the excited state *prior* to any photoinduced transformation. This $Pd_3(dppm)_3CO^{2+}\cdots O_2$ ground state complex is responsible for the photoinduced production of the bisdioxygen compound and can be observed by UV–visible spectroscopy. The low efficiency of the photoreaction (quantum yield (Φ) = 0.033 ± 0.004) is explained by the very short excited state lifetime at 298 K, and the competition of O_2 with solvent molecules to occupy the unsaturated site of the empty cavity in $Pd_3(dppm)_3CO^{2+}$ (i.e., ground state guest–host chemistry). The binding constant for O_2 with $Pd_3(dppm)_3CO^{2+}$ is roughly estimated to range between 1 and 730 M^{-1} in the ground state and is considered to be weak.

Key words: clusters, photochemistry, guest–host, oxidation, dioxygen.

Résumé : Opérant dans l'acétonitrile, on a effectué l'addition photoinduite du O_2 sur le cluster insaturé $Pd_3(dppm)_3CO^{2+}$ (sous la forme d'un sel de $CF_3CO_2^-$). Le produit final, le $Pd_3(dppm)_3(O_2)^{2+}$($\nu(O_2)$ = 838 et 866 cm^{-1}) se forme en plusieurs étapes et on a observé deux intermédiaires photochimiques (probablement le $Pd_3(dppm)_3(O_2)(CO)^{2+}$ et le $Pd_3(dppm)_3(O_2)^{2+}$). On n'a pas pu obtenir de structures par diffraction des rayons X, mais plusieurs données spectroscopiques démontrent que le O_2 se lie au centre Pd_3 sous la forme d'un peroxo-O_2 et qu'il agit comme un donneur de deux électrons qui crée un triple pont avec les atomes métalliques (formant un cluster à 44 électrons). Les très faibles temps de vie de l'état excité (entre 25 et 35 ± 10 ps) obtenus par la photolyse éclair à la picoseconde indiquent que le photoréaction primaire est unimoléculaire et démontrent que la première molécule de O_2 qui s'additionne photochimiquement doit se préassembler dans l'état de transition *avant* toute transformation photoinduite. Ce complexe $Pd_3(dppm)_3CO^{2+}\cdots O_2$ dans l'état fondamental est responsable de la production photoinduite du composé bisdioxygène et on peut l'observer par spectroscopie UV–visible. On explique la faible efficacité de la photoréaction (rendement quantique (Φ) = 0,033 ± 0,004) par le très court temps de vie de l'état excité à 298 K et par la compétition entre le O_2 et les molécules de solvant pour occuper le site insaturé de la cavité de du $Pd_3(dppm)_3CO^{2+}$ (c'est-à-dire la chimie hôte–invité dans l'état fondamental). On évalue d'une façon approximative que la constante de liaison du O_2 pour le $Pd_3(dppm)_3CO^{2+}$ varie de 1 à 730 M^{-1} dans l'état fondamental et on la considère comme faible.

Mots clés : clusters, photochimie, hôte–invité, oxydation, dioxygène.

Introduction

The catalytic oxidation of organics by palladium and platinum metals and their coordination complexes is of great importance with regard to a number of industrial applications such as the catalytic oxidation of ethylene and propene to form 1,2-diol products and ethylene oxide, and oxidation of formic acid, methanol, hydrazine, etc. in fuel cells (1–3). One of the key intermediates in these heterogeneous catalysis processes is the adsorbtion of dioxygen molecules at the catalytic metal surface (1). Surface studies have shown that dioxygen adsorbs molecularly (nondissociatively) onto Pt(111) while it adsorbs dissociatively ($T > 100$ K) and molecularly ($T < 100$ K) on Pd(111), Pd(110), and Pd(100) (4–11). Recently the chemistry of the coordinatively unsaturated tripalladium and triplatinum clusters ($M_3(dppm)_3CO^{2+}$; M = Pd, Pt; dppm = $((C_6H_5)_2P)_2CH_2$) has been reviewed (12), where it was proposed that these clusters be models for reactions on metal surfaces. The complexes are found to be catalysts for the

water–gas shift reaction (M = Pt)(12) and the electroreduction of CO_2 (M = Pd).[2] More relevant to this work, Puddephatt and co-workers also reported the dissociative addition of dioxygen to the cationic $[Pt_3(dppm)_3(\mu\text{-}Re(CO)_3)]^+$ cluster to form the μ^3-oxo complex $[Pt_3(\mu^3\text{-}O)_2(Re(CO)_3)(dppm)_3]^+$ (13). We now wish to report the first example of a stable (at room temperature) dioxygen complex of a trinuclear palladium cluster ($Pd_3(dppm)_3(O_2)_2^{2+}$), which can be considered as a potential oxidizing agent for organic molecules. According to picosecond flash photolysis spectroscopy, the primary photoinduced addition mechanism is found to pass through a unimolecular pathway via a preassembled complex in the ground state, $(Pd_3(dppm)_3CO^{2+})\cdots O_2$.

Experimental section

Materials

The complex $[Pd_3(dppm)_3CO](CF_3CO_2)_2$ was synthesized according to literature procedure (14). The solvents acetonitrile (Fisher), toluene (Fisher), and methanol (Fisher) were purified from procedures outlined in refs. 15 and 16.

Methodology

The photochemical reactions were performed in a homemade water-jacketed cylindrical container (20 cm × 7 cm), which was constantly stirred. Pure dioxygen was introduced (unless stated otherwise) at a constant rate of approximately one needle bubble per second. The bubbling was necessary to evacuate the excess pressure encountered when acetonitrile was slowly evaporated, and to eliminate CO. Two 200 W PTI Hg–Xe arc lamps and two LPS-250 power supplies (PTI) were used at both ends of the cylinder insuring that the solution was in the focal points (i.e., ~4 cm^{-1} from the cylinder). Two Oriel optical filters (cutoff at 450 nm) were placed in front of the lamps during irradiation. The optical density of the $Pd_3(dppm)_3CO^{2+}$–acetonitrile solution was adjusted to be ~1 in a 1 cm cell at 500 nm. These conditions were chosen for the best performance of the setup. The reactions were monitored by UV–visible spectroscopy. Typically the reactions were completed within 3 days (72 h) under constant stirring. The solutions were evaporated until dry, and the yellow product was recrystallized from acetonitrile–ether. The isolated yields were 85% or over. After spectroscopic and elemental analyses the yellow product was identified as $[Pd_3(dppm)_3(O_2)_2](CF_3CO)_2$: Anal. calcd.(%) for $C_{79}H_{66}P_6F_6O_8Pd_3$: C 53.83, H 3.77, P 10.54, F 6.47, O 7.26, Pd 18.11; found (%): C 54.77, H 3.61, P 9.91, O 7.54, Pd 18.03 (by difference F should analyse for 6.14%). It is crucial to keep a good flow of water to insure that the solution temperature stays below ~298 K, otherwise decomposition occurs. On many occasions unsatisfactory analyses were obtained when the temperature rose above ~310 K (i.e., insufficient water cooling).

$[Pd_3(dppm)_3(O_2)_2](CF_3CO_2)$: IR (KBr): $\bar{\nu}$ (cm^{-1}): 838 and 866 (O–O), 558, 542, 600 (Pd–O); UV–vis (CH_3OH, 77 K): λ_{max}(nm)(ϵ): 448 (1200); ^1H NMR (250 MHz, CDCN, 25°C) δ: 3.74 (t, ^2J(P,H) = 13 Hz, 6H, CH_2), 7.5 (complex, 60H, C_6H_5), ^{31}P NMR (120 MHz, CD_3CN, 25°C) δ: −4.62 (decoupled); MS (FAB, 70 kV) *m/z*: 1644 ($Pd_3(dppm)_3(O_2)_2(CF_3CO_2)$), 1600 ($Pd_3(dppm)_3O(CF_3CO_2)$), 1505 ($Pd_3(dppm)_3(O_2)$).

The photochemical quantum yield measurements were performed using the ferrioxalate actinometry method (17). The spectrometer used for monochromatic excitation was an Aminco–Bowman instrument equipped with a single monochromator and a 200-W Hg–Xe lamp (Hanovia). The slits were set at 0.5 mm, and excitation was 488 nm for all samples and standards ($\Phi_{standard}$ = 0.94). The absorbance of the complex solutions was adjusted to a value of 1 (at 488 nm) prior to the photochemical quantum yield measurements. This adjustment was done by weighing the samples and dissolving them in known amounts of solvent. Typical concentrations range from 3.4×10^{-5} to 4.0×10^{-5} M. The calibrations of the standard ferrioxalate actinometric solutions were performed carefully in the dark. The absorbance change at a given irradiation time was followed by UV–visible spectroscopy (Hewlett–Packard 8452A) at 476 nm (i.e., at λ_{max}). The measurements and calibration experiments were performed at least 3 times and made before 10% photoconversion. All the solutions were bubbled with pure O_2(g). At saturated conditions the concentration in acetonitrile for O_2 is $\sim 1 \times 10^{-2}$ M at room temperature (18).

Instrumentation

The FT-IR (4000–400 cm^{-1}) spectra were obtained on a Bomem (MB-102) spectrometer. Proton NMR spectra were measured at 250 MHz on a Bruker WM 250 spectrometer while ^{31}P NMR spectra were recorded at 300 MHz on a Varian spectrometer. Mass spectra were acquired with a Krator MS-50 TCTA spectrometer using an Iontech Saddle Field Source model FAB 11 NF operating at 70 kV with 2 mA current (at the Université de Montréal). The samples were in thioglycerol matrices. UV–visible spectra were obtained on a Hewlett Packard (HP 8452A) diode array spectrophotometer. The elemental analyses for C, H, and O were performed by Guelph Chemical Laboratories, Ltd. (Guelph, Ontario), and in our department using a KEVEX-700 X-ray emission spectrofluorometer operating at 60 kV for Pd and P. In these latter measurements, $PdCl_2$ (Aldrich) and dppm (Aldrich) were used as comparative standards.

Flash photolysis

Picosecond and nanosecond time-resolved measurements were carried out at the former Center for Fast Kinetic Research at Austin (CFKR). The setups were described previously (19).

Results and discussion

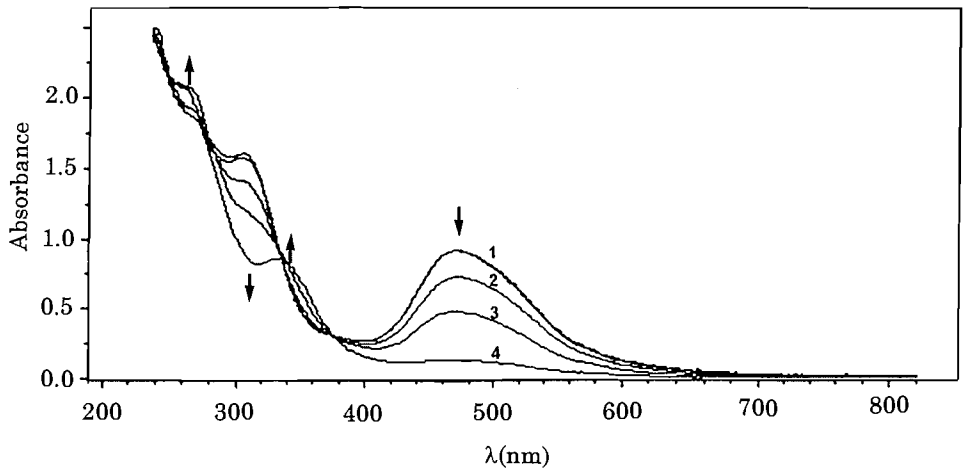
1. Photoaddition

The $Pd_3(dppm)_3CO^{2+}$ complex was originally prepared and described by Puddephatt and co-workers in 1983 (14), and was reported to be air stable. Under visible-light irradiation, the complex slowly reacts in the presence of O_2(g) to produce an unprecedented bis(dioxygen) palladium cluster:

$$[1]\quad Pd_3(dppm)_3CO^{2+} + O_2 \xrightarrow[\text{acetonitrile}]{h\nu > 450\text{ nm, 3 days}} Pd_3(dppm)_3(O_2)_2^{2+}$$

[2] I. Gauthier, I. Lognot, Y. Mugnier, K.T. Aye, K. Hierso, and P.D. Harvey. Manuscript in preparation.

Fig. 1. Typical UV–visible spectrocopic transformation during the irradiation of $Pd_3(dppm)_3CO^{2+}$ in acetonitrile saturated with $O_2(g)$ at 298 K. In a 1-cm cell and a concentration of $\sim 1 \times 10^{-5}$ M in cluster, the photochemical reaction is over in about 4 h.



The reaction requires very precise experimental conditions of solvent, temperature, and light irradiation. Rapid photoinduced decomposition of the starting material is observed when benzene or THF solvents are used, when the solutions rise above room temperature, or when broadband irradiation techniques are employed. In the latter situation, the results are consistent with excitation to upper excited states, which are strongly Pd—CO antibonding (see for instance MO no. 19e) in the $Pd_3(\mu^3\text{-CO})$ frame (20). Irradiation using an optical filter with a 350 nm cutoff (instead of 450 nm) also produced photodegradation of the solutions, indicating that these excited states are not very energetic with respect to the lowest energy excited states. In the second case, the increase in heat (generated by the lamps) decomposed the bisdioxygen product or one of the photochemical intermediates in which dppm-oxide was readily observed (δ ^{31}P NMR = +25.37 ppm vs. H_3PO_4; IR: $\nu(P{=}O)$ = 1062 cm^{-1}, $\nu(C\text{-}P{=}O)$ = 512 cm^{-1}) along with the precipitation of a Pd/PdO black solid (identified by X-ray fluorescence). When an optical filter with a cutoff of 450 nm was used, no detectable photoinduced decomposition of the product was noted by NMR. The solvent dependence of the reactions indicates that the coordinating ability of the solvent stabilizes the photochemical intermediates during the transformations. When the conditions are appropriately set, the photoreaction proceeds cleanly. Clear isosbestic points are observed in the monitoring by UV–visible spectra, indicating that only one stable product is generated (Fig. 1). Occasionally the presence of phosphine oxide was detected but, generally, only as a minor product. The product can be isolated in a reasonably analytically pure state, and the identity of the photoproduct can easily be confirmed by Fast Atom Bombardement (FAB) spectrometry (and spectroscopy). The mass spectra were compared with computed spectra taking into account the natural abundance of the various isotopes. The comparison was adequate within the experimental uncertainties (due to the noise encountered in the spectra).

In theory, the structure of the bisdioxygen product can be determined by various methods including X-ray single crystal crystallography, ^{17}O NMR, and Raman spectroscopy (with ^{18}O-enriched samples), particularly when the binding modes of the oxygen atoms are concerned. Unfortunately all attempts to obtain crystals suitable for X-ray crystallography studies failed. The product also turned out to be very laser sensitive at 1064 nm (Nd: YAG laser) and at 514.5 nm ($Ar^+(g)$ laser) so that no Raman measurement was possible (including micro-Raman and FT-Raman). Finally, we have not been able to obtain $^{17}O_2$ as a reactant via commercial sources, and attempts to measure the ^{17}O NMR spectra based on the natural abundance of dioxygen samples also failed. Further, using enriched ^{17}O or ^{18}O samples appears to be unrealistic due to the large amount of material ($O_2(g)$) necessary to perform these experiments at constant purge.

Fortunately, there is available in the literature a large amount of vibrational data on the interactions of dioxygen at palladium and platinum surfaces, and for some complexes. The presence of the dioxygen molecules is readily demonstrated from the IR absorption spectra. The possibility of the presence of oxo groups (Pd-O-Pd) was quickly ruled out since the ν(PdO) peaks are generally found in the 450–475 cm^{-1} region (according to LEED studies of atomic oxygen chemisorbed onto Pd(100) surfaces, and because no such peak was observed in our spectra). These results are also supported by other results for Pt(111) surfaces (ν(PtO) for Pt-O-Pt is ~490 cm^{-1}) (4) and for Fe-O-Fe groups found in biologically related molecules; ν(FeO) = 486 cm^{-1} (22). On the other hand, the $\nu(O_2)$ frequencies are found at 871, 887, and 726 cm^{-1}, as measured by LEED spectroscopy for O_2 chemisorbed onto Pt(111), Pd(110) and Pd(100) surfaces, respectively (4, 5, 21). Similarly, in complexes of the type $Pt(L)_2O_2$ (L = phosphine or $CH_2{=}CH_2$), IR spectra also exhibit absorptions in the 814–828 cm^{-1} range associated with $\nu(O_2)$ (23). In biologically related Fe dimers bridged by O_2 (in a Fe-(μ^1-O_2)-Fe fashion), $\nu(O_2)$ and ν(FeO) are observed at 844 and 504 cm^{-1}, respectively (24). The IR spectra of the bisdioxygen product (Fig. 2) exhibit medium intensity absorptions at 838 and 866 cm^{-1}, and medium and larger intensity new signals in the 550 and 600 cm^{-1} regions, which are unambiguously assigned to $\nu(O_2)$ and ν(PdO), respectively. The peaks originally observed at 1815 (ν(CO)) and ~475 cm^{-1} (ν(PdC); doublet: a + e presumably in the C_{3v} point group) disappear during irradiation, which is consistent with the CO elimination. The fact that two stretches are observed for $\nu(O_2)$ (838 and 866 cm^{-1}), both in the solid

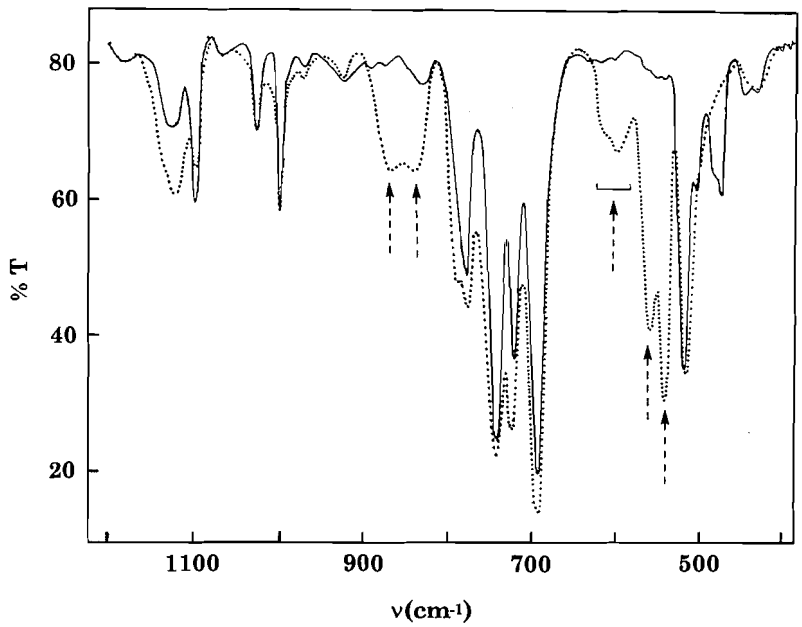
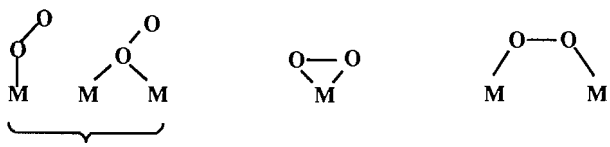
Fig. 2. Comparison of the FT-IR spectra (4 cm^{-1} resolution, 200 scans) for solid $Pd_3(dppm)_3CO^{2+}$ (starting materials, —) and $Pd_3(dppm)_3(O)_2^{2+}$ (pure final product, ...).

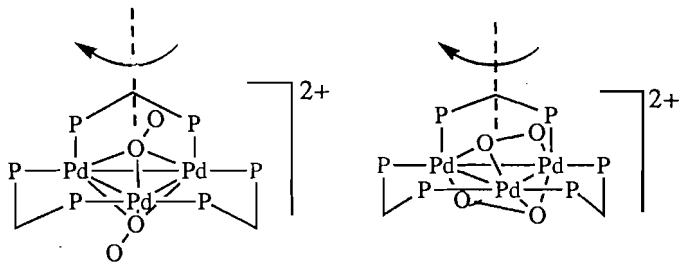


Scheme 1



Type I Type II Type III

Scheme 2



state and in solution, is consistent with the analytical results indicating the presence of two dioxygen ligands. The $\nu(O_2)$ and ν(PdO) values for $Pd^{II}(O_2)(t\text{-BuNC})_2$ are 893 and 484 cm^{-1} and for PdO_2 are 1024 and 427 cm^{-1}, respectively (25, 26), indicating that π back-bonding is (as expected) greater in the Pd_3^{2+} cluster with respect to the electron poorer Pd^{II} centers. However these data alone cannot distinguish between the three types of dioxygen adducts (Scheme 1: Type I, end-on; Type II, side-on; Type III, bridging).

Type II is not possible in this case due to steric hindrance with the *ortho*-hydrogen of the dppm-phenyl groups. This was verified by CPK models using computer modelings (SYBYL 5.5; Triphos Associates, St-Louis, Mo.) of the crystal structure of $[Pd_3(dppm)_3CO](CF_3CO_2)(PF_6)$ (27), in which the cavity is emptied from its $CF_3CO_2^-$ substrate, and replaced by O_2 sitting on one of the Pd atoms. The presence of a sharp and unique singlet in the ^{31}P-{H}-HNMR (–4.62 ppm) and a sharp triplet in the ^1H NMR spectra (3.74 ppm for the CH_2 groups, ^2J(P, H) = 13 Hz), and the relatively low complexity of the FT-IR spectra (Fig. 2), suggests that the molecule is symmetrical (i.e., type I, where one of the oxygens is triply bridging the Pd atoms). Literature data show that indeed linear molecules such as SCN^- and HC≡CH add to the M_3 centers (M = Pd, Pt) quasi-perpendicularly, when bridging in a triply bridging fashion (12).

The decrease in temperature (down to –60°C) did not change the ^1H NMR signal (i.e., in the CH_2 region). These experiments do not prove the true geometry since rapid equilibrum between the two (or more) structures may still be possible. Surface science studies (near-edge X-ray-absorption fine-structure studies) have recently demonstrated that the adsorbed O_2 molecules are oriented perpendicular (Type I) and parallel (Type III) to the bulk surface plane (i.e., Pt(110) surface; ref. 28), which somewhat improved the general idea that dioxygen binds the surface parallel to the surface plane (for instance for Pt(111) and Ag(110); refs. 29, 30). There has been no evidence of equilibrium between the two forms in this work but both are known to exist and must be considered. However the full width at half maximum for the proton signal is ≤6 Hz at 295 K, indicating that motion (or revolution) of the dioxygen molecules on top of the Pd_3 planes must be faster than the NMR time scale. The Type I structure appears to be more convenient for such motion as it does not involve the scission and formation of Pd—O bonds (see Scheme 2).

The O_2 ligands would then act as two-electron donors, and the product would fall in the 44-electron cluster category, a category that is generally encountered in the oxidatively added $M_3(dppm)_3CO^{2+}$ series (M = Pd, Pt). The ^{31}P NMR datum is consistent with the ^{31}P NMR data reported by Puddephatt and co-workers for a very large series of Pd_3 44-electron clusters; these values range from −6.7 to −12.7 ppm (with respect to H_3PO_4) (15, 31, 32), and suggest that no Pd—Pd bond scission occurred during the photoaddition. Further evidence for Pd_3

Scheme 3

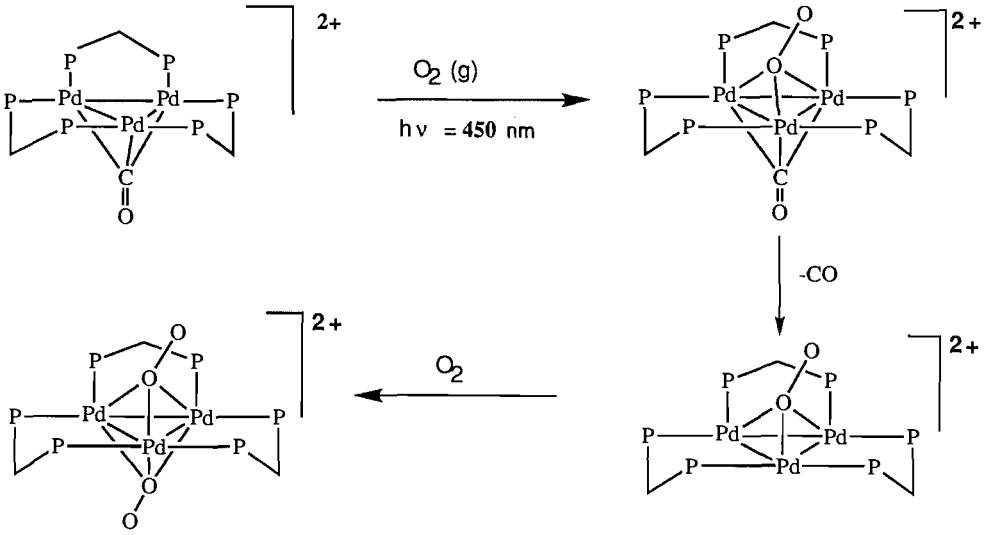


Fig. 3. ^{1}H NMR spectrum of the 4 ppm portion (vs. TMS) of the reaction mixture when the photoreaction vessel is purged with pure O_2(g) prior to photolysis, but not during photolysis. In this case the residue was collected after a few hours of irradiation, evaporated, then (without purification) dissolved in CD_2Cl_2 for NMR analysis. The scheme above the signal represents the coupling constant patterns for the two intermediates (1, 2) and the final product (3).

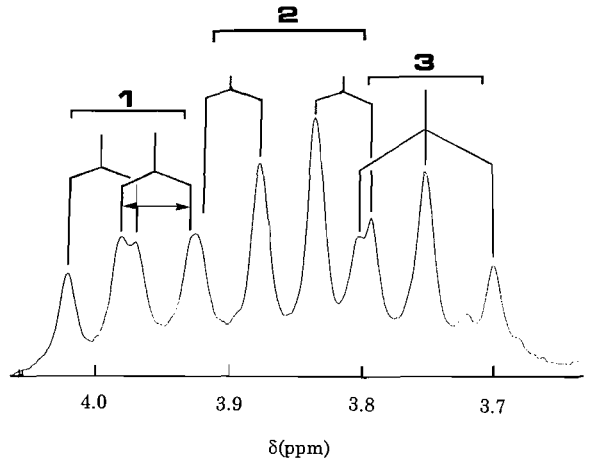

bonding is provided from emission spectroscopy. Typically λ_{emi}(monomer)<λ_{emi}(dimer)<λ_{emi}(trimer) for Pd^0L_4 monomers (~600–620 nm), Pd^I–Pd^I complexes (625–650 nm), and $Pd_3(dppm)_3CO^{2+}$ (720 nm), respectively (20, 33, 34). $Pd_3(dppm)_3(O_2)_2^{2+}$ exhibits an intense luminescence at 77 K centered at 760 nm (ethanol solutions) with a full width at half maximum (fwhm) of ~2800 cm^{-1} and a luminescence lifetime of 25 ± 3 μs. The data compare favorably with those of the $M_3(dppm)_3CO^{2+}$ complexes at 77 K (M = Pd, λ_{emi} = 720 nm, fwhm = 2400 cm^{-1}, τ_e = 2.4 μs (in 2MeTHF); M = Pt; λ_{emi} = 630 nm, fwhm = 2500 cm^{-1}, τ_e = 14 μs (2MeTHF); see ref. 14), and confirm the trinuclear bonding nature of the cluster product. Like $Pd_3(dppm)_3CO^{2+}$, $Pd_3(dppm)_3(O_2)_2^{2+}$ is not luminescent at room temperature. If a Type III structure occurs in which the O_2 molecule would act as a multielectron donor (more than two), then based upon the electron count, Pd—Pd bond scission would be expected. This is obviously not the case.

2. Photochemical intermediates and other properties

During continuous photolysis and O_2(g) bubbling, no photochemical intermediate was observed by ^{1}H NMR and IR during the monitoring. However, when the bubbling was stopped, leaving the rest of the dissolved O_2 to be slowly consumed upon continued irradiation, both ^{1}H NMR and IR spectra exhibited the growth of intermediate signals, followed by a disappearance or a decrease of these same signals upon further O_2(g) purging. By NMR, at the early stage of the irradiation, a first signal appears at 3.97 ppm with a coupling constant of 13 Hz. By IR, a new peak at 850 cm^{-1} is also readily noted (i.e., $\nu(O_2)$). A second signal subsequently appears at 3.85 ppm (coupling constant = 11 Hz) along with the final product signal (3.75 ppm, ^2J(P,H) = 13 Hz). Figure 3 shows a typical ^{1}H NMR spectrum in the 4 ppm region of the photochemical intermediates. The relative intensities of each of these signals depend upon whether further bubbling is provided to the solution; upon new additions of O_2, the first and second signals (3.98 and 3.83 ppm) successively disappeared. The final product signal (3.75 ppm) increased and remained. The two intermediates, the final product, and the starting materials exhibit identical R_f values, by thin-layer chromatography, and identical solubilities, so attempts to separate these were not successful. Upon prolonged irradiation, no new band appears in the IR, and the 850 cm^{-1} band remains as a broad signal (presumably a broad envelope including $\nu(O_2)$ of this intermediate along with those of the final product). Scheme 3 shows the proposed (and simplified) mechanism by which the bisdioxygen product must be formed. Intermediate 1 is assigned to $[Pd_3(dppm)_3(O_2)(CO)]^{2+}$ and Intermediate 2 is believed to be $[Pd_3(dppm)_3(O_2)]^{2+}$ (these are referred to as photochemical intermediates). The absence of efficient π back-bonding in the latter (i.e., 42e$^-$) intermediate implies that the complex is not a stable molecule (35). This is presumably why the acetonitrile solvent appears as a stabilizing agent in this case (by penetrating into the empty cavity and interacting with the Pd_3 center

(35), something that THF and benzene fail to do (i.e., decomposition is observed instead)). In this work, there was no evidence for oxo intermediates (from IR) as known for the $Fe(CO)_5$ and O_2 photoreaction (36). Surprisingly, addition of $(C_6H_5)_3P$ to $[Pd_3(dppm)_3(O_2)_2]^{2+}$ in solution did not lead to any reaction. It is suspected that steric hindrance plays, in part, a role in this inertness.

The quantum yield (Φ) for the photoreaction was 0.033 ± 0.004 based upon the disappearance of the 500 nm band in the UV–visible spectra. This quantum yield can be considered small with respect to other Φ values reported in the literature for inorganic compounds (see, for example, ref. 37) and, in particular, for Pd—Pd bonded complexes (38), but is the largest we have measured in the Pd_3 series. For example, both $M_3(dppm)_3CO^{2+}$ clusters (M = Pd,Pt) photoreact slowly with CH_2Cl_2 and $CHCl_3$ to produce the well-known $M(dppm)Cl_2$ complexes with no, or almost no, by-products for M = Pt and with ~50% yield for M = Pd (the other 50% of the products are uncharacterized). The Φ values in neat $CHCl_3$ and CH_2Cl_2 were in the order of 4×10^{-5} (!) (unpublished results). Photoinduced reactions of the clusters (M = Pd,Pt) with H_2(g), CO(g), and CO_2(g) were also observed but their reactivities were found to be very slow also ($\Phi \sim 0.002$!; unpublished results). In the latter cases the photoproducts are not identified. There are many reasons that could explain the low Φ values: (1) the excited state lifetimes are found to be extremely short ($\tau_1 < 40$ ps, M = Pd; $\tau_1 < 40$ ps, $70 < \tau_2 < 400$ ns, intensity ratio for $\tau_1/\tau_2 = 95/5$, M = Pt; ref. 39); (2) access to the lumophore is sterically hindered by another interacting substrate (i.e., $CF_3CO_2^-$ or CH_3CN) in the ground and excited states; and (3) the biradical-type excited state is delocalized over three metal centers, not localized as in the case of the $M_2(CO)_{10}$ dimers ($2 \times M(CO)_5$; M = Mn, Re; ref. 40). The second reason refers to the presence of guest–host chemistry involving the formation of weak preassembled ground-state complexes of the type cluster···substrates, and will be discussed further below.

Further irradiation (at 350–400 nm) of the bisdioxygen product in neat acetonitrile also led to decomposition similar to that described in the thermal reaction above (Pd/PdO and dppm-oxide). Photoinduced O—O and M—O_2 bond cleavages were previously observed at low-wavelength irradiation (230–330 nm) for the M(111) surfaces (M = Pd, Pt; refs. 41–43). In many ways, the unsaturated "$M_3(dppm)_3CO^{2+}$" clusters appear to behave very similarly to the bulk surfaces (12). Interestingly, photoinduced reaction between coadsorbed H_2 and O_2 on Pt(111) led to the formation of hydroxyls and water (43). Such an experiment has yet to be attempted on the $[Pd_3(dppm)_3(O_2)_2]^{2+}$ cluster.

3. Picosecond flash photolysis

The $Pd_3(dppm)_3CO^{2+}$ complex is nonluminescent at room temperature (20), so excited-state kinetics were followed by picosecond transient spectroscopy. The transient spectra (difference absorption) for $Pd_3(dppm)_3CO^{2+}$ in toluene (as well as in acetonitrile, Fig. 4) are characterized by a bleaching of the 490–500 nm band and the appearance of a broad transient band located at ~600 nm. Both kinetic traces of the bleached band recovery and transient decay (τ_e) are the same and short-lived (toluene, 35 ± 10 ps; acetonitrile 25 ± 10 ps). These lifetimes are in the same range as those reported for the $Pd_2(dmb)_2X_2$ and $Pd_2(tmb)_2X_2$ complexes (dmb = 1,8-diisocyano-*p*-menthane; tmb = 2,5-diisocyano-2′,5′-dimethylhexane; X = Cl, Br; ref. 34). In the latter cases, the low τ_e values are due to the rapid homolytic Pd^I—Pd^I bond scission followed by a rapid recombination. Such behavior is typical for $^1(d\sigma)^1(d\sigma^*)$ excited states generally encountered for d^7–d^7 and d^9–d^9 dimers (34). The lowest energy excited state for the $Pd_3(dppm)_3CO^{2+}$ complex is $a_1 \rightarrow a_2$ where the a_1 MO is weakly Pd—Pd bonding and the a_2 MO is Pd—Pd antibonding (20, 39). Such an excited state is somewhat similar to the $d\sigma d\sigma^*$ one in the M—M scheme. The difference is that the MO is delocalized over three Pd atoms. It is also reasonable to attribute the low τ_e value to homolytic Pd—Pd cleavage followed by the rapid formation of the M—M bond similar to that of the d^7–d^7 and d^9–d^9 dimers.

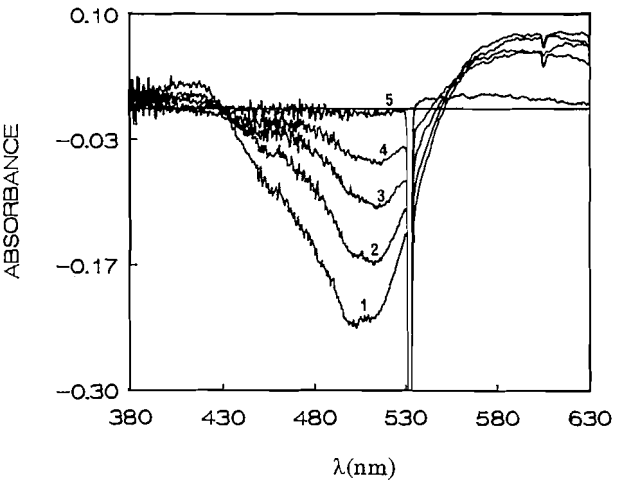

Fig. 4. Typical transient spectra of $Pd_3(dppm)_3CO^{2+}$ in acetonitrile at 298 K (λ_{exc} = 532 nm); delay time between the laser pulses: 1 = 45 ps, 2 = 55 ps, 3 = 65 ps, 4 = 95 ps, and 5 = 105 ps.

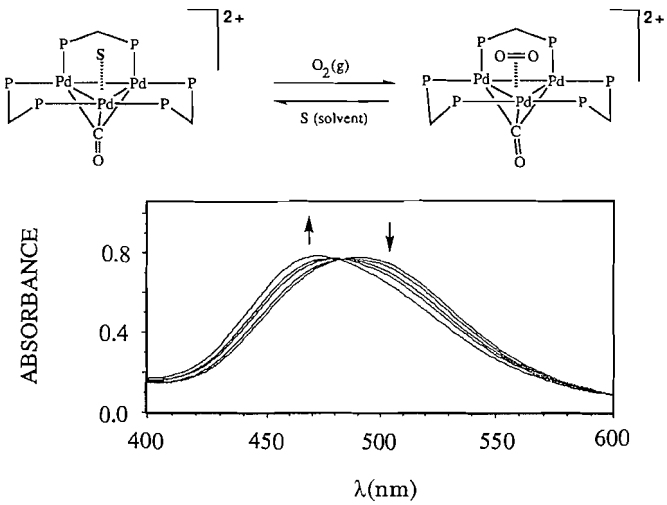
The weak solvent dependence on τ_e is associated with the $Pd_3(dppm)_3CO^{2+}$–solvent guest–host chemistry (27). Because the diffusion rate constants typically range between 10^9 and 10^{10} M^{-1} s^{-1} for common organic solvents (the data are taken from ref. 44; see footnote 12 of this reference) i.e., ~10^8–10^9 s^{-1} (by dividing the rate constants by the solvent concentration; pseudo-rate constant), the excited state deactivation rates ($(3–4) \times 10^{10}$ s^{-1}) appear to be too great to allow any efficient bimolecular process to occur in the excited state. Such an observation is also consistent with the relatively low quantum yields for the photoreaction and indicates that the cluster and the dioxygen molecule must be preassembled prior any photochemical event.

The most unusual result is the fact that no clear O_2 dependence on τ_e is observed, even at saturated conditions ($[O_2]_{sat'd}$ ~ 10^{-2} M in common organic solvents at 298 K, ref. 18). The experimental uncertainties are great (±10 ps) and may prevent the observation of any small decrease in τ_e upon bubbling. Also the concentration of O_2 bonded to the Pd_3 center within the cavity, which is in competition with ~10 M of neat solvent (blocking the cavity) prior to the laser pulse, may be rather low (i.e., 10^{-2} M = $[O_2]_{bonded}$ + $[O_2]_{free}$). The ground-state guest–host equilibrium constant has not been measured but can be estimated by using the following argument. Guest–host behavior is clearly seen from the UV–visible spectra upon light bubbling (Fig. 5). The ground-state

Fig. 5. Spectroscopic changes occurring upon bubbling O_2 into an acetonitrile solution of the unsaturated $Pd_3(dppm)_3CO^{2+}$ cluster in the dark (298 K).



binding of O_2 induces the appearance of a new band located at ~464 nm. This binding is reversible (in the dark) by bubbling Ar(g), or any other gases (H_2, CO, CO_2 ...). The presence of spectroscopic transformation upon purging has been observed for all the solvents investigated, indicating that in the ground state O_2 competitively binds the Pd_3 center despite the fact that the $[O_2]$ at maximum can only be 10^{-2} M (by comparison with the neat solvents ~10 M). Based upon the binding equilibrum constants (K_{11}) measured for neutral organic molecules (including solvents), the lower limit for the K_{11} value for O_2 is ~1 M^{-1} (27). When sodium acetate is added to any of the solutions (toluene, methanol, dimethylformamide, etc.), bubbling O_2 does not induce a spectroscopic change, indicating that the acetate binds far more strongly than O_2, which in turn prevents O_2 from interacting strongly with the Pd_3 center. Because K_{11} for acetate is ~730 M^{-1} (27), the range for K_{11} for O_2 is between 1 and 730 M^{-1} (perhaps being much closer to the lower limit), at least in the ground state. Nonetheless, the ps flash photolysis experiments (i.e., lifetime measurements) indicate that O_2(g) must be close to the Pd_3 center prior to irradiation (preassembled reactants) in order to induce the net photoreaction, and that the solvent definitely plays an "inhibiting" role in the primary step of the phototransformation. The fact that both the spectra and kinetic traces were similar for the coordinating acetonitrile and noncoodinating toluene solvents indicates that the photoinduced decomposition observed for the THF and benzene solutions is not due to processes occurring in the early stage of the multistep photoaddition. This observation supports the model that suggests that acetonitrile must stabilize one of the photochemical intermediates. By facing the evidence that a preassembled ground-state cluster–dioxygen complex is formed, and that the excited state lifetimes are too low to allow efficient bimolecular reactions in the excited state, one has to modify Scheme 3 by adding an extra step as shown in a more detailed Scheme 4.

Final remarks

The (multistep) photoinduced addition of O_2 onto $Pd_3(dppm)_3CO^{2+}$ has been observed for the first time, which makes the reported air stability of the cluster somewhat conditional to photochemistry. Dioxygen binds the Pd_3 center in a peroxo fashion, which represents the first complex in which O_2 acts as a ligand in a trinuclear metal complex. Unfortunately, no crystal suitable for X-ray crystallography could be obtained. However, spectroscopy has provided much evidence for a Type I structure, which makes the product exhibit a 44-electron count. Prior to the photochemical event, uncomplexed O_2 must be very close to the Pd_3 center in order to interact in the particularly short-lived $^1(a_1)^1(a_2)$ excited state for the addition of the first O_2 molecule. The lack of apparent quenching of the transient by O_2(g) is unusual, but demonstrates the extremely low excited-state lifetimes (at 298 K), and the ground-state competitive binding of O_2 with the solvent inside the cavity of the $Pd_3(dppm)_3CO^{2+}$, explaining the low quantum yield of photoaddition of O_2. The $Pd_3(dppm)_3(O_2)_2^{2+}$ complex formed represents *one* model that can mimick the O_2 behavior adsorbed onto the bulk Pd surfaces; in many ways the complex exhibits similar properties including both thermally and photochemically induced O—O bond cleavage, which in this case produces, dppm-oxide among other by-products. In this respect, the use of $Pd_3(dppm)_3(O_2)_2^{2+}$ as an oxidizing agent for organic materials can easily be conceived. The fact that the cavities have a given dimension also implies that the oxidizing power of the cluster may be limited as experienced by the inertness toward $(C_6H_5)_3P$ (size selectivity). Clearly the methods of oxidation would have to be mild as the complex is both thermally and photochemically sensitive.

The photoinduced addition reactivity of O_2 onto $Pt_3(dppm)_3CO^{2+}$ has not been investigated. The preliminary results show that reactions are indeed observed but the rates of

transformation are much slower than in the Pd case. Further, we have noticed that bubbling O_2 into a $Pt_3(dppm)_3CO^{2+}$ solution (in the dark) does not induce any spectroscopic changes normally associated with guest–host chemistry. This phenomenon has yet to be explained.

Evidence of a solvent-mediated barrier to radiationless decay in the $\tilde{B}$ ($^1A_1$) state of thiophosgene in solution

Jieming Li and Ronald P. Steer

Abstract: Thiophosgene, Cl_2CS, has been excited in the near-uv and the resulting quantum yields of $\tilde{B}$–$\tilde{X}$ fluorescence and of Cl_2CS consumption have been measured as a function of solvent composition (perfluoro-*n*-hexane, *n*-hexane, CCl_4), temperature, and excitation wavelength. In agreement with previous work it is shown that (*i*) nonradiative processes dominate the decay of the $\tilde{B}$ state in solution, and (*ii*) perfluoroalkane solvents act as inert "heat baths". The process by which the $\tilde{B}$ state is apparently "quenched" by CCl_4 and *n*-hexane has been discovered. The nonradiative process leading to $\tilde{B}$'s decay involves activation and crossing a barrier, the height of which is a function of the nature and composition of the solvent. CCl_4 and *n*-hexane do not quench the excited state, but instead accelerate its rate of relaxation by lowering the barrier between the bound, radiative portion of the surface and a dark, unbound region. There is evidence that CCl_4 or *n*-hexane form clusters around a Cl_2CS solute molecule in mixed perfluoroalkane–CCl_4 or *n*-hexane solutions. Barrier crossing leads to photodecomposition via at least two parallel paths, one free radical (Cl + ClCS) and the other likely molecular (Cl_2 + CS), the relative contributions of which are a function of excitation wavelength.

Key words: thiophosgene, photochemistry, solvent-mediated barrier crossing.

Résumé : On a excité le thiophosgène, Cl_2CS, dans le proche-uv et on a mesuré les rendements quantiques de la fluorescence $\tilde{B}$–$\tilde{X}$ et de la consommation du Cl_2CS qui en résultent en fonction de la composition du solvant (perfluoro-*n*-hexane, *n*-hexane et CCl_4), de la température et de la longueur d'onde de l'excitation. En accord avec les travaux antérieurs, il est démontré que (*i*) les processus non dissociatifs dominent la dégénérescence de l'état $\tilde{B}$ en solution et (*ii*) les solvants perfluoroalcanes agissent comme des "bains de chaleur" inertes. On a découvert le processus par lequel l'état $\tilde{B}$ est apparemment désactivé par le CCl_4 et par le *n*-hexane. Le processus non radiatif conduisant à la dégénérescence de $\tilde{B}$ implique une activation et le passage d'une barrière dont la hauteur est une fonction de la nature et de la composition du solvant. Le CCl_4 et le *n*-hexane ne désactivent pas l'état excité, mais ils accélèrent plutôt sa vitesse de relaxation en abaissant la barrière entre la portion radiative liée de la surface et la région noire non liée. Il existe des indications à l'effet que le CCl_4 ou le *n*-hexane forment des agrégats autour d'une molécule de Cl_2CS en solution dans des mélanges de perfluoroalcane, CCl_4 ou *n*-hexane. Le passage d'une barrière conduit à une photodécomposition par le biais d'au moins deux voies parallèles, une impliquant un radical libre (Cl + ClCS) et l'autre étant probablement moléculaire (Cl_2 + CS); les contributions relatives des deux sont fonction de la longueur d'onde d'excitation.

Mots cles : thiophosgène, photochimie, passage de barrière déterminé par solvent.

[Traduit par la rédaction]

I. Introduction

Thiophosgene, Cl_2CS, has been studied extensively both in the gas phase and in solution because it offers insight into several important aspects of electronic spectroscopy, photophysics, and photochemistry (1–10). We have been particularly interested in the $\tilde{B}$ ($^1A_1$) state of Cl_2CS, which can relax by a relatively large number of possible parallel and sequential processes and therefore provides a challenging level of complexity. Fortunately, relatively strong $\tilde{B}$–$\tilde{X}$ fluorescence provides a convenient, sensitive experimental means of examining the dynamic behavior of this highly excited polyatomic species both in the isolated molecule and in a wide variety of condensed media.

Spectroscopic experiments on isolated Cl_2CS in cold supersonic expansions have been particularly useful in revealing the details of the $\tilde{B}$ state potential surface (2–4). The location of $\tilde{B}$–$\tilde{X}$ origin (λ = 291.75 nm; 34 277 cm^{-1}) and the wavenumbers of the upper state vibrations have now been established with some confidence as a result of recent optical–optical double resonance experiments (3). Previous studies have also shown that, in the isolated molecule, the quantum yield of emission from low-lying vibrational levels of the $\tilde{B}$ state approaches 1 (11), and a fluorescence-weakening surface crossing occurs with an onset at 1450 ± 50 cm^{-1} above the zero point level (4). Excitation at substantially higher energies (e.g., λ = 248 nm; 40 323 cm^{-1}) produces no observable fluorescence but does result in photodissociation of the molecule via at least two possible channels (10);

[1] $Cl_2CS^v(\tilde{B}) \rightarrow Cl(^2P_{1/2,3/2}) + ClCS(\tilde{X}, \tilde{A}, \tilde{B})$

[2] $Cl_2CS^v(\tilde{B}) \rightarrow Cl_2(^1\Sigma_g^+) + CS(^1\Sigma)$

Both dissociation channels, including several electronically excited states of the radical products in channel [1], are energetically accessible at modest vibrational energies within the $\tilde{B}$ state, but their relative importance has yet to be established with certainty (1). For example, Okabe (9) has reported the quantum yield of Cl atom production is 1 at λ_{ex} = 253.7 nm (39 417 cm^{-1}), whereas Ondrey and Bersohn (10) report ϕ[1] = 0.2 and ϕ[2] = 0.8 for excitation at 248 nm (40 323 cm^{-1}).

In solution the formation of ground state van der Waals dimers of Cl_2CS (12) and the existence of a nearby very weak absorption, tentatively assigned to a "dark", doubly excited state (5), must be taken into account in order to model quantitatively the photophysical processes of the $\tilde{B}$ state (8, 13). When the relaxation of only monomeric Cl_2CS ($\tilde{B}$) is untangled from these complications, one finds that, in contrast to the isolated molecule, radiationless processes account for a very large fraction of decay events in solution at room temperature even when bound portions of the $\tilde{B}$ state are initially populated. More importantly, the radiationless decay rates of these low-lying, apparently bound, levels of the $\tilde{B}$ state are found to be strongly dependent on the nature of the solvent (6, 7). By measuring the decay rates of vibrationally thermalized $\tilde{B}$ states as a function of temperature in dilute, weakly interacting perfluoroalkane solutions we showed (7) that the nonradiative relaxation process exhibits an effective activation energy, E_a, of 1430 ± 80 cm^{-1} (17.1 ± 0.9 kJ mol^{-1}). This value is nearly identical to the vibrational energy of the $\tilde{B}$ state at the onset of the fluorescence weakening process seen in the isolated molecule. In more strongly interacting *n*-hexane or CCl_4 solutions, however, the quantum yields of $\tilde{B}$–$\tilde{X}$ fluorescence are much smaller (6), from which one may infer that the $\tilde{B}$ state lifetimes are much shorter than in perfluoroalkanes.

We have now completed experiments designed to understand more fully the behavior of monomeric Cl_2CS ($\tilde{B}$) in solution. The results demonstrate that solvents other than perfluoroalkanes increase the rate of nonradiative decay of the $\tilde{B}$ state primarily by lowering its effective activation barrier rather than by electronic quenching.

II. Experimental section

$\tilde{B}$–X fluorescence emission and excitation spectra and quantum yields were measured using a Spex, model 222 Fluorolog spectrofluorometer equipped with a "Datamate" computer. The procedure adopted for obtaining accurate values of emission quantum yields with this instrument have been described previously (14). Quinine hydrogen sulfate in 0.5 mol dm^{-3} H_2SO_4 (ϕ_f = 0.52 (15)) was employed as a fluorescence standard. Ultraviolet–visible absorption spectra were taken on a Cary, model 118 spectrophotometer.

Emission lifetimes were measured using a mode-locked Spectra-Physics model 2030 argon ion laser which synchronously pumped a cavity-dumped dye laser operating on rhodamine-6G. The 4 MHz output of the dye laser was frequency-doubled using an angle-tuned KDP crystal (Inrad) to obtain wavelengths in the 285–300 nm region with a maximum power of ca. 0.5 mW at 295 nm. To avoid rotational depolarization artefacts emission was observed at the magic polarization angle using a Zeiss M4QIII quartz prism monochromator and a Hamamatsu R2809 U-07 microchannel plate photomultiplier tube at the input end of a time-correlated single photon counting system. Further details of the laser excitation system, the detection equipment, and data processing methods have been given elsewhere (16).

When emission spectra or quantum yields were determined as a function of temperature, samples were placed in a thermostatted cell, the temperature of which was controlled to ±0.1°C by means of a circulating heat exchange fluid. When mixed perfluoroalkane–alkane or perfluoroalkane–CCl_4 solvents were employed, care was taken to ensure that bulk phase separation did not occur at any of the temperatures chosen for the study.

Thiophosgene (Aldrich) was purified by three trap-to-trap distillations in a glass vacuum line. The purified Cl_2CS was stored under vacuum in the dark at −20°C and was vacuum distilled again just prior to use. Perfluoro-*n*-hexane (PCR) was triply distilled through a one-meter glass column. No hydrogen-containing impurities could be detected by ^1H nmr in the resulting distillate, which was also essentially non-fluorescent. *n*-Hexane and CCl_4 solvents (BDH, Omnisolv) were purified using standard methods and also exhibited no significant fluorescence at the excitation wavelengths employed.

Samples were prepared by degassing the solvent by repeated free–pump–thaw cycles on a vacuum line, followed by condensation of Cl_2CS vapour into the solvent. A calibration curve of absorbance at λ_{max} (255 nm in perfluoro-*n*-hexane) vs. molar concentration of Cl_2CS was prepared by accurately weighing solute and solvent into a cell fitted for vacuum use. After this calibration curve had been established (ϵ_{max} = 4967 M^{-1} cm^{-1} for Cl_2CS in perfluoro-*n*-hexane), concentrations of Cl_2CS were determined routinely by absorbance measurements. In almost all experiments Cl_2CS concentrations were kept below ca. 4×10^{-4} M to minimize the effects of ground state van der Waals dimer formation known to be a problem at higher concentrations (12).

III. Results and discussion

Measurements of the quantum yields of $\tilde{B}$–$\tilde{X}$ fluorescence, ϕ_f, and the single exponential lifetimes, τ_f, of the $\tilde{B}$ state of Cl_2CS in solution permit one to calculate the first-order rate constant for $\tilde{B} \rightarrow \tilde{X}$ radiative decay and the sum of the first-order and pseudo-first-order rate constants for all parallel nonradiative decay process of the $\tilde{B}$ state using the relationships

[3] $k_r = \phi_f/\tau_f$

[4] $\Sigma k_{nr} = (1 - \phi_f)/\tau_f$

By making such measurements on Cl_2CS excited to various bound levels of the $\tilde{B}$ state in dilute perfluoro-1,3-dimethylcyclohexane as a function of temperature, we have previously shown (7) that: (*i*) $k_r = 2.1 \times 10^7$ s^{-1}, (*ii*) the only process contributing significantly to nonradiative decay is activation and barrier crossing leading, presumably, to dissociation, i.e., $\Sigma k_{nr} = k_{diss}$, (*iii*) the temperature dependence of the observed rate constant for nonradiative decay (dissociation) is given by $k_{diss} = k^0_{diss} \exp\{-E_a/RT\}$, and (*iv*) the value of E_a in perfluoro-

Fig. 1. $\tilde{B}$–$\tilde{X}$ fluorescence excitation spectra of 9.6×10^{-5} M Cl_2CS in perfluoro-*n*-hexane as a function of temperature. Emission was observed at a fixed wavelength of 400 nm. For clarity only spectra taken at six temperatures have been plotted.

1,3-dimethylcyclohexane, 17.1 ± 0.9 kJ mol^{-1}, is identical to the vibrational energy of the $\tilde{B}$ state at the onset of fluorescence weakening as measured in the isolated molecule. On the basis of the observations (*ii*), (*iii*), and (*iv*) we previously concluded that the perfluoroalkane solvent in this system acts as a classical heat bath (17) by rapidly exchanging vibrational energy with the excited solute while causing only minimal perturbations of its electronic decay processes. We had also previously shown (6) that values of ϕ_f (and presumably τ_f) are much smaller in other common solvents such as *n*-hexane and CCl_4, and attributed this effect to solvent-assisted radiationless relaxation. The latter was further investigated (7) by determining the rates of apparent quenching of the fluorescent $\tilde{B}$ state when perfluoroalkane solutions were spiked with low concentrations of *n*-hexane and CCl_4. Although the data produced linear Stern–Volmer plots and near diffusion-limited second-order quenching rate constants, we were unable to identify the quenching mechanism.

The present work has been undertaken with the primary aim of determining the process(es) by which solvents assist the nonradiative decay of the $\tilde{B}$ state of Cl_2CS. To this end, we first sought to demonstrate that measurements of the relative intensities of the $\tilde{B}$–$\tilde{X}$ excitation spectra as a function of temperature in dilute ($<10^{-4}$ M) solution yield the same activation parameters as do the measurements of both ϕ_f and τ_f as a function of *T*. Figure 1 shows the $\tilde{B}$–$\tilde{X}$ excitation spectra of 9.6×10^{-5} M Cl_2CS in perfluoro-*n*-hexane for various temperatures between −30 and +20°C. Plotting the relative intensities of the emission, I_{em}, at the maximum of the excitation spectrum ($\lambda_{ex} = 272$ nm) in Arrhenius form reveals an excellent linear ln I_{em} vs. T^{-1} relationship (Fig. 2). The slope yields $E_a = 17.3 \pm 0.5$ kJ mol^{-1} (1446 ± 42 cm^{-1}) which, within experimental error, is identical to the value of $E_a = 17.1 \pm 0.9$ kJ mol^{-1} obtained in perfluoro-1,3-dimethylcyclohexane (7), and confirms that perfluoroalkanes act as inert heat baths in this system. Similar experiments in which Cl_2CS was excited to fluorescent levels of the $\tilde{B}$ state in other pure solvents or two-component solvent systems also yielded good linear Arrhenius plots from which apparent activation energies could be obtained.

The lifetime to the $\tilde{B}$ state is about 40 ns when Cl_2CS is excited to levels near $v = 0$ at low pressures in the gas phase (18). This lifetime diminishes to 4.2 ns in dilute perfluoroalkane solutions at room temperature when exciting at similar wavelengths (7). We have now attempted to measure the decay times of the very weak $\tilde{B}$–$\tilde{X}$ emission observed when Cl_2CS is excited near 290 nm in CCl_4 and *n*-hexane. The lifetimes are too short to measure with our system, which places an upper limit of ca. 10 ps on τ_f in these two solvents.

We also measured the $\tilde{B}$–$\tilde{X}$ fluorescence quantum yields for Cl_2CS as a function of substrate concentration in both CCl_4 and *n*-hexane in order to determine the values of ϕ_f at infinite dilution in these two solvents. The results showed that ϕ_f was only a weak function of Cl_2CS concentration in the 0.5×10^{-4} to 6×10^{-4} M range. Thus, only short extrapolations were required to obtain $\phi_f = 2.4 \times 10^{-4}$ in CCl_4 and $\phi_f = 1.9 \times 10^{-4}$ in *n*-hexane at infinite dilution where neither self-quenching nor self-association occur. The values of ϕ_f are much smaller in CCl_4 and *n*-hexane than those in perfluoroalkanes (6), and appear to scale in about the same proportions as the lifetimes. We therefore conclude that the difference is due to a much larger rate of nonradiative decay in media other than perfluoroalkanes. This conclusion is in full agreement with our previous inferences based on measurements of ϕ_f alone (6, 7). Embedding Cl_2CS in any solvent therefore induces radiationless decay of the $\tilde{B}$ state at rates which are much faster than those of its radiative decay and which are strongly solvent dependent.

When excitation wavelengths in the $272 < \lambda_{ex} < 292$ nm range are employed, the $\tilde{B}$ state will acquire an initial vibrational energy of 0 to ca. 2500 cm^{-1}. It is well-established that vibrational relaxation of polyatomic molecules such as these is essentially complete within a few picoseconds (19, 20) in most common liquid solvents. By measuring the subpicosecond

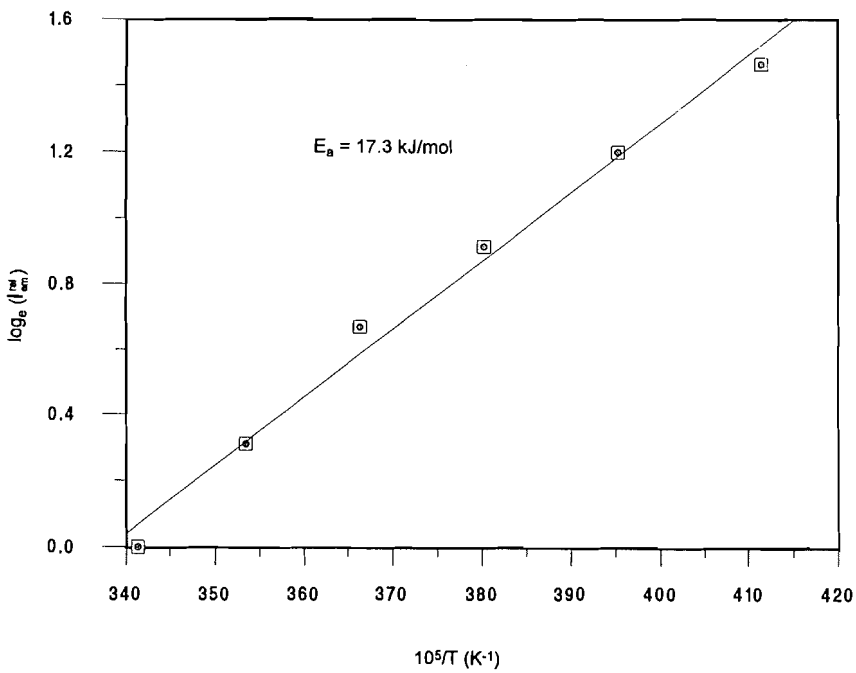
Fig. 2. Arrhenius plot of ln I_{em} vs. T^{-1} for the data presented in Fig. 1. Relative intensities were measured at the maximum of the excitation spectrum, 272 nm, and were normalized to 20°C for convenience.



population relaxation times of the S_1 states of azulene and several of its derivatives as a function of initial vibrational energy content, we have recently demonstrated that perfluoroalkane solvents also behave in a similar fashion.[2] In previous work we had observed only a small (<30%) increase in the nonradiative decay rate when the initial vibrational energy of the $\tilde{B}$ state is increased from 0 to 2150 cm^{-1} (7). In the present work we observe no measurable changes in the shapes of the $\tilde{B}$–$\tilde{X}$ emission spectra of Cl_2CS in any solvent when λ_{ex} is varied in this same range. We therefore conclude that, even in CCl_4 and *n*-hexane where $\tau_f \leq 10$ ps, the electronically excited emitters are in vibrational equilibrium with their surroundings. It is therefore proper to consider quantitative relationships between the apparent activation energies whose measurement has been described previously and solution composition.

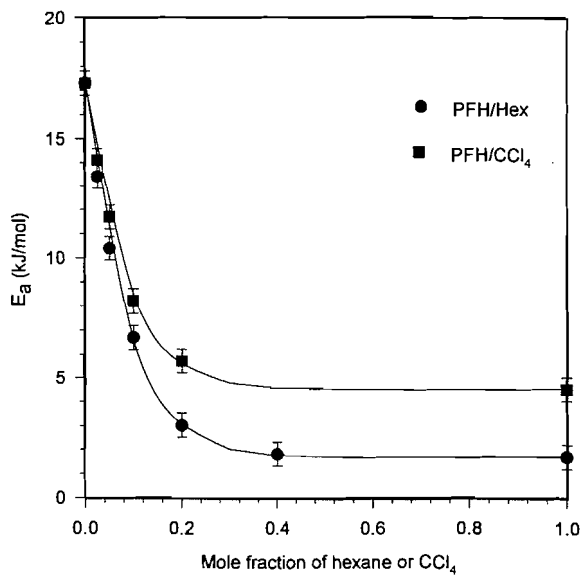
For this purpose we have measured the apparent activation energies, E_a, associated with the nonradiative decay of the $\tilde{B}$ state of Cl_2CS in solvents consisting of homogeneous mixtures of *n*-hexane with perfluoro-*n*-hexane and CCl_4 with perfluoro-*n*-hexane. The data are displayed graphically in Fig. 3. In both solvent systems E_a diminishes monotonically from a value of 17.3 kJ mol^{-1} in pure perfluoro-*n*-hexane to values of 1.7 ± 0.4 kJ mol^{-1} in pure *n*-hexane or 4.5 ± 0.4 kJ mol^{-1} in pure CCl_4.

In an attempt to determine the physical significance of the shapes of these E_a vs. mole fraction curves, a fit was sought between the data and values of E_a calculated using the following empirical equation

$$[5] \quad E_a^{calc} = \{E_a(PF) - E_a(S)\}(X)^n + E_a(S).$$

[2] D.T. Helbach-Helmrich and R.P. Steer. Unpublished results.

Fig. 3. Apparent activation energy, E_a, for the radiationless decay of the vibrationally equilibrated $\tilde{B}$ state of Cl_2CS as a function of solvent composition. The points are experimental data. The lines are calculated using eq. [5] with $n = 11$.



Here $E_a(PF) = 17.3$ kJ mol^{-1}, $E_a(S) = 1.7$ kJ mol^{-1} for S ≡ *n*-hexane or 4.5 kJ mol^{-1} for S ≡ CCl_4, X is the mole fraction of perfluoroalkane, and n is the only adjustable parameter. In both solvent systems the integer which provides the best fit between the values of E_a^{calc} calculated using eq. [5] and those observed by experiment is $n = 11$. When experimental error is accounted for, values of $n = 10$ or 12 would also be acceptable.

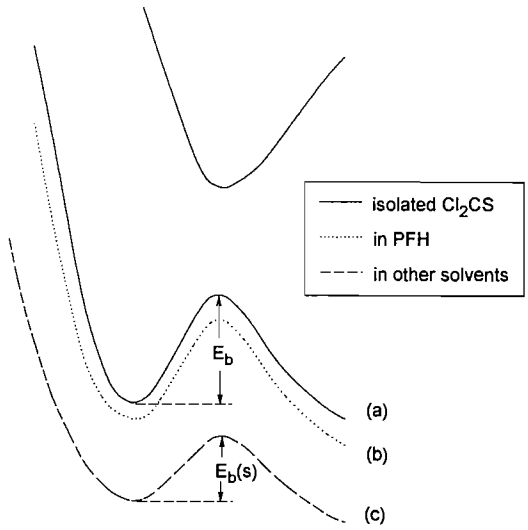
If one considers the perfluoroalkanes to be both chemically and physically inert, then the much faster rates of decay of the $\tilde{B}$ states in the presence of CCl_4 and *n*-hexane could be attributed to simple electronic quenching by the latter. The linear relationships previously obtained (7) when either the fluorescence intensities or the $\tilde{B}$ lifetimes are plotted in Stern–Volmer form as a function of CCl_4 or *n*-hexane concentration ($<10^{-1}$ M) in perfluoroalkane solvent support this interpretation. However, the data presented here provide strong evidence that the interaction between either CCl_4 or *n*-hexane and the *B* state of Cl_2CS does not involve simple electronic quenching via a 1:1 encounter complex or exciplex. First, there is no obvious single quenching "mechanism" which is consistent with all the data. Low-lying excited singlet states which could act as acceptors in an electronic energy transfer process are not available in either *n*-hexane or CCl_4. Quenching could also occur either by electron-transfer or by formation of a charge-transfer stabilized exciplex. However, if excited Cl_2CS were to act as an electron donor, the perfluoroalkanes with their large electron affinities should be the best acceptors, contrary to observation. On the other hand, if the $\tilde{B}$ state were to act as the electron acceptor in a charge-transfer complex then CCl_4 with its lower ionization energy should be a better "quencher" than *n*-hexane, again contrary to observation. Reactive chemical quenching might be possible for *n*-hexane (*vide infra*) but is not possible for CCl_4. Second, there appears to be no reasonable explanation for the fact that the activation energy associated with viscous flow is considerably higher in both CCl_4 (10.2 kJ mol^{-1}) and *n*-hexane (6.9 kJ mol^{-1}) than the values of E_a observed here. Diffusion limited quenching would therefore appear to be ruled out, although the "transient effect" complicates this interpretation when the lifetimes of the $\tilde{B}$ state are as short as they are in CCl_4 and *n*-hexane (21). Finally, the strongly nonlinear variation in E_a with solvent composition (Fig. 3) suggests that 1:1 molecular encounters between excited Cl_2CS and either CCl_4 or *n*-hexane are not responsible for the process which eventually results in fluorescence quenching. In fact, the large value of *n* required to give the best fit of eq. [5] to the data suggests that a process involving several CCl_4 or *n*-hexane molecules acting cooperatively may be operative here.

The onset of fluorescence weakening ca. 1430 cm^{-1} above the zero point level in the $\tilde{B}$ state (4) together with the observation of high yields of chemical decomposition products on excitation to higher levels in the vibrational manifold (9, 10) suggest that the $\tilde{B}$ state, described in zeroth order to be of $^1(\pi, \pi^*)$ configuration, is crossed by a second state which either is itself dissociative or is coupled to a dissociative state. Thus the potential energy hypersurface accessed by one-photon excitation in the near uv is expected to be complex and will exhibit either an avoided crossing if the intersecting state is of $^1A_1$ symmetry or a conical intersection if a state of different symmetry is involved. Irrespective of the nature of the intersecting state, the energy at which it crosses the $\tilde{B}$ surface will determine the height of the barrier between that portion of the surface which carries the oscillator strength and the rest of the surface which is "dark". The model is illustrated in Fig. 4.

We propose that the mechanism whereby species other than perfluoroalkanes increase the rate of nonradiative decay of the $\tilde{B}$ state in solution involves an interaction between excited

Fig. 4. Pictorial representation of a portion of the upper state hypersurface illustrating how the nature of the solvent can affect the height of the barrier to nonradiative decay of the fluorescent $\tilde{B}$ state. (*a*) The isolated molecule, (*b*) perfluoroalkane solvents, (*c*) more strongly interacting solvents.



Cl_2CS and one or more "solvent" molecules which results in a lowering of the effective barrier between the fluorescent bound portion of the surface and a "dark" region (cf. Fig. 4). Since the rate of vibrational activation of bound excited species will be approximately independent of the nature of the solvent (and in any case is much faster than the nonradiative decay rate), a lower barrier will result in a faster rate of barrier crossing, an effective increase in the nonradiative decay rate, a lower fluorescence yield, and a shorter $\tilde{B}$ lifetime, as observed.

We further propose that the distinctly nonlinear variation of E_a with mole fraction of the solvent ($n = 11$ in eq. [5]) may be indicative of a preferential clustering of CCl_4 or *n*-hexane molecules around Cl_2CS in perfluoroalkane solutions. In effect, the assembly of a small number of CCl_4 or *n*-hexane molecules around a single solute species in homogeneous mixed perfluoroalkane solutions would cause the $\tilde{B}$ state to "experience" a primarily non-perfluoroalkane environment even when the mole fraction of perfluoro-*n*-hexane exceeds that of the second solvent component. Such a suggestion is not unreasonable since small aggregates of "solute" species are known to form in homogeneous solutions at temperatures not substantially removed from those at which bulk phase separation occurs (22, 23). Perfluoroalkanes are very "poor" solvents (24), so it is reasonable to assume that the energy gained through dispersive interactions among clustered CCl_4 or *n*-hexane molecules could offset the entropic deficit associated with their formation. Thiophosgene itself forms van der Waals dimers and oligomers at relatively low concentrations in perfluoroalkanes (12). It is also interesting to note that for systems such as mixed noble gas liquids in which dispersive interactions are responsible for solvation enthalpies, the coordination number of the "solute" by the "solvent" is found to be either somewhat greater or somewhat smaller than those of self-solvation (11–13), depending upon the relative sizes and polarizabilities of the species involved (22). A more precise

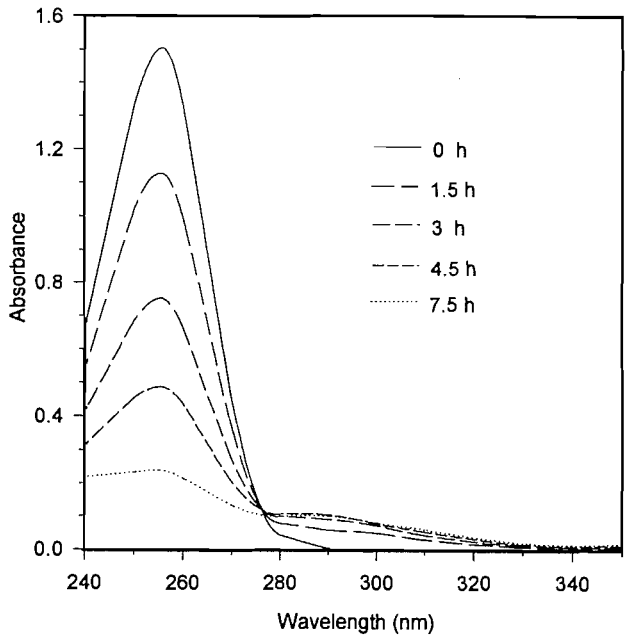
Fig. 5. Near-uv absorption spectra of dilute Cl_2CS in perfluoro-*n*-hexane as a function of photolysis time. Initial $[Cl_2CS] = 3.0 \times 10^{-4}$ M; $\lambda_{ex} = 255$ nm.



interpretation of the extremely non-linear variation of E_a with solvent composition awaits further investigation.

The effects of such clustering would be difficult to observe by standard spectroscopic means. The portion of the upper state which carries most of the oscillator strength is of $^1A_1$, $^1(\pi, \pi^*)$ character and is radiatively coupled to the $^1A_1$ ground state by an electric dipole allowed transition. Solvent effects on $\pi \rightarrow \pi^*$ transitions usually consist of a small red shift in more strongly interacting media. This red shift is a consequence of an increase in polarizability of the solute on excitation which results in a slightly greater dispersive stabilization of the excited species compared with the ground state. The uv absorption spectrum of Cl_2CS follows this pattern; $\lambda_{max} = 255$ nm in perfluoro-*n*-hexane and 257 nm in *n*-hexane. (λ_{max} is almost obscured in CCl_4 due to absorption by the solvent.) The fluorescence excitation spectra also exhibit similar shifts ($\lambda_{max} = 272$ nm in perfluoro-*n*-hexane, 274 nm in *n*-hexane, and 275 ± 1 nm in CCl_4). Because the rate of vibrational relaxation/activation is much faster than the rate of nonradiative electronic relaxation in these liquid solutions, a marked shift in the position of the excitation spectrum is not expected despite the fact that the activation barrier is considerably lower in both CCl_4 and *n*-hexane than in the perfluoroalkanes.

We suggest that the values of E_a are lower in more strongly interacting solvents because the dark state accessed on barrier crossing has a larger solvation energy than that of the radiative $^1(\pi, \pi^*)$ state (cf. Fig. 4). If this suggestion is correct, the dark state would need to have a greater polarizability than the radiative $^1(\pi, \pi^*)$ state since dispersive interactions dominate the solvation process. We have previously shown (5) that monomeric Cl_2CS exhibits a very weak, broad absorption in a region immediately to the red of the strong $\tilde{B}$–$\tilde{X}$ system. Excitation in this region produces no measurable fluorescence, so its upper state is not simply an extension of the bound, radiative $\tilde{B}$ surface into a region where the Franck–Condon factors for the $\tilde{B}$–$\tilde{X}$ transition are small. The dark state could be attributed to a triplet, for example of $^3(n_{Cl}, \pi_{CS}^*)$ or Rydberg character. However, a more interesting and more likely possibility is that the upper state is of primarily $^1A_1$, $^1(\pi^2, n^0, \pi^{*2})$ doubly excited character (25). Such a state is expected to have a larger polarizability than the neighboring $^1(\pi, \pi^*)$ state and would therefore exhibit the larger solvation energy required to produce the lower E_a observed in CCl_4 and *n*-hexane.

Additional strong support for the suggestion that barrier lowering (rather than than simple quenching) is responsible for the increased rate of nonradiative decay in CCl_4 and *n*-hexane can be obtained from an examination of the photochemistry of Cl_2CS in these two solvents compared with the perfluoroalkanes. Figure 5 shows how the near-uv spectra of a dilute solution of Cl_2CS in perfluoro-*n*-hexane change as a function of photolysis time when excited at $\lambda_{ex} = 255$ nm. As photolysis proceeds Cl_2CS is consumed and a broad new absorption feature with a maximum near 290 nm appears. An apparent isosbestic point is located at 276 nm. A detailed examination of these spectra, however, reveals that the isosbestic point is not "clean". This observation suggests that the weak absorption near 290 nm is due to a mixture of products, the composition of which is changing with time. This absorption also fades in the dark after photolysis, indicating that the products are not thermally stable. The identities of the products and their quantum yields are required if a detailed mechanism for the photolysis is to be enveloped. Unfortunately, having to employ only very dilute solutions to avoid the photolysis of ground state van der Waals dimers and problems of product instability made it impossible to accumulate sufficient material to permit analysis. Consequently, the photochemical behavior of uv-excited Cl_2CS had to be inferred from measurements of the quantum yields of consumption of the starting material, ϕ_C. Table 1 presents the value of ϕ_C as a function of the starting concentration of Cl_2CS in perfluoro-*n*-hexane for five different photolysis wavelengths from 285 to 255 nm. Table 2 shows how ϕ_C varies with temperature for one fixed, low concentration of Cl_2CS in perfluoro-*n*-hexane (5.8×10^{-5} M) at two of these wavelengths, 280 nm and 255 nm. We estimate the errors in ϕ_C to be ca. ± 10% at $\lambda_{ex} \leq 280$ nm for concentrations $> 5 \times 10^{-5}$ M and ±30% at $\lambda_{ex} = 285$ nm and at $\lambda_{ex} \leq 280$ nm for all concentrations $< 5 \times 10^{-5}$ M where the absorbance of these dilute solutions is extremely small. Despite these relatively large errors a number of important conclusions can be drawn from the data.

First, all of the quantum yields of Cl_2CS consumption are large. When one accounts for the fact that free radical recombination, reaction [6],

[6] $Cl + ClCS \rightarrow Cl_2CS$

will result in lower net consumption of Cl_2CS, one concludes that a large majority of the nonradiative decay events of the $\tilde{B}$ state either must involve direct bond scission (after barrier crossing) or must access a bound portion of the upper state which is itself strongly coupled to a dissociative state. Second, ϕ_C is significantly larger than 1 for excitation at 285 nm, and is marginally larger than 1 for excitation at $\lambda_{ex} = 280$ nm. This can only occur if Cl_2CS is consumed not only via the primary photolytic acts, reactions [1] and [2], but also in secondary reactions between ground state Cl_2CS and transient intermedi-

ates. The most obvious such processes involve reactions Cl_2CS with Cl or ClCS produced in [1], but reactions between CS (produced in reaction [2]) and Cl_2CS cannot be ruled out. Third, ϕ_C generally *increases* with increasing Cl_2CS concentration up to ca. $4–5 \times 10^{-4}$ M, but levels out at an apparent plateau which is different for different excitation wavelengths. Finally, the profile of ϕ_C as a function of temperature at λ_{ex} = 280 nm is also different from that at λ_{ex} = 255 nm. We conclude that at least two primary photochemical processes are occurring, that the branching ratios among them are a function of λ_{ex}, and that the process which dominates at shorter λ_{ex}

results in a lower net consumption of Cl_2CS. Reactions [1] and [2] would appear to meet these requirements provided the branching ratio favors reaction [2] as λ_{ex} decreases. The recent observation by time-resolved infrared absorption of CS in the products of the flash photolysis of Cl_2CS in CD_3CN at 266 nm (footnote 3, ref. 26) support this suggestion. The general increases in ϕ_C with increasing Cl_2CS concentration likely reflect the competition between second-order radical recombination in bulk solution and pseudo-first-order reaction between the substrate and these intermediates. Diffusive self-quenching of the bound $\tilde{B}$ state ($k_{sq} = 2 \times 10^{10}$ M^{-1} s^{-1}, τ^0 = 4.2 ns (8)) is not important at these low concentrations. However, increasing absorption by ground state van der Waals dimer, whose absorbance constitutes ca. 20% of the total when the analytical concentration of Cl_2CS is 3×10^{-4} M (12), is a complicating factor.

In 1977 Okabe (9) showed that HCl ($\phi \sim 1$) is a major product of the uv photolysis of Cl_2CS in the presence of heptane in the gas phase, viz.,

[7] $Cl + C_7H_{16} \rightarrow HCl + C_7H_{15}$

This and other H-abstraction reactions are also expected when Cl_2CS is photolyzed in liquid *n*-hexane solutions. Such reactions produce alkyl free radicals which can themselves add to Cl_2CS in a manner which has parallel precedence in the photochemistry of aromatic and alicyclic thiones (27, 28). Because this series of reactions would influence ϕ_C in an

[3] B. Wagner. Private communications.

unpredictable way, we concluded that the determination of the quantum yields of Cl_2CS consumption in *n*-hexane solution would yield ambiguous results.

On the other hand, such reactions cannot occur in CCl_4 or in CCl_4–perfluoroalkane mixtures. We therefore reasoned that a comparison of the rates of Cl_2CS consumption in pure perfluoroalkane with those in CCl_4 or CCl_4–perfluoroalkane mixtures would provide valuable insight into the role of CCl_4 in these systems. Table 3 presents the results of photolyzing Cl_2CS at $\lambda_{ex} = 280$ nm in pure CCl_4 and in a mixture in which the mole fraction of CCl_4 in perfluoro-*n*-hexane is 0.05 (ca. 0.25 M). (Note that photolysis at $\lambda_{ex} < 280$ nm is not possible because the solvent is not transparent at these wavelengths.) The values of ϕ_C are comparable to those found when Cl_2CS is photolyzed in pure perfluoroalkane under similar conditions, clearly indicating that CCl_4 does not quench the $\tilde{B}$ state. These observations therefore support the suggestion that CCl_4 and *n*-hexane accelerate nonradiative decay by lowering the barrier between the fluorescent $\tilde{B}$ state and a dark portion of the upper state surface from which dissociation occurs. However, quantitative analyses of the products of the photolysis of Cl_2CS in these solvents are required before this mechanism can be proved conclusively.

IV. Conclusions

By measuring the intensities of $\tilde{B}$–$\tilde{X}$ fluorescence and the quantum yields of substrate consumption as a function of temperature, excitation wavelength, and solvent composition when Cl_2CS is electronically excited in solution we have shown that (*i*) nonradiative processes dominate the decay of the $\tilde{B}$ state, (*ii*) the nonradiative process(es) involve(s) activation and crossing a barrier whose height is a function of the composition of the solvent, (*iii*) perfluoroalkane solvents are inert and act as classical heat baths, (*iv*) CCl_4 and *n*-hexane do not quench the $\tilde{B}$ state, but instead accelerate the rate of its nonradiative decay by lowering the barrier between the bound, radiative portion of the surface and a dark region which is either unbound or strongly coupled to an unbound state, and (*v*) barrier crossing leads to photodecomposition via at least two parallel paths (likely reactions [1] and [2]), the relative importance of which is a function of excitation wavelength.

Excess molar volumes of binary mixtures with 2-pentanone and 1-chloroalkanes at 298.15 and 308.15 K

José M. Pico, Consolación P. Menaut, Eulogio Jiménez, José L. Legido, Josefa Fernández, and M. Inmaculada Paz Andrade

Abstract: Excess molar volumes v^E at 298.15 and 308.15 K and normal atmospheric pressure for the binary mixtures 2-pentanone + 1-chloroalkane (from 1-chlorobutane to 1-chlorooctane) were obtained from measurements of the density with an Anton Paar densimeter. The v^E values for all mixtures were positive, and increase as the 1-chloroalkane length increases. Excess molar volumes depend slightly on the temperature. The same characteristics were found previously for the excess molar enthalpies of the same mixtures. Experimental v^E values are compared with theoretical results using the Prigogine–Flory–Patterson model.

Key words: thermodynamics, liquid mixtures, excess volumes, ketones, chloroalkanes.

Résumé : Utilisant des mesures de densité obtenues à l'aide d'un densimètre d'Anton-Paar, on a déterminé les volumes molaires d'excès, v^E, à 298,15 et 308,15 K et à pression atmosphérique normale pour des mélanges binaires de pentan-2-one + 1-chloroalcanes (allant du 1-chlorobutane au 1-chlorooctane). Les valeurs de v^E de chacun des mélanges sont toutes positives et elles augmentent avec une augmentation de la longueur de la chaîne des 1-chloroalcanes. Les volumes molaires d'excès ne dépendent que légèrement de la température. Antérieurement, on avait trouvé les mêmes caractéristiques pour les enthalpies molaires d'excès des mêmes mélanges. On a comparé les valeurs expérimentales des v^E avec les valeurs théoriques calculées en utilisant le modèle de Prigogine–Flory–Patterson.

Mots cles : thermodynamique, mélanges liquides, volumes d'excès, cetones, chloroalcanes.

[Traduit par la redaction]

Introduction

This work is part of a systematic study on the thermodynamic properties of mixtures of ketones with chloroalkanes. In a first paper (1) we measured excess molar enthalpies of 2-butanone and 2-pentanone with 1-chloroalkanes. We used these h^E values together with the literature values (2, 3) to redetermine new interaction parameters of the Tassios version of the UNIFAC group-contribution model (4, 5). Subsequently, we started to determine experimental excess molar volumes of this kind of mixtures, with an aim to perform, in future, quantitative treatment of these values with the Nitta–Chao group contribution model (6). In a recent paper we reported the v^E values of 3-pentanone or 3-heptanone with 1-chloroalkanes (7). To enlarge the data base needed to calculate the interaction parameters we report in the present paper the experimental excess molar volumes at 298.15 and 308.15 K of 2-pentanone with 1-chloroalkanes (from 1-chlorobutane to 1-chlorooctane). The influence of the position of the ketone group in the molecule of alkanone is analyzed by comparing the v^E values of both isomeric pentanones with 1-chloroalkanes.

The version of the Flory model (8, 9) due to Patterson and co-workers (10–12), named the Prigogine–Flory–Patterson (PFP) model, has been used often recently to correlate and to predict such thermodynamic properties of organic mixtures as h^E, v^E, c_P^E. The PFP model is very useful to analyze the influence of the size, shape, and momentum of the molecules on the behaviour of binary mixtures. In some cases, the differences between theoretical and experimental values have been used to show the occurrence of short-range order effect (13–15). In this paper we have applied this model by determining the interaction parameter X_{12} from excess molar enthalpies of the same mixtures.

Experimental

The sources and the purities of the chemicals were 2-pentanone (Fluka, puriss 99%), 1-chlorobutane (Fluka, puriss 99.5%), 1-chloropentane and 1-chlorohexane (Fluka, puriss 99%), 1-chloroheptane and 1-chlorooctane (Aldrich 99%). All liquids were used without purification, but prior to the measurements they were kept over Union Carbide 0.4 nm molecular sieves (Fluka) and partially degassed. Their densities agree well with the literature values, as can be seen in Table 1 (1, 7, 15–21).

[a]Interpolated from ref. 19.

The measurements of densities were carried out with an Anton–Paar DMA 60/602 vibrating tube densimeter operating under static mode. A Haake F3 thermostat and a digital thermometer Anton–Paar DT 100-30 were used to regulate to better than 0.01 K the temperature inside the vibrating tube.

Before each series of measurements the apparatus was calibrated at atmospheric pressure with double-distilled and degassed water and *n*-heptane (Fluka >0.995). The excess molar volumes were calculated from the densities of the pure liquids and their mixtures. Binary mixtures were prepared by mass with a probable error in the mole fraction of less than 10^{-4}. All molar quantities are based on the IUPAC (22) relative atomic mass table.

Results

Excess molar volumes, v^E, for the five mixtures, (x 2-ketone + $(1 - x)$ 1-chloroalkane), measured at 298.15 and 308.15 K are listed in Tables 2 and 3. These data were fitted by unweighted least-squared polynomial regression to the equation

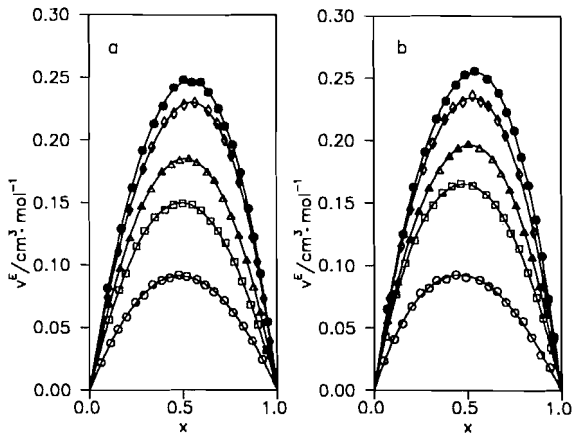
$$[1] \quad v^E/(cm^3\ mol^{-1}) = x(1 - x)\sum_{p=0}^{q} A_p(2x - 1)^p$$

The number of coefficients used in eq. [1] for each mixture was determined by applying an F test (22). The parameters A_p and their standard deviations s are given in Table 4 for all systems. A graphical representation of the experimental values together with the smoothing curves is shown in Fig. 1. We are not aware of any previous measurements of v^E for these mixtures.

Discussion

In all the mixtures studied the molar excess volumes are positive over the whole range of composition. The v^E–x curves are quite symmetrical, and their maximum is slightly skewed towards the region rich in ketone as the 1-chloroalkane length increases. The excess molar volumes increase slightly with temperature, presenting mean differences of about 1% between 298.15 and 308.15 K.

Fig. 1. Experimental excess molar volumes v^E at (*a*) 298.15 K and (*b*) 308.15 K of (x) 2-pentanone + $(1 - x)$ 1-chloroalkane. Experimental points: ○, 1-chlorobutane; □, 1-chloropentane; △, 1-chlorohexane; ◇, 1-chloroheptane; ●, 1-chlorooctane.



The equimolar excess volume $v^E(0.5)$ increases as the 1-chloroalkane chain grows in length, as can be seen in Fig. 2, where n is the number of the carbon atoms in the 1-chloroalkane. This behavior was found before for the excess enthalpies of the same mixtures (1) and for the excess molar volumes of 3-pentanone and 3-heptanone with 1-chloroalkane (7). However, while the variation in the excess molar enthalpies is almost linear with n, v^E increases more rapidly for smaller chloroalkanes. Similar differences between the dependence of h^E and v^E on n were also found by Lorenzana et al. for ester + *n*-alkane mixtures.

The behaviour of these mixtures in terms of efficient packing and formation and breaking of different interactions in the mixing process can be explained as in our previous paper (7) and references therein.

For binary mixtures of isomeric alkanone with 1-chlorohexadecane García et al. (2) have established that excess enthalpies are larger for the unsymmetrical *n*-alkanone than for the symmetrical *n*-alkanone. Figure 2 shows that this fact is

also verified for excess molar volumes in the case of pentanone. The relative differences in v^E for both pentanones varies between 20% and 50%, depending on the 1-chloroalkane, and are bigger than the relative differences for excess enthalpies. The difference in the behaviour of the isomeric alkanones was attributed (2) to the steric hindrance of the adjacent alkyl groups. Our results confirm this hypothesis because in general excess volumes are more affected than excess enthalpies by steric hindrance.

According to the Prigogine–Flory–Patterson theory (10–12) h^E and v^E for binary mixtures are given by

$$[2]\quad \frac{v^E}{(x_1V_1^* + x_2V_2^*)} = \frac{(\tilde{V}^{1/3} - 1)\tilde{V}^{2/3}(\psi_1\theta_2\chi_{12})}{[(4/3)\tilde{V}^{1/3} - 1]P_1^*} - \frac{(\tilde{V}_1 - \tilde{V}_2)^2[(14/9)\tilde{V}^{1/3} - 1]\psi_1\psi_2}{[(4/3)\tilde{V}^{1/3} - 1]\tilde{V}} + \frac{(\tilde{V}_1 - \tilde{V}_2)(P_1^* - P_2^*)\psi_1\psi_2}{P_1^*\psi_1 + P_2^*\psi_2}$$

$$[3]\quad \frac{h^E}{(x_1P_1^*V_1^* + x_2P_2^*V_2^*)} = \frac{[(1/\tilde{V} + \tilde{T}/[(4/3)\tilde{V}^{1/3} - 1]](\psi_1\theta_2\chi_{12})}{P_1^*} - \frac{(1/\tilde{V}_1 - 1/\tilde{V}_2)^2[(2/9)\tilde{V}^{2/3}]\psi_1\psi_2}{[(4/3)\tilde{V}^{1/3} - 1]}$$

where all symbols have the same significance as in the original papers (10–12). The two first terms on right-hand side of eqs. [2]

and [3] are the interactional and the curvature contributions to v^E and h^E, respectively. The third term in eq. [2] is the internal pressure contribution, v_p^E. The interactional terms, $v_{int.}^E$ and $h_{int.}^E$, are usually positive in the absence of hydrogen bond and other specific interactions. The curvature terms, $v_{cur.}^E$ and $h_{cur.}^E$, are always negative because $d^2\tilde{V}/dT^2$ is positive (12). The internal pressure contribution can be positive or negative depending on the sign of $(\tilde{V}_1 - \tilde{V}_2)(\tilde{P}_1 - \tilde{P}_2)$.

The parameters for the pure component liquids required in the calculations are given in Table 5. For 1-chlorobutane and 2-pentanone thermal expansion coefficient, α, and isothermal compressibility, κ_T, were taken from the literature (15, 17). For other pure liquids α was determined from the densities obtained in our laboratory and from those in ref. 19, and κ_T was determined using the McGowan method (23) and experimental data for surface tension (17, 24). From the values in Table 5 we conclude that the internal pressure contribution will be positive in all systems except for the 2-pentanone + 1-chlorobutane at both temperatures (12). The ratios s_1/s_2 were determined according to the original work of Abe and Flory (10).

The parameter X_{12} has been evaluated by using the experimental values of $h^E(0.5)$ for each system except in the case of the mixture with 1-chloroheptane, where $h^E(0.5)$ has been interpolated because of the absence of the experimental data. The theoretical values of both thermodynamic properties h^E and v^E together with their contributions using eqs. [2] and [3] are listed in Table 6.

The X_{12} parameter and the interactional terms of v^E and h^E

are positive, increasing regularly with the chain length of the 1-chloroalkane in the mixture. This behaviour has been reported in the literature (15, 25, 26) with mixtures containing a polar molecule and a alkane. In this latter case X_{12} increases with the length of the alkane.

The interactional term is dominant in h^E, since the curvature contribution is negligible for short-chain 1-chloroalkanes, reaching only 4% for 1-chlorooctane. For the excess molar volume, although the interactional term is the greater contribution the curvature and internal pressure terms are important, especially for larger 1-chloroalkanes.

The PFP predictions are good for 1-chlorobutane and 1-

chloropentane, but not as good when the 1-chloroalkane length increases. The same observation has previously been made for mixtures containing alkanes (24, 25). It seems that when interactions are more important the PFP model predicts excess molar volumes that are larger than experimental values (27, 28).

A study of the vacuum pyrolysis of 1,2,3-benzotriazines. The HeI ultraviolet photoelectron spectra of benzazete and *o*-benzyne

Nick Henry Werstiuk, Chandra Deo Roy, and Jiangong Ma

Abstract: A CW CO_2 laser is used as a directed heat source to carry out the vacuum pyrolysis of 1,2,3-benzotriazine (**1***a*) and 4-methyl-1,2,3-benzotriazine (**1***b*). We report the first HeI photoelectron (pe) spectrum of benzazete (**2***a*), which correlates with ionization energies calculated with HAM/3 using an equilibrium geometry obtained at the ab initio HF/6-31G** level of the theory. The pe spectrum of *o*-benzyne (**3**) obtained in this study correlates with the spectrum published by Zhang and Chen, but not with the spectra reported in two earlier publications.

Key words: 1,2,3-benzotriazines, vacuum pyrolysis, HeI ultraviolet photoelectron spectra, benzazete, benzyne.

Résumé : On a utilisé un laser CW au CO_2 comme source dirigée de chaleur pour effectuer des pyrolyses sous vide des 1,2,3-benzotriazine (**1***a*) et 4-méthyl-1,2,3-benzotriazine (**2***b*). On a déterminé le premier spectre photoélectronqiue au HeI du benzazète (**2***a*) pour lequel il existe une bonne corrélation avec les énergies d'ionisation calculées avec HAM/3, en utilisant une géométrie d'équilibre obtenue par des calculs ab initio au niveau HF/6-31G** de la théorie. Le spectre photoélectronique du *o*-benzyne (**3**) obtenu au cours de ce travail est en bon accord avec le spectre publié par Zhang et Chen, mais il diffère de celui rapporté dans deux travaux antérieurs.

Mots clés : 1,2,3-benzotriazines, pyrolyse sous vide, spectre photoélectronique ultraviolet HeI, benzazète, benzyne.

[Traduit par la rédaction]

Ultraviolet photoelectron spectroscopy (pes) combined with semiempirical or ab initio calculations of equilibrium molecular geometries and molecular orbital (MO) eigenvalues, provides, within the limits of Koopmans theorem (1), a method for ordering the energies of MOs. As a result these studies give fundamental information about the bonding of stable compounds and transient species that is provided by no other technique. To this point, transient species studied with pes generally were prepared by vacuum pyrolysis of compounds with electrically heated furnaces centimetres in length (2, 3). To facilitate the preparation and detection of highly reactive transients in the gas phase, we developed a CW CO_2 laser/pes apparatus and used it successfully to study the vacuum pyrolysis of 6,6-dihalobicyclo[3.1.0]hexanes (4). In this communication we document the results of a study of the pyrolysis of 1,2,3-benzotriazine (**1***a*) and 4-methyl-1,2,3-benzotriazine (**1***b*) with this apparatus. We studied these compounds for three reasons (*a*) we wished to establish the general applicability of using the apparatus to prepare and study highly reactive transients; (*b*) there have been no reports of pe spectra of benzazetes, which appear to be highly reactive, nonisolable compounds (5); (*c*) previous studies produced three different pe spectra for *o*-benzyne (**3**) (6–8). We chose to study **1***a* and **1***b* because Rees and co-workers showed that these compounds decompose at relatively low temperatures (400–500°C) in a closed systems at 0.01 Torr (1 Torr = 133.3 Pa) and give good yields of biphenylene (**4**), the product of the dimerization of **3** (9, 10). Compounds **1***a* and **1***b* also are potential sources of benzazete (1-azabenzocyclobutene) (**2***a*) and 2-methylbenzazete (**2***b*) provided that the vacuum pyrolyses can be carried out under conditions where cyclization of the diradicals formed by extrusion of N_2 competes with fragmentation to **3** and HCN or CH_3CN (Scheme 1).

Scheme 1

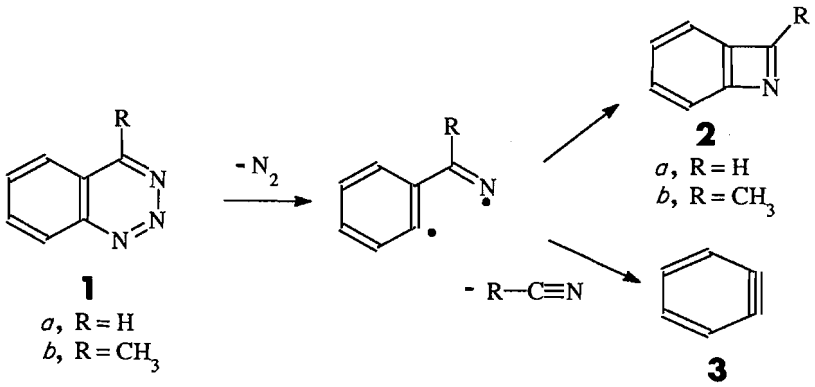

Fig. 1. (*a*) HeI pe spectrum of **1***a* obtained at a probe temperature of 112°C; (*b*) spectrum of the pyrolyzate of **1***a* obtained at a laser power of 40 W; (*c*) spectrum obtained by stripping spectrum 1(*a*) from spectrum 1(*b*); (*d*) spectrum of the pyrolyzate of **1***a* obtained at 54 W (*e*) spectrum of biphenylene (**4**) obtained at ambient temperature.

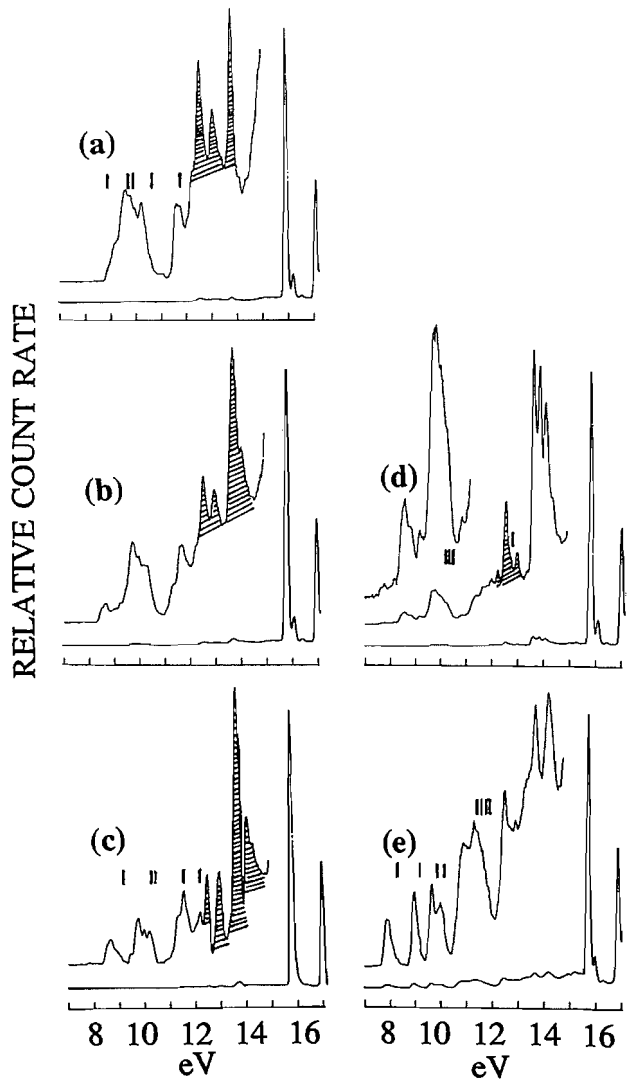

The pe spectra along with vertical expansions in the range 7–14 eV obtained for the pyrolysis of **1***a* and **1***b* at a number of laser power levels[2] are displayed in Figs. 1 and 2, respectively. In this study, N_2 introduced into the source as a make-up gas to maintain the total pressure in the source at around $(5–6) \times 10^{-3}$ Torr (the substrate base pressure was kept low at 10^{-4} Torr) greatly improved the quality of the spectra. The low-IP band of N_2, which has a much higher ionization cross section than the organic molecules, is seen at 15.6 eV in the spectra.[3] Figure 1(*a*) is the spectrum of **1***a* obtained at a probe temperature of 112°C. The solid bars on this spectrum show the five lowest ionization energies (IEs) (8.87, 9.70, 9.84, 10.55, 11.64 eV) of **1***a* calculated with HAM/3 (11) on the equilibrium geometry calculated at the HF/6-31G** level of theory with GAUSSIAN 92 (12). At a laser power of 40 W, there is a significant change in the pe spectrum (Fig. 1(*b*)); a peak appears at 8.8 eV and there is a change in the structure of the band(s) between 9 and 10.8 eV. Of significance is the fact that there is no band(s) between 13.5 and 14.5 eV corresponding to the low-IP band of HCN (13). This result indicates that **1***a* decomposes at a laser power of 40 W without extruding HCN. Figure 1(*c*) shows the result of stripping the

[2] The solid benzotriazine (10–20 mg) was placed in a bottle-shaped quartz reaction vessel that was inserted into a brass probe tip, which was electrically heated or cooled with circulating tap water. Quartz was used to fabricate the reaction vessel because it has a high melting point and, more importantly, it exhibits a very low lateral surface thermal conductivity. The main body of the reaction vessel made of 5 mm o.d. tubing is 1.5–2 cm long. The pyrolysis tube, which is 1.5 cm in length and made of 3 mm o.d. tubing, was constricted at the tip to an i.d. of approximately 1 mm after the sample was loaded. With the tip of the pyrolysis tube positioned 1 cm from the point of intersection with the ionizing photon beam, the 7 mm diameter laser beam was focused to a 1 mm diameter beam with a convex ZnSe lens and directed through a ZnSe window in the source housing to impinge on the tip of the quartz reaction vessel. In this configuration, the focused laser beam produces a hot zone that is approximately 2 mm in length. The pyrolysis reactions were carried out at a source pressure of $(6–7) \times 10^{-3}$ Torr with the fast-pumping valve partially open.

[3] The cross-hatched peaks are due to traces of oxygen (12–13 eV) in the N_2 used as the make-up gas, H_2O (12.6 eV) that is released from the quartz tubing when it is heated with the laser beam, and a shadow peak (13.6 eV) of N_2.

Fig. 2. (*a*) HeI photoelectron spectrum of **1***b*; (*b*) spectrum of the pyrolyzate of **1***b* obtained at 54 W.

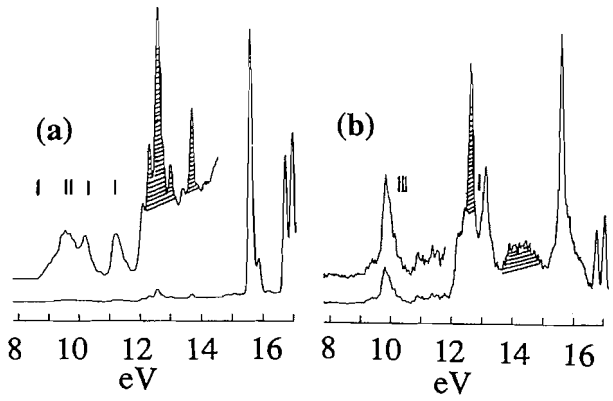

Fig. 3. Optimized equilibrium geometrical structure of benzazete (**2***a*) obtained at the HF/6-31G** level of theory.

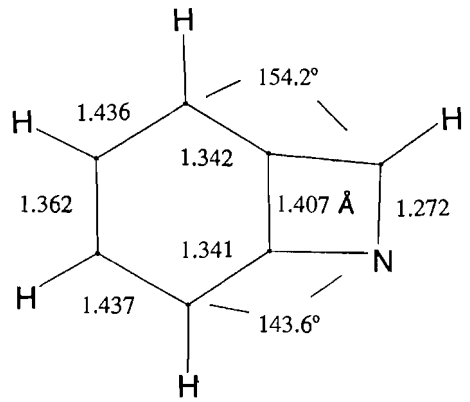

spectrum of **1***a* (Fig. 1(*a*)) from the 40-W spectrum 1(*b*) along with vertical bars that locate the five lowest IEs (9.11, 10.20, 10.26, 11.49, 12.09 eV) of benzazete (**2***a*) obtained with HAM/3 using the HF/6-31G** optimized equilibrium geometry calculated with GAUSSIAN 92. The surprisingly distorted optimized geometrical structure of **2***a* — it must be highly strained — exhibiting alternating long and short C—C bonds is displayed in Fig. 3. The localization of the π bonds means that **2***a* will not be stabilized by resonance to the same degree as benzene. Perhaps it is these factors which give rise to the high reactivity of **2***a*. We take good correlation between the calculated and experimental IEs[4] and the fact that HCN is not produced at 40 W as compelling evidence that Fig. 1(*c*) is the partial pe spectrum of **2***a*. At a laser power of 54 W, further changes occur in the low-IP region of the spectrum (Fig. 1(*d*)), and HCN, identified by the strong band exhibiting vibrational fine structure centered at 14 eV (13), is a product of the pyrolysis. Bars showing the four lowest IEs (10.20, 10.24, 10.35, 12.81 eV) of **3** calculated with HAM/3 using the HF/6-31G** equilibrium geometry are included in this spectrum. The outer valence Green function (OVGF) and extended two-particle-hole Tamm–Dancoff (extended 2ph-TDA) methods, which allow for orbital relaxation and correlation effects and which have successfully predicted the IEs of a range of organic molecules, have been used to calculate the IEs of **3** (14). The OVGF method yields values of 9.55, 9.57, and 9.77 eV for the three lowest IEs. The extended 2ph-TDA method yields values of 9.54, 9.54, and 9.65 eV. Thus the new band(s) between 9.3 and 10.5 eV correlate with the calculated three lowest IEs[5] of **3**. The peak at 8.8 eV corresponds to the lowest IE band of benzazete (Fig. 1(*c*)). Figure 1(*e*) is a display of the pe spectrum of an authentic sample of biphenylene (**4**) along with the eight lowest IEs calculated with HAM/3 on the 6-31G** optimized geometry. That there is only a very weak peak at 7.8 eV in spectrum 1(*d*) establishes that **3** does not dimerize to a significant extent under the experimental conditions used in this study. The spectrum of 4-methyl-1,2,3-benzotriazine (**1***b*) along with the five lowest IEs (8.59, 9.48, 9.60, 10.31, 11.64 eV) calculated at the HAM/3//6-31G** level of theory are shown in Fig. 2(*a*). Because **1***b* tended to decompose when warmed in the quartz reaction vessel for extended periods, the pyrolysis was carried out at 54 W in a short period of time (the temperature of the probe holding the reaction vessel was rapidly increased to 80°C) without N_2 being added as a make-up gas. Unlike the case of **1***a* where the spectrum was obtained by averaging 25 scans using a dwell time of 0.1 s/point, spectrum 2(*b*) was obtained in one scan utilizing a dwell time of 1 s/point. The calculated four lowest IEs of **3** are also shown on this spectrum. As was found in the pyrolysis of **1***a*, the band(s) centered at 9.7 eV correspond to the calculated first three IEs of **3** and as predicted by the calculations there are no additional well-defined bands between 10 and 12.5 eV. The group of bands (excluding the cross-hatched band at 12.6 eV due to H_2O[3]) between 12 and 13.5 eV are due to acetonitrile (13). Given that the calculated four lowest IEs (HAM/3 on the HF/6-31G** optimized geometry) of **2***b* are 8.71, 9.87, 9.93 and 11.05 eV, and there are no bands below 9 eV in spectrum 2(*b*), **1***b* decomposes without forming a significant amount of **2***b*. The low-IE region of spectrum 2(*b*) closely resembles the partial spectrum of **3** (it was generated by supersonic jet/flash vapour pyrolysis of benzocyclobutene-1,2-dione) published by Zhang and Chen (8), but not the spectra reported by two other research groups (6, 7). Thus **1***b* pyrolyzes cleanly to **3** and acetonitrile under the conditions employed in this study without forming significant amount of 2-methylbenzazete and biphenylene.

[4] The HAM/3 HOMO of **2***a* is a π-type MO with coefficients on N=C (0.437 and 0.299), the bridging C=C (–0.398 and –0.392), and on the remaining carbon atoms (–0.071, 0.423, 0.356, and –0.197). HOMO-1 is a π-type MO located predominantly on the phenyl ring (0.295, –0.365, 0.498, –0.164, 0.277, 0.505) with small coefficients being found on N=C (0.107 and –0.109). HOMO-2 is a σ-type in-plane orbital involving N (the lone pair), the carbons of the azete ring, and one of the benzene ring. HOMO-3 is a π-type MO with coefficients on N=C (–0.394 and –0.339), and four carbons of the benzene ring (0.304, 0.435, 0.420, 0.251) excluding the bridging C=C bond.

[5] According to the HAM/3 and HF/6-31G** calculations, the HOMO and HOMO-1 of **3** are π-type MOs and HOMO-2 is the in-plane orbital involving the carbons of the triple bond. Because ab initio calculations at the 4-31G level of theory have shown that the phenyl cation is highly distorted relative to benzene (15), is possible that the radical cation nominally derived from **3** by loss of an electron from this in-plane orbital may exhibit a broad Franck–Condon envelope. Perhaps this accounts for the shape, a relatively sharp peak overlapping a broad band, of the low-IP band(s) of **3**.

Crystal chemistry of tetraradial species. Part 7. Lithium tetrakis(1-imidazolyl)-borate solvate, $Li^{iv}[Li^{iv}(H_2O)(MeOH)][B(C_3H_3N_2)_4]_2 \cdot MeOH$, a 3-dimensional polymer; with observations on the geometry of imidazole rings[1]

Osvald Knop and Pradip K. Bakshi

Abstract: The title compound is a 3-dimensional polymer with a completely ordered triclinic structure ($P\bar{1}$, a = 12.380(2) Å, b = 14.434(2) Å, c = 9.683(3) Å, α = 90.36(2)°, β = 105.44(2)°, γ = 90.75(2)°, Z = 2). Every B atom is tetrahedrally coordinated by N(1) atoms of the imidazole rings, every Li(1) atom is tetrahedrally coordinated by N(3) atoms, and every Li(2) atom is coordinated by two N(3) and two oxygen atoms, one from the H_2O molecule and one from a MeOH molecule. The imidazole rings connected by the B—N(1) and Li—N(3) bonds thus generate a 3-dimensional covalent polymeric network. The MeOH molecules of coordination are hydrogen-bonded to unengaged N(3) atoms, thereby supplementing the covalent bonding system. The H_2O molecules are hydrogen-bonded to the MeOH molecules of solvation to form centrosymmetric $[O_w...O_{MeOH}]_2$ rings, which in turn are connected to the covalent network by O_{MeOH}—H...N(3) bonds to the remaining unengaged N(3) atoms. Every atom in the structure except the H(C) hydrogens is thus involved in the 3-dimensional bond system. The excellent consistency of the bond lengths and endocyclic bond angles ϕ in the eight imidazole rings of the title compound has provided an opportunity for investigating the effect of substitution on the geometry of the imidazole ring in a sample of 17 substituted imidazoles. While the bond lengths have been found at most weakly correlated, the multilinear correlations of the ϕ in this sample are highly significant. Among the substituents the NO_2 group is the most *ipso*-ϕ-expanding and the anionic B (in the title compound) the most *ipso*-ϕ-contracting. Protonation or deprotonation at the N atoms affect the *ipso* C—N—C angles considerably. Limited comparisons are drawn with the results of the classical investigations by Domenicano et al. on the effect of substitution on the geometry of the benzene ring.

Key words: hydrogen bond, imidazole, lithium compounds, polymers, tetrahedral boron ions.

Résumé : Le composé mentionné dans le titre est un polymère tridimensionnel avec une structure triclinique complètement ordonnée ($P\bar{1}$, a = 12,380(2) Å, b = 14,434(2) Å, c = 9,683(3) Å, α = 90,36(2)°, β = 105,44(2)°, γ = 90,75(2)°, Z = 2). Chaque atome de bore est coordonné de façon tétraédrique par les atomes d'azote N(1) du cycle imidazole, chaque atome de lithium Li(1) est coordonné de façon tétraédrique par les atomes d'azote N(3) et chaque atome de lithium Li(2) est coordonné par deux atomes d'azote N(3) et par deux atomes d'oxygène, un provenant de l'eau et l'autre provenant de la molécule de MeOH. Les cycles imidazole reliés par les liaisons B—N(1) et Li—N(3) forment alors un réseau polymérique tridimensionnel. Les molécules de MeOH de coordination sont liées par des liaisons hydrogène aux atomes d'azote N(3) non engagés, renforçant ainsi les liaisons covalentes du système. Les molécules d'eau sont liées par des liaisons hydrogène aux molécules de MeOH de solvatation pour former des cycles centro-symétriques $[O_{eau}...O_{MeOH}]_2$ qui sont à leur tour reliés au réseau covalent par des liaisons O_{MeOH}—H...N(3) aux atomes de N(3) non engagés restants. Chaque atome de cette structure, à l'exception des hydrogènes H(C), est alors impliqué dans le système de liaison tridimensionnelle. L'excellente cohérence existant entre les longueurs de liaison et les angles de liaison endocycliques ϕ dans les huit cycles imidazoles du composé mentionné dans le titre fournit l'opportunité d'étudier l'effet de la substitution sur la géométrie du cycle imidazole dans un échantillon de 17 imidazoles substitués. Alors que les longueurs de liaisons tout au plus correspondent faiblement, les corrélations multilinéaires de l'angle ϕ dans cet

échantillon sont très fortement significatives. Parmi les substituants, le groupe NO_2 est le plus *ipso*-ϕ-dispersant et le groupe anionique B (dans le composé mentionné dans le titre) est le plus *ipso*-ϕ-contractant. La protonation ou la déprotonation des atomes d'azote affecte considérablement les angles *ipso* C—N—C. On établit des comparaisons limitées avec les résultats des études classiques effectuées par Domenicano et al. sur l'influence de la substitution sur la géométrie du cycle benzénique.

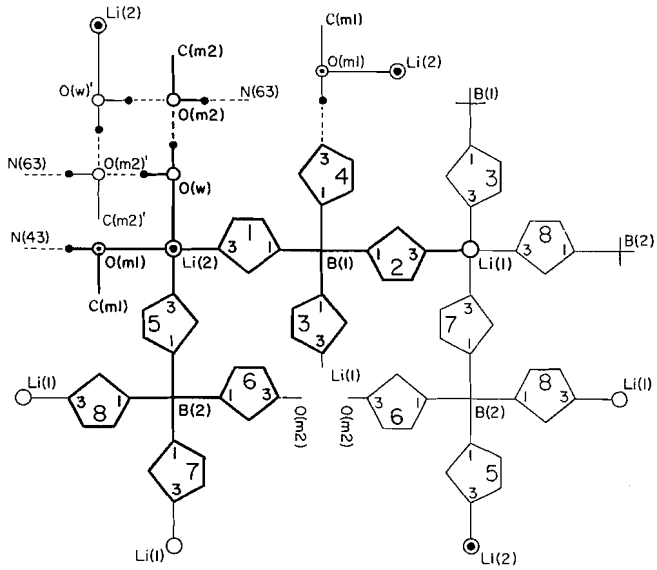
In Part 6 (1) we described the crystal structure of $[Li(H_2O)_4]BPh_4$, in which the four water molecules coordinating the Li^+ ion all form O—H...π hydrogen bonds to the phenyl groups and all the phenyl groups are H-bonded, thus giving rise to a 3-dimensional, completely H-bonded polymeric network. Curious to find out how the O—H...π bonding might compete with other possible interactions, we set out to prepare the Li salt of the tetrakis(1-imidazolyl)borate anion (TIB), $B(C_3H_3N_2)_4^-$, by metathesis of its Na salt (2, 3) with LiCl in aqueous methanol. The colourless crystals resulting from an exploratory experiment turned out to be neither the $Li(H_2O)_4^+$ nor the $Li(MeOH)_4^+$ salt of TIB but the title compound (TC). This has an interesting triclinic structure in which one Li atom is coordinated by four imidazole (Im) nitrogens and another by two nitrogens, an H_2O oxygen, and an MeOH oxygen. The composition of TC can thus be formulated as $Li^{iv}[Li^{iv}(H_2O)(MeOH)][B(C_3H_3N_2)_4]_2 \cdot MeOH$.[1] The basic structure motif corresponding to this formula is represented schematically in Fig. 1, which shows the coordination within the motif as well as the connectivity of the structure, and again in a crystallographic projection (Fig. 2), where the connectivities of the covalent (B—N, Li—N) and the H-bonding networks have been separated for clarity.

The crystal data of TC are assembled in the Experimental and the positional parameters of the nonhydrogen atoms in Table 1. The positional parameters and isotropic temperature factors of the hydrogens (Table A), the anisotropic thermal parameters of the nonhydrogen atoms (Table B), the interatomic distances and bond angles (Table C), and the deviations of the C and N atoms from the best planes through the Im ring skeletons (Table D) have been deposited.[4]

Organization of the structure

The distribution of the B and Li atoms in the TC structure does not lend itself to a simple description. The B atoms are attached exclusively to N(1) atoms[5] (rings 1—4 on B(1), rings 5–8 on B(2)), while the Li—N bonds involve only N(3) atoms, Li(1)—N(3) in rings 2, 3, 7 and 8, Li(2)—N(3) in rings 1 and 5.

Fig. 1. Schematic representation of the basic motif of the title compound. The heavy-line portion corresponds to the formula in text. The oxygen atoms O(w), O(m1), and O(m2) are, respectively, those of the H_2O molecule, the MeOH of coordination, and the MeOH of solvation. Small full circles represent H atoms. Small 1 and 3 stand for N(1) and N(3), respectively; the large numbers identify the imidazole rings.



The N(3) atoms in rings 4 are H-bonded to MeOH molecules m1 coordinated to Li(2), and those in rings 6 are H-bonded to MeOH molecules m2 of solvation, as are the H_2O molecules w. The preferential formation of Li—N bonds on crystallization from MeOH–H_2O thus indicates that the Li—N rather than the Li—O interaction is dominant in these circumstances.

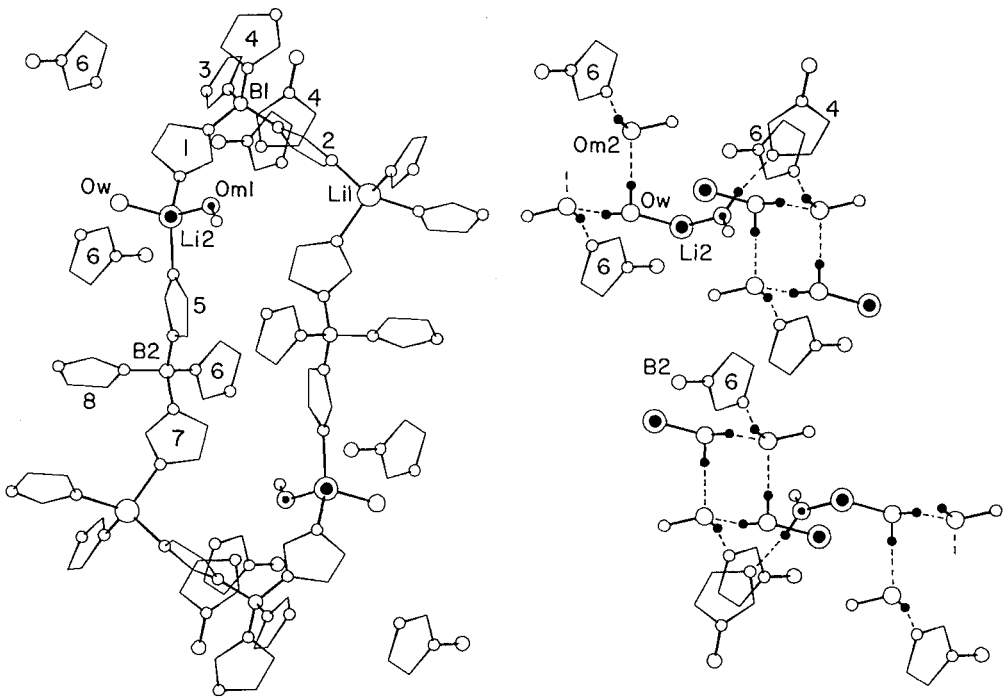
The O(w) and O(m1) atoms are 3-coordinate (Fig. 3), with the Li(2)—O(w) and Li(2)—O(m1) vectors roughly bisecting the angle between the two lone electron pairs on the oxygen atom. The O(m2) oxygen is 4-coordinate.

The anisotropic thermal parameters of all the nonhydrogen atoms are reasonable, with the exception of C(m1) of the coordinated MeOH molecule, for which the U_{ij} values are very large, with U_{ii} between 0.22 and 0.32 Å^2 (Table B). This is the only nonhydrogen atom in the otherwise completely ordered TC structure that shows positional disorder, very likely dynamic. The hypothesis that the large U_{ij} arise from a mixed MeOH,H_2O occupancy was rejected as only marginally probable, as it did not lead to a significant reduction of the U_{ij}(Cm1) and the refined occupancy factor for Cm1 was 0.83(2).

[4] This material can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. Tables A–C have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

[5] *Housekeeping note.* The numbering of the Im ring atoms is standard, cf. Fig. 4. Crystallographic esd's are shown in parentheses. Standard deviations of means of distances, bond angles, etc. are shown in brackets; they do not include the esd's of the component values, and the means are computed with unit weights.

Fig. 2. Crystallographic projection of a portion of the structure of the title compound giving a relatively unobstructed view of the basic motif. (*Left*) Connectivity in the B,Li,Im system; MeOH of solvation (m2) omitted. (*Right*) The H-bonding system only. Both views correspond to the schematic of Fig. 1. Ring H atoms omitted for clarity. The numbers of atoms and rings attached to the B(1), B(2), Li(1), and Li(2) atoms correspond to the atom numbering of Table 1.



Bond lengths and angles

A detailed list of interatomic distances and bond angles in TC is given in Table C. The eight B—N bond lengths are closely similar, with a mean of 1.542[4] Å. The N—B—N valence angles range from 107.8(3)° to 111.6(3)°, with $\sigma = 1.2°$ on the tetrahedral 109.48° mean. There is no indication of a tendency of the BN_4 tetrahedron toward an S_4 symmetry, such as is often observed in the C—B—C valence angle α of the $BC(\alpha)_4$ tetrahedron in the tetraphenylborate anion (4, 5).

The d(Li—N) means for Li(1) and Li(2) are statistically indistinguishable, i.e. there is no observable effect of the mixed N, O coordination at Li(2) on d(Li—N). The mean Li—N bond length, 2.054[14] Å, is within 2σ of the Li—N bond lengths in $[Li^{iv}py_4]$ and in the $[Li^{iv}(Et_8\text{-porphyrin})]^+$ cation (Table 2). However, there seems to be no clear-cut separation between the $d(Li^{iv}—N)$ and the corresponding bond lengths with Li in 3- or 5-coordination in Table 2. With the exception of ring 5 the Li atom is significantly non-coplanar with its associated Im rings.

The Li(2)—O distances, to the H_2O and MeOH oxygens, respectively, fall in the general, broad range of Li^{iv}—O distances (Table 2; ref. 18).

The mean of the two O(w)...O(m2) distances in the planar $[O(w)...O(m2)]_2$ dimer is 2.854[7] Å, i.e. larger than the mean shortest O...O distance in ordinary ice, 2.76[1] Å (Fig. 3). The O...N distances O(m1)...N(43)″ = 2.718(5) Å and O(m2)...N(63)‴ = 2.681[4] Å (Table C) are comparable to the O...N distance in the O—H...N bond in $N_2H_4 \cdot 4MeOH$, 2.682(6) Å (19), but significantly shorter than similar distances in $N_2H_4 \cdot 2MeOH$, 2.730(6) Å (20), and $N_2H_4 \cdot H_2O$, 2.790(6) Å (21).

The imidazole rings

The variation in the (uncorrected) N—C and C—C bond lengths and in the endocylic bond angles ϕ in the eight Im rings of TC is remarkably small. The standard deviations of the means amount to 0.003–0.007 Å for the bond lengths and 0.3–0.4° for the angles (Table C), i.e. the sample populations for the five bond lengths and the five ϕ angles are very homogeneous. The ring skeletons are planar within 0.002[1] Å (Table D). The bond lengths and angles in TC are compared to those in Im, ImH^+, and a number of substituted imidazoles (sample **S**)[6] in Tables 3 and 4.

The d_{23} and d_{34} bond lengths in TC are the same as in unsubstituted Im; d_{12} and d_{51} in TC are increased, and d_{45} is decreased, but the changes are small compared to the respective overall bond-length variations in **S**: the largest difference, $d_{12}(TC) - d_{12}(Im) = 0.012$ Å, is at the limit of 3σ statistics.

While the data of Table 3 are informative in various ways, they also show the general difficulty of establishing a rationale for the sign and magnitude of the changes in d_{ij}(Im) on substitution, especially when more than one substituent is present. In this TC is no exception. The ranges of the individual (uncorrected) bond lengths in **S** are narrow, 0.044–0.058 Å, i.e., on the average ~4% of the bond length. An analysis along

[6] The sample **S** of Table 3 has been assembled mainly on the quality of the structure determinations retrieved from the Cambridge Structural Database, without regard to the nature of the substituents save for their simplicity. It does not include structures in which Im is a ligand to a (heavy) metal atom in a discrete coordination complex or in which the Im ring is part of a larger fused ring system.

the lines of the classical investigations of Domenicano et al. (22–25) into the geometrical effects of substitution in benzene is precluded here partly because of the chemistry of **S** (multiple substitution, unsuitable combinations of substituents) in relation to its size, partly because of the heterocyclic nature of the Im ring. In benzene as reference the endocyclic angles are 120° by symmetry and only one skeletal bond length needs to be determined by experiment, whereas in Im as reference all five bond lengths and all five internal angles of this molecule must be supplied from experiment. It comes therefore as no surprise that such multilinear correlations as we have found to exist between the bond lengths in **S** are weak, although we do not know whether this is due to sampling deficiencies in **S** or to a real lack of correlation. For example, expressing d_{45} in terms of the other four bond lengths one obtains $d_{45} = 0.112 + 0.320d_{12} + 0.708d_{23} + 0.261d_{34} - 0.349d_{51}$ ($n = 18$, $r^2 = 0.56$, $\sigma = 0.009$ Å $\sim$ 20% of d_{45} range). The sums of the bond lengths in the ring range from 6.672 Å in **1** to 6.795 Å in **11** = TC. However, it is probable that this variability comes, like for benzene rings, from uncorrected thermal motion and sample inhomogeneity (25).

The ϕ_i angles offer more scope for informative data analysis. Because of geometrical constraints, and in contrast to the bond lengths, significant correlations can be expected and indeed are observed (see below). In a planar Im ring, $\Sigma\phi_i = 540°$. A change $\Delta\phi_i = \phi_i - \phi_i(\text{Im})$ produced by substitution at atom i will tend to be counteracted by attendant compensating changes of opposite sign in the angles at atoms adjacent to atom i, and $\Sigma\Delta\phi_i = 0$. The existence of such correlations is

suggested by inspection of ϕ_i in Table 4. Indeed, the partial (pairwise) correlation coefficients r_{ij} for adjacent ϕ_i, ϕ_j angles in the Im rings of **S** range from −0.64 to −0.87, whereas for nonadjacent angles they are between −0.02 and +0.54 (Fig. 4). For TC specifically, the expected compensation (>2σ) in the adjacent angles is observed clearly for ϕ_1 and ϕ_2, less clearly for ϕ_3 and ϕ_5, and not for ϕ_5, although where ϕ_4 is involved the smallness and possibly a sign uncertainty of $\Delta\phi_4$ may be a factor:

	ϕ_1	ϕ_2	ϕ_3	ϕ_4	ϕ_5
$\Delta\phi_i$	−2.3(4)°	1.7(4)°	−0.9(5)°	0.5(4)°	1.1(4)°
ϕ_i range in **S**	7.6°	7.1°	6.0°	7.0°	8.1°
% of range	30(5)	24(4)	15(8)	7(6)	14(5)

[g]4,4′,5,5′-Tetranitro-2,2′-biimidazole dihydrate.

[h]Diammonium salt of the 4,4′,5,5′-tetranitro-2,2′-biimidazolium anion.

The change $\Delta\phi_1$ produced by substituting the H atom on N(1) in Im by the anionic B atom is large, about a third of the ϕ_1 range, and negative. Both the sign and the order of magnitude of this $\Delta\phi_1$ are consistent with what is observed on similar substitution in benzene, e.g., in BPh_4^- or for —N—BPh_3 (mean ϕ, 115[1]°, refs. 4 and 5). It is not known whether the smaller $\Delta\phi_1$ in TC is attributable to the electronic difference between N and C or to the smaller local angle deformability of the Im ring compared with the larger 6-membered benzene ring.[7] The magnitude of the change in ϕ_3 associated with the cationic Li addition to N(3) is uncertain, but its sign appears to be correct: $\Delta\phi_3$ obtained from the correlation equation $\phi_3 = f(\phi_1, \phi_2, \phi_3)$ involving the ϕ_i with the three largest $|\Delta\phi_i|$ in TC (see below) is −1.1°, i.e., *statistically* in good agreement with observation.

To place these $\Delta\phi_i$ changes in an overall context of Im geometry and to relate them to the nature of the substituent, the ϕ_i at the substituted atom in **S** are plotted in Fig. 5 (left) against the corresponding ϕ_i in Im, as are also the *dependent* ϕ_i at the unsubstituted atoms (Fig. 5, right). From these plots one can draw the following conclusions:

(1) As seen in Fig. 5 (left), with the exception of ϕ_4(**17**) and ϕ_5(**16**) (cf. below), all the points for NO_2-substituted Im rings in **S** fall above the 45° ($x = y$) line, $\Delta\phi_i(NO_2) > 1.0(3)°$. This means that the NO_2 group expands (or at least does not contract) ϕ at its ring atom, regardless of other substitution(s) on the ring. This parallels the finding of ref. 24 for 1-NO_2-4-X-benzene derivatives: the powerful σ-electron-withdrawing nitro group opens up the *ipso* C—C—C angle by ~2°. The largest $\Delta\phi_i(NO_2)$ in **S** are $\Delta\phi_4$(**6**) = 4.3(3)° and $\Delta\phi_1$(**6**) = 2.8(3)° in 1,4-dinitro-Im, $\Delta\phi_4$(**4**) = 4.0(3)°, and $\Delta\phi_5$(**17**) = 3.7(3)°.

The two exceptions involve the highly substituted 4,4′,5,5′-tetranitro-2,2′-biimidazole **16** and its anion **17**. In the latter, each ring of the 2,2′-biimidazole system carries an anionic charge and has a C_{2v} symmetry, within the esd statistics. The effect of the σ-electron releasing deprotonation at N(1) is to decrease ϕ_1 by a significant amount: $\Delta\phi_1 = -4.8(3)°$. This ϕ_1 reduction requires a compensatory increase in the adjacent angles ϕ_2 and ϕ_5. However, the NO_2 substitution at C(5) causes an increase in ϕ_5 in its own right, and the synergetic

[7] The importance of steric strain (which may result from attaching four Im groups to the B atom) for the magnitude of ϕ_1 in TC is difficult to assess but is likely to be small. In ZPh_4 (Z = C to Pb) the internal angle at C(α) is, within experimental accuracy, the same regardless of the length of the Z—C(α) bond: the C(2)—C(1)—C(6) mean for the series is 117.4[4]°. If steric strain were a factor, this angle would be expected to increase with the Z—C(α) bond length, which increases from 1.55 Å for Z = C to 2.20 Å for Z = Pb (Borecka, Knop, and Cameron, to be published), a significant change.

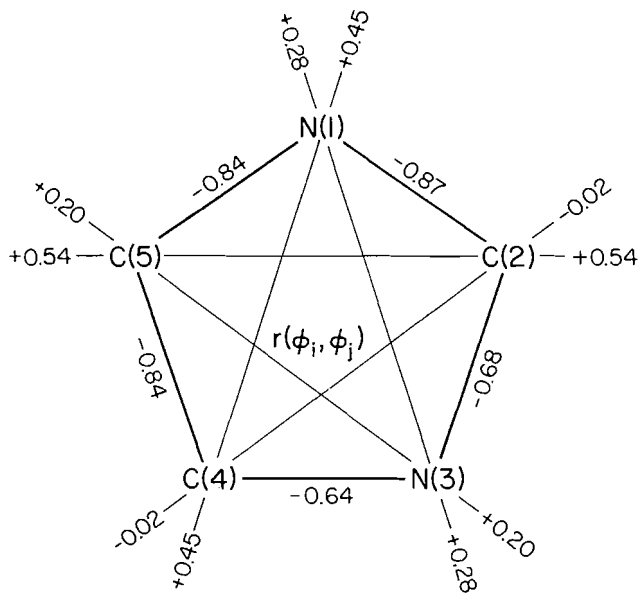
[a]Arranged in the order of increasing ϕ_2 = N(1)—C(2)—N(3). For footnotes see Table 3.

Fig. 4. Atom numbering in the imidazole ring and the pairwise correlation coefficients $r_{ij} = r(\phi_i,\phi_j)$ for the endocyclic ϕ angles in the imidazole rings of sample **S** (Table 4).



effect of the two interventions results in a large $\Delta\phi_5$, 3.7(3)°. The angle ϕ_2, which is expected to increase in consequence of the reduction in ϕ_1, is also affected by the partner-ring substitution at C(2), the combined effect being $\Delta\phi_2$ = 4.1(3)°. The three changes $\Delta\phi_1 + \Delta\phi_2 + \Delta\phi_5$ thus require a total compensation at ca −3.0°, which leaves no scope for a significant *positive* $\Delta\phi_4$ at C(4), the site of the other NO_2 substitution; in fact, $\Delta\phi_4$ = −0.3(3)°. In **16**, $\Delta\phi_4$ = 1.2(3)° and $\Delta\phi_5$ = 0.0(3)°. In contrast to **17**, $\Delta\phi_2$ is only 0.7(3)°. It is thus probable that the unusually large ϕ_2 in **17** is mainly the consequence of the deprotonation at N(1). This, however, does not explain the smallness of $\Delta\phi_2$(**16**).

(2) In TC = **11**, $\Delta\phi_1$ = −2.3(3)°, a significant contraction. This again parallels the substitution in benzene, where the σ-electron-releasing anionic $-BPh_3^-$ group was found (24) to be the most powerful contractor of the *ipso* C—C—C internal angle.[7] Here again the decrease in ϕ_1 (TC) is only about half that observed in BPh_4^- (cf. above). The negative sign of $\Delta\phi_3$ on Li^+ addition is consistent with the electronegativity of Li.

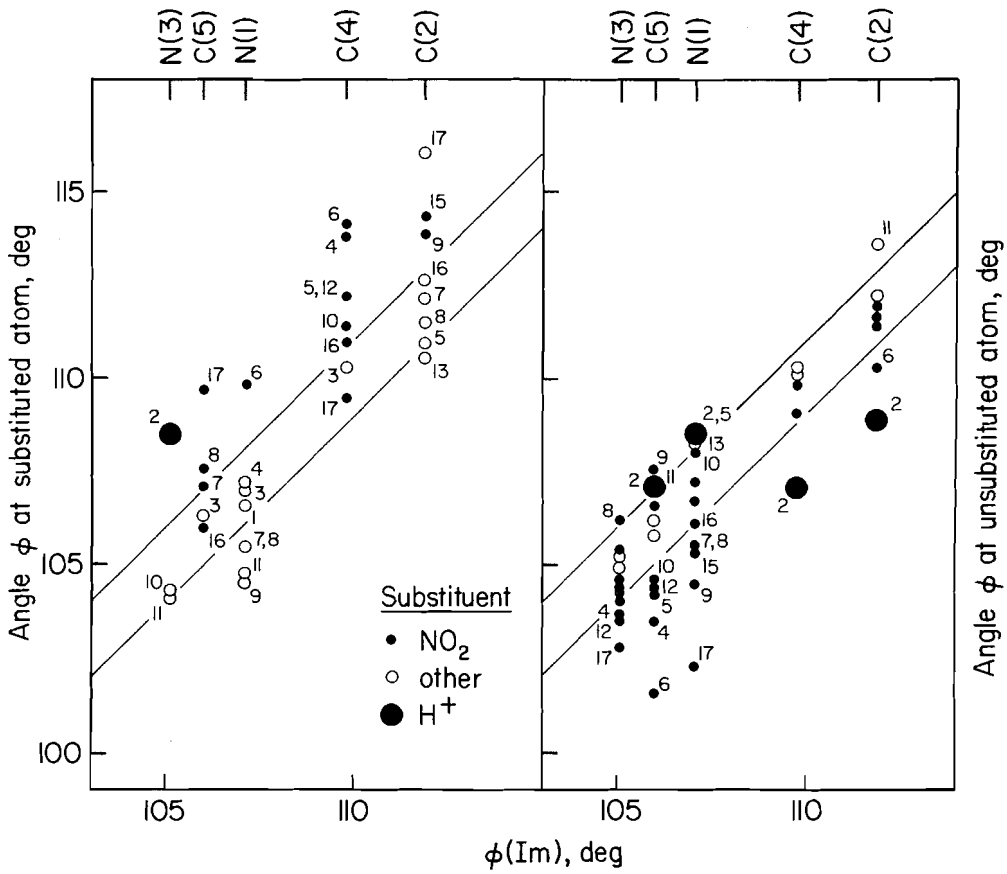
(3) Protonation at N(3) in Im to give ImH^+ (**2**) is associated with a substantial increase in the *ipso* angle, ~3.4°, and with large corresponding changes in the adjacent angles ϕ_2 and ϕ_4. This compares with the change observed in **17** for the opposite process, deprotonation at N(1), for which $\Delta\phi_1$ = −4.8(3)°.

(4) As seen in Fig. 5 (right), large $\Delta\phi$ changes at substituted atoms are compensated, mostly unequally, by corresponding opposite changes at the adjacent atoms. The points in the plot are redistributed accordingly.

Multilinear correlations of ϕ_i

For a sample as diverse as **S** the pairwise correlation coefficients r_{ij} for adjacent angles (Fig. 4) are sufficiently large to make one look for possible *multilinear* interdependence of the ϕ_i. The condition $\Sigma\phi_i$ = 540° reduces the multilinear regression to a four-parameter problem, $\phi_j = a_0 + \Sigma_{mnp} a_i\phi_i$. Indeed, the correlations obtained in the individual regressions are high: $0.88 < r^2 < 0.98$ (Table 5). For example, for the angle ϕ_2 = N(1)—C(2)—N(3) (facing the C=C bond in Im), $\phi_2 = 282.1 - 0.485\phi_1 - 0.859\phi_3 - 0.257\phi_4$ (n = 18, r^2 = 0.972, σ = 0.3° ~ 4% of ϕ_2 range). This high correlation confirms, statistically, the existence of asymmetric compensation of a change in ϕ_2 by changes in the adjacent angles ϕ_1 and ϕ_3, but it also reveals the extent of involvement of angles at second-

Fig. 5. Effect of substitution on the endocyclic angles ϕ_i in imidazole. (*Left*) The endocyclic angle ϕ_i at the substituted atom in the Im rings of Table 4 plotted against the corresponding angle in unsubstituted Im. Code numbers as in Tables 3 and 4. The vertical width of the 45° band is 2°, corresponding approximately to ±3(esd) on ϕ_i. (*Right*) The corresponding plot of ϕ_i at the unsubstituted ring atoms. The rings represented by the small black circles contain at least one NO_2 substituent.



nearest neighbours of C(2). In general, a change in ϕ_i induced by substitution at atom *i* cannot always be accompanied by changes of the opposite sign in the angles at *both* adjacent atoms (Table 4). This is due to the impossibility of satisfying cyclic sign alternation of $\Delta\phi_i$ in an odd-membered planar ring. In this respect the effects of substitution on the ϕ_i in Im differ from those in benzene, investigated by Domenicano et al. (22–25).

While we have not investigated *mixed* ϕ_i,d_{ij} correlations in detail, it seems that they do not add to the information obtained from the angle correlations alone. For ϕ_2, for example, regression on the length d_{45} of the bond opposite ϕ_2 and on the adjacent angles ϕ_1 and ϕ_3 resulted in $r^2 = 0.963$, $\sigma = 0.3° \sim 4\%$ of ϕ_2 range, while a regression of ϕ_2 on ϕ_1 and ϕ_3 alone gave $r^2 = 0.961$, $\sigma = 0.3°$. The contribution of the d_{45} term to ϕ_2 in the regression equation is only of the order of 0.1–0.2°, i.e. comparable to the experimental esd's. A ϕ_2 regression on ϕ_4, ϕ_5, and d_{45} gave $r^2 = 0.83$, $\sigma = 0.7° \sim 10\%$ of ϕ_2 range, with the d_{45} term accounting for only ~0.2% of the combined contribution from the two angles.

Although further statistical inferences could probably be obtained by identifying additional angle correlations in **S** (e.g. possibly concerning π electron involvement), these have not been attempted for fear of *Quis nimis probat nihil probat.*

Conclusions

The title compound is, to our knowledge, a 3-dimensional polymer of a novel type. Its structure is made up of two networks. The primary, covalent network consists of imidazole rings connected by B—N(1) and Li—N(3) bonds in tetrahedral arrays. The secondary, H-bonded network connects the remaining N(3) atoms, uninvolved in the covalent network, to the H_2O and MeOH molecules coordinated to Li(2), with the MeOH molecule of solvation acting as a H-bonding intermediary between the H_2O molecule and an N(3) atom (Fig. 1). The H_2O molecules and the MeOH molecules of solvation form centrosymmetric H-bonded dimer pairs. The Li—N interaction dominates the structure in spite of the ample opportunity for Li—O bonds to form, preferentially, during crystallization.

The homogeneity of the skeletal bond lengths and endocy-

clic bond angles ϕ in the eight imidazole rings of the title compound invites comparison with the geometries of other such rings. A sample of imidazole rings in seventeen compounds (including unsubstituted imidazole as reference) was analyzed for correlations between the bond lengths and between the ϕ angles. While the bond lengths in a ring are not correlated or at most weakly so, multilinear correlations between the ϕ angles are highly significant and reveal the extent of involvement of changes in the angles at the adjacent as well as nonadjacent ring atoms. Among the substituents represented in the sample the NO_2 group is the most powerful expander and the anionic B atom the most powerful contractor of the *ipso* angle in the ring. The general conclusions parallel those formulated for substitutions in benzene by Domenicano et al. (22–25), but important differences arise from the heterocyclic and odd-member character of the imidazole ring.

Experimental

Preparation

Methanolic solutions of LiCl and the commercially available $NaB(C_3H_3N_2)_4$ were combined in a 1:1 molar ratio, a small amount of water was added to reduce the evaporation rate, and the resulting solution was allowed to crystallize by evaporation at room temperature. No effort was made to protect the solution from contact with atmospheric CO_2, a precaution recommended in ref. 2.

Crystallographic data

$B_2C_{26}H_{34}Li_2N_{16}O_3$, fw 654.2. Crystal size, 0.35 × 0.25 × 0.25 mm^3, $\mu_{Mo} = 0.84$ cm^{-1}; Rigaku AFC5R single-crystal diffractometer, λ = 0.71069 Å; θ-range, 2–23°; unit-cell dimensions and orientation matrices from 23 carefully centred reflections; $T \sim 21$°C. Space group $P\bar{1}$ (no. 2); a = 12.380(2) Å, b = 14.434(2) Å, c = 9.683(3) Å, α = 90.36(2)°, β = 105.44(2)°, γ = 90.75(2)°, V = 1668(1) Å^3, Z = 2, ρ_c = 1.303(1) g/cm^3, $F(000)$ = 684. Total reflections measured, 4901; unique reflections, 4648, R_{merg} = 3.2%; unique reflections used ($I > 3\sigma(I)$), 2620. No absorption correction. Although α and γ are very close to 90°, the symmetry is unambiguously triclinic: the three monoclinic space groups with no systematic absences, viz. *Pm*, *P*2, and *P*2/*m*, were ruled out by the unacceptably high $R_{merg}(F^2)$ values, ~90% compared to 3.2% for $P\bar{1}$.

Structure solved by direct methods (43) and refined by TEXSAN-TEXRAY (44), using the $w = 4F_o^2/\sigma^2(F_o^2)$ weighting scheme. Anisotropic temperature factor, exp $[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. The nonhydrogen atoms were refined without constraints. The H(C) atoms were placed geometrically at C—H = 1.08 Å. The H(O) atoms were located from a difference map and then constrained (O—H = 1.00 Å). The H(X) were assigned isotropic temperature factors, $U_{iso} = 1.2U_{eq}$(X); their positions were not refined, R = 3.9%, R_w = 4.0%, G.O.F. = 2.02; d/p = 5.9. Residual electron density in final difference map, −0.20/+0.17 e/Å^3.

Synthèse de divers types d'hétérocycles fonctionnels par décomposition de peroxydes insaturés : réactions compétitives

E. Montaudon, L. Lemée et M-J. Bourgeois

Résumé : La décomposition de peroxydes γ-insaturés substitués dans un solvant bon donneur d'hydrogène peut conduire à deux oxétanes isomères de configuration. La substitution homolytique intramoléculaire consécutive à la première étape d'addition peut être concurrencée par un transfert intramoléculaire d'hydrogène 1,5 suivi d'une cyclisation. Les facteurs influençant cette compétition, non signalée à notre connaissance, sont déterminés.

Mots clés : peroxydes insaturés, oxétanes, substitution homolytique intramoléculaire, transfert d'hydrogène intramoléculaire 1,5.

Abstract: Decomposition of γ-unsaturated substituted peroxides in a good hydrogen donor solvent can lead to two diastereoisomeric oxetans. An intramolecular 1,5 hydrogen shift followed by a cyclization may compete with the homolytic intramolecular substitution following the first addition step. The factors governing this never-reported competition are determined.

Key words: unsaturated peroxides, oxetans, homolytic intramolecular substitution, intramolecular 1,5 hydrogen shift.

Lors d'études antérieures (1), nous avons montré que la décomposition induite de peroxydes insaturés dans un solvant donneur d'hydrogène conduit avec de bons rendements à des hétérocycles fonctionnels, parfois accompagnés de peroxydes adduits. Le peroxyde de 1-allylcycloheptyle et de *tert*-butyle présente un comportement différent puisque, à côté des produits précités, il apparaît un nouveau composé, en quantité non négligeable. La détermination de la structure de ce dernier a entraîné une hypothèse de mécanisme de réaction originale, compétitive de celles habituelles. Ce travail décrit les résultats obtenus lors de cette décomposition et la démonstration du mécanisme proposé.

1. Décomposition du peroxyde de 1-allylcycloheptyle et de *tert*-butyle

La décomposition du peroxyde de 1-allylcycloheptyle et de *tert*-butyle, **1***a*, est effectuée dans les conditions définies précédemment (1), à savoir : chauffage à 100°C durant 12 h d'un mélange constitué de dichlorométhane, peroxyde, peracétate de *tert*-butyle, carbonate de sodium anhydre dans les rapports molaires 100/1/0,5/2. Le dichlorométhane est choisi pou sa simplicité de mise en œuvre; le peracétate de *tert*-butyle joue le rôle d'amorceur radicalaire et le carbonate de sodium est garant de la stabilité de l'oxétane, susceptible de se former, dans les conditions de réaction. À côté du 2-(2,2-dichloroéthyl)-1-oxa-spiro[3,6]décane, **2***a* (30%), et du peroxyde de *tert*-butyle et de 1-(4,4-dichlorobutyl)cycloheptyle, **4***a* (6%), normalement attendus (figure 1), un autre composé, X, est isolé par chromatographie liquide–solide sur alumine (20%).

1.1. Détermination de la structure de X

Le spectre de masse de X, en ionisation chimique, présente un amas isotopique à 236–238–240 dénonçant la présence de 2 atomes de chlore; il s'agit donc d'un composé de formule brute $C_{11}H_8OCl_2$, isomère de **2***a*.

Le spectre infrarouge montre l'absence de fonction OH et de double liaison; X est donc un éther bicyclique.

Dans le spectre RMN ^{13}C, il apparaît un atome de carbone quaternaire, deux tertiaires et huit secondaires. Les déplacements chimiques des carbones tertiaires (C_t) et quaternaire (C_q) (73,5–75,3 et 86,2) suggèrent la présence des motifs C_q-

O-C_t et -$CHCl_2$. Ces informations amènent à imaginer pour X les structures A ou B (figure 1). Les spectres ^{13}C de A et B sont calculés à partir de celui du peroxyde de *tert*-butyle et de 1-(4,4-dichlorobutyl)cycloheptyle, **4***a*. Le substituant «O-Ca» est assimilé à un groupe OR introduit sur les carbones c ou d; les perturbations empiriques induites sont de l'ordre de +51, +5 et −4 sur les positions α, β et γ respectivement (2). Les estimations et les valeurs observées sont rassemblées dans le tableau 1. La comparaison avec le spectre réel indiquerait un meilleur accord avec la structure A : 23,4 et 24,2 ppm (C_e ou C_f); 33,5–33,9 et 37,9 (C_d, C_g ou C_h); 41,5 (C_b).

Le spectre RMN ^1H à 250 MHz comporte trois séries de signaux : un triplet à 5,7 ppm (1 H appartenant à $CHCl_2$), un massif entre 4,6 et 4,5 ppm (1 H) et un autre entre 2,7 et 1,4 ppm (16 H). Le signal observé entre 4,6 et 4,5 ppm est attribuable à un proton situé en α d'un atome d'oxygène. Or on sait que le déplacement chimique de ce type de proton dépend de la taille du cycle auquel il appartient : 3,3–2,8 ppm dans un oxirane, 4,8–4,5 ppm dans un oxétane et 4,2–3,9 ppm dans un tétrahydrofurane (1). X présente donc une structure oxétane.

L'ensemble des techniques spectroscopiques plaide en faveur d'une structure du type oxétanique bicyclique.

Un argument supplémentaire par voie chimique a été recherché. Les oxétanes et tétrahydrofuranes ne présentent pas la même stabilité : l'ouverture des cycles à 4 chaînons est très facile, contrairement à celle de leurs homologues supérieurs (3). Nous avons étudié le comportement d'oxétanes et de tétrahydrofuranes bicycliques (1) (figure 2), lors de leur chauffage à 110°C durant 10 h dans le dichlorométhane, en présence ou non de carbonate de sodium (rapports molaires CH_2Cl_2/hétérocycle/Na_2CO_3 : 100/0,3/2 ou 100/0,3/0). Si les tétrahydrofuranes restent intacts dans les deux cas, les oxétanes, stables en milieu basique, disparaissent en absence de base, se transformant en alcools monocycliques insaturés (figure 2). Un mécanisme de réaction a déjà été proposé (1).

Un échantillon de X, chauffé à 110°C dans le dichlorométhane, disparaît presque totalement (il en reste moins de 5%). De même, lorsque **1***a* est décomposé dans le dichlorométhane en absence de carbonate de sodium, ni **2***a* ni le composé X ne sont observés. Ceci confirme donc l'appartenance de X à la famille des oxétanes.

C'est donc bien la structure A qu'il faut retenir pour le composé X : il s'agit du 1-(4,4 dichlorobutyl)-7-oxa[4.1.1]bicyclooctane, **3***a*.

1.2. Mécanisme de la réaction

La formation des composés **2***a* et **4***a* met en jeu des réactions déjà décrites (1). L'addition d'un radical issu du solvant à la double liaison du peroxyde conduit à un radical adduit. Celui-ci peut évoluer par substitution homolytique intramoléculaire, S_Hi, ou par transfert d'hydrogène issu du solvant. Ce même radical adduit est probablement responsable de la formation de **3***a* : il se réarrangerait par transfert d'hydrogène intramoléculaire 1,5 en un radical isomère qui subirait à son tour les réactions habituelles, à savoir la S_Hi et l'arrachement d'hydrogène au solvant (figure 3). Il est logique d'imaginer que ce transfert 1,5 est réversible.

L'éventualité d'un transfert d'hydrogène 1,6, beaucoup moins souvent observé que le transfert 1,5 (4–6), ne doit pas être retenue car celui-ci donnerait lieu à la formation du composé cyclique B. Or, seuls deux composés hétérocycliques, **2***a* et **3***a*, ont été isolés.

Une telle compétition entre une substitution intramoléculaire et un transfert d'hydrogène intramoléculaire 1,5 condui-

sant à deux cycles différents n'a, à notre connaissance, jamais été signalée dans la littérature.

1.3. Influence de la température

L'influence de la température sur le cours de la réaction a été recherchée en réalisant la décomposition de **1***a* à 60, 80 et 140°C. La stabilité des oxétanes **2***a* et **3***a* dans les conditions opératoires a été testée. Les résultats sont rassemblés dans le tableau 2.

On observe que, à 140, 110 et 80°C, la quantité d'hétérocycles est la même (~50%), mais que le rapport **2***a*/**3***a* diminue nettement, le peroxyde adduit **4***a* restant très minoritaire. À 60°C où le phénomène devrait s'amplifier, la réaction est malheureusement très ralentie. Puisque la réaction de transfert d'un atome d'hydrogène du solvant intervient faiblement, ceci signifie, concernant les réactions unimoléculaires, que le transfert 1,5 est favorisé par rapport à la S_Hi par un abaissement de la température.

1.4. Comparaison avec nos travaux antérieurs

Lors de nos travaux sur les homologues à 6 et 5 chaînons du peroxyde **1***a* (1), un oxétane de type **3***a* a été vainement recherché. Son absence pourrait s'expliquer de deux manières : soit le radical adduit initialement formé ne donne pas lieu à un transfert d'hydrogène intramoléculaire 1,5, soit le radical isomère du radical initial ne peut subir la S_Hi.

L'examen des modèles moléculaires montre que, aussi bien à partir de **1***a* que du peroxyde de 1-allylcyclohexyle et de *tert*-butyle, **1***b*, le transfert semble possible. En effet, dans les deux cas, on peut obtenir l'alignement de la liaison C—H qui va se rompre et de l'orbitale atomique du centre radicalaire initial, indispensable dans l'état de transition (5) (figure 4). Par contre, à partir de l'homologue cyclopentyle, cette géométrie est difficile à envisager.

En ce qui concerne la deuxième étape régie par l'alignement de la liaison O—O et de l'orbitale du carbone radicalaire (7), si elle semble facile avec **1***a*, elle paraît probable quoique plus difficile avec **1***b* (figure 4), mais impossible avec l'homologue cyclopentyle.

Afin d'essayer de rechercher la bonne hypothèse, nous avons décomposé **1***b* dans le tétrachlorure de carbone.

Fig. 4

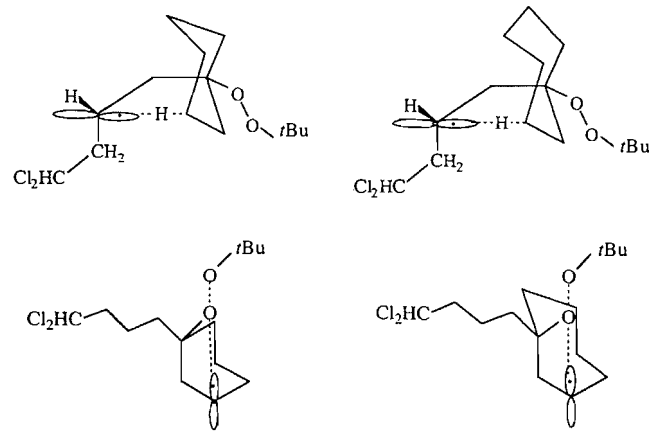

Fig. 5

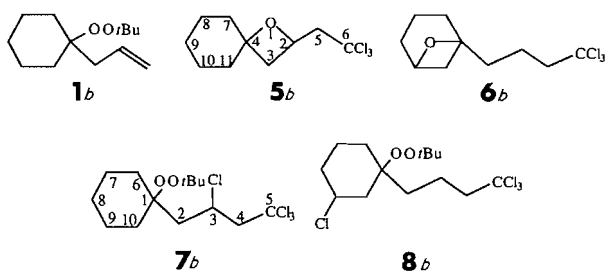


L'atome transféré du solvant au(x) radical(aux) est alors un chlore. Si le transfert 1,5 a lieu, les deux peroxydes adduits susceptibles de se former sont différenciables (figure 5). Cependant, le transfert d'un atome de chlore à partir de CCl_4 étant plus rapide que celui d'un atome d'hydrogène à partir de CH_2Cl_2, la réaction intermoléculaire peut exclure totalement celles intramoléculaires. Afin d'essayer de pallier cette difficulté, nous avons donc diminué la concentration du solant en utilisant un cosolvant, le benzène, relativement inerte dans les conditions de réaction (rapport molaire CCl_4/benzène : 20/80). Après réaction, nous avons isolé et vérifié la formation exclusive de 17% de 2-(2,2,2-trichloroéthyl)-1-oxa-spiro-[3,5]nonane, **5***b*, et de 39% de peroxyde de *tert*-butyle et de 1-(2,4,4,4-tétrachlorobutyl)cyclohexyle, **7***b*.

La présence de **5***b* indique que le transfert de chlore conduisant à **7***b* n'est pas suffisamment rapide pour inhiber d'autres évolutions du radical adduit, et en particulier la S_Hi. Le radical adduit ne semble pas évoluer par transfert d'hydrogène intramoléculaire : en effet, l'oxétane **6***b* et le peroxyde **8***b* qui en seraient issus ne sont pas mis en évidence. Or, si la stabilité dans le milieu de **6***b* (composé particulièrement tendu) n'est pas connue, il n'y a aucune raison pour que **8***b*, de structure très proche de **7***b*, se forme et se décompose dans les conditions de réaction. C'est essentiellement l'absence de **8***b* qui laisse penser que le radical adduit isomère ne s'est pas formé.

Il semble donc que, des deux hypothèses formulées, il faille retenir la première : la conformation du radical adduit serait telle qu'un transfert intramoléculaire 1,5 est impossible dans une structure cyclique à six chaînons, et donc a fortiori à cinq

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

chaînons, contrairement à ce qui est observé avec les homologues à sept chaînons.

2. Étude de la compétition S_Hi / transfert d'hydrogène 1,5

Une confirmation des résultats obtenus avec **1***a* et une meilleure connaissance du mécanisme passent par l'étude de modèles plus simples. Notre choix s'est porté sur les peroxydes acycliques indiqués ci-dessous. Nous nous sommes également intéressés au peroxyde de *tert*-butyle et de 1-méthallylcycloheptyle, **1***g*.

	$CH_2{=}C(R_a)\text{-}CH_2\text{-}C(R_b)\ (OOtBu)\text{-}CH_2\text{-}CH(R_c)CH_3$		
1*c*	$R_a = H$	$R_b = H$	$R_c = H$
1*d*	$R_a = H$	$R_b = H$	$R_c = Me$
1*e*	$R_a = Me$	$R_b = H$	$R_c = H$
1*f*	$R_a = H$	$R_b = Me$	$R_c = H$

2.1. Décompositions induites dans le dichlorométhane

Les composés susceptibles de se former lors de la décomposition des différents peroxydes acycliques dans le dichlorométhane sont présentés dans la figure 6 (Z-X = Cl_2CH-H). L'ensemble des résultats est consigné dans le tableau 3. Tous les produits sont isolés et leur structure déterminée grâce à leur spectre RMN ^{13}C, à l'exception de **4***d* et **4***e* identifiés par couplage CPG-SM dans le mélange réactionnel.

Quelques commentaires peuvent être faits :

(*i*) Les proportions d'oxétane(s) formé(s) sont toujours très supérieures à celles de peroxyde adduit, sauf dans le cas du peroxyde **1***c*. Ces oxétanes sont trisubstitués, sauf ceux issus de **1***c* qui ne sont que disubstitués. Nous avions déjà observé que les hétérocycles à quatre chaînons se forment d'autant mieux qu'ils portent plus de substituants (8). Cette différence avait été attribuée à l'intervention d'un effet Thorpe–Ingold.

(*ii*) La composition de la fraction oxétanique dépend de la classe de l'atome de carbone radicalaire. Lorsque les deux sites dans R et R′ sont secondaires (**1***c*, **1***f* ou **1***a*), les deux oxétanes sont présents, dans des proportions sensiblement voisines. Par contre, lorsqu'un site est secondaire et l'autre tertiaire, le seul oxétane mis en évidence correspond à une S_Hi au sein du radical le plus stable : **3** à partir de **1***d* et **2** à partir de **1***e* et **1***g*.

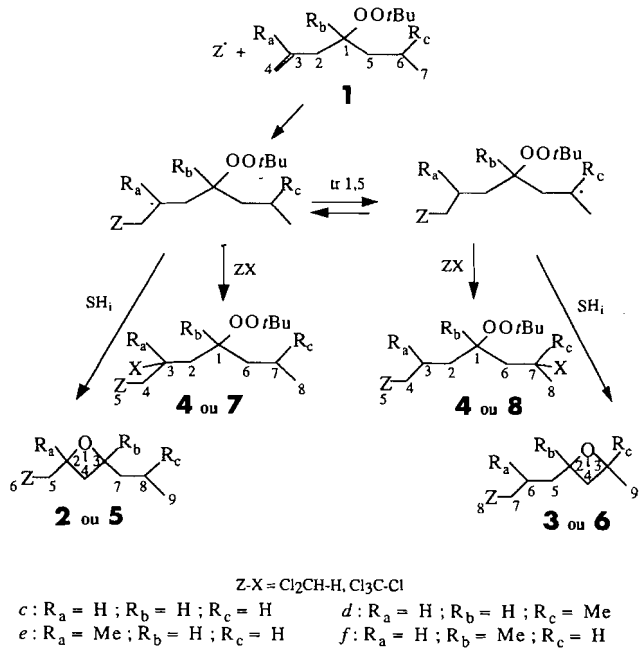
(*iii*) Lorsque l'oxétane peut se présenter sous deux formes diastéréoisomères, celles-ci sont observées (**2***c*, **3***c*, **2***e*, **2***f* et **3***f*).

2.2. Décompositions induites dans le tétrachlorure de carbone

Le peroxyde **1***f* a été décomposé dans le tétrachlorure de carbone. Les produits attendus sont indiqués dans la figure 6 (Z-X = Cl_3C-Cl).

Dans les conditions habituelles, seuls les peroxydes adduits **7***f* et **8***f* ont été obtenus (tableau 4); le transfert d'un atome de chlore aux radicaux adduit et isomère est trop rapide par rapport aux S_Hi. L'emploi de benzène comme cosolvant inerte a permis de ralentir cette étape et de mettre en évidence simultanément la présence des quatre partenaires, lorsque les proportions molaires CCl_4/benzène sont égales à 5/95. Les peroxydes adduits **7***f*, **8***f* et l'oxétane **5***f* ont été isolés et identifiés à partir de différents mélanges; l'oxétane **6***f* a été identifié par couplage CPG-SM.

Fig. 6



Cet ensemble de résultats confirme l'hypothèse de mécanisme initialement avancé.

Conclusion

La décomposition de peroxydes γ-insaturés substitués dans un solvant donneur d'hydrogène peut conduire à deux types d'oxétanes isomères de constitution. L'un provient de l'addition d'un radical issu du solvant à l'insaturation du peroxyde, suivie d'une substitution homolytique intramoléculaire. L'autre met en jeu une réaction concurrente de cette dernière, à savoir un transfert intramoléculaire d'hydrogène 1,5 réversible, lui-même suivi d'une substitution homolytique intramoléculaire. La compétition est gouvernée par la classe des sites radicalaires isomères susceptibles de se former. Signalons qu'une telle compétition, génératrice de deux cycles différents, n'a pas, à notre connaissance, été signalée dans la littérature.

Partie expérimentale

Techniques analytiques

Les analyses en CPG ont été effectuées sur un appareil de type Delsi DI 200 (ionisation de flamme, gaz vecteur : azote), équipé de colonnes capillaires — CPSIL 5 B (longueur 25 m, diamètre intérieur 0,32 mm), OV 1 (longueur 15 m, diamètre intérieur 0,31 mm), BP 20 (longueur 25 m, diamètre intérieur 0,22 mm) — et associé à un intégrateur Intersmat ICR-1B.

Les dosages ont été effectués par la méthode de l'étalon interne. En l'absence des produits de référence, après vérification de la pureté des produits par CPG, les techniques spectroscopiques ont permis de confirmer la structure des composés.

Les spectres RMN ^1H ont été enregistrés sur des appareils

Perkin–Elmer R 24B fonctionnant à 60 MHz et Bruker AC 250 fonctionnant à 250 MHz.

Les spectres RMN ^{13}C ont été effectués sur un appareil Bruker 250 fonctionnant à 62,9 MHz. Les spectres «théoriques» des produits susceptibles de se former sont calculés à partir des spectres de produits très voisins en utilisant une méthode d'incrémentation. Les variations moyennes du déplacement chimique sont estimées selon ref. 2 dans le cas d'introduction d'un atome de chlore ou d'un groupe méthyle en extrémité ou milieu de chaîne; selon ref. 10 dans le cas d'introduction d'un groupe méthyle sur un cycle oxétanique.

Les spectres de masse ont été réalisés sur des appareils VG Micromass 16 F (ionisation par impact électronique) et Fisons VG-autospec (ionisation chimique : NH_3) couplés à un chromatographe en phase gazeuse.

Techniques réactionnelles

Les réactions de décomposition des différents composés peroxydiques sont effectuées sur des mélanges constitués par le dichlorométhane, le peroxyde, l'amorceur et le carbonate de sodium dans les rapports molaires 100/1/0,5/2. La durée et la température des réactions dépendent de la nature de l'amorceur (Am) : perdicarbonate de diéthyle (PDCE) : 60°C, 10 h; peroxyde de benzoyle (PB) : 80°C, 24 h; peracétate de *tert*-butyle (PA) : 110°C, 12 h.

Les conditions propres à chaque expérience sont rappelées dans les tableaux de la partie théorique.

Études analytiques : 2 mL sont introduits dans une ampoule de 10 mL. Celle-ci, fermée hermétiquement, est placée dans un bain d'huile thermostaté posé sur une agitateur magnétique. Les produits de réaction sont identifiés par comparaison des temps de rétention en CPG avec ceux d'échantillons isolés et éventuellement par couplage CPG-SM. Les rendements sont déterminés par CPG directement sur le mélange réactionnel selon la méthode de l'étalon interne.

Études préparatives : 90 mL de solution sont introduits dans un autoclave en acier de 125 mL que l'on place dans le bain thermostaté d'un agitateur magnétique chauffant. Après élimination du solvant, les produits de réaction sont isolés par chromatographie liquide–solide sur alumine neutre désactivée avec 5% d'eau.

Matières premières

Le peracétate de *tert*-butyle est préparé par action de l'hydroperoxyde de *tert*-butyle sur le chlorure d'acétyle en présence de pyridine (11).

Le perdicarbonate de diéthyle est préparé par action du chloroformiate d'éthyle sur le peroxyde de sodium (12).

Les peroxydes proviennent de l'alkylation de l'hydroperoxyde de *tert*-butyle au moyen des alcools correspondants, via leur trichloroacétimidate (méthode A) (13) ou leur mésylate (méthode B) (14). Les alcools sont formés par condensation organomagnésienne (15) du bromure d'allyle et du bromure de méthallyle sur les dérivés carbonylés convenables.

Peroxyde de 1-allylcycloheptyle et de tert-*butyle,* ***1***a : méthode A; rdt = 42%; $Eb_{0,01}$ = 48°C; n_D^{20} = 1,4550. Formation of methyl 2-arylhydrazono-3-oxobutanoates and 2-arylhydrazono-3-oxobutanenitriles during the coupling reaction of arenediazonium ions with methyl 3-aminocrotonate and 3-aminocrotononitrile

D. Sean Brown, Jason V. Jollimore, Marcus P. Merrin, Keith Vaughan, and Donald L. Hooper

Abstract: Reaction of aryldiazonium salts with methyl 3-aminocrotonate (**1**) affords high yields of the methyl 2-arylhydrazono-3-oxobutanoates (**4**); analogous diazonium coupling with 3-aminocrotononitrile (**2**) gives the 2-arylhydrazono-3-oxobutanenitriles (**5**). The hydrazones are the product of diazonium coupling at the C2-vinylic carbon, concomitant with hydrolysis of the 3-amino substituent to the 3-oxo derivative; there is no evidence for the formation of a triazene (**6**), which would be the product of N-coupling. All hydrazones (**4***a–e* and **5***a–d*) have been fully characterized by IR and ^{1}H and ^{13}C NMR spectroscopy; the NMR spectra of the methyl 2-arylhydrazono-3-oxobutanoates (**4**) suggest the presence of two isomeric intramolecularly H-bonded forms in solution. Selected compounds were further characterized by elemental analysis and mass spectrometry. A mechanism is proposed for the conversion of **1** or **2** into **4** or **5**, and these observations are compared with previously reported observations of diazonium coupling reactions with unsaturated systems.

Key words: hydrazone, diazonium, aminocrotonate, aminocrotononitrile, hydrogen bonding.

Résumé : La réaction des sels aryldiazoniums avec le 3-aminocrotonate de méthyle (**1**) conduit avec d'excellents rendements aux 2-arylhydrazono-3-oxobutanoates de méthyle (**4**); des couplages analogues de diazoiques avec le 3-aminocrotonitrile (**2**) donne les 2-arylhydrazono-3-oxobutanenitriles (**5**). Les hydrazones sont les produits du couplage des diazoiques au niveau du carbone vinylique C2, suivi de l'hydrolyse du substituant 3-amino qui conduit au dérivé 3-oxo; il n'y a pas de preuve de la formation d'un triazène (**6**) qui pourrait être le produit du couplage avec l'azote. On a caractérisé complètement toutes les hydrazones (**4***a–e* et **5***a–d*) par la spectroscopie IR et de RMN du ^{1}H et du ^{13}C. Les spectres de RMN des 2-arylhydrazono-3-oxobutanoates de méthyle (**4**) suggèrent la présence de deux formes isomères en solution liées par des liaisons hydrogènes intramoléculaires. On a de plus caractérisé les composés choisis par l'analyse élémentaire et par la spectrométrie de masse. On propose un mécanisme pour la transformation du composé **1** ou **2** en composé **4** ou **5** et on a comparé ces observations avec les observations rapportées antérieurement sur le couplage des diazoiques avec les systèmes insaturés.

Mots clés : hydrazone, diazonium, aminocrotonate, aminocrotononitrile, liaisons hydrogènes.

[Traduit par la rédaction]

Introduction

1-Aryl-3-alkyltriazenes (Ar-N=N-NHR), often referred to as "monoalkyltriazenes," are produced by the coupling reaction of the arene diazonium ion, ArN_2^+, with an alkylamine, RNH_2 (1). Monoalkyltriazenes with a reactive functional group incorporated in the alkyl moiety, e.g., Ar-N=N-NH-CH_2-CO_2Et, are useful synthons for a variety of heterocyclic molecules (2). As part of our continuing interest in the search for new triazene synthons, we were interested in extending our studies to the vinylic triazenes (**6**), which would be useful precursors for monocyclic 1,2,3-triazines. The vinylic triazene (**6**) is formally the product expected from coupling an arenediazonium ion with the amino nitrogen atom of a 3-aminocrotonic acid derivative (e.g., **1** or **2**). However, when we attempted such a synthesis of triazenes of type **6**, we obtained different products, which arise from C-coupling at the C2 vinylic carbon in preference to N-coupling. These products have been identified as the 2-arylhydrazono-3-oxobutanoates

(**4**) from **1** and the 2-arylhydrazonocrotononitriles (**5**) from **2** and in this paper we report the synthesis and identification of both series of hydrazones.

Experimental

All reagents were reagent grade materials purchased from the Aldrich Chemical Co. Ltd., and were used without further purification. Melting points were determined on a Reichert hot-stage microscope and are uncorrected. Infrared spectra were obtained using Nujol mulls, unless otherwise indicated, on a Perkin Elmer 299 spectrophotometer. ^1H and ^{13}C NMR spectra were obtained on the Bruker 250 MHz spectrophotometer of the Atlantic Region Magnetic Resonance Centre at Dalhousie University. Unless otherwise noted, chemical shifts were recorded in $CDCl_3$ solutions at 20°C, and are relative to TMS (1%) internal standard. Mass spectral analysis was performed at the Institute of Marine Biosciences (NRC, Halifax) on a Finnigan Quadrupolar 4500 GC-MS with a temperature-programmed solids probe.

Methyl 2-Arylhydrazono-3-oxobutanoates (4 *a–e*) and 2-arylhydrazono-3-oxobutanenitriles (5*a–d*)

General procedure

The appropriate arylamine (0.01 mol) was dissolved, with gentle warming if necessary, in 2 M hydrochloric acid (30 mL) and diazotized at −5°C to 0°C with sodium nitrite (0.011 mol, 0.76 g) in water (5 mL). The mixture was stirred at −5°C for 0.5 h, and then filtered where necessary, to afford a clear solution of the diazonium salt, which was then treated with a solution of either (*a*) methyl 3-aminocrotonate (**1**) (1.3 g) in 2 M hydrochloric acid (5 mL), or (*b*) 3-aminocrotononitrile (**2**) (1.6 g) in 2 M hydrochloric acid (2 mL). The mixture was again stirred for 0.5 h at 0°C, and then neutralized carefully with either (*a*) sodium acetate trihydrate (20 g) in water, or (*b*) saturated sodium carbonate, respectively. The solid hydrazone formed was isolated by filtration, dried under vacuum, and recrystallized to constant melting point from an appropriate solvent. Yields and physical data of the hydrazones are given in Table 1, and spectroscopic data are shown in Tables 2–5. Mass spectral fragmentation data are given in Tables 6–7.

Results and discussion

The diazonium salt, $Ar\text{-}N_2^+Cl^-$, was prepared in the conventional manner by reaction of the appropriate arylamine in hydrochloric acid with sodium nitrite at low temperature, and then coupled with either methyl 3-aminocrotonate (**1**) or 3-aminocrotonitrile (**2**). Neutralization of the resulting solution gave a high yield of a single yellow product, which could be readily purified by recrystallization. Analysis of the IR, NMR, and mass spectra of these products results in the unequivocal assignment of the hydrazone structure **4** or **5**, rather than the 3-amino-2-arylazo structure **3**, which does not appear to be present even as a minor product of the coupling reaction mixture.

The key to this structural identification is found in the mass spectra of the products. The molecular ions are found to have a *m/z* in agreement with the expected molar mass of the hydrazone, **4** or **5**. The molar mass of the hydrazone is one mass unit higher than the molar mass of the analogous triazene (**6**); furthermore, elemental analysis showed a lower nitrogen content

[a]Chemical shifts in parentheses are assigned to the minor component of the mixture.

than that expected for the triazene, but was consistent with the hydrazone structure. All of the other spectroscopic features of the products are consistent with the hydrazone structure, rather than the triazene structure. Of particular note is the absence of the vinylic proton that should be present in the ^{1}H NMR spectra of **6**.

The methyl 2-arylhydrazono-3-oxobutanoates (**4***a–e*) are obtained in high yield from diazonium coupling with methyl 3-aminocrotonate (**1**). The hydrazones of this series all recrystallize readily from ethyl acetate. The IR spectra of these hydrazones (Table 1) all show the common features of a hydrazone NH at 3140–3180 cm^{-1}, a ketone carbonyl at 1650–1675 cm^{-1}, and the ester carbonyl band at 1680–1690 cm^{-1}. The functional groups present in the *para* position of the aryl moiety are also evident. Three representative examples of this hydrazone series, **4***b*, **4***d*, and **4***e*, were analysed for elemental composition with excellent fit to the expected percentages (Table 8).

The assignment of the hydrazone structure (**4**) is also supported by the ^{1}H NMR spectra (Table 2) and the observed chemical shifts agree very well with those reported by Elguero et al. (3*a*) for the unsubstituted arylhydrazone (**4**, X = H). The

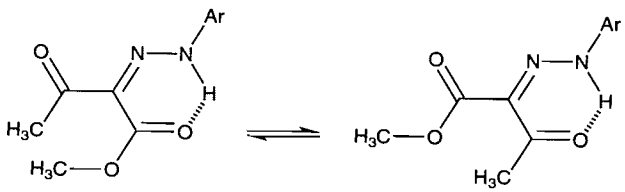
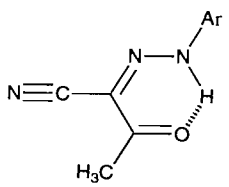
[a]Aromatic: C4 is the carbon atom adjacent to the substituent X.

^{13}C NMR spectra (Table 3) of the hydrazone series (**4**) give further corroboration of the assigned structures. Of particular note is the presence in all five compounds of the keto-carbon atom, which has a resonance of ca. 194 ppm. Other features of the ^{13}C NMR spectra are as expected.

The ^1H NMR spectra of the methyl 2-arylhydrazono-3-oxobutanoates (**4**) all show a doubling of peaks, with a major and a minor component. The composition of the mixture does not change after repeated purification, indicating that these hydrazones exist as an equilibrium mixture. Some doubling of signals is also observed in the ^{13}C NMR spectra. A similar equilibrium was observed with the unsubstituted hydrazone (**4**, X = H) by Elguero et al. (*3a*), who attributed the phenomenon to the existence of two isomeric H-bonded forms (**4***A* and **4***B*):



4*A* **4***B*



5*A*

By analogy with this reported example, it is evident that the major component of the mixtures of H-bonded forms of **4***a–e* is the ketone-carbonyl H-bonded form **4***B*, which is consistent with the NH chemical shift being at higher field. Measurement of the NMR integrals affords the following percent composition (%**4***A*:%**4***B*) for each compound in the series: **4***a*, 20:80%; **4***b*, 15:85%; **4***c*, 40:60%; **4***d*, 28:72%; **4***e*, 30:70%.

The 2-arylhydrazono-3-oxobutanenitriles (**5***a–d*) are obtained in high yield from diazonium coupling with 3-aminocrotononitrile (**2**); physical data of these compounds are presented in Table 1. The IR spectra show the expected hydrazone NH at ca. 3200 cm^{-1}, the keto-carbonyl at ca. 1655 cm^{-1}, and a weak cyano peak at 2180 or 2190 cm^{-1}. The mass spectra of three examples, **5***b*, **5***c*, and **5***d*, were recorded and showed the correct molecular ion mass for the hydrazone structure. Table 4 shows the ^1H NMR data for the cyano-hydrazone series. The spectra are consistent with the presence of a single species, the intramolecularly H-bonded hydrazone **5***A*.

The ^{13}C NMR spectra of the cyano-hydrazones (**5**) are recorded in Table 5. All spectra exhibit the expected chemical shifts: (*a*) cyano-group carbon at ca. 116 ppm; (*b*) keto-carbonyl carbon at ca. 192 ppm, (*c*) a methyl carbon at *ca.* 24 ppm; (*d*) two singlet and two doublet aromatic resonances, and (*e*) the carbon signals of the carbonyl and alkyl groups in the ester function of **5***a* and **5***b*. The imino-group carbon of the hydrazone moiety is observed universally at ca. 110 ppm, which is consistent with the chemical shift reported in the range 103–109 ppm for the imino-carbon atom of a series of ethyl cyano-(arylhydrazono)acetates, Ar-NH-N=C(CN)CO_2Et (3b). The chemical shift of the imino-carbon of the methyl 2-arylhydrazono-3-oxobutanoates (**4**) is observed in the range 126–135 ppm.

Scheme 2

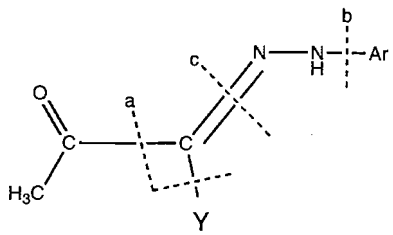

Table 6 shows details of the fragments observed in the mass spectra of the hydrazones **4***a* and **4***e*, with assignments of the major fragments. Table 7 shows a summary of the mass spectral information for the second series of hydrazones, **5***b*, **5***c*, and **5***d*. Both sets of data support the hydrazone structures and have some features in common. However, the major fragmentation pathway is somewhat different for hydrazones of type **4**, which afford an intense fragment corresponding to the moiety ArNHN=C$^+$. This fragment arises from cleavage of both bonds indicated by line "a" in Scheme 2. On the other hand,

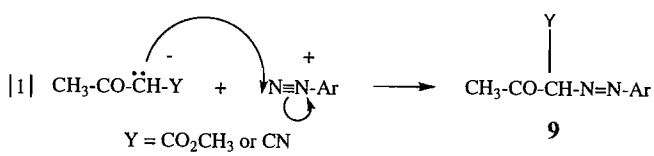
hydrazones of type **5** give major fragments arising from cleavage at bonds "b" and "c", producing respectively the $Ar^{+\cdot}$ and $ArN_2^{+\cdot}$ fragments.

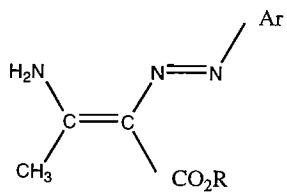
Scheme 1 shows a proposed pathway to explain the formation of the hydrazones (**4** and **5**) from the diazonium coupling reaction. The reaction is initiated by electrophilic attack by the diazonium ion on the π electrons of the alkene; attack at C2 is preferred over attack at C3 because of the anchimeric assistance to the electron flow from the electron lone-pair on the amino-nitrogen atom. The initial attack leads to the intermediate iminium ion (**7**), which deprotonates to give the aylazo-compound (**3**). Isomerization of **3** affords the hydrazone **8**, which hydrolyses rapidly at the imino group in the acidic reaction medium to give the observed product **4** or **5**.

The hydrazonocrotonic acid derivatives (**4** and **5**) formed in the reactions described here are formally the products of diazonium coupling with the carbanion of either methyl acetoacetate or acetoacetonitrile, respectively (reaction [1]):

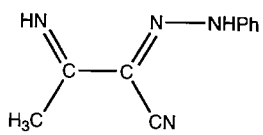


9

The reaction of aryldiazonium salts with carbanions of β-dicarbonyl compounds has been reported by several workers (4), and it was found that the initially formed azo compounds, such as **9**, always isomerize to the preferred hydrazone tautomer. However, no physical data, such as melting points, were reported in these papers. Chattaway and Ashworth (5) and Gasteiger and Strauss (6) reported the formation of keto-hydrazones of type **4** from diazonium coupling with alkyl-acetoacetates, but again no physical data were given; apparently, the ketohydrazones were generated *in situ* for reaction with ammonia to afford the 2-arylazo-3-aminocrotonate (**10**). Similar coupling reactions with β-keto-nitriles, e.g., CH_3COCH_2CN, have been reported for the synthesis of α-arylhydrazono-β-ketonitriles (7).



10

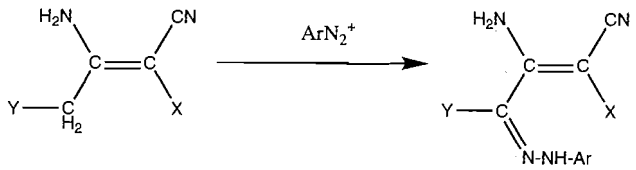


11

One of the original and more elegant examples of diazonium coupling to reactive methylene compounds is the work of Meyer (8), in which the diazonium ion was coupled with β-iminobutyronitrile to give the 2-arylhydrazono-3-ketiminobutanenitrile (**11**). In more recent work, Elnagdi et al. (9) reported further synthetic applications of the 2-arylhydrazono-3-ketiminobutanenitrile (**11**), which is formally the deprotonated form of the hydrazone tautomer of the intermediate (**7**) in our proposed mechanism (Scheme 1).

The reaction of enamines with diazonium salts can follow a different pathway, also leading to hydrazone formation, but via a different mode of attack by the diazonium ion at the α-carbon of an activated alkyl side chain. Thus reaction of 3-amino-2-cyano-2-pentene-1,5-dicarboxylate (**12**) with diazonium ions results in coupling at C4 to afford the hydrazone

(**14**) (10), and in similar fashion diazonium coupling with the tricyano-enamine (**13**) affords the hydrazone (**15**) (11).



12 X=Y=CO_2Et **14** X=Y=CO_2Et

13 X=Y=CN **15** X=Y=CN

Thus the reactions of enamines with diazonium ions can occur by several different options, but none of those reported appear to give rise to a triazene via N-coupling. Furthermore, the reactions reported here represent a different variation on the theme of C-coupling involving hydrazone formation, concomitant with removal of the amino residue by hydrolysis. Further studies will be undertaken to assess the synthetic potential of this reaction in heterocyclic chemistry.

Acknowledgements

We gratefully acknowledge the contribution of the Atlantic Regional Magnetic Resonance Centre for providing NMR spectra, and we thank the National Research Council of Canada for making the mass spectral facility at the Institute for Marine Biosciences (Halifax) available. None of this work would have been possible without the generous financial assistance of the Natural Sciences and Engineering Research Council of Canada, supplemented by a research grant from the Saint Mary's University Senate Research Committee.

Electrochemical investigations on some potential antibacterials, I

Rajeev Jain and M. Damodharan

Abstract: Electrochemical behaviour of the medicinally important 4-(4′-sulphonamoyl)hydrazono-1-phenyl-3-methyl-2-pyrazolin-5-ones has been studied at d.m.e. and glassy carbon electrodes. At d.m.e., all six compounds exhibited a single, well-defined, four-electron wave in the pH range 2.5–12.0. Polarographic four-electron wave was found to be diffusion-controlled and irreversible. Similarly, cyclic voltammetry of these compounds at glassy carbon electrode exhibited a single peak. Peak potential shows shifts towards negative potential with pH, with linear segments up to pH 8.2 and are practically pH independent at higher pH values. An anodic peak at far-off positive potential was observed in the reverse scan, indicating the irreversible nature of the electrode process. Controlled potential electrolysis and coulometric studies gave the value of n as 4.0 ± 0.1 in the pH range 2.5 to 10.0. Out of the two major end products formed, one was identified as sulphanilamide and the other as 1-phenyl-3-methyl-4-amino-2-pyrazolin-5-one on the basis of IR and NMR studies. On the basis of DCP, LSV, CV, CPE, coulometry and spectral analysis, a mechanism has been postulated for the reduction of these compounds at d.m.e. and glassy carbon electrodes.

Key words: polarography, cyclic voltammetry, antibacterials, pyrazolin-5-ones.

Résumé : On a étudié le comportement électrochimique de 4-(4′-sulfonamoyl)hydrazono-1-phényl-3-méthyl-2-pyrazolin-5-ones au niveau d'électrodes d.m.e. et de carbone vitreux. Avec les électrodes d.m.e., à des pH allant de 2,5 à 12,0, les six composés choisis présentent tous une seule vague, bien définie, de quatre électrons. On a établi que cette vague polarographique est contrôlée par la diffusion et qu'elle est irréversible. De la même manière, la voltampérométrie cyclique de ces composés au niveau d'une électrode de carbone vitreux présente un seul pic. Le potentiel du pic présente un déplacement vers le potentiel négatif avec une variation du pH; les segments sont linéaires à des pH allant jusqu'à 8,2 et ils sont pratiquement indépendants du pH à des valeurs de pH plus élevées. Lors du balayage inverse, on a observé un pic anodique à un potentiel extrêmement positif; ceci suggère une nature irréversible pour le processus. Une électrolyse à potentiel contrôlé et des études coulométriques indiquent que, à des pH allant de 2,5 à 10,0, la valeur de n est égale à 4,0 ± 0,1. En se basant sur des études de rmn et d'ir, on a identifié les deux products formés au cours des réactions; l'un est le sulfanilamide et l'autre est la 1-phényl-3-méthyl-4-amino-2-pyrazolin-5-one. En se basant sur les DCP, LSV, CV, CPE, la coulométrie et les analyses spectrales, on propose une mécanisme pour la réduction de ces composés aux électrodes de d.m.e. et de carbone vitreux.

Mots cles : polarographie, voltampérométrie cyclique, antibactériens, pyrazolin-5-ones.
[Traduit par la rédaction]

A review (1, 2) of the electrochemistry of some biologically important organic molecules illustrates very well how modern electrochemical techniques can provide biologically significant information. Electrochemical studies of hydrazones have attracted many workers (3–7) because of their medicinal importance (8, 9). The reduction of hydrazones has been reviewed in detail by Turyan (10). Fundamental contribution in this field has been made by Lund (11) and Kitajev et al. (12–14). The reduction mechanism has been reviewed by Kitajev and Buzykin (15). A four-electron reduction is usually observed in an acidic solution (11–14) involving breaking the N—N bond during the reduction. More recently a four-electron reduction of the hydrazones has been reported (16–18) in acidic as well as in alkaline media with the formation of amino compounds. On the other hand, Zuhri et al. (5) have found a two-electron reduction followed by a hydrolysis that resulted in the formation of the corresponding carbonyl compound. Hydrolysis of the reduced product has also been observed by Lund (7) for similar hydrazones. However, Fahmy et al. (19) have reported further reduction of the amino compound formed after the four-electron reduction to ammonia and ketone in a two-electron wave. However, only a few reports are available on the electroreduction of hydrazones at solid electrodes (20, 21).

An underlying rationale for our studies on the electrochemical reduction of biologically important *N*-heterocyclic molecules is that such studies can lead to information on the reaction routes and mechanisms of biological redox reactions. One of the reasons to investigate the electrochemical behaviour of biologically important compounds is the development of possible correlation based on the mechanistic paths involved and the associated characteristic potentials; e.g., half-wave potentials are a function of electron density and other factors, which are simply related to some biological,

clinical, physical, or chemical property and activity. Furthermore, to broaden our knowledge on electrochemistry and to probe the possibilities of electroanalytical assays, we thought it worthwhile to study in a comprehensive manner the electroreduction behaviour of the medicinally important (22) 4-(4'-sulphonamoyl)hydrazono-1-phenyl-3-methyl-2-pyrazolin-5-ones at d.m.e. and glassy carbon electrodes.

Experimental

Polarographic curves were recorded on an ELICO DC CL 25 polarograph with capillary characteristics $m^{2/3}t^{1/6}$, 3.62 $mg^{2/3}$ $s^{1/2}$, drop time 3.20 s^{-1} at h = 65 cm in 1.0 M KCl solution (0.0 V SCE). Saturated calomel electrode was used as the reference electrode. Temperature coefficient was determined by Nejedly's (23) method. Triply distilled mercury was used for the d.m.e. All the polarograms were recorded at 298 ± 0.1 K.

Voltammograms were recorded on a cyclic voltammograph (BAS, CV-27) with an *x–y/t* recorder (Digital, Model Omnigraph). A three-electrode system was used, glassy carbon as the working electrode, Ag/AgCl in 1.0 M KCl as the referenced electrode, and a platinum wire as the counter electrode. The GC electrode was polished with fine grade emery paper followed by polishing alumina (0.5 μm), washed, and activated by triangular voltage sweeps from +1.0 to −1.4 V at the rate of 5 and 200 mV/s for 15 min. The activated electrode was tested (24) for its activity in ferricyanide–ferrocyanide in 0.1 M KCl solution.

The compounds listed in Table 1 were prepared by the reported (22) procedure. Britton-Robinson buffers (25) were used throughout the electrochemical study. pH of the solutions were measured with a glass electrode. In a typical electrochemical study, e.g., when studying the influence of pH on the cyclic voltammetric behaviour, 1.0×10^{-4} M solutions of these compounds were prepared by mixing 1.0 mL compound (1.0×10^{-3} M in DMF), 3.0 mL DMF (which was necessary to keep the compound in solution), 5.0 mL appropriate buffer, and 1.0 mL (1.0 M) KCl as the supporting electrolyte. Polarograms and voltammograms were recorded after removal of oxygen.

As the products of controlled potential electrolysis (CPE) have been known to differ depending on the nature of the electrode employed (26), controlled potential electrolysis (CPE) was done at d.m.e. and GC electrodes in a microcell (27). For coulometric determination (27) of the number of electrons transferred in the electrode process 2.0 mL of the solution of the depolarizer (1.0×10^{-3}) having 4.0 mL of buffer, 3.0 mL of dimethyl formamide, and 1.0 mL of potassium chloride was electrolysed by applying a potential corresponding to the limiting current of the polarographic wave. From the decrease in current with time during electrolysis, the number of electrons transferred was calculated. Progress of the electrolysis was monitored by recording the polarograms at different intervals of time, until only the background current is attained. Coulometry was done at the GC electrode, using a BAS CV-27 coulometer, the value of Q was directly read, and by applying

$$Q = nFN$$

n was calculated; here N is the number of moles.

Results and discussion

Polarographic behaviour

All 4-(4'-sulphonamoyl)hydrazono-1-phenyl-3-methyl-2-pyrazolin-5-ones (Table 1) exhibited a single, well-defined, four-electron wave in the pH range 2.5–12.0. A comparison of limiting currents of different pyrazolin-5-ones indicates that most of the compounds studied are reduced by the same number of electrons. The nature of the wave was established by recording the polarograms at various heights of mercury reservoir (55 to 95 cm) as well as by studying the effect of concentration ($(1.0–5.0) \times 10^{-4}$ M) on the limiting current. It was observed that the limiting current is directly proportional to the square root of the mercury reservoir height and the concentration of the depolarizer. These facts confirmed that the waves are controlled by diffusion (28). The half-wave potentials were dependent on pH and shifted towards more negative potentials with an increase in pH. The plots of $E_{1/2}$ vs. pH were (Fig. 1) linear up to 8.2 and after that there was a little change in $E_{1/2}$.

Cyclic voltammetry

Cyclic voltammograms of 4-(4'-sulphonamoyl)hydrazono-1-phenyl-3-methyl-2-pyrazolin-5-ones in buffer solutions of pH 2.5–12.0, at different scan rates (50–200 mV/s) and concen-

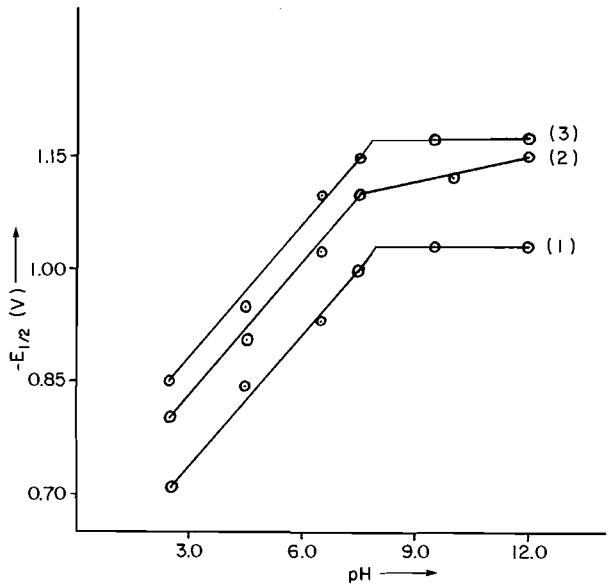
Fig. 1. Plot of $-E_{1/2}$ vs. pH (*1*) 4-[4′-sulphonamoyl]-, (*2*) 4-[4′-guanylsulphonamoyl]-, (*3*) 4-[4′-(4″,6″-dimethylpyrimidinyl)sulphonamoyl]hydrazono-1-phenyl-3-methyl-2-pyrazolin-5-ones at concentration 1.0×10^{-1} M.



trations ((1.0–5.0) $\times 10^{-4}$ M), exhibited not very well-defined, single four-electron peaks. Some typical voltammograms are shown in Fig. 2. This behaviour is in agreement with that observed from polarographic measurements. Peak potentials show shifts towards negative potential with pH, with linear segments up to pH 8.2, and are practically pH independent at higher pH values. An anodic peak at far off positive potential was observed in the reverse scan indicating the irreversible (29) nature of the electrode process. The values of peak potential and peak currents are given in Table 1.

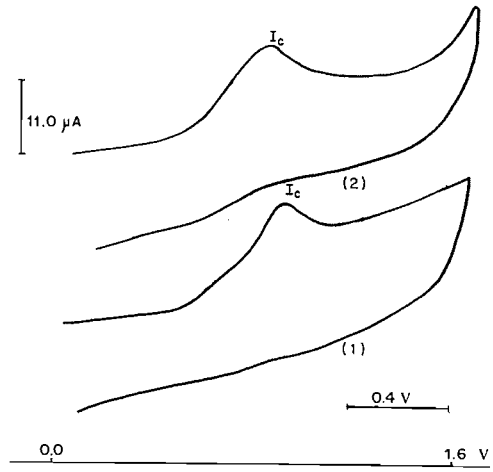
Coulometry and product analysis

Controlled potential electrolysis of these compounds at the plateau potential (−1.0 V) using the mercury pool cathode consumed 4.0 ± 0.2 electrons. The dark yellow colour of the starting solution almost disappeared at the end of the electrolysis. Coulometric studies at slightly more negative potential than the peak potential I_c, using GC electrodes, also gave the value of n as 4.0 ± 0.1 in the pH range 2.5–10.0. A cyclic voltammogram of the solution after exhaustive electrolysis did not exhibit any reduction peak. To characterise the major end products, electrolysis was carried out at pH 2.5, 6.5, and 10.0. The electrolysis resulted in two products on separation by TLC. One of the products was identified as sulphanilamide by comparison with the authentic sample. The other product was identified as 1-phenyl-3-methyl-4-amino-2-pyrazolin-5-one on the basis of IR and NMR studies (ν_{max}^{Nuzol} 3320 (NH_2), 1665 (C=O cyclic), 1600 (C=N), 1650 (heterocyclic five-membered 2-pyrazolin-5-one), δ ($CDCl_3$): 2.1 (1H, CH), 3.17 (3H, CH_3), 4.2 (2H, NH_2), and 7.0–8.0 (5H′, C_6H_5)).

Mechanism

Keeping in view the results of DCP, LSV, CV, CPE, and coulometry, the scheme on the facing page may be proposed for the reduction of these compounds at d.m.e. and GC electrodes.

Fig. 2. Cyclic voltammograms of 4-[4′-sulphonamoyl]hydrazono-1-phenyl-3-methyl-2-pyrazolin-5-one at (*1*) pH 4.5, (*2*) pH 2.5; concentration 1.0×10^{-4} M.



Alternatively, the radical (**I**) could also combine with an electron instead of a proton, but this possibility is ruled out by the fact that such a reduction would involve only two electrons, whereas polarographic data clearly indicate a four electron transfer reaction at the d.m.e.

The above mechanism is supported by a shift of $E_{1/2}$ towards more negative values with pH as protons are consumed in the reduction. As the equilibrium shifts towards the unprotonated form, the $E_{1/2}$ tends to become constant. Dependence of $E_{1/2}$ on pH is described by the equation (28):

$$E_{1/2} = \text{constant} + \frac{RT}{\alpha nF} \ln\left[1 + \frac{[H^+]}{K_a}\right]$$

The plot of $E_{1/2}$ vs. pH is composed of two intersecting linear segments and the pH at the point of intersection of its two linear parts is $\approx pK_1$. Similar steps of the reduction of the hydrazono group involving cleavage of the —N—N— bond have also been proposed by other workers (30–33). Due to an acid–base equilibrium between the structural forms of the compound (NH—N=C— ⇌ NH—NH=C—),[+] the wave height remains pH independent as long as the formation of the acidic form from the basic form is fast enough. As the pH increases and the rate of the protonation decreases, the wave height decreases as well. Ultraviolet–visible spectra of the solution during electrolysis were recorded at different time intervals; at 425 nm the peak due to —NH—N=C— grouping showed a decrease in the peak height after each interval of time and finally the peak disappeared, confirming the above reduction mechanism. The value of P is determined in the usual manner (28).

It was observed that the half-wave potential shifted to more negative potential (34) with increasing concentration of DMF, whereas the limiting current decreases.

Étude de la stéréochimie de la réaction de cycloaddition dipolaire-1,3 de quelques 5-phényl-3,6-dihydro-2*H*-1,4-oxazin-2-ones avec les *N*-méthyl et *N*-phénylmaléimides

Karin Monnier, Gérard Schmitt, Bernard Laude, Marie-France Mercier, Marek M. Kubicki et Michel Jannin

Résumé : La synthèse de six 5-phényl-3,4-dihydro-2*H*-1,4-oxazin-2-ones **1** à partir d'acides aminés est décrite. Ces composés sont des précurseurs d'ylures d'azométhine cycliques hexagonaux comportant un stéréocentre. Ces produits à caractère dipolaire réagissent avec les *N*-phényl et *N*-méthylmaléimides pour donner diastéréospécifiquement des cycloadduits pour lesquels l'approche du dipolarophile s'effectue sur la face la moins encombrée du dipôle et avec le reste maléimido en position *exo*. Malheureusement, on observe une racémisation lors de la réaction de cycloaddition, probablement par suite d'une tautomérie imine–ènamine du dipôle.

Mots clés : α-aminoacides, ylures d'azométhine cycliques, diastéréospécificité.

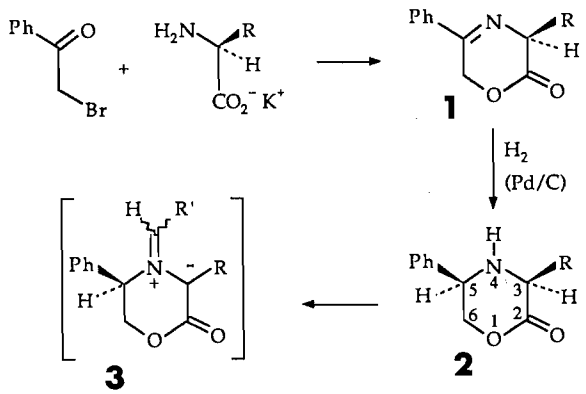
Abstract: Six derivatives of 5-phenyl-3,4-dihydro-2*H*-1,4-oxazin-2-ones **1** were synthetized from α-amino acids. These compounds are precursors of six-membered cyclic azomethine ylids involving one stereocenter. The 1,3-dipolar species react with *N*-methyl and *N*-phenylmaleimides, leading diastereospecifically to cycloadducts where the approach of the dipolarophile occurs from the less hindered side of the 1,3-dipole and with the maleimido moiety in an *exo* position. Unfortunately, racemization was observed during the cycloaddition reaction, presumably owing to reversible imine–enamine transformation.

Key words: α-amino acids, cyclic azomethine ylids, diastereospecificity.

Introduction

La synthèse asymétrique faisant appel à des réactions de cycloaddition dipolaires-1,3 des ylures d'azométhine a mobilisé l'attention de plusieurs équipes (1–9) qui ont eu recours à des auxiliaires chiraux sur le dipolarophile (1, 2), sur le dipôle (3, 4, 9), ou comme catalyseur (6). Récemment, Harwood et coll. (7, 8) ont décrit l'utilisation d'acides α-aminés qui sont des précurseurs bien connus des ylures d'azométhine (10–16), mais qui sont incapables d'exprimer la chiralité originale car cette information est nécessairement perdue lors de la formation de l'ylure d'azométhine par suite de la prototropie. L'idée mise en œuvre par ces auteurs consiste à condenser un composé prochiral avec un acide α-aminé pour créer un nouveau centre de chiralité, dont la configuration sera imposée par celle du carbone asymétrique de l'acide α-aminé précurseur.

Schéma 1



L'auxiliaire prochiral utilisé est la bromacétophénone qui par condensation avec un acide α-aminé conduit à une 3,6-dihydro-2*H*-1,4-oxazin-2-one **1** dont l'hydrogénation asymétrique permet d'obtenir de façon hautement stéréosélective la morpholinone **2** (schéma 1). Cette hydrogénation asymétrique a été étudiée par Caplar et al. (17). Elle s'accompagne du transfert total de la chiralité de l'α-aminoacide sur le centre benzylique formé en position 5. C'est ce nouveau stéréocentre en C-5 qui peut ensuite contrôler la stéréosélectivité de la

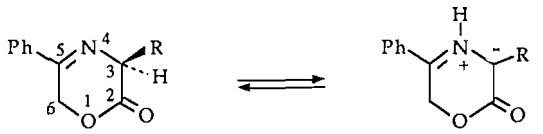
Schéma 2



1

cycloaddition à partir de l'ylure d'azométhine **3** dérivé de la morpholinone **2**.

L'examen de la structure **1** montre qu'on a également affaire à un ylure d'azométhine potentiel dans lequel le dipôle et le groupement activant, ici une fonction lactone, sont tous deux complètement insérés dans un cycle (schéma 2). Certains d'entre nous (18) ont récemment montré que pour ce type de dipôle-1,3 cyclique, l'approche dipôle–dipolarophile est diastéréospécifique et qu'elle conduit uniquement au cycloadduit de structure *exo*, à la différence de ce qui se passe lorsque le dipôle n'est pas complètement inséré (7, 8) dans le cycle, comme dans **3**, où on observe une diastéréosélectivité majoritaire en faveur du cycloadduit *endo*.

L'objectif du présent travail a été de créer un deuxième centre de chiralité sur le modèle de type **1**, et il est évident que seul le carbone 6 pouvait tenir ce rôle (schéma 3). Si au cours de la synthèse de ces ylures d'azométhine ou de leurs précurseurs, on peut séparer les deux épimères résultant de l'introduction de ce nouveau carbone asymétrique, on disposera alors d'un dipôle-1,3 dont l'élément chiral sera le carbone-6. Du fait de la double diastéréospécificité de la réaction (en *anti* du groupe R^1 d'une part et en donnant le cycloadduit *exo* d'autre part), on pouvait espérer obtenir une cycloaddition [3 + 2] conduisant à un seul énantiomère.

Nous avons donc entrepris la synthèse de divers dérivés de la 5-phényl-3,6-dihydro-2*H*-1,4-oxazin-2-one **1** et étudié la stéréosélectivité de leur approche sur les *N*-méthyl et *N*-phénylmaléimides en cycloaddition dipolaire-1,3. Il faut signaler dès à présent que si nous avons bien observé la diastéréospécificité de la réaction, nous n'avons pas réussi à atteindre la pureté optique.

Synthèse des 3,6-dihydro-2*H*-1,4-oxazin-2-ones 1

Nous avons préparé les six composés résultant de la combinaison des substituants R^1 et R^2 indiqués sur le schéma 3. Pour les obtenir, nous avons adapté la séquence des réactions (schéma 3), déjà mises en œuvre par d'autres auteurs (17, 19) pour d'autres substances.

Esters α-cétoliques des acides *N*-(benzyloxycarbonyl)-α-aminés 4

Les α-bromoalkylphénones utilisées sont l'α-bromoacétophénone, l'α-bromopropiophénone et la bromodésoxybenzoïne. Les acides aminés sont la glycine et la L-alanine protégées. Les rendements de ces condensations sont bons ou même excellents (70–97%).

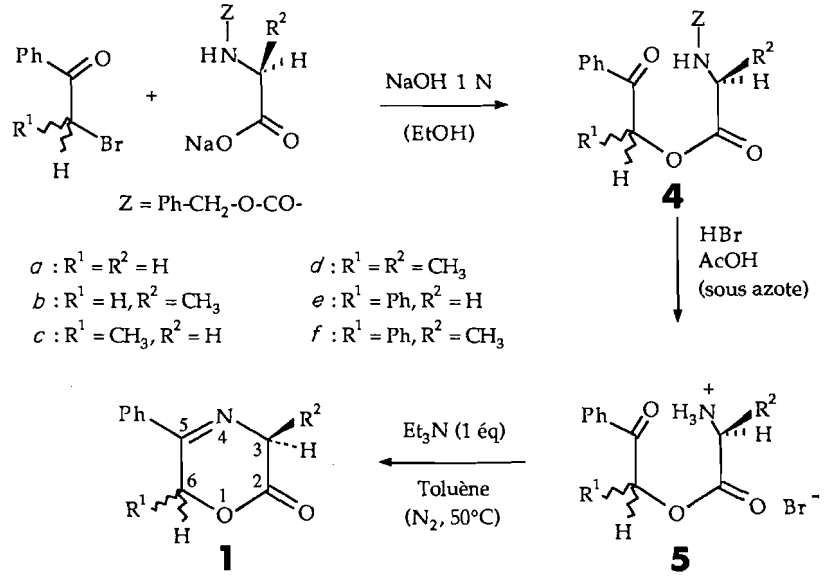
Lorsque R^1 et R^2 sont différents de H (**4***d* et **4***f*), on obtient un mélange de deux épimères. Nous avons pu séparer l'épimère majoritaire par cristallisation fractionnée uniquement dans le cas de **4***f* (R^1 = Ph, R^2 = CH_3). Pour ce qui concerne **4***d*, l'existence des deux diastéréoisomères est mise en évidence par rmn protonique, mais nous n'avons jamais réussi à les isoler ni par cristallisation fractionnée, ni par chromatographie.

Les propriétés physiques et les paramètres spectroscopiques de tous les composés **4** sont décrits en partie expérimentale.

Bromhydrates des esters α-cétoliques de la glycine et de la L-alanine 5

Les composés **4** précédents sont traités par une solution d'HBr à 40% dans l'acide acétique, méthode classique de déprotection des acides *N*-(benzyloxycarbonyl)-α-aminés. Ce traitement permet d'obtenir avec un rendement quasi-quantitatif les bromhydrates **5**. Seuls quatre d'entre eux (**5***a*, *b*, *e*, *f*) ont été isolés à l'état solide. Les deux autres (**5***c*, *d*) sont restés huileux. À partir de l'épimère majoritaire de **4***f*, on pouvait espérer obtenir un seul diastéréoisomère **5***f*. En fait, nous avons obtenu un mélange des deux épimères. Le spectre de rmn ^1H de ce mélange montre que leurs proportions relatives sont de 82 : 18.

Schéma 3



4 **1** **5**

Schéma 4

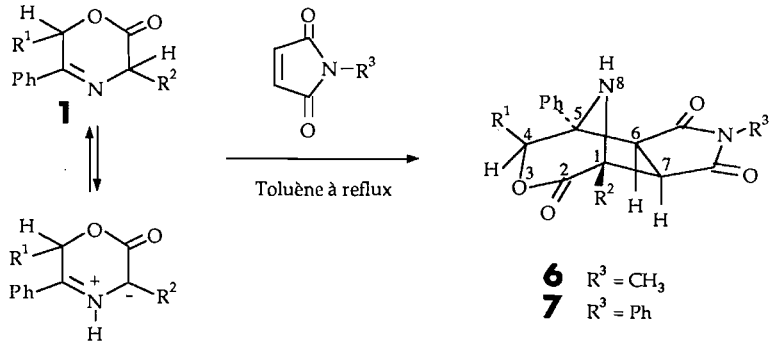


Fig. 1. Approche *endo* des deux réactants.

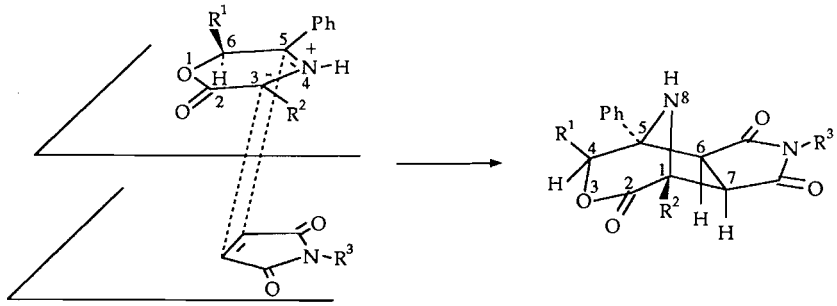

Ces composés sont instables et doivent être immédiatement engagés dans la réaction de cyclisation décrite ci-après.

Les paramètres de rmn ^1H et ^{13}C des bromhydrates qui ont cristallisé sont décrits en partie expérimentale.

Cyclisation des bromhydrates 5. Obtention des 3,6-dihydro-2*H*-1,4-oxazin-2-ones 1

En suivant le mode opératoire décrit dans la partie expérimentale, nous avons préparé les six oxazinones **1**. Les rendements sont relativement médiocres (de 30 à 50%), tout en étant comparables à celui déjà signalé pour le composé **1***a* (19). Ces composés **1** sont très peu stables sauf si, isolés à l'état solide (**1***a* et **1***c*), on les conserve au réfrigérateur. Cette fragilité ne permet pas de les purifier par une technique d'analyse immédiate comme la chromatographie ou la distillation au four tubulaire sous pression réduite lorsqu'ils sont huileux. Nous n'avons donc pas pu séparer les éventuels épimères issus de **4***d* et **4***f*. Cette fragilité avait déjà été signalée par Schulz et Steglich (19) pour des composés du même type. Les composés **1** doivent donc être engagés rapidement dans les réactions de cycloaddition dipolaire-1,3 décrites plus loin.

Malgré leur instabilité, il est possible de tracer les spectres de rmn ^1H en solution dans $CDCl_3$ (cf. partie expérimentale). Seul le produit **1***d* n'a pu être correctement analysé en rmn ^1H, mais la présence de l'ylure d'azométhine potentiel est néanmoins attesté par sa réaction ultérieure de cycloaddition. Parmi les autres composés **1**, seule l'oxazinone **1***f* (R^1 = Ph, R^2 = CH_3) pouvait exister sous forme de deux épimères *cis* et *trans*. L'examen du spectre de rmn ^1H du brut réactionnel huileux montre que l'un des épimères est largement majoritaire (>95%), les signaux de l'autre épimère étant difficilement accessibles dans le «bruit de fond» du spectre. Mais cet isomère majoritaire est peut-être totalement ou partiellement racémisé puisque les réactions de cycloaddition qui ont été engagées avec **1***f* ont conduit à un cycloadduit racémisé. On peut donc légitimement supposer que cet isomère majoritaire n'est pas énantiomériquement pur ou que la racémisation intervient lors de la réaction de cycloaddition.

Réactions de cycloaddition des oxazinones 1 sur les *N*-méthyl et *N*-phénylmaléimides

Ce sont les seuls dipolarophiles qui ont conduit à un cycloadduit. Les esters acrylique, fumarique et maléique ainsi que le diméthylacétylène dicarboxylate n'ont donné aucune réaction. Sur les six ylures d'azométhine potentiels **1**, seul le composé **1***e* n'a pas réagi et quels que soient les essais nous avons toujours observé sa décomposition avant la réaction de cycloaddition. Les cinq autres ont conduit aux cycloadduits **6** et **7** avec des rendements variant entre 20 et 50% (schéma 4).

Diastéréospécificité des réactions de cycloaddition

Toutes ces réactions sont diastéréospécifiques et la stéréochimie est de type *exo* à la fois pour le reste maléimido et pour le substituant R^1 lorsque ce dernier est différent de H.

La disposition stéréochimique du reste maléimido est déterminée à l'aide de la rmn ^1H lorsque R^2 = H. Dans ce cas les spectres de rmn ^1H présentent un signal singulet pour le proton H1. L'absence de couplage entre ce proton H1 et le proton H7 indique que l'angle dièdre H1-C1-C7-H7 est proche de 90°, ce qui impose une disposition *exo* du groupement maléimido. Cela peut sembler étonnant puisque les travaux de Harwood et coll. (7, 8) décrivent l'obtention du mélange *exo/endo* avec une plus grande proportion de ce dernier. Mais il s'agit d'un dipôle-1,3 qui n'est pas complètement inséré dans le cycle hexagonal (schéma 1). Ce résultat avait déjà été observé par Grigg et al. (20), Mkhairi et Hamelin (21) et Lakhlifi et al. (18,

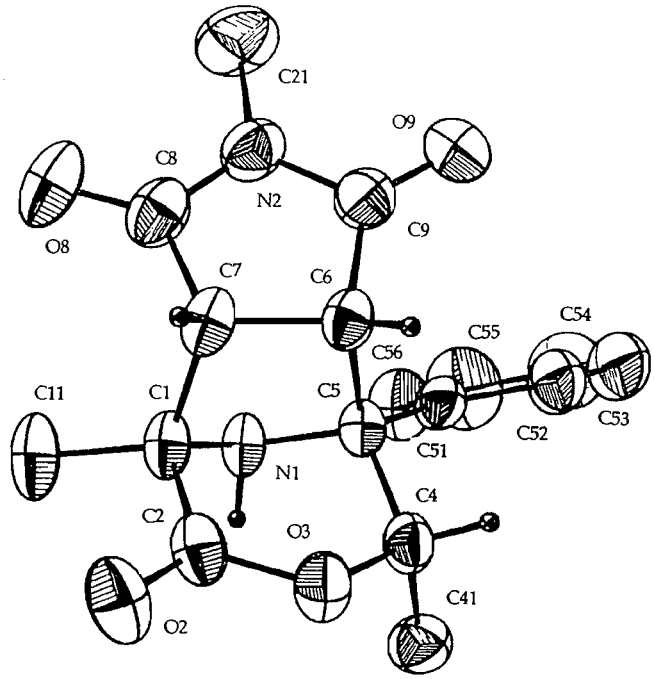
Fig. 2. Structure moléculaire du cycloadduit **6***d*.



22, 23) pour des réactions analogues. Il n'est nullement contradictoire avec la règle «*endo*» puisque, comme le montre la figure 1, la disposition relative du dipôle et du dipolarophile permet une interaction maximale entre le système π du dipôle et celui du groupement maléïmido (18).

La formation des produits **6** et **7** est donc favorisée de deux façon : (*i*) cinétiquement, puisque l'approche est celle qui conduit à l'état de transition le plus stabilisé; (*ii*) thermodynamiquement, puisqu'elle conduit au stéréoisomère le moins encombré.

Dans ces conditions, il n'est pas surprenant que nous n'ayons jamais décelé, dans les bruts réactionnels, la présence d'un composé résultant de l'approche *endo*.

Sur cette même figure 1 nous avons aussi représenté l'approche du dipôle en *anti* par rapport au substituant R^1 ce qui a été prouvé par l'analyse radiocristallographique du cycloadduit **6***d* ($R^1 = R^2 = R^3 = CH_3$). La structure moléculaire de **6***d* est représentée sur la figure 2 et les distances et les angles interatomiques sont rassemblés dans les tableaux 1 et 2 respectivement. Il est raisonnable de penser que tous les cycloadduits **6** et **7** ont la même stéréochimie et que l'approche dipôle–dipolarophile s'est bien effectuée sur le demi-espace le moins encombré du dipôle cyclique.

Nous espérions réussir une synthèse asymétrique par cycloaddition du dipôle **1***f* (R^1 = Ph; $R^2 = CH_3$) où l'un des épimères est largement majoritaire. En fait, on obtient un mélange racémique du cycloadduit comme le montre le dédoublement des signaux des protons H6 et H7 sur le spectre de rmn ^{1}H du composé **6***f* enregistré dans $CDCl_3$ en présence de l'auxiliaire chiral (+)Eu(TFC)$_3$. Il apparaît donc que même si l'on pouvait obtenir un épimère énantiomériquement pur du précurseur **1***f* de l'ylure d'azométhine potentiel, la configuration absolue du carbone asymétrique C-6 est transformée en deux configurations *R* et *S* lors de la réaction de cycloaddition, probablement via deux prototropies ayant lieu lors du chauffage de l'oxazinone **1** (schéma 5). Cette racémisation peut également avoir lieu lors de la formation de **1***f* par traitement du bromhydrate **5***f* à l'aide de triéthylamine. Tout se passe donc comme s'il existait un équilibre entre les deux formes énantiomères de l'ylure d'azométhine, qui conduiront aux deux énantiomères de **6***f* ou **7***f* par cycloaddition sur le *N*-méthyl ou *N*-phénylmaléimide.

Les paramètres spectroscopiques des différents cycloadduits **6** et **7** sont rassemblés en partie expérimentale.

En conclusion, ce travail confirme la diastéréospécificité de l'approche dipôle–dipolarophile lorsque le dipôle-1,3 est complètement inséré dans un cycle, diastéréospécificité conduisant au cycloadduit de structure *exo*. Si le cycle comporte un stéréocentre, l'approche intervient également sur la face la moins encombrée du dipôle. Mais avec le présent modèle la double prototropie qui intervient au cours de la réaction empêche une éventuelle synthèse asymétrique.

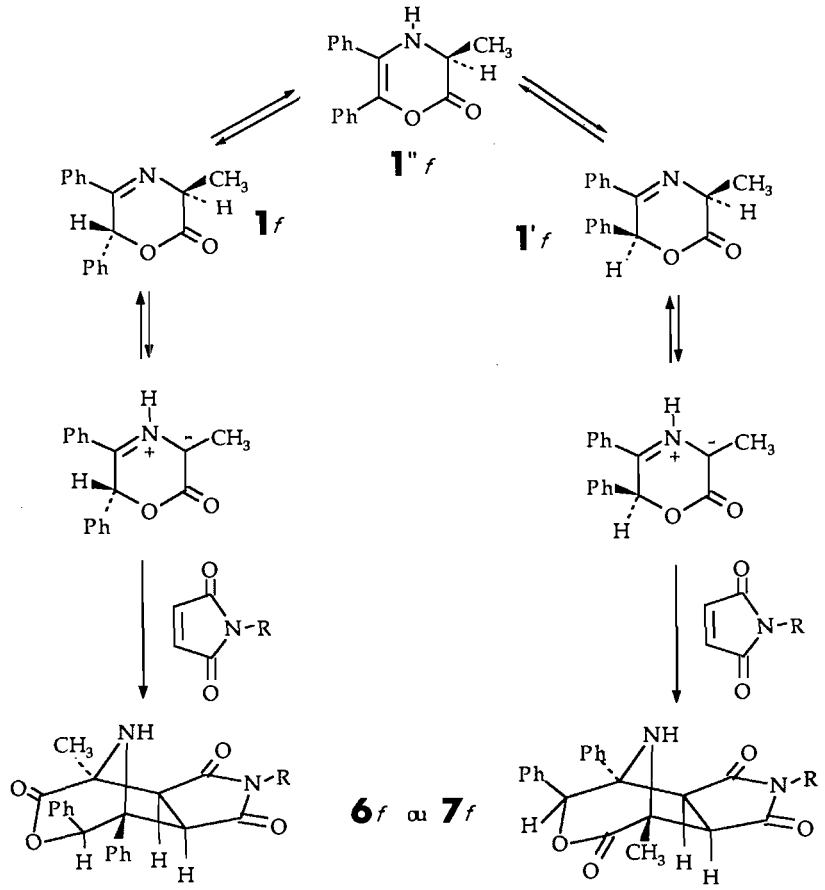
Schéma 5



Partie expérimentale

Les points de fusion déterminés sur banc Kofler ne sont pas corrigés. Les spectres d'absorption ir ont été obtenus avec un spectrophotomètre Beckman IR 33, les produits étant pastillés dans KBr. Les spectres de rmn ^{1}H ont été obtenus avec un spectromètre Bruker-Spectrospin AC 200, les échantillons étant dissous dans $CDCl_3$ ou DMSO-d_6 avec le tétraméthylsilane comme référence interne. Les microanalyses ont été assurées par le Service d'Analyses du CNRS à Vernaison.

1. Synthèse des 5-phényl-3,6-dihydro-2*H*-1,4-oxazin-2-one 1

1.1. Préparation des esters α-cétoliques d'acides N-*(benzyloxycarbonyl)-aminés 4*

Les acides aminés *N*-protégés sont des produits commerciaux.

Mode opératoire général : Dans un réacteur de 250 mL muni d'un agitateur et d'un réfrigérant à reflux, on prépare une solution de 0,10 mol d'acide *N*-(benzyloxycarbonyl)-aminé dans 100 mL de NaOH 1 N et 70 mL d'éthanol. On y ajoute 0,10 mol d'α-bromoalkylphénone. Le mélange est porté à reflux de 1 à 3 h selon les cas. On laisse revenir le milieu réactionnel à température ambiante, puis on effectue les traitements suivants :

Avec R^1 = H, Ph et R^2 = H, CH_3 :

On additionne de l'éthanol jusqu'à ce que la solution devienne claire et limpide. La solution est placée 1 nuit au réfrigérateur. Le produit solide obtenu est filtré, séché et recristallisé dans l'éthanol. Dans le cas où R^1 = Ph et R^2 = CH_3, on obtient deux diastéréoisomères que l'on sépare par cristallisation fractionnée dans l'éthanol.

Avec R^1 = CH_3 et R^2 = H, CH_3 :

La solution est concentrée sous vide afin d'éliminer une partie de l'éthanol, puis on l'extrait à l'éther. La phase organique est lavée plusieurs fois à l'eau, séchée sur Na_2SO_4, puis évaporée sous pression réduite. Le résidu obtenu est huileux. Dans le cas ou R^1 = CH_3 et R^2 = CH_3, on obtient aussi deux diastéréoisomères que nous n'avons pas pu séparer par chromatographie.

N-*Benzyloxycarbonylglycinate de benzoylméthyle 4*a *(R^1 = R^2 = H)* : Durée de la réaction : 1 h, *F* = 96°C, Rdt. 97%; ir : ν(NH) = 3349 cm^{-1}, ν(C=O) = 1760, 1697 cm^{-1}; rmn ^{1}H ($CDCl_3$) : 4,20 (d, 2H, $J_{CH_2\text{-}NH}$ = 6), 5,14 (s, 2H, Ph-CH_2-O), 5,40 (sl, 1H, NH), 5,42 (s, 2H, -O-CH_2-CO), 7,30–7,92 (m, 10 H ar.); rmn ^{13}C ($CDCl_3$) : 42,50 (t, *J* = 140, CH_2-N), 66,50 (t, *J* = 147, CH_2), 67 (t, *J* = 148, CH_2), 127,60–136 (8 signaux des C ar.), 156,10 (s, C=O carbamate), 169,50 (s, C=O ester), 191,20 (s, C=O cétone). Anal. calc. (%) pour $C_{18}H_{17}NO_5$: C66,04, H 5,24, N 4,28; tr. (%) : C 65,93, H 5,32, N 4,17.

N-*Benzyloxycarbonyl-L-alanate de benzoylméthyle 4*b *(R^1 = H, R^2 = CH_3)* : Durée de la réaction : 3 h, *F* = 146°C, Rdt. 88%; ir : ν(NH) = 3367 cm^{-1}, ν(C=O) = 1756, 1689 cm^{-1}; rmn ^{1}H ($CDCl_3$) : 1,55 (d, 3H, *J* = 7, CH_3-CH), 4,55 (dq, 1H, $J_{CH_3\text{-}CH}$ = 7; $J_{CH\text{-}NH}$ = 7, Me-C*H*-NH-), 5,12 (s, 2H, Ph-CH_2-

O), 5,25 (d, 1H, J = 16, 20, -CO-HC*H*-O), 5,29 (sl, 1H, NH), 5,44 (d, 1H, J = 16, 20, -CO-*H*CH-O), 7,30–7,93 (m, 10 H ar.); rmn ^{13}C ($CDCl_3$) : 18,70 (q, J = 130, *C*H_3), 49,80 (d, J = 133, CH), 66,40 (t, J = 139, *C*H_2), 66,90 (t, J = 140, -*C*H_2), 127,70–136,30 (8 signaux des C ar.), 156,30 (s, C=O carbamate), 172,50 (s, C=O ester), 191,40 (s, C=O cétone). Anal. calc. (%) pour $C_{19}H_{19}NO_5$: C 66,85, H 5,61, N 4,10; tr. (%) : C 67,02, H 5,55, N 4,22.

N-*Benzyloxycarbonylglycinate de 1-benzoyléthyle* **4**c (R^1 = CH_3, R^2 = *H*) : Durée de la réaction : 3 h, huile, Rdt. 70%; ir : ν(NH) = 3368 cm^{-1}, ν(C=O) = 1757, 1700 cm^{-1}; rmn ^1H ($CDCl_3$) : 1,54 (d, 3H, J = 6,90, *C*H_3-CH-O), 3,96–4,22 (système AB dédoublé avec J_{AB} = 17, $J_{CH_2\text{-}NH}$ = 6, *C*H_2-NH), 5,10 (s, 2H, *C*H_2-O), 5,38 (t mal défini, 1H, NH), 6,05 (q, 1H, J = 6,90, O-C*H*-CH_3), 7,30–8,02 (m, 10 H ar.); rmn ^{13}C ($CDCl_3$) : 16,30 (q, J = 129, *C*H_3), 41,90 (t, J = 141, *C*H_2-N), 66,10 (t, J = 146, *C*H_2O), 71,70 (d, J = 154, *C*H-O), 127,60–135,80 (8 signaux des C ar.), 156,10 (s, C=O carbamate), 169,20 (s, C=O ester), 195,80 (s, C=O cétone). Anal. calc. (%) pour $C_{19}H_{19}NO_5$: C 66,85, H 5,61, N 4,10; Tr. (%) : C 67,16, H 5,42, N 4,37.

N-*Benzyloxycarbonyl-L-alanate de 1-benzoyléthyle* **4**d (R^1 = R^2 = CH_3) : Mélange des deux épimères non séparés. Durée de la réaction : 3 h, huile, Rdt. 86%; ir : ν(NH) = 3349 cm^{-1}, ν(C=O) = 1752, 1700 cm^{-1}; rmn ^1H ($CDCl_3$) : 1,44–1,57 (quatre doublets imbriqués correspondant aux 6 protons des groupes méthyle de chaque épimère), 4,50 (m, 1H, -C*H*-NH- des deux épimères), 5,12 (sl, 2H, CH_2-O), 5,35 (deux doublets élargis pour les groupes NH de chaque épimère), 6,02 (m, pour le groupe CH_3-C*H*-O de chaque épimère), 7,30–7,95 (m, 10 H ar.); rmn ^{13}C ($CDCl_3$) : 16,90 et 17 (deux signaux correspondant aux groupes *C*H_3-CH-NH de chaque épimère), 18,30 et 18,50 (deux signaux correspondant aux groupes *C*H_3-CH-O de chaque épimère), 49,40 et 49,60 (deux signaux correspondant aux groupes CH_3-*C*H-NH de chaque épimère), 66,80 (un signal correspondant aux groupes *C*H_2-O de chaque épimère), 72,10 et 72,20 (deux signaux correspondant aux groupes CH_3-*C*H-O de chaque épimère), 127,90–136,10 (11 signaux des C ar. des deux épimères), 155,50 et 155,60 (deux signaux correspondant aux C=O carbamate de chaque épimère), 172 et 172,50 (deux signaux correspondant aux C=O ester de chaque épimère), 196 et 196,20 (deux signaux correspondant aux C=O cétoniques de chaque épimère).

N-*Benzyloxycarbonylglycinate de désyle* **4**e (R^1 = *Ph*, R^2 = *H*) : Durée de la réaction : 3 h, F = 122°C, Rdt. 80%; ir : ν(NH) = 3357 cm^{-1}, ν(C=O) = 1751, 1694 cm^{-1}; rmn ^1H ($CDCl_3$) : 4,05–4,28 (système AB dédoublé avec J_{AB} = 17 et ^3J = 6,50, 2H, -CH_2-NH), 5,11 (s, 2H, CH_2-O), 5,31 (t élargi, 1H, NH), 6,92 (s, 1H, Ph-C*H*-O), 7,30–7,98 (m, 15 H ar.); rmn ^{13}C ($CDCl_3$) : 42,60 (t, J = 140,80, *C*H_2-N), 67 (t, J = 146, *C*H_2-O), 78,30 (d, J = 149,50, *C*H-O), 127,90–136,10 (122 signaux pour 18 C ar.), 156,40 (s, C=O carbamate), 169,60 (s, C=O ester), 193 (s, C=O cétone). Anal. calc. (%) pour $C_{24}H_{21}NO_5$: C 71,45, H 5,25, N 3,47; tr. (%) : C 71.67, H 5,12, N 3,52.

N-*Benzyloxycarbonyl-L-alanate de désyle* **4**f (R^1 = *Ph*, R^2 = CH_3) : Durée de la réaction : 3 h, Rdt. global 80%.
Epimère majoritaire, F = 110°C; ir : ν(NH) = 3379 cm^{-1}, ν(C=O) = 1760, 1701 cm^{-1}; rmn ^1H ($CDCl_3$) : 1,56 (d, 3H, J = 7,20, *C*H_3-CH), 4,54 (dq, 1H, $J_{CH_3\text{-}CH}$ = $J_{CH\text{-}NH}$ = 7,20), 5,10 (système AB fortement couplé centré à 5,10 ppm, 2H, CH_2-O), 5,29 (d, 1H, J = 7,20, NH), 6,90 (s, 1H, Ph-C*H*-O), 7,30–7,97 (m, 15 H ar.); rmn ^{13}C ($CDCl_3$) : 18,60 (q, J = 140, *C*H_3-CH), 49,50 (d, J = 145,90, *C*H-CH_3), 66,90 (t, J = 139,50, *C*H_2-O), 78,30 (d, J = 149, *C*H-O), 128,10–136,20 (10 signaux pour 15 C ar.), 155,60 (s, C=O carbamate), 172,60 (s, C=O ester), 193,10 (s, C=O cétone). Anal. calc. (%) pour $C_{25}H_{23}NO_5$: C 71,93, H 5,55, N 3,36; tr. (%) : C 72,12, H 5,41, N 3,27.
Epimère minoritaire, F = 112°C; ir : ν(NH) = 3379 cm^{-1}, ν(C=O) = 1739, 1690 cm^{-1}; rmn ^1H ($CDCl_3$) : 1,44 (d, 3H, J = 7,10, *C*H_3-CH), 4,56 (dq, 1H, $J_{CH_3\text{-}CH}$ = $J_{CH\text{-}NH}$ = 7,10), 5,08 (système AB fortement couplé centré à 5,08 ppm, 2H, *C*H_2-O), 5,26 (d, 1H, J = 7,10, NH), 7,30–7,97 (m, 15 H ar.); rmn ^{13}C ($CDCl_3$) : 18,60 (q, J = 140, *C*H_3-CH), 49,80 (d, J = 145, *C*H-CH_3), 66,90 (t, J = 139,50, *C*H_2-O), 78,20 (d, J = 147, *C*H-O), 128,10–136,20 (10 signaux pour 15 C ar.), 155,50 (s, C=O carbamate), 172,20 (s, C=O ester), 193,20 (s, C=O cétone).

1.2. Synthèse des bromhydrates des esters α-cétoliques d'acides aminés **5**

Mode opératoire général : La préparation et le traitement se font sous atmosphère d'azote. Dans un erlenemeyer bicol de 250 mL, surmonté d'un réfrigérant muni d'une arrivée d'azote, on place 10 g d'ester α-cétolique d'acide *N*-(benzyloxycarbonyl)-aminé. À l'aide d'une ampoule à brome, on additionne goutte à goutte 50 mL d'HBr–CH_3COOH à 40%.

On remarque un dégagement de CO_2 et la réaction est légèrement exothermique. Après 15 min d'agitation, on chauffe le mélange dans un bain d'huile à T = 50°C pendant 5 min. On laisse revenir le milieu réactionnel à température ambiante, puis on lui ajoute 150 mL d'éther anhydre. La solution est placée dans un bain de glace.

Pour R^1 = R^2 = H; R^1 = H, R^2 = CH_3; R^1 = Ph, R^2 = H; R^1 = Ph, R^2 = CH_3, le bromhydrate précipite avec un rendement quantitatif. Le solide est filtré sur verre fritté sous atmosphère d'azote, lavé plusieurs fois à l'éther anhydre et essoré. Ces produits incolores sont très hygroscopiques. Ils sont directement utilisés pour la réaction suivante.

Pour R^1 = CH_3 et R^2 = H, CH_3, le bromhydrate reste à l'état pâteux. On aspire la solution éthérée surnageante à l'aide d'une trompe à eau, et rince plusieurs fois à l'éther anhydre, tout en restant sous atmosphère d'azote. Ces produits pâteux sont utilisés directement pour la réaction suivante.

Les bromhydrates **5** n'ont pas été soumis à l'analyse élémentaire quantitative. Paramètres de rmn ^1H et ^{13}C des bromhydrates **5** isolés à l'état solide (dans D_2O) sont comme suit.

Bromhydrate du glycinate de benzoylméthyle **5**a (R^1 = R^2 = *H*) : rmn ^1H : 4,20 (s, 2H, CH_2-$\overset{+}{N}$), 5,76 (s, 2H, O-CH_2-O), 7,61 (t, 2 H ar.), 7,78 (d, 1H ar.), 7,97 (d, 2 H ar.); rmn ^{13}C : 42,90 (t, J = 146, *C*H_2-$\overset{+}{N}$), 70,90 (t, J = 149,50, *C*H_2-O), 129,40–137,90 (4 signaux des C ar.), 170,60 (s, C=O ester), 198 (s, C=O cétone).

Bromhydrate du L-alanate de benzoylméthyle **5**b (R^1 = *H*, R^2 = CH_3) : rmn ^1H : 1,73 (d, 3H, J = 7,20, *C*H_3-CH-$\overset{+}{N}$), 4,45 (q,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

1H, J = 7,20, C*H*-CH_3), 5,70 (système AB fortement couplé centré à 5,70 ppm), 7,41 (t, 2 H ar.), 7,58 (t, 1 H ar.), 7,76 (d, 2 H ar.); rmn ^{13}C : 16,40 (q, J = 139, CH_3-CH-$\overset{+}{N}$), 49,80 (d, J = 146, -CH-$\overset{+}{N}$), 69,10 (t, J = 149, CH_2-O), 129–136,10 (4 signaux des C ar.), 178–40 (s, C=O ester), 196 (s, C=O cétone).

Bromhydrate du glycinate de désyle **5**e *(R^1 = Ph, R^2 = H)* : rmn ^{1}H : 4,29 (système AB centré à 4,29 ppm, J_{AB} = 17,50, CH_2-$\overset{+}{N}$), 7,42 (s, 1H, Ph-CH-O), 7,45–8,11 (m, 10 H ar.); rmn ^{13}C : 39,70 (t, J = 146, CH_2-$\overset{+}{N}$), 79 (d, J = 152, CH-O), 128,30–134,50 (8 signaux pour 10 C ar.), 167 (s, C=O ester), 195,30 (s, C=O cétone).

Bromhydrate du L*-alanate de désyle* **5**f *(R^1 = Ph, R^2 = CH_3), deux épimères* : rmn ^{1}H : 1,83 (d, 3H, J = 7,20, CH_3 épimère minoritaire), 1,96 (d, 3H, J = 7,20, CH_3 épimère majoritaire), 4,58 (q, 1H, J = 7,20, CH épimère majoritaire), 4,67 (q, 1H, J = 7,20, CH épimère minoritaire), 7,30–8,20 (m, 11H, Ph-CH-O et H ar. des deux épimères); rmn ^{13}C : 15,80 (q, J = 138, CH_3-CH-$\overset{+}{N}$ de l'épimère minoritaire), 16,10 (q, J = 139, CH_3-CH-N de l'épimère majoritaire), 49,40 (d, J = 147, CH-$\overset{+}{N}$ pour les deux épimères), 80 (d, J = 153, CH-O pour les deux épimères), 129,30–135,40 (8 signaux pour les 10 C ar. des deux épimères), 170,40 et 170,70 (s, C=O ester), 196 et 196,20 (s, C=O cétone).

*1.3. Préparation des 3,6-dihydro-2*H*-1,4-oxazin-2-ones* **1**

Mode opératoire général : Sous atmosphère d'azote, dans un erlenmeyer bicol surmonté d'un réfrigérant, on place 5 g du bromhydrate dans 50 mL de toluène anhydre. La solution est chauffée dans un bain d'huile à 50°C pendant 5 min. À ce mélange, on ajoute goutte à goutte un équivalent de triéthylamine en solution dans deux fois son volume de toluène anhydre. Après addition, le mélange est agité 15 min à 50°C. La solution laisse apparaître un précipité blanc qui est filtré. On concentre le filtrat à 20% de son volume sous pression réduite.

Le résidu est additionné d'éther anhydre pour faire précipiter le sel de triéthylammonium encore dissout. On filtre ce sel et réévapore la solution à l'évaporateur rotatif. On obtient un produit solide ou huileux directement utilisé pour les réactions de cycloaddition. Les solides sont purifiés par cristallisation dans l'éthanol pour les analyses spectroscopiques.

*5-Phényl-3,6-dihydro-2*H*-1,4-oxazin-2-one* **1**a *(R^1 = R^2 = H) (19)* : Rdt. 40%, F = 95°C; ir : ν(C=O) = 1739 cm^{-1}; rmn ^{1}H ($CDCl_3$) : 4,55 (t, 2H, J = 2, CH_2-N), 5,39 (t, 2H, J = 2, CH_2-O), 7,40–7,80 (m, 5 H ar.); rmn ^{13}C ($CDCl_3$) : 50,40 (t, J = 142,60, CH_2-N), 67,20 (t, J = 149,80, CH_2-O), 125,90, 128,70, 131,40 et 134 (4 signaux pour 6 C ar.), 162,90 (s, C=N), 166,60 (s, C=O).

2. Cycloaddition des 3,6-dihydro-2*H*-1,4-oxazin-2-ones sur les *N*-méthyl et *N*-phénylmaléimides

Mode opératoire général

La réaction est effectuée sous atmosphère d'azote. On dissout 10 mmol du précurseur de dipôle dans 40 mL de toluène anhydre. À cette solution, on ajoute 12 mmol de dipolarophile et le mélange est porté à reflux pendant une durée variable.

Pour R^1 = R^2 = H, R^3 = CH_3 ou Ph et R^1 = CH_3, R^2 = H, R^3 = CH_3 ou Ph, on obtient un précipité lorsque la solution revient à température ambiante. Le solide est filtré et recristallisé dans l'éthanol.

Pour tous les autres cas, le solvant est évaporé à l'évaporateur rotatif et on obtient une huile à laquelle on ajoute 1 mL d'éthanol et 1 mL de toluène. Un solide cristallise après 24 h au réfrigérateur, il est filtré et lavé à l'éthanol.

3. Analyse radiocristallographique du cycloadduit 6*d*

Les monocristaux incolores de morphologie irrégulière de **6***d* ont été obtenus par recristallisation dans l'éthanol. Le cristal de dimensions approximatives 0,40 × 0,30 × 0,15 mm a été monté sur un diffractomètre CAD4 d'Enraf–Nonius. Les paramètres de la maille élémentaire ont été calculés à partir de 25 réflexions sélectionnées par le programme SEARCH et centrées par SETANG de la bibliothèque SDP. Les extinctions systématiques ($h0l$, $h + l = 2n$; $0k0$, $k = 2n$) ont indiqué le groupe d'espace unique $P2_1/n$ du système monoclinique. Les intensités mesurées ont été conventionnellement corrigées pour les effets de Lorentz et de polarisation. Les données cristallographiques sont rassemblées dans le tableau 3. La structure de **6***d* a été résolue par les méthodes directes (MULTAN de SDP) qui ont permis la localisation des atomes non-hydrogène. Les coordonnées des ces atomes ont été affinées avec les facteurs thermiques anisotropes. Les positions des atomes d'hydrogène ont été calculées à l'aide du programme HYDRO, à l'exception de l'atome H1 (porté par N1) qui a été localisé sur la carte de Fourier-différence. Les atomes d'hydrogène ont été introduits dans les calculs finaux avec les paramètres thermiques isotropes. Les coordonnées des atomes non-hydrogène sont données dans le tableau 4.

Tableaux des données cristallographiques complètes (S1), facteurs thermiques anisotropes (S2), atomes d'hydrogène (S3), distances (S4) et angles (S5) interatomiques (5 pages), ont été déposés comme matériel supplémentaire.[2]

Abstract: The photochemistry and photophysics of 1-phenylcyclobutene and five aryl-substituted derivatives have been studied in various solvents at room temperature. All six compounds fluoresce with quantum yields in the 0.2–0.3 range in cyclohexane and acetonitrile solution. 1-Phenylcyclobutene undergoes [2+2]-cycloreversion ($\phi = 0.09$) to yield phenylacetylene upon photolysis in either hydrocarbon or acetonitrile solution, and undergoes (Markovnikov) solvent addition upon irradiation in methanol solution ($\phi = 0.08$) in addition to cycloreversion. Triplet sensitization and quenching experiments indicate that cycloreversion and methanol addition are both excited singlet state processes. None of the six compounds studied undergo ring opening to the corresponding 2-aryl-1,3-butadiene in detectable yield. Quantum yields for cycloreversion in cyclohexane, acetonitrile, and methanol solution and methanol addition have been determined for the six compounds, along with excited singlet state lifetimes. The quantum yields and rate constants for cycloreversion and methanol addition are both enhanced by substitution with electron-donating groups. The variation in the rate constant for [2+2]-cycloreversion with substituent indicates that there is substantial dipolar character developed in the cyclobutenyl σ-bond framework during the reaction, in almost exact correspondence with that developed in the π system during photoprotonation. No deuterium scrambling is observed in 1-phenylcyclobutene-2,4,4-d_3 after photolysis in pentane solution to ca. 80% conversion, indicating that skeletal rearrangements leading to cyclopropyl carbenes do not occur in the direct photolysis of arylcyclobutene derivatives. A pericyclic mechanism for the photocycloreversion reaction is suggested. Triplet–triplet absorption spectra and triplet lifetimes of 1-phenyl-, 1-(*para*-methylphenyl)-, and 1-(*para*-trifluoromethylphenyl)cyclobutene in hydrocarbon solution are also reported.

Key words: photochemistry, cyclobutene, fluorescence, [2+2]-cycloreversion, substituent effects, nanosecond laser flash photolysis, lifetime, triplet state, styrene, photoaddition

Résumé : On a étudié, dans différents solvants et à différentes températures, la photochimie et la photophysique du 1-phenylcyclobutène et de cinq dérivés aryles substitués. Tous ces six composés entrent en fluorescence avec des rendements quantiques de l'ordre de 0,2 à 0,3 en solution dans le cyclohexane et dans l'acétonitrile. Le 1-phénylcyclobutène subit une cycloélimination [2+2] ($\phi = 0{,}09$) pour conduire au phénylacétylène par photolyse en solution dans un hydrocarbure ou dans l'acétonitrile, avec en plus une addition de solvant (de type Markovnikov) par irradiation dans une solution de méthanol ($\phi = 0{,}08$). Les expériences de sensibilisation du triplet et de désactivation indiquent que la cycloélimination et l'addition de méthanol sont toutes deux des états singulets excités. Aucun des six composés étudiés ne conduit par ouverture du cycle au 2-aryl-1,3-butadiène en quantité décelable. On a déterminé, pour les six composés, les rendements quantiques de la cycloélimination dans des solutions de cyclohexane, d'acétonitrile et de méthanol et de l'addition de méthanol ainsi que les temps de vie de l'état singulet excité. La présence de substituants électrodonneurs augmente les rendements quantiques et les constantes de vitesse de la cycloélimination et de l'addition de méthanol. La variation de la constante de vitesse de la cycloélimination [2+2] indique qu'il se développe un caractère dipolaire très marqué dans les liaisons σ du squelette du groupe cyclobutényle au cours de la réaction et cela correspond presqu'exactement au caractère qui se développe dans les systèmes π au cours de la photoprotonation. On n'observe pas de brouillage du au deutérium dans le 1-phénylcyclobutène-2,4,4-d_3 après la photolyse en solution dans le pentane avec une conversion de 80% environ; ceci indique que le réarrangement du squelette conduisant au carbènes du type cyclopropyle ne se produit pas lors de la photolyse directe des dérivés arylcyclobutènes. On suggère un mécanisme péricyclique pour la réaction de photocycloélimination. On rap-

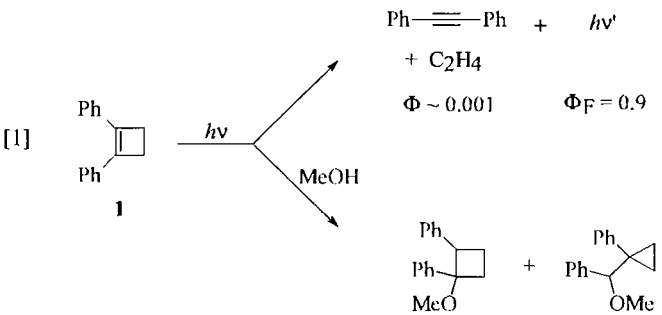
Introduction

The photochemistry of alkyl- and arylcyclobutenes appears to differ in many respects (1, 2). Alkyl-substituted derivatives undergo competing ring opening and [2+2]-cycloreversion upon photolysis in solution. Ring opening is nonstereospecific in most simple cyclobutenes (3, 4), while cycloreversion takes place stereospecifically (5, 6). The quantum yields of these processes vary according to the relative energies of the cyclobutene Rydberg and valence states. Substitution with nonconjugative electron-withdrawing substituents results in a substantial reduction in the quantum yield for cycloreversion and a significant increase in that for ring opening (4). From this it has been concluded that ring opening is a π,π^* singlet



state process, while cycloreversion arises from an excited singlet state with substantial (π,R(3*s*)) Rydberg character. The observation of skeletal rearrangements in the photochemistry of asymmetrically substituted, monocyclic alkylcyclobutenes suggests that cycloreversion may proceed via cyclopropyl carbene intermediates formed by ring contraction (7–9).

While arylcyclobutenes have not been as extensively studied as alkylated derivatives, 1,2-diphenylcyclobutene (**1**) is known to fluoresce efficiently and undergo formal [2+2]-cycloreversion upon photolysis in hydrocarbon solution (see eq. [1]), to the exclusion of ring opening (9–11). This contrasts the behaviour of benzocyclobutenes and Dewar aromatics, which both undergo efficient ring opening upon photolysis in condensed media (12–15). It has been suggested that the failure of arylcyclobutenes to undergo excited state ring opening may be due to simple energetic considerations; the π,π^* singlet state energy is too low to enable cleavage of the cyclobutene C3—C4 bond (1, 2). A second possibility is that the lack of reactivity towards ring opening is for some reason due to polarization of the styrenic C=C bond in the π,π^* excited singlet state. In acyclic and other cyclic phenylalkenes, this polarization is reflected in enhanced basicity and nucleophilicity in the excited state compared to that in the ground state (16–19). This appears to hold true for arylcyclobutenes as well, since photolysis of **1** in alcohol solution results in the formation of ethers consistent with initial protonation of the lowest excited singlet state by the solvent (18).

b: X = 4-CH_3 *e*: X = 4-CF_3
c: X = H *f*: X = 3-CF_3

2

1-Phenylcyclobutene (**2***c*) fluoresces ($\Phi_F = 0.27$) in solution (20) and in the gas phase (21, 22), and affords the styrenic triplet state by intersystem crossing (20, 23, 24). To our knowledge, however, no information on the photochemistry of this molecule exists in the literature. In this paper, we report the results of a study of the effects of aryl substituents on the photochemical and photophysical behavior of 1-phenylcyclobutene, using the series of compounds **2***a–f*. The study of **2***a–f*, which were chosen so as to systematically alter the basicity and polarization of the π,π^* singlet state, was undertaken with several goals in mind. Our primary goals were to determine whether ring opening might become an important mode for excited state decay in phenylated cyclobutenes when the polarization of the C=C bond is altered through appropriate substitution, and to what degree [2+2]-cycloreversion is affected by such alterations in the electronic character of the lowest excited singlet state. The possibility that photocycloreversion proceeds via a similar mechanism to that of alkylcyclobutenes has been investigated with 1-phenylcyclobutene-2,4,4-d_3 (**2***c*–d_3), in which the involvement of a cyclopropylcarbene intermediate should be revealed by scrambling of deuteriums between C4 and C3 in reisolated material after photolysis.

We also wished to examine the effects of substituents on the efficiency of the photoaddition of alcohols to the molecule, as 1-phenylcyclobutene is a rigid analog of styrene, for which the photoaddition of water and alcohols has been studied in detail (19, 25, 26). Styrenes substituted with electron-withdrawing substituents do not undergo photohydration in solution in detectable yield (19, 25, 26). The process involves initial protonation of the excited singlet state, a property that makes electron-donor substituted styrenes useful as precursors for the corresponding 1-phenylethyl cations in time-resolved studies of carbenium ion reactivity (27–29). Presumably, photoprotonation is inefficient in electron-poor analogs because their relatively low excited state basicities render the process too slow to compete effectively with free-rotor excited state relaxation. Thus, arylcyclobutenes may also be potentially suitable as precursors for the study of electron-acceptor substituted benzylic carbenium ions by time-resolved methods. We have studied the photoaddition of methanol to **2***a–f* and have examined the effect of the alcohol on their excited singlet state lifetimes, in order to lay the groundwork for future studies of this type.

Finally, we report the triplet–triplet absorption spectra of 1-phenylcyclobutene (**2***c*) and the 4-methyl- (**2***b*) and 4-trifluo-

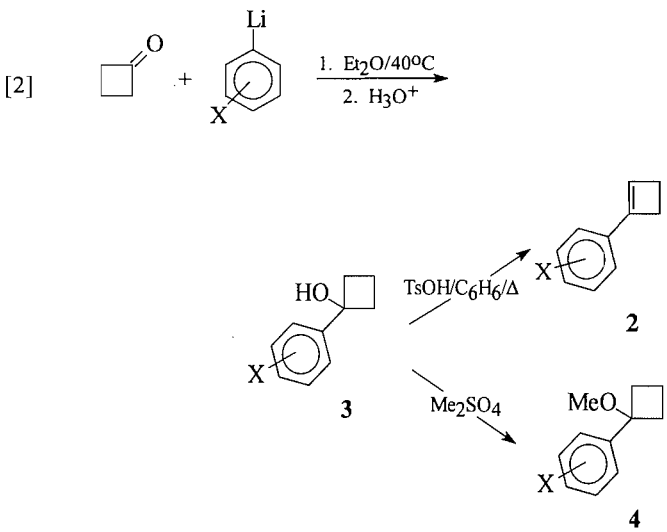
2c-d_3

romethyl- (**2*d***) analogs in cyclohexane solution at room temperature, along with rate constants for triplet–triplet energy transfer to *trans*-piperylene, obtained using nanosecond laser flash photolysis (NLFP) techniques. The triplet states of a wide variety of cyclic and acyclic arylalkenes have already been characterized by such methods (23, 30, 31), but that of 1-phenylcyclobutene has not.

Results

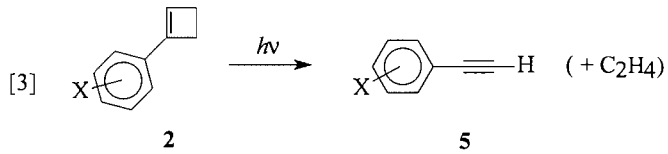
Compounds **2*a–f*** were synthesized by addition of the corresponding aryllithium reagent to cyclobutanone, followed by acid-catalyzed dehydration of the intermediate 1-arylcyclobutanol (**3**; see eq. [2]). The cyclobutanols were also methylated to provide authentic samples of the ethers (**4**) anticipated from the photolysis of the arylcyclobutenes in methanol solution.



[2]

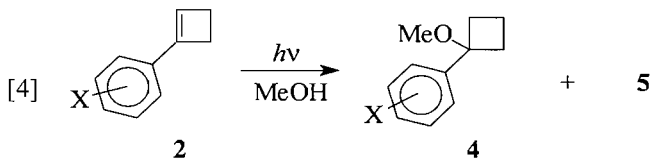
Compound **2*c*–d_3** was synthesized from cyclobutanone-2,2,4,4-d_4 using a similar procedure to that employed for the synthesis of the parent compound (**2*c***). ^{1}H NMR analysis of the compound indicated it to be ca. 93% deuterated at positions 2 and 4 of the cyclobutenyl ring.

Direct irradiation of deoxygenated ~0.002 M solutions of **2*a–f*** in pentane or dried acetonitrile results in the formation of the corresponding arylacetylenes **5*a–f*** in high chemical yield (eq. [3]). In one case (**2*f***), the photolysates also contained substantial amounts of two dimeric compounds. The dimers were not isolated, but were tentatively identified as such on the basis of their mass spectra. The yields of the dimers were significant even when the concentration of **2*f*** was lowered to 2×10^{-4} M. Irradiation of a pentane solution of **2*f*** (2×10^{-4} M) containing 0.02 M 1,3-cyclohexadiene had no effect on the yield of arylacetylene **5*f***, but led to substantial quenching of the formation of the dimeric products.



[3]

Photolysis of a deoxygenated 0.05 M solution of **2*c*–d_3** in acetonitrile-d_3 under similar conditions to those above resulted in the formation of phenylacetylene-*d* (**5*c*–*d***), as verified by GC–MS analysis. Integration of the ^{1}H NMR spectrum of the crude mixture after photolysis to ca. 50% conversion afforded a H3/H4 ratio in the remaining starting material which was indistinguishable from that measured in the unphotolyzed material.



[4]

Direct irradiation of deoxygenated ~0.002 M solutions of **2** in methanol results in the formation of the corresponding 1-aryl-1-methoxycyclobutane **4** (eq. [4]), with substantial quenching of the formation of **5** in each case. No other products were observed to be formed in significant yield from photolysis of any of the compounds studied, so long as the conversions were kept below ca. 30%. At higher conversions, small amounts of reduction products of **2** could be detected in the photolysates; these were tentatively identified as the corresponding arylcyclobutanes by GC–MS. Photolysis of similar solutions in the presence of *trans*-1,3-pentadiene (0.01 M) yielded the same products in approximately the same quantum yields as those carried out in the absence of diene.

Quantum yields for formation of **5** (ϕ_5) and **4** (ϕ_4) from direct irradiation of **2** (to ca. 5% conversion) in deoxygenated pentane and methanol solutions, respectively, were determined by potassium ferrioxalate actinometry and are collected in Table 1. Included in this table are quantum yields for the formation of **5** in acetonitrile solution, which were determined for each compound using the quantum yields in pentane as secondary standards. Quantum yields for formation of **5** in methanol solution were estimated based on the relative yields of **5** and **4** obtained upon photolysis of **2** (to 5–12% conversion) in that solvent.

Photolysis of deoxygenated 0.008 M solutions of **2*c*** in acetonitrile containing varying amounts of methanol between 0 and 16 M were carried out in a merry-go-round apparatus, and product formation was monitored by GC after ca. 2% conversion. Figure 1(*a*) shows the Stern–Volmer plot for quenching of the formation of phenylacetylene (**5*c***) by the alcohol. The slope yields a Stern–Volmer constant of $k_q\tau = 0.046 \pm 0.003$ M^{-1}. Figure 1(*b*) shows a reciprocal plot of the yield of **4*c*** obtained in these experiments as a function of methanol concentration. The data were corrected for the formation of a small amount of a product (presumably the alcohol **3*c***) that has the same retention time as the ether under the GC conditions employed, and which is formed in significant yields in acetonitrile in the absence of methanol. The intercept/slope

[a]Determined at 23 ± 1°C.
[b]Errors in fluorescence quantum yields are ca. 20%.
[c]Errors in lifetimes are ca. 10%.

ratio calculated by least-squares analysis of these data affords $k_q\tau = 0.02 \pm 0.01$ M^{-1}; this value should be considered to be a lower limit owing to the poor precision of the data at lower methanol concentrations.

Steady state fluorescence emission spectra of the six compounds were recorded in deoxygenated acetonitrile and pentane solutions at 25°C, as well as in methanol in the cases of **2***b–d*. The emission bands showed minor fine structure in pentane, but were approximately Gaussian in acetonitrile and methanol, with maxima centred at 320–330 nm. Fluorescence quantum yields were determined using naphthalene as a standard ($\phi_F = 0.23$ (32)) (33), and are listed in Table 2.

The phosphorescence emission spectrum of **2***c* was measured in a methylcyclohexane glass at 77 K. The spectrum (not shown) is similar in position and fine structure to that reported by Ramamurthy et al. for the same compound in thallium-exchanged zeolites (24). The phosphorescence lifetime was determined to be 4.1 ± 0.2 ms in methylcyclohexane at 77 K.

Fluorescence lifetimes were determined for **2***a–f* in deoxygenated pentane, acetonitrile, and methanol solutions using the time-correlated single photon counting technique, and are also included in Table 2. The fluorescence of carefully purified samples of **2***b–f* (monitored at the emission maxima) exhibited single exponential decay kinetics, so long as the number of counts acquired for decay acquisition was kept below 5000. In the case of **2***a*, it was necessary to limit acquisition to less than 2000 counts. GC analysis verified that sample photodecomposition was negligible (i.e., <1%) over the course of these experiments in each case. Oxygen quenches the fluorescence of **2***a–c* efficiently; for example, the lifetime of **2***b* in air-saturated acetonitrile is $\tau_s = 6.0$ ns. This allows a rough estimate of $k_q \sim 2 \times 10^{10}$ M^{-1} s^{-1} for the rate constant for quenching of the excited singlet state of this compound by oxygen in this solvent. On the other hand, there is less than a 10% difference in the lifetimes of **2***d,e* and no difference in those of **2***f* in air- and nitrogen-saturated acetonitrile.

Table 3 contains rate constants for fluorescence (k_F^0) and cycloreversion (k_5) in pentane and acetonitrile solution and cycloreversion and methanol addition (k_4) in methanol, calculated using the quantum yield and lifetime data collected in Tables 1 and 2.

Addition of methanol (0–2 M) to deoxygenated solutions of **2***c* in acetonitrile results in a slight reduction in singlet lifetime: ca. 10% over the concentration range studied. Least-squares analysis of a plot of $1/\tau_s$ vs. methanol concentration over the 0–2 M range (Fig. 1(*c*)) affords a slope of $k_q = (5.1 \pm 1.4) \times 10^6$ M^{-1} s^{-1}. Over a larger concentration range, a plot of $1/\tau_s$ vs. [MeOH] is curved, levelling off to a value of 1.35×10^8 s^{-1} ($\tau_s = 7.4$ ns) for the neat alcohol.

Nanosecond laser flash photolysis (NLFP) experiments employed the pulses (248 nm, 16 ns, 40–80 mJ) from a Kr/F_2 excimer laser and a microcomputer–controlled detection system. Flash photolysis of continuously flowing, extensively deoxygenated isooctane solutions of **2***c* (ca. 6×10^{-5} M) gave

[a]Calculated from quantum yield and lifetime data in Tables 1 and 2.
[b]Fluorescence lifetimes were determined in cyclohexane solution; cycloreversion was determined in pentane solution.

rise to readily detectable transient absorptions in the 300–340 nm region (λ_{max} = 310 nm), which decayed with clean pseudo-first-order kinetics and a lifetime of about 2 μs. Figure 2 shows the transient absorption spectrum obtained from this solution; the insert shows a transient decay trace measured at a monitoring wavelength of 320 nm. Decay traces were collected by signal averaging of four to five separate decays, with correction for the substantial prompt fluorescence emitted by the sample. The presence of oxygen (either added intentionally or due to incomplete deoxygenation) results in substantial reductions in both the initial yield and the lifetime of the transient. The transient is quenched by *trans*-piperylene ($k_q = (1.6 \pm 0.1) \times 10^9$ M^{-1} s^{-1}), and can thus be assigned to the triplet state of **2***c*.

Similar experiments were carried out for 1-(*para*-methylphenyl)- and 1-(*para*-trifluoromethylphenyl)cyclobutene. The triplet–triplet absorption spectrum of **2***b* exhibited λ_{max} = 310 nm, while that of **2***d* was shifted to 320 nm. The triplet lifetimes of both compounds were similar to that of **2***c* in deoxygenated isooctane solution. The triplet–triplet absorptions of **2***b* and **2***d* exhibited similar sensitivities to the presence of oxygen and similar rate constants for quenching by *trans*-piperylene as those from **2***a*. NLFP of extensively deoxygenated solutions containing varying concentrations of **2***d* between 5×10^{-5} and 2×10^{-4} M allowed us to estimate an upper limit of 1×10^9 M^{-1} s^{-1} for the self-quenching rate constant for **2***d*.

Flash photolysis of a deoxygenated, 0.02 M solution of 4-methoxyacetophenone in acetonitrile with a nitrogen laser (337 nm, 6 ns, 4–5 mJ) afforded readily detectable transient absorptions at 385 nm due to formation of the ketone triplet state. The lifetime of the triplet state is quenched upon addition of **2***c* to the solution, with a bimolecular rate constant of $k_q = (2.4 \pm 0.1) \times 10^9$ M^{-1} s^{-1}.

Discussion

The values of ϕ_F (= 0.24) and τ_s (= 12.2 ns) reported here for **2***c* in pentane solution at room temperature are both in reasonable agreement with those reported by Zimmerman et al. for the same compound in methylcyclohexane–isopentane solution at 27°C (ϕ_F = 0.27; τ_s = 15.9 ± 0.9 ns) (20). These workers also reported a value of ϕ_{ISC} = 0.004 for the quantum yield of intersystem crossing in **2***c*, determined by the biacetyl phosphorescence sensitization method (34, 35). Thus, intersystem crossing is over an order of magnitude less efficient than either fluorescence or reaction via [2+2]-cycloreversion (ϕ_{5c} = 0.09), and the combination of these three processes accounts for only about 40% of excited state decay events. Presumably, nonproductive radiationless decay processes account for the rest.

The fluorescence emission maxima of **2***a–f* vary slightly between 320 and 330 nm, but show no regular variation with substituent or solvent throughout the series. On the other hand, the fluorescence quantum yields increase throughout the series in both solvents while the singlet lifetimes decrease, resulting in a fourfold variation in the radiative rate constant k_F^0 (Table 3). The singlet lifetimes are consistently shorter in acetonitrile solution than in pentane for **2***c* and those derivatives bearing electron-donating substituents (**2***a*, *b*). This may be due to the presence of small amounts of water in the polar solvent. Oxygen quenches the lowest excited singlet state of **2***a–c* efficiently ($k_q \sim 2 \times 10^{10}$ M^{-1} s^{-1} for **2***b*), presumably by an electron transfer mechanism (36, 37). In agreement with this, the fluorescence lifetimes of **2***d–f* are approximately the same in air- and nitrogen-saturated solution.

1-Phenylcyclobutene (**2***c*) exhibits readily detectable phosphorescence in a hydrocarbon glass at 77 K, but detection of the triplet in solution at room temperature by nanosecond laser flash photolysis (NLFP) techniques is difficult unless the solutions are *thoroughly* deoxygenated. Presumably, this reflects the rapid quenching of the excited singlet state of **2***c* by molecular oxygen. The triplet–triplet absorption spectrum reported here for **2***c* is similar to that reported previously for 1-phenylcyclopentene (23). The lifetime and UV absorption spectrum of the triplet state of **2***c* appears to be relatively insensitive to substituents on the aryl ring or to solvent polarity. The rate constants for triplet quenching by dienes (e.g., *trans*-piperylene) are significantly slower than the diffusion-controlled rate in both acetonitrile and isooctane, presumably because the triplet energy of **2***c* (ca. 60 kcal/mol (24)) is approximately isothermal with the diene triplet energy. The triplet state of **2***d* is reactive toward dimerization ($k_{sq} \sim 1 \times 10^9$ M^{-1} s^{-1}), but this process proceeds in significant chemical yield only when population of the triplet by intersystem crossing competes

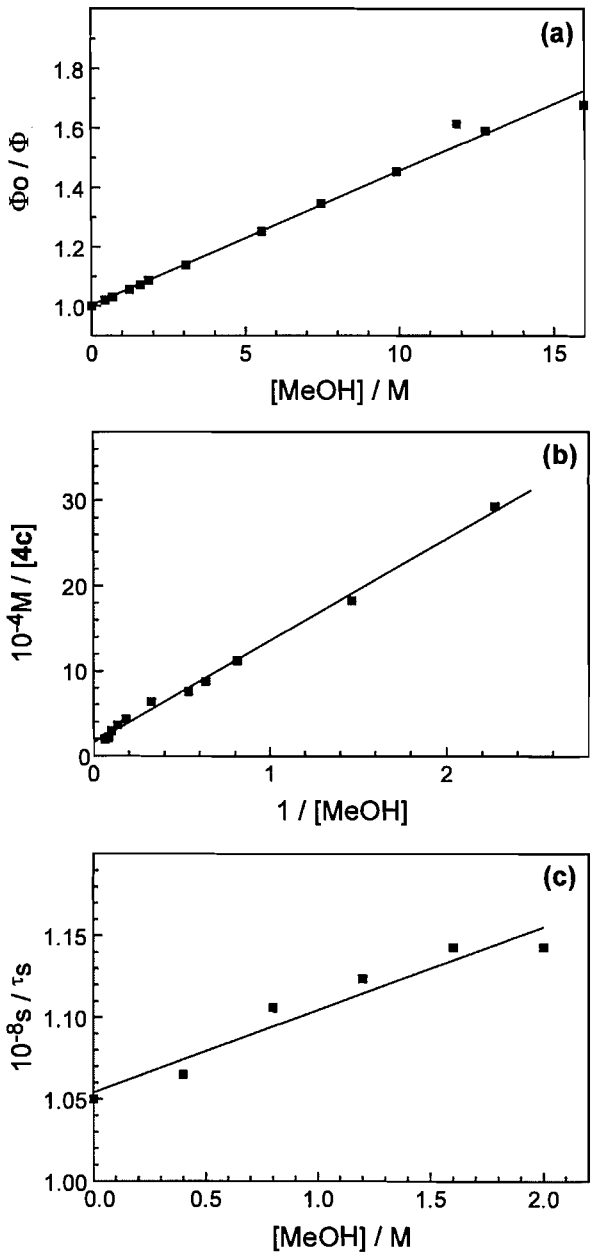
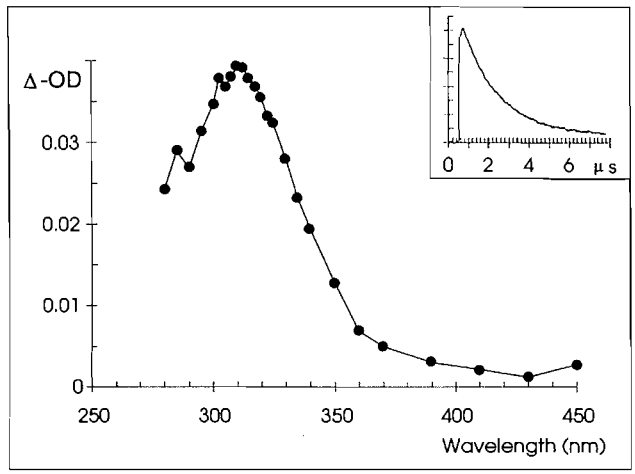
Fig. 1. Quenching of 1-phenylcyclobutene (2*c*) excited singlets by methanol in deoxygenated acetonitrile solution at 23°C: (a) Stern–Volmer plot for the quenching of phenylacetylene (**5***c*) formation; (b) Reciprocal plot for the formation of methyl phenylcyclobutyl ether (**4***c*); (c) quenching of singlet lifetime.



effectively with excited singlet state cycloreversion, as in those derivatives bearing strong electron-withdrawing substituents on the phenyl ring.

Direct irradiation of **2** in aprotic solvents results in the formation of the corresponding phenylacetylene (**5**) in high chemical yield. The reaction is singlet derived, as evidenced by the lack of observable quenching of the formation of **5***c* from photolysis of **2***c* in the presence of diene, and the fact that **5***c* is not formed under triplet sensitization conditions. While there is no significant solvent effect on the quantum yield for cycloreversion for any of the compounds studied (except perhaps for **2***f*), the quantum yields (Table 1) and rate constants (Table 3) for the process decrease markedly throughout the series with increasing substituent electron-withdrawing power.

Fig. 2. The triplet–triplet absorption spectrum of 1-phenylcyclobutene (**2***c*) in deoxygenated isooctane solution, obtained by nanosecond laser flash photolysis techniques. The insert shows a representative decay trace, monitored at 320 nm.



The rate constants for cycloreversion of **2** show only a very qualitative correlation with ground-state substituent constants ($\rho = -1.2 \pm 0.5$ ($r^2 = 0.60$) for the data in pentane solution). That of the *meta*-trifluoromethyl substituted derivative **2***f* correlates particularly poorly with the rest of the compounds in the series. The general inadequacy of ground state substituent constants, particularly for *meta* substituents, in describing substituent effects on excited-state reactions of aromatic compounds is well documented (16, 26, 38–43). The cycloreversion rate constants for **2***a–d,f* correlate somewhat better with the σ_{ex} values of Baldry (which are based on the excited state pK_a values of substituted phenols (38)), but still only qualitatively; $\rho_{ex} = -0.9 \pm 0.4$ ($r^2 = 0.69$). Correlation with the $\sigma^{h\nu}$ scale of McEwen and Yates (based on the photoprotonation of substituted styrenes and phenylacetylenes (26)) is not possible owing to the absence of data for electron-withdrawing substituents other than 4-fluoro.

Electrocyclic ring opening to the corresponding 2-aryl-1,3-butadiene does not occur in detectable yield with any of the compounds studied in this work. From this it can be concluded that efficient ring opening requires that the energy of the lowest excited singlet state be significantly higher than the cyclobutenyl C3—C4 bond energy.

Photolysis of **2** in methanol solution results in the formation of the corresponding Markovnikov addition product **4** in high chemical yield. The reaction occurs from the lowest excited singlet state, as evidenced by the lower fluorescence lifetimes observed for **2***a–d* in methanol compared to those in acetonitrile, the substantial quenching of the formation of cycloreversion products in methanol and methanolic acetonitrile, and the fact that the reaction is not quenched by dienes. In the case of **2***c*, the Stern–Volmer constant obtained from the quenching of phenylacetylene formation by methanol in acetonitrile (Fig. 1(*a*)) agrees with that obtained from the reciprocal plot for the formation of cyclobutyl ether **4***c* (Fig. 1(*b*)) within experi-

[5] 
mental error. The Stern–Volmer constant ($k_q\tau = 0.046 \pm 0.003$ M^{-1}) obtained from least-squares analysis of the data in Fig. 1(*a*) affords a quenching rate constant $k_q = 5.1 \times 10^6$ M^{-1} s^{-1}, in satisfactory agreement with the rather imprecise value measured by single photon counting techniques ($k_q = (5.1 \pm 1.4) \times 10^6$ M^{-1} s^{-1}). It is noteworthy that the rate of quenching of the excited singlet state of **2***c* in acetonitrile, as measured by the above techniques, is approximately an order of magnitude faster than that determined in neat methanol solution (4.4×10^5 M^{-1} s^{-1}; from the Φ_{4c} and τ_s-values for **2***c* in methanol). While we cautiously ascribe this to a simple solvent effect, the difference *should* result in curvature in quenching plots taken over the full range of concentrations between neat acetonitrile and neat methanol.

Most aspects of the excited singlet state quenching of **2** by methanol appear to be analogous to those observed for the quenching of the excited singlet states of acyclic and other cyclic styrene derivatives by water and alcohols (16, 25, 44). As anticipated, however, addition to **2** occurs with measurable efficiency even in the derivatives bearing reasonably strong electron-withdrawing groups. As noted previously for styrene, the regiochemistry and substituent effect on the rates of photoaddition of methanol are consistent with significant π-polarization of the C=C bond in the lowest excited singlet state of 1-phenylcyclobutene. Electron-withdrawing substituents on the phenyl ring reduce the polarization of the C=C bond, lowering its basicity and reducing its reactivity toward photoprotonation. In spite of this qualitative similarity to styrene photoadditions, the magnitude of the substituent effect on the process appears to differ significantly in 1-phenylcyclobutene. This can be seen by comparing the span in the rate constants for methanol addition in **2** to those reported by McEwen and Yates for the rates of water-catalyzed photohydration of substituted styrenes in neutral aqueous solution. These were reported to be 1.86×10^4 M^{-1} s^{-1} for styrene itself, 3.80×10^4 M^{-1} s^{-1} for 4-methylstyrene, and 2.45×10^5 M^{-1} s^{-1} for 4-methoxystyrene (26). The corresponding parameters in the present study are the k_4-values calculated from the ϕ_4 and τ_s^{MeOH} values for **2***a–c* in methanol solution (Table 3), after conversion to second-order rate constants by correcting for the solvent concentration (they vary by only a factor of about two throughout the series of three compounds). For the parent compound, the rate of methanol addition to **2***c* in methanol is ~25 times faster than the rate of water addition to styrene in water. The much less pronounced substituent effect on the rates of methanol photoaddition to **2***c* compared to that on the rates of water photoaddition to styrene may be the result of this substantial difference in absolute reactivity, although it will clearly be necessary to study the photochemistry of the two sets of compounds under more similar sets of conditions before reliable conclusions can be made in this regard.

The mechanism of [2+2]-photocycloreversion in arylcyclobutenes is expected to differ from that in alkylcyclobutenes. In the latter case, previous work has led to the conclusion that cycloreversion derives from a π,R(3*s*)-like state (4) and may involve the intermediacy of cyclopropyl carbene intermediates (7). The π,R(3*s*) state in **2** is expected to be substantially higher in energy than the π,π* singlet state (45), and is thus not expected to play a role in the photochemistry of phenylated systems. Indeed, while there is substantial precedent for Rydberg-derived [1,2]-shifts in the photochemistry of aliphatic alkenes and cycloalkenes (17, 46), there appear to be few examples (47) of such processes (yielding carbenes) in phenylalkene photochemistry. Although the excited singlet state behaviour of most of the phenylalkenes that have been studied is dominated by torsional relaxation (so that carbene-derived products might be difficult to detect in significant yield, particularly when the carbene intermediate can revert to the starting olefin), rearrangements of this type have not been observed even in the torsionally constrained phenylcycloalkenes that have been investigated in detail (44, 48).

Nevertheless, it is interesting to note that the efficiency of photocycloreversion in **2** is subject to a similar polar substituent effect as that observed previously for alkylcyclobutene derivatives (4). We thus felt it was important to study the mechanism of the formal [2+2]-cycloreversion reaction of **2** in greater detail. The photochemistry of 2,4,4-trideuterio-1-phenylcyclobutene (**2***c–d*$_3$) in acetonitrile solution was investigated in order to probe for skeletal rearrangements that might be indicative of the intermediacy of a cyclopropyl carbene in the [2+2]-cycloreversion process. If cycloreversion proceeds via such an intermediate (see eq. [5]), then one would expect to observe scrambling of deuterium between positions 3 and 4 of the cyclobutenyl ring, since carbenes of this type are known to undergo ring expansion to the corresponding cyclobutene in addition to fragmentation to alkene and alkyne (49–51). Examination of the ^{1}H NMR spectrum of an irradiated 0.02 M solution of **2***c–d*$_3$ after ca. 50% conversion offers no evidence for significant scrambling of the label between the two positions. We thus conclude that cyclopropyl carbene intermediates are not formed in the direct photolysis of phenylcyclobutenes to a significant extent; the similarity in the substituent effect on the quantum yield of the process to that in alkylcyclobutenes appears to be coincidental.

The substituent effect on k_5 indicates that there is substantial dipolar character developed in the σ-bond framework dur-

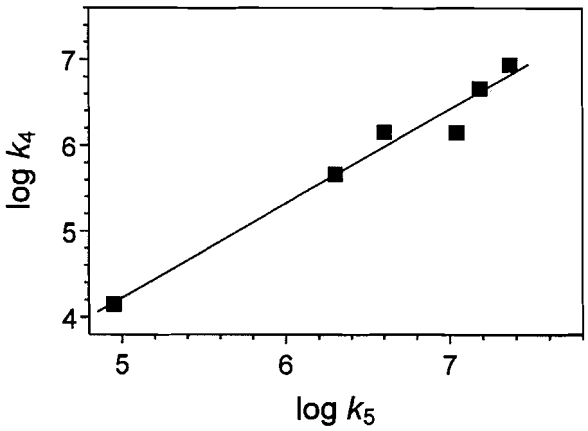
Fig. 3. Log–log plot of the rates of methanol addition (k_4) versus photocycloreversion (k_5) in methanol solution for **2***a–f*.



ing the formal [σ_{2s} + σ_{2s}]-cycloreversion reaction, with positive charge developing at C1 of the cyclobutene ring. This is similar to the polarization experienced in the π-bond framework during photoprotonation; a log–log plot of the rate constants for photocycloreversion (in methanol) versus those for solvent photoaddition (Fig. 3) has a slope of 1.1 ± 0.2 (r^2 = 0.970), indicating an almost exact correspondence between the substituent effects on the two processes. It is reasonable to conclude that the photochemical [2+2]-cycloreversion of phenylcyclobutenes is a concerted process, which proceeds through a transition state of considerable dipolar character in the cyclobutenyl σ-bond framework (eq. [6]). In fact, theory predicts that polar factors should have a pronounced effect on the dynamics of singlet [2+2]-cycloreversion and -cycloaddition when the diagonals of the four-atom array are unequal (52, 53). To our knowledge, this is the first experimental verification of this in excited singlet [2+2]-cycloreversion reactions. In contrast to the substantial effect of polar substituents on the rate of the process, there is little variation in rate with solvent polarity in aprotic solvents (Table 3). Surprisingly, there is a substantial reduction in the rates of cycloreversion of all six compounds in methanol compared to acetonitrile; the origins of this intriguing solvent effect are the subject of continued study.

The substantial photoreactivity that **2***a–f* exhibit towards methanol holds considerable promise for studies of the effects of electron-withdrawing substituents on the kinetics of alkene photoprotonation and on the reactivity of the corresponding benzylic carbenium ions. Further work in this area will be directed at more detailed studies of the photoaddition of alcohols to arylcyclobutenes, and toward establishing a more precise comparison between the reactivity of phenylcyclobutenes and simple styrenes toward excited singlet state protonation.

Experimental

^{1}H NMR spectra were recorded on Bruker AC200 (200 MHz) or AC300 (300 MHz) spectrometers in deuteriochloroform solution, and are reported in parts per million downfield from tetramethylsilane. ^{13}C NMR spectra were recorded on the AC200 spectrometer, and ^{19}F NMR spectra were recorded on the AC300; they are reported in parts per million relative to tetramethylsilane and trichlorofluoromethane, respectively. Infrared spectra were recorded in the gas phase using a GC–FTIR system consisting of a Hewlett-Packard 5890 gas chromatograph (equipped with a 5 m × 0.53 mm HP-1 megabore capillary column (Hewlett–Packard, Inc.)) connected through a Biorad GC/C 32 interface to a Biorad FTS-40 FTIR spectrometer. Ultraviolet absorption spectra were recorded on a Perkin Elmer Lambda 9 spectrometer interfaced to an IBM PS/2-286 microcomputer, or on a Hewlett–Packard HP8451 UV spectrometer. Fluorescence emission and excitation spectra were recorded on a Perkin Elmer LS-5 spectrofluorometer, which is also interfaced to the IBM PS/2-286 and controlled by software supplied by the manufacturer. Gas chromatographic analyses were carried out using a Hewlett–Packard 5890 gas chromatograph equipped with a flame ionization detector, a Hewlett–Packard 3396 integrator, and a HP-1 megabore capillary column (12 m × 0.53 mm; Hewlett–Packard, Inc.) or a DB-1 megabore capillary column (30 m × 0.53 mm, Chromatography Specialties). GC–MS analyses were carried out using a Hewlett–Packard 5890 gas chromatograph equipped with a HP-5971A mass selective detector and a DB-1 microbore capillary column (12 m × 0.2 mm; Chromatographic Specialties, Inc.). Exact Masses were determined on a VGH ZABE mass spectrometer and employed a mass of 12.000 000 for carbon. Semipreparative VPC separations employed a Varian 3300 gas chromatograph equipped with 6 ft × 0.25 in. stainless steel columns consisting of (*a*) 5% OV-101 on Supelcoport or (*b*) 10% QF-1 on 80/100 Chromosorb (Supelco, Inc.).

n-Pentane (Baker Photrex), cyclohexane (BDH Omnisolv),

[6]

For personal use only.

and barium oxide (Mallinckrodt) were used as received from the suppliers. Acetonitrile (Omnisolv) was dried over calcium hydride and distilled under dry nitrogen. Benzene (Baker Analyzed) was purified by several extractions with concentrated sulfuric acid, followed by distillation through a Vigreux column. Tetrahydrofuran (Baker Analyzed) was refluxed over sodium–benzophenone and distilled immediately prior to use. Dimethyl sulfoxide (Caledon) was dried over potassium hydroxide and distilled under reduced pressure. *p*-Toluenesulfonic acid monohydrate was used as received from Matheson. Bromobenzene, 4-bromotoluene, 4-bromoanisole, 4-bromobenzotrifluoride, 4-trifluoromethoxybromobenzene, 3-bromobenzotrifluoride, cyclobutanone, *n*-butyllithium, and *n*-decane were all used as received from Aldrich Chemical Co. Phenylacetylene and 4-tolylacetylene were used as received from Lancaster Chemicals, Inc.

Preparation of compounds

The cyclobutenes **2***a–f* were prepared by acid-catalyzed dehydration of the corresponding 1-arylcyclobutanol (**3**) (54), which was prepared by addition of the appropriate aryllithium to cyclobutanone in anhydrous ether at −40°C. The aryllithium reagents were prepared as solutions in ether from the corresponding bromoarene by lithium exchange using *n*-butyllithium. In the syntheses of **3***a,b,e*, the exchange was accelerated by sonication of the solutions at room temperature. A typical procedure is described below for the preparation of 1-(4-trifluoromethylphenyl)cyclobutene (**2***d*).

*1-(4-Trifluoromethylphenyl)cyclobutene (***2**d)

In an oven-dried 50 mL 2-neck roundbottom flask equipped with a dropping funnel, magnetic stirrer, rubber septum, and nitrogen inlet were placed 4-bromobenzotrifluoride (3.43 g, 0.015 mol) and anhydrous ether (10 mL). The flask was cooled under an atmosphere of dry nitrogen to −40°C with a dry ice – acetone bath, and a 1.6 M hexane solution of *n*-butyllithium (9.5 mL, 0.015 mol) was added dropwise over 1 h. The bath and contents of the flask were then allowed to warm to 0°C over ca. 1 h. The temperature of the resulting yellow solution was again lowered to −40°C, and a solution of cyclobutanone (0.47 g, 0.0067 mol) in anhydrous ether (10 mL) was added dropwise over 1 h. The resulting yellow solution was then allowed to warm to room temperature over a further 1 h. The dark red mixture that resulted was quenched by slow addition of water (20 mL) and then extracted with ether (3 × 10 mL). The combined ether extracts were dried over anhydrous sodium sulfate and filtered. Evaporation of the solvent on a rotary evaporator yielded an orange liquid (1.23 g), which was distilled under vacuum. The major fraction (0.75 g, 0.0035 mol, 70%; bp 87°C (0.3 Torr; 1 Torr = 133.3 Pa); mp 52–54°C), was identified as *1-(4-trifluoromethylphenyl)cyclobutanol* (**3***d*) on the basis of the following spectral data. IR: 3632 (w), 2996 (m), 1328 (s), 1286 (w), 1232 (w), 1172 (m), 1149 (s), 1076 (m), 1017 (w), 846 (w). ^{1}H NMR: δ: 1.55 (br s, 1 H), 1.76 (cplx m, 1 H), 2.08 (brs, 1 H), 2.36 (cplx, m, 2 H), 2.54 (cplx, m, 2 H), 7.62 (s, 4 H). ^{13}C NMR; δ: 12.96, 37.18, 79.60, 125.51, 125.42, 125.36, 125.27, 126.88, 129.0 (q), 156.39. ^{19}F NMR; δ: −62.67. MS, *m/e* (I): 197 (17), 188 (98), 173 (100), 151 (35), 147 (42), 145 (96), 125 (33), 91 (75), 69 (33). Exact Mass, calcd. for $C_{11}H_{11}F_3O$: 216.0762; found: 216.0750.

Significantly higher isolated yields of the cyclobutanols can be obtained using column chromatography (neutral alumina, hexane–ether mixtures) to purify the crude reaction mixtures in the above step.

A solution of **3***d* (0.50 g, 0.0023 mol) and a few crystals of *p*-toluenesulfonic acid in dry benzene (25 mL) was stirred under reflux for 6 h, in a 50 mL roundbottom flask equipped with a glass tube that contained a small thimble filled with granulated calcium chloride and was topped with a reflux condenser. The resulting light brown solution was cooled to room temperature, water (25 mL) was added, and the mixture was extracted with pentane (3 × 10 mL). The combined extracts were washed with saturated aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate, and the solvent was evaporated to yield a light yellow liquid (0.40 g). The product was isolated as a colourless liquid (0.20 g, 0.001 mol, 43%; bp 77°C (1 Torr); mp 20–22°C) by vacuum distillation. Better yields can be obtained by purification of the crude product by column chromatography (neutral alumina; 10% ether in hexane). The product was further purified by semi-preparative gas chromatography, and identified as *1-(4-trifluoromethylphenyl)cyclobutene* (**2***d*) on the basis of the following data. IR: 3056 (w), 2962 (m), 2935 (m), 2852 (m), 1330 (s), 1176 (m), 1149 (s), 1073 (s), 1043 (w), 1019 (w), 900 (w), 846 (m), 765 (w). UV (MeCN), λ_{max}: 260 nm (ε 14 800 M^{-1} cm^{-1}). ^{1}H NMR, δ: 2.40 (m, 2 H), 2.65 (t, J = 4 Hz, 2 H), 6.25 (br s, 1 H), 7.25 (d, J = 8.2 Hz, 2 H), 7.39 (d, J = 8.2 Hz, 2 H). ^{13}C NMR, δ: 26.44, 28.65, 124.32, 125.15, 130.27, 137.89, 145.14, 129.10 (q, CF_3). ^{19}F NMR, δ: −62.70. MS, *m/e* (*I*): 198 (15), 179 (21), 177 (22), 151 (28), 145 (21), 129 (100), 128 (50), 120 (15), 75 (27), 63 (20), 51 (16). Exact Mass, calcd. for $C_{11}H_9F_3$: 198.0656; found: 198.0688.

Cyclobutenes **2***a–c,e,f* were prepared in similar fashion to 2*d*, except that the initial lithium exchange in the cyclobutanol synthesis required less or more vigorous conditions depending on substituent. The yields of the intermediate 1-arylcyclobutanols ranged from 50 to 90% after chromatography, and those of the cyclobutenes from 70 to 90% after isolation by alumina column chromatography. The latter were all subjected to additional purification (>99% by GC) by semipreparative gas chromatography. Spectral and analytical data for the remaining 1-arylcyclobutanols and 1-arylcyclobutenes in the series are listed below.

*1-(4-Methoxyphenyl)cyclobutanol (***3**a): IR: 3576 (m), 2966 (s), 2941 (s), 2883 (m), 1610 (m), 1513 (s), 1472 (m), 1298 (m), 1253 (s), 1224 (m), 1175 (m). ^{1}H NMR, δ: 1.66 (cplx m, 1 H), 1.98 (cplx m, 1 H), 2.36 (m, 2 H), 2.55 (m, 2 H), 3.78 (s 3 H), 7.42 (dd, 2 H), 7.77 (dd, 2 H). MS, *m/e* (*I*): 178 (27), 177 (38), 147 (31), 135 (100), 121 (11), 105 (7), 91 (9), 65 (7).

*1-(4-Methoxyphenyl)cyclobutene (***2**a): IR: 3009 (w), 2956 (m), 2932 (m), 2851 (m), 1605 (m), 1424 (w), 1300 (m), 1258 (s), 1174 (m), 1056 (w), 1038 (w), 835 (m), 760 (w). UV (pentane), λ_{max}: 261 nm (ε 17 900 M^{-1} cm^{-1}). ^{1}H NMR, δ: 2.50 (m, 2 H), 2.77 (t, 2 H), 3.81 (s, 3 H), 6.13 (t, 1 H), 6.84 (dd, J = 2.2, 6.8 Hz, 2 H), 7.26 (dd, J = 2.2, 6.8 Hz, 2 H). ^{13}C NMR, δ: 26.02, 55.29, 113.74, 124.57, 125.55. MS, *m/e* (*I*): 160 (65), 159 (31), 145 (27), 129 (42), 117 (91), 115 (100), 102 (21), 91 (42), 89 (64), 77 (11), 51 (15). Exact Mass, calcd. for $C_{11}H_{12}O$: 160.0888; found: 160.0904.

*1-(4-Methylphenyl)cyclobutanol (***3**b). IR: 3634 (m), 3032 (m),

1-(3-Trifluoromethylphenyl)cyclobutene (**2**f): IR: 2955 (m), 2816 (m), 1601 (w), 1444 (m), 1348 (m), 1327 (s), 1282 (m), 1256 (m), 1181 (s), 1151 (s), 1076 (m), 981 (w), 891 (w), 799 (m). UV (MeCN), λ_{max}: 254 nm (ε 15 100 M^{-1} cm^{-1}). ^{1}H NMR, δ: 2.54 (m, 2 H), 2.81 (t, J = 4.0 Hz, 2 H), 6.38 (t, J = 1.2 Hz, 1 H), 7.43 (m, 4 H). ^{13}C NMR, δ: 26.38, 28.72, 120.93, 123.89, 127.34, 128.74, 129.36, 146.20. ^{19}F NMR, δ: −63.01. MS, *m/e* (*I*): 198 (23), 179 (11), 177 (46), 151 (40), 129 (100), 128 (40), 120 (9), 75 (9), 63 (4), 51 (5). Exact Mass, calcd. for $C_{11}H_9F_3$: 198.0656: found: 198.0649.

2,4,4-Trideuterio-1-phenylcyclobutene (**2**c–d_3) was prepared from cyclobutanone-2,2,4,4-d_4 by a similar procedure to that employed for the parent compound. A mixture of cyclobutanone (1.0 g, 0.014 mol), triglyme (15 mL), deuterium oxide (5.0 mL), and potassium carbonate (5.0 g) was stirred for 24 h at 70°C. After cooling, the resulting solution was extracted with ether (5 × 10 mL). The combined organic extracts were dried with anhydrous sodium sulfate, and then distilled through a short Vigreux fractionating column at atmospheric pressure. Once the ether had distilled off, the receiving flask was cooled to −78°C and attached to two consecutive traps immersed in dry ice – isopropanol, and the temperature of the still was allowed to increase gradually. Deuterated cyclobutanone (0.5 g, 51 % yield) and traces of ethyl ether collected in the receiving flask and the traps. ^{1}H NMR analysis of the distillate indicated that the ketone was ca. 80% tetradeuterated. The material was subjected to a second deuteration cycle as described above, after which the α-proton resonances in the ^{1}H NMR spectrum of the isolated material were undetectable by ^{1}H NMR spectroscopy. A solution of the deuterated ketone (0.29 g, 0.0039 mol) in tetrahydrofuran (10 mL) was cooled at −78°C and treated dropwise with phenyllithium (0.0039 mol). The solution was stirred for 30 min at −78°C, allowed to warm to room temperature, and then quenched by dropwise addition of deuterium oxide (3.0 mL). Work-up as described above afforded a slightly yellow oil (0.505 g), which was purified by silica gel column chromatography and tentatively identified as *1-phenylcyclobutanol-2,2,4,4-*d_4 (mp 43–46°C) on the basis of its mass spectrum: MS, *m/e* (*I*): 152 (0.5), 151 (0.8), 150 (0.2), 122 (48), 105 (100), 93 (26), 78 (81), 77 (68), 51 (33), 30 (5), 29 (4), 28 (3), 27 (1).

1-Phenylcyclobutene-2,4,4-d_3 (**2**c–d_3) was prepared by refluxing a solution of the alcohol from above (0.4 g) in benzene-d_6 (5.0 mL) containing traces of deuterium oxide and *p*-toluenesulfonic acid monohydrate (recrystallized thrice from D_2O) for 5 h. After cooling to room temperature, the solution was washed with a small amount of 5% aqueous sodium hydroxide and dried over anhydrous magnesium sulfate. The solvent was removed on the rotary evaporator to yield a colourless oil (0.35 g), from which **2**c–d_3 was isolated by semi-preparative VPC after bulb-to-bulb distillation. ^{1}H NMR analysis indicated the compound to be >95% deuterated at the

C2 and C4 positions of the cyclobutene ring. IR: 3074 (m), 3039 (m), 2035 (s), 2291 (w), 2226 (m), 2154 (w), 1954 (w), 1798 (w), 1606 (w), 1493 (m), 1447 (w), 1291 (w), 1019 (w), 753 (s). ^{1}H NMR (CD_3CN), δ: 2.48 (s, 2H), 2.81 (m, 0.12 H), 6.32 (t, 0.05 H), 7.31 (m, 5H). MS, *m/e* (*I*): 133 (81), 132 (100), 131 (79), 119 (9), 118 (21), 117 (45), 116 (44), 103 (81), 79 (11), 78 (12), 77 (30), 76 (26), 75 (21), 67 (11), 66 (12), 65 (14), 52 (16) 51 (36), 50 (18), 39 (13).

The 1-methoxy-1-arylcyclobutanes (**4***a–f*) were prepared by stirring a mixture of the corresponding 1-arylcyclobutanol (0.0009 mol), barium oxide (0.005 mol), iodomethane (0.002 mol), and dry dimethyl sulfoxide (10 mL) for 24 h at room temperature. After addition of 5% aqueous hydrochloric acid, extraction with ether, drying and evaporation of the ether extracts, and finally alumina column chromatography (20% ether in hexane), the compounds were isolated as colourless oils in 75–85% yield. They were identified on the basis of their NMR, IR, and mass spectral data, which are listed below.

1-Methoxy-1-(4-methoxyphenyl)cyclobutane (**4**a): IR: 2995 (m), 2953 (m), 1652 (m), 1616 (m), 1558 (m), 1517 (m), 1510 (s), 1305 (m), 1252 (s), 1178 (m), 1135 (m), 1047 (w), 972 (w), 833 (m), 777 (w). ^{1}H NMR, δ: 1.80 (cplx m, 1H), 1.99 (cplx m, 1 H), 2.46 (cplx m, 2 H), 2.55 (cplx m, 2 H), 2.85 (s, 3 H), 3.76 (s, 3 H), 6.89 (d, 2 H), 7.32 (d, 2 H). MS, *m/e* (*I*): 192 (4), 191 (4), 177 (2), 164 (42), 163 (100), 149 (8), 133 (42), 121 (12), 119 (42), 105 (8), 91 (25), 77 (17), 63 (9). Exact Mass, calcd. for $C_{12}H_{16}O_2$: 192.1150: found: 192.1127.

1-Methoxy-1-(4-methylphenyl)cyclobutane (**4**b): IR: 3031 (m), 2995 (s), 2950 (s), 2885 (m), 2830 (m), 1621 (w), 1516 (m), 1296 (m), 1249 (m), 1137 (s), 1090 (m), 1056 (m), 815 (m), 786 (w). ^{1}H NMR, δ: 1.68 (cplx m, 1 H), 1.97 (cplx m, 1 H), 2.36 (s, 3 H), 2.36 (m, 4 H), 2.92 (s, 3 H), 7.15 (d, J = 7.9 Hz, 2 H), 7.28 (d, J = 7.9 Hz, 2 H). ^{13}C NMR, δ: 12.99, 21.06, 32.88, 50.34, 81.34, 126.29, 128.92, 136.78, 140.10. Irradiations were carried out on a 0.5 mL scale in 3 in. × 5 mm quartz tubes, in a Rayonet reactor containing one RPR-254 lamp. For the purposes of product identification, photolyses were taken to ca. 40% conversion, and the products identified by GC–MS, GC–FTIR, and GC coinjection with authentic samples in the cases of phenylacetylene (**5***c*), 4-tolylacetylene (**5***b*), and 4-trifluoromethylphenylacetylene (**5***d*). (57) Identification of the other substituted phenylacetylenes was based on their GC retention times, the prominent parent ion and characteristic fragmentation patterns in their mass spectra (58), and their characteristic IR spectra (obtained by GC–FTIR analyses of the crude photolysis mixtures). Mass and gas phase infrared spectral data for the five substituted phenylacetylenes are given below.

4-Methoxyphenylacetylene (**5**a) *(59)*: IR: 3318 (s), 3083 (w), 3031 (w), 2957 (w), 2925 (w), 2838 (w), 2110 (m), 1650 (w), 1598 (m), 1581 (m), 1508 (s), 1489 (s), 1461 (m), 1443 (m), 1290 (m), 1245 (m), 1180 (m), 1103 (w). MS (58); *m/e* (*I*): 132 (80), 131 (75), 117 (27), 101 (39), 90 (20), 50 (20).

4-Methylphenylacetylene (**5**b) *(59)*: IR: 3317 (s), 3084 (w), 3031 (w), 2962 (m), 2925 (m), 2866 (w), 2111 (m), 1508 (s), 1261 (s), 1215 (m), 1103 (m), 1020 (m), 826 (m), 650 (s), 603 (s), 529 (s). MS, *m/e* (*I*):= 116 (75), 115 (100), 89 (40), 74 (20), 63 (35), 50 (29).

4-Trifluoromethylphenylacetylene (**5**d) *(57)*: IR: 3314 (s), 3083 (m), 3060 (w), 3035 (w), 2928 (w), 2112 (m), 1601 (m), 1575 (w), 1489 (s), 1444 (m), 1401 (w), 1325 (m), 1223 (m), 1172 (m), 1132 (m), 1102 (w), 1071 (m). MS: *m/e* (*I*): 170 (100), 169 (25), 151 (40), 120 (40), 99 (10), 75 (20), 74 (20).

4-Trifluoromethoxyphenylacetylene (**5**e): IR: 3314 (s), 2980 (s), 2828 (s), 2869 (m), 2855 (m), 2112 (w), 1671 (w), 1597 (w), 1574 (w), 1489 (m), 1445 (m), 1380 (w), 1261 (s), 1227 (m), 1100 (s), 1070 (m), 1025 (s). MS, *m/e* (*I*): 186 (100), 167 (30), 120 (17), 117 (15), 99 (20), 85 (15), 75 (25), 74 (31).

3-trifluoromethylphenylacetylene (**5**f) *(57)*: IR: 3314 (s), 3076 (m), 3035 (w), 2923 (w), 2114 (w), 1602 (w), 1579 (s), 1485 (s), 1430 (s), 1348 (s), 1272 (s), 1223 (m), 1174 (s), 1131 (s),

1088 (s), 914 (m). MS: *m/e* (*I*): 170 (100), 169 (30), 151 (40), 120 (42), 99 (10), 75 (20), 74 (30), 69 (10).

Quantum yields were determined by electronic actinometry using a system similar to that described previously (60), and 260 nm excitation. The system was calibrated daily with potassium ferrioxalate. Samples were contained in round (1 cm × 2.54 cm) Suprasil UV cells, which were sealed with rubber septa and deoxygenated with a stream of dry nitrogen prior to photolysis. Quantum yields were calculated from the slopes of plots of product concentration versus accumulated photon counts. Product concentrations were determined by GC relative to an internal standard (*n*-decane) and were corrected for relative FID response factors using working curves.

Relative quantum yield determinations and Stern–Volmer studies were carried out using a Rayonet reactor equipped with a merry-go-round and one 253.7 nm Hg lamp. Relative yields of methyl phenylcyclobutyl ether (**4***c*) from photolysis of **2***c* in methanolic acetonitrile solution were corrected for a small amount of dark reaction for each methanol concentration studied, and for the formation of a product (with identical retention time to **4***c*) in runs carried out in the absence of methanol.

Fluorescence lifetimes were measured at ambient temperature (22–25°C) using a PTI LS-100 single photon counting system and a hydrogen flash lamp. Cuvettes were constructed from 1 cm × 1 cm square Suprasil tubing (Vitro Dynamics Ltd.) and were constricted to 7 mm round tubing at the top of the cell. The cuvettes were sealed using a rubber septum, and the solutions, 0.001–0.005 M in **2**, were deoxygenated with a stream of dry nitrogen for at least 60 min prior to the experiment. Fluorescence decays were recorded using 260 nm excitation and a monitoring wavelength corresponding to the emission maximum of the cyclobutene in the particular solvent being studied. Decays were recorded with 5000–10 000 counts in the maximum channel, and were deconvoluted and analysed using the software provided by the manufacturer. In general, the decays were fit to single or double exponential functions in order to obtain the best possible fit. In cases where the data fit best to a two exponential function, the second component comprised less than ca. 10% of the decay. In each case, the lifetimes reported are the average of at least two independent determinations, the results of which invariably differed by less than 5%. The solutions were checked by GC immediately after determination of the lifetime to verify that no appreciable photodecomposition of the sample occurred during the experiment.

Nanosecond laser flash photolysis experiments employed the pulses (248 nm, ca. 16 ns) from a Lumonics 510 excimer laser filled with F_2/Kr/He mixtures or those (337 nm, ca. 6 ns) from a Lumonics 761M excimer laser filled with N_2/He mixtures, and a microcomputer-controlled detection system (61, 62). Solutions of **2***b–d* were prepared at concentrations such that the absorbance at the excitation wavelength (248 nm) was ca. 0.3 (6×10^{-5} M), and were made to flow continuously from a calibrated 100 mL capacity reservoir through a 3 × 7 Suprasil flow cell. The solutions were deoxygenated with a stream of dry nitrogen in the reservoir for 45 min prior to and continuously throughout flash photolysis experiments. Quenchers were added directly to the reservoir by microlitre syringe as aliquots of standard solutions. Quenching rate constants were calculated by linear least-squares fits of decay rate versus quencher concentration data using Inplot 4.0 (Graphpad, Inc.). Errors are reported as twice the standard deviations obtained from these analyses.

Nascent $HF^{\dagger}$ and $HSO(^2A')$ formations in the elementary reactions of $F + H_2S$ and $HS + O_3$ and the internal energy distributions

Yasunori Yoshimura, Toshio Kasai, Hiroshi Ohoyama, and Keiji Kuwata

Abstract: Chemiluminescence of the vibrationally excited $HF^{\dagger}$ and of the electronically excited HSO* in the $^2A'$ state were observed in the elementary reactions of $F + H_2S$ and $HS + O_3$. In the $F + H_2S$ reaction, the vibrational populations of $HF^{\dagger}$ in $v = 3$ and 4 were found to be nonstatistical but the rotational distribution in the $v = 4$ state was found to be Boltzmann-like with a rotational temperature of 700 K, confirming similar data obtained by different methods. The HSO* emission was observed in the $HS + O_3$ elementary reaction. The spectrum of HSO* characterized by broad vibrational bands indicates nonstatistical excitation for the rotational and vibrational states.

Key words: chemiluminescence, internal energy distribution, $F + H_2S$, $HS + O_3$, $HF^{\dagger}$, HSO^*.

Résumé : On a observé la chimiluminescence de l'excitation vibrationnelle du $HF^{\dagger}$ et de l'excitation électronique du HSO* dans l'état $^2A'$ dans les réactions élémentaires : $F + H_2S$ et $HS + O_3$. On a trouvé dans la réaction $F + H_2S$ que les populations de $HF^{\dagger}$ dans les états $v = 3$ et $v = 4$ ne sont pas statistiques mais que la distribution rotationnelle dans l'état $v = 4$ est du type Boltzmann avec une température rotationnelle de 700 K, confirmant ainsi des données similaires obtenues par différentes méthodes. On a observé l'émission HSO* dans la réaction élémentaire $HS + O_3$. Le spectre du HSO* caractérisé par une large bande vibrationnelle indique une excitation non statistique des états rotationnel et vibrationnel.

Mots clés : chimiluminescence, distribution de l'énergie interne, $F + H_2S$, $HS + O_3$, $HF^{\dagger}$, HSO^*.

[Traduit par la rédaction]

1. Introduction

Sulfur-containing molecules, such as hydrogen sulfide, mercaptans, and sulfur dioxide, are known to be easily oxidized by oxygen and ozone because of the multi-valency of the sulfur atom ranging from S(I) to S(VI). Those compounds have received significant attention because they are relevant to global problems of environmental chemistry (1–6). In the $H_2S + O_3$ reaction, SO_2 and H_2O were observed as the final products and HSO, HS, and SO were estimated as the reaction intermediates (3, 4, 7). There has been an extensively accumulated body of valuable data on these chemical species using the flow method, the flame method (8–11), and the arrested relaxation method (12–14). Practically, these methods afford a relaxation-free environment during the reaction. On the other hand, the use of molecular beams provides us complementary data, which are useful for confirming the available experimental results.

The reaction of $F + H_2S$ is a typical hydrogen extraction with a fast rate of $k = \sim 10^{-11}$ cm^3 molecule^{-1} s^{-1} (15–19). This reaction is 186.6 kJ mol^{-1} exothermic at 0 K and the total available energy is ~197 kJ mol^{-1} (20). This means that the product HF in the ground state can be excited up to $v = 4$. Chang et al. have investigated the HF infrared chemiluminescence for the fundamental and the first overtone and determined the relative populations in the $v = 1 \sim 4$ states. Several experiments using a fast-flow reactor or arrested relaxation have also been carried out (21, 22). The rotational lines of the fundamental emission bands of HF concentrates near 3 μm, thus these bands tend to overlap. These overlaps make it difficult to analyze the rotational distribution. In the present work, we observed the HF chemiluminescence in the visible region for the second overtone ($3 \rightarrow 0$) and the third overtone ($4 \rightarrow 0$). These overtone emissions appear separately in the 670 nm and 860 nm wavelength regions. For the overtone emission measurements, one must also take into account a very small probability of transition if it is compared with the fundamental one. In the vibrationally excited HF, marked as $HF^{\dagger}$, the probability for the $4 \rightarrow 3$ transition is larger than that for the $4 \rightarrow 0$ transition by $\sim 10^6$. Nevertheless, the high sensitivity for photon count detection with a photomultiplier would be able to compensate for the losses.

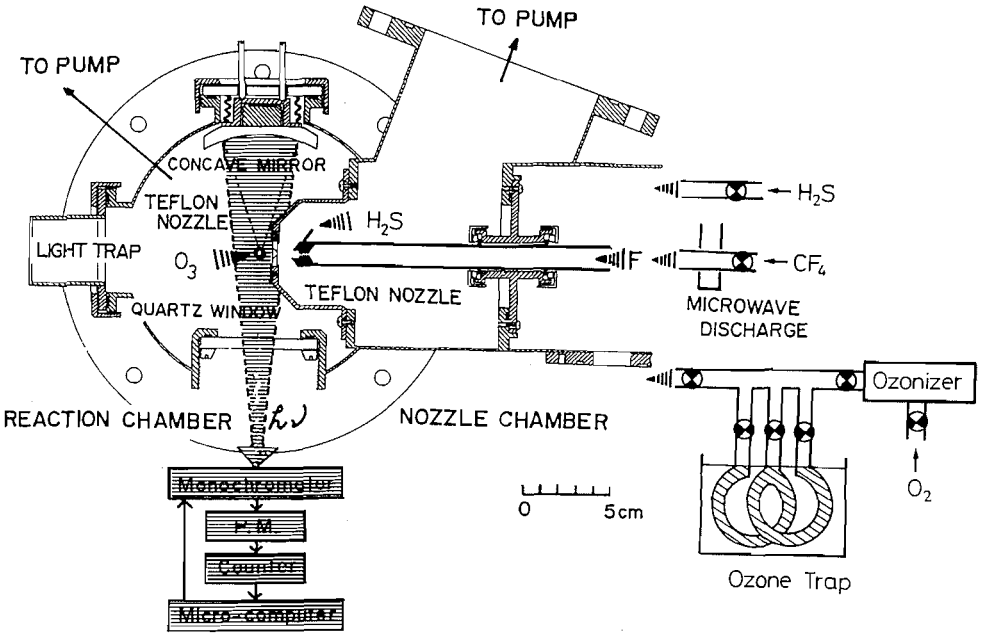
Fig. 1. Cross-sectional view of the reaction chamber and a block diagram for the chemiluminescence measurements. For $HF^{\dagger}$ measurement, the F atoms were directly used without the H_2S flow at the Teflon nozzle (1 mm ϕ in tubing and 3 mm ϕ in nozzle head). For HSO* measurement, the HS radicals were prepared by merging the H_2S flow at the Teflon nozzle and the target molecule O_3 was replaced by H_2S.



This reaction is known to be 295 kJ/mol exothermic (20). In the $H_2S/O/O_3$ reaction at a total pressure of 1 Torr, Schurath et al. observed the HSO chemiluminescence with vibrational structures in the 550–850 nm region, which was assigned to the S—O stretching mode (23(*a*)). They proposed that reaction [1] could be extracted as an elementary reaction. The laser irradiation study of the HSO* emission in the HS/O_3 system at 1 mTorr was done by Kendall et al. and the rotational temperature of HSO* was estimated to be as low as 700 K (23(*b*)).

Direct observations of the reaction using the HS radical beam would be worthwhile to carry out, since it is desirable to decouple the reaction from other possible secondary reactions by utilizing the single collision conditions. The $HSO^* + O_3 \rightarrow HS + 2O_2$ reaction might follow reaction [1] if the O_3 pressure is high (24). In this study, we reinvestigated the $F + H_2S$ reaction under single collision conditions to characterize the HF product, and the co-product HS was utilized as a radical beam in the $HS + O_3$ elementary reaction. The HSO* chemiluminescence was studied to determine the initial distribution of internal energy, and comparison was made with other results to learn more about product energy partition and possible reaction mechanisms.

2. Experimental

Figure 1 shows the cross-sectional view of the reaction chamber and a block diagram for the chemiluminescence measurement. The reaction chamber and the fore-chamber were differentially pumped by a 6-in. (~1300 L/s) and a 4-in. (~580 L/s) diffusion pump, respectively. A liquid nitrogen trap was used in the reaction chamber when necessary, but for safety reasons no trap was used when we used ozone. The background pressure during a run was 8×10^{-3} Pa and the ultimate pressure was $\sim 1 \times 10^{-4}$ Pa. A typical nozzle pressure of a reactant was 0.4–5 Torr (1 Torr = 133 Pa).

For the $HF^{\dagger}$ measurement, the F atoms, generated by microwave discharge of CF_4, effuse from the Teflon nozzle and enter the reaction chamber through a 2-mm ϕ collimator (26, 27). H_2S directly effuses into the reaction chamber and reaction [2] takes place in the reaction volume (the beam intersection). Typical flow rates at the nozzles are 0.5 μmol s^{-1} for CF_4 and 1.1 μmol s^{-1} for H_2S.

[2] $H_2S + F \rightarrow HS + HF^{\dagger}$

For the HSO* measurement, the target H_2S molecule was replaced by O_3 and the HS radicals were prepared by merging the H_2S flow at the Teflon nozzle in the fore-chamber. The F atoms or the HS radical beam cross a diverging beam of reagent molecules at 5 mm above the target nozzle in the reaction chamber. The HS radicals were prepared as in reaction [2] by merging a flow of H_2S with a flow of F atoms at the Teflon nozzle. The beam intensity of HS is estimated by measuring the $HF^{\dagger}$ emission intensity at 670 nm (30). Ozone, produced by an ozonizer and concentrated at a dry-ice ethanol ozone-trap, directly effused into the reaction chamber (27, 31).

Though the target molecules were not collimated in this study, the angular distribution measurement using a nude ion-gauge showed a typical directional profile as a diverging beam similar to the case of the O + NO reaction, where the flux intensity of NO was estimated to be $\sim 10^{17}$ molecules s^{-1} in reaction volume (25). We express the beam intensity here as the unit of flow rate (μmol s^{-1}) at a nozzle, since beam intensity should be proportional to flow rate under the present nozzle conditions (28, 29). Judging from the number density of

Fig. 2. Emission spectrum of HF with the spectral resolution of 3 nm. The flow rate of CF_4 is 0.5 μmol s^{-1} for producing the F atoms, and the flow rate of H_2S is 1.1 μmol s^{-1}. R and P stand for the R- and P-branches.

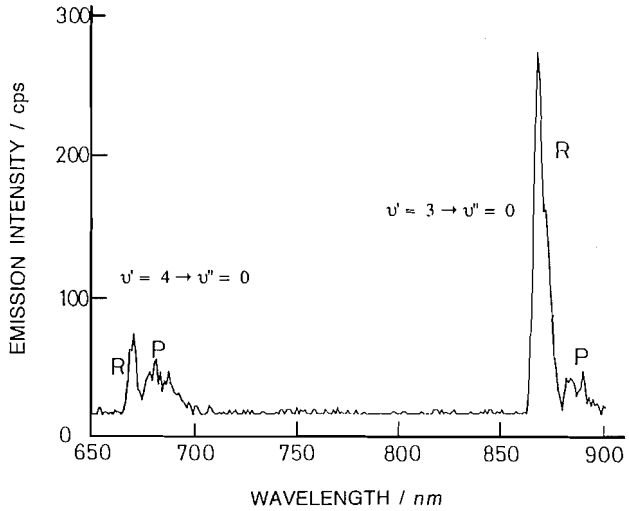

Fig. 3. Dependence of the $HF^{\dagger}$ emission intensity on the flow rate of H_2S at 670 nm (i.e., the R-head of the third overtone band).

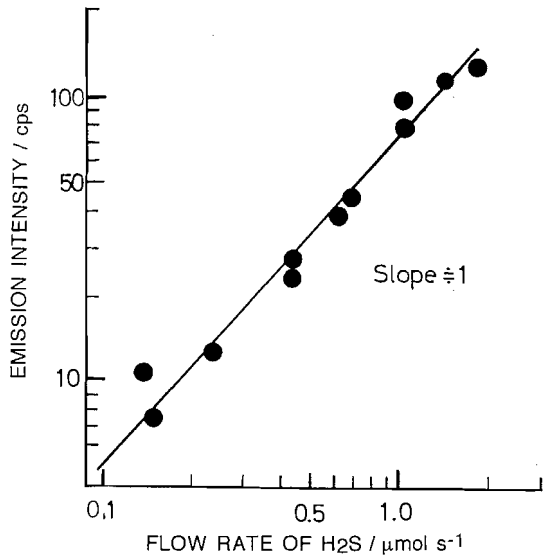

reagents in the reaction volume, the collisional deactivation of products needs to be considered carefully. Thus, the linear relationship between the signal intensity for product emission and the reagent densities has to be checked very carefully if one hopes for reliable data. It is also expected that a directional encounter of the reagents at a right angle will reduce the chance of collisional deactivation in this study. A more detailed characterization of reagent beams is described elsewhere, and the reaction volume was estimated to be a few mm in radius (25).

The product chemiluminescence in the reaction zone is collected by a concave mirror (focal length, 5 cm) in the third direction and focused onto the entrance slit of a monochromator (focal length, 30 cm), followed by a photon count unit. The optical setup confined the detector view as shown in Fig. 1, except that the cone of view of the monochromator was overstated and drawn too widely. In an exact setup, the collimator walls were set out of sight. Any walls of the chamber should be away from the line of sight of the detection, otherwise products would be partly deactivated at the walls and they could be observed. This was tested by inserting various sizes of the view-confine aperture on the quartz window and we indeed observed preferentially an emission from the reaction volume at beam intersection. In addition, we could see the emission signal only if the concave mirror was properly adjusted to the point of the reaction volume. We therefore concluded that the emission we observed came mostly from the crossed beam region. The signal count (cps) was recorded as a function of the monochromator wavelength. The wavelength scan was repeated and the signal counts were accumulated by a microcomputer to improve the signal-to-noise ratio. The background signal was subtracted from our data.

3. Results

3.1 F + H_2S reaction

Figure 2 shows the chemiluminescence spectrum of $HF^{\dagger}$ from 650 to 900 nm, where two overtone bands of $v' = 4 \rightarrow v'' = 0$ and $v' = 3 \rightarrow v'' = 0$ appear. The spectral resolution was 3 nm and we measured each point at 1 nm intervals for 10 s on each point. Since the spectrum is not calibrated for the photomultiplier sensitivity and the efficiency of monochromator transmission in the figure, the apparent intensity in the figure does not reflect the ratio of the $(3 \rightarrow 0)$ and $(4 \rightarrow 0)$ overtones (32). After we corrected for wavelength efficiencies in our detection, we obtained a relative population ratio of 1:1 for $v = 3{:}4$, which includes experimental error and analysis error (>10%). For analysis, we used the rotationally averaged values of the square of the transition matrix elements taken from the experimental values from Sileo and Cool (32). This procedure might bring on some uncertainty, which will be discussed in a later section.

Figure 3 shows the dependence of emission intensity of the $HF^{\dagger}$ third overtone on the H_2S flow rate. The relationship was found to be linear within the uncertainty as the figure shows. This linear relationship confirms the single collision conditions for the H_2S reactant molecule. Because the change in the CF_4 flow rate affected the microwave discharge conditions, it was not possible to examine the dependence of $HF^{\dagger}$ emission on the flow rate of F atoms. Therefore, the CF_4 flow rate was used a constant at an optimum condition for the discharge (0.4 Torr of CF_4 pressure). Since the fluorine atom beam intensity is estimated to be very small, signal linearity with respect to the F atoms would be preserved.

Figure 4 shows the emission spectrum of the third overtone of $HF^{\dagger}$. The spectrum was taken with a 1.2 nm resolution and measured at a 0.2 nm interval. The largest band at 670 nm was assigned the R-head and a series of P-branches, from P(1) to P(9), in the direction of longer wavelengths (33). The rotational distribution of $HF^{\dagger}$ in $v = 4$ was determined by spectral simulation of this spectrum.

Spectral simulation and the rotational distribution of $HF^{\dagger}$ in v = 4

The spectral simulation was carried out via a standard method using eq. [2] (34(*a*)).

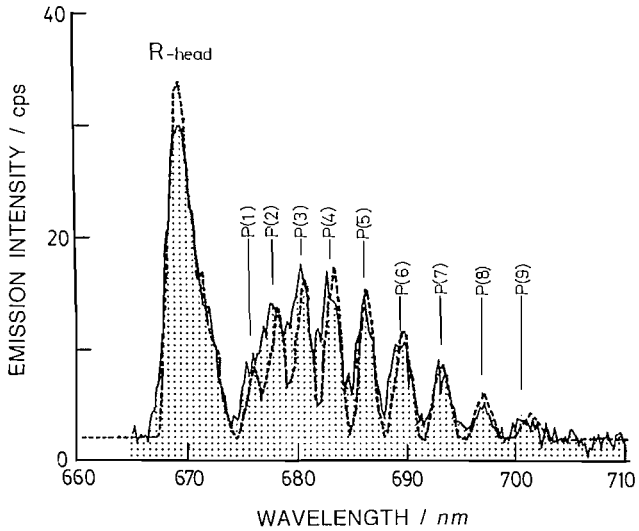
For personal use only.

Fig. 4. Emission spectrum of the third overtone of $HF^{\dagger}$ (shown with the dotted area). The flow rate of CF_4 is 0.4 μmol s^{-1}, and the flow rate of H_2S is 1.1 μmol s^{-1}. The resolution was 1.2 nm at the 0.2 nm scan interval. The assignment of the bands is the R-head from left and the series of the P-branches to the longer wavelengths as shown from P(1) to P(9). The broken line shows the simulated spectrum (see the text).



$$[3]\quad I^{v'J'}_{v''J''} \propto \nu^3 \cdot |R^{v'J'}_{v''J''}|^2 \cdot (hcBv'/kT) \cdot N_{v'} \times \exp\,[-F(v', J')/kT]$$

where ν is the wave number, and $B_{v'}$ and $N_{v'}$ are the rotational constant and the population in the v' vibrational state, respectively. $|R^{v'J'}_{v''J''}|^2$ represents the square of the dipole transition matrix element for $(v', J') \rightarrow (v'', J'')$, and $F(v', J')$ is the term value of the vibrating rotator in the Dunham expression as shown by the following relation (34(*b*)). The third overtone transition of HF corresponds to $(4, J') \rightarrow (0, J'')$ and the term value includes the correction due to the $v = 4$ vibration.

$$F(v, J) = \sum_{i,m} Y_{im}(v + \tfrac{1}{2})[J(J+1)]^m$$

The allowed transitions are the ones with $\Delta J = J' - J'' = +1$ for the R branch, and the one with $\Delta J = -1$ for the P branch. The triangle function was used as the slit function for the monochromator. The rotational temperature, T_R, was systematically varied to determine the best fit with a minimum χ^2. The best fit was obtained with T_R = 700 K, and the simulated spectrum is shown by the dotted line in Fig. 4. Figure 5 represents the initial rotational distribution for $HF^{\dagger}$ in the $v = 4$ thus obtained.

3.2. HS + O_3 reaction

Figure 6 shows the emission spectrum from the reaction volume in the HS + O_3 reaction. The flow rate of O_3 at the nozzle was 1.5 μmol s^{-1}. The spectral resolution was 3 nm. We measured each point at 1 nm intervals for 10 seconds. Even though the signal-to-noise ratio was unavoidably weak under the single collision conditions, the emission profile appears to be very broad when it is compared with the HSO spectra reported earlier (23(*b*)). For confirmation of the single collision conditions, the linearity of the emission intensity with respect to the reagent flow rate was tested.

Fig. 5. Initial rotational distribution for the levels J = 0–8 of $HF^{\dagger}$ in the $v = 4$ state (shown with the filled circles). The open circles are the relative populations for J = 0–7 measured by Chang et al. (cited from ref. 21).

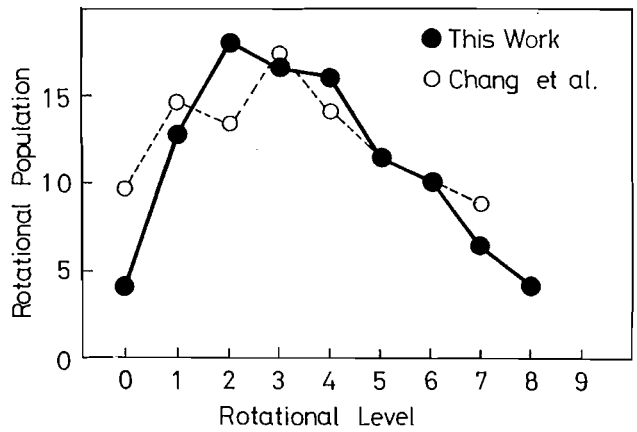


Fig. 6. Emission spectrum from the beam reaction of HS + O_3 with the spectral resolution of 3 nm. The flow rates of CF_4, H_2S, and O_3 are 0.5, 0.3, and 1.5 μmol s^{-1}, respectively. The spectrum of Kendall et al. is shown for reference (cited from ref. 23(*b*)).

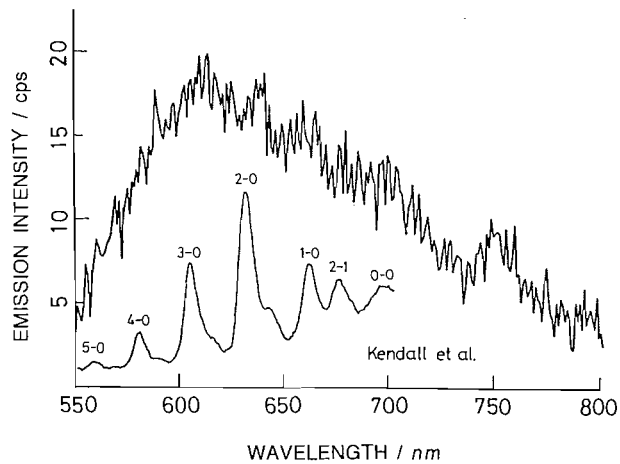

Figure 7 shows the logarithmic plot of peak emission intensity at 600 nm vs. O_3 flow rate. The log–log plot was used to cover a wider range of flow rate. The dependence was found to be linear, with a slope of ~1. The $HF^{\dagger}$ emission at the Teflon nozzle is regarded to be a good measure for the HS beam intensity, since reaction [2] provides an equal number of HS radicals to $HF^{\dagger}$. The emission intensity in the H_2S + O_3 reaction was found to be approximately linear to the $HF^{\dagger}$ emission. Thus, these linear relationships for both reactants confirm that the chemiluminescence shown in Fig. 6 was due to a single collision of HS and O_3, which leads to the HSO* formation.

There remain some ambiguities as to how unreacted reagents of F atoms might keep traveling and react with O_3 in the reaction chamber. This possibility, however, was refuted by experiments because neither the F + O_3 nor the H_2S + O_3 reaction gave any chemiluminescence. Another possibility may be that the vibrationally excited $HF^{\dagger}$ (which is the coproduct of HS at the Teflon nozzle) might react with O_3 to give emissive products like HFO*. But no chemiluminescence was

Fig. 7. Dependence of the emission intensity at 600 nm in Fig. 6 on the flow rate of O_3.

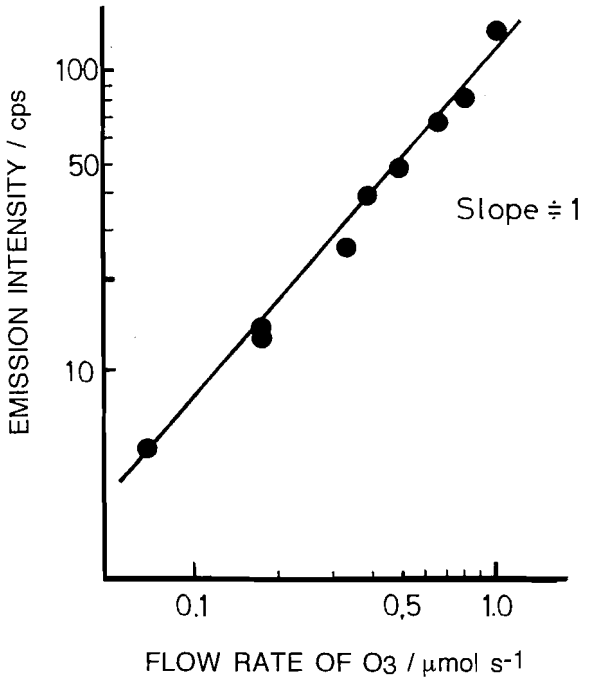

Fig. 8. Emission spectrum from gas–beam reaction of HS + O_3 with the spectral resolution of 3 nm. The flow rates of CF_4, H_2S are 0.5, and 0.4 μmol s^{-1}, respectively. Ozone at the flow rate of 0.9 μmol s^{-1} was confined in the target region of the reaction chamber. The spectrum of Kendall et al. is shown for reference (cited from ref. 23(*b*)).

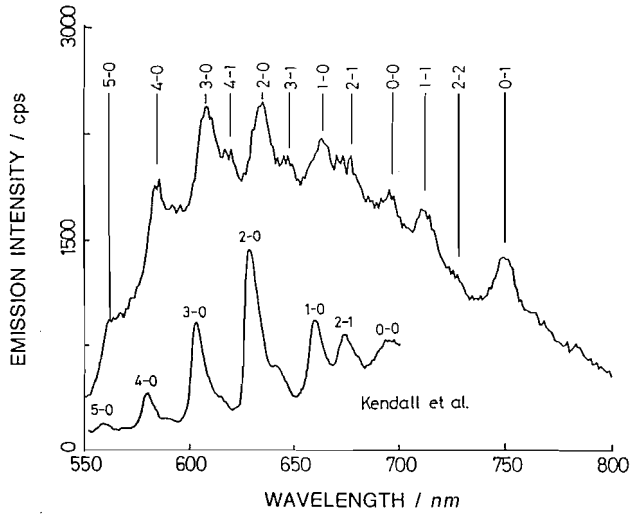
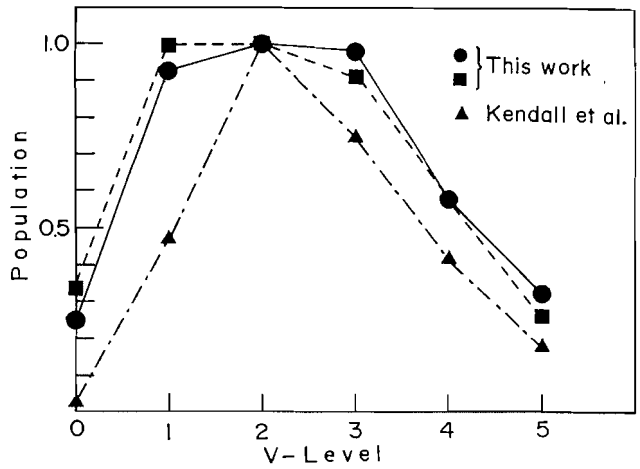


expected judging from the available energy in the $HF^{\dagger}$ + O_3 reaction (20).

To substantiate the hypothesis that the chemiluminescence in Fig. 6 is indeed due to the reaction product HSO*, a gas–beam experiment was carried out by increasing the total pressure of the reactants up to ~1 Pa in the reaction chamber. The HSO* emission intensity increased by a factor of ten. Figure 8 shows the spectrum obtained under such conditions. Since rotational relaxation of the reactant collisions tends to make each vibrational band narrower, the vibrational bands can be assigned, as already reported in ref. 23, to the progression of the S—O stretching mode of HSO* in the $^2A'$ electronic state, which is indicated by the vibrational quantum numbers in Fig. 6.

Fig. 9. Estimated initial distributions of the HSO($^2A'$) vibration. The circles and the squares are obtained by the spectral simulations of Figs. 6 and 8, respectively. The distribution with the triangles is cited from ref. 23(*b*). The three distributions are normalized at $v = 2$.



The cause of the significant broadness of the HSO* emission spectrum in Fig. 6 needs to be considered next. A broadening could happen if more than one vibrational mode is excited together with the S—O stretching mode, and (or) extremely high excitation of the HSO* rotation. First, we carried out the spectral simulation, assuming that the S—O mode of HSO* was preferentially excited. The effects of rotational excitation of HSO* were then tested.

Figure 9 shows the vibrational distribution obtained by simulating the spectrum in either Fig. 6 or Fig. 8. If the energy of reaction is preferentially released in the S—O vibrational mode, HSO* in the $^2A'$ state could be excited up to $v = 15$ (35). Radiative lifetimes from all levels (v', J') can be obtained from the reciprocals of the total Einstein $A_{v',J'}$ coefficient, which is given below, and is proportional to the squared dipole transition moments (36).

$$A_{v',J'} = \left[\frac{1}{2J'+1}\right]\left[(J')\sum_{v''} A_{v',J';v'',J'-1} + (J'+1) \times \sum_{v''} A_{v',J';v'',J'+1}\right]$$

The relative population of v' (after averaging for J') is given by the emission intensity divided by the squared dipole transition moments, which include the Franck–Condon factors. We estimated the Franck–Condon factors from radiative lifetimes for individual vibrational levels observed by Kawasaki and co-workers (37). The spectroscopic parameters for the $^2A' \rightarrow {}^2A''$ transition and the molecular constants were taken from the literature (23(*a*)). Table 1 lists the calculated relative Franck–Condon factors (38–40). We then carried out the spectral simulation to estimate the HSO* rotational distribution. In a sim-

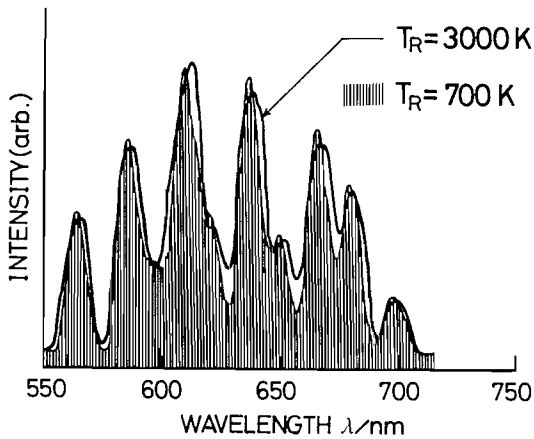
Table 1. Estimated Franck–Condon factors for the vibronic transitions $(v', 2A') \rightarrow (v'', {}^2A'')$ of HSO

$v' \rightarrow v''$	Relative Franck–Condon factors
$7 \rightarrow 0$	2.16
$6 \rightarrow 0$	1.76
$5 \rightarrow 0$	1.46
$4 \rightarrow 0$	1.31
$3 \rightarrow 0$	1.08
$2 \rightarrow 0$	1.00[a]
$1 \rightarrow 0$	0.91
$0 \rightarrow 0$	0.82

[a]The $(2 \rightarrow 0)$ transition is set as 1.00 for normalization purpose.

Fig. 10. Simulated spectra of $HSO(^2A')$ with the estimated rotational temperatures of 3000 K (the solid line) and 700 K (the shaded area). The bandwidths become broad as the temperature increases, but the observed spectrum of Fig. 6 was found to be too broad to simulate.



ulation process, a single rotational temperature and the same band shape of (030) – (000) were assumed for all vibrational bands.

Figure 10 shows the simulated spectra with two estimated temperatures, 3000 K (the solid line) and 700 K (the shaded area). There is a general tendency that the vibrational band becomes broad as the rotational temperature increases. As seen in the figure, neither simulated spectra agrees with the observed one, if we assume that the rotational distribution is Boltzmann. The observed spectrum may reflect a nonstatistical rotational distribution of the HSO* product.

4. Discussion

4.1. F + H_2S reaction

Earlier studies give the relative $HF^\dagger$ vibrational population for $v = 3$ and $v = 4$. Chang and co-workers reported a value of 1:0.75, and the fast-flow reactor experiment done by Agrawalla and Setser gave a value of 1:0.33. The arrested relaxation by Dill et al. yielded 1:0.52. The present work gives a relatively larger population with the ratio of 1.0:~1 (21, 22). As mentioned in the previous section, the uncertainty in our work (>10%) does not make our result superior to the previously reported values. On the other hand, our result is in excellent agreement with those obtained by other methods, confirming the reliability of our data.

The solid circles in Fig. 5 show the rotational distribution of HF in $v = 4$ obtained in this work and the open circles show the one measured by Chang et al. (21(*a*)). This result indicates that the two distributions show a similar tendency on the whole except for a smaller population in the $J = 0$ level in the present study. The fast-flow reactor and the arrested relaxation studies also gave similar HF rotational distributions which extend to the thermochemical limit for several vibrational levels (21(*c*), 22). The present result seems to be in better agreement with the distribution in the arrested relaxation method than the one in the fast-flow reactor.

Energy partition among the products' rotation and translation

The energetics shows that ~90% of the reaction energy is released as vibrational freedom of HF when the molecule is excited up to $v = 4$. The remaining ~3% of the available energy appears in the rotation of HF characterized as $T_R = 700$ K, and the corresponding average rotational energy of HF is ~5 kJ mol^{-1}. The quantity, g_r, defined by eq. [4], is known to be a good measure to test whether or not a rotational distribution is statistical (41, 42).

$$[4] \quad g_r = f_{rot}/(1 - f_{vib}) = 0.03/(1 - 0.9) = 0.3$$

where f_{rot} stands for the fraction of the energy released to the HF rotation, i.e., equal to 0.03 in the present case for $HF^\dagger$ ($v = 4$), and f_{vib} is the fraction of the vibrational excitation, i.e., $f_{vib} = 0.9$. Equation [4] calculates g_r to be 0.3.

If we suppose the energy partitioning is statistical among all freedoms of HF and HS, g_r can be calculated by eq. [5].

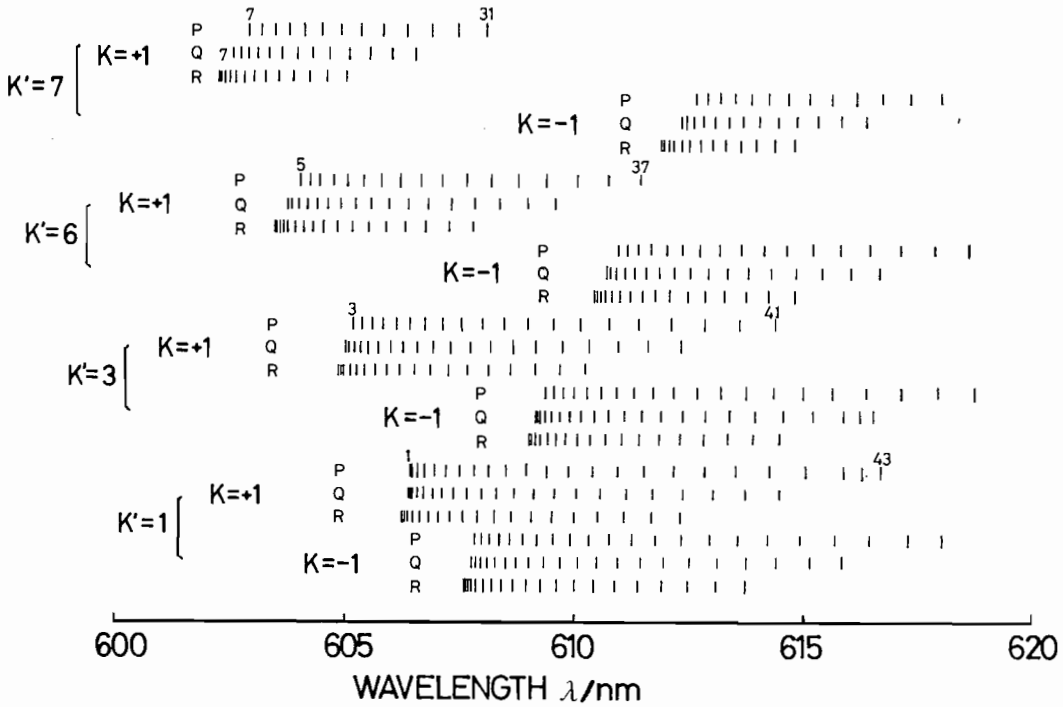
$$[5] \quad g_r = N_{rot}(HF)/[(N_{trans} + N_{rot}(HF) + N_{rot}(HS)] = 2/(3 + 2 + 2) = 0.28$$

where N_{rot} represents the degree of rotational freedom, and N_{trans} is the degree of freedom for the relative translation of the products. The expected g_r becomes 0.28 as previously shown. Good agreement is seen between 0.3 and 0.28; the former is the experimentally observed value using eq. [4] and the latter is the calculated value using eq. [5]. This result suggests that the energy partition in the F + H_2S reaction statistically occurs among the relative translation and rotations of HF and HS. On the other hand, this reaction does not seem to occur in a statistical way for the HF vibrational excitation as already seen in Sect. 3.1.

4.2. HS + O_3 reaction

We have shown that the HSO* spectrum of Fig. 6 observed under the single collision conditions is significantly broad and it is indeed different from the ones in the earlier studies using various methods (1–6, 23(*b*)). Kendall et al. suggested that the rotational relaxation in the reaction system is probably very

Fig. 11. Simulated rotational structure of the $A'(003) \rightarrow A''(000)$ overtone spectrum of HSO.



fast (23(*b*)). If this is the case, the single collision conditions in the present study may enable us to observe such nascent HSO* radicals which are free from rotational relaxation.

Figure 11 shows a simulated structure of rotation for the $A'(003) \rightarrow A''(000)$ overtone spectrum of HSO. K' and K represent the rotational quantum numbers of HSO in the upper and the lower electronic states, respectively. The rotational lines with the higher K tend to extensively populate apart from these band-origins, because the molecular constants of HSO for the $^2A'$ excited state and the $^2A''$ ground state are known to be similar (38–40). This broadening tendency would tell us that a non-Boltzmann distribution of rotation with higher K' levels should be considered in simulating the observed spectrum of HSO* in the elementary reaction [1] (43). The feasibility of excitation in other vibrational modes remains as an open question. It is hoped that future studies can clarify molecular-level mechanisms of such nonstatistical reactions under either the well-defined collisional geometry using the oriented HS radical beam or the well-defined initial states of the reactant molecules using laser excitation and detection (42, 44, 45).

Adamantane-based nitrile sulfides: the generation of the synthetic equivalent of the first bis(nitrile sulfide)

John N. Bridson, Melbourne J. Schriver, and Shuguang Zhu

Abstract: The reaction of 1,3-adamantanedicarbonamide with chlorocarbonylsulfenyl chloride in hot toluene gives two new oxathiazolone derivatives that have had their structures confirmed crystallographically: 1,3-bis(1,3,4-oxathiazol-2-on-5-yl)-adamantane and 1-cyano-3-(1,3,4-oxathiazol-2-on-5-yl)-adamantane. (Crystal data: $C_{10}H_{14}(COC(O)SN)_2$: $P2_1/m$, $a = 10.447(2)$, $b = 7.119(3)$, $c = 10.684(2)$ Å, $\beta = 112.98(1)°$, $V = 731.5(3)$ Å^3, $z = 2$, $D_c = 1.536$ g cm^{-3}, $R = 0.034$, $R_w = 0.029$; $(NC)C_{10}H_{14}(COC(O)SN)$: $P2_1/c$, $a = 9.153(2)$, $b = 19.134(2)$, $c = 7.130(3)$ Å, $\beta = 105.38(2)°$, $V = 1204(1)$ Å^3, $z = 4$, $D_c = 1.447$ g cm^{-3}, $R = 0.038$, $R_w = 0.035$.) The reaction of the precursor with dimethyl acetylenedicarboxylate (DMAD) in refluxing chlorobenzene gave a mixture that was resolved into pure compounds by Kugelrohr sublimation; these were shown to be sulfur, tetramethyl thiophenetetracarboxylate, 1,3-adamantanedinitrile, 1,3-bis(4,5-bis(methoxycarbonyl)-isothiazol-3-yl)-adamantane, and 1-cyano-3-(4,5-bis(methoxycarbonyl)-isothiazol-3-yl)-adamantane. The structures of the two new isothiazole derivatives were confirmed crystallographically. (Crystal data: $C_{10}H_{14}(CNS{\cdot}DMAD)_2$: $Pca2_1$, $a = 15.857(4)$, $b = 11.562(4)$, $c = 13.602(4)$ Å, $V = 2494(2)$ Å^3, $z = 4$, $D_c = 1.424$ g cm^{-3}, $R = 0.057$, $R_w = 0.038$; $C_{10}H_{14}(CN)(CNS{\cdot}DMAD)$: $P2_1/c$, $a = 19.683(2)$, $b = 11.566(3)$, $c = 7.727$ (3) Å, $\beta = 93.30(2)°$, $V = 1756(1)$ Å^3, $z = 4$, $D_c = 1.363$ g cm^{-3}, $R = 0.079$, $R_w = 0.076$.) The pattern of reactivity indicates that the *synthetic equivalent* of the bis(nitrile sulfide) may be present in solution but has a very short lifetime and failed to react at all with 1,3-adamantanedinitrile.

Key words: oxathiazolone, nitrile sulfide, cycloaddition, isothiazole.

Résumé : La réaction du adamantane-1,3-dicarbonamide avec le chlorure de chlorocarbonylsulfényle dans du toluène chaud donne deux nouveaux dérivés oxathiazolone dont les structures ont été confirmées par cristallographie : 1,3-bis(1,3,4-oxathiazol-2-on-5-yl)-adamantane et 1-cyano-3-(1,3,4-oxathiazol-2-on-5-yl)-adamantane. (Les données cristallines du composé $C_{10}H_{14}(COC(O)SN)_2$ sont : $P2_1/m$, avec $a = 10,447(2)$, $b = 7,119(3)$, $c = 10,684(2)$ Å, $\beta = 112,98(1)°$, $V = 731,5(3)$ Å^3, $z = 2$, $D_c = 1,536$ g cm^{-3}, $R = 0,034$, $R_w = 0,029$ et celles du composé $(NC)C_{10}H_{14}(COC(O)SN)$ sont : $P2_1/c$, avec $a = 9,153(2)$, $b = 19,134(2)$, $c = 7,130(3)$ Å, $\beta = 105,38(2)°$, $V = 1204(1)$ Å^3, $z = 4$, $D_c = 1,447$ g cm^{-3}, $R = 0,038$, $R_w = 0,035$.) La réaction du précurseur avec l'acétylènedicarboxylate de méthyle (DMAD) dans le chlorobenzène au reflux donne un mélange que l'on a séparé en composés purs par la sublimation de Kugelrohr pour obtenir : le soufre, le thiophènetétracarboxylate de méthyle, le 1,3-adamantanedinitrile, le 1,3-bis(4,5-bis(méthoxycarbonyl)-isothiazol-3-yl)-adamantane et le 1-cyano-3-(4,5-bis(méthoxycarbonyl)-isothiazol-3-yl)-adamantane. On a confirmé, par cristallographie, les structures des deux nouveaux dérivés de l'isothiazole. (Les données cristallines du composé $C_{10}H_{14}(CNS{\cdot}DMAD)_2$ sont : $Pca2_1$, avec $a = 15,857(4)$, $b = 11,562(4)$, $c = 13,602(4)$ Å, $V = 2494(2)$ Å^3, $z = 4$, $D_c = 1,424$ g cm^{-3}, $R = 0,057$, $R_w = 0,038$ et celles du composé $C_{10}H_{14}(CN)(CNS{\cdot}DMAD)$ sont : $P2_1/c$, avec $a = 19,683(2)$, $b = 11,566(3)$, $c = 7,727$ (3) Å, $\beta = 93,30(2)°$, $V = 1756(1)$ Å^3, $z = 4$, $D_c = 1,363$ g cm^{-3}, $R = 0,079$, $R_w = 0,076$.) L'allure de la réactivité indique que l'*équivalent synthétique* du bis(sulfure de nitrile) peut être présent en solution mais qu'il a un temps de vie très court et qu'il ne réagit pas du tout avec tous les 1,3-adamantanedinitriles.

Mots clés : oxathiazolone, sulfide de nitrile, cycloaddition, isothiazole.

[Traduit par la rédaction]

Introduction

Synthesis of heterocyclic systems via the 1,3-dipolar cycloaddition reaction is a well-established protocol in synthetic chemistry (1). The nitrile sulfides ($R\text{-}C{\equiv}N^+\text{-}S^-$) are a relatively new family of 1,3-dipoles that are typically generated in solution by the thermal decarboxylation of an oxathiazolone derivative (2). These synthetically useful 1,3-dipoles have been shown to be unstable with respect to decomposition to sulfur and the corresponding nitrile. We recently described the generation of the first adamantane-based nitrile sulfide and reported the reaction of these 1,3-dipoles with the C≡C and S≡N triple bonds to give isothiazoles and dithiadiazoles, respectively (3).

The chemistry of carbon–sulfur–nitrogen heterocycles has

recently been an area of intense research. The electron-rich cations and radicals described by Banister and Rawson (4), Oakley and co-workers (5), and Parsons and Passmore (6) that have been generated in the search for new conductive materials have clearly delineated the potential of these systems. Their most recent efforts have focused on the preparation of molecules that contain multiple heterocyclic moieties, usually substituted on aromatic or π-delocalized systems. We are interested in the use of saturated hydrocarbon cages as substrates to stabilize reactive π systems. We have concentrated on the adamantane moiety in this role because there are multiple tertiary carbon atoms in the carbon cage and the substitution of these centres with reactive π systems may provide access to new oligomeric materials. Indeed, recent work on the thermal polymerization of adamantyl alkynes has indicated that useful polymers can be prepared from such systems (7).

Few molecules have been reported that bear more than one site capable of 1,3-dipolar cycloaddition via the nitrile sulfides (1). There were early reports of molecules that bore two of the precursor heterocycles but there is no indication that they were ever used to generate the nitrile sulfides (8). More recently, a polymer backbone substituted with the precursor oxathiazolone heterocycles has been reported and indications of reaction as nitrile sulfides were observed (9).

We have prepared for the first time an adamantane-based molecule that contains two oxathiazolone heterocycles. The reaction of this molecule with an electron-deficient alkyne to give a bis(isothiazole) derivative confirms that the *synthetic equivalent* of a bis(nitrile sulfide) has been generated if not the actual bis(1,3-dipole) itself (the reaction gives the desired products even though the actual identity of the intermediates may be uncertain). The new oxathiazolone and isothiazole derivatives were identified by spectroscopic and analytical techniques and the structures were confirmed by X-ray crystallography. The solid state structures of the oxathiazolone derivatives show limited π delocalization in the heterocycles whilst the isothiazole derivatives are clearly extensively delocalized and the observed distortions from planarity are a result of the steric effect of the adjacent adamantyl group.

Experimental

General procedures

1,3-Adamantanedicarboxylic acid, chlorocarbonylsulfenyl chloride, and dimethyl acetylenedicarboxylate were purchased commercially (Aldrich) and used without further purification. The 1,3-adamantanedicarbonamide was prepared from the dicarboxylic acid following standard procedures given in ref. 10. Toluene (Na) and chlorobenzene (CaH_2) were dried by refluxing with the given drying agent under nitrogen. Reactions involving chlorocarbonylsulfenyl chloride were performed under nitrogen. The reaction mixtures were resolved by fractional sublimation using a Büchi GKR-50 Kugelrohr apparatus operating at 10^{-3} Torr (1 Torr = 133.3 Pa). Melting points were determined on a Mel-Temp II melting point apparatus and are uncorrected. Elemental analyses were carried out at Canadian Microanalytical Service Ltd., Delta, British Columbia, Canada. IR spectra were recorded from Nujol mulls on KBr plates using a Mattson Polaris FT-IR instrument. NMR spectra were recorded on a General Electric 300 MHz instrument (^1H, ^{13}C). Chemical shifts are reported in ppm (high-frequency positive) relative to internal standards (^1H, ^{13}C: TMS). Mass spectra were recorded on a VG Micromass 7070HS double focusing spectrometer. Molecular orbital calculations were made using the HyperChem (Autodesk, version III) suite of semi-empirical programs operating on a 80486 based IBM-compatible computer. Molecules were subjected to a full geometry optimization (Polak–Ribiere conjugate gradient) prior to the single point calculations.

Reaction of $C_{10}H_{14}[C(O)NH_2]_2$ with ClC(O)SCl

Neat chlorocarbonylsulfenyl chloride, ClC(O)SCl (9.4 g, 72 mmol), was added to a mixture of toluene (70 mL) and 1,3-adamantane dicarbonamide, $C_{10}H_{14}[C(O)NH_2]_2$ (4.0 g, 18 mmol), under nitrogen to give a clear yellow solution over a white solid. The solution was heated to 95 ± 5°C for 11 h. The resulting clear orange solution was subjected to rotary evaporation (60°C water bath) to remove the excess ClC(O)SCl and solvent, and a wet yellow solid (6.8 g) was obtained. The mixture was dissolved in $CHCl_3$ and passed through a column (silica gel, 60 mesh) to give a white solid $C_{10}H_{14}[\overline{COC(O)SN}]_2$ (2.9 g, 8.6 mmol, 47.6%). This solid was recrystallized from a 5:1 EtOH:$CHCl_3$ solvent mixture to give clear colourless needle-shaped crystals, mp 134–140°C (dec.); IR (cm^{-1}): 1959w, 1934w, 1896w, 1873w, 1815m, 1803m, 1769ms, 1743ms, 1596 ms, 1262 ms, 1222 ms, 1085 m, 973ms, 921ms. NMR (δ in ppm), ^1H δ(no. of H): 2.315 (m, 2H), 2.222 (s, 2H), 2.066 (m, 2H), 2.024 (m, 2H), 1.980(m, 2H), 1.937(m, 2H), 1.782(2H). ^{13}C δ(assign.): 174.0 (C=O), 165.5 (C=N), 39.7 (C_{quat}), 38.5 (CH_2), 37.8 (CH_2), 34.6 (CH_2), 27.2 (CH). Mass spectrum (EI, 70 eV) *m/z* (%, assign.): 338 (7, M^+), 294 (0.3, $[NS(O)COC]C_{10}H_{14}$ − CNS), 262 (2, $[NS(O)COC]C_{10}H_{14}$ − CN), 236 (46, $C_{10}H_{14}$−[COC(O)SN]), 160 (73, $C_{10}H_{14}$ − CN). Anal. calcd. for $C_{14}H_{14}N_2O_4S_2$: C 49.7, H 4.2, N 8.3, S 19.0%; found: C 49.8, H 4.3, N 8.2, S 19.1%.

From the original column a second white solid [CN]-$C_{10}H_{14}$-[COC(O)SN] (1.1 g, 4.2 mmol, 23.3%) was recovered and recrystallized from acetone to give clear colourless plate-shaped crystals, mp 104–120°C (dec.); IR (cm^{-1}): 2230 w, 1958w, 1895w, 1841w, 1802m, 1764 ms, 1740ms, 1588m, 1247m, 1109m, 1033w, 976ms, 920ms. NMR, ^1H δ(no. of H): 2.196 (m, 4H), 2.04–1.85 (m, 8H), 1.691 (t, 2H). ^{13}C δ(assign.): 173.7 (C=O), 164.7 (C=N), 123.5 (C≡N), 40.3 (C_{quat}), 38.5(C_{quat}), 37.7 (CH_2), 37.3 (CH_2), 34.1 (CH_2), 30.1 (CH), 26.5 (CH_2). Mass spectrum (EI, 70 eV) *m/z* (%, assign.): 262 (7, M^+), 186 (32, $C_{10}H_{14}(CN)_2$), 160 (100, $C_{10}H_{14}$ − CN). $[\overline{COC(O)SN}]_2$ (2.3 g, 6.8 mmol), and DMAD (4.9 g, 34.5 mmol) were dissolved in 50 mL chlorobenzene. The slightly yellow, clear solution turned brown and evolved a gas while it was heated to reflux. The heating was stopped after 12 h at which point the solution was a clear dark red-brown. An oily dark-brown solid (6.1 g) was obtained by solvent evaporation. The solid was dissolved in $CHCl_3$ and passed through a column (silica gel, 60 mesh) to give an oily orange solid (5.5 g). The material was loaded on Kugelrohr distillation apparatus, and heated up to 110°C to remove the by-products: tetramethyl thiophenetetracarboxylate and S_8 (total mass: 0.2 g). The temperature was then raised to 165°C to give the white solid, 1,3-adamantane-dinitrile (0.6 g, 3.0 mmol, 44%), in the outer bulb and a purple sticky solid, 1-cyano-3-(4,5-bis(methoxycarbonyl)-isothiazol-3-yl)-adamantane **1***d* (1.1 g, 3.0 mmol, 44%), in the inner bulb. Decomposition of $C_{10}H_{14}[COC(O)SN]_2$ in DMSO monitored by ^{13}C NMR

A solution of 50 mg $C_{10}H_{14}[COC(O)SN]_2$ and 2 mL DMSO (insoluble at room temperature but soluble above 80°C) was placed in a 5 mm o.d. NMR tube. The reaction was carried out at 135°C and followed by ^{13}C NMR. Spectra ($200 > \delta_C > 100$ ppm) were recorded at 20 min, 1 h, 2 h, and 3 h. The spectra showed that the peaks assignable to the heterocycle (172.99 ppm, 164.43 ppm) decrease and the peak assignable to the nitrile (122.62 ppm) increases as the decomposition reaction proceeds. Only a peak assignable to the nitrile (122.62 ppm) was observed after 1 h.

Reaction of 1,3-bis(1,3,4-oxathiazol-2-on-5-yl)-adamantane and 1,3-adamantane-dinitrile in chlorobenzene

A solution of $C_{10}H_{14}[COC(O)SN]_2$ (0.27 g, 0.8 mmol) and $C_{10}H_{14}(CN)_2$ (0.15 g, 0.8 mmol) in 6 mL of chlorobenzene was placed in a flask fitted with a condenser. The solution was heated to reflux (135°C). The initially clear colourless solution turned to yellow, then brown while it was evolving a gas. The heating was stopped after 4 h and the solvent was evaporated by rotary evaporation. Two NMR samples in $CDCl_3$ were made: (*a*) 1:1 molar ratio starting materials in $CDCl_3$ and (*b*) the residue from the reaction. ^{13}C NMR spectra of the two samples showed that 13 peaks (10 for two adamantane moieties and 3 for C=O, C=N, C≡N) of the starting materials were converted to 6 peaks (5 for adamantane and 1 for C≡N). The product of the reaction was recovered: 1,3-adamantyldinitrile, 0.30 g (1.6 mmol), and S, 0.05 g (1.6 mmol).

X-ray data collection, solution and refinement

Crystals of $C_{10}H_{14}(COC(O)SN)_2$ **1***a* were obtained from a 1:1 solvent mixture of $CHCl_3$ and hexanes. Crystals of $(NC)C_{10}H_{14}(COC(O)SN)$ **1***b*, $C_{10}H_{14}(CNS{\cdot}DMAD)_2$ **1***c*, and $(NC)C_{10}H_{14}(CNS{\cdot}DMAD)$ **1***d* were obtained from ethyl acetate. Unit cell parameters were obtained from the setting angles of accurately centered reflections. The choice of space group was based on systematically absent reflections, packing considerations, and a statistical analysis of intensity distribution and was confirmed by the successful solution and refinement of the structure. All pertinent crystallographic data are summarized in Table 1. Data were collected at room temperature on a Rigaku AFC6S diffractometer (MoKα, λ = 0.71069 Å, graphite monochromator) using the ω–2θ scan technique. The intensities of three representative reflections, which were measured after every 150 reflections, remained constant throughout data collection, indicating crystal and electronic stability. Data were corrected for Lorentz and polarization effects and empirical absorption correction was applied based on DIFABS. Scattering factors were taken from Cromer and Waber (11) and anomalous dispersion effects were included in F_c.

The structures were solved using direct methods (12) to find the heavier elements and the remaining non-hydrogen atoms were located from a series of difference Fourier maps. Hydrogen atoms were included assuming ideal positions (with bond lengths of 0.95 Å) with isotropic thermal parameters 20% greater than the bonded partner. The data set for **1***c* was weak and precluded fully anisotropic refinement of the non-hydrogen atoms. It was clear from the refinement values that the adamantane moiety is sufficiently rigid to permit these atoms to be left isotropic. To improve the data to refined parameters ratio the cutoff of $F^2/\sigma F^2$ was set at 1.00. The analysis of the data from **1***d* revealed that it was not single and several peaks were poorly shaped and (or) had asymmetric and large background counts. These peaks were removed and a list is included in the supplementary material.[2]

All calculations for the structures of **1***a*, **1***b*, **1***c*, and **1***d* were performed using the TEXSAN crystallographic software package (13) and a VAX 3100 work station. Fractional atomic coordinates and isotropic thermal parameters for the non-hydrogen atoms for **1***a*, **1***b*, **1***c*, and **1***d* are given in Tables 2, 3, 4, and 5, respectively, and selected bond lengths and angles for **1**a, **1**b, **1**c and **1**d are given in Table 6. Supplementary material (atomic positional parameters, anisotropic thermal parameters, bond lengths and angles) is available.[2]

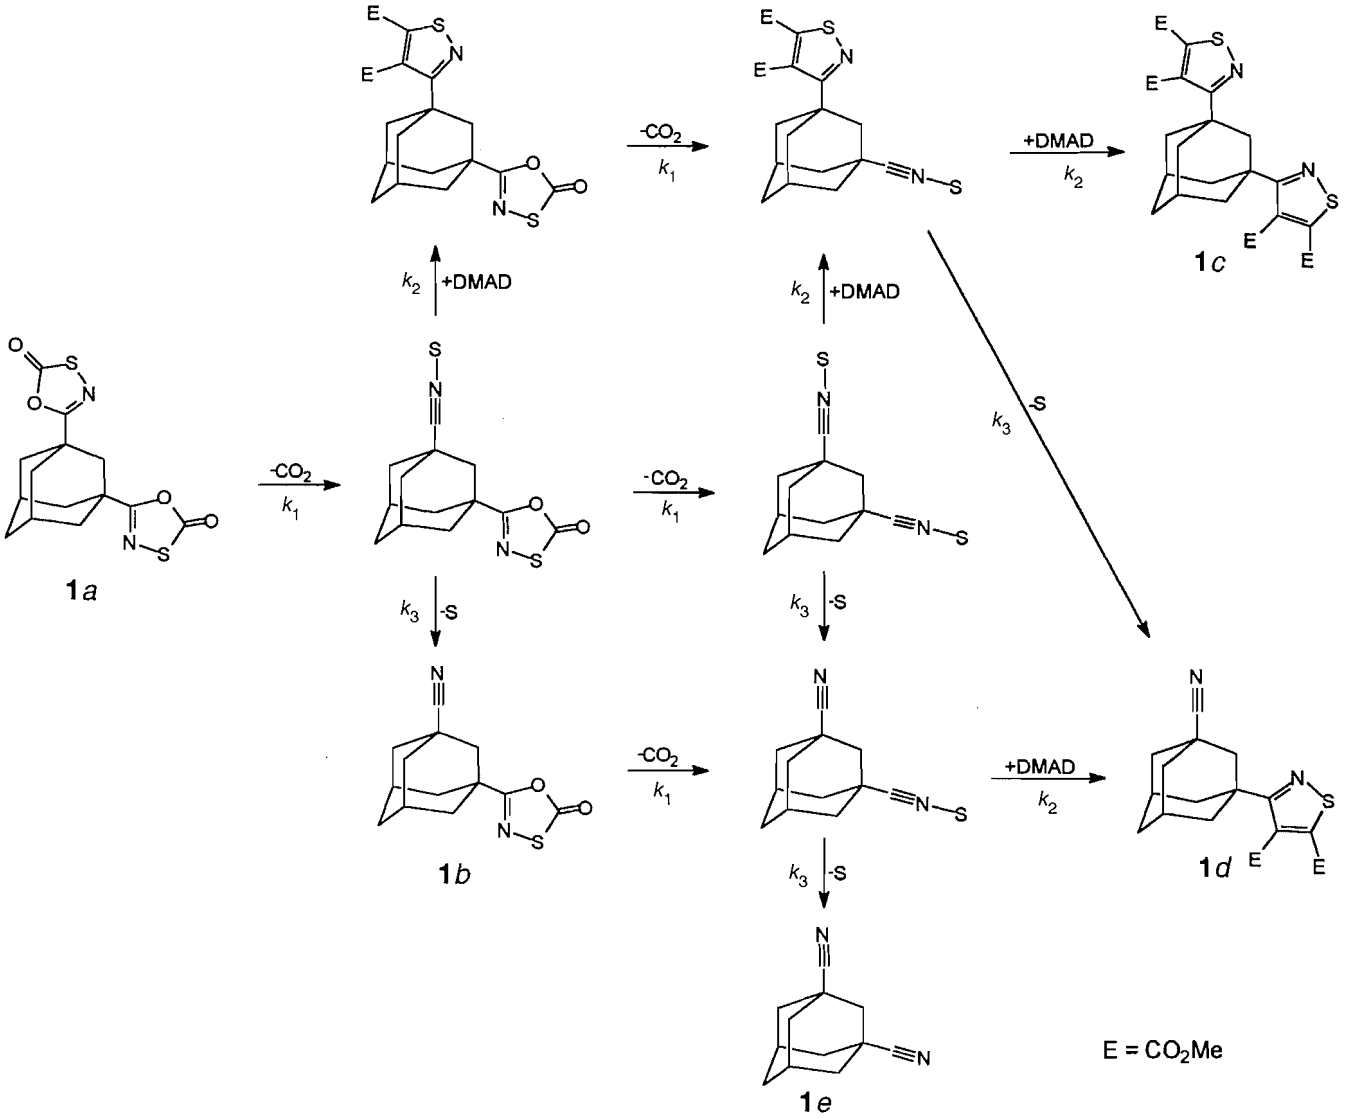
Scheme 1



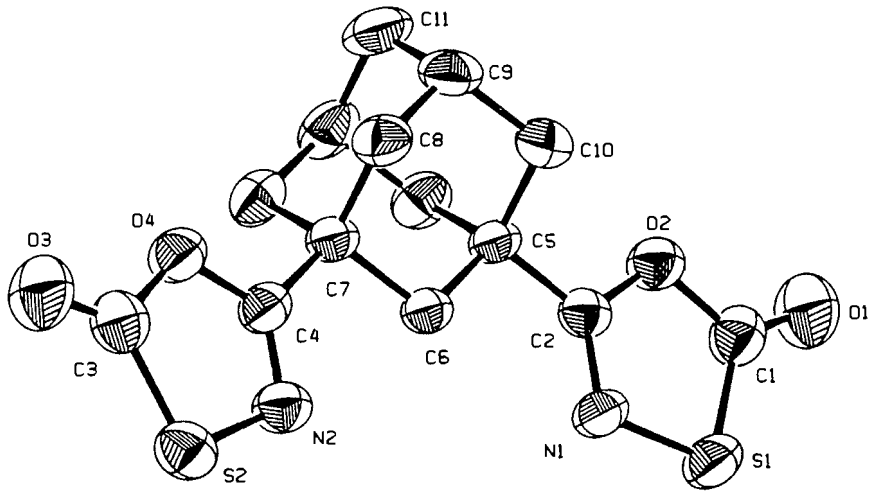
Results and discussion

Preparation of $C_{10}H_{14}[\overline{COC(O)SN}]_2$ and $C_{10}H_{14}(CN)$-$[\overline{COC(O)SN}]$

Reactions of organic amides with chlorocarbonylsulfenyl chloride [ClC(O)SCl] in hot toluene solutions have been reported to give oxathiazolone derivatives [R-$\overline{COC(O)SN}$] in varying yields (2). These compounds are widely used as precursors for the thermal generation of derivatives of the nitrile sulfides (R-C≡N^+-S^-), a family of propargyl allenyl-type 1,3-dipoles (A≡B-C) that have been shown to have an extensive cycloaddition chemistry. Reaction of the 1,3-adamantanedicarbonamide ($C_{10}H_{14}[(C(O)NH_2]_2$) with ClC(O)SCl under N_2 gave two heterocyclic products containing the oxathiazolone heterocycle. The expected bis(oxathiazolone) derivative (**1***a* $C_{10}H_{14}[\overline{COC(O)SN}]_2$) was isolated in 48% recovered yield by column chromatography while a second derivative, which was determined to be the mono(oxathiazolone) (**1***b* $(NC)C_{10}H_{14}$-$[\overline{COC(O)SN}]$), was also isolated in 23% yield. The remaining adamantane species that was obtained from the chromatographic separation was the dinitrile (**1***e* $C_{10}H_{14}(CN)_2$), which was recovered in 21% yield (total recovery of the adamantane-based compounds was approximately 92%). The compounds were clearly identified as oxathiazolone derivatives by the observation of distinctive ^{13}C resonances in the regions 174.2 ± 0.6 ppm (**1***a* 174.0 ppm, **1***b* 173.7 ppm, assigned to C=O) and 162 ± 5.2 ppm (**1***a* 165.5 ppm, **1***b* 164.7 ppm, assigned to C=N). Both compounds were fully characterized spectroscopically and their structures were confirmed by X-ray crystallographic methods.

It is known that the oxathiazolone heterocycles will give the unstable nitrile sulfides in solution, which, if not immediately trapped, will decompose to the corresponding nitrile and sulfur. These experiments indicate that the initial condensation reaction is nearly quantitative to give the desired bis(oxathiazolone) **1***a*. Unfortunately, under the reaction conditions a sig-

Fig. 1. An ORTEP (21) view of $C_{10}H_{14}(\overline{COC(O)SN})_2$ **1***a*.



nificant fraction of the product goes through a stepwise decomposition (loss of CO_2 followed by loss of S) to the mono(oxathiazolone) **1***b* and ultimately to the dinitrile **1***e*. Lower reaction temperatures did not improve the yield of the reaction and left unreacted starting materials. The chemistry of the mono(oxathiazolone) **1***b* will be the subject of future research.

Reaction of $C_{10}H_{14}[\overline{COC(O)SN}]_2$ with DMAD

The reaction of oxathiazolone derivatives with electron-deficient alkynes has been reported to give isothiazole derivatives in high yield (14). Based on the reactivity pattern observed above, it was expected that the reaction of the bis(oxathiazolone) **1***a* with dimethyl acetylenedicarboxylate (DMAD) in refluxing chlorobenzene would give the bis(isothiazole) **1***c*, the mono(isothiazole) **1***d*, and the dinitrile **1***e*. The reaction mixture was resolved by chromatography and Kugelrohr sublimation to give **1***c* in 12% yield, **1***d* in 44% yield, and **1***e* in 44% yield. Unexpectedly, a fourth product (which was usually contaminated with elemental sulfur) was obtained in small amounts and was shown to be tetramethylthiophene tetracarboxylate (S·(DMAD)$_2$). This compound was also isolated and identified by X-ray crystallography (15). The presence of this thiophene derivative is obviously a product of the well-known reaction of DMAD with sulfur and has been reported as one of the products of similar reactions (16). The heterocyclic compounds **1***c* and **1***d* were fully characterized spectroscopically and identified by comparison with the data from the previously reported monosubstituted adamantane derivatives. Analysis of the ^{13}C NMR spectra of these compounds allowed clear identification of the adamantane, methylacetyl ($\delta_{C=O}$ = 173.5 ± 1.0 and 169 ppm; δ_{OMe} = 52.9 ± 0.1 ppm), and isothiazole (δ_{Chet} = 159.2 ± 0.1, 154.6 ± 0.2, and 132.5 ± 0.1 ppm) moieties in **1***c* and **1***d*. The spectroscopic data are fully consistent with the presence of symmetric or asymmetric disubstituted adamantane groups and the appropriate heterocycle or nitrile. The structures of **1***c* and **1***d* were unambiguously determined by X-ray crystallographic methods.

The pattern of products determined for this reaction indicates that under the reaction conditions of concentration and temperature, the decomposition reactions of the nitrile sulfides (k_3) in Scheme 1 are competitive with the cycloaddition reactions (k_2). Indeed, 88% of the isolated adamantane-based products are the result of nitrile sulfide decomposition reactions and only 56% of the isolated adamantane-based products are the result of cycloaddition reactions. These results are consistent with earlier reports on the kinetics of cycloaddition and decomposition of the nitrile sulfides (17). It has been shown that the desulfuration reaction of the nitrile sulfides is a bimolecular process, therefore the extent of decomposition should decrease with dilution (17). These reactions may provide higher yields at lower concentrations and subsequent investigations on the reaction of **1***a* with inorganic π systems will examine this possibility. The recovered yield of the reaction of a monosubstituted adamantane with DMAD was reported to be 27% (3). If the two heterocycles in **1***a* react completely independently, then the percent yield of the total reaction would be expected to be the square of the yield of an individual cycloaddition reaction (predicted yield ~7%). The isolated yield of **1***a* (12%) is higher than expected but this is undoubtedly due to the separation difficulties experienced in the earlier work (3). The pattern of products from this reaction is consistent with totally independent cycloaddition reactions of approximately equal rates and decomposition reactions of approximately equal rates. The high recovered yield of **1***d* may indicate that several routes to the dinitrile **1***d* are possible.

The presence of the bis(nitrile sulfide) is not proven by the presence of the bis(isothiazole) **1***c*. A possible reaction sequence for the separate carbon dioxide extrusion, desulfuration, and cycloaddition reactions is given in Scheme 1. The actual reaction pathway may in fact go through individual nitrile sulfide intermediates with the other oxathiazolone heterocycle intact. Partial confirmation of this thesis may lie in the actual isolation of the nitrile-oxathiazolone **1***b*. The presence of **1***c* in the product mixture does indicate, however, that **1***a* can be used to generate the *synthetic equivalent* of the bis(nitrile sulfide).

Structural features

The solid state structures of **1***a*, **1***b*, **1***c*, and **1***d* have been determined by X-ray crystallography and views of the compounds are presented in Figs. 1, 2, 3, and 4, respectively. The weak-

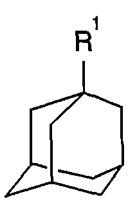
ness of the data set for **1***c* did not allow a fully isotropic refinement of all the non-hydrogen atoms but fully confirms the presence of the two heterocycles bound to the adamantane moiety. No significant intermolecular contacts are observed in the structures.



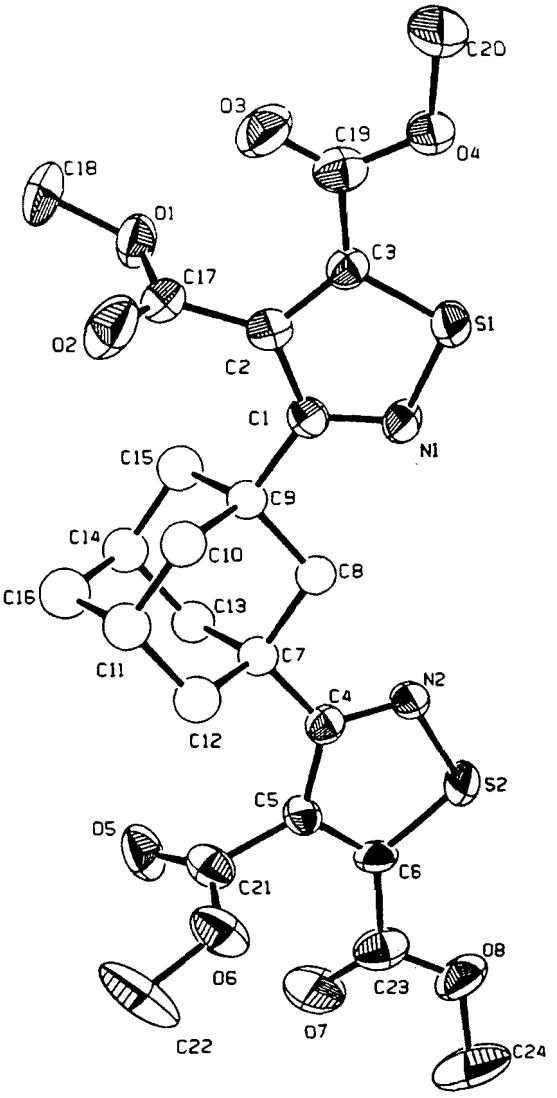
2*a* - $\overline{COC(O)SN}$

2*b* - CNS•DMAD

2*c* - C≡N

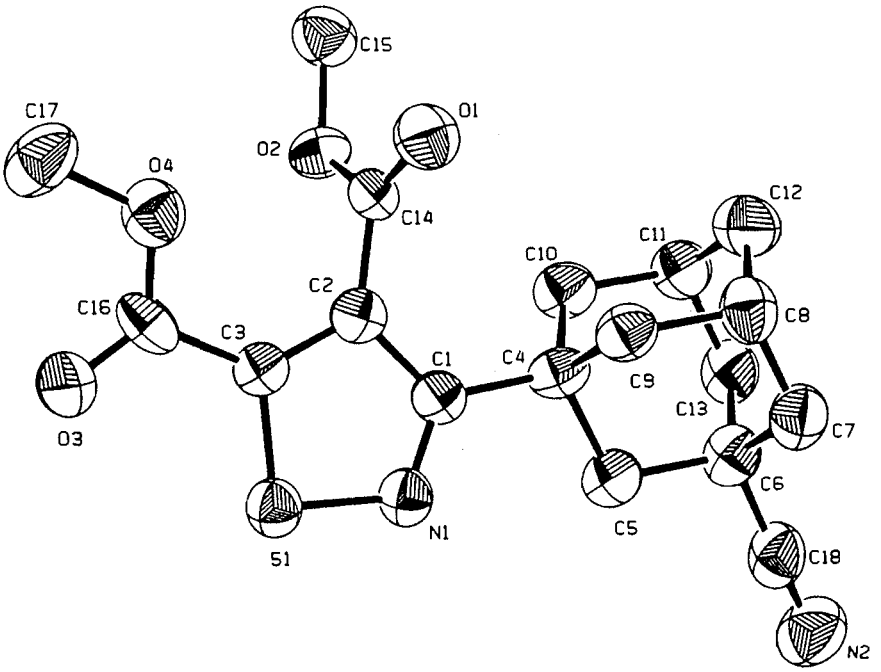
There are no significant differences in the adamantane frameworks of the compounds **1***a*, **1***b*, **1***c*, and **1***d*. The heterocycles are planar, partially delocalized (**1***a* and **1***b*) or fully delocalized (**1***c* and **1***d*) π systems as described previously (3). The nitrile substituents in **1***b* and **1***d* have C—N bond distances consistent with the range expected for alkyl nitriles (*d* C≡N = 1.16 Å (18)). The ester groups in **1***c* and **1***d* are planar and have bond distances and angles consistent with those reported for methylacetyl groups in similar compounds (3). It is noted, however, that in **1***c*, **1***d*, and **2**b the plane of the ester group next to the adamantane moiety is twisted out of the plane of the heterocycle to which it is attached, while the second ester group, which is more distant from the adamantane moiety, essentially lies in the plane of the heterocycle. This twisting is consistently accompanied by a lengthening of the C—C bond (**2***b*: 1.494(6) vs. 1.491(6) Å (3); **1***c*: 1.504(9)\1.500(9) vs. 1.48(1)\ 1.49(1) Å; and **1***d*: 1.509(9) vs. 1.482(9) Å); however, these

Fig. 3. An ORTEP (21) view of $C_{10}H_{14}(CNS{\cdot}DMAD)_2$ **1***c*.



differences are well below the usual test for significance ($\delta > 3\sigma$). In addition, similar observations were made concerning the positioning of the methoxycarbonyl substituents of tetramethyl thiophenetetracarboxylate (15). If the pattern of bond lengthening that is observed is real, then it may be due to the loss of π-bond delocalization that would occur when the methylacetyl group twists out of the plane of the heterocycle. The observed angles by which the proximal ester groups are twisted from the plane of the heterocycles are: **1***c* 87.6/80.9°, **1***d* 75.1°, and **2***b* 89.0° (3). The explanation for the observed geometries of these molecules may be provided by a simple model where the fully planar geometry, which optimizes π-bond delocalization, is not possible because of the steric influence of the adjacent adamantane group. It is noted, however, that geometry optimization calculations (semi-empirical: PM3) indicate that the fully planar isomer of the parent isothiazole heterocycle (H-CNS·DMAD) is the *least* favoured energetically (E_{total} = −2099.9 kcal). Indeed, the isomers of this heterocycle where the proximal methoxycarbonyl (E_{total} = −2104.5 kcal) or both methoxycarbonyl groups (E_{total} = −2105.4 kcal) are twisted 90° from the heterocyclic plane, are

Fig. 4. An ORTEP (21) view of $(NC)C_{10}H_{14}$(CNS·DMAD) **1***d*.

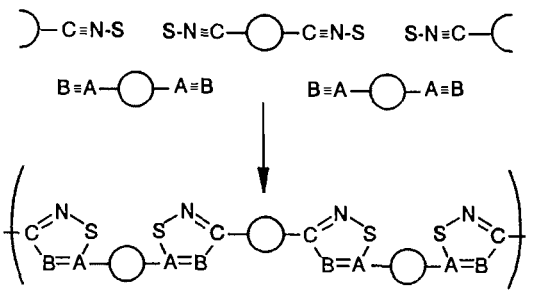


significantly more stable. That the more distant methoxycarbonyl group adopts a geometry in which it is essentially coplanar with the isothiazole heterocycle may be due to the methoxy oxygen atom making contact with the heterocyclic sulfur atom. The oxygen atom would roughly lie on the sulfur–nitrogen bond axis so that the sulfur atom adopts a distorted trigonal bipyramidal geometry. The calculated atomic charges (PM3) on the sulfur (+0.375) and the oxygen (OCH_3: −0.259) atoms are consistent with this type of contact within the molecule. Long-range contacts between sulfur and oxygen atoms in the same molecules were observed previously (19).

The angles subtended by the two substituent groups on the adamantane moieties are close to the ideal expected for a tetrahedral arrangement (ideal: 109.5°; **1***a*: 107.2(2)°, **1***b*: 109.4(2)°, **1***c*: 108.0(5)°, **1***d*: 107.6(6)°), indicating that the adamantane moiety is not strained by substitution with the sterically demanding heterocycles. Indeed, the molecules **1***a* and **1***c* have a molecular C_{2v} symmetry in the solid state with the heterocycle atoms of **1***a* lying on a crystallographic mirror plane.

Table 6 contains the bond distances and angles from the common parts of **1***a* and **1***b* and also compares **1***c* and **1***d*. The data clearly show that the heterocycles do not differ significantly ($\delta > 3\sigma$) regardless of the nature of the second substituent. Indeed, the complete independence of the two heterocyclic centres that was assumed from the experimental data above is confirmed by the data in the table. The oxathiazolone heterocycles in **1***a* and **1***b* have localized C—N π bonds (accepted for C_{sp^2}=N_{sp^2}: 1.28 Å (18); observed: **1***a* 1.276(3)/1.269(3) Å, **1***b* 1.276(3) Å; accepted for C_{sp^2}—S_{sp^3}: 1.75 Å (18), observed: **1***a* 1.756(3)/1.7623 Å, **1***b* 1.753(3) Å) while the isothiazole heterocycles in **1***c* and **1***d* have more delocalized π bonding, with the C—N π bond weaker and the C—S bond stronger (C=N, observed: **1***c* 1.315(7)/1.312(7) Å, **1***d* 1.281(7) Å; C—S, observed: **1***c* 1.716(7)/1.709(7) Å, **1***d* 1.692(7) Å).

Scheme 2



Cycloaddition and polymerization reactions of bis(nitrile sulfides)

The generation of molecules with multiple heterocyclic moieties and the potential for the generation of oligomeric or polymeric systems are crucial areas of new chemistry for the bis(nitrile sulfides). The generation of oligomeric materials by sequential symmetry-allowed cycloaddition reactions has been an area of intense research (20). We have now established that bis(oxathiazolone) molecules can be used to generate molecules bearing multiple heterocyclic systems. Therefore systems such as the bis(1,2,3,5-dithiadiazolyl)-alkyl radicals, which cannot be prepared by current preparative techniques (4–6), may be prepared by reaction of the bis(oxathiazolone) with N≡S-Cl as described in ref. 3. The generation of a series of heterocyclic compounds by reaction of **1***a* with inorganic π systems is now practical. The prerequisites for generating chain molecules from such bis(1,3-dipoles) would be the reactivity and stability of the bis(1,3-dipoles) and the reactivity of the bis(π bonds) according to Scheme 2.

This study has focused on the generation of the *synthetic equivalent* of the first bis(nitrile sulfide) and the reaction of this species with monomeric π systems to establish the pattern of reactivity. It was initially considered possible by the authors

For personal use only.

that the nitrile sulphides generated from **1***a* might undergo premature cycloaddition reactions with the nitrile π bonds in the decomposition products **1***b*, **1***c*, and **1***e*, leading to complex mixtures. The NMR studies reported here and the analysis of the quantitative decomposition reactions of **1***a* clearly indicate that few if any intermediates are observed in the decomposition reaction and that no cycloaddition reaction occurs between the nitrile sulfides and the nitriles generated by decomposition. Indeed, the actual reaction of **1***a* and **1***e* gives a quantitative yield of **1***e* and S_8 and is in agreement with previous studies that indicated that nitrile sulfides, while highly reactive to nitrile π systems, give higher yields with aromatic nitriles or those bearing strongly electron-withdrawing substituents (17). In previous work it was shown by theoretical calculations and the established pattern of reactivity that the aromatic nitrile sulfides have extensively delocalized π systems that may stabilize the 1,3-dipole (3). If this is a reliable analysis, then an aromatic ring may be a more suitable platform for the generation of bis(nitrile sulfides) in polymerization reactions. Indeed, this work indicates that the reaction of an aromatic bis(nitrile sulfide) with an electron-deficient alkyne may provide a better route to the desired polymeric systems.

The compound **1***a* is therefore a useful compound for the generation of a synthetic equivalent to the first bis(nitrile sulfide). The facile and rapid decomposition of the intermediate(s), however, means that the synthetic utility of this compound may be limited to the preparation of mono- and bisheterocyclic compounds as described above.

Kinetic study of the reactions of methoxy-substituted phenacyl radicals

S.V. Jovanovic, J. Renaud, A.B. Berinstain, and J.C. Scaiano

Abstract: The photochemistry of various mono- and dimethoxy-substituted α-bromoacetophenones has been investigated by laser flash photolysis in organic solvents. The short-lived excited singlet states cleave to yield bromine atoms and the corresponding methoxyphenacyl radicals with quantum yields ranging from 0.13 to 0.35. With the exception of 4-methoxy-α-bromoacetophenone (**6**), all other substrates yield readily detectable triplet states; these have π,π^* character and are very poor hydrogen abstractors. Triplet decay does not contribute to methoxyphenacyl radical formation. While methoxyphenacyl radicals may have a spin density as high as 0.3 at the carbonyl oxygen, which accounts for the alkoxy-like visible band in their absorption spectrum, their chemical reactivity is dominated by the radical character at the carbon site. Methoxyphenacyl radicals are modest hydrogen abstractors; for example, reaction of **6** with 1,4-cyclohexadiene occurs with a rate constant of 2.6×10^5 M^{-1} s^{-1}, while for addition to the double bond in 1,1-diphenylethylene the rate constant is 9.4×10^7 M^{-1} s^{-1}. Additions to other double bonds are likely to be slower (e.g., **12** + 1,3-cyclohexadiene, $k \leq 10^5$ M^{-1} s^{-1}). In contrast, reaction with oxygen occurs with $k_q = 2.5 \times 10^9$ M^{-1} s^{-1}. Under the conditions relevant for their participation in paper yellowing, the methoxyphenacyl radicals will be converted to peroxyl radicals. These probably play a key role in the oxidative photodegradation of lignin.

Key words: methoxyphenacyl radicals, α-bromoacetophenones, laser flash photolysis.

Résumé : Faisant appel à la photolyse laser éclair, on a étudié la photochimie de diverses mono- ou diméthoxy-α-bromoacétophénones dans des solvants organiques. Les états singulets excités de courte durée de vie se brisent pour donner des atomes de brome et les radicaux méthoxyphénacyles correspondants, avec des rendements quantiques allant de 0,13 à 0,35. À l'exception de la 4-méthoxy-α-bromoacétophénone (**6**), tous les autres substrats fournissent des états triplets facilement détectables; ils possèdent un caractère π,π^* et une très mauvaise habilité à enlever des hydrogènes. La dégénérescence de l'état triplet ne contribue pas à la formation du radical méthoxyphénacyle. Alors que les radicaux méthoxyphénacyles peuvent posséder une densité de spin allant jusqu'à 0,3 au niveau de l'oxygène du carbonyle, ce qui explique la bande semblable à celle des alcoxy dans leur spectre d'absorption, leur réactivité chimique est dominée par le caractère radicalaire au site carboné. L'habilité des radicaux méthoxyphénacyles à enlever des hydrogènes est modeste; par exemple, la réaction du composé **6** avec le cyclohexa-1,4-diène se produit avec une constante de vitesse de $2{,}6 \times 10^5$ M^{-1} s^{-1}, alors que, pour l'addition à la double liaison du 1,1-diphényléthylène, la constante de vitesse est de $9{,}4 \times 10^7$ M^{-1} s^{-1}. Il est probable que les additions sur d'autres doubles liaisons seront plus lentes (par exemple, pour **12** + cyclohexa-1,3-diène, $k \leq 10^5$ M^{-1} s^{-1}). Par ailleurs, la réaction avec l'oxygène se produit avec une $k_q = 2{,}5 \times 10^9$ M^{-1} s^{-1}. Dans des conditions semblables à celles par lesquelles ils participient au jaunissement du papier, les radicaux méthoxyphénacyles sont transformés en radicaux peroxyles. Ces derniers jouent probablement un rôle dans la photodégradation oxydante de la lignine.

Mots clés : radicaux méthoxyphénacyles, α-bromoacétophénones, photolyse laser éclair.

[Traduit par le rédaction]

Introduction

Photoinduced yellowing of papers manufactured from ultra-high-yield pulps limits their use to low-grade paper products, such as newsprint, catalog, and advertising products. The yellowing process results largely from photoinduced reactions involving the chromophores in lignin; among these, mono- and dimethoxyphenols, methoxyacetophenones, and aryloxyanisoles are believed to play an important role (1). The absorption of light leads to various unstable intermediates, such as aromatic ketone singlets and triplets, phenoxyl, phenacyl, and peroxyl radicals, and presumably singlet oxygen. Ultimately, yellow products such as quinones, oligomers, and other degradation products are formed (1).[2] The knowledge of the kinetics and mechanisms of the reactions of unstable intermediates should advance our understanding of lignin photochemistry in general and lead to rational strategies to inhibit the photoyellowing of paper.

A variety of radical mechanisms are believed to play a role in the photodegradation of lignin. These include the direct

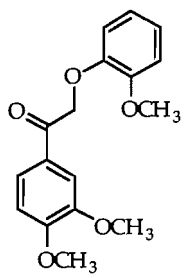
6, 4-CH_3O

7 8 9

photodecomposition of phenols to yield phenoxyl radicals, the abstraction of phenolic hydrogens to yield also phenoxyl radicals, the cleavage of excited states of substituted α-phenoxyacetophenones to produce phenacyl and phenoxyl radicals, and the cleavage of aromatic ketyl radicals (1, 3, 4).

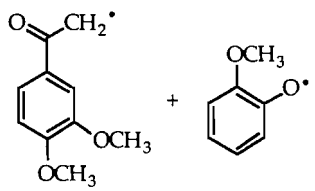
The complexity of lignin is such that studies on native lignin are difficult and their interpretation is frequently inconclusive. Several research groups have employed "designer" model compounds in their studies. These molecules tend to include some of the key features of lignin and, therefore, their behavior can be taken to represent a modest fraction of the reactions that may occur in native lignin. Among these model compounds, α-guaiacoxyacetoveratrone (**1**) has been the subject of numerous studies (3, 5–10).

1



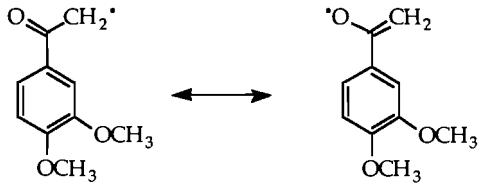
Of the various radicals mentioned above, phenacyl radicals are probably the least understood, yet they may be very important species in the chain of events leading to the oxidative degradation of lignin. In pulp, phenacyl radicals are probably produced by photoinduced cleavage of β-ether bonds in a process resembling the mechanism of decomposition of **1**, reaction [1].

[1] **1** $\xrightarrow{h\nu}$ **2** + **3**



While radical **2** has been written as a carbon-centered species, it can also be written in its canonical form, as an oxygen-centered radical (11), i.e.,

[2]



Recent work has suggested that the "oxy" form of **2** may account for its absorption properties (11), which are reminiscent of those recently reported for cumyloxyl radicals (12, 13). Product studies on the addition of phenacyl radicals to olefins show that these reactions lead to C—C bond formation, thus showing carbon-centered radical behavior (14, 15).

This study was undertaken in an attempt to learn about the kinetics and spectroscopy of **2** and related phenacyl radicals. In our search for spectroscopically "clean" sources of phenacyl radicals, we concluded that substituted α-bromoacetophenones were a convenient source of these radicals. A similar reaction is known in the case of phenacyl sulfides (16). In this report, we have employed laser flash photolysis techniques to study several α-bromoacetophenones and the phenacyl radicals produced in their photodecomposition.

Experimental section

The various substituted α-bromoacetophenones were obtained from either Lancaster or Aldrich and were recrystallized from hexane before use. The same applies to 4-methoxyphenol and 2,6-dimethoxyphenol used in several experiments. Chart 1 illustrates the structures of the phenacyl precursors employed in this study. Ascorbic acid, 1,4-cyclohexadiene, and triethylamine were Aldrich products; sorbic acid was from Sigma. Solvents were Omnisolv grade from BDH.

Laser flash photolysis experiments were carried out using a Lumonics EX-510 excimer laser for excitation (Xe–HCl–He mixtures, 308 nm, ~ ns, 20–80 mJ/pulse). The signals from a monochromator–photomultiplier detector system were initially captured by a Tektronix 2440 digital oscilloscope interfaced to a Macintosh-IIcx computer that provided facilities for experiment control and data capture and processing (11). Nitrogen-saturated samples were flowed through a quartz cell constructed of 7 mm × 7 mm Suprasil square tubing. This ensured that a fresh portion of solution was irradiated by each laser pulse, thus avoiding problems related to sample depletion

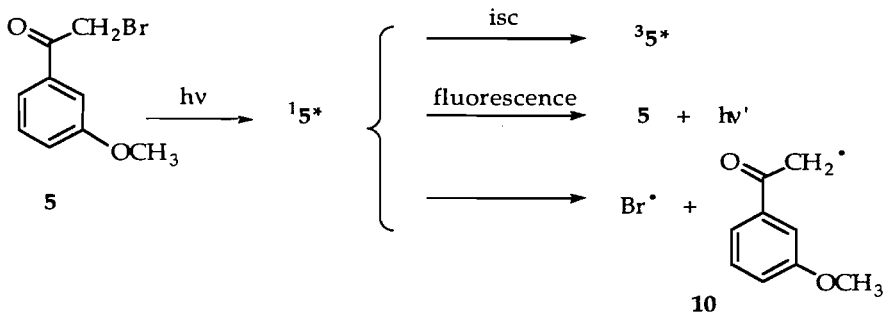
Scheme 1



or product accumulation. Software for the laser system was written in the LabVIEW 2.2 programming environment from National Instruments.

Molecular modeling calculations were performed on a Tektronix CAChe workstation (software version 3.5) using the AM1 UHF semiempirical method, as part of the MOPAC program version 6.1.

Results

Laser excitation (308 nm) of substituted α-bromoacetophenones leads to two detectable transients. These can be characterized as the excited triplet state (detectable in most, but not all cases) and phenacyl radicals. Bromine atoms, produced concurrently with phenacyl radicals, are not detectable in the spectral region of interest; their presence can be readily established by complexation with either benzene or bromide ions (17, 18). Formation of phenacyl radicals competes with intersystem crossing (isc) to the triplet manifold, and in some systems with fluorescence emission, as illustrated for **5** in Scheme 1.

We will show below that the triplet states of these molecules do not yield any significant amounts of phenacyl radicals. These appear to be derived exclusively from the singlet state.

Characterization of the triplet states from ketones 4–9

Laser excitation of deaerated solutions of the ketones in Chart 1 leads, in most cases, to the detection of a reaction intermediate that can be characterized as the ketone triplet state (see Fig. 1). A notable exception is the case of **6**, where the triplet state has not been detected in spite of numerous attempts to do so. Interestingly, no triplet state has been detected in the photochemistry of the parent α-bromoacetophenone (17).

The triplet states were identified through their characteristic behavior toward various quenchers. In particular, conjugated dienes are well-established quenchers of triplet states (19–21). In our case, we employed sorbic acid, **11**, to help identify the triplet states; quenching is expected to involve energy transfer.

For example, in the case of **5**, the triplet state has a lifetime of 2.2 μs in 2-propanol, and was quenched by sorbic acid with a rate constant of 2.2×10^9 M^{-1} s^{-1} at 20°C. For **8** the rate constant was 2.1×10^9 $M^{-1}s^{-1}$. This rate constant is derived from a

11 
Table 1. Rate constants for the quenching of carbonyl triplets by various quenchers in 2-propanol at 20°C.

Triplet	Quencher	k_q (M^{-1} s^{-1})	τ (μs)
4	Sorbic acid	2.2×10^9	2.0
5	Sorbic acid	2.2×10^9	2.2
8	Sorbic acid	2.1×10^9	4.5
9	Sorbic acid	1.6×10^9	1.8
5	Triethylamine	1.8×10^8	2.2
7	Triethylamine	6.5×10^6	5.6

plot of the first-order rate constant for triplet decay as a function of the quencher concentration, i.e.,

[3] $k_{decay} = \tau^{-1} + k_q[\mathbf{11}]$

Representative plots according to eq. [3] are shown in Fig. 2, and the lifetime and quenching data have been summarized in Table 1. The triplet states were also readily quenched by oxygen, as expected.

The monomethoxy-substituted triplet states were readily quenched by triethylamine; for example, in the case of **5**, $k_q = 1.8 \times 10^8$ M^{-1} s^{-1} in 2-propanol as solvent. In contrast, the rate constant for **7** is 6.5×10^6 M^{-1} s^{-1} (Et_3N). It is interesting to note that the molecules in Table 1 do not photoreduce appreciably in alcohols, with $k_q < 5 \times 10^4$ M^{-1} s^{-1} for 2-propanol. The inability to photoreduce in alcohols is characteristic of ketones with low-lying π,π* states, a situation frequently encountered in methoxy-substituted acetophenones (22, 23).

The triplet states (Fig. 1) show maxima around 380 nm for the monosubstituted derivatives, and around 420 nm for the disubstituted ones (compounds **7–9**). A small blue shift (~20 nm) is observed in nonpolar solvents such as hexane.

We were surprised by the failure to detect the triplet state of **6**. Some sensitization experiments were carried out to determine if this was due to the involvement of a very short-lived triplet, or a low yield for its formation.

Xanthone is a convenient sensitizer, since its triplet state is readily detectable and is relatively long-lived in many organic solvents (24). Xanthone was excited at either 355 or 308 nm and the triplet state monitored at 600 nm; its lifetime under our experimental conditions (0.3 mM) was ~6 μs in acetonitrile. Addition of **6** led to efficient quenching with rate constants of $(1.1 \pm 0.1) \times 10^{10}$ M^{-1} s^{-1} and $(4.0 \pm 0.6) \times 10^9$ M^{-1} s^{-1} in ace-

tonitrile and 2-propanol, respectively. These near-diffusion-controlled rate constants suggest efficient energy transfer. However, our attempts to detect the triplet state of **6** were unsuccessful, since no other transient could be detected following decay of the xanthone triplet, under conditions where >90% of the xanthone triplets were quenched by **6**. Given the dynamics of energy transfer for the highest concentration of **6** employed (0.12 mM), this allows us to set an upper limit of 0.5 μs for the triplet lifetime. Clearly, the failure to detect triplet **6** in the direct or sensitized photolysis is due to its short triplet lifetime. Another important observation is that triplet energy transfer from xanthone to **6** does not lead to the formation of the corresponding phenacyl radical. Thus, phenacyl radical formation is a singlet state process.

The yields of phenacyl radicals (vide infra) were not influenced by quenching of the triplet states by sorbic acid, suggesting that, just as in the case of **6**, radicals are normally derived from the singlet state. Similar conclusions have been reached in related systems using CIDNP spectroscopy (8, 9).

To our surprise, the lifetime of the triplet states of the monomethoxy derivatives **4** and **5** showed an unexpected solvent dependence. Thus, the triplet lifetime of **5** was 2.2 μs in 2-propanol (η = 2.2 cP), 500 ns in methanol (η = 0.55 cP), and 400 ns in hexane (η = 0.29 cP). The triplet lifetime was insen-

sitive to changes in the concentration of **5** from 0.08 to 0.3 mM, thus ruling out possible influence of impurity quenching in the ketone as the source of the observed viscosity dependence. The effect may be related to an unusually slow bond rotation. Chlorine influences strongly rates of bond rotation in reaction intermediates derived from chloroacetophenones (25). If this assumption is correct for the bromoacetophenones, it would imply that radiationless triplet deactivation and bond rotation are coupled processes.

Characterization and reactivity of methoxy-substituted phenacyl radicals

The transient spectra of methoxyphenacyl radicals produced by photodecomposition of the substrates in Chart 1 are all rather similar (see Fig. 3), featuring one band in the 320–420 nm region and a weaker one in the 520–600 nm range in polar solvents such as methanol and acetonitrile. The absorption bands for the monomethoxy-substituted derivatives are blue shifted by ca. 20 nm in hexane. The radicals decay by a mixture of first- (or pseudo-first) and second-order processes. Typical half-lives under our experimental conditions for the

radical from **6** in solvents such as methanol, ethanol, 2-propanol, and acetonitrile are in the neighborhood of 10 μs.

The yields of phenacyl radicals from the various precursors in Chart 1 can be readily determined by scavenging the bromine atoms with bromide, to give the readily detectable $Br_2^{\bullet-}$. Bromide was added as NaBr and the concentration of 0.08 M was chosen to ensure that >98% of the bromine atoms would be trapped by bromide (26, 27). The yields obtained are given in Table 2; these were quantified by using α-bromoacetophenone ($\Phi = 0.41$) as a standard (17).

Most experiments were carried out with monomethoxy-substituted phenacyl radicals, particularly those from ketone **6**. Phenacyl radicals react readily with oxygen. A series of measurements were carried out at various oxygen concentrations; these were adjusted by bubbling the samples with oxygen–nitrogen mixtures of known composition. The pseudo-first-order rate constant for radical decay follows eq. [4].

[4] $k_{decay} = k_o + k_{ox}[O_2]$

Figure 4 shows a plot of k_{decay} against oxygen concentration for the reaction of **12**, the radical from **6**, in acetonitrile. From the slope, we obtain $k_{ox} = 2.4 \times 10^9$ M^{-1} s^{-1}; essentially the same number was obtained in methanol. The value is in line with typical reactivities of stabilized carbon-centered free radicals toward oxygen (28). While we did not measure rate constants for other radicals derived from the molecules in Chart 1, experiments in air or oxygen-saturated solution showed that all react readily with oxygen.

1,1-Diphenylethylene is a well-established free radical scavenger (29). Radical addition (reaction [5]) leads to a resonance-stabilized and readily detectable radical, with a characteristic intense absorption in the 330 nm region.

Reaction [5] can be studied by monitoring the decay of the phenacyl radical in the 500-600 nm region, or the formation of the product radical at or around 330 nm. Figure 5 shows a plot of k_{decay} (monitored at 520 nm) against the concentration of $Ph_2C{=}CH_2$ and a representative trace (insert). Monitoring of the reaction by following the phenacyl radical (rather than **13**)

was preferred since it should not be subject to interference by possible addition of Br˙ to 1,1-diphenylethylene. The spectrum of the product is shown in Fig. 6. The plot leads to a surprisingly high rate constant of 9.4×10^7 M^{-1} s^{-1} for reaction of the radical from **6** in acetonitrile. For comparison, *n*-nonyl radicals add with a rate constant of $\sim 3.0 \times 10^5$ M^{-1} s^{-1} at 20°C (29). While these experiments do not provide direct evidence of the mode of attack, we assume that reaction occurs at the carbon center to give **13**, since most of the spin density is at this site (30); the assumption is also consistent with product studies in related systems (14, 15).

[a]In methanol at 20°C following 308 nm laser excitation. Errors estimated as ±20%.

To explore the possibility of efficient scavenging of the methoxyphenacyl radicals, which could shut down the phenacyl route of the paper yellowing, we measured the reactivities of the methoxyphenacyl radicals with well-known radical inhibitors; the results are summarized in Table 3.

Several results in the last few years have suggested that mercaptans may be viable compounds as brightness stabilizers for TMP products (31). In view of this, it seemed important to examine the reactivity of phenacyl radicals toward the S—H bond. The substrate selected for these tests was 2-mercaptoethanol, $HOCH_2$-CH_2SH. The corresponding rate constants in methanol (see Table 1) are in the $(1.4–2.9) \times 10^5$ M^{-1} s^{-1} range. The highest rates of H-abstraction from 2-mercaptoethanol are measured for 4-methoxy- and 2,4-dimethoxyphenacyl radicals. However, the difference between the lowest and highest rate is only a factor of ~2, which suggests that the effect of the methoxy substitution on the benzene ring on the reactivity of the phenacyl radical is indeed very small.

The rate constants for reaction of 4-methoxyphenacyl radi-

cal (**12**) with various potential hydrogen donors that could act as "repair agents" are given in Table 4.

Semiempirical calculations (AM1) on the structure of methoxyphenacyl radicals suggest some oxygen-centered radical character. Thus, in the case of **6**, Fig. 7 shows the key bond orders; these are consistent with ESR data (30) on the radicals (vide infra). Calculated spin densities at the oxygen center are about 0.3; surprisingly this arises largely at the expense of spin density elsewhere in the ring, since the spin density at the carbon radical site remains close to one. Calculations on the ketones that would result from hydrogen abstraction by phenacyl radicals show that the enol tautomer lies generally ca. 10 kcal/mol above the ketone form. Thus, we expect reactions at the oxygen center to be thermodynamically less favorable than those at the carbon center.

Earlier calculations on **6** have already shown that a visible band should be expected for radicals of this type (11).

Discussion

Photodecomposition of substituted α-bromoacetophenones such as those in Chart 1 leads to the rapid and relatively efficient (see Table 2) formation of phenacyl radicals and bromine atoms. The former are readily detectable with laser flash photolysis techniques, while the bromine atoms become "visible" in the presence of suitable complexing agents such as bromide ions or aromatic molecules. Bromine atom elimination occurs from the singlet state of the ketones. If there is any triplet contribution, it must be sufficiently small (<5%) to be undetectable under our experimental conditions. The result is in line with analogous observations in the case of similarly substituted α-phenoxyacetophenones (8–10). Typical aromatic ketones (e.g., benzophenone) undergo intersystem crossing with near-quantitative efficiency to yield a triplet state that is responsible for much of their photochemistry (19); in this sense methoxy-substituted acetophenones are unusual in that the singlet state plays a dominant role in their photochemistry. Phenyl ω-dialkylaminoalkyl ketones provide another example of aromatic ketones where the singlet state is important (32). The triplet states of methoxy-substituted α-bromoacetophenones show typical π,π^* characteristics, and are unreactive in hydrogen abstraction reactions towards typical hydrogen donors such as alcohols. The triplets can be quenched with amines, although with rates significantly below the diffusion-controlled limit. For example, triplet **7** is quenched by triethylamine with a rate constant of only 6.5×10^6 M^{-1} s^{-1}, reflecting the electron-rich characteristics of methoxy-substituted aromatic ketones.

Phenacyl radicals have an electron distribution leading to some radical character at the oxygen center, but mostly at the carbon site. This leads to the calculated bond orders of Fig. 7. The visible absorption band of these radicals is believed to reflect their "oxy" (or n,π^*) characteristic, which makes this particular resonance structure similar to that of cumyloxyl radicals; these have recently been shown to also have an absorption band in the visible region (13).

The spectroscopy and reactivity of phenacyl radicals is consistent with their ESR parameters (30). Thus, the α-hydrogen coupling constants for $C_6H_5COCH_2^{\cdot}$ are approximately 19.6 gauss, compared with 22.3 gauss for the ethyl radical.

While the presence of unpaired electron density at the oxygen center influences the ESR parameters and absorption spectroscopy of the radicals, their reactivity is clearly a reflection of their carbon-centered properties, as reported in recent work by Russell and Kulkarui, and Khanna (14, 15), who showed that phenacyl addition to alkenes occurs with C—C bond formation.

The reaction rate constants of methoxyphenacyl with various "repair agents" appear to be very low (Table 4). The rates with well-known H-atom donors, such as 2-mercaptoethanol and 1,4-cyclohexadiene, $k = 2.8$ and 2.4×10^5 M^{-1} s^{-1}, are two orders of magnitude lower than typical H-atom transfer rates of either simple alkyl, e.g., $k(^{\cdot}CH_3$ + glutathione) = 5×10^7 M^{-1} s^{-1} (33), or alkoxyl radicals (34, 35). The enthalpy change for S-H abstraction by phenacyl from simple aliphatic thiols should be around −2 kcal/mol (BDE[3] ($C_6H_5COCH_2$—H) ~93 kcal/mol and BDE (RS—H) ~91 kcal/mol) (36). The reactions of 4-methoxyphenacyl radicals with well-known electron donors, such 2,6-dimethoxyphenol, 4-methoxyphenol, and ascorbate are slow, $k < 10^6$ M^{-1} s^{-1}. These slow rates of electron transfer suggest that the methoxyphenacyl radicals react mainly as nucleophiles and more like C-centered alkyl than like O-centered alkoxyl radicals. Given the high reactivity towards oxygen, we anticipate that in the context of the photoyellowing of lignin-rich pulp and paper, the fate of phen-

[3] BDE = bond dissociation energy.

acyl radicals will be the formation of the corresponding peroxyl radical, $ArCOCH_2OO^{\cdot}$, which may further contribute to the oxidative degradation of lignin. It would therefore be important to learn more about the reactivity of peroxyl radicals of this type.

Polarographic studies of indium(III) in aqueous medium of sodium azide

Roberto Tokoro, Mauro Bertotti, and Lúcio Angnes

Abstract: In this paper, some aspects of the polarography of indium(III) in azide/hydrazoic acid buffer are presented. The electrode process is mostly governed by diffusion in the complexing medium. Nevertheless, for controlled-potential coulometry (involving a large time window) a catalytic process was observed, ascribed to the reaction of the hydrazoic acid and indium amalgam. The stability of azide complexes of In(III) was studied polarographically, and the formation of four mononuclear species was confirmed by computational analysis of data obtained from polarograms of In(III) in different azide concentrations. The values of the global constants obtained are: $\beta_1 = 3.7 \times 10^3\ M^{-1}$, $\beta_2 = 8.6 \times 10^5\ M^{-2}$, $\beta_3 = 5.0 \times 10^7\ M^{-3}$, $\beta_4 = 2.1 \times 10^9\ M^{-4}$, in a constant ionic strength medium held at 2.0 M with $NaClO_4$. These data are in good agreement with those obtained by potentiometry. The value found for $E^{0'}$ of the In(III)/In couple was -512.2 mV vs. calomel electrode (3 M NaCl), the mean diffusion coefficient of the complex being $(6.1 \pm 0.2) \times 10^{-6}\ cm^2\ s^{-1}$ in perchlorate medium ($T = 25°C$).

Key words: polarography, indium(III), azide, stability constants, catalytic wave.

Résumé : Dans ce travail, on présente quelques aspects de la polarographie de l'indium(III) dans un tampon d'azoture/acide hydrazoïque. Le processus à l'électrode est principalement déterminé par la diffusion dans le milieu complexant. Toutefois, pour la coulométrie à potentiel contrôlé (impliquant une large fenêtre de temps), on a observé un processus catalytique attribué à la réaction de l'acide hydrazoïque avec l'amalgame d'indium. Faisant appel à la polarographie, on a étudié la stabilité des complexes d'azoture avec le In(III) et on a confirmé la formation de quatre espèces mononucléaires par une analyse mathématique des données obtenues à partir de polarogrammes du In(III) à diverses concentrations d'azoture. Les valeurs des constantes globales obtenues sont : $\beta = 3{,}7 \times 10^3\ M^{-1}$, $\beta_2 = 8{,}6 \times 10^5\ M^{-2}$, $\beta_3 = 5{,}0 \times 10^7\ M^{-3}$ et $\beta_4 = 2{,}1 \times 10^9\ M^{-4}$, à une force ionique constante maintenue à 2,0 M par du $NaClO_4$. Ces données sont en bon accord avec celles obtenues par potentiométrie. La valeur trouvée pour $E^{0'}$ dans le couple In(III)/In est de $-512{,}2$ mV vs. électrode au calomel (3 M NaCl) alors que le coefficient moyen de diffusion du complexe est $(6{,}1 \pm 0{,}2) \times 10^{-6}\ cm^2\ s^{-1}$ dans un milieu de perchlorate ($T = 25°C$).

Mots clés : polarographie, indium(III), azoture, constantes de stabilité, vague catalytique.

[Traduit par la rédaction]

Introduction

The study of the chemistry of the azide anion, N_3^-, was introduced in our institute by Senise (1), and afterwards developed by Senise and Neves (2), who observed for the first time the catalytic reduction of hydrazoic acid in the presence of cobalt and zinc cations. This observation led to the work of Tokoro and Neves (3). Thenceforth, attempts were directed towards finding other metal ions that would play a similar role in the reduction of hydrazoic acid, as well as to investigate reactions where the azide anion acts as a catalyst for the reduction of a variety of metals. For this later study, indium(III) seemed very promising. Polarographic studies of the thiocyanate of indium(III) appear in the literature (4–12), whereas the electrochemical behavior of the corresponding isosteric azide complex remains practically unexplored. The pseudo-halides of both the thiocyanate and azide are isosteric and thus the purpose of the present work is the search for and verification of such similarities.

In this paper, electrochemical studies on the In(III) + N_3^- system were carried out in order to investigate the formation of complexes in aqueous solution. Several electrochemical methods have been employed to determine the stability constants of equilibria involving a metallic ion and a ligand, but one of the most widely used is based on polarographic determinations when reversibility conditions are attained. The electrode process was characterized, the suitable parameters were obtained, and finally the dependence of half-wave potential on azide concentration provided data for evaluation of the stability constants.

Experimental

Reagents

A standard solution of indium(III) perchlorate was prepared from pure metallic indium (Fisher Scientific Co. certified reagent) dissolved in an excess of perchloric acid (Merck, PA). Gentle heating was necessary to complete the dissolution of the metal. The excess of acid was used to prevent the for-

mation of hydroxo complexes of indium(III). This solution was diluted with bidistilled water to a final volume of 500.0 mL. The final concentration of indium(III) in this solution was calculated according to the weight of the metallic form, and the final acidity was determined by a potentiometric standard addition method (13). Sodium perchlorate and sodium azide solutions (prepared from Merck PA grade salts) were standardized gravimetrically by drying a known volume of the solutions to constant weight. For microscopic observations, active charcoal purchased from Merck was employed. All the other reagents were used as available commercially. Purity of all the solutions was checked through polarographic determinations.

Apparatus

Polarographic studies were performed with a Metrohm Polarecord 506 and a Tacussel Polaropulse PRG 5. For some preliminary runs, a Leeds and Northup Electrochemograph was also used. Metrohm EA 874 or a EA 876-5 cells were used in most of the polarographic experiments. A dropping mercury electrode, a calomel electrode, and a platinum wire, used as auxiliary electrode, were hermetically sealed in the covers of the cells. The characteristics of the capillary were m = 2.427 mg s^{-1} and τ = 3.33 s at −0.7 V and h = 97 cm, in 2.0 M $NaClO_4$. When tast and pulse techniques were used, the drop time was mechanically controlled; the typical measuring time t_m was 40 ms. Coulometry at controlled potential was carried out with a PAR 173 potentiostat coupled with a PAR 179 integrator. The experiments were carried out in a Metrohm 20 mL cell, equipped with a Fischer magnetic stirrer and a Teflon-coated stirring bar. The working electrode was a mercury pool (5.5 cm^2 area) and a 3 M NaCl calomel electrode was used as reference. It made contact with the solution via a Luggin capillary filled with 2.0 M $NaClO_4$. As auxiliary electrode, a platinum wire was utilized. Microscopic observation were made with an Olympus SZIII-BR-SIT zoom microscope. The pH measurements were carried out with a Micronal B 375 potentiometer and a Metrohm EA 121 combined glass electrode. A Metrohm 274 (5 mL) piston burette with a thin capillary was employed for precise volume additions. All the measurements were run at 25.0 ± 0.5°C, maintained with a Haake ultra-thermostat.

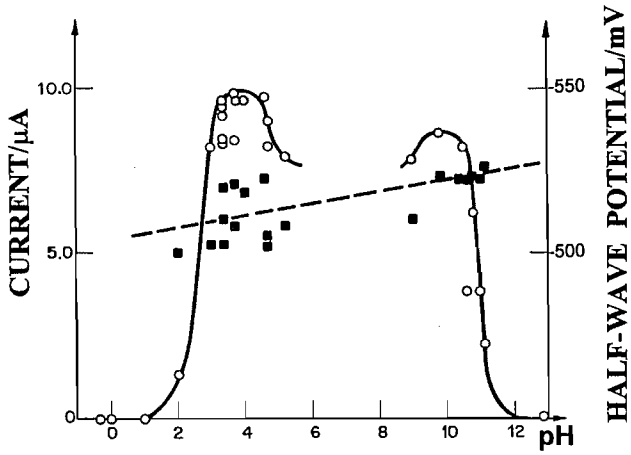
Calibration of instruments

The polarographic measurement systems were calibrated using a standard 0.977 mM cadmium perchlorate solution in 0.1 M $NaClO_4$ supporting electrolyte. The apparatus for the controlled-potential coulometry was calibrated using a standard cadmium(II) solution, and the n value obtained was very close to 2 (deviations in consecutive experiments were not larger than 5%).

Microscopic observations

To perform the microscopic observations of the movement of the solution around the mercury drop surface, small particles of active charcoal were used. To obtain particles of the desired size, 2 g of active charcoal were added to 1 L of bidistilled water, stirred, and were allowed to stand for 10 min. Then the supernatant was transferred to another vessel and the water was gently evaporated. The amount of charcoal obtained was around 50 mg, to be used as contrast.

Fig. 1. Polarographic behavior of 0.7892 mM In(III) in perchlorate medium (I = 2.0 M) as a function of pH (○ limiting current and ■ half-wave potential).



Working conditions

Two distinct solutions, the first (A) containing the metallic ion plus an N_3^-/HN_3 buffer, and the second (B) the metallic ion and hydrazoic acid, were used as previously described in a potentiometric study involving the formation of indium(III) azide complexes (14). Both solutions A and B were prepared directly inside the piston burette and in the polarographic cell, respectively, to avoid exposure to open air and consequently the loss of HN_3 by volatilization. Also, to minimize recontamination of the solutions with oxygen, these two vessels were "washed out" with a flow of nitrogen during 15 min. The composition of solution A (in the piston burette) was 0.300 M NaN_3, 0.100 M HN_3, 7.892×10^{-4} M In(III) at an ionic strength of 2.0 M, maintained with $NaClO_4$. Solution B (prepared directly in the polarographic cell) reached a final volume of 10.00 mL, and had the following composition: 0.100 M HN_3, 7.892×10^{-4} M In(III) at an ionic strength of 2.0 M, also maintained with $NaClO_4$. Both solutions, A and B, were prepared adding suitable volumes of reagents and adjusting with water to the final volume. All the components of the A and B solutions were previously saturated with nitrogen. In the preparation of both solutions, sodium azide was the last to be added, in order to minimize the loss of hydrazoic acid. The small amount of oxygen that could contaminate all the solutions during mixing was shown to be negligible when the polarograms were recorded. The adopted procedure consisted in the addition of known volumes of solution A to the solution B contained in the cell, with the aid of a thin polyethylene capillary adapted to the burette. After each addition, gentle micro bubbling with nitrogen ensured homogeneity, and then the corresponding polarogram was recorded and a precise value for $E_{1/2}$ was determined. Each experiment consisted of a large number of additions so that the analytical concentration of azide in the solution varied from 0.9 to 82.6 mM.

Results and discussion

Preliminary studies

Figure 1 shows that at a pH around 3.8 the polarographic current reaches its maximum intensity for indium(III) in perchlo-

Table 1. Polarographic behavior of 1.578 mM In(III) in different supporting electrolytes.

0.001 M $HClO_4$ + 2.0 M $NaClO_4$	Yes	Small height of wave
4.6×10^{-4} M $HClO_4$ + 2.0 M $NaClO_4$	Yes	Well defined, without minimum
1 mM N_3^- + 20 mM HN_3 + 2 M $NaClO_4$	Yes	Well defined
20 mM HN_3 + 2.0 M $NaClO_4$	Yes	Well defined

rate medium. Using the stability constants of the indium(III) + OH^- system (15) (log β_1 = 10.89, log β_2 = 21.34, and log β_3 = 30.88) to construct the distribution diagram of the species, it is possible to conclude that at pH 3.8 a species with two ligands predominates, the $In(OH)_2^+$ form. These observations agree with the work of Lawson and Aikens (16), who suggested that a dihydroxo-indium(III) complex is the electroactive form in solution.

In noncomplexing medium, In(III) is present as the aquo complex $In(H_2O)_6^{3+}$ and the polarographic wave is absent. From an electrochemical viewpoint, In(III) should behave similarly to the first-row transition metals for which electron transfer from the electrode to the metallic ion occurs through a ligand bridge (17–19). In this respect, the water molecule is not a good bridge for electron transfer. The reduction wave of indium(III) at the dropping mercury electrode is irreversible and very much drawn out in strongly acidified noncomplexing aqueous media such as $NaNO_3$ or $NaClO_4$. The presence of a small amount of certain ligands accelerates the electroreduction of the metallic ion, resulting in the appearance of the polarographic wave. According to data from Table 1, In(III) is electroactive in acidic medium containing chloride ions, where chloro-complex species are formed. The presence of the polarographic wave for In(III) is also observed in acidic HN_3 solutions. This wave can be attributed to the reduction of an In(III)/azide species, which is formed in this acidic medium despite the relatively low pK_a value for the dissociation constant of HN_3 ($K_a = 2.4 \times 10^{-5}$ M) (20).

Complexation processes involve more stable chemical species that require a more negative potential for reduction to occur. Normally a shift of the polarographic wave toward more negative potentials is observed. In the system considered in the present comunication, when a small amount (less than 1 mM) of azide is present in solution, the complexation with indium(III) begins to occur and the polarographic wave appears. Further additions of azide shift the polarographic wave to the expected negative potential side, making studies on the complexing effect possible.

Characterization of the electrode process

To obtain information about the nature of the electrode process, a study involving the variation of the mercury column height was made. The classical relation between the dc polarographic current (along different regions on the wave) and the square root of the height of the mercury column is the origin of the group of straight lines presented in Fig. 2. The linear response shown in this figure, for different potentials picked out along the polarographic wave, gives evidence that the electrode process is controlled by diffusion. In more negative potentials of the limiting region, a minimum appears (between −1.0 and −1.4 V), and in this potential range the current is almost independent of the height of the mercury column. Preliminary studies showed that the deepest current region was achieved at 2.0 M NaN_3, and microscopic observation around the mercury drop showed an upward movement of the solution at −1.2 V. Gas evolution was also observed. The addition of 0.002% Triton X-100 stopped the movement, but the polarographic minimum was still there. Further studies on this subject were not carried out.

Fig. 2. Dependence of dc polarographic current on different heights of the mercury column for a solution containing 1.578 mM In(III) + 0.50 M N_3^- + 0.020 M HN_3, (I = 2.0 M). The currents were measured at different potentials along the polarographic waves: ● −0.850 V (limiting region); ○ −0.760 V ($E_{3/4}$); Δ −0.750 V ($E_{1/2}$); Δ −0.740 V ($E_{1/4}$).

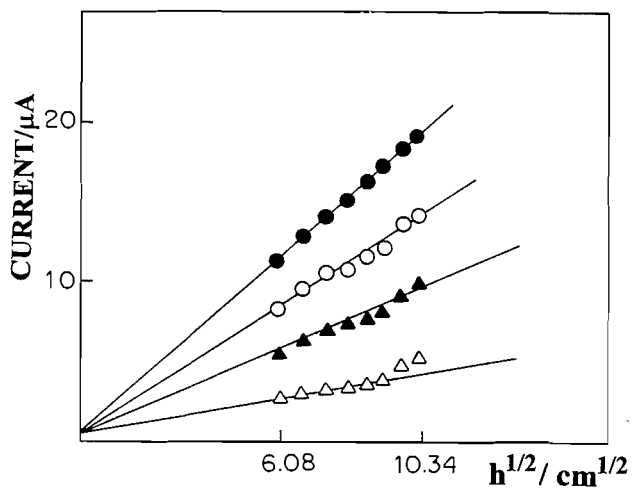

Figure 3 shows the dependence of the normal pulse polarographic current along the wave on the square root of reciprocal pulse widths. A family of straight lines was obtained, demon-

Fig. 3. Dependence of the current on $t_m^{-1/2}$ (t_m = measuring time), the current values being measured at different potentials along the normal-pulse polarograms. Working solution: 0.7892 mM In(III) + 0.1 M N_3^- + 0.020 M HN_3 (I = 2.0 M).

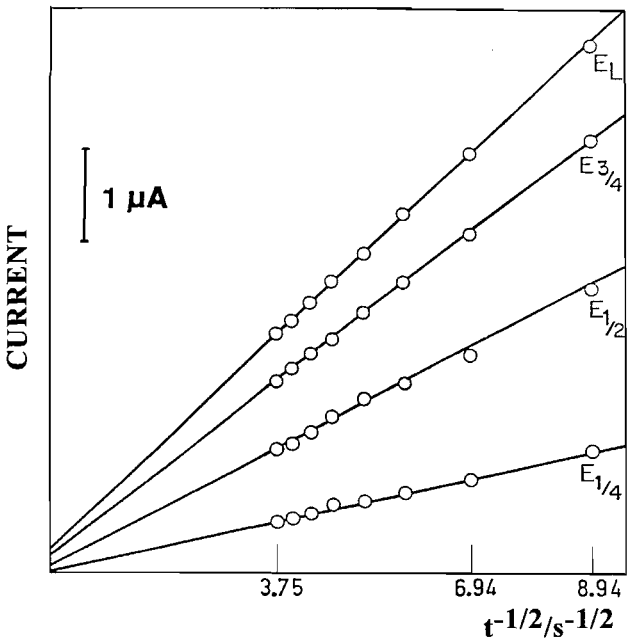

Fig. 4. Normal- and reverse-pulse polarograms of 0.7892 mM In(III) + 0.10 M N_3^- + 0.10 M HN_3 solution (I = 2.0 M). The initial potentials (E_i) for both scans are indicated .

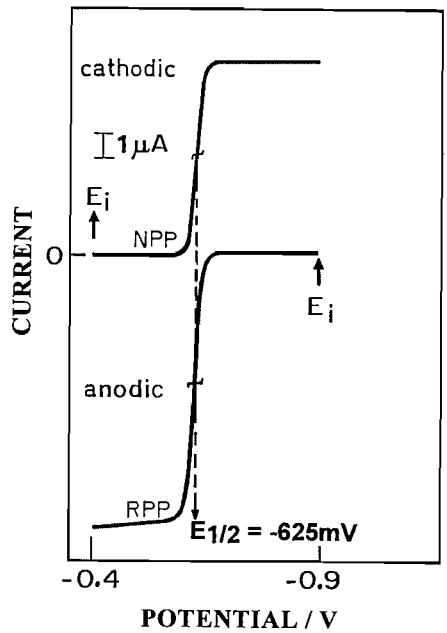

strating that the process is primarily governed by diffusion. The intercepts (up to 8% of the full scale) apparently are not a simple instrumental artifact or due to the back pressure, since previous calibration tests using a known reversible system (iron(III) in saturated ammonium oxalate medium) led to an intercept of only 1–2%. Another means of characterizing the reversibility of an electrode process consists in the comparison of the normal- and reverse-pulse polarographic waves (21–23). The coincidence of $E_{1/2}$ values obtained for the present system in these two runs and the ratio between the cathodic and anodic currents being close to the unity are unequivocal proof of the reversibility of the process. Figure 4 shows the normal- and the reverse-pulse polarograms. The larger anodic current in comparison to the cathodic current can be explained in the light of Galvez's expanding spherical electrode theory (24). Two additional pieces of evidence support of the reversibility of In(III) electroreduction when azide ions are present in solution: (*i*) The tast polarogram run with a 2.0 mM indium amalgam dropping electrode in a solution containing 0.5 M sodium azide and 1.5 mM indium (III) showed a combined wave with the same $E_{1/2}$ value (−680 ± 5 mV) as one obtained with a mercury dropping electrode in a 1.5 mM indium(III) + 0.5 M azide solution. (*ii*) Finally, the dependence of the polarographic current (tast mode) along the wave on the fifth root of the drop time, which varied from 0.4 to 6.0 s, was linear, indicating that the process is predominantly controlled by diffusion transport (25).

The experimental results agree with the study of Moussa et al. (26), in which $k_s = 5.3 \times 10^{-2}$ cm s^{-1} was found for the exchange $In^{3+} + 3\ e^- \rightleftharpoons In(Hg)$ in azide medium, showing that the electron transfer is not the determining step for the electroreduction of In(III) in the complexing medium.

Determination of n and $E_{1/2}$

Since electrochemical reversibility was proven for the In(III)/N_3^- system, the reversible polarographic equation was used to calculate the characteristic parameters n and $E_{1/2}$. These values are presented in Table 2, and were obtained in azide/hydrazoic acid buffers. In all the experiments, the analytical concentrations of the two components (of the buffers) were calculated to maintain the pH around 3, thus hindering the hydrolysis of indium(III). The $E_{1/2}$ values (included in Table 2) changed with the variation of azide concentration, as predicted, and the n value was always slightly smaller than 3.

Coulometric studies

The value of n previously found in polarographic experiments was lower than 3, therefore controlled potential coulometry studies were carried out in the indium(III)/azide system. During electrolysis, the concentration of the remaining electroactive species was monitored by polarographic measurements. A plot of the limiting current against the charge applied, extrapolated to the zero current, yielded experimental values of both Q and n. Several experiments were performed using 0.8 and 1.5 mM In(III) solutions in 0.1 M N_3^- + $x$$HN_3$ buffers, where x was varied from 0.006 to 0.1 M. Potential was applied at the plateau of the polarographic waves. The graphical extrapolation of the data obtained in these experiments provided an n value of 3.5, which increased gradually by increasing the HN_3 concentration in the buffer. The experimental data led to the conclusion that indium(III) is chemically regenerated from the amalgam, due to the oxidative characteristics of hydrazoic acid. This statement was experimentally proven through the detection of ammonium ions in the electrolyzed solutions, as a product of the chemical step reduction of hydrazoic acid. Further coulometric experiments at controlled potential (−0.9 V) in the Cd(II) + 0.1 M N_3^- + 0.05 M HN_3 solution reinforced the

Table 2. Half-wave potential and limiting current data from the polarograms recorded for 0.7890 mM In(III) solutions in different azide/hydrazoic acid buffers (I = 2.0 M maintained with $NaClO_4$). The n values were calculated from the reversible polarographic equation.

[a]$HClO_4$ (5 mM) was added to restrain the dissociation of HN_3.

oxidizing power of HN_3, since the n values obtained were also larger than the expected value (n = 2). Regarding this subject, the formation of ammonium as a HN_3 reduction product has been reported in other electrochemical systems such as Co(II)/HN_3 (3) and Mo(VI)/HN_3 (27).

Table 1 shows that a small polarographic wave appears in the In(III) + 0.001 M $HClO_4$ system in $NaClO_4$ medium. Coulometric experiments were carried out under these experimental conditions. After the application of 10% of the total charge required for exhaustive electroreduction of In(III), the polarogram of the remaining solution showed a higher limiting current than the initial solution. The explanation for this interesting observation could be related to a pH increasing during the electrolysis, since the electroreduction of the $In(OH)_2^+$ species gives rise to displacement of two hydroxide ions. Further, parallel oxidation of the indium amalgam by protons is probably going to occur, contributing to the rise in pH. The equilibrium concentration of the $In(OH)_2^+$ species can be increased after the partial electrolysis in this less acidic medium. According to Fig. 1, the polarographic limiting current depends on the concentration of this species (predominating at pH around 4). Therefore, the current is higher than that obtained for the starting solution (pH around 3), despite the decrease of the analytical concentration of In(III) due to partial electrolysis.

Determination of the stability constants of the complexes

Azide acts as a catalytic ligand under polarographic conditions in which In(III) is electroactive (12). When the azide concentration increases, the half-wave potential shifts to the more negative side, this displacement being due to the complexing effect (Table 2) . The validity of the determination of stability constants by polarography is questionable if certain requirements are not satisfied (28). In our case, the indium(III)/azide complexes are electroactive, the reduction at the electrode is controlled by diffusion, and the complexes are labile (29). Experimental ac polarograms showed no adsorption of complex species at potentials less negative than $E_{1/2}$ and a similar behavior was previously reported for the In(III)/SCN^- system (30). In addition, experiments using different drop times generated polarograms with the same $E_{1/2}$, confirming the absence of coupled chemical reactions and the predominance of diffusive behavior. The kinetic contribution, significant in the coulometric studies, is less critical for the polarographic experiments, as Table 2 demonstrates. Such complicating steps should be fast enough for the overall electrode process to be governed by diffusion. In this way, the study of complex formation could be performed by polarography (31).

To confirm the absence of polynuclear complexes, polarograms in the presence of three different concentrations of indium(III) (0.789 mM, 1.578 mM, and 4.000 mM) in 0.480 M NaN_3 + 0.020 M HN_3 (I = 2.0 M) were recorded and the same $E_{1/2} = -679 \pm 3$ mV was found. This constant value of the half-wave potential shows the formation of only mononuclear species, as was also verified in previous potentiometric studies (14).

Studies of complex formation require knowledge of the conditional potential of the couple In(III)/In in the absence of the ligand, at a given ionic strength. Preliminary studies were carried out to determine this formal potential taking into account some literature information: indium amalgam is sensitive to In^{3+} aquo ions (32, 33); the exact determination of the potential of the reversible couple is difficult due to the reaction between metallic indium and In(III) ions, producing unstable In(I) ions ($K = 1.3 \times 10^{-11}$ M^2) that affect the equilibrium potential (34); In(I) is easily oxidized by protons (35); finally, measurements of the potential in non-acidic or weakly acidic solutions can be affected by the hydrolysis of In(III) (36). Preliminary measurements of the standard potential were carried out using an indium amalgam dropping electrode (~1% w/w), in In(III) solutions. In spite of the relatively good stability of the potentiometric measurements, the standard potential cal-

culated for different concentrations of metallic ion in these solutions was not constant, probably due to the oxidation of the amalgam. Three series of measurements afforded the following values: $E^{0'} = -464.6$ mV, $E^{0'} = -494.1$ mV, and $E^{0'} = -503.6$ mV.

The evaluation of the conditional potential of the In(III)/In couple was made using data for the dependence of the half-wave potential of the polarograms on the analytical concentration of azide, two sets of experimental measurements being obtained. The azide concentration in the solution was evaluated taking into account the azide resulting from dissociation of the hydrazoic acid. The experimental data were plotted and the curve smoothed. Extrapolation to zero azide concentration led to $E^{0'} = -(512.0 \pm 0.5)$ mV. Using this value and the experimental data for $E_{1/2}$, the corresponding values of $F_0(L)$ (Leden's function (37)) were calculated for each analytical concentration of the ligand, L.

$$[1] \quad F_0(L) = \text{antilog}\left(\frac{E_{1/2(L)} - E^{0'}}{0.01972}\right)$$

A nonlinear regression algorithm (38–40) was employed to calculate in an iterative form the stability constants of the complexes from the following equation:

$$[2] \quad F_0(L) = 1 + \beta_1[L] + \beta_2[L]^2 + \ldots + \beta_n[L]^n$$

where β_i corresponds to a global constant for species ML_i and n is the maximum number of species formed.

In a first step, the global constants were calculated by considering the concentration of azide ions as equal to the total concentration of this pseudo-halide in the cell. A first group of stability constants was obtained and used to subtract the amount of azide consumed in the complexation, using Bjerrum's function (41). With the new concentrations of azide ions, a new set of constants was determined. The process was repeated until the equilibrium concentration of the constituents of the system remained unchanged, thus yielding the required equilibrium concentrations.

The plot of the dependence of $E_{1/2}$ values on the equilibrium concentrations of azide is shown in Fig. 5. After a magnification of the scale, the extrapolation to the zero equilibrium concentration yielded $E^{0'} = -(512.2 \pm 0.5)$ mV. This value agrees with that obtained using a computational method of data analysis ($E^{0'} = -511.4$ mV), in which a polynomial regression was employed. With the $F_0(L)$ data, calculated for different azide equilibrium concentrations, the following group of four successive stability constants was found:

$$\beta_1 = 3.7 \times 10^3 \text{ M}^{-1}$$
$$\beta_2 = 8.6 \times 10^5 \text{ M}^{-2}$$
$$\beta_3 = 5.0 \times 10^7 \text{ M}^{-3}$$
$$\beta_4 = 2.1 \times 10^9 \text{ M}^{-4}$$

To evaluate the effect of the error in the determination of the value for the formal potential of the In(III)/In system (due to the graphic extrapolation), a variation of 1 mV was ascribed to the $E^{0'}$. The two new groups of β found were in agreement with the first group of constants, the maximum deviation being 25% for β_1.

Fig. 5. Dependence of the half-wave potential for the 7.892×10^{-4} M indium(III) polarograms on azide equilibrium concentrations.

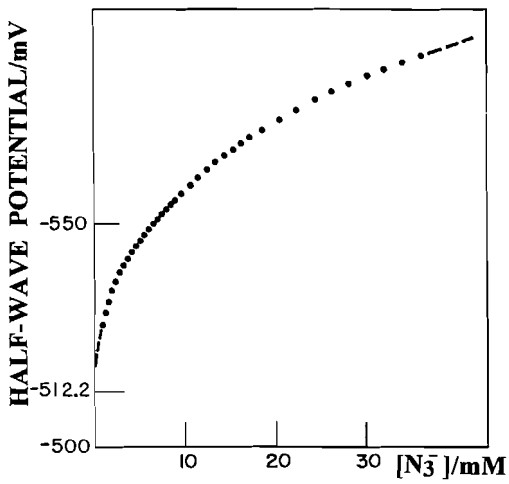

Fig. 6. Distribution diagram for the In(III) and the azide species as a function of free azide concentration.

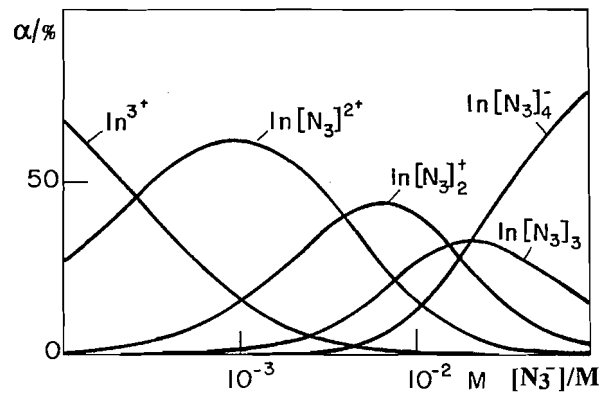

The distribution curve of the complex species, shown in Fig. 6, was calculated using the set of constants presented above ($E^{0'} = -512.2$ mV). The formation of tetra-coordinated species was confirmed according to the following equation, considering the range of concentration up to 100 mM in azide:

$$[3] \quad \frac{\Delta E_{1/2}}{\Delta \log [N_3^-]} = p \times \frac{0.05916}{n}$$

where p corresponds to the coordination number and n to the number of electrons involved in the In(III) reduction.

The formation of mono-azide indium(III) species in solutions containing only hydrazoic acid is favored more than the hydrolysis reaction of the metallic ion, where a mono-hydroxy species could be formed. This assertion is proved considering the equilibria involving the species:

$$HN_3 + In^{3+} \rightleftharpoons In(N_3)^{2+} + H^+ \qquad (\beta_1 . K_{HN_3})$$
$$In(OH)^{2+} + H^+ \rightleftharpoons In^{3}+ + H_2O \qquad (1/K_w . 1/K_{hl})$$
$$In(OH)^{2+} + HN_3 \rightleftharpoons In(N_3)^{2+} + H_2O$$

where β_1 corresponds to the global constant for the mono-azide indium(III) complex, K_{HN_3} the dissociation constant of hydrazoic acid, K_w the dissociation constant of water, and K_{h1} the hydrolysis constant for the mono-hydroxy complex of indium(III).

Using data from the literature (15) and the value for β_1 found in this paper, the global constant for the equilibrium between the hydroxo and azide indium(III) species is 116 M^{-1}. Thus, it is concluded that in the equilibria relating to this study, formation of the hydroxo indium(III) species can be disregarded in the N_3^-/HN_3 buffers. The existence of mixed species at low azide concentrations was not taken into account, since the kinetics of the hydrolysis reaction is slow and the $E_{1/2}$ value for each addition of ligand was reproducible. In addition, when the metallic ion is complexed with azide, the probability of formation of hydroxo complexes is even smaller.

In the formation of complexes, numerous parameters are involved, but those that generally predominate are both the statistical and the ligand effects (41). This latter is the sum of the electrostatic factor and a remaining portion called the "rest effect," which consolidates all the other effects. When the rest effect is negligible, the ligand effect can be represented by the electrostatic factor. The work that must be realized by moving an electrically charged ligand from ML_i to ML_{i+1} represents this factor. The stepwise constants ($K_i = \beta_i/\beta_{i+1}$) of the present system are

$$K_1 = 3.7 \times 10^3\ M^{-1}$$
$$K_2 = 2.3 \times 10^2\ M^{-1}$$
$$K_3 = 5.9 \times 10^1\ M^{-1}$$
$$K_4 = 4.2 \times 10^1\ M^{-1}$$

and they agree with the statistical model for successive complex formation, since $K_i/K_{i+1} > 1$ for $i = 1, 2$, and 3. The importance of the ligand effect can be estimated using eq. [4], proposed by Bjerrum (42) and discussed by Sen (43):

$$[4] \quad \frac{K_i}{K_{i+1}} = \left[\frac{(n - i + 1)(i + 1)}{(n - i)i}\right]x^2$$

where n and i correspond, respectively, to the coordination number and the number of ligands coordinated to metal. When the influence of electrostatic forces in complexation reactions is negligible, the x values according to eq. [4] are unity. However, the calculation of x for $i = 1$, 2, and 3 in the indium(III)/azide system leads, respectively, to 2.44, 1.31, and 0.72. In this way, the contribution of the electrostatic factor in the formation of complexes between In(III) and N_3^- ions cannot be disregarded.

Diffusion coefficient of the complexes

The mean diffusion coefficient of the complexes for the

indium(III)/azide system was calculated using the Ilkovic equation. Polarograms of 0.789 mM indium(III) were recorded over the entire range of azide concentration (0–100 mM), and the height of the waves was used to calculate the corresponding diffusion coefficient assuming $n = 3$. A value of $(6.1 \pm 0.2) \times 10^{-6}$ cm^2 s^{-1} was obtained, and it is in agreement with the value reported in a previous paper (30) for the indium (III)/thiocyanate system.

Conclusions

Analysis of the observed evidence confirms a predominantly diffusion-controlled process on the electrode along the entire wave, as well as in the limiting region, for the electroreduction of In(III) in complexing azide medium. A kinetic contribution was also verified. In the potentials corresponding to the so-called "polarographic minimum," the process is no longer governed predominantly by diffusion.

The determination of the formal potential, $E^{0'}$, for the In(III)/azide system led to the value −512.2 mV, obtained by graphical extrapolation to a condition where the azide was absent. This $E^{0'}$ agrees fairly well with the values from Lawson and Aikens (16) and Naruzawa et al. (46). Good results are also obtained by calculation of this formal potential using the global constants for the system, determined by Bertotti and Tokoro (14), Avsar (49), and Momoki and Ogawa (53) (see Table 3).

Computational analysis of the experimental polarographic data obtained in the present study showed that in this system four successive complexes of indium(III)/azide are formed when the ligand concentration is increased up to 100 mM. This concentration of ligand is sufficiently high to cover the whole range in which the four complexes are formed. The values of the global constants obtained agree with those reported in the literature where other techniques than polarography are described.

The polarographic data also allow the evaluation of the mean diffusion coefficient of the In(III)/azide complexes. The value found is in agreement with the diffusion coefficient for the thiocyanate complex of In(III), reinforcing the evidence regarding the similarity between the azide and thiocyanate pseudo halides.

A detailed shape characterization of regular polypeptide conformations

Gustavo A. Arteca

Abstract: Regular polypeptide conformations include secondary structural motifs such as α-helices and β-strands. The occurrence of some regular conformation is usually deduced from a local analysis of dihedral angles. However, the value of a dihedral angle in itself does not provide any information on the conformation's "shape." This drawback can be circumvented with global, rather than local, macromolecular shape descriptors. Recently, fractal exponents have been proposed as a source of such descriptors. Yet, this approach does not fully capture all essential shape features, since protein backbones are *not* fractal. In this work, we deal instead with a more "natural" characterization of the polymer's global shape that uses both the chain's geometry and "topology." For the geometry, we study the behaviour of molecular size and anisometry. For the chain's folding features, we study the self-entanglements in a polymer fold. We compute these descriptors for all relevant secondary structural motifs. By using self-entaglements and molecular geometry, we provide a view of secondary structure that is both conceptually appealing and also more discriminating than previous ones in the literature.

Key words: molecular shape analysis, protein secondary structure, self-entanglements.

Résumé : Les conformations régulières des polypeptides incluent des motifs de structure secondaire connus comme «hélices α» et «filaments β». Ces conformations sont souvent deduites à partir d'une analyse locale des angles dihédriques. Cependant, la valeur d'un angle dihédrique par elle-même ne donne aucune information sur la forme d'une conformation. Ce problème peut être éliminé si l'on emploie des descripteurs globaux, au lieu de locaux. Récemment, les exposants fractaux ont été introduits à ce propos. Mais cette méthode ne décrit pas bien la forme, car les protéines ne sont pas rigoureusement fractales. Nous suivons ici une voie plus «naturelle», qui utilise la géométrie et la «topologie» de la chaîne polymérique. Pour la description de la forme géométrique, nous étudions la taille et l'anisométrie moléculaires. Pour les caractéristiques des pliements, nous calculons la complexité des enchevêtrements d'une polymère. Tous ces descripteurs sont calculés pour les motifs les plus importants de la structure secondaire. En étudiant les enchevêtrements et la géométrie moléculaire, nous obtenons une description des structures secondaires, laquelle est au même temps intéressant du point de vue conceptuel et aussi plus discriminatoire que d'autres proposées dans la littérature.

Mots clés : analyse de forme moléculaire, structure secondaire des protéines, enchevêtrements.

Introduction

Native protein conformations exhibit well-known hierarchical levels of spatial organization, from primary to tertiary structure (1). On a large scale, a peptide conformation often exhibits entire arrays of atoms that rigidly maintain their spatial positions relative to one another (2, 3). These well-organized, stable ensembles are known as supersecondary structures. These structures are a key element in understanding protein stability and function. Despite the variety of primary sequences, the number of supersecondary structures appears to be limited (4, 5). This observation sustains the modern viewpoint that polypeptide chains with variable composition are "naturally selected" on the basis of their capability to achieve rapidly some specific structural features (6). That is, structural features would appear to be preserved with priority over primary sequences. For this reason, our ability to characterize and recognize the occurrence of specific protein folds has become a central issue in structural biology (7). A number of computational techniques have been developed to classify such features and compare protein architectures. (For reviews on recent work, see refs. 7 and 8.) Yet, there is still a need for efficient methods that account for all relevant aspects of macromolecular shape. In this work we deal with this latter task.

Regular polypeptide conformations correspond to relatively short, periodic three-dimensional (3D) arrays of amino acid residues stabilized by hydrogen bonding. These include the familiar *secondary structural motifs*, such as α-helices and β-strands (9). Other structures do occur, although less frequently (1, 10). These latter include polyglycine and polyproline helical strands, and other types of helices, such as the 3_{10}-helix. The organization of these secondary motifs in specific spatial arrays relative to each other defines the supersecondary structure. In this work, we deal with a novel, detailed characterization of global molecular shape in all the regular conformations that make up a protein's secondary structure.

The occurrence of regular conformations within a protein structure is usually deduced from a *local* analysis of dihedral angles (1, 11). The values of such angles depend on the

For personal use only.

peptide's composition and they vary with local deformations in the motifs. Moreover, the value of a dihedral angle is simply a "label" for a regular conformation. By itself, it does not provide any information on shape or folding features. This latter information can, of course, be retrieved by visually inspecting the molecular backbone on a computer screen. However, any efficient, unbiased analysis will require the use of mathematical tools to quantify molecular shape. The use of *global*, rather than local, descriptors can circumvent the above drawbacks. This is the point of view we adopt in this work.

There are a number of possible global, single-number descriptors that convey aspects of molecular shape. The most obvious are descriptors of molecular size, such as the radius of gyration (12). These parameters depend only on the molecular geometry. They make no explicit use of the sequence in which the atoms are connected (from now on referred to as the "molecular connectivity"). A detailed characterization of molecular shape must incorporate both pieces of information within appropriate global descriptors.

Recently, fractal theory (13) has been used to provide this type of descriptor (14–17). The fractal dimension of a curve is related to some of its some essential shape features. In the case of a protein backbone with n residues, a "fractal exponent" D can be defined from the following scaling relationship (14, 15):

$$[1] \qquad L(m) \sim m^{1-D}$$

where $L(m)$ is the length of the backbone measured with the "scale" of $m \leq n$ residues. When $m = 1$ we find the actual length of the backbone as a sequence of straight-line segments joining the α-carbons. When $m = n$, we find the end-to-end distance of the backbone. In actual fractal curves (i.e., those exhibiting *self-similarity* at each scale considered (13)), the slope in a graph of ln $L(m)$ vs. ln m will provide the fractal dimension D. However, protein backbones are *not* self-similar and the relation between ln L and ln m is poorly linear (15, 16). Therefore D is only an *apparent, approximate* exponent somewhat related to the protein's shape features. Moreover, as shown in ref. 16, the results for D depend strongly on the method used for its computation, and alternative definitions of fractal exponents provide different results (17). Despite these deficiencies, the fractal exponents derived in ref. 16 distinguish between some secondary structural motifs. Strands in β-sheets appear as one-dimensional objects ($D \approx 1.07 \pm 0.05$), whereas α-helices have larger mean fractal exponents ($D \approx 1.4 \pm 0.1$) (16). The discriminating power of these global descriptors is limited, however, by the fact that a self-avoiding random walk in 3D space also has dimensionality $D = 1.4$ (17). Clearly, there is a need for other types of shape descriptors, which, while using the same type of input information, provide a more meaningful characterization of secondary structure.

In this work, we deal with a more natural characterization of the polymer's global shape that also uses its molecular geometry and chain topology. Regarding the chain's folding features, we employ a new approach to studying self-entanglements in a polymer (18, 19). The method, based on the probability of observing double-points ("crossings") in all possible two-dimensional projections of a molecular backbone, measures quantitatively the nature of the polymer fold. In this work, we compute this descriptor for all relevant secondary structural motifs in polypeptides. Its behaviour in terms of number of residues is also determined. The analysis is complemented by comparing the description of self-entanglements with that provided by purely geometrical descriptors. In addition to the familiar radius of gyration, we present here for the first time a characterization of secondary structure in terms of asphericity. By using a joint description of self-entanglements and molecular geometry, we provide a new and concise classification of secondary structure.

The organization is as follows. The next two sections briefly discuss the geometric definition of the secondary structures and the nature of the shape description. The detailed shape characterization is given in a following section. The interpretation of the results and their value for recognition of protein folding features are discussed at the end.

Regular polypeptide conformations

Regular conformations of secondary structural motifs are specified by a single set of Ramachandran dihedral angles φ, ψ, and ω defined from the protein backbone (11). These are model conformations. Actual protein secondary structure may deviate from these ideal angles, while maintaining their overall shape.

Seven secondary structures are studied in this work. Three of them are helices: the (right-handed) α-helix, the 3_{10}-helix, and the π-helix. Two structures are "helicoidal strands," known as polyglycine II and polyproline II conformations. Finally, we consider pure strands, namely, those found in parallel and antiparallel β-sheets.

For all the motifs considered here, the amino acids are found in *trans* conformations. (Otherwise stated, we have $\omega = 180°$.) The following pairs of dihedral angles (ϕ, ψ) define the motifs (1): (*a*) the α-helix: (−58°, −47°); (*b*) the 3_{10}-helix: (−49°, −26°); (*c*) the π-helix: (−57°, −70°); (*d*) the polyglycine II "helical strand": (−80°, 150°); (*e*) the polyproline II "helical strand": (−78°, 149°); (*f*) the strand for an antiparallel β-sheet: (−139°, 135°) (and $\omega = -178°$); (*g*) the strand of a parallel β-sheet: (−119°, 113°).

The first two helices are found in proteins (1, 20), although long 3_{10}-helices are not known. Even though π-helices have not been found experimentally, they are included here because of their interesting shape features. This latter structure is a compact helix with fourfold symmetry. The 3_{10}-helix has threefold symmetry and is the least compact. The α-helix has intermediate properties.

Polyproline does not form α-helices but can be found in a different conformation known as polyproline II. This conformation exhibits threefold symmetry, and comprises small compact loops elongated in a strandlike fashion. For this reason, we refer to it as a "helicoidal strand." Polyglycine, because of the absence of side chains, can appear in a larger number of stable conformations than other polypeptides. The conformation polyglycine II is comparable to polyproline II.

The two β-strands considered here are qualitatively different. The β-strand found in antiparallel sheets is an almost planar ribbonlike structure. The one found in parallel sheets is "pleated," appearing as a twisted ribbon. (These two *strands* are often referred to loosely in the literature as antiparallel and parallel "β-sheets." Properly, a *sheet* comprises several

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

strands. Nonetheless, we shall use both terminologies interchangeably.)

In addition to the angles ϕ, ψ, and ω, other geometrical properties are frequently associated with the α-carbon backbone of regular secondary structures. Two common local parameters are τ, the axial translation per residue, and n_T, the number of residues "per turn." The product $p = \tau n_T$, known as the *pitch* of the motif, is a property used mostly for helices, where the notion of "turn" is meaningful. Two other parameters used for helices are their radius ρ, and the rotation per residue γ (1, 20). This set of local parameters is derived from special features in regular conformations. They cannot be defined for other folds and, thus, they do not constitute a tool to compare shapes of arbitrary conformations. More appropriate descriptors are dealt with in the next section.

Regular conformations model more accurately the stable secondary structures of polypeptides with a single type of amino acids. In our case, we have used *n*-polyalanine to describe all helical and β-strand motifs, where n is the number of residues. (For *regular* conformations, the results are expected to depend little on most chosen single amino acids.) The other two secondary motifs were modelled with *n*-polyglycine and *n*-polyproline. All molecular structures were built by adding residues sequentially, using the dihedral angles quoted above and a standard molecular modeling program (21). The α-carbon backbones derived from these "frozen" conformations are studied in the rest of this work. The conclusions should also be valid if the backbone regular conformation is allowed to relax to an actual energy minimum, within the framework of some standard molecular force field.

Molecular size and shape descriptors

Two groups of global descriptors have been computed for the motifs discussed above. One group of parameters describes molecular size and geometric shape. The second group corresponds to descriptors of entanglement complexity in the protein backbone.

As a classic descriptor of molecular size, we use the radius of gyration R_G (12). The basic properties of R_G for some secondary motifs are well known (1). We include here a quantitative analysis for the sake of comparison with other shape descriptors. The radius of gyration measures the compactness of the backbone, in addition to size. Size parameters scale *linearly* with the number of amino acid residues for the secondary motifs studied here. (In the case of random polymers, the conformationally averaged radius of gyration, $\langle R_G \rangle$, scales as $\langle R_G \rangle \sim cn^{\nu}$, with $\nu < 1$ (12).)

The geometric shape can be conveyed by the chain's *anisometry* (i.e., the deviation from a spherical distribution of atoms). An appropriate parameter is the *asphericity* (22–24):

$$[2] \qquad \Omega = \frac{(I_2 - I_1)^2 + (I_3 - I_2)^2 + (I_3 - I_1)^2}{2(I_3 + I_2 + I_1)^2}$$

where $\{I_i\}$ are the principal moments of inertia of the backbone. This function has been applied to study multidimensional random walks (23, 24). (Equation [2] is used in ref. 22. The parameter defined in refs. 23 and 24 is equivalent to 4Ω, for 3D chains.) For spherical and highly prolate objects, we find $\Omega = 0$ and $\Omega = \frac{1}{4}$, respectively. As far as we know, the asphericity has not been used to characterize secondary structural features, even though it provides a simple descriptor. For regular conformations, Ω varies nonlinearly with the number of residues and tends asymptotically to the limit value of $\frac{1}{4}$. In the Appendix, we deduce the quantitative behaviour of Ω for large n in some secondary structures.

The radius of gyration and the asphericity provide complementary information on size, compactness, and shape derived from the backbone geometry. However, a detailed characterization must include shape descriptors that depend explicitly on the geometry *and* connectivity. Therefore, the third aspect of macromolecular shape that we analyze is the "degree of folding" or the "complexity of self-entanglements" in the chain. In a previous work, we introduced a new shape descriptor to this purpose: the probability distribution of overcrossings (the overcrossing spectrum) (18).

This overcrossing spectrum is defined by the probabilities $\{A_N(n)\}$ of observing an n-atom chain as a projected curve with N bond–bond crossings. We refer to these "double points" resulting from a 2D-projection as *overcrossings*. An actual evaluation of overcrossing probabilities is performed as follows (18): (*a*) the backbone is enclosed by the smallest sphere centred at the centre of mass; (*b*) an arbitrary point $\boldsymbol{r}$ over the sphere is chosen, and the backbone is projected to a plane which is tangent to the surface at $\boldsymbol{r}$. For this projection, we evaluate a number of overcrossings $N(\boldsymbol{r})$; (*c*) the same procedure is repeated for a large number of points randomly distributed over the sphere; (*d*) the probability of observing a given number N of overcrossings is simply computed as the number of projections yielding N crossings divided by the total number of random projections. Details of the algorithm, and applications to several real protein structures, can be found in ref. 18. The overcrossing spectrum uses *all* possible "views" of a backbone. The resulting description is invariant under rigid rotations and translations.

The probability distribution $\{A_N(n)\}$ is in itself a global shape descriptor. The type of overcrossings in a polymer conformation depends not so much on its size or geometric shape, *but on the twists, turns, and various convolutions of the chain*. We refer to these features as "self-entanglements." The main features of the distribution are summarized by two parameters: (1) A^*, the probability of the most probable number of overcrossings N^* (i.e., the maxima of the distribution); (2) $\bar{N}$, the mean number of overcrossings, given by

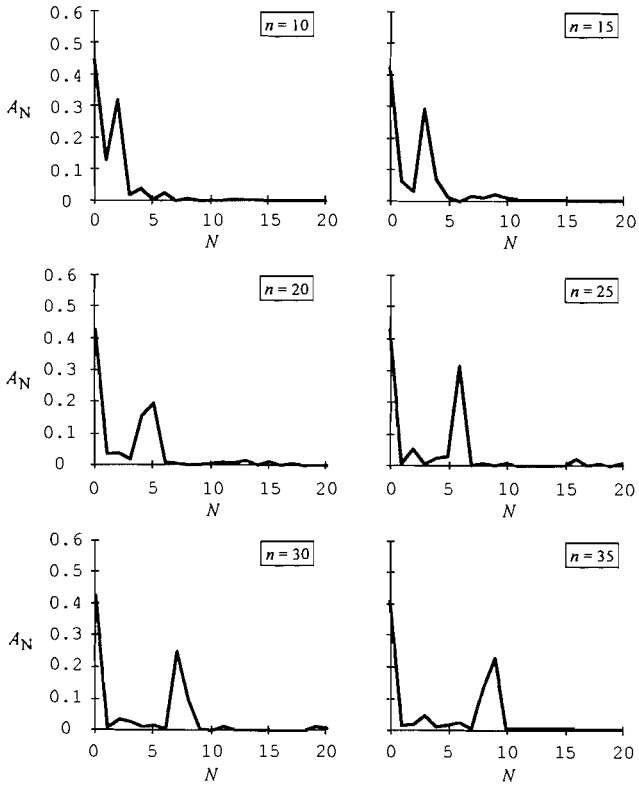
$$[3] \qquad \bar{N} = \sum_{N=0}^{\max N} N A_N(n)$$

where $\max N = (n-3)(n-2)/2$, for a *nonbranched* chain with n residues (18). The nature of the self-entanglements is expressed quantitatively by the descriptors A^* and $\bar{N}$. The more convoluted and entangled the backbone, the larger $\bar{N}$ and the smaller A^*. In contrast, one finds $\bar{N} \to 0$ and $A^* = A_0 \to 1$ for swollen and disentangled chains. In ref. 18, the overcrossing spectra of some rigid protein structures are discussed in some detail. As well, the values of A^* for a number of real (irregular) α-helices found in proteins are compared. Here, we extend this work by carrying out a detailed analysis for all relevant regular secondary motifs using A^* and $\bar{N}$ as shape descriptors.

Typical results for overcrossing spectra of regular con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

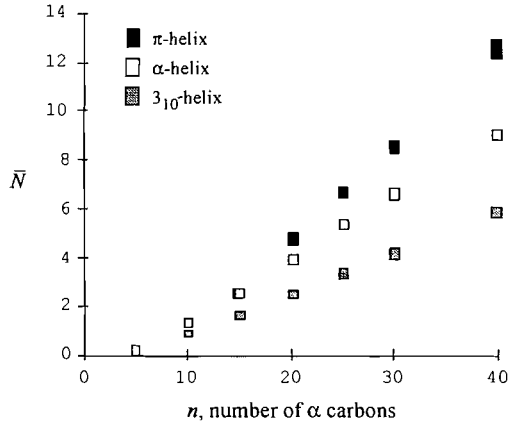
Fig. 1. Comparison of overcrossing spectra for polyalanine α-helices of variable lengths. (Note that in all cases the maximum probability of overcrossings is associated with $N^* = 0$, and it remains approximately constant at $A^* = 0.41$. In contrast, the position of the second maximum in A_N increases with n.)



formations are illustrated in Fig. 1. The figure displays the probabilities of observing $N \leq 20$ overcrossings in regular n-polyalanine α-helices, with $n = 10$, 15, 20, 25, 30, and 35. These spectra (and all others in this work) are derived by averaging the results of 4 different randomizations, with a number of projections ranging between 10 000 and 60 000. The six spectra in Fig. 1 exhibit two large maxima. One is always centred at $N^* = 0$ and corresponds to the maximum probability A^*. This probability appears to change little with n (18). The position of the second maximum, in contrast, increases almost linearly with n. As a result, it is found that the mean number of overcrossings $\bar{N}$ also increases linearly with n. The same trend is found for $\bar{N}$ in all secondary structures, although the $\bar{N}$ values depend on the entanglement complexity. On the other hand, the behaviour of A^* depends strongly on the motif considered, and it can provide a greater discrimination among shapes (see below). (Note that each conformation is characterized in *absolute* terms, and not relative to an (arbitrary) reference structure.)

The four descriptors R_G, Ω, A^*, and $\bar{N}$ are used in a detailed analysis of a given conformation. Intuitively, these descriptors could be related. For instance, one would expect a small radius of gyration, a large mean number of overcrossings, and a spheroid with small anisometry in the case of a compact backbone. However, actual conformations exhibit much richer features. The various aspects of molecular

Fig. 2. Dependence of the mean number of overcrossings $\bar{N}$ on the length of the polypeptide chain, for three types of helices. (The different box sizes represent the error bars due to the numerical evaluation of overcrossing probabilities by averaging the results from various randomizations of the 2D projections.)



shape in regular secondary structures can only be captured when using the above descriptors simultaneously. In the next section the results obtained are discussed in detail.

The shape of secondary structural motifs with variable chain length

The results presented below have been derived from computations on n-polypeptides with $5 \leq n \leq 40$. Longer chains have been considered only in selected cases. Since the chains are in regular conformations, $n = 40$ is large enough to reach the asymptotic limit. The behaviour for large n depends on the shape descriptor considered.

It is found that radius of gyration and the mean overcrossing number increase linearly with n for *all* secondary structural motifs. Therefore, molecular size and entanglement complexity can be characterized by two coefficients c and a:

$$[4] \qquad R_G \approx cn, \qquad \bar{N} \approx n/a$$

The quality of the two correlations in eq. [4] is comparable. For instance, in α-helices:

$$[5a] \qquad R_G \approx (0.41 \pm 0.01)n + (0.7 \pm 0.2) \text{ in Å}, \qquad C_c = 0.99992, \ 10 \leq n \leq 40$$

$$[5b] \qquad \bar{N} \approx n/(3.7 \pm 0.3) + (-1.5 \pm 0.2), \qquad C_a = 0.9997, \ 10 \leq n \leq 40$$

with 95% confidence errors. (C_c and C_a are the corresponding correlation coefficients.) The results for $\bar{N}$ are less accurate than those for R_G due to the algorithm based on averaging over random projections. The individual values of $\bar{N}$ have, at best, an accuracy of 3 significant figures.

Figure 2 compares the mean overcrossing numbers for the three helical secondary structures. The asymptotic behaviour (cf. eq. [4]) requires at least ca. 15 residues to set in. The results allow one to make two observations in com-

Table 1. Characteristic coefficients of molecular size (c) and molecular shape (a) for various secondary structural motifs. The coefficients quantify the linear dependence of the radius of gyration R_G (in Å) and mean number of overcrossings $\bar{N}$ with the number of amino acid residues n. (The errors correspond to 95% confidence intervals. The correlations coefficients for R_G vs. n and $\bar{N}$ vs. n are C_c and C_a, respectively. See text for discussion.)

Motif	R_G coefficient (c, in Å)	C_c	$\bar{N}$ coefficient (a)	C_a
π-Helix	0.268 ± 0.012	0.9995	2.63 ± 0.23	0.9980
α-Helix	0.408 ± 0.007	0.9999	3.68 ± 0.27	0.9997
3_{10}-Helix	0.567 ± 0.004	0.9999	6.10 ± 0.19	0.9998
Polyproline II	0.8951 ± 0.0007	0.9999	24.50 ± 0.41	0.9999
Polyglycine II	0.9008 ± 0.0005	0.9998	24.54 ± 0.49	0.9998
Parallel β-sheet	0.9438 ± 0.0001	0.9999	179 ± 6	0.9998
Antiparallel β-sheet	1.0008 ± 0.0004	0.9999	1900 ± 700	0.9801

paring the helical folds: (a) from the point of view of self-entanglements, all types of helices with 5 or fewer amino acid residues exhibit the same shape features; (b) longer helices are clearly distinct, with π-helices and α-helices resembling each other more closely than the 3_{10}-helices. The latter have the simplest folding (i.e., the least entangled), because of their smaller overcrossing numbers.

The results for the coefficients c and a are collected in Table 1 for all secondary structures. The dimensionless parameter a is a single number that conveys important information on the folding shape. We shall regard it as the *self-entanglement length* of a regular polypeptide conformation. It represents the mean number of residues needed to increase by 1 the average overcrossing numbers in 2D projections. The larger the a value, the less complex the entanglement nature of a conformation, regardless of its size. For a planar conformation we expect $a \to \infty$ (i.e., a regular structure with no entanglements).

From Table 1, we observe that "antiparallel sheets" are the least entangled of all secondary structural motifs. Their very large a value is consistent with an almost planar conformation. Strands in parallel sheets exhibit a marginal degree of folding, since ca. 200 residues are needed to observe one overcrossing. Nevertheless, our approach distinguishes the two motifs, reflecting the fact that the β-strands in parallel sheets are *twisted* ("pleated"), and thus not equivalent to the strands in antiparallel sheets. In contrast, the two strands appear equivalent to other global descriptors, such as the fractal dimension (16).

On the other extreme of the complexity scale, the π-helix is found to be the most entangled of the motifs. This result is consistent with it being the most compact of all structures, i.e., the one with the smallest c coefficient. The polyglycine II and polyproline II motifs have exactly the same self-entanglement length a, and occupy an intermediate position between helices and strands. Since over 20 residues are needed in polyglycine II and polyproline II conformations to produce an average of one overcrossing, these motifs will mostly resemble strands whenever found in actual protein structures.

The interpretation of a as a self-entanglement length is appropriate for *regular* conformations, because of the linear scaling of $\bar{N}$ with n. In medium-size random polymers and in actual proteins, the conformational average of $\bar{N}$ scales as $\langle \bar{N} \rangle \sim n^{\beta}$, with $\beta \approx 1.4$ (19). Hence, within our approach, secondary *and* tertiary structure are distinguished by their different scaling behaviour. A global descriptor such as the fractal dimension produces the same result for a regular α-helix and for an entire globular protein.

The previous analysis can be supplemented by using the descriptors A^* and Ω. The asphericity is derived from the same information used to compute R_G, whereas A^* is extracted from the overcrossing spectra that yielded $\bar{N}$. These descriptors are nonlinear functions of n. As shown below, they allow a greater discrimination in shape features.

Figure 3 shows the maximum overcrossing probabilities for the helical motifs as a function of n. (For completeness, the graph includes the *exact* result $A^* = 1$ for $n = 3$.) As expected, the least entangled 3_{10}-helices exhibit the largest A^* values. The asymptotic behaviour sets in at $n > 15$, where one finds a probability of observing *no overcrossings* in ca. 65% of the projections ($A_0 = A^*$). The α-helices show a similar behaviour, with an almost constant asymptotic probability $A_0 = A^* \approx 0.40$ for large n.

The behaviour of A^* in π-helices (the most entangled motif) is peculiar: it oscillates as a function of n. Overcrossing spectra for π-helices resemble those in Fig. 1, but here the two maxima are closer in height. Hence, the most probable number of overcrossings is not always "0". The oscillations in A^* correspond to helices where $N^* \neq 0$.

Figure 3 summarizes the expected pattern for A^* in helices: a rapid decrease from $A^* \approx 1$ at small n values, reaching either a constant or small oscillating values for larger n. Figure 4 summarizes the results for the asphericity Ω. To reveal more clearly the asymptotic behaviour of Ω, we have added helices with length up to $n = 100$. The asphericity increases rapidly from small values, corresponding to quasi-spherical chains, up to the limit for highly prolate chains. As we show in the Appendix, this limit is reached with a law $\Omega \sim \frac{1}{4} - (\text{const} \times n^{-2})$. Note that the asphericity for π-helices has a minimum at approximately $n \approx 7$. For polypeptides shorter than seven residues, the α-helical conformation is more spherical than the π-helix.

Figures 3 and 4 provide a complementary description of the helices. From the point of view of self-entanglements, long α-helices are closer to π-helices than to 3_{10}-helices. In contrast, from the point of view of anisometry, a long α-helix is almost as prolate as a 3_{10}-helix. This result indicates that

Fig. 3. Dependence of the maximum probability of overcrossings A^* on the length of the polypeptide chain, for three types of helices. (The exact limit $A^* = 1$ for $n = 3$ has been added for completeness. See text for a discussion of the irregular behaviour of A^* in the π-helix.)

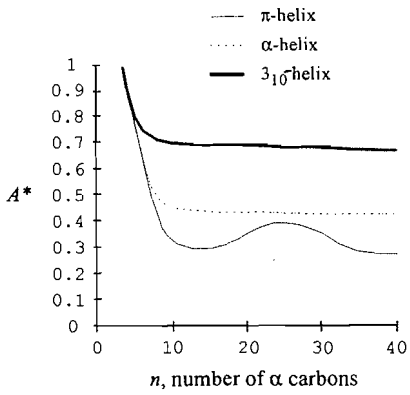

Fig. 4. Dependence of the asphericity Ω with the length of the polypeptide chain, for three types of helices.

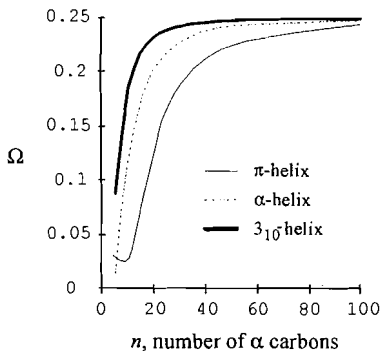

a single global descriptor cannot capture all shape features. By using the present set of properties, we can achieve a more complete characterization of secondary structure.

Figure 5 and 6 show the full shape description in the remaining motifs. The polyproline II and polyglycine II conformations are compared in Fig. 5, whereas Fig. 6 compares the parallel and antiparallel β-sheets.

The comparison of polyproline II and polyglycine II is a critical test since these two conformations are very similar in terms of common local measures (1). The results in Fig. 5 for R_G and Ω indicate that these two motifs are virtually coincident in terms of size, compactness, and anisometry. Similarly, their corresponding mean numbers of overcrossings $\bar{N}$ cannot be distinguished within our computational error (cf. Table 1 for the self-entanglement lengths). Only the maximum probability of overcrossings A^* indicates a small difference in shape features between the two conformations. With this property, we observe that polyglycine II and polyproline II backbones have the same shapes for $n < 20$. Yet, as the probability of no overcrossings $A_0(= A^*)$ decreases faster in polyglycine II chains, we conclude that the latter are slightly more entangled. This difference may stem from the local differences in fold caused by the smaller amino acid residue. This result suggests that A^* can be used as a *discriminating*

Fig. 5. Shape descriptors for regular polyproline II and polyglycine II motifs with variable number of residues. (Only the descriptor A^* indicates small differences between their shapes, in the case of long chains. See Fig. 2 with respect to the error bars.)

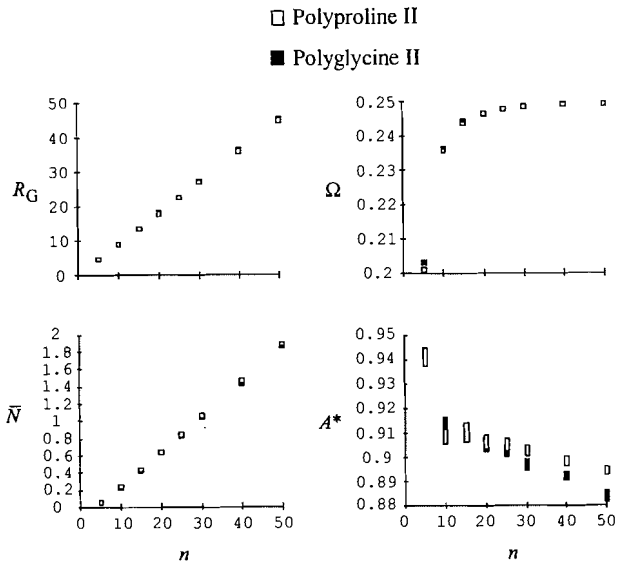

Fig. 6. Shape descriptors for the regular strands in antiparallel and parallel β-sheets with a variable number of residues. (The fact that the parallel strand is nonplanar and twisted ("pleated") is only reflected by the shape descriptors $\bar{N}$ and A^*. The antiparallel strand is almost planar and therefore less entangled. The large error bars for $\bar{N}$ are typical of the computation of overcrossings in objects that are close to planar. See Fig. 2 with respect to the error bars.)

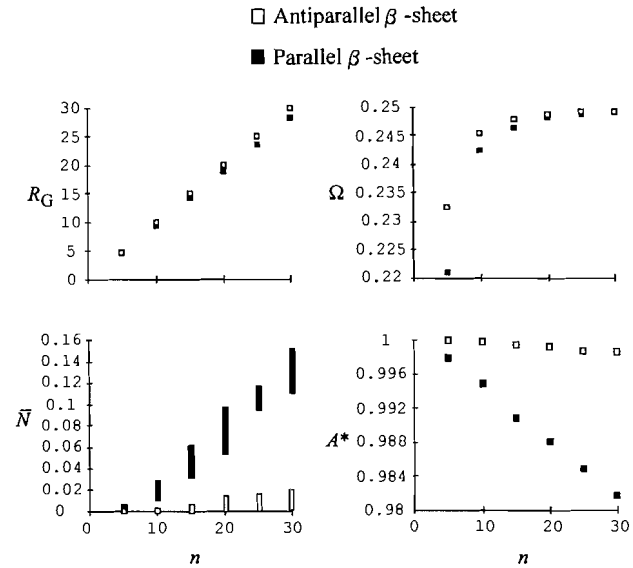

tool, sensitive enough to detect changes of global shapes in polymers with similar conformations but different compositions.

The comparison of β-strands is another critical test, since they have very similar local (1) and global (16) descriptors. From Fig. 6, we make the following observations:

(*a*) the radius of gyration magnifies the size difference for long strands. While strands with $n < 10$ are virtually indistinguishable, long parallel β-sheets are smaller (cf. Table 1); (*b*) the asphericity magnifies the difference in geometric shape for small n. Strands with $n > 20$ have virtually the same anisometry, whereas short parallel β-sheets are less prolate; (*c*) only the descriptors of self-entanglements provide a clear distinction between the two β-sheet motifs. The larger $\bar{N}$ and smaller A^* values for parallel β-sheets imply that the latter are more entangled. (Both objects are, of course, little "entangled" in *absolute* terms, as the A^* and $\bar{N}$ values indicate.)

Summarizing, the difference in structure caused by the "twist" in parallel β-sheets is reflected in the global shape descriptors A^* and $\bar{N}$. This difference cannot be noted when using only geometrical descriptors.

Further comments and conclusions

In conclusion, we have shown that a thorough characterization of secondary structures can be achieved with the use of several descriptors, focusing on different aspects of molecular shape. Our results indicate that descriptors of self-entanglements are "natural" and efficient tools to monitor folding features in regular conformations.

Other properties have been used in the literature to study secondary motifs. With respect to *global* descriptors (16), we believe that our approach discriminates better between similar conformations. As well, it has a conceptual advantage, since self-entanglements can be defined rigorously for any 3D curves. In contrast, a global descriptor such as the fractal dimension assumes a behaviour that is only an approximation for polypeptides (16).

The present analysis goes beyond the information provided by a *local* property. In fact, some familiar local parameters, such as the number of residues per turn n_T, do not describe molecular shape (1). For example, if one stretches a helix elastically, n_T may be conserved. However, the molecular shape would change as the helix becomes less entangled. The present shape descriptors recognize this difference. Other parameters, such as the pitch p or the axial translation τ, only make sense if there is a preferential axis, as in regular conformations. They become meaningless for arbitrary polymers. In contrast, the shape descriptors A^* and $\bar{N}$ can be used in all instances.

From our results, two important observations can be made for A^* and $\bar{N}$. First, the self-entanglement length a (eq. [4]) is a better property than D (eq. [1]) as a single number to represent the global shape of secondary motifs. Second, the dependence of A^* upon n appears to be a discriminating function for motifs, and it allows one to study the effect that a change in amino acids has over the shapes of similar conformations.

This improved analysis of secondary structure contributes to our understanding of protein shapes at their various levels of structural organization. A better representation of protein folding features is a much needed component in the current research to predict tertiary structure from primary sequence (25, 26), develop *de novo* proteins (the "inverse folding problem") (27), and recognize intermediates during folding dynamics (28, 29).

In closing, it should be noted that the methodology presented here is not restricted to the analysis of regular conformations in chain molecules. As shown in ref. 30, we can extend the characterization of self-entanglements to the study of ensembles of several chains. Therefore, our procedure can also be applied to periodic multichain arrays, such as those found for nucleic acids. Work on these systems is underway and will be presented elsewhere.

Appendix

We show here the asymptotic behaviour of the asphericity Ω for helicoidal conformations in terms of n, the number of amino acid residues. Let I_3 be the principal moment of inertia associated with the helical axis. If we now consider regular, perfectly cylindrical helices, the conformations become prolate symmetric tops and the principal moments of inertia associated with the axes perpendicular to the helical axis coincide, i.e., $I_1 = I_2$. In this case, the asphericity becomes (cf. eq. [2]):

$$[A.1] \quad \Omega = \frac{(1 - I_3/I_1)^2}{4(1 + I_3/2I_1)^2}$$

In the asymptotic limit of very long helices, $I_3 \ll I_1$. Expanding eq. [A.1] in power series up to the first order in (I_3/I_1), we obtain:

$$[A.2] \quad \Omega \approx \frac{1}{4} - \frac{3I_3}{4I_1}$$

The limit $\Omega \rightarrow 1/4$ corresponds to the maximum value of asphericity in prolate objects. To obtain the asymptotic behaviour in terms of the number of monomers n, we can estimate the two principal moments of inertia in eq. [A.2] in terms of familiar helical parameters. Let ρ be the radius of the helix, τ the axial translation per residue (i.e., the "helical pitch" divided by the number of residues per turn), and γ the rotation per residue. The values of these parameters can be found in refs. 1 and 20. Since all the main chain atoms in the present model of a helix are identical and lie on the surface of a cylinder, we obtain:

$$[A.3] \quad I_3 \approx n\rho^2$$

For the remaining moment of inertia we proceed as follows. Using centre of mass as the origin, the atoms can be labelled by an index $|i| \leq n/2$, where $i > 0$ corresponds to the positions with positive coordinate along the helical axis. With this notation, the position of each atom along the helical axis becomes $i\tau$. For the same atom, the position along an axis perpendicular to the helical one can be estimated as $\rho \cos(i\gamma)$. Therefore, in the limit of long helices (i.e., where the main contributions come from large $|i|$ values), we have

$$[A.4] \quad I_1 \approx 2\sum_{i=1}^{n/2}[(i\tau)^2 + \rho^2\cos^2(i\gamma)] \approx 2\tau^2\sum_{i=1}^{n/2} i^2 \approx \frac{\tau^2 n^3}{12}$$

where only the largest contribution to a power of n has been retained. Introducing eqs. [A.3] and [A.4] in eq. [A.2], we deduce that the asymptotic behaviour of Ω follows a n^{-2} law:

$$[A.5] \quad \Omega \approx \frac{1}{4} - 9\left(\frac{\rho}{\tau}\right)^2 n^{-2}$$

As an example, for an α-helix we have $\rho \approx 2.5$ Å, $\tau \approx 1.6$ Å, which gives $9(\rho/\tau)^2 \approx 22.0$. This result can be checked numerically by considering polyalanine α-helices of variable length. Using the results for $n = 20$, 25, 30, 35, 50, and 100 polyalanines (see discussion in the article), a least-squares fitting of $\ln(\frac{1}{4} - \Omega)$ vs. $\ln n$ produces:

$$[A.6] \quad \ln\left(\frac{1}{4} - \Omega\right) \approx (-2.02 \pm 0.10)\ln n + (3.1 \pm 0.4)$$

with 95% confidence intervals and a correlation coefficient of 0.9994. Equation [A.6] translates into the asymptotic result: $\Omega \approx \frac{1}{4} - (22 \pm 9)n^{-2.0\pm0.1}$, $n \gg 1$, in good agreement with the prediction [A.5] for α-helices. The anisometry of other helices and secondary structural motifs can be analyzed in a similar fashion.

Abstract: Single-crystal absorption spectroscopy at variable temperature is used to determine exchange couplings between transition metal centers in both the electronic ground and excited states in two new homobimetallic complexes with the formula $[LM(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2ML'](ClO_4)_2$, where M is iron(III) or manganese(III). L and L' denote 1,4,7-triazacyclononane and 1,4,7-trimethyl-1,4,7-triazacyclononane, respectively. Values for the ground state exchange coupling constant J are -295 cm^{-1} and $+10$ cm^{-1} for the iron and manganese compounds, respectively, using $H_{ex} = -JS_1 \cdot S_2$. Exchange interactions in excited states are qualitatively analyzed, indicating that a spin-forbidden transition of the Fe–Fe binuclear unit occurs with significant intensity by the single-ion mechanism, and not as expected by the Tanabe pair intensity mechanism for spin-forbidden transitions, the dominant mechanism for isoelectronic complexes of manganese(II).

Key words: absorption spectra, exchange interaction, magnetic properties, bimetallic complexes of iron(III), bimetallic complexes of manganese(III)

Résumé : La spectroscopie d'absorption de cristaux à température variable est utilisée pour déterminer quantitativement des constantes de couplage d'échange entre les deux centres métalliques de nouveaux complexes binucléaires du fer(III) et du manganèse(III) ayant comme ligands pontants un ligand oxo et deux groupes acétato. Les constantes de couplage J sont de -295 cm^{-1} et $+10$ cm^{-1} pour les composés du fer et du manganèse avec l'opérateur $H_{ex} = -JS_1 \cdot S_2$. L'interaction d'échange dans les états excités est analysée de façon qualitative, indiquant que le mécanisme d'intensité pour transitions d'une unité binucléaire de Tanabe n'est pas effectif dans le composé du fer, contrairement aux observations pour des composés binucléaires du manganèse(II) qui sont isoélectroniques au complexe du fer(III) dans cette étude.

Mots clés: spectroscopie d'absorption, interaction d'échange, propriétés magnétiques, composés binucléaires du fer(III), composés binucléaires du manganèse(III)

1. Introduction

Binuclear complexes of iron and manganese with oxo and carboxylato bridging ligands are important constituents of the active sites in metalloproteins and have been shown to be catalytically active (1–6). A large number of model compounds have been synthesized recently, among them a series of triply bridged binuclear compounds with the μ-oxo-bis(μ-acetato) bridging geometry (5, 7). We present absorption spectra of two homobimetallic compounds of this type with the formula $[LM(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2ML'(ClO_4)_2$. The metal centers M are either iron(III) or manganese(III). L and L' denote 1,4,7-triazacyclononane and 1,4,7-trimethyl-1,4,7-triazacyclononane, respectively. The manganese compound contains one water molecule per formula unit in the crystal. The structure and a variety of physical properties of both compounds are reported in ref. 7. We abbreviate them as {MnMn} and {FeFe} in the following.

The detailed absorption spectra of crystals of {FeFe} and {MnMn} as a function of temperature are used to determine effects of the exchange coupling both in the ground and some excited electronic states, providing new insight into the detailed electronic structure of these compounds. The comparison with existing spectroscopic data on isoelectronic systems shows a large variation of spectroscopic and magnetic properties and therefore considerable potential for the tuning of these properties by chemical variation of the ligand systems and oxidation states of the metal centers. The wide variety of spectroscopic observations and excited state behavior has been extensively studied for binuclear compounds of chromium(III), where a variety of absorption and luminescence techniques can be applied (8, 9). Binuclear complexes of copper(II) have been investigated in detail because of their simple d^1–d^1 hole configuration, making them ideal model systems for experimental and theoretical studies. (8, 10–12) Other metals, such as iron(III) and manganese(III) in this work, have received much less attention (8). The work on

compounds containing Fe^{3+}-O-Fe^{3+} units is summarized in refs. 6 and 13.

2. Experimental

The compounds were obtained as powders from the laboratory of Karl Wieghardt (7). Thin crystalline samples of {FeFe} and {MnMn} used for optical absorption spectroscopy were obtained by slow evaporation of saturated solutions in methanol on quartz plates at room temperature. The samples with typical areas of 0.5 mm^2 were mounted in a helium cryostat (Oxford Instruments CF 1204). The quality of the sample crystals was examined under a microscope between crossed polarizers and extinction directions were determined. Only unpolarized spectra are reported because the polarization direction had no significant effects on band intensities and positions, most likely due a structure with multiple inequivalent sites for the chromophore in the crystal, leading to bimetallic units with different orientation relative to the polarization directions. The crystal structure of {FeFe} and {MnMn} was not determined, but structures with eight formula units per unit cell are reported in ref. 7 for the analogous {FeMn} and {FeCr} compounds. All the spectra were measured with a Varian Cary 5E spectrometer. Commercial computer software was used for conversion of the spectra to a wave-number scale and for the least-squares fits.[2]

3. Spectroscopic Results

The absorption spectrum of {FeFe} is shown in Fig. 1 as a function of temperature. The band positions in the overall spectrum, shown in the inset, are typical for Fe^{3+} compounds in a distorted octahedral coordination with nitrogen and oxo ligands (6, 14). The band positions and estimated molar absorptivities of the room temperature spectrum in Fig. 1 are similar to those of the solution spectrum in ref. 7, with the high molar absorptivities indicating the importance of exchange coupling between the two metal centers. The transitions can be assigned with the Tanabe–Sugano diagram for d^5 systems and by analogy with the detailed assignments of the high-resolution spectra reported for pairs of Fe^{3+} ions in sapphire (14, 15). The unstructured band at 13 000 cm^{-1} corresponds to the $^6A_1 \rightarrow {}^4T_1$ transition in the O point group. Its shape and overall intensity show very little change with temperature. The next band system is the superposition of the $^6A_1 \rightarrow {}^4T_2$ and $^6A_1 \rightarrow {}^2T_2$ transitions, shown in detail in the main part of Fig. 1. We identify four bands with distinct temperature dependencies. The most intense band is centered at 21 230 cm^{-1}, denoted by a square, and shows a decrease in intensity with increasing temperature. The intensity of the band at 19 340 cm^{-1}, denoted by a circle, strongly increases with temperature. Two weak bands at 17 990 cm^{-1} and 23 360 cm^{-1} (triangle in Fig. 1) show a slight increase in intensity with temperature. The different temperature dependencies are caused by exchange interaction between the metal centers and will be discussed in Sect. 4(a). In isoelectronic compounds of manganese(II) the corresponding transitions are weak and at higher energy than for {FeFe},

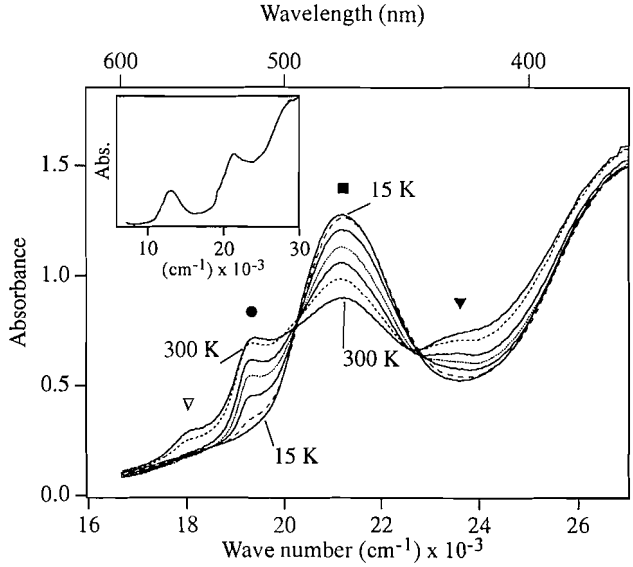
Fig. 1. Single-crystal absorption spectra of {FeFe} as a function of temperature. Main figure: $^6A_1 \rightarrow {}^4T_2$, $^2T_2$ band with intensities determined by thermal population of different levels of the exchange-split ground state of the binuclear system. Bands used for the determination of the exchange coupling parameter J are denoted by the square, circle, and solid triangle symbols. Temperatures for the measurements are 15, 80, 120, 180, 200, 250, and 300 K, top to bottom at the band maximum denoted by the circle. The order is inverted at the band maximum denoted by the square. Inset: overall absorption spectrum at 80 K.



often hidden by the sharp bands corresponding to the $^6A_1 \rightarrow {}^4A_1, {}^4E$ transitions, where initial and final states of the transition arise from the same electron configuration. These are the transitions that were used in the literature to determine exchange coupling constants (14, 16, 17). Their widths are smaller than 50 cm^{-1}, narrower by almost an order of magnitude than the transitions in Fig. 1. From the positions of the $^6A_1 \rightarrow {}^4T_1$ and $^6A_1 \rightarrow {}^4T_2$, $^2T_2$ bands we estimate a value of Dq/B of 1.6 for {FeFe} from the ligand-field diagrams in ref. 18. This value is considerably higher than for manganese(II) compounds due to the trivalent metal ion and it is higher than for iron(III) pairs in sapphire due to the stronger ligand field created by the triazacyclononane ligands.

Figure 2 shows single crystal absorption spectra of the {MnMn} compound as a function of temperature. As for the {FeFe} compound, the band positions and intensities at 300 K are similar to those reported in solution (7). We observe a hot band at 19 230 cm^{-1} superimposed on a more intense band at 20 620 cm^{-1}. This is the only band that changes significantly with temperature and we will use it to determine the ground-state exchange coupling constant for this compound in Sect. 4(b). The band system shown in Fig. 2 is assigned to the spin-allowed $^5E \rightarrow {}^5T_2$ transition of a d^4 transition metal center, split by low-symmetry crystal-field components and vibronic effects. This assignment leads to a Dq/B value of 1.8 (15, 18), very similar to the value of 1.6 determined for {FeFe} and thus supporting our assignment. The temperature dependence of the spectra in Fig. 2 shows evidence for a broad cold band centered at 21 500 cm^{-1}. Its intensity is too low to be quantitatively determined at each temperature. A weak, broad

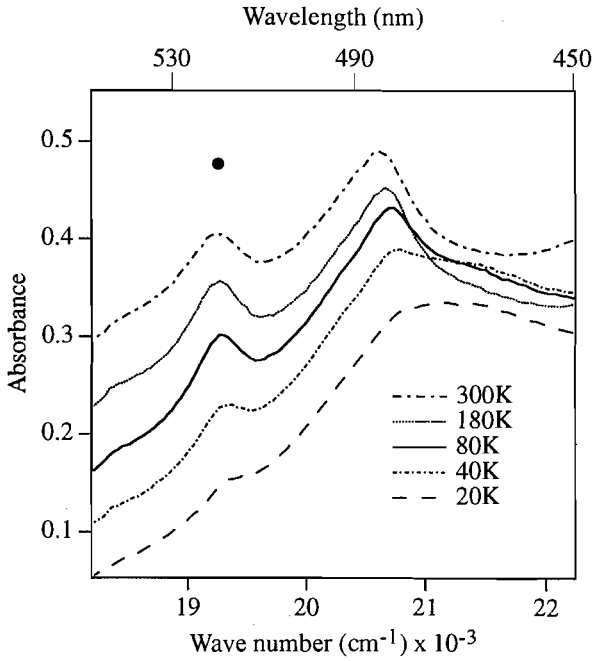
Fig. 2. Single crystal absorption spectra of {MnMn} as a function of temperature. The hot band used to determine the exchange coupling parameter in Fig. 6 is denoted by a circle. The spectra are vertically offset for clarity by 0.06 absorbance units in order of increasing temperature.



shoulder centered at 17 500 cm^{-1} in the absorption spectrum of {MnMn} is assigned as the spin-forbidden $^5E \rightarrow {}^3T_1$ band, the lowest energy transition at the crystal field strength of this compound. Comparison of the spectra of {MnMn} and {FeFe} therefore allows an assignment of the observed bands despite the lack of highly resolved fine structure in the spectra.

4. Discussion

(a) Temperature dependence of the spectrum of {FeFe}

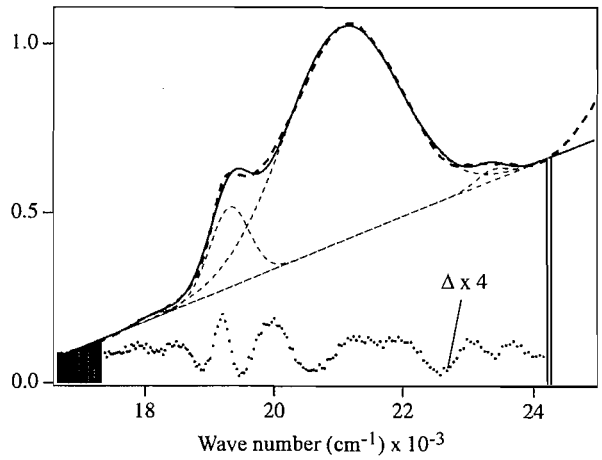
The absorption spectrum in Fig. 1 shows a pronounced temperature dependence of the absorption intensities in the system of bands between 17 200 cm^{-1} and 24 200 cm^{-1}. We determine the intensities of individual bands by fitting a sum of Gaussians to the experimental spectra. The variation of the intensities with temperature allows us to quantitatively determine the exchange coupling parameter J in this new binuclear compound. In the following analysis and for all comparisons with literature values we use the exchange Hamiltonian

$$[1] \quad H_{ex} = -JS_1 \cdot S_2$$

The same operator is used in ref. 7 and we can therefore directly compare the numerical values for the ground state coupling constant J obtained from magnetic measurements with the value from absorption spectra in this work.

We first discuss the temperature-dependent absorption intensities in terms of ground state exchange splittings in the binuclear molecular unit. The absorption bands showing a change of intensity with temperature originate from different levels of the electronic ground state, split by exchange interaction. For the case of a binuclear Fe^{3+} complex, the ground state

Fig. 3. Fit of the absorption spectra in Fig. 1 to a sum of four Gaussians. The experimental spectrum is shown as a dotted line, the best fit as a solid line. The individual Gaussians are denoted by dot-dashed lines. The bottom trace of the graph shows the difference between experiment and fit on the right-hand ordinate scale enlarged by a factor of four. Vertical bars denote the region used for fitting the linear base line.



splits into six levels with total spins ranging from 0 to 5. The energy separations of the levels are J, $2J$, $3J$, $4J$, and $5J$, with increasing pair spin quantum number S. The compound is reported to be antiferromagnetic, therefore the level with $S = 0$ is lowest in energy (7).

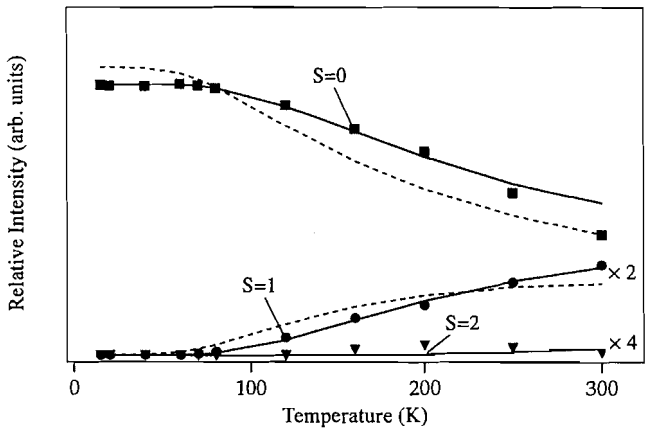
To separate the intensities of the overlapping bands forming the absorption spectrum in Fig. 1, we fitted a sum of four Gaussians to the experimental spectrum. The result of this fit is illustrated in Fig. 3 for the spectrum measured at 200 K, a temperature where all four bands have significant intensities. In a first step, we determined a linear base line from the areas of the spectrum denoted by vertical bars, then we fitted the sum of four Gaussians to the spectrum, using the previously determined linear base line. The base line and the four Gaussians are included in Fig. 3. The residuals of the fit, also included in Fig. 3, show the limits of the model based on Gaussians for an accurate description of the bandshape. The largest differences are found in the region of overlap between bands, and are caused by the assumption of Gaussian bandshapes. It is important to notice that the discrepancies in these regions of low intensity of each Gaussian do not have a large influence on the calculated band intensities. The Gaussians are integrated to calculate the intensity of each transition as a function of temperature, shown in Fig. 4. The band maxima obtained from the fit change by 300 cm^{-1} between 15 and 300 K. This small shift to lower energy indicates that no structural phase transition occurs in the temperature range studied.

The integrated intensities $I(S)$ of absorption transitions from the ground state levels with pair spins S of 0 and 1 are given by eqs. [2] and [3], respectively.

$$[2] \quad I(S=0) = C_0(1 + 3e^{J/kT} + 5e^{3J/kT} + 7e^{6J/kT} + 9e^{10J/kT} + 11e^{15J/kT})^{-1}$$

$$[3] \quad I(S=1) = C_1(3e^{JkT})(1 + 3e^{J/kT} + 5e^{3J/kT} + 7e^{6J/kT} + 9e^{10J/kT} + 11e^{15J/kT})^{-1}$$

Fig. 4. Relative intensities of the absorption bands of {FeFe} originating from ground state levels with pair spin S as a function of temperature. The symbols denote experimental intensities determined from the absorption spectra in Fig. 1. The solid lines are fits to eqs. [2] and [3] for the transitions originating from the ground state levels with pair spins S of 0 and 1, respectively, with a value of -295 cm^{-1} for the exchange coupling parameter J in eq. [1]. The dotted lines denote curves calculated using the literature value of -207 cm^{-1} for J (7).



The scaling factors C_0 and C_1 are necessary because no reliable absolute oscillator strengths can be determined due to the large uncertainties in estimating the thickness of our crystals. Three parameters, J, C_0, and C_1, were adjusted by a least-squares method.[2] The calculated intensities are in very good agreement with the experimental data, as shown in Fig. 4. An average value of -295 ± 8 cm^{-1} was obtained for J, and values of 1904 ± 11 A cm^{-1} and 716 ± 33 A cm^{-1} are obtained for the factors C_0 and C_1, respectively. In a separate step, we fitted the temperature dependence of the high-energy band at 23 530 cm^{-1}, denoted by the solid triangle in Fig. 1. These low intensities were not included in the first stage of the fit because their relative errors are much larger than those of the more intense bands. The value of J was held constant and we adjusted only the parameter C_3 in a fit equation analogous to eq. [3], but for the ground state level with $S = 2$. A value of 312 ± 148 A cm^{-1} was obtained for the scaling constant C_3. The large error reflects the low absolute intensity of the band denoted by the solid triangle in Fig. 1 and is the reason why these intensities were not included in the fit used to determine J. The fit is shown in Fig. 4 and agrees well with the experimental intensities, confirming the J value found from the more intense bands. We conclude that transitions from three of the five ground state levels, those with pair spins of 0, 1, and 2, to different excited states are observed. The coupling constant J obtained from the absorption spectra is in reasonable agreement with the value of -207 cm^{-1} determined from magnetic susceptibility data (7). The difference between the two values is most likely due to the influence of paramagnetic impurities on the magnetic measurements, evident from Fig. 5 of ref. 7 and uncertainties in our Gaussian fitting procedure of the optical spectra. We include in Fig. 4 relative intensities for the two most intense transitions, calculated from eqs. [2] and [3] with the literature value of -207 cm^{-1} for the coupling constant J and by refining the constants C_0 and C_1. This comparison shows that the intensities obtained with both values are reasonable, especially for the band originating from the level with a pair spin S of 1. An underlying assumption to the analysis both in this work and in ref. 7 is that J is considered independent of temperature. This has been shown to be problematic for a bimetallic compound of chromium(III), leading to errors of more than 30% for the J value determined from temperature-dependent measurements (19). Magnetic measurements and optical spectra are expected to be affected in different ways by the temperature dependence of J, causing the discrepancy observed between the two values of J. In view of the fundamentally different physical effects used by the two methods and the underlying assumptions, we conclude that the agreement between our value of J and the literature result is satisfactory and illustrates the potential of optical spectroscopy as an alternative method for the determination of magnetic properties.

The exchange interaction in the ground state of {FeFe} is an order of magnitude larger than for triply bridged Fe^{3+} pairs in sapphire, where an antiferromagnetic interaction with a value of -25 cm^{-1} for J was determined (14). It is interesting to note that the opposite order of the J values is observed for similar systems containing Cr^{3+} ions: a strong antiferromagnetic coupling with values of -115 cm^{-1} (20) and -128 cm^{-1} (21) in the triply-bridged nearest neighbor pairs in ruby and tris-μ-hydroxo-bridged molecular compounds, respectively, and a much weaker coupling of -29 cm^{-1} (22) in a binuclear compound with μ-hydroxo-bis-μ-acetato-bridged chromium ions, similar to {FeFe}. This comparison shows that the prediction of the value of the exchange constant based simply on comparisons of bridging geometries or electron configurations is very difficult.

The {FeFe} compound with its d^5–d^5 electron configuration is a particularly interesting system for a study of the dominant intensity mechanism of the observed absorption transitions. Two mechanisms can contribute to the intensity: the single-ion mechanism and the pair mechanism described by Tanabe and co-workers (9). The spectroscopic signatures of the two mechanisms are different because of their different spin selection rules: $\Delta S = 0, \pm 1$ for the former (23, 24) and $\Delta S = 0$ for the latter mechanism (25, 26). In the {FeFe} compound, a transition with $\Delta S = 0$ is not possible at very low temperature because there exists no excited state with a pair spin of 0 in a d^5–d^5 system. The cold band at 21 230 cm^{-1} therefore gains its intensity by the single-ion mechanism and the spin of the final state of the absorption transition is $S = 1$, most likely a component of the $^6A_1{}^4T_2$ pair state. It is interesting to note that for pairs of manganese(II) ions the corresponding transition is not observed, but the hot bands arising from the $S = 1,2$ ground state components are intense, indicating a Tanabe mechanism, analyzed in detail for a series of fluoride lattices doped with manganese(II) (17, 27). Possible reasons for the efficiency of the single-ion mechanism in {FeFe} compared to the highly symmetrical host lattices doped with manganese(II) are the considerable odd-parity crystal field components in the {FeFe} compound and the larger spin-orbit coupling of iron(III) compared to manganese(II) (28). The Tanabe mechanism could contribute to the intensity of the hot bands observed in {FeFe}, but their intensity, as illustrated for the most intense hot band by the value of C_1, is not higher than the intensity of the cold band, indicating very weak or no contributions by the Tanabe mechanism. This is surprising, because

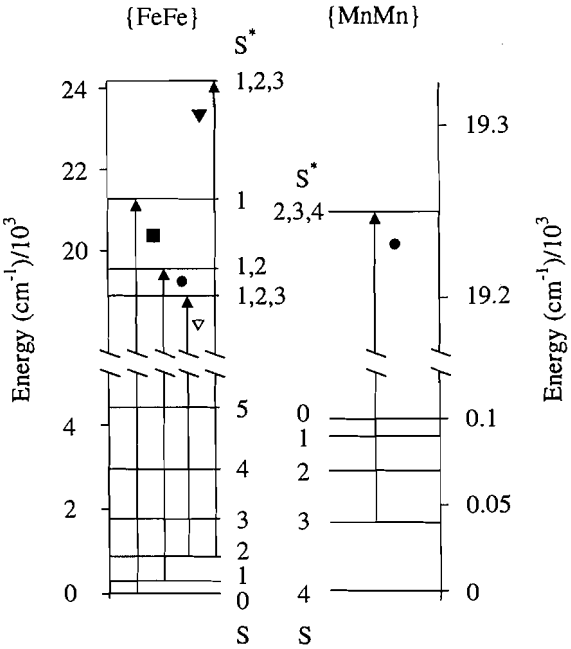
Fig. 5. Energy levels and observed transitions used for the determination of exchange coupling constants in {FeFe} and {MnMn}. The assignments of pair spin quantum numbers are discussed in the text.



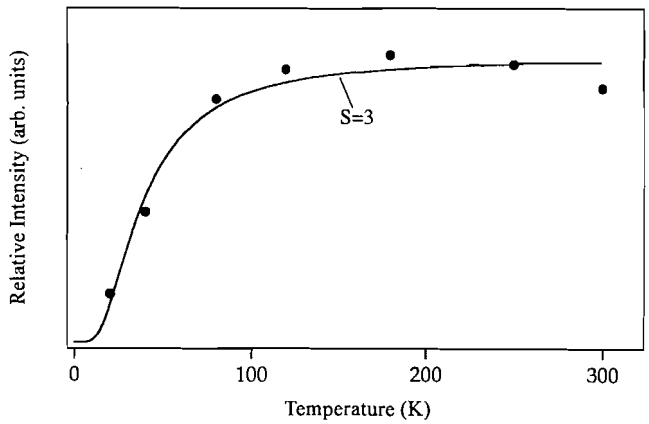
the title compound does not have a center of inversion in the point group of the binuclear molecular unit and therefore fulfills the symmetry requirements of the Tanabe mechanism (9).

The unresolved absorption spectra do not allow us to quantitatively determine excited state exchange coupling constants J^*, but we can nevertheless compare our spectroscopic results to the energetic order of the excited states arising from the $^2T_2$-$^4T_2$ region of the d^5 Tanabe–Sugano diagram (15). Literature assignments of similar spectra of bimetallic compounds of iron(III) include low-energy charge-transfer bands, (6) but we limit our qualitative discussion to *d–d* transitions, based on the similar intensities and widths of all the bands in Fig. 1. All the transitions are schematically illustrated in Fig. 5. The excited state at 21 230 cm^{-1}, determined from the maximum of the cold band, must have a pair spin S^* of 1 and therefore arises from a $^6A_1{}^4T_2$ pair state. Using the selection rules for the single-ion mechanism leads to possible values of 1, 2 or 3 for the pair spins of the final states of the hot bands. They could thus arise both from $^6A_1{}^4T_2$ or from $^6A_1{}^2T_2$ pair states. The Tanabe–Sugano diagram shows that the $^4T_2$ and $^2T_2$ excited states are close in energy for {FeFe}. The interactions between these two states make it impossible to determine a ferromagnetic or antiferromagnetic ordering of the spin levels of the two excited states from our spectra, but the pair spins and single-ion parent state assignments of the bands observed for {FeFe} are confirmed.

(b) Temperature dependence of the spectrum of {MnMn}

The {MnMn} compound shows only one absorption band with a distinct temperature dependence: the hot band centered at 19 230 cm^{-1}. This is the only band that can be used for the calculation of the ground state exchange coupling constant J. It is remarkable to notice that {MnMn} provides a rare example of

Fig. 6. Intensity of the hot band of {MnMn} at 19 230 cm^{-1} in Fig. 2 as a function of temperature. The solid line is a fit to eq. [4] leading to an exchange coupling constant J of +10 cm^{-1}.



a spin-allowed *d–d* transition that is strongly affected by exchange effects. (9) The intensity of the hot band was determined and integrated in the same way as described for {FeFe} and is shown in Fig. 6. The pair spin of a d^4–d^4 system can range from $S = 0$ to $S = 4$, and it is not obvious which of these levels is the initial state of the transition. The comparison with magnetic measurements in ref. 7 shows that a ferromagnetic coupling is expected for this compound, i.e., the level with $S = 4$ is lowest in energy. It is reasonable to assume that the hot band originates from the $S = 3$ level. Its intensity is then given by:

$$[4]\quad I(S=3) = C_3(7e^{-4J/kT})(9 + 7e^{-4J/kT} + 5e^{-7J/kT} + 3e^{-9J/kT} + e^{-10J/kT})^{-1}$$

From the fit of eq. [4] to the experimental intensities we obtained a value of +10 ± 1 cm^{-1} for J, in very good agreement with the literature value of +14 cm^{-1} (7), and a value of 93 ± 3 A cm^{-1} for C_3. The calculated relative intensity is compared to the experimental intensities in Fig. 6. The combination of magnetic measurements and optical spectra of {MnMn} confirms the ferromagnetic coupling, leads to consistent values for the magnitude of the exchange interaction in this compound, and confirms the pair spin of 3 for the initial state of the transition shown schematically in Fig. 5. The pair spin S^* of its final state is 2, 3, or 4 with the intensity mechanisms discussed for {FeFe}.

Stereospecific reactions of aryltellurium(IV) trichlorides with 3-cyclohexene-1-methanol and 3-cyclohexene-1,1-dimethanol: the X-ray crystal structure of 2′,4′-dimethoxyphenyl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride

Bozena Borecka, T. Stanley Cameron, M. Azad Malik, and Barry C. Smith

Abstract: Aryltellurium(IV) trichlorides react with 3-cyclohexene-1-methanol and 3-cyclohexene-1,1-dimethanol to give aryl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichlorides and aryl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichlorides. The structure of 2′,4′-dimethoxyphenyl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride has been determined by single crystal X-ray analysis. The compound $C_{15}H_{20}Cl_2O_3Te$, M_r = 446.8, crystallizes in the monoclinic space group $P2_1/c$ with a = 9.626(2) Å, b = 15.768(5) Å, c = 11.176(3) Å, β = 92.08(1)°, V = 1695.2(5) Å^3, and D(calc) = 1.751 for Z = 4. Tellurium is bonded axially to two chlorines and equatorially to aryl carbon and carbon from the cyclohexyl portion of oxabicyclo[3.2.1]oct-4-yl in a pseudo-trigonal–bipyramidal arrangement having an equatorial lone pair of electrons. Bond lengths are Te—Cl(1) = 2.492(3) Å, Te—Cl(2) = 2.539(3) Å, Te—C(4) = 2.175(10) Å, and Te—C(9) = 2.090(10) Å.

Key words: organotellurium(IV), 3-cyclohexene-1-methanol, 3-cyclohexene-1,1-dimethanol.

Résumé : Les trichlorures d'aryltellure(IV) réagissent avec le 3-cyclohexène-1-méthanol et avec le 3-cyclohexène-1,1-diméthanol pour donner les dichlorures d'aryl (*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellure(IV) et d'aryl (*cis*-1-hydroxyméthyl-*trans*-6-oxabicyclo[3.2.1] oct-4-yl)tellure(IV). On a déterminé la structure du dichlorure de 2′,4′-diméthoxyphényl (*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellure(IV) par cristallographie de rayons X sur un cristal unique. Le composé $C_{15}H_{20}Cl_2O_3Te$, M_r = 446,8, cristallise dans le groupe d'espace monoclinique $P2_1/c$ avec a = 9,626 (2) Å, b = 15,768(5) Å, c = 11,176(3) Å, β = 92,08(1)°, V = 1695,2(5) Å^3 et $D_{(calc)}$ = 1,751 pour Z = 4. Le tellure est lié en position équatoriale à deux chlorures et en position axiale au carbone du groupe aryle et à celui de la portion cyclohexyle du groupe oxabicyclo[3.2.1]oct-4-yl dans une configuration pseudo-bipyramidale–trigonale ayant un doublet libre en position équatoriale. Les longueurs de liaison sont : Te—Cl(1) = 2,492(3) Å, Te—Cl(2) = 2,539(3) Å, Te—C(4) = 2,175(10) Å et Te—C(9) = 2,090(10) Å.

Mots clés : organotellure(IV), 3-cyclohexène-1-méthanol, 3-cyclohexène-1,1-diméthanol.

Introduction

Aryltellurium(IV) trichlorides undergo addition reactions with cycloalkenes to give aryl(*trans*-2-chloro-1-cycloalkyl)tellurium(IV) dichlorides (1–3). Similar reactions in the presence of an alcohol give aryl(*trans*-2-alkoxy-1-cycloalkyl)tellurium(IV) dichlorides as the result of electrophilic addition by aryldichlorotellurium(IV) and nucleophilic attack by alkoxy on the cyclic telluronium intermediates (3, 4). This paper describes reactions of aryltellurium(IV) trichlorides with 3-cyclohexene-1-methanol and 3-cyclohexene-1,1-dimethanol (Fig. 1), which contain alcoholic groups capable of intramolecular nucleophilic attack. The heterotricyclic[3.2.1]- nature of the products is established by NMR spectroscopy and by an X-ray crystallographic investigation of 2′,4′-dimethoxyphenyl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)-tellurium(IV) dichloride.

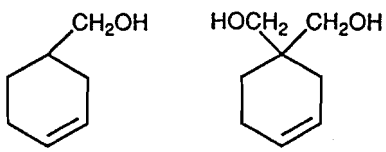
Fig. 1. 3-Cyclohexene-1-methanol and 3-cyclohexene-1,1-dimethanol.



Experimental

In a typical reaction, a mixture of 2,4-dimethoxyphenyltellurium(IV) trichloride (1.50 g, 4.0 mmol) and 3-cyclohexene-1-methanol (0.45 g, 4.0 mmol) in chloroform (50 cm^3) was boiled under reflux (3 h). The red mixture was filtered, shaken with charcoal, and refiltered. The colourless filtrate was evaporated under reduced pressure. Crystallization from light petroleum (bp 40–60°C) gave 2′,4′-dimethoxyphenyl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride (1.19 g, 2.7 mmol, 67%), mp 180°C. The colourless products are stable at room temperature and are soluble in organic solvents. Yields, melting points, and analytical data are summarized in Table 1.

Data collection, structural analysis, and refinement

A suitably sized crystal of 2′,4′-dimethoxyphenyl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride was mounted on a glass fibre. An Enraf–Nonius CAD4 four-circle diffractometer, λ(MoKα) = 0.70926 Å with an ω–2θ scan at 291 K was used to measure the unit cell dimensions and collect the data. The crystal and data collection parameters are listed in Table 2. The unit cell constants were obtained by a least-squares analysis of the diffractometer setting angles of 25 well-centered reflections in the range 2θ = 20–30°. The intensities were reduced to a standard scale using routine procedures (5). Lorentz and polarization corrections were applied and absorption corrections (6) were performed. Scattering factors for neutral atoms (7) were corrected for the real part of anomalous dispersion. All calculations and refinements were performed by SHELX-76 (8).

The systematically absent reflections confirmed the space group as $P2_1/c$. Positions of tellurium were determined from a Patterson map and the remaining non-hydrogen atoms were located in subsequent difference-Fourier syntheses. The structure was refined initially by a full-matrix least-squares procedure with independent isotropic temperature factors on the non-hydrogen atoms. Hydrogen atoms were placed in their geometrically calculated positions, d(C—H) = 1.08 Å. Absorption corrections were then applied. The final refinements with anisotropic temperature factors on the non-hydrogen atoms and individual isotropic temperature factors on the hydrogen atoms gave $R = 0.0462$ and $R_w = 0.0475$ for 1548 unique observed reflections, $I > 3.00\sigma(I)$. A 2-block matrix least-squares method was employed. The function minimized was $\Sigma(\omega|F_o| - |F_c|)^2$ where ω is the weight. No correction for extinction was applied. The final difference map had no recognisable features (maximum peak 0.57 e $Å^{-3}$). The figures were produced with CHEMGRAPH (9). The fractional atomic positional parameters and temperature factors of non-hydrogen atoms are listed in Table 3. Anisotropic thermal parameters for non-hydrogen atoms, a diagram showing thermal ellipsoids, and a table of atomic parameters for hydrogen atoms are available as supplementary material.[2]

Results

Aryltellurium(IV) trichlorides, $ArTeCl_3$ (Ar = *p*-$MeOC_6H_4$, *p*-$EtOC_6H_4$, *p*-$PhOC_6H_4$, 2,4-$(MeO)_2C_6H_3$, and 3,4-$(MeO)_2C_6H_3$), react with 3-cyclohexene-1-methanol or 3-cyclohexene-1,1-dimethanol in chloroform. Analyses and mass spectra of the products are consistent with addition followed by the elimination of hydrogen chloride and the formation of

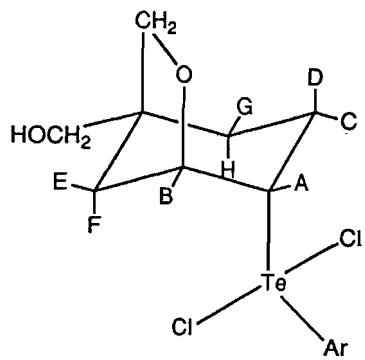
[a] U_{eq} is calculated as: $\{U_{11}(a^*.a)^2 + U_{22}(b^*.b)^2 + U_{33}(c^*.c)^2 + 2(U_{12}.a^*.b^*.a.b.\cos(\gamma) + U_{13}.a^*.c^*.a.c.\cos(\beta) + U_{23}.b^*.c^*.b.c.\cos(\alpha))\}/3$.

condensation products. NMR evidence indicates that the products are aryl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) derivatives. No traces of [2.2.2] heterotricyclic products were detected.

Mass spectra

The mass spectra of aryl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichlorides and aryl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichlorides are characterized by base peaks at M_r 111 and 141, respectively, and molecular ion peaks at the relative molecular mass minus the relative atomic mass of one chlorine atom. Other peaks show the loss of a second chlorine atom and fragments

Fig. 2. Diagrammatic representation of aryl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride with letters A–H assigned to cyclohexyl hydrogen atoms.



corresponding to ArTeCl, ArTe, ArCl, and Ar groups. The data are summarized in Table 4.

Proton NMR spectra

NMR spectra were recorded on a Varian VXR 400 spectrometer. Letters are assigned to the cyclohexyl hydrogens of aryl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride in Fig. 2 in order to assist the discussion of NMR spectra. Cyclohexyl H-CTe and H-CO protons are labelled A and B, respectively. Neighbouring geminal cyclohexyl methylene protons are C (*cis* to Te), D

Table 4. Mass spectra of aryl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichlorides and aryl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichlorides.

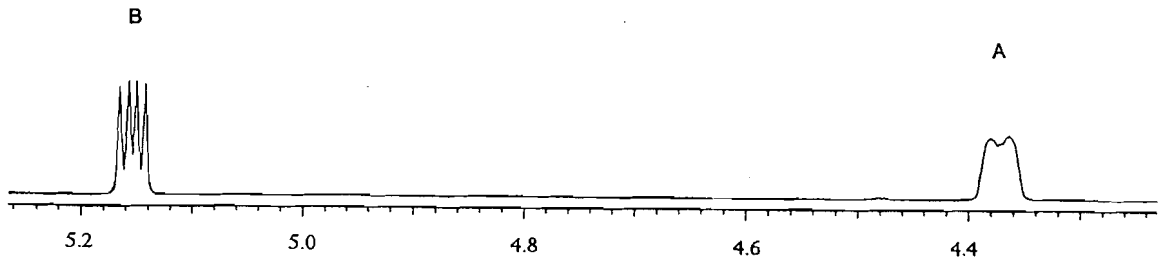
[a]Coupling constants could not be measured accurately.

Fig. 3. Cyclohexyl H-CTe (A) and H-CO (B) proton signals at 400 MHz for 2′,4′-dimethoxyphenyl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride in $CDCl_3$.



(*trans* to Te), E (*cis* to bridging OCH_2), and F (*trans* to bridging OCH_2). The remaining geminal cyclohexyl methylene protons are G (*cis* to bridging CH_2O) and H (*trans* to bridging OCH_2).

The signals for cyclohexyl H-CTe (A) and H-CO (B) protons differ in appearance from the well-resolved six- or eight-line multiplets in aryl(*trans*-2-alkoxy-1-cycloalkyl)tellurium(IV) dihalides (3) caused by strong coupling between *trans*-diaxial protons (^3J 10–12 Hz). Cyclohexyl A and B signals from 2′,4′-dimethoxyphenyl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride are illustrated in Fig. 3. The H-CTe (A) signal appears as two unresolved bands through equatorial–axial coupling, ^3J(A–D) ca.7 Hz, that are broadened by diequatorial coupling, ^3J(A–B) 3.2 Hz, ^3J(A–C) ca. 1 Hz. COSY spectra (described below) indicate further weak coupling with protons F and H. The cyclohexyl H-CO (B) protons appear as four lines through equatorial–axial coupling, ^3J(B–F) 6.0 Hz, and diequatorial coupling, ^3J(A–B) 3.2 Hz; diequatorial coupling with eclipsed proton E is not observed.

Chemical shifts and coupling constants for cyclohexyl A and B protons in aryl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellu-

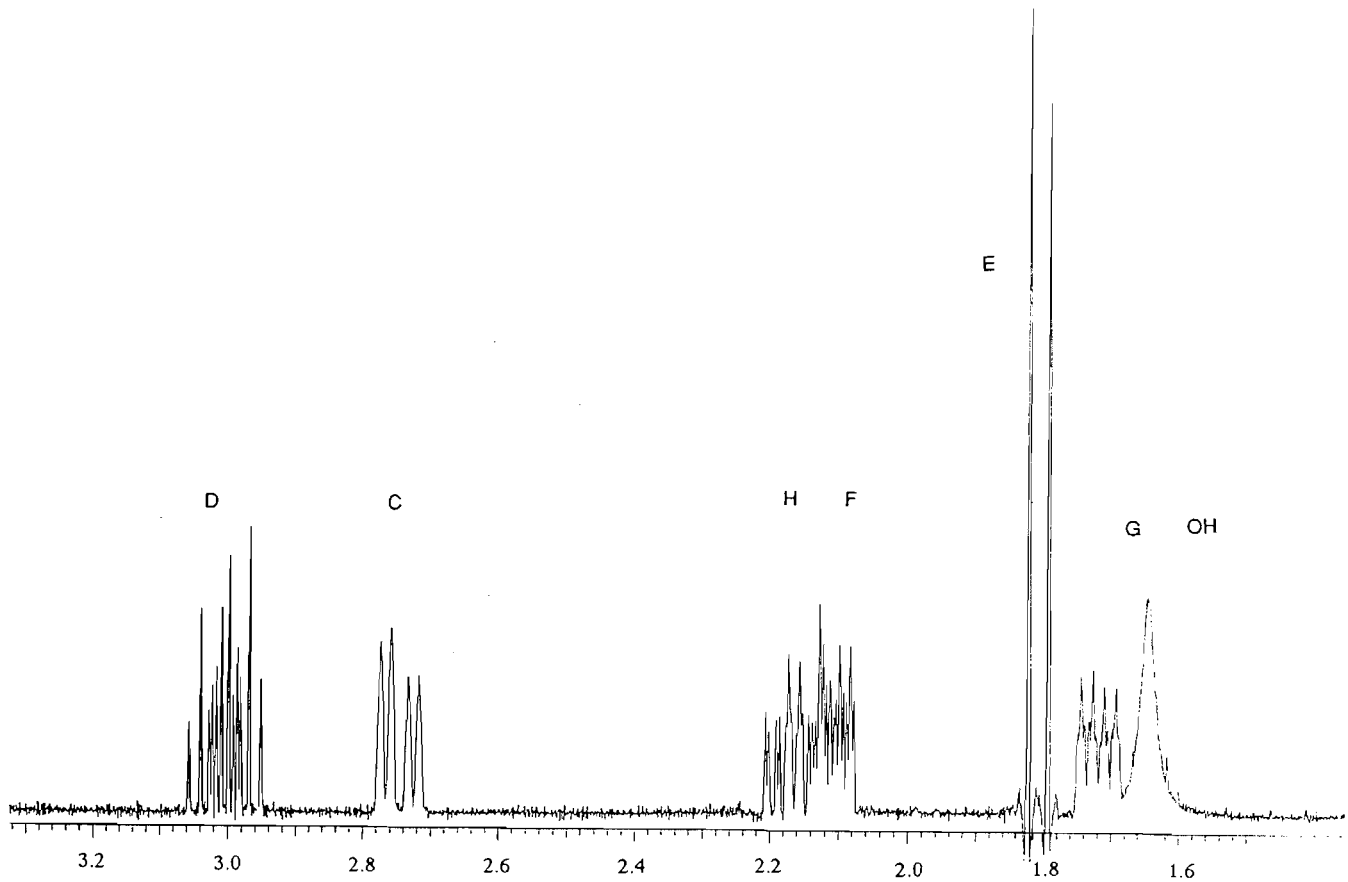
Fig. 4. Resolution-enhanced cyclohexyl methylene proton signals C–H at 400 MHz for 2′,4′-dimethoxyphenyl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride in $CDCl_3$.



rium(IV) dichlorides and aryl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichlorides are summarized in Table 5. Chemical shifts of A protons are similar to those in aryl(*trans*-2-chlorocyclohexyl)tellurium(IV) dichlorides but B protons appear at lower field than those in aryl(*trans*-2-chloro-1-cyclohexyl)tellurium(IV) dichlorides or aryl(*trans*-2-alkoxy-1-cycloalkyl)tellurium(IV) dichlorides (3). The coupling constants establish that A and B protons occupy *trans*-diequatorial positions and confirm that tellurium and oxygen occupy *trans*-diaxial positions in aryl(*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichlorides and aryl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo [3.2.1]oct-4-yl)tellurium(IV) dichlorides.

Resolution-enhanced signals from the three pairs of cyclohexyl geminal methylene protons C to H of 2′,4′-dimethoxyphenyl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride in Fig. 4 confirm the [3.2.1] bridging structure with a cyclohexyl chair conformation in solution. Equatorial proton C appears as four lines through geminal, ^2J(C–D) 16 Hz, and equatorial–axial coupling, ^3J(C–H) 7 Hz, broadened by weak diequatorial coupling, ^3J(A–C) ~ ^3J(C–G) 1 Hz. Axial proton D gives a 12-line signal (triplets of doublets of a doublet) through geminal, ^2J(C–D) 16 Hz, diaxial, ^3J(D–H) 12 Hz, and axial–equatorial coupling, ^3J(A–D) ~ ^3J(D–G) 7 Hz. The simplest signal is the doublet from equatorial proton E, which couples geminally, ^2J(E–F) 12 Hz, but not with eclipsed equatorial proton B. Axial proton F appears as four triplets through geminal, ^2J(E–F) 12 Hz, and axial–equatorial coupling, ^3J(B–F) 6 Hz, and diequatorial coupling with distant protons A and G, ^4J ca. 2 Hz. Equatorial proton G exhibits four lines through geminal, ^2J(G–H) 14 Hz, and axial–equatorial coupling, ^3J(D–G) 7 Hz, that are split into triplets through weaker coupling with equatorial proton C and distant proton F. Axial proton H undergoes geminal, ^2J(G–H) 14 Hz, diaxial, ^3J(D–H) 12 Hz, and axial–equatorial coupling, ^3J(C–H) 6 Hz, to appear as doublets of a broad-centred triplet. Further coupling with one bridging methylene proton, ^4J ca. 2 Hz, causes splitting of the four outer lines and broadening of the two inner bands.

Methylene proton signals from free $HOCH_2$ and bridging OCH_2 groups in the spectrum of *p*-ethoxyphenyl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium (IV) dichloride are illustrated in Fig. 5. Free methanolic methylene protons give the expected four-line signal, ^2J 11 Hz. One bridging OCH_2 methylene proton appears as a doublet, ^2J 8 Hz; the other appears as two pairs of doublets through further coupling with proton H, ^4J 2 Hz. Proton signals from aryl groups and their substituents resemble those in aryl(*trans*-2-chloro-1-cycloalkyl)tellurium(IV) dichlorides and aryl(*trans*-2-ethoxy-1-cycloalkyl)tellurium(IV) dichlorides (3).

A two-dimensional homonuclear shift correlated (COSY) spectrum of 2′,4′-dimethoxyphenyl(*cis*-1-hydroxymethyl-*trans*-6-oxabicyclo[3.2.1]oct-4-yl)tellurium(IV) dichloride confirms that the H-CTe (A) proton couples with cyclohexyl

C-Te slightly lower than C-O as shown in Table 6. Chemical shifts for cycloalkyl C-Te are similar to those in aryl(*trans*-2-chloro-1-cyclohexyl)tellurium(IV) dichlorides (3). The OCH_2 methylene carbons appear below bridging methylene carbons and free methanolic carbons. Cyclohexyl methylene carbons appear at high field.

Discussion

Mechanism

The proposed mechanism for reaction of an aryltellurium(IV) trichloride with 3-cyclohexene-1-methanol is illustrated diagrammatically in Fig. 6. Electrophilic attack by aryldichloro-

tellurium(IV) at the double bond produces a three-membered cyclic telluronium intermediate. Nucleophilic attack by methanolic oxygen with Walden inversion at carbon bonded to axial hydrogen is expected from the Furst–Plattner rule (see, for example, ref. 10). Ring opening gives the observed [3.2.1] tricyclic structure with tellurium and oxygen in adjacent diaxial positions. Postulated intermediates in reactions of aryltellurium(IV) trichlorides with 3-methylcyclohexene have tellurium and chlorine in similar diaxial positions, but ring inversion occurs so that tellurium and chlorine occupy diequatorial positions in aryl(*trans*-2-chloro-*trans*-3-methyl-1-cycloalkyl)tellurium(IV) dichlorides (11).

Structure

The molecule of 2′,4′-dimethoxyphenyl(*trans*-6-oxabicyclo-[3.2.1]oct-4-yl)tellurium(IV) dichloride is shown in Fig. 7. Tellurium has a pseudo-trigonal–bipyramidal configuration with four-coordinate tellurium bonded axially to two chlorines and equatorially to carbons from dimethoxyphenyl and oxabicyclo[3.2.1]oct-4-yl. Nonbonding contacts with tellurium avoid regions of equatorial nonbonding electrons. Long-range interactions between tellurium and chlorine from different asymmetric units, Te...Cl(2B) ($-x$, $-y$, $-z$) 3.771 Å, tie the molecules into the trigonal–bipyramidal arrangements of Fig. 8b.

Tellurium–chlorine bond lengths are Te—Cl(1) 2.492(3) Å and Te—Cl(2) 2.539(3) Å. The Cl(1)—Te—Cl(2) angle is

177.3(1)°. Tellurium–carbon bond lengths are Te—C(4) 2.175(10) Å and Te—C(9) 2.090(10) Å with Te—C(alkyl) longer than Te—C(aryl) (12). The C(4)—Te—C(9) angle is 100.5(4)°. These values are close to corresponding distances and angles in other diorganotellurium(IV) dichlorides (see, for example, ref. 13). The average cyclohexyl C—C bond length is 1.533 Å. The ring has a distorted chain conformation with C(3) at 0.439 Å above and C(8) at 0.899 Å below the plane through C(1), C(2), C(4), and C(5), which forms an angle of 109.26° with the plane through C(1), C(7), O(6), and C(5). Bridging distances are C(1)–C(7) 1.52(2) Å and O(6)–C(7) 1.444(14) Å. The average cyclohexyl C—C—C angle of 109.7°, smaller than 111.3° in cyclohexane (14), and the mean torsional angle of 54.7° are consistent with some flattening of the cyclohexyl ring caused by substituents (15). Selected interatomic distances, interbond angles, and torsional angles are given in Tables 7, 8, and 9, respectively.

Studies on the mechanism of chelate degradation in iron-based, liquid redox H_2S removal processes

Dian Chen, Arthur E. Martell, and Derek McManus

Abstract: Available data on the oxidation of nitrilotriacetic acid (NTA), ethylenedinitrilotetraacetic acid (EDTA), *N*-hydroxyethylethylenediaminetriacetic acid (HEDTA), and other aminopolycarboxylate chelating agents are reviewed and the intermediates and products of the oxidative degradation of each chelating agent are described and compared. The oxidation of these chelating agents occurs during the reoxidation of the ferrous chelate to the ferric chelate, during which a Fenton type side reaction occurs in which hydrogen peroxide is formed and which in turn generates the hydroxyl radical by reaction with ferrous ion. The site of oxidative attack by the hydroxyl radical on these ligands seems to be the $-CH_2-$ groups α to the carboxylate groups, as well as the $-CH_2-$ groups in the ethylene bridges between the nitrogens. The evidence for the implication of the hydroxyl radical as the active oxidant is discussed, and the use of phenyl-*tert*-butylnitrone (PBN) as the trapping agent for the hydroxyl radical is described. The use of chelating agents as Fe^{3+}/Fe^{2+} redox catalysts for the oxidation of H_2S to sulfur that are less reactive toward the hydroxyl radical is recommended.

Key words: chelate degradation, H_2S oxidation, nitrilotriacetic acid (NTA), ethylenedinitrilotetraacetic acid (EDTA), *N*-hydroxyethylethylenediaminetriacetic acid (HEDTA).

Résumé : On passe en revue les données disponibles sur l'oxydation des acides nitrilotriacétique, éthylènedinitrilotétraacétique et *N*-hydroxyéthyléthylènediaminetriacétique ainsi que d'autres agents aminopolycarboxyliques chélatants; dans chaque cas, on décrit et on compare les intermédiaires et les produits de la dégradation oxydante de chacun des agents chélatants. L'oxydation de ces agents chélatants se produit lors de la réoxydation du chélate ferreux en chélate ferrique alors qu'il se produit une réaction secondaire du type de Fenton au cours de laquelle il se forme du peroxyde d'hydrogène qui, à son tour, génère la formation du radical hydroxyle par réaction avec l'ion ferreux. Le site de l'attaque oxydante du radical hydroxyle sur ces coordinats semble être les groupes $-CH_2-$ en α des groupes carboxylates ainsi que les groupes $-CH_2-$ des ponts éthylènes entre les azotes. On discute des données suggérant l'implication du radical hydroxyle comme oxydant actif et on décrit l'utilisation de la phényl-*tert*-butylnitrone (PBN) comme agent de piégeage du radical hydroxyle. Pour l'oxydation du H_2S en soufre, il est recommandé d'utiliser, comme catalyseurs rédox Fe^{3+}/Fe^{2+}, des agents chélatants qui sont moins réactifs vis-à-vis des radicaux hydroxyles.

Mots clés : chélate dégradation, H_2S oxydation, acide nitrilotriacétique, acide éthylènedinitrilotétraacétique, acide *N*-hydroxyéthyléthylènediaminetriacétique.

[Traduit par la rédaction]

Introduction

The oxidation of H_2S to S_8 by oxygen may be represented by the overall reaction

$$[1] \quad H_2S + \tfrac{1}{2}O_2 \rightarrow \tfrac{1}{8}S_8\downarrow + H_2O$$

The oxygen also oxidizes H_2S further, resulting in the formation of soluble products such as thiosulfate and sulfate, which are not as conveniently separated as elemental sulfur. Formation of these undesirable products is to a large extent avoided by carrying out the reaction in two steps with an Fe(III), Fe(II) chelate as a redox catalyst. With the 2:1 nitrilotriacetic acid (NTA, H_3L)–Fe(III) as the catalyst system the reaction sequence would be as follows:

H_2S absorption and oxidation

$$[2] \quad H_2S + 2FeNTA \rightarrow \tfrac{1}{8}S_8 + 2FeNTA^- + 2H^+$$

Reoxidation of the chelate

$$[3] \quad 2FeNTA^- + \tfrac{1}{2}O_2 + H_2O \rightarrow 2FeNTA + 2OH^-$$

In practice the process is usually carried out industrially in two compartments, an absorber and an oxidizer, so that the H_2S and oxygen (or air) do not come into contact. Some mixing is unavoidable since the solution of the oxidized iron(III) chelate

is pumped into the absorber (along with a little dissolved oxygen) to be used over again.

The use of the Fe(III)–NTA chelate as a catalyst for the oxidation of H_2S to S_8 has recently been described (1). Since the data in the literature on the iron(III), (II)–NTA chelates was incomplete, a thorough investigation of this concentration-dependent chelate system was carried out, and the interrelationships of the 1:1 normal and hydroxy iron(III) complexes with the 2:1 chelate have now been described (2).

In this paper the investigation of other Fe(III, II) chelate systems as catalysts for the oxidation of H_2S are described. Since the main problem with the use of NTA is degradation of the ligand, similar considerations apply to the use of substitute ligands in place of NTA. The use of several stabilizers that slow the rate of NTA degradation is explored. Also, the possible role of hydroxyl radical in the oxidation of the organic ligands is described.

Experimental

Materials

The following materials were obtained in the highest purity available and were used without further purification: nitrilotriacetic acid trisodium salt (99%, Aldrich); H_2S (99.5%, Gas Analytical Service); catalase (Biomedicals, Inc., bovine liver, E.C. 1.11.1.6; sterile aqueous solution, activity, 40 000 units per milligram solid, unit definition, one unit decomposes one micromole of H_2O_2 per minute, 25°C, pH 7.0, approx. 30 000 units per millilitre); (ethylenedinitrilo)tetraacetic acid disodium salt (EDTA) (Reagent A.C.S., Matheson, Coleman & Bell); *N*-hydroxyethylethylenediaminetriacetic acid (HEDTA) (98%, GFS Co.); 2,6-pyridinedicarboxylic acid (99%, Aldrich); 2,6-pyridinedimethanol (98%, Aldrich); iminodiacetic acid, disodium salt monohydrate (reagent ACS, Aldrich); *N*-(2-hydroxyethyl)iminodiacetic acid (98%, Aldrich).

2,6-Pyridinediacetic acid (PDA) was synthesized by a modification of the method of Couturier and Petitfaux (3).

2,6-Di(bromomethyl)pyridine

This compound was synthesized by a modification of the method of Baker et al. (4). A 25.0 g sample of 2,6-pyridinedimethanol and 250 mL 48% HBr were refluxed for 18 h. The solvent was removed by vacuum distillation. The residue was refluxed with 120 mL 48% HBr for another 18 h. The solvent was again removed by vacuum distillation and the product was dried at 120°C under vacuum for 2 h. NMR measurement of the product showed it to be pure. The yield is quantitative. ^{1}H NMR (D_2O, ppm): 8.0 (t, 1H, pyridine), 7.5 (d, 2H, pyridine), 4.3 (s, 4H, CH_2).

2,6-Di(cyanomethyl)pyridine

This compound was synthesized by following the method of Baker et al. (4). A mixture of 2,6-di(bromomethyl)pyridine hydrobromide (10.0 g), potassium cyanide (8.5 g), and water (105 mL) was heated at 80–90°C for 5 h. After the mixture was cooled, 50 mL of water was added and the product was extracted with $CHCl_3$. The organic phase was dried with anhydrous $MgSO_4$. The solvent was removed under reduced pressure and the residue was dried at 50°C under vacuum for 2 h. The product was recrystallized from ethanol to give a final yield of 2.8 g (56%). ^{1}H NMR ($CDCl_3$): 7.82 (t, 1H, pyridine), 7.45 (d, 2H, pyridine), 3.96 (s, 4H, CH_2). ^{13}C NMR ($CDCl_3$): 150.7, 138.6, 121.5 (pyridine), 116.7 (CN), 26.3 (CH_2).

2,6-Pyridinediacetic acid

A mixture of 2,6-di(cyanomethyl)pyridine (10.0 g) and concentrated HCl (12 M, 160 mL) was refluxed for 24 h. The excess HCl and solvent were removed and the residue was dissolved in 120 mL water. Activated carbon (2 g) was added to the solution and the mixture was heated to 50°C with stirring for 30 min. It was then filtered and the pH was adjusted to 2.1 by the addition of HCl. White crystals formed after the solution was allowed to stand near 0°C for 4 h. The product, 2,6-pyridinediacetic acid, was filtered off and washed with water until no chloride remained in the filtrate. The product was dried over P_2O_5 under vacuum for 48 h. The weight of the white product obtained was 9.1 g (73%). ^{1}H NMR (D_2O): 8.34 (t, 1H, pyridine), 7.76 (d, 2H, pyridine), 4.08 (m, 1.6 H, CH_2). The proton NMR measurements show that the integration of the H in CH_2 gives only about 1.6 H, far less than 4, which is the theoretical number of H atoms. This does not mean that the product is impure, because in the D_2O solution the hydrogen of the CH_2 groups slowly exchanges with deuterium, so that the integration of hydrogen is less than 4. This interpretation was confirmed by a kinetic investigation. The peak at 4.08 (CH_2) almost disappears after the D_2O solution is allowed to stand for 24 h.

^{13}C NMR (D_2O): 171.4, 148.4, 147.4, 127.5 ppm. The results of the ^{13}C NMR measurements show that there is no single peak for carbon in the CH_2 group. Because the deuterium exchanged with the hydrogen and the deuterium couples with the carbon in the CH_2 group, the ^{13}C resonance of the latter appears only as a small multiple peak. Since no CN peak (carbon in the CN group) was found in the ^{13}C NMR, the hydrolysis of 2,6-(cyanomethyl)pyridine to 2,6-pyridinediacetic acid was considered to be complete. Anal. calcd. for $C_9H_9NO_4 \cdot 0.5H_2O$: C 52.95, H 4.94, N 6.86; found: C 53.00, H 5.02, N 6.80.

Redox reaction equipment and conditions

The redox reaction was carried out in a two-chambered glass apparatus described previously (1), and the pH and redox potential in both the absorber and oxidizer were monitored. The H_2S flow rate was maintained at 2.0 mL min^{-1} and the air flow rate was regulated at 1.0 L min^{-1}. The temperature was maintained at 25.0 ± 1.0°C throughout.

HPLC equipment

An IBM L.C. pump No. 771008 equipped with a chromatography accessory, an UV–visible spectro monitor 3100 (LDC Analytical), and a chart recorder 6885 (Kipp and Zonen) were used.

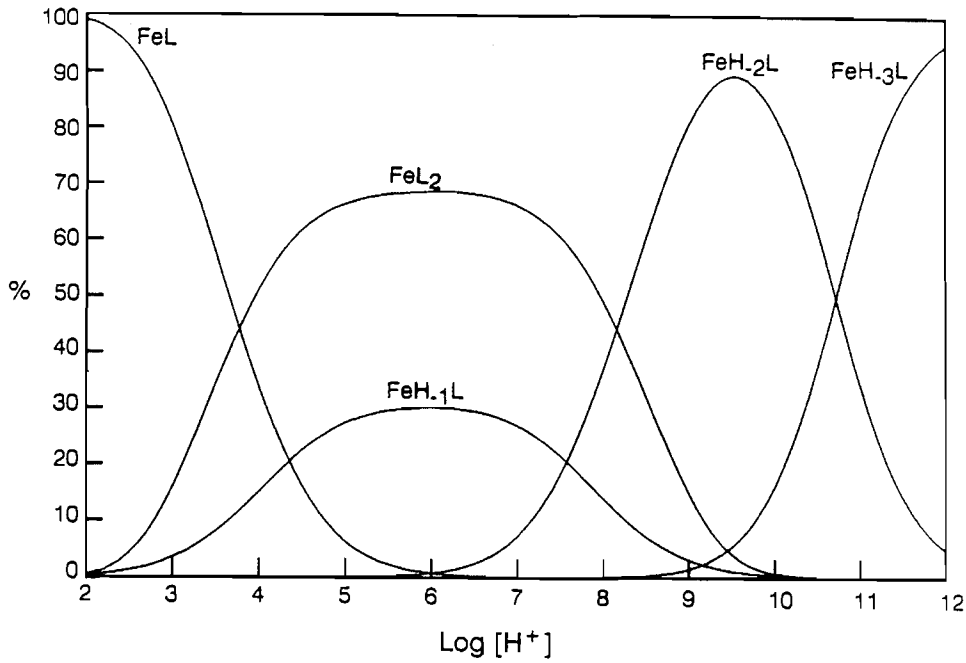
NMR spectra

The proton and ^{13}C NMR spectra were recorded with a Varian X1-200 NMR spectrometer, and chemical shifts are reported in ppm. The internal standard used for NMR measurements in $CDCl_3$ is TMS (tetramethylsilane) and in D_2O is HOD. The ESR spectra were obtained from a Bruker ESR 300 spectrometer.

HPLC analysis and operating conditions

The concentrations of all ligands and intermediates were ana-

Fig. 1. Ten millimolar $[Fe(III)]_0$ (10 mM) and $[NTA]_0$ (20 mM) species as a function of p[H] with % based on total Fe(III) present. Only metal-ion-containing species are plotted. H_{-n} represents $(OH)_n$.



lyzed by HPLC by the method previously described for NTA (1).

The procedure for the preparation of an iron-free sample of pyridine is the same as previously described for NTA (1). The operating conditions used are as follows: column: 250 mm, 4.1 mm; packing, Versapack C_{18}, 10 μm; mobile phase, 18% methanol, 77% water, 4.1% acetic acid; flow rate 1.5 mL min^{-1}; detector UV 260 nm, sample 20 mL, recorder 20 mV full scale, chart speed 0.5 cm min^{-1}.

Calibration of HPLC analysis

The quantitative calibrations for the HPLC analysis of all ligands and intermediates were carried out with varying amounts of known samples of these compounds. The peak heights at the indicated amplification settings were plotted vs. concentration of the species. The linear nature of these plots indicated accurate HPLC determinations of these molecular species over a considerable range of concentration.

Results and discussion

On the basis of the stability constants, and metal chelate constants described previously (2), the distribution curves in Fig. 1 may be derived for the Fe(III)–NTA chelate system for the concentrations employed (0.018 M Fe(III) and 0.036 M NTA). From Fig. 1 it is seen that the ferric–NTA system at the operating pH of 8.5 is quite complex, consisting of about 6% $FeOHL^-$, 64% $Fe(OH)_2L^{2-}$, and 30% FeL_2^{3-} (where NTA is H_3L). Under these conditions the degradation scheme proposed for NTA is represented by the following sequence:

Sequence 1

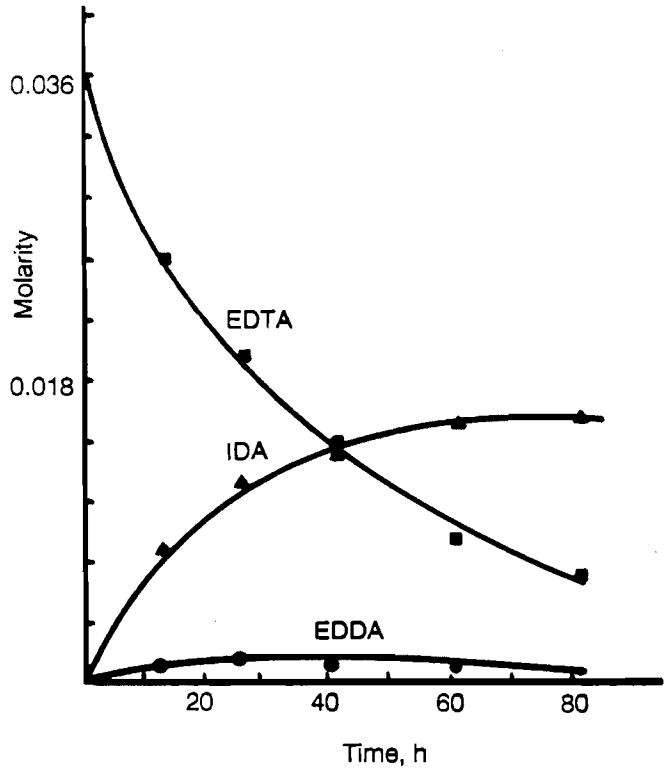
Fig. 2. Degradation of Fe(III)–EDTA at pH 8.5 and 25.0°C; H_2S flow rate 2.0 mL/min (EDTA 0.036 M, Fe(III) 0.018 M).



All of the intermediates shown above, and NTA itself, were quantitatively analyzed by HPLC. The degradation was slow but progressive, with about 80% of the NTA being oxidized in 100 h.

Degradation of EDTA

The degradation of EDTA, illustrated in Fig. 2, shows that over 80% of the EDTA was oxidized in 80 h, and that iminodiacetic acid (IDA) and ethylenediaminediacetic acid (EDDA) were quantitatively determined by HPLC as intermediates in the oxidation process. The following degradation scheme represents a reasonable sequence of oxidation products.

All of the oxidation intermediates shown in sequence 2 equations below are reasonable, being formed by hydroxylation of one of the CH_2 groups, either on the ethylene bridge or side-chain acetate groups. Following hydroxylation, the aldehyde formed by hydrolytic cleavage (not shown) is rapidly converted to the corresponding carboxylate, NTA, or oxalate anions. The NTA would be expected to degrade in turn, as described above. The oxidation and cleavage of each acetate group would be expected to form oxalate ion but, for reasons of clarity, are not shown in the above scheme. The intermediates found and measured quantitatively by HPLC are IDA and symmetrical ethylenediaminediacetic acid (S-EDDA), as indicated by Fig. 2. No NTA was found. The end products of degradation, CO_2 and NH_4^+, are not shown.

The degradation of HEDTA and the rate of formation of IDA are shown in Fig. 3. The formation of IDA can occur by oxidation of HEDTA to EDTA, followed by degradation as described above, or by direct oxidative cleavage of the ethyl-

ene bridge, as indicated by the following sequence of reactions. (sequence 3)

As indicated by Fig. 3, the oxidative degradation of HEDTA is relatively rapid with only 10% of the ligand left after 70 h. A comparison of the relative rates of degradation of NTA, EDTA, and HEDTA, under the operating conditions of pH 8.5 and 0.018 M Fe(III) concentration, is illustrated in Fig. 4. From the plots presented it is apparent that NTA is by far the superior ligand. Since it is also the least expensive, it is the ligand of choice now being used to form the Fe(III), Fe(II) catalytic system for the oxidation of H_2S to S_8.

The 2:1 Fe(III) chelate of 2,6-pyridinedicarboxylic acid (dipicolinic acid) was used as the catalyst for the oxidation of H_2S to S_8 by air, under conditions similar to the tests on NTA, EDTA, and HEDTA, described above, except the pH had to be kept at 6.0 or lower. No measurable degradation was found to occur in a 100 h period. (There is the possibility that the pyridine ring was hydroxylated during this time period but no appreciable effect on the redox reaction was observed.) The lack of oxidative degradation was considered remarkable; however, dipicolinic acid does not form a sufficiently stable iron(III) chelate to keep it from precipitating as $Fe(OH)_3$ at pH

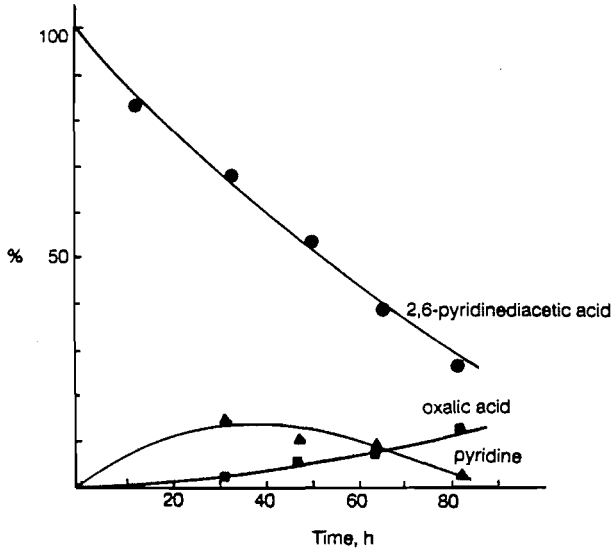

Fig. 6. Degradation of Fe(III) – *N*-(2-hydroxyethyl)iminodiacetic acid at pH 8.5. H_2S flow rate 2.0 mL/min. 100% *N*-(2-hydroxyethyl)iminodiacetic acid = 0.036 M (Fe(III) 0.018 M).

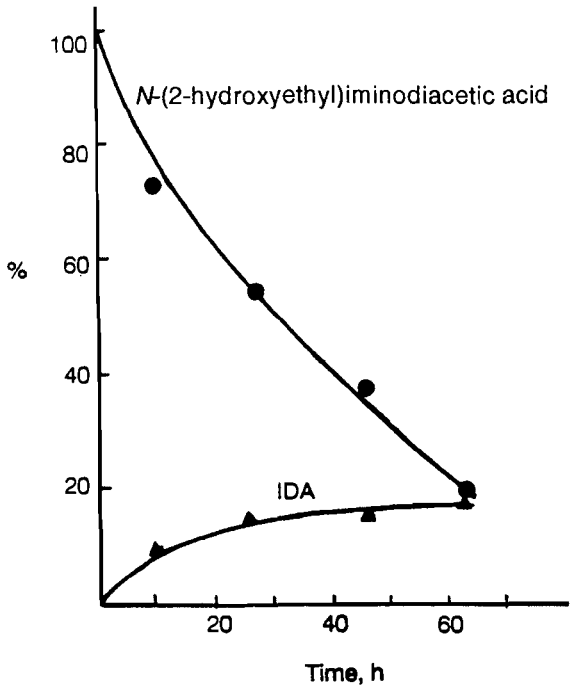

8.5. Therefore the absorption of H_2S gas into the aqueous system would be slowed down and this catalyst system was thus considered unsatisfactory.

Because 2,6-pyridinedicarboxylic acid does not degrade, but does not form a stable enough iron(III) chelate, we decided to investigate a closely related pyridine-containing ligand, which forms more stable Fe(III) chelates: 2,6-pyridinediacetic acid. This new chelating agent has been synthesized and it forms a 2:1 iron(III) chelate that does not precipitate at pH 7.0. The degradation run was therefore made at pH 7.0, and is illustrated in Fig. 5. The rate of degradation is seen to be fairly rapid, with the formation of both pyridine and oxalate in the oxidation process. Oxidative degradation of the ligand probably involves the following sequences of reactions. It is noted that the pyridine ring is also probably hydroxylated.

In the oxidative degradation sequence shown below for EDTA and HEDTA, two of the intermediates are chelating agents that form stable iron(III) complexes, *N*-hydroxyethyliminodiacetic acid (HIDA) and IDA. In fact HIDA has been used as a sequestering agent for Fe(III) in alkaline solution. Figures 6 and 7 show that these chelating agents also undergo oxidative degradation at rates comparable to those indicated above for chelating agents such as NTA, EDTA, and HEDTA.

The use of radical scavengers

A number of additives that function as radical scavengers have been used to slow down (or prevent) radical-induced oxidative degradation. The added material reacts with free radicals, thus preventing them from attacking, hydroxylating, and thus

degrading the organic ligand. There are many such additives that may be used. One of the simplest of all is the chloride ion. Figure 8 shows the beneficial effect of sodium chloride on the rate of degradation of NTA. Even more dramatic effects can be achieved with imidazole and benzoic acid, as Figs. 9 and 10 indicate. (Benzoic acid is discussed in more detail below.) A very effective and inexpensive free radical scavenger is thiosulfate ion, usually supplied as sodium thiosulfate. Figure 11 shows that thiosulfate reduces the rate of degradation of NTA dramatically — almost by an order of magnitude. In the intro-

duction it was indicated that some thiosulfate is generated as a by-product of the H_2S oxidation process, and this would further slow down NTA degradation. Alkali metal thiosulfate is very widely added as a radical scavenger to protect the NTA (or other chelating agent) used as a catalyst for the oxidation of H_2S to S_8 by air (5).

Implication of hydroxyl radical

The radical scavengers described above react with many free radical intermediates and thus slow down the free radical attack on the chelating agent employed. While they would certainly react with hydroxyl radical, they are for the most part nonspecific reagents and their protective effects do not demonstrate the involvement of the hydroxyl radical. The use of catalase is somewhat different, since its function is simply to destroy H_2O_2 by disproportion to oxygen and water, thus slowing down or preventing the formation of hydroxyl radical. Figure 12 shows that catalase does slow down the oxidative degradation of NTA, thus indicating that the hydroxyl radical (6) is the active oxygen species responsible for the oxidation degradation of NTA.

Benzoic acid was used as a probe to explore the role of the hydroxyl radical in the degradation process. Figure 10 shows that not only does the benzoic acid greatly slow the degradation of NTA, but that the benzoic acid degrades much more rapidly (due to hydroxylation) than does NTA. Hydroxylation of benzoic acid produces a mixture of *o*-, *m*-, and *p*-hydroxybenzoic acids (sequence 5), and as indicated by the HPLC

Fig. 12. Degradation of Fe(III)–NTA with catalase (catalase solution added at a dilution of 1:100) at pH 7.0 and 25.0°C; H_2S flow rate 2.0 mL/min (NTA 0.036 M, Fe(III) 0.018 M).

Sequence 5

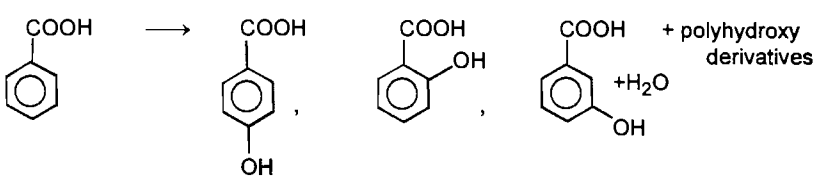

Fig. 14. ESR spectrum of the reaction product of Fe(II)–NTA with H_2O_2 at pH 8.5.

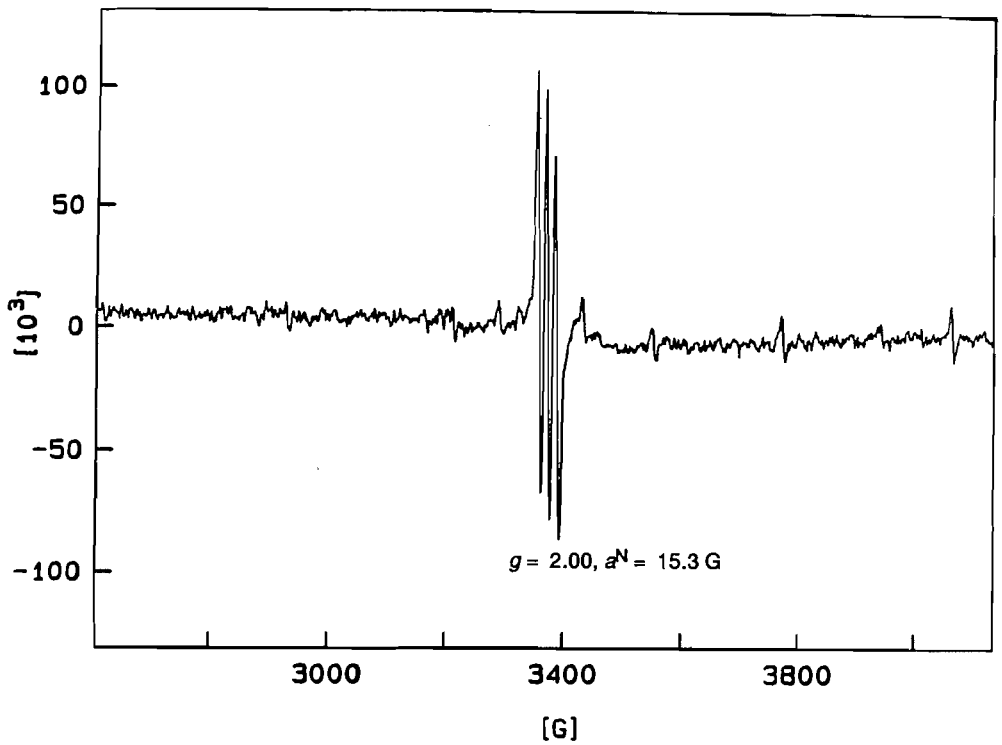
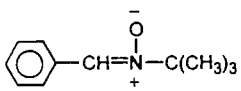


analysis illustrated by Fig. 13. The formation of these hydroxylation products is taken as evidence for the involvement of the hydroxyl radical, as was done by Grinstead (7). There was also evidence for further hydroxylation of benzoic acid in the TLC analysis of reaction products, showing that 2,5- and 2,3-dihydroxybenzoic acids were also formed.

ESR measurements

To further confirm the formation of the hydroxyl radical, phenyl-*tert*-butylnitrone was used as a spin trap and the radical that it generated by hydroxylation by the ·OH radical was detected by its ESR spectrum.

PBN



phenyl-*tert*-butylnitrone (PBN)

The control experiment was carried out on a solution of Fe(II)–NTA (Fe(II) 0.030 M, NTA 0.060 M) (5 mL) mixed with a small amount of 30% H_2O_2 and 30 mg PBN. The pH of the solution was adjusted to 8.5 and the ESR spectra of this solution measured immediately at room temperature gave the ESR spectrum illustrated in Fig. 14. The results show that the Fe(II)–NTA reacts with H_2O_2 to form a radical that reacts with PBN to give rise to ESR peaks at $g = 2.00$ and $a^N = 15.3$ G ($g = 2.006$, $a^N = 15.3$ G) (8). To probe the role of ·OH in the degradation of NTA, a solution of Fe(III)–NTA (Fe(III) 0.030 M, NTA 0.060 M) and PBN (saturated solution) was treated with H_2S and air for 60 min at pH 8.5. The ESR measurement of the reaction solution at room temperature showed that an ESR peak appeared at $g = 2.00$ and $a^N = 15.3$ G (Fig. 15). The new ESR peak had the same characteristics as the one described in the control experiment, and is taken as evidence that the hydroxyl radical was generated during the redox reaction.

Assuming that the oxidative degradation of the chelating agent is initiated by the hydroxyl radical, the following sequence of reactions is now proposed, with the use of NTA as the chelating agent:

[4] $2FeNTA^- + O_2 + 2H_2O \rightarrow 2FeNTA + H_2O_2 + 2OH^-$

[5] $FeNTA^- + H_2O_2 \rightarrow FeNTA + OH^- + {}^{\cdot}OH$

[6] $R^1R^2\overset{+}{N}HCH_2COO^- + {}^{\cdot}OH \rightarrow R^1R\overset{+}{N}H\dot{C}HCOO^- + H_2O$

[7] $R^1R^2\overset{+}{N}H\dot{C}HCOO^- + H_2O + FeNTA \rightarrow R^1R^2\overset{+}{N}H\underset{\displaystyle OH}{\underset{|}{C}}HCOO^- + FeNTA^- + H^+$

[8] $R^1R^2\overset{+}{N}H\underset{\displaystyle OH}{\underset{|}{C}}HCOO^- \rightarrow R^1R^2\overset{+}{N}H_2 + OHCCOO^-$

[9] $OHCCOO^- + \frac{1}{2}O_2 \rightarrow {}^-OOCCOO^- + H^+$

[10] ${}^-OOCCOO^- + 2H^+ + \frac{1}{2}O_2 \rightarrow 2\,CO_2 + H_2O$

$R^1 = R^2 = CH_2COO^-$ NTA

$R^1 = H, R^2 = CH_2COO^-$ IDA

$R^1 = R^2 = H$ glycine

Other chelating agents described in this paper are presumed to undergo similar degradation reactions, the point of initial attack being the CH_2 groups in the acetate side chain or in the ethylene bridge. It is noted that dipicolinic acid, which does not have such methylene groups, degrades at a much slower rate (or not at all). Apparently degradation of the ligand by hydroxylation of the aromatic ring occurs at a much slower rate than does a ligand with readily hydroxylated methylene groups.

The activation of H_2O_2 by Fe(II) chelates (Fenton chemistry) in aqueous solution has been described (9, 10).

$$Fe(II)L^- + H_2O_2 \rightarrow Fe(III)L + OH^- + OH^{\cdot}$$

Such solutions have been shown to react as oxidants with various substrates in the same way as does the hydroxyl radical generated from Fe^{2+} and H_2O_2 without a chelating agent present. In this work the formation of H_2O_2 is indicated as an intermediate by noting that catalase reduced the rate of degradation of NTA. As explained above, H_2O_2 is an intermediate that is required to produce the hydroxyl radical.

Sugimoto and Sawyer (11) reported that in nonaqueous solution the activation of H_2O_2 by Fe(II) for the catalytic and selective oxygenation of hydrocarbon substrates may occur via non-Fenton chemistry pathways. Numerous studies have proposed high-valent iron-oxo intermediates, such as FeO^{3+} (formally Fe^{V}), ferryl complexes, $(L)Fe^{IV}{=}O$ or $(L^{\cdot+})Fe^{IV}{=}O$ (12–16), and $(L)_nFe^{IV}(OH)(OOH)$ (17).

The oxidant that is responsible for the degradation of NTA and other ligands is tentatively considered to be the hydroxyl radical and not a high-valent iron-oxo species. The following factors were considered in coming to this conclusion: (1) The Fe(III)–NTA redox reaction takes place in aqueous media. (2) The oxidation product of H_2S is S_8. If the oxidizing species were an iron-oxo complex, the oxidation product of H_2S would be H_2SO_4, not S_8. (3) The hydroxylation products of benzoic acid are the same as those produced by the $^{\cdot}OH$ radical generated without a chelating agent present (18, 19). (4) The addition of free radical scavengers ($Na_2S_2O_3$, benzoic acid, etc.) slows down the degradation of NTA while there is no effect of these scavengers when the oxidizing species are high-valent iron-oxo compounds (14). (5) ESR measurement of the degradation of Fe(III)–NTA with the trapping agent shows that a new peak appears at $g = 2.00$ and $a^N = 15.3$ G. A similar ESR spectrum generated by Fe(II)–NTA and H_2O_2 is considered due to the hydroxyl radical. (6) The fact that the rate of degradation of NTA increases as the pH is lowered correlates with increased rate of generation of hydroxyl radical as the pH is lowered.

Further work on the development of iron chelate systems as catalysts for the oxidation of H_2S to S_8 will focus on ligands that do not have methylene groups that undergo facile oxidative attack, and on the possible elimination of the hydroxyl radical, which has been identified as the active oxidant in the degradation of the chelating agent.

Antiferromagnetism and metamagnetism in 1,4-diazine and pyridine complexes of nickel(II)

Tom Otieno and Robert C. Thompson

Abstract: Several nickel(II) complexes containing pyridine (py), pyrazine (pyz) or methylpyrazine (mepyz) have been synthesized and characterized by vibrational and electronic spectroscopy, differential scanning calorimetry, and magnetic susceptibility studies to cryogenic temperatures. A comparison of the magnetic properties of the polymeric diazine-bridged complexes, $Ni(pyz)_2X_2$ (X = Cl or NO_3), $Ni(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$, $Ni(mepyz)(NO_3)_2$, and $Ni(pyz)_3(CH_3SO_3)_2.CH_3OH$ with those of the related monometallic systems, $Ni(py)_4X_2$ (X = Cl, $p\text{-}CH_3C_6H_4SO_3$ or CH_3SO_3) and $Ni(mepyz)_4(NO_3)_2.H_2O$ provides evidence for weak antiferromagnetic coupling between metal centers mediated by bridging diazine ligands in the former group of compounds. The magnetic properties were analyzed employing a model for $S = 1$ which takes into account zero-field splitting and employs a molecular field term to account for weak magnetic exchange. The compounds $Ni(pyz)Cl_2$ and $Ni(py)Cl_2$ show metamagnetic behaviour with critical fields of 13 and 2 kOe, respectively, at 2 K. In these compounds nickel ions, linked in chains by bridging chlorides, exhibit intrachain ferromagnetic and interchain antiferromagnetic exchange. In $Ni(pyz)Cl_2$ bridging pyrazine ligands are considered to provide the pathway for the antiferromagnetic coupling resulting in a high critical field.

Key words: nickel(II), pyrazine, pyridine, complexes, metamagnetism, antiferromagnetism.

Résumé : On a synthétisé plusieurs complexes de nickel contenant la pyridine (py), la pyrazine (pyz), la méthylpyrazine (mepyz) et on les caractérisés par spectroscopie vibrationnelle et électronique, par calorimétrie à balayage différentiel et par des études de susceptibilité magnétique à des températures cryogéniques. Une comparaison des propriétés magnétiques des complexes polymères avec la diazine en position de pont, $Ni(pyz)_2X_2$ (X = Cl ou NO_3), $Ni(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$, $Ni(mepyz)(NO_3)_2$, et $Ni(pyz)_3(CH_3SO_3)_2.MeOH$ avec ceux des systèmes monométalliques apparentés $Ni(py)_4X_2$ (X = Cl, $p\text{-}CH_3C_6H_4SO_3$ ou CH_3SO_3) et avec $Ni(mepyz)_4(NO_3)_2,H_2O$, indique dans le premier groupe de composés, l'existence d'un faible couplage antiferromagnétique entre les centres métalliques par l'intermédiare des ligands diazine en position de pont. On a analysé les propriétés magnétiques en utilisant un modèle $S = 1$ qui tient compte du dédoublement au champ zéro et qui utilise un terme de champ moléculaire pour tenir compte du faible échange magnétique. Les composés $Ni(pyz)Cl_2$ et $Ni(py)Cl_2$ présentent un comportement métamagnétique à des champs critiques de 13 et de 2 respectivement à 2 K. Dans ces composés les ions nickel, liés en chaîne par les chlorures en position de pont, subissent un échange ferromagnétique entre les chaînes voisines et un échange antiferromagnétique à l'intérieur d'une chaîne. On pense que dans le composé $Ni(pyz)Cl_2$, les ligands pyrazines en position de pont fournissent une voie d'accès au couplage antiferromagnétique provoquant un champ critique élevé.

Mots cles : nickel(II), pyrazine, pyridine, complexes, métamagnétisme, antiferromagnétisme.

[Traduit par la rédaction]

Introduction

Extensive studies on 1,4-diazine complexes of copper(II) (1–9) and more recently iron(II) (10–13) have demonstrated the potential of pyrazine (pyz), and its C-substituted derivatives, to bridge metal centres and form one-dimensional linear chains and two-dimensional square lattice extended arrays. Two-dimensional hexagonal and three-dimensional diamond-like lattices have also been observed in copper(I) complexes (14). Of particular interest is the ability of these ligands to mediate magnetic exchange in complexes where the metal is in a paramagnetic ground state. The copper, d^9, and iron, d^6, studies have provided several examples of systems in which the metals are coupled antiferromagnetically. The magnitude of the coupling has been related to structural features such as metal–ligand distance and the orientation of the plane of the bridging ligand with respect to the metal/ligand chromophore, the latter affecting the degree of overlap between the ligand π-orbitals and the magnetic orbital(s) on the metal (2, 4, 7).

A better appreciation of the extent to which 1,4-diazine ligands mediate magnetic exchange in extended arrays

Received August 25, 1994.

requires the investigation of other d^n configurations and we report here our studies on some nickel(II), d^8, complexes. Previous studies on such systems include a low-temperature magnetic susceptibility study on $Ni(pd)_2(dmpyz)$ (pd = $CH_3COCHOCCH_3$, dmpyz = 2,5-dimethylpyrazine) which revealed weak antiferromagnetic exchange (15) and high temperature only susceptibility studies on $Ni(pyz)_2Cl_2$ (16). To extend the range of known and characterized compounds of this type we examined the magnetic properties of the complexes formed in the solid state from reactions of pyrazine and methylpyrazine (mepyz) with nickel(II) nitrate, methanesulphonate, and *p*-toluenesulphonate.These particular polyatomic anions were chosen, in part, because earlier work had established infrared spectral criteria for coordination modes of these anions. Hence it was anticipated that infrared data together with electronic spectral data on these complexes could be used profitably in their structural characterization. This is an important consideration in view of the difficulties encountered here and in previous work in obtaining nickel(II) 1,4-diazine complexes in single crystal form suitable for X-ray diffraction studies. Further characterization of the previously studied $Ni(pyz)_2Cl_2$ and $Ni(pyz)Cl_2$, including susceptibility measurements to cryogenic temperatures, are also reported here. In addition, an examination of the low-temperature magnetic behaviour of the related chloro-bridged pyridine complex, $Ni(py)Cl_2$ (17), was prompted by our studies on $Ni(pyz)Cl_2$ which indicated that bridging chloro ligands are mediating magnetic exchange in this compound.

Zero-field splitting of the $^3A_{2g}$ ground term in octahedral nickel(II) complexes can significantly affect the magnetic properties, particularly at very low temperatures (18). To assess the magnitude of this effect in complexes of the type being studied here, magnetic studies are required on monometallic systems in which the probability of intermolecular exchange is minimized. For this purpose we measured low-temperature susceptibilities of the pyridine complexes, $Ni(py)_4X_2$ (where X = Cl, CH_3SO_3, and p-$CH_3C_6H_4SO_3$).

Experimental

Syntheses

All chemicals were at least reagent grade quality and were used without further purification. Although $Ni(pyz)Cl_2$ and $Ni(py)Cl_2$ are sufficiently air-stable that manipulations can be carried out in the atmosphere, samples were stored in vials in a desiccator. The rest of the complexes are hygroscopic and were handled and stored in a nitrogen atmosphere glove box. Since all the metal salts used as reactants were hydrates the dehydrating agent 2,2-dimethoxypropane (2,2-dmp) was routinely added to the solvents.

Nickel(II)-methanesulfonate and -paratoluenesulfonate are not available commercially and were prepared as hydrated salts from nickel(II) chloride hexahydrate and the corresponding silver(I) sulfonate following the literature procedure for the preparation of $Cu(p\text{-}CH_3C_6H_4SO_3)_2$ (19). Heating the solid products to temperatures of up to 140°C for several hours resulted in only partial dehydration, as indicated by the decreased intensity of the infrared bands assigned to OH vibrations. $Ni(py)_4Cl_2$ and $Ni(pyz)_2Cl_2$ were prepared by literature methods (20, 21) and had satisfactory microanalytical results.

Many of the complexes were prepared by a general method in which the appropriate binary nickel(II) salt dissolved in 4–12 mL of methanol containing about 10% v/v 2,2-dmp was added to an excess of the ligand. In the case of pyrazine, the addition was to ligand dissolved in about 5 mL of the methanol/2,2-dmp solvent. The solid products that resulted were isolated by filtration and then washed and dried as described below.

Tetrakis(pyridine)nickel(II) methanesulfonate, $Ni(py)_4(CH_3SO_3)_2$

Prepared by the general method using hydrated nickel(II) methanesulfonate (0.639 g, ~2.6 mmol) and 50 mmol pyridine. The blue precipitate was washed with small amounts of diethylether and dried *in vacuo* for 1.75 h. Anal. calcd. for $NiC_{22}H_{26}N_4S_2O_6$: C 46.74, H 4.64, N 9.91; found: C 46.63, H 4.77; N 10.01.

Tris(pyrazine)nickel(II) methanesulfonate, methanol solvate, $Ni(pyz)_3(CH_3SO_3)_2.CH_3OH$

Prepared by the general method using hydrated nickel(II) methanesulfonate (0.544 g, ~2.2 mmol) and 23.4 mmol pyrazine. The blue precipitate was washed with small amounts of the solvent containing some pyrazine and then dried for 5 h *in vacuo*. Anal. calcd. for $NiC_{15}H_{22}N_6S_2O_7$: C 34.57, H 4.25, N 16.12; found: C 34.50, H 4.50, N 15.88.

Tetrakis(pyridine)nickel(II) p-*toluenesulfonate, $Ni(py)_4$(p-$CH_3C_6H_4SO_3)_2$*

Prepared by the general method using hydrated nickel(II) *p*-toluenesufonate (0.868 g, ~2.2 mmol) and 124 mmol pyridine. The blue precipitate was washed with small quantities of the solvent and diethylether and then dried for 3.5 h *in vacuo*. Anal. calcd. for $NiC_{34}H_{34}N_4S_2O_6$: C 56.92, H 4.78, N 7.81; found: C 57.12, H 4.94, N 7.85.

Mono(pyrazine)nickel(II) p-*toluenesulfonate, $Ni(pyz)$(p-$CH_3C_6H_4SO_3)_2$*

Prepared by the general method using hydrated nickel(II) *p*-toluenesufonate (0.963 g, ~2.4 mmol) and 24.5 mmol pyrazine. The blue precipitate was dried, *in vacuo*, for 2.5 h at room temperature and then for 13 h at 85°C and finally for 6 h at 100°C to give a pale green product. Anal. calcd. for $NiC_{18}H_{18}N_2S_2O_6$: C 44.93, H 3.77, N 5.82; found: C 45.00, H 3.75, N 6.01.

Bis(pyrazine)nickel(II) nitrate, $Ni(pyz)_2(NO_3)_2$

Prepared by the general method using 7.05 mmol nickel(II) nitrate hexahydrate and 38.6 mmol pyrazine. The blue precipitate was dried *in vacuo* for 6 h. Anal. calcd. for $NiC_8H_8N_6O_6$: C 28.02, H 2.35, N 24.51; found: C 27.78, H 2.57, N 24.70.

Tetrakis(methylpyrazine)nickel(II) nitrate monohydrate, $Ni(mepyz)_4(NO_3)_2.H_2O$

A solution of 4.22 mmol nickel(II) nitrate hexahydrate in 5 mL of ethanol containing about 10% v/v 2,2-dmp was added to 39 mmol of methylpyrazine and the mixture allowed to sit. After several days a blue precipitate formed. The supernatant liquid was decanted off and the solid washed with small amounts of the solvent and then dried *in vacuo* for 3 h. Anal. calcd. for $NiC_{20}H_{26}N_{10}O_7$: C 41.62, H 4.54, N 24.27; found: C 41.75, H 4.74, N 24.14.

Mono(methylpyrazine)nickel(II) nitrate, Ni(mepyz)$(NO_3)_2$
This light blue complex was prepared by thermolysis of $Ni(mepyz)_4(NO_3)_2.H_2O$ at 90°C, *in vacuo*, for 13 h. Anal. calcd. for $NiC_5H_6N_4O_6$: C 21.69, H 2.18, N 20.24; found: C 21.81, H 2.26, N 20.45.

Mono(pyridine)nickel(II) chloride, Ni(py)Cl_2
A sample of $Ni(py)_4Cl_2$ was heated *in vacuo* at 140°C for 5 h during which time the color changed from blue to yellow. Anal. calcd. for $NiC_5H_5NCl_2$: C 28.77, H 2.41, N 6.71; found: C 28.97, H 2.51, N 6.62.

Mono(pyrazine)nickel(II) chloride, Ni(pyz)Cl_2
A sample of $Ni(pyz)_2Cl_2$ was heated at 255–258°C for 3 h under a stream of nitrogen gas to give a pale yellow product. Anal. calcd. for $NiC_4H_4N_2Cl_2$: C 22.91, H 1.92, N 13.36; found: C 22.89, H 1.91, N 13.47.

Physical measurements

Differential scanning calorimetry (DSC) studies in the 35–450°C temperature range were made using equipment and procedures previously described (22). For the current studies the measuring cell atmosphere was nitrogen gas at a flow rate of 50 mL min^{-1}. Infrared spectra in the range 4 000 – 250 cm^{-1} were recorded on a Perkin-Elmer Model 598 spectrometer using samples mulled in Nujol or hexachlorobutadiene and pressed between KRS-5 plates (Harshaw Chemical Co.). Calibration was achieved using polystyrene; band frequencies are considered accurate to ±3 cm^{-1}. Electronic spectra in the 25 000 – 5 000 cm^{-1} range were recorded on either a Cary 14 or a Cary 5 UV-VIS-NIR spectrophotometer. Samples were mulled in Nujol and sandwiched between quartz glass plates with a second set of plates containing only Nujol placed in the reference beam. Magnetic susceptibilities over the temperature range ~2 to ~82 K were measured for all compounds at an applied field of 9 225 Oe using a P.A.R Model 155 vibrating sample magnetometer as previously described (23). This instrument was also used to obtain the 2549, 5251, and 7501 Oe data reported here for $Ni(py)Cl_2$. Samples were held in Kel-F capsules. A Quantum Design (MPMS) SQUID magnetometer was used to obtain the magnetization data for field dependence studies on $Ni(py)Cl_2$ and $Ni(pyz)Cl_2$. Procedures involving the use of this instrument were described previously (24). Magnetic susceptibilities were corrected for diamagnetism of all atoms (nickel, −11; $CH_3SO_3^-$, −35; p-$CH_3C_6H_4SO_3^-$, −89; NO_3^-, −20; water, −13; methanol, −34; pyridine, −49; pyrazine, −45; methylpyrazine, −57) and temperature independent paramagnetism of nickel, 200. All corrections are in units of 10^{-6} cm^3 mol^{-1}. Carbon, hydrogen, and nitrogen analyses were performed by P. Borda of this department.

Results

Synthesis and Thermoanalysis

Addition of excess pyrazine or methylpyrazine to a methanol/2,2-dmp solution of the appropriate nickel salt led to the isolation of complexes of composition $Ni(pyz)_3(CH_3SO_3)_2.CH_3OH$, $Ni(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$, $Ni(pyz)_2(NO_3)_2$, and $Ni(mepyz)_4(NO_3)_2.H_2O$. Attempts to obtain methylpyrazine complexes of the sulphonates by this general method failed to yield analytically pure samples.The general method was used successfully, however, to obtain the pyridine complexes $Ni(py)_4(CH_3SO_3)_2$ and $Ni(py)_4(p\text{-}CH_3C_6H_4SO_3)_2$. Thermoanalysis studies indicated sequential loss of neutral ligands for many of the complexes (Table 1) and suggested the possibility of obtaining bulk samples of some intermediate species by thermolysis. Thus it was possible to obtain a bulk sample of the compound $Ni(mepyz)(NO_3)_2$ by the thermolysis of $Ni(mepyz)_4(NO_3)_2.H_2O$. Thermoanalysis data for the former compound are included in Table 1. Attempts to obtain bulk samples of intermediates of the other complexes by thermolysis were not successful except in the case of the chloride derivatives. $Ni(py)_4Cl_2$ and $Ni(pyz)_2Cl_2$ were prepared by literature methods (20, 21) and the thermolysis of bulk samples of these was used to obtain $Ni(py)Cl_2$ and $Ni(pyz)Cl_2$. Thermochemical studies on all four of these chloro complexes have been reported previously (25–28) and our thermoanalysis data are in agreement with the earlier work.

Spectroscopic studies

The UV-VIS-NIR spectra of $Ni(py)_4Cl_2$ and $Ni(pyz)_2Cl_2$ obtained in this work were in agreement with reported spectra (20, 29, 30); data for the other complexes have been deposited as supplementary material.[2] The spectra are consistent with pseudo- octahedral geometry. Evidence for lower than O_h symmetry is seen in the splitting of the band assigned to the $^3A_{2g} \rightarrow {}^3T_{2g}$ transition. This is clearly observed in all of the spectra except those of $Ni(pyz)Cl_2$ and $Ni(mepyz)(NO_3)_2$ where the band is, nonetheless, very broad.

Selected anion and neutral ligand bands with assignments, obtained from the infrared spectra of the complexes, have also been deposited.[2] A careful examination of the infrared spectra gave no evidence for non-coordinated neutral ligand in any of the complexes. The absorptions that occur at 405, 605, and 1 583 cm^{-1} in free pyridine are shifted to higher frequencies in the complexes, as expected (31–33). In pyrazine complexes, the infrared band which occurs at 417 cm^{-1} in the free ligand shows significant shifts on coordination (11–13, 34). Shifts of this band to ~450 cm^{-1} usually indicate monodentate coordination, whereas shifts to significantly higher frequencies generally indicate a bridging mode of coordination (35). $Ni(pyz)_2(NO_3)_2$, $Ni(pyz)_2Cl_2$, $Ni(pyz)Cl_2$, and $Ni(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ exhibit bands consistent with bridging pyrazine, whereas the spectrum of $Ni(pyz)_3(CH_3SO_3)_2.CH_3OH$ suggests the presence of both bridging and terminal pyrazines. It has been noted that bands at 410 and 472 cm^{-1} in free methylpyrazine show significant shifts to higher frequencies on coordination (36). Such shifts are observed in both $Ni(mepyz)(NO_3)_2$ and $Ni(mepyz)_4(NO_3)_2.H_2O$, with larger shifts in the former complex relative to those in the latter, possibly reflecting bridging and terminal diazine ligands respectively.

Monodentate or bidentate coordination of a sulfonate group is expected to result in a splitting of the SO_3 asymmetric stretching mode, υ_4 (33). Significant band splitting of this type is seen in all of the sulfonate complexes studied here and, based on previous work on related complexes (1, 11), the mag-

nitude of the splitting is consistent with bidentate sulfonate coordination in $Ni(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ and monodentate coordination in the others. Analysis of the infrared bands assigned to internal vibrations of the nitrate ion (37) may also be used to distinguish between monodentate and bidentate coordination (38). The spectra of the nitrates studied here support bidentate anion coordination in $Ni(mepyz)(NO_3)_2$ and monodentate coordination in the other complexes.

Magnetic properties

Complete magnetic data have been deposited as supplementary material.[2] Of the complexes studied here the four of the type NiL_4X_2 exhibit the smallest temperature dependence in μ_{eff} values. A plot of μ_{eff} versus temperature for $Ni(py)_4Cl_2$ is shown in Fig. 1. The μ_{eff} versus temperature behavior of $Ni(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ is similar to that of the above group while the complexes $Ni(pyz)_2Cl_2$, $Ni(mepyz)(NO_3)_2$, and $Ni(pyz)_3(CH_3SO_3)_2.CH_3OH$ show greater decreases in μ_{eff} below 25 K. The magnetic moment of $Ni(pyz)_2(NO_3)_2$ shows a significant decrease with temperature over the whole temperature range studied; in addition, the magnetic susceptibility of this compound exhibits a maximum at 3 K.

The magnetic properties of $Ni(pyz)Cl_2$ and $Ni(py)Cl_2$ are dramatically different from those of the other complexes. At an applied field of 9 225 Oe the magnetic moments of

Fig. 1. Magnetic moment versus temperature plots for (*a*) $Ni(py)Cl_2$, (*b*) $Ni(pyz)Cl_2$, and (*c*) $Ni(py)_4Cl_2$. The moments were calculated from susceptibility data obtained at a magnetic field strength of 9 225 Oe.

Fig. 2. Selected magnetization isotherms for $Ni(pyz)Cl_2$: ○ (2 K), ∇ (8 K), □ (20 K).

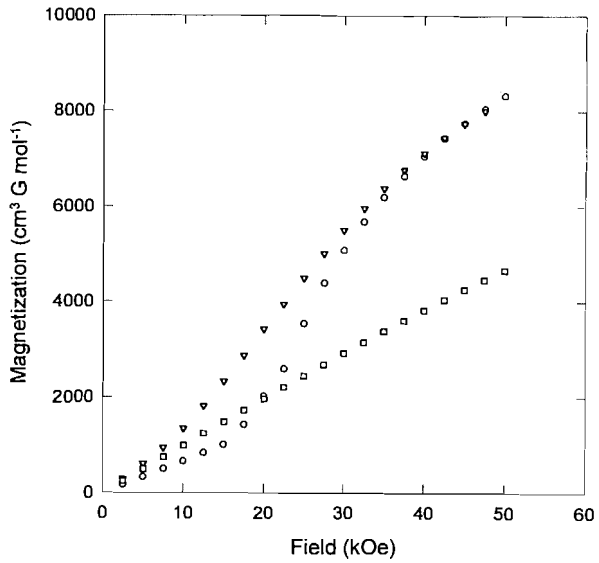

Fig. 3. Selected magnetization isotherms for $Ni(py)Cl_2$: ○ (2 K), ∇ (10 K), □ (20 K), Δ (35 K).

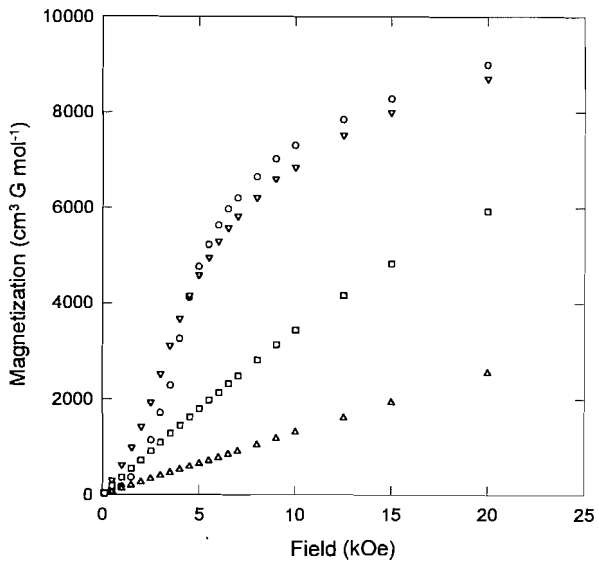
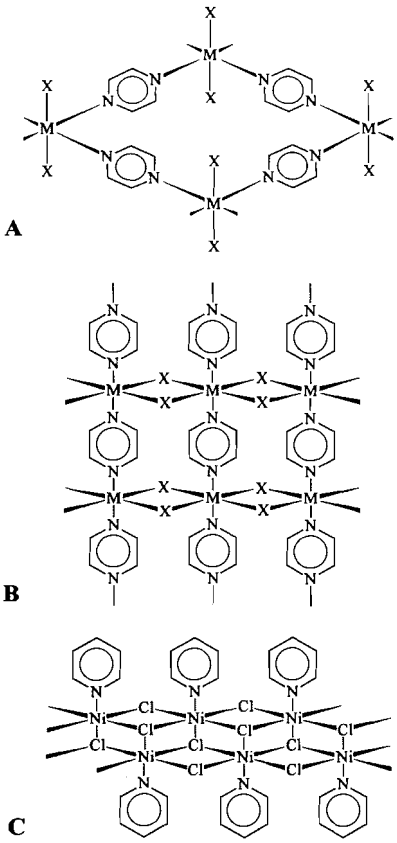


$Ni(pyz)Cl_2$ and $Ni(py)Cl_2$ exhibit maxima of 3.99 and 7.72 μ_B at 17 and 14 K, respectively (Fig. 1). The susceptibility of $Ni(pyz)Cl_2$, which shows no measurable field dependence between 2 549 and 9 225 Oe, passes through a maximum at 10 K. At field strengths above 12 000 Oe and at low temperatures the susceptibility of this complex is field dependent; magnetization versus applied field plots for selected temperatures are displayed in Fig. 2. Of all the complexes studied here, only $Ni(py)Cl_2$ shows a field dependence of the susceptibility between 2 549 and 9 225 Oe over the temperature range studied. As the temperature is lowered below 80 K, the susceptibility increases and is essentially field independent until ~15 K.

Fig. 4. Proposed structures: **A** = $M(pyz)_2X_2$, **B** = $M(pyz)X_2$, **C** = $Ni(py)Cl_2$



Below this temperature it becomes field dependent with the susceptibility leveling off below ~5 K at values of 0.734, 0.827, and 0.918 $cm^3 mol^{-1}$ for fields of 9 225, 7 501, and 5 252 Oe, respectively. At 2 549 Oe, however, the susceptibility passes through a maximum of 0.830 $cm^3 mol^{-1}$ at 11 K and decreases to 0.460 $cm^3 mol^{-1}$ at 2.1 K. Magnetization versus applied field plots for selected temperatures are displayed in Fig. 3.

Discussion

$Ni(pyz)_2X_2$ and $Ni(py)_4X_2$ complexes

On the the basis of spectroscopic evidence, Goldstein et al. (16, 39) proposed an extended sheet structure for $Ni(pyz)_2Cl_2$ in which nickel ions are bridged in a two-dimensional square lattice array by pyrazine ligands and six-coordination about the metal ion is achieved by axially bonded chloride ions. This type of structure, shown in Fig. 4, has been confirmed by single crystal X-ray structural determinations in a number of related bis(pyrazine) complexes, namely: $Co(pyz)_2Cl_2$, $Cu(pyz)_2(ClO_4)_2$, $Cu(pyz)_2(CH_3SO_3)_2$, and $Fe(pyz)_2(NCS)_2$ (2, 4, 10, 39). Our spectroscopic results are in agreement with the earlier studies on $Ni(pyz)_2Cl_2$ and are consistent with a similar sheet structure for the analogous $Ni(pyz)_2(NO_3)_2$. On the basis of high-temperature magnetic susceptibility studies, Goldstein et al. (16) had concluded that $Ni(pyz)_2Cl_2$ is mag-

netically dilute. The low-temperature studies reported here reveal weak magnetic concentration effects. In these $Ni(pyz)_2X_2$ complexes the metal chromophore is NiN_4X_2 and before discussing their magnetic properties in detail it is appropriate to consider first the monometallic $Ni(py)_4X_2$ analogues.

$Ni(py)_4Cl_2$ is known to have a *trans*-octahedral structure (40) and, on the basis of similarities in their electronic spectra, the compounds.$Ni(py)_4X_2$ (X = CH_3SO_3 and p-$CH_3C_6H_4SO_3$) and $Ni(mepyz)_4(NO_3)_2.H_2O$ likely exhibit the same geometry. This conclusion is supported by evidence from infrared spectroscopy that the anions involved are coordinated in a monodentate fashion. The *trans*-octahedral structure has been confirmed for the iron analogues of the methanesulfonate and p-toluenesulfonate compounds (33).

In view of the monometallic nature of these complexes any intermolecular exchange would be expected to be very weak. The measured moments at the higher temperatures studied are relatively temperature independent and of a magnitude normally observed for magnetically dilute nickel(II) complexes of this type (41). The decrease in magnetic moments at the lower temperatures studied is caused by the effects of zero-field splitting, ZFS (18), accompanied possibly by very weak exchange effects. Accordingly, we examined fits of the magnetic susceptibility employing the previously published equation for the susceptibility, χ_m, of an $S = 1$ system including ZFS (42), with χ_m modified by the molecular field approximation to include the effects of weak spin interactions (43). The equation employed for the exchange-corrected susceptibility, χ'_m, is:

$$\chi'_m = (\chi_m/[1 - (2zJ/Ng^2\mu_B{}^2)\chi_m])$$

where J is the exchange coupling constant, z is the number of interacting nearest neighbors, and the remaining terms have their usual meaning. In the fitting procedure D, the zero-field splitting parameter, g, and zJ were employed as variable parameters and best fit values of these are given in Table 2. Fits of experimental data to the model were made using a nonlinear least-squares procedure with the following function minimized:

$$F = \left[\frac{1}{n}\sum_{i=1}^{n}\left(\frac{\chi^i_{calc} - \chi^i_{obs}}{\chi^i_{obs}}\right)^2\right]^{1/2}$$

where n is the number of data points. The F value provides a measure of the goodness of fit between experiment and theory. Excellent fits as judged visually and by the the value of F were obtained for all four compounds. In all cases $|D| >> |zJ|$, a necessary requirement for applying the molecular field approximation (18). Values of D are in the range 5–9 cm^{-1}; this compares with the reported values of $D = 4.35$ cm^{-1} for $[Ni(C_5H_5NO)_6][ClO_4]_2$, -19 cm^{-1} for $Ni(py)_2Cl_2$, and -23 cm^{-1} for $Ni(pyrazole)_2Br_2$ (44). Ignoring intermolecular exchange (setting $J = 0$) gives poorer agreement between experiment and theory and generates D values ranging from 2% higher for the tosylate complex to 40% higher for the chloride derivative. The very small values of $|zJ|$ confirm that any exchange in these complexes is extremely weak.

The magnetic properties of the two $Ni(pyz)_2X_2$ complexes studied here indicate that there is stronger antiferromagnetic exchange in comparison to that present in the tetrakis(ligand) complexes. In view of the proposed sheet structures for these pyrazine complexes, attempts were made to analyze their magnetic data using Lines high-temperature series expansion for a two-dimensional square-lattice $S = 1$ antiferromagnetic system in the Heisenberg limit (45). Satisfactory agreement between experiment and this theory was not obtained for $Ni(pyz)_2(NO_3)_2$. A satisfactory fit of the data for $Ni(pyz)_2Cl_2$ to this model was obtained with the parameters $J = -0.38$ cm^{-1} and $g = 2.17$ ($F = 0.0066$); however, since the model ignores ZFS effects and since $|D|$ is likely to be significantly greater than the $|J|$ determined, we consider the fit to be fortuitous. Assuming ZFS is significantly larger than the exchange in these complexes, we analyzed the data according to the ZFS model modified to include the effects of weak spin interactions as described above. Excellent fits were obtained for both compounds (Table 2) and although the $|zJ|$ values are significantly greater than those obtained for the tetrakis(ligand) complexes, they are still less than 10% of the $|D|$ values making the application of the molecular field approximation appropriate. It should be noted that, as would be expected, the D values are very comparable to those of the monometallic complexes with similar chromophores, namely $Ni(py)_4Cl_2$ and $Ni(mepyz)_4(NO_3)_2.H_2O$. The stronger antiferromagnetic coupling in $Ni(pyz)_2(NO_3)_2$ may be a consequence of the weaker coordinating strength of the nitrate compared to chloride. This could yield stronger metal–pyrazine interactions resulting in enhanced exchange effects.

The ability of pyrazine to mediate antiferromagnetic ex-

For personal use only.

change between nickel(II) centers is demonstrated by these results; however, the magnitude of the exchange appears to be quite weak when comparisons are made with iron and copper $M(pyz)_2X_2$ systems previously studied. To compare complexes with different d^n configurations it is appropriate to compare values of $4S^2J$ (where S is the total spin) rather than J (46). For the two $Ni(pyz)_2X_2$ complexes studied here, taking $z = 4$, the value of $-4S^2J$ is 0.14 cm^{-1} for X = Cl and 0.52 cm^{-1} for $X = NO_3$. These are an order of magnitude smaller than the values of $-4S2J$ determined for $Cu(pyz)_2(ClO_4)_2$ (5.2 cm^{-1}) and for $Fe(pyz)_2X_2$, where $X = CH_3SO_3$, CF_3SO_3, and NCS (2.9, 3.2 and 5.8 cm^{-1}, respectively) (4, 11, 12). It had been suggested earlier that the exchange in $Fe(pyz)_2(NCS)_2$ is weaker than in $Cu(pyz)_2(ClO_4)_2$ (10); however, the $4S^2J$ data do not support this. More important perhaps is the fact that the exchange is very similar in the two compounds, in spite of the fact that, as was pointed out previously (10), the canting of the pyrazine rings with respect to the MN_4 chromophore is almost identical in the two compounds, while the Fe—N distances are greater than the Cu—N distances. This might have been expected to lead to weaker exchange in the Fe case. It was suggested in the earlier work that the unpaired electron density in the t_{2g} orbital set of the iron compound is providing additional pathways for antiferromagnetic exchange and this is offsetting the effect of the longer Fe—N distances. In the complexes studied in the current work, the Ni—N bond distances are also likely to be greater than the corresponding distances in the copper complexes. In the case of nickel, however, the effect of long M—N bonds is not offset by unpaired t_{2g} electron density and this may account for the weak coupling in the nickel complexes. The canting of the pyrazine rings with respect to the NiN_4 chromophore is also an important factor in determining the strength of magnetic exchange; however, this aspect cannot be explored further in the absence of more detailed structural information.

Ni(diazine)X_2 complexes and $Ni(pyz)_3(CH_3SO_3)_2.CH_3OH$

Goldstein and Unsworth (47) suggested a structure for $Ni(pyz)Cl_2$ in which chains of nickel ions, doubly-bridged by chloride ions, are cross-linked by bidentate bridging pyrazine molecules to form an overall extended sheet structure. Our spectroscopic data are in agreement with the earlier work and support such a structure, shown in Fig. 4. This type of structure has been observed in $Cu(pyz)Cl_2$ and $Cu(pyz)Br_2$ (9). Spectroscopic evidence in this study supports six-coordinate structures involving bridging 1,4-diazine ligands and bidentate anions for $Ni(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ and $Ni(mepyz)(NO_3)_2$. Likely structures involve chains of 1,4-diazine bridged metal ions which are either isolated with six-coordination achieved by bidentate chelating anions or are cross-linked by bidentate bridging anion groups to form a sheet structure like that proposed for $Ni(pyz)Cl_2$. An example of the former structural type is provided by $Cu(pyz)(NO_3)_2$ (5) while the latter structural type has been proposed previously for $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ (11). The electronic and infrared spectra of $Ni(pyz)_3(CH_3SO_3)_2.CH_3OH$ are consistent with a structure involving a linear chain of pyrazine-bridged nickel ions with six-coordination completed by the other two pyrazine ligands and the methanesulfonate ions.

A qualitative comparison of the magnetic properties of $Ni(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$, $Ni(mepyz)(NO_3)_2$, and $Ni(pyz)_3(CH_3SO_3)_2.CH_3OH$ with those of the bis(pyrazine) derivatives discussed above, indicates the magnitude of exchange is comparable or slightly smaller in the complexes being considered here. In view of the comments made above regarding the relative magnitudes of exchange coupling and ZFS we consider it inappropriate to analyze the magnetic properties of these complexes employing one-dimensional or two-dimensional models which ignore ZFS effects (45, 48, 49). Analysis of the data employing the ZFS model modified to account for weak exchange as described above results in good agreement between experiment and theory (Table 2). The values of the ZFS parameter, D, are comparable to those of the bis(pyrazine) complexes and the values of $|zJ|$ are smaller, again validating the use of the molecular field approximation. Assuming that any weak exchange in these compounds is being mediated primarily by bridging pyrazine ligands and setting z = 2 yields $-J$ values in the range 0.018 – 0.047 cm^{-1} for the monopyrazine bridged complexes compared to the $-J$ values of 0.035 and 0.13 cm^{-1} for the bis(pyrazine) bridged compounds. In summary, antiferromagnetic exchange in nickel(II) complexes containing bridging 1,4-diazine ligands is very weak and is little affected by the number of bridging diazines.

In a conference report (50) on the low-temperature magnetic properties of $Ni(pyz)Cl_2$ it was stated that the complex exhibits a Néel temperature of ~10 K and ferromagnetic behavior above this temperature. The maximum observed in the magnetic susceptibility versus temperature data at 10 K in the present work indicates antiferromagnetic coupling. That the behaviour is not simple antiferromagnetic, however, is evident from the magnetic moment data (Fig. 1). At ~80 K the moment is greater than that of $Ni(py)_4Cl_2$ and rises to even higher values as the temperature is lowered, indicative of ferromagnetic exchange. The moment goes through a maximum as the temperature is lowered further. We interpret this result as follows. The nickel ions are coupled ferromagnetically in chains via the bridging chloride ions and there is interchain antiferromagnetic coupling via bridging pyrazine ligands. Magnetic behaviour of this type is exhibited in a number of linear chain metamagnetic materials such as NiL_2X_2 (X is Cl or Br and L is pyrazole or pyridine) (51) and $M(py)_2Cl_2$ (M is Co, Fe, or Ni) and $Fe(py)_2(NCS)_2$ (52, 53). Unlike the situation described for $Ni(pyz)Cl_2$, however, in these complexes the interchain antiferromagnetism is mediated by non-bonding interactions. In order to examine $Ni(pyz)Cl_2$ for metamagnetic behavior, we examined the field-dependence of its magnetization at low temperatures (Fig. 2). Metamagnetic transitions were clearly observed below 10 K. The critical field, H_c, defined as the extrapolation of the linear portion of the magnetization, M, vs. field curve to the $M = 0$ axis (52), is 13 kOe at 2 K for $Ni(pyz)Cl_2$. A measure of the strength of intrachain ferromagnetic coupling may be obtained by extrapolation of the high-temperature portion of a Curie–Weiss (χ^{-1} versus T) plot to low temperatures (51). Such an analysis gives $J = 4$ cm^{-1} for $Ni(pyz)Cl_2$. Interesting comparisons can be made with $Ni(py)_2Cl_2$, a metamagnetic compound which exhibits ferromagnetic coupling with $J = 4$ cm^{-1} and a critical field, $H_c = 3$ kOe (51). The similarity in the two J values is consistent with the fact that in both compounds the ferromagnetic coupling is thought to take place along -$NiCl_2$- chains, in other words by identical pathways.The critical field is affected

by the strength of the antiferromagnetic interaction between the ferromagnetically coupled chains. The stronger the interaction the higher is H_c. In $Ni(py)_2Cl_2$ the Ni atoms in the $-NiCl_2-$ chains are capped by pyridine ligands and the interchain coupling is through space (non-bonding interactions) and the critical field is 3 kOe. In $Ni(pyz)Cl_2$ the $-NiCl_2-$ chains are cross-linked by pyz ligands and the higher H_c observed (13 kOe) is consistent with these ligands providing a significant antiferromagnetic pathway for exchange.

$Ni(py)Cl_2$

Our work on $Ni(pyz)Cl_2$ prompted a more detailed investigation of the magnetic behaviour of $Ni(py)Cl_2$. For this pyridine compound Goldstein and Hughes (17) proposed a double-strand halide-bridged polymeric chain structure in which each metal ion is surrounded by one pyridine ligand, two bicoordinate halide ions, and three tricoordinate halide ions, as depicted in Fig. 4. Each nickel ion is bonded to four nickel neighbours by bridging chlorides with the potential for ferromagnetic coupling within the double strand chains and interchain antiferromagnetic coupling through non-bonding interactions leading to metamagnetic behaviour. Earlier high-temperature magnetic susceptibility studies (300–90 K) had indicated the presence of ferromagnetic exchange. (54), and our cryomagnetic studies confirm metamagnetism. Qualitatively, the behaviour is similar to that of $Ni(pyz)Cl_2$. The magnetic moment versus temperature plot shows a maximum (Fig. 1) and the magnetization data (Fig. 3) show metamagnetic transitions below 10 K. As a consequence, perhaps, of the fact that each nickel is chlorine-bridged to four nearest neighbour nickels in $Ni(py)Cl_2$, the ferromagnetic interactions are stronger in this system compared to the interactions in the pyrazine analogue. This is evidenced by the higher magnetic moment values (Fig. 1) and larger value of J (8 cm^{-1}, determined as described above). The magnetization data indicate a critical field, H_c, of 2 kOe at 2 K for $Ni(py)Cl_2$, a value much smaller than that in $Ni(pyz)Cl_2$ but similar to that reported for $Ni(py)_2Cl_2$ (52). This is consistent with the fact that, as in the latter compound, the antiferromagnetic interchain effects are mediated by non-bonding interactions.

Summary and conclusions

This work has shown that in complexes of the type Ni(1,4-diazine)$_x$X$_2$, in which nickel(II) ions are linked by bridging diazine ligands in extended chains (for $x = 1$) or sheets (for $x = 2$), and in which the X anions are not involved significantly in mediating exchange, the diazine ligands are capable of transmitting antiferromagnetic interactions between metal centers. The magnitude of the interaction is significantly weaker than that seen in analogous copper(II) systems. It is suggested that this is a consequence of longer metal—N bond lengths which are not compensated for by the existence of additional antiferromagnetic pathways via t_{2g} unpaired electron density as is present in analogous iron(II) compounds. The ability of pyrazine to transmit antiferromagnetic interactions between nickel(II) ions was further demonstrated in the analysis of the metamagnetic behaviour of $Ni(pyz)Cl_2$. The relatively high critical field observed for this compound compared to those found for $Ni(py)_2Cl_2$ and $Ni(py)Cl_2$ is interpreted as a direct result of significant antiferromagnetic interactions mediated by the bridging pyrazine ligands.

Solvent effects on the reactivity of solvated electrons with $NO_{3,s}^-$ in C_1 to C_4 alcohols

Yixing Zhao and Gordon R. Freeman

Abstract: The rate constants $k_2(e_s^- + NO_{3,s}^-)$ in pure C_1 to C_4 alcohol solvents at 298 K increase with *increasing* viscosity and *decreasing* permittivity. Thus the reactivity increases with decreasing diffusivity and increasing coulombic repulsion, so the Debye–Smoluchowski model does not apply. The effective reaction radius κR_r increases with decrease of effective trap depth E_r/τ of the electrons in the solvent: $\kappa R_r = C_\tau(E_r/\tau)^{p_\tau}$. Values of κR_r and E_r/τ change with temperature, and values of p_τ fall in four categories: ~0.0 for water and methanol; ~1.3 for primary alcohols; 0.6 for secondary alcohols; 1.8 for *tert*-butanol. The C—H groups participate in the $e_s^- + NO_{3,s}^-$ reaction.

Key words: alcohol solvents, solvated electron, nitrate ion, reactivity, solvent effects.

Résumé : Les constantes de vitesse $k_2(e_s^- + NO_{3,s}^-)$ dans des alcools allant de C_1 à C_4 comme solvants à 298 K augmentent lorsque la viscosité augmente et lorsque la permittivité diminue. Ainsi la réactivité augmente lorsque la diffusivité diminue et lorsque la répulsion coulombienne augmente de telle sorte que le modèle de Debye–Smoluchowski ne s'applique pas. Le rayon effectif de la réaction κR_r augmente avec la diminution de la profondeur du piège effectif E_r/τ des électrons dans le solvant. $\kappa R_r = C_\tau(E_r/\tau)^{p_\tau}$. Les valeurs de κR_r et de E_r/τ varient avec la température, et les valeurs de p_τ diminuent pour les quatre catégories: ~0,0 pour l'eau et le méthanol; ~1,3 pour les alcools primaires; 0,6 pour les alcools secondaires; 1,8 pour le *tert*-butanol. Les groupes C—H participent dans la réaction $e_s^- + NO_{3,s}^-$.

Mots clés : solvants alcooliques, électron solvaté, ion nitrate, réactivité, effets des solvants.

[Traduit par la rédaction]

Introduction

Elucidation of the reactivity of e_s^- with $NO_{3,s}^-$ in water and in alcohol solvents is a long-standing problem (1–11). The reaction rate constant k_2 of e_s^- with many solutes in a series of alcohols follows the Smoluchowski–Debye model, and increases with increasing fluidity ($1/\eta$) of the solvent (11, 12). By contrast, the rate constant $k_2(e_s^- + NO_{3,s}^-)$ increases approximately linearly with *decreasing* fluidity in a series of alcohol solvents at 298 K (11). This increase in reaction rate accompanied by a decrease in diffusion rate points to the behavior of a reactant encounter pair. The value of $k_2(e_s^- + NO_{3,s}^-)$ also increases with decreasing trap depth of e_s^-, as represented by the optical absorption energy E_r (13, 14). However, there is lack of overall correlation in all C_1 to C_4 alcohols, including secondary and tertiary alcohols (9, 10). Therefore, in this paper we bring together data to advance the understanding of the reaction in all C_1 to C_4 alcohols.

Data

Values of k_2 in the different solvents were taken from refs. 3, 4, 6, 7, 9–11 and are listed for 298 K in Table 1.

Kinetic properties of the solvents are viscosity η (15–17) and dielectric relaxation (electric dipole rotation) time (18–22). Values are collected in Table 1.

The tenacity with which an electron is held in a solvation site is assumed to be related to the e_s^- optical absorption energy (23). Electrons with lower optical absorption energies tend to be more reactive (13, 14, 24), so the energy E_r half way up the low energy side of the absorption band is chosen for correlations with reaction rate constants (Table 1).

Discussion

Transport properties

Figure 1*A* shows correlations of k_2 ($e_s^- + NO_{3,s}^-$) with solvent viscosity η. The rate constants in the primary alcohols *increase* with η; those in the secondary alcohols are higher but have a similar tendency; k_2 is higher in the tertiary alcohol, and the highest in water. This indicates chemical participation of solvent molecules in the reaction (9). The higher the η value, the more difficult it is for the reactants in an encounter pair to diffuse apart, giving more time for reaction to occur. The probability of reaction during an encounter must increase as η^m with $m \approx 2$, because the encounter frequency decreases approximately as η^{-1}.

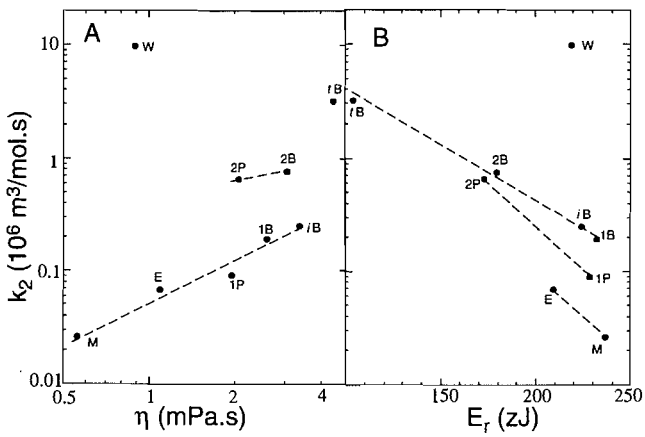
Fig. 1. Correlations of k_2 with η (*A*) and E_r (*B*) in C_1 to C_4 alcohols and water at 298 K (Table 1).



Trap-depth model and modification

The Smoluchowski model is used to investigate the transport properties in diffusion-controlled reactions. However, reactivity is also often dependent on the solvation energy of the reactants, especially of e_s^- (13, 14, 24). The mean free energy of solvation of electrons in water, −162 kJ/mol at 298 K (25), is similar to the optical absorption energy E_{Amax} = 166 kJ mol (26). This supports the search for correlations of k_2 with optical absorption energy E_r.

Figure 1*B* shows correlations of $k_2(e_s^- + NO_{3,s}^-)$ with E_r at 298 K. Among the butanols k_2 decreases with an increase in E_r. The values of k_2 also decrease with decreasing number of carbons, from 4 to 1. However, k_2 is largest in water.

The dielectric relaxation times τ of the series of alcohols (excluding *tert*-butanol) at different temperatures vary approximately linearly with η (Fig. 2). The equation of the line in Fig. 2 is:

[1] $\tau(ps) = 195[\eta(mPa \cdot s) - 0.30]$

The reported values of τ for *tert*-butanol at 298 K (20–22) are much smaller than eq. [1] indicates for η = 4.45 mPa·s, and those at 323 K and 343 K were obtained by extrapolation from lower temperatures (21, 22). The smaller ratio of τ/η for *tert*-butanol probably has to do with the sphere-like structure of the molecules, which can rotate and reorient faster than the chain-like butanols.

Correlations of electron solvation times with the intermediate dielectric relaxation time τ_2 (27), and of electron transfer reaction rate constants with the longitudinal relaxation τ_L (28) have been made. However, we use the longest relaxation time $\tau_1 = \tau$ for our general correlation with $k_2(e_s^- + NO_{3,s}^-)$, because τ_1 data are more complete.

The layered structures of Figs. 1*A* and *B* suggest that a more basic correlation might be found. From the Smoluchowski–Debye model (6, 9, 10) one can get:

[2] $k_2 = 4\pi N_A(D_e + D_s)\kappa R_r f$

where N_A is Avogadro's constant, D_i is the diffusion coefficient of *i*, R_r is the center-to-center reactant separation when reaction occurs, and κ is the probability that reaction occurs during one encounter and equals unity for diffusion-controlled reactions. The quantity κR_r is called an effective reaction radius; values have been estimated from the values of k_2 by factoring out the Debye coulombic factor *f* and approximate values of the diffusion coefficients (conductances) of the ionic reactants:

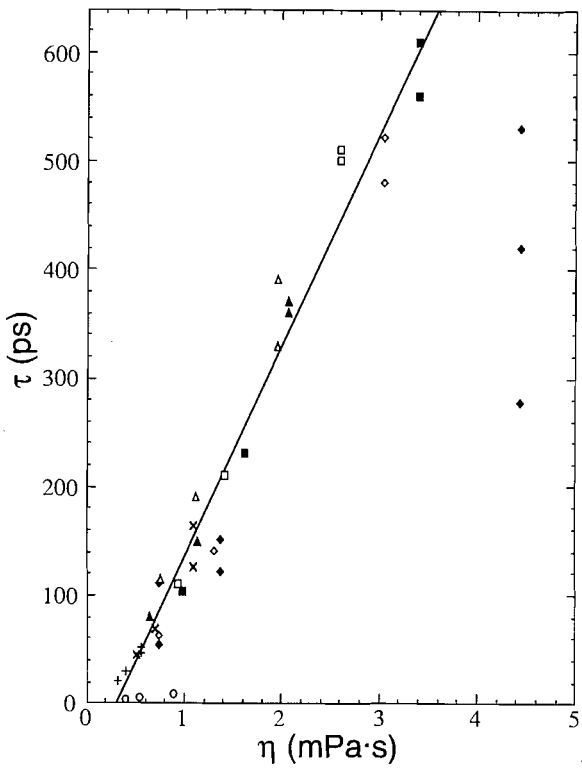
Fig. 2. Correlation of viscosity η and dielectric relaxation time τ of C_1 to C_4 alcohols and water at 298, 323, and 343 K. Some of the values of τ are extrapolated from those at lower temperatures. The symbol for each solvent is followed by the references for η; τ. Water, ○, 12; 15. Methanol, +, 12; 15,16. Ethanol, ×, 12; 15,16. 1-Propanol, △, 12; 15,16. 2-Propanol, ▲, 13; 15,16. 1-Butanol, □, 12; 15,17. *i*-Butanol, ■, 14; 15,17. 2-Butanol, ◇, 14; 15,17. *tert*-Butanol, ◆, 14; 17–19. The line through all data (except those for water and *tert*-butanol) represents eq. [1].



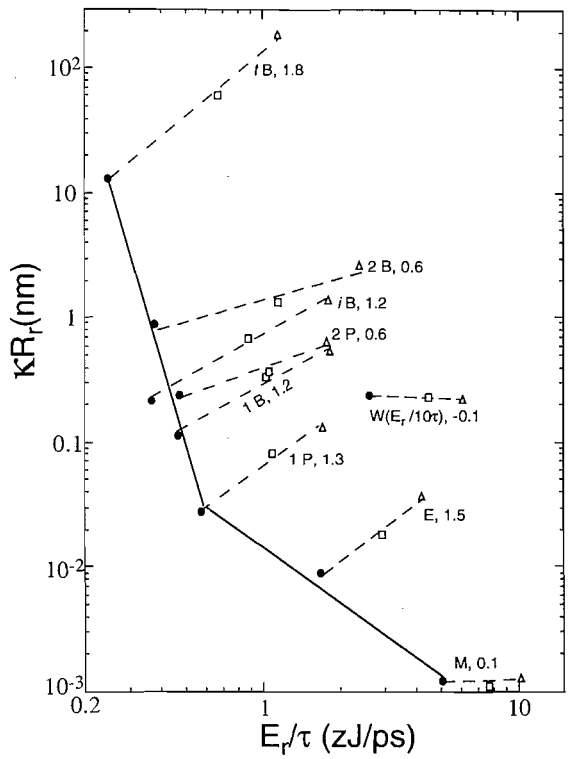
$$[3] \quad \kappa R_r(m) \approx 1 \times 10^{-16} k_2/fT\Lambda_0$$

where Λ_0 (S·m^2/mol) is the molar conductance of the reactant electrolyte solutions. To obtain accurate values of κR_r we would require accurate values of conductance of solvated electrons in the alcohols, but they are not available. At this stage we are looking for trends. A log–log plot of apparent κR_r values against E_r/τ at 298 K provides a better overall correlation of the reactivities in the C_1 to C_4 alcohols (black circles and full line in Fig. 3) than did the plots in Fig. 1. The value of κR_r at 298 K decreases with increasing trap depth of e_s^- and with decreasing relaxation time in the series of solvents. The value of κR_r in water is $\sim 10^2$ times higher than that extrapolated for an alcohol at the same value of E_r/τ (Fig. 3), which implies that the reaction is different in water.

A plot of κR_r against E_r/η shows a correlation similar to that in Fig. 3, as expected because of the linear relationship between τ and η.

In the C_1 to C_4 alcohol series at 298 K, if (*1*) the alcohol has a longer carbon chain, (*2*) the chain is more branched, or (*3*) the branch point is closer to the hydroxyl group, then E_r/τ is lower and κR_r is higher. This correlation might indicate that a longer and more branched chain alcohol has more difficulty to

Fig. 3. Correlation of apparent κR_r values and E_r/τ in C_1 to C_4 alcohols and water at 298 K (●), 323 K (□), and 343 K (△). The label of each dashed line identifies the solvent and the slope.



orient its —O—H dipole in the field of the electron or ion to solvate them, and that slower or less exoergic solvation results in a higher reaction rate constant with NO_3^-. The quantity E_r/τ can be understood as an effective trap-depth, since E_r is approximately equal to the binding energy of the e_s^- to its solvent site, and τ is related to the time during which the electron remains in a higher-than-equilibrium energy state after jumping to a new site. Similar correlations might be obtained with E_r/τ_2 or E_r/τ_L, but sufficient data are not available.

The values of κR_r and E_r/τ in a given alcohol usually increase with temperature (Fig. 3), and can be expressed by the empirical equation

$$[4] \quad \kappa R_r = C_\tau (E_r/\tau)^{p_\tau}$$

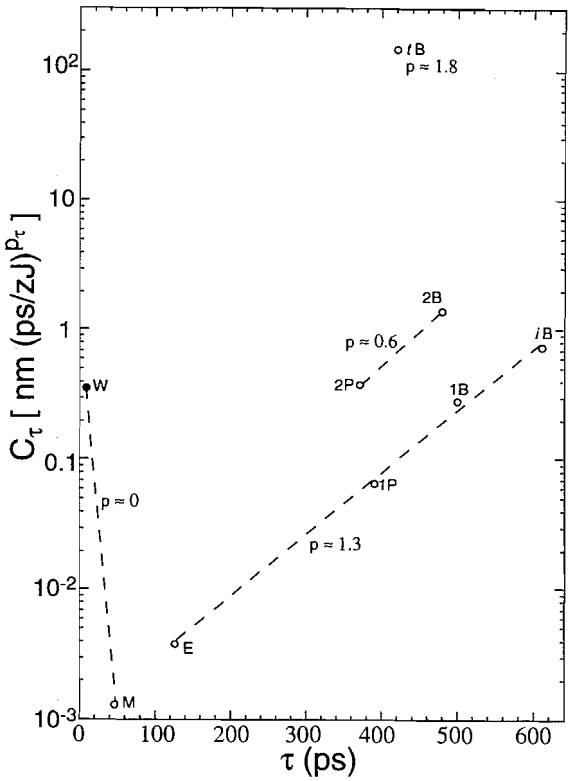
The slope of the line for a given alcohol in Fig. 3 equals p_τ, and the value of κR_r at $E_r/\tau = 1$ zJ/ps gives C_τ. There are four groups of p_τ values: ~0.0 for water and methanol, 0.6 for secondary alcohols, ~1.3 for primary alcohols, and 1.8 for *tert*-butanol. We do not understand the step size of 0.6.

Correlations of C_τ with τ are shown in Fig. 4. The four groups of p_τ probably indicate four different types of solvation structure in alcohols: *tertiary* alcohols, *secondary* alcohols, *primary* alcohols, and methanol. Water remains an exception.

It has been suggested that solvent molecules participate chemically in the reaction $e_s^- + NO_{3,s}^-$ in water and alcohols (4, 9). Reactivity in *tert*-butanol is highest; it has a relatively long dielectric relaxation time, and it has the maximum number of —CH_x groups attached to the α-carbon atom of the alcohol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Fig. 4. Correlation of C_τ (eq. [4]) with τ (298 K) of C_1 to C_4 alcohols and water. The dashed lines connect species having same p_τ values.



On the other hand, methanol has the lowest reactivity, the shortest dielectric relaxation time and no —CH_x groups attached to the α-carbon atom.

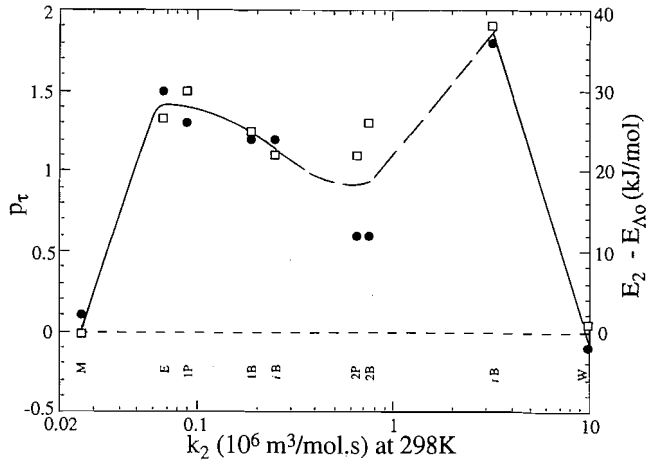
The correlations in Fig. 4 suggest two aspects of the solvent effect on the reaction: (*1*) solvation structure (packing form), and (*2*) solvent reorientation time. The reactivity in *tert*-butanol is higher than in the secondary alcohols. On the one hand, the solvation structure in *tert*-butanol results in a relatively high mobility of electrons in that alcohol (29); the mobility might be higher than it is in secondary alcohols. On the other hand, as e_s^- approaches $NO_{3,s}^-$ the C—H's of the three groups on the $HOC(CH_3)_3$ molecules that solvate the electron are accessible to the NO_3^- and product NO_3^{2-}, so there are more chances for reaction to occur than in secondary alcohols, and more chances in secondary than in primary alcohols. Methanol has no far reaching β-C—H's, so it has the lowest reactivity in this series.

In a given group of alcohols in Fig. 4 (for example, in primary or secondary alcohols), reactivity increases with solvent molecular reorientation time τ. This is because after the reaction

[5] $e_s^- + NO_{3,s}^- \rightarrow NO_3^{2-}$

the O—H dipole of the in-between molecule that solvated the electron tends to rotate in the field of the new NO_3^{2-} ion. The longer the relaxation time (τ, τ_2, or τ_L), the higher is the chance for the NO_3^{2-} ion to react with a C—H of the alcohol that was associated with e_s^-.

Fig. 5. Correlation of p_τ (●) and E_2–$E_{\Lambda 0}$ (□) with $k_2(e_s^- + NO_{3,s}^-)$ in C_1 to C_4 alcohols and water at 298 K.



[6] $NO_3^{2-} + RR'CHOH \rightarrow NO_2^- + OH^- + RR'\dot{C}OH$

Therefore, from 2-propanol to 2-butanol and from ethanol to *i*-butanol, the reactivity increases with an increase in τ (Fig. 4). It is not clear why methanol falls into a group with water ($p_\tau \approx 0$).

Figure 5 shows plots of p_τ and $E_2 - E_{\Lambda 0}$ against k_2, where E_2 is the Arrhenius activation energy of the reaction (e_s^- + $NO_{3,s}^-$) in a pure alcohol, and $E_{\Lambda 0}$ is the Arrhenius activation energy of molar conductivity of lithium nitrate in the same alcohol. Both p_τ and $E_2 - E_{\Lambda 0}$ are temperature coefficients; p_τ is from apparent values of κR_r (Fig. 3) whereas $E_2 - E_{\Lambda 0}$ contains the Debye *f* factor. Both contain any non-ion-like mobility of e_s^-. Methanol and water are at opposite ends of the curve, which indicates that the reaction e_s^- + $NO_{3,s}^-$ in methanol has a different mechanism from that in water. The latter is a nearly diffusion-controlled reaction and the former is entropy-controlled (30). Throughout the series the variations of p_τ and $E_2 - E_{\Lambda 0}$ are similar. The peak at *tert*-butanol seems to be associated with a high mobility of e_s^- in that solvent (29).

Ironcyclopentadienyl mediated 2-alkyl-2-arylphenylsulphonylacetonitrile synthesis

Alaa S. Abd-El-Aziz, Christine R. de Denus, and Harold M. Hutton

Abstract: A unique route to the synthesis of 2-alkyl-2-arylphenylsulphonylacetonitriles via the nucleophilic aromatic substitution (S_NAr) of chloroarene cyclopentadienyliron complexes with 2-alkyl phenylsulphonylacetonitriles has been investigated. Reactions of chloroarene complexes (**1***a–d*) with 2-alkyl phenylsulphonylacetonitrile (**2***a,b*) in the presence of K_2CO_3 in DMF at room temperature led to the formation of complexes **3***a–d* and **4***a,c,d* in good yields. The use of alkylated phenylsulphonylacetonitriles as nucleophiles in the reactions with the *p*-dichlorobenzene complex (**1***e*) allowed the formation of the disubstituted complexes (**5**, **6**). Photolytic demetallation provided an efficient route to the liberation of the arylated phenylsulphonylacetonitriles **7***a–d*, **8***a,c,d*, **9**, and **10**.

Key words: chloroarene, phenylsulphonylacetonitrile, nucleophilic substitution.

Résumé : On explore une méthode originale de synthèse des 2-alkyl-2-arylphénylsulphonylacétonitriles via la substitution aromatique nucléophile (S_NAr) des complexes du chloroarènecyclopentadiényl de fer avec les 2-alkylphénylsulphonylacétonitriles. Les réactions des complexes de choroarènes (**1***a–d*) avec le 2-alkylphénylsulphonylacétonitrile (**2***a,b*) en présence de K_2CO_3 dans le DMF à la température ambiante conduisent, avec de bons rendements, à la formation des complexes **3***a–d* et **4***a,c,d*. L'emploi des phénylsulphonylacétonitriles alkylés comme nucléophiles dans la réaction avec le complexe de *p*-dichlorobenzène (**1***e*) permet la formation de complexes disubstitués (**5**, **6**). La démétallation photolytique fournit une excellente voie d'accès à la libération des phénylsulphonylacétonitriles **7***a–d*, **8***a,c,d*, **9** et **10**.

Mots cles : chloroarène, phénylsulphonylacétonitrile, substitution nucléophile.

[Traduit par la rédaction]

Introduction

Since the displacement of the chloro group in the η^6-chlorobenzene-η^5-cyclopentadienyliron complex by a number of nucleophiles was first reported (1), numerous publications have appeared describing the use of these complexes in the synthesis of various organic molecules (2–10). Other metal moieties such as chromium tricarbonyl ($Cr(CO)_3$), manganese tricarbonyl ($Mn(CO)_3^+$), and cyclopentadienylruthenium ($CpRu^+$) have been used in the activation of the haloarene ring towards nucleophilic substitution reactions (11–18). In a recent review, Astruc has shown the flexibility of such systems as well as the advantages for the use of $CpFe^+$ over the above metal moieties (19). The advantage of using the $CpFe^+$ moiety is primarily due to the activating ability of this group towards displacement reactions. This was demonstrated clearly by the kinetic study carried out by Knipe et al. (20, 21). As well, the low toxicity and cost of this type of $FeCp^+$ complexation makes this route attractive in the synthesis of substituted aromatic compounds. Our research interest is focused on the use of the $CpFe^+$ complexes of chloroarenes in the synthesis of potentially biologically active molecules (2–5). We recently reported that chloroarene complexes can undergo nucleophilic aromatic substitution (S_NAr) with ethyl cyanoacetate or phenylsulphonylacetonitrile, leading to carbon–carbon bond formation (4, 5). In these studies, we demonstrated that photolysis of these arylated ethyl cyanoacetate or phenylsulphonylacetonitrile complexes led to the liberation of the compounds from their metal moieties in very high yields. These compounds are very valuable precursors to alkanoic acids and heterocyclic compounds that are known for their great importance in the pharmaceutical industry (22–28). One of the most important alkanoic acids is 2-(4-isobutylphenyl)propanoic acid, which is widely known as Ibuprofen. This compound exhibits anti-inflammatory and antipyretic activity and has been used successfully in the treatment of general muscle pain and stiffness, as well as in the treatment of patients with rheumatoid arthritis (29–32).

There are a number of routes to the synthesis of alkanoic acids that involve the conversion of alkyl aryl ketones into esters using thallium-promoted rearrangement followed by hydrolysis (33, 34). Other routes include Darzen's condensation reaction or the conversion of alkyl aryl ketones to aldehydes followed by oxidation to give the alkanoic acids (35, 36). One of the most interesting routes to the synthesis is the

arylation of phenylsulphonylacetonitriles, which are converted to alkanoic acids via alkylation and reductive desulphonation, followed by hydrolysis (25). This synthesis allows for the introduction of alkyl groups after the arylation of phenylsulphonylacetonitrile. To date there are few reports on the synthesis of arylated phenylsulphonylacetonitriles that have been shown to be converted to alkanoic acids (25, 37, 38). Suzuki et al. have shown that arylation of phenylsulphonylacetonitrile could be achieved via the displacement of an iodo group of an aryl iodide using a carbon nucleophile (25). This nucleophile was generated from the reaction of phenylsulphonylacetonitrile and sodium hydride in the presence of a copper salt as catalyst and HMPA as solvent. In a recent report Sakamoto et al. demonstrated that arylation could also be possible using either aryl iodide or aryl bromide in the presence of palladium(0) catalyst and DME as solvent (38). The harsh experimental conditions as well as the unreactivity of aryl chlorides, and the difficulty of introducing various substituents in the benzene ring, indicates that the new method we developed in the arylation of phenylsulphonylacetonitrile via the aid of the $CpFe^+$ moiety is a practical route to the synthesis of these compounds (4).

As an extension of our previous study, we carried out the alkylation process prior to the arylation step, which gives rise to a more flexible route to the synthesis of alkanoic acids. As well, the alkylation of phenylsulphonylacetonitrile allows for the possibility of dinucleophilic substitution reactions with dichlorobenzene complexes.

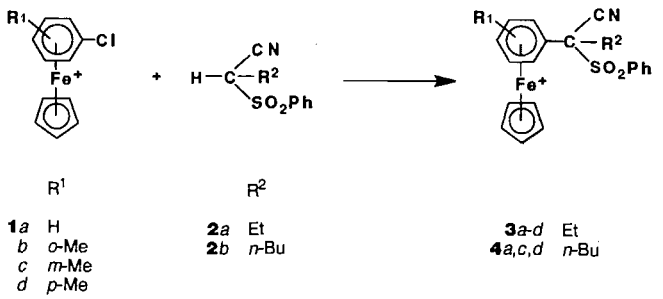
Results and discussion

Among the most important synthetic routes to carbon–carbon bond formation are the reactions of cyclopentadienyliron complexes of chloroarenes with various carbon nucleophiles. In our recent report on the synthesis of arylated phenylsulphonylacetonitriles, we presented a novel method for the preparation of a large number of these compounds. In the present work, we would like to demonstrate further the flexibility and efficiency of our cyclopentadienyliron-mediated methodology. In this paper, we present our recent investigation of the alkylation of phenylsulphonylacetonitrile prior to the substitution reactions with arene complexes. The alkylation allows for variation in the length of the carbon chain of the phenylsulphonylalkane nitrile as well as for the possibility of double nucleophilic substitution with dichlorobenzene complexes.

Alkylation of phenylsulphonylacetonitrile was conducted by generating the carbon nucleophile using sodium ethoxide, followed by the reaction with either ethyl bromide or *n*-butyl bromide to give **2***a* and **2***b*, respectively, as described in the experimental section. These two compounds were previously prepared by Lamm and Ankner using ion-pair alkylation (39). The yields of these reactions were slightly higher than the literature values. The ^1H NMR of these compounds are in agreement with those reported in the literature. Full characterization of **2***a* and **2***b* is reported in the experimental section.

The reactions of 1.0 mmol of complexes **1***a–d* with 1.05 mmol of compounds **2***a* or **2***b* in the presence of potassium carbonate in DMF, at room temperature, gave rise to the displacement of the chloro group by the carbon nucleophiles. The products were isolated as yellow solids in yields ranging from 69 to 96%. It is important to note that the reaction of compound **2***a* with *o*-chlorotoluene complex (**1***b*) gave the desired complex with lowest yield. On the other hand, reaction of compound **2***b* with *o*-chlorotoluene complex (**1***b*) failed to give the substituted complex; instead, decomposition of the starting complex took place.

Scheme 1



Complexes **3***a-d* and **4***a,c,d* were characterized using ^1H and ^{13}C NMR as well as IR and elemental analysis. In all the ^1H NMR spectra (200 MHz) of the product complexes, **3***a–d* and **4***a,c,d*, a very distinct singlet appeared in the range 5.29–5.36 ppm, which is evidence of the cyclopentadienyl (Cp) resonance. In some cases, where the complexed arene contains a methyl group in the *ortho* or *meta* position, **3***b*, **3***c*, **4***c*, we observed the presence of two Cp resonances of equal intensity. This result is in agreement with our recent work in which we observed preferential orientation of the arene substituent, allowing for different magnetic environments for the possible rotamers (40). This behavior was also observed with the arene methyl group. It is important to note that the methylene group in the α-position of the alkylphenylsulphonylacetonitrile group appears as an AB system. The splitting pattern and the coupling constant are given in the detailed experimental section. ^{13}C NMR (50 MHz) lends evidence in support of the ^1H NMR evaluation. For example, the carbon spectra of complex **3***b* was quite complex, showing two Cp resonances at 79.35 and 79.43 ppm and two arene methyl resonances at 21.39 and 22.03 ppm. The arene carbons also appeared as 12 resonances, further demonstrating the presence of two conformers of equal populations (see Scheme 1).

In the reactions of dichlorobenzene complexes with phenylsulphonylacetonitrile, disubstitution reactions could take place provided that a different nucleophile, such as an oxygen- or sulphur-containing nucleophile, could be used prior to the arylation step (4). In that study, we displaced a chloro group using an oxygen-containing nucleophile, followed by substitution with the carbon nucleophile generated from phenylsulphonylacetonitrile. We would like also to note that no disubstituted materials were obtained, owing to the deprotonation of the resulting arylated phenylsulphonylacetonitrile complex. This phenomenon is of course due to the basic reaction conditions, which allow for the deprotonation of the methine proton from the complex and the formation of a neutral zwitterion cyclohexadienyliron complex as shown in Scheme 2. This zwitterion would thus be more electron rich than the starting dichlorobenzene complex (**1***e*), and hence the second chlorine atom would be rendered incapable of undergoing a second substitution.

The alkylation of phenylsulphonylacetonitrile prior to nucleophilic aromatic substitution allows for the displacement

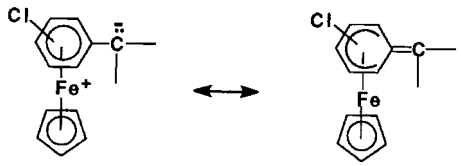
Scheme 2



of one or two chlorine groups in the dichlorobenzene complexes. In this study, we would like to demonstrate that by alkylating the phenylsulphonylacetonitrile, the reaction could proceed under similar conditions to give the disubstituted products. As an example, we carried out the reaction of the *p*-dichlorobenzene complex (**1***e*), with an excess of either nucleophile **2***a* or **2***b*, in the presence of potassium carbonate and DMF. In these reactions, it was noted that longer reaction times were necessary in order to produce the disubstituted complexes (**5**, **6**) in good yields (Scheme 3). This is in agreement with our previous results on double nucelophilic substitution using alkylated diethyl malonate (8). The *p*-disubstituted complexes were chosen because of the importance of many *p*-disubstituted alkanoic acid esters that exhibit some form of biological activity. The disubstituted complexes (**5**, **6**) were obtained in good yields and were fully characterized. It is very important to note that in these spectra the splitting patterns became much simpler due to the plane of symmetry possessed by the complexes.

Decomplexation of the arylated alkylphenylsulphonylacetonitrile complexes led to the liberation of the free substituted arenes in very high yields. One of the most efficient methods of obtaining the free arenes from their complexes is photolytic demetallation (41–44) (Scheme 4). By dissolving the complex in a mixture of acetonitrile and dichloromethane and irradiating it with a Xenon lamp for a short period of time, it is possible to isolate the desired organic compounds (**7***a–d*, **8***a,c,d*, **9**, **10**) via column chromatography. The monosubstituted compounds were obtained as oils or solids, while the disubstituted compounds were isolated as white solids. The identities of all products were confirmed by ^{1}H and ^{13}C NMR, IR, and MS spectroscopy, as well as by melting points. The major differences in the NMR spectra of these compounds from those of the complexes were the absence of the cyclopentadienyl peak(s) and the shift of the arene peaks to a lower field. As well, we no longer observed any evidence of isomers in the compounds, which allows for simpler spectral patterns. In conclusion, this methodology demonstrates our ability to prepare 2-alkyl-2-arylphenylsulphonylacetonitriles under mild conditions and very high yields. As well, aryl di(alkylphenylsulphonylacetonitrile) could be synthesized via the proposed reaction schemes.

Experimental

^{1}H and ^{13}C NMR spectra were recorded at 200 and 50 MHz, respectively, on a Varian Gemini 200 NMR spectrometer, with chemical shifts (ppm) being calculated from the solvent signals. Deuteroacetone and deuterochloroform were used as solvents for the complexed and free 2-alkyl-2-aryl-phenylsulphonylacetonitriles, respectively. Coupling constants were calculated in hertz (Hz). MS were obtained on a Hewlett–Packard 5970 Series mass selective detector, by electron impact (70 V). Signal positions are given in *m/z* units. IR were recorded on a Perkin–Elmer model 781 spectrophotometer. Melting points were measured in a capillary using a Mel-Temp II and are uncorrected. All new compounds gave satisfactory elemental analyses.

Starting materials

Starting complexes **1***a–e* were prepared by ligand exchange reactions (45). Anhydrous aluminum chloride, aluminum powder, ferrocene, chloroarenes, reagent grade solvents, and ammonium hexafluorophosphate are commercially available and were used without further purification. Silica gel 60–100 mesh was used in the column chromatographic purification of the liberated arenes.

Synthesis of ethyl or butylphenylsulphonylacetonitrile (**2***a,b*)

In a flame-dried 250 mL 3-necked flask, equipped with a stir bar and condenser fitted with a calcium chloride tube, was placed 30 mL of absolute ethanol. Sodium (0.780 g; 34 mmol) was added to the ethanol over a period of 30 min. After all the sodium reacted with the ethanol, 5.44 g (30 mmol) of phenylsulphonylacetonitrile was added to the warm solution of the sodium ethoxide. Without delay, 3.2 mL (43 mmol) of ethyl bromide or 4.6 mL (43 mmol) of butyl bromide was added slowly to the solution, upon which it turned a slightly yellow color. The reaction mixture was refluxed for 8 h and left to sit in a dark place for 1 week, during which time a white precipitate formed. The mixture was then filtered, the reaction flask washed with ethanol, and the solution also filtered. To this mixture, 25 mL of distilled water and 0.5 mL of concentrated hydrochloric acid were added. The mixture was then transferred to a separatory funnel and the aqueous sodium bromide solution was drawn off. Following drying over magnesium sulphate, the ethanol was removed using a rotary evaporator to

produce a yellow oil. Purification of this oil using column chromatography gave unreacted phenylsulphonylacetonitrile, and monalkylated and dialkylated products.

2-Ethylphenylsulphonylacetonitrile **2**a
Colorless oil, 2.28 g (36.3%); ν_{max} (KBr) (cm^{-1}): 1158, 1340 (SO_2), 2340 (CN): ^1H NMR: 1.10 (3H, t, *J* 7.2 Hz, CH_3), 1.90 (1H, m, CH_2), 2.22 (1H, m, CH_2), 3.87 (1H, dd, *J* 4.6, 10.5 Hz, CH), 7.96 (4H, m, SO_2Ph), 8.00 (1H, m, SO_2Ph); ^{13}C NMR: 11.06 (CH_3), 20.68 (CH_2), 58.77 (CH), 113.76 (CN), 129.50 (4C, SO_2Ph), 135.14 (SO_2Ph), 135.50 (quaternary SO_2Ph); *m/z*: 209 (M^+, 6%).

2-Butylphenylsulphonylacetonitrile **2**b
Colorless oil, 2.25 g (31.6%); ν_{max} (KBr) (cm^{-1}): 1160, 1340 (SO_2), 2340 (CN); ^1H NMR: 0.90 (3H, t, *J* 7.2, CH_3), 1.35 (2H, m, CH_2CH_3), 1.89 (2H, m, $CH_2CH_2CH_3$), 2.22 (2H, m, $CH_2CH_2CH_2CH_3$), 3.87 (1H, dd, *J* 4.6, 10.5, CH), 7.59–7.67 (4H, m, SO_2Ph), 7.80–8.02 (1H, m, SO_2Ph); ^{13}C NMR: 13.54 (CH_3), 22.65 (CH_2CH_3), 26.81 ($CH_2CH_2CH_3$), 31.59 ($CH_2CH_2CH_2CH_3$), 57.56 (CH), 113.90 (CN), 129.58 (4C, SO_2Ph), 135.21 (SO_2Ph), 135.58 (quaternary SO_2Ph); *m/z*: 237 (M^+, 4.5%).

Nucleophilic substitution reactions

Monosubstitution
A mixture of 1.0 mmol of starting chloroarene complex, 2.5 mmol of potassium carbonate, 1.05 mmol of **2***a* or **2***b*, and 10 mL of *N,N*-dimethyl formamide was stirred at room temperature, under a nitrogen atmosphere, for 7 h. The resulting red reaction mixture was then filtered into 10 mL of 10% hydrochloric acid, the reaction flask washed with acetone, and the washings were also filtered. The acetone was then removed under reduced pressure and a concentrated aqueous solution of ammonium hexafluorophosphate was added to the filtrate, at which time the product precipitated as a yellow solid. After 10 min the product was collected by filtration, and washed with water followed by diethyl ether.

Photolytic demetallation. General procedure for photolysis

Samples (0.5 mmol) of each of the complexes **3***a–d*, **4***a*, *c*, *d*, **5**, and **6**, were separately dissolved in a mixture of dichloromethane and acetonitrile (30 mL: 10 mL) in a Pyrex tube. The solution was deoxygenated by bubbling nitrogen through it after which the reaction tube was fitted into a photochemical apparatus equipped with a Xenon lamp and irradiated at room temperature for 4 h. The solvent was concentrated to a volume of 1–2 mL using rotary evaporation. The residue was applied to a silica gel column, which was then washed with hexane and eluted with chloroform. Removal of the solvent from the eluate gave the expected liberated arenes with the following yields and spectral data.

*Ethyl phenyl(phenylsulphonylacetonitrile) (7*a*):* isolated as a light cream-colored solid; 0.114 g, 80%; mp 89–91°C. ν_{max} (KBr) (cm^{-1}): 1158, 1340 (SO_2), 2340 (CN); ^1H NMR: 1.02 (3H, t, *J* 7.3, CH_3), 2.63 (2H, m, CH_2), 7.34 (6H, m, ArH and SO_2Ph), 7.63 (4H, m, ArH and SO_2Ph); ^{13}C NMR: 9.21 (CH_3), 25.02 (CH_2), 73.20 (quaternary C-CH_2CH_3), 116.31 (CN), 128.21 (quaternary ArC), 128.49, 128.52, 128.53, 128.65, 128.73 (5C, ArC), 129.98, 130.50 (4C, SO_2Ph), 133.81 (quaternary SO_2Ph), 134.69 (SO_2Ph); *m/z*: 285 (M^+, 1.0%).

*Ethyl (o-tolyl)phenylsulphonylacetonitrile (7*b*):* isolated as a colorless oil; 0.136 g, 91%. ν_{max} (KBr) (cm^{-1}): 1156, 1355 (SO_2), 2305 (CN); ^1H NMR: 1.07 (3H, t, *J* 7.3, CH_3), 2.31 (3H, s, $ArCH_3$), 2.57 (1H, m, CH_2), 2.90 (1H, m, CH_2), 7.08–7.69 (9H, m, ArH and SO_2Ph); ^{13}C NMR: 9.24 (CH_3), 21.76 ($ArCH_3$), 26.98 (CH_2), 67.09 (quaternary C-CH_2CH_3), 117.64 (CN), 125.10 (quaternary ArC), 126.38, 128.84 (3C, ArC), 130.08, 130.79 (4C, SO_2Ph), 133.31 (ArC), 134.20 (quaternary SO_2Ph), 134.87 (SO_2Ph), 140.34 (quaternary ArC); *m/z*: 299 (M^+, 1.0%).

*Ethyl (m-tolyl)phenylsulphonylacetonitrile (7*c*):* isolated as a light cream-colored solid; 0.127 g, 85%; mp 84–85.5°C. ν_{max} (KBr) (cm^{-1}): 1158, 1330 (SO_2), 2300 (CN); ^1H NMR: 1.05 (3H, t, *J* 7.4, CH_3), 2.28 (3H, s, $ArCH_3$), 2.68 (2H, m, CH_2), 7.20 (4H, m, ArH), 7.44 (2H, m, SO_2Ph), 7.57 (3H, m, SO_2Ph); ^{13}C NMR: 9.23 (CH_3), 21.29 ($ArCH_3$), 24.91 (CH_2), 73.22 (quaternary C-CH_2CH_3), 116.43 (CN), 125.54 (ArC), 127.99 (quaternary ArC), 128.57(2C, ArC), 129.23 (ArC), 130.59, 130.72 (4C, SO_2Ph), 133.85 (quaternary SO_2Ph), 134.68 (SO_2Ph), 138.62 (quaternary ArC); *m/z*: 299 (M^+, 1.0%).

*Ethyl (p-tolyl)phenylsulphonylacetonitrile (7*d*):* isolated as a light cream-colored solid; 0.120 g, 80%; mp 90–92°C. ν_{max} (KBr) (cm^{-1}): 1160, 1330 (SO_2), 2305 (CN); ^1H NMR: 1.04 (3H, t, *J* 7.4, CH_3), 2.37 (3H, s, $ArCH_3$), 2.67 (2H, m, CH_2), 7.14 (2H, d, *J* 6.4, ArH), 7.26 (2H, d, *J* 6.3, ArH), 7.42 (2H, m, SO_2Ph), 7.60 (3H, m, SO_2Ph); ^{13}C NMR: 9.21 (CH_3), 21.13 ($ArCH_3$), 25.05 (CH_2), 73.03 (quaternary C-CH_2CH_3), 116.48 (CN), 125.05 (quaternary ArC), 128.47, 128.65 (4C, ArC), 129.47, 130.62 (4C, SO_2Ph), 133.66 (quaternary SO_2Ph), 134.66 (SO_2Ph), 140.29 (quaternary ArC); *m/z*: 299 (M^+, 1.0%).

Abstract: A spectrophotometric method, called the Indicator Increment Method, is described in which varying amounts of a complexing indicator are added to a sample and the visible spectra recorded after each addition. Through multiple equilibrium calculations the free metal ion concentration, as well as total metal and total ligand concentrations, can be estimated in systems that contain a single metal ion and one ligand. The technique was tested successfully for the determination of free magnesium in the presence of NTA, phosphate, or oxalate using calmagite as indicator. The method requires the approximate conditional stability constant of the metal–ligand complex to be known beforehand.

Key words: ionized magnesium, indicator increment method, spectrophotometry.

Résumé : On décrit une méthode spectrophotométrique, appelée méthode de l'incrément d'indicateur, dans laquelle on ajoute des quantités variables d'un indicateur complexant à un échantillon et on détermine son spectre visible après chaque addition. Utilisant des calculs d'équilibres multiples, on peut évaluer la concentration de l'ion métallique libre ainsi que les concentrations totales du métal et du coordinat dans des systèmes contenant un seul ion métallique et un seul coordinat. On a évalué la technique avec succès pour la détermination du magnésium libre, en présence de NTA, de phosphate ou d'oxalate, en utilisant de la calmagite comme indicateur. La méthode nécessite de connaître à l'avance la constante de stabilité conditionnelle approximative du complexe métal–coordinat.

Mots cles : magnésium ionisé, méthode de l'incrément d'indicateur, spectrophotométrie.

[Traduit par la rédaction]

Introduction

The measurement of uncomplexed metal ion concentrations in solutions containing bound or complexed metal is of biological and environmental interest because it is usually the free, or hydrated, form that more readily undergoes reaction. Knowledge of free ion levels in solution is needed in, for example, industrial applications in metallurgy, electroplating, and food processing (1), clinical measurement of physiologically important ionic calcium and magnesium in serum and urine (2–5), biomedical investigations of mechanisms such as formation of kidney stones (6–9), and environmental studies (10, 11). The major methods in use at this time for these determinations are ion selective electrode potentiometry and spectrophotometry, although other techniques have been described, including ion exchange, voltammetry, dialysis, and multiple equilibria calculations from total analysis.

Spectrophotometric methods have been especially useful in the determination of metal ions in biological systems. An example is the determination of calcium with Arsenazo III (12). A modification of the general technique, called the Sample Ion Increment Method (SIIM) (13), gives improved sensitivity over a broader range of sample concentrations. With the SIIM method, a known quantity of indicator is added to the sample and the absorbance measured, then a known increment of the species to be determined is added and the absorbance remeasured. The second measurement determines the extent of "species buffering" in the original sample and permits correction for complexation by the indicator. We describe here a different approach, called the Indicator Increment Method (IIM), which uses equilibrium calculations based on absorbance measurements following addition of varying amounts of indicator rather than metal ion. Like the SIIM method, the IIM method is useful for metal–ligand systems with low metal ion buffer capacity, a situation where the simple spectrophotometric method is not applicable. For a system containing a single metal ion and ligand, the method allows the estimation

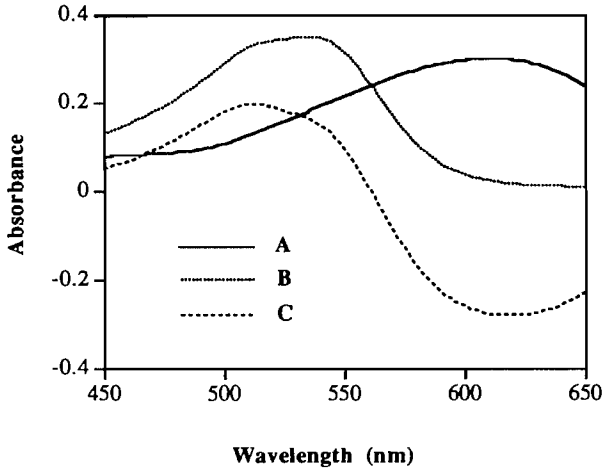
The maximum in the difference spectrum occurs at 512 nm and the minimum at 616 nm.



of not only the free metal ion concentration but also the total metal and total ligand concentrations.

Experimental

Reagents and chemicals

A 5×10^{-3} M solution of $Mg(NO_3)_2$ was prepared by dissolving 0.6410 g of $Mg(NO_3)_2 \cdot 6H_2O$ (Baker Analyzed Reagent) in 500 mL pure water. Commercial calmagite (Terochem Laboratories, Edmonton, Canada) was found by spectrophotometric titration with a standard solution of $Mg(NO_3)_2$ to have a purity of 69%, a level adequate for the two-wavelength method used in this study. Concentrations of calmagite solutions (1 mM) were calculated on the basis of this purity. Solutions were adjusted to an ionic strength of 0.1 by addition of 1.0 M KNO_3 (BDH analytical reagent), which had been passed through a column of Dowex® Chelating Resin (Sigma) to remove polyvalent cations (14). All other chemicals were analytical grade and were used without further purification. Distilled water was passed through a Barnstead NANOpure water purification system before use.

Instrumentation

All pH measurements were made with a Fisher Accumet® model 520 pH/ion meter and a glass–calomel electrode pair calibrated with commercial buffers (Fisher). Spectrophotometric measurements were made in a constant temperature room thermostated at 25 ± 1°C on a Hewlett–Packard model 8451A diode array spectrophotometer with 1-cm silica cells; the spectra were stored on 3.5 in. floppy disks for later processing.

Procedure

The molar absorptivity values of calmagite at 512 and 616 nm were determined by measuring the absorbance of a series of solutions at pH 10 and ionic strength 0.1. These wavelengths were chosen because the difference between the molar absorptivities of the Mg^{2+}–calmagite complex and the free indicator was largest at these values (see Fig. 1). Absorption coefficients for the Mg^{2+}–calmagite complex at these wavelengths were determined by measuring the absorbances of a series of solutions containing varying excess amounts of Mg^{2+} and a constant calmagite concentration. Incomplete complexation of calmagite was estimated and corrected for by an iteration method using an estimated initial conditional stability constant for the complex. The actual conditional stability constant of the Mg^{2+}–calmagite complex was determined by measuring, at 512 and 616 nm, a second series of solutions containing differing amounts of Mg^{2+} and calmagite; a value of 2.56×10^5 M^{-1} was found under the experimental conditions used. This compares satisfactorily with a reported value of 4.87×10^5 M^{-1}, measured using the continuous variation method in 0.1 M potassium chloride (15).

For each magnesium – nitrilotriacetic acid (Mg^{2+}–NTA) experiment, 0.4, 0.6, and 0.8 mL increments of 1.06×10^{-3} M calmagite solution were added to a set of three 25-mL volumetric flasks containing 20 mL of a magnesium–NTA solution. Sufficient 1.0 M KNO_3 was added to each of the flasks to adjust the final ionic strength to 0.1 after dilution to 25 mL. The pH of each solution was adjusted to near 10 by addition of dilute NaOH, followed by a small amount of pH 10 NH_3–NH_4NO_3 buffer. Absorbances were measured at 512 and 616 nm for each of the solutions after dilution to 25 mL with pure water. Two additions of indicator provide sufficient information to solve the equations, but we usually added indicator solution three times so that three pairs of results (termed 1,2; 1,3; and 2,3) could be used in the calculation of $[M_T]_0$, $[F_L]_0$, and $[M]_0$ in each solution.

A similar procedure was followed for the other systems with the exception of the Mg^{2+}–K_2HPO_4 study, where phosphate provided adequate buffering on its own.

Theory

Equations for calculation of free metal ion concentrations by the Indicator Increment Method (IIM) are developed here for three systems, one consisting of a metal ion M and a ligand H_nL that react to form a single metal–ligand complex ML, a second the same but including formation of complexes of the type ML, MHL, MH_2L, ... , and a third including formation of both ML and ML_2.

Case 1. Determination of free metal ion concentration in a solution containing metal ion, protonated ligand, and metal–ligand complex

The free metal ion concentration $[M]_0$ in an unknown solution is determined by adding a known amount of an indicator H_nI that forms a 1:1 colored complex, $[MI]_i$, with the metal. First $[MI]_i$ is calculated, then $[M]_i$, as follows (charges on the ions have been omitted for simplicity):

The absorbance A_0 of a sample solution of volume V_0 in a cell of pathlength b is measured at two wavelengths; here 512 nm (A_0^{512nm}) and 616 nm (A_0^{616nm}) were selected. A known quantity of indicator ligand H_nI is added to the solution and a new absorbance A_i measured (as A_i^{512nm} and A_i^{616nm}) at the two wavelengths in the new volume V_i. The difference in absorbance values between the two wavelengths is used for the calculations ($A_0 = A_0^{512nm} - A_0^{616nm}$, $A_i = A_i^{512nm} - A_i^{616nm}$).

Then

$$[1] \quad A_i - A_0 \frac{V_0}{V_i} = \epsilon_{MI} b[MI]_i + \Sigma\epsilon' b([F_I]_i - [MI]_i)$$

where

$$\Sigma\epsilon' = \alpha_{H_nI}\epsilon_{H_nI} + \alpha_{H_{n-1}I}\epsilon_{H_{n-1}I} + \ldots + \alpha_I\epsilon_I$$

The α terms are the fractions of uncomplexed indicator in each of its protonated forms; the ϵ terms are the corresponding absorption coefficient differences at the two wavelengths of the subscript species. $[F_I]_i$ is the total indicator concentration in the solution being measured. Once $[MI]_i$ has been measured, $[M]_i$ can be obtained from the relation

$$[2] \quad [MI]_i = \frac{[MI]_i}{K'_{MI}\{[F_I]_i - [MI]_i\}}$$

where K'_{MI} is the conditional stability constant for the metal–indicator complex. The free metal ion concentration in the initial solution $[M]_0$ may be calculated from the stability constant expression K'_{ML} once $[M_T]_0$ and $[F_L]_0$ have been determined. Their values are obtained by use of the expressions described in the next section.

(i) Determination of total metal $[M_T]_0$ and total ligand $[F_L]_0$ concentration in a solution containing M, H_nL, and ML

Consider a sample solution containing a metal ion M and an auxiliary ligand H_nL for which ML is the only major metal ligand complex formed. The species present under these conditions are M, L, ML, HL, H_2L, ... , H_nL. An indicator H_nI that forms only the single colored complex MI is now added to the sample solution. The total concentration of auxiliary ligand $[F_L]$ is given by

$$[F_L] = [L] + [HL] + \ldots + [H_nL] + [ML]$$

and the fraction of uncomplexed auxiliary ligand α_L by

$$\alpha_L = \frac{[L]}{[F_L] - [ML]}$$

The conditional stability constant K'_{ML} for formation of ML is the product of the thermodynamic stability constant K_{ML} and α_L:

$$K'_{ML} = K_{ML}\alpha_L = \frac{[ML]}{[M]\{[F_L] - [ML]\}}$$

Rearranging gives

$$[3] \quad [ML] = \frac{K'_{ML}[F_L][M]}{1 + K'_{ML}[M]}$$

If now a solution containing indicator H_nI is added to an original sample solution having a total metal ion concentration of $[M_T]_0$ and a total ligand concentration of $[F_L]_0$, both complexation of metal by the indicator and dilution occurs. Under these conditions $[F_L]_i = [F_L]_0\, V_0/V_i$ and $[M_T]_i = [M_T]_0\, V_0/V_i = [M]_i + [ML]_i + [MI]_i$. Then

$$[4] \quad [ML]_i = [M_T]_0\,(V_0/V_i) - [M]_i - [MI]_i$$

From eq. [3], $[ML]_i$ can also be written as

$$[5] \quad [ML]_i = \frac{V_0}{V_i}\,\frac{K'_{ML}[F_L]_0[M]_i}{1 + K'_{ML}[M]_i}$$

Combining eqs. [4] and [5] and rearranging,

$$[6] \quad [M_T]_0(V_0/V_i) + (V_0/V_i)\,[M]_iK'_{ML}\{[M_T]_0 - [F_L]_0\} - \{[M]_i([M]_i + [MI]_i)K'_{ML} + ([M]_i + [MI]_i)\} = 0$$

Separating terms in $[M_T]_0$ and $[F_L]_0$,

$$[7] \quad (V_0/V_i) + [M]_iK'_{ML}V_0/V_i)[M_T]_0 - ([M]_iK'_{ML}V_0/V_i)[F_L]_0 - ([M]_i + [MI]_i)(1 + K'_{ML}[M]_i) = 0$$

If $[MI]_i$, $[M]_i$, V_0, V_i, and K'_{ML} are known, eq. [7] becomes an expression of the form

$$[8] \quad a_i[M_T]_0 + b_i[F_L]_0 + c_i = 0$$

where

$$a_i = (V_0/V_i) + [M]_iK'_{ML}V_0/V_i$$

$$b_i = -\,[M]_iK'_{ML}V_0/V_i$$

and

$$c_i = -\,([M]_i + [MI]_i)(1 + K'_{ML}[M]_i)$$

If indicator solution is added twice and absorbance measurements are made after each addition, two equations of the form of eq. [8] can be written, from which values of $[M_T]_0$ and $[F_L]_0$ can be obtained.

(ii) Calculation of $[M]_0$

The value of $[M]_0$ may now be obtained from the K'_{ML} expression

$$[9] \quad K'_{ML} = \frac{[ML]_0}{[M]_0([F_L]_0 - [ML]_0)} = \frac{[M_T]_0 - [M]_0}{[M]_0([F_L]_0 - [M_T]_0 + [M]_0)}$$

By rearrangement to quadratic form,

$$[10] \quad K'_{ML}[M]_0^2 + \{K'_{ML}([F_L]_0 - [M_T]_0) + 1\} \times [M]_0 - [M_T]_0 = 0$$

Solution of this equation gives the free metal ion concentration in the original system $[M]_0$.

Case 2. Determination of $[M_T]_0$, $[F_L]_0$, and $[M]_0$ when protonated metal complexes of the type ML, MHL, MH_2L, ... form

If a series of soluble metal complexes form that contain protons or hydroxyl ions, and the conditional overall stability constants are known for each complex, then a modification of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

previously described approach can be used. For the simplest case, when the only additional species is MHL, the mass balance equations for the original solution are

$$[11] \quad [M_T]_0 = [M]_0 + [ML]_0 + [MHL]_0$$

and

$$[12] \quad [F_L]_0 = [L]_0 + [HL]_0 + [ML]_0 + [MHL]_0$$

For ML in this system,

$$[13] \quad K'_{ML} = K_{ML}\alpha_L = \frac{[ML]_0}{[M]_0\{[F_L]_0 - ([ML]_0 + [MHL]_0)\}}$$

while for MHL

$$[14] \quad K'_{MHL} = K_{MHL}\alpha_{HL} = \frac{[MHL]_0}{[M]_0\{[F_L]_0 - ([ML]_0 + [MHL]_0)\}}$$

Combining eqs. [13] and [14] gives

$$[15] \quad [ML]_0 + [MHL]_0 = \frac{[M]_0[F_L]_0(K'_{ML} + K'_{MHL})}{1 + [M]_0(K'_{ML} + K'_{MHL})}$$

For the more general case where polyprotonated metal ligand complexes of the type MH_2L or MH_3L form in significant concentrations, eq. [15] becomes

$$[16] \quad [ML]_0 + [MHL]_0 + [MH_2L]_0 \ldots = \frac{[M]_0[F_L]_0(K'_{ML} + K'_{MHL} + K'_{MH_2L} + \ldots)}{1 + [M]_0(K'_{ML} + K'_{MHL} + K'_{MH_2L} + \ldots)} = \frac{[M]_0[F_L]_0K'_\Sigma}{1 + [M]_0K'_\Sigma}$$

A similar expression can be written to take into account the formation of complexes containing hydroxyl ions of the type $M(OH)_xL$.

When indicator is added as described in Case 1, solution conditions are shifted from "0" to "i", giving $[F_L]_i = V_0/V_i[F_L]_0$ and $[M_T]_i = V_0/V_i\,[M_T]_0$. From eq. [16]

$$[17] \quad [ML]_i + [MHL]_i + [MH_2L]_i \ldots = \frac{V_0}{V_i}\,\frac{[M]_i[F_L]_0K'_\Sigma}{1 + [M]_iK'_\Sigma}$$

and from mass balance

$$[18] \quad [ML]_i + [MHL]_i + [MH_2L]_i \ldots = \frac{V_0}{V_i}\,[M_T]_0 - [M]_i - [MI]_i$$

Combining eqs. [17] and [18], and rearranging, gives

$$[19] \quad \left\{\frac{V_0}{V_i}(1 + [M]_iK'_\Sigma)\right\}[M_T]_0 - \left\{\frac{V_0}{V_i}[M]_iK'_\Sigma\right\}[F_L]_0 - \{([M]_i^2 + [M]_i[MI]_i)K'_\Sigma + [M]_i - [MI]_i\} = 0$$

This is an equation of the form

$$[20] \quad a_1[M_T]_0 + b_1[F_L]_0 + c_1 = 0$$

Addition of a second increment of indicator and remeasurement gives a second equation

$$[21] \quad a_2[M_T]_0 + b_2[F_L]_0 + c_2 = 0$$

which when solved simultaneously with eq. [20] gives values for $[M_T]_0$ and $[F_L]_0$. A value for $[M]_0$ can then be obtained from eqs. [11] and [15].

Case 3. Estimation of $[M_T]_0$, $[F_L]_0$, and $[M]_0$ when metal–ligand complexes ML and ML_2 form

When both 1:1 and 1:2 metal–ligand complexes form, the relationships are

$$[M_T]_0 = [M]_0 + [ML]_0 + [ML_2]_0$$

and

$$[F_L]_0 = [L]_0 + [HL]_0 + [H_2L]_0 + \ldots + [H_nL]_0 + [ML]_0 + 2[ML_2]_0$$

Let

$$[F_L]_0^* = [L]_0 + [HL]_0 + [H_2L]_0 + \ldots + [H_nL]_0$$

Then

$$[22] \quad [F_L]_0 = [F_L]_0^* + [ML]_0 + 2[ML_2]_0$$

Since

$$\beta'_{ML} = \frac{[ML]_0}{[M]_0\,[F_L]_0^*} \quad \text{and} \quad \beta'_{ML_2} = \frac{[ML_2]_0}{[M]_0[F_L]_0^{*2}}$$

then

$$[23] \quad [ML]_0 + [ML_2]_0 = \beta'_{ML}[M]_0[F_L]_0^* + \beta'_{ML_2}[M]_0[F_L]_0^{*2}$$

On addition of indicator H_nI,

$$[24] \quad [ML]_i + [ML_2]_i = \beta'_{ML}[M]_i[F_L]_i^* + \beta'_{ML2}[M]_i[F_L]_i^{*2}$$

and, from mass balance for $[M_T]$,

$$[25] \quad [ML]_i + [ML_2]_i = \frac{V_0}{V_i}\,[M_T]_0 - [M]_i - [MI]_i$$

When $[F_L]_0 >> [M_T]_0$, then $[F_L]_0^* \approx [F_L]_0$, and $[F_L]_i^* \approx [F_L]_0^*(V_0/V_i)$ Substituting into eq. [24], and combining with [25], gives upon rearrangement

$$[26] \quad \frac{V_0}{V_i}\,[M_T]_0 - \frac{V_0}{V_i}\,\beta'_{ML}[M]_i[F_L]_i^* - \left(\frac{V_0}{V_i}\right)^2\beta'_{ML_2}[M]_i[F_L]_i^{*2} - [M]_i - [MI]_i = 0$$

Upon addition of another increment of indicator solution and measurement of [MI] after the addition, values of V_0, V_1, V_2, $[M]_1$, $[M]_2$, $[MI]_1$, and $[MI]_2$ can be obtained. With knowledge of β'_{ML} and β'_{ML_2}, the pairs of equations

$$a_1[M_T]_0 + b_1[F_L]_0^* + c_1[F_L]_0^{*2} + d_1 = 0$$

and

$$a_2[M_T]_0 + b_2[F_L]_0^* + c_2[F_L]_0^{*2} + d_2 = 0$$

can be solved to obtain $[M_T]_0$ and $[F_L]_0^*$. Then $[M]_0$ can be found from

$$[27] \quad [M]_0 = \frac{[M_T]_0}{1 + \beta'_{ML}[F_L]_0^* + \beta'_{ML_2}[F_L]_0^{*2}}$$

Results and Discussion

Application of Case 1 to the Mg^{2+} – nitrilotriacetic acid system

The ligand NTA (nitrilotriacetic acid), which is reported to form only a 1:1 complex with magnesium (16), was selected to test the applicability of Case 1. The conditional stability constant of the Mg^{2+}–NTA complex in concentration terms (log $K' = 5.31$) was obtained from the literature (16) by multiplying the literature value by the fraction α of unprotonated ligand (L^{-3}) present ($\alpha_{L^{-3}} = 0.69$ at pH 10).

Possible formation of $MgOH^+$ at pH 10 was considered. A stability constant for this species at ionic strength 0.1 is not available, but a log K value of 2.1 was calculated from the value reported at infinite dilution, 2.58 (17), and the extended Debye–Hückel equation. Using this value, the fraction of magnesium present as $MgOH^+$ at pH 10 was estimated to be 0.012, a level sufficiently small to be neglected for the purpose of this work. Another possible competing ligand was NH_3 coming from the small amount of NH_3 buffer used. The final concentration of NH_3 in the solution, 3×10^{-3} M, was so small, however, that formation of a magnesium–ammonia complex was considered to be negligible.

To reduce measurement uncertainty in the IIM method it is important to select the appropriate amount of indicator to be added in each increment. The amount should be sufficient to cause a significant equilibrium shift in the original system, since the larger the shift the more accurate the results. It should not be too large, however, or the initial ionic strength of the solution may be shifted enough to affect the conditional stability constants of metal–indicator and metal – auxiliary ligand complexes.

An equilibrium shift means that the free metal ion concentration is reduced when indicator is added. Such a shift will only be seen in solutions where the metal ion buffer capacity is low. For systems with high metal ion buffer capacity, the free metal ion concentration will not be affected by indicator addition. In this situation a simple direct spectrophotometric method can be used. Thus the IIM method offers a complimentary tool for conventional spectrophotometric free metal ion determinations.

A summary of the results, calculated on a Macintosh computer using a BASIC program written for the purpose,[2] is shown in Table 1. It can be seen that agreement between experimental and calculated values is acceptable considering the low concentrations being measured.

Application of Case 2 to magnesium–K_2HPO_4 system

The ligand K_2HPO_4 at a total concentration of 2.5 mM was selected to verify Case 2 because it forms magnesium complexes mainly in the form of $MgPO_4^-$ and $MgHPO_4$. At pH 10, 98.2% of the phosphate is in the form of HPO_4^{2-}, with the

remainder present as PO_4^{3-}. The conditional stability constants for the $MgPO_4^-$ and $MgHPO_4$ species in concentration terms were calculated from literature values (18) corrected to pH 10. Also, potassium ion complexation was taken into account through the relation $K_{MgL} = K'_{MgL}(1 + K_{KL}[K^+])$. Ionic strength effects were corrected for using the Davies equation; a log K'_Σ value of 2.23 was obtained at ionic strength 0.1 and pH 10. The wavelengths used, as well as all other experimental conditions, were as in Case 1. The results, Table 2, show the measured values of $[M]_0$ to agree well with the calculated ones. Values for $[M_T]_0$ and $[F_L]_0$ also agree well with the initial amounts taken.

Application of Case 3 to the magnesium–oxalic acid system

Oxalate forms two relatively stable complexes with magnesium, ML and ML_2. At pH 10, nearly 100% of oxalate is in the $C_2O_4^{2-}$ form. The conditional stability constants at pH 10, calculated from literature data (19), are 575 for K_{ML} and 17 400 for K_{ML_2}. A small amount of NH_3 (final $C_{NH_3} = 3 \times 10^{-3}$ M) was added to buffer the system after initial adjustment to near pH 10 with NaOH. All other conditions were the same as in Case 1. The results, shown in Table 3, indicate quite satisfactory agreement.

Effect of K'_{ML} value on results

For all three cases discussed above, values of the metal–auxiliary ligand conditional stability constants are needed in order to carry out the calculations. The effect of the values chosen for these conditional stability constants on the results found

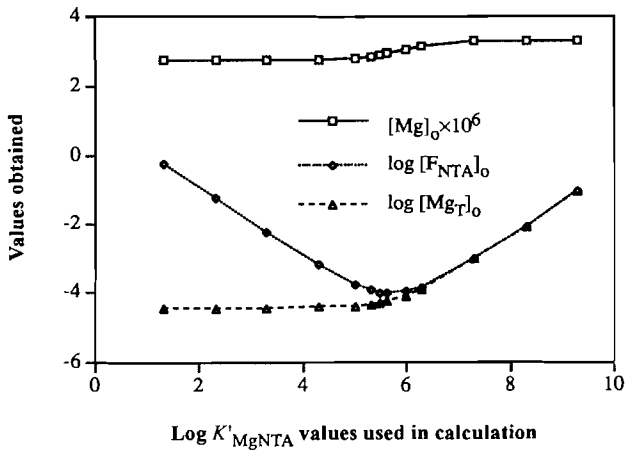
Fig. 2. Effect of variation in value of K'_{MgNTA} used on calculated free metal ion concentrations (plotted as calculated value $\times 10^6$), and on calculated total ligand and total metal ion concentrations (plotted as log values).



for the free metal ion, total ligand, and total metal ion concentrations was studied using the experimental data for solution 1 of Case 1. Changing $K'_{Mg\text{-}NTA}$ from the calculated literature value of 2.0×10^5 shows that the free magnesium ion concentration shifts from −4% of the original value for a 10 000 times smaller $K'_{Mg\text{-}NTA}$ to +16% of the original for a 10 000 times larger $K'_{Mg\text{-}NTA}$ (see Fig. 2). This means that estimation of free metal ion concentrations is still possible even though the conditional stability constant of the metal–ligand complex is not known precisely.

On the other hand, calculated values for total ligand concentrations are unacceptably large when $K'_{Mg\text{-}NTA}$ is made 10 000 times smaller, and they decrease as $K'_{Mg\text{-}NTA}$ increases until $K'_{Mg\text{-}NTA}$ is close to $K'_{Mg\text{-}calmagite}$ (2.6×10^5), then increase with further increases in $K'_{Mg\text{-}NTA}$. Calculated values for total metal ion concentrations do not change much when $K'_{Mg\text{-}NTA}$ is smaller than $K'_{Mg\text{-}calmagite}$, but increase as $K'_{Mg\text{-}NTA}$ becomes close to $K'_{Mg\text{-}calmagite}$, and become essentially identical to calculated total ligand concentrations when $K'_{Mg\text{-}NTA}$ is larger than $K'_{Mg\text{-}calmagite}$. This suggests that accurate estimation of total ligand and total metal ion concentrations is not feasible unless the conditional stability constant of the metal–ligand complex is known in advance with reasonable accuracy.

Similar results were obtained when both free and total species concentrations were evaluated for Cases 2 and 3.

Conclusions

An advantage of the IIM method is that both total metal ion and total ligand concentrations can be obtained in addition to the concentration of free metal ion. Also, the method is especially useful for metal–ligand systems with low metal ion buffer capacity, a situation where the traditional simple spectrophotometric method is not applicable. A disadvantage is that preliminary information on the ligand and its conditional stability constant with the metal must be available or determined beforehand, although an estimation of the free metal ion concentration is still possible when the conditional stability constant is not known. Also, the magnesium–calmagite system used here requires measurements to be made at a known pH near 10 and at constant ionic strength. Other metals that form complexes with calmagite, such as calcium, may interfere by competing with magnesium for the indicator. However, the approach is suitable for situations where species concentrations in a defined metal–ligand system are to be monitored. The precision and accuracy of the free magnesium measurements can be considered to be satisfactory, in light of the limited availability of alternative methods.

Subpicosecond vibrational relaxation of the S_1 states of azulene and guaiazulene in solution

Dietrich Tittelbach-Helmrich, Brian D. Wagner, and Ronald P. Steer

Abstract: The S_1 population decay times of azulene and 1,4-dimethyl-7-isopropylazulene (guaiazulene) in solution have been determined as a function of their initial vibrational energy content, E^i_{vib}, using a pump–probe experiment with subpicosecond time resolution. The S_1 lifetime of azulene does not depend on E^i_{vib} for energies up to 1760 cm^{-1}, whereas the lifetime of the shorter-lived S_1 state of guaiazulene is independent of E^i_{vib} only for energies up to ~1000 cm^{-1}. At higher energies, the lifetime decreases with increasing E^i_{vib}, and exhibits the same behavior in two structurally different solvents. It is suggested that internal conversion to the electronic ground state from a vibrationally unrelaxed S_1 state is responsible for the effects observed in guaiazulene, and that intramolecular vibrational redistribution occurs with a time constant of several hundred femtoseconds.

Key words: pump–probe spectroscopy, azulene, femtosecond processes.

Résumé : Utilisant une expérience de pompe–sonde avec un temps de résolution inférieur à la picoseconde, on a déterminé les temps de dégénérescence de la population S_1 de l'azulène et du 1,4-diméthyl-7-isopropylazulène (guaïazulène) en solution en fonction de leur contenu énergétique vibrationnel initial, E^i_{vib}. Le temps de vie de l'état S_1 de l'azulène ne dépend pas de E^i_{vib} pour les énergies allant jusqu'à 1760 cm^{-1} alors que celui de l'état S_1 du guaïazulène, qui est beaucoup plus court, n'est indépendant de E^i_{vib} que jusqu'à des énergies d'environ 1000 cm^{-1}. À des énergies plus élevées, le temps de vie diminue avec une augmentation de E^i_{vib} et il présente le même comportement dans deux solvants de structures différentes. Il est suggéré que la conversion interne d'un état S_1 qui n'a pas subi de relaxation vibrationnelle vers l'état électronique fondamental est responsable pour les effets observés avec le guaïazulène et qu'une redistribution vibrationnelle intramoléculaire se produit avec une constante de temps de plusieurs centaines de femtosecondes.

Mots clés : spectroscopie pompe–sonde, azulène, processus femtosecond.

[Traduit par la rédaction]

1. Introduction

Picosecond pump–probe methods have been used for 20 years to investigate the fast relaxation processes of the first excited singlet state (S_1) of azulene and related molecules in condensed media (1–8). In these experiments the pump pulse populates S_1 and the probe pulse, after appropriate variable temporal delay, probes S_1 by exciting fluorescence from S_2. When these experiments are carried out in solution the amount of vibrational energy deposited in the molecule by the probe laser is not critical because the fluorescent S_2 state is photostable and relatively long-lived (ca. 1–2 ns for azulene in several solvents (9)) whereas vibrational thermalization occurs in a much shorter period (for a review, see ref. 10). Emission is therefore always observed from the vibrationally relaxed S_2 state. On the other hand, the amount of vibrational energy deposited in the molecule by the pump laser may be important because the S_1 states have population decay times that are much shorter, of the order of 0.5–5 ps (1–8).

Several previous experiments employed a single pulsed laser to generate both pump and probe beams, and one such experiment examined the effect of the initial vibrational energy, E^i_{vib}, on the lifetime of S_1 (11). The latter investigation

reported no measurable change in the picosecond decay rate of the S_1 state of azulene in dichloroethane or methylcyclohexane solution at $E^i_{vib} \leq 4800\ cm^{-1}$, but was conducted with equipment that only permitted the observation of variations greater than a factor of 2 or 3. Very recently, however, Matsumoto et al. (6) reported that they had measured the vibrational relaxation time within the S_1 state of azulene in ethylene glycol and found it to decrease from 300 fs at $E^i_{vib} = 850\ cm^{-1}$ to 50 fs at $E^i_{vib} = 1630\ cm^{-1}$. The fact that in the same experiment they measured an S_1 population decay time that was a factor of ca. 2 too long (8) could cast some doubt on these results.

We have developed a two-photon fluorescence experiment with subpicosecond time resolution and have determined the effect of E^i_{vib} on the population decay rates of azulene and 1,4-dimethyl-7-isopropylazulene (guaiazulene) in several solvents. The results indicate that the S_1 population decay of guaiazulene may be used as a fast internal clock against which the rates of its vibrational thermalization may be calibrated.

2. Experimental section

The sub-picosecond pump–probe laser system used in this work was described in detail previously (7). Briefly, the output of a mode-locked Spectra-Physics Nd:YAG laser is passed through a fibre optic pulse compressor and an SHG crystal to generate 532 nm light, which synchronously pumps a Spectra-Physics dye laser operating on DCM. The dye laser produces approximately 70–100 mW of average power, consisting of trains of mode-locked pulses having a $sech^2$ shape and a FWHM of ca. 0.5 ps, as measured using an autocorrelation technique (7). The dye laser output is split into two beams of approximately equal intensity, generating pump and probe beams. The pump beam is mildly focussed onto the contents of a 0.1 mm path length quartz cell, while the probe beam is passed through an optical delay line before being focussed onto the same cell in a colinear, counterpropagating fashion. Fluorescence in the near-uv–visible is collected, passed through band-pass filters to remove scattered exciting light, and detected with a single photon counting photomultiplier tube.

The instrument response function (IRF) is measured by determining the intensity of two-photon excited fluorescence from the S_1 state of an ultraviolet laser dye (e.g., α-NPO) as a function of the pump–probe delay time. The IRF is typically near Gaussian in shape with a FWHM of ca. 1.3 ps, due principally to jitter between the two trains of pulses. This FWHM is an improvement by a factor of nearly 2 over our previous two-color (two dye-laser) pump–probe experiments (7), and allows the measurement of shorter lifetimes than previously possible in the two-color mode. The excited state population decay constant of the sample is obtained by deconvolution of the measured $S_2 \rightarrow S_0$ fluorescence intensity vs. optical delay profile and the IRF measured under identical conditions. Deconvolution was effected using the standard Marquardt algorithm, assuming a single exponential population decay function for the S_1 state, as previously described (7). A recent, detailed analysis of two-photon, one- and two-color, pump–probe, laser–molecule interactions using a semi-analytic perturbative approach has shown that reliable population decay constants can be obtained with the procedures used here (12). The precision of the lifetime measurements in the present experiments is typically ca. 80 fs.

Azulene and guaiazulene (Aldrich), acetonitrile (BDH, Omnisolv), and perfluoro-*n*-hexane (PCR) were all used as received. Cyclohexane (BDH, Omnisolv) was fractionally distilled before use. The solutions were ca. 6×10^{-3} M in concentration. All experiments were conducted at room temperature, 20 ± 1°C.

3. Results and discussion

We previously measured the population decay times of the S_1 states of azulene, guaiazulene, and several other substituted azulenes in solvents of varying polarity, viscosity, and structure (7, 8). Variations in the population decay times (of the vibrationally relaxed S_1 states) were found to be governed exclusively by the Franck–Condon factors for the $S_1 \rightsquigarrow S_0$ radiationless transition, which decrease approximately exponentially with increasing S_1–S_0 electronic energy spacing, $\Delta E(S_1–S_0)$. No effect of changing the excitation wavelength, and hence E^i_{vib}, was observed on the S_1 lifetime of azulene. However, the temporal resolution of our experiment is now significantly better than when these measurements were first carried out, and we therefore redetermined the S_1 lifetimes of azulene in cyclohexane for pump wavelengths from 685 to 620 nm, which provide between 230 and 1760 cm^{-1} of excess vibrational energy in the nascent excited state. Again, no effect was observed, and a constant value of $\tau = 1.00 \pm 0.08$ ps was determined, in perfect agreement with our previous result (7). This indicates that the rate of vibrational relaxation within S_1 is faster than the rate of internal conversion from S_1 to S_0, so that excited state depopulation occurs from the vibrationally relaxed S_1 state. Such behavior is typical of polyatomic molecules in condensed phase (Vavilov's law). However, for guaiazulene, whose S_1–S_0 energy gap is smaller and which therefore has a shorter S_1 lifetime, a significant increase in the rate of population decay was observed with increasing E^i_{vib}. The results are shown in Fig. 1 where $\log(\tau^{-1}) = \log(\Sigma k_{nr})$ is plotted vs. E^i_{vib}.

The following observations are significant and form the basis for further comment. (*i*) The global average values of $\tau(S_1)$ for guaiazulene at low E^i_{vib} are 0.53 ± 0.08 and 0.52 ± 0.03 ps in perfluoro-*n*-hexane and cyclohexane, respectively. (*ii*) The values of $\tau(S_1)$ for guaiazulene in both cyclohexane and perfluoro-*n*-hexane decrease (apparently exponentially) with increasing E^i_{vib}, in contrast to azulene itself. (*iii*) No significant difference is found between the profiles of $\tau(S_1)$ (or $\log_{10}(\Sigma k_{nr})$, Fig. 1) vs. E^i_{vib} for guaiazulene in two structurally different solvents.

The values of $\tau(S_1)$ obtained when guaiazulene is excited to low E^i_{vib} ($\lesssim 1000\ cm^{-1}$) yield values of $\log(k_{nr})$ that fall squarely on the plot of the energy-gap law constructed previously from data taken for six azulene derivatives in six different solvents (Fig. 2) (7, 8). We note that $\Delta E(S_1–S_0)$ for guaiazulene is almost identical in both perfluoro-*n*-hexane and cyclohexane, so identical lifetimes of the thermalized S_1 states are to be expected in these two solvents if the energy-gap law (13) accurately describes the rates of radiationless decay in these systems. We therefore conclude that (*i*) the energy-gap law does model the $S_1 \rightsquigarrow S_0$ radiationless process reasonably well, at least over the limited range of $\Delta E(S_1–S_0)$ examined here (Fig. 2); (*ii*) the S_1 state of guaiazulene cannot be distinguished from a vibrationally relaxed excited state when $E^i_{vib} <$

Fig. 1. Plot of $\log_{10}(\Sigma k_{nr})$ vs. E^i_{vib} for the S_1 population decays of azulene in cyclohexane, chx, and guaiazulene in cyclohexane and perfluoro-*n*-hexane, pfh. The sets of data were taken in three independent series; the value for guaiazulene in cyclohexane at low E^i_{vib} is therefore not exactly the same as the global average value referred to in the text and shown in Fig. 2.

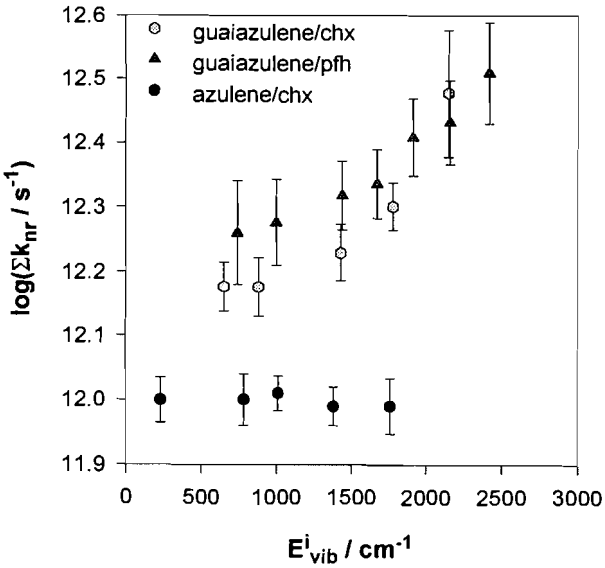

Fig. 2. Plot of $\log(\Sigma k_{nr})$ vs. S_1–S_0 energy gap for azulene and five derivatives in several solvents of different polarity at room temperature. The initial vibrational energy content of S_1 is less than 1000 cm^{-1} in all cases.

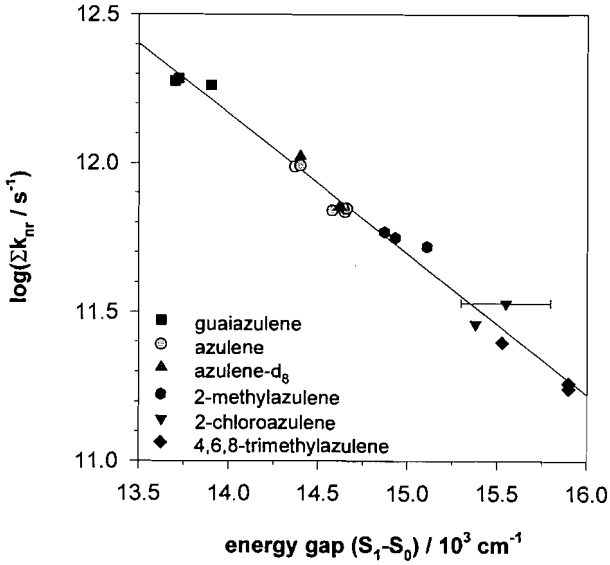

1000 cm^{-1}; and (*iii*) when $E^i_{vib} > 1000$ cm^{-1} the S_1 state of guaiazulene must be undergoing population decay from a vibrationally unrelaxed ensemble with more favorable Franck–Condon factors for $S_1 \rightsquigarrow S_0$ relaxation since at these excitation energies $\log_{10}(\Sigma k_{nr})$ values fall well above the line for the energy-gap law correlation.

An increase in k_{nr} with increasing E^i_{vib} is often observed when a polyatomic molecule retains its initial vibrational energy (as, for example, in the isolated molecule), and this behavior has been accounted for in the theory of radiationless transitions (14, 15). Such increases in k_{nr} (decrease in $\tau(S_1)$) have been observed in supersonically expanded azulene; increases by factors of about 2 at $E^i_{vib} = 1394$ cm^{-1} (16) and 3.5 at $E^i_{vib} = 2417$ cm^{-1} (17) compared with $E^i_{vib} = 0$ are found. Because we see no change in k_{nr} for azulene in cyclohexane at $0 < E^i_{vib} \leq 1760$ cm^{-1}, vibrational relaxation must occur on a time scale that is significantly faster than the population decay time, 1 ps in this case. This result does not provide a definitive check on the vibrational relaxation measurements of Matsumoto et al. (6), however, because differences in $\tau(S_1)$ measurable by us are expected only when E^i_{vib} is relatively large, i.e., >1000 cm^{-1}, whereas at such E^i_{vib} Matsumoto et al. find vibrational relaxation times that are faster than the temporal resolution of our equipment.

On the other hand, the observation of an increase in k_{nr} with E^i_{vib} for guaiazulene shows that, for this trialkyl-substituted derivative, vibrational relaxation is not complete in solution during its subpicosecond S_1 lifetime. This increase in k_{nr} with E^i_{vib} can therefore be used as a fast internal clock with which the rate of vibrational relaxation can be timed. For guaiazulene in either cyclohexane or perfluoro-*n*-hexane this rate is of the order of a few hundred femtoseconds at $E^i_{vib} \sim$ 1000–2000 cm^{-1}. Measurement of the precise relaxation rates and a determination of whether they are due to intramolecular or intermolecular relaxation must await a determination, from linewidth measurements, of the lifetimes of the isolated guaiazulene molecule as a function of E^i_{vib}. The lack of effect when cyclohexane, which has high-frequency C–H oscillators, is replaced by perfluoro-*n*-hexane, which does not, tends to suggest that the effects of a finite rate of intramolecular vibrational redistribution in guaiazulene are being observed here.

Abstract: The effect of electron-withdrawing substituents, *meta*- or *para*-cyano, on the reactivity of the radical cation of arylalkenes and alkanes has been determined. The radical cations were generated by single electron transfer (set) to an electron-accepting photosensitizer. Three reactions were studied: (*i*) the addition of nucleophile to the radical cation of arylalkenes, (*ii*) cleavage of the benzylic carbon–carbon bond of the radical cation of arylalkanes; and (*iii*) the deprotonation of the benzylic carbon–hydrogen bond of the radical cation of arylalkanes. The radical cations of 4-(1-phenylethenyl)benzonitrile (**1***b*), 3-(1-phenylethenyl)benzonitrile (**1***c*), 4-(2-methoxy-1-phenylethyl)benzonitrile (**2***b*), 3-(2-methoxy-1-phenylethyl)benzonitrile (**2***c*), *cis*- and *trans*-5-cyano-2-methoxy-1-phenylindane (**6***b-cis* and *-trans*), and 6-cyano-3-phenylindene (**7***b*) were generated, by single electron transfer to the lowest excited singlet state of 1,4-dicyanobenzene (**3**), in acetonitrile–methanol. The radical cations of **1***b*, **1***c*, and **7***b* react with methanol to yield the *anti*-Markovnikov adducts (**2***b*, **2***c*, and **6***b-cis* and **6***b-trans*). The radical cations of **2***b*, **2***c*, and **6***b-trans* cleave at the benzylic carbon–carbon bond to give products derived from the radical and carbocation fragments. The radical cation of **6***b-cis* deprotonates from the benzylic position with subsequent formation of the diastereomer, **6***b-trans*. This behaviour can be explained/predicted on the basis of the proposed mechanisms for these reactions. Molecular orbital calculations (AM1) support the conclusions.

Key words: photosensitized, electron transfer, radical ions, radicals, molecular orbital calculations (AM1).

Résumé : On a déterminé l'effet de substituants électroattracteur, les groupes *méta*- et *para*-cyano, sur la réactivité de cations radicaux d'arylalcènes et alcanes. On a généré les cations radicaux par le transfert d'un seul électron à un photosensibilisateur accepteur d'électron. On a étudié trois réactions : (*i*) l'addition d'un nucléophile sur le cation radical des arylalcènes; (*ii*) le clivage de la liaison carbone–carbone benzylique du cation radical des arylalcanes et (*iii*) la déprotonation de la liaison carbone–hydrogène benzylique du cation radical des arylalcanes. On a généré les cations radicaux des 4-(1-phényléthényl)benzonitrile (**1***b*), 3-(1-phényléthényl)-benzonitrile (**1***c*), 4-(2-méthoxy-1-phényléthyl)benzonitrile (**2***b*), 3-(2-méthoxy-1-phényléthyl)benzonitrile (**2***c*), *cis*- et *trans*-5-cyano-2-méthoxy-1-phénylindane (**6***b-cis* et *-trans*) et 6-cyano-3-phénylindène (**7***b*) par un transfert d'un seul électron à l'état singulet excité le plus bas du 1,4-dicyanobenzène (**3**), en solution dans l'acétonitrile–méthanol. Les cations radicaux des composés **1***b*, **1***c* et **7***b* réagissent avec le méthanol pour donner des adduits *anti*-Markovnikov (**2***b*, **2***c* et **6***b-cis* et **6***b-trans*). Les radicaux cations **2***b*, **2***c* et **6***b-trans* se clivent au niveau de la liaison carbone–carbone benzylique pour donner des produits dérivés des fragments radicalaires et carbocationiques. Le cation radical **6***b-cis* se déprotone en position benzylique avec la formation subséquente de son diastéréoisomère, le composé **6***b-trans*. On peut expliquer/prédire ce comportement en se basant sur les mécanismes proposés pour ces réactions. Des calculs d'orbitales moléculaires (AM1) sont en accord avec ces conclusions.

Mots cles : transfert d'électron, ions radicaux, radicaux, calculs d'orbitales moléculaires (AM1).

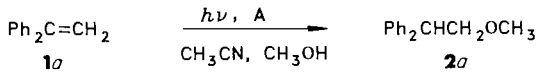
Introduction

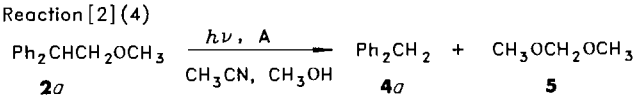
It is becoming increasingly evident that reactions of radical ions, generated by photo-induced single electron transfer (set), have significant synthetic utility (2). Three reactions that are of particular interest to us are (*i*) the addition of nucleophiles to the radical cation of arylalkenes, a reaction that can yield the *anti*-Markovnikov addition product; (*ii*) the carbon–carbon bond cleavage of radical cations, which ultimately yields products derived from the radical and carbocation fragments; (*iii*) the deprotonation of the radical cation, a reaction that can be used to invert the configuration at a saturated carbon centre. Archetypical examples of these processes are illustrated in reactions [1]–[3] (3–5).

Reaction [1] (3)

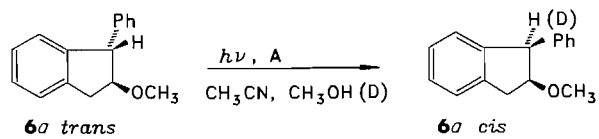


A = 1,4-dicyanobenzene (**3**, an electron-accepting photosensitizer)

Reaction [2] (4)



Reaction [3] (5)



6a trans *6a cis*

Full appreciation of the utility of these reactions is dependent upon establishing their scope and limitations. This understanding is usually couched in terms of the reaction mechanism. The effects of variation in structure and the effects of substitution by electron-donating and electron-withdrawing groups must be understood, for each step of the reaction mechanism, before reactivity will be predictable. We have made some progress; the mechanisms proposed for reactions [1]–[3] are summarized in Schemes 1–3 (3–5). A previous publication in this series describes the effects of an electron-donating group, *meta*- or *para*-methoxy (6). This study has now been extended; we report here upon the influence of an electron-withdrawing group, *meta*- or *para*-cyano substitution, on these reactions.

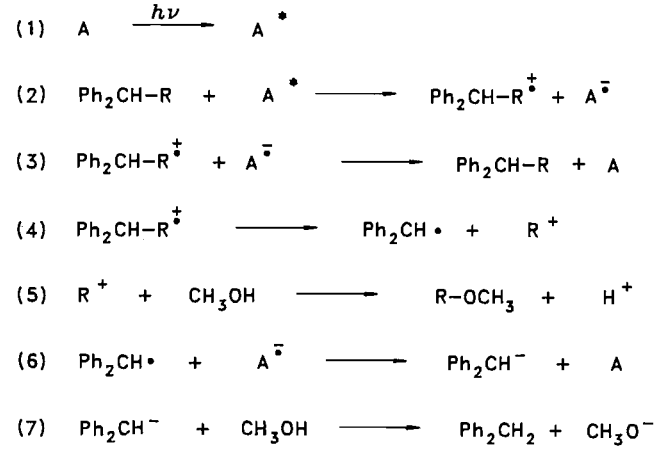
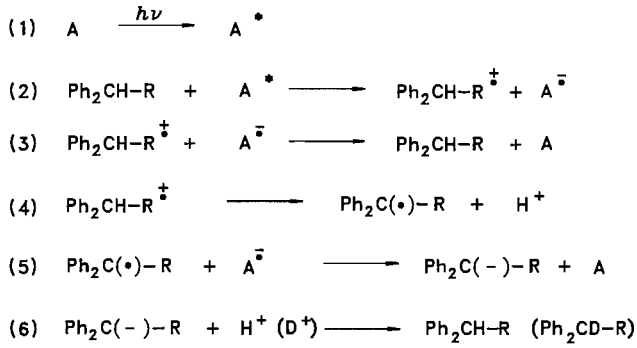
A = 1,4-dicyanobenzene (an electron-accepting photosensitizer)

Scheme 2. The mechanism for the photosensitized (electron transfer) carbon–carbon bond cleavage (reaction [2]) (4).



Scheme 3. The mechanism for the photosensitized (electron transfer) isomerization involves deprotonation of the radical cation, reduction of the resulting radical, and reprotonation of the anion (reaction [3]) (5).



Results

The compounds chosen for study are shown in Fig. 1; all except 4- and 3-(1-phenylethenyl)benzonitrile (**1***b*, **1***c*) are new compounds. The alkenes (**1***b*, **1***c*, and **7***b*) were prepared by dehydration of the alcohols obtained from the Grignard reaction. The procedure used for the preparation of 6-cyano-3-phenylindene (**7***b*) is summarized in Scheme 4.

The irradiation conditions were similar to those used in previous studies; hence, the results can be compared. Acetonitrile–methanol (3:1) solutions of the arylalkene or alkane (0.1 M) and 1,4-dicyanobenzene (**3**) (0.05 M) were irradiated, through Pyrex, with a 1 kW medium-pressure mercury vapour lamp. The temperature was held at 10°C. Progress of the reaction was followed by capillary column gas chromatography with a mass selective detector (gc/ms). Products were gener-

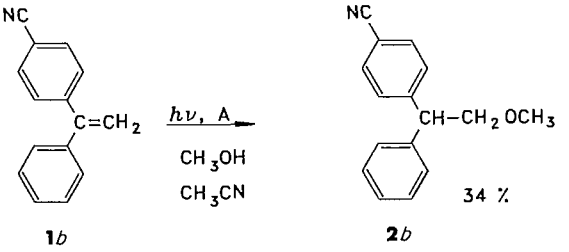
ally isolated by dry-column flash chromatography (dcfc) on silica gel or by preparative gas chromatography (prep gc).

The major products formed upon irradiation of 4-(1-phenylethenyl)benzonitrile (**1***b*) and 3-(1-phenylethenyl)benzonitrile (**1***c*) were the *anti*-Markovnikov addition products, 4-(2-methoxy-1-phenylethyl)benzonitrile (**2***b*) and 3-(2-methoxy-1-phenylethyl)benzonitrile (**2***c*) (reactions [4] and [5]). The structures assigned to these products were based upon analysis of the ^1H and ^{13}C nmr and mass spectra. The first evidence for these structures (**2***b* and **2***c*) was the observation of the molecular ions at *m/z* 237 ($M^{+\cdot}$) and base-peaks at *m/z* 192 ($M^{+\cdot}$ − 45, indicative of the loss of a methoxy methylene group) in the mass spectrum. The ^1H nmr spectra have the characteristic ABX patterns for the alkyl hydrogens and singlets for the methoxy methyl groups.

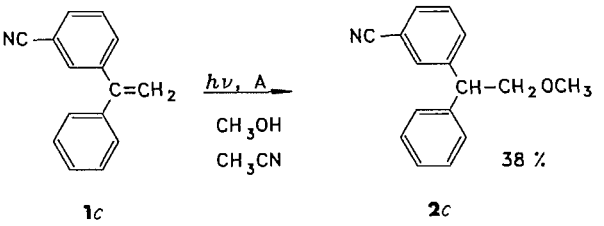
The *anti*-Markovnikov adducts, *cis*-**6***b* and *trans*-**6***b*, were formed from 6-cyano-3-phenylindene (**7***b*) under these conditions (reaction [6]). The *cis* and *trans* isomers were obtained in almost equal amounts (*cis*-**6***b*:*trans*-**6***b*, 4:3). The structures assigned to these isomers were also based upon an analysis of ^1H nmr spectra. The ^1H nmr spectra of the *cis* and *trans* isomers of **6***a*, and of the *para*-methoxy-substituted derivatives (**6***d*), show vicinal coupling between the bis-benzylic proton (X) and the proton adjacent to the methoxy group (Y) as part of an ABXY pattern in the aliphatic region. In every case, the observed coupling constant (J_{XY}) is slightly larger for the *trans* than for the *cis* isomer. For the parent system (**6***a*), J_{XY}: *trans*, 6.3; *cis*, 6.2 Hz. The stereochemistry of *trans*-**6***b* (J_{XY}:

Reaction [4]

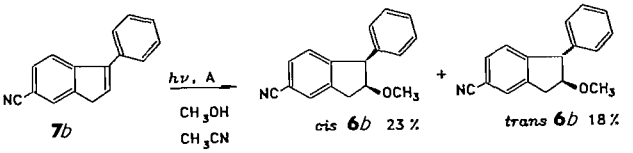


A = 1,4-dicyanobenzene (**3**)

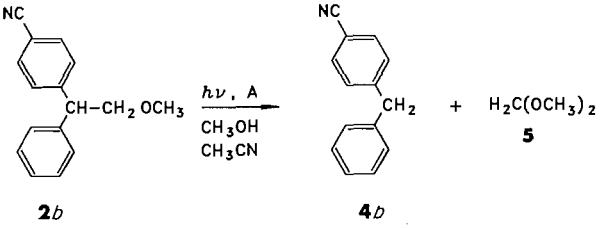
Reaction [5]



Reaction [6]



Reaction [7]



Reaction [8]

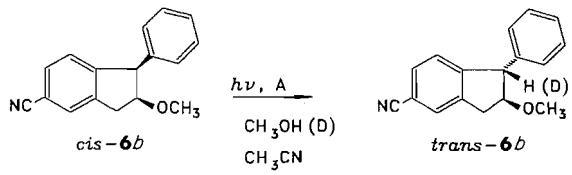
5.80 Hz) and *cis*-**6***b* (J_{XY}: 5.55 Hz) was assigned on this basis.

Both 4-(2-methoxy-1-phenylethyl)benzonitrile (**2***b*) and 3-(2-methoxy-1-phenylethyl)benzonitrile (**2***c*) cleave upon irradiation under these conditions (reactions [7] and [8]). The products, 4-benzylbenzonitrile (**4***b*) and 3-benzylbenzonitrile (**4***c*), were positively identified by comparison (^{1}H nmr, ir spectra) with authentic samples.

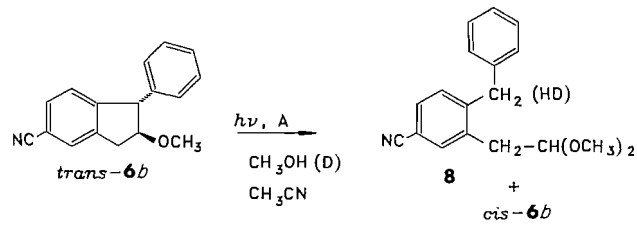
Irradiation of acetonitrile–methanol solutions of 1,4-dicyanobenzene (**3**) and *cis*-**6***b* leads to isomerization, formation of *trans*-**6***b*; no cleavage product was observed until a significant concentration of the *trans* isomer was attained (reaction [9]). When this irradiation was carried out in acetonitrile–methanol-O-*d* (3:1) deuterium was incorporated at the bis-benzylic position of the *trans*-**6***b* formed. In marked contrast, starting with *trans*-**6***b*, irradiation leads to formation of the cleavage product, 4-benzyl-3-(2,2-dimethoxy)ethyl benzonitrile (**8**), and to isomerization to the *cis* isomer (reaction [10]). The structure of the cleavage product (**8**) was established by analysis of the ^{1}H nmr spectrum. The crystalline 2,4-dinitrophenylhydrazone derivative of **8** was also fully characterized (^{1}H nmr and combustion analysis).

When the irradiation of *trans*-**6***b* was carried out in acetonitrile–methanol-O-*d* (3:1) solution, the mass spectrum of the cleavage product (**8**) indicated essentially quantitative incorporation of one deuterium atom. The ^{1}H nmr spectrum of **8**, isolated from this reaction mixture, showed that the deuterium is incorporated exclusively at the bis-benzylic position (4.11 ppm).

Reaction [9]



Reaction [10]



Molecular orbital calculations (AM1 (7)) were carried out to provide information regarding the structures and the spin and charge distribution on the radical cations of the arylalkenes, **1***a*–*e*$^{+\cdot}$. These results are summarized in Fig. 2.

Table 1. The oxidation potentials of some aryl alkenes and alkanes and the free energy change (ΔG_{ET}, calculated) for the electron transfer process from these potential donors to the excited singlet state of 1,4-dicyanobenzene (**3**).

Oxidation potentials of several compounds of interest, measured by cyclic voltammetry in acetonitrile solution, are reported in Table 1.

Discussion

Generation of the radical ions

The first three steps in the proposed mechanisms for reactions [1]–[3] are the same. The arylalkenes and arylalkanes are essentially transparent to irradiation of wavelengths longer than 280 nm, the short-wavelength cutoff of the Pyrex filter. The long-wavelength absorption of 1,4-dicyanobenzene (**3**) extends beyond 280 nm. Excitation leads to the first excited singlet state, the ^1L_b state, of **3**. This singlet state has a sufficiently long lifetime (9.73 ns (4)) to allow bimolecular quenching, by a rapid single electron transfer mechanism, by prospective donors.

The free energy changes associated with the electron transfer processes (ΔG_{ET}), calculated by the Weller equation, are listed in Table 1. The rate of the electron transfer process is expected to be diffusion controlled when the oxidation potential of the donor is <2.4 V (sce), that is, when ΔG_{ET} is more negative than ca. −5 kcal mol^{-1} (9).[3] Rate constants measured by the fluorescence quenching technique are consistent with this expectation (4). All of the arylalkenes studied have oxidation potentials less than 2.4 V; therefore, step 2, Scheme 1, should occur at the diffusion-controlled rate. The only compounds studied that have oxidation potentials above this limit are the *meta*- and *para*-cyanophenyl-substituted ethers **2***b* and **2***c*. Still, in these cases, electron transfer is exergonic; radical ion formation can, and obviously does, occur.

Back-electron transfer, step 3, Schemes 1–3, is favourable in every case. This process is exergonic by >3 V; this is sufficient to retard the process, i.e., the rate of back-electron trans-

[3] All of the oxidation and reduction potentials mentioned in this paper are referenced against the saturated calomel electrode (sce).

fer falls within the Marcus inverted region (10). Rapid reactions, including solvent separation of the radical-ion pair, can compete with this mode of deactivation (11).

The addition of nucleophiles to the radical cations of arylalkenes

Step 4 of Scheme 1, addition of nucleophile (i.e., methanol) to the arylalkene radical cation, requires positive charge density on the terminal alkene carbon. The rate of addition of methanol to the radical cation $\mathbf{1}a^{+\cdot}$, within the methanol-solvation cage of the radical-ion pair, has been measured (3×10^9 s^{-1} (12)). Methoxy substitution greatly retards this reaction; the addition of methanol to the radical cation of 1,1-dianisylethylene has been estimated to be 10^7 M^{-1} s^{-1}, almost two orders of magnitude slower than the addition to $\mathbf{1}a^{+\cdot}$ (12–14). This is clearly a reflection of the reduced positive charge density on the terminal carbon of the alkene; the positive charge is largely associated with the *para*-methoxy groups.

In previous publications we have described the application of (relatively) high-level *ab initio* molecular orbital calculations (UHF/STO-3G) to explain/predict radical cation reactivity (6, 15). The calculated spin and charge distributions on the radical cations of the model compounds, 3- and 4-vinylanisole, are consistent with the proposed mechanism for the reactions of **1***d* and **1***e* (6). This type of calculation becomes computer-time prohibitive for large molecules and we have now applied semi-empirical molecular orbital calculations (AM1) to the problem. The calculated structure and spin and charge distribution for the radical cations $\mathbf{1}a$–$e^{+\cdot}$ are summarized in Fig. 2.

The unsubstituted 1,1-diphenylethylene radical cation ($\mathbf{1}a^{+\cdot}$) is symmetric (C_2); the spin and charge are distributed equally over both phenyl rings and the dihedral angles between the planes of the rings and the alkene are identical (30°). There is significant spin and charge density on the terminal carbon of the alkene. This is consistent with the observed reactivity, nucleophilic (methanol) attack at this position (reaction [1]).

The fully optimized structure of the *para*-methoxy derivative ($\mathbf{1}d^{+\cdot}$) is not symmetric; the dihedral angle between the plane of the *para*-methoxy-substituted ring and the alkene is significantly smaller than that for the unsubstituted ring (14° vs. 49°). *para*-Methoxy substitution of the radical cation increases the interaction between the methoxy-substituted ring and the alkene. This increased interaction is also reflected in the bond length between the methoxy-substituted ring and the alkene. The calculations show that the charge density on the terminal carbon of the double bond of $\mathbf{1}d^{+\cdot}$ is the lowest of the derivatives studied. Furthermore, the ratio (spin density)/(charge density) at the terminal carbon is greatest (3.8) with this derivative. These calculations are consistent with the observed reactivity of $\mathbf{1}d^{+\cdot}$, a slower rate of nucleophilic attack at the terminal carbon relative to radical addition initiated by attack of the terminal carbon on the neutral molecule (6).

The conjugative interaction between the *meta*-methoxy-substituted ring and the double bond is not as dominant as in the *para*-methoxy derivative. The dihedral angles between the planes of the two aryl rings and the alkene are now nearly identical (29° vs. 30°), and are essentially the same as that calculated for the unsubstituted case. The charge density on the terminal carbon of the alkene is again high on the radical cation of the *meta*-methoxy derivative, the ratio of (spin density)/(charge density) (2.7) is decreased, and nucleophilic attack at the terminal position is observed (6).

The calculations indicate that the structures and the spin and charge distribution for the *para*- and *meta*-cyano-substituted derivatives are similar to one another. The dihedral angles and bond lengths indicate that conjugative interaction between the unsubstituted phenyl ring and the double bond is greater than with the cyano-substituted ring. The positive charge density on the terminal carbon of the alkene is even greater in the radical cation of these cyano derivatives than it is in the unsubstituted case. The observed reactivity is consistent: nucleophilic attack on the terminal carbon (reactions [4] and [5]).

Step 5, Scheme 1, reduction of the bis-benzylic radical to the anion by the radical anion $\mathbf{3}^{-\cdot}$, should be favourable in the unsubstituted case and for the *para*- and *meta*-cyano derivatives. The reduction potentials of the 1,1-diphenylethyl, the 1-(3-cyanophenyl)-1-phenylethyl, and the 1-(4-cyanophenyl)-1-phenylethyl radicals are −1.34, −1.1, and −0.9 V (16). The reduction potential of 1,4-dicyanobenzene (**3**) is significantly more negative (−1.66 V) (4). This step is favourable even in the case of the *para*-methoxy- (−1.5 V) and *meta*-methoxy- (−1.3 V) substituted derivatives (6).

Step 6, Scheme 1, protonation of the bis-benzylic anion, will be favourable and rapid in every case. The ratio of stereoisomers (*cis*-**6***b*/*trans*-**6***b*, 4:3) initially formed in reaction [6] reflects differences in the rate of protonation; there is a preference for protonation from the less hindered side of the bis-benzylic anion.

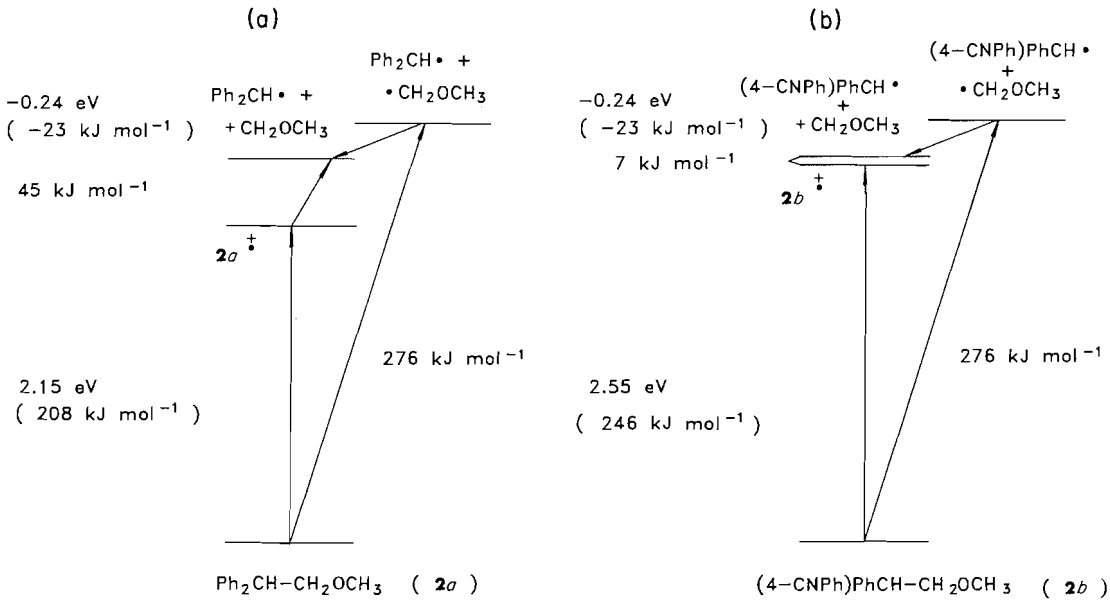
The observations regarding the addition of nucleophile (methanol) to the radical cations of these arylalkenes are nicely accounted for on the basis of these mechanistic considerations.

The carbon–carbon bond cleavage of radical cations

Carbon–carbon bond cleavage of a radical cation yields the radical and carbocation fragments; that fragment radical having the lower oxidation potential becomes the carbocation (step 4, Scheme 2) (17). In consideration of the cleavage of the radical cations $\mathbf{2}b^{+\cdot}$ and $\mathbf{2}c^{+\cdot}$, the oxidation potential of the (3-cyanophenyl)phenylethyl and (4-cyanophenyl)phenylethyl radicals will be significantly greater than that of the methoxymethyl radical (−0.24 V) (16). Cleavage occurs (reactions [7] and [8]), as expected, to give the diarylethyl radical and the α-oxy carbocation.

The fact that the *para*- and *meta*-methoxy-substituted derivatives (**2***d* and **2***e*) do not cleave can be attributed to unfavourable thermodynamic factors. Thermochemical data determine an activation energy greater than 100 kJ mol^{-1} for cleavage of the *para*-methoxy derivative (**2***d*). Cleavage of the radical cation of the unsubstituted methyl 2,2-diphenylethyl ether ($\mathbf{2}a^{+\cdot}$) requires significantly less energy, ca. 45 kJ mol^{-1}, and cleavage of the radical cations of the *para*- and *meta*-cyano derivatives ($\mathbf{2}b^{+\cdot}$ and $\mathbf{2}c^{+\cdot}$) require even less (7 kJ mol^{-1}) (Fig. 3). These differences can be attributed largely to the effect of the substituent on the oxidation potential of the ether (**2***a*–*e*). The oxidation potentials, listed in Table 1, show the expected trend: methoxy substitution lowers the oxidation potential by ca. 0.5 V, cyano substitution increases the oxidation potential by ca. 0.4 V. Previous studies have defined the practical limit

Fig. 3. Thermochemical cycles useful for estimating the bond dissociation energy of the radical cations of (*a*) methyl 2,2-diphenylethyl ether (**2***a*); (*b*) 4-(2-methoxy-1-phenylethyl)benzonitrile (**2***b*).



for this step, less than ca. 60 kJ mol^{-1}, in order for cleavage to be competitive with deactivation by back-electron transfer (17, 18).

There is an additional reason why the radical cation of the *meta*-methoxy derivative, $\mathbf{2e}^{+\cdot}$, does not cleave. The singly occupied molecular orbital (SOMO) has the *para*-quinoidal structure, with high charge density associated with the methoxy group; there is little spin or charge density on the *ipso* position attached to the benzylic carbon–carbon bond. The SOMO of the unsubstituted derivative, $\mathbf{2a}^{+\cdot}$, and of the cyano derivatives, $\mathbf{2b}^{+\cdot}$ and $\mathbf{2c}^{+\cdot}$, will have the *para*-quinoidal configuration, largely involving the unsubstituted phenyl ring, with high spin and charge density on the *ipso* position.

Deprotonation of the radical cation

The increase in the acidity of radical cations relative to the neutral molecules is well recognized (19). The pK_a of the bis-benzylic hydrogen of the radical cation of methyl 2,2-diphenylethyl ether ($\mathbf{2a}^{+\cdot}$) may be as low as −14, certainly acidic enough to deprotonate in this solvent mixture (acetonitrile–methanol) (6). This dramatic increase in acidity, quantitatively estimated with thermochemical cycles similar to those in Fig. 3, is largely associated with the oxidation potential of the neutral molecule. The effect of substituents on the stability of the 1,1-diarylethyl radical is relatively small. For compounds with similar carbon–hydrogen bond dissociation energies, an increase of 0.1 V in the oxidation potential corresponds to an increase of 2 pK_a units in the acidity of the radical cation (19). While deprotonation is exergonic in every case ($\mathbf{2a}$–$\mathbf{e}^{+\cdot}$), this process is kinetically slow. The labile hydrogen is not hydrogen bonded in the neutral molecule and there is a significant solvent reorganization required upon deprotonation.

The importance of conformation influencing radical cation reactivity

The reactivity of the diastereomeric indane derivatives, *cis*-**6** and *trans*-**6**, is of particular interest. In the parent system, the radical cations of both *cis*-**6***a* and *trans*-**6***a* undergo deprotonation and subsequent isomerization; no carbon–carbon bond cleavage was observed. The spin and charge density, delocalized in the singly occupied molecular orbital (SOMO), is largely distributed over the fused aryl ring. The vulnerable bis-benzylic carbon–carbon bond is almost orthogonal to the SOMO and cleavage is not observed. On the other hand, the bis-benzylic carbon–hydrogen bond is favourably orientated for overlap with the SOMO and the bis-benzylic proton is therefore acidic. Deprotonation, reduction of the resulting bis-benzylic radical to the anion by the 1,4-dicyanobenzene radical anion ($\mathbf{3}^{-\cdot}$), followed by protonation/deuteration, can account for the observed isomerization and deuterium incorporation (reaction [3]).

Table 2 summarizes the results of molecular mechanics calculations (MM3 (20)) identifying conformers of *cis*-**6***a* and *trans*-**6***a*. All of the minima within 4 kJ mol^{-1} of the global minimum are listed. We make the logical assumptions that the optimum conformation for benzylic bond cleavage will have a 90° dihedral angle between the plane of the aryl ring bearing the SOMO and the bond to break, and that the conformations of the neutral molecule and the radical cation are similar, at least with respect to the benzylic bonds (21). Furthermore, cleavage of the benzylic carbon–carbon bond, with formation of the α-oxy carbocation, requires overlap of a nonbonding pair of electrons on the oxygen with the vulnerable carbon–carbon anti-bonding orbital (σ*) (Fig. 4). The optimum dihedral angle between the methoxy-methyl group and the vulnerable carbon–carbon bond will be 60° in the starting conformation, increasing up to 90° at the transition state; the α-oxy carbocation is planar. Deviation of the dihedral angle, away from the optimum, will increase the barrier for cleavage as a function of $\cos^2\theta$.

For the unsubstituted derivative $\mathbf{6a}^{+\cdot}$, the SOMO will be largely associated with the fused aryl ring. The dihedral angle is favourable for deprotonation, particularly for the *trans* isomer (85°, 99% effective overlap), and is unfavourable for car-

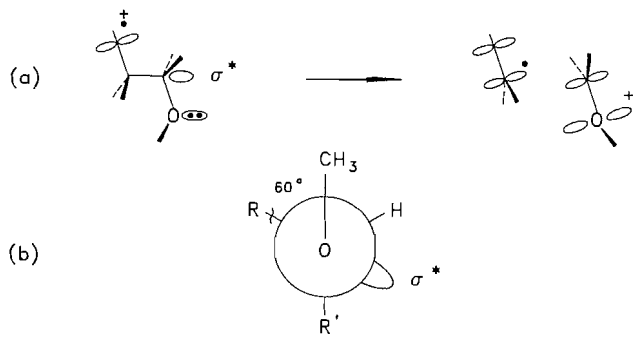
Fig. 4. The importance of conformation for radical cation carbon–carbon bond cleavage.



bon–carbon bond cleavage (20°, 10%). *para*-Methoxy substitution moves the SOMO to the unfused ring. Carbon–carbon bond cleavage might now occur, there are low-energy conformers that have nearly optimum dihedral angles; however, as described above, the energy barrier for cleavage is too great. Deprotonation can compete, even though a 26° dihedral angle allows only 20% effective overlap.

Differences in the reactivity of the diastereomers, *cis*-**6***b* and *trans*-**6***b*, can now be explained. Cyano substitution on the fused ring moves the SOMO out onto the unfused phenyl ring. The SOMO will have the *para*-quinoidal structure with high spin and charge density on the *ipso* position. The oxidation potentials of both *cis* and *trans* isomers are high enough (2.1 V) to render carbon–carbon bond cleavage energetically feasible. *cis*-**6***b*$^{+\cdot}$ deprotonates but does not cleave (reaction [9]); *trans*-**6***b*$^{+\cdot}$ deprotonates *and* cleaves (reaction [10]). The global minimum of the *cis* isomer is oriented favourably (26°, 20% effective overlap) for deprotonation; neither of the low-energy conformers of the *trans* isomer is in a favourable orientation for deprotonation (12°, 4% effective overlap). The conformation of the methoxy methyl group is poorly oriented (170°) for carbon–carbon bond cleavage in the global minimum of both isomers; however, the next higher conformer of both isomers should be reactive. *cis*-**6***b*$^{+\cdot}$ deprotonates from the global minimum; *trans*-**6***b*$^{+\cdot}$ cannot; instead, *trans*-**6***b*$^{+\cdot}$ cleaves from the next higher energy conformer. Deprotonation of the *trans* isomer may involve the third, higher energy, conformer.

Experimental

General methods

The ^{1}H and ^{13}C nmr spectra were recorded on either a Nicolet 360 NB (361.1 or 90.8 MHz) or a Bruker AC 250 (250.1 or 62.9 MHz) nmr spectrometer, and are reported in parts per million (ppm) downfield from tetramethylsilane. Infrared spectra (ir) were recorded on either an air-purged Perkin–Elmer 180 or on a Nicolet 205 infrared spectrometer and are reported in wavenumbers (ν) relative to the 1602 cm^{-1} absorption of polystyrene film. Mass spectra (ms) were recorded on a Hewlett–Packard 5970 series mass selective detector and are reported as *m/z* (relative intensity). Exact Mass determinations were carried out using a ZAB-E spectrometer. Elemental analyses were performed by Canadian Microanalytical Services Inc., Delta, B.C., and agreed to within ±0.3 of the calculated values. Melting points were determined using a Cybron Corporation Thermolyne melting point apparatus linked to a digital thermocouple, and were corrected.

The photochemical reactions were followed by gas chromatography (gc) using either an HP 5890 GC, fitted with a 5% phenyl methyl silicone fused silica WCOT column (25 × 0.20 mm, 0.33 μm film thickness), coupled to an HP 5970 mass selective detector (gc/ms); or an HP 5890 GC, fitted with a DB-1701 fused silica WCOT column (30 m × 0.25 mm, 0.25 μm film thickness), with a flame ionization detector (gc/fid).

The photoproducts were usually isolated by dry column flash chromatography (dcfc) on thin-layer chromatography (tlc) grade silica gel (Merck) eluting with an ethyl acetate – hexane solvent gradient (22). Preparative gas chromatography (prep gc) was carried out using a Varian Aerograph 90-P, fitted with a 3/8 in. × 6 ft aluminum column packed with 5% SE-30 on Chromosorb W 60/80 NAW.

Materials

Solvents were fractionally distilled. Acetonitrile (Fisher, ACS grade) was distilled successively from sodium hydride and phosphorus pentoxide, and was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h under a nitrogen atmosphere, and fractionally distilled. The 1,4-dicyanobenzene (**3**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Acetylbenzonitrile (3- and 4-), iodobenzene, and cyanobenzyl bromide (3- and 4-) were also obtained from Aldrich Chemical Co. 5-Bromo-1-indanone was obtained from MTM Research Chemicals.

Cyclic voltammetric measurements

Oxidation potentials were measured by cyclic voltammetry using an apparatus similar to that previously described (23). The working electrode was a platinum sphere (1 mm diameter), while the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (sce), which was connected to the solution by a Luggin capillary. The electrolyte was tetraethylammonium perchlorate (0.1 M TEAP) and the solvent was acetonitrile. Substrate concentrations were typically 5 mM. As the anodic waves were irreversible, the half-wave potentials were taken as 0.028 V before the anodic peak potentials, using a 200 mV s^{-1} sweep rate (8).

Irradiations

Irradiations were carried out using a CGE 1 kW medium-pressure mercury vapour lamp contained in a water-cooled quartz immersion well. The temperature was generally maintained at 10°C. The solvent was acetonitrile–methanol (3:1 by volume) at a typical concentration of 1,4-dicyanobenzene (**3**) 0.05 M and reactant 0.1 M. Solutions were placed in 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, degassed by ebullition with dry nitrogen, and sealed.

Preparation of compounds

*3-(1-Phenylethenyl)benzonitrile (**1**c)*

The phenyl Grignard reagent was prepared from iodobenzene (20.4 g, 0.1 mol) and magnesium metal turnings (2.43 g, 0.1 mol) in anhydrous diethyl ether (40 mL). This solution of phenylmagnesium iodide was added dropwise to a solution of 3-acetylbenzonitrile (5.0 g, 0.034 mol) in diethyl ether:benzene (2:1 by volume, 350 mL) and the mixture was stirred overnight at room temperature. The reaction mixture was poured into cold saturated aqueous ammonium chloride (200 mL) and the product was extracted with ether. The combined ether extract was washed with water and then dried over magnesium sulphate. Evaporation of the solvent give a light yellow oil, which was dissolved in dichloromethane (100 mL). A solution of thionyl chloride (12.2 g, 0.102 mol) in dichloromethane (70 mL) was added and this mixture was refluxed for 6 h. The solvent and excess thionyl chloride were evaporated, the residue was dissolved in ether, and the resulting solution was washed with saturated aqueous sodium bicarbonate, saturated aqueous sodium chloride, and was then dried over magnesium sulphate. Evaporation of the solvent gave the crude alkene (**1***e*), which was purified by chromatography (dcfc) using a hexane – ethyl acetate solvent gradient (0–10%, gradually increasing the concentration of ethyl acetate until the eluent was 10% ethyl acetate in hexane). The purified alkene was isolated as a colourless oil (3.56 g, 50% yield). 3-(1-Phenylethenyl)benzonitrile (**1***c*); ir (neat film, P.-E.), ν: 2225 (CN); ^{1}H nmr ($CDCl_3$, 360NB) δ: 7.62–7.25 (m, 9H), 5.56 (s, 1H), 5.49 (s, 1H); ^{13}C nmr ($CDCl_3$, 360NB) δ: 148.11 (s), 142.67 (s), 140.10 (s), 132.47 (d) , 131.72 (d), 131.14 (d), 129.01 (d), 128.43 (d), 128.23 (d), 128.03 (d), 118.72 (s), 116.09 (t), 112.39 (s); ms *m/z*: 205 ($M^{+\cdot}$, 90), 204 (100), 190 (88), 178 (21), 177 (19), 77 (24), 76 (22), 75 (19), 51 (29). This compound has been reported previously (24).

*4-(1-Phenylethenyl)benzonitrile (**1**b)*

Phenylmagnesium iodide was prepared by slowly adding iodobenzene (24.4 g, 0.120 mol), with stirring, to magnesium turnings (2.91 g, 0.120 mol) and anhydrous diethyl ether (80 mL) in a cooled, nitrogen-purged flask. The resulting solution was added dropwise, with stirring, into a solution of 4-acetylbenzonitrile (6.0 g, 0.041 mol) in anhydrous diethyl ether (350 mL). This mixture was stirred overnight at room temperature. The crude reaction mixture was poured into a cold, saturated, aqueous solution of ammonium chloride (200 mL). The product was extracted into diethyl ether. The combined ether extract was washed with water and then dried over magnesium sulphate. Evaporation of the solvent gave the alcohol, an oil, which was not fully characterized, but was used directly in the next step. 4-(1-Phenyl-1-hydroxyethyl)benzonitrile; ms, *m/z*: 223 ($M^{+\cdot}$, 5), 208 ($M^{+\cdot} - CH_3$, 100), 205 (24), 190 (27), 130 (82), 102 (35), 77 (38), 51 (33).

Thionyl chloride (7.52 g, 0.063 mol) was added to a solution of the alcohol dissolved in dichloromethane (100 mL). This mixture was heated, under reflux, overnight. The solvent and excess thionyl chloride were evaporated. The crude product was taken up in diethyl ether (70 mL), washed with water, and dried over magnesium sulphate. Evaporation of the solvent gave the alkene (**1***b*), which was purified by chromatography (dcfc), eluting with a hexane – ethyl acetate solvent gradient (0–10%), to a colourless oil. 4-(1-Phenylethenyl)benzonitrile (**1***b*) (4.2 g, 49% from the ketone); ir (neat film, P.-E.): 3080(w), 3020(w), 2220(s, CN), 1650(m), 1600–1480(s); uv: λ_{max} = 234 nm, log e = 4.29; ^{1}H nmr ($CDCl_3$, 360NB)) δ: 7.57 (d, 2H, 8.3 Hz), 7.39 (d, 2H, 8.3 Hz), 7.33–7.24 (m, 5H), 5.56 (s, 1H), 5.52 (s, 1H); ^{13}C nmr ($CDCl_3$, AC250) δ: 148.71 (s), 146.09 (s), 140.21 (s), 132.10 (d), 128.87 (d), 128.49 (d), 128.28 (d), 128.18 (d), 118.90 (s), 116.77 (t), 111.34 (s); ms *m/z*: 205 ($M^{+\bullet}$, 100), 204 (92), 190 (93), 177 (19), 102 (17), 77 (26), 51 (49). The observed spectra (ir, ^{1}H nmr) are similar to those previously reported for this compound (25).

*6-Cyano-3-phenylindene (**7**b)*

This alkene was prepared by a three-step procedure starting with 5-bromo-1-indanone (Scheme 4). A mixture of 5-bromo-1-indanone (8.5 g, 0.04 mol), cuprous cyanide (4.12 g, 0.05 mol), and dimethylformamide (10 mL) was refluxed under nitrogen for 4 h. The resulting brown mixture was poured into a solution of hydrated ferric chloride (19 g) and concentrated hydrochloric acid (10 mL) in water (60 mL); this mixture was kept at 60–70°C for 15 min. The organic layer was separated and the aqueous layer was extracted with toluene (2 × 25 mL). The extracts were combined with the organic layer, filtered, washed with dilute hydrochloric acid (4 × 25 mL), water, and

saturated aqueous sodium bicarbonate (3 × 20 mL), and dried with sodium sulphate. Evaporation of the solvent gave 5-cyano-1-indanone as a solid (4.5 g, 70%), mp 128.9–130.1°C. 5-Cyano-1-indanone; ir (KBr, Nic.), ν: 3050 (w), 2925 (w), 2361 (m), 1690 (m), 1615 (m), 1500 (s); ^{1}H nmr ($CDCl_3$, AC250) δ: 7.65–7.86 (m, 3H), 3.23 (2H, AA′ part 3.50, 8.50 Hz), 2.78 (2H, XX′ part, 3.50, 8.50 Hz); ^{13}C nmr ($CDCl_3$, AC250) δ: 205.32 (s), 154.85 (s), 140.02 (s), 131.04 (d), 130.93 (d), 124.47 (d), 118.00 (s), 117.64 (s), 36.18 (t), 25.70 (t); ms *m/z*: 157 (68), 156 (32), 129 (100), 128 (34), 102 (39), 101 (26), 75 (26), 51 (76).

Phenylmagnesium iodide prepared from iodobenzene (12.45 g, 0.061 mol) and magnesium metal turnings (1.48 g, 0.061 mol) in anhydrous diethyl ether (80 mL) was added dropwise to a solution of 5-cyano-1-indanone (4.5 g, 0.029 mol) in the solvent mixture benzene (150 mL) – anhydrous ether (100 mL). The resulting solution was heated under reflux for 7 h, cooled, and poured into saturated aqueous ammonium chloride (150 mL). The product was extracted into diethyl ether, dried, and the solvent was evaporated. The residue was then added to a stirred cold solution of thionyl chloride (6.8 g) in dichloromethane (80 mL), and the resulting solution was refluxed for 14 h. The solvent and excess thionyl chloride were evaporated and the residue was dissolved in ether, washed with saturated aqueous sodium bicarbonate, saturated aqueous sodium chloride, and was then dried over magnesium sulphate. Evaporation of the solvent gave the crude alkene (**7***b*), which was purified by chromatography (dcfc), eluting with a hexane – ethyl acetate solvent gradient (0–3%), to give 6-cyano-3-phenylindene (**7***b*) as a colourless solid (2.95 g, 48%, mp 71.5–72.1°C); ir (KBr, Nic.), ν: 3050 (w), 2226 (s), 1665 (m), 1609 (m), 1487 (m), 1449 (s), 832 (s), 759 (s), 699 (s); ^{1}H nmr ($CDCl_3$, AC250) δ: 7.75–7.24 (m, 8H), 6.78 (t, 1H, 1.9 Hz), 3.54 (d, 2H, 1.9 Hz); ^{13}C nmr ($CDCl_3$, AC250) δ: 148.4 (s), 145.2 (s), 144.9 (s), 135.0 (d), 134.8 (s), 130.8 (d), 128.9 (d), 128.2 (d), 127.7 (d), 127.4 (d), 120.9 (d), 120.0 (s), 108.0 (s), 38.3 (t); ms *m/z*: 217 (100), 216 (38), 214 (11), 190 (11), 189 (11). *Irradiation of 3-(1-phenylethenyl)benzonitrile (**1**c) and 1,4-dicyanobenzene (**3**) in acetonitrile–methanol (reaction [5])*

A solution of 3-(1-phenylethenyl)benzonitrile (**1***c*) (0.75 g, 3.7 mmol) and 1,4-dicyanobenzene (**3**) (0.5 g, 3.7 mmol) in acetonitrile–methanol (3:1, 40 mL) was degassed by nitrogen ebullition for 5 min and irradiated through Pyrex until the alkene was consumed (>90%). The volatile components of the photolysate were removed on a rotary evaporator and the residue was chromatographed (dcfc), eluting with a hexane – ethyl acetate solvent gradient. The ether, 3-(2-methoxy-1-phenylethyl)benzonitrile (**2***c*), was obtained as a light yellow oil (330 mg, 38%). The analytical sample was purified by prep gc, ir (neat film, P.-E.), ν: 3029 (w), 2926 (m), 2898 (m), 2228 (s), 1607 (m), 1500 (m), 1496 (m), 1453 (m), 1112 (s), 700 (s); ^{1}H nmr ($CDCl_3$, AC250) δ: 7.55–7.17 (m, 9H), 4.30 (dd, 1H, 7.15, 7.15 Hz), 3.92 (dd, 1H, 7.15, 10.30 Hz), 3.82 (dd, 1H, 7.15, 10.30 Hz), 3.37 (s, 3H); ^{13}C nmr ($CDCl_3$, AC250) δ: 143.82 (s), 140.77 (s), 133.11 (d), 131.96 (d), 130.29 (d), 129.25 (d), 128.83 (d), 128.21 (d), 127.14 (d), 119.07 (s), 112.50 (s), 75.39 (t), 59.05 (q), 50.60 (d); ms *m/z*: 237 ($M^{+\bullet}$, 44), 207 (25), 192 (100, $M^{+\bullet} - 45$ ($-CH_2OCH_3$)), 190 (49), 165 (43), 102 (5), 77 (10), 51 (13). Anal. calcd. for $C_{16}H_{15}NO$: C 80.98, H 6.37, N 5.90; found: C 80.61, H 6.35, N 5.88.

*Irradiation of 4-(1-phenylethenyl)benzonitrile (**1**b) and 1,4-dicyanobenzene (**3**) in acetonitrile–methanol (reaction [4])*

A solution of 4-(1-phenylethenyl)benzonitrile (**1***b*) (1.2 g, 6.0 mmol) and 1,4-dicyanobenzene (**3**) (0.5 g, 3.8 mmol) in acetonitrile–methanol (3:1, 80 mL) was degassed by nitrogen ebullition for 5 min and irradiated through Pyrex until the alkene was consumed (>90%). The volatile components of the photolysate were removed on a rotary evaporator and the residue was chromatographed (dcfc), eluting with a hexane – ethyl acetate solvent gradient. The ether, 4-(2-methoxy-1-phenylethyl)benzonitrile (**2***b*), was obtained as a light yellow oil (482 mg, 34%). A sample for analysis was purified by prep gc; ir (neat film, P.-E.) ν: 2920(s), 2230(s), 1609(s), 1500(s), 1498(s), 1457(s), 1110(s), 700(s); ^{1}H nmr ($CDCl_3$, 360NB) δ: 7.58 (d, 2H, 8.22 Hz), 7.36 (d, 2H, 8.22 Hz), 7.33–7.17 (m, 5H), 4.32 (dd, 1H, 7.15, 7.15 Hz), 3.93 (dd, 1H, 10.30, 7.15), 3.89 (dd, 1H, 10.30, 7.15 Hz), 3.37 (s, 3H); ^{13}C nmr ($CDCl_3$, AC250) δ: 147.84 (s), 140.72 (s), 132.28 (d), 129.23 (d), 128.81 (d), 128.22 (d), 127.13 (d), 119.01 (s), 110.37 (s), 75.33 (t), 59.05 (q), 51.08 (d); ms *m/z*: 237 ($M^{+\bullet}$, 42), 207 (24), 192 (100, $M^{+\bullet} - 45$ ($-CH_2OCH_3$)), 190 (57), 165 (50), 102 (6), 51 (21). Anal. calcd. for $C_{16}H_{15}NO$: C 80.98, H 6.37, N 5.90; found: C 81.02, H 6.35, N 5.77.

*The photosensitized (electron transfer) cleavage of 3-(2-methoxy-1-phenylethyl)benzonitrile (**2**c), reaction [8]*

A solution of 3-(2-methoxy-1-phenylethyl)benzonitrile (**2***c*) (23.7 mg, 0.10 mmol) and 1,4-dicyanobenzene (**3**) (10 mg, 0.08 mmol) in acetonitrile–methanol (3:1, 1 mL) was degassed by nitrogen ebullition and irradiated through Pyrex. Progress of the reaction was followed by gc/fid; at 50% conversion, the yield of 3-benzylbenzonitrile (**4***c*) was 70%. The structure of this product was established by comparison (gc/fid, gc/ms, retention time, and fragmentation pattern) with an authentic sample.

*The photosensitized (electron transfer) cleavage of 4-(2-methoxy-1-phenylethyl)benzonitrile (**2**b), reaction [7]*

When a solution of 4-(2-methoxy-1-phenylethyl)benzonitrile (**2***b*) and 1,4-dicyanobenzene (**3**) in acetonitrile–methanol (3:1) was irradiated through Pyrex, as described above for the *meta* isomer, carbon–carbon bond cleavage also occurred. The yield of 4-benzylbenzonitrile (**4***b*), estimated by gc/fid, was 75% at 50% conversion.

*Preparation of 3-benzylbenzonitrile (**4**c)*

Anhydrous aluminium chloride (0.17 g, 1.28 mmol) was added, in small portions, with stirring, to a benzene (70 mL) solution of 3-cyanobenzyl bromide (5 g, 0.025 mol), cooled in an ice bath. The resulting mixture was refluxed for 10 h, then cooled in an ice bath, and ice (10 g) was cautiously added, followed by water (100 mL). The organic layer was separated and washed with dilute hydrochloric acid and with water, and then dried over anhydrous calcium chloride. The solvent was evaporated and the residue distilled; 3-benzylbenzonitrile (**4***c*) (4.22 g, 86%) was obtained in the fraction boiling between 138 and 144°C (0.1 Torr; 1 Torr = 133.3 Pa), which crystallized to colourless crystals: ir (neat film, Nic.), ν: 3025 (w),

2920 (w), 2229 (s), 1599 (m), 1582 (m), 1495 (s), 1483 (s), 1454 (m), 1436 (w), 1075 (w), 1030 (w), 786 (s), 759 (m), 715 (s), 700 (s), 688 (s); ^{1}H nmr ($CDCl_3$, AC250) δ: 7.51–7.19 (m, 9H), 4.03 (s, 2H); ^{13}C nmr ($CDCl_3$, AC250) δ: 142.74 (s), 139.57 (s), 133.55 (d), 132.41 (d), 130.00 (d), 129.36 (d), 129.03 (d), 128.89 (d), 126.77 (d), 119.05 (s), 112.53 (s), 41.46 (t); ms *m/z*: 193 ($M^{+\bullet}$, 100), 190 (15), 165 (28), 91 (13). This compound has been reported previously (26).

*Preparation of 4-benzylbenzonitrile (**4**b)*

The procedure used for the preparation of the *meta* isomer (**4***c*), described above, was used for the preparation of this isomer. Starting with 4-cyanobenzyl bromide (5 g, 0.025 mol) and aluminium chloride (0.17 g, 1.28 mmol) in dry benzene (70 mL), 4-benzylbenzonitrile (**4***b*) (3.85 g, 78%) was obtained from the distillation fraction boiling at 142–144°C (0.1 Torr). This sample solidified, mp 49.0–50.0°C; ir (neat film, Nic.), ν: 2927 (w), 2861 (w), 2222 (s), 1602 (s), 1483 (s), 1448 (s), 1414 (s), 1176 (s), 860 (s), 797 (s), 729 (s), 706 (s); ^{1}H nmr ($CDCl_3$, AC250) δ: 7.56 (d, 2H, 7.93 Hz), 7.34–7.14 (m, 7H), 4.02 (s, 2H); ^{13}C nmr ($CDCl_3$, AC250) δ: 146.80 (s), 139.38 (s), 132.33 (d), 129.68 (d), 129.01 (d), 128.81 (d), 126.72 (d), 119.06 (s), 110.04 (s), 42.00 (t); ms *m/z*: 193 ($M^{+\bullet}$, 100), 190 (14), 165 (24), 91 (10). This compound has been reported previously (26).

*Irradiation of 6-cyano-3-phenylindene (**7**b) and 1,4-dicyanobenzene (**3**) in acetonitrile–methanol (reaction [6])*

A solution of 6-cyano-3-phenylindene (**7***b*) (506 mg, 2.33 mmol) and 1,4-dicyanobenzene (**3**) (236 mg, 1.84 mmol) in acetonitrile–methanol (3:1) (23 mL) was irradiated through Pyrex with the 1 kW mercury vapour lamp. Analysis of the ^{1}H nmr spectrum of the reaction mixture indicated **7***b* was consumed and gc/ms showed two new peaks, with similar retention times and mass spectral fragmentation patterns, attributed to the ethers, *cis*-**6***b* and *trans*-**6***b*. The solvent was evaporated and the crude reaction mixture was separated by chromatography (dcfc) using a solvent gradient of 2–5% ethyl acetate in hexane as the eluent. A colourless oil (100 mg, 18%), obtained in the earlier fractions, was assigned the *trans* isomer (*trans*-**6***b*). Another colourless oil (127 mg, 23%), in later fractions, was assigned the *cis* isomer (*cis*-**6***b*).

*Photosensitized irradiation of 5-cyano-2-methoxy-1-phenylindane (*cis- *and* trans-**6**b*) and 1,4-dicyanobenzene (**3**) in acetonitrile–methanol*

A solution of 5-cyano-2-methoxy-1-phenylindane (1:2.5, *cis*-**6***b*:*trans*-**6***b*) (170 mg, 0.7 mmol) and 1,4-dicyanobenzene (**3**) (130 mg, 1 mmol) in acetonitrile–methanol (3:1, 10 mL) was irradiated through Pyrex at 10°C. Progress of the reaction was followed by gc/ms and gc/fid. The *cis*/*trans* ratio remained unchanged. After 61% conversion, the acetal, 4-benzyl-3-(2,2-dimethoxy)ethyl benzonitrile (**8**) (51 mg, 43%), was isolated by chromatography (dcfc) using an ethyl acetate – hexane solvent gradient (0–20%): 4-benzyl-3-(2,2-dimethoxy)-ethyl benzonitrile (**8**): ir (neat film, Nic.), ν: 3027 (w), 2937 (s), 2832 (m), 2228 (s), 1602 (m), 1495 (s), 1450 (s), 1121 (s), 1071 (s), 701 (m): ^{1}H nmr ($CDCl_3$, AC250) δ: 7.56–7.08 (m, 8H), 4.30 (t, 1H, 5.47 Hz), 4.11 (s, 2H), 3.28 (s, 6H), 2.91 (d, 2H, 5.47 Hz); ^{13}C nmr ($CDCl_3$, AC250) δ: 145.03 (s), 139.14 (s), 137.05 (s), 134.32 (d), 131.03 (d), 130.18 (d), 128.73 (d), 128.66 (d), 126.49 (d), 119.02 (s), 110.28 (s), 104.65 (d), 53.90 (q, two OCH_3 groups), 39.18 (t), 36.22 (t); ms *m/z*: 249 (9), 218 (11), 217 (13), 204 (5), 190 (5), 75 ($-CH(OCH_3)_2$, 100).

4-Benzyl-3-(2,2-dimethoxy)ethyl benzonitrile (**8**) was converted into the crystalline 2,4-dinitrophenylhydrazone derivative by the standard method (27). Recrystallization from ethanol – ethyl acetate gave the 2,4-dinitrophenylhydrazone, mp 212.2–213.2°C; ^{1}H nmr ($CDCl_3$, AC250) δ: 10.87 (s, 1H), 9.12 (d, 1H, 2.60 Hz), 8.31 (dd, 1H, 9.61, 2.60 Hz), 7.78 (d, 1H, 9.61 Hz), 7.59 (dd, 1H, 7.78, 1.68 Hz), 7.55 (d, 1H, 1.68 Hz), 7.34 (d, 1H, 7.78 Hz), 7.17 (t, 1H, 5.3 Hz, the imine hydrogen), 7.29–7.20 (3H, overlap with solvent ($CHCl_3$) peak), 7.07–7.02 (m, 2H), 4.14 (s, 2H), 3.74 (d, 2H, 5.3 Hz, the methylene hydrogens next to the imine). When the ^{1}H nmr was taken in C_6D_6 solution, the imine hydrogen was shifted to 6.07 (t, 1H, 5.4 Hz), coupled to the methylene hydrogens at 3.28 (d, 2H, 5.4 Hz). Anal. calcd. for $C_{22}H_{17}N_5O_4$: C 63.61, H 4.12, N 16.86; found: C 63.44, H 4.11, N 17.15.

When a small sample of pure *trans* isomer (*trans*-**6***b*) was irradiated under the conditions described above, the acetal (**8**) was formed immediately; the *cis* isomer (*cis*-**6***b*) was formed more slowly. When a small sample of pure *cis* isomer (*cis*-**6***b*) was irradiated, formation of the *trans* isomer (*trans*-**6***b*) was observed immediately; no acetal (**8**) was detected until an appreciable amount of the *trans*-**6***b* was present.

Photosensitized irradiation of trans-*5-cyano-2-methoxy-1-phenylindane (*trans-**6**b*) in acetonitrile–methanol-O-d (3:1).*

A solution of *trans*-5-cyano-2-methoxy-1-phenylindane (*trans*-**6***b*) and 1,4-dicyanobenzene (**3**) in acetonitrile–methanol-O-*d* (3:1) was irradiated. Progress of the reaction was followed by gc/ms (single-ion monitoring) and gc/fid. After 60% conversion, ms indicated deuterium incorporation in the *cis* and *trans* isomers (5% and 3%, $M^{+\cdot}$) and in the acetal (**8**)

(>90%, $M^{+\cdot} - 32$ (CH_3OH)). The mixture was separated by chromatography (dcfc), eluting with an ethyl acetate – hexane (0–8%) solvent gradient. Analysis of the ^1H nmr spectra of **8** indicated nearly quantitative incorporation of one deuterium at the bis-benzylic position. There was no indication of deuterium incorporation at the mono-benzylic position.

Design and synthesis of near-infrared absorbing pigments. I. Use of Pariser–Parr–Pople molecular orbital calculations for the identification of near-infrared absorbing pigment candidates

Denis Désilets, Peter M. Kazmaier, and Richard A. Burt

Abstract: The usefulness of the Pariser–Parr–Pople molecular orbital method for the identification of near-infrared absorbing pigment candidates for photogenerator applications is outlined. Several pigments based on the well-known class of photogenerators *N,N'*-dialkyl-3,4,9,10-perylenetetracarboxylic diimides were investigated and pigments of the dibenzoperylene, bisanthene, and zethrene classes were identified as the most promising candidates of the series. On the basis of the predictions, 7,8,15,16-dibenzo[*a*, *j*]perylenetetracarboxylic diimide was prepared and the validity of the calculations was verified.

Key words: photoconductor, near-infrared, Pariser–Parr–Pople calculations, polycyclic aromatic hydrocarbon, aceanthrene green.

Résumé : On présente des données montrant l'utilité de la méthode des orbitales moléculaires Pariser–Parr–Pople pour l'identification de pigments pouvant être des candidats pour une absorption dans le proche infrarouge pour des applications comme photogénérateurs. On a étudié plusieurs pigments dérivés de la classe bien connue de photogénérateurs des diimides de l'acide *N,N'*-dialkylpérylène-3,4,9,10-tétracarboxylique et on a identifié des pigments des classes du dibenzopérylène, du bisanthène et du zéthrène comme les candidats les plus prometteurs de la série. Sur la base de ces prédictions, on a préparé le diimide de l'acide dibenzo-[*a*, *j*]pérylène-7,8,15,16-tétracarboxylique et on a vérifié la validité des calculs.

Mots clés : photoconducteur, proche infrarouge, calculs Pariser–Parr–Pople, hydrocarbure polycyclique aromatique, acéanthrene vert.

[Traduit par la rédaction]

Introduction

Diimide (**1**) and bis(benzimidazole) (**2**) derivatives of 3,4,9,10-perylenetetracarboxylic dianhydride (Scheme 1) are well-known pigments and have been used in a wide variety of applications (1–5). These compounds have proven to be photogenerating materials with high photosensitivity in the visible, low dark decay, and excellent cyclic stability (6–9). Because of the increased interest in near-infrared photosensitive materials for laser printing applications, it would be highly desirable to design photogenerators with these properties and which would be photosensitive at the gallium aluminium arsenide (GaAlAs) diode laser wavelength around 780 nm. The preparation of polycyclic aromatic imides and benzimidazole derivatives is expected to be difficult because of the insolubility of these pigments and also because the available synthesis methodology for polycyclic aromatics is very substrate specific. In view of these constraints, it is essential to have a calculational method that would predict the spectral response of a pigment prior to embarking on a lengthy synthesis process.

molecules such as azos, quinone, and cyanine-type dyes in the visible region (10–12). This paper will report on the application of this method to the identification of near-infrared absorbing polycyclic aromatic imide pigment candidates.

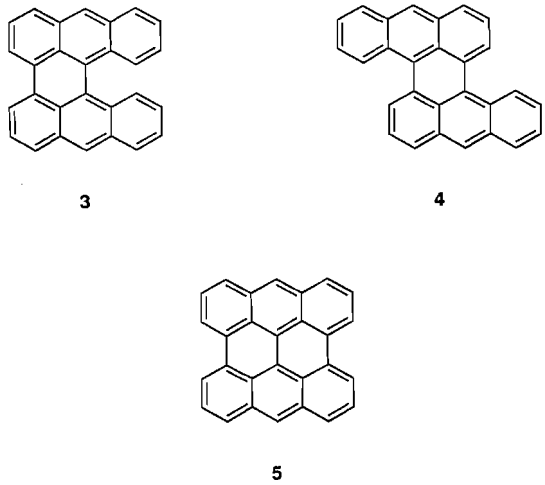
Results and discussion

Description of the method

In optoelectronic devices such as photoreceptors, the photogenerator pigment is used in the form of a dispersion in a polymer matrix. An ideal method for screening potential near-infrared photogenerator pigments would identify derivatives possessing the required absorptivity in the near-infrared, for the pigment as a solid state dispersion in a binder polymer. Unfortunately, calculations of solid state spectra are beyond the scope of the PPP method and of any other currently available molecular orbital program since these programs have been parameterized to reproduce solution or gas phase results.

To circumvent this problem, a solution absorption maximum has been calculated for candidate near-infrared photogenerator pigment structures and these solution absorption values with the corresponding oscillator strengths (a measure of the area under the absorption peak) were compared to a known, benchmark photogenerator of the polycyclic pigment class with a photosensitivity in the visible. The solid state absorption maximum was estimated by assuming that aggregation for the candidate compound would be comparable to that observed for the benchmark compound. Fortunately, the correct prediction of a red shift in the molecular absorption is far more important than the accurate prediction of the solid state absorption maximum of the candidate pigment because the absorption broadens considerably in the solid state and the candidate pigment will function in a device as long as the absorption maximum has been shifted far enough into the infrared to provide a region of uniform light absorption for the diode laser. Furthermore, because of the high loadings in the devices, the useful range extends beyond the pigment solid state absorption maximum. For example, *N,N*-dimethyl-3,4,9,10-perylenetetracarboxylic diimide, with absorption maxima at 461, 493, and 530 nm in solution and at 485 and 575 nm in the solid state, still provides a flat xerographic spectral response from 445 to 580 nm (Fig. 1). The xerographic spectral response curve is a standard test to measure the panchromaticity of a photoreceptor (7). It is obtained by plotting the inverse of the exposure energy required to reduce the surface potential by half versus the wavelength of the light source. Similarly, the bis(benzimidazole) derivative (**2**) has absorptions at 545 and 665 nm in the solid state and provides flat xerographic spectral response from 490 to 710 nm (6).

Scheme 2



PPP calculations are designed to handle planar systems. For our purposes polycyclic aromatic pigments are assumed to be planar and all rings have been approximated by regular hexagons or pentagons. This approximation is a reasonable assumption since the calculated values have been shown to be much more dependent on the PPP parameters required for the calculations than on the molecular bond angles and bond lengths (11). This can be demonstrated by comparing dibenzo[*a,o*]perylene (**3**) and dibenzo[*a,j*]perylene (**4**) to bisanthene (**5**) (Scheme 2). In the case of the dibenzoperylenes, molecular mechanics calculations as well as CPK models indicate that the two anthracene units should be distorted from planarity on the order of 20°–30° whereas bisanthene is planar. The results of Table 1 show that the predictive power of the PPP calculations is not seriously compromised by assuming a planar system for the dibenzoperylenes.

In addition to the absorption maximum, PPP calculations provide an estimate of the oscillator strength (*f*), which is

related to the area under the absorption band. Since the extinction coefficient is related to the height of the band, the two quantities are linearly related only if the band widths are the same and if the bands are symmetrical. Since high absorption is a prerequisite for achieving high photosensitivity, the oscillator strengths are useful in determining the extinction coefficients and, therefore, the photosensitivity of a pigment. However, since PPP parameters have been selected to provide the correct estimates for dye and pigment absorption maxima, the parameterization is necessarily non-optimal vis-a-vis the oscillator strength. Thus, oscillator strength estimates often lead to poor correlation within a particular compound class (11) and they can only be used as a qualitative tool.

In the examples studied in this paper, we selected *N,N'*-dialkyl-3,4,9,10-perylenetetracarboxylic diimides (**1**) as the benchmark compounds and, therefore, we need a shift of the order of 200 nm to extend the 580 nm photosensitivity limit of these photogenerator pigments to 780 nm. Ideally, since the calculated absorption of the benchmark diimide is at 469 nm, suitable near-infrared absorbing candidates should have their calculated absorption near 670 nm on the basis of this 200 nm shift or near 590 nm on the basis of a constant energy shift (15) calculated from the difference between the calculated absorption and the observed absorption in the solid state for the benchmark perylene pigment. On the other hand, if we extend the conjugation by using a bis(benzimidazole) derivative instead of a diimide, the required shift to extend the 710 nm photosensitivity limit of the bis(benzimidazole) perylene towards the desired 780 nm wavelength is now only 70 nm. Thus, diimides with a calculated absorption maxima around 540 nm (wavelength shift) or 500 nm (energy shift (15)) become good candidates.

The calculations were done on a wide variety of polycyclic diimides (Scheme 3) and the results are presented in Table 2. The following observations can be made.

Table 2. Pariser–Parr–Pople calculated absorptions and oscillator strengths in cyclohexane for the compounds of Scheme 3.

Polyarenes

One simple concept for achieving infrared photosensitivity would be to increase conjugation by extending the aromatic structure in a linear sense. Consequently, linear polyarenes were investigated and a series is represented by compounds **6–11**. These pigments were not found to be good candidates for near-infrared activity for two reasons. First, to obtain a red shift of the absorption vis-a-vis the benchmark, one needs to go to five or six fused rings as in **10** and **11**. For very long annelated systems like this, imide substitution imparts very little *n*-character (acceptor) to the kernel. Therefore since higher polyacenes are unstable (16), the same behavior is expected for the diimide derivatives. Second, the low oscillator strengths associated with these compounds suggest they would not have high enough extinction coefficients to be usable pigments.

Simple polycyclic arenes

Another approach would be to take a known photogenerator such as **1** and simply extend the conjugation by fusing benzene rings to the chromophore. Initially calculations were done on some simple polycyclic arenes in which the conjugation of the perylene nucleus was extended by merging with extra aromatic rings in the bay region of the chromophore. As seen by the results for compounds **12–16**, this class does not seem very promising. Extension of the conjugation as in the coronene case (**14**) does in fact shift the absorption maximum in a hypsochromic sense rather than the bathochromic shift intuitively expected. Furthermore, the oscillator strength is low, being identically zero for those compounds with 3-fold symmetry. Extraordinary extension of the conjugation, as in the ovalene case (**16**), brings very little improvement of the values, indicating that the difficult synthesis of the material should not be attempted. An interesting observation highlighting the usefulness of the PPP method can be made when comparing compounds **14** and **15** to the coronene nucleus **13**. One can see that the introduction of two imide units on coronene increases the maximum absorption wavelength from 373 to 441 nm but that one cannot further increase the position of the absorption by adding one more unit. The introduction of this supplementary unit in fact decreases the position of the absorption to 407 nm. These examples indicate that simple intuition based on the principle of the efficacy of extended conjugation without a detailed analysis of the excitation process does not provide a reliable guide for predicting the impact of structural change on the absorption maximum and oscillator strength of these materials.

Anthanthrenes

The importance of using PPP calculations in the design of new near-infrared photogenerator materials can be illustrated by a consideration of anthanthrenes. Diimides and bis(benzimidazole) derivatives of anthanthrene in which the substitution of the nucleus is the same as that in compound **17** have been reported in the literature (17–20). Calculations predict that there would be no substantial advantage if such derivatives were prepared. However, the calculations predict that a shift of the absorption could be achieved if the anthanthrene nucleus were substituted as in **18**. On the other hand, replacing the two six-membered ring anhydrides in **18** with two five-membered ring units as in **19** gives no wavelength advantage. The ability to predict which isomeric anthanthrenes provide the optimum absorption maximum shift again shows the usefulness of the PPP method for pigment design.

Perylenes

Extending the conjugation of perylene diimide **1** by inserting an extra naphthalene ring between the two naphthalene rings of perylene as in the terrylene **20** leads to a substantial improvement over the perylene derivative. Since the preparation of tetraalkyl-substituted terrylene and related derivatives has been reported recently in the literature (21–24), the synthesis of the corresponding diimides can be considered. Calculations indicate that dibenzoperylene or bisanthene derivatives **21–23** would lead to much better candidates for near-infrared absorbing diimide pigments. The expected shift of the absorption towards the near-infrared is of the order of 140–170 nm compared to the benchmark diimide **1**. However, deviation from planarity that might affect photosensitivity of these derivatives is expected in the case of compounds **21** and **22**, but compound **23** is predicted to be planar.

Zethrenes

Zethrenes are an interesting class of pigments that are predicted by PPP calculations to have substantial near-infrared shifts. The quinoid bond fixation leads to long-wavelength absorption for the corresponding hydrocarbons (ref. 13, pp. 447–466). With relatively small increase in molecular weight, zethrene derivatives such as **24** and **25** are predicted to experience a considerable shift towards the near-infrared as well as a large increase of the extinction coefficient. Their calculated oscillator strength values are among the highest of the series

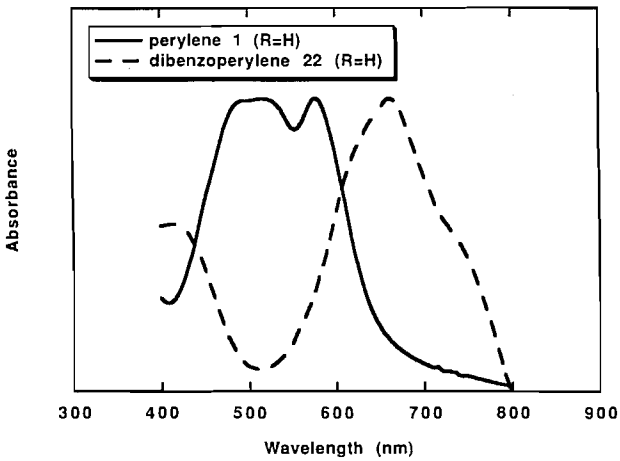
Fig. 2. Normalized solid state absorption spectra of the perylene diimide **1**, R = H, and of the dibenzoperylene **22**, R = H.



and they are predicted to give highly absorbing near-infrared pigments.

Experimental verification

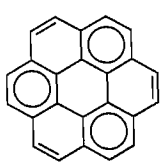
To verify the reliability of the PPP method for predicting potential infrared photogenerating candidates, the synthesis of 7,8,15,16-dibenzo[*a,j*]perylenetetracarboxylic diimide (**22**, R = H) was undertaken and will be reported in the following paper. The absorption spectrum in a vinyl acetate binder is shown in Fig. 2 and compared with that of the benchmark 3,4,9,10-perylenetetracarboxylic diimide (**1**, R = H). As one can see, the calculations provided a reliable guide for the prediction of the absorption maximum. The observed 160 nm bathochromic shift is larger than the 136 nm shift calculated on the basis of a simple wavelength shift but smaller than the 220 nm shift calculated on the basis of a constant energy shift (15).

Conclusion

PPP calculations provide an important tool for predicting the absorption maxima of potential near-infrared photogenerator pigments. Intuition, based on the principle of extended conjugation, is an unreliable guide for predicting the impact of ring fusion to the chromophore and cannot determine which isomeric diimide derivative has the longest absorption maximum combined with the highest oscillator strength.

Compounds with 3-fold symmetry such as coronene derivative **15** have a forbidden low-energy transition. Furthermore, the effect of extended conjugation is offset by ground stabilization as shown in resonance structure **26** (Scheme 4). In contrast, bond fixation can favorably impact the absorption maximum as in dibenzoperylenes (**21–23**) and zethrenes (**24, 25**). The identification and preparation of the dibenzoperylene derivative **22** (R = H) verifies the efficacy of this methodology.

Scheme 4



26

Computational

Pariser–Parr–Pople calculations were performed using parameters based on the ones published by Griffiths (11). Molecular mechanics calculations were done using the MMX parameters reported by Gajewski et al. (25).

Experimental

Preparation of 7,8,15,16-dibenzo[*a, j*]perylenetetracarboxylic diimide 22 (R = H)

The dibenzoperylene **22** (R = H) was prepared as reported by Kardos (26). The structure was determined as described in the following paper.

Preparation of the pigment films and measurement of the absorption spectra

The absorption spectra of the pigments were obtained by following the protocol of Loutfy (27). The pigment (180–200 mg) was suspended in a solution of poly(vinyl acetate) in methylene chloride (1.5% by weight, 10 mL) and ball-milled for 24 h with 1/8 in. stainless steel shot. The film was prepared by draw-down coating using a wire-wound rod (No. 6). The absorption spectrum was measured using a Cary 5 UV–Vis–NIR spectrophotometer.

Acknowledgments

The authors wish to thank Dr. T. I. Martin for helpful discussions and support throughout the near-infrared polycyclic aromatic photogenerator project. We would also like to express our sincerest appreciation to Professor J. Griffiths (University of Leeds) for providing a copy of the PPP program and for helpful comments. We also thank B. Keoshkerian for obtaining a copy of the program and P. Blaney for translating it into Fortran.

Design and synthesis of near-infrared absorbing pigments. II. Structure determination of aceanthrene green and derivatives

Denis Désilets, Peter M. Kazmaier, Richard A. Burt, and Gordon K. Hamer

Abstract: The reported structure of aceanthrene green, a pigment prepared by potassium hydroxide fusion of 1,9-anthracenedicarboxylic imide, was found to be incorrect. The structure of the pigment is reassigned to 7,8,15,16-dibenzo[*a,j*]perylenetetracarboxylic diimide on the basis of COSY, NOESY, and inversion–recovery ^{1}H NMR experiments. *N*-Alkyl- or *N*-phenyl-1,9-anthracenedicarboxylic imides, aceanthryleno[1,2-*b*]quinoxaline, and a benzimidazole derivative of 1,9-anthracenedicarboxylic anhydride were found to give the same dibenzo[*a,j*]perylene structure when reacted in potassium hydroxide. The electronic spectra of these derivatives is reported and it is shown that, as predicted by Pariser–Parr–Pople calculations, they absorb in the near-infrared. Finally, a mechanistic outline for the fusion is proposed on the basis of AM1 and frontier molecular orbital calculations.

Key words: photoconductor, near-infrared, aceanthrene green, alkalifusion, polycyclic aromatic hydrocarbon.

Résumé : On a trouvé que la structure proposée antérieurement pour l'acéanthrène vert, un pigment préparé par fusion de l'imide de l'acide anthracène-1,9-dicarboxylique avec de l'hydroxyde de potassium, est incorrecte. En se basant sur des expériences COSY, NOESY et d'inversion–récupération en RMN du ^{1}H on lui a réattribué la structure du diimide de l'acide dibenzo[*a,j*]pérylène-7,8,15,16-tétracarboxylique. On a trouvé que par réaction, par fusion avec de l'hydroxyde de potassium, les *N*-alkyl- ou *N*-phénylimides de l'acide anthracène-1,9-di- carboxylique, l'acéanthryléno[1,2-*b*]quinoxaline et un dérivé benzimidazole de l'anhydride de l'acide anthracène-1,9-dicarboxylique conduisent tous à la même structure dibenzo[*a,j*]pérylène. On rapporte les spectres électroniques de ces dérivés et il est montré, tel que prédit par des calculs de type Pariser–Parr–Pople, qu'ils absorbent dans le proche infrarouge. Enfin, en se basant sur des calculs d'orbitales moléculaires AM1 et frontières, on propose un aperçu du mécanisme pour la fusion.

Mots cles : photoconducteur, proche infrarouge, acéanthrène vert, fusion alcaline, hydrocarbure polycyclique aromatique.

[Traduit par la rédaction]

Introduction

Pigments absorbing in the near-infrared, at the gallium aluminium arsenide (GaAlAs) or indium phosphide (InP) diode laser wavelengths, have become the subject of an increasing number of studies. For example, near-infrared absorbing pigments are required for applications in xerographic printing, optical recording, and laser filters (1–4). As reported in the previous paper (5), diimide **1** (Scheme 1) or bis(benzimidazole) **2** derivatives of 1,6,7,16-dibenzo[*a,o*]perylenetetracarboxylic dianhydride are interesting candidates as near-infrared absorbing pigments for laser printing applications. Although no structure determination was ever published, the pigment aceanthrene green was reported by Chemical Abstract (6), Color Index (7) and other authors (8–10) as having the 1,6,7,16-dibenzo[*a,o*]perylenetetracarboxylic diimide structure **3**. Aceanthrene green was prepared by Kardos (11) in 1913 using a potassium hydroxide fusion on 1,9-anthracenedicarboxylic imide followed by an air oxidation. It has been considered industrially but has never achieved commercial importance (8, 9, 12–24). However, Kardos proposed structure **4** for the compound on the basis of elemental analysis and most probably from mechanistic considerations (10). It is worth mentioning that the stoichiometry of structure **3** agrees more closely with the reported elemental analysis than does that of structure **4**.

This paper will report on the structure of aceanthrene green and on some of its derivatives prepared by potassium hydroxide fusion. Studies directed towards an understanding of the mechanism of the fusion reaction will also be presented.

Results and discussion

Preparation and structure determination of aceanthrene green and derivatives

With the help of Pariser–Parr–Pople calculations (25, 26) it was found that aceanthrene green, as represented by structure **3** (Scheme 1), should absorb near 615 nm (5). This represents a bathochromic shift of 145 nm compared with the calculated absorption of the well-known diimide perylene pigment **5** at 470 nm. One can therefore envision derivatives of perylene pigments such as **1** or **2** that would be near-infrared absorbing.

The synthesis of aceanthrene green was repeated as originally described by Kardos (11). After preparing the imide **6** (Scheme 2), the fusion was carried out in molten potassium hydroxide at 250°C and it was followed by an air oxidation. The dark-green solid obtained after the reaction was found to be a mixture composed of the *trans*-dibenzoperylene[2] **7** and of the *cis*-dibenzoperylene[2] **3**, reported in the literature as aceanthrene green, in a ratio of 6.8:1. The assignment of the structure was done with the help of COSY (27, 28), NOESY (29, 30), and inversion–recovery (31) ^{1}H NMR experiments after the material was found to be soluble in a mixture of chloroform and trifluoroacetic acid. The COSY experiment (Fig. 1) shows the presence of a two-spin (H2 and H3 of the anthracene unit[3]) and a four-spin system (H5, H6, H7, and H8 of the anthracene unit) in both components, indicating that the position of the fusion is indeed at C4 and C9 in both isomers. A NOESY experiment showed an interaction between H3 and H5′ in the major isomer, but not in the minor one. This allows for the assignment of the *trans* structure to the major isomer. Furthermore, the inversion–recovery experiment (Fig. 2) shows that there are two slow- and two fast-relaxing protons for the major component, and one fast- and three slow-relaxing protons for the minor component. AM1 and PCMODEL calculations show that, for the *trans* isomer, the distance between H3 of one of the anthracene units and H5′ of the other unit is around 2.13–2.37 Å, which is less than the 2.48–2.46 Å distance between two vicinal protons. On the other hand, in the *cis* isomer, the distance between H5 and H5′ is calculated to be 2.74–3.05 Å, which is larger than the 2.48–2.46 Å distance between two adjacent protons. H3 and H3′ of this isomer were found to be 2.03–2.19 Å apart, which is shorter than the vicinal distance. Therefore, the major isomer can again be assigned to the *trans* structure with the fast-relaxing H3 and H5 and the slow-relaxing, isolated H2 and H8. The minor structure can be assigned to the *cis* isomer with the fast-relaxing H3 and the slow-relaxing H2, H5, and H8. The complete assignment of the ^{1}H NMR peaks can then be done in the following way. In the *trans* isomer, the COSY experiment leaves only one possibility for the assignment of the fast-relaxing protons at 8.74 ppm in a two-spin system and at 8.81 ppm in a four-spin system, and of the slow-relaxing protons at 9.05 ppm in a two-spin system and at 10.03 ppm in a four-spin system. These peaks can be assigned to H3, H5, H2, and H8, respectively. The remaining peaks at 7.97 and 8.10 can then be assigned to H6 and H7, respectively, with the help of the COSY spectrum. In the *cis* isomer, the fast-relaxing proton at 8.94 ppm and the slow-relaxing proton at 9.11 ppm, both in a two-spin system, can be assigned to H3 and H2, respectively. However, since both H5 and H8 are slow-relaxing in the *cis* isomer, the assignment of the peaks has to be done on the basis of the similar environment for H8, H7, and H6 and of the different environment for H5 in both isomers. Therefore, the peak at 7.53 ppm can be assigned to H6 (7.97 ppm for the *trans* isomer), the one at 7.98 ppm to H7 (8.10 ppm for the *trans* isomer), the one at 9.87 ppm to H8 (10.03 ppm for the

[2] Throughout this discussion, we will refer to *trans*-dibenzoperylene instead of dibenzo[*a,j*]perylene and to *cis*-dibenzoperylene instead of dibenzo[*a,o*]perylene.

[3] For simplicity, we will refer to the anthracene nucleus numbering for the explanation of the NMR results.

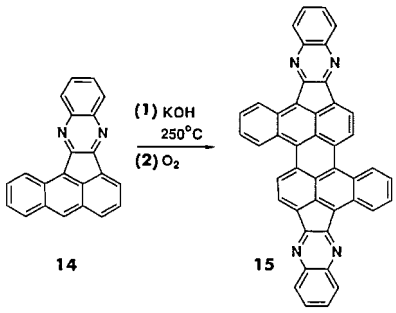
Scheme 3



trans isomer), and the one at 7.68 ppm to H5 (8.81 ppm for the *trans* isomer). This assignment is further supported by the fact that H5 is expected to be faster relaxing than H8 due to the presence of an extra H5 proton from the other anthracene unit. The inversion–recovery experiment shows that this is indeed the case. The material was also characterized by mass spectrometry and infrared spectroscopy. The yield of the reaction was calculated to be 64% based on the assigned structure.

The reaction was also carried out on the *N*-methyl, *N*-propyl, and *N*-phenyl derivatives of 1,9-anthracenedicarboxylic imide (**8**–**10**). In contrast with the results obtained for the fusion of the simple imide, it was found that these derivatives give only the *trans* isomer with traces of impurities that could not be assigned to the *cis* isomer.

Potassium hydroxide fusion of anthracene derivatives is known elsewhere in the literature. In 1954, Bradley and Pexton reported their results on the fusion of the quinoxaline **14** (Scheme 3) (32) and, after obtaining the same material by fusion of the quinoxaline derivative brominated at position 10 of the anthracene moiety, they concluded that the compound was a dibenzo derivative having either the *cis* or the *trans* regiochemistry. After reinvestigating this reaction, it was found that, here again, only the *trans* isomer **15** is obtained. The structure of the fused quinoxaline was determined by the same series of experiments that were used for the structure determination of the diimides.

The COSY experiment (Fig. 3) showed the presence of two four-spin systems and one two-spin system. The two-spin system was assigned to H2 and H3 of the anthracene unit. The NOESY experiment showed an interaction between H3 and H5′, enabling the assignment of the *trans* structure to the material and of the two four-spin systems. As a matter of fact, both the two-spin and the four-spin systems of the anthracene unit were found in an almost identical position as those of the diimide derivative. The total assignment of the structure was done with the help of inversion–recovery experiments, as in the case of the diimide. Both H3 and H5 were found to be fast relaxing and H8 was found to be slow relaxing. However, in contrast with the results obtained for the diimide, H2 was found to be fast relaxing and this can be explained by the presence of a deuterium (from the deuterated trifluoroacetic acid) on the closest nitrogen of the quinoxaline ring. The protona-

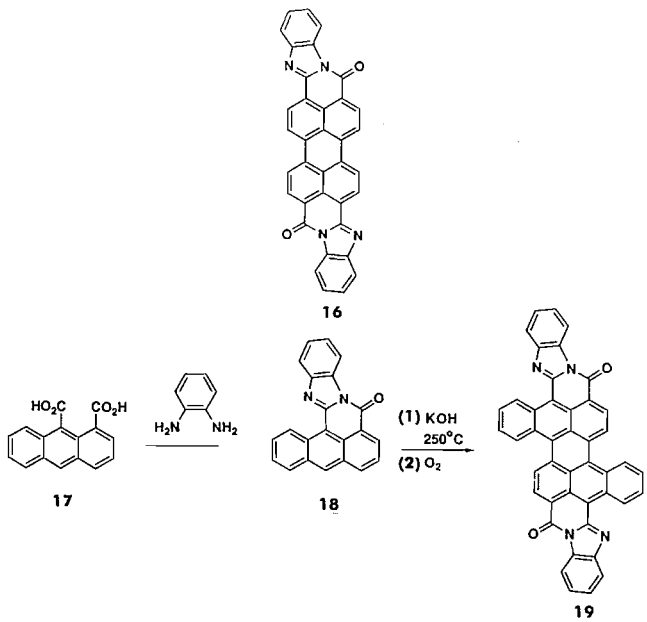
Scheme 4



tion occurs at this position because protonation on the other nitrogen would lead to a severe interaction with the peri proton (H8) of the anthracene unit. This protonation allowed for the assignment of the protons on the benzene ring since the fast-relaxing doublet at 8.68 ppm could then be assigned to Ha (Fig. 3) of the benzene ring and the slow-relaxing one at 8.35 ppm to Hd.

The preparation of the bis(benzimidazole) derivative of *trans*-dibenzoperylenetetracarboxylic dianhydride, the near-infrared absorbing analog of the bis(benzimidazole) perylene pigment **16** (Scheme 4), required the synthesis of the benzimidazole derivative of 1,9-anthracenedicarboxylic anhydride. Although two regioisomers were expected on reaction with 1,2-phenylenediamine, surprisingly, only one isomer was obtained. The compound was identified as having structure **18** after characterization by ^{1}H NMR. The assignment was done in the following way. First, the H2 proton was identified at 8.90 ppm on the basis that it is the only doublet with only one minor coupling constant and also on the basis of similarity of the chemical shift when compared with the simple diimides. The carbonyl carbon was then identified in the ^{13}C NMR at 160.75 ppm, the imine carbon being at 150.06 ppm. The correlation between H2 and the carbonyl carbon was then demonstrated by a selective INAPT experiment (33, 34), thus showing that the carbonyl carbon is two atoms away from C2. With one isomer in hand, it was then possible to prepare the bis(benzimidazole) derivative of *trans*-dibenzoperylene by a route that yields one and only one regioisomer. This contrasts with the mixture of "*cis*" and "*trans*" bis(benzimidazole) perylenes obtained when 3,4,9,10-perylenetetracarboxylic dianhydride is reacted with 1,2-phenylenediamine in the industrial preparation of this pigment.

The benzimidazole derivative **18** was fused in molten potassium hydroxide as described earlier but, unfortunately, it was not possible to satisfactorily purify the bis(benzimidazole) derivative of *trans*-dibenzoperylene (**19**) due to its very low solubility. Solvent washes and extractions proved to be inadequate while attempts at purification by means of train sublimation (35) proved unsuccessful. However, TLC and doping ^{1}H NMR experiments showed that no starting material was present in the mixture. ^{1}H NMR in a mixture of trifluoroacetic acid and chloroform showed a complex spectrum, not only because the additional protons of the benzene ring showed a complex AA'BB' system but because of additional components in the mixture. Since overlapping of the peaks also seems to be more extensive than in the case of the other dibenzoperylenes, attempts were made to shift the position of the peaks with the addition of another cosolvent. Thus, addition of benzene was found to give the peak separation required for the structure determination. With the help of a COSY experiment in a mixture of trifluoroacetic acid, chloroform, and benzene (1:1:4) (Fig. 4), the *trans*-dibenzoperylene structure could again be assigned to the major component by the same process as described earlier.

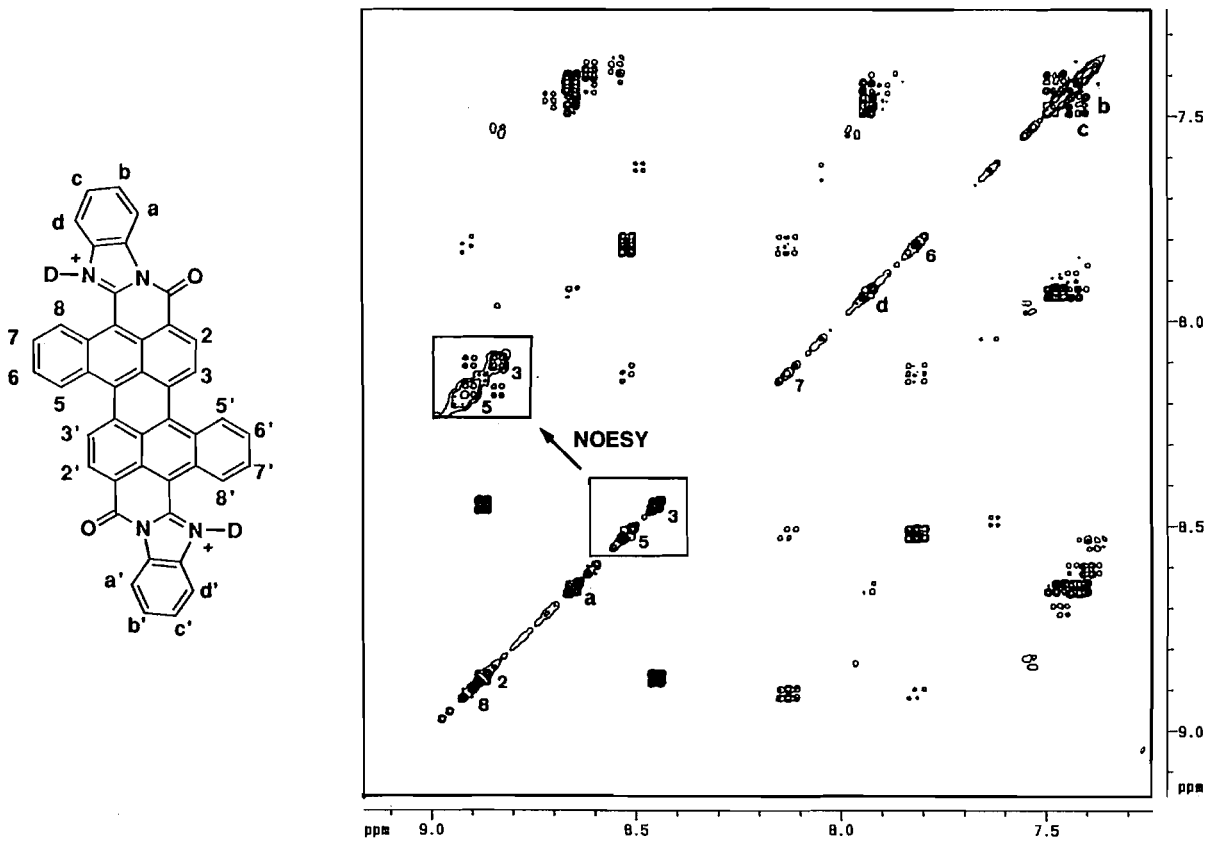
A tentative assignment of the protons of the phenyl ring was done in the following way. It was assumed that, as in the case of the quinoxaline, a deuteration occurred on the heterocyclic benzimidazole ring, enabling a fast relaxation of the neighbouring protons at positions 8 and d. Inversion–recovery experiments showed that H8 was indeed fast relaxing and H2 was slow relaxing as opposed to both being slow relaxing as in the case of the diimides. The multiplet at 8.65 ppm, which was found to be slow relaxing, was assigned to Ha and the multiplet at 7.93 ppm, which was found to be fast relaxing, was assigned to Hd. This enabled the assignment of the lower field part of the multiplet at 7.45 ppm to Hc and the high-field part to Hb.

The material was also characterized by mass spectrometry and only the fused material was detected. The infrared spectrum of the material was very closely related to that of the starting material, further confirming the structure.

Electronic absorption spectra of the dibenzoperylene derivatives

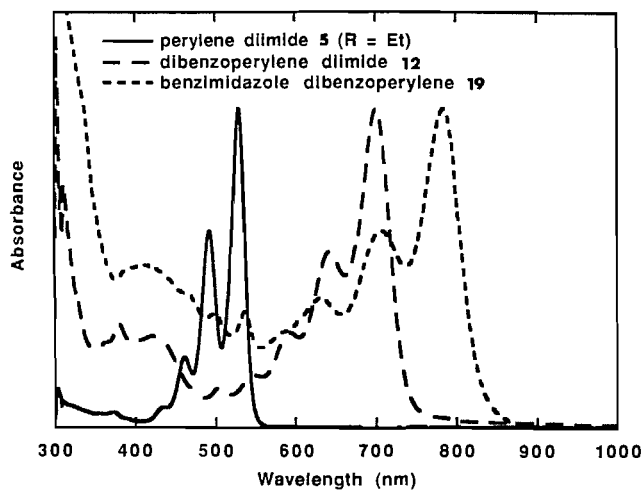
As discussed earlier, the electronic absorption of the dibenzoperylene derivatives is predicted to be shifted towards the near-infrared when compared to that of simple perylene derivatives. For example, Pariser–Parr–Pople calculations (5, 25, 26) predict that the *trans*-dibenzoperylenetetracarboxylic diimide derivative should absorb near 605 nm whereas the calculated absorption of the perylene analog is near 470 nm. This represents a calculated shift of 135 nm towards the near-infrared. The electronic spectra of the *trans*-dibenzoperylene derivatives were measured in 1,2,4-trichlorobenzene. The spectra of the *N,N'*-dipropyl diimide and of the bis(benzimidazole) *trans*-dibenzoperylene derivatives are presented in Fig. 5 and compared with that of *N,N'*-diethyl-3,4,9,10-perylenetetracarboxylic diimide (**5**, R = Et). The extinction coefficient of the *N,N'*-dipropyl derivative at 701 nm was found to be 35 300 L mol^{-1} cm^{-1}, which is very similar to the value for the 546 nm band of the corresponding hydrocarbon, *trans*-dibenzoperylene, reported as 31 600 L mol^{-1} cm^{-1} in MeOH (36). This value of the extinction coefficient is considerably lower than those reported for simple perylene diimide derivatives. For example, the value for the 524 nm peak of *N,N'*-dipropyl-3,4,9,10-perylenetetracarboxylic diimide is 78 730 L mol^{-1} cm^{-1} when measured in chlorofom (37). These lower values reflect the fact that the dibenzoperylene nucleus is distorted

Fig. 4. 400 MHz ^1H–^1H COSY spectrum of the bis(benzimidazole) **19** with NOESY insert. COSY mixing pulse, 45°; NOESY mixing time, 500 ms (ca. $1.2 \times t_1$).



from planarity, therefore having a reduced amount of overlap between the two π-systems of the individual anthracene units. The *N,N'*-dimethyl and *N,N'*-diphenyl diimide derivatives had spectra that were almost identical to that of the *N,N'*-dipropyl derivative whereas the simple diimide derivative was found to be insoluble in 1,2,4-trichlorobenzene. As predicted by the calculations, the absorption of the *trans*-dibenzoperylene derivatives is shifted towards the near-infrared, compared to that of the perylene derivative, as seen in Fig. 5. The experimental bathochromic shift of the absorption around 170 nm is larger than the 135 nm shift calculated on the basis of a simple wavelength shift, but very close to the 180 nm shift calculated on the basis of a constant energy shift (38) obtained from the difference between the calculated absorption and the experimental absorption in 1,2,4-trichlorobenzene of the perylene diimide analog. There is an additional 85 nm shift towards the near-infrared for the absorption of the bis(benzimidazole) derivative of *trans*-dibenzoperylene **19** at 785 nm. This absorption is now well within the emission wavelength spectrum of the gallium aluminium arsenide semiconductor laser.

Fig. 5. Comparison of the electronic absorption spectrum of a perylene diimide with those of the dibenzoperylene derivatives (normalized spectra).



Theoretical studies on the mechanism of the reaction

The preferential formation of the *trans* isomer over the *cis* analog deserves some comment. Even though the *cis* isomer of dibenzoperylene looks more hindered than the *trans* isomer, molecular mechanics and AM1 calculations show that they are of comparable stability and that one is not significantly more strained than the other. If one accepts this evidence for comparable thermodynamic stability then the answer to the variable selectivity in the fusion reaction must have its origin in kinetic control.

With the help of molecular orbital calculations, an attempt was made to develop a mechanistic outline for the reaction that would account for the preferential formation of the *trans*-

dibenzoperylene. As the first step of the reaction, it is reasonable to consider the formation of an arylide. To locate the site of proton abstraction on the ring, the heats of formation of each of the different arylides for the three systems studied were calculated. The calculations were performed using the AM1 parameters (39) and the results are presented in Table 1. In the case of the imide, the formation of a dianion was considered because of the higher acidity of the imide proton.

The results show that proton abstraction at position 10 is favored in all cases, followed by abstraction at position 4. Furthermore, in all cases, the difference is large enough (greater or equal than 3.1 kcal/mol) to account for proton abstraction at position 10 as a major reaction even at 250°C.

It was then assumed that the next step in the reaction would involve an attack of the HOMO of the anion on the LUMO of a neutral anthracene unit. Figure 6 shows the HOMO of the arylide and the LUMO of the neutral unit of the *N*-methyl derivative calculated using the semiempirical AM1 scheme in MOPAC. As expected, the HOMO of the anion is highly localized at position 10, which is the site of formation of the anion. As can be seen by looking at the LUMO, position 4 of the anthracene is favored over position 10 for a vinylogous Michael-type addition. Carbon 4 is connected to the carbonyl carbon through carbons 4a, 9a, and 1 whereas carbon 10 is isolated. The atomic orbitals situated on carbons 4, 4a, 9a, 1, and the C=O moiety are the most significant contributors to the LUMO orbital of the anthracene imide derivative. A mechanistic outline such as the one presented in Scheme 5 can then be proposed to explain the formation of the *trans* isomer. Similar results are obtained when the calculations are performed on the bis(benzimidazole) and bis(quinoxaline) derivatives.

If the anion were to form at position 4 instead of position 10, then the *cis* isomer would be obtained. This is probably why a larger amount of the *cis* isomer is formed when the simple

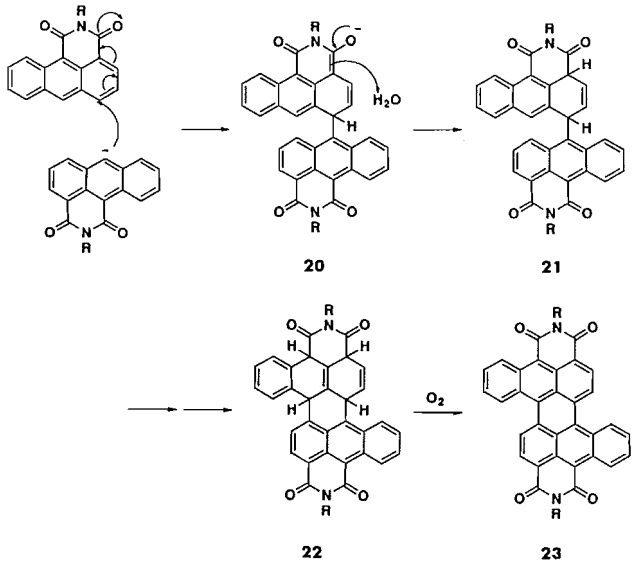
Scheme 5



anthracene imide is fused, since the difference in heats of formation of the anion between positions 10 and 4 is smaller compared with the other anthracene derivatives, as shown in Table 1 (3.5 kcal/mol for the imide derivative vs. 4.2 kcal/mol for the methyl derivative and 5.0 kcal/mol for the bis(quinoxaline) derivative). This smaller difference in the heats of formation favouring the anion at position 10 can also be used to explain the less selective formation of the bis(benzimidazole) derivative **19** since the value is 3.1 kcal/mol in favor of the anion formation at position 10.

Conclusion

Potassium hydroxide fusions have been used extensively in the dye and pigment field. With the advent of mass spectrometry and powerful NMR techniques, it is now possible to reinvestigate the structure of the materials obtained. Since the reaction described in this paper leads to reasonably pure products, it might be useful to reinvestigate previously obtained materials that were not considered useful at the time because of an unknown structure. One might gain a more profound understanding of the mechanism of the fusion and apply these principles to the preparation of highly complex pigments. Presently, synthetic routes leading to these types of pigments are limited due to the low solubility of the intermediates obtained, which inhibits further manipulation. The advantage of the potassium hydroxide fusion route is that one deals with simple, soluble intermediates up to the last step, which then gives a reasonably pure product. The results of this work show that this methodology is useful for the preparation of near-infrared-absorbing perylene type of pigments. Although it was not possible to prepare the analytically pure bis(benzimidazole) derivative of *trans*-dibenzoperylenetetracarboxylic dianhydride, ^{1}H NMR analysis, mass spectrometry, and infrared spectroscopy show that the material is present as a major component in the mixture.

Finally, the results on the investigation of the mechanism of the reaction demonstrate that theoretical calculations can be applied to the determination of a mechanistic outline. However, since these are preliminary studies, more elaborate calculations taking into effect the high temperature and polarity of the molten potassium hydroxide media have to be done in order to confirm the theory.

Computational

AM1 calculations were performed using the parameters reported by Dewar et al. (39). Pariser–Parr–Pople calculations were performed using parameters based on those published by Griffiths (26). Molecular mechanics calculations were done using the MMX parameters reported by Gajewski et al. (40).

Experimental

Melting points were determined using a Thomas–Hoover or an Electrothermal capillary melting point apparatus and are uncorrected. Mass spectrometry was carried out with a Finnigan 4500 MAT instrument by the electron impact method. IR spectra were recorded on a Nicolet 20DX FT-IR spectrophotometer. Electronic spectra measurements were acquired using a Cary 5 UV–Vis–NIR spectrophotometer. NMR spectra were recorded at ambient temperature (27°C) on a Bruker AMX-400 spectrometer operating at 400.14 MHz for ^{1}H and 100.62 MHz for ^{13}C using a 5 mm ^{1}H/^{13}C dual probe. Samples (4–8 mg/mL) were prepared in $CDCl_3$ or CF_3COOD–$CDCl_3$, 1:1 v/v, containing a small amount of TMS as an internal chemical shift reference; C_6D_6 was used as a cosolvent for **19**. The ^{1}H spectra were measured at a digital resolution of 0.08–0.16 Hz/point with a 45° pulse and a 5 s recycle time. Recovery times between 100 ms and 1.2 s with a recycle delay of 10 s were employed for inversion–recovery (31) relaxation experiments. The ^{13}C–{^{1}H} selective INEPT (INAPT) spectra were recorded using a pulse sequence adapted from Bax et al. (33, 34); the ^{1}H selective excitation was provided by a rectangular pulse of 25 Hz nominal width (90° pulse, 10 ms). Standard pulse sequences and phase cycling schemes (41) were used to record ^{1}H–^{1}H COSY (27, 28) and phase-sensitive (TPPI) NOESY (29, 30) spectra. The COSY mixing pulse was 45° (28) and the NOESY mixing time was 500–800 ms, depending on the T_1 values of the sample; the recycle delay was 3 s. For compounds **7** and **15**, a total of 256 1K FIDs of 4 (COSY) or 16 scans each (NOESY) were acquired; for **19**, 512 2K FIDs of 16 scans each were acquired for both COSY and NOESY. The data sets were multiplied in both t_1 and t_2 dimensions by a cosine-bell squared (COSY) or sine-bell squared (NOESY) function and zero-filled once in t_1. The COSY matrix was processed in magnitude mode and the NOESY-TPPI matrix in phase-sensitive mode. The contour plots shown in Fig. 1,3, and 4 have been symmetrized for clarity of presentation.

1,9-Anthracenedicarboxylic imide (6)

1,9-Anthracenedicarboxylic anhydride (11) (5.00 g), ammonium acetate (250 g), and water (25 mL) were slowly heated to 110°C under an ammonia atmosphere. Heating was continued for 2 h and the melt was cooled to room temperature. The solid mass was added to 1 L of water. The resulting solid was filtered and washed with water. Train sublimation (35) of the crude material gave the imide **6** (3.98 g, 80%) as orange needles; mp 302–304°C (lit. (11) mp 293–294°C). 909, 860, 799, 733, 500 cm^{-1}. ^1H NMR ($CDCl_3$; the assignment was done by decoupling and inversion–recovery (31) experiments) δ: 7.68 (ddd, 1H, J = 8.4, 6.6, and 0.9 Hz, H6), 7.78 (dd, 1H, J = 8.4 and 7.1 Hz, H3), 7.88 (ddd, 1H, J = 9.1, 6.7, and 1.4 Hz, H7), 8.16 (d, 1H, J = 8.5 Hz, H5), 8.44 (dd, 1H, J = 8.4 and 0.9 Hz, H4), 8.77 (dd, 1H, J = 7.0 and 1.3 Hz, H2), 8.92 (s, 1H, H10), 10.01 (dd, 1H, J = 9.2 and 0.8 Hz, H8) ppm.

N-Methyl-1,9-anthracenedicarboxylic imide (8)

A suspension of 1,9-anthracenedicarboxylic acid (42) (4.58 g, 17.2 mmol) in 1-methyl-2-pyrrolidinone (90 mL) under nitrogen was heated to 125°C for 30 min to enable complete conversion to the anhydride. The mixture was cooled to 30°C and 40% aqueous methylamine (8.9 mL, 105 mmol) was added dropwise. The solution was heated to 75°C for 45 min and poured into 750 mL water with stirring. After filtration, the solid was washed with water and dried. Recrystallization from acetone yielded the imide **8** (2.33 g, 52%) as orange needles; mp 229–230°C. IR (KBr) ν_{max}: 1690, 1651, 1563, 1534, 1437, 1408, 1318, 1279, 1098, 897, 799, 745, 731, 525 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.61 (s, 3H, NCH_3), 7.62 (ddd, 1H, J = 8.4, 6.6, and 0.8 Hz, H6), 7.68 (dd, 1H, J = 8.3 and 7.1 Hz, H3), 7.80 (ddd, 1H, J = 9.1, 6.7, and 1.4 Hz, H7), 8.06 (d, 1H, J = 8.4 Hz, H5), 8.28 (dd, 1H, J = 8.4 and 0.9 Hz, H4), 8.71 (dd, 1H, J = 7.0 and 1.2 Hz, H2), 8.73 (s, 1H, H10), 9.93 (dd, 1H, J = 9.1 and 0.5 Hz, H8) ppm.

N-Propyl-1,9-anthracenedicarboxylic imide (9)

A suspension of 1,9-anthracenedicarboxylic acid (42) (6.50 g, 24.4 mmol) in 1-methyl-2-pyrrolidinone (200 mL) under nitrogen was heated to 125°C for 15 min to enable complete conversion to the anhydride. A solution of *n*-propylamine (8.80 g, 149 mmol) in 1-methyl-2-pyrrolidinone (70 mL) was slowly added and heating was continued for 45 min. The mixture was then cooled to room temperature and diluted with 600 mL water while stirring. The pH was adjusted to 3 with 2 M hydrochloric acid and the resulting solid was filtered, washed with water, and dried. Recrystallization from ethanol yielded the imide **9** (6.73 g, 95%) as orange needles; mp 170–171°C. IR (KBr) ν_{max}: 1684, 1647, 1564, 1435, 1402, 1372, 1352, 1217, 1109, 895, 795, 739 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 1.07 (t, 1H, J = 7.4 Hz, CH_3), 1.84 (sextet of multiplet, 2H, J = 7.5 and <1.8 Hz, CH_2), 4.24 (m, 2H, NCH_2), 7.61 (ddd, 1H, J = 8.4, 6.6, and 1.1 Hz, H6), 7.71 (dd, 1H, J = 8.4 and 7.1 Hz, H3), 7.81 (ddd, 1H, J = 9.2, 6.6, and 1.5 Hz, H7), 8.08 (doublet of quintet, 1H, J = 8.4 and 0.7 Hz, H5), 8.31 (ddd, 1H, J = 8.4, 1.3, and 0.6 Hz, H4), 8.73 (dd, 1H, J = 7.1 and 1.3 Hz, H2), 8.77 (s, 1H, H10), 9.98 (ddd, 1H, J = 9.1, 1.8, and 0.9 Hz, H8) ppm.

N-Phenyl-1,9-anthracenedicarboxylic imide (10)

A suspension of 1,9-anthracenedicarboxylic acid (42) (4.50 g, 16.9 mmol) in 1-methyl-2-pyrrolidinone (180 mL) under nitrogen was heated to 125°C for 15 min to enable complete conversion to the anhydride. Aniline (9.60 g, 103 mmol) was slowly added and the solution was stirred at 180°C. Two additional portions of aniline (9.60 g, 103 mmol) were added after 7 h and 23 h. After 28 h of heating, the mixture was cooled, poured into 600 mL water, and the pH was adjusted to 3 with 6 M hydrochloric acid. The solid was filtered, washed with water, and dissolved in 800 mL dichloromethane. The dichloromethane was extracted with 0.5 M sodium hydroxide (2 × 250 mL), water (3 × 250 mL), 0.5 M hydrochloric acid (1 × 250 mL), and water (3 × 250 mL). The dichloromethane fraction was dried over magnesium sulfate and evaporated. The solid obtained was recrystallized from acetone to give the imide **10** (3.07 g, 56%) as greenish-yellow needles; mp 272–274°C. IR (KBr) ν_{max}: 1694, 1647, 1563, 1370, 1319, 1217, 735, 706 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.40 (m, 2H, phenyl), 7.52 (m, 1H, phenyl), 7.61 (m, 2H, phenyl), 7.65 (ddd, 1H, J = 8.3, 6.7, and 1.1 Hz, H6), 7.79 (dd, 1H, J = 8.4 and 7.0 Hz, H3), 7.81 (ddd, 1H, J = 9.2, 6.6, and 1.4 Hz, H7), 8.16 (doublet of quintet, 1H, J = 8.4 and 0.7 Hz, H5), 8.44 (ddd, 1H, J = 8.4, 1.3, and 0.5 Hz, H4), 8.82 (dd, 1H, J = 7.1 and 1.3 Hz, H2), 8.92 (s, 1H, H10), 9.96 (ddd, 1H, J = 9.2, 1.9, and 0.9 Hz, H8) ppm.

Benzimidazole derivative of 1,9-anthracenedicarboxylic anhydride (18)

1,9-Anthracenedicarboxylic acid (42) (16.2 g, 60.8 mmol) was refluxed in acetic acid (700 mL) for 15 min under argon. 1,2-Phenylenediamine (19.7 g, 183 mmol) was added. After refluxing for 4 h, another portion of 1,2-phenylenediamine (19.7 g, 183 mmol) was added, followed by another (10.0 g, 9.25 mmol) after 22 h. The reaction mixture was cooled after 24 h and most of the acetic acid was evaporated. The residue was dissolved in 1.5 L dichloromethane and extracted with 1 M hydrochloric acid (3 × 350 mL), water (2 × 250 mL), saturated sodium bicarbonate (3 × 250 mL), brine (2 × 250 mL), and finally water (250 mL). The dichloromethane phase was dried on magnesium sulfate and evaporated to give the crude material (15.8 g). Purification by flash chromatography yielded the desired benzimidazole derivative **18** (10.6 g, 54%) as orange-red needles; mp 233–234°C. IR (KBr) ν_{max}: 1690, 1559, 1520, 1451, 1402, 1360, 1329, 750, 714 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.51 (m, 2H, phenylene), 7.64 (ddd, 1H, J = 8.4, 6.6, and 1.1 Hz, H6), 7.75 (dd, 1H, J = 8.3 and 7.0 Hz, H3), 7.88 (ddd, 1H, J = 9.1, 6.6, and 1.4 Hz, H7), 7.98 (m, 1H, phenylene), 8.09 (doublet of quintet, 1H, J = 8.4 and 0.7 Hz, H5), 8.39 (ddd, 1H, J = 8.4, 1.3, and 0.6 Hz, H4), 8.64 (m, 1H, phenylene), 8.68 (s, 1H, H10), 8.90 (dd, 1H, J = 7.1 and 1.3 Hz, H2), 10.62 (ddd, 1H, J = 9.1, 1.8, and 0.9 Hz, H8) ppm. ^{13}C NMR ($CDCl_3$) δ: 114.80, 116.05, 120.23, 123.09, 125.30, 125.48, 125.72, 126.30, 126.73, 127.94, 129.46, 129.54, 130.46, 131.02, 131.44, 132.49, 133.40, 133.64, 136.52, 144.10, 150.06, 160.75 ppm.

Aceanthrene green (7) (7,8,15,16-dibenzo[*a*,*j*]perylenetetracarboxylic diimide; *trans* isomer) contaminated with 1,6,7,16-dibenzo[*a*,*o*]perylenetetracarboxylic diimide (3) (*cis* isomer)

Potassium hydroxide (12.0 g, 214 mmol) was mixed with water (1.80 g, 100 mmol) to form a thick paste. The imide **6** (3.00 g, 12.1 mmol) was added and the mixture was heated to 250–260°C in a zirconium crucible using a sand bath. The mixture was stirred with a spatula every 15 min and after 90 min of heating, it was slowly added to water (60 mL). Air was bubbled into the suspension while stirring. After 6 h, the mixture was neutralized and filtered. The resulting solid was slurried several times in water and then acetone to yield aceanthrene green (1.91 g, 64%); mp >300°C. IR (KBr) ν_{max}: 1680,

N,N'-Diphenyl-7,8,15,16-dibenzo[*a,j*]perylenetetracarboxylic diimide (13)

A process similar to that described for the preparation of aceanthrene green was used for the fusion of the imide **10**. Purification of the crude, slightly soluble material by flash chromatography using chloroform gave the diimide **13** in 8% yield; mp >300°C. IR (KBr) ν_{max}: 1692, 1657, 1564, 1420, 1387, 1331, 1211, 745 cm^{-1}. UV–Vis–NIR (1,2,4-trichlorobenzene) λ_{max}: 704, 645, 593, 548, 504, 430, 381 nm. ^1H NMR (CF_3CO_2D–$CDCl_3$ 1:1) δ: 7.44 (m, 4H, phenyl), 7.64 (m, 6H, phenyl), 7.95 (ddd, 2H, J = 8.7, 6.8, and 1.2 Hz, H3, H11), 8.04 (ddd, 2H, J = 9.1, 6.7, and 1.3 Hz, H2, H10), 8.75 (d, 2H, J = 7.8 Hz, H5, H13), 8.85 (d, 2H, J = 8.6 Hz, H4, H12), 9.08 (d, 2H, J = 7.9 Hz, H6, H14), 9.93 (doublet of multiplet, 2H, J = 9.1 and <0.6 Hz, H1, H9) ppm.

Preparation of the bis(quinoxaline) derivative of 7,8,15,16-dibenzo[*a,j*]perylenetetracarboxylic dianhydride (15)

The compound was prepared as described by Bradley and Pexton (32). IR (KBr) ν_{max}: 1599, 1560, 1432, 1415, 1280, 1272, 1224, 1176, 1113, 761 cm^{-1}. ^1H NMR (CF_3CO_2D–$CDCl_3$ 1:1) δ: 8.07 (ddd, 2H, J = 8.4, 6.8, and 1.2 Hz, H3, H11), 8.12 (ddd, 2H, J = 8.3, 6.8, and 1.0 Hz, H2, H10), 8.17 (ddd, 2H, J = 8.2, 7.1, and 1.4 Hz, H4, H4′ of phenylene), 8.23 (ddd, 2H, J = 8.3, 7.0, and 1.4 Hz, H3, H3′ of phenylene), 8.35 (dd, 2H, J = 8.1 and 1.4 Hz, H5, H5′ of phenylene), 8.68 (dd, 2H, J = 8.1 and 1.4 Hz, H2, H2′ of phenylene), 8.95 (d, 2H, J = 7.9 Hz, H6, H14), 9.06 (d, 2H, J = 7.9 Hz, H5, H13), 9.10 (d, 2H, J = 8.7 Hz, H4, H12), 9.67 (dd, 2H, J = 8.7 and 1.0 Hz, H1, H9) ppm. MS *m/z*: 604 (100 M^+), 302 (98, $M^+/2$). Anal. calcd. for $C_{44}H_{20}N_4$: C 87.40, H 3.33, N 9.27%; found: C 87.16, H 3.32, N 9.03%.

Preparation of the bis(benzimidazole) derivative of 7,8,15,16-dibenzo[*a,j*]perylenetetracarboxylic dianhydride (19)

A process similar to that described for the preparation of aceanthrene green was used for the fusion of the benzimidazole derivative of 1,9-anthracenedicarboxylic anhydride **18** to yield the crude bis(benzimidazole) derivative **19** in 44% yield. Partial purification was achieved by dissolving a portion of the crude material (500 mg) in trifluoroacetic acid (50 mL) and heating at 70°C. Acetic acid (80 mL) was slowly added to the solution while maintaining the temperature at 70°C. After cooling to room temperature, the suspension was filtered. The resulting solid was washed with trifluoroacetic acid–acetic acid (1:3) and slurried several times in acetone. Drying under high vacuum yielded the impure bis(benzimidazole) derivative **19** (310 mg, 62%); mp >300°C. IR (KBr) ν_{max}: 1690, 1564, 1518, 1449, 1383, 1356, 1343, 1267, 764, 747 cm^{-1}. UV–Vis–NIR (1,2,4-trichlorobenzene) λ_{max}: 785, 708, 632, 537, 499, 411 nm. ^1H NMR (CF_3CO_2D–$CDCl_3$–benzene-d_6 1:1:4) δ (major peaks only): 7.45 (m, H3, H3′, H4, H4′ of benzene ring), 7.81 (t, J = 7.7 Hz, H3, H11), 7.93 (m, H5, H5′ of benzene ring), 8.13 (t, J = 7.7 Hz, H2, H10), 8.45 (d, J = 7.9 Hz, H5, H13), 8.52 (d, J = 8.7 Hz, H4, H12), 8.65 (m, H2, H2′ of benzene ring), 8.87 (d, J = 7.9 Hz, H6, H14), 8.96 (d, J = 8.4 Hz, H1, H9) ppm. MS *m/z* (%): 636 (100, M^+), 318 (39 $M^+/2$). Anal. calcd. for $C_{44}H_{20}N_4O_2$: C 83.01, H 3.17, N 8.80%; found: C 81.23, H 3.19, N 8.58%.

Acknowledgment

The authors would like to thank Dr. T. I. Martin for his support throughout the near-infrared polycyclic aromatic photogenerator project and for helpful discussions.

Generation of oxindole-2-thiones (thiols) via dilithiated *N-tert*-Boc-anilines. Synthesis of a sulfur analog of MK886[1]

Alicia Cervantes, Claudia A. Contreras, Angel Guzman, Elena E. Vale, Esperanza Velarde, Sylvie L. Berthiaume, and Joseph M. Muchowski

Abstract: The N,C-dilithiated derivatives of the *N-tert*-butoxycarbonyl-2-alkylthiomethylanilines **5***a–c* and the *N-tert*-butoxycarbonyl-2-alkoxycarbonylmethylanilines **11***a*, *b* were converted into the *N-tert*-butoxycarbonyloxindole-2-thiones(thiols) **7***a–c* and **14***a*, *b*, respectively, by sequential reaction with carbon disulfide and methyl iodide. Compound **7***b* was converted into **10***d*, the sulfur analog of MK886.

Key words: *N-tert*-butoxycarbonyl-2-alkylthiomethylanilines, dilithiation, *N-tert*-butoxycarbonyl-2-alkoxycarbonylmethylanilines, *N-tert*-butoxycarbonyloxindole-2-thiones.

Résumé : Utilisant une séquence de réactions impliquant le disulfure de carbone et l'iodure de méthyle, on a transformé les dérivés N,C-dilithiés des *N-tert*-butoxycarbonyl-2-alkylthiométhylanilines (**5***a–c*) et des *N-tert*-butoxycarbonyl-2-alkoxycarbonylméthylanilines (**11***a*, *b*) en *N-tert*-butoxycarbonyloxindole-2-thiones (**7***a–c*) et 2-thiols (**14***a*, *b*) respectivement. On a transformé le produit **7***a* en **10***d*, l'analogue sulfuré du MK886.

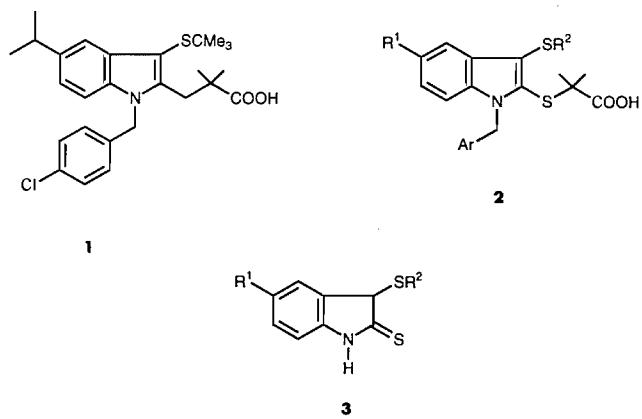
Mots clés : *N-tert*-butoxycarbonyl-2-alkylthiométhylanilines, dilithiation, *N-tert*-butoxycarbonyl-2-alkoxycarbonylméthylanilines, *N-tert*-butoxycarbonyloxindole-2-thiones.

[Traduit par la rédaction]

MK886 (**1**, Scheme 1) is a potent and specific inhibitor of leukotriene biosynthesis by virtue of its ability to block (and reverse) the translocation of 5-lipoxygenase from the cytosol to the cellular membrane (1). Replacement of the methylene carbon in the C-2 side chain of **1** by a sulfur atom, as in **2**, would lengthen this chain by about 0.5 Å (2), a change that was not expected to have a significant impact on the biological activity. This paper describes the synthesis of 3-alkylthiooxindole-2-thiones and the use of one of these compounds to prepare the direct sulfur analog of MK886.

Compound **1** has been prepared (3) by saponification of the corresponding ester, which in turn was prepared by a Fischer indole synthesis from 1-(4-chlorobenzyl)-1-(4-isopropylphenyl)hydrazine hydrochloride and methyl 2,2-dimethyl-5-(*tert*-butylthio)-4-oxopentanoate. Application of the Fischer method to the generation of **2** would be synthetically difficult.

Scheme 1



A particularly attractive route to this class of compounds appeared to be sequential S- and N-alkylation of the appropriate 3-alkylthiooxindole-2-thiones **3**. Although **3** is, in principle, available by the thioalkylation of oxindole-2-thione dianion, we chose to study an approach to these compounds based on the consecutive reaction of *N*-(*tert*-butoxycarbonyl)-*o*-toluidine dianions (4) with a dialkyl disulfide and carbon disulfide.

To establish the viability of the above concepts, *tert*-Boc-*o*-toluidine (**4***a*) was converted into the dianion with *s*-butyllithium (−40°C/THF) and treated with di-*tert*-butyldisulfide. The sulfide **5***a* (Scheme 2) obtained in this way was converted into the dianion (*s*-BuLi) and reacted with 3 equivalents of carbon disulfide. Work-up of the reaction mixture at this stage gave a mixture of several products that was not studied. If, however,

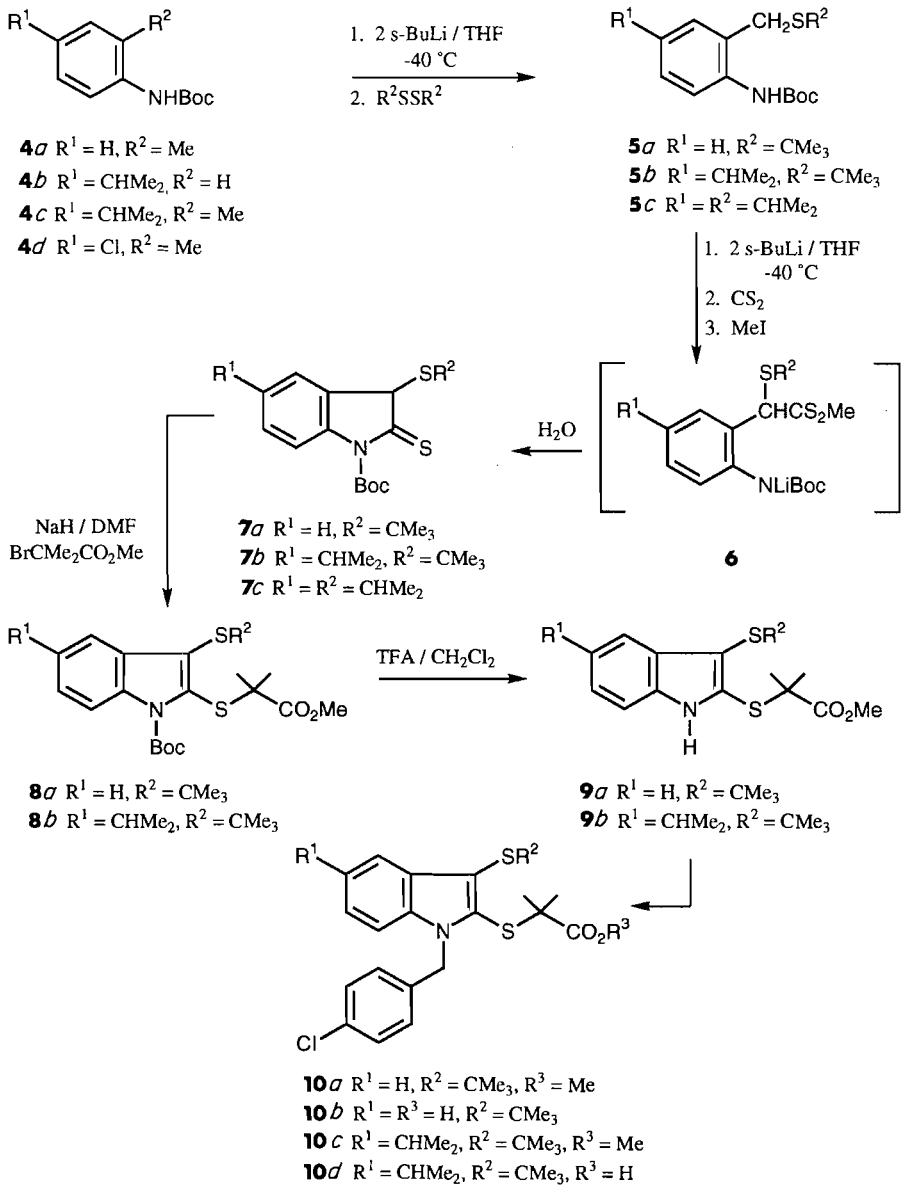
Scheme 2

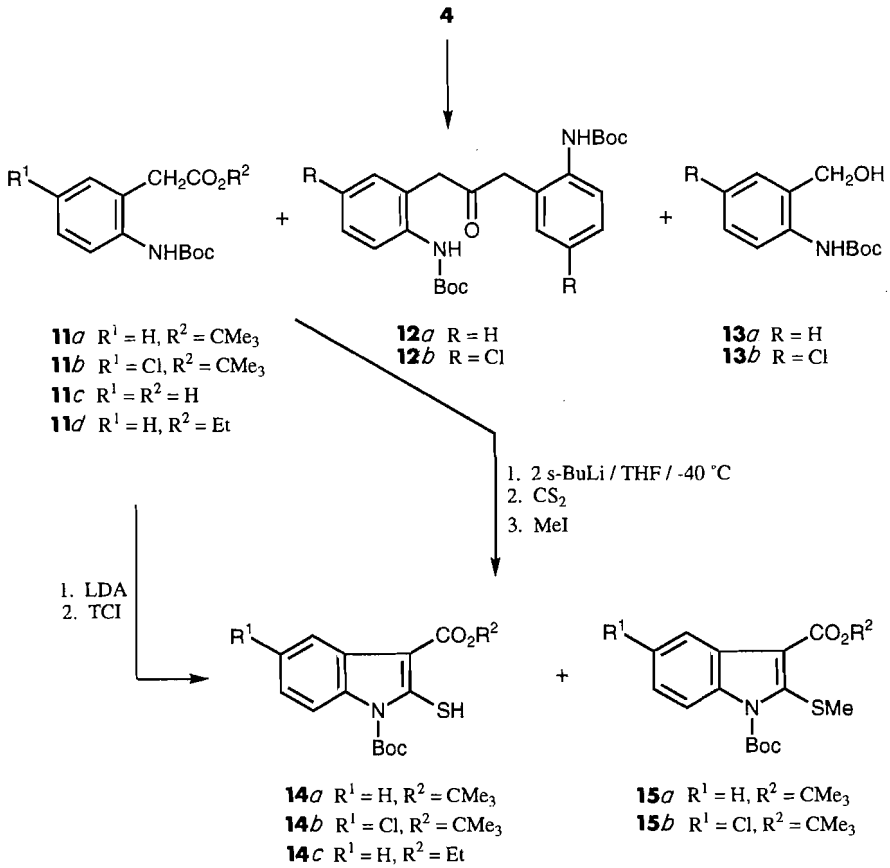


methyl iodide (1.1 equiv.) was added to the dianion – carbon disulfide reaction mixture, work-up after 1 h gave 1-*tert*-Boc-3-*tert*-butylthiooxindol-2-thione (**7***a*) directly. Obviously, cyclization of the intermediate lithiated dithio ester **6** occurred spontaneously in the reaction mixture or during the course of the work-up procedure. The conversion of **7***a* into the MK886 analog **10***b* was then effected by a four-step sequence beginning with S-alkylation of the sodium salt of **7***a* with methyl 2-bromo-2-methylpropionate followed by removal of the *tert*-Boc group, N-alkylation of the sodium salt of **9***a* with 4-chlorobenzyl bromide, and finally saponification.

To prepare the direct analog **10***d* of MK886, 4-isopropyl-*tert*-Boc-aniline (**4***b*) was lithiated with 2.5 equivalents of *tert*-butyllithium at −10°C and then treated with 1 equivalent of methyl iodide. The crude *o*-tolyl compound **4***c* was then converted into the sulfides **5***b* and **5***c* in 33 and 44% overall yields, respectively, based on **4***b*.[4] Both **5***b* and **5***c* were converted into the corresponding oxindoles **7***b* and **7***c*, and the former

[4] This difficult lithiation, which occurred in >65% yield based on isolated **5***c*, was effected under the conditions reported (5) for the generation of dilithio-*tert*-Boc-aniline. It has recently been alleged (6) that the degree of *o*-lithiation reported by us for *tert*-Boc-aniline could not be repeated. We have reproduced the reported yields of electrophile-trapped products on numerous occasions but, as has been pointed out by us (7), it is important that the THF–pentane ratio originally reported (ca. 2:1; *tert*-butyllithium is sold in pentane solution) be adhered to. When this precaution is taken, even complex, enolizable electrophiles give acceptable product yields on quite substantial scales (8). The report of Stanetty et al. (6) indicates that the lithiation of *tert*-Boc-aniline is much less sensitive to the conditions using diethyl ether as the solvent, and we concur with their observations.

Scheme 3



was transformed into **10***d* by the reaction sequence used to prepare **10***b*.

Compound **10***d* inhibited ionophore-stimulated leukotriene synthesis in human leukocytes with a potency ca. 1/3 of that reported (IC_{50} = 102 nm) for MK886(1).[5] Since the bioavailability in animals (e.g., rats) was quite poor, no attempt was made to establish if this inhibition was due to 5-lipoxygenase translocation blockade.

The ease of synthesis of **7***a–c* prompted us to determine if this route to oxindole-2-thiones had a broader applicability than that embodied by these compounds. Therefore the dianion of the *tert*-Boc-*ortho*-toluindine (**4***a*) was subjected to the reaction conditions that successfully generated **7***a–c* from **5***a–c*. A very complex mixture of products was obtained that was not studied. Based on the plausible assumption that the anion-stabilizing alkylthio moiety in **5***a–c* contributes to the success of the above process, the acetic acid esters **11** are also logical substrates. The *tert*-butyl esters **11***a, b* were prepared (40–50% yield) by the addition of the dianions of **4***a* and **4***d* to di-*tert*-butyl dicarbonate[6] at low temperature. Small amounts of the ketones **12***a, b* and the alcohols **13***a, b* (derived from adventitious oxygen) were also produced in these reactions. Generation of the dianions corresponding to **11***a, b* and subsequent reaction with carbon disulfide and methyl iodide gave a mixture of products from which the expected thiols **14***a, b* (15–30%) and the S-methyl compounds **15***a, b* (5–30%) derived therefrom were separated by column chromatography. To eliminate the inconvenience of preparing the *tert*-butyl esters and to the obviate S-methylthio ether formation, the dianion of **4***a* was carboxylated, and the carboxylic **11***c* was converted into the ethyl ester **11***d*. The dianion of **11***d*, generated in this case with LDA, was treated with thiocarbonyldiimidazole.[7] The thiol **14***c* was indeed obtained as the major product, but only in 35% yield. This reaction nevertheless deserves further examination.

Compounds **14***a–c* apparently exist in the thiol form as indicated by the low-field position (δ 8,3–8.4) of the exchangeable proton in the nmr spectrum. By comparison, compounds **7***a–c* show a sharp singlet at δ 5.7–5.8 clearly consistent with the thione form.

Experimental

The physical constants of the compounds reported herein were obtained as described previously (9).

4-Isopropyl-*N*-*tert*-butoxycarbonylaniline (**4***b*)

This compound was prepared by the general method described previously (4, 5). The crude product was purified by column chromatography on silica gel using hexane – ethyl acetate

[5] We thank M. Ernest and S. Panah, Institute of Biological Sciences, for providing us with this data.

[6] The normal mode of addition gave **12** as a major product.

[7] We thank Professor L.E. Overman, University of California, Irvine, for this suggestion

(97:3) as the eluting solvent. The pure material was obtained as a solid (97% yield) that, after crystallization from hexane, had mp 104–105°C; ir (KBr): 3313, 1696, 1609, 1598 cm^{-1}; nmr (200) δ: 1.21 (d, 6H, J = 7.0 Hz, Me_2CH), 1.51 (s, 9H, Me_3CO), 2.86 (sept, 1H, J = 7.0 Hz, Me_2CH), 6.42 (bs, 1H, NH), 7.20 (q, 4H, J = 8.7 Hz, H-2, 3, 5, 6). Anal. calcd. for $C_{14}H_{21}NO_2$: C 71.45, H 8.99, N 5.95; found: C 71.74, H 8.96, N 5.94.

2-Methyl-4-chloro-*N-tert*-butoxycarbonylaniline (*4d*)

Although this compound has been reported previously (4), its physical properties have not. It was obtained in 98% yield by the reported method (4) as a solid that, after trituration with ether and drying, had mp 95.5–97°C; nmr (300) δ: 1.51 (s, 9H, Me_3CO), 2.22 (s, 3H, Me), 6.20 (bs, 1H, NH), 7.13 (m, 1H, H-5), 7.16 (d, 1H, J = 2.5 Hz, H-3), 7.75 (d, 1H, J_o = 8.4 Hz, H-6). Anal. calcd. for $C_{12}H_{16}ClNO_2$: C 59.62, H 6.67, N 5.80; found: C 59.77, H 6.53, N 5.74.

2-*tert*-Butylthiomethyl-*N-tert*-butoxycarbonylaniline (*5a*)

A solution of *s*-butyllithium in cyclohexane (1.17 M, 72 mL, 84.2 mmol) was added to a stirred solution of **4***a* (7.0 g, 33.6 mmol; prepared in 96% yield from *o*-toluidine by the standard procedure (4, 5) in dry THF (120 mL) cooled to −40°C (N_2 atmosphere). After 20 min, a solution of di-*tert*-butyldisulfide (6.0 g, 33.6 mmol) in dry THF (50 mL) was added, and stirring at −40°C was continued for 30 min. The solution was diluted with water, the product was extracted into ethyl acetate, the extract was dried over sodium sulfate, and the solvent was removed in vacuo. Crystallization of the solid residue from hexane gave **5***a* (8.57 g, 86% yield), mp 104–105°C; ir ($CHCl_3$): 3356, 1728, 1593 cm^{-1}; nmr (90) δ: 1.39 (s, 9H, Me_3CS), 1.53 (s, 9H, Me_3CO), 3.74 (s, 2H, CH_2S), 7.25–7.35 (m, 3H), 7.44 (bs, 1H, NH), 7.82 (d, 1H, J_o = 8.1 Hz). Anal. calcd. for $C_{16}H_{25}NO_2S$: C 65.04, H 8.53, N 4.74, S 10.86; found: C 65.33, H 8.31, N 4.81, S 10.83.

Generation of the sulfides 5*b* and 5*c*

A 1.9 M solution of *tert*-butyllithium in pentane (23.7 mL, 45 mmol) was added to a stirred solution of **4***b* (4.7 g, 20 mmol) in dry THF (60 mL), and cooled to −70°C in a nitrogen atmosphere, at a rate such that the temperature stayed below −65°C. After 15 min, the temperature was raised to −20°C where it was maintained for 2 h. At this time, methyl iodide (2.84 g, 20 mmol) was added, and after 30 min at −20°C the solution was diluted with water and worked up as described for the synthesis of **5***a*. The crude product consisted of the starting material and **4***c* in a ca. 7:3 ratio as ascertained by the nmr spectrum; nmr (90) δ: 1.22 (d, 6H, J = 6.7 Hz, Me_2CH), 1.52 (s, 9H, Me_3CO), 2.23 (s, 3H, 2-Me), 2.82 (sept, 1H, J = 6.7 Hz, Me_2CH), 6.14 (bs, 1H, NH), 6.96–7.29 (m, 2H, H-3, 5), 7.61 (d, 1H, J_o = 9.1 Hz, H-6). The crude product was used without purification for the synthesis of **5***b* and **5***c*, using the technique described above for the synthesis of **5***a*.

2-tert-*Butylthiomethyl-4-isopropyl*-N-tert-*butoxycarbonylaniline (*5b*)*

Obtained as a solid (33% overall based on **4***b*) after purification by tlc on silica gel using hexane – ethyl acetate (94:6) as the developing solvent. After crystallization from hexane, it had mp 74–75°C; ir (KBr): 3369, 3334, 1725, 1590 cm^{-1}; nmr (200) δ: 1.21 (d, 6H, J = 6.9 Hz, Me_2CH), 1.42 (s, 9H, Me_3CS), 1.52 (s, 9H, Me_3CO), 2.85 (sept, 1H, J = 6.9 Hz, Me_2CH), 3.73 (s, 2H, CH_2S), 7.06 (d, 1H, J_m = 2.1 Hz, H-3), 7.12 (dd, 1H, J_o = 8.2 Hz, J_m = 2.1 Hz, H-5), 7.30 (bs, 1H, NH), 7.64 (d, 1H, J_o = 8.2 Hz, H-6). Anal. calcd. for $C_{19}H_{31}NO_2S$: C 67.61, H 9.26, N 4.14, S 9.50; found: C 67.73, H 9.12, N 4.09, S 9.45.

2-Isopropylthiomethyl-4-isopropyl-N-tert-*butoxycarbonylaniline (*5c*)*

Obtained in 44% yield overall (based on **4***b*) after purification by preparative tlc on silica gel using hexane – ethyl acetate (99:1) as the developing solvent; ir ($CHCl_3$): 3434, 3360, 1722, 1590 cm^{-1}; nmr (200) δ: 1.20 (d, 6H, J = 6.9 Hz, Me_2CH), 1.28 (d, 6H, J = 6.9 Hz, Me_2CHS), 1.52 (s, 9H, Me_3CO), 2.72–3.00 (m, 2H, Me_2CH, Me_2CHS), 3.74 (s, 2H, CH_2S), 6.99 (d, 1H, J_m = 2.1 Hz, H-3), 7.12 (dd, 1H, J_o = 8.3 Hz, J_m = 2.1 Hz, H-5), 7.29 (bs, 1H, NH), 7.67 (d, 1H, J_o = 8.3 Hz, H-6). Anal. calcd. for $C_{18}H_{29}NO_2S$: C 66.84, H 9.04, N 4.33, S 9.89; found: C 66.80, H 8.92, N 4.28, S 9.85.

Synthesis of the oxindole-2-thiones 7*a*–7*c*

The synthesis of **7***a* was typical. A solution of *s*-butyllithium in cyclohexane (23 mL of a 1.17 M solution; 27 mmol) was added to a solution of **5***a* (3.2 g, 10.8 mmol) in dry THF (40 mL) cooled to −40°C in a nitrogen atmosphere. After 20 min, carbon disulfide (1.95 mL, 2.46 g, 32.4 mmol) was added at −30°C, followed 10 min thereafter by methyl iodide (1.69 g, 11.9 mmol). The solution was stirred at −30°C for 1 h, water was added, and the mixture was worked up as described for **5***a*. The crude product was purified by column chromatography on silica gel using hexane – ethyl acetate (98.5:1.5) to elute the desired material as an oil (2.77 g, 76% yield); ir ($CHCl_3$): 1733 cm^{-1}; nmr (200) δ: 1.38 (s, 9H, Me_3CS), 1.74 (s, 9H, Me_3CO), 5.81 (s, 1H, H-3), 7.16–7.29 (m, 1H, H-4), 7.60–7.65 (m, 2H, H-5, 6), 8.02–8.07 (m, 1H, H-7); MS (EI) *m/z*: 337 (M^+, 14), 281 (27), 225 (100), 181 (22), 57 (76). This compound was not characterized further.

3-tert-*Butylthio-5-isopropyl*-N-tert-*butoxycarbonyloxindole-2-thione (*7b*)*

Obtained in 64% yield as an oil after purification by column chromatography on silica gel using hexane – ethyl acetate (95:5) as the eluting solvent; ir ($CHCl_3$): 1729 cm^{-1}; nmr (200) δ: 1.29 (d, 6H, J = 6.9 Hz, Me_2CH), 1.37 (s, 9H, Me_3CS), 1.72 (s, 9H, Me_3CO), 3.02 (sept, 1H, J = 6.9 Hz, Me_2CH), 5.78 (s, 1H, H-3), 7.1 (m, 1H, J_o = 8.6 Hz, J_m = 2.0 Hz, $J_{3,6}$ = 0.4 Hz, H-6), 7.48 (d, 1H, J_m = 2.0 Hz, H-4), 7.94 (d, 1H, J_o = 8.6 Hz, H-7). Anal. calcd. for $C_{20}H_{29}NO_2S_2$: C 63.30, H 7.70, N 3.68, S 16.86; found: C 63.21, H 7.65, N 3.52, S 16.75.

3-Isopropylthio-5-isopropyl-N-tert-*butoxycarbonyloxindole-2-thione (*7c*)*

Obtained in 65% yield as an oil after purification by column chromatography on silica gel using hexane – ethyl acetate (99:1) to elute the product; ir ($CHCl_3$): 1729, 1611 cm^{-1}; nmr (200) δ: 1.28 (d, 6H, J = 6.7 Hz, Me_2CH), 1.31 (d, 6H, J = 6.9 Hz, Me_2CHS), 1.72 (s, 9H, Me_3CO), 3.02 (sept, 1H, J = 6.9 Hz, Me_2CHS), 3.24 (sept, 1H, J = 6.7 Hz, Me_2CH), 5.66 (s, 1H, H-3), 7.12 (dd, 1H, J_o = 8.7 Hz, J_m = 1.8 Hz, H-6), 7.43 (d,

1H, J_m = 1.8 Hz, H-4), 7.94 (d, 1H, J_o = 8.7 Hz, H-7). Anal. calcd. for $C_{19}H_{27}NO_2S_2$: C 62.42, H 7.44, N 3.83, S 17.54; found: C 62.37, H 7.19, N 3.87, S 17.62.

Synthesis of the indoles 8*a* and 8*b* by alkylation of the oxindole-2-thiones 7*a* and 7*b*

The synthesis of **8*a*** was typical. A solution of **7*a*** (2.7 g, 8 mmol) in dry DMF (30 mL) was added to a stirred suspension of 50% sodium hydride in mineral oil (0.422 g, 8.8 mmol) in dry DMF (30 mL) in a nitrogen atmosphere at room temperature. When hydrogen evolution had ceased, methyl 2-bromo-2-methylpropionate (1.45 g, 8 mmol) was added, and the solution was stirred for 20 min. The reaction mixture was then worked up as for **5*a*** to give solid **8*a***, which, after crystallization from hexane (63% yield), had mp 89–90°C; ir (KBr): 1741, 1723, 1603 cm^{-1}; nmr (200) δ: 1.29 (s, 9H, Me_3CS), 1.44 (s, 6H, $SCMe_2$), 1.72 (s, 9H, Me_3CO), 3.67 (s, 3H, OMe) 7.24–7.41 (m, 2H, H-5, 6), 7.80–7.85 (m, 1H, H-4), 8.00–8.04 (m, 1H, H-7). Anal. calcd. for $C_{22}H_{31}NO_4S_2$: C 60.38, H 7.14, N 3.20, S 14.65; found: C 60.47, H 6.97, N 3.13, S 14.87.

Compound **8*b*** was obtained as an oil (76% yield) after purification by tlc on silica gel using hexane – ethyl acetate (9:1) as the developing solvent; ir ($CHCl_3$): 1748, 1728 cm^{-1}; nmr (200) δ: 1.29 (s, 9H, Me_3CS), 1.31 (d, 6H, J = 6.8 Hz, Me_2CH), 1.71 (s, 9H, Me_3CO), 3.03 (sept, 1H, J = 6.8 Hz, Me_2CH), 3.68 (s, 3H, OMe), 7.26 (dd, 1H, J_o = 8.7 Hz, J_m = 1.9 Hz, H-6), 7.66 (d, 1H, J_m = 1.9 Hz, H-4), 7.93 (d, 1H, J_o = 8.7 Hz, H-7). Anal. calcd. for $C_{25}H_{37}NO_4S_2$: C 62.61, H 7.77, N 2.92, S 13.34; found: C 62.58, H 7.70, N 3.12, S 13.08.

Synthesis of the indoles 9*a* and 9*b* by N-deprotection of 8*a* and 8*b*

A solution of the *N-tert*-butoxycarbonyl compound in dry dichloromethane (10–20 mL/g indole derivative) containing trifluoroacetic acid (1 mL/g of indole derivative) was stirred at room temperature for 3 h. The solution was diluted with dichloromethane, washed with 5% sodium bicarbonate solution, dried over sodium sulfate, and evaporated in vacuo. The solid residue was crystallized from hexane.

Compound **9*a*** obtained in 80% yield, had mp 119–121°C; ir ($CHCl_3$): 3461, 3358, 1718 cm^{-1}; nmr (200) δ: 1.28 (s, 9H, Me_3CS), 1.53 (s, 6H, $SCMe_2$), 3.82 (s, 3H, OMe), 7.13–7.28 (m, 2H), 7.36–7.41 (m, 1H), 7.74–7.78 (m, 1H), 9.61 (bs, 1H, NH). Anal. calcd. for $C_{17}H_{23}NO_2S_2$: C 60.52, H 6.87, N 4.15, S 18.97; found: C 60.69, H 6.75, N 4.09, S 18.99.

Compound **9*b***, obtained in 88% yield, had mp 106–107°C; ir (KBr): 3306, 1706 cm^{-1}; nmr (200) δ: 1.28 (s, 9H, Me_3CS), 1.30 (d, 6H, J = 6.8 Hz, Me_2CH), 1.52 (s, 6H, $SCMe_2$), 3.02 (sept, 1H, J = 6.8 Hz, Me_2CH), 3.81 (s, 3H, OMe), 7.13 (dd, 1H, J_o = 7.5 Hz, J_m = 2.0 Hz, H-6), 7.32 (d, 1H, J_o = 7.5 Hz, H-7), 7.60 (d, 1H, J_m = 2.0 Hz, H-4), 9.48 (bs, 1H, NH). Anal. calcd. for $C_{20}H_{29}NO_2S_2$: C 63.28, H 7.70, N 3.69, S 16.89; found: C 63.52, H 7.65, N 3.68, S 16.73.

Synthesis of the *N-p*-chlorobenzylindoles 10*a* and 10*c* by N-alkylation of 9*a* and 9*b*

The synthesis of **10*a*** was typical. A solution of the indole compound **9*a*** (0.340 g, 1 mmol) in dry DMF (4 mL) was added to a stirred suspension of 50% sodium hydride in mineral oil (0.053 g, 1.1 mmol) in dry DMF (3 mL) maintained in a nitrogen atmosphere at room temperature. When hydrogen evolution had cease, *p*-chlorobenzyl bromide (0.205 g, 1 mmol) was added, and stirring was continued for 30 min. The reaction solution was then worked up as described for the synthesis of **8*a*** and **8*b***. The crude product was purified by preparative tlc on silica gel using hexane – ethyl acetate (85:15) as the developing solvent.

Compound **10*a*** was obtained as a foam in 75% yield; ir ($CHCl_3$): 1725 cm^{-1}; nmr (200) δ: 1.28 (s, 9H, Me_3CS), 1.47 (s, 6H, $SCMe_2$), 3.67 (s, 3H, OMe), 5.58 (s, 2H, CH_2), 6.87 (d, 1H, J = 8.5 Hz), 7.15–7.26 (m, 5H), 7.83–7.88 (m, 1H). Anal. calcd. for $C_{24}H_{28}ClNO_2S_2$: C 62.38, H 6.10, Cl 7.67, N 3.03, S 13.87; found: C 62.46, H 6.08, Cl 7.63, N 2.96, S 13.80.

Compound **10*c*** was isolated in 64% yield as a foam after purification by preparative tlc on silica gel using hexane – ethyl acetate (9:1) as the eluting solvent; ir ($CHCl_3$): 1725 cm^{-1}; nmr (200) δ: 1.28 (s, 9H, Me_3CS), 1.29 (d, 6H, J = 6.9 Hz, Me_2CH), 1.46 (s, 6H, $SCMe_2$), 3.01 (sept, 1H, J = 6.9 Hz, Me_2CH), 3.68 (s, 3H, OMe), 5.52 (bs, 2H, CH_2), 6.89 (d, 2H, J = 8.5 Hz, H-2′,6′), 7.08–7.26 (m, 4H, H-6, 7, 3′, 5′), 7.68 (s, 1H, H-4). Anal. calcd. for $C_{27}H_{34}ClNO_2S_2$: C 64.32, H 6.79, Cl 7.03, N 2.77, S 12.72; found: C 64.27, H 6.72, Cl 6.90, N 2.61, S 12.58.

Synthesis of the carboxylic acids 10*b* and 10*d* by saponification of 10*a* and 10*c*

A solution of the methyl ester in methanol (10–15 mL/mmol ester) containing sodium hydroxide (1.2–2 mmol/mmol ester) and water (1–2 mL/mmol ester) was stirred at room temperature overnight or heated at reflux for 4 h. The solvent was removed in vacuo, water was added to the residue, and the solution was made acidic with 6 N hydrochloric acid. The product was extracted with ethyl acetate, and the extract was washed with water, dried over sodium sulfate, and evaporated in vacuo. The solid residue was crystallized from hexane.

Compound **10*b***, obtained in 88% yield, had mp 174–176°C; ir ($CHCl_3$): 2664, 2584, 1703 cm^{-1}. Anal. calcd. for $C_{23}H_{26}ClNO_2S_2$: C 61.65, H 5.85, Cl 7.91, N 3.12, S 14.31; found: C 61.52, H 5.71, Cl 7.98, N 3.00, S 14.26.

Compound **10*d***, isolated in 89% yield, had mp 155–156°C; ir ($CHCl_3$): 2651, 2547, 1703 cm^{-1}. Anal. calcd. for $C_{26}H_{32}ClNO_2S_2$: C 63.71, H 6.58, Cl 7.23, N 2.85, S 13.08; found: C 63.67, H 6.65, Cl 7.35, N 2.81, S 13.01.

tert*-Butyl 2-*tert*-butoxycarbonylaminophenyl acetate 11*a

A −40°C solution of the dianion of **4*a***, prepared as described for the synthesis of **5*a*** from **4*a*** (5.00 g, 24.0 mmol) in THF (85 mL) and 1.34 M *s*-butyllithium in cyclohexane (45.0 mL, 60.3 mmol), was cannulated into a stirred solution of di-*tert*-butyldicarbonate (5.8 mL, 5.50 g, 25.2 mmol) in dry THF (21 mL) at −70°C (N_2 atmosphere) at a rate such that the reaction temperature did not exceed −70°C. Within 5 min of the addition, the solution was poured into an excess of aqueous ammonium chloride solution. The products were extracted into ethyl acetate, the extract was dried over magnesium sulfate, and the solvent was removed in vacuo. The residual mixture was separated by column chromatography on silica gel using hexane – ethyl acetate (95:5) to elute the products.

Compound **11*a*** was obtained as a solid (3.70 g, 50.0% yield based on **4*a***) that had mp 82–85°C after crystallization from hexane; ir ($CHCl_3$): 3396, 1723, 1591 cm^{-1}; nmr (200) δ: 1.45 (s, 9H, Me_3CO), 1.53 (s, 9H, Me_3CO), 3.52 (s, 2H, CH_2), 7.03

For personal use only.

(td, 1H, J_o = 7.6 Hz, J_m = 1.5 Hz, H-4 or H-5), 7.20 (td, 1H, J_o = 7.6 Hz, J_m = 1.5 Hz, H-5 or H-4), 7.29 (dd, J_o = 7.6 Hz, J_m = 1.5 Hz, H-6), 7.71 (bs, 1H, NH), 7.81 (bd, 1H, J_o = 7.6 Hz, H-3). Anal. calcd. for $C_{17}H_{25}NO_4$: C 66.42, H 8.19, N 4.55; found: C 66.53, H 8.20, N 4.60.

In addition, a small amount of **12***a* (0.331 g, 6.7%) was isolated as a solid that, after crystallization from hexane, had mp 128–130°C; ir ($CHCl_3$): 3426, 3368, 1719, 1590 cm^{-1}; nmr (200) δ: 1.50 (s, 18H, Me_3CO), 3.80 (s, 4H, CH_2), 6.98–7.12 (m, 4H), 7.03 (bs, 2H, NH), 7.24–7.30 (m, 2H), 7.68 (bd, 2H, J_o = 8.1 Hz, H-3, 3′); MS (EI) *m/z*: 440 (M^+). Anal. calcd. for $C_{24}H_{32}N_2O_4$: C 68.15, H 7.32, N 6.36; found: C 68.15, H 7.39, N 6.40.

There was also isolated a much more polar material (0.250 g, 4.6%), which, on the basis of its spectroscopic properties, was assumed to be 2-*tert*-butoxycarbonylaminobenzyl alcohol (**13***a*), as an oil; ir ($CHCl_3$) 3601, 3396, 1723, 1525 cm^{-1}; nmr (200) δ: 1.53 (s, 9H, Me_3CO), 1.80 (bs, 1H, OH), 4.69 (s, 2H, CH_2), 7.02 (td, 1H, J_o = 7.6 Hz, J_m = 1.5 Hz, H-4 or H-5), 7.18 (dd, 1H, J_o = 7.6 Hz, J_m = 1.5 Hz, H-6), 7.65 (bs, 1H, NH), 7.82 (td, 1H, J_o = 7.6 Hz, J_m = 1.5 Hz, H-5 or H-4); MS(EI) *m/z*: 223 (M^+). This compound was not characterized further.

tert-Butyl 2-*tert*-butoxycarbonylamino-4-chlorophenyl acetate 11*b*

This compound was prepared in a manner similar to **11***a* except that *tert*-butyllithium was used to generate the dianion of **4***d* (8), and that the crude product was separated into **11***b* and a mixture of **12***b* and **13***b* by column chromatography on silica gel using hexane – ethyl acetate (95:5) as the eluting solvent.

Compound **11***b* was obtained in 38–43% yield (based on **4***d*) as a solid that had mp 90–91°C after crystallization from dichloromethane; ir ($CHCl_3$): 3395, 1723 cm^{-1}; nmr (200) δ: 1.45 (s, 9H, Me_3CO), 1.52 (s, 9H, Me_3CO), 3.48 (s, 2H, CH_2), 7.19 (dd, 1H, J_o = 8.4 Hz, J_m = 2.5 Hz, H-5), 7.25 (d, 1H, J_m = 2.5 Hz, H-3), 7.70 (bs, 1H, NH), 7.77 (bd, 1H, J_o = 7.5 Hz, H-6). Anal. calcd. for $C_{17}H_{24}ClNO_4$: C 59.72, H 7.07, Cl 10.37, N 4.09; found: C 59.80, H 7.11, Cl 10.55, N 4.11.

The mixture of **12***b* and **13***b* was separated by tlc on silica gel using toluene–acetone (98:2) as the developing solvent. This gave **12***b* and **13***b* as solids in ca. 4% and 10–13% yields, respectively.

Compound **12***b* had mp 192–193.5°C after crystallization from dichloromethane–methanol. Anal. calcd. for $C_{25}H_{30}Cl_2N_2O_5$: C 58.92, H 6.25, Cl 13.75, N 5.43; found: C 58.62, H 5.81, Cl 13.71, N 5.61.

Compound **13***b* had mp 89–90°C after crystallization from hexane; ir ($CHCl_3$): 3601, 3394, 1723 cm^{-1}; nmr (200) δ: 1.52 (s, 9H, Me_3CO), 2.03 (t, 1H, J = 5.8 Hz, OH), 4.65 (d, 2H, J = 5.8 Hz, CH_2O), 7.16 (d, 1H, J_m = 2.3 Hz, H-6), 7.43 (dd, 1H, J_o = 8.7 Hz, J_m = 2.3 Hz, H-4), 7.59 (bs, 1H, NH), 7.89 (d, 1H, J_o = 8.7 Hz, H-3). Anal. calcd. for $C_{12}H_{16}ClNO_3$: C 55.92, H 6.25, Cl 13.75, N 5.43; found: C 56.10, H 6.30, Cl 13.86, N 5.48.

tert-Butyl 1-*tert*-butoxycarbonyl-2-mercaptoindole-3-carboxylate 14*a* and *tert*-butyl 1-*tert*-butoxycarbonyl-2-methylthioindole-3-carboxylate 15*a*

A solution of 1.08 M *s*-butyllithium in cyclohexane (18.6 mL, 20 mmol) was added to a stirred solution of compound **11***a* (3.0 g, 9.76 mmol) in dry THF (150 mL) at −40 to −35°C in an argon atmosphere. The solution was stirred for 45 min at −40°C and then carbon disulfide (1.76 mL, 2.23 g, 29 mmol) dissolved in THF (10 mL) was added, followed after 20 min by methyl iodide (0.66 mL, 1.50 g, 10.6 mmol). The reaction temperature was raised to 0°C, and after 45 min the reaction mixture was worked up as for **11***a*. The crude product was separated by column chromatography on silica gel into **14***a* and **15***a* using hexane – ethyl acetate (98:2) as the eluting solvent.

Compound **14***a* was obtained as a yellowish-green solid (1.113 g, 33% yield) that, after crystallization from hexane, had mp 92–94°C; ir ($CHCl_3$): 1738, 1702, 1657 cm^{-1}; nmr (200) δ: 1.68 (s, 9H, Me_3CO), 1.73 (s, 9H, Me_3CO), 7.22 (td, 1H, J_o = 7.5 Hz, J_m = 2.2 Hz, H-5 or H-6), 7.27 (td, 1H, J_o = 7.5 Hz, J_m = 2.2 Hz, H-6 or H-5), 7.95–8.09 (m, 2H, H-4, 7), 8.40 (s, 1H, SH); MS(EI) *m/z*: 349 (M^+). Anal. calcd. for $C_{18}H_{23}NO_4S$: C 61.87, H 6.63, N 4.00; found: C 61.86, H 6.70, N 4.11.

Compound **15***a* was obtained (1.130 g, 32% yield) as an oil; ir ($CHCl_3$): 1741, 1698 cm^{-1}; nmr (200) δ: 1.68 (s, 9H, Me_3CO), 1.71 (s, 9H, Me_3CO), 2.55 (s, 3H, SMe), 7.27 (td, J_o = 7.7 Hz, J_m = 2.3 Hz, H-5 or H-6), 7.31 (td, 1H, J_o = 7.7 Hz, J_m = 2.3 Hz, H-6 or H-5), 7.90–8.04 (m, 2H, H-4, 7); MS (EI) *m/z*: 363 (M^+). Anal. calcd. for $C_{19}H_{25}NO_4S$: C 62.78, H 6.93, N 3.85; found: C 62.18, H 6.75, N 3.98.

tert-Butyl 1-*tert*-butoxycarbonyl-2-mercapto-5-chloroindole-2-carboxylate 14*b* and *tert*-butyl 1-*tert*-butoxycarbonyl-2-methylthio-5-chloroindole-2-carboxylate 15*b*

This mixture was obtained in the same manner as described for **14***a* and **15***a* except that it was separated into its components by flash column chromatography using hexane – ethyl acetate (95:5) as the eluting solvent. Compounds **14***b* and **15***b* were obtained in 15 and 5% yields, respectively.

Compound **14***b* was a solid that had mp 75–77°C after crystallization from hexane; ir ($CHCl_3$): 1742, 1660, 1608 cm^{-1}; nmr (200) δ: 1.68 (s, 9H, Me_3CO), 1.72 (s, 9H, Me_3CO), 7.19 (dd, 1H, J_o = 9.0 Hz, J_m = 2.1 Hz, H-6), 7.96–8.00 (m, 2H, H-4, 7), 8.40 (s, 1H, SH). Anal. calcd. for $C_{18}H_{22}ClNO_4S$: C 56.31, H 5.77, N 3.65; found: C 56.30, H 5.80, N 3.76.

Compound **15***b* was obtained as an oil; ir ($CHCl_3$): 1725 cm^{-1}; nmr (300) δ: 1.68 (s, 9H, Me_3CO), 1.70 (s, 9H, Me_3CO), 2.55 (s, 3H, SMe), 7.26 (dd, 1H, J_o = 8.9 Hz, J_m = 2.2 Hz, H-6), 7.87 (d, 1H, J_o = 8.9 Hz, H-7), 7.99 (d, 1H, J_m = 2.2 Hz, H-4). This compound was not characterized further.

Ethyl 2-*tert*-butoxycarbonylaminophenyl acetate 11*d*

Potassium carbonate (1.41 g, 10.2 mmol) was added to a stirred solution of the crude carboxylic acid **11***c* (2.35 g, 9.3 mmol), prepared as described by Clark et al. (8), in DMF (25 mL), and after 0.5 h ethyl iodide (0.82 mL, 1.62 g, 10.2 mmol) was added. After a further 2 h, the reaction mixture was poured into water and extracted with ethyl acetate; the extract was washed with water and dried over magnesium sulfate. Removal of the solvent in vacuo gave an oily residue that was purified by column chromatography on silica gel using hexane – ethyl acetate (95:5) as the eluting solvent. Compound **11***d* was obtained as an oil (2.14 g, 82% yield); ir ($CHCl_3$): 3377, 1725, 1603, 1585 cm^{-1}; nmr (200) δ: 1.29 (t, 3H, J = 7.1 Hz, OCH_2CH_3), 1.60 (s, 9H, Me_3CO), 3.63 (s, 2H,

CH_2), 4.13 (q, 2H, J = 7.1 Hz, OCH_2CH_3), 7.07–7.33 (m, 3H), 7.68 (bs, 1H, NH), 7.80 (d, 1H, J_o = 8.1 Hz). Anal. calcd. for $C_{15}H_{21}NO_4$: C 64.49, H 7.57, N 5.01; found: C 64.53, H 7.61, N 4.98.

Ethyl 1-*tert*-butoxycarbonyl-2-mercaptoindole-3-carboxylate 14*c*

A solution of compound **11***d* (0.459 g, 1.64 mmol) in dry THF (10 mL) was added to a stirred solution of lithium diisopropylamide, prepared from diisopropylamine (0.5 mL, 0.36 g, 3.6 mmol(and 1.3 M *n*-butyllithium in hexane (2.78 mL) in dry THF (15 mL), cooled to −78°C, at a rate such that the reaction temperature did not exceed −70°C. After 0.5 h, thiocarbonyldiimidazole (0.87 g, 4.9 mmol) was added and stirring at −78°C was continued for 2 h, followed by 0.67 h at −40°C. The reaction mixture was diluted with water and extracted with hexane. The extract was dried over magnesium sulfate and evaporated in vacuo. The residue was purified by column chromatography on silica gel using hexane – ethyl acetate (95:5) to give the product as a solid (0.175 g, 33% yield) that had mp 66°C after crystallization from ether–hexane; ir ($CHCl_3$): 1740, 1664 cm^{-1}; nmr (200) δ: 1.50 (t, 3H, J = 7.1 Hz, Me), 1.75 (s, 9H, Me_3CO), 4.47 (q, 2H, J = 7.1 Hz, CH_2), 7.19–7.35 (m, 3H, H-5-7), 8.01–8.12 (m, 1H, H-4), 8.26 (s, 1H, SH). Exact Mass calcd. (*m/z*) for $C_{16}H_{19}NO_4S$: 321.1035; found: 321.1032.

Preparation of diversely protected 2-azido-2-deoxyglycopyranoses from glycals

Stanislas Czernecki and Ebtissam Ayadi

Abstract: A new and efficient preparation of diversely protected 2-azido-2-deoxyglycopyranosides from the corresponding glycals is described. The glycals are first transformed into protected phenyl 2-azido-2-deoxyselenoglycopyranosides by azido-phenylselenylation. Two procedures were employed according to the protecting groups present: sodium azide and diphenyldiselenide in the presence of (diacetoxyiodo)benzene for peracetylated glycals (Procedure A) or trimethylsilyl azide and tetra-*n*-butylammonium fluoride in the presence of *N*-phenylselenophthalimide for perbenzylated glycals (Procedure B). A *gluco–manno* mixture (90%) is obtained from protected D-glucal whereas only the *galacto* isomer is formed from protected D-galactal (75%). The compatibility of the second procedure with one free hydroxyl group and a variety of protecting groups was verified with 1,5-anhydro-2-deoxy-3,4-*O*-isopropylidene-D-*lyxo*-hex-1-enitol and its 6-*O*-acetyl, 6-*O*-allyl, 6-*O*-benzyl, and 6-*O*-*tert*-butyldimethylsilyl derivatives as well as with 1,5-anhydro-4,6-*O*-benzylidene-2-deoxy-D-*lyxo*-hex-1-enitol and its 3-*O*-acetyl and 3-*O*-benzyl derivatives, which were transformed into phenyl 2-azido-2-deoxy-α-D-selenogalactopyranoside derivatives in good yield. In the second step, hydrolysis of these selenoglycosides afforded diversely protected glycopyranoses in high yield. Peracetylated derivatives were hydrolyzed in the presence of *N*-iodosuccinimide, whereas mercury trifluoroacetate was employed for 3,4-*O*-isopropylidene, 4,6-*O*-benzylidene, and perbenzylated derivatives. In some cases the two steps can be carried out without isolation of the intermediate selenoglycoside.

Key words: glycals, 2-azido-2-deoxygalactopyranose, 2-azido-2-deoxyglucopyranose, selenoglycosides.

Résumé : On décrit une nouvelle préparation efficace de divers 2-azido-2-désoxyglycopyranosides protégés de diverses manières à partir des glycals correspondants. Dans la première étape, on transforme les glycals en 2-azido-2-désoxysélénoglycopyranosides de phényle protégés par azidophénylsélénylation. On a utilisé deux méthodes suivant la nature des groupes protecteurs présents : azoture de sodium et diphényldisélénure en présence de (diacétoxyiodo)benzène avec les glycals peracétylés (méthode A) ou azoture de triméthylsilyle et fluorure de tétra-*n*-butylammonium en présence de *N*-phénylsélénophtalimide avec les glycals perbenzylés (méthode B). On obtient un mélange *gluco–manno* (90%) à partir du D-glucal alors que l'on obtient uniquement l'isomère *galacto* à partir du D-galactal (75%). Utilisant le 1,5-anhydro-2-désoxy-3,4-*O*-isopropylidène-D-*lyxo*-hex-1-énitol et ses dérivés 6-*O*-acétyl-, 6-*O*-allyl-, 6-*O*-benzyl- et 6-*O*-*tert*-butyldiméthylsilyl- ainsi que le 1,5-anhydro-4,6-*O*-benzylidène-2-désoxy-D-*lyxo*-hex-1-énitol et ses dérivés 3-*O*-acétyl- et 3-*O*-benzyl- qui ont été transformés en dérivés du 2-azido-2-désoxy-α-galactopyranoside de phényle avec de bons rendements, on a vérifié la compatibilité de la deuxième méthode avec la présence d'un groupe hydroxyle libre et de divers groupes protecteurs. Dans la deuxième étape, l'hydrolyse de ces sélénoglycosides fournit divers glycopyranoses protégés avec des rendements élevés. On a hydrolysé les dérivés peracétylés en présence de *N*-iodosuccinimide alors que l'on a utilisé du trifluoroacétate de mercure pour les dérivés 3,4-*O*-isopropylidène, 4,6-*O*-benzylidène et perbenzylés. Dans certains cas, on a effectueé les deux étapes sans isoler les sélénoglycosides intermédiaires.

Mots clés : glycals, 2-azido-2-désoxygalactopyranose, 2-azido-2-désoxyglucopyranose, sélénoglycosides.

[Traduit par la rédaction]

Introduction

Protected 2-azido-2-deoxy derivatives of galactose and glucose are extensively used for the synthesis of biologically important 2-amino-2-deoxygalactose- (and glucose-) containing oligosaccharides (1, 2). Due to the small size of the azido group, 2-azido-2-deoxyglycopyranosyl donors are generally used as reactive intermediates. Depending on the leaving group and the promotor used, they can induce either a 1,2-*cis* or a 1,2-*trans* stereochemistry (2) and regeneration of the amino function is possible under mild conditions. They are generally prepared in two steps from the corresponding glycals: azidonitration followed by transformation of the obtained 2-azido-1-nitrate adducts into various glycosyl donors by displacement of the anomeric nitrate by halide ions as described by Lemieux and Ratcliffe (3) or by using potas-

sium *O*-ethyl dithiocarbonate (4). Efficient glycosyl donors such as trichloroacetimidates (5) and fluorides (6) can also be prepared after hydrolysis of the anomeric *O*-nitrate. Several methods were reported for the latter transformation (5, 7, 8).

We recently disclosed a new route to protected 2-azido-2-deoxyglycopyranoses in which azido-phenylselenylation of protected glycal afforded a phenyl 2-azido-2-deoxyselenoglycoside that was readily hydrolyzed (9). We now report full details with extension of this methodology to several diversely protected glycals to demonstrate its compatibility with a variety of protecting groups employed in oligosaccharide synthesis.

Results and discussion

Treatment of 3,4,6-tri-*O*-acetyl-d-glucal (**1***a*) and 3,4,6-tri-*O*-acetyl-d-galactal (**2***a*) with (diacetoxyiodo)benzene (1.4 equiv.) and sodium azide (2.4 equiv.) in the presence of diphenyldiselenide (0.6 equiv.) in methylene chloride at room temperature afforded phenyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-1-seleno-α-d-glycopyranosides in good yield (Table 1, entries 1 and 3). From **1***a* the *gluco* (**5***a*) and *manno* (**6***a*) isomers were obtained in 91% yield as an inseparable mixture. From the integration of H1 signals in the ^1H NMR spectrum of the mixture, the proportion was found to be 3:2. Interestingly, only the α anomers were formed, as indicated by the values of the H1,H2 coupling constants (5.3 Hz for the *gluco* isomer and ≈0 Hz for the *manno* isomer). From **2***a*, only one compound, the α-*galacto* isomer **7***a*, was formed and isolated in crystalline form (92%). No *talo* isomer **8***a* could be detected in the ^1H NMR spectrum of the crude mixture, although it is known that some *talo* azidonitrate (4–8%) is formed in azidonitration of protected d-galactal (3, 4). The regio- and the stereochemistry of this reaction can be rationalized by addition of an electrophilic azido radical (10) formed in situ by oxidation of azide ion (11) to C2 of the electron-rich double bond of the glycal, generating an anomeric radical by the anomeric effect in the α configuration. Further reaction with diphenyldiselenide affords the α-selenoglycosides.

When perbenzylated glycals **1***b* (12) and **2***b* (13) were reacted under the same conditions, perbenzylated phenyl 2-azido-2-deoxy-1-seleno-α-d-glycopyranosides were obtained in low yield, in agreement with recent results (14). This could be due to oxidative cleavage of the benzyl group under reaction conditions. Interestingly, when **1***b* and **2***b* were reacted with azidotrimethylsilane (2 equiv.), tetra-*n*-butylammonium fluoride (0.2 equiv.), and *N*-phenylselenophthalimide (*N*-PSP, 2 equiv.) in methylene chloride, phenyl 2-azido-3,4,6-tri-*O*-benzyl-2-deoxy-1-seleno-α-d-glycopyranosides were obtained in good yield. As above, a mixture of *gluco* (**5***b*) and

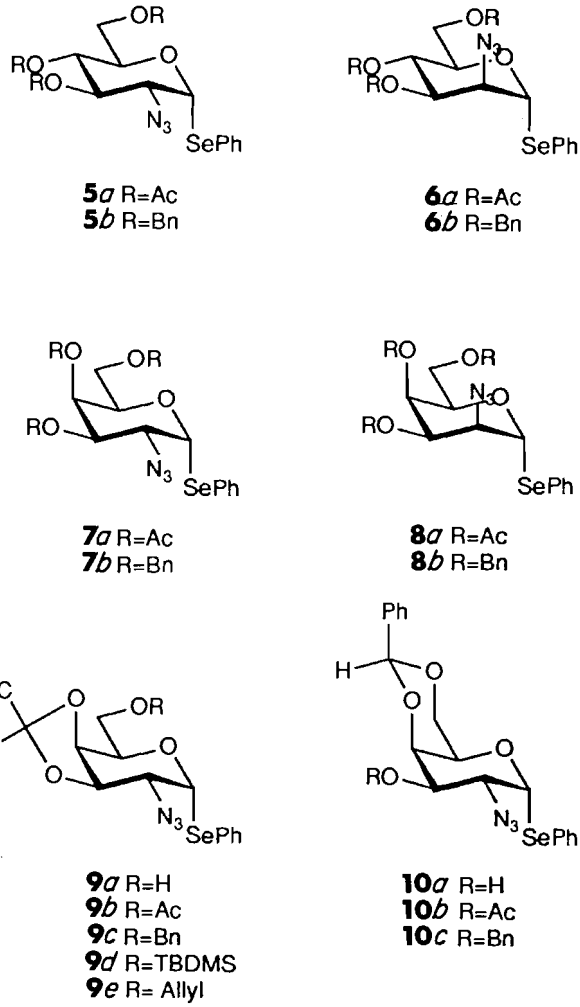
manno (**6***b*) isomers was obtained (82%) with low diastereoselectivity (70:30) from the *glucal* derivative **1***b*, whereas complete diastereocontrol was observed and the α-*galacto* selenoglycoside **7***b* was obtained as the sole product (75%) from **2***b*. The regio- and diastereochemical outcome of the reaction was verified by ^{1}H NMR spectroscopy. The chemical shifts of H1 of **5***b*, **6***b*, and **7***b* (5.95, 5.85, and 5.93 ppm, respectively) are in agreement with the values already reported for selenoglycosides (15–17) and azido sugars (18). the presence of the phenylseleno group of C1 was further confirmed by hydrolysis leading to 2-azido-2-deoxyglycopyranose derivatives (vide infra). Transformation of **7***a* into **7***b* by deacetylation and benzylation (see Experimental) definitively confirmed that the regioselectivity of the reaction was the same as above.

Although more work is necessary to understand and to rationalize these results, similar changes in regioselectivity in azido-phenylselenylation have already been observed with exocyclic alkenes (19).

The compatibility of this methodology with many protecting groups was further demonstrated with diversely protected D-galactal derivatives, which are often employed in oligosaccharide synthesis: 1,5-anhydro-2-deoxy-3,4-*O*-isopropylidene-D-*lyxo*-hex-1-enitol (**3***a*) (20) and its 6-*O*-acetylated (**3***b*) (20), 6-*O*-benzylated (**3***c*) (20), and 6-*O*-*tert*-butyldimethylsilylated (**3***d*) derivatives. The compatibility with the benzylidene group, which is very sensitive to oxidation and to radical reactions, was also demonstrated with 1,5 anhydro-4,6-*O*-benzylidene-2-deoxy-D-*lyxo*-hex-1-enitol (**4***a*) (20) and its 3-*O*-acetyl (**4***b*) (4) and 3-*O*-benzyl (**4***c*) (20) derivatives.

Azido-phenylselenylation of acetylated derivative **3***b* according to procedure A was very slow, but the same diastereocontrol was observed and the α-*galacto* selenoglycoside **9***b* was obtained (Table 1, entry 7). Better results were obtained with procedure B, which was employed for the transformation of **3***b*, **3***c*, **3***d*, **4***b*, and **4***c* into protected 2-azido-2-deoxy-1-seleno-α-D-galactopyranosides in good yield (see Table 1). For **3***d*, in which a *tert*-butyldimethylsilyl group was present, tetra-*n*-butylammonium fluoride was omitted, the reaction time was longer than with other glycals, and the yield of **9***d* slightly lower (66%). Transformation of **9***d* into **9***b* by desilylation and acetylation further confirmed that the regioselectivity was the same with both methods. The *galacto* configuration of the resulting 2-azido-2-deoxyselenoglycosides was confirmed by ^{1}H NMR spectroscopy. For **9***b*, **9***c*, **9***d*, and **9***e*, the values of coupling constants of H2 with H1 (≈5 Hz indicating a *cis* relationship) and with H3 (6–7 Hz) were in agreement with values already reported for such 3,4-*O*-isopropylidene *galacto* derivatives (20). For **10***b* and **10***c* the corresponding coupling constants ($J_{1,2}$ = 5.2 Hz and $J_{2,3}$ = 10.5 Hz) clearly indicated the α-D-*galacto* configuration.

Interestingly, azido-phenylselenylation by procedure B was also possible in the presence of one unprotected hydroxyl group and compounds **3***a* and **4***a* were transformed into **9***a*[2] and **10***a* (Table 1, entries 5 and 11). Although the reaction was not as clean and the yield was lower, this possibility is interesting because **9***a* and **10***a* could eventually serve as glycosyl acceptors as well as glycosyl donors.



Furthermore, it was verified that the reaction can be successfully carried out in the presence of an *O*-allyl ether. For that purpose, 6-*O*-allyl-1,5-anhydro-2-deoxy-3,4-*O*-isopropylidene-D-*lyxo*-1-enitol **3***e* was prepared from **3***a*. Azido-phenylselenylation of **3***e* according to procedure B was highly selective and protected 2-azido-2-deoxy-1-seleno-α-D-galactopyranoside **9***e* was obtained in 74% yield. The product formed by double azido-phenylselenylation was isolated (3%) and characterized by ^{1}H NMR.[3]

These easily obtained 2-azido-2-deoxyselenoglycosides were subjected to hydrolysis to generate the anomeric hydroxyl. Owing to the *soft* nature of the selenium atom, *soft* catalysts such as heavy metal salts were evaluated.

When ether-oxides or acetals were present as protecting group, hydrolysis was complete in 30 min at room temperature in the presence of mercury trifluoroacetate in wet tetrahydrofuran and the protected 2-azido-2-deoxyglycopyranoses were obtained in good yield (see Table 1). When mercury acetate was employed, some 1-*O*-acetyl derivative was also

[2] In this case the regioselectivity was not complete and a small amount (7%) of 3,4-*O*-isopropylidene-2-phenylseleno-β-D-galactopyranosyl azide was also formed, isolated, and characterized by analysis and spectroscopic methods (see experimental).

[3] ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.20 (s, 3H, CH_3), 1.40 (s, 3H, CH_3), 3.10-3.80 (m, 6H), 3.90-4.30 (m, 4H), 4.50 (m, 1H, $J_{2,3}$ = 7.2 Hz, H2), 5.80 (d, 1H, $J_{1,2}$ = 5 Hz, H1), 7.10-7.70 (m, 10 H, aromatic).

formed. Hydrolysis of the *gluco–manno* mixture of **5***b* and **6***b* afforded a mixture of **11***b* and **12***b* that could be separated by flash chromatography, and **11***b* was obtained in crystalline form (66%).

Under these conditions, the hydrolysis of acetylated derivatives **5***a*, **6***a*, and **7***a* was very slow, presumably because the electron-withdrawing effect of the acetoxy group does not favor the formation of the carbenium ion. When *N*-iodosuccinimide (5 equiv.) was employed instead of mercury trifluoroacetate, the reaction was complete in 12 h at room temperature. From **5***a*–**6***a*, an inseparable mixture of **11***a* and **12***a* was obtained, whereas the *galacto* azido-selenoglycoside **7***a* was transformed into **13***a* (87%).

The complete stereocontrol obtained in the *galacto* series makes this procedure very useful. For convenience, it was verified with **2***b* that the two steps can be carried out without purification of the intermediate azido-selenoglycoside **7***b*. In this case, after azido-phenylsenylation, the precipitate was filtered off and the solvent evaporated. Hydrolysis of the crude **7***b* afforded **13***b* after flash chromatography (72% overall yield).

Conclusion

The presently described transformation of protected glycals into 2-azido-2-deoxyglycopyranosides represents a new and very efficient method for the preparation of these important intermediates in oligosaccharide synthesis (21). The overall yield obtained for the preparation of these 2-azido-2-deoxyglycopyranoses compares favorably with yields previously reported for azidonitration followed by hydrolysis. The success of the process in the case of D-galactal derivatives is particularly remarkable because only the *galacto* isomer is obtained in high yield, affording an easy access to galactosamine donors. Another advantage of this methodology is its compatibility with a variety of protecting groups including acetates, acetals, allyl ethers, benzyl ethers, benzylidene groups, and silyl ethers as well as with one nonprotected hydroxyl group. The mild conditions employed would also allow extension of this methodology to glycals derived from disaccharides.

Experimental

General procedures

Melting points were measured with a Thomas–Hoover apparatus and are uncorrected. IR spectra were recorded with a Unicam spectrometer. ^{1}H NMR spectra were recorded on a Bruker AM 200 spectrometer. Optical rotations were measured on a Perkin–Elmer 141 polarimeter in a 10 cm cell at 22°C. Analytical TLC was performed on Merck aluminum precoated plates of silica gel 60 F-254 with detection by UV and by spraying with 6 N H_2SO_4 and heating about 2 min at 300°C. For flash chromatography, Merck silica gel 60 (230–400 mesh) and anhydrous solvents were employed. Solvents were evaporated under reduced pressure in a rotary evaporator below 30°C.

Microanalyses were performed at the Service de Microanalyse de l'Université Pierre et Marie Curie.

N-Phenylselenophthalimide (*N*-PSP) was prepared according to Nicolaou et al. (22).

*1,5-Anhydro-2-deoxy-3,4-*O*-isopropylidene-6-*O*-tert-butyldimethylsilyl-*D*-lyxo-hex-1-enitol* **3***d*

To a solution of **3***a* (20) (500 mg, 2.68 mmol) and imidazole (456 mg, 6.7 mmol) in DMF (5 mL), *tert*-butyldimethylsilylchloride (505 mg, 3.35 mmol) was added. The reaction was stirred at 46°C for 48 h. The solvent was evaporated and the residue partitioned between H_2O and Et_2O (20 mL, 1:1) and

Sodium hydride (60%, 146 mg, 3.48 mmol) was added in small portions to a solution of ***3a*** (590 mg, 3.17 mmol) in DMF (10 mL) under stirring and cooling in ice-water. The mixture was then stirred for 30 min at room temperature, allyl bromide (304 μL, 3.48 mmol) was added dropwise, and the mixture was stirred overnight at room temperature. Excess NaH was destroyed with MeOH and the reaction mixture partitioned between H_2O and CH_2Cl_2 (30 mL, 1:1). The aqueous layer was reextracted with CH_2Cl_2 (2 × 5 mL). The combined organic phase was washed with H_2O until the pH was neutral and then dried ($MgSO_4$). Evaporation afforded a residue, which was chromatographed on silica gel. Elution with EtOAc–hexane (1:10) afforded ***3e***: 584 mg (81%) as an oil. R_f 0.63 (EtOAc–hexane 1:9); $[\alpha]_D$ 14.2 (*c* 1, CH_2Cl_2); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.30 (s, 3H, CH_3), 1.50 (s, 3H, CH_3), 3.65–3.85 (2dd, 2H, $J_{5,6}$ = 5 Hz $J_{5,6'}$ = 7.6 Hz, $J_{6,6'}$ = 10.2 Hz, H6, H6′), 4.10 (m, 1H, H4), 4.20 (m, 3H, CH_2 allyl, H5), 4.7 (dd, 1H, $J_{3,4}$ = 6.2 Hz, H3), 4.80 (m, 1H, $J_{2,4}$ = 1.5 Hz, $J_{2,3}$ = 2.8 Hz, H2), 5.30 (m, 2H, CH=*CH*$_2$), 5.90 (m, 1H, *CH*=CH$_2$), 6.40 (d, 1H, $J_{1,2}$ = 6.3 Hz, H1). Anal. calcd. for $C_{12}H_{18}O_4$: C 63.69, H 8.01; found: C, 63.43, H 8.16.

Typical procedures for azido-phenylselenylation

Procedure A

To a stirred solution of glycal (1 mmol), diphenyldiselenide (0.6 mmol), and sodium azide (2.4 mmol) in dichloromethane (4 mL) under argon, (diacetoxyiodo)benzene (1.4 mmol) was added. The mixture was stirred at room temperature during 48 h until TLC indicated completion of the reaction. The solution was diluted with dichloromethane (20 mL) and washed with 5% aqueous $NaHCO_3$ (2 × 8 mL). The aqueous layer was reextracted with dichloromethane (2 × 5 mL), the organic layer was washed until neutral pH, dried over $MgSO_4$, filtered, and evaporated. The crude product was purified by column chromatography on silica gel.

Procedure B

To a stirred solution of glycal (1 mmol), azidotrimethylsilane (2 mmol), and tetra-*n*-butylammonium fluoride (0.2 mmol) in dichloromethane (10 mL) under argon, was added *N*-PSP (2 mmol). The mixture was stirred at room temperature during 48 h. The solvent was evaporated, toluene (15 mL) was added, the precipitated salts were filtered off, and the crude mixture was concentrated and purified by column chromatography on silica gel. The following 2-azido-2-deoxy-1-seleno-α-d-glycopyranosides were prepared using one of these procedures.

*Phenyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-1-seleno-*α*-*d*-glucopyranoside* ***5a*** *and* α-d-*mannopyranoside* ***6a***

Procedure A: yield (91%), oil; R_f 0.75 (CH_2Cl_2–Et_2O 9:1); IR (neat): 2119 (N_3), 1757 (OAc) cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) *gluco* isomer δ: 2.00–2.20 (3s, 9H, OAc), 3.90–4.00 (dd, 1H, $J_{6',6}$ = 12.21 Hz, $J_{6,5}$ = 1.96 Hz, H6), 4.00–4.10 (dd, 1H, $J_{2,3}$ = 10.15 Hz, H2), 4.25–4.35 (dd, 1H, $J_{6',5}$ = 4.89 Hz, H6′), 4.50 (m, 1H, $J_{5,4}$ = 10.4 Hz, H5), 5.20–5.50 (m, 2H, H3, H4), 5.95 (d, 1H, $J_{1,2}$ = 5.39 Hz, H1), 7.15–7.20 (m, 5H, aromatic); *manno* isomer δ: 2.10–2.30 (3s, 9H, OAc), 4.20 (2dd, 2H, $J_{6,6'}$ = 12.24 Hz, $J_{6,5}$ = 2.16 Hz, $J_{6',5}$ = 5.15 Hz, H6, H6′), 4.37 (dd, 1H, $J_{2,3}$ = 2.95 Hz, H2), 4.45 (m, 1H, H5), 5.25–5.45 (m, 2H, H3, H4), 5.80 (d, 1H, $J_{1,2}$ = 1.27 Hz, H1), 7.20–7.70 (m, 5H, aromatic). Anal. calcd. for $C_{18}H_{21}O_7N_3Se$: C 45.96, H 4.50, N 8.93; found: C 46.35, H 4.47, N 9.00.

*Phenyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-1-seleno-*α*-*d*-galactopyranoside* ***7a***

Procedure A: yield (92%), solid, mp 104–105°C; R_f 0.75 (CH_2Cl_2–Et_2O 9:1); $[\alpha]_D$ +170 (*c* 1, CH_2Cl_2); IR (KBr): 2119 (N_3), 1757 (OAc) cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.20 (3s, 9H, OAc), 4.05 (2dd, 2H, $J_{6,5}$ = 7.1 Hz, $J_{6,6'}$ = 11.4 Hz, H6, H6′), 4.30 (dd, 1H, $J_{2,3}$ = 10.8 Hz, H2), 4.70 (bt, 1H, H5), 5.15 (dd, 1H, $J_{3,4}$ = 3.2 Hz, H3), 5.50 (dd, 1H, $J_{4,5}$ = 1.1 Hz, H4), 6.00 (d, 1H, $J_{1,2}$ = 5.4 Hz, H1), 7.20–7.70 (m, 5H, aromatic). Anal. calcd. for $C_{18}H_{21}O_7N_3Se$: C 45.96, H 4.50, N 8.93; found: C 46.06, H 4.50, N 9.08.

*Phenyl 2-azido-3,4,6-tri-*O*-benzyl-2-deoxy-1-seleno-*α*-*d*-glucopyranoside* ***5b*** *and* -α-d-*mannopyranoside* ***6b***

Procedure B: yield (82%), oil; R_f 0.75 (CH_2Cl_2–hexane 9:1); IR (neat): 2119 (N_3) cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.50–4.30 (m, 6H, H2, H3, H4, H5, H6, H6′), 4.40–5.00 (m, 6H, $3CH_2$ benzyl), 5.85 (bs, 0.3H, H1 *manno*), 5.95 (d, 0.7 H, $J_{1,2}$ = 4.98 Hz, H1 *gluco*), 7.00–7.70 (m, 20H, aromatic). Anal. calcd. for $C_{33}H_{33}O_4N_3Se$: C 64.49, H 5.41, N 6.83; found: C 64.43, H 5.48, N 7.00.

*Phenyl 2-azido-3,4,6-tri-*O*-benzyl-2-deoxy-1-seleno-*α*-*d*-galactopyranoside* ***7b***

Procedure B: yield (75%), oil; R_f 0.75 (CH_2Cl_2–hexane 9:1); $[\alpha]_D$ +157 (*c* 1, CH_2Cl_2); IR (neat): 2119 (N_3) cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.40–3.65 (m, 3H, H5, H6, H6′), 3.75 (dd, 1H, $J_{3,2}$ = 10.48 Hz, $J_{3,4}$ = 2.65 Hz, H3), 4.05 (d, 1H, H4), 4.30–5.00 (m, 7H, $3CH_2$ benzyl, H2), 5.93 (d, 1H, $J_{1,2}$ = 5.22 Hz, H1) 7.10–7.70 (m, 20H, aromatic) Anal. calcd. for $C_{33}H_{33}O_4N_3Se$: C 64.49, H 5.41, N 6.83; found: C 64.59, H 5.59, N 7.02.

*Phenyl 6-*O*-acetyl-2-azido-2-deoxy-3,4-*O*-isopropylidene-1-seleno-*α*-*d*-galactopyranoside* ***9b***

Procedure B: yield (91%), solid, mp 86–88°C; R_f 0.59 (EtOAc–hexane 1:4); $[\alpha]_D$ +237.7 (*c* 1, CH_2Cl_2); IR (KBr): 2119 (N_3), 1750 (CO) cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.15 (1s, 3H, CH_3), 1.25 (1s, 3H, CH_3), 2.00 (1s, 3H, OAc), 4.00 (t, 1H, $J_{4,5}$ = 1.65 Hz, $J_{5,6}$ = 5.5 Hz, $J_{5,6'}$ = 4.91 Hz, H5), 4.10–4.20 (m, 4H, H3, H4, H6, H6′), 4.30 (dd, 1H, $J_{2,3}$ = 6.05

For personal use only.

Hz, H2), 5.90 (d, 1H, $J_{1,2}$ = 4.95 Hz, H1), 7.10–7.80 (m, 5H, aromatic). Anal. calcd. for $C_{17}H_{21}O_5N_3Se$: C 47.89, H 4.96, N 9.86; found: C 47.98, H 4.96, N 9.99.

*Phenyl 2-azido-6-*O*-benzyl-2-deoxy-3,4-*O*-isopropylidene-1-seleno-*α*-*D*-galactopyranoside* **9**c

Procedure B: yield (84%), oil; R_f 0.57 (EtOAc–hexane 1:9); $[\alpha]_D$ +202.8 (*c* 1, CH_2Cl_2); IR (neat): 2119 (N_3) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.40 (1s, 3H, CH_3) 1.55 (1s, 3H, CH_3), 3.70–3.90 (m, 2H, $J_{5,6}$ = 6.61 Hz, $J_{5,6'}$ = 5.11 Hz, $J_{6,6'}$ = 12.3 Hz, H6, H6′), 4.00 (t, 1H, $J_{4,5}$ = 1.4 Hz, H5), 4.05–4.45 (m, 2H, H3, H4), 4.60 (dd, 2H, CH_2 benzyl), 4.70 (1H, $J_{2,3}$ = 6.91 Hz, H2), 5.9 (d, 1H, $J_{1,2}$ = 4.95 Hz, H1), 7.00–7.60 (m, 10H, aromatic). Anal. calcd. for $C_{22}H_{25}O_4N_3Se$: C 55.69, H 5.31, N 8.86; found: C 55.62, H 5.28, N 9.00.

*Phenyl 2-azido-2-deoxy-3,4-O-isopropylidene-6-*O*-tert-butyldimethylsilyl-1-seleno-*α*-*D*-galactopyranoside* **9***d*

Procedure B: yield (66%), oil; R_f 0.56 (EtOAc–hexane 1:12); $[\alpha]_D$ +170.3 (*c* 1, CH_2Cl_2); IR (neat): 2119 (N_3) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.00 (1s, 6H, $2CH_3$, silyl), 0.80 (1s, 9H, $3CH_3$, silyl) 1.35 (1s, 3H, CH_3), 1.50 (1s, 3H, CH_3), 3.65–3.95 (m, 3H, $J_{6,6'}$ = 10.2 Hz, $J_{5,6}$ = 6.6 Hz, $J_{5,6'}$ = 6.4 Hz, H6, H6′, $J_{2,3}$ = 7.7 Hz, H2), 4.10–4.30 (m, 2H, $J_{3,4}$ = 5.3 Hz, H3, $J_{4,5}$ = 2.36 Hz, H4), 4.45 (m, 1H, H5), 5.75 (d, 1H, $J_{1,2}$ = 5.02 Hz, H1), 7.1–7.7 (m, 5H, aromatic). Anal. calcd. for $C_{21}H_{33}O_4N_3SeSi$: C 50.59, H 6.67, N 8.42; found: C 50.33, H 6.77, N 8.34.

*Phenyl 2-azido-3,4,6-tri-O-benzyl-2-deoxy-1-seleno-*α*-*D*-galactopyranoside* **7**b *from* **7**a

A solution of **7***a* (235 mg, 0.5 mmol) and NaOMe (1 M, 0.8 mL) in MeOH (1 mL) was stirred at room temperature until deacetylation was complete (15 h). After neutralization with Amberlite resin IRN 77 (H^+ form) and filtration, evaporation of the solvent afforded a crude product (197 mg), which was dissolved in DMF (2.5 mL). After cooling at 0°C, NaH (60%, 80 mg, 2 mmol) was added. After stirring 1 h, benzyl bromide (200 μL, 1.65 mmol) was added and the mixture stirred at room temperature until TLC indicated completion of the reaction (15 h). Excess NaH was destroyed with MeOH and the reaction mixture partitioned between H_2O and CH_2Cl_2 (30 mL, 1:1). The aqueous layer was reextracted with CH_2Cl_2 (2 × 5 mL). The combined organic phase was washed with H_2O until neutral pH, and dried ($MgSO_4$). Evaporation afforded a residue, which was chromatographed on silica gel. Elution with CH_2Cl_2–hexane (1:1) afforded **7***b*: 253 mg (82%) as an oil identical to **7***b* prepared by azido-phenylselenylation of **2***b*.

*Phenyl 6-*O*-acetyl-2-azido-2-deoxy-3,4-*O*-isopropylidene-1-seleno-*α*-*D*-galactopyranoside* **9**b *from* **9**d

To a solution of **9***d* (20 mg, 0.04 mmol) in THF (100 μL) was added *n*-Bu_4NF (1.1 M THF solution, 35 mL). Completion of the reaction was observed after stirring 30 min at room temperature. After evaporation, the residue was dissolved in pyridine (25 μL), and Ac_2O (12 μL, 0.12 mmol) was added. After stirring overnight at room temperature, evaporation and coevaporation with toluene afforded a residue, which was chromatographed on silica gel. Elution with EtOAc–hexane (1:16) afforded crude **9***b* (12 mg, 70%). Recrystallization from absolute EtOH afforded an analytical sample identical to **9***b* prepared by azido-phenylselenylation of **3***b*.

*Phenyl 2-azido-2-deoxy-3,4-*O*-isopropylidene-1-seleno-*α*-*D*-galactopyranoside* **9**a

Procedure B: yield (59%), oil; R_f 0.79 (EtOAc–hexane 1:9); $[\alpha]_D$ +167.7 (*c* 1, CH_2Cl_2); IR (neat): 2119 (N_3), 3400 (OH) cm^{-1}, ^1H NMR (200 MHz, $CDCl_3$) δ: 1.38 (1s, 3H, CH_3), 1.55 (1s, 3H, CH_3), 1.78 (1s, 1H, OH), 3.70–3.90 (m, 2H, H6, H6′), 3.90–4.00 (dd, 1H, $J_{2,3}$ = 7.5 Hz, H2), 4.15–4.35 (m, 2H, $J_{3,4}$ = 5.34 Hz, H3, H4), 4.40–4.60 (m, 1H, H5), 5.80 (d, 1H, $J_{1,2}$ = 5.15 Hz, H1), 7.10–7.60 (m, 5H, aromatic). Anal. calcd. for $C_{15}H_{19}O_4N_3Se$: C 46.88, H 4.98, N 10.93; found: C 46.86, H 5.28, N 10.93.

*3,4-*O*-Isopropylidene-2-phenylseleno-*β*-*D*-galactopyranosyl azide*

Procedure B: yield (7%), oil; R_f 0.56 (EtOAc–hexane 1:9); $[\alpha]_D$ +31.4 (*c* 1, CH_2Cl_2); IR (neat): 2119 (N_3), 3400 (OH) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.30 (1s 3H, CH_3), 1.40 (1s, 3H, CH_3), 2.50 (1s, 1H, OH), 3.40 (dd, 1H, $J_{1,3}$ = 6.7 Hz, H2), 3.70–4.20 (m, 5H, H3, H4, H5, H6, H6′), 4.60 (d, 1H, $J_{1,2}$ = 10.5 Hz, H1), 7.10–7.80 (m, 5H, aromatic). Anal. calcd. for $C_{15}H_{19}O_4N_3Se$: C 46.88, H 4.98, N 10.93; found: C 47.82, H 5.27, N 10.66.

*Phenyl 6-*O*-allyl-2-azido-2-deoxy-3,4-*O*-isopropylidene-1-seleno-*α*-*D*-galactopyranoside* **9**e

Procedure B: yield (74%), oil; R_f 0.42 (EtOAc–hexane 1:12); $[\alpha]_D$ +223.8 (*c* 1, CH_2Cl_2); IR (neat): 2119 (N_3) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.30 (1s, 3H, CH_3), 1.50 (1s, 3H, CH_3), 3.50–3.80 (2dd, 2H, $J_{5,6}$ = 7.10 Hz, $J_{5,6'}$ = 5 Hz, $J_{6,6'}$ = 10.5 Hz, H6, H6′), 3.85–4.00 (m, 3H), 4.15 (m, 2H, CH_2 allyl), 4.60 (m, 1H), 5.05–5.25 (m, 2H, CH=CH_2), 5.75 (d, 1H, $J_{1,2}$ = 5.1 Hz, H1), 5.80–5.90 (m, 1H, CH=CH_2), 7.10–7.70 (m, 5H, aromatic). Anal. calcd. for $C_{18}H_{23}O_4N_3Se$: C 50.94, H 5.46, N 9.90; found: C 51.15, H 5.29, N 9.93.

*Phenyl 2-azido-4,6-*O*-benzylidene-2-deoxy-1-seleno-*α*-*D*-galactopyranoside* **10**a

Procedure B: yield (68%), solid; mp 116–117°C; R_f 0.57 (ether–hexane 1:4); $[\alpha]_D$ +155.8 (*c* 1, CH_2Cl_2); IR (KBr): 2119 (N_3), 3400 (OH) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.6 (1s, 1H, OH), 4.00 (dd, 1H, $J_{5,6}$ = 3.41 Hz, $J_{6,6'}$ = 10 Hz, H6), 4.05 (m, 3H H3, H5, H6′), 4.20 (d, 1H, $J_{4,5}$ = 1 Hz, H4), 5.55 (s, 1H, PhCH), 4.30 (dd, 1H, $J_{2,3}$ = 10.05 Hz, H2), 6.05 (d, 1H, $J_{1,2}$ = 5.03 Hz, H1), 7.20–7.60 (m, 10H, aromatic). Anal. calcd. for $C_{19}H_{19}O_4N_3Se$: C 52.78, H 4.43, N 9.72; found: C 52.93, H 4.45, N 9.46.

*Phenyl 3-*O*-acetyl-2-azido-4,6-*O*-benzylidene-2-deoxy-1-seleno-*α*-*D*-galactopyranoside* **10**b

Procedure B: yield (73%), solid; mp 135–137°C; R_f 0.50 (EtOAc–hexane 1:4); $[\alpha]_D$ +307.9 (*c* 1, CH_2Cl_2); IR (KBr): 2119 (N_3), 1750 (OAc) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 2.20 (1s, 3H, OAc), 4.00–4.30 (m, 3H, $J_{5,6}$ = 1.8 Hz, $J_{5,6'}$ = 1.45 Hz, $J_{6,6'}$ = 12.75 Hz, H5, H6, H6′), 4.40–4.60 (m, 2H, H2, H4), 5.10 (dd, 1H, $J_{2,3}$ = 10.8 Hz, $J_{3,4}$ = 3.38 Hz, H3), 5.60 (1s, 1H, PhCH), 6.10 (d, 1H, $J_{1,2}$ = 5.2 Hz, H1), 7.20–7.70 (m, 10H, aromatic). Anal. calcd. for $C_{21}H_{21}O_5N_3Se$: C 53.16, H 4.46, N 8.85; found: C 53.18, H 4.55, N 8.88.

Phenyl 2-azido-3-O-benzyl-4,6-O-benzylidene-2-deoxy-1-seleno-α-D-galactopyranoside ***10***c

Procedure B: yield (76%), solid; mp 141–143°C; R_f 0.63 (EtOAc–hexane 1:4); $[\alpha]_D$ +143.3 (*c* 1, CH_2Cl_2); IR (KBr): 2119 (N_3) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 3.80 (dd, 1H, $J_{2,3}$ = 10.37 Hz, $J_{3,4}$ = 3.35 Hz, H3), 3.95–415 (m, 3H, H5, H6, H6′), 4.25 (d, 1H, H4), 4.40 (dd, 1H, H2), 4.80 (dd, 2H, *J* = 12.08 Hz, $PhCH_2$), 5.50 (1s, 1H, PhCH), 6.05 (d, 1H, $J_{1,2}$ = 5.20 Hz, H1), 7.20–7.60 (m, 15H, aromatic). Anal. calcd. for $C_{26}H_{25}O_4N_3Se$: C 59.77, H 4.82, N 8.04; found: C 60.01, H 4.97, N 7.82.

Typical procedures for hydrolysis

Procedure C

A solution of the protected phenyl 2-azido-2-deoxy-α-D-selenoglycopyranoside (1 mmol) in THF–H_2O (2 mL, 1:1) was treated at room temperature with *N*-iodosuccinimide (5 mmol). After 12 h the mixture was diluted with EtOAc (10 mL), and washed with saturated K_2CO_3 (10 mL). The aqueous layer was reextracted with EtOAc (2 × 5 mL). The organic layer was washed until neutral pH, dried over $MgSO_4$, filtered, and evaporated. The crude product was purified by column chromatography on silica gel.

Procedure D

A solution of the protected phenyl 2-azido-2-deoxy-α-D-selenoglycopyranoside (1 mmol) in THF–H_2O (2 mL, 1:1), was treated at room temperature with mercury trifluoroacetate (1.5 mmol). After 30 min the mixture was diluted with EtOAc (10 mL), and washed with saturated K_2CO_3 (10 mL). The aqueous layer was reextracted with EtOAc (2 × 5 mL). The combined EtOAc layer was washed with 5% aqueous Na_2S (10 mL). The aqueous layer was reextracted with EtOAc (2 × 10 mL), the organic layer was washed until neutral pH, dried over $MgSO_4$, filtered, and evaporated. The crude product was purified by column chromatography on silica gel.

3,4,6-Tri-O-acetyl-2-azido-2-deoxy-D-glucopyranose ***11***a *and mannopyranose* ***12***a

Procedure C was applied to the mixture of **5***a* and **6***a* to give a mixture of **11***a* and **12***a* (5) in 90% yield. Anal. calcd. for $C_{12}H_{17}O_8N_3$: C 43.50, H 5.17, N 12.68; found: C 43.68, H 4.98, N 12.66.

3,4,6-Tri-O-acetyl-2-azido-2-deoxy-D-galactopyranose ***13***a

Procedure C was applied to **7***a* to give known **13***a* (5) in 87% yield. Anal. calcd. for $C_{12}H_{17}O_8N_3$: C 43.50, H 5.17, N 12.68; found: C 43.59, H 5.32, N 12.69.

2-Azido-3,4,6-tri-O-benzyl-2-deoxy-D-glycopyranose ***11***b *and mannopyranose* ***12***b

Procedure D was applied to the mixture of **5***b* and **6***b* to give a mixture of **11***b* and **12***b*, which was chromatographed on silica gel. The first fraction gave known **11***b* (23) (66%) as a solid; mp 97°C. Anal. calcd. for $C_{27}H_{29}O_5N_3$: C 68.19, H 6.14, N 8.83; found: C 67.99, H 6.14, N 8.95.

The second fraction afforded **12***b* (12%) as a syrup, R_f 0.52 (ether–hexane 2:1); IR (neat): 2119 (N_3), 3400 (OH) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 3.40 (m, 1H), 3.50–3.95 (m, 7H), 4.00–4.30 (m, 4H, $J_{2,3}$ = 3.56 Hz, $J_{3,4}$ = 9.12 Hz, H4), 4.45–5.00 (m, 9H, $J_{1,2}$ = 1.63 Hz, H2), 5.15 (s, 1H, H2), 7.10–7.60 (15H, aromatic). Anal. calcd. for $C_{27}H_{29}O_5N_3$: C 68.19, H 6.14, N 8.83; found: C 68.62, H 6.16, N 8.79.

A mixture of **11***b* and **12***b* was obtained in 15% yield.

2-Azido-3,4,6-tri-O-benzyl-2-deoxy-D-galactopyranose ***13***b

Procedure D was applied to **7***b* to give known **13***b* (5) in 87% yield. Anal. calcd. for $C_{27}H_{29}O_5N_3$: C 68.19, H 6.14, N 8.83; found: C 68.17, H 6.10, N 8.68.

6-O-Acetyl-2-azido-2-deoxy-3,4-O-isopropylidene-D-galactopyranose ***14***a

Procedure D was applied to **9***b* to give known **14***a* (8) in 79% yield. Anal. calcd. for $C_{11}H_{17}O_6N_3$: C 45.98, H 5.82, N 14.62; found: C 46.12, H 5.82, N 14.63.

2-Azido-6-O-benzyl-2-deoxy-3,4-O-isopropylidene-D-galactopyranose ***14***b

Procedure D was applied to **9***c* to give known **14***b* (7) in 87% yield. Anal. calcd. for $C_{16}H_{21}O_5N_3$: C 57.30, H 6.31, N 12.53; found: C 57.45, H 6.42, N 12.66.

3-O-Acetyl-2-azido-4,6-O-benzylidene-2-deoxy-D-galactopyranose ***15***a

Procedure D was applied to **10***b* to give known **15***a* (7) in 87% yield. Anal. calcd. for $C_{15}H_{17}O_6N_3$: C 57.73, H 5.11, N 12.53; found: C 57.62, H 5.17, N 12.52.

2-Azido-3-O-benzyl-4,6-O-benzylidene-2-deoxy-D-galactopyranose ***15***b

Procedure D was applied to **10***c* to give **15***b* in 82% yield as a syrup; R_f 0.52 (EtOAc–hexane 2:3); IR (neat): 2119 (N_3), 3400 (OH) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 2.90 (1s, 1H, OH), 3.35 (1s, 1H, OH), 3.40 (dd, 1H, $J_{2,3}$ = 10.2 Hz, $J_{1,2}$ = 3.45 Hz, H2), 3.80–4.40 (m, 11H), 4.50 (1H, d, $J_{1,2}$ = 8.01 Hz, H1β), 1.75 (1s, 4H, $PhCH_2$), 5.40 (1s, 1H, H1α), 5.50 (1s, 2H, PhCH), 7.20–7.60 (m, 20H, aromatic). Anal. calcd. for $C_{20}H_{21}O_5N_3$: C 62.65, H 5.52, N 10.96; found: C 62.62, H 5.36, N 11.09.

6-O-Allyl-2-azido-2-deoxy-3,4-O-isopropylidene-D-galactopyranose ***14***c

Procedure D was applied to **9***e* to give **14***c* in 88% yield as a syrup; R_f 0.53 (EtOAc–hexane 1:3); IR (neat): 2119 (N_3), 3400 (OH) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.20–1.30 (2s, 6H, 2 CH_3), 1.50–1.70 (2s, 6H, $2CH_3$), 2.50 (s, 1H, OH), 3.20–4.20 (m, 14 H), 4.30–4.45 (m, 3H), 4.50 (d, 1H, $J_{1,2}$ = 8.2 Hz, H1β), 5.20 (m, 4H, $2CH{=}CH_2$), 5.25 (d, 1H, $J_{1,2}$ = 3.3 Hz, H1α), 5.8 (m, 2H, $2CH{=}CH_2$). Anal. calcd. for $C_{12}H_{19}O_5N_3$: C 50.51, H 6.71, N 14.72; found: C 50.33, H 6.86, N 14.79.

Note added in proof

Since the submission of this paper the separation of **5***b* and **6***b* was made possible by using a less polar eluent (ether–hexane 1:11) for column chromathography on silica gel. From **1***b* (1.248 g, 3 mmol), **6***b* was obtained as a syrup (518 mg, 28%), oil; R_f 0.60 (ether–hexane 1:4); $[\alpha]_D$ +83 (*c* 1, $CHCl_3$); IR (neat): 2119 (N_3) cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 3.75 (dd, 1H, $J_{5,6}$ = 1.75 Hz, $J_{6,6'}$ = 10.9 Hz, H6), 3.85 (dd, 1H $J_{5,6'}$ = 4.5 Hz, H6′), 4.00–4.15 (m, 3H, H3, H4, H5), 4.21 (dd, 1H,

$J_{2,3}$ = 3Hz, H2), 4.60–4.79 (m, 6H, $3CH_2$ benzyl), 5,85 (d, 1H, $J_{1,2}$ = 1.4 Hz, H1), 7.10–7.50 (m, 20H, aromatic) and **5***b* as crystals (1.135 g, 61.6%), mp 86–89°C; R_f 0.45 (ether–hexane 1:4); $[\alpha]_D$ +99 (*c* 1, $CHCl_3$); IR (KBr): 2119 (N_3) cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 3.88 (dd, 1H, $J_{5,6}$ = 2 Hz, $J_{6,6'}$ = 10.1 Hz, H6), 4.05–4.25 (m, 4H, H2, H3, H4, H6′), 4.58 (m, 1H, H5), 4.88–5.3 (m, 6H, $3CH_2$ benzyl), 5.95 (d, 1H, $J_{1,2}$ = 5 Hz, H1), 7.20–7.70 (m, 20H, aromatic).

Order–disorder effects in clathrates. A crystallographic and ^{35}Cl NQR spectroscopic study of CCl_3X guest molecules (X = Cl, Br, CH_3, CN, NO_2, H) in hexakis(phenylthio)benzene

L. Pang, F. Brisse, and E.A.C. Lucken

Abstract: X-ray crystallography and NQR spectroscopy have been jointly used to study CCl_3X-hexakis(phenylthio)benzene (HPTB) (X = Cl, Br, CH_3, CN, NO_2, H) clathrates. The crystal of the non-clathrated HPTB is triclinic, $P\bar{1}$, $a = 9.5614(7)$, $b = 10.2088(13)$, $c = 10.6193(11)$ Å, $\alpha = 68.45(1)°$, $\beta = 76.98(1)°$, $\gamma = 65.62(1)°$, $Z = 1$; crystals of the clathrates with CCl_3CH_3, CCl_3Br, CCl_3NO_2, and CCl_3CN are isostructural and trigonal, $R\bar{3}$, $a = 14.18$–14.32, $c = 20.47$–20.62 Å, $Z = 3$. The trigonal host cavity of HPTB clathrates contains two CCl_3X guest molecules, and the X group occupies either the axial or one of the equatorial positions and thus undergoes a molecular order/disorder depending upon its nature. Dipole–dipole interactions between host and guest molecules are considered here to explain this order/disorder effect quantitatively.

Key words: clathrates, crystal structures, NQR, hexakis(phenylthio)benzene.

Résumé : On a utilisé conjointment la cristallographie des rayons X et la spectroscopie RQN pour étudier les clathrates CCl_3X-hexakis(phénylthio)benzène (HPTB) (X = Cl, Br, CH_3, CN, NO_2 et H). Les cristaux du HPTB qui n'est pas sous la forme de clathrate sont tricliniques, $P\bar{1}$, $a = 9,5614(7)$, $b = 10,2088(13)$ et $c = 10,6193(11)$ Å, $\alpha = 68,45(1)°$, $\beta = 76,98(1)°$ et $\gamma = 65,62(1)°$, $Z = 1$; les cristaux sous la forme de clathrate avec du CCl_3CH_3, CCl_3Br, CCl_3NO_2 et CCl_3CN sont isostructuraux et trigonaux, groupe d'espace $R\bar{3}$, $a = 14,18$–$14,32$, $c = 20,47$–$20,62$ Å, $Z = 3$. La cavité trigonale hôte des clathrates de HPTB contient deux molécules invitées de CCl_3X et les groupes X occupent soit la position axiale ou l'une des positions équatoriales et ils subissent donc un ordre/désordre moléculaire dépendant de leur nature. On considère que dans ces cas, les interactions dipôle–dipôle entre les molécules hôtes et invitées peuvent expliquer quantitativement cet effet ordre/désordre.

Mots clés : clathrates, structures cristallines, RQN, hexakis(phénylthio)benzène.

[Traduit par la rédaction]

Introduction

Order–disorder phenomena are usually observed in inclusion compounds or clathrates (1). It is generally agreed that the guest molecules are disordered in the host cavity because of the weak intermolecular host–guest interactions occurring at the level of van der Waals forces (2). The guest molecules can easily adopt many molecular orientations associated with different but undistinguished local potential minima. In a clathrate where the guest molecule and the host cavity do not have the same symmetry, the guest molecules are statistically distributed over a large number of molecular orientations, so that the orientational disorder is always present in the crystals. However, in a clathrate where the guest molecule has the same symmetry as that of the host cavity, the order and disorder effects are controlled by the two factors: (1) intermolecular interactions, and (2) steric effect.

[a]Number of the host molecules in the unit cell.

Hexakis(phenylthio)benzene (HPTB) has been shown to form clathrates with small organic solvents (3). An early crystallographic investigation (4) revealed that the clathrate of CCl_4 crystallizes in the space group $R\bar{3}$ and has a host cavity with threefold symmetry similar to that of Dianin's compound (5). A comparison with Dianin's compound indicates that the HPTB molecules form a cage-type clathrate whose cavity is slightly longer and can thus imprison two guest molecules of the size of CCl_4, giving a host:guest ratio of 1:2. In fact, the HPTB molecule does also form clathrates with CCl_3CH_3, CCl_3Br, CCl_3CN, CCl_3NO_2, and CCl_3H (3).

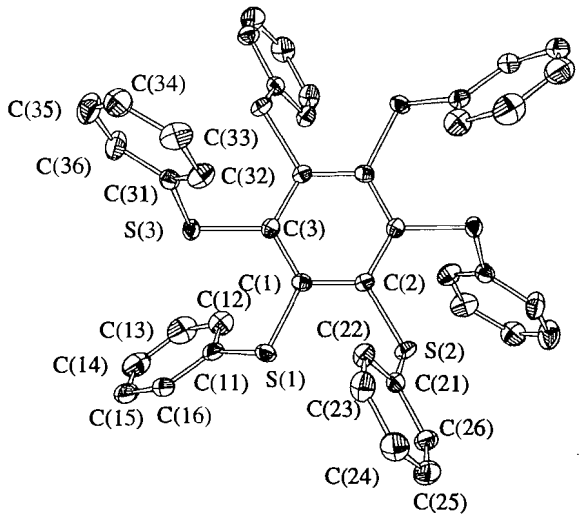
Pang et al. studied some chlorine-containing guest molecules in different inclusion compounds. It was shown that specific host–guest dipole–dipole interactions play a role in the order–disorder effects for the twofold symmetric guest molecules CX_2Cl_2 (X = Cl, Br, CH_3, H) in the cavities of the Werner complexes $Ni(SCN)_2$(3-methylpyridine)$_4$ (6). The authors also showed that a steric effect predominates in the order–disorder effect in the case of threefold symmetric guest molecules CCl_3X (X = F, Cl, Br, I, CH_3, CN, NO_2, H) in the cavities of Dianin's compound (7). We report here the results of a crystallographic and NQR spectroscopic study of HPTB clathrates with CCl_4, **2**, CCl_3CH_3, **3**, CCl_3Br, **4**, CCl_3NO_2, **5**, CCl_3CN, **6**, CCl_3H, **7**, as guest molecules. The structure of HPTB in its nonporous phase **1** is also reported.

Results and discussion

X-Ray crystallography

Crystal data of compounds **1** and **3–6** are summarized in Table 1. Molecule **1** (HPTB) and the atomic numbering adopted are shown in Fig. 1. A selection of the geometrical parameters of these compounds is given in Tables 2 and 3.

Fig. 1. ORTEP drawing of the HPTB with the atomic numbering adopted for all the compounds.



Description of the host molecule and cavity

Crystals of compound **1**, the nonporous form or the non-clathrated phase, crystallize in a triclinic unit cell of space group $P\bar{1}$. Since there is only one HPTB molecule per unit cell, its centre must coincide with a crystallographic centre of symmetry. The HPTB molecule has normal bond lengths and bond angles (see Table 2). The central benzene ring and the six side benzene rings are nearly planar and the sulphur atoms are displaced, on the average, by 0.036 Å from the central benzene ring but deviate by an average of 0.17 Å from the side rings. The six side rings are alternatively up and down from the central ring. The orientations of the side rings with respect to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

central ring are characterized by the ϕ and ψ torsion angles (see Table 2). The values taken by the ϕ angle are in the range 52°–68°. The ψ angle is around 28° in **3–6**. In **1**, however, two of the ψ angles have values of ~35° while the third one is 5°.

The clathrates **3–6**, for which the host:guest ratio is 1:2, are isostructural (space group $R\bar{3}$) with the CCl_4–HPTB clathrate (4) and have essentially the same host cavity. The host molecules in these clathrates have similar conformations to that of the non-clathrated phase. Their geometrical parameters are compared in Table 2. The cavity formed by HPTB molecules is a trigonal, centrosymmetric, hourglass-shaped cage. Two HPTB molecules at $z = 0$ and 1 form the top and bottom of the cage while molecules at $z = \frac{1}{3}$ and $\frac{2}{3}$ build the sides of the cage. The largest regions of the cavity (diameter ~6.9 Å) are at $z = \frac{1}{3}$ and $\frac{2}{3}$. The cavity, with a volume of about 297 Å^3 (8), can accommodate two molecules of CCl_4 (88 Å^3), CCl_3CH_3 (88 Å^3), CCl_3Br (93 Å^3), CCl_3NO_2 (90 Å^3), CCl_3CN (90 Å^3), CCl_3H (68 Å^3) (7).

A stereo pair of clathrate **3** is shown in Fig. 2. The two ordered CCl_3CH_3 molecules are disposed in such a way that the equatorial chlorine atoms are located in the larger region of the cavity while the methyl groups on the C_3 axis face one another and point towards the centre of the cavity.

Order–disorder effects of CCl_3X in the trigonal cavity

The clathrates **3–6** have a rigid host cavity that accommodates two CCl_3X molecules. Each of these may adopt any of three possible orientations: the X group is in the axial position and points toward the centre (orientation I) or to the top (or the bottom) of the cavity (orientation III); the X group is in one of the three equatorial positions (orientation II). Under the threefold symmetry of the cavity, these orientations are triply degenerate. The combination of two of the three orientations yields six distinct situations for the two CCl_3X guest molecules present in the cavity (see Fig. 3). It is clear that under the threefold symmetry and the centrosymmetry only the structures *a* (I + I) and *f* (III + III) are ordered whereas the structures *b–e* are disordered because of the presence of substructures. The above-mentioned orientations are *on symmetry* since the axial atoms are on the C_3 axis and the other atoms, in the equatorial positions, are equivalent. However, it is possible that the guest molecules are *off symmetry* when the axial atoms are not on the C_3 axis and the axial bond does not coincide with the rotation axis. As a consequence, the atoms in the equatorial positions are no longer equivalent. It is because of these *off-symmetry* orientations that the clathrates often present many molecular-disordered situations. The molecular orientations of the guests in clathrates **2–6** and their relative occupancy factors as obtained in this X-ray study are shown in Fig. 4.

Clathrate **3** has an ordered structure because the CCl_3CH_3 molecule is only *on symmetry* in orientation I. The two methyl groups face one another and point towards the centre of the cavity, while the chlorine atoms occupy the equatorial positions so that the guest molecules are in the ordered structure *a* (Fig. 3).

Clathrate **4** has two molecular orientations, I and II, with respective occupancy factors of 25 and 75%. This clathrate may be represented by the three situations, *a*, *b*, and *d* of Fig. 3. Orientation I is *off symmetry* since the C—Br bond does not coincide with the C_3 axis. Furthermore, the bromine atoms of the two molecules in the cage cannot point towards each other since the C—Br bond is longer than the C—Cl bond and because of the larger van der Waals radius of Br compared to that of Cl. Consequently, structure *a* is unlikely and the clathrate is assumed to be 50% in structure *b* and 50% in structure *d*. In structure *d* the molecules are *on symmetry* in orientation II; thus there are two chlorine sites: axial and equatorial sites that are in a ratio of 1 to 2; in structure *b* the molecules are half *on symmetry* in orientation II and half *off symmetry* in orientation I so that there is one axial site and four slightly different equatorial sites for the chlorine atoms.

Clathrate **5**, observed in three orientations, I, II, and III with respective occupancy factors of 50, 35, and 15%, is disordered. The three orientations of the guest, CCl_3NO_2, are all *off symmetry*, and the guest may be present in all six situations *a–f* in any proportion. Since each of them has six chlorine sites, the molecular structure is completely disordered.

The CCl_3CN molecule in clathrate **6** has also three *off-symmetry* orientations, I, II, and III with occupancy factors of 45, 20, and 35%. As the C-C≡N group is longer (2.58 Å) and C—Cl (1.77 Å) it would be difficult for the two neighboring CCl_3CN molecules to have the cyano groups pointing towards one another (as in structure *a*). Thus, only structures *b–f* are possible. The major orientation I (45%) indicates that the cyano groups are preferably located in the axial position pointing towards the end of the cavity (structure *f*).

^{35}Cl NQR spectroscopy

The NQR spectra of clathrates **2–4** obtained at 77 K are shown in Fig. 5. Two close and intense lines of intensity ratio 1:3 were observed for clathrate **2**. This is consistent with the observed crystal structure for CCl_4–HPTB in which the molecule is *on symmetry* with one axial and three identical equatorial chlorine atoms (structure *a*).

The strong single NQR line of **3** implies that CCl_3CH_3 is also in the ordered structure *a*, thus the chlorine atoms can only be located at the equivalent equatorial positions, and the methyl groups are preferably in the axial position pointing towards the centre of the cavity. This interpretation is confirmed by the above X-ray work.

From the NQR point of view, when molecules adopt different molecular orientations, the chemical environment or the electric-field-gradient tensors around the resonant nucleus is slightly changed from one orientation to another, so that the NQR lines spread over a wide region of frequency. If the separation between NQR lines is smaller than or nearly equal to the line width, only a broad band consisting of many closed lines is observed. This is the case for clathrate **4**.

The spectrum of **4** consists of two weak and broad signals, which give unambiguous proof that CCl_3Br is present in different molecular orientations. Thus, the two signals of intensity ratio about 1:2 reveal the existence of two distinct chlorine sites but the weak intensities and large line widths imply that these sites are perturbed by a small molecular disorder effect. As established in the X-ray work, the CCl_3Br molecule has a major (75%) orientation II *on symmetry*. In this case, the axial and the two equatorial chlorine sites yield an intensity ratio of 1:2. However, the minor (25%) orientation I is *off symmetry*. This affects the electronic gradient field of the major molecules and acts as an impurity causing the weakening and broadening of the signals.

The clathrates **5–7** did not show any NQR signals at 77 K.

The absence of NQR signals may be due to both statistical and dynamical disorder effects. Thus, the quasi 3-fold symmetric molecule CCl_3NO_2 in **5** may not only adopt different structures but the NO_2 group may also rotate around the C—N bond. This intermolecular rotation produces a fluctuation on the electric-field-gradient tensors (or a significant molecular inhomogeneity) of the resonant nuclei on the same and neighbouring guest molecules, so that the relaxation time T_2* is too short for the resonances to be observable.

The CCl_3CN guest molecule occupies roughly the same molecular volume as CCl_3CH_3. However, its slightly longer C-C≡N group has greater oscillation amplitudes, thus causing a dynamical effect. As shown in the X-ray work, the CCl_3CN molecule is statistically disordered. This is the main reason for the disappearance of the NQR signals.

The guest molecule in clathrate **7** has the smallest molecular volume. It is evident that, in the cavity, the $CHCl_3$ molecules can undergo a molecular reorientation by interchanging three orientations within the various possible structures. Consequently, for the clathrates **5**–**7**, both the statistical disorder effect and the high-amplitude motion are responsible for the disappearance of the NQR signals at relatively low temperatures.

Host–guest interaction

The nonbonded van der Waals forces are usually considered to be responsible for the host–guest interactions in organic inclusion compounds although, in some particular cases, electrostatic interactions and hydrogen bonding are also important factors. It is expected that the dipole–dipole interactions do exist and play an important role in the host–guest interactions when both the host cavity and the guest molecules have significant dipole moments.

Table 4 contains dipole moments for the CCl_3X guest molecules and the HPTB host molecule calculated by semi-empirical methods (see Experimental). An excellent agreement with the experimental results is observed for the CCl_3CH_3 (1.76 debye (14)) and CCl_3Br (0.21 debye) (15)) molecules.

Since the HPTB host cavity is of the trigonal symmetry, the x and y components of its dipole moment should be zero, so that only the z component needs to be considered. The sign and the magnitude of the z-component dipole moment of the

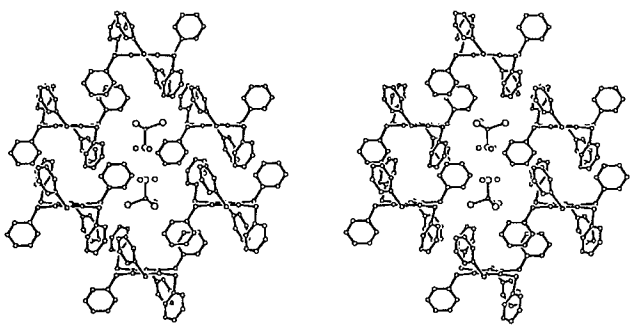
Fig. 2. Stereo pair showing the CCl_3CH_3 molecules in the HPTB cage (clathrate **3**).



CCl_3X guest molecule depend upon its molecular orientation. Thus, when the CCl_3X guest molecules are in orientation I or III, that is, when the X group is located in the axial position and pointing towards either the centre or the ends of the cavity, each guest molecule has a *z*-component dipole moment of the same magnitude but of opposite sign. Thus, because the symmetry axis of the guest molecule coincides with the *z* axis, these orientations correspond to the largest *z* component. The positive and negative signs of the dipole moment are associated with a vector oriented from X to the trichloromethyl group (or vice versa) when the molecules are in orientation I. This description is reversed when the molecules are in orientation III. When the guest molecules are in orientation II, e.g., when the X group is in the equatorial position, the *z* component has a smaller magnitude and is of the opposite sign with respect to orientation I, because the molecular axis does not coincide with the *z* axis.

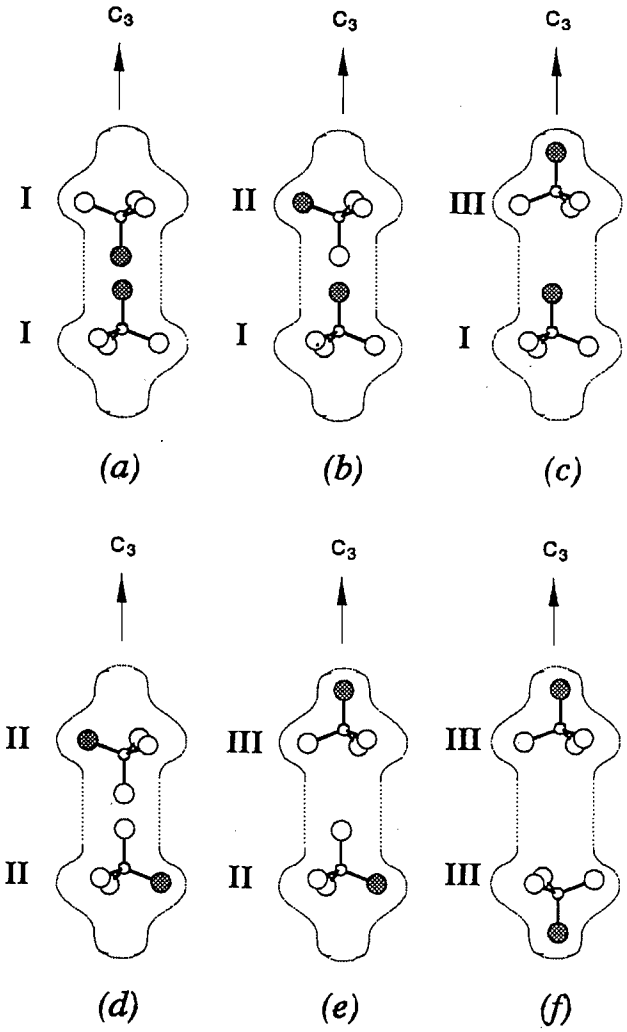
Table 4. Calculated *z* component and total electric dipole moment (debye) of the CCl_3X guest molecules (in orientations I, II, and III) and of the HPTB host molecule.

Molecule	Orientation I	II	III	Total
CCl_4	0.00	0.00	0.00	0.00
CCl_3CH_3	1.75	−0.59	−1.75	1.75
CCl_3Br	0.22	−0.07	−0.22	0.22
CCl_2NO_2	−2.55	0.60	2.55	2.55
CCl_3CN	1.16	−0.52	−1.16	1.16
CCl_3H	1.16	−0.52	−1.16	1.16
HPTB	0.00			0.00
HPTB (half)	0.72			0.72

Since the HPTB molecule is centrosymmetric, its dipole moment is zero. However, each "half HPTB molecule" has a dipole moment of 0.72 debye along the *z* axis. The evidence for a multiple moment in the host cavity can be visualized in Fig. 6. The crystallographic analysis reveals that one CCl_3X

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Fig. 3. The six possible molecular structures CCl_3X within three orientations in the HPTB trigonal cavity.

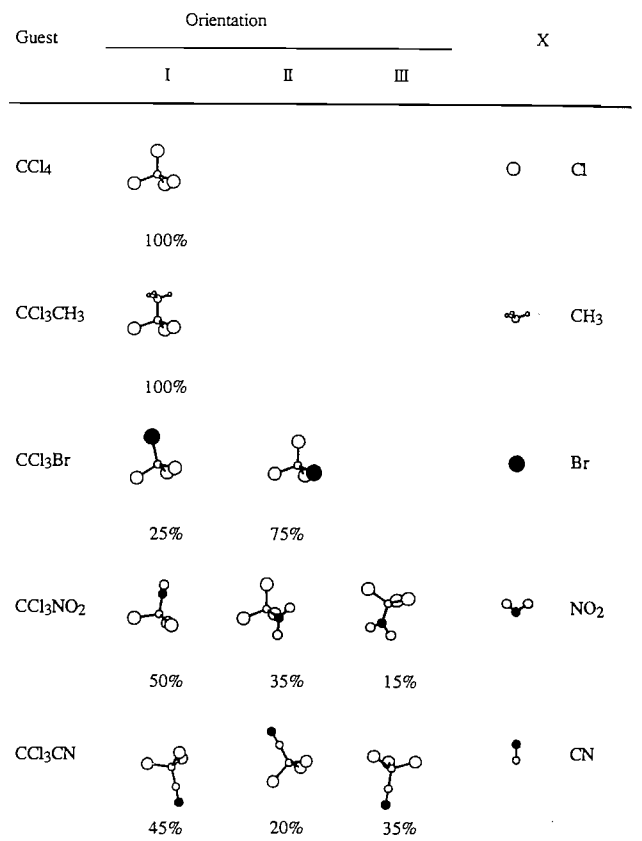


guest molecule may occupy only half of the cavity at $z = 0.2$–0.5 (or at $z = 0.5$–0.8). Only the four closest HPTB molecules (numbered 1–4 Fig. 6; three at $z = \frac{1}{3}$ and one at $z = 0$) contribute to the dipole moment of half the host cavity, consisting of two dipole moments whose vectors go from $z = \frac{1}{2}$ and $\frac{1}{6}$ to $z = \frac{1}{3}$.

When the CCl_3CH_3 guest molecule is in orientation I or III, its dipole moment vector is parallel to that of the host cavity, so that the dipole–dipole interaction is favourable. Since the methyl group has higher nonbonded energy when it is pointing to the bottom than when it is pointing towards the centre of the cavity, orientation III is not observed. The CCl_3CH_3 guest molecule in orientation II has smaller and opposite dipole moment (relative to orientation I), which results in an unfavourable dipole–dipole interaction. Consequently, the CCl_3CH_3 guest molecule can only be present in orientation I *on symmetry*, which gives the ordered structure *a*.

The situation is different for the CCl_3Br guest molecule. There is a weakly favourable dipole–dipole interaction because of the small dipole moment of the guest molecule in orientations I and III. However, because of its high nonbonded energy (steric factor), orientation III cannot be considered. Orientation II has a nearly zero dipole–dipole interaction

Fig. 4. Summary of the observed orientations and disorder of the CCl_3X guest molecules in the HPTB trigonal cavity.



because the CCl_3Br guest molecule has a *z*-component dipole moment of only -0.07 debye. In the absence of a strongly favourable dipole–dipole interaction, orientations I and II are all possible for the CCl_3Br molecule. Thus results in a disorder and may give structures *a*, *b*, and *d*.

Although CCl_3NO_2 and CCl_3CN are slightly polar guest molecules, they cannot give favourable dipole–dipole interactions in any of the three orientations because their dipole moment vectors are all in the opposite direction to that of the host cavity, so that the three molecular orientations may be present and disordered structures are to be expected for these guest molecules.

The smaller $CHCl_3$ guest molecule has two possible orientations, I and III, that give favourable dipole–dipole interactions, whereas orientation II is unlikely due to its slightly unfavourable dipole–dipole interactions.

Experimental

Sample preparation

Hexakis(phenylthio)benzene (HPTB) was prepared according to MacNicol et al. (9), mp 178–179°C; *M* (mass spectrum) 726; τ (NMR in $CDCl_3$) 2.7–3.2 (30H, complex, aromatic). The crystals of **1**, the stable non-clathrated phase, were grown from its solution in CCl_3CN. The crystals appeared after the solution was heated and quickly cooled. The clathrates **2**–**7** were prepared by a slow recrystallization from a solution of the host molecule in the corresponding guest solvents. The

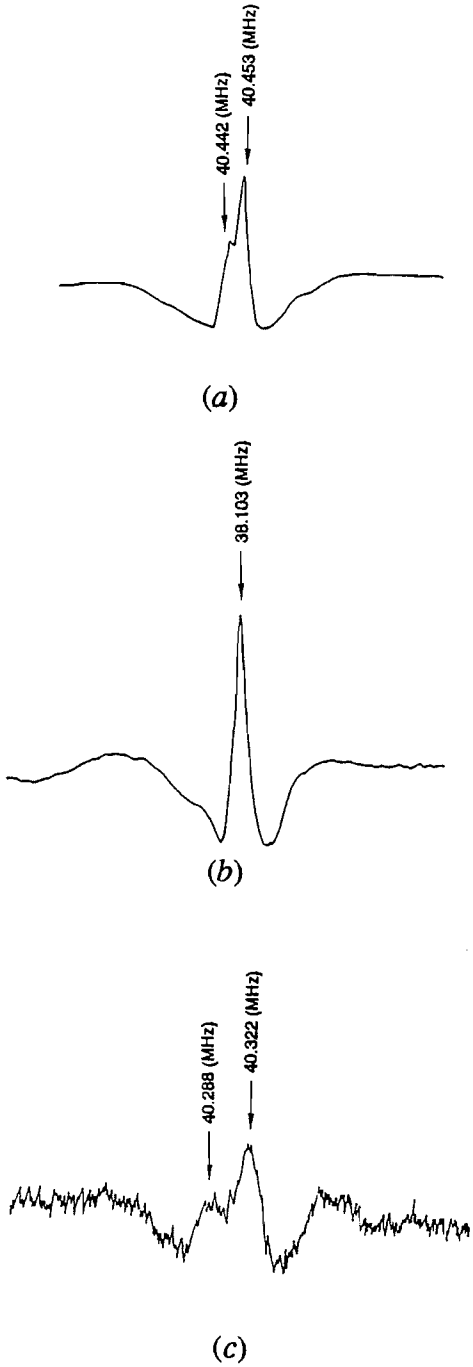
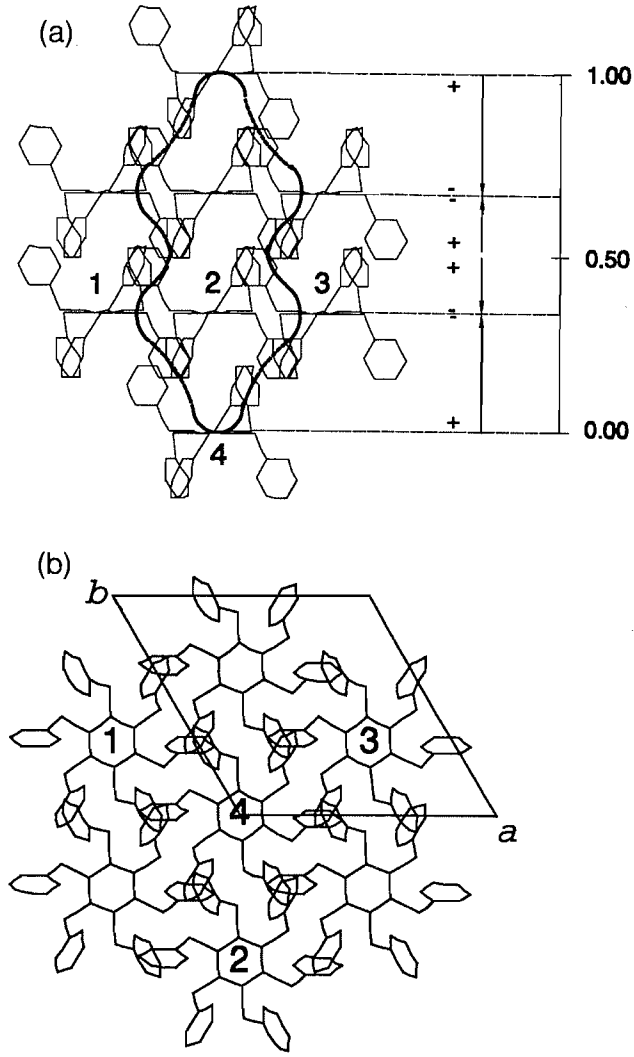
Fig. 5. ^{35}Cl NQR spectra at 77 K of the clathrates (*a*) **2**, (*b*) **3**, and (*c*) **4**.



host:guest ratio was obtained for clathrates **2–7**, using either ^1H NMR analysis, crystal density measurement, or thermogravimetry,[2] which confirms the previously published results except for clathrate **5** (3) (mp 179°C, **2**; 183°C, **3**; 178°C, **4**; 180°C, **5**; 179°C, **6**; 180°C, **7**).

Fig. 6. Multiple moment of the HPTB host cavity; (*a*) view perpendicular to the *c* axis; (*b*) view down the *c* axis.



Crystal structure determination of compounds 1–6

The single crystals were selected and removed from the mother liquor, quickly mounted on a glass fibre, and cooled for the X-ray intensity data collection at low temperature. The crystal densities were obtained by pycnometry using cyclohexane–CCl_3Br mixtures.

The unit-cell parameters were established and the reflection intensities were collected at 220 K on a Nonius CAD4 diffractometer using graphite-monochromatized Cu*K*α radiation (λ = 1.54178 Å). A summary of the crystal data, intensity mea-

[2] The error of the host to guest ratio of the clathrates **2–7** determined by NMR analysis and crystal density measurements is within 5%. However, only the nearest integer values were taken as the host:guest ratio for the clathrates. Thermogravimetry gives a more precise method to determine the host:guest ratio; for example, **3** forms 1:2 (host:guest) clathrate (found: loss of CCl_3CH_3 after 4 h at 50–70°C/25 Torr, 26.76 (1 Torr = 133.3 Pa); $C_{42}H_{30}S_6{\cdot}2CCl_3CH_3$ requires 26.84); **4** forms 1:2 (host:guest) clathrate (found: loss of CCl_3Br after 4 h at 50–70°C/25 Torr, 35.24; $C_{42}H_{30}S_6{\cdot}2CCl_3Br$ requires 35.29); **5** forms 1:2 (host:guest) clathrate (found: loss of CCl_3NO_2 after 12 h open air at room temperature, 31.15; $C_{42}H_{30}S_6{\cdot}2CCl_3NO_2$ requires 31.14).

surements, structure determinations, and refinements is given in Tables 1 and 5.[3]

Refinement of ordered and disordered structures

The structures of the host HPTB in the non-clathrated phase and in the clathrate compounds are all ordered and can be refined without difficulty. The non-hydrogen atoms of HPTB were refined anisotropically. In the course of the refinement, the following constraints were applied: C—Cl = 1.77 ± 0.02 Å, C—Br = 1.90 ± 0.02 Å, C—N = 1.45 ± 0.02 Å, N—O = 1.22 ± 0.02 Å, C—C′ = 1.44 ± 0.02 Å, C′≡N = 1.13 ± 0.02 Å, Cl...Cl = 2.93 ± 0.02 Å, and Cl...Br = 3.00 ± 0.02 Å. The evidence for the molecular disorder can be immediately seen from high atomic thermal parameters ($U_{eq} > 0.25$ Å^2). Difference Fourier syntheses, calculated after the refinement had converged, revealed some strong new residual peaks that correspond to the guest molecule in another orientation. These new peaks were added to the refinement. To determine the occupancy factors, the isotropic thermal parameters were kept at fixed values while an overall occupancy factor was refined for each partial molecule. When the R index improved significantly, the model was accepted; otherwise, the same procedure was repeated until a satisfactory solution was obtained. After convergence, the occupancy factors were kept constant, while the atomic thermal parameters were allowed to vary individually. During the last cycle, the atomic thermal parameters and the occupancy factors were slightly adjusted.

In our work, two or three models were required to describe the disorder of the guest molecules inside the HPTB host cavities. The residual electron density differences indicate that these are sufficient. Thus, clathrate **3** was refined with one model without constraining the CCl_3CH_3 molecule; clathrate **4** was refined with two models; clathrates **5** and **6** were refined with three models.

The guest molecule in **3** and that with the 75% occupancy in **4** were refined anisotropically. All other disordered molecules in **4**, **5**, and **6** were given isotropically.

^{35}Cl NQR spectroscopy

Freshly prepared samples for NQR spectroscopy were briefly

[3] Tables of atomic coordinates, bond lengths and angles, and thermal parameters for compounds **1** and **3–6** can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

The tables of atomic coordinates and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

sucked dry and immediately sealed in glass vials. The NQR spectra at 77 K were measured on a Decca superregenerative spectrometer, frequencies being compared to harmonics from an internal crystal-controlled oscillator. Temperatures were measured with a Hewlett–Packard 2802A digital thermometer by using a platinum thermocouple (precision ±0.5°C).

Electric dipole moment calculation

The electric dipole moments of the guest molecules and of the HPTB molecule were calculated using AM1 semi-empirical quantum mechanics (16) with HyperChem™ Release 2 package[4] running on an 80486 50 Hz IBM-compatible personal computer.

The geometries of the guest molecule were constructed manually and minimized with the molecular mechanics force field (17). Two molecular orientations were considered in the calculation: X groups are located on either the axial or equatorial position, which does not change the total dipole moments but, rather, their components along the x, y, and z axes. The geometry of the HPTB molecule was taken from our crystallographic study; the total and the half of the HPTB molecule were calculated, respectively. The guest molecules were finally minimized with AM1 semi-empirical quantum mechanics, which employed the Polak–Ribiere conjugate gradient technique. The minimizations were terminated when the maximum derivative of all atoms was less than a value of 0.1 kcal mol^{-1} $Å^{-1}$. The dipole moment of the HPTB host molecule was determined with the AM1 method using single point calculation. The results obtained are shown in Table 4. The calculated total energies, atomic coordinates and charges, and dipole moments of the molecules under consideration have been deposited (see footnote 3).

Electrochemical behavior of amidine hydrochlorides and amidines

Benoit Daoust and Jean Lessard

Abstract: The electrochemical behavior of *N,N*-dimethyl-*N'*-phenylformamidine hydrochloride was studied on a platinum electrode. The oxidation peak at +0.90 V vs. Ag/Ag^+ 0.01 M (in CH_3CN – 0.1 M $LiClO_4$) was assigned to the oxidation of the chloride anion. *N,N*-Dimethyl-*N'*-(4-chlorophenyl)formamidine and *N,N*-dimethyl-*N'*-(2-chlorophenyl)formamidine were isolated from the preparative electrolysis of this amidine hydrochloride. The electrochemical behavior of *N*-phenylbenzamidine hydrochloride and *N*-phenylcyclohex-3-enecarboxamidine hydrochloride was also studied at platinum and at vitreous carbon. Cyclic voltammetry of a number of amidines was performed. Only *N*-arylbenzamidines showed a reduction peak at potentials less negative than −3.0 V vs. Ag/Ag^+ 0.01 M (discharge potential of the medium at vitreous carbon). Preparative electrooxidations of all amidines studied were unsuccessful because of strong and rapid passivation of the anode.

Key words: amidine, electrochemical oxidation, chloride, amidine hydrochloride.

Résumé : Le comportement électrochimique du chlorhydrate de la *N,N*-diméthyl-*N'*-phénylformamidine a été étudié sur une électrode de platine. Le pic d'oxydation à +0.90 V vs. Ag/Ag^+ 0.01 M (dans CH_3CN – 0.1 M $LiClO_4$) a été attribué à l'oxydation de l'anion chlorure. La *N,N*-diméthyl-*N'*-(4-chlorophényl)formamidine et la *N,N*-diméthyl-*N'*-(2-chlorophényl)formamidine ont été isolées de l'électrolyse préparative de ce chlorhydrate d'amidine. Le comportement électrochimique du chlorhydrate de la *N*-phénylbenzamidine et du chlorhydrate de la *N*-phénylcyclohex-3-ènecarboxamidine a également été étudié sur platine et sur carbone vitreux. Plusieurs amidines ont été étudiées par voltammétrie cyclique. Seules les *N*-arylbenzamidines ont donné un pic de réduction à un potentiel supérieur à −3.0 V vs. Ag/Ag^+ 0.01 M (potentiel de décharge du milieu sur carbone vitreux). Il n'a pas été possible d'effectuer l'électrooxydation préparative des amidines à cause d'une forte et rapide passivation de l'anode.

Mots clés : amidine, oxydation électrochimique, chlorure, chlorhydrate d'amidine.

[Traduit par la rédaction]

Introduction

Amidines have been studied mainly as precursors of the synthesis of biologically active compounds (1) but have been the subject of few electrochemical studies (2–5). In 1977, Barbey and Caullet (2) studied the electrochemical behavior of an amidine hydrochloride, *N,N*-dimethyl-*N'*-phenylformamidine hydrochloride (**1**HCl). They assigned the anodic wave at $E_{½}$ = 0.89 V vs. Ag/Ag^+ 0.01 M in the voltammogram of **1**HCl in CH_3CN – 0.1 M $LiClO_4$ at a rotating platinum disc electrode to the oxidation of the imino nitrogen of the amidine group. By means of cyclic voltammetry and preparative electrolyses, we have reassigned this wave to the oxidation of the chloride anion. We have extended the electrochemical study to two other amidine hydrochlorides and have also looked at the cyclic voltammetric behavior of a number of amidines.

Electrochemical behavior of amidine hydrochlorides. *N,N*-Dimethyl-*N'*-phenylformamidine hydrochloride (1HCl)

Oxidation behavior

In their study of the electrochemical behavior of **1**HCl, in CH_3CN – 0.1 M $LiClO_4$, Barbey and Caullet (2) showed that the oxidation wave at $E_{½}$ = +0.89 V vs. Ag/Ag^+ 0.01 M in the linear sweep voltammogram (LSV) at platinum corresponds to a one-electron process. Considering that the amino nitrogen was protonated (see $\mathbf{1}H^+$ in Scheme 1), they assigned this wave to the oxidation of the electron pair of the imino nitrogen of $\mathbf{1}H^+$ to give the dication radical **2** (Scheme 1). Upon adding 1 mole of $HClO_4$ per mole of **1**HCl, they observed the disappearance of the oxidation wave and explained this loss of elec-

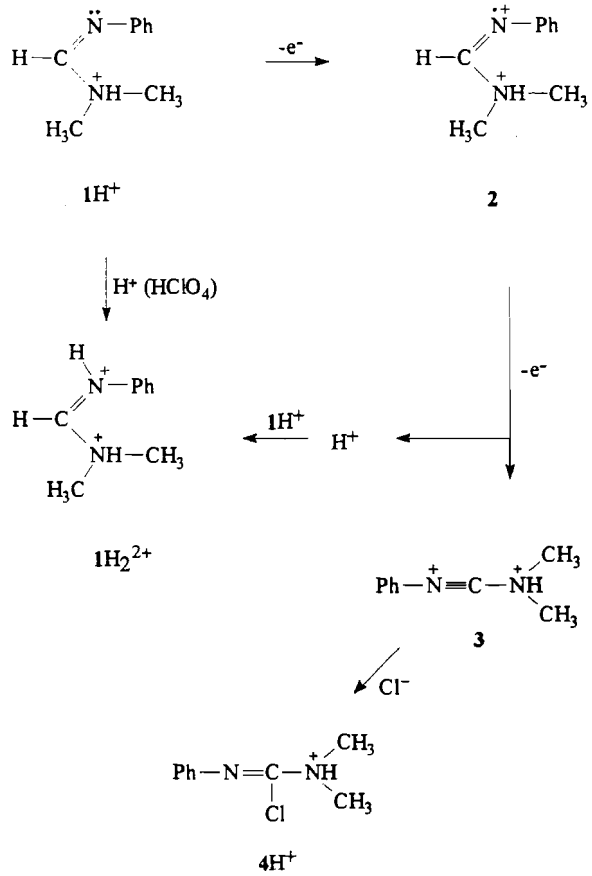
Scheme 1 (Proposition of Barbey and Caullet (2))



troactivity by protonation of the imino nitrogen to form the dication $\mathbf{1}H_2^{2+}$ (Scheme 1). During the potentiostatic preparative electrolysis of **1**HCl (+1.0 V vs. Ag/Ag^+ 0.01 M), the authors noted the disappearance of the oxidation wave and the appearance of a reduction wave at $E_{1/2}$ = +0.55 V in the LSV. They attributed this new wave to the reduction of the dication **3** (Scheme 1). After the electrolysis, they isolated a product which they assumed was the perchlorate of the chloroamidine **4** (**4**$HClO_4$) and proposed the mechanism shown in Scheme 1 for its formation. It is noteworthy that this mechanism corresponds to a two-electron process while coulometric experiments indicated a one-electron process. The authors explained this result by the fact that half of **1**HCl molecules would be eliminated from the oxidation process by protonation of the imino nitrogen with the protons formed in the oxidation of **2** to **3** (Scheme 1).

We decided to reinvestigate the electrochemical behaviour of **1**HCl on the basis that the observed oxidation potential (+0.90 V vs. Ag/Ag^+ 0.01 M) appeared too low for the oxidation of a protonated amidine. Furthermore, the oxidation of the protonated amidine cannot involve the electron pair of the imino nitrogen as suggested by Barbey and Caullet (2) since it is the most basic of the two nitrogens due to charge delocalization (stabilization) of the conjugate acid, and it is the nitrogen that is protonated (6, 7). As shown below, the anodic wave at +0.90 V is due to the oxidation of the chloride anion.

Voltammetric behavior of 1HCl

The cyclic voltammogram of **1**HCl on platinum (CH_3CN – 0.1 M $LiClO_4$) is presented in Fig. 1*A*. An oxidation peak at $E_p(ox1)$ = +0.90 V vs. Ag/Ag^+ 0.01 M corresponding to the oxidation wave reported by Barbey and Caullet (2) is observed (Table 1, entry 1). This oxidation peak is also present in the voltammogram of LiCl (Fig. 1*C*) (Table 1, entry 13). According to literature data (8), the voltammogram of LiCl on a platinum rotating disc electrode in CH_3CN – Et_4NClO_4 0.1 M shows two oxidation waves at $E_{1/2}(ox1)$ = +1.1 V and $E_{1/2}(ox2)$ = +1.7 V vs. SCE, which would correspond to +0.8 V and +1.4 V vs. Ag/Ag^+ 0.01 M. These two oxidation waves were attributed to reactions [1] and [2], respectively. Thus, the oxidation

[1] $3Cl^- - 2e^- \rightleftharpoons Cl_3^-$

[2] $2Cl_3^- - 2e^- \rightleftharpoons 3Cl_2$

peak at $E_p(ox1)$ = +0.90 V must be ascribed to the oxidation of the chloride anion. The absence of the second oxidation peak at ca. +1.4 V in Fig. 1*C* is not due to strong ion pairing between Cl_3^- and the lithium cation ($LiClO_4$ as supporting electrolyte) because it was absent also in the cyclic voltammogram of LiCl and that of Et_3NHCl in CH_3CN – 0.1 M Et_4NClO_4 using the same platinum electrode as that used in Fig. 1*C*. The discrepancy between our results and those published by Kolthoff and Coetzee (8) could be due to a difference in the state of the electrode surface resulting from a different electrode pretreatment.

The cathodic peak at +0.58 V in Fig. 1*C* is due to the reduction of Cl_3^- (reverse of reaction [1]) so the cathodic peak at +0.57 V ($E_p(red1)$) in Fig. 1*A* must be due also to the reduction of Cl_3^- and not to the reduction of the dication **3** (Scheme 1) as proposed by Barbey and Caullet (2). The fact that the peak is much smaller in Fig. 1*A* than in Fig. 1*C* suggests that some Cl_3^- does react with the protonated amidine (**1**H^+), as shown by the preparative oxidation (see below).

The cyclic voltammogram of **1**$HClO_4$ (Fig. 1B) does not show any anodic peak at ca. +0.90 V nor any cathodic peak at ca. +0.58 V. The disappearance of those two peaks upon changing the counter anion from Cl^- (Fig. 1*A*) to ClO_4^- (Fig. 1*B*) provides further evidence that they are really due to the oxidation of Cl^- and the reduction of Cl_3^-, respectively, and not to the oxidation of the protonated amidine **1**H^+ and the reduction of the dication **3** (Scheme 1).

Upon adding perchloric acid to the electrolytic solution of **1**HCl, the oxidation peak at +0.90 V decreases in intensity (Fig. 2*B*) and disappears completely when 1 equivalent has been added (Fig. 2*C*). As mentioned above, Barbey and Caullet (2) reported a similar observation for the linear sweep voltammogram of **1**HCl in the presence of $HClO_4$. Furthermore, as shown in Figs. 2*B* and 2*C*, the addition of $HClO_4$ to **1**HCl gives rise to a new oxidation peak, a shoulder at ca. +1.4 – 1.5 V, and to a small reduction peak at +0.70 V. The addition of a second equivalent of $HClO_4$ does not cause any further change in the cyclic voltammogram (voltammogram identical to that of Fig. 2*C*) except for the appearance of the reduction peak of $HClO_4$ at –0.39 V. The same behavior is observed in the cyclic voltammogram of Et_3NHCl upon adding $HClO_4$: disappearance of the oxidation peak at +0.90 V, appearance of the shoulder at +1.4–1.5 V, and appearance of a reduction peak at

−0.39 V when more than 1 equivalent of $HClO_4$ is added. Thus, only 1 equivalent of $HClO_4$ reacts with **1**HCl and Et_3NHCl. The identical behavior of **1**HCl and Et_3NHCl suggests that the amidine moiety is not involved in the disappearance of the oxidation peak for the chloride anion. Indeed, the disappearance of the oxidation peak at +0.90 V is due to protonation of the chloride anion by $HClO_4$ (eq. [3]), which is a stronger acid than HCl ($pK_{a\ HClO_4\ (H_2O)} = -10$; $pK_{a\ HCl\ (H_2O)} = -7$) and the appearance of the peak at +1.4–1.5 V is due to the oxidation of the undissociated HCl formed (eq. [3]), as con-

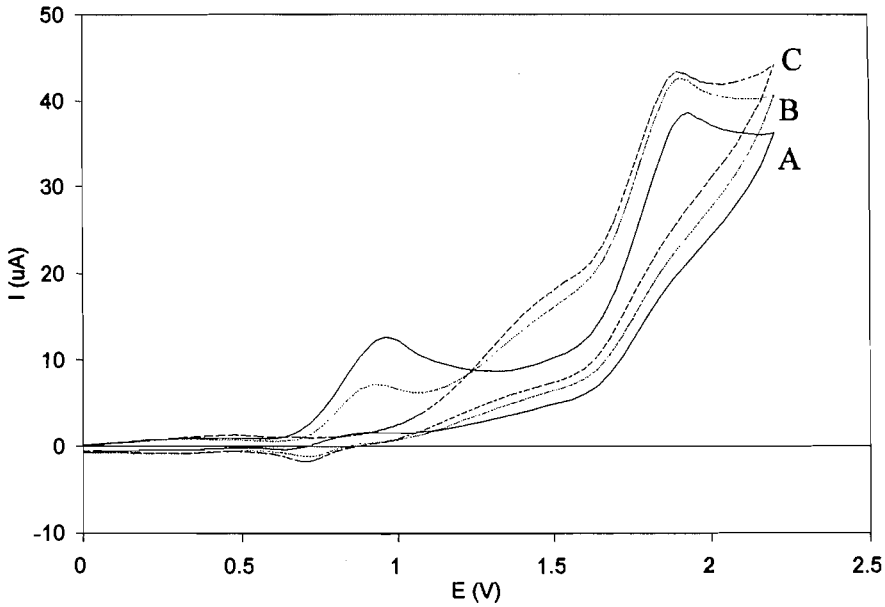
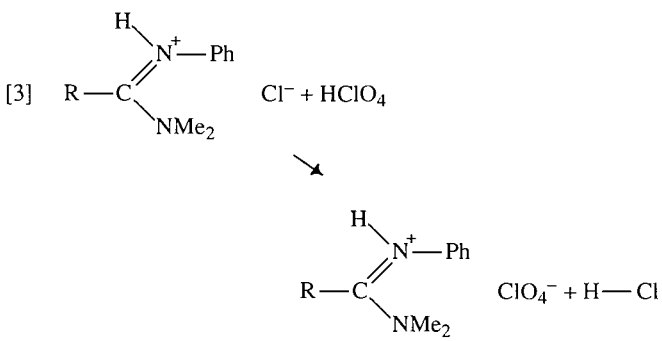
Fig. 2. Cyclic voltammetry of **1**HCl (5 mM) in CH_3CN – 0.1 M $LiClO_4$ on a Pt electrode: (*A*) **1**HCl alone; (*B*) plus 0.5 equivalent of $HClO_4$; (*C*) plus 1 equivalent of $HClO_4$. Sweep range: 0–+2.2 V vs. Ag/Ag^+ 0.01 M; sweep rate: 100 mV/s.



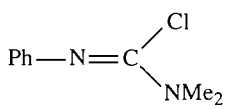


firmed by the absence of an oxidation peak at +0.90 V and the presence of a broad peak at +1.4–1.5 V in the cyclic voltammogram of anhydrous HCl in CH_3CN – 0.1 M $LiClO_4$. Upon adding water, the broad peak changes to a narrower peak at +0.90 V due to regeneration of the chloride anion since H_3O^+ ($pK_{a\,(H_2O)} = -1.75$) is a weaker acid than HCl: $HCl + H_2O \rightarrow H_3O^+Cl^-$. These results show clearly that the amidinium cation $\mathbf{1}H^+$ is not protonated to the dication $\mathbf{1}H_2^{2+}$ contrarly to Barbey and Caullet's hypothesis (2) (see Scheme 1). As with **1**HCl, the addition of 1 equivalent of $HClO_4$ to a solution of **10**HCl and **11**HCl in CH_3CN – 0.1 M $LiClO_4$ resulted in a shift of the oxidation peak of Cl^- from +0.84 to +1.20 V for **10**HCl and from +0.90 to +1.32 V for **11**HCl.

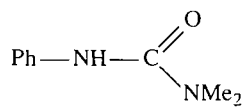
The second oxidation peak at $E_p(ox2) = +1.78$ V vs. Ag/Ag^+ 0.01 M in the voltammograms of both the hydrochloride **1**HCl (Fig. 1*A*) and the perchlorate **1**$HClO_4$ (Fig. 1*B*) could be attributed to the oxidation of the protonated amidine. The preparative oxidation of these salts at +1.7 V consumed 2 moles of electrons per mole of salt. However no product (starting material or reaction products) could be recovered or detected from these oxidations after the usual basic work-up and extraction.

Preparative electrooxidation of 1HCl

The potentiostatic preparative electrolysis of **1**HCl (see the Experimental) carried out under the same conditions as those used by Barbey and Caullet (2) (E_w = +0.75 V, CH_3CN – 0.1 M $LiClO_4$), consumed 1.5 moles of electrons per mole of **1**HCl and gave 72% of the parent amidine **1** and 14% of two chlorinated products after alkaline work-up and ether extraction. The major chlorinated product (13%) was identified as *N,N*-dimethyl-*N'*-(4-chloro)phenylformamidine (**5**) and the minor one (≤1%) as *N,N*-dimethyl-*N'*-(2-chloro)phenylformamidine (**6**) (see Scheme 2) by comparison (^1H and ^{13}C NMR, IR and mass spectra) with authentic samples synthesized as described by Pedersen (9). It is noteworthy that neither the chloroamidine **4**, which Barbey and Caullet (2) claimed to have isolated as the perchlorate salt (**4**$HClO_4$), nor its hydrolysis product, *N,N*-dimethyl-*N'*-phenylurea (**9**), were detected.



4



9

Reaction of amidine 1 with electrogenerated chlorine

Since the oxidation of **1**HCl at +0.75 V (Table 2, entry 1) generates chlorine according to reaction [1], the chlorinated products **5** and **6** must arise from the electrophilic chlorination of the protonated amidine during the electrolysis and (or) of the amidine (which should be a better nucleophile than the protonated form) during the basic work-up. When chlorine was generated by electrolyzing LiCl at platinum in CH_3CN – 0.1 M $LiClO_4$ (E_w = +0.75 V, 1 mole of electrons per mole of salt), then the circuit was opened and 0.16 equivalent of **1**$HClO_4$ was added to the electrolysis medium (Table 2, entry 2); the

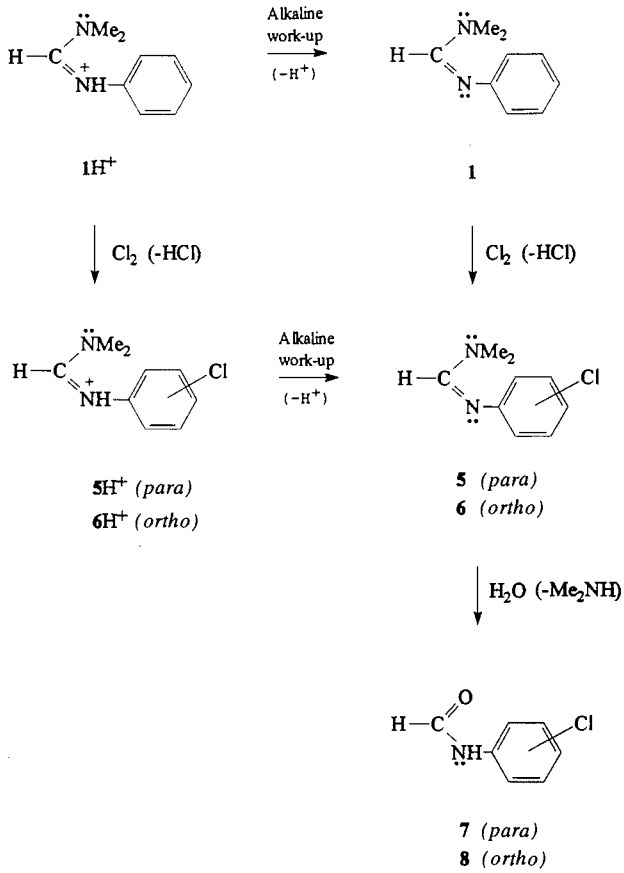
Scheme 2



products obtained after the usual work-up, separation, and analysis were the parent amidine **1** (90%) and the *para*-chloro derivative **5** (10%). Adding amidine **1** to chlorine electrogenerated as above also led, after the same isolation procedure, to the chlorinated amidines **5** (11%) and **6** (≤1%). Only 8% of amidine was recovered. In addition, the products of hydrolysis of **5** and **6**, 4-chloroformanilide (**7**)(~10%) and 2-chloroformanilide (**8**)(~1%), respectively (see Scheme 2), and some dichlorinated amidines (5%) were detected by GLC in the crude reaction mixture and identified by GC–MS.

Reduction behavior

To complete the electrochemical study of **1**HCl, its reduction was studied both by cyclic voltammetry and preparative electrolysis. The cyclic voltammogram of a solution of **1**HCl in CH_3CN – 0.1 M $LiClO_4$ at platinum (Fig. 3*A*) shows a reduction peak at −1.33 V (see E_p(red2) in entry 1, Table 1)[2]. After the addition of 1 equivalent of $HClO_4$, the cyclic voltammogram shows a new reduction peak at −0.62 V in addition to the peak at −1.33 V (compare Fig. 3*B* and 3*A*).[2] The preparative reduction of the latter solution at −0.62 V consumed 1 mole of electrons per mole of substrate and gave, after the usual basic work-up and ether extraction, the parent amidine **1** in a quantitative yield. Coulometric measurements on this same solution at −1.33 V (second reduction peak) revealed a two-electron process and the preparative electrolysis gave the amidine **1** in a 94% yield. Based on the oxidation results, the electrochemical behavior just described can be readily explained by eqs. [4] and [5]. The addition of 1 equivalent of $HClO_4$ to a solution of **1**HCl gives **1**$HClO_4$ and HCl (eq. [3]), as already pointed out. Reduction of the latter gives rise to the reduction peak at −0.62 V (eq. [4]), the current of which indeed increases upon addition of anhydrous HCl. The reduction peak at −1.33 V corresponds to the reduction of the proton of the monoprotonated amidine **1**H^+ to hydrogen and amidine **1** (eq. [5]). Upon adding more than 1 equivalent of $HClO_4$ to the electrolytic solution of **1**HCl, a third reduction peak appears at −0.39 V and increases with the amount of $HClO_4$ added (Fig. 4). This peak corresponds to the reduction of $HClO_4$ as mentioned above (see Oxidation behavior) and as confirmed by the cyclic voltammogram of a 4.5 mM solution of $HClO_4$ in CH_3CN – 0.1 M $LiClO_4$. The presence of this peak in Fig. 4 shows clearly that only 1 equivalent of $HClO_4$ reacts with **1**HCl and that $HClO_4$ is not an acid strong enough to further protonate the monoprotonated amidine **1**H^+, as already pointed out (see Oxidation behavior).

[4] $H—Cl + e^- \longrightarrow \frac{1}{2}H_2 + Cl^-$

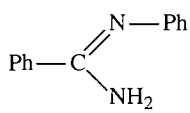
Hydrochlorides of amidines 10 (10HCl) and 11 (11HCl)

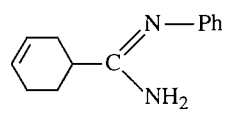
Oxidation behavior

At platinum

When compared to the cyclic voltammogram of **1**HCl, the voltammograms of *N*-phenylbenzamidine hydrochloride (**10**HCl) and *N*-phenylcyclohex-3-enecarboxamidine hydrochloride (**11**HCl) at platinum in CH_3CN – 0.1 M $LiClO_4$ also exhibit an anodic peak at ca. +0.90 V, which corresponds to the oxidation of the chloride anion (eq. [1]) (see E_p(ox1) in Table 1, entries 5 and 9). In the case of **10**HCl, the cathodic peak corresponding to the reduction of electrogenerated chlorine is also observable at +0.56 V (E_p(red 1), entry 5). However, for **11**HCl, this reduction peak is absent in the voltammogram, probably as a result of reaction of the electrogenerated chlorine with the cyclohexene ring to give dichlorides and (or)



10



11

[2] The origin of the weak anodic peaks at −0.80 V in Fig. 3*A* and −0.33 and −0.93 V in Fig. 3*B* can be attributed to the oxidation of chemisorbed hydrogen.

Table 2. Preparative electrolysis of **1**HCl and LiCl at platinum.[a]

Entry	Compound (c = 0.02 M)	E_{app}[b] (V)	Moles of e⁻ per mole of salt	Yield of products[c] (%)

Fig. 3. Cyclic voltammetry on a Pt electrode: (*A*) **1**HCl (6.8 mM); (*B*) **1**HCl (6.8 mM) plus 1 equivalent of $HClO_4$ in CH_3CN – 0.1 M $LiClO_4$. Sweep range: 0–−2.5 V vs. Ag/Ag^+ 0.01 M; sweep rate: 100 mV/s.

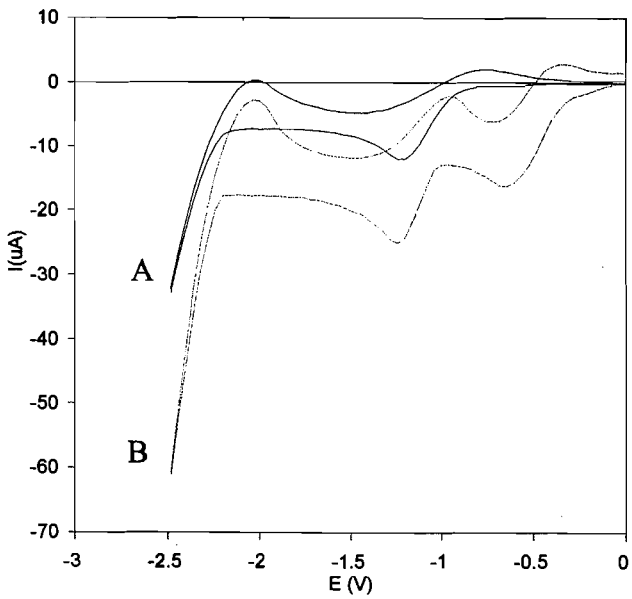

Fig. 4. Cyclic voltammetry of **1**HCl (6.8 mM) in CH_3CN – 0.1 M $LiClO_4$ on a Pt electrode: (*A*) plus 1.5 equivalents of $HClO_4$; (*B*) plus 2.0 equivalents of $HClO_4$; (*C*) plus 3.0 equivalents of $HClO_4$. Sweep range: 0–+2.5 V vs. Ag/Ag^+ 0.01 M; sweep rate: 100 mV/s.

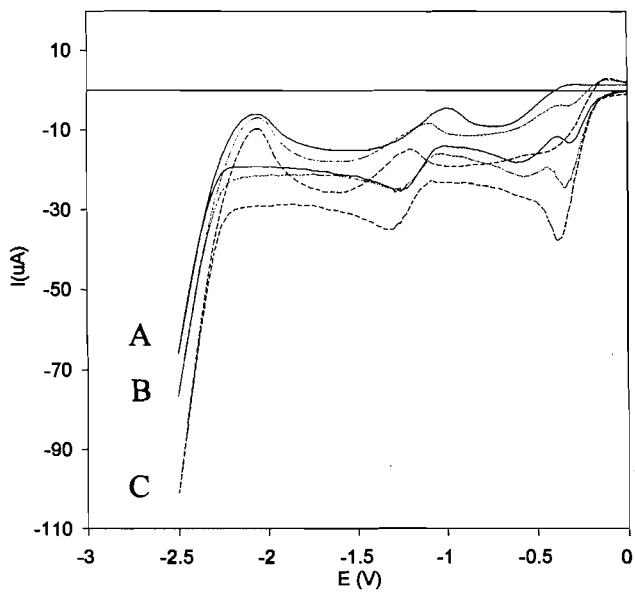

allylic chlorides. Attempts to isolate such chlorinated derivatives from preparative electrolyses of **11**HCl were, however, unsuccessful. Controlled potential oxidations of **11**HCl at +0.90 V or +1.0 V using a charge corresponding to 1 mole of electrons per mole of salt led to only the partial recovery (35–75%) of the parent amidine **11** after basic work up. The recovery of the parent amidine **10** in the preparative oxidation of **10**HCl after basic work up was even lower (0–40%). In addition to the peak at +0.90 V (E_p(ox1)), the voltammograms of **10**HCl and **11**HCl at platinum also show a second oxidation peak (E_p(ox2)) but at a less positive potential (+1.28 V and +1.45 V, respectively, see Table 1, entries 5 and 9) than that of **1**HCl (E_p(ox2) = +1.78 V, entry 1 and Fig. 1*A*). In the case of **1**HCl (entry 1), E_p(ox2) was tentatively attributed to the oxidation of the protonated amidine (**1**H^+) (see above), the same peak being present also in the voltammogram of **1**$HClO_4$ (entry 3). However, the potential of the second oxidation peak differs for **10**HCl (E_p(ox2) = +1.28 V, entry 5) and **10**$HClO_4$ (E_p(ox2) = +2.06 V, entry 7). Furthermore, a second oxidation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

peak is present in the voltammogram of **11**HCl (E_p(ox2) = +1.45 V, entry 9) but is absent in the voltammogram of **11**$HClO_4$ (entry 11). Therefore, the origin of E_p(ox2) in the voltammograms of the amidine hydrochlorides is not known. The preparative oxidations of **10**HCl and **11**HCl at a potential corresponding to E_p(ox2) consumed 2 moles of electrons per mole of hydrochlorides. No product nor any parent amidine could be isolated after the usual basic work-up followed by extraction with ether.

At vitreous carbon

The potential of the first oxidation peak is the same for both hydrochlorides (E_p(ox2) = +1.54 V for **10**HCl and +1.55 V for **11**HCl) and is absent in the voltammograms of **10**$HClO_4$ and **11**$HClO_4$ (entries 8 and 12, respectively). Therefore, it can most probably be attributed to the oxidation of the chloride anion. Interestingly, LiCl is oxidized at a more positive potential (E_p(ox1) = +1.00 V, entry 14) at vitreous carbon than the chloride ion of **10**HCl and **11**HCl, whereas the oxidation potential (E_p(ox1)) at platinum is the same for LiCl, **10**HCl, and **11**HCl (see entries 13, 5, and 9, respectively), as already mentioned. The chloride anion of amine hydrochlorides is also oxidized at more positive potentials on vitreous carbon than LiCl but at less positive potentials than the chloride ion of **10**HCl and **11**HCl, and the oxidation potential depends on the structure of the amine: E_p(ox1) = +1.12, +1.13 and +1.25 V for $Et_2NH{\cdot}Cl$, $(CH_3)_2NH{\cdot}HCl$, and pyridine hydrochloride, respectively. The more difficult oxidation of the chloride ion of amidine and amine hydrochlorides when compared to LiCl as well as the differences in the oxidation potential with the structure of the amidine/amine moiety could be attributed to the adsorption of the protonated (or unprotonated) amidine/amine. The controlled potential oxidation at vitreous carbon of **10**HCl and **11**HCl at the potential of the first anodic peak (E_w = +1.5 V) consumed 2 moles of electrons per mole of salt and not 1 mole as in the preparative oxidation at platinum at +0.90 V. These oxidations led to the complete destruction of the organic moiety since no product nor parent amidine could be detected after the usual basic work-up and extraction with ether.

The second oxidation peak in the voltammograms of **10**HCl and **11**HCl at vitreous carbon appears at potentials (E_p(ox2) = ca. +2.05 V, Table 1, entries 6 and 10) similar to those of the oxidation peak observed in the voltammograms of **10**$HClO_4$ and **11**$HClO_4$ at both vitreous carbon (E_p(ox2) = ca. +1.95 V, entries 8 and 12) and platinum (E_p(ox2) = +2.06 V for **10**$HClO_4$, entry 7). Again, no product or parent amidine could be isolated from the preparative oxidations at a potential (+2.0 V) corresponding to that of the second oxidation peak.

Reduction behavior

The electrochemical reduction of the hydrochlorides and perchlorates of amidines **10** and **11** was studied by cyclic voltammetry in the 0 to ca. −3 V range and by preparative electrolysis. The voltammetric data are recorded in Table 1. At platinum, the voltammograms of **10**HCl, **10**$HClO_4$, **11**HCl, and **11**$HClO_4$ show only one irreversible reduction peak (entries 5, 7, 9, and 11), as in the cyclic voltammograms of **1**HCl and **1**$HClO_4$ (entries 1 and 3). As in the case of **1**HCl and **1**$HClO_4$, this reduction peak corresponds to the reduction of the proton of the protonated amidines **10**H^+ and **11**H^+ since the preparative electrolysis at the peak potential consumed 1 mole of electrons per mole of salt to give the parent amidine in high yield (95–100%).

At vitreous carbon (Table 1, entries 6, 8, 10, and 12), the cyclic voltammograms of **10**HCl, **10**$HClO_4$, **11**HCl, and **11**$HClO_4$ also show a peak corresponding to the reduction of H^+ of the protonated amidine, as confirmed by the preparative electrolysis at the peak potentials: Q = 1 mole of electrons per mole of salt, parent amidine as the sole product isolated in 88–90% yield. The reduction potentials are more negative at vitreous carbon (E_p(red 1) = −1.78 to −2.31 V) than at platinum (E_p(red 1) = −1.16 to −1.72 V), as expected for the reduction of protons since the overpotential for proton reduction is known to be higher at vitreous carbon than at platinum (10).

The structure of the amidine to which the proton is attached has a definitive influence on the reduction potential of the proton. Both at platinum and at vitreous carbon, the peak potential and hence the ease of proton reduction increase in the order **11**H^+, **1**H^+, and **10**H^+: E_p(red2) = −1.43, −1.33, and −1.20 V, respectively for the hydrochlorides at Pt (entries 9, 1, and 5); −1.72, −1.43 , and −1.16 V, respectively, for the perchlorates at Pt (entries 11, 3, and 7); −2.24, −1.99, and −1.82 V, respectively, for the hydrochlorides at vitreous carbon (entries 10, 2, and 6); −2.31, −2.14, and −1.78 V, respectively, for the perchlorates at vitreous carbon (entries 12, 4, and 8).

The voltammograms of **10**HCl and **10**$HClO_4$ at vitreous carbon exhibit a second reduction peak at −2.66 V and −2.87 V, respectively (E_p(red3) in Table 1, entries 6 and 8). This second peak should correspond to the reduction of the parent benzamidine **10** liberated after reduction of the acidic proton, which occurs at *ca.* −1.2 V as seen above. Indeed, the voltammetric reduction of *N*-phenylbenzamidine (**10**) at vitreous carbon in the same medium gives a peak at −2.81 V (see Table 3, entry 3) and addition of benzamidine **10** to a solution of **10**HCl or **10**$HClO_4$ causes an increase of the current of the second reduction peak.

Amidines

Oxidation behavior

The oxidation and reduction peak potentials of amidine **1** and of amidines **10–20**, determined by cyclic voltammetry, are reported in Table 3. At platinum, the voltammograms of the *N*-phenylamidine **1** and the *N*-phenylamidines **10–18** all show two irreversible oxidation peaks, a first peak between +0.70 and +0.84 V vs. Ag/Ag^+ 0.01 M and a second peak in the range of +1.83–+2.40 V. At vitreous carbon, the voltammograms of the *N*-phenylamidines **10–17** show only the first oxidation peak between +0.60 and +0.80 V whereas the second oxidation peak is present at +1.92 V (entry 20) in the voltammogram of the *N,N'*-diphenylamidine **18**. The voltammograms of the *N*-cyclohexylamidines **19** and **20** differ from those of the other amidines in showing an anodic peak at +1.26–+1.34 V at both platinum (entries 21 and 23) and vitreous carbon (entries 22 and 24). It is noteworthy that, according to the ^1H NMR spectra and to Prevorsek (11), the *N*-phenylamidines **1** and **10–18** exist as the tautomer possessing the phenyl group on the imino nitrogen (even if the phenyl ring is out of the plane and thus not fully conjugated with the amidine moiety (12)) whereas the prefered tautomer of the *N*-cyclohexylamidines **19** and **20** has the cycloalkyl substituent on the amino nitro-

gen. Thus, an amidine with an alkyl substituent on the amino nitrogen and an unsubstituted imino nitrogen gives an additionnal oxidation peak at ca. +1.3 V when compared to a *N*-phenylamidine.

On the other hand, the structure of the amidine has little influence on the first anodic peak potential. At platinum, *N*-cyclohexylamidine (**19**) is the easiest to oxidize (+0.65 V, Table 3, entry 21) and *endo N*-phenylnorborn-5-ene-2-carboxamidine (**16**) the most difficult to oxidize (+0.84 V, entry 15). At vitreous carbon, the easiest amidine to oxidize is *exo N*-phenylnorborn-5-ene-2-carboxamidine (**17**) (+0.60 V, entry 18) and the most difficult to oxidize is *N*-phenylcyclohex-3-ene carboxamidine (**11**) (+0.80 V, entry 6). So there is no particular trend. There is also no particular trend for the second oxidation peak at platinum but the range of oxidation potentials is wider, with +1.83 V for the amidine **11** (entry 5) and +2.40 V for the amidine **14** (entry 11).

The cyclic voltammograms of all the amidines, scanning from 0 V to +2.2 or +2.5 V, showed clearly the passivation of the anode both at platinum and at vitreous carbon. On platinum, the formation of a golden layer was easily seen and this layer could be destroyed only with nitric acid (≥1 M). This passivation was such that it was impossible to carry out any coulometric determination or any preparative oxidation at potentials corresponding to the peak potentials of the cyclic voltammograms. The passivation is not due to the polymeriza-

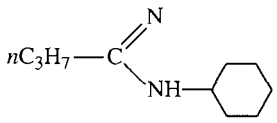
19



20

tion of acetonitrile that was reported to occur when oxidizing amines in that solvent (13) since passivation occurred also when the electrooxidation was carried out in dichloromethane or DMF. The passivation has to be attributed to polymerization of the amidine initiated by its oxidation.

Reduction behavior

We also studied the voltammetric reduction of the amidines at platinum and at vitreous carbon. As can be seen from Table 3 (entries 3, 4, 14, and 20), only the *N*-arylbenzamidines **10, 15,** and **18** with at least one phenyl group on one of the amidine nitrogens were reducible at potentials less negative than −3.0 V vs. Ag/Ag^+ 0.01 M, the discharge potential of the solvent or supporting electrolyte at vitreous carbon. None were reducible at platinum, the discharge potential being −2.5 V. The peak potentials vary from −2.81 V for amidine **10** (entry 3) to −2.46 V for amidine **18** (entry 20). As expected, the benzamidine **18** with two phenyl rings attached to the amidine nitrogens (one on each nitrogen) is easier to reduce than the benzamidines **10** and **15** with only one phenyl group on one of the amidine nitrogens. Even if one of the two phenyl groups on the amidine nitrogens in **18** is twisted out of the plane of the amidine moiety, it still exerts an electron-withdrawing effect. *N*-(4-Chlorophenyl)benzamidine (**15**) is easier to reduce (−2.60 V, entry 14) than *N*-phenylbenzamidine (**10**) (−2.81 V, entry 3) because of the electronwithdrawing (inductive) effect of the chlorine. In the voltammogram of *N*-(4-chlorophenyl)benzamidine (**15**), the second reduction peak at −2.84 V is due to *N*-phenylbenzamidine (**12**), as confirmed by an increase of the current of that peak when adding **10** to the electrolytic solution of **15**. *N*-Phenylbenzamidine (**10**) results from the reduction of the C—Cl bond of **15** and is most probably reduced to *N*-benzylaniline and ammonia at −2.84 V through a four electron – four-proton process. The reduction of benzamidines to benzylamines has already been reported by Heb and Bluemcke (14).

Conclusion

We have shown that the oxidation peak at +0.90 V vs. Ag/Ag^+ 0.01 M in the voltammogram of *N,N*-dimethyl-*N'*-phenylformamidine hydrochloride (**1**HCl) at a platinum electrode is not due to the oxidation of the protonated amidine cation ($\mathbf{1}H^+$) as proposed by Barbey and Caullet (2) but to the oxidation of the chloride anion. This same peak is also present in the voltammograms of *N*-phenylbenzamidine hydrochloride (**10**HCl) and *N*-phenylcyclohex-3-enecarboxamidine hydrochloride (**11**HCl). Preparative oxidations of **1**HCl at +0.75 V gave, after basic work-up, the parent amidine (72%) together with some 14% of products resulting from electrophilic chlorination of the aromatic ring. No chlorinated products were detected from the controlled potential oxidation of **10**HCl and of **11**HCl, and the recovery of the parent amidine was low.

All *N*-phenylamidines investigated (see **1**, and **10–18**) gave two irreversible oxidation peaks (at ca. +0.7–0.8 V and +1.9 V) at platinum and only one (at ca. +0.7 V) at vitreous carbon while the *N*-cyclohexylamidines **19** and **20** gave three irreversible oxidation peaks (at ca. +0.7, +1.3, and +1.9 V) at platinum and two (at ca. +0.7 and +1.3 V) at vitreous carbon. Strong passivation of the anode attributed to the deposition of an amidine polymer or oligomer on the electrode (formation of a golden layer) was observed in the preparative oxidations of each and every one of the amidines studied in CH_3CN–Bu_4NBF_4 as well as in CH_2Cl_2–Bu_4NBF_4. Only the *N*-arylbenzamidines gave a reduction peak before the discharge of the medium at vitreous carbon.

Experimental

General

Melting points were determined on a Buchi apparatus and are uncorrected. Infrared (IR) spectra were recorded on a Perkin Elmer 1600 Series FTIR. Proton and ^{13}C nuclear magnetic resonance (NMR) spectra were obtained on a Bruker AC-300 instrument. Mass spectra were obtained with a Hewlett Packard (HP) 5971 mass selective detector coupled with a HP 5890 Series II gas chromatograph. Exact Masses were determined with a VG Micromass ZAB-2F instrument.

Solvent and electrolyte

Technical grade acetonitrile was purified as described in ref. 15. Technical grade dichloromethane was distilled over CaH_2 and kept under argon. Tetrabutylammonium tetrafluoroborate (Bu_4NBF_4) prepared from tetrafluoroboric acid and tetrabutylammonium bromide (15) was recrystallized from 95% ethanol or acetonitrile. It was then dried in vacuum at 100°C for 12 h. Commercially available $LiClO_4$ (BDH) was dried in the same manner.

Electrochemical instrumentation and methods

For all voltammetric analyses as well as preparative electrolyses, solutions were deoxygenated with dry and oxygen-free nitrogen. A nitrogen atmosphere was maintained over the solution throughout the experiments. The cyclic voltammetry experiments were performed with a Princeton Applied Research (PAR) 173 potentiostat coupled to a PAR 175C

function generator in a two-compartment cell containing 3 mL of electrolyte solution or with a PAR 273 potentiostat in a two-compartment cell containing 8 mL of electrolyte solution. The working electrode was either a 1 mm^2 platinum disk or a 7.45 mm^2 vitreous carbon disk. The auxiliary electrode was a platinum wire or a vitreous carbon rod. Platinum and vitreous carbon electrodes were polished using 0.3 μm micropolish alumina (Buehler) before each use. Potentials were measured with respect to an Ag/Ag^+ 0.01 M (in acetonitrile) electrode.

The preparative electrolyses were carried out with an Electrosynthesis Company (ESC) 410 potentiostat having an ESC 640 coulometer and an ammeter connected in series within the auxiliary circuit; a two compartment glass H-cell (volume of each compartment = 12.5 or 25 mL) having a Nafion-324 (E-I du Pont de Nemours & Co) membrane as separator was used. The working electrode was either a 2 cm^2 platinum grid or 3.18 cm^2 vitreous carbon rod. The auxiliary electrode was a 2 cm^2 platinized platinum grid. The reference electrode was an Ag/Ag^+ 0.01 M electrode.

Amidines

N,N-*Dimethyl* N′-*phenylformamidine* (***1***)
Compound **1** was prepared according to the method described by Pedersen (9). *N,N*-dimethylformamide (50 mL, 47 g, 0.64 mol), P_2O_5 (15 g, 0.11 mol), and acetanilide (10.12 g, 0.075 mol) were refluxed for 2 h. The reaction mixture was cooled to ambient temperature and 400 mL of 1 M NaOH was added slowly. Extraction with ether yielded 6.75 g (61%) of **1**: bp 100°C/1.5 Torr (lit. (9) bp 70–72°C/0.1 Torr) (1 Torr = 133.3 Pa); IR ($CHCl_3$) cm^{-1}: 3010 (C-H arom.), 2930 (C-H aliph.), 1636 (C=N), and 1103 (C-N); ^1H NMR ($CDCl_3$) δ: 2.94 (s,6H), 6.98 (m,3H), 7.25 (m,2H), 7.46 (s,1H) ppm; ^{13}C NMR ($CDCl_3$) δ: 34.1 (CH_3), 39.7 (CH_3), 120.9 (CH), 122.0 (CH), 128.6 (CH), 151.6 (C), 153.0 (N-C=N) ppm; HMRS, *m/z*: 148.0998; calcd. for $C_9H_{12}N_2$: 148.1000.

N-*Phenylbenzamidine* (***10***)
Compound **10** was prepared according to the method described by Cooper and Partridge (16). Aniline (9.3 g, 0.1 mol) was dissolved in 25 mL of toluene and $NaNH_2$ (4 g, 0.1 mol) was added. After refluxing for 2 h, benzonitrile (10.3 g, 0.1 mol) was added, reflux was maintained overnight, then 125 mL of 2 N HCl was added slowly. The solution was extracted with 4 portions (100 mL) of ether to give 7.3 g of **10** (37%): mp 115–117°C (lit. (16) mp 114–115°C); IR (KBr) cm^{-1}: 3510 and 3404 (NH_2) and 1049 (C-N); ^1H NMR ($CDCl_3$) δ: 1.7 (broad peak, 1H), 6.99 (d, J = 7.8 Hz, 2H), 7.13 (t, J = 7.5 Hz, 1H), 7.32 (t, J = 7.5 Hz, 2H), 7.47 (m, 5H) ppm; ^{13}C NMR ($CDCl_3$) δ: 121.5 (CH), 122.9 (CH), 126.7 (CH), 128.5 (CH), 129.4 (CH), 130.5 (CH) ppm; HRMS, *m/z*: 196.0994; calcd. for $C_{13}H_{12}N_2$: 196.1000.

N-*Phenylcyclohex-3-enecarboxamidine* (***11***)
11 was prepared by the method described by Cooper and Partridge (16), with cyclohex-3-enecarbonitrile instead of benzonitrile. The yield was 46%: mp 88–90°C; IR ($CHCl_3$) cm^{-1}: 3518 and 3409 (NH_2), 3029 and 3012 (C-H arom. and C-H alkene), 2926 (C-H aliph.), 1643 (N-C=N), and 1589 (C-N); ^1H NMR ($CDCl_3$) δ: 1.73 (m,1H), 2.10 (m,2H), 2.30 (m,1H), 2.51 (m,1H), 4.04 (broad peak, 1H), 5.72 (m,2H), 6.87 (d, J = 7.9 Hz, 2H), 7.00 (t, J = 7.4 Hz, 1H), 7.29 (t, J = 7.8 Hz, 2H ppm); ^{13}C NMR ($CDCl_3$) δ: 24.9 (CH_2), 26.7 (CH_2), 29.3 (CH_2), 40.2 (CH), 121.8 (CH), 122.8 (CH), 125.6 (CH), 126.9 (CH), 129.4 (CH), 149.1 (C), 162.0 (N-C=N) ppm; HRMS, *m/z*: 200.1314; calcd. for $C_{13}H_{16}N_2$: 200.1313.

N-*Phenylacetamidine* (***12***)
12 was prepared by the same method as that used to obtain **10**, with acetonitrile instead of benzonitrile. The yield was 22%: mp 62–64°C; IR (KBr) cm^{-1}: 3527 and 3412 (NH_2), 3020 (C-H arom.), 2979 (C-H aliph.), 1663 (N-C=N), 1597 (NH_2), and 1050 (C-N); ^1H NMR ($CDCl_3$) δ: 2.03 (s,3H), 4.47 (broad peak, 1H), 6.86 (d, J = 7.5 Hz, 2H), 7.01 (t, J = 7.8 Hz, 1H), 7.29 (t, J = 7.8 Hz, 2H) ^{13}C NMR ($CDCl_3$)δ: 77.2 (CH_3), 121.8 (CH), 122.6 (CH), 129.2 (CH), 149.6 (C), 155.3 (N-C=N) ppm; HRMS, *m/z*: 134.0843; calcd. for $C_8H_{10}N_2$: 134.0844.

N-*Phenylphenylacetamidine* (***13***)
13 was prepared by the same method as that used to obtain **10**, with phenylacetonitrile instead of benzonitrile. The yield was 45%: mp 136–138°C; IR (KBr) cm^{-1}: 3510 and 3404 (NH_2), 3020 (C-H arom.), 2979 (C-H aliph.), 1655 (N-C=N), 1597 (NH_2), and 1050 (C-N); ^1H NMR (C_6D_6) δ: 3.4 (s,2H), 3.6-3.8 (broad peak, 1H), 6.98 (t, J = 7.5 Hz, 1H), 7.05 (d, J = 7.8 Hz, 2H), 7.21 (s,5H), 7.25 (t, J = 7.8 Hz, 2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 43.0 (CH_2), 121.7 (CH), 122.8 (CH), 127.1 (CH), 128.9 (CH), 129.0 (C-H), 129.4 (C-H), 136.5 (C), 149.0 (C), 157.5 (N-C=N) ppm; HRMS, *m/z*: 210.1155; calcd. for $C_{14}H_{14}N_2$: 210.1157.

N-*Phenylbutanamidine* (***14***)
Compound **14** was prepared by the same method as that used to obtain **10**, with butyronitrile instead of benzonitrile. The yield was 14%: mp 66–67°C; IR (KBr) cm^{-1}: 3527 and 3412 (NH_2), 3020 (C-H arom.), 2971 (C-H aliph.), 1665 N-C=N), 1597 (NH_2), and 1050 (C-N); ^1H NMR ($CDCl_3$) δ: 1.01 (t, J = 7.4 Hz, 3H), 1.72 (6 peaks, J = 7.5 Hz, 2H), 2.33 (t, J = 7.7 Hz, 2H), 4.59 (broad peak, 1H), 6.92 (d, J = 7.2 Hz, 2H), 7.07 (t, J = 7.5 Hz, 1H), 7.32 (t, J = 7.8 Hz, 2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 13.6 (CH_3), 20.6 (CH_2), 38.2 (CH_2), 121.7 (CH), 122.6 (CH), 129.3 (CH), 149.6 (C), 158.2 (N-C=N) ppm; HRMS, *m/z*: 162.1153; calcd. for $C_{10}H_{14}N_2$: 162.1157.

N-*(4-chlorophenyl)benzamidine* (***15***)
15 was prepared according to the method described by Cooper and Partridge (16) with a 22% yield: mp 101–106°C (lit. (16) mp 103–106°C); IR ($CHCl_3$) cm^{-1}: 3513 and 3405 (NH_2), 3000 (C-H arom.), 1640 (N-C = N), and 1578 (NH_2); ^1H NMR ($CDCl_3$) δ: 4.85 (broad peak, 1H), 6.93 (d, J = 8.6 Hz, 2H), 7.33 (d, J = 8.6 Hz, 2H), 7.45 (m,3H), 7.84 (br d, 2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 123.1 (CH), 126.8 (CH), 128.2 (CH), 128.6 (CH), 129.1 (CH), 129.5 (C), 130.7 (C), 135.29 (C), 148.1 (N-C=N) ppm; HRMS, *m/z*: 230.0608; calcd. for $C_{13}H_{11}N_2Cl$: 230.0611.

N-*Phenylnorborn-5-enyl-2-carboxamidines* (***16+17***)
These compounds were prepared by the same method as that used to obtain **10**, with norborn-5-ene-2-carbonitrile (as a mixture of *endo* and *exo* epimers) instead of benzonitrile. The yield was 39%. The two epimeric amidines, *endo* **16** and *exo*

17, were easily separated by flash chromatography on silica gel (ethanol as eluent). *endo* **16**: mp 95–97°C; IR ($CHCl_3$) cm^{-1}: 3507 and 3404 (NH_2), 3000 (C-H arom. and alkene), 2975 (C-H aliph.), 1639 (N-C=N), 1586 (NH_2), and 1048 (C-N); ^1H NMR ($CDCl_3$)δ: 1.3–1.5 (m,3H), 2.03 (m,1H), 2.95 (s,1H), 3.10 (m,1H), 3.18 (s,1H), 4.47 (broad peak, 1H), 6.08 (m,1H), 6.31 (m,1H), 6.83 (d, J = 7.1 Hz, 2H), 6.99 (t, J = 7.4 Hz, 1H), 7.28 (t, J = 7.8 Hz, 2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 30.6 (CH_2), 42.9 (CH_2), 43.7 (CH), 47.0 (CH), 50.5 (CH), 121.9 (CH), 122.9 (CH), 129.3 (CH), 132.2 (CH), 138.2 (CH), 148.7 (C), 160.7 (N-C=N) ppm; HRMS, *m/z*: 212.1308; calcd. for $C_{14}H_{16}N_2$: 212.1313. *exo* **17**: mp 83–85°C; IR ($CHCl_3$) cm^{-1}: 3516 and 3407 (NH_2), 3062 and 3012 (C-H arom. and alkene), 1642 (N-C=N), 1589 (NH_2), and 1047 (C-N); ^1H NMR ($CDCl_3$) δ: 1.44 (m,2H), 1.72 (d, J = 8.4 Hz, 1H), 2.09 (t of d, J = 11.6 and 4.0 Hz, 1H), 2.23 (m,1H), 2.94 (s,1H), 3.08 (s,1H), 4.5–5.0 (broad peak, 1H), 6.14 (m,2H), 6.89 (d, J = 7.5 Hz, 2H), 7.04 (t, J = 7.4 Hz, 1H), 7.30 (t, J = 7.8 Hz, 2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 30.8 (CH_2), 41.6 (CH_2), 43.6 (CH), 46.5 (CH), 46.7, 122.1 (CH), 123.2 (CH), 129.4 (CH), 136.1 (CH), 138.3 (CH) ppm; HRMS, *m/z*: 212.1308; calcd. for $C_{14}H_{16}N_2$: 212.1313.

N,N′-*Diphenylbenzamidine* (***18***)
18 was prepared according to the method described by Khanolkar et al. (17) with a 23% yield: mp 146–148°C; IR ($CHCl_3$) cm^{-1}: 3434 and 3382 (NH), 3062 and 3011 (C-H arom.), 1632 (N-C=N), and 1590 (NH); ^1H NMR ($CDCl_3$) δ: 6.48 (s,1H), 6.68 (m,1H), 6.9–7.4 (m,12H), 7.65 (m,1H) ppm; ^{13}C NMR ($CDCl_3$) δ: 121.4 (CH), 122.1 (CH), 122.2 (CH), 123.3 (CH), 123.5 (CH), 128.4 (CH), 128.6 (CH), 129.1 (CH), 129.4 (CH), 129.7 (C), 130.1 (C) ppm; HRMS, *m/z*: 272.1311; calcd. for $C_{19}H_{16}N_2$: 272.1313.

N-*Cyclohexylbenzamidine* (***19***)
19 was prepared according to the method described by Partridge et al. (16). Aluminum trichloride (12 g, 0.09 mol) was added very slowly to benzonitrile (10.3 g, 0.1 mol) and cyclohexylamine (9.9 g, 0.1 mol) in order to maintain the reaction temperature below 100°C. Then, 100 mL of cold water was added. After filtration, 3.98 g (22% yield) of **19** was obtained: mp 116–118°C; IR ($CHCl_3$) cm^{-1}: 3443 and 3323 (NH), 3000 (C-H arom.), 2934 (C-H aliph.), 1608 (N-C=N), and 1049 (C-N); ^1H NMR ($CDCl_3$) δ: 1.1–1.3 (m,4H), 1.3–1.5 (m,2H), 1.61 (m,1H), 1.73 (m,1H), 2.08 (m,2H), 3.6–3.9 (broad peak, 1H), 7.36 (m,3H), 7.50 (m,2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 24.9 (CH_2), 25.8 (CH_2), 33.1 (CH_2), 49.7 (CH), 125.9 (CH), 128.6 (CH), 129.8 (CH), 138.7 (C) ppm; HRMS, *m/z*: 202.1464; calcd. for $C_{13}H_{18}N_2$: 202.1470.

N-*Cyclohexylbutanamidine* (***20***)
20 was prepared according to the procedure used for the preparation of **19** by substituting benzonitrile with butyronitrile. The yield was 8%: mp between 0 and 20°C; IR ($CHCl_3$) cm^{-1}: 3448 (NH), 2965 and 2934 (C-H aliph.), 1613 (N-C=N), and 1050 (C-N); ^1H NMR ($CDCl_3$) δ: 0.92 (t, J = 7.8 Hz, 3H), 1.10 (m,4H), 1.33 (t of q, J = 12.0 and 3.0 Hz, 2H), 1.60 (m,5H), 1.93 (m,2H), 2.07 (t, J = 7.8 Hz, 2H), 3.52 (broad peak, 1H) ppm; ^{13}C NMR ($CDCl_3$) δ: 13.5 (CH_3), 20.4 (CH_2), 24.9 (CH_2), 25.8 (CH_2), 33.2 (CH_2), 39.7 (CH_2), 49.1 (CH) ppm; HRMS, *m/z*: 168.1625; calcd. for $C_{10}H_{20}N_2$: 168.1626.

Amidine salts

N,N-*Dimethyl* N′-*phenylformamidine hydrochloride* (***1HCl***)
The corresponding amidine **1** (622 mg, 4.2 mmol) was added to 10 mL of water and 0.1 N HCl was added until everything dissolved. After the water was evaporated, 581 mg (75% yield) of the desired hydrochloride was obtained: mp 238–240°C; IR (KBr) cm^{-1}: 3018 (C-H arom.), 2975 (C-H aliph.), 1697 (C=N), and 1137 (C-N); ^1H NMR (CD_3OD) δ: 4.49 (s,3H), 4.62 (s,3H), 8.50 (t, J = 7.1 Hz, 1H), 8.60 (m,4H), 9.78 (s,1H) ppm; ^{13}C NMR (CD_3OD) δ: 37.5 (CH_3), 44.4 (CH_3), 120.8 (CH), 128.0 (CH), 130.9 (CH), 155.3 (C) ppm.

N-*Phenylbenzamidine hydrochloride* (***10HCl***)
This compound was prepared according to the procedure used for the preparation of **1**HCl, with 85% yield: mp 230°C (dec.); IR (KBr) cm^{-1}: 3033 (C-H arom.) and 1659 (N-C=N); ^1H NMR (CD_3OD) δ: 7.52 (t, J = 7.7 Hz, 3H), 7.61 (d, J = 7.6 Hz, 2H), 7.69 (t, J = 7.7 Hz, 2H), 7.81 (t, J = 7.6 Hz, 1H), 7.93 (d, J = 8.4 Hz, 2H) ppm; ^{13}C NMR (CD_3OD)δ: 126.6 (CH), 129.4 (CH), 130.3 (CH), 130.6 (CH), 131.6 (CH), 135.4 (C), 166.2 (N-C=N) ppm.

N-*Phenylcyclohex-3-enecarboxamidine hydrochloride* (***11HCl***)
11HCl was prepared according to the procedure used for the preparation of **1**HCl, with 100% yield: mp 190–194°C; IR (KBr) cm^{-1}: 3030 (C-H arom. and C-H alkene), 2820 (C-H aliph.), and 1676 (N-C=N); ^1H NMR (D_2O) δ: 2.0 (m,1H), 2.12 (m,1H), 2.25 (m,2H), 2.45 (m,2H), 2.9 (m,1H), 5.80 (m,2H), 7.35 (d, J = 7.8 Hz, 2H), 7.45 (t, J = 7.5 Hz, 1H), 7.50 (t, J = 7.8 Hz, 2H) ppm; ^{13}C NMR (CD_3OD) δ: 25.8 (CH_2), 26.8 (CH_2), 29.7 (CH_2), 40.6 (CH), 125.2 (CH), 126.8 (CH), 127.9 (CH), 130.3 (CH), 131.5 (CH), 135.0 (C), 173.3 (N-C=N) ppm.

N,N-*Dimethyl*-N′-*phenylformamidine perchlorate* (***1HClO$_4$***)
The corresponding amidine **1** (600 mg, 2.4 mmol) was added to 10 mL of water and 0.1 N $HClO_4$ was added until everything was dissolved. The water was evaporated, after which 474 mg (47% yield) of the desired perchlorate was obtained: mp 154–155°C; IR (KBr) cm^{-1}: 3060 (C-H arom.), 2976 (C-H aliph.), 1701 (N-C=N), and 1136 (C-N); ^1H NMR (CD_3OD) δ: 3.20 (s,3H), 3.36 (s,3H), 7.34 (m,3H), 7.47 (d of t, J = 7.6 and 2.0 Hz, 2H), 8.20 (s,1H ppm); ^{13}C NMR (CD_3OD)δ: 37.3 (CH_3), 44.1 (CH_3), 119.8 (CH), 127.2 (CH), 130.3 (CH), 153.7 (C) ppm.

Authentic samples

N,N-*Dimethyl*-N′-*(4-chlorophenyl)formamidine* (***5***)
5 was prepared according to the procedure used for the preparation of **1** by substituting acetanilide by 4-chloroacetanilide. The yield was 86%: bp 140–150°C/2–3 Torr; IR ($CHCl_3$) cm^{-1}: 3000 (C-H arom.), 2924 (C-H aliph.), 1637 (N-C=N), and 1103 (C-N); ^1H NMR, ($CDCl_3$) δ: 2.94 (s,6H), 6.83 (m,2H), 7.15 (m,2H), 7.41 (s,1H) ppm; ^{13}C NMR ($CDCl_3$) δ: 34.2 (CH_3), 40.0 (CH_3), 122.2 (CH), 127.1 (CH), 128.7 (C), 150.6 (C), 153.3 (N-C=N) ppm; HMRS, *m/z*: 182.0610; calcd. for $C_9H_{11}N_2Cl$: 182.0611.

N,N-*Dimethyl* N′-*(2-chlorophenyl)formamidine (6)*
6 was prepared according to the procedure used for the preparation of amidine **1** by substituting acetanilide by 2-chloroacetanilide. The yield was 85%: bp 166–168°C/2–3 Torr; IR ($CHCl_3$) cm^{-1}: 3010 (C-H arom.), 2930 (C-H aliph.), 1634 (N-C=N), and 1104 (C-N); ^1H NMR ($CDCl_3$) δ: 3.04 (s,6H), 6.87 (m,2H), 7.13 (d of t, J = 7.6 and 1.5 Hz, 1H), 7.34 (d of d, J = 7.9 and 1.5 Hz, 1H), 7.45 (s,1H) ppm; ^{13}C NMR ($CDCl_3$) δ: 34.4 (CH_3), 40.2 (CH_3), 121.3 (CH), 121.4 (CH), 123.0 (CH), 127.3 (CH), 129.6 (C), 153.5 (N-C=N) ppm; HRMS, *m/z*: 182.0610; calcd. for $C_9H_{11}N_2Cl$: 182.0611.

Preparative electrolyses

Electrooxidation of N-N-*dimethyl*-N′-*phenylformamidine hydrochloride (1HCl) (Entry 1, Table 2)*
Hydrochloride **1**HCl (62 mg, 0.34 mmol), in CH_3CN – 0.1 M $LiClO_4$, was electrolyzed on a platinum electrode in a two compartment H-cell at an anodic potential of +0.75 V until the current was 10% of its starting value (2 moles of electrons per mole of **1**HCl). The anolyte was evaporated to dryness in vacuo and 20 mL of 5% $NaHCO_3$ was added to the residue. Extraction with ether (3 × 20 mL) yielded 50 mg of a yellowish solid. The three products detected by TLC (ethanol as eluent) were separated by flash chromatography on silica gel (ethanol as eluent). The less polar fraction consisted of *N,N*-dimethyl-*N′*-(2-chlorophenyl)formamidine (**6**) (<1 mg, <1% yield), identical (^1H and ^{13}C NMR, MS) to an authentic sample. The second fraction consisted of *N,N*-dimethyl-*N′*-(4-chlorophenyl)formamidine (**5**) (8 mg, 13% yield), identical (^1H and ^{13}C NMR, MS) to an authentic sample. The more polar fraction consisted of *N,N*-dimethyl-*N′*-phenylformamidine (**1**) (36 mg, 72% yield).

Electrooxidation of LiCl followed by the addition of 1HClO$_4$ (entry 2, Table 2)
LiCl (60 mg, 1.415 mmol), in CH_3CN – 0.1 M $LiClO_4$, was electrolyzed on a platinum electrode in a two-compartment H-cell at an anodic potential of +0.90 V until the current was 10% of its starting value (1 mole of electrons per mole of LiCl). The electrodes were disconnected and **1**$HClO_4$ (56 mg, 0.23 mmol) was added. After 12 h, work-up of the solution was carried out as above and two spots were observed on TLC (ethanol as eluent). Amidines **5** (4 mg, 10% yield) and **1** (31 mg, 90% yield) were isolated by flash chromatography on silica gel (ethanol as eluent).

Electrooxidation of N-*phenylbenzamidine hydrochloride (10HCl)*
Compound **10**HCl (58 mg, 0.25 mmol), in CH_3CN – 0.1 M $LiClO_4$, was electrolyzed on a platinum electrode in a two compartment H-cell. Two electrolyzes were carried out, one at an anodic potential of +0.90 V and the other at +1.40 V, until the current was 10% of its starting value. A third electrolysis was carried out at a constant current of 2 mA. The charge passed corresponded to 2 moles of electrons per mole of **10**HCl. After the usual work-up, only the parent amidine **10** (0–40% yield) was observed in all cases (identified and quantified by GLC using an authentic sample).

Electrooxidation of N-*phenylcyclohex-3-enecarboxamidine hydrochloride (11HCl)*
Three electrolyses were carried out exactly as above. After the usual work-up, only the corresponding amidine **11** (35–75% yield) was observed in all cases.

Electroreduction of N-*phenylbenzamidine hydrochloride (10HCl)*
Compound **10**HCl (13 mg, 0.055 mmol), in CH_3CN – 0.1 M $LiClO_4$, was electrolyzed on a vitreous carbon electrode in a two compartment H-cell, at a cathodic potential of −1.8 V, until the current was 10% of its starting value (1 mole of electrons per mole of **10**HCl). After the usual work-up, only the parent amidine **10** was obtained (11 mg, 100% yield).

Compound **10**HCl (16 mg, 0.069 mmol), under the same conditions as above, was also electrolyzed three times at −2.6 V until the current was 10% of its starting value (5–8 moles of electrons per mole of **10**HCl). After the usual work-up, the major product was again the parent amidine **10** (25–50% yield). However, in one of these experiments, *N*–benzylaniline was detected by GC–MS.

Electroreduction of N-*phenylcyclohex-3-enecarboxamidine hydrochloride (11HCl)*
Compound **11**HCl (10 mg, 0.042 mmol), in CH_3CN – 0.1 M $LiClO_4$, was electrolyzed on a vitreous carbon electrode in a two compartment H-cell, at a cathodic potential of −2.2 V, until the current was 10% of its starting value (1 mole of electrons per mole of **11**HCl). After the usual work-up, only the parent amidine **11** was obtained (7 mg, 90% yield).

Dependence upon temperature of the excess molar volumes of tetrahydropyran + *n*-alkane mixtures

R. Bravo, M. Pintos, and A. Amigo

Abstract: Excess molar volumes V^E, at 288.15 and 308.15 K and normal atmospheric pressure, are reported for the binary mixtures tetrahydropyran + *n*-alkanes (C_7–C_9). From the results, the differential coefficient $(\partial V^E/\partial T)_p$ was estimated over the entire range of mole fractions. The Prigogine–Flory–Patterson theory and its applicability in predicting V^E is tested.

Key words: Excess molar volumes, digital densimeter, tetrahydropyran, *n*-heptane, *n*-octane, *n*-nonane, Prigogine–Flory–Patterson theory.

Résumé : On a déterminé les volumes molaires d'excès, V^E, de mélanges binaires de tétrahydropyrane et de *n*-alcanes (C_7–C_9), à 288,15 et 308,15 K et à la pression atmosphérique normale. À partir de ces résultats, on a évalué le coefficient différentiel, $(\partial V^E/\partial T)_p$, pour tout l'ensemble des fractions molaires. On a évalué la théorie de Prigogine–Flory–Patterson et son utilité à prédire V^E.

Mots clés : volumes molaires d'excès, densimètre digital, tétrahydropyrane, *n*-heptane, *n*-octane, *n*-nonane, théorie de Prigogine–Flory–Patterson.

1. Introduction

This work is part of an extensive study of excess thermodynamic properties for a large number of solvent pairs. As a complement to previous work (1–3) we report here the excess molar volumes V^E of binary mixtures of tetrahydropyran + *n*-alkanes (*n*-heptane, *n*-octane, and *n*-nonane) at 288.15 and 308.15 K and atmospheric pressure, over the entire range of mole fractions. The results were used to calculate the differential coefficient describing the variation of the excess molar volume with isobaric changes of temperature.

The aim of the present study was also to investigate the effect on the excess molar volumes V^E of the variation of temperature and hydrocarbon chain length of the alkane molecule. We found that the symmetry and magnitude of V^E curves are influenced mainly by structural factors.

Thermodynamic excess properties of liquid mixtures containing molecules of different size and shape have been very successfully discussed on the basis of molecular statistics using the Prigogine–Flory–Patterson (PFP) theory (4–11). In the present investigation, the PFP theory is applied to the binary mixtures analyzed and the predicted V^E are compared to the experimental values.

2. Experimental

The sources and purities of the chemicals used were as follows: tetrahydropyran (THP), Fluka, puriss. p.a. 99.5%; *n*-heptane, Fluka, puriss. p.a. 99.5%; *n*-octane, Fluka, puriss. p.a. 99.5%; and *n*-nonane, Fluka, purum 99%. All liquids were used without further purification, and before use were stored in the dark over molecular sieves (Union Carbide Type 4A) and were partially degassed.

Mixtures were prepared by mass using a Mettler H51 (precision of 1×10^{-5} g) and air-tight stoppered bottles. Conversion to molar quantities was based on the 1985 table issued by IUPAC (12). The possible error in the molar fractions is estimated to be $<10^{-4}$. The densities were measured by an Anton Paar digital precision densimeter (model DMA 60/602) operated in the static mode and capable of a precision of better than 3×10^{-3} kg m^{-3}. A Heto circulating thermostat (type 04 PT 623) maintained the temperature constant to within 0.01 K. Bidistilled degassed water and dry air were used as calibrating substances (13, 14).

Densities of the pure liquids at the temperature of interest in this work, together with some values from the literature (3, 15–18), are given in Table 1.

3. Theory

The excess volumes of THP + *n*-alkanes can be understood reasonably well on the basis of the Prigogine–Flory–Patterson theory of mixtures. In this theory the excess molar volume can be expressed as the sum of three terms: an interactional term that is proportional to the Flory χ_{12} parameter, a free volume contribution that originates from a difference in the degree of thermal expansion between the two compo-

nents, and a P^* contribution that arises from the differences in the internal pressures and reduces the volumes of the components.

The following brief sketch of the model is intended to make clear the physical meaning of its parameters.

Van and Patterson's approximate expression of V^E (9) in terms of the three contributions is

$$[1] \qquad \frac{V^E_{\text{Interactional}}}{(xV^*)_1 + (xV^*)_2} = \frac{(\tilde{V}^{1/3} - 1)\tilde{V}^{2/3}\psi_1\theta_2\chi_{12}}{[(4/3)\tilde{V}^{-1/3} - 1]\tilde{V}}$$

$$[2] \qquad \frac{V^E_{\text{Curvature}}}{(xV^*)_1 + (xV^*)_2} = -\frac{(\tilde{V}_1 - \tilde{V}_2)^2((14/9)\tilde{V}^{-1/3} - 1)\psi_1\psi_2}{[(4/3)\tilde{V}^{-1/3} - 1]\tilde{V}}$$

$$[3] \qquad \frac{V^E_{P^*\text{effect}}}{(xV^*)_1 + (xV^*)_2} = \frac{(\tilde{V}_1 - \tilde{V}_2)(P^*_1 - P^*_2)\psi_1\psi_2}{P^*_2\psi_1 + P^*_1\psi_2}$$

where the contact energy fraction ψ_i is given by

$$[4] \qquad \psi_1 = (1 - \psi_2) = (\Phi P^*)_1/[(\Phi P^*)_1 + (\Phi P^*)_2]$$

The reduction parameters of the components or solutions are obtained through the relationships of the Flory model (6), i.e., eqs. [5]–[10].

The reduced volume for pure substance i is defined in terms of the thermal expansion coefficients α_i

$$[5] \qquad \tilde{V}_i = \left[\frac{[1 + (4/3)\alpha_i T]}{(1 + \alpha_i T)}\right]^3$$

At zero pressure, the reduced volume and temperature satisfy the reduced equation of state

$$[6] \qquad \tilde{T}_i = (\tilde{V}_i^{1/3} - 1)/(\tilde{V}_i^{4/3})$$

Table 2. Parameters for the pure components.

Liquid	V^* (cm^3 mol^{-1})	P^* (J cm^{-3})
Heptane	113.65[a]	431[a]
Octane	127.89[a]	439[a]
Nonane	142.24[b]	435[b]
THP	77.12[c]	663[c]

[a]Reference 19.
[b]Reference 20.
[c]Reference 21.

where the reduced temperature for a mixture is defined as

$$[7] \qquad \tilde{T} = \frac{(\Phi P^* \tilde{T})_1 + (\Phi P^* \tilde{T})_2}{(\Phi P^*)_1 + (\Phi P^*)_2 - \Phi_1\theta_2\chi_{12}}$$

and the characteristic pressure is

$$[8] \qquad P^*_i = (\alpha_i/\kappa_i)T(\tilde{V}_i)^2$$

The segment fraction ϕ_i and the site fraction θ_i are defined as

$$[9] \qquad \Phi_1 = (1 - \Phi_2) = (xV^*)_1/[(xV^*)_1 + (xV^*)_2]$$

and

$$[10] \qquad \theta_1 = (1 - \theta_2) = \Phi_1/[\Phi_1 + (\Phi s)_2/s_1]$$

The parameter s_1/s_2 is the ratio of the surface contact sites per segment for the respective components.

Table 2 contains, for all pure components used in this work, the characteristic parameters necessary for the application of the PFP theory. The reducing parameters for the *n*-alkanes have been obtained from refs. 19 and 20. To calculate these parameters for THP, the dependence of the density upon temperature and pressure must be known. This dependence was estimated using the Lydersen–Greenkorn–Hougen method (21). In both cases the reducing parameters determined are taken to be constant within the temperature and pressure range considered here. The ratio s_1/s_2 has been approximated (22) by

$$[11] \qquad s_1/s_2 = (V^*_2/V^*_1)^{1/3}$$

where V^*_i is the hard core volume.

As in Flory's original theory of nonpolar molecules, χ_{12} is an adjustable mixing parameter and it was calculated from the experimental V^E data. χ_{12} is supposed to be a constant parameter independent of temperature.

4. Results and discussion

The experimental values of V^E at the temperatures 288.15 and 308.15 K are summarized in Table 3.

All mixtures exhibit positive V^E values, increasing with the length of the hydrocarbon chain of the alkane. The x vs. V^E curves are almost symmetrical about $x = 0.5$. The plot of V^E at 308.15 K for the binary mixture THP + *n*-heptane,

given in Fig. 1, is a typical example of the results obtained in this work. As can be seen from Table 3, the excess molar volume increases with the temperature.

A function of the form

$$[12] \quad V^E/(\text{cm}^3\ \text{mol}^{-1}) = x(1-x) \times \sum_{i=1}^{n}\sum_{j=1}^{3} A_{ij}(T-T_0)^{j-1}(2x-1)^{i-1}$$

where T_0 is the reference temperature (T_0 = 298.15 K), was fitted to the results for each mixture using the ordinary (unweighted) least-squares method. In this fit we include our experimental results obtained for the same binary mixtures at the temperature 298.15 K (3). The parameters A_{ij} and the standard deviation s of the fit are listed in Table 4. These parameters were used to calculate the solid curves in Figs. 1 and 2.

Values of $(\partial V^E/\partial T)_p$ calculated using eq. [12] for the system THP + n-heptane at 308.15 K are plotted in Fig. 2. Curves for the excess partial molar quantities V_i^E and $(\partial V_i^E/\partial T)_p$ of component i (i = 1 for THP, i = 2 for n-heptane) at 308.15 K are also included in Figs. 1 and 2.

The predictions of V^E using the PFP theory are excellent for the mixtures analyzed, as shown by Fig. 1. This can be seen by considering the results in Table 5. For all the mixtures studied the interactional term was found to be positive, being the most important contribution. The magnitude and sign of

Evaluation of thermodynamic parameters on highly correlated chemical systems: a spectrophotometric study of the 1:1 and 1:2 equilibria between I_2 and R_4todit = 4,5,6,7-tetrathiocino[1,2-*b*:3,4-*b*′]diimidazolyl-1,3,8,10-tetraalkyl-2,9-dithione; (R = Bu, Me (new data); Et, Ph (reinvestigation)). Crystal and molecular structure of the charge-transfer complex Bu_4todit·$2I_2$

Francesco Bigoli, Paola Deplano, Maria Laura Mercuri, Maria Angela Pellinghelli, Antonio Sabatini, Emanuele F. Trogu, and Alberto Vacca

Abstract: The reactions between Bu_4todit and I_2 in $CHCl_3$ solution have been investigated by spectrophotometry at different temperatures. Evidence for the stepwise formation of the 1:1 and 1:2 charge-transfer complexes has been obtained by computer analysis of the experimental data. The stability constants of both complexes and the corresponding standard enthalpy and entropy changes have been calculated. The 1:2 complex has been characterized in the solid state by an X-ray structural study: the crystals of Bu_4todit·$2I_2$ are monoclinic, space group $C2/c$, $a = 16.352(6)$, $b = 9.376(5)$, $c = 23.470(7)$ Å, $\beta = 99.78(2)°$, $Z = 4$, $R = 0.0579$. The molecular structure shows that the two thionic sulfur atoms coordinate two diiodine molecules, the bond distances and angles being similar to those observed previously in Et_4todit·$2I_2$. On the contrary, the solution studies disagree with the previous investigations on Et_4todit and Ph_4todit, where the absorbance data were explained assuming the formation of the 1:1 complex only. A new calculation procedure for the least-squares minimization of spectrophotometric data, based on Powell's direct search method, has been developed. This procedure allows for the refinement of the standard enthalpy and entropy changes from a set of absorbance data at different temperatures. Convergence has been attained for the reaction of diiodine with Bu_4todit and Me_4todit (new data) and also for Et_4todit and Ph_4todit (old data).

Key words: equilibrium constants, charge-transfer complexes, Fourier transform–Raman, X-ray, I_2-thioamides.

Résumé : Faisant appel à la spectrophotométrie, on a étudié les réactions entre le Bu_4todit et le I_2, en solution dans le chloroforme, à diverses températures. En se basant sur une analyse par ordinateur des données expérimentales, on a obtenu des données suggérant une formation par étapes de complexes de transfert de charge 1 : 1 et 1 : 2. On a calculé les constantes de stabilité des deux complexes ainsi que les changements correspondants d'enthalpie et d'entropie standard. On a caractérisé les complexes 1 : 2 à l'état solide par diffraction des

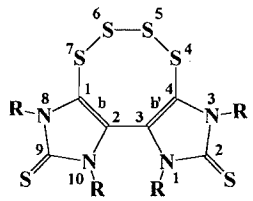
rayons X : les cristaux de Bu_4todit·$2I_2$ sont monocliniques, groupe d'espace *C2/c*, *a* = 16.352(6), *b* = 9.376(5), *c* = 23,470(7) Å, β = 99,78(2)°, *Z* = 4, *R* = 0,0579. Les structures moléculaires montrent que les deux atomes de soufre thionique sont coordonnés à deux molécules d'iode et que les longueurs et les angles des liaisons sont semblables à ceux observés antérieurement pour le Et_4todit·$2I_2$. Par contre, les études en solution sont en désaccord avec les résultats des études antérieures sur le Et_4todit et le Ph_4todit dans lesquelles des données d'absorbance ont été expliquées en faisant l'hypothèse qu'il n'existait que des complexes 1 : 1. On a mis au point une nouvelle méthode de calcul pour la minimisation, par la technique des moindres carrés, des données spectrophotométriques; elle est basée sur la méthode de recherche directe de Powell. Cette procédure permet de raffiner les changements d'enthalpie et d'entropie standard à partir d'un ensemble de données d'absorbance à diverses températures. On a pu obtenir une convergence pour la réaction du diiode avec le Bu_4todit et le Me_4todit (nouvelles données) ainsi que pour le Et_4todit et le Ph_4todit (données antérieures).

Mots clés : constantes d'équilibre, complexes de transfert de charge, Raman par transformation de Fourier, rayons X, I_2-thioamides.

[Traduit par la rédaction]

Introduction

The new series of heterocycles R_4todit = 4,5,6,7-tetrathiocino[1,2-*b*:3,4-*b'*] diimidazolyl-1,3,8,10-tetraalkyl-2,9-dithione, which is depicted below for clarity (1), is a class of polyfunctional donors containing two equivalent thiocarbonyl groups located in positions far apart in the molecule.



R_4todit

Consequently, these molecules may act as bridging ligands in the preparation of polynuclear metal complexes, and indeed a variety of metal–sulfur polymers have been characterized (2–4). Also, these molecules react with diiodine to produce molecular complexes. In the case of R = Et, the expected 1:2 complex was isolated in the solid state, and characterized by X-ray diffractometric studies. In $CHCl_3$ solutions, instead, only the 1:1 complex seemed to exist in the concentration range explored (5), as was also found in the case of the R = Ph derivative (6). These results were unexpected since, due to the structural and electronic features of the ligand, the coordination at one thionic sulfur should not significantly affect the donor capability of the other.

Both the equilibrium constants and the molar absorptivities of the 1:1 complex had been calculated simultaneously from spectrophotometric data using the computer program SUPERSPEC (7) derived from SUPERQUAD. Despite many attempts it was not possible to fit the experimental data by means of models different from the 1:1 case. We tentatively explained these intriguing results by assuming that "complexes of stoichiometry higher than 1:1 exist in solution at oversaturation or incipient precipitation conditions" (5). However, another reason for the failure to identify the 1:2 complex may be related to the procedure used in analysing the spectrophotometric data. Such procedures, including the one used by SUPERSPEC, are all based on the assumption that the following equation, derived from the well known Lambert–Beer law, is valid:

$$[1] \quad A = l\Sigma c_i\epsilon_i$$

where A is the absorbance of the solution at a given wavelength, l is the optical path length, and c_i and ϵ_i, are, respectively, the molar concentrations and molar absorptivities (at the same wavelength) of the absorbing species. These methods allow the simultaneous determination of both molar absorptivities and equilibrium constants β. In fact, the concentrations of the absorbing species are a function of the equilibrium constants, $c_i = f_i(\beta)$, and, as a consequence, the absorbances A are also β dependent:

$$[2] \quad A = \Sigma f_i(\beta)\epsilon_i$$

This equation is nonlinear with respect to the parameters β and ϵ_i, and even contains the product of these quantities. This introduces a strong correlation between the parameters and, in some cases, the least-squares minimization process may fail, as the matrix of the normal equations may be nearly singular. Such a correlation may be resolved if the spectra of solutions that contain the various absorbing species in a wide range of mutual molar ratios are available. Another source of correlation may derive from the greater or lesser proximity of the molar absorptivity values of the different species; if these values are identical any method of refinement will fail.

Recently, the synthesis of R_4todit molecules of varying R substituents was stimulated by the fact that they show anticancer activity, which depends on the alkyl substituents (8). Among these the *n*-butyl derivative showed higher solubility than others previously investigated. Hence we decided to perform an extensive solution study on the Bu_4todit compound. The formation of 1:1 and 1:2 complexes was clearly shown using the computer program SUPERSPEC, although a similar attempt to solve the Me_4todit–diiodine system in the same concentration range by considering the formation of both the 1:1 and 1:2 species was unsuccessful. The discrepancy between these results prompted us to develop a new refinement strategy for the analysis of this type of experimental data, which could solve, coherently and satisfactorily, both the systems described above (R = Bu and Me) and those previously reported (R = Et and Ph).

Experimental

Synthesis

Twice sublimed I_2, and $CHCl_3$ (stored over molecular sieves) were Carlo Erba ACS grade. The donors Me_4todit and

Bu_4todit were prepared according to ref. 1. Anal. calcd. for Bu_4todit ($C_{22}H_{36}N_4S_6$): C 48.58, H 6.69, N 10.53, S 35.32; found: C 48.14, H 6.61, N 10.21, S 35.05.

When mixed with I_2 in $CHCl_3$, in ratios varying between 1:2 and 1:10 (ligand:I_2), the analytical and spectroscopic results on the solids obtained by slow evaporation of the reagent solution are always the same according to the formulation R_4todit·$2I_2$ (R = Me, Bu). In the R = Bu case, the 1:2 complex was isolated in the form of lustrous red-brown crystals suitable for X-ray diffraction studies.

Anal. calcd. for Me_4todit·$2I_2$ ($C_{10}H_{12}N_4S_6I_4$): C 13.45, H 1.36, N 6.30, S 21.66; found: C 12.90, H 1.09, N 6.11, S 20.80.

Anal. calcd for Bu_4todit·$2I_2$ ($C_{22}H_{36}N_4S_6I_4$): C 25.01, H 3.43, N 5.30, S 18.21; found: C 24.83, H 3.32, N 5.61, S 17.95.

Spectroscopic measurements

IR spectra (cm^{-1}) were recorded on a Perkin Elmer model 983 spectrophotometer as KBr pellets.

Me_4todit·$2I_2$: 2923vw, 1518m, 1445s, 1367s, 1332m, 1223w, 1154s, 1101w, 1079w, 1035ms 861m, 829m, 762w, 728w, 707w, 617w, 533m, 418ms, 381w, 300w, 273m, 242w, 219w.

Bu_4todit: 2960s, 2940ms, 2878ms, 1437s, 1405vs, 1335s, 1360s, 1337m, 1295m, 1220vs, 1197w, 1155w, 1118w, 938w, 900w, 860vw, 830vw, 737vw, 640vw, 432w, 420w.

Bu_4todit·$2I_2$: 2956w, 2925w, 2857w, 1518m, 1461w, 1448s, 1405*vs*, 1390s, 1344m, 1310m, 1295m, 1251w, 1217s, 1176w, 1151s, 1117mw, 1069w, 948w, 937mw, 919w, 814m, 763w, 736w, 696w, 562w, 496w, 412w.

FT–Raman spectra (resolution ±4 cm^{-1}) were recorded on a Bruker RFS 100 Fourier Transform Raman spectrophotometer, operating with an exciting frequency of 1064 nm (Nd:YAG laser). The power level of the laser source was 300 mW for the solution samples, and varied between 10 and 30 mW for the solid samples. The detection of the signal was made with an indium–gallium–arsenide detector operating at room temperature. The $CHCl_3$ solutions and the solid samples were introduced, respectively, into a suitable cell (Suprasil 300, HELLMA cell of 0.5 cm thickness) and into a capillary tube and then fitted into the compartment designed for 180° scattering geometry. Five solutions having constant concentration of the donor and increasing concentrations of I_2 in the ratios 1:0.5, 1:1, 1:2, 1:4, and 1:6 for each derivative were prepared. Due to the different solubility of the adducts, the concentrations of the donors were as follows: [Me_4todit] = 1.65×10^{-3} mol dm^{-3}; Bu_4todit = 1.25×10^{-2} mol dm^{-3}; [Et_4todit] = 6.25×10^{-3} mol dm^{-3}; [Ph_4todit] = 2.50×10^{-3} mol dm^{-3}.

Solution studies

Electronic spectra were measured at different temperatures in the 10–35°C range in $CHCl_3$ solutions with a Cary 5 spectrophotometer equipped with a temperature probe accessory connected to a thermostatable multicell block.

Me_4todit: a set of eight solutions containing a fixed I_2 concentration (5.00×10^{-4} mol dm^{-3}) and variable Me_4todit concentrations ranging from 2.50×10^{-4} to 5.00×10^{-3} mol dm^{-3} (in the ratios [I_2]:[Me_4todit] = 1:0.5; 1:1; 1:1.5; 1:2; 1:3; 1:4; 1:6; 1:10) was prepared, and the spectra were recorded in the 450–550 nm range using 1 cm silica cells. Three other sets of solutions were prepared with a fixed Me_4todit concentration ((a) 2.50×10^{-4} mol dm^{-3}; (b) 6.04×10^{-5} mol dm^{-3}) and variable I_2 concentrations ranging from (a) 5.00×10^{-4} to 1.00×10^{-2} mol dm^{-3} (in the ratios [Me_4todit]:[I_2] = 1:2; 1:4; 1:8; 1:12; 1:20; 1:32; 1:40); (b) 1.21×10^{-4} to 6.04×10^{-3} mol dm^{-3} (in the ratios [Me_4todit]:[I_2] = 1:2; 1:4; 1:10; 1:20; 1:40, 1:60; 1:80; 1:100), and their spectra were measured in the range 260–450 nm in 1 mm silica cells. In the third set of solutions, the donor concentration was 2.50×10^{-4} mol dm^{-3} and I_2 concentrations ranged from 5.00×10^{-5} to 5.00×10^{-4} mol dm^{-3} (in the ratios [Me_4todit]:[I_2] = 1:0.2; 1:0.4; 1:0.6; 1:0.8; 1:1; 1:1.4; 1:1.8; 1:2) and their spectra were recorded between 550 and 270 nm.

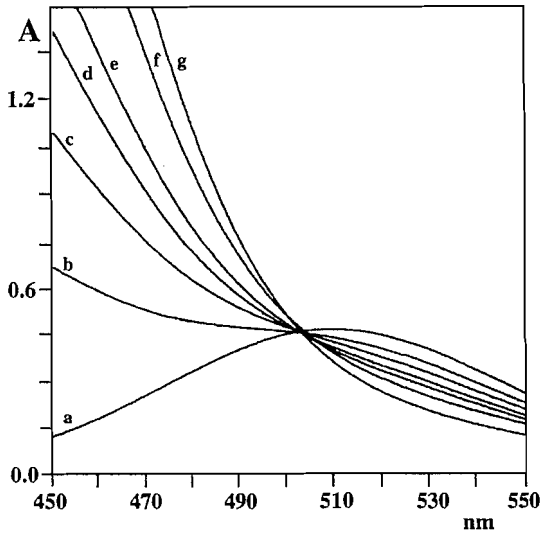

Fig. 1. Visible spectra at 293 K in a 1.0 cm cell of $CHCl_3$ solutions containing constant amounts of I_2 ($c = 5.0 \times 10^{-4}$ mol dm^{-3}) and variable Bu_4todit concentrations in the ratios: (a) 1:0; (b) 1:0.25; (c) 1:0.5; (d) 1:1; (e) 1:1.5; (f) 1:2; (g) 1:10.

Bu_4todit: a set of seven solutions containing fixed I_2 concentration (5.00×10^{-4} mol dm^{-3}) and variable Bu_4todit concentrations ranging from 1.25×10^{-4} to 5.00×10^{-3} mol dm^{-3} (in the ratios [I_2]:[Bu_4todit] = 1:0.25; 1:0.5; 1:1; 1:1.5; 1:2; 1:4; 1:10; see Fig. 1) was prepared, and the spectra were recorded in the 450–550 nm range in 1 cm silica cells. Another set of 13 solutions was prepared with a fixed Bu_4todit concentration (2.50×10^{-4} mol dm^{-3}) and variable I_2 concentrations ranging from 2.50×10^{-4} to 1.00×10^{-2} mol dm^{-3} (in the ratios [Bu_4todit]:[I_2] = 1:0.2; 1:0.4; 1:0.6; 1:0.8; 1:1; 1:1.4; 1:1.8; 1:2; 1:4; 1:8; 1:12; 1:20; 1:40; see Fig. 2), and their spectra were measured in the range 260–550 nm in 1 mm silica cells. In a third set of solutions, the donor concentration was 5.00×10^{-5} mol dm^{-3} and I_2 concentrations ranged from 1.25×10^{-4} to 5.00×10^{-3} mol dm^{-3} (in the ratios [Bu_4todit]:[I_2] = 1:2.5; 1:5; 1:10; 1:20; 1:40; 1:60; 1:80; 1:100), and their spectra were recorded between 500 and 270 nm. The previously reported data were used to reinvestigate the cases of the R = Et and Ph derivatives (5, 6). In addition, for R = Et, a set of 13 solutions was prepared with a fixed Et_4todit concentration (2.50×10^{-4} mol dm^{-3}) and variable I_2 concentrations ranging from 2.50×10^{-4} to 1.00×10^{-2} mol dm^{-3} (in the ratios [Et_4todit]:[I_2] = 1:0.2; 1:0.4; 1:0.6; 1:0.8; 1:1; 1:1.4; 1:1.8; 1:2; 1:4; 1:8; 1:12; 1:20; 1:40), and the absorbances were monitored in the 260–550 nm range, using 0.1 cm quartz cells.

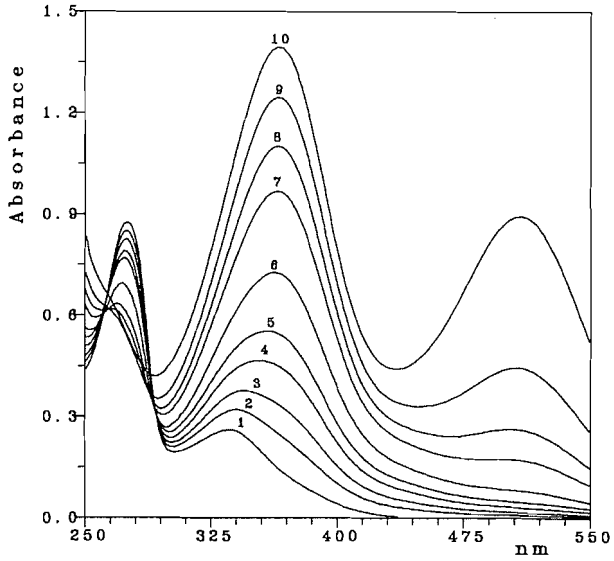
Fig. 2. UV–visible spectra at 293 K in a 0.1 cm cell of $CHCl_3$ solutions containing fixed amounts of Bu_4todit ($c = 2.5 \times 10^{-4}$ mol dm^{-3}) and variable I_2 concentrations in the ratios: (1) 1:0; (2) 1:0.4; (3) 1:0.8; (4) 1:1.4; (5) 1:2; (6) 1:4; (7) 1:8; (8) 1:12; (9) 1:20; (10) 1:40.



Calculations

The program SUPERSPEC derived from SUPERQUAD has previously been described (7). It was used to refine simultaneously the equilibrium constants and the molar extinction coefficients from the experimental absorbances every ten nanometers in the 250–550 nm range at six different temperatures. The total number of experimental points was: Me_4todit = 2078, Bu_4todit = 2115, Ph_4todit = 871, Et_4todit = 1260. The values of $\Delta H°$ and $\Delta S°$ were calculated by least-squares fitting of the corresponding ln β versus $1/T$ according to the van't Hoff equation.

The same experimental data were used to calculate $\Delta H°$, $\Delta S°$, and the molar extinction coefficients by POWELSPEC, a new program that uses Powell's direct search minimization method (9). The assumption was made that molar absorptivity values ϵ_i do not vary in the temperature range explored. Schemes 1 and 2 demonstrate the main differences between the two programs.

X-ray crystallography

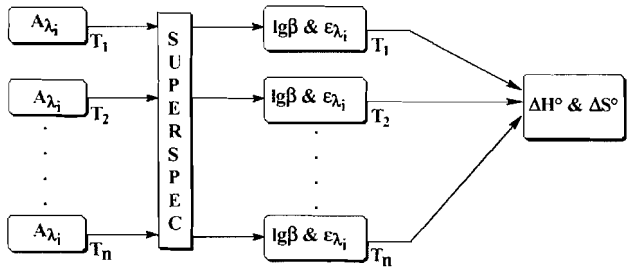
Crystal data are as follows:

$C_{22}H_{36}N_4S_6I_4$; MW = 1056.531; monoclinic, space group $C2/c$, a = 16.352(6), b = 9.376(5), c = 23.470(7) Å, β = 99.78(2)°(by least-squares refinement from the θ values, in the range 8°–17°, of 30 reflections accurately measured), U = 3546(3) $Å^3$, D_c = 1.979 Mg m^{-3}, Z = 4, $F(000)$ = 2016, Mo-Kα radiation (λ = 0.71073 Å), μ= 38.38 cm^{-1}. Crystal dimensions: 0.13 × 0.21x × 0.26 mm^3.

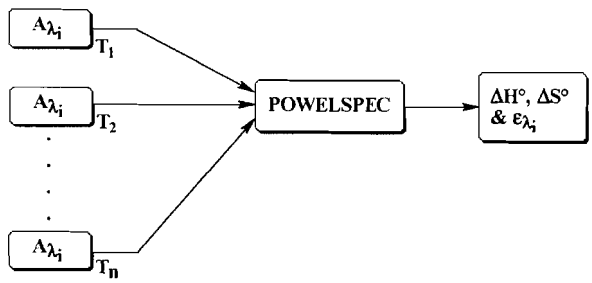
Data collection and processing

Data collection was made on a Siemens AED diffractometer with Nb-filtered Mo-Kα radiation using the θ–2θ scan mode. Of a total of 4231 measured reflections ($\pm h$, $\pm k$, $\pm l$), 1393 having $I \geq 2\sigma(I)$ were considered as observed and were employed in the analysis. The recorded intensities were corrected for the Lorentz polarization factor, for absorption (maximum and minimum values 1.23820, 0.79242), and extinction (maximum and minimum values 1.22639, 0.86078) following the empirical method of Walker and Stuart (10*a*).[2]

Scheme 1



Scheme 2



Structure analysis and refinement

The structure was solved by Patterson and Fourier methods and refined by full-matrix least squares, with anisotropic thermal parameters for all non-hydrogen atoms excluding those of the substituents groups, using the SHELX-76 program (11).

The coordinates of the hydrogen atoms placed at their geometrically calculated positions were not refined, but introduced in the final structure factor calculation with a single-refined isotropic thermal parameter (U = 0.1939(252) $Å^2$).

The scattering factors and corrections for anomalous dispersion effects were those from ref. 12. The weighting scheme used in the final cycles was $w = 0.8921(\sigma^2(F_o) + 0.001719F_o^2)^{-1}$. Final convergence was reached at an R value of 0.0579 (R' = 0.0697). The final electron density difference synthesis showed no peaks >0.94 and <−1.05 e $Å^{-3}$. The programs ABSORB (10*b*), PARST (13), PLUTO (14), and ORTEP (15) were used. Calculations were carried out on the Gould-Sel 32/77 computer of the C.N.R. Centro di Studio per la Strutturistica Diffrattometrica. Final atomic coordinates are in Table 1, bond distances and angles in Table 2.[3]

[2] The program ABSORB (10*b*) was used.

[3] Tables of fractional atomic coordinates for the H atoms and anisotropic thermal parameters have been deposited. Copies of these tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

The table of fractional atomic coordinates has also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

Results and Discussion

The spectrophotometric data concerning the reactions of Bu_4todit and I_2 were analysed using the computer program SUPERSPEC (see Experimental). Assuming that both complexes Bu_4todit·I_2 and Bu_4todit·$2I_2$ are present at equilibrium, convergency is attained for all temperatures, the root-mean-square error on the absorbances being less than 0.01. The values of the complex formation constants are listed in Table 3. The values of the enthalpy and entropy changes interpolated from the van't Hoff plot (correlation coefficients 0.999 and 0.991 for the 1:1 (**I**) and 1:2 (**II**) complexes, respectively) are also reported in Table 3.

It must be noted that the agreement between $\Delta H^\circ_{\mathbf{I}}$ and $\Delta S^\circ_{\mathbf{II}}$ obtained for this complex and the corresponding values of the previously investigated complexes (4, 5) is very poor. Moreover, further results (see solution FT–Raman studies) suggested similar interaction strengths between the donors and I_2. This poor agreement seems to indicate that the old results are questionable.

These conflicting results induced us to study another compound of the R_4todit class, namely, the R = Me derivative. The reaction of this ligand with diiodine was investigated spectrophotometrically, using concentration ranges of the reagents as close as possible to those used in the Bu_4todit investigation. The computer refinement of these data, using SUPERSPEC, converged at all temperatures for the equilibrium model consisting of the 1:1 and 1:2 complex species. Unfortunately, the fit of experimental and calculated data was less satisfactory and the dependence of the ln β values versus $1/T$ was far from being linear. In fact, in this system high values of the correlation coefficients among the parameters (equilibrium constants and molar absorptivities) were found. In addition, the values of the calculated molar absorptivities of the Me_4todit complexes were quite different at the different temperatures, whereas this behaviour was found neither for the ligand Me_4todit nor for Bu_4todit or its complexes.

For this reason we thought it advisable to carry out a refinement using the spectrophotometric data of Me_4todit at all temperatures simultaneously, and assuming that (*i*) the equilibrium model is that of the stepwise addition of two diiodine molecules to the ligand, (*ii*) the molar absorptivities are constant quantities within the temperature range investigated, and (*iii*) the values of the formation constants follow the van't Hoff equation. In this procedure the function to be minimized is the sum of the weighted squared residuals between experimental and calculated absorbances, *U*, and the refinable parameters are the ΔH°, ΔS° values and the molar absorptivities of the two complexes. The equilibrium constants are calculated using the formula:

$$[3] \quad -RT \ln \beta = \Delta H^\circ - T\Delta S^\circ$$

The calculation was performed with a new program, POWELSPEC, which uses Powell's direct search minimization method (9). The ΔH° and ΔS° values obtained are reported in Table 4. They appear realistic when compared with those previously obtained for Bu_4todit using SUPERSPEC.

A POWELSPEC refinement of Bu_4todit yielded ΔH° and ΔS° values close enough to the SUPERSPEC results. The small differences, which are, however, significant even considering the error limits of the parameters, can be ascribed to the different assumptions of the two minimization methods. In particular, the standard deviations of the parameters are significantly smaller in the POWELSPEC refinement. This is due both to the constraints regarding temperature dependence of the formation constants and constancy of the molar absorptivity and to

Table 3. Logarithms of the equilibrium constants (standard deviations in parentheses) calculated by means of SUPERSPEC, and standard enthalpy and entropy changes for the 1:1 (**I**) and 1:2 (**II**) complexes between Bu_4todit and I_2 in $CHCl_3$ solutions.

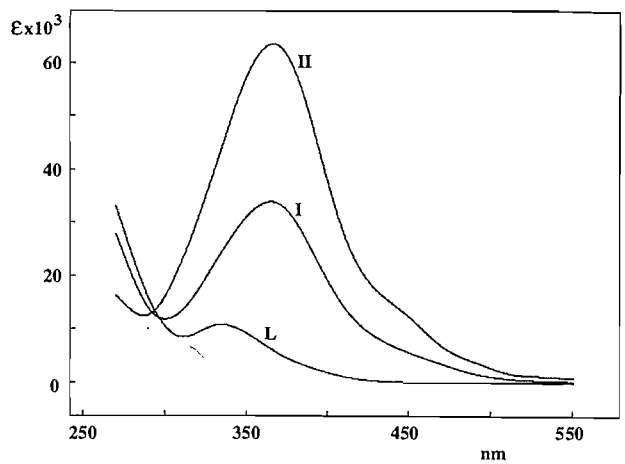
the higher value of the ratio between experimental data and parameters to be refined.

These encouraging results induced us to also reconsider the equilibria between diiodine and the Et_4todit and Ph_4todit ligands, on the basis of the model consisting of the two complexes. After processing the old data with POWELSPEC, convergency was attained, and the $\Delta H°$ and $\Delta S°$ values of the refined parameters are close to the corresponding values obtained for the other two systems. Once convergence is reached, the standard deviations of the parameters and their correlation coefficient were calculated by inversion of the matrix of the second derivatives of the function U, the derivatives being obtained by numerical differentiation. With these values, the estimated errors in the log β values are calculated using the standard procedure for the propagation of variance. This method of calculating errors is derived from the method first used in LETAGROP (16). The whole set of results is summarized in Table 4 and a comparison of values obtained previously and in this work is reported in Table 5.

The calculated spectra of the 1:1 and 1:2 complexes of diiodine and Bu_4todit are reported as an example in Fig. 3. The new strong bands at 370 nm are attributed to the charge-transfer transitions, while the characteristic band of I_2 is blue-shifted and appears as a shoulder at 450 nm. The characteristic free ligand band is blue-shifted and does not appear in the wavelength range explored. The main features of the spectra of the other complexes are similar.

The new calculation procedure used by the program POWELSPEC is significantly more time consuming than that used by SUPERSPEC. However, it appears to be more reliable, robust, and stable, as convergence was reached for all systems under investigation. The occasional failures of SUPERSPEC are ascribed to the critical step of inversion of the normal equations matrix, which may be ill-defined and nearly singular, when the parameters are highly correlated. On the contrary,

Fig. 3. Calculated UV–visible spectra of the 1:1(**I**) and 1:2 (**II**) complexes between Bu_4todit (**L**) and I_2 at 283 K in $CHCl_3$ solutions. The spectrum of the free ligand is reported for comparison.



Powell's method does not require inversion of any matrix for direct search of the minimum.

It is noteworthy that all systems have been solved in terms of the same equilibrium model (which includes the 1:2 complex species isolated both previously and now in the solid state) and that the corresponding values of the thermodynamic functions fall in the range of medium-strong adducts. In particular, the values of $\Delta H°_I$ and $\Delta S°_I$ are comparable to those previously determined for the reaction of diiodine with the corresponding monothiones (17). This supports our results.

Fourier transform – Raman spectroscopy

The FT–Raman spectra of $CHCl_3$ solutions obtained by addition of increasing amounts of I_2 to the R_4todit being investigated show the same features in the characteristic region of the

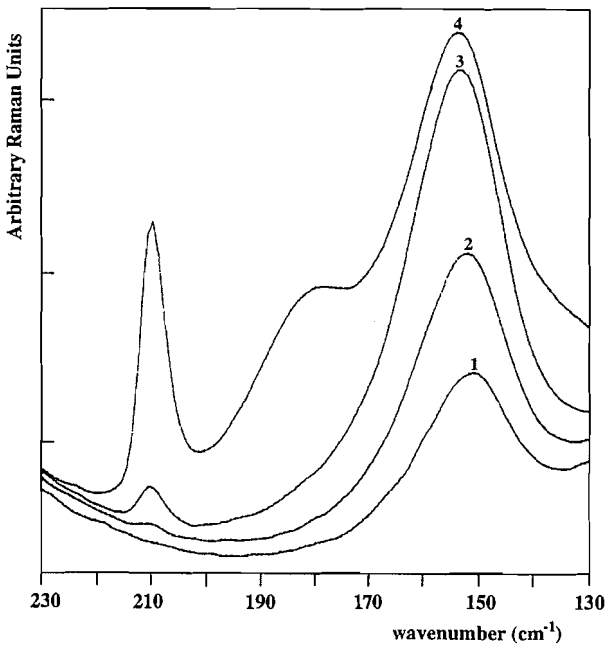
Fig. 4. FT–Raman spectra in a 0.5 cm cell of $CHCl_3$ solutions of Bu_4todit ($c = 1.25 \times 10^{-2}$ mol dm^{-3}) and variable I_2 concentrations in the ratios: (1) 1:0.5; (2) 1:1; (3) 1:2; (4) 1:4.



I–I vibrations, and the Bu_4todit+I_2 case is reported as an example in Fig. 4. One peak at 152 cm^{-1}, which is neither present in the spectrum of the donors nor in that of I_2, arises on addition of diiodine to the donors. This peak is attributed to the stretching vibration of coordinated I_2. Uncoordinated I_2, instead, shows the peak due to the stretching vibration at 210 cm^{-1} (18). A negative shift of the ν(I–I) vibration, and therefore a lowering of the force constant, is expected when I_2 interacts with a donor, since the formation of a complex leads to a decrease in I—I bond order, in agreement with a MO description that shows that the HOMO has some σ^* I—I antibonding character (19). Stronger interaction leads to larger negative shifts of the ν(I–I) peak. This was verified in a series of I_2 complexes for which structural data were available (20).

An identical position for the ν(I–I) peak in all adducts, therefore, suggests that the interaction between I_2 and the R_4todit is of the same strength. The sequence found in the series investigated (Ph < Et≈Me < *n*-Bu) suggests an increase in interaction strength on increasing the electrodonation power of the R substituents; this seems to contrast with the FT–Raman results. However, solution Raman studies seem to be more informative in determining the interaction strength, since thermodynamic functions may contain large contributions due to solvation effects.

The shoulder at 180 cm^{-1}, which appears in the more concentrated solutions ($[I_2] > 5.0 \times 10^{-2}$ mol dm^{-3}), is also present in the spectrum of free iodine solutions at the same concentration, falls at the same position as in solid I_2 (21), and is attributed to autoassociated I_2.

The FT–Raman spectra of the solid complexes (R_4todit·$2I_2$) show the characteristic ν(I–I) vibrations at 146 cm^{-1} (R = Et), 157 cm^{-1} (R = Bu), 167–146 cm^{-1} (R = Me), 171 cm^{-1} (R = Ph). Solid state effects could be invoked to explain the differences found in the position of this peak in solution and in the solid state. However, a comparison of the R = Et and R = Bu complexes of known X-ray structures shows that while a greater reduction of the I—I distance is found in the R = Bu case, an unexpectedly lower shift is observed in the ν(I–I) band.

Crystal structure of Bu_4todit·$2I_2$

The molecular structure of this neutral molecular compound, which, like Et_4todit·$2I_2$(5) and bis(morpholinothiocarbonyl)–bis(diiodine)(22), belongs to a series with two S heteroatoms in the donor and two diiodine molecules as acceptors, is shown in Fig. 5 together with the atomic numbering scheme. Excluding the substituents, the structural data of the ligand molecule are similar to those observed in the uncomplexed molecules of the corresponding tetraethyl (1) and tetraphenyl

Fig. 5. Perspective view of the Bu_4todit·$2I_2$ molecule with a non-hydrogen atom numbering scheme.

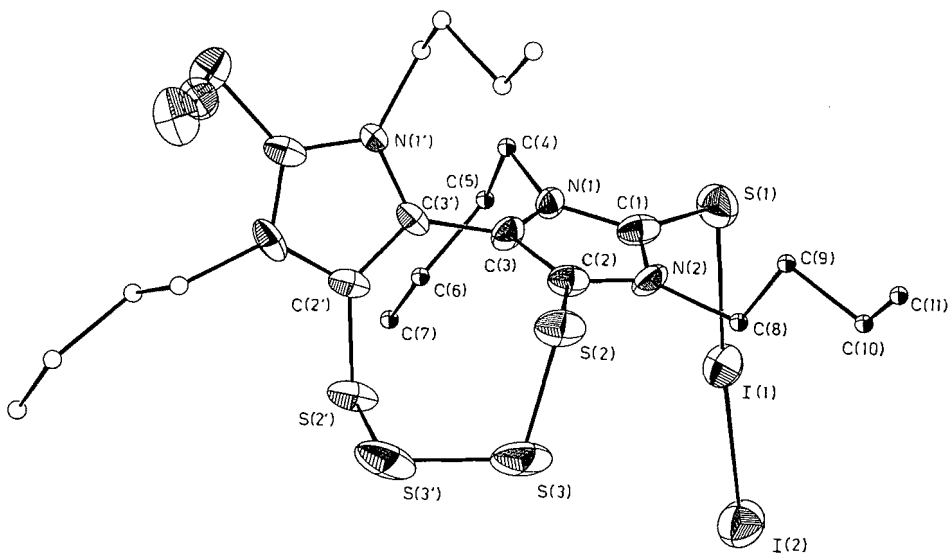


Fig. 6. Projection of the structure viewed along *b*.

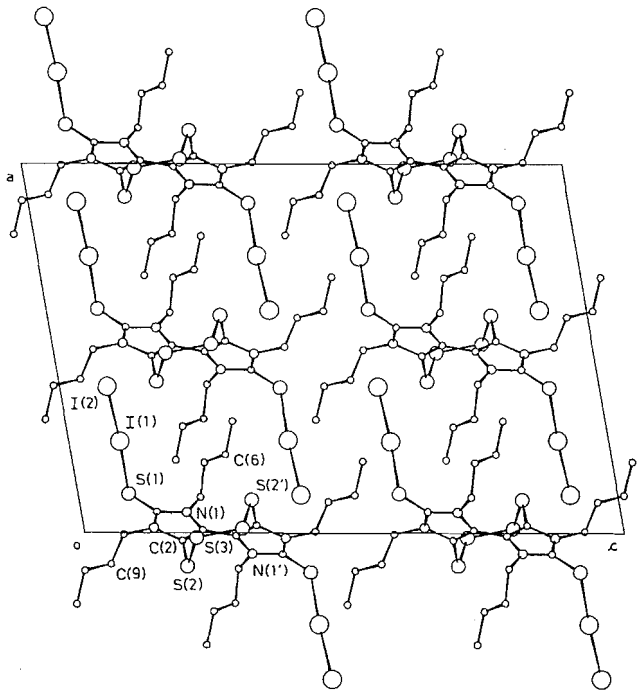

(6) derivatives in the bis-diiodine adduct and in the complexes of the tetraethyl derivative with $CuCl_2$ (3), $CdCl_2$ (2), and CuI (4). The analogies include the presence of a twofold axis, the orientation of the two imidazoline rings (N1-C3-C3′-N1′: −70(2)°) determined by the mutually opposite disposition of the butyl groups, and the chair conformation of the eight-membered ring. The imidazoline ring is not exactly planar (maximum deviation 0.027(15) Å for C(1)). The two butyl groups show different conformations, as a consequence of the minimum hindrance, since only the C(8)-C(9)-C(10)-C(11) moiety is in the extended shape. In fact, C(6) is +syn-clinal with respect to N(1) (N(1)-C(4)-C(5)-C(6); 61(2)°) and C(7) is anti-periplanar with respect to C(4) (C(4)-C(5)-C(6)-C(7): 172(2)°), both C(10) and C(11) are anti-periplanar with respect to N(2) and C(8), respectively (N(2)-C(8)-C(9)-C(10); 168(2)°, C(8)-C(9)-C(10)-C(11); −156(2)°). In the C(1)-S(1)-I(1)-I(2) moiety, which is roughly planar (maximum deviation 0.018(16) Å for C(1)) and roughly perpendicular to the imidazoline ring (I(1)-S(1)-C(1)-N(1): −101(1)°; I(1)-S(1)-C(1)-N(2): 77(1)°), the bond distances and angles are similar to those observed in the corresponding adduct $Et_4todit \cdot 2I_2$.

As shown in Fig. 6, here interactions of type $I_2 \cdots I_2$ are not present, owing to the hindrance of the substituents. The most relevant contacts determining the packing are: I(2)···S(3) (1/2+*x*, *y*−1/2, *z*) 3.775(6) Å; S(2)···S(3)(−*x*, *y*, 1/2−*z*) 3.299(7) Å; S(3)···C(7)(1/2−*x*, 1/2+*y*, 1/2−*z*) 3.52(2) Å; C(5)···C(7)(1/2−*x*, *y*−1/2, 1/2−*z*) 3.68(3) Å; C(7)···C(11) (1/2+*x*, 1/2−*y*, 1/2+*z*) 3.61(4) Å; and C(11)···C(11) (−1/2−*x*, 1/2−*y*, −*z*) 3.77(5) Å.[3]

Conclusions

The results of this investigation show that systems that could not be refined using the conventional SUPERSPEC program have been solved satisfactorily with POWELSPEC. However, it should be remembered that two hard constraints have been imposed in this algorithm: *(i)* the temperature independence of the molar absorptivities and *(ii)* the validity of the van't Hoff equation in the temperature range investigated. Moreover, this computer program is remarkably slower and does not directly provide standard deviation values for the parameters. In our opinion, SUPERSPEC should be employed whenever possible, and POWELSPEC is to be considered a valid alternative when the correlation among parameters produces a nearly singular matrix of the normal equations, and precludes the convergence of most of Newton's minimization methods. By applying POWELSPEC it was possible to solve the case of the equilibrium reaction of R_4todit (R = Et,Ph) with diiodine, for which SUPERSPEC gave wrong results involving a 1:1 model, as well as that of R_4todit (R = Me, *n*-Bu), in terms of the stepwise addition of two I_2 molecules to the ligand. The $\Delta H°$ sequence found with the R substituents is not confirmed by FT–Raman results, which suggest a very similar I_2–R_4todit interaction strength for all R derivatives investigated. This discrepancy is ascribed to solvation effects that affect the $\Delta H°$ values. Structural data on Bu_4todit are similar to those previously obtained in the bis-diiodine complex of the corresponding tetraethyl derivative.

On the basis of these results, there is no doubt that both the equilibrium model and the thermodynamic functions obtained here for Et_4todit and Ph_4todit must replace the corresponding results reported previously.

Solvated electron mobility in liquid *tert*-butanol

Yixing Zhao and Gordon R. Freeman

Abstract: The mobility μ_e of solvated electrons in liquid *tert*-butanol was estimated from the measured rate constant of the diffusion-controlled reaction $e_s^- + H_s^+ \rightarrow H_s$, combined with the measured molar conductivities of perchloric acid and ammonium perchlorate solutions; T = 300–330 K. The values $\mu_e = 4.1 \times 10^{-8}$ m^2 V^{-1} s^{-1} at 300 K and $E_\mu = 41$ kJ mol^{-1} indicate that electrons migrate by a hopping mechanism in liquid *tert*-butanol. This contrasts with the ion-like diffusion mechanism of e_s^- in methanol and ethanol.

Key words: *tert*-butanol, solvated electron, activation energy, mobility.

Résumé : On a évalué la mobilité μ_e des électrons solvatés dans le *tert*-butanol liquide à partir de la constante mesurée pour la réaction contrôlée par diffusion $e_s^- + H_s^+ \rightarrow H_s$ combinée aux conductivités molaires mesurées de solutions d'acide perchlorique et de perchlorate d'ammonium, à des températures allant de 300 à 330 K. Les valeurs de $\mu_e = 4{,}1 \times 10^{-8}$ m^2 V^{-1} s^{-1}, à 300 K et $E_\mu = 41$ kJ mol^{-1} indiquent que, dans le *tert*-butanol liquide, les électrons migrent par un mécanisme de saut. Ce comportement contraste avec le mécanisme de diffusion ressemblant aux ions qui l'on observe pour les e_s^- dans le méthanol et l'éthanol.

Mots clés : *tert*-butanol, électron solvaté, énergie d'activation, mobilité.

[Traduit par la rédaction]

Introduction

The mobilities of electrons in alcohols are difficult to measure directly, for two reasons: (*i*) proton transfer reactions (acid–base autodissociation) of alcohols produce a relatively high intrinsic conductivity, which means that relatively high concentrations of e_s^- must be used to obtain a sufficiently high e_s^- conductance signal above the background conductance; (*ii*) the large radiation pulse dose needed to produce the high, uniform e_s^- concentration in the sample requires equipment that is available at only two or three labs in the world (1–5).

The accurate interpretation of measured rates of reactions of e_s^- requires knowledge of the values of their diffusion coefficients D_e (or the mobilities μ_e) and activation energies. Values of μ_e and E_μ in water are well established (5). Values of μ_e in alcohols are less certain, and the E_μ values have not been measured (1–3, 6).

Values of μ_e in water, methanol, and ethanol are similar to those of the hydroxide (5) and respective alkoxide (1) ions. In mixed methanol/water and ethanol/water solvents this similarity appears to persist, judging from the solvent composition dependences of rate constants of diffusion-controlled reactions (7–9). However, in isopropanol (3) and larger alcohols (2, 3) μ_e appears to be larger than the mobility of a normal anion or alkoxide ion. These measurements have not been repeated, and must therefore be viewed with caution. In support of them, our study of e_s^- reactivity in *tert*-butanol (10) provides evidence that μ_e in *tert*-butanol is about 10 times higher than the mobility of a normal anion in this alcohol. The relevant data are presented below.

Experimental and results

The purified alcohol contained 5×10^{-4} mole fraction of water (10). Up to 1×10^{-5} mole fraction more water was added with the $HClO_4$ to measure the rate constant and molar conductance.

The experimental techniques are described in the following paper (10).

The sum of the mobilities of e_s^- and H_s^+, $(\mu_e + \mu_{H^+})$, in *tert*-butanol was estimated from the measured rate constant k_2 of the diffusion controlled reaction $e_s^- + H_s^+ \rightarrow H_s$ (10). A rearranged version of the Smoluchowski–Debye–Nernst–Einstein equation was used (11):

$$[1] \qquad \mu_e + \mu_{H^+} = 1.48 \times 10^{-16} k_2 / f T \mathcal{F} \kappa R_r$$

where f is the Debye coulombic interaction factor, T is the temperature, $\mathcal{F}$ is the Faraday, κ is the probability of reaction per encounter and is near unity for $e_s^- + H_s^+$ in alcohols (12), and R_r is the center-to-center encounter radius of $e_s^- + H_s^+$ and is taken as 1.6 nm in *tert*-butanol (10). The Debye factor is given by

$$[2] \qquad f = \frac{x}{e^x - 1}$$

$$[3] \qquad x = -\xi^2 / 4\pi\varepsilon_0 \varepsilon R_r k_B T$$

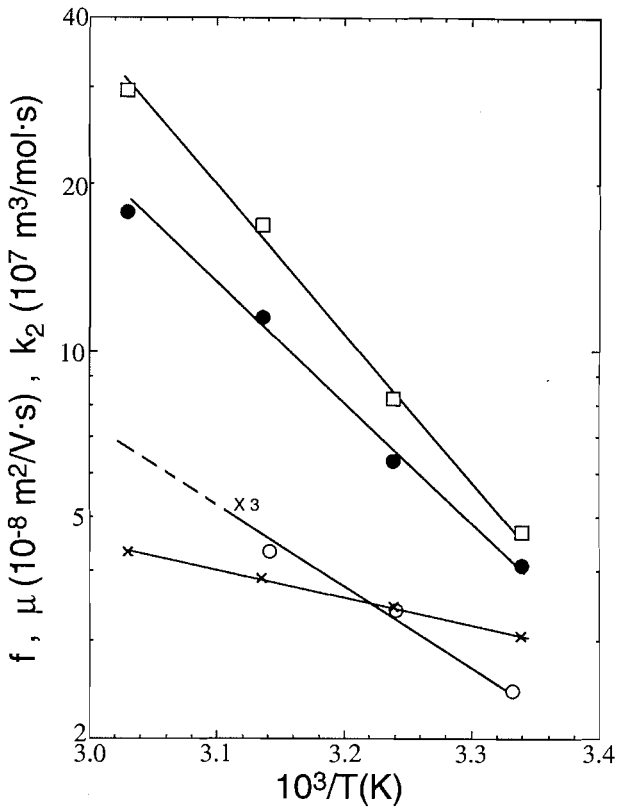
Fig. 1. Arrhenius plots. □, $k_2(e_s^- + H_s^+)$; ×, Debye f; ○, μ_{H^+}; ●, μ_e; in pure *tert*-butanol solvent.



where ξ is the proton charge, ε is the relative permittivity of the medium between the proton and electron at R_r, and k_B is Boltzmann's constant.

An Arrhenius plot of $k_2(e_s^- + H_s^+)$ is shown in Fig. 1, for temperatures 299.5–330.0 K; E_2 = 50 kJ mol^{-1}. The value of κR_r was taken as constant at 1.6 nm (10). The values of the Debye factor f calculated from known values of ε (Table 1) are included in Fig. 1; E_f = 10 kJ mol^{-1}.

From the measured molar conductances of dilute solutions of $HClO_4$ and NH_4ClO_4 (Table 2), we estimated the ratio $\mu_{H^+}/\mu_{ClO_4^-}$ and hence μ_{H^+}; $\mu = \lambda/\mathcal{F}$. In ethanol at 298 K the mobility of ClO_4^- is near the geometric mean of those of NH_4^+ and H^+ (Table 3). For lack of better information we assumed the same to apply in *tert*-butanol solvent, and subdivided the conductances of $NH_4^+ClO_4^-$ and $H^+ClO_4^-$ in this way. The geometric factor is given by $\Lambda_0(HClO_4)/\Lambda_0(NH_4ClO_4)$. The values of μ_{H^+} are included in Fig. 1; $E_{\mu H^+} \approx 28$ kJ mol^{-1}.

The derived values of μ_e are listed in Table 1 and plotted in Fig. 1; $E_{\mu_e} = 41$ kJ mol^{-1}.

[b]Concentration: 6–30 mmol m^{-3}.

Discussion

Protons diffuse by a Grotthus (H^+ exchange) mechanism in alcohols, which allows H^+ to migrate 4.8 times faster than NH_4^+ and 2.2 times faster than ClO_4^- in *tert*-butanol at about 300 K (Table 2). The 5×10^{-4} mole fraction of water in the alcohol evidently did not quench the Grotthus mechanism. The activation energy of the H^+ exchange mechanism (28 kJ mol^{-1}) is 1.6 times larger than that of normal ion transport (17 kJ mol^{-1} for NH_4^+ and ClO_4^- (10)).

Electrons migrate even faster than protons in *tert*-butanol, and the activation energy is larger (41 kJ mol^{-1}, Table 3). The mobility ratio e_s^-/H_s^+ is 5 at 300 K and 8 at 330 K (Fig. 1). The high mobility and high activation energy indicate that electrons in *tert*-butanol migrate by a hopping mechanism.

The value of E_{μ_e} = 41 kJ mol^{-1} is only slightly larger than E_τ = 39 kJ mol^{-1} for molecular electric dipole rotation (Table 3). We suggest that thermally agitated dipole rotation of the solvating molecules is the process that activates the electron hopping.

Solvent effects on the reactivity of solvated electrons with ions in *tert*-butanol/water mixtures

Yixing Zhao and Gordon R. Freeman

Abstract: Reactions of e_s^- with the ions $NO_{3,s}^-$, $NH_{4,s}^+$, and H_s^+ showed different variations of rate with solvent composition in *tert*-butanol/water mixtures from 0 to 100 mol% water. In pure *tert*-butanol solvent at 298 K the respective values of k_2 (10^6 m^3 mol^{-1} s^{-1}) are 3.2, 13, and 42. The estimated value of reaction radius R_r depends on the minimum number of solvent molecules needed between e_s^- and the reactant ion to attain the static values of ε of the bulk solvent used in the calculation of the Debye factor f; R_r is assumed to be larger in the alcohol-rich region than in the water-rich region, because the solvent molecules are larger. The Smoluchowski–Debye–Nernst–Einstein model is used to evaluate the effective reaction radius κR_r, where κ is the probability of reaction per encounter; κR_r decreases from pure *tert*-butanol to pure water. In the water-rich region the activation energies E_2 of the efficient reactions, 11–24 kJ mol^{-1}, are similar to $E_{\Lambda 0}$ of the reactant electrolyes, 12–23 kJ mol^{-1}. For the inefficient reactant NH_4^+ ClO_4^-, E_2 = 30 kJ mol^{-1}. The high values of E_2 = 43–53 kJ mol^{-1} in pure *tert*-butanol solvent are attributed to a high activation energy for diffusion of e_s^- in this solvent.

Key words: *tert*-butanol/water solvents, solvated electron, ions, reactivity, solvent effects.

Résumé : Les vitesses de réaction des e_s^- avec les ions $NO_{3,s}^-$, $NH_{4,s}^+$ et H_s^+ présentent des variations différentes avec la composition des mélanges de solvant *tert*-butanol/eau en allant de 0 à 100% en eau. Dans le *tert*-butanol pur, à 298 K, les valeurs relatives de k_2 (10^6 m^2 mol^{-1} s^{-1}) sont 3,2, 13 et 42. La valeur estimée du rayons de réaction R_r dépend du nombre minimal de molécules de solvant requis entre le e_s^- et l'ion réactif pour atteindre les valeurs statiques de ε de l'ensemble du solvant utilisée par le facteur f de Debye; comme les molécules de solvant sont plus volumineuses que celles de l'eau, on considère que R_r est plus élevé dans la région riche en alcool que dans la région riche en eau. On a utilisé le modèle de Smoluchowski–Debye–Nernst–Einstein pour évaluer le rayon réactionnelle efficace, κR_r, dans lequel κ est la probabilité de réaction par rencontre; κR_r diminue en allant du *tert*-butanol pur à l'eau pure. Dans la région riche en eau, les énergies d'activation E_2 des réactions efficaces, 11–24 kJ mol^{-1}, sont semblables aux valeurs de $E_{\Lambda 0}$ des électrolytes qui réagissent, 12–23 kJ mol^{-1}. Pour le réactif inefficace NH_4^+ ClO_4^-, E_2 = 30 kJ mol^{-1}. On attribue les valeurs élevées de E_2 = 43–53 kJ mol^{-1} observées dans le *tert*-butanol à une énergie élevée d'activation de la diffusion des e_s^- dans ce solvant.

Mots clés : solvants *tert*-butanol/eau, électron solvaté, ions, réactivité, effets de solvants.

Introduction

The reactivity of solvated electrons e_s^- depends mainly on the natures of the coreactant and solvent (1–5). The study of rates of reaction of e_s^- with solutes in different solvents provides useful information about solvent effects, which helps us understand the behaviour of electrons and the nature of solvents. The reaction rates in single component and mixed solvents are related to transport properties, as in Smoluchowski-type models for diffusion-controlled reactions (1, 3, 4, 6–8), and relative energy levels of the reactants, as in the electron trap-depth model (2, 7, 8*a*). Electron reaction rates with inefficient capturers are larger when the electron solvation energy, represented by the optical absorption energy E_r (2), is smaller.

The physical properties of *tert*-butanol/water mixed solvents vary markedly with composition (9, 10). The present paper reports a continuation of the study of e_s^- reaction rates in this solvent system (11).

Experimental

The *tert*-butanol was obtained from BDH (Assured grade, 98%), and later from Fluka (>99.7%). The purification method was similar to that in ref. 11*a*. *tert*-Butanol was dried at 304 K for at least one week on Davison 3Å molecular sieves, then bubbled with UHP argon (99.999%, Liquid Carbonic Canada) and treated with sodium borohydride (2 g

L^{-1}) under argon at 323 K for 24 h. Then the alcohol was fractionally distilled under argon through an 80 × 2.3 cm column packed with glass beads (6 mm). The first 20–25% of the distillate was discarded; distillate was collected after there was no further reduction in optical absorption between 260 and 280 nm, which is due to carbonyl compounds (12). The middle 50% portion was collected and stored in a flask under argon positive pressure. The water content, measured by Karl–Fisher titration, was 0.05 mol%. The solvated electron half-life after a 100 ns pulse of 340 fJ (2.1 MeV) electrons (4 J kg^{-1}) at 300 K was over 10 μs.

Perchloric acid (70 wt% in water, reagent) was obtained from Fisher Scientific. $LiNO_3$ (99.999% Gold label), NH_4NO_3 (99.999%), $LiClO_4$ (reagent grade), and NH_4ClO_4 (99.8%) were from Aldrich.

Techniques of sample solution preparation, irradiation, and optical measurements were the same as described in ref. 13. Conductance measurement was as in ref. 14.

Results and discussion

tert-BuOH/water mixed solvents

tert-Butanol is completely miscible with water. The following mol% of water in *tert*-butanol were used for rate constant measurements of all solutes: 0, 5, 10, 30, 50, 70, 90, 97, 100. Measurements of electrical conductance were done in the same solvents, except 5 mol%.

Rate constants

The reactions are

$$[1] \qquad e_s^- + ROH_s \rightarrow RO_s^- + H_s \qquad k_1$$

$$[2] \qquad e_s^- + S_s \rightarrow \text{Products} \qquad k_2$$

The observed first-order decay rate constant k_{obs} ($= k_1 + k_2$ [S]) in a given solvent was measured for the pure solvent and six concentrations of solute S. The value of k_1 might include a contribution from trace impurities in the solvent: $k_1 = k_1' + k_i$[I]. The value of the second-order rate constant k_2 was obtained from the slope of a plot of k_{obs} against solute concentration. The values of k_2 for each solvent were measured at temperatures from 273 to 343 K, except in pure *tert*-butanol whose mp is 298.7 K.

Arrhenius plots of k_2 for the four solutes ($Li_s^+ + NO_{3,s}^-$), ($NH_{4,s}^+ + NO_{3,s}^-$), ($NH_{4,s}^+ + ClO_{4,s}^-$), and ($H_s^+ + ClO_{4,s}^-$) are given in Figs. 1–4. Table 1 contains the symbols for these figures. The reaction parameters are listed in Table 2.

The value of k_2 for the reaction of $e_s^- + (Li_s^+ + ClO_{4,s}^-)$ is very small, being 110 m^3 mol^{-1} s^{-1} in water and 660 m^3 mol^{-1} s^{-1} in *tert*-butanol at 298 K (Table 2). Thus the large value of k_2 of ($Li_s^+ + NO_{3,s}^-$) is due to $NO_{3,s}^-$, of ($H_s^+ + ClO_{4,s}^-$) is due to H_s^+, and of ($NH_{4,s}^+ + ClO_{4,s}^-$) is due to $NH_{4,s}^+$ (Table 2).

The solvent composition dependence of k_2 at 298 K is shown in Fig. 5. Values of the optical absorption energy E_T (15), relative permittivity (16), and viscosity (10) are shown for comparison.

The value of k_2 of ($NH_{4,s}^+ + NO_{3,s}^-$) in the water-rich region is due to $NO_{3,s}^-$, and in the alcohol-rich region is due to $NH_{4,s}^+$. This conclusion agrees with earlier work (14). In the alcohol-rich solvents the rate constants for $NH_{4,s}^+$ are about

Table 1. Symbols in Fig. 1–4.

Symbol	mol% water	Symbol	mol% water
■	0	△	70
×	5	▲	90
◆	10	+	97
□	30	○	100
◇	50		

10 times higher than those for $NO_{3,s}^-$ (Fig. 5). The Coulombic attraction of the opposite charges ($NH_{4,s}^+ + e_s^-$) and repulsion of the like charges ($e_s^- + NO_{3,s}^-$) is the main cause of this difference (see Debye factor f in Table 2).

The value of k_2 ($e_s^- + H_s^+$) stays $\geq 2 \times 10^7$ m^3 mol^{-1} s^{-1} at all solvent compositions. It is higher than those of the other three reactions. In the region of 30–100 mol% water, the variation of the k_2 of H_s^+ is very different from those of the reactions with $NO_{3,s}^-$ and $NH_{4,s}^+$ (Fig. 5).

Addition of 5–10 mol% of water to *tert*-butanol decreases the rate constant of each reaction by a factor of 0.5 to 0.3 (Fig. 5). We attribute this to a decrease in mobility of e_s^-, which is unusually high in pure *tert*-butanol (17).

The variation of k_2 with solvent composition between 50 and 100 mol% of water is different for each of the four solutes (Fig. 5). The variation of k_2 ($NO_{3,s}^-$) varies in the expected way with viscosity η and relative permittivity ε, but not with e_s^- trap depth E_r (2). In the water-rich region (100–70 mol%), values of k_2 for $NO_{3,s}^-$ and ($NH_{4,s}^+ + NO_{3,s}^-$, mainly due to $NO_{3,s}^-$) increase as diffusion rates increase (viscosity decreases). In the alcohol-rich region (0–50 mol% water), k_2 for $NO_{3,s}^-$ increases as the viscosity *increases*, indicating a change of reaction mechanism.

Reaction radius and Debye factor f

For a diffusion-controlled reaction of e_s^- with a solute of charge $z\xi$ the Smoluchowski–Debye equation (18) is

$$[3] \qquad k_2 = 4\pi N_A (D_e + D_s) R_r f$$

where N_A is Avogadro's constant, D_i is the diffusion coefficient of i, and R_r is the average center-to-center reactant separation when reaction occurs. The Debye factor f is given by

$$[4] \qquad f = \frac{x}{(e^x - 1)}$$

$$[5] \qquad x = -\frac{z\xi^2}{4\pi\varepsilon_0\varepsilon R_r k_B T}$$

where x is the ratio of the coulombic energy of the reactants at R_r to the thermal agitation energy $k_B T$, and ε is the relative permittivity of the medium between the reactants at separation R_r. The factor f reflects the effect of the coulombic interaction between the two reactants on the probability that they will approach each other to within the distance R_r at which reaction can occur.

Values of R_r are not well defined and can be quite different for different solutes and solvents; the estimated value

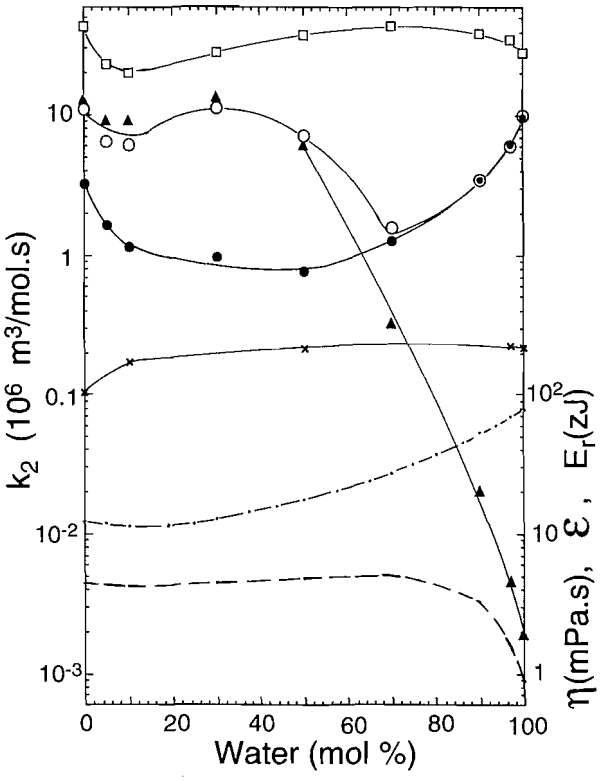
Fig. 5. Solvent composition dependence of k_2 in *tert*-butanol/water mixtures at 298 K. The solutes are ●, $Li_s^+ + NO_{3,s}^-$; ○, $NH_{4,s}^+ + NO_{3,s}^-$; ▲, $NH_{4,s}^+ + ClO_{4,s}^-$; □, $H_s^+ + ClO_{4,s}^-$. Physical parameter reference lines are ×, E_r (15); - · - relative permittivity ε (16); - - - viscosity, η (10).



also depends on the method of estimation. Sometimes R_r estimated from the Smoluchowski–Debye equation [3] is called the effective reaction radius (R_{eff}) to distinguish it from the real reaction radius R_r. Milosavljevic and Micic (6) estimated R_{eff} for reactions of e_s^- with several solutes in methanol or ethanol mixed with water, using the Smoluchowski equation and estimated values of diffusion coefficients. For nitrobenzene in methanol/water solvents they obtained $R_{eff} = 0.8$ nm in pure water solvent, 0.9 nm in 20 mol% methanol, and 1.2 nm in pure methanol. For nitrobenzene in ethanol/water solvents they obtained $R_{eff} = 0.9$ nm in water, 0.7 nm in 20 mol% ethanol, and 1.3 nm in pure ethanol. However, Lai and Freeman (8*a*) used $R_r = 0.8$ nm for nitrobenzene over the whole range of water mixtures with methanol or ethanol.

Tunuli and Farhataziz (19) applied equation [3] to the reaction of e_s^- with Ag_s^+ in C_{1-10} alcohols. They used different methods to estimate R_r and obtained $R_r = 1.22$–1.28 nm for methanol, 1.42–1.48 nm for ethanol, 1.52–1.74 nm for 1-propanol, and 1.54–2.0 nm for 1-butanol.

Schwarz and Gill (1) calculated effective reaction radii r_r in the study of the diffusion-controlled reactions of e_s^- with $NH_{4,s}^+$, Ag_s^+ and other solutes in ethanol. For charged solutes, they used eqs. [6] and [7] to calculate r_r:

$$[6] \qquad r_r = r_c/[1 - \exp(-r_c/r_0)]$$

$$[7] \qquad r_c = -\frac{z\xi^2}{4\pi\varepsilon_0\varepsilon k_B T}$$

where r_c is the distance at which the coulombic interaction between the ions equals the thermal agitation energy $k_B T$, and r_0 is the center-to-center separation of the solvated reactant ions in contact. Schwarz used $r_0 = 1.1$ nm and the static value of ε of the bulk solvent in eqs. [6] and [7]. The reactants (electron and ion) are solvated, which means each reactant is surrounded by a layer of ethanol molecules oriented by the charge–dipole interaction. The average diameter of an ethanol molecule is about 0.4 nm, which with the radii of the electron cavity and the solute ion gives $r_0 \approx 1.1$ nm. Since there are only two solvent molecules between the two charged reactants and they cannot reorient freely, the relative permittivity ε of these two molecules is less than the static value of bulk ethanol. The static value of ε probably requires at least one more solvent molecule between those that solvate the reactant ions, or a minimum of $r \approx 1.5$ nm. The value of r_c in ethanol is 2.3 nm at 298 K, for $z = 1$ and $\varepsilon = 24.3$. The use of the simple ratio r_c/r_0 in eq. [6] requires that the same value of ε be applicable for both r_0 and r_c. This is improbable for $r_0 = 1.1$ nm in ethanol. If we release the "contact" restriction and replace r_0 in eq. [6] by R_r of eq. [3] then r_r in eq. [6] equals $R_r f$ in eq. [3].

For neutral solutes, eq. [8] was used (1).

$$[8] \qquad k_1' r_r = r_0 + \left(\frac{2}{b}\right)(\ln Z_0 + 0.57)$$

where $Z_0 = 2v^{1/2}/b(D_e + D_s)^{1/2}$, v and b are from the fitted reaction probability $\beta(r)$ based on electron transfer through overlapping wavefunctions ("tunneling", refs. 1, 20):

$$[9] \qquad \beta(r) = \gamma \exp[-b(r - r_0)]$$

where $v \approx 10^{15}$ cycles/s is the orbital oscillation frequency of the solvated electron, and $b^{-1} \approx 10^{-10}$ m is the separation distance $(r - r_0)$ where the reaction probability is decreased by a factor of 1/3 from the value v at contact $(r - r_0 = 0)$.

For mixed solvents the values of the diffusion coefficient of e_s^- are not known, so it is difficult to estimate the reaction radius. Therefore, for the reactions of e_s^- with $NO_{3,s}^-$ and H_s^+ in propanols (21) and butanols (13, 14, 21*b*), fixed values of R_r were used for f factor calculation in eqs. [4] and [5], namely, $R_r(e_s^- + NO_{3,s}^-) = 1.5$ nm, $R_r(e_s^- + H_s^+) = R_r(e_s^- + NH_{4,s}^+) = 1.0$ nm. Then κ, the probability that reaction occurs during one encounter, was inserted into [3] (21):

$$[10] \qquad k_2 = 4\pi N_A(D_e + D_s) f \kappa R_r$$

where κR_r can be considered as an effective reaction radius.

One might expect R_r to be larger when the solvating molecules are larger, hence larger for alcohol solvation than for water solvation. In most *tert*-butanol/water mixtures, from 30–100 mol% of water, e_s^- is preferentially solvated by water (15), so $R_r(e_s^- + NO_{3,s}^-) = 1.5$ nm and $R_r(e_s^- + NH_{4,s}^+) = 1.0$ nm are still used. This implies that there are, including the solvating molecules, about four water molecules between e^- and NO_3^-, and about three between e^- and NH_4^+ when reaction occurs. In pure *tert*-butanol, there could be about three and a half *tert*-butanol molecules between e^- and NO_3^-, and three between e^- and NH_4^+ to attain the bulk, static value of ε between the charges. The diameter of *tert*-butanol is about 0.5 nm, which gives a center-to-center $R_r(e_s^- + NO_{3,s}^-) = 2.1$

Table 3. Estimated values of R_r (nm) in *tert*-BuOH/water mixtures.[a]

Water (mol%)	$R_r(e_s^- + NO_{3,s}^-)$ (nm)	$R_r(e_s^- + NH_{4,s}^+)$ (nm)
0	2.1	1.6
5	1.9	1.4
10	1.8	1.3
30	1.6	1.1
50–100	1.5	1.0

[a] R_r is assumed to be relatively insensitive to temperature.

nm and $R_r(e_s^- + NH_{4,s}^+) = 1.6$ nm by the replacement of water molecules whose van der Waals diameter is 0.29 nm.[2] In the solvent region 0–30 mol% of water, the relative numbers of *tert*-butanol and water molecules between the reactants gradually change and the values of R_r gradually decrease. The values of R_r are listed in Table 3, and are assumed to be relatively insensitive to temperature. The corresponding values of f are in Table 2; the values of f for H_s^+ are the same as for $NH_{4,s}^+$.

The value of k_2 is dependent on both R_r and the factor f (eq. [10]), while f is dependent on R_r, the charge of the reactant ion, and the ε of the solvent between the electron and ion (eqs. [4] and [5]). Figure 6 shows the solvent composition dependence of εR_r and hence f for the reactions $e_s^- + NO_{3,s}^-$ and $e_s^- + NH_{4,s}^+$ (or H_s^+). As εR_r increases the coulombic interaction becomes weaker; f decreases towards unity for e_s^- reaction with a cation, and increases toward unity for reaction with an anion.

Normalized rate constants k_2/f

Equation [10] can be rearranged to eq. [11]:

$$[11] \qquad k_2/f = 4\pi N_A(D_e + D_s)\kappa R_r$$

where k_2/f normalizes the rate constant for the coulombic effect. Figure 7 shows the changes of k_2/f with solvent composition for different solutes in *tert*-butanol/water mixtures at 298 K. The method described in ref. 13 was used to calculate k_2/f for $e_s^- + (NH_{4,s}^+ + NO_{3,s}^-)$. The k_2/f curves for different solutes are closer together than are the k_2 curves in Fig. 5.

Molar conductivity of solutes

The solvent composition dependences of molar conductivities of all four solutes at 298 K are shown in Fig. 8 and listed in Table 2. The concentration ranges used in conductance measurements were close to those used to determine rate constants. The measured value of Λ for $LiNO_3$ in *tert*-butanol is about 0.46×10^{-4} S m^2 mol^{-1}, compared to 3.86×10^{-4} S m^2 mol^{-1} for $LiClO_4$. This indicates that (Li_s^+ $NO_{3,s}^-$) ion pairs form in *tert*-butanol. The value of $\Lambda_0 = 1.9$

[2] Reference 22. $r_{vdW} = \left(\frac{3}{4\pi N_A} \cdot \frac{b}{4}\right)^{1/3} = 4.63 \times 10^{-9} b^{1/3}$.

Fig. 6. Dependence of Debye f on εR_r for $Li_s^+ + NO_{3,s}^-$ (●) and $NH_{4,s}^+ + ClO_{4,s}^-$ (▲) in *tert*-butanol/water mixtures at 298 K. The numbers on the curves are mol% of water.

Fig. 8. Composition dependence of Λ_0 in *tert*-butanol/water at 298 K. Symbols are as in Fig. 5.

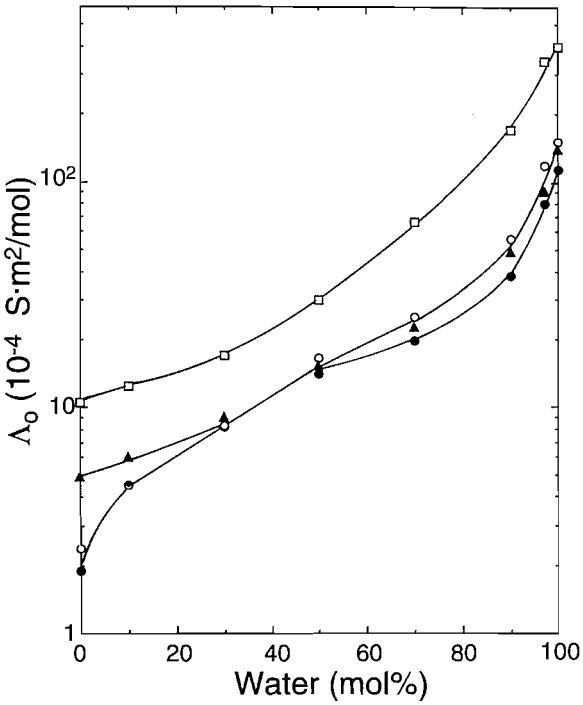

Fig. 9. Solvent composition dependence of r_d of *tert*-butanol/water mixtures at 298 K. Symbols are as in Fig. 5. - - - represents η (10).

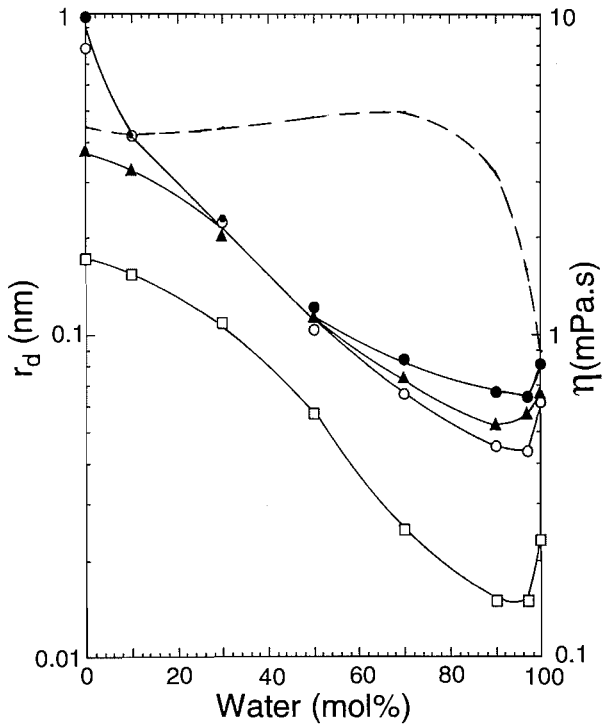


$\times 10^{-4}$ S m^2 mol^{-1} for $Li^+_s + NO^-_{3,s}$ in *tert*-butanol is estimated from the values of the other three solutes $Li^+_s + ClO^-_{4,s}$, $NH^+_{4,s} + ClO^-_{4,s}$, and $NH^+_{4,s} + NO^-_{3,s}$ (Table 2, Fig. 8). The ion pairing will be discussed in a later paper.

The values of Λ_0 are proportional to the mobilities μ_i of the ions (23):

$$[12] \qquad \Lambda = \nu_+\lambda_+ + \nu_-\lambda_-$$

where ν_+ is the number of cations and ν_- is the number of anions in a formula of the electrolyte, and

$$[13] \qquad \lambda_i = z_i\mu_i F = \frac{z_i^2 D_i F^2}{RT}$$

where λ_i is the molar conductivity of ion i, z_i is the number of charges of the ion, F is the Faraday constant, and R is the gas constant. Substitution of D_i by the Stokes–Einstein relation (23),

$$[14] \qquad D_i \approx \frac{k_B T}{6\pi\eta r_{di}}$$

where r_{di} is the effective hydrodynamic radius of the solvated ion, gives

$$[15] \qquad \lambda_i \approx \frac{z_i^2 F^2}{N_A 6\pi\eta r_{di}}$$

For the 1:1 electrolytes ($z = 1$) in the present study, the effective radius r_d for mutual diffusion of the positive and negative ions is

$$[16] \qquad r_d \approx \frac{F^2}{N_A 6\pi\eta\Lambda_0} = 8.2 \times 10^{-16}/\eta\Lambda_0$$

where $r_d^{-1} = (r_{d+}^{-1} + r_{d-}^{-1})$ (21*c*).

The values of r_d decrease as the water content of the solvent increases up to 90–97 mol%, pass through a minimum and increase somewhat toward pure water solvent (Fig. 9). The decrease of D_i on going from water to *tert*-butanol is due to the increasing viscosity of the solvent and the larger size of the molecules that solvate the ions. The reason for the apparent decrease of r_d upon addition of a few percent of alcohol to water is that the viscosity of the bulk solvent increases considerably, due to a more ordered structure of the mixed solvent (24), while the ions are selectively solvated by the water and presumably remain in lower viscosity microzones (21*c*). Use of the bulk viscosity in eq. [16] makes r_d appear to decrease.

Smoluchowski–Debye–Nernst–Einstein model

Diffusion coefficients from eq. [13] can be substituted in eq. [11]:

$$[17] \qquad k_2/f = \frac{4\pi k_B T}{\xi^2}(\lambda_e + \lambda_i/z_i^2)\kappa R_r$$

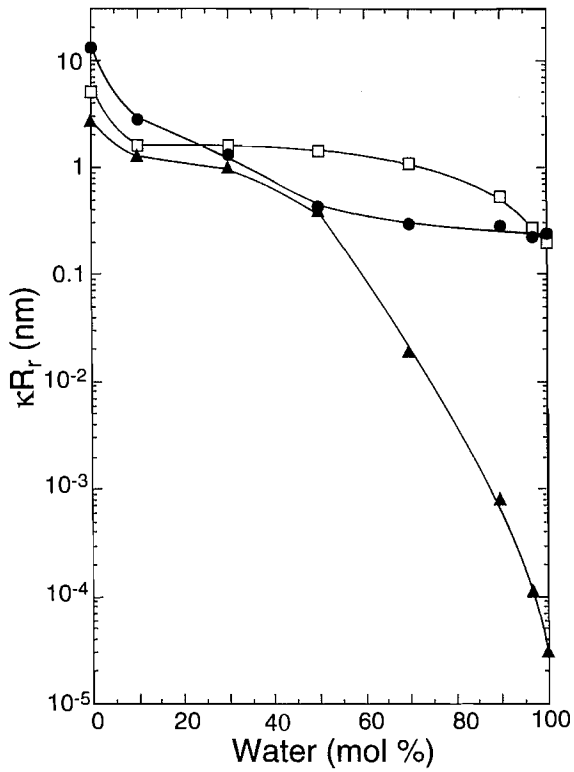
which can be rearranged to

$$[18] \qquad \kappa R_r = 1.48 \times 10^{-16} k_2/(\lambda_e + \lambda_i/z_i^2) f\, T$$

where λ_e is the molar conductivity of e^-_s. For the solutes studied in his work, $z_i = \pm 1$. In water, the diffusion of e^-_s dominates the relative motion of each pair except that with H^+_s (21*b*). The values of the individual ionic conductivities in the mixed solvents are unknown, so an approximation is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Fig. 10. Solvent composition dependence of apparent values of κR_r in *tert*-butanol/water mixtures at 298 K. Symbols are as in Fig. 5.



made in order to estimate κR_r from measured molar conductivities of the electrolytes. In water:

$[\lambda_e + \lambda(H_s^+)]/\Lambda_0(H_s^+, ClO_{4,s}^-) = 1.3$ (21b), so $\kappa R_r = 1.1 \times 10^{-16}\ k_2/\Lambda_0(H_s^+, ClO_{4,s}^-)fT$; $[\lambda_e + \lambda(NO_{3,s}^-)]/\Lambda_0(Li_s^+, NO_{3,s}^-) = 2.3$ (21b), so $\kappa R_r = 0.6 \times 10^{-16}\ k_2/\Lambda_0(Li_s^+, NO_{3,s}^-)fT$; $[\lambda_e + \lambda(NH_{4,s}^+)]/\Lambda_0(NH_{4,s}^+, ClO_{4,s}^-) = 1.6$ (14), so $\kappa R_r = 0.9 \times 10^{-16}\ k_2/\Lambda_0(NH_{4,s}^+, ClO_{4,s}^-)fT$. For the lack of anything better, these equations were used for all solvent compositions to estimate κR_r.

The estimated values of κR_r are plotted in Fig. 10. The curves are again different from those in Figs. 5 and 7. The value of κR_r for each solute increases continuously with increasing *tert*-butanol content. This indicates that the reactivity of e_s^- with all solutes gradually increases on going from water to *tert*-butanol solvent.

For all solutes in pure *tert*-butanol solvent the apparent values of κ are much larger than unity, in spite of the large values of R_r chosen, 2.1 nm for $NO_{3,s}^-$ and 1.6 nm for $NH_{4,s}^+$ and H_s^+. The true value of κ can not be greater than unity. The apparent values of κ for the reaction $e_s^- + H_s^+$ in 10–70 mol% water are slightly larger than 1 (Table 4), but they are within the uncertainty of the approximations. From $k_2(e_s^- + H_s^+)$ in *tert*-butanol the mobility of e_s^- in this solvent is estimated to be $\mu(e_s^-) \approx 4 \times 10^{-8}$ m^2 V^{-1} s^{-1} at 298 K, and $E_{\mu e} \approx 41$ kJ mol^{-1} (17).

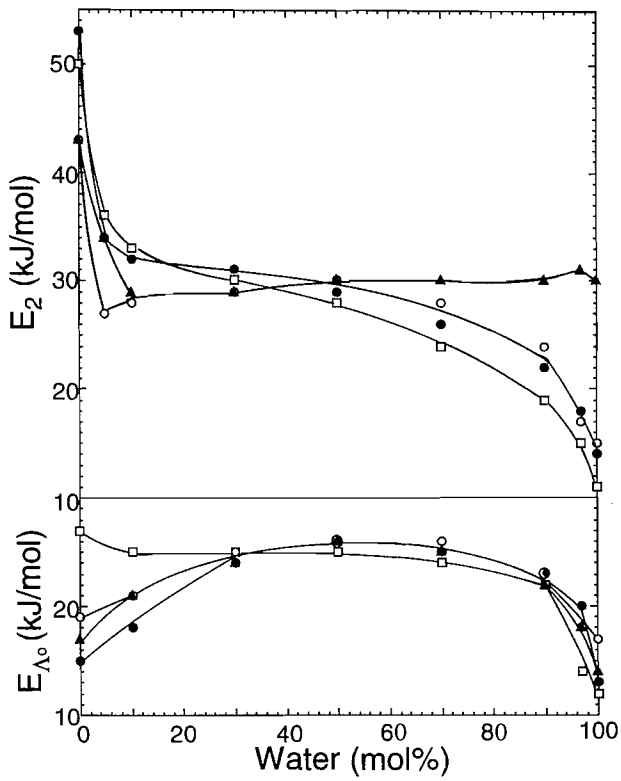
E_2 and $E_{\Lambda 0}$

The solvent dependences of the Arrhenius activation energies E_2 of reaction and $E_{\Lambda 0}$ of mobility for all four solutes are

Table 4. Apparent κ values in *tert*-butanol/water mixtures at 298 K.

Water (mol%)	$\kappa(NO_{3,s}^-)$	$\kappa(NH_{4,s}^+)$	$\kappa(H_s^+)$
100	0.16	3.1×10^{-5}	0.20
97	0.15	1.1×10^{-4}	0.27
90	0.19	7.9×10^{-3}	0.53
70	0.20	0.019	1.07
50	0.27	0.37	1.45
30	0.82	0.88	1.42
10	1.4	0.95	1.24
0	6.1	1.7	3.3

Fig. 11. Solvent composition dependence of E_2 and $E_{\Lambda 0}$ in *tert*-BuOH/water mixtures. Symbols are as in Fig. 5.



plotted in Fig. 11. The values of E_2 increase from water to alcohol, whereas $E_{\Lambda 0}$ for the salts have a maximum at 50 mol% water.

For reaction [2] to occur, the reactants e_s^- and $S^{\pm 1}$ must diffuse together

[19] $\quad e_s^- + S^{\pm 1} \rightleftharpoons [e_s^-, S^{\pm 1}] \qquad k_d, k_{-d}$

then react

[20] $\quad [e_s^-, S^{\pm 1}] \rightarrow P \qquad k_{20}$

From the steady-state approximation one obtains

$$[21] \qquad k_2 = \frac{k_d k_{20}}{k_{-d} + k_{20}}$$

If $k_{20} > k_{-d}$, then $k_2 \approx k_d$ and E_2 should be close to $E_{\Lambda 0}$. For the reactions $e_s^- + NO_{3,s}^-$ and $e_s^- + H_s^+$ in the water-rich region of 100–70 mol% of water, the reactions are not far from diffusion-controlled and E_2 and $E_{\Lambda 0}$ are similar (Tables 2 and 4). For $NH_{4,s}^+$ in 100–70 mol% of water the rate constants are low, and the values of E_2 are much higher than $E_{\Lambda 0}$.

In the alcohol-rich region from 50 to 10 mol% water, the values of E_2 do not change much, while $E_{\Lambda 0}$ decreases somewhat. In the solvents 10 to 0% water E_2 increases greatly, while $E_{\Lambda 0}$ for the salts decrease and that for $HClO_4$ remains constant. The increase of E_2 is attributed to a large temperature coefficient of diffusion of e_s^-, which reaches 41 kJ mol^{-1} in pure *tert*-butanol (17).

Abstract: The reactions of amines and amino alcohols with diisopropyl or diethyl *R,R*- or *S,S*-tartrate and $Ti(O^iPr)_4$ were examined by ^1H and ^{13}C NMR to obtain and characterize nonfluxional complexes with the tartrate units in novel binding modes. The mildly acidic 8-hydroxyquinoline and *N*-phenyl-*N*-benzoylhydroxylamine selectively formed the products of a double O^iPr substitution, $Ti_2(tartrate)_2(ligand)_2(O^iPr)_2$, and the products of double tartrate substitution, $Ti(ligand)_2(O^iPr)_2$, while 2,4-pentanedione formed only the latter. Basic amino alkanols formed diastereomerically pure $Ti_2(tartrate)_2(aminoalkoxide)(O^iPr)_3$ species. *N,N*-Dimethyl-2-aminoethanol (H*dmae*) also and uniquely formed monomeric $Ti(tartrate)_2(Hdmae)_2$ species that could be described as doubly zwitterionic. Secondary or tertiary amines formed triply C_2-symmetric $Ti_3(tartrate)_4(amine)_2(O^iPr)_4$ assemblies. Some minor components were believed to be μ-O^iPr species. All mixed complexes except $Ti(tartrate)_2(Hdmae)_2$ contained chelating and bridging tartrate units, without coordination by ester carbonyls. A nonchelating, nonbridging tartrate unit was also present in the amino alcohol cases. Primary amines, aromatic amines, and hydrazines all failed to provide identifiable complexes. As well, *N,N*-dibenzylhydroxylamine failed to generate in solution the complex that had previously been characterized by X-ray crystallography. Amidst the rich chemistry of Ti^{IV}-tartrate systems, the evident selectivities in product formation were ascribed to macro-ring closures that are specifically directed by the electronic nature of the addend. Transient O^iPr-bridged intermediates were also implicated.

Key words: mixed Ti^{IV} alkoxides, chiral Ti^{IV} alkoxides, enantiospecific complexation.

Résumé : Dans le but d'obtenir et de caractériser des complexes qui ne sont pas en fluxion d'unités tartrates dans de nouveaux modes de liaison, on a étudié les réactions des amines et des aminoalcools avec les *R,R*- ou *S,S*-tartrates de diisopropyle ou de diéthyle, en présence de $Ti(O^iPr)_4$, en faisant appel à la RMN du ^1H et du ^{13}C. Les 8-hydroxyquinoléine et *N*-phényl-*N*-benzoylhydroxylamine qui sont légèrement acides forment sélectivement les produits d'une double substitution, $Ti_2(tartrate)(ligand)_2(O^iPr)_2$ et les produits d'une double substitution du tartrate, $Ti(ligand)_2(O^iPr)_2$; par ailleurs, la pentane-2,4-dione ne donne que ce dernier type de composé. Les aminoalcools basiques forment des espèces $Ti_2(tartrate)_2(aminoalcoolate)(O^iPr)_3$ qui sont diastéréomériquement pures. Le *N,N*-diméthyl-2-aminoéthanol (H*dmae*) réagit de la même manière et ne forme que l'espèce monomère $Ti(tartrate)_2(Hdmae)_2$ que l'on peut décrire comme zwitterionique. Les amines secondaires ou tertiaires forment des assemblées $Ti_3(tartrate)_4(amine)_2(O^iPr)_4$ de symétrie C_2. On croit que quelques composants mineurs sont des espèces μ-O^iPr. Tous les complexes, à l'exception du $Ti(tartrate)_2(Hdmae)_2$, contiennent des unités tartrates chélatantes servant de pont sans coordination par les groupes carbonyles des esters. Une unité tartrate non chélatante ne servant pas de pont est aussi présente dans les cas des aminoalcools. Les amines primaires, les amines aromatiques et les hydrazines n'ont donné lieu à aucun complexe identifiable. De la même manière, la *N,N*-dibenzylhydroxylamine, en solution, n'a pas donné lieu à la formation du complexe qui a été caractérisé antérieurement par cristallographie à l'aide de rayons X. Dans la riche chimie des systèmes du Ti^{IV}-tartrate, les sélectivités évidentes dans la formation de produits est attribuée à des fermetures de macrocyles qui sont dirigés spécifiquement par la nature électronique du produit additionné. Des intermédiaires transitoires comportant des ponts O^iPr sont aussi impliqués.

Mots clés : alcoolates mixtes du Ti^{IV}, alcoolates chiraux du Ti^{IV}, complexation énantiospécifique.

[Traduit par la rédaction]

Introduction

Our interest in Ti^{IV} complexes of chiral dialkoxide ligands (diolates) is rooted in the usefulness of the tartrate ester complexes in chiral catalysis (1). The motive of our work (2–5) has been to understand the origins of that success in order to develop new catalysts. While drawing upon the large base of knowledge concerning reactivity and selectivity (1), our efforts have been directed at the characterization, mainly by NMR, of the structures of the catalysts in solution, both directly and by contrast with those of numerous analogues. A set of observational criteria has evolved that allows one to distinguish between chelating and non-

chelating diolate units and to decide if the side-chain groups are coordinated (3).

The Katsuki–Sharpless catalysts (1) are fluxional because the side-chain ester groups are reversibly and weakly bound, complicating the study of their structures and their interactions with substrates. We recently undertook to examine certain mixed complexes for two reasons: Firstly, the loosely bound ester groups could be supplanted by more stably bound groups from companion ligands, permitting an easier characterization. Two existing X-ray structures (6) were to serve as controls. Secondly, acting as "proxies" for the catalytic substrates, companion ligands could provide mixed species that model the catalytic intermediates.

A rich chemistry has emerged, which this paper assembles and discusses. As well as presenting more complete details of the mixed ligand species already communicated (4, 5), many new examples and an entirely new and unique tartrate binding mode are reported for the first time. Overall, the products were formed with surprising selectivity, providing three new tartrate binding modes and evidence of transient O^{i}Pr bridges. Further insights have also been gained into reactivity, the Katsuki–Sharpless catalyst structure, and new catalyst designs.

Experimental section

General

Diisopropyl *R,R*- or *S,S*-tartrate, diethyl *R,R*-tartrate, and titanium tetraisopropoxide were freshly distilled. $CDCl_3$ was dried over $Mg(ClO_4)_2$. Unless otherwise stated, NMR spectra were obtained at 19–20°C on a Bruker AM-300 instrument operating at 300 MHz for ^1H or 75.1 MHz for ^{13}C, using pulse sequences from the Bruker library. Integration was performed digitally, at times after digital enhancement of the resolution, which was achieved by zeroing the last half of a 16-kbyte-long FID and zero-filling an additional 48 kbytes before Fourier transformation. Baseline correction was at times used to integrate AB quartets. Spectra were also obtained with simultaneous irradiation of the CH_3 region to simplify the OC*H* region and to establish the numbers and positions of OC*H* heptets. Single-frequency homo-decoupling (^1H–^1H) and hetero-decoupling (^1H–^{13}C) and 2-dimensional shift correlation experiments were used to establish connectivities. ^1H–^{13}C couplings were measured by gated decoupling. Chemical shifts are reported in ppm from TMS and coupling constants are in hertz (Hz). For AB quartets, the J_{AB} and calculated $\Delta\delta$ values are reported. Abbreviations include v for very, b for broad, h for heptet, and m for multiplet. J_{app} denotes apparent couplings. Mass spectrometry was performed by Dr. B. Khouw on a VG instrument (York) or on a ZAB-80 instrument at the McMaster Regional Centre for Mass Spectroscopy. EI experiments were conducted at 70 eV. CI experiments with NH_3 and FAB in various matrices were less informative.

Unless specifically indicated in the results section, reaction mixtures were obtained in one or more ways, depending on which reagent, if any, needed to be added last or whether the proportion of a reagent was to be varied. Solutions 37–42 mM in Ti_2*dipt*$_2$(O^{i}Pr)$_4$ were prepared in $CDCl_3$, with due care to exclude moisture, by mixing appropriate amounts of reagents in volumetric flasks. Such solutions were useful for a few days. Weighed amounts of solid addends were then added, as such or diluted in $CDCl_3$, to 0.4 mL aliquots. Liquid materials were measured by microsyringe and added neat or diluted in some $CDCl_3$. Equivalently, 0.4 mL of a 0.16 M stock $CDCl_3$ solution of H_2*dipt* or H_2*det* was treated with 18 μL of Ti(O^{i}Pr)$_4$ (1 equiv.) by microsyringe, then with successive aliquots of addends (solid or liquid). In reverse order, 18 μL of neat Ti(O^{i}Pr)$_4$ were diluted with 0.4 mL of $CDCl_3$, treated with appropriate amounts of addend as above, whence the simple binary reactions could be analyzed, and then with various aliquots of the stock tartrate solutions. Alternatively, weighed or volumetrically measured addends were diluted with the tartrate stock solution, then treated with aliquots of neat Ti(O^{i}Pr)$_4$. In some cases, additional amounts of reagents could be added later. Most reaction mixtures were reexamined after several days.

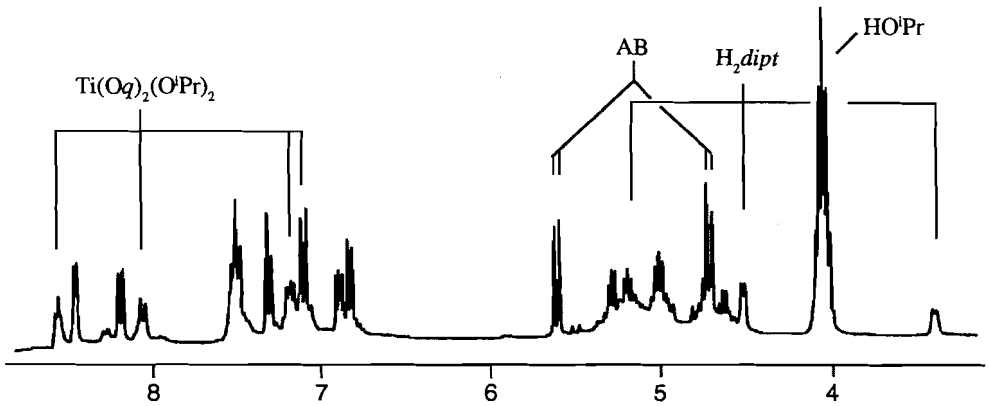
Results

The reactions reported here were essentially instantaneous. The products were often many. They often participated in equilibria and were all, to various degrees, sensitive to moisture. Our experimental approach has therefore been to analyze reaction mixtures in situ by NMR, with corroboration by mass spectrometry whenever possible. (Only EI experiments with relatively stable molecules of moderate size have ever been fruitful.) Aside from assisting the elucidation of product structures, this approach has allowed us to rapidly examine a large number of reaction mixtures, to vary the reactant ratios and the order of mixing at will, to quantitate the product ratios, to detect minor products and transesterification, to assess ligand exchange reactivity, to monitor equilibria, and to look for longer-term changes in product composition.

8-Hydroxyquinoline

With 0.5 equivalent of Ti(O^{i}Pr)$_4$, 8-hydroxyquinoline (HO*q*) produced the bright yellow Ti(O*q*)$_2$(O^{i}Pr)$_2$ according to eq. [1]. As with Ti(*acac*)$_2$(O^{i}Pr)$_2$ (7), diastereotopic pairs of C*H*$_3$ signals in the ^1H NMR spectra confirmed the *cis* geometry in

Fig. 1. Aromatic and OC*H* regions of the ^{1}H NMR spectrum of a 3:3:4 mixture of $Ti(O^iPr)_4$, H_2*dipt*, and HO*q* in $CDCl_3$. Unmarked peaks are assigned to complex **1**. The OC*H* and O*H* signals from unreacted H_2*dipt* are coupled.



$Ti(Oq)_2(O^iPr)_2$ (8). At 1:1 reaction ratios, the same products were produced but with half of the $Ti(O^iPr)_4$ left unreacted. As was surmised in regard to the reaction of 2,4-pentanedione (H*acac*) (9), the first equivalent of HO*q* reacted more slowly with tetracoordinate $Ti(O^iPr)_4$ than did the second equivalent with the putative pentacoordinate intermediate. As would be expected of hexacoordinate complexes, both $Ti(Oq)_2(O^iPr)_2$ and $Ti(acac)_2(O^iPr)_2$ were completely inert toward additional amounts of either reactant and toward diisopropyl *R,R*-tartrate (H_2*dipt*).

[1] $Ti(O^iPr)_4 + 2\ HOq \rightarrow [Ti(Oq)(O^iPr)_3 + HOq + HO^iPr]$

$\rightarrow Ti(Oq)_2(O^iPr)_2 + 2\ HO^iPr$

The reverse reaction, i.e., using preformed $Ti_2dipt_2(O^iPr)_4$, was more fruitful. With H*acac*, the tendency to form $Ti(acac)_2(O^iPr)_2$ was so pronounced that no well-defined mixed complex could be detected. With HO*q*, the results of numerous experiments led to eq. [2].

[2] $3\ Ti_2dipt_2(O^iPr)_4 + 8\ HOq \rightarrow 2\ Ti_2dipt_2(Oq)_2(O^iPr)_2$

$+ 2\ Ti(Oq)_2(O^iPr)_2 + 2\ H_2dipt + 4\ HO^iPr$

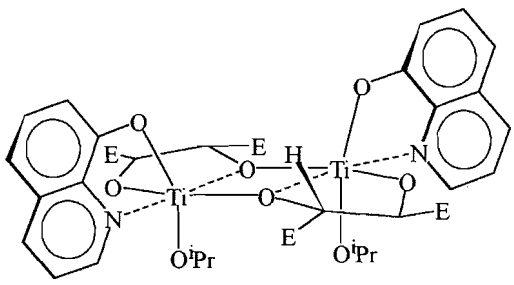
All reactions produced both $Ti(Oq)_2(O^iPr)_2$ and a new product, $Ti_2dipt_2(Oq)_2(O^iPr)_2$, whose structural assignment is detailed below. With ≤4/3 equivalents of HO*q* present per Ti, they were formed in about equal amounts with the liberation of an equal amount of H_2*dipt*, according to integration ratios in the ^{1}H NMR spectra. With >4/3 equivalents, free HO*q* was also present and relatively more $Ti(Oq)_2(O^iPr)_2$ was produced. With < 4/3 equivalents, there was unused $Ti_2dipt_2(O^iPr)_4$, which was indirectly detected: it reacted with the liberated H_2*dipt* to give an ill-defined, fluxional but reproducible, mixture of products, with recognizable NMR signal patterns, that we call "tartrate-excessive material" for convenience. This mixture arises whenever H_2*dipt* and $Ti(O^iPr)_4$ are mixed in >1:1 ratios. As with that mixture, samples with <4/3 HO*q* equivalents per Ti were also more sensitive to hydrolysis by adventitious H_2O than were samples with ≥4/3 equivalents, confirming the presence of the moisture-sensitive $Ti_2dipt_2(O^iPr)_4$. (Such hydrolysis produces white flocculent Ti-containing solids and free H_2*dipt*. $Ti_2dipt_2(Oq)_2(O^iPr)_2$ was more resistant but, over a few days, gave way to the more robust $Ti(Oq)_2(O^iPr)_2$. This too later partially decomposed, probably to μ-oxo dimeric species (10)). Samples with exactly 4/3 equivalents of HO*q* per Ti had neither free HO*q* nor unreacted $Ti_2dipt_2(O^iPr)_4$ (Fig. 1).

Given that some H_2*dipt* was liberated, one could attempt to preclude it by increasing the Ti:H_2*dipt* ratio. Unfortunately, mixtures of $Ti_2dipt_2(O^iPr)_4$ and $Ti(O^iPr)_4$ form $Ti_2dipt(O^iPr)_6$ only partially (2). Without a complete conversion, a subsequent reaction with HO*q* will be more complicated as all three species can react separately with HO*q*. Indeed, a 3:2:4 mixture, from $Ti_2dipt_2(O^iPr)_4$ + $Ti(O^iPr)_4$ + 4 HO_q, and all other mixtures with <1 equivalent of H_2*dipt* per Ti, produced more $Ti(Oq)_2(O^iPr)_2$, less $Ti_2dipt_2(Oq)_2(O^iPr)_2$, and more of the tartrate-excessive material.

The new product was evidently unreactive toward H_2*dipt*, HO*q*, or HO^{i}Pr, as was true of $Ti(Oq)_2(O^iPr)_2$. This inertness, along with its sharp NMR signals, suggested hexacoordination. The NMR spectra indicated a single, new type of tartrate moiety because of an AX pattern ($\Delta\delta = 0.90$, $J = 9.3$) that correlated to well separated O*C*H peaks ($\Delta\delta = 5.33$) in the ^{13}C NMR spectra. This contrasted with the singlets produced by the fluxional $Ti_2dipt_2(O^iPr)_4$ (2) but resembled the AX system (J_{AX} = 8.3) produced by $[Cp_2Zrdipt]_2$ at 233 K (11). There were two distinct ester O*C*H heptets with a corresponding pair of O*C*H peaks and two *C*=O peaks, but both of these lay near the position of the *C*=O signal from free H_2*dipt*. This contrasted with the widely separated ester signals produced by $Ti_2(tartrate)_2(O^tBu)_4$ (5, 12), $Ti_2dipt_2(O^iPr)_4$, and $Ti_2dipt(O^iPr)_6$ (2) that were attributed to the presence of one Ti-bound side chain with downfield-shifted signals, and one that remained free with relatively stationary signals. Clearly, the *dipt* unit in the new product was asymmetrically and rigidly bound but neither of its ester carbonyls was coordinating, as in the Zr complex. Also present were one new TiO^{i}Pr O*C*H heptet, the corresponding O*C*H peak, and one new set of quinoline resonances. Signal integration matched a 1:1:1 ratio of these new quinoline, tartrate, and TiO^{i}Pr moieties.

These observations were consistent with a C_2-symmetric dimer of $Ti(dipt)(Oq)(O^iPr)$, with a Ti_2O_2 core, hexacoordination, rigidity, and inertness. Structure **1** was drawn by analogy with crystalline **2** (6) and because tartrate units are prone to bridge (6, 13). The orientation of the O*q* units drawn in **1**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.



1 E = COO^iPr

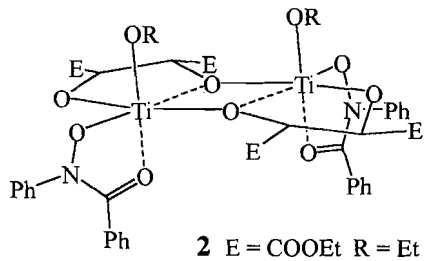
was suggested by other observations: one tartrate OC*H* signal was, according to experience, unusually upfield in the ^1H NMR spectrum, at 4.68 ppm *vs.* 5.11 ppm for $Ti_2dipt_2(O^iPr)_4$, and the TiO*C*HMe_2 signal was downfield by ≈3 ppm from its more usual position near 78 ppm in the ^{13}C NMR spectrum. Accordingly, **1** places the TiO^iPr group in a deshielding region of the aromatic moiety while the bridging OC*H* finds itself in the shielding region of the O*q* attached to the other metal.

N-Benzoyl-*N*-phenylhydroxylamine

To verify that the solid-state structure reported for **2** (6) could be reproduced in solution, analogous reactions with the hydroxamic acid *N*-benzoyl-*N*-phenylhydroxylamine (HO*bpa*) were undertaken. With $Ti(O^iPr)_4$ alone, HO*bpa* had a lesser tendency to form the 2:1 complex than did HO*q* or H*acac* and a 1:1 reactant ratio produced a *ca.* 3:1 mixture of $Ti(Obpa)_2(O^iPr)_2$ and $Ti(Obpa)(O^iPr)_3$ according to eq. [3]. This left some unreacted $Ti(O^iPr)_4$.

[3] $7\ Ti(O^iPr)_4 + 7\ HObpa \rightarrow 3\ Ti(Obpa)_2(O^iPr)_2 + Ti(Obpa)(O^iPr)_3 + 3\ Ti(O^iPr)_4$

$Ti(Obpa)_2(O^iPr)_2$ was readily identified. More of it was produced when less $Ti(O^iPr)_4$ or more HO*bpa* was initially present and it was inert toward added HO*bpa* or H_2dipt. In contrast, $Ti(Obpa)(O^iPr)_3$ was reactive. It gave rise to very broad TiO^iPr and HO^iPr OC*H* signals due to rapid alcohol–alkoxide exchanges, a behaviour ascribable to pentacoordination. A second equivalent of HO*bpa* per Ti converted the $Ti(Obpa)(O^iPr)_3$ and the free $Ti(O^iPr)_4$ to $Ti(Obpa)_2(O^iPr)_2$. However, the treatment with H_2dipt was complicated by the presence of the large amount of free $Ti(O^iPr)_4$.



2 E = COOEt R = Et
3 E = COO^iPr R = ^{i}Pr
4 E = COOEt R = ^{i}Pr

A clearer picture emerged when preformed $Ti_2dipt_2(O^iPr)_4$ was treated with HO*bpa*. In analogy with the HO*q* case, a new product arose that was assigned the formula $Ti_2dipt_2(Obpa)_2(O^iPr)_2$. This was accompanied by $Ti(Obpa)_2(O^iPr)_2$ and some free H_2dipt but, at a starting Ti:HO*bpa* ratio of 1:1, the ratio of $Ti_2dipt_2(Obpa)_2(O^iPr)_2$ to $Ti(Obpa)_2(O^iPr)_2$ was about 3:1. The reaction was approximately described by eq. [4], with the quantitation being complicated by several overlaps in the ^1H NMR spectra and the presence of the aforementioned tartrate-excessive material, which resulted from the H_2dipt and $Ti(O^iPr)_4$ side-products. Equation [4] suggests that a 7:8 Ti:HO*bpa* ratio should avoid the liberation of $Ti(O^iPr)_4$. This was not entirely successful as the rate of mixing and dissolution of the solid HO*bpa* probably influenced the exact outcome.

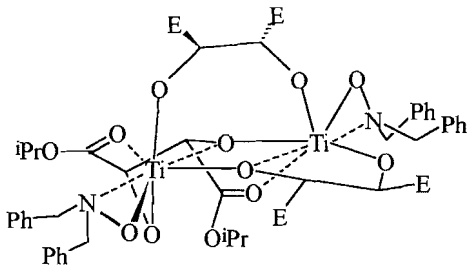
[4] $4\ Ti_2dipt_2(O^iPr)_4 + 8\ HObpa \rightarrow 3\ Ti_2dipt_2(Obpa)_2(O^iPr)_2 + Ti(Obpa)_2(O^iPr)_2 + 2\ H_2dipt + Ti(O^iPr)_4 + 4\ HO^iPr$

The NMR signals were similar to those of $Ti_2dipt_2(Oq)_2(O^iPr)_2$ and included a wide AB system ($\Delta\delta$ = 0.204, J = 9.05) from the single tartrate unit. Overall, the spectra were entirely consistent with **3**, the isopropoxy analogue of **2** (6), and provided the first link between solution-state and solid-state structures.

An attempt was made to cleanly produce the 2:2:2 complex and to clarify the OC*H* region by adding $Ti(O^iPr)_4$ to a 1:1 mixture of H_2det and (dissolved) HO*bpa*. This was not completely successful as much alkoxy scrambling (OEt ↔ O^iPr) took place through transesterification and subsequent alcohol–alkoxide exchange. The mixed complex could not be fully characterized but a new AB system (J_{AB} = 8.8), consistent with structure **4**, was readily discerned.

N,N-Dibenzylhydroxylamine

This ligand was of interest because of the reported crystal structure **5** (6) and because it is a stable analogue of ^{t}BuOOH,



5 E = COO^iPr

the oxidant used in the Katsuki–Sharpless asymmetric epoxidation (1). However, only complex spectra with broad signals resulted from the addition of *N,N*-dibenzylhydroxylamine ($HONBn_2$) to preformed $Ti_2dipt_2(O^iPr)_4$. A 2:3:2 Ti:H_2 *dipt*:$HONBn_2$ mixture was somewhat cleaner, showing two AB quartets (J = 13.2 and 14.9) due to benzylic methylenes, but the tartrate signals were all broad and much free H_2dipt was still present. The ^{13}C NMR spectrum was not very informative: pairs of CH_2 peaks due to Ti-bound $ONBn_2$ were found, but the Ti-bound tartrate signals were broad and weak and resembled those in the parent $Ti_2dipt_2(O^iPr)_4$ (2). These disappointing reactions served to remind us that crystalline samples are not necessarily representative of reaction mixtures.

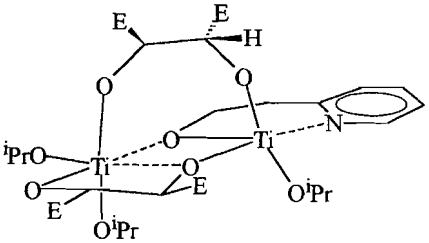
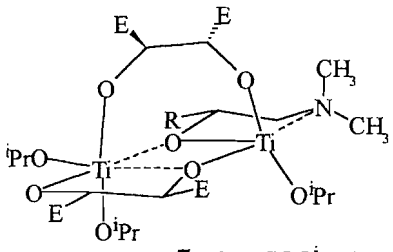
Alkanolamines

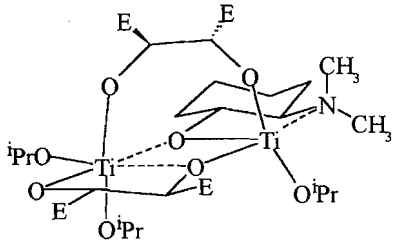
In a previous communication (4), it was reported that alkanolamines (denoted generically as H*AA*) formed single diastereomers of $Ti_2dipt_2(AA)(O^iPr)_3$ complexes. These were obtained by treatment of the preformed $Ti_2dipt_2(O^iPr)_4$ with 0.5 equivalent per Ti of an achiral or a homochiral H*AA* or with 1 equivalent of a racemic H*AA*, in which case one H*AA* enantiomer remained unreacted. They were also produced by treatment of the preformed $Ti(AA)(O^iPr)_3$ complexes with H_2dipt, in which case half or one antipode of the H*AA* was liberated. Thus, compounds **6** and **7** were from the achiral 2-(2-hydroxyethyl)pyridine (HO*epy*) and *N,N*-dimethyl-2-aminoethanol (H*dmae*), respectively, while the racemic *N,N*-dimethyl-1-amino-2-propanol (H*dmap*) and *N,N*-dimethyl-*trans*-2-aminocyclohexanol (H*dmac*) provided **8** and **9**, respectively, as



6 E = COO^iPr



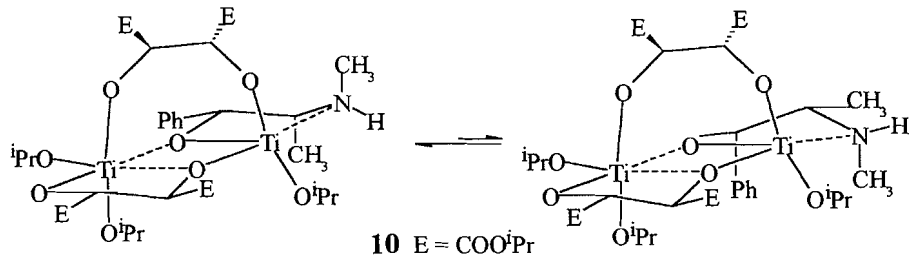
7 E = COO^iPr R = H
8 E = COO^iPr R = CH_3
12 E = COOEt R = CH_3



9 E = COO^iPr
13 E = COOEt

single diastereomers. As evidence of the enantiospecificity, free *S,S*-H*dmac* was separated from the reaction of *rac* material by size-exclusion chromatography (4). Further, (−)-(1*R*,2*S*)-ephedrine [(−)-H*eph*] similarly formed **10** but (+)-(1*S*,2*R*)-ephedrine [(+)-H*eph*] gave only complex, undecipherable spectra. Instead, (+)-H*eph* reacted with $Ti_2(S,S\text{-}dipt)_2(O^iPr)_4$ to afford *ent*-**10**.

Mass spectroscopy of the H*dmac* mixture showed peaks



10 E = COO^iPr

attributable to **9** and to $Ti_2dipt_2(R,R\text{-}dmac)(S,S\text{-}dmac)(O^iPr)_2$ (4). As there was no sign of the latter product in solution, a substitution of O^iPr by the free *S,S*-H*dmac* must have occurred during evaporation of the sample on the EI probe. This also occurred during an attempted isolation of the 2:2:1 species. The stoichiometry has since been confirmed by mass spectrometry of a sample of $Ti_2dipt_2(dmae)(O^iPr)_3$ (*m/z* 826) generated without excess H*dmae*.

Reference 4 presents a sample ^1H NMR spectrum. In all cases, the patterns were as follows. Two equally intense sets of skeletal OC*H* and O*CH* signals indicated two distinct *dipt* units. There was no sign of ester carbonyl coordination and, given the stoichiometry of reaction, this implied that one metal was pentacoordinate. One tartrate unit resembled those in **1** and **3**, producing an AB quartet with J_{AB} consistently in the 9.1–9.4 Hz range, and modest chemical shift differences between O*CH* peaks. These signals were therefore assigned to the rigid, chelating, and bridging *dipt* units depicted in **6–10**. The second set of signals was an AX system with more variability in J_{AX} (7.2–8.6 Hz). This set was therefore assigned to a relatively flexible *dipt* that lacked the chelation feature. The A doublet was unusually far downfield, near 5.6 ppm. This was attributed to the OC*H* attached to the pentacoordinate Ti (explicitly drawn in **6**) suffering a deshielding by the nearby ester carbonyl on the other, chelating, tartrate unit. Pentacoordination was manifested as broadened signals for HO^iPr and any unreacted or liberated H*AA*, as was the case with the $Ti(dmae)(O^iPr)_3$ and $Ti(dmap)(O^iPr)_3$, which were known to be monomeric and therefore pentacoordinate (14), and with $Ti(Oeph)(O^iPr)_3$, which is also monomeric according to mass spectrometry. The bridging by the amino alkoxide oxygens depicted in **6–10** is reasonable given that those oxygens are more basic than those in the tartrate and less hindered than in O^iPr. Such bridges would spatially fix the carbinol centres and allow for enantiospecific complexation.

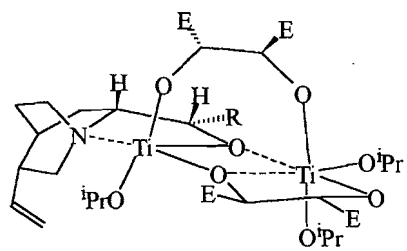
The ephedrine case had some peculiarities. Firstly, one $TiOCH(CH_3)_2$ heptet was unusually upfield, nearly overlapping that of HO^iPr, and was coupled to two far upfield CH_3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

doublets. Shielding by the phenyl group might be responsible. Secondly, minor peaks (visible most clearly in the aromatic region and at the benzylic position) suggested the coexistence of the conformational isomer depicted, probably arising in relief of steric interactions involving the *N*-CH_3, which, in turn, would attempt to avoid 1,2-interactions with the *C*-CH_3.

These 2:2:1 mixed complexes were invoked to explain the oxidative resolution of *N,N*-1-trisubstituted H*AA* reported by Miyano et al. (15), whereby the complexation, and not the oxidation, is enantioselective. It was also proposed that the absolute stereochemistry of a homochiral H*AA* could be assigned according to which tartrate antipode will give rise to the characteristic NMR patterns (4). To illustrate the operational simplicity and the generality of the method, even with a complex H*AA*, consider the case of (+)-cinchonine (H*cin*), whose absolute stereochemistry leads one to expect a well-defined mixed complex only with *S,S*-tartrate. A small sample (17.8 mg) of the sparingly soluble free base was suspended in $CDCl_3$ and treated with 2 equivalents of $Ti(O^iPr)_4$ in $CDCl_3$ solution, whereupon it dissolved with shaking and formed the 1:1 complex, leaving half the $Ti(O^iPr)_4$ unreacted. Half of that solution was transferred to a fresh NMR tube and each tube was treated with one or the other antipode of H_2*dipt* in $CDCl_3$ solutions such that each tube had a 2:2:1 Ti:*dipt*:*AA* ratio. The tube with *R,R-dipt* displayed a complicated, undecipherable spectrum of broad signals, while that with *S,S-dipt* showed a clean spectrum of a single species (**11**) with the characteristic patterns. Thus, without special precautions with regard to atmospheric moisture, the prediction was quickly borne out. Even smaller samples could have been used with dilute solutions of the reagents. Small excesses of either reagent are tolerated and the amino alcohols are, in principle, recoverable.

The spectra of the H*cin* complexes were fairly easy to analyse because of the shifts induced by complexation. Each of the quinoline resonances, the olefinic and carbinol OC*H* signals were readily found. After the first reaction with $Ti(O^iPr)_4$, the OC*H* signal shifted downfield and the olefinic signals shifted upfield, presumably owing to the influence of the *syn* quinoline portion brought into proximity by chelation. This situation persisted after the addition of the tartrate, confirming that the cinchonine remained chelated. Several aliphatic multiplets were also shifted downfield. Unlike the H*eph* case, however, which is also a *cis* substituted amino alcohol, no isomerism was found in this case, probably due to a lack of flexibility at the amino end.



11 E = COO^iPr R = 4-quinolinyl

We now report that diethyl *R,R*-tartrate (H_2*det*) formed analogous mixed complexes **12** and **13** in reactions with $Ti(O^iPr)_4$ *without transesterification*. This confirms the absence of carbonyl coordination. By adding the H_2*det* or the $Ti(O^iPr)_4$ last, to avoid transesterification, a 2:2:2 H_2*det*:Ti$(O^iPr)_4$:H*dmap* mixture afforded a clear spectrum fitting structure **12**, in which the ester OCH_2 signals were well removed from the OC*H* region. The same occurred with H*dmac* to give **13**, but not with H*dmae* (*vide infra*). With **12** and **13**, the AB quartets had a large J_{AB} as before (9.1 and 9.2 Hz), but the AX system exhibited smaller J_{AX} values (5.0 and 5.3 Hz) than with **8** or **9**. This provided further support for the assignment of this AX system to a more flexible, nonchelated, and nonbridging tartrate unit.

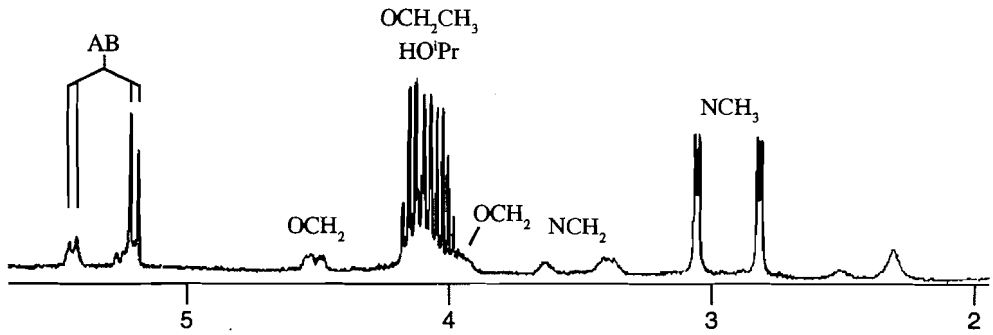
The special case of 2-*N,N*-dimethylaminoethanol

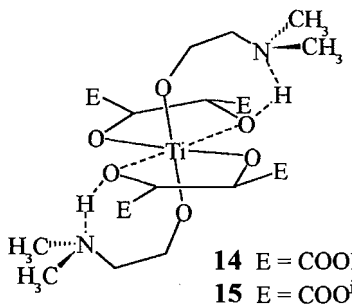
When a sample of **7** had been allowed to stand for 4 days, signals from a new species emerged. The unusual appearance and positions of these signals promised an interesting origin. These same new signals also arose as a minor contaminant of **7** when H*dmae* had been added immediately after mixing H_2*dipt* with $Ti(O^iPr)_4$. The possibility of a transesterification involving H*dmae* could be ruled out since the mixing time was short and because there was no spectral evidence of that exchange. The new species could be prepared directly by adding $Ti(O^iPr)_4$ to mixtures of H_2*det* or H_2*dipt* and H*dmae*. Depending on the reactant ratio used, this was at times accompanied by various amounts of **7** and (or) free H*dmae* and (or) free tartrate. The reactions with H_2*det* were cleanest and their ^1H NMR spectra had a relatively uncluttered OC*H* region that allowed more complete signal assignments (see Fig. 2).

Most notable were new, downfield-shifted NCH_3 (diastereotopic) pairs of peaks but there were also a pair of upfield-shifted NCH_3 peaks, a broad signal at 11.5–12 ppm, likely due to an exchangeable H, and a new AB quartet in which the (downfield) A portion was significantly broader than the B portion. The latter suggested a chelating tartrate unit but with weaker coupling than in the previously described cases (J_{AB} = 8.22 with H_2*det*, 8.80 with H_2*dipt*). There was only one new tartrate OCH peak, but the ester *C*=O and OCH_2 peaks were paired. Their positions and the absence of transesterification suggested that neither carbonyl was coordinated. There were no new TiO^iPr signals at all and, therefore, no new TiO^iPr groups. New pairs of OCH_2 and NCH_2 multiplets were also found. Irradiation of the broad 11.5–12 ppm signal produced a collapse of both NCH_3 pairs into two singlets and a simplification of at least one NCH_2 multiplet (the other overlapped the HO^iPr heptet). This suggested the presence of *protonated amino groups*, where the N*H* (at very low field) was coupled to NCH_2 and to both kinds of NCH_3. The downfield positions of the OCH_2 multiplets clearly indicated that the *dmae* units were attached to the metal but the upfield positions of the NCH_3 peaks indicated that the N was not. Integration revealed a 1:1 *det*:*dmae* ratio in the new product, but the Ti content could only be estimated at <1 equivalent by examining several reaction stoichiometries. From the generic formula Ti_x-det_y(H*dmae*)$_y$, the equation $4x-2y = 0$ leads to $x = y/2$. With bidentate *det* and monodentate *dmae*, even the simplest formula (x = 1 and y = 2) affords hexacoordination.

To fit the available information, the two new species were drawn as **14** and **15**. They could be described as doubly zwitterionic and H-bonded. The H-bonding depicted would maintain diastereotopic NCH_3 groups and account for the broadness of both the N*H* and the downfield tartrate OC*H* signals. (The irradiation of the low-field N*H* did not sharpen the

Fig. 2. OC*H* region of the ^{1}H NMR spectrum of a 1:2:2 mixture of Ti(O^{i}Pr)$_4$, H$_2$*det*, and H*dmae* in $CDCl_3$, assigned to complex **14**.



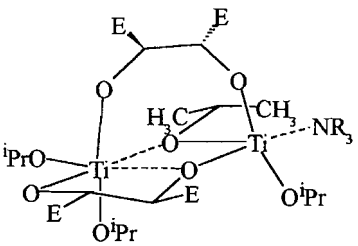


14 E = COOEt
15 E = COO^{i}Pr

downfield (A) portion of the tartrate AB system.) Severe broadening would also account for the visible presence of only one tartrate skeletal OC*H* peak. These are the first instances of well-defined species bearing two tartrate units per Ti. The basicity at N and the absence of strong steric repulsions were key, as neither H*epy*, which was probably insufficiently basic, nor H*dmap*, which was probably too bulky, showed any trace of analogous species.

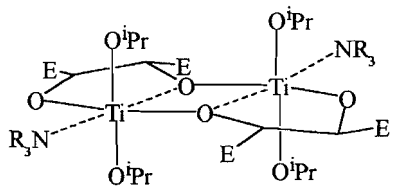
Simple amines

The reactions with simple amines were initially explored in anticipation that they would form either analogues of the amino alcohol complexes with a novel, bridging O^{i}Pr group (**A**) or analogues of the HO*q* and HO*bpa* complexes (**B**). Analogues of **14** and **15** were also possible.



A

E = COO^{i}Pr or COOEt



B

As communicated earlier (5), NEt_3 and NH^iPr_2 were found to instead produce the 3:4:2 mixed complexes **16** and **18**, using NMR signal integration and many titration experiments to decide the stoichiometry. We now report that $NHEt_2$ and *N,N,N′,N*-tetramethyl-1,2-diaminoethane (Me_4en) will form analogous complexes **17** and **19**, respectively, and that H$_2$*det* can also be used, affording **20**–**23**. Clean spectra resulted from mixing H$_2$*dipt*, Ti(O^{i}Pr)$_4$, and amine at 3:4:2 ratios or by treating 2:1 H$_2$*det*–amine mixtures with 3/4 equivalents of Ti(O^{i}Pr)$_4$ per tartrate without fear of transesterification. With <4/3 equivalents of tartrate per Ti present, the parent Ti$_2$(tartrate)$_2$(O^{i}Pr)$_4$ was also present (with transesterification, if using H$_2$*det*). With >4/3 equivalents of tartrate or <2/3 equivalents of amine per Ti, the complex set of signals typical of tartrate-excessive material appeared. No amide formation was ever detected.

As illustrated in Fig. 3, the adducts were characterized by single, sharp, AB quartets, entirely similar to those previously described and assigned to chelating and bridging tartrate units

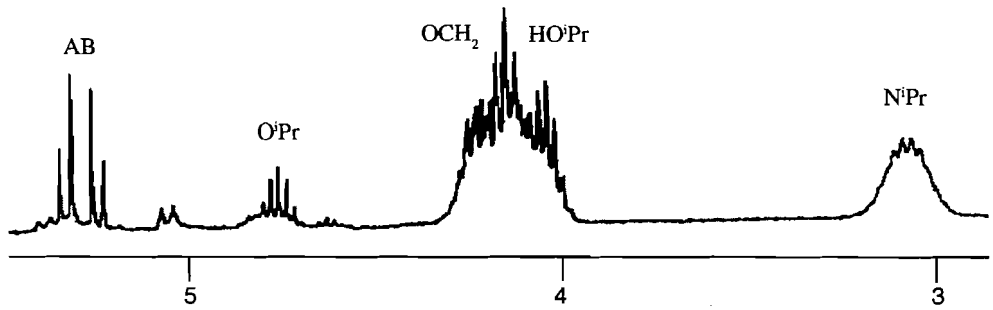
Fig. 3. OC*H* region of the ^{1}H NMR spectrum of a 3:4:2 mixture of $Ti(O^iPr)_4$, H_2*det*, and NH^iPr_2 in $CDCl_3$, assigned to complex **22**. Note the minor doublets above 5 ppm.



(J_{AB} = 9.1–9.4 with H_2*dipt*, 8.2–9.3 with H_2*det*), along with two new, sharp and closely spaced, ester OC*H* heptets (or OCH_2 quartets) and one sharp O^{i}Pr heptet. ^{13}C NMR concurred and also confirmed the absence of ester coordination. The amine signals were also interesting: in the $NHEt_2$ case, for instance, two broad CH_2 quintets appeared some 0.5 ppm downfield of the position where the quartet from free $NHEt_2$ appears, and the N*H* signal was very broad and near 8.7 ppm. This indicated a single type of amine coordinated to a metal in a chiral environment, with diastereotopic CH_2 groups coupled to the NH. With progressive additions of further amine, the quintets melded, shifted upfield, and eventually became the quartet of free $NHEt_2$. Thus, bound and free amine were rapidly exchanging. Using H_2*det* greatly simplified the OC*H* region. Thus, the ratio of the AB quartet to the TiO^{i}Pr heptet could be fairly accurately measured at about 2:1 from a 1:1 *det*:O^{i}Pr ratio. Hence, from the generic formula $Ti_x det_y(O^iPr)_{4x-2y}(amine)_n$, $y/(4x-2y) = 1$ leads to $y/x = 4/3$, which concurred with the results of the titration experiments. To place four equivalent but asymmetrically bound tartrate units and four equivalent O^{i}Pr groups about three Ti centres requires that n be 2. Structures **16**–**23** could then be drawn.

These complexes were labile and involved in equilibria with the parent $Ti_2(tartrate)_2(O^iPr)_4$ species, the tartrate-excessive material, and the free amines. Indeed, heating a 1:1:1 mixture to 50°C and recooling demonstrated that $Ti_2 dipt_2(O^iPr)_4$ and the free amine were favoured at higher temperatures.

Two other phenomena were noted with the two secondary amines. Firstly, when these were added to preformed $Ti_2 dipt_2(O^iPr)_4$, a second, more minor, product was also present. They gave rise to AX systems that included a doublet far downfield (at 5.4–5.5 ppm), reminiscent of those in the amino alcohol complexes. Due to overlaps, the partner doublet was found only in the $NHEt_2$ case, at 4.6 ppm. These AX systems may signal the partial formation of the O^{i}Pr-bridged analogues **A** originally predicted. Secondly, 2:3:1 Ti:tartrate:$NHEt_2$ or NH^iPr_2 mixtures produced another minor product whose tartrate unit gave rise to a broad and much weaker doublet of doublets with $J \approx 8.25$ (confirmed by decoupling and correlation spectroscopy), which partially overlapped the sharp AB quartet of the major, 4:3:2 product (see Fig. 3). However, no additional ^{13}C signals could be detected to attribute to these minor products. We speculate that they were analogues of **14** and **15**.

The weaker base morpholine produced only broad ^{1}H NMR signals when added to H_2*dipt*–$Ti(O^iPr)_4$ mixtures, but when $Ti(O^iPr)_4$ was added to a 2:1 H_2*det*:morpholine mixture, an analogous 4:3:2 product (J_{AB} = 8.8) seemed to form; however, its signals overlapped a large amount of broad resonance in the OC*H* region, and it could not be fully characterized. Reactions with *n*-propylamine, *tert*-butylamine, phenylhydrazine, 2-hydroxyethylhydrazine, pyridine, 4-dimethylaminopyridine, and 2,2′-bipyridine all failed to produce well-defined species, giving complex spectra or only broadened signals. Perhaps fast *O*-to-*N* transacylation took place with the primary amines and hydrazines while the pyridines were perhaps too poorly basic.

H-C coupling constants

In many cases, the tartrate $^1J_{HC}$ (145.5–155.6 Hz) and $^2J_{HC}$ (3.1–7.1 Hz) values could be measured from ^{1}H-coupled ^{13}C NMR spectra. In other cases, this was not possible (weak signals, signal overlaps, and ambiguities in assignment). The general observation was that, for every OCH pair suspected to belong to a chelating tartrate unit, one was always associated with a stronger $^1J_{HC}$ and a stronger $^2J_{HC}$. The nonchelated tartrate units of the tartrate–amino alcohol mixed complexes also gave rise to paired O*C*H signals of differing $^1J_{HC}$ values (though the $^2J_{HC}$ values were more similar).

The significance of the $^2J_{HC}$ values is not clear but $^1J_{HC}$ values are associated with the hybridization and *s* character at C. We postulate that these differences in $^1J_{HC}$ arise from π-type donation by O in the bridging OCH, on the one hand, or in a terminal OCH at pentacoordinate Ti, on the other. Among other changes, both kinds of π donation are associated with a lengthening of the O—C bond (7, 12, 16).

Discussion

Tartrate esters adopt a variety of binding modes in the solid state (6, 7) but, until part of the present work was recently communicated (4, 5), only two had been identified in solution. One is tridentate coordination, with chelation by the diol part, bridging of two Ti by one of the two diolate oxygens, and coordination by an ester or amide carbonyl group. This is adopted by $Ti_2(dipt)(O^iPr)_6$ and its analogue from *meso*-H_2*dipt*, by $Ti_2(tartrate)_2(O^iBu)_4$ species, and by a crystalline tartramide complex (6). The second binding mode differs from the first only in that it lacks the chelation feature. It is adopted by $Ti_2 dipt_2(O^iPr)_4$, the Katsuki–Sharpless asymmetric epoxidation catalyst (1), by two $Ti_3(tartramide)_2(O^iPr)_8$ complexes in solution (2, 5), and by the crystalline tartrate salts of transition metals (17). Of the three new binding modes seen here, the most prevalent is that in which the side-chain

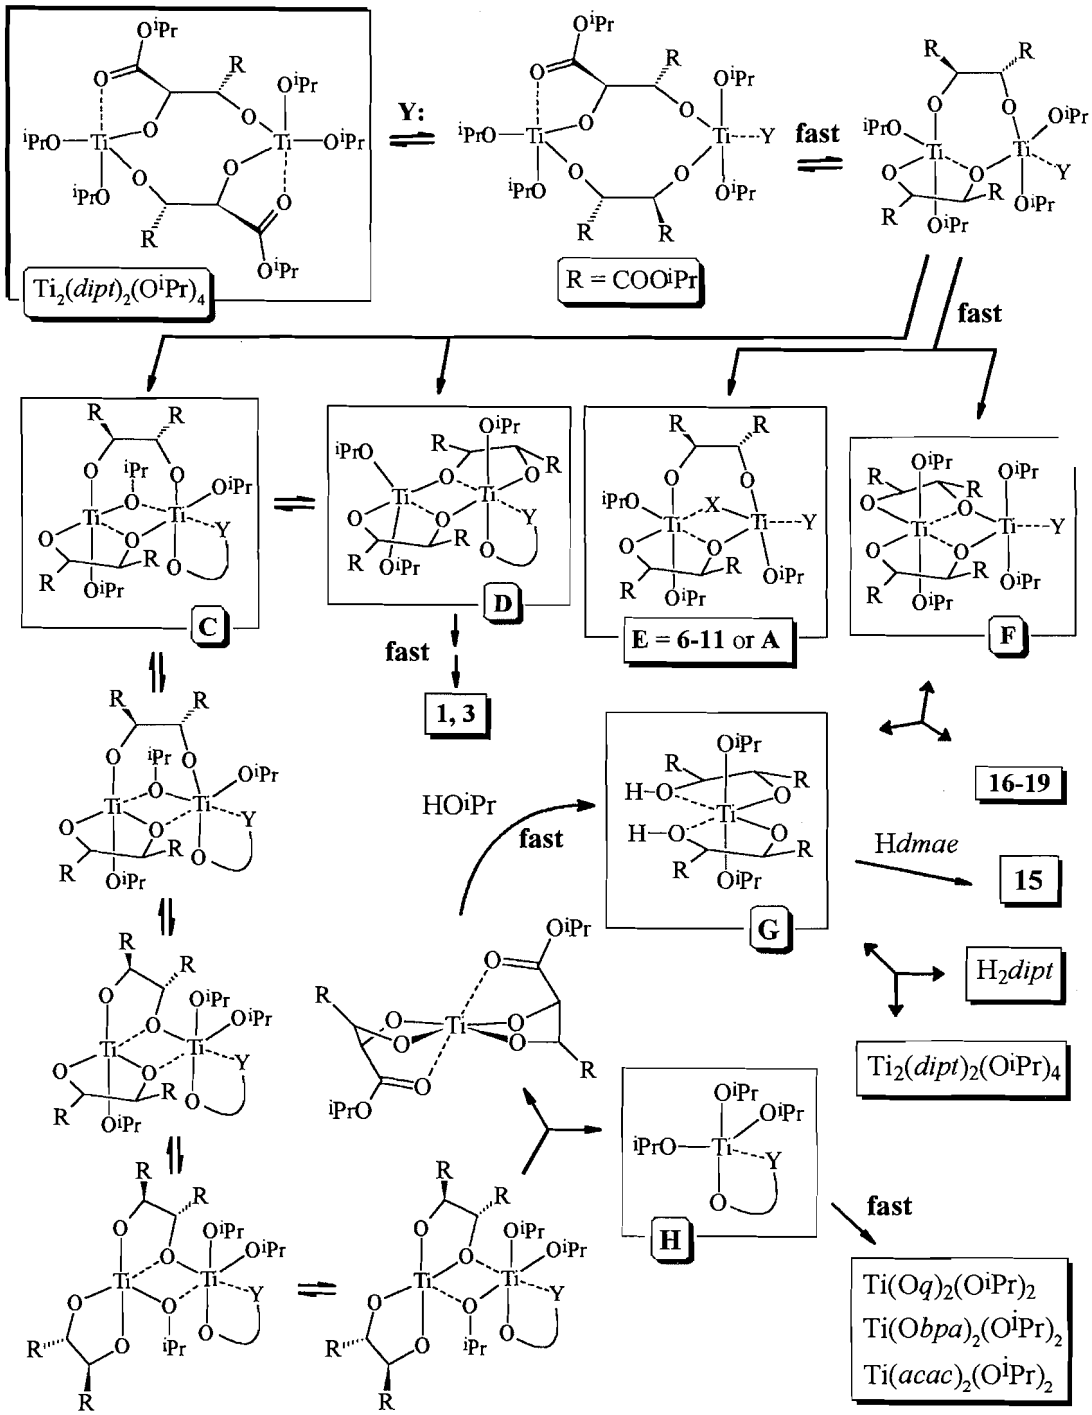
Scheme 1



coordination is simply replaced by that of another group of external origin. This mode has also been found several times in the solid state (6, 7). The fourth mode, found in solution in the amino alcohol complexes and present in the crystalline **5** (6), involves only terminal ligation with the spanning of two metal centres. The fifth, involving mononuclear species **14** and **15**, is unprecedented.

The reactions described herein were selective in that other, plausible products did not form: with HO*q* and HO*bpa*, no product of the simultaneous replacements of O^{i}Pr and tartrate were apparent. The reactions with amino alcohols were enantiospecific. In the reactions with amines, other products (**A** and **B**) were anticipated.

Scheme 1 attempts to assemble and rationalize most of our observations in the reactions of $Ti_2dipt_2(O^iPr)_4$. Though the geometries at Ti, the ligand positions, and the sequence of events may not be exactly correct, it describes a likely origin of the observed selectivities: the various products observed can all be viewed as resulting from an initial macro-ring closure triggered by the binding of an addend Y onto the reactive

$Ti_2dipt_2(O^iPr)_4$. The architecture of the condensed adducts **C–F** then depends on which metal contributes the second bridge, and this in turn depends on the electron-donating ability and the bulk of the addend.

Consider the reactions of HO*q*, HO*bpa*, and H*acac*. They substitute an electron-rich group, O^iPr, with a poorer one. The second bridge should therefore originate at the other metal, favouring hexacoordination at the electron-poor metal in **D** and (or) **C**. (The closure sequence may in fact be the opposite of that drawn.) Though not depicted, the pentacoordinate centres in **C**, **D**, and structures following **C** may be partially stabilized by the binding of a tartrate ester group but this would be strenuous, weak, and reversible (3). The conversion of **D** to the observed products **1** and **3** is self-evident. The further reaction of **C** is depicted economically, but other routes are possible. Through fast, intramolecular ligand reorganizations, this effects a net exchange of tartrate and O^iPr substituents between metals so as to place the relatively more electron-rich O^iPr groups on the electron-poorer metal. Once the segregation is accomplished, we speculate that dissociation produces a pentacoordinate intermediate **H**, which is rapidly trapped by a second equivalent of the addend (eqs. [1] and [3]), and $Ti(dipt)_2$, which can be quenched by ambient HO^iPr to give **G** and take its place in the fluxional mixture we call tartrate-excessive material. This dissociation could instead be triggered by an external attack by HO^iPr, H_2dipt or something else to produce **G** directly or other members of the family of tartrate-excessive materials. That mixture partly liberates H_2dipt while regenerating $Ti_2dipt_2(O^iPr)_4$. As required by eq. [2], the intermediacy of equal amounts of **C** and **D** from HO*q* will ensure that one of every three *dipt* units initially available will be liberated as H_2dipt and that equal amounts of **1** and $Ti(Oq)_2(O^iPr)_2$ will be produced. Similarly, eq. [4] corresponds to a 3:1 preference for **D** over **C**. The reaction with H*acac* apparently proceeded exclusively through **C**.

On the other hand, the bulky and electron-rich aminoalcohols and amines add electron density and the second bridge should originate from the electron-rich metal. Closure to **F** and (or) **E** then favours hexacoordination at the electron-poorer metal. (With amino alcohols, the opposite closure sequence may occur.) When an amino alkoxide O is available as a relatively compact and electron-rich bridge, **E** (i.e., **6–11**) is favoured over **F**. With amines, this electronic preference is offset by steric congestion and the less electron-rich tartrate O is used to form the bridge in **F**, though **E** (i.e., the minor products **A**) can also form with the less bulky secondary amines. In the absence of excess H_2dipt, the reaction of amines can go no further and can only revert to starting materials. (Only with amines are the reactions entirely reversible.) The presence of excess tartrate produces tartrate-excessive material, probably including **G**, which can react reversibly with **F** to give the dominant amine adducts **16–19** in the presence of sufficient amine. Finally, the unusual H*dmae* adduct **15** can be formed from **G** by simple substitutions.

Scheme 1 also explains other observations. Firstly, the absence of **B**-type amine adducts is logical since the electron-donating ability of amino-type N disfavours the intermediacy of a **D**-like precursor to **B**. Secondly, the "wrong" antipode combinations in the amino alcohol reactions would be expected to give a fluxional mixture of adducts resulting from (reversible) formation of **F** and (or) O^iPr-bridged **E**, with the additional possibility of oligomeric assemblies. Complex, undecipherable spectra were in fact obtained. Finally, it is not too surprising that $HONBn_2$ produced complex reaction mixtures. As a bidentate, the Lewis basicity of $HONBn_2$ is probably closer to that of HO*q* than to that of amino alcohols. Both **C**- and **D**-derived products can be expected. (The crystallized product **5** can be viewed as a **D**-derived architecture, whether this came from $Ti_2dipt_2(O^iPr)_4$ or from a 3:2 *dipt*:Ti assembly.) But $ONBn_2$ is probably a poor, facultative bidentate and much of it may be monodentate, simply involved in exchanges with HO^iPr. With excess H_2dipt, it may end up scrambled among the components of the tartrate-excessive material. Further, the small "bite" of bidentate $ONBn_2$ enables the binding of other groups, including HO^iPr and ester carbonyls, to produce heptacoordination. This too may be a fluxional affair.

While the details of Scheme 1 remain uncertain, three conclusions seem inevitable. Firstly, Scheme 1 requires that $Ti_2dipt_2(O^iPr)_4$ have the 10-membered macrocyclic form depicted, a structure that has been the subject of some controversy (5); it would be very difficult to account for the products otherwise. In particular, the condensed, **D**-like form preferred by the Sharpless group (1, 6, 12) would be expected to give products with only **D**-derived architectures.

Secondly, the reactions that require internal reorganizations or ligand exchanges must be fast. Indeed, because H_2det can be used in the reactions with amines and amino alcohols, they evidently proceeded faster than could transesterification. Most of the steps depicted involve pentacoordination (or strained hexacoordination if ester carbonyls are allowed to coordinate) while the observed end products are relatively inert thermodynamic sinks (**6–13** retain some ligand exchange reactivity). In regard to the design of new catalysts for asymmetric reactions, it is interesting to note that $Ti_2dipt_2(O^iPr)_4$ itself is fluxional, not "well-defined," and its structure was indirectly deduced (2, 3, 5). Much of its success in catalyzing the Katsuki–Sharpless asymmetric epoxidation of allylic alcohols (1) can be ascribed to its avoidance of a thermodynamic sink (3, 5). A successful catalyst therefore need not be well-defined but should possess this same ability. Accordingly, **C–G** all have desirable architectures.

Finally, it would be difficult to account for the selective formation of $Ti(Oq)_2(O^iPr)_2$, $Ti(Obpa)_2(O^iPr)_2$, and $Ti(acac)_2(O^iPr)_2$ without invoking transient O^iPr bridges. As well, O^iPr-bridged **A**-type complexes from amines are an undeniable possibility. Such bridging has only once been directly observed, by low-temperature ^{13}C NMR spectroscopy of $Ti(O^iPr)_4$ (18), but their presence has been invoked in several cases, such as $Ti_2dipt(O^iPr)_6$ (2, 3). Only steric congestion seems to impede their more ready formation, for structures **1–13**, **16–23**, and others (6, 7) all involve bridging by secondary carbinol oxygens, and O^iPr is more Lewis basic than tartrate. The significance of such bridges is that they may well play a role in the Katsuki–Sharpless catalytic system, serving to rigidify the reaction template. During that reaction, the allylic alcohol substrate and the oxidant are initially loaded onto $Ti_2dipt_2(O^iPr)_4$ by exchange with O^iPr groups. The subsequent enantioselective O transfer was earlier rationalized on a **D**-like template (1, 6, 19). If, like $ONBn_2$, ^tBuOO is considered a relatively electron-poor bidentate (20), then both **C**- and **D**-like assemblies are possible. Bridging O^iPr or allyloxide groups (**C**) would in fact be electronically preferred over a second tar-

trate bridge (**D**), and the small "bite" of ^{t}BuOO (20) might well accommodate any additional steric demands.

Scheme 1 is but one window on the rich chemistry manifested by Ti^{IV}-tartrate systems and much of it, undoubtedly, is yet unexposed.

Manifestations of noncovalent bonding in the solid state. 6.[1] $[H_4(cyclam)]^{4+}$ (cyclam = 1,4,8,11-tetraazacyclotetradecane) as a template for crystal engineering of network hydrogen-bonded solids

S. Subramanian and Michael J. Zaworotko

Abstract: A series of salts of composition $[H_4(cyclam)]X{\cdot}nH_2O$, where cyclam = 1,4,8,11-tetraazacyclotetradecane and X = $4Cl^-$ (**1**, $n = 4$), $4Br^-$ (**2**, $n = 4$), $4I^-$ (**3**, $n = x$), $4ClO_4^-$ (**4**, $n = 2$), $4CNS^-$ (**5**, $n = 2$), $2SO_4^{2-}$ (**6**, $n = 6$), and (p-$CH_3C_6H_4SO_3^-$) (**7**, $n = 0$) have been prepared and crystal structures of **1**, **2**, **4**, **5**, **6**, and **7** have been determined by single crystal X-ray crystallography. **1**, **2**, **3**, **4**, and **7** were prepared by crystallizing cyclam with a large excess of the corresponding acid whereas the thiocyanate, **5**, and the sulphate, **6**, salts were prepared by metathesis of the perchlorate salt, **4**, with KCNS and K_2SO_4, respectively. Crystal data: **1**: orthorhombic, *Pnnb*, $a = 7.7962(16)$, $b = 14.278(4)$, $c = 17.787(4)$ Å, $V = 1979.9(8)$ Å^3, $Z = 4$, $D_c = 1.39$ Mg m^{-3}, $R_f = 0.051$, and $R_w = 0.069$ for 1176 reflections with $I > 3\sigma(I)$. **2**: triclinic, $P\bar{1}$, $a = 7.6860(8)$, $b = 7.8848(9)$, $c = 9.6385(11)$ Å, $\alpha = 105.111(16)°$, $\beta = 95.495(18)°$, $\gamma = 102.464(17)°$, $V = 543.43(12)$ Å^3, $Z = 1$, $D_c = 1.82$ Mg m^{-3}, $R_f = 0.034$, and $R_w = 0.041$ for 1530 reflections with $I > 3\sigma(I)$. **4**: monoclinic, $P2_1/n$, $a = 8.4519(11)$, $b = 15.9248(12)$, $c = 9.2981(17)$ Å, $\beta = 106.243(18)°$, $V = 1201.5(3)$ Å^3, $Z = 2$, $D_c = 1.76$ Mg m^{-3}, $R_f = 0.052$, and $R_w = 0.068$ for 1902 reflections with $I > 3.0\sigma(I)$. **5**: triclinic, $P\bar{1}$, $a = 8.2996(7)$, $b = 9.0061(15)$, $c = 9.2015(15)$ Å, $\alpha = 107.60(3)°$, $\beta = 97.738(14)°$, $\gamma = 108.863(9)°$, $V = 599.44(15)$ Å^3, $Z = 1$, $D_c = 1.309$ Mg m^{-3}, $R_f = 0.038$ and $R_w = 0.049$ for 1856 reflections with $I > 4\sigma(I)$. **6:** triclinic, $P\bar{1}$, $a = 7.8687(5)$, $b = 8.8396(12)$, $c = 9.0405(25)$ Å, $\alpha = 68.547(16)$, $\beta = 85.332(9)$, $\gamma = 78.473(7)°$, $V = 573.43(18)$ Å^3, $Z = 1$, $D_c = 1.693$ Mg m^{-3}, $R_f = 0.053$ and $R_w = 0.076$ for 1441 reflections with $I > 3\sigma(I)$. **7**: triclinic, $P\bar{1}$, $a = 8.533(3)$, $b = 9.110(3)$, $c = 15.3605(21)$ Å, $\alpha = 82.475(17)°$, $\beta = 74.307(20)°$, $\gamma = 73.26(3)°$, $V = 1099.0(5)$ Å^3, $Z = 1$, $D_c = 1.343$ Mg m^{-3}, $R_f = 0.042$ and $R_w = 0.052$ for 2460 reflections with $I > 2.5\sigma(I)$. **1**, **2**, **4**, **5**, **6**, and **7** exhibit extensive network hydrogen bonding between the anions, cations, and, if appropriate, water molecules of crystallization. The dimensionality of the hydrogen-bonded networks is dependent upon the nature of the anion and the number of water molecules of crystallization since the cation adapts a centrosymmetric exodentate conformation in all six salts.

Keywords: crystal engineering, cyclams, network hydrogen bonding.

Résumé : On a préparé une série de sels de composition $[H_4(cyclam))]X{\cdot}nH_2O$, dans lesquels cyclam = 1,4,8,11-tétraazacyclotétradécane et X = $4\,Cl^-$ ($n = 4$), $4\,Br^-$ (**2**, $n = 4$), $4I^-$ (**3**, $n = x$), $4\,ClO_4^-$ (**4**, $n = 2$), $4CNS^-$ (**5**, $n = 2$), $2\,SO_4^{2-}$ (**6**, $n = 6$) et $4(p$-$CH_3C_6H_4SO_3^-)$ (**7**, $n = 0$) et on a déterminé les structures cristallines des composés **1, 2, 4, 5, 6** et **7** par diffraction des rayons X. On a préparé les composés **1, 2, 3, 4** et **7** par cristallisation du cyclame avec un grand excès de l'acide correspondant alors que l'on a préparé les sels de thiocyanate, **5,** et de sulfate, **6**, par métathèse du perchlorate, **4**, avec respectivement du KCNS et du K_2SO_4. Les données cristallines sont les suivantes. **1** : orthorhombique, *Pnnb*, $a = 7{,}7962(16)$, $b = 14{,}278(4)$ et $c = 17{,}787(4)$ Å, $V = 1979{,}9(8)$ Å^3, $Z = 4$, $D_c = 1{,}39$ Mg m^{-3}, $R_f = 0{,}051$ et $R_w = 0{,}069$ pour 1176 réflexions avec $I > 3\sigma(I)$; **2** : triclinique, $P\bar{1}$, $a = 7{,}6860(8)$, $b = 7{,}8848(9)$ et $c = 9{,}6385(11)$ Å, $\alpha = 105{,}111(16)°$, $\beta = 95,495\ (18)°$ et $\gamma = 102{,}464(17)°$, $V = 543.43(12)$ Å^3, $Z = 1$, $D_c = 1{,}82$ Mg m^{-3}, $R_f = 0{,}034$, and $R_w = 0{,}041$ pour 1530 réflexion avec $I > 3\sigma(I)$. **4** : monoclinique, $P2_1/n$, $a = 8.4519(11)$, $b = 15.9248(12)$ et $c = 9{,}2981(17)$ Å, $\beta = 106{,}243(18)°$, $V = 1201{,}5(3)$ Å^3, $Z = 2$, $D_c = 1{,}76$ Mg m^{-3}, $R_f = 0{,}052$, and $R_w = 0{,}068$ for 1902 réflexions with $I > 3.0\sigma(I)$; **5** : triclinque, $P\bar{1}$, $a = 8{,}2996(7)$, $b = 9{,}0061(15)$, et $c = 9{,}2015(15)$ Å, $\alpha = 107{,}60(3)°$, $\beta = 97{,}738(14)°$, $\gamma =$

108,863(9)°, V = 599,44(15) Å^3, Z = 1, D_c = 1,309 Mg m^{-3}, R_f = 0,038 and R_w = 0,049 pour 1856 réflexions avec $I > 4\sigma(I)$. **6** : triclinique, $P\bar{1}$, a = 7,8687(5), b = 8,8396(12), c = 9,0405(25) Å, α = 68,547(16)°, β = 85,332(9)°, γ = 78,473(7)°, V = 573,43(18) Å^3, Z = 1, D_c = 1,693 Mg m^{-3}, R_f = 0,053 and R_w = 0,076 pour 1441 réflexions avec $I > 3\sigma(I)$. **7**: triclinique, $P\bar{1}$, a = 8,533(3), b = 9,110(3), c = 15,3605(21) Å, α = 82,475(17)°, β = 74,307(20)°, γ = 73,26(3)°, V = 1099,0(5) Å^3, Z = 1, D_c = 1,343 Mg m^{-3}, R_f = 0,042 et R_w = 0,052 pour 2460 réflexions avec $I > 2{,}5\sigma(I)$. Les composés **1**, **2**, **4**, **5**, **6**, et **7** présentent tous un réseau important de liaisons hydrogènes entre les anions, les cations et, dans les cas appropriés, avec les molécules d'eau de cristallisation. Puisque le cation adopte une conformation exodentate centrosymétrique dans chacun de ces six sels, les dimensions des réseaux des liaisons hydrogènes dépendent de la nature de l'anion et du nombre de molécules d'eau de cristallisaiton.

Mots clés : genie de cristaux, cyclams, réseaux des liaisons hydrogènes.

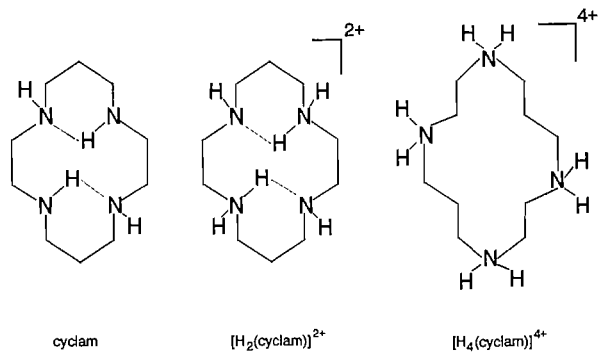
[Traduit par la rédaction]

Introduction

Exploitation of noncovalent interactions between molecular or ionic components for the rational design of solid state structures that might exhibit interesting electrical, magnetic, and optical properties, i.e., crystal engineering, is a current theme of solid state research (1–3). A fundamental principle of crystal engineering is that a given set of structural units (neutral molecules or, in the case of salts, cations and anions) will form networks defined by the spatial orientation of the moieties that engage in noncovalent bonding. In particular, it is becoming increasingly evident that the specificity, directionality, and predictability (4) of intermolecular hydrogen bonding can be utilized to assemble supramolecular structures of, at the very least, controlled dimensionality, if not predictable bulk physical properties. Indeed, hydrogen bonding has been exploited to design and construct one- (4–7), two- (8–11), or three- (12–14) dimensional solid state structures. However, this should not imply that all molecules or ions are suitable candidates for crystal engineering purposes. One has to carefully examine the functionality and geometry of molecules or ions before one attempts to exploit them for crystal engineering purposes. For example, carboxylic acid (12) and pyridone (13) functional groups are exploitable since they contain both hydrogen bond donor and hydrogen bond acceptor moieties that are geometrically disposed towards *self-assembly* (i.e., they are self-complementary). On the other hand, moieties such as the ammonium cation and oxyanions are incapable of self-assembly in the absence of a second complementary component since they are multifunctional hydrogen bond donors and acceptors, respectively. However, they would be complementary with each other, so salts that contain such moieties would be expected to engage in *strict* or *modular self-assembly* (15). Cocrystals can also represent examples of strict self-assembly.

There are several potential applications for crystal engineers to focus upon and a particularly topical application concerns design of solids that exhibit second-order nonlinear optical properties such as second harmonic generation, SHG. SHG activity is possible in as wide an array of compounds as inorganics (KH_2PO_4, $LiNbO_3$), organics (nitroanilines) (16), organometallics (ferrocene derivatives and acetylides) (17, 18), and organic cation salts (7, 19–24). The aforementioned examples represent single-component self-assembly. Self-assembly of two components of a salt requires that both the cation and the anion must be multifunctional, rigidly exodentate, and complementary. In our attempts to identify and utilize structural units that would lead to the formation of 1D, 2D, or 3D solids, we embarked upon a structural investigation of salts of the macrocyclic tetracation $[H_4(cyclam)]^{4+}$, which adapts an *exodentate* conformation. This observation is in contrast to that of cyclam itself (25), in which an *endodentate* conformation exists (see Scheme 1), facilitating coordination to transition metal cations (26). Surprsingly, very few salts of cyclam have been structurally characterized and those known are limited to its dication, $[H_2(cyclam)]^{+2}$ (27, 28). A dioxalate salt of the tetracation $[H_4(cyclam)]^{+4}$ has been reported, but it was not subjected to X-ray crystallographic study (27). In this study, we report full details of an X-ray structure we have communicated (29), along with the X-ray structures of five new simple $[H_4(cyclam)]^{4+}$ salts. The focus of the present study concerns whether or not $[H_4(cyclam)]^{4+}$ can act as a reliable template for crystal engineering and how the number and spatial orientation of hydrogen bond acceptors (i.e., counterions and (or) solvent molecules) influences crystal packing.

Scheme 1. Conformations of cyclam, $[H_2(cyclam)]^{2+}$, and $[H_4(cyclam)]^{4+}$.



Experimental

Cyclam, purchased from Strem Chemicals, Inc., perchloric acid (75%) and KCNS, purchased from Fisher Scientific Co., and all the other chemicals, purchased from Aldrich Chemical Co., were used without further purification. IR spectra were recorded on a Perkin–Elmer 1600 series FTIR using solid state reflectance technique (oven dried KBr crystals). Melting points were recorded on a Fisher–Johns apparatus and were not corrected.

Caution! Perchlorate salts are potentially explosive and should not be dried in an oven or over a hot plate. It is advis-

able to prepare them in small quantities and filter them using fritted funnels and store them wet.

Preparation of $[H_4(cyclam)]Cl_4 \cdot 4H_2O$ (1)
Cyclam (0.200 g, 0.998 mmol) was dissolved in 20 mL of 4 M HCl and the solution was allowed to evaporate slowly at room temperature, affording large colourless crystals of $[H_4(cyclam)]Cl_4 \cdot 4H_2O$. Yield: 0.406 g (0.970 mmol, 97.2%); mp: melts sharply at 284°C with decomposition. IR (cm^{-1}): 3775 (weak), 3547, 3439, 3027, 2953, 2795, 2714, 2631, 2495, 2421 (all strong); 2150, 2008, 1882, 1784 (all very weak), 1650 (N-H asym), 1580, 1450, 1367(C-H); 1308, (all strong) 1270, 1210, 1154, 1107 (all medium); 1066 (strong), 1049, 984, 909, 858, 816, 768, 747 (all medium)

Preparation of $[H_4(cyclam)]Br_4 \cdot 4H_2O$ (2)
Cyclam (0.100 g, 0.499 mmol) was dissolved in 8 mL of 4 M HBr and the solution was allowed to evaporate slowly at room temperature to form large colourless crystals of the title compound. Yield 0.250 g (0.419 mmol, 84.1%); mp: melts at 281°C with decomposition. IR (cm^{-1}): 3458 (N-H); 2986, 2745 (C-H); 2413, (NH_2^+); 1614, 1569, 1474, 1443, 1363, 1297, 1122, 1082, 1012, 901, 856, 821, 750.

Preparation of $[H_4(cyclam)]I_4 \cdot xH_2O$ (3)
Solid cyclam (0.400 g, 2.00 mmol) was added in small portions to 10 mL of 48% hydroiodic acid. A copious white precipitate formed instantaneously. Water (15 mL) was added to a suspension of this precipitate and the mixture was boiled until a clear solution was formed. Upon cooling to room temperature, colourless clusters of transparent crystals that lose moisture rapidly to form an opaque anhydrous solid were afforded. Yield: 1.31 g (1.84 mmol, 92.2% (anhydrous)); mp: melts at 265°C and turns brown. IR (cm^{-1}): 3394 (N-H); 2954 (C-H); 2519 ($>NH_2^+$); 1625, 1616, 1570, 1558, 1540, 1521, 1506, 1474, 1438, 1414, 1368, 1298, 1116, 1078, 1010, 903, 893, 844, 754, 742. The anhydrous salt was observed to be soluble in boiling methanol, affording a colorless solution. However, upon storage this solution was observed to turn brown and deposit dark brown crystals, presumably of a triiodide salt.

Preparation of $[H_4(cyclam)](ClO_4)_4 \cdot 2H_2O$ (4)
Cyclam (0.200 g, 0.998 mmol) was dissolved in 5 mL of water and 5 mL of 70% perchloric acid was added dropwise. A white crystalline precipitate formed instantaneously. The mixture was stirred well, cooled in an ice bath, filtered under suction, and washed successively with methanol and ether. Yield: 0.76 g. The wet precipitate was not dried for safety reasons. About 0.200 g of the salt was dissolved in 15 mL of water and diluted with 70% perchloric acid for a final concentration of approximately 30–35% acid. This solution was cooled at 5°C for several days at which point large blocks of colourless crystals had formed. mp: turned slightly brown at 185°C and melted into a dark liquid above 285°C. IR (cm^{-1}): 3929, 3562, 3485 (water/H-bonds), 3166, 3086 (C-H), 2855, 2745, 2674 (H-bonds), 2342, 2002 ($>NH_2^+$, ammonium cation), 1619, 1579 (N-H, asym), 1478, 1428, 1393 (C-C), 1302, 1207, 1096 (broad, ClO_4^-), 1007, 936, 896, 841, 745.

Preparation of $[H_4(cyclam)](CNS)_4 \cdot 2H_2O$ (5)
4 (0.500 g, 0.783 mmol) was dissolved in 6 mL of water and to this 0.330 g (3.4 mmol) of KCNS in 6 mL of water was added. On standing in an ice bath, most of the $KClO_4$ precipitated and was removed by filtration. The mother liquor was cooled at 5°C for 2 days until the final traces $KClO_4$ crystallized. The solution was again filtered and the mother liquor was concentrated slowly (at 40°C) on a warm hot plate until the solution was reduced to less than 2 mL. The solution was allowed to cool and left to stand overnight, at which point long colourless crystals were obtained. Yield: 0.328 g (0.694 mmol, 88.6%); mp: melts sharply at 154°C with decomposition. IR (cm^{-1}): 3448, 3367, 3025, 2965, 2764, 2393, 2072 (CNS), 1614 (N-H), 1569, 1456, 1418, 1383, 1312, 1278, 1147, 1112, 1077, 981, 931, 861, 770, 735.

Preparation of $[H_4(cyclam)](SO_4)_2 \cdot 6H_2O$ (6)
To a solution of 0.218 g (1.25 mmol) of K_2SO_4 in 5.0 mL of water, a solution of 0.400 g (0.626 mmol) of wet **4** in 5.0 mL of water was added. A crystalline white precipitate of $KClO_4$ formed instantaneously. The mixture was cooled in an ice bath for 1 h to ensure complete precipitation of $KClO_4$ and was then filtered. The resulting filtrate was left to evaporate at room temperature, affording colourless crystals of **6**. Yield: 0.280 g (0.555 mmol, 88.0%); mp: melts at 244–245°C with decomposition. IR (cm^{-1}): 3458, 3317 (broad, strong, water); 3016 (C-H); 2694, 2523 ($>NH_2^+$ cation); 1624, 1574, 1499, 1458, 1378, 1333, 1297, 1273, 1217 (all sharp, medium); 1132, 1062 (broad, strong, sulphate); 986, 906, 786, 750 (sharp, medium).

Preparation of $[H_4(cyclam)](tosylate)_4$ (7)
To a solution of 0.200 g (0.998 mmol) of cyclam in 10 mL of methanol was added a solution of 0.760 g (4.00 mmol) of *p*-$CH_3C_6H_4SO_3H \cdot H_2O$ in 10 mL of water. The resulting homogeneous solution was layered with tetrahydrofuran and left to stand at room temperature. Large crystals of $[H_4(cyclam)](p\text{-}CH_3C_6H_4SO_3)_4$ were obtained. A second crop of crystals was obtained from the mother liquor. Yield: 0.830 g (0.934 mmol, 93.6%); mp: melts into a clear liquid at 264°C without decomposition. IR (cm^{-1}): 3659, 3471 (v weak, moisture), 3253, 3018, 2845, 2496 (strong), 1949 (v weak), 1626 and 1606 (C=C), 1460, 1426 (medium strong), 1315, 1284 (weak), 1218, 1172 & 1122 (sulphonate), 1037, 1006, 976, 861, 810, 780, 740, 705, 680.

X-ray crystallography
Single crystals suitable for X-ray crystallography were mounted and sealed in thin-walled glass capillaries and optically centred on the goniometer of an Enraf–Nonius CAD4 diffractometer. The experimental parameters used for data collection and structure refinement are presented in Table 1. Listings of atomic positional coordinates for all non-hydrogen atoms for compounds **1**, **2**, **4**, **5**, **6**, and **7** are presented in Tables 2–7. All structures were solved by direct methods using the PC version of the NRCVAX (30) programme package locally implemented on IBM-compatible 80486 computers. Values of $R = \Sigma(F_o - F_c)/(F_o)$, $R_w = [(\Sigma w((F_o - F_c)^2/\Sigma w F_o^2]^{1/2}$, and GOF = $[(\Sigma w((F_o - F_c)^2/(\text{no. of reflns.} - \text{no. of parameters})]^{1/2}$ were determined. Weights based on counting statistics were used, the weight modifier, k, being determined empirically via statistical analysis of the variation in intensity of the standard reflections. All the non-hydrogen atoms were refined anisotropically.

B_{iso} is the mean of the principal axes of the thermal ellipsoid.

Methylene, aromatic C-H, and ammonium hydrogen atoms were calculated (d_{C-H} = 1.08 Å) and the methyl hydrogen atoms of the tosylate anion in salt **7** were located from difference Fourier map inspection and fixed during the refinement. In compound **1**, water molecules were observed to be disordered; 3.75 molecules of water were found per cation and they were refined with isotropic temperature factors and site occupancy as a variable. In compound **7**, the final difference Fourier map revealed a peak worth 1 e/Å^3 that was assumed to be a water oxygen atom. Refinement of site occupancy afforded a site occupancy value of 0.095. Final fractional coordinates for all atoms, selected interatomic distances and angles, and thermal parameters are available as supplementary material.[3]

[3] Listings of complete atomic positional parameters, anisotropic thermal parameters, and interatomic distances for **1, 2, 4, 5, 6,** and **7** have been deposited and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of atomic positional parameters and interatomic distances have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

Results and discussion

The salts were prepared by various methods depending upon the nature of the anion. Salts **1**, **2**, **3**, **4**, and **7** were prepared by direct crystallization of cyclam from concentrated aqueous solutions of these acids. The thiocyanate, **5**, and sulphate, **6**,

B_{iso} is the mean of the principal axes of the thermal ellipsoid.

were prepared by metathesis of $[H_4(cyclam)](ClO_4)_4$ with KCNS and K_2SO_4, respectively. The latter reactions proceed because $KClO_4$ is sparingly soluble. The filtrates were concentrated to give the required salts in crystalline form. Attempts to prepare crystals of $[H_4(cyclam)][HSO_4]_4 \cdot xH_2O$ based on a similar reaction between $KHSO_4$ and **4** yielded crystals of **5** only. Therefore, it does not appear that the hydrogen sulphate salt can be obtained by this method.

Cyclam and its derivatives have been extensively used in the study of coordination chemistry of transition metal ions in different oxidation states and many of these complexes have been characterized by single crystal X-ray crystallography (26). However, only two of its dicationic salts, $[H_2(cyclam)](ClO_4)_2$ (27) and $[H_2(cyclam)](CF_3SO_3)_2$ (28), have been characterized by X-ray crystallography. These studies indicate that $[H_2(cyclam)]^{2+}$ adapts an *endodentate* conformation (see Scheme 1) with the nitrogen atoms oriented towards the center of the macrocyclic cavity. A similar conformation is observed in the structure of cyclam itself (25). The stabilization of such a conformation can be attributed to strong intraionic hydrogen bonding (31). Differences in networking between the two salts can be attributed to the poor polarizability and hydrogen-accepting tendencies of perchlorate compared to that of trifluoromethanesulphonate.

It is known that all four nitrogen atoms of cyclam can be protonated under strongly acidic conditions (32) and the preparation of $[H_4(cyclam)][(COO)_2]_2$ has been described. However, no X-ray structural studies of the tetracation salts were reported until we began our studies. Unlike cyclam and its dication, $[H_2(cyclam)]^{2+}$, the tetracation, $[H_4(cyclam)]^{4+}$, adapts an *exodentate* conformation in the structures of salts we reported previously (24, 29) and in all six structures described herein. In other words, the nitrogen atoms are oriented away from the ring cavity, occupying positions as far away as possible from each other on the ring periphery (Scheme 1). The ORTEP (33) perspective view presented in Fig. 1, which could represent any of the six salts, reveals that the ethylene bridges are *transoid* and the propylene bridges ($^{N}\backslash/\backslash/^{N}$) adapt a "w"

conformation. Electrostatic repulsion between the positive charges on the secondary ammonium centers makes observation of such a conformation reasonable. The most salient feature from the perspective of crystal engineering is that all eight protons of $[H_4(cyclam)]^{4+}$ are accessible for interionic hydrogen bonding and are spatially oriented in a manner that approximates 4-fold symmetry. Of course, $[H_4(cyclam)]^{4+}$ is unable to self-assemble since it is incapable of functioning as a hydrogen bond acceptor. However, it will be complementary with molecules or anions that are capable of acting as hydrogen bond acceptors . $[H_4(cyclam)]^{4+}$ is therefore functionally related to the cubanes ($[M(CO)_3(\mu_3\text{-}OH)]_4$, M = Mn, Re) we have utilized for strict self-assembly of 3D diamondoid solids (14). It is clearly capable of not only forming 1D and 2D networks, but also 3D networks. The precise nature of networks sustained by $[H_4(cyclam)]^{4+}$ will be determined by the number of available hydrogen bond acceptors from the anions and (or) the solvents of crystallisation and their spatial orientation. The remainder of this discussion focusses upon the nature of hydrogen bonding in salts of $[H_4(cyclam)]^{4+}$ and how the functionality of the anions influences the crystal architecture. The structural features of the salts are discussed individually below. Intracation and intraanion distances and angles are within expected ranges and the analysis focusses upon hydrogen bonding. It is assumed that hydrogen bonds are present for X—H···Y if the X···Y distance is within the sum of the van der Waals radii of atoms X and Y (34).

$[H_4(cyclam)]Cl_4 \cdot 4H_2O$ (1)

Preliminary details concerning 1 have been communicated (29). The cation lies around a crystallographic inversion center and is hydrogen bonded to eight adjacent cations via N—H···Cl···H—N bridges (N···Cl 3.065(3)–3.242(3) Å). The ability of the chloride anions to hydrogen bond obtusely (N···Cl···N angles are 128.98(8)° and 144.45(9)°) facilitates the formation of a 3D network. As Fig. 2 reveals, cations on adjacent layers eclipse each other and there are two microchannels, (*i*) and (*ii*), that run parallel to the *a*-axis. Each channel contains two molecules of water per cation. In microchannel (*ii*) the water molecules are disordered so it cannot be determined if they self-assemble as oligomers or as a polymer. This is a common observation in solids that contain microchannels that are filled with water molecules (35). However, microchannel (*i*) has the requisite diameter and placement of hydrogen bond acceptors to allow ordering of the water molecules, which exist as symmetrical 1D polymers. Such ordering of water molecules is to our knowledge unique and is presumably facilitated by hydrogen bonding of water oxygen O—H moieties to chloride ions along the walls of the microchannels. The hydrogen atoms that bridge water molecules could not be located since crystallographic symmetry requires that they must be disordered, but those that are hydrogen bonded to chloride anions could be located (O—H···Cl(2), 2.27 Å; 176°). The O···O distances within this water polymer are 2.728(10) and 2.736(10) Å, which compare closely with the O···O distances in ice (2.750–2.793 Å) (36, 37) and a water dimer that was encountered in a host–guest complex (2.805 Å) (38).

$[H_4(cyclam)]Br_4 \cdot 4H_2O$ (2)

One half of the cation, anions, and water molecules constitute the asymmetric unit because once again the cation lies around a crystallographic inversion center. All the anions and the water molecules are involved in network hydrogen bonding with the cation such that cations on successive layers eclipse one another. However, no microchannels were observed in this structure since, although the stoichiometry is the same as that for **1**, the nature of the networking is entirely different. The bromide anions bridge both cations and water molecules. A portion of the network involving the bromide anions, water molecules, and the $[H_4cyclam]^{4+}$ nitrogen atoms is shown in Fig. 3. All four lone pairs of Br2 are involved in hydrogen bonding interactions between adjacent cations through N1—H···Br2···H—N2 bridges. Thus, N1 of one cation is bridged through Br2 (Br2···N1, 3.371(4) Å) to N2 of an adjacent cation (Br2···N2, 3.330(4) Å). Br2 also shows interactions with O1 and O2 (O1···Br2, 3.370(4) Å; O2···Br2, 3.502(5) Å). Br1 exhibits three prominent hydrogen bonding interactions, bridging both water molecules and linking to N1. The hydrogen bond distances are Br1···O1, 3.417, Br1···O2, 3.653, and Br1···N1, 3.236(4) Å, respectively. Presumably, the larger size of bromide ions and their involvement in bridging water molecules precludes formation of microchannels and water polymers.

Fig. 2. ORTEP perspective view of the *bc* plane in **1**. Microchannels *i* and *ii* are parallel to the *a*-axis and microchannel *i* contains the ordered polymer of water molecules.

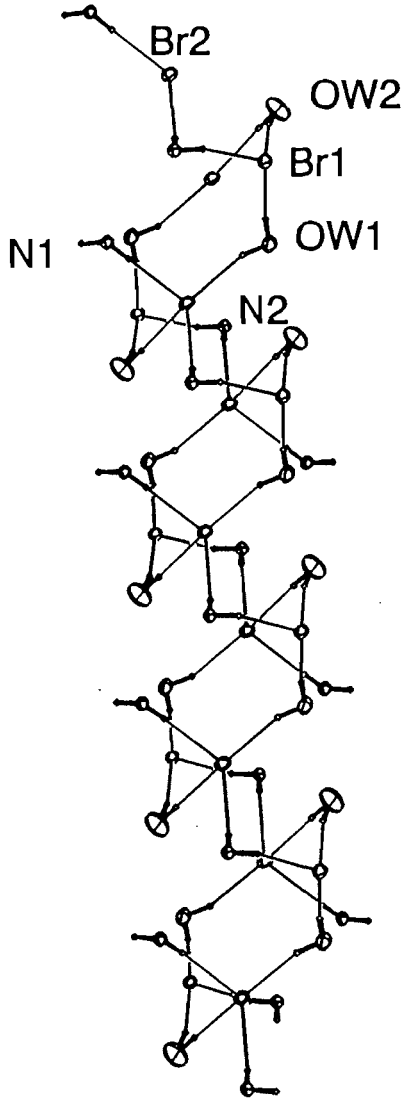

Fig. 4. ORTEP perspective view of a portion of the network in **4**.

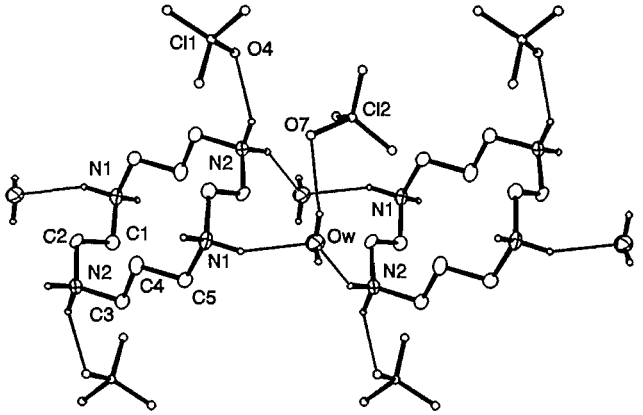

Fig. 5. ORTEP perspective view of a portion of the network in **5**.

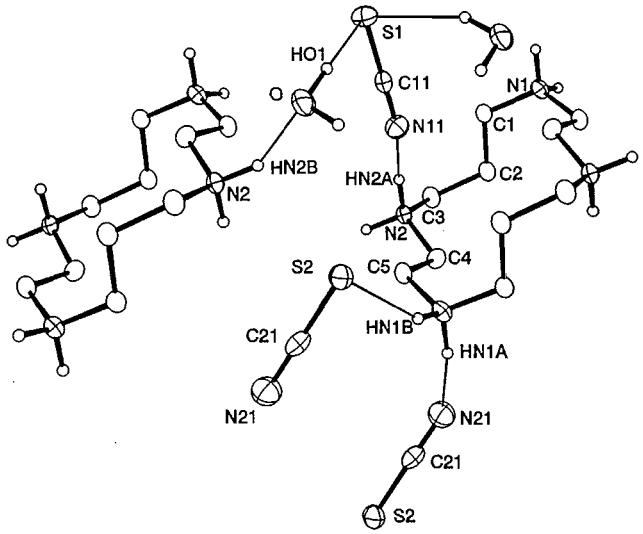


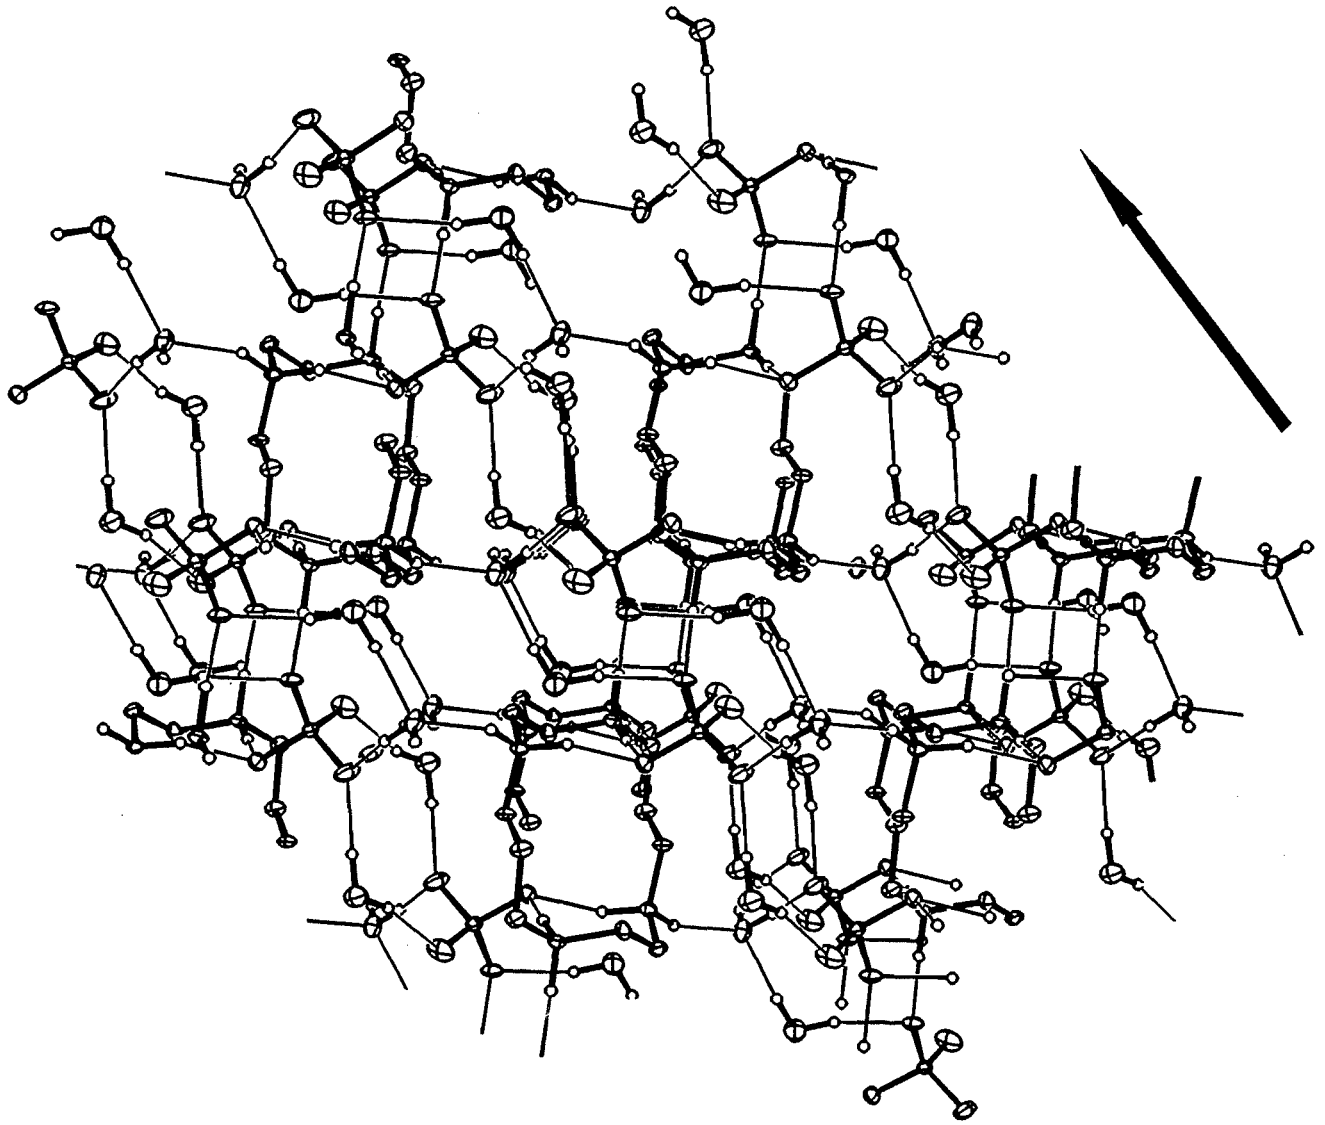
$[H_4(cyclam)](ClO_4)_4 \cdot 2H_2O$ (4)

An ORTEP perspective of the network hydrogen bonding in **4** is shown in Fig. 4. The perchlorate anion is generally regarded as being a weak hydrogen bond acceptor and it does not act as a strong hydrogen bond acceptor in the network. Neighbouring cations are joined sidewise through two N1—H···Ow···H—N2 (N2···Ow, 3.032(4) Å; N1···Ow, 2.979(4) Å) hydrogen bonds that manifest themselves as linear tapes. There are only two crystallographically independent perchlorate anions because the cation lies around a crystallographic inversion centre and they are terminally bound. Though terminally bound, the perchlorates show multiple points of contact, to NH_2^+ moieties as well as to water molecules: N1···O2, 3.051(4) Å; N1···O7, 3.083(4) Å; N2···O6, 2.989(4) Å between perchlorate oxygen atoms and nitrogen atoms; O_w···O1, 2.979(5) Å, Ow···O2, 3.033(4) Å, and Ow···O7, 2.934(4) Å between perchlorate oxygen atoms and water molecules. These interactions are much stronger than those observed (<3.5 Å) in $[H_2$-(cyclam)$](ClO_4)_2$ (31) and can be attributed to the higher charge on the tetracation.

$[H_4(cyclam)](CNS)_4 \cdot 2H_2O$ (5)

An ORTEP perspective of the network hydrogen bonding in **5** is illustrated in Fig. 5. One half of the cation, two anions, and one water molecule constitute the asymmetric unit since the cation once again lies around a crystallographic inversion center. The two crystallographically independent thiocyanate ions are linear (N-C-S, 179.16(19)° and 178.77(22)°) and both are involved in hydrogen bonding, but in different modes. One set of thiocyanate ions generates a bridging N1—H···S2—CN2···H—N1 motif and two such motifs link adjacent cations. Because both hydrogen atoms of N1 on neighbouring cations are involved (N1···S2, 3.326(19) Å; N1···N21, 2.766(3) Å) a 12-membered centrosymmetric hydrogen bond stabilized macrocyclic ring motif is formed. This 12-membered ring motif and the 14-membered ring $[H_4(cyclam)]^{4+}$ cation alternate to form 1D strands in which N1 is the spiro atom common to both rings. These strands are cross-linked by the second set of thiocyanate ions and the water molecules. N11 is linked to HN2A of the cations (N2···N11, 2.877(3) Å) while HN2B is bonded to S1 of the anion through a molecule of water

Fig. 6. ORTEP perspective view of a portion of the network in **6**. The arrow is parallel to the sheets formed by sulphate anions and water molecules.



(N2···O, 2.758(2) Å; O···S1, 3.282(2) and 3.358(2) Å). A 2D network is therefore afforded.

$[H_4(cyclam)](SO_4)_2 \cdot 6H_2O$ (6)

An ORTEP perspective of the networking in **6** is shown in Fig. 6. The cation lies around an inversion center and hence the asymmetric unit is defined by one half of the cation, one anion, and three water molecules. Sulphate anions are good hydrogen bond acceptors and the structure can be regarded as 3D since there are sheets of sulphate anions and water molecules cross-linked by $[H_4(cyclam)]^{4+}$ cations. Adjacent $[H_4(cyclam)]^{4+}$ cations are cross-linked through two N2—H···O1—S—O2···H—N1 bridges (O1···N2, 2.702(4) Å; O2···N1, 2.788(4) Å). O2 also interacts with N2 (O2···N2, 2.849(3) Å). The other two oxygen atoms of the sulphate anion do not interact with the cation. Rather, they interact with water molecules. Each water molecule is hydrogen bonded to a sulphate oxygen atom (O1··· Ow1, 2.883(4); O3···Ow3, 2.756(4) Å; O4···Ow2, 2.760(4) Å). The oxygen atoms of the water molecules Ow1 and Ow2 also show hydrogen bonding interactions with N1 (N1···Ow1, 2.796(4) Å; N1···Ow2, 2.790(4) Å).

$[H_4(cyclam)](p\text{-tosylate})_4$ (7)

The cation once again lies around a crystallographic inversion center so there are only two independent anions. Figure 7 presents an ORTEP view of the cation and illustrates how the anions are hydrogen bonded to the NH_2^+ moieties. All the hydrogen atoms of the cation and two of the oxygen atoms of the *p*-toluenesulfonate anions are engaged in hydrogen bonding. NH_2^+ moieties are linked to crystallographically equivalent NH_2^+ groups on neighbouring cations through N—H··· O—S—O···N—H bridges (N2···O2, 2.765(3) Å; O3···N2, 2.749(3); N1···O11, 2.708(3) Å; N1···O12, 2.903(3) Å). Thus, the networking generates a 2D sheet of cations bridged by *p*-toluenesulfonate anions. The hydrophobic toluene rings project outwards on both sides of the 2D sheet. Hence, the overall crystal structure can be described as layers of ionic networks separated by hydrophobic regions (Fig. 8). The hydrogen bond

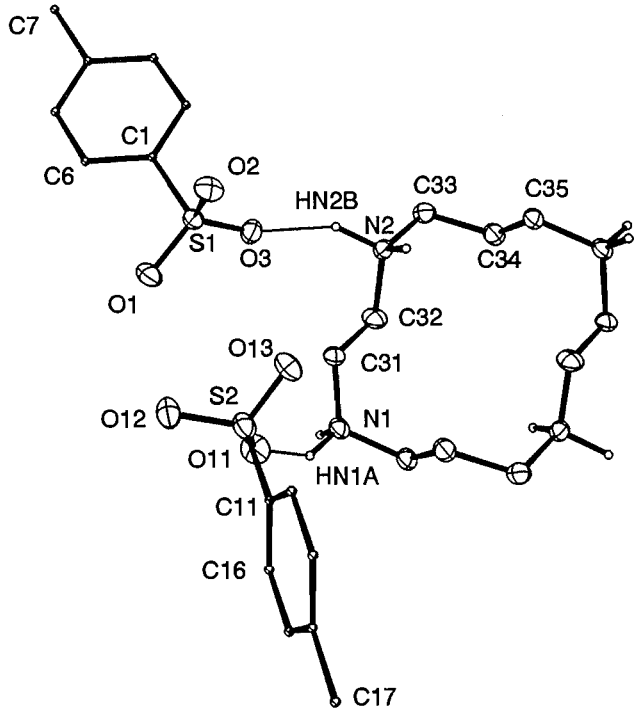
Fig. 7. ORTEP plot of the cation and the two unique *p*-tosylate anions.



angles vary in the range of 144.7°–167.8°. The N—H···O—S—O··· N—H bridges involve both hydrogen atoms of each NH_2^+ moiety and therefore form 12-membered rings similar to those found in the thiocyanate salt. Although there are no water molecules involved in the hydrogen bonding network there appears to be one solvent water molecule that partially occupies a hydrophobic cavity (see experimental section).

The salts reported herein possess many common structural features. The symmetric tetracation lies around an inversion center in all the structures and adapts the same *exo*-dentate conformation irrespective of the dimensionality of the network. The anions play a significant role in the network hydrogen bonding. All six structures clearly conform to the hydrogen bonding rules delineated by Etter (31). Water plays a dominant role in bridging the cations only when the anions are nominally weak hydrogen bond acceptors. In the absence of water and in the presence of surplus hydrogen bond acceptors, as in **7**, all the strong hydrogen bond donors are utilized. It is perhaps surprising that the halide salts adapt dramatically different solid state structures. The observation of a 1D water polymer in **1** is serendipitous but can be rationalized. That the iodide salt, **3**, loses moisture so readily suggests that it possesses an architecture more similar to **1** than to **2**. If so, the microchannels would be expected to be larger and not bind the water molecules as strongly. This would explain the observed behaviour. The ionic nature of these salts demands aqueous media for the formation of single crystals and hence competition from water as a hydrogen bond donor/acceptor is unavoidable. The absence of water molecules in **7** is presumably a reflection of the relatively high strength of the hydrogen bond accepting capabilities of sulfonate anions (28) and the hydrophobic tolyl groups.

In summary, it is clear that $[H_4(cyclam)]^{4+}$ consistently adapts a centrosymmetric exodentate conformation that facilitates network hydrogen bonding. The nature of the resulting network can be 1D, 2D, or 3D depending upon the nature of the counterion (i.e., its hydrogen bond accepting capabilities and geometry) and the number of solvent molecules. Unfortunately, none of the six new structures is polar. This is because the center of inversion present in $[H_4(cyclam)]^{4+}$ manifests itself crystallographically. Derivatives of cyclam that possess no center of symmetry would be expected to be much more predisposed to crystallize in polar space groups and would therefore be worthy of further study.

Fig. 8. ORTEP view of a portion of the network in **7** that illustrates how the tolyl moieties orient themselves to form hydrophobic regions above and below the hydrogen bonded sheet.

Thermochemistry of the liquid bismuth(III) oxide – boron oxide: a new solvent for oxide melt solution calorimetry

Jacques Rogez and Jean Claude Mathieu

Abstract: In solution calorimetry, the choice of solvent is important. Some criteria for this choice for oxide melt solution calorimetry are reviewed. A new solvent is proposed and the corresponding physicochemical study is presented. Some structural interpretations are suggested for these Bi_2O_3–B_2O_3 melts.

Key words: thermochemistry, calorimetry, high temperature, oxide melt.

Résumé : En calorimétrie de dissolution le choix du solvant est important. Quelques éléments de ce choix sont revus. On propose un nouveau solvant et son étude physicochimique est présentée. Des interprétations structurales sont suggérées pour ces liquides Bi_2O_3–B_2O_3.

Mots clés : thermochimie, calorimétrie, température élevée, oxyde fondu.

Introduction

The determination of the enthalpic quantities corresponding to the formation of solid compounds, and liquid or solid solutions, is the aim of calorimetry. For oxide systems, within the temperature range where measurements may be done (typically up to 1700 K), direct reaction between the reactants is always difficult and often even impossible due to the low reaction rates (slow diffusion processes of the elements, slow interface reactions or high viscosities). As a result, for such studies, solution calorimetry, which consists in comparing the destruction energies of the networks of products and reagents, has rapidly become indispensable where the choice of solvent is difficult.

From a very early stage the curiosity of scientists has been attracted to dissolution phenomena. In alchemic tradition all the liquids that dissolve certain solids were called "menstrui." The origin of this word stems from the revolution period of the moon, and refers to the generally long duration of this process. In the seventeenth century the chemist Boerhaave defined a "menstruum" as a substance that, "if it were applied to another, following the rules of the art, would break it so finely that the particles of the solvent would nearly completely mingle with those of the solute" (1).

In oxide solution calorimetry, the original idea was to perform the dissolution in the temperature range where the calorimetric experiments are the easiest and also the most accurate, i.e., around ambiant temperature. For a recent example see ref. 2. Acidic and basic aqueous solvents are commonly used. An important drawback to this method is the generally great difference between the measured thermal effects of the dissolution reactions and the expected enthalpy, which can be some percentage of the former. Moreover, the enthalpy of the reaction of formation is calculated from at least two different solution reactions, which further increases the inaccuracy.

To overcome this difficulty, it was proposed to use a solvent the chemical nature of which is quite similar to that of the solute, even if the experimental setup imposes a ticklish problem. The final expected enthalpy and the dissolution energy should be of about the same magnitude. One of the main constraints of this choice is the need to carry out the measurements at high temperature. The studies are generally performed between 500 and 1200 K in a fluxmeter.

Nevertheless, these two measurement methods complement one another well. By means of thermodynamic cycles it is possible to verify the agreement between the measured and estimated quantities such as heat capacities and, in particular, the melting and transition enthalpies.

During the last 20 years, only a few groups of researchers have ventured and persevered in the difficult technology of high-temperature solution calorimetry in molten oxide melts. The aim has very often been the study of compounds of geological interest. O.J. Kleppa and co-workers at the University of Chicago were the pioneers in this technique (3). Later, A. Navrotsky at Princeton University and two groups in Grenoble (France) and in Moscow (CEI) used this method. Such equipment has already enabled the authors to perform thermochemical studies of, for example, the albite–orthoclase and the Na_2O–K_2O–SiO_2 systems (4, 5).

Various solvents have been investigated by the different groups; in most cases the $2PbO$–B_2O_3 melt has been used. The aim of this paper is to propose a new solvent, and the corresponding thermochemical study is presented.

The choice of a solvent

The choice of a solvent is crucial for successful solution calorimetry. This paper is restricted to studies of oxide systems.

Received June 6, 1994. Revision received December 14, 1994.

The particular conditions the solvent must satisfy have been distinguished from the restricting conditions imposed by the calorimetric setup.

(*i*) The solvent must obviously dissolve the constituents of the systems under consideration. Calorimetric dissolution experiments are long and tedious, and the price to be paid, in time, for a measurement is heavy. For this reason, the chosen melt should be able to dissolve a large number of acid and basic constituents without showing a great difference between the dissolution enthalpies. Thus, the results obtained for various systems can be compared and corroborated. This last condition is satisfied when the solvent presents a buffer character in the sense of the acid-basic reactions in oxide systems as defined by Flood and Förland (6). Generally speaking, the main problem of the experimental investigations is the reproducibility of the measurements. In oxide solution calorimetry it often amounts to a few percent, for example, 4% for SiO_2 in the $2PbO–B_2O_3$ melt at 970 K (7). In some cases it may be worse, as stated by Shearer and Kleppa for the dissolution of MgO in $2PbO–B_2O_3$ (±20%) (8). We have also observed such a discrepancy in a previous study of the $MgO–Cr_2O_3$ system by solution calorimetry in the same solvent. The choice of solvent is always a compromise between fast dissolution kinetics, which induces the use of a strong reagent, and a measured energy that is not too high. In aqueous solvents this dilemma is neatly solved by varying the solvent concentration.

The vapor pressure of the solvent must remain very low within the temperature range investigated. During the runs the quantity of solvent must not significantly change and, in the case of a multicomponent melt, the composition must not vary by differential vaporization. From this viewpoint, those simple oxides whose melting points are very low, such as OsO_4, Re_2O_7, or, to a lesser degree, TeO_2, are not suitable. In most cases the sample is thermally stabilized above the melt surface before the dissolution. If the equilibrium pressure above the melt is too high, the sample may react with the solvent vapor before the expected dissolution in the liquid state.

The solvent must present a low viscosity in order to keep the dissolution rate relatively high. Pure boron oxide, for example, has too high a viscosity at 1070 K. The stirring that is necessary in most cases must be mechanically possible without damaging the stirring setup. If the basic constituent is a network former melt, the other constituents have to include some network modifiers in order to diminish the viscosity, which depends on the degree of polymerization.

The solvent is commonly prepared outside the calorimeter by melting the various oxides or by thermal decomposition of the corresponding carbonates. Toxicity is then a significant factor in the choice of solvent. Some oxides, such as B_2O_3, Sb_2O_3, MoO_3, and Bi_2O_3 are not known as toxic reagents. The cations or the metallic atoms of other oxides are toxic after ingestion or inhalation (As_2O_3, V_2O_5, PbO, with cumulative effect). In this sense the handling of the solvent must be easy. A melt that is insensitive to moisture is more suitable for extended storage.

Generally, the enthalpies of formation or the enthalpies of transition are deduced from the partial dissolution enthalpies at infinite dilution. Extrapolation to zero concentration is easier the less the dissolution enthalpy varies with composition. Indeed, a linear dependence with a low or zero slope has been observed in many systems. Though perfect chemical homogeneity in the liquid is sometimes difficult to obtain when, for example, partial crystallizations or vitrifications inducing chemical segregations occur during the quench; the values are generally not sensitive to small concentration differences between batches coming from the same primary melt.

Table 1. The melting temperatures T_f (in K) of simple oxides whose melting points are less than 1400 K (10–12).

Chemical formula	T_f (K)
OsO_4	313
Re_2O_7	570
As_2O_3	585
B_2O_3	723
TeO_2	660
Sb_2O_3	929
V_2O_5	943
MoO_3	1075
Bi_2O_3	1098
PbO	1170
GeO_2	1389

Most of these conditions are satisfied when the solvent presents some buffer properties with respect to the acid and basic oxides. A discussion of this point has been already given by Kleppa (9). The choice of $PbO–B_2O_3$ as solvent has been mainly justified by the low variation of the partial enthalpy in the composition range $x_{PbO} = 0.45$ to $x_{PbO} = 0.8$. In addition, the phase diagram presents a wide liquid zone around the eutectic composition close to the compound $2PbO·B_2O_3$. When a new solvent is selected this characteristic should be a criterion in the choice of the best composition.

(*ii*) The calorimetric configuration imposes some conditions on the choice of solvent.

The melting point must be sufficiently low to be within the temperature range of the calorimeters, which generally offer a maximum temperature of about 1300 K. At higher temperature technological problems appear in the mechanical behaviour of the setup. As shown in Table 1 very few single oxides are convenient. Polyconstituent oxides, which present lower melting points as eutectics, are more suitable. It can be mentioned that in oxide systems very low euctectics are not common and most systems show binary or ternary high-melting-point compounds. At present, the greatest number of dissolution experiments with various solvents have been performed between 950 and 1250 K.

The solvent must not interact with the measurement cell atmosphere, which is generally air. The chosen oxide or mixture of oxides will then be stable under a 0.21 atm partial pressure of oxygen (1 atm = 101.3 kPa).

Another important consideration is the reactivity of the solvent with respect to the material constituting the crucible and the stirring equipment. For good heat transfer to the fluxmeter, a metallic crucible having high thermal conductivity is necessary. Pure gold and silver, which are oxide melt resistant, are generally chosen. The dissolution time is important as the metal of the crucible may be exposed to attack of the solvent for long periods. The kinetics of this dissolution reaction must remain very slow. Even if the dissolution rate is low, mechan-

For personal use only.

ical damage may occur. For example, during local remelting for strengthening some parts of a platinum crucible, some bubbles of alkaline metal or oxide were observed on the crucible walls, which had been previously exposed to $NaBO_2$–$LiBO_2$ solvent. The presence of lithium in the melt may induce a diffusion of this alkaline element into the grain boundaries of the metal and may then cause it to become brittle. The break may occur during further handling of the crucible at ambiant temperature when renewing the solvent between two dissolutions. Diffusion into the grain may also occur if the solubility of the foreign element in the crucible metal is high enough. Tin with respect to platinum is a good example of this phenomenon. If a compound is formed, the diffusion process can be stopped. If the melting point of the corresponding compound is quite near the dissolution temperature, the brittleness at high temperature may increase. Our experience gives a lifetime for platinum crucibles of about 50 runs in $2PbO$–B_2O_3 melt and 10 runs in $NaBO_2$–$LiBO_2$ melt. Finally, the cost of the crucible, which is mainly a labour cost even for precious metals, must be taken into account.

The kinetics of the dissolution reaction must be fast compared to the characteristic time for stability of the calorimeter. Typically, the dissolution time should not be greater than 1 h. This rate depends greatly on transport phenomena in the liquid state, interface reactions during the dissolution being generally rapid. The liquidus slope of the solute–solvent phase diagram gives an indication of the dissolution rate. Thus, most experiments are performed by stirring in the melt, which homogenizes the liquid and also increases the dissolution rate. This kind of setup imposes a measurement of the stirring energy by performing a blank run after each dissolution; this then doubles the experimental time.

In conclusion, it seems that pure oxides cannot satisfy these constraints. The solution lies in multicomponent melts including acidic and basic oxides. Because of the toxicity of PbO a new solvent was sought. Solvents based on B_2O_3 are good candidates, as boron oxide is the lowest melting oxide that satisfies the criteria of toxicity, vapor pressure, and cost. Alkaline earth – boron oxide melts present too high vapor pressures. The alkaline earth – boron oxide systems show phase separations in the liquid phases and the eutectics are very close to those of the pure oxides. Finally, bismuth oxide – boron oxide melts were selected; as the Bi_2O_3–B_2O_3 and PbO–B_2O_3 phase diagrams are similar, it may be expected that the two melts behave similarly. In the following, the thermodynamic study of the Bi_2O_3–B_2O_3 melt is presented.

Physicochemical study of the system Bi_2O_3–B_2O_3 at 1023 K

The thermochemical properties of the $Bi_2O_{3(1-x)}$–B_2O_{3x} system in the liquid state have been investigated in the composition range $0.1 < x < 0.8$.

Preparation of the solvent

The starting materials are Extra Pure bismuth(III) oxide and Pro Analysi boric acid as provided by Merck. For each composition, about 80 g of solvent are prepared by reacting boric acid with bismuth oxide in a platinum crucible. The two weighed powders are carefully mixed and introduced into an open-air furnace whose temperature is electronically controlled. At the beginning of the reaction, the temperature is raised slowly in order to control the thermal decomposition of the boric acid. As a final stage of the process, the melt is kept at 1123 K during 1 h. After quenching on a stainless steel plate, the ground solid is melted again at the same final temperature for homogenization.

Measurements of the partial mixing enthalpies

The starting materials for the solute samples are anhydrous boron trioxide provided by Merck (Pro Analysi quality) and the same bismuth(III) oxide as that used for the solvent. As mentioned in Table 2, about 0.08 mole of solvent is used for each melt composition.

The calorimetric measurements are performed in a twin Tian–Calvet-type calorimeter at 1023 K in air. The experimental high-temperature equipment has been described previously (4). The inner diameter of the heat flux sensor is 17 mm and the pure platinum crucible as 70 mm in height and 14 mm in inner diameter. Before dissolution the ground sample (typically <100 μm) is thermally equilibrated on a platinum cup just above the free surface of the melt inside the calorimetric cell. Hence, the solute and the solvent are at the same temperature before the reaction. Dissolution begins when the cup is introduced into the liquid by a vertical motion of the calorimetric equipment. Automatic vertical shaking of the cup increases the global dissolution rate. Thermal effects due to the transfer of the cup into the measurement cell and the stirring motion are measured just after completion of the reaction by carrying out the same experiment without a sample. The reproducibility of this blank run is about 95%; it represents about 20% of the overall thermal effect. The thermogram is automatically integrated by a microcomputer.

Results

In Table 2 and Fig. 1 the partial mixing enthalpies of Bi_2O_3 and B_2O_3 referred to solid Bi_2O_3 and liquid B_2O_3 are reported for the various concentrations. The inaccuracy is about ±4 kJ mol^{-1} except for $x_{B_2O_3} = 0.2$ where the discrepancy between the Bi_2O_3 partial enthalpies is higher. The partial enthalpies do not vary within the error margin in the solute composition ranges $0 < y_{Bi_2O_3} < 0.004$ and $0 < y_{B_2O_3} < 0.011$. It may then be expected that these values represent the partial mixing enthalpies. For the B_2O_3-rich composition only one value is available because of the too-high viscosity of the melt and the close proximity of this concentration to the phase separation curve in the liquid state, which induces a lower dissolution rate. In only one run did the molten sample not remain stacked in the cup without dissolution.

The curves in Fig. 1 fit the results, taking into account the Gibbs–Duhem relation. The integrating pole is $x_{B_2O_3} = 0.4$, $\Delta H_{B_2O_3} = -48.7$ kJ mol^{-1}. The Bi_2O_3 partial enthalpy at $x = 0$ corresponds to the melting enthalpy given by Robie et al. (10); $\Delta H_f = 16.74$ kJ mol^{-1}.

In the concentration range $0.2 < x_{B_2O_3} < 0.75$ the partial enthalpies do not vary significantly. Consequently this behaviour induces a flat curve for the integral mixing enthalpy referred to the two liquids at around −45 kJ mol^{-1}.

After each run and for each melt composition, the resulting liquid was quenched on a stainless steel plate. Because of the heterogeneity of the sample temperature, the mean cooling rate can be estimated at 10 K s^{-1} in the liquidus temperature

Table 2. Partial mixing enthalpies of Bi_2O_3 and B_2O_3 in B_2O_3–Bi_2O_3 melts at 1023 K. The quantities $N_{B_2O_3}$ or $N_{Bi_2O_3}$ per μmol represent the amounts of solute dissolved in each run. The quantity N_s per mmol of the solvent is reported for each bath.

		101	−33.3

range. For the composition $x_{B_2O_3} = 0.1$ the solid phase is a dark crystal without an apparent glassy phase. At $x = 0.2$ and 0.4, quenching results in a mixture of a glass with crystals (dark for 0.2 and yellow for 0.4). For $x_{B_2O_3} = 0.6$–0.8 a yellow-orange glass without a crystalline phase was always observed. An X-ray analysis was performed on the $x = 0.1$–0.2–0.4 crystalline phases. The two former samples include the α Bi_2O_3 and the $2Bi_2O_3{\cdot}B_2O_3$ compounds. At $x = 0.2$ the percentage of this compound is more important than in the $x = 0.1$ sample. The presence of the $12Bi_2O_3{\cdot}B_2O_3$ compound cannot be ensured in the $x = 0.2$ crystalline phase. This latter compound is not observed in the $x = 0.4$ sample, which contains only the $2Bi_2O_3{\cdot}B_2O_3$ compound.

Discussion

A comparison between the physicochemical properties of the liquids Bi_2O_3–B_2O_3 and PbO–B_2O_3 is attempted.

First, the liquid PbO–Bi_2O_3 is stable enough to form an eutectic whose melting point is 190 K lower than the lowest melting point of the constituent oxides ($T_{fBi_2O_3}$ = 1098 K; T_{fPbO} = 1159 K). In the solid state the respective solubilities are weak. However, the existence of a large intermediate high-temperature b.c.c. solid solution indicates that the two elements are compatible with oxygen in a single lattice (13).

Considering the various solid bismuth and lead oxides, it appears that these elements differ in the possible valence states. Assuming that oxygen adopts in all cases the −2 valency, Pb may present the 2, 8/3, 3, and 4 valencies and Bi the 2, 3, and 5. Comparison of the thermodynamic properties of these compounds shows that the more stable oxides (from 900 K to higher temperatures) are PbO (valency +2) and Bi_2O_3 (valency +3). All the other Bi oxides decompose at low temperature and sometimes before the hypothetic melting points. These two valence states may be considered to be the only ones present in the liquid. If the melting point is an indication of the stability of a compound, PbO and Bi_2O_3 resemble each other closely.

A greater similarity is found between the Bi_2O_3–B_2O_3 and PbO–B_2O_3 phase diagrams if the lead oxide is written as Pb_2O_2. In the two systems a wide liquid domain is observed at 1000 K, which indicates a greater stability of these phases. The minima of the integral mixing enthalpies are −47 kJ mol^{-1} in the Bi_2O_3–B_2O_3 system and −26 kJ mol^{-1} for the PbO–B_2O_3 melt. These values indicate a higher stability of the former liquid. In the Pb_2O_2–B_2O_3 system the minimum of the liquidus is about 750 K as compared to 900 K in the other system. In both cases a phase separation in the liquid state is observed on the boron-rich side.

Designating the $a Bi_2O_3{:}b B_2O_3$ and $a Pb_2O_2{:}b B_2O_3$ solid compounds by $a{:}b_{Bi}$ and $a{:}b_{Pb}$, the 1:4 and 2:1 ratios are common to both systems. Corresponding to the $3{:}5_{Bi}$ composition, three lead compounds that melt peritectically are mentioned ($5{:}8_{Pb}$, $9{:}16_{Pb}$, and $1{:}16_{Pb}$). The phase diagrams differ with respect to the $3{:}5_{Bi}$, $12{:}1_{Bi}$, and the $1{:}1_{Pb}$, which have no corresponding $3{:}5_{Pb}$, $12{:}1_{Pb}$, and $1{:}1_{Bi}$. Among these three compounds only the $3{:}5_{Bi}$ melts congruently. Assuming a partial ionic decomposition of the corresponding melts, the borate

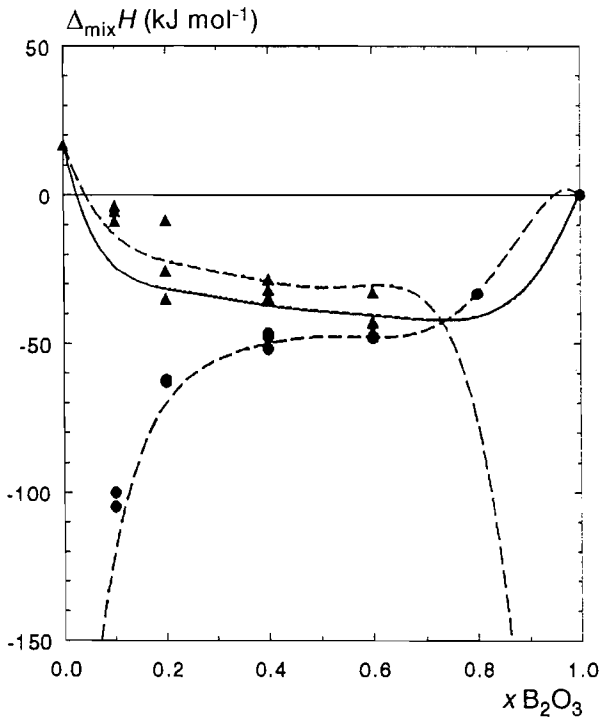
Fig. 1. Integral and partial mixing enthalpies in the B_2O_3–Bi_2O_3 liquid system at 1023 K referred to liquid B_2O_3 and solid Bi_2O_3. Dotted lines: partial mixing enthalpies; ●: $\Delta_{mix}H_{Bi_2O_3}$; ▲: $\Delta_{mix}H_{B_2O_3}$. Solid line: integral mixing enthalpy.



entities corresponding to these particular compositions may be expected in the presence of three-coordinated boron. Table 3 shows that the linear borate anions may be $(B_4O_7)^{-2}$ or $(B_4O_7\text{-}O\text{-}B_4O_7)^{-6}$, which present a double oxygen–boron bonding (-B═O) at each end of the chains; BO_2^-, which presents only one -B═O entity; and $(B_2O_5)^{-4}$, which has no double bonding between B and O. The more acid the melt, the more probable are anions with a double bond. Such behaviour has been observed in silicate melts where the following reaction is favoured by an increase in temperature, i.e., when the acidity of melt also increases:

$$(Si_2O_5)^{-2} = (SiO_3)^{-2} + SiO_2$$

In the two systems studied it is necessary to call upon cationic entities such as $(Pb_2O)^{+2}$, $(Bi_3O_2)^{+5}$, $(Bi_2O_2)^{+2}$, or $(BiO)^+$ in the basic composition range. It appears in this scheme that the polymerization of the cation arises in the Bi_2O_3–B_2O_3 system at a greater boron concentration than in the PbO–B_2O_3 system.

As an acid–base function can be defined with respect to the proton in the aqueous milieu, in molten oxide chemistry an acid will be any compound containing one or several particles able to accept an oxygen anion. The basic reaction can be written as (6):

$$\text{base} = \text{acid} + O^{-2}$$

The basicity of a melt is measured via the oxygen activity in the liquid or the value of the constant of the former equilibrium. An oxide is all the more acidic the weaker its dissociation and the lower the oxygen anion concentration in the melt. The corresponding element is then all the more electronegative. As the temperature rises the acidity of the melt increases. For example, SiO_2 behaves as an acid at 1300 K but decomposes as a basic compound into Si^{+4} and $2O^{-2}$ at higher temperature. An amphoteric oxide is a compound that is able either to give or to retain an oxygen anion.

Table 3. Possible ionic decompositions of some solid compounds (Bi_2O_3 or Pb_2O_2)$_a$(B_2O_3)$_b$ written *a*:*b*, in systems Bi_2O_3–B_2O_3 and Pb_2O_2–B_2O_3.

a:*b*	Bi_2O_3–B_2O_3 system	Pb_2O_2–B_2O_3 system
1:4	$2Bi^{+3}(B_4O_7\text{-}O\text{-}B_4O_7)^{-6}$	$Pb^{+2}(B_4O_7)^{-2}$
1:3	$Bi^{+3}\,3(BO_2)^-$	
1:2		$Pb^{+2}\,2(BO_2)^-$
3:5	$(Bi_3O_2)^{+5}\,5(BO_2)^-$	
1:1		$2Pb^{+2}(B_2O_5)^{-4}$
2:1	$2(Bi_2O_2)^{+2}(B_2O_5)^{-4}$	$2(Pb_2O)^{+2}(B_2O_5)^{-4}$
12:1	$10(Bi_2O_3)\,4(BiO)^+(B_2O_5)^{-4}$	

Lead oxide is a moderately strong base, as Pb^{+2} is a weak acid. Boron oxide acts as a strong acid. On the electronegativity scale O is at 3.5 whereas B is at 2.0, Bi is at 1.9 and Pb at 1.8 (14). It can be assumed that boron oxide and bismuth oxide present about the same acidity and the acid–base behaviour in the Bi_2O_3–B_2O_3 system will be different from that in the PbO–B_2O_3 system. The Bi—O bonding will probably present a less ionic character than that of Pb—O, and will approach the nature of the B—O bonding.

The integral and partial mixing Gibbs free energies corresponding to such an acid–base melt will show some particularities. The Darken function will exhibit some maxima at compositions corresponding to stable entities in the melt (15). In other words, a sharp dependence of the partial thermodynamic functions upon composition will be observed around these particular concentrations. In the present case and to a first approximation, the partial mixing enthalpies will determine the most probable acidic or basic entities that take part in the acid–base reaction of the two oxides. In the concentration regions where the acidity does not vary significantly, the partial thermodynamic function will exhibit a plateau. The solution will then show a buffer character.

Such an analysis was performed by Holm and Kleppa on the previously measured partial mixing enthalpies in PbO–B_2O_3 melts (16). Some sharp variations of these thermodynamic functions are observed around the compositions $x_{B_2O_3} = 0.16$–0.2 and $x_{B_2O_3} = 0.55$–0.6. Assuming that lead is in the Pb^{+2} state, these concentrations correspond to oxygen/boron ratios of 4–3.5 and of 1.91–1.83, respectively. The authors attribute these anomalies to the appearance of some borate anions: BO_4^{-5}, $B_2O_7^{-8}$ corresponding to the same O/B ratios 4–3.5, and $(B_8O_{15})^{-6}$ or $(B_4O_7\text{-}O\text{-}B_4O_7)^{-6}$ (O/B = 1.88). These suggestions are founded on the possible bonding of boron and oxygen atoms in borate glasses. A buffer region lies between these two concentrations.

In the Bi_2O_3–B_2O_3 liquid, such anomalies are observed at $x_{B_2O_3} = 0.05$–0.15 (O/B = 10–30) and $x_{B_2O_3} = 0.75$–0.85 (O/B = 1.77–2). The buffer conditions are realized for $0.4 < x_{B_2O_3} < 0.6$. As in the PbO–B_2O_3 melt, the O/B = 1.77–2 ratio may be

attributed to the formation of borate anions $(B_8O_{15})^{-6}$ or $(B_4O_7\text{-}O\text{-}B_4O_7)^{-6}$. This assumption is confirmed by the great stability of the solid compound $1{:}4_{Bi}$ (O/B = 1.88; T_f = 988 K). For the former entity the high O/B ratio cannot be explained with only a boron-polymerized anion. At this concentration oxygen-bismuth cations are formed.

From analyses of the crystalline phases of the quenching products, it may be thought that, as in the $12{:}1_{Bi}$ compound, some Bi_2O_3, $(BiO)^+$ or $(Bi_2O_3)^{+2}$, and $(B_2O_5)^{-4}$ entities appear in the melt for an O/B ratio of about 10–30. The nature of the cation cannot be described precisely from enthalpic measurements alone but it can be established that oxygen–boron cationic entities are present. From this viewpoint further structural characterizations would be of great interest.

$Bi_2O_{3(1-x)}$–B_2O_{3x} melts as solvents

To verify the ability of these melts to dissolve various solutes, dissolutions of simple oxides such as SiO_2 in the quartz and glassy form, and of Cr_2O_3, MgO, $FeO_{1.132}$, and some glassy melts of MgO–SiO_2 have been carried out in the $8Bi_2O_3$–$2B_2O_3$ melt at 923 K. The dissolution enthalpies lie between 0 and −40 kJ mol^{-1}. No significant variations as a function of solute concentration in the melt were observed. These dissolution enthalpies remain in all cases about 20–30 kJ mol^{-1} lower than those obtained in 2PbO–B_2O_3.

The thermodynamic study of the carnegieite crystal – glassy nepheline transition in $4Bi_2O_3$–$6B_2O_3$ liquid was successfully performed at 1023 K (17).

All the experiments were carried out in a platinum crucible of 0.3 mm thickness. No chemical attack or weight variations were observed during the runs. For the composition richest in B_2O_3 the diameter of the crucible became larger during the cooling, producing some mechanical damage. Such phenomena were not observed for lower $x_{B_2O_3}$ contents. For experiments of long duration, a diffusion of Bi in the crucible metal may occur. On the platinum-rich side of the Bi–Pt phase diagram a eutectic at 1003 K is mentioned, between the pure Pt and the Bi:Pt compound whose melting point is 1038 K (18). For previously mentioned reasons, experiments of long duration at temperatures higher than 1000 K will perhaps be difficult.

It seems that for $0.4 < x_{Bi_2O_3} < 0.6$ the buffer conditions are realized.

Considering the dissolution experiments, it appears that the viscosities of the PbO–B_2O_3 and Bi_2O_3–B_2O_3 melts are very similar.

Although indications regarding the toxicity of chemicals are very scarce, it has been established that the Bi compounds are less toxic than the Pb compounds.

Form these remarks it can be concluded that Bi_2O_3–B_2O_3 melts are good solvents for oxide melt solution calorimetry.

Densities, viscosities, and refractive indexes of *tert*-butyl methyl ether + butyl alcohols at 298.15 K

Roque Riggio, Hector E. Martinez, Norma Z. de Salas, and Juan F. Ramos

Abstract: Densities, viscosities, and refractive indexes of three binary systems, *tert*-butyl methyl ether + *n*-butanol, + *sec*-butanol, + isobutanol, have been determined at 298.15 K and atmospheric pressure over the complete composition range. We also report calculated excess properties including molar volume, viscosity, and Gibbs free energy for the activation of flow for these systems.

Key words: binary systems, excess properties.

Résumé : On a déterminé les densités, les viscosités et les indices de réfraction de trois systèmes binaires de l'oxyde de *tert*-butyle et de méthyle + *n*-butanol (ou + *sec*-butanol ou + isobutanol) à 298,15 K et à la pression atmosphérique à concentrations couvrant toutes les compositions. On rapporte aussi les propriétés en excès qui ont été calculées, y compris le volume molaire, la viscosité et l'énergie libre de Gibbs pour l'activation de l'écoulement de ces systèmes.

Mots clés : systèmes binaires, propriétés en excès.

Introduction

The present work forms part of our programme on the measurement of transport properties of electrolyte and non-electrolyte solutions containing alcohols as one of the components (1–4).

In this contribution we report on the measured values of densities, viscosities, and refractive indexes, at 298.15 K and atmospheric pressure, of binary mixtures of *tert*-butyl methyl ether (MTB) + *n*-butanol (B_1), + *sec*-butanol (B_2), + isobutanol (B_3).

From the above-mentioned properties we compute several excess properties including: molar volume (V^E), viscosity (η^E), and Gibbs free energy for activation of flow (G^{*E}).

Experimental

Materials

All chemicals (Merck-Darmstadt p.a) were dried over anhydrous K_2CO_3 and fractionally distilled under a nitrogen atmosphere. The middle fraction was collected and stored over molecular sieves (0.3 nm for alcohols and 0.4 nm for ether) in order to prevent water absorption. The mixtures were prepared by using a Mettler H11 balance and then stored in air-tight stoppered bottles.

Density (ρ)

Densities of both the pure components and their mixtures were determined by an Anton Paar DMA46 calculating density meter with a built-in thermostat. The accuracy was estimated to be ± 0.1 kg m^{-3}.

Viscosity (η)

Viscosities of both the pure components and their mixtures were determined by a Cannon–Feske viscosimeter, which was calibrated with doubly distilled water and benzene. The accuracy was estimated to be $\pm 0.5\%$.

Refractive index (n_D)

Refractive indexes of both the pure components and their mixtures (sodium D line) were measured with a Bausch–Lomb Abbé-3L refractometer. The accuracy was estimated to be ± 0.0001. For both viscosity and refractive index, a thermostatically controlled bath, constant to ± 0.01°C, was used.

Results

The experimental data for the pure liquids investigated in this work are reported in Table 1, along with the literature values for comparison. Experimental data of densities, viscosities, and refractive indexes of the binary mixtures at 298.15 K are given in Table 2.

The excess functions for these binary systems were computed by using the following Redlich–Kister–Kind equation:

$$[1] \quad X^E = x_i x_j \sum_{k=0}^{n} a_k (2x_i - 1)^k$$

[a]Units: V^E, m^3 mol^{-1}; η^E, mPa s.

where X^E denotes either V^E, η^E, or G^{*E}, x_i and x_j are the molar fractions of components i and j, respectively, the a_k denotes polynomial coefficients. In each case, the optimum number of coefficients was ascertained through an examination of the variation of the standard error of estimate with n:

$$[2] \quad \sigma_y = [E(X^E_{obs} - X^E_{calc})^2/(n_{obs} - n)^{1/2}$$

where n_{obs} is the number of measurements.

In turn, the excess properties were calculated by using the following equations:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

Fig. 1. Molar excess volumes of the systems at 298.15 K.

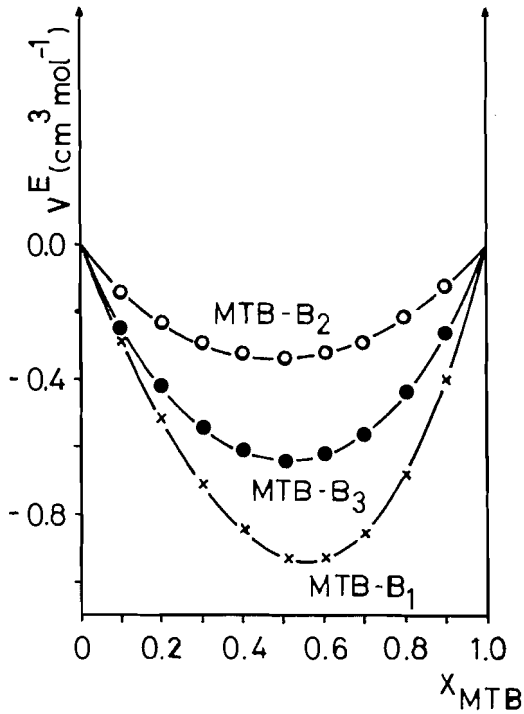

Fig. 2. Excess viscosities of the systems at 298.15 K.

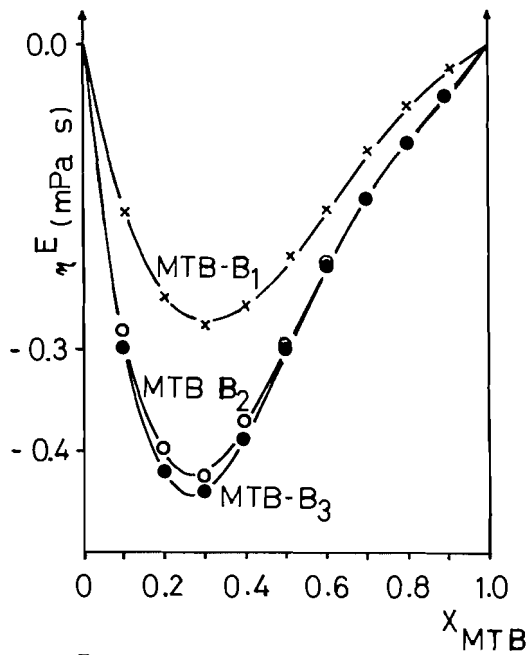


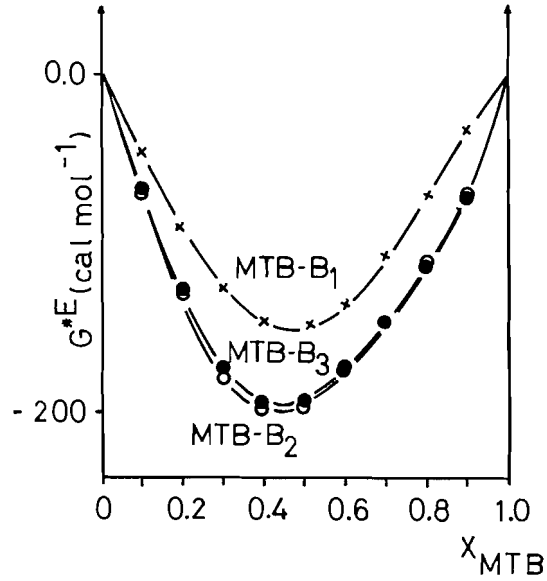
[3] $V^E = [(x_1M_1 + x_2M_2)/\rho] - (x_1V_1 + x_2V_2)$

[4] $\eta^E = \eta - \eta^{id} = \eta - \exp(x_1 \ln \eta_1 + x_2 \ln \eta_2)$

[5] $G^{*E} = RT[\ln \eta V - (x_1 \ln \eta_1 V_1 + x_2 \ln \eta_2 V_2)]$

where M_1 and M_2 are the molecular weights of the pure components, V, V_1, and V_2 are the molar volumes of each mixture and its pure components, η, η_1, and η_2 are the viscosities of each mixture and its pure components, respectively, and η^{id} is the viscosity of ideal mixture.

Fig. 3. Molar excess free energies of viscous flow activation by the systems at 298.15 K.



In Table 3 we report the a_k coefficients for the excess functions of eq. [1] as well as the corresponding standard deviations for each one of the binary systems mentioned before.

Discussion

It is well known that the alcohols involved in this research are substances associated by hydrogen bonding (5, 6). When alcohols are mixed with polar solvents some specific interactions occur due to breakdown of the hydrogen bonds (7). Here we report on the determination of the following excess properties: molar volumes (V^E), viscosities (η^E), and free energies of viscous flow (G^{*E}).

The excess volumes calculated at 298.15 K are plotted against composition in Fig. 1. We note that negative values are obtained for all cases. The increments for the V^E's are in the following order:

$$MTB + B_1 < MTB + B_3 < MTB + B_2$$

Usually, this behaviour is expected for mixtures in which positive contributions caused by disruption of the hydrogen-bonded-alcohol structure are dominated by the geometrical fitting of the ether into the remaining alcohol structure, and by specific interactions due to formation of multimers of alcohol and ether molecules. The lower values for B_1 followed by the B_3 and B_2 mixtures are in good agreement with the slight possibility of a geometric ordering due to the restructuring of the alcohol and the position of the alcohol function at the secondary carbon (8).

Figure 2 shows that for all systems η^E is negative over the whole composition range. The shapes of the viscosity–composition curves are characteristic for those systems containing a component capable of molecular association (9). It can be observed that viscosity decreases to a greater extent on the initial addition of ether to alcohols. Negative deviations occur when dispersion forces are responsible, which is in complete agreement with the conclusions reached for the V^E's.

In Fig. 3 we show the variation of G^{*E} values with compo-

sition for all three systems. According to previous reports (10, 11), this parameter can be considered as a valid measure of molecular interaction. In our case, the negative G^{*E} values lead us to conclude that repulsive forces are dominant.

The almost linear variation of the refractive indexes for the three systems in terms of the composition is in agreement with the conclusion of Loiselier (12) for a large number of ideal and nonideal systems. Neither the polar characteristic of the MTB nor the existence of hydrogen bonding in alcohols seems to have any important effect on the linear dependence of this property upon concentration.

Abstract: Electrophilic aromatic nitration under mild conditions of 4-hydroxyphthalonitrile gave 4-hydroxy-3-nitrophthalonitrile and 4-hydroxy-5-nitrophthalonitrile, while bromination yielded 3-bromo-4-hydroxyphthalonitrile, 4-bromo-5-hydroxyphthalonitrile, and 3,5-dibromo-4-hydroxyphthalonitrile. Iodination gave 4-hydroxy-5-iodophthalonitrile and 4-hydroxy-3,5-diidophthalonitrile. Coupling of 4-iodophthalonitrile, 3-iodophthalonitrile, and 5-iodo-2,3-dicyanonaphthalene with *trans*-1,2-bis(tri-*n*-butylstannyl)ethene gave *trans*-1,2-bis(3,4-dicyanophenyl)ethene, *trans*-1,2-bis(2,3-dicyanophenyl)ethene, and *trans*-1,2-bis(6,7-dicyanonaphthyl)ethene. Photocyclization of a dilute solution of *cis*- or *trans*-1,2-bis(3,4-dicyanophenyl)ethene in dioxane gave a 1:1 mixture of 2,3,6,7- and 2,3,5,6-tetracyanophenanthrenes separable by chromatography.

Key words: phthalonitriles, naphthalenedicarbonitriles, phenanthrenetetracarbonitriles, electrophilic substitution.

Résumé : La nitration électrophile aromatique du 4-hydroxyphtalonitrile, dans des conditions douces, conduit au 4-hydroxy-3-nitrophtalonitrile et au 4-hydroxy-5-nitrophtalonitrile alors que sa bromation fournit du 3-bromo-4-hydroxyphtalonitrile, du 4-bromo-5-hydroxyphtalonitrile, et du 3,5-dibromo-4-hydroxyphtalonitrile. L'iodation fournit du 4-hydroxy-5-iodophtalonitrile et du 4-hydroxy-3,5-diiodophtalonitrile. Le couplage des 4-iodophtalonitrile, 3-iodophtalonitrile et 5-iodo-2,3-dicyanonaphtalène avec du *trans*-1,2-bis(tri-*n*-butylstannyl)éthène fournit du *trans*-1,2-bis(3,4-dicyanophényl)éthène, du *trans*-1,2-bis(2,3-dicyanophényl)éthène et du *trans*-1,2-bis(6,7-dicyanonaphtyl)éthène. La photocyclisation d'une solution diluée des isomères *cis*- et *trans*-1,2-bis(3,4-dicyanophényl)éthène dans le dioxane fournit un mélange 1 : 1 des 2,3,6,7- et 2,3,5,6-tétracyanophénanthrènes que l'on peut séparer par chromatographie.

Mots clés : phtalonitriles, naphtalènedicarbonitriles, phénanthrènetétracarbonitriles, substitution électrophile.

[Traduit par la rédaction]

Some substituted aromatic *o*-dinitriles are widely used in the synthesis of phthalocyanines (1), polymers, and intermediates in organic syntheses (2). Most common methods of their synthesis include cyanation of aromatic halides (2) or more recently triflates (3), nucleophilic substitution of nitrophthalonitriles (4–6), aromatic coupling using, for example, 4-iodophthalonitriles mediated by palladium catalysts (7, 8), Diels–Alder addition of fumaronitrile or dicyanoacetylene to substituted dienes and furans (9), and multistep synthesis involving the transformation of aromatic *o*-diacids via imides and diimides (10) to dinitriles (11–13). Direct electrophilic aromatic substitution of aromatic *o*-dinitriles is generally not used owing to the presence of the two deactivating electron-withdrawing nitrile groups and the fact that these groups are susceptible to hydrolysis during the strongly acidic conditions of these reactions. Our interests in phthalocyanine synthesis led us to prepare a variety of multisubstituted phthalonitriles, bisaromatic-*o*-dinitriles, naphthalenedicarbonitriles (5-substituted-2,3-dicyanonaphthalenes), and phenanthrenetetracarbonitriles, using a wide variety of methods including rarely used electrophilic aromatic substitution reactions and photocyclization.

Iodination, nitration, and bromination of 4-hydroxyphthalonitrile (1)

A recent paper by Gaude et al. (14) described the direct iodination of phenols by iodine nitrate and we thought that this procedure could be successful in the direct iodination of 4-hydroxyphthalonitrile (**1**)(15) as the two nitrile groups may not sufficiently deactivate phenol **1** towards electrophilic aromatic substitution. Thus, treatment of **1** with iodine nitrate in acetonitrile for 2 h at room temperature gave a mixture, separable by flash chromatography, of 4-hydroxy-3,5-diiodophthalonitrile (**2**) and 4-hydroxy-5-iodophthalonitrile (**3**) in 5 and 2.5% yield, respectively (Scheme 1).

The poor yields of **2** and **3** (probably as a result of the electron-deactivating cyano groups of **1**) and the possibility of converting nitro groups into diazonium salts and iodo groups

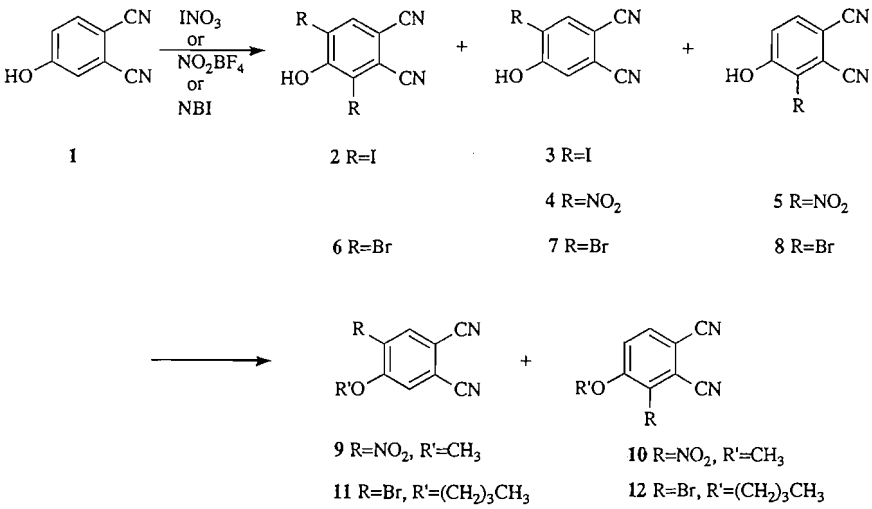
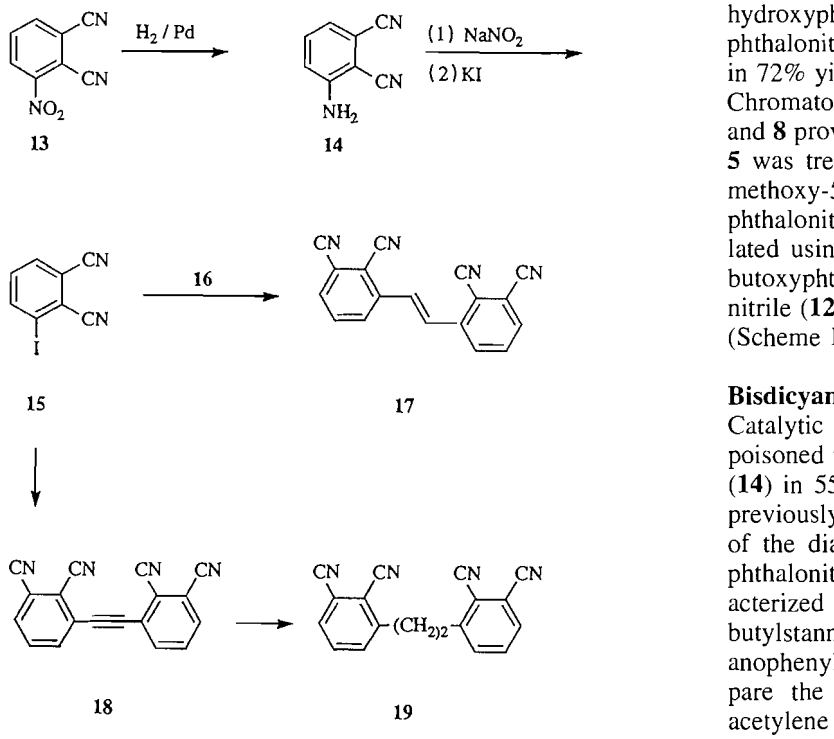
Scheme 1



Scheme 2



led us to consider direct nitration of **1**, using the mild nitrating reagent nitronium tetrafluoroborate (16). Nitration of **1** with nitronium tetrafluoroborate in acetic acid at room temperature, followed by flash chromatography (17) and vacuum liquid chromatography (18) of the reaction mixture, gave 4-hydroxy-5-nitrophthalonitrile (**4**) and 4-hydroxy-3-nitrophthalonitrile (**5**) in 15 and 13% yield, respectively (Scheme 1).

Since the yields of **4** and **5** were still unsatisfactory, we decided to try a rarely used brominating agent, *N,N*-dibromoisocyanuric (NBI) acid (19, 20) known to brominate aromatic compounds containing both activating and deactivating substituents. Although sulfuric acid is used in this procedure, the reaction time is short and the temperature low. Hence, **1** was reacted with NBI in concentrated sulfuric acid for 10 min at room temperature to give 3,5-dibromo-4-hydroxyphthalonitrile (**6**) and a mixture of monobromo-4-hydroxyphthalonitriles consisting of 4-bromo-5-hydroxyphthalonitrile (**7**) and 3-bromo-4-hydroxyphthalonitrile (**8**) in 72% yield that was inseparable by flash chromatography. Chromatography of the product mixtures of **4** and **5** and of **7** and **8** proved to be quite tedious. Hence the mixture of **4** and **5** was treated with diazomethane to give the less polar 4-methoxy-5-nitrophthalonitrile (**9**) and 4-methoxy-3-nitrophthalonitrile (**10**), while the mixture of **7** and **8** was alkylated using K_2CO_3 and 1-bromobutane to give 4-bromo-5-butoxyphthalonitrile (**11**) and 3-bromo-4-butoxyphthalonitrile (**12**) in 30 and 34% overall yield from **1**, respectively (Scheme 1).

Bisdicyanoarylethenes from dicyanoiodoarenes

Catalytic reduction of 3-nitrophthalonitrile (**13**) (21) with a poisoned palladium catalyst (22) gave 3-aminophthalonitrile (**14**) in 55–83% yields, which are considerably higher than previously reported (23). Diazotization of **14** and treatment of the diazonium salt with potassium iodide gave 3-iodophthalonitrile (**15**), only mentioned in an article but not characterized (24). Coupling of **15** with *trans*-1,2-bis(tri-*n*-butylstannyl)ethene (**16**) (25) gave *trans*-1,2-bis(2,3-dicyanophenyl)ethene (**17**) in 59% yield. In an attempt to prepare the *cis* isomer of **17**, iodo **15** was coupled with acetylene and a palladium catalyst (7, 8) to give 1,2-bis(2,3-dicyanophenyl)ethyne (**18**). Catalytic hydrogenation of **18** over a Lindlar catalyst as previously described did not result in semi-hydrogenation and only starting material was recovered. Hydrogenation over palladium on charcoal afforded the fully saturated 1,2-bis(2,3-dicyanophenyl)ethane (**19**) (Scheme 2).

Bromination (9) of 2,3-dimethyl–1-nitrobenzene (**20**) gave 2-bromomethyl-3-dibromomethyl–1-nitrobenzene (**21**), which on treatment (9) with sodium iodide in *N,N*-dimethylformamide and fumaronitrile (**22**) yielded the known 5-iodo-2,3-dicyanonaphthalene (**23**), prepared by a different route (26). Reduction of **23** (26), gave 5-amino-2,3-dicyanonaphthalene (**24**) (26), which upon diazotization and treatment with potassium iodide gave the unknown 5-iodonaphthalene-2,3-dicarbonitrile (**25**). Coupling of **25** with **16** gave *trans*-1,2-bis(6,7-dicyanonaphthyl)ethene (**26**) (Scheme 3). Both

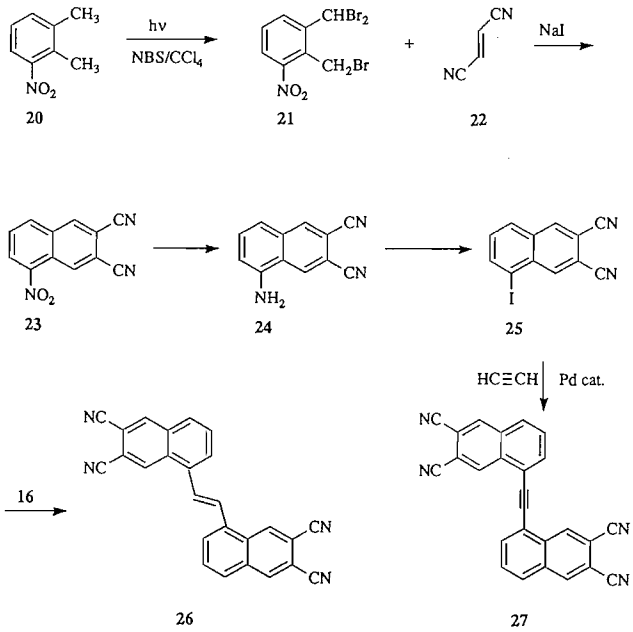
Scheme 3



arylethenes **17** and **26** were extremely insoluble compounds, which likely caused attempts at subsequent reactions to fail. In an attempt to make a more soluble *cis* isomer of **26**, compound **25** was coupled with acetylene in the presence of copper iodide and bis(triphenylphosphine)palladium dichloride (7, 8) to give 1,2-bis(6,7-dicyanonaphthyl) ethyne (**27**) in 54% yield (Scheme 3). This highly insoluble compound also proved resistant to semi-hydrogenation.

2,3,6,7-Tetracyanophenanthrene (31) and 2,3,5,6-tetracyanophenanthrene (32)

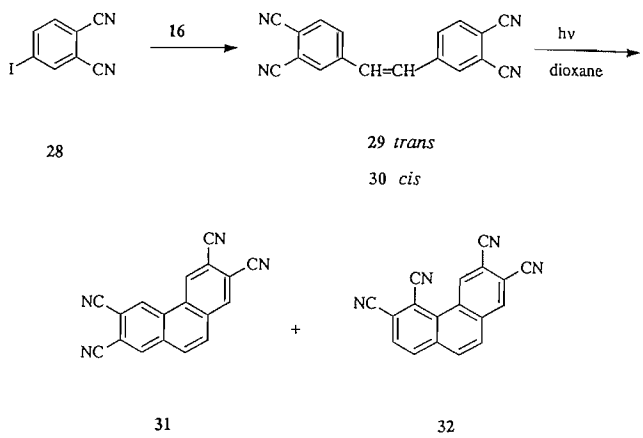
Attempts to induce photocyclization (27–29) of **17** and **26** to give exclusively one isomer of tetracyanoarenes failed, probably because of their extreme insolubility. In a search for more soluble precursors, 4-iodophthalonitrile (**28**) (8) was coupled with **16** to give *trans*-1,2,bis(3,4-dicyanophenyl)ethene (**29**) in 94% yield. The *cis* isomer (**30**) has previously been made in our laboratory (26). Although **29** and **30** were both highly insoluble in most solvents, photocyclization of **29** and **30** was effected in a dilute solution of dioxane to afford a 1:1 mixture of 2,3,6,7-tetracyanophenanthrene (**31**) and 2,3,5,6-tetracyanophenanthrene (**32**) in 60–75% yield (Scheme 4). Regioselectivity in stilbene-like photocyclization reactions can vary, depending on the substituent (30).

The separation of this mixture was finally achieved using flash chromatography and slow elution with ethyl acetate – hexane (1:3) over 12 days to give pure **31** and **32**. A third possible isomer, namely 3,4,5,6-tetracyanophenanthrene, was not detected in any of the photocyclization experiments.

Spectroscopic analysis

All nitriles exhibited typical nitrile absorption at 2220–2240 cm^{-1} in their infrared spectra. The NMR spectra of all compounds were consistent with their structures. The structure of the tribromo derivative **21**, however, was determined by the fact that long-range coupling occurred between the proton at C-4 and the $CHBr_2$ group to give a doublet of doublets (see

Scheme 4



Experimental), and hence the $CHBr_2$ group is at the 3 position.

A NOESY spectrum of compound **25** exhibited long-range coupling between the singlet at 8.88 ppm (H-C1) and the doublet at 8.20 ppm (H-C8). Thus, the other singlet at 8.61 ppm is H-C4, the doublet at 8.49 is H-C6, and the triplet at 7.62 is H-C7. The HH-COSY and NOESY spectra of **32** (Figs. 1 and 2) clearly exhibited a singlet at 9.03 ppm (H-C1) coupled to a doublet at 8.31 ppm (H-C10), while the singlet at 10.03 ppm is uncoupled and is ascribed to H-C9, which shows long-range coupling to H-C8 at 8.65 ppm, leaving the remaining doublet at 8.47 ppm for H-C7. All new compounds exhibited parent ions in their mass spectra and satisfactory elementary analysis or high-resolution mass spectra (HRMS).

The ready availability of multisubstituted phthalonitriles, bisphthalonitriles, and tetracyanophenanthrenes will enable the preparation of unusual phthalocyanines.

Experimental

Matheson high-purity argon was used to maintain inert atmosphere conditions. Infrared (IR) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs. Nuclear magnetic resonance (NMR) spectra for proton and carbon were recorded on a Bruker AM300 NMR spectrometer unless otherwise stated. TMS was used as the internal standard. The positions of the signals are reported in δ units. The splittings of the signal are described as singlets (s), doublets (d), triplets (t), quartets (q), pentets (p), hextets (h) doublets of doublets (dd), broad (br), or multiplets (m). The ultraviolet–visible spectra (UV–VIS) were recorded on a Varian CARY 2400 spectrophotometer UV–VIS–NIR. Mass spectra (MS) were recorded at 70 eV using a VG Micromass 16F mass spectrometer for molecules less than 900 amu or a Kratos Profile in the EI mode. The number in parentheses after the indicated ion shows the percentage of the base peak represented by that ion. The high-resolution mass spectra (HRMS) were obtained at 70 eV of a DEI model using a ZAB-E double focusing spectrometer of BE geometry. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Flash chromatography was performed using silica gel of particle size 20–45 μm. All reactions were stirred with a magnetic stirrer. Ultrasound activation was carried out using a Branson 1200 sonicator. All

Fig. 1. The ^1H–^1H COSY NMR spectrum of 2,3,5,6-tetracyanophenanthrene (**32**) in DMSO-d_6.

solvents were freshly distilled before use. Microanalysis were performed by Guelph Chemical Laboratory Ltd., Guelph, Ontario. Thin-layer chromatography (TLC) was performed using silica gel G as the absorbent.

4-Hydroxy-3,5-diiodophthalonitrile (2) and 4-hydroxy-5-iodophthalonitrile (3)

Silver nitrate (0.85 g, 5 mmol) in 15 mL of acetonitrile was added dropwise to a solution containing 1.27 g of iodine (5 mmol) in 30 mL of acetonitrile, while the solution was stirred at 0°C. After 5 min, the precipitate of silver iodide (about 2.5 mmol) was filtered off and then compound **1** (0.72 g, 5 mmol) in 10 mL of acetonitrile was added to the filtrate. The resulting solution was stirred at room temperature for 2 h. An additional precipitate of silver iodide (about 2.5 mmol) was filtered off. The filtrate was washed with a solution of sodium bisulfite. The organic layer was dried over anhydrous magnesium sulfate for 2 h. The crude product was chromatographed on silica gel with petroleum ether and toluene (1:1). The first fraction gave a small amount of a yellow band. The second fraction was collected to give, in 5% yield, 70 mg of compound **3**; mp 237–239°C; IR (KBr, cm^{-1}): 3320 (OH), 3070, 2950, 2900, 2850, 2230 (CN), 1570, 1550, 1480, 1330, 1280, 1170, 1120, 900; ^1H NMR (DMSO-d_6) δ: 9.50 (s, 1H, O*H*), 8.52 (s, 1H, *H*-C6 or *H*-C3), 8.48 (s, 1H, *H*-C3 or *H*-C6); MS *m/z*: 270 (M^+, 100). Exact Mass calcd. for $C_8H_3N_2IO$: 269.9289; found: 269.9289. Further elution gave, in 2–3% yield, 52 mg of compound **2**; mp 290°C (dec.); IR (KBr, cm^{-1}): 3360(O-H), 2240(C≡N), 1550, 1552, 1440, 1380, 1302, 1240, 1130, 920; ^1H NMR (DMSO-d_6) δ: 8.43 (s, 1H, *H*-C6), 4.3 (br, s, 1H, O*H*). Exact Mass calcd. for $C_8H_2N_2I_2O$: 395.8255; found: 395.8255.

*4-Hydroxy-5-nitrophthalonitrile (**4**) and 4-hydroxy-3-nitrophthalonitrile (**5**)*

To a 50 mL round-bottomed flask, compound **1** (1 g, 6.9 mmol), nitronium tetrafluoroborate (1.37 g, 10.35 mmol) (from Aldrich Chemical Company Ltd.), and 30 mL of acetic acid were added. The mixture was stirred at room temperature for 6 h and then poured into 100 mL of water. The resulting solution was extracted with ethyl acetate. The combined organic layer was washed with water and sodium bicarbonate solution and then dried over anhydrous magnesium sulfate. Magnesium sulfate was filtered off. The filtrate was chromatographed on a flash silica gel column by elution with ethyl acetate and hexane (v/v = 2:1). The first fraction was collected to give, in 15–16% conversion, 200 mg of compound **4** as a yellow solid; mp 182–184°C; IR (KBr, cm^{-1}): 3280 (OH), 2250 (C≡N), 1630, 1565 (NO_2), 1320 (NO_2), 1280, 1120, 740; ^1H NMR (DMSO-d_6) δ: 8.64 (s, 1H, *H*-C6), 7.62 (s, 1H, *H*-C3), 4.3 (br, s 1H, O*H*); MS *m/z*: 189 (M+, 100). Anal. calcd. for $C_8H_3N_3O_3$: C 50.81, H 1.60, N 22.22; found: C 50.84, H 1.28, N 21.98. Continuous elution with the same eluant gave 500 mg of the unreacted starting material **1**. Further elution with ethyl acetate gave, in 13–14% conversion, 180 mg of compound **5**, also as a yellow solid; mp >320°C; IR (KBr, cm^{-1}): 3400(OH), 2230 (C≡N), 1590, 1530 (NO_2), 1475, 1380, 1340 (NO_2), 1270, 840, 690; ^1H NMR (DMSO-d_6) δ: 7.75 (d, J = 9 Hz, 1H, *H*-C6), 7.04 (d, J = 9 Hz, 1H, *H*-C5); MS *m/z*: 189 (M+, 100). Exact Mass calcd. for $C_8H_3N_3O_3$: 189.0174; found: 189.0180.

*3,5-Dibromo-4-hydroxyphthalonitrile (**6**), 4-bromo-5-hydroxyphthalonitrile (**7**), and 3-bromo-4-hydroxyphthalonitrile (**8**)*

A solution of 10 g (35.2 mmol) of *N,N*-dibromoisocyanuric

For personal use only.

acid (NBI) (16) in 100 mL of concentrated H_2SO_4 was added in one portion to a solution of 7.8 g (54.2 mmol) of 4-hydroxyphthalonitrile (**1**) (12) in 100 mL of conc. H_2SO_4 at room temperature. The mixture was stirred for 10 min and then poured onto 800 g of ice. The resulting precipitate was filtered and the filtrate extracted three times with ethyl acetate. The extract was washed with water, a 2% solution of $NaHCO_3$, water, and dried over anhydrous $MgSO_2$. Evaporation of the solvent gave a mixture of products. Flash chromatography on silica gel and elution with ethyl acetate gave in the early fractions, in 12% yield, 2.0 g of 3,5-dibromo-4-hydroxyphthalonitrile (**6**) as a yellow-white solid, mp 269–271°C, IR (KBr, cm^{-1}): 3280 (OH), 2214 (CN); ^1H NMR (DMSO-d_6) δ: 11.16 (s, 1H, O-H), 8.38 (s, 1H, *H*-C6); MS *m/z*: 302 (M+, 100). Anal. calcd. for $C_8H_2Br_2N_2O$: C 31.83, H 0.67, N 9.28; found: C 31.82, H 0.65, N 9.00.

Further elution with ethyl acetate and evaporation of the solvent gave 2.1 g of a mixture of monobromo compounds. The original precipitate was extracted four times with ethyl acetate (leaving a residue of isocyanuric acid) and the extract dried, filtered, and evaporated as above to give an additional 6.6 g for an overall yield of 72% of an inseparable mixture of 4-bromo-5-hydroxyphthalonitrile (**7**) and 3-bromo-4-hydroxyphthalonitrile (**8**); 1H NMR (DMSO-d_6) δ: 11.16 (s, O-*H*), 8.39 (s, *H*-C6 (**7**)), 8.08 (s, *H*-C3 (**7**), 7.81 (d, *H*-C6) (**8**)), 7.30 (d, *H*-C3 (**8**)).

*4-Methoxy-5-nitrophthalonitrile (**9**)*

To 30 mg of compound **4** (0.16 mmol) in 20 mL of anhydrous ether, diazomethane (300 mg) in 30 mL of anhydrous ether was added dropwise at room temperature during a 30 min period. The evaporation of the ether gave, in 92% yield, 30 mg of compound **9**; mp 94–96°C; IR (KBr, cm^{-1}): 3060, 2940, 2220 (C≡N), 1900, 1600, 1550, 1520 (NO_2), 1390, 1350, 1190, 1100, 980, 750; ^1H NMR ($CDCl_3$) δ: 8.2 (s, 1H, *H*-C6), 7.5 (s, 1H, *H*-C3), 4.1 (s, 3H, C*H*$_3$); MS *m/z*: 203 (M^+, 100). Anal. calcd. for $C_9H_5N_3O_3$: C 53.21, H 2.48, N 20.68; found: C 53.49, H 2.29, N 20.53.

*4-Methoxy-3-nitrophthalonitrile (**10**)*

To 30 mg of compound **5** (0.16 mmol) in 20 mL of anhydrous ether, diazomethane (300 mg) in 30 mL of anhydrous ether was added dropwise at room temperature during a 30 min period. The solution was continuously stirred for 30 min. The evaporation of the ether gave, in 89% yield, 29 mg of compound **10**; mp 110–112°C; IR (KBr, cm^{-1}): 3090, 2980, 2240 (C≡N), 1920, 1600, 1540 (NO_2), 1480 1360, 1280, 1060, 850, 780; ^1H NMR ($CDCl_3$) δ: 7.91 (d, *J* = 8.9 Hz, 1H, *H*-C6), 7.41 (d, *J* = 8.9 Hz, 1H, *H*-C5), 4.07 (s, 3H, C*H*$_3$); MS *m/z*: (M^+, 100). Anal. calcd. for $C_9H_5N_3O_3$: C 53.21, H 2.48, N 20.68; found: C 53.30, H 2.30, N 20.73.

*4-Bromo-5-butoxyphthalonitrile (**11**) and 3-bromo-4-butoxyphthalonitrile (**12**)*

To 50 mL of *N,N*-dimethylformamide (DMF) were added 4.0 g (18 mmol) of the mixture of **7** and **8**, 4.7 g of K_2CO_3, and 4.5 g of 1-bromobutane. The mixture was stirred at 90°C for 2 h and then poured into 200 mL of water. The mixture was extracted twice with benzene and the extract washed twice with water and dried over anhydrous $MgSO_4$. The solvent was evaporated to give 7.6 g of a solid mixture. The mixture was separated by flash chromatography on silica gel using benzene–hexane (1:1) as eluant to give, in the first fractions, in 34% yield, 4-bromo-5-butoxyphthalonitrile (**11**); mp 117–119°C; IR (KBr, cm^{-1}): 2230 (CN); ^1H NMR ($CDCl_3$) δ: 7.93 (s, 1H, *H*-C6), 7.18 (s, 1H, *H*-C3), 4.13 (t, *J* = 4.2 Hz, 2H, OC*H*2), 1.88 (m, 2H, OCH$_2$C*H*$_2$), 1.56 (m, 2H, CH$_3$C*H*$_2$), 1.01 (t, *J* = 4.9 Hz, 3H, C*H*$_3$); MS *m/z*: 278 (M^+, 31). Anal. calcd. for $C_{12}H_{11}BrN2O$: C 51.64, H 3.97, N 10.04; found: C 52.04, H 4.03, N 10.02.

Further elution gave 3-bromo-4-butoxyphthalonitrile (**12**) in 30% yield; mp 116–117°C; IR (KBr, cm^{-1}): 2235 (CN); ^1H NMR ($CDCl_3$) δ: 7.79 (d, *J* = 5.8 Hz, 1H, *H*-C6), 7.11 (d, *J* = 5.8 Hz, *H*-C3), 4.14 (t, *J* = 4.2 Hz, 2H, C*H*$_2$), 1.87 (m, 2H, OCH$_2$C*H*$_2$), 1.55 (m, *J* = 3.7 Hz, 2H, CH$_3$C*H*$_2$), 1.00 (t, *J* = 4.9 Hz, 3H, C*H*$_3$); MS *m/z*: 278 (M^+, 76). Anal. calcd. for $C_{12}H_{11}BrN_2O$: C 51.64, H 3.97, N 10.04; found: C 51.76, H 3.86, N 9.95.

*3-Aminophthalonitrile (**14**)*

Nitrophthalonitrile (**13**) (21) was prepared using the procedure of Campagna et al. (12, 13) in 95% yield. The selective reduction of **13** was facilitated using a poisoned catalyst (22, 23). A mixture of 2.5 g of 5% palladium on barium sulfate and 5 mg of thiourea in 2.5 mL of methanol was shaken for 1 h. The solvent was evaporated and the brown residue homogenized.

A suspension of 4.5 g (26 mmol) of **13** in 100 mL of dry dioxane–ethanol (3:1) containing 750 mg of the poisoned catalyst was hydrogenated at 30 psi (1 psi = 6.9 kPa) in a Parr hydrogenation bottle for 1 h at room temperature. The yellow solution was concentrated and purified by flash chromatography using toluene–acetonitrile (5:1) as eluant to give 3.1 g (83% yield) of **14** as a yellow powdery solid, mp 210–212°C (lit. (31) mp 195–198°C).

*3-Iodophthalonitrile (**15**)*

Compound **14** (3.1 g, 21.7 mmol) was mixed with concentrated hydrochloric acid (62 mL) and ice (155 g), and sodium nitrite (2.35 g, 34.1 mmol) in water (20 mL) was added in one portion. After 1.5 h at 5°C, the solution was filtered. The diazonium salt solution was added dropwise to a stirred cool solution of potassium iodide in 30 mL of water. The resulting dark brown mixture was stirred for 0.5 h. This mixture was added to benzene and the solution was washed with cold water, cold 5% $NaHCO_3$, cold water, cold saturated $Na_2S_2O_3$, and again with cold water. The benzene solution was dried over anhydrous magnesium sulfate, filtered, and concentrated to a small volume. Chromatography on 200 g of normal grade silica gel and elution with benzene gave, in 62% yield, 3.3 g of pure **15** as white crystals, mp 167–169°C; IR (KBr, cm^{-1}): 3090, 2240 (CN), 1580, 1550, 1450, 1430, 1210, 1130, 810, 730; ^1H NMR ($CDCl_3$) δ: 8.16 (d, *J* = 8 Hz, 1H, Ar*H*-6), 7.78 (d, *J* = 8 Hz, 1H, Ar*H*-4), 7.40 (t, *J* = 8 Hz, 1H, Ar*H*-5); MS *m/z*: 254 (M^+), 202, 127, 100. Anal. calcd. for $C_8H_3N_2I$: C 37.82, H 1.19, N. 11.03, I 49.95; found: C-38.36, H 1.10, N 11.20, I 49.81.

trans-*1,2-Bis(2,3-dicyanophenyl)ethene (**17**)*

To a 50 mL round-bottomed flask equipped with a magnetic stirrer were added 3-iodophthalonitrile (**15**) (132 mg, 0.52 mmol), compound **16** (157.6 mg, 0.26 mmol), toluene (25.0 mL), and tetrakis(triphenylphosphine) palladium(0) (18.6 mg, 0.016 mmol). The resulting mixture was deoxygenated with a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

stream of argon for 5 min. The reaction flask was placed in an oil bath at 100–120°C and stirred under argon at this temperature until TLC analysis indicated that **15** was consumed (10 h). The reaction mixture was allowed to cool to room temperature and kept under argon overnight. The precipitate was filtered off and washed with toluene and diethyl ether to give, in 59% yield, 45 mg of compound **17** as an off-white solid; mp >330°C; IR (KBr, cm^{-1}): 3080, 2230 (C≡N), 1580, 1470, 1440, 1270, 1200, 1160, 801, 740. MS *m/z*: 280 (M^+, 100). Anal. calcd. for $C_{18}H_8N_4$: C 77.14, H 2.86, N 20.00; found: C 77.24, H 2.39, N 20.27.

*1,2-Bis-(2,3-dicyanophenyl)ethyne (**18**)*

By a procedure previously described (7, 8), 3.0 g (11.8 mmol) of **15**, 80 mL of dry, freshly distilled diethylamine, and 25 mg (0.133 mmol) of bis(triphenylphosphine) palladium dichloride was placed into a 250 mL two-necked flask, equipped with a magnetic stirrer, a condenser, and a gas inlet tube. The flask was flushed with argon and a moderate stream of dry acetylene was passed through the solution for 9 h at room temperature. A pale pink precipitate was observed. This mixture was evaporated and the remaining residue was washed with water, methanol, and diethyl ether. The crude product was extracted with methanol in a Soxhlet extractor for 12 h until the extract was almost clear. This process removed brown impurities. The pale pink compound was dried to give, in 88% yield, 1.44 g of **18**, mp >300°C. This product is sufficiently pure that it can be used directly without further purification. Two recrystallizations of a small sample of **18** from acetonitrile gave white crystals of pure **18**, mp >300°C; IR (KBr, cm^{-1}): 3090, 2240 (CN), 1590, 1480, 1450, 1340,1290, 1190, 810, 710; ^{1}H NMR (DMSO-d_6, 300 MHz) δ: 8.25 (d, J = 8 Hz, 2H, Ar*H*-6), 8.16 (d, J = 8 Hz, 2H, Ar*H*-4), 8.01 (t, J = 8 Hz, 2H, Ar*H*-50; MS *m/z*: 278(M^+), 251, 224, 200, 176, 139. Anal. calcd. for $C_{18}H_6N_4$: C 77.69, H 2.17, N 20.13; found: C 77.42, H 2.08, N 20.78.

*1,2-Bis-(2,3-dicyanophenyl)ethane (**19**)*

A suspension of 0.200 g (0.72 mmol) of **18** in 150 mL of acetonitrile containing 50 mg of 10% palladium on charcoal was hydrogenated at 65 psi in a Parr hydrogenation bottle for 4 h at room temperature. The clear solution was filtered from the catalyst and concentrated. The compound was purified by flash chromatography using acetonitrile as eluant to give 0.190 g (94% yield) of **19** as yellow needles, mp 246–248°C; IR (KBr, cm^{-1}): 3090–2920, 2230 (CN), 1590, 1480, 820, 750; ^{1}H NMR (DMSO-d_6, 300 MHz) δ: 8.01 (d, J = 8 Hz, 2H, Ar*H*-6), 7.81 (t, J = 8 Hz, 2H, Ar*H*-5), 7.72 (d, J = 8 Hz, 2H, Ar*H*-4), 3.28 (s, 4H, CH_2CH_2O; MS *m/z*: 282(M^+), 255, 226, 201, 141. Anal. calcd. for $C_{18}H_{10}N_4$: C 76.58, H 3.57, N. 19.84; found: C 76.32, H 3.69, N 19.99.

*2-Bromomethyl-3-dibromomethylnitrobenzene (**21**)*

To a 1000 mL one-necked round-bottomed flask, charged with 500 mL of carbon tetrachloride, 3-nitro-*o*-xylene (**20**) (10 g, 66 mmol) (from Aldrich Chemical Company Ltd), *N*-bromosuccinimide (70.88 g, 396 mmol), and 200 mg of benzoyl peroxide were added. The mixture was irradiated using a 270 W sun lamp for 12 h or until TLC analysis indicated that the 3-nitro-*o*-xylene (**20**) was consumed. A precipitate was formed and the hot solution was filtered. The filtrate was concentrated, preabsorbed on a small amount of flash silica gel, and then loaded on a 5 cm diameter column containing flash silica gel and eluted with cyclohexane. The second fraction was collected to give 17 g of compound **21** in 83% yield; mp 67–68°C: IR (KBr cm^{-1}): 3080, 3020, 1520 (NO2), 1440, 1380 (NO2), 1255, 1230, 1140, 930, 850, 820, 780, 745, 680, 640; ^{1}H NMR ($CDCl_3$) δ: 8.28 (d, J = 7.3 Hz, 1H, *H*-C_6), 7.86 (dd, J = 7.3, 1.0 Hz, 1H, *H*-C4), 7.59 (t, J = 8 Hz, 1H, *H*-C5), 7.12 (brs, 1H, C*H*Br_2), 4.72 (s, 2H, CH_2Br); ^{13}C NMR ($CDCl_3$) δ: 143.0, 135.0, 131.2, 130.2, 126.5, 125.9, 34.4, 21.4; MS *m/z*: 306 (M^+−79), 308, 310, 384 (M^+−1), 386, 388, 390. Exact Mass calcd. for $C_8H_6Br_3NO_2$: 383.7871 (M^+−H); found 383.7873.

*5-Aminonaphthalene-2,3-dicarbonitrile (**24**)*

Nitronaphthalene-2,3-dicarbonitrile (**23**), prepared from **19** and fumaronitrile (**22**) by the procedure of Kovshev et al. (*9a*), gave, upon hydrogenation as for the preparation of **13** above, the known **24**, mp 256–258°C (lit. (26) mp 257–258°C).

*5-Iodonaphthalene-2,3-dicarbonitrile (**25**)*

A solution of concentrated H_2SO_4 (12 mL) and ice (50 g) was cooled to 0°C on a salt–ice bath. Compound **24** (300 mg, 1.6 mmol) was added to this solution followed by an aqueous solution of sodium nitrite (176.5 mg, 2.56 mmol). The resulting solution was stirred for 1 h at 0°C and then added dropwise to 20 mL of an aqueous solution of sodium iodide (5 g), which was vigorously stirred and kept below 3°C. After 0.5 h at 3°C, the dark brown solution was allowed to slowly warm to room temperature. Benzene (50 mL) was added to the dark brown solution. After stirring for 10 min, the resulting mixture was filtered. The organic layer was separated and washed with cold water, 10% $NaHCO_3$, cold water, a cold saturated solution of $Na_2S_2O_3$, again with cold water, and then dried over anhydrous magnesium sulfate for 2 h. The magnesium sulfate was filtered off. The filtrate was concentrated to a small volume and chromatographed on a column containing regular grade silica gel using toluene as the eluant to give, in 46% yield, 270 mg of compound **25** as a yellow solid; mp 243°C; IR (KBr, cm^{-1}): 3080, 2240, (C≡N), 1540, 1430, 918, 900, 800; ^{1}H NMR (DMSO-d_6) δ: 8.88 (s, 1H, *H*-Cl), 8,61 (s, 1H, H-C4), 8.48 (d, J = 8 Hz, 1H, *H*-C6), 8.19 (d, J = 8 Hz, 1H, *H*-C8), 7.62 (t, J = 8 Hz, 1H, *H*-C7): ^{13}C NMR (DMSO)-d_6) δ: 142.3, 139.4, 137.5, 134.0, 133.0, 132.0, 129.8, 116.0, 115.9, 110.8, 109.9, 100.3; MS *m/z*: 304 (M^+, 100). Anal. calcd. for $C_{12}H_8N_2$: C 47.40, H 1.66, N 9.21; found: C 47.76, H 1.55, N 8.94.

trans-*1,2-Bis(6,7-dicyanonaphthyl)ethene (**26**)*

To a 50 mL round-bottom flask equipped with a magnetic stirrer, 5-iodonaphthalene-2,3-dicarbonitrile (**25**) (300 mg, 0.96 mmol), compound **16** (290 mg, 0.48 mmol), toluene (25.0 mL), and tetrakis(triphenylphosphine)palladium(0) (33.5 mg, 0.029 mmol) were added. The resulting mixture was deoxygenated with a stream of argon for 5 min. The reaction flask was placed in an oil bath at 100–120°C and stirred under argon at this temperature until TLC analysis indicated that **25** was consumed (about 10 h). The reaction mixture was allowed to cool to room temperature and remained under argon overnight. The precipitate was filtered and washed with toluene and diethyl ether to give, in 80% yield, 150 mg of compound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 65.111.164.53 on 09/08/12
For personal use only.

26 as a green-yellow solid; mp >330°C; IR (KBr, cm^{-1}): 3050, 2220 (C≡N), 1450, 1370, 1360, 1340, 960, 901, 801, 750. Exact Mass calcd. for $C_{26}H_{12}N_4$: 380.1061; found: 380.1064.

1,2-Bis(6,7-dicyanonaphthyl)ethyne (27)

Compound **25** (265 mg, 0.87 mmol), 25 mL of dry, freshly distilled diethylamine, 25 mg of copper(I) iodide (0.133 mmol), and 20 mg of bis(triphenylphosphine)palladium dichloride (0.028 mmol) were added to a 100 mL two-necked round-bottomed flask, which was equipped with a magnetic stirrer, a condensor, and a gas inlet tube. The flask was first flushed with argon and then a moderate stream of dry acetylene was bubbled though the solution for 6 h at room temperature. A brown precipitate was produced. The precipitate was filtered off and extracted continuously with methanol in a Soxhlet apparatus for about 12 h, or until the extract was colourless. The precipitate in the thimble was dried in an oven at 100°C for 2 h, to give, in 54% yield, 178 mg of compound **27** as a brown solid; mp >330°C; IR (KBr, cm^{-1}): 3060, 2230 (C≡N), 1580, 1260, 1180, 900, 800, 750; MS *m/z*: 378 (M^+, 100). Exact Mass calcd. for $C_{26}H_{10}N_4$: 378.0905; found: 378.0917.

trans-*1,2-Bis(3,4-dicyanophenyl)ethene (29)*

To a 50 mL round-bottomed flask equipped with a magnetic stirrer, 4-iodophthalonitrile (**28**) (517 mg, 1.96 mmol), compound **16** (594 mg, 0.98 mmol), toluene (5.0 mL, freshly distilled over sodium), and tetrakis(triphenylphosphine)palladium(0) (21.7 mg, 0.018 mmol) (from Aldrich Chemical Company Ltd) were added. The resulting mixture was deoxygenated with a stream of argon for 5 min. The reaction flask was placed in an oil bath at 100–120°C and stirred under argon at this temperature until TLC analysis indicated that **28** was consumed (about 10 h). The reaction mixture was allowed to cool to room temperature and remained under argon overnight. The precipitate was filtered off and washed with toluene and diethyl ether to give, in 98% yield, 279 mg of compound **29**; mp >330°C; IR (KBr, cm^{-1}): 3050, 2220 (C≡N), 1590, 1490, 1415, 1325, 960, 910, 840, 725; ^{1}H NMR (DMSO-d_6) δ:8:41 (s, 2H, *H*-C2), 8.17 (d, J = 8.2, *H*-C5), 8.07 (br, d, J = 8.2, 2H, *H*-C6), 7.71 (s, 2H, *HC*=C*H*); MS *m/z*: 280 (M^+, 100). Anal. calcd. for $C_{18}H_8N_4$: C 77.13, H 2.88, N 19.95; found: C 76.96, H 2.57, N 19.64.

2,3,6,7-Tetracyanophenanthrene (31) and 2,3,5,6-tetracyanophenanthrene (32)

To 90 mL of dioxane in a Pyrex tube (40 x 5 cm), *trans*-**29** (40 mg, 0.14 mmol) or *cis*-**30** (26) (40 mg, 0.14 mmol) and iodine (25 mg, 0.19 mmol) were added. The suspension was sonicated until all particulates were dissolved. The tube was placed in a Rayonet photochemical reactor and irradiated for 9 h (the wavelength emitted by the lamps used was in the range of 257–350 nm). In the irradiation of **29** a trace amount of precipitate was removed by filtration. The solution was washed with a saturated solution of sodium bisulfite and then with ethyl acetate. The organic layer was separated and dried over anhydrous $MgSO_4$. After filtering the $MgSO_4$, the solution was concentrated. The concentrated solution was preadsorbed on a small amount of flash silica gel, then loaded on a column containing TLC grade silica gel G and eluted slowly over a 12 day period with hexane – ethyl acetate (3:1). The first fraction gave, in 31 and 40% yield from **29** and **30**, respectively, 12.2 and 15.9 mg of compound **31**; mp >330°C; IR (KBr, cm^{-1}): 3065, 3040, 2240 (C≡N), 1595, 1245, 920; 1H NMR (DMSO-d_6) δ: 9.86 (s, 2H, *H*-C1, *H*-C8), 8.99 (s, 2H, *H*-C4, *H*-C5), 8.33 (s, 2H, *H*-C9, *H*-C10); ^{13}C NMR (DMSO-d_6) δ: 136.1, 134.2, 132.1, 130.6, 130.3, 116.1, 115.9, 112.6, 111.7; MS *m/z*: 278 (M^+, 100). Anal. calcd. for $C_{18}H_6N_4$: C 77.69, H 2.17, N 20.13; found: C 77.33, H 2.34, N 19.88.

Further elution with the same solvents gave, in 28 and 36% yields from **29** and **30**, respectively, 11.0 and 14.2 mg of compound **32**; mp >330°C; IR (KBr, cm^{-1}): 3395, 2220 (C≡N), 1585, 925, 870; ^{1}H NMR (DMSO-d_6) δ: 10.07 (s, 1H, *H*-C4), 9.03 (s, 1H, *H*-C1), 8,67 (d, J = 8.4, 1H, *H*-C8), 8.47 (d, J = 8.4, 1H, *H*-C7), 8.39 (d, J = 8.9, 1H, *H*-C9), 8.31 (d, J = 8.9, 1H, *H*-C10); ^{13}C NMR (DMSO-d_6) δ: 136.4, 125.9, 135.5, 134.8, 131.4, 131.1, 130.5, 128.9, 127.4, 118.5, 117.8, 116.4, 116.2, 115.6, 112.6, 112.0, 111.1; MS *m/z*: 278 (M^+, 100). Anal. calcd. for $C_{18}H_6N_4$: C 77.69, H 2.17, N 20.13; found: C 77.20, H 2.33, N 19.91.

Sulfonyl esters 6. Elucidation of the first sequence in the Trithioorthoformate Reaction

James Clayton Baum, Bradley Eugene Black, Laura Precedo, John Edward Goehl, and Richard Francis Langler

Abstract: The one-pot conversion of a mercaptan and an aryl methanesulfonate into a trithioorthoformate is described. The intermediacy of a sulfide-sulfonate ester is firmly established. Experimental and computational results permit the formulation of a possible pathway for the formation of the intermediate sulfide-sulfonate ester.

Key words: single electron transfer, sulfonate esters, sulfide-sulfonate esters.

Résumé : On décrit une conversion unipotique d'un mercaptan et d'un méthanesulfonate d'aryle en un trithioorthoformate. On a établi sans ambiguïté qu'un ester sulfure-sulfonate agit comme intermédiaire. Les résultats expérimentaux et les calculs permettent de formuler une voie réactionnelle possible pour la formation de l'intermédiaire sulfure-sulfonate.

Mots clés : transfert d'un seul électron, esters sulfonates, esters sulfure-sulfonate.

[Traduit par la rédaction]

Introduction

Some time ago (1), we reported the sulfonyl transfer reaction shown in eq. [1].

[1] $CF_3CH_2OSO_2CH_3 + PhCH_2SH \xrightarrow{CH_3ONa} [CH_3SO_2OCH_3] + PhCH_2SCH_3$ (27%)

Recent work (2–4) employed sodium hydride as the base and hexamethyl phosphoramide (HMPA) as the solvent. We now report the results shown in eq. [2].

[2] 
This reaction we have dubbed the Trithioorthoformate Reaction. The present report discloses our findings and conclusions about the processes that introduce the first thio *p*-tolyl group.

Results and discussion

When phenyl methanesulfonate was replaced by phenyl ethanesulfonate, no trithioorthoformate **1** was formed, suggesting that the methine carbon is more likely to come from phenyl methanesulfonate than from HMPA. The failure of the reactions shown in eqs. [4] and [5] to produce any trithioorthoformates containing simple thiophenyl groups suggests that the phenoxysulfonyl group is the last to be replaced in the conversion of phenyl methanesulfonate into **1**.

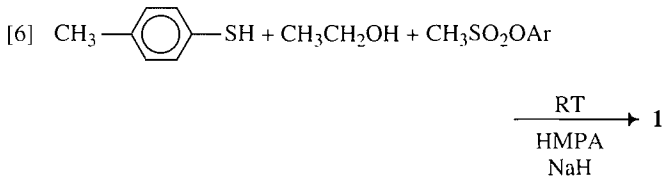
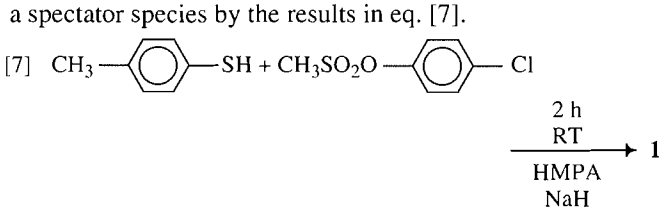
To improve the chances of isolating one or more of the intermediates, we carried out reactions at room temperature and varied the sulfonate ester structure. Equation [6] shows the general reaction and Table 1 presents our results.

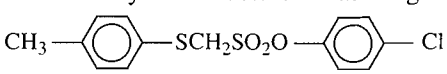


Because signals for a potential intermediate were observed in the ^{1}H nmr spectrum of the crude when the reaction was carried out with *p*-chlorophenyl methanesulfonate, further exploration employed that sulfonate ester. Ethanol was shown to be a spectator species by the results in eq. [7].



The trithioorthoformate reaction occurs between the mercaptan and the sulfonate ester, proceeding by sequential replacement of two protons and the aryloxysulfonyl group initially attached to the methanesulfonate methyl carbon.

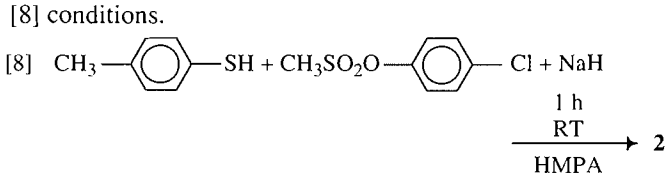
When the crude product from eq. [6] (Table 1, case 2) was repeatedly chromatographed, a sulfonyl-containing product with ^{1}H nmr δ: 7.33 (8H), 4.40 (2H, s), and 2.33 (3H, s) was isolated in 6% yield. Structure **2** was assigned to this compound.



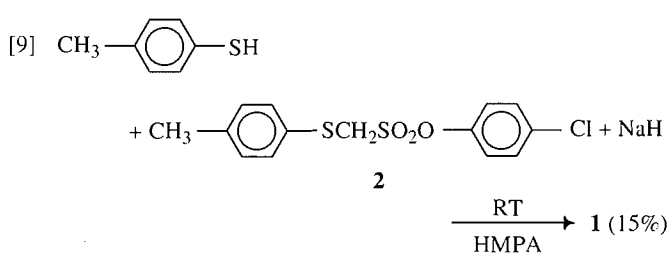
2

An unambiguous, independent synthesis of **2** from *p*-chlorophenyl chloromethanesulfonate was completed (4), thus lending support to our initial pathway conclusions (eqs. [2]–[7]). Compound **2** was also oxidized to the corresponding sulfone-sulfonate ester, which was fully characterized.

The yield[2] of **2** was raised to 27% in HMPA by varying eq. [8] conditions.



The intermediacy of **2** in the trithioorthoformate reaction was confirmed by the results shown in eq. [9] (cf. results on CH_3SO_2O-◯-Cl in Table 1)



[2] Routine production of **2** was less costly and faster (reaction time: 0.5 h) when the reaction was conducted in DMSO (yield: 29%).

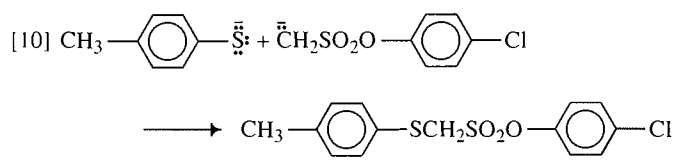
Table 1. Reaction of *p*-toluenethiol with various aryl methanesulfonates — the Trithioorthoformate Reaction. Correlation of yields of *p*-tolyl trithioorthoformate (**1**) with the LUMO eigenvalues of the sulfonates.

Methanesulfonate ester	LUMO[a] eigenvalue (eV)	Yield **1** (%)
CH_3SO_2O—◯	0.3516	0
CH_3SO_2O—◯—Cl	−0.0201	4
CH_3SO_2O—◯—SO_2CH_3	−0.6193	30
CH_3SO_2O—◯(Br, Br)—Br	−1.0038	0[b]
CH_3SO_2O—◯—NO_2	−1.9839	0[b]

[a]LUMO eigenvalues were calculated using the ZINDO program (3, 5).
[b]Complete discussions of the reactions of the tribromophenyl and nitrophenyl sulfonates have been presented in refs. 2 and 3, respectively.

It is now clear that eq. [8] represents an overview of the first sequence when the reaction is conducted with *p*-chlorophenyl methanesulfonate.

The most perplexing feature of the mechanism associated with eq. [8] can be formulated as shown below:



The oxidizing agent in this reaction must selectively oxidize at least one of the reactants in the presence of a substantial excess of sodium hydride.[3]

A priori, the plethora of established oxidizing agents for the conversion of mercaptans to disulfides (6) makes it likely that the mercaptide anions would be oxidized in preference to the sulfonate-stabilized carbanions. In accord with that supposition, eq. [6] reactions in which we used *p*-tolyl mercaptan as a reactant afforded *p*-tolyl disulfide (yields up to 63%). Equation [11] provides good support for the intermediacy of the disulfide in the formation of trithioorthoformate **1**.

It is noteworthy that both intermediates **2** and *p*-tolyl disulfide increase the yield of trithioorthoformate **1** (5%, Table 1), when they are introduced as starting materials (**1**, 15%, eq. [9], and **1**, 23%, eq. [11]).

An overview of the first sequence of the trithioorthoformate reaction is presented in Scheme 1.

The principal oxidizing agent might be atmospheric oxy-

[3] Sodium hydride may act as a reducing agent: see ref. 4 and references therein.

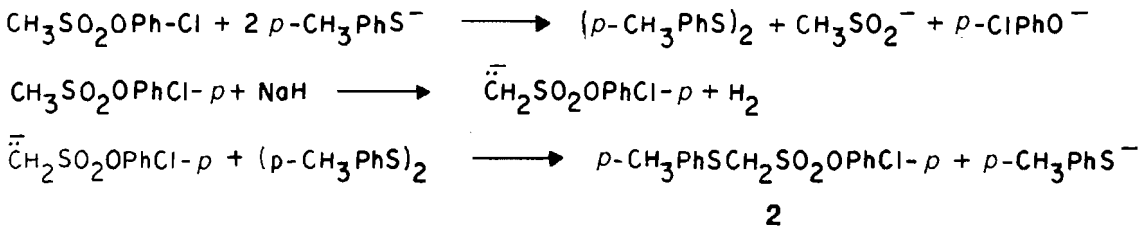
Scheme 1



[11] CH_3SO_2O—C$_6$H$_4$—Cl + (CH$_3$—C$_6$H$_4$—S)$_2$ + NaH

RT, HMPA ⟶ **1** (23%) + **2** (17%) + CH_3SO_2O—C$_6$H$_4$—Cl (0%)

gen. However, (*i*) the eq. [8] reaction proceeds normally under a nitrogen atmosphere and (*ii*) a HMPA solution of *p*-tolyl mercaptide anions furnishes *p*-tolyl disulfide in only 27% yield after exposure to air at room temperature for 1 h 5 min.

Recently published results (2), eq. [12], make it very likely that the sulfonate esters themselves serve as the principal oxidizing agents.

[12] CH_3SO_2O—C$_6$H$_2$(Br)$_2$—Br + CH$_3$—C$_6$H$_4$—SH + NaH

RT, HMPA ⟶ (CH$_3$—C$_6$H$_4$—S)$_2$ (98%)

In accord with previous discussions (2, 4), we propose that a likely redox mechanism would involve single electron transfer (SET).[4] The facility of such processes should vary with the LUMO energy of the oxidant.

Equations [13] and [14] contrast with the corresponding results for *p*-chlorophenyl methanesulfonate (eqs. [8] and [11]), which can be readily rationalized from the LUMO eigenvalues provided in Table 1.

[13] CH_3SO_2OPh + CH$_3$—C$_6$H$_4$—SH + NaH

RT, HMPA ⟶ (CH$_3$—C$_6$H$_4$—SCH_2SO_2OPh **3** (7%) + CH_3SO_2OPh (59%)

[14] CH_3SO_2OPh + (CH$_3$—C$_6$H$_4$—S)$_2$ + NaH

RT, HMPA ⟶ **3** (7%) + **1** (24%) + CH_3SO_2OPh (37%)

First, consider the reactions that employ the mercaptan. The relatively high-lying phenyl methanesulfonate LUMO leads to slow oxidation (SET), a low yield of sulfide-sulfonate ester **3**, and a very substantial amount of unchanged phenyl methanesulfonate (59%). In contrast, the lower lying *p*-chlorophenyl methanesulfonate LUMO leads to more facile oxidation (SET), quadruple the yield of sulfide-sulfonate ester **2**, and only 7% recovered sulfonate ester (eq. [8]).

Reactions with disulfide alleviate the need for an oxidation step in order to form trithioorthoformate **1**. Both phenyl methanesulfonate and *p*-chlorophenyl methanesulfonate should have methyl protons with comparable acidity so that carbanion formation (as assumed in eq. [10]) would proceed smoothly in both cases. These reactions give low yields of sulfide–sulfonate esters **2** or **3** and comparable yields of the trithioorthoformate **1** (eqs. [11] and [14]). Note the complete consumption of the chloroester (eq. [11]) versus the recovery of a third of the phenyl methanesulfonate (eq. [14]).

The results in equations [8], [11], [13], and [14] suggest an interesting series of experiments. Assume that the sulfide-sulfonate esters **2** and **3** are formed as shown in eq. [15].

[15] CH_3SO_2OAr + NaH ⟶ $\bar{C}H_2SO_2OAr$ + (*p*-$CH_3PhS)_2$

S_N2 ↓

p-$CH_3PhSCH_2SO_2OAr$ + *p*-CH_3PhS^-

If the reaction shown in eq. [15] were a simple S_N2 substitution, then the yield of sulfide-sulfonate ester **2** should decrease as the amount of disulfide is decreased in consecutive runs. *But*, if the sulfonate ester is a redox reagent that can oxidize mercaptide anions back to disulfide then the outcome should be very different.

Initially, a decrease in the amount of disulfide would produce fewer mercaptide anions. In turn, the amount of methanesulfonate consumed by mercaptide anions[5] would be

[4] Note the earlier proposal by Wenkert et al. (7) that the β-chlorination of indole anions proceeds by SET from the indole anion to benzenesulfonyl chloride.

[5] *p*-Chlorophenyl methanesulfonate and **2** should accept an electron with comparable facility based on the ZINDO calculated eigenvalues for their LUMOs, which are −0.0201 and +0.0207 eV, respectively.

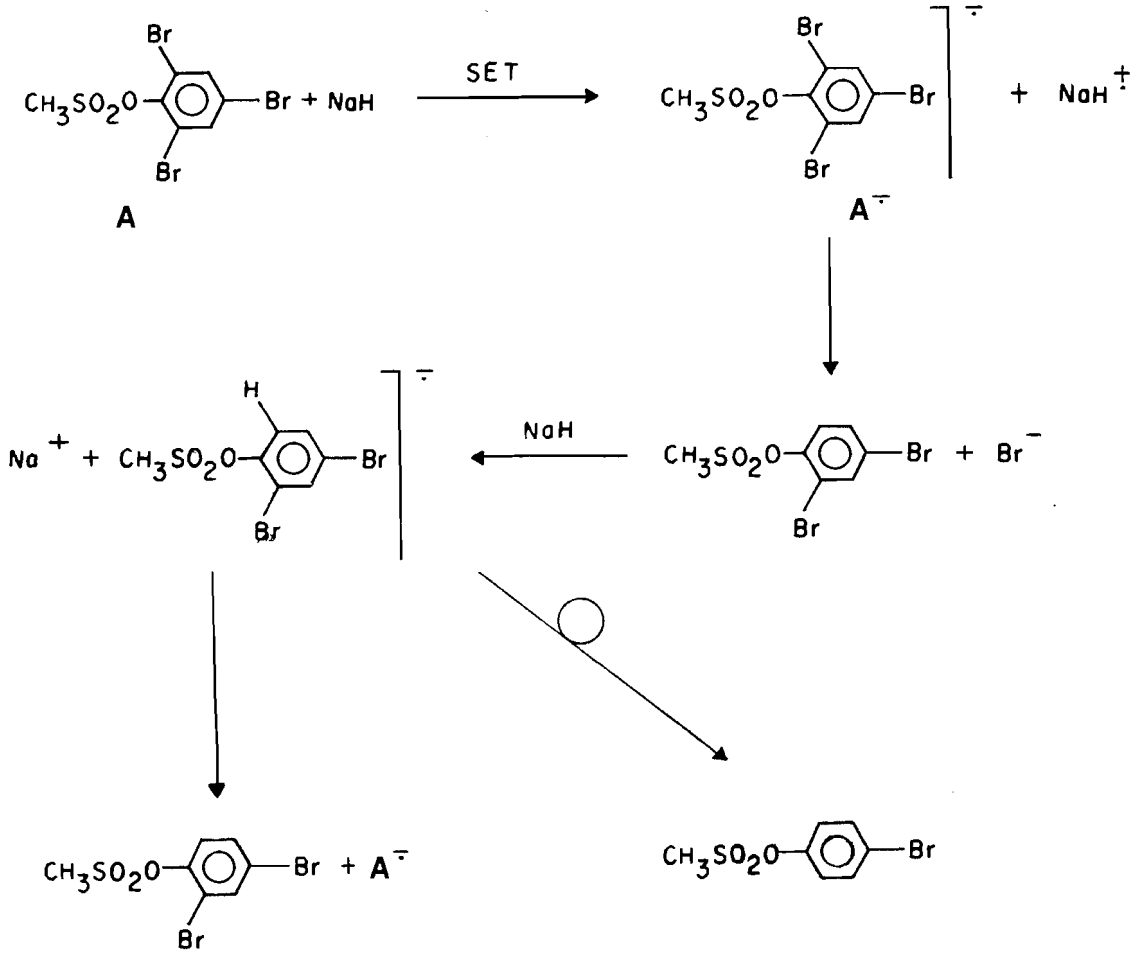
Scheme 2



reduced and more methanesulfonate carbanions should be available to carry out the substitution that produces sulfide-sulfonate **2**. Thus, initially, the yield of sulfide-sulfonate ester would *increase* when the amount of disulfide is *decreased*. Of course the yield of **2** will ultimately have to decrease as the amount of added disulfide nears zero. Analysis of eq. [15], assuming that all mercaptide anions produced would reduce any sulfonate ester present, leads to the conclusion that the sulfide-sulfonate ester yield should reach a maximum for the reaction in which the *p*-chlorophenyl sulfonate/*p*-tolyl disulfide ratio is approximately 1:0.5.

This series of reactions was conducted in the same manner and on the same scale as described in the experimental section under "Reaction of *p*-chlorophenyl methanesulfonate with *p*-tolyl disulfide" (except the amount of disulfide was reduced from run to run). Our results follow the form: ratio methanesulfonate/disulfide (grams of sulfide-sulfonate ester **2** isolated), 1:1 (0.765 g), 1:0.5 (1.297 g), 1:0.4 (1.068 g), 1:0.3 (0.843 g). Note that simple S_N2 substitution uncomplicated by redox chemistry should have given the following results: 1:1 (0.765 g), 1:0.5 (0.382 g), 1:0.4 (0.306 g), and 1:0.3 (0.229 g). In our view, these results offer very strong support for the role of *p*-chloromethanesulfonate as oxidant and virtually eliminate any other oxidant from consideration.

Are mercaptide anions the exclusive reductants in these reactions or can sodium hydride also initiate SET reactions with aryl methanesulfonates? A recently reported study (4) of reactions between aryl methanesulfonates and sodium hydride established routine formation of two products.

$$[16]\quad CH_3SO_2OAr + NaH \xrightarrow[HMPA]{RT} CH_3SO_2CH_2SO_2OAr + ArOH$$

Reactions described in the present report that employed either *p*-tolyl mercaptan or *p*-tolyl disulfide (e.g., eqs. [6], [7], [11]) failed to furnish any sulfone-sulfonate esters. Apparently sulfonate-stabilized carbanions sulfenylate more rapidly than they decompose to form sulfene[6] and phenoxide ions. We proposed that eq. [16] reactions, which produced phenols exclusively, were proceeding by SET from sodium hydride to the aryl methanesulfonate (LUMO eigenvalues ≤ -1 eV).

As part of the present work, we subjected 2,4,6-tribromophenyl methanesulfonate to reaction with sodium hydride. Given the LUMO eigenvalue (Table 1) for 2,4,6-tribromophenyl methanesulfonate, the high yield of the tribromophenol and the absence of a product sulfone-sulfonate ester are expected results. The selective displacement of *ortho* bromine atoms is entirely inconsistent with the formation of a Meisenheimer complex (3). Such behaviour is consistent with

[6] Reference 4 concludes that sulfene is an intermediate in the formation of aryl sulfone–sulfonates as depicted in eq. [16].

[17] 
SET-induced dechlorination of *p*-chlorophenyl methanesulfonate (8).

At the suggestion of a referee, we repeated the eq. [17] reaction in the presence of *m*-dinitrobenzene. No debrominated sulfonate esters were formed, suggesting that debromination was accomplished by a radical-anion chain SET mechanism (8*b*–8*e*) as depicted in Scheme 2.

The failure of the tribromophenyl sulfonate ester in Table 1 to produce any trithioorthoformate **1**, despite its obvious ability to oxidize mercaptide anions (LUMO eigenvalue −1.0038 eV) may now be attributed to its facile reduction by NaH. The nitrosulfonate ester (LUMO eigenvalue −1.9839 eV) undergoes nucleophilic aromatic substitution with mercaptide anions (3).
